The intensity of the pale yellow emission as followed by the p.m. tube rose to a plateau value in the presence of excess NO (Fig. 2). The falloff in intensity observed in a hundred-fold excess of NO is due to the geometry of the system. Since the photomultiplier tube is a finite distance from the mixing jets and the distance for $t_{1/2}$ for step 1 varies from ~15 to ~0.15 cm for a 1–100 fold excess, the photon flux in the solid angle viewed by the p.m. tube will vary some with the flow rate of NO. The more rigorous criterion of linearity of I_{em} with F_2 flow at a constant [NO] is fulfilled, however, as can be seen in

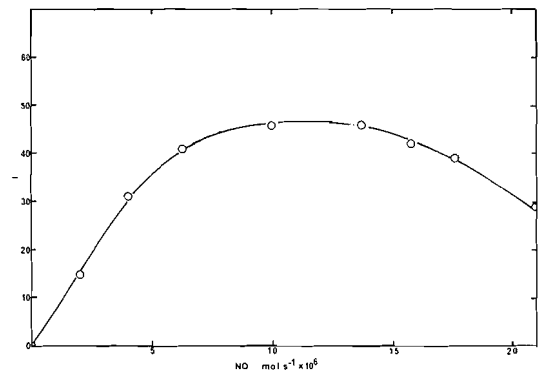

FIG. 2. Emission intensity in arbitrary units *vs.* the nitric oxide flow rate. F_2 flow 0.14 × 10^{-6} mol s^{-1}. Argon flow 300 × 10^{-6} mol s^{-1}. Total pressure = 3.7 Torr.

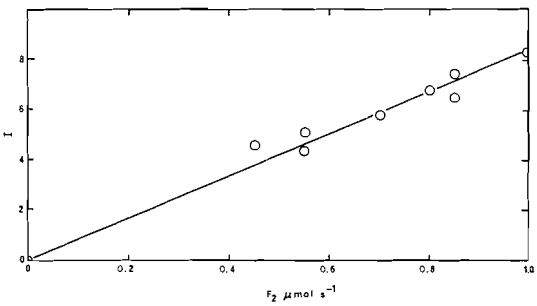

FIG. 3. Emission intensity in arbitrary units *vs.* the fluorine flow rate. NO flow rate 12 × 10^{-6} mol s^{-1}. Total pressure, 3.7 Torr.

Fig. 3. This is predicted by the reaction scheme of Johnston and co-workers (23, 24), modified to include heterogeneous removal of F atoms on the Pyrex surface.

[1] $F_2 + NO \rightarrow FNO + F$

[2] $F + NO + M \rightarrow FNO^* + M$

[3] $FNO^* \rightarrow FNO + h\nu$

[4] $FNO^* + M \rightarrow FNO + M$

[5] $F \xrightarrow{\text{wall}} \text{Product } (SiF_4)$

The assumption of steady-state conditions in the flow tube gives the following expression for the emission intensity I_0.

$$[6]\quad I_0 = \{k_1k_2[F_2][NO]^2[M]\}/\{k_2k_3[NO][M] + k_2k_4[NO][M]^2 + k_4k_5[M] + k_3k_5\}$$

The emission intensity is linearly dependent on

the F_2 concentration for a given third body M and constant NO concentration.

When a reactant R—X was mixed with the NO, the photomultiplier output was observed to decrease. This could be ascribed to any of three different causes: (*i*) F_2 + R—X competing successfully with step 1, (*ii*) the polyatomic molecule R—X being a much more efficient quencher in step 4 than the monatomic carrier gas Ar, (*iii*) F + R—X competing successfully with step 2. The first possibility was eliminated for each reactant since a blank run with F_2 and reactant produced no condensable products as determined by the gas chromatograph. It is also pertinent that no emission was observed from any of these blank runs.

The second possible cause was tested by using CF_4 as the reactant. Flow rates of CF_4 up to 10% of the argon carrier gas flow caused no decrease in the photomultiplier current, in fact it increased slightly ($I_0/I = 0.96 - 0.98$). An additional test was supplied by the reactant $CBrF_3$ where $I_0/I = 1.0$ when [RX] $\simeq$ [NO] = [Ar]/15.

The third possibility is then incorporated into the general reaction scheme.

[7] $$F + R—X \rightarrow XF + R$$

together with steps for removal of the radical R,

[8] $$R + NO \rightarrow RNO$$

[9] $$R + F_2 \rightarrow RF + F$$

[10] $$R + FNO \rightarrow RF + NO$$

[11] $$R + F \rightarrow RF$$

[12] $$R + R \rightarrow R_2$$

The mode of removal of R will affect the observed emission only if it produces or removes F atoms. Therefore, we must consider the relative importance of steps 9 and 11. Product analysis could not differentiate between [9], [10], and [11]. Furthermore, the reactivity of FNO in the Pyrex traps does not allow analysis of the products formed in the primary reaction. One can, however, arrive at an order of magnitude rate estimation by considering the relevant rate constants and concentrations. The available bimolecular rate constants for the reactions of CH_3, C_2H_5, and CF_3 and NO are $\sim 10^{11}$ cm^3 mol^{-1} s^{-1} (25–27). The only published values for reaction 9 are for R = H, and the room temperature value is $\sim 2 \times 10^{12}$ cm^3 mol^{-1} s^{-1} (3). When these values are substituted in the rate expressions, the result is

$$\frac{\text{Rate [8]}}{\text{Rate [9]}} > \frac{5}{1}.$$

It is reasonable to assume that k_{10} will not be greater than k_8. Thus, the contribution of step 10 will also be negligible. It is also possible to neglect [11] and [12] relative to [8] under the present experimental conditions. Bearing these facts in mind, the new expression for I is

[13] $$I = k_1k_2[F_2][NO]^2[M]/(k_3 + k_4[M])(k_2[NO][M] + k_5 + k_7[RX])$$

Dividing [6] by [13]

[14] $$\frac{I_0}{I} = 1 + \frac{k_7[RX]}{k_2[NO][M] + k_5}$$

which can be rearranged to give

[15] $$\left(\frac{I_0}{I} - 1\right)^{-1} = \frac{k_5}{k_7[RX]} + \frac{k_2'[NO]}{k_7[RX]}$$

where k_2' is the second order rate constant for step 2.

The data from CHF_3 is plotted in Fig. 4 according to [15]. We conclude from the linearity of the plot that reactions which are second order in radical concentrations, [11] and [12], do not contribute to the removal of R and F, and that steps [1]–[5], [7], and [8] adequately describe the system. The slope is (2.91 $\pm$ 0.08) $\times 10^{-2}$ and the non-zero intercept is (1.99 $\pm$ 0.88) $\times 10^{-2}$. All of the slopes and intercepts,

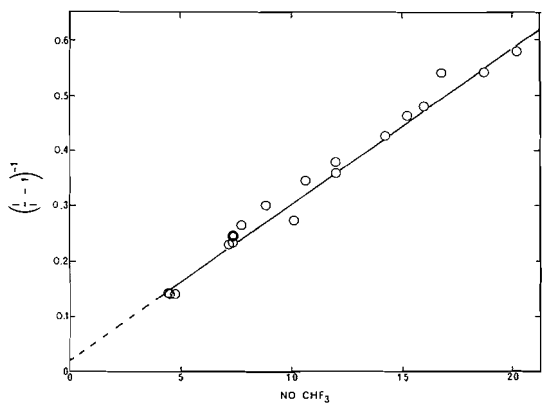

FIG. 4. Dependence of $((I_0/I) - 1)^{-1}$ on the [NO]/[CHF_3] ratio. Total pressure 3.7 Torr. Fluorine flow rate 0.7×10^{-6} mol s^{-1}, nitric oxide flow rate 12×10^{-6} mol s^{-1}.

*Unitless, see Fig. 3.

Figs. 4–7 are listed in Table 1 together with the derived values for k_5. The error limits associated with the experimental data represent the standard deviation as determined from a least squares fit to the data.

The results can be conveniently subdivided into three parts: (*i*) hydrohalocarbons + HCl, (*ii*) perhalocarbon, and (*iii*) group V molecules. Those compounds in division (*i*) were characterized by the property of requiring only a low concentration of reactant to effectively reduce the photomultiplier current almost to the background level ($I_0/I \sim 100$ when [NO]/[RX] ~ 10). On the other hand, those compounds in division (*ii*) required much larger concentrations of reactant ($I_0/I \sim 2$ when [NO]/[RX] ~ 1) to reduce the photomultiplier current at all. The two compounds in division (*iii*) exhibited behavior between the two extremes. In addition,

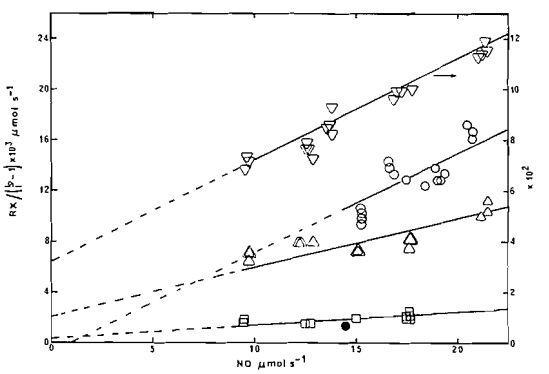

FIG. 5. Dependence of $[RX]/((I_0/I) - 1)$ on the [NO]. the PH_3 behavior was anomalous. The intensity of emission decreased when PH_3 was added to the NO flow but, after the PH_3 and NO were turned off and while the F_2 and Ar were still flowing, the intensity first increased then fell off "exponentially" with time to the zero level after a lapse of approximately 5 min. After this

was observed, the I_0 value would not return to its original level without extended (overnight) pumping on the reaction vessel or prolonged flow of F_2 + excess NO in Argon.

Discussion

The derived values of k_5 listed in Table 1 represent the only available values for the non-homogeneous removal of F atoms in a Pyrex tube. The order of magnitude value from this study is $\sim 10\ s^{-1}$. This suggests that every collision with the wall does not effectively remove the fluorine atom. The scatter, which is random, in the determined values further suggests that the nature of the surface plays a significant role in the ultimate fate of the F atoms which collide with the wall. However, this will not affect the relative rates of reaction as long as self heating effects are eliminated. This condition applies in the present work.

Absolute rate constant values for the reaction between F and R—X derived from the reported rate constant for $F + NO + Ar \rightarrow FNO + Ar$ (11) are compared with available velocity constants in Table 2. The agreement is very good for the hydrogen containing reactants.

A common feature of the abstraction reactions (Table 2) is the low energy barriers to reaction. This is not unexpected in view of the exothermicity of these reactions. This would seem to suggest that the trends in the magnitude of the derived rate constants in Table 3 would have their basis in the A-factor of the Arrhenius expression for k. If such is the case, we can postulate that, in the thermodynamic formulation of the rate constant, the activated complex must become more rigid as one goes from $[F\cdots H\cdots CH_3]^+$ to $[F\cdots H\cdots CF_3]^+$. It is certain that the geometry of the intermediate will change as fluorine atoms replace the protium atoms on methane since the resultant radical changes from D_{3h} symmetry (CH_3) to C_{3v} symmetry (CF_3). This property could be monitored in the HF product. For CHF_3, a greater fraction

of the total available energy should appear in the vibrational and rotational levels of the HF but the distribution within the vibrational levels would be more nearly statistical. The period during which the F atom approaches and before the "heavy" non-rearranged CF_3 radical moves away would allow "equilibration" of the available energy. This is in contrast to the CH_4 case where during formation of the HF bond the forming radical (CH_3) changes geometry (an exothermic process) and allows less redistribution of available energy because of a shorter interaction time. The HF bond should thus possess population inversion in its vibrational–rotational levels.

The two group V molecules are also interesting. The measured rate constant for NH_3 is less than that for methane even though the exothermicities are very similar. Qualitatively, the thermodynamic ΔS^* must be positive since, in the activated complex, the NH_3 moiety will lose the property of inversion. This effect will not be as serious in the physically larger PH_3 molecule and this is reflected in the greater room temperature rate constant.

The reaction of F atoms with $CBrF_3$ is endothermic. From the values given in Table 3 for the enthalpy charge and the room temperature velocity constant reported here the A-factor must be of the same order of magnitude as for the other molecules studied.

The inclusion of this molecule illustrates the versatility of this experimentally simple method of following the rates of fluorine atom reactions. A simple, yet powerful method because of its self-monitoring feature.

The Molecular Structures of the Polysulfuryl Fluorides by Vapor Phase Electron Diffraction: $S_2O_5F_2$ and $S_3O_8F_2$

J. LAWRENCE HENCHER

Department of Chemistry, University of Windsor, Windsor, Ontario

AND

S. H. BAUER

Baker Chemical Laboratories, Cornell University, Ithaca, New York 14850

Received November 20, 1972

The molecular structures of the polysulfuryl fluorides, $S_2O_5F_2$ and $S_3O_8F_2$, were determined by vapor phase electron diffraction. In each case it was assumed that a single rotomer was more stable than all others, by at least 2.5 kcal mol^{-1}. The possibility that the sample consisted of a mixture of conformations of comparable stabilities was not explored.

The thermally averaged r_g parameters for $S_2O_5F_2$ are as follows: S=O = 1.398 ± .002 Å; S—F = 1.525 ± 0.005 Å; S—O = 1.611 ± 0.005 Å; ∠SOS = 123.6 ± 0.5°; ∠OS=O = 106.1 ± 0.9°; ∠FS=O = 106.6 ± 0.6°; ∠O=S=O = 126.8 ± 1.2°; ∠OSF = 102.4 ± 1.8°; $\tau_{FS/OS'}$ = 53.8 ± 2.7°; $\tau_{F'S'/OS}$ = 73.7 ± 2.4°. The r_g parameters for $S_3O_8F_2$ are: S=O = 1.402 ± 0.003 Å; S—F = 1.525 ± 0.012 Å; S—O = 1.613 ± 0.006 Å; ∠OSO = 97.8 ± 1.0°; ∠SOS = 123.6 ± 1.2°; ∠OS=O = 106.5 ± 0.8°; ∠FS=O = 105.5 ± 1.2°; ∠O=S=O (bridge) = 128.8 ± 1.4°; ∠O=S=O = 128.5 ± 1.4°; ∠OSF = 101.3 ± 1.5°; $\tau_{SO/SO}$ = 295.3 ± 0.9°; $\tau_{FS/OS}$ = 319.4 ± 2.2°. The standard errors listed are three times the calculated values and are believed to encompass the non-random errors in the analysis.

Les structures moléculaires des fluorures de polysulphuryle, $S_2O_5F_2$ et $S_3O_8F_2$, ont été élucidées par la diffraction des électrons en phase vapeur. Dans chacun des cas, il fut estimé qu'un seul rotamère était plus stable que tous les autres par au moins 2.5 kcal/mol^{-1}. Par suite la possibilité que l'échantillon comporte un mélange de conformations ayant des stabilités comparables n'a pas été explorée. Les paramètres moyennés thermiquement pour le $S_2O_5F_2$ sont les suivants: S=O = 1.398 ± 0.002 Å; S—F = 1.525 ± 0.005 Å; S—O = 1.611 ± 0.005 Å; ∠SOS = 123.6 ± 0.5°; ∠OS=O = 106.1 ± 0.9°; ∠FS=O = 106.6 ± 0.6°; ∠O=S=O = 126.8 ± 0.5°; ∠OSF = 102.4 ± 1.8°; $\tau_{FS/OS'}$ = 53.8 ± 2.7°; $\tau_{F'S'/OS}$ = 73.7 ± 2.4°. Les paramètres pour le $S_3O_8F_2$ sont: S=O = 1.402 ± 0.003 Å; S—F = 1.525 ± 0.012 Å; S—O = 1.613 ± 0.006 Å; ∠OSO = 97.8 ± 1.0°; ∠SOS = 123.6 ± 1.2°; ∠OS=O = 106.5 ± 0.8°; ∠FS=O = 105.5 ± 1.2°; ∠O=S=O (pont) = 128.8 ± 1.4°; ∠O=S=O = 128.5 ± 1.4°; ∠OSF = 101.3 ± 1.5°; $\tau_{SO/SO}$ = 295.3 ± 0.9°; $\tau_{FS/OS}$ = 319.4 ± 2.2°. Les erreurs standards mentionnées représentent trois fois les valeurs calculées et tiennent compte, semble-t-il, des erreurs qui ne sont pas imputables au hasard lors de l'analyse. [Traduit par le journal]

Can. J. Chem., **51**, 2047 (1973)

Introduction

Although it appears that no detailed structures have been reported for $S_2O_5F_2$ and $S_3O_8F_2$, polysulfuryl structures have been proposed on the basis of their infrared and Raman spectra (1, 2). Gillespie and Robinson (3, 4) predicted values for the S—O bond lengths (1.40 Å, terminal and 1.66 Å ,bridge) and ∠O=S=O (120–122°) from correlations of these parameters with force constants and vibrational frequencies.

The structures of the ions $S_2O_7^{2-}$ (5) and $S_3O_{10}^{2-}$ (6, 7) (isoelectronic with $S_2O_5F_2$ and $S_3O_2F_2$, respectively) are notable for the shortness of the terminal S=O separation compared to that in SO_4^{2-} (8) and the larger than tetrahedral bridge angles, ∠SOS. The bridge S–O distance is apparently shorter than a single bond length. Cruickshank (7) attributed these structural effects to an increase in dπ–pπ bond orders, due to delocalization of the lone pair electrons associated with the bridge oxygen. A recent molecular orbital study of the S—O bond by Bartell, Su, and Yow (9) supports involvement of the lone pair electrons but favors a different involvement of the sulfur d orbitals.

The sulfuryl halides exhibit short S—O bonds compared with $SO_2(CH_3)_2$ (10). Either of the above theoretical viewpoints favors increased d orbital utilization, in this case because of the polarizing effect on sulfur by the attached halogen atoms (9, 11).

Because the above interesting factors are presumed to be present in the polysulfuryl fluorides, a structural study was undertaken.

Experimental

The samples were obtained in break-seal bottles from R. J. Gillespie of McMaster University. Both samples were produced by fluorination of liquid SO_3 (1). The sample of $S_2O_5F_2$ distilled at 51–52 °C (1 atm) and the sample of $S_3O_8F_2$ distilled at 29–31 °C under a reduced pressure of 3 Torr.

Convergent mode, sectored electron diffraction patterns were recorded on the Cornell Apparatus (12). The nozzle was maintained at about 20 °C. Diffraction patterns were recorded on 4 × 5 in. Kodak Process Plates at 25 and 75 kV for nozzle to plate distances of 12.94 and 26.24 cm. Useful diffraction patterns thus covered the range $5 < q < 140$ Å^{-1} where $q = (40/\lambda) \sin(\theta/2)$. Scale factors were obtained from MgO diffraction patterns recorded concurrently with the gas patterns (13).

Tracings of the diffraction patterns were recorded on a Jarrell Ash microphotometer equipped with a rotating sample stage. The center of each plate was located by an exposed spot from the undeflected beam. Procedures for reducing the above data to relative intensities have been described elsewhere (13–15). The relative intensities are presented for $S_2O_5F_2$ and $S_3O_8F_2$ in Figs. 1 and 2, respectively. Tables of these values, interpolated at integral q, are available from the Depository of Unpublished Data.[1]

Analysis

The experimental molecular intensity was calculated for each set of data depicted in Figs. 1 and 2 according to

$$M_{exp}(q) = [(I(q)/B(q)) - 1]$$

where $I(q)$ is the experimental sectored intensity and $B(q)$ is the background. The resultant curves were then spliced into two composite $(\pi/10)qM_{exp}(q)$ curves for each molecule, as follows:

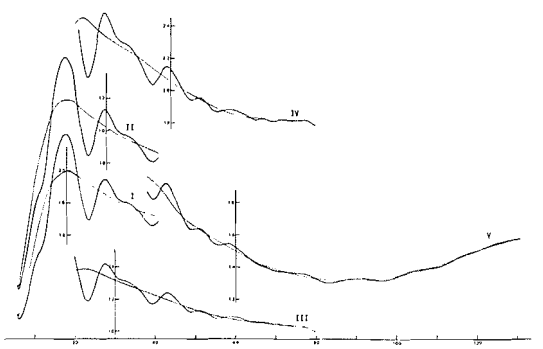

FIG. 1. The sectored diffraction patterns for $S_2O_5F_2$ with deduced backgrounds.

[1]Tables of relative intensities are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

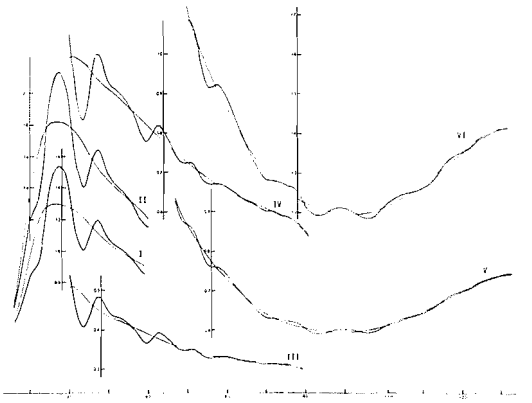

FIG. 2. The sectored diffraction patterns for $S_3O_8F_2$ with deduced backgrounds.

$S_2O_5F_2$ (Set 1 from curves I, IV, and V. Set II from curves II, III, and V of Fig. 1); $S_3O_8F_2$ (Set I from curves I, III, and V. Set II from curves II, IV, and VI of Fig. 2). Each composite was analyzed independently by a least squares procedure (13) which incorporated the Hartley modification (16). Correlation of errors between data points was allowed for by means of a non-diagonal weight matrix (17).

The elastic and inelastic scattering factors inserted in the computer program were those of Tavard *et al.* (18). Phase shifts were calculated from the Bonham and Ukaji expressions (19). Anharmonicity corrections were included in the theoretical $(\pi/10)qM(q)$ curves (20, 21). The structures were parametrized in terms of Hilderbrandt's (22) standard coordinate types; the calculated parameter values are based on the $r_g(0)$ distances.

Results for $S_2O_5F_2$

Two models were tested for $S_2O_5F_2$. One model was assigned C_2 symmetry about the bridge oxygen atom. (A single parameter specified the $-SO_2F$ group rotation about the S—O bridge bonds.) The other model was unsymmetrical and required an independent rotational parameter for each $-SO_2F$ group.

Since it proved impossible to determine all mean square amplitudes independently, they were grouped as follows: $l_1 \equiv l_{S=O} = 0.04$ Å; $l_2 \equiv l_{S-O} = l_{S-F} = 0.05$ Å; $l_3 \equiv l_{OS=O} = l_{FS=O} = l_{O=S=O} = 0.06$ Å; $l_4 \equiv l_{OSF} = 0.065$ Å; l_5 (distances separated by four atoms) $\equiv 0.0884$ Å; l_6 (all other distances) $\equiv 0.123$ Å. Values for l_1–l_4 were based on the known values for SO_2F_2

(23) and modified by trial and error variation over a $\pm 10\%$ range. The others were determined by least squares while the remaining parameters were constrained. A least squares analysis was carried out for the geometrical parameters and resolution factor while the mean square amplitudes were constrained as outlined above. A systematic variation of the initial values of the rotational parameter(s) over all the staggered and eclipsed conformations resulted in several solutions for each of the above models. The refined values of the rotational parameters and the R factors for these solutions, labelled A–E, are presented in Table 1 for Data Set I. The values of the other parameters did not differ appreciably for the better fitting solutions. Substantially the same results were obtained from the data in Set II. The solutions B–E were tested against the "overall best fit", solution A, according to the R factor significance tests proposed by Hamilton (24, 25). On this basis the alternative solutions for the unsymmetrical model, B–D were rejected as less than 0.5% probable. The comparison test (25) favored solution A over solution E at the 99.5% confidence level.

The "overall best fit" solutions for Sets I and II are listed in Table 2. The arithmetic average parameters given in the third column were inscribed on the structure presented in Fig. 3. The $(\pi/10)qM_{exp}(q)$ and radial distribution curves are shown for Set I in Figs. 4 and 5, respectively. The interatomic distances are given in Table 3 and the correlation matrix is presented in Table 4.

The correlation matrix contains no large elements and therefore the selected parameters were essentially independently determinable. Although all the final calculations were based on optimum fitting of the $(\pi/10)qM_{exp}(q)$ curve, the radial distribution function (Fig. 5) illustrates

the process of structure determination. What initially appeared as a difficult resolution problem, exhibited by the second peak of the radial distribution curve was apparently offset by the facts that the S . . . S distance (third peak) was substantially resolved, and that the parameters determining the second peak had to be consistent with the remainder of the curve. The large estimated errors, particularly for OSF and O=S=O are nevertheless a reflection of this problem.

Results for $S_3O_8F_2$

The same approach used for $S_2O_5F_2$ was used for $S_3O_8F_2$. A symmetric model (C_{2v} symmetry) was assumed and a converged least squares solution could not be obtained without making the following constraints: the skeletal S—O (bridge) bonds were assumed equal; the terminal S=O bonds were assumed equal; and, the O—S=O angles were assumed equal. The "best fit" model is illustrated in Fig. 6. A systematic variation of the initial values of the conformation determining parameters led to several distinct least squares converged solutions which are given in Table 5. Alternatives to the "best fit" solution were rejected by the R test (22) as less than 0.5% probable. In all runs, the mean square amplitudes were constrained as follows: $l_1 = l_{S=O} = 0.039$ Å; $l_2 = l_{S-F} = l_{S-O} = 0.053$ Å; $l_3 = l_{OS=O} = l_{FS=O}\ l_{O=S=O} = l_{OSF} = l_{SOS} = l_{OSO} = 0.065$ Å; l_4 (2.844 − 3.267 Å) = 0.075 Å, l_5 (3.472 − 3.955 Å) = 0.097 Å; l_6 (4.117 − 4.462 Å) = 0.110 Å; l_7 (4.665 − 6.262 Å) = 0.154 Å.

The "best fit" parameter values are presented in Table 6. The interatomic distances and the correlation matrix are given in Tables 7 and 8, respectively. The experimental molecular scat-

tering, $(\pi/10)qM_{exp}(q)$ and the radial distribution curves are shown in Figs. 7 and 8, respectively. As was the case with $S_2O_5F_2$, the valence angles could be determined because the S . . . S distance was resolved and because the accepted valence angles had to be consistent with the well structured outer region of the radial distribution curve.

Discussion

The structures of $S_2O_5F_2$ and $S_3O_8F_2$, given in Tables 2 and 6, show that the bond lengths fall within the expected limits, and the valence bond angles at sulfur follow the valence shell electron pair repulsion theory predictions (26). The bridge angles, ∠SOS, are not significantly different from

those in the ions $S_2O_7^{2-}$ and $S_3O_{10}^{2-}$, and $S_5O_{16}^{2-}$ (37). A comparison of the principal geometric parameters with those in the several related species is presented in Table 9, which does, however, reveal several interesting variations.

Due to the necessary constraints that were made to the structure at the central sulfur atom, the alternation in S—O bond length along the chain, exhibited by these ions, could not be observed for $S_3O_8F_2$; however, the closeness of the value obtained (1.613 Å) to that in $S_2O_5F_2$ (1.611 Å) suggests that the difference in lengths is comparable to the estimated uncertainty (±0.006 Å) in this bond length.

The largest difference between the structures of the polysulfuryl fluorides and the sulfuryl halides is in the values of ∠O=S=O. Possibly, this increase in O=S=O angle reflects an increase in the S=O (terminal) bond orders. Bond orders for $S_2O_5F_2$ calculated on the basis of Cruickshank's scheme (7) are $1.6 < n_{S=O} < 2.375$, and $1.2 < n_{S-O}$ (bridge) < 1.25, compared with $1.5 < n_{S=O} < 2$ in SO_2F_2. The lower and upper limits are given for fluorine included or not included, respectively, in the dπ–pπ scheme; the lower limits coincide with the values calculated for $S_2O_7^{2-}$ by the above author (7). A larger bond order is indicated for $S_2O_5F_2$ at both limits. The trend to a larger S=O (terminal) bond order in the polysulfuryls than in SO_2F_2 is indicated by the corresponding shorter S=O bond lengths in the former compounds. While the difference in interatomic distances is marginal it is consistent with the larger O=S=O. That the S—F bond is short in both $S_2O_5F_2$ and $S_3O_8F_2$ compared with SO_2F_2 is consistent with its inclusion in the delocalization scheme. The S—O (bridge) bond length in both compounds is significantly smaller

than that in either $S_2O_7^{2-}$ or $S_3O_{10}^{2-}$ (average 1.63 Å) but agrees well with those in $(SO_3)_\infty$, $C_2H_5SO_4^-$, and HSO_3^- in which the bond orders are similar.

The apparent disagreement of the values of S—O and ∠O=S=O with the predictions of Gillespie and Robinson (3, 4) does not disprove the correlation between bond length and force constants but does illustrate the uncertainties involved in their method. The results for the valence parameters are consistent with delocalization of the bridge oxygen electrons throughout the molecule. Although the Cruickshank dπ–pπ bonding scheme may lack quantitative validity, it correctly predicts the structural trends in the present case.

The rotational conformations determined for $S_2O_5F_2$ and $S_3O_8F_2$ represent the best accommodation of the structural parameters to the data. It is assumed that all the other conformations are at least 2.5 kcal mol^{-1} less stable and therefore do not affect the electron diffraction patterns.

We extend our thanks to Professor R. J. Gillespie for helpful discussion. The financial support of the National Research Council of Canada and the Materials Science Center at Cornell University (ARPA-SD-68) is gratefully acknowledged.

Complete Variational Treatment of the Hydrogen Molecule. I. The Full Electronic Hamiltonian

R. E. KARI,[1] A. C. H. CHAN,[2] G. HUNTER, AND H. O. PRITCHARD[3]

Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received November 7, 1972

The hydrogen molecule is treated with the $\nabla_1 \cdot \nabla_2$-term regarded as part of the Hamiltonian, rather than as a perturbation as was done by Kolos and Wolniewicz. Specimen results are presented for H_2 and D_2.

La molécule d'hydrogène a été étudiée en considérant que le terme $\nabla_1 \cdot \nabla_2$ fait partie de l'Hamiltonien, plutôt qu'en considérant que celui-ci est une perturbation comme il a été envisagé par Kolos et Wolniewicz. On présente des exemples de résultats obtenus pour H_2 et D_2.

A detailed review of the discrepancies which existed between the theoretical calculations and the experimental observations for the hydrogen molecule was made a few years ago by Wilkinson and Pritchard (1). At that time it appeared that for the ground state ($X^1\Sigma_g^+$), (*a*) the calculated dissociation energy was too large by about $4\ cm^{-1}$, and (*b*) the calculated vibrational spacings of the low vibrational states were too large, the discrepancy being correlated with the nuclear reduced masses for H_2, HD, and D_2; there was also a slight suspicion that the calculated rotational spacings could be marginally high. Since then, it has been shown by Herzberg (2) that the experimental value for the dissociation energy was in error by between 4 and $5\ cm^{-1}$, and the position now is that the agreement between theory and experiment is as satisfactory as one could expect. The discrepancy in the vibrational spacings still remains, and is certainly not experimental in origin (1). Further, it represents all the more of a theoretical challenge because it is now known that the Born–Oppenheimer method predicted the first three vibrational spacings of the H_2^+ molecule (3, 4) correctly, to within the experimental accuracy (5), and that agreement for some of the lower rotational spacings is equally satisfactory. There is also excellent agreement between experimental (6) and theoretical (3) vibrational spacings for HD^+. If the Born–Oppenheimer method works for H_2^+, there seems no *a priori* reason why it should not also work for H_2, and therefore we have undertaken a thorough re-examination of the theoretical treatment of the ground state of the hydrogen molecule.

We accept at the outset that Kolos and Wolniewicz's 100-term infinite-mass calculation is correct and has converged to an acceptable limit (7) and we suppose that there is a defect in the subsequent evaluation of the vibrational spacings from the infinite-mass internuclear potential. Assuming that the Born–Oppenheimer method is valid (1) we can envisage two reasons why the correct result may not have been obtained: (*i*) that the calculation of the dc_i/dR required for the calculation of the expectation value of ∇_R^2 is an ill-conditioned problem (ref. 8, eq. 27); (*ii*) that it is logically incorrect to treat the $\nabla_1 \cdot \nabla_2$-term in the Hamiltonian in parallel with the ∇_R^2-term (8). We will address a future publication to (*i*) the rigorous calculation of the dc_i/dR, and in this paper we address ourselves to (*ii*) the rigorous treatment of the $\nabla_1 \cdot \nabla_2$-term.

We have noted previously that the $\nabla_1 \cdot \nabla_2$-term should properly be considered as part of the electronic Hamiltonian (9), and to treat it as do Kolos and Wolniewicz (8) means that the operator ∇_R^2 is operating on an incorrect electronic wave function. The effect is obviously small, but could be significant, especially if the correction to the effective internuclear potential were to be skewed about a point near the equilibrium internuclear separation. The expectation value of the operator $\nabla_1 \cdot \nabla_2$ is about $6\ cm^{-1}$ compared with a total energy of about $250\,000\ cm^{-1}$ (8), say one part in 40 000 which would imply that there

should be a correction to the electronic wave function of order 1 in 200 from this term. The subsequent effect of this error on the calculated expectation value for ∇_R^2 is hard to predict with confidence since it is a complicated function of derivatives of the electronic wave function. One has two choices: either one can follow the method of Kolos and Wolniewicz, but treat the $\nabla_1\cdot\nabla_2$- and ∇_R^2-perturbations in tandem, or one can include the $\nabla_1\cdot\nabla_2$-term in the electronic Hamiltonian, thereby losing the simplification that the same electronic wave functions can be used to describe H_2, HD, and D_2. The former choice is logically unacceptable. The first order perturbation correction to the energy would be the Kolos and Wolniewicz result, but to calculate the first order perturbation correction to the wave function, one has to know the (unperturbed) wave functions for excited states of the molecule. In this sense, one would be including part of the non-adiabatic coupling correction in a supposed attempt to calculate the adiabatic energy, and it would be impossible to identify how much non-adiabatic correction had been assimilated into the mass polarization term! Therefore, in this paper, we follow the approach of Gray, Hunter, and Pritchard (10), with the $\nabla_1\cdot\nabla_2$-term included in the original Hamiltonian: this method has the advantage that it is variational throughout, *i.e.* at the Born–Oppenheimer stage, at the adiabatic stage, and at the non-adiabatic stage, the calculated energies are always upper bounds. We do not propose at this time to go beyond the adiabatic approximation, however. We begin with the system of coordinates[4] as defined in Fig. 1 and by standard procedures factorize out the motion of the center of mass of the system, arriving at a kinetic-energy operator T (in atomic units), relative to the center of mass of the system, of the form

$$[1]\quad T = -\tfrac{1}{2}\left\{\frac{1}{\mu_{A1}}[\nabla_\alpha^2 + \nabla_\beta^2] + \frac{2}{M_A}[\nabla_\alpha\cdot\nabla_{AB} + \nabla_\beta\cdot\nabla_{AB} + \nabla_\alpha\cdot\nabla_\beta] + \frac{1}{\mu_{AB}}\nabla_{AB}^2\right\}$$

where

$$[2]\quad \frac{1}{\mu_{A1}} = \frac{M_A + M_1}{M_A M_1} = \frac{M_A + M_2}{M_A M_2} = \frac{1 + M_A}{M_A}$$

and

$$\frac{1}{\mu_{AB}} = \frac{M_A + M_B}{M_A M_B}$$

Now, transforming from center-of-mass coordinates to mid-point-of-the-bond coordinates (7, 10), the kinetic energy operator becomes

$$[3]\quad T = -\tfrac{1}{2}\left\{\nabla_1^2 + \nabla_2^2 + \frac{1}{4\mu_{AB}}(\nabla_1 + \nabla_2)^2 + \frac{1}{\mu_{AB}}\nabla_R^2 + \frac{1}{\mu_A}(\nabla_1\cdot\nabla_R + \nabla_2\cdot\nabla_R)\right\}$$

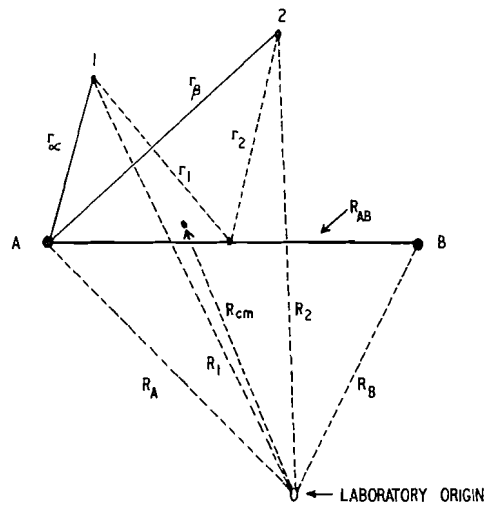

FIG. 1. Illustration of relationship between the two sets of coordinate systems used in the Born–Oppenheimer separation for H_2 and D_2. Center of mass coordinates: $\boldsymbol{r}_\alpha = \boldsymbol{R}_1 - \boldsymbol{R}_A$, $\boldsymbol{r}_\beta = \boldsymbol{R}_2 - \boldsymbol{R}_A$, $\boldsymbol{R}_{AB} = \boldsymbol{R}_B - \boldsymbol{R}_A$. Mid-point of bond coordinates: $\boldsymbol{r}_1 = \boldsymbol{r}_\alpha - \frac{1}{2}\boldsymbol{R}_{AB}$, $\boldsymbol{r}_2 = \boldsymbol{r}_\beta - \frac{1}{2}\boldsymbol{R}_{AB}$, $\boldsymbol{R} = -\boldsymbol{R}_{AB}$.

[4]The choice of systems of coordinates is arbitrary, and largely a matter of convenience, as was noted by Kolos (7). We would at this time add that the three different coordinate systems for effecting the diatomic Born–Oppenheimer separation discussed by Hirschfelder *et al.* (11, 12) are related by a scale parameter (or synonymously by a reduced mass factor in the electronic kinetic energy operator). Whatever coordinate system is used initially, the subsequently determined electronic wave function must be scaled so that the adiabatic electronic energy tends to the correct separated atom limit (9, 10). After this scaling, the electronic wave function is unique: *i.e.* coordinate system independent, so that the calculated adiabatic correction to the electronic energy is also unique. Hirschfelder *et al.*'s discussion of the relative merits of their three different coordinate systems based upon the relative magnitudes of their apparent adiabatic corrections (which included different implicit scaling corrections for each case) is therefore an artefact from the point of view of the essential nature of the Born–Oppenheimer separation.

TABLE 1. Eigenvalues and expectation values calculated via eqs. 5*a* and 5*c* for H_2 and D_2 with $\alpha = 1.0$ and $R = 1.4$ a.u., using the same 20th order wave function as was used by Kolos and Wolniewicz (8): energies in a.u.; $M_A^H = 1836.11686$ a.u., $M_A^D = 3670.4119$ a.u.

$E = E_5 + \varepsilon_6 + \varepsilon_7$	−1.1739949686	−1.1741686169	−1.1739950561*	−1.1741686388*

*An asterisk marks the solution of an eigenvalue equation, and represents the stage in the calculation at which the total energy E is strictly variational.
†Now includes ε_6 and ε_7: the expectation values for the infinite-mass ∇_i^2-terms are 1.1742291971 a.u. and 1.1744703444 a.u., respectively.

where

$$[4] \qquad \frac{1}{\mu_A} = \frac{M_A - M_B}{M_A M_B}$$

a well-known result (7, 13). For the present, we will confine our attention to the homonuclear molecules H_2 and D_2, with the simplification that the last term in eq. 3 drops out because μ_A^{-1} becomes zero: the complete treatment of the heteronuclear HD would require the retention of this term; eq. 3 then becomes

$$[5] \quad T = -\tfrac{1}{2}\left\{\left(1 + \frac{1}{2M_A}\right)(\nabla_1^2 + \nabla_2^2) + \frac{1}{M_A}\nabla_1 \cdot \nabla_2 + \frac{2}{M_A}\nabla_R^2\right\}$$

where M_A is now either the mass of the proton or the deuteron in atomic units.

Our treatment differs from that of Kolos and Wolniewicz in two respects.[5] They solved the Schrödinger equation with an infinite-mass kinetic energy operator

$$[5a] \qquad T = -\tfrac{1}{2}(\nabla_1^2 + \nabla_2^2)$$

and treated the terms $(2M_A)^{-1}\nabla_1^2$, $(2M_A)^{-1}\nabla_2^2$, $M_A^{-1}\nabla_1 \cdot \nabla_2$, and $2M_A^{-1}\nabla_R^2$ as perturbations. A superior procedure, as we have shown previously (9, 10), would have been to include the first two of these terms in the Hamiltonian, *viz.*

$$[5b] \quad T = -\tfrac{1}{2}\left(1 + \frac{1}{2M_A}\right)(\nabla_1^2 + \nabla_2^2)$$

treating only $M_A^{-1}\nabla_1 \cdot \nabla_2$ and $2M_A^{-1}\nabla_R^2$ as perturbations. The advantage of this slight modification is that the energy (also the wavefunction) is variational at this stage, thereby reducing the uncertainty in the final computed energy. We re-emphasize here that it is quite unnecessary to perform the Born–Oppenheimer separation in the traditional way using infinite-mass nuclei with the natural electronic mass. The version we have described before for H_2^+ etc. (3, 9, 10) which uses a different reduced electronic mass for each molecule is equally valid, and in fact superior as we have just mentioned because one has a variational solution at a later stage in the development of the calculation. Better still is to attempt to solve the Schrödinger equation for H_2 and D_2 with the $\nabla_1 \cdot \nabla_2$-term included in the Hamiltonian, *i.e.*

$$[5c] \quad T = -\tfrac{1}{2}\left\{\left(1 + \frac{1}{2M_A}\right)(\nabla_1^2 + \nabla_2^2) + \frac{1}{M_A}\nabla_1 \cdot \nabla_2\right\}$$

In this way the electronic wave function which will be used to determine the ∇_R^2-correction will be both complete and strictly variational; likewise, the effective Born–Oppenheimer potential, to which this correction is to be added to determine the final rotation–vibration energy levels, is also strictly variational. The required manipulations are lengthy, and will be made available

[5] We note that there is a misprint in the original expression for the Hamiltonian matrix element given by Kolos and Roothaan (14): in their eq. 15 there is a superfluous coefficient 2 associated with the $K_{\bar{p}+1,\,\bar{q}\bar{s}}^{\bar{\mu}}$ term.

TABLE 2. Expectation values, in cm^{-1}, for the finite-mass and mass-polarization kinetic energy correction terms; 1 a.u. = 219474.72 cm^{-1}

	Equation 5*a*		Equation 5*c*	
Quantity	H_2	D_2	H_2	D_2
∇_i^2-term	70.2078	35.1213	70.1790	35.1141
$\nabla_1 \cdot \nabla_2$-term	6.0528	3.0279	6.0433	3.0255
Total = $\varepsilon_6 + \varepsilon_7$	76.2607	38.1493	76.2222	38.1396

in thesis form shortly (15). Suffice to say at this stage that one requires the same integrals in either the Kolos and Wolniewicz procedure and in ours. However, since the computation of the integrals consumes about 90–95% of the computing time required to perform the calculation for a single pair of values of α and R, the fact that eq. 5*c* is different for each isotopic species is of minimal consequence; the same integrals are required for either H_2 or D_2 with only slightly different scaling factors.

In Table 1 we reproduce specimen results for the same 20th order wave function as is listed in Table 5 of ref. 8, for the exponent $\alpha = 1.0$ and internuclear separation $R = 1.4$ a.u. It can be seen that at this stage in the calculation, there is excellent agreement between the two methods, as one would expect. We conclude therefore that the source of the discrepancy between theory and experiment in respect of the vibrational spacings must, for reasons such as we have outlined at the beginning of this paper, be located in the calculation of the ∇_R^2-term. Table 2 lists, for comparison purposes the expectation values for the finite mass correction and the mass polarization terms corresponding to the wave functions obtained from eqs. 5*a* and 5*c*: they agree very closely of course, with the *percentage* error in the total correction being less for D_2 than for H_2 by a factor of about two.

"Transitions vibrationnelles simultanées" d'un donneur et d'un accepteur de proton[1]

ANDRÉ BURNEAU ET JACQUES CORSET

Laboratoire de Spectrochimie Moléculaire, Université de Paris VI, 75230 Paris Cedex O5 et Laboratoire de Chimie Physique, C.N.R.S., 2 rue Henri Dunant, 94320 Thiais

Reçu le 14 novembre 1972

Des absorptions dans le proche infrarouge mettant en jeu simultanément des vibrations de plusieurs molécules, sont mises en évidence pour des mélanges renfermant un donneur de protons RXH et un accepteur R′AB. Les donneurs étudiés sont: le chloroforme, l'eau, le pentachlorophénol, et le méthanol, et les accepteurs: l'acétonitrile, l'acétone, le diméthylsulfoxyde, et la pyridine; pour comparaison, le sulfure de carbone et l'hexachloroacétone sont aussi utilisés comme solvants. On observe non seulement des combinaisons νXH + νAB et νXH + $\nu_3(CS_2)$ mais aussi νXH + νR′, vers 6500 cm^{-1}, si R′ renferme des liaisons CH; ces absorptions à 6500 cm^{-1} n'existent pas si l'on utilise une base R′AB complètement deutériée. Les résultats suggèrent une corrélation entre l'augmentation d'intensité, par formation de liaisons hydrogène, des bandes νXH et de celle des transitions simultanées. Ces transitions, dont l'intensité est quelquefois plus grande que celle des harmoniques 2νXH, contribuent notablement au spectre des donneurs de protons dans le proche infrarouge. Il est probable que ces conclusions, fondées sur l'étude de liaisons hydrogène relativement faibles, peuvent être étendues à des interactions plus fortes; mais l'élargissement des bandes d'absorption rend difficile l'observation des transitions simultanées dans le cas de liaisons hydrogène fortes.

Absorptions simultaneously involving the vibrations of two molecules are brought out of the near infrared spectra of mixtures containing a proton donor RXH and an acceptor R′AB. The donors under study are: chloroform, water, pentachlorophenol, and methanol, and the acceptors: acétonitrile, acetone, dimethylsulfoxide, and pyridine; for comparison, carbon disulfide and hexachloracetone are also used as solvents. Not only the combinations νXH + νAB and νXH + $\nu_3(CS_2)$ are observed, but also νXH + νR′, at about 6500 cm^{-1}, if R′ contains CH bonds; these absorptions at 6500 cm^{-1} do not exist when fully deuterated bases R′AB are used. A correlation between the intensity increase, through hydrogen bonding, of the νXH bands and that of the simultaneous transitions is suggested by the results. In the assignment of the near infrared spectra of proton donors, it is important to take into account the simultaneous transitions because their intensity is sometimes greater than that of the overtones 2νXH. It is likely that these conclusions, founded on the study of relatively weak hydrogen bonds, may be extended to stronger interactions; but the width of the absorption bands in the case of strong hydrogen bond makes the observation of the simultaneous transitions difficult.

Can. J. Chem., 51, 2059 (1973)

Introduction

Au cours de l'étude, dans le proche infrarouge, du spectre de l'eau en interaction avec des solvants organiques accepteurs de protons (1–5), nous avons observé des absorptions mettant en jeu simultanément des vibrations de la molécule d'eau et des molécules de bases. Nous avons pu mettre en évidence de telles transitions vibrationnelles dans d'autres systèmes donneur–accepteur de protons: nous avons déjà publié des résultats préliminaires (6, 7). D'autres auteurs avaient montré l'existence de ce phénomène soit dans des mélanges de gaz comprimés (8, 9), soit dans des phases condensées, à l'état liquide (10–14) ou solide (par ex. 15, 16).[2]

Jusqu'à ces dernières années, il y avait peu d'observations sûres de transitions simultanées dans des mélanges susceptibles de former des liaisons hydrogène. Nous avons donc essayé de savoir si ce phénomène constitue une propriété générale de la liaison hydrogène et de préciser le rôle qu'elle peut y jouer. Pour cela nous avons examiné à la fois des mélanges RXH–BAR′ et RXH–CS_2, le sulfure de carbone étant un solvant quasi inerte.[3] Dans les premiers mélanges, nous avons observé non seulement des transitions νXH + νAB mais aussi νXH + νR′. Dans certains cas, la comparaison du spectre du soluté RXH dans le solvant BAR′ hydrogéné et deutérié nous a permis de prouver l'existence de telles transitions. Dans d'autres cas l'interprétation

[1]Avec la collaboration technique de Jean Limouzi.

[2]Dans la suite nous utiliserons, à propos de ce phénomène, l'expression "transitions vibrationnelles simultanées", suivant en cela les premiers auteurs, plutôt que celle de "double excitation" (13, 15).

[3]RXH désigne le donneur de protons et R′AB un solvant organique ayant un groupement diatomique basique AB et un ou plusieurs radicaux R′.

du spectre en terme de transition simultanée est probable, sans pour cela être univoque.

Conditions expérimentales

Les spectres ont été enregistrés à l'aide de spectromètres Perkin Elmer 225, Beckman IR 12, et Cary 14, celui-ci étant équipé d'un potentiomètre d'échelle 0–2 ou 0–0.2 unités d'absorbance. La température de stabilisation des solutions dans les faisceaux du Cary 14 est d'environ 30 °C. La largeur de fente spectrale a été maintenue à une valeur égale, au plus, au dixième de la largeur à mi-hauteur de la bande observée. Dans les figs. 1 à 5, les abscisses sont linéaires en longueur d'ondes mais les maximums d'absorption sont repérés en cm^{-1}. La précision de la mesure du nombre d'ondes au maximum d'absorption est estimée, sauf indication contraire, de 1 à 5 cm^{-1}, suivant la forme de la bande. Mais, quand il y a recouvrement de bandes, ou quand ces dernières sont larges, il est possible que le maximum d'absorption ne corresponde que de façon approchée à la position de la transition étudiée. De plus, la fréquence du maximum de certaines bandes, faisant intervenir un vibrateur associé, varie avec la concentration du mélange.

Le "spectre de mesure" est celui d'une solution renfermant des concentrations données de soluté et de solvant, sous une épaisseur e. Le "spectre de référence" est défini théoriquement comme celui qui ne correspond

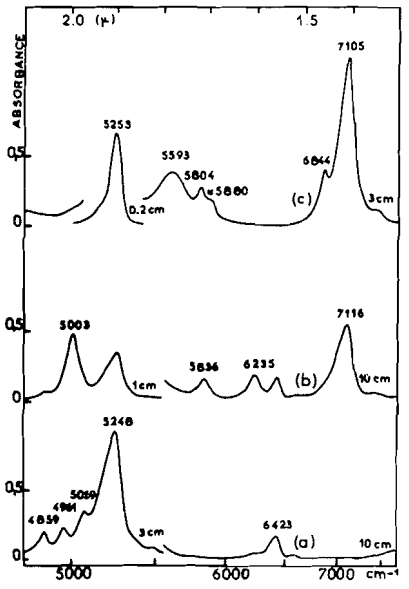

FIG. 2. Spectres d'absorption de H_2O, DHO, et D_2O en solution dans l'acétonitrile-d_3. Concentrations (M): (*a*) D_2O:1 (*b*) D_2O:0.72; DHO:0.25; H_2O:0.03 (*c*) H_2O:1. Les épaisseurs sont indiquées près des spectres.

qu'aux molécules de solvant dans cet échantillon. Les figs. 1 à 5 ont été obtenues en soustrayant le spectre de référence du spectre de mesure, dans les régions où le solvant n'absorbe que modérément: elles représentent à la fois le spectre du soluté et le spectre éventuel des transitions simultanées. La soustraction a été faite soit par le calcul, soit directement par compensation dans les deux faisceaux du spectromètre Cary 14, en utilisant des cuves convenablement appariées.

Le spectre de référence ne peut pas être obtenu exactement, car il dépend des interactions moléculaires avec le soluté. Pour en obtenir la meilleure approximation, nous avons souvent préparé une solution de référence renfermant un volume de tétrachlorure de carbone égal au volume de soluté dans la solution de mesure, le tétrachlorure de carbone étant inerte et n'absorbant pas dans les régions spectrales étudiées. Sous l'épaisseur *e*, le nombre de molécules de solvant contenues dans les échantillons de référence et de mesure est un peu différent si les volumes de mélange soluté–solvant et CCl_4–solvant ne sont pas identiques; l'état de certaines molécules de solvant dans les deux solutions peut aussi être un peu différent. Cependant, nous pensons que les résultats présentés dans les figs. 1 à 5 sont fiables, surtout pour les solutions diluées, parce que nous avons sélectionné les régions spectrales où le solvant est suffisamment transparent et où les absorptions sont peu sensibles aux interactions. Des défauts de compensation dus à des bandes fines de solvant ont parfois été observés sur des absorptions larges du soluté; ils ne faussent pas l'allure générale du spectre du soluté mais interdisent d'en connaître le profil rigoureux; les régions spectrales correspondantes sont repérées par des courbes en tirets (---) dans les figs. 1 à 5.

Pour préparer les solutions, nous avons utilisé les solvants hydrogénés pour spectrophotométrie, de chez Prolabo, desséchés sur tamis moléculaire 4A; dans le cas du chloroforme, du tamis 5A a été ajouté pour éliminer l'alcool. Le pentachlorophénol provenait de chez Eastman Kodak. Les solvants deutériés ont été

fournis par C.E.A. France (taux isotopique 99.3 à 99.8%); l'alcool CD_3OH a été préparé à partir de CD_3OD par hydrolyse de l'alcoolate CD_3ONa. Les solvants deutériés ont été utilisés soit pour prouver l'existence de transitions simultanées, soit uniquement à cause de leur transparence. Nous avons vérifié qu'il n'y avait pas d'échange isotopique entre le soluté et le solvant dans les mélanges étudiés ici. Nous nous sommes assurés en particulier que les bandes entre 5800 et 5900 cm^{-1}, dans le spectre du mélange H_2O–CD_3CN ne sont pas dues à l'apparition d'acétonitrile hydrogéné dont les harmoniques 2νCH pourraient absorber dans cette région. Pour cela nous avons examiné le spectre du solvant ayant servi à préparer la solution, après séchage sur tamis moléculaire 4A. Au contraire, nous avons observé un échange isotopique entre les donneurs de protons et l'acétone-d_6. Nous n'avons pas retenu les résultats obtenus avec les mélanges CH_3OH–$(CD_3)_2CO$ parce que la bande observée vers 5200 cm^{-1} peut être non seulement la transition simultanée νOH(CH_3OH) + νCO($(CD_3)_2CO$), mais aussi l'harmonique 2νOD du méthanol CH_3OD qui apparaîtrait au cours du spectre: l'existence de la transition simultanée, très probable, nécessiterait une étude soignée de la cinétique d'échange pour être prouvée. Cependant, l'échange isotopique est suffisamment lent dans le mélange H_2O–$(CD_3)_2CO$ pour que le spectre puisse être étudié, en particulier vers 6500 cm^{-1}.[4]

Résultats

Nous avons étudié des solutions renfermant comme donneurs de protons RXH(D): le chloroforme (6) (figs. 6 et 7), l'eau (figs. 1 et 2, tableau 1), le pentachlorophénol (fig. 3) et le méthanol (figs. 4 et 5, tableaux 2 à 4), et comme accepteurs R′AB divers solvants: l'acétonitrile, l'acétone, le diméthylsulfoxyde (DMSO), et la pyridine. Afin de comparer les propriétés des mélanges avec ou sans liaison hydrogène, nous avons aussi examiné les solutions de méthanol et de chloroforme dans le sulfure de carbone (figs. 4 et 6, tableau 4), et l'hexachloroacétone.

L'attribution préalable du spectre des molécules RXH en solution dans le tétrachlorure de carbone (figs. 4 et 5, tableau 2) (2, 6), dans les régions où sont attendues les transitions simultanées, permet de discuter l'existence de ces dernières.

Mise en évidence des transitions simultanées

Chloroforme

Une transition simultanée νCH($CHCl_3$) + $\nu_3(CS_2)$ mettant en jeu l'absorption la plus intense du sulfure de carbone vers 1520 cm^{-1} avait déjà été mise en évidence (11, 12). Nous avons également démontré l'existence, dans des mélanges chloroforme–accepteurs de protons, des transitions simultanées apparaissant dans des régions spectrales très différentes: νCH($CHCl_3$) + νCN(CD_3CN), νCH($CHCl_3$) + νCO($(CD_3)_2CO$), et νCH($CHCl_3$) + νSO($(CD_3)_2SO$). Ces résultats ayant déjà fait l'objet d'une communication (6), nous n'en reprendrons pas l'analyse ici.

TABLEAU 1. Transitions simultanées dans les mélanges eau–acétonitrile-d_3 (cm^{-1})

Eau		νOH (D)*	νOH (D) + νCN Calcd†	νOH (D) + νCN Obs*
H_2O	ν_1	3544	5811	5804
	ν_3	3629	5896	≈5880
DHO	νOH	3577	5844	5836
D_2O	ν_1	2593	4860	4859
	ν_3	2698	4965	4961

*Fréquences observées pour le mélange eau (concentration totale ≈ 1 *M*) – acétonitrile-d_3.
†Nous avons utilisé νCN = 2267 cm^{-1}, fréquence correspondant à la solution de CD_3CN (fraction molaire 0.25) dans l'eau.

Eau

Nous avons attribué antérieurement le spectre des molécules H_2O, D_2O, et HOD libres, en solution dans le tétrachlorure de carbone (2). Dans les solutions diluées d'eau dans les solvants accepteurs de protons, l'eau est peu autoassociée et l'examen des transitions fondamentales et harmoniques a permis de montrer que la plupart des molécules d'eau sont engagées dans des complexes 1–2 (R′AB...HOH...BAR′); il ne reste une quantité notable de complexes 1–1 (HOH...BAR′) que si la molécule de base est assez encombrante (2, 5, 18).

Transitions νOH(H_2O) + νCH (base) vers 6500 cm^{-1} (fig. 1)

Dans la région de l'harmonique 2νOH, le spectre de la molécule H_2O en solution dans un solvant basique hydrogéné comporte toujours deux massifs d'absorption vers 7000 et 6500 cm^{-1} (fig. 1) (2, 19–22). En opposition, il n'existe pas d'absorption distincte vers 6500 cm^{-1} si l'on utilise un solvant complètement deutérié, toutes les autres conditions d'enregistrement étant identiques (courbes en pointillé).

Le fait que les spectres de l'eau dépendent de la substitution isotopique du solvant prouve que la bande vers 6500 cm^{-1} ne correspond pas

[4]Cet échange devient rapide dans les mélanges H_2O–$(CD_3)_2CO$–CCl_4. Une étude récente (17) est consacrée à la catalyse de la dédeutération de l'acétone-d_6 en milieu acide ou basique.

uniquement à des vibrations internes de la molécule d'eau: cette bande doit être attribuée à des transitions de combinaisons mettant en jeu simultanément des vibrations de H_2O et de la base. Les seules vibrations qui soient communes à toutes les bases hydrogénées sont celles des groupements CH_3 (ou CH de la pyridine). En effet, les squelettes des molécules utilisées sont très différents: CCN, CCO, CSO, C_5N. De plus, la somme des fréquences vOH + vCH (fig. 1) est de l'ordre de 6500 cm^{-1}. Nous attribuons donc la bande vers 6500 cm^{-1} à la transition simultanée $\nu OH(H_2O) + \nu CH$ (base) (6). Des observations et une attribution analogues ont été faites par Rossarie *et coll.* pour des mélanges d'alcools et d'acétonitrile (14).

Pour les mélanges eau–base hydrogénée, les interprétations antérieures de la bande vers 6500 cm^{-1} doivent être révisées (2, 19–21). En particu-

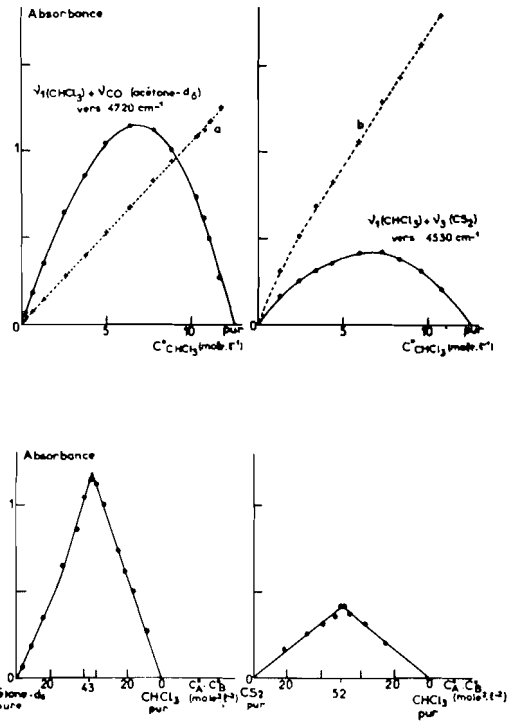

FIG. 6. Evolution de l'absorbance des transitions simultanées pour les mélanges chloroforme–acétone-d_6 (à gauche) et chloroforme – sulfure de carbone (à droite) en fonction de la concentration en chloroforme (en haut) et du produit des concentrations des deux constituants du mélange (en bas). Epaisseur de cuve = 2 cm.

Pour comparaison, courbes en pointillés: (*a*) bande ($\nu_1 + 2\nu_4$) du chloroforme en solution dans le tétrachlorure de carbone, composante vers 5413 cm^{-1}; (*b*) bande ($2\nu_1 + \nu_4$) du chloroforme en solution dans le sulfure de carbone, vers 7075 cm^{-1}.

lier, il n'est pas évident que l'harmonique $2\nu_1(H_2O)$ se situe dans cette région, comme nous l'avions d'abord admis à la suite de Greinacher *et coll.* (2, 19).

Transitions $\nu OH(D)$ (eau) + $\nu CN(CD_3CN)$ (fig. 2)

Pour les mélanges H_2O–CD_3CN (courbe *c*) on ne peut trouver aucune transition intramoléculaire entre 5300 et 6400 cm^{-1}, en combinant les fréquences des vibrations fondamentales de la molécule d'eau soit 1633, 3544, et 3629 cm^{-1}. Les bandes à 5593, 5804, et vers 5880 cm^{-1} doivent donc impliquer d'autres degrés de libertés que ceux correspondant aux seules vibrations internes de H_2O. Nous attribuons les absorptions vers 5804 et 5880 cm^{-1} aux transitions $\nu_1(H_2O)$ + $\nu CN(CD_3CN)$ et $\nu_3(H_2O)$ + $\nu CN(CD_3CN)$ (tableau 1). Il faut remarquer qu'il y a dégénérescence accidentelle entre les vibrations $\nu_a CD_3$ et νCN dans la molécule CD_3CN à l'état liquide (23); il y a donc ambiguïté entre les attributions ν_1 + νCN, ν_3 + νCN, et ν_1 + $\nu_a CD_3$, ν_3 + $\nu_a CD_3$. La bande à 5593 cm^{-1} est observée à la fois dans les mélanges H_2O–CH_3CN et H_2O–CD_3CN, elle ne peut donc être attribuée à une transition simultanée $\nu(H_2O)$ + $\nu_s CD_3$; par ailleurs, la somme des fréquences correspondrait mal. Nous avons en outre observé une absorption analogue pour toutes les solutions de H_2O dans un solvant basique suffisamment transparent; nous l'attribuons à la combinaison $\delta(H_2O)$ + $\nu(H_2O)$ + ν_L entre les vibrations de valence et de déformation de l'eau et les mouvements librationnels du complexe.[5]

Pour les solutions D_2O–CD_3CN (courbe *a*) on observe quatre bandes dans la région 2νOD vers 4700–5500 cm^{-1}. Les bandes à 5069 et 5248 cm^{-1} sont tout à fait analogues aux deux absorptions à 6844 et 7105 cm^{-1} observées pour H_2O dans la région 2νOH (courbe *c*) et sont donc attribuables à des transitions intramoléculaires de même que l'absorption à 6423 cm^{-1}.[6] Mais celles à 4859 et 4961 cm^{-1} n'ont pas leur équivalent dans le spectre de H_2O.[6] Bien qu'un certain nombre de transitions impliquant les seules vibrations de D_2O puissent apparaître dans cette région, il est probable que leur contribution est faible, comme pour H_2O. Nous attribuons les bandes à 4859 et 4961 cm^{-1} aux transitions ν_1 (D_2O) + ν CN(CD_3CN), et ν_3 (D_2O) + ν CN(CD_3CN): les fréquences observées sont extrêmement voisines des fréquences calculées en faisant la somme des fréquences des vibrations fondamentales (tableau 1).

Le spectre (*b*) correspond essentiellement à une solution de HOD et de D_2O dans CD_3CN. En faisant la corrélation avec le spectre de D_2O seul (courbe *a*), on constate que les bandes à 5003, 6235, 7116, et 5836 cm^{-1} mettent en jeu la molécule HOD mais pas D_2O. Les trois premières sont attribuables à des combinaisons des vibrations internes de cette molécule;[6] mais on n'observe aucune absorption notable de HOD entre 5500 et 6000 cm^{-1}, que ce soit à l'état gazeux (24), en solution dans le CCl_4 (2) ou dans l'acétone-d_6. Par contre, la valeur 5836 cm^{-1} correspond assez bien à la somme νOH(HOD) + νCN(CD_3CN). Il est logique que cette absorption n'apparaisse que dans l'acétonitrile et à une fréquence intermédiaire entre celle des transitions ν_1 + νCN et ν_3 + νCN du complexe CD_3-CN...HOH...NCCD_3.

[5]L'écart de fréquence entre la transition (ν_2 + ν_3) à 5253 cm^{-1} et la bande à 5593 cm^{-1} est en effet du même ordre de grandeur que la fréquence de la bande observée vers 400 cm^{-1} pour les solutions de H_2O dans l'acétonitrile (43) et attribuée à des mouvements librationnels (résultats à paraître).

[6]Résultats à paraître.

Pentachlorophénol

Parmi les donneurs de protons RXH étudiés, nous avons choisi le pentachlorophénol parce que le groupement R ne renferme aucun atome d'hydrogène, comme dans le cas du chloroforme (6): ceci facilite l'examen du spectre dans le proche infrarouge. Le groupement OH du pentachlorophénol est plus acide que ceux des autres chlorophénols (25, 26): il est susceptible de former une liaison hydrogène relativement forte même avec l'acétonitrile.

Pour le pentachlorophénol en solution dans le tétrachlorure de carbone, la vibration de valence ν OH est à une fréquence relativement faible, 3525 cm^{-1} parce qu'il y a chélation sur les atomes de chlore en ortho (27, 28). Au-dessus de 3950 cm^{-1}, on observe en plus de l'harmonique 2νOH à 6869 cm^{-1}, trois groupes de combinaisons (A, B, et C) impliquant la vibration νOH et centrés respectivement vers 4200, 4750, et 5950 cm^{-1}.

Pour le pentachlorophénol en solution dans l'acétonitrile-d_3, la bande correspondant à la vibration νOH subit une diminution de fréquence de 225 cm^{-1} et est fortement élargie par rapport à la solution dans le tétrachlorure de carbone; en dessous de 1600 cm^{-1}, les autres vibrations mises en jeu dans les combinaisons A, B, et C sont peu perturbées. On comprend donc que les absorptions vers 3971 et 4520 cm^{-1} ne soient plus résolues et aient subi une diminution de fréquence de 200–250 cm^{-1}, tandis que la diminution est double pour la bande 2νOH à 6446 cm^{-1}.[7] Deux attributions peuvent être proposées pour la bande à 5563 cm^{-1}: elle peut correspondre soit au massif C, soit à la transition simultanée νOH (pentachlorophénol) + νCN(CD_3CN). Si l'on admet que la bande à 5563 cm^{-1} correspond au massif C, il convient d'expliquer que l'abaissement de fréquence soit de près de 400 cm^{-1} par rapport à la solution dans le tétrachlorure de carbone, soit environ 150 cm^{-1} trop grand. Pour cela on peut invoquer une résonance de premier ordre entre les niveaux 2νOH et les transitions du groupe C. Mais il nous paraît étonnant qu'une résonance puisse avoir un tel effet sur les fréquences, surtout lorsque les maximums des deux bandes sont séparés de près de 900 cm^{-1}. Par contre, la fréquence 5563 cm^{-1} correspond à la somme νOH (pentachlorophénol) + νCN-(CD_3CN) dans le mélange pentachlorophénol–acétonitrile-d_3. Il est donc probable que cette transition simultanée intervienne dans le spectre de ce mélange.

Méthanol

Le tableau 2 contient l'attribution, au-dessus de 4700 cm^{-1}, des principales absorptions des molécules CH_3OH et CD_3OH en solution dans le tétrachlorure de carbone. La valeur des coefficients d'anharmonicité rassemblés dans le tableau 3 indique que cette attribution est raisonnable.[8] Les bandes les plus intenses sont les combinaisons intramoléculaires νOH + δOH, νOH + δCH_3 (CD_3), et 2νOH (fig. 4). Pour CH_3OH, le massif compris entre 5670 et 6020 cm^{-1} (fig. 5) peut correspondre à de nombreuses transitions: $2\nu CH_3$, $\nu CH_3 + 2\delta CH_3$, $\nu CH_3 + 2\delta$OH. Dans les régions des combinaisons νOH + νCH_3 (fig. 4*a*) et νOH + νCD_3 (fig. 5), $\nu_1 + \nu_3$ est la plus intense (14). Signalons que les fréquences que nous avons mesurées pour ces absorptions diffèrent notablement de celles reportées par Rossarie *et coll.* (14), probablement à cause d'une erreur d'étalonnage de ces derniers.

Solutions dans le sulfure de carbone (fig. 4a)

Les spectres des méthanols en solution dans le sulfure de carbone sont tout à fait semblables à ceux observés pour les solutions dans le tétrachlorure de carbone: la plupart des absorptions ne subissent qu'un faible déplacement de fréquence (tableau 2). Cependant, le spectre de CD_3OH comporte une absorption supplémentaire à 5149 cm^{-1} qui correspond exactement à la transition simultanée ν_1 (CD_3OH) + ν_3 (CS_2) (tableau 4). Le spectre de la solution de CH_3OH dans le sulfure de carbone comporte une épaule nette vers 5140 cm^{-1} qui s'interprète aussi comme la transition simultanée ν_1 (CH_3OH) + ν_3 (CS_2).

Solutions dans l'acétonitrile (figs. 4b et 5)

Dans une solution méthanol–acétonitrile de concentration 0.8 *M* en méthanol, celui-ci est peu autoassocié puisque l'on n'observe qu'une faible épaule vers 3450 cm^{-1} (31). Les vibrations intramoléculaires les plus perturbées sont ν_1, qui diminue d'environ 100 cm^{-1}, et ν_6 qui augmente de 50 cm^{-1} par rapport aux solutions dans

[7]L'allure de la bande côté haute fréquence semble indiquer que certains groupements OH, en faible proportion, restent chélatés en solution dans l'acétonitrile.

[8]La transition $2\nu_1 + \nu_6$ permet d'obtenir des valeurs de x_{11}, à l'aide de la relation [4] de la référence 4, en excellent accord avec celles déjà connues (30) qui sont fournies par les éqs. 1 à 3 (4).

le tétrachlorure de carbone.[9] D'autres modifications du spectre peuvent correspondre à l'apparition de transitions simultanées.

Le spectre de CD_3OH dans l'acétonitrile-h_3 comporte une bande à 6503 cm^{-1} qui n'existe pas pour les solutions du même alcool dans l'acétonitrile-d_3 (fig. 4*b*). Ce phénomène a aussi été observé pour l'éthanol et le cyclohexanol par d'autres auteurs (14) et nous l'avons discuté ci-dessus dans le cas de l'eau: la bande à 6503 cm^{-1} correspond à la transition simultanée $\nu_1(CD_3OH) + \nu CH_3(CH_3CN)$ (tableau 4). Cette bande est aussi observée vers 6485 cm^{-1} pour CH_3OH; mais dans ce cas, elle se superpose aux combinaisons intramoléculaires ($\nu_1 + \nu CH_3$) de CH_3OH dont l'absorption propre peut être repérée vers 6470 et 6383 cm^{-1} à partir de la solution dans l'acétonitrile-d_3. Pour la solution de CD_3OD dans l'acétonitrile-h_3, nous avons observé la transition simultanée équivalente, soit $\nu_1(CD_3OD) + \nu CH_3(CH_3CN)$, vers 5555 cm^{-1}. Rossarie *et coll.* ont admis que seule la vibration ν_s CH_3 de l'acétonitrile contribue à ces absorptions (14); les résultats portés dans le tableau 4 suggèrent en effet que la contribution de ν_s CH_3 à 2942 cm^{-1} est la plus grande, mais nous ne pouvons pas affirmer, à la précision de nos mesures, que celle de $\nu_a CH_3$ soit négligeable.

La mise en évidence des transitions simultanées $\nu OH + \nu CN$ vers 5800 cm^{-1} est plus délicate parce que les alcools absorbent dans cette région. Pour CD_3OH en solution dans l'acétonitrile-d_3, l'absorption entre 5600 et 5900 cm^{-1} (fig. 5) n'est pas attribuable uniquement au massif ($\nu_1 + \nu CD_3$) de CD_3OH, parce que ce massif a subi, comme ν_1, une diminution de fréquence d'environ 100 cm^{-1} par rapport à la solution dans le tétrachlorure de carbone, et que l'absorption la plus intense est probablement du côté des basses fréquences comme dans le tétrachlorure de carbone. Nous pensons donc que la transition $\nu_1(CD_3OH) + \nu CN(CD_3CN)$ contribue à la bande à 5808 cm^{-1}. Pour CH_3OH, on attend que le massif entre 5600 et 6100 cm^{-1} (fig. 5) soit peu modifié, quand on passe du tétrachlorure de carbone à l'acétonitrile comme solvant, dans la mesure où il ne fait pas intervenir la vibration νOH. L'augmentation d'intensité très nette vers 5808 cm^{-1} correspond donc à la transition $\nu_1(CH_3OH) + \nu CN(CD_3CN)$, à la même fréquence que $\nu_1(CD_3OH) + \nu CN$.

Nous avons aussi observé, pour CD_3OD en solution dans l'acétonitrile-h_3 et -d_3, deux bandes à 4877 et 4885 cm^{-1} que nous attribuons à $\nu_1(CD_3OD) + \nu CN(CH_3CN)$ et $\nu_1(CD_3OD) + \nu CN(CD_3CN)$ (tableau 4), plutôt qu'aux combinaisons ($\nu_1 + \nu CD_3$) de CD_3OD parce que celles-ci sont attendues à une fréquence plus petite. Nous avons aussi vérifié que ces bandes n'étaient pas attribuables à la combinaison ($\nu_1 + \nu_6$) de CD_3OH provenant de l'échange partiel de CD_3OD: aucune absorption appréciable n'apparaissait dans la région $2\nu OH$, vers 7030 cm^{-1}. L'intensité des deux bandes à 4885 et 4877 cm^{-1} est très voisine: la contribution des vibrations $\nu_a CD_3$ de CD_3CN est donc beaucoup plus faible que celle de la vibration νCN.

Discussion

Il n'est pas facile de prouver l'existence de transitions simultanées. D'une part les deux constituants du mélange sont rarement assez transparents. Nous n'avons observé avec certitude que des transitions simultanées impliquant des vibrations de valence (tableau 5) parce qu'elles apparaissent dans les régions spectrales les plus favorables et sont peut-être les plus intenses. D'autre part, il est d'autant plus difficile de mettre en évidence une transition simultanée que la liaison hydrogène est forte, à cause de l'élargissement des bandes. Par exemple, pour le mélange HCl–acétonitrile, nous n'avons pas pu délimiter une région spectrale où l'absorption ne correspondrait qu'à une transition simultanée, alors que la transition $\nu HCl + \nu_3(CS_2)$ serait vraisemblablement observable. Nous avons néanmoins démontré l'existence de transitions $\nu OH + \nu R'$ dans des mélanges H_2O – bases R'AB, $\nu CH + \nu AB$ dans des mélanges $CHCl_3$–R'AB (6), et $\nu OH + \nu CN$ dans H_2O–acétonitrile. Nous avons aussi montré que l'interprétation du spectre dans le proche infrarouge peut être erronée si l'on ne tient compte que des vibrations intramoléculaires.

Nature des molécules impliquées dans les transitions simultanées

Les transitions simultanées observées en solution entre deux molécules A et B, éventuellement susceptibles d'interactions par liaison hydrogène,

[9]L'harmonique $2\nu OH$ devient très large ($\Delta\nu_{1/2} \approx$ 300 cm^{-1}) et si dissymétrique qu'on ne peut donner une signification précise aux fréquences et aux coefficients d'anharmonicité obtenus à partir des maximums d'absorption et portés entre parenthèses dans les tableaux 2 et 3.

TABLEAU 5. Coefficients d'extinction apparents approchés des bandes de transitions simultanées observées $\nu_s + \nu_{s'}$*

ν_s	ν_3 CS_2	νCO $(CCl_3)_2CO$	νCN CD_3CN	νCO $(CD_3)_2CO$	νSO $(CD_3)_2SO$	νCH CH_3CN	νCH $(CH_3)_2CO$	νCH $(CH_3)_2SO$	νCH C_5H_5N
νCH ($CHCl_3$)	6	<1	3	13	21				
νCD ($CDCl_3$)	3								
ν_1 } (H_2O)			7			3	4	6	6
ν_3 }			4						
ν_1 } (D_2O)			5						
ν_3 }			4						
νOH (HOD)			6						
νOH (CH_3OH)	4					2			
νOH(CD_3OH)	5		~7			2			
νOD (CD_3OD)			~6			~2			
νOH (C_6Cl_5OH)			8						

*Unités: $100 \times \varepsilon$(l mol^{-1} cm^{-1}), avec $\varepsilon = (1/cl) \log_{10} (I_0/I)$. Ces coefficients d'extinction sont apparents parce qu'ils ne tiennent pas compte des molécules non complexées: on a en effet utilisé pour concentration celle du soluté introduit dans la solution. D'autre part ces valeurs sont approchées et ne peuvent donner qu'une idée approximative des rapports d'intensité, d'autant plus que la largeur des bandes de transitions simultanées peut être très différente suivant les cas: par exemple $\Delta\nu_{1/2}$ est environ trois fois plus grand pour la bande νOH(C_6Cl_5OH) + νCN(CD_3CN) que pour νOH(HOD) + νCN(CD_3CN).

TABLEAU 6. Intensités approximatives de quelques transitions infrarouges* et Raman†

	CS_2	R′AB $(CCl_3)_2CO$	CD_3CN	CH_3CN	$(CD_3)_2CO$	$(CD_3)_2SO$	$(CH_3)_2SO$
νAB(R′AB)	418‡ (0)	42		2§ (75)	115		122
νCH($CHCl_3$)	4 (31)	5	21		39	75	

*Les intensités infrarouges sont exprimées en 10^8 A (cm^2 molécule^{-1} s^{-1}) avec $A = 1/cl \int \log_n (I_0/I)\, d\nu$ (32). Sauf indication contraire, les intensités des bandes νAB de R′AB et νCH de $CHCl_3$ ont été obtenues respectivement à partir de solutions de R′AB dans le chloroforme et de $CHCl_3$ dans R′AB. Pour νAB, ces valeurs sont approximatives car nous avons tenu compte de l'ensemble des absorptions auxquelles peuvent contribuer ces vibrations.

†On a porté entre parenthèses quelques valeurs de $g_j(45\alpha_j'^2 + 7\gamma_j'^2)$ en (cm^4 g^{-1}) obtenues à l'état gazeux, d'après la référence 33.

‡Il s'agit de l'intensité de la bande ν_3 (CS_2) d'après la référence 34.

§D'après la référence 32.

peuvent se faire soit entre deux molécules voisines A et B libres (hypothèse I), soit à l'intérieur d'un complexe (hypothèse II), soit entre la molécule A dans un complexe et une molécule B de la couche de solvatation de ce complexe (hypothèse III).

Les tableaux 1 et 4 montrent que les vibrations νXH impliquées dans les transitions simultanées observées sont celles des vibrateurs associés. Mais il est difficile de préciser, par l'examen des fréquences, si les groupements AB ou R′ appartiennent à une molécule R′AB complexée (II) ou non (III): ces groupements peuvent en effet contribuer à plusieurs vibrations (fig. 1) (6, 35) et sont peu sensibles à la formation de liaisons hydrogène faibles.

Pour le mélange chloroforme–acétone, la formation de liaisons hydrogène ne peut pas être détectée par l'examen des fréquences mais seulement par l'augmentation d'intensité de la bande νXH (tableau 6) (36). Nous avons néanmoins essayé d'établir une corrélation entre l'intensité des transitions simultanées et la quantité de complexes dans le mélange. On peut en effet faire varier la concentration en complexes, suivant les lois des équilibres, soit en fonction des proportions du mélange binaire, soit en diluant ce mélange par un solvant inerte.

Influence de la proportion du mélange

Nous avons repris une étude analogue à celle que Ketelaar et Hooge ont faite pour le mélange CS_2–Br_2 (11). Nous espérions obtenir des conclusions plus nettes avec le mélange chloroforme–acétone parce que les interactions y sont probablement plus fortes que pour CS_2–Br_2. Pour comparaison, nous avons examiné le mélange chloroforme – sulfure de carbone.

Pour les mélanges sans interaction importante (I), nous admettons, par analogie avec la théorie cinétique des gaz, que l'absorbance de la transition simultanée est proportionnelle au

For personal use only.

nombre de chocs moléculaires par unité de volume, donc au produit des concentrations $C_A{}^0 C_B{}^0$ des constituants A et B introduits dans le mélange (37). Au contraire, si les transitions simultanées se font à l'intérieur d'un complexe (II), leur absorbance dépend de la constante d'équilibre comme la concentration en complexes C_{AB}. Avec l'hypothèse III, on attendrait un résultat intermédiaire, l'absorbance étant proportionnelle au produit $C_{AB}C_B$ dans le mélange.

Nos résultats (fig. 6) ne permettent pas de mesurer la concentration correspondant au maximum d'absorbance de la transition simultanée avec suffisamment de précision pour choisir entre les hypothèses I et II, suivant les critères définis dans la référence (11). La variation d'absorbance est plus près d'une droite si l'on utilise comme variable le produit des concentrations des constituants A et B, plutôt que la concentration d'un seul constituant; mais l'interprétation détaillée des courbes est compliquée par la présence éventuelle de complexes 2–1 (38). Toutefois la fig. 6 a l'intérêt de prouver l'existence des transitions simultanées d'une façon indépendante de celle utilisée plus haut, puisque leur absorbance passe par un maximum contrairement à celle des transitions intramoléculaires.

Effet de dilution

Dans l'hypothèse I, l'absorbance par unité de longueur est inversement proportionnelle au carré du volume

$$[1] \qquad \frac{A}{l} = aC_A{}^0 C_B{}^0 = a\frac{n_A{}^0 n_B{}^0}{V^2}$$

Dans l'hypothèse II, on a, pour un complexe 1–1:

$$[2] \quad \frac{A}{l} = a'C_{AB} = \frac{a'}{2V}\left\{\left(n_A{}^0 + n_B{}^0 + \frac{V}{K_c}\right) \pm \left[\left(n_A{}^0 + n_B{}^0 + \frac{V}{K_c}\right)^2 - 4n_A{}^0 n_B{}^0\right]^{1/2}\right\}$$

en utilisant la constante K_c exprimée en fonction des concentrations.

La fig. 7 représente l'effet de dilution par le tétrachlorure de carbone sur les transitions $\nu_1(CHCl_3) + \nu CO((CD_3)_2CO)$ et $(\nu_1 + 2\nu_4)$ du chloroforme. L'absorbance de cette dernière transition est inversement proportionnelle au volume, suivant la loi de Beer-Lambert (courbe en trait plein). Au contraire pour la transition simultanée, la variation d'absorbance n'est linéaire ni en $1/V$, ni en $1/V^2$. Ces résultats

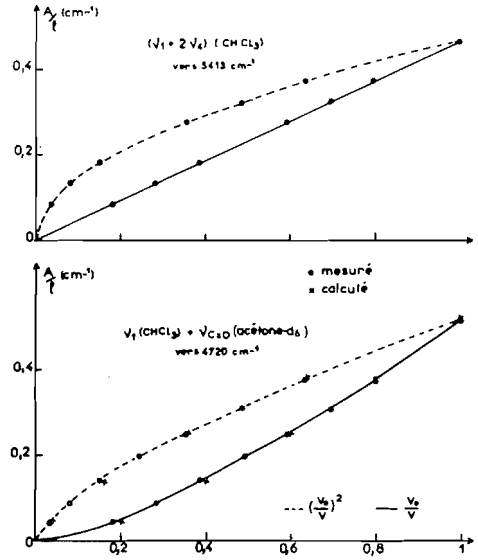

FIG. 7. Effet de la dilution par le tétrachlorure de carbone sur l'intensité de la transition νCH + νCO, dans le mélange chloroforme–acétone-d_6 (en bas) et sur la combinaison $(\nu_1 + 2\nu_4)$ du chloroforme en solution dans le tétrachlorure de carbone (en haut). Fraction molaire en $CHCl_3$ = 0.68, dans le mélange binaire initial de volume V_0.

indiquent que les transitions simultanées mettent bien en jeu au moins une molécule complexée. Les résultats expérimentaux sont en assez bon accord avec les points obtenus par le calcul, en utilisant dans la formule 2 la valeur $K_c = 0.21$ mol^{-1} applicable au complexe 1–1 (36, 39, 40); mais on n'en tirera pas argument pour l'hypothèse II à cause de l'existence possible d'une certaine proportion de complexe 2–1 dans le mélange.

Influence de la force de la liaison hydrogène sur l'intensité des transitions simultanées

Un modèle électrostatique simple a permis de formuler des règles de sélection pour les transitions simultanées dans les phases denses (8, 9, 41). Selon ce modèle, l'interaction électrique a lieu entre deux molécules voisines A et B. En première approximation, on peut se limiter au moment dipolaire induit directement par A dans B et par B dans A: l'existence de transitions $\nu_s + \nu_{s'}$ est due à la non nullité des produits:

$$\left(\frac{\partial\alpha}{\partial q_s}\right)_A\left(\frac{\partial\mu}{\partial q_{s'}}\right)_B \quad \text{et} \quad \left(\frac{\partial\alpha}{\partial q_{s'}}\right)_B\left(\frac{\partial\mu}{\partial q_s}\right)_A, \; q_s \text{ et } q_{s'}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

étant des coordonnées normales des molécules A et B, α et μ étant la polarisabilité et le moment dipolaire de ces molécules. Dans cette approximation, on peut observer des transitions simultanées même si les deux molécules ne sont pas polaires; mais il est nécessaire que l'une au moins des deux vibrations considérées ν_s et $\nu_{s'}$ soit active en infrarouge et l'autre en Raman (41). Cependant, en deuxième approximation, il faudrait tenir compte du moment créé "en retour" (8): on pourrait alors observer des transitions simultanées même si, pour les molécules isolées, les deux vibrations considérées ne sont actives qu'en Raman et pas en infrarouge, à condition que l'une au moins des molécules ait un moment dipolaire permanent. En résumé les principaux paramètres qui déterminent l'intensité des transitions simultanées dans deux molécules A et B sont la distance entre ces molécules, leur orientation relative, la variation de leur moment dipolaire et de leur polarisabilité au cours des vibrations considérées.

On peut se demander si la liaison hydrogène renforce l'intensité des transitions simultanées. Les résultats du tableau 5 ne permettent pas de déductions précises. On constate toutefois que l'intensité des transitions simultanées pour les solutions de chloroforme augmente dans l'ordre de basicité du solvant, soit hexachloroacétone,[10] acétonitrile, acétone, et DMSO (tableau 5 et réf. 6). Cependant la force de la liaison hydrogène n'est pas le seul paramètre qui change entre ces solutions. Le fait que l'intensité infrarouge de $\nu_3(CS_2)$ est environ 200 fois plus grande que celle de $\nu CN(CH_3CN)$ (tableau 6) peut expliquer que la transition $\nu CH(CHCl_3) + \nu_3(CS_2)$ soit plus intense que $\nu CH(CHCl_3) + \nu CN(CD_3CN)$, contrairement à ce que laisserait prévoir la force de la liaison hydrogène. D'un autre côté, la transition $\nu CH(CHCl_3) + \nu SO((CD_3)_2SO)$ est beaucoup plus intense que $\nu CH(CHCl_3) + \nu_3(CS_2)$, bien que $\nu_3(CS_2)$ soit nettement plus intense en infrarouge que νSO; mais il faut remarquer que le terme

$$\left(\frac{\partial\alpha}{\partial q_{AB}}\right)_{R'AB}\left(\frac{\partial\mu}{\partial q_{CH}}\right)_{CHCl_3}$$

intervient pour les transitions $\nu CH + \nu AB$ mais pas pour $\nu CH + \nu_3(CS_2)$ puisque $(\partial\alpha/\partial q_3)_{CS_2}$ est nul. Ainsi la liaison hydrogène favorise probablement les transitions simultanées, non seulement en contribuant au rapprochement des molécules mais aussi par l'augmentation de $\partial\mu/\partial q$ qu'elle entraîne toujours pour les vibrations νXH et qui est illustrée pour le chloroforme dans le tableau 6.

En utilisant l'acétone-d_6 et l'hexachloroacétone, nous avons choisi des solvants de basicités très différentes, mais les plus voisins possible du point de vue des propriétés infrarouge et Raman. L'observation de la transition $\nu CH(CHCl_3) + \nu CO((CCl_3)_2CO)$ est incertaine; mais, si elle existe, elle est au moins 10 à 20 fois moins intense que $\nu CH(CHCl_3) + \nu CO((CD_3)_2CO)$. Malheureusement ce résultat ne permet pas de prouver définitivement le rôle particulier de la liaison hydrogène dans les transitions simultanées; en effet, la bande νCO de l'hexachloroacétone est deux à trois fois moins intense en infrarouge, et environ cinq fois moins intense en Raman, que celle de l'acétone-d_6.

En conclusion, remarquons que la contribution des transitions simultanées au spectre d'absorption dans le proche infrarouge peut être importante: ainsi, la fig. 1 montre que, pour le mélange eau–DMSO, la bande $\nu OH + \nu CH_3$ n'est pas beaucoup plus faible que celle correspondant à toutes les transitions intramoléculaires $2\nu_1$, $\nu_1 + \nu_3$, $2\nu_2 + \nu_3$,... de H_2O qui absorbent dans cette région. Nous avons aussi constaté que la transition $\nu CH(CHCl_3) + \nu SO((CD_3)_2SO)$ est plus intense que l'harmonique $2\nu CH$ du chloroforme dilué dans le DMSO-d_6 (6).

Nous exprimons notre gratitude à Mademoiselle Josien, Professeur à l'Université de Paris VI, pour l'intérêt avec lequel elle a suivi l'ensemble de ce travail.

[10]Il a déjà été remarqué que les halogénocétones sont peu basiques (42). Nous-mêmes avons observé que la fréquence νOH du pentachlorophénol en solution dans l'hexachloroacétone, vers 3522 cm^{-1}, est pratiquement la même que pour la solution dans le tétrachlorure de carbone: ceci indique que le pentachlorophénol y reste essentiellement chelaté. L'hexachloroacétone est donc beaucoup moins basique que l'acétonitrile dans lequel la fréquence νOH du pentachlorophénol est de 3300 cm^{-1} environ.

One of the compounds obtained by reacting acetylacetone with oxoethoxodichlorobis(triphenylphosphine)rhenium(V) has been shown by single crystal X-ray diffraction to be *trans*-dichlorobis(pentane-2,4-dionato)rhenium(IV). The crystals are triclinic, $a = 8.032(4)$, $b = 8.344(6)$, $c = 7.429(6)$ Å, $\alpha = 118.1(2)$, $\beta = 92.3(2)$, $\gamma = 55.5(2)°$, $P\bar{1}(C_i^1$, No. 2), $Z = 1$. Intensities were measured with a microdensitometer from photographs recorded on an integrating precession camera. Of the 991 measured reflections all were observed and 984 were used in the refinement. The structure was refined by full matrix least squares to an R_2 value of 0.0685. The compound was found to be a *trans*-monomer, in contrast to the dimeric structure claimed to exist in solution. The ligand atoms bonded to rhenium lie almost exactly at the apices of an octahedron and the bond lengths (Re—Cl, 2.326(8); Re—O1, 1.97(1); Re—O2, 2.01(1) Å) are in the range expected.

La diffraction de rayons X sur monocristal a montré que l'un des composés obtenu dans la réaction de l'acétylacétone sur l'oxoethoxodichlorobis(triphénylphosphine)rhénium(V) est le *trans*-dichlorobis(pentanedionato-2,4)rhénium(IV). Les cristaux sont tricliniques avec $a = 8.032(4)$, $b = 8.344(6)$, $c = 7.429(6)$ Å, $\alpha = 118.1(2)$, $\beta = 92.3(2)$, $\gamma = 55.5(2)°$, $P\bar{1}(C_i^1$, No. 2), $Z = 1$. Les intensités ont été mesurées avec un microdensimètre à partir des photos enregistrées sur une caméra intégratrice en précession. Les 991 réflexions mesurées ont toutes été observées et 984 d'entre elles ont été utilisées dans le raffinement. La structure a été raffinée par la matrice des moindres carrés jusqu'à une valeur de R_2 de 0.0685. Le composé est un monomère *trans*, contrairement à la structure dimère qu'on pensait exister en solution. Les atomes de ligands liés au rhénium sont presque exactement sur les sommets de l'octaèdre et les longueurs de liaison (Re—Cl, 2.326(8); Re—O1, 1.97(1); Re—O2, 2.01(1) Å) sont dans l'intervalle attendu.

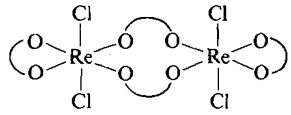
Introduction

Several types of β-ketoenolate complexes of rhenium have been synthesized (2, 3). Many of these complexes synthesized by Grove *et al.* (3) can exist in different isomeric forms. In order to understand the mechanism of the unusual reaction which gives rise to so many different products it is necessary to know, at least, the detailed molecular structure of the products. To this end we have examined the crystal structures of the reaction products by single crystal X-ray methods.

The product obtained by the reaction of oxodichloroethoxobis(triphenylphosphine)rhenium(V) with refluxing acetylacetone was claimed to be $[ReCl_2(C_5H_7O_2)_2]_2$ (3). Analysis indicated the stoichiometry was $ReCl_2(C_5H_7O_2)_2$ and molecular weight determinations in solution indicated that the material was dimeric. On the basis of infrared spectra and simple arguments about probable coordination numbers of the rhenium atoms the following structure was proposed.

[1]A preliminary report of the structure of the compound appeared in ref. 1.

[2]To whom correspondence should be addressed.



The structure contains two bridging acetylacetonate groups bonded to the rhenium atoms through the oxygen atoms (3). However, no X-ray structure work was reported. Preliminary X-ray work has shown that the compound is a monomer in the solid state and should be named *trans*-dichlorobis-(2,4-pentanedionato)rhenium (IV) (1) and more recently it has been shown the monomeric *trans* structure exists in solution and in the gas phase (4). We describe here the refinement of the crystal structure of this compound.

Experiments

Analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee.

Rhenium metal was obtained from the Rhenium Divison, Chase Brass and Copper Co. Inc., Solon, Ohio. Perrhenic acid was obtained as a solution from S. W. Shattuck Chemical Co., Denver, Colorado. Both materials were used to prepare samples of the grey-green isomer of oxoethoxodichlorobis(triphenylphosphine)rhenium(V) starting material (5). The products of the two reactions were identical. *trans*-Dichlorobis(pentane-2,4-dionato)rhenium(IV) was prepared by the method used by Grove *et al.* (3) to prepare "tetrachlorobis(pentane-2,4-dionato)-μ_2-(pentane-2,4-dionato)dirhenium(IV)."

Anal. calcd. for $C_{10}H_{14}Cl_2O_4Re$: C, 26.4; H, 3.1; Cl, 15.6. Found: C, 26.6; H, 3.1; Cl, 16.1.

Orange plate-like single crystals, suitable for X-ray studies were obtained by slow evaporation of a solution in a 75:25 v/v benzene – carbon tetrachloride solvent mixture at 26–27 °C.

X-Ray Studies

A crystal ($0.15 \times 0.4 \times 0.6$ mm^3) showing uniform extinction under a polarizing microscope was chosen for structural studies. It was mounted along the direction of the longest dimension. Precession photographs of the crystal showed it was triclinic. Precession photographs of the zero layers along [100] and [1$\bar{2}\bar{1}$] were calibrated with a crystal of TiO_2 (rutile) ($a = 4.5929(5)$, $c = 2.9591(3)$ Å (6)) and accurate parameters were calculated. The density of a few crystals were determined by flotation in a tetrabromoethane – carbon tetrachloride mixture. Crystal data are

$C_{10}H_{14}Cl_2O_4Re$ f.w. = 455.3

Triclinic, $a = 8.032(4)$, $b = 8.344(6)$, $c = 7.429(6)$ Å, $\alpha = 118.1(2)$, $\beta = 92.3(2)$, $\gamma = 55.5(2)°$, $V = 334.0$ Å^3, $P\bar{1}(C_i^1$, No. 2), $\rho_o = 2.18$, $Z = 1$, $\rho_c = 2.18(2)$ (23 °C, MoKα, $\lambda = 0.71069$ Å) $\mu = 97.1$ cm^{-1}.

Reflection intensities for the first four layers perpendicular to [100] and the first five layers perpendicular to [1$\bar{2}\bar{1}$] were obtained from films recorded on an integrating precession camera using zirconium filtered MoKα radiation. All intensities were measured using a Joyce–Loebl microdensitometer and then corrected for Lorentz and polarization effects. No absorption corrections were made, and this could introduce a maximum error in F of 10%: the average error would be considerably less than 10%. Standard errors were assigned to each reflection according to the methods of Ibers (7) and Hughes (8) and weights $w = 1/\sigma^2$ were used through the refinement.

Solution of the Structure

The unit cell is triclinic with space group $P1$ or $P\bar{1}$. The centrosymmetric space group was assumed at the beginning of this work and this was confirmed from the Patterson maps as well as subsequent refinement of the structure. Thus the rhenium atom is at a center of symmetry and this was chosen as the origin of the cell. The chlorine and oxygen atoms were located from the Patterson projections on (01$\bar{2}$) and (210). The remaining non-hydrogen atoms were found from successive Fourier synthesis and least squares refinements. At this stage, temperature factors, which were treated as isotropic in the initial refinement, were made anisotropic. The structure was further refined using a full matrix least squares programme CUDLS written by J. S. Stephens for the CDC 6400 computer. Refinement was terminated when no shift of atom parameters greater than $1/10\sigma$ was observed and $R_1 = 0.072$ and $R_2 = 0.0685$.[3] Of the 991 reflections measured, 984 were used in the final refinement. Seven reflections of doubtful accuracy, because they were near the backstop shadow, were given zero weight. The data set recorded represents about 55% of the approximately 1800 reflections which are accessible using a precession angle of 30°. Scattering curves used in the refinement process were obtained from the International tables (9) for Cl, O, and C and from Cromer and Waber (10) for Re. Anomalous dispersion corrections for rhenium and chlorine were taken from Cromer (11).

A difference Fourier map calculated using the structure factors listed in Table 2 had no residual peaks outside plus or minus 1% of the rhenium atom peak. The final atom parameters are shown in Table 1 and the values of F_o and F_c are given in Table 2.[4]

Results and Discussion

Figure 1, which, with Fig. 2, was produced by the ORTEP program written by Johnson (17), shows one complete molecule and the bond lengths and angles are listed in Table 3. The rhenium atom is at the origin of the unit cell, and the shortest Re—Re distance, about 7.4 Å, corresponds to the two rhenium atoms related by the c translation, and thus the compound is monomeric. For the monomer, *cis* and *trans*

[3] $R_1 = \dfrac{\Sigma|\,|F_o| - |F_c|\,|}{\Sigma|F_o|}$; $R_2 = \left(\dfrac{\Sigma\omega(|F_o| - |F_c|)^2}{\Sigma\omega F_o^2}\right)^{1/2}$

configurations are possible; the *trans* configuration was the one found. The pseudo-octahedral coordination around rhenium is elongated along the Re—Cl direction, but the Re—Cl distance (2.326(8) Å) is quite short when compared to values for Re(V) complexes (typically 2.40–2.43(1) Å (12 and references therein)), although the distance is insignificantly different from the 2.353(4) Å found for K_2ReCl_6 (13). The Re—O bond lengths (average 1.99(1) Å) are possibly slightly shorter than Cotton's calculated value for the Re(V)—O single bond (2.04 Å) (14) suggesting that, although the bond order is close to one, some multiple bonding occurs between the oxygen atom and the rhenium atom. The O—Re—O and Cl—Re—O angles are very close to 90° (±1°) required for ideal octahedral coordination at the metal, and thus the inter- and intrachelate ring O—O distances are nearly equal (2.84(1) and 2.80(1) Å, respectively). Bond distances between equivalent sets of atoms within the acetylacetone group differ by about 2σ in the extreme cases and the average values of 1.28 (O—C), 1.39 (C—C ring), and 1.53 Å (C—methyl) agree with values found previously (15).

The ReO1O2 plane and the best weighted least squares plane through O1C1C2C3O2 are almost coplanar (dihedral angle 3.4°) and only one of the methyl carbon atoms, C4, and the rhenium atom are displaced from the latter plane (both 0.08 Å) on the same side. In view of the large positional error of C4 (0.03 Å) this is hardly significant. Both methyl groups show very large thermal motion, and as can be seen in Fig. 1 the motion is probably caused by twisting of the β-ketoenolate ring about an Re—C2 axis. It will be noted that the thermal motion is not symmetric; the motion of C5 is

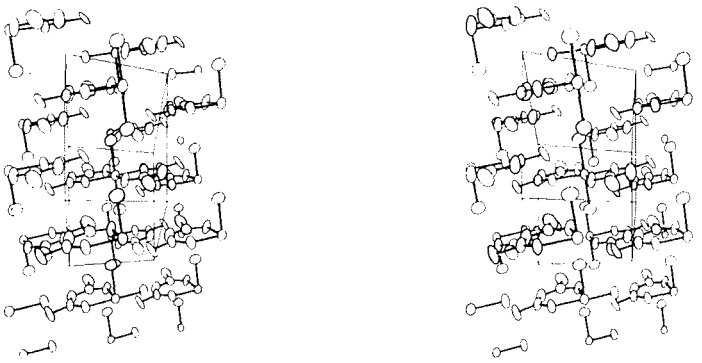

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of $Re(acac)_2Cl_2$ viewed down the b^* axis. The c and a axes run roughly parallel to the horizontal and vertical edges of the paper respectively. The unit cell outlined is shifted by 1/2,1/2,1/2 from the cell used in all calculations in this work.

larger than C4. Both these effects have been observed previously in β-ketoenolate complexes (see references in ref. 15).

The molecules are situated in the unit cell such that the Cl—Re—Cl unit lies almost along the a axis and the molecules form a line. Intermolecular contact along the line is between chlorine atoms. Adjacent lines are arranged such that β-ketoenolate rings on molecules within two adjacent lines are interleaved. Thus, a β-ketoenolate group on a molecule at 0,0,0 in the unit cell is interleaved with β-ketoenolate groups on molecules at $0,1,\bar{1}$ and $1,1,\bar{1}$. In the c direction the chlorine atoms contact the β-ketoenolate groups of adjacent molecules, which are arranged such that the chlorine contact is with one methyl group and the central CH group of a particular β-ketoenolate group. In the b^* direction intermolecular contact is primarily between the chlorine atom on one molecule and a methyl group and its nearest oxygen atom in the β-ketoenolate ring of the next molecule (up or down).

We confirm that previous claims that $Re(C_5H_7O_2)_2Cl_2$ is dimeric (3, 16) are incorrect for the solid state.

We thank the National Research Council of Canada for financial support of this work.

Received January 5, 1973

The $Sn_{1-x}Sb_xO_2$ system has been studied by means of ^{119}Sn and ^{121}Sb Mössbauer spectroscopy. The presence of an unresolved quadrupole splitting in SnO_2 is confirmed. The data show that the oxidation states of the tin and antimony are IV and V, respectively. The conduction electrons resulting from Sb substitution are distributed over the entire lattice. As the Sb content increases, the ^{119}Sn isomer shift and s electron density at the Sn nucleus also increase, as expected for a conduction band composed largely of Sn 5s orbitals.

Le système $Sn_{1-x}Sb_xO_2$ a été étudié à l'aide de la spectroscopie Mössbauer du ^{119}Sn et du ^{121}Sb. La présence d'une scission des raies qui n'a pas été expliquée et qui est causée par la présence d'un quadrupole a été confirmée. Les données démontrent que les états d'oxydation de l'étain et de l'antimoine sont respectivement IV et V. Les électrons responsables de la conduction résultant d'une substitution du Sb sont distribués sur le réseau entier. En même temps que la teneur en Sb augmente, le déplacement isomérique du ^{119}Sn et la densité des électrons s au noyau Sn augmentent tous deux tel que prévu pour une bande de conduction composée surtout d'orbitales 5s du Sn.

Introduction

Stannic oxide, SnO_2, is a semiconducting oxide with the rutile crystal structure and an energy gap of 3.4 eV (1, 2). Because of its high conductivity, transparency, chemical and thermal stability, films of this oxide have been produced commercially for many years. It is well known that the electrical conductivity can be controlled by the use of Sb as a donor impurity. Minimum resistivity is obtained with 1–5% Sb. Larger Sb concentrations lead to increased resistance, probably because of increased lattice disorder. Electrical properties have also been measured on SnO_2:Sb single crystals (3), which can be produced by high-temperature, gas-phase reactions.

Because $Sn_{1-x}Sb_xO_2$ exhibits n-type electrical properties, it is generally assumed that the Sb is present as Sb(V), since to preserve electroneutrality, x atoms of Sb(V) would cause reduction of $x/2$ atoms of Sn(IV) to $x/2$ Sn(II) and provide x electrons to the conduction band. Alternatively, half of the entering Sb(V) could be reduced to Sb(III) with the same effect. However, since the electrical properties of SnO_2:Sb are essentially identical to oxygen-deficient SnO_{2-x} where no Sb^{3+} states are present, Sn(II) is more likely. Electrical properties are not always unambiguous indicators of oxidation states, however, and it would be helpful for our understanding of SnO_2 to verify the oxidation state of the Sb dopant by another technique.

Mössbauer spectroscopy often provides a convenient means for the identification of oxidation states (4) and, in addition, gives information about local site symmetries. We have, therefore, carried out an investigation of the $Sn_{1-x}Sb_xO_2$ system, for x up to 0.1, by this technique.

Experimental

Preparation of Compounds

Solutions of the mixed cations were prepared by dissolving appropriate amounts of reagent grade $SnCl_4 \cdot 5H_2O$ in H_2O to give a final concentration of ~ 0.2 *M*. The Sb was dissolved in aqua regia and added to the Sn solution, to which a small amount of HCl (5 cc/l) was added to prevent premature precipitation of the Sb. The solution was rapidly stirred and ammonia solution was slowly added to p$H = 7$. The resultant gelatinous precipitate was then heated in the mother liquor for ~ 2 h at ~ 100 °C, and washed several times with distilled water, accompanied by several settling and decantation steps. The final product was filtered and dried under vacuum at 100 °C. Portions of these products were heated to 600 °C in air for 16 h; those containing

TABLE 1. Composition and firing conditions for $Sn_{1-x}Sb_xO_2$

Formula	Code	Firing conditions
SnO_2	40A	25 °C (air)
$Sn_{0.97}Sb_{0.03}O_2$	31B	80–100 °C (vac)
$Sn_{0.95}Sb_{0.05}O_2$	31C	85–100 °C (vac)
$Sn_{0.90}Sb_{0.10}O_2$	31D	85–100 °C (vac)
SnO_2	40C	600 °C 40 h
$Sn_{0.97}Sb_{0.03}O_2$	34B	600 °C 16 h
$Sn_{0.95}Sb_{0.05}O_2$	34C	600 °C 16 h
$Sn_{0.90}Sb_{0.10}O_2$	34D	600 °C 16 h

Sb developed a blue coloration indicative of solid solution formation. X-Ray diffractometer tracings were taken before and after heating with a Norelco diffractometer. Compositions with pure Sn and 3, 5, and 10 mol% Sb were prepared and are listed in Table 1. Samples with 33 and 67 mol% Sb, which are well above the solubility limits of Sb in SnO_2, were also prepared to provide a spectrum containing both combined and unreacted Sb.

Mössbauer Spectra

The Mössbauer system used in this study has been previously described (5). The sources used were $Ba^{119m}SnO_3$, and $Ba^{121m}SnO_3$ obtained from New England Nuclear, and maintained at room temperature (295 °K) throughout. Calibration of the drive velocity was carried out with a ^{57}Co/Pd source and a standard iron foil. The samples for ^{119}Sn spectra all contained 10 mg Sn/cm^2 while those for ^{121}Sb spectra contained $\sim$20 mg Sb/cm^2. ^{119}Sn Spectra of samples of spectroscopically pure SnO_2 were interspersed with the spectra of the other samples and have been used as the reference to which all chemical isomer shifts have been referred. These Sn spectra were computer fitted using the program written by Stone (6). The tin data have been analyzed by fitting the absorption envelope to one Lorentzian line, with no constraints, and to two overlapping Lorentzian lines having equal widths and intensities. In every case, the two line fit was statistically better, as evidenced by the significantly lower χ_A^2 (Table 2), and visually, as shown in Fig. 1. Antimony-121 spectra were fitted as has been described (7) and are referred to InSb at 77 °K as zero velocity.

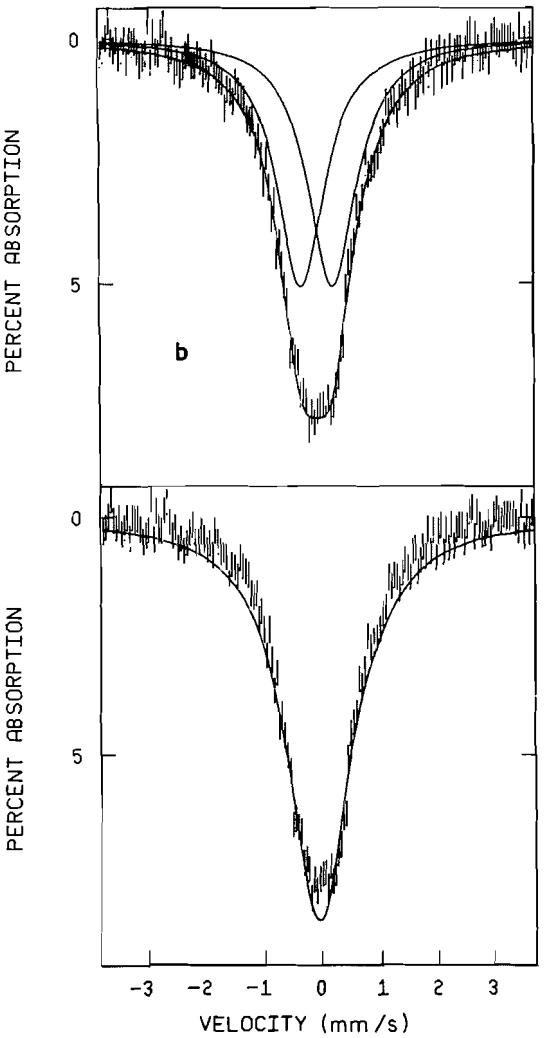

FIG. 1. Mössbauer spectrum of SnO_2 at 295 °K. (*a*) fitted to a single Lorentzian; (*b*) fitted to two Lorentzians with equal width and intensities.

Results and Discussion

X-Ray

The products dried at 100 °C showed a very broad rutile pattern corresponding to a particle size of about 25 Å. The products heated to 600 °C showed sharper peaks and X-ray line broadening calculations give a particle size of 60 to 90 Å, depending on the Sb content. Although no nonrutile peaks were observed in the sample with the highest Sb content (10 mol%), the presence of a second phase cannot be ruled out, since even 5% excess Sb oxide might be present and not observed assuming its X-ray pattern also consisted of weak, broad peaks. The regular increase in line broadening suggests that the Sb is in solid solution, however, with the increased broadening being due to increased asymmetry of the lattice, not to particle size effects.

Mössbauer

In the early tin Mössbauer work, one of the principle source matrices used was SnO_2, since it gave a high recoilless fraction at room temperature. However, some workers have claimed variations in line width depending upon the method of preparation (8) suggesting that the exact composition of the SnO_2 may be in doubt.

*Errors in the isomer shifts are ±0.01 mm/s for ^{119}Sn and ±0.075 mm/s for ^{121}Sb.

In addition, there have been claims for the detection of a unique quadrupole splitting in SnO_2 (9, 10) but little information was provided as to the computational methods used to judge the quality of the spectra; indeed, in one case (10) the quality of the spectra was rather poor. Other groups have attempted to resolve the quadrupole splitting problem in SnO_2 by the application of a magnetic field (11, 12) but this has proved inconclusive.

The crystallographic data for SnO_2 have been re-refined by Baur and Khan (13) and it is clear that the tin atom has six near oxygen neighbors at 2.05 Å: small differences in the Sn—O distances are not statistically significant. However, the O—Sn—O angles are not all equal, and the arrangement of the six oxygens about the Sn is distorted as shown in Fig. 2. This would, of course, give rise to an appreciable asymmetry at the Sn nucleus and a quadrupole splitting would be expected. Whether or not this splitting would be detectable in the Mössbauer spectrum would depend upon its magnitude in relation to the line width parameter, and this is the root of the controversy. Clearly, from an examination of the SnO_2 spectra, (Fig. 1*a*, *b*) there is no *well resolved* quadrupole splitting. However, Fig. 1*a* and the x^2 values indicate that this absorption envelope cannot be fitted to a single Lorentzian line shape. When the absorption is fitted to two lines, a much more significant fit is obtained as Table 2 (x^2 357–393 for 392 degrees of freedom) and Fig. 1*b* show. Analysis of the data in this way clearly shows the presence of a quadrupole splitting of 0.53 mm/s which agrees well with the values reported by Stockler *et al.* (10). This splitting is half the observed line width and therefore just on the limits of resolution. Of the other SnO_2 samples examined, the air dried sample has the same isomer shift and a slightly larger quadrupole splitting, while the one fired at 600 °C has both a higher isomer shift and quadrupole splitting. Compared to the air-dried sample, these differences are small and within experimental error. For reasons discussed below, we believe the isomer shift for SnO_2 (600 °C) to be significantly different from spec. pure SnO_2.

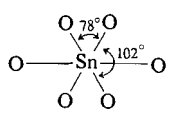

FIG. 2. Arrangement of O atoms about Sn.

The $Sn_{1-x}Sb_xO_2$ samples fired at 85–100° are not single phase systems, since the Sb has not yet entered the SnO_2 rutile lattice. As expected, the ^{119}Sn spectra are not significantly different from samples of undoped SnO_2 prepared under similar conditions. The ^{121}Sb chemical isomer shift indicates that the antimony exists as Sb(V) (14). On firing at 600° the Sb enters the rutile structure to give a single phase system.

Electrical neutrality is preserved by reduction of $x/2$ Sn or Sb atoms to Sn(II) or Sb(III), but the electrons released from these reductions are not localized at the ionic sites where they were created, but are delocalized throughout the entire lattice. The rate at which these electrons

are being transferred must be greater than the time for the Mössbauer transition to occur (3.5×10^{-9} s) since no resonance spectra corresponding to either reduced species is observed: concentrations of Sn(II) or Sb(III) as low as 0.4 mol % can be detected under normal conditions. In cases where $x \gg 0.1$, and which X-ray analysis shows to be not a single phase, the ^{121}Sb spectra show the presence of some Sb(III) as well as Sb(V). It is well known that prolonged heating of any antimony oxide results in the formation of Sb_2O_4 which has been demonstrated to contain Sb(III) and Sb(V) (14). The Sb(III) resonance observed is probably the result of such a reaction on the uncombined, excess Sb oxide fraction.

The quadrupole splitting results from the interaction of the nuclear quadrupole moment of the excited state of ^{119}Sn with an electric field gradient. This electric field gradient arises as a result of an asymmetry of valence electrons and/or an asymmetry of neighboring ions. Replacement of a Sn by an Sb atom in the structure will change the lattice contribution to the electric field gradient at the Sn nuclei remaining and this should result in a change in quadrupole splitting from SnO_2 to $Sn_{1-x}Sb_xO_2$. Such a change is indeed observed and, although small, is outside experimental error. The fact that the magnitude of the quadrupole splitting increases indicates that the valence and lattice contributions to the electric field gradient tensor are of the same sign. Whether this sign is positive or negative cannot be ascertained from the data presented here, though this could probably be obtained from a lattice sum calculation. We were unable to satisfactorily analyze the ^{121}Sb spectra in terms of a significant quadrupole interaction, which is not too surprising in view of the large natural line width of the ^{121}Sb resonance and the small quadrupole interaction noted in the ^{119}Sn spectra. This was somewhat disappointing since the sign of the interaction would have been obtained had the splitting been resolvable.

A good correlation is observed between the ^{119}Sn chemical shift and the amount of Sb dopant in the lattice, Fig. 3. Since this plot extrapolates to the chemical shift value for the SnO_2 samples fired at 600°, we believe that the shift reported for this sample is significant. Because the $\delta r/r$ term in the isomer shift expression has a positive sign for ^{119}Sn (15, 16) the

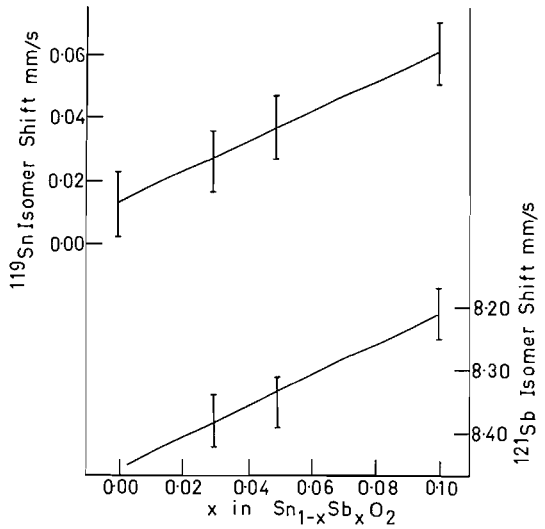

FIG. 3. Plots of ^{119}Sn and ^{121}Sb isomer shifts *vs.* x in the $Sn_{1-x}Sb_xO_2$ system.

increase in isomer shift indicates an increase in s electron density at the nucleus. A similar increase in s electron density at the Sb is also noted but because $\delta r/r$ for Sb is negative (17, 18) this is observed as a decrease in isomer shift. Also, since $\delta r/r$ for ^{121}Sb is greater than that for ^{119}Sn, larger shifts are recorded. Because of the good correlation of both Sn and Sb chemical shifts with the amount of Sb dopant, we conclude that the systems up to and including $Sn_{0.9}Sb_{0.1}O_2$ are indeed single phase, and the X-ray broadening is due to increased asymmetry.

Since the conduction electrons are in band states, not localized levels, every Sn and Sb atom in the lattice will be affected; therefore, the increase in s electron density with increasing conduction electron density is quite reasonable, because the conduction band is composed largely of 5s orbitals (19).

Crystal Structure and Phase Transformations of Sodium Diarsenate, $Na_4As_2O_7$

KIANG Y. LEUNG AND CRISPIN CALVO

Department of Physics and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received November 16, 1972

Sodium diarsenate at room temperature is monoclinic with lattice parameters $a = 5.969(1)$, $b = 10.126(1)$, $c = 12.272(3)$ Å and $\beta = 92.87(2)°$. There are four formula units per cell with space group $C2/c$. The structure was refined by full-matrix least-squares to a final R value of 0.027 utilizing 1157 reflections measured on a Syntex PĪ automatic diffractometer. The anion, consisting of two AsO_4 tetrahedra sharing a common oxygen atom, with a bridging angle of 123.5° at that oxygen atom, lies on a two-fold axis. The bridging As—O bond lengths are 1.783 Å and the average terminal As—O bond length is 1.658 Å uncorrected for thermal motion. Both Na ions show fivefold coordination to oxygen atoms. One of these sodium ions has a long interaction (2.852 Å) with the bridging oxygen atom of the anion. $Na_4As_2O_7$ undergoes a series of phase transformations between room temperature and 220 °C, and a further major transformation near 680 °C.

Le sodium diarsénate est monoclinique à la température ambiante avec comme paramètres du réseau $a = 5.969(1)$, $b = 10.126(1)$, $c = 12.272(3)$ Å et $\beta = 92.87(2)°$. La maille contient quatre unités et le groupe spatial est $C2/c$. La structure a été raffinée par la matrice des moindres carrés jusqu'à une valeur finale R de 0.027, après utilisation de 1157 réflexions mesurées sur un diffractomètre Syntex PĪ automatique. L'anion sur un axe d'ordre deux, est constitué de deux tétraèdres AsO_4 avec un atome d'oxygène en commun, l'angle de portage étant de 123.5° sur cet atome d'oxygène. Les longueurs de liaison As—O du pont sont de 1.783 Å et la longueur moyenne finale pour la liaison AsO est de 1.658 Å, sans apporter de correction pour le mouvement thermique. Les deux ions Na exhibent une coordination de 5 avec les atomes d'oxygène, l'un de ces ions ayant une interaction lointaine (2.852 Å) avec l'atome d'oxygène du pont de l'anion. $Na_4As_2O_7$ subit une série de transformations de phase entre la température ambiante et 220 °C, et une autre transformation majeure près de 680 °C.

Introduction

To date, little accurate data exists on the structure of systems containing condensed tetrahedral AsO_4 groups. A number of diarsenates have been found to crystallize as analogues of the mineral thortveitite (1), but in these cases, as in all other structures isotypic with thortvietite, ambiguity exists as to the detailed bonding because of disorder at the bridging oxygen atom (2, 3). An additional interest in this system arises because its chemical analog, $Na_4P_2O_7$, manifests a rich variety of phase transformations between room temperature and 600 °C (4–7).

The crystallography of systems containing diortho anions with an overall stoichiometry of $M_2X_2O_7$ and tetrahedrally coordinated X ions have been extensively explored (8, 9). Polymorphic behavior has been noted for a large number of the compounds having this formulation (10–13). The crystallography of systems with the stoichiometry of MX_2O_7 is less well explored but again a number of polymorphs have been reported (14, 15). On the other hand, the crystallographic nature of compounds with composition $M_4X_2O_7$ has been rather ignored, although phase transformations have been reported for $Na_4P_2O_7$, (4–6) $Li_4P_2O_7$ (16, 17) and $Li_4As_2O_7$ (17).

The bonding in those diortho systems with divalent metal cations has been correlated on the basis of local electroneutrality (18). These correlations contain very little of the chemistry of the atoms and ions explicitly in the model since they are related to only the formal charge on the ion and not on the higher moments of this charge density. However, in order to investigate this question further, additional accurate structure resolutions, where the cation to oxygen atom radius and the electronegativities are varied, seem desirable. Further, an understanding of the nature of the transformations in these systems require structural studies of these phases.

Experiments

Crystals of $Na_4As_2O_7$ were grown directly from the melt at 850 °C. The initial charge was formed by heating $Na_2HAsO_4 \cdot 7H_2O$ to about 900 °C. Preliminary photographic work utilizing precession cameras established the space group to be either Cc of $C2/c$ on the basis of the

For personal use only.

extinction conditions. Reflections were absent when $h + k$ = odd or when l = odd and $k = 0$.

The differential thermal analysis traces, taken with the Dupont 900 system, are shown in Figs. 1 and 2. They indicate a transformation near 690 °C and a series of endothermic transformations between room temperature and 220 °C. Melting occurs at 848 °C.

The solid state transformation at 692 °C upon heating is immediately reversible but a single crystal heated to above this transformation decomposed into a powder. However, the transformations between room temperature and 300 °C do not reappear immediately. Figure 2 indicates how these peaks reappear when the sample is allowed to stand at room temperature for a period extending through a number of days.

A ground sphere, 0.01 cm in radius, was used to collect data for the phase stable at room temperature, both for accurate parameters and for the resolution of the crystal structure. The 2θ values of 15 reflections were accurately centered using a Syntex automatic diffractometer and the lattice parameters fitted to these values by least-squares. These results were obtained at 22 °C using MoKα̅ radiation monochromatized with graphite ($\lambda = 0.71069$ Å) and are:

Crystal Data

$Na_4As_2O_7$ f.w. = 353.79
$a = 5.969(1)$, $b = 10.126(1)$, $c = 12.272(3)$ Å, $\beta = 92.87(2)°$, $V = 740.85$ Å^3, $\rho_{exp} = 3.12$g/cm^3, $\rho_{calcd} = 3.16$ g/cm^3, $Z = 4$, space group $C2/c$.

Peaks were scanned at a rate varying between 2 and 24° per min, depending upon the peak count rate. Backgrounds were counted on either side of the peak for the same time period as used in scanning the peak. Reflections whose intensities, after correction for background, were less than 3σ, where σ was determined from counting statistics, were regarded as unobserved. A total of 1157 unique reflections were collected ($2\theta_{max} = 65°$) of which 1011 were regarded as observed. These were corrected for Lorentz, polarization, absorption ($\mu R = 0.59$), using programs in the X-ray 71 package, and extinction as proposed by Larson (19).

The positions of the arsenic atoms were determined form Patterson functions and those of the remaining

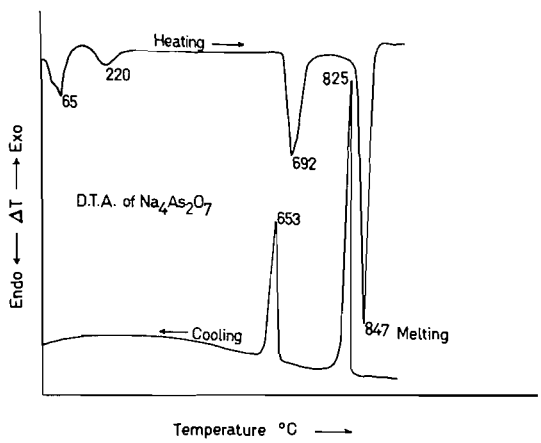

FIG. 1. Differential thermal analysis trace of $Na_4As_2O_7$. Temperatures in degree C are superimposed.

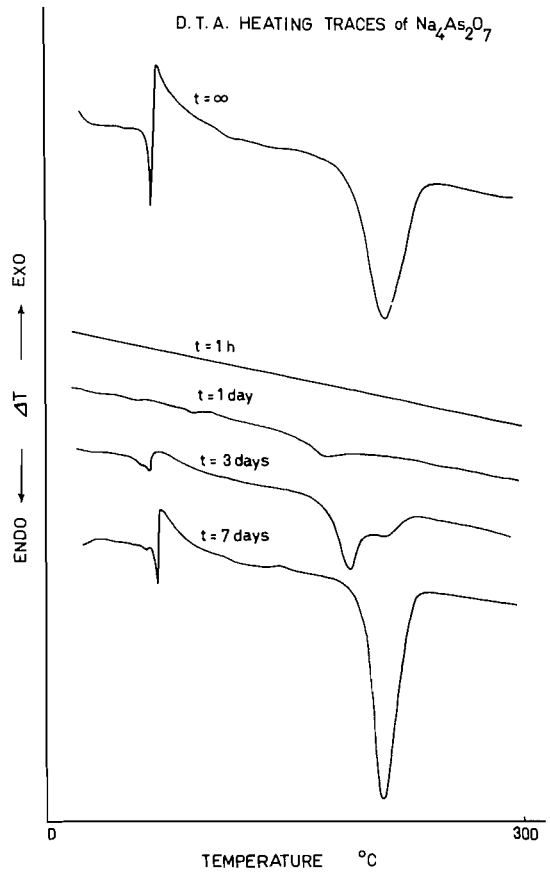

FIG. 2. Differential thermal analysis trace upon heating of $Na_4As_2O_7$ as a function time spent at room temperature between heatings.

atoms determined from difference syntheses. These maps were all consistent with space group $C2/c$. The structure was refined with full matrix least-squares written for the CDC 6400 by J. S. Stephens. Atomic scattering factors for Na^+, As, and O^- obtained from the International Tables for X-ray Crystallography (20) were corrected for dispersion. Convergence was obtained with unit weights and isotropic thermal parameters and then independent anisotropic thermal parameters were varied. For the final refinement weights were set = $\{7.4 - 0.26\ F_o + 0.0031\ F_o^2\}^{-1}$ with coefficients chosen so that $\omega|F_{obs} - F_{calcd}|^2$ would be independent of F_o. No variation of $\Delta F = F_{obs} - F_{calcd}$ with $\sin\theta/\lambda$ was noted. The final R value is 0.027 while $R_\omega = (\Sigma\omega|F_o - F_c|^2/\Sigma\omega F_o^2)^{1/2}$ is 0.037. No residual peaks could be discerned in the final electron density map. The final atomic positional parameters are found in Table 1. Table 2 contains a comparison of the observed and calculated structure factors. The mean deviation of a reflection of unit weight is 0.98.[1]

[1]Table 2 is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Description of the Structure

The structure of $Na_4As_2O_7$ consists of anions, formed from AsO_4 groups sharing one corner, arranged in layers, $\frac{1}{2}$ c axis length thick, parelleling the *ab* plane. In each layer the anions are arranged in a hexagonal pattern as seen in Fig. 3 with the As—As vector of any anion at 32.6° to the c axis. The anion contains a crystallographic two-fold axis through the bridging oxygen atom and the As—O—As bond angle is 123.5°. Thus O(3)*a*, O(4)*a*, O(3)*c*, and O(4)*c*, defined in Table 4, lie within 1/4 Å of a plane parallel to the *ab* plane, but O(2)*a* and O(2)*c* do not, as is shown in Fig. 4. Adjacent layers are generated by a center of symmetry, with the anions, regarded as spheres, in this context, showing a pseudo-hexagonal packing.

Na(1) lies between the terminal oxygen atoms of three anions in one layer and nearly directly below an anion in an adjacent layer, as seen as in Fig. 4. It is coordinated to five oxygen atoms contributed by these four anions and bridges across one of these As_2O_7 groups. Na(2) and As nearly have the same z values. Na(2) shares a bridging oxygen atom, O(1)*a*, and a terminal oxygen atom, O(2)*c*, with one anion while the remaining oxygen atoms arise from three additional anions.

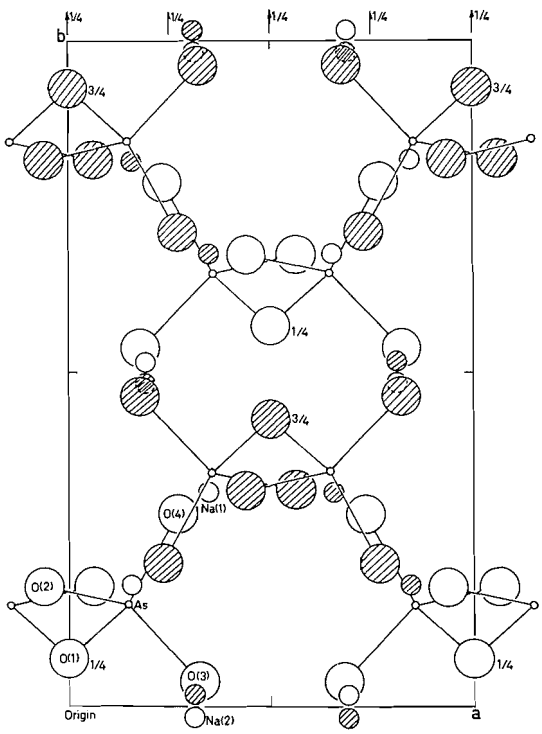

FIG. 3. The structure of $Na_4As_2O_7$ shown in projection onto the *ab* plane. The open circles represent those Na and oxygen atoms within the layer defined by $0 \leq z < 1/2$ and the cross hatched ones those Na and oxygen atoms within the layer defined by $1/2 \leq z < 1$. The largest circles represent oxygen atoms while the smallest ones are arsenic atoms. The intermediate ones represent sodium ions.

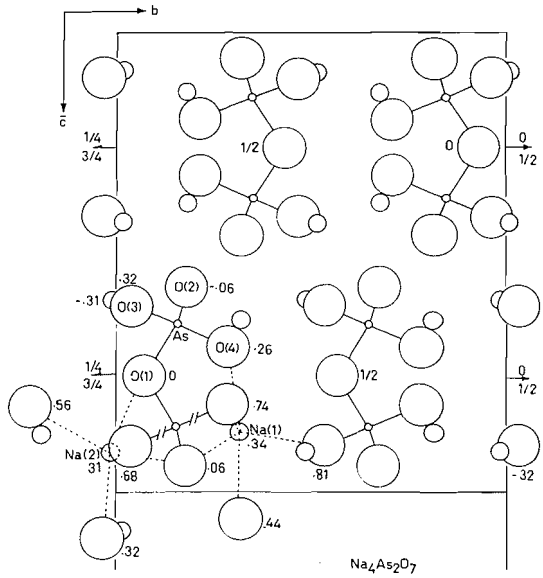

FIG. 4. The structure of $Na_4As_2O_7$ viewed in projection onto the *bc* plane. The small circles are As atoms while the large open ones represent oxygen atoms. The intermediate sized circles are sodium ions.

The bridging oxygen atom of the anion lies on a two-fold axis separated by 1.783(2) Å from the As, noted in Table 3. The terminal As—O bond lengths are substantially and significantly shorter, ranging from 1.655 to 1.659 Å. The minimum thermal corrections to these bonds is 0.003 Å, for the bridging, and 0.002 Å or less for the terminal bonds, based upon the method of Busing and Levy (21). Individual terminal As—O bond lengths are not significantly different. All the O—As—O angles in a tetrahedron that involve the bridging oxygen atom are less than the ideal value, while the remaining angles are all larger than ideal. The As—O—As angle is rather small at 123.5° and results, in part, from the interaction of the bridging with two Na(2) ions.

Each Na ion has only five oxygen atoms within 3.0 Å. The Na(1)—O bond lengths are fairly uniformly distributed between 2.347(3) and

129.2°. The Na(2)—O(1)*a* interaction is 2.852 Å long and compares with an interaction of 2.426 Å between the bridging oxygen atom and Na(1) in sodium pyrophosphate (6).

Discussion

The structure of $Na_4As_2O_7$ bears considerable resemblance to that of the room temperature polymorph of $Na_4P_2O_7$ (6). The latter structure is orthorhombic with space group $P2_12_12_1$ and unit cell dimensions of $a = 9.367$, $b = 5.390$ and $c = 13.480$ Å. The anion is formed from two PO_4 groups sharing a common oxygen atom with a bridging P—O—P angle of 127.5°. The angle that the P—P vector of the anion subtends with the *c* axis is 9°. This structure also contains layers of pseudo-hexagonally arranged anions and as a result of small displacements assumes a *C* centered cell, with a doubled *c* axis, above 400 °C. Three anions in one layer and three in an adjacent layer are approximately related by a 6_3 axis which becomes a crystallographic symmetry element above 550 °C. Half of the cations lie near this pseudo-axis as shown in Fig. 5. The remaining cations lie between the anion layers and are coordinated to five oxygen atoms. Each anion is stabilized with a non-linear X—O—X group by one strong interaction with one Na^+ in contrast to two weak ones in $Na_4As_2O_7$. In $Na_4P_2O_7$ the anion deviates by about 25° from an eclipsed configuration when viewed parallel to the P—P vector while the comparable average dihedral angle in $Na_4As_2O_7$ is 11°.

As Fig. 5 shows, the bridging oxygen atoms in adjacent layers in $Na_4As_2O_7$ nearly superimposed in projection and a relative shift of 1.8 Å together with the loss of the two-fold axis are needed to establish a pseudo 6_3 axis relationship between the oxygen atoms. In addition, considerable rearrangement of cations is needed to transform from one structure to the other. The phase transformations in $Na_4P_2O_7$ are related to disorder in the direction of the bridging oxygen atom – sodium ion interaction. The fact that O(1) is bonded to two sodium ions precludes similar transformation in $Na_4As_2O_7$.

Typical behavior in X_2O_7 systems has O(1) with the largest amplitude, but in $Na_4As_2O_7$ O(2), one of the terminal oxygen atoms has the largest amplitude. This may be a result of the fact that O(1) is bonded to two cations, whereas in the previous cases the bridging oxygen atom

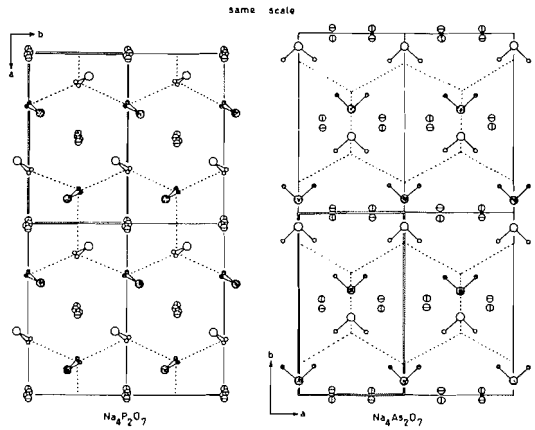

FIG. 5. A comparison of the X—O—X groups and the Na ions bonded to the bridging oxygen atom in $Na_4As_2O_7$ and $Na_4P_2O_7$. The sodium ions are shown as circles with either a horizontal or vertical line. The bridging oxygen atoms are shown with either an open or spotted circle. The smaller circles are X ions with X = As or P.

of the X_2O_7 group bonds strongly to at most one cation. These thermal amplitudes provide no strong evidence for the impending phase transformation however.

The Pauling electrostatic valency (22) is 2.90 at O(1) and 1.85 at the terminal oxygen atoms. From Baur's (18) linear relationship between bond length and electrostatic valency and coefficients derived by Krishnamachari (23) the predicted bond length would be 1.78 Å and 1.675 Å for the As—O(—As) as As—O bond lengths respectively. On the other hand, if the Na(2)—O(1) bonds were ignored they would lead to a greater discrepancy. A more systematic treatment for bonds of varying length has been proposed by Brown and Shannon (24) who show that the bond strength, *s*, can be fitted with a curve of the form $s = C_o(r_o/r)^n$, where r_o and *n* are found by least squares and C_o is given as the formal charge divided by the "normal" coordination number. Table 4 shows the individual bond strengths and the sum about each element. In Table 5 the individual X—O bond lengths are compared with those predicted on the assumption that the calculated valency contribution from the Na^+ is errorless and the difference between the formal charge on the oxygen atom and its formal charge is used to calculate the X—O bond length. Errors in these predicted bond lengths arises from two sources: the

individual errors in the Na—O bond lengths and the errors in the estimated values of n and r_o. Only the former contributions are included in Table 5. The agreement in $Na_4As_2O_7$ has to be regarded as reasonably good despite the fact that the effects of thermal motion on the apparent bond lengths have not been applied to either any of the data used. Systematic deviations leading to predicted values of bridging P—O(—P) bonds and smaller terminal ones seem to appear in both these compounds.

The Bonding of a Silicon Atom with a Phenyl Ring: the Photoelectron Spectrum of Phenylsilane

RONALD ALLAN NEILL MCLEAN[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received December 11, 1972

The first band in the photoelectron spectrum of phenylsilane, which is caused by two ionization processes, is shifted to higher energy compared with the corresponding band in the carbon analog, toluene. In particular the highest energy orbital of phenylsilane appears to be stabilized compared to that in toluene probably due to (p → d) π bonding.

La première bande dans le spectre photoélectronique du phénylsilane qui est produit par deux processus d'ionisation, est déplacée vers les plus hautes énergies lorsqu'on compare celle-ci avec la bande correspondante de son analogue dans la série carbonée, le toluène. En particulier, l'orbitale de plus haute énergie du phénylsilane semble être stabilisée si on la compare avec celle du toluène probablement par des liaisons π (du type p → d). [Traduit par le journal]

Can. J. Chem., 51, 2089 (1973)

In our studies (1) of the use of photoelectron spectroscopy for measuring the π bonding interaction between silicon and neighboring atoms, we have obtained the photoelectron spectrum (p.e.s.) of phenylsilane. The spectra of most monosubstituted benzenes indicate that substituent groups can have a considerable effect on the highest energy π orbitals of the phenyl ring, (2, ref. 3, chapt. 11). Groups which have a strong π interaction with the phenyl ring remove the degeneracy present in the highest energy π orbitals of benzene. It was hoped that the lowest energy band in the p.e.s. of phenylsilane, as in the halosilanes (1), would provide some information on π interactions involving the silicon atom.

The photoelectron spectrum of phenylsilane in the region of interest shows that the first band extending from 9.0–9.8 eV has two unresolved components. The first has an adiabatic ionization potential (i.p.) of 9.09 eV and a vertical i.p. of 9.18 eV. The second component, which is much broader, probably has a vertical i.p. of *ca.* 9.43 eV. The carbon analog, toluene, has a somewhat different first band which extends from 8.80–9.60 eV. In this case, the adiabatic i.p. of the first component at 8.80 eV is the vertical and the other component is more clearly resolved than in phenylsilane, with vertical i.p. of 9.35 eV. Although it is obvious that there is vibrational structure on these bands in both compounds, it is too complex to be resolved completely. The first component in each has a progression with spacing *ca.* 800 cm^{-1} partially resolved. This is likely to be the symmetric ring breathing mode as in benzene itself (ref. 3, chapt. 10). Except for a band with maximum at 11.0 eV in phenylsilane (assigned to ionization from a σ bonding orbital involving silicon), the spectra of phenylsilane and toluene are similar at higher energy.

Even without assigning each component of the first band, it is obvious that at least one of the orbitals is considerably more stable in phenylsilane than in toluene. This would be the expected result if the greater π attracting ability of the SiH_3 group more than overcame its expected greater σ donating ability. The latter would have raised the energy of the benzene ring π levels. Additional evidence for this assignment appears in the comparison with benzene itself. The first band in the p.e.s. of benzene (ref. 3, chapt. 10) has a vertical and adiabatic i.p. of 9.24 eV and the band extends to *ca.* 9.7 eV. Therefore the π levels in benzene are at about the same energy as those in phenylsilane, *i.e.* the SiH_3 group is a similar electron attracting group to —H. However, before proceeding with the discussion of these molecules we should compare the results with those of another system which had previously been studied.

The first band in the p.e.s. of phenyltrimethylsilane was compared with that of its carbon analog, *t*-butylbenzene, by Vignollet *et al.* (4). In contrast to the present result, in trimethylsilyl-

[1]Present address: Department of Chemistry, University of Ife, Ile-Ife, Nigeria.

benzene the first band was shifted to lower energy compared to benzene with a splitting of only 0.2 eV. The spectra produced in ref. 4 also indicated that as a whole, the band was shifted to lower energy compared to *t*-butylbenzene. It was concluded from these results that any π attracting ability of the Si atom was overcome by the electron releasing effect caused by the three methyl groups. In addition it could be inferred from the relative positions of the bands in trimethylsilylbenzene and its carbon analog that the net electron releasing effect of the silicon atom was less than that of the carbon atom. This is in disagreement with our present results.

However, an examination of the full spectra of trimethylsilylbenzene and *t*-butylbenzene (ref. 3, p. 296), reveals a slight error in the earlier presentation of the first bands, Firstly, the band in the silicon compound is quite definitely at higher energy than that in the carbon compound, thus bringing the results into agreement with our observations. Secondly, the splitting in the first band of trimethylsilylbenzene is rather greater than 0.2 eV and is about the same as, though more distinct than, that which we observe in silylbenzene. Therefore any conclusions we make from the spectrum of silylbenzene also hold for trimethylsilylbenzene.

The assignment of the components of the bands to ionization from symmetry orbitals is not straightforward, because of the several variable interactions between the ring and the substituent. However, as the a'' orbital (a_2 in C_{2v}) has no electron density at the 1 position of the benzene ring we expect it to be about the same energy in benzene and toluene. Therefore assuming Koopman's theorem to hold, the a'' orbital in toluene has energy -9.35 eV and the a' orbital, -8.80 eV. This assignment is also consistent with the donating effect of the CH_3 group as the a' orbital would be raised in energy by this interaction.

In phenylsilane the a'' level (-9.43 eV) is at slightly lower energy than in toluene. However, there is a considerable stabilization of the a' level (at -9.18 eV) compared to toluene and, although this must be partly due to the reduced M—H donating effect, we believe in line with our earlier results, (1), that there must be some stabilization due to interaction with the Si d orbitals and σ^* (Si—H) orbitals. The same arguments hold for the trimethyl derivatives. Because of the very similar energy levels in the methylated and non-methylated species, it seems that in contrast to the earlier conclusions the inductive effect of the methyl groups have very little influence in these systems. This should be compared with the high energy level in the following halides: CH_3Cl, -11.30 eV (5); $(CH_3)_3CCl$, -10.61 eV (6); SiH_3Cl, -11.65 eV (1), and $(CH_3)_3SiCl$, *ca.* -10.8 eV (7). In these examples the methyl group obviously has a considerable effect on the highest energy level, but the levels in the substituted benzenes discussed here are high enough in energy to be little affected by methyl groups on the substituent atom.

In the light of these results, some recent CNDO/2 calculations on silyl and methyl substituted unsaturated hydrocarbons (8) deserve comment. These calculations, despite not including d orbitals in the silicon basis set, indicated that the $-CH_3$ group acted as a donor and the $-SiH_3$ group as a π acceptor, in agreement with our conclusion. However, although the calculated order of the first ionization potentials is correct for benzene (13.85 eV) > silylbenzene (12.97 eV) > toluene (12.87 eV) it is obvious that the inclusion of d orbitals in the silicon basis set will improve silylbenzene's value relative to benzene and toluene. Our results indicate that the first i.p. of silylbenzene is very close to that of benzene and much higher than that of toluene. Therefore although it is unnecessary to include d orbitals on silicon to predict most of the groundstate properties, it has been shown (9) that to predict the correct relative energies for silicon and carbon compounds, d orbitals must be included in the silicon basis set.

Some earlier Pariser–Parr–Pople calculations carried out by Perkins (10) on *p*-disilylbenzene, indicated, correctly in the light of our present results, that a silicon atom has little net effect on the π *bonding* orbitals of benzene, but a significant stabilizing effect on the antibonding orbitals.

In conclusion, it can be stated that when a silyl group is substituted on a benzene ring it has little net effect on the bonding π electron energies but a net π attracting effect compared to substitution by a methyl group. Further, substitution of the hydrogens of this silyl group with methyl groups also has little effect on π electron levels.

I thank Professors C. A. McDowell and D. C. Frost of the University of British Columbia for the use of their photoelectron spectrometer and their interest in this work, and Dr. A. B. Cornford for some experimental assistance.

^{13}C Nuclear Magnetic Resonance Studies. 29. ^{13}C Spectra of Some Alicyclic Methyl Esters[1]

M. GORDON, S. H. GROVER,[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario

Received January 29, 1973

The shielding effects of the carbomethoxyl group on neighboring carbons in the cyclohexane and *trans*-decalin ring systems have been characterized by ^{13}C n.m.r. examination of ten model compounds. The data show that sufficient differences are exhibited by axial and equatorial groups to permit stereochemical assignments in related systems. The observed trends are compared with those produced by other functional groups. The three-, four-, and five-membered ring cycloalkae carboxylic acid esters were also examined.

Les effets de blindage du groupe carbométhoxyle sur les carbones voisins dans les systèmes cyclohexane et *trans*-décaline ont été étudiés par la r.m.n. du ^{13}C sur dix composés modèles. Les données obtenus montrent que des différences suffisantes existent pour les groupes axial et équatorial pour permettre des attributions stéréochimiques dans ces systèmes. Les tendances observées ont été comparées avec celles causées par d'autres groupes fonctionnels. Les esters d'acide carboxylique cyclique de trois, quatre et cinq unités ont également été examinés. [Traduit par le journal]

Can. J. Chem., **51**, 2092 (1973)

Introduction

In general, the effects of various substituents on the ^{13}C shieldings of neighboring carbons are found to be additive within families of compounds. Consequently, the positions of ^{13}C absorptions for related materials may often be predicted with good precision in a wide variety of systems (1). These trends are of special interest in "fixed" systems, as opposed to freely rotating cases, since the shielding effects of specific groups tend to exhibit marked geometrical dependencies (2). This feature can be valuable for signal assignments in complex spectra and in many cases permits the assignment of stereochemistry. A good example of the utility of these trends for signal assignments has been provided by the complete analysis of the ^{13}C spectra of a series of steroids (3), while the stereochemistry of the A/B ring fusion in steroids is readily determined from the C-19 shielding (4).

The relatively common occurrence of the carbomethoxyl group in natural products prompts one to determine whether the sensitivity of its substituent effects is sufficient to provide another means of characterizing its configuration in alicyclic systems. To this end, we have examined the ^{13}C spectra of some methyl cyclohexane- and *trans*-decalylcarboxylates having both axial and equatorial carbomethoxyl groups. In addition, two conformationally mobile cyclohexane derivatives were included to investigate the possibility of utilizing the ^{13}C data, obtained at ambient temperature, for conformational analysis. Since the dangers associated with the use of proton data obtained at a single temperature for this purpose have been demonstrated by Jensen and coworkers (5), similar difficulties may be anticipated for the ^{13}C approach although reasonable results have been found for some substituents (2*b*, 6). To compare the effects of the carbomethoxyl group on alicyclic carbons in smaller rings, the three-, four-, and five-membered cycloalkanecarboxylates were also examined.

Experimental

The ^{13}C spectra were obtained for 15–20% (w/v) solutions in benzene and/or in deuteriochloroform. The benzene solutions were examined in 12 mm sample cells at 15.1 MHz using a computer-controlled (Varian 620i) HA-type spectrometer equipped with a "homebuilt" proton decoupler (7) and a Varian V4336 probe.[3] The decoupled solvent signal served as an internal ^{13}C lock. With the proton decoupler frequency centered on the benzene protons, the presence or absence of noise modulation furnished noise-decoupled or off-resonance decoupled spectra, respectively. The $CDCl_3$ solutions were examined using a Varian XL-100-15 spectrometer operating in the Fourier transform mode. The solutions were contained in 10 mm tubes which were placed in a

12 mm sample tube containing D_2O, the signal of which was used as the lock.

All peak positions are reported relative to internal tetramethylsilane, a few drops of which were added to the $CDCl_3$ solutions; in benzene the positions were measured relative to the solvent and converted to the TMS scale with the factor 128.7 p.p.m. The precision of the measurements is ± 0.05 p.p.m.

All of the materials employed in this work are known compounds and were available to us from earlier studies (8, 9). In general, the carboxylic acids were prepared and converted to the methyl esters by treatment with diazomethane in the usual manner.

Results and Discussion

The shielding results for the monocyclic esters in $CDCl_3$ solutions are listed in Table 1, together with the solvent shifts found for benzene solutions. The data for the *trans*-decalin derivatives are given in Table 2 in which the values for *trans*-decalin itself are included for comparison; the results for the bicyclic systems were obtained only in $CDCl_3$ solutions. With the exception of the C-2 and -3 signals in the cyclopentane and cyclohexane derivatives, the assignment of individual signals in the spectra of the monocyclic materials is straightforward. Since the general pattern of shielding effects of a variety of substituents leads to a downfield shift of the β-carbon signals and an upfield shift for the γ-carbons, relative to their positions for the parent compound (1), the lower field signal of the C-2/C-3 pair has been assigned to the former nuclei. Although relatively few ^{13}C results for aliphatic methyl esters have been reported (1*b*, 10), the carbomethoxyl effects along an alkyl chain are unexceptional; the substituent shifts are: α, 20; β, 3; γ, −2.5; δ, 0.8, and ε, 0.6 p.p.m. Similar trends are expected for the common alicyclic rings on the basis of results for other substituents.

With the assignments listed in Table 1, one can compare the shieldings of indvidual carbons with the values for the parent hydrocarbons to extract the substituent effects. These results are collected in Table 3. The cycloalkane shieldings reported by Burke and Lauterbur (11) were converted to the TMS scale with the factor 193.7 p.p.m. while the *t*-butylcyclohexane data of Roberts *et al.* (12) were converted using 192.8 p.p.m. (1*b*, 13).

With the exception of the cyclopropyl ester, the trends are similar for each compound. The carbomethoxyl group strongly deshields the directly-bonded carbon while the β-carbons are much less affected in all but the cyclopropyl case. A wide variety of substituents cause a similarly large downfield shift at these carbons ranging from 8–15 p.p.m. (14). If the highfield position of cyclopropane itself is primarily caused by a ring-current effect as originally suggested (11), the marked β effect of these substituents could be ascribed to a diminution of the ring current by the electronegative substituents. It should be noted that the β effects of the carbonyl-containing functional groups tend to be *ca.* 2–3 p.p.m. in aliphatic derivatives; a number of such examples has been collected and discussed in relation to the substituted cyclopropanes (1*b*).

The observed tendency for γ-carbons to absorb upfield from their positions in the corresponding hydrocarbons is quite general for a wide variety of substituents and has been attributed to steric perturbations arising from *gauche* interactions of the substituent and the hydrogen on the γ-carbon (1). While this interpretation is perfectly valid for the alicyclic systems having axial substituents (*syn*-axial interactions with the three- and five-hydrogens) it is apparent that the γ-carbons are significantly shifted upfield in compounds in which the carbomethoxyl group is either held in an equatorial orientation or preferentially exists therein because of destabilizing influences in the axial form. For example, the γ-carbon (C-3) in the cyclobutyl ester exhibits one of the largest upfield shifts although one expects that the quasi-equatorial conformation for the carbomethoxyl group on a four-membered ring is much more stable than the quasi-axial. It may be noted that C-3 in cyclobutanol also exhibits a large upfield shift (11.3 p.p.m.) relative to cyclobutane; this γ effect is appreciably larger than the corresponding shift caused by an axial hydroxyl group in various "fixed" alkylcyclohexanols, *e.g.* 6.6–7.2 p.p.m. (12). Clearly steric perturbations cannot account for these effects if the primary assumption regarding the preferred conformation of monosubstituted cyclobutanes is correct. Analogous trends, however, have been found for the norbornyl series (15–17) for which C-6 is shielded in both *exo*- and *endo*-2-substituted norbornanes relative to its position in norbornane. For each case, *endo*-substituents cause a larger shift but the effects of *exo*-groups are appreciable, usually >1 p.p.m. For example, the γ effects of the hydroxyl at C-6 in the nor-

*The α, β, γ, and δ factors are the effects through one, two, three, and four bonds, respectively, given by the difference, $\delta_C^{RCOOMe} - \delta_C^{RH}$; positive values denote downfield shifts.
†*trans*-Decalyl skeletons only; the orientation of COOMe is indicated.

bornanols are −9.7 and −5.2 p.p.m. respectively, while in the corresponding carbomethoxyl derivatives the shifts are −5.0 and −1.4 p.p.m. (15) in the *endo*- and *exo*-esters, respectively. Grutzner *et al.* (15) suggested that the trends for the effects of the *exo*-groups are reminiscent of the well-known W pattern for long-range couplings and that the shielding effects may arise from a similar interaction, namely, overlap of the back lobes of the *exo*-bonding orbitals on C-2 and -6. If this is a contributing factor it follows that such interactions will be even more likely in cyclobutanes because of the closer approach of the carbons involved (C-1 and -3); *viz.* 1.9 *vs.* 2.5 Å.

The data for benzene solutions, listed as incremental shifts in Table 1, show that the carboxyl and methoxyl carbons are shielded in benzene while the remaining carbons are deshielded relative to their values in chloroform. Presumably hydrogen bonding of the carbonyl oxygen with chloroform is responsible for the decreased shielding of the carboxyl carbon which is relayed to the methoxyl carbon. With the exception of the quaternary carbons of the *t*-butyl group, the remaining carbons exhibit a consistent shift of 0.4 ± 0.1 p.p.m. in benzene. Apparently the decreased shift for the quaternary carbons results from the fact that these nuclei are more or less shielded from direct interaction with the solvent by the neighboring methyl groups.

Turning to the *trans*-decalin derivatives (Table 2) it becomes apparent that the trends are similar to those found for the cyclohexyl examples. The axial carboxyl carbons absorb at slightly higher fields than their equatorial counterparts while the methoxyl carbon shielding is essentially independent of the orientation of the COOMe group. To compare the shielding effects of the substituent, the differences between *trans*-decalin and the decalyl esters are included in Table 3; the values for *trans*-decalin (Table 2) agree well with the earlier rapid-passage data (18). (In both Tables the axial ester is the first of each pair listed.) The remarkably good agreement between the shielding effects for the 2-carbomethoxy *trans*-decalins and the 4-*t*-butylcyclohexyl derivatives strongly supports the assignments given in Table 2. In contrast, some of the effects listed for the 1-carbomethoxyl cases differ significantly but the apparent discrepancies for methine carbons are not unexpected since this behavior has been noted for a number of norbornyl derivatives (15). Grutzner *et al.* found that deshielding effects of various substituents are attenuated at methine carbons relative to the shifts exhibited by methylene carbons and possible reasons for the trend were discussed (15). This may also account for the somewhat reduced α effect of the axial 1-carbomethoxyl group relative to those found for the 2-decalyl and 4-*t*-butylcyclohexyl cases. It is interesting that carbons separated by four or more bonds from the carbomethoxyl group tend to absorb at slightly higher fields than the analogous centers in the parent hydrocarbon. The largest γ factor for the equatorial esters is found for C-8 in the *cis*-1-decalyl isomer; this is completely consistent because C-8 and the carbomethoxyl group are *gauche* and the γ effect is essentially the same as that for C-8 in the *trans*-1-decalyl derivative. On the other hand, the enhanced γ factors for C-3 and -10 in the latter case are somewhat surprising although there seems little doubt that the assignments are correct. In any event the overall trends are qualitatively consistent with other results.

The consistency of the substituent effects in the 2-decalyl and 4-*t*-butylcyclohexyl systems indicates that either may be employed as models for "pure" axial and equatorial methyl esters with which conformational analysis of the carbomethoxyl group could be done by application of the Eliel equation (19), $K_e = (\delta^{obsd} - \delta^{ax})/(\delta^{eq} - \delta^{obsd})$. As has been noted (1*b*), ^{13}C spectra may, *in principle*, offer advantages for conformational analysis in this simple fashion since more than one center shows a shielding dependence on substituent geometry. Qualitatively the data in Table 3 for the α-, β-, and γ-carbons in the cyclohexyl and 4-*t*-butylcyclohexyl esters appear to support this notion. For each, the effects in the conformationally mobile compound lie between those for the model axial and equatorial compounds and are closer to the latter as expected. Quantitatively, however, it is apparent that different K_e values are obtained depending on which of the positions is chosen. To allow for the small perturbations caused by the anchoring group in the fixed systems the substituent effects listed in Table 3 should be employed rather than the observed shieldings. Since the difference between axial and equatorial substituents is largest at the α-carbon it would appear to be the best choice for estimations of K_e. Since both the 4-*t*-butyl and 2-decalyl systems should be good models, it follows that the α-carbon data for each are equally appropriate; but K_e values, estimated using each of the two, differ by more than a factor of two; *viz.* 4.9 and 10.7. These results clearly show the weakness of the simple approach and emphasize the need for low-temperature studies of the unsubstituted cyclohexyl ester to determine the conformational equilibrium constant, K_e. At best, the present room temperature data indicate the conformational free energy of the carbomethoxyl group to be *ca.* 1.2 ± 0.2 kcal/mol, in agreement with the accepted value (20).

On the positive side, however, it is clearly apparent that the differences in the shielding effects of axial and equatorial carbomethoxyl groups are sufficiently large that stereochemical assignments of configuration for the COOMe group can be made from the ^{13}C data for related systems such as terpenes. Since structures having geminal methyl and carbomethoxyl groups are commonly encountered in nature, the relative orientations of these substituents are of interest and the results for the 1-methylcyclohexanecarboxylates show that the assignment of stereochemistry would be straightforward from the ^{13}C shieldings, especially that of the methyl group.

We wish to thank the National Research Council of Canada for generous support of this work.

Stereospecific Conjugate Alkenyl Group Transfer to α,β-Enones Using Vinylalane Reagents

JOHN HOOZ AND ROBERT B. LAYTON[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 29, 1973

trans-Alkenyl alanes (easily prepared by hydroalumination of an acetylene) promote the stereospecific 1,4- delivery of the olefinic unit to conjugated ketones. This new conjugate addition reaction provides easy access to *trans*-γ,δ-unsaturated ketones which would otherwise be available with difficulty.

Les alcènylalcanes *trans* (facilement obtenus par hydroalumination d'un acétylenique) introduisent de façon stéréospécifique-1,4 l'unité-oléfine aux cétones conjuguées. Cette nouvelle réaction d'addition conjugée rend les cétones γ,δ insaturées *trans* facilement accessibles, alors que ces dernières sont difficiles à préparer par d'autres voies. [Traduit par le journal]

Can. J. Chem., 51, 2098 (1973)

The β-vinylation of conjugated enones via organocopper "ate" complexes has previously been shown to provide a highly useful, general procedure for appending unsaturated residues to cyclic and acyclic substrates (1) (eq. 1)[2] irrespective of substitution pattern.

[1] $(-C=C-)_2CuLi\cdot L + -C=C-C=O$ (acyclic or cyclic) $\rightarrow -C=C-C-C-C=O$ (acyclic or cyclic)

Several subsequent reports corroborating these results and providing additional interesting applications and extensions of this methodology have appeared, including examples illustrating that the stereochemistry of unsaturation in the organocopper reactant is retained in the product (2–5). This outcome is also contingent on other prior important observations that retention of double bond geometry is preserved, both in: (*i*) converting precursor alkenyl halide to the corresponding lithio species (6, 7), and (*ii*) transforming the resultant organolithium derivative to the appropriate organocopper reagent (8) (eqs 2 and 3).

[2] $C=C(X) \longrightarrow C=C(Li)$

[3] $C=C(Li) \longrightarrow C=C(Cu)$

An effective and unique alternative approach to transferring unsaturated ligands (of the sp type)[3] to conjugated enones makes use of readily available mixed dialkylalkynylalane reagents (eq. 4). This finding (12), in conjunction with a

[4] $R_2AlC\equiv CR' + -C=C-C=O \rightarrow R'C\equiv C-C(-CH-C=O)$

preceding body of evidence,[4] prompted the

[1]Holder of a 1967 Science Scholarship. This work was abstracted in part from a thesis submitted by R. B. Layton to the Faculty of Graduate Studies and Research of the University of Alberta in partial fulfillment of the requirements of the Ph.D. degree, December 13, 1971, and has been discussed in part at the Synthetic Methods and Design Symposium, Carleton University, Ottawa, Canada April 25, 1972.

[2]L = an appropriate complexing reagent (incorporating phosphorus, sulfur; *cf.* (1) and refs. therein).

[3]Although vinylic units can be transferred 1,4- to conjugated enones, albeit in varying degrees of efficiency, from either organocopper (1) or aluminum intermediates (*vide infra*), the situation is considerably different for the conjugate transfer of alkynyl groups. Alkynylcopper reagents are completely ineffective at promoting 1,4-delivery of an acetylenic unit (9, 10) as are acetylenic Grignard reagents (using copper (salt) catalysis (11)), whereas organoalane reagents are uniquely successful (12).

[4]Mixed organoalanes (dialkylalkynyl and di- and trialkylalkenyl) react with a variety of electrophilic functionality in a remarkably specific manner to deliver, almost invariably, only the unsaturated ligand (12–14) in new C—C bond formation.

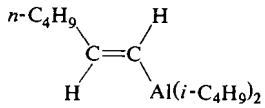
present brief study to explore the possible synthetic potential of conjugate alkenyl transfer from mixed olefinic alanes. In addition to the stereochemical implications inherent in such a study, our prior experience led us to anticipate that some useful synthetic generalizations could emerge regarding the respective efficiencies of Al (and Cu) reagents for conjugate transfer of unsaturated groups. Moreover, since vinylalanes with varying substitution patterns (mono-, di-, and tri-) are available from the appropriate acetylene,[5] the possibility existed of obviating the synthetically tedious, intermediate steps (synthesis of respective *cis*- or *trans*-vinyl halide, followed by eqs. 2 and 3) generally employed when alkenylcuprates are used for conjugate addition.[6]

Diisobutyl *trans*-1-hexenylalane (**1**) was generated by the hydroalumination (diisobutylaluminum hydride) of 1-hexyne (eq. 5). Subsequent

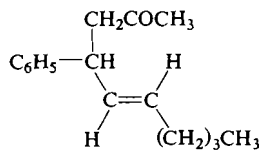
[5] $n\text{-}C_4H_9C{\equiv}CH + (i\text{-}C_4H_9)_2AlH \longrightarrow$



1

reaction with benzalacetone (1.25 h, room temperature, ligroin–benzene solvent) produced, after a hydrolytic work-up, a 67% yield of the product of conjugate transfer of the *trans*-hexenyl unit (eq. 6) (i.r. (film) 1710 (C=O), 970 (*trans*-

[6] $C_6H_5CH{=}CH{-}\overset{O}{\overset{\|}{C}}{-}CH_3 \longrightarrow$



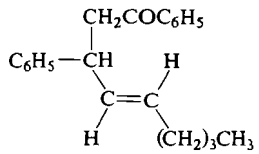
CH=CH) cm^{-1}; n.m.r. ($CDCl_3$) δ 5.45 (m, 2H, $J_{H,H}$ = 15 Hz); mass spectrum, *m/e* M^+ 230).

[5]The hydroalumination of alkynes (with $i\text{-}Bu_2AlH$) involves a *cis*- addition of the Al—H bond to the triple bond to provide (monosubstituted) *trans*-vinylalanes from terminal alkynes and (disubstituted) *cis*-vinylalanes from disubstituted acetylenes. The carbalumination of disubstituted alkynes (using R_3Al) involves a *cis*-addition of the C—Al bond to produce the tri-substituted vinylalane. (15–17).

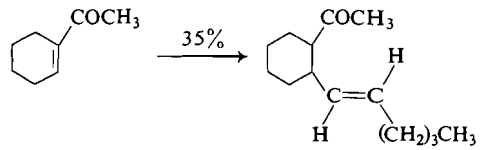
[6]Isomerically pure vinyl halides may also be synthesized by halogenolysis of vinylalanes (18).

The reaction of **1** with several other α,β-enones gave the results summarized in eqs. 7–9.

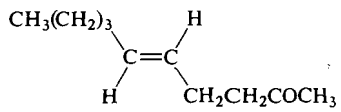
[7] $C_6H_5CH{=}CHCOC_6H_5 \xrightarrow{60\%}$



[8]



[9] $CH_2{=}CH{-}COCH_3 \xrightarrow{30\%}$



In all instances only the unsaturated ligand of **1** is delivered in 1,4-fashion, and the *trans*-stereochemistry is retained. The selectivity of mixed unsaturated alane **1** thus parallels that encountered previously for acetylenic alane reagents (12), although with somewhat diminished efficiency.

Yields are highest for enone systems carrying a β-aryl substituent (eqs. 6 and 7), a result also analogous to alkynyl conjugate transfer reactions using mixed acetylenic alanes.

Recently, the reduction potentials of a wide variety of α,β-unsaturated carbonyl compounds have been measured in an effort to determine the suitability of substrates toward conjugate addition of organocuprates and possibly other organometallic reagents (19). It was found that a β-phenyl group has a stabilizing effect of +0.4 V (energy difference between intermediate anion radical and parent unsaturated carbonyl system). At present we have no firm experimental evidence to either support or reject the possible intermediacy of anion radicals in conjugate transfer reactions employing organoaluminum reagents. Although undoubtedly a number of complex factors (structural type, geometry, temperature, solvent, etc. (12)) are responsible for promoting successful conjugate addition, we merely note at this time that, among the numerous param-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

eters, the yields of conjugate addition products also appear to correlate well with the reduction potentials.

The lower yield observed for methyl vinyl ketone (eq. 9) is not entirely unexpected in view of its notorious tendency toward base-catalyzed condensation/polymerization reactions.[7]

Although no rigorous attempts have been made to maximize yields, we briefly explored the effect of more polar coordinating solvents such as ether and tetrahydrofuran on the course of the reaction.

In hydrocarbon media, the yield of conjugate addition product for methyl vinyl ketone was *ca.* 15%; addition of an equal volume of ether as cosolvent increased the yield to 30% (eq. 9).

Use of the more strongly coordinating base tetrahydrofuran, however, resulted in the complete suppression[8] of 1,4-addition when acetylcyclohexene was employed as substrate (eq. 8).

Corresponding observations have been made elsewhere which also illustrate the dramatic and influential effect that (apparently) subtle variation of reaction conditions exert on the course of conjugate additions (12). Each substrate doubtless possesses its own unique characteristics, and experimentation is required to define optimal reaction parameters.[9]

Treatment of transoid enones, such as 2-cyclohexenone or isophorone with reagent **1** gave rise to complex mixtures from which no conjugate transfer products could be isolated.[8,10]

[7]Indeed, as a consequence of this tendency, this simple substrate represents a fairly stringent methodological challenge. In connection with a discussion of conjugate additions to enones, it has been noted (20) for example, that "the only examples of organocopper conjugate addition to methyl vinyl ketone involve a lithium divinylcuprate (1) and cuprous chloride catalysis of *m*-methoxybenzylmagnesium chloride (21)." In addition to the present example acetylenic alane reagents (12) and organoboranes (22) may be included.

[8]These reactions are conveniently monitored by i.r. spectroscopy. I.r. analysis of a hydrolyzed aliquot showed complete disappearance of conjugated enone (CO) absorption due to starting material, and considerable hydroxyl absorption. In this, as in the cases of 2-cyclohexenone and isophorone, attempts at isolating or assessing the (presumed) 1,2-addition products from the crude mixture were fruitless, owing to the sensitivity of the tertiary diallylic alcohols.

[9]See footnote 11 of ref. 12 for several additional examples of the effect of reaction variables on conjugate addition and related reactions.

[10]Dialkyl acetylenic alane reagents also fail to effect conjugate addition of the alkyne unit to transoid enones (12).

Despite these intrinsic limitations, it is clear that the directness of this approach, the ease and availability of reagents, and the clean stereochemical outcome, recommend this method as a potentially useful new synthetic device for effecting the stereospecific conjugate transfer of alkenyl groups to enones.

Two recent reports have appeared in connection with synthetic approaches towards prostoglandins which offer promise of widening the range of conjugate addition reactions promoted by Al reagents. Originally, it was noted that the 1,4-alkyne transfer process was restricted to enones capable of adopting a cisoid geometry (12). This has recently been extended by Searle workers, who, employing triacetylenic alanes, have found that a (cyclic) transoid enone structural type can also be accommodated (23). Although inherently wasteful of two organic residues, this extension nonetheless permits direct access to acetylenic ketones which would otherwise be available rather circuitously.

It has also been observed that *trans*-vinyl Al "ate" complexes react with conjugated ketones to transfer only the vinyl ligand in a 1,4-manner and the *trans*-stereochemistry is retained (24). Since this reaction is applicable to transoid enones, it complements the results described here for vinylalanes.

The new alkylation procedure described herein, taken as a body with other recent developments, demonstrates the extraordinary effectiveness and selectivity of conjugate transfer of unsaturated groups promoted by alane (or alanate) reagents. Also, the ready availability of both *cis*- and *trans*-substituted vinylaluminum reagents (25) by hydroalumination of alkynes, combined with the present results, clearly contribute to the expectation that this methodological approach should make possible by further extension the conjugate delivery of either *cis*- or *trans*-substituted vinylic groups to a broad range of enone structures with retention of olefinic geometry.

Experimental

General Considerations

I.r. spectra were recorded using a Unicam SP 1000 i.r. spectrophotometer. N.m.r. spectra were obtained on a Varian A-60 spectrometer using deuteriochloroform as solvent and tetramethylsilane as internal reference. Mass spectra were measured by Dr. A. M. Hogg and his associates using an A.E.I. Model MS-2 spectrometer at an ionization potential of 70 eV. Ligroin, b.p. 63–75°, supplied by Eastman Kodak Co., was successively treated with $KMnO_4$, concentrated H_2SO_4, $KMnO_4$, H_2O, then

refluxed over CaH_2 and distilled from CaH_2 prior to use. Diisobutylaluminum hydride was obtained from Ventron Corp. A representative experimental procedure is described for the conjugate addition to benzalacetone.

4-Phenyl-trans-5-decen-2-one

1-Hexyne (90 mmol) was hydroaluminated with diisobutylaluminum hydride (14.3 ml) in 55 ml of ligroin for 2 h at 50° (18). A solution of benzalacetone (40 mmol) in 20 ml of a mixture of ligroin–benzene (1:1 by volume) was added (0.5 h) at 25°. After stirring the mixture for an additional 0.75 h, i.r. analysis of a dried (Na_2SO_4) ether extract of a hydrolyzed (ice – concentrated HCl) aliquot indicated the complete consumption of starting material; analysis by g.l.p.c. indicated a 67% yield of 4-phenyl-*trans*-5-decen-2-one; i.r. (film) 1710, 1600, 1490, 1450, 970, 700 cm^{-1}; n.m.r. ($CDCl_3$) δ 7.15 (s, 5, C_6H_5), 5.45 (m, 2, CH=CH), 3.79 (q, 1, —C*H*—C_6H_5), 2.75 (d, 2, $COCH_2$), 1.98 (s, 3, CH_3CO), 1.95 (m, 2, —C*H*$_2$—CH=), 1.25 (m, 4, $(CH_2)_2$), 0.8 (t, 3, C*H*$_3$CH$_2$); mass spectrum *m/e* 230 (25), 172 (38), 159 (31), 131 (34), 129 (35), 117 (71), 105 (16), 91 (71), 43 (100).

Anal. Calcd. for $C_{16}H_{22}O$: C, 83.43; H, 9.63. Found: C, 83.79; H, 9.50.

The Preparation of Specifically Deuterated *trans*-Cinnamyl Alcohol and *trans*-Cinnamic Acid

DONALD G. LEE AND JAMES R. BROWNRIDGE[1]

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan S4S 0A2

Received January 16, 1973

The reduction of ethyl phenylpropiolate by lithium aluminum hydride results in partial reduction of the triple bond to give *trans*-cinnamyl alcohol. If ethyl phenylpropiolate is reduced by $LiAlD_4$ followed by work-up with acetone and H_2O the product is the specifically labeled compound, *trans*-3-phenyl-2-propen-1-ol-1,1,2-d_3. If the ester is reduced with $LiAlH_4$ followed by work-up with acetone-d_6 and D_2O the product is *trans*-3-phenyl-2-propen-1-ol-*O*,3-d_2. Oxidation of these two products by sodium ruthenate leads to formation of *trans*-cinnamic acid-α-*d* and *trans*-cinnamic acid-β-*d*, respectively.

La réduction de phénylpropiolate d'éthyle par l'hydrure de lithium et aluminium a pour résultat une réduction partielle de la triple liaison pour conduire à l'alcool cinnamique *trans*. Si ce même ester est réduit par $LiAlD_4$ puis traité par l'acétone et l'eau, le produit obtenu est le phényl-3 propène-2 ol-1 d_3-1,1,2 *trans*, spécifiquement marqué. L'ester est réduit par $LiAlH_4$ puis traité par l'acétone *d*-6 et D_2O, le produit est le phényl-3 propène-2 ol-1 d_2-*O*,3 *trans*. L'oxydation de ces deux composés par le ruthénate de sodium conduit à l'acide cinnamique *trans*, α-*d* et β-*d* respectivement.

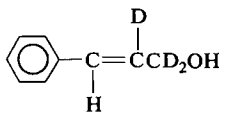
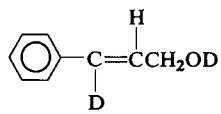
Can. J. Chem., **51**, 2102 (1973)

The use of specifically labeled organic compounds has become an important procedure in the study of organic reaction mechanisms. In particular, the ability to specifically incorporate deuterium is important for two reasons: (*i*) for the study of isotope effects (1) and (*ii*) because deuterium substitution greatly simplifies proton n.m.r. spectra (2).

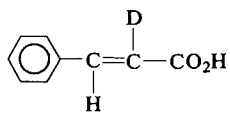
We have developed a method which has permitted us to prepare two deuterated cinnamyl alcohols (**1** and **2**) and the corresponding cinnamic acids (**3** and **4**). Although the method as we have used it is specific for these four compounds it is quite likely that it may have general application to many other compounds of this type.



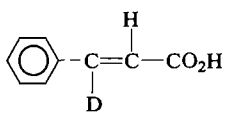
1



2



3



4

Compound **1** was prepared by the partial reduction of ethyl phenylpropiolate (3) with $LiAlD_4$ as indicated in Scheme 1, whereas compound **2** was prepared by reduction with $LiAlH_4$ followed by work-up with acetone-d_6 and dilute D_2SO_4 in D_2O as shown in Scheme 2. The cinnamic acids were obtained by oxidation of the corresponding cinnamyl alcohols with sodium ruthenate (4).

The compounds were identified by use of i.r. and n.m.r. spectroscopy. The proton n.m.r. spectra for compounds **1–4** which provide unambiguous proof of their structures, have been placed in the Depository of Unpublished Data.[2]

The acetone was added in each case to react with any excess reductant before the hydrolysis step was attempted (5). It was observed that if unlabeled acetone was used in Scheme 2 no labeled product was obtained. Presumably an intermediate carbanion capable of abstracting a proton from acetone is formed in the reaction. A probable mechanism for the reaction is outlined in Scheme 3.

Experimental

trans-3-Phenyl-2-propen-1-ol-1,1,2-d_3

Ethyl phenylpropiolate (6.0 g) in 30 ml of anhydrous ether was added from a dropping funnel to 2.18 g of $LiAlD_4$ in 150 ml of absolute ether at room temperature

(3). The solution was then refluxed for 3 h, after which the excess reductant was decomposed with 20 ml of anhydrous acetone followed by 60 ml of cold dilute (0.1 *M*) H_2SO_4. The aluminum hydroxide which precipitated was dissolved by adding 60 ml of 20% H_2SO_4 and the resulting two layers separated. The aqueous layer was extracted with 3 × 50 ml of ether which was combined with the original ether layer and dried over anhydrous calcium chloride. The ether was evaporated and the residue distilled (80°/0.15 mm) to give 3.34 g (71%) of *trans*-3-phenyl-2-propen-1-ol-1,1,2-d_3 which was identified from its i.r. and n.m.r. spectra.

trans-3-Phenyl-2-propen-1-ol-O,3-d_2

As described above, ethyl phenylpropiolate (6.0 g) was reduced with 1.97 g of $LiAlH_4$. After refluxing for 3 h the excess reductant was cautiously decomposed with 3 ml of acetone-d_6 in 20 ml of absolute ether followed by 50 ml of cold dilute (0.1 *M*) D_2SO_4 in D_2O and then by 50 ml of 20% D_2SO_4 in D_2O. The two layers which formed were separated and the aqueous layer extracted as before. The combined ether extracts were dried and evaporated, and the residue distilled to give 3.43 g (73%) of *trans*-3-phenyl-2-propen-1-ol-*O*,3-d_3 which was identified from its i.r. and n.m.r. spectra.

trans-Cinnamic Acid-α-d

This compound was prepared by the oxidation of *trans*-3-phenyl-2-propen-1-ol-1,1,2-d_3 with sodium ruthenate (4). The deuterated cinnamyl alcohol (1.98 g) was suspended in 150 ml of 1.0 *M* aqueous NaOH cooled in an ice–water bath and 604 ml of 0.048 *M* Na_2RuO_4 were added from a dropping funnel. The reaction mixture was stirred continuously and allowed to warm to room temperature overnight. The mixture was filtered through a fine frit to remove the black ruthenium dioxide (RuO_2) which formed, and the filtrate extracted with 3 × 75 ml of ether. The ether layer was dried with anhydrous calcium chloride and evaporated using a water aspirator to leave a liquid (0.3 g, 22% by weight of the total reaction products) which was subsequently identified as benzaldehyde by i.r. and n.m.r. spectra. The aqueous layer was acidified and reextracted with 3 × 75 ml of ether. The ether in turn was dried, filtered, and evaporated leaving a yellow residue. Recrystallization of the residue from ethanol–water gave *trans*-cinnamic acid-α-*d* (1.08 g, 50% yield) identified by i.r. and n.m.r. spectra, m.p; 135–136°, lit. (6) 135°.

trans-Cinnamic Acid-β-d

The oxidation of the *trans*-3-phenyl-2-propen-1-ol-*O*,3-d_2 was carried out in the same manner as described above. The alcohol (0.686 g) was oxidized by 650 ml of 0.0155 *M* Na_2RuO_4 to yield 0.40 g (53% yield) of *trans*-cinnamic acid-β-*d* identified from its i.r. and n.m.r. spectra; m.p. 135–136°.

As was the case for *trans*-cinnamic acid-α-*d*, another reaction product (0.15 g, 27% by weight of the total reaction products) was isolated from the ether layer in the extraction step. The impure sample again appeared to be benzaldehyde. More specifically, one would expect the product to be benzaldehyde-α-*d* as was shown by n.m.r.

The isolation of benzaldehyde from both oxidation procedures indicates that cleavage of the carbon–carbon double bond in the alcohols is a substantial side reaction.

The Position of Phosphate Groups in the Phosphonomannan of *Hansenula capsulata*, as Determined by Carbon-13 Magnetic Resonance Spectroscopy[1]

PHILIP A. J. GORIN

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan S7N 0W9

Received December 18, 1972

The carbon-13 magnetic resonance spectrum of a phosphate of 2-*O*-β-D-mannopyranosyl-α,β-D-mannose was compared with that of the unphosphorylated disaccharide. The positions and number of the signals of C-5's which are coupled to phosphorus-31, together with other spectral data show that the phosphate group is on C-6 of the reducing end-unit (**2**, Fig. 1). This differs from a previous assignment (**1**), thus necessitating a revision (**4**) to the structure **3** proposed for the parent *Hansenula capsulata* phosphonomannan.

Le spectre de résonance magnétique du carbone-13 pour le phosphate, de β-D-mannopyranosyl-2-*O* D-mannose-α,β est comparé à celui d'un disaccharide non-phosphorylé. Les positions et le nombre de signaux correspondant aux positions C-5 qui sont couplés au phosphore-31, ont montré ainsi que d'autres données spectrales que le groupe phosphate se trouve sur la position C-6 de l'unité réductrice terminale (**2**, fig. 1). Ce résultat diffère de l'attribution antérieure (**1**) ce qui, par conséquent entraîne un changement (**4**) en faveur de la structure **3** proposée pour le phosphonomannane *Hansenula capsulata* parent.

[Traduit par le journal]

Can. J. Chem., **51**, 2105 (1973)

The carbon-13 magnetic resonance (c.m.r.) spectra of polyhydroxy compounds have been compared with those of their *O*-methyl ethers, both in the inositol (*1*), pentopyranose and hexopyranose series (2, 3). It was found that the carbon resonance of the $^{13}CHOCH_3$ group in the *O*-methyl ether is approximately 8 p.p.m. downfield from that of the corresponding $^{13}CHOH$ group in the unsubstituted compound. The resonances of the signals of the other carbon atoms were either identical or differed to only a relatively small extent, on going from one compound to the other. By using this observation it has been possible to assign signals to certain carbons in polyhydroxy compounds (1, 2, 4) and conversely it should be possible to identify *O*-methyl ethers by comparison of their c.m.r. spectra with already rationalized spectra of the parent polyhydroxy compound.

An analogous approach is applicable to phosphates since Mantsch and Smith (5) obtained the c.m.r. spectra of the 2′-, 3′- and 5′-phosphates of uridine and found that the resonances of carbons were displaced downfield on phosphorylation of their adjacent hydroxyl groups. In addition it was found by these and earlier workers (6) that both $^{13}C–O–^{31}P$ and $^{13}C–C–O–^{31}P$ coupling takes place in the ribofuranose portion of various nucleotides.

These spectral properties have now made it possible to locate certain of the phosphate groups in the phosphonomannan of *Hansenula capsulata* NRRL Y-1842 (for references to this and other phosphonomannans see ref. 7). Although the polysaccharide gives solutions that are too viscous for spectral studies, a phosphate of 2-*O*-β-D-mannopyranosyl-α,β-D-mannose can be obtained on partial acid hydrolysis which is amenable to examination. Periodate oxidation data suggested that the phosphate group was on one of the C-6's, the non-reducing end-unit being favored (8); (**1**, Fig. 1). In the present study the c.m.r. spectrum of the disaccharide phosphate has been rationalized and the location of the phosphate group determined using the c.m.r. spectra of α- and β-D-mannose, 2,6-di-*O*-methyl-α,β-D-mannose, α,β-D-mannose-2-*d*, α,β-D-mannose-6-phosphate, 2-*O*-β-D-mannopyranosyl-α,β-D-mannose, and methyl β-D-mannopyranoside, on which spectral assignments are available or can be determined.

In general c.m.r. spectra were obtained using solutions of carbohydrate in deuterium oxide maintained at 27 °C. Phosphates were examined as free acids since the acidic form of α,β-D-mannose-6-phosphate gave a well defined spec-

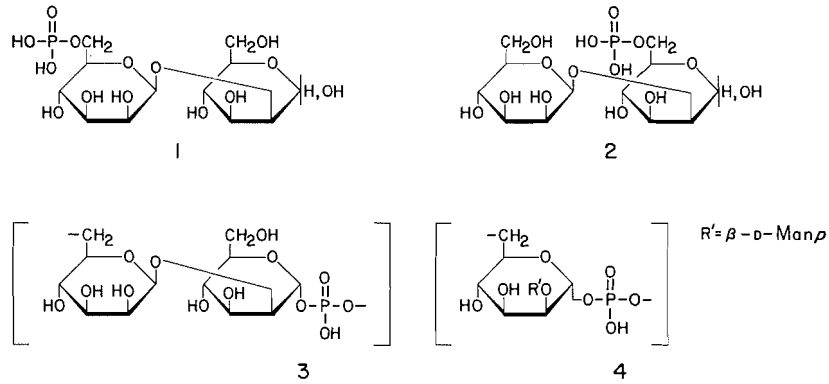

FIG. 1. Old and revised structures for the phosphonomannan of *Hansenula capsulata* and the derived mannobiose-6-phosphate.

trum, whereas the potassium salt gave a C-5 signal that was partially obscured by the C_β-3 signal. C-6 signals of unsubstituted hexoses are generally located at higher field than those of other carbons, and are assignable by the known shielding effect of the substituents on CH_2OH groups (9). However, C-6 signals of CH_2OP groups are more difficult to assign since they are closer to other signals because of the deshielding effect of the phosphate group. They were characterizable, however, by reference to spectra obtained with only partial proton decoupling. The CH_2 groups gave triplets arising from ^{13}C–H coupling, each of the signals being finely split by virtue of ^{13}C–O–^{31}P coupling.

The c.m.r. signals of α- and β-D-mannose have been assigned to carbon atoms by Dorman and Roberts (2) and by Perlin and coworkers (3). Their separate assignments agree except for the relative locations of the C-3 and -2 signals of β-D-mannose, which are at δ_C 73.6 and 71.8 (Table 1). The conclusions of Dorman and Roberts are shown to be correct by comparing the displacements of the ^{13}C signals on going from α,β-D-mannose to 2,6-di-*O*-methyl-α,β-D-mannose (Table 1). The C_β-6 signals are displaced from δ_C 61.6 to 71.3 (or δ_C 70.5) and the C_β-2 signals from δ_C 71.8 to 81.9. The C_β-3 signal at δ_C 73.6, which is not affected by substitution of the adjacent hydroxyl, is displaced only 0.3 p.p.m. to δ_C 73.9. A further confirmation of the assignments could be made by examination of the c.m.r. spectrum of α,β-D-mannose-2-*d*, prepared by an analogous method to that of Isbell *et al.* (10). The C_α-2 and C_β-2 signals should be very small because of the presence of an adjacent deuterium nucleus (11) and it was found that the signals at δ_C 71.2 and 71.8, corresponding respectively to C_α-2 and C_β-2, could not be detected (Table 1).

In agreement with the results of Mantsch and Smith (5) the c.m.r. spectra of α,β-D-mannose and α,β-D-mannose-6-phosphate contain many signals with common resonances (Table 1; Fig. 2 spectra A and C). The resonances of C-1, -2, -3, and -5 signals had undergone little change on phosphorylation whereas the C-6 resonances in the phosphate were displaced 2.2 p.p.m. downfield. The C-6 resonances of the α- and β-phosphate are at δ_C 63.7 with $^2J_{^{13}C-^{31}P}$ = 7 Hz. C_α-5 and C_β-5 signals of α,β-D-mannose (2) at δ_C 72.9 and 76.7 correspond to those in the phosphate at δ_C 72.6 ($^3J_{^{13}C-^{31}P}$ = 7 Hz) and 76.1 ($^3J_{^{13}C-^{31}P}$ = 7 Hz), respectively.

2-*O*-β-D-Mannopyranosyl-α,β-D-mannose was obtained from the mannobiose phosphate (8) by the action of alkaline phosphatase. The structure proposed by Slodki for the disaccharide (8) was confirmed as follows. In a methylation-fragmentation study the 3,4,6-tri-*O*- and 2,3,4,6-tetra-*O*-methyl derivatives of methyl α,β-D-mannopyranoside were obtained and characterized by g.l.c. (12, 13), thus indicating 2-*O*-substitution. The configuration of the linkage is β since the specific rotation of 2-*O*-D-mannopyranosyl-D-mannitol, derived by sodium borohydride reduction, is −43°, lower than +45° reported for 2-*O*-α-D-mannopyranosyl-D-mannitol (14).

The c.m.r. spectrum of 2-*O*-β-D-mannopyranosyl-α,β-D-mannose is complex (Table 1; Fig. 2; spectrum B) but assignments for the C-6

TABLE 1. Chemical shifts and assignments of c.m.r. signals of mannose and derivatives

Compound	Downfield difference of chemical shifts of assigned signals from that of external TMS, contained in a coaxial capillary in p.p.m. (δ_C)
1. α,β-D-Mannose (2)	94.5 (C_α-1) 94.1 (C_β-1) 76.7 (C_β-5)† 73.6 (C_β-3) 72.9 (C_α-5) 71.8 (C_β-2) 71.2 (C_α-2) 70.8 (C_α-3) 67.5 (C_α-4) 67.1 (C_β-4) 61.6 (C_α-6, C_β-6)
2. α,β-D-Mannose-6-phosphate	94.8 (C_α-1) 94.4 (C_β-1) 76.1 (C_β-5; J 7 Hz) 73.3 (C_β-3) 72.6 (C_α-5; J 7 Hz) 71.9 (C_β-2) 71.3 (C_α-2) 70.6 (C_α-3) 67.1 and 66.7 (αβC4) 63.7 ($C_{\alpha\beta}$-6; J 5 Hz)
3. 2-*O*-β-D-Mannopyranosyl-α,β-D-mannose*	101.4 (C_β-1′) 99.2 (C_α-1′) 94.1 (C_β-1) 92.4 (C_α-1) 80.0 (C_β-2) 78.6 (C_α-2) 76.9 (C_β-5, $C_{\alpha\beta}$-5′) 73.3 ($C_{\alpha\beta}$-3′, C_β-3) 73.1 (C_α-5) 72.4 71.9 71.4 71.0 70.8 70.2 67.7 and 67.3 ($C_{\alpha\beta}$-4, $C_{\alpha\beta}$-4′) 61.6 and 61.3 (C-6′, $C_{\alpha\beta}$-6)
4. Phosphate of 2-*O*-β-D-mannopyranosyl-α,β-D-mannose*	101.4 (C_β-1′) 99.1 (C_α-1′) 94.3 (C_β-1) 92.5 (C_α-1) 79.8 (C_β-2) 78.3 (C_α-2) 76.9 ($C_{\alpha\beta}$-5′) 75.7 (C_β-5, J 7 Hz) 73.3 ($C_{\alpha\beta}$-3′, C_β-3) 72.7 72.1 (C_α-5, J 8 Hz) 71.3 70.8 70.0 67.7 and 67.3 ($C_{\alpha\beta}$-4′, $C_{\alpha\beta}$-4, C_β-4) 64.6 ($C_{\alpha\beta}$-6, J 5 Hz) 61.6 (C-6′)
5. 2,6-Di-*O*-methyl-α,β-D-mannose	94.5 (C_β-1) 91.3 (C_α-1) 81.9 (C_β-2) 81.6 (C_α-2) 75.3 (C_β-5) 73.9 (C_β-3) 72.1 (C_α-5) 71.3 and 70.5 (C_α-3, C_β-6, C_α-6) 67.9 (C_α-4) 67.7 (C_β-4) 59.2 and 59.0 ($OCH_3$2, $OCH_3$6)
6. α,β-D-Mannose-2-*d*	94.5 (C_β-1) 94.2 (C_β-1) 76.8 (C_β-5) 73.6 (C_β-3) 72.9 (C_α-5) 70.7 (C_α-3) 67.5 (C_α-4) 67.3 (C_β-4) 61.6 (C_α-6, C_β-6)

*The carbons with prime numbers are those of the non-reducing end, carbons with nonprime numbers are those of the reducing end, α and β refer to the anomeric configuration of the reducing end.
†Underlined shifts are those used directly in assignment of position of the phosphate group in the mannobiose phosphate.

(from a ^1H coupled c.m.r. spectrum) and C-5 signals can be made. The latter assignment can be made since it has been found in this laboratory (15) that the c.m.r. spectrum of a D-mannopyranosyl unit in an oligosaccharide undergoes little change on substitution with another D-mannopyranosyl unit, except that the resonance of the carbon attached to the glycosyl unit is displaced downfield. Based on this finding the positions of the signals of C-5′ of the non-reducing end-units and C-5 of the reducing end-units of the α- and β-anomers can be predicted by reference to the chemical shifts of C-5 signals of methyl β-D-mannopyranoside (3) and α- and β-D-mannose (2).

Inspection of the c.m.r. spectrum of the unknown phosphate of 2-*O*-β-D-mannopyranosyl-α,β-D-mannose (Table 1; Fig. 2; spectrum D) shows that it resembles that of the unphosphorylated disaccharide except for the C-5 and -6 regions. One C-6 signal of the phosphate has a resonance of δ_C 61.6 corresponding to those at δ_C 61.6 and 61.3 for the C-6's of the disaccharide. The other C-6 signal is coupled (J = 5 Hz) and is displaced 3.2 p.p.m. downfield due to substitution by a phosphate group. The C-5 portions of the phosphate spectrum contain two signals with three-bond ^{13}C–^{31}P coupling. These signals correspond respectively in their resonances and coupling constants (δ_C 72.1, J = 8 Hz; δ_C 75.7, J = 7 Hz) to the C_α-5 and C_β-5 signals of α,β-D-mannose-6-phosphate (δ_C 72.6, J = 7 Hz; δ_C 76.1, J = 7 Hz), respectively, thus indicating a phosphate substituent on O-6 of the reducing end (Fig. 1; **2**). The other possibility, suggested by Slodki (8) namely that the CH_2OP group is located as the non-reducing end-unit (Fig. 1; **1**) is ruled out since its spectrum would contain only one coupled C-5 signal in the vicinity of the corresponding resonance from methyl β-D-mannopyranoside (ref. 3; corrected to δ_C 76.3, for an external TMS standard).

The phosphate was not amenable to a confirmatory methylation-fragmentation experiment, incorporating the Kuhn reaction. The products, following conversion to methyl glycosides, were examined by g.l.c., but only methyl glycosides

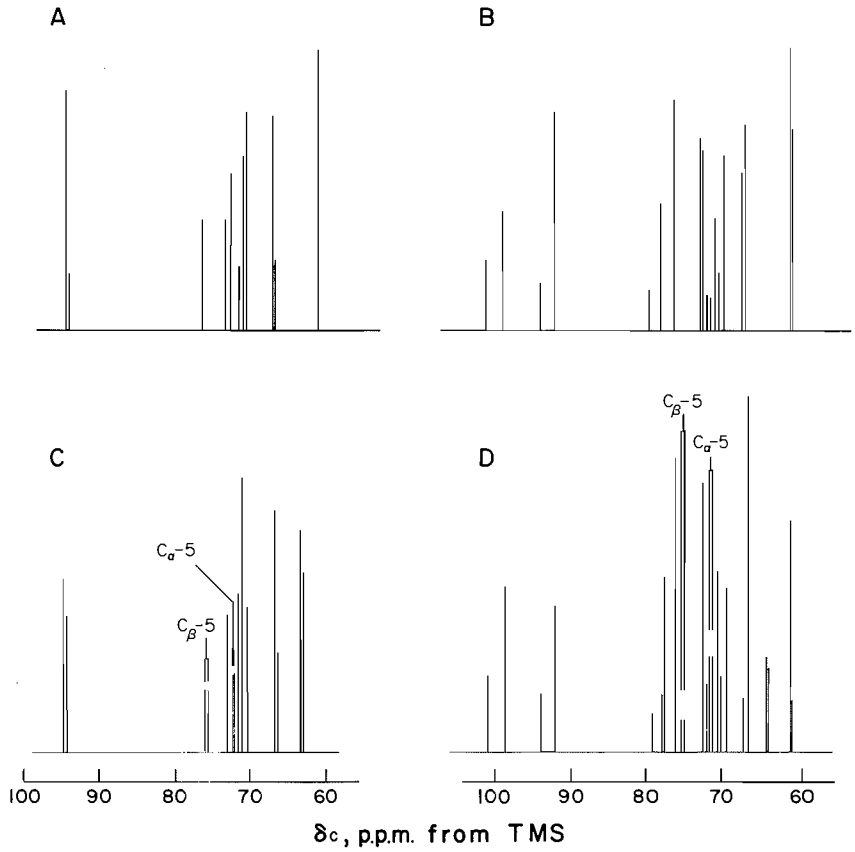

FIG. 2. C.m.r. spectra of α,β-D-mannose (A), α,β-D-mannose-6-phosphate (C), 2-*O*-β-D-Mannopyranosyl-α,β-D-mannose (B), and 2-*O*-β-D-Mannopyranosyl-α,β-D-mannose-6-phosphate (D).

of 2,3,4,6-tetra-*O*-methyl-D-mannose, from the non-reducing end, could be detected. The fate of the phosphorylated unit was not determined.

The structure of the phosphonomannan of *H. capsulata* which was assigned a high proportion of repeating unit **3** (Fig. 1) is therefore incorrect (8). Instead a more highly branched structure must be proposed with a high proportion of a repeating unit containing α-D-mannopyranose units connected by (1 → 6)-phosphorodiester linkages, with each unit substituted in the 2-position by a β-D-mannopyranose unit (Fig. 1; **4**).

Experimental

C.m.r. spectra were obtained using a Varian XL-100-15 n.m.r. spectrometer with Fourier transform and D_2O solutions (4 ml) of 0.3–1.0 g of compound contained in 12 mm diameter × 8 in. tubes at a temperature of 27°. The sweep width was 5000 Hz, the acquisition time 0.4 s and the pulse width 50 μs. 1000–5000 Transients were used, the exact number depending on the sample size and the type of compound examined. Chemical shifts are expressed in p.p.m. and are based on the downfield difference of the resonance signal and that of external TMS contained in a coaxial capillary. Coupling constants *J* are in Hz.

The barium salt of D-mannose-6-phosphate was obtained from Sigma Chemical Co., St. Louis, Mo. It was converted to the free acid by shaking in an aqueous solution with Amberlite 1R120 (H^+ form), followed by filtration and evaporation. 2,6-Di-*O*-methyl-D-mannose was prepared by acid hydrolysis (0.5 *M* H_2SO_4, 100°, 18 h) of methyl 2,6-di-*O*-methyl-α-D-mannopyranoside (16).

Isolation and Characterization of 2-O-β-D-Mannopyranosyl-α,β-D-mannose

The mannobiose phosphate (1.0 g) in water (50 ml) containing sodium bicarbonate (250 mg) was treated with alkaline phosphatase (0.3 ml; from *E. coli*, No. P-4253 supplied by Sigma Chemical Co.) and the solution was deionized with Amberlite 1R120 (H^+ form) and Dowex 1-X8 (bicarbonate form), filtered, and evaporated. The product (0.70 g) had $[\alpha]_D^{25}$ −36° (*c*, 0.3 H_2O). P.m.r. data (D_2O at 70°; shifts are based on the downfield difference δ of the signal from that of a tetramethylsilane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

external standard): δ 5.86 (J = 2 Hz), 5.35 (H-1's of α-anomer); δ 5.57, 5.50 (H-1's of β-anomer). The two sets of signals were in a 2.4:1 ratio. The 2-*O*-β-D-mannopyranosyl-D-mannitol, derived by reduction with aqueous sodium borohydride, had $[\alpha]_D^{25}$ −43° (*c*, 0.3 H_2O), corresponding to a β-linkage (2-*O*-α-D-mannopyranosyl-D-mannitol has $[\alpha]_D^{25}$ +45° (14) and gave a single anomeric signal at δ 5.41).

The linkage position in the reducing disaccharide was confirmed by successive Kuhn methylation, hydrolysis, and treatment with methanolic hydrogen chloride. The products were characterized by g.l.c. of the free glycosides and the mixture obtained on trimethylsilylation as methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-mannoside and methyl 3,4,6-tri-*O*-methyl-α,β-D-mannoside (12, 13), thus indicating a 2-*O*-substituted mannobiose.

An analogous experiment was carried out with the mannobiose phosphate (**2**; Fig. 1), but the only identifiable product was methyl 2,3,4,6-tetra-*O*-methyl-α,β-D-mannopyranoside arising from its non-reducing end unit.

The author would like to thank Mr. M. Mazurek for carrying out c.m.r. spectral determinations.

Proton Magnetic Resonance Studies of Rotational Isomerism in Halotoluene Derivatives. IX. Rotational Barriers and Conformational Energy Differences in $\alpha,\alpha,\alpha',\alpha',\alpha'',\alpha''$, 2,4,6-Nonachloromesitylene

J. PEELING,[1] B. W. GOODWIN,[1] T. SCHAEFER, AND J. B. ROWBOTHAM[2]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received January 2, 1973

The activation parameters for the rotation of the dichloromethyl groups in the two conformations of α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene are reported for solutions in toluene-d_8 and in methylene chloride. In addition, free energies of activation are given for solutions in bromochloromethane, trichloroethylene, and in carbon disulfide. The free energies of activation are lower in the toluene solution than in the other solutions. The entropies of activation are near zero, perhaps slightly negative. The symmetrical conformation is more stable than the unsymmetrical one in all the solvents.

Les paramètres d'activation pour la rotation des groupes dichlorométhyles dans les deux conformations de l'α,α,α′,α′,α″,α″,2,4,6-nonachloromésitylène ont été rapportés pour des solutions dans le toluène-d_8 et le dichlorométhane. De plus, les énergies libres d'activation ont été présentées pour les solutions dans le bromo chlorométhane, trichloroéthylène, et disulfure de carbone. Les énergies libres d'activation sont plus basses dans le toluène que pour les autres solvants; les entropies d'activation sont proches de zéro, voire même légèrement négatives. La conformation symétrique est plus stable que celle qui est non symétrique dans tous les solvants. [Traduit par le journal]

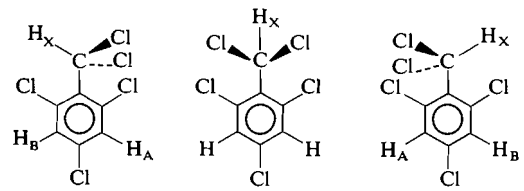
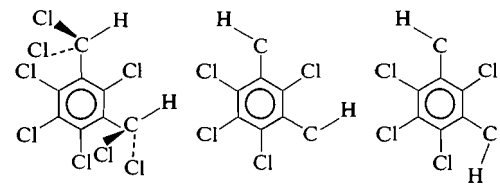
Introduction

The preferred conformation of the dihalomethyl group in halotoluene derivatives is one in which its C—H bond lies in the plane of the aromatic ring (1–3). The conformation of highest energy, the transition state, is evidently that in which the C—H bond lies in a plane perpendicular to the aromatic ring (4). The energy difference between these conformations in a number of compounds can be measured by monitoring the temperature dependence of their p.m.r. spectra. For example, in α,α,2,4,6-pentachlorotoluene (PCT) rotation by π radians about the sp^2–sp^3 carbon–carbon bond converts **1** to **3** via **2**, thereby interchanging the chemical



1 **2** **3**

shifts of the ring protons (1). The shape of the ring proton spectrum therefore depends on the rate of rotation, allowing the extraction of the parameters of activation from **1** to **2**. The chemical shift of the side-chain proton, H_x, is invariant to the rotation. On the other hand, in α,α,α′,α′,2,4,5,6-octachloro-*m*-xylene (MOCX)



6 **5** **4**

rotation of one of the dichloromethyl groups in any one of **4**, **5**, and **6** converts one conformation into another and the shape of the side-chain proton spectrum now depends on the rotation rate (2). The activation parameters obtained from the side-chain proton spectra in MOCX agree rather well with those from the ring proton spectra in PCT, although it is not possible to distinguish between activation energies for, say, conversion from **4** to **5** and from **5** to **6**.

In α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene (NCM) the effect of the exchange process on the chemical shifts is somewhat more involved than in PCT or MOCX. Thus, rotation of one of the dichloromethyl groups in **7** converts **7** to

7 8

8 but only rotation of H_3—CCl_2 in **8** will convert **8** back to **7**. Rotation of either of the other two groups in **8** produces an equivalent conformation **8**. But note that any one of these rotations, whether intra- or interconformational, interchanges the chemical shifts of some or of all of the protons and it proves possible to determine the activation parameters for the conversion from **7** to **8** as well as from **8** to **8**.

This paper describes the synthesis of NCM and the determination of its intramolecular activation parameters in toluene-d_8 and methylene chloride solutions. The solubility of NCM in common solvents is restricted but it has been possible to measure the free energy differences between **7** and **8** in a few additional solvents. The free energies of activation for the above conversions are also measured in these solvents.

Experimental

(1) Preparation of NCM

Chlorine gas was bubbled through a solution of mesitylene in CCl_4 in the presence of iron powder until the proton resonance spectrum indicated complete chlorination of the ring positions. After recrystallization, the 2,4,6-trichloromesitylene was further chlorinated in the presence of u.v. light as described for PCT (5). The chlorination was terminated when the proton resonance peaks arising from monochloromethyl groups disappeared. The product was recrystallized twice from CCl_4, m.p. 187–189 °C.

(2) Spectral Measurements

Solutions of NCM, 3.0 mol % in toluene-d_8 and 1.5 mol % in CH_2Cl_2, CH_2ClBr, CCl_2=CHCl, and CS_2, were carefully degassed. Each contained a small amount of tetramethylsilane (TMS) as an internal reference and locking material. The low concentrations of NCM prevented precipitation at low temperatures. Great care was taken in avoiding line shape distortions from saturation or filtering while recording the proton resonance spectra at a sweep rate of 0.02 Hz/s on an HA100-D spectrometer. Calibration of peaks has been described previously (6) as has the measurement of sample temperatures (6).

Results and Discussion

(1) The Exchange Processes

The protons are isochronous in **7** but anisochronous in **8**, so that the proton resonance spectrum displays four peaks at temperatures where rotation about the sp^2–sp^3 carbon–carbon bonds is slow. When one of the dichloromethyl groups in **7** undergoes a rotation by π radians, H_2 exchanges with H_1, H_3, and H_4 of **8**. The latter is converted back to **7** only by rotation of the group H_3—CCl_2 but, because **8** can be produced from **7** in three equivalent ways, the *a priori* probability of the process **7** → **8** is the same as that of the process **8** → **7**. Of course the rate constants for the rotations of the different dichloromethyl groups are determined by their barriers and these need not be the same in **7** and **8**.

Rotation by π radians of the group H_1—CCl_2 in **8** exchanges H_3 and H_4 to form an equivalent **8**. Similarly, rotation of H_4—CCl_2 exchanges H_1 and H_3 to yield another **8**. In both processes the rotating group leaves the shift of its own proton unchanged. Finally, there is no internal rotational process which causes exchange between H_1 and H_4 in **8**.

(2) Assignment of Peaks in Region of Slow Exchange

Figure 1 displays the proton resonance spectrum of NCM in CH_2Cl_2 at temperatures where the exchange is slow. Table 1 gives the chemical shifts for each of the four peaks in toluene-d_8 and CH_2Cl_2 solutions. The three peaks of equal intensity arise from the three anisochronous protons of conformation **7**.

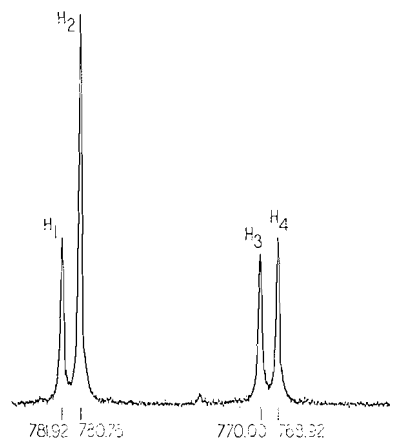

FIG. 1. The p.m.r. spectrum at 100 MHz of a 1.5 mol % solution of NCM in CH_2Cl_2 at 236.6 °K. The assignment of the peaks to conformations **7** and **8** is discussed in the text.

TABLE 1. Proton chemical shifts* of α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene in toluene-d_8 and methylene chloride

Solvent	T(°C)	H_1	H_2	H_3	H_4
C_7D_8 (3.0 mol %)	−36.3	7.3773	7.3172	7.0902	7.0154
CH_2Cl_2 (1.5 mol %)	−36.6	7.8192	7.8076	7.700	7.6892
$\Delta(CH_2Cl_2 - C_7D_8)$†	—	0.4419	0.4904	0.6098	0.6738

*In p.p.m. downfield from internal TMS.
†Shift in CH_2Cl_2 − shift in C_7D_8, a positive value representing an upfield shift in the aromatic solvent.

(a) Steric Crowding

The peak at 7.808 p.p.m. in CH_2Cl_2 solution clearly arises from the symmetrical conformation **7**. The other peaks can then be assigned to the individual protons in **8** on the basis of their degree of steric interaction with neighboring chlorine atoms, as was done for MOCX (2).[3] For a regular geometry (tetrahedral angles at the side-chain carbon atoms, etc.) the ring Cl–H distance in conformation **1** is 0.5 Å shorter than the sum of the Cl–H van der Waals radii, indicating a high degree of steric crowding even for the actual geometry in **7** and **8**. The time-dependent electric fields from the ring chlorine atom interfere with the diamagnetic charge circulation about the proton (7). The ensuing deshielding is proportional to r^{-6}, where r is the Cl–H distance. Consequently only very slight changes in r (less than 0.1 Å) in the region of the van der Waals contact distance can cause marked changes in the chemical shift of the proton (8).

Consider now the nearest neighbors [L,M] in the [L] Cl_2C—H...Cl [M] moieties of **7** and **8**. For H_1 and H_2 one has [L,M] = [Cl,Cl_2] while for H_3 and H_4 one has [L,M] = [Cl,H]. In terms of relative steric crowding it is therefore reasonable to assign H_1 and H_2 to the peaks at 7.808 and 7.819 p.p.m., respectively (H_2 being known anyway), while H_3 and H_4 are assigned to the high field (greater shielding) peaks at 7.700 and 7.689 p.p.m. from internal TMS. To differentiate (at second order) between H_3 and H_4 one may consider next-nearest neighbors [K,N] in [K,L] Cl_2C—H...Cl [M,N]. One finds [K,N] = [Cl_2,Cl] for H_3 and [H,Cl] for H_4 and assigns H_3 to the peak at lower field, *i.e.*, at 7.700 p.p.m. A similar argument rationalizes the relative shifts of H_1 and H_2.

[3]Calculations based on static electric fields arising from the C—Cl bond dipoles did not reproduce the relative chemical shifts of the protons in MOCX (2).

(b) Aromatic Solvent Induced Shifts (9)

The disc-shaped toluene solvent molecules pack about the solute NCM molecule in such a way that, on average, the solute protons are more often situated above or below than in the plane of solvent molecules (10). The magnetic field from the relatively large induced magnetic moment in the benzene ring will therefore cause a net shielding of the solute protons. This field decreases as the cube of the distance from the solvent molecule and thus the largest aromatic solvent induced shift occurs for those protons which most closely approach the toluene molecule.

The steric model attributes the lowest field peak of NCM in CH_2Cl_2 solution to the proton experiencing the largest degree of steric crowding. Presumably the solvent molecule in the toluene solution can approach this proton least closely. Hence one expects and finds (Table 1) a rough correlation between the aromatic solvent induced shifts and the shielding of the protons of NCM in CH_2Cl_2 solution.

(c) Exchange Broadening

As discussed above, H_3 can exchange its chemical shift with those of all other protons in **7** and **8**, while H_1 and H_4 cannot undergo mutual exchange. In the region where the rotation rate of the $CHCl_2$ group is fast enough to cause noticeable broadening of the individual peaks of Fig. 1, the degree of broadening of the peak of H_3 should therefore be greater than for the other three peaks. In fact, the peak at 7.700 p.p.m. in CH_2Cl_2 solution undergoes exactly this behavior. In toluene solution the peak at 7.090 p.p.m. also displays greater broadening in the region of slow exchange, in agreement with the assignment in Fig. 1 and Table 1 and consistent with the assumed order of the aromatic solvent induced shifts in Table 1.

The internal consistency of the three spectral effects suggests that the assignment of the peaks to the protons in **7** and **8** is a reliable one.

(3) Relative Populations of the Conformational Isomers

The calculation of spectral line-shapes as a function of exchange rate requires the relative populations of **7** and **8** as a function of temperature. For the toluene-d_8 solution these were obtained from the relative areas of the two low-field peaks at five temperatures between 202.7 and 240.2 °K. For the solution in CH_2Cl_2 the relative populations were found from eight spectra between 236.6 and 275.6 °K, using the relative areas of the four peaks.

As discussed for MOCX (2) the translational, vibrational, and rotational entropy differences of **7** and **8** are either 0 or about 0.02 e.u. and are neglected. There exists an entropy contribution of R ln 3 for **8** and hence one may write the equilibrium constant as

$$[1] \qquad K = x_8/x_7 = 3 \exp(-\Delta H/RT)$$

where x_8 and x_7 are the mole fractions of **8** and **7** and $\Delta H = H_8 - H_7$ is the enthalpy difference.

The measurements gave $\Delta H = 335 \pm 15$ cal/mol in toluene-d_8 and populations calculated from these values gave theoretical spectra in excellent agreement with experiment between 202.7 and 308.0 °K. At higher temperatures the peaks had coalesced to a single broad band. Similarly, one found $\Delta H = 380 \pm 20$ cal/mol for the CH_2Cl_2 solution and good agreement with experiment up to 304.6 °K.

Relative populations of **7** and **8** were also determined at 232.2 °K for solutions in CS_2, $CHCl{=}CCl_2$, and CH_2ClBr. The results are given in Table 2 and are discussed further below.

(4) The Line-shape Theory and Computer Program

As there is no observable spin–spin interaction between the non-equivalent protons in **8**, the McConnell formulation (11) of the Bloch equations under conditions of exchange was appropriate. The expression for the complex magnetization contained six independent pre-exchange lifetimes τ, four population terms, and four effective T_2 terms. The computer program in Fortran IV took as input data the four populations and T_2 values, the six pre-exchange lifetimes and the frequencies of the exchanging sites. The six independent pre-exchange lifetimes gave separately the rate constants for the inter-conformational conversions between **7** and **8** and the intraconformational conversions from **8** to **8**. A scaling factor allowed the computed spectra to be plotted on a Calcomp plotter. The computations were done on an IBM 360/65 system and the line-shape fitting procedure followed that described for ABX FIT (5).

TABLE 2. Enthalpy differences* between ground state conformations of α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene in several solvents

Solvent	Dielectric constant (25 °C)	$\Delta H = H_8 - H_7$ (cal/mol)
CH_2BrCl	8.4	296 ± 30

(5) Fitted Spectra and Activation Parameters

(a) Temperature Dependence of Peak Positions

Accurate rate constants are contingent upon accurate internal chemical shifts of the exchanging sites at each temperature (12). For the CH_2Cl_2 solution the peak positions vary as $1/T$ between 236.6 and 270.9 °K. The shifts obtained from the regression line agreed extremely well with the experimental spectra and were also used to calculate the site frequencies in the presence of exchange.

In toluene-d_8 solution, where the peak positions were more strongly dependent on temperature, no single function of internal shift versus either T or $1/T$ gave completely satisfactory agreement with experiment. A combination of these functions was used in such a way that the simulated spectra agreed with experiment between 208.9 and 287.1 °K. Extrapolated shift values were then used to fit a further fourteen spectra up to 356.8 °K.

The internal shifts in the other solvents varied only very slightly between 232.2 and 255.2 °K and the exchange rates were determined only at 305.6 °K, very near the coalescence temperature. The free energies of activation were insensitive to immoderately large variations in the internal shift.

(b) Linewidths in the Absence of Exchange

These were assumed to depend on the magnetic field inhomogeneity, which was controlled by monitoring the linewidth of an impurity peak some p.p.m. to high field of the NCM proton peaks. Effective T_2 values for the four sites were

TABLE 3. Activation parameters for the internal rotation processes in α,α,α′,α′,α″,α″,2,4,6-nonachloromesitylene

Parameter	C_7D_8 (3.0 mol %)	CH_2Cl_2 (1.0 mol %)
8 → 7		
E_a (kcal/mol)	15.24 ± 0.25 (0.70)*	16.30 ± 0.40 (0.49)
log A	12.42 ± 0.18 (0.53)	13.00 ± 0.29 (0.35)
$\Delta H‡$ (kcal/mol)	14.69 ± 0.24 (0.72)	15.69 ± 0.40 (0.49)
$\Delta S‡$ (cal/mol °K)	−3.55 ± 0.80 (2.48)	−1.10 ± 1.32 (1.59)
8 → 8		
E_a (kcal/mol)	15.58 ± 0.25 (0.73)	16.70 ± 0.40 (0.49)

$\Delta H‡$ (kcal/mol)	14.98 ± 0.25 (0.73)	16.09 ± 0.41 (0.49)
$\Delta S‡$ (cal/mol °K)	−3.68 ± 0.81 (2.48)	−1.04 ± 1.33 (1.60)

*The errors not in parentheses are the standard deviations from the linear regression line. Errors in parentheses are *maximum* errors arising from uncertainties in site frequencies and linewidth corrections as discussed in the text.

calculated from the linewidths obtained from a number of spectra at low temperatures and could be checked against the linewidth of the impurity peak.

(c) Fitted Spectra

Only spectra showing considerable exchange broadening were fitted, those between 275.6 and 336.9 °K in CH_2Cl_2 solution and between 258.7 and 356.8 °K in toluene-d_8. Pre-exchange lifetimes for all the exchange processes were extracted at 22 temperatures for the toluene solution and at 16 temperatures for the CH_2Cl_2 solution. In Fig. 2 computed and observed spectra are portrayed at a few representative temperatures for the latter solution.

Plots of ln k *vs.* $1/T$ and of ln (k/T) *vs.* $1/T$, based on the Arrhenius and transition state formulations (12), were prepared for each exchange process in the toluene and CH_2Cl_2 solutions. The linear regression lines had a correlation coefficient of 0.997 for the former and of 0.995 for the latter solution. The activation parameters and their least squares errors are given in Table 3.

(d) Maximum Error Estimates

The r.m.s. errors in Table 3 measure the precision of fit of the rate constant data to straight lines of the type presented in Fig. 3. However, they do not measure systematic errors arising from inaccuracies in the site frequencies, in effective T_2 values and in the temperature measurements. Such errors were estimated as follows:

(i) Site frequency errors

For the CH_2Cl_2 solution the standard deviations from the least squares analysis of the chemical shifts as a function of $1/T$ gave a new

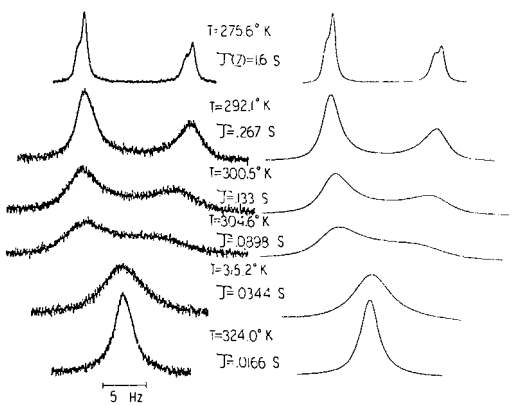

FIG. 2. Calculated and experimental p.m.r. lineshapes at a few representative temperatures are given for a 1.5 mol % solution of NCM in CH_2Cl_2. The pre-exchange lifetimes are indicated for conformation **7**; see text.

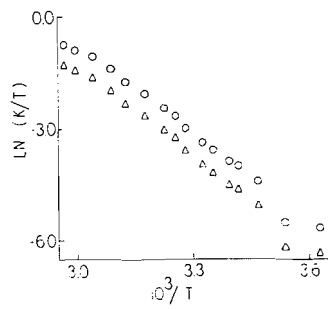

FIG. 3. Plots of ln k/T *vs.* $1/T$ for the activated rotation of the dichloromethyl groups in NCM in CH_2Cl_2 solution. The triangles refer to the process **8** → **8** and the circles to **8** → **7**. The correlation coefficients of the regression lines are both 0.995.

$CHCl{=}CCl_2$ (1.5)	305.6	16.12 ± 0.12	16.55 ± 0.12

*kcal/mol.
†Ambient probe temperature, being 1 °K lower for the first two solutions because the magnet housing was altered in the interval between the two sets of measurements.

set of site frequencies. These were incorporated into a second line-shape analysis of all spectra above the coalescence temperature. The new set of pre-exchange lifetimes yielded a new set of activation parameters. Their deviation from the original set of parameters was taken as the maximum error arising from inaccuracies in site frequencies. A similar procedure was followed for the toluene solution.

(ii) Effective T_2 errors

T_2 values for the four peaks were calculated from the linewidths measured at a number of low temperatures. The standard deviations gave maximum and minimum T_2 values for each site and these values were used in fitting the computed to the observed spectra in the region of exchange, again allowing an estimate of maximum error in the activation parameters arising from inaccuracies in linewidth corrections.

(iii) Errors in temperature

These are important when there exists only a small temperature range in which rate constants can be extracted from the exchange-broadened spectra. For example, the error in E_a due to an error in T is given (13) by eq. 2. Here σ^2 is a mean square error and ΔT is the temperature

$$[2] \qquad (\sigma_{E_a}/E_a)^2 = (2T^2/\Delta T^2)\,(\sigma_T/T)^2$$

range. In the present work the standard deviation of the temperature was not larger than 0.3 °K. Thus, even for the CH_2Cl_2 solution, where ΔT was only 61.3 °K, the error in E_a introduced by errors in temperature is small relative to the errors introduced by errors in the rate constants. For the toluene solution ΔT was 99.1 °K.

In Table 3 the errors in parentheses are estimates of the maximum errors arising from the three systematic error sources described here. The larger maximum errors in the activation parameters for the toluene solution reflect the larger uncertainties in the site frequencies.

(e) Free Energies of Activation, $\Delta G‡$

These were determined for all five solutions at the normal operating temperature of the magnet and are given in Table 4. The quoted errors include all sources described above but are considerably smaller than those given in Table 3 for a number of reasons. The uncertainty in the ambient temperature is minimal and the latter also happens to be very near the coalescence temperature of the spectra where the lineshape is most sensitive to changes in the rate constant but least sensitive to changes in the site frequencies and in effective T_2 values.

(6) Discussion of Activation Parameters

(a) Free Energy Profile for Rotation

The free energy profile is depicted in Fig. 4, conformation **7** being more stable than **8**. The transition states are indicated by **7′**, **8′**, and **8″**, in which one of the C—H bonds of a side-chain is rotated by π/2 radians out of the plane of the ring,[4] analogous to **2**. It proved impossible to obtain good line-shape fits unless **8′** and **8″**, the transition states for the two processes **8** → **8**, were isoenergetic to within 200 cal/mol and unless **7′**, the transition state for the process **7** → **8**, had a lower free energy than either **8′** or **8″**.

It is interesting to compare the conformations of the transition states of NCM (**8′**, **7′**, and **8″**) with the ground-state conformations **4**, **5**, **6** of MOCX and **9**, **10**, **11** of α,α,α′,α′,2,4,6-hepta-

[4]Previous calculations (14) based on rigid geometries gave the transition state as one in which the C—Cl bond of the side-chain eclipsed the ring C—Cl bond. The calculations of Mannschreck and Ernst (4) allow for bond bending and stretching and clearly give **2** as the transition state of **1**.

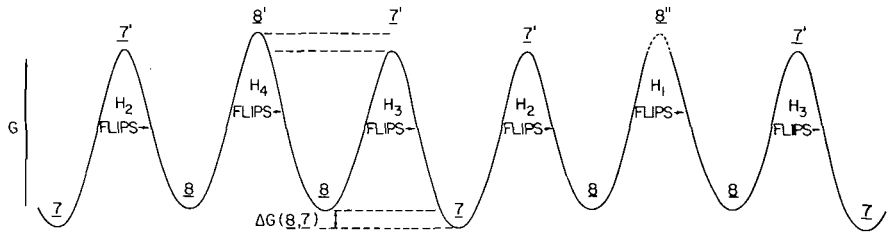

FIG. 4. A free energy profile for the rotation of the dichloromethyl groups in conformations **7** and **8** of NCM. The protons in these groups are numbered in accordance with structures **7** and **8** of the text. Note that the ground state **7** is more stable than the ground state **8** but that **8′** and **8″** are not necessarily of equal free energy; see text.

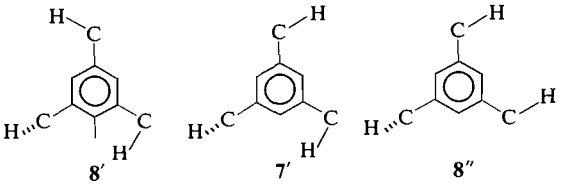
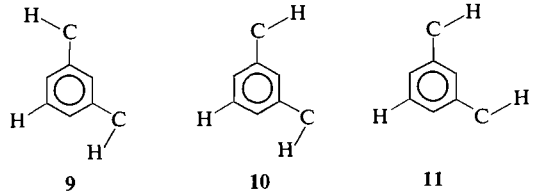


8′ **7′** **8″**



9 **10** **11**

chloro-*m*-xylene (MHCX). The similarities within the groups of structures **4**, **8′**, **9**; **5**, **7′**, **10**; and **6**, **8″**, **11** are clear. Now, it has been shown (2) that **4** and **6** are isoenergetic and of higher energy than **5** and also that **9** and **11** are less stable than **10**. By analogy it is then expected that **8′** and **8″** have approximately the same free energy, higher than that of **7′**. Such comparisons suggest that, in crowded molecules like NCM, steric interactions throughout the conformation and not only in the region of the rotating group are important in determining the energy of the transition state. It is probably coincidental that $\Delta G‡$ (**8** → **8**) − $\Delta G‡$ (**8** → **7**) equals $G_8 - G_7$ to within experimental error (Tables 2 and 4).

(b) Solvent Dependence of the Activation Parameters

$\Delta G‡$ is about 350 cal/mol lower in toluene than in the other solvents (Table 4). A speculative interpretation holds that in the ground state the rather polar C—H bond of the side-chain cannot effectively approach the π electron cloud of the toluene solvent molecules. In the transition state a C—H bond is rotated by π/2 radians out of the plane of the ring, this conformation being somewhat stablilized by a Cl_2C^-—H^+ ... π(acceptor ... donor) interaction with the solvent in a fashion analogous to the hydrogen bond occuring between chloroform and benzene (15, 16).

E_a values in the CH_2Cl_2 solution are about 1 kcal/mol higher than in the toluene solution, as are the respective $\Delta H‡$ values (Table 3). For the latter about half the difference is caused by the more negative $\Delta S‡$ values in the toluene solution, which might be anticipated on the basis of the interaction model above. However, it is a moot point whether in fact the $\Delta S‡$ are significantly different from 0 in either solution.

(c) Comparison With Other Molecules

The $\Delta G‡$ values for NCM are up to 1 kcal/mol higher than in PCT (5) or MOCX (2) for the toluene solutions. In the latter the $\Delta S‡$ values are also near zero, indicating that the higher $\Delta G‡$ values in NCM do indeed reflect the greater steric crowding expected in this molecule.

(7) Solvent Effect on Ground State Stabilities

Conformation **7** has no net dipole moment for symmetry reasons. Conformation **8** will have a net dipole moment and its stability should increase relative to that of **7** as the dielectric constant of the solvent increases (17–21). As can be seen in Table 2 this surmise is not borne out, **8** being least stable relative to **7** in CS_2. If the dipole moment of **8** is small, higher terms in the multipole interaction with the electric fields from the solvent may predominate over the dipolar term, perhaps accounting for the data in Table 2.

The greater stability of the symmetrical form **7** is probably caused by the steric crowding in the vicinity of ring carbon atom 4 in **8**, an interaction which is absent in **7**.

^{13}C Nuclear Magnetic Resonance Studies on Molecular Association. I. Self-association of Dipolar Molecules

HAZIME SAITÔ,[1] YUJI TANAKA, SACHIKO NAGATA, AND KENKICHI NUKADA[2]

Basic Research Laboratories, Toray Industries, Inc., Kamakura, Japan

Received June 26, 1972[3]

Self-association of dipolar substances is studied by ^{13}C magnetic resonance. The dilution shifts in carbon tetrachloride are analyzed in terms of the monomer–dimer equilibrium. Downfield ^{13}C shifts of the nitrile and carbonyl groups are observed for the formation of the dimer of acetone, acetonitrile, and ethyl acetate. Upfield ^{13}C shifts, on the other hand, are observed in the methyl and methylene groups of acetone, methylethyl ketone, ethyl acetate, acetonitrile, propionitrile, nitromethane, nitroethane, *N,N*-dimethylformamide, and *N,N*-dimethylacetamide. The equilibrium constants are 0.1–0.5 in units of mole fraction. The downfield ^{13}C shifts of the nitrile and carbonyl groups are interpreted in terms of electric (reaction) field effects imposed by another molecule through dimer formation. The alternation of polarity by polarization of the X–Y group explains the upfield ^{13}C shifts of methyl and methylene groups as shown in the following scheme: $H_3^+—C^-—X^+—Y^-$, where X—Y stands for C=O, C≡N, and NO_2 groups which have been classified as $-I^-$ groups by Pople and Gordon.

La libre association de substances dipolaires a été étudiée à l'aide de la résonance magnétique du ^{13}C. Les déplacements induits par les dilutions dans le tétrachlorure de carbone sont interprétés en terme d'équilibre du monomères–dimère. Les déplacements à champ faible du ^{13}C des groupes nitriles et carbonyle sont observés lors de la formation du dimère de l'acétone, de l'acétonitrile et de l'acétate d'éthyle. Les déplacements à champ fort du ^{13}C, d'autre part, sont observés pour des groupes méthyles et méthylènes de l'acétone de la cétone de méthyle et d'éthyle, de l'acétole dé'éthyle, de l'acétonitrile, du propionitrile du nitrométhane, du nitroéthane, de la *N,N*-diméthyl formamide, et de la *N,N*-diméthyl acétamide. Les constantes d'équilibre sont évaluées à 0.1–0.5 en unités de fraction molaire. Les déplacements à champ faible du ^{13}C des groupes nitriles et carbonyles sont interpretés en termes d'effets de champ électrique (réaction) imposé par un autre molécule lors de la formation du dimère. L'alternance de la polarité causée par la polarisation du groupe X—Y explique les déplacements à champ fort du ^{13}C des groupes méthyles et méthylènes. Tel qu'indiqués dans le schéma: $H_3^+—C^-—X^+—Y^-$, où X—Y représentent les liens C=O, C≡N, et des groupes NO_2 qui ont tous été classifiés comme des groupements $-I^-$ par Pople et Gordon.

Can. J. Chem., **51**, 2118 (1973)

Introduction

Recently much attention has been devoted to studies of molecular association by heteronuclear magnetic resonance spectroscopy. Especially in the hydrogen bond system, X—H···Y, studies of X or Y chemical shifts by heteronuclear magnetic resonance are superior to conventional proton spectra with regard to the detection of the charge transfer and/or polarizing effects of the X—H bond. The sensitivity of the chemical-shift displacement due to a slight variation of electron distribution is significantly enhanced by a contribution of the paramagnetic current around the heteroatom under consideration. Therefore, if adequate accuracy of the chemical-shift measurement is attained, a slight variation of the electron distribution, which is unable to be observed by proton spectra, should result in appreciable movement of the chemical shift of the heteroatom. For this reason several sets of data using this method have been accumulated (1–14).

Few studies, on the other hand, have been aimed, using magnetic resonance, at the electrostatic interaction such as the dipolar association which may not be associated with electron transfer as in hydrogen bonding and the charge transfer complex. The equilibrium constant of this sort of association may be generally small owing to the smaller electrostatic energy in comparison with the former. The energy of the dipolar association should be sufficiently larger than kT to stabilize the dipolar pair. It has been suggested that this condition should be easily attained in the case of larger dipoles such as 5 D in the interdipole length ~5 Å (15).

Dipolar association has been postulated in the studies of dimerization of nitrobenzene by ^{19}F n.m.r. (16), of dioxane, nitroaniline, and pyridinium dicyanomethylide by dipole moment (15), association between DMSO and nitriles by i.r. (17), and metalorganic compounds by p.m.r. (18). Self-association of acetone (19) and cyclopentanone (20) was also demonstrated by a study of the partition of ketones between water and carbon tetrachloride. A spectroscopic investigation is expected to offer further evidence of such a dipolar association. In this paper, we report a study of ^{13}C shifts on self-association of ketones, nitriles, nitrocompounds, amides, and related dipolar molecules by the dipole–dipole interaction.

Experimental

Measurements of ^{13}C chemical shifts were performed mainly by the ^{13}C INDOR method (21–23). A Varian HA-100 spectrometer was used with a probe doubly tuned to accept 25.15 MHz ^{13}C irradiation frequency as well as 100 MHz proton frequency used for a monitor of the ^{13}C satellite peak. An NMR Specialties HD-60B heteronuclear spin decoupler equipped with a Hewlett-Packard 200 ABR audio frequency oscillator was used to drive 25.15 MHz modulated frequency. All measurements were carried out in the frequency sweep mode with a small amount of TMS dissolved into samples to serve for the field-frequency stabilization. The irradiation power of ^{13}C nucleus was maintained as low as possible. The ^{13}C INDOR spectra, manually swept, were traced on a Varian G-14 external recorder. The accurate irradiation frequency was monitored for each of the inner two peaks of the methyl carbon quartet with a Takeda-Riken TR-3977 radio frequency counter. For this purpose, slightly increased irradiation power was provided to the frequency counter at the exact ^{13}C resonance condition. The measurements were repeated at least five times, and the means of the two inner-peak-frequencies were averaged. By this procedure absolute resonance frequencies of the carbon signal at the unchanged magnetic field which was attained by the field frequency control with TMS signal were obtained. The analyses of dilution curves of ^{13}C signals in carbon tetrachloride were performed with this frequency scale. For convenience ^{13}C chemical shifts were expressed relative to that of neat dioxane, which was determined by replacing with the sample under consideration. The accuracy of the ^{13}C chemical shifts is below $\pm$ 2Hz ($= \pm 0.08$ p.p.m.).

The INDOR method described above renders the observation of ^{13}C shifts of the carbonyl and nitrile groups impossible when they are not directly bonded to protons. In these cases ^{13}C spectra were obtained by the direct method using a frequency sweep at 25.15 MHz on a Varian XL-100-12 spectrometer. This spectrometer has three simultaneously available radio frequency channels, including ^{13}C observing channel, a lock channel (deuteron or proton frequency), and an irradiation channel. The field stabilization was performed by methyl proton or deuteron signals from solute molecules via the lock channel. The samples were contained in 8 mm o.d. tubes. A Varian C-1024 time averaging computer was used to accumulate the spectrum. Accumulation of 500 scans was necessary to observe the broader nitrile carbon which resulted from coupling to the ^{14}N in 0.3 mol fraction carbon tetrachloride solution. Correction of the magnetic field due to the displacement of the lock proton or deuteron shifts is found unnecessary: the displacement is at most 0.02 p.p.m. which is within the experimental error (± 0.08 p.p.m.).

The solvent used in these dilution studies was CCl_4 in all cases. With a view to clarifying a contribution of the reaction field effect, ^{13}C shifts of acetonitrile were examined in various solvents (10 mol %): carbon tetrachloride, dioxane, ethyl acetate, pentachloroethane, diethyl ether, tetrachloroethane, dichloroethane, acetone, nitromethane, acetonitrile, and dimethylsulfoxide. For this purpose a deuteron signal of benzene-d_6 sealed in a capillary inserted into 8 mm o.d. tube was employed for the lock signal. A small amount of cyclohexane (less than 5%) dissolved in the samples was used as a reference of ^{13}C shift.

All materials, which contained ^{13}C in natural abundance, were prepared by distillation after standing over molecular sieve.

Results

To begin with, we investigated the variation of ^{13}C shifts of acetone in carbon tetrachloride solution both by the direct and the INDOR method, as shown in Fig. 1. The upfield and downfield shifts upon increasing concentration of the solute are denoted for the methyl and carbonyl carbons, respectively. A plot of the methyl ^{13}C shift against the carbonyl shifts in Fig. 1 exhibits a linear relationship as illustrated in Fig. 2. Similar results are found for acetonitrile and ethyl acetate. On the basis of these results we postulated that it is possible to ascribe the variation of ^{13}C shifts to a certain molecular interaction. To clarify and support this postulate we analyzed the dilution curves of acetone (Fig. 1), acetonitrile, and ethyl acetate with a model of monomer-dimer equilibrium.[4] With the procedure developed by Happe (24) the equilibrium constant and association shifts Δu are obtained (Tables 1 and 2), which is defined

[4]Although some questions would be raised upon the accuracy of the equilibrium constant deduced from mole fraction units (ref. 25) used in this study and the possibility of higher aggregates, it is our objective of this paper to examine the existence of molecular association in polar molecules and to inquire about the nature of the liquid through the variation of ^{13}C shift. The assumption was made that trimers and higher polymers are not significant because of the fit realized using only monomers and dimers.

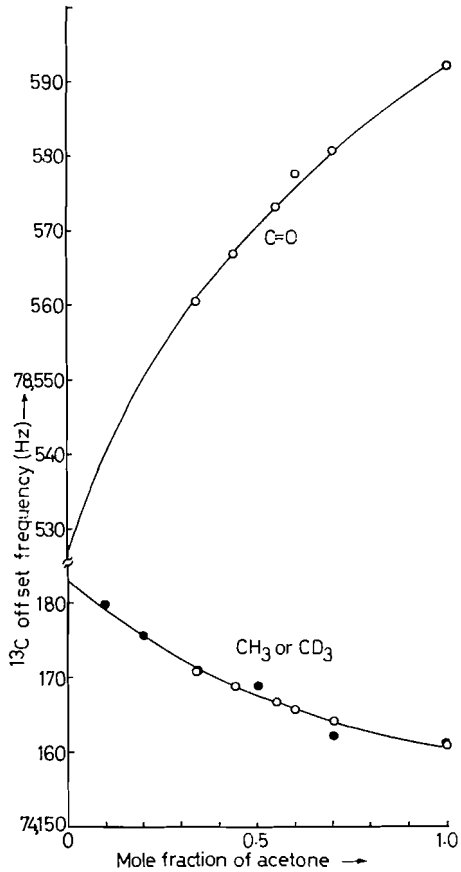

FIG. 1. Plots of the methyl and carbonyl ^{13}C shifts of acetone *vs.* the concentration in carbon tetrachloride. (○: obtained by the direct method with acetone-d_6, ●: obtained by the INDOR method.) ^{13}C shifts are expressed as the sweep-offset frequency in the deuteron lock mode by acetone-d_6. Higher frequency in the frequency sweep mode corresponds with downfield in the field sweep method. Solid lines were obtained by the equilibrium constant, which was calculated by the dilution curve of methyl ^{13}C signal, $K = 0.51$.

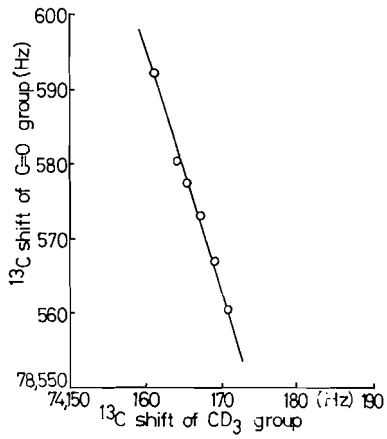

FIG. 2. Plot of ^{13}C shifts of methyl group *vs.* those of the carbonyl group.

TABLE 1. ^{13}C association shifts of dipolar compounds ($CH_3X—Y$)

	^{13}C association shift Δu^a		
	X—Y	Methyl	Proportionality constant^b f
$(CH_3)_2C=O$	−5.9	2.0	−0.34
CH_3CN	−6.9	3.6	−0.52
$CH_3COOCH_2CH_3$	−2.6	3.6	−1.4

$^a\Delta u$ = δ(dimer) − δ(mono), where δ(dimer) and δ(mono) stand for ^{13}C shifts of the dimer and monomer, respectively (in p.p.m.).
$^b\Delta\delta^{13}C(Me) = f\Delta\delta^{13}(X—Y)$, where $\delta^{13}C(Me)$ and $\delta^{13}C(X—Y)$ stand for ^{13}C shifts of methyl and X—Y groups, respectively.

as δ(dimer) − δ(mono), where δ(dimer) is the ^{13}C shift in the dimer and δ(mono) is the ^{13}C shift in the monomer at infinite dilution in carbon tetrachloride. The equilibrium constants thus obtained reproduce the experimental dilution curves.

We also examined methyl and methylene ^{13}C shifts of dipolar substances such as methylethyl ketone, propionitrile, nitromethane, nitroethane, *N*,*N*-dimethylformamide (DMF), and *N*,*N*-dimethylacetamide (DMA) when diluted in CCl_4. The equilibrium constants given in Table 2, $K = 0.1$–0.5 (mol fraction)$^{-1}$, are much smaller than those of the usual hydrogen bond system, $K > 1$. All of the methyl (methylene) ^{13}C shifts except for α methylene group of nitroethane listed in Table 2 show upfield shifts, whereas the corresponding proton signals, methyl or methylene, are displaced downfield. Plots of ^{13}C shifts of acetonitrile *vs.* $(\varepsilon - 1)/(2\varepsilon + 2.5)$ are shown in Fig. 3.

Discussion

Concerning the downfield ^{13}C shifts of the carbonyl[5] and nitrile groups, and the upfield methyl and methylene groups of dipolar molecules by molecular association, three possible explanations come to mind: (*1*) intermolecular magnetic anisotropy, (*2*) the electric (reaction) field effect, (*3*) the inductive effect owing to the

[5]The possibility of hydrogen bonding through the enol form of acetone was discounted by the fact that the enol concentration in pure acetone was reported to be about 2×10^{-4} % (ref. 26). Such a small concentration is incapable of forming intermolecular hydrogen bonds to yield such larger downfield and upfield ^{13}C shifts of the carbonyl and methyl groups, respectively.

TABLE 2. Variations of ^{13}C chemical shifts[a] (in p.p.m.) due to the dipolar associations and their equilibrium constants

		^{13}C shifts[e]				^{1}H shifts (p.p.m.)[e]	
		δ(mono)	δ_1–δ(mono)	K^f	Δu	δ_1–δ(mono)	Δu^g
Acetone		36.40	0.88	0.51	2.0	−0.02	∼−0.02

[a] ^{13}C shifts of methyl group adjacent to the substituent unless otherwise noted.
[b] Methylene carbon adjacent to the substituent group.
[c] β-Methyl carbon.
[d] *N*-Methyl group.
[e] δ(mono) denotes the ^{13}C or proton shifts extrapolated into infinite dilution in carbon tetrachloride solution with respect to dioxane and TMS, respectively. δ_1 stands for the shifts of neat state. Δu = δ(dimer) − δ(mono), where δ(dimer) and δ(mono) stand for ^{13}C shifts of the dimer and monomer, respectively.
[f] In units of (mol fraction)$^{-1}$, error less than 20%.
[g] Δu of the proton shifts is calculated with use of proportionality of ^{13}C shift to the proton shift.

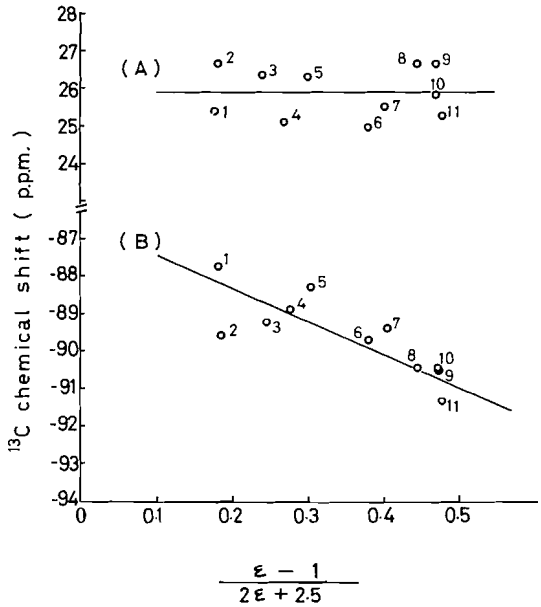

FIG. 3. Plots of ^{13}C solvent shifts of acetonitrile in 10 mol % solution in various solvents (in p.p.m. relative to cyclohexane) against $(\varepsilon - 1)/(2\varepsilon + 2.5)$. (A): Methyl group, (B): nitrile group. Solvents: (1) carbon tetrachloride, (2) dioxane, (3) ethylacetate, (4) pentachloroethane, (5) diethylether, (6) tetrachloroethane, (7) dichloroethane, (8) acetone, (9) nitromethane, (10) acetonitrile, (11) dimethylsulfoxide.

polarization of the substituent dipole, X—Y. Explanations (*1*) and (*2*) are through-space effects, while (*3*) is a through-bond effect.

The intermolecular magnetic anisotropy effect is expected to have the same magnitude of contribution both on proton and ^{13}C nuclei, because it depends primarily upon the molecular geometry. In many cases displacements of the ^{13}C shifts due to molecular association are at least ten times larger than those of proton shifts, although this ratio is only five times in the case of nitro compounds (Table 2). Therefore this is not the major contribution to the displacements of shifts, especially for ^{13}C chemical shift. ^{13}C chemical shifts have been so far explained in terms of the paramagnetic shielding effect which is related to electron density and mean excitation energy.[6] Some authors (23, 32–34) have pointed out the contribution of the electric field effect on ^{13}C chemical shifts. Becconsall *et al.* (23)

[6] It has been reported that there appears a correlation between the electron density and the ^{13}C chemical shift. This is primarily caused by a contribution of the term of the inverse cube of mean 2p electron radius in the paramagnetic current (27). It is generally said that the upfield shift of ^{13}C chemical shift arises from the increased electron density (28–31), if the mean excitation energy remains constant.

studied the variation of methyl ^{13}C shifts of methyl iodide and acetonitrile in various solvents and concluded that the use of effective dielectric constant was necessary for the application of the reaction field theory to the displacement of ^{13}C chemical shifts. Figure 3 shows ^{13}C shifts of the nitrile group of acetonitrile is approximately linearly dependent on $(\varepsilon - 1)/(2\varepsilon + 2.5)$, while that of methyl group is not. This result shows that the polarization of the nitrile group is related to the electric field effect. Because of the short-lived character of the dipolar pair, as expected from the smaller equilibrium constants, this model is not discriminated from the continuum model such as the reaction field theory. It seems likely that the dipolar field of one dipole is responsible for the polarization of another, the simplest antiparallel model being illustrated in Fig. 4. This sort of orientation was proposed by Dannhauser and Flueckinger (35) with their dielectric study of some nitriles. This explains the downfield ^{13}C shift of the carbonyl and nitrile[7] groups in terms of the electric field effect.[8]

The polarization of the substituent dipole would induce the migration of electrons into the neighbor alkyl group. Pople and Gordon (38) proposed the presence of an alternate polarization in compounds with dipolar substituents such as carbonyl, nitrile, and nitro groups ($-I^-$ group). A schematic of the alternate polarization due to the $-I^-$ group, X—Y, is shown as:

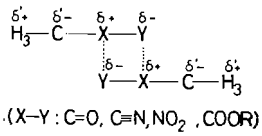

FIG. 4. Antiparallel orientation of CH_3X—Y molecule by the dipole–dipole interaction.

$$H_3{}^+—C^-—X^+—Y^- \quad (X—Y = C{=}O,\ C{\equiv}N,\ NO_2)$$

The additional polarization of the α methyl group, $H_3{}^+—C^-$, by the polarization of $X^+—Y^-$ group, which is induced by the electric field effect described above, makes the ^{13}C and proton signals of this group shift upfield and downfield, respectively.[9] This explanation is in good agreement with experimental data. Similarly the upfield ^{13}C shifts of α methylene groups except for nitroethane are interpreted in terms of the above scheme. It is not clear at present why the α methylene carbon signal of nitroethane does not obey the scheme described above. The β methyl ^{13}C shifts of the ethyl group are shown to undergo the upfield shift due to association (Table 2). This result indicates that the polarization for the ethyl group should be $H_3{}^+C^-—H_2{}^+C^-—X^+—Y^-$ instead of $H_3{}^-C^+—H_2{}^+C^-—X^+—Y^-$ proposed by Pople and Gordon (38.)

It is expected from the above scheme that the amount of the upfield methyl (methylene) ^{13}C shift is proportional to that of the X—Y ^{13}C shift: $\Delta\delta^{13}C(Me) = f\Delta\delta^{13}C(X - Y)$. This relation is shown in Fig. 2. The proportionality constant, f, is given in Table 1. The variation of ^{13}C shifts in DMA and DMF is similarly interpreted in terms of the alternation of polarity: the group of $O^- = C—N^+$ is regarded as the substituent of the $-I^-$ effect.[10,11]

[7]Recently Alei, Jr. and coworkers reported that the ^{15}N liquid association shift of $CH_3C^{15}N$ is +11.3 p.p.m. with respect to the shift in the vapor phase (36). The upfield shift of ^{15}N shift is in accordance with the expectation, $C^+{\equiv}{}^{15}N^-$.

[8]However, no correlation was found between ^{13}C shifts and the reaction field. This result indicates that contribution other than the reaction field might account for the upfield ^{13}C shift of the methyl group. An estimate of the reaction field effect on methyl ^{13}C shifts will be made as follows. According to Horsley and Sternlicht (32), the electric field effect on the ^{13}C resonance of the C—X group is expressed as: $\Delta\sigma_{C-X} = A_{C-X}E_{11}$, where E_{11} is the field component along the bond direction. A_{C-X} is related to the bond polarization, b_{11}, (37) and the bond length, R_{C-X} by the following formula: $A_{CX} = 200b_{11}/(eR_{C-X}) \times 10^{-6}$. The electric field constant $A_{C\equiv N}$ for the nitrile group is calculated to be 11.1×10^{-11}, which is four times larger than A_{CH} of C—H bond (3.0×10^{-11}) (32). If a uniform reaction field (E_{11}) is held along the direction of the C≡N bond, the component along the C—H bond will be $E_{11} \times \cos 70° = 0.34E_{11}$. Accordingly, it is easily recognized that the movement of the methyl ^{13}C shift ($\Delta\sigma_{C-H}$) by the reaction field effect is much smaller than that of nitrile group ($\Delta\sigma_{C\equiv N}$), since $\Delta\sigma_{C\equiv N}/\Delta\sigma_{C-H} \sim 11$.

[9]Similar increased polarization is expected in the case of hydrogen bond formation with protic solvents. Upfield ^{13}C shifts of the methyl group in acetone and acetonitrile are observed (39).

[10]Head-to-tail dipolar association has been proposed for *N,N*-disubstituted amides such as DMF and DMA (40–43).

[11]Momany *et al.* (44) showed by the CNDO/2 calculation of the parallel-plane dimer of *N*-methyl formamide that the more stable complex is the one with the higher degree of charge separation in the molecules of the complex. Then we might consider the electron redistribution mechanism such that a portion of the nitrogen lone pair electrons are donated to the neighboring methyl group through the pseudo π orbital in order to attain the charge separation of stabilization.

CNDO–MO Study of the Ozonide Ion and Related Species

JOHN M. SICHEL[1]

Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec 10, Québec

Received January 8, 1973

The unpaired electron in the ozonide ion (O_3^-) is expected to occupy an antibonding molecular orbital; yet published experimental results indicate a shorter bond length and larger force constants than in neutral ozone. Molecular orbital calculations in the CNDO approximation are reported for this ion and related species (O_3, SO_2, SO_2^-, OF_2^+, OF_2), using both the CNDO/2 and CNDO/BW parametrizations. Both methods predict that the bond lengths in O_3^- are 0.04 Å longer than in O_3, in agreement with qualitative molecular orbital theory, and that the bond angle is 1° less than in O_3. The CNDO/BW method predicts that the electron affinity of O_3 is higher than that of the O atom, in agreement with experiment, since a stabilizing exchange effect outweighs the antibonding nature of the orbital occupied by the extra electron.

Dans l'ion ozonide l'électron célibataire doit se trouver sur une orbitale moléculaire antiliante. Au contraire les résultats expérimentaux actuels indiquent des liaisons plus courtes et des constantes de force de rappel plus grandes que pour la molécule d'ozone. J'ai calculé les orbitales moléculaires pour cet ion et d'autres espèces semblables (O_3, SO_2, SO_2^-, OF_2^+, OF_2) dans l'approximation "CNDO" et avec des paramètres établis selon les méthodes "CNDO/2" et "CNDO/BW". Les deux méthodes s'accordent pour prédire que les liaisons en O_3^- sont plus longues de 0.04 Å que dans la molécule neutre en accord avec la théorie qualitative des orbitales moléculaires, et que l'angle au sommet est de 1° plus petit que dans O_3. La méthode "CNDO/BW" prédit que l'affinité électronique de O_3 est supérieure à celle de l'atome O, en accord avec l'expérience, puisqu'un effet stabilisateur d'échange a plus d'influence que l'effet antiliant de l'orbitale occupée par l'électron additionnel.

Can. J. Chem., **51**, 2124 (1973)

The ozonide ion (O_3^-) is of interest to quantum chemistry since experimental data for this species are in conflict with predictions of simple molecular orbital (MO) theory. According to the usual orbital theory for AB_2 molecules (1), an extra electron added to the ozone molecule should occupy an orbital which is A–B antibonding and B–B′ bonding. The ozonide ion should therefore have "looser bonds" than the neutral ozone molecule; one expects an increase in bond length and a decrease in stretching force constant. Also the bond dissociation energy should be lowered, or equivalently the electron affinity of O_3 should be less than that of the O atom. A detailed analysis of the relationship between orbital bonding character and the effect of orbital occupation on molecular properties has been given by Peyerimhoff *et al.* (2). This type of prediction is in fact correct in most cases, and other simple theoretical methods lead to similar predictions for the ozonide ion (3).

Published experimental evidence, however, indicates that O_3^- may be more tightly bound than expected:

(*i*) Azaroff and Corvin (4) found an O—O bond length of 1.19 Å in KO_3 by X-ray diffraction on a powder sample. This may be compared with 1.278 Å in O_3(5).

(*ii*) The i.r. spectrum of metastable NH_4O_3 recorded at low temperature by Herman and Giguère (3) showed a strong band at 800 cm^{-1}, and two much weaker ones at higher frequencies. In the light of the X-ray diffraction data these authors assigned the band at 800 cm^{-1} to the bending mode ν_2 of the O_3^- ion. (*cf.* 704 cm^{-1} for the O_3 molecule). However, this assignment must now be changed to ν_3, the antisymmetric stretching mode (*cf.* 1050 cm^{-1} in O_3), according to a recent isotope shift study of the O_3^- ion in an Ar matrix by Jacox and Milligan (6).

(*iii*) Finally, Byerly and Beaty (7) have determined an electron affinity of 2.1 ($\pm$0.1) eV for ozone by photodetachment from O_3^-, whereas the electron affinities of O and O_2 (for comparison) are 1.478 and 0.44 eV respectively (8). This corresponds to a bond dissociation energy for O_3^- of 1.7 eV (to O_2 and O^-), compared with 1.04 eV for O_3(9).

MO Calculations

In view of the conflict between the above

results and simple MO theory, a quantitative MO calculation of the equilibrium geometry and electronic structure of O_3^- and several related species (O_3, SO_2, SO_2^-, OF_2^+, OF_2) was undertaken using the CNDO approximation (10).

Within the framework of the CNDO approximation, there are a number of parameters to be chosen, for which several sets of recipes have been proposed (11–17), each set defining an MO "method". In this paper I have used two methods parametrized to predict the geometries of molecules containing arbitrary first-row atoms: (*i*) the well-known "CNDO/2" method of Pople and Segal (12), and (*ii*) the "CNDO/BW" method of Boyd and Whitehead (17). The latter method combines atomic parameters from the work of Sichel and Whitehead (13), interatomic electron-repulsion integrals calculated by the formula of Ohno (18), and core-repulsion integrals and core resonance parameters calibrated (17) to fit bond energies and bond lengths of selected molecules. In fact Boyd and Whitehead published several parameter sets (17) which lead to similar values of molecular properties (19, 20). I have used their set I except where otherwise indicated.

The CNDO/BW calculations were performed using the FORTRAN program of Boyd and Whitehead, except that the Jacobi-method matrix diagonalization subroutine was replaced by a faster Householder-method subroutine (21). For open-shell molecules the SCF equations for an unrestricted single determinant were solved as in the work of Pople and Segal (12). The CNDO/2 computations were performed using a modified version of this program. All calculations were optimized with respect to both bond length and bond angle, using an iterative cubic interpolation procedure.

Results

Electronic Configurations

In all calculations the set of occupied orbitals was found to be in accord with the Walsh diagram (1), although the exact order of orbital energies varied somewhat between the two methods and (for open-shell species) between the two spins. Thus, both O_3^- and SO_2^- had the expected $^2B_1$ configurations, which are consistent with the electron spin resonance spectra (22–24).

Bond Lengths

Calculated and experimental bond lengths for the species of interest are shown in Table 1. Both MO methods agree in the prediction that $r_e(O_3^-) > r_e(O_3)$. Molecular orbital calculations should reliably predict trends in bond lengths between species differing by one electron (2). The CNDO/BW method yields an accurate value for $r_e(O_3)$ so that the value of $r_e(O_3^-)$ should be of similar accuracy. For CNDO/2, $r_e(O_3)$ is too low by 0.1 Å so that it is expected that $r_e(O_3^-)$ is similarly low, despite the fortuitous closeness to the reported X-ray value. The low value of $r_e(OF_2)$ further supports this argument. As both MO methods predict an increase of about 0.04 Å, it is suggested that the true bond length in O_3^- is about 1.32 Å, in disagreement with the value of Azaroff and Corvin (4).

Furthermore, the wavefunction for O_3^- shows no reason to expect tighter bonding than in O_3. The extra electron occupies a $2b_1$ (or π^*) antibonding orbital as expected from the Walsh rules (1), and reduces the π-bond order (between bonded O atoms) from 0.702 in O_3 to 0.353 in O_3^-. (By coincidence, these values are valid for both CNDO/BW and CNDO/2 at the appropriate equilibrium geometries.) This trend is in agreement with the matrix i.r. results of Jacox and

†Not equal to values in ref. 12 where the experimental bond length was assumed.
‡Reference 5.
§Reference 4. This value was supported in ref. 3 on the basis of a force constant analysis, but the analysis is vitiated by an algebraic error. If the error is corrected, a complex value of the bond angle is found for a force field of the form assumed (K. Herman, private communication).
‖Reference 6.
¶Reference 25.

Milligan (6). For SO_2^-, where the only i.r. data indicate a lower stretching force constant than in SO_2(25), there is a similar reduction of π-bond order from 0.707 in SO_2 to 0.353 in SO_2^- (CNDO/BW). Also for OF_2^+, the coefficients of the highest occupied orbital are similar to those of O_3^- and SO_2^-, and the CNDO/2 method predicts that $r_e(OF_2^+) < r_e(OF_2)$ as expected. It seems likely, therefore, that the extra electron in O_3^- does occupy an antibonding orbital in accord with the Walsh rules, and that $r_e(O_3^-) > r_e(O_3)$.

Bond Angles

Table 2 lists the calculated and experimental bond angles. Both MO methods predict only a very slight change in bond angle upon the addition of an electron to ozone. As CNDO/BW predicts (20) a more accurate bond angle for O_3 (116.7°) when parameter set III of ref. 17 is used, a calculation for O_3^- was performed using this parameter set. An equilibrium bond angle of 116.9° was found (for r_e = 1.307 Å), showing again that *differences* in predicted properties between species differing by a single electron are relatively invariant to changes in the MO method. On this basis the true bond angle for O_3^- should be close to 116°.

The small predicted decrease in angle from O_3 to O_3^- is surprising, as the Walsh diagram for AB_2 molecules (1) would suggest a larger decrease upon occupation of the $2b_1$ orbital, whose energy is supposed to decrease with decreasing bond angle due to bonding between the pπ orbitals on the terminal O atoms. However calculations for various values of the bond angle show that the decrease of the $2b_1$ orbital energy with decreasing angle is actually very small in O_3^-, since the bonding effect is almost exactly offset by the increased electrostatic repulsion between the electronic charge distributions on the terminal O atoms, when an extra electron is added to O_3.

Possible Asymmetric Geometry

The above results were obtained assuming a C_{2v} symmetry (two equal bond lengths). It is possible, however, that some excited states of SO_2 and ClO_2 may have (26–29) unequal bond lengths (C_s symmetry). After finding the C_{2v} equilibrium geometry for each molecule, therefore, the possibility of such an asymmetric geometry was examined by calculating the energy for geometries ($r_1 = r_e + \delta r$, $r_2 = r_e - \delta r$, $\theta = \theta_e$). The result is that all species are predicted to have C_{2v} symmetry except for SO_2^-, for which a double minimum was found with δr = 0.03 Å and a small potential barrier of 0.03 eV. This barrier is too small to be significant in view of the approximate nature of the calculation; and *ab initio* calculation including d orbitals (at least) should be necessary to settle the question. In any case, the matrix i.r. spectrum of SO_2^- shows that such a molecular asymmetry, if it exists, must be small (25).

Electron Affinities

Calculated electron affinities and detachment energies are shown in Table 3. The values given were obtained by subtraction of total energies for O_3 and O_3^- at the appropriate geometries, and do not correspond to orbital energies. The large

*Reference 7.
†Reference 30.

difference between the two MO methods arises because the CNDO/BW method employs atomic parameters (13) calibrated to reproduce atomic valence-state ionization potentials and electron affinities separately, and the CNDO/2 method does not.

A question of some interest is why the electron affinity of O_3 is larger than that of the O atom (experimental value 1.478 eV (8)), although the additional electron occupies an (A–B) antibonding orbital. This trend is reproduced in the calculated values (for the CNDO/BW method the valence-state electron affinity of O is 2.534 eV), so that it is worthwhile examining the results for the source of the extra stabilization energy, at least in the CNDO model considered. The CNDO/BW energy of the unoccupied $2b_1$ orbital in ozone is -3.592 eV, so that most of the extra stability is correlated with this virtual orbital energy, which may be analyzed as:

$$\varepsilon_{2b_1} = -A_0 + \varepsilon_{chg} + \varepsilon_{exch} + \varepsilon_{AB} + \varepsilon_{BB'}$$
$$= (-2.534 - 0.733 - 8.854 + 7.687 + 0.841)\ \text{eV}$$

In this equation A_0 is the valence-state electron affinity of the oxygen atom, ε_{chg} is the energy associated with the term in the diagonal CNDO Hamiltonian matrix elements due to interaction with net charges, and ε_{exch} is the energy associated with the exchange terms in the same diagonal matrix elements. ε_{AB} is the term due to the off-diagonal matrix elements between π orbitals on a central and an end atom, and $\varepsilon_{BB'}$ similarly for two end atoms.

It can be seen that the positive term ε_{AB} due to antibonding between adjacent atoms is outweighed by the stabilizing "exchange" interaction which diminishes the net repulsion between electronic charge distributions of the same spin. In the CNDO approximation only the intraorbital exchange energy is considered; it remains to be seen whether a similar picture will emerge from a more refined calculation which includes the electron-interaction integrals neglected here.

Force Constants

Molecular orbital calculations can be used to predict potential energy surfaces and therefore force constants, although accurate values should not be expected from semiempirical methods which have not been explicitly calibrated to predict force constants. Calculated and experimental force constants are shown in Tables 4 and 5. A valence force field with no interaction force constants has been assumed. For an AB_2 molecule this takes the form

$$\Delta E = f_r(r - r_e)^2 + \tfrac{1}{2}f_\alpha(\alpha - \alpha_e)^2$$

For O_3 and O_3^-, both methods grossly overestimate the stretching force constant f_r. For

TABLE 4. Stretching force constants (f_r in mdyn/Å)

CNDO/2 this is not surprising in view of the values calculated (33) for other molecules, especially those containing oxygen. For CNDO/BW, the computed values for other molecules (19, 20) are on the whole better, but significantly the prediction for O_3 (19) is poor.

O_3^- is predicted to have a lower f_r than O_3 as indicated by the matrix i.r. spectrum (6), but the significance of this prediction must be regarded as doubtful given the size of the error in the actual values. For SO_2 and SO_2^-, the CNDO/BW values are better and SO_2^- is correctly predicted to have the lower stretching force constant.

For the bending force constants (Table 5), both absolute values and trends are poorly predicted.

Conclusion

Molecular orbital calculations in the CNDO approximation indicate that the bond lengths in O_3^- are longer than in O_3, in agreement with simple theory and with recent i.r. data but in disagreement with the result of Azaroff and Corvin (4). The calculations succeed in predicting that the electron affinity of O_3 is higher than that of O, if parameters are used which have been calibrated to predict ionization potentials and electron affinities separately.

I wish to thank Professor Paul A. Giguère for suggesting this problem and for his continued interest and advice. I also thank his colleague, Dr. Kazimiera Herman, for many helpful discussions.

I am grateful to Prof. M. A. Whitehead and his research group for the CNDO/BW computer program, and to the National Research Council of Canada for a research grant.

Thermodynamic and Transport Properties of Sodium Benzoate and Hydroxy Benzoates in Water at 25 °C

JACQUES E. DESNOYERS, ROBERT PAGÉ, GÉRALD PERRON, JEAN-LUC FORTIER, PAUL-ANDRÉ LEDUC AND ROBERT F. PLATFORD

Département de chimie, Université de Sherbrooke, Sherbrooke, P.Q. and Canada Centre for Inland Waters, Burlington, Ontario

Received December 27, 1972

The densities, heat capacities, heats of dilution, osmotic coefficients, viscosities, and conductivities of sodium benzoate and the ortho, meta, and para isomers of sodium hydroxybenzoate have been measured in water at 25 °C. The densities and heat capacities of phenol solutions and the osmotic coefficients of aqueous potassium benzoate have also been determined. The addition of an —OH or a —COONa group on a benzene ring has little effect on the properties related to the effective size of the solute (apparent molal volume, B_η viscosity coefficient, and ionic conductivity) but decreases significantly the apparent molal heat capacity. The addition of an —OH group in the meta or para position of sodium benzoate has a similar effect. The large negative contribution to the heat capacity probably reflects the solute–solvent hydrogen bonding. The ortho isomer, which can form an internal hydrogen bond, has a significantly different behavior from that of the other isomers.

The excess properties show no evidence of association at low concentrations although some specific interaction is apparent for the ortho isomer at high concentration. There seems to be some cation–anion structural attraction with the meta and para isomers which again may be related to the hydrogen-bonding ability of these solutes. Sodium and potassium benzoates show signs of association above 1 *m*.

Les densités, capacités calorifiques, chaleurs de dilution, coefficients osmotiques, viscosités, et conductivités du benzoate de sodium et des isomères ortho, méta, et para des hydroxybenzoates de sodium ont été mesurés dans l'eau à 25 °C. Les densités et capacités calorifiques des solutions de phénol et les coefficients osmotiques des solutions de benzoate de sodium ont aussi été déterminées. L'addition de groupements —OH ou —COONa sur un noyau de benzène a peu d'effet sur les propriétés reliées à la dimension effective du soluté (volume apparent molaire, coefficient B_η de viscosité, conductivité ionique) mais décroît de façon appréciable les capacités calorifiques apparentes molaires. L'addition d'un groupement —OH en position méta ou para sur le benzoate de sodium a un effet semblable. La grande contribution négative de ces groupements à la capacité calorifique reflète probablement les effets de liaison hydrogène entre le soluté et le solvant. L'isomère ortho, qui peut former une liaison hydrogène interne, se comporte différemment des autres isomères.

Les propriétés d'excès ne démontrent aucune évidence d'association aux faibles concentrations, même s'il semble y avoir des interactions spécifiques pour l'isomère ortho aux plus fortes concentrations. Il semble y avoir des attractions structurales cation–anion avec les isomères méta et para, interactions qui sont probablement reliées aux possibilités de liaisons hydrogène avec le solvant. Les benzoates de sodium et de potassium semblent s'associer aux concentrations supérieures à 1 *m*.

Can. J. Chem., **51**, 2129 (1973)

Introduction

Systematic studies of aqueous solutions have usually been limited to model electrolyte systems such as alkali halides (1), tetraalkylammonium halides (2), *n*-alkylamine hydrobromides (3–6), or nonelectrolyte systems such as aliphatic alcohols (7), and cyclic ethers (8). Compared to aliphatic solutes the properties of aromatic solutes seem much harder to understand; ions such as tetraphenyl phosphonium, arsonium, and boride appear as either overall structure breakers or makers depending on the property examined (9, 10) and, despite their large size, bolaform dipyridinium salts are often strong structure breakers (11). In addition to the presence of π electrons, the rigidity of the aromatic rings may also influence the behavior of aqueous aromatic solutes. Despite these anticipated difficulties, the importance of their biochemical properties justifies further investigation of their aqueous solutions.

In a continuing study of the hydration of aromatic ions, it was felt useful to examine the three geometrical isomers of monosodium hydroxybenzoates and compare them with sodium benzoate. The addition of a terminal hydroxy group on an aliphatic chain has in general little effect on the solute partial molal volume (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This series could therefore be a good starting point to study substituent effects and internal hydrogen bonding on solute–solvent and solute–solute interactions. For example, Stein and Tomkiewicz (13) suggested from an n.m.r. study that sodium orthohydroxybenzoate associates in water through π electron interaction while the other two isomers are unassociated.

Relatively few properties of these solutes have been examined in water. Besides a few spectral (14, 15) and solubility (16) measurements most of the studies have been concerned with the ionization and reactivity of the acids. In view of the complexity of the possible solute–solvent and solute–solute interactions it was felt that most of the thermodynamic and transport properties should be determined in water, *i.e.*, densities, heat capacities, ionic conductivities, viscosities, and excess free energies, enthalpies, and entropies. The densities and heat capacities of phenol and the osmotic coefficients of potassium benzoate solutions were also determined to help in the interpretation.

This family of compounds has important biochemical interests; sodium benzoate is a food preservative and salicylic acid has well-known analgesic properties. It is our hope that systematic studies with such solutes will eventually help in understanding their biochemical activity and specificity.

Experimental

The salts used in this study will be abbreviated by: BzNa (sodium benzoate), *o*-HyBzNa, *m*-HyBzNa, and *p*-HyBzNa for the three isomers of sodium hydroxy benzoates. The *o*-HyBzNa (Fisher Scientific) was purified by dissolution in cold absolute ethanol and precipitation with diethyl ether. The other salts were prepared by neutralizing the corresponding acids (Eastman Kodak) with NaOH in methanol. From the p*H* of the aqueous solutions it was ascertained that only the —COOH proton was neutralized.

The acids were purified prior to neutralization by treating the methanol solutions with alumina until all coloration disappeared. The neutralized salts were purified in the same way as *o*-HyBzNa. All these salts showed signs of decomposition when heated or exposed to light when wet. Heating of the solutions was therefore avoided and the salts were dried under vacuum.

All solutions were prepared by weight with water redistilled from an alkaline permanganate solution. The molalities were converted to molarities whenever necessary using the measured densities. All measurements were made on fresh solutions to avoid any decomposition upon standing. In the concentration ranges studied hydrolysis of the weak acid salts caused negligible errors. The temperature was kept at 25 °C and regulated to ±0.002 °C throughout.

The techniques used for density (3), viscosity (4), conductivity (4), heat capacity (17), heat of dilution (18), and isopiestic (19) measurements have all been described elsewhere. The precision of the derived data has also been discussed therein.

Results

The equivalent conductivities Λ were analyzed with the Fuoss–Onsager equation (20),

$$[1]\quad \Lambda = \Lambda_0 - A_\Lambda c^{1/2} + E_\Lambda c \log c + J_\Lambda c$$

where A_Λ and E_Λ are known parameters which can be calculated from the standard conductivities Λ_0 and the properties of the solvent and J_Λ is an adjustable parameter related to solute–solute interaction and to the distance of closest approach a_Λ. The relative viscosities η_r were treated with an extended form (4) of the Jones and Dole equation,

$$[2]\quad \eta_r = \eta/\eta_0 = 1 + A_\eta c^{1/2} + B_\eta c + C_\eta c^2$$

where A_η can be calculated from Λ_0 using Falkenhagen's equation (21), the B_η viscosity parameter depends on the size and hydration of the solute and C_η is an empirical parameter. The apparent molal volumes, heat capacities, and relative enthalpies are given as a function of molarities or molalities by

$$[3]\quad \phi_v = \phi_v^0 + A_v c^{1/2} + B_v c$$

$$[4]\quad \phi_c = \phi_c^0 + A_c c^{1/2} + B_c c$$

$$[5]\quad \phi_L = A_L m^{1/2} + B_L m + C_L m^{3/2} + D_L m^2 + E_L m^{5/2}$$

where the parameters of the limiting Debye–Hückel theory are respectively $A_v = 1.868$, $A_c = 28.99$, and $A_L = 1975$ for 1:1 electrolytes in water at 25 °C (the units of ϕ_v, ϕ_c, and ϕ_L are respectively $cm^3\ mol^{-1}$, $J\ K^{-1}\ mol^{-1}$, and $J\ mol^{-1}$). All higher coefficients measure the deviation from the Debye–Hückel theory for solute–solute interactions.

The osmotic and activity coefficients, φ and γ are obtained in the usual way from isopiestic data (22),

$$[6]\quad \phi = 1 - \frac{2.303A\gamma}{A^3 I} \times \left\{1 + AI^{1/2} - 2\ln(1 + AI^{1/2}) - \frac{1}{1 + AI^{1/2}}\right\} + BI + CI^2 + DI^3 + EI^4$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and

$$[7] \quad \ln \gamma = \frac{-2.303A\gamma I^{1/2}}{1 + AI^{1/2}} + 2BI + \frac{3}{2}CI^2 + \frac{4}{3}DI^3 + \frac{5}{4}EI^4$$

where $A\gamma$ is the limiting Debye–Hückel slope, 0.5085 and I is the ionic strength given by $\frac{1}{2}\sum Z_i^2 m_i$. Again all other parameters are adjustable and reflect ion–ion interactions.

Equations 1 to 7 were used to fit all the data, at least at low concentrations. With phenol, the same equations were used for ϕ_v and ϕ_c except for the $c^{1/2}$ term which was removed since phenol behaves like a nonelectrolyte. The viscosities and conductivities are plotted in Fig. 1, the apparent molal volumes and heat capacities in Fig. 2 and the activity coefficients in Fig. 3. The parameters of eq. 1 to 5 are summarized in Table 1 and those of eq. 6 and 7 in Table 2. The actual experimental data are available elsewhere.[1]

Discussion

Solute–solvent interactions should be discussed in terms of the functions ϕ_v^0, ϕ_c^0, B_η, and

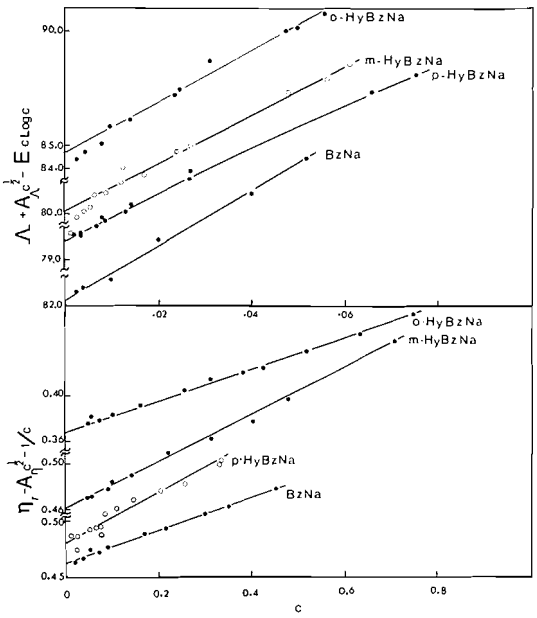

FIG. 1. Viscosities and conductivities of sodium benzoate and hydroxybenzoates in water at 25 °C.

Λ_0 since they are independent of solute–solute interactions. With the present solutes the interactions are not simple, and we can at best predict their signs. Adding an —OH or —COONa group will increase the degrees of freedom and size of the solute; as such the intrinsic contribution should increase ϕ_v^0, B_η, and ϕ_c^0 and de-

crease Λ_0. Any strong coulombic hydration (charge–dipole type) should influence the —COONa group but not —OH; this should be reflected mostly in a decrease in ϕ_v^0 and Λ_0 and increase in B_η. Coulombic hydration probably decreases ϕ_c^0 to some extent, but this effect seems to be small compared with other types of interactions such as the structural ones.

Changes in structural interactions (1) can have a significant influence on the properties of these solutes. The structure-breaking effect will decrease ϕ_c^0, ϕ_v^0, and B_η and increase Λ_0. The structure-making (hydrophobic) interactions will have the opposite effect on ϕ_c^0, B_η, and Λ_0 but have little influence on ϕ_v^0 (there is a compensation between the cavity effect and increase in ice-likeness near hydrophobic solutes (2, 3)).

With the present solutes extra interactions may also arise from inter and intra molecular hydrogen bonding, from the π electrons, from the rigidity of the molecules and from mesomeric and inductive effects. The complexity of all these interactions is such that we cannot hope to find a unique interpretation for all the properties. Still, through a careful examination of the data, we do hope to be able to show the relative importance of the different interactions.

Hydration of —OH and —COONa Groups

The effect of adding an —OH and a —COONa group on the benzene ring is illustrated in Fig. 4 where the changes in ϕ_v^0 and ϕ_c^0 are compared for benzene, phenol, BzNa, and *p*-HyBzNa in water at 25 °C. The volume and heat capacity data for benzene are taken from the literature (9).

The effective sizes of the —OH and —COONa group are small in water as evidenced from the small value of $\Delta\phi_v^0$ corresponding to the addition of one of these groups. The addition of a second group has an even smaller effect on ϕ_v^0. The same is also true for the changes in B_η and Λ_0 when *p*-HyBzNa is compared with BzNa; these differences are $\Delta B_\eta = 0.02$ l mol^{-1} and $\Delta\Lambda_0 = -2.5$ conductance units. The effect on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

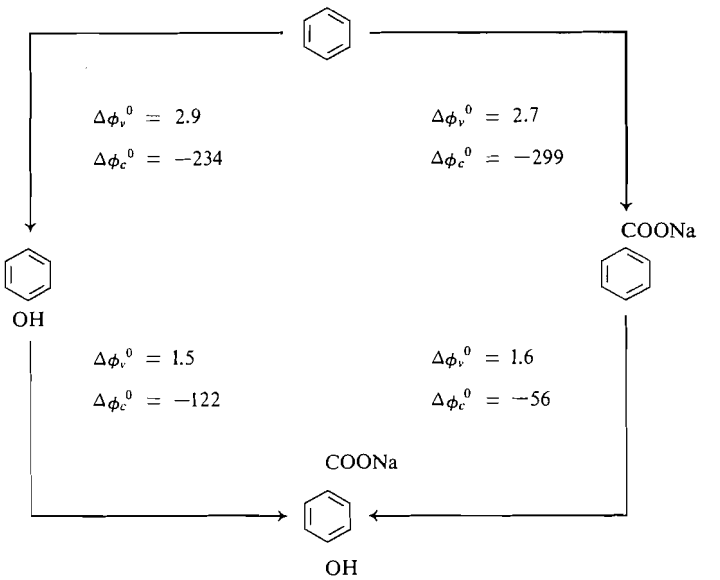

FIG. 4. Effect of the addition of an —OH and a —COONa group on ϕ_c^0 and ϕ_v^0 of benzene.

ϕ_v^0 of adding an ionic $-COO^-$ group would be larger (if ϕ_v^0 of Na^+ is taken as -7 cm^3 mol^{-1} (1), $\Delta\phi_v^0 = 10$ cm^3 mol^{-1}) but still less than the intrinsic contribution expected from the group molecular weight. The small overall contribution of the —OH group is not limited to aromatic compounds; for example ϕ_v^0 of $(C_2H_4OH)_4NBr$ (177 cm^3 mol^{-1}) (12) is about the same as that of Et_4NBr (174 cm^3 mol^{-1}) at 25 °C.

It is tempting to attribute the small effective size of these groups to hydrogen bonding with water, but a comparison of ϕ_v^0 of most aliphatic alcohols in *n*-heptane (23) shows that they are within 1 cm^3 mol^{-1} of the molar volume of the corresponding alkane. Therefore even in nonpolar solvents the effective size of the —OH group is negligible. The exact reason for this is not clear at the moment but it has something to do with the solute molecule itself rather than with structural interactions with the solvent.

The changes in ϕ_c^0 when the groups —OH and —COONa are added to the benzene ring are large and negative while the intrinsic contribution would be expected to be positive. Again this observation is general since ϕ_c^0 of ethanol is 70 J K^{-1} mol^{-1} smaller than that of ethane in water (24).

The interpretation of the heat capacity contribution of the —OH group is easier if it is compared with the corresponding enthalpy. Krishnan and Friedman (25) have shown that the difference between the enthalpy of hydration of the —OH group and that of the terminal —H of the corresponding alkane is constant for most normal alcohols and alkanes and is given at 25 °C by

$$[8]\quad \Delta H^{g\rightarrow w}(OH) = \Delta H_h^0(ROH) - \Delta H_h^0(RH) \simeq -35 \text{ kJ mol}^{-1}$$

Corresponding to this function we may define the heat capacity of hydration related to the replacement of an —H atom by an —OH group,

$$[9]\quad \Delta C_p^{g\rightarrow w}(OH) = \phi_c^0(ROH) - \phi_c^0(RH) - C_p^g(ROH) + C_p^g(RH) \simeq -90 \text{ J K}^{-1} \text{ mol}^{-1}$$

at 25 °C. The data for the heat capacity of the solutes in water (24) and in the gas phase (26) are taken from the literature.

It is surprising that the enthalpy and heat capacity of hydration of the —OH group have the same sign. Since the strength of an interaction usually decreases with temperature, the signs of the corresponding ΔH and ΔC_p are normally opposite. It is therefore probable that $\Delta H^{g\rightarrow w}(OH)$ and $\Delta C_p^{g\rightarrow w}(OH)$ are reflecting different interactions.

The possible components of enthalpies of hydration are given, following Krishnan and Friedman (25), by

$$[10]\quad \Delta H^{g\rightarrow w}(OH) = \Delta H(CAV) + \Delta H(VDW) + \Delta H(HB) + \Delta H(STR)$$

where ΔH(CAV) is the enthalpy associated with the process of making a cavity in the solvent to accommodate the solute, ΔH(VDW) with van der Waals and polarization interactions, ΔH(HB) with solute–solvent hydrogen bonding and ΔH(STR) with structural interactions. A corresponding equation may again be written for the heat capacities,

$$[11]\quad \Delta C_p^{g\rightarrow w}(OH) = \Delta C_p(CAV) + \Delta C_p(VDW) + \Delta C_p(HB) + \Delta C_p(STR)$$

The separation of $\Delta H^{g\rightarrow w}$(OH) and $\Delta C_p^{g\rightarrow w}$(OH) into different contributions is somewhat artificial. For example, a good part of hydrophobic hydration can be considered as the work of forming a cavity in water (27). By analogy with the air–water interface there is an increase in the structure of water around the cavity since the —OH group of a water molecule prefers to be hydrogen bonded to another water molecule rather than dangle freely in the cavity. In eqs. 10 and 11 the terms ΔH(CAV) and ΔC_p(CAV) refer to the formation of a cavity in an ideal non-hydrogen-bonded liquid and any accompanying change in hydrogen bonding is considered part of ΔH(STR) and ΔC_p(STR).

These contributions cannot really be determined separately. Still some idea of their relative importance may be obtained indirectly from the properties of non-aqueous solvents and pure liquids. The difference in the enthalpy of transfer, corresponding to the replacement of an —H by an —OH group, from the gas phase to propylene carbonate is $\Delta H^{g\rightarrow PC}(OH) = -21$ kJ mol^{-1} and to dimethylsulfoxide $\Delta H^{g\rightarrow DMS}(OH) = -37$ kJ mol^{-1} (25). With these aprotic solvents, ΔH(HB) and ΔH(STR) are absent. Since these enthalpies of transfer are of the same order of magnitude as those in water, it seems that a good part of $\Delta H^{g\rightarrow w}$(OH) is probably due to the terms H(CAV) + H(VDW) and, as in the case of volumes, have little to do with the particular nature of water. Therefore most of this enthalpy comes from the change in standard state and polarization effects and not from the interactions involving hydrogen-bonding of the solvent.

With $\Delta C_p^{g\rightarrow w}$(OH), the sign of the contributions ΔC_p(CAV) + ΔC_p(VDW) can also be estimated from the properties of pure liquids. Most heat capacities of liquids are larger than those of the corresponding gases. The overall contribution of the two terms ΔC_p(CAV) + ΔC_p(VDW) should therefore be positive. The negative $\Delta C_p^{g\rightarrow w}$(OH) must consequently come from the terms ΔC_p(HB) and ΔC_p(STR).

The interaction between an —OH group and water must be weak since it has little effect on ϕ_v^0, B_η, Λ_0, and enthalpies. On the other hand it must be very temperature dependent to explain the large change in ϕ_c^0. This weak interaction most probably has something to do with the intermolecular hydrogen bond ROH---H_2O. All systems involving hydrogen bonds have abnormally negative ϕ_c^0 (ϕ_c^0 of H_{aq}^+ is much more negative than Li_{aq}^+ (28)) or positive excess heat capacities (this is the case for example of the tetrabutylammonium carboxylates (29)). The ROH---H_2O interaction probably has a negative enthalpy contribution, and it is not unreasonable to assume that this weak interaction strengthens with respect to the H_2O---H_2O interaction as the temperature increases, thus accounting for the negative ϕ_c^0 contribution. In other words temperature weakens the H_2O---H_2O hydrogen bond more than the ROH---H_2O bond, which is not unreasonable considering the difference in the spatial arrangement of these hydrogen-bonded systems.

Comparison of the Ortho, Meta, and Para Isomers

The parameters ϕ_v^0, ϕ_c^0, B_η, and Λ_0 are compared in Fig. 5 for the three geometrical isomers and BzNa. The behavior of Λ_0 is, at least qualitatively, the mirror image of B_η. Since B_η is proportional, and Λ_0 inversely proportional, to the effective size of the moving particle, it seems that both parameters are measuring the same effect; *o*-HyBzNa moves more readily in the solution than either NaBz or the other isomers. On the other hand, ϕ_v^0 of *o*-HyBzNa is significantly larger than that of the other solutes. The presence of an internal hydrogen bond with *o*-HyBzNa will have two main consequences; the free rotation of the —COO^- group will be hindered and the hydrogen bonding with the solvent will be decreased. The decrease in interactions may well explain the higher mobility. Also the increase rigidity will hinder the adaptation to the structure of the liquid and the solute may well occupy more space. Further studies on substituted aromatic solutes in water involving no intramolecular hydrogen bonds and studies

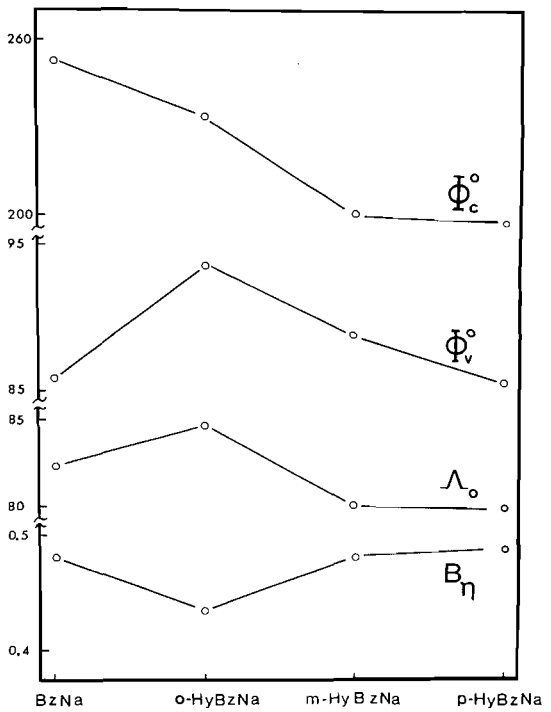

FIG. 5. Standard thermodynamic and transport properties of sodium benzoate and hydroxybenzoate in water at 25 °C.

in non-aqueous solvents would be necessary to confirm these explanations.

The ϕ_c^0 of *o*-HyBzNa is on the other hand more difficult to account for. With many systems ϕ_c^0 and ϕ_v^0 behave similarly. In this respect the higher value of ϕ_c^0 of *o*-HyBzNa is consistent with ϕ_v^0. The internal hydrogen-bonding and reduction in inter-molecular hydrogen bonding would support an increase in ϕ_c^0 when compared with *p*-HyBzNa. On the other hand we would expect it to be even larger than BzNa which is contrary to the experimental observation. It therefore seems that whatever the origin of the interactions with the solvent which causes a decrease in ϕ_c^0 when an —OH group is added to a molecule, it is not fully cancelled by the internal hydrogen bonding.

Except possibly for ϕ_v^0, the difference between the behavior of *m*-HyBzNa and *p*-HyBzNa is small. The observed differences could be related to geometrical factors (the para —OH group may fit slightly better in the structure of water) or inductive effects (larger for para). On the other hand resonance structures cannot readily be written for these solutes in the ionized form, which excludes probably any significant contribution from the mesomeric effect.

Solute–Solute Interactions

The molar excess thermodynamic functions (30) are defined by

$$[12] \qquad G^{EX} = \nu RT(1 - \phi + \ln\gamma)$$

$$[13] \qquad H^{EX} = \phi_L$$

$$[14] \qquad S^{EX} = (H^{EX} - G^{EX})/T$$

where ν, the number of ions formed during the dissociation, is 2 for 1:1 electrolytes.

These functions are plotted in Fig. 6 and compared with the corresponding Debye–Hückel limiting law (DHLL) for BzNa, *o*-HyBzNa, *m*-HyBzNa, and *p*-HyBzNa.

There is more solute–solute attraction with the hydroxybenzoates than with NaBz as evidenced from the more negative G^{EX}. On the other hand, there is no evidence for ion association at low concentrations; the ionic conductance and G^{EX} are all regular. On the other hand, at high concentrations, there are signs of specific ion–ion interactions with *o*-HyBzNa as seen from the cross-over of $\ln\gamma$ when compared with the other hydroxybenzoates (Fig. 3). It is doubtful however if these interactions are as large as

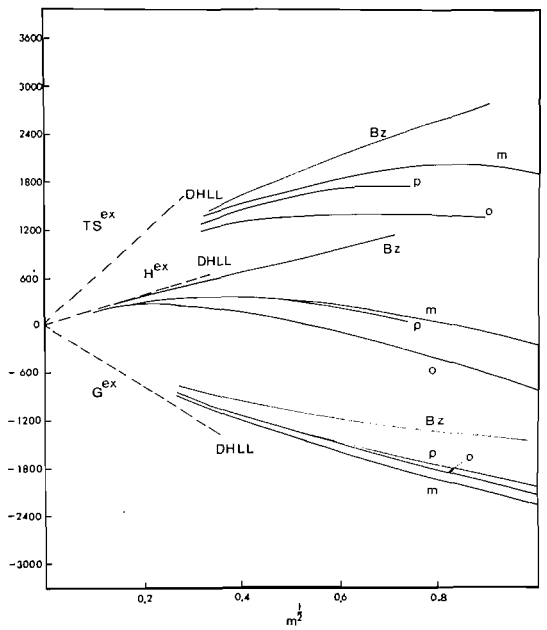

FIG. 6. Excess thermodynamic functions of sodium benzoate and hydroxybenzoates in water at 25 °C.

was suggested by Stein and Tomkiewicz (13). As with the properties related to solute–solvent interactions, *m*-HyBzNa and *p*-HyBzNa behave similarly with all the excess properties. At low concentrations ($m < 0.5$), BzNa follows very closely the DHLL with H^{EX} and S^{EX}; but the hydroxybenzoates show negative deviations from the DHLL suggesting some cation–anion structural interactions (31).

The activity data of BzNa (Fig. 3) show a peculiar behavior at high concentrations; the activity coefficient goes through a plateau near 1 *m* above which the activity coefficient shows a steady decrease. The activity of BzK was also measured in order to verify the generality of this effect and the plateau is again present, suggesting some association above these concentrations. Even though there was no evidence of strong hydrophobic character at low concentrations there may be some association similar to micelle formation at these high concentrations.

Information on solute–solute interactions can also be obtained from the parameters, B_v, B_c, J_Λ, and a_Λ of Table 1 which represent the deviations from the DHLL on the corresponding excess functions. These parameters are compared in Fig. 7 for the four sodium salts and phenol. Again BzNa shows no sign of important structural interactions at low concentrations, *m*-HyBzNa and *p*-HyBzNa show some attraction probably of structural origin; hydrophilic–hydrophilic structural attraction (cation-anion) would be reflected in a positive B_c and B_v, a smaller J_Λ and larger a_Λ (31, 32). It should be noted however that the B_v and B_c of *m*-HyBzNa and *p*-HyBzNa are abnormally large and are comparable to those for NaF: $B_v = 0.64$ (31), $B_c = 26$ (28). This again could be related to the particular behavior of hydrogen-bonding solutes (29). The excess properties of *o*-HyBzNa are anomalous since with heat capacities *o*-HyBzNa behaves like the other HyBzNa, with volumes like BzNa and with conductance between BzNa and the other HyBzNa. No simple explanation can at present be offered for these trends.

Finally we could note that the concentration dependence parameters B_v and B_c of phenol in water are comparable with those of BzNa. It therefore seems that, once corrected for the DHLL, the excess properties of BzNa are similar to those of phenol suggesting that the solute–solute interactions involving the —OH group are similar to those of —COONa.

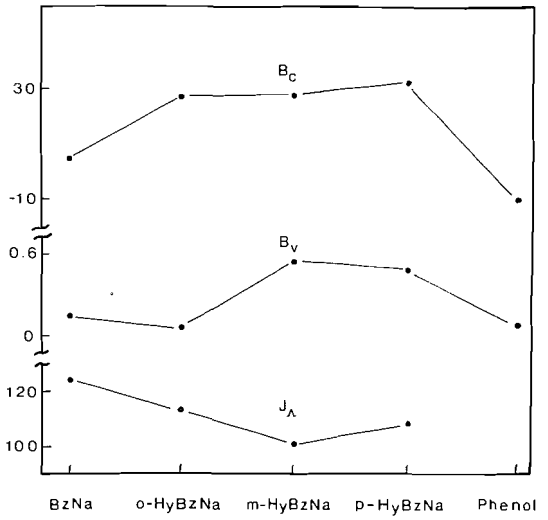

FIG. 7. Comparison of the parameters B_c, B_V, and J_Λ for phenol, sodium benzoate, and hydroxybenzoates in water at 25 °C.

Conclusion

A comparison of the thermodynamic and transport properties of BzNa, HyBzNa, and phenol show that (1) The addition of an —OH or —COONa group on a benzene ring has little effect on properties related to the effective size of the solute in water but decreases significantly the heat capacity. (2) The properties of *m*-HyBzNa and *p*-HyBzNa are similar with all standard and excess properties but those of *o*-HyBzNa are significantly different. (3) All excess properties are normal at low concentrations but do indicate some specific interactions at higher concentrations.

The interpretation of the thermodynamic and transport properties of the substituted benzoates is not simple and most of the explanations offered in terms of solute–solvent and solute–solute interactions are at present speculative. The present study emphasizes the importance of examining many complimentary properties when information on the solvation of complex molecules is sought; otherwise quite erroneous conclusions could easily be drawn. We do hope that the trends observed and the deductions made will be useful in guiding further studies towards a final elucidation of the important interactions between hydrogen-bonding solutes and water.

On the Unimolecular Decomposition of the tert-Butoxy Radical

C. K. YIP AND H. O. PRITCHARD[1]

Center for Research in Experimental Space Science, York University, Downsview, Ontario

Received November 16, 1972

It is argued that a large apparent pressure dependence in the rate of decomposition of the tert-butoxy radical should not be interpreted in terms of unimolecular reaction theory; the effect is probably heterogeneous in origin.

La dépendance très grande du taux de décomposition des radicaux tert-butoxy sur la pression ne devrait pas être interprété en termes d'une réaction unimoléculaire; un effet de nature hétérogène en est probablement l'origine. [Traduit par le journal]

Can. J. Chem., 51, 2138 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

It is becoming accepted practice to treat the pressure dependence of the formation of products in complex radical systems in terms of unimolecular reaction theories: this has been done recently, for example, for the tert-butoxy radical produced both thermally (1) and photochemically (2) from di-tert-butyl peroxide; it is the purpose of this note to caution that there can be large pressure effects which do not have their origins in unimolecular fall-off behavior. The thermal decomposition of di-tert-butyl peroxide (DTBP) proceeds, in the presence of high pressures of hydrocarbon (RH), according to (3)

[1] $$\text{DTBP} \rightarrow 2t\text{-BuO}$$

[2] $$t\text{-BuO} \rightarrow \text{acetone} + CH_3$$

[3] $$t\text{-BuO} + \text{RH} \rightarrow t\text{-BuOH} + \text{R, etc.}$$

The results presented below are taken from our previous studies of this reaction with RH = propane or cyclopropane (3–5), and the experimental techniques used have been adequately described elsewhere (3–6).

Figure 1 shows an attempt to deduce the ratio of k_3/k_2 from the rates of formation of *t*-BuOH and acetone at three temperatures, using RH = propane: the diagram is remarkably like those already published for the thermal decompositions of the acetyl (7) and tert-butoxy (1) radicals. Note: (*i*) the large scatter of the points at the lowest temperature where both k_2 and k_3 are low. Figure 2 shows similar results found with RH = cyclopropane at one temperature (115 °C), but in two separate reaction vessels. Note that (*ii*) the results probably separate into two distinct sets, both of which would appear to extrapolate to k_3/k_2 of between 0.05 and 0.1 l mol^{-1} at infinite hydrocarbon concentration; (*iii*) the scatter is largest at low cyclopropane concentrations where $R_3 \propto k_3[\text{RH}]$ is low, especially so because k_3 is extremely small for cyclopropane (4); (*iv*) in two experiments where the vessel had been packed, the effect was probably marginally significant at low hydrocarbon concentration, but inconclusive

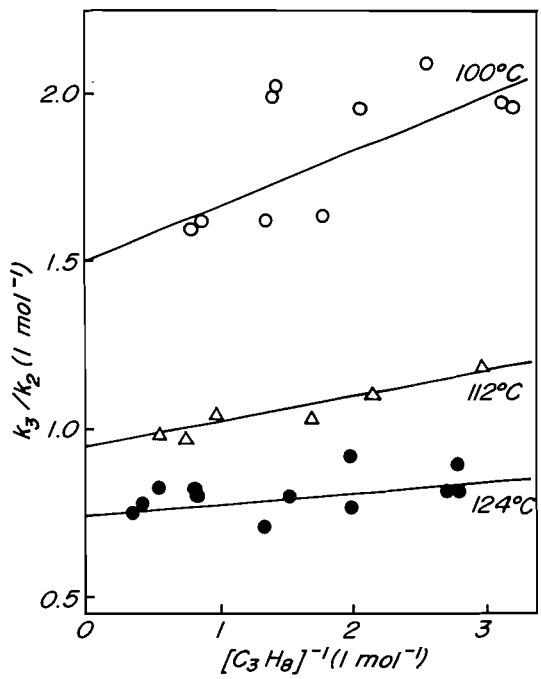

FIG. 1. Apparent variation of k_3/k_2 with hydrocarbon concentration for RH = propane, at three temperatures; data taken from refs. 3 and 5.

[1]Nuffield Foundation Visiting Fellow, Physical Chemistry Laboratory, Oxford University, 1972–1973.

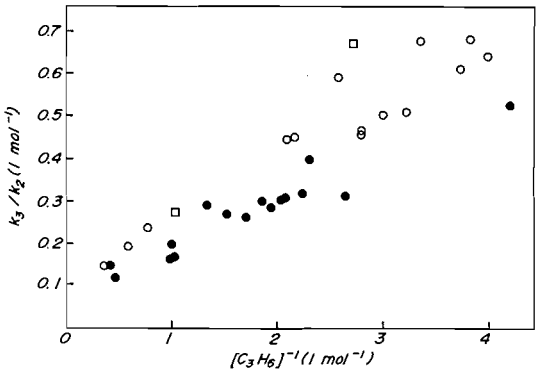

FIG. 2. Apparent variation of k_3/k_2 with hydrocarbon concentration for RH = cyclopropane at 115 °C: open and closed points represent measurements made in two different reaction vessels; square points represent measurements made in a reaction vessel packed with steel balls; data taken from refs. 4 and 5.

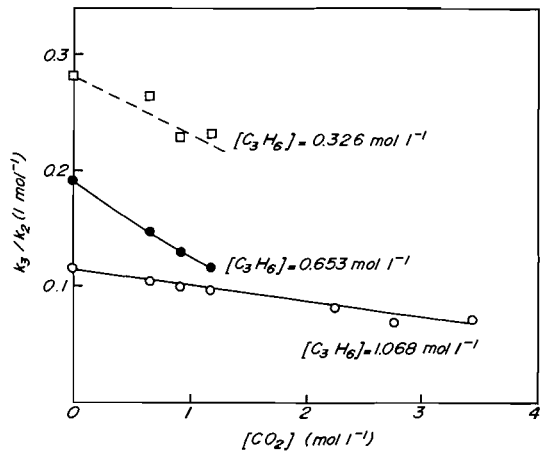

FIG. 3. Apparent variation of k_3/k_2 with carbon dioxide concentration for RH = cyclopropane at 115 °C.

at high hydrocarbon concentration; (*v*) the variation of k_3/k_2 with pressure over the range $0 < [RH]^{-1} \leqslant 3$ l mol^{-1} is at least a factor of four for cyclopropane at 115 °C in Fig. 2, but, at most, only a factor of about 1.3 for propane at the same temperature (*c.f.* Fig. 1).

Points *i* to *iv* can easily be understood if either k_2 or (more probably) k_3 were heterogeneous. Point *v* shows that the pressure dependence cannot be due to fall-off in k_2, since the effect for the *same* radical in different substrates is quite different; furthermore, it seems very likely that for this radical, $p_{1/2}$ is of the order of 100 mm total pressure (say 4×10^{-3} mol l^{-1}) at these temperatures (8), so that at our much greater concentrations (roughly 0.25 to 2.5 mol l^{-1}) a factor of four or more variation in k_2 does not make any sense.

Figure 3 shows the results of a third series of experiments (also at 115 °C) with RH = cyclopropane, in which, using three fixed initial concentrations of cyclopropane, successively larger amounts of carbon dioxide were added. Note that: (*vi*) these experiments were carried out in sequence in one reaction vessel, and are apparently much more reproducible than those shown in Fig. 2: however, those with the lowest cyclopropane concentration show the highest scatter; (*vii*) at the highest pressures, the results seem to be tending towards a value of k_3/k_2 around 0.07 l mol^{-1}, consistent with the results in Fig. 2: however, they do not extrapolate in any simple way using inverse concentrations (*e.g.* $[CO_2]^{-1}$, [total substrate]$^{-1}$, etc.) as the horizontal coordinate; (*viii*) the effect of adding cyclopropane seems to be somewhat greater than the effect of adding carbon dioxide: for example, considering the point at [RH] = 0.653 and $[CO_2]$ = 0.648 mol l^{-1}, increasing [RH] to 1.068 mol l^{-1} reduces k_3/k_2 from 0.147 to 0.104 l mol^{-1}, but keeping [RH] constant and changing $[CO_2]$ to about 1.06 mol l^{-1} would only reduce k_3/k_2 to about 0.120 l mol^{-1}.

Points *vi* and *vii* would be consistent with a heterogeneous component, as, in fact, is point *viii*. Since CO_2 and C_3H_6 have almost identical molecular masses, the diffusion coefficients for CO_2 and C_3H_6 only differ in the molecular-size factor: the cyclopropane molecule is larger than the carbon dioxide molecule, and one would therefore expect cyclopropane to be rather more effective than carbon dioxide in preventing the diffusion of tert-butoxy radicals to the walls in search of labile hydrogen atoms; the effect would not, however, amount to as much as a factor of two in the diffusion coefficients, and in consequence, the slightly greater efficiency for cyclopropane which we observe seems to be reasonable.

One could contrive an explanation of these results in terms of differing reactivities of $(RH)_n$ and $(RH)_n(CO_2)_m$ clusters at these pressures, but it would be hard to account for the increasing scatter at low pressures and temperatures: thus, we conclude that there can be marked pressure dependence in free radical reactions, possibly caused by heterogeneous effects, and the practice of ascribing all the

pressure dependence to unimolecular fall-off demands positive proof that such effects are absent.

Dielectric Constant, Density, and Enthalpy of Transition of Cyclohexane and Neopentane at 500 Atmospheres

HEMMING ART-MING CHEW AND RAYMOND KAI-CHOW CHAN[1]

Department of Chemistry, University of Western Ontario, London, Ontario

Received February 7, 1973

A cell has been described for the simultaneous measurement of the dielectric constant and volume changes at the phase transition of solids at low temperatures and pressures up to 500 atm. The dielectric constants of the high temperature phase of cyclohexane and neopentane at 10 kHz increase with decreasing temperature according to the Clausius–Mossotti equation. The low temperature solid phase of both nonpolar substances has considerably high shear strength and it is suggested that the dielectric data of these substances in the literature may have considerable errors. The enthalpies of fusion and solid–solid transition at 500 atm have been calculated from the experimental results.

Une cellule a été décrite pour mesurer simultanément la constante diélectrique et les changements de volume lors de la transition de phases des solides aux basses températures et sous des pressions atteignant 500 atm. Les constantes diélectriques de la haute température de phase pour le cyclohexane et le néopentane à 10 kHz augmentent lorsque la température décroît selon l'équation de Clausius Mossotti. La phase solide à basse température de ces deux substances non polaires a un pouvoir considérable de cisaillement et on pense que les données de la littérature concernant la constante diélectrique de ces substances comportent des erreurs appréciables. Les enthalpies de fusion et de transition solide–solide sous 500 atm ont été calculées à partir des résultats expérimentaux. [Traduit par le journal]

Can. J. Chem., 51, 2141 (1973)

Introduction

Crystalline solids are generally known to have a negative temperature coefficient of high frequency dielectric constant. This behavior is adequately described by the Clausius–Mossotti equation which suggests that the polarizability of a molecule is independent of temperature. Ice (1) and crystalline methanol (2), in which the contribution due to the infrared polarization decreases with temperature causing their high frequency dielectric constants to decrease with temperature, show departure from this general rule. Crowe and Smyth (3) have reported that several nonpolar solids also show this unusual behavior. While they offered no explanation, their results implied that the density of these solids decreased with temperature. The main objective of our studies is to resolve this anomaly.

A serious problem in the study of the dielectric behavior of solids is caused by the presence of voids of undeterminable dimensions resulting from the cracks in the sample or from the shrinking of the sample away from the electrodes. A dielectric cell in which both could be avoided is an essential prerequisite. We describe an apparatus for the simultaneous, but independent, measurement of the density and dielectric constant of solids. As far as we are aware this is the first apparatus of this type reported for the measurements on solids.

[1]To whom correspondence should be addressed.

Experimental

The dielectric cell designed for the measurement of dielectric constant and volume changes is shown in Fig. 1. All parts are made from stainless steel except the tension spring. L is an 8 cm diameter, 6 cm long block to accommodate the low electrode J and high electrode K. G is a mushroom-shaped piston with O-ring seals H, sliding into M where the solid is contained. G is fastened to the movable plate F which has a container N attached to it. The parallel plate air capacitor D, E is contained in N. The high electrode D of the air capacitor can be moved vertically through the plate P by means of a 40 threads per in. micrometer A with the tube B acting as a guide. The tension spring C is held in place by P and 4 binding posts O. The electrodes D, E, J, and K are electrically insulated by mica, Teflon, and epoxy cement. The force constant of spring C was calibrated by means of a Carver model K laboratory press. The spring is capable of exerting a maximum pressure of 550 atmospheres to a 6.2 mm diameter piston. The friction of the O-ring seals is negligible as shown by the reproducibility of the dielectric results in the heating and cooling part of the cycle (Fig. 4). The pressure exerted on the sample M, which is applied by the tension spring C through G, can be controlled by adjusting the positions of the nuts Q on the binding posts.

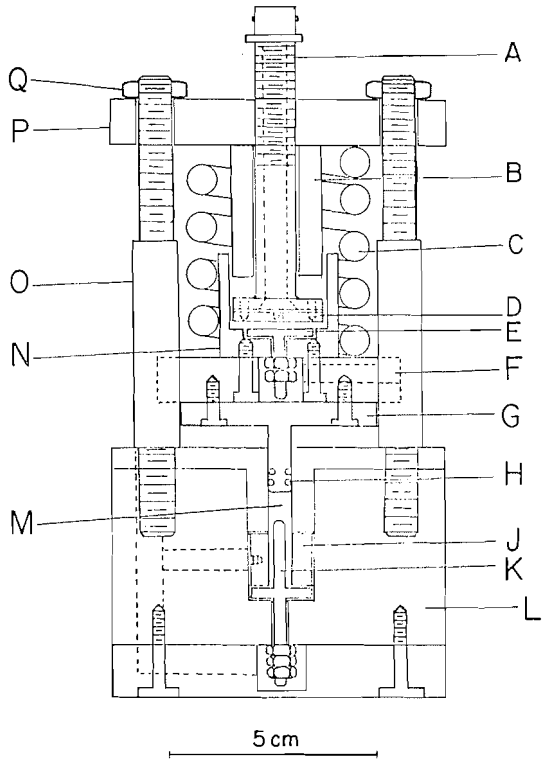

FIG. 1. The cell for dielectric constant and volume measurements.

The capacitance in air of the dielectric cell J K M was 1.048 pF. A calibration with CCl_4 at room temperature showed no stray capacitance in the assembly or in the electrical leads. The complete assembly was kept inside a large metal block with heating wires wound around it and was insulated with polyurethane foam. The insulated metal block was kept in liquid nitrogen contained in a metal dewar. The temperature was controlled and measured with copper–constantan thermocouples. The large thermal capacity of the dielectric cell provided excellent stability of temperature. The variation of temperature inside the solid sample was within ± 0.1 °C. The capacitance bridge and the associated assembly have been described earlier (4).

Measurements were done at constant pressure at different temperatures. Any change in the volume of the solid sample M, caused by thermal expansion or phase transition, produced a change in the distance between D and E. Since the air capacitance between D and E is inversely related to the separation between them, the vertical displacement of G can be easily calculated. Errors caused by the thermal expansion of the metal components of the assembly were too low to make any significant difference in our results.

In order to determine the coefficient of thermal expansion of the solid, it is necessary to know its volume at that temperature. For relatively less volatile substances a known volume of the liquid at room temperature can be introduced into the cell and from the values of the coefficient of thermal expansion, the volume can be calculated at each temperature. For volatile substances *e.g.* neopentane (b.p. 9.5 °C) this method is not convenient and, therefore, the following method was used.

According to the Clausius–Mossotti equation

$$[1] \qquad \frac{\varepsilon - 1}{\varepsilon + 2} = \frac{w[P]}{M(V_0 - \Delta V)} = \frac{d[P]}{M}$$

where w is the weight of the substance occupying V_0 cm^3 at a reference temperature, ΔV is the change in volume at any temperature from the reference temperature, $[P]$ is the molar polarization, and d is the density. Equation 1 can be approximated, after rearrangement, by

$$[2] \qquad \frac{\varepsilon - 1}{\varepsilon + 2} = \frac{w[P]}{MV_0} + \frac{w[P]}{MV_0^2}\Delta V$$

Since the molar polarization of a nonpolar substance is largely due to the electronic polarization, it would be independent of temperature, pressure, or phase transition. The initial volume V_0 can thus be obtained from the ratio of the intercept to the slope of a plot of $(\varepsilon - 1)/(\varepsilon + 2)$ against ΔV. Figure 2 shows such a plot for the high temperature solid phase of neopentane at 500 atm. Note that no knowledge of the density or the weight of the substance is required for this determination.

The enthalpies of fusion and solid–solid transition

were measured by a Perkin–Elmer DSC-1B differential scanning calorimeter.

Fischer certified spectranalyzed grade cyclohexane was distilled fractionally with calcium hydride before use. Metheson chemically pure grade neopentane with specified purity of 99.0% minimum was fractionally distilled in a vacuum apparatus and was collected at Dry Ice temperature. The sample was transferred into the dielectric cell inside a pre-cooled dry box at −20 °C.

Results

The measured values of the dielectric constant and density of cyclohexane and neopentane are given at 500 atm and different temperatures in Tables 1 and 2, respectively. Also included are the molar polarization, [P], calculated from eq. 1, and the density data of Green and Scheie (5) for solid cyclohexane at 1 atm. Figures 3 and 4 show the plots of the dielectric constant against temperature at 500 atm along with the atmospheric pressure data from Crowe and Smyth for cyclohexane (3), and Philippe and Piette for neopentane (6).

Our values of the dielectric constant for the solid phases are not only higher than those in the literature, but they also have a qualitatively different temperature dependence. This qualitative difference is seen immediately for cyclohexane after application of only 10 atm pressure and remains unchanged when the pressure is removed. It is evident that the dielectric data for cyclohexane and neopentane in the literature were obtained on solid samples which had voids in them. Under pressure these voids disappear and the sample remains compact even after removal of the pressure. The apparent dielectric constant of a solid containing air gaps (4) is given by

$$[3] \qquad \varepsilon_{app} = \frac{\varepsilon_s}{1 + \delta(\varepsilon_s - 1)}$$

where ε_s is the correct value of the dielectric constant of the solid, and δ is the fractional width of air gaps in the solid sample. The value of δ estimated for Crowe and Smyth's sample at −80 °C would be 5%.

Discussion

Cyclohexane freezes at 6.7 °C at atmospheric pressure to a crystalline solid, I, which transforms to another solid phase, II, at −87.1 °C (7). Neopentane also has two solid phases, the crystalline solid, I, is formed at −16.6 °C and then transforms to phase II at −133.2 °C (8). In both cases the phase I is plastic, in that it readily deforms under pressure, and

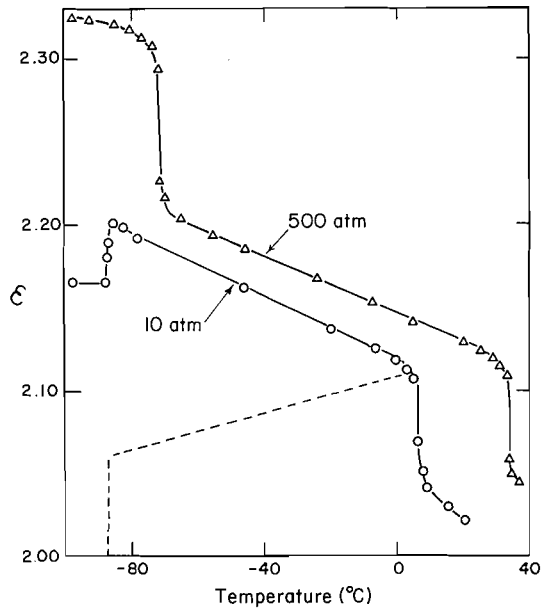

FIG. 3. Dielectric constant against temperature for cyclohexane at 10 and 500 atm and at 10 kHz. The dashed line represents the data of Crowe and Smyth at atmospheric pressure.

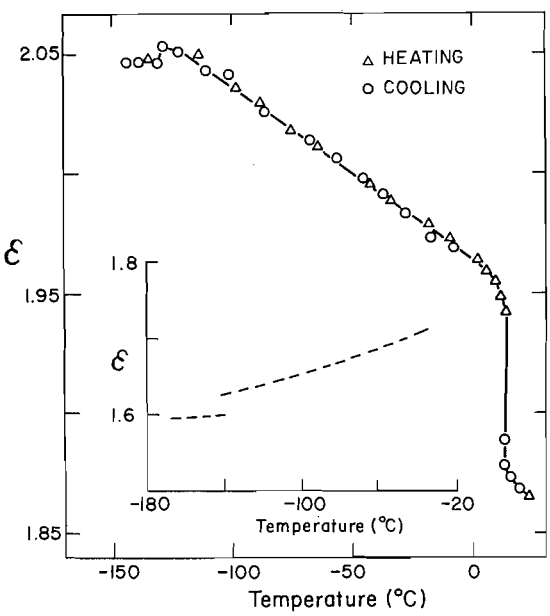

FIG. 4. Dielectric constant against temperature for neopentane at 500 atm and 10 kHz. The insert is the data of Philippe and Piette at atmospheric pressure.

the phase II is relatively hard and brittle (9). Considerably higher pressure is required to deform the phase II. This was evident in the result of our measurement of the effect of pressure on the change in the dielectric constant at I → II transition. It was found that at least 250 atm pressure is required to cause the dielectric constant of cyclohexane to increase at the phase transition. Typical results for cyclohexane are shown in Fig. 3 where the I → II transition at 10 atm produces a decrease in dielectric constant but the same transition at 500 atm produces an increase in dielectric constant. Clearly, the voids produced by the change in density during the I → II transition, which cause an apparent decrease in the dielectric constant, disappear on the application of a minimum pressure of 250 atm. The pressure required to compact the phase II of neopentane is higher than 500 atm as seen in Fig. 4. Thus the values of the dielectric constant and density for the phase II of neopentane are not reliable because of the much lower transition temperature and high shear strength of the solid.

It is worth noting that the comparative measurement of the plasticity of solids by Michels (10) also showed that in the vicinity of the transition temperature, the pressure required to force the low temperature solid phase through a bore is many times higher than that required for the high temperature solid phase.

The calculated values of the molar polarization at 500 atm from the experimental values of dielectric constant and density given in Tables 1 and 2 are 26.9 ± 0.1 and 25.7 ± 0.1 cm^3 mol^{-1} for cyclohexane and neopentane, respectively. This constancy also suggests the essential correctness of our density measurements.

It is worth pointing out that at 20 °C and 1 atm the average literature value of ε for liquid cyclohexane, 2.023 (12, 13) is 0.54% lower than that of n_D^2, 2.034 (14). It is unlikely that this rather unusual situation is due to experimental errors. It is conceivable that the strong ultraviolet absorption of liquid cyclohexane starting at 1800 Å (11) has a tail extending down to the visible region. This additional contribution to n_D^2 may make it larger than ε. Liquid hydrogen at −253 °C shows similar unusual behavior with ε = 1.228 and n_D^2 = 1.232 (15).

‡Reference 17.

The coefficient of thermal expansion at 0 °C and 500 atm for solid cyclohexane derived from dielectric constant is $5.4 \times 10^{-4}\,°C^{-1}$ in reasonable agreement with $5.8 \times 10^{-4}\,°C^{-1}$ obtained from density. The corresponding values for solid neopentane are 5.6×10^{-4} and $5.4 \times 10^{-4}\,°C^{-1}$. The atmospheric density values of Green and Scheie (5) for solid cyclohexane are 1.4% lower than those at 500 atm (Table 1). They found a slightly higher value of $6.8 \times 10^{-4}\,°C^{-1}$ for the coefficient of thermal expansion, which is in fair agreement with the value of $6.3 \times 10^{-4}\,°C^{-1}$ obtained from the dielectric measurements at 0 °C and 10 atm (4). The decrease in the coefficient of thermal expansion with pressure seen here was expected.

The pressure coefficient of dielectric constant $(\partial\varepsilon/\partial p)_T$ at −40 °C for solid cyclohexane calculated from measurements at 10 and 500 atm is $5.1 \times 10^{-5}\,atm^{-1}$, corresponding to a compressibility of $3.2 \times 10^{-5}\,atm^{-1}$ based on the Clausius–Mossotti equation. The extrapolated compressibility at 25 °C is $4.6 \times 10^{-5}\,atm^{-1}$ compared with Bridgman's value of $5.1 \times 10^{-5}\,atm^{-1}$ (16).

Another quantity that is of interest in this work is the effect of pressure on the enthalpy of transition. It can be shown that the difference between the enthalpies of transition at atmospheric and higher pressure is not negligible. The change of enthalpy of transition with respect to pressure for a substance transforming from phase 2 to phase 1 is

$$[4] \quad \left(\frac{\partial \Delta H}{\partial p}\right)_T = (V_1 - V_2) - T(V_1\alpha_1 - V_2\alpha_2)$$

where V_1 and V_2 are the molar volumes; α_1 and α_2 are the coefficients of thermal expansion of phases 1 and 2, respectively. This equation enables one to determine the enthalpy of transition at 500 atm. The calculated values of the change in enthalpy of fusion and of solid–solid transition together with other experimental data are summarized in Table 3. An inspection of eq. 4 shows that a substantial decrease of ΔH with respect to pressure is expected for small ΔV, and large T and $\Delta\alpha$, These conditions are optimal for fusion of cyclohexane. At 500 atm the enthalpy of fusion for cyclohexane decreases by 24% compared to 4.4% for neopentane. On the contrary, the enthalpy of solid–solid transition for cyclohexane hardly changes at all with pressure. It is because the low transition temperature renders the terms with opposite signs in eq. 4 almost identical. The enthalpy of transition decreases by only 0.6% for a pressure change of 500 atm. ΔT is the elevation of fusion or transition temperature at 500 atm, which can also be calculated with the aid of the Clapeyron equation. The calculated values of ΔT using the average values of ΔH and temperature are in fair agreement with the experimental values of ΔT obtained from dielectric measurements.

Examination of Possible Non-Arrhenius Behavior in the reactions

$$H + C_2H_6 \rightarrow H_2 + C_2H_5$$
$$H + CH_4 \rightarrow H_2 + CH_3$$
$$CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$$

THOMAS C. CLARK AND JOHN E. DOVE

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received August 29, 1972

We present a simplified form of the bond-energy–bond-order method of calculating rate coefficients which can be applied to reactions involving multi-atom reactants. Rate coefficients for the reactions

[1] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[2] $H + CH_4 \rightarrow H_2 + CH_3$

[3] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

are calculated for $300 < T < 1800$ °K. The Arrhenius plots of the calculated coefficients are curved, but in the temperature range 400–850 °K where most kinetic measurements have been made the curvature is not large enough to be readily detected. However deviations from a linear Arrhenius plot should be observable if rate measurements are extended to higher temperatures by, *e.g.*, shock tube experiments. The calculated rate coefficients at 300–1800 °K are fitted by the expressions

$$k_1 = 10^{-0.27\pm0.03}T^{3.5} \exp -(5200 \pm 70)/RT$$
$$k_2 = 10^{1.35\pm0.02}T^{3.0} \exp -(8750 \pm 40)/RT$$
$$k_3 = 10^{-3.26\pm0.01}T^{4.0} \exp -(8280 \pm 30)/RT$$

in liter mole second units. These expressions contain powers of T which in each case are greater than predicted by the classical limit of transition state theory. For all three reactions there is now some experimental evidence that the predicted curvature does occur. Some consequences of this behavior are examined.

Nous présentons une forme simplifiée de la méthode énergie de liaison – ordre de liaison pour le calcul des coefficients de vitesse, qui peut être applicable aux réactions engageant des réactants multi-atomiques. Les coefficients de vitesse pour les réactions

[1] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[2] $H + CH_4 \rightarrow H_2 + CH_3$

[3] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

ont été calculés entre $300 < T < 1800$ °K. Les courbes d'Arrhénius des coefficients calculés sont recourbées, mais dans l'intervalle de température 400–850 °K où la plupart des mesures cinétiques ont été faites, la courbure n'est pas suffisamment forte pour être détectée facilement. Cependant, les déviations par rapport à la droite d'Arrhénius peuvent être observées si les mesures de vitesse ont été effectuées à des températures plus élevées, par exemple par des expériences de "shock-tube". Les coefficients de vitesse calculés entre 300–1800 °K satisfont aux expressions

$$k_1 = 10^{-0.27\pm0.03}T^{3.5} \exp -(5200 \pm 70)/RT$$
$$k_2 = 10^{1.35\pm0.02}T^{3.0} \exp -(8750 \pm 40)/RT$$
$$k_3 = 10^{-3.26\pm0.01}T^{4.00} \exp -(8280 \pm 30)/RT$$

en unités litre mole seconde. Ces expressions contiennent des puissances de T qui sont dans chaque cas plus élevées que celles prévues par la limite classique de la théorie de l'état de transition. Pour ces trois réactions il existe maintenant une preuve expérimentale confirmant la courbure prédite. Quelques conséquences de ce fait ont été examinées. [Traduit par le journal]

Can. J. Chem., 51, 2147 (1973)

Introduction

It is customary to use the Arrhenius law to represent the temperature dependence of experimentally measured rate coefficients for bimolecular elementary gas reactions. However, in the case of several important elementary bimolecular reactions in gaseous hydrocarbon chemistry, experimental data indicate a discrepancy in that the rate coefficients at high temperatures lie above the Arrhenius line de-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rived from low temperature data. Since there are good theoretical reasons (1*a*) to expect deviations from the Arrhenius law, we decided to investigate the possibility that this discrepancy may be a real effect rather than being due to experimental error. Accordingly, we have used activated complex theory to calculate, over a large temperature range, the rate coefficients of three elementary reactions important in hydrocarbon pyrolysis, namely

[1] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[2] $H + CH_4 \rightarrow H_2 + CH_3$

[3] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

In each case, our calculated absolute values of the rate coefficients correlate the experimental data well. The predicted deviations from the Arrhenius law, particularly above 1000 °K, are large enough to be experimentally significant; the deviations are particularly large in the case of reaction 3.

In our calculations, we have used basically the modified three-center reaction models of Johnston (2), but have applied to them a later formulation of the B.E.B.O. transition state method given by Johnston and Parr (1, 3). We have introduced some approximations of our own which greatly simplify the calculations. The method, with these additional approximations, provides a convenient way of estimating absolute rate coefficients for reactions involving polyatomic species. It also enables an estimate to be made of the error introduced by using the Arrhenius law to extrapolate rate coefficients from one temperature range to another.

By using the B.E.B.O. formulation, we can break down an overall temperature dependence into four components. The first is the usual exponential term containing the potential energy of activation. The second is the temperature raised to some power determined by the classical limit of the partition functions. The third term allows for the temperature variation of quantum effects on the vibrations of the reactants and activated complex. The last is the temperature dependence of the quantum mechanical tunnelling correction for motion along the reaction coordinate. The effect of each contribution can be examined.

Several workers (4–8) have studied reaction 1 over the range 500–900 °K; their rate coefficients are scattered, but in fair agreement. Clark *et al.* (9) suggest that k_1 at 1350 °K is about 50% larger than the value expected from the Arrhenius rate parameters of Baldwin and Melvin (4).

Kurylo and Timmons (10) used a discharge flow system with e.s.r. detection of H atoms to obtain reliable coefficients for reaction 2 over the range 426–727 °K. Other data on reaction 2 (11–14) include two points above 1500 °K which lie above an Arrhenius line through the lower temperature data (11). Dove and Wagner (15) studied the reaction of H atoms with CH_4 at temperatures up to 1100 °K in a discharge–flow system and found agreement with Kurylo and Timmons at lower temperatures; however they observed an apparently anomalously high rate of consumption of H atoms above 850 °K which might indicate departures of k_2 from an Arrhenius form.

In previous kinetic studies (16–19) of reaction 3, its rate has generally been measured relative to that of some reference reaction. We have combined the relative rates with recent data (22–24) on the reference reactions to obtain absolute rate coefficients for reaction 3. The rate coefficients thus obtained from the various studies are found to be in good agreement with one another and to indicate an Arrhenius activation energy of 11.5 to 12.5 kcal mol^{-1} at about 500 °K. McNesby (16) studied the reaction

[3*a*] $CD_3 + C_2H_6 \rightarrow CD_3H + C_2H_5$

whose rate coefficient is expected (16) to be very close to that of reaction 3. At 1350 °K, Clark, Izod, and Kistiakowsky (9) deduced a value for k_3 from studies of high temperature reactions of methyl radicals which was more than 10 times that expected by extrapolation of McNesby's rate parameters. In addition, Clark and Izod (20) deduced that the Arrhenius activation energy for [3] is at least 14 kcal/mol over the range 1200–1500 °K. Recent flow system experiments by Pacey and Purnell (21) have yielded rate coefficients near 1000 °K which are significantly greater than predicted from McNesby's data, and their activation energy of about 16 kcal mol^{-1} is even larger than the value suggested by Clark and Izod for higher temperatures. It is therefore of considerable interest to know the full form of the theoretical temperature dependence of reaction 3, in order to determine whether these apparent discrepancies in the values of k_3 can be genuinely due to the failure of a simple Arrhenius form.

Method of Calculation

Basic Formulation

In the basic three-center reaction (1*b*), an atom A plus diatom BC, with properties R_{BC}, l_{BC}, ω_{BC}, Γ_{BC} give a linear complex A..B..C, with properties R_{BC}', l_{BC}', l_{BEND}, R_{AB}, l_{AB}, ω_1, ω_{BEND}, Γ_1, Γ_{BEND}, Γ_{RC}. The R's are internuclear separations, and ω's are vibration frequencies. $l = (2\pi kT/F)^{1/2}$ is a classical vibration amplitude, and F is a force constant. The imaginary frequency ω_{RC} is associated with motion along the reaction coordinate over a potential energy barrier of height V. A factor w_i, which is an imaginary number, corrects for interaction terms in the force constant matrix (1*c*). The factors Γ are vibrational quantum corrections (1*b*). Γ_{RC} is the real quantum correction for the imaginary frequency ω_{RC} and is a tunnelling correction factor. The factor β allows for a geometric factor, and any reaction path degeneracy or electronic partition function contributions. For R and l in Å, and ω in cm^{-1}, the rate coefficient for the basic three-center reaction is given in 1 mol^{-1} s^{-1} by

$$k = 1.81 \times 10^7 \beta \Gamma_{RC} \omega_{RC} \frac{R_{BC}'^2 R_{AB}^2}{w_i R_{BC}^2} \times \frac{l_{BC}' l_{AB} l_{BEND}^2}{l_{BC}} \frac{\Gamma_1 \Gamma_{BEND}^2}{\Gamma_{BC}} \exp\left(\frac{-V}{RT}\right)$$

Modifications for Complex Reagents

To allow for the case that there is a multiatom group, such as ethyl, at the center "C", the model of Johnston (2) was adopted. It is:

$$\begin{aligned} &A + B—C—D \rightarrow A...B...C—D \\ \textit{e.g.}\ &H + H—CH_2—CH_3 \rightarrow H...H...CH_2—CH_3 \\ &H + H—C—H_3 \rightarrow H...H...C—H_3 \end{aligned}$$

The force constants associated with each of two perpendicular bending frequencies about ⟨BCD in the complex were calculated as the corresponding reactant force constants multiplied by the bond order of B—C in the complex. The vibrational amplitude term to be introduced into the formula as a result of the presence of the multiatom group at C is simply the reciprocal of the bond order of B—C in the complex. The quantum corrections Γ were calculated from the vibration frequencies of the reactant molecule and complex. In the present work, the bending frequency introduced into the complex was estimated by multiplying the corresponding frequency of the reactant molecule by the square root of the bond order of B—C in the complex. The term introduced into the three-center formula by the molecule at site C with two degenerate bending frequencies ω and a bond order n for B—C in the complex is thus:

$$\frac{1}{n}\left(\frac{\Gamma(\sqrt{n}\omega)}{\Gamma(\omega)}\right)^2$$

We took ω to be the average of the bending frequencies of ethane for reactions 1 and 3, and of methane for reaction 2.

For the case that there was a multi-atom reagent such as methyl at A, the three-center model was modified by introducing (2) a pseudo-diatom E—A as follows:

$$\begin{aligned} &H_3—C + H—CH_2—CH_3 \rightarrow H_3—C...H...CH_2—CH_3 \\ &E—A + B—C—D \rightarrow E—A...B...C—D \end{aligned}$$

First, a geometrical factor $1/4\pi$ should be introduced (1*d*, 2). Two perpendicular bending modes ⟨EAB occur in the complex which were absent in the reactants. Thus two additional vibrational amplitude factors l and two quantum correction factors Γ must be introduced into the simple three-center formula. To allow for CH_3 at the center A, we thus introduce a factor $l^2\Gamma^2/4\pi$.

The bending force constants introduced into the complex by reagent methyl were calculated as follows. An average bending frequency for methane was calculated. A "*G*-factor" (1*e*) for the linear triatomic model H_3—C—H was then used to deduce a bending force constant for the molecule. To find this force constant in the complex, the molecular force constant was multiplied by the C—H bond order in the complex (1*e*, 2). We then used a *G*-factor for the H_3—C...H bend in the complex, to deduce the vibration frequency.

Use of these approximations avoids the lengthy **FG** matrix procedure for finding the bending frequencies of the complex (1*e*). Any resulting uncertainty in the frequencies will be reflected only in the quantum corrections Γ deduced from these frequencies, and thus will vanish at high enough temperatures. For the case of $CH_3 + C_2H_6$ at 400 °K, we have compared our calculated combined quantum correction for the bending frequencies with the correction calculated using frequencies from a complete vibrational analysis by Johnston (2). The excellence of the agreement, within 3%, is

TABLE 1. Input parameters and calculated complex properties

Input parameters		Value		
		Reaction 1 $H + C_2H_6$	Reaction 2 $H + CH_4$	Reaction 3 $CH_3 + C_2H_6$
Masses (a.m.u.)	A	1	1	15

almost certainly fortuitous, but the comparison indicates that these approximations are unlikely to introduce any serious error even at low temperatures.

Potential Energy of Activation

We have used the formulation of Johnston and Parr (3), in which the changes in potential energy due to the breaking of one bond and the formation of another are calculated as the sum of three terms. Two of these terms use an empirical relationship between bond order and bond dissociation energy to calculate the interactions A...B and B...C; we consider these terms to remain valid when complicated reagent molecules are involved. The third term is the triplet repulsion between center A and center C. (In each case, when calculating D_e from D_0^0, we included the zero point energies of those molecular vibrations which change when the model molecule is transformed to the complex. The relevant parameters of the model molecules are given in Table 1.) In the simple three-atom case, the triplet repulsion term is calculated from the dissociation energy D_{CA} of the diatomic molecule CA. When complicated reagents are used, it becomes uncertain what is the appropriate dissociation energy to use. Therefore we have explored the use of D_{CA} as a variable parameter, choosing it to give a good fit to the experimental rate coefficient at about 550 °K. Below 500 °K there is an increasing uncertainty

in the tunnelling factor and other quantum corrections.

Starting with D_{CA} equal to the model bond dissociation energy CH_3—CH_3 for reactions 1 and 3, and CH_3—H for reaction 2, we found that satisfactory results were obtained for reaction 2. However for reactions 1 and 3 D_{CA} needed to be increased by about 10%. The upper short lines in Figs. 1 and 3 show the rate coefficients calculated when D_{CA} was set equal to the bond dissociation energy as defined above. The lower long solid curves show the rate coefficients obtained when D_{CA} was increased. Note, incidentally, that the general shapes and curvatures of these lines are independent of moderate variations in D_{CA}.

Tunnelling Corrections

Tunnelling corrections Γ_{RC} were evaluated for Eckart potentials with the calculated potential energy of activation V and reaction frequency ω_{RC} of the effective mass of the model (1*b*, 1*e*, 1*f*). We found it convenient to read Γ_{RC} from smooth curves drawn through a plot of $\log_{10}\Gamma_{RC}$ against u_{RC} $(=h\nu_{RC}/kT)$ for various values of α_1 and α_2. Here $\alpha = V/h\nu$; α_1 uses V measured relative to the potential energy minimum of the reactants, and α_2 uses V measured relative to the potential minimum of the products. The data were taken from Table 2.2 of ref. 1.

The shape and height of the calculated activation barrier can be significantly influenced by the value assumed for D_{CA}. We have therefore investigated the possibility that our calculated values of Γ_{RC} might be sensitive to the exact choice of D_{CA}. However we find that for these reactions the 10% increase in D_{CA} alters Γ_{RC} by less than 50% at 300 °K and by smaller amounts at higher temperatures. We believe therefore that our procedure for evaluating the Eckart tunnelling correction is not very seriously in error over most of the temperature range. We are however concerned both about the possibilities of appreciable errors in the calculation of Γ_{RC} near 300 °K and about possible defects in the one-dimensional Eckart tunnelling correction itself at low temperatures. Calculated values of Γ_{RC} for reactions 1, 2, and 3 are 5.6, 3.7, and 3.9 at 400 °K, and as large as 28, 11, and 12.2 at 300 °K.

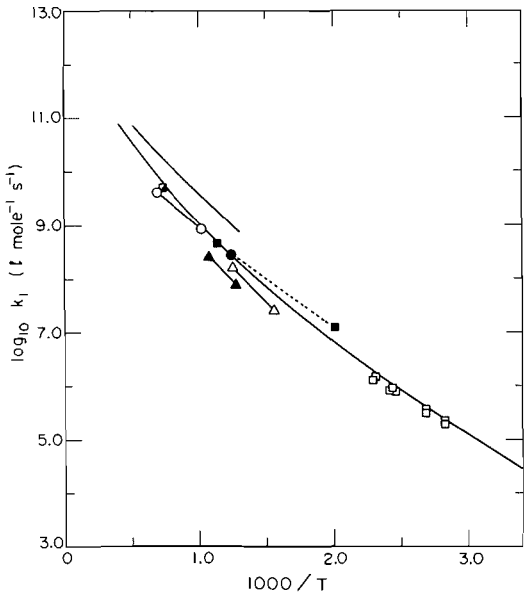

FIG. 1. Temperature dependence of reaction 1, H + $C_2H_6 \rightarrow H_2 + C_2H_5$. Upper solid curve: calculation with D_{CA} equal to bond dissociation energy. FIG. 3. Temperature dependence of reaction 3, $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$. Upper solid curve: calculation with D_{CA} equal to bond dissociation energy. Lower solid curve: calculation with D_{CA} increased by ~10%. Dashed line: calculated data of ref. 2. Experimental data points; ● ref. 9,20, ▲ref. 16, △ ref. 18, ■ ref. 19, ○ ref. 21.

them, rate coefficients were calculated at 300, 400, 650, 750, 900, 1100, 1350, 1500, 1800 °K, and curves drawn through the points. Experimental data from the literature are also shown. Where possible, data points derived from individual experiments are plotted. However, in some cases (noted in the captions) only two points are shown for an experimental study; these data points were calculated at the lower and upper temperature limits of the study, using the published rate parameters.

H + C_2H_6

Figure 1 is an Arrhenius plot showing a set of calculated coefficients and sets of experimental values. The calculated curve falls within the experimental values in absolute magnitude and gives a reasonable activation energy. The Russian workers (5,6) report values from explosion limits lower than those obtained by more direct methods. Although the set of calculated coefficients is a curve, it should be noted that it approximates well to a straight line between 400 and 850 °K. Serious deviations from this line occur only when data from outside this temperature region are added. Similar curved Arrhenius plots can be seen in the paper by Johnston and Parr (3) for related reactions. It is interesting to note that the curve agrees well with the data of Berlie and Le Roy (8), and with the recent data of Dove and Wagner (15) obtained using e.s.r. detection of H-atoms in a flow system. Agreement is satisfactory with the higher temperature data of Fenimore and Jones (7), and Clark and Izod (20).

To find an analytic form to describe the temperature dependence, the set of coefficients was fitted by the method of least squares to the function:

$$k = AT^n \exp(-E_a/RT)$$

where n was varied in steps of 0.5 between 0.0 and 5.0. The standard deviations in A and E_a were found to be smallest when $n = 3.5$. This empirical power of n is larger by +2.0 than the power expected from simple classical transition state theory.

If a least squares Arrhenius line were fitted to experimental data, or to the theoretical rate coefficients, in the region 400–850 °K, extrapolation to higher temperatures would underestimate the rate coefficients by a factor of about 2 at 1500 °K, and of 3 at 1800 °K. In this case, the size of these errors is close to the scatter in the available experimental rate data, but the difference is nevertheless of the same order at 1350 °K as the increase in k_1 suggested by Clark *et al.* (9) for this temperature.

From the least squares fit, we conclude that our calculated values for k_1 are best described by the expression:

$$k_1 = 10^{-0.27\pm0.03} T^{3.5} \exp(-5200 \pm 70/RT) \quad l\ mol^{-1}\ s^{-1}$$

H + CH_4

Figure 2 shows the calculated rate coefficients and the experimental data (5, 10–14, 20) on an Arrhenius plot. The calculated coefficients are in very good agreement with the experimental data of Kurylo and Timmons (10) which were obtained using a discharge flow system with e.s.r. detection. Note that the data of Majury and Steacie (12) were actually obtained for the reaction −2 and have been converted to values for reaction 2 using the thermodynamic equilibrium constant. Any uncertainties in the equilibrium constant will therefore be reflected in the derived values of k_2. Also, the data of Klein and co-workers (14) are for the reactions of D

with CH_4. Again a straight line well describes the temperature dependence between 350 and 800 °K despite tunnelling and quantum effects at these lower temperatures. Deviations from such a line occur above 1000 °K where the rate coefficients are approaching a classical description.

On fitting the theoretical data to the form

$$k_2 = AT^n \exp(-E_a/RT)$$

in the same way as for reaction 1, the best fit was found when $n = 3.0$:

$$k_2 = 10^{1.35\pm0.02}T^{3.0} \exp(-8750 \pm 40/RT) \quad \text{l mol}^{-1}\ \text{s}^{-1}$$

The predicted rate coefficient at 1500 °K is about 2.0 times the value obtained by Arrhenius extrapolation of data below 800 °K.

$CH_3 + C_2H_6$

Figure 3 shows rate coefficients from McNesby (16), Wijnen (18), Trotman-Dickenson *et al.* (19), Pacey and Purnell (21), and the high temperature data of Clark and Izod (20). Relative rate data from refs. 16, 18, and 19 yielded values of k_3 by combination with other rate expressions (22–24). The solid curve calculated by the B.E.B.O. method with slightly increased D_{CA} provides a partial reconciliation of high and low temperature data. The calculated coefficients are in excellent agreement with experimental values near 500 °K and near 1000 °K. Our calculations indicate that the simple Arrhenius extrapolation of rate data for the range 400 to 900 °K will predict a rate coefficient too low by a factor of 4 at 1500 °K. Thus for free radical abstraction reactions of this kind, quite substantial errors can be introduced if a linear Arrhenius extrapolation of low temperature data is made. In fact, the values of k_3 calculated using our model are still about a factor of 3 smaller than the high temperature data of Clark and Izod, so that the experimental Arrhenius plot appears to have even more curvature than we have calculated.

Using the same least squares procedure as used for reactions 1 and 2, the best form for describing the calculated coefficients was found to be

$$k_3 = 10^{-3.26\pm0.01}T^{4.0} \exp(-8280 \pm 30/RT) \quad \text{l mol}^{-1}\ \text{s}^{-1}$$

The exponent n was 4.0, which is greater by 1.5 than the classical value for a linear reaction complex.

Contributions to the Temperature Dependence

The B.E.B.O. formulation of transition state theory does not give a simple analytic functional description of the temperature dependence but it does allow various contributions to be examined. The rate coefficient can be written as

$$k = \gamma T^x \Gamma_{RC} \prod^i \Gamma_i \exp(-V/RT)$$

where $T^{1/2}$ comes from each classical vibrational amplitude so that $x = 5/2$ for reaction 3, $x = 3/2$ for reactions 1 and 2; Γ_{RC} is the tunnelling correction; $\prod^i \Gamma_i$ is the appropriate product of quantum corrections, one for each vibrational frequency involved in reactants and complex, γ is a temperature-independent parameter. Using the standard definition of an Arrhenius activation energy, $E_a = -R\mathrm{d}(\ln k)/\mathrm{d}(1/T)$ the variation of E_a about V can be expressed as:

$$E_a - V = xRT - R\mathrm{d}(\ln \Gamma_{RC})/\mathrm{d}(1/T) - R\,\mathrm{d}(\ln \prod^i \Gamma_i)/\mathrm{d}(1/T)$$

Figure 4 shows the calculated values of $(E_a - V)$, and the individual contributions to $(E_a - V)$, plotted against $1/T$ for reaction 1. Curve I includes all contributions, curve II omits the contribution from the Eckart tunnelling correction. Incidentally, if the Wigner tunnelling correction formula (1*b*) is used, $(E_a - V)$ is found to be between the solid and heavy dashed curves in Fig. 4. Below about 900 °K, the variation of E_a with $1/T$ is relatively slow, and in our calculations this variation is dominated by the Eckart tunnelling factor. The contributions to $(E_a - V)$ from T^x and Γ_i nearly cancel below 900 °K, so that in this temperature range the vibrations make only a small negative contribution to the temperature dependence.

Below 1000 °K, the calculated values of E_a do not vary rapidly with $1/T$, but the variation is still sufficiently large that it should be experimentally detectable. The available experimental data give some support for this prediction of the calculations. For reaction 1, the data of Berlie and Le Roy (8) at 300–600 °K indicate a lower activation energy than data over the range 500–1100 °K, as can be seen from Fig. 1. For reaction 3 there is stronger evidence of low temperature curvature, as shown by the data (16, 18, 19) in Fig. 3.

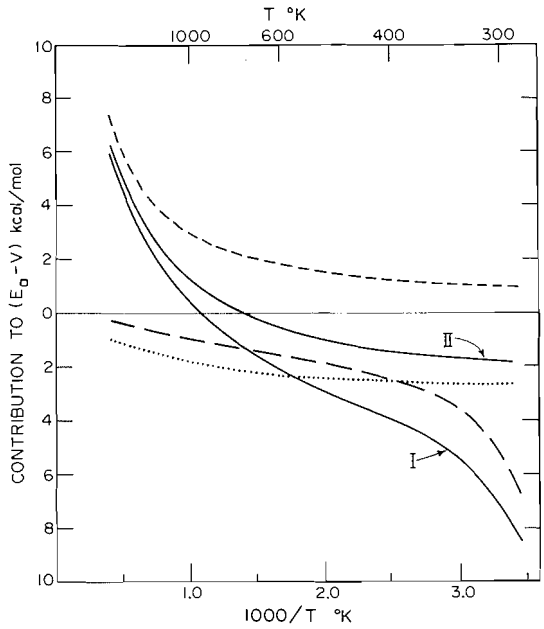

FIG. 4. Temperature dependence of the calculated activation energy for reaction 1: Solid curve I variation of $(E_a - V)$, Solid curve II variation of $(E_a - V)$ without the Eckart tunnelling contribution, – – – Eckart tunnelling contribution, · · · contribution from quantum corrections on stable vibrations, --- contribution from classical $T^{3/2}$ temperature dependence of pre-exponential factor.

The most notable feature of Fig. 4 is the continuing increase in $(E_a - V)$ above 1000 °K. It is this increase which is reflected in the high temperature curvature of the calculated lines in Figs. 1–3. This curvature is due mainly to the T^x term in the expression for k, and is little affected by the tunnelling factor. The other reactions show the same general behavior as depicted in Fig. 4, and the high temperature curvature is even greater in the case of reaction 3 for which $x = 5/2$.

Conclusions

We have shown that the simplified B.E.B.O. method can be used to describe the temperature dependence of rate coefficients for several H-transfer reactions involving complicated reagents over a wide temperature range. The Arrhenius plot of the calculated rate coefficients is continuously curved, but for the temperature range 400–900 °K the predicted curvature is not particularly obvious. However the calculated Arrhenius activation energy increases rapidly with temperature above 1000 °K, especially where the reaction involves abstraction by a radical.

The Rate Coefficient for $CH_3 + H_2 \rightarrow CH_4 + H$ Measured in Reflected Shock Waves; A Non-Arrhenius Reaction

THOMAS C. CLARK AND JOHN E. DOVE

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received August 29, 1972

Dynamic sampling of reacting gas mixtures behind reflected shock waves has been used to determine the concentration *vs.* time profiles of the products of the recombination chain reactions of methyl radicals in the presence of molecular H_2. The radicals were produced by the rapid pyrolysis of azomethane. By analysis of profiles from experiments in the temperature range 1272–1370 °K we have deduced a value of the rate coefficient of reaction 5: $CH_3 + H_2 \rightarrow CH_4 + H$.

$$k_5 = 4.6 \pm 1.4 \times 10^7 \text{ l mol}^{-1} \text{ s}^{-1} \text{ at } 1340 \text{ °K}$$

It is shown that although this value of k_5 does not lie on the Arrhenius line drawn through lower temperature data, it does lie close to the upward curved Arrhenius plot of values of k_5 calculated by the B.E.B.O. transition state method. Taking a mean activation energy calculated by the B.E.B.O. method, our results suggest the following description for k_5 over the temperature range 1200 to 2000 °K:

$$k_5 = 10^{10.19 \pm 0.30} \exp(-15\,500/RT) \text{ l mol}^{-1} \text{ s}^{-1}$$

Un échantillon dynamique de mélanges gazeux en réaction derrière des chocs d'onde en réflexion a été utilisé pour déterminer les profils de concentration par rapport au temps, des produits de réaction de recombinaison de chaînes des radicaux méthyles en présence de H_2 moléculaire. Les radicaux ont été produits par la pyrolyse rapide de l'azométhane. Par analyse des profils issus des expériences dans l'intervalle de température 1272–1370 °K, nous avons déduit une valeur du coefficient de vitesse pour la réaction 5: $CH_3 + H_2 \rightarrow CH_4 + H$.

$$k_5 = 4.6 \pm 1.4 \times 10^7 \text{ l mol}^{-1} \text{ s}^{-1} \text{ à } 1340 \text{ °K}$$

Bien que cette valeur de k_5 ne se situe pas sur la droite d'Arrhenius obtenue à partir des données correspondants aux plus basses températures, nous avons montré que celle ci est proche du graphique d'Arrhenius courbé en montant et tirée des valeurs de k_5 calculées par la méthode B.E.B.O. sur l'état de transition. En prenant une énergie d'activation moyenne calculée par la méthode B.E.B.O., nos résultats suggèrent la description suivante pour k_5 dans l'intervalle de température de 1200 à 2000 °K:

$$k_5 = 10^{10.19 \pm 0.30} \exp(-15\,500/RT) \text{ l mol}^{-1} \text{ s}^{-1}$$

Introduction

The methyl radical has been shown (1–4) to play an important part in the high temperature chain decomposition of several gaseous hydrocarbons such as methane, ethane, and butane. A knowledge of the reactions of CH_3 is therefore essential to an understanding of these decomposition processes. In recent studies (4, 5), a shock tube coupled to a time-of-flight mass spectrometer has been used to study the high temperature reactions of methyl radicals generated by the rapid pyrolysis of azomethane or dimethyl mercury. The rate of combination of methyl radicals, and the rate of their reaction with ethane, $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$. have been studied in this way. In the present work we have used the same experimental techniques to, determine the rate of reaction of methyl radicals with hydrogen,

[5] $$CH_3 + H_2 \rightarrow CH_4 + H$$

at high temperatures (1272–1370 °K) by pyrolyzing azomethane in the presence of added molecular hydrogen.

The rate coefficient for reaction 5 has been measured at low temperatures by various workers (6–11) whose results are not in very satisfactory agreement. The data of Majury and Steacie for $400 \leqslant T \leqslant 570$ °K are generally accepted as reliable (10–12), although there seems to be no clear reason to reject the data of Davison and Burton (7) or Anderson and Taylor (8). However all of the determinations of the rate coefficient for reaction 5 have been made at temperatures below 600 °K, and there is only one estimate (9) of k_5 above 600 °K. The coefficient for the reverse reaction −5, although more extensively studied (13–16), has been determined reliably only below 800 °K. Since recent calcula-

tions (17) have shown that the extrapolation of low temperature data by means of an Arrhenius plot can give a low estimate of a rate coefficient at higher temperatures, we considered it important to determine k_5 at temperatures nearer to those encountered in the pyrolyses of hydrocarbons.

Experimental

The apparatus has been described in detail previously (18). Reacting gas was directly sampled from behind reflected shock waves through a 0.1 mm orifice into the rapidly pumped ion source of a time-of-flight mass spectrometer. Mass spectra were photographically recorded at 20 μs intervals over the 300 to 400 μs duration of an experiment. Shock waves were produced using He or He/N_2 driver gas and 5 Torr initial pressure of reactant mixture containing 0.2 to 2% reagent diluted by neon. The heights of the mass peaks of each species were measured relative to the *m/e* 40 peak of a small known amount of argon included in the mixture as a reference gas. By utilizing the known mass spectrometric sensitivities relative to Ar, as determined in experiments with mixtures of known composition, absolute concentrations could be calculated. This procedure has been described elsewhere (4, 19). An electron energy of 25.0 eV was used in the ion source. Most of the other experimental details including the origin and purification of reagents were exactly as described previously (4). The hydrogen used in this work was Matheson "ultra high purity" grade (99.999%) and was used without further purification.

We performed two sets of experiments. The first repeated as closely as possible previous experiments (4) on azomethane pyrolysis, which were carried out in very similar apparatus, and acted as a standard. A mixture containing 0.16% azomethane, 0.26% argon, and 99.58% neon was used. The second mixture contained 1.87% added molecular hydrogen, 0.16% azomethane, 0.21% argon, and 97.76% neon. The amount of hydrogen added was the minimum which would give measurable changes in the reaction product concentrations. In order to obtain more reliable concentration–time profiles for the reaction products from the somewhat scattered data, the technique of grouping experiments (4, 19) was used. The results of two or three experiments at closely similar temperatures were combined, and the data were averaged. The temperature range of the experiments was restricted to approximately 1250 to 1400 °K. Below 1250° K the dissociation of azomethane was inconveniently slow, whereas above 1400 °K interpretation of the results was made more difficult by redissociation of the product ethane and by the further reaction of ethylene product to form acetylene.

Results

Figure 1 shows the time dependence of the concentrations of ethane, methane, and ethylene determined at 1325, 1340, and 1370 °K, as described above. The contours represent estimated uncertainty limits on the concentrations. We show the results of standard experiments and experiments performed with added hydrogen at the same mean temperatures. As can be seen, the principal effect of adding molecular hydrogen is to cause a significant increase in the amount of methane formed. Methane shows a principal mass peak at *m/e* 16 which is larger, for equal concentrations, than the ethane peak at *m/e* 30 or the fragment peak at *m/e* 26 used to determine ethylene. Thus relatively low concentrations of methane can be determined. Ethylene is difficult to determine since the most useful peak at *m/e* 26 requires correction for the contribution from ethane fragmentation. The correction introduces some further scatter and uncertainty into the data. Thus, in interpreting our data, we have concentrated on explaining the changes in the methane product profiles.

At lower temperatures, the amount of CH_4 formed in the standard experiments was expected to be very small, so that experiments were made using the mixture with added H_2 only. Figure 2 shows the results of these experiments at 1270 and 1311 °K.

Interpretation

The chain mechanism used previously (4) to explain the combination of methyl radicals and the effect of added ethane is:

$$[1] \qquad CH_3 + CH_3 \xrightarrow{(M)} C_2H_6$$

$$[2] \qquad CH_3 + C_2H_6 \rightarrow C_2H_5 + CH_4$$

$$[3] \qquad C_2H_5 \xrightarrow{(M)} C_2H_4 + H$$

$$[4] \qquad H + C_2H_6 \rightarrow C_2H_5 + H_2$$

In the previous work (4) the effect of added ethane was to produce larger, much more easily measured, concentrations of methane and ethylene, and k_1, k_2, and k_4 were determined. In the presence of added molecular hydrogen, the reaction

$$[5] \qquad CH_3 + H_2 \rightarrow CH_4 + H$$

is expected to become important. We have interpreted our present data in terms of reactions 1 to 5. The reaction rate equations for this mechanism were numerically integrated, using values of k_1, k_2, and k_4 taken from refs. 4 and 19, and choosing k_5 to fit the methane profiles in the later part of the reaction time. Several of the reverse reactions also had to be taken into account; in each case the rate coefficient of the reverse reaction was

calculated from the forward rate coefficient and the equilibrium constant from ref. 20.

Calculated and experimental profiles are compared in Figs. 1 and 2. The observed methane behavior was well described when $k_5 = 4.6 \times 10^7$ l mol^{-1} s^{-1} at 1340 °K. The small changes in the ethane profiles that occur when H_2 is added were also described. The temperature range of our studies was too small to allow a determination of the energy of activation. However the activation energy could be estimated as 15.5 kcal mol^{-1} from the known endothermicity of the reaction and a calculated activation energy for the reverse reaction (17). With the assumption of this activation energy, the rate coefficient can be expressed as $k_5 = 10^{10.19} \exp(-15\,500/RT)$ l mol^{-1} s^{-1}.

The effects of possible small errors in the value of the equilibrium constant K_5 were investigated, and it was found that changing k_{-5} by a factor of 2 did not affect our conclusions about k_5. In view of the difficulty of measuring ethylene accurately, we have not placed great emphasis on fitting the ethylene profiles. In the absence of added H_2, the calculations tend to underestimate the observed ethylene concentrations, and this has been commented on previously (4). With added

For personal use only.

hydrogen, the ethylene profiles are fitted satisfactorily at 1272, 1312, and 1325 °K. However at 1340 and 1370 °K, the calculations overestimate the ethylene concentration. Although we do not consider this discrepancy serious, we have considered several other elementary reactions which might affect the observed profiles.

The reverse reaction −4 might be expected to reduce the formation of ethylene. However, we have calculated k_{-4} by the B.E.B.O. method (17); even when k_{-4} is increased to 10 times the calculated value, the effects of reaction −4 are negligible. The reaction −4 could become important if the concentration of C_2H_5 were large. Reduction of k_3 would tend to increase $[C_2H_5]$. However k_3 would need to be reduced by a factor of at least 50. The value of k_3 used in our calculations was calculated for the appropriate conditions of temperature and pressure using R.R.K.M. theory and models based on the work of Lin and Laidler (21) and Setser and Rabinovitch (22). Both models gave $k_3 \sim 3 \times 10^6$ s^{-1} at 150 Torr and 1350 °K. We feel that it is improbable that this value is in error by as much as a factor of 10.

We also considered reaction

$$[6] \qquad CH_3 + H \xrightarrow{(M)} CH_4$$

which might affect the yield of methane. We estimated the rate coefficient for this reaction from the thermodynamic equilibrium constant and a calculated value of the rate coefficient k_{-6} for the reverse reaction. We calculated k_{-6} for our experimental temperature and pressure by the R.R.K.M. theory using the model of Setser and Rabinovitch (22). The value of k_6 required to affect the methane formation significantly is 5×10^{10} l mol^{-1} s^{-1}, whereas our calculated value was 2.5×10^9 l mol^{-1} s^{-1}.

These various calculations show that the concentration changes observed when molecular hydrogen is added to the combining methyl radicals are best described by including reaction 5 with a rate coefficient $k_5 = 4.6 \times 10^7$ l mol^{-1} s^{-1} at 1340 °K. Our experimental results are also adequately described by values of k_5 within the range ±30% of this value. However additional uncertainties are introduced by possible errors in the values of the other rate coefficients used in our calculations. Taking these into account, we feel that k_5 is determined within a factor of 2.

Discussion

The lower limit for our value of k_5 determined at 1340 °K is 2.3×10^7 l mol^{-1} s^{-1}. As can readily be seen from Fig. 3, even this lowest value for k_5 is significantly higher than would be given by a straight-line Arrhenius extrapolation of the low temperature direct measurements (11, 15) of k_5. It should be noted that the rate coefficient of reaction 2 reported (4, 19) at 1350 °K was also significantly larger than predicted from low temperature data. In a recent paper (17) we have pointed out that there are theoretical reasons to expect appreciable non-linearity of Arrhenius plots for free radical abstraction reactions; this non-linearity becomes most noticeable when measurements are extended into the temperature range of shock tube studies. The long solid curve in Fig. 3 shows the temperature dependence of k_5 calculated by the B.E.B.O. method as described previously (17); the parameters used in the calculation were those employed for our earlier calculation (17) of k_{-5}, the rate coefficient for the back reaction. Our calculated curve has the same

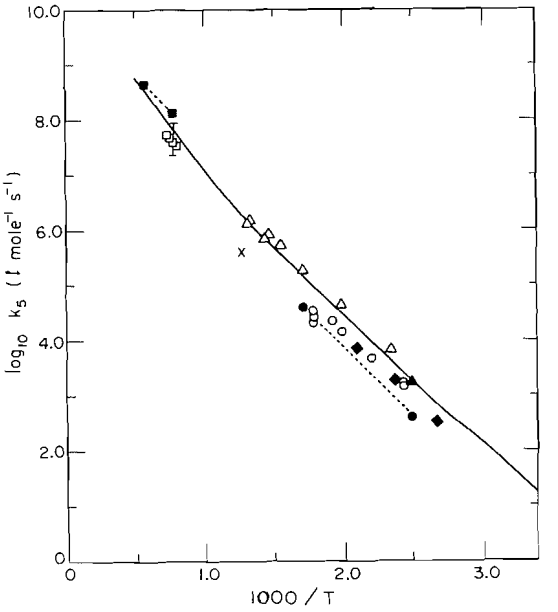

FIG. 3. Arrhenius plot for k_5. Solid curve: B.E.B.O. calculation, this work; ▲, calculated point (24); ○, experimental data (15); ●, upper and lower temperature points of rate parameters (7); ×, experimental data point (9); △, calculated from experimental k_{-5} (13) and thermodynamic equilibrium constant (20); ■, calculated from experimental k_{-5} (14) and thermodynamic equilibrium constant; □, experimental data, this work; ◆, experimental data (11).

form as an earlier calculation by Johnston (23), and agrees well with a point calculated by Polanyi (24) who used a method based on a L.E.P.S. surface. It can be added that our calculated k_5 and k_{-5} closely reproduce the thermodynamic equilibrium constant (20). As shown in Fig. 3, and as expected from our previous paper (17), our calculated values of k_5 also agree well with those deduced by multiplying the equilibrium constant K_5 by Kurylo and Timmons' (13) experimental values of k_{-5}.

Though the agreement among the various experimental data in Fig. 3 is fairly good, the values of k_5 obtained from data (13, 14) on the reverse reaction are systematically 2 to 3 times as large as the directly measured values of k_5. This discrepancy could very well arise from small errors in the experimental measurements. However another possibility which should be mentioned is that the thermodynamic equilibrium constant K_5 is somewhat too high. In this connection, we note that the current value (20) of K_5 (which we have used) is about 10 times larger at 600 °K than that obtained from data in the 1st edition of the JANAF tables, and that this increase is largely due to a change in the recommended ΔH_{f0}^{0} of CH_3 from +32.8 to +35.62 kcal mol^{-1}. If the heat of formation of CH_3 were taken as +34.4 kcal mol^{-1} (this change of 1.2 kcal mol^{-1} should, however, be compared with the currently quoted (20) JANAF uncertainty of ± 0.2 kcal mol^{-1}), the kinetic measurements of forward and reverse rates would agree with one another quite well. Such a change in the thermochemistry would, of course, also affect the calculated potential energy of activation and necessitate a slight revision of the B.E.B.O. calculations, but we find that none of our basic conclusions would be changed.

The above considerations about K_5 do not, in any case, appreciably influence the evaluation of our experimental k_5 at temperatures close to 1340 °K. Our experimental findings do thus support the Arrhenius curvature predicted by transition state calculations and underscore the need for determining rate coefficients at temperatures close to those at which they are to be applied. If we accept the activation energy calculated by the B.E.B.O. method (using current JANAF data) at 1500 °K, and our rate coefficient k_5 at 1340 °K, then the following expression would be expected to hold to within a factor of 2 for k_5 between 1200 and 2000 °K:

$$k_5 = 10^{10.19} \exp(-15\,500/RT)\ \text{l mol}^{-1}\ \text{s}^{-1}$$

Received April 24, 1972[3]

Several crystalline 1:1 adducts of quaternary alkyl ammonium salts with simple aromatic compounds have been prepared. Adduct formation appears to be restricted to certain salt–solvent pairs when the alkyl substituent is *n*-butyl or *i*-amyl, the anion is iodide, perchlorate, nitrate, or picrate and the aromatic compound is benzene, fluorobenzene, or toluene. The standard enthalpy and entropy changes of adduct formation at 25 °C have been obtained from vapor pressure measurements. A linear relationship between these thermodynamic parameters is expressed in the form of an isokinetic temperature. An absorption band at 14.4 μ appears to be characteristic of this series.

Plusieurs produits d'addition (1:1) cristallins ont été proposés à partir de sels d'ammonium quaternaire d'alcoyles et de composés aromatiques simples. La formation de ces produits semble être limitée à certaines paires, solvant-sel, lorsque le groupe alcoyle est le *n*-butyle ou l'*i*-amyle, lorsque l'anion est l'iodure, le perchlorate, le nitrate ou le picrate et aussi lorsque le groupe aromatique est le benzène, le fluorobenzène ou le toluène. Lors de la formation de ces produits à 25 °C, les variations d'enthalpie et d'entropie ont été obtenues à partir de mesures de la tension de vapeur. On exprime la relation linéaire présente entre ces paramètres thermodynamiques sous forme d'une température isocinétique. Une bande d'absorption à 14.4 μ semble être caractéristique de cette série de composés.

The formation of solid adducts in 1:1 mole ratio between benzene and tetra-*n*-butyl ammonium perchlorate (1), nitrate (2), and picrate (3) has been reported previously. The work reported here seeks to show that the phenomenon is quite general among a number of quaternary alkyl ammonium salts and simple aromatic compounds. Evidence for the extent of adduct formation has been sought through a systematic variation of cation alkyl substituents, anions, and organic compounds. Adduct formation has been found to occur between certain salt–solvent pairs where (*i*) the cation is $(n\text{-butyl})_4N^+$, $(i\text{-amyl})_4N^+$, or $(i\text{-amyl})_3(n\text{-butyl})N^+$; (*ii*) the anion is iodide, perchlorate, nitrate or picrate; and (*iii*) the organic compound is benzene, fluorobenzene, or toluene.

Experimental

Materials

The quaternary alkyl ammonium iodides were prepared in the usual manner from purified tertiary amines and alkyl iodides; nitrates were obtained by metathesis of the quaternary ammonium iodides with silver nitrate. The bromide and the perchlorate salts were prepared from the corresponding hydroxides by neutralization with hydrobromic and perchloric acids, respectively. All salts were purified by multiple recrystallizations and melting points served as an indication of purity: tetra-*n*-propylammonium nitrate (hereafter abbreviated Pr_4NNO_3), m.p. 268–269° (d), tetra-*n*-butyl ammonium iodide (Bu_4NI), m.p. 146°, tetra-*n*-butyl ammonium nitrate (Bu_4NNO_3), m.p. 120°, tetra-*n*-butyl ammonium perchlorate (Bu_4NClO_4), m.p. 210°, tetra-*n*-butyl ammonium bromide (Bu_4NBr), m.p. 117–118°, triisoamyl-*n*-butyl ammonium iodide ($i\text{-Am}_3BuNI$), m.p. 122°, triisoamyl-*n*-butyl ammonium perchlorate ($i\text{-Am}_3BuNClO_4$), m.p. 101–103°, tetraisoamyl ammonium iodide ($i\text{-Am}_4NI$), m.p. 148°, tetraisoamyl ammonium nitrate ($i\text{-Am}_4NNO_3$), m.p. 142°, tetraisoamyl ammonium perchlorate ($i\text{-Am}_4NClO_4$), m.p. 116–117°, and tetra-*n*-amyl ammonium nitrate ($n\text{-Am}_4NNO_3$), m.p. 98–100°.

Benzene, fluorobenzene, and toluene were either of spectrophotometric or reagent quality and were normally used without further purification. Cyclopentadiene was distilled at 50 °C from a mixture of cyclopentadiene and its dimer and stored at −25 °C.

[3]Revision received February 8, 1973.

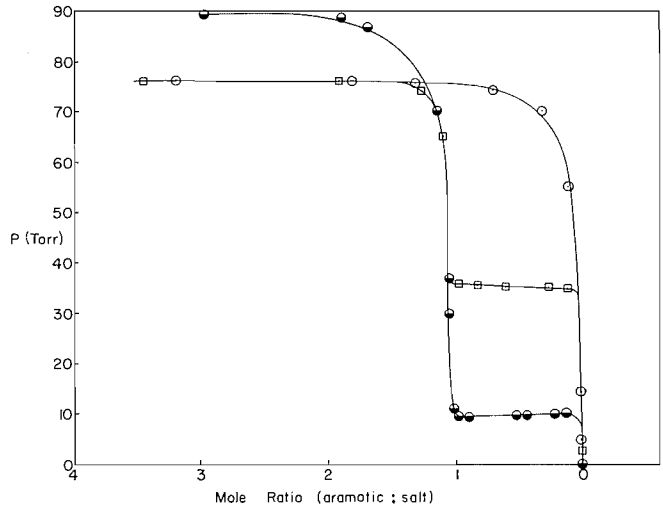

FIG. 1. Vapor pressure–composition curves indicating adduct formation for the systems in *i*-$Am_3BuNClO_4$–benzene ◒ and Bu_4NClO_4–fluorobenzene □. No adduct formation is observed for the system *i*-Am_4NNO_3–fluorobenzene ○.

Vapor pressure – composition curves were determined at 25 °C by means of relatively simple mercury manometer systems having removable sample flasks. Each flask contained initially approximately 1 g of salt per ml of solvent, such as would produce a molar excess of solvent. The flask was warmed in a water bath, evacuated, and the vapor pressure of the solvent was allowed to come to equilibrium over a period of up to several hours, and recorded. All mercury manometer readings were corrected to 0 °C. The flask was then removed from the apparatus, dried, capped, and weighed. Vapor pressure – composition curves were then constructed as shown in Fig. 1; a step-curve displaying a break at 1:1 mole salt–solvent ratio and similar to that previously illustrated (2), was taken as evidence of adduct formation. Vapor pressure – temperature measurements of the molecular adducts were obtained in the range 0–50 °C by submersion of the sample flasks in thermostatted water baths. The maximum expected error in pressure measurements is estimated at ± 0.5 mm. Phase diagrams were constructed in the usual manner from experiments in which appropriate known amounts of salt and solvent were sealed in heavy-walled glass tubing. The tubes were then attached to a shaker and immersed in an oil bath, the temperature of which was raised slowly until the last trace of solid had disappeared.

When adduct-forming salts were added to dry benzene and warmed, two liquid layers were observed. The salt content of the upper layer has been shown (1, 3) to be extremely low, being of the order of 10^{-2} *M*, while that of the lower layer was approximately 10–20 mol %. The two-layer system is often quite stable over a period of weeks.

U.v. absorption spectra of Bu_4NNO_3 and Bu_4NClO_4 with benzene in cyclohexane, with benzene in ethanol, and in pure benzene were determined using Unicam SP800 and Beckmann DB-G spectrophotometers. U.v. spectra of solid samples of Bu_4NNO_3 and the Bu_4NNO_3–C_6H_6 adduct were recorded on the SP800.

I.r. absorption spectra of mulls of Bu_4NNO_3, Bu_4NClO_4, *i*-Am_4NClO_4, *i*-$Am_3BuNClO_4$, *n*-Am_4NNO_3 in benzene, and Bu_4NNO_3 and *n*-Am_4NNO_3 in fluorobenzene were obtained using a Perkin–Elmer 621 grating spectrophotometer.

Results

In Table 1 are summarized the experimental results obtained from vapor pressure – composition studies of all quaternary ammonium salt – solvent pairs studied. For those systems in which adducts were found, the vapor pressure of the adduct is given in Torr at 25 °C.

Data from vapor pressure – temperature measurements of the adduct were treated by the least-mean-square method to obtain the slope *a*, and intercept *b*, from the data expressed in the form $\log P(\text{Torr}) = a/_T + b$. The values obtained for the parameters *a* and *b* for the adducts studied are shown in Table 2; they constitute a concise form of the experimental results obtained for the nine systems examined in detail. Calculated probable errors for the values of *a* are as given and for the values of *b* are ± 0.2.

Adduct formation from solid salt and liquid aromatic solvent may be represented as

[1] $$R_4NX_{(s)} + Ar_{(l)} \rightleftharpoons (R_4NX{-}Ar)_{(s)}$$

which may be regarded as the sum of

[2] $$Ar_{(l)} \rightleftharpoons Ar_{(v)}$$

and

[3] $$R_4NX_{(s)} + Ar_{(v)} \rightleftharpoons (R_4NX{-}Ar)_{(s)}$$

ΔG_1^0 values, at 25 °C, for reactions of type [1] were calculated directly from $\Delta G^0 = 2.303\ RT \log P_0/P$, where P_0 is the vapor pressure of the pure solvent, and P is that of the adduct. The values obtained are given in Table 2 and are summarized in Table 3. Literature values (4) for the temperature variation of vapor pressure of benzene, fluorobenzene, and toluene were used to calculate ΔH^0 for reactions of type [2], *i.e.* ΔH_2^0: the values obtained were 8170, 8160, and 8840 cal mol^{-1}, respectively. The experimental results for the temperature variation of adduct vapor pressure were used for the calculation of ΔH_3^0. The enthalpy of solid complex formation from solid salt and liquid solvent, ΔH_1^0 was then calculated as the sum of ΔH_2^0 and ΔH_3^0. The entropy of adduct formation, ΔS_1^0 was calculated from

§Reference 3.

[4] $$\Delta S_1^0 = (\Delta H_1^0 - \Delta G_1^0)/T$$

The values are shown in Table 2.

Phase diagrams were obtained for two salt–solvent adduct-forming pairs, *i*-Am_4NNO_3–C_6H_6 and *i*-Am_4NI–C_6H_6 and were very similar in general form to that noted previously for Bu_4NNO_3–C_6H_6 (2). Congruent melting points at approximately 1:1 mole ratio were measured as 76 °C for the *i*-Am_4NNO_3–C_6H_6 system and as 110 °C for the *i*-Am_4NI–C_6H_6 system. Both complexes showed evidence of being largely dissociated in the fused state.

Both solution and solid u.v. spectra of Bu_4NClO_4–C_6H_6 and Bu_4NNO_3–C_6H_6 displayed no significant changes in the character of component absorptions nor any new peaks in the range 195–700 mμ.

It had been reported earlier (2) that the "complex" Bu_4NNO_3–C_6H_6 displayed a new absorption peak at 14.4 μ; we have confirmed the existence of this peak in this "complex" and have found that it occurs in the "complex" forming systems Bu_4NClO_4–C_6H_6, *i*-Am_4NClO_4–C_6H_6, and *i*-$Am_3BuNClO_4$–C_6H_6, but is absent for a mixture of *n*-Am_4NNO_3 and C_6H_6 which has been found not to form an adduct. Preliminary work has indicated that fluorobenzene–salt system spectra follow the same pattern; no peak at 14.4 μ was observed in the case of non-adduct forming *n*-Am_4NNO_3–C_6H_5F mixture while one was observed in the case of an adduct forming Bu_4NNO_3–C_6H_5F mixture.

Discussion

There are three general classes of molecular complexes, *viz.* hydrogen-bonded, clathrate, and charge transfer. While no definite conclusions are drawn as to the nature of the interaction which leads to adduct formation, meaningful comparison with other work can be made and the trends of the data obtained are significant. The band at 14.4 μ which appeared in the i.r. spectra at each of the adducts is probably assignable to C—H out-of-plane bending of the aromatic species held in a crystal lattice, as previously suggested (2). No absorption band was observed in the spectra of solutions of adducts.

In a series of related reactions involving moderate changes in structure the enthalpies and entropies vary, but usually not independently. The relationship between ΔH and ΔS is shown in Fig. 2. The isokinetic temperature obtained from the slope of least squares is 325 °K. This linear change of ΔH with ΔS for a series of related equilibrium involving moderate changes in structure has been reported by several authors (7). The data of Keefer and Andrews (5) with substituted benzene–iodine complexes and those of Yada *et al.* (6) with aliphatic amine – iodine complexes yield isokinetic temperatures of 585 and 542 °K, respectively. The data for the benzene–iodine complex is shown in line with our data for benzene–alkyl quaternary ammonium complexes.

Some of the adducts of this series are quite strongly bonded as is seen from the magnitudes of the enthalpy changes. This tends to eliminate hydrogen bonding as the principal mode of interaction.

All of the adducts are formed in a strict 1:1 stoichiometric ratio and with a steady and reproducible vapor pressure. Such observations are not consistent with clathrate formation.

It is significant that no indication of charge transfer was observed in the u.v. absorption spectra, and the apparent lack of absorption is not readily attributable to the low resolving power or low sensitivity of the instruments used. However, absorption due to the adduct may be masked by the strong bands of benzene. There are many cases of complexes so described

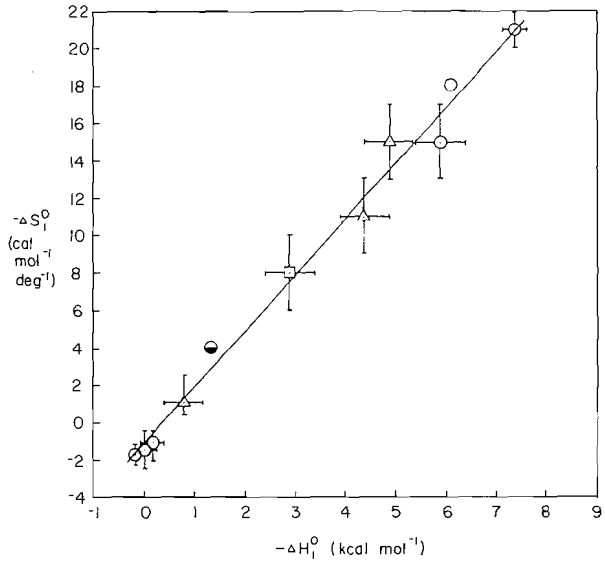

FIG. 2. Variations in ΔS_1^0 with ΔH_1^0 for adduct formation. ○ Benzene – quaternary alkyl ammonium salts (q.a.a.s.) adducts; △ fluorobenzene – q.a.a.s. adducts; □ toluene–q.a.a.s. adduct; ◒ benzene–iodine adduct (ref. 5).

(7) in which absorption due to supposed charge transfer has not been demonstrated. It should be noted that a weak band ($\varepsilon < 10$) near 300 mμ, due to absorption by NO_3^-, was observed for both solid salt and solid complex spectra. Benzene and substituted benzenes have been observed to form charge transfer complexes with I_2 (5), as have aliphatic primary, secondary, and tertiary amines (6), and it may not be unreasonable to suggest that substitution of I_2 by quaternary ammonium salts may lead to similar complex formation.

Total Synthesis of Eremophilane-type Sesquiterpenoids: (±)-Eremophilenolide, (±)-Tetrahydroligularenolide, and (±)-Aristolochene

EDWARD PIERS[1] AND MICHAEL BERT GERAGHTY

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received January 8, 1973

The total synthesis of the racemic forms of the eremophilane-type sesquiterpenoids eremophilenolide (**2**), tetrahydroligularenolide (**3**), and aristolochene (**4**) is described. The octalone **7** was converted via an efficient, regioselective route into the keto ester **12**, which served as a common synthetic intermediate for the preparation of the three sesquiterpenoids. Successive subjection of **12** to alkylation, hydrolysis, and decarboxylation afforded the keto acid **14**. Hydrogenation of the latter provided both the *cis*-fused keto acid **20**, which was readily converted into (±)-eremophilenolide (**2**), and the *trans*-fused keto acid **15**, which was similarly transformed into (±)-tetrahydroligularenolide (**3**). Conversion of **12** into the dithioketal **23**, followed by desulfurization and treatment of the resultant olefinic ester **25** with excess methyllithium, provided the olefinic alcohol **27**. Dehydration of the latter yielded (±)-aristolochene (**4**).

La synthèse totale des formes racémiques des sesquiterpénoïdes érémophilènolide (**2**) du type érémophilane, tétrahydroligularénolide (**3**) et l'aristolochène (**4**) est décrite. L'octalone **7** a été converti en passant par un chemin régiosélectif efficace en céto-ester **12**, qui sert d'intermédiaire synthétique commun pour la préparation de trois sesquiterpénoïdes. Lorsque l'on soumet **12** successivement à une alcoylation, à une hydrolyse et à une décarboxylation, l'on obtient alors un céto-acide **14**. L'hydrogénation de ce dernier produit conduit à la fois au céto-acide réuni de manière *cis* **20** qui a été transformé immédiatement en érémophilènolide-(±) (**2**) et au céto-acide réuni de manière *trans* **15** qui a été transformé, de la même façon, en tétrahydroligularenolide-(±) (**3**). La transformation de **12** en dithiocétal **23**, suivi par une désulfurisation et par le traitement de l'ester oléfinique résultant **25** avec du méthyllithium en excès, conduit à l'alcool oléfinique **27**. La déshydratation de ce dernier composé conduit à l'aristolochène-(±) (**4**).

The number of known, naturally occurring eremophilane-type[2] sesquiterpenoids has increased markedly over the past few years (1, 2). To date, approximately 70 different eremophilane-type natural products have been isolated and subjected to structural elucidation. On the other hand, in spite of considerable total effort on the part of a number of research groups, only a few of the structurally fairly-simple members of this class have yielded to total synthesis.[3] We report in this paper the total synthesis of (±)-eremophilenolide (**2**),[4] (±)-tetrahydroligularenolide (**3**), and (±)-aristolochene (**4**).

(+)-Eremophilenolide was isolated (20) from *Petasites officinalis* Moench. and was subsequently shown (21) to possess structure and absolute stereochemistry as depicted in **2**. This compound can be considered as the parent of a small number of eremophilane-type sesquiterpenoids possessing the α,β-unsaturated γ-lactone moiety. Although (−)-tetrahydroligularenolide (**3**) has not as yet been isolated from natural sources, it has been obtained in high yield by palladium-catalyzed hydrogenation of the naturally occurring (−)-ligularenolide (**5**) (22) (absolute configuration as shown). The hydrocarbon (−)-aristolochene, isolated from the roots of *Aristolochia indica*, has been shown (23) to possess structure and absolute configuration as depicted in **4**. This compound is a double bond isomer of the well-known sesquiterpene hydrocarbon (+)-valencene (**6**) (24, 25, 7*b*).

The preparation of the three sesquiterpenoids **2**, **3**, and **4** was accomplished via a common

[1]Fellow of the Alfred P. Sloan Foundation, 1970–1972.

[2]The parent carbon skeleton and the normally-employed numbering system for the eremophilane-type sesquiterpenoids are shown in formula **1**.

[3]To date, the following eremophilane-type and structurally closely related aristolane-type sesquiterpenoids have been totally synthesized: (±)-aristolone (3, 4), (±)-calarene (5), (±)-dehydrofukinone (6), (±)-eremoligenol (7), (±)-eremophil-3,11-diene (8), (±)-eremophilene (7), (±)-fukinone (9–11), (+)-hydroxyeremophilone (11*b*), (±)-ishwarane (12), (±)-*iso*-nootkatone (α-vetivone) (13, 14*a*), (−)-*iso*-nootkatone (α-vetivone) (14*b*), (±)-nootkatone (14*a*, 15, 16), (−)-nootkatone (14*b*), (±)-7-*epi*-nootkatone (14*a*, 17), (±)-tetrahydroeremophilone (18), (±)-valencene (7*b*), and (±)-valerianol (7*b*).

[4]For a preliminary communication, see ref. 19.

4 5 6

synthetic intermediate, the keto ester **12**. The latter was obtained from the octalone **7** (26) by means of the efficient and completely regioselective synthetic route outlined in Scheme 1. Conversion of **7** into the corresponding hydroxymethylene derivative **8** (9), followed by dehydrogenation of the latter with 2,3-dichloro-5,6-dicyanobenzoquinone (27) in dioxan, afforded in 93% overall yield the cross-conjugated keto aldehyde **9**. Oxidation of compound **9** with silver oxide (28) and esterification of the resultant carboxylic acid (**10**) with silver oxide and methyl iodide afforded the keto ester **11** in 85% overall yield. Reduction of **11** with sodium borohydride in pyridine (29) gave, in 86% yield, the crystalline β-keto ester **12**. An alternative, direct conversion of the octalone **7** into the keto ester **12** involving base-promoted condensation of the former with dimethyl carbonate was also considered. However, on the basis of literature precedent (30), it was felt that a reaction of this type would result in carbomethoxylation of **7** at C-1 as well as at the desired position (C-3). Indeed, this direction conversion was later attempted (11*b*) and the product, although claimed to be **12**, was not obtained crystalline and no criterion of purity was given.

Attempted alkylation of **12** with ethyl 2-bromopropionate under a variety of conditions failed. In each case, starting material was recovered in high yield. However, when the sodium enolate of compound **12** was allowed to react with methyl bromoacetate in hot benzene, the desired keto diester **13** was obtained in quantitative yield (see Scheme 1). As shown by the p.m.r. spectrum, this material consisted largely of one diastereomer, and, although the stereochemistry was not rigorously established, literature precedent (30) indicated that the newly alkylated center should possess the configuration shown in **13**. In any event, this point was not crucial, since the next step of the synthesis involved hydrolysis and decarboxylative removal of the tertiary carbomethoxy moiety.

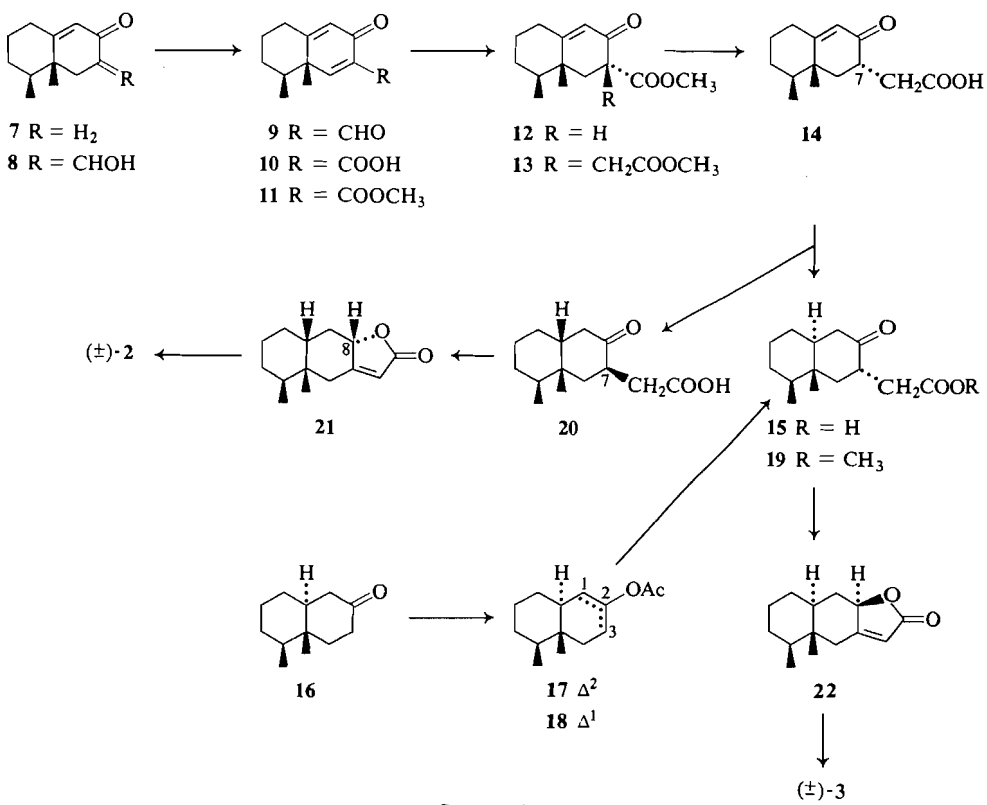
Treatment of the diester **13** with sodium hydroxide in refluxing ethanol–water provided the crystalline keto acid **14** in 82% yield. The stereochemistry of the latter was undoubtedly as indicated, since the epimeric (at C-7) compound would contain a 1,3-diaxial interaction between the angular methyl group and the acetic acid side chain.

In order to obtain (from **14**) a synthetic intermediate suitable for elaboration into (±)-tetrahydroligularenolide (**3**), it was necessary to reduce the carbon–carbon double bond of **14** so as to produce the corresponding *trans*-fused decalone system. On the other hand, reduction to a *cis*-fused decalone was necessary for the production of an intermediate suitable for conversion into (±)-eremophilenolide (**2**).

Hydrogenation of **14** in ethanol over palladium-on-charcoal produced a quantitative yield of the *trans*-fused keto acid **15**. That this hydrogenation had, in fact, afforded the *trans*-fused decalone system was shown conclusively by an independent synthesis of **15**. Thus, treatment of the known decalone **16** (26) with isopropenyl acetate-*p*-toluenesulfonic acid (31) afforded a mixture of the corresponding enol acetates **17** and **18**, in a ratio of approximately 3:2. Reaction of this mixture with 2 equiv of methyllithium in dimethoxyethane (31), followed by addition of methyl bromoacetate, gave a mixture of compounds from which the keto ester **19** could be isolated by column chromatography. Alkaline hydrolysis of **19** yielded the keto acid **15**, identical in all respects with the product obtained by hydrogenation of **14**.

Subjection of compound **14** to hydrogenation with palladium-on-charcoal under basic conditions (ethanolic sodium hydroxide) afforded a quantitative yield of a mixture of the *cis*-fused decalone **20** and the previously obtained *trans*-fused compound **15**, in a ratio of approximately 2:3. At this stage, considerable effort was expended in order to find conditions which would increase the proportion of the desired *cis*-fused decalone **20**. Eventually it was found that hydrogenation of **14** in ethanolic sodium hydroxide using rhodium-on-carbon as catalyst gave improved results. However, under these conditions the ketone carbonyl group was also reduced and it was therefore necessary to oxidize

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 1

the initially formed hydrogenation product. This was readily accomplished by means of ruthenium dioxide – sodium periodate in basic medium (32). There was thus obtained, in high yield, a mixture of **20** and **15** in a ratio of approximately 3:2. The two keto acids were obtained in pure form by careful fractional crystallization of this mixture from hexane–benzene. Since both the hydrogenation and oxidation reactions were carried out under basic, epimerizing conditions, the stereochemistry of the *cis*-fused keto acid should be as indicated in **20**. The latter, on the basis of conformational analysis, would be more stable than the corresponding epimeric (at C-7) compound.

Treatment of the *cis*-fused keto acid **20** with *p*-toluenesulfonic acid in refluxing toluene afforded, in 55% yield, crystalline (±)-11-demethyleremophilenolide (**21**). Since the latter is formed under equilibrating conditions, this compound would be expected to possess the stereochemistry shown in **21** (see ref. 21). This expectation was shown to be correct by the p.m.r. spectrum of the product. The proton at C-8 appeared as a poorly resolved, overlapped pair of doublets, with a width at half-height of 19 Hz, obviously indicating that this proton had an axial orientation. Alkylation (trityl sodium in ether–benzene) of **21** with methyl iodide gave, in 61% yield, racemic eremophilenolide (**2**), which exhibited i.r. and p.m.r. spectra identical with those of an authentic sample of natural (+)-eremophilenolide.[5] This represents the first total synthesis of an eremophilane-type sesquiterpenoid containing the α-methyl-α,β-unsaturated γ-lactone functionality.

Subjection of the *trans*-fused keto acid **15** to a sequence of reactions identical with that described above afforded successively (±)-11-demethyltetrahydroligularenolide (**22**) (94%) and (±)-tetrahydroligularenolide (**3**) (59%). Although an authentic sample of (−)-tetrahydroligularenolide was not obtained, the data

[5]We are very grateful to Professor V. Herout for a sample of (+)-eremophilenolide.

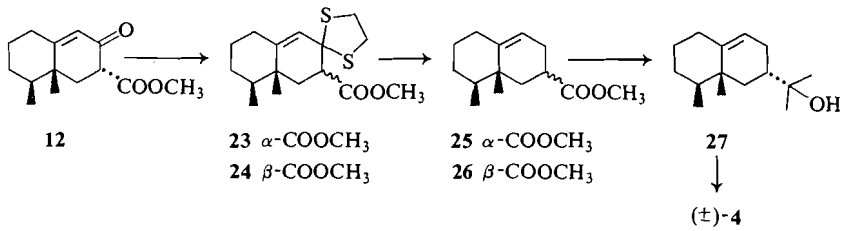

SCHEME 2

obtained from the i.r. and p.m.r. spectra of the synthetic racemate agreed very well with the published data (22).

The keto ester **12** also served as a synthetic intermediate for the preparation of (±)-aristolochene (**4**) (see Scheme 2). Treatment of the former with 1,2-ethanedithiol in acetic acid in the presence of boron trifluoride etherate afforded, in quantitative yield, an epimeric mixture of dithioketal esters **23** and **24**, in a ratio of approximately 4:1. The former could readily be isolated in pure form by fractional crystallization of the mixture from methanol. Desulfurization of **23** with Raney nickel in refluxing ethanol, followed by purification of the crude product by preparative g.l.c. gave the olefinic ester **25**, in 63% yield. Alternatively, desulfurization of a mixture of **23** and **24** (ratio 1:2) yielded a mixture of the olefinic esters **25** and **26** (ratio 1:2). Equilibration of the latter mixture with sodium methoxide in methanol, followed by purification of the resultant material (ratio of **25**:**26** = 9:1) by preparative g.l.c., also provided pure **25**.

When the olefinic ester **25** was allowed to react with an excess of methyllithium in refluxing ether, the olefinic alcohol **27** was obtained in 95% yield. Dehydration of the latter with thionyl chloride in pyridine at 0°, followed by purification of the crude product by column chromatography on silver nitrate-impregnated silica gel, gave (43% yield) pure racemic aristolochene (**4**). This material exhibited spectra (i.r. and p.m.r.) and g.l.c. retention times identical with those of authentic (−)-aristolochene.[6]

Experimental

Melting points and boiling points are uncorrected. The u.v. spectra were measured in methanol solution on a Unicam, model SP 800 spectrophotometer. Routine i.r. spectra were recorded on either a Perkin–Elmer model 137 or 710 spectrophotometer, while all comparison spectra were recorded on a Perkin–Elmer model 457 spectrophotometer. The p.m.r. spectra were taken in deuteriochloroform solution on Varian Associates spectrometers, models T-60, A-60, and/or HA-100. Signal positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. The g.l.c. was carried out on Aerograph g.l.c. units, models 700 or 90-P. A column (10 ft × 1/4 in.) packed with 20% Apiezon J on 60/80 mesh Chromosorb W was employed for all analyses. The column temperature and carrier gas (helium) flow-rate (ml/min) are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Preparation of Keto Aldehyde **9**

To a solution of 5.0 g (24.2 mmol) of the hydroxymethylene derivative **8** in 250 ml of dry dioxan was added a solution of 5.8 g (29.8 mmol) of 2,3-dichloro-5,6-dicyanobenzoquinone in 250 ml of dry dioxan. The reaction mixture was stirred under an atmosphere of nitrogen at room temperature for 10 min and then diluted with 1150 ml of dichloromethane. The resulting mixture was filtered and the filtrate was passed through a short column of neutral alumina. The alumina was eluted with an additional 500 ml of dichloromethane. Evaporation of the combined dichloromethane solution afforded 4.7 g (95%) of the crystalline keto aldehyde **9**. An analytical sample, obtained by recrystallization of the crude product from hexane, exhibited m.p. 64.5–66°; u.v. λ_{max} 245 mμ (ε 12 600); i.r. ($CHCl_3$) ν_{max} 1700, 1660, 1625, 1600 cm^{-1}; p.m.r. τ −0.33 (s, 1, —CHO), 2.17 (s, 1, β-vinyl H), 3.80 (broad s, 1, α-vinyl H), 8.76 (s, 3, tertiary methyl), 8.87 (unresolved m, 3, secondary methyl).[7]

[6]We are very grateful to Dr. T. R. Govindachari for a sample of (−)-aristolochene.

[7]In the p.m.r. spectrum of each of compounds **4**, **9**–**15** inclusive, **23**, **25**, and **27**, the signal due to the secondary methyl group appeared as a broad band, with very little resolution, while in compounds **3** and **22** this signal appeared as a poorly resolved doublet. Presumably this was, in each case, due to virtual coupling (see reference 33). In contrast, the secondary methyl group of compounds **2**, **20**, and **21** gave rise, in each case, to a clean, well-resolved doublet with the expected coupling constant (6–7 Hz). This observation was eventually used quite consistently to distinguish between those compounds of this series possessing a *trans* (or *trans*-like) ring fusion and those possessing a *cis* ring fusion.

Preparation of Keto Acid ***10***

To a stirred solution of silver nitrate (19.1 g, 0.112 mol) and the keto aldehyde **9** (11.0 g, 0.054 mol) in a mixture of ethanol (200 ml) and water (160 ml) was added dropwise, over a period of 1 h, a solution of sodium hydroxide (8.8 g, 0.22 mol) in water (300 ml). After the reaction mixture had been stirred for an additional 2 h, it was filtered through Celite. The filtrate was evaporated under reduced pressure to a small volume. The residue was diluted with water, washed once with ether, and acidified with 6 *N* hydrochloric acid. The resulting mixture was thoroughly extracted with ether. The combined extracts were washed with brine and then dried over anhydrous magnesium sulfate. Removal of the solvent gave 10.7 g (89%) of the crystalline keto acid **10**. An analytical sample was obtained by recrystallization from hexane–benzene and exhibited m.p. 105°; u.v. λ_{max} 253 mμ (ε 9740); i.r. ($CHCl_3$) ν_{max} 3600–2280 (broad), 1745, 1650, 1600 cm^{-1}; p.m.r. τ −3.55 (broad s, 1, —COOH), 1.57 (s, 1, β-vinyl H), 3.67 (broad s, 1, α-vinyl H), 8.72 (s, 3, tertiary methyl), 8.84 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32. Found: C, 70.88; H, 7.30.

Preparation of the Keto Ester ***11***

Silver oxide (18.5 g, 0.080 mol) was added to a solution of the keto acid **10** (8.8 g, 0.040 mol) in 240 ml of methanol. To the resultant mixture was added a solution of methyl iodide (11.3 g, 0.078 mol) in 160 ml of methanol. The reaction mixture was stirred at room temperature for 45 min, filtered, and the filtrate was evaporated under reduced pressure. The residue was dissolved in ether and the resulting solution was washed with aqueous sodium bicarbonate, with brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residue under reduced pressure afforded 9.0 g (96%) of the keto ester **11**, b.p. 147° at 0.1 mm; $n_D^{19.5}$ 1.5388; u.v. λ_{max} 245 mμ (ε 10 550); i.r. (film) ν_{max} 1740, 1720 (shoulder), 1660, 1640 (shoulder) cm^{-1}; p.m.r. τ 2.25 (s, 1, β-vinyl H), 3.85 (broad s, 1, α-vinyl H), 6.12 (s, 3, —$COOCH_3$), 8.79 (s, 3, tertiary methyl), 8.90 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74. Found: C, 71.53; H, 7.84.

Preparation of Keto Ester ***12***

To a solution of 7.02 g (0.03 mol) of the keto ester **11** in 45 ml of pyridine was added 1.13 g (0.03 mol) of powdered sodium borohydride. External cooling (ice-bath) was required initially to keep the temperature of the reaction mixture below 50°. After the solution had been stirred for 30 min, it was poured into rapidly stirring 2 *N* hydrochloric acid (360 ml). The resulting mixture was extracted thoroughly with ether. The combined extracts were washed with brine, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. Recrystallization of the residual crude crystalline material from hexane – ethyl acetate gave 5.35 g (76%) of pure keto ester **12**. Column chromatography (silica gel) of the material obtained from the mother liquors afforded an additional 0.7 g (10%) of the desired compound **12**. An analytical sample of keto ester **12** exhibited m.p. 108–108.5°; u.v. λ_{max} 240 mμ (ε 14 920); i.r. ($CHCl_3$) ν_{max} 1740, 1670, 1620 cm^{-1}; p.m.r. τ 4.31 (broad s, 1, vinyl H), 6.30 (s, 3, —$COOCH_3$), 6.57 (pair of doublets, 1, —CH—$COOCH_3$, J = 13.0, 6.0 Hz), 8.88 (s, 3, tertiary methyl), 9.08 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: C, 71.02; H, 8.64.

Preparation of the Keto Diester ***13***

To a solution of the keto ester **12** (5.29 g, 22.4 mmol) in dry benzene (180 ml), under an atmosphere of nitrogen, was added 1.04 g (24.6 mmol) of sodium hydride (56% in dispersion oil). When the evolution of hydrogen had ceased (approximately 20 min), 7.5 g (49.0 mmol) of methyl bromoacetate was added all at once. The reaction mixture was gradually heated to 80°, and then refluxed for 2.5 h. The cooled reaction mixture was poured into dilute hydrochloric acid, and the layers were separated. The aqueous layer was extracted further with ether. The combined benzene layer and ether extracts were washed twice with brine and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residual oil under reduced pressure gave a quantitative yield of the keto diester **13** as a viscous oil, b.p. 162–164° at 0.07 mm; u.v. λ_{max} 242 mμ (ε 13 760); i.r. (film) ν_{max} 1740, 1720 (shoulder), 1665, 1640 (shoulder) cm^{-1}; p.m.r. τ 4.22 (broad s, 1, vinyl H), 6.35, 6.41 (s, s, 6, methoxy methyls), 8.98 (s, 3, tertiary methyl), 9.12 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.84. Found: C, 66.29; H, 7.82.

Preparation of Keto Acid ***14***

The keto diester **13** (6.5 g, 21.1 mmol) was dissolved in 210 ml of 5:1 ethanol–water containing 30 g (0.75 mol) of sodium hydroxide and the resulting solution was refluxed under an atmosphere of nitrogen for 30 min. Most of the ethanol was removed under reduced pressure. The residue was diluted with water, washed once with ether, and then acidified with 6 *N* hydrochloric acid. The resulting mixture was extracted with ether, the combined extracts were washed with brine, and then dried over anhydrous magnesium sulfate. Removal of the ether gave 5.0 g of a viscous oil which crystallized on standing. Recrystallization from benzene–hexane gave 3.1 g of pure keto acid **14**. Distillation of the material obtained from the mother liquors (b.p. 190–205° (hot-box) at 0.2 mm), followed by recrystallization of the distillate afforded an additional 1.0 g of keto acid **14** (total yield 82%). An analytical sample exhibited m.p. 127.5–128°; u.v. λ_{max} 238 mμ (ε 14 750); i.r. ($CHCl_3$) ν_{max} 3600–2400 (broad), 1710, 1665, 1620 cm^{-1}; p.m.r. τ −1.30 (broad s, 1, —COOH), 4.28 (broad s, 1, vinyl H), 8.85 (s, 3, tertiary methyl), 9.10 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: C, 71.15; H, 8.47.

Preparation of the cis-Fused Keto Acid ***20*** *and the trans-Fused Keto Acid* ***15***

Hydrogenation of the keto acid **14** was carried out at atmospheric pressure and room temperature. A solution of **14** (118 mg, 0.5 mmol) in 3 ml of freshly prepared 0.2 *N* ethanolic sodium hydroxide containing 30 mg of 5% rhodium-on-carbon was hydrogenated until 2 equiv

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of hydrogen were taken up (approximately 5 h). The reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in distilled water (4 ml) and 6 mg of ruthenium dioxide was added. To the resulting stirred mixture was added, dropwise, a freshly prepared 5% solution of sodium periodate in distilled water, until the yellowish color of ruthenium tetroxide persisted. The reaction mixture was treated with a few drops of 2-propanol, and then filtered. The filtrate was acidified with dilute hydrochloric acid and then thoroughly extracted with ether. The combined ether extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 120 mg of crystalline material, which consisted of a mixture of the *cis*-fused keto acid **20** and the *trans*-fused keto acid **15**, in a ratio of approximately 3:2 (based on the p.m.r. spectrum). Both of the compounds could be obtained in pure form by repeated fractional crystallization of the mixture from varying proportions of hexane–benzene. Although the actual amount of each isomer isolated from the mixture varied somewhat from experiment to experiment, the less soluble compound (*trans*-fused keto acid **15**) was secured in approximately 30% yield, while the more soluble isomer (*cis*-fused keto acid **20**) was obtained in approximately 30–35% yield.

The *trans*-fused keto acid **15** exhibited m.p. 139–140°; i.r. ($CHCl_3$) ν_{max} 3600–2400 (broad), 1705 cm^{-1}; p.m.r. τ 0.04 (broad s, 1, —COOH), 9.00 (s, 3, tertiary methyl), 9.12 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.56; H, 9.30. Found: C, 70.80; H, 9.15.

The *cis*-fused keto acid **20** exhibited m.p. 114.5–115°; i.r. ($CHCl_3$) ν_{max} 3600–2400 (broad), 1708 cm^{-1}; p.m.r. τ −1.27 (broad s, 1, —COOH), 9.09 (s, 3, tertiary methyl), 9.12 (d, 3, secondary methyl, J = 7.0 Hz).

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.56; H, 9.30. Found: C, 70.42; H, 9.10.

(±)-11-Demethyleremophilenolide (21)

A solution of the keto acid **20** (50 mg, 0.21 mmol) in 12 ml of dry toluene containing 15 mg of *p*-toluenesulfonic acid was refluxed gently under a Dean–Stark water separator in a nitrogen atmosphere for 3 h. The cooled solution was washed with dilute aqueous sodium bicarbonate, with brine and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residue gave 45 mg of material which crystallized on standing. Recrystallization from hexane yielded 25.5 mg (55%) of the pure lactone **21**, m.p. 112–112.5°; u.v. λ_{max} 216 mμ (ε 14 830); i.r. ($CHCl_3$) ν_{max} 1780, 1745, 1650 cm^{-1}; p.m.r. τ 4.31 (unresolved m, 1, vinyl H, $w_{1/2}$ = 4.0 Hz), 5.26 (broad, unresolved m, 1, C_8H, $w_{1/2}$ = 19.0 Hz), 7.10 (d, 1, C_6H-equatorial, J = 14.0 Hz), 8.99 (s, 3, tertiary methyl), 9.23 (d, 3, secondary methyl, J = 6.0 Hz).

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15. Found: C, 76.30; H, 9.30.

(±)-Eremophilenolide (2)

To a stirred solution of (±)-11-demethyleremophilenolide (**21**) (68 mg, 0.31 mmol) in 3 ml of dry benzene under an atmosphere of nitrogen was added, dropwise, an ethereal solution of trityl sodium until the red color of the base persisted. After the resulting solution had been stirred at room temperature for 30 min, methyl iodide (142 μl, 2.28 mmol) was added all at once. The solution was stirred for 6 h, diluted with ether, washed with cold water, then brine, and dried over anhydrous magnesium sulfate. Removal of the solvents gave a crude product which was chromatographed over silica gel. Elution with hexane afforded triphenylmethane. Further elution with ether gave 73 mg of material which crystallized on standing. Recrystallization from ether gave 31 mg of pure (±)-eremophilenolide (**2**). Subjection of the material from the mother liquors to column chromatography on silica gel yielded an additional 13 mg of **2** (total yield 61%). An analytical sample of (±)-eremophilenolide (**2**) exhibited m.p. 110.5–111.5°; u.v. λ_{max} 220 mμ (ε 14 600); i.r. ($CHCl_3$) ν_{max} 1740, 1690 cm^{-1}; p.m.r. τ 5.37 (broad unresolved m, 1, C_8H, $w_{1/2}$ = 20.5 Hz), 7.11 (d, 1, C_6H-equatorial, J = 14.5 Hz), 8.21 (unresolved m, 3, vinyl methyl), 8.97 (s, 3, tertiary methyl), 9.20 (d, 3, secondary methyl, J = 6.0 Hz). The i.r. and p.m.r. spectra of this material were identical with those of an authentic sample of natural (+)-eremophilenolide.

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 76.58; H, 9.60.

Preparation of the trans-Fused Keto Acid 15

(a) By Hydrogenation of 14 Under Neutral Conditions

A solution of the keto acid **14** (21 mg, 0.089 mmol) in 2 ml of ethanol was hydrogenated at atmospheric pressure and room temperature over palladium-on-charcoal (11 mg) until uptake of hydrogen ceased. Filtration of the reaction mixture, followed by evaporation of the filtrate under reduced pressure afforded a quantitative yield of the *trans*-fused keto acid **15**, shown to be identical (m.p., i.r., and p.m.r. spectra) with the minor product obtained by hydrogenation of the keto acid **14** under basic conditions (*vide supra*).

(b) By Alkylation of the Decalone 16

A solution of the decalone **16** (180 mg, 1 mmol) in 25 ml of isopropenyl acetate containing 100 mg of *p*-toluenesulfonic acid was slowly heated under a Dean–Stark water separator. The acetone – isopropenyl acetate mixture was slowly distilled until the residual volume was about 4 ml. The cooled reaction mixture was poured into aqueous sodium bicarbonate and the resulting mixture was extracted thoroughly with ether. The combined ether extracts were washed with brine and dried over anhydrous magnesium sulfate. Removal of the ether, followed by distillation of the residual oil, afforded 220 mg of the mixture of enol acetates **17** and **18**, b.p. 80–90° (hot-box) at 0.1 mm, in a ratio of approximately 3:2. On the basis of the p.m.r. spectrum, the major compound was the Δ^2-isomer.

A solution of the mixture of enol acetates **17** and **18** in dry dimethoxyethane was added dropwise via a syringe to a stirred solution of methyllithium (2 mmol) in 1.5 ml of dimethoxyethane. To the resulting solution was added, all at once, 0.5 ml of methyl bromoacetate, stirring was continued for 1 min, and the reaction mixture was then poured into cold dilute hydrochloric acid. The resulting mixture was extracted with ether, and the combined ether extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvents gave 237 mg of crude material. Subjection of the latter to column chromatography on silica gel afforded the keto ester **19**, which, upon hydrolysis at room temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with potassium hydroxide in methanol, provided the crystalline keto acid **15**. The latter was shown to be identical (m.p., i.r., and p.m.r. spectra) with the keto acid **15** prepared as described above.

(±)-11-Demethyltetrahydroligularenolide (22)

A solution of the *trans*-fused keto acid **15** (44 mg, 0.19 mmol) in 12 ml of dry toluene containing 15 mg of *p*-toluenesulfonic acid was refluxed gently for 3 h in an atmosphere of nitrogen under a Dean–Stark water separator. The cooled solution was washed with cold, dilute aqueous sodium bicarbonate, with brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent and distillation of the residual material afforded 38 mg (94%) of (±)-11-demethyltetrahydroligularenolide (**22**), m.p. 94–95°. An analytical sample, obtained by recrystallization of this material from hexane, exhibited m.p. 98–99°; u.v. λ_{max} 216 mμ (ε 14 870); i.r. ($CHCl_3$) ν_{max} 1780, 1745, 1645 cm^{-1}; p.m.r. τ 4.34 (unresolved m, 1, vinyl H, $w_{1/2}$ = 4 Hz), 5.33 (unresolved m, 1, C_8H, $w_{1/2}$ = 19 Hz), 7.25 (d, 1, C_6H-equatorial, J = 13.0 Hz), 9.15 (poorly resolved d, 3, secondary methyl, J = 5.5 Hz), 9.36 (s, 3, tertiary methyl).

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15. Found: C, 76.15; H, 9.03.

(±)-Tetrahydroligularenolide (3)

To a stirred solution of the lactone **22** (85 mg, 0.39 mmol) in 4 ml of dry benzene under an atmosphere of nitrogen was added, dropwise, an ethereal solution of trityl sodium until the red color of the base persisted. After the resulting solution had been stirred at room temperature for 35 min, methyl iodide (160 μl, 2.5 mmol) was added in one portion. The reaction mixture was stirred at room temperature for 6 h, then diluted with ether and poured into ice–water. The organic layer was separated, washed with brine, and dried over anhydrous magnesium sulfate. Removal of the solvents gave 234 mg of residual material which was subjected to column chromatography on silica gel. Elution of the column with hexane yielded triphenylmethane, while elution with ether afforded 82 mg of crude crystalline product. Recrystallization from hexane–ether, followed by further purification (column chromatography) of the material obtained from the mother liquors, provided 53 mg (59%) of pure (±)-tetrahydroligularenolide (**3**), m.p. 91.5–92°; u.v. λ_{max} 220 mμ (ε 14 990); i.r. ($CHCl_3$) ν_{max} 1740, 1685 cm^{-1}; p.m.r. τ 5.38 (unresolved m, 1, C_8H, $w_{1/2}$ = 21 Hz), 7.24 (d, 1, C_6H-equatorial, J = 14.0 Hz), 8.21 (unresolved m, 3, vinyl methyl), 9.09 (poorly resolved d, 3, secondary methyl, J = 5.5 Hz), 9.42 (s, 3, tertiary methyl). Although an authentic sample of (−)-tetrahydroligularenolide was not obtained, the i.r. and p.m.r. data given above agree very well with the published data (22).

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 76.65; H, 9.31.

Preparation of the Thioketal Derivative 23

To a solution of the keto ester **12** (1.22 g, 5.2 mmol) in 30 ml of acetic acid was added 2.5 ml of 1,2-ethanedithiol and 1.5 ml of boron trifluoride etherate. The mixture was stirred under nitrogen for 26 h and then diluted with ether. Excess solid sodium bicarbonate was added and the resulting mixture was carefully diluted with cold water. The organic layer was separated, washed successively with aqueous sodium bicarbonate, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of solvent afforded 1.67 g (100%) of crude crystalline material. The p.m.r. spectrum of this material indicated that it was an epimeric mixture of **23** and **24**, in a ratio of approximately 4:1. One recrystallization of this material from methanol yielded 1.16 g (72.5%) of the pure dithioketal **23**, m.p. 110.5–111°; i.r. ($CHCl_3$) ν_{max} 1728 cm^{-1}; p.m.r. τ 4.52 (broad s, 1, vinyl H), 6.32 (s, 3, $-COOCH_3$), 6.52–6.99 (m, 5, $-SCH_2CH_2S-$ and C_7H), 9.07 (s, 3, tertiary methyl), 9.15 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{16}H_{24}O_2S_2$: C, 61.50; H, 7.74; S, 20.52. Found: C, 61.64; H, 7.84; S, 20.35.

The material obtained from the mother liquors of the above recrystallization consisted of compounds **23** and **24** in a ratio of approximately 1:2. Attempts to isolate a pure sample of **24** by column chromatography of this material were not successful.

Preparation of the Olefinic Ester 25

(a) From the Dithioketal 23

To a solution of the dithioketal **23** (594 mg, 1.9 mmol) in 80 ml of ethanol was added about 20 g of W-2 Raney nickel and the resulting mixture was refluxed with stirring under nitrogen for 15 min. The reaction mixture was filtered and the filtrate was evaporated under reduced pressure. Distillation of the residual material gave 373 mg of an oil, b.p. 120° at 0.15 mm, which was shown by g.l.c. analysis (205°, 105) to consist mainly of one compound, accompanied by two minor components. The desired, major component was isolated by preparative g.l.c. (200°, 90), yielding 264 mg (63%) of pure olefinic ester **25**, n_D^{20} 1.4979; i.r. (film) ν_{max} 1735, 808 cm^{-1}; p.m.r. τ 4.72 (unresolved m, 1, vinyl H), 6.36 (s, 3, $-COOCH_3$), 9.06 (s, 3, tertiary methyl), 9.14 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97. Found: C, 75.46; H, 10.04.

(b) From a Mixture of Dithioketals 23 and 24

A mixture of compounds **23** and **24** (180 mg, 1:2), obtained from the mother liquors of recrystallization of impure **23** (*vide supra*), was subjected to desulfurization with Raney nickel under conditions identical with those described above. Distillation of the crude product gave 102 mg of material which was shown by g.l.c. analysis (205°, 105) to consist mainly (85%) of the epimeric olefinic esters **25** and **26** (approximately 1:2). A solution of this material in 10 ml of 0.82 *M* sodium methoxide in methanol was refluxed under nitrogen for 20 h. The cooled solution was poured into dilute aqueous acetic acid and the resulting mixture was extracted with ether. The combined extracts were washed with water, with brine, and then dried over anhydrous magnesium sulfate. Removal of the solvents, followed by distillation of the residual material, afforded 65 mg of an oil. G.l.c. analysis (205°, 105) of the latter revealed that the ratio of **25** to **26** was now approximately 9:1. The major component, isolated from the mixture by preparative g.l.c. (205°, 105), was shown (i.r. and p.m.r. spectra) to be identical with **25**, prepared as described above.

Preparation of the Olefinic Alcohol 27

An ethereal solution of methyllithium (6 mmol) was added to a cold (0°) solution of the olefinic ester **25**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(222 mg, 1 mmol) in 8 ml of anhydrous ether. The resulting solution was refluxed under nitrogen for 2.5 h, cooled, and poured into a mixture of Dry Ice in water. The ether layer was separated, successively washed with water and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which, upon distillation under reduced pressure, afforded 212 mg (95%) of the olefinic alcohol **27**, b.p. 125–130° (hot-box) at 0.25 mm; n_D^{20} 1.5075; i.r. (film) ν_{max} 3380, 810 cm^{-1}; p.m.r. τ 4.71 (unresolved m, 1, vinyl H), 8.84, 8.85 (s, s, 6, $-C(OH)(CH_3)_2$), 9.08 (s, 3, tertiary methyl), 9.14 (unresolved m, 3, secondary methyl).

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 80.93; H, 11.67.

(±)-Aristolochene (4)

To a solution of the olefinic alcohol **27** (160 mg, 0.72 mmol) in 5.2 ml of pyridine at 0° was added, dropwise, 520 µl of thionyl chloride. The resulting solution was stirred under a nitrogen atmosphere at 0° for 1 h and then poured into cold, aqueous sodium bicarbonate. The resulting mixture was extracted with ether and the combined extracts were evaporated under reduced pressure. The residue was taken up in ether and the resulting solution was washed successively with water and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent gave 134 mg of crude material. Subjection of the latter to column chromatography on silver nitrate-impregnated silica gel (15%) gave, upon elution with hexane–ether, 57 mg (43%) of pure (±)-aristolochene (**4**), i.r. (film) ν_{max} 3075, 3030, 1645, 887, 810 cm^{-1}; p.m.r. τ 4.70 (unresolved m, 1, vinyl H, $w_{1/2}$ = 9.0 Hz), 5.31 (unresolved m, 2, $=CH_2$, $w_{1/2}$ = 3.0 Hz), 8.29 (unresolved m, 3, vinyl methyl), 9.06 (s, 3, tertiary methyl), 9.17 (unresolved m, 3, secondary methyl). This material exhibited i.r. and p.m.r. spectra identical with authentic (−)-aristolochene.

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.40; H, 11.90.

Comment: Concerning the Paper of R. P. Mariella and K. H. Brown "A Novel S_N1 Displacement: The Reaction of Tertiary Amines with Acetic Anhydride"

YA. L. GOL'DFARB AND L. I. BELEN'KII

N.D. Zelinsky Institute of Organic Chemistry of the Academy of Sciences of the U.S.S.R., Moscow, B-334, Leninskii Prospekt, 47, U.S.S.R.

Received October 12, 1972

The remarks on the paper of Mariella and Brown (1) concern three points: (*1*) some similar data from the literature were not mentioned; (*2*) the mechanism proposed does not take into account the possibility of catalysis of the reaction; and (*3*) the interpretation of the process as S_N1 displacement is not compatible with known data.

Les remarques concernant la publication de Mariella et Brown englobent trois points: (*1*) des résultats semblables ne sont pas mentionnés dans la littérature; (*2*) le mécanisme proposé ne tient pas compte de la possibilité d'une catalyse de la réaction; (*3*) l'interprétation du processus envisagé comme étant une réaction de déplacement S_N1 n'est pas en accord avec les résultats connus jusqu'à présent.

[Traduit par le journal]

Can. J. Chem., 51, 2174 (1973)

Recently a paper appeared in this Journal describing the cleavage of some tertiary amines by acetic anhydride in which a mechanism for the process was postulated (1). Unfortunately the authors of this paper did not mention that similar reactions had been studied previously. Tiffeneau and Fuhrer (2) had shown at the beginning of the century that tertiary amines bearing benzyl or substituted benzyl groups at the nitrogen atom are cleaved on heating with acetic anhydride while the amines of another structure (*e.g.*, *N*,*N*-dialkyl anilines) are not. They had shown further that the same conditions were suitable for cleavage of some alkaloids having benzyl-like fragments at the nitrogen atom (such as nicotine) (3). Drefahl *et al.* (4) (ref. 2 in ref. 1) had studied the effect of various para-substituents in *N*,*N*-dimethyl benzyl amine on the ability of the latter to undergo cleavage. They had also demonstrated the possibility of splitting *N*,*N*-dimethyl cinnamylmethyl amine as well as the stability of *N*,*N*-dimethyl allyl amine under the conditions used. We have studied the acetic anhydride cleavage of the ArCHR—N bond in *N*-benzyl pyrrolidine, *N*-benzyl piperidine, nicotine, *N*-methylanabasine, *N*-methyl α-phenyl pyrrolidine, -piperidine, -hexamethylene imine as well as some *N*-alkyl polyalkylene imines with no substituent in the α-position (such as *N*-alkyl pyrrolidines and *N*-methyl hexamethylene imine). In our opinion, only the cleavage of dimethyl tert-butyl amine seems to be of fundamental interest among the transformations described by Mariella and Brown (1).

We believe that there is a similarity in mechanism among the cleavage of tertiary amines (5, 6), ethers (7), and thioethers (8) by acid anhydrides or halides and nucleophilic reactions of carboxylic acid derivatives (in particular, anhydrides and halides) *i.e.* esterification, aminolysis, etc. It is known that such reactions are catalyzed by acids and bases. In particular, we have found that acetic acid effectively catalyzes the cleavage of tertiary amines by acetic anhydride. If acetic acid is specially removed from acetic anhydride by distillation over magnesium, the cleavage of amines proceeds very slowly or does not take place at all (5). The ionization of both components is known (9, 10) to increase in the system, acetic acid – acetic anhydride. This fact can explain the high acceleration of aromatic amines acylation by acetic anhydride in the presence of acetic acid (10, 11). Also suggested (12) was another explanation of the same phenomenon in terms of a concerted mechanism dealing with the catalytic effect of unionized CH_3COOH molecules. Both of these schemes are valid for the case of catalytic activity of acetic acid in the cleavage reaction of tertiary amines with acetic anhydride (5).

Purification of acetic anhydride was not mentioned in the paper of Mariella and Brown and therefore, under the conditions used by the authors (1), catalysis by traces of acetic acid was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[1] 
[2] 
possible. Sodium acetate, in the presence of which the reaction was carried out (1), may also act as a catalyst. Nevertheless, the participation of any catalyst was not considered in the reaction mechanism proposed by Mariella and Brown (1). Another weakness in their mechanism appears to be the purely speculative statement about S_N1 degradation of the intermediate complex, although the authors (1) do discuss the ratio of rates of the reaction single steps (no kinetic data are presented in their paper). As we have shown (5) (*cf.* (3)) no racemization takes place in the course of cleavage of the pyrrolidine ring in nicotine by acetic anhydride. This fact is not compatible with the S_N1 mechanism in its conventional sense. In principle, the retention of optical activity may arise in monomolecular reactions (*i.e.* S_N1 with inversion or S_Ni with retention of configuration). However, additional (kinetic, in particular) information is needed to reach such a conclusion.

Taking into account the retention of optical activity and acetic acid catalysis of nicotine cleavage, it is more logical to propose an S_N2-type mechanism for the reactions described (1). For instance, the mechanism of the reaction catalyzed by acetate ion may be described by eqs. 1 and 2.

The influence of acetic acid as a catalyst on the cleavage of tertiary amines under the action of acetic anhydride was clearly demonstrated by us not only for heterocyclic amines but for aromatic amines as well (*e.g.* *N,N*-dimethyl *p*-methoxybenzyl amine (5)). The reported phenomenon appears to be of general importance since the same catalytic effect of acetic acid was observed by us for the case of ether cleavage (*e.g.* ethyl benzyl ether (7)). In their reply to this comment (15) Mariella and Brown referred to certain papers where no mention of this catalytic effect is to be found. Therefore these references have no bearing on the question under discussion. At the same time it may be noted that Denney and Greenbaum (13) (ref. 8*a* in the reply (15)) have considered the participation of a base in the reaction of anhydrides with amines. We use a similar consideration while discussing the mechanism of acetate anion participation (see above). It is regrettable that in both their paper (1) and reply (15) Mariella and Brown did not discuss the possible role of potassium acetate in the reactions of acetic anhydride with tertiary amines.

Mariella and Brown rejected the S_N2-type mechanism, relying on the fact that benzyl acetate (but not methyl acetate) formation results from interaction of acetic anhydride with benzylic tertiary amines. However it is well known that S_N2 reactions of ammonium salts whose structures are closely related to that of the supposed intermediate considered in ref. 1 proceed predominantly with displacement of the benzyl (but not the methyl) group (*e.g.* ref. 14).

The S_N1 type of mechanism suggested by Mariella and Brown rests mainly on the published data (4) about the effect of the substituent in the benzene ring on the yields of the products: the electron-releasing substituents facilitate the reaction while electron-withdrawing ones slow it down. This fact was related to the differences in stability of respective benzyl cations. However one may find in the paper of Mariella and Brown (1) (see Experimental) data showing the following order for the ease of cleavage: *N,N*-dimethyl benzyl amine > *N,N*-dimethyl benzhydryl amine > *N,N*-dimethyl trityl amine (the yields of acetates are 40, 25 and $<10\%$ respectively). It is difficult to account for this order based on the S_N1 mechanism since the stability of respective cations changes in the opposite direction in this series.

The formation of a quantity of the α-phenyl-

allyl acetate observed by Mariella and Brown in the cleavage of *N,N*-dimethyl cinnamyl amine (1) may be considered to be a result of an S_N2' mechanism which may be favored due to the steric hindrances for the attack at the CH_2-group adjacent to nitrogen atom. The presence of such steric hindrances is evident from the inspection of space-filling molecular models of the respective intermediate.

In conclusion we would like to note that the mechanism of the cleavage of tertiary amines with acetic anhydride given by Mariella and Brown is clearly an oversimplification and several other mechanisms should also be considered in addition to the one suggested in our comment.

Comment: Concerning the Cleavage of Tertiary Amines With Acetic Anhydride

R. P. MARIELLA[1] AND K. H. BROWN

Department of Chemistry, Loyola University, Chicago, Illinois and Continental Can Company, Chicago, Illinois

Received December 29, 1972

The failure of methyl-substituted tertiary amines to yield methyl acetate on cleavage by acetic anhydride indicates that the mechanism proposed by Gol'dfarb and Belen'kii cannot be correct. The results of cleavage of cinnamyldimethylamine are offered as support for the mechanism proposed by Mariella and Brown. Catalysis by acetic acid is not considered to be important.

La tentative pour synthétiser l'acétate de méthyle par clivage d'amines tertiaires substituées par des méthyles à l'aide de l'anhydride acétique s'étant révélée un échec, il en ressort alors que le mécanisme proposé par Gol'dfarb et Belen'kii ne saurait être juste. Les résultats du clivage de la cinnamyldiméthylamine sont rapportés afin de justifier le mécanisme proposé par Mariella et Brown. On considère que la catalyse par l'acide acétique n'est pas un facteur déterminant. [Traduit par le journal]

It is appropriate now to extend and make further comment on the article "A Novel S_N1 Displacement: The Reaction of Tertiary Amines with Acetic Anhydride" which appeared recently in this Journal (1). Several points concerning the original paper of Mariella and Brown are currently being disputed (2).

The concern of Gol'dfarb and Belen'kii (2) that adequate citation of literature was not made in the paper by Mariella and Brown, while perhaps well intentioned, is certainly not completely researched itself. Three previous papers concerned with the reaction of tertiary amines and acetic anhydride have been published (3–5). Mariella and Brown, in their article (1), gave reference only to the paper by Drefahl *et al.* (4), which was concerned with the structural factors affecting the cleavage of tertiary amines of the benzyldimethyl type. The para-substitution results of the experiments were important in developing a basis for the S_N1 mechanism that was proposed by Mariella and Brown. Drefahl's article itself gave reference to the work of Tiffeneau and Fuhrer (3) so it was deemed unnecessary to re-cite the paper by Tiffeneau in the article of Mariella and Brown. Tiffeneau's work (3) consisted of the acetylation of various tertiary amines. However, the structural implications of the reaction as regards the type of tertiary amines were only cursorily examined. A detailed examination of the work done by Tiffeneau and Fuhrer and of that by Drefahl *et al.* was published in the Ph.D. Dissertation of K. H. Brown (6).[2] Gol'dfarb and Belen'kii certainly could have examined the original source of the Mariella and Brown work had they so desired. Gol'dfarb and Belen'kii's paper "The Effect of Structural and Other Factors on the Cleavage of Tertiary Amines with Acetic Anhydride" (5), as reported by Chemical Abstracts (7), gave only information on the cleavage of heterocyclic tertiary amines by acetic anhydride. In most cases the amines considered were of the benzyl type, and very little structural information concerning non-benzyl type tertiary amines was available from their work. Mariella and Brown are certainly obliged to cite the paper of Gol'dfarb and Belen'kii (5) since it does relate to the more complete study in question.

Indeed, much more is of interest in the paper of Mariella and Brown than merely the cleavage of dimethyl *tert*-butyl amine as suggested by Gol'dfarb and Belen'kii in their "comment" (2). Nowhere in the published literature is any complete structural information available on the reaction of tertiary amines with acetic anhydride. Drefahl *et al.*'s work (4) deals only with the cleavage of benzyl–nitrogen bonds. Tiffeneau's work mentions allyl, phenethyl, and phenyl as groups attached to the tertiary nitrogen. Gol'dfarb and Belen'kii dealt with the benzyl situation or a few others with alkyl substitution on nitrogen. As shown in Table 1 of the paper by Mariella and Brown, a complete structural list of

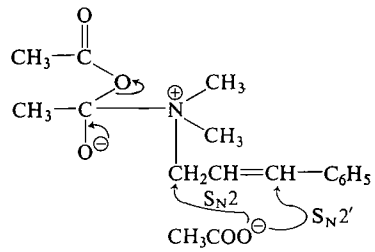
tertiary amines was examined under identical conditions as concerned their reactivity with acetic anhydride. Information and data concerning mechanistic conclusions were obtained by Mariella and Brown which were not available from other sources.

We do not believe that acid catalysis occurs in the reaction of tertiary amines with acetic anhydride. Certainly if there was any acetic acid present, it would be un-ionized in the reaction medium, acetic anhydride. Denney and Greenbaum show a mechanism of the reaction of anhydrides with amines to proceed without invoking acid catalysis (8). Similarly, Eliel and Anderson have cleaved benzyldimethyl amine with various esters without the use of catalysts (9). Thus, the contention that acetic acid catalysis is required to explain the results of Mariella and Brown is not a valid criticism of the work.

Among the evidence used to choose a mechanistic pathway was the reaction of cinnamyldimethyl amine. The cinnamyl group, C_6H_5-$CH{=}CHCH_2$, can be considered as an extended allyl group or as a vinylogous benzyl group since structurally it is, in fact, both of these. If one considers the cinnamyl group as a vinylogous benzyl group, the cleavage of the C—N bond in cinnamyldimethylamine is not surprising since by the rule of vinylogy the introduction of a vinyl group between the reaction site and another unsaturated portion of the molecule should give the new compound similar reactivity. Hence $C_6H_5CH_2$—$N(CH_3)_2$ and $C_6H_5(CH{=}CH)$-CH_2—$N(CH_3)_2$ should be of similar reactivity, and, in fact, they are found to be similarly reactive with acetic anhydride.

Interestingly, the reaction of the cinnamyldimethylamine with acetic anhydride gave two products; 60% cinnamyl acetate $CH_3C(=O)OCH_2$-$CH{=}CHC_6H_5$ and 30% α-phenylallyl acetate, $CH_3C(=O)OCH(C_6H_5)CH{=}CH_2$. This is a "typical" product spread for an allylic rearrangement. What seems to have happened is that attack of acetate occurs at two sites of an extended allylic cation *i.e.*, $C_6H_5CH{=}CH{-}CH_2^{\oplus} \leftrightarrow C_6H_5$-$CH(\oplus){-}CH{=}CH_2$. Attack at the primary cationic site would give the cinnamyl acetate while attack at the secondary cationic site would give the α-phenylallyl acetate. The resubmission of the pure cinnamyl acetate to reaction conditions gave only pure cinnamyl acetate and none of the rearranged α-phenylallyl acetate, indicating that equilibration of the product acetates does not occur. An S_N2 attack of acetate on the intermediate below would then give only cinnamyl acetate since there would be no free carbonium ion to resonate. An S_N2' mechanism, with attack at the γ-carbon involves an allylic shift which is



second order and occurs where S_N2 conditions hold, but only where α-substitution sterically retards normal S_N2. It is quite unlikely that an S_N2' mechanism would be operative in the case at hand (10). An S_N1 type mechanism, however, would permit the rearranged product to be formed since the S_N1 proceeds through several stages of ion formation: an "intimate" ion pair, a solvent separated ion pair, and the dissociated ions. Reaction products may result from attack of the nucleophile at any stage. The allylic shift observed in the cinnamyl case could occur during the dissociated ion stage or at the solvent separated ion stage. Also, partial inversion could occur in the "intimate" ion-pair stage since the carbonium ion might still retain its original configuration (10). More evidence for the establishment of an S_N1 type mechanism for the cleavage of tertiary amines by acetic anhydride comes from the work of Drefahl *et al.* (4). Splitting of the C—N bond in *t*-amines with acetic anhydride was observed to be most readily accomplished in those systems which favor ionization to a carbonium ion.

The mechanistic scheme presented by Gol'dfarb and Belen'kii cannot be correct. If R″ or R‴ in their scheme were CH_3, methyl acetate would form. No methyl acetate was found in any of the reactions studied by Mariella and Brown. One of the reasons that two methyl groups on the nitrogen was chosen as a basic structural feature was that the methyl groups were sterically noninterfering and chemically inert. Special attention

was given to try and detect *any* methyl acetate formed during the reaction, but none was detected. Gol'dfarb and Belen'kii merely submit their mechanistic scheme, but offer no further testimony to its validity. Mariella and Brown, however, go much further in that the results of many experiments are used to explain their proposed mechanism, and the results are themselves explained by the mechanism. Furthermore, the reaction of benzyldimethylamine with specially purified acetic anhydride alone gave a 29% yield of benzyl acetate.[3] Thus, the reaction proceeds in the same manner without the necessity of catalysis by acetic acid or sodium acetate.

[3]In order to remove any acetic acid from acetic anhydride, the 98.5% purity acetic anhydride was treated with coarse magnesium filings at reflux for 5 days according to the method of Calcott, English, and Wilbur (11). The acetic anhydride was then fractionally distilled directly into the pre-dried flask which was used for the ensuing reaction. Freshly distilled benzyldimethylamine was added to the acetic anhydride, and the mixture was stirred at reflux for 24 h, using a calcium chloride drying tube to protect against atmospheric moisture contamination. The reaction product, benzyl acetate, was isolated by the same procedure as previously reported (1).

The Crystal and Molecular Structure of Acetamidopentaamminecobalt(III) Perchlorate. A Conjugate Base of Nitrogen Bonded Acetamide

MICHAEL LOUIS SCHNEIDER, GEORGE FERGUSON,[1] AND ROBERT JAMES BALAHURA

Chemistry Department, The University, Guelph, Ontario, N1G 2W1

Received January 3, 1973

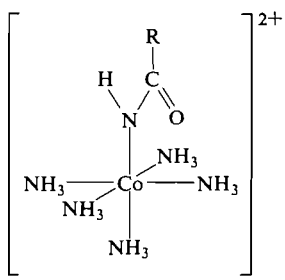
The crystal and molecular structure of acetamidopentaamminecobalt(III) perchlorate, $[CH_3CONHCo(NH_3)_5]^{2+}.2ClO_4^-$, has been determined from three-dimensional X-ray data obtained by diffractometer methods. The crystals are monoclinic, space group $P2_1/n(C_{2h}^5$, No. 14) with four formula units in a unit cell of dimensions $a = 13.250(6)$, $b = 10.318(6)$, $c = 10.676(5)$ Å, $\beta = 98.34(3)°$. The structure has been refined by block-diagonal least-squares methods with anisotropic thermal parameters to a final residual R of 0.055 for 1340 observed reflexions. The crystal structure consists of discrete octahedral cations and tetrahedral perchlorate anions. The Co—N (amide) distance is short (1.911(8) Å) while the *trans* Co—N (ammine) bond is long (1.994(8) Å) compared to the equatorial Co—N distances which average 1.963(13) Å. The bond distances in the amide group, C—O 1.267(12) Å and C—N 1.339(12) Å, indicate that a delocalized system plays an important role in the ground state structure of the cation.

La structure moléculaire et cristalline du cobalt(III) acétamidopentaammine perchlorate $[CH_3CONHCo(NH_3)_5]^{2+}.2ClO_4^-$ a été déterminée à l'aide des données tridimensionnelles obtenus des rayons X par des méthodes de diffractométrie. Les cristaux sont monocliniques, de groupe spatial $P2_1/n(C_{2h}^5$, No. 14) comportant quatre unités fondamentales par maille unitaire de dimension $a = 13.250(6)$, $b = 10.318(6)$, $c = 10.676(5)$ Å, $\beta = 98.34(3)°$. La structure a été raffinée par la méthode des moindres carrés (bloc-diagonale) avec des paramètres thermiques anisotropiques jusqu'a un factor d'accord $R = 0.055$ et ce pour tenir compte des 1340 réflexions observées. La structure cristalline consiste en des cations distincts octaédriques et en des anions perchlorates tétraédriques. La longueur de la liaison Co—N (amide) est courte (1.911(8) Å) alors que le lien *trans* Co—N (amine) est long (1.994(8) Å) comparativement aux distances équatoriales Co—N qui mesurent en moyenne 1.963(13) Å. Les longueurs du lien du groupe amide, C—O 1.267(12) Å et C—N 1.339(12) Å indiquent qu'un système délocalisé joue un rôle important dans la structure de l'état stationnaire du cation. [Traduit par le journal]

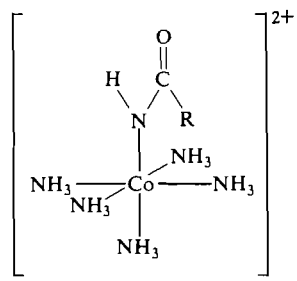
Can. J. Chem., 51, 2180 (1973)

Introduction

In the reaction of pentaamminecobalt(III) complexes, steric requirements may exert large effects on reaction rates, implying that the orientation of the ligand containing the reaction site may be crucial. As an example, the two extreme orientations of *N*-bonded formamide (R = H) and acetamide (R = CH_3) complexes with pentaamminecobalt(III) are shown in **1** and **2**.



1



2

[1]To whom correspondence should be addressed.

The chromium(II) reduction of these complexes (1, 2) proceeds according to the equation

$$(NH_3)_5CoNHCOR^{2+} + Cr^{2+} \xrightarrow{H^+} (OH_2)_5CrOCRNH_2 + Co^{2+} + 5NH_4^+$$

the acetamide complex being reduced thirty times slower than the formamide one. As the reductant attacks at the carbonyl oxygen it is tempting to ascribe this rate difference to a change in orientation of the ligand and to attribute orientation (**2**, R = H) to the formamide and (**1**, R = CH_3) to the acetamide derivative. Nuclear Overhauser studies on the formatopentaamminecobalt(III) ion have shown that in d_6-DMSO an orientation analogous to (**2**) is adopted (3). As crystals of the acetamide derivative (**1**, R = CH_3) were readily available, we undertook an X-ray analysis to establish the orientation of the ligand in the solid state. Crystals of the formamide derivative could not be obtained in a suitable crystalline form at this time.

Experimental

Crystal Data for Acetamidopentaamminecobalt(III) perchlorate $C_2H_{19}Cl_2CoN_6O_9$ f.w. = 401.1 Monoclinic a = 13.250(6), b = 10.318(6), c = 10.676(5) Å, β = 98.34(3)°. V = 1444.1 Å^3, Z = 4, ρ_c = 1.84 (21 °C; MoKα, λ = 0.71069 Å). Space group $P2_1/n$ (C_{2h}^5, No. 14). Linear absorption coefficient for X-rays (λ = 0.71069 Å) μ = 16.56 cm^{-1}, $F(000)$ = 821.

The space group was determined uniquely from the systematic absences in the $h0l$ and $0k0$ reflexions as $P2_1/n$. This non-standard space group with equivalent positions $\pm(x,y,z; 1/2 + x, 1/2 - y, 1/2 + z)$ was chosen for convenience. The cell dimensions were obtained from a least-squares treatment of the setting angles of 12 reflexions. The crystal chosen for the data collection was a small thin plate {101} with approximate dimensions 0.02 × 0.2 × 0.3 mm^3. Intensity data were collected to a maximum Bragg angle θ of 25° with our Hilger and Watts Y290 diffractometer. The θ–2θ scan technique was used with a symmetric scan of 0.7° and a scan rate of 0.6 deg/min. Stationary crystal/stationary counter measurements were made of the background counts (17.5 s duration) at each end of the integrated scan. The maximum variation in intensity of standard reflexions was less than 1.2%. The intensities were corrected for Lorentz and polarization factors but not for absorption. Of the 2240 independent reflexions measured, 1340 were considered "observed" ($I > 3\sigma(I)$ where $\sigma(I)$ = [scan + 4 (background)]$^{1/2}$.

Structure Solution and Refinement

The coordinates of the cobalt atom were found from inspection of the three-dimensional Patterson function and the remaining Cl, O, N, and C atoms located by application of the heavy atom method (4). In all calculations of F_c, atomic scattering factors of Cromer and Mann (5) were used for the non-hydrogen atoms and those of Stewart, Davidson, and Simpson (6) for the hydrogen atoms. Corrections were applied for anomalous dispersion of Co and Cl (7). Five cycles of block diagonal least-squares refinement of the non-hydrogen atomic coordinates and isotropic thermal parameters reduced $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$ to 0.092. The non-hydrogen atoms were then allowed to vibrate anisotropically. After the third anisotropic refinement cycle, when R_1 was 0.062, a difference synthesis was calculated but yielded no chemically significant information; in particular we could detect none of the 19 hydrogen atoms in the structure although diffuse electron density was observed around some NH_3 and CH_3 positions. Accordingly a disordered model for the NH_3 and CH_3 hydrogen atoms, with the hydrogen of the acetamido ligand in its calculated position, was allowed for in the structure factor calculations; no hydrogen parameters were refined. Refinement was complete in three more cycles when R_1 = 0.055 and $R_2 = [\sum w(F_o - F_c)^2/\sum wF_o^2]^{1/2}$ = 0.068. The weighting scheme used in the final cycles of refinement was w = 1 if $F_o \leqslant 65.0$, $w = 65/F_o$ if $F_o > 65.0$; unobserved reflexions were given zero weight. On the last cycle of refinement the average shift for all parameters was 0.16 e.s.d., the maximum shift

in positional parameter was 0.58 e.s.d., and that for the thermal parameters was 1.06 e.s.d. The X-ray system (8) versions of 1970 and 1972 was used for all major crystallographic calculations; the University of Canterbury data reduction program (9) was used to process our diffractometer tapes and the program to calculate the disordered hydrogen atom position was obtained from Ammon (10). The final positional parameters are listed in Table 1, thermal parameters in Table 2, and interatomic distances and angles in Table 3. A table of observed structure amplitudes and calculated structure factors has been placed with the Depository of Unpublished Data.[2]

[2]Photocopies of the table of observed and calculated structure factors may be obtained at a nominal charge from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Description of Structure and Discussion

The structure consists of discrete $[Co(NH_3)_5NHCOCH_3]^{2+}$ cations and perchlorate anions. A view of the cation geometry is in Fig. 1. The environment of the cobalt atom is octahedral with a mean *cis* N—Co—N angle of 90.0°.

That the acetamide is nitrogen-bonded to the cobalt atom is clearly established by the physical evidence (1) and confirmed by the successful refinement of this structure. The oxygen atom of the acetamide ligand is pointing between two equatorial *cis* ammines with the methyl group directed away from the Co atom; an exactly similar orientation has been found for the acetatopentaamminecobalt(III) ion (11). The O...N(ammine) intramolecular contact distances, 2.988(10), 2.900(10), do not preclude N—H...O hydrogen bonding but as hydrogen atoms could not be located unequivocally, no real evidence can be produced for it. Even in the absence of

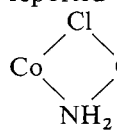
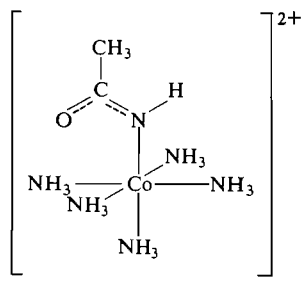
proven intramolecular hydrogen bonding consideration of relative sizes of the carbonyl oxygen *viz-a-viz* the methyl group would favor the conformation found here.

The N—Co bond *trans* to the amide is slightly longer (1.994(8) Å) than the mean of the four equatorial bonds (1.963(13) Å) and the Co—N(amide) distance (1.911(8) Å) is significantly shorter. These distances may be compared with the average N—Co value found in $Co(NH_3)_6^{3+}$ (1.968 Å) (12) and the shorter value (1.903 Å) reported for the N—Co bonds in $(NH_3)_4$



(13). The bond lengths in the amide group are very interesting; the C—O bond length 1.267(12) Å is longer than would be expected for a C=O double bond, 1.23 Å (14), while the C—N distance, 1.339(12) Å, is identical to that found in pyridine 1.340(1) Å (15). Clearly a delocalized system (**3**) is important in the ground state structure of the cation. Lending support to this are the infrared spectra of the acetamide and related complexes. The carbonyl



3

stretching frequency for $(NH_3)_5CoNH_2COCH_3^{3+}$ is at 1700 cm^{-1} and for its conjugate base (**3**) at 1560 cm^{-1}, whereas in the free acetamide ν(C=O) appears at 1714 cm^{-1}. These large differences between the carbonyl stretching frequencies of the acidic and basic forms may be rationalized in terms of delocalization in the N—C—O system of the conjugate base, which is not possible in the acidic form. Similar spectral features are found in the acidic and basic forms of the formamide complex ($(NH_3)_5$-

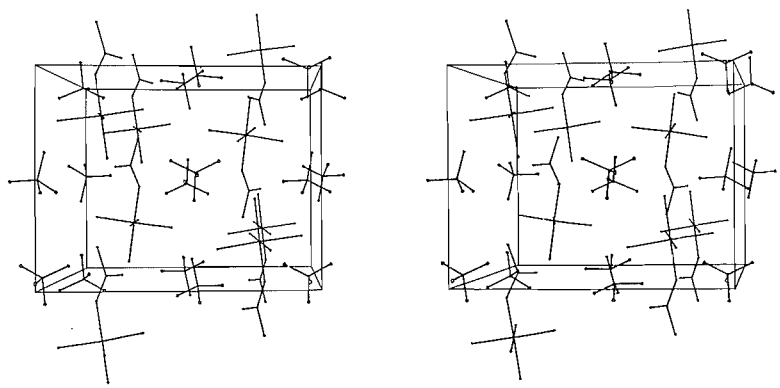


FIG. 2. Stereo-diagram of the contents of the unit cell viewed along the *c*-axis.

$CoNH_2CHO^{3+}$, $\nu C{=}O = 1675\ cm^{-1}$; and $(NH_3)_5CoNHCHO^{2+}$, $\nu C{=}O = 1600\ cm^{-1}$) indicating a similar delocalization.

The other bonded distances in the structure are normal. The Csp^2—Csp^3 distance 1.51(1) Å lies in the range of values usually found for such bonds. The perchlorate anions have their expected tetrahedral geometry with mean O—Cl—O angle 109.3° and mean Cl—O 1.39 Å.

The molecular packing is shown in Fig. 2. The cations and perchlorate ions pack in layers parallel to [011]. Planes of perchlorate ions are found at $x = 0$ and 0.5 with the cations at $x = 0.25$ and 0.75. The shorter intermolecular contacts are listed in Table 3, and for the most part involve ammine or amide N...O(perchlorate) contacts. An analysis of these distances in terms of possible hydrogen bonding would be at best speculative as no hydrogen atoms were located. However, the amide nitrogen N(1) is 3.06(2) Å from a neighboring perchlorate oxygen (O(4)) and the geometrical arrangement (Cl—$\hat{O}$...N 113.9(7), C—$\hat{N}$(H)...O 119.4(7)°) is consistent with this being a weak hydrogen bond.

We are grateful to the National Research Council of Canada for operating grants (A5975 to GF and A6642 to RJB) and for a computing grant (CO357 to GF). All the calculations were performed on the University of Guelph IBM 370/155 computer.

Application de la Trichromie Complémentaire à l'étude des complexes métalliques en solution

M. MORIN, M. M. PETIT-RAMEL, ET J. P. SCHARFF

Laboratoire de Chimie Minérale, Université Claude-Bernard Lyon I, 43, Boulevard du 11 Novembre 1918, 69 – Villeurbanne, France

ET

M. R. PÂRIS

Laboratoire de Chimie de Coordination, Université de Dijon, 6, Boulevard Gabriel, 21 – Dijon, France

Reçu le 31 octobre 1972

L'intérêt de la spectrophotométrie trichrome comme méthode d'investigation des équilibres complexes en solution a été démontré à l'aide d'une dizaine d'exemples originaux faisant intervenir divers cations métalliques bivalents (cuivre, vanadyle) ou trivalents (fer, aluminium, yttrium, lanthane) complexés par différents coordinats organiques.

La détermination des coordonnées trichromatiques complémentaires permet la mise en évidence rapide de la formation de complexes colorés simples ou mixtes (en particulier bimétalliques); de leurs domaines d'existence et du nombre d'espèces en solution.

Les limites inhérentes à la méthode sont discutées mais néanmoins celle ci se révèle d'une utilité incontestable pour une première approche des phénomènes de complexation, que l'on doit ensuite compléter par une étude plus quantitative en utilisant les méthodes classiques.

Complementary tri-stimulus spectrophotometry appears as an interesting method for investigation of metal complex equilibria in solution. This has been demonstrated on various examples including bivalent (copper, vanadyl) or trivalent (iron, aluminum, yttrium, lanthanum) metal ions coordinated by several organic ligands.

The formation, p*H* range of existence, and the number of absorbing species in colored solutions of binary or ternary (particularly bimetallic) systems are easily determined by calculation of the complementary tri-stimulus co-ordinates.

The advantages (and disadvantages) of the technique are discussed. This qualitative method appears to be very useful for a first approach of coordination phenomena but needs to be completed by quantitative studies using classical methods.

Can. J. Chem., **51**, 2186 (1973)

Introduction

Le principe de l'emploi de la trichromie complémentaire pour l'étude rationnelle des indicateurs colorés a été mis au point en 1960 par Reilley et ses collaborateurs (1, 2). Ce domaine d'application a donné lieu à de nombreuses publications parmi lesquelles nous pouvons retenir la revue exhaustive de Kotrly (3) ainsi que l'article récent de Kotrly et Vytras (4).

Quelques travaux (5–10) ont montré la valeur de cette méthode d'investigation des équilibres en solution notamment en ce qui concerne les complexes mixtes bimétalliques.

Pour notre part nous avons montré que la méthode pouvait permettre de déceler la formation de complexes métalliques colorés ainsi que le nombre d'espèces en solution et leurs domaines d'existence et ceci beaucoup plus rapidement qu'au moyen des procédés classiques.

Nous illustrerons les possibilités et les limites de la méthode par quelques exemples caractéristiques relatifs à des complexes simples et à des complexes mixtes, soit bimétalliques (du type $M_mM'_{m'}L_n$), soit constitués par un ion métallique et deux coordinats différents (du type $ML_nL'_{n'}$).

Principe des methodes utilisées

Méthode spectrophotométrique trichrome

Nous ne reviendrons pas sur les calculs fondamentaux développés dans l'article original de Reilley (1), nous contentant de poser l'équation générale des coordonnées chromatiques (limitée au terme du premier ordre).

$$[1] \qquad P_r = G_r - J(Q_r - G_r)$$

où les symboles P_r, G_r, et Q_r désignent respectivement les coordonnées chromatiques de la

couleur observée, de la couleur incidente et de la couleur absorbée (couleur complémentaire). P_r est alors représenté par les coordonnées trichromatiques x, y, z, se déduisant des flux X, Y, Z (transmittances) par les relations:

$$x = \frac{X}{X + Y + Z}$$

[2] $$y = \frac{Y}{X + Y + Z}$$

$$z = \frac{Z}{X + Y + Z}$$

Dans le cas de la trichromie complémentaire, (seule méthode utilisée dans ce travail), Q_r est représenté par les coordonnées trichromatiques complémentaires u, v, w définies par les relations:

$$u = \frac{U}{U + V + W}$$

[3] $$v = \frac{V}{U + V + W}$$

$$w = \frac{W}{U + V + W}$$

pour lesquelles nous allons expliciter d'une manière concrète et directement utilisable les trois fonctions U, V, et W.

En effet, le principe des déterminations expérimentales consiste à mesurer simultanément avec le pH, au cours d'une neutralisation progressive par la soude, l'absorption lumineuse de solutions de complexes. Après avoir tracé les spectres d'absorption à différents pH, trois domaines du spectre sont sélectionnés et plusieurs longueurs d'onde, en général dix, sont pointées dans chacun d'eux.

La valeur de l'absorbance A est lue pour chaque longueur d'onde et on en fait la somme R dans chaque domaine r

[4] $$R_{(r)} = \sum_{1}^{10} A_r$$

r peut varier de 1 à 3 (3 domaines) et la somme de toutes les absorptions à chaque longueur d'onde sera caractérisée par une fonction U, dans le premier domaine; V, dans le second et W dans le troisième.

U, V, W étant proportionnelles à la concentration de la substance colorée, il en résulte que les "coordonnées de la couleur" u, v, w seront indépendantes de cette même concentration.

La somme $J = U + V + W$ est la "concentration optique" de la solution de complexe. Elle est reliée à la concentration analytique c par la relation

[5] $$J = A \times c \times l$$

où A est l'absorbance totale et l la longueur de la cuve spectrophotométrique.

Dans le cas d'un équilibre simple du type

[6] $$M + L \rightleftarrows ML$$

où M représente l'ion métallique, L l'agent chélatant, et ML le complexe formé par les deux espèces; on peut écrire

[7] $$c_M = [M] + [ML]$$

[8] $$c_L = [L] + [ML]$$

c_M et c_L étant les concentrations totales des réactifs.

Si l'ion métallique est coloré et le coordinat incolore, on peut évaluer successivement les fonctions u, v, w dans le spectre visible. Or nous avons vu que ces fonctions étaient indépendantes de la concentration de l'espèce considérée. D'autre part, si à partir d'un certain pH, le complexe est entièrement formé, un seul colorant ML absorbera, à la dissociation près de celui-ci et la fonction $u = f(c)$, par exemple, présentera un palier correspondant à l'existence de la seule espèce absorbante. Comme la concentration d'une espèce complexe en équilibre est liée directement au pH de la solution, du fait de la forme protonée du coordinat, le graphe $u = f(\text{p}H)$ présentera une ligne droite parallèle à l'axe des pH. Les portions non parallèles à l'axe des abscisses indiquent les zones de transition d'une forme en l'autre.

L'existence d'une seule espèce étant mise en évidence, la colorimétrie trichrome peut encore nous renseigner utilement sur la formation d'un équilibre simple entre deux espèces. Dans ce cas, on constate que les fonctions $u = f(v)$ ou $u = f(w)$ ou encore $v = f(w)$ sont des fonctions linéaires; lorsqu'elles perdent leur linéarité, on peut supposer que l'on se trouve en présence de plus de deux espèces. Il est également possible de prévoir que lorsque l'une de ces fonctions devient ponctuelle, l'équilibre est détruit au profit d'une seule espèce et nous sommes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ramenés dans les conditions où $u = f(pH)$ reste constante.

Ainsi lorsque nous sommes en présence d'un système inconnu, on peut par le simple tracé d'une série de spectres d'absorption révéler l'existence, soit d'une espèce colorée unique, soit d'un équilibre entre deux espèces, soit encore la présence de plus de deux espèces absorbantes.

Nous illustrons ces trois étapes de la trichromie complémentaire en étudiant des équilibres de complexes connus du point de vue de leur stabilité ionique, ce qui nous permettra d'apprécier la validité de la méthode en même temps que ses limites.

Méthode de calcul de la répartition des différentes espèces

Dans le but de tester les résultats de la méthode précédente nous pouvons calculer les courbes de répartition des espèces en fonction du pH. Le calcul est aisé lorsque l'on connait, ce qui est le cas ici, les constantes de stabilité ionique des divers complexes mis en jeu (8, 12–14).

Dans tous les cas nous avons utilisé une méthode de calcul par approximations successives, dérivée de la méthode d'itération dite "de Newton" et facilement adaptable sur ordinateur.

En effet dans les cas les plus complexes envisagés (espèces mixtes $ML_nL'_{n'}$ et $M_mM'_{m'}L_n$) on dispose des 3 équations exprimant les concentrations totales des trois constituants. On est donc ramené à la résolution de 3 équations F_1, F_2, F_3 non linéaires à trois inconnues X_1, X_2, X_3 (pouvant être [M], [L], [L'] ou [M], [M'], [L]).

On cherche donc les solutions X_1^0, X_2^0, X_3^0 des équations

$$F_i(X_1,X_2,X_3) = 0$$

Il faut pour cela résoudre le système linéaire

$$[9] \qquad \sum_{j=1}^{3} \frac{\partial F_i}{\partial X_j} \cdot dX_j + F_i(X_1,X_2,X_3) = 0$$

avec $dX_j = X_j^0 - X_j$

Le processus d'itération est le suivant: en se donnant des valeurs de départ X_1^1, X_2^1, X_3^1, l'ordinateur calcule les $\partial F_i(X_1^1,X_2^1,X_3^1)/\partial X_j$ et $F_i(X_1^1,X_2^1,X_3^1)$ puis résout le système [9] qui a pour inconnues les dX_j. Les nouvelles valeurs $X_j + dX_j$ sont alors calculées et l'itération est poursuivie jusqu'à ce que $|dX_j/X_j| \leqslant \varepsilon$; ε définissant la précision recherchée.

Resultats expérimentaux

Cas des complexes simples ML_n

(a) Une seule espèce colorée ML existe dans un large domaine de pH

Un exemple particulièrement significatif nous est fourni par le complexe que forment les ions ferriques avec l'acide éthylénediamine-*N*-*N*'-di(*o*-hydroxyphénylacétique). D'après l'étude de Anderegg et L'Eplattenier (11), un seul complexe rouge de stabilité ionique remarquable ($\log \beta_1 = 33.91$) se forme dans une zone de pH allant de 3 à 10. Nous avons pu confirmer ces conclusions en traçant un faisceau de spectres dans le domaine 385–560 nm (où les ions ferriques n'absorbent pas) et en déterminant les courbes $u,v,w = f(pH)$. Les trois fonctions présentent un palier parallèle à l'axe des pH dans le domaine considéré (fig. 1) montrant ainsi l'existence de la seule espèce colorée ML.

(b) Formation successives de plusieurs espèces colorées en fonction du pH

Notre premier exemple concerne les complexes des ions ferriques avec l'acide sulfo-5-salicylique (H_3L). Nous avons montré antérieurement l'existence dans ce système de trois complexes successifs ML, ML_2, et ML_3 dont les constantes de stabilité ont été déterminées potentiométriquement (12): $\log \beta_1 = 12.08$; $\log \beta_2 = 23.22$, et $\log \beta_3 = 30.24$.

Nous avons tracé les spectres d'absorption dans la région 385–535 nm pour différents rapports $R = c_L/c_M$ de réactifs engagés et nous donnons à titre d'exemple les courbes $u,v,w = f(pH)$ obtenues dans le cas où $R = 30$ (fig. 2). Nous avons fait figurer également les courbes de répartition représentant les concentrations des espèces ML_n, en fonction du pH, calculées à

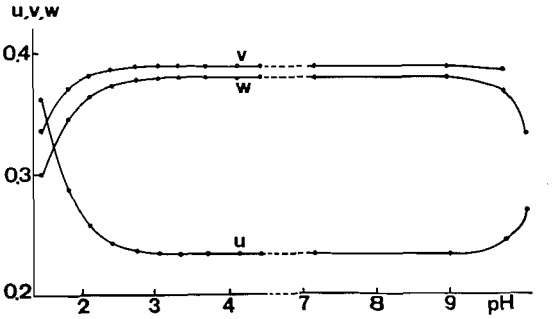

FIG. 1. Courbes $u,v,w = f(pH)$ pour le système Fe(III) – acide éthylènediamine-*N*-*N*'-di-(*o*-hydroxyphénylacétique). $[Fe]_T = [L]_T = 3.10^{-4}$ *M*.

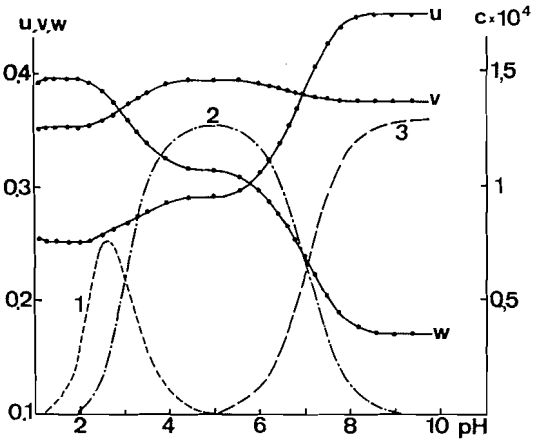

FIG. 2. Méthode trichrome (traits pleins) et courbes de répartition (traits discontinus) pour le système Fe(III) – acide sulfo-5-salicylique. (1) FeL; (2) FeL_2; (3) FeL_3. $[Fe]_T = 1.290 \times 10^{-4}$ *M*; $[L]_T = 3.750 \times 10^{-3}$ *M*.

l'aide des valeurs des constantes indiquées ci-dessus.

On observe de façon très nette le palier correspondant à la formation du premier complexe FeL (coloration violette intense) pour des p*H* compris environ entre 1.50 et 2.50. Les courbes de répartition montrent qu'au delà de p*H* = 2.50 l'espèce ML_2 existe de façon notable, on a donc équilibre entre deux espèces colorées distinctes, ce qui explique que le premier palier des courbes *u,v,w* soit limité à cette valeur.

De même le palier correspondant à la formation du deuxième complexe ML_2 (coloration rouge orangé) est peu marqué. Les courbes de répartition montrent en effet que cette espèce n'existe pratiquement jamais seule en solution mais qu'elle est en équilibre soit avec le premier complexe (p*H* < 5) soit avec le troisième (p*H* > 5). Enfin on observe le palier correspondant à la formation du troisième complexe ML_3 (coloration jaune) pour des p*H* supérieurs à 8.50 en accord avec la courbe de répartition qui montre qu'à partir de cette valeur la concentration en ML_2 devient négligeable et qu'une seule espèce colorée subsiste au sein de la solution.

Cependant il faut souligner que l'existence d'un palier sur les courbes $u,v,w = f(pH)$ ne permet pas de conclure de façon indubitable à l'existence d'une seule espèce colorée. Nous pouvons illustrer ce fait dans le cas des complexes ferriques de l'acide pyrocatécholdisulfonique-3,5: nous avons démontré en effet (13) l'existence de quatre complexes MHL, ML, ML_2, et ML_3 dont deux (MHL et ML) possèdent le même coefficient d'extinction moléculaire.

Les spectres d'absorption exploités dans la région 410–710 nm permettent de tracer les coordonnées trichromatiques complémentaires comme nous l'avons fait sur la fig. 3 pour $R = c_L/c_M = 10$.

L'interprétation des résultats peut se faire d'une façon analogue au cas précédent sauf en ce qui concerne le premier palier observé pour des p*H* < 3. En effet dans ce cas les courbes de répartition montrent que dans cette zone de p*H* acide, deux complexes colorés (bleu–vert) MHL et ML coexistent et ces deux espèces se trouvent avoir le même coefficient d'extinction moléculaire. Cet exemple nous permet d'illustrer de manière tangible les limites de la méthode trichrome.

La méthode trichrome nous a permis, jusque là, d'observer les différents paliers correspondant aux formations successives des complexes simples, au sein d'un même système.

Dans l'exemple suivant, nous allons en atteindre la limite d'utilisation, du fait de l'apparition, non plus successive, mais simultanée, d'au moins deux espèces; c'est le cas du système cuivre–valine, dont la formation a été largement étudiée par diverses techniques: potentiométrique, spectrophotométrique, polarimétrique etc... (14).

Après en avoir calculé la constante de stabilité, nous avions pu tracer les courbes de répartition des espèces en présence: Cu(val), $Cu(val)_2$ et l'ion Cu^{2+} libre en fonction du p*H* (fig. 4), qui mettent en évidence, dès p*H* 6, l'existence d'une

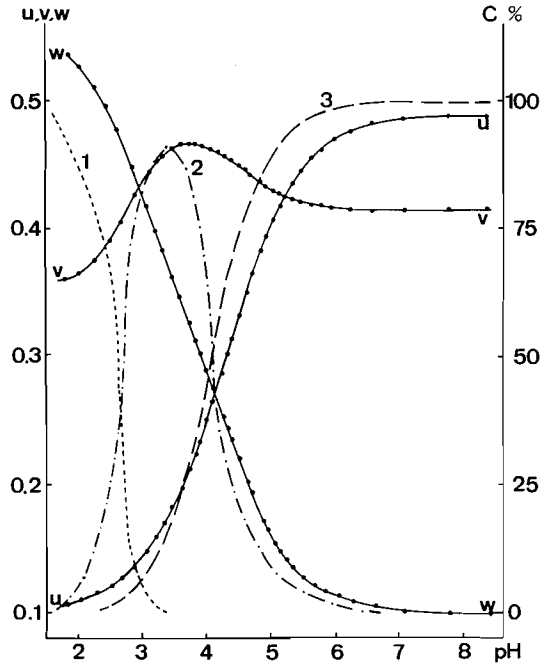

FIG. 4. Méthode trichrome (traits pleins) et courbes de répartition (traits discontinus) pour le système Cu(II)-valine. (1) Cu(II); (2) Cu(val); (3) $Cu(val)_2$. $[Cu]_T = 3.336 \times 10^{-3}$ *M*; $[val]_T = 1.600 \times 10^{-2}$ *M*.

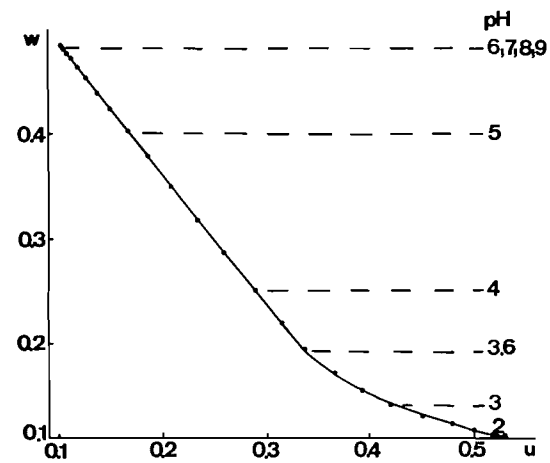

FIG. 5. Courbe $w = f(u)$ pour le système Cu(II)-valine.

espèce absorbante unique, $Cu(val)_2$, ce qui apparait nettement sur le tracé des courbes $u,v,w = f(pH)$ (fig. 4).

D'autre part, l'analyse d'une fonction $w = f(u)$ (fig. 5) montre d'abord:

(*i*) de p*H* 2 à p*H* 3, une variation linéaire caractéristique de la présence de deux espèces qui sont en effet, le cuivre non complexé et le premier complexe Cu(val).

(*ii*) de p*H* 3 à p*H* 3.6, une zone incurvée, restreinte, supposant la présence de plus de deux espèces. En effet, les courbes de répartition font apparaitre la formation simultanée de trois espèces: le cuivre non complexé et les deux espèces chélatées Cu(val) et $Cu(val)_2$.

(*iii*) de p*H* 3.6 à p*H* 6, la fonction redevient parfaitement linéaire et représentative de l'équilibre:

$$Cu(val) + val \rightleftarrows Cu(val)_2$$

(*iv*) enfin à partir de p*H* 6, la fonction devient ponctuelle puisque nous sommes en présence d'une seule espèce $Cu(val)_2$.

Cas des complexes mixtes bicoordinats $ML_nL'_n$

Nous examinerons tout d'abord les données relatives au système Fe(III) – acide sulfo-5-salicylique (H_3L) – acide nitrilotriacétique (H_3L') pour lequel nous avons montré l'existence d'un complexe mixte de formule MLL′ dans un vaste domaine de p*H* allant de 2 à 10. La constante de stabilité ionique $\beta_{11} = [MLL']/[M][L][L']$ a été déterminée potentiométriquement et affinée par nos méthodes habituelles: $\log \beta_{11} = 26.59$.[1]

L'exploitation des spectres d'absorption dans la région 383–560 nm conduit aux courbes $u,v,w = f(pH)$ que nous avons représentées sur la Fig. 6 pour le rapport 1:10:10.

On constate que les trois courbes présentent un palier remarquable dans la zone de p*H* considérée. Le calcul de la répartition des espèces montre que ces paliers sont limités d'une part

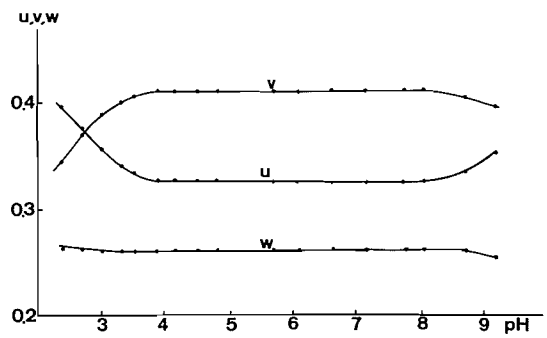

FIG. 6. Courbes $u,v,w = f(pH)$ pour le système Fe(III) – acide sulfo-5-salicylique – acide nitrilotriacétique. $[Fe]_T = 3.600 \times 10^{-4}$ *M*; $[L]_T = [L']_T = 3.600 \times 10^{-3}$ *M*.

For personal use only.

vers les pH acides par l'existence de l'espèce [FeNTA] et d'autre part vers les pH alcalins par la formation de [$Fe(ASS)_3$]. Nous avons également détecté la présence d'une espèce hydroxydée [FeNTA(OH)] qui coexiste avec l'espèce mixte dans la même région de pH. Cependant ce complexe étant incolore, il n'altère pas les coordonnées trichromatiques et l'on a bien dans ce cas une seule espèce mixte colorée en solution.

Il faut noter que nous avons obtenu des résultats analogues dans le cas du système Fe(III) – acide dihydroxy-2,4 benzoique – acide nitrilotriacétique.

Par contre, si nous examinons maintenant le système mixte cuivre–glycine–valine, le tracé des courbes de répartition (fig. 7) pour lesquelles nous n'avons retenu que le rapport $[M]_T:[L]_T:[L']_T = 1:1:1$ (le plus favorable à la formation de l'espèce mixte) indique en premier lieu, que trois espèces absorbantes sont simultanément présentes à partir de pH 7: le complexe mixte Cu(gly)(val) (environ 50%) et les deux complexes simples $Cu(val)_2$ et $Cu(gly)_2$ dans la proportion de 25% environ. En nous reportant au principe

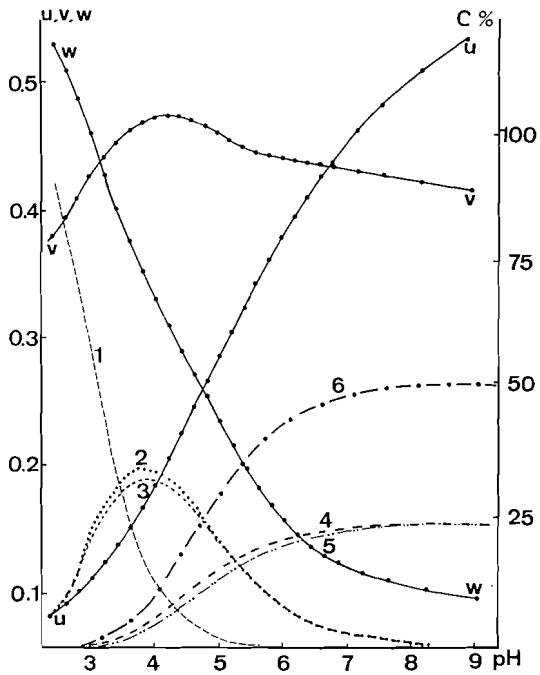

FIG. 7. Méthode trichrome (traits pleins) et courbes de répartition (traits discontinus) pour le système Cu(II)–glycine–valine. (1) Cu(II); (2) Cu(gly); (3) Cu(val); (4) $Cu(gly)_2$; (5) $Cu(val)_2$; (6) Cu(gly)(val) $[Cu]_T = 4.170 \times 10^{-3}$ M; $[gly]_T = [val]_T = 4.200 \times 10^{-3}$ M.

de la méthode trichromatique, les différentes fonctions $u,v,w = f(pH)$ ne doivent pas présenter de palier caractéristique d'une seule espèce absorbante. Ceci est parfaitement vérifié sur la fig. 7 où les trois courbes u, v, w ne présentent aucune partie horizontale.

La substitution des courbes $w = f(u)$ aux courbes $u = f(pH)$, par exemple, n'apporte aucune précision supplémentaire et nous arrivons ici en limite d'utilisation de la méthode, dont les possibilités peuvent être résumées ainsi:

(*i*) la présence d'une seule espèce absorbante se traduit par un palier sur les courbes $u = f(pH)$ et par un point sur les courbes $u = f(v)$.

(*ii*) la présence simultanée de deux espèces absorbantes ne se détectant pas sur les courbes $u = f(pH)$ conduit par contre à une fonction linéaire pour $u = f(v)$.

(*iii*) enfin lorsque ces dernières fonctions ne sont plus rectilignes, nous pouvons en conclure qu'il y a plus de deux espèces absorbantes en présence.

Cas des complexes mixtes bimétalliques $M_mM'_mL_n$

Ces complexes bimétalliques ne semblent pas avoir beaucoup retenu l'attention jusqu'ici; cependant, si leur formation parait relativement rare, à priori, elle peut se révéler extrêmement gênante au cours de la mise au point de dosages complexométriques simultanés de plusieurs métaux. C'est ainsi qu'en 1961, Flaschka, Butcher, et Speights (7), vérifièrent par la trichromie, l'existence d'un tel complexe mixte entre l'acide tartrique, le cuivre et l'aluminium.

Dans un précédent mémoire (8), nous avons pu mettre en évidence, grâce à la méthode trichrome, l'existence du complexe bimétallique formé entre l'acide tartrique, le cuivre et l'yttrium. Comme l'ion tartrate et l'ion citrate ont sensiblement les mêmes propriétés en ce qui concerne la chélation mixte (au nombre de fonctions acides et alcooliques près), il nous a paru intéressant d'étudier le comportement de l'ion citrate, d'une part en présence de cuivre et d'yttrium et d'autre part en présence de cuivre et de lanthane. La méthode trichrome était évidemment tout indiquée dans cette première approche.

Les mesures se font dans un premier temps sur les solutions contenant les citrates de cuivre seuls, considérés comme espèces simples, puis dans un deuxième temps sur les espèces mixtes de

citrate de cuivre–yttrium dont nous ne connaissons pas le nombre à priori.

A partir des deux faisceaux de spectres obtenus dans le domaine de 500 à 850 nm, nous pouvons tracer les coordonnées de la couleur complémentaire u, v, et w pour les complexes simples et u', v', et w' pour les complexes mixtes (fig. 8). Nous observons pour chacune des fonctions, deux paliers caractérisant, dans une zone de pH déterminée, la présence d'une seule espèce colorée et d'une seule espèce mixte, bien différenciées l'une de l'autre. On peut donc en déduire, de prime abord, qu'il se forme entre pH 7 et pH 9 une espèce mixte unique dont la formule $[YCuCit_2(OH)_2]$ a été déterminée par des mesures conjointes d'absorbance et de pH.[2]

Des courbes analogues ont été obtenues pour les systèmes citrates et tartrates de cuivre–lanthane.

Un dernier exemple concerne la recherche d'éventuels complexes entre l'acide citrique et les ions aluminium et vanadyle c'est-à-dire $Al_n(VO)_{n'}$ Cit_m. Or l'examen des coordonnées trichromes en fonction du pH montre que les

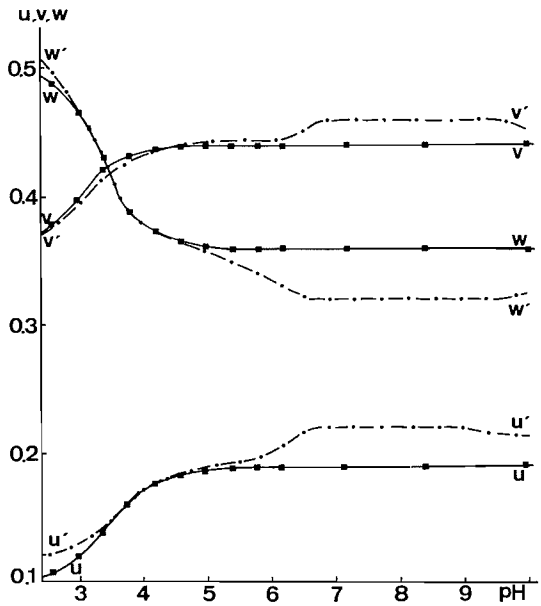

FIG. 8. —, Courbes $u,v,w = f(pH)$ pour le système Cu(II) – acide citrique. $[Cu]_T = 3.060 \times 10^{-3}$ M, $[Cit]_T = 1.500 \times 10^{-2}$ M; - · · · -, Courbes $u',v',w' = f(pH)$ pour le système Cu(II) – Y(III) – acide citrique. $[Cu]_T = 3.060 \times 10^{-3}$ M; $[Y]_T = 3.000 \times 10^{-3}$ M; $[Cit]_T = 1.500 \times 10^{-2}$ M.

[2]J. Inorg. Nucl. Chem: à paraitre.

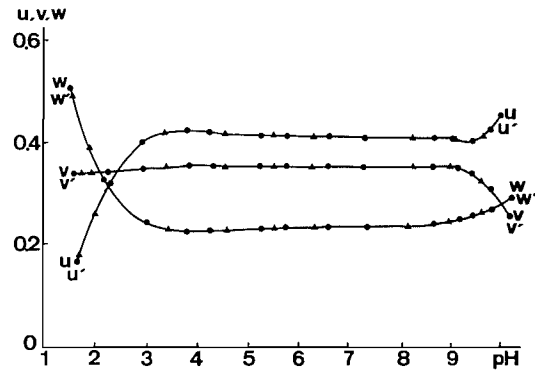

FIG. 9. ●, Courbes $u,v,w = f(pH)$ pour le système VO(II) – acide citrique; ▲, Courbes $u',v',w' = f(pH)$ pour le système Al(III) – VO(II) – acide citrique. $[VO^{2+}]_T = 5.952 \times 10^{-3}$ M; $[Al]_T = 5.952 \times 10^{-3}$ M; $[Cit]_T = 3.000 \times 10^{-2}$ M.

courbes $u = f(pH)$; courbes u, v, w (pour le système vanadyle – acide citrique) et u', v' w' (pour le système aluminium – vanadyle – acide citrique) sont parfaitement confondues (fig. 9).

La présence d'un palier important entre les pH 5 et 9 permet de prévoir un seul citrate simple de vanadyle 1:1 signalé par divers auteurs (15, 16) et après addition d'un sel d'aluminium, il n'y aura que la juxtaposition des citrates simples d'aluminium avec ce même citrate de vanadyle. La formation du complexe mixte bimétallique est donc irréalisable du fait de la grande stabilité du citrate simple de vanadyle (ou de son dimère) (17), interdisant toute compétition avec l'aluminium.

Partie expérimentale

Toutes les mesures de cette étude ont été réalisées à la température standard de 25 °C ± 0.1, en milieu de force ionique 0.5 M maintenue constante par du nitrate de sodium excepté dans le cas des systèmes cuivre–valine et cuivre–glycine–valine où l'électrolyte support était du perchlorate de sodium.

Protométrie

Les mesures de pH ont été effectuées à l'aide d'un compensateur Metrohm E 388 (électrodes Metrohm: type EA 109 UX pour l'électrode en verre et EA 404 pour l'électrode de référence). Les solutions étaient placées dans des cellules thermostatées Tacussel type RMO6 et maintenues sous atmosphère d'azote.

L'étalonnage de la chaine de mesure était vérifié quotidiennement à l'aide des solutions tampons étalons de Bates: biphtalate de potassium 0.05 M (pH = 4.005) et borax 0.05 M (pH = 9.196). La correspondance entre le pH lu et la concentration analytique des protons a été également établie pour chaque cas.

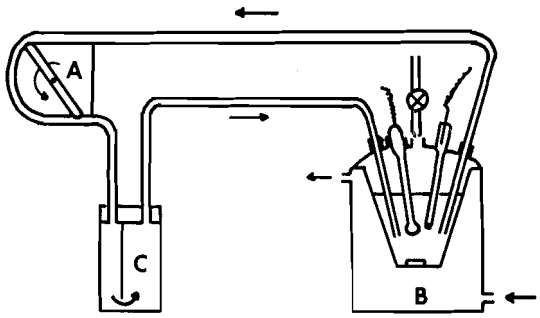

FIG. 10. Schéma de l'appareillage: (*A*) pompe péristaltique; (*B*) cellule potentiométrique; (*C*) cellule spectrophotométrique.

Spectrophotométrie

Le principe de nos déterminations spectrophotométriques consiste à mesurer simultanément avec le p*H*, au cours d'une neutralisation progressive par une base, l'absorption lumineuse de solutions contenant les différents constituants du système. Grâce à une pompe péristaltique (A) la solution circule en permanence de la cellule "potentiométrique" RMO6 Tacussel thermostatée (B) à la cellule "spectrophotométrique" (C) qui est une cuve à circulation (Fig. 10). Nous enregistrons ainsi grâce à un spectrophotomètre Beckman DK 2 A les spectres d'absorption de la solution pour différentes valeurs du p*H*, à différentes longueurs d'onde.

Conclusions

La confrontation de la technique exposée, avec d'autres méthodes spectrophotométriques classiques, et nous pensons particulièrement à la méthode des variations continues et ses extensions (méthodes de Vosburgh et Cooper, de Bent et French, du rapport moléculaire de Yoe et Jones etc...) nous incite à reconnaitre la trichromie complémentaire comme une investigation préliminaire à une étude spectrophotométrique, puisqu'aucune indication sur la stoechiométrie des espèces formées ne peut-être recherchée. Il n'en demeure pas moins, que nous avons démontré, au cours de ce travail, l'intérêt de la spectrophotométrie trichrome, pour la mise en évidence rapide de la formation de complexes colorés simples et mixtes, de leurs domaines d'existence et du nombre d'espèces en solution en fonction du p*H*.

Nous avons volontairement limité cette étude à un aspect purement qualitatif, l'expérience ayant montré qu'une étude quantitative précise des phénomènes de complexation doit être effectuée par des méthodes plus fines, telles que la potentiométrie (ou la polarimétrie dans le cas de coordinats optiquement actifs), méthodes que nous avons employées largement pour l'étude des systèmes envisagés ici (8, 12–14).

C'est d'ailleurs dans le but de tester la valeur des résultats de la méthode trichrome que nous avons étudié des systèmes dont nous avions déterminé antérieurement les constantes de stabilité ionique ce qui nous permettait de calculer les courbes de répartition des différentes espèces en fonction du p*H*. Cette distribution a pu être confirmée dans tous les cas par les résultats de la méthode trichrome qui apparait donc comme une méthode graphique extrêmement simple à mettre en œuvre et donnant des résultats concordant parfaitement avec ceux obtenus par des méthodes expérimentales et mathématiques beaucoup plus fastidieuses (détermination des constantes de stabilité et calcul des courbes de répartition des espèces).

Les limites de la méthode apparaissent dans quelques cas particuliers (existence de deux espèces ayant le même coefficient d'extinction moléculaire ou existence simultanée d'espèces colorées et incolores).

D'autre part la précision obtenue peut être améliorée, notamment par l'emploi de la méthode d'ordonnée pondérée (4) qui s'est montrée supérieure à la méthode des ordonnées selectionnées que nous avons employée pour le calcul des paramètres *u,v,w*. De plus un traitement des données sur ordinateur peut permettre l'automatisation de l'acquisition des coordonnées trichromes (18).

Cependant le processus que nous avons utilisé, présente un tel caractère de simplicité, que la méthode est extrêmement avantageuse pour une première approche d'un système inconnu et beaucoup plus rapide que les méthodes graphiques de Coleman, Varga, et Mastin (19) ou du rang de la matrice de Hugus et El-Awady (20) impliquant l'étude de nombreuses solutions et un traitement mathématique relativement long.

Néanmoins, nous insistons tout particulièrement sur le fait que toutes ces méthodes fournissent essentiellement des renseignements qualitatifs: l'existence et la formule des complexes dans certaines conditions seulement. La résolution précise et complète d'un système nécessite, en outre, qu'une telle étude soit complétée par des mesures quantitatives au moyen des méthodes classiques de la chimie de coordination.

Received December 7, 1972

The simultaneous interaction of solvated electrons with strongly solvating water molecules and weakly solvating dimethylsulfoxide (DMSO) molecules has been studied by pulse radiolysis. In all DMSO/H_2O mixtures investigated the solvated electrons have a single absorption band with a maximum intermediate between that of pure DMSO ($\lambda_{max} > 1500$ nm) and that of water ($\lambda_{max} = 720$ nm). There is a nearly linear relationship between the photon energy of λ_{max} and the bulk dielectric constant, indicating that the optical properties of solvated electrons in the mixtures are not dominated by the water. A minimum is observed in the variation of $G\varepsilon_{max}$ with DMSO/H_2O composition which may be associated with intermolecular structure. In mixtures containing >0.2 mole fraction DMSO the solvated electrons have half-lives of 11–18 ns.

The radiation produced oxidizing species in DMSO has a half-life of 1–4 μs and an absorption band centered at 600 nm. This species seems to be present in all DMSO/H_2O mixtures.

Pure DMSO gives a free-ion yield in the range 1.2 to 1.8, as determined separately for the oxidizing and reducing species by bromide and anthracene scavenging experiments respectively. This free-ion yield is in keeping with the dielectric constant of DMSO of 46. The yields in fully deuterated DMSO are ~30% higher than in the protonated material.

L'interaction simultanée des électrons solvatés sur des molécules d'eau fortement solvatantes et des molécules de diméthylsulfoxyde (DMSO) faiblement solvatantes a été étudiée par radiolyse pulsée. Dans tous les mélanges DMSO/H_2O étudiés, les électrons solvatés ont une bande d'absorption simple dont le maximum se situe entre celui du DMSO pur ($\lambda_{max} > 1500$ nm) et celui de l'eau ($\lambda_{max} = 720$ nm). Une relation presque linéaire existe entre l'énergie du photon du λ_{max} et la constante diélectrique du mélange, montrant ainsi que les propriétés optiques des électrons solvatés dans ces mélanges ne sont pas masquées par l'eau. On a observé un minimum dans la variation de $G\varepsilon_{max}$ avec la composition DMSO/H_2O, ce fait peut être associé à une structure intermoléculaire. Dans les mélanges > 0.2 en fractions molaire de DMSO, les électrons solvatés ont des demi-vies de 11–18 ns. L'espèce oxydante produite par la radiation dans le DMSO a une demi-vie de 1–4 μs et une bande d'absorption centrée à 600 nm. Cette espèce semble être présente dans tous les mélanges DMSO/H_2O. Le DMSO pur donne un rendement en ion libre de 1.2 à 1.8, déterminé séparément sur l'espèce oxydante et réductrice par les expériences de piégeage par le bromure et l'anthracène respectivement. Ce rendement en ion libre est en accord avec la constante diélectrique du DMSO de 46. Les rendements dans le DMSO totalement deutérié sont de ~30% plus élevés que pour le DMSO protoné. Introduction

We have previously shown that the solvated electron (e_s^-) in dimethylsulfoxide (DMSO) is very weakly trapped, as evidenced by an absorption band in the near i.r. similar to that found in hydrocarbons (1). This was attributed to the strictly aprotic nature of DMSO which permits solvation of negative ions only through weak ion–dipole interactions. On the other hand, DMSO has a high dielectric constant ($D_s = 46$ at 25 °C), a large dipole moment (4.3 D), and readily solvates positive ions. The free-ion yield of reducing species was measured by the use of N_2O at 0.08 M to be 1.8 ± 0.2 (2). Anthracene (A) has been used as an electron scavenger in pulse radiolysis studies by Koulkes-Pujo *et al.* (3) and Hayon (4) to give yields of $G(A^-)$ of 0.64 and 1.62 respectively. These results will be discussed later in relation to our data using A as an electron scavenger and Br^- as a scavenger for the oxidizing species.

The nature of solvated electrons in many media is being actively investigated. The absorption spectra, and yields, of electrons solvated in binary mixtures of solvents are of interest, particularly when the extent and mode of

solvation by the individual solvents differ markedly. Hydrocarbon–alcohol mixtures have been studied in this regard (5–8) but these mixtures are inhomogeneous (9) and clusters of the polar solvent can act as trapping centers for electrons which would otherwise have been lost through geminate recombination. A related effect was noted in formamide/water mixtures where only hydrated electrons were observed. Since in formamide itself no solvated electrons could be detected and were presumed to react rapidly, aggregates of water molecules seemed to simply provide trapping sites (10).

DMSO appears to be an interesting hydrocarbon-like solvent for studying binary mixtures with water because it possesses a high dielectric constant, with a concomitant fairly large free-ion yield, and it is completely miscible with water; in fact DMSO/H_2O mixtures show more intermolecular structure than do the pure liquids (11–16).

Our study on DMSO/H_2O mixtures provides information on the solvated electron and on the fate of the oxidizing species in binary mixtures. We also report measurements on the free-ion yield in pure DMSO.

Experimental

Absorption spectra of transient species were measured by pulse radiolysis methods using 6, 10, 40, or 300 ns pulses (typically 0.4, 0.5, 2, and 5 krad, respectively) of 35 MeV electrons from the linac at the National Research Council of Canada. For the wavelength range below 450 nm a photomultiplier (XP1003) was used as the analyzing light detector, for the range 450–1000 nm a Si photodiode (HP-4207 or EG&G YAG-100) and for the range 750–1500 nm a Ge photodiode (Philco Ford L-4521) was used. Small variations in dose from pulse to pulse were monitored by a secondary emission chamber, or the data were normalized by using the split light-beam detection technique.

In pure DMSO the half-life of the solvated electron was 14 ± 1 ns in agreement with our earlier report (1). In most of the DMSO/H_2O mixtures studied the decay was even faster than in pure DMSO and invariably first order. The solvated electron spectra were usually obtained from the maximum absorption observed when using a 40 ns pulse. However, too much decay of the electron occurs during a 40 ns pulse to permit the determination of $G\varepsilon$. The following method was used to determine $G\varepsilon$ at 1000 nm while $G\varepsilon$ at the other wavelengths were calculated from $G\varepsilon_{1000}$ and the spectra determined with 40 ns pulses. Electron pulses of nominally 6 ns width at half-height were used. The whole detection system had a rise-time of ~4 ns and consisted of a Si photodiode (HP-4207), a 110 MHz pulse amplifier (Keithley 105) and 500 MHz oscilloscope (Tektronix 7904 with 7A19 amplifier). A small component of the response of the HP-4207 has a rise time of μs (see next paragraph). This characteristic of photodiodes has been discussed by Seddon *et al.* (17). We established that this small slow component does not lead to significant errors in kinetic measurements over the first few tens of ns by observing the fast response of the detection system to the Cerenkov emission produced by the irradiation pulse from a piece of Suprasil backed by a mirror at the proper angle to send Cerenkov light through our lens system. The displayed Cerenkov signal reached its maximum 7.5 ns after the start of the pulse, fell to 5% of its maximum 14 ns after the start and to 1% of its maximum 19 ns after the start of the pulse. The pulse, measured in this way, was 8 ns wide at half-maximum. The transient absorptions due to e_s^- in DMSO and water mixtures containing 0.93, 0.72, 0.43, 0.28, and 0.20 mole fraction DMSO were measured at 1000 nm using this fast detection system. The wavelength was set by an interference filter centered at 1000 nm and having a 100 nm bandpass. The maximum absorbance due to e_s^- in DMSO and its water mixtures occurred close to 10 ns after the start of the pulse. The half-life of e_s^- in each solution was determined from a plot of the first order decay. Figure 1 shows the transient absorption due to e_s^- in pure DMSO and the first order plot of the decay. A close approximation to the absorbance corresponding to all the e_s^- produced in a pulse was obtained by extrapolating the decay plot back to mid-pulse (7 ns) as shown in Fig. 1. For all solutions the

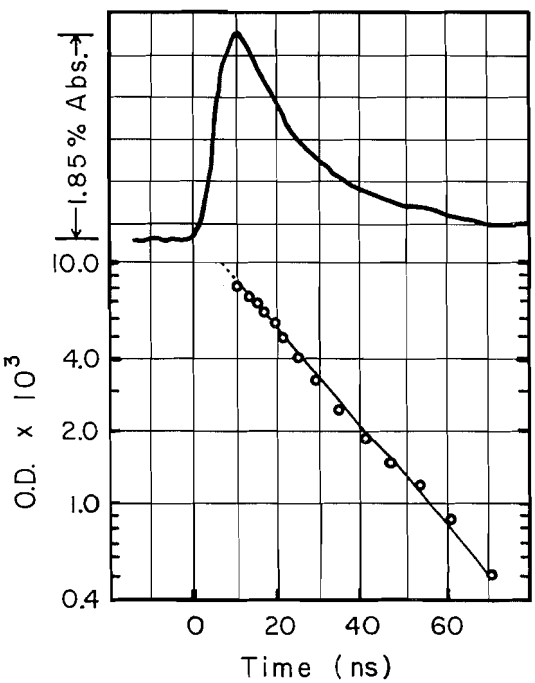

FIG. 1. A copy of the oscilloscope trace of the absorption at 1000 nm due to the e_s^- in DMSO produced by a 6 ns pulse. The sensitivity is 100 mV/div and the sweep speed 10 ns/div. The decay of the absorbance is shown below the trace and the first order line is extrapolated back to mid-pulse.

extrapolation was small, with O.D.(mid-pulse)/O.D.(max) falling between 1.12 and 1.23. The value of the optical density extrapolated to mid-pulse was used to calculate $G\varepsilon$ at 1000 nm for each solution.

Dosimetry was done with 5×10^{-3} *M* KSCN solutions saturated with N_2O, for which $G\varepsilon_{500}((CNS)_2^-) = 4.2 \times 10^4\ M^{-1}\ cm^{-1}\ (100\ eV)^{-1}$ (18). A potential source of error in measuring $G\varepsilon_{1000}(e_s^-)$ arises from the small component of the HP-4207 response which is slow. We compared the responses of the HP-4207 Si photodiode and the XP 1003 photomultiplier to the absorption due to e_{aq}^- at 715 nm produced by 6 ns pulses under conditions such that the $t_{1/2}$ of e_{aq}^- was 50 μs. Based on the assumption that the photomultiplier response is accurate, the HP-4207 photodiode responded to 86 ± 2% of the absorption at 10 ns, 88 ± 2% at 100 ns and > 99% at 3 μs. To cancel out this potential error, the absorption due to $(CNS)_2^-$ was also measured at short times (100 ns after the pulse) in doing dosimetry for the short-lived e_s^-. This source of error did not exist in measurements made with the EG&G Si photodiode because this detector did not exhibit a slower second component of response, though its initial rise was somewhat slower than that of the HP-4207.

The water was doubly distilled and the vapor, mixed with oxygen, passed through a quartz tube at 750 °C to oxidize organic impurities. Solutions were deaerated by bubbling with pure argon. The solvated electron absorption and decay rates were found to be essentially independent of the method of purification of the DMSO (1). Other chemicals were reagent grade or better.

Results and Discussion

(a) Spectra of Solvated Electrons and an Oxidizing Species in Pure DMSO and Fully Deuterated DMSO

In agreement with previous reports (1, 3) the absorption spectrum of transient species produced in the radiolysis of pure liquid DMSO at room temperature consists of three principal bands. These can be attributed to different species because of their distinct decay characteristics. The bands are: (*i*) a broad absorption stretching into the i.r. with $\lambda_{max} > 1500$ nm with half-life 14 ± 1 ns which we attribute to the solvated electron; (*ii*) a fairly broad band centered at 600 nm attributed to an oxidizing species (either solvent cations or their decomposition products and designated as Ox) whose half-life is 1–4 μs; and (*iii*) absorption bands progressing from 600 nm into the u.v. which arise from at least two species possessing half-lives of ~10 μs and >100 μs.

Figure 2 shows the electron band ($\lambda_{max} > 1500$ nm) and the absorption due primarily to Ox obtained in pure $(CH_3)_2SO$ and pure $(CD_3)_2SO$. The latter absorption, in $(CH_3)_2SO$, consists mainly of a band, due to Ox, with $\lambda_{max} = 600$ nm and $t_{1/2} = 1.6$ μs and a band with $\lambda_{max} < 400$ nm and $t_{1/2} \sim 10$ μs. The initial absorbance was deduced by extrapolation to the end of the pulse from times when the electron band had fully decayed. The spectrum which we attribute to Ox is shown in Fig. 3 as spectrum 2. This was obtained by subtracting from the initial absorption (spectrum 1, Fig. 3) an amount equivalent to a component with $t_{1/2} = 10$ μs. The band centered at 600 nm decays in a first-order manner with half-lives which varied between 1.6 and 4.1 μs on different days. The reason for this variation is not known. However, $G\varepsilon_{max}$ for spectrum 1 of Fig. 3 varied by only ±12% despite the large variation in half-lives.

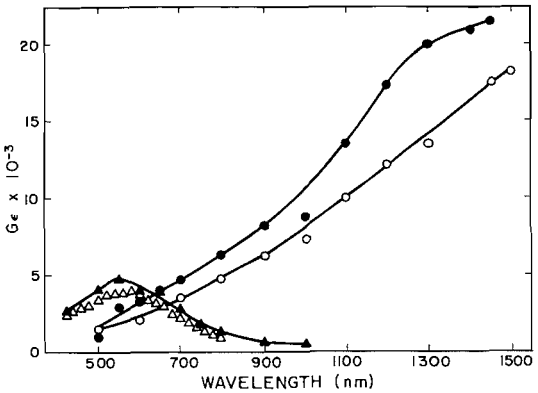

FIG. 2. Transient spectra observed in pure $(CH_3)_2SO$ and pure $(CD_3)_2SO$. Circles represent the initial absorption by solvated electrons only. Triangles refer to the initial absorption which is not due to solvated electrons. ○ and △ are for $(CH_3)_2SO$, ● and ▲ are for $(CD_3)_2SO$.

With short pulses no absorption at all could be detected at $\lambda > 1600$ nm using the Ge detector. This arises from the fact that the Ge detector becomes too slow and inefficient beyond that wavelength (19, 20) to measure the small short-lived absorption due to e_s in this system. However, observations of the steady state absorption during a long radiation pulse (>1 μs) with slower i.r. detectors indicates that the maximum extinction coefficient for the electron band occurs between 1600 and 1800 nm and that $G\varepsilon_{max}$ is <25% larger than $G\varepsilon$ at 1500 nm (1).[2]

Reasons for assigning the broad absorption band with $\lambda_{max} > 1500$ nm to the solvated electron in DMSO include the following: (*i*) its shape, intensity, and position resemble that found in irradiated glassy hydrocarbon com-

[2]Private communication from Dr. E. A. Shaede.

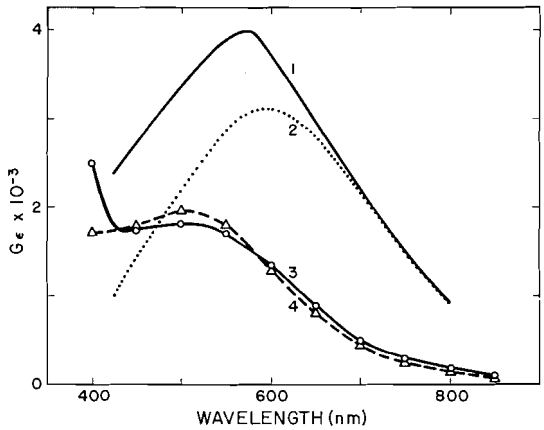

FIG. 3. Curve 1 (same as △ in Fig. 2) is the initial absorption in pure DMSO corrected for absorption by the solvated electron. Curve 2 is the spectrum of the oxidizing species ($t_{1/2}$ = 1.6 μs) in pure DMSO. Curve 2 was obtained by subtracting from Curve 1 an amount equivalent to a component with $t_{1/2}$ = 10 μs. Curve 3 is the initial absorption in 0.2 mole fraction DMSO corrected for absorption due to the solvated electron. Curve 4 is the absorption in 0.2 mole fraction DMSO 0.7 μs after the pulse. In each case a 300 ns, 5 krad pulse was used.

pounds and attributed to trapped electrons; (*ii*) it is eliminated by the presence of known electron scavengers such as Ag^+, N_2O, anthracene, CCl_4, and H^+; (*iii*) it is unaffected by the presence of added Br^-, or small amounts of water; (*iv*) the equivalent increase in both bands shown in Fig. 2 on using deuterated DMSO suggests that the species responsible have a common origin, such as the primary ionization event, and participate in common reactions, such as neutralization.

Substantial evidence for the assignment of the band centered at 600 nm to the primary or secondary oxidizing species formed concurrently with e_s^- includes the following: (*i*) in the presence of Br^- the 600 nm band was eliminated and replaced by the Br_2^- absorption band, (*ii*) high concentrations of efficient electron scavengers which may interrupt geminate ion neutralization increased the 600 nm absorption (*e.g.* 0.5 *M* Ag^+ increased it by ~90%), (*iii*) the absorption is not diminished by the electron scavengers N_2O, anthracene, H^+, and Ag^+, (*iv*) substituting with deuterated DMSO causes the same change as for the electron band indicating a common origin for the two species. Herring and McLean (21) have indicated that the energy separation between the first adiabatic and second vertical ionization potentials in the photoelectron spectrum of a molecule may be equated with the optical absorption band of a cation, in some cases. This energy gap is only 1.4 eV for DMSO (22), which would correspond to a band at ~900 nm for $DMSO^+$ if the ground and first excited states of $DMSO^+$ have similar geometries and comparable solvation energies in liquid DMSO. It is worth noting that in the photoelectron spectrum of $(CH_3)_2S$ the analogous energy level separation is 2.6 eV (22) which corresponds to 480 nm.

Figure 2 shows that $G\varepsilon$ is ~30% larger in the case of the deuterated material for both of these absorption bands. This implies that the 30% difference arises from a change in G rather than ε. Thus, as in water (23, 24), the fraction of ions which become free-ions is substantially larger for the deuterated compound. This is not readily explained in terms of models of geminate recombination based just on bulk dielectric constants, but rather is consistent with a wider *initial* distribution of solvated electrons. This could stem from either (or both) the thermalization and solvation processes. In media of high dielectric constant the material containing the heavier isotope may be less efficient in scattering epithermal electrons, and its longer dielectric relaxation time may result in a more sluggish solvating process.

(*b*) *Free-Ion Yields in Pure DMSO*

(i) Solvated Electrons

Figure 4 shows the values of $G\varepsilon$ at 750 nm for the anthracene negative ion (A^-) resulting from reaction 1 at four concentrations up to

$$[1] \qquad e_s^- + A \rightarrow A^-$$

the solubility limit of anthracene in DMSO. We determined the spectrum of A^- in DMSO and find λ_{max} = 740 nm which can be compared to the λ_{max} ~ 725 nm found in acetonitrile (4). The data points shown in Fig. 4 for A^- at 750 nm have already been corrected for absorption due to the oxidizing species at 750 nm (by measuring the absorption of the latter at 550 nm for each anthracene solution and applying corrections given by the ratio of $\varepsilon_{750}/\varepsilon_{550}$ for the oxidizing species) and likewise for the solvated electron (whose absorbance was monitored at 1275 nm in order to apply the appropriate correction at 750 nm for each concentra-

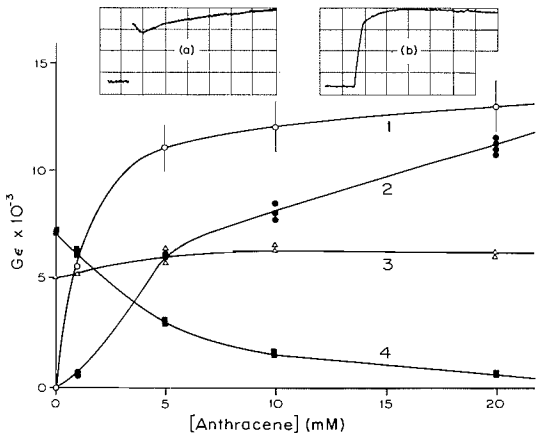

FIG. 4. Graph showing the scavenging of solvated electrons in pure DMSO by anthracene and the formation of anthracene ions. The pulse width was 40 ns. Curve 1: Maximum value of $G\varepsilon$ at 750 nm due to A^-; Curve 2: $G\varepsilon$ at 750 nm due to A^- immediately at the end of the pulse; Curve 3: $G\varepsilon$ at 550 nm due largely to the oxidizing species as observed 100 to 200 nsec after the pulse; Curve 4: $G\varepsilon$ due to solvated electrons at 1250 nm as observed from the maximum absorption during the pulse (not corrected for decay during the pulse nor for detector response time). Insets: (*a*) Oscilloscope trace at 750 nm with 10^{-3} *M* anthracene present. (Vertical scale 1 mV/div, horizontal 200 ns/div.) (*b*) Oscilloscope trace at 750 nm with 10^{-2} *M* anthracene present. (Vertical scale 2 mV/div, horizontal 100 ns/div.)

tion). Typical oscilloscope traces for the absorption at 750 nm in 10^{-3} and 10^{-2} *M* solutions of anthracene in DMSO are shown as insets in Fig. 4. At the lower concentration (inset *a*) the contribution made by the short-lived e_s^- is readily seen. In both traces the contribution from the oxidizing species decreases only slightly over the time period shown since its half-life is about 2 μs.

At all concentrations of anthracene the absorbance due to A^- consists of two components, one of which builds in during the pulse and is larger at the higher concentrations, and another which grows in after the pulse and whose rate of growth increases with [A]. These effects can be recognized by comparison of the traces shown as insets. Figure 4 shows how the immediate $G\varepsilon$ (curve 2) and the maximum $G\varepsilon$ observed after the pulse (curve 1) change with concentration. It should be noted that the latter increases much more rapidly with concentration than the immediate absorption and that the slow component builds in at a much slower rate than the electron decay (as seen by the insets). This suggests that anthracene scavenges the anionic product resulting from reaction of the solvated electron with the solvent, as well as either the solvated electron or its precursor or both.

The effect of anthracene on the yields of oxidizing species and electrons, as measured by the absorptions at 550 and 1250 nm, respectively, are also shown as a function of [A] in Fig. 4. In the work of Hayon (4) and Koulkes-Pujo *et al.* (3) anthracene was used at 5×10^{-3} *M*. It can be seen that at this concentration A reduced the observed yield of e_s^- to $\sim\frac{1}{2}$ its yield in the pure system but that the anthracene then scavenged the decay product of most of these unscavenged electrons. At 2×10^{-2} *M* the observed solvated electron yield was reduced to about 10% but the total yield of A^- was not much higher than at 5×10^{-3} *M*. We suggest that the total yield of A^- at 5×10^{-3} *M* anthracene approximates the free electron yield. It is possible that the small increase in absorbance at 550 nm caused by the addition of anthracene is due to absorption by A^-. By assuming that the extinction coefficient (ε) of A^- at its λ_{max} of 740 nm = $0.99 \times 10^4\ M^{-1}\,cm^{-1}$ (4) we derive from our spectrum of A^- that $\varepsilon = 0.96 \times 10^4\ M^{-1}\,cm^{-1}$ at 750 nm. With this value we calculate $G(A^-)$ at 5×10^{-3} *M* anthracene to be 1.2 ± 0.15. This is very close to $G(N_2)$ from N_2O solutions at $[N_2O] \sim 2 \times 10^{-2}$ *M* but lower than the limiting yield (2). Hayon's value of 1.62 (4) is somewhat larger than this but possibly was not corrected for the significant absorbance by the oxidizing species at the wavelength used to determine $G(A^-)$. The much lower yield of Koulkes-Pujo *et al.* of 0.64 (3) is more difficult to reconcile with ours unless the solvent anions (or whatever is formed from the reaction of e_s^- with DMSO) are consumed by the products from the positive ions prior to their being scavenged by A in their system at 5×10^{-3} *M* in A. It must be noted that in their study the dose per pulse was $\sim 10^2$ times higher and the species responsible for their 625 band decayed according to second order kinetics. Their value of 0.64 may then be equivalent to $G(A^-)$ formed immediately in our system. Bensasson and Land (25) have recently reported a value of ~ 1.4 using biphenyl as an electron scavenger at 10^{-2} *M* and noted that this increases to 1.8 at 10^{-1} *M* biphenyl. Assuming a free-ion yield of 1.2 we calculate ε for e_s^- to be $15\,000\ M^{-1}\,cm^{-1}$

at 1500 nm in pure DMSO, and the indications are that ε_{max} does not exceed this by more than 25%.[2]

(ii) Oxidizing Species

In the presence of 10^{-2} *M* KBr the electron band was unaffected, but the band at 600 nm was eliminated and a new absorption band centered at 375 nm was produced. The 375 nm band is attributed to Br_2^- by analogy with aqueous systems (26). It presumably arises in a two-step process involving the oxidizing species ($DMSO^+$ or its decay product) by way of an intermediate which could be a simple charge-transfer complex as in reaction sequence [2].

$$[2] \quad Ox + Br^- \rightarrow [Br \leftarrow Ox]^- \xrightarrow{Br^-} Br_2^- + Ox^-$$

The spectrum obtained in the bromide solutions is shown in Fig. 5 and is similar to that reported previously (3). At $[Br^-] > 10^{-2}$ *M* the 600 nm band was totally eliminated, thereby indicating complete scavenging of the oxidizing species responsible for that absorption. The inset of Fig. 5 shows the concentration dependence of the 375 nm absorption on a semi-log plot.

A concentration independent value of $G\varepsilon = (1.5 \pm 0.1) \times 10^4$ was obtained with $[Br^-] > 10^{-2}$ and is identical to that reported by Koulkes-Pujo *et al.* (3). If we assume that ε_{max} for Br_2^- in DMSO is the same as the recently reported value for Br_2^- in H_2O, namely $1.2 \times 10^4\ M^{-1}\ cm^{-1}$ (26), then $G(Br_2^-) = 1.3 \pm 0.15$. This value is approximately equal to the yield of A^- at 5×10^{-3} *M* anthracene and would suggest that the free-ion yield in DMSO is 1.3 ± 0.15, as measured for both oxidizing and reducing species at scavenger concentrations of $\sim 10^{-2}$ *M*. However, the value for $\varepsilon_{max}(Br_2^-)$ in water at 360 nm is also reported to be $\sim 0.83 \times 10^4\ M^{-1}\ cm^{-1}$ (27–29) from which one calculates $G(Br_2^-) = 1.8 \pm 0.2$ in DMSO. This yield is in line with the N_2 yield from N_2O solutions (2) at high $[N_2O]$ and the biphenylide yield (25) at high [biphenyl], and also with the value obtained by Kemp *et al.* (30) for $TMPD^+$ ions in DMSO solutions of tetramethylphenylenediamine (TMPD). Uncertainties in the extinction coefficients of A^- and Br_2^- and in the concentration range where geminate scavenging becomes significant enable us to conclude only that the free-ion yield for pure DMSO lies in the range 1.2 to 1.8. This range fits an empirical correlation between free-ion yield and dielectric constant for a wide range of solvents (4, 31).

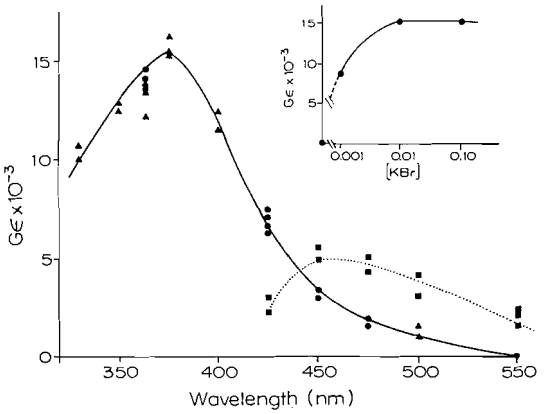

FIG. 5. Absorption spectra for KBr solutions in DMSO. Solid curve refers to Br_2^- spectra; dotted curve refers to transient precursor of Br_2^-. ▲, Br_2^- from 0.1 *M* KBr solution; ●, Br_2^- from 0.01 *M* KBr solution; ■, transient precursor of Br_2^- at 0.01 *M* KBr. Inset: Plot of $G\varepsilon$ at 375 nm for Br_2^- *vs.* [KBr].

The mechanism by which Br_2^- appears to be formed in DMSO can be compared with the analogous reaction in water (26, 29). From the oscilloscope traces for 10^{-2} or 10^{-3} *M* Br^- in DMSO it was evident that the absorption at 375 nm did not build in during the pulse. Furthermore, we seem to have observed an intermediate species formed as a precursor to Br_2^- with an absorption band centered at 450–500 nm. This could readily be distinguished from the 600 nm band because its absorption was almost zero at 650 nm in a 10^{-3} *M* Br^- solution and it decayed with a half-life of ~ 0.8 μs. The latter rate was approximately the same rate with which the Br_2^- absorption at 375 nm built in at this Br^- concentration. At 10^{-2} *M* Br^- both rates were much faster. Thus the transient absorption band, which is shown in Fig. 5, is attributed to an intermediate in reaction 2, perhaps the charge-transfer complex indicated above. An approximate relationship has been found between $h\nu_{max}$ and ionization potential for Br atom charge-transfer complexes with several hydrocarbons and brominated hydrocarbons (32), and the λ_{max} which would be predicted by applying this correlation for the Br atom charge-transfer complex in DMSO (I.P. of DMSO = 8.85 eV (33) is ~590 nm. However, there seems to be no good reason for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

this relationship to be followed by donor molecules which are as dissimilar as DMSO is to hydrocarbons and brominated hydrocarbons (34). In addition, the complex in reaction 2 may have a negative charge because Ox could be uncharged, so the above-mentioned relationship may be totally irrelevant to this case.

Since 10^{-3} *M* Br^- produces Br_2^- from only about half the free oxidizing species (see inset of Fig. 5), the intermediate of reaction 2 must have an alternative fate besides reaction with Br^-. This other process could be reaction with DMSO.

Absorption due to the 400–500 nm intermediate is fully developed at the end of the 40 ns pulse even in 0.001 *M* KBr, which suggests that $t_{1/2}$ for the oxidizing species is $\leqslant 5 \times 10^{-11}$ s in 0.1 *M* KBr. One might expect species undergoing geminate combination to be scavenged on this time-scale, and therefore the yield of e_s^- should increase; however no increase was observed. This implies that the electron can undergo a spur reaction with the intermediate with the same efficiency with which it reacts with the oxidizing species of DMSO.

(*c*) *Solvated Electrons in DMSO/H_2O Mixtures*

For DMSO/H_2O mixtures two easily resolvable absorption bands are observed for wavelengths >400 nm. One corresponds to the oxidizing species with a maximum at ~600 nm and is comparatively long-lived ($t_{1/2}$ 1 to 4 μs). The other is very short-lived and is attributed to solvated electrons. Figure 6 shows the spectra for the latter species in mixtures consisting of 0, 0.20, 0.28, 0.43, 0.72, 0.93, and 1.0 mole fraction DMSO. Only a single absorption band is obtained for the solvated electron in each mixture. These spectra have been corrected for absorption by the band centered at 600 nm. In the case of pure water the observed solvated electron band corresponds quite closely to the published spectrum of e_{aq}^-, with $G\varepsilon = 4.3 \times 10^4$ molecule $(100\ eV)^{-1}$ M^{-1} cm^{-1} at 720 nm (35).

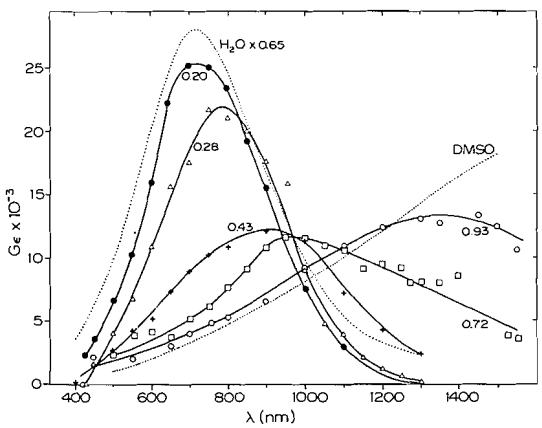

FIG. 6. Absorption spectra of solvated electrons in DMSO/H_2O mixtures; 0, 0.20, 0.28, 0.43, 0.72, 0.93, and 1.0 mole fraction DMSO. The data for pure water have been multiplied by a factor of 0.65 relative to the others. These spectra represent the short-lived solvated electron band only, the longer lived 600 nm band and u.v. bands having been subtracted from the observed absorbances.

(*i*) *Lifetimes of e_s^-*

By following the decay of the absorption at 1000 nm (where the 600 nm band absorption is negligible for all mixtures) after 6 ns pulses it was established that the decay of e_s^- invariably followed first-order kinetics for DMSO/H_2O mixtures (*e.g.* see Fig. 1). Thus the solvated electron appears to decay by reaction with DMSO. The pseudo first-order rate constants obtained are indicated in Table 1 as half-lives (column 6), together with the observed λ_{max}, the width-at-half-height (ΔW), and $G\varepsilon_{max}$ for each mixture. A second-order rate constant was calculated for each mixture from the observed first-order decay rate combined with the bulk concentration of DMSO. These calculated rates are given in column 7 of Table 1 and appear to go through a maximum between 0.43 and 0.20 mole fraction DMSO. At a mole fraction of 0.017 the rate constant is 2.9×10^6 M^{-1} s^{-1} but the rate constant seems to be decreasing as the concentration of DMSO decreases. Meissner *et al.* (36) reported a value of 1.7×10^6 M^{-1} s^{-1} for the reaction of e_s^- with DMSO in alkaline solutions of DMSO slightly more dilute than 0.017 mole fraction.

(*ii*) *Magnitude of $G\varepsilon_{max}$*

Figure 7*a* shows the magnitude of $G\varepsilon_{max}$ for each mixture as a function of composition. As these data have been compensated for decay during the pulse, the minimum in $G\varepsilon_{max}$ between 0.43 and 0.93 mole fraction DMSO apparently does not arise from the faster decay rate of e_s^-, rather both effects may result from the same properties of the solutions. It also seems unlikely that the minimum in $G\varepsilon_{max}$ arises from a minimum in ε_{max} alone and hence we presume that it largely represents the variation in the radiation yield. Our speculation that ε_{max} does

TABLE 1. Properties of solvated electrons in DMSO/H_2O mixtures

*Data taken from ref. 11.
†Calculated from the observed pseudo-first order rate constant and the bulk concentration of DMSO.

not vary in this manner is based simply on the near constancy of ΔW over the full range (Table 1) and the fact that our calculated value of ε_{max} for pure DMSO is quite comparable to ε_{max} for pure water. Therefore, it must be considered whether the minimum in $G\varepsilon_{max}$ between 0.4 and 0.9 mole fraction DMSO can be reasonably attributed to a minimum in $G(e_s^-)$. It is unlikely that a pronounced minimum in $G(e_s^-)$ could result from a marked decrease in the yield of ions escaping geminate recombination (free-ion yield). Firstly, as shown later, the free-ion yield of the concomitant oxidizing species does not show a similar minimum in these same mixtures. Secondly, the bulk dielectric constant for the mixtures changes monotonically with composition (no minimum) and varies only from 80 to 46 over the full range, and so ought not to lead to any pronounced minimum. Perhaps a minimum in $G(e_s^-)$ is the result of a decreased fraction of the free electrons which become solvated. The lifetime of e_s^- is shortest where $G\varepsilon_{max}$ shows the minimum, so that e_s^- reacts faster in the mixture than in pure DMSO. Conceivably, the precursor electron states might also be more reactive in the mixtures. On the other hand, it is possible to interpret a minimum in the fraction of free electrons which become solvated in terms of the structure of DMSO/H_2O mixtures. The yield of solvated electrons should depend on (*a*) the density of pre-existing cavities in the liquid that are suitable as trapping sites, and/or (*b*) the ease with which existing cavities can be modified under the influence of the electric field of the electrons so that they have the dimensions of suitable traps. Many studies of the structure of DMSO–water mixtures have been made (10–14), and the general conclusion

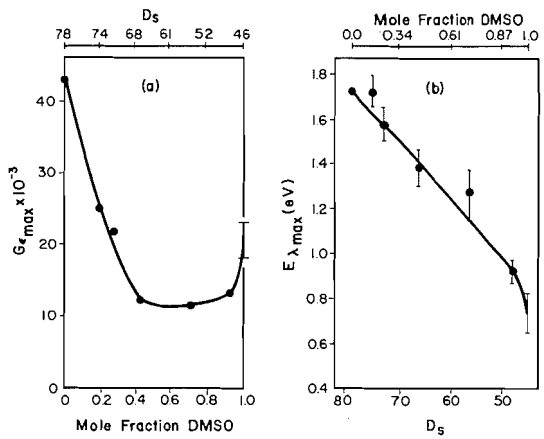

FIG. 7. (*a*) Values of $G\varepsilon_{max}$ for the solvated electron absorption bands (Fig. 6) plotted against the mole fraction DMSO for DMSO/H_2O mixtures. (*b*) Photon energy of the absorption band maxima for the solvated electron in DMSO/H_2O mixtures plotted against the bulk static dielectric constant (25 °C) of the mixture. Non-linear axes showing dielectric constant and mole fraction for (*a*) and (*b*) respectively are given as top abscissae.

drawn from density, viscosity, dielectric, and thermodynamic data is that 2:1, water:DMSO, association occurs to a considerable extent at room temperature. Further, a plot of the energy–volume coefficient, the energy required per unit volume to enlarge a cavity in the solvent, against mole fraction DMSO starts at a low value for pure water, rises quickly to a maximum in the region 25–35 mol% DMSO and then declines slowly as the DMSO is increased to 100% (16). Thus $G\varepsilon$ (and presumably G) and the inverse of the energy–volume coefficient change in a rather similar fashion with composition and this suggests that factor (*b*) above is important in

determining the probability of solvation of electrons in these mixtures. However, the concentration of voids might be a minimum around 33 mol% DMSO where the intersolvent bonding is greatest, so factor (*a*) could also be an important, or even the only, factor in determining solvated electron yields.

Bensasson and Land (25) have reported that in the range pure water to ~0.1 mole fraction DMSO the absorbance at 825 nm due to e_{aq}^- decreases in proportion to the energy directly deposited in the water. This led them to suggest that the decrease results because electrons formed in the DMSO do not lead to e_{aq}^-. Our observation that e_s^- in DMSO/H_2O mixtures have single absorption bands intermediate between that in pure water and that in pure DMSO leads us to the different conclusion that the absorption band at low DMSO concentrations, though very similar to that in water, is due to e_s^- and not simply to e_{aq}^-. Koulkes-Pujo *et al.* (37) have reported increasing values of (rate of decay of e_s^-)/$G(e_s^-)$ with increasing DMSO concentration up to 0.08 mole fraction DMSO. Their observation is consistent with an increased decay rate and/or a lower yield of e_s^- with increased concentration of DMSO.

(*iii*) *Variation of* λ_{max}

The λ_{max} of e_s^- in pure DMSO occurs at much longer wavelengths than it does in many other solvents with lower dielectric constants, for example alcohols (38). At the same time, a correlation between the photon energy at the absorption band maxima ($E_{\lambda max}$) and the measured bulk dielectric constants (D_s) of DMSO/H_2O mixtures may exist. The plot of $E_{\lambda max}$ *vs.* D_s in Fig. 7*b* shows that this plot is approximately linear, within experimental error, out to 0.9 mole fraction of DMSO. This suggests a regularly increasing cavity radius and charge delocalization with increasing DMSO content in the mixtures. In addition, the absorption band width-at-half-height (in energy units), ΔW, is fairly constant despite the widely different solvation energies provided by the two solvents separately. If only a small number of molecules were involved in the solvation shell one would expect an enhanced ΔW for mixtures of such dissimilar solvents (39).

In fact the results are somewhat surprising when it is noted that water solvates negative ions by strong hydrogen-bonding whereas DMSO can provide only very feeble solvation of anions through ion–dipole interactions. DMSO is strictly aprotic and should behave like a saturated hydrocarbon, albeit a highly polar one, towards negative ions; and yet, for solvated electrons, the data of Fig. 7*b* indicates that the optical properties of e_s^- in these mixtures are not dominated by the water. This is in sharp contrast to the situation reported for *n*-hexane/ethanol mixtures (6) (perhaps for the reasons mentioned in the Introduction and because of the change in local dielectric constant (40)) and somewhat at variance with the case of tetrahydrofuran/water mixtures (41), where the absorption bands are dominated by the hydroxylic component. It is much more analogous to mixtures of water with alcohols (38) or ammonia (41, 42), or ethylenediamine–tetrahydrofuran mixtures (41).

(*iv*) *Low Temperature Glasses*

Solvated electrons are not stable in pure DMSO and DMSO/H_2O mixtures even in rigid glasses at 77 °K. This was demonstrated using optical absorption spectroscopy during pulse radiolysis, as in the liquid phase experiments, and by e.s.r. studies on γ-irradiated glasses (43). Whereas a DMSO/H_2O glass at 77 °K showed absorption at 600 nm corresponding to a stabilized oxidizing species there was no detectable absorption attributable to a trapped electron lasting longer than ~1 μs. Furthermore, in extensive e.s.r. studies on crystalline DMSO and DMSO-d_6 and on glassy DMSO/H_2O mixtures at 77 °K, no trapped electron signal could be detected. Even when electrons were generated in the e.s.r. cavity by u.v. photolysis of $K_4Fe(CN)_6$ in DMSO/H_2O glasses at 77°K the electrons produced were not stabilized but underwent reaction to produce CH_3 radicals (43). In non-polar hydrocarbon glasses, electrons can readily be trapped and immobilized for long periods at low temperatures, so these effects in DMSO must be attributed to a process with a low activation energy by which the electron can interact with a DMSO molecule of the solvation shell.

(*d*) *The Oxidizing Species in DMSO/H_2O Mixtures*

The 600 nm absorption band which was observed in pure DMSO was also evident in all the DMSO/H_2O mixtures. The position of the

band was almost unaltered by changing the composition from 1.0 to 0.2 mole fraction DMSO. Only the magnitude of the absorbance changed progressively with composition. Furthermore the decay rate of the DMSO oxidizing species was largely unaffected by the composition.

For mixtures containing <0.3 mole fraction DMSO, other absorption bands in the range 400 to 600 nm were very evident. These had different decay characteristics and partly obscured the 600 nm band, thus making it difficult to obtain quantitative measurements of the 600 band in these predominantly aqueous mixtures. For instance, a separate and distinct absorption band with $\lambda_{max} \sim 500$ nm was observed. This 500 nm band grew in after the pulse and decayed more slowly than the 600 nm band. In a 0.2 mole fraction mixture the 500 nm band reached its maximum absorbance ~ 0.7 μs after the end of a 0.3 μs pulse and decayed with a half-life of ~ 12 μs; whereas, in a mixture consisting of 0.066 mole fraction DMSO, the maximum was not reached until ~ 2 μs after the pulse. Thus its formation rate decreased with decreasing DMSO content. The complex behavior in 0.2 mole fraction DMSO can be seen by examination of curves 3 and 4 of Fig. 3. Curve 3 is the spectrum of the initial absorption and curve 4 is the spectrum 0.7 μs later. For wavelengths below 425 nm the situation is also very complicated. For instance, at 400 nm the initial absorbance arises from at least three species with half-lives of approximately 1, 10, and >100 μs. Furthermore, the initial absorbance at 400 nm relative to that at 600 nm is much higher in the 0.2 mole fraction DMSO mixture than it is in pure DMSO. At wavelengths above 600 nm a large fraction of the absorption is due to the Ox band centered at 600 nm with $t_{1/2} = 2$ μs. However, because the 500 nm band overlaps the 600 nm band in dilute solutions the 600 nm band could only be monitored on its long wavelength tail. Thus the absorption was monitored at 715 nm in all mixtures and found to have a half-life for decay of 3 ± 1 μs. The decay rate varied somewhat with dose per pulse and with the total dose accumulated by the sample but not in a consistent or readily identifiable manner. Despite this variation in decay rate the relative values of $G\varepsilon$ of the different mixtures were reproducible.

This procedure, of having to use 715 nm to monitor the oxidizing species which has λ_{max} at 600 nm, was rather unsatisfactory because the band appears to get slightly narrower, or λ_{max} shifts to shorter wavelengths, with progressively increasing water content. Thus the ratio of absorbance at 715 nm to that at 600 nm gets smaller with decreasing DMSO fraction. Nevertheless, this was the only way to explore the yield of oxidizing species over the full composition range. Despite its shortcomings and these uncertainties in the quantitativeness of the data for low DMSO content there is quite interesting information to be gleaned from this study of the oxidizing species in a binary mixture.

The $G\varepsilon$ measured at 715 nm for 300 ns pulses in each DMSO/H_2O mixture is plotted against both mole fraction and electron fraction in Fig. 8. Since the electron fraction is approximately proportional to the dose absorbed by DMSO this latter plot would be a straight line if the yield were proportional to the dose absorbed by the DMSO molecules. For DMSO/H_2O mixtures one might predict an enhanced yield of free-cations of DMSO above the product of (G for the oxidizing species in pure DMSO) × (electron fraction DMSO) for two reasons. Firstly, because of its higher dielectric constant

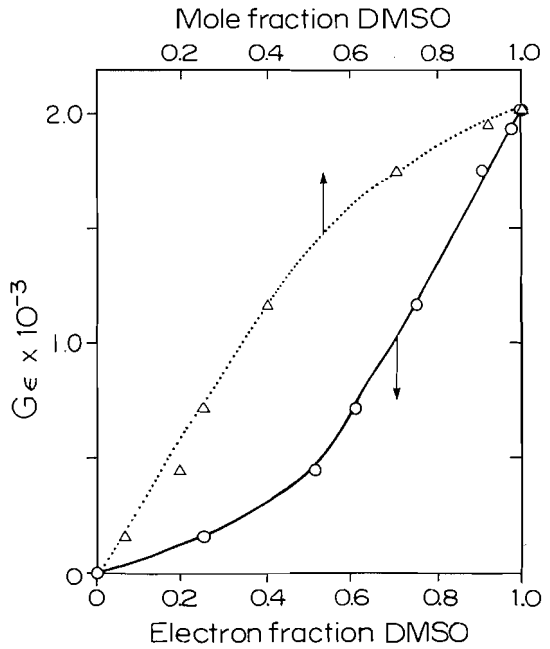

FIG. 8. Variation of $G\varepsilon$ at 715 nm due to the oxidizing species for DMSO/H_2O mixtures as a function of electron fraction DMSO and mole fraction DMSO.

the presence of water should decrease geminate recombination and hence increase the free-ion yield of electrons and solvent cations. In this regard, it was found that for a mixture consisting of 0.72 mole fraction DMSO the absorption at 600 nm was almost doubled when $\sim 0.5\ M$ Ag^+ was added to the mixture. Similar increases were found in pure DMSO and are believed to result from an enhanced free-ion yield arising from the capturing of electrons which were otherwise fated to geminate recombination. This enhancement arises both from the high concentration of Ag^+ and the fact that the product, Ag^0, is uncharged, thus interrupting geminate neutralization. On both these counts, the failure of anthracene to increase $G(Ox)$, as shown in Fig. 4, is understandable. Secondly, the ionization potential of DMSO is 8.85 eV (33) which is lower than that of H_2O (12.6 eV). Consequently, in the initial disbursement of energy deposition, if there were collective excitation processes leading to preferential ionization of the component of lower ionization potential, then the presence of water should have enhanced the effective yield of DMSO cations. Both these factors would cause the electron fraction plot in Fig. 8 to be convex upwards, whereas it is convex downwards. However, the data could acquire its observed form from a narrowing, or a shift to slightly shorter wavelengths, of the 600 nm band as the water content increased. This factor could dominate the variation of absorbance at 715 nm with composition. The curvature of the electron fraction plot (Fig. 8) corresponds in direction to the minimum in the $G\varepsilon$ of e_s^- (Fig. 7*a*) and could mean that the free-ion yield is less in mixtures where there is strong intermolecular bonding. However, this correspondence does not hold in detail because in solutions of $\geqslant 0.72$ mole fraction DMSO the yield of oxidizing species of DMSO is almost proportional to the dose deposited in DMSO molecules. In contrast the value of $G\varepsilon_{max}$ for e_s^- is close to its minimum at 0.72 mole fraction DMSO.

The most striking conclusion suggested by Fig. 8 is that there is no important charge-transfer, proton-exchange, or radical interactions between water and the DMSO oxidizing species or its precursor cation. The species responsible for the 600 nm band seems to be largely unaffected by any exchange of H_2O molecules for DMSO molecules in its immediate environment; because its formation, reaction half-life, and optical absorption properties are only altered slightly. (It should be noted that in the 0.5 electron fraction mixture there are 6.5 water molecules for every DMSO molecule.) In hydrocarbon media, various proton acceptors such as ammonia and ethanol (44, 45) have been used as efficient scavengers of the hydrocarbon positive ions. However, we must conclude that the oxidizing species of DMSO does not appear to undergo proton transfer to water. Thus, the proton-transfer or charge-exchange behavior of DMSO is quite different from that of the non-polar aprotic solvents. This is probably a reflection of the strongly dipolar character of DMSO and its facility to afford strong solvation to cations, comparable in fact to that provided by water.

We are most grateful to Dr. K. Lokan and Mr. G. Teather for assistance with the experimental procedures. Photochemistry of 2,4-Cyclooctadienone I.[1] In Benzene and Toluene[2]

GORDON L. LANGE AND ELI NEIDERT
Chemistry Department, University of Guelph, Guelph, Ontario
Received September 13, 1972

Irradiation of 2,4-cyclooctadienone (**1**) in benzene or toluene is shown to give in >80% yield two head-to-head dimers. The ring fusions are shown to occur at the α,β-positions of the dienone with *trans–cis* and *trans–anti-trans* stereochemistry. Both dimers may be epimerized to the same product with *cis–anti-cis* ring fusions. Evidence is presented to show that the singlet state is responsible for the *cis–trans* isomerization of **1** to the highly reactive intermediate *trans,cis*-2,4-cyclooctadienone. This intermediate can dimerize in a thermal 2 + 2 cycloaddition or can be generated at −78° and then trapped by 1,3-dienes in a Diels–Alder reaction. A mechanism for the dimerization reaction is discussed.

L'irradiation de la cyclooctadiène-2,4 one (**1**) dans le benzène ou le toluène conduit à deux dimères tête-tête avec un rendement >80%. Les fusions de cycle se produisent sur les positions α,β de la diénone avec la stéréochimie *trans–cis* et *trans–anti-trans*. Les deux dimères peuvent être épimérisés en un même produit avec des fusions de cycle *cis–anti-cis*. L'état singulet responsable de l'isomérisation *cis–trans* de **1** en un intermédiaire hautement réactif *trans–cis* cyclooctadiène-2,4 one, a été prouvé. Cet intermédiaire peut se dimériser selon une cycloaddition [2 + 2] thermique ou bien engendré à −78° puis piégé par des dienes-1,3 selon une réaction de Diels Alder. Un mécanisme pour la réaction de dimérisation a été discuté.
[Traduit par le journal]

Can. J. Chem., **51**, 2207 (1973)

Introduction

The photochemistry of unsaturated cyclooctanones has been the subject of a number of recent publications. Eaton and Lin reported (1) that upon u.v. irradiation, *cis*-2-cyclooctenone was isomerized to *trans*-2-cyclooctenone which either dimerized in a thermal cycloaddition or was trapped by a 1,3-diene in a Diels–Alder reaction. Paquette and Eizember (2) and Crandall *et al.* (2) irradiated 3-cyclooctenone and concluded that an initial Norrish type 1 cleavage was the primary photochemical process involved. Büchi and Burgess (3), and later Chapman and co-workers (3), examined the photochemistry of 2,4,6-cyclooctatrienone and reported that it cleaved to give a ketene intermediate and isomerized to the *trans,cis,cis*-trienone, which underwent a number of thermal reactions. The photochemistry of 2,6- (4, 5) and 2,7-cyclooctadienone (6) has also been reported.

Cantrell and Solomon discussed (4) the photochemistry of 2,4-cyclooctadienone (**1**) with ether, pentane, and methanol as solvents. They reported the isolation in 6–10% yield of a head-to-head, *cis–anti-cis* dimer (m.p. 174°) formed by a 2 + 2 cycloaddition at the α,β positions of two dienone molecules. In the present paper we report our results on the photochemistry of **1** in benzene and toluene. The conclusions differ in a number of important structural and mechanistic aspects from those reported previously (4). In the following paper the photochemistry of **1** in the solvent methanol is discussed.

Results and Discussion

Structure of Dimers

Irradiation of a 1% solution of 2,4-cyclooctadienone (**1**) in benzene using a 350 mμ u.v. source resulted in the rapid disappearance of starting material and the formation in high yield (85%) of a mixture of two dimers, which were readily separated by fractional crystallization from ethyl acetate. Dimer **2** (33%), m.p. 174.5–175.0°, was found to be identical (spectral properties, mixed m.p.) to that prepared and isolated as described previously (4). Dimer **3** (52%), m.p. 89–90°, had not been reported previously. The i.r. spectra indicate that the cycloadditions took place across the α,β-positions and although the n.m.r. spectra will not be discussed in detail they are entirely consistent with the structures to be proposed.

Treatment of either **2** or **3** with methanolic potassium hydroxide at room temperature for 50 h resulted in epimerization to the same dimer, **4**, m.p. 126–127°. Epimerization to this dimer (**4**) indicates that **2** and **3** differ only in their con-

1 9 2 3 4 5 6

figurations at the cyclobutyl positions *alpha* to the carbonyl groups and that either one or both ring fusions in each dimer are *trans*.[3] This result invalidates the *cis–anti-cis* structure proposed previously (4) for the dimer with m.p. 174°. It was reported (4) that the diol diester obtained from this dimer by hydrogenation, Baeyer–Villager oxidation, hydrolysis, and esterification was cleaved relatively slowly by lead tetraacetate, suggesting the presence of a *trans*-1,2-cyclobutanediol moiety. It should be noted that dimer **2**, our proposed structure for the compound with m.p. 174°, would be expected to undergo the same series of reactions in the manner described.

To establish the stereochemistry of the ring fusions in **2**, **3**, and **4**, the conversion of the dimers to known hydrocarbons was attempted. A modified Wolff–Kishner reduction (8) of **2** gave diene **5**, which was identical to the *trans–anti-trans* dimer of *cis,trans*-1,3-cyclooctadiene (9).[4] All attempts to convert **3** or tetrahydro **3**, m.p. 105–106°, to hydrocarbons were unsuccessful presumably because of the close proximity of the carbonyl groups. Hydrogenation of **4** gave tetrahydro **4**[5,6], m.p. 67.0–68.5°, which was converted to a saturated hydrocarbon by preparation of the ethanedithiol diketal followed by Raney nickel desulfurization. This product, **6**, m.p. 57–58°, was identical to the hydrogenation product of the *cis–anti-cis* dimer of *cis,trans*-1,3-cyclooctadiene (9). These conversions conclusively establish the ring fusions in dimers **2** and **4** and as a consequence of the epimerization experiment the structure of **3** can only be as depicted.

Mechanistic Considerations

Having established the structures of the products formed upon irradiation of **1**, next it was appropriate to examine the mechanism of formation of the two dimers, **2** and **3**. In particular, it was desired to examine (*a*) the nature of the excited state involved in the photochemical step, (*b*) the structure of the dimer precursor, if indeed such an intermediate existed, and finally (*c*) the mechanism of the dimerization step itself.

When oxygen, a well-known triplet quencher, was bubbled through a benzene solution of **1** during irradiation, the rate of disappearance of dienone was the same as in a control experiment in which nitrogen was used. Similarly, 0.01–1.0 *M* concentrations of the triplet quencher 1,3-cyclohexadiene (E_T 53 kcal/mol) (10) had no effect on the rate of disappearance of **1**. The quantum yield of intersystem crossing of **1** as determined by the sensitized dimerization of 1,3-cyclohexadiene was found to be <0.01 relative to a value of unity for benzophenone (11). These results suggest that the excited state in the photochemical step is either a singlet or a short-lived triplet. Triplet sensitization experiments were used to differentiate between these two possibilities.

[3]*Trans*-fused bicyclo[6.2.0]alkanones epimerize to the *cis*-fused ketones under alkaline conditions: see refs. 1 and 7.

[4]We thank Dr. Osborn for experimental details prior to publication of their full paper (9).

[5]Tetrahydro **2** has m.p. 70–71° although it was previously reported (4) as a syrup.

[6]Eaton and Lin (1) reported the isolation of two dimers, m.p. 88–90° and 133–134°, upon irradiation of 2-cyclooctenone in cyclohexane. Neither of these dimers is the same as the tetrahydro derivatives of **2**, **3**, or **4**. We thank Prof. Eaton for experimental details in the preparation of the 2-cyclooctenone dimers.

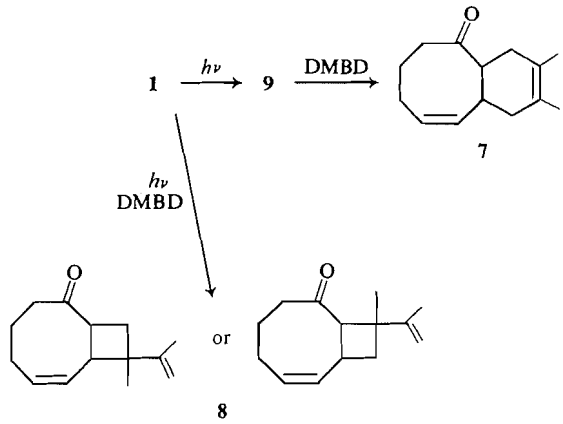
Benzene solutions of **1** were irradiated in the presence of the following triplet sensitizers such that the sensitizer absorbed the indicated percentage of incident irradiation: xanthone (99%)[7] (E_T 74.2 kcal/mol) (13), benzophenone (82%) (E_T 68.5 kcal/mol) (13) and Michler's ketone (99%) (E_T 61 kcal/mol) (13). In all three sensitized irradiations there was a very significant decrease in the rate of disappearance of **1**. Although the triplet energy of **1** has not been determined it would be expected to be below that of at least the first two sensitizers. Thus there is no evidence of triplet sensitization and the photochemically reactive state of **1** must be an excited *singlet*.

Next, it was necessary to determine the nature of the photochemical reaction and the structure of the dimer precursor. Benzene (m.p. 5.5°) solutions obviously could not be used for the proposed low temperature experiments but it was found that toluene (m.p. −95°) was a very suitable alternative solvent. Irradiation of a 1% solution of **1** in toluene at room temperature gave a combined yield of 82% dimers **2** and **3**. A similar irradiation was conducted at −78° using a specially constructed low temperature apparatus and the solution was divided into two portions. To one was added a 15-fold excess of the trapping reagent 2,3-dimethyl-1,3-butadiene (DMBD)[8] and both samples were allowed to warm slowly to room temperature. The portion without added diene gave a 40% yield of dimers **2** and **3** and 60% unreacted **1** while the other portion gave a decreased yield of dimers (32%), unreacted **1** (62%) and a crystalline Diels–Alder adduct, **7** (6%); m.p. 45–47°. The spectral data, particularly the presence of two similar methyl groups at τ 8.4 in the n.m.r. spectrum is convincing evidence for the proposed structure of **7**. Irradiation of **1** at room temperature in the presence of 15-fold excess of DMBD gave dimers **2** and **3** (46%) and two adducts: **7**, (15%) and **8** (35%). The strong band in the i.r. spectrum of **8** at 889 cm^{-1} for the terminal methylene



group and the two different methyl singlets in the n.m.r. spectrum (τ 8.4 and 8.7) were particularly useful in assigning a structure to this adduct.

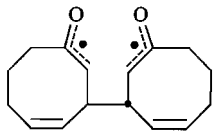
Adduct **8** must have been formed in a photochemical 2 + 2 addition as it was not formed in the trapping experiment. Similar cycloadditions of 1,3-dienes and cycloalkenones have been reported (14). The trapping experiment also showed that the Diels–Alder adduct, **7**, was a thermal 2 + 4 product. This adduct was not formed when a toluene solution of **1** and DMBD was allowed to stand in the absence of light. Thus adduct **7** must have been formed by reaction of DMBD with a highly reactive ground-state species, namely *trans,cis*-2,4-cyclooctadienone (**9**). Cantrell and Solomon (4) reported the formation of *trans*-fused Diels–Alder adducts upon irradiation of **1** in furan and suggested **9** was the reactive species but no low temperature trapping experiments were conducted.

Finally, the dimerization itself must be discussed and an explanation provided for the formation of two dimers. Irradiation of **1** in benzene at concentrations of 0.08 *M* (1%) and 0.38 *M* resulted in the same 44:56 ratio of dimers **2** and **3**,[9] respectively. Similarly, irradiation of **1** in toluene (at room temperature or −78°), in methanol or in the presence of 1,3-dienes caused no change in the dimer ratio. Addition of trapping reagents such as dienes after irradiation of **1** at −78° also caused no change in this ratio but did result in a decreased yield of dimers, indicating competition for the intermediate **9**. Therefore, the dimers must be

[7]To ensure that self-quenching by the sensitizer (12) was not involved, the concentration of xanthone was varied such that it absorbed 90 and 62% of the irradiation and it was found that the rate of disappearance of **1** increased as expected.

[8]This diene was particularly useful as n.m.r. spectroscopy could readily distinguish between the 2 + 2 and the 2 + 4 adducts of **1** and DMBD. When other dienes such as piperylene were used as trapping agents the yield of adducts was higher but the structural assignments were not as straightforward.

[9]Dimer ratios were determined by g.l.c. and as the two peaks overlapped slightly the determinations were accurate to ±3%.



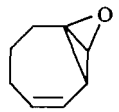
10

formed from two molecules of **9** in a two-step thermal process in which the initially formed diradical, **10**, closes in either a conrotatory or a disrotatory manner to give **2** or **3**, respectively. A similar mechanism has been proposed for the thermal dimerization of *cis,trans*-1,3-cyclooctadiene (9). It was previously suggested (4) that dimerization of **1** proceeded via addition of an excited triplet of **1** to ground-state **1**.

Conclusions

Irradiation of 2,4-cyclooctadienone (**1**) in benzene or toluene resulted in the formation of two dimers, **2**, m.p. 174.5–175.0° and **3**, m.p. 89–90°, in a combined yield of >80%. The structure previously proposed (4) for the former was shown to be in error while the second dimer had not previously been reported. The reason for the high yield of dimers in benzene and toluene as compared with the low yields (8–10% of **2**) in pentane and ether (4) may simply be a reflection of the number of readily abstractable hydrogens available on the solvents (Cantrell reported considerable quantities of polymer formed in pentane and ether) although it is surprising that toluene with three benzylic hydrogens would be such an effective solvent.

From the ultraviolet spectral data (see Experimental) it can be concluded that **1** possesses an intense ($\varepsilon \sim 5800$) π-π^* maximum at ~270 mμ and a weak ($\varepsilon \sim 50$) n-π^* maximum at ~345 mμ. The irradiations could be accomplished using a 350 mμ source and a uranium glass filter ($\lambda > 330$ mμ) (15) and under these conditions it would be expected that almost all the irradiation would be absorbed by the n-π^* band although the tail of the π-π^* band does extend beyond 330 mμ. As the photochemical reaction of **1** is not affected by triplet quenchers, as there is no evidence of intersystem crossing from the singlet to the triplet state and as the reaction is not assisted by triplet sensitizers, we conclude that the singlet state is involved in the photochemical step. Noyori and co-workers (16) reported irradiation of 2-cyclooctenone in methanol to give a methanol adduct via *trans*-2-cyclooctenone is not affected by diene quenchers and a recent review suggested (17) the reactive state in this isomerization may also be a singlet. We believe that the photochemical reaction itself is the *cis–trans* isomerization of the α,β-double bond of **1**. Another possibility that should at least be mentioned is the photochemical formation, possibly via the n-π^* singlet, of an intermediate such as **11**, which could then open to give **9** and other products. Similar intermediates have been suggested by others (7, 18), but in no case, including the present investigation, is there any evidence for their existence.



11

The singlet state *cis–trans* isomerization of **1** results in the formation of the highly strained and highly reactive intermediate, *trans,cis*-2,4-cyclooctadienone (**9**). We have presented no spectroscopic evidence for such a species but the low temperature trapping experiments with DMBD leave no doubt that such an intermediate exists and is stable at −78°. Additional evidence for the existence of **9** will be presented in the following paper. This dienone (**9**) has the capability of undergoing ground-state reactions such as dimerization, isomerization to **1** and 2 + 4 addition to suitable trapping reagents such as 1,3-dienes. An attempt to react **9** with cyclopentene gave none of the expected product indicating that a more reactive alkene was required. Corey and co-workers (7) found that *trans*-2-cyclooctenone reacted with 1,1-dimethoxyethylene to give a cycloaddition product but did not react with cyclopentene.

Comparison of the dimerization of **9** with that of *cis,trans*-1,3-cyclooctadiene (9) revealed (*a*) only head-to-head dimers were formed and (*b*) the two most abundant dimers in each investigation had *cis–trans* and *trans–anti-trans* ring fusions. These similarities suggest that a common mechanism may be involved. In the case of the diene dimerization it was proposed that the 1,4-diradical was stabilized because both radicals were allylic while in the present case the diradical **10** is stabilized by the adjacent carbonyl groups. Closure in either a conrotatory or a disrotatory manner then gives the two major dimers.

The formation of dimers has been reported in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

the irradiation of 2-cycloheptenone (18*a*),[10] 2-cyclooctenone (1), and 2,4,6-cyclooctatrienone (3*b*) but the structures have not been elucidated. Comparison of the stereochemistry of the dimers with those reported here would be of interest particularly as the two dimers of 2-cyclooctenone reported by Eaton and Lin (1) are not the same as any of the tetrahydro derivatives of **2**, **3**, and **4** (see footnote 6).

Experimental

Infrared (i.r.) spectra were recorded on a Beckman Model IR5A spectrophotometer and nuclear magnetic resonance (n.m.r.) spectra were recorded on a Varian A-60A spectrometer using tetramethylsilane as internal standard (TMS, $\tau = 10.0$). Resonance splittings are indicated as singlet (s), doublet (d), triplet (t), doublet of doublets (dd), and multiplet (m). Ultraviolet absorption (u.v.) spectra were recorded on a Unicam SP-800 spectrophotometer and mass spectral (m.s.) analyses were determined on a Varian Mat CH7 low resolution spectrometer.

Analytical thin layer chromatography (t.l.c.) was carried out on 0.25 mm silica gel GF-254 plates while preparative t.l.c. was accomplished on 1.0 mm silica gel PF-254 plates. The solvent system used in each instance will be specified. Column chromatography separations were done on silica gel, 50–200 mesh. Gas liquid phase chromatography (g.l.c.) analyses and separations were run on an Aerograph "Autoprep" Model A-700 with a thermal conductivity detector and the peak areas were determined by triangulation and were not corrected for differences in thermal response. The columns used were: column A, 6 ft × 0.25 in., 20% Carbowax 20M on 60/80 mesh Chromosorb W; column B, 20 ft × 0.375 in., 30% SE 30 on 45/60 mesh Chromosorb W; column C, 6 ft × 0.25 in., 20% SE 30 on 60/80 mesh Chromosorb W. The carrier gas used was helium with a flow rate of 60 ml/min in the 0.25 in. columns and 180 ml/min in the 0.375 in. column. The temperature for the column will be specified. Spinning band distillations were done on a Nester/Faust 117 apparatus with an 18 in. column length.

Microanalyses were performed by H. S. McKinnon, Department of Chemistry, University of Guelph and A. G. Gygli, Toronto, Ontario. All melting points were determined on a Gallenkamp apparatus and are uncorrected. Solvents used in the irradiations were refluxed over calcium hydride and distilled.

Normal irradiations were accomplished in Pyrex or uranium glass (Corning no. 3320) (15) tubes using a Rayonet Photochemical Reactor Model RPR-100 with 16 low-pressure 350 mμ lamps. All samples were deoxygenated by bubbling dry, high purity nitrogen through the solution for 15–30 min depending on the volume of solution. The specially constructed apparatus used in the low temperature experiments consisted of an inner cold finger (60 mm diameter), for the Dry Ice – acetone mixture, surrounded by a cylindrical liner for the irradiation solution which was in turn surrounded by a larger cylindrical liner (100 mm diameter) which could be evacuated to prevent condensation forming on the outside of the apparatus. The solution cavity had a capacity of ~150 ml and a tube run to the bottom of the cavity could be used for degassing the solution or introducing additional reagents as required. The apparatus could be placed conveniently inside the Rayonet Reactor.[11]

Preparation of 2,4-Cyclooctadienone (1)

The procedure of Heap and co-workers (20) was followed and the product after distillation on a spinning band column showed one peak on column A, 140° and column C, 140°. The i.r. and n.m.r. spectral bands for **1** have been recorded in detail but we include here the u.v. maxima in several solvents; λ_{max} (EtOH) 278 mμ (ε 5850); λ_{max} (cyclohexane) 268 mμ (ε 5800), 346 mμ (ε 51); λ_{max} (benzene) 343 mμ (ε ~ 50). The longer wavelength band in ethanol could not be resolved from the 278 mμ band and the shorter wavelength band in benzene was masked by the solvent.

Irradiation of 1 in Benzene

Irradiation of 1.2 g (0.01 mol) of **1** in 120 ml anhydrous benzene at 10–12° in a Pyrex or a uranium glass tube resulted in the rapid disappearance of starting material. G.l.c. analysis (column C, 140°) showed complete consumption of **1** in 4 h. A g.l.c. tracing (column C, 242°) of the crude product showed only two peaks at retention times of 18.7 and 20.8 min in a ratio of 43:57, respectively.

The solvent was removed under vacuum and the residue was triturated with 30 ml ethyl acetate (4) leaving crude dimer **2** as a gray residue. Filtration followed by recrystallization from 1:1 ethyl acetate:benzene yielded 398 mg (33%) pure **2** as colorless crystals, m.p. 174.5–175.0°. G.l.c. analysis (column C, 242°) showed a single peak with retention time 18.7 min. Spectral properties of **2** were as follows; i.r. (KBr) 3000, 1698, 1445, 1345, 1310, 1115, 914, 722, 685 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.24 (4H, m, vinyl), 6.60 (2H, m, —CHCO—), 7.25 (2H, m, —CHC=), 7.43–8.60 (12H, m).

Anal. Calcd. for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25. Found: C, 78.85; H, 8.37.

The solvent was removed from the ethyl acetate filtrate above and the viscous syrup was left in the refrigerator (6°) overnight at which time crystallization had occurred (this dimer would not crystallize if the irradiation was not carried to complete consumption of **1**). Recrystallization from absolute ethanol yielded 625 mg (52%) pure **3** as long, clear crystals, m.p. 89–90°. G.l.c. analysis (column C, 242°) showed one peak with retention time 20.8 min. Spectral properties of **3** were as follows; i.r. (KBr) 3000, 1695, 1355, 1182, 720 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.18 (2H, m, vinyl), 4.53 (2H, m, vinyl), 5.83 (1H, t, $J = 10$ Hz, —CHCO—), 6.47 (1H, d with fine splitting, $J = 10$ Hz, —CHCO—), 6.72–8.90 (14H, m).

Anal. Calcd. for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25. Found: C, 78.83; H, 8.21.

[10]A head-to-head *cis–anti-cis* structure has recently been reported for one of the secondary products from the thermal dimerization of *trans*-2-cycloheptenone (19).

[11]We thank Miss A. Hostetter of the Department of Chemistry, University of Guelph, for the construction of this apparatus.

An analytical t.l.c. separation of the two dimers could be effected with three passes of chloroform to give the following R_f's: **2**, 0.60: **3**, 0.41. A similar irradiation to that described above using toluene as solvent gave the dimers in a combined yield of 82% (**2**:**3** in a ratio of 42:58).

*Formation of Epimer **4** from Dimers **2** and **3***

A solution of 420 mg (1.72 mmol) **3** and 8.4 g potassium hydroxide in 84 ml methanol was stirred at room temperature under nitrogen for 50 h. To the slightly colored solution was added 400 ml water and the aqueous phase was extracted with chloroform (5 × 50 ml). The combined chloroform extracts were washed with water (2 × 50 ml), saturated brine (2 × 50 ml) and dried ($MgSO_4$). Removal of the solvent under reduced pressure gave 420 mg crude epimer. Recrystallization from 40:60 ethyl acetate:ethanol yielded 320 mg (76%) pure **4** as long crystals, m.p. 126–127°. G.l.c. analysis (column C, 242°) showed only one peak with retention time 20.3 min; i.r. (KBr) 3000, 1692, 1430, 1298, 1043, 732, 718 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.30 (4H, m, vinyl), 5.95 (2H, dd, J = 7 and 2 Hz, —$\overset{|}{C}$HCO), 6.64 (2H, d with fine splitting, J = 7 Hz, —$\overset{|}{C}$HC═), 7.10–8.60 (12H, m).

Anal. Calcd. for $C_{16}H_{20}O_2$: C, 78.65; H, 8.25. Found C, 78.46; H, 8.36.

Similar treatment of 80 mg of **2** yielded 45 mg (58%) of **4**, m.p. 126–127°. The epimers from **2** and **3** had identical g.l.c. retention times as well as i.r. and n.m.r. spectra. A 50:50 mixture of the two epimers had a melting point of 126–127°.

*Wolff–Kishner Reduction of **2***

This modified Wolff–Kishner reduction is similar to a reported procedure (8) for ketones in which there is a possibility of an epimerization side reaction. To a solution of 0.50 g (2.1 mmol) of **2** in 35 ml refluxing absolute ethanol was added 2.5 ml (42.5 mmol) 85% hydrazine hydrate. The solution was heated to reflux for 3.5 h and then poured into a stirred solution of 1.6 g (40 mmol) sodium hydroxide in 35 ml diethylene glycol at 70°. The reaction mixture was continuously distilled while the temperature was raised from 70 to 200°. The temperature was maintained at 200–210° for 5.5 h. The pot residue and distillate were combined, poured into 250 ml water and this aqueous phase extracted with chloroform (5 × 50 ml). The combined extracts were washed with saturated brine (1 × 50 ml) and dried ($MgSO_4$). Removal of the solvent gave a brown syrup, which exhibited no carbonyl absorption in its i.r. spectrum. The crude product was filtered through 10 g silica gel using 150 ml pentane as the eluting solvent. Removal of the solvent gave 0.38 g (87%) of a viscous, colorless syrup which on g.l.c. analysis (column B, 240°) showed a major peak (80%) at 53 min with a slight shoulder at shorter retention time. The major peak was collected from g.l.c. (column B) as a colorless solid; m.p. 30–31°; i.r. (neat) 3010, 2920, 2850, 1456, 1445, 890, 797, 760, 730, 700 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.15–4.80 (4H, m, vinyl), 7.50–9.00 (20H, m). These properties were identical to an authentic sample of **5** which was prepared as reported (9) for comparison. The mixed melting point of the Wolff–Kishner product with an authentic sample of **5** was 30–31°.

Similar treatment of **3** and **4** resulted in the formation of an insoluble precipitate upon reaction with hydrazine hydrate.

*Preparation of Tetrahydro **2**, **3**, and **4***

A solution of 0.10 g (0.41 mmol) of **2** in 50 ml absolute ethanol was vigorously stirred with a catalytic amount of 10% palladium on charcoal under 1 atm of hydrogen until two equivalents of hydrogen were consumed. The reaction mixture was filtered through a mat of filter-aid and the solvent removed. In order for crystallization to occur it was necessary to remove the last traces of alcohol. The compound had previously been reported (4) as a syrup. Recrystallization of the crude saturated dimer from hexane yielded 82 mg (82%) of pure tetrahydro **2** as white crystals; m.p. 70–71°; i.r. (KBr) 1690, 1445, 1332, 1261, 1160 cm^{-1}; n.m.r. ($CDCl_3$) τ 6.71 (2H, m, —$\overset{|}{C}$HCO—), 7.55 (4H, m, —CH_2CO—), 7.90–8.80 (18H, m).

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found C, 77.45; H, 9.94.

Similar treatment of 0.10 g (0.41 mmol) of **3** followed by recrystallization from hexane yielded 79 mg (79%) of tetrahydro **3**; m.p. 105–106°; i.r. (KBr) 1685, 1450, 1235, 1148, 893, 870 cm^{-1}; n.m.r. ($CDCl_3$) τ 5.95 (1H, t, J = 8 Hz, —$\overset{|}{C}$HCO—), 4.68 (1H, doublet with fine splitting, J = 8 Hz, —$\overset{|}{C}$HCO—), 7.40–9.00 (22H, m).

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found C, 77.06; H, 9.92.

Similarly, 0.10 g (0.41 mmol) of **4** yielded 85 mg (85%) of tetrahydro **4**; m.p. 67–68°; i.r. (KBr) 1685, 1450, 1222, 1170, 896, 866, 740 cm^{-1}; n.m.r. ($CDCl_3$) τ 6.14 (2H, d, J = 9 Hz, —$\overset{|}{C}$HCO—), 7.30–8.00 (6H, m), 8.00–9.00 (16H, m).

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74. Found: C, 77.68; H, 9.96.

*Conversion of Tetrahydro **4** to Hydrocarbon **6***

To a solution of 0.16 g (0.65 mmol) of tetrahydro **4** in 3 ml ethanedithiol at room temperature was added 2 ml 98% boron trifluoride etherate and the reaction mixture was stirred 5 h. The homogeneous reaction was then poured into an excess of a chilled sodium hydroxide solution and this aqueous phase was extracted with chilled chloroform (8 × 25 ml) and the combined extracts were washed with chilled water (3 × 30 ml), with saturated brine (3 × 50 ml) and dried ($MgSO_4$). Removal of the solvent gave the crude ethanedithiol diketal which was not purified.

To a solution of this crude diketal in 150 ml absolute ethanol was added 6 g of Raney nickel (W-2) (21) and the suspension was stirred and heated to reflux for 15 h (22). The Raney nickel was filtered and the solvent removed to give 120 mg (85%) crude hydrocarbon which g.l.c. analysis (column B, 250°) showed to consist of 70% of a component with a retention time of 47 min. This compound was collected by g.l.c. as a white solid; m.p. 57–58°; i.r. (KBr) 2900, 1452, 1445, 1358, 953, 875, 848, 744 cm^{-1}. An authentic sample of **6** was prepared as described (9) and was found to be identical to this hydrocarbon prepared by reduction of **4**. The m.p. of a mixture was not depressed.

Irradiation in Presence of Oxygen

Two identical 1% solutions of **1** in benzene were placed in Pyrex tubes. Through one was bubbled high purity nitrogen for 20 min prior to and during the irradiation while through the other was bubbled oxygen for 20 min prior to and during the irradiation. After 30 min of irradiation the amount of **1** consumed in both cases was determined by g.l.c. (column C). Values of 23.5 and 23.0% consumption of **1** were observed for the nitrogen and oxygen experiments, respectively.

Quenching Experiments with 1,3-Cyclohexadiene

Five solutions of 1% of **1** in benzene were made 0.01, 0.05, 0.10, 0.50, and 1.0 *M* in 1,3-cyclohexadiene and placed in matched Pyrex tubes along with a sixth which contained no diene. Each of the solutions was degassed with purified nitrogen and then uniformly irradiated in a "merry-go-round" apparatus for 20 min. The consumption of **1** in each solution was determined by g.l.c. (column C) relative to an internal standard (*n*-dodecane). The solution without added diene showed 63% consumption of **1** while the values for the other solutions in order of increasing concentration of added diene were 62, 64, 62, 66, and 64% respectively.

Intersystem Crossing Measurements (11)

One benzene solution was made 0.05 *M* in benzophenone and 0.15 *M* in 1,3-cyclohexadiene while a second was made 0.177 *M* in **1** and 0.15 *M* in 1,3-cyclohexadiene. At these concentrations the amount of light absorbed by the two solutions was the same. Both solutions were irradiated uniformly using a "merry-go-round" apparatus and after 5 min the yield of cyclohexadiene dimers was determined in each solution by g.l.c. (column C, 160°). Two dimer peaks (retention times 10.5 and 13.2 min) were observed in the benzophenone solution but these were absent in the other solution. After a total of 15 min irradiation the dimer peaks were considerably larger in the former solution but still absent in the latter and the same was true after 25 min irradiation but by this time the concentration of **1** had decreased significantly in the second solution. Thus no indication of intersystem crossing could be detected within the limits of our measurements.

Sensitization Experiments

The proportion of light absorbed by the components was calculated by determining their relative absorbances at 346 mμ. Four 10 ml benzene solutions each 0.082 *M* (1%) in **1** were placed in matched Pyrex tubes. The first contained no additional compounds, the second contained 340 mg (1.73 mmol) xanthone (E_T 74.2 kcal/mol) (absorbed 99% of irradiation), the third contained 430 mg (2.36 mmol) benzophenone (E_T 68.5 kcal/mol) (82% of irradiation) and the fourth contained 45.2 mg (0.168 mmol) 4,4′-bis(dimethylamino) benzophenone (E_T 61.0 kcal/mol) (99% of irradiation). The four tubes were degassed and then irradiated simultaneously in a "merry-go-round" apparatus for 30 min and the consumption of **1** was determined by g.l.c. (column C) relative to the internal standard *n*-dodecane. The consumption in the first tube was 38% while in the three tubes containing the triplet sensitizers there was no measureable consumption of **1**.

To ensure that self-quenching (12) was not a complication in the xanthone sensitization experiment, the following experiment was conducted. Three 5 ml benzene solutions each 0.082 *M* in **1** were placed in matched Pyrex tubes. To the first was added nothing, to the second was added 5.4 mg (0.028 mmol) xanthone (to absorb 62% of the irradiation) and to the third was added 27.8 mg (0.142 mmol) xanthone (90% of irradiation). The solutions were degassed and uniformly irradiated for 50 min. G.l.c. analysis showed **1** had been consumed to the extent of 58, 18, and 6%, respectively. These values are proportional to the amount of irradiation absorbed by **1** and show that self-quenching was not the reason for the lack of sensitization by xanthone.

Irradiation of 1 with DMBD

A solution of 100 mg (0.82 mmol) **1** and 1.0 g (12 mmol) 2,3-dimethyl-1,3-butadiene (DMBD) in 10 ml benzene was degassed and irradiated for 4 h. The solvent and excess diene were removed under reduced pressure and the residue, upon analysis by programmed g.l.c. (column C, 200–240°), showed five peaks. The first peak (35%, retention time 10.8 min) was collected as a colorless syrup and assigned structure **8**; i.r. (neat) 3050, 3010, 2880, 1700, 1645, 1450, 1370, 1200, 1128, 889, 755 cm^{-1}; n.m.r. ($CDCl_3$) τ 4.00–4.50 (2H, m, —CH=CH—), 5.30–5.50 (2H, m, $\diagdown\!\!\diagup C{=}CH_2$), 6.9–9.3 (10H, m), 8.38 (apparent 3H, s, $CH_3{-}\overset{|}{C}{=}$), 8.73 (apparent 3H, s, $CH_3{-}\overset{|}{C}{-}$); m.s. molecular ion at *m/e* 204. The second peak (4%, retention time 12.5 min) was not isolated. The third peak (15%, retention time 15.8 min) was collected as a white solid and assigned structure **7**; m.p. 45–47°; i.r. (CCl_4) 3010, 2890, 1700, 1420, 1288, 1250, 868, 693 cm^{-1}; n.m.r. ($CDCl_3$) 4.40–4.75 (2H, m, —CH=CH—), 7.2–8.5 (12H, m), 8.38 (apparent 6H, s, $-C(CH_3){=}C(CH_3)-$); m.s. molecular ion at *m/e* 204. The remaining two peaks (46%) had retention times of 32 and 38 min and were assigned to the dimers **2** and **3**.

Low Temperature Irradiation of 1 in Toluene

A solution of 1.22 g (10 mmol) of **1** in 125 ml toluene was placed in the specially constructed low temperature apparatus described previously and irradiated for 2.5 h at −78°. The solution was divided into two equal portions. The first portion was allowed to slowly warm to room temperature, the solvent was removed and the residue upon analysis by programmed g.l.c. (column C, 150–240°) showed 60% **1** and 40% dimers **2** and **3** (42:58). To the second portion was added 12 g DMBD and the solution was allowed to warm to room temperature. G.l.c. analysis of the residue indicated 62% **1**, 6% **7**, and 32% dimers **2**, and **3** (43:57).

When 12 g of piperylene was substituted for DMBD in the trapping experiment above, two adducts (*m/e* 190) were obtained in a combined yield of 12%.

Photochemistry of 2,4-Cyclooctadienone. II[1] In Neutral and Acidic Methanol

GORDON L. LANGE AND ELI NEIDERT

Department of Chemistry, University of Guelph, Guelph, Ontario

Received September 13, 1972

Irradiation of 2,4-cyclooctadienone (**1**) in neutral dry methanol resulted in the formation of 3-methoxy-4-cyclooctenone (18%) and two head-to-head 2 + 2 dimers (combined yield 64%). A similar irradiation in acidic methanol (0.001 *N* HCl) caused a dramatic change in the products formed. A new compound, the dimethyl ketal of *trans,cis*-2,4-cyclooctadienone was formed in 67% yield along with the two dimers (<10%). A mechanism is proposed whereby the photochemically derived *trans,cis*-2,4-cyclooctadienone reacts in thermal processes to give the products described. Low temperature trapping experiments which support this hypothesis are discussed.

L'irradiation du cyclooctadiène-2,4 one (**1**) dans du méthanol neutre anhydre a conduit à la formation du méthoxy-3 cyclooctène-4 one (18%) ainsi qu'à celle de deux dimères 2 + 2 (tête-tête avec un rendement combiné de 64%). Une irradiation similaire dans du méthanol acidifié (0.001 *N* HCl) a provoqué un changement important dans les produits obtenus. Un nouveau composé, la diméthyl cétal du *trans,cis*-cyclooctadiène-2,4 one, a été obtenu avec un rendement de 67% en même temps que les deux dimères (10%). On propose un mécanisme selon lequel la *trans,cis* cyclooctadiène-2,4 one obtenue photochimiquement réagit selon un processus thermique pour donner les produits observés. On discute des résultats obtenus lors d'expérience de captage à basse température qui sont en accord avec cette hypothèse.

Can. J. Chem., **51**, 2215 (1973)

Introduction

Irradiation of medium-ring unsaturated ketones in methanol results in the formation of a variety of products involving the solvent. Both 2-cycloheptenone (1) and 2-cyclooctenone (2) upon irradiation in methanol gave the 3-methoxy ketone by addition of solvent across the double bond. In the case of the second ketone, it was shown (2) that the methoxy derivative was formed as a result of thermal nucleophilic attack of methanol on *trans*-2-cyclooctenone, which was formed by photoisomerization of the *cis*-enone. Similarly, irradiation of 2,6-cyclooctadienone in methanol gave 7-methoxy-3-cyclooctenone via the *trans,cis*-dienone (3, 4). Of course, ketenes are often formed upon irradiation of ketones and in methanol solvent the product isolated is the methyl ester (5).

The photochemistry of a number of medium-ring cross-conjugated dienones in methanol has also been investigated. Irradiation of 2,6-cycloheptadienone gave initially the 3-methoxyenone and upon prolonged irradiation dimethoxy adducts were formed (6). Irradiation of both 2,7-cyclooctadienone (7) and 2,8-cyclononadienone (8) gave bicyclic methoxy ketones as the major products and in the latter case the *trans,cis*-dienone was shown to be the precursor of the products. In contrast, irradiation of 2-cyclododecenone in protic or aprotic solvents resulted in photochemical deconjugation of the enone (9).

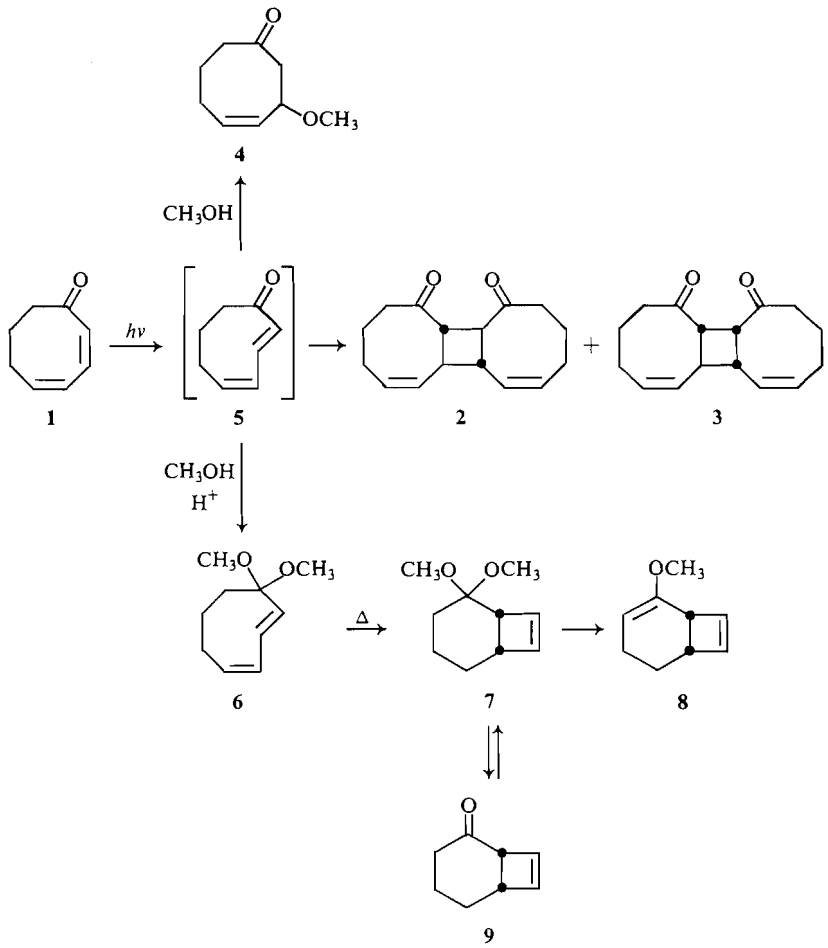
Irradiation of 2,4-cyclooctadienone (**1**) in methanol has been reported (3) to give 3-methoxy-4-cyclooctenone (30%) and a head-to-head dimer, m.p. 174° (6.5%). The structure of this dimer was discussed in the preceding paper (10). Here we wish to report our findings on the products formed upon irradiation of **1** in neutral and acidic methanol and to discuss some experiments designed to elucidate the mechanism of formation of these compounds.

Results and Discussion

Irradiation of a 1% solution of 2,4-cyclooctadienone (**1**) in dry, neutral methanol with a 350 mμ u.v. source gave dimers **2** (28%) and **3** (36%) and 3-methoxy-4-cyclooctenone (**4**) (18%) as determined by gas liquid chromatography (g.l.c.) using hexadecane as internal standard. Dimer **2**, m.p. 174.5–175.0, was crystallized from an ethyl acetate solution of the irradiation mixture and was shown to be the same as the *trans-anti-trans* dimer isolated from the irradiation of **1** in benzene (10). The other dimer (**3**) could not be crystallized from the mother liquor after removal

[1]For Part I, see preceding paper.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



of **2** but its g.l.c. retention time and physical properties (after separation by g.l.c.) left no doubt that it was the *trans–cis* dimer, m.p. 89–90°, which was also obtained in the benzene irradiation (10). The irradiation was repeated using the conditions described by Cantrell and Solomon (3) (0.6% solution, Hanovia 450-W lamp, Pyrex filter) and essentially the same product distribution as outlined above was obtained. The earlier investigators had not reported (3) finding dimer **3** in their irradiation mixture. It should be noted that the ratio of dimers **2**:**3** was 44:56, the same as that found in the benzene and toluene irradiations (10).

When the irradiation was conducted in very dilute acidic methanol there was a dramatic change in the products formed. Irradiation of a 1% solution of **1** in acidic methanol (0.001 *N* HCl) with a 350 mμ source gave only a trace of the methoxyenone (**4**) and less than 10% combined yield of dimers **2** and **3**. But, g.l.c. analysis showed a new peak (~60%) with a retention time of 3 min relative to 10 min for **1** and 18 min for **4**. This volatile product was collected by g.l.c. and found to have the following spectral properties; i.r. no carbonyl absorption; n.m.r. (CCl_4) τ 3.94 (1H, d, $J = 3$ Hz, vinyl), 4.12 (1H, d, $J = 3$ Hz, vinyl), 5.38 (1H, q), 6.54 (3H, s, CH_3—O—), 6.78 (2H, broad s, —C(—)—H at ring fusion), 7.80–8.50 (4H, m, methylene); m.s. molecular ion at *m/e* 136. The n.m.r. spectrum of this compound exhibited some striking similarities to the cyclobutene protons in the spectra of bicyclo[4.2.0]oct-7-en-2-one (**9**) (11) and its ethylene ketal (12). Also, the τ 5.38 resonance is appropriate for the vinyl proton of an enol ether moiety in a 6-membered ring (13). On the basis of this spectral informa-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion and further considerations to be discussed later, the enol ether structure **8** was assigned to this product.

Next it was necessary to explain the formation of **8** from the starting dienone **1**. Heating of dimethyl or diethyl ketals in the presence of a trace of acid is a known procedure for the preparation of enol ethers (13). Also, g.l.c. analysis of dimethyl ketals has been reported (14) to give enol ethers by elimination of methanol. Thus, the bicyclic ketal **7** is a logical precursor to **8**. A sample of **7** was prepared by ketalization of the known bicyclic ketone **9** (11) using trimethylorthoformate in acidic methanol. Injection of **7** onto the g.l.c. column gave only one peak which was collected and found to be identical to **8** thus proving that under our g.l.c. conditions elimination of methanol from **7** was occurring.

The origin of the bicyclic ketal must now be considered. Examination by t.l.c. (silica gel, 15% ether/petroleum ether) of the crude product from irradiation of **1** in acidic methanol revealed a major u.v. positive spot (R_f 0.5) different from **1** (R_f 0.3). Separation of this major band by preparative t.l.c. gave in 67% yield a product (**6**) which possessed the following spectral features: i.r. strong absorption in the region 1150–1050 and at 965 cm^{-1} and no carbonyl band; λ_{max} (CH_3OH) 233 mμ (ε 3150); n.m.r. (CCl_4) τ 3.48–3.96 (2H, m, vinyl), 4.23–4.65 (2H, m, vinyl), 6.83 (6H, s, $>C(OCH_3)_2$), 7.4–9.1 (6H, m, methylenes); m.s. molecular ion at *m/e* 168. The data suggests the compound is a conjugated diene containing a dimethyl ketal moiety. For purposes of comparison, the dimethyl ketal of **1** was prepared by reaction of the dienone with trimethylorthoformate in acidic methanol. This product was also purified by t.l.c. and was found to have quite different spectral properties than those presented above. The i.r. spectrum had no strong absorption in the 900–1000 cm^{-1} region, the u.v. spectrum (λ_{max} (CH_3OH) 239 mμ (ε 7380)) exhibited a much more intense absorption and the n.m.r. spectrum showed two methoxy singlets for the ketal moiety. The mass spectra of the two compounds also had some obvious differences. The u.v. spectra of *cis,cis*-1,3-cyclooctadiene (λ_{max} (cyclohexane) 228 mμ (ε 5620)) (15) and *trans,cis*-1,3-cyclooctadiene (λ_{max} 230.5 mμ (ε 2630)) (15) provided useful comparisons with the ketals. The i.r. spectrum of the *trans,cis*-diene showed strong absorptions at 952 and 970 cm^{-1} which were absent in the *cis,cis*-isomer (15). In addition, photoproduct **6** upon injection onto a g.l.c. column showed only one peak at 3 min which was shown to be identical to **8**, while the dimethyl ketal of **1** gave a peak at 10.5 min which analyzed for the expected composition. From all this evidence it was concluded that **6** must be the dimethyl ketal of *trans,cis*-2,4-cyclooctadienone. The strong band in its i.r. spectrum at 965 cm^{-1} is indicative of a *trans* double bond and the low extinction coefficient in the u.v. spectrum is indicative of a conjugated diene system in which the double bonds are forced into a non-planar conformation by strain (16).

Fonken and co-workers reported (17) that upon heating *trans,cis*-1,3-cyclooctadiene at 80° it isomerized quantitatively to bicyclo[4.2.0]oct-7-ene. If ketal **6** underwent a similar conversion it would be further evidence for the assigned structure. When **6** was heated in refluxing toluene (110°) for 1 h it was converted in >95% yield to the bicyclic ketal **7** as judged by i.r., n.m.r., and analytical t.l.c. Thus injection of **6** onto the g.l.c. column must have resulted in electrocyclic ring closure to **7** followed by elimination of methanol to give **8**.

We propose that **6** was formed from *trans,cis*-2,4-cyclooctadienone (**5**) by ketalization in the acidic methanol solution thus providing even more direct evidence for the existence of the reactive intermediate **5**. Presumably the driving force behind this reaction was the relief of strain in **5** by conversion of the sp^2 hybridized carbonyl carbon to the sp^3 ketal carbon. Another possible route to **6** could be photochemical *cis-trans* isomerization of the ketal of **1**, the latter being formed under the acidic reaction conditions. This possibility was eliminated when it was found that no ketal could be detected when **1** was allowed to sit in acidic methanol (0.001 *N* HCl) for several hours in the dark.

A further insight into the mechanism of the methanol irradiations was provided by some low temperature trapping experiments. A toluene solution[2] of **1** was irradiated at −78°, the u.v. source was turned off and dry neutral methanol

[2]In the preceding paper (10) it was shown that toluene was a suitable solvent for both low and room temperature irradiations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was added to the irradiated solution, which was then allowed to warm to room temperature. Examination of the products by g.l.c. using an internal standard showed 7% of methoxyenone **4**, 16% dimer **2**, 22% dimer **3**, and the remainder was starting material. The experiment showed that **4** was indeed formed in a thermal reaction by the addition of methanol to the reactive intermediate **5**.

In a parallel experiment, acidic methanol (7×10^{-4} *N* HCl) was added to a toluene solution of **1** which had been irradiated at −78°. G.l.c. analysis of the products showed 20% of **8** (indicating 20% of **6** actually present in the reaction mixture), 12% combined yield of dimers **2** and **3** and the remainder was **1**. The experiment shows that the *trans,cis*-ketal **6** was formed by an acid catalyzed, ground state reaction of methanol with some reactive intermediate, namely **5**.

The rate of disappearance of **1** in dry methanol was about the same as that in benzene but was about twice that in acidic methanol (0.001 *N* HCl) using the standard irradiation conditions. Some of the inefficiency in these photoreactions is probably the result of thermal isomerization of **5** to starting dienone **1**. In the acidic methanol irradiation, acid catalyzed isomerization of **5** to **1** would result in the decreased rate of disappearance of **1** which was observed. Eaton similarly reported (18) the sensitivity of *trans*-2-cyclooctenone to traces of acid. In our acidic methanol irradiation the concentration of acid is very critical. At a concentration of 0.01 *N* HCl, the rate of disappearance of **1** is very markedly decreased while at 10^{-4} *N* HCl very little **6** is formed and the reaction resembles the normal neutral methanol irradiation.

Conclusions

Irradiation of 2,4-cyclooctadienone (**1**) in dry methanol resulted in the formation of methanol addition product **4** and dimers **2** and **3**. The latter dimer (**3**) had not been reported by previous investigators (3). Irradiation of **1** in acidic methanol (0.001 *N* HCl) gave a good yield of the strained ketal **6** plus a reduced yield of the two dimers. Low temperature trapping experiments showed that the precursor to all these products was the highly reactive *trans,cis*-2,4-cyclooctadienone (**5**), formed in a photochemical *cis–trans* isomerization from **1**. The acid catalyzed formation of ketal **6** illustrates a new and novel method for trapping reactive photochemical intermediates.

Experimental

Spectroscopic instruments and analytical and photochemical equipment were as described in the preceding paper (10). G.l.c. analyses and separations were performed on an Aerograph "Autoprep" Model A-700 using the following columns: column A, 6 ft × 0.25 in., 20% Carbowax 20M on 60/80 mesh Chromosorb W; column B, 6 ft × 0.25 in., 20% SE 30 on 60/80 mesh Chromosorb W. Spectro grade methanol was refluxed with magnesium for 4 h and distilled.

Irradiation of 1 in Neutral Methanol

Irradiation with a 350 mμ source of a solution of 1.2 g (0.01 mol) of **1** in 120 ml dry methanol in a Pyrex tube resulted in the disappearance of starting dienone within 4 h. The solvent was removed and the residue, upon trituration with ethyl acetate, gave a crystalline solid, m.p. 174.5–175.0°, which was shown to be dimer **2** by comparison with a sample from the benzene irradiation of **1** (10). Dimer **3** could not be crystallized from the mother liquor. The complete irradiation mixture was dissolved in chloroform and subjected to g.l.c. analysis (column B, 275°) with hexadecane as internal standard. Product distribution was as follows: 3-methoxy-4-cyclooctenone (**4**) (18%), whose spectral properties were the same as those previously described (3), and dimers **2** (28%) and **3** (36%), whose physical properties after g.l.c. separation were the same as reported in our preceding paper (10).

When 1.2 g (0.01 mol) of **1** in 200 ml dry methanol was irradiated in a Pyrex tube with a 450-W Hanovia type L lamp for 4 h as described by Cantrell and Solomon (3), essentially the same product distribution as detailed above was obtained.

Irradiation of 1 in Acidic Methanol

(*a*) A solution of 1.2 g (0.01 mol) of **1**, 9 μl (0.11 mmol) conc. hydrochloric acid and 120 ml dry methanol in a Pyrex tube was irradiated with a 350 mμ source for 8 h at which time less than 5% of **1** remained. The solvent was removed and the residue, upon g.l.c. analysis (column B, 275°) with internal standard hexadecane, showed less than 10% combined yield of dimers **2** and **3**. An additional g.l.c. analysis (column A, 136°) showed a new peak (~60%) with a retention time of 3 min, starting dienone **1** (< 5%) at 10 min and only a trace of methoxyenone **4** at 18 min. The product at 3 min, which was shown to be **8**, was collected by preparative g.l.c. (column A) and found to have the following spectral properties; i.r. (neat) 3030, 2900, 1650, 1370, 1212, 1158, 798, 780, 725 cm^{-1}; n.m.r. (CCl_4) τ 3.94 (1H, d, J = 3 Hz, vinyl), 4.12 (1H, d, J = 3, vinyl), 5.38 (1H, q, H—C=C—O—), 6.54 (3H, s, CH_3O—), 6.78 (2H, broad s, —C—H at ring fusion), 7.80–8.50 (4H, m, methylene); m.s. molecular ion at *m/e* 136.

Anal. Calcd. for $C_9H_{12}O$: C, 79.38; H, 8.89. Found: C, 79.46; H, 8.98.

(*b*) A solution of 194 mg (1.59 mmol) of **1**, 1.5 μl (0.018 mmol) conc. hydrochloric acid and 19 ml dry methanol in a uranium glass tube (10) was irradiated with a 350 mμ source for 8 h. The solvent was immediately removed at room temperature and the mixture was separated by preparative t.l.c. (15% dry ether/petroleum ether). The major u.v. positive band at R_f 0.5 was re-

moved and yielded 179 mg (67%) of ketal **6**; i.r. (CCl_4) 3010, 2925, 1635, 1138, 1107, 1075, 1057, 965, 680 cm^{-1}; λ_{max} (CH_3OH) 233 mμ (ε 3150); n.m.r. (CCl_4) τ 3.48–3.96 (2H, m, vinyl), 4.23–4.65 (2H, m, vinyl), 6.83 (6H, s, $>C(OCH_3)_2$), 7.4–9.1 (6H, m, methylene); m.s. molecular ion at *m/e* 168. G.l.c. analysis (column A, 136°) of this compound showed only one peak at 3 min which was identical to **8**. Although the ketal **6** is thermally and hydrolytically unstable the following analysis was obtained for the material separated by t.l.c.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.41; H, 9.92. Found: C, 71.84; H, 9.97.

Preparation of Bicyclic Ketal 7

A solution of 100 mg (0.82 mmol) bicyclic ketone **9** (11) and 110 mg (1.04 mmol) trimethylorthoformate in 0.25 ml of a 0.5% solution of *p*-toluenesulfonic acid in dry methanol was left at room temperature for 3 h. The solvent was removed at room temperature and the crude product was separated by preparative t.l.c. (15% dry ether/petroleum ether) to give 12 mg ketone **9** (R_f 0.30) and 66 mg (55% based on reacted ketone) bicyclic ketal **7** (R_f 0.45); i.r. (CCl_4) 3090, 3030, 2920, 1110, 1055, 713 cm^{-1}; n.m.r. (CCl_4) τ 3.81 (1H, d, J = 3 Hz, vinyl), 3.98 (1H, d, J = 3 Hz, vinyl), 6.88 (6H, s, $>C(OCH_3)_2$), 6.80–7.00 (2H, m, $-\overset{|}{\underset{|}{C}}-H$ at ring fusion), 8.00–8.60 (6H, m, methylene); m.s. molecular ion at *m/e* 168. G.l.c. analysis (column A, 136°) of this compound showed only one peak at retention time 3 min which was shown to be enol ether **8**.

Preparation of Dimethyl Ketal of 1

A solution of 300 mg (2.5 mmol) of **1** and 300 mg (2.8 mmol) trimethylorthoformate in 0.5 ml of a 1% solution of *p*-toluenesulfonic acid in dry methanol was left for 1.8 h at room temperature. The solvent was removed and the reaction mixture was separated by preparative t.l.c. (30% dry ether/petroleum ether) to give 73 mg (18%) of the dimethyl ketal of **1** (R_f 0.65); i.r. (CCl_4) 3010, 2930, 1630, 1218, 1152, 1108, 1090, 716 cm^{-1}; λ_{max} (CH_3OH) 239 mμ (ε 7380); n.m.r. (CCl_4) τ 3.8–5.1 (4H, m, vinyl), 6.48 (3H, s, $-OCH_3$), 6.81 (3H, s, $-OCH_3$), 7.5–9.1 (6H, m, methylene); m.s. molecular ion at *m/e* 168. G.l.c. analysis (column A, 136°) showed only one peak at retention time of 10.5 min.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.41; H, 9.92. Found: C, 71.82; H, 9.97.

Thermal Isomerization of Ketal 6

A solution of 50 mg ketal **6** in 5 ml dry toluene was heated to reflux for 1 h. The solvent was removed and examination of the residue by i.r., n.m.r., and analytical t.l.c. revealed that it consisted of >95% bicyclic ketal **7**.

Low Temperature Trapping Experiments

(*a*) A solution of 250 mg (2.04 mmol) of **1** and 125 mg hexadecane (internal standard) in 125 ml dry toluene was placed in a specially constructed low temperature apparatus (10) and irradiated at −78° with a 350 mμ source for 1.5 h. The u.v. source was turned off and 50 ml dry methanol was added with mixing. The solution was allowed to slowly warm to room temperature and the solvents were removed under reduced pressure. Examination of the products by g.l.c. (column A, 136°; column B, 160–275°) showed 7% methoxyenone **4**, 18% dimer **2**, 25% dimer **3** and the remainder was **1**.

(*b*) A solution of 250 mg of **1** and 125 mg hexadecane in 125 ml dry toluene was irradiated at −78° as described above and after turning off the u.v. source a solution of 4 μl conc. hydrochloric acid in 60 ml dry methanol was added with mixing. The solution was allowed to warm to room temperature and the solvents were removed. Examination of the residue by g.l.c. using the conditions as above showed 20% enol ether **8**, 12% combined yield of dimers **2** and **3** and the remainder was **1**. Analytical t.l.c. (15% dry ether/petroleum ether) indicated that **1** was the major component and that ketal **6** was present in about one-third the concentration of **1**.

The Geometry of the Methyloxocarbonium Ion Trimer: A CNDO/BW Study

JAMES DOUGLAS PULFER[1] AND MICHAEL ANTHONY WHITEHEAD[2]

The Chemistry Department, McGill University, P.O. Box 6070, Montreal 101, Quebec

Received November 15, 1972

Within the Boyd–Whitehead CNDO theory three consistent methods were developed to calculate the carbon–oxygen infrared frequency of several oxocarbonium ions. The first method, type I, showed that the parameters of the CNDO/BW theory are not useful for predicting bond angles. Type II established a correlation between the C(α)—C bond length and the carbon–oxygen frequency. Type III predicted the correct trend for the homologous series of alkyloxocarbonium ions; however, the calculated frequency was consistently higher than experiment by 20–50 cm^{-1}. Conjugation effects were estimated by applying the above methods to the phenyloxocarbonium ion.

Variations on two possible configurations of the methyloxocarbonium ion trimer were studied. The protonated, planar diacetylmethenyloxocarbonium ion, Ac_2HCCO^+, was shown to be the most stable. A type II calculation estimated the C(α)—C bond to be about 1.37 Å. A type III calculation showed the possibility of the existence of the methyloxocarbonium ion dimer.

A l'intérieur de la théorie CNDO de Boyd–Whitehead, trois méthodes cohérentes furent développées pour calculer la fréquence d'absorption en infra-rouge du groupe carbone-oxygène pour plusieurs ions oxocarboniums. La première méthode, type I, a montré que les paramètres de la théorie CNDO/BW ne sont pas utiles lors de la prédiction des angles de liaison. Le type II a permis d'établir une corrélation entre la longueur du lien C(α)—C et la fréquence du lien carbone–oxygène. Le type III a permis de prédire la tendance correcte pour une série homologue d'ions alcoyloxocarboniums; cependant, la fréquence calculée a été constamment plus élevée que les valeurs expérimentales par 20 à 50 cm^{-1}. Les effets de conjugaison ont pu être estimés en appliquant les méthodes ci-haut mentionnées à l'ion phényl oxocarbonium.

Les changements dans les deux conformations possibles du trimère de l'ion méthyloxo carbonium ont été étudiés. La forme protonée et planaire de l'ion diacétylméthènyloxocarbonium, Ac_2HCCO^+, est la plus stable, comme il est démontré. Un calcul selon le type II a permis d'estimer que la longueur de la liaison C(α)—C est d'environ 1.37 Å. Un calcul du type III nous a permis de montrer la possibilité d'existence du dimère de l'ion méthyloxocarbonium. [Traduit par le journal]

Introduction

There continues to be considerable scientific interest in the geometries and charge distributions of the alkyl-, acyl-, and aryloxocarbonium ions. These ions have been shown to be the active electrophillic reagents in Friedel–Crafts reactions. When Seel (1) first reported the presence of the stable, crystalline methyloxocarbonium tetrafluoroborate $(CH_3CO^+)(BF_4^-)$ salt it was thought (2, 3) that the principle acylating agent in Friedel–Crafts reactions was the linear methyloxocarbonium ion; however, no clear statement could be made on this problem for a number of reasons: Wuhrmann and Susz (4) were the first to report the presence of a weakly absorbing infrared frequency in the $CH_3COCl{\cdot}AlCl_3$ complex at 2200 cm^{-1}, in addition to the strongly absorbing frequency at 2300 cm^{-1}. Cook (5) showed that the 2200 cm^{-1} band was almost nonexistent in the freshly prepared complex, yet in a solution of nitrobenzene the 2300 cm^{-1} band was almost completely replaced by the one at 2200 cm^{-1}. Cassimatis *et al.* (6) have also reported that during attempts to recrystallize the methyloxocarbonium tetrachloroaluminate salt from liquid sulfur dioxide, the crystalline complex converted partly to an amorphous, less structured mass, and the presence of both frequencies was detectable from this material.

For the above reasons, further investigation into the chemistry of the methyloxocarbonium ion has been necessary. Germain *et al.* (7) have isolated two chemically distinct salts from a mixture of acetyl chloride and aluminium trichloride: the familiar methyloxocarbonium tetrachloroaluminate (**1**) and the trimer salt. They postulated that the trimer is the protonated, planar diacetylmethenyloxocarbonium ion, Ac_2HCCO^+; how-

ever, they did not discount the possibility that it might be the diacetylmethyloxocarbonium ion, Ac_2CHCO^+.

The skeleton structure and electron charge distribution of the cation in **1** is thought to be known (8, 9); the same cannot be said of the trimer. LeCarpentier and Weiss (9) are in the process of elucidating the crystal structure of the recrystallized tetrachloroaluminate salt of the trimer by X-ray techniques. One of the purposes of the present paper is to theoretically investigate the relative stability of the two most likely conformations of the trimer by means of the Boyd–Whitehead (10, 11) bond length dependent CNDO theory. The two principle structures of the trimer considered have been shown in Figs. 1, 2, and 3.

To discuss the possible conformations of the trimer, it was necessary to study the stereochemistry and charge structures of some related oxocarbonium ions and to try to correlate the geometry of these structures to the observed infrared frequency in a theoretical manner. The phenyloxocarbonium ion and the homologous series of alkyloxocarbonium ions, starting with the methyloxocarbonium ion, were particularly useful. Two major attempts have been put forward to elucidate the structure and electron configuration of the methyloxocarbonium ion. Boer (12) did an X-ray study of the crystal structure of the methyloxocarbonium hexafluoroantimonate salt. Based on the results of that work, the NEMO method (13) was used to try to obtain the electron configuration of the ion. In this calculation it was assumed that the hydrogen atoms were in the tetrahedral positions. An interesting result was obtained. Carbon atom C_2, in Fig. 4, had a formal positive charge of

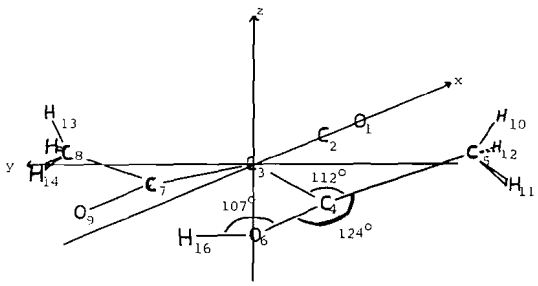

FIG. 1. Coordinates for the protonated planar acetyl- and diacetylmethenyloxocarbonium ions. In the former case, the C_7 atom is replaced by a hydrogen atom. All atoms except the hydrogens, are in the x–y plane.

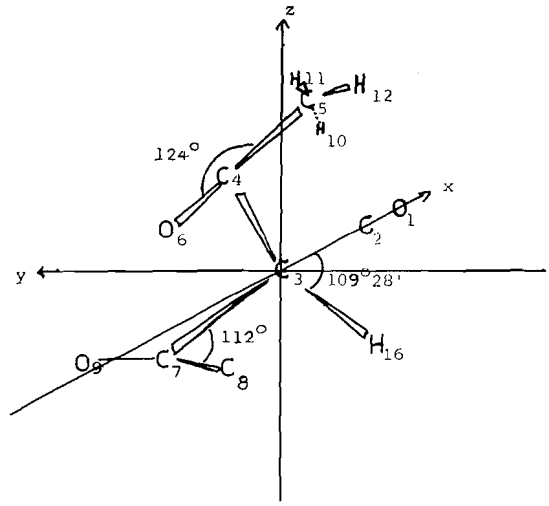

FIG. 2. Coordinates for the diacetylmethyloxocarbonium ion. The $O_6C_4C_5$ plane is rotated 60° to the x–z plane; hydrogen atoms 11 and 12 are staggered with respect to the C_4—O_6 bond. The atoms C_1, C_2, C_3, and C_4 are in the x–z plane. The C_7—C_8 bond bisects angle C_7—C_3—H_{16}.

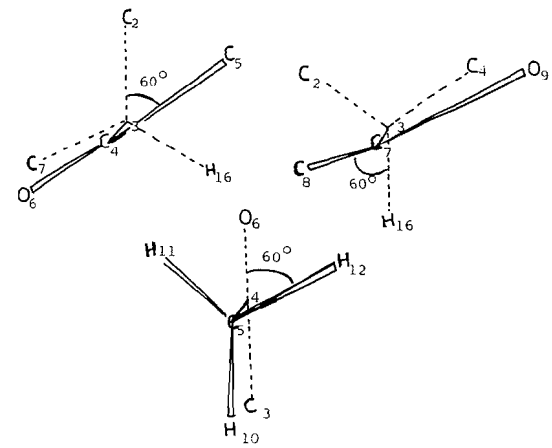

FIG. 3. The sterographic choice of angles used to generate the coordinate system of the diacetylmethyloxocarbonium ion.

1.18 electrons on it. Boer's X-ray work showed that the C_2—C_3 bond length was 1.385 Å.

Veillard and co-workers (8) performed a series of *ab initio* calculations on the methyloxocarbonium ion where the geometry of the C_2—C_3 bond was optimized. After a reasonable value was obtained for this bond, the positions of the three methyl hydrogens were optimized. Both optimizations were carried out with respect to the total energy of the ion. These calculations showed

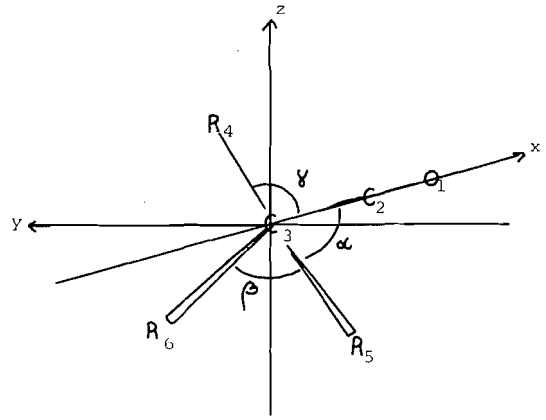

FIG. 4. The coordinates of the alkyloxocarbonium ions: $R_4 = R_5 = R_6$ = Hydrogen, CH_3CO^+; $R_4 = CH_3$, $R_5 = R_6 = H$, $C_2H_5CO^+$; $R_4 = R_5 = CH_3$, $R_6 = H$, $i\text{-}C_3H_7CO^+$; $R_4 = R_5 = R_6 = CH_3$, $t\text{-}C_4H_9CO^+$.

that the C_2—C_3 bond was longer than that reported by Boer, around 1.452 Å. Le Carpentier and Weiss (9) have recently verified this value by X-ray analysis. The *ab initio* charge distribution showed that carbon atom C_2 had a net positive charge of 0.605 electrons. This appears to be a much better estimate, the rest of the formal positive charge being delocalized onto the three equivalent hydrogen atoms in the molecule–ion. The optimum position of the hydrogen atom was found to be the tetrahedral position.

The structures and electron configurations of the other cations in the homologous series are generally less well known. Le Carpentier and Weiss (14) have published some refined results of X-ray studies done on the structure of the ethyl- and isopropyloxocarbonium ions. The structure of the latter ion does not differ significantly from their earlier results (15). The *ab initio* charge distribution of the isopropyloxocarbonium ion has been calculated using a contracted set of gaussian s and p type orbitals (8). The charge on the carbon atom, C_2, was found to be +0.733, and the C_2—C_3 bond was 1.46 Å. There is no X-ray analysis of the tert-butyloxocarbonium hexafluoroantimonate salt.

Veillard and co-workers (8) have pointed out that the molecular structure of methyl cyanide is very similar to the corresponding isoelectronic methyloxocarbonium ion. Corresponding structural data is not available for isobutyronitrile; however, the average length of the C_2—C_3 bond in nitriles of the type $-\overset{|}{\underset{|}{C_3}}-C_2\equiv N$ is around 1.464 Å (16) which is 0.014 Å longer than the length of the corresponding bond in the isopropyloxocarbonium ion (14). The difference is not large and can be partly explained by the higher positive charge located on carbon atom C_2 of the oxocarbonium ion. As a result, the C_2—C_3 bond of the tertbutyloxocarbonium ion was assigned a length of 1.46 Å, which is the same as the comparable bond in tert-butyl cyanide (17).

In addition to these ions, the phenyloxocarbonium ion was studied, in order to estimate how well the various types of calculations might predict the geometry and infrared stretching frequency of a highly conjugated system. The X-ray structure of the phenyloxocarbonium hexafluoroantimonate salt has not been done although the X-ray structure of the covalent complex $Cl_5Sb—O=\overset{|}{\underset{Cl}{C}}—C_6H_5$ has (18). In this complex, the corresponding C_2—C_3 bond was found to be 1.51 Å, an elongated π bond. A much shorter bond would be expected for the ionic salt; consequently, this bond had to be estimated from available data for the isoelectronic phenyl cyanide molecule. Two independent microwave studies of this molecule (19, 20) have shown C_2—C_3 values of 1.4509 Å and 1.419 Å. The shorter length was chosen for these calculations because of the shortening effect of the positive charge at C_2 (Fig. 5).

The infrared spectra are known for all the oxocarbonium ions, including the trimer. The possible existence of the methyloxocarbonium ion dimer was also investigated. No infrared data are available to prove the existence of this ion in solution; however, there is the possibility that the stretching frequency of it might be masked by the stretching frequency of the trimer.

The Calculation

The molecular orbitals and the total energy of each of the organic oxocarbonium ion conformations was evaluated within the LCAO-MO-CNDO-BW approximation (10, 11). The core resonance integral was evaluated as an "overlap ionization potential" between two atomic orbitals k and l on atoms A and B, *i.e.*

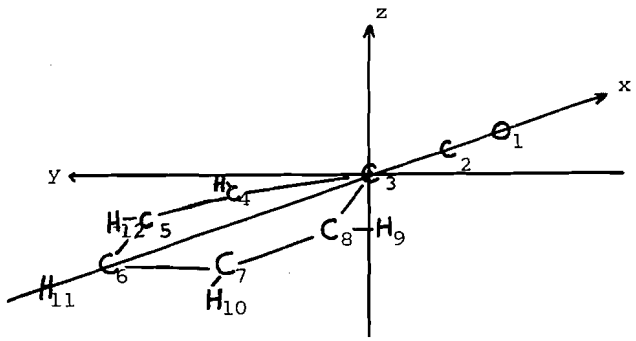

FIG. 5. Coordinates for the aryloxocarbonium ion $C_6H_5CO^+$. $\angle C_4C_3C_8 = 120°$, $\angle C_3C_8H_9 = 120°$, $\angle C_3C_2O_1 = 180°$.

$$[1] \qquad H_{kl} = \beta_{AB}\{I_k + I_l\}S_{kl}$$

Here I_k is the Hinze–Jaffé valence state ionization potential of the kth atomic orbital and S_{kl} is the overlap between the two Slatar type atomic orbitals k and l.

In these calculations, the nuclear–nuclear core repulsion terms between two atoms A and B, N_{AB}, was evaluated as a weighed average between the point charge nuclear repulsion term and the appropriate electron charge interaction between atoms A and B

$$[2] \quad N_{AB} = \lambda_{AB}(Z_AZ_B/R_{AB}) + (1 - \lambda_{AB})Z_AZ_B\gamma_{AB}$$

Here λ_{AB} was defined as

$$[3] \qquad \lambda_{AB} = \exp(-\alpha_{AB}R_{AB})$$

The electron–electron repulsion integral γ_{AB}, in eq. 2, is an average electron repulsion integral between two atoms A and B. It was evaluated by Ohno's method (21), and modified by Sichel and Whitehead (22) to take into account the relative proportions of γ_{ss}, γ_{sp}, γ_{pp}, and $\gamma_{pp'}$, required to yield a homopolar bond within the CNDO approximation.

In Boyd's thesis (23) it is shown that if eqs. 1 and 2 are used to calculate the core resonance integrals and the nuclear–nuclear core repulsion integrals then slightly better and more consistent force constants were obtained than by other methods of calculating H_{kl} and N_{AB}. The parameters, α_{AB} and β_{AB} were determined from diatomic molecules where the internuclear distance was accurately known. The α_{AB} and β_{AB} used in the present calculations were evaluated in the manner outlined above. This set of characteristic constants have been designated parameter set I by Boyd and Whitehead.

In the current calculations the CNDO/BW computer program was fitted with a subprogram for efficiently calculating the optimum geometry of the molecule. This subprogram makes use of a method first developed by Fletcher and Powell (24). A gradient vector for any initially selected geometry was computed for several molecular geometry parameters. From this gradient vector, the subprogram determines the direction of the steepest descent and steps in that direction. The stepsize of each parameter is determined by the size of the partial derivatives of each of the variables. At the new position, another gradient vector and a second total energy were calculated. If the program has stepped too far then a quadratic fit of the points available is made and a new position of the minimum energy found. The process is repeated until the total minimum energy agreed to a specified tolerance, 1×10^{-5}. The method has quadratic convergence and has proven to be superior to other existing methods (24).

Once the optimum geometry was calculated by this method, the several variables employed in the calculation were frozen and the bond length of the carbon oxygen bond was set at two positions bracketing the lowest energy position. A useful stepsize was 0.02 Å. At this stepsize, the anharmonic nature of the potential well of the carbon–oxygen bond was minimized. This made it possible to calculate the force constant using only three points. If the shape of the potential energy curve was badly skewed, *i.e.* one of the terminal points on the interval of interest had a much higher energy than the other, then more points were calculated and a higher order polynomial was used to approximate the total energy function.

The interpolating polynomial was the Newton forward difference polynomial (25). The total energy of the molecule was expressed as a function of the carbon–oxygen bond length.

$$[4]\quad E(s) = E_1 + \frac{s}{1!}\Delta E_1 + \frac{s(s-1)}{2!}\Delta^2 E_1 + \frac{s(s-1)(s-2)}{3!}\Delta^3 E_1 + \ldots$$

Δ is the forward difference operator defined as

$$[5]\quad \Delta^n E_1 = \Delta^{n-1} E_2 - \Delta^{n-1} E_1$$

In general, E_m is the total energy of the ion corresponding to a carbon–oxygen bond length x_m where

$$[6]\quad x_m = x_e + \{(n + 1 - 2m)/2\}h, \qquad n \text{ odd}$$

The equilibrium bond length, x_e, was usually the value calculated by the Fletcher–Powell minimization procedure, n is the total number of points in the interpolating polynomial and h is the stepsize between various consecutive points. The variable s, in eq. 4, is a simple function of the bond length x where

$$[7]\quad x = x_e + sh$$

Equation 4 yields a simple relationship for the second derivative of the energy with respect to the carbon–oxygen bond length if three interpolating points were used.

$$[8]\quad \frac{\partial^2 E}{\partial x^2} = \frac{\Delta^2 E_1}{h^2}$$

If the bond has a large degree of anharmonic character to it, then further points must be included in the interpolating polynomial and an equilibrium bond length must be calculated in order to evaluate the second derivative. For most cases, eq. 8 was sufficient to numerically evaluate the second derivative.

Let k_{CO} be the force constant of the carbon–oxygen bond. The second derivative was identified with the force constant.

$$[9]\quad k_{CO} = \{\Delta^2 E_1/h^2\} \cdot K$$

Here K is a conversion factor, from eV/Å^2 to ergs/cm^2. This force constant was used to calculate the infrared stretching frequency.

$$[10]\quad \bar{\nu}_{CO} = \frac{1}{2\pi ch}\sqrt{\frac{\Delta^2 E_1 \cdot K}{\mu_{CO}}}$$

The constant c is the speed of light and μ_{CO} the reduced mass of the carbon–oxygen bond; h is the stepsize mentioned previously.

Results

In order to calculate a consistent carbon–oxygen infrared stretching frequency for a wide range of organic oxocarbonium ions a systematic approach had to be developed. The methyl-, ethyl-, isopropyl-, tert-butyl-, and phenyloxocarbonium ions were used as a basis for testing the three different methods of calculating this particular frequency. In the first method, designated type I, all nearest neighbor geometries that might have an influence on the electron charge structure of the linear chain O_1—C_2—C_3, seen in Fig. 4, were simultaneously varied so as to achieve the most stable geometry. Consequently, all bond lengths shown in Fig. 4 were varied, with the exception of the carbon–hydrogen bonds in the methyl radicals (R_4, R_5, and R_6). These were fixed at 1.09 Å. The bond angles α, β, and γ were also varied at the same time. The resulting geometries for the first three ions mentioned in this series have been presented in Table 1 along with the total energy minimum.

The carbon–oxygen bonds for the methyl- and ethyloxocarbonium ions have been found to be slightly longer (~0.018 Å) than those in the literature; and for the isopropyloxocarbonium ion the calculated carbon–oxygen bond has been shown to be insignificantly longer (~0.008 Å). In general, the slightly longer carbon–oxygen bond lengths are mainly the result of an overestimation of the core nuclear–nuclear repulsion energy terms in the Boyd–Whitehead CNDO theory. In Boyd's thesis (23) there was a discussion of this problem for the carbon monoxide molecule, and the singly ionized carbon monoxide ion. The core nuclear–nuclear repulsion energy terms for carbon monoxide were calculated using eq. 2, and were compared to the Morse potential curve. The calculated values were shown to be consistently too large for all but the equilibrium internuclear distance (1.128 Å). As a consequence, *cataris parebus*, any overestimation of the core repulsion terms will result in an overestimation of the subsequently calculated bond length. Boyd's thesis also shows that parameter set I overestimates the correct bond length for the ionized carbon monoxide molecule by 0.012 Å. These results imply that, within the limitations

of the theory, the carbon–oxygen bond lengths calculated for the alkyloxocarbonium ions are in reasonably good agreement with experiment.

The carbon–carbon bond lengths presented in Table 1 are also consistently overestimated when compared to experiment. This is primarily due to an overestimation of the core repulsion terms as well. For the two oxocarbonium ions with methyl groups substituted for hydrogens at the C_3 position, the average overestimation for the carbon–carbon $C_2—C_3$ bond is 0.08 Å. The observation implies that in chemically similar systems, it may be possible to apply this overestimation as a correction to any carbon–carbon bond length computed by the Boyd–Whitehead CNDO theory.

The computed angles of the three ions studied by type I calculations were interesting. The angles of the methyloxocarbonium ion were found to be very close to the ideal. This is the same result as was found by Veillard and co-workers (8). In the case of the ethyloxocarbonium ion the angles are close to those found for the isoelectronic ethyl cyanide molecule (26). There is a slight widening of the H—C—H angle, probably due to the increase in the angle γ, which is the result of the increase in the non-neighbors electron–electron repulsion terms between the methyl group and the linear carbon–carbon–oxygen skeleton chain $C_3—C_2—O_1$. The angles found for the isopropyloxocarbonium ion show that the single hydrogen attached to the C_3 carbon atom has floated to a position that allows it to bond with maximum overlap to the carbon p_y atomic orbital. This calculated result arises because the Boyd–Whitehead theory was not parameterized to take non-neighbor interactions explicitly into account (10, 11, 23). As a result,

there is a general tendency to overestimate non-neighbor repulsive forces. In the case of the hydrogen atom this has lead to the anomalous result where the angle α is 87°.

The two methyl groups experience roughly the same electron–electron repulsions from the linear carbon–carbon–oxygen C_3—C_2—O_1 systems as did the methyl group in the ethyloxocarbonium ion, as a result the movement of the hydrogen atom to the energetically more stable position has allowed the angle γ to widen further than in the case of the ethyloxocarbonium ion. The angle β has decreased, when compared to the ethyloxocarbonium ion. This was possible because of the significant lengthening of the carbon–hydrogen bond.

Type I calculations do not reproduce a consistent trend in the observed carbon–oxygen infrared frequency of the methyl-, ethyl-, and isopropyloxocarbonium ions. Figure 6 shows that the curve plotted from the calculated infrared frequencies does not consistently reproduce the shape of the experimental curve. Both the ethyl- and the isopropyloxocarbonium ions gave frequencies larger than necessary to reproduce a smooth, consistent approximation to the experimental curve. Consequently, as a method of calculating the frequency of the carbon–oxygen bond, the type I calculation proved to be generally unacceptable. The shape of the total energy surface of the carbon–oxygen bond is not well reproduced by type I calculations, even though this type of calculation generally gives the lowest possible energy. As was previously pointed out, the inconsistency of this type of calculation may be partly the result of parameterization. The CNDO/BW theory has been parameterized for bond length dependence and not for non-neighbor dependence. A new, greatly expanded set of parameters would have to be developed, to take into account the non-neighbor effects.

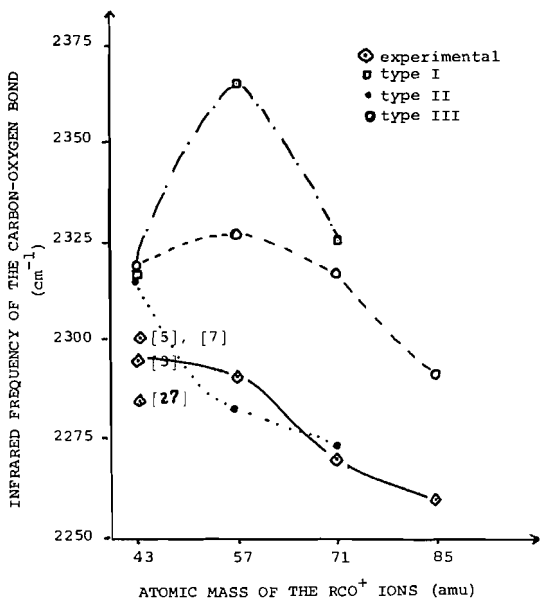

FIG. 6. The frequency of the carbon–oxygen bond as a function of the atomic mass of the alkyloxocarbonium ions where R = CH_3, C_2H_5, i-C_3H_7, t-C_4H_9.

A second method, type II, was developed. The length of the carbon–carbon bond adjacent to the carbon–oxygen bond has a critical effect on the shape of the total energy surface of the ions in the region of the carbon–oxygen bond. This has been described by many authors (6, 7). The extent of the conjugation along the carbon–carbon–oxygen (C_3—C_2—O_1) chain directly affects the frequency of the carbon–oxygen bond. The smaller the conjugation effects, the higher the frequency. For example, the frequency of the methyloxocarbonium ion bond is around 2300 cm^{-1} (3, 7, 27) whereas the phenyloxocarbonium ion carbon–oxygen frequency has been measured to be 2212 cm^{-1}.

Those observations can be rationalized by looking at the gross charge structure of the carbon–carbon–oxygen system. The bulk of the positive charge resides on the carbon atom bonding with oxygen. Typical results have been presented in Table 2. The calculated value for the methyloxocarbonium ion, +0.73 compares favorably with the *ab initio* result obtained by Veillard and co-workers (8) which was +0.605. This high positive charge is thought to be responsible for the high carbon–oxygen frequency observed for the methyloxocarbonium ion. The observed frequency is about 160 cm^{-1} higher than that of the carbon monoxide molecule. The major difference between these two stretching frequencies is the difference in the positive charge on the carbon atom. Any change in this high positive charge causes a corresponding change in the net negative charge on the oxygen atom. In Table 2 it can be seen that the total differential charge density on the oxygen atom increases regularly as the positive charge on the carbon atom C_2 decreases. In the limiting case, carbon monoxide

would be expected to have the largest total differential charge on the oxygen atom. In preliminary calculations this was the case. The presence of the positive charge has the effect of equalizing the electronegativities of the oxygen and carbon atoms. The result is a higher carbon–oxygen bond order in the oxocarbonium ions than in carbon monoxide. This implies a larger force constant and a higher frequency; all observed frequencies of the oxocarbonium ions are higher than carbon monoxide.

Conjugation of the skeleton chain delocalizes the positive charge on the carbon atom and, as a consequence, lowers the stretch frequency towards that of the free carbon monoxide frequency. A comparison of the results for the planar protonated diacetylmethenyloxocarbonium ion, Ac_2HCCO^+, with those for the tetrahedral case, shown in Table 3, supports the above arguments. The conjugated species has a larger negative charge on the oxygen atom and a smaller total bond order for the carbon–oxygen bond. The calculated infrared stretching frequencies, in Table 4, show that the conjugated ion has a much lower stretching frequency than the tetrahedral case.

For the above reasons, type II calculations were devised as an improvement on the type I calculations and as a method for correlating the C_2—C_3 bond length to the observed frequency. The extent of the conjugation of the carbon–carbon–oxygen (C_3—C_2—O_1) skeleton chain is governed, in large part, by the length of the carbon–carbon bond, and as was previously pointed out, the bond length dependent theory overestimates the carbon–carbon bond lengths. Consequently, in type II calculations, the experimental bond length, when available, or a reasonable estimate of it, based on microwave studies of the isoelectronic alkyl- or phenyl cyanides was substituted. The experimental bond lengths ought to increase the degree of conjugation of the chain; and lower the calculated frequency of the carbon–oxygen bond provided all other aspects of the calculation remain the same. In the type II calculations, no attempt was made to vary the bond angles, those found in type I calculation were used without change. The carbon–oxygen and carbon–radical bonds, *i.e.* C_3—R_4, C_3—R_5, and C_3—R_6, were simultaneously varied to find a new energy minimum. The calculated infrared frequencies were placed in Table 4. In general, the frequencies have been lowered to values very close to experimental; however, Fig. 6 shows that

the correct trends are not predicted by this method. It does show that if the correct carbon–carbon bond length is substituted then reasonable values, close to the observed infrared frequency, could be calculated.

A third method, type III, was devised. The CNDO/BW theory was parameterized for bond length dependence. This parameterization took no account of angular correlation between non-neighbor groups. This implied that angular variation in CNDO/BW calculations might have little meaning. As a consequence, idealized chemical bond angles might be just as reasonable as those obtained by an explicit calculation. The concept of an ideal chemical bond is a simple one. If a chemically related system has nearly tetra-

hedral bond angles, then type III calculations would be set up to fix the bond angles in an ideal tetrahedral position. For example, the nearly tetrahedral bond angles of the isoelectronic ethyl cyanide molecule would be a good indication of the ideal angles for the ethyloxocarbonium ion. They would be tetrahedral. In type III calculations, the bond lengths of the carbon–oxygen C_2—O_1, carbon–carbon C_2—C_3, and carbon–radical C_3—R_4, C_3—R_5, and C_3—R_6 bonds were simultaneously varied to find a global energy minimum. The resulting frequencies are uniformly higher than the experimental ones, as can be seen in Fig. 6; however, the trend in the experimental frequencies was reproduced. Of the three methods considered, type III calculations have shown the most consistent results for reproducing the experimental trend of the observed infrared frequencies. The results of the type III CNDO/BW calculations are presented in Tables 1, 2, and 4. If the methyloxocarbonium ion is omitted as a special case, then type III calculations consistently yield frequencies that are about 35 cm^{-1} higher than experiment.

A further calculation could be devised whereby the carbon–carbon C_2—C_3 bond length could be fixed at a chemically reasonable value and the other bond lengths varied along the same idealized angles as were used in type III calculations. This method was used on the phenyloxocarbonium ion and the trimer. It is, in fact, a modification of the type II method. The drawback with this calculation is a lack of generality; however, for specific ions, it can aid in pinpointing the correct C_2—C_3 bond lengths.

Type III calculations have been outlined, in the preceding paragraphs, for the consistent calculation of the infrared stretching frequency of the carbon–oxygen bond in the homologous series of alkyloxocarbonium ions; however, this general scheme was not comprehensive enough. In addition to the aliphatic oxocarbonium ions, it was necessary to ascertain the reliability of the type III calculations for a highly conjugated ion like the phenyloxocarbonium ion. This calculation predicted a rather long carbon–carbon C_2—C_3 bond length, 1.51 Å. The isoelectronic phenyl cyanide molecule has a carbon–carbon length between 1.4509 Å (19) and 1.419 Å (20), the average of these two values being 0.075 Å smaller than the result given by the Boyd–Whitehead calculation. Consequently, the bond length is probably overestimated by at least that length. This analysis has important implications for applying the modified type II calculations to the phenyloxocarbonium ion.

The type III calculation showed a frequency 93 cm^{-1} higher than the experimental value of 2212 cm^{-1} for the phenyloxocarbonium ion. This implied that in cases of high conjugation, the infrared frequency calculated by this method may be overestimated by as much as 90–100 cm^{-1}. In absolute terms this is not very satisfactory. A comparison of the results in Table 4 shows that the calculated infrared frequencies of the phenyloxocarbonium ion are of the same order of magnitude as those for the aliphatic series; however, as has been pointed out previously, type III calculations are only valuable for being able to consistently predict a trend within a series of chemically similar molecule–ions. It is this property that makes them useful. As a consequence of this, caution must be exercised when analyzing the absolute values that result from a type III calculation. This type can point out certain possibilities and trends, but more detailed calculations must follow.

Two modified type II calculations have been carried out on this system in order to try to isolate the major factor that contributes to this rather large error in the frequency. In the first case, type II_1, the carbon–carbon bond was estimated to be the same as the isoelectronic phenyl cyanide molecule (20). The bond angles at O_1, C_2, and C_3 were fixed at ideal values: 120° at C_3 and 180° at C_2. The benzene ring was slightly distorted. The C_3—C_4 type bonds were made a bit longer, 1.402 Å; the others were fixed at 1.394 Å. This was in keeping with the findings of Casado *et al.* (19). The carbon–oxygen bond was the only variable. This calculation gave a frequency of 2277 cm^{-1}, 65 cm^{-1} too high. The frequency and bond lengths are presented in Tables 4 and 5. The C_2—C_3 bond used was about 0.09 Å smaller than the type III value. By shortening this bond there has been a 30 cm^{-1} improvement in the frequency. As in the case of the aliphatic ions, there appears to be a direct correlation between the C_2—C_3 bond length and the calculated frequency.

In the second, modified type II_2, calculation the carbon–carbon bond was estimated as approximately the same as the bond length between two carbon atoms in the sp hybridized valence state. The result was a calculated frequency 4 cm^{-1} above the experimental value. In this calculation the benzene ring was not

*The $C_2—C_3$ bond is taken from microwave studies of the isoelectronic phenyl cyanide.
†The $C_2—C_3$ bond is estimated as a carbon–carbon sp–sp bond length.

distorted. The $C_2—C_3$ bond was shortened 0.171 Å when compared with the type III value. This may seem a large change, however, there is some justification for this type II_2 calculation. Casado *et al.* (19) have shown that electrophillic substituents, like the cyanide radical, distort the shape of the benzene ring. Figure 5 shows the $C_4—C_3—C_8$ bond angle as 120°; however, if an electron withdrawing substituent is situated at the C_3 position, this angle opens up to around 122°, and the carbon–carbon $C_3—C_4$ bonds of the benzene ring lengthen from the normal length of 1.394 Å to 1.402 Å. If this bond angle widened still further, as it might for the $C^{\delta+}—O^{\delta-}$ substituent, then the sp^2 hybridization of the carbon atom C_3 would undergo further reorganization towards an sp hybridized state. Carbon atom C_2 is already in an sp hybridized valence state. In addition, the mean average radii of the electrons in the sp valence state localized on carbon atom C_2 are probably shortened as a result of the large positive charge carried by that carbon atom (+0.73). The net effect of these three factors will be to considerably shorten the $C_2—C_3$ bond, possibly to 1.339 Å which is the carbon–carbon bond length in acetylene.

It would appear that the type III calculation has overestimated the $C_2—C_3$ bond in the phenyloxocarbonium ion more than when the same calculation was applied to the aliphatic series. In the homologous series of ions, the overestimation varied, but was generally around 0.08 Å. It would appear that the same bond in the phenyloxocarbonium ion has been overestimated by between 0.09 Å and 0.17 Å. This leads to the interesting observation that the type III bond length calculation may act as a reflection of the degree of conjugation. The higher the degree of conjugation between the $C_3—C_2—O_1$ chain and the rest of the molecule, the longer the overestimation. For example, the results of type III calculations on the homologous series of alkyloxocarbonium ions have shown that in the cases where the overestimation of the bond length was small, the corresponding overestimation of the frequency was also small. In conclusion, the difference between the calculated and observed frequencies can be directly correlated to the overestimation of the bond length: both within the homologous series and for a highly conjugated system. It is with this conclusion in mind that one must interpret any type III results. Thus in the case where there is almost no possibility of conjugation, as with the methyloxocarbonium ion, the overestimation of the infrared frequency is about 20 cm^{-1}. A reasonably accurate bond length would be expected and this is what is observed. On the other end of the scale, in a highly conjugated system the frequency is in error by 90 cm^{-1} and it is reasonable to suppose that the bond length is also quite a bit larger than the actual figure.

These observations have interesting implications for the applicability of this work to the shapes and structures of the methyloxocarbonium ion dimer and trimer. Modified type II calculations could point the way to an accurate estimation of the bond lengths of the $C_3—C_2—O_1$ skeleton shown in Fig. 1, whereas type III calculations could indicate which, of several possible configurations, is the most stable and, because of its consistency within a given series, point the way to the possible existence of the dimer.

The geometry of the methyloxocarbonium ion trimer is not known although it is thought to be a protonated planar diacetylmethenyloxocarbonium ion (7) as shown in Fig. 1. To apply type III calculations, it is necessary to know the

idealized valence state of carbon atom C_3; consequently two cases were studied. The first considered C_3 in the sp^3 state. The geometry employed for this calculation has been shown in Figs. 2 and 3. The bond lengths were varied and the bond angles were fixed. In this case, five bond lengths were simultaneously varied, the $C_2—O_1$, $C_2—C_3$, $C_3—C_4$, $C_4—O_6$ and the $C_3—H_{16}$ bond lengths. The results of this work have been shown in the last column of Table 6. Two features of note in this calculation are the lengths of the $C_3—C_4$ and $C_4—O_6$ bonds. In the former, the bond length is a long sigma bond and, in the latter case, a shortened pi bond. Normally a carbon–carbon sigma bond would be about 1.54 Å; the calculated length was 1.664 Å. This is probably overestimated by at least 0.08 Å and, if that correction is applied, the result is a bond length of about 1.58 Å, which is an elongated carbon–carbon sigma bond. On the other hand, the normal carbon–oxygen pi bond for the acetyl chloride molecule is 1.25 Å. The corresponding bond in this ion is 1.173 Å which is probably overestimated by about 0.02 Å. The considerable shortening of this bond can be described, in part, by the charge on the carbon atom C_4. As is shown in Table 3 this carbon atom is almost carrying as much formal positive charge as carbon C_2. One other significant feature of this calculation is the energy of the ion. The total energy of this ion is −1906.81 eV.

A second study was carried out where carbon atom C_3 was assigned an sp^2 hybridized valence state. The idealized geometry of this ion is shown in Fig. 1. This is the protonated planar ion favored by Germain *et al.* (7). The hydrogen is situated in a double well potential between the two acetyl radical oxygen atoms. A preliminary calculation showed that the ion was most stable when the oxygen–carbon bonds of the acetyl radicals were nearly parallel and the $O_9—C_7—C_8$ axis was rotated 2° counterclockwise with respect to the x–y plane, *i.e.* counterclockwise in the sense of looking along the $C_3—C_7$ bond from C_3. Starting with this preliminary geometry, six bond lengths were simultaneously varied in this calculation; these six variables were the $C_2—O_1$, $C_2—C_3$, $C_3—C_4$, $C_4—O_6$, $C_7—O_9$, and $O_6—H_{16}$ bonds. The results have been shown in Table 6 as a type III calculation. The total minimum energy of this configuration is −1907.64 eV. This result shows that the planar case is more stable by 19.3 kcal/mol. Tentatively one could conclude that the methyloxocarbonium ion trimer is the protonated planar diacetylmethenyloxocarbonium ion.

A comparison of the stretch frequencies, calculated for the two geometries, provides inconclusive evidence. The tetrahedral case gave a frequency of 2278 cm^{-1}, the planar case, a frequency of 2234 cm^{-1}. This would appear to favor the planar case, as the observed frequency is 2200 cm^{-1}; however, this is not the case. Recall that when type III calculations were applied to the aliphatic ions, the overestimation was around 35 cm^{-1}. In addition, for a moderately conjugated system such as this one, the overestimation is probably around 70 cm^{-1}. If these corrections are applied to the two calculations then in the former case it would become around 2240 cm^{-1} and in the latter about 2160 cm^{-1}.

The gross structure of the ion is probably the planar protonated species. This conclusion is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

based upon the calculated relative stabilities of the two ions. To obtain a more accurate geometry, a modified type II_2 calculation was initiated. With this calculation it is possible to refine the calculated estimates of some of the more important bond lengths such as the C_2—C_3 bond. The results are presented in Table 6. In this calculation, the angles were fixed in idealized positions, and the carbon–carbon C_2—C_3 bond was estimated at 1.375 Å. This estimation was based upon comments made by Veillard and co-workers (8) about the unpublished results of the *o*-methylphenyloxocarbonium ion structure (28). The carbon–carbon C(α)—C bond of this ion has been found by X-ray analysis, to be 1.387 Å, considerably shorter than had been expected; consequently a similar bond length was substituted for that bond in the planar trimer ion. All other bond lengths were frozen at the equilibrium distance established by the type III calculation, except the carbon–oxygen bond. It was varied to find the equilibrium position of this bond for this new geometry. The result was a much less stable ion; however, the infrared frequency, given in Table 4, was only 12 cm^{-1} above the experimentally found value. The stability of the ion could have been greatly improved by relaxing all other bond lengths of significance; however, this is an extremely costly calculation and, besides which, the relative stabilities of the two major cases has already been established. Also, it has already been shown that the major factor influencing the carbon–oxygen stretch frequency is the conjugation of the carbon–carbon bond with the contiguous carbon–oxygen bond. This result, taken together with the results found for the length of the carbon–carbon bond in the phenyloxocarbonium ion tend to suggest that the C_2—C_3 bond length for the planar trimer is between 1.374 Å and 1.387 Å and that the general shape of the ion is that found in Fig.1. The lengths of the other bonds are not as accurately known as this one. In general, those bonds reported for the type II_2 calculation, in Table 3, approximate the geometry of this ion, within the limitations of the theory.

As well as the trimer, there is the interesting possibility that the dimer of the methyloxocarbonium ion might exist. Preliminary calculations have shown that the planar acetylmethenyloxocarbonium ion is more stable than the tetrahedral case. A modified type III calculation was performed on the planar configuration of the dimer.

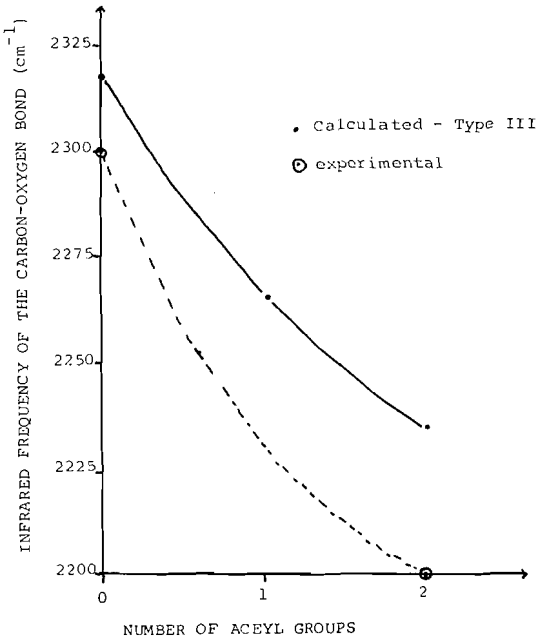

FIG. 7. The frequency of the carbon–oxygen bond as a function of the number of planar acetyl groups substituted in the methyloxocarbonium ion.

In this calculation, the bond lengths found for the planar trimer ion are substituted in all equivalent positions in the dimer except the carbon–carbon, C_2—C_3, and the carbon–oxygen bond C_2—O_1. These two were freely varied to find a global energy minimum. The results have been presented in Table 6. The calculated frequency has been reported in Table 4 at 2265 cm^{-1}. If the experimental values of the methyloxocarbonium ion and the protonated planar diacetylmethenyloxocarbonium ions are plotted along with the type III calculated values of the methyl-, protonated acetylmethenyl-, and diacetylmethenyloxocarbonium ions, shown in Fig. 7, then it is possible to observe a trend similar to the trend found for the type III calculations of the alkyloxocarbonium ions. If this trend is regular, then the experimental value of the protonated acetylmethenyloxocarbonium ion ought to lie at about 2225 cm^{-1}. This value has not been recorded; however, this may be due to the masking effect of the trimer peak. The possibility of its existence shows promise for interesting future work.

The Electrical Polarization of 1,4-Dicyanobenzene

HELMUT HUBER AND GEORGE F WRIGHT

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received November 6, 1972

The anomalous total electric polarization of 1,4-dicyanobenzene has been shown not to be due to high atom polarization by dielectric constant measurement of the solid substance and by its spectral absorption in the far i.r. However the evaluation of atom polarization from the spectral absorption is questioned because these absorptions have a large temperature coefficient in the 50–150 cm^{-1} region. The apparent dipole moment of 1,4-dicyanobenzene in solution has been measured and found to be temperature-dependent.

On a montré que l'anomalie dans la polarisation électrique totale du dicyano-1,4 benzène n'était pas causé par la polarisation des atomes appartenant à des niveaux élevés. Ce fait fut démontré par la mesure de la constante diélectrique de la substance solide et par son spectre d'absorption dans le lointain i.r. Cependant, l'évaluation de la polarisation des atomes à partir du spectre d'absorption est remise en question à cause de la présence d'un coefficient élevé de température pour ces absorptions dans la région de 50 à 150 cm^{-1}. Le moment dipolaire apparent du dicyano-1,4 benzène en solution a été mesuré et est relié à la température.

Introduction

The polarizations of certain substances in weak 1–5 MHz fields have long been anomalous (1). Such substances are typified by diametrically-opposed substituents. In view of their formally-apparent centrosymmetry such substances might be expected to be devoid of the charge separation called dipole moment. No doubt it was for this reason that when a total polarization (P_T) much more than that which could be attributed to electron polarization (P_E) was found by experiment it was considered to be due to a large atom polarization (P_A). Thus on the basis that

$$P_T = P_E + P_A + P_O$$

then if orientation polarization (P_O) were non-existent, *i.e.* if the nominally centrosymmetric-molecule did not have a dipole moment, the large difference between P_R and P_E would necessarily be a large P_A.

Therefore symmetrically-substituted substances like 1,4-benzoquinone, diarylmercuries, 1,4-dinitrobenzene, *sym*-tetramethylcyclobutanediones and others were said to have abnormally-high atom polarizations (1) although no measurements were made. Instead a theory was proposed (2) to explain abnormally-high atom polarization because of energy imparted to the diametrically-opposed dipoles in such substances by the electric fields imposed upon them.

This postulation of abnormally-high atom polarization in these substances showing anomalous total polarization has been vitiated for several reasons. First a direct method (3) for measurement of combined electron and atom polarization ($P_D = P_E + P_A$ where P_D is called distortion polarization) has been devised which shows that P_A is not abnormally-high in 1,4-benzoquinone (4), 1,4-dinitrobenzene (5), *sym*-tetramethylcyclobutanedione (6), and diphenylmercury (7). Secondly it has been shown in the same publications that the dipole moments that may be calculated from the total polarizations of these substances are temperature-dependent over the range 10–60 °C. According to the prevalent assumption that electron and atom polarization are largely temperature-independent, the temperature-dependent dipole moment must be real, *i.e.* attributable to orientation polarization.

Among the nominally centrosymmetric substances showing unexpected polarization according to the Debye construct is 1,4-dicyanobenzene (1). Since this seeming anomaly was originally attributed to abnormal atom polarization we have now measured it (3). We find that in compressed wafers, the dielectric constant (extrapolated to zero thickness, Fig. 1) is 2.813. Since the density by the air-displacement method (8) is 1.284 at 20° the distortion polarization (P_D) may

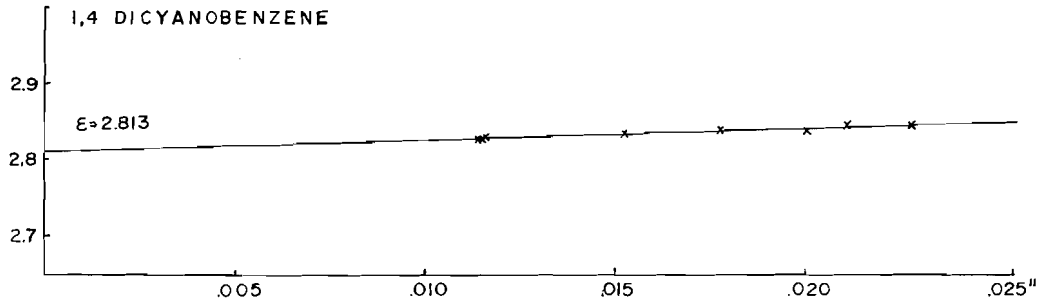

FIG. 1. Dielectric constants *vs.* solid wafer thickness.

TABLE 1. Calculated atom polarizations (P_{A_j}) from spectral absorptions for 1,4-dicyanobenzene in polyethylene wax *vs.* the wax in the reference beam

Spectrometer	ν (cm^{-1})	dν (cm^{-1})	Base line 1	Base line 2	I_0	I	Γ_j	P_{A_j}

IR-11	362	20	33		0.0273	0.0222	256	0.07
IR-11	530	52	19		0.0435	0.0366	381	0.02
IR-11	558	67	18–16		0.0498	0.0263	1720	0.10
IR-11	643	36	14–13		0.0253	0.0187	380	0.02

be calculated as 37.4 cc or only 2.4 cc more than the value of 35.1 cc for electronic polarization calculated from bond polarizabilities (9). This difference of 2.4 cc for P_A (less than 10%) cannot be called an abnormally-high atom polarization. Certainly it cannot account for the unexpected total polarization observed in solutions of 1,4-dicyanobenzene.

There is another way of evaluating atom polarization. Whiffen (10) has used the Kramers–Kronig relationship between molecular refraction and spectral absorption to evaluate P_A for certain substances in the gaseous phase. This relationship takes into account the observation that the electrical reactance of a system becomes greater at the low-frequency side of each resonant absorption band because the masses involved in the intramolecular vibration can "follow" the alternating field at frequencies lower but not higher than the resonant frequency. For each jth absorbance the difference in reactance is designated as a partial atom polarization, P_{A_j}, evaluated by Whiffen's equation

$$P_{A_j} = \frac{NC}{3\pi^2} \int \frac{I_0/I \, d\nu}{\nu_j^2 c}$$

where N is the Avogadro number, C is the vacuum velocity of light, I_0/I is the reciprocal absorption, ν is the specific frequency, c is the concentration, and dν is the width of absorption band. Leaving aside the question whether the vacuum velocity of light is applicable in the condensed phase the summation of these partial atom polarizations in the 50–1000 cm^{-1} range where the contributions are significant is

$$P_A = \Sigma P_{A_j}$$

and where the greatest contributions will come from the absorptions at the lowest frequencies.

The spectra of 1,4-dicyanobenzene in polyethylene wax (3) have been scanned over the 900–50 cm^{-1} range in two spectrometers, the Beckman IR-11 (concentration 15%, path length 0.371 mm) and the Perkin–Elmer 301 (concentration 10%, path length 0.352 mm) and are shown in Table 1 where Γ is the modulus

$$\Gamma = \frac{\log (I_0/I) \, d\nu}{L \cdot c \cdot \nu}$$

L being the path length in mm, c being the concentration and ν the frequency. The band

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

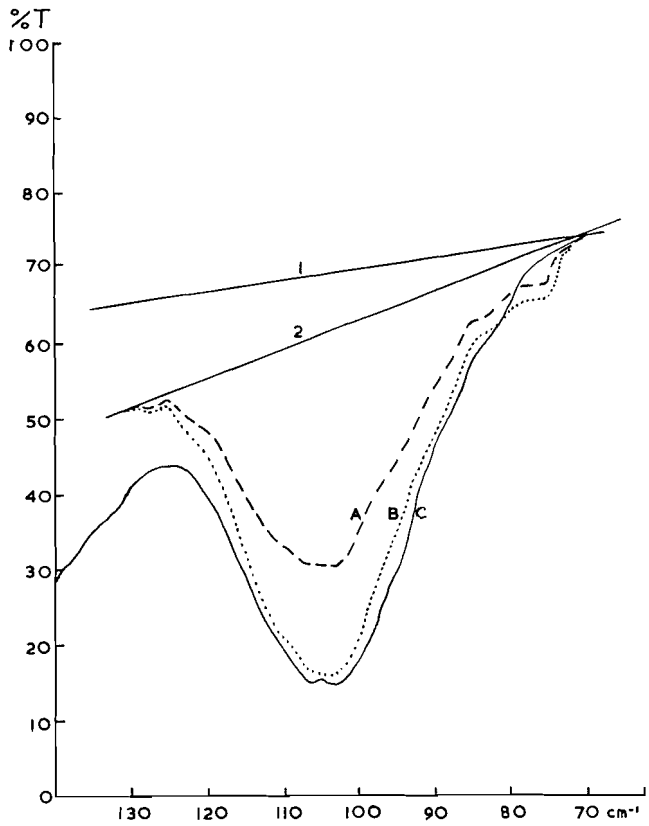

FIG. 2. Spectral absorptions of 1,4-dicyanobenzene in polyethylene wax. (A) PE 301, 10% concentration; (B) PE 301, corrected for 15% concentration; (C) IR-11, 15% concentration; with baselines 1 and 2.

(approximately 103 cm^{-1}) which makes the largest contribution to P_A is shown in Fig. 2.

Because of considerable overlap between this band and one at 159 cm^{-1} of lesser contribution it has been difficult to evaluate the band areas. However, we have chosen two arbitrary baselines, 1 and 2, for calculation of I_0. The calculated values, together with those of lesser contribution are shown in Table 1 using Charney's calculation (11) of each P_{A_j} in terms of $cm^2\ mol^{-1}$ which are comparable with the electrical polarization values

$$P_{A_j} = \Gamma_j(3\pi^2\nu_j)^{-1}$$

It may be seen that the total, $\sum P_{A_j}$, lies between 3.54 and 3.18 $cm^2\ mol^{-1}$. These values are less than 11% of MR_D (35.1 cc) calculated from bond polarization (9) and less than 10% of the distortion polarization determined from compressed wafers. They cannot account for the total polarization found for 1,4-dicyanobenzene.

However, the meaning of the $\sum P_{A_j}$ value ascertained in the condensed phase according to the use of the Kramers–Kronig relationship by Charney *et al.* (11) and others may be questioned. If similar samples on which the data of Table 1 are based are studied at temperature from +40 to −194 °C, profound changes are observed.

First, the "peak" of the absorption at 103 cm^{-1} (+40) is shifted to 108.6 cm^{-1} at −194 °C. Likewise the absorption peak at 155 cm^{-1} (+40°) is shifted to 164 cm^{-1} at −194°. Incidentally the bands at higher frequencies do not shift measurably.

This shift in peak frequency might be attributed to contraction of the crystal lattice although data subsequently to be presented contra-indicate this explanation. However, the other change with decreasing temperature is more profound. It is found that Γ_j increases 337% at j = 164 cm^{-1} at −194° over the value at +40°. Again the intensities at higher frequencies do not change appreciably.

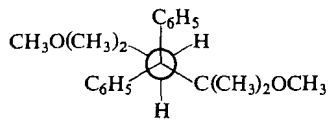
TABLE 2. Spectra of 2,5-dimethoxy-2,5-dimethyl-3,4-diphenylhexane

Sample state	Concentration (%)	Absorption (cm^{-1})	ΣP_{A_J}	$\Sigma P_{A_J/\varepsilon}$
Glass at +40 °C	31	ν_J 99--111--122--163--207		
		P_{A_J} 0.6--0.2--0.2--0.1--0.3	1.4	0.9
Glass at −190 °C	31	ν_J 101--111--121--164--211		
		P_{A_J} 1.0--0.5--1.1--0.24--0.8	3.6	2.3
Pure, in wafer at +40°	100	ν_J --109------156--187--206		
		P_{A_J} --1.2------0.7--0.1--0.2	2.2	1.4
In polypropylene wax at −190 °C	20	ν_J ---109---147---180---211		
		P_{A_J} --3.6---0.1--0.6--0.6	4.9	3.2

The consequence of these changes is an apparent $\sum P_{A_J}$ at −194° for 1,4-dicyanobenzene of 13.6 cc. The gradual change in $\sum P_A$ over temperatures intermediate between +40 and −194° indicates that higher summations would have been found if we had been able to determine the spectrum at temperatures lower than −194°. It may be noted that the value of 13.6 cc when added to MR_D exceeds the total polarization found for 1,4-dicyanobenzene in benzene (Table 3).

Of course the spectral behavior in the crystalline state might not be comparable with the polarization behavior in solution. We have not been able to make a direct comparison for dicyanobenzene, but the data obtained for *dd,ll*-2,5-dimethoxy-2,5-dimethyl-3,4-diphenylhexane is informative. The earlier studies of this substance (12) showed that it exhibited a temperature-variant dipole moment. The Newman stereochemical diagram for one conformation of this substance



indicates that the observed moment may be attributed to the pivotal bond (13).

This is one of the few substances which we have been able to study spectroscopically in the far i.r. in a state which apparently is not crystalline. Either low solubility or very high background absorption in media such as benzene, carbon tetrachloride, tetrachlorethylene etc. have, so far for us, precluded meaningful solution spectra in this region. However, we have been able to prepare a glass of 31% concentration in polystyrene in which *no* (at least visible) crystallization has occurred. Therefore, we have been able to compare spectra in this glass with those in the pure crystalline state and in a dispersion in polypropylene wax at several temperatures. The data are shown in Table 2.

The magnitude of $\sum P_{A_J}$ may seem to be discrepant from the wafer-measured P_A of −5.7 cc found by capacitance measurement. However, if this anomalously-negative value is adjusted in terms of the phenyl effect (2.0–2.5 cc per phenyl group) (14), it may be seen that at room temperature the spectral and electric values are comparable in magnitude. They are even closer if the spectral $\sum P_{A_J}$ is divided by the dielectric constant, ε, in order to take into account the lower velocity of radiation through the non-gaseous substrate. This agreement probably is fortuitous. Despite the imprecision in the glassy state (due to background absorption from the polystyrene) it is apparent that in the glassy as well as in the crystalline state dimethoxy-dimethyldiphenylhexane shows a strong and temperature-dependent absorption at frequencies between 99 and 211 cm^{-1}. That is to say it behaves like the substances, including 1,4-dicyanobenzene, which show anomalously-high total electric polarizations. If one can assume that our glassy state is non-crystalline then the increased absorption at low temperatures cannot be attributed to the crystal lattice or even to the crystalline state.

In view of all these observations it is questionable whether absorption spectra are useful for evaluation of P_A when they are applied to evaluation of P_A at frequencies below 200 cm^{-1}. Alternatively one may consider whether the unexpected total polarization of 1,4-dicyanobenzene may be due to orientation polarization.

A careful study of the change in total orientation in respect of temperatures between 20 and 40° has now been made in the apparatus described earlier (15) with results shown in Table 3.

The apparent dipole moments have been calculated both from the Vogel values for MR_D and from the measured distortion polarization at 23 °C. The results show small but consistent increase in apparent moment in respect of increasing temperature.

It may be seen from Table 3 that the magnitude of the dipole moment (μ) differs in benzene from the larger values found in dioxane. In consideration of the space swept out of the solvent by the candidate substance (16) this difference is not unexpected in view of the small ($\mu = 0.4$ D) but real dipole moment of the dioxane (17) which surrounds this space by contrast to benzene. It is not clear how this difference could be attributed to atom polarization.

In order to relate the apparent moment of 1,4-dicyanobenzene with its thermal behavior one may consider the absorptions in the far i.r. in a different way. The idea that thermal agitation might give rise to orientable dipoles was once considered (2) and then refuted because of the mismatch between the calculated resonance frequency of off-axis bending (*ca.* 10^{13} Hz) and the frequency (*ca.* 10^6 Hz) of electrical polarization measurement. The argument is reasonable, but it leads to the alternative that anomalous total polarization of nominally centrosymmetric molecules must be due to abnormally high atom polarization. The argument has not been reopened since actual measurements (3) showed that in fact such high atom polarizations were not found. The temperature dependence of the apparent moment of 1,4-dicyanobenzene suggests that thermal agitation should again be considered as a cause of orientation polarization in ostensibly centrosymmetric substances.

Perhaps the assignment of specific modes of intramolecular motion to bonds at frequencies below 200 cm^{-1} is not realistic. Inspection of the absorption at *ca.* 103 cm^{-1} for 1,4-dicyanobenzene (Fig. 2) shows that it is by no means simple. Contributions from difference bands in the near i.r., from combinations, and from harmonics in the low frequency region must make large contributions. Indeed the continuous background absorption by benzene and carbon tetrachloride below 150 cm^{-1} (and below their normal vibration modes) must be due to these contributions. It may be significant that none of the spectrometers available to us irradiate the sample monochromatically.

Experimental

Equipment

Dielectric measurements were made in the equipment described previously (15, 3, 12).

Spectral measurements were for the most part made in a Beckman IR-11 spectrometer kindly loaned to us by the U.S. Army. The few attempts to examine solutions in benzene, diozane, and other solvents were made in polyethylene cells (1 mm spacing) supplied by Beckman Instruments Ltd. Dispersions of crystalline sample were prepared as described earlier (3) but in most cases polypropylene (Eastman Epolene) rather than polyethylene wax was used as the dispersing medium because of its relative transparency in the spectral region (80–150 cm^{-1}) of interest.

Temperature-variant spectral studies were made in the regulable low-temperature cell holder sold by Beckman Instruments Inc. (Part No. 195793) which is conveniently adaptable to the IR-11 spectrometer. By means of a perforated rubber sheet 0.25 in. thick under the flange of this cell holder the sample compartment can be maintained water-free. The outer part of the cell holder is equipped with vacuum-tight polypropylene windows (0.625 in. thick) which are retained by aluminium rings (Fig. 3). The inner part (including the liquid nitrogen reservoir, heaters, and thermocouple) encloses a special cell shown in Fig. 4 which has been designed for the Epolene wax wafers or the glassy films which have been examined in this apparatus. The space between the inner and outer part of the complete cell holder is maintained during use at a pressure of 0.001–0.003 Torr to which, of course, the sample must be subjected. In order to compensate for the general opacity of the two polypropylene windows an attenuator (Fig. 5) is used in the reference beam in the same manner as it is used with the pure samples described below.

Pure samples of 0.075 mm thickness are prepared in the die used for fabrication of 0.25 in. diameter wafers with which the dielectric constant of solid substances is determined (3). The sample is similarly ground to ensure random orientation of the crystalline particles. The thin wafers are installed in a sample holder equipped with

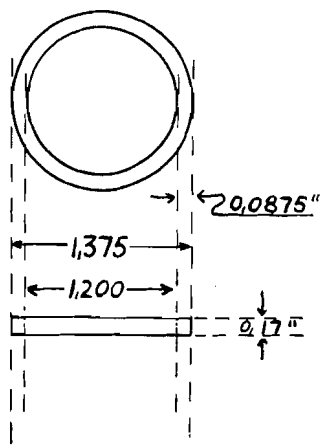

FIG. 3. Retainer ring.

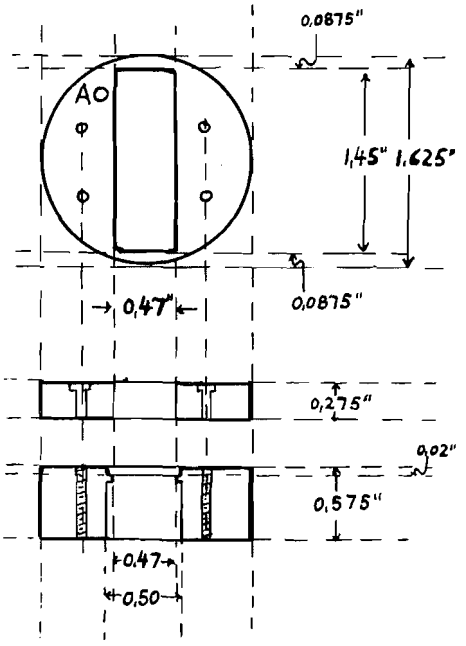

FIG. 4. Sample holder, low temperature cell.

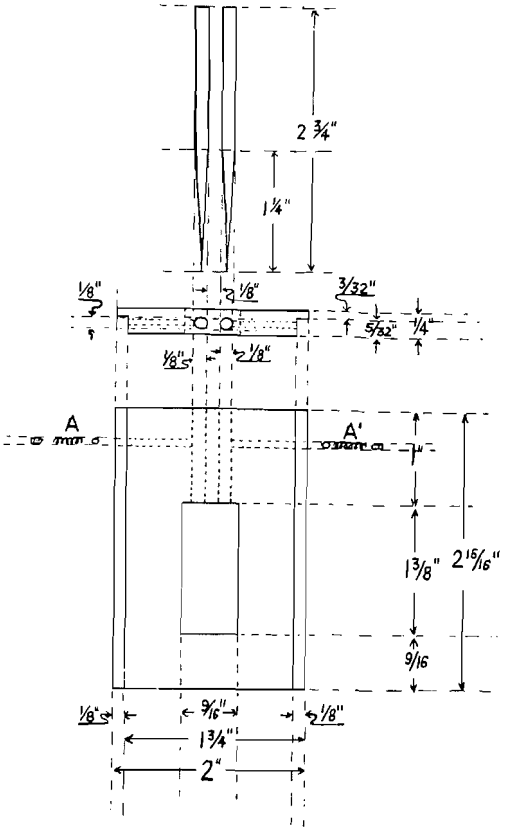

FIG. 5. Attenuator.

tripod screws for position adjustment. This holder may be installed in the reflecting beam condenser (Beckman Part No. 135517) adaptable to the IR-11 at low frequencies. Compensation for reflection losses is accomplished in the reference beam by the attenuator (Fig. 5).

Glassy films are prepared with either polymethylmethacrylate or polystyrene as the glassing matrix. Either of these polymers is dissolved in boiling acetone, butanone-2, or benzene, depending on the solubility of the candidate substance. Then the latter is dissolved at the desired or possible concentration (30–80%) and the solution is evaporated to a viscous melt at about 100°. This molten mass is poured evenly over a hot polished metal plate and evaporation of the volatile solvent is continued (very slowly so as to avoid formation of bubbles) until it is complete. When the plate is cooled to room temperature the glassy film may be peeled off, its thickness measured (about 0.2 mm) and then installed in a cardboard sample holder or in the variable temperature cell holder described above. The technique is not always successful. In any case the film is allowed to stand overnight to ascertain whether spontaneous crystallization occurs. If it does not, then the glass seems to be stable over a long period of time.

The 1,4-dicyanobenzene used in this study has been purified by crystallization from hot acetic acid and hot benzene but the crystals must be ground finely before vacuum drying in order to release solvent, m.p. 227–225°. The 2,5-dimethoxy-2,5-dimethyl-3,4-diphenylhexane has been purified according to procedures previously described (12). Benzene (previously freed from toluene by partial freezing) and dioxane were purified by techniques already described (8).

The authors are grateful to the National Research Council of Canada and the Defence Research Board of Canada for grant funds which made these studies possible.

Spectroscopic Properties of a Series of Vinyl–Platinum Complexes

T. G. APPLETON,[1] M. H. CHISHOLM,[2] H. C. CLARK,[3] AND L. E. MANZER

Department of Chemistry, University of Western Ontario, London 72, Ontario

Received November 27, 1972

Nuclear magnetic resonance, infrared, and Raman data are given for the series *trans*-$PtRXQ_2$ and *trans*-$[PtRQ_2L]^+$, where R =  , Q = $(PCH_3)_2C_6H_5$, L = neutral ligand, and Z = anionic ligand. The coupling constants between ^{195}Pt and the trifluoromethyl ^{19}F nuclei and between ^{195}Pt and the vinyl proton H_v both correlate linearly with $^2J_{Pt-CH_3}$ for the corresponding methylplatinum complexes. The results are explained in terms of platinum hybridization in the Pt—C bond dominating the coupling constant.

Les résultats obtenus à l'aide des spectroscopies de résonance magnétique nucléaire, infrarouge et Raman, sont rapportés pour plusieurs composés du type *trans*-$PtRXQ_2$ et *trans*-$[PtRQ_2L]^+$ où R =  , Q = $(PCH_3)_2C_6H_5$, L = coordinat neutre et Z = coordinat anionique. Les constantes de couplage entre ^{195}Pt et le noyau ^{19}F du groupe trifluorométhyle et entre le ^{195}Pt et le proton H_v du groupe vinyle sont toutes deux reliées linéairement à $^2J_{Pt-CH_3}$ des complexes méthyl platine correspondants. Les résultats sont interprétés en fonction de l'hybridation le long du lien Pt—C qui est le facteur principal en ce qui a trait à la constante de couplage. [Traduit par le journal]

Can. J. Chem., 51, 2243 (1973)

Introduction

A considerable body of evidence has now been collected which supports the contention that the coupling constants $^2J_{Pt-CH_3}$ in methylplatinum(II) complexes, *trans*-$Pt(CH_3)XQ_2$ and *trans*-$[Pt(CH_3)Q_2L]^+$ are determined mainly by properties of the Pt—C bond, in particular the nature of the bonding hybrid orbital used by platinum. For example, $^2J_{Pt-CH_3}$ correlates linearly with $^1J_{Pt-C}$ (1) within a series of methylplatinum complexes and with $^1J_{Pt-H}$ (2) and $^1J_{Pt-P}$ (3) in corresponding hydrido and phosphonato complexes respectively. $^2J_{Pt-CH_3}$ can thus be used as a measure of the *trans*-influence (4) of the ligand *trans* to the methyl group. $^2J_{Pt-CF_3}$ in trifluoromethyl platinum complexes *trans*-$Pt(CF_3)Q_2X$ and *trans*-$[Pt(CF_3)Q_2L]^+$ (2) can also be used as a measure of the *trans*-influence of X^- or L, since $^2J_{Pt-CF_3}$ in these complexes correlates linearly with $^2J_{Pt-CH_3}$ in the corresponding methylplatinum complexes (except for points representing $Sb(C_6H_5)_3$ and to a lesser extent CO). Since the line passed through the origin it was argued that π-bonding did not make an appreciable contribution to the Pt—CF_3 bond and that the Pt—CF_3 coupling

(*b*) Z = L, *n* = 1

both the trifluoromethyl ^{19}F nuclei and the vinyl proton H_v show appreciable coupling to ^{195}Pt. However, these two couplings have substantially different paths, although both are over three bonds and are thus somewhat more complex than one bond (*e.g.* $^1J_{Pt-C}$) or two bond (*e.g.* $^2J_{Pt-CH_3}$) coupling constants. It was of interest to determine whether the effect of varying the ligand *trans* to the vinyl group on $^3J_{Pt-C-CF_3}$ and $^3J_{Pt-C=C-H_v}$ was similar to that of varying L or X on $^2J_{Pt-CH_3}$ in corresponding methylplatinum complexes.

Experimental

The complex $Pt\{C(CF_3)=C(OCH_3)H\}\{P(CH_3)_2C_6H_5\}_2Cl$ was prepared as previously described (5).

Analyses were obtained from Schwarzkopf Microanalytical Laboratory Inc., Woodside, N.Y., and Chemalytics Inc., Tempe, Arizona.

In most cases the complexes were extremely difficult to crystallize. Since they were all prepared by similar methods, only a few examples will be outlined.

^1H and ^{19}F spectra were run on a Varian HA-100 spectrometer, the former at 100 MHz with tetramethylsilane as internal reference-lock signal and the latter at 94.1 MHz with "Freon-11" ($CFCl_3$) as the internal reference. Infrared spectra were run as Nujol mulls between CsI disks. Raman spectra were recorded on a Cary 82 spectrometer using a (5145 Å) laser.

Preparation of $[Pt\{C(CF_3)C(OCH_3)H\}Q_2\{As(C_6H_5)_3\}]PF_6$

To an acetone solution of $PtClQ_2\{C(CF_3)C(OCH_3)H\}$ (0.166 g) was added $AgPF_6$ (0.067) in 2 mls of acetone. The solution was magnetically stirred for 1 min and the AgCl removed by centrifugation to give a clear colorless solution. Triphenylarsine (0.082 gm) in acetone was added and the solvent removed on a rotary evaporator to give a clear oil. The oil was taken up in dichloromethane and ether was slowly added until the solution became cloudy. The solution was cooled at −15 °C for 10 h to give white crystals of the desired salt in 65% yield.

Preparation of $[PtQ_2\{C(CF_3)C(OCH_3)H\}(:\overline{CCH_2CH_2CH_2—O})]PF_6$

$AgPF_6$ (0.066 g) in 2 ml of acetone was added to an acetone solution of $PtClQ_2\{C(CF_3)C(OCH_3)H\}$ (0.164 g). The AgCl was removed by centrifugation and $HC{\equiv}CCH_2CH_2OH$ (0.030 g) was added. The solution was stirred for 10 min and the acetone was removed on a rotary evaporator to give a clear oil. The oil was dissolved in dichloromethane, and the addition of diethylether yielded white crystals of the carbene salt in 72% yield.

Preparation of $Pt\{C(CF_3)C(OCH_3)H\}Q_2(NO_2)$

To an acetone solution of $PtClQ_2\{C(CF_3)C(OCH_3)H\}$ (0.160 g) was added $AgClO_4$ (0.052 g). The AgCl was removed by centrifugation and $NaNO_2$ (0.018 g) was added. The solution was stirred for 15 min and the solvent removed on the rotary evaporator. The complex was extracted with dichloromethane and the addition of *n*-hexane gave only an oil. Attempts at recrystallization with a variety of solvents were unsuccessful.

Preparation of $[Pt(C_6H_5)\{P(CH_3)_2(C_6H_5)\}_3](PF_6)$

$AgPF_6$ (0.100 g) was added to $PtCl(C_6H_5)Q_2$ in 5 ml of acetone. The silver chloride was removed by centrifugation and 0.05 ml of $P(CH_3)_2C_6H_5$ was added. The solution was evaporated to dryness, extracted with dichloromethane and passed through a 1 in. Florisil column, eluting with dichloromethane. The volume of the solution was reduced and hexane added. Cooling to 0 °C yielded white crystals which were filtered and washed with diethyl ether. Yield 0.208 g; m.p. 178–180 °C.

Anal. Calcd. C, 43.3; H, 4.6; Found, C, 43.2; H, 4.3.

Results

Characterization, infrared and Raman data for new complexes are given in Table 1 and nuclear magnetic resonance data are given in Table 2.

In the ^1H n.m.r. spectra, the phosphine methyl resonances give overlapping triplets (with satellites from coupling to ^{195}Pt) due to restricted rotation of the vinyl group about the Pt—C bond. This does not necessarily imply extensive π-bonding since there would be considerable steric hindrance to such rotations. The original complex (5) **1** (*a*), X = Cl is exceptional in not showing this P—CH_3 group inequivalence. The inequivalence is most marked when Z is a ligand which would be expected to produce anisotropic chemical shifts, *e.g.* CN^- and I^-. The vinyl proton resonance also appears as a triplet due to coupling with the two equivalent ^{31}P nuclei and is accompanied by ^{195}Pt satellites. The trifluoromethyl resonance appears as a singlet in the ^{19}F n.m.r. spectra and although coupled to ^{195}Pt, no ^{31}P coupling is observed.

In Fig. 1, $^3J_{Pt-C-CF_3}$ and $^3J_{Pt-C=C-H_v}$ for the complexes, **1**, are plotted against $^2J_{Pt-CH_3}$ for the corresponding methylplatinum complexes. Except for the point representing L = $Sb(C_6H_5)_3$ both coupling constants in the vinyl complexes **1**(*b*) correlate linearly with $^2J_{Pt-CH_3}$ in corresponding methylplatinum complexes. Since several points lie off the line (for reasons to be discussed later) least squares approximation equations to the lines would be meaningless. However, one point to be noted is that the lines do not appear to pass through the origin. Although the line representing the neutral compounds, **1**(*a*), in Fig. 1, is nearly coincident with that of the cations, previous work (2) has suggested that a distinction should be drawn between the neutral compounds and the cations. We have therefore preserved this distinction although the data of Fig. 1 suggests that it may not be a real one.

In Fig. 2, $^3J_{Pt-C-CF_3}$ is plotted against $^3J_{Pt-C=C-H_v}$. A straight line is obtained which again does not pass through the origin.

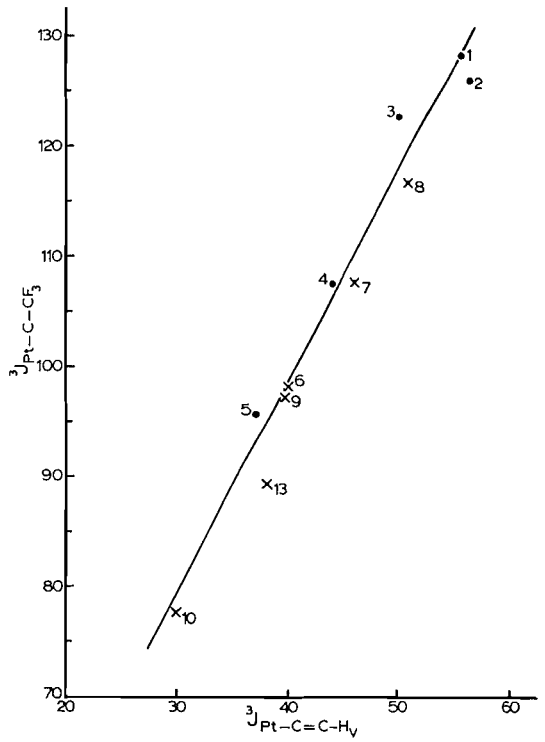

FIG. 2. A plot of $^3J_{Pt-F}$ against $^3J_{Pt-H_v}$ for a series of vinylplatinum complexes. *trans*-Pt{C=C(H$_v$)(CF$_3$)(OCH$_3$)}Q_2Z. The numbers are from Table 2.

Discussion

Properties of the [—C(CF$_3$)=C(OCH$_3$)H] *Group*

Spectroscopic results for some complexes *trans*-$PtRLQ_2^+$ are given in Table 3 to allow a comparison between the properties of the 1-trifluoromethyl-2-methoxyvinyl group and the other organo(R) groups. When Z = C_2H_5NC, CO, or CN^- the C≡X stretching frequency is sensitive to the effective charge on platinum(2) (as pointed out by Hall and Fenske (6) this could include the effect on Pt orbitals of an adjacent positive C atom). The C≡X stretching frequencies clearly show that the effective positive charge on platinum in these vinyl complexes is intermediate between that for R = CH_3 and CF_3.

$^3J_{Pt-P-CH_3}$ for the phosphine *trans* to R in $[RPtQ_3]^+$ has been used to indicate the n.m.r. *trans*-influence (2) of R^-. All the organo (R) groups listed in Table 3 have a high *trans*-

TABLE 3. Spectroscopic data for the complexes *trans*-$PtRZ\{P(CH_3)_2C_6H_5\}_2^+$

R	Z = $P(CH_3)_2C_6H_5$ $J_{Pt-P-CH_3}$ *cis* to R	Z = $P(CH_3)_2C_6H_5$ $J_{Pt-P-CH_3}$ *trans* to R	Z = CO ν_{CO}	Z = C_2H_5NC ν_{NC}	Z = CN^- ν_{CN}	Reference

influence, however the *trans*-influence of the vinyl group is lower than that of the other R groups. For comparison the compound with $R = C_6H_5$ was studied since the phenyl group also has an sp^2-hybridized carbon atom. The coupling constant $^3J_{Pt-P-CH_3}$ *trans* to C_6H_5 suggests that this group has a significantly higher n.m.r. *trans*-influence than the other R groups studied. (This conclusion has been supported by coupling constants in some organoplatinum(IV) complexes(7)).

Factors Affecting $^3J_{Pt-C-CF_3}$ *and* $^3J_{Pt-C=C-H_v}$

The linear relationships between these coupling constants in the series **1** (Fig. 2) and between these couplings and $^2J_{Pt-CH_3}$ in the corresponding complexes *trans*-$PtCH_3Q_2Z$ suggests that the variations in the coupling constants in the series over the observable range is dominated by variations in Pt hybridization in the Pt—C bond, caused by variations in the *trans*-influence of Z. The appropriate form of the Fermi contact expression for the coupling $^3J_{Pt-C-CF_3}$ is shown in eq. 1 (see ref. 2),

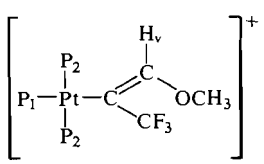
$$[1]\quad {}^3J_{Pt-C-CF_3} \propto \alpha^2{}_{Pt}\alpha^2{}_F\gamma_{Pt}\gamma_F f\left(-C\begin{matrix}=C\\ -C\end{matrix}\right) [\psi_{Pt(6S)}(0)]^2[\psi_{F(2S)}(0)]^2(\Delta E)^{-1}$$

where γ_X is the gyromagnetic ratio of nucleus X, α_X^2 is the s-character of the bonding hybrid orbital used by X. $[\psi_{X(NS)}(0)]^2$ is the NS electron density at the nucleus X, $f\left(-C\begin{matrix}=C\\ -C\end{matrix}\right)$ is a function of the geometric and electronic factors controlling transmission of coupling through the vinyl group to the CF_3 group, ΔE is a mean singlet-triplet excitation energy. An analogous expression may be written for coupling to the vinyl proton $^3J_{Pt-C=C-H_v}$. Thus within a *closely related series* coupling constants to the nuclei in the vinyl group can be used as an indication of the *trans*-influence of the ligand *trans*- to the vinyl group *provided* that the electronic and geometrical structure of the vinyl group remains nearly constant. The equation applies only to a purely covalent bond, and any decrease in covalency will cause the coupling constant to decrease. The expression can presumably be generalized for a coupling over *n*-bonds according to eq. 2.

$$[2]\quad {}^nJ_{Pt-A-B---M-X} \propto \gamma_{Pt}\gamma_X\alpha^2{}_{Pt}\alpha^2{}_X F(—A—B---M—)[\psi_{Pt(6S)}(0)]^2[\psi_{X(NS)}(0)]^2(\Delta E)^{-1}$$

If this "Fermi Contact" term is dominant, and if F(—A—B---M—) remains nearly constant over the series of compounds concerned, such a coupling constant can be used in a similar way to $^2J_{Pt-CH_3}$, $^1J_{Pt-P}$, etc. The provision that F(—A—B---M—) remain constant is clearly important. An example is provided by the coupling $^3J_{Pt-N-C-H}$. This coupling is dependent on the nature of the ligand *trans* to nitrogen (8) (*i.e.* depends on $\alpha^2{}_{Pt}$) but can be affected to a similar extent by changing the geometry of the Pt—N—C—H fragment (8–10).

The tris-phosphine cation, **2**, is interesting from an n.m.r. point of view since $^4J_{(P_2-F)} = 0$,

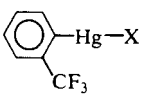


2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$^4J_{(P_1-F)} = 9.4$, $^4J_{(P_2-H_v)} = 2.2$, and $^4J_{(P_1-H_v)} = 4.6$ Hz. These couplings are in line with the well-known tendency of indirect couplings to be larger between *trans* related ligands than between *cis*-ligands.

That the plots in Figs. 1 and 2 do not appear to pass through the origin may have several possible explanations. For example: (*i*) π-bonding between the filled Pt dπ orbitals and empty vinyl π* orbitals could cause a curvature for ligands Z of hypothetically high *trans*-influence (*i.e.* for hypothetical ligands with greater *trans*-influence than alkoxy-carbenes). If this were the reason for the lines not passing through the origin, π-bonding would have to remain nearly constant for the complexes under consideration here. This may be reflected in the small variations in $\nu_{C=C}$ for the vinyl complexes. (*ii*) As well as the appropriate form of eq. 2, the couplings may contain a constant "through space component", as suggested for the complexes, **3** (11).



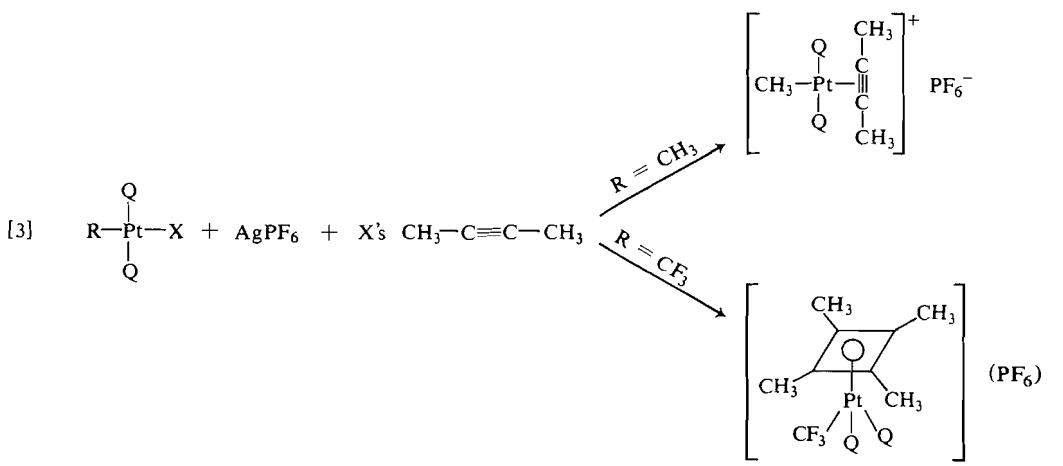
3

If this were the case both $^3J_{Pt-C-CF_3}$ and $^3J_{Pt-C=C-H_v}$ would have to have a through-space component. (*iii*) With ligands of "hypothetically" high *trans*-influence a rehybridization of the vinyl group may occur and the geometrical and electronic factor f(—AB---M) may not remain constant. This is very likely to be the case. However, because of the observed good correlations it appears that f(—AB---M—) does remain constant over the range of complexes studied and $^3J_{Pt-F}$ and $^3J_{Pt-H_v}$ may be used in a similar way to *e.g.* $^2J_{Pt-CH_3}$.

In a previous paper (2) we noted that the ligands CO and $Sb(C_6H_5)_3$ gave points which deviated from the linear plot of $^2J_{Pt-F}$ against $^2J_{Pt-H}$ for the series *trans*-$[PtRL\{P(CH_3)_2(C_6H_5)\}_2]^+$, where R = CH_3 and CF_3 and L = a neutral donor ligand. We suggested that a possible rationale for this observation lay in the synergic bonding properties of CO and $Sb(C_6H_5)_3$ *i.e.* the *trans*-influence of these ligands was dependent on Pt-d to ligand π or π* bonding which in turn was sensitive to the electron density on the metal. In Fig. 1 the point representing the complex $Sb(C_6H_5)_3$ still deviates from the line whilst for L = CO and $CH_3C{\equiv}CCH_3$ (which are generally accepted to utilize a synergic bonding mechanism) there is no such discrepancy. Thus it now seems unlikely that the deviation is entirely attributable to synergism but rather that, for some unknown reason, the value of $^2J_{Pt-CH_3}$ is anomalous for the triphenylstibine complex.

Reactivity

Since the vinyl group is intermediate between CF_3 and CH_3 in electronegativity it was of interest to react the parent compound with $AgPF_6$ in the presence of dimethylacetylene since the course of the reaction is dependent on the organo(R) group and the solvent. For R = CH_3 a stable acetylenic cation is obtained (12) while for R = CF_3 dimerization in acetone occurs to give a cyclobutadiene complex (13) (eq. 3).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[4] $\mathbf{1}(a) + AgPF_6 + H{-}C{\equiv}C{-}CH_2CH_2{-}OH \xrightarrow[\text{Acetone}]{}$  PF_6^-

For R = $C(CF_3){=}C(OCH_3)H$ we were unable to isolate a crystalline complex, however the n.m.r. spectra showed only the presence of the acetylene complex and no evidence of cyclobutadiene formation.

The alkoxycarbene complex was prepared by removal of the chloride from **1**(*a*) with $AgPF_6$ in the presence of the acetylene 1-butyn-4-ol (eq. 4). The reaction appears to be quite general for platinum (13–16) and has been extended to iridium(III) (17).

Photooxidation of Azomethane[1]

ROBERT SHORTRIDGE AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pa., 16802

Received December 15, 1972

The photooxidation of azomethane has been studied at 25 °C and O_2 pressures up to 100 Torr in order to ascertain quantitatively the fate of CH_3O_2 and CH_3O radicals by measuring the quantum yields of CH_3OOH and CH_3OOCH_3 production. The generally accepted reactions include

[3] $2CH_3O_2 \rightarrow 2CH_3O + O_2$

[4*a*] $2CH_3O \rightarrow CH_3OH + CH_2O$

[4*b*] $\rightarrow CH_3OOCH_3$

[5] $CH_3O_2 + CH_3O \rightarrow CH_3OOH + CH_2O$

[6] $CH_3O + O_2 \rightarrow CH_2O + HO_2$

The appropriate rate constant ratios were found to be: $k_5/k_3^{1/2}k_4^{1/2} = 0.31$, $k_{4a}/k_{4b} = 8.9$, and $k_6/k_4^{1/2} = 0.021\ M^{-1/2}\ s^{-1/2}$. The estimated accuracy of these values is ±30%.

La photoxydation de l'azométhane a été étudiée à 25 °C et sous des pressions d'O_2 supérieures à 100 Torr en vue d'étudier quantitativement le sort des radicaux CH_3O_2 et CH_3O par la mesure des rendements quantiques de formation de CH_3OOH et CH_3OOCH_3. Les réactions généralement acceptée comprennent:

[3] $2CH_3O_2 \rightarrow 2CH_3O + O_2$

[4*a*] $2CH_3O \rightarrow CH_3OH + CH_2O$

[4*b*] $\rightarrow CH_3OOCH_3$

[5] $CH_3O_2 + CH_3O \rightarrow CH_3OOH + CH_2O$

[6] $CH_3O + O_2 \rightarrow CH_2O + HO_2$

Les rapports des constantes de vitesse sont: $k_5/k_3^{1/2}k_4^{1/2} = 0.31$, $k_{4a}/k_{4b} = 8.9$, et $k_6/k_4^{1/2} = 0.021\ M^{-1/2}\ s^{-1/2}$. La précision de ces valeurs est évaluée à ±30%. [Traduit par le journal]

Can. J. Chem., **51**, 2251 (1973)

Introduction

We have reexamined the photooxidation of azomethane to determine quantitatively the formation of CH_3OOH and CH_3OOCH_3 from CH_3O_2 and CH_3O radicals. There have been numerous previous investigations of the fates of CH_3O_2 and CH_3O radicals (1), but some conflicts still exist. A convenient source of these radicals is from the photooxidation of azomethane. The mechanism which has generally been accepted is

[1] $CH_3N_2CH_3 + h\nu \rightarrow 2CH_3 + N_2$

[2] $CH_3 + O_2(+M) \rightarrow CH_3O_2(+M)$

[3] $2CH_3O_2 \rightarrow 2CH_3O + O_2$

[4*a*] $2CH_3O \rightarrow CH_3OH + CH_2O$

[4*b*] $\rightarrow CH_3OOCH_3$

[5] $CH_3O_2 + CH_3O \rightarrow CH_2O + CH_3OOH$

[6] $CH_3O + O_2 \rightarrow CH_2O + HO_2$

[7] $CH_3O_2 + HO_2 \rightarrow CH_3OOH + O_2$

The primary photochemical act produces N_2, which can be used as an actinometer, since its quantum yield is unity over a wide range of conditions both in the absence and presence of O_2 (2).

The rate constant ratios which govern CH_3OOH production, $k_5/k_3^{1/2}k_{4a}^{1/2}$ and $k_6/k_{4a}^{1/2}$, were reported by Heicklen and Johnston (3), to be 0.15 and 0.020 $M^{-1/2}\ s^{-1/2}$, respectively at 25 °C. However in the Heicklen and Johnston work, which examined the photooxidation of CH_3I by mass spectral techniques, no direct calibration was made for CH_3OOH; its parent mass spectral sensitivity was assumed to be the same as that for C_2H_5OOH. Also no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

other accurate determinations of these ratios have been reported.

The rate constant ratio governing CH_3OOCH_3 production, k_{4a}/k_{4b}, has been reported to be between 9 and 12 by Heicklen and Johnston in the same study. Again no direct calibration was made for CH_3OOCH_3; its parent mass spectral peak sensitivity was assumed to be the same as that for $C_2H_5OOC_2H_5$. Furthermore Dever and Calvert (4), using $CH_3N_2CH_3$ photooxidation, did not find CH_3OOCH_3 as a product and concluded that $k_{4a}/k_{4b} > 60$. This finding is more in line with the large rate constant for reaction 4*a* reported by Yee Quee and Thynne (5) (see ref. 1 for a complete discussion).

The present experiments were conducted to extend the earlier study of Heicklen and Johnston (3), which had used CH_3I as the methyl radical source and had been limited to O_2 pressures less than 10 Torr. In the present study, the O_2 pressure has been extended to 100 Torr, and $CH_3N_2CH_3$ was employed instead of CH_3I as a source of CH_3 radicals to avoid the complications associated with iodine atom production.

Experimental

The experimental apparatus and procedure were identical to those reported elsewhere (6). Reaction mixtures were photolyzed in a 500 cc spherical glass vessel at 25 ± 2 °C. The reaction gases exited continuously through a capillary tube connected to 8 mm Pyrex tubing which led through a pinhole to a modified E.A.I. Quadrupole Model 160 mass spectrometer. Only the rates of growth of the CH_3OOH (*m/e* 47 and 48) and the CH_3OOCH_3 (*m/e* 62) product peaks were monitored, inasmuch as the very large background peaks due to N_2 and O_2 effectively prevented observation of the CH_2O (*m/e* 30) and the CH_3OH (*m/e* 31 and 32) product peaks.

The mass spectral sensitivities relative to the *m/e* 58 parent peak of azomethane were determined for the *m/e* 48 peak of CH_3OOH and the *m/e* 62 peak of CH_3OOCH_3. It was necessary to synthesize authentic samples of these two products for this calibration, and the method described by Rieche (7) was followed, except that the CH_3OOH was separated from its ether solution by pumping at about −80 °C in vacuo rather than by the distillation procedure described in the article. Strong surface absorption of both compounds complicated these calibrations, as did a metal surface catalyzed decomposition reaction of CH_3OOH to yield H_2O plus CH_2O. A value of 0.60 ± 0.10 was determined to be the sensitivity of the (*m/e* 62) peak of CH_3OOCH_3 relative to the (*m/e* 58) parent peak of azomethane, and a value of 0.35 ± 0.10 was obtained for the relative sensitivity of the *m/e* 48 peak of CH_3OOH.

In order to generate quantum yields, the *m/e* peak height ratios (48/58) and (62/58) were plotted *vs.* time. The slopes of these plots yielded the rates of production of the CH_3OOH and CH_3OOCH_3 products, when corrected for the relative sensitivity calibration factors and multiplied by the pressure of azomethane present. These product rates were converted to quantum yields by dividing by the N_2 production rate in separate actinometer experiments in the absence of O_2, but at the same $CH_3N_2CH_3$ pressure.

Results

Quantum yields were obtained in a series of runs in which the O_2 pressure was varied from 3 to 104 Torr and the $CH_3N_2CH_3$ pressure maintained at 9–10 Torr. All of the experiments were done at a total pressure of approximately 100 Torr, with N_2 being used as the pressurizing gas when necessary.

A complication in monitoring the CH_3OOH production was encountered with the *m/e* 48 peak, though not with the adjacent *m/e* 47 cracking peak, growing irreproducibly in the dark at higher O_2 pressures. This phenomenon increased in severity with increasing O_2 pressure, and did not seem to involve azomethane, inasmuch as samples containing *only* O_2 at comparable pressures also exhibited (*m/e* 48) peak growth in the dark. It is conceivable that this result can be explained at least in part by the formation of O_3^+ in the mass spectrometer itself. Unfortunately, this problem was responsible for the upper limit of approximately 100 Torr of O_2 in this investigation.

The growth of the mass spectral product peaks was small. Thus, the average uncertainty in most of these quantum yield figures is probably at least as great as in the previous study (3), *i.e.* about 30–40%.

In Table 1 the quantum yield of CH_3OOCH_3, $\Phi\{CH_3OOCH_3\}$, is observed to decrease somewhat with an increase in $[O_2]/I_a^{1/2}$, the fundamental parameter in this system, where I_a is the absorbed intensity. The quantum yield of CH_3OOH production, $\Phi\{CH_3OOH\}$, is about 0.3 at low values of $[O_2]/I_a^{1/2}$, but increases as $[O_2]/I_a^{1/2}$ increases.

Discussion

The mechanism consisting of reactions 1–7 leads to the following rate laws

TABLE 1. Product quantum yields in the photooxidation of azomethane at 25 ± 2 °C and $[CH_3N_2CH_3]$ = 9–10 Torr*

					ave. = 8.9 ± 1.5

*Total pressure in all runs was approximately 100 Torr, which was obtained by adding N_2 where necessary.
†$F \equiv (1 - \Phi\{CH_3OOH\} - \Phi\{CH_3OOCH_3\})/\Phi\{CH_3OOCH_3\}$.

$$F \equiv \frac{1 - \Phi\{CH_3OOH\} - \Phi\{CH_3OOCH_3\}}{\Phi\{CH_3OOCH_3\}} = \frac{k_{4a}}{k_{4b}}$$

$$F' = \frac{k_5}{(2k_3k_4)^{1/2}} + \frac{k_6[O_2]/I_a^{1/2}}{k_4^{1/2}(2 - \Phi\{CH_3OOH\})^{1/2}}$$

where

$$F' \equiv \frac{\Phi\{CH_3OOH\}}{(2 - \Phi\{CH_3OOH\})^{1/2}(1 - \Phi\{CH_3OOH\})^{1/2}}$$

Values of F are computed from the data and listed in Table 1. Their average value of 8.9 ± 1.5 gives k_{4a}/k_{4b} good agreement with the value of 9–12 reported by Heicklen and Johnston (3).

The quantity F' is computed and plotted *vs.* $[O_2]/I_a^{1/2}(2 - \Phi\{CH_3OOH\})^{1/2}$ in Fig. 1. The plot is reasonably linear. A least square treatment of the data yields a slope of 1.55×10^{-4} (Torr s)$^{-1/2}$ and an intercept of 0.22. These values give $k_6/k_4^{1/2} = 0.021\ M^{-1/2}\ s^{-1/2}$ and $k_5/(k_3k_4)^{1/2} = 0.31$. The former value

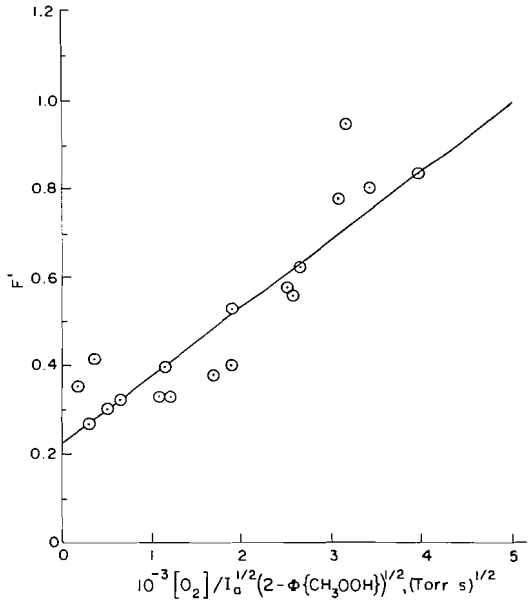

FIG. 1. Plot of $F' \equiv \Phi\{CH_3OOH\}/(2 - \Phi\{CH_3OOH\})^{1/2}(1 - \Phi\{CH_3OOH\})^{1/2}$ *vs.* $[O_2]/I_a^{1/2}(2 - \Phi\{CH_3OOH\})^{1/2}$ in the photooxidation of $CH_3N_2CH_3$ at 25 °C.

For personal use only.

is in good agreement with the value of $0.019\ M^{-1/2}\ s^{-1/2}$ reported by Heicklen and Johnston (3), but the latter value is about a factor of two higher than reported by them.

Finally it should be pointed out that our results provide further evidence against the Russell mechanism (8) in the gas phase. The Russell mechanism is

$$2CH_3O_2 \rightarrow CH_3OH + CH_2O + O_2$$
$$\rightarrow CH_3OOCH_3 + O_2$$

This mechanism predicts that CH_3OOH should not be produced and that $\Phi\{CH_3OOCH_3\}$ should be invariant to $[O_2]/I_a^{1/2}$, both contrary to our findings.

The authors wish to thank Drs. H. A. Wiebe and C. W. Spicer for their help. Comments from Dr. K. O. Kutschke and one referee were of great benefit. This work was supported by the Environmental Protection Agency through the Office of Air Programs under Grant No. AP 01044, for which we are grateful.

Commentaire: Observation par spectrometrie infrarouge d'une reaction parasite lors de la reduction de l'acide hexachloroplatinique

MICHEL PRIMET ET MICHEL-VITAL MATHIEU

Institut de Recherches sur la Catalyse, C.N.R.S., 39, boulevard du 11 Novembre 1918, 69100, Villeurbanne, France

Reçu le 6 octobre 1972

Au cours de la préparation de platine supporté par réduction de l'acide chloroplatinique au moyen d'hydrogène, l'acide chlorhydrique formé réagit avec la fluorine constituant les fenêtres de la cellule infrarouge. La chimisorption ultérieure d'eau conduit à l'observation de bandes ν(OH) attribuées à des hydrates du chlorure de calcium.

During the preparation of supported platinum by hydrogen reduction of hexachloroplatinic acid, the hydrochloric acid formed reacts with the fluorine windows of the infrared cell. The subsequent chemisorption of water gives bands due to $CaCl_2$ hydrates.

Can. J. Chem., **51**, 2255 (1973)

La plupart des catalyseurs platine supporté sont préparés par imprègnation du support au moyen d'acide hexachloroplatinique. L'obtention du métal s'effectue par une réduction au moyen d'hydrogène et s'accompagne de la formation d'acide chlorhydrique. La mesure de l'aire métallique du platine est effectuée par des cycles de titration de l'oxygène adsorbé par l'hydrogène gazeux ou de l'hydrogène adsorbé par l'oxygène gazeux. Quelle que soit la stoechiométrie proposée pour les équations de titration (1–4), l'eau formée serait fixée par le support hydrophile.

Dans les catalyseurs préparés à partir de H_2PtCl_6, une quantité non négligeable de chlore est fixée par le support (5); les propriétés de la phase métallique peuvent donc être perturbées par la présence de l'halogène de même que les schémas proposés pour les cycles de titration H_2–O_2. A la suite de nombreux auteurs (6–8), nous avons donc repris l'étude par spectrométrie infrarouge des interactions du platine déposé avec l'hydrogène, l'oxygène et l'eau.

La méthode de préparation des échantillons est semblable à celle utilisée par d'autres auteurs (6). Le support (Cab-O-Sil H 5 ou Aerosil Degussa) est imprègné par une solution aqueuse de H_2PtCl_6 jusqu'à une teneur en platine de 16%. La cellule utilisée (9) est équipée de fenêtres en fluorine ou en bromure de potassium.

Le solide résultant de l'imprègnation par H_2PtCl_6 est traité à 400 °C sous 200 Torr d'hydrogène pendant une dizaine d'heures, puis mis sous vide à la même température. L'adsorption d'eau sous sa tension de vapeur saturante à température ambiante fournit une large bande centrée vers 3400 cm^{-1} qui disparaît par désorption à 200 °C. Elle est attribuée à de l'eau adsorbée sur la silice. Par contre, l'introduction d'une faible quantité d'eau (2×10^{-2} mmol) fournit un spectre (Fig. 1*a*) présentant deux bandes à 3500 et 3450 cm^{-1}. Celles-ci sont également observées sur le spectre des fenêtres en fluorine de la cellule (Fig. 1*b*), de même que deux autres à 1615 et 1630 cm^{-1} plus difficilement détectables avec le catalyseur à cause de l'absorption de l'échantillon dans ce domaine spectral. Ces quatre bandes sont effacées par une mise sous vide à 25 °C pendant une dizaine d'heures et reformées dans les mêmes conditions.

Au cours de la réduction à 400 °C, un dépôt huileux se forme sur les fenêtres de la cellule; par mise sous vide, la fenêtre apparaît comme dépolie et sa transparence diminue. Lorsque le solide réduit à 400 °C est placé en présence d'hydrogène à température ambiante, puis évacué à 25 °C, l'introduction d'oxygène provoque une sensible augmentation des bandes ν(OH) et des bandes des groupes hydroxyles liés par liaison hydrogène. Aucune bande nouvelle dans le domaine 3550–3300 cm^{-1} n'a pu être détectée.

L'action à 25 °C de faibles incréments de vapeur d'eau sur une silice traitée par HCl à 400 °C fournit les mêmes bandes qu'avec l'échantillon précédent. On pouvait alors penser à une attaque de la silice par HCl avec formation d'un composé volatil qui, condensé sur les fenêtres de la cellule, subirait une hydrolyse en présence de vapeur d'eau. La faible transparence

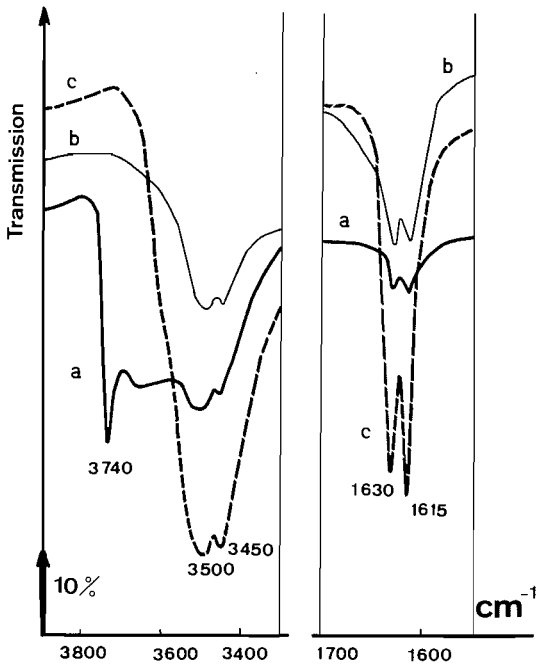

FIG. 1. (*a*), Spectre infrarouge d'un échantillon Pt/SiO_2 à 16% Pt réduit à 400 °C sous H_2, puis sous vide à 400 °C, soumis à l'action de 20 µmol H_2O à température ambiante; (*b*), spectres des fenêtres en CaF_2 de la cellule contenant l'échantillon précédent; (*c*), spectre infrarouge de $CaCl_2$ déshydraté sous vide à 150 °C et soumis à l'action de la vapeur d'eau à 25 °C.

de CaF_2 dans le domaine des vibrations Si—O nous a conduit à reprendre les mesures avec des fenêtres en KBr. Nous n'avons pas retrouvé les bandes vers 3500 et 1600 cm^{-1} mentionnées plus haut; aucune vibration dans le domaine spectral 2000–400 cm^{-1} n'a pu être attribuée à une liaison Si—O. L'hypothèse d'une attaque de la silice par HCl est donc à rejeter.

La nature des fenêtres semble seule responsable des résultats obtenus. Nous avons donc soumis un disque de CaF_2 à l'action de 400 Torr HCl à 25 °C pendant une vingtaine d'heures (un dépôt blanchâtre se forme); après action de la vapeur d'eau, nous retrouvans les bandes à 3500, 3450, 1630, et 1615 cm^{-1} alors qu'une fenêtre de KBr ne fournit pas ces maximums d'absorption dans les mêmes conditions. Seule l'attaque par HCl des fenêtres avec formation de $CaCl_2$ ou de KCl peut expliquer nos résultats expérimentaux. L'action de l'eau sur les produits de réaction conduit à la formation d'hydrates responsables des bandes observées tant que la quantité d'eau introduite reste faible; or $CaCl_2$ fournit de nombreux hydrates (10) alors que KCl ne possède pas d'hydrates connus (11).

Nous avons vérifié cette conclusion en enregistrant le spectre de $CaCl_2$ déshydraté sous vide à 150 °C, puis soumis à l'action de quantités croissantes d'eau à 25 °C (Fig. 1*c*), nous retrouvons les bandes ν(OH) et δ (H_2O) mentionnées plus haut. Ces dernières sont éliminées lors d'un traitement prolongé sous vide de l'échantillon.

L'adsorption d'éthylène sur un disque de fluorine présentant les bandes précédentes ou sur un échantillon de $CaCl_2$ partiellement hydraté entraîne la disparition des maximums d'absorption précédemment détectés et leur remplacement par des bandes relativement larges à 3400 et 1620 cm^{-1}. Une évacuation de l'éthylène entraîne la réapparition des quatre bandes avec diminution d'intensité. Cette perturbation de l'eau liée au chlorure de calcium doit être à rapprocher de celle observée par Kiselev et coll. (12) lors de l'interaction des groupes OH de la silice avec des composés éthylèniques.

En conclusion, le platine supporté ne semble pas présenter de groupes OH superficiels lors des séquences de titration H_2–O_2 ou lors d'une chimisorption d'eau. En conséquence, l'eau formée au cours des opérations de titration ne se dissocie pas sur le métal, ce qui n'invalide pas les équations proposées (1–4). Par contre, au cours de la réduction de H_2PtCl_6 par H_2, l'acide chlorhydrique formé attaque la fluorine en produisant du chlorure de calcium qui peut fournir des hydrates responsables de bandes ν(OH) dans le domaine spectral où des espèces Pt–OH semblent avoir été détectées (6). Une réaction parasite analogue a conduit French et coll. (13) à conférer une acidité protonique à de la silice dispersée dans KBr. Cette réaction parasite est selon Eischens et coll. (14) l'échange des ions K^+ du support KBr par les ions NH_4^+ issus de l'ammoniac gazeux en présence d'eau.

Comment: Reply to Primet and Mathieu Concerning the Infrared Observation of PtOH Species

B. A. Morrow and P. Ramamurthy

Department of Chemistry, University of Ottawa, Ottawa, Canada, K1N 6N5

Received January 18, 1973

The i.r. absorption bands due to $CaCl_2$ hydrates, formed on CaF_2 windows during the preparation of silica supported platinum from H_2PtCl_6, should not be confused with those of surface Pt—OH species which are formed by other methods.

Les hydrates de chlorure de calcium formés, sur les fenêtres de fluorites des cellules infrarouges, durant la préparation de platine supporté par de la silice par réduction de l'acide chloroplatinique donnent, dans l'I.R. des bandes d'absorption qu'il ne faut pas confondre avec celles des espèces provenant de Pt—OH qui si trouvent à la surface et qui sont formées par d'autres méthodes.

[Traduit par le journal]

Can. J. Chem., 51, 2258 (1973)

In the preceding paper (1) Primet and Mathieu have implied that our previously reported infrared bands at 3497 and 3544 cm^{-1}, which we attributed to surface PtOH species (2), might also be due to hydrates of $CaCl_2$. This cannot be true for the following reasons:

(*1*) In our spectra, two distinct infrared bands were reported (not a doublet) and these were about 50 cm^{-1} to higher wavenumber than theirs. The 3497 cm^{-1} band is produced only when O_2 is added to a hydrogen covered platinum surface, and the 3544 cm^{-1} band can be produced when water is added to a "reduced" oxygen treated sample. The reader is referred to our original paper for details (2), but better quality spectra showing these features are shown in Fig. 1. The 3497 cm^{-1} band is broader than the sharp 3544 cm^{-1} band and in some instances appears to show some poorly resolved doublet structure. The spectrum in Fig. 1*a* shows this feature as evidenced by a shoulder near 3515 cm^{-1}.

(*2*) Our spectral features are extremely reproducible and can be observed in clean cells equipped with either NaCl or CaF_2 windows. Further, the spectra can be reproduced on silica-supported platinum samples which had been "regenerated" hundreds of times and which were over a year old. Primet and Mathieu's bands presumably can only be seen after the initial reduction of a new SiO_2/H_2PtCl_6 disc, or if they are subsequently observed, the hydrate bands are of diminished intensity.

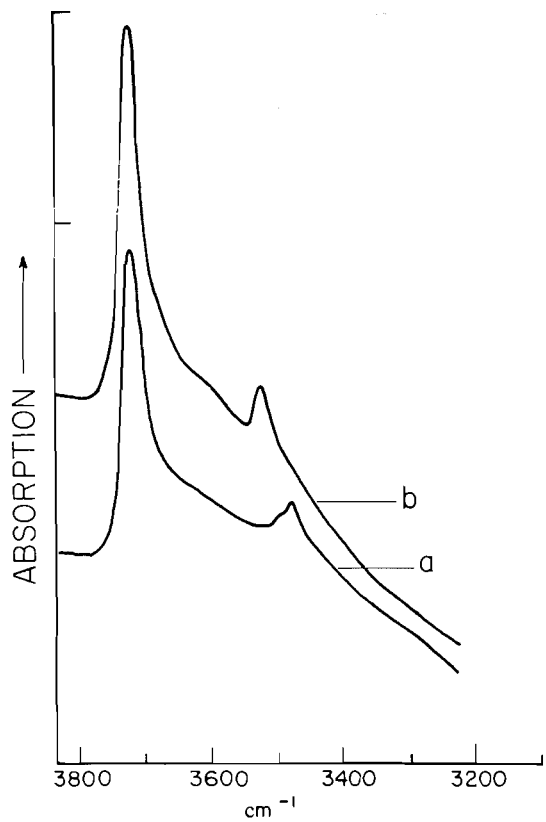

FIG. 1. Infrared spectra of hydroxyl groups on silica-supported platinum. (*a*) 3497 cm^{-1} band. (*b*) 3544 cm^{-1} band. The strong band at 3750 cm^{-1} is due to silica. Ordinate scale refers to the (*b*) spectrum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*3*) Our bands are not removed following prolonged evacuation at room temperature, whereas theirs are removed by this operation.

(*4*) Our observations concerning the addition of ethylene are quite different from those reported by Primet and Mathieu. Indeed, we find that our PtOH bands disappear after adding *any* hydrocarbon and the very intense and well known PtCO band near 2050 cm^{-1} is observed, or it is near 2000 cm^{-1} when a C^{13} hydrocarbon is used (3).

(*5*) Finally, no bands attributable to materials on the cell windows (in the absence of the SiO_2/Pt sample which can be moved at will away from the infrared beam) have ever been detected. This has been checked continuously over a two year period. Further, no bands near 1600 cm^{-1} have ever been detected, a point which has also been checked carefully.

We must stress that the absorptions which we attribute to PtOH surface species are relatively weak in comparison with the SiOH bands of the support and are best observed when the silica itself has been preheated to about 800 °C prior to impregnation with H_2PtCl_6 from anhydrous acetone. The heat treatment makes the support relatively hydrophobic (4) and drives off all of the adsorbed water and removes most of the interacting surface hydroxyl groups which are responsible for the broad tail in the 3700–3300 cm^{-1} region of the spectrum of silica, and the anhydrous acetone prevents extensive rehydration during impregnation. In our experience, unless these precautions are taken, the 3497 and 3544 cm^{-1} bands can almost be obscured by the strong background spectrum near 3500 cm^{-1} due to physically adsorbed water and hydrogen bonded silanol groups.

We can speculate that the failure to detect these bands by earlier workers might be due to these effects, or it is possibly due to the fact that in much of the earlier work (5, 6) alumina has been used as a support and we have already stated why we cannot observe the PtOH bands in this case (2). We should also stress, that only when O_2 is added to "hydrogen covered" platinum do we observe these infrared bands, and in agreement with Darensbourg and Eischens (7) we find no evidence to suggest that H_2O dissociates on pure platinum, or that when H_2 is added to a platinum surface which has been pretreated with O_2, that anything other than water is formed.

Charge Density Distribution in Vanadium Complexes

D. R. EATON AND K. L. CHUA
Department of Chemistry, McMaster University, Hamilton, Ontario
Received November 2, 1972

An empirical method for investigating the effect of substituents on the charge distribution of transition metal complexes is presented. This method is based on the measurement of n.m.r. chemical shifts of paramagnetic compounds and is applied to a series of V(III) complexes. Measurements are reported on the sixteen isomers which result from the systematic replacement of CH_3 groups by CF_3 groups in V(III) trisacetylacetonate. Ninety-nine of the possible 100 ^1H and ^{19}F chemical shifts have been measured. Substituent shifts of several thousand Hz are observed and have been interpreted using a model invoking charge redistribution in both σ and π orbitals. Similar experiments involving phenyl substituents are also reported. The model adopted enables the data to be fitted with a precision of around 2%. The substituent parameters derived from this model are discussed in terms of changes in electron density and the results compared with substituent effects in aromatic compounds. The important differences arise from the three dimensional nature of metal complexes which leads to interactions between the σ and π electrons of a type not found in simple aromatic compounds. The significance of these results to the rationalization of ligand effects on ligand exchange and catalytic reactions is discussed.

Afin d'étudier l'effet des substituants sur la distribution des charges dans des complexes de métaux de transition, on a élaboré une méthode empirique. Cette méthode est basée sur la mesure des déplacements chimiques en r.m.n. de composés paramagnétiques et est appliquée à une série de complexes du V(III). Des mesures furent effectuées sur les seize isomères obtenus lors de la substitution systématique des groupes CH_3 par des groupes CF_3 dans le tris V(III)acétylacétonate. On a mesuré 99 des 100 déplacements chimiques possibles du ^1H et du ^{19}F. Des déplacements induits par les substituants de plusieurs milliers de Hz ont été observés et ont été interprétés en utilisant un modèle impliquant des redistributions des charges dans les orbitales σ et π. On a rapporté aussi des expériences similaires impliquant des substituants phényles. Le modèle adopté a permis d'obtenir des données avec une précision d'environ 2%. Les paramètres des substituants obtenus de ce modèle sont discutés en fonction des changements dans la densité électronique et les résultats sont comparés avec les effets de substituants dans les composés aromatiques. Les différences importantes proviennent de la nature tridimensionelle des complexes métalliques qui implique des interactions entre les électrons σ et π qui ne se retrouvent pas chez les composés aromatiques simples. On discute de l'importance de ces résultats en ce qui a trait à la rationalisation des effets des coordinats sur l'échange des coordinats ainsi que sur les réactions catalytiques.

[Traduit par le journal]

Can. J. Chem., 51, 2260 (1973)

Introduction

We have previously reported (1) n.m.r. studies of complexes of V(III) with mixed ligands and have suggested that experiments of this kind provide a convenient approach to the study of the transmission of substituent effects in transition metal complexes. This topic has significance with respect to the understanding of variations in ligand exchange rates and mechanism with changes in ligand structure. In this earlier paper a qualitative interpretation of the mode of action of substituent effects in these transition metal complexes was proposed and it was concluded that the important parameter was the charge density on the ligand atoms attached to the metal. It was also indicated that it was intended to extend these studies to develop at least an empirical quantitative scale of substituent effects. The present paper represents our efforts in this direction.

β-Diketonate complexes of V(III) have been utilized in this study. These are six coordinated compounds with basically octahedral geometry. The trisacetylacetonate may be regarded as the parent compound of the series. The ligand protons of this compound show large isotropic n.m.r. shifts relative to the free ligand or a diamagnetic complex which have been attributed (2–4) to contact interactions resulting from partial delocalization of the unpaired electrons from the metal d orbitals to the lowest unoccupied ligand π^* orbitals. The basic experiment consists of measuring the change in isotropic shift of a given proton which occurs when there is a change of substituent on one of the other ligands. The substituent changes observed are

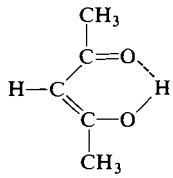
TABLE 1. No. of isomers and resonances of V(III)/acac/tfac/hfac system

Compound	Isomers	Resonances		
		CH_3	CF_3	CH
$V(acac)_3$	1	1	—	1
$V(hfac)_3$	1	—	1	1
$V(acac)_2(hfac)$	1	2	1	2
$V(acac)(hfac)_2$	1	1	2	2
$V(tfac)_3$	2	4	4	4
$V(acac)_2(tfac)$	1	5	1	3
$V(acac)(tfac)_2$	3	8	4	7
$V(hfac)_2(tfac)$	1	1	5	3
$V(hfac)(tfac)_2$	3	4	8	7
V(acac)(tfac)(hfac)	2	6	6	6
Total	16	32	32	36

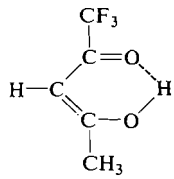
quite large (the total spread is often several thousand Hz at 100 MHz for a given resonance in a series of substituted compounds) so that experimentally the method is quite sensitive. The *ab initio* calculation of isotropic shifts for transition metal complexes is however fraught with a number of hazards. We have therefore preferred to adopt a more empirical approach to the analysis of the results. This type of approach is exemplified by the use of the various Hammett and Taft σ parameters (5) to describe substituent effects in aromatic compounds. The present case is however substantially more complex than that of aromatic substitution. We have to consider three interconnected π systems in different planes, d orbitals rather than p orbitals are involved, and the octahedral geometry in the lower symmetry of these chelated complexes offers five different substituent positions rather than the three of aromatic systems (ortho, meta, and para). The net result is that rather a large number of parameters are required. A convincing empirical analysis therefore demands a large amount of data. In the present paper we attempt to justify our method of analysis by presenting an essentially complete data set for one system and have then applied the method to other substituents for which we have rather less data.

Results for CH_3 and CF_3 Substitution

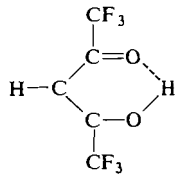
N.m.r. spectra of mixed V(III) complexes were obtained by the method described previously (1). Consider first the compounds which can result from the systematic substitution of CF_3 groups for CH_3 groups in the compound $V(acac)_3$. We use the abbreviations acac = acetylacetone (structure **1**), tfac = trifluoroacetylacetone (structure **2**), hfac = hexafluoroacetylacetone (structure **3**). The resulting compounds are tabulated in Table 1. There are a total of 16 different molecules which give rise to 32 chemically distinct CH_3 resonances, 32 CF_3 resonances, and 36 CH resonances. Figure 1 shows the sixteen structures for the general case with two different substituents X and Y and provides the key to the numbering system adopted to present the data.



1 acac



2 tfac



3 hfac

Table 2 presents the observed CH_3 isotropic shifts for the system in which X = CH_3, Y = CF_3. All 32 resonances have been identified and assigned. The isotropic shifts vary from −4054 to −6660 Hz at 100 MHz and 37 °C. We have previously reported (1) the four shifts arising from the three compounds involving acac and hfac. Assignments to compounds with different stoichiometries are unambiguous. Thus in a typical experiment in which hfac is added incrementally to $V(acac)_3$ the two new CH_3 resonances which appear initially are assigned to $V(acac)_2(hfac)$ and the third which appears later to $V(acac)(hfac)_2$. The assignments are then checked by adding acac to $V(hfac)_3$. CH_3 and CH assignments for compounds involving tfac were obtained by using deuterated acac.

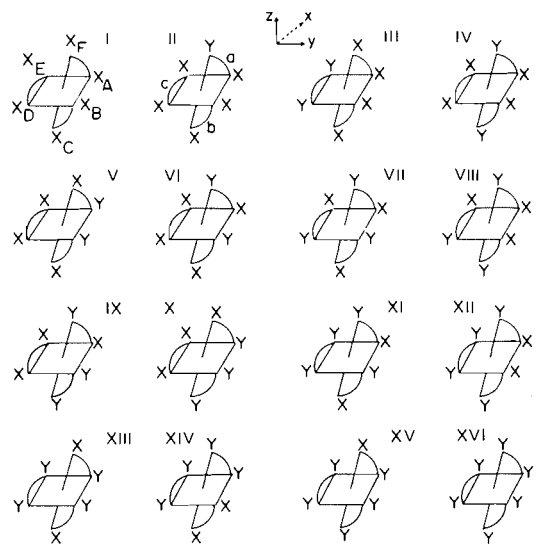

FIG. 1. The sixteen isomers obtained by systematic substitution of a tris chelate $V(XX)_3$.

These experiments enabled the resonances of the tfac ligands to be distinguished from those of the acac ligands. All the compounds except V(acac)(tfac)(hfac) can be identified by experiments involving appropriate pairs of binary mixtures. Lines from V(acac)(tfac)(hfac) were identified by obtaining a variety of spectra from ternary mixtures and eliminating lines previously assigned to other mixed chelates. When two or more isomers of a given compound exist the relative intensities of lines usually sufficed to make assignments to individual isomers. For example in the simple case of $V(tfac)_3$ four CH_3 peaks are observed, three of which are of equal intensity (4). The three of equal intensity must be assigned to the *trans* isomer and the remaining peak to the *cis* isomer. Assignments of lines within a given isomer are based on agreement between observed frequencies and those calculated by the procedure described below. Table 3 gives similar data for the ^{19}F CF_3 shifts. Again all 32 possible resonances have been observed. The range in this case is from −3410 to −5724 Hz at 100 MHz (37 °C) and the assignments are based on experiments similar to those described for the CH_3 spectra. Three of these frequencies were reported previously (1). Thirty-five of the possible 36 CH frequencies are reported in Table 4. The missing resonance belongs to one of the isomers of V(acac)(tfac)(hfac) and is in all probability overlapped by stronger CH_3 resonances present in the complex mixtures used. The spread of the shifts is in this case larger, ranging from −1330 to −5980 Hz at 100 MHz (37 °C). Six of these shifts were reported in the earlier

paper. Thus overall 99 of the possible 100 pieces of data have been obtained.

Analysis of the Data

Examination of the experimental results contained in Tables 2–4 shows that there are clearly large substituent effects of the type defined in the introduction but there is no simple pattern to the data. The most obvious qualitative feature is that increasing CF_3 substitution increases the CH_3 shifts whereas increasing CH_3 substitution decreases the CF_3 shifts. The CH shifts generally follow the trend of the CH_3 or CF_3 groups on the same ligand but the changes are proportionately greater. There are however several exceptions and numerous irregularities in this trend. We have previously suggested a qualitative interpretation of these observations. Our present analysis is based on a modified version of this earlier interpretation.

The model we have adopted is based on the following assumptions.

(*a*) The isotropic shifts arise from contact rather than dipolar interactions. Evidence in favor of this assumption has been presented previously (1, 3) and we do not consider that dipolar interactions represent a significant source of error.

(*b*) The ground states of all these V(III) chelates are orbitally nondegenerate and arise from the e^2 configuration in D_3 symmetry. This point seems to be well established (1) and it is not necessary to consider the type of effects La Mar and Van Hecke (6) have demonstrated for orbitally degenerate ground states.

(*c*) The dominant contact interaction arises from spin transfer from the metal d orbitals to the lowest anti-bonding ligand π^* orbital.[1] A corollary of this assumption is that the observed shifts are proportional to the spin transferred according to the well known McConnell (7) model. In making this assumption we are following the conclusions of several groups (2–4) who have studied isotropic shifts of vanadium complexes. It should be realized though, that even if metal-to-ligand π^* spin transfer is the dominant effect there may be smaller contributions from other mechanisms which could disrupt quantitative analysis.

[1]Only a small amount of mixing with the π^* orbitals is necessary so interactions involving orbitals well separated is energy suffice to cause the shifts. See, for example, ref. 15 for a recent theoretical calculation.

(*d*) The substituent effects are additive, *i.e.*, the effect on the charge distribution of substituting two CF_3 groups on $V(acac)_3$ at specified positions is the sum of the effects of single substitution at the two individual positions. Additivity appears to hold approximately for aromatic systems. The test of this assumption can only lie in the agreement between observed and calculated shifts. It must be expected though that the lack of additivity will be one of the factors leading to incomplete agreement between calculated and experimental values.

Consider first the CH_3 shifts. Figure 2*a* illustrates the overlap between the $p\pi^*$ orbital of the oxygen of a ligand in the *xy* plane and the d_{xz} orbital of vanadium. Based on the above assumptions the neighboring CH_3 shift will be proportional to the amount of spin transferred from the d orbital to the p_π orbital. This in turn depends on two factors, namely the population of the d_{xz} orbital and the ability of the p_π orbital to accept an electron. The first factor was considered in the earlier paper. If all three ligands are identical the occupied d orbitals have the form $(1/\sqrt{2})(d_{xz} - d_{yz})$ and $(1/\sqrt{6})(2d_{xy} - d_{xz} - d_{yz})$. The charge density in the d_{xz} orbital equals that in the d_{xy} and d_{yz} orbitals and has a value of 2/3. This is true for any compound in which the threefold symmetry

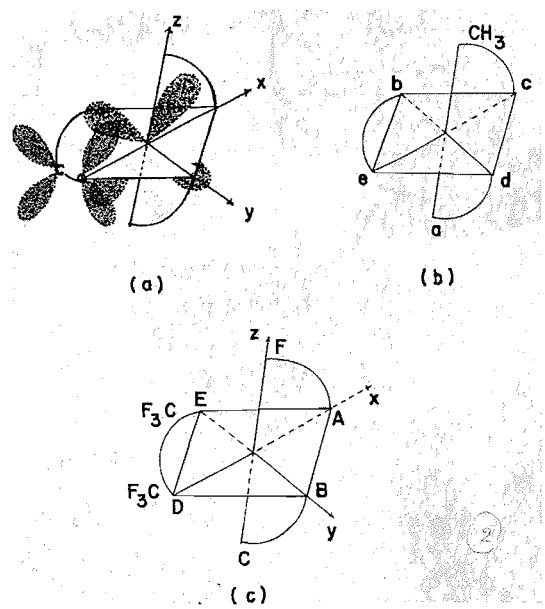

FIG. 2. (*a*) Overlap of d_{xz} and ligand p_π^* orbitals. (*b*) Labelling of substituent parameters. (*c*) Axis system for $V(acac)_2(hfac)$.

axis is retained, *e.g. cis*-V(tfac)$_3$. For less symmetric cases the form of the occupied orbitals is changed and the occupation values of d_{xy}, d_{xz}, and d_{yz} correspondingly modified. Thus in the extreme case in which the *xy* plane is occupied by a symmetric electron withdrawing ligand which exerts a tetragonal crystal field distortion very much greater than the trigonal distortion present in all these tris chelates the occupied orbitals are d_{xy} and $(1/\sqrt{2})(d_{xz} - d_{yz})$ reducing the population of d_{xz} to 1/2 and increasing that of d_{xy} to 1. The form of the orbitals for intermediate cases was given in ref. 1. In general the population of a d orbital in a plane occupied by oxygens bearing more electron attracting substituents will be increased at the expense of d orbitals in planes containing less electron attracting substituents. The application of this generalization will be considered below.

The second factor mentioned above, namely the ability of the oxygen to accept π electrons, will depend on the charge on the oxygen atom. The more positive charge the greater is the electron accepting ability. Alternatively the more positive the charge the lower the π^* orbital and the better the interaction with the half filled d_π orbital. We might therefore anticipate an inductive effect whereby an electron withdrawing substituent, operating through the σ bonds will induce positive charge to some extent on the more distant oxygens. In principle the effect will be different for each of the five non-neighboring oxygens since none are equivalent by symmetry.

Based on these considerations we have used the empirical eq. 1 to correlate the CH_3 shifts.

$$[1]\quad \Delta\nu = \Delta\nu_0(1 + x)(1 + a + b + c + d + e)$$

The term $(1 + x)$ takes account of the change in d orbital population and $(1 + a + b + c + d + e)$ of the change in the oxygen charge resulting from the inductive effect of substituents in the five possible positions. Both of these factors reduce to unity for the unsubstituted V(acac)$_3$ so that $\Delta\nu_0$ is simply the CH_3 shift for this compound.

This equation was utilized in the following manner in the analysis of the CH_3/CF_3 system. Figure 2*b* shows the labelling of the substituent positions relative to the CH_3 group under consideration. The parameter *a* refers to the *trans* substituent and *b*, *c*, *d*, and *e* to the four nonequivalent *cis* positions. In calculating the CH_3 shifts the relevant parameter is included for each position bearing a CF_3 group and omitted for each position bearing a CH_3 group. Thus for example for the two nonequivalent CH_3 groups of V(acac)$_2$(hfac) the inductive factors are $(1 + a + d)$ and $(1 + b + e)$. Reference to Figs. 1 and 2*b* enables the factors for other CH_3 resonances to be obtained by inspection. The evaluation of the d orbital population factor is perhaps best illustrated by the example shown in Fig. 2*c*. With the axis system as shown d_{xz} and d_{yz} are equivalent but d_{xy} is unique. Further the *xy* plane contains two CF_3 substituents (assumed to be electron withdrawing) and the *xz* and *yz* planes one each. d_{xy} will therefore gain population at the expense of d_{xz} and d_{yz}. We therefore write the population factor as $(1 + x)$ for d_{xy} and $(1 - x/2)$ for d_{xz} and d_{yz}. Inspection of Fig. 2*a* and 2*c* shows that the CH_3 groups A and B obtain spin density by interaction with d_{xy} and the CH_3 groups C and F by interaction with d_{yz} or d_{xz}. The contact shift expressions for these resonances are therefore

$$\Delta\nu_A = \Delta\nu_0(1 + x)(1 + a + d)$$

$$\Delta\nu_C = \Delta\nu_0(1 - x/2)(1 + b + e)$$

Similarly for the CH_3 of V(acac)(hfac)$_2$ we obtain

$$\Delta\nu = \Delta\nu_0(1 + x/2)(1 + a + b + d + e)$$

For the complexes with no two fold symmetry axis d_{xy}, d_{xz}, and d_{yz} all have different populations and two parameters *x* and *y* are required. Appropriate expressions for all 32 CH_3 groups can be readily obtained. The parameters were obtained as follows. Initially it was assumed that *x* has a constant value for all d orbitals the planes of which differ by one CF_3 group as is the case in the above example. No *y* values are then required. If the planes defining the d orbital differed by two CF_3 groups a value equal to twice that assumed above was used. The CH_3 frequencies of V(acac)$_2$(hfac), V(acac)(hfac)$_2$, *cis*-V(tfac)$_3$, and V(acac)$_2$(tfac) were then used to obtain values of the six unknowns *x*, *a*, *b*, *c*, *d*, and *e*. It turned out that the *cis* substituent constants *b*, *d*, and *e* had virtually identical values so the number of adjustable parameters was reduced to four. These four parameters were then further adjusted to give the best fit to all 32 frequencies. The agreement is rather satisfactory. (Standard deviation 5.6%, see

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

below.) The agreement can of course be improved by treating x as an adjustable parameter for each compound. The possible variations are not very large since changes in x which improve the agreement for one frequency tend to make it worse for other frequencies. The final calculated frequencies were obtained by optimizing the x and y values and then making a further small adjustment to the substituent parameters. Final calculated frequencies are shown in Table 2. A plot of calculated *vs.* experimental values using this final parameter set is shown in Fig. 3. The standard deviation of the calculated from the experimental values is 1.28% of the total spread of the shifts. (It seems more reasonable to express the standard deviation as a percentage of total spread than of the absolute values. It is actually 0.62% of the average shift.) Of the 1.28% about 0.5% error is attributable to inaccuracies in the measurements and the remainder reflects the inadequacies of the model.

The CF_3 data were treated in exactly the same manner except that the substituent parameter was included for each position bearing a CH_3 group and omitted for each position bearing a CF_3 group rather than *vice versa*. Final calculated frequencies are included in Table 3. The standard deviation of the calculated frequencies is in this case 2.19% of the total spread of the shifts.

The CH frequencies require a slightly modified

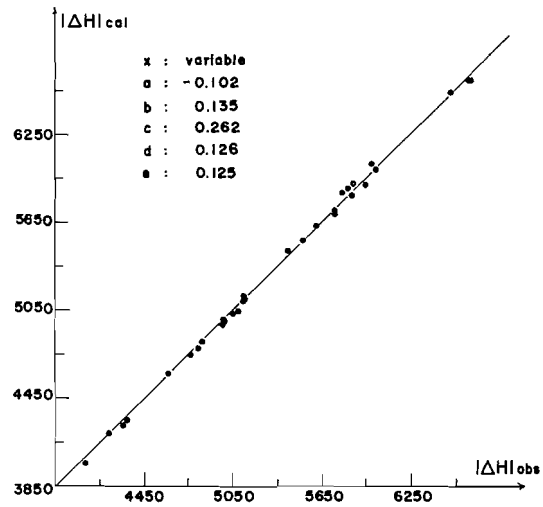

FIG. 3. Comparison of calculated and observed CH_3 chemical shifts. Model with variable x. Shifts in Hz at 100 MHz. CH_3/CF_3 system.

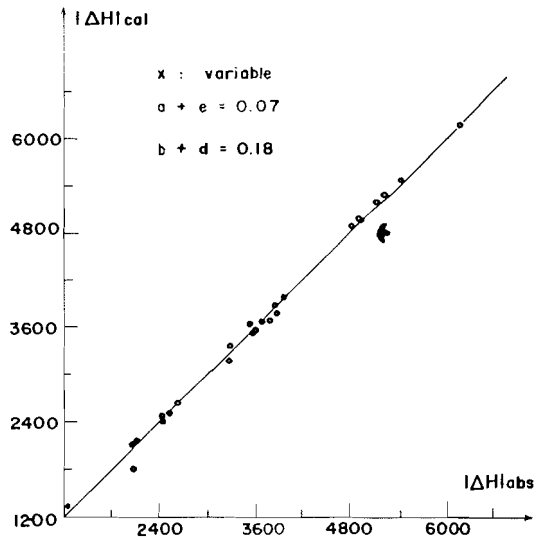

FIG. 4. Comparison of calculated and observed CH shifts. Shifts in Hz at 100 MHz. CH_3/CF_3 system.

procedure. Spin density can reach the γ carbon equally well through either of the two β-diketone oxygens. It is appropriate therefore to include in the population and substituent factors the parameters relating to both oxygens. Thus for example for the acetylacetone CH in $V(acac)_2$-(hfac) the expression becomes

$$\Delta\nu_a = \Delta\nu_0(1 + x_{xy} + x_{yz})[1 + (a + d) + (b + e)]$$
$$= \Delta\nu_0(1 + x/2)(1 + a + b + d + e)$$

Similarly for the CH of the hexafluoroacetylacetone we obtain

$$\Delta\nu_c = \Delta\nu_0(1 - x)(1 - 2a - 2b - 2d - 2c)$$

$\Delta\nu_0$ is obtained in the first case from $V(acac)_3$ and in the second case from $V(hfac)_3$. An average value was used for tfac resonances. It should be noted that a positive substituent parameter is used to express the substituent effect of a CF_3 group on an oxygen bearing a CH_3 and an equal but negative value to allow for the effect of a CH_3 on an oxygen bearing a CF_3. Examination of the above equations and those for the remaining 34 CH shifts shows that the only substituent parameters encountered are the combinations $(a + e)$ and $(b + d)$. In addition to x we have therefore only two variables. Analysis then proceeded in the same manner as for the CH_3 and CF_3 shifts. A plot of calculated *vs.* experimental values using the final parameters is shown in Fig. 4. In this case the standard

deviation is 1.97% of the total spread. The calculated frequencies are shown in Table 4. The various parameters derived from the above analyses are collected together in Tables 5 and 6.

Discussion

The validity of an empirical analysis such as that described above is subject to several criteria. First of all it is obvious that the parameters used must reproduce the experimental data with reasonable accuracy. We regard the agreement obtained above as satisfactory. The 1 or 2% discrepancies can very reasonably be ascribed to inadequacies in the model. The most important of these are probably the assumption of a single delocalization mechanism and of additivity of the substituent effects. Secondly the parameters should be internally consistent. Thus if from the CH_3 results we deduce a drift of electrons from *cis* positions towards an oxygen ligand bearing a CF_3 substituent the CF_3 results must indicate enhanced electron density at the CF_3 oxygen obtained from neighboring *cis* CH_3 bearing oxygens. Such consistency should be reflected in opposite signs for corresponding parameters derived from the CH_3 and CF_3 analyses. This result is indeed obtained apart from a small inconsistency in the *e* parameter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

for the CF_3 results. In this case we obtain a small positive value rather than a small negative value. This discrepancy could possibly be rationalized in terms of a direct *cis* interaction with the relatively bulky CF_3 group but we do not believe that it detracts seriously from the overall trend of the results. Similarly the CH parameters should bear some relationship to the CH_3 parameters. Again the zero value of $a + e$ agrees with the opposite signs found for the individual CH_3 parameters and the positive value of $b + d$ is qualitatively as expected. The d orbital population values obtained from the three sets of data are displayed in Table 6. If the model were rigorously correct the three values for a given orbital should be identical. Not surprisingly this equality does not hold particularly well. However there is good agreement in the signs of the changes in orbital populations with substitution and in the overall magnitude of the effect (0–15%). This is probably as much as can be expected. It should be noted that the main discrepancy is that the CH shifts indicate larger population changes than do the CH_3 and CF_3 shifts. This implies that the CH shifts are more sensitive to changes in π spin density than the CH_3 or CF_3 shifts. This is reasonable since other mechanisms such as σ delocalization are certainly expected to be more pronounced at the CH_3 or CF_3 positions.

A final criterion for accepting the analysis is that the results should be physically plausible. This aspect is illustrated by the charge distributions shown diagrammatically in Fig. 5 for two typical complexes. $V(acac)_2(tfac)$ has a single electron withdrawing CF_3 group. This exerts an inductive effect through the σ bonds of the system increasing the positive charge at each of the four *cis* oxygens (Fig. 5*a*). The effect at the oxygen belonging to the same chelating ligand is roughly twice as great as at the other positions. This seems reasonable in view of the availability of an alternative pathway through the σ bonds of the ligand. A little of the negative charge thus withdrawn leaks across to the oxygen *trans* to the substituent. Although not anticipated prior to the analysis of the data, in retrospect this result can be correlated with the many reports of unique *trans* effects in transition metal complexes. In addition to this direct inductive effect on the charge distribution in the σ system of the molecule there is also a polarization of the charge in the metal d orbitals not involved in σ bonding.

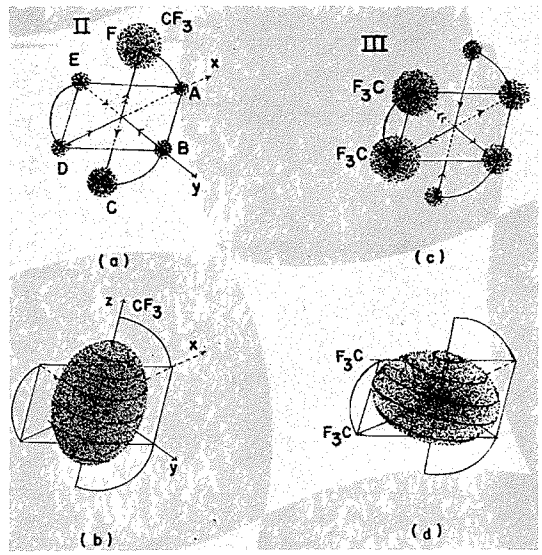

FIG. 5. σ and π charge distribution in two complexes (see text for description).

Instead of there being a spherical distribution of such charge it tends to accumulate in planes containing the electron withdrawing CF_3 group (Fig. 5*b*). In this case the two d orbitals in the planes containing the CF_3 bearing oxygen have gained approximately 5% in population and the orbital in the plane not containing the CF_3 group has lost 10%. Since these are the orbitals involved in π bonding to the ligands there are corresponding changes in the π interactions with the different ligands. These result in enhanced delocalization to the π^* orbitals of ligands not bearing the electron attracting substituent and diminished delocalization to the CF_3 bearing ligand. $V(acac)_2(hfac)$ has two CF_3 substituents and the charge distribution arises from the superposition of the inductive and polarization effects of the two taken individually. The net result is that the two CH_3 bearing oxygens in the same plane as the hfac ligand lose very little negative charge but the two out of this plane lose substantially (Fig. 5*c*). At the same time the d orbitals containing the unpaired electrons are polarized leading to a 12% gain of charge density in the plane of the hfac and a 6% loss in each of the perpendicular planes (Fig. 5*d*). Thus the parameters obtained from the analysis lead to a plausible rationalization of the effect of substituents on the charge distribution of the complexes.

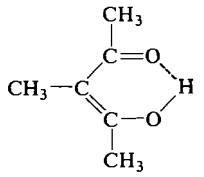
Results with Other Ligands

The analysis described above has been extended to several other mixed chelate systems. Initially we sought one further check on the validity of the model. This involves the use of the γ methyl substituted ligand **4**.



4

The proton n.m.r. spectrum of the tris V(III) complex of this ligand was originally reported by Forman, Murrell, and Orgel in 1959 (2). They observed that the shift of the γCH_3 resonance was opposite in sign to that of the CH in $V(acac)_3$ and this was interpreted as evidence for π spin delocalization. Subsequent investigators have supported this conclusion with other evidence. We argued previously, mainly on the basis of the temperature dependence of the isotropic shifts of the mixed complexes, that the mechanism involved does not change on passing from symmetric to unsymmetric complexes and hence that the evidence in favor of π delocalization in the symmetric complexes implied π delocalization in the unsymmetric complexes. Since our analysis rests on this assumption more direct evidence seemed desirable. Mixed complexes with ligand **4** provide this evidence. For π delocalization in an aromatic system McConnell (7) showed that:

$$a_H = Q\rho_C$$

where a_H is the proton hyperfine coupling and ρ_C the carbon p_π spin density. Theory predicts that Q will be negative for a hydrogen attached to the aromatic carbon and positive for a methyl group so attached (8), hence the change in sign of the CH and C—CH_3 contact shifts. If Q were a true constant in both cases we would expect the C—CH_3 and C—H shifts to be opposite in sign and proportional to each other in magnitude for all mixed complexes in which the C—H is replaced by C—CH_3. Unfortunately it has been shown (9) that Q_{CH_3}, although always positive in sign, can vary in magnitude from compound to compound. If there is π delocalization it is therefore to be expected that the signs of the C—H and C—CH_3 shifts will always be opposite

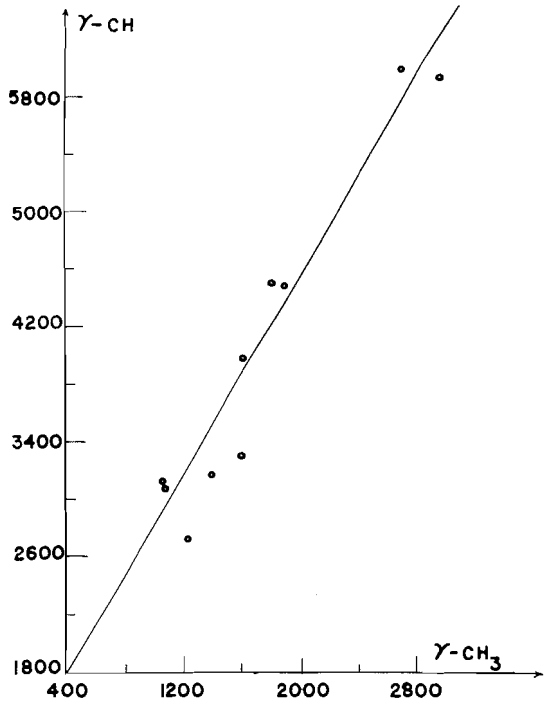


FIG. 6. Variation of γ-CH_3 and γ-CH shifts.

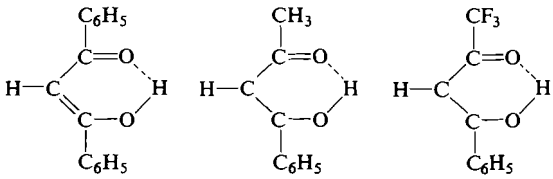
and that the magnitudes will be roughly proportional. The plot in Fig. 6 shows that this expectation is fulfilled. The deviation from strict linearity could result either from variations in Q_{CH_3} or from contributions to the shifts from sources other than π delocalization or from a combination of both effects. In any event it appears that π delocalization is predominant. The isotropic shifts for these mixed complexes are given in Table 7.

We next report results involving mixed complexes with the ligands **5**, **6**, and **7**.



5 **6** **7**

Several investigators (10–13) have provided evidence that a phenyl substituent appears to be rather more electron donating than a methyl substituent in these β-diketonate ligands and our earlier results on the isotropic shifts of V(III) complexes were consistent with this conclusion.

The spectra of mixed complexes containing CF_3 and C_6H_5 substituents and CH_3 and C_6H_5 substituents have therefore been examined. Table 8 contains the experimentally observed contact shifts for 26 of the possible 32 CF_3 resonances in the CF_3/C_6H_5 system and Table 9 the CH shifts of this system. Thirty of the possible 36 resonances are reported. Analysis proceeded along the lines described for the CH_3/CF_3 system and calculated frequencies are included in Table 9. Figure 7 shows a plot of observed *vs.* calculated frequencies for the CH shifts. A detailed analysis of the shifts of protons on the phenyl ring has not been attempted since the multiplicity of lines creates a considerable assignment problem. Shifts in the CH_3/C_6H_5 system are relatively small and analysis has been confined to the CH_3 resonances. Fourteen of the possible 32 frequencies are reported in Table 10. Derived substituent parameters and d orbital population factors for these two systems are collected together in Tables 5 and 11.

Discussion

The substituent parameters for the phenyl compounds follow the pattern previously discussed. Those derived from the CH_3 shifts are all opposite in sign to the corresponding parameters obtained with CF_3 substituents confirming that a phenyl group does indeed have an opposite effect to a CF_3 group in these transition metal complexes. It is interesting to note that

the *trans* parameter for phenyl *vs.* methyl is quite large but the *cis* parameters are all considerably smaller than those obtained for CF_3. Thus the phenyl group donates electrons to the *cis* positions but withdraws from the *trans* position to such an extent that the net effect is electron withdrawing. This is to be contrasted with CF_3 which withdraws from *cis* positions and donates to the *trans* position but also has a large net withdrawing effect. The parameters obtained from the CF_3 and CH data reflecting the competition of a phenyl group with a CF_3 group are quite similar to those obtained from the CH_3/CF_3 system. It is interesting that the anomaly of a small positive value for *e* is again observed. The orbital population factors in Table 11 also show no new features. They are quite scattered with one or two anomalously high values but the trends relating to the direction of polarization of charge in the metal d_π orbitals are quite clear.

Finally we add some general remarks on the significance of these results. The substituent parameters should be regarded as qualitative indicators of the charge distribution in the σ system. In this respect they are similar to the various Hammett and Taft σ parameters for substituted aromatic compounds. The latter parameters are also often derived from n.m.r. chemical shifts and there are parallel hazards in deriving charge density information from measurements of a variable which is only indirectly related to charge. Confidence in the significance of aromatic substituent parameters rests on their ability to correlate a large variety of diverse physical measurements. If obtained by n.m.r. a given substituent parameter is usually derived from the measurement of a single chemical shift. For transition metal complexes data on substituent effects are much less accessible

and confidence in the significance of the parameters presented here rests on their ability to correlate a large body of n.m.r. data. Direct proportionality between a substituent parameter and the charge on a ligand atom is not implied and is not required if only qualitative discussion of the charge distribution is intended. Similarly we would not place any reliance on the numerical values for orbital populations but merely regard them as a qualitative indication of the movement of charge around the metal atom. Examination of the results keeping in mind these reservations reveals a number of interesting aspects of substituent effects which are unique to transition

metal complexes. First of all the movement of charge resulting from unsymmetric substitution is very much greater than that resulting from symmetric substitution. This can be seen most directly by comparing the CH shifts of the symmetric complexes $V(acac)_3$ (−3292 Hz), *cis*-$V(tfac)_3$ (−3328 Hz), and $V(hfac)_3$ (−3734 Hz) with those of an unsymmetric compound, *e.g.* $V(hfac)_2(tfac)$ (−5010, −4220, and −1916 Hz). In the series of symmetric complexes there is an increasing shift representing more charge transfer to the electron withdrawing ligands. In the unsymmetric compound the spread of the shifts is nearly an order of magnitude larger than the difference between $V(acac)_3$ and $V(hfac)_3$. Thus the majority of the charge redistribution represents movement from one ligand to another rather than from the metal to the ligands. We believe that this point has major significance with respect to the activation of substrate molecules in homogeneous catalysis. Thus it is a common observation that catalytic efficiency can depend crucially on the nature of ancillary ligands not directly involved in the reaction. The above observation suggests an obvious rationale for such dependence.

The pattern of charge migration from one ligand to another is revealed in the analysis presented. As with aromatic substitution both σ and π effects are involved. For these three dimensional complexes there are inter-relationships between the σ and π systems not found in planar compounds. A result of this is that there is an inherent tendency for charge movement in the σ and π systems to be opposed. Thus in the present case negative charge moves from acac to hfac ligands in the σ system but from hfac to acac in the π system. Basically this arises because there is charge in d orbitals orthogonal to the σ bonding system which has a spherical distribution in a symmetric complex. In the presence of an unsymmetric ligand field this spherical distribution is distorted to a prolate or oblate spheroid and the distortion is such that the more electron donating ligand has π interactions with the high electron density region. It seems that this effect may also have important mechanistic significance. For example in a complex of suitable geometry an electron withdrawing substituent at a remote point could not only diminish the charge density in the σ bond of a coordinated olefin but could concurrently enhance the density in the olefin π* orbital resulting from back donation. Such a synergistic effect provides an attractive rationale for olefin activation.

A further comparison with aromatic substituent effects is of some interest. Generally an inductively electron withdrawing substituent will qualitatively, if not quantitatively, exert the same influence at the ortho, meta, or para positions of an aromatic molecule. In these transition metal complexes the sign of the effect differs for *cis* and *trans* positions. This difference can again be related to the complexities inherent in a three dimensional system compared to a two dimensional system. Ligands *trans* to each other utilize common metal orbitals to form σ bonds. Ligands *cis* to each other interact with orthogonal metal orbitals. In the latter case the charge distributions in the two metal ligand bonds are polarized leading to a net inductive movement of charge from one ligand to the other. In the former case the involvement of a common metal orbital results in charge gained by the electron withdrawing ligand being shared with the *trans* ligand. This feature could also have considerable significance to substrate activation in catalysis. The implication is that the relative positions of two ligands in a catalytic intermediate may be crucial to the activation process.

In conclusion it seems that the type of qualitative arguments used to rationalize substituent effects on reaction rates and mechanisms in organic chemistry may find application in transition metal chemistry. They must however be used with some sophistication and with due regard to the complications which result from the three dimensional nature of metal complexes.

Experimental

Sources of Chemicals

VCl_3 and V(III) trisacetylacetonate were obtained from the Research Organic/Inorganic Chemical Co. Acetylacetone, hexafluoroacetylacetone, 1,3-diphenyl-1,3-propanedione, 1,1,1-trifluoroacetylacetone, 1-benzoylacetone, and 4,4,4-trifluoro-1-phenyl-1,3-butanedione were purchased from Eastman Kodak Co., and 3-methyl-2,4-pentanedione from Koch Light Lab.

Preparation of Compounds

Deuterated acetylacetone was prepared by adding to acetylacetone in an excess of D_2O, a small amount of sodium carbonate. The mixture was refluxed for 24 h, cooled, and extracted with anhydrous ether. This process was repeated four times, and the mixture then distilled. The fraction boiling at 129 °C was collected. Purity was established by the absence of a proton n.m.r. spectra. It

was further characterized by the isotropic shifts of mixed chelates with $V(hfac)_3$ or $V(\phi\text{—}\phi)_3$.

The complexes $V(hfac)_3$, $V(tfac)_3$, $V(tf\phi)_3$, $V(\phi\text{—}\phi)_3$-$V(\phi\text{—}ac)_3$, and $V(\gamma\text{-Me—}acac)_3$ were prepared by a method analogous to that described by Morris *et al.* (14).

CCl_4 was heated with the passage of N_2 through a side-tube for about 5 min. The respective ligand and VCl_3 were then added and the mixture refluxed for 2 h with stirring. Continuous passage of N_2 gas prevented air-oxidation of the compound. The resulting solution was filtered in a nitrogen atmosphere while hot and the filtrate allowed to cool after which the solvent was removed by vacuum distillation. The resulting brown solid was purified by either recrystallization from CCl_4 or by vacuum sublimation. The former method was employed if the ligand in its pure form is a liquid whereas the alternative was used if it is a solid.

Proton spectra were obtained on a Varian HA-100 instrument using TMS internal reference. ^{19}F spectra were obtained similarly with $CFCl_3$ internal reference, at 94.1 Mc/s and the shifts converted to 100 Mc/s. All spectra were recorded at 37 °C.

The Infrared and Raman Spectra of Powdered and Single-Crystal Barium Chlorate Monohydrate and -deuterate

JOHN E. BERTIE, ANTON M. HEYNS,[1] AND OSCAR OEHLER[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received January 10, 1973

The infrared and Raman spectra of polycrystalline and single-crystal $Ba(ClO_3)_2 \cdot H_2O$ and $Ba(ClO_3)_2 \cdot D_2O$ have been obtained. The observed bands have been assigned to the various Davydov components of the intramolecular modes and colattice modes. For the water molecule, all of the fundamentals of H_2O, HDO, and D_2O have been located, the anharmonicities of the bending modes have been determined, and those of the stretching modes are essentially the same as for water vapor. The intermolecular coupling is very weak. The effective harmonic force field for the water molecules has been calculated. The stretch–stretch interaction constant is much smaller than for water vapor, reflecting a smaller separation of the asymmetric and symmetric stretching modes. The intermolecular vibrations of the water molecules have been located. For the chlorate ions, in spite of the disorder due to the ^{37}Cl, the spectra can be interpreted in terms of unit cell modes, albeit as a first approximation. The isotope shift of the symmetric Cl—O stretching mode appears to be unusually large. The far-infrared spectra have been tentatively assigned to translational and rotational vibrations involving the Ba^{2+} and ClO_3^- ions.

Les spectres en infrarouge et en Raman ont été obtenus pour les espèces polycristallines et monocristallines de $Ba(ClO_3)_2 \cdot H_2O$ et de $Ba(ClO_3)_2 \cdot D_2O$. Les bandes observées ont été attribuées aux diverses composantes Davydov des modes intramoléculaires. Toutes les bandes fondamentales appartenant à l'H_2O au HDO et au D_2O ayant été localisées, on a pu déterminer pour la molécule d'eau les anharmonicités des modes de torsion; pour celles des modes d'élongation, on a pu déterminer qu'elles étaient identiques à celles obtenues de la vapeur d'eau. Le couplage intermoléculaire est très faible. On a calculé, toujours pour les molécules d'eau, le champ effectif de la force harmonique.

La constante d'interaction élongation-élongation est beaucoup plus petite que dans le cas de la vapeur d'eau, ce qui traduit une séparation plus faible des modes d'élongation asymétrique et symétrique. On a localisé les vibrations intermoléculaires des molécules d'eau. Pour les ions chlorates, malgré la perturbation causée par la présence du ^{37}Cl, les spectres peuvent être interprétés en fonction des modes d'une maille élémentaire, bien que ce ne soit possible qu'en première approximation. Le déplacement isotopique du mode d'élongation symétrique du lien Cl—O semble être anormalement élevé. Les spectres en lointain infrarouge ont été attribués hypothétiquement aux mouvements de translation et de rotation des ions Ba^{2+} et ClO_3^-. [Traduit par le journal]

Can. J. Chem., **51**, 2275 (1973)

Introduction

The crystal structure of $Ba(ClO_3)_2 \cdot H_2O$ is well-known from X-ray (1) and neutron-diffraction (2) studies. The two water molecules in the primitive unit cell are equivalent and are situated on the two-fold axis. Their motion has been studied extensively by deuteron and proton magnetic resonance (3–10) and neutron scattering (11, 12) methods. Infrared (13–16) and Raman (17) spectral studies of polycrystalline $Ba(ClO_3)_2 \cdot H_2O$ have been reported, but the vibrational spectra of single crystals have not been previously obtained using polarized light

Experimental

Single crystals of $Ba(ClO_3)_2 \cdot H_2O$ and $Ba(ClO_3)_2 \cdot D_2O$ were grown by two methods.

(i) Evaporation Method (2)

90 g of $Ba(ClO_3)_2 \cdot H_2O$ (General Chemicals Division, Morristown, N.J., U.S.A.) were dissolved in 300 g of distilled water. After passing the solution through a sintered glass filter, the water was evaporated at a rate of 20 g daily. The resulting single crystals had dimensions up to 1 cm.

(ii) Cooling Method

86 g of $Ba(ClO_3)_2 \cdot H_2O$ were dissolved in 114 g of water at 80 °C. This solution was cooled to room temperature in a closed vessel at a rate of 4 °C per day. A seed crystal was put into the saturated solution at 70 °C, and clear crystals were obtained with dimensions up to 1 cm.

The cooling method was also used for growing $Ba(ClO_3)_2 \cdot D_2O$ single crystals. $Ba(ClO_3)_2 \cdot H_2O$ was recrystallized twice from heavy water, the second time using the cooling method. The product so obtained was

judged to be about 95% deuterated from the relative intensities of the OH and OD stretching bands.

The orientation of the crystal axes was determined by X-ray precession and Weissenberg methods. To prepare single-crystal infrared samples plates were cut, using a diamond saw, with the desired orientation and a thickness of about 500 μ. They were then glued to a glass plate with Glyptal cement, and were ground to the required thickness, using bauxite 600 and kerosene. A polyethylene or cesium iodide window was then stuck to the exposed face of the sample using paraffin wax. The glass plate was removed by immersing the glass – sample – window sandwich in acetone for 24 h, and the sample was ready for study. If the sample was found to be too thick it could be affixed to the glass plate again, the window removed by warming the wax, and the sample reground. However, it was found to be impossible to prepare single crystal films thinner than about 20 μ, and this placed severe limitations on the utility of the results obtained. The polycrystalline infrared samples were mulls in Nujol or Fluorolube.

The infrared spectra were recorded using Beckman I.R. 12 and I.R. 11 spectrophotometers, and a Beckman-R.I.I.C. FS 720 interferometer. The resolution was 1 to 2 cm^{-1} for the polycrystalline samples and 2 to 4 cm^{-1} for the single-crystal samples. The spectrometers were calibrated using the standard gases (18). The details of the interferometric methods have been published elsewhere (19). For the polarization studies, Perkin–Elmer wire-grid polarizers were used. The low-temperature samples were held in a Beckman-R.I.I.C. VLT2 variable temperature unit, or in an improved version of this cell constructed in this laboratory.

The Raman spectrometer consisted of a SPEX model 1401 monochromator, SPEX sample-illuminating and detector optics, a cooled FW-130 photomultiplier and photon counting electronics. The 4880 Å line from a Carsons Laboratories model 10SP Ar^+/Kr^+ laser was used to excite the spectra, at a power of about 50 mW after filtering to remove unwanted emission lines. The collecting optics were stopped at $f/1.2$ or 0.9, and the spectral slit width was less than 1 cm^{-1} for all spectra. Single crystals of dimensions 5 × 2 × 2 mm were used and, after determining the orientation of the crystal axes by X-ray methods, the crystal was studied under a polarizing microscope to determine the principal indicatrix axes. The crystal was then aligned in the Raman instrument as described in the next section. The single crystals were mounted on a goniometer head for the room temperature studies. For the low-temperature Raman spectra, the powder and single crystal samples were held in a capillary tube mounted in a SPEX, Harney–Miller cell. To change the polarization of the incident beam and sample the scattered light, a 90° polarization rotator and an analyzer were used. A polarization scrambler was always used immediately in front of the entrance slit. The instrument was calibrated to ±1 cm^{-1} using liquid carbon tetrachloride (20), indene (21), and the manufacturer's statement of linearity to within 1 cm^{-1}, no evidence against this statement having been found. The reproducibility of the frequencies was much better than 1 cm^{-1}, however, and differences of 1 cm^{-1} between lines seen under different polarizations could be determined with certainty.

Crystal Structure and Optical Properties

$Ba(ClO_3)_2 \cdot H_2O$ crystallizes in the monoclinic space group $I2/c(C_{2h}^6)$, with four molecules per unit cell and the unit cell parameters $a = 8.916$ Å, $b = 7.832$ Å, $c = 9.425$ Å, and $\beta = 93°39'$ (2). The Ba^{2+} ions and H_2O molecules are situated on the 2-fold axes (parallel to the b crystal axis) and the ClO_3^- ions are on general positions. It has been shown (2) that the average bond distances and angles of the ClO_3^- ion in $Ba(ClO_3)_2 \cdot H_2O$ agree with those found in $KClO_3$ and $NaClO_3$, the Cl—O bond distances varying from 1.480–1.489 Å and the O—Cl—O bond angles ranging from 105.1–107.1°. The primitive unit cell, from which the selection rules for the vibrational spectra are derived, contains two formula units.

The refractive indices of $Ba(ClO_3)_2 \cdot H_2O$ were determined (1) to be: $\alpha = 1.5622$, $\beta = 1.5777$, and $\delta = 1.635$; the optic axial piane is (010) and the acute bisectrix for the sodium D-line lies at 23.75° to the c-axis with $2V = 55.5°$.

The best alignment of these crystals for Raman spectroscopy is with the incident and scattered light propagating perpendicular to the unique b-axis (22). Because of the shape and size of our crystals, it was more convenient to obtain the spectra at 90 °K with the incident light propagating perpendicular to the b and c axes, along what will be called the x-axis in this paper and which is very close to the a-axis of the crystal, and the scattered light propagating along the b-axis. The crystals were carefully aligned in this configuration by rotating them about the c-axis until the lines at 611 and 621 cm^{-1} in $Ba(ClO_3)_2 \cdot H_2O$ showed complete extinction under $x(bc)b$ and $x(cc)b$ scattering geometries, respectively. (The geometry designation follows ref. 23.) These bands are weak in Fig. 7 but this alignment procedure was, of course, done at gain settings sufficient to yield full-scale deflection under the appropriate polarization. The room temperature crystals were aligned in the same way, and the results were checked by recording spectra with the incident and scattered beams propagating perpendicular to the b-axis, along the indicatrix directions for the sodium-D line. The spectra obtained with this alignment were almost identical to those obtained while collecting the light along the b-axis, indicating that the symmetry conclusions drawn from the spectra collected along b are correct.

Results and Discussion

The infrared and Raman spectra of polycrystalline $Ba(ClO_3)_2 \cdot H_2O$ and $Ba(ClO_3)_2 \cdot D_2O$ are shown in Figs. 1 to 4 and the frequencies and assignments of the bands observed are in Tables 1 and 2. No bands were observed in the frequency regions omitted from Fig. 3. The general features of the assignment are clear. The H_2O stretching vibrations occur at 3500 to 3600 cm^{-1}, the corresponding D_2O vibrations are at 2570 to 2670 cm^{-1}, the H_2O deformation is at 1609 cm^{-1}, the D_2O deformation at 1183 cm^{-1},

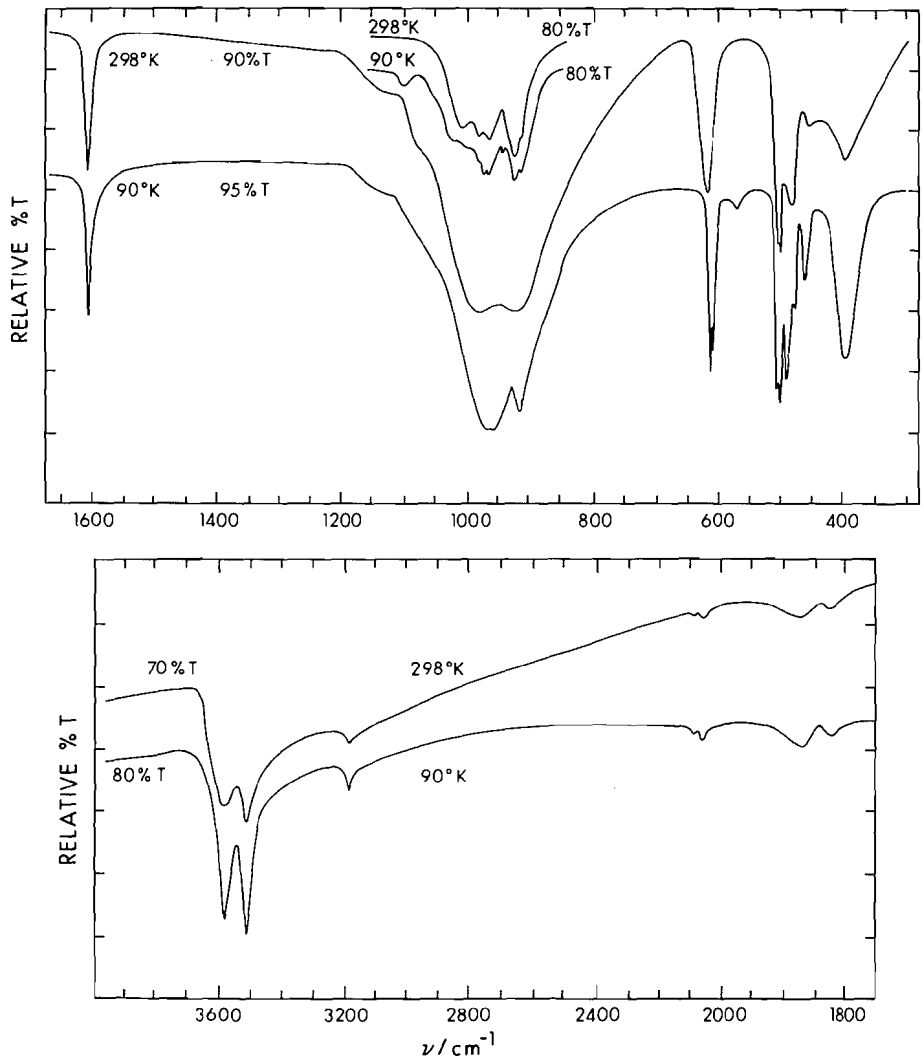

FIG. 1. The infrared spectra of powdered $Ba(ClO_3)_2 \cdot H_2O$ at 300 and 90 °K. Composed from spectra of mulls in Nujol and Fluorolube. The divisions on the intensity scale are 20% T apart.

the Cl—O stretching modes are at 900 to 1000 cm^{-1} and the ClO_3^- deformation modes lie between 470 and 620 cm^{-1}. The vibrations derived from the rotational and translational displacements of the water molecules and chlorate ions and from the translational displacements of the Ba^{2+} ions all lie below about 470 cm^{-1}. Symmetry permits all of these displacements to contribute to each vibration and the assignments are not obvious. However, the frequency shifts upon deuteration indicate that the vibrations at 454 and 395 cm^{-1} in the hydrate and 348 and 290 cm^{-1} in the deuterate primarily involve rotational displacements of the water molecules, and those at 234 and 207 cm^{-1} in the hydrate and 225 and 200 cm^{-1} in the deuterate primarily involve water translational displacements (16).

Upon lowering the temperature some of the bands sharpen and become more intense, and additional fine structure is seen. This is shown for the infrared spectra in Figs. 1 and 2, and similar effects were seen in the Raman spectra. In this respect it should be noted that even at

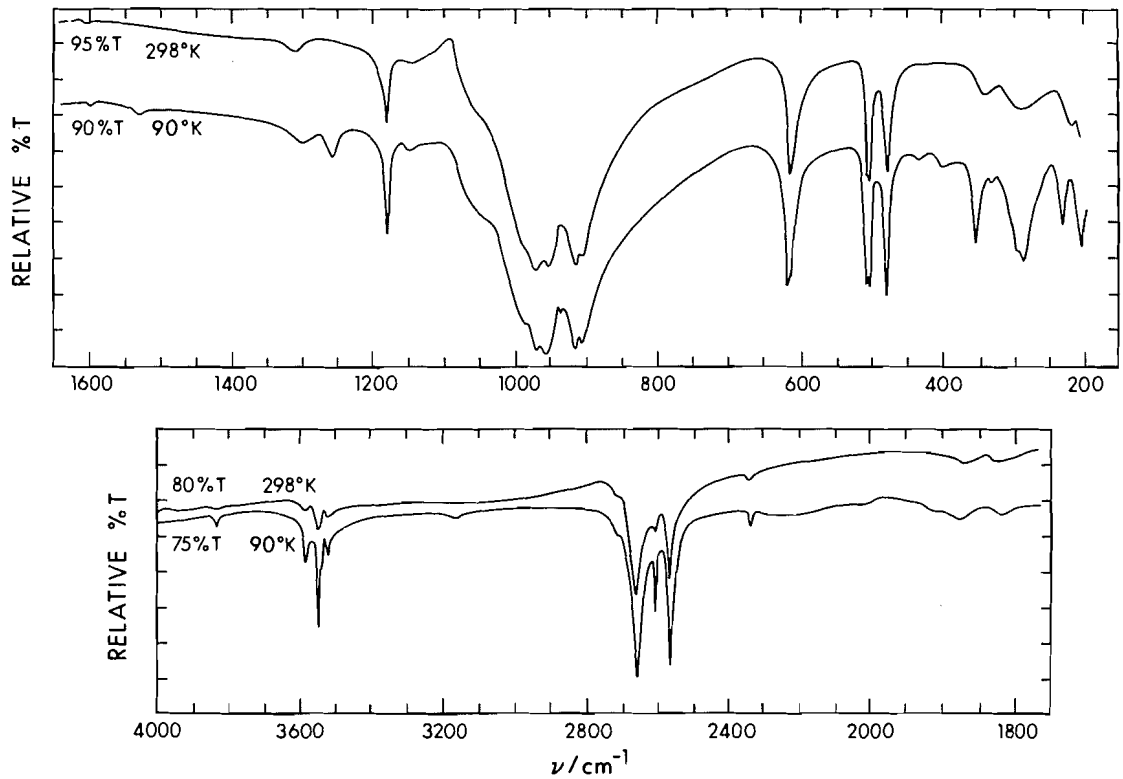

FIG. 2. The infrared spectra of powdered $Ba(ClO_3)_2 \cdot D_2O$ at 300 and 90 °K. Composed from spectra of mulls in Nujol and Fluorolube. The divisions on the intensity scale are 10% T apart.

liquid nitrogen temperatures the bands due to the Cl—O stretching modes are not well resolved in the infrared. These bands are much more complicated than the corresponding Raman bands and may be influenced by reflection effects, longitudinal optic modes, and combination and overtone bands.

The detailed assignment of the spectra will now be discussed using the single crystal polarization data. This is shown in Figs. 5–7 and the frequencies and assignments of the peaks under the various polarizations are given in Tables 1 and 2. The single crystal Raman spectra of $Ba(ClO_3)_2 \cdot D_2O$ are not reproduced, because they were very similar to those of $Ba(ClO_3)_2 \cdot H_2O$ with only the differences that are clear from Table 2. The single crystal infrared spectra were obtained only for samples at 300 °K. These infrared spectra were not of high quality due to the small area of the samples and, therefore, we only report those polarizations which were completely clear. The infrared polarizations became increasingly confused below 400 cm^{-1}, particularly for the hydrate, and no usable infrared polarization data could be obtained below 300 cm^{-1}.

Vibrations of Water Molecules

The water molecules lie on the 2-fold axes of the crystal and the symmetric OH stretching modes form the representation $A_g + A_u$ and the asymmetric OH stretching modes form $B_g + B_u$ under the unit cell group, which is isomorphous with the point group C_{2h}. The single crystal infrared data clearly show the A_u mode (*b*-polarized) at 3516 cm^{-1} in H_2O and 2574 cm^{-1} in D_2O, and the B_u modes (*ac*-polarized) at 3584 and 2668 cm^{-1} in H_2O and D_2O, respectively (Figs. 5 and 6). In the Raman spectra the A_g modes appear at 3514 and 2572 cm^{-1} with the B_g modes at 3582 and 2666 cm^{-1} for H_2O and D_2O, respectively (Table 2 and Fig. 7). The latter two bands could only be detected at low temperature. The intermolecular coupling of the water stretching modes causes the frequency separation between the u- and

*The bands due to B_u modes were polarized in the *ac* plane and those due to A_u modes were polarized parallel to the *b*-axis.
†ν_i' refers to modes of the water molecule; ν_i refers to modes of the ClO_3^- ion numbered according to C_{3v} symmetry. R = rotational and T = translational.
‡The bands assigned to HDO were observed under *b* and *ac* polarizations. The ν_3', ν_2', and ν_1' bands of H_2O in the deuterate were *ac*, *b*, and *b* polarized, respectively.

g-components and is, therefore, extremely weak in this crystal. This can be understood because the water molecules are not hydrogen-bonded to each other and are well separated in the lattice.

The infrared spectra of $Ba(ClO_3)_2 \cdot D_2O$ (Figs. 2 and 6) also show the bands due to the HDO impurity. The 3550 cm^{-1} band is present with similar strengths in the *b* and *ac* polarizations (hereafter termed *abc*-pol.), and arises from the OH stretch of the HDO molecules in the predominantly deuterated lattice. It is accompanied by polarized bands due to the symmetric (3516 cm^{-1}, *b*-pol.) and asymmetric (3584 cm^{-1}, *ac*-pol.) stretching modes of the H_2O molecules in the lattice. The clear appearance of all three of these features can only occur when intermolecular coupling is weak; if it is not weak, bands due to intermolecular OH neighbors confuse the identification of those due to intramolecular OH neighbors. The OD stretching vibration of the HDO molecules occurs at 2619 cm^{-1} (*abc*-pol., Fig. 6).

The strong, *b*-polarized, infrared band at 1609 cm^{-1} in $Ba(ClO_3)_2 \cdot H_2O$ (Fig. 5) clearly arises from the A_u HOH angle deformation mode, ν_2', and the corresponding DOD-mode is at 1183 cm^{-1} (Fig. 6). The DOH bending mode occurs at 1416 cm^{-1} (*abc*-pol., Fig. 6). The Raman-active, A_g deformation mode was not observed, even at low temperatures. The predominantly *b*-polarized band at 3185 cm^{-1}

in $Ba(ClO_3)_2 \cdot H_2O$ is assigned to the overtone, $2\nu_2'$. Because the intermolecular coupling is so weak for the OH stretching modes it is undoubtedly a very good approximation to assume that all of the HOH deformation modes lie within 2 or 3 cm^{-1} of the zero-wave-vector, A_u mode. Therefore, 3185 cm^{-1} can be regarded as the overtone of the zero-wave-vector, A_u and A_g deformations at 1609 cm^{-1}.

The energy levels for the bending modes can be represented by

$$G(v) = (v + 1/2)\,\omega_e + (v + 1/2)^2\,\omega_e x_e$$

if the coupling to other modes is ignored (20). Substituting $G(2) - G(0) = 3185$ cm^{-1} and $G(1) - G(0) = 1609$ cm^{-1}, it follows that for the H_2O molecules in $Ba(ClO_3)_2 \cdot H_2O$, $\omega_e = 1642$ cm^{-1} and $\omega_e x_e = -16.5$ cm^{-1}. $\omega_e x_e$ for HDO and D_2O can be calculated from that for H_2O by multiplying by ρ^2, where ρ^2 is the ratio of the appropriate **G**-matrix elements (20, 24). $\omega_e x_e$ is, thus, found to be -12.56 cm^{-1} for HDO and -8.62 cm^{-1} for D_2O. Using these values, $G(2) - G(0)$ can be calculated to be 2807 and 2348 cm^{-1} for HDO and D_2O, respectively. The bands occurring at 2806 cm^{-1} (*abc*-pol.) and 2350 cm^{-1} (*b*-pol.) in the infrared spectra of partially hydrated $Ba(ClO_3)_2 \cdot D_2O$ (Fig. 6) are therefore assigned to $2\nu_2'$ (HDO) and $2\nu_2'(D_2O)$, respectively.

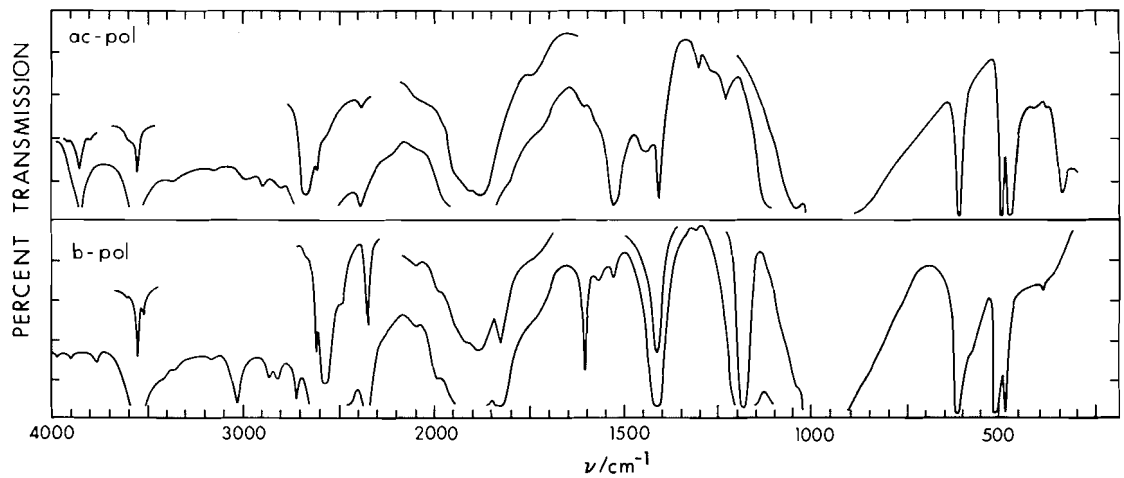

FIG. 6. The infrared spectra of single-crystal $Ba(ClO_3)_2 \cdot D_2O$ at 300 °K, polarized in the *ac* plane (upper) and parallel to the *b*-axis (lower).

This study has yielded complete data on the fundamental vibration frequencies of water in $Ba(ClO_3)_2 \cdot H_2O$. The data were used to calculate the effective intramolecular force field in two ways. First the nine observed frequencies were fitted using the four intramolecular force constants and the program FPERT (25) to yield the calculated frequencies and force constants shown in the left hand side of Table 3. The average error for the H_2O, HDO, and D_2O molecules was 9.2 cm^{-1} or 0.44%, the standard deviation was 12.2 cm^{-1} and the largest individual deviation was 23.8 cm^{-1}. In the second method the observed frequencies were converted to harmonic frequencies in the following way. The deformation modes were corrected using the anharmonicity constants derived above. The stretching modes were corrected using the gas phase values of the anharmonicity constants x_{11}, x_{33}, and x_{13} (26). The harmonic frequencies so obtained are shown in Table 3. The nine frequencies were fitted using the four force constants to yield the calculated frequencies and force constants shown on the right hand side of Table 3. The average error for the three molecules was 0.9 cm^{-1} or 0.046%, the standard

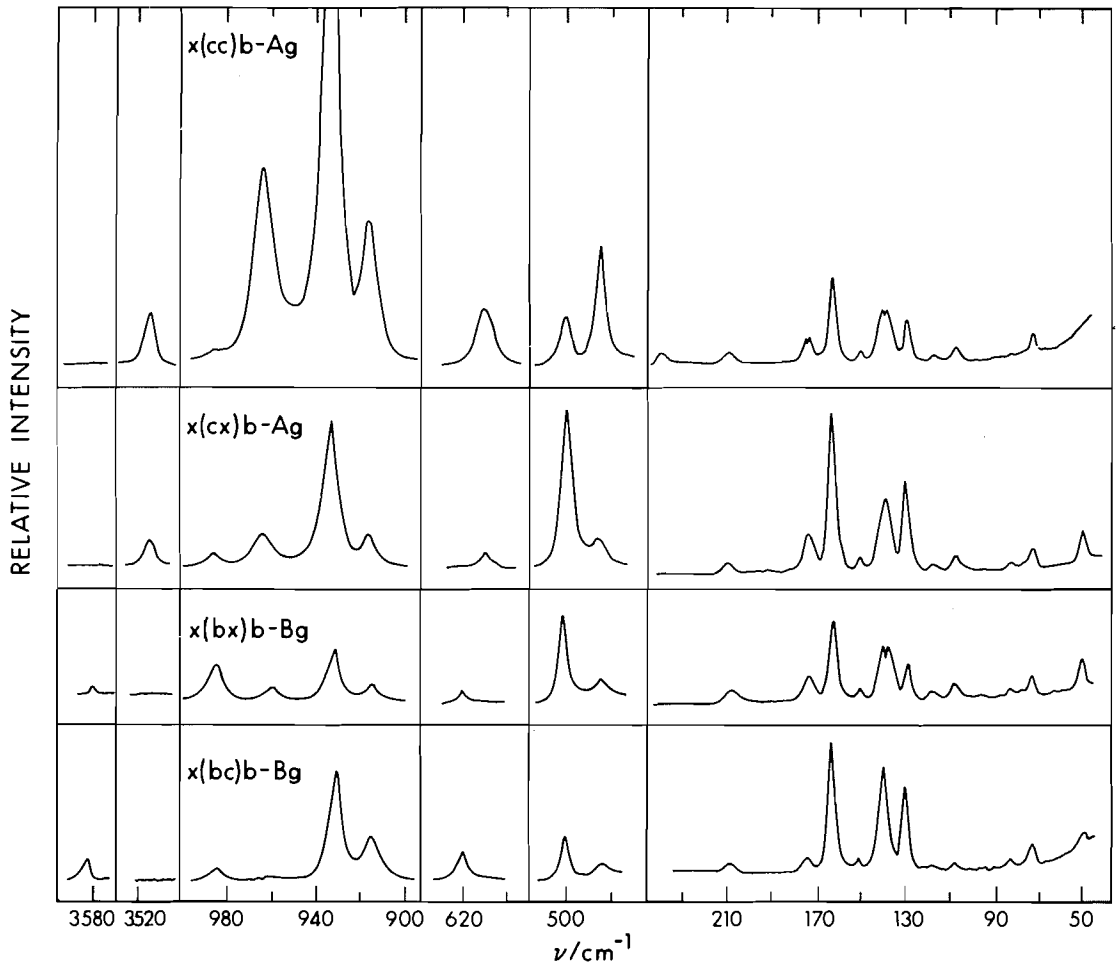

FIG. 7. The Raman spectra of single-crystal $Ba(ClO_3)_2 \cdot H_2O$. The bands above 3500 cm^{-1} and below 250 cm^{-1} are from a sample at 90 °K, and the remaining bands are from a sample at 300 °K. The divisions on the frequency scale are all 20 cm^{-1} apart.

deviation was 1.3 cm^{-1}, and the largest individual deviation was 2.4 cm^{-1}. The close agreement obtained indicates that the gas phase anharmonicities are a good approximation to the true ones for this system.

It is relevant to compare these results with those obtained by Fifer and Schiffer (27) for four hydrates and water vapor. The hydrogen bonding in $Ba(ClO_3)_2 \cdot H_2O$ is weaker than in their hydrates (27). The separation $\nu_3' - \nu_1'$ for H_2O and D_2O is found in this work to be 68 and 94 cm^{-1}, respectively, much smaller than the values 99 and 117 cm^{-1} found for water vapor (26), but larger than the values 29 to 48 cm^{-1} for H_2O and 79 to 83 cm^{-1} for D_2O found for the hydrates of reference 27. The value of F_{rr} found by fitting harmonic frequencies is -0.014 (Table 3), much smaller than the gas-phase value of about -0.1 (27), and this clearly reflects the smaller $\nu_3' - \nu_1'$ separation. The value of F_{rr} cannot be compared with those given by Fifer and Schiffer for other hydrates, because of their different treatment of the anharmonicity and the very low weight assigned to ν_2' in their fitting procedure. However, the differences between $Ba(ClO_3)_2 \cdot H_2O$ and water vapor are in qualitative agreement with the trend pointed out in ref. 27.

There are three rotational vibrations for each water molecule. They can be called the twisting mode, in which the molecules rotate about the two-fold axis, and the wagging and rocking

modes, representing rotation about the axis in and out of the HOH plane, respectively. The twisting modes of the two water molecules form the representation $A_g + A_u$ under the unit cell group. These do not directly change the orientation of the dipole moment of the water molecule, so the A_u mode can only absorb radiation by changing the induced dipole moments. It is, therefore, expected to absorb more weakly than the wagging and rocking modes in which the direction of the molecular dipole oscillates. These latter modes each form the representation $B_g + B_u$ under the unit cell group. The water rotational modes absorb at 460 and 395 cm^{-1} in the hydrate and at 360 and 291 cm^{-1} in the deuterate. These frequencies are for a sample at 90 °K and at this temperature the absorption is quite strong and sharp (Figs. 1, 2, 4). For a sample at 300 °K the absorptions are much broader and have maxima at 454 and 395 cm^{-1} for the hydrate and at 348 and 290 cm^{-1} for the deuterate (Figs. 1, 2, Table 1). The infrared spectra of single crystals at 300 °K (Figs. 5, 6) show that the bands at 454, 395, and 348 cm^{-1} are predominantly *ac*-polarized and therefore arise from the B_u wagging and rocking modes. There appears to be a significant *b*-polarized component at 395 cm^{-1} in the hydrate which could be assigned to the A_u twisting mode. However a weak feature at 570 cm^{-1} in the hydrate is also *b*-polarized and shifts on deuteration (15), possibly to 400 cm^{-1}, and this may be due to the A_u twist. The only Raman line that can be assigned to water rotational vibrations is at 478 cm^{-1}, in the hydrate at 300 °K, and its polarization shows that it arises from a B_g mode.

Chiba (5) has calculated from deuteron magnetic resonance data that the water rocking mode should lie to high frequency of the wag and the twist, which should be nearly degenerate. His actual frequencies cannot be expected to be too accurate but are 330 and about 245 cm^{-1} for D_2O which correspond to about 450 and 335 cm^{-1} for H_2O. Inelastic neutron scattering studies of single crystals (12) have placed the rock at 477 cm^{-1} and the twist and the wag at 395 ± 5 or 457 ± 6 cm^{-1} in the hydrate. Thus, all of the available data, except the neutron peak at 457 cm^{-1} (12), is consistent with the assignment of the A_u twisting mode at 395 cm^{-1} in the hydrate and 290 cm^{-1} in the deuterate, and the rock and the wag at 454 and 395 cm^{-1} in the hydrate and 360 and 291 cm^{-1} in the deuterate. It is probable that the higher frequency mode is predominantly the rocking vibration, but symmetry permits the wagging and rocking

motions to contribute to the same vibrations, which probably explains the polarization of the neutron scattering peak at 457 cm^{-1} (12).

The difference of 24 cm^{-1} between the frequency of the infrared band at 454 cm^{-1} and that of the Raman band at 478 cm^{-1} suggests that the intermolecular coupling may be much larger for the rotational vibrations of the water molecules than for the OH stretching modes. This conclusion must be regarded with caution, however, because the chlorate deformation modes near 480 cm^{-1} have significantly different frequencies in the hydrate and deuterate which probably arises from interaction with the water rotational modes in the hydrate.

The translational vibrations of the water molecules form the representation $A_g + A_u$ for translation along the 2-fold axis and $2B_g + 2B_u$ for translation perpendicular to the 2-fold axis. The bands at 245 and 216 cm^{-1} in the infrared spectra of powdered $Ba(ClO_3)_2 \cdot H_2O$ at 90 °K shift to low frequency by about 4% on deuteration, and can be assigned to ungerade translational vibrations of the water molecules. Similarly the Raman bands at 245 and 209 cm^{-1} at 90 °K, shift to 234 and 203 cm^{-1} in the deuterate and can be assigned to the gerade translational modes of the water molecules. The interpretation of the Raman polarization data is unclear, because both peaks appear to arise from A_g modes, with a B_g mode contributing to the lower frequency one, yet only one A_g mode and two B_g modes are expected.

Vibrations of Chlorate Ions

Normal crystals of $Ba(ClO_3)_2 \cdot H_2O$ are disordered because every fourth chlorine atom is ^{37}Cl. This disorder should only significantly affect the selection rules for the ClO_3^- intramolecular and intermolecular modes and, of course, any other modes that couple with them. In practice, the spectra can be interpreted as though the disorder were not present, because the Raman spectra show reasonably sharp bands with well-defined polarization, as do the infrared spectra of the ClO_3^- deformation modes. The infrared spectra of the Cl—O stretching modes are clearly complicated by factors such as reflection effects and the possible appearance of longitudinal modes, and it does not seem useful to try to assign them. In the following we assign the Raman spectra of the Cl—O stretching and ClO_3^- deformation modes and the infrared spectrum of the deformation vibrations to the various factor group or Davydov components of the vibrations of $^{35}ClO_3^-$ and $^{37}ClO_3^-$. It is apparent that this is a gross simplification because each unit cell contains one $^{37}ClO_3^-$ ion on the average, and it is probable that the bands observed correspond to intensity-weighted density of states curves. However, in the absence of a more rigorous treatment of the spectra of such crystals, the following is presented as a first approximation to the correct assignment, on the understanding that A_g, B_g, etc. are used to concisely describe the polarization behavior of the peaks, rather than to imply that the crystal modes have this symmetry.

The free ClO_3^- ion belongs to the point group C_{3v}, and its vibrations can be classified as the $\nu_1(A_1)$ and $\nu_3(E)$ stretching vibrations, occurring in the range 900–1000 cm^{-1}, the totally symmetric bending vibration, $\nu_2(A_1)$, occurring at about 620 cm^{-1} and the asymmetric bending vibrations, $\nu_4(E)$, at 480–510 cm^{-1} (22, 28, 29). The ClO_3^- ions lie on general positions in the crystal and each A_1 mode of the free ClO_3^- ion yields the representation $A_g + A_u + B_g + B_u$ under the unit cell group. The strongest band in the Raman spectrum of the hydrate, at 934 cm^{-1}, is assigned to the A_g component of the Cl—O stretching mode, ν_1. The B_g component of this mode appears at 931 cm^{-1}. The bands at 918 cm^{-1} (A_g) and 915 cm^{-1} (B_g) are about one-quarter as intense as the ν_1 band and are therefore assigned to the ν_1 mode of $^{37}ClO_3^-$. However, it is clear that the one $^{37}ClO_3^-$ ion per unit cell cannot vibrate in this mode at two distinct frequencies and, in fact, in $Ba(ClO_3)_2 \cdot D_2O$ the A_g and B_g components coincide at 916 cm^{-1}. Different frequencies for the infrared and Raman peaks due to ν_1 of $^{37}ClO_3^-$ have been reported for $KClO_3$ (22). This was interpreted (22) as due to dynamic coupling between the vibrations of $^{35}ClO_3^-$ and $^{37}ClO_3^-$ ions which, if the lack of selection rules because of the disorder is recognized, is equivalent to saying that different parts of the density of states curve have different activities in the two types of spectra. In the case of $Ba(ClO_3)_2 \cdot H_2O$ there is evidence that the first overtone of the water rocking mode at 454 cm^{-1} influences this region and may be responsible for the different frequencies of the A_g and B_g components at 918 and 915 cm^{-1}. Apart from the different fre-

For personal use only.

quencies for the hydrate and deuterate mentioned above, this evidence lies in the relative intensity of these peaks to those, at about 933 cm^{-1}, due to ν_1 of $^{35}ClO_3^-$. In the single crystal spectra at 300 °K these peaks are about one-quarter as intense as those due to ν_1 of $^{35}ClO_3^-$. In the spectrum of the deuterate at 90 °K the intensity ratio is still one-quarter but in that of the hydrate at 90 °K it is one-third. Further, in the Raman spectrum of the powdered deuterate at 300 °K the intensity ratio is one-quarter, as for the single crystal, but the ratio for the powdered hydrate at 300 °K is nearer to two-thirds. These differences are not understood, but they do support the postulate that a phenomenon occurs in the hydrate that does not occur in the deuterate, and this is most obviously attributable to the influence of the overtone of the water rotational mode at 454 cm^{-1}. Even without these complications, the assignment of the bands near to 916 cm^{-1} to the ν_1 mode of $^{37}ClO_3^-$ implies a much greater isotope shift for this mode than is calculated or usually found (22, 28, 29). No explanation can be offered for this, nor is any reasonable alternative assignment apparent.

The appearance of the A_u (615 cm^{-1}), B_u (620 cm^{-1}), A_g (611 cm^{-1}), and B_g (621 cm^{-1}) modes near 620 cm^{-1} in the infrared and Raman spectra of single crystals of $Ba(ClO_3)_2 \cdot H_2O$, indicates that the assignment of these bands to the different components of the symmetric ClO_3^- deformation mode, ν_2, is correct. In the Raman spectra of the deuterate, particularly at lower temperatures, a weak shoulder was seen to occur at 614 cm^{-1}. This lies about 4 cm^{-1} below the average of the frequencies of the four components assigned to $^{35}ClO_3^-$, and its assignment to ν_2 of $^{37}ClO_3^-$ is consistent with the isotope shift usually observed for this mode (28, 29).

The degeneracy of the E-vibrations is lifted under the C_1 site symmetry and the $\nu_3(E)$ and $\nu_4(E)$ modes each yield the representation $2A_g + 2A_u + 2B_g + 2B_u$ under the unit cell group. The single crystal Raman spectra of $Ba(ClO_3)_2 \cdot H_2O$ clearly show two bands at 986 and 965 cm^{-1}, representing the A_g components of the asymmetric stretching modes. The corresponding B_g components were observed at 986 and 959 cm^{-1}.

In the infrared spectra of single crystals of $Ba(ClO_3)_2 \cdot H_2O$, the two b-polarized bands (A_u) at 508 and 485 cm^{-1} and the corresponding ac-polarized bands (B_u) at 504 and 485 cm^{-1} are assigned to the asymmetric, ClO_3^- bending vibrations, ν_4. In the Raman spectra the A_g components of these modes are observed at 500 and 486 cm^{-1} while the B_g components appear at 500 and 484 cm^{-1}.

From this data the site frequency for ν_2 can be determined as 617 and 616 cm^{-1} in the hydrate and deuterate, respectively, by averaging the frequencies of the factor group components. Without the frequencies of the A_u and B_u components, the site frequency for ν_1 can only be estimated as about 932 cm^{-1} in both compounds. The frequencies of the site-group components of the degenerate modes can only be estimated as 985 and 963 cm^{-1} for ν_3 in both compounds, 503 and 485 cm^{-1} for ν_4 in the hydrate, and 504 and 482 cm^{-1} for ν_4 in the deuterate, under the assumption that the site splitting is much greater than the factor group splitting. The results for $KClO_3$ (22) suggest that this assumption may not be valid.

In both the polycrystalline and single crystal infrared spectra, several overtone and combination bands of the Cl—O stretching vibrations were observed in the range 1830–2000 cm^{-1}. These bands are listed in Table 1 along with their polarizations, and are shown in Figs. 5 and 6. The samples studied at 90 °K were too thin to show many of these bands.

Lattice Vibrations Involving the Ba^{2+} and ClO_3^- Ions

The $\boldsymbol{k} = 0$ lattice vibrations of the Ba^{2+} and ClO_3^- ions in $Ba(ClO_3)_2 \cdot H_2O$ form the representation $7A_g + 7A_u + 8B_g + 8B_u$, including the acoustic modes which are identified as $A_u + 2B_u$. As expected from the number of lattice vibrations, the far-infrared and Raman spectra of polycrystalline $Ba(ClO_3)_2 \cdot H_2O$ and $Ba(ClO_3)_2 \cdot D_2O$ are complex. The single crystal Raman spectra show that the majority of these bands are due to both A_g and B_g modes. The single crystal far-infrared spectra also failed to show useful differences in different polarizations.

The translational vibrations of the Ba^{2+} and ClO_3^- ions and the rotational vibrations of the ClO_3^- ions all appear in all four irreducible representations of the unit cell group, and therefore can be expected to interact to yield mixed translational and rotational vibrations. About the only basis for any assignments is the argument that, because the motion of ions is involved, the predominantly translational vibra-

†Reference 22.

tions should be strong in the infrared and weak in the Raman. The rotational vibrations of the ClO_3^- ions are likely to be strong in both, although if any vibrations correspond mainly to rotation about the axis of the ClO_3^- group they may be weak in both types of spectra because the intra-ion contributions to the dipole moment and polarizability changes during this motion are only non-zero through the distortion of the ion from C_{3v} symmetry. Because of the simple basis for these ideas the predictions are not expected to hold entirely, but they do enable some tentative assignments to be made.

On this basis, the bands at 184, 152, 110, 108, 105, and 95 cm^{-1} (at 100 °K) (Tables 1, 2, Figs. 3 and 4) are assigned to predominantly translational vibrations. The bands near to 171, 136, and 130 cm^{-1} in both types of spectra, and possibly the band at 163 cm^{-1} in the Raman, are assigned to rotational vibrations about the axes perpendicular to the bisector of the ClO_3^- group, while the Raman bands near 116 and 82 cm^{-1} are assigned to rotational vibrations about the bisector. No assignment of the remaining bands appears to be worthwhile. There is a remarkable similarity between some of the frequencies in $Ba(ClO_3)_2 \cdot H_2O$ and those in $KClO_3$ and $NaClO_3$ (Table 4). The reason for this similarity is unclear, considering the different crystal structures and, presumably, quite different force fields in the different crystals, but the agreement between the frequencies appears to be too extensive to be coincidence. Therefore these frequencies presumably correspond to predominantly ClO_3^- vibrations.

The uncertainty in the above assignments should be abundantly clear, but there appears to be no way of improving on this with the present data.

The National Research Council of Canada is thanked for financial support of this work. We are grateful to Professor R. D. Morton of the Geology Department, University of Alberta, for his advice on cutting and grinding crystal plates.

Temperature and Pressure Dependence of ^{35}Cl Nuclear Quadrupole Resonance in $BiCl_3$

G. C. GILLIES AND R. J. C. BROWN

Department of Chemistry, Queen's University, Kingston, Ontario

Received January 18, 1973

The temperature and pressure dependences of the two ^{35}Cl nuclear quadrupole resonances in $BiCl_3$ have been measured. At constant pressure, the temperature coefficients are markedly different and this difference is shown to be due to volume effects associated with different intermolecular bonding.

L'influence de la température et de la pression sur les deux résonances nucléaires quadrupolaires du ^{35}Cl dans $BiCl_3$ a été mesurée. A pression constante, les coefficients de température marquent une certaine différence qui est due aux effets de volume associés aux diverses liaisons intermoléculaires.

Introduction

The ^{35}Cl nuclear quadrupole resonance (n.q.r.) spectrum of bismuth trichloride consists of two lines, near 19.1 and 16.0 MHz (1). The crystal structure (2) indicates that one chlorine atom in the molecule is close to one extra-molecular bismuth atom, and two "face-bridging" chlorine atoms are each close to two extra-molecular bismuth atoms; the two face-bridging chlorine atoms are reported to be not quite equivalent. Intermolecular bonding has been suggested as a cause of the low values for the n.q.r. frequencies (1), and of the difference between the Raman spectra of gaseous and solid $BiCl_3$ (3); since there are at least two different chlorine atom sites in the solid, the n.q.r. spectrum provides an opportunity for studying two cases of intermolecular bonding in the same sample. The original n.q.r. results (1) indicate that the two resonance frequencies have markedly different temperature dependences, the lower frequency line having a positive temperature coefficient. The present study was undertaken to determine the temperature and pressure coefficients of the two resonance frequencies near room temperature.

Experimental

Details of the spectrometer, and of the equipment used for controlling the temperature and pressure, have been reported previously (4). The resonance frequencies were measured between 238 and 338 K at atmospheric pressure, and at pressures up to 275 MN m^{-2} at temperatures near 298 K.

Results and Discussion

Both resonance frequencies varied essentially linearly with changes in temperature and pressure over the ranges investigated, with the following coefficients. For the 16.0 MHz resonance

$$(\partial\nu/\partial T)_P = +0.38 \pm 0.03 \text{ kHz K}^{-1}$$

$$(\partial\nu/\partial P)_T = -1.22 \pm 0.01 \text{ kHz (MN m}^{-2})^{-1}$$

and for the 19.1 MHz resonance

$$(\partial\nu/\partial T)_P = -1.94 \pm 0.04 \text{ kHz K}^{-1}$$

$$(\partial\nu/\partial P)_T = -0.38 \pm 0.01 \text{ kHz (MN m}^{-2})^{-1}$$

The values of the resonance frequencies at 25 °C were 15 959 ± 1 and 19 159 ± 1 kHz, respectively. The positive temperature coefficient of the lower resonance frequency is confirmed, and it is seen to be associated with a strongly negative pressure coefficient, as in other cases of positive temperature coefficients. The temperature coefficients of the resonance frequencies under constant volume conditions can be obtained from the following equation (5):

$$[1] \qquad \left(\frac{\partial\nu}{\partial T}\right)_V = \left(\frac{\partial\nu}{\partial T}\right)_P + \frac{\alpha}{\beta}\left(\frac{\partial\nu}{\partial P}\right)_T$$

The ratio of thermal expansion coefficient to isothermal compressibility (α/β) has been estimated as $\alpha/\beta \lesssim 3.3$ MN m^{-2} K^{-1} (4), and so for the 16.0 MHz resonance,

$$(\partial\nu/\partial T)_V \cong -3.6 \text{ kHz K}^{-1}$$

while for the 19.1 MHz resonance

$$(\partial\nu/\partial T)_V \cong -3.2 \text{ kHz K}^{-1}$$

The marked difference in the temperature coefficients of the two resonances disappears when the simple corrections for volume changes are made. There are no data available on the asymmetry parameter of either resonance, and so it will be assumed that both asymmetry parameters are small enough that their variations with temperature and pressure produce negligible effects on the observed resonance frequencies; the observed coefficients of the resonance frequencies are then ascribed entirely to variations in the nuclear quadrupole coupling constants. The temperature dependence of the coupling constant at constant volume reflects the effects of lattice vibrations on the time-averaged electric field gradient tensor, and the above result indicates that the two chlorine atom sites are affected by lattice vibrations in approximately the same way. The difference between the two sites lies instead in the different volume dependences of the coupling constants, a result which is consistent with the different intermolecular bonding at the two sites.

It has been shown previously (4) that the temperature coefficient of the ^{209}Bi coupling constant in $BiCl_3$ at constant volume is too large to be accounted for on the basis of vibrational averaging. In the theory of vibrational averaging due to Bayer (6), the temperature dependence of the electric field gradient tensor is calculated assuming that the size and shape of the unit cell, and the average positions of the atoms within the unit cell, remain constant, while the amplitudes of the torsional oscillations increase as the temperature is raised. By combining $(\partial\nu/\partial T)_P$ with $(\partial\nu/\partial P)_T$ using eq. 1, the temperature dependence at constant volume is obtained, but this result contains possible contributions from changes of shape of the unit cell (at constant volume), and changes of the average atomic positions within the unit cell. Hence no numerical comparison of $(\partial\nu/\partial T)_V$ with Bayer theory is justified, beyond observing that the correct order of magnitude is obtained for both ^{35}Cl resonances.

Equipment for this work was purchased using grants from the National Research Council of Canada and the Advisory Research Committee of Queen's University. One of us (G.C.G.) thanks the National Research Council of Canada for the award of a scholarship.

Pyrolysis of Trifluoroacetaldehyde

MICHAEL T. H. LIU, LEON F. LOUCKS, AND ROBERT C. MICHAELSON

Department of Chemistry, University of Prince Edward Island, Charlottetown, Prince Edward Island

Received October 30, 1972

The thermal decomposition of trifluoroacetaldehyde has been studied over the 460–520 °C temperature range, and at pressures from 4 to 400 mm Hg. The experimental rate equation in the high-pressure region is of the form: Rate = $k[CF_3CHO]^{3/2}$ where

$$k = 10^{13.8\pm0.1} \exp(-50\,500 \pm 300/RT)\ cc^{1/2}\ mol^{-1/2}\ s^{-1}$$

The results are consistent with a mechanism initiated by a first order process and terminated by a second order recombination of two CF_3 free radicals. At lower pressures (40 mm Hg), the ratio of k_{init}/k_{term} is pressure dependent and the overall order increases. The effects of added inert gas confirm this pressure dependence.

La décomposition thermique du trifluoracétaldéhyde a été étudiée dans l'intervalle de température 460–520 °C et sous des pressions de 4 à 400 mm Hg. L'équation de vitesse expérimentale dans la région de haute pression est de la forme vitesse = $k[CF_3CHO]^{3/2}$ où

$$k = 10^{13.8\pm0.1} \exp(-50\,500 \pm 300/RT)\ cc^{1/2}\ mol^{-1/2}\ s^{-1}$$

Les résultats sont compatibles avec un mécanisme initié selon un processus de premier ordre puis terminé par une recombinaison de second ordre de deux radicaux libres CF_3. Aux basses pressions (40 mm Hg), le rapport $k_{initial}/k_{final}$ dépend de la pression et l'ordre global augmente. Les effets de gaz inerte ajouté confirment l'influence de la pression. [Traduit par le journal]

Can. J. Chem., 51, 2292 (1973)

Introduction

Arthur and Bell (1) studied the kinetics of the thermal decomposition of trifluoroacetaldehyde at temperatures between 471 and 519 °C, and at pressures up to 180 mm Hg. The main products were trifluoromethane and carbon monoxide in equal amounts together with small amounts of hexafluoroethane and hydrogen. The order of the reaction was 3/2 and the mechanism postulated involved a second-order initiation and third-order termination process.

More recently, Liu and Laidler (2, 3) have reinvestigated the pyrolysis of acetaldehyde over the 480–540 °C temperature range. The mechanism proposed was essentially that of the Rice–Herzfeld scheme, together with a number of other elementary processes. Côme and coworkers (4, 5) published findings similar to those reported by Liu and Laidler. There is general agreement that the experimental results are compatible with a radical chain mechanism which is initiated by a first-order process, and terminated by a second-order combination of methyl radicals. According to the results of Liu and Laidler, the overall order of the thermal decomposition of acetaldehyde is 1.5 at high pressures (> 100 mm Hg) and increases to 1.7 at pressures below 20 mm Hg. These results suggest that both the initiation and termination steps become pressure dependent at low pressures. In view of the apparent differences between the thermal decompositions of acetaldehyde and trifluoroacetaldehyde, the present work was undertaken to see if the pyrolysis of trifluoroacetaldehyde was indeed substantially different from that of acetaldehyde.

Experimental

Trifluoroacetaldehyde (K and K Laboratories Inc.) was prepared from the hydrate by passing the hydrate under vacuum through a column of P_2O_5 packed in glass wool. Bath temperatures up to 90 °C were required to force the hydrate through the column. The trifluoroacetaldehyde was further dried by passing it several times through U-tubes packed with P_2O_5 and then trapped over Na_2CO_3 to remove any residual trifluoroacetic acid. This product was distilled under vacuum from a trap at −95 °C (toluene slush) to a trap at −127 °C (*n*-propanol), with a volatile fraction being trapped with liquid N_2. Gas chromatographic analysis of the purified sample indicated no impurities in excess of 0.1%. The infrared spectrum of the aldehyde at 25 mm Hg agreed with those of Husted and Ahlbrecht (6) and of Dodd, Roberts, and Woodward (7). The infrared spectrum of the high volatility fraction discarded in the distillation revealed the presence of C_2F_4 as an impurity of the original aldehyde; care was taken to remove this impurity.

The decomposition was carried out in a conventional static system. The reaction vessel was a quartz cylinder 418 ml in volume, with a s/v ratio of 0.7 cm^{-1}, enclosed

For personal use only.

in a furnace consisting of an electrically heated steel cylinder. The temperature of the vessel was controlled to within 0.3 °C by means of a Thermoelectric Model 400 temperature controller.

To initiate a run the trifluoroacetaldehyde was admitted to the vacuum line manifold and a 2 l bulb, and was expanded from this volume to the reaction vessel with the opening of a stopcock. At the end of the run the stopcock was opened and all condensable materials were trapped immediately in spiral traps at −196 °C. The non-condensable fraction was collected in a gas burette. For chromatographic analysis, the gaseous products were swept through a 2-meter Porapak Q column at room temperature and were detected with a hot filament unit.

Pressure measurements in the low-pressure region below about 40 mm Hg, were made with a silicone oil manometer and at higher pressures with a mercury manometer with the mercury surfaces covered with silicone oil.

Prior to every pyrolysis run, some trifluoroacetaldehyde was pyrolyzed in the reaction vessel (usually about 20 mm of reactant). All materials were evacuated from the vessel just before a run and more reactant was admitted to the vessel soon after the run. This procedure was followed to eliminate or reduce surface effects which were mentioned by Arthur and Bell (1), and which in our early runs appeared to cause inconsistent rates of reaction. Examination of the reaction vessel after prolonged use revealed no visible deposits on the surface.

Results and Discussion

Products of the reaction were equimolar amounts of carbon monoxide and trifluoromethane along with small amounts (~0.2% of the total CO for runs at 480 °C and 100 mm Hg reactant) of hexafluoroethane. These were fractionated in a conventional apparatus and identified by gas chromatography.

Reaction rates cited in the discussion are rates of production of CO extrapolated to zero time from a series of runs of varying duration. The overall order of the reaction was examined in detail at 480 °C. Figure 1 reveals that the overall order of the reaction is 3/2 at pressures greater than about 40 mm Hg in agreement with the conclusion of Arthur and Bell (1). However, at lower pressures, a region not investigated extensively by Arthur and Bell, the order of the overall reaction increases as the pressure is lowered (Fig. 2). The overall order is about 1.85 at a pressure of 4 mm Hg. Also shown in Fig. 2 are the results of Liu (3) for the decomposition of acetaldehyde. The rates of decomposition of trifluoroacetaldehyde are less than those of acetaldehyde but the behavior of an increase in the order to a value greater than 3/2 at low pressures is evident in both cases.

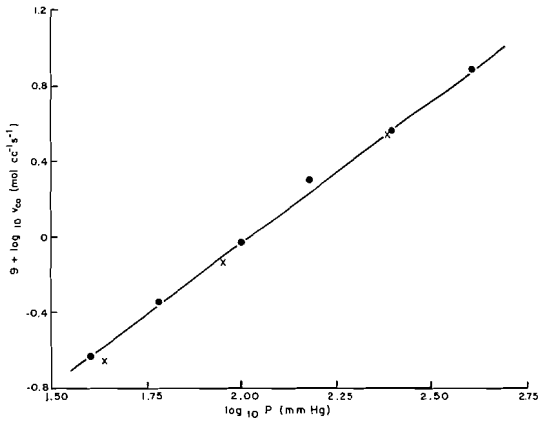

FIG. 1. A plot of the $\log_{10}$ of the overall rate of reaction as a function of the $\log_{10}$ of the pressure of trifluoroacetaldehyde (the high-pressure region). The data indicated by × were obtained early in the study while the data indicated by ○ were obtained in a later series of runs. The solid line was drawn with a slope of 3/2.

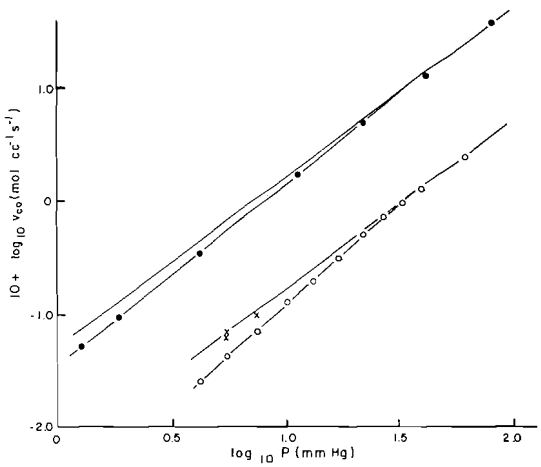

FIG. 2. A plot of the $\log_{10}$ of the overall rate of reaction as a function of the $\log_{10}$ of the pressure of trifluoroacetaldehyde (the low-pressure region): ○, trifluoroacetaldehyde at 480 °C; ×, trifluoroacetaldehyde at 480 °C with CO_2 added; ●, acetaldehyde at 540 °C (data from ref. 3). The solid lines indicate a slope of 3/2 as an extension of high-pressure data.

The fall-off in the rate at lower pressures to produce the higher order was tested by the addition of inert gas. In Fig. 2 the solid straight lines were drawn with the slope of 3/2 for the cases of acetaldehyde and trifluoroacetaldehyde. The addition of 200 mm Hg CO_2 to runs at 5.6 and 7.5 mm Hg trifluoroacetaldehyde increased the rate appreciably and the addition of 250 mm Hg CO_2 to 5.6 mm Hg trifluoroacetaldehyde in-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

creased the rate to the value expected for an overall order of 3/2 (Fig. 2). These experiments confirm the change in order at low pressure and show that 250 mm Hg CO_2 is effective in restoring the reaction to high-pressure conditions.

The temperature dependence of the overall rate was studied in the high-pressure region at a pressure of 100 mm Hg of trifluoroacetaldehyde. The Arrhenius plot provided in Fig. 3 yields the overall rate constant $k = 10^{13.8\pm0.1} \exp(-50\,500 \pm 300/RT)\ cc^{1/2}\ mol^{-1/2}\ s^{-1}$. The activation energy is in good agreement with the value of 49 kcal mol^{-1} obtained by Arthur and Bell. Also the value of $10^{12.2}\ l^{1/2}\ mol^{-1/2}\ s^{-1}$ obtained by Arthur and Bell for the A factor is in good agreement with our experimental frequency factor of $10^{13.8}\ cc^{1/2}\ mol^{-1/2}\ s^{-1}$. The absolute value of the rate constants obtained in this study and in the study of Arthur and Bell agree within a factor of 2, with Arthur and Bell's value being the greater. The reason for the discrepancy in the absolute values is not known.

To explain the experimental observations the following kinetic scheme is suggested for the high-pressure decomposition of trifluoroacetaldehyde.

[1] $CF_3CHO \rightarrow CF_3 + CHO$

[2] $CHO \rightarrow CO + H$

[3] $H + CF_3CHO \rightarrow H_2 + CF_3CO$

[4] $CF_3 + CF_3CHO \rightarrow CF_3H + CF_3CO$

[5] $CF_3CO \rightarrow CF_3 + CO$

[6] $CF_3 + CF_3 \rightarrow C_2F_6$

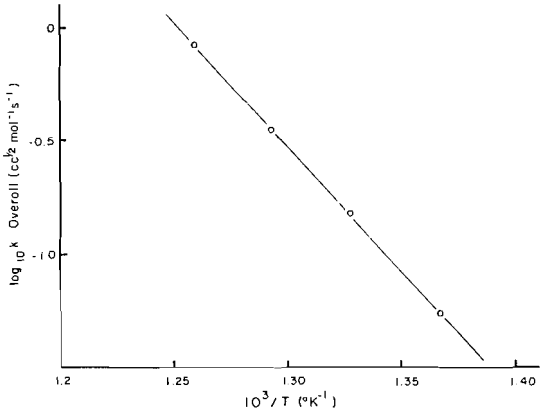

FIG. 3. Arrhenius plot of the overall rate constant for trifluoroacetaldehyde.

A steady-state treatment of the reaction scheme leads to the following expression:

$$v_{CO} = k_4\left(\frac{k_1}{k_6}\right)^{1/2}[CF_3CHO]^{3/2}$$

The low yield of C_2F_6 relative to that of CO and CF_3H satisfies the condition of long chains and thus the above expression can satisfy the rate of production of CO. Furthermore, under these conditions, the rate of formation of CO is equal to the rate of decomposition of trifluoroacetaldehyde and hence is equal to the overall rate of reaction. The relative concentrations of CF_3CO and CF_3 in the reaction system determines which termination process will be important. The steady state condition leads to

$$\frac{[CF_3CO]}{[CF_3]} = \frac{k_4}{k_5}[CF_3CHO]$$

With the use of literature values of $k_4 = 10^{12} \exp -8\,800/RT$ cc $mol^{-1}\ s^{-1}$ (8) and $k_5 = 2.6 \times 10^{10} \exp -10\,000/RT\ s^{-1}$ (9), values of $[CF_3CO]/[CF_3]$ were estimated to be in the range of 10^{-3} to 10^{-4}. It is therefore reasonable to conclude that the termination must involve the recombination of two CF_3 radicals.

Overall Order

The value of 3/2 for the experimental order of reaction in the high pressure region is satisfied by the mechanism given by reactions 1–6. From the Goldfinger rules it follows that a mechanism involving second-order initiation and ββM termination would also satisfy the overall order of 3/2; this was the mechanism suggested by Arthur and Bell. However, such a mechanism could not explain a fall-off in the overall rate constant in the low-pressure region, as both initiation and termination reactions are already pressure dependent. The experimental results for trifluoroacetaldehyde at low pressures show a change in the overall order to values greater than 3/2 and approaching 2. This change is satisfied by the change in the order of reaction 1 to second-order conditions at low pressures, with the termination reaction remaining as the second-order combination of trifluoromethyl radicals, *i.e.* k_{init} shows a pressure dependence while k_{term} is constant and still pressure independent. At even lower pressures, one would anticipate that the combination of the trifluoromethyl radicals would become third order and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

then, with the second-order initiation reaction, the Goldfinger rules would predict a return to 3/2 order overall kinetics.

A comparison of the changes in the overall order of the reactions of acetaldehyde and trifluoroacetaldehyde can be made from Fig. 2, in which it is seen that the shape of the curves is much the same in the two cases. However, it is apparent that the fall-off in CF_3CHO is more pronounced than that of CH_3CHO. This suggests that in the CH_3CHO pyrolysis, the fall-off for CH_3 combination overlaps the pressure dependence of the initiation reaction, while such an overlap is much less readily observed for the CF_3 combination in the case of CF_3CHO pyrolysis.

Ratio of Rate Constants for Initiation and Termination

The pressure dependence of the initiation and termination reactions has been examined in a more detailed form as given in Fig. 4. For the proposed reaction scheme it follows that $k_{overall} = (k_1/k_6)^{1/2} k_4$. The value of k_4 at 480 °C was calculated from the data of Morris and Thynne (8). From the experimental $k_{overall}$ and this value of k_4, k_1/k_6 values were calculated and plotted as a function of pressure in Fig. 4 in a log–log plot. The fall-off of the rate constant ratio is more clearly evident in this figure. The form of the pressure dependence requires a pressure dependence of k_1. This pressure dependence is again seen to commence at about 40 mm Hg and at the lowest pressures studied, for which the slope of the curve in Fig. 4 is about 0.8, the order of the initiation reaction would be 1.8. The effect of added carbon dioxide on the k_1/k_6 ratio is shown again in Fig. 4.

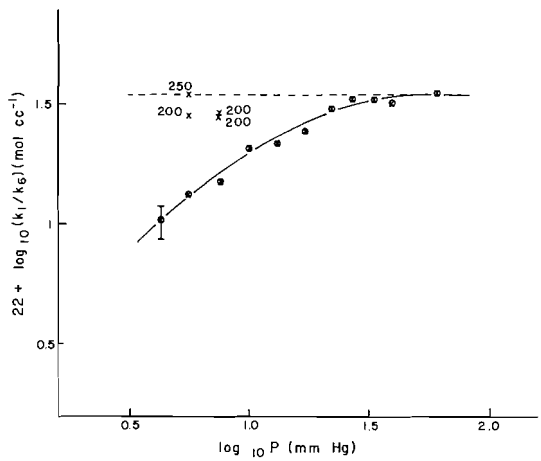

FIG. 4. Plot of $\log k_1/k_6$ against $\log P$ at 480 °C, showing the effects of CO_2. The dashed line is the extension of the high-pressure limit. ⊗, no CO_2 added; ×, CO_2 added at pressures indicated, mm Hg.

The experimental observations described in this paper are satisfied by the reaction scheme given by reactions 1–6. However, the rate enhancement observed by Arthur and Bell for the addition of CO_2 to runs at 75 and 100 mm Hg of CF_3CHO would not be expected. Although the magnitude of the rate enhancement in Arthur and Bell's work (about 25–30% increase for 150–200 mm Hg CO_2) was less than that which we have observed in the low-pressure region (about 40–50% increase for 200 mm Hg CO_2), it was none-the-less a pronounced effect. We regret that in the present study the effect of CO_2 on the rate was not examined in the high-pressure region and we recognize that the rate enhancement in the high-pressure region remains as an unsolved problem in defining the mechanism unequivocally.

Arrhenius Parameters and Bond Dissociation Energies

As already discussed, the A factor and the activation energy determined in this study for the overall reaction in the high-pressure region were in close agreement with the values of Arthur and Bell. A prediction for the value of A_1 can be made with the use of the expression:

$$\log A_{overall} = \tfrac{1}{2} \log A_1 - \tfrac{1}{2} \log A_6 + \log A_4$$

Thus from our experimental value of $\log A_{overall} = 13.8$ and from Morris and Thynne's value of 5.3 for $\log A_4 - \tfrac{1}{2} \log A_6$ it follows that $A_1 \simeq 10^{17.0}$ s^{-1}. Although this value is somewhat high it is in reasonably good agreement with values previously obtained for the unimolecular initiation steps in the pyrolyses of acetaldehyde (2) and ethane (10).

In a similar manner an estimate of the activation energy of reaction (1) can be obtained from the value of $E_4 - \tfrac{1}{2}E_6 = 8.8 \pm 0.2$ kcal/mol reported by Morris and Thynne, combined with our overall activation energy of 50.5 ± 0.3 kcal/mol; it follows that $E_1 \simeq 83$ kcal/mol.

The activation energy E_1 is related to the bond dissociation energy $D(CF_3—CHO)$ which, to a close approximation, may be taken to have the same value. Thus $D(CF_3—CHO) \simeq 83$ kcal/mol. This value may be compared with the

corresponding value of $D(CH_3—CHO) = 79.0 \pm 2.0$ obtained by Liu and Laidler (2) in the pyrolysis of acetaldehyde. It is interesting to note the increase in the bond dissociation energy of the fluorinated compound over that of the hydrogen analog, an increase which in this case amounts to 4.4 kcal/mol. There has been an accumulation of evidence that such an increase is the general case. Studies of $D(CF_3—H)$ by Amphlett, Coomber, and Whittle (11) and Goy, Lord, and Pritchard (12) have provided values in the range of 106.0 to 106.3 kcal/mol, such values being about 2–2.5 kcal/mol greater than $D(CH_3—H)$. The results of Tschuikow-Roux (13), Farmer *et al.* (14), Coomber and Whittle (15), and Goy, Lord, and Pritchard (12) indicate that $D(CF_3—CF_3)$ is about 93–97 kcal/mol, a value about 5–9 kcal/mol greater than $D(CH_3—CH_3)$. Furthermore, Amphlett and Whittle (16) have shown that $D(CF_3CO—H) = 91.1 \pm 2$ kcal/mol and that $D(CF_3CO—H) - D(CH_3CO—H) = 4.1$ kcal/mol. In view of the trend which indicates the increase in bond dissociation energy of various bonds in fluorinated compounds over that of the corresponding hydrogen compounds, it appears that $D(CF_3—CHO) \simeq 83$ kcal/mol is very much of the magnitude expected.

Proton Transfer Kinetics in Medium-strong Inorganic Acids[1]

DAVID CHARLES HODGKIN AND PEETER KRUUS

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received August 14, 1972[2]

A method of obtaining relative and absolute rate constants for proton transfer equilibria is described. It is suitable for equilibria of the type

$$H_2O + HA \underset{k_r}{\overset{k_d}{\rightleftarrows}} H_3O^+ + A^-$$

in dilute ($< 0.1\ M$) solutions of medium strong inorganic acids. To obtain absolute values of k_d, k_r it is necessary to know the value of ΔV^0 for the equilibrium. Ultrasonic absorption data for aqueous solutions of H_3PO_4, H_3AsO_4, and H_2SO_4 at 20, 10, and 0 °C are presented together with data at 20 °C for H_3PO_3, H_2SeO_3, HIO_4, $NaHSO_4$, $KHSO_4$, and NH_4HSO_4. From analysis of the concentration dependence of the excess absorption, values of K_a are calculated for these acids, and values of k_d, k_r for those where ΔV^0 is available. The K_a obtained are in reasonable agreement with literature values except for HIO_4 and H_2SeO_4. The absolute values of k_r for H_3PO_4, H_3AsO_4, and HSO_4^- indicate that the diffusion controlled recombination process postulated is complete when the ions are about 15 Å from each other.

Une méthode d'obtention des constantes de vitesse relative et absolue pour l'équilibre de transfert du proton a été décrite. Cette méthode convient pour l'équilibre du type

$$H_2O + HA \underset{k_r}{\overset{k_d}{\rightleftarrows}} H_3O^+ + A^-$$

en solutions diluées ($< 0.1\ M$) d'acides inorganiques de force moyenne. Pour obtenir les valeurs absolues de k_d et k_r, il a été nécessaire de connaître la valeur ΔV^0 de l'équilibre. Les données de l'absorption ultrasonique pour les solutions aqueuses de H_3PO_4, H_3AsO_4, et H_2SO_4 à 20, 10, et 0 °C ont été présentées de même que celles de H_3PO_3, H_2SeO_3, KIO_4, $NaHSO_4$, $KHSO_4$, et NH_4HSO_4 à 20 °C. L'analyse de l'excès d'absorption en fonction de la concentration a permis de calculer les valeurs K_a de ces acides et les valeurs k_d, k_r pour ceux dont le ΔV^0 est connu. Les K_a obtenus sont d'un bon accord avec les valeurs de la littérature sauf pour KIO_4 et H_2SeO_4. Les valeurs absolues de k_r pour H_3PO_4, $H_3AsO_4^-$ montrent que le processus postulé pour la recombinaison contrôlée par diffusion, est total lorsque les ions sont séparés de 15 Å environ les uns des autres. [Traduit par le journal]

Can. J. Chem., **51**, 2297 (1973)

Introduction

Estimates for the rate constants for proton transfer reactions in sulfuric acid solutions were made in 1954 by Eigen (1). His calculations were based on the ultrasonic absorption data of Kurtze and Tamm (2).

Since that time, rapid proton transfer in aqueous acid equilibria of the type

$$[1] \qquad HA + H_2O \underset{k_r}{\overset{k_d}{\rightleftarrows}} A^- + H_3O^+$$

has been studied by various means: nuclear magnetic resonance (3), Raman spectroscopy (4), temperature (5) and electric field (6–8) jump techniques, as well as by ultrasonic absorption (9, 10). Such studies have been conducted in various types of solutions: inorganic compounds (3, 4, 6), organic acids (5, 7), proteins (9, 10), as well as for water itself (8). Summaries of proton transfer rates can be found in refs. 11 and 12.

It has generally not been possible to observe the relaxation of such proton-transfer equilibria directly through ultrasonic absorption. The small excess absorption and the difficulty in working with acid solutions make it unlikely that precise enough data can be obtained at the necessary high frequencies, even though apparatus for measurements at such frequencies has become available, *e.g.* ref. 13.

The relaxation time τ can however also be calculated from the measured excess absorption α'/f^2 at low frequencies. For such an analysis,

it is necessary to assume which equilibrium is responsible for the absorption, and to have some thermodynamic data for this equilibrium.

Due to the greater complexity of organic acids, numerous equilibria are present in their solutions which could give rise to ultrasonic absorption. A measurable amount of excess absorption at low frequencies and low concentrations due to equilibria such as that shown in [1] is present also only in medium-strong acids.

An investigation of the concentration dependence of the ultrasonic absorption of 6 medium-strong inorganic acids was carried out. The results are interpreted as due to equilibria of the type shown in [1]. Experimental values of the equilibrium constants can be obtained from the resulting analysis. Absolute values of the rate constants k_d and k_r can be obtained if ΔV^0 for the equilibrium is available.

Experimental

The apparatus and procedure used for the ultrasonic absorption measurements have been described previously (14). Most measurements were carried out at 31.8 MHz with apparatus A (14). Only for a few systems was an extended frequency range (3.5 to 52 MHz) used.

The precision of individual absorption measurements was better than 1%, as judged on the basis of the standard error for obtaining the slope of attenuation *vs.* distance plots. The inaccuracy in the excess absorption, α'/f^2, is of course greater than this. Estimated error limits are given in the large scale plots in Fig. 4. The excess absorption is the relatively small difference between two readings, $\alpha'/f^2 = (\alpha/f^2)_{solution} - (\alpha/f^2)_{water}$.

There are also inaccuracies present due to errors in temperature, especially close to 0 °C, where difficulties were encountered in maintaining constant temperature. This can be seen from the values of the standard deviation:

$$[2]\quad \sigma = \sqrt{\frac{1}{(n-3)}\sum_{i=1}^{n}[(\alpha'/f^2)_{calcd} - (\alpha'/f^2)_{exp}]^2}$$

Column 8 of Table 1 shows σ to be considerably larger for systems at 0 °C.

All solutions were prepared using distilled water redistilled from potassium permanganate solution. Reagent grade acids and salts from Fisher, Anachemia, CIL, or Baker were used without further purification. Stock solutions were made up and their concentrations determined by titration using a pH meter. It is estimated that the concentrations of the subsequently prepared solutions were accurate to better than 2%.

Theoretical Background

The excess absorption, α'/f^2, caused by a relaxation is given by (11):

$$[3]\quad (\alpha'/f^2) = \frac{2\pi^2\kappa_r}{v\kappa_0}\cdot\frac{\tau}{1+\omega^2\tau^2}$$

Here κ_0 is the static compressibility, which can be related to density ρ and the speed of ultrasound v as $\kappa_0 = 1/v^2\rho$. The contribution to the

For personal use only.

adiabatic compressibility from the relaxing equilibrium is given by κ_r. It can be expanded to be of the form

$$[4] \quad \kappa_r = -\frac{1}{V}\left[\left(\frac{\partial V}{\partial P}\right)_T + \left(\frac{\partial V}{\partial T}\right)_P \cdot \left(\frac{\partial T}{\partial P}\right)_S\right]$$

As $(\partial T/\partial P)_S$ is small for aqueous solutions, the second term in eq. 4 can be neglected when ΔH^0 for the equilibrium is not extremely large. The derivative $(\partial V/\partial P)_T$ can be expanded in terms of θ, the degree of advancement of the equilibrium. Thus

$$[5] \quad \kappa_r = -\frac{1}{V}\left(\frac{\partial V}{\partial \theta}\right)_T\left(\frac{\partial \theta}{\partial P}\right)_T = -\Delta V\left(\frac{\partial \theta}{\partial \ln K}\right)_T\left(\frac{\partial \ln K}{\partial P}\right)_T$$

When the approximation $\Delta V = \Delta V^0$ is made, then κ_r becomes:

$$[6] \quad \kappa_r = \frac{(\Delta V^0)^2}{RT}\cdot\left(\frac{\partial \theta}{\partial \ln K}\right)_T$$

When activity coefficients can be assumed to be unity, then the relationships for τ and $(\partial\theta/\partial \ln K)$ are relatively simple. The relaxation time τ for a reaction as shown in eq. 1 is

$$[7] \quad 1/\tau = k_d + k_r([A^-] + [H_3O^+])$$

The derivative

$$[8] \quad \frac{\partial \theta}{\partial \ln K} = \frac{c\xi(1-\xi)}{(2-\xi)}$$

where c is the stoichiometric concentration and ξ the degree of dissociation.

The value of ξ is related to c and the equilibrium constant K_a by

$$[9] \quad \xi = \frac{-K_a + \sqrt{K_a^2 + 4K_a c}}{2c}$$

The excess absorption (α'/f^2) can then be obtained by appropriate substitution

$$[10] \quad (\alpha'/f^2) = \frac{2\pi^2(\Delta V^0)^2\rho v}{RT}\cdot\frac{c\xi(1-\xi)}{(2-\xi)}\cdot\frac{1}{k_r}\frac{1}{(K_a + 2\xi c)}$$

The expression has been written in a form where k_r and K_a $(= k_d/k_r)$ can be considered as adjustable parameters.

Equations 9 and 10 neglect the effect of activity coefficients. The complete relationships including activity coefficients can be obtained in (11). The derivatives with respect to the degree of dissociation of activity coefficients of the species involved must be known, including the activated state complex.

The acids H_3PO_4, H_3AsO_4, HIO_4, H_2SeO_3, and H_3PO_3 are sufficiently weak so that [9] and [10] can be used for analysis with reasonable accuracy. An 0.05 M solution of H_3PO_4 has approximately $\xi \approx 0.33$, ionic strength ≈ 0.016, $\gamma_\pm^2 \approx 0.93$. This introduces some error ($\sim 3\%$) in the value of ξ calculated through [9]. The error due to neglect of terms of the form $d \ln \gamma_\pm^2 / d \ln \xi$ can in this case be estimated to be of the order of 2% (11). As only a few of the experimental points considered were at concentrations > 0.05 M, the neglect of activity coefficients seems justified in the light of the accuracy of the experimental data.

Equation 10 and a modified form of [9] were also used to analyze the data for $NaHSO_4$ solutions. In this case the ionic strength is higher, so that the errors introduced are greater. In addition, the neglect of absorption due to ion pairing equilibria involving Na^+ and SO_4^{-2} may not be justified. The results for $NaHSO_4$ are thus of a rather approximative nature.

The experimental data was fitted with eq. 10 by choosing a value of ΔV^0 and then using k_r and K_a as adjustable parameters. In adjusting k_r and K_a to give the smallest standard deviations (eq. 2), the following routine was used. A range of values of K_a was chosen. For each value of K_a, the value of k_r giving the smallest standard deviation was then calculated from the relation

$$[11] \quad k_r = \frac{\sum_{i=1}^{n} ((\text{Eq. } 10)_i \times k_r)^2}{\sum_{i=1}^{n} ((\text{Eq. } 10)_i \times k_r)(\alpha^1/f^2)_{\text{expti}}}$$

The symbol $(\text{Eq. } 10)_i \times k_r$ indicates the expression in the r.h.s. of [10] times k_r with the values of c_i and ξ_i (from eq. 9) for the ith data point included. The set K_a, k_r giving the smallest σ was then chosen.

Even if activity coefficients are neglected, the analysis of sulfuric acid solution data is more complex. Equation 8 now becomes

$$[12] \quad \left(\frac{\partial \theta}{\partial \ln K}\right) = \frac{\xi(1+\xi)(1-\xi)}{2-(1-\xi)^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and eq. 9 becomes:

$$[13] \quad \xi = \frac{-c - K_a + \sqrt{(c + K_a)^2 + 4K_a c}}{2c}$$

Although eq. 7 is still valid, its form is different when expressed in terms of k_r, K_a, and c. The H_2SO_4 data were analyzed with neglect of activity coefficients taking account of the changes expressed in eqs. 12 and 13.

The H_2SO_4 data was also analyzed using the more accurate forms (11) of eqs. 12 and 7, but leaving [13] unchanged. The activity coefficients were calculated from the Debye–Hückel equation (15). The use of experimental activity data leads to difficulties, as single ion activities are needed, including that of the activated complex. Incorporating changes in eq. 13 would lead to computational difficulties, which seem unjustified in the light of the accuracy of the data.

Results

Figure 1 shows the ultrasonic absorption in aqueous H_3PO_4 solutions up to saturation (14.3 *M*). A smooth curve has been drawn through the points. There may, however, be maxima and minima in the curve as in the case of sulfuric acid (16). α_c refers to the value of the classical absorption arising from viscosity, $\alpha_c/f^2 = 8\pi^2\eta/3v^3$. The absorption was measured as a function of frequency for solutions 0.1, 1.0, 7.0, 14.3 *M* in H_3PO_4. No sign of a relaxation was observed within the frequency range 3.5 to 52 MHz, *i.e.* α/f^2 was constant with frequency within experimental error. As can be seen in Fig. 1, there is an increase in the absorption at small concentrations. Figure 2 shows the absorption at small concentrations (0 to 0.15 *M*) at three temperatures. The data shown in this figure was fitted with eq. 10 using k_r and K_a as adjustable parameters. The results are shown in Table 1, rows 1 to 3 inclusive.

In fitting the H_3PO_4 data, the value of ΔV^0 chosen was -16.2 cm^3 mol^{-1} (15). A value of -15.5 cm^3 mol^{-1} has also been reported (17). As (α'/f^2) varies as $(\Delta V^0)^2$, then k_r would be diminished by nearly 10% if the latter value would be used. The same value of ΔV^0 was used

for the three temperatures examined. This can make the calculated value of k_r of the order of 20% smaller than the actual value at 0 °C (10% at 10 °C) if ΔV^0 for H_3PO_4 has the same temperature dependence as for H_2O. For the H_3O^+–OH^- equilibrium, ΔV^0 changes from -26.1 to -23.4 cm^3 mol^{-1} in the 20 degree interval 5 to 25 °C (15). The values of v used throughout were for 20 °C, 1.48×10^5 cm s^{-1}; for 10 °C, 1.43×10^5 cm s^{-1}; for 0 °C, 1.40×10^5 cm s^{-1}. The variation of v and ρ with concentration up to 0.1 M is negligibly small.

In the case of the H_3PO_4 at 20 °C, two curves are shown in order to indicate the sensitivity of eq. 10 to variation in K_a. This sensitivity is also shown in Fig. 7, where k_r and σ are plotted as a function of K_a for H_3AsO_4 at 10 °C. The value of k_r is not very sensitive to changes in K_a. It should be noted that the value of k_r is predominantly determined by data in the higher concentration range, while K_a (and thus k_d) is more sensitive to data in the low concentration range.

Figure 3 shows the curves for H_3AsO_4 corresponding to Fig. 2. Again the fit at 0 °C has a considerably greater standard deviation due to greater imprecision in the experimental data. Data for 3 other medium-strong acids (HIO_4, H_2SeO_3, H_3PO_3) are shown in Fig. 4. In this case (α'/f^2) is plotted *vs.* c to show the amount of imprecision in the data.

In fitting the data in Figs. 3 and 4, a value of -16.0 cm^3 mol^{-1} was used for ΔV^0 in the absence of any literature values. Values of this order of magnitude seem common for equilibria of the type considered (15).

Absorption measurements were taken at 20 °C also for three strong acids, $HClO_4$, HNO_3, and HCl. In this case, no increase in absorption over that of pure water was noted in solutions up to 0.12 M. The value of ξ is in this case so great that $(1 - \xi) \approx 0$, *i.e.* $\alpha'/f^2 \approx 0$.

Figure 5 shows data for H_2SO_4. The 0 °C data are shown with the curve obtained when activity coefficients are neglected. The shape of the experimental and calculated curves are qualitatively different at higher concentrations. The experimental α'/f^2 continues to rise while the calculated α'/f^2 decreases. It was not possible to obtain a meaningful fit for the 0 °C data with consideration of activity coefficients.

The 10 and 20 °C data for H_2SO_4 are shown fitted with the equation taking partial account

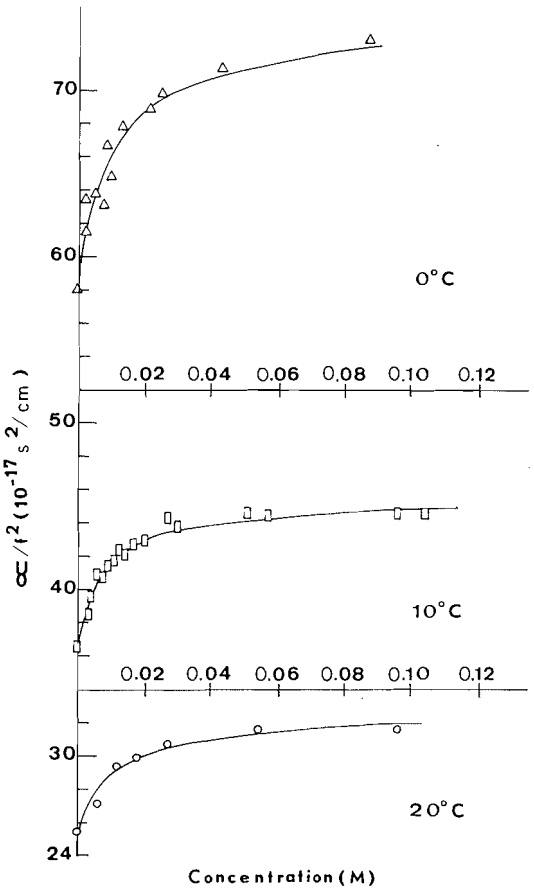

FIG. 3. Ultrasonic absorption in aqueous arsenic acid solutions: ○, 20 °C; □, 10 °C; △, 0 °C; —, Least squares fit (Table 1 rows 4–6).

of activities. The resulting values of ΔV^0 found were -14.3 cm^3 mol^{-1} at 20 °C and -15.5 cm^3 mol^{-1} at 10 °C. This is in good agreement with the literature value -15.5 cm^3 mol^{-1} (18) used for the other H_2SO_4 calculations. Higher values, -20.2 cm^3 mol^{-1} (19) have been reported.

Data for $NaHSO_4$, $KHSO_4$, and NH_4HSO_4 solutions are shown in Fig. 6. The curve shown is for the $NaHSO_4$ data, Table 1 row 10. In this case, as well as in the case of rows 11, 13, and 15, only points below 0.10 M were used to get the best values of K_a and k_r. This makes the neglect of activity coefficients less critical. The data for the 3 salts are completely overlapping within experimental error as seen in Fig. 6. This indicates that ion pairing of the cations with SO_4^{2-} ions may not be of much importance at this temperature, and that the discrepancy between the calculated K_a and that found from other experi-

Discussion

(a) Values of K_a

The equilibrium constants obtained by fitting the experimental curves with eq. 10 are in reasonable agreement with literature values in some cases (Table 1, rows 1, 2, 3, 4, 9, 15). In other cases, they differ considerably from values in the literature. Three literature values can be found for the K_a of H_3PO_3: 1.0×10^{-2} (20), 1.62×10^{-2} (21), and 5.0×10^{-2} (22). The experimental value 1.42×10^{-2} is closest to the second value. It is thus possible that the differences in the values of K_a for HIO_4 and H_2SeO_3 may also be due to unreliable literature values rather than to large errors in the experimental data and its interpretation. Precise values for K_a for medium-strong acids seem difficult to obtain (23).

In the case of HSO_4^-, the differences are however most likely due to an oversimplified model used to interpret the data. The calculated value of γ at 0.10 m^{-1} was in good agreement with experimental values (0.22 as compared to 0.29), but the neglect of activity coefficients in calculating ξ most likely introduces substantial errors. Nevertheless, the values of k_d obtained by neglecting and including activity coefficient effects are not very different (Table 1, rows 11, 12 and 13, 14). The k_r values differ more, as expected, because they are primarily determined by experimental points at higher concentrations (eq. 10), where activity coefficient effects are greater.

(b) Values of k_r, k_d

The excess absorption in the systems studied has been assumed to be due to the single step

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

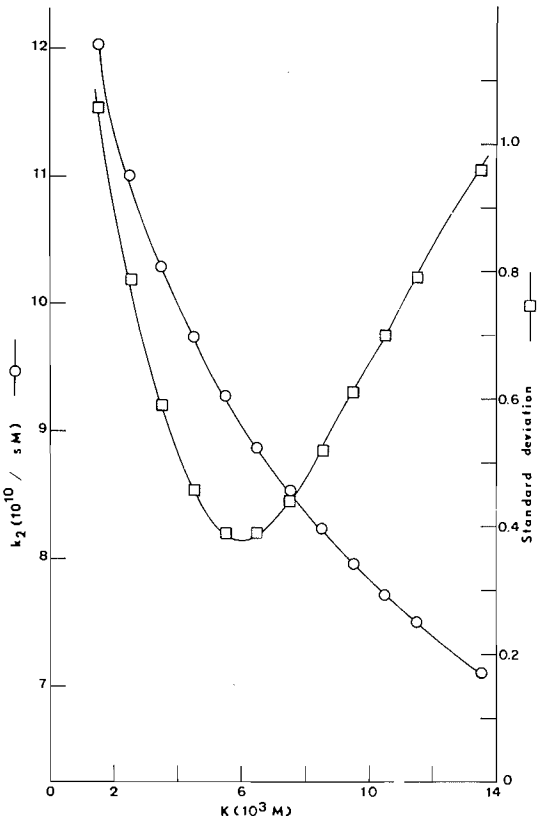

FIG. 7. Variation of k_2 and σ with K in arsenic acid solutions at 10 °C (Table 1, row 5) —○—, k_2 (eq. 16); —□— σ (eq. 2).

equilibrium shown in eq. 1. A more sophisticated model (1) describes the process in two steps:

$$[14]\quad H_3O^+ + A^- \underset{k_2}{\overset{k_1}{\rightleftarrows}} H_3O^+ \,.\, A^- \underset{k_4}{\overset{k_3}{\rightleftarrows}} H_2O + HA$$

Step one is the equilibrium between the free ions and an ion-pair (equilibrium constant $K_{1,2}$). Step two is the equilibrium between the ion-pair and the chemically bonded acid ($K_{3,4}$). Covington *et al.* (23) have discussed this mechanism in some detail.

If it is assumed that step one is rate-determining, then the rate constant k_r in Table 1 can properly be considered to be that for a diffusion-controlled process of the formation of the ion-pair, k_2. Debye (24) has constructed a theory to describe such a process. In the limit of infinite dilution, k_2 can be written as

$$[15]\quad k_2 = \frac{4\pi(D_+ + D_-)}{1000\varepsilon k T} N z_+ z_- e_0^2 \times \left[\exp\left(\frac{z_+ z_- e_0^2}{a\varepsilon k T}\right) - 1\right]^{-1}$$

Here D_+ and D_- are the diffusion coefficients and z_+e_0, z_-e_0 the charges on the cation and the anion, ε is the dielectric constant, N Avogadro's number, k Boltzmann's constant, and a the ion-size parameter describing the distance between ions when the reaction is "complete".

For 1–1 electrolytes, [15] reduces simply to

$$[16]\quad k_2 = 5.32 \times 10^{14}\,(D_+ + D_-) \times [\exp(7.1 \times 10^{-8}/a) - 1]^{-1}$$

The increase in ε cancels approximately the decrease in T in the range 20 to 0 °C. There are several simplifications involved in obtaining eq. 16. However, the use of more sophisticated theories (25, 26) seems unjustified in the light of the limited precision of the experimental results.

The rate constant k_d in the framework of a two-step model must be considered as the ion-pair dissociation rate k_1 of step one, multiplied by the equilibrium constant $K_{3,4}$. The relationship for k_1 derived by Eigen (1) cannot be used directly to analyze the experimental values for k_d.

Values of the activation energy of the recombination reaction can be estimated from the data assuming an Arrhenius form. These estimates are independent of the value of ΔV^0 chosen, if the temperature-independence of ΔV^0 is assumed. The values obtained for H_3PO_4 and H_3AsO_4 are of the order of 4 kcal mol^{-1}, *i.e.* of a magnitude characteristic of diffusion controlled reactions. From [16] it can be seen that this is essentially the activation energy for diffusion.

Values of the distance parameter a can be calculated from the values of k_r. Values of the diffusion coefficients can be calculated from values of the conductivity through the Nernst–Einstein relation (15). Values for D_- were in cases estimated due to the lack of conductivity data. Such estimates are not crucial as $D_+ \gg D_-$ in all cases.

The values of a obtained at the three temperatures for both H_3PO_4 and H_3AsO_4 were in the range 11 to 15 Å. When $a = 15$ Å, the reaction is "complete" when two water molecules are between the ions. The radius of a water molecule

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

is assumed 2.8 Å, while the radius of H_3O^+ and A^- are assumed 1.7 and 2.5 Å, respectively (15).

The same type of analysis was not carried out for the HSO_4^- k_r values listed in Table 1 as their uncertainty is quite large. A more realistic value of k_r for HSO_4^- can be obtained from the more reliable k_d value combined with values of K_a obtained by other methods. When such values of k_r are used, then the a value for HSO_4^- is in the range 11 Å (at 0 °C) to 17 Å (at 20 °C).

The k_r values for H_3PO_3, HIO_4, and H_2SeO_3 are unrealistically large, even in comparison to the H_3O^+–OH^- recombination rate ($k_r = 13 \times 10^{11}$ M^{-1} s^{-1}) (8). These high values may be due to the estimated ΔV^0 being substantially too high. A value of ΔV^0 of approximately -10 instead of -16 cm^3 mol^{-1} would bring the k_2 values down to normal size. The model used to interpret the data may also be at fault. For example, HIO_4 could be present in part in other forms, such as H_5IO_6, $H_4IO_6^-$, $H_3IO_6^{2-}$ (22).

Only for the system HSO_4^- is it possible to compare the above results with those of other workers. Eigen (1) estimated the value of k_r to be 10^{11} M^{-1} s^{-1} and k_d to be 1.5×10^9 s^{-1}. These values are directly comparable to the values 8.4×10^{10} M^{-1} s^{-1} and 1.4×10^9 s^{-1} obtained in this study taking the experimental value of k_d and the literature value of K_a. Irish and Chen (4) obtained a value of 6.4×10^{11} M^{-1} s^{-1} for k_r, but considerably higher concentrations were used in this Raman study. The value of k_r for acetic acid as obtained from a field jump technique (7) is of a similar size as the values reported here for inorganic acids, 7.2×10^{10} M^{-1} s^{-1}.

Conclusions

Experimental data of excess ultrasonic absorption *vs.* concentration in dilute (<0.1 M) solutions of medium-strong inorganic acids can be interpreted with success in terms of the proton-transfer equilibrium present. The experimental curves can be fitted satisfactorily by a two parameter equation. If the ΔV^0 for the equilibrium is known, the absolute values for the rate constants k_r, k_d can be calculated. Without knowledge of ΔV^0, only relative values, *i.e.* K_a, can be obtained.

Experimental data for 6 such acids has been obtained and interpreted to obtain K_a values, and rate constants where ΔV^0 values are available. The K_a values obtained are in reasonable agreement with the literature values for H_3PO_4 and H_3AsO_4 at 3 temperatures and for H_3PO_3 with one of the 3 literature values available at 20 °C. Agreement of the K_a values of HSO_4^-, HIO_4, and H_2SeO_3 with literature values is poorer. In the first case it is most probably due to incomplete consideration of activity coefficient effects, while in the latter cases it may well be due to inaccurate literature values.

The temperature dependence of the k_r values yields reasonable values for the activation energy of the proposed diffusion-controlled reaction. Absolute values of k_r indicate a reaction distance parameter of approximately 15 Å for H_3PO_4, H_3AsO_4, and HSO_4^- indicating that the recombination reaction is essentially complete when the ions are within 2 water molecules of each other. Values of k_r for H_3PO_3, HIO_4, and H_2SeO_3 are unrealistically high when the ΔV^0 value for H_3PO_4 is assumed for them. This may be due to a ΔV^0 for these acids considerably different from those measured for other acids or due to an inadequate model for the equilibrium.

A reanalysis of the ultrasonic data on availability of more accurate thermodynamic data can result in more accurate absolute values of k_r and k_d for such systems. Such an approach seems as promising as the extension of ultrasonic studies to higher frequencies, where sufficiently precise measurements in such acidic systems have not been made as yet.

Laser-induced Transient Bleaching of Trapped Electrons in Alkali Halide Single Crystals

ROGER MAY AND DAVID C. WALKER

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received January 12, 1973

F-center electrons in KBr and KI crystals at room temperature are almost totally bleached during the intense light pulse from a Q-switched ruby laser. Recovery of the absorbance is largely complete within microseconds of the end of the pulse such that net loss of trapped electrons, which would result in permanent bleaching, is negligible ($\phi < 10^{-2}$). Transient bleaching seems to result from both a loss of F-centers to form F′-centers and saturation of optical transitions for both the F and F′ bands. Comparisons of transient bleaching effects at 633, 1152, and 694 nm for KBr and KI strongly imply that the trapped electron absorption bands in crystals arise from single optical transitions which are homogeneously broadened. The rate at which the ground state of the F-center is repopulated following laser photolysis is of the order of 10^{-9} s and is very much slower than the analogous process in hydrated electrons. Results are also presented for additively colored and γ-induced F-centers and for F- and F′-centers bleached by ruby laser pulses at low temperatures.

Les électrons du centre F des cristaux de KBr et KI sont presque totalement décolorés à la température ambiante par la lumière intense pulsée d'un laser au rubis Q. L'absorbance retrouvée est quasiment complète à quelques microsecondes de la fin de la pulsation de sorte que la perte nette en électrons piégés, résultant d'une décoloration permanente, est négligeable ($\phi < 10^{-2}$). La décoloration transitoire semble résulter à la fois des pertes en centre F pour former F′ et de la saturation des transitions optiques pour les deux bandes F, F′. Les comparaisons des effets de décoloration transitoire à 633, 1152, et 694 nm pour KBr et KI impliquent fortement que les bandes d'absorption des électrons piégés dans les cristaux proviennent de transitions optiques simples, élargies de façon homogène. La vitesse à laquelle l'état fondamental du centre F est repeuplé dans la photolyse laser, est de l'ordre de 10^{-9} s, c'est à dire beaucoup plus lente que le processus analogue pour les électrons hydratés. Les résultats ont été également présentés pour d'autres couleurs, pour les centres F et F′ décolorés par laser au rubis pulsé aux basses températures.

Introduction

The nature of optical absorption bands of electrons trapped in crystals (*viz.* F-centers) or low temperature amorphous solid (*viz.* e_t^-) has been the subject of much experimental and theoretical investigation. Several photobleaching studies using low intensity illumination have been reported on F-centers (1, 2) and trapped electrons in glasses (3). In those experiments, measurements were made of the net bleaching effects (spectral shifts and quantum yields for electron loss) for the permanent changes resulting from photobleaching.

The application of short, high intensity light pulses from Q-switched ruby lasers has afforded a new perspective to such investigations since it permits very short-lived transient effects to be studied. Mahr (ref. 1, p. 243) has reviewed a series of experiments which employed a Q-switched ruby laser to photolyse F-centers in alkali halide crystals at liquid N_2 temperatures and to follow the relaxation processes occurring *after* the light flash, but with a time resolution which did not permit submicrosecond events to be studied. It has been shown, in this laboratory, that electrons solvated in liquid water at room temperature do not show non-linear absorption during 20 ns ruby laser pulses; thereby indicating a very short lifetime ($< 6 \times 10^{-12}$ s) for the photoexcited state of the hydrated electron when photolyzed at its absorption band maximum (4).

It has been our aim to employ ruby laser photolysis to reveal the nature and origin of optical absorption bands of trapped and solvated electrons, to decide whether the excited state is bound or free, and if the band is homogeneously or heterogeneously broadened. A preliminary account of some of our observations has recently been published (5).

In this paper we describe experiments on the laser photolysis of F-centers (electrons trapped at anion vacancies) in single crystals of potassium bromide and iodide *at room temperature* and

F′-centers (electron pairs trapped at anion vacancies) in crystals of potassium bromide and chloride at low temperatures. Several studies of transient bleaching effects of F-centers at low temperatures (typically 80 °K and lower) have been reported previously (ref. 1, p. 243, 6, 7, 8). For instance, Swank and Brown (6) showed that a comparatively long-lived (μs) relaxed excited state of the F-center existed at 80 °K and that the lifetime decreased sharply with increasing temperature so that it could not be measured by them at temperatures >110 °K. In addition Hirai *et al.* (7) studied the formation and decay of F-centers following nanosecond pulse radiolysis and concluded that some electrons were trapped via the relaxed excited state at 80 °K in crystals containing anion vacancies.

In order to answer fully the questions itemized above, it would be preferable to conduct nanosecond flash photolysis at various wavelengths appearing in different regions of the absorption band of one type of trapped electron. However, suitable lasers are not available at high enough powers and, in order to utilize a high power ruby laser to maximum advantage, we selected various media in which the 694 nm ruby laser line appeared in different regions of F and F′ absorption bands. It can be seen in Fig. 1 that for the F-center in KBr at room temperature 694 nm is on the low energy side of λ_{max} and in KI 694 nm is at the F-band maximum. At 77 °K the F-center in KI can be selectively bleached and has been the subject of previous study (ref. 1, p. 243). Similarly F′-centers in KBr and KCl can be selectively bleached at reduced temperatures (where they are stable).

In this study we have used low power c.w. helium/neon lasers, affording lines at 632.8 and 1152 nm, as sources of analyzing light for kinetic photometry. Study of Fig. 1 will show that these laser lines are conveniently positioned to interrogate the behavior of F- and F′-centers both during and immediately after ruby laser photolysis.

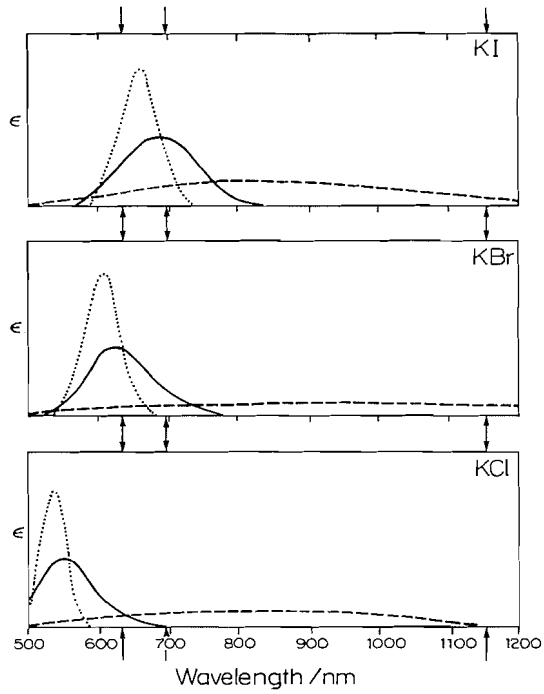

FIG. 1. Representative absorption spectra of F- and F′-centers for KCl, KBr, and KI crystals at various temperatures. ε is the relative extinction coefficient. Solid lines are F-centers at ~298 °K, dotted lines are F-centers at 77 °K and dashed lines are F′-centers at 77 °K. The arrows indicate the wavelengths of the lasers employed, 694, 633, and 1152 nm.

Experimental

Production of F-centers

Single crystals of KBr and KI (Harshaw) of thicknesses varying from 0.25 to 2 cm were polished on opposite faces. For the majority of the experiments described below, F-center coloration to selected absorbances was achieved in these crystals by γ-irradiation in a ^{60}Co source at room temperature. F-center concentrations $\leq 6 \times 10^{16}$ centers cm^{-3} were used throughout. For other experiments (*vide infra*) the crystals were additively colored with potassium vapor in a dual temperature furnace (ref. 2, p. 34). Prior to laser photolysis experiments F-center concentrations in both types of colored crystals were estimated from spectrophotomeric measurements using Smakula's equation and tabulated values of refractive index and oscillator strength (1, 2).

Laser Photolysis

Laser photolysis was performed on the apparatus shown schematically in Fig. 2. The ruby laser (TRG 104A, nominally 1 J of λ = 694.3 nm light) was triggered by shorting contacts on a leaf-type light shutter, E (Ilex). A bleachable dye cell was employed as a Q-switch to produce a 20 ns pulse (FWHM) with maximum intensities of 2×10^{26} photon cm^{-2} s^{-1}. A small fraction of the ruby laser pulse was reflected by a quartz plate M onto a silicon pin photodiode, T (Hewlett Packard, Type 5082-4203, operated at a reverse bias of 20 V) to yield a trigger signal, synchronous with the ruby pulse, for the two oscilloscopes O_1, O_2 (Hewlett Packard, Type 183; Tektronix 7904 with 7A16 and 7B92 plug-in units).

The intensity of 694.3 nm light incident on the sample S was varied by positioning, at *a*, a combination of four spectrophotometric cells C containing aqueous copper sulfate solutions. These solutions could not be bleached significantly at the intensities employed and hence acted

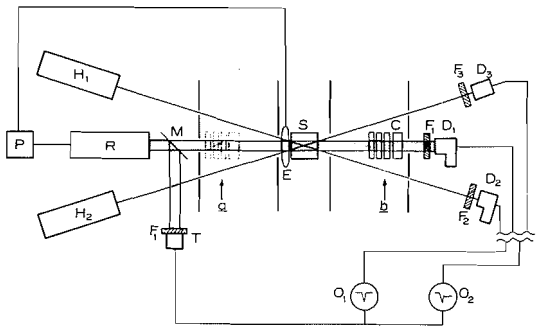

FIG. 2. Schematic diagram of apparatus. S, sample (for low temperature experiments, contained in a Dewar vessel); R, ruby laser head; P, ruby laser power supply, triggered by E; E, leaf-type light shutter; H_1, He/Ne laser, 633 nm; H_2, He/Ne laser, 1152 nm; M, quartz plate; T, Si photodiode (HP 5082–4203) acting as trigger for oscilloscopes; D_1, detector (694 nm), Hamamatsu R213 photomultiplier; D_2, detector (633 nm), R.C.A. 1P28 photomultiplier; D_3, detector (1152 nm), Philco Ford L 4521 Ge photodiode; O_1, O_2, oscilloscopes, Tektronix 7904, Hewlett–Packard 183; F_1, F_2, F_3, narrow band-pass interference filters, as per text; C, Four spectrophotometric cells containing concentrated aqueous solutions of $CuSO_4$ as per text, which could be positioned at either *a*, ahead of S, or *b* behind S.

as linear attenuators. The remaining $CuSO_4$ cells were positioned at *b* such that, in the absence of non-linear absorption by the sample at S, the incident light intensity on the photomultiplier D_1 (Hamamatsu R213) would be the same for identical pulses. The four cells employed had absorbances at 694 nm of 0.5, 1.0, 1.5, and 3.5. Filter F_1 consisted of a 694.3 nm narrow band pass interference filter and neutral density filters of total absorbance, $A = 2.5$.

Ruby laser light which was scattered by the sample and light attenuators was many times more intense than conventional analyzing light sources could cope with, despite the use of four light baffles shown in Fig. 2. To overcome this difficulty, two low power c.w. helium/neon lasers, H_1 (Spectra Physics, Type 132, 2 mW at 632.8 nm) and H_2 (Optics Technology, Type 233, ~2 mW at 1152 nm) placed at angles of about 15° to the ruby laser axis, were employed to provide monochromatic probe beams for kinetic photometry. The use of these c.w. lasers imposed an obvious limitation on spectral investigations but possessed the advantages that kinetic observations could be readily made *during* as well as after the ruby laser pulse and that their pencil beams could be easily directed through only the photolyzed volume element of sample. Even so both detectors D_2 (R.C.A. 1P28 photomultiplier) and D_3 (Philco Ford germanium photodiode, type L 4521) had to be shielded from scattered light by filters F_2 (*four* narrow band pass interference filters, 632.8 nm) and F_3 (1152 nm narrow band pass interference filter and two thicknesses of Kodak Wratten Filter No. 87A). The light shutter, E, was kept open for only 1/100*th* of a second to make the total exposure of the sample to He/Ne laser light trivial compared to that delivered by a ruby laser pulse.

In any particular run, two of the three signals (from D_1, D_2, and D_3) were selected and monitored separately on the oscilloscopes O_1 and O_2. Oscilloscope traces were photographed using Polaroid cameras.

For experiments conducted at reduced temperatures, the sample S was contained in a Dewar vessel with transparent windows. This was either filled with filtered liquid nitrogen for experiments at 77 °K, or alternatively, cold dry nitrogen, boiled from a reservoir of liquid nitrogen, was flowed into the Dewar at various rates such that photolysis could be carried out at selected temperatures between 77 and 300 °K. Crystal temperatures were measured by a copper/constantan thermocouple using a standard potentiometer.

A sample of F-centers at 77 °K was obtained by simply immersing a room temperature irradiated KI crystal in liquid nitrogen. F′-centers were produced *in situ* in KBr and KCl crystals by photolysis of the F-band at reduced temperature with a suitably filtered 30 W projector lamp (9). Crystal temperatures of 123 and 183 °K were used for the experiments on F′-centers in KBr and KCl, respectively, the F′-centers being stable at these temperatures.

Control Experiments

Control experiments were performed on stable solutions of organic dyes which have been shown to exhibit non-linear absorption of 694.3 nm light (10, 11). In this way synchronization of the firing sequence was established and the fast time response of the photoelectric detection systems demonstrated.

Figure 3 shows oscilloscope traces obtained when an aerated $\sim 10^{-5}$ *M* solution of vanadyl phthalocyanine in 1-chloronaphthalene was photolyzed. This solution had respective absorbances at 633 and 694 nm of 0.47 and 1.98 (in a 1 cm path length cell) as determined in a spectrophotometer. Trace (*a*) shows the ruby pulse pro-

file under non-bleaching conditions (*i.e.* all the copper sulfate cells C at position *a*, peak incident 694 nm light intensity at S of 6×10^{19} photon cm^{-2} s^{-1}) and (*b*) the profile observed when the ruby beam was unattenuated at the sample S (all cells C in position *b*, maximum incident 694 nm light intensity of 2×10^{26} photon cm^{-2} s^{-1}). The increased signal observed in (*b*) represents a change in transmission from 0.011 to 0.34 which can be expressed as the "fraction bleached", $(A^0 - A)/A^0 = 0.77$ (where A is the absorbance at high incident intensity and A^0 the absorbance under "normal" spectrophotometric conditions, equivalent to all $CuSO_4$ attenuators being at *a*). Trace (*c*) was taken simultaneously with (*b*) and shows the transient effect monitored at 633 nm. The fraction bleached at 633 nm at the pulse maximum was 0.30 and this loss of absorption was observed to repair on a timescale slightly longer than the ruby pulse.

An aerated 10^{-5} *M* solution of methylene blue in water was similarly photolyzed. This solution had $A^0_{694\ nm} = 0.35$ and $A^0_{633\ nm} = 0.97$. Under similar conditions as Fig. 3*a*, *b*, and *c* the fractional bleaching was found to be 0.78 at 694 nm (at the pulse maximum) and 0.57 at 633 nm (at the end of the pulse). As Fig. 3*d* shows, the recovery of 633 nm absorption after the pulse took place on a much longer timescale than for vanadyl phthalocyanine.

Results

The data given in Fig. 4 show the transmitted pulse intensity at the pulse maximum (monitored by D_1) as a function of incident ruby pulse intensity for two irradiated KI crystals having initial absorbances at 694 nm of 0.45 and 1.0. It can be seen that at high pulse intensities the samples are extensively bleached. Similar observations were made with KBr crystals. The inset to Fig. 4 displays observed ruby pulse profiles for the case, (*1*), of low incident ruby intensity, where there is no bleaching, and the case, (*2*), of high incident intensity. The extent of bleaching, narrowing of the pulse and delay of the maximum transmission are evident from comparison of these traces.

Simultaneous monitoring at 633 nm yielded traces such as those presented in Fig. 5. Both frames of Fig. 5 show superpositions of several traces taken with different ruby pulse intensities (see legend). At low light intensities, $\lesssim 10^{23}$ photon cm^{-2} s^{-1}, *only* permanent bleaching of the F-band occurs, the quantum yield of which is very small, $< 10^{-2}$. At intermediate intensities *all* the photobleaching during the pulse lasts for tens of nanoseconds thereafter. At the highest intensities available there is essentially *complete* bleaching during the pulse, of which only ~70% persists after the pulse. The fraction persisting is independent of light intensity once >70%

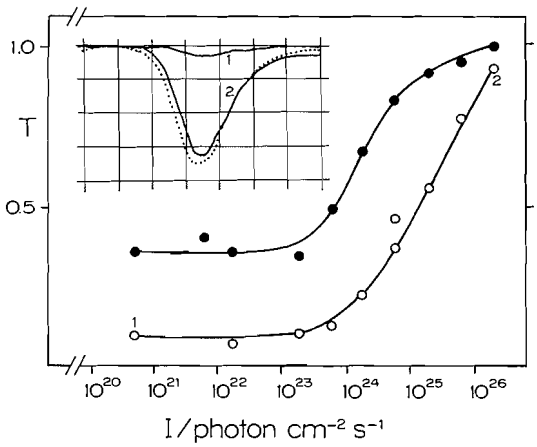

FIG. 4. Transmittance of ruby laser pulse measured at pulse peak at various intensities incident on sample of F-centers in KI crystal at ~295 °K for $A_{694}{}^0 = 0.45$ (solid circles) and $A_{694}{}^0 = 1.0$ (open circles). Inset shows oscilloscope tracings for points 1 and 2 on Fig. 4. The dotted line indicates the profile of incident ruby pulse. Vertical: 10 mV per division, horizontal: 10 ns per division.

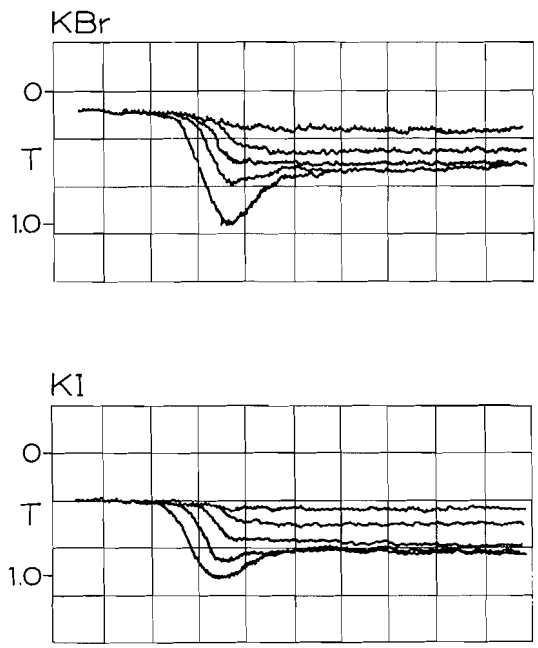

FIG. 5. Oscilloscope tracings showing the transmittance of KI and KBr at 633 nm for five different intensities of ruby light incident upon the crystals (2×10^{23}, 6×10^{23}, 6×10^{24}, 6×10^{25}, and 2×10^{26} photon cm^{-2} s^{-1} for KI and 2×10^{24}, 6×10^{24}, 2×10^{25}, 6×10^{25}, and 2×10^{26} photon cm^{-2} s^{-1} for KBr; in both cases progressing downwards.) Initial absorbance at 694 nm of KI was 1.0 and KBr was 0.5. Vertical: 50 mV per division, horizontal: 10 ns per division.

bleaching during the pulse has been achieved. This persistent portion recovers with an initial first-order half-life of 0.4 and 7.5 μs for KBr and KI, respectively. However, this repair of absorption does not obey first or second order rate equations for the whole period of recovery.

Similar data to that described above have been obtained for samples with various initial absorbances (at 694 nm) from 0.25 to 1.0 and arising from thick (20 mm) or thin (5 mm) crystals of KBr and KI at low and high F-center concentrations. The extent of transient bleaching processes was evidently not strongly dependent on either absorbance of the sample (at 694 nm) or on F-center concentration.

In order to compare bleaching phenomena at different wavelengths it is convenient to express bleaching by the function $(A^0 - A)/A^0$, termed fraction bleached, which is independent of the extinction coefficient at the different wavelengths. Figures 6 and 7 collate pertinent data for KI and KBr, respectively. For both crystals it can be seen that during the pulse peak the fraction bleached at 633 and 694 nm are essentially coincident. In KBr, F-centers are 50% bleached by a light flux of ~20 photons per F-center, whereas bleaching sets in at lower intensities for KI where the corresponding 50% bleaching value was ~10 at a comparable F-center concentration.

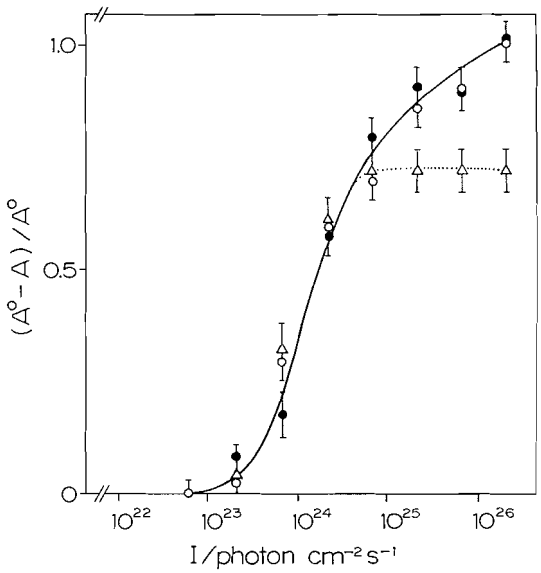

FIG. 6. Fraction bleached, $(A^0 - A)/A^0$, as a function of incident ruby laser intensity, for KI $A_{694}{}^0 = 1.0$. (A^0 is the absorbance at low intensity and A the absorbance at intensity I.) ○, 694 nm at pulse peak; ●, 633 nm during ruby laser pulse peak; △, 633 nm at the end of the ruby laser pulse.

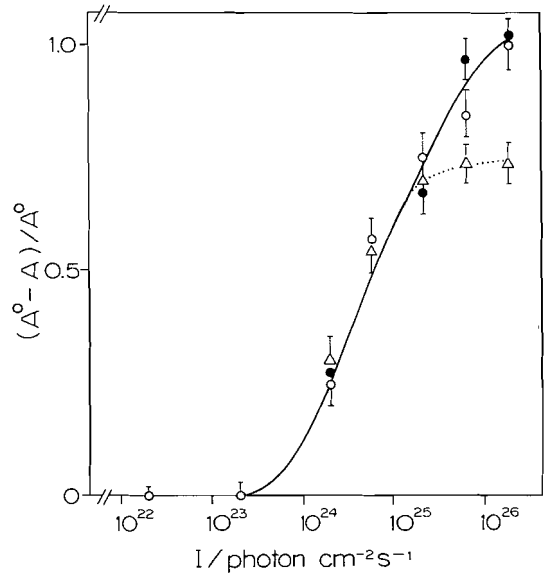

FIG. 7. Fraction bleached, $(A^0 - A)/A^0$, as a function of incident ruby laser intensity, for KBr $A_{694}{}^0 = 0.5$. ○, 694 nm at pulse peak; ●, 633 nm during ruby laser pulse peak; △, 633 nm at the end of the ruby laser pulse.

Transient effects were also monitored at 1152 nm. As Fig. 8 demonstrates, it was found that the ruby pulse induced transient absorption in crystals of KI at 1152 nm. (Analogous results were obtained with KBr.) Some of this absorption appeared during the ruby pulse and some "grew in" over a period of about 1 μs after the pulse.[1] As suggested by a comparison of Fig. 8*c* with Fig. 8*b* the decay of this transient absorption is kinetically coupled to the rate of recovery of F-center absorption at 633 nm. Although at ruby intensities less than $\sim 10^{24}$ photon cm^{-2} s^{-1} the small signals observed at 1152 nm defied actual quantitative comparison with transient

[1]This growing-in of absorption after the pulse cannot be attributed to a significant slow component in the detector's response (as noted in general for Ge detectors (17), because, in several cases, only instantaneous or stepwise changes are observed, see Fig. 9*d* for instance. Furthermore, it cannot arise from concurrent F-band fluorescence at 1152 nm (8) because, in a repeat experiment with the 1152 nm laser switched off, no signal was detected by the photodiode, D_3. Our experimental arrangement was designed to minimize scattered ruby light and consequently had a very low efficiency for observing any fluorescence.

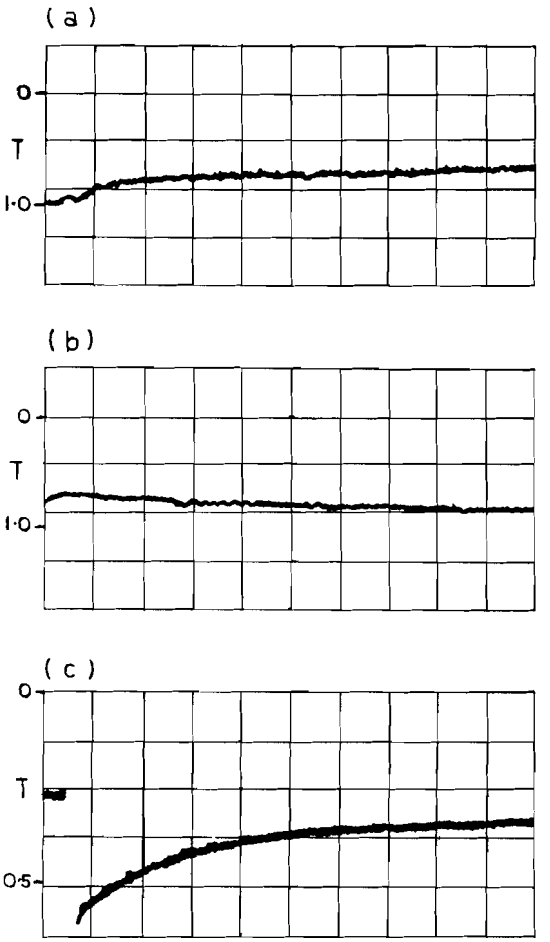

FIG. 8. Oscilloscope traces showing transient changes in transmission in KI at 1152 and 633 nm with cells C in position *b*. (*a*) Absorption created at 1152 nm by ruby pulse, vertical: 5 mV per division, horizontal: 50 ns per division; (*b*) same as (*a*) except horizontal scale is 2 μs per division; (*c*) transient effects at 633 nm monitored simultaneously with (*b*), vertical: 10 mV per division, horizontal: 2 μs per division.

signals at 633 nm, it appeared that the production of end-of-pulse absorption at 1152 nm was a similar function of intensity as the end-of-pulse bleaching at 633 nm.

Laser photolysis of potassium doped crystals of potassium iodide (5 mm thick, initial absorbance at 694 nm, $A_{694}{}^{0} = 0.48$) and potassium bromide (5 mm thick, $A_{694}{}^{0} = 0.10$) produced transient bleaching phenomena which were indistinguishable from the effects reported above for γ-irradiated crystals.

Several low temperature experiments were also performed. A KI crystal containing F-centers ($A_{694}{}^{0} = 0.33$) was exposed to ruby pulses at 77 °K. This caused bleaching at 633 nm only *during* the pulse and this bleaching repaired (see Fig. 9*a*) in a first order manner with a lifetime of 1.4 μs. This recovery rate is in agreement with an earlier observation (ref. 1, p. 243, 12).

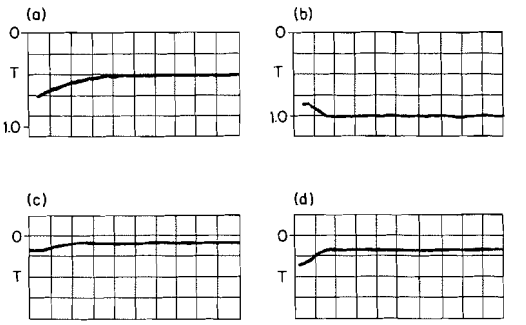

FIG. 9. Oscilloscope traces showing transient effects at low temperatures in KI, KCl, and KBr: (*a*) photolysis of F-centers in KI crystal at 77 °K monitored at 633 nm, vertical: 20 mV per division, horizontal: 1 μs per division; (*b*) photolysis of F′-centers in KCl crystal at 183 °K, monitored at 633 nm; (*c*) photolysis of F′-centers in KBr crystal at 123 °K, monitored at 633 nm; (*d*) photolysis of F′-centers in KBr crystal at 123 °K, monitored at 1152 nm. For (*b*), (*c*), and (*d*) vertical: 5 mV per division, horizontal: 50 ns per division.

A KCl crystal containing F′-centers at 183 °K was also subjected to laser photolysis. Figure 9*b* shows the transient effect observed at 633 nm. It can be seen that essentially all the absorbance which was initially present at this wavelength was bleached during the ruby pulse and this was permanent bleaching. Similar observations were made between 120 and 220 °K, the temperature range studied. No transient effects were observed at 1152 nm. Also the low initial absorbance at 694 nm would have imparted large errors to estimates of bleaching at 694 nm and thus transmitted ruby pulse profiles were not monitored in these experiments.

A sample of F′-centers in KBr was also subjected to ruby laser photolysis at 123 °K. As Fig. 9*c* and *d* show there was a production of absorbance at both 633 and 1152 nm during the ruby pulse. This production occurred only during the pulse and these changes of absorbance were permanent.

Discussion

A primary observation from the above results is that very similar bleaching phenomena during

the pulse peak were observed at 633 and 694 nm for F-centers in both KI and KBr crystals at room temperature. Since 633 nm is on the peak of the KBr F-band but on the high energy tail for KI, whereas 694 nm is on the low energy tail for KBr but on the peak for KI, it follows that the coincidence of the bleaching during the pulse strongly suggests that these bands consist entirely of one optical transition which is homogeneously broadened. This is in agreement with theoretical studies (ref. 1, p. 54) in which the ground and excited states are described by 1s and 2p wave functions, respectively. The fact that bleaching sets in at lower intensities for KI than for KBr is qualitatively consistent with the higher extinction coefficient at 694 nm of the F-band in KI.

A second striking effect observed is that, although transient bleaching occurs at comparatively low light fluxes, only a very small fraction of this results in permanent bleaching. In fact, permanent bleaching was so small it was barely detectable after one ruby pulse. However, an estimate of the quantum yield for permanent bleaching of $\phi \lesssim 10^{-2}$ was made for KBr and KI crystals by measuring the net change in transmission at 633 nm caused by several ruby pulses and by calculating the photons absorbed by subtracting the total transmitted light from the total incident light.

Whereas permanent bleaching of F-centers by ruby pulses was insignificant, transient bleaching was prominent. This means that the deexcitation processes leading to the repopulation of the ground state are comparatively slow. It is clear that the transient effects observed cannot be accounted for simply in terms of a 2-level energy scheme involving absorption, stimulated emission and deexcitation processes, because: (*i*), the data shown in Figs. 6 and 7 do *not* fit eq. 1 which may be derived for such a scheme (4),

$$[1] \qquad A^0 - A = 2\varepsilon I_i(1 - 10^{-A})10^3/k_{21}$$

where I_i is the incident intensity (in einstein cm^{-2} s^{-1}) and k_{21} the first order rate constant describing all processes other than stimulated emission by which the excited state is deexcited to the ground state; and (*ii*), the induced absorbance at 1152 nm and the post-pulse effects at 633 nm indicate the involvement of at least one additional transient state. However, some indication of the timescale of the deexcitation processes may be inferred in the following way, and is worthwhile doing for comparison with other types of stabilized electron states.

Considering only ruby laser intensities at which the fraction bleached is very small, say ~ 0.05, then the depletion of the ground state is trivial and the photo-excited state may be regarded as having a low photo-stationary concentration during the pulse peak. This situation approximates to the 2-level scheme to which eq. 1 applies. Taking data for KI from Fig. 6, $(A^0 - A)/A^0 = 0.05$ at $I = 2 \times 10^{23}$ photons cm^{-2} s^{-1} for which $A^0 = 1.0$ and $\varepsilon_{694} = 1.2 \times 10^5$ M^{-1} cm^{-1}, one evaluates k_{21} to be 1.4×10^9 s^{-1}. Furthermore, under these conditions the sample had absorbed $\sim 1.8 \times 10^{15}$ photon cm^{-2} up to the mid-pulse, whereas there were 5×10^{15} F-centers cm^{-2} in the light beam. Thus, 5% bleaching set in when there were ~ 0.36 photons absorbed per F-center per cm^2; which means that the quantum yield for transient bleaching of the ground state was *ca.* 0.14. This then implies that processes which lead to other transient states, and which compete with the direct deexcitation of the excited state, have smaller rate constants than $\sim 0.14k_{21}$, *i.e.* $< 2 \times 10^8$ s^{-1}.

Evidently the rate at which the ground state of the F-center electron in KI at room temperature is repopulated, following photolysis by 694 nm light, is more than two-orders of magnitude slower than the analogous processes in the case of the hydrated electron in liquid water at room temperature (4). Also, this mean lifetime of $\sim 0.7 \times 10^{-9}$ s is long enough to represent spontaneous radiative decay in the case of the crystals, as judged by their absorption band. Comparable data can be derived for KBr, where the higher light intensity required to reach 0.05 bleaching arises simply from its smaller ε_{694}.

The additional transient species involved, which is responsible for the transient absorption at 1152 nm and for some of the absorption at 633 nm immediately at the pulse end, is probably the F′-center. The spectra of F′-centers have been established at reduced temperatures (9) and included in Fig. 1. It can be seen that F′-centers also absorb 694 and 633 nm light. These centers are unstable at room temperature and spontaneously degrade into F-centers. Consequently, we propose that F′-centers are involved as transient species in these experiments. The photolyses at low temperatures show that F′-centers may also be bleached by ruby laser pulses, so that both their formation and bleaching must be considered in the mechanism of the overall photo-bleaching processes.

A plausible energy level scheme, which qualitatively explains the three photobleaching processes monitored at 633 nm, is shown in Fig. 10. (The F-band manifold of this scheme has been postulated previously (1, 2).) Levels 1 and 2 are respectively the 1s and 2p levels of the F-center. The conduction band (level 3) may be populated thermally from the 2p state of the F-center and from the relaxed 2p state (not shown). The ground state of the F′-center (level 4) may be formed by capture of a conduction band electron by an F-center. The F′-center probably has no bound excited state (9). The various k's are the kinetic rate constants of conversion between the levels noted as subscripts. σ and ρ are the respective absorption cross sections of the F- and F′-centers at 694 nm. (We have included the possibility of stimulated emission for the (2p → 1s) transition of the F-center but a similar process between the conduction band and the F′-center is unlikely because of the density of states in the conduction band.)

At high ruby pulse intensities the near 100% bleaching corresponds to a total saturation of optical transitions of F and F′ electrons. Within a very short time after the end of the pulse electrons populate only the 1s levels of the F- and F′-centers, and the microsecond recovery processes are attributable to thermal decomposition of F′-centers to reform F-centers. At intermediate intensities the predominant process is the conversion of F- to F′-centers; *i.e.* k_{34} is significantly greater than k_{31} in accordance with Pick's observation that at temperatures above 150 °K an F-center has a significantly greater cross-section for capture of another electron than has a vacancy (13, ref. 2, p. 110).

It is of interest to note that the induced bleaching effects are indistinguishable between γ-irradiated crystals (which contain positive hole centers) and potassium doped crystals (which contain no hole bands). Consequently, electrons liberated from F-centers by the ruby light were not recombining with positive holes in the γ-irradiated crystals and the permanent bleaching (observed to have a low quantum yield) must arise from electrons being "lost" by other processes, such as the formation of stable electron aggregate centers.

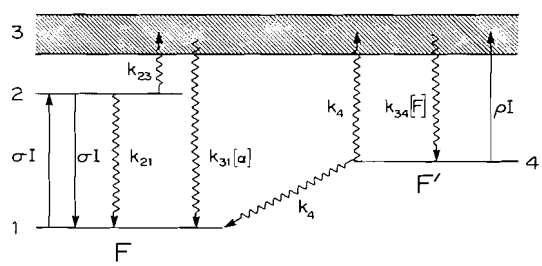

FIG. 10. Proposed energy-level scheme showing absorption and stimulated emission at 694 nm and first order rate constants for interconversion between states. (See text for details.)

Quantitative interpretation of the bleaching data in terms of the energy level scheme (Fig. 10) is complex. Since the transmitted ruby pulse is observed to be asymmetrically shaped with respect to the incident pulse, the system does not reach a photo-stationary state during the pulse so the peak transmitted intensities cannot be readily analyzed at high intensities (14).

A correlation of the loss of absorbance at 633 nm with the production of absorbance at 1152 nm can lead to an estimate of extinction coefficients of the F′-center at 1152 nm. For a particular irradiated KI crystal having an initial absorbance of 0.59 at 633 nm photolyzed with an unattenuated ruby pulse, the absorbance at the end of the pulse was 0.165 compared to a production of absorbance of 0.10 at 1152 nm. Let us assume that the extinction coefficients of the F′-center at 633 and 1152 nm are equal. (This is certainly approximately true at 77 °K (9) and hence, by analogy with the behavior of the F-center (Fig. 1), it is likely to be so at room temperature where, if anything, the spectrum will be broader and the extinction coefficient less wavelength dependent.) Then at the end of the pulse only ~0.065 units of absorbance are due to the F-center and hence ~89% of the F-center electrons were converted to F′-centers by the ruby pulse. If we take the F-center extinction coefficient at 633 nm to be $8.3 \times 10^4\ M^{-1}\ cm^{-1}$ at room temperature (obtained from the F-band spectrum using Smakula's equation, ref. 2), then we calculate the F′-center extinction coefficient at 633 nm to be $3.8 \times 10^4\ M^{-1}\ cm^{-1}$ at room temperature. This may be compared to the 77 °K value of 2.6×10^4 (obtained from ref. 9).

We have noted above that the optical transitions of the F′-center are saturated at high light intensities and indeed near 100% transmission of samples is seen at 633 nm. However, as Fig. 8*a* demonstrates, at comparable light intensities there is transient absorption at 1152 nm produced *during* the ruby pulse peak. This observation could have one of the following implications. Firstly, that the F′ band is heterogeneously

broadened (*i.e.* the overall band is a composite of several overlapping bands, only some of which are bleached by the pulse). This is contrary to theoretical predictions (9). Secondly, that other *unstable* centers, as well as F′, are absorbing at 1152 nm. This latter implication can also explain the high apparent F′ extinction coefficient which was obtained above. It is most likely that these centers are aggregates of the F-center. M and N bands must be ruled out because of their stability at room temperature, as must the unstable R-bands which one would predict not to absorb 1152 nm light (15). In fact, the most likely candidate is an ionized R_2 center, R_2^+, which has been observed by a phase sensitive detection technique in the c.w. laser photolysis of F-centers in KBr (16). The R_2^+ center is an ionized form of the R_2 center which in turn may be considered as an aggregate of two adjacent F-centers (2). The transient effects seen at 1152 nm at room temperature may thus be explained by the following reaction sequence;

$$[2] \qquad F + \alpha \rightleftarrows R_1, R_2^+$$

$$[3] \qquad F' + \alpha \rightleftarrows R_2$$

$$[4] \qquad \alpha + e \rightarrow F \qquad (k_{31})$$

$$[5] \qquad F + e \rightleftarrows F' \qquad (k_{34}/k_{43})$$

where α represents an anion vacancy. It is evident that processes 2 and 3 cannot be easily included in Fig. 10. During the ruby pulse electrons are lost from F-centers and the resulting anion vacancy may interact with F′- or remaining F-centers to form R and R^+ centers. These centers may decay by undergoing further aggregation steps which result in net bleaching of F-centers. Alternatively, these centers may decay by the reverse of processes 2 and 3 above. Indeed the low quantum yield for net bleaching strongly suggests that these latter reactions are predominant. The growth in absorption at 1152 nm immediately after the pulse is accounted for by the decay of R and R^+ centers. The non-first order decay of transient absorption (Fig. 8*b*) at 1152 nm is probably due to overlapping absorption of R_2^+ and F′-centers and the fact that the individual decay rates of R and F′-centers may each dominate at different times during the overall decay to reform F-centers.

The observations at low temperature may also be qualitatively described in terms of the energy level scheme in Fig. 10. At liquid nitrogen temperatures, thermal escape of electrons from the 2p level of the F-center, and from its relaxed state, to the conduction band is likely to be rather slow. Instead, the electrons may ultimately largely populate the relaxed excited state where they have a much longer lifetime (1.4 μs in KI) than at higher temperatures (ref. 1, p. 243, ref. 12).

Finally, the results of Fig. 9*b*, *c*, and *d* show that the F′-center in KCl and KBr at reduced temperature is permanently bleached by the ruby pulse. This is observed as loss of F′ absorption at 633 nm in KCl, and formation of F from F′ resulting in an increase of 633 nm absorption in KBr where $\varepsilon_F > \varepsilon_{F'}$. The increase in absorption at 1152 nm in KBr (Fig. 9*d*) would suggest that one or more F-aggregate centers, which are stable at this temperature, are also formed as a result of F′-photolysis.

We gladly acknowledge Dr. K. E. Rieckhoff for supplying a sample of vanadyl phthalocyanine; Dr. B. A. Saunders for experimental advice concerning additive coloration of crystals; and the Defence Research Board and National Research Council of Canada for financial support.

A Study of the Proton Nuclear Magnetic Resonance Spectra of Aryl and Mono- and Disubstituted *N*-Methylazoles

RICHARD NOEL BUTLER
Department of Chemistry, University College, Galway, Ireland

Received December 27, 1972

Proton n.m.r. spectra of 111 substituted azoles are compared. The influence of the azole ring on the chemical shifts of substituent phenyl protons is discussed. A correlation between *N*-methyl chemical shifts and the structural characteristics of the *N*-methyl group in mono- and disubstituted azoles is noted.

On compare les spectres r.m.n. du proton de 111 azoles substitués. On discute de l'influence de l'anneau du groupe azole sur les déplacements chimiques des protons appartenant à un substituant phényle. De même on note une corrélation entre les déplacements chimiques du groupe *N*-méthyle et les caractéristiques structurales du *N*-méthyle dans les azoles mono et disubstitués. [Traduit par le journal]

In recent years a collection of n.m.r. spectra of a wide range of azoles has been built up in separate studies of synthetic and other aspects of azole chemistry. These, when combined, provide useful structural information on the azoles. In this work the p.m.r. spectra of 111 substituted azoles are compared and discussed.

Arylazoles

The effects of the different azole systems on the proton resonances of a substituent phenyl group are summarized in Table 1. Fraser and Haque (1) have reported the upfield shift in the meta- and para-protons ($H_{m,p}$) of the phenyl ring and the accompanying downfield shift in the ortho protons (H_o) on changing a methyl group from the 1- to the 2-position of a methyl substituted-5-phenyltetrazole (compare compounds **5** and **10**, Table 1). The overall effect relative to benzene is considered to arise from a combination of ring anisotropy, nitrogen anisotropy, and an electron donating resonance interaction between the rings in compound **10** which is absent or very small in compound **5** (1–9). A comparison (Table 1) of the relative changes in the chemical shifts of the $H_{m,p}$ and H_o phenyl protons of the following pairs of compounds, **4** *vs.* **9**; **4** *vs.* **8**; **1** *vs.* **6**; **2** and **3** *vs.* **7** shows that this is a general effect in the azoles. In each case changing the *N*-methyl group from the β- to the γ-atom (relative to the atom to which the phenyl group is bonded) results in an upfield shift in the $H_{m,p}$ signal (column 5, Table 1, Part II) and a downfield shift in the H_o signal (column 4, Table 1, Part II). When the *N*-methyl group occupies the β-position, the interaction is lost or greatly diminished and the phenyl protons give a single signal only (compare compounds **1–5**).

The ortho deshielding phenomenon and its disappearance in β-methyl derivatives has been noted previously in substituted phenylpyrazoles (6–9) and also in 3-phenylpyridazines (10), 2,2′-bipyridyl (4, 5), and in aryl-triazines and tetrazines (3). The loss of the interaction has been ascribed to a loss of coplanarity between the rings (6–12) which causes a diminution of the anisotropic effects and a disruption of the resonance interaction. If, as expected, the extent of coplanarity loss is similar for the compounds **1–5** (Table 1, Part I), it is of interest to note the increased deshielding of the phenyl protons with successive replacement of —CH= by —N= in the heterocyclic ring. This probably reflects an increased electron-withdrawing inductive effect in the higher azoles with a possible contribution from nitrogen anisotropy in the case of the tetrazole **5**. Column 5 of Table 1, Part II, shows that the upfield shift of $H_{m,p}$ on going from a β- to a γ-substituted phenylazole also appears to undergo an increase with the number of nitrogen atoms in the ring, suggesting that the factors causing this shielding shift are stronger in the higher azoles. The downfield shift in H_o, which arises simultaneously, is, on the other hand, relatively insensitive to the number of nitrogen atoms in the ring, *e.g.* compounds **6–9**, suggesting that the ortho-deshielding arises from anisotropic effects with little, if any, contribution from the resonance interaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Since all of the compounds **6–10** contain an sp^2 nitrogen atom β- to the phenyl ring a special nitrogen anisotropic effect (including paramagnetic effects of the lone pair and a possible weak hydrogen bonding contribution (2–4)) must be included in the deshielding for these compounds. That such an effect contributes to the ortho-deshielding is suggested from a comparison of compounds **11–13** (Table 1), none of which contains an sp^2 nitrogen atom β to the phenyl ring but all of which contain a ring current. The special ortho-deshielding of compound **12** resulting from removal of the β-Me substituent in compounds **11** and **13** is considerably less than that of the compounds **6–10** while the $H_{m,p}$ shielding is comparable to that of the other diazoles. A comparison of the changes in the ortho-deshielding (column 4, Table 1, Part II) for the compounds **12** → **6–9** → **10** is of interest since it represents the following structural changes about the *C*-phenyl group, =CH—C(Ph)=CH— → —CH=C(Ph)—N= → =N—C(Ph)=N—. Each step involves replacing a β-CH= group by an sp^2 nitrogen atom and the relatively large deshielding for the first step probably reflects a gain in coplanarity as well as —N= anisotropy, whereas the second step, **6–9** → **10** may be an indication of the special contribution of —N= anisotropy. Hence the data in Table 1 suggest that the overall ortho-deshielding relative to benzene is made up of contributions from (*i*) an inductive effect varying with the number of nitrogen atoms in the ring (Table 1, Part I); (*ii*) a ring current effect, *ca.* 0.15 p.p.m. (the average value of the H_o deshielding of the compounds **6–9** less the deshielding due to one =N— atom (0.16 p.p.m.); (this is somewhat greater than the shift for compound **12** since the two β-CH= groups probably cause some loss of coplanarity between the rings), and (*iii*) a nitrogen anisotropic effect, *ca.* 0.16 p.p.m. for each =N— atom β to the phenyl ring (the difference between the average H_o deshielding for compounds **6–9** and compound **10**).

The correlations noted in Table 1 are for arylazoles where the phenyl group is attached to the azole ring at a carbon atom. It is possible that a different transmission of effects could obtain when the phenyl group is attached to the azole ring at a nitrogen atom. A complete set of data on directly comparable β-substituted and β-unsubstituted compounds for the full azole series where the phenyl group is bonded to a nitrogen atom is not readily available. A β-unsubstituted series of 1-*p*-nitrophenylazoles has,

TABLE 1. Chemical shifts (τ) of phenyl protons of arylazoles[a]

PART I:

[i]Differences from compounds **11** and **13**, the β-methyl isomers.

however, been studied (9). Shifts, which were compared directly with nitrobenzene and not with the non-coplanar β-substituted derivatives, gave a value of 0.1 p.p.m. for the ring current effect and 0.7 p.p.m. for the ortho-deshielding in molecules containing two sp^2 nitrogen atoms β to the *N*-phenyl group. This latter value was recognized as a "global" value containing all the effects of the $=\dot{N}-$ atoms and as such included the effects represented by the shifts in Table 1, Part I. Hence there is reasonable agreement between the data herein for *C*-phenylazoles and those reported for *N*-phenylazoles (9). This is best illustrated by using the conclusions from the present approach to predict the shifts for the *N*-phenylazoles and *vice versa*. Taking a ring current effect of 0.15 p.p.m. a deshielding of 0.16 p.p.m. for the effect of each β-sp^2 nitrogen atom and azole inductive effects from Table 1, Part I, (for diazoles 0.1 p.p.m., the average of compounds **1**, **2**, and **11**) gives the following calculated deshielding shifts for the ortho-protons of 1-*p*-nitrophenylazoles: pyrazole, 0.41 p.p.m. (observed (9), 0.40 p.p.m.); imidazole, 0.25 (0.09); 1,2,3-triazole, 0.51 (0.49); 1,2,5-triazole, 0.67 (0.80); 1,2,3,4-tetrazole, 0.68 (0.48). The agreement is reasonable since errors are expected in the values taken from Table 1, Part I, where the azole ring has a methyl substituent. Using the approach of Elguero *et al.* (9) to predict the ortho-deshielding, relative to benzene, of the compounds in Table 1 gives the following: compound **6**, calculated 0.45 p.p.m. (observed, 0.53); **7**, 0.45 (0.43); **8**, 0.45 (0.51);

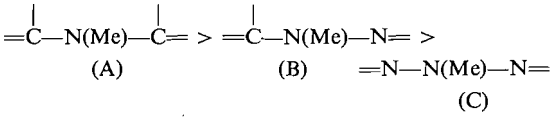
For personal use only.

9, 0.45 (0.47); **10**, 0.80 (0.86); **12**, 0.10 (0.13), a somewhat better agreement because the complexities of breaking down the "global" sp^2 nitrogen effect do not arise.

Comparison of the magnitudes of the shift differences in Table 1 suggests that anisotropic effects dominate the shifts in the lower azoles and that other effects, such as resonance and inductive effects, may make an appreciable contribution to shifts in the higher azoles, particularly the tetrazoles.

N-Methylazoles

The n.m.r. chemical shifts of *N*-alkyl groups are widely used for structural assignments of isomeric substituted azoles (13–27, 38–43). The *N*-methyl chemical shifts for 105 *N*-methylazoles, measured under similar conditions, are compared in Table 2. In general the τ value for *N*-methyl groups decreases with increasing number of nitrogen atoms in the heterocyclic ring. Within a particular class, the chemical shift (τ) of the *N*-methyl group decreases in the following order for the structure units



This relationship also applies in an approximate manner across the azole series for comparable compounds. A comparison of the *N*-methyl parent compounds **14** (A unit), diazoles **15** (A unit) and **22** (B unit), triazoles **43** and **48** (B units), **49** (A unit), **44** (C unit), tetrazoles **66** (B unit), **67** (C unit) exemplifies the trend. For *N*-methylpyrrole, **14**, and the diazole series, **15**–**42**, the *N*-methyl signal is above 6.0 τ except for compounds **19** and **26** which contain a NO_2 group interacting with the ring. For triazoles and tetrazoles containing the unit B, the *N*-methyl signal is generally between 5.8–6.0, and is less than 5.8 τ when the unit C is present. Exceptions occur, not unexpectedly, when a strongly activating group, *e.g.* NH_2, is near the *N*-methyl group. The relationship between the chemical shift and the structural units A, B, and C within a particular series is apparent from comparisons of the data in Table 2. For example, with tetrazoles the signal of the 1-alkyl isomer (B unit) is generally 0.15–0.35 p.p.m. upfield from that of the corresponding 2-alkyl isomer (C unit) and with 1,2,4-triazoles the signal of the 4-alkyl isomer (A unit) is 0.1–0.25 p.p.m. upfield from that of the corresponding 1- or 2-alkyl isomers (B units). (Since solvent effects are appreciable, *cf.* refs. 50 and 51, *e.g.* compound **53**, Table 2, comparisons should be confined to data measured in the same solvent.)

The decreased shielding of the *N*-methyl group for the structural series C < B < A probably reflects the greater electron-withdrawing characteristics of the —N= moiety over the —CH= moiety. Lynch[1] has observed a direct correlation between the electron density on the nitrogen atom and the chemical shift of the bonded methyl group (Table 3) which explains the trends noted herein. Electron densities were calculated by the simple HMO method (with α *N*-methyl = α + β, and α_N = α + 0.5β) or by the Wheland–Mann SCF method. Previously correlations have been reported between electron densities and (*i*) proton and ^{13}C chemical shifts of ring C—H groups in azoles (32–34, 50) and (*ii*) amino proton chemical shifts in amino-substituted azoles (23, 35, 36).

Limitations of the Structure — Chemical Shift Relationship

The relationship between the chemical shift of an *N*-methyl group and its appearance in an A, B, or C structural unit began to break down for trisubstituted azoles, the compounds in Table 2 being generally monosubstituted azoles and disubstituted azoles where one of the substituents is the *N*-methyl group. For example the *N*-methyl chemical shifts of 60 trisubstituted pyrazoles ranged between 5.72–7.02 τ and the specific values depended on the nature, type, and combination of substituents (7–9, 51). This is readily explained in terms of Lynch's correlation[1] since it is to be expected that increasing substitution will outweigh structural effects in governing electron densities in the ring. The order of shielding noted for the structural units A, B, and C will also be limited with compounds containing substituents which may interact more strongly with the *N*-alkyl group of one isomer than with that of the other. Thus, for example,

[1]Prior to the submission of this paper B. M. Lynch, Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia, had independently arrived at a direct correlation between calculated electron densities and *N*-methyl chemical shifts in azoles (Table 3). Professor Lynch, who was a referee, offered his data for inclusion in this paper.

TABLE 3. Correlation of methyl proton shifts in *N*-methylazoles with HMO and Wheland–Mann electron densities[a]

Species	NMe shift τ[b] Observed	Calcd. from HMO	Calcd. from W–M	q_{HMO}	q_{W-M}
1-Methylpyrrole	6.45	6.44	6.46	1.518	1.405
1-Methylimidazole	6.30	6.28_5	6.31_5	1.498	1.393
1-Methylpyrazole	6.19	6.16	6.18	1.482	1.382
4-Methyl-1,2,4-triazole	6.17	6.17	6.11	1.483	1.376
1-Methyl-1,2,4-triazole	6.00	6.03	5.98	1.466	1.365
1-Methyl-1,2,3-triazole	5.87	5.87	5.92	1.445	1.360
1-Methyltetrazole	5.73	5.80	5.73	1.437	1.344
2-Methyltetrazole	5.54	5.49	5.54	1.397	1.328

[a]Data and calculations of B. M. Lynch. See footnote 1.
[b]Slopes of linear regression lines:
Shift = $(-5.519 \mp 0.60) + (7.881 \pm 0.411)q_{HMO}$; standard deviation = 0.042 p.p.m.; correlation coefficient $r = 0.992$.
Shift = $(-10.367 \mp 0.67) + (11.976 \pm 0.49)q_{HMO}$; standard deviation = 0.033 p.p.m.; correlation coefficient $r = 0.995$.

we have noted (24) that with some 5-substituted 1- and 2-methyltetrazoles where the 5-substituent interacts strongly with the ring the chemical shifts of the 1- and 2-methyl groups are similar. In terms of the electron density correlation (Table 3), this implies that the electron density of the 1-N atom was decreased relative to that of the 2-N atom by the 5-substituent although local anisotropic effects could also contribute to such a phenomenon. Some of the compounds in Table 2 display similar effects which arise when substituents such as NO_2, NH_2 are present. For example the compounds **3**, **18**, **19**, **26**, **35**, **36**, **52**, and **72**, fit the general trends rather poorly although the A, B, C structural relationship still holds for directly comparable pairs. However, despite these limitations the trends noted herein will be of value for future structural assignment for isomeric derivatives of the higher azoles.

Rearrangements in the Diterpenoid Series. Part II. The Diazotization of Methyl 15-β-amino-13-isopropyl-17-noratis-13-en-18-oate

WILLIAM A. AYER AND PANDURANG D. DESHPANDE

Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1

Received January 22, 1973

Treatment of methyl 15-β-amino-13-isopropyl-17-noratis-13-en-18-oate (**1***b*) with sodium nitrite – acetic acid gives rise to a variety of products, including nitrated compounds and norketones. The structures of seven of the products have been established. The reaction of methyl 16-isopropylidene-7,17-secoacon-8(15)-en-18-oate (**2**) with nitrous acid and with dinitrogen tetroxide is described. A simple method for transforming isocyanates to primary amines is presented.

La réaction du méthylamino-β-15 isopropyl-13 noratis-17 ène-13 oate-18 (**1***b*) avec de l'acide acétique – nitrite de sodium donne lieu à plusieurs produits parmi lesquels on trouve des composés nitrés et des norcétones. Les structures de sept de ces produits ont été élucidées. La réaction du méthyl isopropylidene-16 secoacon-7,17 ène-8(15) oate-18 (2) avec de l'acide nitreux et du tétroxyde de diazote est décrite. Une méthode simple pour la transformation des isocyanates en amines primaires est décrite.

[Traduit par le journal]

Can. J. Chem., **51**, 2323 (1973)

In Part I of this series (1) we described the rearrangement of the tosylate **1***a*, which has an atisane skeleton, into the diene **2** which has an aconane skeleton. This rearrangement serves as a model for the proposed (2, 3) biosynthetic transformation of atisine-type alkaloids into alkaloids of the aconitine series. At the same time we have investigated the deamination of the amine **1***b* to see if this method of generating a carbonium ion at C-15 would also lead to rearrangement of the atisane skeleton to an aconane skeleton. This paper dsscribes the rather unexpected results of this latter investigation.

The amine **1***b* was prepared via the acid **1***c*, in turn prepared in 65% yield by Diels–Alder addition of acrylic acid to methyl levopimarate (**3**). Esterification of **1***c* with diazomethane gave the diester **1***d* of known (4) structure and stereochemistry. The transformation of acid **1***c* into the amine **1***b* proved more difficult than was anticipated. When the acid **1***c* was subjected to the conditions of the Schmidt reaction (5) only a small amount (*ca.* 10%) of basic material was obtained. The major product, isolated from the non-basic fraction, was a compound $C_{24}H_{35}NO_3$ to which structure **4** is assigned. The i.r. and n.m.r. spectra (see Experimental) are consistent with the structure, and treatment of the isocyanate **5**, prepared as described below, with concentrated sulfuric acid in chloroform gave compound **4**. It thus appears that acid-catalyzed cyclization of the intermediate isocyanate (arrows in **5**) occurs in preference to hydrolysis and decarboxylation under the conditions of the Schmidt reaction. Efforts to open the lactam ring in **4** by either acid- or base-catalyzed hydrolysis were unsuccessful. An attempt was made to open the lactam ring via the imino-ether **6** (6, 7), prepared by treating **4** with triethyloxonium fluoroborate. However, hydrolysis of **6** with either aqueous acetic acid or aqueous sulfuric acid led only to the regeneration of lactam **4**.

Failure of the Schmidt reaction to give good yields of the desired amine **1***b* prompted us to investigate the Curtius rearrangement (8) of the azide **1***e*. The acid **1***c* was transformed to the acid chloride and this was treated with a solution of sodium azide in acetone. The product consisted of a mixture of the acyl azide **1***e* (2140 cm^{-1}) and the isocyanate **5** (2260 cm^{-1}) as shown by the i.r. spectrum. When this mixture was heated briefly in benzene complete transformation to isocyanate **5** was effected. When the isocyanate **5** was chromatographed over silica gel it was transformed, in part, into the lactam **4**. Various attempts at acid-catalyzed hydrolysis also led primarily to the formation of lactam **4**, usually accompanied by small amounts (5–15%) of the desired amine **1***b*. Attempted hydrolysis under basic conditions gave a different neutral product. This compound was not investigated in detail, but is believed to

be the *sym*-urea **7**, since it showed bands in the i.r. at 3440, 1670, and 1500 cm^{-1}, characteristic (9) of such compounds. *sym*-Ureas are frequently encountered as byproducts in the hydrolysis of isocyanates (8).

In view of the problems encountered in the hydrolysis of the isocyanate we decided to explore a method for the transformation **5** → **1***b* which does not appear to have been exploited previously. Reduction of the isocyanate **5** with sodium borohydride in dimethoxyethane gave the *N*-formyl compound **1***f* in virtually quantitative yield. Acid-catalyzed hydrolysis of **1***f* then gave the amine **1***b* in 75% overall yield from the isocyanate **5**. The amine **1***b* was obtained as a viscous oil which was purified via the crystalline hydrochloride. Since the configuration of the isocyanate group in **5** is assured (retention of configuration expected in the Curtius rearrangement (8); the isocyanate is readily transformed to lactam **4**) and since neither the borohydride reduction nor the hydrolysis of the *N*-formyl compound should lead to inversion, the amino group in **1***b* may be assigned the *endo*-configuration.

With a satisfactory method available for the synthesis of the amine **1***b*, attention was now turned to a study of its deamination. Investiga-

tions of the deamination of *endo*-5-aminobicyclo[2.2.2]oct-2-ene (**8***a*) have shown (10, 11) that this compound rearranges in good yield to *exo*-bicyclo[3.2.1]oct-3-en-2-ol (**9**) in aqueous solution, and to a mixture of **9** and the corresponding acetate in glacial acetic acid. The amine **1***b* was diazotized under a variety of conditions (aqueous fluoroboric acid, aqueous hydrochloric acid, aqueous acetic acid, glacial acetic acid). In each case the nonbasic product was a mixture of several components as revealed by its spectroscopic (i.r. and n.m.r.) characteristics and t.l.c. behavior. When a solution of the hydrochloride of **1***b* in glacial acetic acid was treated with an excess of sodium nitrite, nonbasic material was obtained in about 70% yield. A colorless, crystalline product, $C_{23}H_{33}N_3O_8$, separated from an ether solution of the mixture in 12% yield. Early attempts to separate the remaining components of the mixture were unsuccessful. When the diazotization was conducted in aqueous acetic acid a complex mixture of products again resulted. After considerable experimentation a separation procedure was developed (see Experimental) which led to the isolation of seven different crystalline com-

pounds, including the compound $C_{23}H_{33}N_3O_8$ mentioned above. The molecular formulas of the products, together with their melting points, are listed in Table 1. The assignment of structure to these products is outlined first and then is followed by a discussion of the possible modes of formation.

Compound A, $C_{25}H_{30}O_4$, was assigned structure **10***a* on the following basis: i.r. and n.m.r. spectra indicated the presence of the carbomethoxyl and secondary acetoxyl groups, two methyl groups on saturated carbon (singlets at τ 9.16 (C-10 methyl) and 8.85 (C-4 methyl)), and two methyls on unsaturated carbon (broadened singlets at 8.46 and 8.37). The signal for the proton on C-15 (atisane numbering, see **1**) appeared as an octet with couplings of 9, 3, and 1.5 Hz. The coupling constants of 9 and 3 Hz are consistent with those observed (12) for *vicinal* protons in bicyclo[2.2.2]octane systems. The 1.5 Hz coupling is presumably a W-plan coupling with the *anti* proton on C-14. Methanolysis of **10***a* gave the alcohol **10***b* which on oxidation with Jones' reagent afforded the corresponding ketone, confirming the secondary nature of the hydroxyl function. Structure **10***a* was confirmed by degradation to the known (13) ketoolefin **11**. Ozonolysis of **10***a* gave ketone **12***a* which was hydrolyzed to the alcohol **12***b* and this in turn was transformed to the cathylate **12***c*. Pyrolysis of **12***c* at 240–250° gave the keto olefin **11**. Although we were unable to obtain a sample of **11** for direct comparison, the melting point and spectral properties agree well with those reported (13) for **11**. When compound **10***a* was treated with acetic acid saturated with hydrogen chloride the product showed t.l.c. behavior very similar to that of the known (1) acetate **13**. Although the n.m.r. spectrum indicated that the product was a mixture, the major component gave rise to signals identical with those observed for **13**. This is regarded as confirmatory evidence that the acetoxyl group in **10***a* is *endo* and located at C-15.

TABLE 1. Products isolated after treatment of amine **1***b* with nitrous acid

Product	Formula	M.p. (°C)
A	$C_{25}H_{30}O_4$	145–146
B	$C_{22}H_{32}O_5$	218–222
C	$C_{25}H_{37}NO_6$	130–131
D	$C_{20}H_{28}O_3$	132–133
E	$C_{23}H_{33}N_3O_8$	176–178
F	$C_{23}H_{32}N_2O_6$	136–137
G	$C_{23}H_{33}NO_5$	Amorphous

Compound B, $C_{22}H_{32}O_5$, on first consideration seemed rather anomalous in that the n.m.r. spectrum revealed the presence of only two *C*-methyl groups (singlets at τ 9.14 and 8.84) indicating the loss of two *C*-methyl groups during the deamination process. It was soon recognized however that compound B is identical with the ketoacetate **12***a* obtained on ozonolysis of **10***a*.

Compound C, $C_{25}H_{37}NO_6$, which was isolated in only *ca.* 3% yield, is assigned structure **14** on the basis of the following considerations. Although the highest peak in the mass spectrum appeared at *m/e* 400 and corresponded to an ion $C_{25}H_{36}O_4$, elemental analysis established the presence of nitrogen and is consistent with the molecular formula given. The presence of a nitro group was deduced from the i.r. spectrum which showed absorption bands at 1540 and 1340 cm^{-1}, indicative of a nitro group located on saturated carbon (14). The n.m.r. spectrum of **14** was very informative. The carbomethoxyl and acetoxyl methyls give rise to singlets at τ 6.35 and 8.06, respectively, and the proton *geminal* to the acetoxyl group appears as a doublet of doublets (J = 8 and 2 Hz) at τ 5.36. The C-10 methyl appears at τ 9.34 (shielded by the C_{13}—C_{14} double bond (15)) and the C-4 methyl appears at τ 8.83, while the remaining two methyl groups give rise to singlets at τ 8.24 and 8.28. Since the C—C double bond must be located at 13,14-position (shielding of the C-10 methyl, olefinic proton at τ 4.15) the low chemical shift value for these methyls indicates that the nitro group is located on the same carbon.[1]

As mentioned earlier, the highest mass peak in the mass spectrum appears at *m/e* 400 and corresponds to the loss of HNO_2 from the molecular ion. Elimination of HNO_2 from tertiary nitro compounds upon electron impact is known to be a facile process (17). Attempts to bring about thermal elimination of nitrous acid from **14** were unsuccessful as were attempts to remove the nitro function by hydrogenolysis.

Compound D, $C_{20}H_{28}O_3$, was also isolated in very small amounts and in common with compound B (**12***a*) showed signals for only two

[1]The methyl groups of 2-nitropropane resonate at τ 8.45 (16).

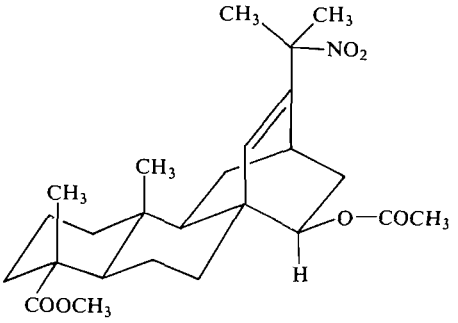
For personal use only.

methyl groups in its n.m.r. spectrum. The presence of a conjugated ketonic function was indicated by absorption in the i.r. at 1670 and 1625 cm^{-1} and in the u.v. at 243 nm. Comparison of compound D with the unsaturated ketone **15** prepared previously (1) revealed their identity.

The determination of the structures of compounds E, F, and G proved to be the most difficult, but was facilitated by the finding that the colorless compound E, which contains



14

19 X = H

three nitro groups, readily eliminates the elements of nitrous acid when chromatographed over basic alumina to give the yellow compound F, $C_{23}H_{32}N_2O_6$, containing only two nitro groups. Our attention was thus first directed to compound F, to which we assign structure **16***a*. The i.r. spectrum shows absorption bands attributable to nitro groups on both saturated (1545, 1350 cm^{-1}) and unsaturated (1500, 1320 cm^{-1}) carbon (14). The u.v. spectrum, λ_{max} 229 and 348 nm, is consistent with the presence of the nitrodiene chromophore.[2] In the n.m.r. spectrum, the isopropyl methyls resonate at τ 8.24 and 8.20, similar to those in **14**, the C-4 methyl at 8.54, and the C-11 methyl[3] at 9.32. Molecular models indicate that the C-11 methyl lies in the shielding cone of the C_7-C_8 double bond, and that the C-4 methyl is proximate to the nitro group at C-7, perhaps explaining its abnormally low chemical shift. The olefinic proton at C-15

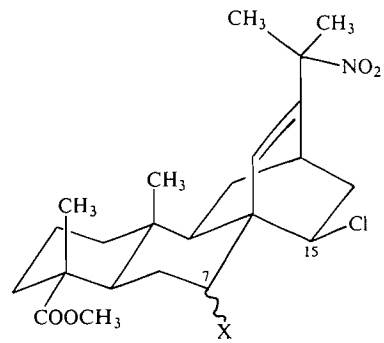
[2]5-Methyl-2-nitro-2,4-hexadiene absorbs at 230 nm (ε 7700) and 335 nm (ε 11 700) (18).

[3]As in the previous paper (1), compounds such as **15** and **16***a*, containing an aconane skeleton, are numbered as derivatives of aconane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

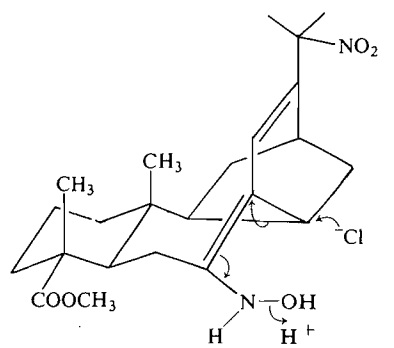
gives rise to a sharp singlet at τ 2.80, the low chemical shift again perhaps attributable to a deshielding effect of the nitro group at C-7. Catalytic hydrogenation of **16***a* over platinum in ethyl acetate led to a mixture of products from which it was possible to separate a dihydro compound, **17**, in which the C_7-C_8 double bond has been saturated. In this compound the i.r. spectrum shows absorption for nitro groups on saturated carbon only (1540 and 1350 cm^{-1}). In the n.m.r. the signal for the C-11 methyl appears at τ 8.95 and the olefinic proton appears at 4.69. A one-proton multiplet at τ 5.28 is attributable to the proton on C-7. Catalytic hydrogenation of **16***a* over platinum-in-ethanol in the presence of hydrochloric acid gave an 85% yield of basic material, indicating reduction of a nitro group or groups to the amino form. Acetylation of the basic fraction and crystallization from methanol gave a compound $C_{25}H_{41}NO_3$, formulated as the *N*-acetyl compound **18**. Observations pertinent to the structural assignment include the appearance in the n.m.r. spectrum of signals due to an isopropyl group, lack of olefinic absorption, evidence for the presence of a secondary amide, and the similarity of the chemical shifts of the various *C*-methyl groups in **18** to those in the known compound **19** (1).

Compound **18** was the major product (55% yield) isolated from the catalytic hydrogenation (followed by acetylation) in ethanol–HCl. In addition two other crystalline compounds were isolated, each in about 10% yield. One of these had spectroscopic properties very similar to **18** (the mass spectra are virtually identical) and is believed to be the C-7 epimer of **18**. The other minor product has the molecular formula $C_{25}H_{37}N_2O_5Cl$ and is assigned structure **20***a* in which the atisane skeleton has been regenerated from the aconane skeleton. In a parallel series of experiments in which the crude basic product from the catalytic hydrogenation was treated with methanesulfonyl chloride – pyridine rather than acetylated the methanesulfonamide **20***b* (along with the sulfonamides corresponding to **18**) was isolated.[4] The mass spectrum of **20***b* did not show a parent peak. The molecular formula $C_{24}H_{37}N_2O_6SCl$ was inferred from the composition of the ion of highest mass (*m/e* 470, exact mass corresponding to $C_{24}H_{37}NO_4{}^{32}S^{35}Cl$, $M^+ - NO_2$) and supported by combustion analysis. The i.r. spectrum showed absorption bands attributable to sulfonamide (3360, 1140 cm^{-1}), carbomethoxyl (1725 cm^{-1}), and nitro (1545, 1350 cm^{-1}) groups. The n.m.r. spectrum was very similar, except for the signals associated with the sulfonamide group (τ 6.90 (SO_2—CH_3), 5.97 (C-7 proton), 5.07 (N*H*), to that of compound **14**. Pertinent signals include (corresponding signals of **14** in brackets) C-10 methyl τ 9.30 (9.34), C-4 methyl 8.82 (8.83), methyls *geminal* to nitro 8.22 and 8.26 (8.22 and 8.24), carbomethoxyl 6.29 (6.35), C-14 proton 4.15 (4.15), C-15 proton 5.72, J = 8.5 and 3 Hz (5.36, J = 8 and 2 Hz). One possible pathway from **16***a* to **20***c* involved reduction to the hydroxylamine **21** and rearrangement as indicated by the arrows in **21**. Reduction of the resulting imine leads to **20***c*. Alternatively rearrangement



20

a X = $NHCOCH_3$
b X = $NHSO_2CH_3$
c X = NH_2



21

[4]Since the sulfonamide **20***b* proved more amenable to isolation and purification than amide **20***a*, the majority of the structural studies on this compound were carried out on the sulfonamide. The results obtained with the amide parallel those with the sulfonamide (see Experimental).

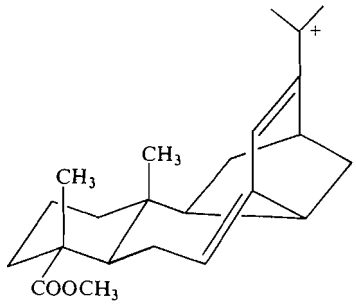
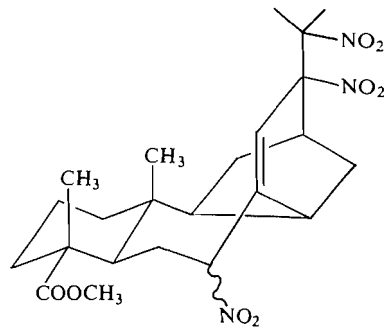
22



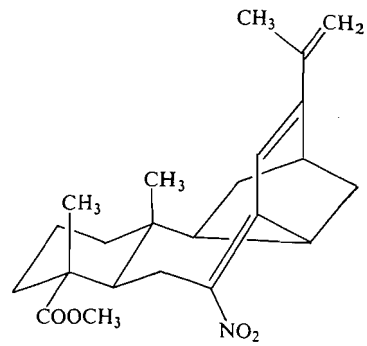
23

could occur at the *C*-nitroso stage leading to the C-7 oximino compounds which could be reduced to **20***c*.

Compound E is assigned structure **22**. When E is chromatographed over basic alumina it loses the elements of nitrous acid and compound **16***a* is formed. The molecular formula was deduced from a consideration of the mass spectrum and from the results of elemental analysis. The highest peak in the mass spectrum appears at *m/e* 433, corresponding to an ion resulting from loss of NO_2 from the molecular ion (mw 479). The base peak in the mass spectrum is at *m/e* 341 ($C_{23}H_{33}O_2$ by h.r.m.s.) and corresponds to an ion such as **23** formed by elimination of three molecules of nitrogen dioxide. The olefinic proton (C-15) appears in the n.m.r. as a broadened singlet at τ 3.92 and is not coupled to the proton geminal to the nitro group at C-7 (τ 5.12). This leads us to favor structure **22** over structure **24** which otherwise accommodates most of the available information. The chemical shift of the C-11 methyl group (τ 8.93) is similar to that in compound **17** (τ 8.95) as is that for the C-4 methyl (τ 8.63 in **22**, 8.69 in **17**) which also supports the location of the double bond at the 15,16-position rather than the 8,15-position. The two remaining methyl groups resonate at τ 8.21, consistent with the presence of a nitro group on the same carbon. Further evidence for the structure of the trinitro compound comes from the alternative mode of formation described below.



24



25

Compound G, $C_{23}H_{33}NO_5$, is formulated as **16***b*. Its spectroscopic characteristics are very similar to those of **17** except that **16***b* shows hydroxyl absorption in the i.r. and does not show absorption for a nitro group on saturated carbon. In the n.m.r. the methyl groups geminal to the hydroxyl appear at τ 8.53 and 8.58 (8.20 and 8.24 in **16***a*). When the alcohol **16***b* was subjected to hydrogenation over platinum in the presence of acid and the resulting basic product acetylated compound **18**, previously derived from **16***a*, was obtained.

Attempted dehydration of **16***b* with thionyl chloride in methylene chloride gave the chloro compound **16***c* which on hydrogenation–acetylation also furnished **18**. Alcohol **16***b* was successfully dehydrated to the yellow triene **25** using *p*-toluenesulfonic acid in benzene. The nitrotriene showed absorption maxima in the u.v. at 258 and 382 nm. The presence of the isopropenyl group is indicated by olefinic protons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

at τ 4.80 and 4.59 and vinylic methyl at 8.00 in the n.m.r. as well as by a band in the i.r. spectrum at 900 cm^{-1}. The remaining spectral data are consistent with **16***a*. The formation of the conjugated triene **25** provides important evidence that the substituted isopropyl group in **16***a* and *b* is located on the chromophoric group in those compounds.

With the structures of the many and varied (**10***a*, **12***a*, **14**, **15**, **16***a*, **22**, **16***b*) products of the "deamination" of amine **1***b* reasonably well established we turn now to a consideration of their possible mode of formation.[5]

It has frequently been observed that the products resulting from treatment of a primary amine with nitrous acid differ from those resulting from related solvolytic reactions (19). The amine **8***a*, however, on diazotization undergoes rearrangement to give **9** (10, 11), behavior similar to that observed when the tosylate **8***b* is solvolyzed. In Part 1 of this series it was shown that the tosylate **1***a* undergoes facile rearrangement to the diene **2**. Although the diene **2** could not be detected among the deamination products, three of the nitro compounds, **16***a*, *b*, and **22**, possess the rearranged skeleton of **2**. Since nitration of olefins has been observed under diazotizing conditions (*e.g.*, the formation of ω-nitrocamphene from camphene and sodium nitrite – acetic acid (20)) we decided to investigate the possibility that the rearranged nitro compounds arise via the diene **2**. Indeed when an acetic acid solution of diene **2** was treated with an excess of sodium nitrite the trinitro compound **22** was isolated by direct crystallization in 13% yield. In view of this it was of interest to see whether the use of a limited amount of sodium nitrite in the deamination of **1***b* would lead to the diene **2**. Accordingly amine **1***b* in aqueous acetic acid was treated with 1 equiv of sodium nitrite. Nonbasic material was isolated in *ca.* 16% yield. Crystallization from ether afforded the trinitro compound **16***b*. Chromatography of the residue after crystallization gave the dinitro compound **16***a* plus a noncrystalline material rich in the nitroalcohol **16***b* as indicated by i.r. and t.l.c. The diene **2** could not be detected. It thus appears that the diene **2** may be formed during the nitrous acid treatment but if so its further reaction with the reagent to give nitrated materials competes successfully with deamination of the amine.

Nitrous acid as such is not known to be involved in addition reactions of olefins. It can however give rise to a variety of oxides of nitrogen (NO, NO_2, N_2O_3, N_2O_4) (21) which are reactive towards olefins (22, 23). Dinitrogen tetroxide, for example, adds to olefins to produce *vicinal* dinitro compounds, nitronitrites and, in the presence of oxygen, nitronitrates. The nitronitrites are unstable and readily hydrolyzed to nitroalcohols (22, 23). Similar nitro compounds, along with nitronitroso adducts, are obtained from olefins and nitrous anhydride (23). Although no nitronitroso adducts were isolated, it is possible that they are formed and then oxidized by oxygen to dinitro compounds. Since complete product balance was not obtained, these may also have been formed but have escaped detection. In the following discussion, which is intended to be illustrative rather than definitive, dinitrogen tetroxide is portrayed as the attacking species. The same products may be derived from nitrous anhydride addition, followed by oxidation.

1,4-Addition[6] of N_2O_4 to the diene **2** leads to the dinitro compound **26***a* and nitronitrite **26***b*. Elimination of nitrous acid from **26***a* gives the diene **27***a*. 1,2-Addition of N_2O_4 to **27***a* can give rise to the trinitro compound **22**, which on elimination of nitrous acid gives **16***a*. A similar elimination–addition–elimination sequence on **26***b* leads (via **27***b*) to the nitronitrite **16***d* which after hydrolysis gives nitroalcohol **16***b*. The formation of ketone **15** may be rationalized in terms of 1,2-addition to give nitronitrite **28***a*. Hydrolysis to give **28***b* followed by a reverse Henry reaction (24) (arrows in **28**) either during the alkaline work-up or during the chromatography over alumina would lead to **15**. Homolytic cleavage of nitrite **28***a* could also lead to **15**.

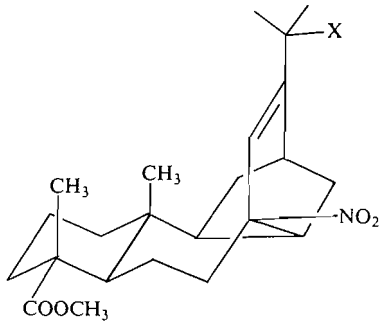
At this stage we decided to see whether any of the postulated intermediates could be detected in the reaction of the diene **2** with dinitrogen tetroxide itself. When an acetic acid solution of the diene was treated with an excess of N_2O_4

[5]Since in many cases the complexity of the product mixtures formed meant that good material balances were not obtained, the following mechanistic speculation is intended only as an aid to the interpretation of the results. For the sake of brevity, usually only one possible pathway is discussed.

[6]An initial 1,2-addition and a subsequent 1,4-addition is also possible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the trinitro compound **22** was obtained in 24% yield. Chromatography of the remaining material provided the dinitro compound **16***a* in 13% yield. The only other product which could be isolated in pure form was the nitroacetate **14**, *in which the bicyclo[2.2.2]octane system had been regenerated from the bicyclo[3.2.1]octane system.* Thus the experiment undertaken to gain information regarding the intermediates between the diene and compounds **22**, **16***a*, and **16***b* failed in this respect, but it did suggest that at least some of the products of the original "deamination" which possess the bicyclo[2.2.2]-system may be derived via the diene **2**. As illustrated in Scheme 1, the nitronitrite **28***a* is a possible intermediate in the formation of both **14** and the ketoacetate **12***a*. Loss of the nitrite group as a nitrite ion (the same intermediate carbonium ion may be generated by electrophilic attack of NO_2^+ on the diene **2**) and rearrangement as indicated by the dashed arrows in Scheme 1 leads to **14**. Fragmentation of **28***a* as indicated by the full arrows (Scheme 1) could give rise to the enol nitrite **29** which on hydrolysis would give **12***a*.



26

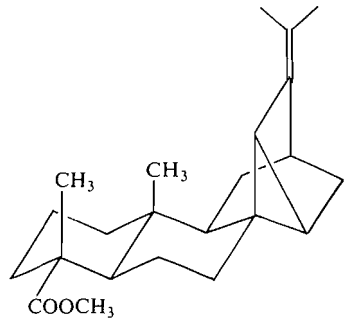
28

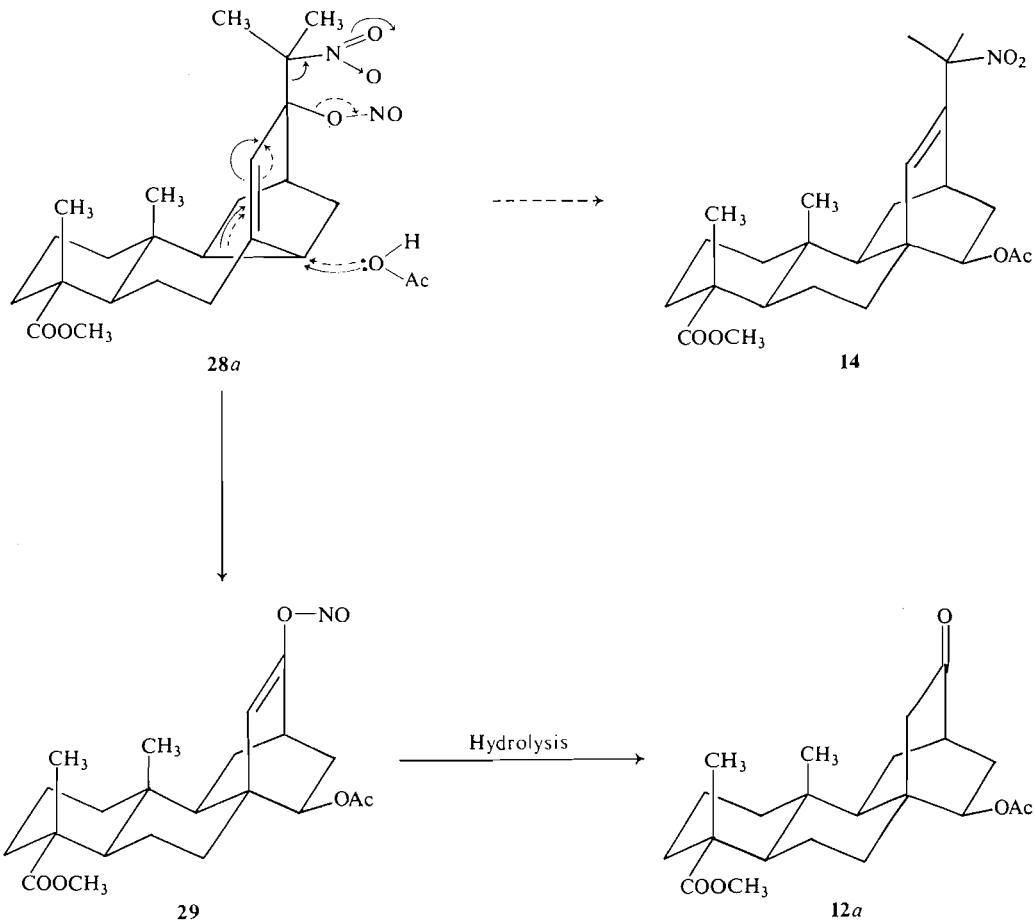
a R = NO
b R = H



30

The formation of a compound **10***a* is difficult to explain unless it results from acid-catalyzed rearrangement of the diene **2** either by non-terminal protonation at C-15 followed by rearrangement, or by protonation at the isopropylidene group, rearrangement to **13**, and subsequent migration of the double bond in **13**. When the diene **2** was treated with acetic acid – perchloric acid at room temperature, a mixture of the double bond isomers **10***a* and **13***a* was obtained. However, none of **13** could be detected in the product resulting from treatment of amine **1***b* with sodium nitrite – acetic acid. The intermediacy of a vinylcyclopropane (**30**) in the formation of **10***a* from **1***b* cannot be excluded, although this would also involve a (presumably) unfavorable non-terminal protonation in the ring-opening step.

In conclusion we draw attention to the fact that the "deamination" of amine **1***b* takes a much different course than that observed with



SCHEME 1

the simpler bicyclooctene **8***a*. It does seem probable, however, that the diene **2** is the first-formed product. It is possible that its highly strained nature makes it very susceptible to further reaction, accounting for our failure to isolate **2** directly from the deamination.

Experimental

Melting points were determined on a hot-stage and are uncorrected. Unless otherwise stated i.r. spectra were determined in carbon tetrachloride, u.v. spectra in 95% ethanol, and n.m.r. spectra in deuteriochloroform with tetramethylsilane as internal standard. Mass spectra were determined on an A.E.I. MS-2H or A.E.I. MS-9 mass spectrometer and are reported as *m/e* (relative intensity). High resolution measurements (h.r.m.s.) were performed on the latter instrument. Alumina, unless otherwise specified, means basic alumina of activity II–III (Brockmann scale). Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°. Microanalyses were performed by G. Gygli, Toronto, and D. Mahlow of this department.

*Methyl 15-β-Carboxy-13-isopropyl-17-noratis-13-en-18-oate (**1c**) (3)*

A solution of methyl levopimarate (10 g, 32 mmol, prepared by esterification of levopimaric acid (25) with ethereal diazomethane) and acrylic acid (20 ml) in benzene (50 ml) was heated under reflux for 9 h. The solution was cooled, concentrated, and the residue was dissolved in ether, dried, and concentrated to give a white solid (12 g). The white solid was dissolved in acetone (60 ml), cyclohexylamine (4.5 ml) added, and the resulting precipitate filtered and washed with cold acetone to give the cyclohexylamine salt of **1***c* (10 g). The salt was suspended in ether (200 ml) and shaken with 10% phosphoric acid (100 ml). The ether layer was washed (H_2O), dried ($MgSO_4$), and concentrated to give acid **1***c* (7.8 g, 20 mmol, 62.5%): m.p. 166–167° (from Skellysolve B); i.r. 3200–2400 (carboxyl OH), 1720, 1700 (C=O of acid, ester) cm^{-1}; n.m.r. τ 9.38 (s, 3, C-10 methyl), 8.95 (d, 6, J = 7 Hz, isopropyl methyls), 8.83 (s, 3, C-4 methyl), 6.28 (s, 3, methoxyl), 4.57 (s, 1, H-14), −0.95 (s, 1, COO*H*).

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.23; H, 9.28. Found: C, 74.53, H, 9.10.

the known diester **1***d* (4) identical (m.p., mixed m.p., i.r.) with an authentic sample.

*Schmidt Reaction on Acid **1**c. Isolation of Lactam **4***

A solution of hydrazoic acid (10 ml) in chloroform was added to a solution of acid **1***c* (1.94 g, 5 mmol) in chloroform (25 ml). The mixture was warmed (40°) and concentrated sulfuric acid (3 ml) was added with stirring during a 2.5 h period. The reaction mixture was diluted with water and the layers separated. The aqueous fraction was basified (Na_2CO_3), and extracted with ether. The ether extract was washed (H_2O), dried (Na_2SO_4), and concentrated to give basic product (0.215 g, 11%). The chloroform fraction was washed (H_2O), dried ($MgSO_4$), and concentrated to give nonbasic product (1.41 g, 72%). This was treated with ethereal diazomethane and a portion (0.91 g) of the product chromatographed over silica gel (36 g). Elution with benzene (100 ml) gave 298 mg of an unidentified material. Elution with benzene–ether (1 :1, 200 ml) gave lactam **4** (421 mg) which crystallized from methanol as colorless plates, m.p. 237–238°: i.r. (Nujol) 3360 (NH), 1705 (C=O of ester), 1690 (C=O of lactam) cm^{-1}; n.m.r. τ 9.21 (s, 3, C-10 methyl), 8.85 (s, 3, C-4 methyl), 8.33 (s, 3, isopropylidene methyl), 8.18 (s, 3, isopropylidene methyl), 6.34 (s, 3, methoxyl), 3.86 (s, 1 N*H*).

Anal. Calcd. for $C_{24}H_{35}NO_3$: C, 74.80; H, 9.09; N, 3.63. Found: C, 74.63, 74.32; H, 9.30, 9.20; N, 3.55.

*Attempted Hydrolysis of the Lactam **4** via the Imino-ether **6***

A solution of lactam **4** (102 mg) in methylene chloride (3 ml) was added to a solution of triethyloxonium fluoroborate (165 mg) in methylene chloride (2 ml) and the mixture stirred overnight, then diluted with 10% potassium carbonate solution and the layers separated. The aqueous layer was extracted with methylene chloride, the methylene chloride fractions combined, washed (H_2O), dried ($MgSO_4$), and concentrated to give imino-ether **6** (91 mg); i.r. ($CHCl_3$) 1710 (C=O of ester), 1640 (C=N) cm^{-1}; n.m.r. τ 9.27 (s, 3, C-10 methyl), 8.88 (s, 3, C-4 methyl), 8.80 (t, 3, J = 7 Hz, OCH_2CH_3), 8.42 (s, 3, isopropylidene methyl), 8.37 (s, 3, isopropylidene methyl), 6.48 (s, 3, methoxyl), 6.00 (d, 2, J = 7 Hz, OCH_2CH_3).

A solution of imino-ether **6** (91 mg) in 10% acetic acid – dioxane (1 :1, 20 ml) was heated under reflux for 4 h, then left at room temperature overnight. The solution was concentrated and the residue dissolved in ether. The ether solution was washed (10% Na_2CO_3, H_2O), dried ($MgSO_4$), and concentrated to give lactam **4** (86 mg).

Hydrolysis of imino-ether **6** with 1 *N* sulfuric acid – dioxane (1 :1) also gave lactam **4**.

*Transformation of Isocyanate **5** to Lactam **4***

Concentrated sulfuric acid (1.5 ml) was added dropwise to a warm (40°) stirred solution of isocyanate **5** (540 mg) in chloroform (25 ml). The reaction mixture was then diluted with water and extracted with chloroform. The chloroform extract was washed (H_2O), dried (Na_2SO_4), and concentrated. The product was treated with ethereal diazomethane and chromatographed over silica gel. Elution with benzene–ether (1 :1, 200 ml) gave lactam **4** (72 mg).

*Curtius Reaction on Acid **1**c. Formation of Isocyanate **5***

A solution of acid **1***c* (10 g), thionyl chloride (5 ml), and dry benzene (100 ml) was heated under reflux for 5 h. Excess thionyl chloride was removed by repeated codistillation with benzene, and the solution was concentrated to give the acid chloride (10 g): i.r. 1800 (C=O of acid chloride), 1720 (C=O of ester) cm^{-1}.

To a cooled (5–10°), stirred solution of acid chloride (10 g) in acetone (100 ml) was added during 1 h a solution of sodium azide (2 g) in water (6 ml). The reaction mixture was stirred at 5–10° for one additional hour, then allowed to warm to room temperature and stand for 2 h. The reaction mixture was diluted with water. The oil which separated was taken up in benzene and the benzene removed at reduced pressure. The product thus obtained was a mixture of azide **1***e* and isocyanate **5**: i.r. 2260 (N=C=O), 2140 (N=N=N), 1720 (C=O of ester) cm^{-1}. The mixture was dissolved in dry benzene (60 ml) and the solution was heated under reflux for 3.5 h. Concentration of the solution gave isocyanate **5**: i.r. 2260 (N=C=O), 1720 (C=O of ester) cm^{-1}. Isocyanate **5** (3.6 g) was chromatographed over silica gel (120 g). Elution with benzene (200 ml), benzene–ether (3 :1, 100 ml), ether (100 ml), and ether–chloroform (1 :1, 50 ml) gave isocyanate **5** (2.4 g). Elution with chloroform (200 ml) and chloroform–methanol (9 :1, 200 ml) gave a mixture of isocyanate **5** and lactam **4** (0.33 g). Elution with chloroform–methanol (4 :1, 200 ml) gave lactam **4** (0.8 g).

*Acidic Hydrolysis of Isocyanate **5***

A solution of isocyanate **5** (1.02 g), concentrated hydrochloric acid (25 ml), and dimethoxyethane (40 ml) was heated under reflux for 3 h. The solution was cooled, neutralized (Na_2CO_3), and concentrated. The residue was dissolved in ether, extracted with dilute hydrochloric acid, washed (H_2O), dried, and concentrated to give nonbasic material (0.61 g). Crystallization from methanol gave lactam **4** (0.08 g).

The acidic extract and the washings were combined, basified (Na_2CO_3), and extracted with ether to give amine **1***b* (0.17 g, 17%), identical (i.r., t.l.c.) with that obtained by hydrolysis of the *N*-formyl compound, **1***f*.

*Alkaline Hydrolysis of Isocyanate **5***

A suspension of isocyanate **5** (720 mg), 50% aqueous potassium hydroxide (10 ml), and benzene (10 ml) was heated under reflux for 2 h, then left at room temperature overnight. The suspension was diluted with benzene and the layers separated. The benzene layer was extracted with dilute hydrochloric acid, washed (H_2O), dried ($MgSO_4$), and concentrated to give nonbasic material (656 mg, 91%). A portion of the product (265 mg) was chromatographed over silica gel (14 g). Elution with benzene–ether (1 :1) and crystallization from methanol gave a compound believed to be the *sym*-urea **7** (150 mg): m.p. 158–161°; i.r. 3440 (NH), 1720 (C=O of ester), 1670, 1500 (C=O of *sym*-urea) cm^{-1}.

The acidic extract and washings were combined, basified (Na_2CO_3), and extracted with ether. The ether extract gave 15 mg (2%) of basic product.

*Methyl 15-β-Amino-13-isopropyl-17-noratis-13-en-18-oate (**1**b)*

A solution of isocyanate **5** (10 g) in dimethoxyethane (60 ml) was added to a stirred suspension of sodium borohydride (2.5 g) in dimethoxyethane (400 ml). After

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

24 h the reaction mixture was concentrated and the residue treated with dilute hydrochloric acid (1 *N*, 120 ml). The product was extracted with ether, the ether extract washed (H_2O), dried ($MgSO_4$), and concentrated to give the *N*-formyl compound **1***f* (10 g): i.r. 3435, 3400 (NH), 1715 (C=O of ester), 1680 (C=O of amide) cm^{-1}; n.m.r. τ 9.36 (s, 3, C-10 methyl), 8.97 (d, 6, J = 6 Hz, isopropyl methyls), 8.86 (s, 3, C-4 methyl), 6.36 (s, 3, methoxyl), 4.67 (br s, N*H*), 4.67 (s, 1, C=C*H*), 1.96 (s, 1, C*H*O).

A solution of *N*-formyl compound **1***f* (10 g) and ethanolic hydrochloric acid (3:1, 280 ml) was heated under reflux for 5 h. The solution was cooled, neutralized (Na_2CO_3), and concentrated. The residue was diluted with water (200 ml) and ether (300 ml) added. The aqueous layer and the precipitate at the interface of the two layers were separated. The ether layer was extracted with dilute hydrochloric acid, washed (H_2O), dried, and concentrated to give nonbasic material (1.7 g). The acidic extract and washings were combined, basified (Na_2CO_3), and extracted with ether. The ether extract was dried ($MgSO_4$) and concentrated to a viscous oil (7 g). The oil was dissolved in anhydrous ether, cooled (0°), and saturated with hydrogen chloride. Excess solvent was removed and the concentrated solution cooled (0°). The hydrochloride salt of amine **1***b* which precipitated was collected and recrystallized from methyl acetate: yield 6.8 g; m.p. 210–214°; i.r. (Nujol) 3440 (NH_2), 1720 (C=O of ester), 1600, 1580, 1500 cm^{-1}; n.m.r. τ 9.36 (s, 3, C-10 methyl), 8.89 (d, 6, J = 7 Hz, isopropyl methyls), 8.83 (s, 3, C-4 methyl), 6.29 (s, 3, methoxyl), 4.52 (s, 1, C=C*H*), 2.03 (br s, 3, $\overset{+}{N}H_3$).

Anal. Calcd. for $C_{23}H_{38}NO_2Cl$: C, 69.79; H, 9.61; N, 3.54. Found: C, 68.95, 68.56; H, 9.35, 9.37; N, 3.37. (The poor analytical results are attributed to the hygroscopic nature of this salt).

Basification of an aqueous solution of the amine hydrochloride followed by extraction with ether afforded amine **1***b* as a viscous oil. Analytical data were obtained on a sample purified by molecular distillation (120°, 0.05 mm): i.r. 3500–3200 (NH_2), 1720 (C=O of ester), 1660, 1240 cm^{-1}; n.m.r. τ 9.38 (s, 3, C-10 methyl), 8.97 (d, 6, J = 7 Hz, isopropyl methyls), 8.85 (s, 3, C-4 methyl), 6.35 (s, 3, methoxyl), 4.74 (s, 1, C=C*H*).

Anal. Calcd. for $C_{23}H_{37}NO_2$: C, 76.88; H, 10.30; N, 3.90. Found: C, 77.05, 76.74; H, 10.35, 10.37; N, 3.55.

Deamination of Amine 1b. Isolation of Products

Sodium nitrite (700 mg, 10 mmol) was added over a period of 75 min to a stirred solution of amine hydrochloride (2 g, 5 mmol) in glacial acetic acid (16 ml). The mixture was stirred overnight, then sodium nitrite (350 mg, 5 mmol) added and stirring continued for 2 h. The reaction mixture was diluted with ice-cold sodium hydroxide (12 g in 80 ml H_2O) and extracted with ether. The brown, gummy residue was dissolved in ether. The ether fractions were combined, washed (H_2O, dilute HCl, H_2O), dried ($MgSO_4$), and concentrated to give nonbasic product (1.275 g, 71%).

The nonbasic product was dissolved in ether (5 ml) and stored in the cold (0°) overnight. Removal of the supernatant ether solution gave 203 mg (12%) of crystalline trinitro compound **22**: m.p. 175.5–178°; i.r. ($CHCl_3$) 1725 (C=O of ester), 1570, 1550, 1350, 1325 (NO_2) cm^{-1}; n.m.r. τ 8.93 (s, 3, C-11 methyl), 8.63 (s, 3, C-4 methyl), 8.21 (s, 6, isopropyl methyls), 6.25 (s, 3, methoxyl), 5.12 (m, 1, C*H*NO_2), 3.92 (br s, 1, H-15); mass spectrum 433 (M − 46, 2), 386 (10), 357 (27), 341.2481 calcd. for $C_{23}H_{33}O_2$, found 341.2485 (100), 281 (39), 121 (31), 91 (32); mol. wt. (osmometric) 509 (CH_2Br_2).

Anal. Calcd. for $C_{23}H_{33}N_3O_8$: C, 57.61; H, 6.94; N, 8.76; O, 26.69. Found: C, 57.94, 58.25; H, 7.19, 7.03; N, 8.76; O, 26.00.

The noncrystalline material from several experiments was combined (total 2.5 g) and chromatographed over alumina (72 g). Gradient elution with benzene and benzene–ether gave material containing mainly nitro compounds, gradient elution with ether and ether–chloroform gave material containing alcohols.

The chromatographic fractions rich in nitro compounds were combined (206 mg) and chromatographed over neutral alumina (8 g, activity IV). Elution with Skellysolve B gave acetate **10***a* (26 mg) which crystallized from methanol: m.p. 145–146°; i.r. 1740–1730 (C=O of ester), 1380, 1250 cm^{-1}; n.m.r. τ 9.16 (s, 3, C-10 methyl), 8.85 (s, 3, C-4 methyl), 8.46 (s, 3, isopropylidene methyl), 8.37 (s, 3, isopropylidene methyl), 8.02 (s, 3, OCOC*H*$_3$), 7.36 (m, 1, C*H*OAc), 6.37 (s, 3, methoxyl), 5.48 (octet, 1, J = 1.5, 3.5, 9 Hz, H-15); mass spectrum 402 (4), 342 (53), 327 (42), 267 (48), 121 (37), 107 (100).

Anal. Calcd. for $C_{25}H_{38}O_4$ (mol. wt. 402.2770): C, 74.59; H, 9.51. Found (402.2763 (h.r.m.s.)): C, 74.42, 74.94; H, 9.33, 9.41.

Elution with Skellysolve B – benzene (9:1, 225 ml) gave yellow, crystalline dinitro compound **16***a* (23 mg); m.p. 136–137° (from ethanol) λ_{max} 348 (ε 6190), 229 nm (ε 6750); i.r. ($CHCl_3$) 1725 (C=O of ester), 1615 (C=C), 1545, 1350 (NO_2), 1500, 1320 (C=CNO_2) cm^{-1}; n.m.r. τ 9.32 (s, 3, C-11 methyl), 8.54 (s, 3, C-4 methyl), 8.24 (s, 3, isopropyl methyl), 8.20 (s, 3, isopropyl methyl), 6.32 (s, 3, methoxyl), 2.80 (s, 1, H-15); mass spectrum 432 (1), 403.2359 calcd. for $C_{23}H_{33}NO_5$, found 403.2353 (2) 402 (3), 386.2331 calcd. for $C_{23}H_{32}NO_4$, found 386.2334 (100), 135 (19), 121 (25), 107 (49), 91 (38).

Anal. Calcd. for $C_{23}H_{32}N_2O_6$: C, 63.87; H, 7.46; N, 6.48. Found: C, 63.73, 63.87; H, 7.47, 7.60; N, 6.37, 6.39.

Elution with Skellysolve B – benzene (7:3, 135 ml) gave nitroacetate **14** (30 mg); m.p. 130–131° (from Skellysolve B); i.r. ($CHCl_3$) 1730 (C=O of ester), 1540, 1370, 1340 (NO_2) cm^{-1}; n.m.r. τ 9.34 (s, 3, C-10 methyl), 8.83 (s, 3, C-4 methyl), 8.28 (s, 3, isopropyl methyl), 8.24 (s, 3, isopropyl methyl), 8.06 (s, 3, OCOC*H*$_3$), 7.42 (br s, 1, C*H*NO_2), 6.35 (s, 3, methoxyl), 5.36 (d of d, 1, J = 2, 8 Hz, C*H*OAc), 4.15 (s, 1, C=C*H*); mass spectrum 400 (M − 47, 8), 340 (13), 314 (100), 254 (10), 132 (43).

Anal. Calcd. for $C_{25}H_{37}NO_6$: C, 67.09; H, 8.33; N, 3.13. Found: C, 67.10; H, 8.34; N, 3.30.

Elution with benzene (180 ml) gave material (51 mg) which was rechromatographed on silica gel to give unsaturated ketone **15** (14 mg), m.p. 132–133° (from Skellysolve B). This compound was identical (m.p., spectra) with the previously described (1) material.

The chromatographic fractions rich in alcohols were combined and acetylated (total 790 mg). Crystallization from methanol gave acetate **10***a* (80 mg). The noncrystalline material was chromatographed over neutral alumina (26 g, activity IV). Elution with Skellysolve B – benzene (85:15) gave dinitro compound **16***a* (24 mg). Elution with Skellysolve B – benzene (1:1) gave nitroacetate **14** (98 mg). Elution with benzene (100 ml) gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ketoacetate **12***a* (39 mg) which was recrystallized from methanol: m.p. 218–222°; i.r. 1720 (C=O of ester, ketone), 1405, 1370 cm^{-1}; n.m.r. τ 9.14 (s, 3, C-10 methyl), 8.84 (s, 3, C-4 methyl), 7.98 (s, 3, $OCOCH_3$), 6.36 (s, 3, methoxyl), 5.34 (br d, 1, C*H*OAc); mass spectrum 376 (5), 316 (22), 290 (100), 257 (63), 121 (90).

Mol. wt. Calcd. for $C_{22}H_{32}O_5$: 376.2249. Found (h.r.m.s.): 376.2247.

Further elution with benzene (250 ml) gave nitroalcohol **16***b* as a wax: λ_{max} 362 (ε 5560), 236 nm (ε 6250); i.r. ($CHCl_3$) 3590 (OH), 1720 (C=O of ester), 1610 (C=C), 1500, 1320 (C=CNO_2) cm^{-1}; n.m.r. τ 9.35 (s, 3, C-11 methyl), 8.53 (s, 3, C-4 methyl), 8.58 (s, 6, isopropyl methyls), 6.28 (s, 3, methoxyl), 2.82 (s, 1, H-15); mass spectrum 403 (20), 386 (29), 385 (26), 368 (33), 356 (18), 338 (27), 137 (50), 135 (74), 121 (27), 109 (46), 81 (48), 69 (19), 67 (26), 55 (49), 43 (100).

Mol. wt. Calcd. for $C_{23}H_{33}NO_5$: 403.2359. Found: 403.2373.

Hydrolysis of Acetate 10a

A solution of acetate **10***a* (24 mg) and sodium methoxide (5 mg) in methanol (2.5 ml) was allowed to stand at room temperature for 80 h. The solution was diluted with water, acidified (HCl), and extracted with chloroform. The chloroform extract was washed (H_2O), dried ($MgSO_4$), and concentrated to give alcohol **10***b* (22 mg); i.r. 3600 (OH), 1720 (C=O of ester), 1240 cm^{-1}; n.m.r. τ 9.14 (s, 3, C-10 methyl), 8.84 (s, 3, C-4 methyl), 8.46 (s, 3, isopropylidene methyl), 8.37 (s, 3, isopropylidene methyl), 6.58 (br d, 1 C*H*OH), 6.36 (s, 3, methoxyl). The mass spectrum showed an apparent molecular ion at *m/e* 360.

Oxidation of Alcohol 10b

Jones' reagent (3 drops) was added to a stirred, cooled (10°) solution of alcohol **10***b* (22 mg) in acetone (4 ml). The reaction mixture was stirred for 5 min, then neutralized (K_2CO_3), diluted with water, and extracted with chloroform. The chloroform extract was washed (H_2O), dried ($MgSO_4$), and concentrated to give a ketone (18 mg) which was purified by molecular distillation: i.r. 1725 (C=O of ester, ketone), 1410, 1245 cm^{-1}; n.m.r. τ 9.06 (s, 3, C-10 methyl), 8.83 (s, 3, C-4 methyl), 8.44 (s, 3, isopropylidene methyl), 8.30 (s, 3, isopropylidene methyl), 6.37 (s, 3, methoxyl). The mass spectrum showed an apparent molecular ion at *m/e* 358.

Conversion of Acetate 10a to Ketoolefin 11

Ozone was bubbled into a cooled (−70°) solution of acetate **10***a* (59 mg) in ethyl acetate (40 ml) at a rate of 0.025 ml/s for 4 min. The blue solution was maintained at −70° for 2 h, allowed to warm to room temperature, then concentrated. The residue was diluted with water (15 ml), 30% hydrogen peroxide (1.5 ml) added, and the mixture heated on a steam bath for 1.5 h. The reaction mixture was cooled and extracted with chloroform. The chloroform extract was dried ($MgSO_4$) and concentrated to give ketoacetate **12***a* (56 mg), identical with that described above.

A solution of ketoacetate **12***a* (25 mg) and potassium hydroxide (2.5 g) in aqueous methanol (1:3, 25 ml) was heated under reflux for 5 h. Methanol was removed, the solution diluted with water, acidified (HCl), and extracted with chloroform. The chloroform extract was washed (H_2O), dried ($MgSO_4$), and concentrated. Treatment with ethereal diazomethane gave ketoalcohol **12***b* (22 mg): m.p. 215–223°.

Freshly distilled ethyl chloroformate (0.6 ml) was added dropwise to a cooled (0°) solution of ketoalcohol **12***b* (22 mg) in pyridine (0.8 ml). A red crystalline solid precipitated. More ethyl chloroformate (0.3 ml) was added and the mixture allowed to stand at room temperature overnight. The reaction mixture was diluted with water, acidified (HCl), and extracted with chloroform. The chloroform extract was washed (H_2O), dried ($MgSO_4$), and concentrated. The residue (30 mg) was dissolved in benzene, filtered through alumina and concentrated to give cathylate **12***c* (21 mg): i.r. 1750–1740 (C=O of ester), 1425, 1370, 1270 cm^{-1}.

Cathylate **12***c* was subjected to pyrolysis in a sealed tube at 240–250° for 1.5 h. The product was sublimed at reduced pressure (95°) to give the known ketoolefin **11** (13 mg): m.p. 166–169° (lit. (13) 166–168°); i.r. (KBr) 1720, 1610 cm^{-1} (lit. (13) 1724, 1616 cm^{-1}).

Attempted Conversion of Acetate 10a to Acetate 13

A solution of acetate **10***a* (67 mg) in glacial acetic acid (3 ml) saturated with hydrogen chloride was allowed to stand at room temperature for 48 h. The solution was concentrated. T.l.c. (silica gel) of the residue showed a single spot, even when mixed with either acetate **13** or acetate **10***a*. The n.m.r. spectrum show signals characteristic of both **13** (τ 9.37 (C-10 methyl), 8.93 (isopropyl doublet), 8.07 (acetoxyl CH_3)) and **10***a* (τ 9.16 (C-10 methyl), 8.02 (acetoxyl CH_3)) in a ratio of approximately 1:2.

Attempted Pyrolysis of Nitroacetate 14

Nitroacetate **14** (25 mg) was impregnated on glass beads in a glass tube and heated to 280–295° at 36 mm for 2 h. The oily material (7 mg) which distilled showed no nitro group absorption in the i.r. spectrum. However, the n.m.r. spectrum showed three signals in the carbomethoxyl region, τ 6.33–6.38, and t.l.c. indicated the presence of several components.

Attempted Hydrogenolysis of Nitroacetate 14

A solution of nitroacetate **14** (18 mg) in methanol (30 ml) was subjected to hydrogenation over Adams' catalyst (30 mg) at room temperature and 50 p.s.i. for 24 h. The solution was filtered and concentrated. The residue was dissolved in benzene, filtered through alumina, and concentrated to give 13 mg of unchanged nitroacetate **14**.

Hydrogenation of Dinitro Compound 16a

(i) Ethyl Acetate

A solution of dinitro compound **16***a* (100 mg) in ethyl acetate (30 ml) was hydrogenated over Adams' catalyst (33 mg) at room temperature and atmospheric pressure for 1 h. The solution was filtered and concentrated to give a mixture of compounds (95 mg). The residue was dissolved in ether and separated into basic (12 mg) and nonbasic (72 mg) fractions. The nonbasic fraction was acetylated and chromatographed over silica gel (6 g). Elution with benzene (125 ml) gave compound **17** (17 mg); m.p. 140–140.5° (from ethanol); i.r. ($CHCl_3$) 1720 (C=O of ester), 1605, 1540, 1350 (NO_2) cm^{-1}; n.m.r. τ 8.95 (s, 3, C-11 methyl), 8.69 (s, 3, C-4 methyl), 8.31 (s, 6, isopropyl methyls), 6.35 (s, 3, methoxyl), 5.28 (m, 1, C*H*NO_2), 4.69 (s, 1, H-15); mass spectrum 388.2488 calcd. for $C_{23}H_{34}NO_4$, found 388.2489 (M − 46, 8),

(ii) Ethanol

A solution of dinitro compound **16***a* (43 mg) in 95% ethanol (30 ml) was hydrogenated over Adams' catalyst (20 mg) at room temperature and atmospheric pressure for 1 h. The solution was filtered, concentrated, and acetylated. The acetylated material (45 mg) was chromatographed over neutral alumina (3 g, activity II). Elution with benzene (60 ml) gave compound **18** (14 mg): m.p. 80–81° (from methanol); i.r. ($CHCl_3$) 3370 (NH), 1715 (C=O of ester), 1660 (C=O of amide), 1540, 1375 cm^{-1}; n.m.r. τ 9.15 (d, 3, J = 6 Hz, isopropyl methyl), 9.14 (d, 3, J = 6 Hz, isopropyl methyl), 8.87 (s, 3, C-11 methyl), 8.75 (s, 3, C-4 methyl), 8.00 (s, 3, $NCOCH_3$), 6.34 (br s, 1, H-7), 6.33 (s, 3, methoxyl), 3.0 (br s, 1, N*H*); mass spectrum 403.3086 calcd. for $C_{25}H_{41}NO_3$, found 403.3081 (22), 344.2712 calcd. for $C_{23}H_{36}O_2$, found 344.2715 (100), 329 (67), 301 (58), 285 (95), 284 (78), 273 (48), 269 (50), 241 (30), 213 (21), 133 (32), 109 (42), 107 (32), 105 (43).

Anal. Calcd. for $C_{25}H_{41}NO_3$: C, 74.40; H, 10.24; N, 3.47. Found: C, 74.57; H, 10.24; N, 3.49.

(iii) Ethanol – Hydrochloric Acid

A solution of dinitro compound **16***a* (170 mg) in concentrated hydrochloric acid (few drops) and ethanol (40 ml) was hydrogenated over Adams' catalyst for 7 h. The solution was filtered and concentrated. The residue was dissolved in ether and separated into nonbasic material (24 mg) and basic material (118 mg). The basic material was acetylated. Crystallization from methanol gave compound **18** (70 mg). The noncrystalline material was chromatographed over alumina (4 g). Elution with benzene–ether gave compound **18** (13 mg). Further elution with benzene–ether gave the compound epimeric at C-7 with compound **18** (17 mg); i.r. ($CHCl_3$) 3360 (NH), 1725 (C=O of ester), 1540, 1350 cm^{-1}; n.m.r. τ 9.13 (d, 3, J = 6 Hz, isopropyl methyl), 9.11 (d, 3, J = 6 Hz, isopropyl methyl), 8.88 (s, 3, C-11 methyl), 8.72 (s, 3, C-4 methyl), 7.97 (s, 3, $NCOCH_3$), 6.26 (s, 3, methoxyl), 6.10 (br s, 1, H-7), 4.66 (br s, 1, N*H*); mass spectrum 403 (fragmentation pattern as for compound **18**).

Elution with chloroform gave compound **20***a*: m.p. 235–236° (dec.); i.r. ($CHCl_3$) 3435 (NH), 1725 (C=O of ester), 1675 (C=O of amide), 1540, 1500, 1350 cm^{-1}; n.m.r. τ 9.27 (s, 3, C-10 methyl), 8.83 (s, 3, C-4 methyl), 8.25 (s, 3, isopropyl methyl), 8.21 (s, 3, isopropyl methyl), 7.91 (s, 3, $NCOCH_3$), 6.35 (s, 3, methoxyl), 5.95 (br d, 1, H-15), 5.37 (m, 1, H-7); mass spectrum 482 (2), 480 (5), 398 (100), 374.2013 calcd. for $C_{23}H_{31}O_2{}^{35}Cl$, found 374.2017 (52), 38 (3), 36 (11).

Mol. wt. Calcd. for $C_{25}H_{37}N_2O_5{}^{35}Cl$: 480.2392. Found (h.r.m.s.): 480.2395.

In another experiment, the basic product from hydrogenation was treated with methanesulfonyl chloride in pyridine. Crystallization from methanol gave the sulfonamide corresponding to **18**: m.p. 177° (from methanol); i.r. ($CHCl_3$) 3325 (NH), 1705 (C=O of ester), 1330, 1150 cm^{-1}; n.m.r. τ 9.16 (d, 3, J = 6 Hz, isopropyl methyl), 9.13 (d, 3, J = 6 Hz, isopropyl methyl), 8.88 (s, 3, C-11 methyl), 8.75 (s, 3, C-4 methyl), 7.12 (s, 3, NSO_2CH_3), 6.70 (br s, 1, H-7), 6.32 (s, 3, methoxyl), 3.87 (br d, 1, J = 6 Hz, N*H*); mass spectrum 439.2757 calcd. for $C_{24}H_{41}NO_4{}^{32}S$, found 439.2752 (55), 360 (66), 344 (100), 329 (39), 301 (24), 285 (68), 284 (56), 217 (93), 105 (50), 81 (58), 79 (54).

The noncrystalline material (147 mg) was chromatographed over alumina (9 g). Elution with benzene–ether gave the sulfonamide described above (14 mg). Elution with benzene–ether (1 :1, 60 ml) and ether (180 ml) gave the C-7 epimeric sulfonamide (14 mg): m.p. 206–209° (from methanol); i.r. ($CHCl_3$) 3380 (NH), 1720 (C=O of ester), 1330, 1150 cm^{-1}; n.m.r. τ 9.11 (d, 3, J = 6 Hz, isopropyl methyl), 9.10 (d, 3, J = 6 Hz, isopropyl methyl), 8.89 (s, 3, C-11 methyl), 8.78 (s. 3, C-4 methyl), 7.09 (s, 3, NSO_2CH_3), 6.54 (br s, 1, H-7), 6.34 (s, 3, methoxyl), 5.66 (s, 1, J = 7.5 Hz, N*H*); mass spectrum 439.2757 calcd. for $C_{24}H_{41}NO_4{}^{32}S$, found 439.2752.

Elution with chloroform (60 ml) gave compound **20***b* (50 mg): m.p. 188–191° (from Skellysolve B – ether); i.r. ($CHCl_3$) 3360 (NH), 1725 (C=O of ester), 1545, 1340 (NO_2) cm^{-1}; n.m.r. τ 9.30 (s, 3, C-10 methyl), 8.82 (s, 3, C-4 methyl) 8.26 (s, 3, isopropyl methyl), 8.22 (s, 3, isopropyl methyl), 6.90 (s, 3, NSO_2CH_3), 6.29 (s, 3, methoxyl), 5.97 (d, 1, J = 10 Hz, H-7), 5.72 (d of d, 1, J = 8.5, 3 Hz, H-15), 5.07 (d, 1, J = 10 Hz, N*H*), 4.15 (br s, 1, H-14); mass spectrum 470.2129 calcd. for $C_{24}H_{37}NO_4{}^{32}S^{35}Cl$, found 470.2129 (M − 46, 54), 377 (32), 375 (96), 315 (58), 313 (43), 312 (56), 144 (100), 107 (72), 38 (2), 36 (7)

*Conversion of Nitroalcohol **16b** to Compound **18***

A solution of nitroalcohol **16***b* (40 mg) and hydrochloric acid (few drops) in ethanol was hydrogenated over Adams' catalyst. The hydrogenated material on work-up gave basic (9 mg) and nonbasic (21 mg) fractions. The basic fraction was acetylated. Crystallization from methanol gave compound **18** (3 mg), identical (t.l.c., i.r.) with that described above.

*Attempted Dehydration of Nitroalcohol **16b***

A solution of nitroalcohol **16***b* (80 mg) and thionyl chloride (1 ml) in methylene chloride (10 ml) was allowed to stand at room temperature for 18 h. The solution was concentrated by codistillation with benzene to give compound **16***c*: λ_{max} 357, 237 nm; i.r. ($CHCl_3$), 1720 (C=O of ester), 1610, 1500, 1320 cm^{-1}; n.m.r. τ 9.33 (s, 3, C-11 methyl), 8.51 (s, 3, C-4 methyl), 8.23 (s, 3, isopropyl methyl), 8.17 (s, 3, isopropyl methyl), 6.29 (s, 3, methoxyl), 2.87 (s, 1, H-15).

Anal. Calcd. for $C_{23}H_{32}NO_4Cl$: Cl, 8.42. Found: Cl, 7.90, 8.47.

Compound **16***c* was hydrogenated in ethanol (30 ml) over Adams' catalyst at room temperature and atmospheric pressure for 2 h. The solution was filtered, concentrated, acetylated, and the product chromatographed over alumina (5 g). Elution with benzene–ether gave compound **18**.

*Acid-catalyzed Dehydration of Nitroalcohol **16b***

A solution of nitroalcohol **16***b* (25 mg), and *p*-toluenesulfonic acid (2.5 mg) in dry benzene (25 ml) was heated under reflux for 1 h. The solution was cooled, then diluted with ether (40 ml). The benzene–ether solution

For personal use only.

was washed (5% Na_2CO_3, H_2O), dried ($MgSO_4$), and concentrated to give compound **27** (24 mg): u.v. λ_{max} 382 (ε 5450), 258 nm (ε 6270); i.r. ($CHCl_3$) 1730 (C=O of ester), 1620 (C=C), 1600, (C=C), 1500, 1320, 900 cm^{-1}; n.m.r. τ 9.34 (s, 3, C-11 methyl), 8.50 (s, 3, C-4 methyl), 8.00 (s, 3, C=C—CH_3), 6.29 (s, 3, methoxyl), 4.80 (s, 1, C=CH_2), 4.59 (s, 1, C=CH_2), 2.77 (s, 1, C=CH); mass spectrum 385 (2), 368 (2), 223 (36), 57 (100).

Reaction of Diene 2 with "Nitrous Acid"

Sodium nitrite (50 mg) was added over a 15 min period to a stirred solution of diene **2** (47 mg) in glacial acetic acid (1 ml). The reaction mixture was allowed to stand overnight, then 50 mg of sodium nitrite was added and the mixture was stirred for 1 h. The reaction mixture was diluted with water, basified (10% NaOH), and extracted with ether. The ether extract was washed (H_2O), dried ($MgSO_4$), and concentrated. Crystallization from ether gave trinitro compound **22** (7 mg, 13%).

Deamination of Amine 1b With Limited Sodium Nitrite

Sodium nitrite (190 mg, 2.7 mmol) was added in portions over a 1 h period to a stirred solution of amine **1***b* (970 mg, 2.7 mmol) in aqueous acetic acid (11 ml). The solution was stirred for 3 h, then separated into basic and nonbasic (165 mg, 16%) material. Crystallization from ether gave trinitro compound **22** (6 mg, 4%). The noncrystalline material (145 mg) was chromatographed over alumina (6 g). Gradient elution with benzene and benzene–ether (32:1) gave dinitro compound **16***a* (12 mg, 7%). Elution with benzene–ether (9:1) gave a mixture (10 mg) of dinitro compound **16***a* and ketone **15**. Elution with ether–chloroform gave nitroalcohol **16***b* (14 mg, 9%).

Reaction of Diene 2 with N_2O_4 in Acetic Acid

A solution of dinitrogen tetroxide (125 mg) in acetic acid (4 ml) was added over a period of 20 min to a stirred solution of diene **2** (185 mg) in glacial acetic acid (10 ml). The solution was stirred for 1 h, then diluted with water and extracted with ether. The ether extract was washed (H_2O), dried ($MgSO_4$), and concentrated. Crystallization from ether gave trinitro compound **22** (57 mg, 24%). The noncrystalline material (178 mg) was chromatographed over alumina (8.5 g). Elution with benzene gave dinitro compound **16***a* (22 mg, 13%). The residue from this crystallization was chromatographed over silica gel. Elution with benzene–ether gave material (7 mg) which crystallized from ethanol when seeded with nitroacetate **14**. Identity with **14** was established by i.r. and t.l.c.

Treatment of Diene 2 with Acetic Acid – Perchloric Acid

A solution of diene **2** (58 mg) and 70% perchloric acid (3 drops) in glacial acetic acid (3.5 ml) was allowed to stand at room temperature for 20 h. The reaction mixture was diluted with water and extracted with chloroform. The chloroform extract was washed (H_2O), dried ($MgSO_4$), and concentrated. The oil (65 mg) obtained was chromatographed over alumina (4 g). Gradient elution with Skellysolve B and Skellysolve B – benzene gave unchanged diene **2** (23 mg). Elution with benzene gave a mixture of acetate **10***a* and acetate **13** (24 mg) as established by n.m.r. Hydrolysis of the mixture of acetates ($KOH-CH_3OH$), followed by esterification (CH_2N_2) and chromatography over alumina yielded, after crystallization from Skellysolve B, the alcohol derived by hydrolysis of **13**, m.p. 92–93°, identical (i.r. and t.l.c.) with a known (1) sample.

We wish to thank Dr. R. V. Lawrence for a very generous sample of the levopimaric acid – acrylic acid Diels–Alder adduct, the National Research Council of Canada for financial support, and the University of Alberta for a dissertation fellowship (to P.D.D.). The authors gratefully acknowledge the help of A. M. Hogg, R. N. Swindlehurst, and G. Bigam in the determination of the n.m.r., i.r., and mass spectra, and L. M. Browne for assistance in various phases of this work.

Resolution, Racemization, and Ring Opening of an *o,m'*-Bridged Biphenyl

E. W. WARNHOFF AND P. REYNOLDS-WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received January 24, 1973

The ease of racemization and ring cleavage of the dissymmetric *o,m'*-bridged biphenyl **1** has been examined. Although **1** is structurally stable at least to 100°, it racemizes rapidly in the vicinity of 60°. However, if the nitrogen is converted into a better leaving group by quaternization or protonation, the bridge is quickly broken below 80° by nucleophilic displacement at the benzylic carbon atom. U.v. evidence for strain in **1** is presented.

La facilité de racémisation et de rupture de cycle dans le biphényle dissymétrique ponté en *o,m'*-**1** a été examinée. Bien que **1** possède une structure stable au moins jusqu'à 100°, il se racemise rapidement au voisinage de 60°. Cependant, si l'azote est transformé en un meilleur groupe partant par quaternization ou protonation, la rupture du pont est rapide au dessous de 80° par déplacement nucléophile sur l'atome de carbone benzylique. La tension dans **1** a été mise en évidence par u.v.

The anhydromethine **1** obtained from the Hofmann elimination on the alkaloid caranine **2** (1, 2) has the unusual structure of a biphenyl bridged by a four-atom chain at the *o,m'*-positions. The fact that the bridge of structure **1** could not be completed with Stuart–Briegleb models unless the individual benzene rings were non-planar shows not only that the molecule is strained, but also that the bridge must strongly hinder interconversion of the two atropisomers **3** and **4** (3). The fortunate circumstance that one of the four bridge atoms is a benzylic amino nitrogen allowed demonstration of the hindrance and strain by rendering both optical resolution and bridge cleavage facile. Although there are examples of *m,m'*- and many examples of *o,o'*-bridged biphenyls which have been resolved (4), compound **1** is the only example of an optically active *o,m'*-bridged biphenyl of which we are aware, and as promised earlier (1, footnote 8), we are reporting further chemistry of this interesting molecule.

The strain inherent in **1** ,because of the bridge, first became apparent when the methiodide of the anhydromethine was prepared at room temperature (1). The initial methiodide **5***a* underwent ring scission by nucleophilic attack of iodide on the benzylic carbon to displace the tertiary amine (**5***a* → **6**) which was then quaternized by excess methyl iodide to yield the isolated product **7**. In agreement with this interpretation we now find that quaternization with methyl *p*-toluenesulfonate at room temperature does allow isolation of **5***b*, presumably because of the greatly reduced nucleophilicity of *p*-toluenesulfonate ion compared to iodide ion.

The anhydromethine appears to be stable so long as the nitrogen atom is not positively charged by quaternization or protonation. Even the salts of the anhydromethine with acids whose anions are relatively weak nucleophiles ($HClO_4$, HCl, picric acid) are stable at room temperature, but on warming solutions of these salts in water or ethanol the bridge is readily broken. Thus when **1** was refluxed in 1% aqueous hydrochloric acid, the bridge was broken by displacement of the protonated nitrogen to form the secondary amino alcohol **8***a*. The structure **8***a* was confirmed by acetylation to an *N*-monoacetate **8***d* and an O,*N*-diacetate **8***e*. When the perchlorate or picrate salts were refluxed briefly in ethanol, the bridge was broken by nucleophilic attack of ethanol on the benzylic carbon atom and formation of the ethyl ether **8***b*. Although the above salts were stable at room temperature, the anhydromethine was not stable on dissolution in trifluoroacetic acid at 38°. The n.m.r. spectrum of **1** in trifluoroacetic acid at this temperature gave a triplet for the protonated *N*-methyl absorption (instead of a doublet) and a two-proton singlet at δ 5.29 from the benzylic methylene group, both absorptions requiring the presence of **8***c* with the N protonated (5).

The anhydromethine **1**, m.p. 92–92.5°, as originally prepared from its dissymmetric precursor **2** (1) at 120° was optically inactive, and proof that the molecule could maintain dissymmetry at room temperature was first secured by

resolving the racemic compound at room temperature via its di-*p*-toluyl-L-tartaric acid salt (see Experimental). The (+) enantiomer **4** (3) so obtained had m.p. 75–78° and was of unknown optical purity. At room temperature in solution the anhydromethine is optically stable for at least several days. It was this optical stability at room temperature which prompted the Hofmann degradation of caranine methiodide at room temperature with potassium *t*-butoxide–dimethylsulfoxide which yielded the (−) atropisomer **3** as reported previously (3). When atropisomer **4** was heated to its melting point, it was interconverted with **3** with resolidification to the higher melting racemate **3** + **4**. Enantiomer **4** could also be racemized by boiling (65°) in methanol solution. The loss of optical activity in these two experiments was due to atropisomer interconversion (**4** ⇌ **3**) and not to bridge cleavage because the product in both cases was the racemic anhydromethine **1**.

Further evidence of the strain in this *o,m′*-bridged biphenyl is the characteristic change in the u.v. chromophore (Fig. 1) brought about by bridge cleavage. The benzene rings of **1** are not coplanar and may not even be individually planar whereas the benzene rings of the cleavage product are certainly planar and they may assume a more nearly coplanar arrangement.[1] Yet another example of this distortion of the u.v. chromophore by the short four-atom *o,m′*-bridge in a closely related molecule is the spectrum of the acetylation product of α-

dihydrocaranone **9** (1) compared to the spectrum of 2-(3′,4′ methylenedioxyphenyl)-cyclohexen-2-one (**10**) (Fig. 2).

Experimental

Many of the general procedures are in footnote 19 of ref. 1. Some i.r. spectra were recorded on a Beckman IR-10 instrument. The n.m.r. spectra were recorded on a Varian HA-100 instrument with $CDCl_3$ solutions. Some analyses were by Chemalytics, Inc., Tempe, Arizona.

Caranine Anhydromethine Methotosylate (5b)

A solution of 50 mg of pure **1** and 100 mg of methyl tosylate in 16 drops of CH_3CN was allowed to stand at room temperature for 8 days. Two crops of crystals were obtained totalling 84 mg (99%) of the quaternary tosylate salt **5***b*, m.p. 135–140°; δ 2.24 (s, 3H, $ArCH_3$), 2.5–~3.5 (m, $ArCH_2$), 3.24 (bs, 6H, $+N(CH_3)_2$), 3.5–4.5 (2m, 4H, CH_2NCH_2), 6.0 (AB, 2H, OCH_2O), and 6.5–8.0 (m, 10H, ArH).

Caranine Anhydromethine Perchlorate

To a solution of 50 mg of (±)anhydromethine **1** in 2 ml of HOAc was added 0.2 g of $NaClO_4$. After solution of the $NaClO_4$, the amine perchlorate precipitated. Centrifugation, decantation, and washing with HOAc gave after drying 50 mg (73%) of colorless crystals, m.p. 128–130°. The salt was recrystallized at room temperature by solution in methanol followed by addition of ether. Two such recrystallizations gave 13 mg of long needles, m.p. 132–133°. The u.v. spectrum was identical with that of (±) and (+) **1**.

Anal. Calcd. for $C_{17}H_{17}NO_2 \cdot HClO_4$ (mol. wt. 367.8): C, 55.51; H, 4.93; N, 3.81. Found: C, 55.50; H, 4.93; N, 3.90.

Regeneration of the free base from the perchlorate at room temperature gave recovered (±)anhydromethine **1** whose i.r. and u.v. spectra were identical with those of authentic (±) **1**.

Hydrolysis of Caranine Anhydromethine 1

A solution of 350 mg (1.31 mmol) of (±) **1** in 20 ml of 1% aqueous HCl was refluxed for 1 h. Basification and ether extraction gave 315 mg (84%) of colorless oil which was chromatographed on 10 g of alumina. No trace of **1** remained. EtOAc and EtOAc–EtOH eluted 294 mg of liquid secondary aminoalcohol **8***a*, ν_{max} ($CHCl_3$) 3700–2400 cm^{-1} (broad H-bonded OH and NH) (the two characteristic sharp peaks of **1** at 1307 and 1325 cm^{-1} were absent); λ_{max} (EtOH) 259 (7100) and 294 nm (5500).

The 294 mg of liquid was dissolved in 4 ml of acetic anhydride and allowed to stand at room temperature for 10 min. The solution was diluted with aqueous HCl and extracted with ether. The ether solution was washed with aqueous KOH and water and was then dried and evaporated to leave 295 mg (87%) of colorless liquid N-acetyl derivative **8***d*, ν_{max} ($CHCl_3$) 3435 (OH) and 1635 (amide C=O), λ_{max} (EtOH) 259 (7050) and 294 nm (5600).

A portion (40 mg) of the product **8***a* from another hydrolysis was allowed to react with 1 ml of acetic anhydride in 1 ml of pyridine at room temperature for 6 h. The reaction mixture was partitioned between water and ether. The ethereal layer was washed with dilute aqueous H_2SO_4, 10% aqueous $NaHCO_3$, and saturated

aqueous NaCl before being dried over $MgSO_4$. Evaporation of the ether left 45 mg (87%) of colorless oily diacetate **8***e*; ν_{max} (CS_2) 1742 (ester C=O) and 1650 cm^{-1} (amide C=O); δ ($CDCl_3$) 2.08 (s, 6H, CH_3COO and $CH_3C(=O)N$), 2.8–3.0 (m, 5H, Ar—CH_2CH_2—N—CH_3),[2] 3.60 (m, 2H, —CH_2N—C=O), 4.89 (s, 2H, $ArCH_2OAc$), 5.99 (s, 2H, O—CH_2—O), 6.75 (s, 1H, Ar—H), 6.94 (s, 1H, ArH), 7.05–7.45 (m, 4H, ArH).

Anal. Calcd. for $C_{21}H_{23}NO_5$ (mol. wt. 369.4): C, 68.28; H, 6.28; N, 3.79. Found: C, 68.32; H, 6.41; N, 3.30.

Alcoholysis of Caranine Anhydromethine (1)

(*a*) The (±)anhydromethine was stable in neutral ethanol. When 10 mg of (±) **1** was refluxed in 0.5 ml of 99% ethanol for 5 min and allowed to crystallize, there was obtained 6.5 mg of recovered (±) **1**, m.p. 92–92.5° undepressed on admixture with starting material.

(*b*) A 57-mg sample of the perchlorate of (±) **1** was dissolved in 5 ml of 95% ethanol and refluxed for 10 min. Regeneration of free base by basification and extraction with ether gave 40 mg of colorless liquid ring-opened ethyl ether **8***b*. The product was evaporatively distilled at 150° (0.05 Torr), ν_{max} ($CHCl_3$) ~3300 cm^{-1} (broad NH); λ_{max} (EtOH) 258 (6400) and 293 nm (4840).

Anal. Calcd. for $C_{19}H_{23}NO_3$ (mol. wt. 313.4): 1 OC_2H_5, 14.37. Found: OC_2H_5, 13.61.

(*c*) A solution of 42 mg of the picrate of (±) **1** (1) in 5 ml of a mixture of chloroform and 99% ethanol was refluxed for 10 min. Regeneration of the base by passage through 1 g of basic alumina with chloroform eluate gave 20 mg (75%) of colorless liquid ring-opened ethyl ether whose i.r. and u.v. spectra were identical with the sample prepared from the perchlorate salt in section *b*.

Resolution of Caranine Anhydromethine (1)

To a solution of 405 mg (1.52 mmol) of anhydromethine **1** in 10 ml of 95% ethanol was added a solution of 613 mg (1.52 mmol) of di-*p*-toluyl-L-tartaric acid in 9 ml of 95% ethanol. Crystals precipitated almost immediately and the reaction mixture was allowed to stand for 2 days at room temperature. Filtration and washing with 95% ethanol left 638 mg (62%) of white crystals, m.p. 150–154°.

A 549-mg portion of the salt was basified with aqueous NaOH, and the precipitate was centrifuged, washed with water and dried at room temperature to yield 211 mg (94%) of white crystals, m.p. 73–76°. One recrystallization from methanol with minimum heating to effect solution gave 196 mg of long prisms of (+) **1**, m.p. 75–78°, $[\alpha]_D$ +21° (*c*, 0.95 in chloroform); λ_{max} (EtOH) 256 (8270) and 303 nm (7000).

Anal. Calcd. for $C_{17}H_{17}NO_2$ (mol. wt. 267.3): C, 76.38; H, 6.41; N, 5.24. Found: C, 76.25; H, 6.34; N, 5.49.

The mixed m.p. with racemic **1**, m.p. 92–92.5°, was 73–92°.

A 30-mg sample of (+) **1** was heated at 78° for 10 min during which time it melted and then slowly recrystallized completely. The resolidified material had m.p. 92–92.5°, $[\alpha]_D$ 0° (*c*, 1.72 in chloroform). The i.r. spectrum of the racemized material was identical with that of the (+) **1**.

During recrystallization of (+) **1**, if the methanol solution was boiled for ~10 min, the anhydromethine that crystallized had m.p. 92–92.5° and was racemic.

2-(3′,4′-Methylenedioxyphenyl)-cyclohex-2-en-1-one (10)

A solution of 370 mg (1.70 mmol) of 2-(3′,4′-methylenedioxyphenyl)-cyclohexanone (7), m.p. 93–94°, in 5 ml of CCl_4 was stirred (magnetic bar) and treated dropwise with a solution of 297 mg (1.85 mmol) of Br_2 in 4 ml of CCl_4. The reaction mixture was then diluted with more CCl_4, washed with water, dried, and concentrated. The residual oil was dissolved in 5 ml of 2,6-lutidine and refluxed in a N_2 atmosphere for 10 min. The dehydrobromination mixture was diluted with ether, and the lutidine was extracted with aqueous HCl. Evaporation of the dried ether solution left 341 mg (93%) of oil that crystallized. One recrystallization from ethyl acetate–cyclohexane gave 150 mg, m.p. 85–98°. Several more recrystallizations from ethyl acetate followed by sublimation at 90° (0.05 Torr) gave colorless blades of pure **10**, m.p. 99–100°, ν_{max} ($CHCl_3$) 1670 cm^{-1} (C=C—C=O); λ_{max} (EtOH) 238 (9750) and 294 nm (4200).

Anal. Calcd. for $C_{13}H_{12}O_3$ (mol. wt. 216.2): C, 72.21; H, 5.59. Found: C, 72.21; H, 5.62.

Sublimation was necessary to remove ethyl acetate of crystallization which was not removed by drying at elevated temperature.

[2]The N—CH_3 absorption consisted of two peaks, Δδ 5 Hz, which coalesced on raising the temperature to 50°. The two peaks are attributed to slowly interconverting conformers of **8***e*.

The Fragmentation Mechanism of Cyclobutanol

JOHN L. HOLMES[1]

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

AND

ROBIN T. B. RYE

Department of Chemistry, Sir George Williams University, Montreal 107, Quebec

Received January 5, 1973

The mass spectra of cyclobutanol and three ^2H labelled analogs have been studied. The losses of C_2H_4 and $C_2H_5^{\cdot}$ from the molecular ion involve specific fragmentations. Only $CH_3^{\cdot}$ loss from the α-cleaved molecular ion[2] clearly involves hydrogen atom scrambling; this fragmentation also proceeds by a specific mechanism involving C-2 and hydroxyl hydrogen atoms. Loss of water from the molecular ion involves all the hydrogen atoms but in a complex, non-random manner.

Les spectres de masse du cyclobutanol et de trois analogues marqués au deutérium ont été étudiés. Les pertes de C_2H_4 et $C_2H_5^{\cdot}$ à partir de l'ion moléculaire se font par des fragmentations spécifiques. Seule la perte de $CH_3^{\cdot}$ à partir de l'ion moléculaire α clivé implique de façon nette un déplacement au hasard d'un atome d'hydrogène; cette fragmentation se fait également selon un mécanisme spécifique engageant les atomes de C-2 et d'hydrogène hydroxyle. La perte d'eau à partir de l'ion moléculaire engage tous les atomes d'hydrogène selon un mécanisme complexe et non au hasard. [Traduit par le journal]

Can. J. Chem., **51**, 2342 (1973)

The mass spectrum of cyclobutanol has been briefly discussed by Natalis (1) and by Budzikiewicz, *et al.* (2). We have examined the mass spectra of some deuterium labelled cyclobutanols in order to determine whether any of the mechanisms recently proposed for the primary fragmentations of cyclohexanol (3) apply to the C_4 alcohol.

Results and Discussion

Relative peak intensities for the 70 eV mass spectrum of cyclobutanol are shown in Table 1; they agree with published data. Also given in Table 1 are peak intensities for cyclobutanol-OD, 1-d_1-cyclobutanol and 2,2,4,4-d_4-cyclobutanol.

There are only two peaks with relative intensity greater than 10% in the mass spectrum of cyclobutanol. The base peak (*m/e* 44) is accompanied by a weak first field-free region metastable consistent with fast elimination of C_2H_4 from the molecular ion. Under such conditions little hydrogen atom scrambling would be expected. For 2,2,4,4-d_4-cyclobutanol the base peak appears at *m/e* 46 ($M - C_2H_2D_2$): comparison of the peak intensity ratio (*m/e* 46)/(*m/e* 45) in this compound with the equivalent ratio in the unlabelled alcohol shows (after correction for incomplete labelling) that no significant hydrogen scrambling occurs prior to ethylene loss. Similar results are obtained for the d_1-alcohols. Thus ethylene elimination involves the loss of two adjacent methylene groups. The same fragmentation processes have been shown to take place in 1-methyl (4) and 1-ethyl cyclobutanols (5).

The second most intense peak in the mass spectrum (*m/e* 43; relative intensity, 30%) arises mainly through loss of $C_2H_5^{\cdot}$ from the molecular ion. The appropriate metastable is observed, and it is approximately 30 times more intense than that for ethylene loss. If it is assumed that the ratio of total ethylene loss to total ethyl radical loss is the same in the deuterated cyclobutanols as in the unlabelled material a simple calculation shows that there is negligible contribution from loss of $C_2H_4D^{\cdot}$ to the peak at *m/e* 43 in the mass spectrum of 1-d_1-cyclobutanol. For cyclobutanol-OD, however, approximately 50% of the observed peak intensity at *m/e* 43 is due to loss of $C_2H_4D^{\cdot}$ from the molecular ion; in the metastables the loss of $C_2H_4D^{\cdot}$ accounts for 60% of the total ethyl radical loss. Although this latter value is close to that expected for random selection from seven hydrogens and one deuterium in the elimination of the ethyl radical ($C_2H_4D^{\cdot}$:

*Relative intensities are not corrected for incomplete labelling or for contribution from ^{13}C.

$C_2H_5^{\bullet}$ = 5:3), only a specific elimination mechanism can account for the results obtained for the 1-d_1-alcohol. A specific, rather than a random selection of hydrogen is also required by the results obtained from the 2,2,4,4-d_4-cyclobutanol; the observed ratio of $C_2H_3D_2^{\bullet}$ loss to $C_2H_2D_3^{\bullet}$ in the metastable ion peaks is 35:23, with negligibly small metastables observed for loss of $C_2H_4D^{\bullet}$ and $C_2H_5^{\bullet}$. We conclude that loss of ethyl radical involves the abstraction of a hydrogen atom from specific sites in the α-cleaved molecular ion, *i.e.* from the hydroxyl group and from C-2. The results for the d_4-alcohol also show that *either* there is an isotope effect leading to a preference for hydrogen over deuterium *or* geometrical factors favor abstraction from the hydroxyl group rather than from C-2.

A satisfactory mechanism for ethyl radical loss from cyclohexanol could not be proposed (3) mainly because of uncertainty as to the site of hydrogen abstraction. As the evidence now points to a mechanism involving the α-cleaved molecular ion[2] for ethyl radical loss in both cyclohexanol and cyclobutanol, identification of the abstraction sites in the latter compound may provide the key to the interpretation of the earlier results. This possibility is being given careful study. Ethylene loss from the two compounds occurs apparently by quite different mechanisms; in cyclohexanol involvement of the α-cleaved molecular ion is indicated, whereas C_2H_4 elimination from cyclobutanol is so rapid a process that no metastable ion peak is observed.

A number of other fragmentation processes are worthy of mention even though they give rise to only minor peaks in the mass spectrum.

(i) M — Water, m/e 54

Water loss from the molecular ion is not a favored process, with the peak at *m/e* 54 having

[2]In each case, "α-cleaved ion" will be taken as referring to fission of the 1,4 carbon–carbon bond.

a relative intensity of *ca.* 1%. The metastable abundance data for water loss from the labelled compounds (Table 2) shows that the elimination involves all ring positions. However, as can be seen from Table 2, the relative abundances are not those for complete hydrogen atom scrambling. The preponderance of HOH loss in every case indicates an isotope effect, and the results cannot be fitted to a single mechanism. Molecular geometry renders water loss from the ring-intact form of the molecular ion improbable; we conclude that it takes place primarily from the (rearranged) α-cleaved ion.

(ii) M − OH, m/e 55

In the peaks the intensity ratio $(M - {}^{\prime}OH)^+/(M - HOH)^+$ is close to 2:1; in the metastables, however, the ratio is approximately 1:12. The results for the labelled compounds also show that the hydroxyl group is lost rapidly, before the molecular ion can undergo any appreciable hydrogen atom scrambling (compare unlabelled and -OD alcohols, Table 1). We infer that the hydroxyl group is lost from the ring-intact form of the molecular ion. In cyclohexanol, hydroxyl is not lost from the molecular ion but the comparable fast process is the stereo-specific water loss (3).

(iii) M − Methyl, m/e 57

Methyl loss from the molecular ion gives a significant peak (relative intensity, 3.5%) in the spectrum. In the deuterated alcohols metastable ion peaks are observed for the loss of all possible labelled methyl radicals; relative abundance data are given in Table 2. For the d_1-alcohols the deviations from the random value of the $(M - CH_3)^+/(M - CH_2D)^+$ ratio are small, but significant. For the 2,2,4,4-d_4-cyclobutanol the departure from the random distribution is considerable. The observed values can be well explained by the summation of a random and a specific mechanism. In the mono-deuterated compounds the specific mechanism must yield the "excess" $CH_3^{\bullet}$ and/or $CH_2D^{\bullet}$ loss, while in the d_4-alcohol it must account for the observed "excess" of $CHD_2^{\bullet}$ and $CD_3^{\bullet}$. In the compounds studied, the specific mechanism accounts for approximately 15% of the total methyl loss from the molecular ion.

The suggested specific mechanism involves loss of the terminal carbon from the α-cleaved molecular ion, the third hydrogen atom coming from either C-2 or hydroxyl. The evidence for this proposal is as follows: the ratio of $CH_3^{\bullet}$ to $CH_2D^{\bullet}$ loss for 1-d_1-cyclobutanol indicates excess $CH_3^{\bullet}$ over that required for a random process. The observed ratio of 2.1:1.0 may be divided into a random $CH_3^{\bullet}$ loss (1.7), a specific $CH_3^{\bullet}$ loss (0.4), and a random loss of $CH_2D^{\bullet}$ (1.0). Similarly for cyclobutanol-OD the observed ratio of $CH_3^{\bullet}$ to $CH_2D^{\bullet}$ (2.0:1.1) may be divided into a random $CH_3^{\bullet}$ loss (1.7), a specific $CH_3^{\bullet}$ loss (0.3), a random $CH_2D^{\bullet}$ loss (1.0), and loss of $CH_2D^{\bullet}$ by the specific process (0.1), the latter indicating that the hydroxyl hydrogen atom is involved in the specific methyl loss. (It was not possible, however, quantitatively to determine the relative involvement of C-2 and hydroxyl hydrogens.) For 2,2,4,4-d_4-cyclobutanol, the observed loss of $CH_3^{\bullet}$ and $CH_2D^{\bullet}$ can be wholly assigned to the random process, with the specific elimination accounting for the "excess" $CHD_2^{\bullet}$ and $CD_3^{\bullet}$. The loss of $CD_3^{\bullet}$ in excess of the random value identifies C-2 as an abstraction site.

A recent study has been made by McAdoo *et al.* (5) of the isomeric $C_4H_8O^{+\bullet}$ ions generated from 1-ethyl cyclobutanol and a variety of ketone precursors. All these ions display specific fragmentations for the loss of ethyl and methyl radicals which are at variance with our observations. Moreover, the proposed structures for their $C_4H_8O^{+\bullet}$ ions were $[CH_3CH_2COCH_3]^{+\bullet}$, $CH_3CH^{\bullet}(CO^+H)CH_3$, and $CH_3CH_2(CO^+H)$-$CH_2^{\bullet}$ and therefore we conclude that β-cleavage in cyclobutanol is not a significant process.

In cyclohexanol $CH_3^{\bullet}$ is lost from $(M - HOH)^{+\bullet}$ rather than from the molecular ion (3). The analogous process occurs in the fragmentation of cyclobutanol; a very weak metastable was observed for the loss of $CH_3^{\bullet}$ from $(M - OH)^+$. No attempt was made to determine whether this methyl loss was random or specific because earlier work has shown (6) that $C_4H_7^+$ ions from various precursors undergo complete hydrogen and carbon atom randomization prior to methyl radical elimination. Loss of $CH_3^{\bullet}$ from $(M - HOH)^{+\bullet}$ in the cyclobutanol fragmentation is inferred from the appearance of the peak at *m/e* 39, although no metastable was observed for this process; it has been shown that $C_4H_6^{+\bullet}$ ions lose $CH_3^{\bullet}$ readily (7).

(iv) M − H, m/e 71; (M − H) − H, m/e 70

Loss of the C-1 hydrogen atom has been identified as the origin of the $(M - 1)^+$ peak in

the mass spectrum of cyclohexanol. In the mass spectrum of cyclobutanol, peaks at *m/e* 71 $(M - 1)^+$ and *m/e* 70 show that two hydrogen atoms can be lost from the molecular ion. No metastable was observed for the process $(M - H)^+$, but a weak metastable corresponding to $(M - H) - H$ was found. Analysis of the ion peaks at *m/e* 73 (M), 72, and 71 in the mass spectrum of cyclobutanol-OD shows that the hydroxyl hydrogen atom and one other are lost from the molecular ion with approximately equal ease; the contributions of $(M - H)^+$ and $(M - D)^+$ to the appropriate peak intensities being in the ratio of 3:2.3, respectively. The mass spectrum of 1-d_1-cyclobutanol yielded similar results, confirming the loss of the C-1 hydrogen atom.

Experimental

All spectra were obtained using an A.E.I. MS-902S double focusing mass spectrometer which had been modified to permit defocused operation. Metastable abundance ratios were determined at constant accelerator potential (8) except in the case of 2,2,4,4-d_4-cyclobutanol. For this compound the metastable ion peaks corresponding to loss of $CD_3^{\cdot}$ and HOH overlap. The normal ion peak at *m/e* 58 in the d_4-alcohol is a doublet, with the high mass component arising from the loss of HOH. At moderate resolution ($M/\Delta M \sim 3000$) it was possible to separate the metastable transitions leading to each component of the doublet using the accelerating voltage scan technique (9). All spectra and metastables were measured with an ionizing energy of 70 eV and a source temperature of approximately 100 °C.

Cyclobutanol was prepared from cyclobutanone (Aldrich) by reduction with lithium aluminum hydride. Cyclobutanol-OD was prepared from the alcohol by exchange with D_2O, and was run with excess D_2O in the mass spectrometer. Reduction of the ketone with lithium aluminum deuteride, followed by reduction of the complex with water gave 1-d_1-cyclobutanol. Base-catalyzed exchange of cyclobutanone with D_2O (10) gave 2,2,4,4-d_4-cyclobutanone, which upon reduction with lithium aluminum hydride gave the corresponding alcohol. All the alcohols were purified by g.l.c.

We wish to thank Mr. P. Coulombe for experimental assistance. One of us (J.L.H.) thanks the National Research Council of Canada for financial support.

Synthesis of Phenols from Diazonium Tetrafluoroborates; a Useful Modification

D. E. HORNING, D. A. ROSS, AND J. M. MUCHOWSKI[1]

Bristol Laboratories of Canada, Candiac, Quebec

Received January 3, 1973

It is shown that phenols are obtained in good yield by the decomposition of aromatic diazonium tetrafluoroborates in refluxing trifluoroacetic acid containing potassium trifluoroacetate.

On démontre que des phénols peuvent être obtenus avec de bons rendements par décomposition des tétrafluoroborates de sel de diazonium aromatique par reflux dans l'acide trifluoroacétique contenant du trifluoroacétate de potassium. [Traduit par le journal]

Can. J. Chem., 51, 2347 (1973)

On several occasions, we have encountered aromatic amines (*e.g.* **1***a* and **2***a*) the diazonium salts of which could not be converted to phenols (**1***d* and **2***b*) under any of the usual (1–4) conditions. This publication describes simple modifications of known procedures (2, 3) which enable one to effect the above transformation with considerable ease. For example, when a solution of the diazonium tetrafluoroborate **1***b* was boiled under reflux in trifluoroacetic acid, containing an equivalent of potassium trifluoroacetate,[2] the salt (**1***b*) could no longer be detected after 20 h. Dilution of this solution with water resulted in the spontaneous hydrolysis of the trifluoroacetate **1***c* to give the phenol **1***d* in high yield. The phenol **2***b* was obtained in a similar way from **2***a*, but in this case the intermediate trifluoroacetate was cleaved by treatment with alkali.

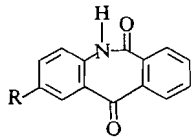
b R = $N_2^+BF_4^-$
c R = $OCOCF_3$
d R = OH



2

a R = NH_2
b R = OH

The synthesis of phenolate esters by the decomposition of diazonium salts in pure carboxylic acid solvents,[3] in particular in glacial acetic acid, has long been known (1), but yields of these esters generally have not exceeded 60% (see, however, ref. 5). In addition, it must be pointed out that Gottstein *et al.* (3) recently have diazotized certain 4-aminoquinolines in trifluoroacetic acid. The salts were then decomposed to phenols (at 5°) by the addition of water. The method described above therefore represents a relatively minor modification of the work of these investigators. It is, however, a modification which is vital, since neither **1***d* nor **2***b* were preparable under the conditions described by these workers. It is because of the exceptional utility[4] of this modified procedure that the work described herein has been submitted for publication.

Experimental

The melting points were determined in a Gallenkamp melting point apparatus and are not corrected. The i.r. spectra were measured with a Perkin–Elmer 237B grating spectrophotometer or a Unicam SP-200G i.r. spectrophotometer. The n.m.r. spectra were recorded with a Varian A-60A spectrometer and are expressed in p.p.m. (δ) from internal tetramethylsilane.

2-Methyl-5-aminoisocarbostyril (1)

This amine was prepared from the nitro compound by

[1]To whom enquiries should be addressed at: Syntex, S. A., Division de Investigacion, Calle Carretera Mexico-Toluca No. 2822, Apartado Postal 10-820, Mexico 10, D.F.

[2]The yields of phenols were considerably diminished in the absence of the salt.

[3]The use of formic acid containing sodium formate was also investigated, but the phenols **1***d* and **2***b* thus obtained were always contaminated with substantial amounts of the products of reductive deamination.

[4]Phenol was produced in > 75% yield by this procedure, and it has recently (6) been shown that simple acylamino phenols are also readily prepared by this method.

a modification of the method of Balcom and Furst (7) as described below.

A solution of 2-methyl-5-nitroisocarbostyril (6.18 g, 30.3 mmol; prepared in 85–95% yield by the alkaline ferricyanide oxidation of 2-methyl-5-nitroisoquinolinium iodide (8)) in absolute ethanol (300 ml) containing 100% hydrazine hydrate (6.5 g) and Raney nickel catalyst (1 teaspoon), was heated under gentle reflux for 1 h. The catalyst was removed by filtration through Celite, and the filtrate was evaporated to dryness *in vacuo*. The residue was crystallized from benzene (charcoal) to give the product in two crops; 3.91 g (m.p. 147–149°) and 0.50 g (m.p. 145–146°). Recrystallization of the first crop did not improve its melting point; λ_{max} ($CHCl_3$) 3450, 3375, 1650, 1635, 1598, 1570 cm^{-1}.

Anal. Calcd. for $C_{10}H_{10}N_2O$: C, 68.95; H, 5.79. Found: C, 68.96; H, 6.00.

2-Methyl-5-hydroxyisocarbostyril (2)

Concentrated hydrochloric acid (35 ml) was added to a stirred suspension of the amine (12.2 g, 70 mmol) in water (70 ml) and the mixture thus obtained was cooled to 0° and treated in the usual manner with a solution of sodium nitrite (5.30 g) in water (10 ml). After ½ h at 0°, a solution of sodium tetrafluoroborate (10.98 g) in water (35 ml) was added, and after a further ½ h the product was collected by filtration, washed with a small amount of ice-water and then with a large amount of ether. After drying in a stream of air the solid (15.2 g, 80%) had m.p. 135° dec.

Solid potassium carbonate (3.9 g, 28 mmol) was added cautiously at 0° to trifluoroacetic acid (120 ml), and then the diazonium tetrafluoroborate (15.2 g, 56 mmol) was added all at once. The resultant was stirred at reflux temperature (with protection from moisture) until the solution no longer (20 h) gave a positive test for the diazonium salt (alkaline β-naphthol). The solution was added to water (300 ml), and after 1 h at room temperature the resultant was stored at 0° for 20 h. The tan-colored solid which crystallized was collected by filtration and recrystallized (charcoal) from hot water. The white solid thus obtained (9.0 g, 91%) had m.p. 225–227.5° dec.; λ_{max} (Nujol) 3260–2400 (broad hump), 2733, 1640, 1619, 1585, 1550 cm^{-1}; δ(DMSO-d_6) 3.59 (s, 3H), 6.88 (d, 1H, $J_{3,4}$ = 7.7), 7.34 (q, 1H, J_o = 7.8, J_m = 2.0), 7.44 (t, 1H, J_o = 7.8), 7.50 (d, 1H, $J_{3,4}$ = 7.8), 7.85 (q, 1H, J_o = 7.8, J_m = 2.0). After dissolution of the phenol, the integrated intensity of the DOH peak (this absorption shifted from δ 3.37 to 3.89 on addition of the phenol) increased by precisely the amount required for one proton.

2-Hydroxy-5,6-dihydro-11H-dibenzo[b,e]azepine-6,11-dione (4)

Fluoroboric acid (48%, 300 ml) was added to a suspension (23.8 g, 100 mmol) of the amine (9) in water (400 ml). A solution of sodium nitrite (7.1 g) in water (25 ml) was added in the usual manner at 10–15° and then the solution was cooled to 0°. The solid was collected by filtration, washed successively with ice-cold 10% fluoroboric acid, ice-cold 2-propanol, and ether. After drying in a stream of air the salt weighed 29.9 g (89%).

A solution of the diazonium salt (46.3 g, 137 mmol) in trifluoroacetic acid (500 ml) containing potassium carbonate (9.7 g, 70 mmol) was heated under reflux until a negative diazonium salt test was obtained (72 h). The solvent was removed *in vacuo*, water was added to the residue, and the mixture was extracted with ethyl acetate. The organic phase was extracted with dilute sodium hydroxide, the alkaline phase was made acidic with hydrochloric acid and the product was collected by filtration (after the mixture had first been cooled in ice). The crude product thus obtained was digested with hot ethyl acetate, filtered, and the filtrate after cooling was passed over silica gel (Brinkman, Act II, 40 g per gram of crude phenol). The yellow-colored product (23.02 g) was contained in the first few hundred milliliters of the eluate. Reextraction of the insoluble material from above with hot ethyl acetate and subsequent purification by chromatography gave an additional 1.52 g of the product (total of 24.54 g, 75%). This material was homogeneous by t.l.c. (silica gel, 2% methanol in chloroform) and after sublimation at 200°/0.005 mm it had m.p. 267–269°; λ_{max} (Nujol) 3410, 3150, 1675, 1653 cm^{-1}; δ (DMSO-d_6) 6.76–7.62 (m, 5H), 7.82–8.08 (m, 2H), 9.50 (s, 1H, w_H = 30), 10.60 (d, 1H, $J \sim 1$).

Anal. Calcd. for $C_{14}H_9NO_3$: C, 70.29; H, 3.79; N, 5.86. Found: C, 70.10; H, 3.80; N, 5.95.

The *O*-methyl ether was prepared in 68–72% yield by heating an acetonitrile solution of the potassium salt (generated by treatment of the phenol with potassium carbonate in hot acetonitrile) with a slight excess of dimethyl sulfate. After recrystallization from acetonitrile this material had m.p. 244–245°; λ_{max} (Nujol) 3190, 1670, 1660 cm^{-1}; δ (DMSO-d_6) 3.80 (s, 3H), 7.12–7.83 (m, 6H), 8.05–8.31 (m, 1H), 10.80 (s, 1H, w_H = 6).

Anal. Calcd. for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.37; N, 5.53. Found: C, 71.04; H, 4.24; N, 5.51.

Five-membered Heterocyclic Thiones. Part III.[1] 1,2,5-Thiadiazole-3-thiones

D. E. HORNING AND J. M. MUCHOWSKI[2]
Bristol Laboratories of Canada, Candiac, Quebec
Received November 22, 1972

Stable salts of 3-mercapto-1,2,5-thiadiazoles were prepared by the alkaline hydrolysis of the corresponding *N,N*-dimethylthionocarbamates.

Les sels stables de mercapto-3 thiadiazoles-1,2,5 ont été préparés par l'hydrolyse alcaline des *N,N*-diméthylthionocarbamates correspondants. [Traduit par le journal]

Can. J. Chem., **51**, 2349 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

During the past decade, the chemistry of 1,2,5-thiadiazoles has been investigated in considerable detail (2). These studies have encompassed, among other compounds, the remarkably stable, completely enolic, 3-hydroxy derivatives. The corresponding 3-mercapto compounds have not heretofore been described, although at least one unsuccessful attempt to prepare such substances has been reported (3). This publication describes the synthesis of stable salts of two 3-mercapto-1,2,5-thiadiazoles, one of which is the parent member of the series.

The preparation of the title compounds (see Scheme 1) was based on the rearrangement of thionocarbamates to thiolcarbamates which has been successfully utilized by Newman and Karnes for the conversion of phenols to thiophenols (4). The method was first applied to 4-cyano-3-hydroxy-1,2,5-thiadiazole because it was considered that an electron-withdrawing group at C-4 would impart added stability to the product **5**, irrespective of whether it existed in the thione or the thiol form. Oxygen acylation of **1** (R = CN) was easily accomplished with dimethylthiocarbamyl chloride, and the thionocarbamate thus produced (**2**, R = CN; $\nu_{C=S}$ = 1562 cm^{-1}; see Table 1) rearranged to the thiolcarbamate (**3**, R = CN; $\nu_{C=O}$ = 1693 cm^{-1}) at 130°. Hydrolysis of the thiolcarbamate occurred in refluxing ethanolic potassium hydroxide solution and was accompanied by the expected hydration of the nitrile function. The crude, stable, potassium salt (**4**, M = K) was characterized as the 4-methoxycarbonylmethyl derivative (**6**, R = $CONH_2$, R′ = CH_3)[3] and as the readily purifiable dicyclohexylammonium salt (**4**, M = $(C_6H_{11})_2NH_2$).

In a manner similar to that described above, the parent hydroxy thiadiazole (**1**, R = H) gave a thionocarbamate (**2**, R = H), the rearrangement of which required more vigorous conditions (170°, 3 h) than did the aforementioned cyano analog (**2**, R = CN). Hydrolysis of the thiolcarbamate (**3**, R = H) was effected in the usual manner to give a mixture of salts from which a crystalline mercuric salt (M = Hg/2) could be obtained with ease. The presence of the thiolate in the salt mixture was further substantiated by the preparation of the 4-carboxymethyl derivative (**6**, R = R′ = H; obtained by saponification of the crude, oily, methyl ester).[3]

The thiols derived from the above salts were much less stable than the corresponding hydroxy compounds. Indeed, extraction of the acidified aqueous solution of the crude potassium salt of the parent thiol failed to yield any alkali soluble

[1]For Part II, see ref. 1.

[2]To whom enquiries should be addressed at: Syntex, S.A., Division de Investigacion, Calle Carretera Mexico-Toluca No. 2822, Apartado Postal 10-820, Mexico 10, D.F.

[3]A referee has expressed some reservations concerning the assigned site of alkylation of the ambident anionic system in the salts **4** (R = H, $CONH_2$). In our opinion there can be little doubt that *S*- and not *N*-alkylation occurred in view of the well-known fact that a wide variety of compounds containing the —N—C=S system alkylate, either as the neutral or the anionic species, essentially exclusively on sulfur (6). Indeed, we are unaware of deviations from this pattern irrespective of whether the —N—C=S group is incorporated in an heterocyclic or an acyclic system.

Finally, the n.m.r. spectra (see Table 1) of compounds **6** (R = H, R′ = CH_3 and R = $CONH_2$, R′ = CH_3) are consistent with the assigned structure (*e.g.* the —SCH_2— group in 2-allylthiobenzothiazole appears at δ 3.95 (7)).

material. The 4-carboxamido derivative was, however, sufficiently stable to be isolable, but a specimen left at room temperature for 1 day was only 50% soluble in dilute sodium hydroxide solution.

The solution i.r. spectrum ($CHCl_3$) of 3-mercapto-4-carboxamido-1,2,5-thiadiazole (**5**, R = $CONH_2$) was devoid of absorptions in the 2600–2500 cm^{-1} region[4] showing that the thione tautomer was the major if not exclusive species present under these conditions.

[4]The SH stretching absorption of thiophene 2- and 3-thiols is reported (5) to occur in the 2540–2510 cm^{-1} region, and 2-methyl-1,2,3-triazole-4-thiol has a strong band at 2540 cm^{-1} (8).

Experimental

The melting points were determined in a Gallenkamp m.p. apparatus and are not corrected.

*3-Cyano-4-hydroxy-1,2,5-thiadiazole (**1**, R = CN)*

This compound was prepared from isonitrosocyanoacetamide and sulfur dichloride according to Ross and Smith (3) but with the following modification: The solid residue obtained after evaporation of the reaction mixture was dissolved in sodium carbonate solution (100 g/l) and the solution was washed with ether. The aqueous phase was made acidic with 10% hydrochloric acid, the product was extracted into ether, the extract was dried over sodium sulfate, treated with activated charcoal and then evaporated *in vacuo*. The residual solid (61–63% yield) had m.p. 157–160° (lit. (3) m.p. 157–160°).

*3-Hydroxy-1,2,5-thiadiazole (**1**, R = H)*

This compound was prepared from glycinamide (9) and

sulfur monochloride as described by Weinstock *et al.* (10) except that the crude product was first freed of impurities by solution in sodium carbonate, etc., as described above for the 4-cyano derivative.

4-Cyano-1,2,5-thiadiazol-3-yl-N,N-dimethylthionocarbamate (2, R = CN)

The general procedure of Newman and Karnes (4) was modified as follows: A 55% dispersion of sodium hydride in mineral oil (6.25 g) was washed with hexane, layered with dry DMF (125 ml), and cooled with stirring, in an atmosphere of dry nitrogen, to 0°. The hydroxy nitrile (16.5 g, 130 mmol) was added portionwise, and when gas evolution was complete, dimethylthiocarbamyl chloride (17.6 g, 143 mmol) was added all at once. The cooling bath was removed, and after 20 h at room temperature the solution was poured into ice-water. The mixture was extracted with benzene, the extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was crystallized from benzene – petroleum ether (b.p. 30–60°) to give a yellow solid (21.22 g, 76%), m.p. 84–87°. Recrystallization of this material (charcoal) gave an analytical specimen, m.p. 85–87°.

Anal. Calcd. for $C_6H_6N_4OS_2$: C, 33.63; H, 2.82; N, 26.15. Found: C, 33.68; H, 2.80; N, 26.20.

1,2,5-Thiadiazol-3-yl-N,N-dimethylthionocarbamate (2, R = H)

This compound was prepared in the same way as the above cyano derivative except that the crude oily thionocarbamate was purified by dry column chromatography (11) on silica gel (Brinkman, Activity II–III, 10 g/g substrate) using 2% methanol in chloroform (v/v) as the eluant. The first 200 ml of the eluate (reaction scale, 200 mmol) was discarded, and the next 600 ml contained the pure thionocarbamate (26.83 g). An additional small amount of the product (1.39 g), which was slightly contaminated with more polar substances, was contained in the next 100 ml of the eluate. The main fraction was sufficiently pure to be used in the next step. A portion of this fraction was analyzed.

Anal. Calcd. for $C_5H_7N_3OS_2$: C, 31.73; H, 3.73; N, 22.20. Found: C, 31.79; H, 3.78; N, 22.22.

4-Cyano-1,2,5-thiadiazol-3-yl-N,N-dimethylthiolcarbamate (3, R = CN)

The thionocarbamate (20.5 g, 96 mmol) was heated in an oil bath at 130° under an atmosphere of nitrogen for 40 min. The deeply-colored material was slurried with ether (800 ml), the mixture was filtered, the filtrate was treated with activated charcoal, and finally evaporated *in vacuo*. The residual yellow solid (16.03 g, 78.5%) had m.p. 74–78° and was sufficiently pure to be used in the next step. Recrystallization of this material from benzene–cyclohexane gave a white solid m.p. 79–81°.

Anal. Calcd. for $C_6H_6N_4OS_2$: C, 33.63; H, 2.82; N, 26.15. Found: C, 33.75.; H, 2.80; N, 26.20.

1,2,5-Thiadiazol-3-yl-N,N-dimethylthiolcarbamate (3, R = H)

The chromatographically pure thionocarbamate (18.6 g) was stirred in a nitrogen atmosphere at 170° for 3 h. The deeply-colored oil was dissolved in a small amount of 2% methanol in chloroform, absorbed onto silica gel (20 g, Brinkman, Act II–III) and dried *in vacuo*. This material was placed on top of a dry packed column of silica gel (200 g) and the column was developed with 2% methanol-in-chloroform (100 ml fractions). Fractions 2–3 contained the starting material (5.76 g), and fractions 4–6 contained the product (12.46 g). The recovered starting material was subjected to the above rearrangement conditions (170°, 2.5 h) and after chromatography there was obtained 1.47 g of starting material, and 4.10 g of the thiolcarbamate. The combined product was distilled to give the pure thiolcarbamate (14.12 g, 76%), b.p. 107–108°/0.05 mm. A portion of this material was redistilled for analysis.

Anal. Calcd. for $C_5H_7N_3OS_2$: C, 31.73; H, 3.73; N, 22.20. Found: C, 31.73; H, 3.76; N, 22.46.

4-Carboxamido-1,2,5-thiadiazole-3-thiol dicyclohexylammonium salt (4, R = $CONH_2$)

A solution of 4-cyano-1,2,5-thiadiazol-3-yl-*N,N*-dimethylthiolcarbamate (14.0 g, 65.5 mol) in absolute ethanol (400 ml) containing potassium hydroxide (20.4 g of a 45 wt. % solution, 164 mmol) was heated under reflux for 1 h. The yellow solid (10.0 g, 76.5%; m.p. 265–267° dec.) which separated on cooling was collected by filtration and dried *in vacuo*. This salt was not readily recrystallized, and could not be obtained analytically pure. It was, however, sufficiently pure to be used for alkylation purposes. The thiol was characterized as its dicyclohexylammonium salt which was prepared in the following manner: The crude potassium salt (1.0 g) was dissolved in water, the solution was acidified with 10% hydrochloric acid, and the product was immediately extracted into ethyl acetate. The extract was dried over sodium sulfate and evaporated *in vacuo*. The white solid which remained (594 mg, m.p. 117–121°) was immediately dissolved in ethanol and added to an equimolar amount of ethanolic dicyclohexylamine. Dilution of the solution to turbidity with ether caused the crystallization of the salt (1.01 g), m.p. 166–169°. Recrystallization gave material with m.p. 168–170°.

Anal. Calcd. for $C_3H_3N_3OS_2$:$C_{12}H_{23}N$: C, 52.60; H, 7.65; N, 16.36. Found: C, 52.38; H, 7.67; N, 16.61.

1,2,5-Thiadiazole-3-thiol mercuric salt (4, R = H)

1,2,5-Thiadiazol-3-yl-*N,N*-dimethylthiolcarbamate was hydrolyzed in the manner described for the 4-cyano derivative. The ethanolic solution of the product was evaporated *in vacuo* to give a yellow solid (17.0 g from a 74.6 mmol reaction) which was not easily freed from inorganic materials. It could be shown by alkylation with methyl bromoacetate or by conversion to the mercuric salt, that the above mixture contained *ca.* 62% by weight of the potassium salt. This therefore corresponded to a 90% yield of the thiolate. The mercuric salt was prepared as follows: A solution of the crude salt (1.26 g, 5 mmol) was dissolved in water and the p*H* of the solution (p*H* meter) was adjusted to p*H* 7 by the addition of a few drops of glacial acetic acid. A solution of mercuric acetate (0.8 g, 2.5 mmol) in water (10 ml) was added and the precipitated solid (1.0 g), m.p. 177–180°, was collected by filtration and dried *in vacuo*. Crystallization of this solid from acetone gave material with m.p. 177–179°.

Anal. Calcd. for $C_2HN_2S_2$:0.5 Hg: C, 11.05; H, 0.46; N, 12.88. Found: C, 11.10; H, 0.58; N, 12.98.

4-Carboxamido-3-methoxycarbonylmethylthio-1,2,5-thiadiazole (6, R = H, R′ = CH_3)

The crude potassium salt described above (1.99 g, 10 mmol) and methylbromoacetate (1.8 g, 11.8 mmol) in

methanol (10 ml) was heated under reflux for 1 h. The solution was evaporated *in vacuo*, the residue was treated with hot benzene and filtered. The filtrate on cooling deposited a crystalline solid (1.12 g, 48%) m.p. 144.5–146°. Recrystallization gave material with m.p. 145–146°.

Anal. Calcd. for $C_6H_7N_3O_3S_2$: C, 30.89, H, 3.03; N, 18.01. Found: C, 30.84; H, 3.05; N, 17.88.

3-Carboxymethylthio-1,2,5-thiadiazole (6, R = R′ = H)

(a) From Crude Potassium-1,2,5-thiadiazole-3-thiolate

A solution of the crude salt (1.06 g) in methanol (50 ml) containing an excess of ethyl bromoacetate (1.9 g, 12.4 mmol) was heated at reflux temperature for 1 h. The cooled mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was diluted with water, and the product was extracted into dichloromethane. The extract was dried over sodium sulfate, the solvent was removed *in vacuo*, and the residue was evaporatively distilled at 95–105°/0.05 mm to give the ester (803 mg, 4.23 mmol). On the basis of the yield of the ester obtained, the crude salt described above contained a minimum of 62% by weight of the potassium thiolate. Redistillation of the ester (b.p. 72–74°/0.005 mm) did not remove a small amount of an impurity (< 10%). The ester was therefore saponified as follows. A solution of the ester (380 mg, 2 mmol) in 50% aqueous methanol (20 ml) containing 45 wt. % aqueous potassium hydroxide (250 mg, 2 mmol) was boiled under reflux for 1.25 h. Most of the methanol was removed *in vacuo*, the residue was extracted with benzene, and the aqueous phase was then made acidic with 10% hydrochloric acid. The product crystallized (326 mg, 92%) and had m.p. 127–129°. Two recrystallizations of this material from water gave a solid with m.p. 128–129°.

Anal. Calcd. for $C_4H_4N_2O_2S_2$: C, 27.26; H, 2.29; N, 15.90. Found: C, 27.05; H, 2.31; N, 15.97.

(b) From the Mercuric Salt

Following the method of Soderback (12) for the conversion of mercuric thiolates to sodium thiolates, the mercuric salt (784 mg, 1.8 mmol) was added portionwise to a stirred solution of sodium sulfide nonahydrate (385 mg, 1.6 mmol) in water at 0°. After 30 min at 0°, the test for soluble sulfide ion (sodium plumbite solution) was negative. The mixture was filtered through Celite, the filtrate was diluted with methanol (50 ml), and methyl bromoacetate (400 mg, 2.63 mmol) was added. The solution was heated at reflux temperature for 1 h and then processed in the manner described above to give the crude ester which was saponified without purification. There was obtained a solid (145 mg, 31% based on methyl bromoacetate), m.p. 126–127° identical to the carboxylic acid prepared by method *a*.

Five-membered Heterocyclic Thiones. Part IV.[1] 1,2,4-Thiadiazole-3-thiolates and 1,2,4-Thiadiazole-5-thione

G. LACASSE AND J. M. MUCHOWSKI[2]
Bristol Laboratories of Canada, Candiac, Quebec
Received November 28, 1972

1,2,4-Thiadiazole-5-thione (**2***a*) was synthesized from the corresponding 5-bromo compound. An alternative synthesis of the known 3-methyl-1,2,4-thiadiazole-5-thione is described. It was shown by i.r. spectroscopy that the parent compound and its 3-methyl derivative existed in the thione form in the solid state.

Mercuric-1,2,4-thiadiazole-3-thiolate (**5**) was prepared by cleavage of the corresponding disulfide with mercury. The mercuric salt was converted to a stable (in solution) sodium salt, but the free thio compound was not isolable.

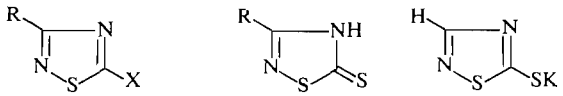
Le thiadiazole-1,2,4 thione-5 (**2***a*) a été synthétisé à partir du composé correspondant bromo-5. On décrit une nouvelle synthèse du composé connu suivant, le méthyl-3 thiadiazole-1,2,4 thione-5. Il a été montré à l'aide de la spectroscopie i.r. que le composé parent et son dérivé méthyl-3 existe à l'état solide sous la forme thione.

Le thiolate-3 mercurique de thiadiazole-1,2,4 (**5**) a été préparé par clivage à l'aide du mercure du disulfure correspondant. Le sel mercurique a été converti en un sel de sodium stable (en solution) mais le composé thio libre n'a pu être isolé. [Traduit par le journal]

Can. J. Chem., **51**, 2353 (1973)

There are two possible 1,2,4-thiadiazole thiols, and ring-substituted representatives of each isomer are known (2,3), but the parent members have not, to our knowledge, been previously described.

3-Substituted-1,2,4-thiadiazole-5-thiones (**2**, Scheme 1) are easily prepared (4) by the base-promoted fragmentation of the corresponding isothiouronium salts (*e.g.*, **1***b*, **1***e*) which in turn are obtained from the readily available (4–7) 5-chloro compounds (1, X = Cl) and thiourea. When the conditions are suitably modified, this method is also applicable to the synthesis of the parent thione (**2***a*).



1 **2** **3**

a R = H; X = Br

b R = H; X = S—C(=NH_2^+)—NH_2 Br^-

c R = H; X = SCH_3

d R = CH_3; X = Cl

e R = CH_3; X = S—C(=NH_2^+)—NH_2 Cl^-

f R = CH_3; X = S—P(=O)$(ONa)_2$

a R = H
b R = CH_3

SCHEME 1

The isothiouronium bromide **1***b* (prepared in the usual way from the bromo compound **1***a*), when treated with slightly less than 2 equiv of alkali at room temperature, followed by careful acidification to p*H* 3, gave the crystalline thione **2***a* in 52% overall yield. The structure of this compound was fully substantiated by its elemental analysis and spectral properties (see Table 1), and by conversion to a very stable potassium salt **3** and an oily *S*-methyl ether **1***c*.

The known 3-methyl analog **2***b* of **2***a* was prepared (for comparative purposes) from **1***d* via the isothiouronium salt **1***e* according to the published procedure (4). This thione could also be obtained by the acid-catalyzed decomposition of the salt **1***f* which was prepared from the chloro compound **1***d* and trisodium thiophosphate. This latter substance has often been used to prepare aliphatic thiols from the corresponding halo alkanes (see ref. 8 for example),[3] but to our knowledge it has not heretofore been utilized for the synthesis of heterocyclic thiones.

[1]For Part III, see ref. 1.

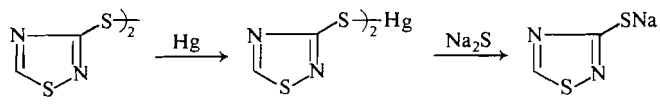
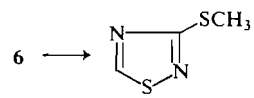
[c]Nujol mull.
[d]Recorded in KBr.
[e]Liquid film.





SCHEME 2

3-Mercapto-5-substituted-1,2,4,-thiadiazoles are prepared in several ways (ref. 2, pp. 567–573 and ref. 3, pp. 147–150) none of which is general. The parent member of this series was obtained from the known (9) disulfide **4** (Scheme 2) in a manner identical to that described by Soderback (10) for the preparation of the 5-chloro analog. Thus, cleavage of the above disulfide with mercury gave the stable mercuric salt **5** of 1,2,4-thiadiazole-3-thiol, which was transformed to the corresponding sodium salt **6** with sodium sulfide. The stability of the free thio compound was minimal since extraction of an acidified aqueous solution of the sodium salt did not result in the isolation of any alkali soluble material. Furthermore, it was not possible to isolate the sodium salt **6**, but its presence in solution was confirmed by transformation to the known (11) crystalline *S*-methyl ether **7**.

The solid state i.r. spectrum of 1,2,4-thiadiazole-5-thione (**2***a*) and its 3-methyl analog **2***b* were devoid of absorptions in the 2600–2500 cm^{-1} region,[4] showing that the thione tautomer predominated under these conditions. This contention is supported by the presence of a strong band, tentatively assigned to the C=S stretching

[4]A referee has suggested that the absorption at 2660 cm^{-1} for **2***a* cannot be ignored. In fact, it is exceedingly unlikely that this band is due to the mercapto form of **2***a*, since it is well-known that the SH stretching absorption of a wide variety of mercaptans occurs within the specified region (12). For example, for thiophene-2- and 3-thiols this absorption occurred at 2540–2510 cm^{-1} (13), while isoxazole-5-thiols absorbed at 2550 cm^{-1} (14), and 2-methyl-1,2,3-triazole-4-thiol had a strong band at 2540 cm^{-1} (15). The absence of an absorption in this region for compounds in which thione–thiol tautomerism is possible is now generally considered to be diagnostic of the thione form (16).

U.v. spectroscopy is also often utilized for the study of thione–thiol tautomerism. To be useful, however, the u.v. of an *N*-alkyl and an *S*-alkyl derivative must be compared to that of the thione (thiol), and even then a definite conclusion is often not possible (16).

vibration, at 1222 cm^{-1} in **2***a* and 1233 cm^{-1} in **2***b*.[5]

Experimental

The melting points were determined in a Gallenkamp m.p. apparatus and are not corrected.

*1,2,4-Thiadiazole-5-thione (**2***a*) *and potassium-1,2,4-thiadiazole-5-thiolate (**3**)*

A solution of 5-bromo-1,2,4-thiadiazole (9.10 g, 59.5 mmol (19)), in absolute ethanol (250 ml) containing thiourea (4.50 g, 59.1 mmol) was boiled under reflux in a nitrogen atmosphere for 2 h. The solution was evaporated to 50 ml *in vacuo*, 1 *N* sodium hydroxide (118 ml) was added, and the resultant was stirred at room temperature in an atmosphere of nitrogen for 20 min. The solution was extracted with ether (discarded) and the aqueous phase was made acidic to p*H* 3 (p*H* meter) with 4 *N* sulfuric acid. The product was extracted into ether, the extract was dried over sodium sulfate, and evaporated *in vacuo* ($T \leq 20°$) to give the crude crystalline thiol. This material could not be recrystallized; for analysis a small portion of this substance was sublimed at 65°/0.005 mm to give a solid m.p. 93°.

Anal. Calcd. for $C_2H_2N_2S_2$: C, 20.33; H, 1.71; N, 23.71. Found: C, 20.06; H, 1.62; N, 23.90.

The crude thiol from above was dissolved in absolute ethanol (25 ml), an equimolar amount of 1 *N* alcoholic potassium hydroxide was added, and the solution was diluted with dry ether (400 ml). The solid (4.27–5.11 g, 46–55% based on the bromo compound), m.p. 220° dec. was collected by filtration. Crystallization of this material from ethanol–ether (2:3) did not raise the melting point.

Anal. Calcd. for $C_2HN_2S_2K$: C, 15.37; H, 0.65; N, 17.93. Found: C, 15.53; H, 0.74; N, 17.92.

*5-Methylthio-1,2,4-thiadiazole (**1***c*)

A mixture of methyl iodide (3.42 g, 24 mmol) and water (45 ml) containing potassium-1,2,4-thiadiazole-5-thiolate (2.50 g, 16 mmol) was stirred at room temperature for 18 h. The product was extracted into dichloromethane, the extract was dried over sodium sulfate, and evaporated *in vacuo*. The residual oil was distilled at reduced pressure, and a fraction (1.62 g, 77%), b.p. 30–32°/0.1 mm was collected.

Anal. Calcd. for $C_3H_4N_2S_2$: C, 27.25; H, 3.05; N, 21.19. Found: C, 27.36; H, 3.05; N, 21.28.

*1,2,4-Thiadiazol-3-yl Disulfide (**4**)*

The 3-*t*-butylthio-1,2,4-thiadiazole which was required, was prepared by the method of Goerdeler and Budnowski (11) from *t*-butylisothiouronium chloride (20) and dichloromethanesulfenyl chloride (11). It contained an impurity which lacked an aromatic proton absorption in the n.m.r. spectrum. Although this material could be removed at this stage by column chromatography on silica gel, in general it was more conveniently separated at the disulfide stage. The disulfide, was prepared by the partial chlorination (9) of the above sulfide, but the quantity of chlorine was adjusted to the true sulfide content as determined from the n.m.r. spectrum. The crude product was purified by dry column chromatography (21) on silica gel (Brinkman, *ca.* Act. II, 20 g/g of substrate) using chloroform as the eluant. A portion (13 g) of the disulfide when purified in this way (100 ml fractions) gave a crystalline solid (8.4 g, from fractions 16–25), m.p. 116–119° (reported (9) m.p. 119°). The n.m.r. spectrum (1:1 DMSO-d_6 – $CDCl_3$) consisted of a singlet at δ 10.38.

*Mercuric-1,2,4-thiadiazole-3-thiolate (**5**)*

The cleavage of the disulfide was effected by the method of Soderback (10). A mixture of the disulfide (3.4 g, 14.5 mmol), mercury (10 ml), and dry ether (100 ml) was shaken mechanically for 18 h. The ether was decanted and the residual mixture was suspended in ether and decanted from the mercury. The product was collected by filtration, and dried *in vacuo*. It had m.p. 195° dec. (6.2 g, 98%) and could be recrystallized from a large amount of benzene, but the melting point was not improved.

Anal. Calcd. for $C_4H_2N_4S_4Hg$: C, 11.05; H, 0.46; N, 12.88. Found: C, 11.15; H, 0.53; N, 12.97.

*Generation of Sodium-1,2,4-thiadiazole-3-thiolate in situ and Preparation of 3-Methylthio-1,2,4-thiadiazole (**7**)*

The method described by Soderback (10) was used. The above mercuric salt (1.01 g, 2.32 mmol) was added at 0° to a stirred solution of sodium sulfide nonahydrate (504 mg, 2.1 mmol) in water (50 ml). The mixture was stirred in a nitrogen atmosphere at 0° for ½ h, methyl iodide (640 mg, 4.5 mmol) was added, and stirring at room temperature was then maintained for 18 h. Ether was added to the mixture, and after thorough agitation the mixture was filtered through Celite. The ether phase was separated, dried over sodium sulfate, and evaporated *in vacuo*. The residual oil was distilled to give a fraction b.p. 38–40°/0.05 mm (500 mg, 90%). On crystallization from petroleum ether (b.p. 30–60°) at −70°, a solid, m.p. 32° (reported (11), m.p. 32.5°), with physical properties different from 5-methylthio-1,2,4-thiadiazole, was obtained. The n.m.r. spectrum (CCl_4) showed two singlets at δ 2.73 (3H) and 9.88 (1H).

*3-Methyl-1,2,4-thiadiazole-5-thione **2**b*

A mixture of the chloro thiadiazole (**1***d*; 1.34 g, 10 mmol) and an aqueous solution of trisodium thiophosphate (3.40 g, 20 mmol) was stirred at room temperature until solution of the chloro compound had occurred (66 h). The solution was extracted with benzene, and the aqueous phase was made acidic with concentrated hydrochloric acid at 0°. The solid which precipitated (1.27 g, 96%) had m.p. 147–149° (reported (4), m.p. 151°) and was spectroscopically (i.r., n.m.r.) indistinguishable from the thiol prepared by the isothiouronium salt method (4).

[5]The position of this absorption varies considerably (17, 18) and its diagnostic value is thus limited.

Tricyclic Hydrocarbons. II. Carbon-13 Nuclear Magnetic Resonance Spectroscopy as a Method for Unambiguous Structure Determination

GERALD WALLACE BUCHANAN[1] AND ROBERT HARLAN WIGHTMAN

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received February 14, 1973

Carbon-13 n.m.r. spectroscopy is demonstrated to be unique as an unambiguous and general method for determining structure in a series of isomeric tricyclic benzenoid hydrocarbons. Observed carbon shieldings for the tricyclic materials are discussed and compared with those for related bicyclic and monocyclic compounds.

On a démontré que la spectroscopie r.m.n. du carbone-13 représente la seule méthode générale et précise pour attribuer les structures d'une série d'hydrocarbures benzènoides tricycliques isomériques. Les blindages des carbones observés pour les produits tricycliques sont discutés et comparés avec ceux reliés aux composés bicycliques et monobicycliques et monocycliques.

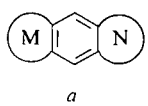
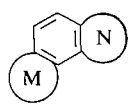
Introduction

The lack of facile and unambiguous structure proofs for tetra-substituted benzenoid hydrocarbons has hindered a variety of investigations. Early workers relied on oxidative degradation reactions, which were both time and material consuming, to produce tetracarboxylic acids of a given substitution pattern (1). For some time disagreement regarding structural assignments for these compounds existed (2).

Specifically, the problem involves identification of the linear (*i.e.* 1,2,4,5-substituted) *vs.* the angular (1,2,3,4-substituted) molecules. The six isomeric pairs denoted below will be discussed



a



b

1 M = N = 5 **4** M = N = 8 **7** M = 0; N = 5
2 M = N = 6 **5** M = 5; N = 6 **8** M = 0; N = 6
3 M = N = 7 **6** M = 5; N = 7 **9** M = 0; N = 7
10 M = 0; N = 8

in relation to the corresponding bicyclic materials **7, 8, 9,** and **10** (M and N refer to the size of the saturated carbocyclic ring).

The necessity for a generally applicable method of isomer differentiation in these compounds is clear from the recent work of Markl and Fuchs (3) in which structures for **4***a* and *b* have been erroneously assigned. Historically a combination of i.r., u.v., and ^{1}H n.m.r. spectra combined with identification of all precursors in the synthetic sequence have been used in an attempt to solve this problem. In principle the linear and angular isomers should be distinguishable on the basis of the i.r. bands ascribed to the out-of-plane C—H deformation vibrations of the aromatic protons (4). The presence of border-line and combination bands, however, complicates the application of this procedure. In the u.v. spectra the linear arrangement in **1** and **2** produces small bathochromic shifts relative to the angular, but this trend does not persist for the 7–7 and 8–8 isomers **3** and **4** (5). Early investigators in this area assumed that a given isomeric structure followed directly from the synthetic sequence (6). Although identification of precursors is possible (7), it has been demonstrated recently (8, 9) that some of the previously accepted synthetic routes give anomalous products. Furthermore, the mass spectral fragmentation patterns of each pair of isomers are essentially identical (10).

Due to the symmetry of the molecules, the ^{1}H n.m.r. spectra for the aromatic protons do not provide a useful method of isomer identification and the highly coupled methylene regions are difficult to analyze. It is known that carbon-13 n.m.r. (c.m.r.) chemical shifts are an order of magnitude more sensitive to structural change than ^{1}H shieldings (11) and in addition, proton decoupled c.m.r. spectra can be readily analyzed. We herein report the

Results and Discussion

An example of the numbering scheme used for the linear and angular isomers is presented below for compounds **4***a* and *b*. To facilitate discussion, the methylene carbon shieldings are collected in Table 1 and those for aromatic carbons are in Table 2.

(*a*) *Methylene carbons*

In **1***a*, **2***a*, **3***a*, **4***a*, **7**, **8**, **9**, and **10**, the α-carbon resonances were assigned from specific ^1H decoupling experiments since it is well known that benzylic protons resonate at lower field

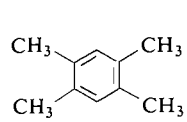
than those further removed from the aromatic ring. These assignments for **1***a*, **3***a*, **7**, and **9** were supported by the observed integrated intensity ratios. Differences in nuclear Overhauser enhancements for methylene carbons of this type will be minimal. With the exception of **2***a*, **2***b*, **7**, and **8**, no carbon shifts have been reported for the present compounds. Observed methylene shieldings for these four molecules are in reasonable agreement with earlier findings (12, 13).

Examination of the data in Table 1 indicates that methylene carbons in **1***a*, **2***a*, **3***a*, and **4***a* have nearly identical chemical shifts to their bicyclic counterparts **7**, **8**, **9**, and **10** respectively. Apparently no measurable effects are transmitted between the remote alicyclic rings in the linear series. Extension of these observations to the 5–6 linear (**5***a*) and 5–7 linear (**6***a*) tricyclic molecules permits unambiguous assignment of resonances.

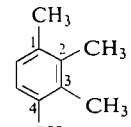
The low field shift (32.9 p.p.m.) observed for the γ-carbon in the seven-membered rings of **3***a* and **9** compared with the γ-carbon shift of *ca.* 28.5 p.p.m. in **4***a* and **10** merits comment. From the early work of Grant and Paul (14) the effects of alkyl substitution on the c.m.r. shieldings of saturated alicyclic hydrocarbons were established. Replacement of an α-hydrogen by carbon causes a deshielding of *ca.* 9 p.p.m., and replacement of a β-hydrogen by carbon causes a further deshielding of comparable magnitude. The γ-carbon of **3***a* and **9** has two α-CH_2's and two β-CH_2's whereas *each* γ-carbon of **4***a* and **10** has only one α-CH_2 and two β-CH_2 groupings. Accordingly a considerable downfield shift of the γ-carbon in **3***a* and **9** relative to **4***a* and **10** would be expected.

A similar approach can be used to explain the relatively high field β-carbon shift in **3***a* and **9** (28.4 p.p.m.) compared to that of 32.5 p.p.m. for the β-carbon of **4***a* and **10**. Each β-carbon in **3***a* and **9** possesses two α-CH_2's and *no* β-CH_2 substituents, whereas in **4***a* and **10** each β-carbon has two α-CH_2's and one β-CH_2 group.

Assignments for the angular isomers **1***b*, **2***b*, **3***b*, and **4***b* are based on the assumption that the α-, β-, and γ-carbon resonances will be similar to those in the linear series since remote alicyclic interactions for these carbons have been shown to be minimal. Inter-ring interactions are expected however for the α′-, β′-, and γ′-carbons due to steric factors. No doubt



11

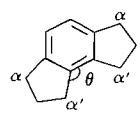


12

the most pronounced effects will occur at the α′-position.

In this context it is important to recall the results of Woolfenden and Grant (15) for durene **11** and prehnitene **12**. The methyls of durene resonate at δ 19.1 whereas those for prehnitene appear at 20.4 and 15.3 p.p.m., respectively. The 2,3-methyl groups of **12** are shielded by *ca.* 5 p.p.m., relative to the 1,4-substituents, a result explained by Grant and Cheney (16) on the basis of sterically induced charge polarization in the C—H bonds. The upfield shifts in the α′-carbon resonances of **2***b*, **3***b*, and **4***b* relative to the α-positions are reminiscent of the methyl shift differences in **12** (*ca.* 5 p.p.m.) and can be reasonably interpreted on similar steric grounds.

It is interesting to note that the α′-carbon of **1***b* is shifted upfield by only 1.4 p.p.m. relative to its α counterpart. Examination of molecular models shows that due to the smaller internal angles in the five-membered rings, the angle θ will increase in **1***b* relative to the



1*b*

corresponding angle in **2***b*, **3***b*, and **4***b*. As a consequence the α′-carbons will be pulled farther apart and the non-bonded repulsions between the methylene protons attenuated, causing the α′-carbons to be correspondingly less shielded.

Employing **1***b* and **2***b* as models, methylene resonances for the 5–6 angular isomer **5***b* can now be assigned with confidence. Here the upfield shift in the α′-resonance (relative to α) of the six-membered ring is less (2.6 *vs.* 4.5 p.p.m.) than in **2***b*, due to the angle distorting effect of the five-membered ring. Conversely the upfield α′-shift in the five-membered ring is greater (1.8 *vs.* 1.4 p.p.m.) than in **1***b*, as expected from substitution of a six-membered ring in the angular position. Additional support for the α- and α′-values for all angular isomers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was gained from specific proton decoupling experiments on the benzylic hydrogens.

Analogously **1***b* and **3***b* serve as models for the 5–7 angular isomer **6***b*. Again, fusion of the five-membered ring relieves some of the Van der Waals repulsion at the α′-hydrogens of the seven-membered ring, resulting in a smaller upfield shift for this α′-carbon relative to α (3.4 p.p.m.) than is observed in **3***b* (5.6 p.p.m.).

(*b*) *Aromatic Carbons*

Assignments for the linear isomers **1***a*, **2***a*, **3***a*, and **4***a* are straightforward since absorptions for carbons bearing no directly bonded protons retain their singlet structure in the off-resonance decoupling experiment. From the shieldings in **1***a* and **2***a*, assignments in the 5–6 linear isomer **5***a* follow directly. Quaternary carbons in **6***a* have nearly identical shieldings as expected, in view of results for **1***a* and **3***a*.

For **9** and **10**, shifts for C-3,6 *vs.* C-4,5 were assigned by analogy with **8** (12). It is interesting to note the similarity in the C-4,5 shieldings with that of benzene (128.7 p.p.m.). In the case of **7**, the bracketed values in Table 2 indicate a possibility of reversed assignments. Nevertheless it is clear from data for **1***a* and **7** that fusion of a five-membered ring induces appreciable upfield shifts in resonances of C-3 and -6 relative to larger ring materials.

Resonances for C-5 and -6 of the angular isomers **1***b*, **2***b*, **3***b* and **4***b* can be clearly assigned from the off-resonance decoupling experiment due to the inherent symmetry of these molecules. It is not possible, however, to unambiguously assign the quaternary carbons C-1,4 *vs.* C-2,3 in these angular isomers. In any event only small differences (1–2 p.p.m.) separate the resonances.

Using **1***b* and **2***b* as models, assignments for **5***b* follow directly, with the possible interchange of C-1 with -2 and C-3 with -4 resonances. Similarly, employing **1***b* and **3***b*, data for **6***b* can be rationalized.

Conclusions

It is abundantly clear that ^{13}C n.m.r. constitutes a superior method for structure determination in tricyclic hydrocarbons. Nearly all methylene carbon resonances can be unambiguously assigned and isomeric trends explained on steric grounds. Difficulties in assignment of quaternary aromatic carbon resonances on the basis of chemical shifts are obvious and no doubt T_1 measurements will be invaluable in this area in the future.

Experimental

Materials

The tricyclic hydrocarbons were synthesized as previously described (8): Compounds **7, 8, 11,** and **12,** were commercially available samples and were used without further purification. Benzsuberane (**9**) is readily available from 1-benzsuberone which can be obtained commercially (17). Benzocyclooctene (**10**) was prepared according to the procedure of Wittig *et al.* (18).

Spectra

The c.m.r. spectra were obtained at 25.2 MHz using a Varian XL-100-12 NMR spectrometer, most commonly under conditions of complete proton noise decoupling. Spectral accumulations were accomplished with a Varian C-1024 time-averaging computer. Samples were contained in 8 mm tubes and were examined as 0.5 *M* solutions in $CDCl_3$ containing 2% TMS as an internal standard. Off-resonance decoupling experiments were carried out with the proton frequency offset approximately 500 Hz from the center of the proton spectral region.

We thank Mr. A. E. Gustafson for preparation of a sample of benzocyclooctene. Generous financial support from the National Research Council of Canada is gratefully acknowledged.

Activity Determination of Cobalt in Cobalt–Gold Alloys

S. S. WANG and J. M. TOGURI

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario M5S 1A4

Received January 15, 1973

Activities of cobalt in cobalt–gold liquid alloys from 1250 to 1335 °C were determined by equilibrating the alloy with pure solid CoO under a CO/CO_2 gas mixture of known oxygen partial pressure. The cobalt activities were calculated from the cobalt content of the alloys after equilibration. The activities of gold were calculated by Gibbs–Duhem integration. In the present study, both activities showed positive deviations from ideality. In the terminal region, the cobalt–gold system was found to behave as a regular solution. The temperature effect on the activities was found to be negligible.

Les activités du cobalt dans des alliages liquides cobalt–Au pour des températures allant de 1250 à 1335 °C ont été déterminées par équilibration de l'alliage avec du CoO pur solide sous une atmosphère gazeuse CO/CO_2 possèdant une pression partielle connue d'oxygène. Les activités inhérentes au cobalt ont été évaluées à partir du contenu en cobalt des alliages après équilibration. Les activités de l'or ont été calculées en utilisant une intégration du type Gibbs–Duhem. Dans la présente étude, les deux activités ont montré des déviations positives comparativement au cas idéal. Dans la région terminale, le système Au–cobalt possède un comportement que l'on peut assimiler à celui d'une solution régulière. L'effet de la température sur les activités est négligeable. Introduction

Data on the thermochemical properties of liquid cobalt–gold alloys are not available. Since these data were required in a study of the cobalt losses to slags, the present study was undertaken. Over the temperature range of interest, the phase diagram of the cobalt–gold system indicates that the composition range of the liquid alloy is limited to a cobalt concentration of approximately 75 at. % (1). Consequently, the activity determinations have been limited to this range.

The method adopted to determine the activities of cobalt in liquid cobalt–gold alloys was to equilibrate the alloys with pure solid CoO and a CO/CO_2 gas mixture of known oxygen partial pressure. The standard state of the cobalt chosen was that of pure supercooled liquid cobalt. The equilibrium involved is

$$[1] \qquad 2CoO_{(s)} = 2Co_{(l)} + O_{2(g)}$$

The equilibrium constant for this reaction is

$$[2] \qquad K_1 = \frac{a_{Co}{}^2 P_{O_2}}{a_{CoO}{}^2}$$

where a's are the respective activities and P_{O_2}, the partial pressure of oxygen.

Although CoO displays deviations from stoichiometry, this deviation is very small particularly in the temperature and oxygen pressure range of this study, as indicated by Smith and Masson (2). Since gold does not enter into solution with the oxide phase, the activity of CoO is assumed to be unity. The cobalt activity can then be expressed as

$$[3] \qquad a_{Co} = \left(\frac{K_1}{P_{O_2}}\right)^{1/2}$$

For the case of pure cobalt, $a_{Co} = 1$ and

$$[4] \qquad P_{O_2}{}^{\text{pure Co}} = K_1$$

Consequently,

$$[5] \qquad a_{Co} = \left(\frac{P_{O_2}{}^{\text{pure Co}}}{P_{O_2}}\right)^{1/2}$$

where P_{O_2} and $P_{O_2}{}^{\text{pure Co}}$ are the oxygen partial pressures at which CoO is in equilibrium with a Co–Au alloy and pure Co respectively. The value of $P_{O_2}{}^{\text{pure Co}}$ can be calculated from a knowledge of the standard free energy change ($\Delta G_1{}^0$) for reaction 1. Using the thermodynamic values recommended by Kubaschewski, Evans, and Alcock (3), the $\Delta G_1{}^0$ can be expressed as

$$[6] \quad \Delta G_1{}^0 = 119\,423 - 0.1T \ln T - 37.26T$$

Experimental

The experimental apparatus used for this study has been described in detail previously (4). It consisted of an alumina reaction tube heated by a temperature controlled molybdenum furnace. The reaction tube contained an alumina tray cemented to an alumina thermocouple protection tube. This assembly, including alumina baffles,

rested on an alumina gutter to avoid cracking the main reaction tube during the quenching operation. The temperature variation was ±3 °C over a 2 in. zone.

The required oxygen pressure in the furnace was obtained by using C. P. Matheson grade CO and CO_2. These gases were passed through a Drierite column to remove moisture. The CO_2 was also passed through a copper getter furnace (≃500 °C) to remove residual traces of oxygen. The gas flows were controlled by use of calibrated flow meters. The total flow rate of the CO and CO_2 was 500 ml min^{-1}.

For the oxygen potentials required in this study, the P_{CO_2}/P_{CO} ratio was in the range where the carbon deposition reaction is thermodynamically unfavorable (5).

The purity of the cobalt used in this study was 99.99% while the purity of gold was 99.95%. The alloys were prepared by induction heating under a hydrogen atmosphere.

The experimental procedure was as follows. Approximately 1 g of the prepared alloy was set inside a zirconia crucible and covered with approximately 1 g of solid oxide powder. The crucible was placed into one of the holes of the alumina tray. The system was closed and flushed with argon gas. The tray was slowly pushed into the reaction tube until the hot zone was reached. The gas was then switched to a CO_2/CO gas mixture and the system was left to equilibrate for at least 48 h. After the required time elapsed, the CO_2/CO gas mixture was switched again to purified argon and the samples were quenched by pulling the tray assembly out into the cold regions of the furnace.

Preliminary experiments were carried out to determine the time required for equilibrium. Three alloy samples of the same initial composition were used under the same conditions except over three different equilibrating times; 12 h, 24 h, and 48 h. It was found that 24 h was sufficient. However, to insure the attainment of equilibrium 48 h was adopted as the equilibrating time.

Cobalt was analyzed by an atomic absorption technique as well as spectrophotometrically. Gold was determined by a gravimetric technique using a 5% aqueous hydroquinone solution.

The stoichiometry of the cobalt oxide, after the cobalt activity measurements, was examined by X-ray techniques using the Debye–Scherrer camera. The diffraction patterns showed that the form of the cobalt oxide corresponded to CoO.

Visual examination as well as X-ray diffraction analysis indicated that there was no interaction between CoO and the zirconia crucible.

Results and Discussion

The experimental results for the cobalt activities are presented in Table 1. The accuracy of the activity measurements are estimated to be ±5%. The activities of gold were calculated by use of the Gibbs–Duhem integration. Figure 1 shows the obtained activity–composition curves.

Both cobalt and gold activities exhibit positive deviations from ideality.

From Fig. 1, the effect of an 85 °C temperature change on the cobalt activity appears to be negligible.

Kubik and Alcock (6) determined the activities of cobalt in solid cobalt–gold alloys between 750 and 1000 °C by an EMF method using ThO_2–$YO_{1.5}$ as the solid electrolyte. The determined activities showed large positive deviation from ideality. Their data at 1000 °C is shown for comparison in Fig. 1.

In Fig. 2 $\ln \gamma_{Co}$ values obtained in the present study are plotted against X_{Au}^2 while in Fig. 3 the corresponding $\ln \gamma_{Au}$ values are plotted against X_{Co}^2. The experimental points for $X_{Co} < 0.5$ can be fitted onto a straight line. In the case of $\ln \gamma_{Au}$, the straight line passes through the origin. However, in the case of $\ln \gamma_{Co}$, the straight line does not pass through the origin. The equations for both lines were found by a least square fitting technique as

$$[7] \qquad \ln \gamma_{Au} = -0.0006 + 0.863 X_{Co}^2$$

and

$$[8] \qquad \ln \gamma_{Co} = -0.107 + 0.848 X_{Au}^2$$

Darken (7) has suggested that for most liquid binary metallic systems there appears to exist two terminal compositional regions and a central region. In the two terminal regions, the thermodynamic behavior of the solution is relatively simple, while in the central region the thermodynamics of the solution appear to be much more complicated. In the two terminal regions, if the activity coefficient of the solvent can be represented as

$$[9] \qquad \ln \gamma_{solvent} = \alpha X_{solute}^2$$

from the Gibbs–Duhem equation,

$$[10] \qquad X_{solvent}\, d \ln \gamma_{solvent} + X_{solute}\, d \ln \gamma_{solute} = 0$$

the activity coefficient of the solute can be calculated as

$$[11] \qquad \ln \gamma_{solute} = \alpha X_{solvent}^2 + I$$

where I is the integration constant. If eqs. 9 and 11 are to hold over the entire composition, then I must be zero. However, these relations generally do not apply beyond the terminal region. Thus, in the terminal region there is no requirement that I must be zero.

The present experimental results, as shown in eqs. 7 and 8, follow the forms eqs. 9 and 11. The corresponding α value from eq. 7 is 0.863 while that from eq. 8 is 0.848.

For regular solutions, it is well known that the partial molar heat of mixing of component i can be expressed as,

$$[12] \qquad \Delta \bar{H}_i = RT \ln \gamma_i$$

and the integral heat of mixing of a binary alloy as,

$$[13] \qquad \Delta H^M = X_1\, RT \ln \gamma_1 + X_2\, RT \ln \gamma_2$$

The $\Delta \bar{H}_{Co}$, $\Delta \bar{H}_{Au}$, and ΔH^M at 1250 °C were calculated by use of eqs. 12 and 13, and are

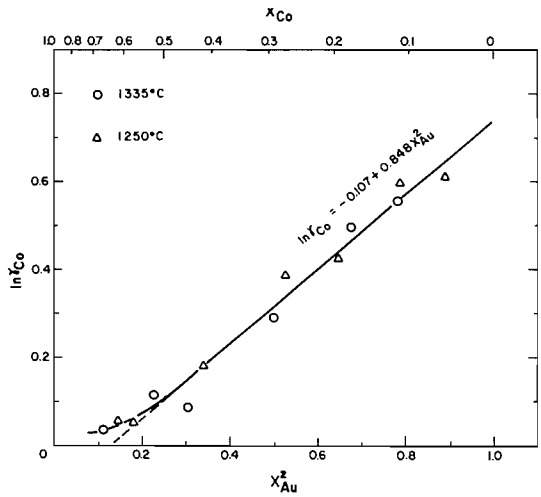

FIG. 2. Relationship between $\ln \gamma_{Co}$ and X_{Au}^2.

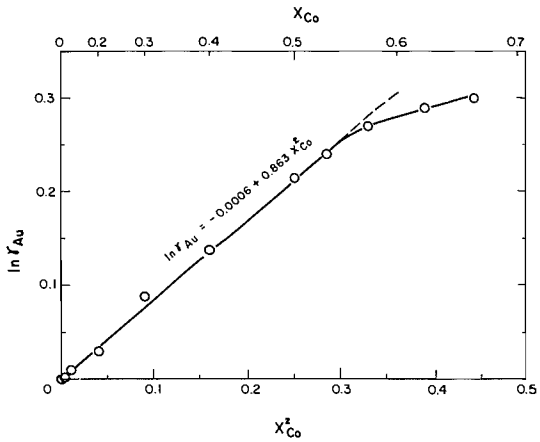

FIG. 3. Relationship between $\ln \gamma_{Au}$ and X_{Co}^2.

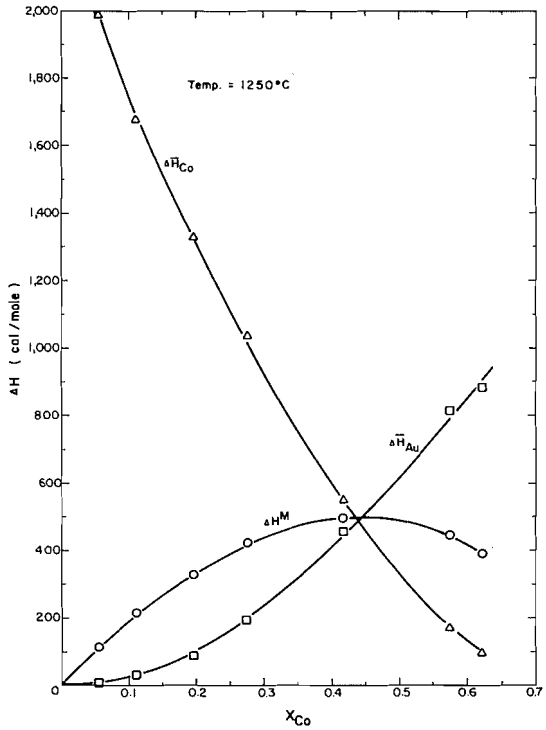

FIG. 4. Calculated enthalpy *vs.* composition at 1250 °C.

plotted in Fig. 4. The maximum integral heat of mixing is 500 cal/mol. Since the heat values for this system are very small, the effect of temperature change on the activity is expected to be negligible. This can be predicted from the van't Hoff expression

$$\left(\frac{\partial \ln a_i}{\partial T}\right)_P = -\frac{\Delta \bar{H}_i}{RT^2}$$

Figure 1, which illustrates the activity–composition relation, shows the insensitive effect of temperature on the activity measurements.

The effect of dissolved oxygen in the cobalt–gold alloys on the activities of cobalt and gold was assumed to be negligible. This was based on the investigation of Averin, Polyakov, and Samarin (8) who determined the solubility of oxygen in liquid cobalt as 0.19, 0.24, and 0.28 wt. % at 1550, 1600, and 1650 °C respectively. These values were confirmed recently by Tankins *et al.* (9) who obtained 0.20 wt. % at 1550 °C.

Conclusions

The activities of cobalt in the cobalt–gold liquid alloys over the temperature range of 1250–1350 °C have been determined. The activities of gold have been calculated by the Gibbs–Duhem integration. Both activities show positive deviation from ideality. The temperature effect on the activities is negligible. The binary alloys behave as a regular solution in the terminal region.

The authors thank the National Research Council of Canada for financial support. The cobalt analysis of the alloys were carried out by Falconbridge Research Laboratories for which the authors are grateful.

On the Mechanism and Substituent Effects of the Tl(III) Oxidation of Phenylethylenes in Methanol

L. NADON, M. TARDAT, M. ZADOR, AND S. FLISZAR

Department of Chemistry, University of Montreal, Montreal, Quebec

Received June 12, 1972[1]

The oxidation of phenylethylenes by $Tl(NO_3)_3$ in methanol proceeds rapidly and selectively to give the products resulting from the migration of aryl groups, *i.e.*, (*i*) the 1,1-dimethoxy-2-phenylethanes from the corresponding styrenes, (*ii*) the phenylacetones from the α-methylstyrenes, and (*iii*) the two possible deoxybenzoines from the 1,1,-diphenylethylenes. The kinetic results, which indicate the formation of the thallic–organic intermediate to be the rate determining step, are discussed in terms of the mechanism of reaction and show the role of the coordination of Tl(III). Hammett's relationship, with $\rho = -4.2$, describes the substituent effects for the competitive oxidation of ring-substituted styrenes and α-methylstyrenes. The relative migratory aptitudes of aryl groups, as determined from the oxidation products of ring-substituted 1,1-diphenylethylenes, is correlated to Brown's σ^+ constants, with $\rho^+ = -2.27$.

L'oxydation des phényléthylènes par le nitrate thallique dans le méthanol conduit rapidement et de manière sélective aux produits résultant de la migration des groupes aryles, c.à.d. (*i*) les diméthoxy-1,1 phényl-2 éthanes à partir des styrènes correspondants, (*ii*) les phénylacétones à partir des α-méthylstyrènes, et (*iii*) les deux désoxybenzoïnes possibles à partir de diphenyl-1,1 éthylènes. Les résultats cinétiques, qui indiquent que la formation de l'intermédiaire organo–thallique constitue l'étape déterminante, sont discutés en termes mécanistiques et, de plus, illustrent le rôle de l'état de coordination du Tl(III). La relation de Hammett, avec $\rho = -4.2$, décrit l'effet de substituants dans l'oxydation compétitive de styrènes et d'α-méthylstyrènes substitués sur le noyau. L'aptitude migratoire relative des groupes aryl, déterminée dans l'étude des produits d'oxydation de diphényl-1,1 éthylènes substitués sur le noyau, est en corrélation avec les constantes σ^+ de Brown, avec $\rho^+ = -2.27$.

Can. J. Chem., **51**, 2366 (1973)

The oxidation of a great number of olefins by thallic salts has been the object of intensive recent studies (1–13), from the point of view of both preparative organic chemistry and of the interesting mechanistic implications. From Henry's fundamental studies, including product distributions and kinetic considerations, a basic mechanistic proposal has developed for the oxidation of a variety of simple olefins by Tl(III) in aqueous acid solutions (1, 2). The oxidation of cyclic olefins, *e.g.* the cyclohexenes, in aqueous (5) and in methanol (4) solutions, the oxidation of chalcones in methanol (8), as well as the oxidation of numerous aromatic olefins, *e.g.* styrene and derivatives thereof, by $Tl(NO_3)_3$ in methanol solution (6) have been investigated.

It appeared that the product distributions depend strongly on the specific experimental conditions. This prompted the present study on $Tl(NO_3)_3$ oxidation in methanol, which considers (*i*) kinetic aspects, (*ii*) the relative reactivity of substituted styrenes, and (*iii*) the migration of substituted phenyl groups in the oxidation of ring substituted 1,1-diphenylethylenes.

[1]Revision received February 27, 1973.

Results and Discussion

Kinetic Studies

The product analysis reported in detail in the Experimental Section indicates that the oxidation of styrene and selected derivatives thereof in methanol solution yields *quantitatively* the dimethylacetals of the corresponding arylethanals.[2]

$$ArCH{=}CH_2 + Tl(NO_3)_3 + 2\,CH_3OH \rightarrow ArCH_2{-}CH(OCH_3)_2 + TlNO_3 + 2HNO_3$$

Styrene and α-methylstyrene were selected for the kinetic studies. At 25 °C, the reaction with thallic salt occurs rapidly, even at low concentrations of both reactants ($\sim 10^{-3}$ *M*). The rate of olefin consumption follows second order kinetics [1],

$$[1] \qquad -d[\text{Olefin}]/dt = k[\text{Olefin}][Tl(III)]$$

as indicated by Fig. 1, expressed in terms of the integrated rate law.

[2]The oxidation of styrene and *p*-bromostyrene by $Tl(NO_3)_3$ in methanol has been reported (6) to give appreciable amounts of glycol ethers, *i.e.* the 1-aryl-1,2-dimethoxyethanes (50–60%). Our investigation fails to confirm this, as explained in the Experimental section.

TABLE 1. Rate constants for the $Tl(NO_3)_3$ oxidation of styrene and α-methylstyrene*

Olefin	T (°C)	$[HNO_3]$ (M)	$[LiNO_3]$ (M)	$[H_2O]$ (M)	k (M^{-1} s^{-1})
Styrene	5	3.5×10^{-3}	5×10^{-3}	0	3.2
	15			0	6.2
	25			0	12
	35			0	19
	25	5×10^{-3}	15×10^{-3}	0	13.5
	25	15×10^{-3}	5×10^{-3}	0	12.6
	25	20×10^{-3}	0	0	15.6
α-Methylstyrene	5	3.5×10^{-3}	5×10^{-3}	0	27
	15			0	48
	25			0	73
	35			0	110
Styrene	25	3.5×10^{-3}	5×10^{-3}	0	12
				0.28	10.7
				0.56	8.5
				1.11	8.7

*$[Tl(NO_3)_3] = 1.0 \times 10^{-3}$ M, [olefin] $= 1.0 \times 10^{-3}$ M, solvent = methanol.

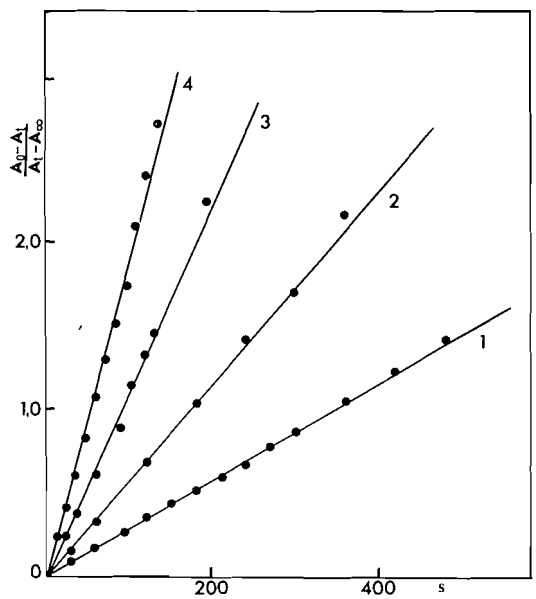

FIG. 1. Integrated second-order rate law for the $Tl(NO_3)_3$ oxidation of styrene. (1) $T = 5$ °C; (2) $T = 15$ °C; (3) $T = 25$ °C; (4) $T = 35$ °C. Solvent = methanol; $[Tl(NO_3)_3] = 1.0 \times 10^{-3}$ M; [styrene] $= 1.0 \times 10^{-3}$ M; $[LiNO_3] = 5 \times 10^{-3}$ M; $[HNO_3] = 3.5 \times 10^{-3}$ M.

The rate constants which were measured under various experimental conditions are indicated in Table 1.

The present kinetic results are thus in accord with those reported by Henry (1) for thallic oxidations in water and by Ouellette *et al.* (9) for the oxidation of styrenes by thallic acetate in acetic acid which both indicate the reactions to be first order in each reactant. It is noted, however, that our rate constants are about 50 times greater than those determined from the thallium acetate oxidation (9) in acetic acid. This can be due to the low stability of the Tl(III)–NO_3 complexes (14), resulting in a highly ionic character of the dominant species Tl^{3+} and $TlNO_3^{2+}$. Indeed, such complexes as TlX_2^+ and TlX_3 which should prevail in acetic acid for $Tl(OAc)_3$ are known to be less reactive (3, 10).

The results given in Table 1 also indicate that the rates are *not inhibited* by the presence of excess nitric acid. This supports the oxidation mechanism suggested by Henry (1) in which the slow step is the formation of the organo-thallic intermediate **1**, eq. 2. In fact, if the decomposition [3] into final products were the slow process, the over-all rate would decrease as the nitric acid concentration is increased.

$$[2]\quad TlX_3 + ArCH{=}CH_2 + CH_3OH \overset{\text{slow}}{\rightleftharpoons} Ar{-}CH(OCH_3){-}CH_2{-}TlX_2 + HX$$

$$[3]\quad \mathbf{1} + CH_3OH \xrightarrow{\text{fast}} \text{Products} + TlX + HX$$

A consideration of all the results reported in the literature indicates that step [3] consists in a competition between two possible reaction paths. These are indicated in Scheme 1, which unifies the proposals which have been considered (2, 5, 6, 9) for various specific experimental conditions and is capable of explaining the depen-

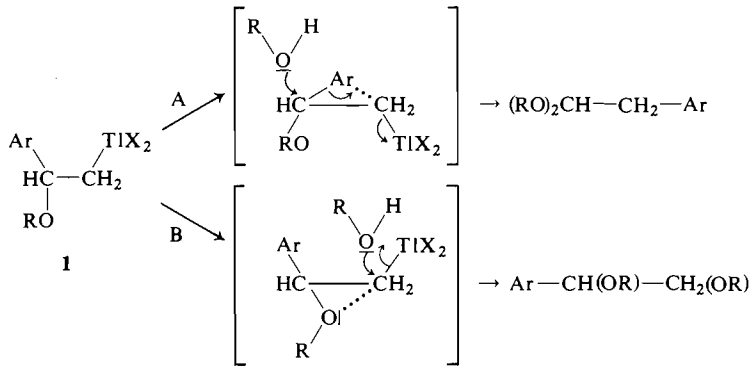

SCHEME 1

dence of the product distribution on the nature of the participating solvent.

As indicated in Scheme 1 for the phenylethylenes, two major modes (A and B) of reaction can take place, *i.e.*, (*i*) path A implying the participation and migration of the phenyl group, already demonstrated by labelling techniques (8, 9), and (*ii*) path B, implying the participation (or even migration) of the OR group of **1**. Such a participation of OR should be favored over an S_N2 substitution of Tl by a solvent molecule, as demonstrated in the case of rigid cyclohexenes (5).

The discrimination between paths A and B depends on the solvent which is used and, hence, on the nature of the OR group in **1**, and on the nature of the migrating group.[3] The formation of dimethylacetals from the corresponding styrenes, which has turned out to be practically quantitative (see Experimental section), is a clear illustration of path A: the phenyl migration is at any rate considerably more important than any participation of the methoxy group. Such a behavior can be attributed to the fact that usually the methoxy group is a poor participating agent. The results which were observed for the 4′-methoxychalcone (8) also support the preferential migratory aptitude of the phenyl group over the participation of the methoxy group.

When the nature of the OR group is changed for a good participating group, it is conceivable that path B may be preferred. This would namely be the case in acetic acid solution (9), where OR = OAc, because the acetoxy is known to be an excellent participating group (11, 15). Alternatively, in cases where the phenyl group is replaced by a group whose migratory aptitude is poor, the relative importance of path B over A is increased to the extent that it may be significant even in methanol solution. This appears to occur in the oxidation of cyclohexene in methanol (6), where path B (formation of diether) represents 15%, as compared to 85% for path A.[4]

It may now be regarded that the product formation (step [3]) is satisfactorily rationalized. From the kinetic point of view, it is, however, step [2] on which attention shall be focused.

The results in Table 1 indicate that α-methylstyrene reacts about 5–10 times faster than styrene, in the range of temperatures investigated. The effect of methyl substitution is thus similar but less pronounced to that observed for the relative reactivities of propylene *vs.* ethylene (2).

The activation parameters calculated from the results of Table 1 are $\Delta H^{\neq} = 9.9 \pm 0.5$ kcal, $\Delta S^{\neq} = -25 \pm 1.5$ e.u. (styrene) and $\Delta H^{\neq} = 7.1 \pm 0.5$ kcal, $\Delta S^{\neq} = -26 \pm 1.5$ e.u. (α-methylstyrene). These activation enthalpies are, hence, similar to the value (7.9 kcal) determined for the $Tl(OAc)_3$ oxidation of *p*-methylstyrene in acetic acid (9).

A more striking observation concerns the influence of water, even in small amounts, on the reaction rates: the presence of 1–2% of water causes a significant decrease of k (Table 1). This

[3]No difference between thallium acetate and nitrate is observed in the product distribution under otherwise identical conditions.

[4]The values have been obtained by measuring the reaction products from the oxidation of cyclohexene, where they are, for path A, cyclopentanecarboxaldehyde and, for path B, the stereoisomeric 1,2-dimethoxycyclohexanes. These results are in full agreement with those reported in the literature (6).

TABLE 2. Influence of chloride ions on the rate of oxidation of styrene*

$[Cl^-]$ (M)	R_i ($M\ s^{-1}$) Observed	Calculated
0	10.1×10^{-6}	10.1×10^{-6}
2.5×10^{-4}	8.9×10^{-6}	8.0×10^{-6}
5.0×10^{-4}	5.8×10^{-6}	5.9×10^{-6}
7.5×10^{-4}	3.8×10^{-6}	4.0×10^{-6}
1.0×10^{-3}	2.3×10^{-6}	1.8×10^{-6}
1.5×10^{-3}	0.6×10^{-6}	0.9×10^{-6}
2.0×10^{-3}	$\leq0.3\times10^{-6}$	0
5.0×10^{-3}	$<3\times10^{-10}$	0

*$[Tl(ClO_4)_3] = 1.0\times10^{-3}M$, [styrene] $= 1.0\times10^{-3}M$, $T = 25$°C, $[HClO_4] = 0.2\ M$, solvent = 80% (v/v) methanol – 20% (v/v) water.

can be explained either in terms of a preferential coordination of Tl(III) by water or else in terms of a partial hydrolysis of Tl(III), both of which processes would result in a less reactive thallium species.

The role of the coordination of the thallic ion is further illustrated by the influence of chloride ions, which are known to give stable complexes with Tl(III) (16), on the reaction rates. As indicated by the results in Table 2, chloride ions cause a marked retarding effect on the reaction rates. In order to avoid any interference by nitrate ions, these experiments were carried out in perchloric medium, using (for safety) a 80% (v/v) methanol – 20% water mixture as solvent.

From these results, it may be concluded that $TlCl^{2+}$ is the only Cl-containing reactive species. This, because the rate drops considerably (to less than 3% of its initial value) when $[Cl^-]/[Tl(III)] = 2$, in which case the predominant species is $TlCl_2^+$, instead of $TlCl^{2+}$. Higher chloride concentrations prevent, for all practical purposes, the reaction to occur: this is observed with a ratio $[Cl^-]/[Tl(III)] = 5$, where the predominant species are $TlCl_3$ and $TlCl_4^-$.

These qualitative arguments, deduced from Table 2, lead to the following quantitative interpretation of these results. On the assumption that the stability constants of the various thallium complexes are in the present conditions at least as large as in water,[5] the concentrations $[Tl^{3+}]$ and $[TlCl^{2+}]$ can be evaluated as in ref. 10. Hence, the overall initial rate R_i is

$$[4]\quad R_i = [\text{styrene}]\,(k_{Tl}[Tl^{3+}] + k_{TlCl}[TlCl^{2+}])$$

As indicated in Table 2, the calculated initial rates (eq. 4) are in satisfactory agreement with the corresponding experimental rates, thus supporting the interpretation given above.

The observation that the reactivity of $TlCl^{2+}$ ($k_{TlCl} = 1.8\ M^{-1}\ s^{-1}$) is lower than that of Tl^{3+} ($k_{Tl} = 10.1\ M^{-1}\ s^{-1}$) indicates that the electrostatic effect due to the lowering of the ionic charge is the dominating factor. This is contrary to what had been observed previously in the case of the oxidation of 1,2-cyclohexanedione under similar circumstances, where the present effect was overruled by an opposed "catalytic" effect (10).

Relative Reactivity of Substituted Styrenes

A further insight into the reaction mechanism is given by the study of substituent effects on the rate constants. The relative rates of oxidation of ring-substituted styrenes and α-methylstyrenes have been determined by a competitive method, using excess amounts of olefins with respect to Tl(III). Because the ratio of the products formed is equal to the ratio of the reaction rates, the ratio of the rate constants can be deduced from eq. 5, which is based on the assumption of first order reactions with respect to each olefin (eq. 1).[6]

$$[5]\quad [\text{Product-1}]/[\text{Product-2}] = k_1(\text{Ol-1})/k_2[\text{Ol-2}]$$

It has been verified that k_1/k_2 is independent of the Tl(III) concentration and of the temperature (Table 3).

The reproducibility of the measurements is satisfactory (Table 4), despite the great differences of reactivity which are observed between the invidivual olefins. Each determination of k_1/k_2 has been repeated a minimum of 6 times, and the final results are indicated in Table 5 with a confidence limit of 95%.

It is noted that the results in Table 5 are expressed with respect to the unsubstituted phenylethylene in terms of k_X/k_H, where X stands for the substituent in the phenyl ring. These results

[5]This assumption is verified by analogy with cases where the stability constants are known. There is an increase of stability for complexes of this type due to greater electrostatic interactions in the less polar solvent.

[6]This assumption is further confirmed by the fact that the ratios k_1/k_2 calculated by means of eq. 5 are independent of the ratios of the olefin concentrations.

TABLE 3. Effect of the experimental conditions on the relative rates of Tl(III) oxidation of ring-substituted styrenes in methanol

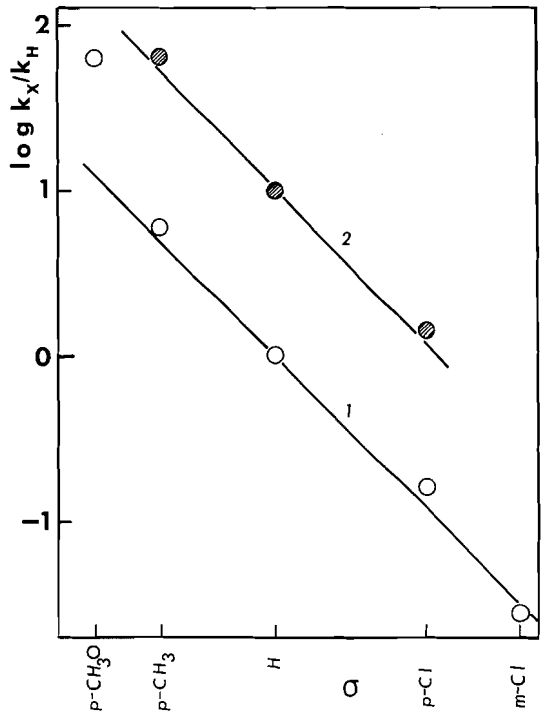

FIG. 2. A verification of Hammett's relationship for the rates of Tl(III) oxidation of ring-substituted styrenes (1) and α-methylstyrenes (2) in methanol. The scale for (2) is shifted by 1 log unit (σ(*p*-CH_3O) = −0.268; σ(*p*-CH_3) = −0.170; σ(H) = 0; σ(*p*-Cl) = +0.227; σ(*m*-Cl) = +0.373).

can be interpreted in terms of Hammett's relationship (Fig. 2).[7]

The negative slope ρ = −4.2 clearly indicates that the overall reaction is favored by electron-releasing substituents; the large ρ value reflects the extreme sensitivity of thallic oxidations to electronic effects. Such a behavior has been noted previously for alkyl substituted ethylenes (2) and for styrenes in acetic acid solution (9). In the latter case, a similar dependence of the reaction rates on substituent effects has been noted, although in acetic acid the product distribution

[7]This correlation is far superior to that which can be obtained using Brown's σ^+ values.

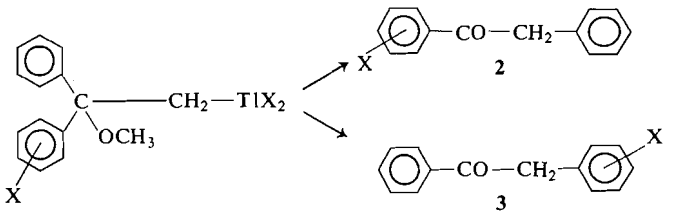

SCHEME 2

is quite different from that observed in methanol. This is in line with the earlier suggestion that the formation of intermediate **1** is rate determining in both methanol and acetic acid.

The ring-substituted α-methylstyrenes react approximately 10 times faster than their styrene analogs. The only oxidation products are the corresponding phenylacetones (Table 1, Experimental section), and *no methylacetophenone could be detected.* This not only indicates that pathway A is followed, but also that any methyl migration is negligible. From the results in Table 5, it also follows that $\rho = -4.2$. Hence, from the observation that the same ρ values are observed for the styrenes and for the α-methylstyrenes, it can be deduced that the methyl group does not exhibit any steric effect which would perturb the transmission of the electronic effects due to the aromatic ring.

Relative Migratory Aptitude of Aryl Groups

Ouellette's studies (9) on the oxidation of styrenes in acetic acid have provided interesting information on the migratory aptitudes of aryl groups. These results, which fit nicely into the proposed mechanism (Scheme 1), represent from this point of view a comparison between the migratory aptitude of the aryl group (path A) *vs.* the participation of OR (path B). The results indicate that electron-releasing substituents on the phenyl group favor its migration.

In methanol solution, however, only path A implying phenyl migration is followed. The relative migratory aptitude of aryl groups can be studied from the competition between two aryl groups under like environment. Derivatives of 1,1-diphenylethylene were chosen for this purpose. Thus, two different carbonyl compounds are formed, depending upon which aryl group has undergone migration (Scheme 2). The deoxybenzoine **2** arises from the migration of the unsubstituted phenyl group, whereas **3** is due to the migration of the substituted one.

TABLE 6. Relative migratory aptitude of aryl groups in the Tl(III) oxidation of 1,1-diphenylethylenes in methanol at 25°

Substituent X	Proportion of **2**	Proportion of **3**	k_X/k_H
m-Cl	0.115	0.885	0.130±0.008
p-Cl	0.341	0.659	0.520±0.005
H			1.000
p-CH_3	0.838	0.162	5.17±0.07
p-CH_3O	≥0.98	≤0.02	≥50

The results reported in Table 6 indicate that electron-releasing substituents attached to a phenyl group favor its migration. In this, the present results agree with those reported by Ouellette *et al.* (9) for the oxidations in acetic acid.

The relative migratory aptitudes are expressed in terms of k_X/k_H, which can be correlated by means of a Hammett equation (Fig. 3). The best fit is obtained by using Brown's σ^+ parameters. The $\rho^+ = -2.27$ value thus calculated for the aryl migration following only path A compares favorably with the ρ^+ value (−1.7) which was determined (9) from the competition between aryl migration and 1,2-diacetate formation.

The present results are, hence, in line with the previous suggestions (6, 8, 9) that the aryl groups migrate toward a carbon atom possessing a more or less developed positive character. The present mechanistic suggestion (Scheme 1) would require a $C^{\delta+}$ character, and the C—Tl bond cleavage is assumed to be concerted with the aryl migration. This is supported by the recent stereochemical study of the oxidation of rigid cyclohexenes (5) which indicated that the decomposition of the organo-thallic intermediate is *not* initiated by the cleavage of the C—Tl bond. The partial positive charge on the C atom under consideration would, of course, result from the important electron-affinity of the Tl to which it is attached.

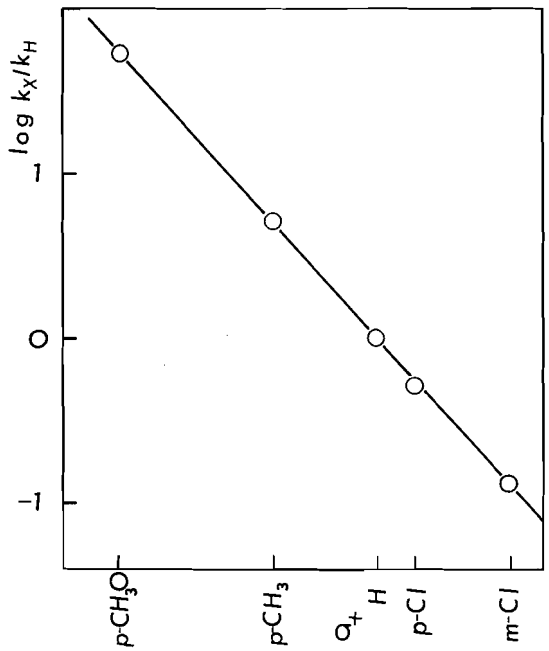

FIG. 3. Hammett plot for the relative migratory aptitudes of aryl groups in the Tl(III) oxidation of ring-monosubstituted 1,1-diphenylethylenes in methanol ($\sigma^+(p\text{-}CH_3O) = -0.778$; $\sigma^+(p\text{-}CH_3) = -0.311$; $\sigma^+(H) = 0$; $\sigma^+(p\text{-}Cl) = +0.114$; $\sigma^+(m\text{-}Cl) = +0.399$).

Conclusions

The oxidation of phenylethylenes by $Tl(NO_3)_3$ in methanol proceeds rapidly and selectively to give the products resulting from the migration of aryl groups, *i.e.* (*i*) the 1,1-dimethoxy-2-phenylethanes from the corresponding styrenes, (*ii*) the phenylacetones from the α-methylstyrenes and (*iii*) the two possible deoxybenzoines from the 1,1-diphenylethylenes.

Kinetic results indicate the reaction to be first order in each reactant. The rate determining step appears to be the formation of the organo–thallic intermediate. The retarding effect of water and Cl^- ions on the reaction rates illustrates the importance of the state of coordination of Tl(III).

Electron-releasing substituents enhance strongly the overall rate of oxidation of ring-substituted styrenes and α-methylstyrenes. The oxidation of ring-substituted 1,1-diphenylethylenes in methanol indicates that electron-releasing substituents strongly favor the migration of the corresponding aryl group, which is in line with the view that the aryl groups migrate toward a $C^{\delta+}$ atom.

Experimental

The thallic nitrate was prepared by dissolving 15 g of thallic oxide in 20 ml concentrated nitric acid, at 60 °C. After cooling, the crystallized $Tl(NO_3)_3 \cdot 3H_2O$ was filtrated and dried in vacuum. The thallic perchlorate solution was prepared by dissolving thallic oxide in aqueous $HClO_4$. The olefins were purchased or prepared and purified by standard methods. The methanol was dehydrated following a standard procedure (17).

The identification of the reaction products was, in general, made by g.l.c. retention times, comparison with authentic samples, and n.m.r. analysis. The g.l.c. analyses were carried out by means of an F and M 5750 gas chromatograph using two different 6 ft columns. For the analysis of the reaction products from the ring-substituted styrenes, 10% Carbowax 20M on Chromosorb PAW-DMCS and Polyphenyl 6 ring columns were used at 142°. The same columns were used at 125° for the oxidation products of the various α-methylstyrenes. For the 1,1-diphenylethylenes, Silicone Rubber UC-W98 (150°) and Polyphenyl 6 ring (195°) columns were used.

The nature of the products, and their yields, obtained from the oxidation of all the olefins investigated, are given in Table 7.

The observation that the oxidation of styrene yields only the dimethylacetal of phenylacetaldehyde, was verified by a comparison with a commercial (Aldrich) sample of acetal. It was also verified that, after acid hydrolysis, only phenylacetaldehyde is obtained. However, to insure a complete hydrolysis, the methanol had to be evaporated and the acetal treated during 1 h with 2 *N* H_2SO_4. Otherwise, the g.l.c. analysis indicates the presence of unreacted acetal. These results were confirmed by test experiments carried out with authentic samples of acetal. The absence of 1-phenyl-1,2-dimethoxyethane in the reaction products was confirmed by means of authentic samples of this product. The acetal and the diether can be separated in g.l.c. on Carbowax 20 M columns and also possess n.m.r. spectra which facilitate their analysis. In the acetal, in CCl_4 solution, the two methoxy groups give a single signal at 3.20 p.p.m. The CH_2 group is revealed by a doublet at 2.8 p.p.m., and the tertiary H by a triplet at 4.4 p.p.m. In the diether, the methoxy groups give two signals at 3.20 and 3.25 p.p.m., the tertiary proton consists of a quartet centered at 4.2 p.p.m., and the CH_2 group a complex signal at 3.4 p.p.m.

The acetals obtained from the oxidation of substituted styrenes have been isolated, after filtration of the thallous nitrate, by washing the methanol solution with a carbonate solution, followed by an extraction by means of ether. The n.m.r. results in CCl_4 solution, with reference to TMS, are indicated in Table 8.

In all cases, the hydrolysis of the acetals has been made in order to confirm the production of the corresponding aldehyde.

The oxidation product from α-methylstyrene has been identified by a comparison with a sample of pure phenylacetone, by g.l.c. (on 2 different columns) and by n.m.r. analysis. The g.l.c. analysis, using acetophenone as internal standard, indicated a yield of 99% of phenylacetone. The n.m.r. spectra of the phenylacetones obtained from their corresponding α-methylstyrenes are indicated in Table 9.

The oxidation product from 1,1-diphenylethylene was identified in g.l.c. by a comparison with a sample of

deoxybenzoine is observed in g.l.c., using *p*-methoxybenzophenone as internal standard. The identification of all the reaction products was made by comparison with pure samples of 4′-methoxy-, 4′-methyl-, and 4′-chloro-deoxybenzoines, and 4-methoxy-, 4-methyl-, and 4-chlorodeoxybenzoines, all of which were prepared and purified according to literature methods (18).

Kinetic Method

The course of each reaction was followed by ultraviolet spectrophotometry at 270–290 mμ, thus measuring the decrease in olefin concentration. The interpretation of the results was made by means of the integrated second order rate law $x/(a - x) = (A_0 - A_t)/A_t - A_\infty) = kat$, where a = [olefin] = [Tl(III)] and x = concentration of reaction product at time t. The quantities A_0, A_t, and A_∞ are, respectively, the absorbances at time $t = 0$, $t = t$, and $t = \infty$. The rate constant k was calculated from the regression line, as illustrated in Fig. 1. It has been verified that no variation in k occurs when the concentration of the reactants was changed by a factor of 4. Reproducible k values can only be obtained when due care is taken to avoid any polymerization of the olefin while setting up the experiments. The statistical analysis of the results indicates a reproducibility of the k values within 5%.

The competitive kinetic measurements were made by adding 5 ml of a 0.1 *M* solution of thallic nitrate to 5 ml of a solution 1 *M* in each olefin. In most cases, styrene was used as reference compound. Because of the great difference in reactivity between styrene and *m*-chlorostyrene, 0.1 *M* styrene solutions and concentrations of 0.5–1.0 *M* of *m*-chlorostyrene were used, with a 0.02 *M* concentration in thallic nitrate. For the experiments with *p*-methoxystyrene, *p*-methylstyrene was used as reference.

The possible influence of nitrate ions was examined. The kinetic study has revealed a slight increase of the reaction rate by added nitrate ions. However, in the present experimental conditions, a 3-fold excess of nitrate ions in form of $LiNO_3$ does not alter significantly the *ratios* k_X/k_H. For example, in the presence of excess NO_3^-, $k_X/k_H = 6.7$ for the *p*-methylstyrene/styrene system, which compares favorably with the results reported in Table 3.

The financial support given by the National Research Council of Canada is gratefully acknowledged.

Rationalization of Carbon-13 Magnetic Resonance Spectra of Yeast Mannans and Structurally Related Oligosaccharides[1]

P. A. J. GORIN

Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan

Received January 2, 1973

The carbon-13 magnetic resonance (c.m.r.) spectra of oligosaccharides, derived from yeast mannans by partial acetolysis, contain signals at δ_c 93.1–105.4 (C-1's) and 79.2–81.2 (C-2's and/or C-3's substituted by mannopyranosyl units). They were assigned on the basis of (*a*) carbons deshielded by attached mannopyranosyl units have resonances at lower field than those of unsubstituted carbons and (*b*) comparison under carefully controlled conditions of the relative sizes of signals of comparable carbons, which have the same resonances, in members of two different homologous series of oligosaccharides. The c.m.r. spectra of certain mannans containing (1 → 6)-linked α-D-mannopyranose main-chains could then be rationalized since they have many signals with resonances in common with those of oligosaccharides, which are derived by partial acetolysis and contain the structures of the side chains.

Les spectres de résonance du carbone-13 (r.m.c.) de certains oligosaccharides, obtenus des mannanes de la levure par acétolyse partielle, contiennent des signaux à δ 93.1–105.4 (C-1) et δ_c 79.2–81.2 (C-2 et/ou C-3 substitué par des unités du type mannopyranosyle). Ceux-ci furent attribués en se basant sur (*a*) l'énoncé suivant lequel les carbones déblindés par les unités mannopyranosyles qui lui sont rattachées résonnent à champ plus faible que les carbones non-substitués et (*b*) la comparaison, dans des conditions strictements contrôlées, des importances relatives des signaux appartenant à des carbones semblables, lesquels résonnent au même endroit, dans les membres de deux séries homologues différentes d'oligosaccharides. Les spectres r.m.c. de certains mannanes contenant des chaînes principales d'α-D-mannopyranoses liés de manière 1 → 6, peuvent alors être rationalisés puisqu'ils possèdent plusieurs signaux que l'on peut assimiler à ceux d'oligosaccharides, qui sont obtenus par acétolyse partielle et qui possèdent les ramifications des chaînes latérales. [Traduit par le journal]

Can. J. Chem., 51, 2375 (1973)

The p.m.r. spectra (1) of yeast mannans can be used as fingerprints for identification and classification of the parent organism. In certain cases the chemical shifts of certain signals are indicative of the presence of certain structures, for example H-1 signals at higher field than δ 5.45 indicate β-D-mannopyranose units (2) and those with δ 5.80 indicate successive (1 → 2)-linked α-D-mannopyranose units (3). The fingerprint and the assignment approaches can be readily extended to carbon-13 magnetic resonance (c.m.r.) spectra of oligosaccharides (4, 5) and polysaccharides (6), since when proton decoupling is used the signals are well-defined with resonances that are reproducible to an accuracy of 1 Hz (0.04 p.p.m.). The present study concerns the assignment of signals of certain resonances to chemical structures in oligosaccharides derived from yeast mannans by partial acetolysis. The presence of signals with the same resonance in the c.m.r. spectrum of a mannan can then serve as an indication of chemical structure. In certain cases when the c.m.r. spectra of the oligosaccharides could not be rationalized it was still possible to use the C-1 portions of the spectrum as fingerprints in identification of related structures in yeast mannans.

The majority of ascomycetous yeasts form cell-wall mannans or galactomannans with main chains of (1 → 6)-linked α-D-mannopyranose units substituted in their 2-positions by α-linked sugar units.[2] The linkages in the side chain vary widely and can be 2-*O*-linked α- or β-D-mannopyranose units or 3-*O*-linked α-D-mannopyranose units, which can be arranged in many combinations (7). The variations of chemical structure are reflected mainly in the c.m.r. signals at low field δ_c 77.2–105.4, which arise from C-1 and from C-2 and/or C-3 that are mannosylated (see ref. 4 for similar effects on the c.m.r. spectrum of laminaribiose). In order to rationalize the c.m.r. spectra of mannans the signals of derived oligosaccharides were first assigned. Two groups of oligosaccharides were examined,

[1]NRCC No. 13152.

[2]In *Citeromyces matritensis* mannan the side chains are α- and β-linked to the main chain (2).

those containing only α-linkages and those with α- and β-linkages or β-linkages alone.

(1) Oligosaccharides Containing α-D-mannopyranose Units

In the following discussion the δ_c 93.1–105.4 region which contains C-1 signals is referred to as region A. Region B is used to denote the region between δ_c 79.2 and 81.2 which contains C-2 and/or C-3 signals. These signals are at much lower field than the others (8), because of the deshielding effect of the adjacent *O*-mannosyl group on the carbon atom.

The c.m.r. spectra of a homologous series of (1 → 2)-linked α-D-mannopyranoside oligosaccharides having from two to five units in length contain regions A and B that lend themselves readily to interpretation (see Table 1). The signals at δ_c 94.3–94.4 in region A belong to C-1 of the reducing ends. They are at higher field than other C-1 signals because they are not deshielded by attached mannosyl units. The signals at δ_c 102.1–102.2 arise from C-1's of internal mannopyranosyl units since they are absent from the mannobiose spectrum. By elimination the signals at δ_c 103.4 arise from C-1 of the non-reducing end unit.

It is perhaps significant that these assignments agree with those that can be made on considering the relative sizes of the C-1 signals on one hand and the C-2 signals on the other in a homologous series of (1 → 2)-linked oligosaccharides, despite the potential for the signal response of each carbon to be different (Table 1). The variation in signal size can be due to three factors, namely, difference in the speed of spin-lattice relaxation, different magnitude of nuclear Overhauser effect (n.O.e.), and an insufficiency of data points defining the c.m.r. spectrum. By a process of elimination the former is likely of greatest importance. Allerhand *et al.* (9) have shown that carbon atoms in sucrose have almost identical n.O.e.'s and in recording a c.m.r. spectrum of an oligosaccharide one data point is used every 0.6 Hz to define a signal with a half-height linewidth of 3–7 Hz. The c.m.r. spectra of the homologous series of oligosaccharides, obtained consecutively with as little variation of conditions as possible, showed an increase of the relative sizes of certain C-1 and -2 signals as the series is ascended in a stepwise fashion. Increases in size were observed for the signals at δ_c 102.1–102.2 corresponding to C-1 of internal units and in those at δ_c 80.0 which arise from C-2 of internal units.

Signal assignments can be made in a similar fashion for signals in the c.m.r. spectra of a related homologous series of oligosaccharides (Table 2). These differ from the above series (Table 1) in that the (1 → 2)-linkage attaching the non-reducing end-unit to the adjacent unit is replaced by a (1 → 3)-linkage. As can be seen from Table 1 (nos. 1–4) and Table 2 (nos. 1–3) oligosaccharides in each series have the same resonances for C-1 of the internal units, non-reducing and reducing end-units, and for C-2 of 2-*O*-substituted reducing end-units and internal units. A new signal at δ_c 79.8 corresponding with

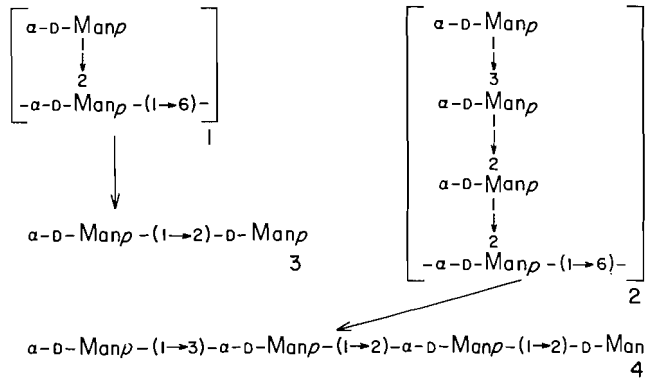

FIG. 1. Structural relationship of portions of mannans of *Saccharomyces fragilis* and *Endomycopsis fibuliger* (**1**) and *Saccharomyces cerevisiae* (**2**) with oligosaccharides (**3** and **4** respectively) formed on partial acetolysis.

C-3 of a 3-*O*-substituted internal unit was also detected in the new series. Unfortunately in region A the signals arising from C-1 of non-reducing end-units and 3-*O*-substituted internal units are superimposed.

The values for resonances of comparable signals in the c.m.r. spectra of D-Man*p*$\overset{13\alpha}{\text{——}}$D-Man*p*$\overset{13\alpha}{\text{——}}$D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p*,D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p*$\overset{13\alpha}{\text{——}}$D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p* and a linear mannan containing α-(1 → 3)-linkages are also recorded in Table 2. As can be seen, they deviate very little from the values obtained from comparably linked structures in each homologous series of oligosaccharides (Tables 1 and 2).

(2) Oligosaccharides Containing β-D-*Mannopyranose Units Only or Mixed* α- *and* β-D-*Mannopyranose Units*

The c.m.r. spectra of (1 → 2)-linked β-D-mannopyranose oligosaccharides of two to four units in length and a pentasaccharide containing mixed α- and β-linkages were prepared.

In the spectra of the three β-(1 → 2)-linked oligosaccharides some of the chemical shifts in regions A and B of comparable carbons do not correspond on going from one compound to another. Furthermore, the c.m.r. spectra were much more complex than those summarized in Tables 1 and 2: instead of the α-anomer alone appreciable proportions of both α- and β-anomers were present. However, since certain of the signals have resonances within a limited range (see Experimental) some assignments for the tri- and tetrasaccharide spectra can be made. These are as follows: C-1 of α-anomeric reducing end-unit, δ_c 93.8–94.0, β-anomeric reducing end-unit δ_c 95.3; C-1 of non-reducing end-unit, δ_c 100.7–101.2; internal unit, δ_c 102.8. In the mannobiose spectrum the C_β-2 (δ_c 83.2) and C_α-2 resonances (δ_c 80.0) can be assigned with certainty.

Regions A and B of the spectrum of D-Man*p*$\overset{12\alpha}{\text{——}}$D-Man*p*$\overset{12\beta}{\text{——}}$D-Man*p*$\overset{1,2\beta}{\text{——}}$D-Man*p*$\overset{1,2\alpha}{\text{——}}$D-Man (Experimental) could not be rationalized. Only the C-1 signal of the reducing end at δ_c 94.4 corresponded in chemical shift with any previously assigned signal.

(3) Mannans Having a (1 → 6)-Linked α-D-*Mannopyranose Main Chain*

(i) Mannans of Saccharomyces fragilis and Endomycopsis fibuliger

Each mannan has a relatively simple structure consisting mainly of (1 → 6)-linked α-D-mannopyranose main-chain with each unit substituted in the 2-position with a single-unit α-D-mannopyranose side chain (Fig. 1, **1**). The structures differ slightly in that the *Endomycopsis fibuliger* mannan has a small proportion of *O*-α-D-mannopyranosyl-(1 → 3)-α-D-mannopyranose side chains (10, 11) whereas the minor side chain of *Saccharomyces fragilis* mannan is *O*-α-D-mannopyranosyl-(1 → 2)-α-D-mannopyranose (1). The virtually identical c.m.r. spectra (Fig. 2: A and B) lend themselves readily to interpretation. By analogy with the oligosaccharides of the (1 → 2)-linked α-D-mannopyranose series (Table 1) the signals at δ_c 103.9 corresponds to C-1 of the reducing end-units, which shows that the other C-1 signal at δ_c 100.3 belongs to the 2,6-di-*O*-substituted units. Also readily assignable are the C-2 signals at δ_c 80.4 which arise from 2,6-di-

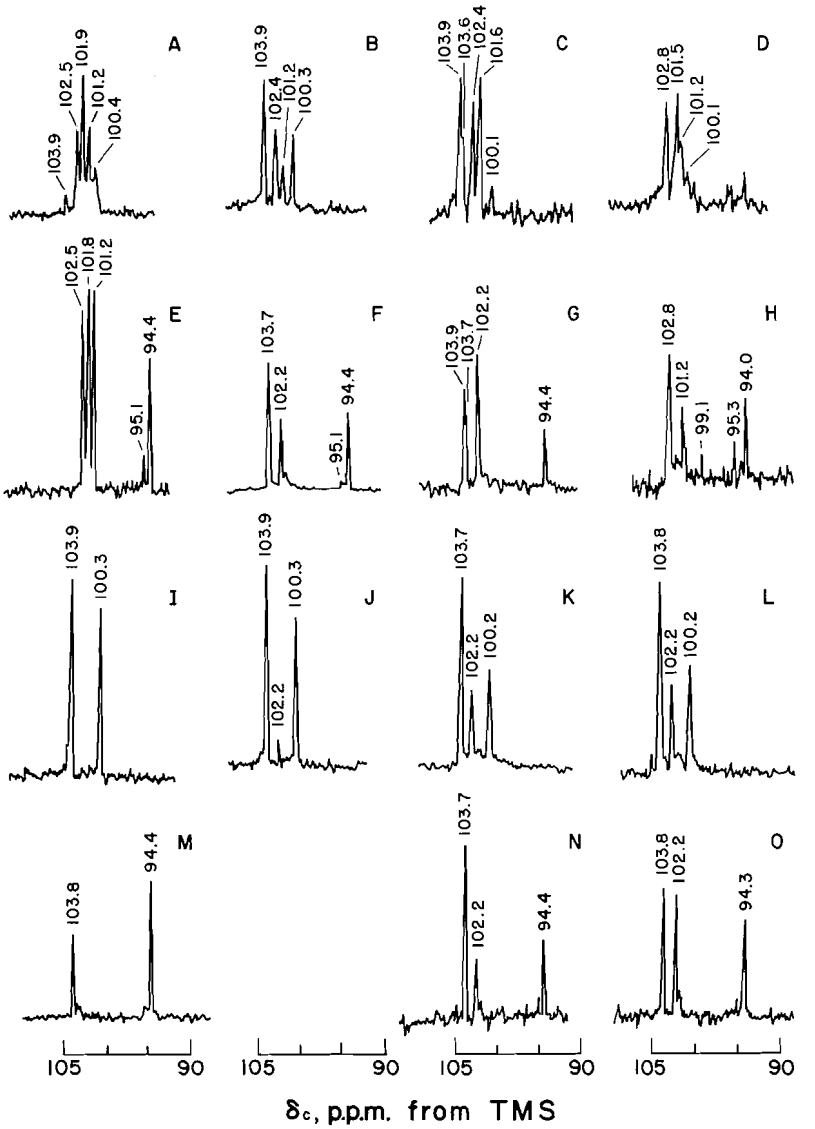

FIG. 2. Region A of c.m.r. Spectra of (*a*) Mannans of *P. pastoris* (A), *M. reukaufii* (B), *D. hansenii* (C), *C. matritensis* (D), *E. fibuliger* (I), *S. fragilis* (J), *S. cerevisiae* (K), and *S. rouxii* (L); (*b*) $M\overset{1,2\alpha}{\text{—}}M\overset{1,2\beta}{\text{—}}M\overset{1,2\beta}{\text{—}}M\overset{1,2\alpha}{\text{—}}M$ (E), $M\overset{1,3\alpha}{\text{—}}M\overset{1,3\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M$ (F), $M\overset{1,2\alpha}{\text{—}}M\overset{1,3\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M$ (G), $M\overset{1,2\beta}{\text{—}}M\overset{1,2\beta}{\text{—}}M\overset{1,2\beta}{\text{—}}M$ (H), $M\overset{1,2\alpha}{\text{—}}M$ (M), $M\overset{1,3\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M$ (N) and $M\overset{1,2\alpha}{\text{—}}M\overset{1,2\alpha}{\text{—}}M$ (O).

O-substituted units. In the *S. fragilis* spectrum the small signal at δ_c 102.3 corresponds to C-1 to the 2-*O*-linked side-chain units.

(ii) Mannans of Saccharomyces cerevisiae and Saccharomyces rouxii

The mannan from bakers yeast (*Saccharomyces cerevisiae*) has a main chain consisting of (1 → 6)-linked α-D-mannopyranose units α-substituted in the 2-positions by side chains, the longest of which is D-Man*p*$\overset{1,3\alpha}{\text{—}}$D-Man*p*$\overset{1,2\alpha}{\text{—}}$D-Man*p*$\overset{1,2\alpha}{\text{—}}$ (Fig. 1, **2**; (12)). Regions A and B of the c.m.r. spectrum of the mannan contains five well-defined signals. These can be assigned by reference to the already assigned signals of D-Man*p*$\overset{1,3\alpha}{\text{—}}$D-Man*p*$\overset{1,2\alpha}{\text{—}}$D-Man*p*$\overset{1,2\alpha}{\text{—}}$D-Man

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(Table 2). It follows (Fig. 2, N and K) that the signal at δ_c 103.7 arises from C-1 of the non-reducing end-units and 3-*O*-substituted units and the signal at δ_c 102.3 from the 2-*O*-substituted units. By analogy with the c.m.r. spectra of the mannans of *E. fibuliger* and *S. fragilis* the signal at δ_c 100.2 should arise from 2,6-di-*O*-substituted units. Region B contains only signals, at δ_c 80.0 and 80.2, although there are carbons from three structurally different units that would be expected to give signals in this region, namely C-2's of 2-*O*- and 2,6-di-*O*-substituted units and C-3 of 3-*O*-substituted units.

The mannan of *Saccharomyces rouxii* has a main chain with (1 → 6)-linked α-D-mannopyranose units substituted in the 2-positions mainly with *O*-α-D-mannopyranosyl-(1 → 2)-α-D-mannopyranose side chains ((11, 13); Fig. 1). It resembles the mannan of *S. cerevisiae* except that it lacks terminal D-Man*p*$\underline{\underline{\ }}^{13\alpha}$ units. The only distinguishing feature of regions A and B of the c.m.r. spectra is that the low field signal of *S. cerevisiae* mannan is at δ_c 103.7 (Fig. 2, K; Table 2) whereas that of the *S. rouxii* mannan is at 103.8 p.p.m. (Fig. 2, L; Table 2). It can be observed that exactly the same chemical shifts of δ_c 103.7 and 103.8 were found for C-1's of oligosaccharides of related structure (Table 2, no. 2 and Table 1, no. 2, respectively; Fig. 2, N and O).

In order to check whether any substituted main-chain units can be detected in the mannans of *S. rouxii* and *S. cerevisiae* the c.m.r. spectrum of a (1 → 6)-linked α-D-mannopyranan (11, 14) was prepared. Its C-1 signal was at δ_c 101.2 and the absence of the resonance in the c.m.r. spectra of the mannans reaffirms (1) that the unsubstituted structural unit is absent.

(iii) Mannans of Metschnikowia reukaufii, Debaryomyces hansenii, Pichia pastoris, and Citeromyces matritensis

It was evident that most of the mannans give C-1 signals (region A) with many resonances in common with those of the longest oligosaccharide formed following partial acetolysis, a technique that preferentially splits (1 → 6)-linkages (13) as depicted in Fig. 1. The only marked difference in the c.m.r. spectra is that the mannan often gives a signal at δ_c 100.3 corresponding to 2,6-di-*O*-substituted units, whereas in the oligosaccharide the same unit has been converted to a reducing end which has a C-1 resonance at much higher field δ_c 94.4.

Taking this into account it should be possible to postulate a possible chemical structure of an unknown mannan using region A of the spectrum as a fingerprint.

Selected examples of spectral resemblance are presented in Fig. 2. The parent yeast and longest oligosaccharide obtained from the mannan are as follows: (M = D-mannopyranose): *E. fibuliger* (M$\underline{\underline{\ }}^{1,2\alpha}$M; spectrum M), *S. fragilis* (M$\underline{\underline{\ }}^{1,2\alpha}$M; spectrum M), *S. rouxii* (M$\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,2\alpha}$M; spectrum O), *S. cerevisiae* M$\underline{\underline{\ }}^{1,3\alpha}M\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,2\alpha}$M; spectrum N), *Metschnikowia reukaufii* (M$\underline{\underline{\ }}^{1,3\alpha}M\underline{\underline{\ }}^{1,3\alpha}M\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,2\alpha}$M; spectrum F), *Debaryomyces hansenii* (M$\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,3\alpha}M\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,2\alpha}$M; spectrum C), *Pichia pastoris* (M$\underline{\underline{\ }}^{1,2\alpha}M\underline{\underline{\ }}^{1,2\beta}M\underline{\underline{\ }}^{1,2\beta}M\underline{\underline{\ }}^{1,2\alpha}$M; spectrum E) and *Citeromyces matritensis* (M$\underline{\underline{\ }}^{1,2\beta}M\underline{\underline{\ }}^{1,2\beta}M\underline{\underline{\ }}^{1,2\beta}$M; spectrum H). As can be seen from Fig. 2 there is a considerable resemblance between the spectra of the oligosaccharides and their parent mannans. In the case of the *D. hansenii* an additional signal at δ_c 101.2 is present in the spectrum of the mannan which is likely from C-1 of an unsubstituted main-chain unit. Similarly, the c.m.r. spectrum of *C. matritensis* mannan differs from that of the (1 → 2)-linked β-D-mannopyranose oligosaccharide in that the former contains only a small signal at δ_c 101.2 corresponding to non-reducing end-units. Instead it contains a strong signal at δ_c 101.5 which likely arises from C-1's of 2,6-di-*O*-substituted units.

(iv) The Mannan from Rhodotorula glutinis

The mannan from *Rhodotorula glutinis* contains alternate (1 → 3)- and (1 → 4)-linked β-D-mannopyranose units (15) and as a solution in D_2O at 70° it gives a simple c.m.r. spectrum consisting of 12 signals, each arising from the 12 structurally distinguishable carbon atoms of the repeating unit. A partial assignment was made following preparation of the c.m.r. spectrum of the (1 → 4)-linked β-D-mannopyranan from ivory nuts (16) dissolved in 5% NaOD in D_2O. Since the mannan is insoluble in D_2O it is necessary to use the same alkaline solvent for the spectral determination on the mannan from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Rhodotorula glutinis. The spectrum of the (1 → 4)-linked β-D-mannopyranan could be rationalized by referring to the assignments of Dorman and Roberts (8) for β-D-mannose. The resonances of C-2 to -6 of the mannan corresponded closely with those of β-D-mannose with the exception of C-4, which was at 9.6 p.p.m. lower in the mannan with its resulting superimposition on the C-5 signal. A number of the resonances appeared in the c.m.r. spectrum of the mannan from *Rhodotorula glutinis*, but only the two widely-spaced C-1 signals could be assigned with certainty. The other assignments, also presented in the Experimental, are somewhat more tentative with the exception of the C-3 signal of the 3-*O*-substituted units which is downfield from the other C-2 to -6 signals.

In some of the mannobioses the signals of carbons substituted by mannosyl group can be assigned. The deshielding effect of the *O*-mannosyl unit can then be calculated by comparison of the chemical shift of the *O*-substituted carbon with that of the corresponding carbon in α- and β-D-mannose (8), whichever is appropriate (Table 3). For example the downfield displacement of the C-2 signal of 2-*O*-α-D-mannopyranosyl-α-D-mannose is 8.0 p.p.m., compared with that of the C-2 of α-D-mannose. Downfield displacements of the same order were found for C-3 of 3-*O*-α-D-mannopyranosyl-α-D-mannose (7.3 p.p.m.) and 2-*O*-β-D-mannopyranosyl-α-D-mannose (7.6 p.p.m.). Likewise the C-2 signal of 2-*O*-β-D-mannopyranosyl-β-D-mannose is at 8.4 p.p.m. lower field and C-3 signal of 3-*O*-α-D-mannopyranosyl-β-D-mannose is at 7.3 p.p.m. lower field than the corresponding carbons in β-D-mannose.

A greater variation of the downfield displacement values was found on comparing the chemical shifts of C-1′ of α- and β-linked mannobioses, respectively, with those of C-1 of α- and β-D-mannose. Of the values recorded in Table 3, perhaps the most intriguing are those of 2-*O*-β-D-mannopyranosyl-α-D-mannose (5.3 p.p.m.) and its β-anomer (7.4 p.p.m.). The factor or factors responsible for the large difference in values of these relatively more sterically hindered mannobioses will be further investigated.

Experimental

Nuclear Magnetic Resonance Spectroscopy

C.m.r. spectra were obtained using a Varian XL-100-15 n.m.r. spectrometer with Fourier transform on 5% solutions of sugar in D_2O (4 ml) at 70°. Under these conditions approximately 24 000 transients are required. The spectra incorporated 4096 data points with a sweep width of 5000 Hz (198.4 p.p.m.). When comparison of signal size was carried out, the spectra were obtained consecutively, a sweep width of 2500 Hz being used with a correspondingly greater number of transients. In each run the acquisition time was 0.4 s, the pulse width 50 μs, and the maximum decoupling power (10 W) was used, which was centered on 500 Hz downfield from the ^1H resonance of TMS corresponding to the approximate center of the p.m.r. spectra. The hetero-noise bandwidth was 2000 Hz.

Chemical shifts are in p.p.m., the term δ_c describing the downfield difference of the signal resonance and that of external TMS contained in a coaxial capillary. Under such conditions the methyl signal of an internal standard, acetone, was δ_c 31.2 p.p.m.

Some of the c.m.r. spectra of oligosaccharides and mannans are recorded in Tables 1 and 2 and Fig. 2 together with assignments. The other spectra referred to in the above discussion are as follows.

(1) Ivory nut mannan in 5% NaOD in D_2O at 30°

101.7 (C-1), 78.8 (C-4, -5), 73.5 (C-3), 72.2 (C-2), 62.1 (C-6).

(2) Rhodotorula glutinis mannan in 5% NaOD in D_2O at 30°

In the following assignments M^3 and M^4 refer to the 3-*O*- and 4-*O*-substituted β-D-mannopyranose units, respectively, to which the following carbon atoms belong: 101.7 (M^4, C-1), 98.0 (M^3, C-1), 81.2 (M^3, C-3), 78.8 (M^4, C-5), 77.1 (M^4, C-4), 75.4 (M^3, C-5), 73.4 (M^4, C-3), 72.3 (M^4, C-2), 68.9 (M^3, C-2), 66.9 (M^3, C-4), 62.9 (M^3, C-6), 62.0 (M^4, C-6).

(3) 2-O-β-D-Mannopyranosyl-αβ-D-mannose (17)

102.8 (C-1′ of β-anomer), 100.7 (C-1′ of α-anomer), 95.3 (C-1 of β-anomer), 93.7 (C-1 of α-anomer), 81.4 (C-2 of β-anomer), 80.0 (C-2 of α-anomer).

(4) O-β-D-Mannopyranosyl-(1 → 2)-O-β-D-mannopyranosyl-(1 → 2)-αβ-D-mannose (2)

102.8 (C-1 of internal unit), 100.9 (C-1 of non-reducing end-unit), 94.4 (C-1 of β-anomeric reducing end-unit), 93.8 (C-1 of α-anomeric reducing end-unit), 80.6, 80.4 (C-2 of internal unit and α-anomeric reducing end-unit).

(5) O-β-D-Mannopyranosyl-(1 → 2)-O-β-D-mannopyranosyl-(1 → 2)-O-β-D-mannopyranosyl-(1 → 2)-αβ-D-mannose (2)

102.8 (C-1 of internal units), 101.2 (C-1 of non-reducing end-unit), 95.3 (C-1 of β-anomeric reducing end-unit), 94.0 (C-1 of α-anomeric reducing end-unit), 81.2, 81.0, 80.2 (C-2 of 2-*O*-substituted units).

(6) O-α-D-Mannopyranosyl-(1 → 2)-O-β-D-mannopyranosyl-(1 → 2)-O-β-D-mannopyranosyl-(1 → 2)-O-α-D-mannopyranosyl-(1 → 2)-αβ-D-mannose (2)

102.5, 101.7, 101.6, 101.2 (C-1 of non-reducing end-unit and internal units), 95.1 (C-1 of β-anomeric reducing end-unit, small signal) 94.4 (C-1 of α-anomeric reducing end-unit), 80.8 (β-anomer), 80.2, 80.0, 78.7, 78.5 (C-2 of substituted units).

(7) 3-O-α-D-Mannopyranosyl-αβ-D-mannose (21)

103.8 (C-1′ of α and β-anomer), 95.8 (C-1 of α-anomer)

Dakin Oxidation of *o*-Hydroxyacetophenone and some Benzophenones: Rate Enhancement and Mechanistic Aspects

M. B. HOCKING

Research Department, Dow Chemical of Canada, Ltd., Sarnia, Ontario and Department of Chemistry, University of Victoria, Victoria, British Columbia

Received July 6, 1972[1]

A synthetic aqueous alkaline hydrogen peroxide solution, made up to approximate the concentrations of caustic and hydrogen peroxide expected from water washing of aerated sodium amalgam, readily oxidized *o*-hydroxyacetophenone to catechol. The relevance of a proposed ester intermediate of this reaction is discussed, and also the possibility of using *o*-hydroxybenzophenone (originating from phenylbenzoate) as a substrate is briefly considered.

Une solution synthétique d'eau oxygénée alcaline a été réalisée pour avoir des concentrations approximatives en caustique et eau oxygénée semblables à celles attendues des eaux de lavage d'amalgame de sodium aéré. Cette solution oxyde facilement l'*o*-hydroxyacétophénone en catéchol. L'intermédiaire ester proposé pour cette réaction a été discuté, la possibilité d'utiliser l'*o*-hydroxyacétophénone (issu du benzoate de phényle) comme substrat a été considérée brièvement. [Traduit par le journal]

Can. J. Chem., **51**, 2384 (1973)

Introduction

Dakin reported (1) in 1909 that alkaline hydrogen peroxide will oxidize *o*- or *p*-hydroxy aromatic aldehydes, **1**, to the corresponding dihydroxyaromatic, **2** (see Scheme 1). While he carried out preliminary investigations with some hydroxyacetophenones, the scope with acetophenones was widened (2, 3) and benzylic ketones included (4) by the later work of Baker and co-workers. Dakin oxidation has been cursorily reviewed (5–7). Mechanistic interpretations have been drawn (5) from the related Baeyer–Villiger oxidation of carbonyl-labelled *p*-methoxyacetophenone, in which it was found that all the label was retained in the carbonyl (8). This finding has since been supported, again by analogy, with retention of the label in the catechol formed when salicylaldehyde is oxidized with oxygen-labelled hydrogen peroxide (9).

X or Y = OH

2
X or Y = OH

SCHEME 1

Dakin oxidation appears capable of satisfying several useful ends not previously considered. It could provide an outlet of greater value than caustic soda for the sodium amalgam produced in mercury cell chlor–alkali production. Aeration of the amalgam, followed by washing with water, gives a dilute aqueous solution of sodium hydroperoxide and sodium hydroxide in water (10) (eqs. 1 and 2). We wished to demonstrate

[1] $$4Na/Hg + O_2 \rightarrow 2Na_2O/Hg$$

[2] $$Na_2O/Hg + 2H_2O \rightarrow NaOH + NaOOH + Hg + H_2\uparrow$$

that this relatively cheap oxidizing solution could be used directly, avoiding the expensive steps of neutralization and distillation required to isolate hydrogen peroxide. *o*-Hydroxyacetophenone appeared to be a useful test substrate, yielding catechol on oxidation. However, as normally run, Dakin oxidation uses only one equivalent of base for each equivalent of hydrogen peroxide (11), and is too slow (16–24 h (11)) to be commercially attractive. The aim of our experiments was to determine a set of conditions where high yields may be achieved in a short reaction time, and, complementary to this, to briefly study mechanistic aspects and alternative substrates for this oxidation.

Experimental

ortho-Hydroxyacetophenone was purchased from Aldrich Chemical Company, checked for purity by n.m.r., and used as received. Caustic was "Dowflake", Dow Chemical of Canada production material, 99.6% purity. Sodium carbonate (anhydrous) and hydrogen peroxide (30%) were Fisher reagent grade chemicals. A Fisher

[a]Experiments 1–7 in glass, remainder in polyethylene (see Fig. 1).
[b]Experiments 1 and 2 in 710 ml of water, 3 in 200 ml, all others in 275 ml.
[c]Sodium hydroxide unless otherwise stated.
[d]From a starting temperature of 28°, non-thermostatted.
[e]Peroxide remained in those reactions where the time is parenthesized.
[f]Yields based on hydroxyacetophenone consumed. Crude yields by isolation for experiments 1–3, all others by u.v. determination.
[g]Repetition of experiments 4 and 5 in polyethylene, and work-up by salting and ether extraction (see experimental) followed by purification by sublimation gave pure yields of 84 and 52% respectively.
[h]Experiment was thermostatted prior to, and during the reaction, at 49°.
[i]Alkanox and Amway, trade name detergents.

"Accumet" p*H* meter (model 310) was used for p*H* determination and standardized immediately prior to measurement on a buffer near the p*H* to be measured. U.v. spectra were obtained on a Beckman DK-2 ratio recording spectrophotometer.

Hydrogen Peroxide Standardization

Ten-milliliter aliquots of a 1:50 dilution of 30% H_2O_2 were titrated, in acetic acid (25 ml) and aqueous KI (10 ml of 50%) containing 5 drops of 3.7% $(NH_4)_2MoO_4$ catalyst (9), with 0.100 *N* $Na_2S_2O_3$. Titrant (53.1 ml) was required establishing a stock solution H_2O_2 strength of 32 vol % (39.8 wt. %). The density of the stock 30% H_2O_2 at 25° was 1.1325, indicating (9) 36 wt. % H_2O_2. All experiments, except no. 19, were run using portions of the same lot of hydrogen peroxide, the strength of which was periodically checked.

Reaction Vessel Pretreatment

New 500-ml glass vessels were thoroughly washed with methylene chloride, detergent, and hot water and rinsed with distilled water. Ten milliliters of 30% H_2O_2 was added and the vessel filled with 0.1 *N* NaOH and left at room temperature for 24 h. Immediately prior to use, it was thoroughly rinsed with distilled water. Polyethylene vessels were made up from new 500-ml wash bottles pretreated in the same way as the glass vessels.

Peroxide Titrations

Frequent blanks were carried out to improve reproducibility. The reaction aliquot was swirled into a freshly mixed solution of 10% KI (5 ml) and 3.7% $(NH_4)_2MoO_4$ (5 drops) in acetic acid (10 ml) and allowed to stand 20 min before titrating. Standardized (0.100 *N*) sodium thiosulfate was the titrant and starch solution was added near the end point to facilitate determination.

Dakin Oxidation of ortho-Hydroxyacetophenone

The base (usually 0.1 mol, see Table 1) was dissolved, with magnetic stirring, in distilled water (usually 275 ml) in a pretreated polyethylene wash bottle. The ortho-hydroxyacetophenone (usually 13.6 g; 0.1 mol) was then

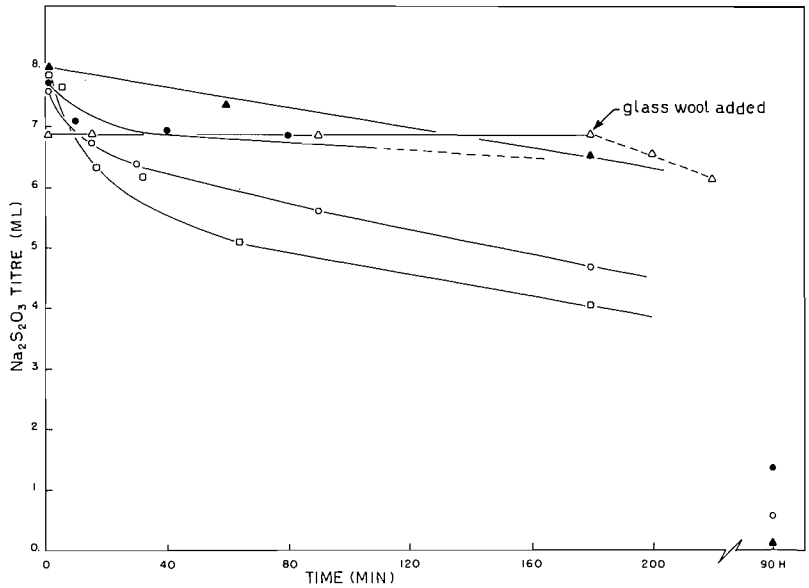

FIG. 1. Stability of aqueous hydrogen peroxide in various alkaline media at 28°. Blanks: NaOH in glass, ●; NaOH + Na_2CO_3 in polyethylene, △; NaOH + Na_2CO_3 in glass, ○; NaOH in polyethylene, ▲; NaOH + Na_2CO_3 at 50° in polyethylene, □.

added, the temperature of the solution adjusted to 28 °C and the 30% hydrogen peroxide (9.4 ml; 0.12 mol) added all at once, with continued stirring throughout. During each reaction the temperature was noted at frequent intervals. Six to eight aliquots of 1 or 2 ml each, depending on the stage of the reaction, were removed at timed intervals during the reaction and titrated iodometrically for peroxide content.

Unreacted starting material was recovered, after slightly acidifying the reaction mixture with glacial acetic acid, by azeotroping with about 100 ml of the water on a boiling water bath under slightly reduced pressure. The insoluble ketone was separated, the rest of the aqueous distillate was saturated with salt and extracted with 2 or 3 small portions of methylene chloride and the combined organic phases dried ($MgSO_4$). Careful distillation of the methylene chloride yielded the unreacted *o*-hydroxyacetophenone. In one or two reactions, when the aqueous distillate after extraction was examined by u.v. absorption, there was evidence of traces (2–10 mg of each) of muconaldehyde and muconic acid, which had been previously observed in peracetic acid oxidations of catechol (12). Approximately 35 mg of catechol had also come over. At no time could any of the intermediate *o*-hydroxyphenylacetate be detected by i.r. or n.m.r. analysis.

The catechol was determined initially by acidifying (acetic acid) the distilland to avoid p*H*-induced shift of the catechol u.v. absorption maximum, making it up to a measured volume with distilled water and then obtaining a catechol concentration figure by comparing the u.v. absorption with that shown by a series of standards. For actual isolation of the catechol three methods were used. The most efficient method was saturation of the aqueous solution with salt and extraction with 5 or 6 small portions of ether (experiment 19). The catechol (4.6 g; 89%) was obtained upon drying and distillation of the ether from the combined extracts. Both of the other work-up methods required initial removal of the water under reduced pressure on a steam bath. One used exhaustive Soxhlet extraction with toluene, the thimble contents being re-ground several times during the extraction. This was used in experiments 1–7, 12, 14, 16, and 17. The other involved trituration of the solid residue with several portions of hot acetone followed by distillation of the combined extracts to remove the acetone (experiments 8 and 9). The catechol was then separated from the traces of salts also extracted by the acetone by vacuum distillation.

Peroxide Stability Experiments

These were conducted in various solutions in the same way as the oxidation experiments above, but as blanks without substrate present (Fig. 1).

Dakin Oxidation of p-Hydroxyacetophenone

To a solution of *p*-hydroxyacetophenone (13.6 g; 0.1 mol) and sodium hydroxide (4 g; 0.1 mol) in distilled water (275 ml) in a polyethylene vessel was added 30% hydrogen peroxide (9.4 ml; 0.12 mol) with stirring. The solution remained homogeneous on the addition of peroxide, in contrast to the *o*-ketone experiments. A small portion of the above solution was placed in an n.m.r. tube, and was scanned in the region of the acetyl methyl at 2 min intervals. As determined by titration for peroxide and by the decrease in the acetyl methyl, and formation and increase of the acetate methyl n.m.r. signals, the rate of this reaction was about the same as the rates of reaction with *o*-hydroxyacetophenone.

Hydroquinone Monoacetate

A low yield of hydroquinone monoacetate was obtained by the method of Olcott (13). From a 1 g mole-scale reaction, 4 g of cream colored crystals of the monoester was obtained (m.p. from benzene–hexane 56–60°, lit. (13) 62–63°; proton n.m.r. H_2O from external tetramethylsilane gave: acetate methyl, δ 2.72 p.p.m.; aromatic, 7.38 p.p.m.; integrals 3:4).

Competitive Oxidation–Hydrolysis of p-Hydroxyacetophenone – Hydroquinone Monacetate

p-Hydroxyacetophenone (136.3 mg) and solid sodium hydroxide (40 mg) were dissolved in water (2.7 ml) in a test tube. Hydroquinone monoacetate (152.4 mg) and 30% hydrogen peroxide (113.2 mg) were added simultaneously and the mixture vigorously agitated. A sample, removed and examined by n.m.r., showed a small proton resonance peak for ketone methyl and large peaks for ester and sodium acetate methyls (shifts, from external tetramethylsilane, δ 2.97, 2.72, and 2.35 p.p.m. respectively). Identification was confirmed by seeding with authentic materials. An iodine–thiosulfate titer on a 1-ml aliquot showed that no peroxide remained.

The experiment described above was repeated, but with a preliminary n.m.r. examination of the mixture of all components before peroxide addition. At this point the sharp ketone methyl and ester methyl peak heights were 125 and 112 mm respectively. After peroxide had been added (diluting the solution somewhat), methyl peak heights were: acetate ion 102 mm, ester 50 mm, ketone 15 mm.

Repetition of the experiment two further times, but with 2 equiv of sodium hydroxide (80 mg) and twice the original amount of water (5.4 ml) present initially showed methyl peak heights for acetate ion, 133 and 110 mm, ester, 46 and 29 mm, and ketone, 13 and 10 mm at the end of the reactions.

When the monoester was omitted from the reaction mixtures, no ester methyl was observed during n.m.r. scans at 1 min intervals for the duration of the reaction, and the *p*-hydroxyacetophenone oxidation proceeded more slowly than in the presence of ester. When ketone was omitted from reaction mixtures, ester hydrolysis proceeded more rapidly than in its presence.

Attempted Oxidation of Benzophenone

Using 4 equiv of base and peroxide on a 0.1 g molar scale under the standard Dakin oxidation conditions, only unchanged starting material was obtained.

Oxidation of o-Hydroxybenzophenone

To a stirred solution of the ketone (9.6 g) and sodium hydroxide (4.8 g) in water (200 ml) was added 1 equiv of 30% hydrogen peroxide (5 ml). After 1.5 h virtually no peroxide was left. The components were separated by acidifying (HCl), saturating with salt, and extracting with ether, followed by extractive separations of the acid, phenolic water-soluble, and phenolic water-insoluble fractions. Benzoic acid (1.35 g, m.p. and mixed m.p. 121–123°, and by g.c. retention time), catechol (0.25 g, identified as above, plus n.m.r.), and unchanged starting material (8 g, by g.c. retention time and n.m.r.) were obtained. No salicylic acid could be detected.

When repeated on twice the scale using 5 equiv of peroxide, 10 g of benzoic acid, 4.1 g of catechol, and 1 g of unchanged starting material were obtained.

Oxidation of p-Hydroxybenzophenone

To a stirred solution of the ketone (19.8 g) and sodium hydroxide (18 g) in water (400 ml) was added 30% hydrogen peroxide (45 ml). Peroxide loss was slow, so the reaction was warmed for 1 h in a water bath at 70°. Work-up by the method used for the ortho isomer yielded 2.5 g of benzoic acid and 14.55 g of unchanged starting material. No phenolic product was isolated or detectable.

Oxidation of 4-Hydroxy-4′-methylbenzophenone

This reaction was carried out in exactly the same way as the above using 21.2 g of ketone. *p*-Toluic acid (1.1 g) (m.p. and mixed m.p. 177–180°) and 19 g of unchanged starting material were obtained. No phenolic product was detected.

Oxidation of 2-Furfural

2-Furfural (19 g; freshly redistilled, cut boiling at 156–157°) was added all at once, with stirring to a solution of caustic (8 g) and 30% hydrogen peroxide (18.4 ml) in distilled water (400 ml). After 30 min, when no peroxide was left by titration of an aliquot, the solution was acidified, saturated with salt, and extracted with ether. Separation of the combined extracts into a neutral and an acidic fraction yielded 9.9 g of unchanged 2-furfural (pure, by g.c.) from the former, and 2.4 g crude (0.5 g pure) of 2-furoic acid (m.p. and mixed m.p. 133–134°, and by n.m.r.) from the latter.

A blank reaction (Cannizzaro) carried out as above but omitting the peroxide gave 10 g of unchanged starting material, and 4 g crude (1.2 g pure) 2-furoic acid. No 2-furfuryl alcohol could be detected by n.m.r. in the recovered starting material.

Results and Discussion

The already-optimized procedure of Dakin (11) for the oxidation of salicylaldehyde was taken as a starting point for the study of Dakin oxidation of *o*-hydroxyacetophenone. The effect of a number of variables on conversions and yields is summarized in Table 1.

It was found that doubling the ratio of caustic to hydrogen peroxide in the reaction significantly increased the rate. Twenty to thirty minutes at temperatures of the order of 30° was sufficient to give nearly complete reaction without any loss in conversion or yield from that attainable under normal Dakin conditions. Either 2 equiv of caustic, or a mixture of 1 equiv of sodium carbonate plus 1 equiv of caustic for each equivalent of peroxide gave this result. Thus, experiments 3, 4, 8, 9, and 12 gave faster reactions (See Fig. 2) and similar or better conversions and yields than experiments 1 and 6, which were carried out under normal Dakin conditions. An exception to this generalization was experiment 5, which gave a 96% yield but only 54% conversion. While this should have given as good results as experiment 12 (93 and 98% respec-

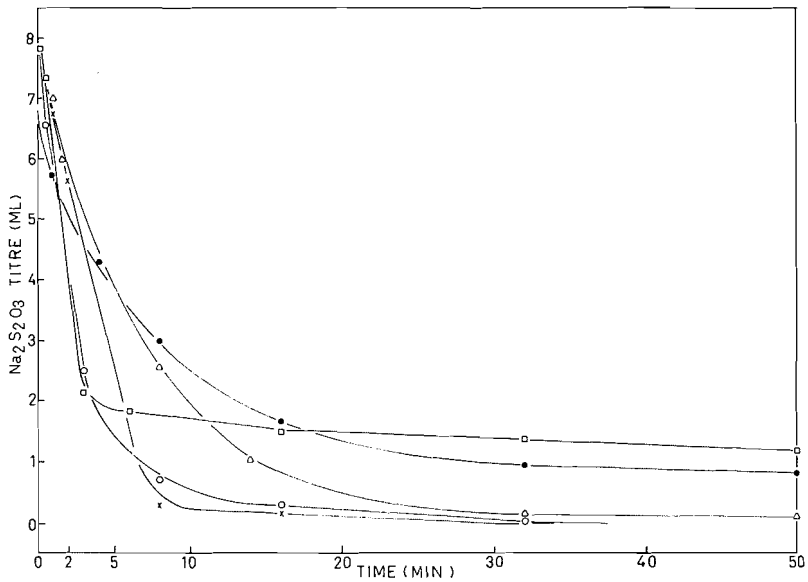

FIG. 2. Peroxide titre *vs.* time for Dakin oxidations at room temperature. Equivalents of base used per equivalent of substrate: 1 NaOH + 1 Na_2CO_3 = ○ (4); 1 NaOH = □ (6), 2 Na_2CO_3 = △ (7); 2 NaOH = X (12), 2 NH_4OH = ● (17). Experiment numbers are given parenthetically.

tively), spontaneous peroxide decomposition in the glass vessel perhaps was responsible for the lower conversion. That this is a likely explanation is shown in Figure 1.

Use of 2 equiv of sodium carbonate, the effect of full carbonation of the alkaline peroxide, results in a significant lengthening of the reaction time, and slightly reduces the conversion and yield (experiment 7).

From the inhomogeneity of reactions using 1 mol of caustic per mol of substrate, and from the homogeneous solutions obtained in the reactions using 2 equiv of base, it appeared that homogeneity may largely be the determining factor for the rate and yield improvements. To test this theory, two experiments (13 and 14) were carried out using 1 equiv of base plus just sufficient synthetic detergent to maintain homogeneity. These reactions gave initial rates as fast as and yields comparable to those obtained by the use of 2 mol of base. However, they still showed the same very slow disappearance of the last 15% of peroxide (Figure 2 and Table 2), found in reactions containing only 1 mol of base, without detergent.

The faster rates throughout the reaction in the presence of 2 equiv of base are probably the result of a p*H* effect combined with a homogeneity difference. In order to determine the effect of a change in p*H* and at the same time to determine whether or not another base could be used in place of caustic or sodium carbonate, reactions were tried using trisodium phosphate, sodium silicate, ammonium hydroxide, and sodium molybdate as alternatives. Other possible bases were too expensive, too insoluble, or could not be obtained by neutralizing aerated sodium amalgam washings to be worth considering for a process. Sodium phosphate, on a sodium ion equivalence basis (*i.e.* as would be obtained on neutralization of NaOOH + NaOH with phosphoric acid), gave only 56% conversion but still a reasonably high yield (experiment 10). When used in conjunction with 1 equiv of caustic the conversion rose significantly but the yield remained at about 86%. This was lower than the yields obtained in reactions using 2 equiv of caustic or caustic–carbonate as the base. Sodium silicate, with which the expected (14) significant spontaneous decomposition of hydrogen peroxide did not materialize, gave a very high conversion and yield (experiment 15). Ammonium hydroxide in conjunction with caustic gave a very high conversion and yield, but alone was not quite so effective and gave a more tarry crude product than any other reaction. Sodium molybdate, as anticipated (14), caused rapid spontaneous decomposition of the

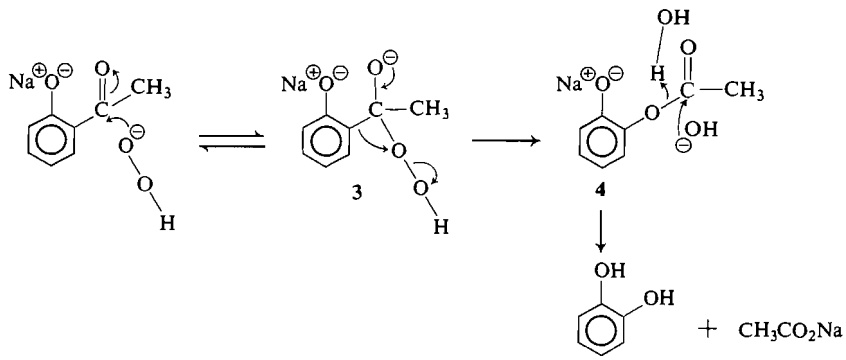

SCHEME 2

peroxide, and gave the lowest conversion (22%) and yield (about 30%) of any reaction in this series.

When the variations in the base are correlated with the p*H* measured before and after the reaction (Table 2), a number of observations can be made. Those reactions where conditions were such that the p*H* remained high (above about 10.5) throughout the reaction are those which were fast with high yields. The one exception is that of the reaction containing molybdate anion. This incurred visible spontaneous peroxide decomposition and, because of the resultant low conversion, the p*H* remained high. The p*H* dropped to 10 or below in the reactions involving sodium phosphate alone, ammonium hydroxide, and those using 1 equiv of caustic or less, with or without detergent, giving lower yields.

The p*H* effect can be explained by considering the hydroperoxide anion concentration. Probably the initial step of a Dakin oxidation involves attack of a hydroperoxide anion on the carbonyl carbon (5), see Scheme 2. Hence, the higher the concentration of hydroperoxide anion, the more rapidly the oxidation should proceed. Since the pK_a of hydrogen peroxide is 11.75 (14), at a p*H* of 11.75 half of the hydrogen peroxide will be dissociated to the hydroperoxide anion while at a p*H* of 9.75 the relative hydroperoxide anion concentration is only 1% of this.[2] Thus, as the p*H* of the oxidizing media falls to 9.5–10 it can

[2]The p*H* range for maximum capricious decomposition of hydrogen peroxide lies in the region of 9.5–12, presumably because it is the region where a significant concentration of hydroperoxide anion, the least stable species of this equilibrium, is present.

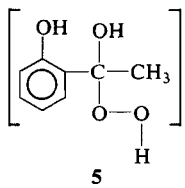
be expected that a significant decrease in oxidation rate will result. This effect may be the explanation for the very slow final rates observed in experiments 6, 10, 13–17, and 19, where the final p*H* dropped to 10 or below.

Another factor which may contribute to the higher rates at high p*H* is the greater proportion of dissociated phenol in the substrate being oxidized. Phenyl migration is more facile in an intermediate with an ionized hydroxyl, **3**, than in an intermediate in which the hydroxyl is protonated, **5**, which will predominate below a



5

p*H* of about 10. The latter is not only likely to retard the reaction by shifting the first equilibrium to the left, but may permit competition of methyl with phenyl migration (no salicylic acid was observed in our reactions). Also, ring oxidation is more likely to compete with acyl oxidation in **5** than in **3**, with its far less electrophilic ring. This may account for the somewhat lower yields observed in a number of the low p*H* experiments.

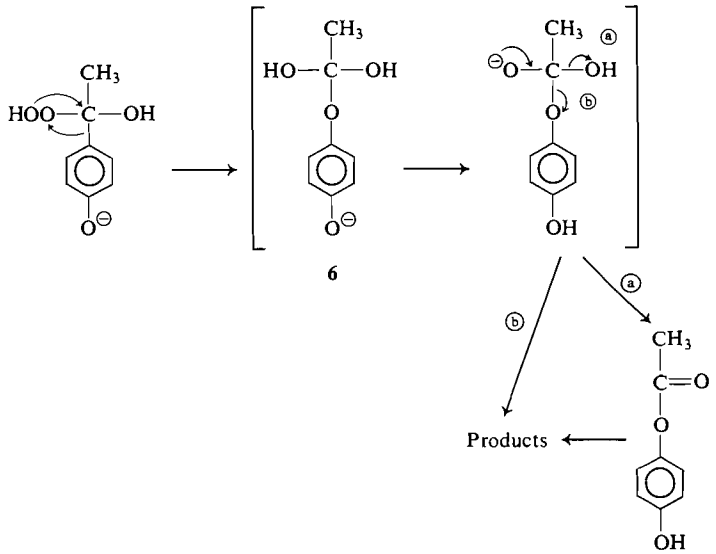
In an attempt to observe the ester intermediate **4**, only 0.5 equiv of caustic was used in experiment 19. Even with this low caustic ratio the p*H* was sufficiently high for the oxidation to proceed rapidly, and should the ester hydrolysis be significantly slower than oxidation, nearly all the substrate should be oxidized while only half of the ester formed would hydrolyze. Only half the peroxide was consumed in the reaction. Thus, either ester hydrolysis was very fast or the reaction proceeds via a different path. The former explanation is supported by a kinetic study of Hansen (15) on the hydrolysis of catechol monoacetate, in which he found that the second order rate constant is 1175 mol^{-1} s^{-1} at 25°, more than 700 times the rate of hydrolysis of phenyl acetate.

Without anchimeric assistance from the ortho-hydroxyl, the rate of hydrolysis of hydroqinone monoacetate is closer to that of phenyl acetate (15). Accordingly, after an initial preparative scale oxidation of *p*-hydroxyacetophenone to verify the adequacy of the reaction conditions, several competitive oxidation–hydrolysis experiments were undertaken between this ketone and hydroquinone monoacetate. These demonstrated, under a variety of conditions, that *p*-hydroxyacetophenone is more rapidly oxidized than is hydroquinone monoacetate hydrolyzed to the same product, hydroquinone. The somewhat more rapid ester hydrolysis noted in the absence of ketone than in its presence was probably a consequence of more prolonged promotion by the greater availability of hydrogen peroxide (16). This supports the contention that, at least in the oxidation of *p*-hydroxyacetophenone, true ester intermediacy is unlikely.

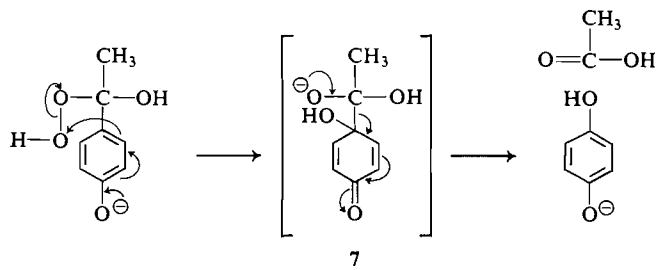
Transitory intermediacy of species such as **6**, **7**, or **8** could lead to the observed products without ever going through the formation of an ester (Schemes 3–5 do not require ester intermediacy). Of the decomposition pathways (*a*) and (*b*) open to intermediate **6**, alternative (*b*) is more acceptable because phenolate anion is a much better leaving group than hydroxyl ion, and because no ester formation was observed. The formation of intermediate **7** is supported by our finding that, over the p*H* range studied, the higher the p*H* the faster the reaction (Tables 1 and 2), a result easier to explain by the formation step of **7** (*i.e.* direct involvement of phenolate anion), than by the formation step of **6**. Kratzl and co-workers (17) have proposed intermediacy of perester, **8**, to support their agreement with our contention that ester intermediacy is unlikely. They suggest that the perester arises via hydroperoxide radical ring attack followed by aromatization of the quinonoid intermediate. Since perester lifetime is short, our results are also compatible with this suggested pathway.

It is possible that phenyl benzoate, prepared from the cheap industrial raw materials phenol and benzoic acid, might be thermally rearranged to a mixture of hydroxybenzophenones. With this in mind, a few Dakin oxidations were tried with this type of substrate. With 1 equiv of oxidizing agent, about 10% oxidation was achieved with *o*-hydroxybenzophenone. With 5 equiv of oxidant there was about 80% reaction with the ortho isomer, but only about 5% with *p*-hydroxybenzophenone or 4-hydroxy-4′-methylbenzophenone. Benzophenone itself was recovered unchanged.

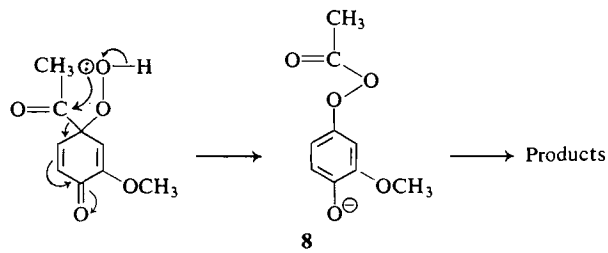
Clean autoxidation of 2-furfural to 2-furoic



SCHEME 3



SCHEME 4



SCHEME 5

acid cannot be achieved. Hence, it was hoped Dakin conditions might be appropriate. It was found, however, that straight Cannizzaro conditions (*i.e.* only caustic present), with no peroxide, gave better results than Dakin conditions. During the course of these experiments Kulnevich *et al.* (18) reported obtaining 2-hydroxyfuran by acidic hydrogen peroxide oxidation of 2-furfural.

Thermal Unimolecular Isomerization of 3-Methyl-3-vinyldiazirine

MICHAEL T. H. LIU AND K. TORIYAMA

Department of Chemistry, University of Prince Edward Island, Charlottetown, P.E.I.

Received November 20, 1972

The thermal isomerization of 3-methyl-3-vinyldiazirine in various solvents has been investigated over the temperature range 40–75 °C. The reaction was kinetically first order and unimolecular. The experimental results indicate that this isomerization, as well as the other diazirine decomposition so far investigated, is consistent with a two-step mechanism.

L'isomérisation thermique de la méthyl-3 vinyl-3 diazirine a été étudiée dans divers solvants entre 40 et 75 °C. La réaction est cinétiquement du premier ordre et unimoléculaire. Les résultats expérimentaux indiquent que cette isomérisation, de même que la décomposition de l'autre diazirine étudiée jusqu'à maintenant est en accord avec un mécanisme en deux étapes.

Introduction

Many investigations on carbene chemistry with the use of diazirines have been reported (1), but the nature of the initial mechanistic step involved in their pyrolysis is not well understood. In the gas phase pyrolysis of 3-chloro-3-alkyldiazirines, Frey and Liu (2) have provided some evidence for the intermediate production of carbenes and proposed a transition state for the decomposition of diazirine in which the two carbon–nitrogen bonds are broken simultaneously. Schmitz (3), on the other hand, has argued that an ionic mechanism is more likely to occur, while Mitsch and co-workers (4, 5) favor a mechanism involving the transient existence of diazomethane prior to its loss of nitrogen. Recently, we have studied the thermal decomposition of 3-chloro-3-aryldiazirines (6) and suggested a mechanism involving the breaking of one of the C—N bonds. This process would lead to a diradical and a diazomethane intermediate. We had concluded that the contribution of the latter is probably small due to the lack of solvent effects. The isomerization of 3-methyl-3-vinyldiazirine has been investigated before (7), but the kinetic studies of this process were not measured. The present work was undertaken primarily to obtain the Arrhenius parameters for this isomerization in the hope that the mechanism for diazirines decomposition could be understood.

Experimental

3-Methyl-3-vinyldiazirine was prepared by reacting methyl iodide in the presence of silver nitrate with 3-methyl-3-[β-diethylamino-ethyl]-diazirine according to the method of Schmitz *et al.* (7). The n.m.r. spectrum showed a singlet (CH_3) at τ 8.8 p.p.m. and a multiplet (vinyl grouping) centered at τ 4.95 p.p.m. The solvents used in kinetics studies were carefully dried and distilled before use. Pyrolyses were carried out in sealed tubes immersed in an oil bath which was maintained to ±0.1 °C in the temperature range from 40 to 80 °C. Gas chromatography analysis was conducted with the use of a Perkin–Elmer Flame instrument fitted with a hydrogen flame detector. The rates of reaction were measured by following the disappearance of diazirine (isooctane as an internal standard). The 6 ft column was packed with chromosorb coated with 20% Carbowax 400. The injection and column temperatures were 25 °C. Reproducibility of duplicate analyses was better than 2%. Reaction rates followed by u.v. spectra were measured with Unicam SP 800 at the characteristic absorption of diazirine (λ 378 nm). The detailed experimental procedure was described in our earlier work (6).

Results and Discussion

The thermal isomerization of 3-methyl-3-vinyldiazirine was first order in various solvents, giving primarily 3-methyl-pyrazole according to eq. 1.

[1] 
In the cases of carbon tetrachloride and of ethanol solution, the yield of 3-methyl-pyrazole was estimated to be at least 95% by comparison with the u.v. and i.r. spectra of the authentic sample. A small percentage of volatile material was obtained, with the retention time of the chromatographic peak being consistent with butadiene. When *N,N*-dimethylformamide

TABLE 1. Rate constants ($10^4 k$ s^{-1}) for the thermal decomposition of 3-methyl-3-vinyldiazirine

Solvent	Temperature (°C)								Method

Aqueous AcOH (90% v/v)	—	—	—	4.02	—	—	—	—	U.v.

(DMFA) and diethylene glycol monoethyl ether (DEGME) were the solvents, the only product was 3-methyl-pyrazole. Table 1 shows the rate constants obtained at each temperature. The energies of activation and the pre-exponential factors, calculated by the least squares method, yielded the following eqs. 2–5. The error limits

$$[2] \quad k_{CCl_4} = 10^{13.70\pm0.10} \times \exp(-25\,600 \pm 200/RT)\ s^{-1}$$

$$[3] \quad k_{DMFA} = 10^{13.60\pm0.06} \times \exp(-25\,400 \pm 100/RT)\ s^{-1}$$

$$[4] \quad k_{DEGME} = 10^{13.70\pm0.10} \times \exp(-25\,500 \pm 120/RT)\ s^{-1}$$

$$[5] \quad k_{EtOH} = 10^{13.70\pm0.05} \times \exp(-25\,600 \pm 200/RT)\ s^{-1}$$

(standard deviations) are those calculated by normal statistical methods.

In considering the mechanism of diazirine decomposition, the initial problem to be dealt with is a choice between a concerted and a two-step mechanism. With this problem in mind, the Arrhenius parameters for various diazirines in Table 5 of ref. 6 were examined. The present study indicates that there is a decrease in activation energy of 3-methyl-3-vinyldiazirine of about 1–2 kcal mol^{-1} from that of 3-chloro-3-phenyldiazirines. The minor solvent effects suggest that the solute–solvent interaction must be nearly the same for both the reactant and transition state. In the thermal decomposition of diazirine, two C—N bonds are broken in the course of the reaction, while only one C—N bond is broken in the isomerization process. If the decomposition occurs by the simultaneous rupture of both bonds, then we may expect a different transition state for the decomposition and the isomerization. However, it is noted that the A factors ($\Delta S^{\ddagger} \sim 2$ e.u.) for the isomerization are similar to those of other diazirine decompositions. This feature indicates that the thermal reaction of all diazirines takes on a similar transition state in gas phase as well as in solution and suggests that, for the decomposition reaction, the breaking of the two C—N bonds occurs in a step-wise manner.

A proposed two-step mechanism (Scheme 1) could involve either a diradical intermediate as in path A or a polar intermediate as in path B. First, we shall look at the evidence for path A by comparing the energy of activation for 3-methyl-3-vinyldiazirine with that for 3,3-dimethyldiazirine (8). For the latter compound a value of 33.16 kcal mol^{-1} was reported for the decompositions carried out at 4 Torr which is in the "fall-off" region. Bridge *et al.* (9) have studied the thermal decomposition of 3-chloro-3-methyldiazirine both at 4 Torr and in the high pressure region. At 4 Torr, the rate constant has fallen to about 75% of its high pressure value. The energies of activation were 27.18 kcal mol^{-1} ($P = 4$ Torr) and 31.07 kcal mol^{-1} ($P = \infty$). It is therefore reasonable to assume that the value of the energy of activation corresponding to k_∞ for 3,3-dimethyldiazirine would be at least 35 kcal mol^{-1}. Although it might be argued that a comparison of this kind is not strictly permissible because this was a reaction in solution, there is reason to believe that such comparison may be meaningful since the parameters for diazirine decomposition are not solvent dependent (6, 7). This statement is substantiated by the results of preliminary investigations of the thermal decomposition of 3-chloro-3-ethyldiazirine in cyclohexene (10) where the ratio $k_{gas}/k_{cyclohexene} = 10^{0.17} \exp(-0.85/RT)$. The lowering of the activation energy by ~ 10 kcal for the vinyl compound is reasonable for the formation of a diradical intermediate such as the one

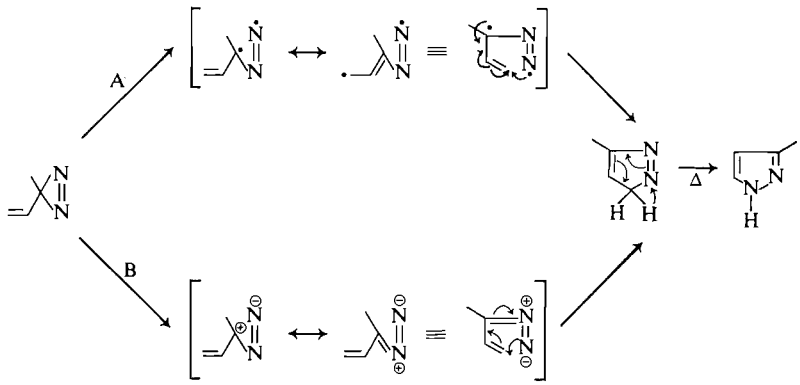


SCHEME 1

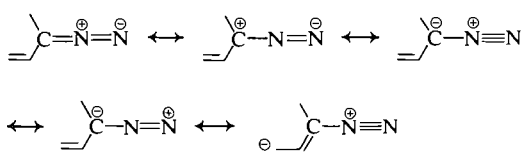
TABLE 2. A comparison of solvent effects for some diazirines. The relative rate constants $k_{solvent}/k_{CCl_4}$ at 75 °C are listed

	EtOH	Aqueous AcOH	DMSO	DMFA	DEGME
3-Chloro-3-phenyldiazirine	1	1	1.7	—	1.2
3-Methyl-3-vinyldiazirine	1	1*	—	1.4	1.3

*The comparison was made at 55 °C.

given in path A. More detailed arguments for this statement can be found in ref. 11.

Furthermore, the solvent effects for the isomerization as well as the decomposition of diazirine are shown in Table 2. It is observed that the rate acceleration effect given by $k_{solvent}/k_{CCl_4}$ for 3-chloro-3-phenyldiazirine and 3-methyl-3-vinyldiazirine showed an increase when polar solvents were employed. The effect is rather small and a larger effect would be expected if the rate determining step involved the re-arrangement of diazirine to an ionic intermediate. However, the experimental results of this work do not conclusively rule out the possibility of an ionic mechanism. Path B is equally probable if one considers that the resonance forms of methylvinyldiazomethane consist of linear structures with opposing dipoles:



It is seen that the participation of these resonance structures will lead to a compensation in net polarity. Although the dipole moments of methylvinyldiazirine and methylvinyldiazomethane are not known, the dipole moments for these compounds are probably not very different. It is, therefore, not surprising that the observed solvent effect is small. It is also known that the rearrangement of vinyldiazomethane (diazopropene) to pyrazole (12) can occur at room temperature. The rate constants are comparable to those of the isomerization. While there is sufficient evidence that a step-wise mechanism occurs in diazirine decomposition, it is not certain whether the intermediate is of a diradical or an ionic nature.

Grateful acknowledgement is made by one of us, M.T.H.L., for a grants-in-aid of research from National Research Council of Canada and from the Senate Research Committee of U.P.E.I. The authors wish to thank the referees for their valuable comments.

Synthesis of Nucleotides from 8,2′-Thioanhydropurine Nucleosides[1]

KELVIN K. OGILVIE AND LEWIS A. SLOTIN[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received January 8, 1973

The 5′-mono and diphosphates of the common 8,2′-thioanhydropurine nucleosides have been prepared and studied with 5′-nucleotidase. alkaline phosphatase, and adenylate kinase. Procedures for the preparation of protected anhydronucleosides and their incorporation into dianhydronucleoside monophosphates have been developed. These nucleotides have been found to be completely resistant to spleen and snake venom phosphodiesterases but are readily converted with Raney nickel into the natural 2′-deoxynucleotides.

Les mono-5′ et diphosphates des nucléosides communs thio-8 anhydro-2′ purine ont été préparés et étudiés avec la nucléotidase-5′, la phosphatase alcaline et la kinase adénylate. Des méthodes pour la préparation d'anhydronucléosides protégés et pour l'incorporation de ceux-ci dans des monophosphates de dianhydronucléoside ont été élaborées. Ces nucléotides se sont montrés complètement résistants aux phosphodiestérases de la rate et du venin de serpent mais se sont facilement transformés avec du nickel de Raney en déoxy-2′ nucléotides naturels. [Traduit par le journal]

Can. J. Chem., **51**, 2397 (1973)

Introduction

Cyclonucleosides (anhydronucleosides) are important analogs of natural nucleosides. They are characterized by having, in addition to the *N*-glycoside linkage, a covalent linkage either directly or via bridging atoms between the 2′, 3′, or 5′ carbons of the sugar and a carbon or nitrogen atom (other than the nitrogen of the glycoside bond) of the purine or pyrimidine base. Previous reports from our laboratory have described convenient methods for obtaining 8,2′-thioanhydropurinenucleosides (1), and the use of anhydropyrimidine nucleosides in the synthesis of anhydro- and arabinonucleotides (2). We wish now to describe the synthesis of anhydropurine nucleoside mono- and diphosphates and dianhydropurine nucleoside monophosphates, their behavior toward certain enzymes, and their conversion to naturally occurring nucleotides. While this work was in progress the synthesis of oligomers of 8,2′-thioanhydroadenosine 5′-phosphate (3*a*) and the synthesis of a dinucleoside monophosphate of 8,2′-anhydro-8-oxy-9-B-D-arabinofuranosyladenine (3*b*) were reported.

Results and Discussion

8,2′-Thioanhydropurine Nucleoside 5′-Mono- and 5′-Diphosphates

An efficient method for the synthesis of monophosphates of natural nucleosides was developed by Yoshikawa *et al.* (4). This method allows the selective 5′-phosphorylation of unprotected nucleosides using partially hydrolyzed phosphoryl chloride in a trialkylphosphate solvent. This method eliminates both the need for protection of either amino or hydroxyl groups and the necessity of absolute dryness generally required in phosphorylations (5).

8,2′-Thioanhydroadenosine (**1***a*), 8,2′-thioanhydroguanosine (**1***b*), and 8,2′-thioanhydroinosine (**1***c*) were successfully converted to their corresponding phosphates **2***a–c* using a large excess of phosphoryl chloride in wet triethyl phosphate (see Scheme 1). **2***a* was obtained in 92% yield and was identical to an authentic sample prepared by cyclization of 2′-O-tosyl-8-bromoadenosine 5′-phosphate (6). The structure of **2***a* was further confirmed by Raney nickel reduction to 2′-deoxyadenosine 5′-phosphate which was dephosphorylated with 5′-nucleotidase to give 2′-deoxyadenosine. Yields of **2***b* and *c* were 43 and 74% respectively and these compounds were identified by Raney nickel reduction to the corresponding 2′-deoxynucleoside 5′-phosphates and subsequent dephosphorylation with 5′-nucleotidase to the natural nucleosides 2′-deoxyguanosine and 2′-deoxyinosine.

The monophosphates **2***a–c* were converted to the diphosphates **3***a–c* via the morpholidate procedure (7). Compounds **2** were treated with morpholine and *N,N*-dicyclohexylcarbodiimide

c X = OH, Y = H

2 *a–c*

3 *a–c*

SCHEME 1

(DCC) in refluxing aqueous *t*-butanol and the reactions were monitored by electrophoresis at p*H* 7.5. The morpholidates of **2***b* and *c* were obtained in quantitative yields while the morpholidate of **2***a* was produced in 78% and was purified by paper chromatography prior to phosphorylation to **3***a*.

The morpholidates were treated with phosphoric acid and tri-*n*-butylamine in pyridine (8) yielding the diphosphates **3***a–c* in yields of 46, 38, and 43% respectively. The structures were confirmed by electrophoresis, paper chromatography, and phosphate analysis (9).

Enzyme Reactions on the Mono- and Diphosphates

(A) 5′-Nucleotidase

This enzyme selectively removes phosphate from the 5′-position of natural nucleotides. The exact requirements of the enzyme with respect to the nature of the base ring are not known. However it does appear that both the structure (10) and conformation (11–13) of the base ring may be important. In the case of the 5′-monophosphates **2***a–c*, none were substrates of 5′-nucleotidase (6).

(B) Alkaline Phosphatase

This enzyme catalyzes the dephosphorylation of mononucleotides and its action seems to be completely independent of the nature of the base ring (12). As expected all of the compounds **2***a–c* were completely dephosphorylated with alkaline phosphatase.

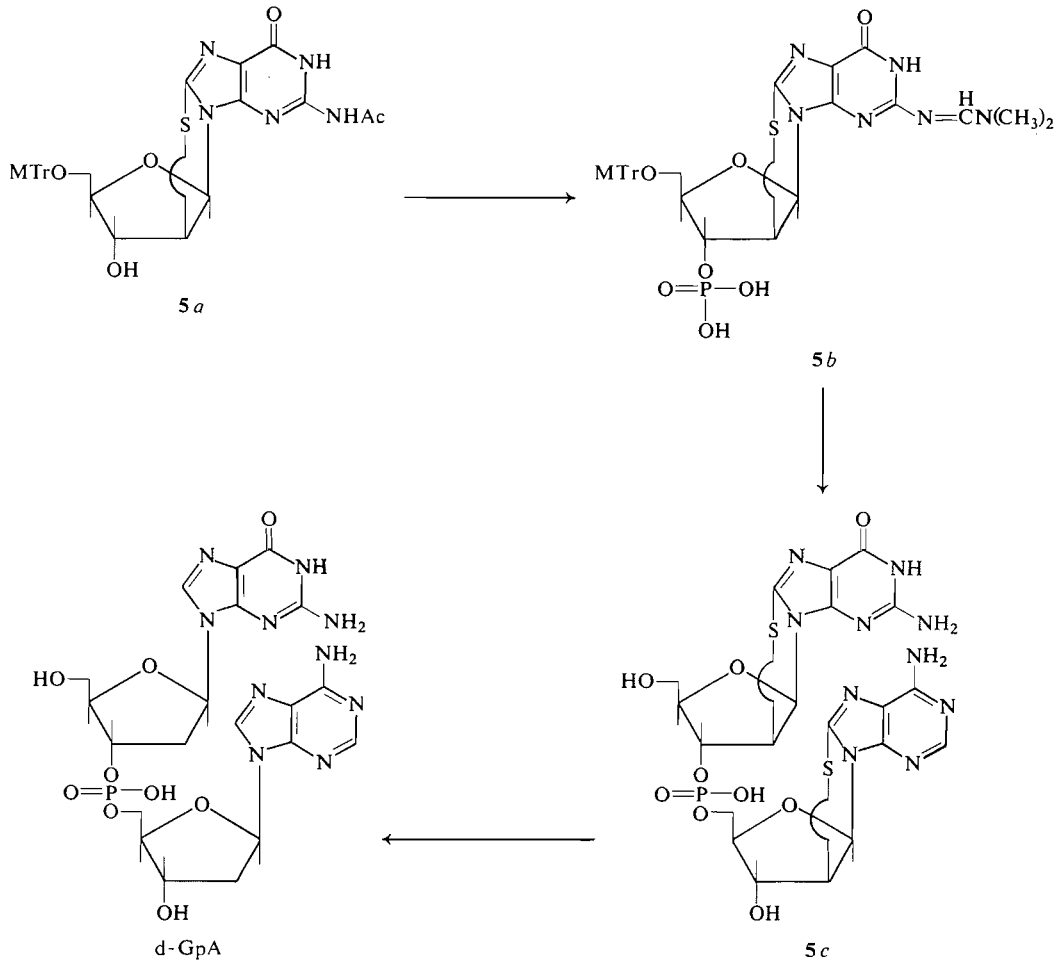
(C) Adenylate Kinase

This enzyme can convert adenosine 5′-monophosphate (AMP) into adenosine 5′-diphosphate (ADP) and under other conditions will cause the conversion of ADP to AMP and ATP. However neither **2***a* nor **3***a* acted as substrates of adenylate kinase.

Synthesis of Dinucleoside Monophosphates

To test the possibility of incorporating an anhydropurine nucleoside into a nucleotide chain (3), N^6,$O^{3'}$-dibenzoyl-8,2′-thioanhydroadenosine (**4***d*) was condensed with a slight excess of 5′-*O*-monomethoxytritylthymidine 3′-phosphate (14) in pyridine using mesitylenesulfonyl chloride (MSCl). The product (7) was treated with acetic acid to remove the trityl group and chromatographed on paper in solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



SCHEME 2

A (which also removes the 3′-benzoyl group). The desired product (R_f^A 0.42) was characterized by chromatography and electrophoresis and was treated with spleen phosphodiesterase, producing thymidine 3′-phosphate and N^6-benzoyl-8,2′-thioanhydroadenosine (nucleotide/nucleoside = 1.12). The yield of the nucleotide in this reaction was 20%, and 15% when DCC replaced MSCl as condensing agent.

For the preparation of dianhydronucleoside monophosphates, derivatives with both ring-amino groups and 5′-hydroxyl positions protected were necessary. The compounds 5′-*O*-monomethoxytrityl-N^6-benzoyl-8,2′-thioanhydroadenosine (**4***a*), 5′-*O*-monomethoxytrityl-N^2-acetyl-8,2′-thioanhydroguanosine (**5***a*), and 5′-*O*-monomethoxytrityl-8,2′-thioanhydroinosine (**6***a*) were prepared by the general procedures developed by Khorana and co-workers for natural nucleosides (15).

The synthesis of 8,2′-thioanhydroguanylyl-(3′–5′)-8,2′-thioanhydroadenosine (**5***c*) illustrates (Scheme 2) the general synthesis of the dinucleoside monophosphates. Compound **5***a* was phosphorylated using β-cyanoethylphosphate (3 equiv) and DCC in pyridine. The cyanoethyl group was removed using methanol – concentrated ammonium hydroxide (1 : 1) at 45° for 10 h. These conditions also remove *N*-acyl groups making it necessary to reblock ring amino groups. This is easily accomplished using dimethylformamide dimethyl acetal which introduces the dimethylaminomethylene group at amino positions (16). The resulting intermediate **5***b* was dissolved in 50% aqueous pyridine and passed through a Dowex 50W-X8 (pyridinium form) column. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

resulting compound was dried and stirred with **4***d* in pyridine in the presence of more Dowex resin and DCC for 11 days. Protecting groups were removed by first using methanolic ammonia followed by 80% acetic acid and the nucleotide **5***c* was obtained in 22% yield. This nucleotide was completely resistant to both spleen and snake venom phosphodiesterases and was fully characterized including Raney nickel reduction to the known compound deoxyguanylyl-(3′–5′)-deoxyadenosine (17).

8,2′-Thioanhydroinosinyl-(3′–5′)-8,2′-thioanhydroadenosine (**6***c*) and 8,2′-thioanhydroadenylyl-(3′–5′)-8,2′-thioanhydroadenosine (**4***c*), were similarly obtained in 8 and 30% yields starting from **6***a* and **4***a* respectively. Both of these nucleotides were completely resistant to snake and spleen phosphodiesterases. **6***c* was reduced to deoxyinosinyl-(3′–5′)-deoxyadenosine which was fully characterized by enzymes. **4***c* had been prepared previously (18) and was reduced to the known deoxyadenylyl-(3′–5′)-deoxyadenosine (17)

These results clearly indicate that all of the 8,2′-thioanhydropurine nucleosides can be incorporated into anhydronucleotide chains. These anhydronucleotides are of considerable interest in their own right (18) and can be converted with Raney nickel into the naturally occurring 2′-deoxynucleotides.

Experimental

General Methods

Descending paper chromatography was carried out using Whatman 3MM paper. The solvent systems employed were: solvent A, isopropyl alcohol – concentrated ammonium hydroxide – water (7:1:2); solvent B, ethanol–water (7:3); solvent C, *n*-butanol–ethanol–water (4:1:5, organic phase); solvent D, 1 *M* ammonium acetate – ethanol (3:7); solvent E, 0.5 *M* ammonium acetate – ethanol (3:7, adjusted to p*H* 3.5 with acetic acid); solvent F, *n*-propanol – concentrated ammonium hydroxide – water (55:10:35). The solvents were prepared on a volume basis. Thin-layer chromatography was carried out employing the ascending technique in closed jars which were not coated with absorbent paper. All thin-layer chromatography was run on Eastman Chromagram Sheets 6060, silica gel with fluorescent indicator, on strips 10 cm × 2 cm. Thick-layer chromatography was carried out on glass plates (20 cm × 20 cm) coated with a 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd.). Paper electrophoresis was performed using Whatman 3MM paper in a Savant Flat Plate electrophoretic chamber with a Savant Model HV power supply operated at 2000 V for 1 h; the solution was a triethylammonium bicarbonate buffer (0.05 *M*, p*H* 7.5), prepared by making 15.15 g triethylamine up to 31 volume with water and then bubbling 20 g carbon dioxide through the solution. Nucleosides and their derivatives were detected on paper chromatograms, thin and thick-layer sheets using a u.v. light source (Mineralite, output ~254 nm). Compounds containing trityl or *p*-monomethoxytrityl groups were detected on chromatography by spraying with 10% perchloric acid solution and drying them in a stream of warm air.

I.r. spectra were obtained on a Perkin–Elmer 337 recording instrument using KBr disks for sample preparation. U.v. spectra were obtained on a Cary Model 14 recording spectrophotometer.

Melting points were determined on a Fisher–Johns melting point apparatus and are reported uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee. Samples submitted to them were prepared by crystallization, lyophilization, or precipitation from tetrahydrofuran with hexane followed by heating in a drying apparatus over P_2O_5. In some cases the molecular formula includes fractional moles of solvent as a correction for the analysis. These corrections are added only when a corresponding weight loss was detected on extensive drying of the sample. Phosphate analyses were performed by the method of Lowry and Lopez (9) using ammonium molybdate and ascorbic acid. After release of the phosphate from the nucleotide following alkaline phosphatase action, the phosphate concentration was measured on a Zeiss PMQ 9 absorption spectrometer at 700 nm as the phosphomolybdate. This value is reported relative to the same reaction on an equal concentration of adenosine 5′-monophosphate.

Reagents and Chemicals

Reagent grade pyridine was distilled from *p*-toluene – sulfonyl chloride, redistilled from calcium hydride, and stored over Linde molecular sieves. Reagent grade *N*,*N*-dimethyl-formamide was dried by distillation from calcium hydride and stored over Linde molecular sieves. Reagent grade acetic anhydride was distilled from phthalic anhydride and stored in the dark. *n*-Butanol and phosphoryl chloride were freshly distilled before use. Reagent grade mesitylenesulfonyl chloride purchased from Aldrich was recrystallized from pentane and stored under pentane in the dark. Pyridinium Dowex was prepared by forming a column of Dowex 50W-X8(H^+ form) and washing first with 0.1 *N* HCl(11), then water (11), then 10% aqueous pyridine (11), and finally water (11). Pyridinium mono-β-cyanoethyl phosphate was prepared from the barium salt by passage over a column of Dowex 50W-X8 resin (pyridinium form). The clear solution containing the pyridinium salt was first concentrated to a small volume and then lyophilized to a gum. The gum was dissolved in pyridine and diluted to a known volume and stored in a sealed flask under refrigeration. Sodium hydrogen sulfide solution (40%) was prepared by dissolving 18 g sodium sulfide in 50 ml of water and adding 6.0 g of sodium bicarbonate in small amounts until complete dissolution occurs. Methanol (50 ml) was added with stirring and cooling below 20 °C. Following filtration and washing with methanol the filtrate is concentrated to one-tenth the volume and stored under refrigeration.

Natural nucleosides were purchased from Sigma Chemical Company.

TABLE 1. Properties of anhydronucleoside mono- and diphosphates and isolated 2′-deoxynucleoside 5′-monophosphates

Compound	R_f^F	Rm^{Tp}(p*H* 7.5)	λ_{max} (H_2O) (nm)
2*a*	0.27	0.92	276, 219
2*b*	0.19	0.79	263, 280sh
2*c*	0.33	0.83	265
2′-Deoxyadenosine 5′-phosphate	0.45	0.99	260
2′-Deoxyguanosine 5′-phosphate	0.26	0.88	255, 270sh
2′-Deoxyinosine 5′-phosphate	0.41	0.92	249
3*a*	0.35	1.13	275
3*b*	0.23	0.97	267, 280sh, 263sh
3*c*	0.15	1.01	265

Enzyme Assays

(a) Spleen Phosphodiesterase

Lyophilized spleen phosphodiesterase (10–15 units) obtained from Nutritional Biochemicals Corp. was dissolved in 1 ml of 0.01 *M* sodium pyrophosphate buffer adjusted to p*H* 6.5 with phosphoric acid. An aliquot (0.1 ml) of this solution, 0.2 ml of 0.05 *M* ammonium acetate (adjusted to p*H* 6.5 with acetic acid), and 0.1–1 mg of the nucleotide substrate were incubated at 37 °C. The solution was then applied to Whatman 3MM paper as a band and developed with solvent A. Nucleoside and nucleotide bands were cut out, eluted with water and diluted to a volume of 10 ml. Absorbances were adjusted by using blanks cut from papers treated in the same way as the sample material. The term O.D. unit refers to the extinction of the absorbing material in 1 ml of neutral solution in a quartz cell with a 1-cm path length.

(b) Snake Venom Phosphodiesterase

Two hundred units of snake venom phosphodiesterase obtained from Calbiochem were dissolved in 1 ml of tris-(hydroxymethyl)aminomethane buffer (adjusted to p*H* 9.2 with 0.1 *N* HCl). An aliquot (0.2 ml) of the enzyme solution was added to the nucleotide material (~1 mg) and incubated at 37 °C. The same procedure as in section *a* was then followed.

(c) 5′-Nucleotidase

5′-Nucleotidase (0.5 mg) from Sigma Chemical Co. was dissolved in a p*H* 9.0 buffer (50 ml 0.025 *M* borax and 4.6 ml 0.1 *M* HCl) along with 1 mg nucleotidic material and the solution incubated at 37 °C for 1 h.

(e) Alkaline Phosphatase

Nucleotidic material (1 mg) was treated with 0.1 ml of a suspension of alkaline phosphatase in ammonium sulfate (Sigma Chemical Co.) along with 1 ml p*H* 10.4 buffer (50 ml 0.05 *M* sodium bicarbonate and 16.5 ml of 0.1 *M* sodium hydroxide) and incubated at 37 °C for 5 min.

(e) Adenylate Kinase

(i) Two units of adenylate kinase (Sigma Chemical Co.), nucleotidic material (1 mg), and 0.1 ml p*H* 7.6 buffer (50 ml of tris(hydroxymethyl)aminomethane and 40.3 ml 0.1 *M* HCl) were mixed and the solution incubated at 37 °C for 4 h.

(ii) The conditions were the same as part *i* except 2 mg ATP and 3.4 mg magnesium sulfate were also added.

General Procedures

All reactions of more than 0.2 mmol of the limiting reagent were carried out in tightly stoppered ground glass joint flasks. Reactions of less than 0.2 mmol of the limiting reagent were carried out in Pyrex test tubes (10 ml, screw cap type). Reactions requiring drying by solvent evaporation were performed by evaporation under reduced pressure and air was readmitted through a column (30 cm × 2 cm) of anhydrous magnesium perchlorate.

Synthesis of 8,2′-Thioanhydropurine Nucleoside 5′-Monophosphates (2a-c)

In a typical experiment 200 mg of thioanhydro nucleoside was added to a cold (0 °C) solution of phosphoryl chloride (10 equiv) and water (0.4 equiv) in triethyl phosphate (5 ml). Complete dissolution occurred after 0.5 h and the reaction was continued at 0 °C for an additional 5.5 h. Excess ether was added, the mixture centrifuged, decanted, and the precipitate washed with ether. The resulting solid was dissolved in cold water (2 ml) and stirred at 0 °C for 2 h. Both 8,2′-thioanhydroadenosine 5′-monophosphate (**2***a*) and 8,2′-thioanhydroinosine 5′-monophosphate (**2***c*) precipitated upon addition of excess ethanol. The yield of **2***a* was 236 mg (92%) and the product was identical to that prepared as in the literature (6). The yield of **2***c* was 188 mg (74%). For the guanosine derivative, the aqueous solution was applied to paper chromatograms and developed in solvent F. The band at R_f 0.19 was eluted with water and lyophilized to give 106 mg of 8,2′-thioanhydroguanosine 5′-monophosphate (**2***b*, 43%). General properties of the monophosphates are listed in Table 1 and **2***a–c* were further characterized below.

The monophosphates were dissolved in water and refluxed with Raney nickel for 3 h. Following filtration through Celite powder the products were isolated on paper chromatography in solvent F. Compounds **2***a–c* led respectively to 2′-deoxyadenosine 5′-monophosphate, 2′-deoxyguanosine 5′-monophosphate, and 2′-deoxyinosine 5′-monophosphate. The properties of these are listed in Table 1. Each of the deoxynucleotides was then dissolved in a borate buffer (p*H* 9) and incubated at 37 °C with 5′-nucleotidase. Analysis of the reaction mixtures on paper chromatography showed complete conversion to the corresponding 2′-deoxynucleosides which were identical with authentic samples.

8,2′-Thioanhydroadenosine 5′-Diphosphate (3a)

8,2′-Thioanhydroadenosine 5′-monophosphate (50 mg, 0.14 mmol) was refluxed in a *t*-butanol – water mixture (1:1, 2 ml) to which 0.05 ml morpholine had been added. To this refluxing solution, a solution of DCC (115 mg, 0.56 mmol) in *t*-butanol was added dropwise over a period of 3 h. After this time an electrophoresis showed 70% conversion to a new compound (Rm^{T_P} 0.36). Further addition of 4 equiv of morpholine and DCC did not increase the yield after an additional 3 h. The reaction was then filtered and applied directly to paper chromatograms which were developed in solvent F. The band at R_f 0.62 was eluted with water and lyophilized to yield 47 mg (79%) of the morpholidate (R_f^c 0.16, R_f^F 0.62, Rm^{T_P} 0.36 (p*H* 7.5), λ_{max} (H_2O) 275 nm). The morpholidate was not further characterized but was dried by repeated evaporation of pyridine (5 × 0.5 ml). To the residue was added tri-*n*-butylamine (0.95 ml) as well as inorganic phosphoric acid (0.014 ml) which had been previously dried by repeated evaporation of pyridine (5 × 0.5 ml). The mixture was further dried by pyridine evaporation, pyridine added (1.5 ml), and the reaction stirred at room temperature for 48 h. The reaction mixture was then applied to paper chromatograms which were then developed in solvent F. The band at R_f 0.35 was eluted with water and lyophilized giving **3***a* (12.9 mg) in a yield of 46%. The band at R_f 0.62 was eluted with water and lyophilized yielding 10.2 mg of unreacted morpholidate. Properties are listed in Table 1. Phosphate analysis of **3***a* relative to an equal concentration of adenosine 5′-monophosphate was 2.11.

8,2′-Thioanhydroguanosine 5′-Diphosphate (3b)

8,2′-Thioanhydroguanosine 5′-monophosphate (**2***b*, 50 mg, 0.13 mmol) was dissolved in *t*-butanol – water (1:1, 1 ml) to which was added 0.13 ml morpholine. The solution was refluxed for 2 h during which time 90 mg DCC in *t*-butanol (1 ml) was added dropwise. Electrophoretic analysis revealed complete conversion to the morpholidate (R_f 0.54, Rm^{T_P} 0.46 (p*H* 7.5), λ_{max} (H_2O) 265, 280 sh). The solution was filtered and concentrated to dryness *in vacuo*. The residue was extracted twice with ether and then dried by repeated evaporation of pyridine (5 × 0.5 ml). To this was added tri-*n*-butylamine (0.095 ml) as well as inorganic phosphoric acid (0.014 ml) which had been previously dried by repeated evaporation of pyridine. The reaction was further dried by pyridine evaporation, then dissolved in 1.0 ml of pyridine and stirred at room temperature for 2 days. Applying the reaction mixture to paper chromatograms and development in solvent F gave two nucleotide bands R_f 0.54 and 0.23. The band at R_f 0.54 was eluted with water and lyophilized giving 17.3 mg unreacted morpholidate. The band at R_f 0.23 was eluted with water and yielded 22.8 mg **3***b* (37.9%) upon lyophilization (properties are recorded in Table 1). Phosphate analysis of **3***b* relative to an equal concentration of adenosine 5′-monophosphate was 1.93.

8,2′-Thioanhydroinosine 5′-Diphosphate (3c)

8,2′-Thioanhydroinosine 5′-monophosphate (**2***c*) was quantitatively converted to the morpholidate by the same method used above. Electrophoresis showed Rm^{T_P} 0.45 (p*H* 7.5). The 5′-diphosphate **3***c* was synthesized by the procedure outlined above. The paper chromatograms in solvent F gave two bands R_f 0.15 and 0.62. The band at R_f 0.62 was eluted with water and lyophilized to recover 12.8 mg of unreacted morpholidate. The band at R_f 0.15 was also eluted with water and lyophilized to yield **3***c* (26 mg, 43%). (Properties of **3***c* are listed in Table 1). Phosphate analysis of **3***c* relative to an equal concentration of adenosine 5′-monophosphate was 2.19.

Enzyme Studies on 2a–c and 3a 5′-Nucleotidase

One milligram each of **2***a–c* were separately dissolved in 1 ml of buffer solution (p*H* 9.0, 0.025 *M* borax), 0.5 mg of 5′-nucleotidase added, and the solution incubated at 37 °C for 1 h. Examination of the reaction mixtures by paper chromatography and electrophoresis showed no dephosphorylation. However, using the same concentration, adenosine 5′-monophosphate was completely converted to adenosine in 2 min.

Alkaline Phosphatase

Treatment of **2***a–c* with an alkaline phosphatase suspension in ammonium sulfate in the presence of 1 ml of buffer solution (p*H* 10.5, 0.05 *M* ammonium bicarbonate) and incubation at 37 °C gave rapid quantitative hydrolysis to the corresponding thioanhydro nucleosides (**1***a–c*).

Adenylate Kinase (Myokianase)

8,2′-Thioanhydroadenosine 5′-diphosphate (**3***a*, 1 mg, 0.002 mmol), adenylate kinase (1 μl, 2 units) and 0.1 ml tris-buffer (p*H* 7.6) were incubated at 37 °C. Continuous monitoring of the reaction mixture by paper chromatography and electrophoresis for 4 h showed no detectable change in the starting material.

8,2′-Thioanhydroadenosine 5′-monophosphate (**2***a*, 1 mg, 0.003 mmol), adenylate kinase (1 μl, 2 units), ATP (2 mg, 0.003 mmol), magnesium sulfate (3.4 mg, 0.03 mmol), and 0.1 ml tris-buffer (p*H* 7.6) were incubated at 37 °C. Continuous monitoring of the reaction mixture by paper chromatography and electrophoresis showed no detectable change in the starting material.

5′-O-Monomethoxytrityl-N⁶-benzoyl-8,2′-thioanhydroadenosine (4a)

8,2′-Thioanhydroadenosine (**1***a*, 5 g, 17.8 mmol) was dissolved in pyridine and benzoyl chloride (9 ml, 75 mmol) added. The reaction was stirred at room temperature for 2 h, poured into ice water and the aqueous solution extracted with chloroform. After drying over sodium sulfate the chloroform solution was concentrated to a small volume and 11.8 g of white precipitate m.p. 118–119 °C formed upon addition of excess hexane.

Without further purification 5.15 g of this material was dissolved in ethanol–pyridine (3:2, 100 ml), 60 ml 2 *N* sodium hydroxide – ethanol (1:1) added and the solution allowed to stand at room temperature for 5 min. An excess of Dowex 50W-X8 resin (H^+) was added, the solution filtered and the resin washed with warm DMF. The filtrate and washings were combined, concentrated to dryness and the residue washed with ether. Dissolution of the residue in DMF and addition of excess ether gave 1.87 g of a white powder. 1.03 g of this material, monomethoxytrityl chloride (0.99 g, 3.2 mmol) and pyridine (40 ml) were stirred at room temperature overnight. The solution was poured into ice water, extracted with chloroform and the chloroform solution dried over sodium sulfate. Following filtration of the chloroform and concentration to a small volume, **4***a* precipitated (1.55 g, 87%, m.p. 134–136 °C) upon addition of hexane. Chroma-

tographic and spectral properties are recorded in Tables 2 and 3 respectively.

Anal. Calcd. for $C_{37}H_{31}N_5O_5S$: C, 67.56; H, 4.75; N, 10.65. Found: C, 66.66; H, 4.80; N, 10.41.

*N^6,$O^{3'}$-Dibenzoyl-8,2′-thioanhydroadenosine (**4***d*)*

Compound **4***a* (0.9 g, 1.35 mmol) and benzoic anhydride (3.66 g, 16.2 mmol) were added to pyridine (8 ml) and the resulting solution stirred in the dark at room temperature for 24 h. The reaction was washed with hexane and the resulting oil was concentrated to a gum using ethanol to aid in the removal of the solvent. The residue was dissolved in tetrahydrofuran and 931 mg of material, m.p. 128–130 °C, precipitated as a white solid upon addition of hexane.

Without further purification 0.8 g of this material was dissolved in 80% acetic acid and heated on a steam bath for 15 min. The solution was poured into ice–water with vigorous stirring and the precipitate removed by filtration. The solid was washed with ether and dried to yield **4***d* (18), as a white powder (0.5 g, 96.5%, m.p. 173–174 °C). Chromatographic and spectral properties are recorded in Tables 2 and 3.

Anal. Calcd. for $C_{24}H_{19}N_5O_5S \cdot \frac{1}{2}H_2O$: C, 57.82; H, 4.04; N, 14.05. Found: C, 58.17; H, 4.13; N, 13.38.

*N^2-Acetyl-8,2′-thioanhydroguanosine (**5***d*)*

8,2′-Thioanhydroguanosine (**1***b*, 1.0 g, 3.37 mmol) and tetraethylammonium hydroxide (3.5 ml) were rendered anhydrous by repeated evaporation of pyridine (5 × 20 ml). Pyridine (20 ml) and acetic anhydride (10 ml) were added and the reaction was stirred at room temperature for 24 h after which time a white precipitate formed. The mixture was heated on a steam bath for 3 min to dissolve the precipitate, cooled to room temperature, acetic anhydride added (5 ml), and the solution stirred overnight at room temperature. The reaction was then concentrated to dryness using ethanol–pyridine (3:2, 25 ml) and 2 *N* sodium hydroxide – ethanol (1:1, 15 ml) was added. Following stirring of this solution for 10 min at room temperature an excess of Dowex 50W-X8 resin (H^+) was added. The solution was filtered and the resin washed with hot DMF. The filtrate and washings were combined, concentrated to a small volume and applied to thick-layer plates. One development in chloroform–ethanol (7:3) gave a band at R_f 0.25. This band was eluted with THF concentrated to a small volume and the product precipitated (700 mg, 61%) as a white powder (m.p. 237 °C dec.) upon addition of ethanol. Chromatographic and spectral properties are listed in Tables 2 and 3.

Anal. Calcd. for $C_{12}H_{13}N_5O_5S \cdot \frac{1}{2}H_2O$: C, 41.38; H, 4.05. Found: C, 41.24; H, 4.17.

*5′-O-Monomethoxytrityl-N^2-acetyl-8,2′-thioanhydroguanosine (**5***a*)*

Compound **5***d* (680 mg, 2.0 mmol) and monomethoxytrityl chloride (1.92 g, 6.21 mmol) were dissolved in pyridine (10 ml) and stirred at room temperature for 48 h. The reaction was then added slowly to ice water

with vigorous stirring. The resulting precipitate was removed by filtration, dissolved in chloroform, and dried over sodium sulfate. The chloroform solution was filtered, concentrated to a small volume and **5***a* precipitated (598 mg, 50%, m.p. 188 °C dec.) upon addition of excess ether. Chromatographic and spectral properties are listed in Tables 2 and 3.

Anal. Calcd. for $C_{32}H_{29}N_5O_6S$: C, 62.83; H, 4.78; N, 11.45. Found: C, 62.72; H, 4.81; N, 10.85.

5′-O-Monomethoxytrityl-8,2′-thioanhydroinosine (6a)

8,2′-Thioanhydroinosine (**1***c*, 0.5 g, 1.78 mmol) was dried by repeated evaporation of pyridine. DMF (2 ml) and pyridine (25 ml) were added along with monomethoxytrityl chloride (1.64 g, 5.33 mmol) and the solution stirred at room temperature for 4 days. The solution was then poured into ice water. The aqueous mixture was extracted with chloroform (3 × 100 ml) and the chloroform dried over sodium sulfate. Following filtration the chloroform was concentrated to a small volume and **6***a* (330 mg, 33.6%) precipitated as a white powder (m.p. 164–166 °C) upon addition of hexane. Chromatographic and spectral properties are listed in Tables 2 and 3. This compound was identical in all respects to an authentic sample (19).

Thymidylyl-(3′-5′)-N^6-benzoyl-8,2′-thioanhydroadenosine (7)

Compound **4***d* (17 mg, 0.034 mmol) and 5′-*O*-monomethoxytritylthymidine 3′-phosphate (30 mg, 0.05 mmol) were dried by repeated evaporation of pyridine (5 × 1 ml). Mesitylenesulfonyl chloride (10.6 mg, 0.068 mmol) and pyridine (1 ml) were added and the reaction stirred at room temperature for 24 h. Cold water (2 ml) was added and the solution continued stirring for an additional 24 h. Following concentration to dryness, the residue was dissolved in 80% acetic acid (1 ml) and heated on a steam bath for 15 min. After cooling the solution was applied to paper chromatograms and developed in solvent A. The band at R_f 0.42 was eluted with water and lyophilized to give 7 (4.8 mg, 19%). The product had Rm^{T_p} 0.25 and the u.v. spectrum in water showed a maximum at 267.5 nm and a shoulder at 300 nm. Compound 7 could also be obtained using DCC as condensing agent (nucleotide–nucleoside–DCC 1:2:4, 96 h) in 14.6% yield.

Approximately 8.5 $O.D._{260}$ units of 7 were treated with spleen phosphodiesterase for 24 h at 37 °C using standard procedures. The work-up yielded 4.7 $O.D._{267}$ units of T_p(R_f^A 0.10) and 10.8 $O.D._{300}$ units of benzoyl-8,2′-thioanhydroadenosine (R_f^A 0.88). The ratio nucleotide/nucleoside was 0.92. Treatment of 8.5 O.D. units of 7 with snake venom phosphodiesterase under standard conditions led to no detectable degradation.

8,2′-Thioanhydroadenylyl-(3′–5′)-8,2′-thioanhydroadenosine (4c)

Compound **4***a* (167 mg, 0.25 mmol) and β-cyanoethyl phosphate (pyridinium form) (1.5 ml, 0.75 mmol) were dried by repeated evaporation of pyridine (5 × 2 ml). This anhydrous mixture was then dissolved in pyridine (10 ml) and DCC (1.2 g, 5.9 mmol) was added. After standing at 45 °C for 18 h, pyridine–water (3:1, 30 ml) was added and the solution filtered to remove dicyclohexylurea. The filtrate was extracted with three 40 ml portions of hexane. The aqueous pyridine solution was kept at room temperature for 24 h and then evaporated to dryness *in vacuo*. Methanol – concentrated ammonia (1:1, 24 ml) was added to the residue and the resulting solution heated for 10 h at 45° and then concentrated to dryness. DMF (2 ml) and dimethylformamide dimethylacetal (0.2 ml) were added, the solution stirred at room temperature overnight, and then evaporated to dryness. The residue was dissolved in 50% aqueous pyridine and the solution passed through a column of Dowex 50W-X8 (pyridinium form) resin. The column was washed with 50% aqueous pyridine and the eluant concentrated and dried by repeated evaporation of pyridine. The resulting 5′-*O*-monomethoxytrityl-N^6-dimethylaminomethylene-8,2′-thioanhydroadenosine 3′-phosphate (**4***b*) was not purified further but used directly in the condensation reaction.

Compound **4***b* (~0.09 mmol), N^6,$O^{3'}$-dibenzoyl-8,2′-thioanhydroadenosine (**4***d*, 60 mg, 0.1 mmol) and Dowex 50W-X8 (pyridinium form, 0.5 ml) resin were rendered anhydrous by pyridine evaporation. To the anhydrous residue was added pyridine (2 ml) and DCC (246 mg, 1.2 mmol) and the mixture was stirred at room temperature for 11 days. Fifty percent aqueous pyridine (2 ml) was added, the solution filtered and the filtrate extracted with three 20 ml-portions of hexane. The aqueous pyridine layer was kept at room temperature for 24 h and then evaporated. The residue was dissolved in methanol saturated with ammonia at 0 °C (30 ml), kept at 35 °C for 24 h, and then evaporated. The residue was dissolved in 80% acetic acid (10 ml) and heated on a steam bath for 12 min. The solution was cooled and applied to eight paper chromatograms which were then developed in solvent A. The band at R_f 0.20 was eluted with water and gave 16.5 mg (**4***c*, 29.5%) upon lyophilization. The properties of product **4***c* were identical in all respects to those reported in the literature (18); R_f^A 0.20, R_f^B 0.42, R_f^C 0.08, R_f^F 0.43, Rnl^{pA} 0.28 (p*H* 7.5), λ_{max} (H_2O) 271 nm. The product was converted with Raney nickel to deoxyahenylyl-(3′–5′)-deoxyadenosine (15).

Compound **4***c* itself was completely resistant to snake venom and spleen phosphodiesterases at 37 °C for 24 h.

8,2′-Thioanhydroguanylyl-(3′–5′)-8,2′-Thioanhydroadenosine (5c)

5′-*O*-Monomethoxytrityl-N^2-dimethylaminomethylene-8,2′-thioanhydroguanosine 3′-phosphate (**5***b*) was prepared from **5***a* by the same method outlined above for the synthesis of **4***b*. Following passage of an aqueous pyridine solution of **5***b* through a Dowex 50W-X8 (pyridinium) column and drying, the nucleotide was condensed with N^6,$O^{3'}$-dibenzoyl-8,2′-thioanhydroadenosine (**4***d*) using DCC and the procedure outlined earlier. Following basic and acidic deblocking procedures and work-up on paper chromatograms in solvent A, the band at R_f 0.07 was eluted with water and lyophilized to give **5***c* (11.6 mg, R_f^A 0.07, R_f^B 0.40, R_f^C 0.04, R_f^F 0.40, Rm^{pA} 0.24 (p*H* 7.5), λ_{max} (H_2O) 268, 276sh, 220sh). Incubation of the dinucleotide at 37 °C for 24 h with snake venom and spleen phosphodiesterases showed no degradation.

Approximately 5 mg of the dinucleotide in water (1 ml) was refluxed with 1 spoonful of Raney nickel for 6 h. The solution was cooled, filtered with the aid of Celite powder and the filtrate applied to a paper chromatogram.

After development in solvent A, the band at R_f 0.17 was eluted with water and the u.v. spectrum in water showed a maximum at 258 nm.

8,2′-Thioanhydroinosinyl-(3′–5′)-8,2′-thioanhydroadenosine (6c)

Compound **6a** (50 mg, 0.09 mmol) and β-cyanoethyl phosphate (pyridinium form, 0.36 ml, 0.18 mmol) were dried by repeated pyridine evaporation (5 × 1 ml). Mesitylenesulfonyl chloride (59 mg, 0.27 mmol) and pyridine (1 ml) were added and the reaction stirred at room temperature for 7 h. Cold distilled water (1 ml) was added and the reaction stirred at room temperature for 16 h. An additional 1 ml of water was added followed by a saturated salt solution (5 ml). Extraction of the aqueous solution with chloroform resulted in all the phosphorylated material being dissolved in the chloroform. The chloroform solution was concentrated to dryness, 9 *M* ammonium hydroxide added (3 ml) and the solution heated at 60 °C for 1 h. The reaction mixture was applied to paper chromatograms which were developed in solvent A. The band at R_f 0.23 was eluted with water and lyophilized to yield 49 mg of material (R_f^A 0.23, R_f^B 0.72, R_f^C 0.07, Rm^{Tp} 0.65 (p*H* 7.5), λ_{max} (H_2O) 267, 230sh). Forty-seven milligrams of this material was dissolved in 50% aqueous pyridine (5 ml) and passed through a column of Dowex 50W-X8 (pyridinium form) resin. The column was washed with 50% aqueous pyridine and the eluate concentrated to dryness and then rendered anhydrous by repeated pyridine evaporation (5 × 2 ml). To the anhydrous residue was added **4d** (60 mg, 0.1 mmol), DCC (246 mg, 1.2 mmol), and pyridine (2 ml) and the reaction stirred at room temperature for 11 days. Following the same work-up as described above, 4.5 mg of **6c** (8.1%) was obtained from the band at R_f 0.10 in solvent A. (R_f^A 0.10, R_f^B 0.49, R_f^C 0.04, R_f^F 0.45, Rm^{pA} 0.27 (p*H* 7.5), λ_{max} 267.5 nm). The product was completely resistant to spleen and snake venom phosphodiesterases.

Compound **6c** (~3 mg) was dissolved in 0.5 ml water and refluxed with 0.5 spoonful of Raney nickel for 6 h. The mixture was cooled and applied to a paper chromatogram which was developed in solvent A. The band at R_f 0.19 was eluted with water (u.v. maximum (water) 253 nm) and lyophilized. This product (5.5 O.D. units) was incubated with snake venom phosphodiesterase for 7 h at 37 °C. Paper chromatographic examination of the reaction mixture in solvents A, B, and F showed complete degradation to 2′-deoxyinosine (2.79 O.D. units) and 2′-deoxyadenosine 5′-phosphate (3.2 O.D. units). The ratio of nucleotide/nucleoside was 1.09.

Vinyl Azides as Diazoenamines

A. N. THAKORE, J. BUCHSHRIBER, AND A. C. OEHLSCHLAGER
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia
Received December 11, 1972

Reaction of vinyl azides with nitrosyl tetrafluoroborate yields 1,2,5-oxadiazoles and 1,2,4-oxadiazoles depending on the structure of the azide. Reaction of 1,2-dialkyl vinyl azides with nitryl tetrafluoroborate gives 2-oxo-1,2,5-oxadiazoles in high yields whereas 1-aryl-2-alkyl vinyl azides gave moderate yields of 3-aryl-1,2,5-oxadiazoles and 5-aryl-1,2,4-oxadiazoles. Acyl chlorides condense with vinyl azides in the presence of aluminum chloride to yield oxazoles. Dimethyl acetylenedicarboxylate condenses with vinyl azides by cycloaddition of the azido function with the alkyne and by cycloaddition of the vinyl group with the alkyne. The latter process occurs only under the influence of $AlCl_3$. The observed reactions are viewed as involving the participation of vinyl azides as *N*-diazoenamines.

La réaction des azotures de vinyle sur le tétrafluoroborate de nitrosyle conduit aux oxadiazoles-1,2,5 et oxadiazoles-1,2,4 dépendant de la structure de l'azoture. La réaction des azotures de dialkyl-1,2 vinyle sur le tétrafluoroborate de nitryle mène aux oxo-2 oxadiazoles-1,2,5 avec des rendements élevés tandis que les azotures d'aryl-1 alkyl-2 vinyle conduisent aux aryl-3 oxadiazoles-1,2,5 et aryl-5 oxadiazoles-1,2,4. Les chlorures d'acyle se condensent aux azotures de vinyle en présence de chlorure d'aluminium pour donner des oxazoles. L'acétylène dicarboxylate de diméthyle se condense aux azotures de vinyle par cycloaddition de la fonction azoture sur l'alkyne et par cycloaddition du groupe vinyle sur l'alkyle. Cette dernière ne se produit qu'en présence de $AlCl_3$. Les réactions observées ont été examinées sous l'angle d'une participation des azotures de vinyle sous forme de *N*-diazoénamines.

Introduction

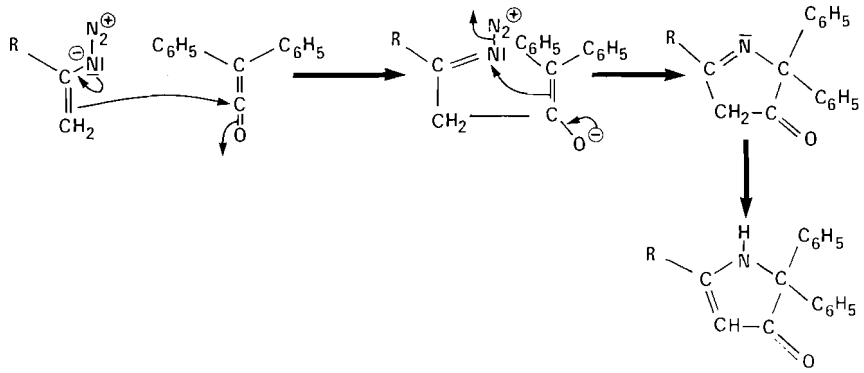
The synthetic utility of enamines lies principally in their ability to react with electrophiles at the β-vinyl carbon and undergo cycloaddition at the carbon–carbon double bond (1). The ease of synthesis of the vinyl azide function (2), coupled with HMO calculations (3) and spectral characteristics (3, 4), which indicate there is appreciable electron density at the β-vinyl carbon, make this functional group a logical choice for reaction with electrophiles. The reactions of vinyl azides with acids produce amides via a route most easily rationalized as occurring via protonation of the β-vinyl carbon (5). Reactions with halogens lead to α-haloketones by similar involvement of the β-vinyl carbon (6). The recently reported (7) reactions of vinyl azides with diphenylketene revealed similar nucleophilic behavior of the β-vinyl carbon (see Scheme 1). This latter process may be considered a member of a general class of reactions in which the azide participates as an *N*-diazoenamine.

We have found that vinyl azides react readily with several electrophilic reagents to yield products expected to result from this and closely related transformations (see Scheme 2).

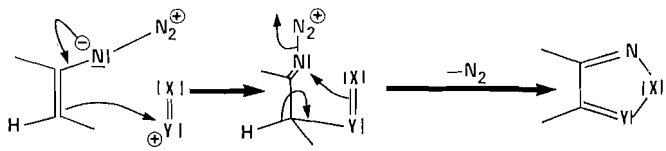
Results and Discussion

Reaction of nitrosyl tetrafluoroborate ($NOBF_4$) with vinyl azides in cold (−15°) acetonitrile results in smooth evolution of nitrogen and production of 1,2,5-oxadiazoles and 1,2,4-oxadiazoles, depending on the structure of the azide. Thus, reaction with 1,2-dialkyl substituted vinyl azides (**1***a–c*) for short periods (30 min – 1 h) followed by addition of water and separation of the organic products gave moderate yields of 1,2,5-oxadiazoles (**2***a*, *b*) (8) and lesser amounts of amides (**3***a–c*). When the reactions were allowed to proceed for extended periods (18 h) the yields of oxadiazoles increased to near 80% while those of the amides decreased to less than 10%. The decreased yields of amides upon prolonged reaction time suggests these products arise from hydrolysis of the azides promoted by the acid (5) (HBF_4) presumably generated during oxadiazole formation.

Reaction of the *trans*-1-azido-1-phenylpropene



SCHEME 1



SCHEME 2

(**1***d*) with $NOBF_4$ gave, in addition to the expected 1,2,5-oxadiazole (**2***c*) a comparable amount of 1,2,4-oxadiazole (**4***a*) considered to be formed as shown in Scheme 3. The proposed route to **4** was supported by the detection of benzonitrile in the reaction mixture.

Reactions of 2-alkyl substituted vinyl azides such as **1***e* with $NOBF_4$ gave moderate yields of amides. No evidence for synthetically useful yields of heterocyclic products was obtained.

Reaction of 1,2-dialkyl substituted vinyl azides (**1***a*, *b*) with nitryl tetrafluoroborate (NO_2BF_4) gave high yields of 2-oxo-1,2,5-oxadiazole (**5**, Scheme 4). Extension of this reaction to the 1-aryl-2-alkyl substituted **1***d* gave N_2O, 1,2,5-oxadiazole (**2***c*), 1,2,4-oxadiazole (**4***a*), and benzonitrile. The latter three products were formed in similar proportions to that observed in the reaction of $NOBF_4$ with this azide. In a similar manner reaction of α-azidostyrene (**1***f*) with NO_2BF_4 gave **2***d* and **4***b*. As was the case with reaction with $NOBF_4$, the reaction of 2-alkyl substituted vinyl azides (**1***e*) with NO_2BF_4 did not give synthetically useful yields of heterocyclic products.

We consider the mechanism most consistent with these observations to be that depicted in Scheme 4, where both the $NOBF_4$ and NO_2BF_4 reactions proceed via a common intermediate, **6**. It is noteworthy that **1***d* gives only the product **4***a* of alkyl migration of intermediate **6**. Protonation of **1***d* has been reported (5) to yield amides **3***d* and *e* in a ratio of 0.6:1. Since the latter is considered to be the product of phenyl migration in an intermediate resembling **6**, we expected a product arising from this migration to be present in this reaction. The formal product of phenyl migration in this case would be an α-oximino amide or conceivably an α-keto amido. A v.p.c./mass spectral analysis of the reaction mixture failed to detect a product with a molecular weight corresponding to either of these possibilities.

In an effort to extend the reactions of NO^+ and NO_2^+ with vinyl azides to other electrophiles we studied their reactions with acyl chlorides under a variety of conditions. Reaction of acetyl chloride with **1***a* and *b* at room temperature resulted in evolution of nitrogen and gave, on hydrolytic work, amides **3***a* and *b* as the only identifiable products. In the presence of aluminum chloride the same reaction proceeded with evolution of nitrogen to give a 70% yield of 2,3,5-trimethyl oxazole, **7**.

Although we have not investigated appropriately substituted acyl chlorides which enable one to differentiate the several attractive mechanisms that may be envisioned for the production

7

of oxazole products from this reaction, we have investigated the reaction of 1-azido-1-phenylpropene (**1***d*) with acetyl chloride. This reaction yielded oxazoles **8**, **9**, and **10** in 17, 7, and 1% yields respectively. These products may be envisioned as being formed by several alternate mechanisms (Scheme 5). Fowler and Hassner (8) have previously demonstrated that reaction of benzoyl chloride with 2-phenyl-3-methyl azirine gives 2,5-diphenyl-4-methyl oxazole (analogous to **8**) via an *N*-benzoyl chloroaziridine.[1]

Thermal (room temperature → 80 °C) reactions of ketene dimer, phenyl isocyanate, benzyl chloride, methyl iodide, cyclohexanone, carbon disulfide, methyl chloroformate, and benzenediazonium tetrafluoroborate with vinyl azides **1***a* and *b* did not produce synthetically useful yields of heterocyclic products. Indeed reactions with these potential electrophiles in several solvents (CH_3CN, $(C_2H_5)_2O$, C_6H_6) with and without added aluminum chloride lead to reactions with solvent (*e.g.* phenylacetamide from benzenediazonium tetrafluoroborate and acetonitrile) and conversion of azides to amides upon hydrolytic work-up.

Since enamines readily undergo cycloaddition reactions with dipolarophilic reagents, we explored the reaction of dimethyl acetylene dicarboxylate (DMAD) with azides **1***a* and *b*. Depending on the reaction conditions either 1:1 or 2:1 DMAD:azide adducts were obtained. Reaction of **1***b* with DMAD at room temperature for 3 days gave triazole **11** (Scheme 6), whose n.m.r. spectrum was unambiguous. In addition to two methoxyl resonances (δ 3.98), two vinyl methyl resonances (one at δ 1.41 appearing as a quartet of quartets (J = 3.5, 0.5 Hz) and a second at 2.19 appearing as a quintet (J = 0.5 Hz)) were evident. A vinyl hydrogen appeared as a quartet of quartets J = 3.5, 0.5 Hz at δ 5.83. This pattern is characteristic of the *trans*-vinyl system of the starting azide **1***b* (4, 5).

This reaction could be catalyzed by addition of aluminum chloride (1 h) but resulted in a significantly lower yield (90 *vs.* 55%) and with formation of a second product (16%). This second product possessed a molecular weight and elemental analysis corresponding to the addition of 2 mol of DMAD to 1 mol of the vinyl azide. It was observed that both azides **1***a* and *b* gave this product in comparable yields. Thus the stereochemistry of the vinyl group is inconsequential or destroyed during this reaction. This 2:1 adduct was the major (55%) product when the reaction was performed by addition of azide to a solution containing a two-fold or greater excess of DMAD and an equivalent of aluminum chloride. It was shown that the 1:1 adduct (11) could not be induced to react further with DMAD in the presence of aluminum chloride, thus it is not a precursor of the 2:1 adduct.

The n.m.r. spectrum of the 2:1 adduct revealed four distinct methoxyl groups, a methyl singlet (δ 2.03), a methyl doublet (δ 0.95, J = 7 Hz), and a methine quartet (δ 3.28). Although both structures **12** and **13** (Scheme 6) are reasonable formulations for the 2:1 adduct based on mechanistic arguments and are consistent with elemental analysis and n.m.r. data, the pyrolytic conversion of the adduct to vinylic products indicates **12** is correct. Thus heating the adduct to 170° produced a mixture of two isomers, the major of which exhibited an n.m.r. spectrum which possessed, in addition to four methoxyl signals, a vinyl methyl singlet (δ 2.84), a vinyl methyl doublet (δ 1.72, J = 7 Hz), and a vinyl hydrogen quartet (δ 6.88, J = 7 Hz). The n.m.r. spectrum of the minor pyrolysis product also contained four methoxyl signals, a vinyl methyl singlet (δ 2.75), a vinyl methyl doublet (δ 1.91, J = 7 Hz), and a vinyl hydrogen quartet (δ 6.20, J = 7 Hz). This observation is compatible with a cyclobutene → butadiene conversion and thus most consistent with **12** as the initial adduct. *A priori* four products (**14**–**17**) could be expected from **12** of undefined stereochemistry. The doublet resonance of the terminal vinyl methyl group (δ 1.72) of the major pyrolysis

[1]A referee has suggested that **8** and **10** could easily be explained by involvement of the antiaromatic *N*-acetyl-2-azirine, **i**.

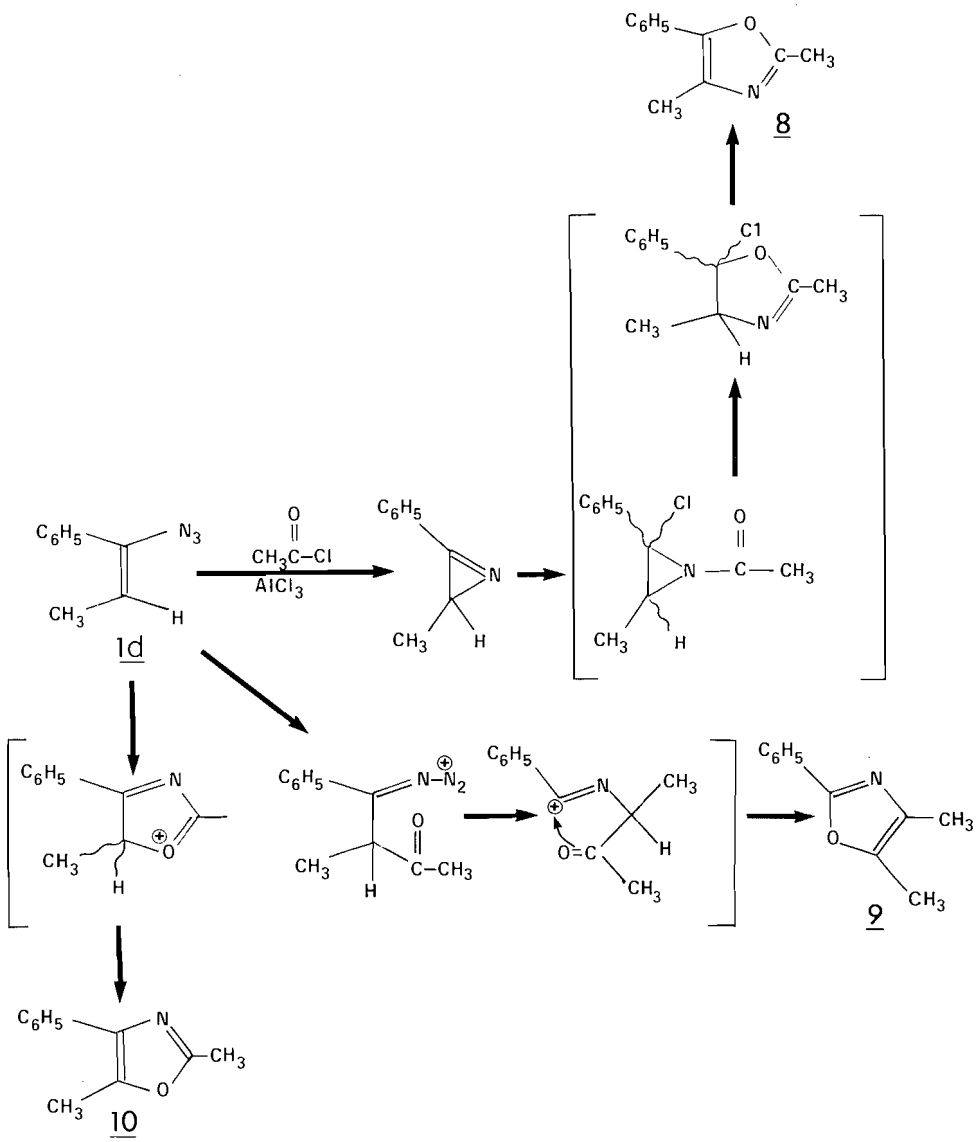

SCHEME 5. Reaction of 1-azido-1-phenylpropene with acetyl chloride.

product is at higher field than the same group of the minor product. This observation allows assignment of a *trans* relationship to this methyl and its vicinal carbomethoxy neighbor in the major isomer and a *cis* relationship in the minor isomer (9).

Comparison of the relative chemical shifts of the vinyl hydrogens associated with the carbons containing these terminal methyls confirms this assignment. The relative stereochemistry of the quaternary methyl and vicinal carbomethoxy about the nitrogen bearing double bonds of the dienic pyrolysis product was deduced by inspection of the chemical shifts of the resonances due to the quaternary methyls. The signal due to this group was at higher field in the major isomer than in the minor isomers. This indicates the quaternary methyl and carbomethoxy function are *cis* to each other in the major isomer and have a *trans* relationship in the minor isomer (9). The major pyrolysis product is thus **14** and the minor product is **15**. Since these two products interconvert thermally under the pyrolysis conditions they would probably inter-

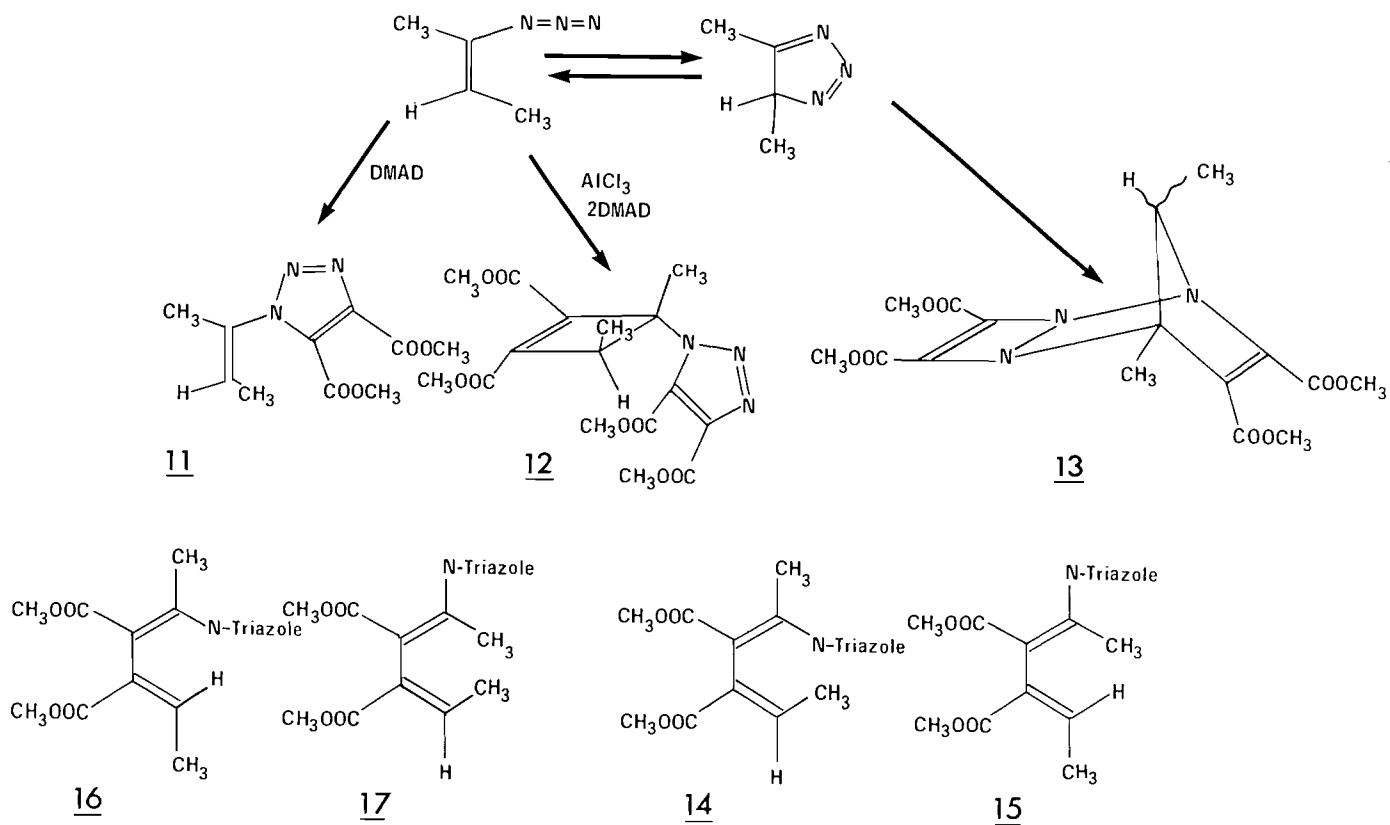

SCHEME 6. Reaction of vinyl azides with dimethylacetylene dicarboxylate (DMAD).

convert with **16** and **17**. Thus, although the stereochemistry of **12** implied by these results is as shown it cannot be assigned with certainty. As noted above both **1***a* and *b* gave **12** in the aluminum chloride catalyzed addition of DMAD to the olefinic linkage of the vinyl azide. In both reactions a triazole was formed. In the case of reaction of **1***b* triazole **11** was formed whereas reaction of **1***a* gave the triazole isomeric with **11** about the olefinic linkage. This suggests the catalyzed addition of DMAD to the olefinic bond of the vinyl azide is stepwise. This addition must be the initial reaction in the formation of the 2:1 adduct since the triazoles (**11**) are not converted to **12** under the reaction conditions.

It can be seen from the above examples that vinyl azides are potentially useful synthetic intermediates when viewed as *N*-diazoenamines.

Experimental

Melting points were obtained on a Fisher–Johns apparatus and are uncorrected. I.r. spectra were recorded with a Perkin–Elmer 457 grating spectrometer. U.v. spectra were recorded on a Unicam SP800 spectrometer. N.m.r. spectra were obtained with Varian A 56/60 and HX100 Spectrometers using tetramethylsilane as an internal standard ($\delta = 0$). Mass spectra were obtained using a Hitachi–Perkin–Elmer RMU6E Spectrometer and an ionization voltage of 80 eV.

Reaction of 1a and b with $NOBF_4$

To a solution of **1***a* or *b* (10) (1 g, 10.3 mmol) in 10 ml acetonitrile at 0° under He was added 1.2 g (20 mmol) $NOBF_4$ over 30 min, nitrogen (mass spectra) evolution was immediate. After 1 h of further stirring the reaction was quenched with water and extracted with three 100-ml portions of ether. The solvent was removed by fractional distillation and the residue fractionated at 20 mm (65°) to yield 0.70 g (~68%) of 3,4-dimethyl-1,2,5-oxadiazole (**2***a*, lit. (11) b.p. (760 mm) 155–156°) which was identified by comparison of its mass and n.m.r. spectra with those published (11) for this compound.

The undistilled residue (0.3 g) was chromatographed on 20 g SiO_2. Initial elution with benzene–methanol (99:1 v/v) gave 0.2 g (19%) of *N*-ethyl acetamide (**3***a*) (5). Continued elution with this solvent system gave 0.1 g (9%) *N*-methyl propionamides (**3***b*) (5). Both amides gave expected i.r., n.m.r., and mass spectra.

This experiment was repeated using 1 g of **1***a* or *b* and allowing the reaction to proceed for 30 min. After this time one-half of the reaction mixture was removed, diluted with water, and extracted (3 × 100 ml) with ether. The ethereal extract was concentrated and analyzed by g.l.p.c. (15% Versamide 900 on Chrom W, 3 ft × 1/8 in. column; temperature programmed 50–150° at 10°/min; using *o*-chlorotoluene as an internal standard) to yield (calcd.) 78–80% of **2***a*, 11% of **3***a*, and 6% of **3***b*. After 18 h the second half of the reaction was similarly analyzed to yield 92–94% of **2***a*, and 1% of a mixture of **3***a* and *b*.

Reaction of 1c with $NOBF_4$

Reaction of **1***c* (1 g, 6.6 mmol) in 10 ml of acetonitrile at 0° under He with 0.89 g (7.6 mmol) of $NOBF_4$ for 1 h followed by the hydrolytic work-up described above gave organic products which were chromatographed on 20 g SiO_2. Elution with benzene gave 0.76 g (75%) of 3,4-hexamethylene-1,2,5-oxadiazole (**2***b*); ν_{max} (film) 2920, 2860, 1450, 1180, 1010, and 930 cm^{-1}; λ_{max} (MeOH) 220 mμ (ε 2420); n.m.r. (CCl_4), δ 2.88 (4H J = 6 Hz, t) and 1.60 (8H, m).

Mol. wt. Calcd. for $C_8H_{12}N_1O$: 152.0949. Found [M^+]: 152.0959.

Continued elution with benzene–methanol (99:1) yielded 9% of lactam **3***c*, m.p. 72.5–73° (lit. (12) m.p. 72–73°); ν_{max} (KBr) 3280 and 1700 cm^{-1}.

Reaction of 1d with $NOBF_4$

To 0.556 g (3.5 mmol) of **1***d* in 15 ml acetonitrile at −10° under He was added a slurry of $NOBF_4$ (0.41 g, 3.1 mmol) in acetonitrile (30 ml). Nitrogen (mass spectra) evolution was immediate. After 18 h at room temperature the solution was quenched with water and extracted continuously with ether. Concentration of the extract gave a solution which was analyzed by g.l.p.c. (2% SE30 on Chrom G, 5 ft × 1/8 in., temperature programmed 50–170° at 6°/min). Reaction products **2***c* (8.8%), **4***a* (12%), and benzonitrile (6%) were identified by mixed injection of authentic samples and comparison of mass spectra obtained on preparatively isolated samples. Yields were calculated *vs.* added internal standard (nitrobenzene).

An authentic sample of 3-phenyl-4-methyl-1,2,5-oxadiazole (**2***c*) was prepared by reaction of 1-oxo-3-methyl-4-phenyl-1,2,5-oxadiazole (13) with PCl_5 (14).

An authentic sample of 3-methyl-5-phenyl-1,2,4-oxadiazole (**4***a*) was prepared by the method of Eloy (15).

Reaction of 1e with $NOBF_4$

The reaction of **1***e* with $NOBF_4$ in acetonitrile was carried out as described above for **1***d*. After the usual hydrolytic work-up the reaction extract was analyzed by a g.l.p.c. (SE 30, temperature programmed 50–290° at 4°/min) mass spectral combination. The only products detectable in more than 5% amounts *vs.* an internal standard were amides (5) (~30%) derived from hydrolysis of the azides (M^+ 115).

Reaction of 1a and b with NO_2BF_4

To 0.5 g (5.2 mmol) **1***a* or *b* in 20 ml of ether at −10 °C under He was added dropwise a solution of 0.68 g (5.5 mmol) NO_2BF_4 in 10 ml of ether. Nitrogen (mass spectra) evolution was immediate. The reaction was allowed to warm to room temperature and was stirred at this temperature for 1 h. After hydrolysis and ether extraction fractional distillation yielded 0.3 g (51%) of **5** (b.p. (16 mm) 100°) which gave a mass spectra identical to that published (11). Analysis of the nonvolatile portion by g.l.p.c. (Versamide 900) *vs.* an internal standard revealed 20% of a mixture of **3***a* and *b*. Repetition of the experiment for 18 h yielded 0.49 g (83%) of **5**.

Reaction of 1d with NO_2BF_4

To the azide (0.5 g) in 10 ml acetonitrile at −10° under He was added a molar equivalent of NO_2BF_4 in the same solvent (20 ml). Upon addition gas evolution (N_2 and

N_2O by mass spectral analysis) occurred. After addition (25 min) the solution was stirred at room temperature for 24 h then worked-up by addition of water, extraction with ether, and concentration of the extract. Product identification (**2***c* (17%), **4***a* (24%), benzonitrile (5%)) was made by g.l.p.c./mass spectra analysis (SE 30 column) as described for the $NOBF_4$ **1***d* reaction. Although yields are lower than for reaction of **1***a*, *b* with NO_2BF_4 the alternate products corresponding to **5** and amides were not present. Authentic **5** (R = C_6H_5, R′ = CH_3 and R = CH_3, R′ = C_6H_5) (13) as well as amide hydrolysis products (5) were available for comparisons.

Reaction of ***1****f with* NO_2BF_4

To a 15 ml solution of 1.15 g (8.6 mmol) NO_2BF_4 in acetonitrile at 0° under He was added 1.25 g (8.6 mmol) **1***f* in 12 ml acetonitrile. The solution was stirred at room temperature for 18 h and worked-up in the usual manner. Analysis of the organic products by g.l.p.c./mass spectra (SE 30) indicated two major components both of which possessed $[M]^+$ 146. These were separated by preparative g.l.p.c. (SE 30) and identified as **2***d* (16) (8%) and **4***b* (17) (12.5%) by comparison of n.m.r. and mass spectra with literature values.

Reaction of ***1****a and b with Acetyl Chloride*

To a solution of acetyl chloride (0.81 g, 10 mmol) in 10 ml of dry ether under He was added vinyl azide (**1***a* or *b*), (1.0 g, 10.3 mmol) during 1 h. The evolution of nitrogen was smooth. After stirring for 8 h the reaction was quenched with 10% aqueous $NaHCO_3$. Continuous extraction with ether followed by solvent removal gave only amides **3***a* (5) and *b* (5) (g.l.p.c./mass spectra, Versamide 900).

Repetition of the above using 1.4 g (10.5 mmol) $AlCl_3$ in the initial ether solution gave, after work-up, 1.03 g (70%) of an oil. Distillation (b.p. (15 mm) 65°) of the oil gave 0.8 g (70%) of 2,4,5-trimethyl oxazole (**7**) identified by g.l.p.c., mass spectra and n.m.r. comparison with an authentic sample (18).

Reaction of ***1****d with Acetyl Chloride*

To a solution of acetyl chloride (0.39 g, 5 mmol) in ether (8 ml) under He containing $AlCl_3$ (0.67 g, 5 mmol) was added **1***d* (0.8 g, 5 mmol). The solution was stirred for 2–18 h and worked-up in the usual manner. Analysis by g.l.p.c./mass spectra (5% DEGS on Chrom W, 6 ft × 1/8 in. column, 100° for 30 min, 100–180° at 3°/min) revealed **8** (17%), **9** (7%), **10** (~1%), and amides (3%). Comparison of preparatively g.l.p.c. isolated samples with authentic samples (**8** (19), **9** (20), **10** (19), amides (5)) confirmed the identity of the products.

Reaction of ***1****a and b with DMAD*

Uncatalyzed

An ether solution (20 ml) containing 0.5 g **1***b* (5.2 mmol) and 0.7 g DMAD (4.9 mmol) was stirred for 3 days. Concentration of the solution gave 0.99 g 90% of triazole **11** (b.p. (0.1 mm) 150°) ν_{max} (KCl): 2930, 1735, 1550, 1450, 825, and 810 cm^{-1}.

Mol. wt. Calcd. for $C_{10}H_{13}N_3O_4$: 239. Found (M^+): 239.

$AlCl_3$ Catalyzed

To a solution of 1 g (7 mmol) DMAD and 0.95 g (7.1 mmol) $AlCl_3$ in 20 ml of ether was added 0.7 g (7.1 mmol) of **1***b*. The reaction was stirred for 18 h then quenched with excess 10% aqueous $NaHCO_3$, extracted with ether and chromatographed on 20 g of SiO_2. Elution with petroleum ether gave 0.4 g (23.5%) **11**. Elution with 95:5 petroleum ether : chloroform gave 0.30 g (13%) of **12**, m.p. 98–99°. Repetition of this experiment using an excess of DMAD gave unreacted DMAD, no **11**, and raised the yield of **12** to 15%.

The first experiment was repeated using reverse addition of reactants. Thus *trans*-2-azido-2-butene (**1***b*, 0.5 g, 5.2 mmol) was dissolved in 20 ml of dry ether and the solution cooled to −20 °C. To this was added aluminum chloride (0.8 g) followed by dropwise addition of DMAD (0.7 g, 4.9 mmol). The mixture was warmed to room temperature and after stirring overnight it was diluted with aqueous 10% $NaHCO_3$ until it was weakly basic. Continuous extraction with ether gave 1.00 g of oil. Direct chromatography on 30 g of SiO_2 using 95:5 chloroform – petroleum ether as eluent gave 0.7 g (55%) of **11**.

Similarly reaction of *cis*-2-azido-2-butene (2 g, 20.8 mmol) was added dropwise to a solution of 2.4 g of $AlCl_3$ and DMAD (2.5 g, 17.8 mmol) in 20 ml of ether. After the usual work-up the residual oil was chromatographed on 100 g of SiO_2. Elution with petroleum ether gave 0.9 g of the *cis*-isomer of triazole **11**; ν_{max} (KBr) 2930, 1735, 1550, 1450, 825, and 810 cm^{-1}; n.m.r. ($CDCl_3$): δ 5.85 (1H, quartet, J = 7 of quartet, J = 1 Hz), 3.98 (3H, s), 3.95 (3H, s), 2.21 (3H, sextet, J = 1 Hz), and 1.85 (3H, d, J = 7 of quartet, J = 1 Hz).

Mol. Wt. Calcd. for $C_{10}H_{13}N_3O_4$: 239. Found (M^+): 239.

Elution with 95:5 petroleum ether – chloroform gave 0.2 g (3%) of **12**.

Anal. Calcd. for $C_{16}H_{19}N_3O_8$ ([M^+] 381): C, 50.39; H, 4.99. Found (381): C, 50.52; H, 5.02.

Reaction of ***11*** *with DMAD in the presence of* $AlCl_3$

To a solution of 0.1 g of **11** in 5 ml of ether containing 0.1 g $AlCl_3$ was added 0.2 g DMAD. The reaction was stirred overnight at room temperature then quenched with aqueous 10% $NaHCO_3$. The mixture was continuously extracted with ether which was concentrated. The residue was chromatographed on 20 g SiO_2. Using petroleum ether as the eluent 0.18 g DMAD was recovered. Using 95:5 petroleum ether – chloroform as the eluent 0.08 g of **11** was recovered. T.l.c. analysis of the fractions which would contain **12** revealed its absence.

Pyrolysis of ***12***

A solution of (0.038 g) of **12** in 0.4 ml of nitrobenzene was heated in an n.m.r. tube at 165° for 3 h. The signals due to **12** disappeared and signals attributable of **14** and **15** appeared. Integration of the spectra taken in nitrobenzene after the sample was cooled to room temperature revealed the **14**:**15** ratio to be 87.4:12.6. Because of the interconversion of **14** and **15** at 165° and under conditions necessary for their g.l.p.c. separation analysis was obtained on the mixture obtained from preparative g.l.p.c. (SE 30).

Anal. Calcd. for $C_{18}H_{19}N_3$ ([M^+] 381): C, 50.39; H, 4.99. Found (381): C, 50.47; H, 4.85.

We wish to thank the National Research Council of Canada for financial support of this work through an

operating grant to A.C.O., the Ogilvie Flour Co. Ltd. for a postgraduate fellowship to A.T., and G. Owen of this department for development of g.l.p.c./mass spectrometer interface.

The Reaction of Methyl Radicals with Neopentane

PHILIP D. PACEY
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received January 17, 1973

Neopentane was pyrolyzed in a flow reactor system at 793–953 K and 20–400 mm Hg. The rate constant for the initiation reaction,

$$neo\text{-}C_5H_{12} \rightarrow CH_3 + t\text{-}C_4H_9$$

calculated from the observed C_2H_6 yield, was $10^{17.7\pm0.3}$ exp $(-356 \pm 6$ kJ mol$^{-1}/RT)$ s^{-1}, in good agreement with earlier determinations in other temperature ranges. The rate constant of the reaction,

$$CH_3 + neo\text{-}C_5H_{12} \rightarrow CH_4 + neo\text{-}C_5H_{11}$$

calculated from the observed CH_4 and C_2H_6 yields, was $10^{10.5\pm0.1}$ exp $(-67 \pm 2$ kJ mol$^{-1}/RT)$ l mol^{-1} s^{-1}, four to ten times faster than predicted on the basis of earlier work at 404–608 K. From 404–953 K, the Arrhenius plot for this reaction is strongly curved.

Le néopentane a été pyrolysé dans un réacteur en système continu à 793–953 K et 20–400 mm Hg. La constante de vitesse pour la réaction d'initiation,

$$néo\text{-}C_5H_{12} \rightarrow CH_3 + t\text{-}C_4H_9$$

calculée à partir du rendement en C_2H_6 observé, est de $10^{17.7\pm0.3}$ exp $(-356 + 6$ kJ mol$^{-1}/RT)$ s^{-1}, en bon accord avec les déterminations antérieures dans d'autres domaines de température. La constante de vitesse de la réaction,

$$CH_3 + néo\text{-}C_5H_{12} \rightarrow CH_4 + néo\text{-}C_5H_{11}$$

calculée à partir des rendements en CH_4 et C_2H_6, est de $10^{10.5\pm0.1}$ exp $(-67 \pm 2$ kJ mol$^{-1}/RT)$ l mol^{-1} s^{-1}, c'est à dire quatre à dix fois plus rapide que celle prévue à partir des travails précédents effectués à 404–608 K. Dans la zone de température de 404 à 953 K, le tracé d'Arrhénius pour cette réaction est fortement recourbé.

[Traduit par le journal]

Can. J. Chem., 51, 2415 (1973)

The usual method of generation of CH_3 for the study of the metathetical reactions of methyl radicals is the photolysis of acetone or other substrates (1, 2). The rate of formation of CH_4 by the hydrogen abstraction reaction, for example,

[1] $$CH_3 + neo\text{-}C_5H_{12} \rightarrow CH_4 + neo\text{-}C_5H_{11}$$

is compared with the rate of formation of C_2H_6 by the reaction

[2] $$CH_3 + CH_3 \rightarrow C_2H_6$$

The rate constant of reaction 2, k_2, is known from other sources, so k_1 can be calculated. In the temperature range of photolysis, 300–600 K, most reactions like [1] have Arrhenius activation energies of 30–50 kJ mol^{-1} and pre-exponential factors of about 10^8 l mol^{-1} s^{-1}.

These results do not agree with higher temperature studies, in which the CH_3 radicals are generated by thermal decomposition of molecules (3). Specifically, recent studies (4–6) of the reactions of CH_3 with C_2H_6 and n-C_4H_{10} at temperatures above 800 K indicate that (*a*) the rate constants are greater than would be predicted from low temperature data, (*b*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

activation energies are about 70–90 kJ mol^{-1}, and (*c*) pre-exponential factors are 10^{10}–10^{12} l mol^{-1} s^{-1}. These results suggest that the Arrhenius plots for these reactions are not straight lines but curves. Arrhenius plot curvature is a rarely observed phenomenon, and is of considerable theoretical interest (7). However, the high temperature data are not as extensive as the photolytic data, and combinations of reactions, rather than the single reaction 2, were required at high temperatures to measure the CH_3 concentration.

The object of the present study was to study the reaction of CH_3 with neopentane (2,2-dimethylpropane), reaction 1, using the thermal decomposition of neopentane itself as a source of CH_3. This system is particularly convenient for study, as reaction 1 should be the only source of CH_4 and reaction 2 the only source of C_2H_6.

The Pyrolysis of Neopentane

Neopentane pyrolysis has recently been the subject of three studies in static systems at temperatures from 713 to 873 K (8–10). Data from the three laboratories are in excellent agreement. A mechanism consisting of reactions 1 and 2 and reactions 3–6 explains the rates of formation of the major products. The mechanism

[3] $$neo\text{-}C_5H_{12} \rightarrow CH_3 + t\text{-}C_4H_9$$

[4] $$t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_8 + H$$

[5] $$H + neo\text{-}C_5H_{12} \rightarrow H_2 + neo\text{-}C_5H_{11}$$

[6] $$neo\text{-}C_5H_{11} \rightarrow CH_3 + i\text{-}C_4H_8$$

also explains the reaction order of 3/2 and overall activation energy of 210–243 kJ mol^{-1} observed in the static systems.

Taylor *et al.* (11) have studied the decomposition at higher temperatures (920–1070 K) using very low pressures of neopentane in nitrogen diluent in a flow reactor system. They observed an order of unity and an activation energy of 337 kJ mol^{-1}. However, Baronnet *et al.* (9) have shown that this behavior is predicted by the above mechanism at high temperatures and low pressures, when the chain length of the reaction is very short.

Steady-state analysis of the above mechanism leads to the following relation between the initial rates of formation of CH_4 and C_2H_6:

[7] $$\frac{k_1}{k_2^{1/2}} = \frac{R^0_{CH_4}}{[neo\text{-}C_5H_{12}]} \cdot \left(\frac{1}{R^0_{C_2H_6}}\right)^{1/2}$$

This expression is identical to that used in photolytic work, except that an extra term for reaction of CH_3 with the radical source is not required here.

At the reaction times accessible in static pyrolysis systems (of the order of minutes) observed rates of product formation are significantly less than extrapolated initial rates because of inhibition of the reaction by the isobutene formed. Values of rate constants derived depend greatly on the particular method of extrapolation used (3). For this reason, eq. 7 has not previously been directly applied to the determination of k_1. Côme *et al.* (12) studied the pressure variation of $k_1/k_2^{1/2}$ at one temperature. They assumed

[8] $$R^0_{C_2H_6} = R^0_{H_2} + R^0_{i\text{-}C_4H_{10}} - R^0_{i\text{-}C_5H_{10}}$$

where $i\text{-}C_4H_{10}$ and $i\text{-}C_5H_{10}$ were minor products. Halstead *et al.* (8) calculated k_1, assuming values of k_2 and k_3 to determine $[CH_3]$ by a steady-state calculation.

Reaction 2 is the only reaction resulting in net removal of radicals in the above mechanism, and reaction 3 is the only source of radicals. To maintain a steady radical concentration, the rates of reactions 2 and 3 must be equal. Thus

[9] $$k_3 = \frac{R^0_{C_2H_6}}{[neo\text{-}C_5H_{12}]}$$

Equation 9 was used to determine k_3 by Halstead *et al.* (8). They calculated $R^0_{C_2H_6}$ by assuming it was equal to $R^0_{H_2}$, and extrapolating observed rates of formation of these species to a common point at reaction time $t = 0$. Baronnet *et al.* (9) also determined k_3, assuming eq. 8 was true. Tsang (13) determined k_3 by measuring the CH_4 formed when neopentane was pyrolyzed at about 1200 K in the presence of toluene in a shock tube. In the present work, k_3 has been determined directly from eq. 9, using data from flow reactor studies, from which initial rates can be estimated more readily.

Experimental

The apparatus was similar to that used in a previous study (5).

Neopentane (Phillips Research Grade, 99.88%) was purified by trap-to-trap distillation and, on the day of an experiment, by prolonged and repeated degassing at −196 or −95 °C (toluene slush). The major impurity remaining was *iso*-butane, 0.01 mol %. Impurities of CH_4 and C_2H_6 varied from 1–5 p.p.m.

Three 75 cm-long quartz reactors were used; their internal diameters and surface to volume ratios (S/V)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

were, respectively, (*i*) 1.7 cm, 3.1 cm^{-1}; (*ii*) 0.8 cm, 9.9 cm^{-1}; (*iii*) 0.2 cm, 23 cm^{-1}. Along the axes of reactors (*i*) and (*ii*) was placed a 0.4 cm outside diameter quartz thermocouple well. Reactor (*iii*) was placed along the axis of a 0.8 cm inside diameter quartz tube, which held a moveable thermocouple.

During an experiment, temperatures were measured at 2.5 cm intervals along the reactor using a platinum – platinum – 13% rhodium thermocouple. The computer program described in ref. 5 showed that 93% of the reaction occurred within ±5 °C of the average temperature of reaction during a typical experiment. Reactor diameters, temperatures, and reactant pressures were limited to prevent the endothermicity of the reaction from cooling the gases in the center of the vessel. Using the formula discussed in ref. 5, the maximum temperature drop from reactor wall to axis from this cause was calculated to be 1 °C. To prevent the cooler entering gases from distorting the temperature profile, flow rates were limited to 0.1 mol/h or less. For this flow rate, using method (*i*) of Mulcahy and Pethard (14), the error in the measured reaction rate may be calculated to be 5%.

The reaction products were analyzed by gas chromatography. A 1 m long, 12% NaOH-on-alumina column at 40 °C was used for most analyses, and a 1.5 m, 10% squalane-on-chromosorb P column at 0 °C for products of high molecular weight. Hydrogen was measured with a thermal conductivity detector, and the hydrocarbons with a flame ionization detector.

Results

More than 100 experiments[1] have been performed at reactor temperatures from 793–953 K, reaction pressures from 20–400 mm Hg, and reactor residence times from 0.05–5.1 s, corresponding to conversions varying from 0.1–6.1%. The two major products, methane and isobutene, were formed in equal quantities and together constituted from 90–99.5 mol % of all the products. As reported by earlier workers (8, 9), the yield of hydrogen always exceeded that of ethane, the ratio $[H_2]/[C_2H_6]$ varying from 1.2–2.4. Minor products observed were ethylene, propylene, propane, and 2-methyl-1-butene. Ethylene appeared to be a primary product; the mechanism by which it is formed is not well understood (8). Propylene and propane were secondary products. As reported and interpreted by Baronnet *et al.* (9), the yield of 2-methyl-1-butene was similar in magnitude to the difference $([H_2] - [C_2H_6])$.

Dependence of Rates on Reaction Time

Figures 1*a* and *b* show the dependence of the rates of formation of CH_4 and C_2H_6 on the reactor residence time at 68 mm Hg and 834 K, and 100 mm Hg and 913 K, respectively. In all four cases the rates of product formation decrease as the reaction time increases. A similar effect was observed in the static pyrolysis of neopentane (8, 9), and was shown to be caused by self-inhibition of the reaction by the isobutene formed; in some of these studies the rate observed at the shortest attainable reaction time was less than half of the estimated initial rate. In this flow system much shorter reaction times could be achieved, and the extrapolated initial rates were always within 10% of the nearest observed rate. The solid lines in the figures were calculated by the method of least squares.

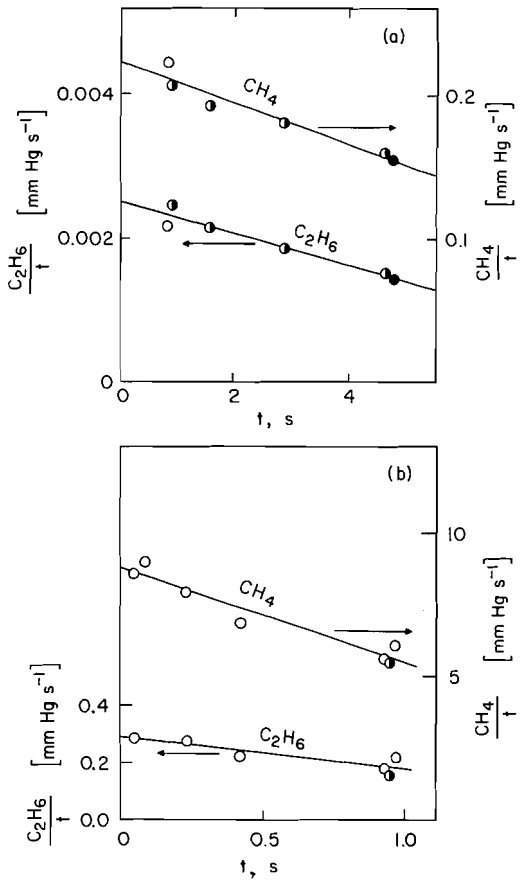

FIG. 1. Rates of formation of CH_4 and C_2H_6 as a function of reactor residence time for pyrolysis of neopentane at (*a*) 68 mm Hg and 834 K and (*b*) 100 mm Hg and 913 K. ●, Reactor (*i*), S/V = 3.1 cm^{-1}; ◑, reactor (*ii*), S/V = 9.9 cm^{-1}; ○, reactor (*iii*), S/V = 23 cm^{-1}.

[1]Tables of data are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0R6.

Figures 1*a* and *b* also show that the observed rates were independent of the surface to volume ratio of the reactors.

Dependence of Rates on Pressure

The dependence of the initial rates of formation of CH_4 and C_2H_6 on reaction pressure is shown in Figs. 2 and 3 for reaction at 840 and 914 K, respectively.

In both cases, the data on C_2H_6 formation correlate well with the dashed lines of slope equal to 1.0. This behavior is predicted by the mechanism provided that the initiation reaction 3 is first order and that reaction 2 is the only termination reaction.

The initial rates of CH_4 formation in Fig. 2 correlate well with the dashed line of slope equal to 1.5. As the rate of CH_4 formation is, within 10%, equal to the rate of neopentane removal, the overall reaction is also of order 3/2, in agreement with the results of static pyrolyses (8–10).

In Fig. 3, for a higher reaction temperature, the CH_4 data at high pressures agree with the dashed line of slope 1.5, but the low pressure data lie above this line. This effect was previously observed in static pyrolysis by Baronnet *et al.* (9). They showed that the observation could be explained by the pressure dependence of the recombination rate constant, k_2. At the higher

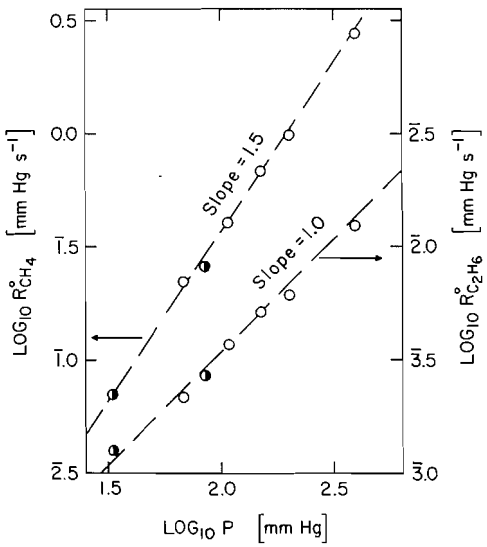

FIG. 2. Order plots for CH_4 and C_2H_6 formation in neopentane pyrolysis at 840 K. ◑, Reactor (*ii*); ○, reactor (*iii*). The dashed lines have slopes of exactly 1.5 and 1.0, respectively, as predicted by the mechanism.

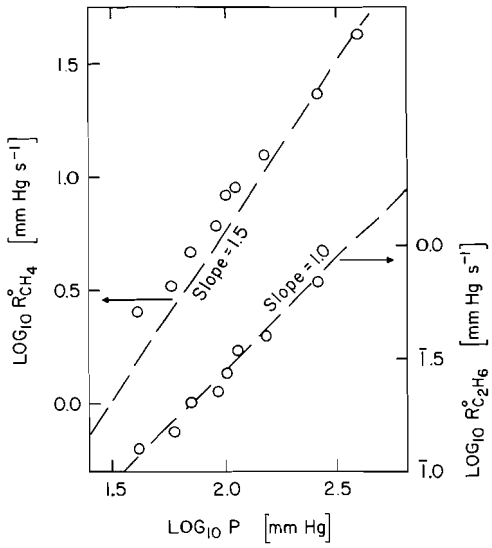

FIG. 3. Order plots for CH_4 and C_2H_6 for pyrolysis of neopentane in reactor (*iii*) at 914 K. The dashed lines have slopes of 1.5 and 1.0, respectively, as suggested by the mechanism.

temperatures of the present experiments (793–953 *vs.* 723–803 K), this pressure dependence should be more pronounced.

The pressure dependence of k_2 causes difficulties in the calculation of k_1 from eq. 7. If the precise value of k_2 were known at every pressure and temperature, it could be substituted in eq. 7 and k_1 determined. However, this pressure dependence is not known with certainty (15). It is necessary, then, either to work at high pressures, where k_2 is pressure independent, or to extrapolate low pressure data to high pressures. Lin and Back (16) have shown that the rate constant of the reverse of reaction 2 can be extrapolated to high pressures using a Lindemann–Hinshelwood plot. It follows that k_2, which must have identical pressure dependence to k_{-2}, can also be extrapolated in this manner.

Two Lindemann–Hinshelwood plots, for reaction temperatures of 953 and 914 K, respectively are shown in Fig. 4. The straight lines were determined by the method of least squares. For the reverse reaction, Lin and Back (16) found that $P_{1/2}$, the pressure at which k_{-2} has dropped to one-half its high pressure value, was 54 mm Hg at 958 K. From Fig. 4, $P_{1/2}$ at 953 K is estimated to be 37 ± 4 mm Hg. In agreement with theory and previous experiments (15), the

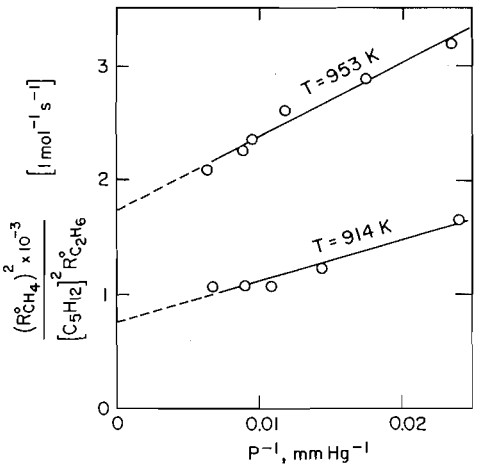

FIG. 4. Lindemann-Hinshelwood style plots for the experimental function, $R^0_{CH_4}{}^2\,[C_5H_{12}]^{-2}\,R^0_{C_2H_6}{}^{-1}$, at varying reaction pressures in reactor (*iii*) at temperatures of 953 and 914 K.

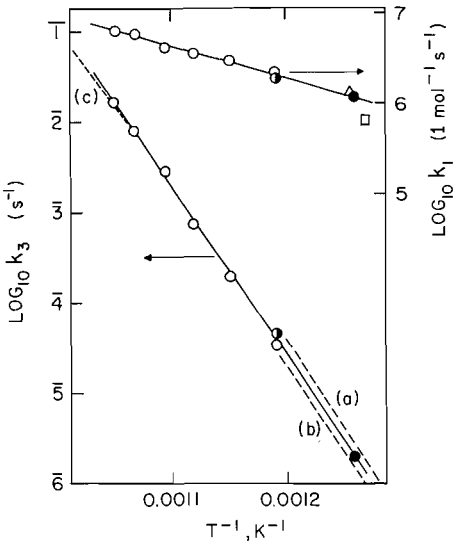

FIG. 5. Arrhenius plots for the rate constants k_1 and k_3. ●, Reactor (*i*); ◑, reactor (*ii*); ○, reactor (*iii*); □, calculated from the data of ref. 12; △, calculated from the data of ref. 8; (*a*) from the data of ref. 8; (*b*) extrapolated from the low temperature data of ref. 9; (*c*) extrapolated from the high temperature data of ref. 13. The solid lines are least squares lines through the data of this work.

values of $P_{1/2}$ estimated became smaller, and farther outside the experimental pressure range, at lower temperatures.

The aim of these experiments was not to study the pressure dependence of k_2, which will not be considered further, but to find the limiting, high pressure value of $R^0_{CH_4}{}^2[C_5H_{12}]^{-2}$-$R^0_{C_2H_6}{}^{-1}$, and then, using eq. 7 to calculate k_1. The extrapolated, high-pressure values of $k_1/k_2{}^{1/2}$ in most cases differed from the nearest observed value by less than 10%, and in all cases differed by less than 20%.

Variation of Reactor Temperature

To calculate k_1 from these high pressure extrapolations, the recently determined value (17) of $k_2 = 2.43 \times 10^{10}$ l mol^{-1} s^{-1} was used. This rate constant was assumed to be temperature independent in the high pressure limit considered here. The resulting values of k_1 (circles) are shown in the form of an Arrhenius plot in the upper part of Fig. 5. For comparison, values of k_1 have been calculated with this value of k_2 from the highest temperature estimates of ref. 8 (triangle) and ref. 12 (square). Both values lie within ±40% of the least squares line through the data of this work. The differences may result from the different methods of extrapolation used.

The Arrhenius activation energy derived from Fig. 5 for k_1 is 67 ± 2 kJ mol^{-1}, where here and subsequently the quoted uncertainty is the standard deviation. This activation energy is much greater than the values 42–50 kJ mol^{-1} found in experiments at lower temperatures and listed in Table 1. The pre-exponential factor from Fig. 5, $10^{10.5\pm0.1}$ l mol^{-1} s^{-1}, is one or two orders of magnitude greater than the low temperature values. Even among the low temperature data in Table 1, there is some indication of a general trend to greater values of $\log_{10} A$ and E_A as the average reaction temperature increases.

The initiation rate constant, k_3, was calculated using eq. 9. Values of k_3 at the same reaction temperature, but different pressures, were averaged and are shown in the lower part of Fig.5. Standard deviations of individual values from the average at a particular temperature were in the range from 4–21%. The solid line was determined by the method of least squares. The dashed line (*a*) represents the highest temperature, static pyrolysis data of Halstead *et al.* (8). Line (*b*) is extrapolated from the static pyrolysis data of Baronnet *et al.* (9). Line (*c*) is extrapolated from data obtained by Tsang (13) by high temperature pyrolysis of neopentane with toluene in a shock tube. In all cases, the

agreement between values of k_3 determined by flow pyrolysis and by previous work is excellent.

The solid line leads to the following Arrhenius expression for k_3: $k_3 = 10^{17.7\pm0.3} \cdot \exp(-356 \pm 6\ kJ\ mol^{-1}/RT)\ s^{-1}$. Previous workers have found $k_3 = 10^{18.05\pm0.58} \cdot \exp(-359 \pm 9/RT)$ (8); $k_3 = 10^{16.8} \exp(-343/RT)$ (9); and $k_3 = 10^{16.1} \exp(-327/RT)\ s^{-1}$ (13). The final expression has been reexamined by Tsang (22), who has suggested a revised expression $k_3 = 10^{16.8} \exp(-342/RT)\ s^{-1}$. All the activation energy measurements then would fall in the range 350 ± 9 kJ mol^{-1}, which is exceptional agreement.

Discussion

Comparison with Low Temperature Experiments

Figure 6 allows a more complete comparison of values of k_1 determined by flow pyrolysis (open circles) with those determined by photolysis (squares, ref. 19; triangles, ref. 18; inverted triangles, ref. 20) and the mercury-photosensitized decomposition of neopentane (filled circles, ref. 21). In refs. 18, 19, and 21, k_1 was determined relative to k_2; the results have been recalculated using k_2 from ref. 17. In ref. 20, k_1 was determined relative to the rate constant for the reaction

[10] $CD_3 + (CD_3)_2\ CO \rightarrow CD_4 + CD_3{\cdot}CO{\cdot}CD_2$

The value of k_{10} assumed in ref. 20 was twice as great as that found in four recent investigations (1). This could explain the fact that k_1 from ref. 20 is twice as great as k_1 from ref. 19. The original authors of ref. 18 suggested the lower values calculated for k_1 could have been caused by uneven light illumination.

The straight, dashed line (*a*) in the figure is a least squares line through the data of Trotman-Dickenson *et al.* (19). It can be seen that the pyrolysis data lie well above this line, by 0.7–1.0 log units, or a factor of 5–10. We shall next consider whether it is possible that the pyrolytic data could be in error by such a factor.

Line (*a*), least squares line through the data of ref. 19; (*b*), $k_1 = \Gamma\ 10^{10.2} \exp(-67\ kJ\ mol^{-1}/RT)\ l\ mol^{-1}\ s^{-1}$, where Γ is the tunnelling factor for a truncated parabola from ref. 27; (*c*), $k_1 = 10^{7.8} \exp(-40/RT)\ l\ mol^{-1}\ s^{-1} + 10^{11.2} \exp(-80/RT)\ l\ mol^{-1}\ s^{-1}$.

Possible Systematic Errors

Errors in k_1 could arise from errors in any of the other factors in eq. 7; each will be examined in turn.

The discrepancy in Fig. 6 could be explained

if 80–90% of the CH_4 were formed by another reaction, for example, reaction of CH_3 with an impurity, or with H atoms, *t*-butyl radicals or C_5H_{11} radicals, or reaction at a surface.

The major impurity present was isobutane. In all cases CH_4 yields observed were at least ten times as great as the original isobutane concentration. It is impossible that impurities could contribute major quantities of CH_4.

The steady-state concentrations of H, *t*-C_4H_9, and *neo*-C_5H_{11} have been estimated from the mechanism (particularly, reactions 4–6 and the observed rates of formation of H_2, C_2H_6, and C_4H_8, respectively). The rate constant for reaction 5 was assumed equal to the value found by Baldwin and Melvin (23) for the analogous reaction with ethane. The rate constants used for reactions 4 and 6 were those favored by Benson and O'Neal (24). Under all experimental conditions, the calculated concentrations of all three species were lower than the concentration of CH_3. Since reaction 2 is very rapid (about one collision in four is effective), CH_3 must form C_2H_6 via reaction 2 more frequently than it forms CH_4 by any reaction with H, *t*-C_4H_9, or *neo*-C_5H_{11}. C_2H_6 was formed an order of magnitude slower than CH_4, so these reactions, even if their rate constants equalled k_2, could only contribute a maximum of 0.5% of the observed CH_4.

The fact that identical rates were observed in reactors of three different surface to volume ratios indicates that surface reactions could not contribute a major proportion of the CH_4.

The only other ways of removing the discrepancy in Fig. 6 would be to suggest that $R^0_{C_2H_6}$ was underestimated by a factor of 25–100 or that k_2 was overestimated by a factor of 25–100. The first hypothesis can be ruled out by the very short extrapolations required in Figs. 1*a* and *b* and the good agreement between values of k_3 from this work and previous experiments. The second hypothesis would require that k_2 be temperature independent from 300–608 K, and then develop a negative activation energy of 50 kJ mol^{-1} at high temperatures. This is not in accord with the available data (15).

The low temperature data are reasonably consistent among themselves and agree well with experiments on a large number of related reactions (1). It does not seem likely that they can be greatly in error.

It is probable, then, that the values of k_1 in Fig. 6 are correct, and that the Arrhenius plot for this reaction is a curve.

Interpretation

The Arrhenius plot curvature is similar to that observed in studies of the reactions of CH_3 with C_2H_6 and *n*-C_4H_{10} and of C_2H_5 with C_4H_{10} (4–6). The results reported herein are more extensive, however, and the method of calculation simpler.

There are several possible explanations of the observed curvature: the presence of several low frequency vibrations in the transition state, substantial vibrational anharmonicity in the transition state, quantum mechanical tunnelling through the activation energy barrier, and contribution to reaction from more than one reactant state or more than one transition state. Of these, the effect of vibrational anharmonicity is difficult to evaluate quantitatively, but the others will be tested.

According to transition state theory (25), low frequency vibrations in the transition state should each contribute a factor of T to the pre-exponential factor, leading to curvature of the Arrhenius plot in the direction observed. In order to explain the observed magnitude of the curvature, however, it would be necessary to postulate that there are eight or nine more low frequency vibrational modes in the transition state than in the reactants throughout the range 404–953 K. But the low pre-exponential factors observed at low temperatures for reactions of this type suggest that there are very few low frequency vibrations in the transition state (26).

A rough estimation of the effect of tunnelling on this reaction can be seen from curve b in Fig. 6, which shows the function, $k_1 = \Gamma\, 10^{10.2} \exp(-67\ \text{kJ mol}^{-1}/RT)\ \text{l mol}^{-1}\ \text{s}^{-1}$. Here Γ is the tunnelling factor calculated by Sharp and Johnston (27) for the very similar reaction $CF_3 + CH_4 \rightarrow CF_3H + CH_3$, assuming an activation barrier to reaction shaped like a truncated parabola. These tunnelling factors fitted the experimentally observed kinetic isotope effect for that reaction, which is very similar to the kinetic isotope effect for the reaction of CH_3 with C_2H_6 (25). The other factors in the expression for k_1 were chosen to attempt to match curve b to the experimental data.

The figure shows that curve b is close to the

data, but its curvature, or rate of change of slope, is not as great as that of the experimental data. It is quite possible, nevertheless, that a different model for tunnelling could explain both the observed curvature for reaction 1 and the kinetic isotope effect for related reactions.

Curve c in Fig. 6 represents the function, $k_1 = 10^{7.8} \exp(-40 \text{ kJ mol}^{-1}/RT)\ 1 \text{ mol}^{-1} \text{ s}^{-1} + 10^{11.2} \exp(-80 \text{ kJ mol}^{-1}/RT)\ 1 \text{ mol}^{-1} \text{ s}^{-1}$. This function corresponds to a model in which reaction 1 proceeds by two paths, either via two transition states, or from two different reactant vibrational quantum states, or from two types of methyl radicals, as suggested by Hay (28). The model, though crude, can be fitted to the experimental data, as the figure shows.

It is possible that several of these effects may contribute to the observed curvature. At present, the range of the data is not sufficient to distinguish between them.

The low temperature activation energies for the hydrogen abstraction reactions of methyl radicals have been extensively correlated with the bond dissociation energies of the bonds being broken (29, 30). Implicit in these correlations is the assumption that the low temperature activation energies are approximately equal to the height of the activation barrier. If tunnelling occurs, this assumption is not valid. The significance of these correlations is thus reduced.

Whether tunnelling occurs or not, it is clear that the Arrhenius plot for this reaction is a curve. Arrhenius expressions adequately represent the experimental data only within narrow temperature ranges.

The author wishes to thank Prof. J. H. Purnell for his encouragement and the National Research Council of Canada for a grant in support of this research.

Received December 11, 1972

Non-empirical double zeta quality molecular orbital calculations on $^{-}CH_2OH$ as a function of the C—O bond length (r), the rotational angle about the C—O bond (θ), and the pyramidal angle at carbon (ϕ) are described. From the stretching potential curve, $E(r)$, it is shown that dissociation of $^{-}CH_2OH$ proceeds to give CH_2 and OH^{-}. The rotation–inversion surface, $E(\theta,\phi)$, has two types of minima; in both cases the most favorable pyramidal angle at carbon is 105°. The lower minimum corresponds to a structure (the Y conformation) having the hydroxyl proton on the external bisector of the HCH angle. The higher minimum is 6.67 kcal/mol less stable and corresponds to a structure (the W conformation) having the hydroxyl proton on the internal bisector of the HCH angle. The relationship of these results to the *gauche* effect is discussed and it is noted that at certain internuclear distances the nuclear–nuclear repulsion term (E_{nucl}) may overcome the tendency of adjacent electron pairs and polar bonds to exist preferentially in that conformation which has the maximum number of *gauche* interactions between these electron pairs or polar bonds.

The topomerization of $^{-}CH_2OH$, *i.e.*, the conformational transformation from one Y conformation into another, proceeds, via the W conformation as an intermediate, by two separate events, *viz.* rotation about the C—O bond, having a barrier of 10.58 kcal/mol, and pyramidal inversion at carbon, with a barrier of 20.52 kcal/mol. Some factors governing the relative importance of rotation and inversion in degenerate racemization are discussed.

In its ground electronic state CH_3O^{-} is 22.18 kcal/mol more stable than $^{-}CH_2OH$. However, in the low-lying excited states all conformations of $^{-}CH_2OH$ are stabilized relative to CH_3O^{-}. The most stable excited state structure of $^{-}CH_2OH$ corresponds to the energy maximum for rotation–inversion of the ground electronic state.

Les calculs non-empiriques d'orbitales moléculaires (qualité double zeta) sur $^{-}CH_2OH$ sont décrits en fonction de la longueur du lien C—O (r), de l'angle de rotation autour du lien C—O (θ), ainsi que de l'angle pyramidal du carbone (ϕ). A partir de la courbe du potentiel d'élongation, il est démontré que la dissociation de $^{-}CH_2OH$ conduit à la formation de CH_2 et OH^{-}. La surface rotation–inversion $E(\theta,\phi)$, possède deux types de minima; dans les deux cas, l'angle pyramidal le plus favorable au carbone est de 105°. Le minimum le plus bas correspond à une structure (la conformation Y) possédant le proton du groupe hydroxyle sur la bissectrice extérieure de l'angle HCH. Le minimum le plus élevé est de 6.67 kcal/mol moins stable et correspond à la structure (la conformation W) possèdant le proton du groupe hydroxyle sur la bissectrice interne de l'angle HCH. La relation de ces effets avec l'effet *gauche* est discuté; de plus l'on note qu'à certaines distances internucléaires, le terme englobant la répulsion noyau–noyau (E_{nucl}) peut surpasser la tendance des paires adjacentes d'électrons et des liens polaires à exister préférentiellement dans cette conformation qui possède le nombre maximum d'interactions *gauches* entre ces paires d'électrons ou ces liens polaires.

La topomérisation de $^{-}CH_2OH$, *i.e.*, la transformation conformationnelle à partir d'une conformation Y vers une autre, se produit, en passant par la conformation W intermédiaire, selon deux étapes, *viz.* rotation autour du lien C—O ce qui représente une barrière de 10.58 kcal/mol et inversion pyramidale au carbone ce qui représente une barrière de 20.52 kcal/mol. Plusieurs facteurs concernant l'importance relative de la rotation et de l'inversion en ce qui a trait à la racémisation dégénérée sont discutés.

Dans son état électronique fondamental CH_3O^{-} est de 22.18 kcal/mol plus stable que $^{-}CH_2OH$. Cependant dans les plus bas états excités, toutes les conformations de $^{-}CH_2OH$ sont stabilisées comparativement à CH_3O^{-}. La structure du $^{-}CH_2OH$ correspondant à l'état excité le plus stable correspond à l'énergie maximum pour la rotation–inversion de l'état électronique fondamental.

Introduction

In the course, of *ab initio* theoretical studies related to the *gauche* effect (1–3) we have been interested in the rotation–inversion behavior of carbanions adjacent to a heteroatom (4–7) or second carbanionic center (3). The original work (4–7), which led to the discovery of the *gauche* effect, was performed using minimal basis sets. Calculations of this quality correctly anticipated the tendency of species containing adjacent electron pairs or polar bonds to exist preferentially in that conformation which contains the maximum number of *gauche* interactions between these electron pairs or polar bonds. However, it could not be expected (8) that all of the details of rotation–inversion surfaces associated with such systems, required for an understanding of the physical basis of the *gauche* effect, would be basis set invariant. Therefore, the more recent work, which is being performed with this objective in mind (2, 3, 9–11), employs in all cases basis sets of at least double zeta quality. At the present time this level of calculation represents the practical limit for systems of interest to us.

The work reported here deals with an investigation of hydroxymethylcarbanion, $^{-}CH_2OH$, the tautomeric form of CH_3O^{-}, which can be viewed as the simplest carbanion having an adjacent oxygen atom. This anion is isoelectronic and isoprotic with H_2NOH, whose rotational potential (shown in Fig. 1) has already received some attention (12, 13).

A point of special interest in the geometry optimization of $^{-}CH_2OH$ was the accurate determination of the energetics of the process,

$$H^{+} + {}^{-}CH_2OH \rightarrow CH_3OH$$

required for a comparison of the proton affinities of $^{-}CH_2OH$ and $^{-}CH_2SH$. It is an experimental fact (14) that the kinetic acidity of a proton at a carbon adjacent to sulfur is several orders of magnitude greater than that of a proton at carbon adjacent to oxygen. This has been attributed to d_{π}–p_{π} stabilization of the intermediate in the former case (14, 15). Since it has not been necessary to postulate d-orbital conjugation to account for the *stereochemical* properties of sulfur-stabilized carbanions (1, 4–7), it seemed reasonable to suppose that some, as yet unrecognized, non-conjugative explanation might account for the *chemical* difference between oxygen and sulfur.

Method

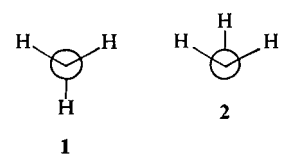
An extensive contracted Gaussian basis set was employed which has been optimized for C and O atoms by Huzinaga (16), and by Basch *et al.* for H (17). For $^{-}CH_2OH$ this consisted of a total of 80 GTF contracted to 26 basis functions, corresponding to a double zeta basis set. The same basis set was used for a study of CH_3O^{-}, CH_3OH, and $CH_3OH_2^{+}$ (9). Since the Hartree–Fock limit was approached quite well in the CH_3OH calculation, the results for $^{-}CH_2OH$ were expected to be reliable. All computations were performed on an IBM 360/65 computer using the IBMOL 4 system (18).

Results and Discussion

The Conformational Hypersurface of $^{-}CH_2OH$

To generate a complete conformational hypersurface of $^{-}CH_2OH$ it would have been necessary to determine the variation of the total energy with respect to each of the $3N - 6$ internal coordinates. For practical reasons, however, it is customary in an *ab initio* calculation to investigate the effects of only one, two or, perhaps, three internal coordinates. For $^{-}CH_2OH$ the independent variables selected for study were the C—O bond length (r), rotation about the C—O bond (θ), and pyramidal inversion at carbon (ϕ), because it seemed likely that these would have the greatest effects upon the stereochemistry of the anion.

The resulting four-dimensional hypersurface $E(r,\theta,\phi)$ was then generated in two stages. In the initial stage, variation of r was examined and two cross-sections of the hypersurface were obtained, corresponding to tetrahedral bond angles at carbon ($\phi = 110°$) and, using the energy minima of H_2NOH as a guide (12, 13), the 0° (**1**, termed the Y conformation) and 180° (**2**, termed the W conformation) rotational conformations ($\theta = 0$, 180°). These results, presented in Table 1 and illustrated in Fig. 2, indicate minima at 1.500 (**1**) and 1.508 Å (**2**).



1 **2**

It is possible, using these data, to identify the products of dissociation of $^{-}CH_2OH$. Only heterolytic bond cleavage can be considered, because of the closed shell SCF treatment, and

two such processes might be proposed as indicated in eqs. 1 and 2.

[1] $^{-}:CH_2—OH \rightarrow :CH_2 + OH^{-}$

[2] $^{-}:CH_2—OH \rightarrow :CH_2^{2-} + OH^{+}$

Equation 1 was expected to represent the favored route, on the basis of simple electronegativity arguments. Moreover, because the ground state of OH^+ has triplet multiplicity, this species does not represent a closed shell problem. The energetics of both routes were computed, with the results shown in Table 2. Clearly route [2] is less favorable, by almost 0.8 hartree. However, it is also evident that our calculations converge to slightly higher values than the energies of the dissociated products. It is possible that these correspond to a local maximum in the Morse potential; such maxima in theoretically computed potential curves have been observed previously (19) and have also

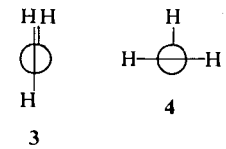
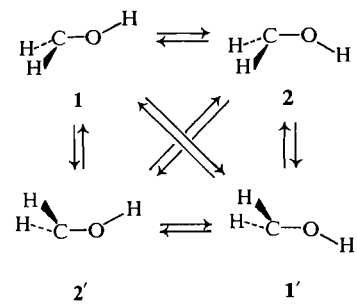
been detected experimentally, in predissociation (20). Alternatively, the present result may simply be an artefact of the particular geometry employed.

In the second stage of the work, a rotation–inversion surface $E(\theta,\phi)$ was generated using the experimental C—O bond length of methanol (1.428 Å). This was done to facilitate a direct comparison with the previous calculations on the parent compound (CH_3OH) and the tautomeric form (CH_3O^-) of $^{-}CH_2OH$ (9). The computed total energy values and their components are summarized in Table 3, and the rotation–inversion surface for this C—O bond length is shown in Fig. 3. This figure shows the energy maximum, corresponding to structure **3**, and two equivalent saddle points (**4**), as well as the two minima corresponding to **1** and **2**. The Y conformation, as in H_2NOH, represents the lowest minimum on the energy surface. Two cross-sections of this surface associated with inversion at carbon are shown in Fig. 4 and five cross-sections, associated with rotation about the C—O bond, are given in Fig. 5. The energy components of two of these rotational curves, $\phi = 120°$ (planar configuration at carbon) and $\phi = 110°$ (tetrahedral configuration at carbon) are shown in Fig. 6.



Topomerization of $^{-}CH_2OH$

With Figs. 3–5 in hand it is possible to provide a theoretical discussion of the process, referred to as "degenerate racemization" (21*a*), or "topomerization" (21*b*), whereby a species such as $^{-}CH_2OH$ transforms itself by some combination of rotation and inversion from one structure into an identical or enantiomeric structure. Scheme 1 illustrates the various possible routes for such a process in the present case.



SCHEME 1. Topomerization of $^{-}CH_2OH$. Horizontal arrows: rotation along the C—O bond or in-plane inversion at oxygen. Vertical arrows: pyramidal inversion at carbon. Diagonal arrows: rotation–inversion.

†Tetrahedral bond angles at carbon.

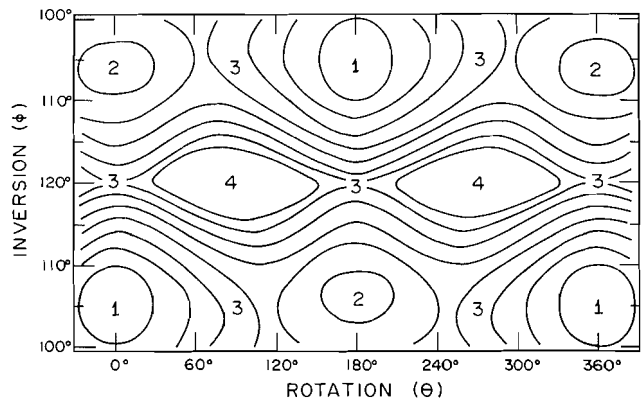

FIG. 3. Rotation–inversion surface ($E(\theta,\phi)$) of $^{-}CH_2OH$ at the methanol C—O bond length (1.428 Å).

The meaning of Scheme 1 is that the interconversion of **1** and **1′** (≡ **1**) must involve one of the following combinations: (*A*) rotation about the C—O bond and pyramidal inversion at the carbanionic center; (*B*) rotation about the C—O bond and in-plane inversion at oxygen; (*C*) in-plane inversion at oxygen and pyramidal inversion at carbon. In each case the process may be characterized by a single barrier (*i.e.*, combined rotation–inversion) or by two discrete barriers (*i.e.*, via an intermediate) which may or may not have equal heights. The problem then is to select the favored route from these twelve possibilities.

Structure **3**, which represents the barrier for combined rotation–pyramidal inversion, is 33.6 kcal/mol less stable than **1**. Although the barrier to in-plane inversion was not computed in the

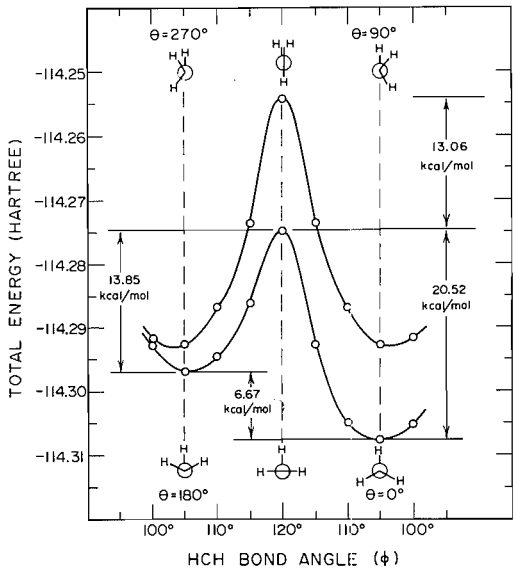

FIG. 4. Two inversion cross-sections of the rotation–inversion surface of $^{-}CH_2OH$. Upper curve: the cross-section through $\theta = 90°$ ($\equiv 270°$). Lower curve: the cross-section through $\theta = 0°$ ($\equiv 180°$).

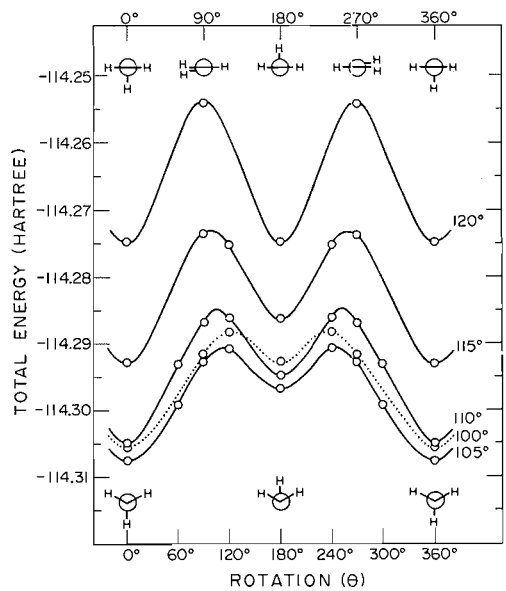

FIG. 5. Five rotational cross-sections of the rotation–inversion surface of $^{-}CH_2OH$.

present work, this barrier must also be greater than 30 kcal/mol since calculations employing the same type of basis set used here (9) give values of 31.5 kcal/mol for in-plane inversion of both H_2O and CH_3OH. The energetics associated with path *A*, via **2** ($\equiv$ **2′**) as an intermediate, are shown in Fig. 7. The barrier height is 20.52 kcal/mol in this case so that path *A*, with stepwise rotation and pyramidal inversion, is clearly the route of topomerization of $^{-}CH_2OH$. Moreover, of the two events depicted in Fig. 7, rotation about the C—O bond requires less energy. The topomerization of $^{-}CH_2OH$ may, therefore, be described as (pyramidal) inversion-dominated. This conclusion would not be affected by the addition of d-type functions to carbon or the simultaneous addition of d-type functions to carbon and p-type functions to hydrogen, because these cause an increase in the inversion barrier (22).

The rotational potential of $^{-}CH_2OH$, shown in the bottom curve of Fig. 5, corresponds closely to that of H_2NOH, shown in Fig. 1. It is very probable, therefore, that the conclusion just reached for $^{-}CH_2OH$ can be extended to H_2NOH. Indeed, it has been demonstrated experimentally that degenerate racemization of alkyl-substituted hydroxylamines is an inversion-dominated process (23).

It is now of interest to inquire into the factors which can be expected to govern the mechanism of degenerate racemization in the general case $R_nX—YR_m$ (n, m = 1, 2; X, Y = C^-, N, O, P, S) (**5**). The following empirical observations facilitate the discussion:

(*i*) For rotation-dominated processes, two-fold barriers are in the range 10 ± 5 kcal/mol (H_2O_2 (24), H_2S_2 (25), N_2H_4 (26), FCH_2OH (2)), three-fold barriers are in the range 5 ± 3 kcal/mol (27) (C_2H_6, C_2H_5F, CH_3NH_2), and six-fold barriers are in the range 0–1 kcal/mol (9, 10).

(*ii*) For pyramidal inversion-dominated processes, barriers associated with central atoms of the First Row are almost an order of magnitude less than those associated with atoms of the Second Row (CH_3^- (5.2 kcal/mol; (22)) < SiH_3^- (39.9 kcal/mol; (28)); NH_3 (5.5 kcal/mol (29)) < PH_3 (37.2 kcal/mol; (30)); OH_3^+ (<1 kcal/mol; (31)) < SH_3^+ (28 kcal/mol; (32)).

(*iii*) Directly attached electron-withdrawing substituents cause an increase, and electron-releasing substituents a decrease in barriers to pyramidal inversion (33–36). Symmetrical systems of the First Row ($C_2H_4^{-2}$ (3), hydrazines (37, 38)) show slightly increased ($\sim$2–3 kcal/mol barriers to pyramidal inversion (relative to the corresponding methyl or hydrogen-substituted analogs (36)) because of electron pair – electron pair repulsive interactions which, in general,

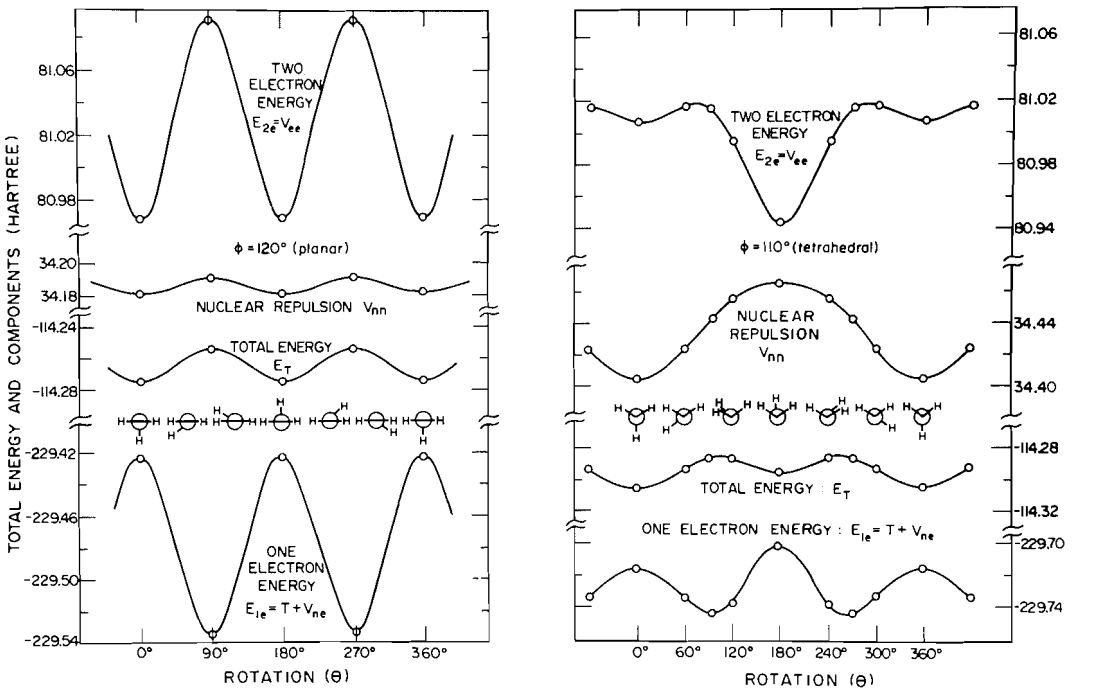

FIG. 6. The total energy of $^{-}CH_2OH$ and its components associated with rotational cross-sections through $\phi = 120°$ (planar geometry at carbon) and $\phi = 110°$ (tetrahedral geometry at carbon).

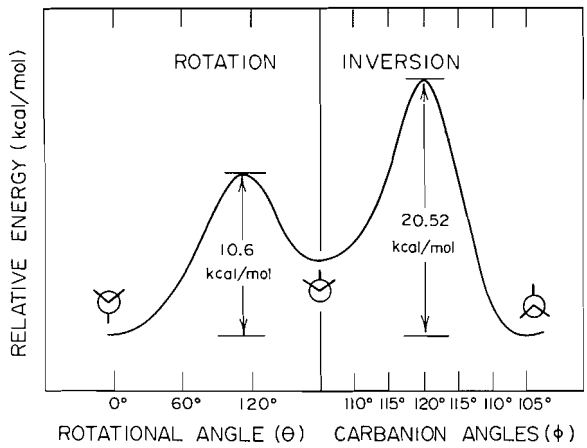

FIG. 7. The energetics of the preferred route of degenerate racemization of $^{-}CH_2OH$.

have less effect than electronegativity differences. Surprisingly, symmetrical systems below the First Row (diphosphines (26.2 kcal/mol; (39)), diarsines (27 kcal/mol; (40)) are reported to have *lower* inversion barriers than the parent phosphines and arsines (42–46 kcal/mol (34)).[1]

[1]For a "modicum of doubt" concerning the diarsine value, see ref. 34*a*; and for evidence that the value quoted for diphosphine actually refers to an association–dissociation process, see ref. 34*b*.

(*iv*) p_π–d_π conjugative effects have relatively little effect on barriers to pyramidal inversion (33, 34), but p_π–p_π conjugation can confer substantial stabilization upon the planar intermediate in the inversion process (41, 42) and, thus, cause a decrease in the barrier.

In view of the relative magnitudes of the barriers, it can be seen that when X or Y is an atom below the First Row, and pyramidal inversion at this center is possible, this will be the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dominant process associated with degenerate racemization. The situation is more interesting when the inversion center is an atom of the First Row because rotation and inversion have comparable barriers. The electron pair repulsive effects noted above cause inversion to be dominant in $C_2H_4^{-2}$ and in hydrazines. The electron-withdrawing effect of oxygen (χ_C, 2.55; χ_N, 3.04, χ_O, 3.44 (43)) causes a sufficient increase in the barrier at adjacent carbon or nitrogen to make pyramidal inversion at these centers the dominant process in $^-CH_2OH$ and substituted hydroxylamines. However, the electron-releasing effect of sulfur (χ_S, 2.58 (43)) has the opposite effect on adjacent nitrogen and, in sulfenamides, degenerate racemization is rotation dominant (44). Aminophosphines (χ_P, 2.19 (43)) have a trigonal planar structure at nitrogen (11) because of the substantial electron release from P to N.

Relationship of the Present Results to the gauche Effect

The formal definition of the *gauche* effect given in the Introduction predicts the W conformation **2** to be more stable than the Y conformation **1**. This prediction is incorrect. Although **2** is a minimum on the rotation–inversion surface, it is 6.67 kcal/mol less stable than **1**. We believe (2, 3) that the *gauche* effect of adjacent electron pairs is the result of a tendency of these electron pairs to behave as though they have no stereochemical significance, *i.e.*, a quasi-spherical structure. According to this view, termed rule 3 of the *gauche* effect, the tendency towards the *gauche* effect is bond pair – bond pair > bond pair – lone pair > lone pair – lone pair. Although this formulation has predictive utility (1) it should be noted that it is based on the electronic component of the total energy term. This quantity, E_T, contains, besides the electronic component ($E_{elec} = V_{ne} + V_{ee} + T$), the nuclear–nuclear repulsion term ($V_{nn} = V_{nucl}$).

The total energy difference between **1** and **2** is given by

$$\begin{aligned}\Delta E_T &= E_T^1 - E_T^2 \\ &= (E_{elec}^1 + E_{nucl}^1) - (E_{elec}^2 + E_{nucl}^2) \\ &= (E_{elec}^1 - E_{elec}^2) + (E_{nucl}^1 - E_{nucl}^2) \\ &= \Delta E_{elec} + \Delta E_{nucl}\end{aligned}$$

The data of Table 1 indicate that, at each of the C—O bond lengths examined in the present work, ΔE_T and ΔE_{nucl} are negative quantities and ΔE_{elec} is positive. Consequently, the more crowded conformation **2** is stabilized relative to **1** by a more negative electronic term and, at the same time, is destabilized by a more positive nuclear term. The balance between the two effects is such that nuclear–nuclear destabilization outweighs the electronic stabilization. Figure 8 shows these changes in $-\Delta E_T$, $-\Delta E_{nucl}$, and Δ_{elec} as a function of C—O bond length. It is evident that the energy difference between the two upper curves ($-\Delta E_T = -\Delta E_{elec} - \Delta E_{nucl}$) has its maximum numerical value in the region of the optimized C—O bond length (1.500 Å). As the C—O distance increases, both ΔE_{nucl} and ΔE_{elec} decrease numerically, and their sum, ΔE_T, also decreases numerically because ΔE_{nucl} is more greatly affected by the change in the bond length.

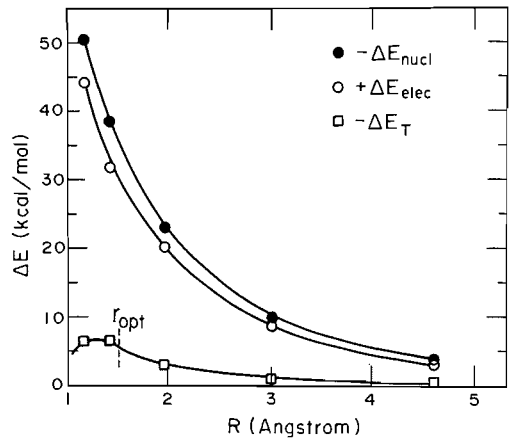

FIG. 8. A plot of ΔE_{elec}, $-\Delta E_{nucl}$, and $-\Delta E_T$ ($\Delta E = E_1 - E_2$) for conformations **1** and **2** as a function of C—O bond length.

These considerations reveal that there may be exceptions to rule 3 of the *gauche* effect (45, 46) depending on the balance between the nuclear and electronic terms which, in turn, will depend upon both the internuclear distance and the sizes and types of ligands attached to the central atoms X and Y (*cf.* **5**).[2] It should also be noted that this analysis of the structure of $^-CH_2OH$ in terms of nuclear and electronic interactions is a conformational analog of the stretching potential of a diatomic system. This type of analysis seems to have general utility (47).

[2]In $^-CH_2SH$ the W conformation is more stable than the Y conformation because $\Delta E_{elec} > \Delta E_{nucl}$ (7, 48).

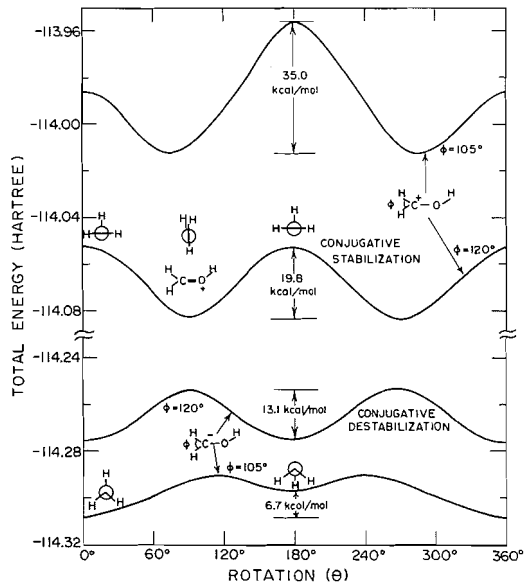

FIG. 9. A comparison of the rotational potentials of $^{-}CH_2OH$ and $^{+}CH_2OH$ at $\phi = 105°$ and $\phi = 120°$.

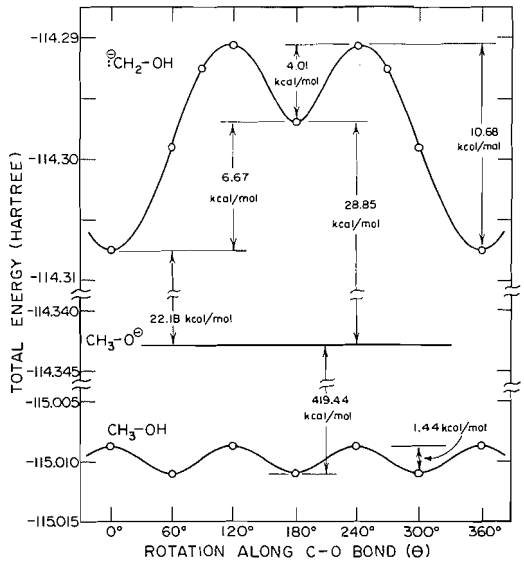

FIG. 10. The energy of CH_3O^- and the rotational potentials of CH_3OH and $^{-}CH_2OH$ (at $\phi = 105°$).

Figure 9 shows the rotational potentials of $^{-}CH_2OH$ and $^{+}CH_2OH$ at $\phi = 105°$ (the optimized pyramidal angles of the anion) and at $\phi = 120°$ (the optimized angles at carbon for the cation). The 120° curves show the contrasting effects of *conjugative stabilization* (19.8 kcal/mol with respect to the reference state $\mathbf{4}^{+}$) and *conjugative destabilization* (49, 50) (13.1 kcal/mol with respect to the reference state $\mathbf{4}^{-}$). As expected, the two curves have opposite phase. The 105° curves also have opposite phase.

Tautomerization of $^{-}CH_2OH$

Figure 10 shows the rotational potentials of methanol (9), $^{-}CH_2OH$ in its most favored pyramidal configuration at carbon ($\phi = 105°$), as well as the energy of methoxide ion (9). The energetics associated with the removal of a methyl proton from CH_3OH are 441.62 kcal/mol and the resulting anion, $^{-}CH_2OH$, is 22.18 kcal/mol less stable than its tautomer CH_3O^-. Although this latter energy difference is in the range expected for a ground state process, we considered that the transition state for tautomerization (*cf.* eq. 3) might not be accessible in a thermal process. It was of interest, therefore,

[3] 

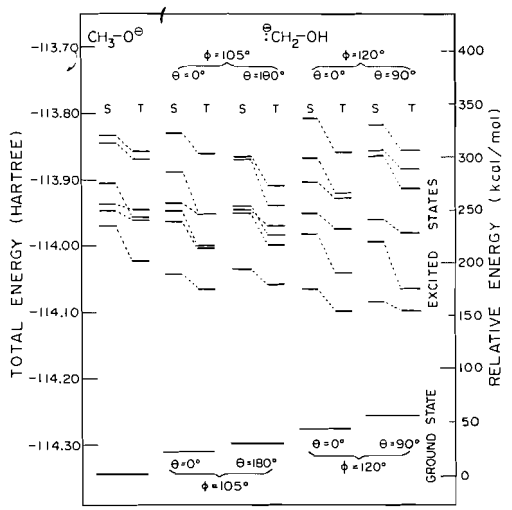

FIG. 11. A comparison of singlet and triplet energy levels of CH_3O^- and $^{-}CH_2OH$.

to examine the possibility of inducing tautomerization photochemically.

Comparison of the energy levels of CH_3O^- (first two columns of Fig. 11) with those of $^{-}CH_2OH$ shows that all conformations of the carbanion are stabilized relative to CH_3O^- in the low-lying excited states. Figure 11 also shows a reversal of ground state conformational properties of the carbanion similar to that noted for FCH_2OH (51). This effect is sufficiently large

to cause the ground state structure (3) corresponding to conjugative destabilization to become the most stable structure in the excited states.

A more detailed analysis of the energetics associated with the photochemical interconversion of CH_3O^- and $^-CH_2OH$, and their relationship to the relative ease of abstraction of the O—H and C—H protons of CH_3OH, is in preparation.

We thank the National Research Council of Canada for financial support of this work and for the award of a Special Grant.

Dihedral Angular Dependence of H—N—C—H Coupling Constants. Protonated Amines in Trifluoroacetic Acid

ROBERT R. FRASER, ROGER N. RENAUD,[1] JOHN K. SAUNDERS,[2] AND YUK Y. WIGFIELD

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received February 12, 1973

Measurements of vicinal H—N—C—H coupling constants in the conjugate acids of two tertiary amines having known rigid conformations provide support for the validity of the Karplus relation for this type of coupling constant. Seven vicinal coupling constants agree to within 0.5 Hz with those calculated from the expression $J = 9.8 \cos^2 \phi - 1.8 \cos \phi$.

Les mesures des constantes de couplage H—C—N—H dans les acides conjugués de deux amines tertiaires de conformations rigides connues permettent d'établir la validité de la relation de Karplus pour ce type de constante de couplage. Sept constantes de couplage vicinal sont en accord, à 0.5 Hz près, avec celles calculées utilisant l'expression $J = 9.8 \cos^2 \phi - 1.8 \cos \phi$.

It is well known that, under conditions of slow exchange, vicinal H—N—C—H coupling constants are observed in the n.mr. spectra of the conjugate acids of alkylamines (1). Such conditions obtain when spectra of alkyl or aryl amines are determined using trifluoroacetic acid (TFA) as solvent (2, 3). An extensive survey of the difference in chemical shift between protons α to nitrogen in amines versus their conjugate acids in TFA was carried out by Ma and Warnhoff (3). In addition to providing characteristic shift data, they pointed out that the multiplicity of the signal for the α-protons revealed the primary, secondary or tertiary nature of the amine. Subsequently, little advantage has been taken of TFA as a solvent for n.m.r. studies of amines. Surprisingly also, very little data concerning the angular dependence of H—N—C—H coupling constants in this solvent has appeared (*vide infra*). We wish to describe the measurement of a number of these coupling constants and the assessment of their adherence of the Karplus relation (4).

The Karplus relationship is undoubtedly the most general and useful stereochemical relationship in n.m.r. spectroscopy. In a recent review (4), Anet and Anet document the large number of cases in which H—X—Y—Z systems exhibit a dependence of the magnitude of the H–Z coupling constant on the dihedral angle between the H—X and Y—Z bonds. In addition a number of more recent papers offer further examples of a Karplus type behavior of the vicinal coupling constants in the $^{19}F—C—C—H$ (5), $^{13}C—O—C—H$ (6), $^{13}C—N—C—H$ (6), $^{31}P—S—C—H$ (7), P—O—C—H (8), $^{199}Hg—C—C—H$ (9), and $^{13}C—C—O—^{31}P$ (10) structural units. The exact form of the Karplus equation varies considerably, a number of different geometric expressions to approximate the $[\cos]^2$ dependence of J on the dihedral angle ϕ having been utilized (11–13). We will employ the form $J = A \cos^2\phi + B \cos\phi + C$(14). Refinements of the equation to include the effects of orientation of electronegative substituents (15) need not be considered here.

Both experimental (16–19) and theoretical (19) evidence has been presented that H—C—N—H coupling constants in amides have a dihedral angular dependence. The same is likely true for H—C—N—H couplings when the nitrogen is tetracoordinate and positively charged. The first such indication was described by Lambert and coworkers (20) who ascribed the observed splittings of 10.0 and 2.3 Hz in the $^{+}NH_a—CH_a$ portion of *N*-methylpiperidinium ion to J_{aa} and J_{ae} respectively. Subsequently values for J_{aa} of 7.5–9.6 and for J_{ae} of 1–2 Hz have been reported for a variety of nitrogen heterocycles by several groups of workers (21–

TABLE 1. N.m.r. spectral parameters for 0.2 *M* solutions of **1** and **2** in TFA

	Chemical shifts*						Coupling constants† (Hz)						
Compound	H_A	H_B	H_C	H_D	H_M	H_X	AB	AX	BX	CD	CX	DX	MX
1	3.43	4.26	3.92	4.09		8.0‡	−12.1	10.0	3.9	−13.0	0.0	4.6	
2	4.69	5.17			5.78	8.0	−14.0	7.8	6.0				7.5

*Reported on the δ scale (p.p.m. downfield from TMS).
†Both **1** and **2** in TFA showed a coupling constant of 5.3 Hz for $J_{H-\overset{+}{N}-CH_3}$. No resolvable long-range coupling could be detected for either compound.
‡Not observable, but has been seen at δ 8.0 (23) when the rate of relaxation at nitrogen is sufficiently rapid.

23, 36). Since the existing data is limited to examples of vicinal couplings between protons having $\phi = 60$ or 180° in flexible six-membered rings whose chair–chair equilibria could not be precisely determined, we have examined the H—N—C—H couplings in two protonated amines in which five different dihedral angles are present. The results support the originally proposed (20) Karplus relation for these coupling constants.

Previous studies in this laboratory involved the synthesis of two conformationally fixed tertiary amines: the bridged biaryl amine, **1** (24) and the isoindoline, **2** (25). Dissolution of **1** in TFA produces a single conjugate acid which possesses two asymmetric structural features. Rotation about the bond joining the two aromatic rings is prevented by the ortho-methyl groups (26) thus preserving the biaryl asymmetry. And since deprotonation of the conjugate acid of **1** is slow on the n.m.r. time scale, the nitrogen atom acts as a pseudoasymmetric center. For these reasons the n.m.r. spectrum of **1** in TFA shows separate signals for each of the four protons α to nitrogen.[3] Each of these is coupled with the N—H proton and with its diastereotopic partner. The spectrum was rigorously analyzed as an ABCDX spectrum to yield the parameters listed in Table 1.

Measurements on a Dreiding model of **1** indicate the protons of one methylene group to have φ's of 40 and 160° (±5°), and those of the other methylene group to have φ's of 40 and 80°. Assignment of the n.m.r. signals is made in the following way. The largest vicinal coupling, J_{AX}, is attributed to the proton having $\phi = 160°$ on the basis of the previous results (20–23). H_B, the diastereotopic partner of H_A, is identified by its geminal splitting with H_A. Since H_D has a vicinal splitting of the same magnitude as H_B, it is assigned to the proton having the same φ as H_B (40°). The remaining proton H_C has $\phi = 80°$. These assignments are illustrated in the three-dimensional formulae of Fig. 1.[4]

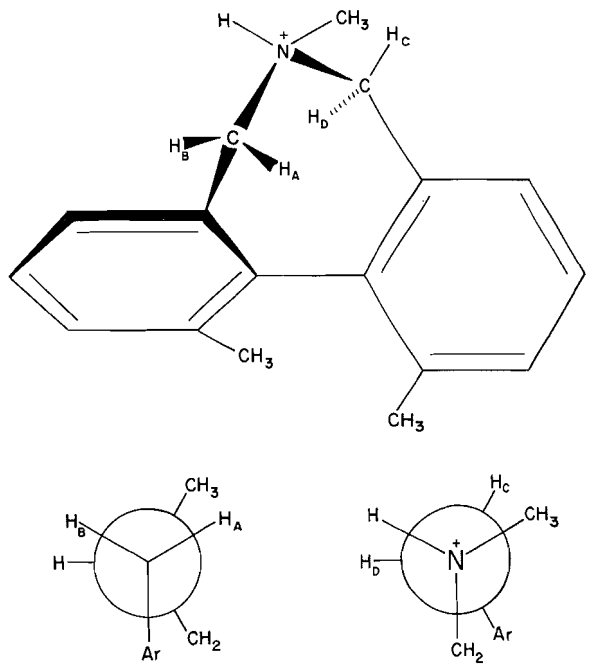

FIG. 1. A three-dimensional representation of **1**-H^+ in TFA showing the proton assignments.

[3]The spectrum was measured during simultaneous spin-decoupling of the ^{14}N nucleus and also the aromatic protons. This reduced the line-widths of the α-protons from 0.6 to 0.2 Hz.

[4]The three alternative assignments all lack any correlation between $J_{H-N-C-H}$ and φ. In view of the widespread adherence of vicinal coupling constants to the Karplus relation these alternatives appear highly unlikely.

	H_B	120	6.0	3.3 (6.2)*
1 and **2**	$\overset{+}{N}—CH_3$	$\frac{2(60°) + 180°}{3}$	5.3	4.9

*Calculated for the conformation of 2 in which there is a distortion of 15° from complete planarity.

The spectrum of **2** in TFA reveals the presence of two conjugate acids in a ratio of 4:1. Accurate peak measurements were possible for the absorptions due to the major isomer only. Analysis of the $CH_2—\overset{H}{\overset{|}{\overset{+}{N}}}$ pattern as an ABX system gave the parameters listed in Table 1. The two methylene protons show unequal coupling (6.0 and 7.8 Hz) to the proton on nitrogen in **2**-H^+. It is usually found that in five-membered heterocyclic compounds $J_{cis} > J_{trans}$ (4). Exceptions to this rule[5] are limited to a few saturated heterocycles (27, 28) and in one case an unsaturated heterocycle studied by Anet and Muchowski (30). They observed $J_{trans} = J_{cis}$ in the two isomeric 2,3-dimethylindolines. Nevertheless, sufficient examples of heterocycles with a double bond in the ring and having $J_{cis} > J_{trans}$ are known (31) to cause Anet and Anet to conclude that assignments on this basis are reliable (4). It is therefore reasonable to assign the *cis* configuration to the protons in **2**-H^+ which exhibit the larger vicinal coupling constant.

The methine proton in **2**-H^+ shows only one splitting of 7.5 Hz. This proton *is most likely*[6] *cis* to H_A since both are coupled equally with H_X. The assignments made on this basis are shown in Fig. 2. Finally, as Table 1 shows, in both **1** and **2** in TFA the $H—\overset{+}{N}—CH_3$ coupling is 5.3 Hz.

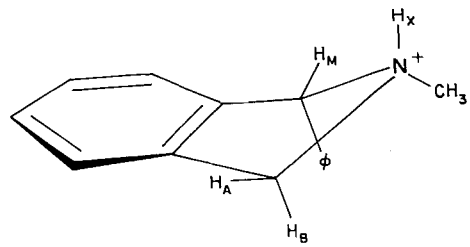

FIG. 2. The most probable configuration and conformation for the major isomer of **2**-H^+ in TFA.

Discussion

It is noteworthy that the vicinal H—C—N—H coupling constants in the conjugate acids of **1** and **2** vary considerably as do their respective dihedral angles. The best agreement obtainable between the observed J's and those calculated from the dihedral angle is provided by eq. 1.

$$[1] \qquad J = 9.8 \cos^2 \phi - 1.8 \cos \phi$$

As indicated in Table 2, agreement is obtained to within 0.5 Hz in all cases except for $J_{120°}$ in **2** which has $J_{exp} > J_{calcd}$ by 2.7 Hz. This particular deviation from eq. 1 is very likely due to a puckering of the five-membered ring as has been previously encountered in substituted indanes (32). If an angular distortion of 15° from planarity in the direction shown in Fig. 2 is assumed, then the calculated values (given in brackets in Table 2) for J in **2**-H^+ agree to within 0.5 Hz with the

[5]An apparent exception has been eliminated by the recent X-ray determination of the configuration of toxol (29).

[6]One might question the fact that this assignment requires the methyl and phenyl groups to be *cis* in the more abundant isomer. It is, however, most probable that the 4:1 ratio of the two conjugate acids reflects the relative rates of protonation of **2** from the two sides since Booth and Little have shown this to be a kinetically controlled process in a study of *cis*-3,5-dimethylpiperidine in TFA (23).

experimental ones. It can be concluded that the vicinal coupling constants determined herein have magnitudes consistent with the predictions of the Karplus relation, thereby providing support for the proposals of previous workers (20–23). Such dependence of J on geometry should prove to be of considerable value in the conformational analysis of amines.[7]

Without wishing to detract from the usefulness of the Karplus relation in the present instance, it is important to recall its limitations. Jackman and Sternhell (33) have discussed in considerable detail the different factors which can influence the magnitude of vicinal coupling constants. Difficulties in assessing the importance of factors other than dihedral angle led these authors to conclude that angles cannot be determined to better than 10° under the best of conditions using vicinal coupling constant data. Their conservative attitude must also apply to the present case.

Experimental

All n.m.r. measurements were made using a Varian HA-100 spectrometer equipped with an NMR Specialties SD-100 spin-decoupler. Line positions were obtained from an average of five measurements and are accurate to better than 0.15 Hz. Coupling constants obtained from the exact analysis will have similar accuracy. Melting points are uncorrected. Calculation of the ABCDX system was carried out using the NMR CAL program on a Nicolet 1083 computer.

N-Methyl-6,7-dihydro-1,11-dimethyl-5H-dibenz[c,e]-azepine (1)

This compound was prepared by methylation (Clarke–Eschweiler) of the corresponding secondary amine (24) in essentially quantitative yield. The product, after crystallization from methanol–water, had m.p. 93–94°; (lit. (26) m.p. 50.5–52°); n.m.r. (δ scale) 2.15 (6H, s) 2.25 (3H, s) 3.17 (4H, AB_q, J = 12) 7.1–7.3 (6H, m).

In view of the discrepancy between its melting point and that previously reported, **1** was converted to its methiodide which, after crystallization 4 times from ethanol, had m.p. 258–259° (lit (26) m.p. 256°).

Anal. Calcd. for $C_{18}H_{22}NI$: C, 56.98; H, 5.85, N, 3.69. Found: C, 56.65; H, 6.13; N, 3.61.

2-Methyl-1-phenylisoindoline (2)

The synthesis of this compound has been reported previously (35).

[7]With the aid of these vicinal coupling constants, the conformation of *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz-[*d*, *f*]azocine could be unambiguously determined (34).

The Electrical Polarizations of Mercuric Chloride and Dimethylmercury

HELMUT HUBER AND GEORGE F WRIGHT

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received November 17, 1972

The apparent dipole moments calculated from solutions of mercuric chloride and dimethylmercury have been found to alternate between high and low values over the temperature range extending from 8.5 to 50 °C. The significance of this alternation is discussed.

Les moments dipolaires apparents calculés pour des solutions de chlorure mercurique et de diméthylmercure alternent suivant la température qui varie de 8.5 à 50 °C, entre des valeurs hautes et basses. L'importance de cette alternance est discutée. [Traduit par le journal]

Introduction

A quandary arose in 1934 when it was found (1) that diphenylmercury and some 4,4′-disubstituted derivatives which would appear structurally to be centrosymmetric (therefore devoid of moment) did in fact exhibit total electrical polarizations which might be interpreted as evidence for dipole moments. Shortly this apparent anomaly was interpreted as abnormally high atom polarization (P_A) (2) but later a method for measuring P_A was devised (3) and perfected. Insofar as these measurements are meaningful they indicate that the candidate compounds do not display abnormally high atom polarizations. The difference between the total polarizations and the sum of the measured P_A plus the estimated electron polarization (P_E) must then according to the Debye concept (2) be attributed to orientation polarization (P_0). The latter is expressed by the Debye construct as dipole moment.

In any circumstance the combined $P_A + P_E$, *i.e.* the distortion polarization (P_D), by the Debye construct ought to be practically temperature independent. Therefore the total polarizations of solutions in media of low or unmeasurable dipole moment containing diphenylmercury (4), benzoquinone (5), 1,4-dinitro-benzene (6), and other substances (7) were determined over a range of temperatures extending from 8.5 to 50°. As might be expected the total polarizations differed in respect of temperature. However, unexpectedly the dipole moments calculated from these total polarizations also were temperature-dependent. Because the latter phenomena are not in accord with the Debye construct they have been described as apparent dipole moments. Recently 1,4-dicyanobenzene (9) has been included in the same category.

In order to explain this temperature dependence it has been proposed (8) that the ostensibly-symmetric substances are in fact excited to dissymmetric states which react with the electric field to show an orientation polarization. The extent of P_0 can be accounted for only if it be assumed that 20–40% of the molecules are excited. The ambient environment ought amply to supply the necessary energy. Moreover the variation in apparent moment must be related to the temperature of the environment.

We have sought a correlative phenomenon to relate to this temperature-dependence and have found only that the substances which display it all have strong absorption bands in the 50–200 cm^{-1} spectral region. Moreover these absorption bands have been found to change markedly in intensity over the temperature range of 79–313 °K. This intensity variance has been reported in detail for 1,4-dicyanobenzene (9).

It must be pointed out that the absorbances, which are too broad for detailed analysis, have been determined in the absorption spectrometers currently available.

No obvious way of demonstrating the hypothesis for temperature-dependence of dipole moments has heretofore been apparent to us. First our temperature range for measurement has been limited at best to 8.5–50 °C. Second some of the apparent moments increase with increasing temperature while others decrease. It seems obvious that the molecular species which we have examined are too complex for simple interpretation.

Consequently we have sought simpler candi-

dates. The first to be examined is mercuric chloride, with only 4 degrees of freedom. A polarization greater than that expected for this nominally-linear molecule has earlier been reported (10) and has been attributed to non-linearity of Cl—Hg—Cl in benzene solution.

We have first examined the possibility that this "abnormal" polarization might be due to high distortion polarization, $P_E + P_A = P_D$. This determination of P_D in solid wafers (where P_0 is not expected) was at first fraught with difficulty. Although mercuric chloride is largely unionized, even in aqueous solution, we found that a reaction occurs between the mercury in our Au–Hg amalgam (3) and mercuric chloride. This reaction inactivated our electrical circuit. However it has been found that the interposition of a very thin layer of Petrolatum between the amalgam and the wafer prevents this reaction and permits a precise determination. The plot of apparent dielectric constant *vs.* wafer thickness is linear leading to an extrapolated ε at zero thickness of 5.560. The density (5.44 at 20°) has been determined by air displacement in the apparatus earlier described (11), so the distortion polarization is found to be 30.1 cc. Since the molecular refraction calculated according to Eisenlohr is 24.7 cc the difference, P_A, is 5.4 cc. This is appreciable (18% of P_D) but it cannot account for the polarization in solution.

The total polarization of mercuric chloride in benzene solution has been determined from 8.5 to 50 °C at 13 different temperatures. Because of the low solubility at least five complete determinations were made at each temperature. The results are presented in Table 1, and these results are plotted in Fig. 1. The dipole value for 50° is not included because the imprecision is greater than those shown by the vertical limits drawn in the figure. It may be noted in Table 1 that in consideration of the values for dipole moment with respect to temperature for this triatomic molecule there is a difference from those of the more complex substances examined previously. It may be seen that this apparent moment of mercuric

chloride increases, and then decreases twice over the temperature range examined.

For further consideration of this behavior it may be informative to refer to the far-i.r. absorption spectrum shown in Fig. 2. The lowest frequency band shifting from 76 to 77 cm^{-1} during a temperature change from 313 to 79 °K in the solid state has its counterpart (at 70 cm^{-1}) in the vapor-phase spectrum (12) of this substance (attributed to molecular bending) but the very broad band (dv = 38 to 44 cm^{-1} from 313 to 79 °K) is not mentioned by Klemperer and Lindemann and is observed only in the condensed state where its peak shifts from 105 to about 110 cm^{-1} over the same temperature range. If the 76–77 cm^{-1} band represents the Cl—Hg—Cl bending frequency (12) in all states then the broad band of large integrated intensity at 105–110 cm^{-1} would seem to be a complex of excitations characteristic of bending in the condensed state. The greater-than-twofold increase in intensity for this band at 79 °K *vs.* 313 °K would indicate that these excitations are characteristic of the higher temperature; *i.e.* a greater population at −194° is in the ground state and thus available for excitation by the imposed radiation of the spectrometer.

If indeed these excited states were distributed between unsymmetrical ones which can be oriented by the electromagnetic field at 0.5 MHz and symmetrical ones which cannot be so oriented then the relative populations of these states at different temperatures would be expected to affect the apparent moments shown in Fig. 1. Specifically one might conclude that the ambient temperature at 25 °C contributes largely to symmetrical excited states by contrast to those at 14 and 34 °C which contribute largely to unsymmetrical states. It is unfortunate that the limitations of our technique preclude examination outside the +8.5–50° range; the cyclic behavior might continue in either direction.

The case of mercuric chloride is a special one. Polarization studies with mercuric bromide in benzene show only a downward trend of apparent moment with increasing temperature. The results, shown in Table 2 are based on a measured distortion polarization of 37.3 cc. It may be significant that the far-i.r. spectral absorption, shown in Fig. 3, occurs at frequencies of 50 and 72–74.5 cm^{-1}. The band at 50 cm^{-1} probably corresponds with that observed at 41 cm^{-1} by Klemperer and Lindemann at 973 °K. Both bands are approximately of equal width and equal intensity at 313 °K. The increased intensity

at 79 °K is less than doubled. So mercuric chloride and bromide behave differently.

On the other hand the polarization behavior of dimethylmercury resembles to some extent that of mercuric chloride. This more complex substance, being a liquid, cannot be examined spectroscopically by our i.r. equipment in condensed states because of general background absorption, either pure or in benzene or carbon tetrachloride. Likewise laser-induced Raman spectra are uninformative, either in the liquid state at 313 °K or when rapidly condensed from vapor to solid at 79 °K. However the measurements of electrical polarization as recorded in Table 3 show the cyclic temperature dependence. The change of moment is idealized in Fig. 4 as interconnected points, each representing the average of at least five complete determinations. As might be expected the magnitude of apparent moment is greatest in dioxane and least in cyclohexane, benzene being intermediate.

Thus two relatively simple candidates show an alternating dependence in moment upon changes of near-ambient temperatures. Other temperature-dependent moments have not shown such alternating behavior. But in retrospect we were originally probably misled by the apparent linearity in moment-diminution for benzoquinone (5) with increasing temperature. Certainly the similar variation for diphenylmercury

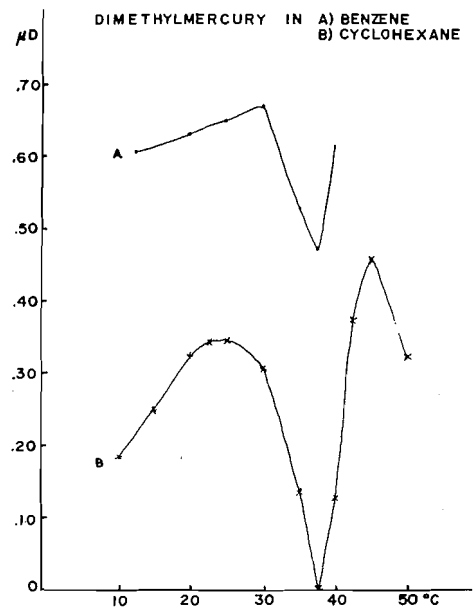

FIG. 4. Dipole moment *vs.* temperature.

(4), for 1,4-dinitrobenzene (6) and other complex substances has not shown a linear relationship. We do not know how the values of these moments change at temperatures outside the range of our instrument (13).

Some may ask why this moment-temperature dependence has not been observed for the large

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

number of substances whose moments have been determined (14). We suggest that such variations may be hidden within polarizations due to permanent moments. They may be observable when precision of measurement exceeds by an order of magnitude our present ± 0.001 pF. Extension of the temperature range by pressurization of the test-capacitance may also be helpful.

It may also be asked whether in view of simpler physical methods for determination of molecular structure it is worthwhile to pursue the tedious techniques of electrical polarization measurements at various temperatures. We have tried to assemble an instrument in which the specific volume and the dielectric constant of a single sample could be determined for a range of temperatures at one time, within the present limits of precision during the time period (30 min) needed for a determination We have not been successful. but in principle such an instrument could be built. An air capacitance of about 1000 pF would be desirable.

Finally it may be asked whether, in view of the relatively-simple though less precise determination of electrical polarization in the gaseous phase, there is sufficient information to be gained from the condensed phases to warrant study. From the viewpoint of the chemist the appreciable number of chemical reactions that occur in the liquid phase is a sufficient answer.

Experimental

The techniques used in this study have been outlined previously (13, 6, 3). Mercuric chloride and bromide have been crystallized from ethanol before use. Dimethylmercury was purified by distillation at 96 °C.

Solute Radical Inactivation of the Sulfhydryl Enzyme Papain – Sensitization and Protection[1]

G. M. GAUCHER, BARBARA L. MAINMAN, AND D. A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4
Received January 12, 1973

Particularly pure N_2O-purged papain solutions (2×10^{-5} *M*; p*H* 6.8) were irradiated at 0 °C for different times with ^{60}Co γ-rays, in the presence of 10–30 m*M* solutions of acetate, isobutanol, and thiocyanate. In comparison to OH radicals, these solute radicals substantially enhanced papain inactivation. Calculated inactivation probabilities per papain–radical reaction (*i.e.* 0.43 for OH and 1.00 for solute radicals) support this finding.

In situ protection of both N_2-purged and N_2O saturated papain solutions by cysteine was found to occur only at cysteine: papain molar ratios above 15:1, while below this ratio substantial sensitization occurred, reaching a maximum at a 2:1 ratio. This enhanced inactivation of papain at low cysteine concentrations is primarily repairable in nature, and probably due to CysS· attack on papain's active site sulfhydryl. Only at relatively high cysteine:papain ratios (>30) can protection be ascribed simply to radical scavenging.

Des solutions particulièrement pures de papaine, libérées de N_2O, (2×10^{-5} *M*; p*H* 6.8) furent irradiées à 0 °C pendant des temps variables avec des rayons-γ ^{60}Co, en présence de solutions 10–30 m*M* d'acétate, d'isobutanol, et de thiocyanate. En comparaison des radicaux OH, ces radicaux dissous favorisent de manière significative l'inactivation de la papaine. Les probabilités calculées d'inactivation par réaction radical–papaine (*i.e.* 0.43 pour OH et 1.00 pour radicaux dissous) sont en accord avec les résultats trouvés.

La protection *in situ* des solutions de papaine, libérées en N_2 et saturées en N_2O, par la cystéine n'est seulement valable que pour un rapport molaire cystéine:papaine supérieure à 15:1 alors qu'en-dessous de ce rapport une sensibilisation non-négligeable se produit et atteint un maximum pour un rapport 2:1. Cette inactivation favorisée de la papaine à des concentrations faibles en cystéine est principalement reparable dans la nature et semble causée par l'attaque du CysS· sur la fonction sulphydryle composant le site actif de la papaine. On ne peut avoir une protection assimilable au trappage radicalaire par la cystéine qu'à des rapports relativement élevés cystéine:papaine (>30). [Traduit par le journal]

Can. J. Chem., **51**, 2443 (1973)

Introduction

A previous publication (1) from this laboratory reported a study of the radiolysis of the sulfhydryl protease, papain, in dilute aqueous solutions. The overall radiation sensitivity of the enzyme was high compared to that of other enzymes, but, as in earlier work (2), it was found that a substantial fraction of the inactivated papain molecules could be reactivated by post-irradiation chemical repair with 1000-fold excess of cysteine. From a comparison of *G* (inactivation) in N_2O-saturated and N_2-purged solutions it was concluded that e_{aq}^- was more effective in deactivating papain than OH and that it also gave a higher yield of repairable inactivation.

The papain solutions used in this early work were 10^{-2} *M* in sodium acetate (p*H* 6.9) and contained two species of protein, active and inactivatable papain, at a total concentration of 2.1×10^{-5} *M*. In addition to recent chromatographic developments (3) which have made it possible to obtain much purer papain preparations, we have found it possible to omit the sodium acetate and hence irradiate essentially solute-free papain solutions. These changes represent a considerable simplification of the system and we have therefore redetermined the inactivation yields. The experimental procedures and results will be given in greater detail elsewhere. The purpose of this paper is to report the extremely high specificity of $\cdot CH_2CO_2^-$, isobutanol radicals, and certain other radicals for the inactivation of papain. The results are of considerable interest since the high concentration of organic molecules in the cytoplasm of living cells will undoubtedly provide large numbers of aliphatic and other free radicals — not only through direct action, but also by the scavenging of OH, H, and e_{aq}^- formed from water. The present data show that such solute radicals are potentially highly damaging to macromolecular

targets such as sulfhydryl enzymes, and they shed further light on the phenomenon of protection.

Experimental

The present experiments were carried out with a standardized preparation of high activity papain for which the average k_{cat} of 44 preparations was 11.50 ± 0.91 s^{-1} *vs.* a k_{cat} of 5–6 for commercial crystalline papain (1). Similar high activity papain preparations have recently been reported (4). In our presently utilized procedure, partially purified activated papain is bound to a papain-specific inhibitor linked to an agarose gel, which is supported in a chromatography column (3). After washing with eight column volumes of 2×10^{-2} *M* sodium acetate (p*H* 6), the active enzyme was eluted with N_2-purged double-distilled water and made up to the desired concentration immediately before use. The resulting solution contained less than 10^{-4} *M* sodium acetate.

All papain solutions were bubbled further with N_2 or N_2O and then transferred to radiation cells sealed from the atmosphere. After exposure to ^{60}Co radiation, aliquots were assayed for sulfhydryl content and enzymatic activity as previously described (1). The latter assay was carried out both with and without a post-irradiation preassay incubation with cysteine to effect repair (see above and ref. 1).

For nitrogen-purged solutions the above procedure gave the same *G* inactivation values as: (*a*) preparations in which the sodium acetate (p*H* 6) wash solution was replaced with a 2×10^{-2} *M* $NaClO_4$ solution, resulting in an even further reduction in the final acetate concentration, and (*b*) preparations in which the papain solutions in distilled water were made up to 2×10^{-2} *M* in $NaClO_4$ prior to irradiation. The identical yields observed in distilled water and in the presence of the radiochemically inert (5) $NaClO_4$ in *b* show that increasing the electrolyte concentration up to 2×10^{-2} *M* is without effect on the inactivation yields. However, since excessively high concentrations such as 0.1 *M* may have an effect, the electrolyte concentrations in the present experiments were kept $\leq 20 \times 10^{-2}$ *M*.

Results and Discussion

Figure 1 shows plots of the percentage residual activity *vs.* irradiation time for 2×10^{-5} *M* N_2O-purged solutions of papain containing various added solutes. Since all solvated electrons form OH in reaction 1, the total initial yield of OH

[1] $$e_{aq}^- + N_2O + H^+ \rightarrow N_2 + OH$$

radicals is 5.9 per 100 eV (6). From the known rate constants for the reactions of OH with papain (7), CNS^- and isobutanol (8) and assuming homogeneous kinetics, it can be shown for the conditions in Fig. 1 that ≥90% of OH would have undergone reactions 2–4 in preference to reaction with papain. For the case of acetate the

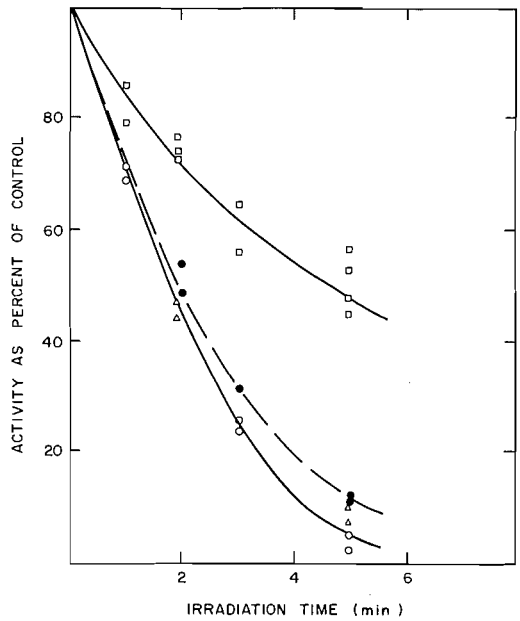

FIG. 1. Dose-inactivation plots for ~2×10^{-5} *M* aqueous papain solutions irradiated at 0 °C with ^{60}Co γ-rays at a dose rate of 5.75 ± 0.09 × 10^{16} eV ml^{-1} min^{-1} under N_2O and in the presence of various solutes. p*H* of acetate solutions = 6.9, all others = 6.2 ± 0.2. All enzyme activities were determined without post irradiation repair. □, no added solute; ○, 20 m*M* isobutanol; △, 10 m*M* NaSCN; ●, 20 m*M* Na Acetate.

[2][2] $$OH + C_4H_9OH \rightarrow H_2O + R\cdot$$

[3] $$OH + CNS^- \rightarrow OH^- + CNS\cdot$$

[4] $$CNS\cdot + CNS^- \rightarrow \cdot(CNS)_2^-$$

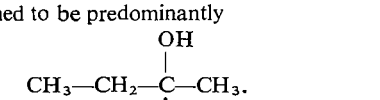
proportion undergoing reaction 5 under our conditions is about 65% (5, 8). The radicals

[5] $$OH + CH_3CO_2^- \rightarrow H_2O + \cdot CH_2CO_2^-$$

formed in reactions 2, 3–4, and 5 attack papain and the dose-inactivation plots in Fig. 1 clearly show that there is enhanced inactivation where OH is replaced by either $\cdot CH_2CO_2^-$, R·, or $\cdot(CNS)_2^-$.

The magnitude of *G* (inactivation) calculated from the initial slopes of plots such as those in Fig. 1 represents the combined damage caused by OH or the solute radicals formed from it, the hydrogen atom (G_H = 0.6 (9)) and molecular

[2]R· is assumed to be predominantly



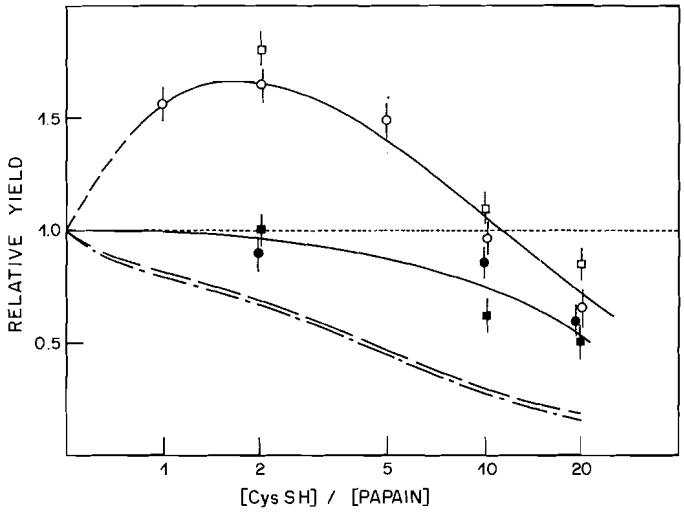


FIG. 2. Relative inactivation yields as a function of [CysSH]/[Papain]. Relative yield = G (inactivation, cysteine present)/ G (inactivation, cysteine absent). Solid and open points indicate relative yields for non-repairable and total inactivation respectively while circles and squares are for N_2- and N_2O-purged solutions respectively. The —·- line is the calculated fraction of OH radicals reacting with papain in N_2O-saturated solutions, and the — — line the corresponding fraction of total radicals (OH and e_{aq}^-) reacting with papain in N_2-purged solutions.

hydrogen peroxide ($G_{H_2O_2}{}^M = 0.75$ (9)). Redpath (10) has cited unpublished results which discount the importance of H as an inactivating agent and we shall also neglect it. Hydrogen peroxide on the other hand produces ~60% repairable and 40% non-repairable damage to papain (11). After allowing for these contributions the inactivation caused by each of the above radicals can be calculated and compared with the total yields of these radicals to give the net probability of papain inactivation per radical. These probabilities are given in Table 1.

The sulfhydryl group of cysteine 25 is essential to the activity of papain and analysis for this group (see ref. 1 for assay method) indicates that a large fraction of the inactivation by $\cdot CH_2CO_2^-$ occurs via the destruction of this cysteine residue, the initial attack being probably:

TABLE 1. Probability of inactivation per reaction of papain with various free radicals

Radical	Total inactivation	Non-repairable inactivation
OH	0.43±0.08	0.11
$\cdot(CNS)_2^-$	1.00±0.08	0.31
R· (isobutanol)	1.00±0.08	0.53
$\cdot CH_2CO_2^-$	1.00±0.08	0.54

[6] Papain—SH + $\cdot CH_2CO_2^- \rightarrow$

Papain—S· + $CH_3CO_2^-$

A similar situation occurs with the isobutanol radical and the enhanced inactivation observed here with $\cdot(CNS)_2^-$ is in agreement with a recent publication of Redpath (10). The high specificity of certain free radicals for the inactivation of papain is thus confirmed and extended by this report. Furthermore the fact that these radicals are either negatively charged or apolar is in agreement with the presence of positive (12) and apolar (13) sub-sites at the active site of papain.

There is considerable interest in the protection of biological molecules by cysteine and related thiols. In our earlier paper the protection of papain against non-repairable radiochemical damage was demonstrated using 6×10^{-5} M nitrogen-purged enzyme solutions and cysteine: papain ratios of 2:1, 5:1, and 10:1. Because of the possible complicating effects of the presence of both acetate and inactive papain in our earlier study, the phenomenon has been reinvestigated. In addition the measurements have been extended to include total and non-repairable damage in both nitrogen-purged and N_2O-saturated solutions. In these experiments cysteine concentrations were sufficiently low (see Fig. 2) compared to those routinely used under our

postirradiation repair conditions (*i.e.* a molar ratio cysteine:papain of 1000:1), so that any chemical repair by cysteine as in reaction 7, which is relatively slow (1, 14), would be

[7] PapainSSCys + CysSH → PapainSH + CysSSCys

negligible. Hence any protective effect of cysteine must be ascribed to faster reactions such as: (*a*) radical scavenging as in reactions 8, 8*a*, and 9

[8] $e_{aq}^- + CysSH \rightarrow Cys\cdot + SH^-$

[8*a*] $Cys\cdot + CysSH \rightarrow CysH + CysS\cdot$

[9] $OH + CysSH \rightarrow H_2O + CysS\cdot$

or (*b*) *in situ* repair of unstable papain radicals, as in reactions 10 and 11.[3]

[10] Papain—H + OH → Papain· + H_2O

[11] Papain· + CysSH → Papain—H + CysS·

G values for inactivation in the presence of various concentrations of cysteine were obtained from plots such as those in Fig. 1. The ratio *G* (inactivation, cysteine present):*G* (inactivation, cysteine absent), termed the "relative yield", is plotted against cysteine:papain in Fig. 2. Generally interpreted, relative yields of less than unity indicate protection, while those greater than unity indicate sensitization.

From the known (5, 7, 8) rate constants of reactions 9 and 10, and assuming homogeneous kinetics, one can calculate the fraction of OH which should react with papain at each cysteine:papain ratio. Likewise from the rate constants (5, 7) of reactions 8 and 12, the fraction of elec-

[12] $e_{aq}^- + Papain \rightarrow Papain^-$

trons reacting with papain can be calculated. The average of the two is given by the dashed line in Fig. 2 and should correspond to the fraction of total radicals (e_{aq}^- + OH) which attack papain in N_2-purged solutions. The OH fraction, given by the dot-dashed line, should correspond to the fraction of OH attacking papain in the N_2O-saturated solutions. If the products of reactions 8, 8*a*, 9, and 11 did not react with papain then the relative yields should follow these lines or even lie below them, if reaction 11 yields active papain. As can be seen, whether with or without post-irradiation repair, the relative yields both for N_2-purged and N_2O-saturated solutions all lie substantially above these lines, indicating that protection by straightforward radical scavenging does not occur. Also it should be noted that reaction 11 may yield inactive papain (see below).

Of particular interest is the observation that at low cysteine:papain ratios, where most OH (and e_{aq}^- in N_2-purged solution) react with papain, the relative yield for total inactivation shows a strong sensitization which reaches a maximum at cysteine:papain ≃ 2. There may be a number of factors contributing to this complex behavior. For example, adsorption of cysteine onto charged sites of the enzyme may alter the nature of the free radical reactions with papain, causing a higher inactivation efficiency. Also fixation of damaged papain rather than restoration to the active form is possible in reaction 11 (*cf.* the effects reported in ref. 17). However, almost all of the enhanced damage is repairable and this coupled with present knowledge (16, 18) of the radiation chemistry of SH compounds suggests that the formation of CysS· radicals in reactions 8, 8*a*, 9, and 11, and their subsequent attack on the enzyme is more important. Hence, we propose that the following reactions are involved.

At high cysteine:papain ratios or in the absence of papain, CysS· radicals would be expected (16, 18) to disappear through the reactions:

[13] $CysS\cdot + CysS^- \rightleftharpoons CysSS^-Cys$

[14] $CysS\cdot + CysSS^-Cys \rightarrow CysS^- + CysSSCys$

However, in the presence of papain and with low cysteine:papain ratios reactions 15 and 16

[15] $CysS\cdot + PapainS^- \rightleftharpoons PapainSS^-Cys$

[16] $CysS\cdot + PapainSS^-Cys \rightarrow CysS^- + PapainSSCys$

should be favored, since the pK_a of the SH group of papain will be lower than that of cysteine due to hydrogen-bonding interactions (12) at the active site. Since PapainSSCys is known (14) to be repairable via reaction 7 this could well explain the substantial enhancement of repairable damage. The fact that the relative yields with repair by CysSH are also above the dashed line in Fig. 2 suggests that CysS· radicals are also capable of causing non-repairable damage. These radicals are thermochemically more stable and

[3]This reaction has not actually been observed, but one assumes that it should proceed with a rate constant of about $10^6\ M^{-1}\ s^{-1}$ or larger as with lysozyme free radicals (15) and other large radical species (16).

thus less reactive than OH. In addition to the high selectivity for RS^- anions, CysS· may have an affinity for papain's active site imidazolium ion by virtue of its carboxylate anion (12). This and other reactions with other amino acid residues located in close proximity to this imidazolium ion could lead to the observed non-repairable inactivation.

Further investigations are underway to pinpoint more clearly the reasons for the sensitization of papain inactivation at low cysteine concentrations. However, the present work has clearly demonstrated that the protection of a sulfhydryl enzyme by another thiol can be a highly complex phenomenon. In fact if our interpretation is correct, the efficiency of the protector will depend not only on k_8/k_{12} and k_9/k_{10}, but also on k_{13}/k_{15} and K_{13}/K_{15}. Thus, as in the present instance, a sulfhydryl protector may be a sensitizer under certain conditions. In this connection it is interesting to note that some non-sulfhydryl sensitizers may also exhibit protective effects at higher concentrations (see ref. 19 and references cited therein).

Finally, the high efficiency with which isobutanol, acetate, and thiocyanate radicals inactivate papain, is particularly relevant to radiobiology, given the high probability of forming cytoplasmic solute radicals. At present the efficiency of such radicals appears to be due largely to their selectivity for papain's active site sulfhydryl, and such effects are likely to apply to other biologically important enzymes.

The Preparation of 1,1′-Carbonyl- and 1,1′-Sulfinyl-dipyrazoles and their Reactions with Carbonyl Compounds

K. I. THE, L. K. PETERSON, AND E. KIEHLMANN

Chemistry Department, Simon Fraser University, Burnaby 2, British Columbia

Received January 18, 1973

The compounds 1,1′-carbonylbis(3-methylpyrazole) (**1**), 1,1′-carbonylbis(3,5-dimethylpyrazole) (**2**), and 1,1′-sulfinyldipyrazole (**3**) have been prepared. They react with aldehydes and ketones in the presence of metal ion catalysts to form 1,1′-alkylidenedipyrazoles together with carbon dioxide, from **1** and **2**, or sulfur dioxide, from **3**. Tetrapyrazol-1-ylmethane results from the pyrolysis at 200° of 1,1′-carbonyldipyrazole in the presence of cobalt(II) chloride.

La préparation du carbonyl-1,1′ bis (méthyl-3 pyrazole) (**1**), carbonyl-1,1′ bis (diméthyl-3,5 pyrazole) (**2**) et sulfinyl-1,1′ dipyrazole (**3**) a été rapportée. Ces composés réagissent sur les aldéhydes et cétones en présence de catalyseurs ion métallique pour conduire aux alkylidène-1,1 dipyrazoles et gaz carbonique pour le **1** et **2** et anhydride sulfureux pour **3**. Le tétrapyrozyl-1 méthane résulte de la pyrolyse à 200° du carbonyl-1,1′ dipyrazole en présence de chlorure de cobalt(II). [Traduit par le journal]

Can. J. Chem., **51**, 2448 (1973)

As previously reported (1, 2), 1,1′-carbonyldipyrazole reacts with various carbonyl compounds in the presence of metal salt catalysts, liberating carbon dioxide to form 1,1′-alkylidenedipyrazoles. We have now prepared the related compounds 1,1′-carbonylbis(3-methylpyrazole), 1,1′-carbonylbis(3,5-dimethylpyrazole), and 1,1′-sulfinyldipyrazole in order to study steric and electronic substituent effects.

Experimental

Elemental analyses were performed by the departmental analyst. Melting points are uncorrected. The n.m.r. spectra[1] were recorded on a Varian A 56/60 using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were determined with a double-focusing RMU-6E Hitachi Perkin–Elmer instrument, and for all compounds reported below (**1–13**), the mass corresponding to the observed parent peak was in agreement with the calculated molecular weight.[2]

Preparation of 1,1′-Carbonylbis(3-methylpyrazole) (1)

3-Methylpyrazole (0.10 mol) in dry ether (50 ml) was added slowly, under a nitrogen atmosphere, to a stirred ethereal (200 ml) suspension of sodium amide (0.10 mol); the mixture was stirred for 16 h at 25° and then heated at reflux temperature for 4 h. With the reaction vessel attached to the vacuum system, phosgene (0.05 mol) was condensed onto the mixture, which was initially held at −78° for 1 h, then heated under reflux for several hours, again under a nitrogen atmosphere. The sodium chloride precipitate (0.10 mol) was filtered off and the solvent was distilled under N_2 to give a yellow solid which was purified by zone fractionation under vacuum to yield pure **1**, m.p. 68–69°, in 80% yield.

Anal. Calcd. for $C_9H_{10}N_4O$: C, 56.8; N, 29.4; H, 5.3. Found: C, 56.5; N, 29.6; H, 5.2.

N.m.r.: τ 7.63 (s, 3H, CH_3), 3.68 (d, 1H, 4-H, J = 3.0 Hz), 1.37 (d, 1H, 5-H, J = 3.0 Hz).

Preparation of 1,1′-Carbonylbis(3,5-dimethylpyrazole) (2)

Compound **2** was prepared from 3,5-dimethylpyrazole according to the method used for compound **1**; m.p. 85–86° (lit. (3) 89–90°); yield, 70%.

Anal. Calcd. for $C_{11}H_{14}N_4O$: C, 60.6; N, 25.7; H, 6.4. Found: C, 60.8; N, 25.8; H, 6.5.

N.m.r.: τ 7.75 (s, 3H, 3-CH_3), 7.52 (d, 3H, 5-CH_3, J = 1.0 Hz), and 3.95 (m, 1H, 4-H).

Preparation of 1,1′-Sulfinyldipyrazole (3)

Compound **3** was prepared in the same way as 1,1′-carbonyldipyrazole (2), using thionyl chloride in place of phosgene; yield, 55%; m.p. 73–74°.

Anal. Calcd. for $C_6H_6N_4OS$: C, 39.5; N, 30.8; H, 3.2. Found: C, 39.6; N, 31.1; H, 3.4.

N.m.r.: τ 2.23 (q, 1H, 3-H, J_{34} = 1.6, J_{35} = 0.5 Hz), 3.53 (q, 1H, 4-H, J_{45} = 2.7, J_{34} = 1.6 Hz), and 2.00 (q, 1H, 5-H, J_{45} = 2.7, J_{35} = 0.5 Hz).

Reactions of 1 with Carbonyl Compounds

(*a*) With acetone: The following procedure is typical of all reactions in this section. A mixture of **1** (0.90 mmol), dry acetone (~5 ml), and cobalt(II) chloride (~4 mg) was heated in a sealed tube at 90–95° for 16 h to liberate CO_2 quantitatively (only traces of CO_2 were detected at 25°). The solid product was purified by zone fractionation under vacuum to yield 2,2-bis(3-methylpyrazol-1-yl)-propane (**4**); yield, 70%; m.p. 101–102°.

[1]N.m.r. spectra and bands showing unresolved fine structure are signified by an asterisk.

[2]The mass spectra of compounds **1–13** exhibited strong parent peaks in all cases. Major fragments corresponding to loss of pyrazolyl or methylpyrazolyl moieties were observed. Compounds **1**, **2**, and 1,1′-carbonyldipyrazole gave rise to di(methylpyrazolyl), and dipyrazolyl recombination species, respectively.

Anal. Calcd. for $C_{11}H_{16}N_4$: C, 64.7; N, 27.5; H, 7.8. Found: C, 65.2; N, 27.6; H, 8.0.

N.m.r.: τ 7.80 (s, 6H, $C(CH_3)_2$, 7.72 (m, 6H, 3-CH_3), 3.98 (d*, 2H, 4-H, J = 2.3 Hz) and 2.78 (d*, 2H, 5-H, J = 2.3 Hz).

(*b*) Acetone-d_6 gave 2,2-bis(3-methylpyrazol-1-yl)-hexadeuteropropane (**5**); yield, 85%; m.p. 102–103°.

N.m.r.: τ 7.73 (s*, 3, CH_3), 4.00 (d*, 1H, 4-H, J = 2.4 Hz), 2.83 (d*, 1H, 5-H, J = 2.4 Hz).

(*c*) Acetaldehyde gave 1,1-bis(3-methylpyrazol-1-yl)-ethane (**6**); yield, 65%.

Anal. Calcd. for $C_{10}H_{14}N_4$: C, 63.2; N, 29.5; H, 7.4. Found: C, 63.2; N, 28.6; H, 7.6.

N.m.r.: τ 7.78 (s*, 6H, ring-CH_3), 4.00 (d*, 2H, 4-H, J = 2.3 Hz), 2.55 (m*, 2H, 5-H), 3.60 (9, 1H, >CH—CH_3, J = 6.7 Hz), and 7.83 (m*, 3H, >CH—CH_3).

(*d*) Cyclobutanone gave 1,1-bis(3-methylpyrazol-1-yl)-cyclobutane (7); yield, 75%; m.p. 43.5–45°.

Anal. Calcd. for $C_{12}H_{16}N_4$: C, 66.7; N, 25.9; H, 7.4. Found: C, 66.6; N, 25.6; H, 7.6.

N.m.r.*: 7.73 (s, 6H, CH_3), 3.98 (d, 2H, 4-H, J = 2.4 Hz), 2.77 (d, 2H, 5-H, J = 2.4 Hz), 7.93 and 6.83 (m, 6H, —$(CH_2)_3$—).

(*e*) Cyclopentanone gave 1,1-bis(3-methylpyrazol-1-yl)-cyclopentane (**8**); yield, 30%; m.p. 121–122°.

Anal. Calcd. for $C_{13}H_{18}N_4$: C, 67.8; N, 24.4; H, 7.8. Found: C, 67.7; N, 24.3; H, 7.9.

N.m.r.*: τ 7.75 (s, 6H, CH_3), 4.00 (d, 2H, 4-H, J = 2.4 Hz), 2.68 (d, 2H, 5-H, J = 2.4 Hz), 8.17 and 7.13 (m, 8H, —$(CH_2)_4$—).

(*f*) 4-Methylcyclohexanone gave 1,1-bis(3-methylpyrazol-1-yl)-4-methylcyclohexane (**9**); yield, 60%; m.p. 77.5–78.5°.

Anal. Calcd. for $C_{15}H_{22}N_4$: C, 70.1; N, 21.8; H, 8.2. Found: C, 69.9; N, 21.6; H, 8.5.

N.m.r.: τ 9.13 (m, 3H, —CH_2—CH(—CH_3)—), 7.72 and 7.75 (2s, 6H, —N=C(—CH_3)—), 4.13 and 3.92 (2d*, 2H, 4-H, J = 2.3 Hz), 3.13 and 2.43 (2d*, 2H, 5-H, J = 2.3 Hz), and 7–9 (complex band, 9H, cyclohexane ring).

Reactions of 2 with Ketones

The procedure was essentially the same as that used with compound **1** above, except that temperatures of 150–170° were required to facilitate reaction.

(*a*) Acetone gave 2,2-bis(3,5-dimethylpyrazol-1-yl)propane (**10**); yield, 65%; m.p. 80–81.5°.

Anal. Calcd. for $C_{13}H_{20}N_4$: C, 67.3; N, 24.1; H, 8.6. Found: C, 67.5; N, 24.1; H, 6.6.

N.m.r.: τ 7.77 (s, 6H, 3-CH_3), 4.17 (broad band, 2H, 4-H), 8.32 (d, 6H, 5-CH_3, J = 0.8 Hz), and 7.87 (s, 6H, >$C(CH_3)_2$).

(*b*) Cyclobutanone gave 1,1-bis(3,5-dimethylpyrazol-1-yl)-cyclobutane (**11**); yield, 50%; m.p., 72–73°.

Anal. Calcd. for $C_{14}H_{20}N_4$: C, 68.8; N, 22.9; H, 8.2. Found: C, 68.9; N, 22.6; H, 8.3.

N.m.r.: τ 7.78 (s, 6H, 3-CH_3), 4.22 (m*, 2H, 4-H), 8.13 (d, 6H, 5-CH_3, J = 0.8 Hz), 8.00 and 6.73 (complex bands, 6H, —$(CH_2)_3$—).

(*c*) With methyl ethyl ketone, CO_2 was evolved quantitatively, together with a difficult-to-purify oil and 3,5-dimethylpyrazole. The latter was identified by i.r., n.m.r., and mass spectra. The expected compound 2,2-bis(3,5-dimethylpyrazol-1-yl)-butane was not detected.

(*d*) With cyclohexanone, CO_2 was evolved quantitatively together with an impure oil and 3,5-dimethylpyrazole. The expected compound 1,1-bis(3,5-dimethylpyrazol-1-yl)-cyclohexane was not detected.

Reactions of 3 with Ketones

(*a*) With acetone: A typical procedure was as follows: Dry acetone (~5 ml), 1,1′-sulfinyldipyrazole (2.05 mmol), and a catalytic amount of dry $CoCl_2$ were sealed under vacuum into a reaction vessel and cooled in liquid nitrogen. On warming from −196° to room temperature, a blue solution, gradually turning yellow, was observed. After 16 h, the products were SO_2 (quantitatively), identified by its i.r. spectrum and vapor phase molecular weight (M(calcd.), 64.06; M(obsd.), 63.8), and a residue of solids which was purified by zone fractionation to yield 2,2-dipyrazol-1-ylpropane (75% yield), identified by its m.p. and i.r., mass, and n.m.r. spectra (2, 4).

(*b*) Cyclobutanone gave 1,1-dipyrazol-1-ylcyclobutane (80% yield) by its m.p. and i.r., mass, and n.m.r. spectra (2).

(*c*) Cyclopentanone, a reaction temperature of 120–130° was required; the product was identified as 1,1-dipyrazol-1-ylcyclopentane (35% yield) by its m.p. and i.r., mass, and n.m.r. spectra (2, 4).

(*d*) 4-Methylcyclohexanone gave 1,1-(dipyrazol-1-yl)-4-methylcyclohexane at room temperature, in 60% yield, and identified by its m.p. and i.r., mass, and n.m.r. spectra (2).

The Reaction of 1,1′-Carbonyldipyrazole with Benzophenone

A preliminary experiment indicated that no reaction occurs between 1,1′-carbonyldipyrazole and benzophenone in the presence of a catalytic amount of cobalt(II) chloride in refluxing THF (2). However, when equimolar quantities (1.75 mmol) of these two reagents and a trace of dry $CoCl_2$ were heated in a sealed tube at 190–200° for 16 h, carbon dioxide (1.16 mmol) and a mixture of brown solid and liquid products was formed. The solid was purified by zone fractionation and recrystallization from methanol, yielding white crystals of diphenyldipyrazol-1-ylmethane (**12**); yield, 25%; m.p. 153–154°.

Anal. Calcd. for $C_{19}H_{16}N_4$: C, 76.0; N, 18.7; H, 5.3. Found: C, 75.6; N, 18.8; H, 5.3.

N.m.r.: τ 3.83 (q, 2H, 4-H, J_{45} = 2.5, J_{34} = 1.8 Hz), 2.53 (m, 4H, 3-H and 5-H), 3.07 and 2.72 (m, 10H, C_6H_5).

The Pyrolysis of 1,1′-Carbonyldipyrazole

Pure 1,1′-carbonyldipyrazole was found to be stable up to 180°; however, a sample (2.34 mmol) heated at 190° for 16 h, in the presence of a catalytic amount of dry $COCl_2$, yielded CO_2 (0.97 mmol) and a brown residue. Tetrapyrazol-1-ylmethane (**13**) was separated from the residue by zone fractionation; yield, 50%; m.p., 146–147° (lit. (4), 146–147°).

N.m.r.: τ 2.07 (q, 3-H, J_{34} = 1.8, J_{35} = 0.7 Hz), 3.45 (q, 4-H, J_{45} = 2.9, J_{34} = 1.8 Hz), and 2.23 (q, 5-H, J_{45} = 2.9, J_{35} = 0.7 Hz).

Discussion

1,1′-Carbonylbis(3,5-dimethylpyrazole) (**2**) and the new compounds 1,1′-carbonyl-bis(3-methylpyrazole) (**1**) and 1,1′-sulfinyldipyrazole (**3**) are obtained in high yield by the reaction of

[1] 
1 14

the appropriate sodium pyrazolide salt with either phosgene or thionyl chloride, in a manner analogous to the procedures reported in the literature for the synthesis of 1,1′-sulfinyldiimidazole (5) and various derivatives of 1,1′-carbonyldipyrazole (1, 3, 6–8) and 1,1′-carbonyldiimidazole (9). Compound **1** is obtained as a single substance, there being no evidence for the formation of the isomeric 1,1′-carbonylbis-(5-methylpyrazole) or the mixed isomer **14** (eq. 1).

Thus N-1, though more remote than N-2 from the electron-releasing methyl group, is clearly the more nucleophilic center in the methylpyrazolide anion. Compounds **1**–**3** are sensitive to moisture, being hydrolyzed to free base and carbon dioxide or sulfur dioxide. They are readily characterized on the basis of m.p., elemental analysis, and i.r., mass, and p.m.r. spectral measurements; the assignment of the lowest-field resonance to H-5 of **1** and **3** is related to the electron-withdrawing effect of the C=O or S=O group attached at N-1. The resonances of the 3- and 5-methyl groups in compound **2** can be distinguished on the basis of similar arguments (10).

Like 1,1′-carbonyldipyrazole, compounds **1**, **2**, and **3** react with aldehydes and ketones, in the presence of catalytic amounts of cobalt(II) chloride, to yield dipyrazol-1-ylmethanes and CO_2 and SO_2 (eq. 2). However, whereas most

[2] $$(py)_2XO + R_2CO \rightarrow R_2C(py)_2 + XO_2$$

X = C or S
py = pyrazol-1-yl, 3-methylpyrazol-1-yl, or 3,5-dimethylpyrazol-1-yl

of the reactions of 1,1′-carbonyldipyrazole occur at room temperature, more vigorous conditions *viz.* 100–110° and 160–180°, are required with compounds **1** and **2**, respectively. Although the sulfinyl compound **3** reacts readily at room temperature, it is less reactive than the corresponding carbonyl compound as shown by the exclusive formation of carbon dioxide when acetone was allowed to compete for both reagents. It is noteworthy that Staab and Wendel (5) have reported the opposite reactivity order for the corresponding imidazole derivatives. The reactivity decrease in the series 1,1′-carbonyldipyrazole > **1** > **2** clearly indicates that both the 3- and the 5-methyl substituent are sterically active during the course of the reaction; unfortunately, one cannot deduce, from this evidence alone, the relative significance of steric effects on individual steps of the detailed reaction mechanism.

Bulky groups also influence the reactivity of the ketones. Thus, the catalytic reaction of 1,1′-carbonyldipyrazole with benzophenone only occurs at 190–200° to give diphenyldipyrazol-1-ylmethane (**12**); and 1,1′-carbonyldipyrazole condenses with itself at 190–200°, in the presence of cobalt(II) chloride, to yield tetrapyrazol-1-ylmethane (**13**) (eqs. 3 and 4). Neither reaction

[3] $$(py)_2CO + (C_6H_5)_2CO \xrightarrow[190\text{–}200^\circ]{CoCl_2} (py)_2C(C_6H_5)_2 + CO_2$$

[4] $$2(py)_2CO \xrightarrow[190\text{–}200^\circ]{CoCl_2} (py)_4C + CO_2$$

is observed in the absence of catalyst. Interestingly, 1,1′-carbonyldipyrazole reacts preferentially with benzophenone (eq. 3) rather than with itself (eq. 4) which is consistent with the general rule that resonance interactions of the type

$$>N-\overset{|}{C}=O \leftrightarrow >\overset{\oplus}{N}=\overset{|}{C}-\overset{\ominus}{O}$$

make the carbonyl carbon of an amide less electropositive, *i.e.*, less susceptible to nucleophilic attack than that of a ketone. In view of this fact, it is surprising indeed that 1,1′-carbonyldipyrazole reacts *at all* according to eq. 4; one may

attribute the enhanced reactivity of its carbonyl group, relative to simple amide systems, to a preferred delocalization of the nitrogen lone pair of electrons over the aromatic pyrazole ring, rather than over the three atoms forming the amide group. I.r. spectroscopic measurements (2) provide further support for this interpretation.

Our studies with 1,1′-carbonylbis(3,5-dimethylpyrazole) (**2**) indicate a dramatic limitation to the number of stable derivatives which may be obtained with ketones. Thus, acetone and cyclobutanone react at 160° in the established typical fashion, yielding 2,2-bis(3,5-dimethylpyrazol-1-yl)propane (**10**) and 1,1-bis(3,5-dimethylpyrazol-1-yl)cyclobutane (**11**), respectively. The comparable reactions with methyl ethyl ketone and with cyclohexanone, on the other hand, produce carbon dioxide, 3,5-dimethylpyrazole and unidentified oils which are presumably decomposition products of the desired 1,1′-alkylidene(3,5-dimethylpyrazoles). A study of models suggests several favorable conformations for **10** and **11**, respectively. However, models of the unknown 2,2-bis(3,5-dimethylpyrazol-1-yl)butane and 1,1-bis(3,5-dimethylpyrazol-1-yl)cyclohexane are sterically congested, locked structures; considerable interaction between the N-2 lone electron pair and the C-3 proton of the hydrocarbon moiety could lead to facile decomposition.

The authors wish to express their sincere thanks to Maki Belluce for technical assistance and to the National Research Council of Canada for financial support.

The Use of Polymer Supports in Organic Synthesis. II.[1] The Syntheses of Monoethers of Symmetrical Diols

JACK Y. WONG AND CLIFFORD C. LEZNOFF
Department of Chemistry, York University, Downsview, Ontario

Received January 25, 1973

An insoluble polymer support system was used as a unique method of blocking one functional group of a completely symmetrical difunctional compound. The monotetrahydropyranyl and monotrityl ethers of the symmetrical diols, HO—$(CH_2)_n$—OH, where n = 2, 4, 6, 8, and 10, were prepared. Reaction conditions for the preparation of the monotetrahydropyranyl ether of 1,10-decanediol were optimized.

Un système impliquant un support polymérique insoluble a été utilisé pour bloquer un groupe fonctionnel d'un composé difonctionnel complètement symétrique. Les éthers monotétrahydropyranylé et monotritylé des diols symétriques HO—$(CH_2)_n$—OH, où n = 2, 4, 6, 8, et 10, ont été préparés. Les conditions expérimentales pour la préparation de l'éther monotétrahydropyranylé du décanédiol-1,10 ont été optiminiséa. [Traduit par le journal]

For personal use only.

The concept of using an insoluble polymer support as a selective blocking group of one functional group of a completely symmetrical difunctional compound was recently demonstrated (1). In this paper the syntheses of monotetrahydropyranyl and monotrityl ethers of the completely symmetrical diols, HO—$(CH_2)_n$—OH, where n = 2, 4, 6, 8, and 10 are described.

The commercially available Merrifield resin (2) (2% cross-linked polystyrene beads with 1.7 mmol of —CH_2Cl groups/g of resin, obtained from Schwarz/Mann) was modified, according to the procedure of Kusama and Hayatsu (3), to an insoluble polymer containing acid chloride groups, (P)—C_6H_4—CH_2COCl (**1**). The acid chloride **1** contained 0.8 mequiv. Cl/g of polymer as determined by the modified Vollhard procedure (4). Polymer **1** contains only one in six functionalized phenyl groups along the polymer chain and hence the acid chloride polymer **1** acts as a dilute reagent.

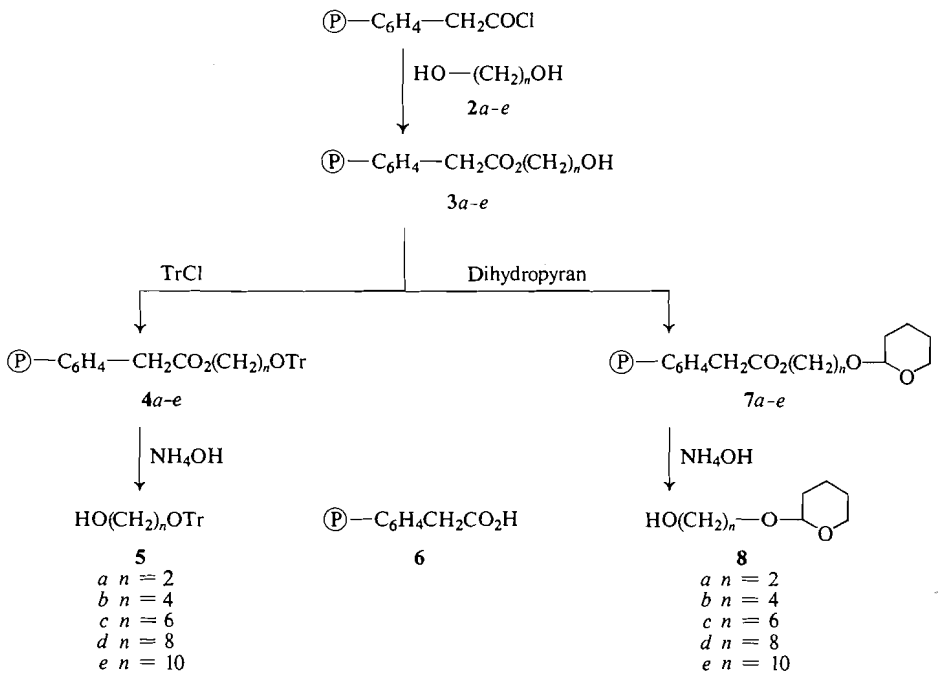
In a typical reaction sequence as outlined in Scheme 1, resin **1** and an excess of symmetrical diol, **2***a–e*, reacted in pyridine to give the resin, **3***a–e*, in which one of the alcohol groups was attached to the insoluble polymer through an ester linkage.[2] The unreacted excess diol can be readily recovered by simple filtration of this polymer. This reaction represents a selective blocking of one alcohol group of a completely symmetrical diol. The minimum amount of the diol attached to the polymer was determined by base hydrolysis of **3***a–e* to give back the starting diol. It is recognized that base hydrolysis of **3***a–e* could be incomplete even after long reaction times and hence the amount of diol obtained after base hydrolysis represents a minimum amount of diol attached to the polymer. The polymer **3***a–e* contained approximately 0.05–0.2 mmol of **2***a–e* per gram.

Reaction of resin esters **3***a–e* with trityl chloride in pyridine (5, 6) gave the resin trityl ether, **4***a–e*. Base hydrolysis of **4***a–e* gave the monotrityl ethers **5***a–e* in amounts ranging from 0.048 mmol of **5***e*/g of **4***e* to as much as 0.087 mmol of **5***a*/g of **4***a*. In addition, the acid polymer **6** was recovered.

The monotrityl ethers, **5***a–e*, were hydrolyzed with 80% acetic acid (5) to give trityl alcohol and the parent diols, **2***a–e*, in a 1:1 ratio. Elemental analysis and the mass spectral data of **5***a–e* were entirely consistent with the assigned structures. Ethers, **5***a–e* gave parent ions in their mass spectra. In addition, all spectra of **5***a–e* showed a base peak at m/e 243 resulting from the cleavage of the ethers and the formation of the bulky trityl cation. This mode of cleavage of bulky tertiary ethers is well documented (7). The i.r. spectra of **5***a–e* showed broad O—H absorption at 3450 cm^{-1} and

[1]For Part I, see ref. 1.

[2]The possibility exists that two adjacent phenyl rings are functionalized and hence both ends of the symmetrical diols, **2***a–e*, could attach themselves to the polymer. The use of a large excess of diol greatly diminishes the chance of this occurring.



SCHEME 1

aromatic absorption at 1600 cm^{-1}. The i.r. spectra of **3***a–e* and **4***a–e* were uninformative.

The quantity of **5***a–e* from **3***a–e* was not as high as expected and it was suspected that the bulkiness of the trityl group was inhibiting the base hydrolysis of **4***a–e*. In an experiment designed to test this hypothesis resin **4***e* was treated with concentrated HCl in dioxane to give the diol **2***e* and trityl alcohol in 0.12 mmol/g of **4***e*. Thus the yield of the tritylation step is quite high and the moderate quantity of **5***e* obtained is likely due to the inefficiency of the base hydrolysis of **4***e*. The bulkiness of the trityl group may add to the inefficiency of the final base cleavage reaction resulting in decreased quantities of **5***a–e*. Thus some mono trityl ether remains attached to the polymer.

In an attempt to see if polymer **6** was reusable, **6** was converted back to the acid chloride **1**, by treatment with thionyl chloride, and the sequence of reactions repeated using 1,10-decanediol, **2***e*, as a model.

The quantity of **5***e* obtained from once used polymer was less than 50% of that obtained using fresh polymer **1** (see Experimental). The used polymer **6** was again converted to **1** and the sequence repeated a second time using alcohol **2***b*. The yield of **5***b* from twice used polymer was less than 25% of that obtained using fresh polymer **1**. If one considers that base hydrolysis of polymer **4***b* is incomplete because of the inefficiency of the base cleavage and perhaps the bulkiness of the trityl group, then it is reasonable to expect that the used polymer **6** has less carboxy groups liberated and hence available for subsequent reactions. It should also be noted that every subsequent recyclization of polymer **6** resulted in a browner polymer.

Thus, in the formation of monotrityl ethers the base cleavage of the ether from the polymer is incomplete resulting in lower yields and the polymer liberated is not highly suitable for regeneration as subsequent cycles result in even lower yields.

The polymer support synthesis of monotrityl ethers of symmetrical diols gave the monoethers in moderate quantities on a mole basis. In order to demonstrate the formation of monoethers of symmetrical diols in higher quantities on a mole basis, it was decided to synthesize the monotetrahydropyranyl ethers of the symmetrical diols **2***a–e*. The reduced steric requirements of the tetrahydropyranyl group as compared to the trityl group should result in higher yields of monoethers.

Reaction of resin **3***a–e* in anhydrous dioxane

with excess dihydropyran, anhydrous sodium sulfate and *m*-benzene-disulfonic acid as a catalyst gave, after 48 h at room temperature,[3] resin **7***a–e*. Subsequent base cleavage of **7***a–e* yielded resin **6** and **8***a–e* in quantities averaging 0.035 mmol/g of **7***a–e*.

The reaction of **3***a–e* with dihydropyran was incomplete as evidenced by the isolation of the parent diols, **2***a–e*, from the base cleavage of **7***a–e*. The monotetrahydropyranyl ethers, **8***a–e*, were separated from the parent diols, **2***a–e*, by preparative t.l.c. on alumina prepared from an aqueous slurry containing 1% sodium bicarbonate. T.l.c. on silica gel, even prepared with sodium bicarbonate always resulted in hydrolysis of **8***a–e* to **2***a–e* and dihydropyran. The pure tetrahydropyrans, **8***a–e* were rechromatographed on alumina containing 1% sodium bicarbonate and pure **8***a–e* showed no evidence of hydrolysis on this adsorbant system, thus showing that the starting diols obtained in the hydrolysis of **7***a–e* were, in fact, due to incomplete reaction of **3***a–e* and not due to hydrolysis of **8***a–e* in the work-up of the reaction.

The monotetrahydropyranyl ethers, **8***a–e*, were hydrolyzed on silica gel to give dihydropyran and the parent diols, **2***a–e*, in a 1:1 ratio. Elemental analysis and the mass spectral data of **8***a–e* were entirely consistent with the assigned structures. Ethers, **8***c–e* exhibited very weak parent ions in their mass spectra, while **8***a–b* showed no parent ions at all. In addition, however, **8***a–e* all exhibited the tetrahydropyranyl cation as the base peaks of the spectra. The weak parent ions and the formation of the tetrahydropyranyl cation is consistent with published data on the mass spectra of tetrahydropyranyl ethers (8).

The i.r. spectra of the monotetrahydropyranylethers **8***a–e* were almost identical to each other; and showed much broader absorptions at 3450 (O—H) and 1080 cm^{-1} (C—O—C) than the diols **2***a–e*. The i.r. spectra of **7***a–e* were uninformative and were not useful for characterization.

[3]The reaction of diols **2***a–e* with **1** to give **3***a–e* for the preparation of the trityl ethers, **5***a–e*, were conducted partially at higher temperatures (see Experimental). Although more diol became attached to the polymer at higher temperatures, it was felt that the more inaccessable functional groups reacted at these higher temperatures resulting in loss of starting material and deterioration of the polymer.

The resin **6** recovered from the hydrolysis of **7***a–e* was converted back to polymer **1**, by treatment with thionyl chloride, and the sequence of reactions leading to **8***e* was repeated. The quantity of **8***e* obtained from once-used polymer was only 50% of that obtained from the fresh polymer and hence polymer **6** generated from the hydrolysis of **7***a–e* is also not a very suitable regenerable polymer and exhibits similar characteristics to polymer **6** regenerated from the hydrolysis of **4***a–e*. Thus the inefficiencies of the base cleavage reaction of **4***a–e* and **7***a–e* and the deterioration of the polymer by $SOCl_2$[4] appear more responsible for the incomplete regeneration of **1** from **6** than the bulkiness of the trityl group of **4***a–e*. One of the drawbacks of organic synthesis on insoluble polymer support systems is the long reaction times involved in the various reactions on the insoluble polymer. It was thus decided to do a time study on the various reactions leading to the formation of **8***e* as a model system.

Polymer **1** was reacted with **2***e* at various times as shown in Table 1. Subsequent base cleavage of the product **3***e* for 48 h gave back the starting diol, **2***e*, in maximum yield for a reaction time of **1** with **2***e* of 48 h showing that for the initial attachment of the diol to the polymer, the standard time of reaction, 48 h, was optimum.

The reaction of **3***e* with dihydropyran for different times was performed. As shown in Table 2, reaction was essentially complete after 24 h instead of the standard reaction time of 48 h. In fact the yield of **8***e*, obtained after base hydrolysis of **7***e* was slightly lower for longer reaction times.

The effect of time on the base hydrolysis of **7***e* was next examined. As indicated in Table 3, base hydrolysis of **7***e* to yield **8***e* was complete after 48 h. Thus the standard conditions were best for the base cleavage step.

Thus a practical general method of synthesizing monotrityl and monotetrahydropyranyl ethers of symmetrical diols has been outlined.

The insoluble polymer support synthesis of monotrityl ethers of symmetrical diols is preferable to the synthesis of the monotetrahydropyranyl ethers of symmetrical diols as they are obtained in higher quantities, while the tetra-

[4]The polymer turns pale brown on treatment with $SOCl_2$.

hydropyranyl ethers are always contaminated by starting diol which must be separated by preparative t.l.c.

The use of insoluble polymers as blocking groups of other symmetrical difunctional organic compounds is in progress using means other than the inefficient base hydrolysis of products from the insoluble polymer. The search for a more regenerable polymer is also under investigation.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Unicam SP1000 i.r. spectrophotometer using neat compounds or Nujol mulls. Mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. Silica gel, and alumina, prepared with a 1% $NaHCO_3$ aqueous slurry, were used for thin and thick-layer chromatography. [Microanalyses were performed by Dr. C. Daessle of Montreal and G. Gygli of Toronto.

*Acid Chloride Resin **1***

The Merrifield resin (2) (2% cross-linked polystyrene beads having 1.7 mmol of $-CH_2Cl$ groups/g of resin was obtained from Schwarz/Mann and converted to **1** according to the procedure of Kusama and Hayatsu (3). Resin **1** contained 0.8 mmol Cl/g of polymer as determined by the modified Vollhard procedure (4).

Preparation of the Alcohol Resins, 3a–e

A typical example is given for the preparation of resin 3*e*. A suspension of 4.12 g of Ⓟ—C_6H_4—CH_2—COCl in 30 ml of anhydrous pyridine and 2.71 g of 1,10-decanediol, **2***e*, was stirred under exclusion of moisture ($CaCl_2$-tube) at room temperature for 24 h and at 100 °C for 24 h. The resin was collected by filtration and washed three times with pyridine, three times with pyridine–water (1:1), three times with water, three times with ethanol, and finally three times with ether.

Preparation of the Trityl Resins, 4a–e

A standard procedure is given for the synthesis of **4***e*. A mixture of 3.02 g of resin 3*e* and 2.0 g of chlorotriphenylmethane in 40 ml of anhydrous pyridine were stirred for 48 h at room temperature under exclusion of moisture ($CaCl_2$-tube). The resin was then collected by filtration and washed four times with pyridine, three times with pyridine–water (3:1), three times with pyridine–water (1:1), six times with water, three times with ethanol–water (1:1), once with acetone, three times with ethanol, and at least three times with dry ether.

Release of the Monotritylalcohols, 5a–e, from Resins 4a–e

In a standard procedure, 3.22 g of resin **4***e* was treated with 20 ml of a 1:1 mixture of dioxane and concentrated ammonia in a stoppered flask with magnetic stirring for 48 h. The resin was filtered and washed six times with water, once with acetone, three times with ethanol, and three times with ether. The aqueous filtrate was extracted with three aliquots of ether. The combined ether extracts were washed six times with water, dried over Na_2SO_4 and evaporated to give a slightly impure oil which was purified by preparative t.l.c. on silica gel (eluant 10% $CHCl_3$ – 90% C_6H_6) to give 0.0645 g of analytically pure **5***e* (see Table 4 for physical and mass spectra data on **5***a–e*). No starting diol **2***e* was detected.

Preparation of the Tetrahydropyranyl Ether Resins 7a–e

In a typical procedure, 4.01 g of resin 3*e* (prepared by reaction of **1** with **2***e* for 48 h at room temperature only) was suspended in 30 ml of anhydrous dioxane. Excess dihydropyran (5.00 g) and 0.10 g of *m*-benzenedisulfonic acid was added as a catalyst. To the mixture was added 2.00 g of anhydrous sodium sulfate to absorb liberated water and the reaction was stirred for 24 h under exclusion of moisture ($CaCl_2$-drying tube). The resin was filtered, neutralized with anhydrous pyridine (to prevent hydrolysis of the monopyranyl ether) and filtered twice. Then the resin was washed twice with pyridine–water (1:1), ten times with water (to remove sodium sulfate), three times with ethanol, and at least three times with dry ether.

Release of the Monotetrahydropyranyl Alcohols, 8a–e, from Resins 7a–e

A suspension of 4.01 g of resin 7*e* and 30 ml of a 1:1 mixture of dioxane and concentrated ammonium hydroxide was stirred for 48 h at room temperature. The resin was filtered and washed as before in the preparation of **5***a–e*. An identical work-up as before yielded an impure oil. Preparative t.l.c. on alumina prepared with a 1%

Total Synthesis of Spirobenzylisoquinoline Alkaloids. Part III. (±)-Ochrobirine[1]

STEWART MCLEAN AND JOHN WHELAN
Department of Chemistry, University of Toronto, Toronto, Ontario
Received November 8, 1972

The route to spirobenzylisoquinoline alkaloids through a Pictet–Spengler cyclization of a suitable 1,2-indanedione has been modified, by the introduction of a 3-bromo substituent into the indanedione, with a view to providing a general synthesis of spirobenzylisoquinoline alkaloids bearing two oxygen functions on ring C. A highly stereoselective synthesis of (±)-ochrobirine has been achieved.

L'accès aux alcaloïdes du type spirobenzylisoquinoléine par une cyclisation selon Pictet–Spengler d'une indane dione-1,2 adéquate, a été modifié par l'introduction d'un substituant bromo-3 sur l'indanedione en vue d'obtenir une synthèse générale d'alcaloïdes spirobenzylisoquinoléine porteurs de deux fonctions oxygénées sur le cycle C. Une synthèse hautement stéréosélective de l'ochrobirine (±) a été réalisée.

The term spirobenzylisoquinoline alkaloids has been applied to a group of alkaloids isolated from certain *Corydalis* and *Fumaria* species and having the skeleton shown in **1**. This structural class has been recognized for a relatively short time, and all members of it known at present can be described by structure **1** in which variations of substitution occur only in rings A and C (1). In ochotensimine (**1***a*) and ochotensine (**1***b*), the first members of this class to be recognized (2), ring C carries a single substituent, a methylene group at C-14; alkaloids with oxygen functions (at carbonyl or carbinol oxidation levels) at one or both of positions 9 and 14 have been described more recently. We reported in 1968 (3) the first total synthesis of a member of this class, (±)-ochotensimine, and since then the descriptions of several syntheses of this alkaloid, ochotensine, and some of the alkaloids with oxygen functions in ring C have appeared.

The synthetic plan of the majority of the successful syntheses of these alkaloids has been related to the one we used to synthesize ochotensimine: the condensation of an indanedione (such as **2**) with a phenylethylamine (such as **3**), each suitably substituted, followed by manipulation of the functionality of the intermediate to provide the target molecule. Ochrobirine (**1***c*) (4), for example, has been synthesized from the methylenedioxyindanetrione (**2** with C=O in place of C—X) and subsequent reduction of the dione intermediate (**4** with C=O in place of C—X) (5, 6); **1***c* is also an example of a spirobenzylisoquinoline alkaloid that has been synthesized by a different route proceeding, nevertheless, through the same dione intermediate (7). We recognized that our original synthetic plan could be developed into a general synthesis of those spirobenzylisoquinoline alkaloids with two oxygen functions on ring C if a suitable functional group could be introduced into position 3 of the indanedione precursor (**2**). In principle at least, this group (X), which could subsequently be converted into an oxygen function distinguishable from the aromatic ketone already present, would allow control to be maintained throughout the synthesis of both functionality and stereochemistry at the sites destined to be C-9 and -14 in the final product, and provide controlled routes to any of the target alkaloids.

We have found that the substituent X most suitable for this purpose is bromine and we have converted the methylenedioxyindanedione **2***a*, already available to us from our earlier work (3), to its monobromo derivative **2***b*. A Pictet–Spengler reaction of **2***b* with the dihydroxyphenylethylamine **3**, produced the spiro compound **4***a* which appears to be a single epimer and, although its stereochemistry is not proven at this stage, its subsequent fate can most readily be explained if it is the epimer shown in **5**.

The phenolic hydroxyl groups were protected by conversion to a mixed carbonate and the

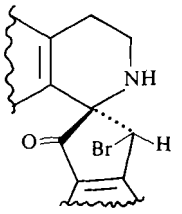
nitrogen was then formylated with acetic–formic anhydride. The product **4***b* was treated with aqueous acetic acid containing silver acetate in order to replace the bromine with a hydroxyl group and form **4***c*. This reaction appears to have taken place with net inversion at the reaction site and produced the alcohol **4***c* with the same configuration at C-9 as ochrobirine (as illustrated in **6**). The alcohol **4***c* was protected as its tetrahydropyranyl ether and the protecting groups were removed from the catechol system, which was then methylenated to provide an intermediate possessing the methylenedioxybenzene moiety found in ochrobirine (**1***c*) and several other spirobenzylisoquinoline alkaloids.



5

7

The alcohol function was regenerated by hydrolysis of the tetrahydropyranyl ether, the ketonic and amide carbonyl functions were reduced with lithium aluminum hydride, and (±)-ochrobirine (**1***c*) (the stereochemistry is illustrated by **7**) was isolated. This material formed crystals, m.p. 237–241°, identical in spectroscopic and t.l.c. characteristics with the authentic alkaloid; comment has been made previously (6, 7) on the variation in the values reported for the melting point of ochrobirine,

and our value is in accord with that reported by Manske and coworkers (6).

This route was explored first starting with the unsubstituted parent 1,2-indanedione (**8***a*) because of its greater accessibility, and the details of the reactions in the exploratory model series and in the main series (leading to alkaloids) can conveniently be discussed together. The reaction sequence produced a series of highly functionalized intermediates, most of which were fairly unstable and resisted isolation and purification by standard procedures; none was obtained crystalline. It was, therefore, generally necessary to carry forward to the next step material in as pure a condition as could be obtained in the circumstances; in each case a reference sample was purified until it appeared to be homogeneous by t.l.c. (or a mixture of epimers in the case of tetrahydropyranyl ethers), and characterized by spectroscopic methods. Our description of the details of the reaction steps, including their stereochemical features, is based on these data, a reasonable expectation for the predictability of recognized processes, and the successful outcome of the synthetic sequence, which has led to an alkaloid of established structure and stereochemistry (4); consequently, this synthesis of **1***c* does not serve in the usual sense to confirm the structure and stereochemistry assigned to the alkaloid, instead the assignments made to the alkaloid show the most probable course, particularly with respect to stereochemistry, followed by the synthesis.

Monobromination of the indanedione **8***a* under controlled conditions provided an excellent yield of **8***b*; care was required to prevent dibromination and other unwanted reactions from occurring, and the methylenedioxy derivative (**2***a*) appeared to be even more sensitive to the reaction conditions, but essentially quantitative conversion could be achieved under the correct conditions. The Pictet–Spengler reaction of **8***b* with the hydrochloride of dihydroxyphenylethylamine **3** provided the spiro compound **9***a* in good yield (50%); in the main series the yield of **4***a* was even better (>70%). In both series the appearance in the n.m.r. spectrum of a single peak in the range characteristic of the proton at the C-Br position pointed to the production of a single epimer at C-9. The bromo ketones were readily degraded by base, but the bromine resisted displacement under a wide range of conditions that used external nucleophiles that were not strong bases. Attempts to introduce an oxygen function directly at an earlier stage by acetoxylation of **8***a* did not lead to the desired isomer. We turned, therefore, to an approach which would introduce a substituent capable of providing intramolecular assistance in the displacement of the bromine. To this end the *N*-formyl derivative **9***b* was prepared by the action of acetic–formic anhydride on the derivative of **9***a* in which the phenolic hydroxyl groups had been protected as mixed carbonates; these conversions were carried out in excellent yields both in the model series and in the main series where **4***b* was obtained. Treatment of **9***b* with silver acetate in hot aqueous acetic acid now led to a clean replacement of the bromine by a hydroxyl group. It seems probable, therefore, that the *N*-formyl group has served, as intended, to provide intramolecular assistance in the displacement of the bromine (8), and this appears to be possible only when these groups have the *trans*-relationship depicted in **5**; furthermore, the solvolysis must then have taken place with net inversion of configuration at C-9 since parallel results were obtained (with a yield of 90% under slightly milder solvolysis conditions) in the main series and the product obtained (**4***c*) can be assigned the *cis*-configuration shown in **6** because it led ultimately, under conditions where no further stereochemical change at C-9 would be expected, to ochrobirine, which has been assigned this configuration at C-9 (4).

Careful basic hydrolysis of the carbonate **9***c* regenerated the catechol in ring A and this was methylenated by treatment with methylene iodide and base in dimethylformamide in the

For personal use only.

presence of a copper catalyst (3, 9). An acceptable but not good yield of the desired methylenedioxybenzene derivative (**9***d*) was obtained, but several by-products were also isolated; in the main series the situation was even worse and the yield of desired product (15%) from **4***c* was considered to be unacceptably low. Since it appeared probable that the β-hydroxy ketone of ring C was largely responsible for the difficulty encountered in the methylenation reaction, in the main series the hydroxyl function was protected as its tetrahydropyranyl derivative prior to methylenation. The methylenation reaction was now highly successful and an excellent yield of the methylenedioxy compound was obtained. (Spectroscopic evidence indicated that the tetrahydropyranyl derivatives existed as pairs of epimers differing in configuration in the tetrahydropyran ring; this was of no consequence with respect to the development of the stereochemistry of the alkaloidal skeleton.) We have commented previously (3) on the desirability of carrying out the formation of a methylenedioxybenzene moiety early in a synthesis and before sensitive functional groups are present because of the vigorous conditions required to effect methylenation of a catechol; in the present synthesis, however, the activated phenolic character of **3** was required to obtain an acceptable yield of product in the Pictet–Spengler step, and the recent description of a relatively mild methylenation reaction (8) was of critical value to our synthetic plan.

In the model series, after the formyl group had been removed by hydrolysis, it was found that the presence of the hydroxyl group prevented successful completion of the Eschweiler–Clarke *N*-methylation reaction. Consequently, in the main series hydrolysis was carried out under conditions that removed only the tetrahydropyranyl group and formed **4***d* (the sequence from **4***c* was carried out with an over-all yield greater than 85%), and both the ketone and the amide carbonyl groups were reduced by addition of lithium aluminum hydride. (±)-Ochrobirine (**1***c*) uncontaminated by the epimeric diol was obtained (in 53% yield); the stereoselectivity of this reduction is most readily attributed, as has been proposed by others (5, 6), to internal delivery of hydride to the carbonyl group at C-14 from an aluminum hydride complex formed first at the C-9 hydroxyl group. Under the conditions we used some *N*-demethylochrobirine was also isolated, resulting from reductive removal of the *N*-formyl group by the lithium aluminum hydride; however, this yielded further (±)-ochrobirine (19% from **4***d*) on re-formylation and lithium aluminum hydride reduction.

Experimental

Melting points were determined on a Thomas-Kofler micro hot stage. Spectrometers used were a Perkin–Elmer 237B or 257 for i.r. spectra, a Unicam SP800 for u.v. spectra, a Varian T-60 for n.m.r. spectra, a CEC 21-490 for mass spectra, and an AEI MS-902 for accurate mass measurements. Unless otherwise indicated, chloroform solutions were used to obtain i.r. spectra and the wavelengths of significant absorptions are reported in μ, and chloroform-*d* solutions (with tetramethylsilane as internal standard) were used to obtain n.m.r. spectra and chemical shifts are reported on the τ scale followed in parentheses with an indication of the multiplicity of the signal (singlet, doublet, etc. are abbreviated to their initial letters) and the number of protons associated with it. Since the intermediates obtained were non-crystalline and generally unstable, they could not be characterized by microanalysis; some were too unstable to provide satisfactory mass spectra, the parent-molecule ion frequently being absent and ions indicative of thermal degradations being present, but the *m/e* values of the more abundant ions (followed in parentheses by an indication of their relative abundance) and the accurate mass measurements of certain significant ions are reported for key intermediates where these values could be obtained.

*The 3-Bromo-1,2-indanediones (**8***b*, **2***b*)

(a) Model Series

Pyridinium bromide perbromide (800 mg; 2.5 mmol) was added to a solution of 1,2-indanedione (3) (290 mg; 2.0 mmol) in 25 ml of glacial acetic acid and the mixture was heated on a steam bath with vigorous swirling. As soon as the red color faded (5–10 min), the reaction mixture was poured into 400 ml of ice-water and thoroughly extracted with methylene chloride. The extract, after it had been washed with water until neutral, afforded 3-bromo-1,2-indanedione (**8***b*) (390 mg; 1.7 mmol) as an unstable amber oil. Spectroscopic characteristics: i.r. 5.64, 5.77; n.m.r. 1.8–2.4 (complex; 4), 4.34 (s; 1); mass spectrum 226, 224 (equal intensity; mol. ions corresponding to $C_9H_5BrO_2$).

(b) Methylenedioxy Series

4,5-Methylenedioxy-1,2-indanedione (3) (190 mg; 1.0 mmol) was brominated with pyridinium bromide perbromide (400 mg; 1.25 mmol) under the same conditions, and the bromo derivative **2***b* (280 mg; 1.0 mmol) was obtained as an unstable amber oil. Spectroscopic characteristics: i.r. 5.65, 5.81; n.m.r. 2.65 (AB q, J = 8 Hz, int. chem. shift 33 Hz; 2), 3.67 (narrow m; 2), 4.46 (s; 1).

The Spiro Skeletons (Pictet–Spengler Cyclization)

(a) Model Series

A mixture of the bromo dione **8***b* (390 mg; 1.7 mmol) and β-(3,4-dihydroxphenyl)ethylamine hydrochloride (429 mg; 2.25 mmol) in 30 ml of absolute ethanol was heated at 68–70° with vigorous stirring under nitrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for 24.5 h. The reaction mixture was cooled, diluted with 250 ml of 3% hydrochloric acid, and extracted with methylene chloride. The aqueous solution was cooled to 0°, very carefully neutralized (to Fisher short range Alkacid ribbon) by the addition of solid sodium bicarbonate, and thoroughly extracted with methylene chloride. This extract afforded the bromospiroisoquinoline **9***a* (300 mg; 0.83 mmol) as a dark unstable oil. Spectroscopic characteristics: i.r. 2.75, 2.81, 3.05 (broad), 5.80; n.m.r. ($CDCl_3$–CH_3OD): 1.9–2.8 (complex; 4), 3.29 (s; 1), 3.95 (s; 1), 4.24 (s; 1) (remainder of the spectrum obscured by solvent).

Methyl chloroformate (*ca.* 2.4 mmol) was added dropwise to a stirred solution of **9***a* (300 mg; 0.83 mmol) in 25 ml of pyridine cooled to 0°. The reaction mixture was allowed to warm up to room temperature and stirring was continued for 20 h. Solvent was removed by vacuum distillation at room temperature, and the residue was taken up in methylene chloride, washed with water, and recovered in the usual manner as an amber oil (i.r. 5.65, 5.79).

This intermediate was redissolved in 10 ml of methylene chloride cooled to 0°, and 1 ml of acetic–formic anhydride was added dropwise to the stirred solution. The solution was allowed to warm up to room temperature and stirring was continued for 20 h. Solvent was removed at reduced pressure, the residue was dissolved in methylene chloride which, after it had been washed with water, afforded the formylated product **9***b* (382 mg; 0.76 mmol) as an amber oil. Spectroscopic characteristics: i.r. 5.63, 5.77, 5.96; n.m.r. 1.76 (s; 1), 1.9–2.6 (complex; 4), 2.78 (s; 1), 3.49 (s; 1), 4.38 (s; 1), 6.10 (s; 3), 6.20 (s; 3), 5.6–7.2 (complex; 4).

(b) Methylenedioxy Series

3-Bromo-4,5-methylenedioxy-1,2-indanedione (**2***b*) (280 mg; 1.0 mmol) and β-(3,4-dihydroxyphenyl)ethylamine hydrochloride (221 mg; 1.16 mmol) in 15 ml of absolute ethanol formed, under the conditions described above, the spiro compound **4***a* (286 mg; 0.71 mmol) which was isolated as an unstable yellow solid. (N.m.r. ($CDCl_3$–CH_3OD): 2.66 (AB q, J = 8 Hz, int. chem. shift 26 Hz; 2), 3.38 (s; 1), 3.76 (narrow m; 2), 4.00 (s; 1), 4.39 (s; 1) remainder of spectrum obscured by solvent.) This intermediate was immediately treated with methyl chloroformate and then acetic–formic anhydride under the conditions used in the model series, and the intermediate **4***b* (322 mg; 0.58 mmol) was isolated as an amber foam. Spectroscopic characteristics: i.r. 5.64, 5.79, 5.96; n.m.r. 1.78 (s; 1), 2.75 (AB q, J = 8 Hz, int. chem. shift 30 Hz), 2.81 (s; 1), 3.47 (s; 1), 3.85 (narrow m; 2), 4.43 (s; 1), 6.16 (s; 3), 6.22 (s; 3), 5.8–7.2 (complex; 4); mass spectrum 468(3), 364(10), 350(30), 349(100), 348(29), 334(13), 305(13), 293(15), 277(27), 276(28), 248(20), 220(14), 191(19), 190(20), 177(16), 164(17), 163(22), 123(14), 117(17); mass measurements 468.09020 (P-Br, $C_{23}H_{18}O_{10}N$, 468.09307), 349.05639 ($C_{16}H_{13}O_9$, 349.05596; $C_{19}H_{11}O_6N$, 349.05864).

Displacement of Bromine

(a) Model Series

Silver acetate (490 mg; 3.0 mmol) was added to a solution of the protected bromo spiro compound **9***b* (382 mg; 0.75 mmol) in 25 ml of 90% aqueous acetic acid, and the mixture was vigorously stirred at 100–105° under nitrogen with exclusion of light for 10 h. The reaction mixture was cooled, diluted with 400 ml of ice-water, and thoroughly extracted with methylene chloride. The extract, after it had been washed with water, afforded the hydroxy compound **9***c* (200 mg; 0.45 mmol) as an amber oil. Spectroscopic characteristics: i.r. 5.63, 5.77, 6.03; n.m.r. ($CDCl_3$–CH_3OD) 1.76 (s; 1), 2.0–2.6 (complex; 4), 2.80 (s; 1), 3.62 (s; 1), 4.80 (s; 1), 6.10 (s; 3), 6.21 (s; 3) (remainder of spectrum obscured by solvent).

(b) Methylenedioxy Series

The same reaction was carried out with **4***b* (254 mg; 0.59 mmol), carrying the methylenedioxy group in ring D, and the hydroxy compound **4***c* (210 mg; 0.53 mmol) was isolated as a brown solid after a reaction time of 8 h. Spectroscopic characteristics: i.r. 5.64, 5.79, 6.03; n.m.r. 1.78 (s; 1), 2.78 (AB q, J = 8 Hz, int. chem. shift 28 Hz; 2), 2.82 (s; 1), 3.55 (s; 1), 3.86 (narrow m; 2), 4.78 (broadened s, sharpened on addition of D_2O; 1), 6.12 (s; 3), 6.18 (s; 3), 5.8–7.4 (complex; 4); mass spectrum 467(37), 440(40), 439(57), 424(34), 412(36), 380(38), 366(34), 350(75), 349(91), 336(65), 334(74), 322(100), 321(62), 320(35), 293(46), 279(47), 277(72), 262(46), 249(32), 222(34), 221(36), 220(55), 219(40), 192(37), 191(47), 190(38), 178(38), 177(72), 165(47), 163(90), 151(35), 137(42); mass measurements 467.08433 (P-H_2O, $C_{23}H_{17}O_{10}N$, 467.08525), 349.05606 ($C_{16}H_{13}O_9$, 349.05596; $C_{19}H_{11}O_6N$, 349.05864), 322.07087 ($C_{18}H_{12}O_5N$, 322.07154).

Methylenation

The hydroxy compound **4***c* (146 mg; 0.30 mmol) in 5 ml of dry methylene chloride was refluxed with 0.04 ml of dihydropyran and a trace of *p*-toluenesulfonic acid for 1.5 h under nitrogen. The mixture of epimeric tetrahydropyranyl derivatives (182 mg), which showed two spots on t.l.c., was isolated in the usual manner, and then dissolved in 15 ml of methanol. A solution of sodium bicarbonate (100 mg; 1.2 mmol) in 10 ml of water was added over a period of 10 min to the stirred methanol solution, which was kept at room temperature and under nitrogen. After a further 4 h, the solution was diluted with 150 ml of water and extracted with methylene chloride. The phenolic material (128 mg) obtained from the extract was dissolved in 30 ml of dimethylformamide containing methylene iodide (50 mg; 1.8 mmol), potassium carbonate (300 mg; 2.3 mmol), and cupric oxide (200 mg). The reaction mixture was blanketed with nitrogen, stirred vigorously, and heated to 120–125° for 1.5 h. It was then cooled, diluted with 350 ml of ice-water, and thoroughly extracted with methylene chloride. The extract afforded a residue (129 mg), a mixture of epimeric tetrahydropyranyl derivatives, which was dissolved in 12 ml of 0.5 *N* hydrochloric acid; the reaction mixture was stirred at room temperature under nitrogen for 2.5 h, diluted with 200 ml of water and thoroughly extracted with methylene chloride. After it had been washed with water, the extract was evaporated and the methylenedioxy compound **4***d* (100 mg; 0.26 mmol) was obtained as an amber solid. Spectroscopic characteristics: i.r. 5.81, 6.05; n.m.r. 1.70 (s; 1), 2.74 (AB q, J = 8 Hz, int. chem. shift 29 Hz; 2), 3.34 (s; 1), 3.80 (s; 2), 3.95 (s; 1), 4.13 (narrow m; 2), 4.78 (broadened s, sharpened on addition of D_2O; 1), 5.6–7.5 (complex; 4).

(±)-Ochrobirine

Lithium aluminum hydride (0.35 mmol) as an 0.05 *M*

solution in ether was added dropwise to a stirred solution of the keto amide **4***d* (32 mg; 0.084 mmol) in 40 ml of dry tetrahydrofuran at 0° under nitrogen. Stirring was continued for a further 2.5 h while the reaction mixture was allowed to warm up to room temperature; solid lithium aluminum hydride (30 mg; 0.8 mmol) was then added and the solution was refluxed for 30 min. The solution was cooled to 0°, and excess lithium aluminum hydride was carefully decomposed by dropwise addition of cold 5% hydrochloric acid. The solution was diluted with 25 ml of water, made basic with solid sodium bicarbonate, and thoroughly extracted with methylene chloride. After it had been washed with water, the extract afforded a residue which was subjected to preparative layer chromatography on silica gel G with elution by 85:14:1 methylene chloride – methanol – concentrated ammonium hydroxide. This provided (±)-ochrobirine (16 mg; 0.044 mmol) and its *N*-demethyl analog (8 mg; 0.022 mmol). The latter was *N*-formylated under the conditions described above, and then reduced with lithium aluminum hydride (15 mg; 0.40 mmol) in refluxing tetrahydrofuran to provide a further supply of (±)-ochrobirine (6 mg; 0.016 mmol). The (±)-ochrobirine was recrystallized from acetone–hexane and obtained as cream-colored prisms, m.p. 237–241° (lit. 235 (6), 210–212 (7), 185–187° (5)). The t.l.c. behavior (three systems) and n.m.r., i.r., u.v., and mass spectra were identical to those of an authentic sample of the alkaloid and the spectroscopic values corresponded to those reported (5–7) for natural and synthetic materials.

We thank the National Research Council of Canada for financial support of this work; fellowship support to J. Whelan from his source and from Kodak Canada Ltd., is also gratefully acknowledged. Professor D. B. MacLean of McMaster University provided friendly encouragement and the reference samples and spectra.

The Cumulative Acceleration by Methyl Substituents on the Rate of Addition of 4-Chlorobenzenesulfenyl Chloride to Olefins[1]

GEORGE H. SCHMID AND DENNIS G. GARRATT

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received February 22, 1973

The rate of addition of 4-chlorobenzenesulfenyl chloride to ethylene and all six of its methylated derivatives has been measured in 1,1,2,2-tetrachloroethane at 25° by means of the stopped flow and a competitive technique. A plot of log k_{rel} *vs.* the number of methyl groups on the carbon–carbon double bond is linear. This establishes that the methyl groups have a cumulative acceleration on the rate contrary to previous reports. The use of the competitive method of obtaining rates of arenesulfenyl chloride additions to olefins suffers from the fact that thermodynamically rather than kinetically controlled product mixtures are often formed.

La vitesse d'addition du chlorure de chloro-4 benzènesulfènyle sur l'éthylène et ses six dérivés méthylés, a été mesurée dans le tétrachloro-1,1,2,2 éthane à 25° par les techniques de compétition et de flux bloqué. Le tracé du log k_{rel} en fonction du nombre de groupes méthyle sur la double liaison carbone–carbone est une droite; ceci montre que les groupes méthyle ont un effet d'accélération cumulatif sur la vitesse contrairement aux publications antérieures. L'utilisation de la méthode compétitive dans l'obtention des vitesses d'addition des chlorures d'arène sulfényle pêche par la fait que les produits thermodynamiques se forment souvent de préférence aux produits cinétiques. [Traduit par le journal]

Can. J. Chem., **51**, 2463 (1973)

Introduction

The fact that methyl substituents on a carbon–carbon double bond have a cumulative acceleration on the rates of electrophilic addition for reactions in which a bridged intermediate is involved in their mechanism was first pointed out by Bartlett and Sargent (2). Such a substituent effect has been observed in the epoxidation of olefins by peracetic acid (3) and the ionic bromination (4) and chlorination (5) of olefins.

A very different effect of methyl substitution is observed in the acid-catalyzed hydration of simple alkenes where the rate-determining step is the addition of a proton to the double bond to form an open carbonium ion, with resultant concentration of charge upon *one* of the carbon atoms of the double bond (6). Thus an olefin such as isobutylene, which can form a tertiary carbonium ion, reacts at least 1000 times faster than propylene which can form only a secondary carbonium ion. Further substitution of methyl groups at the less methylated end of the double bond produces no increase in the hydration rate of the compound. Consequently no cumulative acceleration by methyl substitution is found for a reaction in which an open ion is involved in its reaction mechanism.

[1]Reaction of Sulfenyl Chlorides and their Derivatives. VIII. For Part VII, see ref. 1.

The mechanism of the addition of alkane and arene sulfenyl chlorides to olefins is known to involve a bridged episulfonium ion (7). Consequently the rate of this addition reaction should exhibit such cumulative acceleration by methyl substitution. Thaler (8) found that the relative rates of addition of methanesulfenyl chloride to a series of olefins obtained using a competition technique do not show such a cumulative effect. Beverly and Hogg (9) on the other hand have found that the rate of addition of 2,4-dinitrobenzenesulfenyl chloride to a number of olefins gives a linear Taft plot.

We wish to report experimental results which will reconcile the results of Thaler and Hogg.

Results

We have measured the rate of addition of 4-chlorobenzenesulfenyl chloride to ethylene (**1**) and all its methylated derivatives (**2**–**7**) in 1,1,2,2-tetrachloroethane (TCE) at 25 °C by means of the stopped flow technique using a Durrum–Gibson stopped-flow spectrophotometer. The rate of disappearance of 4-chlorobenzenesulfenyl chloride was followed by measuring the decrease in its absorption at 392.5 nm. The addition was found to exhibit normal second order kinetics, first order in olefin and first order in sulfenyl chloride to 80% completion of the reaction. The rate data are presented in Table 1.

TABLE 1. The specific rate constants for the addition of 4-chlorobenzenesulfenyl chloride to a series of methyl substituted ethylenes in tetrachloroethane at 25°

Compound	No. of methyl groups	k_2 (M^{-1} s^{-1})	k_{rel}	No. of runs
Ethylene (**1**)	0	65.1 ± 3.0	1.0	8
Propene (**2**)	1	205 ± 18	3.14	6
cis-2-Butene (**3**)	2	1340 ± 100	20.6	16
trans-2-Butene (**4**)	2	434 ± 13	6.66	11
Isobutylene (**5**)	2	551 ± 50	8.46	6
2-Methyl-2-butene (**6**)	3	3030 ± 210	46.5	25
2,3-Dimethyl-2-butene (7)	4	7760 ± 540	119	30

	R_1	R_2	R_3	R_4
1	H	H	H	H
2	CH_3	H	H	H
3	CH_3	H	CH_3	H
4	CH_3	H	H	CH_3
5	CH_3	CH_3	H	H
6	CH_3	CH_3	CH_3	H
7	CH_3	CH_3	CH_3	CH_3

We have also determined the relative rates by means of competition experiments using 4-chlorobenzenesulfenyl chloride rather than methanesulfenyl chloride used by Thaler. Using this method, equimolar excesses of two olefins were allowed to react with an inadequate supply of 4-chlorobenzenesulfenyl chloride. The product composition was determined by g.l.c. as well as n.m.r. and was found to vary with time. When the product composition was determined immediately after mixing, the product ratios so obtained were identical within experimental error to the values obtained by means of the stopped flow technique. If the reaction mixture was allowed to stand at 25° for as long as several days an equilibrium mixture was finally obtained. These data are given in Table 2.

TABLE 2. Product composition under kinetic and thermodynamic control of the addition of 4-chlorobenzenesulfenyl chloride to a series of methyl substituted ethylenes in tetrachloroethane at 25°

Compound	Product composition		k_{rel}*
	Initial	Equilibrium	
Ethylene (**1**)	1.0	1.0	1.0
Propene (**2**)	3.0	0.8	3.14
cis-2-Butene (**3**)	21	7.3	20.6
trans-2-Butene (**4**)	6.7	2.6	6.66
Isobutylene (**5**)	8.5	1.18	8.46
2-Methyl-2-butene (**6**)	46.4	9.11	46.5
2,3-Dimethyl-2-butene (7)	120	7.47	119

*Determined by stopped flow technique.

Discussion

From the data in Table 1, it is clear that there is a corresponding increase in the rate of addition of 4-chlorobenzenesulfenyl chloride with an increase in the number of methyl groups on the olefin. The cumulative nature of this increase is illustrated in Fig. 1 in which the log k_{rel} for addition of bromine, chlorine, and 4-chlorobenzenesulfenyl chloride is plotted against the number of methyl groups on the double bond. These data for the addition of 4-chlorobenzenesulfenyl chloride are clearly consistent with the findings of Hogg as well as our expectations regarding the mechanism of arenesulfenyl chloride addition to olefins but are contrary to the findings of Thaler.

The data in Table 2 explain why the results of Thaler do not appear to be consistent with the data in Table 1. The product composition depends upon whether the experiment is carried out under conditions of kinetic or thermodynamic control. The results of Thaler using the competition technique appear to have been obtained under conditions of thermodynamic

rather than kinetic control. Considerable evidence has been presented that the kinetically controlled adducts, formed from the addition of alkane and arenesulfenyl chlorides, can undergo isomerization (10) under conditions of thermodynamic control. Such *anti*-Markownikoff isomerization is occurring in this system and can be detected by n.m.r. The initial and final product compositions for the additions where such

isomerization can be detected are given in Table 3. Furthermore it has recently been reported (11) that an exchange of arenesulfenyl chloride can occur between an adduct and an olefin. This too occurs under the conditions of the competition experiment. Thus our results, as well as those of Thaler can be explained in the following way. Addition of 4-chlorobenzenesulfenyl chloride to an equimolar excess of ethylene and propene will give initially a mixture of products containing predominently the propene adducts **8** and **9** since they are the kinetically favored products. With time an exchange will occur to form an equilibrium mixture of adducts **8**, **9**, and **10** containing predominently **10**. As previously noted this exchange most likely occurs by reformation of the episulfonium ions **11** and **12** as illustrated in Scheme 1. The adducts of 4-chlorobenzenesulfenyl chloride undergo exchange slowly enough that we can observe the kinetically controlled product distribution in the competition experiments as well as equilibration to the

thermodynamic product distribution. Use of methanesulfenyl chloride rather than 4-chlorobenzenesulfenyl chloride would be expected to accelerate the exchange reaction and as a result the observed product distribution would not be that of kinetic control. To support this view, we have found that the equilibrium for exchange between 2-chloropropyl methyl sulfide and isobutylene is established within 1 h at room temperature in *n*-heptane. Clearly exchange was occurring in the competitive experiments carried out by Thaler.

Our results are in accord with those of Thaler in one respect. From the plot in Fig. 1 it is clear that the cumulative effect of methyl groups on the rate is least for the addition of 4-chlorobenzenesulfenyl chloride and greatest for the addition of chlorine. Thus the methyl substituents on the episulfonium ion contribute less toward delocalizing the positive charge than do the methyl substituents on the bromonium or chloronium ion. This is consistent with the ability of the three heteratoms to support a positive charge; S > Br > Cl.

Experimental

All melting and boiling points are uncorrected. Microanalyses were carried out by A. B. Gygli Microanalysis Laboratory, Toronto, Ontario.

The *olefins* were obtained commercially and their purity was verified by g.l.c. and n.m.r.

4-Chlorobenzenesulfenyl chloride was prepared as previously described (12).

1,1,2,2-Tetrachloroethane was purified as previously described (12).

Kinetics

Solutions for kinetic runs were prepared in general by direct weighing. If the olefin was a gas at room temperature, the gas was bubbled into a given quantity of solvent and its' concentration was determined by titration with a standard solution of 4-chlorobenzenesulfenyl chloride. After the kinetic runs, the olefin concentrations were redetermined. No loss of olefin by evaporation was ever detected. The kinetics were carried out as previously described (12).

Product Composition

The reactions were carried out in n.m.r. tubes immersed in a constant temperature bath at 25°. The olefin was added dropwise as quickly as possible into a sulfenyl chloride solution in $CDCl_3$. The n.m.r. tubes were placed in pulverized Dry Ice as soon as the reaction was complete as determined by a colorless solution. The n.m.r. measurements were carried out on a Varian T-60 instrument at 30° (probe temperature). The n.m.r. tubes were then replaced in the bath (25°) until equilibrium composition was observed.

Analytical samples were prepared using analytical grade 4-chlorobenzenesulfenyl chloride and the commercially available olefins. The reactions were carried out in ACS grade methylene chloride at room temperature. On removal of the solvent the adducts were often analytically pure as determined by n.m.r. and g.l.c. Otherwise they were purified by g.l.c. or distillation. The physical properties and chemical analysis of the adducts are given in Table 4. Selected n.m.r. data are presented in Table 5.

Exchange Reactions with Methanesulfenyl Chloride Adducts

The existence of exchange between adducts of methanesulfenyl chloride and alkenes in *n*-heptane at 25° was shown by adding 2-chloropropyl methyl sulfide to a solution of isobutylene. Within 10–15 min of addition the characteristic peaks of the adduct of *p*-chlorobenzenesulfenyl chloride and isobutylene apeared in the n.m.r.

Competitive Experiments With 4-Chlorobenzenesulfenyl Chloride

To solutions equimolar in each of two olefins, *e.g.* ethylene and propene, was added enough 4-chlorobenzenesulfenyl chloride to account for 35–45% of the olefin present. Samples were immediately injected into the g.l.c. using a 1/4 in. × 13 ft column of 5% Carbowax on Chromosorb G to separate the products. All adducts were easily separated (except for Markownikoff – *anti*-Markownikoff isomers). Injections were continued over several days until equilibrium was observed to have been reached. The instrument was calibrated to show linearity of peak area versus concentration dependence for the adducts.

Photoreactions of Nitroso Compounds in Solution.[1] XXIII. A Novel Oxidative Photoreaction of Nitrosamines and Nitrosamides

Y. L. CHOW, J. N. S. TAM, C. J. COLÓN, AND K. S. PILLAY

Department of Chemistry, Simon Fraser University, Burnaby, British Columbia

Received May 31, 1972[2]

Novel oxidations attending the photorearrangement of a nitrosamide and the photoaddition of nitrosamine are described and compared with the corresponding non-oxidative photoreactions.hWith proper filters, disproportionation during photorearrangement of *N*-nitrosohexylacetamide and tautomerization during nitrosopiperidine photoaddition to cyclohexene can be minimized to give improved yields of the *anti*-dimers of *C*-nitroso compounds. These side reactions are shown to be exclusively derived from secondary photoreactions of the *C*-nitroso compounds. In the presence of oxygen, the courses of the photoreactions are diverted cleanly to form nitrate esters. Oxygen reacts with nitric oxide, both in the free state and when paired with the C-radical thus diverting the course of the reaction. The rate constant of radical combination between a C-radical and nitric oxide is estimated to be in the range of 2×10^7 s^{-1}.

De nouvelles oxydations accompagnant le photoréarrangement de la nitrosamide et la photoaddition de la nitrosamine sont décrites et comparées avec les photoréactions non-oxydantes correspondantes. Avec des filtres convenables, la dismutation durant le photoréarrangement de la *N*-nitrosohexylacétamide et la tautomérisation durant la photoaddition de la nitrosopiperidine au cyclohexène peuvent être réduites au minimum pour ainsi donner de meilleurs rendements en dimères-*anti* des composés *C*-nitroso. Ces réactions parasites proviennent, tel qu'il a été démontré, exclusivement de photoréactions secondaires des composés *C*-nitroso. En présence d'oxygène, le cheminement des photoréactions est nettement modifié pour former des esters nitrate. L'oxygène réagit avec l'oxyde nitrique, à la fois à l'état libre et lorsque pairé au C-radical, pour ainsi dévier le chemin de la réaction. La constante de vitesse de la combinaison radicalaire entre le C-radical et l'oxyde nitrique semble se situer dans les alentours de 2×10^7 s^{-1}.

Introduction

It has been established that various nitroso derivatives are photolabile (2–6). Photorearrangements of *N*-nitrosoamides (2–4) and nitrites (5) in neutral solutions are characterized intramolecularly by the exchange reaction between an δ-hydrogen atom and the nitroso group. Photoreaction of a nitrosamine requires the presence of an acid (6); photoaddition to an olefin, however, finds no parallel in the photolysis of *N*-nitrosamides and nitrites. In spite of the wide difference in their reaction pattern, there are certain mechanistic features common to these photoreactions: namely recombination of an alkyl radical and nitric oxide (or a nitric oxide donor) in the product forming step (2, 7). We have reported that, in the course of the photorearrangement of nitrites, oxygen not only fails to quench the photoreaction but diverts the major reaction pathway to form the rearranged nitrates (8) which can be regarded as the oxidation products of the corresponding *C*-nitroso compounds. This new photooxidation process is now found to be a common feature for the photoreactions of *N*-nitrosamides and *N*-nitrosamines. In view of the clean and efficient reaction, this photooxidation is a potentially useful method for nitrate ester synthesis. The purpose of this paper is to describe these photooxidative processes and to compare them with the corresponding non-oxidative photoreactions.

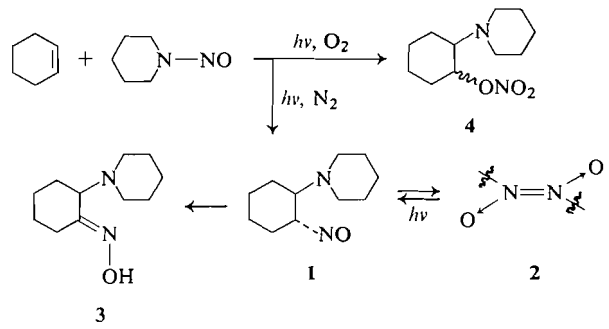
Results

Photoaddition of Nitrosamines

We have established that in the presence of an acid a nitrosamine photolytically adds to cyclohexene to give *trans*-1-nitroso-2-aminocyclohexane (**1**) as the primary product (9, 10). The reactions of a *C*-nitroso alkane such as **1**, has been fairly well studied by us (6, 10) and other groups (11, 12); those reactions which are relevant to the present discussion are summarized in the lower part of Scheme 1. Recently, Mackor and de Boer have suggested that the oximation process **1** → **3** is also promoted by light (13). In general, photoaddition carried out under an inert gas in a Pyrex apparatus gives *anti*-dimer **2**

[1]For paper XXII of this series, see ref. 1.

[2]Revision received April 10, 1973.



SCHEME 1

and oxime **3** in which the yield of **2** is low owing to light-catalyzed decompositions (6, 9, 10).

When photoaddition of *N*-nitrosopiperidine to cyclohexene was carried out with light >350 nm at $-25 \sim -50°$, the u.v. absorption at 290 nm due to *anti*-dimer **2** increased rapidly to a maximum then decreased slowly on prolonged irradiation. Under the usual work-up (9, 10) 2-piperidinocyclohexanone oxime **3** was obtained in good yield in addition to a small quantity of dimer **2**. After the absorbance at 290 nm reached its maximum value, the photolysis was terminated and the reaction mixture worked-up under the conditions given in the Experimental, a crude dimer fraction could be isolated in 30–35% yield. In view of the slow decomposition to the oxime **3** and incomplete photoaddition, the yield of *anti*-dimer **2** was actually higher than that indicated. The dimer was shown to be the *anti*-dimer of *trans*-1-nitroso-2-piperidinocyclohexane as indicated by the strong i.r. absorption at 1210 cm^{-1} and the n.m.r. signal at τ 4.43.

However, the u.v. profile of *N*-nitrosopiperidine photoaddition to cyclohexene showed a simple zero order decrease of 345 nm band intensity without emergence of the *anti*-dimer peak at 290 nm when a stream of oxygen was substituted for nitrogen. Under a less rich supply of oxygen, the *anti*-dimer absorption appeared during the photoaddition with reduced intensity; this dimer absorption disappeared on prolonged irradiation under oxygen. From these photolysates the hydrochlorides of *cis*- and *trans*-1-nitrato-2-piperidinocyclohexane (**4**) were isolated by fractional crystallization. The i.r. spectrum of the crude basic extract exhibited a weak peak at 1715 cm^{-1} indicating the presence of a minor amount of 2-piperidinocyclohexanone **6** (9). The free bases **4** were unstable on standing and, on attempted chromatography, were decomposed to a dark red resin. The crude product was however reduced with hydrazine hydrate catalyzed by Pd/C (14) to a mixture of *cis*- and *trans*-2-piperidinocyclohexanol (**5**) in a good yield; this reagent specifically reduced the nitrates **4** to the corresponding alcohols **5** leaving cyclohexanone **6** as the stable hydrazone. The n.m.r. spectrum of the crude basic extract showed methine proton signals at τ 6.65 (the axial proton of *trans*-**5**) and 5.92 (the equatorial proton of *cis*-**5**) in the ratio of 67:33. This ratio indicates that the isomeric ratio of nitrates *trans*-**4**:*cis*-**4** was about 2:1. The chromatography of cyclohexanols **5** was, however, only partially successful giving semi-pure *trans*-**5** as a low melting solid. Attempted *p*-nitrobenzoylation of **5** was not successful; cyclohexanols **5** were recovered. Treatment of cyclohexanols **5** with acetic anhydride in pyridine gave the expected acetates which, on chromatography, were decomposed to starting material **5**.

Under similar irradiation conditions, oxidative photoaddition of *N*-nitrosodimethylamine to cyclohexene cleanly gave a mixture of the hydrochlorides of *trans*- and *cis*-1-nitrato-2-dimethylaminocyclohexane (**4**, dimethylamino instead of piperidino group). The isomeric ratio is nearly 1:1 as indicated by the n.m.r. spectrum. The crude residue was reduced by sodium borohydride to give a mixture of *trans*- and *cis*-2-dimethylaminocyclohexanol.

Photorearrangement of Nitrosamides[3]

We have established that irradiation of *N*-nitroso-*N*-hexylacetamide (**7**) in a Pyrex appar-

[3]A part of this result was published as a preliminary account (31).

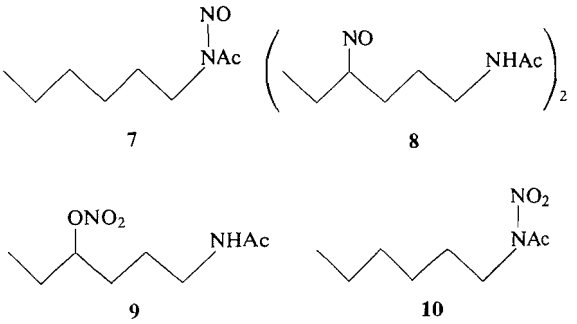
TABLE 1. Percentage yields* of products in the photolysis of *N*-nitroso-*N*-hexylacetamide (**7**) in benzene

Entry	Condition	**8**	**11**	**10**	**9**	Remark
1	N_2, >280 nm	37	37	6	20	†
2	He, >280 nm	45	30	1	18	†
3	N_2, >400 nm	58	42	0	0	
4	O_2, >280 nm	0	10	12	43	‡
5	O_2, >280 nm	0	22	11	44	†, §
6	O_2, >400 nm	0	26	12	47	

*The percentages were calculated on the basis of 1 mol of the product being produced from 1 mol of the nitrosamide.
†Nitrobenzene and nitrophenols were detected.
‡Nitrobenzene (5%), *o*-nitrophenol (4%), *p*-nitrophenol (2%), and *N*-formylacetamide were isolated.
§The experiment was run under oxygen pressure (400 mm Hg).

atus (transparent above 280 nm) under an inert atmosphere leads to the rearrangement product, *N*-(4-nitrosohexyl)acetamide which is isolated as *anti*-dimer **8**, and minor quantities of oxidation products, *N*-(4-nitratohexyl)acetamide (**9**) and *N*-nitro-*N*-hexylacetamide (**10**) (2). In addition *N*-hexylacetamide (**11**) and other minor products derived from β-scission of the amido radical and oxidation of the solvent (such as nitrobenzene and nitrophenols from benzene) were also isolated (15*a*). Reasons have been presented to suggest that the oxidation products, nitrate **9** and nitroamide **10**, are derived from a disproportionation of nitric oxide and are not due to oxygen present as an impurity in the inert gas (2, 15*a*). In the accompanying paper (16) these disproportionation processes have been shown to arise from photolysis of *anti*-dimer **8**. It follows that if the absorption peak of *anti*-dimer **8** at 290 ~ 340 nm is not irradiated, the disproportionation can be prevented. As expected when nitrosamide **7** was irradiated with a light source >400 nm, *anti*-dimer **8** was obtained in a good yield in addition to the parent amide **11**; no oxidation products, such as nitrate **9**, nitroamide **10**, and nitrophenols, were detected (Table 1). The ratio of the two products **8** and **11** remained essentially unchanged over a 10-fold increase of the initial concentration of nitrosamide **7**.

Under oxygen atmosphere, irradiation of a benzene solution of nitrosamide **7** through a Pyrex filter or with light >400 nm resulted in the formation of the oxidation products, nitrate **9**, nitroamide **10**, and the parent amide **11** (Table 1). The oxidation products of benzene (nitrobenzene and nitrophenols) were also obtained by no *anti*-dimer **8** was isolated; weak dimer absorption at



7 **8** **9** **10**

290 nm could be observed if oxygen supply was low. The yields of nitrate **9** remained in the vicinity of 50% with 10-fold increase in the concentration of **7**. Curiously, on irradiation of a benzene solution of nitrosamide **7** saturated with nitric oxide in a Pyrex vessel, neither the rate of photolysis was retarded nor were oxidation products, such as **9** or nitrobenzenes, detected; from the photolysate only *anti*-dimer **8** (36%) and the parent amide **11** (57%) were obtained. A benzene solution saturated with a commercial nitric oxide exhibited an u.v. absorption maximum in the 290–350 nm region which was possibly due to the absorption of nitrogen dioxide[4] (either in NO_2 or N_2O_4 forms).

Discussion

While the primary photoproduct is a *C*-nitroso compound in both photorearrangement of a

[4]This absorption is no longer observable in a solution of nitric oxide purified in a vacuum line. The solubility of NO in water is 7.34 ml/100 ml at 0°, in ethanol 26.3 ml/100 ml at 25° (quoted from Handbook of Chemistry and Physics, 46th ed., The Chemical Rubber Co., Cleveland, Ohio, 1965). In cyclohexane, the NO concentration has been determined to be 2.06×10^{-3} *M* at 800 Torr and 20 °C (ref. 15*b*).

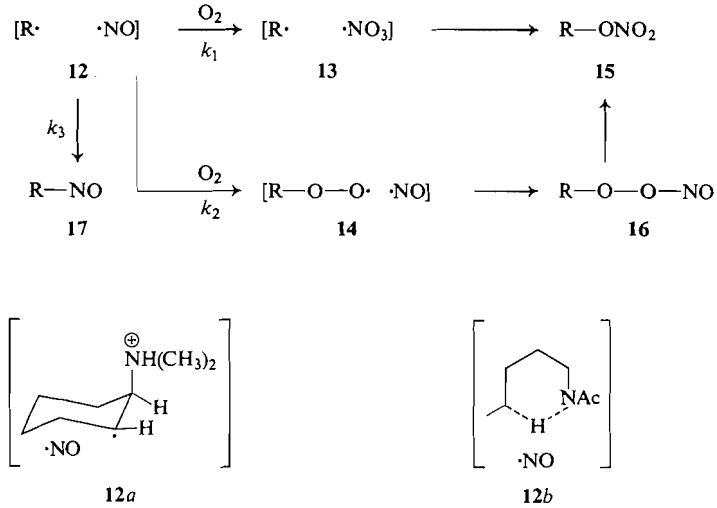
nitrosamide and photoaddition of a nitrosamine, the final products of these two photoprocesses are quite different after irradiation in a Pyrex apparatus. In the former case considerable amounts of oxidation products, nitrate **9** and nitroamide **10**, are formed and in the latter case tautomerization product, oxime **3**, is the major one. In the accompanying paper it is shown (16) that the *C*-nitroso intermediates are undergoing a secondary reaction; in the former case it is a light-catalyzed disproportionation reaction and in the latter a tautomerization as in Scheme 1. It is suggested that the discrepancy between the disproportionation pathway on one hand and the tautomerization pathway on the other arises from the difference in media as well as in the structures. The tautomerization of **1** is catalyzed by the protic solvent and an acid (10–12); in the accompanying paper (16), light-catalyzed tautomerization of **1** will be discussed. Obviously if the dimer of the *C*-nitroso compound is preserved in the photolysate by avoiding irradiation at its absorption wavelength (about 290 nm) during the photolysis, the secondary reactions of *anti*-dimers **2** and **8** will not occur. The improved yields of *anti*-dimers **2** and **8** observed in those photolyses equipped with an appropriate filter system support this argument. It is noteworthy that under such selective excitation conditions the photolysis of a nitrosamide is completely free from any oxidation product (2, 15*a*) and the photoaddition of nitrosamine gives no detectable secondary photoproducts (6, 17). Some pertinent examples of the selective excitation of *N*-nitrosamides are described in the thesis written by one of us (18), and others are under further investigation (19).

There are a few questions arising from the wavelength-dependent photorearrangement of nitrosamide **7**, to which unfortunately there are no satisfactory explanations at the moment since the mechanism of the nitrosamide photorearrangement has not been well established (2–4, 15*a*). These questions will be discussed on the basis of the currently accepted mechanism (2–4) which, although undoubtedly only a simplified version of the true mechanism, should, nevertheless, serve to identify some of the inadequacies of our present understanding. First of all, the use of commercial NO gives essentially the same product pattern **8** and **11** as that of the >400 nm nitrosamide photorearrangement. The conclusion that the observed disproportionation in the >280 nm photorearrangement is derived from the secondary photolysis of *C*-nitroso dimer **8** is supported by the observation that impurities in NO gas, absorbing at 290–350 nm, act as an internal filter to block the irradiation of dimer **8**. It further leads us to a surprising conclusion that externally added NO does not participate in the disproportionation and also does not promote the formation of *C*-nitroso compound; it scarcely even scavenges the amido radical to regenerate **7**, in view of the photolysis rate remaining unaffected. Although in this case it is very tempting to ascribe a "cage effect"[5] to photodissociated radical pair **12**, this assumption does not seem to be a compelling one since it will be shown later that the radical pair **12** is reacting with oxygen efficiently. The well documented fact that NO in condensed or solid phase is predominantly N—N bonded in polymeric forms (21) leads us to assume that the external NO is similarly associated in solution. Such polymeric NO present in the bulk may neither interact nor exchange with NO in **12**. A proposal of a "tight radical pair" for **12** appears reasonable and can account for this as well as >400 nm photolysis under nitrogen. The presence of a radical pair in red-light photolysis of a *C*-nitroso monomer has been demonstrated by de Boer's group recently (11*b*).

Disproportionation of nitric oxide in the course of a radical reaction is known (22). In the accompanying report (16) we shall demonstrate that photolysis of *anti*-dimer **8** through Pyrex causes disproportionation through dissociation to the corresponding *C*-radical and NO as the primary step. No doubt this explains the product pattern observed in the >290 nm photorearrangement under nitrogen. It follows that NO generated in the photolysis of *anti*-dimer **8** is different from that generated by >400 nm irradiation of nitrosamide **7**. Since red-light photolysis (>690 nm) of 2-nitroso-2-methylpropane also causes disproportionation (11*b*), it is untenable to assume a difference in vibrationally excited NO being responsible for this discrepancy. It is more probable that a "tight radical pair" **12***b* is formed and collapses immediately to *C*-nitroso monomer of **8** in photo-

[5]In the photolysis of nitrites, Akhtar and Pechat (20) reported that no "cage effect" is involved in the rearrangement.



SCHEME 2

rearrangement of **7**. In other words, the difference arises from states of "bound" NO and "free" NO.

We have presumed that the H-atom source in the formation of parent amide **11** comes from benzene as the result of displacement reactions by $\cdot NO_3$ and $\cdot NO_2$ formed during >280 nm photolysis. This clearly does not explain the formation of **11** in the >400 nm photorearrangement of **7** since no nitrobenzenes are isolated. Although benzene might be considered as the source by a direct H-atom transfer to the amido radical, this has not been substantiated by finding a dehydrogenation product (such as biphenyl) in the photolysate. There must be a certain amount of stabilization in an amido radical which makes the H-atom abstraction from benzene rather improbable. At present the H-atom source in the formation of the parent amide **11** remains a challenging question.

Returning now to the photolyses in the presence of oxygen, the reaction pathway is cleanly diverted to the formation of oxidation products such as nitrates **4** and **9**. From the fact that the oxidation occurs exclusively even if irradiation has been carried out with a pertinent filter system (to avoid irradiation of the *anti*-dimer peak), it is concluded that *anti-dimers 2 and 8 are not necessary intermediaries for the oxidation process.* It is envisaged that oxygen intercepts the radical pair, such as **12**, before its collapse to *C*-nitroso compound **17**. In view of the argument presented above for the photorearrangement of *N*-nitrosamides, this stage can be represented by radical pair **12***b*. The mechanism of *N*-nitrosamine photoaddition elucidated by us (7) suggests the corresponding radical pair is **12***a* but not necessarily a "tight" one. The oxidation of the radical pair **12** can follow either one of the two possibilities to give radical pair **13** or **14** (Scheme 2). Peroxy nitrite **16** is expected to be an unstable species which rearranges rapidly to **15**, very likely through the peroxy bond scission.

An overview of the various photoprocesses is provided in Scheme 2. It is now in order to discuss the relative importance and the implications of these processes. First of all, the rate of radical combination[6] (**12** → **17**) is nearly equal to the rate of either oxidation processes (**12** → **13** or **14**) as demonstrated by the partial formation of *C*-nitroso compound **17** (equivalent to dimer **2** and **8**) under a limited supply of oxygen; at a higher supply of oxygen, radical pair **12** is totally intercepted and there is no u.v. absorption of the dimer **2** or **8** at 290 nm. Assuming the oxidation has a diffusion controlled rate constant (k_1 or $k_2 = 10^{10}\ M^{-1}\ s^{-1}$) (24) the upper limit of k_3 can be estimated to be $2.2 \times 10^7\ s^{-1}$ at the oxygen concentration of $4.5 \times 10^{-2}\ M$ at 25°

[6]Studies in gas phase kinetics show that the bimolecular rate constants of combinations of methyl radical with oxygen and with nitric oxide are about the same $10^8\ M^{-1}\ s^{-1}$ (23).

(25). We have argued that the recombination rate constant k_3 must be very high in order to explain the stereospecific formation of *trans*-1-nitroso-2-dimethylaminocyclohexane observed previously (17) and the analogue **1** obtained in the present work; in relative sense k_3 must be much faster than that of the cyclohexane ring inversion in **12***a*; the rate of the ring inversion, however, cannot be reliably estimated at present. The success of the present oxidation process derives from the fact that at moderate concentrations of oxygen, radical pair can be intercepted before its collapse; thus the photoreaction is cleanly diverted to nitrate formation.

The relative importance of the two oxidation processes (**12** → **13** or **14**) may be discussed now. Studies in gas phase kinetics show that the reaction of NO with oxygen is complex and no *a priori* prediction of the relative rates is possible (26). The clean nitrate formations suggests that oxygen does not attack the radical pair in a random manner. If the pathway **12** → **14** → **16**→ **4** was the correct mechanism, it would have afforded *trans*-nitrate **4** stereospecifically, assuming pernitrite **16** rearranges to **4** by the peroxy bond scission. This pathway is clearly untenable since experimentally we have observed scrambling of the stereochemistry in nitrate-**4** (*trans*:*cis* = 2:1). The alternative pathway **12** → **13** → **4** can accommodate the stereochemical result and is the more likely mechanism. The combination of nitrogen trioxide with radical R· is probably a slower process than the ring inversion in **12***a*. Isolation of nitrophenols during the oxidative photorearrangement also supports the intermediacy of nitrogen trioxide which has been proposed to attack benzene followed by the nitrate rearrangement leading to these nitrophenols (15*a*). Among other radicals present during the oxidative photorearrangement, neither oxygen nor NO is known to attack the benzene nucleus; a peroxy radical attack requires a circuitous route to yield nitrophenols.

Attention should be called to the fact that the present oxidative photoreaction is a simple and clean preparative method for nitrate esters that requires no strong nitric acid nor expensive silver nitrate. Furthermore, nitrates are stable to photolysis. While the hydrochloride of nitrate **4** is stable to ordinary operations, the free base is unstable due to a base catalysed decomposition of the nitrate moiety. Apparently one of these decompositions is the elimination of nitrous acid to give ketone[7] **6** which is always found as a minor product during the liberation of the free base **4** (2) but is absent in the crude hydrochloride of **4**. The stereochemical consequence of this oxidative photoaddition gives a mixture of *trans*- and *cis*-**4** in 2:1 ratio. Assuming that various possible side reactions during isolation and reduction of nitrate **4** operate nearly identically with both the *cis*- and *trans*-isomeric compounds, this ratio is indicated by the ratio of the isomeric cyclohexanols **5** obtained by the specific reduction. It is interesting that the acetates of cyclohexanols **5** are hydrolyzed back to **5** on adsorbing on an alumina column. The hydrolysis is no doubt facilitated by the displacement of the acetate group assisted by the neighboring amino group participation (27). Since *p*-nitrobenzoate group is a better leaving group than acetate, the hydrolysis may have taken place more rapidly during working-up.

Finally, it is important to mention that oxygen does not quench the excited states of nitrosamines and nitrosamides from which the primary photoprocesses occur. In view of the generally accepted fact that a triplet state is susceptible to an oxygen quenching (28), it may be suggested that the photoreaction is initiated from a singlet state of the nitroso compounds. In the case of photodecompositions of nitrosopiperidine, our kinetic studies by flash excitation (7) have verified the singlet state reaction. A similar study on nitrosamide photodecomposition does not allow us to draw a conclusion since both singlet and triplet sensitization lead to the decomposition (18).

Experimental

For the general conditions of experiments and spectroscopy, see our previous publication (6). For the photolysis a Hanovia medium pressure mercury lamp (654A36, 200 W) was used in conjunction with a suitable filter system. A Pyrex photolysis apparatus cut off the light source below 290 nm. For > 350 nm light source, a filter solution of 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene perchlorate (0.01% aqueous solution) or a Norex filter (29) was used. For > 400 nm light source, a sodium nitrite sodium phthalate solution (30) was used as filter which cut off the light energy below 400 nm.

Photoaddition of N-Nitrosopiperidine

A solution of *N*-nitrosopiperidine (4.5 g), cyclohexene

[7]The ketone could have been formed through a peroxy radical intermediate as has been proposed by de Boer's group in the related oxidative study of nitrosocyclohexane (13). Apparently this process is not important in the present case.

(4.9 g), concentrated hydrochloric acid (3.5 ml), and methanol (500 ml) was irradiated with a light source > 350 nm at −25° for 2 h. Sodium carbonate (5.5 g) was added to the blueish green photolysate with stirring. The white precipitate (1.73 g) was filtered and washed with water. Partial concentration of solvent gave a second crop of crystals (550 mg). The combined crops were recrystallized from a mixture solvent of methylene chloride – methanol to give white crystals of the *anti*-dimer of *trans*-1-nitroso-2-piperidinocyclohexane (**2**): m.p. 170–172°; i.r. 1210, 1185, 1100, 1055, 1030, and 695 cm^{-1}; n.m.r. τ 4.43 ($w_{1/2}$ = 25 Hz, 1H) and 6.8–7.8 (m, 5H).

Subsequent precipitates obtained by evaporation of solvent contained mostly 2-piperidinocyclohexanone oxime (**3**) (9) contaminated with a minor amount of the *anti*-dimer **2**.

Oxidative Photoaddition of N-Nitrosopiperidine

A solution of *N*-nitrosopiperidine (6.84 g, 0.06 mol), cyclohexene (3.28 g, 0.04 mol) and concentrated hydrochloric acid (6 ml) in methanol (340 ml) was irradiated under oxygen atmosphere at −10° for 3 h. A filter solution of 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene perchlorate, was circulated through the cold finger. The bulk of methanol was removed and the residual solution was washed with ether and was neutralized with potassium carbonate to p*H* 7.5. The basic extract (6.8 g) showed strong absorptions at 1625, 1275, and 865 cm^{-1} for a nitrate group and a medium peak at 1715 cm^{-1} for a carbonyl group.

The crude basic fraction was reduced with hydrazine hydrate in the presence of Pd/C in methanol solution (14) for 18 h. The reduced product was isolated in the usual manner to give an oil which exhibited no i.r. absorptions typical of nitrate and carbonyl groups. The oil was distilled under 0.5 mm Hg to give the major fraction of b.p. 84° (4.2 g): i.r. 3440, 1305, 1105, 1080, and 1060 cm^{-1}; n.m.r. τ 5.92 (m, $w_{1/2}$ = 7 Hz), 6.28 (D_2O exchangeable), and 6.65 (dt, J = 4 and 9 Hz): *m/e*(%) 183(M^+), 140(12), 125(35), 124(100), 111(54), 98(93), and 84(50). This fraction solidified at room temperature. The solid was chromatographed on an alumina column. Elution with methylene chloride gave a fraction which showed single spot on a t.l.c. plate. This fraction was distilled to give *trans*-2-piperidinocyclohexanol (**5**): n.m.r. τ 7.47(m), 6.68 (dt, J = ~4 and 11 Hz).

When the above solid was treated with *p*-nitrobenzoyl chloride in pyridine and was worked-up in the usual manner, the starting material, a mixture of *cis*- and *trans*-2-piperidinocyclohexanol, was recovered.

Acetylation with acetic anhydride – pyridine gave a crude product which shows i.r. absorption at 1735 and 1240 cm^{-1}. Chromatography of the crude acetylation product on an alumina column gave the acetate of the *cis*-cyclohexanol **5** which was sublimed at 55°/0.02 mm: i.r. 2860, 2800, 1735, and 1240 cm^{-1}; n.m.r. τ 4.63 ($w_{1/2}$ = 6 Hz, 1H), 7.46 (m), 7.95 (s, 3H), and 8.35 (m); *m/e*(%) 225(9), 182(19), 166(10), 125(12), 124(100), 111(6), 110(5), 98(8), 84(9) and 43(8). This acetate gradually decomposes on storage. Further elution afforded a mixture of *cis* and *trans*-cyclohexanol **5**.

In a separate experiment, a solution of *N*-nitrosopiperidine (2.3 g, 0.02 mol), cyclohexene (2.56, 0.03 mol), and concentrated hydrochloric acid (2 ml, 0.024 mol) in methanol (140 ml) was irradiated under similar conditions. The methanol was evaporated to a small volume under vacuum at a water bath temperature of 10° (if heated, the solution darkens). The methanol was cooled to 0° and then ether was added gradually to produce slight cloudiness from which crystals (1.1 g) appeared upon standing: m.p. 159–161° (dec.). They were recrystallized three times from 2-propanol to give the hydrochloride of *cis*-1-nitrato-2-piperidinocyclohexane (4); m.p. 169–170°; i.r. 2500, 1640, 1266, and 870 cm^{-1}; n.m.r. (D_2O) τ 4.47 (m, $w_{1/2}$ = 12 Hz, 1H), 6.76 (m, 3H), 7.12 (m, 2H), 8.33 (m, 14H).

Anal. Calcd. for $C_{11}H_{21}N_2O_3Cl.H_2O$: C, 47.05; H, 7.48; N, 9.98; Cl, 12.65. Found: C, 46.82; H, 7.89; N, 10.12; Cl, 12.56.

The mother liquor was cooled for another 3 months at −10° to give a second crop of crystals (300 mg) which showed in the n.m.r. spectra a broad multiplet at τ 4.77. These crystals were recrystallized three times from a mixture of 2-propanol – ether to afford the hydrochloride of *trans*-1-nitrato-2-piperidinocyclohexane (4): m.p. 134–137°; i.r. 3250, 2650, 2530, 1630, 1270, and 880 cm^{-1}; n.m.r. (D_2O) τ 4.77 (m, $w_{1/2}$ = 25 Hz, 1H), 6.65 (b, 5H), 8.15 (m, 14H).

Anal. Calcd. for $C_{11}H_{21}N_2O_3Cl$: C, 49.90; H, 7.95; N, 10.58; Cl, 13.40. Found: C, 50.10; H, 7.76; N, 10.42; Cl, 13.27.

Oxidative Photoaddition of N-Nitrosodimethylamine

A solution of *N*-nitrosodimethylamine (1.48 g, 0.02 mol), cyclohexene (3.28 g, 0.04 mol), and concentrated hydrochloric acid (2 ml) in methanol (130 ml) was photolyzed in the similar manner under oxygen for 1.5 h. The usual work-up afforded the hydrochlorides of *cis*- and *trans*-2-dimethylamino-1-nitratocyclohexane; darkened at 109° and decomposed at 119–122° with evolution of a gas; i.r. 1640, 1280, and 870 cm^{-1}; n.m.r. (D_2O) τ 4.3 (m, $w_{1/2}$ = 10 Hz, 1H), 4.7 (m, $w_{1/2}$ = 25 Hz, 1H), 6.5 (superimposed double triplet, J = 3.5 ~ 4 and 12 Hz, 2H), 7.1 and 7.2 (two singlets, 6H), 7.5–7.9 (m, 8H).

Anal. Calcd. $C_8H_{17}N_2O_2Cl$: C, 42.76; H, 7.57; N, 12.47; Cl, 15.81. Found: C, 42.87; H, 7.47; N, 12.35; Cl, 15.70.

The mother liquor of 4 was evaporated to give a syrup which was dissolved in methanol (50 ml). The solution was treated with $NaBH_4$ (1.54 g, 0.04 mol) added in small portions while stirring. After 12 h the solution was treated with concentrated hydrochloric acid (20 ml) and then with water (40 ml). Basification of the solution and extraction with CH_2Cl_2 afforded, upon evaporation of the CH_2Cl_2, an oil (2.2 g) of the *cis* and *trans* mixture (ratio 1:1) of 2-dimethylaminocyclohexanol: i.r. 3450, 1270, 980, 960, and 880 cm^{-1}; n.m.r. τ 6.0 (m, 1H); 7.0 (m, 1H), 7.8 (s, 6H), 7.8 – 9.2 (m, 8H).

Photolysis of N-Nitroso-N-hexylacetamide (7)

A benzene solution of nitrosamide **7** was photolyzed in the same apparatus as above and the results were summarized in Table 1. The isolation and characterization of the products follows the procedure of the previous publication (2).

Nitrate **9** was reduced with lithium aluminum hydride followed by a treatment with benzoyl chloride – pyridine to give *N*-(4-benzoyloxyhexyl)-*N*-ethylbenzamide: i.r. 1720, 1630, 1275, and 1115 cm^{-1}; n.m.r. τ 9.04 (t, 3H,

J = 7 Hz), 8.88 (t, 3H, J = 7 Hz), 4.97 (m, 1H); m/e(%) 353(M^+), 248(3), 232(4), 162(15), 105(100), and 77(35).

For the photolysis under nitric oxide atmosphere, a manometric pressure device was used to maintain the pressure at 1 atm. Before the introduction of nitric oxide, the whole system was carefully displaced with helium gas.

For the photolyses under oxygen, the supply of oxygen was regulated to 1 ~ 3 bubbles per second. Other procedures follow those described in photorearrangement.

The authors thank the National Research Council of Canada, the Defence Research Board of Ottawa and the President's Research Fund of Simon Fraser University for financial support of this work.

Photoreactions of Nitroso Compounds in Solution.[1] XXIV. Photooxidation and Photodecomposition of *C*-Nitroso Compounds

Y. L. CHOW, J. N. S. TAM, AND K. S. PILLAY

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 31, 1972[2]

Irradiation of the *anti*-dimers of *C*-nitroso compounds under nitrogen caused dissociation to the corresponding *C*-nitroso monomer which underwent photodisproportionation, tautomerization, and dimerization. Similar irradiation underhoxygen led principally to nitrate and nitro compound formation. The disproportionation of *N*-(4-nitrosohexyl)acetamide was shown to occur by photodissociation of the *C*-nitroso monomer to the alkyl radical and nitric oxide. Under an oxygen atmosphere, those *C*-nitroso compounds which could undergo facile photodissociation were quickly oxidized to nitrates. As a result, mixtures of the corresponding *cis*- and *trans*-*C*-nitrates were obtained from the *anti*-dimer of *trans*-1-nitroso-2-chlorocyclohexane. The *anti*-dimer of *trans*-1-nitroso-2-piperidinocyclohexane was photolytically tautomerized to the corresponding oxime under nitrogen and was oxidized chiefly to the *C*-nitro compound under oxygen; the two processes obviously share a common intermediate. Mechanisms for these photoprocesses are suggested.

L'irradiation dans une atmosphère d'azote des dimères-*anti* de composés *C*-nitroso a provoqué la dissociation de ceux-ci pour donner le monomère *C*-nitroso correspondant lequel a subi une photodismutation, une tautomérisation et une dimérisation. Une irradiation similaire dans une atmosphère d'oxygène a conduit principalement à la formation des produits nitrate et nitro. La dismutation de la *N*-(nitroso-4 hexyl) acétamide se produit par photodissociation du monomère *C*-nitroso en radical alcoyle et en oxyde nitrique tel qu'il a été démontré. Sous une atmosphère d'oxygène, ces composés *C*-nitroso qui peuvent subir une photodissociation facile ont été très rapidement oxydés en nitrates. Par suite, à partir du dimère-*anti* du *trans* nitroso-1 chloro-2 cyclohexane on a pu obtenir un mélange des *C*-nitrates *cis* et *anti* correspondants. Le dimère *anti* du *trans* nitroso-1 piperidino-2 cyclohexane a été tautomérisé photolytiquement pour donner l'oxyme correspondant sous azote et a été oxydé surtout en composé *C*-nitro sous oxygène; ces deux processus doivent nécessairement posséder un intermédiaire commun. Par suite, on suggère des mécanismes pour ces procédés photochimiques. [Traduit par le journal]

There are many experimental features of nitrosoalkane chemistry that cannot be satisfactorily explained in terms of conventional electronic and steric theories. A nitrosoalkane solution will spontaneously form an equilibrium mixture of monomer **1** and dimers **2** and **3** (2), although the driving force remains obscure (3). The dimers have been shown to possess an azodioxy linkage **2** and **3** in ambient conditions and are colorless in contrast to a deep blue to green color exhibited by the monomer (2). In solution, *primary* and *secondary* nitrosoalkanes have a great tendency to exist as the dimers, whereas the *tertiary* analogs remain mostly monomeric (4). Both electronic and steric effects have been invoked to explain this difference (2–6).

Having an α-hydrogen, *primary* and *secondary* nitrosoalkanes may also irreversibly tautomerize to the corresponding oximes **4**. Although this tautomerization is generally slower than the dimerization process, it is accelerated by acid and base catalysis (7–9). Recently, de Boer's group (10), expanding upon the earlier work of Gowenlock and Trotman (2), has demonstrated that a colorless *anti*-dimer **2**, when irradiated at 320–360 nm at a low temperature, dissociates into a blue–green nitrosoalkane **1** which spontaneously dimerizes at about −70° to the corresponding less stable *syn*-dimer **3**. The latter compound is thermally transformed to the *anti*-dimer on slight warming (see Scheme 1).

C-Nitroso monomers generally exhibit weak absorptions near 680 (ε ~10) and 270 nm (ε ~80), and a strong one at 220 nm (ε *ca.* 5000). The former two bands have been assigned to $n_N \rightarrow \pi^*$ (11) and $n_O \rightarrow \pi^*$ (12) transitions respectively. The long wavelength absorption for an *anti*-dimer **2** occurs in the 280 ~ 300 nm region and that of a *syn*-dimer **3** around 260 ~ 275 nm. Pertinent to the present discussion, it

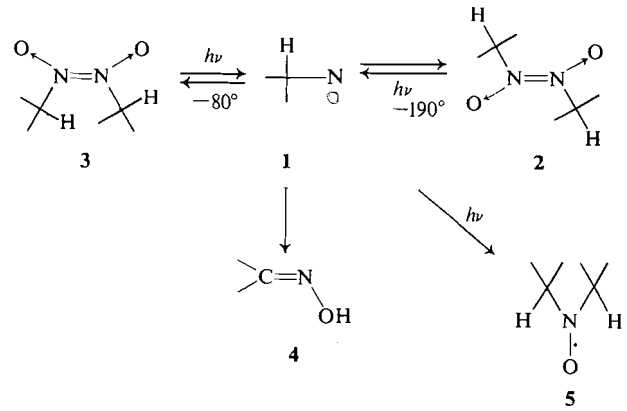


SCHEME 1

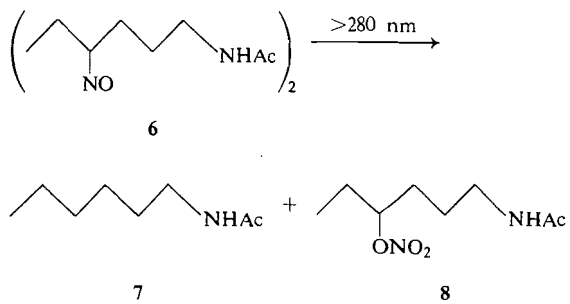
should be mentioned that photolysis of a *C*-nitroso monomer gives a stable radical, nitroxide **5**, in which the primary photochemical act has been shown to be dissociation to alkyl and nitric oxide radicals (13, 14). Suggestions of other types of *C*-nitroso compound photoreactions, such as reduction (15), lack convincing proof and may well be the result of secondary reactions. For a *C*-nitroso group, an electronically excited state analogous to that of a carbonyl group (16) is conceivable, but has not been well defined. In connection with our studies of nitrosamine and nitrosamide photolysis, we have been investigating photoreactions of *C*-nitroso compounds. A recent report on the photooxidation of nitrosocyclohexane (17) prompts us to disclose our results on oxidative and non-oxidative photoreactions of some *C*-nitroso compounds.

Results

Photodecomposition

Since our source of *C*-nitroso compounds were dimers, throughout this report irradiation was carried out in a Pyrex apparatus (energy cut-off <290 nm) so that both dimer and monomer absorption bands were excited; the former excitation promoted the dissociation of dimers **2** or **3** to the corresponding monomer (10).

Irradiation of a benzene solution of the *anti*-dimer of *N*-(4-nitrosohexyl)acetamide (**6**) (18) in a Pyrex flask under nitrogen caused a rapid disappearance of the u.v. absorption peak at 290 nm and gave *N*-(4-nitratohexyl)acetamide (**8**) (18) and *N*-hexylacetamide (**7**) in the ratio of *ca.* 1:3. The oxime corresponding to the tautomerization was not detected in the photolysate. This product distribution suggests that a disproportionation of the *C*-nitroso compound has occurred in which nitrate **8** was formed at the expense of two other *C*-nitroso molecules. However, a similar irradiation of *anti*-dimer **6** in a solution saturated with a commercial nitric oxide resulted in the recovery of the starting material **6** nearly quantitatively.



The *anti*-dimer of *trans*-1-nitroso-2-chlorocyclohexane (**9**) was prepared by addition of nitrosyl chloride to cyclohexene (19–21). On irradiation of a benzene solution of the *anti*-dimer **9** under nitrogen, a white crystalline precipitate formed on the surface of the reaction vessel. The white solid melted at 135–140° and exhibited u.v. absorption at 275 nm which is gradually shifted to 298 nm on standing in a dark place. Recrystallization of this precipitate from benzene gave only the *anti*-dimer **9** as white crystals. This precipitate was the corresponding *syn*-dimer of *trans*-1-nitroso-2-chlorocyclohexane. The crude product isolated from benzene solution exhibited i.r. absorption at 1640, 1280, and 880 for a nitrate and for an *anti*-dimer at 1450 and 1210 cm^{-1}, but no i.r. absorption for a nitro group. Chromatography of this crude

product afforded *anti*-dimer **9** and a fraction which was shown to contain *trans*-1-nitrato-2-chlorocyclohexane (**10**) and cyclohexyl chloride in nearly equal amounts. An analysis by v.p.c. showed that the peak of the *trans*-nitrate **10** contained a small shoulder which was tentatively assigned to the corresponding *cis*-nitrate. Photodecomposition of the *anti*-dimer **9** in a methanol solution was very slow; from the photolysate, *N,N,O*-tri(2-chlorocyclohexyl)hydroxylamine (**11**) was obtained in addition to nitrates **10** and cyclohexyl chloride.

When a methanol solution of the *anti*-dimer of *trans*-1-nitroso-2-piperidinocyclohexane (**13**) (22) containing hydrochloric acid was irradiated at 5 °C, 65–75% of *anti*-1-piperidinocyclohexanone oxime (**14**) was obtained. The tautomerization was slow at room temperature in the absence of irradiation. The crude product showed no i.r. absorption due to a nitrate or a nitro group. Although there were trace amounts of other products, they could not be isolated in pure states. In this photodecomposition as well as the above two cases, there were always traces of other by-products that could be stable radical compounds of nitroxides as de Boer's group has shown by e.s.r. spectroscopy (23). The diffused n.m.r. signals shown by the crude product indicated the presence of paramagnetic substances, although lack of an e.s.r. facility prevented us from confirming this.

Photooxidation

When the photolysis of **6** was carried out under an atmosphere of oxygen instead of nitrogen, nitrate **8** was produced cleanly and in excellent yield. That this was a genuine photooxidation process was established by the fact that a benzene solution of *anti*-dimer **6** saturated with oxygen was stable indefinitely when stored in a dark place. That the oxidation was not initiated by a singlet oxygen (24) (generated, possibly, by a self-photosensitization) was demonstrated by the failure of a methanol solution of **6** to undergo a change when singlet oxygen was generated *in situ* by rose bengal photosensitization.

Oxidative irradiation of *anti*-dimer **9** in a methanolic solution containing perchloric acid or in a benzene solution caused quick disappearance of the *anti*-dimer absorption at 295 nm and precipitation of *syn*-dimer **9**. During the methanol solution photolysis the new absorption at 275 nm due to the corresponding *syn*-dimer was also observed. Owing to precipitation of the *syn*-isomer the photolysis required a prolonged irradiation for completion. From these photolyses *trans*-1-nitrato-2-chlorocyclohexane (**10**) and *trans*-1-nitro-2-chlorocyclohexane (**12**) were isolated by column chromatography. The corresponding *cis*-isomer of **12** was not detected in the photolysate in spite of careful chromatography. The presence of a small amount of the

For personal use only.

cis-isomer of nitrate **10** is suggested by the v.p.c. analysis in which a small shoulder appeared at a slightly longer retention time than that of *trans*-**10**. Some chromatographic fractions of **10** also showed a weak n.m.r. signal at about τ 6.0 that can be assigned to the CHCl proton of the *cis*-isomer. The weak i.r. absorption at 3400 and in the 900–1000 cm^{-1} region, observed in the crude product obtained from the photooxidation in the methanol solution, leads us to suspect the presence of a small amount of the corresponding oxime from tautomerization; this oxime was not isolated. The *trans*-configuration in both cases was assigned on the basis of the large coupling constants of the methine protons in nitrate **10** and nitro compound **12**. Analysis of the product by v.p.c. showed that the photooxidation afforded nitrate **10** and nitro compound **12** in nearly 1:1 ratio. Extensive efforts to reduce the nitrate and nitro groups in **10** and **12** have failed. A mixture of lithium aluminum hydride and aluminum chloride, or catalytic hydrogenation, reduced these functional groups as well as cleaved C—Cl bond to variable extents.

Photooxidation of *anti*-dimer **13** in a benzene solution gave a tarry crude product which showed strong i.r. absorption at 1550, 1320, 1620, and 1270 cm^{-1} and medium absorption at 1710 cm^{-1}. The tarry material was not present in the crude product when the photooxidation was carried out in methanol in the presence of hydrochloric acid: the crude product (hydrochloride salts) exhibited weak i.r. absorptions at 1720, 1635, 1240 and strong absorptions at 1550 and 1450 cm^{-1}. It was shown that this crude product contained *cis*- and *trans*-1-nitro-2-piperidinocyclohexane (**16**) as the major product and minor amounts of *cis*- and *trans*-1-nitrato-2-piperidinocyclohexane (**15**) (1) and 2-piperidinocyclohexanone. The salt was hydrogenated in the presence of platinum catalyst, and then neutralized to give a crude mixture of free bases; the i.r. spectrum showed that the nitrate and nitro groups were completely reduced. Acetylation of the crude base and chromatography gave a small amount of 2-piperidinocyclohexanol (a mixture of *cis*- and *trans*-isomers) (1) and the remainder as various mixtures of *trans*- and *cis*-1-acetamido-2-piperidinocyclohexane (**17**). The ratio of the *cis*- to *trans*-isomer **17** was determined, from an analysis of the n.m.r. spectrum, to be 2:3. From the n.m.r. spectrum of a chromatographic fraction containing *trans*-**17** as the major product, the *trans*-configuration was readily determined from the coupling pattern of the methine proton ($CHNHCOCH_3$). In other fractions, although two methyl signals for the acetyl group were discernible, the chemical shift of the methine proton of the *cis*-**17** was apparently superimposed on that of *trans*-**17**. However, it was fortunate that signals due to the methine as well as methyl protons of *cis*- and *trans*-**17** were well separated when the n.m.r. spectrum of a mixture was determined in the presence of a shift reagent, tris(dipivaloylmethanato)europium (25). In agreement with a *cis*-isomer being a better chelating ligand than a *trans*-isomer, it is pertinent to mention that the signals of methyl and methine protons of the *cis*-**17** were shifted downfield much more than those of *trans*-**17**. In the present case the chemical shift differences of methyl and methine protons were merely <10 Hz in a $CDCl_3$ solution, the corresponding shift differences in the presence of the europium complex were 74 and 48 Hz respectively. This observation may possibly prove useful for differentiating the configurations of isomers.

Discussion

Owing to the facile interconversion of *C*-nitroso compounds under photolytic conditions, it is usually difficult to be certain whether an observed reaction should be attributed to a nitroso monomer or its dimer. For this reason, the reactions of both monomers and dimers are treated together here, except for those steps where a clear distinction can be made. The results described above and those published earlier encompass a wide range of reactions that compete with each other in deciding the fate of a photoexcited *C*-nitroso compound. The favored pathway is decided by the structure of the *C*-nitroso compound as well as by the reaction conditions. Under the experimental irradiation conditions, all the dimers **6**, **9**, and **13** rapidly dissociate to the corresponding monomers, which then undergo further photoreactions. In the case of *anti*-dimer **6**, it is a rapid disproportionation, for **9** a rapid recombination mixed with a slow disproportionation, while for dimer **13** it is overwhelmingly a tautomerization.

Disproportionation during photolysis of dimer **6** has some precedent in nitrite photolysis (26) and in a free radical reaction in the presence of external nitric oxide (27, 28). The primary photoprocess is no doubt the well established step of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

homolytic dissociation to give a C-radical and nitric oxide (13, 14). Owing to an internal filter effect associated with commercial nitric oxide which hinders photoexcitation of the dimer absorption at 295 nm, the identity of the generated nitric oxide with respect to the external one could not be determined.[3] It is clear that the oxidation products obtained in >290 nm photolysis of *N*-nitroso-*N*-hexylacetamide are derived from this disproportionation process of **6** which is the primary photorearrangement product (1, 18); the mechanism of this disproportionation process has been discussed elsewhere (26–29).[4] The lack of disproportionation reactions during >400 nm photolysis of the nitrosamide (1) suggests that the reactive intermediates (either C-radical or nitric oxide) generated in this photolysis are not the same as those generated in the photolysis of *anti*-dimer **6**. We have suggested that a "tight radical pair" generated in >400 nm photolysis prevents liberation of the nitric oxide which ordinarily initiates disproportionation (1). Red-light photolysis (>680 nm) of 2-nitroso-2-methylpropane also yields *t*-butylnitrate and allied disproportionation products[5] (30) in which the presence of a radical pair has been demonstrated. It is believed that only when the members of the radical pair are genuinely "free" from each other, can disproportionation (and nitroxide formation) occur.

The photolysis of *anti*-dimer **9** under nitrogen is more complicated due to the relatively fast formation of the *syn*-dimer of **9** by a kinetically controlled dark reaction. In comparison to the *syn*-dimers of nitrosocyclohexane and other nitrosoalkanes, *syn*-**9** is surprisingly stable; however, the factors responsible for this stability remain unknown. The slow photodissociation of monomer **9** yields disproportionation products as well as hydroxylamine **11**; the latter is apparently formed via the corresponding nitroxide.

Predominant tautomerization during the photolysis of *anti*-dimer **13**, no doubt, has its origin in the proximity of the proton-donating piperidinium group at the 2-position with respect to the *C*-nitroso moiety. In view of the large difference in the rates of irradiated and thermal tautomerizations under comparable conditions, we believe that there is a certain amount of light catalysis in the process. Mackor and de Boer (17, 31) have reported a red-light catalyzed tautomerization of nitrosocyclohexane monomer (generated at 80°) in cyclohexane to yield cyclohexanone oxime in *ca.* 90% yield; in this photolysis e.s.r. signals of the corresponding nitroxide has been detected but no disproportionation product has been reported. One may envisage a vibrationally excited *C*-nitroso monomer, probably derived from a radiationless decay of an electronically excited manifold, to undergo facile tautomerization. Alternatively, photoexcitation may create a dipolar *C*-nitroso species, such as **18**, which triggers a facile proton transfer.

Generally speaking, the results of *anti*-dimer photooxidation in Pyrex apparatus and those of red-light photooxidation of nitrosocyclohexane (17) and 2-nitroso-2-methylpropane (30) can be characterized by the formation of nitrates and nitro compounds, although the ratios can vary considerably. It should be mentioned that nitro compounds were not formed in our photolysis under nitrogen and that the oxidations are genuine photoreactions as shown by control reactions in the dark. Also, the oxidations are not initiated by a singlet oxygen (24). Furthermore, the photooxidation takes place from a *C*-nitroso monomer since no reaction has been observed without irradiation at the dimer absorption near 290 nm.

Inspection of the oxidation products shows that all the nitrates obtained as the result of photooxidation of the *anti*-dimers have lost the stereochemical integrity of the original *trans*-configuration. In contrast, nitro compound **12** maintains the original *trans*-configuration of *anti*-dimer **9**. The conditions used in the photooxidation of *anti*-dimer **13** do not allow us to predict the stereochemical consequences since the scrambling of the configuration in **16** can have arisen from nitro–nitronate tautomeric equilibrium (32) through acid or base catalysis. The dissimilarity in the stereochemical results

[3]For a discussion of the polymeric state of nitric oxide in solution see ref. 1.

[4]For obvious reasons gas kineticists (ref. 28) favor the generation of $\cdot NO_3$ by disproportionation of three molecules of NO. In solution it is more likely NO attacks a *C*-nitroso monomer to form the azonitrate ester intermediate which eliminates nitrogen to give nitrate (27). The absence of the corresponding nitro compound in our photolysis products supports the latter mechanism (however, see ref. 31 for a comparison).

[5]An assumption that only a vibrationally excited ·NO from >290 nm photolysis can undergo disproportionation becomes questionable from this experiment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

suggest that nitro and nitrate formations occur by separate pathways. Indeed, during red-light photooxidation of nitrosocyclohexane, Mackor and de Boer have observed that while the yields of nitrocyclohexane increase as the reaction temperature is lowered, the yield of cyclohexyl nitrate remains virtually stationary.

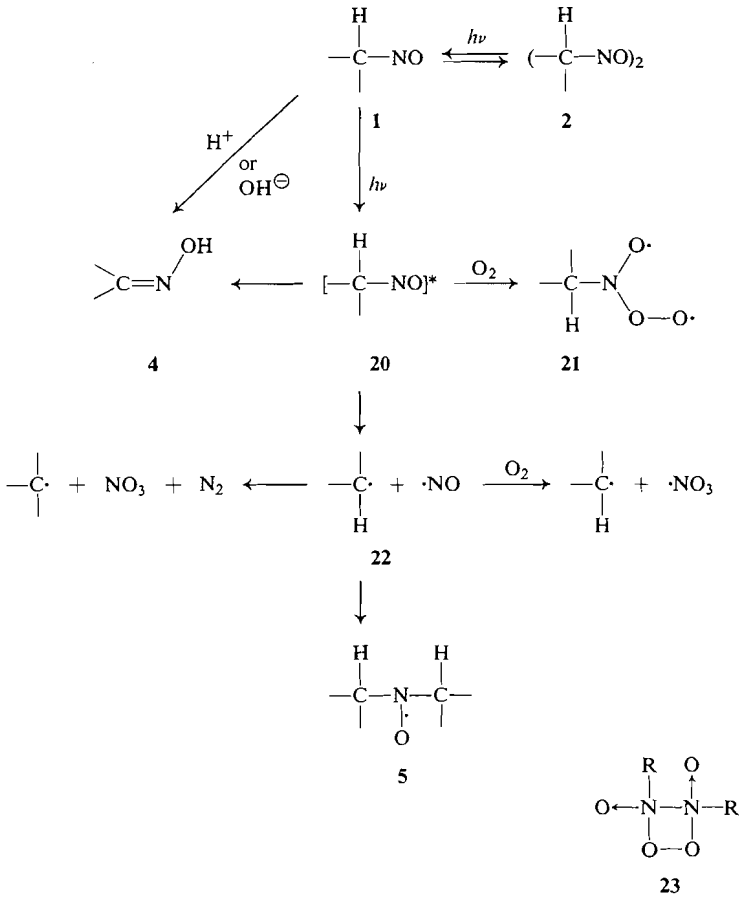
In photooxidations, scrambling of the nitrate configurations means that at some point the C—NO bonds of the monomer must be broken and that C—ONO_2 bonds are formed. It follows that the nitrate formation must be derived from photodissociation of *C*-nitroso monomers which is the common pathway to disproportionation. Under the photooxidation conditions, clearly the generated nitric oxide is quickly intercepted by oxygen to become nitric trioxide[6] (28). The combination of the alkyl radical with nitric trioxide completes the oxidation process to give the corresponding nitrate, which is stable to further irradiation. This mechanistic interpretation shares a common principle with the oxidation during nitrosamine photoaddition and nitrosamide photorearrangement described in the preceding paper (1); namely, oxygen captures nitric oxide quickly regardless of the existence of the latter as the radical pair. This mechanism requires that any dimer which can undergo photodissociation should be able to undergo photooxidation to form the corresponding nitrate; the efficiency of this is determined by the lifetime of the *C*-nitroso monomer and its ease of C—N bond scission. In agreement, the *C*-nitroso monomer of dimer-**6** photodisproportionates most efficiently and, therefore, is oxidized exclusively to nitrate whereas the ones derived from dimer **9** and **13** are oxidized only partially to nitrate **10**, owing to its facile dimerization and nitro compound formation (*vide infra*).

Since conservation of the *trans*-configuration in the formation of nitro compound **12** requires that the C—NO bond remain intact during the reaction, it follows that some primary photochemical act other than photodissociation must be responsible for the oxidation to the nitro compound. A perspective view of product patterns in the photolysis of various *C*-nitroso compounds leads us to believe that the nitro compound formation process in photooxidation shares a common reactive intermediate with the process[7] of tautomerization in the corresponding photolysis under nitrogen. Tentatively we ascribe a vibrationally excited state of a *C*-nitroso monomer, such as **18**, to this intermediate. Probably oxygen captures such an excited species instantaneously, before it can undergo other processes, leading to a diradical **19** which is also proposed by de Boer's group (17, 30). In the presence of a suitable substrate, peroxy radical **19** may abstract an H-atom (from ethylbenzene) or add (to styrene) (30); otherwise **19** may shed the extra oxygen atom by oxidizing another *C*-nitroso monomer to give two nitro compounds. Without going into detail, the various photochemical processes of *C*-nitroso compounds can be summarized in Scheme 2. We assume that the same excited state **20** is responsible for all the primary photochemical reactions. Studies are underway to see if there is more than one excited state involved in the photoprocesses and what type(s) of excited state are involved.

The mechanism of the nitro group formation discussed above assumes excited *C*-nitroso monomers as the reactive species, on the basis of (*i*) the facile dissociation of a *C*-nitroso dimer to the corresponding monomer on irradiation at $-190°$ (10), and (*ii*) the formation of the corresponding *C*-nitro compound during photooxidation of a *C*-nitroso monomer (17, 30) with red-light. At present an alternative possibility of the excited dimers **9** and **13** being the reactive species cannot be ruled out completely. Conceivably a photoexcited dimer may react with oxygen to form an intermediate **23** which then decomposes to a nitro compound such as **12** and **16**. If this is the case, it may be inferred that *anti*-dimer **6** photodissociates to the monomer readily and is photooxidized totally to nitrate **8**, whereas photoexcited *anti*-dimers **9** and **13** have a sufficiently long lifetime to react with oxygen directly to give nitro compounds **12** and **16**. The validity of this interpretation awaits clarification in future.

[6]Depending on the structure, oxygen and alkyl radical combination is no doubt also possible. Such a pathway has been found in the photooxidation of nitrosocyclohexane (17).

[7]Perhaps the dimerization process can be included if it is also a light-catalyzed reaction; an unambiguous proof is, however, not available at present.



SCHEME 2

Experimental

The apparatus and conditions for spectroscopic analyses were the same as those described in the previous publication (1). The photolysis was carried out in a Pyrex apparatus with a Hanovia mercury lamp 654A36 (200 W).

Photolysis of the anti-dimer of N-(4-Nitrosohexyl)-acetamide (6)

(A) A benzene solution (220 ml) of *anti*-dimer **6** (101 mg) (18) was photolyzed under nitrogen for 2 h. The solvent was evaporated to give an oil (105 mg). This crude oil was chromatographed on a silicic acid column to give *N*-(4-nitratohexyl)acetamide (**8**, 32 mg) (18) the parent amide (**7**, 57 mg) and *anti*-dimer **6** (19 mg).

(B) A solution of *anti*-dimer **6** (10 mg) in benzene (15 ml) was purged with helium and was saturated with nitric oxide. The solution was irradiated for 1 h and was evaporated to give a solid residue which contained *anti*-dimer **6** as shown by t.l.c. and i.r. analysis. The same solution kept at room temperature in the dark for 48 h also gave the unreacted *anti*-dimer **6**.

(C) A solution of *anti*-dimer **6** (20 mg) in benzene (30 ml) was irradiated under oxygen for 4 h. The crude residue showed strong i.r. absorptions at 1625, 1275, and 865 cm^{-1}. Preparative t.l.c. separation gave nitrate **8** (15.3 mg) and a trace amount of the parent amide **7**.

(D) A solution of *anti*-dimer **6** (60 mg), rose bengal (25 mg), and methanol (100 ml) was irradiated in the presence of oxygen with a tungsten lamp (500 W) for 10 h during which the absorption peak at 293 nm decreased less than 5%. The recovered product was shown to be *anti*-dimer **6**.

Photolysis of the anti-Dimer of trans-1-Nitroso-2-chlorocyclohexane (9)

(A) The dimer was prepared according to the method of Ponder *et al.* (19) and was recrystallized from absolute ethanol: m.p. 150–152° (lit. (19) 152–153°); n.m.r. τ 4.28 (m) and 5.5 in the ratio of 1:1; i.r. 1460 and 1210 cm^{-1}.

A solution of *anti*-dimer **9** (1 g) in benzene (100 ml) was photolyzed under nitrogen atmosphere. In 0.5 h, a precipitate covered the photocell. The white crystals were scraped off the surface of the photocell now and then, and irradiation was continued for 7 h. The crystalline precipitate (260 mg) was washed with ether and dried overnight: m.p. 135–140°. An ethanol solution of the crystals exhibited u.v. absorption at 275 nm which shifted gradually to 295 nm after 10 h. Recrystallization from benzene gave white crystals that exhibited the identical

For personal use only.

i.r., n.m.r., and mass spectra as those of *anti*-dimer **9**. The residue from the photolysate showed i.r. absorption at 1640, 1450, 1285, 1210, and 850 cm^{-1}. Alumina chromatography of this crude product gave **9** (540 mg) and a fraction of oil; i.r. 1635, 1280, 860, and 750 cm^{-1}; n.m.r. τ 5.05 (m), 6.10 (m), and 6.4 (m). V.p.c. analysis of the oil (on a 3% SE 30 column at 90°) showed that cyclohexylchloride and *trans*-1-nitrato-2-chlorocyclohexane (**10**) were present in nearly 1:1 ratio. However, the peak of the latter compound exhibited a weak shoulder which was tentatively assigned to the corresponding *cis*-isomer of **10**.

A solution of *trans*-dimer **9** (1 g) in methanol (100 ml) was photolyzed under nitrogen for 37 h until the 295 nm peak disappeared. After the usual working-up, the crude oil (950 mg) was taken up in methanol from which a white solid (145 mg) deposited. Recrystallization of the solid from methanol gave white crystals of *N,N,O*-tri(2-chlorocyclohexyl)hydroxylamine (**11**); m.p. 110–112°, i.r. 1045 and 730 cm^{-1}, *m/e* 381, 383, 385, 264, 266, 229, and 231. The residue obtained from the removal of **11** exhibited strong absorption at 1640, 1285, 850, and 750 cm^{-1}. V.p.c. analysis of the oil showed that cyclohexyl chloride and **10** were present in 1:1 ratio.

(B) A solution of *trans*-dimer **9** (1 g) in methanol containing aqueous perchloric acid (1.2 g) was photolyzed under oxygen. The original u.v. absorption of the *trans*-dimer at 295 nm shifted to 275 nm in 0.5 h irradiation and *cis*-dimer precipitated out gradually. The precipitate disappeared slowly and finally the peak at 275 nm disappeared after 5 h irradiation. In a benzene solution the same situation was observed.

The benzene photolysate was evaporated to give a resin which showed i.r. absorption at 1725(w), 1630(s), 1550(s), 1375(s), 1280(s). This resin was chromatographed on an alumina column. With petroleum ether *trans*-1-nitrato-2-chlorocyclohexane (**10**) was eluted and was sublimed to give an oil; i.r. 1630, 1280, 860, and 750 cm^{-1}; n.m.r. τ 8.35 (m, 6H), 7.78 (m, 2H), 6.10 (dt, J = 4 and 8 Hz, 1H) and 5.02 (dt, J = 4 and 8 Hz, 1H); *m/e* (% at 15 eV) 136 (10), 134 (30), 121 (40), 119 (100), 85 (80), 84 (90), 70 (55), 69 (65).

Continuing elution with petroleum ether gave mixtures of nitrate **10** and nitro compound **12** and, finally, with 20% benzene in petroleum ether a fraction of oil which showed a single spot on t.l.c. This oil was distilled to a colorless oil of *trans*-1-nitro-2-chlorocyclohexane (**12**); i.r., 1550, 1370, 850, and 745 cm^{-1}; n.m.r. τ 5.495 (dt, J = 10 and 4 Hz, 1 H) and 5.735 (dt, J = 10 and 4 Hz; 1H); *m/e* (%) 127 (4), 118 (1.7), 116 (4.6), 97 (4), 81 (100), 79 (31) and 77 (12).

Analysis of the crude product by v.p.c. (3% SE 30 column at 90°) from either photooxidation in methanol or in benzene showed that the ratio of nitrate **10** (R_t 2.7 min) and nitro compound **12** (R_t 3.2 min) is about 1:1. The shoulder corresponding to *cis*-isomer of **10** is also observed in the former peak.

Photolysis of the anti-Dimer of trans-1-Nitroso-2-piperidinocyclohexane (13)

(A) A solution of *anti*-dimer **13** (250 mg) (22), concentrated hydrochloric acid (0.3 ml), and methanol (300 ml) was photolyzed under nitrogen for 0.5 h. The methanol solution was basified, evaporated, and extracted with methylenechloride. After working-up, the crude resin was chromatographed to give 2-piperidinocyclohexanone oxime (**14**, 145 mg).

(B) The *anti*-dimer (1.0 g) and concentrated hydrochloric acid (2.5 ml) in methanol (500 ml) was irradiated through a Pyrex filter, under oxygen atmosphere for 1 h. The solvent was evaporated to give a semi-solid; the i.r. spectrum of which exhibited weak absorptions at 1720 and 1635 cm^{-1} but strong absorptions at 1550, 1450, and 1370 cm^{-1} for a nitro group. Chromatography on an alumina column gave several fractions of mixtures of *cis*- and *trans*-1-nitro-2-piperidinocyclohexanes (**16**) which exhibited n.m.r. signals at τ 5.33 (dt, J = 11 and 5 Hz) and 5.15 (m, $w_{1/2}$ = 6 Hz) in various ratios.

The crude product was hydrogenated in MeOH in the presence of platinum black and the free base (840 mg) was liberated with potassium carbonate. The free base (420 mg) was acetylated with acetic anhydride and sodium acetate. The crude product (360 mg) was isolated in the usual manner to afford an oil: 3300, 1640, 1540, 1265 cm^{-1}; n.m.r. τ 8.05(s) and 7.93(s) in the ratio of 3:2. Chromatography of this oil in an alumina column gave various mixtures of *trans*- and *cis*-1-acetamido-2-piperidinocyclohexane (**17**, 35%) and a mixture of *cis*- and *trans*-2-piperidinocyclohexanol (13%) (1). One of the acetamido fractions contained *ca.* 85% of the *trans*-isomer and was sublimed to give an oil: i.r. 3300, 1640, 1545, 1305, 1255, and 1100 cm^{-1}; n.m.r. 8.05 (s), 7.57(m) and 6.63(dt, J = 10 and 4 Hz, 1H) and 3.27 (NH); *m/e* (%) 224 (M^+), 179 (15), 165 (15), 124 (67), 110 (18), 98 (23), 84 (50) and 41 (100). The *trans*-isomer **17** was also prepared by reduction of the *anti*-dimer **13** with lithium aluminum hydride in ether.

A mixture of *cis*- and *trans*-acetamide in $CDCl_3$ solution in the presence of tris(dipivaloylmethanato)-europium exhibited signals at τ 4.63 (m, $w_{1/2}$ = 23 Hz) and 6.47 (s) for the *trans*-isomer and 3.83 (m, $w_{1/2}$ = 10 Hz) and 5.24(s) for *cis*-isomer.

The Dehydrogenation and Dehydration of 2-Propanol Vapor on Manganese Ferrite

EUGENE FRANCIS MCCAFFREY AND ROBERT ANDERSON ROSS
Department of Chemistry, Lakehead University, Thunder Bay, "P", Ontario
Received September 8, 1972

The dehydrogenation and dehydration of 2-propanol on manganese ferrite has been studied between 306 and 362 °C. The selectivity for dehydrogenation was constant throughout the temperature range. At 362 °C a trace of condensation of the alcohol to mesityl oxide was detected, <0.1% v/v of the reaction products.

La déhydrogénation et la déhydratation du propanol-2 sur la ferrite de manganèse ont été étudiées entre 306 et 362 °C. La sélectivité en faveur de la déhydrogénation s'est avéré constante à toutes les températures. A 362 °C une trace de condensation de l'alcool en oxyde de mésityle a pu être détectée <0.1% v/v des produits de la réaction. [Traduit par le journal]

Can. J. Chem., **51**, 2486 (1973)

Introduction

This article describes some experiments on the catalytic reactions of 2-propanol over manganese ferrite. The work was carried out to see if any links could be found with previous studies on alcohol decompositions using spinel oxide catalysts (1, 2) and also with recent experiments in which manganese(II) oxide was evaluated as a catalyst in the simultaneous dehydration and dehydrogenation of 2-propanol vapor (3).

Experimental

Apparatus and Procedure

The all-glass flow system and the methods of analysis have been described previously (3). To establish the experimental conditions for which the reaction rate was not influenced by external or internal diffusion, the influence of space velocity, catalyst mass, and particle size were studied in the usual manner (3). As a result the kinetic measurements were performed at atmospheric pressure with a flow rate of 300 ml min^{-1} (normal temperature and pressure) and the catalyst particle size was kept less than 0.1 mm.

All reaction rate measurements were made after the establishment of a steady activity level.

Materials

Manganese ferrite, $MnFe_2O_4$, was prepared by heating manganese(II) oxide (3) and iron(III) oxide (99.99% w/w Alfa Inorganics Inc.) to 1300 °C in flowing nitrogen for 48 h. The final X-ray powder photograph confirmed the $MnFe_2O_4$ structure (4). The surface area was 0.22 m^2 g^{-1} (B.E.T. krypton; −196 °C; σ = 21.5 Å^2).

2-Propanol and acetone were "spectroquality" reagents and their u.v. absorption characteristics were the same as those given on their accompanying certificates. All gaseous reagents and the nitrogen carrier (Canadian Liquid Air Ltd.) were 99.99% pure.

Results and Discussion

The activity of the ferrite was tested at 400 °C with 1 g of the material and an alcohol partial pressure of 9.37 Torr. The catalyst was stable and carbon dioxide was not detected in the reaction products.[1]

The Effect of 2-Propanol Partial Pressure on the Reaction Rates

The partial pressure of 2-propanol was varied between 3.17 and 15.62 Torr at 362 and 306 °C. There was a very slight but measurable trend for the selectivity for dehydrogenation to decrease with increase in the alcohol partial pressure at 306 °C. Approximate values of 0 and 0.2 were determined from logarithmic plots (3) for the reaction orders with respect to 2-propanol partial pressure for both reactions at 306 and 362 °C, respectively. These low values of reaction orders probably indicate that the catalyst surface was highly saturated with adsorbed alcohol.

The Effects of Hydrogen and Propylene

At 362 °C the effect of varying the total hydrogen partial pressure from 1.00 to 51.67 Torr on the rates of reaction of 9.37 Torr partial pressure alcohol was examined. The reaction rates increased slightly and monotonously with increase in the hydrogen partial pressure over the entire

pressure range such that with 51.67 Torr total hydrogen pressure the rates of dehydrogenation and dehydration had increased by about 36 and 28%, respectively. When the added hydrogen was removed on completion of the experiments, the catalyst activity returned to its original level after 2 h. Hydrogen has also been reported to enhance the rate of the dehydrogenation reaction over chromia-alumina catalysts (5) possibly by increasing the donor nature of the catalyst. However, it may be more likely that a fairly insensitive adsorption/desorption equilibrium condition exists between hydrogen and some adsorbed species.

From 306 to 362 °C with propylene partial pressure from 0.10 to 50.77 Torr and 9.37 Torr alcohol partial pressure, propylene had no real influence on the rates of either the dehydrogenation or dehydration reactions. This may be interpreted in terms of a very rapid saturation of adsorption sites or that an extremely fast desorption of propylene occurs.

The Effects of Water Vapor and Acetone

The effect of changing the total water vapor partial pressure from 0.11 to 2.86 Torr was studied at 362 °C with 9.37 Torr partial pressure alcohol. The rates of both reactions were slightly depressed by addition of water vapor. The maximum effect was observed with 2.86 Torr total water vapor pressure when the values of the rates of dehydration and dehydrogenation were lowered by 7 and 18%, respectively. After the removal of the added water vapor, the catalyst activity returned to its original value in 30 min.

The very small dependence of the rate of dehydration on the partial pressure of water vapor differs from the results found with manganese(II) oxide, where the order of the dehydration reaction with respect to water vapor pressure was -0.5 (3). However, the result is similar to that established for reaction of 2-propanol over nickel(II) oxide (6) and the earlier result for dehydration of ethanol over γ-alumina (2). These observations indicate that manganese ferrite is much less susceptible to poisoning by water vapor than was manganese(II) oxide (3) which points to possible differences in the types of dehydration sites on the two catalysts. Adsorption of water vapor on coordination unsaturated species (7) on the surface of manganese(II) oxide might be expected to form a more stable intermediate adsorbed complex than that on the ferrite.

At 362 °C and with 9.37 Torr alcohol partial pressure, the acetone partial pressure was varied from 1.00 to 5.43 Torr. Both reaction rates were depressed monotonously and in step such that the selectivity for dehydrogenation remained constant over the pressure range and an approximate reaction order of -0.1 with respect to acetone partial pressure was determined for each reaction. The activity for the dehydrogenation reaction returned to within 3% of its initial value when the added acetone was removed from the system. However, the activity for dehydration was permanently reduced by 12% at the steady level of catalyst activity.

The Effect of Temperature on the Reaction Rates

Experiments were carried out with 9.37 Torr partial pressure 2-propanol at various temperatures from 306 to 362 °C. The rates of the dehydrogenation and the dehydration reactions as well as the selectivity for dehydrogenation are given in Table 1. At 362 °C, mesityl oxide composed less than 0.1% v/v of the reaction products.

The selectivity observed with manganese ferrite does not differ significantly from that found for manganese(II) oxide (3), several other transition metal oxides (6), and magnesium, calcium, strontium, and barium oxides (8). On the other hand, it has been reported that dehydration of 2-propanol was favored on nickel ferrite catalysts (1). Since both nickel and manganese ferrites are inverse spinels (9), the difference in their selectivities appears not to be related to the cation distribution within the

TABLE 1. Effect of temperature on the rates of dehydrogenation, r_1, and dehydration, r_2, of isopropyl alcohol over manganese ferrite using 9.37 Torr partial pressure alcohol

Catalyst temperature (°C)	Rate of dehydrogenation (mol m^{-2} s^{-1}) $\times 10^8$	Rate of dehydration (mol m^{-2} s^{-1}) $\times 10^8$	Selectivity $\frac{r_1}{r_1 + r_2}$
362	126.0	14.4	0.90
349	92.0	10.5	0.90
336	61.2	6.7	0.90
324	40.0	4.6	0.90
306	17.9	2.2	0.89

lattice. Such a relationship has been proposed to account for selectivity differences shown by a series of alumina-spinel oxides in the decomposition of ethyl alcohol (2).

Determination of Excess Volumes of Cyclohexane + Benzene Mixtures with a Mechanical Oscillator Densimeter[1]

OSAMU KIYOHARA[2] AND G. C. BENSON

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received February 28, 1973

Two methods of calibrating an Anton Parr densimeter were investigated. Values of the excess volume of cyclohexane + benzene mixtures obtained from density measurements at 25 °C with this instrument agree well with results in the literature.

Deux méthodes d'étalonnage, d'un densimètre Anton Parr ont été envisagées. Les volumes d'excès des mélanges cyclohexane + benzène ont été calculés à partir des densités mesurées, à 25 °C, avec cet appareil; l'accord avec les résultats rapportés dans la littérature est excellent.

This note reports values of excess volumes obtained from measurements of density on the system cyclohexane + benzene with an oscillator type densimeter (Digital Densimeter DMA O2C, manufactured by Anton Parr K.G.). The primary purpose of the work was to examine the suitability of this instrument for studying the excess volumes of mixtures of nonelectrolytes.

The DMA O2C densimeter is based on a design developed by Kratky and co-workers (1–3). In it, the density of a fluid (gas or liquid) is determined by measuring the resonant frequency of a mechanical oscillator, a U-shaped Duran 20 glass tube, filled with the fluid. The method assumes a linear relation

$$[1] \qquad d = AT^2 + B$$

between the density, d, of the fluid and the square of the period, T, of the oscillator. A and B are constants of the instrument and their values are determined by calibration with two fluids of known densities, water and air generally being used for this purpose. Under favorable circumstances, differences in density can be determined within $\pm 1.5 \times 10^{-6}$ g cm^{-3}, thus the instrument is well suited to the study of dilute aqueous solutions and to the determination of partial molar volumes (2, 4–6). However, this accuracy is limited to differences which are less than about 0.05 g cm^{-3}. The operating manual for the DMA O2C points out that the approximation associated with the use of eq. 1 leads to errors which increase in the measurement of larger density differences, and gives an upper bound of $\pm 1 \times 10^{-3}$ g cm^{-3} for differences of 3 g cm^{-3}. Recently, the DMA O2C has been used to determine densities of mixtures of organic liquids and to obtain excess volumes for systems in which the variation in density is much greater than 0.05 g cm^{-3} (7, 8). It is therefore important to study in more detail the suitability of the densimeter for such measurements.

Two different ways of calibrating the densimeter were investigated. Method I followed the manufacturer's instructions, and used water and air as standards. The water was twice distilled in a Pyrex still, and prior to its use it was boiled to remove dissolved air. The temperature of the oscillator chamber was controlled at 25.000 ± 0.002 °C. It was monitored continuously with a quartz thermometer and the observed oscillator periods were corrected to 25.000 °C. François *et al.* (9) reported that their densimeter was sensitive to changes in atmospheric pressure. To investigate this effect further, our densimeter was placed in a metal box with a window, and the pressure was increased above the ambient by about 15 Torr. This experiment failed to reveal any clear-cut pressure dependence and, within the reproducibility of the measurements, the change in the period of the oscillator filled with air agreed with the value estimated from the increase in the density of the air.

The second calibration (method II) was carried out over a more limited range of density, 0.74–1.05 g cm^{-3}, and should therefore give a better description of the behavior of the oscillator for densities of interest in our work.

Oscillator periods were determined for water and ten organic liquids for which the densities (relative to water) were measured in a magnetic float densimeter (10). The method of least squares was used to fit eq. 1 to the results and the standard error of estimate for the representation was 0.000057 g cm^{-3}. Over the range of density considered in method II, the values of the density at 25 °C derived from the two calibrations are related by the equation

$$[2] \qquad d_I = 1.0002663 d_{II} - 0.0002952$$

Thus a density of 0.7 g cm^{-3} will be low by about 1×10^{-4} g cm^{-3} if the instrument is calibrated by method I. Although eq. 2 is characteristic of our particular densimeter, it should also provide an approximate indication of the error which can occur when this type of instrument is used without a careful calibration for the range of density under investigation.

In deriving excess volumes from density results, there will be some cancellation between systematic errors in the densities of the mixtures and of the pure components. However, the use of a calibration based only on water and air can lead to significant errors in the excess volume when the densities of the components are very different.

Powell and Swinton (11) have suggested that the system cyclohexane + benzene be adopted as a standard for testing dilatometers. Samples of cyclohexane and benzene were purified chromatographically and a series of mixtures of known mole fractions were prepared from these by weight, applying corrections for buoyancy effects. Densities at 25 °C were obtained from the densimeter readings, using the calibration by method II. The results for cyclohexane and benzene were 0.773598 and 0.873524 g cm^{-3}, respectively. The values of the excess volume, V^E, for the mixtures are summarized in Table 1. These are represented by the least squares equation

$$[3] \quad V^E/\text{cm}^3\,\text{mol}^{-1} = x(1-x)[2.61313 - 0.10497(1-2x)]$$

where x is the mole fraction of cyclohexane. The standard error of estimate for this representation is 0.0017 cm^3 mol^{-1}.

Our values of V^E can be compared with values measured recently by dilatometric (12) and magnetic float (10) techniques. A least squares analysis was carried out on the three sets of results, assigning equal statistical weight to each of the 132 points. This led to the equation

$$[4] \quad V^E/\text{cm}^3\,\text{mol}^{-1} = x(1-x)[2.60446 - 0.09188(1-2x) + 0.03492(1-2x)^2]$$

with a standard error of estimate equal to 0.0018 cm^3 mol^{-1}. Figure 1 shows a plot of the deviations of the individual experimental results from eq. 4. Also shown are curves representing the deviations of the smoothed results for each of the investigations. It can be seen that most of the deviations are less than ±0.5%, and that our results are in good agreement with the values obtained by the other methods. For the system

Further Studies of γ-Irradiated Propylene Carbonate Glasses

ERIC A. SHAEDE

Saskatchewan Accelerator Laboratory, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

AND

MARTYN C. R. SYMONS[1]

Chemistry Department, The University of Leicester, Leicester LE1 7RH, England

Received January 30, 1973

An earlier postulate, that physically trapped electrons (e_t^-) are responsible for a narrow e.s.r. singlet at $g = 2.0028$ formed by exposure of glassy propylene carbonate to ^{60}Co γ-rays at 77 °K, is re-examined. An alternative, that propylene carbonate radical anions are formed, in which the extra electron is largely confined to an antibonding orbital on the carbonate moiety, is favored. The primary new evidence for this anion is the detection of satellite e.s.r. lines which were lost on bleaching or thermal decay of the central line, and which occurred in the correct field regions to be assigned to ^{13}C hyperfine structure from the carbonate carbon of the anion.

The complicated set of proton hyperfine lines is now assigned largely to the radical **1** and the mechanisms by which this radical may be formed are discussed. The previously observed temperature dependence of the proton hyperfine features can now be understood in terms of thermal restrictions on the motions of the methyl group and the adjacent methylene protons.

On a étudié de nouveau un ancien postulat selon lequel des électrons piégés physiquement (e_t^-) sont responsables de l'étroit singulet en R.S.E. à $g = 2.0028$ consécutivement à l'exposition du carbonate de propylène vitreux à des rayons-γ ^{60}Co à 77 °K. On favorise une autre alternative selon laquelle il se formerait des anions radicalaires du carbonate de propylène où l'électron en surplus serait surtout limité à une orbitale anti-liante de l'entité carbonate. Le nouvel argument principal en faveur de cet anion est la détection de bandes satellites en r.s.e. lesquelles sont perdues lors de la décoloration ou de la dégénérescence thermique de la bande centrale et qui apparaissent dans les bonnes régions du champ pour pouvoir être attribuées à la structure hyperfine du ^{13}C appartenant au carbone du carbonate de l'anion. Le patron compliqué des bandes hyperfines du proton est maintenant attribué surtout au radical **1** et les mécanismes responsables de la formation de ce radical sont discutés. La relation déjà observée entre les bandes hyperfines du proton et la température peut maintenant être expliqué en termes de restrictions thermiques sur les mouvements du groupe méthyl et des protons du groupe méthylène adjacent. Introduction

This paper describes a continuation of a recent study (1) of radiation effects in glassy propylene carbonate (4-methyl-2-dioxolone; hereafter, PC), which reference should be consulted for an introductory survey of the subject. In this (1), a central narrow e.s.r. singlet was tentatively assigned to physically trapped electron centers (e_t^-) such as are commonly encountered in irradiated saturated aliphatic compounds such as alcohols, ethers, amines, and hydrocarbons (2). We now advance evidence which goes against this earlier hypothesis, and suggest instead that the central singlet is a property of propylene carbonate anions.

A detailed interpretation of the complex set of proton hyperfine lines previously detected is also offered, and an attempt is made to explain the effect of changes in temperature on these hyperfine features.

[1]To whom correspondence should be addressed.

Experimental

Details were as described previously (1) except that a more powerful ^{60}Co source was used, giving a nominal dose rate of *ca.* 4 Mrad. h^{-1}. Aqueous solutions covering a range of concentrations all appeared glassy, and gave well resolved e.s.r. sextets when Mn^{2+} salts were added (3).

Results and Discussion

(a) The Central Singlet

Our new experiments have confirmed all the previously reported details pertaining to this singlet, of which Figs. 2 and 3 of ref. 1 are typical. Factors in favor of the trapped electron (e_t^-) theory have been presented in detail (1). Some arguments against the concept are now considered.

(*i*) The *g*-value is slightly greater than that of the free-spin (2.0028 as against 2.0023), whilst all those for well established e_t^- centers are slightly less than 2.0023.

(*ii*) The optical absorption thought to be associated with this center comprised a broad band in the 300–500 nm region, having a maximum at *ca.* 370 (1). This is a higher energy band than any previously found for e_t^- centers and since the band energy increases as the trap depth increases, this implies an extremely deep trap. However, it is general experience that the deepest traps are formed by compounds containing hydroxyl groups, and it has been elegantly demonstrated by Smith and Pieroni (4) that the hydroxyl protons are directly responsible for this depth. We would therefore have expected to find that e_t^- centers in propylene carbonate had an absorption band to long wavelengths of the bands for alcohols which are found in the 500–600 nm region (2).

(*iii*) It is known that carbonate ions react with electrons to give CO_3^{3-} ions (5), and that carboxylic acids can give $(RCO_2H)^-$ anions (6). By analogy, it might be expected that carbonate esters would give the corresponding anions by electron capture. Since O-protonation or O-alkylation has only a minor effect upon the magnetic properties of ions such as CO_2^- or PO_3^{2-} (7), we would expect PC^- to have *g*-values close to those for CO_3^{3-}, ($g_\parallel = 2.0016$, $g_\perp = 2.0032$), (5), but with *g* closer to the free-spin value, the ^{13}C hyperfine tensor components close to, but somewhat larger than, those for $^{13}CO_3^{3-}$ ($A_\parallel(^{13}C) = 171.3$ G, $A_\perp(^{13}C) = 111.3$ G) (5). Thus the *g*-value of 2.0028 is quite reasonable for PC^-, the isotropy being either fortuitous, or arising because the anion is rotating rapidly.

The best test of the radical anion theory would therefore be to detect e.s.r. features for radicals containing ^{13}C. Hyperfine structure in the expected regions has indeed been detected (Fig. 1*a*), and these lines were selectively lost on photobleaching or thermal annealing (Fig. 1*b*). Since these lines appear as anisotropic features centered on the main singlet with about the required relative intensities, we assign them to PC^- radical anions, and conclude that the isotropy of the g-tensor is fortuitous.

The derived ^{13}C hyperfine data ($A_{iso} = 153$ G, $2B = 28$ G) are reasonable for the carbonate carbon in PC^-. The increase in A_{iso} relative to CO_3^{3-} (131 G) is as expected in view of the

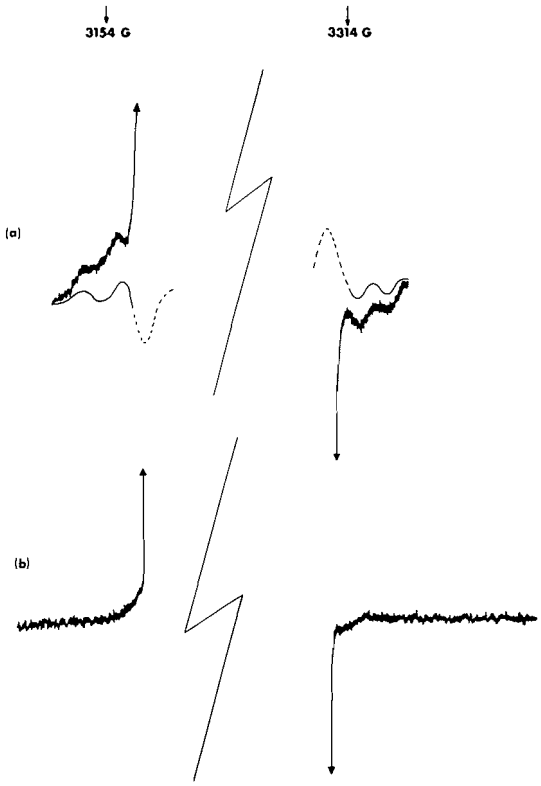

FIG. 1. First derivative e.s.r. spectra for propylene carbonate glasses after exposure to ^{60}Co γ-rays at 77 °K showing the wings of the main features at very high gain: (*a*) before decay of the central line, showing features assigned to PC^- radicals containing ^{13}C, and (*b*) after decay of the central line, at the same gain, showing loss of these features.

effective increase in the electronegativity of two of the ligands (7–9). The relatively small $2B$ value is not expected, but probably results from a slight libration of the anion at 77 °K. Alternatively the features taken as perpendicular (Fig. 1*a*) may be cross-over lines for a non-axial symmetric A-tensor. Indeed, the changes closely parallel those induced by crystal-field changes and librations in the hyperfine parameters for NO_2, CO_2^-, and PO_3^{2-} radicals (10). We conclude that, despite the strong arguments that can be made in favour of e_t^- centers (1), the species is, in all probability, PC^-. An important fact apparently favouring e_t^- was the marked ease of saturation of the singlet species (1). However, RCO_2H^- radicals are also very readily saturated (11), so that this is not diagnostic. We conclude that the center is almost certainly PC^- rather than e_t^-.

One interesting result of this suggestion is that CO_3^- radical anions may, in part, be formed by photochemical breakdown of these anions:

[1] 
These anions (CO_3^-), previously detected both by their optical and e.s.r. spectra in the irradiated glasses (1), were found to increase markedly in concentration during ultraviolet photolysis.

An important observation in the previous study of the e.s.r. singlet (1) was its rather rapid decay even at 77 °K. This decay seemed to be characterized by non-homogeneous second-order kinetics (1). Since we are now able to conclusively assign the e.s.r. line to PC^-, it is necessary to re-examine the decay process. One would hardly expect such a large species as PC^- to be mobile at 77 °K and similarly, as will be elaborated on later, the expected stable counter species PCH^+ would also be immobile. Therefore it is necessary to postulate that the electrons are only very weakly bound to the propylene carbonate molecules in a low energy antibonding orbital. A rapid exchange reaction 2,

[2] $$PC^- + PC \rightarrow PC + PC^-$$

must exist in the glassy matrix to allow charge transfer through the medium until neutralization occurs via reaction 3,

[3] $$PC^- + PCH^+ \rightarrow PC + \text{"PCH"}$$

The "PCH" species would most likely spontaneously decompose, possibly to give the radical species **1** (which will be shown later to be the major other paramagnetic species present) and molecular hydrogen.

(b) The Proton Hyperfine Components

A typical e.s.r. spectrum of the type under consideration is given in Fig. 2*a*, and also in Figs. 2*b*, 4*a*, and 4*b* of ref. 1. Because of the effect of various physical constraints upon certain of these components, it was suggested that they comprise three sets of doublets, designated B, D, and E, with proton coupling constants of 42, 83, and 124 G respectively (1).

We now find that very similar spectra are obtained when γ-irradiated aqueous glasses are annealed. Initially, the e.s.r. spectra of such glasses were dominated by the characteristic features of hydroxyl radicals, but on controlled thermal annealing these were lost, and replaced by features very similar to those in Fig. 2*a* (see Fig. 2*b*). By far the most probable reaction for hydroxyl radicals is (12):

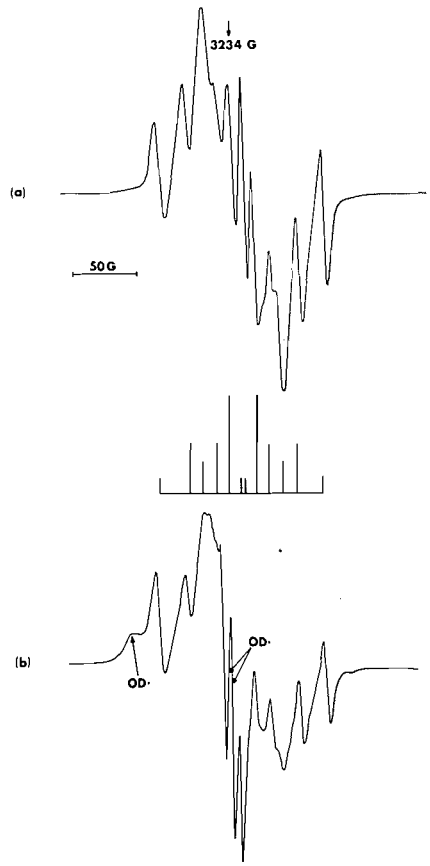

FIG. 2. First derivative e.s.r. spectra for propylene carbonate after exposure to ^{60}Co γ-rays at 77 °K, showing features assigned to

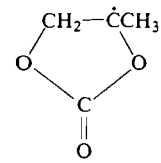

radicals (*a*) for the pure material; the stick spectrum reconstruction underneath represents the predicted lines using $a(CH_3) = 22$ G and $a(CH_2) = 31.5$ G; (*b*) for an aqueous (D_2O) solution, after partial annealing, showing features assigned to ȮD radicals also.

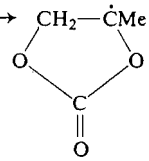
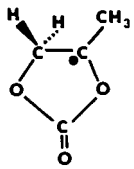
[4] $\cdot OH + PC \longrightarrow CH_2{-}\dot{C}Me + H_2O$



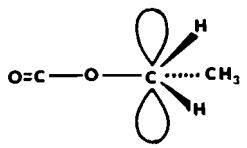
1

and we have therefore endeavored to explain these features, together with the changes noted previously (1) entirely in terms of species **1**. The most reasonable e.s.r. spectrum for **1** would com-



1

prise a 1:3:3:1 quartet of coupling *ca.* 20 G from the methyl group, each line being split further into 1:2:1 triplets by the methylene protons. This would occur provided the conformation is symmetrical, as in **2**, in which case the methylene



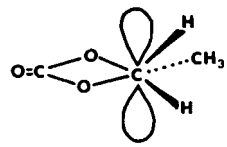
2

proton coupling would be *ca.* 30 G (13). (These values are reduced from those for comparable hydrocarbon radicals because of slight delocalization onto the oxygen atom (13).)

However, libration about the C—C bond, or any static spread over a range of conformations, would render the methylene protons inequivalent, and this would change the 1:2:1 triplet into 1:(1 + 1):1 sets of lines, with the central doublet liable to appear as a single broad line. Thus the spectrum might well comprise sets of triplets having a narrow–broad–narrow appearance, the outer lines remaining narrow because these dynamic or static effects are out-of-phase modulations, which leave the sum of the hyperfine coupling constants of the two protons approximately unchanged.

Similarly, free rotation for the methyl group might well be inhibited at 77 °K. This often results in a narrow–broad–broad–narrow appearance of the four lines, for similar reasons.

Just these sorts of changes are indeed found in the spectra under consideration. A stick spectrum reconstruction, based on radical **1**, with $a(CH_3) = 22$ G and $a(CH_2) = 31.5$ G is given under Fig. 2*a*. The resolved $M_I = \pm 1/2$ lines from the methyl groups are clearly broadened relative to the $M_I = \pm 3/2$ components, but on heating the normal 1:3:3:1 intensities are found (*cf.* Fig. 7*a* of ref. 1). Again, the central lines are often very broad in the spectra in ref. 1, although in several instances they are of nearly the correct intensity (*cf.* Fig. 2*a*). In spectra for the frozen aqueous solutions these lines are clearly detected (Fig. 2*b*) which suggests that the preferred conformation is the symmetric form indicated in **2**, rather than a twisted configuration as in **3**.



3

We conclude that **1** is the major radical species responsible for these hyperfine components. Nevertheless the various changes outlined in ref. 1 cannot all be accommodated in terms of restricted rotation effects, and it seems probable that at least one other radical is present in low concentration. We have been unable to distinguish separate features however.

Radical **1** is in fact the most likely species to be formed in irradiated propylene carbonate glasses. The primary actions of the radiation may be represented as [5],

[5] $PC \rightsquigarrow PC^*, PC^+, e^-$

We now know that the fate of the electrons is captured by the matrix to form PC^-. The primary positive ion PC^+ very likely immediately transfers a proton to one of the adjacent PC molecules to form radical species **1** and PCH^+ which presumably would be stable. Radical species **1** may also be formed via reaction 3 discussed above or it may be formed from PC* (*i.e.* propylene carbonate electronically excited by the radiation) via reactions 6 and 7,

[6] $PC^* \rightarrow \mathbf{1} + H\cdot$

[7] $PC + H\cdot \rightarrow \mathbf{1} + H_2$

since the tertiary hydrogen bond is the most

For personal use only.

easily broken. Thus the overall yield of radical **1** in irradiated PC could be quite large.

One of us (E.A.S.) wishes to thank the University of Saskatchewan for financial support.

Hydrated Electrons Formed in the Flash Photolysis of Ag° and Tl°

NORMAN BASCO, SUNIL K. VIDYARTHI, AND DAVID C. WALKER
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received February 14, 1973

The transient species Ag^0, formed in the reduction of Ag^+ by hydrated electrons, may be photodissociated to e_{aq}^- again by light in the absorption band of Ag^0 centered at ~315 nm.

$$Ag^0 \xrightarrow{h\nu} Ag^+ + e_{aq}^-$$

It suggests that this band is a charge-transfer-to-solvent band. The photon energy threshold for photoionization of Ag^0 (3.0 eV) is substantially smaller than the vacuum photoelectric work function of silver metal (4.5 eV). Analogous results were obtained in solutions of Tl^+ indicating that Tl^0 may also yield e_{aq}^- on photolysis at ~300 nm. The experiments utilized a double flash photolysis technique, in which hydrated electrons were produced by u.v. photolysis of SO_4^{2-} in the first flash, reacted with Ag^+ or Tl^+ to give the short-lived intermediates Ag^0 (lifetime ~60 μs) and Tl^0 (lifetime < 20 μs) which were photolyzed by a second flash containing light in a restricted wavelength range.

Les espèces transitoires contenant Ag^0, obtenues de la réduction de Ag^+ par des électrons hydratés, peuvent être photodissociées de nouveau pour donner des e_{aq}^- par la lumière à la bande d'absorption de Ag^0 centrée à ~315 nm.

$$Ag^0 \xrightarrow{h\nu} Ag^+ + e_{aq}^-$$

Ce fait suggère que cette bande en est une typique d'un transfert de charges au solvant. La limite énergétique du photon pour la photoionisation de Ag^0 (3.0 eV) est beaucoup plus petite que la fonction de travail photoélectrique (dans le vide) de l'argent métallique (4.5 eV). Des résultats analogues furent obtenus pour des solutions de Tl^+ ce qui signifient que le Tl^0 peut aussi libérer des e_{aq}^- lors de la photolyse à ~300 nm. Les expériences furent basées sur la technique de photolyse à double éclair dans laquelle les électrons hydratés sont produits par la photolyse en u.v. du SO_4^{2-} lors du premier éclair, puis ont réagi avec du Ag^+ ou Tl^+ pour donner naissance aux intermédiaires (existence éphémère) Ag^0 (temps de vie ~60 μs) et Tl^0 (temps de vie < 20 μs) qui sont photolysés par la suite à l'aide d'un second éclair composé de lumière possédant des longueurs d'onde discrètes. [Traduit par le journal]

Can. J. Chem., 51, 2497 (1973)

Introduction

Pulse radiolysis studies of hydrated electron reactions with several transition metal ions have led to the identification of some "unusual" oxidation states, in which the transient ions, or atoms, created have strong optical absorption bands in the region of 300 nm in liquid solutions (1–4) and glassy matrices (5, 6). An analogous species is Ag^0 formed by reaction 1

[1] $Ag_{aq}^+ + e_{aq}^- \rightarrow Ag^0 \quad k_1 = 3.2 \times 10^{10}\ M^{-1}\ s^{-1}$ (2)

which has a lifetime governed largely by reaction 2.

[2] $Ag^0 + Ag^+ \rightarrow Ag_2^+ \quad k_2 = 5.9 \times 10^9\ M^{-1}\ s^{-1}$ (4)

Ag^0 has also been detected and identified by e.s.r. in γ-irradiated low temperature solids containing Ag^+ ions (7, 8).

Results have recently been reported on the observation of a transient species produced in the double flash photolysis of aqueous $NaOH/H_2$ solutions, in which hydrated electrons created in the first flash by u.v. photolysis of OH^- (and other anions) react to form transient species which may then be photolyzed by the second flash which contains light of restricted wavelengths (9, 10). In this paper we wish to report experiments of a similar nature involving Ag^0 and Tl^0 as the intermediates.

Experimental

The apparatus has been described in detail elsewhere (10). It consists basically of a 42.5 cm suprasil reaction vessel placed between two conventional 50 cm suprasil flash photolysis lamps called "main" and "auxiliary". Spaces are provided so that Corning color glass light filters may be placed between either lamp and the reaction vessel. The lamps can be fired successively at any time delay down to a microsecond. The flashes are typically 20 μs width-at-half-height. The main was used at 625 J and the auxiliary at 825 J energy. Monitoring of absorbing species was conducted in two ways, firstly by a spectro flash and spectrograph combination and secondly by laser photometry. The latter permits absorptions to be

7-54†	231(411)	236(401)	253(390)	283(367)	298(353)
0-53	279	290	303	334	344
0-52	339	342	350	380	389
3-74	385	390	415	461	497
3-70	486	493	507	548	573

*Error limit = ±3 nm.
†7-54 has a transmission band in the relevant region of the spectrum. The wavelengths in brackets indicate the long wavelength limits of this band. The maximum transmission at ~320 nm is an absolute transmission of 89%.

observed *during* and after the flashes but of course only at the laser wavelength. A 7 mW He/Ne laser was used as the monitoring light source in the experiments reported here for following transient changes in the absorbance of hydrated electrons at 633 nm. The Corning glass filters used in this work had the transmission characteristics shown in Table 1.

Solutions of Ag_2SO_4 with Na_2SO_4 were made from "Analar" grade Ag_2SO_4 and Na_2SO_4 dissolved in triply distilled water as described (10) and deoxygenated by bubbling with pure He gas. Concentrations of Ag^+ in the range 10^{-5} to 10^{-6} *M* were selected so that e_{aq}^- would react almost exclusively with Ag^+, according to reaction 1, but not too rapidly so that there was adequate absorption due to e_{aq}^- for it to be conveniently monitored during and after the flashes. A typical half-life of ~3–15 μs for e_{aq}^- was convenient. Since e_{aq}^- was produced at ~10^{-6} *M* by the main flash, loss of e_{aq}^- in bimolecular decay reactions was not serious. Na_2SO_4 was generally present at ~10^{-3} *M* so that there was suitable light absorption from the main flash to create ~10^{-6} *M* e_{aq}^-. For experiments with thallous, Tl_2SO_4 was used in place of Ag_2SO_4. For experiments requiring a scavenger for the oxidizing species "Aristar" grade 2-propanol and "Analar" grade sodium formate were utilized.

Results

In Ag_2SO_4/Na_2SO_4 solutions the short wavelength light ($\lambda < \sim 220$ nm) of the main flash (no light filter between it and the reaction vessel) was absorbed by SO_4^{2-} according to reaction 3

$$[3] \qquad SO_4^{2-} + h\nu \rightarrow e_{aq}^- + SO_4^-$$

to generate hydrated electrons (11, 12). Strong absorption of the 633 nm laser light by e_{aq}^- occurs during the main flash as shown in Fig. 1, e_{aq}^- being the only species in these systems absorbing significantly at this wavelength. This reacts rapidly with Ag^+. With a 0-53 filter between the auxiliary lamp and reaction vessel an auxiliary absorption peak such as that shown in

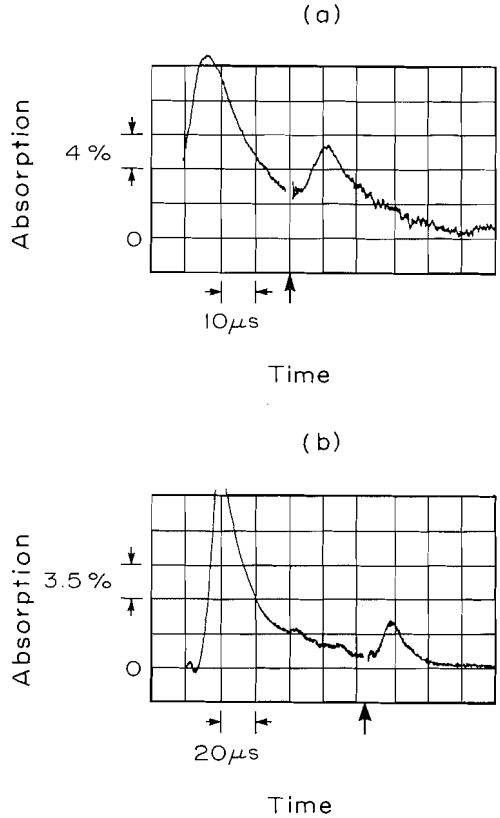

FIG. 1. Oscilloscope traces showing absorption by e_{aq}^- at 633 nm during main and auxiliary flashes in a 10^{-5} *M* solution of Ag^+ in 10^{-3} *M* Na_2SO_4. A 0-53 filter was included between the auxiliary lamp and the reaction vessel. The arrow indicates the triggering pulse for the auxiliary lamp, (*a*) shows a time delay of 35 μs and (*b*) for 95 μs between the main and auxiliary flashes.

Fig. 1 was obtained. This shows traces obtained for 35 and 95 μs delays between main and auxiliary flashes. At very short delay times the second absorption peak was comparable in size to the first peak showing that most of the hydrated electrons originally formed were regenerated by the second flash containing only $\lambda > 270$ nm.

The magnitude of the second absorption peak decreased with increasing delay time between the firing of the main and auxiliary lamps. Figure 2 shows these data for a solution containing Ag^+ at 5×10^{-6} *M*, the ordinate being proportional to the concentration of the intermediate at various times compensated for small variations in the main flash intensity as registered by the hydrated electron concentration in the main absorption peak. The decay of the transient

TABLE 2. Ratio of peak absorbances (due to e_{aq}^-) in auxiliary/main flashes for Ag^+ (5×10^{-6} *M*) and Tl^+ (2×10^{-5} *M*) solutions with various light filters between the auxiliary lamp and reaction vessel for the same delay time between flashes (60 μs for Ag^+, 30 μs Tl^+)

Filter	9-54	7-54	0-53	0-52	3-74	3-70
Ag^+, *A*(aux)/*A*(main)	0.19	0.15	0.11	0.06	0.03	<0.01
Tl^+, *A*(aux)/*A*(main)	0.35	0.31	0.27	0.20	<0.04	<0.04

species was approximately first order, as indicated by the inset of Fig. 2, with a half-life of ~42 μs.

On adding an additional layer of the 0-53 filter the absorption in the auxiliary peak was reduced significantly for a given delay time. On replacing the 0-53 filter by a 0-52 filter the auxiliary absorption peak was reduced to about half that found for the same delay with 0-53. On further exchanging the filter to 3-74 the absorption was reduced to ~25% that found with 0-53 whereas 3-70 eliminated the auxiliary absorption peak. These data are included in Table 2 for a 5×10^{-6} *M* Ag^+ solution. These filter experiments indicate: (*a*) almost all e_{aq}^- may be regenerated by one auxiliary flash containing $\lambda > 270$ nm at short times, so the absorption is substantial at $\lambda > 270$; (*b*) a considerable fraction of the absorption band leading to photoregeneration of e_{aq}^- lies in the range 270 to 320 nm; (*c*) the band responsible is fairly broad and certainly extends to ~400 nm.

Absorption spectra were taken at various times after either flash using light from an 80 J spectroflash directed down the length of the reaction vessel and focussed onto the slit of a small Hilger and Watts quartz prism spectrograph containing 35 mm HP4 photographic film. Immediately after the main flash the absorption spectrum corresponded quite closely to that of e_{aq}^-, as reported previously (10). Figure 3 shows the spectrum obtained for three conditions: (*i*) 35 μs after the main flash, when ~90% of e_{aq}^- had reacted with Ag^+ present at $\sim 10^{-5}$ *M*; (*ii*) 13 μs after the auxiliary lamp which was fired 38 μs

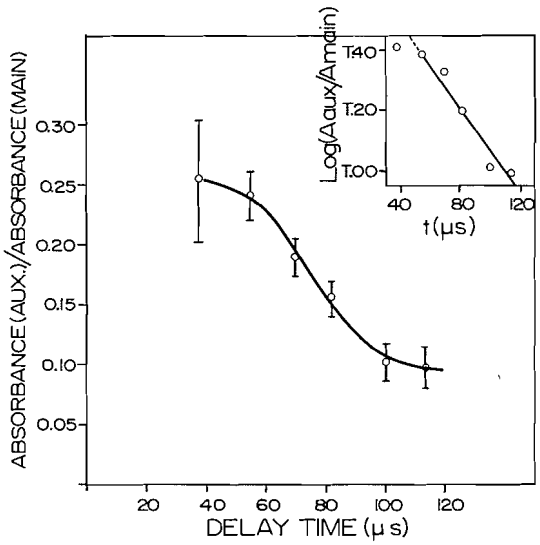

FIG. 2. Plot showing the decay of the transient as a function of time in a 5×10^{-6} *M* Ag^+ solution. The ordinate is the ratio of absorbances due to hydrated electrons during the peak of the auxiliary flash relative to the main flash. The abscissa represents the time delay between the flashes. Inset shows the same information plotted according to first-order rate law. (The particularly large uncertainty in the first data point arises mainly from the existence of significant absorption still by e_{aq}^- from the main flash).

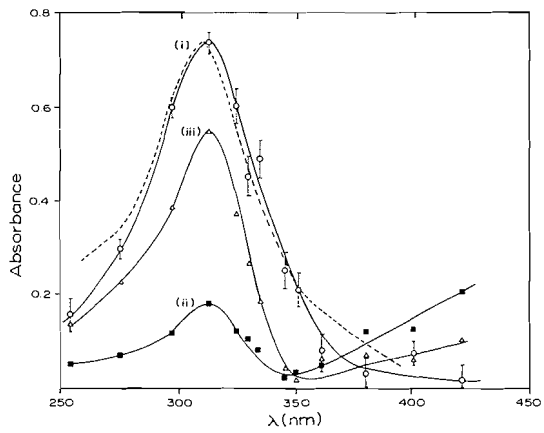

FIG. 3. Absorption spectra in the wavelength range 250 to 425 nm for a 10^{-5} *M* Ag^+ solution taken under the following conditions: (*i*) 35 μs after the main flash (⊙). (*ii*) 13 μs after the firing of the auxiliary flash (*i.e.* during the auxiliary flash) which was fired 38 μs after the main flash (△). (*iii*) 30 μs after the auxiliary flash which was fired 38 μs after the main flash (■). A 0-53 filter was included between the auxiliary lamp and the reaction vessel. The dashed line is a published spectrum assigned to Ag^0(3).

after the main. In this experiment a 0-53 filter was present between the auxiliary lamp and the reaction vessel; and (*iii*) 30 μs later, when e_{aq}^- had again reacted with Ag^+.

Further evidence that products of reaction 1 were responsible for the auxiliary absorption peak is derived from experiments using various Ag^+ solutions. For instance, it was shown that SO_4^- radicals, formed in reaction 3, were not involved because comparable traces to those of Fig. 1 were obtained from the following two solutions: (*a*) 3 m*M* Na_2SO_4, 5 μ*M* Ag_2SO_4 and 1 m*M* 2-propanol (2-propanol is reputed to react rapidly with SO_4^- radical ions (13)) and (*b*) 3 m*M* NaOH, 5 μ*M* Ag_2SO_4 and 1 m*M* HCOONa. In this latter solution e_{aq}^- was formed by photolysis of OH^- ($OH^- \xrightarrow{h\nu} OH + e_{aq}^-$) and the OH radical scavenged by formate ions. This latter mixture also shows that Ag^{2+} ions from reaction 4 are not responsible for the auxiliary absorption peak. Ag^{2+} could be formed in reaction 4 (the OH perhaps arising from SO_4^- in the SO_4^{2-} experiments) but is excluded by the presence of the formate.

[4] $$Ag^+ + OH \rightarrow Ag^{2+} + OH^-$$

Solutions of thallous ions were studied in an analogous manner. For a solution containing 10^{-5} *M* Tl_2SO_4 and 10^{-3} *M* 2-propanol traces similar to Fig. 1 were obtained and on changing the filters the data of Table 2 were found for a delay between main and auxiliary of 30 μs. The intermediate was evidently photodissociated mainly by light centered around ~300 nm. In this case the transient decayed more rapidly than in the Ag^+ system. Reactions 5 and 6 are known to occur (2, 14) and are expected to be involved here as with the Ag^+ system, but where $k_6 > k_2$ (14).

[5] $$Tl^+ + e_{aq}^- \rightarrow Tl^0 \quad k_5 \sim 1.1 \times 10^{10}\ M^{-1}\ s^{-1}$$ (2)

[6] $$Tl^0 + Tl^+ \rightarrow Tl_2^+$$

Discussion

The laser photometry data indicate that hydrated electrons, produced during the main flash by far u.v. photolysis of SO_4^{2-} in reaction 3, react rapidly with Ag^+ according to reaction 1, thereby creating a transient species (half-life ~ 42 μs at 5×10^{-6} *M* Ag^+) which can be photodissociated by the auxiliary lamp to yield e_{aq}^- again. Light filter experiments show that the transient is photolyzed by wavelengths centered around 300 nm but extending to 400 nm. This is entirely consistent with the spectra shown in Fig. 3. Curve (*i*) shows the spectrum of the transient 35 μs after the main flash, curve (*ii*) its loss during the auxiliary flash, and (*iii*) its formation again 30 μs after the auxiliary flash. Absorption at long wavelengths in curve (*ii*) also corroborate the formation of e_{aq}^-. The transient evidently has an absorption band centered ~315 ± 5 nm and this is the band which leads to photodissociation to e_{aq}^-.

Also sketched in Fig. 3 is the spectrum reported by Baxendale *et al.* (3) with λ_{max} at 310 nm and assigned by them to Ag^0 which compares very closely to our transient. Consequently we conclude that photolysis during the Auxiliary flash can be represented by photoionization process [7].

[7] $$Ag^0 \xrightarrow{h\nu} Ag^+ + e_{aq}^-$$

This conclusion is corroborated by a comparison of the estimated extinction coefficient, and by the decay kinetics displayed in Fig. 2. We estimated the extinction coefficient of Ag^0 at λ_{max} (315 nm) by the following procedure. The flash intensity absorbed is given by the analytical form, $I_a = ate^{-bt}$ (15) where b is $1/t_{max}$. The value of a was obtained experimentally from a solution which was the same as that of Fig. 3 except that it contained no Ag^+ (*i.e.*, e_{aq}^- very long-lived) because in this solution the maximum absorbance could be related directly to the total number of electrons formed, *i.e.* a/b^2. It is now assumed that all e_{aq}^- react with Ag^+ to give Ag^0 and that the latter decay by reaction 2 with $k_2 = 6 \times 10^9\ M^{-1}\ s^{-1}$. Thus $[Ag^0]$ at 35 μs was calculated by integration of the equations

$$d[e_{aq}^-]/dt = a\,te^{-bt} - k_1[Ag^+][e_{aq}^-]$$

$$d[Ag^0]/dt = k_1[Ag^+][e_{aq}^-] - k_2[Ag^+][Ag^0]$$

This value of $[Ag^0]$ at 35 μs was used to evaluate the extinction coefficient of Ag^0 from the experimental absorbance shown in Fig. 3, curve (*i*). The value obtained was about $2.5 \times 10^4\ M^{-1}\ cm^{-1}$, which compares remarkably well with the published value of $2.3 \times 10^4\ M^{-1}\ cm^{-1}$ at 313 nm (3*b*).

The rate of decay of the transient is consistent with it being Ag^0 but not with Ag_2^+ or Ag^{2+}. Ag_2^+ is formed in reaction 2 and may decay by reaction 8 to yield Ag^{2+} (4, 16).

[8] $Ag_2^+ + Ag^+ \rightarrow Ag^{2+} + Ag_2^0 \quad k_8 = 3.8 \times 10^9\ M^{-1}\ s^{-1}$ (4)

Both Ag_2^+ and Ag^{2+} are believed to absorb at $\lambda < 400$ nm and the 310 nm band has recently been tentatively assigned to Ag_2^+ rather than Ag^0 (16). However when we calculate the time at which Ag^0, Ag_2^+, and Ag^{2+} reach their maximum concentrations, by the procedure indicated above using the published values of k_1, k_2, and k_8 and our $[Ag^+]$, then we find the maxima occur essentially during the main flash for Ag^0, 50–85 μs afterwards for Ag_2^+ and at even later times for Ag^{2+}. Thus our laser photometry data can only be explained if Ag^0 was the photodissociated species. The decay shown in Fig. 2 yields a value of $k_2 = 3.3 \times 10^9\ M^{-1}\ s^{-1}$ for reaction 2, which is somewhat smaller than the published values, averaging $6 \times 10^9\ M^{-1}\ s^{-1}$ (4, 16).

A similar interpretation may be applied to the results on Tl^+ solutions which strongly implies that Tl^0 was the short-lived transient which may be photodissociated by light between 250–350 nm giving e_{aq}^- according to process [9].

[9] $$Tl^0 \xrightarrow{h\nu} Tl^+ + e_{aq}^-$$

The thallous system seems to be quite similar to the silver system except that Tl^0 decays more rapidly.

The occurrence of process [7] implies that the absorption band of Ag^0 centered around 315 nm corresponds to a charge-transfer-to-solvent (CTTS) band. This is supported by the high oscillator strength of 0.63 which we calculate for the transition based on the spectrum of Fig. 3 and the value of ε_{max} evaluated above. It may be a common feature of the unusual valence state species (hyper-reduced states), many of which absorb in this spectral region, for these bands to be CTTS bands. Indeed, when Ni^{2+} solutions were examined in this same way rather similar effects were found, which implies that the transient ion Ni^+ may be photodissociated again into Ni^{2+} and e_{aq}^- by light ~300 nm. Rather similar results were obtained with other transition metal ions but not with Cu^{2+}. (It should be noted that these transients were very short-lived and could not be involved in our experiments on the bimolecular combination of e_{aq}^- (10) even if transition metal ions were present as trace impurities.)

Attempts to produce e_{aq}^- by flash photolysis of metallic silver in this apparatus, either in the form of a semi-transparent silver mirror or as colloidal particles, have been unsuccessful. It should be noted however that the photon energy threshold for process [7] is at about 3.0 eV (~400 nm), which is about 1.5 eV smaller than the vacuum photoelectric work function for silver metal (17).

We are grateful to the National Research Council of Canada and the Defence Research Board of Canada for financial support of this research.

Effect of Solute–Solute Interaction on Molecular Luminescence in Rigid Glasses: Anomalous Thioxanthenone Phosphorescence and Anthracene Fluorescence[1]

R. O. Loutfy,[2] D. F. Williams, and R. W. Yip

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received March 14, 1973

The phosphorescence spectra and lifetimes of thioxanthenone in a number of rigid matrices at 77 °K was found to be dependent on the concentration, rate of cooling of the glass, and on the wavelength of excitation. At 77 °K and at concentrations greater than $\sim 5 \times 10^{-5}$ *M*, aggregates of thioxanthenone are believed to be responsible for a new phosphorescence band at 472 nm, and a corresponding absorption band at 390–395 nm.

The formation of aggregates is also believed to be responsible for the variations, with excitation wavelength, of the fluorescence lifetime of anthracene in polymethacrylate at ambient temperatures.

Le spectre de phosphorescence et les durées de vie de la thioxanthénone dans un certain nombre de matrices rigides à 77 °K, dépendent de la concentration, de la vitesse de refroidissement du verre et de la longueur d'onde d'excitation. A 77 °K et pour des concentrations supérieures à $\sim 5 \times 10^{-5}$ *M*, on pense que les agrégats de thioxanthénone formés sont responsables d'une nouvelle bande de phosphorescence à 472 nm et de la bande d'absorption correspondante à 390–395 nm.

De même, cette formation d'agrégats est tenue pour responsable des variations, avec la longueur d'onde d'excitation, de la durée de fluorescence de l'anthracène dans le polyméthacrylate aux températures ambiantes. [Traduit par le journal]

Can. J. Chem., **51**, 2502 (1973)

Recently, several examples of anomalous phosphorescence involving aromatic ketones in low temperature glasses have been reported (1–5). They have variously been attributed (*i*) to the population of two singlet manifolds of the same molecule (Michler's ketone) (1), (*ii*) to differences in local environment (Michler's ketone) (2), (*iii*) to the existence of two different conformations of the solute molecule (butyrophenone) (3), and (*iv*) to photoproducts (1-indanone and 1-tetralone) (4). In the present note, we report two further examples of anomalous luminescence, involving simple aromatic molecules, which are unlikely to be due to the above causes or to impurity. We have observed anomalous phosphorescence from dilute solutions of thioxanthenone in glass matrices (10^{-5}–10^{-4} *M*) at 77 °K and anomalous fluorescence from anthracene in polymethyl methacrylate (10^{-4} *M*). We suggest that anomalous emission originate from aggregates in both cases even though many of the features of the emission were similar to those which could be due to triplet excimer (6) and to the population of two emitting triplet states (a violation of Kasha's rule (7)) by intersystem crossing from two singlet states of the same molecule (1). The results stress the importance of carrying out low temperature absorption and phosphorescence excitation measurements under different conditions when investigating possible instances of triplet excimer emission or emission from two triplet states of the same molecule. In contrast to the usual suggestion of *slow* cooling of dilute solutions in the preparation of glass matrices for emission study, our results clearly show that to minimize aggregation, it is necessary to *rapidly* cool dilute solutions. Even under these very improbable conditions, some aggregation can be observed.

The phosphorescence spectrum of a dilute sample (1×10^{-5} *M*) of thioxanthenone in 4:1 methylcyclohexane–isopentane (MCIP) or methylcyclohexane (MC) matrices at 77 °K was similar to that reported earlier (8). At higher concentrations (5×10^{-5}–10^{-4} *M*), however, the phosphorescence spectrum in MCIP (or EPA) and the lifetime was dependent on the wavelength of excitation. As shown in Fig. 1, a new phosphorescence band at 472 nm became more pronounced (relative to the normal peak at 443 nm) as the excitation wavelength was

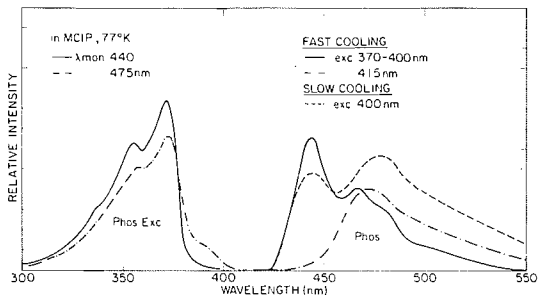

FIG. 1. Phosphorescence and phosphorescence excitation spectra of 10^{-4} *M* thioxanthenone in MCIP at 77 °K (*a*) fast cooling phosphorescence: (—) λ_{ex} 370 or 400 nm; (- - -) λ_{ex} 415 nm, phosphorescence excitation: (—) λ_{mon} 440 nm and (- - -) λ_{mon} 475 nm, (*b*) slow cooling phosphorescence (---) λ_{ex} 400 nm.

increased above the absorption maximum at 380 nm. The new phosphorescence band at 472 nm decayed exponentially with a $\tau = 0.13$ s in MCIP or EPA (λ_{ex} 400 nm, λ_{mon} 475 nm), whereas the normal emission decayed with a $\tau = 0.16$ s in EPA and 0.15 s in MCIP (λ_{ex} 363 nm, λ_{mon} 440 nm). These observations were similar to those reported for Michler's ketone (1) and Michler's thione (6) and could be due to excitation of two different singlet states (of the same molecule) as postulated recently by Klöpffler (1), but which may be due to excimer emission, aggregate emission, or microcrystalline emission.

We therefore searched for (and found) an absorption band which corresponded to the phosphorescence band at 472 nm. Both the absorption and phosphorescence excitation spectra[3] of thioxanthenone in MCIP (or EPA) (1×10^{-4} *M*) at 77 °K revealed a weak shoulder at ~390 nm (395 nm in EPA). At room temperature, the shoulder was absent. These observations, particularly the latter one, appear to rule out impurity as an explanation. Since at 77 °K, there exists a ground state absorption which corresponds to the emission at 472 nm, excimer emission is also ruled out.

The phosphorescence spectrum of thioxanthenone crystal at 77 °K showed a structureless emission (λ_{max} 510 nm) $\tau = 0.098$ s which was independent of the wavelength of excitation. In view of these observations, the most likely explanation for the anomalous phosphorescence is due to aggregate formation and not microcrystals. The degree of aggregation depends upon both solute concentration and the solvent used. The aggregate emission in MCIP was displaced to the red from that in EPA.

Aggregation was confirmed when we studied the effect of rate of cooling of the glass matrix on the phosphorescence spectrum. A sample prepared by cooling over several hours exhibited a definite peak at long wavelength, whereas this sample rapidly-cooled showed only a slight shoulder (see Fig. 1).

Lifetime measurements were used as one sample quality control for a recent experimental investigation concerning the differences between the temperature dependence 300–1.8 °K of the fluorescence lifetime of anthracene in polymethyl methacrylate solutions and anthracene single crystals (9). Naturally for any meaningful comparison, particularly at low temperatures, it was necessary to show that no solute aggregation had taken place. As a test for the absence of aggregates the fluorescence lifetime at 4 °K was measured as a function of emission wavelength. Occasionally the sample fluorescence lifetime was not independent of emission wavelength, indicating aggregation, though the solute concentration was $\sim 10^{-5}$ *M* and aggregation was not expected. Furthermore samples seemingly produced under exactly the same conditions did not always show the same extent of aggregation, and indeed aggregation was sometimes completely absent even for more concentrated solutions. No other experimental probe was found to be as sensitive to aggregation as the fluorescence decay rate in this case, though under extreme conditions absorption studies also showed crystallite formation.

[3]Excitation spectra were obtained using a Farrand Spectrofluorimeter Mark I.

Crystal Structure of 1,3,5,7-Tetrasulfur-2,4,6,8-tetramethylimide, $S_4(NCH_3)_4$

ALISTAIR L. MACDONALD AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received January 15, 1973

Crystals of $S_4(NCH_3)_4$ are orthorhombic, $a = 25.483(6)$, $b = 15.842(3)$, $c = 5.642(2)$ Å, $Z = 8$, space group *Fdd*2, required molecular symmetry C_2. The structure was determined with CuKα diffractometer data by Patterson and Fourier methods, and refined by full-matrix least-squares methods to $R = 0.067$ for 473 observed reflexions. The eight-membered ring has a crown conformation, with approximate C_{4v} symmetry, and the bonds at each nitrogen atom are slightly but significantly non-planar. Mean bond lengths are S—N = 1.677(4), C—N = 1.479(7) Å.

Les cristaux de $S_4(NCH_3)_4$ sont orthorhombiques, $a = 25.483(6)$, $b = 15.842(3)$, $c = 5.642(2)$ Å, $Z = 8$, groupe d'espace *Fdd*2, la symetrie minimum de la molecule est C_2. La structure a été determinée à partir de methodes de Patterson et Fourier, et a été affinée par les methodes moins carrées (matrice complète) à $R = 0.067$ pour 473 reflexions observées. La cycle de huit membres a une conformation d'un coronne, la symetrie étant à peine de C_{4v}, et les liaisons à chaque atome de nitrogene sont significament non-plans. Les distances moyennes des liaisons sont S—N = 1.677(4), C—N = 1.479(7) Å.

Can. J. Chem., **51**, 2504 (1973)

Introduction

There are eight known compounds of general formula $S_{8-x}(NH)_x$, $x = 0$–4, in which no two nitrogen atoms are adjacent, and the crystal structures have been determined for S_8 (1), S_7NH (2), three isomers of $S_6(NH)_2$ (2–4), $S_5(NH)_3$ (5), and $S_4(NH)_4$ (6, 7). All contain molecules with eight-membered puckered rings, and each molecule lies on a crystallographic two-fold symmetry element, except 1,3-$S_6(NH)_2$ (4). All the corresponding *N*-methyl sulfur imides are known (8), but no structural analyses have been reported. A puckered ring has been predicted for $S_4(NCH_3)_4$ (9), and dipole moment measurements suggest non-planar S_2NC groupings (8 and references therein). We now describe an X-ray crystal study of $S_4(NCH_3)_4$.

Experimental

Crystals of $S_4(NCH_3)_4$ (9) from hexane are colorless needles (usually several cm in length) elongated along *b*; since the crystals shattered when cut normal to the needle axis, it proved difficult to obtain one suitably small for the X-ray analysis, but eventually one of dimensions 0.2 × 0.5 × 0.2 mm was found, and the crystal data were determined from film and diffractometer measurements:

$C_4H_{12}N_4S_4$ f.w. = 244.4

Orthorhombic, $a = 25.483(6)$, $b = 15.842(3)$, $c = 5.642(2)$ Å, $V = 2277.7$ Å^3, $\rho_o = 1.437$ (flotation in aqueous KI), $Z = 8$, $\rho_c = 1.425$ (20 °C, CuKα, $\lambda = 1.5418$ Å, $\mu = 70$ cm^{-1}). Space group Fdd^2 (C_{2v}^{19}), from systematic absences.

Intensities were measured on a Datex-automated G.E. XRD 6 diffractometer, with a scintillation counter, CuKα radiation (Ni filter and pulse-height analyzer), and a θ–2θ scan over a range in 2θ of (1.80 + 0.86 tan θ) degrees at a speed of 2° min^{-1}, with background counts at each end of the scan. All 611 independent reflexions with $2\theta \leqslant 146°$ were measured, and 473 were classified as observed, having $I > 3\sigma(I)$, where $\sigma^2(I) = S + B + (0.03S)^2$, S = scan count, B = normalized background count. The intensity of a check reflexion, measured every 30 reflexions, fell to 50% of its initial value during the data collection; comparison with films indicated a uniform reduction for all reflexions, and because of the difficulty of obtaining suitable crystals the same crystal was used throughout, and the check reflexion data were used to reduce all intensities to the same scale. Structure amplitudes were derived as usual; no absorption correction was made.

Structure Analysis

The molecule is required to have C_2 symmetry. The structure was determined by Patterson and electron-density methods, and refined by full-matrix least-squares methods, finally with anisotropic thermal parameters, scattering factors from ref. 10, and anomalous dispersion corrections for sulfur ($\Delta f' = 0.03$, $\Delta f'' = 1.2$). Hydrogen atoms could not be located. The weighting scheme was $\sqrt{w} = 1$ when $|F_o| \leqslant 57$, $\sqrt{w} = 57/|F_o|$ when $|F_o| > 57$, $\sqrt{w} = 0.3$ for unobserved reflexions, and the final R values were 0.067 for the observed reflexions, and 0.081 for all data. Measured and calculated structure factors are in the Depository of Unpublished Data.[1]

Final positional and thermal parameters are in Table 1.

[1]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

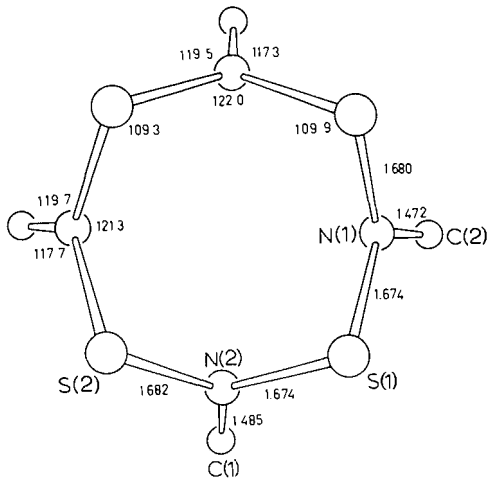

FIG. 1. Bond lengths and angles in $S_4(NCH_3)_4$; standard deviations for S—N, N—C, N—S—N, S—N—S, S—N—C are 0.009, 0.015 Å, 0.4, 0.6, 0.8°, respectively.

Discussion

The molecule (Fig. 1) contains an eight-membered, puckered ring of alternating sulfur and nitrogen atoms, with a crown conformation, and with the methyl groups bonded to nitrogen; the molecular symmetry is approximately C_{4v}. All the atoms of one type (S, N, or C) lie in one plane parallel to (001); the distance between the S and N planes is 0.67 Å, and that between the N and C planes is 1.34 Å. The geometry at each of the two independent nitrogen atoms is slightly but significantly non-planar, with the carbon atoms displaced by 0.28 and 0.29 Å from the SNS planes, the N—C bonds being 11° out of these planes. Similar nonplanarity may be present in $S_4(NH)_4$, where the N—H bonds make angles of 10° with the SNS planes, although the deviations are not statistically significant (11).

The thermal parameters correspond approximately to rigid-body vibration, with some additional motion of the methyl groups. The minimum translational motion (root-mean-square displacement 0.17 Å) is along c, *i.e.* the C_2 (approximate C_4) molecular axis, with displacements of 0.19 and 0.23 Å approximately along the cross-ring N...N directions. Minimum rotational motion (3.7°) is about the C_2 axis, with rotations of 4.3 and 5.4° about axes normal to C_2 and to S—N bonds.

Bond lengths and angles are included in Fig. 1. The mean S—N bond length is 1.677(4) Å (1.686 Å if a thermal motion correction is applied), the value in $S_4(NH)_4$ being 1.674(4) Å. This length is intermediate between the sum of the single-bond radii (1.74 Å) and the double-bond length of 1.54 Å found in $N_4(SF)_4$ (12), suggesting an intermediate bond order (13) and delocalization of nitrogen lone-pair electrons, in agreement with the observation that $S_4(NCH_3)_4$ is an extremely weak base (14). However the S—N—S—N torsion angles, 91.8 and 94.6°, and the N—S—N valency angles, 109.3 and 109.9°, are similar to the values in S_8, 99.3 and 107.8°, and it has been argued (15) that if the bonds in S_8 are single-bonds, then 1.67 Å is the expected single-bond length for S—N bonds involving sp^3 hybridization at sulfur. The mean C—N bond distance, 1.479(7) Å (1.485 Å if corrected for thermal liberation), is normal. The valency angles are close to the values expected for sp^3 hybridization at sulfur and sp^2 at nitrogen.

The crystal structure is shown in Fig. 2. Intermolecular contacts are normal, the shortest being S...C, 3.90; S...S, 3.925; C...C, 3.92 and 4.01 Å.

Solvation of Cl^- and O_2^- with H_2O, CH_3OH, and CH_3CN in the gas phase

R. YAMDAGNI, J. D. PAYZANT, AND P. KEBARLE

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received February 16, 1973

Determination of the temperature dependence of the equilibrium constants $K_{n,n-1}$ for the reactions $A^-B_n = A^-B_{n-1} + B$ where A^- equals Cl^- and O_2^- and B is HOH, CH_3OH, or CH_3CN leads to the corresponding $\Delta H^0_{n-1,n}$, $\Delta G^0_{n-1,n}$, and $\Delta S^0_{n-1,n}$ values. The experimental technique is based on mass spectrometric detection of ions escaping from a high pressure ion source. At $n = 1$, Cl^- is solvated most strongly by methanol, then CH_3CN and HOH. At higher n a cross over is observed with water becoming the best solvent. These results are in agreement with the positive transfer enthalpies and free energies for Cl^- from the liquid solvents HOH → CH_3OH and HOH → CH_3CN reported in the literature.

O_2^- is solvated more strongly than Cl^- appearing thus as an ion of "size" intermediate between Cl^- and F^-. Again CH_3OH gives the highest interaction for $n = 1$, however for $n > 1$ water gives stronger interactions.

La détermination de l'influence de la température sur les constantes d'équilibre $K_{n,n-1}$ pour les réactions $A^-B_n = A^-B_{n-1} + B$ où $A^- = Cl^-$ et O_2^- et B = HOH, CH_3OH, et CH_3CN, conduit aux valeurs correspondantes pour $\Delta H^0_{n-1,n}$, $\Delta G^0_{n-1,n}$ et $\Delta S^0_{n-1,n}$. La technique expérimentale est basée sur la détection par spectrométrie de masse, des ions sortant d'une source d'ions à haute pression. Pour $n = 1$, Cl^- est le plus solvaté par le méthanol puis CH_3CN et HOH. Pour n plus élevé, une interversion se produit et c'est l'eau qui devient le meilleur solvant. Ces résultats sont en accord avec les enthalpies et énergies libres de transfert pour Cl^- dans les solvants liquides HOH → CH_3OH et HOH → CH_3CN, rapportées dans la littérature.

O_2^- est solvaté plus fortement que Cl^- indiquant ainsi que la taille de cet ion est intermédiaire entre Cl^- et F^-. CH_3OH montre encore la plus forte interaction pour $n = 1$, cependant pour $n > 1$, c'est l'eau qui conduit aux interactions les plus fortes. [Traduit par le journal]

Introduction

A comparative study of the gas phase solvation of the halide ions by water and acetonitrile molecules was published earlier (1). The present work extends the study to the O_2^- ion and includes methanol as a new solvent. The O_2^- ion is an important ion in the ionosphere and troposphere (2) where it results from electron capture by O_2. The superoxide ion O_2^- is stable also in condensed phases. Thus paramagnetism and X-ray crystal studies of the solid metal superoxides (NaO_2, KO_2, etc.) have shown (3) that these contain discrete free radical anions O_2^-. The O_2^- ion although unstable in aqueous solution plays an important role in biological systems (4). The superoxide ion is stable in aprotic solvents. Solutions of alkylamine superoxide in aprotic solvents have been used to study the reactivity of the superoxide ion as a nucleophilic reagent (5).

In the gas phase the O_2^- ion forms stable hydrates $O_2^-(H_2O)_n$ (6) and other solvates: $O_2^-(CH_3OH)_n$, $O_2^-(CH_3CN)_n$ etc. Thus the stabilities of these solvates can be studied and some interesting information on this symmetric singly charged diatomic ion can be obtained.

All measurements described in the present work are based on the determination of the temperature dependence of the gas phase equilibria $(n,n-1)$ observed in a high pressure mass spectrometer ion source.

$$(n,n-1) \qquad A^-B_n = AB^-_{n-1} + B$$

Experimental

The apparatus and method of measurement have been described in considerable detail elsewhere (7, 8). Only a brief outline will be given here. The equilibrium constants $K_{n-1,n}$ were determined by mass spectrometric detection of ions escaping from the reaction chamber-ion source. At equilibrium the $K_{n-1,n}$ are given by

$$K_{n-1,n} = \frac{P_{A^-(B)_n}}{P_{A^-(B)_{n-1}} P_B} \approx \frac{I_{A^-(B)_n}}{I_{A^-(B)_{n-1}} P_B}$$

$$K_{n,n-1} = 1/K_{n-1,n}$$

where P_X represents the partial pressures in the ion source and I_X the mass spectrometrically detected ion intensities of the respective species. It is assumed that the measured ion intensity ratios reflect the ratio of the partial pres-

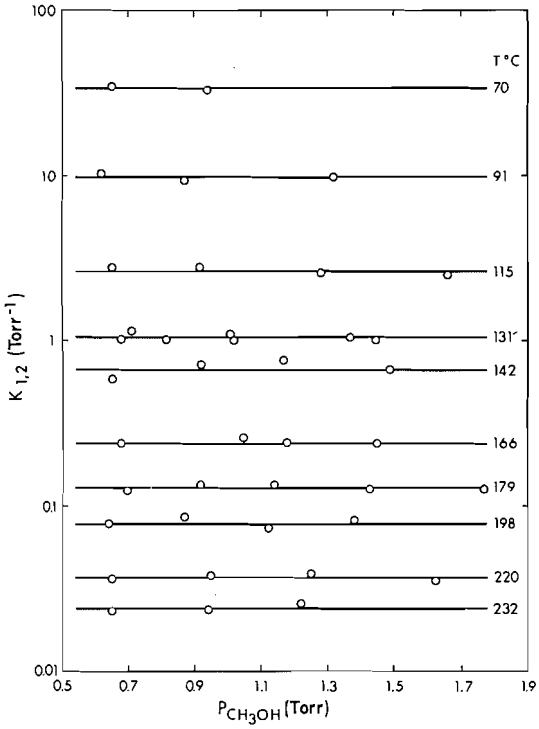

FIG. 1. Equilibrium constants $K_{1,2}$ for the reaction $O_2^-.CH_3OH + CH_3OH = O_2^-(CH_3OH)_2$ as a function of methanol pressure. Total pressure is 4.0 Torr (O_2).

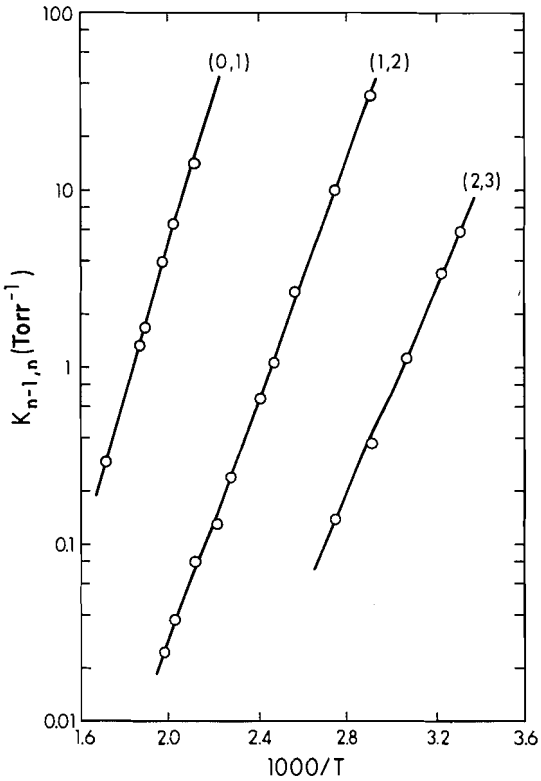

FIG. 2. Van't Hoff plots of equilibrium constants $K_{n-1,n}$ for reactions $(n-1,n)$: $O_2^-(CH_3OH)_{n-1} + CH_3OH = O_2^-(CH_3OH)_n$, $n = (1, 2, 3)$.

sures. In a typical experiment the pressure of carrier gas (O_2) in the ion source is ~5 Torr and the partial pressure of solvent vapor is varied over the 0.5–2.0 Torr range. Under these conditions the half life of the forward clustering reactions $(n-1,n)$ is short ($t_{1/2} < 30$ μs) (2). Since the average ion spends about 1 ms in the ion source (9) and undergoes a large number of collisions the measured ion intensities should give the thermodynamic equilibrium concentrations.

A 2 kV electron beam of $\sim 10^{-8}$ A entering the ion source through a narrow slit (1.5 × 0.01 mm) is used for ionization. The ions are sampled from the ion source through a slit (1.5 × 0.01 mm) which is mounted about 4 mm below the plane of the electron beam. The liquid solvent was kept in a thermostated bulb and its vapor was introduced through a capillary into the flowing (~25 atm cc min^{-1}) carrier gas. The flow rate was monitored with a calibrated flowmeter and the partial pressure of the solvent in the ion source was calculated by "weight loss" measurements (7, 8).

The negative ion O_2^- was observed in O_2 (9), and is presumably produced by third body capture of thermal electrons:

$$e + 2O_2 = O_2^- + O_2$$

The Cl^- ion was generated by the addition of small quantities (~0.01 Torr) of CCl_4 (6) to the carrier gas. The reaction probably involved is dissociative electron capture by CCl_4:

$$e + CCl_4 = Cl^- + CCl_3$$

The Cl^-, CH_3OH, and CH_3CN experiments described in this paper were done before the pulsed electron multiscaling technique was developed (7). Therefore the kinetics of the approach to the equilibria $(n-1,n)$ was not studied for that system. The O_2^- values were obtained with the multiscaling technique.

The absolute accuracy of the quoted ΔH° and ΔG° values is difficult to assess. Most accurate are the ΔG° values corresponding to the experimental temperature range. The ΔH° values and ΔG°_{298} values depend on a correct evaluation of the slope in the Van't Hoff plots. The standard deviation of the slope corresponds generally to less than ±3% of the ΔH° values. However, the error is probably closer to ±5%. The largest actual error is expected in the ΔS° values since the least square treatment used does not take into account systematic deviations of the measured equilibrium constants and temperature.

Results and Discussion

The equilibrium constants for the reaction

$$A^-B_{n-1} + B = A^-B_n$$

were measured at different temperatures with

§Reference 1.

various solvent (B) pressures. A typical case is shown in Fig. 1 where the equilibrium constants are plotted against the CH_3OH pressure. It can be seen that the equilibrium constants are independent of solvent pressure within experimental error. The Van't Hoff plots ($n = 1, 2, 3$) for the O_2^- methanol system are shown in Fig. 2. The thermodynamic values of ΔH^0, ΔS^0, and ΔG^0 were derived from such plots for all the systems studied and are listed in Table 1. Some previous data from this laboratory are also included in the table for comparison.

For a visual comparison, the variation of $\Delta H^0_{n-1,n}$ with n for the ions F^-, O_2^-, and Cl^- are shown in Fig. 3. We may start the discussion with the behavior of Cl^- which is a typically "medium size" spherical negative ion. The highest $\Delta H^0_{1,0}$ value is observed with CH_3OH followed by CH_3CN and HOH. Methanol and water are both protic solvents while CH_3CN is aprotic. The dependence of the $\Delta H^0_{1,0}$ interactions (of Cl^-) on the nature of the protic solvents RH was examined in an earlier paper (10) which dealt with hydrogen bonding to negative ions. It was concluded that the $\Delta H^0_{1,0}$, which corresponds to the dissociation energy of the hydrogen bond $D(Cl^-—HR)$, increases with the proton donating power, *i.e.*, with the gas phase acidity of HR. The higher $\Delta H^0_{1,0}$ for methanol relative to water was ascribed to a higher gas phase acidity of methanol which was in agreement with gas phase acidity measurements by Brauman (11). The present results extend the comparison to higher n. In Fig. 3 one observes that methanol remains a better "solvent" also for higher n but that the difference between methanol and water decreases. Extrapolation of these $\Delta H^0_{n,n-1}$ values indicates a possible cross over, *i.e.* a larger ΔH^0 for water at the $\Delta H^0_{5,4}$ step. Earlier gas phase solvation work (1, 9) has indicated that the trends in the $\Delta H^0_{n,n-1}$ values observed even for only the first four or five steps reflect differences in the total single ion enthalpies and free energies of solvation. This seems to be the case also for the Cl^-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

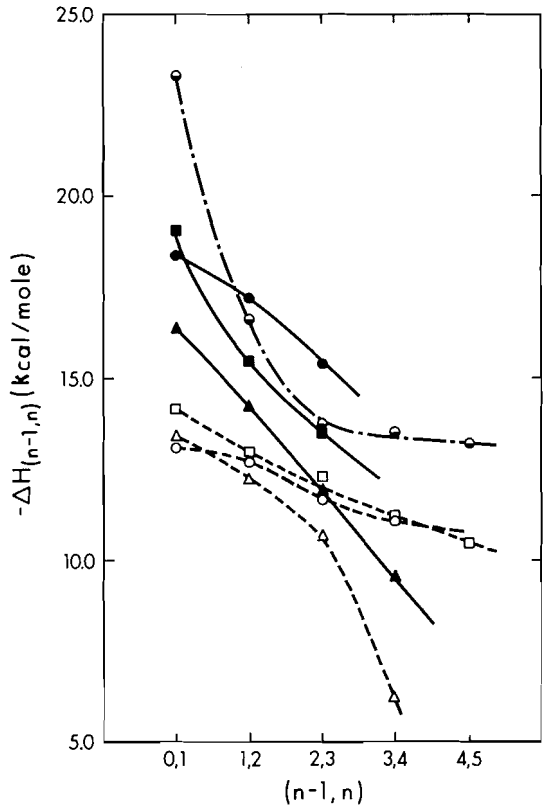

FIG. 3. Plot of $-\Delta H^0_{n-1,n}$ for solvation reaction in the gas phase: ●, $O_2^-(H_2O)_n$; ■, $O_2^-(CH_3OH)_n$; ▲, $O_2^-(CH_3CN)_n$; ○, $Cl^-(H_2O)_n$; □, $Cl^-(CH_3OH)_n$; △, $Cl^-(CH_3CN)_n$; ◑, $F^-(H_2O)_n$.

solvation by water and methanol. Since the measured differences between the $\Delta H^0_{n,n-1}$ for methanol and water are small and followed by a possible cross over, the present results indicate only a small difference between the total enthalpies of solvation of Cl^- by water and methanol. Choux and Benoit (12) have estimated a small positive enthalpy for transfer of Cl^- from H_2O to CH_3OH: $\Delta H_{transfer} = +1.9$ kcal/mol. If this estimate is correct then the indicated cross over in Fig. 3 is probably real. The free energy differences (Table 1) show a trend similar to that of the ΔH^0 differences, however the relative decrease of the $\Delta G^0_{n,n-1}$ for methanol is more rapid, such that a reversal with water becoming more favored is observed already for the $\Delta G^0_{4,3}$ step. This suggests that the free energy of Cl^- transfer from HOH to CH_3OH should be positive and larger than the corresponding ΔH^0 transfer, a result which is in agreement with conclusions of Parker and co-workers (13).

A comparison between the $\Delta H^0_{n,n-1}$ and $\Delta G^0_{n,n-1}$ values for Cl^- and the other halide ions and the protic and aprotic solvents HOH and CH_3CN was reported earlier (1). The most significant finding was that acetonitrile at close range (low n) gives stronger interactions than water but that the interactions become very much less favorable at high n. Furthermore it was found (1) that the small ions (F^-) showed stronger interactions with water while the interaction with acetonitrile became relatively more favorable as the size of the ion increased. This result was found to be in agreement with transfer enthalpies and free energies for the liquid solvents (HOH → aprotic solvent) which had been determined (12, 13) to be positive for small ions (F^-) becoming progressively smaller and turning negative for large ions (I^-).

The solvation of O_2^- (Fig. 3 and Table 1) fits similar general trends. The $\Delta H^0_{n,n-1}$ values of Fig. 3 show that O_2^- falls between F^- and Cl^- and may thus be considered as an ion which has a "radius" falling between those of F^- and Cl^-. Correspondingly the difference between the values for HOH and CH_3CN observed for O_2^- is larger than that observed for the larger Cl^- ion. It is also found that the solvation by methanol becomes unfavorable at much smaller $n,n-1$ values since a crossover occurs already after $\Delta H^0_{1,0}$. We are led to expect that ion transfer from the liquid solvent water to methanol should show transfer enthalpies which decrease as the size of the ion is increased. This is borne out by the determinations of Choux and Benoit (12).

Of course the O_2^- ion is not spherically symmetrical. The simple MO description puts the three outer electrons in the doubly degenerate nonbonding $2_p\pi_g$ orbital. This means that in the unperturbed O_2^- the negative charge should be spread out to the two ends of the ion. One would expect that the presence of a molecule like HOH and CH_3OH with a partially positively charged hydrogen atom will induce a partial shift of electronic charge to the one side of the O_2^- ion with the polar molecule attaching itself effectively to that side. The behavior of O_2^- as an ion "smaller" than Cl^- is thus not unexpected. The addition of a second and further molecules might then engage both oxygen atoms. Unfortunately the data in Fig. 3 do not seem to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

show a consistent behavior. Thus the hydrates show a small fall off between $\Delta H^0_{1,0}$ and $\Delta H^0_{2,1}$ (compared to that of F^-) however the methanol results give a fairly large fall off for the same step.

From the general position of the O_2^- in Fig. 3 one can predict that its total enthalpy of hydration will be close but lower than that for F^-. Since $\Delta H_h(F^-) = -113$ kcal/mol and $\Delta H_h(Cl^-) = -81.3$ kcal/mol (14) one might expect a $\Delta H_h(O_2^-) \approx -100$ kcal/mol. The transfer enthalpy from water to methanol should be small and positive while that to acetonitrile also positive but considerably larger.

Free-energy Relationships in Coordination Chemistry. III. A Comprehensive Index to Complex Stability

E. NIEBOER[1] AND W. A. E. MCBRYDE

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 7, 1972

Efforts to relate metal-complex stability constants to some property of the metal ions involved have led to the development of a correlating numerical index Q with the following characteristics: (*i*) Q is a two parameter quantity involving ionic charge and electronegativity, which may assume different values for a particular metal according to the type of ligand with which complexes are formed; (*ii*) linear relationships are obtained for plots of log K_{ML} *vs.* Q for various metals and more than thirty ligands. The effect of the thermodynamic and structural properties of ligands and metal complexes on the slope and intercept in this correlation is discussed. Two new indices to class b behavior are introduced, one for metal ions and one for ligands. The index Q is shown to be related to other published indices of ionic or covalent, class a or class b, behavior of metals and ligands; the alternative ways of assigning Q may be regarded as reflecting the varying degrees of ionic or covalent character in the complexes of a given metal.

Dans le but de relier les constantes de stabilité métal-complexe à certaine propriété des ions métalliques, on a développé un indice numérique de corrélation Q possèdant les caractéristiques suivantes: (*i*) Q est un paramètre double engageant la charge ionique et l'électronégativité. Il peut avoir des valeurs différentes pour un métal particulier selon le type de ligand avec lequel les complexes se forment. (*ii*) Des relations linéaires ont été obtenues en portant log K_{ML} en fonction de Q pour divers métaux et pour plus de trente ligands. L'effet des propriétés thermodynamique et structurale des ligands et des complexes métalliques sur la pente et l'ordonnée à l'origine dans cette corrélation, a été discuté. Deux nouveaux indices de classe b ont été introduits, un pour les ions métaux et un pour les ligands. L'indice Q peut être relié à d'autres indices publiés, ionique ou covalent, classe a ou classe b, comportement des métaux et ligands; les autres méthodes d'attribution sur Q peuvent refléter des degrés variables dans le caractère ionique ou covalent des complexes pour un métal donné. [Traduit par le journal]

Can. J. Chem., 51, 2512 (1973)

Introduction

The classification of donors and acceptors in inorganic reactions has provided a useful framework for the rationalization of metal-complex formation in solution. The original division of acceptors (metal ions) by Ahrland, Chatt, and Davies (1) into class a and class b was based on complex stability in solution as measured by equilibrium constants. These ideas were then extended to the ligand donor atoms: class a donors (*e.g.*, N, O, F) are preferred by class a acceptors, and class b donors (*e.g.*, P, S, Cl) by class b acceptors. More recently Ahrland (2–5) has made the generalization that class a reactions in aqueous medium tend to be entropy stabilized, while class b interactions tend to be enthalpy controlled (exothermic). This thermodynamic criterion is useful, but cannot be used in a clear-cut diagnostic test for any individual reaction (see below).

Pearson's concept (6–10) of hard and soft acids and bases (h.s.a.b.) is a more comprehensive analysis of chemical reactivity. Class a donors and acceptors are referred to as "hard" and the corresponding class b entities are designated "soft". Donor atoms were characterized by a consideration of properties such as polarizability, redox potential, and electronegativity, and by a comparison of their relative affinities for the acids H^+ (hard) and CH_3Hg^+ (soft). Acceptors were then characterized by their preference for the "hard" and "soft" bases. The ability of donor and acceptor atoms to participate in π-back bonding was also considered to be an essential feature of "soft" behavior by Arhland and Pearson.

The use of the vague terms "soft" and "hard" has been criticized (11) on the grounds that they cannot be associated with a single known physical parameter such as polarizability, or with bonding phenomena such as π-back bonding. Williams and Hale (11), Klopman (12), and Jørgensen (13) all agree that the gross fea-

tures of class a and class b behavior are explained satisfactorily by the relative importance of ionic and covalent bonding as modified by solvent effects. London energies and classical polarization may also be important, but are more difficult to assess. Jørgensen (13) expresses the opinion that additional stabilization may also be achieved when one partner of a covalent bond has a low ionization energy and the other has low-energy continuum orbitals. The second atom is then able to take over a small amount of electron density from the first. This charge invasion of continuum orbitals of low energy is thought to take place in systems where the traditional π-back bonding has been implied.

Several indices of class a and b behavior for acceptors and donors have been reported. Craig and Nyholm (14) have proposed $R = \sum I_M(r_M + r_L)/Z^2$ as an index to the character of metal ions; here $\sum I_M$ is the sum of the ionization energies of the metal up to charge Z, and r_M and r_L are ionic radii of the metal and ligand respectively. Class b character is assigned to an ion when $R > 19$, class a when $R < 15$, and intermediate character for $15 < R < 19$. Williams and Hale (11) noted that large values of the similar parameter $\sum I_M r_c$ (in which r_c is the interionic distance in halides) were found for the elements with strongest b character. For a series of bivalent halides the reciprocal of this parameter multiplied by 0.85 closely matched the fraction of ionic character calculated for the partial ionic/covalent bond model (15). The implication here is that a high degree of covalent bond character correlates with class b character in metal ions. Klopman (12) has reproduced in part, and with good agreement, the series of "hard" and "soft" central atoms and ligands established empirically by Ahrland *et al.* and Pearson (1–10). He calculated acceptor and donor electronegativities in solution from ionization energies, electron affinities, ionic sizes, and hydration energies. A related "softness" parameter has been defined by Ahrland (5); and another proposed by Pearson and Mawby (16) also agrees well with Klopman's index.

The present work is concerned with correlation of the magnitude of stability constants with properties of the metal ion. It is surprising that the class a and b indices just mentioned have not been widely tested as indices of complex stability in solution, though other atomic parameters have been employed for a long time (17–19). Thus charge/size ratios for ions have found limited application for class a acceptors. Functions such as Z^2/r_M and Z^2/r_{eff} must be employed when ions of different charge type are considered. The effective radius, r_{eff}, is the sum of the cationic crystal radius r_M and an amount related to the radius of the donor atom of the ligand. For instance, ionic hydration energies vary linearly with $Z^2/(r_M + 0.85)$ (11, 20). The most comprehensive and successful correlation achieved so far is that between log K_{ML} (74.5% by volume of dioxane) of acetylacetone and dibenzoylmethane complexes with the last stepwise ionization potential or with ZX_M, where X_M is the Haissinsky electronegativity, of the metal ion (17, 19, 21–25).

Our attempts to apply these parameters to such systems as EDTA met with very limited success. However, these efforts led to the development of a new index, hereafter described as Q, which is somewhat related to the ZX_M scale, and somewhat related to other parameters by which metals and ligands have been categorized. The value of Q for a given metal, though arrived at empirically, appears in many cases to be dependent on the ligand with which it has been combined. This is taken to reflect the variation in size and especially in bonding character of different donor atoms. In working with the new index we became aware of other derived parameters by which ligands could be characterized and metal–ligand stabilities correlated, and of a new scale for the classification of acceptors.

The Stability Index Q

The index Q may be defined as follows:

$$[1] \qquad Q = (a\delta ZX_M + bX_M^2)/(a + b)$$

In this, X_M is the electronegativity of the metal ion according to Allred (26) and Z is the ionic charge; a and b are integral weighting factors (0, 1, 2....); δ is a parameter calculated with the aid of Slater atomic shielding constants (27) and is intended to compensate in the case of certain elements for an effective increase in electronegativity due to small size or extra covalent bonding character. For some metal ions the choice of integers a and b or of the parameter δ appears to depend on the ligand with which the metal is combined. The particular ways in which

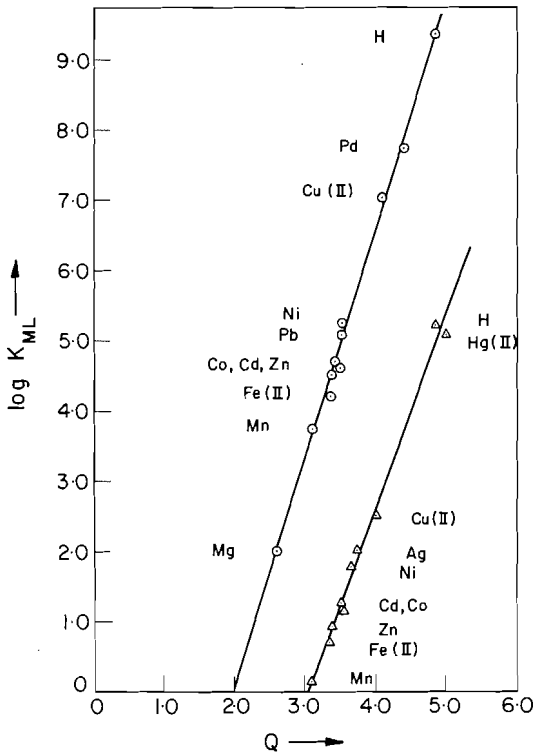

FIG. 1. Metal complex stabilities of hydroxide and fluoride ions as a function of Q: open circles and lower Q-scale, hydroxide ion (μ = 0; 20, 25 °C); open triangles and upper Q-scale, fluoride ion (μ = 0.5 M $NaClO_4$, 25 °C).

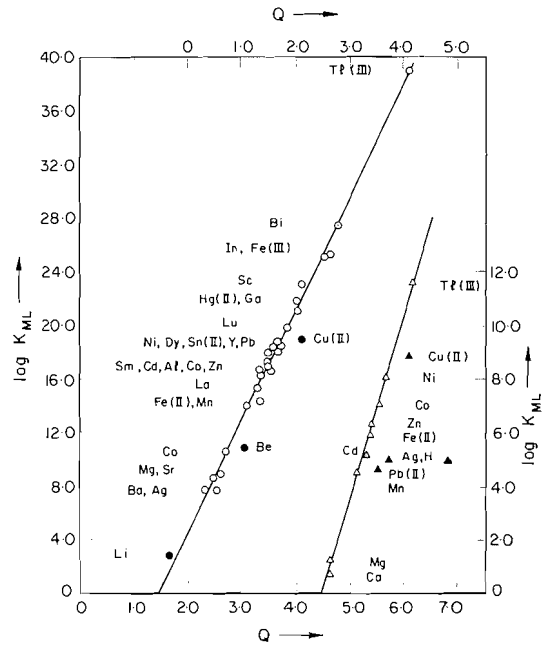

FIG. 2. Metal complex stabilities of ethylenediaminetetraacetic acid and 1,10-phenanthroline as a function of Q: open and closed circles and lower Q-scale, EDTA (μ = 0.1 M, 20 °C); open and closed triangles and upper Q-scale, 1,10-phenanthroline (μ = 0.1 M, 25 °C). The data represented by the closed symbols were omitted from the regression analyses.

Q values are assigned to individual ions are specified in the next section.

It was found that when the first stepwise stability constants for the complexes of a given ligand with a series of metal ions were plotted against the appropriate Q values of the metal ions, a straight-line relationship ensued. The results of a regression analysis of over thirty ligand systems are summarized in Table 1, and are represented for seven ligands in Figs 1–4. The slopes, intercepts, correlation coefficients r (28), and the standard deviations of log K_{ML} were evaluated by a routine least-squares treatment that assigned all "error" to the ordinate. The data employed[2] (29) in the regression analysis were selected with care to include information obtained under the same experimental conditions, preferably by one group of workers. The comparisons were further limited to stability constants for 1:1 metal–ligand complexes mainly because of availability of data, but also to minimize steric and configurational contributions to the free energies examined.

From these linear correlations two parameters emerge which, as will be shown, have considerable capacity for the characterization of metal–ligand stabilities. These are the slope ρ and the intercept on the Q axis, Q_{int}.

Q-Values for Metal Ions

The specific assignment of Q values to metal ions is shown in Table 2. At first glance these assignments seem arbitrary but in fact they were arrived at rather easily. Although comments on the variation of Q for a given metal among different ligands will be reserved for a later section, it is evident from Table 2 that the index is independent of the nature of the ligand for enough metal ions to enable a characteristic plot of log K_{ML} *vs.* Q to be established in each case.

[2]Tabular form of the actual data are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

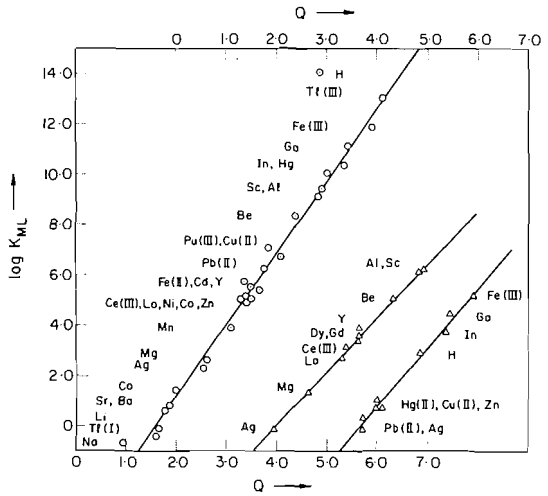

FIG. 3. Metal complex stabilities of salicylaldehyde and pyridine as a function of Q: open circles, salicylaldehyde (50%, by volume of dioxane, 25 °C); open triangles, pyridine (μ = 0.5 M, 25 °C).

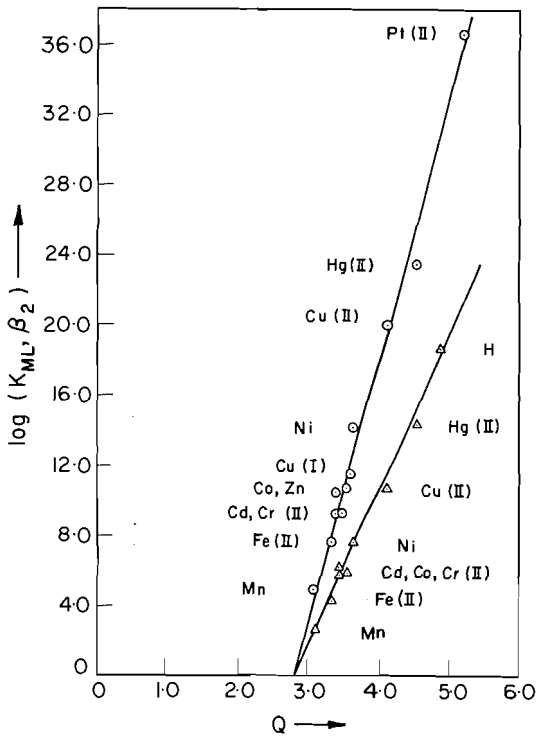

FIG. 4. Metal complex stabilities of ethylenediamine as a function of Q: open circles, log β_2 (μ = 1 M, 25 °C); open triangles, log K_{ML} (μ = 1 M, 25 °C).

Additional metal ions could then be fitted to the regression line by a suitable choice of the weighting coefficients, a and b, or by the use of the coefficient δ mentioned previously, and discussed in more detail in the next section. Average electronegativity values (ref. 26, Table 3) were employed in the computation of Q, although values from Table 2 in the same paper occasionally improved the fit to the linear correlations for Co^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, and Ca^{2+}. Since electronegativity is not a uniquely defined characteristic of an atom or ion, its value for a particular metal may exhibit some variation according to the method by which it was assigned or to the ligand with which it is combined. For instance Allred's values are based on the enthalpies of formation of metal halides, and show a dependence on the nature of the halide. In the case of Co^{2+} and Ni^{2+}, X_M values of 1.88 and 1.91, respectively, were suitable for most ligands, but values of 1.85 and 1.87, respectively, gave better correlation for pure oxygen donors. When $\log K_{ZnL} > \log K_{CdL}$, $X_M = 1.64$ for Cd^{2+} but when $\log K_{CdL} > \log K_{ZnL}$ a value of $X_M = 1.74$ was employed. A value of 1.69 was used for Zn^{2+} except for ligands *1*, *2*, and *4*, where Allred's average value (1.65) gave better results. For Ca^{2+} a value of 1.0 was adequate for all ligands except 5 and 6 where the choice of 1.05 provided a better fit. No value for the electronegativity of Cu^{2+} was reported by Allred. A value of 2.02 was found to be consistent with most of the linear correlations obtained, although the value of 2.00 reported elsewhere (30, 31) gave improved fits for the halide ions, ammonia, and pyridine.

As indicated in Table 2 a characteristic Q value can be associated with each functional group. For polyfunctional ligands the Q value related to the entire ligand molecule is evaluated by taking the arithmetic mean of the Q values appropriate to each functional group. For instance, in the case of EDTA, aluminum has a value

$$Q = 4[(X_M^2 + ZX_M)/2] + 2X_M^2/6$$
$$= (2ZX_M + 4X_M^2)/6.$$

Evaluation of δ

The assignment of δ values by means of Slater screening constants is arbitrary, though supported by some degree of logic. The shielding constant S (27) subtracted from the nuclear

*When $Q = ZX_M + \delta ZX_M$, a has a value of unity and b of zero; similarly when $Q = X_M^2$, b has a value of unity and a of zero; a and b both have values of unity when $Q = (ZX_M + X_M^2)/2$. This covers all cases in this table.
†$Q = X_M^2$ transfers these ions from line I to line II of Cl^- and Br^-.

charge A provides a rough measure of the effective screened nuclear charge at the periphery of an atom or ion. The factor δ in this work takes the form of the ratio of two $(A - S)$ values. In the case of the three small ions (H^+, Li^+, Be^{2+}) the $(A - S)$ values compared (Table 3) are for a typical alkali or alkaline earth metal ion and the value for the related "atypical" small ion.

As indicated earlier, electronegativities are known to depend on the nature of the chemical bond and the bonding orbitals for which they are evaluated (32–35). It appears (Table 2) that when the Allred X_M values are used, ZX_M adequately describes the reactivity of Ba^{2+}, Ca^{2+}, and Sr^{2+} with the halide ions and oxygen donors of relatively low Q_{int} values (Table 1). However,

[b]The average value for *n*s and $(n - 1)$d.
[c]The average of the preceeding average and $(A - S)$.

for most ligands these values are too small. The δ values in Table 3 for these ions are thought to correct their electronegativity values for the increased effective nuclear charge that is expected if the ligand donor electrons are exposed to a field that is intermediate between that acting on a $(n - 1)$d and a *n*s electron. The $(n - 1)$d and *n*s orbitals are known to be comparable for these ions (ref. 20, pp. 48–51). Since electronegativity values have been shown to be a function of the effective nuclear charge (36), the use of Slater rules seems reasonable. Similar arguments are applicable for Sc^{3+}.

Ions with d^{10} configuration are believed to be capable of easy distortion by an anion, and this should increase the effective nuclear charge of the cation (14, 37). In addition, the energy difference between the d^{10} ground state and the lowest d^9s excited state is quite small for Cu^+, Ag^+, Au^+, and Hg^{2+} (38). Thus a higher effective nuclear charge would result from ds mixing. In our evaluation of δ the average effective nuclear charges of the ground and excited states are compared to that of the ground state.

The small standard deviations associated with individual log K_{ML} values in the Q correlation for these atypical ions indicate that δ has empirical validity.

Factors Influencing the Slope ρ

It is evident from Table 1 and Figs. 1–5 that ρ varies widely. In addition, it is evident that the steeper slopes correspond to greater complex stabilities for ligands with comparable values of Q_{int}. The most obvious dependence of ρ is on the number of donor groups:[3] $\rho_{27}(K_{ML})/2\rho_{28} = 0.93$; $\rho_{26}/2\rho_{27}(K_{ML}) = 0.83$; $\rho_{27}(\beta_2)/2\rho_{27}(K_{ML}) = 0.87$; $\rho_9/(\rho_{23} + \rho_{30}) = 0.93$; $\rho_{21}/(\rho_{28} + \rho_{11A}) = 0.86$. These ratios of slopes reflect Bjerrum's statistical effect (17). The effect of Brønsted–Lowry basicity difference is illustrated by pyridine, *30*, and ammonia, *28*: $\rho_{28}/\rho_{30} = 1.69$. Since ions of both traditionally accepted class a and b behavior are correlated for these ligands (Fig. 3), Pearson's classification of pyridine as "softer" than ammonia is questionable. In fact, group electronegativity evaluation for these ligands (39) rank ammonia as the less electronegative of the two. In the Lewis sense, pyridine is the poorer electron donor.

In the sequence F^- (ρ = 2.2, 2.5), Cl^- (ρ = 2.4, 2.6), OH^- (ρ = 2.8), Br^- (ρ = 3.3, 3.5), and CN^- ($\rho/4$ = 10) a good relationship exists between the slopes and Klopman's "softness"

[3]We designate by ρ_j the slope found in the regression analysis for the ligand numbered *j* in Table 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

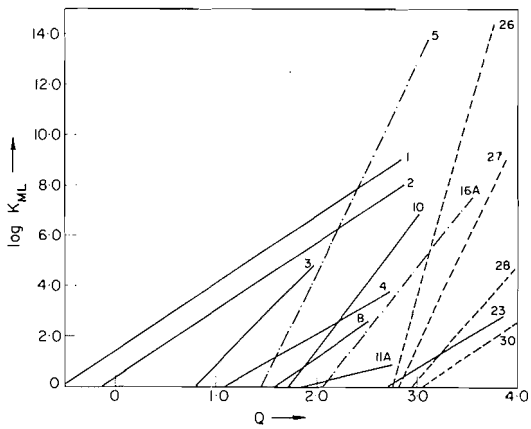

FIG. 5. Metal complex stabilities as a function of Q. The ligand numbers correspond to those in Table 1; numbers *1, 2, 3, 4, 8, 10, 11A* and *23* are oxygen donors; *26–28, 30* are nitrogen donors; while *5* and *16A* are nitrogen–oxygen donors.

parameter (12), where softness increases in the order $F^- < OH^- < Cl^- < Br^- \ll CN^-$ (see also Ahrland (5)). Klopman takes into account the relative energies in solution of the occupied "frontier" (valence) orbitals of the donor and acceptor. When these are comparable, electron transfer is favorable (class b behavior). Consequently, the slopes in the sequence carboxyl ($\rho = 1.0$), enol ($\rho = 2.32$), phenol ($\rho = 2.52$), OH^- ($\rho = 2.84$) probably reflect the increasing class b behavior of these functional groups.

The chelate effect and perhaps ring size (r.s.) are evident in the following ligand series: $\rho_{25}/2\rho_{30} = 1.24$, r.s. = 5; $\rho_{15}/(\rho_{23} + \rho_{11A}) = 1.41$, r.s. = 6; $\rho_{20A}/(\rho_{30} + \rho_{11A}) = 1.22$, r.s. = 5; $\rho_{10}/2\rho_{23} = 1.05$, r.s. = 5.

The normal and structural substituent effects defined in Part I (28) also exhibit diagnostic behavior in the present correlations. The normal substituent effect gives lower values of ρ as electron-withdrawing substituents reduce the availability of donor electrons: $\rho_{12}/\rho_{15} = 0.84$; $\rho_{7A}/\rho_9 = 0.93$; $\rho_3/\rho_{10} = 0.77$. A more vivid illustration of this is provided by the family of salicylaldehyde ligands treated in Part I (28), the data for which are not reported in Table 1: $\rho_{substituted}/\rho_{unsubstituted} = 0.91$ (5-chloro), 0.86 (4-chloro), 0.83 (3-chloro), 0.63 (5-nitro). The Q_{int} values are nearly identical for all these numbers. This we believe is also diagnostic of a normal substituent effect. For the remaining members of this salicylaldehyde family the ratio of slopes continues to decrease, but is accompanied by a change in Q_{int} to lower values: $\rho_{substituted}/\rho_{unsubstituted} = 0.60$ (3-nitro), 0.06 (3,5-dinitro). Excessively charged substituents such as nitro and sulfo groups are known to cause the breakdown of linear free-energy relationships (Parts I (28) and II (40)), and this is reflected in the change in Q_{int}.

In contrast, constancy of slope ρ and changes in Q_{int} are diagnostic of the structural substituent effect: $\rho_1/\rho_2 = 1.0$; $\rho_{24}/\rho_{25} = 1.0$; and perhaps for the ligands *9*, *20A*, and *21*, $\rho_{21}/\rho_9 = 1.0$; $\rho_{20A}/\rho_9 = 0.93$.

Factors Influencing the Q_{int} Value

Changes in Q_{int} (ΔQ_{ij}) will be designated negative when the value for ligand i is algebraically greater than that for ligand j, and *vice versa*. As just indicated, such changes accompanied by constancy of the slope ρ appear to be diagnostic of the structural substituent effect. The following are illustrative examples: $\Delta Q_{25,24} = -0.22$; $\Delta Q_{2,1} = -0.40$; $\Delta Q_{21,20A} = -0.12$; $\Delta Q_{21,9} = -0.74$. Changes in solvent are characterized primarily by changes in Q_{int}, although in this case a small change in ρ occurs also: $\Delta Q_{4,2} = -1.22$; $\Delta Q_{19,14} = -0.25$.

Incorporation of a single functional group into an aromatic system is accompanied by a shift of Q_{int} to higher values: $\Delta Q_{4,19} = 1.15$; $\Delta Q_{11A,22A} = 0.67$; $\Delta Q_{8,23} = 1.10$; $\Delta Q_{28,30} = 0.10$. If these observations are combined with the occurrence of high Q_{int} values for nitrogen donors and relatively low Q_{int} values for oxygen donors, the conclusion is suggested that the higher the Q_{int} value of a ligand the greater is its class b character for complex formation in solution. Supporting evidence for this is found in the case of cyanide ion.

It thus appears that both ρ and Q_{int} increase with class b behavior. This has prompted us to consider the quantity $\rho\Delta Q_{int}/n$ (where n represents the number of monodentate ligand atoms or the total number of donor groups in a multidentate ligand) as a comprehensive index of class b character. Calculated values of this index are given in the last column of Table 1. Notice, for instance, the order of class b character suggested by the values of this parameter in the following series of ligands: OH^- (4.54); pyr. (8.39); Cl^-

(8.71, line II); F^- (8.81, line II); Br^- (12.14, line II); NH_3 (13.75); CN^- (30.2).

The behavior of the halides requires some further discussion. As shown in Table 1 these ions give rise to two regression lines; they appear to exhibit ambivalence toward the correlation sought (see Fig. 1 for fluoride). This may be taken to signify that they partake of both class a and b character. The traditionally class a metal ions for the most part fall on line I and those of intermediate and class b character on line II. The only deviations from this pattern are observed for Hg^{2+}, Ag^+, and Tl^+, which fall on line I in the case of Cl^- and Br^-, and Tl^{3+} which fits either line ($Q = ZX_M$, line II; $Q = X_M^2$, line I). These ions still have a large favorable entropy contribution to the free energy in their reaction with these anions (3), and this may account for their association with the class a group. In addition, it is perhaps consistent with our arguments (see below) that for the anions of greater class b character (Cl^-, Br^-) $Q = X_M^2$ for nearly all metal ions whereas for the fluoride ion $Q = ZX_M$. In the case of the former ligands, $Q = X_M^2$ places the lanthanides on line I and $Q = ZX_M$ places them on line II, in a fashion similar to that for Tl^{3+}. Pearson (9, 10) classifies F^- and Cl^- as "hard" and Br^- as borderline. The present study suggests that these three ions have more in common than is currently accepted.

Another interesting pattern may be deduced from the data on Table 1. It concerns the relationship of nitrogen–oxygen donors to the parent nitrogen donor compound. Two interesting series may be discerned: ligands *5*, *18A*, *27*, and *6*, *16A*, *21*, *28*. The former is related to ethylenediamine and the latter to ammonia by progressive N-substitution by acetate arms. The ρ values are nearly constant within each family, while Q_{int} changes in almost regular increments: $\rho_5(8.36)$, $\rho_{18A} = 8.62$, $\rho_{27} = 8.63$; $\Delta Q_{5,18A} = +0.71$ and $\Delta Q_{18A,27} = +0.65$; similarly $\rho_6(5.3)$, $\rho_{16A} = 5.08$, $\rho_{21} = 4.87$, $\rho_{28} = 4.66$; $\Delta Q_{6,16A} = +0.54$, $\Delta Q_{16A,21} = +0.34$, $\Delta Q_{21,28} = +0.55$. The parameter $\rho Q_{int}/n$ also decreases rapidly in each family as more oxygen functional groups are attached. These observations will be interpreted in the following section.

Thermodynamic Considerations

It will be beneficial to introduce some aspects of Prue's treatment of the thermodynamics of metal complex formation (41). The change in free energy ΔG^0 is expressed as

$$[2] \qquad \Delta G^0 = -RT \ln \bar{v} - RTb + w'$$

where $\bar{v}$ represents the partition function quotient which in its simplest approximation may be replaced by the molar volume of the metal complex; $-RTb$ is the molar electrostatic energy, and w' the temperature-independent covalent term. RTb and w' contribute to ΔH^0 but not to ΔS^0. In addition, temperature-dependent functions of $\bar{v}$ and b contribute to ΔH^0 and ΔS^0, and a term $R \ln \bar{v}$ must also be added to ΔS^0. Any changes in the vibrational, rotational, and translational motions that accompany metal complex formation, including those of solvent, can contribute to all three thermodynamic quantities through the partition function terms. Such contributions are expected to be the largest for reactions in a polar medium such as water.

A consideration of volume changes shown (42) to accompany ion associations in solution is also pertinent. Neutralization of carboxylic acids is accompanied by large molar volume changes (*e.g.*, +11 ml/mol for protonation of acetate ion). The presence of a positive charge, as, for instance, in the monoprotonated glycine molecule, reduces the magnitude of this effect somewhat. Protonation of amines is generally characterized by sizeable negative molar volume changes (*e.g.*, −6 ml/mol for ammonia). In this case the presence of a negative charge makes the volume change more positive, while a positive charge makes it considerably more negative. For example, addition of a second proton to the monoprotonated form produces the following volume changes for the indicated species: ethylenediamine, −11 ml/mol; EDTA, −2 ml/mol. A linear correlation has been observed for changes in entropy and volume on ionization of fifty-three aqueous acids (43). Such volume changes have been shown to contribute as much as 0.5 kcal/ml to the free energy change for these reactions (42, 43). A similar relationship would appear to apply for metal-complex formation reactions.

The thermodynamic form of such contributions has not been determined but entry through the partition function term in eq. 2 seems likely, since volume increments should parallel changes in the vibrational, rotational, and translational

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

motion of solvent molecules. Schwarzenbach (44) in his evaluation of the effective dielectric constants for proton transfer reactions involving bases of the type just mentioned does not consider contributions to the free energy from volume changes. Sizeable volume changes can be shown to accompany some of the reactions treated by Schwarzenbach, and thus his values of the microscopic dielectric constant are likely underestimated.

An examination of metal-ligand enthalpies and entropies (29, 45) reveals that metal complex formation with neutral ligands such as ammonia or ethylenediamine is accompanied not only by negative enthalpy changes, but also by negative entropy changes. The latter reflect the negative volume changes discussed above for the protonation of these ligands. It is also readily confirmed that the formation of metal complexes with oxygen–nitrogen donors is characterized by both favorable ΔH^0 and ΔS^0 values (29, 45). We envisage, by analogy with the protonation reactions discussed, that N-substitution by acetate arms in nitrogen donor molecules results in a more positive molar volume change for the corresponding metal-complex formation reaction. Consequently, oxygen–nitrogen donors have, so to speak, the best of two worlds: the large positive entropy characteristic of oxygen donors (positive molar volume change) and the large negative enthalpy characteristic of the more class b nitrogen donors. The observed shift to lower Q_{int} values that accompanies the successive incorporation of carboxyl groups and the retention of the relatively high ρ value of the parent N-donor are interpreted to reflect this duality, respectively. Schwarzenbach (45) has also discussed the possibility that highly charged ligands promote a low effective dielectric constant and a more positive temperature dependence of this parameter, which would make ΔH^0 more negative. Further investigation may well reveal some relationship between these dielectric and volume effects.

The available enthalpy–entropy data (3, 4, 29, 45) support another general trend: ligands with high Q_{int} values tend to participate in enthalpy-favored reactions, while reactions of ligands with low Q_{int} values tend to be largely entropy-dominated. The molar volume changes accompanying the protonation of OH^- and the phenoxide ion also substantiate such a comparison: 21.3 ml/mol (Q_{int} = 1.6) and 17–18 ml/mol (Q_{int} = 2.7), respectively.

It is expected that drastic structural changes such as those observed for a family of ligands exhibiting the structural substituent effect make an important contribution to the partition function terms. The factors likely to contribute will necessarily be properties solely (28) of the ligand, of which the following are examples: molecular volume or bulk of ligand, a more favorable conformational change owing to ligand rigidity (44), a vibrational, rotational, or translational change for solvent molecules on complex formation, due to the release of ligand-induced electrostriction. The specific hydrogen bonding to water molecules observed for 2,2′-bipyridyl and 1,10-phenanthroline (46) is an example of the latter. In addition, it should be emphasized that a systematic increase in the hydrophobicity (44, 47–49) of ligands in a related series may produce a reduction in the effective dielectric constant and a concomitant positive increase in the temperature gradient of this parameter. This would render the ΔH^0 values of complex formation more negative (44)[4]. Lowering of the microscopic dielectric constant would of course, also increase the magnitude of the *RTb* term in eq. 2. The analogy of the structural substituent effect (constant ρ and large ΔQ_{ij}) and the medium effect is striking (*e.g.*, Fig. 5, lines 1, 2, 4).

Ligand Architecture

In an earlier section we have emphasized several systematic trends in ρ and Q_{int} values which characterize various aspects of ligand architecture. Some of these special effects are illustrated in Fig. 5: number of donor atoms, lines *26*, *27*, *28*, as well as the pairs *10,23* and *5,16A*; the structural substituent effect, lines *1*, *2*; the medium effect, lines *2*, *4*; and the systematics of N,O-donors by pairs *5,27* and *16A,28*. Two additional features about the relationship of N,O-donors to the parent N- and O-constituents are of interest. The first concerns the Q_{int} changes discussed for N-substitution by acetate. The Q_{int} values of simple N,O-ligand systems are approximated well by the arithmetic mean of the values exhibited by the parent N and

[4]It is for this reason that an exothermic reaction need not necessarily imply class b behavior.

TABLE 4. Classification of metal ions

Class	Ions[a]
Class a	Li(1.39), K^+(1.46), Na^+(1.55), Rb^+(1.56), Cs^+(1.57), Ba^{2+}(1.74), Sr^{2+}(1.78), Ca^{2+}(1.84), La^{3+}(2.42), Ce^{3+}(2.45), Pr^{3+}(2.48), Nd^{3+}(2.51), Mg^{2+}(2.58), Sm^{3+}(2.59), Y^{3+}(2.65), Gd^{3+}(2.69), Dy^{3+}(2.74), Ho^{3+}(2.75), Er^{3+}(2.77), Tm^{3+}(2.81), Be^{2+}(2.85), Lu^{3+}(2.87), Sc^{3+}(3.07), Pu^{3+}(3.15), Al^{3+}(3.50), Np^{3+}(3.59), U^{3+}(3.72), Mn^{2+}(3.96), Ti^{2+}(4.15).
Borderline	Zn^{2+}(4.54), V^{2+}(4.60), Cr^{2+}(4.66), Ga^{3+}(4.82), In^{3+}(5.26), Fe^{2+}(5.39), Cd^{2+}(5.51), H^+(5.52), Co^{2+}(5.61), Fe^{3+}(5.72), Ni^{2+}(5.73), Tl^+(5.90), Sn^{4+}(5.99), Sn^{2+}(6.38), Cu^{2+}(6.41), Cu^+(6.53),
Class b	Pb^{2+}(7.18), Tl^{3+}(7.49), Hg^{2+}(7.80), Ag^+(7.85), Bi^{3+}(7.87), Pd^{2+}(8.28), Pb^{4+}(9.18), Pt^{2+}(9.41), Au^+(14.32).

[a]The value of the quantity $(X_M)^2(r_M + 0.85)$ is given in parentheses following each ion. X_M values are from (26), and r_M values from ref. 20, pp. 151–153 and (51).

O donor ligands: for example,

$$Q_{int}(\text{glycine}) = \tfrac{1}{2}\,(Q_{int}(\text{acetic acid}) + Q_{int}(\text{ammonia}))$$

This additivity principle is consistent with that mentioned earlier in connection with the individual Q values of metal ions in correlations of N,O-donors.

The second point of interest is the observation of two lines for the correlation in some N,O-donor systems (*7A,7B*; *16A,16B*; *18A,18B*; *20A,20B*) and for carboxylic acids (*11,22*). The lanthanide cations, the alkaline-earth ions, and sometimes H^+ and Pb^{2+}, fall on the B lines, while all other metal ions considered fall on the A lines. The latter correlations are accepted as normal. The B lines for N,O-donor ligands have low Q_{int} values (Table 1) which are characteristic of the oxygen function in the ligand, and have slopes that are considerably smaller than that expected for the parent nitrogen functional group. This distinction between A and B lines disappears when the ratio of the number of oxygen donor groups to nitrogen donor groups reaches 2:1 (alkaline earths) or 3:1 (lanthanide cations). The interpretations now rendered to explain these observations are largely speculative, but they are actually susceptible to experimental substantiation (*e.g.*, by n.m.r.). The observed Q_{int} and ρ values suggest that B-line metal ions exhibit a reduced affinity for the nitrogen donor atom compared to the A-line ions. This reduced affinity may imply an "outer" sphere interaction. In contrast, the two lines for the 1:1 acetate complexes would seem to imply that B-line ions form "inner" sphere 1:1 complexes, while the A-line ions form "outer" sphere complexes with the acetate ion. "Outer sphere" complexes are often comparable in stability to "inner sphere" complexes (50).

New Indices to Class b Behavior

The quantity $(X_M)^2(r_M + 0.85)$ has been found to reproduce (Table 4) the various metal-ion classifications reviewed in the Introduction; here r_M is the cationic crystal radius and 0.85 is an appropriate constant assumed to reflect the radius of O and N donor atoms (20). The division of metal ions into class a, borderline, and class b categories in Table 4 is arbitrary. The choice of the above function finds additional justification from the fact that values of $d/(X_M)^2 r_e$, with d a suitable scaling constant and r_e the equilibrium internuclear distance in chloride complexes, closely match the fractional ionic characters calculated for solid chloride complexes (11, 15, 52).

We have already discussed the success of the quantity $\rho Q_{int}/n$ in reproducing established class b character of ligands. It is informative to interpret Q_{int} as the Q value of the hypothetical metal ion for which $K_{ML} = 1$. This common point of reference conveniently arranges the ligands according to the magnitude of the Q values of these hypothetical metal ions. Consequently, ligands of low Q_{int} values (*e.g.*, EDTA) have $K_{ML} > 1$ even for metals with small values (<2) of the index Q, while ligands of high Q_{int} values (*e.g.*, ammonia) have $K_{ML} < 1$ for these same metal ions.

Significance of the Parameter Q

The quantity Z^2/r_e is accepted as a good index to metal-complex formation reactions of as-

sumed high ionic character (17, 20). In the previous section we introduced the parameter $(X_M)^2 r_c$ as a suitable index to class b behavior. If we accept the conclusion of Williams and Hale (11) and Klopman (12) that class a character is the ability of acceptors and donors to participate in electrostatic interactions, and class b character in covalent interactions, then the index Q may be visualized as the geometric mean of an ionic and a covalent index: $Q = (Z^2/r_c \cdot (X_M)^2 r_c)^{1/2} = ZX_M$. There is also evidence (52–54) that for complexes of relatively low ionic character $(X_M)^2/r_c$ may be regarded as proportional to the ionic energy. In this case Q would reduce to the value $(X_M)^2$, the value used in all correlations of the borderline metal ions of the first-row transition series (d^6 to d^9 ions) and for correlations of nearly all metal ions with anions of moderate class b character such as chloride and bromide ions.

The parameter Q may also be considered as the geometric mean of the quantities $\sum I_M$ and $(X_M)^2$. Sanderson (55) has illustrated the existence of a linear relationship between $(\sum I_M)^{1/2}$ and Z. In fact, $(\sum I_M)^{1/2} = (2.5 \pm 0.3)Z$ for most of the metal ions considered in the present correlations. Consequently, $Q = \text{constant} \cdot (\sum I_M \cdot (X_M)^2)^{1/2}$. The sum of the ionization potentials measures the electron-attracting power of a gaseous metal ion, and $(X_M)^2$ the electron-attracting power of an ion in a complex molecule (34). Both quantities are important in the partial ionic/covalent model of bonding (11, 15, 52–54).

We conclude from these deliberations linking Q to established ionic and covalent indices and to atomic properties important in the partial ionic/covalent bond model, and from the thermodynamic considerations set out earlier that eq. 2 adequately describes metal complex formation in solution. Thus the gross features of metal complex formation are determined by the thermal contributions to the free energy and the relative magnitudes of the ionic and covalent energies. All these contributions are obviously dependent on the nature of both the ligand and metal ion. The success and versatility of the index Q, we believe, is in part due to the incorporation of the ligand-dependent parameters a, b, and δ in its definition (eq. 1). In addition, the ligand dependence of the Q-correlations is taken into account, and indeed is estimated, by the parameters ρ and Q_{int}. The weakness of previous correlations of this sort has been the omission of any allowance for this dependence of complex stability on the nature of the ligand, and this has led to their limited applicability. In contrast, the dependence of the Q-correlations on the ligand as measured by ρ and Q_{int} allowed a novel and systematic discussion of ligand architecture and of other factors important in complex formation. The large number and diversity of the ligand systems and metal ions treated also attest to a versatility lacking for other indices. The successful correlation of the metal complex stabilities of a ligand with metal ions of both extreme class a and class b character is especially noteworthy. (See, *e.g.*, Figs. 1–4).[5]

Finally, abnormal behavior of metal ions in their reaction with ligands may be detected when unusually large deviations occur in the Q-correlations. For example, the destabilizations characteristic of Cu(II), Pb(II), Ag(I), and H(I) complexes with 1,10-phenanthroline and 2,2′-bipyridyl discussed in Part I (28) show up clearly in Fig. 2. The deviations observed for the Cu(II)–, Be(II)–EDTA complexes in Fig. 2 suggest that the magnitudes of the respective

[5]We agree with a referee that a comment on the relation of the correlations of the present study to the dual parameter scale for the strength of Lewis acids and bases introduced by Misono and co-workers (56, 57) is warranted. Our index Q and their "hardness" parameter X $(=(X_M^2 + \Sigma I_n + 2X_M \Sigma I_n^{1/2})/10)$ have similar contributions, and our parameter $X_M^2(r_M + 0.85)$ and their "softness" index Y $(= 10\,(I_n/I_{n+1})(r_M/n^{1/2}))$ yield similar metal ion classifications (see Table 4). In fact, for many ions the magnitude of the parameter $(X + Y)/2$ most closely resembles our Q values. However, this agreement must be fortuitous because of the arbitrary nature of defining Q, X, and Y. The work of Misono *et al.* differs from ours in that metal complex stabilities are fitted to a two-parameter equation $(\log K_{ML} = \alpha X + \beta Y + \gamma)$ rather than a single-parameter one $(\log K_{ML} = \rho Q + \text{intercept})$. In addition, the systems treated by them are mostly simple monodentate ligands (our ligand numbers *4*, *8*, *11*, *28*, *30–33*, oxalate, and thiosulfate). The large deviations observed from the two parameter equations for metal ions of distinct class b character required (57) a re-evaluation of Y by an iterative procedure using the experimental stability data $(\log K_{ML} = \alpha' X + \beta' Y' + \gamma')$. Very few of these improved values (Y') are available. The trend observed for the ligand parameter β' seems to parallel that described for the ligand index $\rho Q_{int/n}$.

A successful single-parameter equation seems to us more useful than a two-parameter equation, since the former is simpler by one variable. Also their emphasis on the relationship of covalency to "hardness" seems suspect in the light of the evidence reviewed and discussed in the present work.

stability constants (provided the experimental data are reliable) are unusually low.

This work was supported by a grant from the National Research Council of Canada for which grateful acknowledgment is made. One of the authors (E.N.) records his thanks for the award of a National Research Council of Canada Postgraduate Fellowship. We also thank Mrs. J. L. McCourt of this laboratory for assistance with the statistical analyses.

Oxidation of Some Transition-Metal Cyanide Compounds by Hydroxyl Radical

W. L. WALTZ, S. S. AKHTAR, AND R. L. EAGER

Department of Chemistry and Chemical Engineering and the Saskatchewan Accelerator Laboratory, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 6, 1973

The oxidation of some transition-metal cyanide compounds by hydroxyl radical in aqueous media has been investigated by pulse radiolysis. For compounds of the type, $M(CN)_6^{4-}$ where M is Fe, Ru, and Os, and for $Mo(CN)_8^{4-}$, the mechanism of their reaction with hydroxyl radical involves single electron transfer with the formation of the intensely colored metal complexes of the same stoichiometry as the starting materials. The u.v.–visible absorption spectra for these products for the iron, ruthenium, and osmium systems are reported along with the associated second order rate constants for their formation. The reaction of $Mo(CN)_8^{4-}$ with hydroxyl radical has been studied by a competition technique using sodium bicarbonate. The values of the second order rate constants are near those expected of diffusion-controlled reactions and they range between *ca.* 5×10^9 to 1×10^{10} M^{-1} s^{-1}.

L'oxydation de quelques composés métal de transition-cyanure par le radical hydroxyle en milieu aqueux, a été étudiée par radiolyse pulsée. Pour les composés du type $M(CN)_6^{4-}$ où M = Fe, Ru et Os et pour $Mo(CN)_8^{4-}$, le mécanisme de la réaction avec le radical hydroxyle fait intervenir un transfert simple d'électron avec formation de complexes métalliques intensément colorés de même stoechiométrie que les produits de départ. Les spectres d'absorption u.v.–visible de ces produits dans les systèmes fer, ruthénium et osmium, ont été rapportés de même que les constantes de vitesse de second ordre associées à leur formation. La réaction de $Mo(CN)_8^{4-}$ avec le radical hydroxyle a été étudiée par une technique de compétition utilisant le bicarbonate de sodium. Les valeurs des constantes de vitesse du second ordre sont voisines de celles que l'on attend pour des réactions contrôlées par diffusion et leur domaine s'étend de 5×10^9 à 1×10^{10} M^{-1} s^{-1}. [Traduit par le journal]

Can. J. Chem., **51**, 2525 (1973)

Introduction

In the radiolysis of aqueous media near neutral p*H*, the hydrated electron, e_{aq}^-, and the hydroxyl radical, OH, occur as the primary reducing and oxidizing species, respectively (1). While numerous studies of the reactions of the hydrated electron with transition metal complexes have been carried out (1–3), relatively few reports have been presented on the reactions of OH with metal complexes (2, 4). The reaction mechanisms of hydroxyl radical with metal complexes can potentially involve either electron or atom transfer. Such reactions are not only of fundamental interest in the area of radiation chemistry but also in a broader sense to the study of inorganic reaction mechanisms. A case in point is the reaction of OH with ferrocyanide ion, reaction 1 (2, 4–7),

$$[1] \quad OH + Fe(CN)_6^{4-} \rightarrow OH^- + Fe(CN)_6^{3-}$$

that involves an electron transfer mechanism with the formation of the stable and intensely light-absorbing ferricyanide product. The characteristics of this reaction have also provided a sound basis for the use of this reaction in radiation dosimetry, particularly in conjunction with pulse radiolysis, and as a standard for determining rate constants for hydroxyl radical reactions by competition techniques (5–7). Of further interest to this study is the recent report (8) that the reactions of transition metal pentacyanonitrosyl ions with OH radical exhibit a linear free energy relationship. In this context, we wish to report the results of a pulse radiolysis investigation of the reactions of OH radical with a series of stable transition-metal cyanides involving systems capable of exhibiting well characterized higher oxidation states of the metal center.

Experimental

The technique of pulse radiolysis used in this work, involving spectrophotoelectric recording, is similar to that described elsewhere (1, 9), although in this case the monitoring light source was a 150 W xenon arc lamp and the detector was a RCA 1P28 photomultiplier tube (five stages used). The initial absorbance of the hydrated electron at 578 nm ($\varepsilon = 1.09 \times 10^4$ M^{-1} cm^{-1} (10)) in aqueous 10^{-3} *M* NaOH and 10^{-3} *M* methanol solutions was used to set the dose level. Changes in the dose level from one pulse to another were monitored with a secondary electron emission monitor (s.e.m.). The s.e.m. was used to normalize the data points to a common dose for the evaluation of absorption changes in competition

experiments and in the determination of product spectra. The molar extinction coefficients, ε, of the absorbing products were determined relative to that of e_{aq}^- (*vide supra*) assuming that the yield of e_{aq}^- to be essentially equal to that of OH radical (1).

Triply distilled water was used to prepare all solutions. The compounds, $K_4[Ru(CN)_6]\cdot 3H_2O$ and $K_4[Mo(CN)_8]\cdot 2H_2O$, were kindly supplied by Dr. A. W. Adamson, and $K_4[Os(CN)_6]\cdot 3H_2O$ was obtained from City Chemical Corporation (New York). Reagent quality (Shawinigan) $K_4[Fe(CN)_6]\cdot 3H_2O$ and $NaHCO_3$ were used. Isopropanol (Fisher Spectroscopic Grade and BDH Aristar) and methanol (Fisher Spectroscopic Grade) were used without further purification. Nitrous oxide (Matheson, minimum purity 98.0%) was further purified by trap-to-trap distillation where necessary. All other materials were of reagent quality. The syringe and degassing-bulb techniques used for the preparation and handling of solutions were similar to those described elsewhere (3). The solutions were prepared on the day of use, and those containing cyanide materials were protected from light.

Results and Discussion

On irradiation of neutral or slightly alkaline aqueous solutions, the primary radical species formed are the hydrated electron, e_{aq}^-, hydroxyl radical, and to a lesser extent hydrogen atom (1, 3). The reactions of e_{aq}^- with the cyanides of Fe(II), Ru(II), Os(II), and Mo(IV) are relatively slow processes (2, 11) so that the decay of e_{aq}^- in aerated media will involve principally reaction 2

$$[2] \qquad e_{aq}^- + O_2 \rightarrow O_2^- \text{ (or } HO_2)$$

while in saturated nitrous oxide solutions its decay will be via reaction 3 to give OH radical (1, 3).

$$[3] \qquad e_{aq}^- + N_2O \rightarrow N_2O^- \xrightarrow{H^+} N_2 + OH$$

In aerated media, both OH and O_2^- (or HO_2 in acidic media, pK_a 4.5 (1)) will be present after the pulse while in N_2O saturated solutions OH will be the major radical species. Previous studies (*5b*, 6) on the oxidation of ferrocyanide by HO_2 and O_2^- indicate that HO_2 is nearly five orders of magnitude slower in reactivity than OH and that O_2^- is unreactive so that on time scales shorter than a millisecond as used here the reactions of O_2^- and HO_2 with $Fe(CN)_6^{4-}$ are negligible. The other cyano compounds studied are weaker reducing agents than ferrocyanide with the possible exception of $Os(CN)_6^{4-}$ so that the reactions of O_2^- and HO_2 with these materials are expected to be of negligible importance. This expectation seems to be borne out as no changes in the levels of absorption of the products formed initially by the reactions of OH (*vide infra*) were observed for time scales as long as 1 ms after the pulse.

On irradiation of neutral, aerated solutions containing $Fe(CN)_6^{4-}$, $Ru(CN)_6^{4-}$, or $Os(CN)_6^{4-}$, a rapid increase in optical absorption in the blue and near u.v. regions occurs and leads to the attainment of a stable level of absorption. If the solutions are saturated with nitrous oxide, the final absorbance is now about twice that of the aerated solutions. Plots of the optical spectra of the stable products for the osmium and ruthenium systems are shown in Fig. 1. The stable product of irradiated aqueous $Ru(CN)_6^{4-}$ exhibits peaks at 470 ($\varepsilon = 920\ M^{-1}\ cm^{-1}$) and at 330 nm ($\varepsilon = 2140\ M^{-1}\ cm^{-1}$) and a shoulder at 355 nm. These features are in accord with the qualitative spectrum reported (12) for $Ru(CN)_6^{3-}$.[1] The spectrum of tetrabutylammonium hexacyanoosmium(III) measured in ethanol (13) shows peaks at 412 ($\varepsilon = 1450\ M^{-1}\ cm^{-1}$) and at 332 nm ($\varepsilon = 1680\ M^{-1}\ cm^{-1}$) and this corresponds closely to that for irradiated $Os(CN)_6^{4-}$ media with peaks at 410 ($\varepsilon = 1400\ M^{-1}\ cm^{-1}$) and at 325 nm ($\varepsilon = 1520\ M^{-1}\ cm^{-1}$).

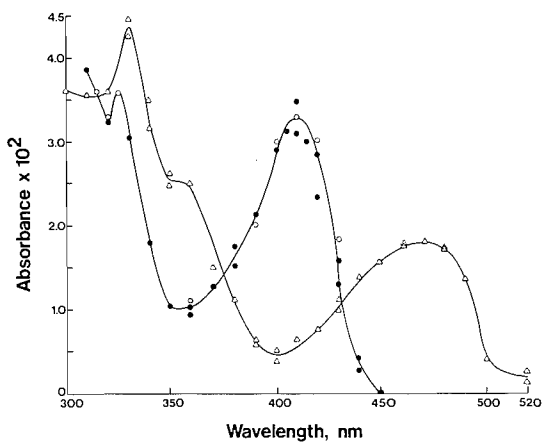

FIG. 1. Absorption spectra of the stable products arising from irradiation of aerated, aqueous solutions of $Os(CN)_6^{4-}$ and $Ru(CN)_6^{4-}$. △, $2 \times 10^{-4}\ M\ K_4[Ru(CN)_6]$, $[OH]_{max} \sim 5.0\ \mu M$. ○ and ●, $1 \times 10^{-4}\ M\ K_4[Os(CN)_6]$. The spectrum is comprised of points from two separate experiments at $[OH]_{max} \sim 5.9\ \mu M$. Half-band width of 4 nm for the monochromator; light path length of 4 cm.

[1]The peak given here as 470 nm is reported (12) at 455 nm, however the spectrum shown in the article suggests that the peak is actually closer to 470 nm.

TABLE 1. Values for the rate constants for the reactions of hydroxyl radical

Compound	Concentration	$k_c \times 10^{9a-d}$ (M^{-1} s^{-1}, ~25 °C)	Method of determination	E^0 (V, $M^{n+} - M^{n+1}$)
$K_4[Fe(CN)_6]$	80–140 μ*M*	11.2 ± 1.7 (21)	Formation of product	−0.36[e]
	2 m*M*	8.0	Isopropanol competition	
$K_4[Ru(CN)_6]$	40–200 μ*M*	5.7 ± 0.8 (31)	Formation of product	−0.86[f]
	1 m*M*	4.4	Isopropanol competition	
$K_4[Os(CN)_6]$	50–200 μ*M*	10.3 ± 1.2 (36)	Formation of product	—
	1 m*M*	8.6	Isopropanol competition	
	0.1 m*M*	10.2	Methanol competition	
$K_4[Mo(CN)_8]$	3–20 m*M*	5.8 ± 0.6	$NaHCO_3$ competition (50 m*M*)	−0.73[e]
$NaHCO_3$	50 m*M*	0.036 ± 0.003 (6)	Formation of product	—
	50 m*M*	0.038	Isopropanol competition	

[a]The values of k_c determined from the rates of formation of products are the average values for both aerated and N_2O saturated solutions. The numbers in parentheses represent the number of determinations. The wavelengths of observation were 420 nm for $Fe(CN)_6^{3-}$; 330, 355, and 470 nm for $Ru(CN)_6^{3-}$; 330 and 410 nm for $Os(CN)_6^{3-}$.
[b]The values of k_c derived from alcohol competition are based upon the rate constants for the reaction of hydroxyl radical with isopropanol of 2.15×10^9 M^{-1} s^{-1} and with methanol of 9.0×10^8 M^{-1} s^{-1}. The wavelengths of observation were 410 nm for $Fe(CN)_6^{3-}$ and $Os(CN)_6^{3-}$ and 350 nm for $Ru(CN)_6^{3-}$.
[c]The experiments involving $NaHCO_3$ were carried out in N_2O saturated solutions (p*H* ~8.2) and the wavelength of observation of CO_3^- was 578 nm.
[d]The value of k_c for $Mo(CN)_8^{4-}$ is based upon an average value for the reaction of HCO_3^- and OH of 3.7×10^7 M^{-1} s^{-1}.
[e]Cited in ref. 21.
[f]Reference 12.

For ferrocyanide solution, the product exhibited a peak at 420 nm ($\varepsilon = 1040$ M^{-1} cm^{-1}) in excellent agreement with the reported values for $Fe(CN)_6^{3-}$ (1, 5, 6, 12, 13).

The kinetics of formation of the foregoing product materials were investigated under conditions where the concentrations of the metal complexes were in great excess of the maximum OH concentrations. Under these conditions, the formation of products obeyed a first order rate law. The apparent first order rate constants for the ruthenium and osmium systems were independent of dose (*ca.* 1 to *ca.* 6 μ*M* $[OH]_{max}$) and of wavelength, and they were the same whether the solutions were aerated or saturated with N_2O. Concentration studies indicated that the observed first order rate constants, k_{obs}, were linearly dependent on the concentrations of the metal complexes: the second order rate constants, k_c, evaluated from the values of k_{obs} are summarized in Table 1. The value of k_c of $(1.12 \pm 0.17) \times 10^{10}$ M^{-1} s^{-1} found in this study for $Fe(CN)_6^{4-}$ corresponds well with previously reported values of $(1.25 \pm 0.1) \times 10^{10}$ (5) and $(9.3 \pm 0.5) \times 10^9$ M^{-1} s^{-1} (7) obtained by pulse radiolysis.

As a confirmation of the participation of OH radical in these reactions, the competition reactions in aerated media between the metal complexes and the alcohols, isopropanol and methanol, whose reactions with OH have been well characterized (1, 2, 7), were carried out. The effect on the absorbance, *A*, of the product, by the presence of alcohol was found to be described by eq. 4

$$[4] \qquad \frac{A_0}{A} = 1 + \frac{k_{alc}[\text{alcohol}]}{k_c[\text{complex}]}$$

where A_0 is the absorbance in the absence of alcohol, and where k_{alc} and k_c are the respective second order rate constants for the particular alcohol and for the complex. The values obtained for k_c taking as the values of k_{alc} for isopropanol and methanol to be 2.15×10^9 and 9.0×10^8 M^{-1} s^{-1}, respectively, (7) are summarized in Table 1. These are in agreement within an experimental error of *ca.* 15% with the directly measured values; however the values obtained using isopropanol are consistently low. The reason for this is not apparent; the presence of impurities seems to be ruled out as two different sources of isopropanol were used.

The foregoing results indicate that $Ru(CN)_6^{4-}$ and $Os(CN)_6^{4-}$ react with hydroxyl radical by a single electron transfer mechanism in analogy to the well established behavior of $Fe(CN)_6^{4-}$, reaction 1. Both the nature of the product spectra and independence of the rate of product formation on wavelength indicate that $Ru(CN)_6^{3-}$ and $Os(CN)_6^{3-}$ are the sole observed products. The lack of dose dependence on the rate of

For personal use only.

formation of the products confirms that the bimolecular recombination reaction of OH was not significant in the measurements.

Sharma (14) has shown through ^{60}Co irradiation studies that $Mo(CN)_8^{4-}$ also reacts with OH via a single electron transfer to give $Mo(CN)_8^{3-}$. Because $Mo(CN)_8^{3-}$ absorbs in the same region as the intensely absorbing and photosensitive $Mo(CN)_8^{4-}$ (11), it was not feasible to monitor directly the reaction of $Mo(CN)_8^{4-}$ and OH. Instead this reaction was observed indirectly by its competition with the reaction of HCO_3^- with OH. The reactions of OH with HCO_3^- and CO_3^{2-} lead to the formation of CO_3^- that absorbs intensely in the visible region with a peak at 600 nm (15–18). Since rate constants reported for the reactions of OH with HCO_3^- and CO_3^{2-} seem dependent upon conditions, the rate constant for the HCO_3^- used in this work was determined by both direct and competition measurements under the same conditions as used for the measurement of the $Mo(CN)_8^{4-}$ reaction. These values (Table 1) are in accord with the previously reported values for HCO_3^- that range from 1 to $8 \times 10^7\ M^{-1}\ s^{-1}$ (16–18). Included in Table 1 is the value of k_c for the reaction of $Mo(CN)_8^{4-}$ and OH evaluated using an average value of $3.7 \times 10^7\ M^{-1}\ s^{-1}$ for the bicarbonate reaction.

The reactions of hydroxyl radical with $Fe(CN)_6^{4-}$, $Ru(CN)_6^{4-}$, $Os(CN)_6^{4-}$, and $Mo(CN)_8^{4-}$ clearly involve a single electron transfer mechanism to yield complexes of the same stoichiometry with the metal center in the next higher oxidation state, and the second order rate constants are near those expected of diffusion-controlled reactions. In contrast, the reactions of OH with $Fe(CN)_5NO^{2-}$, $Co(CN)_5NO^{3-}$, $Mn(CN)_5NO^{3-}$, and $Cr(CN)_5NO^{3-}$ are somewhat slower (8, 18*b*). The rate constants for these pentacyanonitrosyl complexes range between $1.2 \times 10^7\ M^{-1}\ s^{-1}$ for the iron complex to $4.0 \times 10^9\ M^{-1}\ s^{-1}$ for the chromium system, and a linear free energy relationship (l.f.e.r.) is exhibited between the logarithms of the rate constants and the stretching frequencies of the coordinated NO group. In the case of the cyano complexes, the near diffusion-controlled values of the rate constants indicate that the transition states are close to the levels of the starting materials. As such, the degree of selectivity of any possible l.f.e.r. would be expected to be quite small. In this regard, it should be noted that the Ru(II) and Mo(IV) systems that are much weaker reducing agents than is ferrocyanide as shown by their half-cell potentials (see Table 1), are only slightly less reactive towards hydroxyl radical.

The difference in reactivity between the pentacyanonitrosyl complexes and the cyano complexes may be a manifestation of different mechanisms of reaction with hydroxyl radical. While the identities of the initial reaction products for the nitrosyl systems are uncertain, the results of an investigation of $Fe(CN)_5NO^{2-}$ by Buxton and co-workers (18*b*) suggest that the reaction with OH does not involve either electron transfer or detachment of NO. Thus the reaction mechanism of the pentacyanonitrosyl complexes may involve OH addition possibly to the coordinated NO group in contrast to the electron transfer mechanism encountered for the cyano complexes. Several additional features are suggestive in regard to the possibility of OH addition to the coordinated NO group. The l.f.e.r. exhibited by the nitrosyl systems shows that the lower is the NO stretching frequency the higher is the value of the rate constant for the OH reaction (8). Thus the nitrosyl complexes with the higher rate constants are those with a relatively higher electron density on the NO group (19). If the reactions of the nitrosyl complexes with OH involved electron transfer, it might be expected that $Mn(CN)_5NO^{3-}$ with an E^0 of -0.6 V (20) would be more reactive than either $Ru(CN)_6^{4-}$ or $Mo(CN)_8^{4-}$ (see Table 1) whereas it is found to be less reactive ($k_c = 2.4 \times 10^9\ M^{-1}\ s^{-1}$ (8)).

A final point concerns the use of the cyano compounds for pulse radiolysis dosimetry and competition kinetics. Ferrocyanide has proven particularly advantageous owing in part to its high reactivity towards OH and to the intense absorption of the ferrocyanide product at 420 nm. In this regard, the high reactivity of $Ru(CN)_6^{4-}$ coupled with the intense absorption of the ruthenium(III) product at a somewhat longer wavelength (470 nm) than that for ferrocyanide may prove to be useful. An additional advantage for the ruthenium system is that while both the iron and ruthenium complexes are quite photosensitive to light in the blue – near u.v. region (10), the ruthenium system should be less susceptible to photolytic degradation owing to its lower intrinsic absorption in this region (12). It should be noted however that the long term

stability of $Ru(CN)_6^{3-}$ is less than that of $Fe(CN)_6^{3-}$ (12), although this does not appear to be a complication on the time scales employed in pulse radiolysis.

We wish to acknowledge the financial support for this investigation by the National Research Council of Canada. It is also a pleasure to acknowledge the technical assistance of Messrs. D. Jennings and E. Kozar for help in operation of the accelerator and of Mr. D. Storer for the development of the s.e.m.

Complex Fluoroanions in Solution. IV. Fluorocomplexes involving MoF_6, MoF_6^-, and MoF_5[1]

S. BROWNSTEIN

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received April 4, 1973

Complexes of MoF_5 or MoF_6^- with BF_3, AsF_5, TaF_5, and NbF_5 have been prepared and partially characterized by infrared and fluorine resonance spectroscopy and X-ray powder diffraction. MoF_6 was not found to form complexes with binary fluorides nor fluoroanions.

Les complexes de MoF_5 ou de MoF_6^- avec du BF_3 ,AsF_5, TaF_5 et NbF_5 ont été synthétisés et caractérisés partiellement à l'aide de la spectroscopie infrarouge et de résonance du fluor ainsi qu'à l'aide de la diffraction des rayons-X (poudre). Il a été trouvé que le MoF_6^- ne forment pas de complexes avec des fluorures binaires ainsi qu'avec des fluoro anions. [Traduit par le journal]

Can. J. Chem., **51**, 2530 (1973)

Introduction

There are now many examples of fluorine bridging in solution to yield complex fluoroanions (ref. 1 and references cited therein). It is not yet clear what factors are responsible for the stability of certain complex fluoroanions and the instability of others and more information is required to explain the results reported thus far. Since complex fluoroanions of WF_4 have been obtained an investigation of molybdenum fluoride species appeared promising (1).

Molybdenum hexafluoride forms charge transfer complexes with $(CH_3)_4X$, where X is Si, Ge, or Sn (2). It also reacts with methylmethoxosilanes or dimethyl sulfite to give methoxomolybdenum(VI) fluorides (3). Reactions with organic bases to give hepta- or octaco-ordinate structures, as with WF_6, have also been reported (4). Alkali metal salts of MoF_6^- have been prepared and are isostructural with the corresponding tungsten and rhenium salts (5). The nitrosyl salt has also been synthesized and its infrared spectrum recorded (6). Complexes of MoF_5 with acetonitrile and chloroacetonitrile have been prepared and their infrared spectra described (7).

Experimental

All sample preparation and handling was done with standard vacuum line techniques or using a vacuum dry box. Those portions of the vacuum line which might come in contact with molybdenum hexafluoride were constructed with stainless steel bellows valves employing Teflon seats. Reagent and solvent purification and storage were accomplished as previously described (8, 9).

[1]NRCC No. 13277.

Molybdenum hexafluoride, purchased from Ozark-Mahoning Ltd., was used without further purification. Potassium hexafluoromolybdate (5), nitrosyl hexafluoromolybdate (6), and molybdenum pentafluoride (10) were prepared by established procedures.

Tetra-n-butylammonium Hexafluoromolybdate, (TBA)MoF_6

(TBA)I and MoF_6, in excess, were allowed to react in sulfur dioxide as solvent and all volatile materials were then pumped off under high vacuum. The pale cream powder has an X-ray powder diffraction pattern similar to (TBA)MF_6, where M is Ta, Nb, Sb, or W.

Anal. calcd. for (TBA)MoF_6: Mo, 21.2. Found: Mo, 20.1.

Fluorine resonance spectra were obtained on a Varian Associates HA-100D spectrometer operating at 94.1 MHz. Chemical shifts are reported as p.p.m. from internal $CFCl_3$. X-Ray powder photographs were taken with Cu radiation in 114 mm diameter Debye-Scherer cameras. Infrared spectra of the compounds dispersed in potassium bromide disks were obtained with a Perkin–Elmer 621 spectrophotometer.

Results and Discussion

No change in the fluorine resonance spectra and hence no interaction was observed in methylene chloride and in sulfur dioxide solutions between MoF_6 and BF_3, PF_5, AsF_5, TaF_5, NbF_5, MoF_5, (TBA)BF_4, and (TBA)SbF_6. Therefore molybdenum hexafluoride is not very reactive as a fluorine donor nor as a fluorine acceptor in fluorine bridge bonding. Molybdenum pentafluoride was found to be unreactive with BF_3 and PF_5 in all the solvents investigated and with AsF_5 in fluorotrichloromethane as solvent. However in sulfur dioxide, sulfuryl chlorofluoride, and methylene chloride solutions there is a rapid reaction with the solvent in the

presence of AsF_5, SbF_5, TaF_5, or NbF_5 to give a complex mixture. These reactions were not further investigated.

When PF_5 is added to a suspension of $KMoF_6$ in liquid sulfur dioxide the fluoride resonance spectrum of phosphorus pentafluoride is clearly evident, but with BF_3 or AsF_5 as the binary fluoride no fluorine resonance spectrum is observed. With the two latter fluorides a yellow-orange solution was obtained. The solution was decanted from the solid and all volatile materials removed under high vacuum. The solids were found, by X-ray powder diffraction patterns, to be KBF_4 and $KAsF_6$, respectively. With TaF_5 and NbF_5 as the binary fluorides $KTaF_6$ and $KNbF_6$ were obtained in the same manner. These results may be explained in terms of reaction 1 where N is boron and $x = 3$ and where N is arsenic, tantalum, and niobium and $x = 5$.

$$[1] \qquad KMoF_6 + NF_x \rightarrow KNF_{x+1} + MoF_5$$

The yellow compound MoF_5 is soluble in sulfur dioxide to give a yellow-orange solution and does not produce a high resolution fluorine resonance spectrum since it is paramagnetic. Reaction 1 is similar to that observed with KWF_6 except for the fact that WF_5 is not stable and reacts further to give identifiable products (1).

The fluorine resonance spectra of reaction mixtures containing equimolar quantities of PF_5, BF_3, or AsF_5 with nitrosyl hexafluoromolybdate were similar to those obtained with potassium hexafluoromolybdate. However with $NOMoF_6$ as starting material and BF_3, an X-ray diffraction photograph of the solid, remaining after removal of volatile materials under vacuum, indicated the presence of $NOMoF_6$ and a new compound, not $NOBF_4$. With AsF_5 as the binary fluoride, $NOAsF_6$ and a new compound, not $NOMoF_6$, were found in the solid residue. It therefore seems that in these cases a complex fluoroanion is formed and continues to exist to some extent in the solid phase.

The infrared spectrum of nitrosyl hexafluoromolybdate was obtained, with some difficulty, by deposition on the cell windows directly from the vapor phase (6). Extensive hydrolysis was found to occur in Nujol mulls and KBr disks. These results were confirmed in the present studies. It was found that in addition to various peaks from hydrolysis products produced in the KBr disks a strong band attributed to a molybdenum fluorine stretch was observed at 550 cm^{-1} for $KMoF_6$ and at 560 cm^{-1} for $NOMoF_6$. The infrared spectrum of the reaction product of $NOMoF_6$ and BF_3 has, in addition to the lines previously observed from hydrolysis products, a strong line at 570 cm^{-1} from a molybdenum–fluorine stretch and three lines at 1040, 1080, and 1120 cm^{-1} attributed to boron–fluorine stretching frequencies. The latter three lines agree in position and intensity with those found at 1030, 1080, and 1120 cm^{-1} for NH_4BF_4 in a KBr disk (11). The infrared spectrum of the reaction product of $NOMoF_6$ and AsF_5 has a strong molybdenum–fluorine stretching frequency at 570 cm^{-1} and very strong bands at 700 and 390 cm^{-1} attributed to arsenic–fluorine stretching and bending modes. Infrared absorption lines are found at 700 and 398 cm^{-1} in $(TBA)AsF_6$ (8). From the combined results of fluorine resonance and infrared spectra and X-ray powder diffraction data it seems safe to conclude that a complex fluoroanion species is produced by reaction of $NOMoF_6$ with BF_3 and with AsF_5.

With silver as cation there is good evidence from fluorine resonance and infrared spectroscopy and X-ray powder diffraction studies for complex fluoroanion formation between MoF_5 and BF_4^-. In this case the complex is soluble in methylene chloride and a strong line is found at 145.5 from fluorine bonded to boron in the complex anion along with a much weaker line at 151.0 p.p.m. from BF_4^-. There does not appear to be any complex formation between MoF_5 and PF_6^-, AsF_6^-, nor SbF_6^- with silver and tetrabutylammonium as cations.

The clearest evidence for complex fluoroanions involving Mo(V) is found with silver and tetrabutylammonium as cations. The fluorine resonance spectrum of an equimolar solution of $(TBA)NbF_6$ and MoF_5 is shown in Fig. 1. Those peaks marked with an asterisk are attributed to $Nb_2F_{11}^-$ and have been reported previously (9). The major remaining peaks at −199.4, −161.1, and perhaps 142 p.p.m. are assigned to fluorines bonded to niobium in structure **1**, where X is niobium.

They are listed in Table 1 along with other reported complex fluoroanions of niobium for purpose of comparison. Since there is an unpaired electron on molybdenum(V) it is unlikely that fluorine resonance signals would be observed for fluorines directly bonded to molyb-

1

denum. The line at −199.4 is assigned to F_5 and that at −161.1 to F_4 from comparison with the chemical shifts found for other niobium containing complex fluoroanions. The observed intensity ratio of 1:4.7 is consistent with this assignment considering the errors introduced by different line widths and probably different relaxation times. The hetero-anion $MoNbF_{11}^-$ is 1.25 times more abundant than the homo-anion $Nb_2F_{11}^-$. A possible route for the formation of $Nb_2F_{11}^-$ is by reaction (2) which is analogous to the reactions

[2] $2MoNbF_{11}^- \leftrightarrows Nb_2F_{11}^- + Mo_2F_{11}^-$ or $MoF_5 + MoF_6^-$

previously discussed for the disproportionation of polyfluoroanions involving tantalum, niobium, and antimony (9).

The fluorine resonance spectrum of an equimolar solution of $AgTaF_6$ and MoF_5 is shown in Fig. 2. Those peaks marked with an asterisk are attributed to $Ta_2F_{11}^-$ and have been reported previously (9). The doublet at −89.9 with a spin–spin splitting of 240 Hz is assigned to F_5 on the basis of its chemical shift and the magnitude of its spin coupling which is assigned as $J_{3,5}$. These values are listed in Table 1 along with those for fluorine bonded to tantalum in other complex fluoroanions to facilitate a comparison. The triplet at −58.6 is assigned to F_4 with equal spin coupling constants $J_{3,4}$ and $J_{4'5}$ of 26 Hz. The F_5 resonance is not sufficiently sharp to resolve this coupling although there is a suggestion of it. The observed intensity ratio of 1:4.1 for F_5 and F_4 is consistent with this assignment. The peak at −43 is from unreacted TaF_6^- and those at −148, −120, and −85 are from fluorine on molybdenum in hydrolyzed species. These lines vary in relative

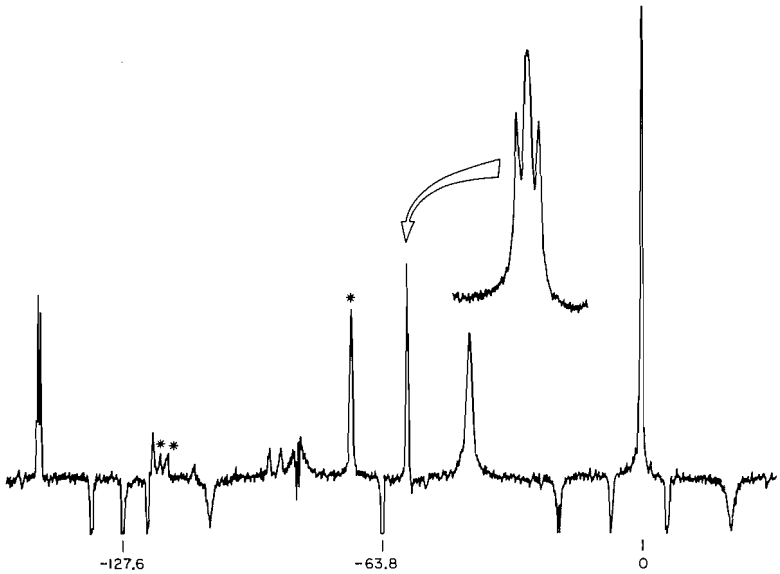

FIG. 2. The fluorine resonance spectrum of an equimolar methylene chloride solution of $AgTaF_6$ and MoF_5 at −105°.

TABLE 2. The effect of a binary fluoride upon the chemical shift of a probe nucleus

Probe nucleus	Chemical shift with binary fluoride (p.p.m.)				
	MoF_5	WF_4	NbF_5	TaF_5	SbF_5
Equatorial F on tantalum	−58.6	−65.6	−69.4	−72.0	−78.6
Terminal F on tantalum	−89.9	−94.6	−108.7	−115.1	−125.7
Equatorial F on niobium	−161.1	−138	−145.5	−149.4	−156.5
Terminal F on niobium	−194.4		−191.3	−197.4	−205

intensity from sample to sample with both silver and tetra-*n*-butylammonium as cations.

It is possible to order the relative electron withdrawing abilities of a binary fluoride as part of a polyfluoroanion from its effect upon the chemical shifts of a particular fluorine species in the other part of the polyfluoroanion (9). From the change in chemical shift for both the equatorial and terminal fluorines bonded to tantalum one obtains the following order of electron withdrawing ability. $MoF_5 < WF_4 < NbF_5 < TaF_5 < SbF_5$. Using the terminal fluorine bonded to niobium as a probe the order is $NbF_5 < MoF_5 < TaF_5 < SbF_5$. From the equatorial fluorines bonded to niobium the order $WF_4 < NbF_5 < TaF_5 < SbF_5 < MoF_5$ is obtained. The data summarizing these results are listed in Table 2. Although there are irregularities in the position of MoF_5 in the niobium complex fluoroanions it appears that this method may have promise in ordering the results obtained from studies of complex fluoroanions.

The author wishes to thank Miss Gayle Benson for preliminary studies with MoF_6 and $NOMoF_6$.

Total Synthesis of (±)-Trachylobane, a Pentacyclic Diterpenoid with a Tricyclooctane System

R. B. KELLY, J. EBER, AND H. K. HUNG

Department of Chemistry, University of New Brunswick, Saint John, New Brunswick

Received March 6, 1973

A total synthesis of (±)-trachylobane, a pentacyclic diterpenoid possessing a tricyclo[3.2.1.$0^{2,7}$]octane system, is described. Completion of the synthesis of trachylobane confirms the validity of the structure assigned to this diterpenoid and provides corroboration of structures assigned to diterpenoids from which it has been obtained as a conversion product.

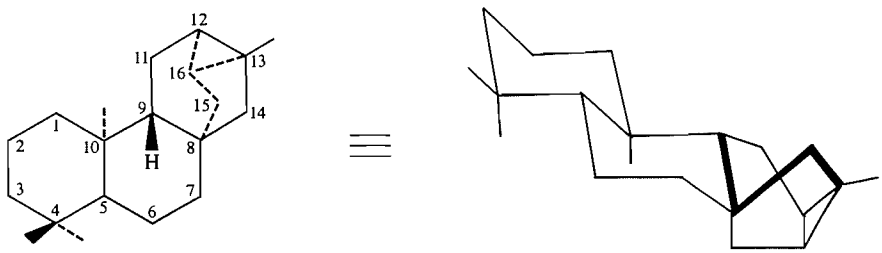
On décrit une synthèse totale du (±)-trachylobane, un diterpénoide pentacyclique possédant un système tricyclo[3.2.1.$0^{2,7}$]octane. En complétant ainsi la synthèse du trachylobane, on a confirmé la structure assignée à ce diterpénoide et corroboré les structures proposées aux diterpénoides desquels il a été obtenu comme produit de conversion. [Traduit par le journal]

Can. J. Chem., **51**, 2534 (1973)

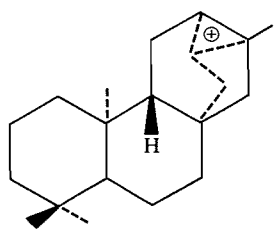
Trachylobane (**1**) is the naturally occurring (1) parent hydrocarbon of a group of biogenetically important diterpenoidal acids and alcohols which are characterized by a tricyclo[3.2.1.$0^{2,7}$]-octane system incorporated into ring C (1–3). The isolation from *Trachylobium* of diterpenoids possessing the trachylobane skeleton was first reported in 1965 (2) and since then further reports of the isolation of new members of the trachylobane group have appeared (3). It was not until 1971, however, that the parent hydrocarbon, trachylobane (**1**), was isolated from natural sources.

The trachylobane skeleton has, for some time, been associated with interesting speculations regarding the biogenesis of the diterpenes. In fact, ten years before the discovery of the trachylobane group, a non-classical carbonium ion (**2**) related to trachylobane was suggested as an intermediate in the biosynthesis of various diterpenoidal skeleta (4). Consequently, the eventual discovery of the trachylobanes in nature inspired considerable experimentation directed toward interconversions involving trachylobane and the tetracyclic diterpenoids (*e.g.* 2*c*, 5).

The tricyclooctane system present in the



1



2

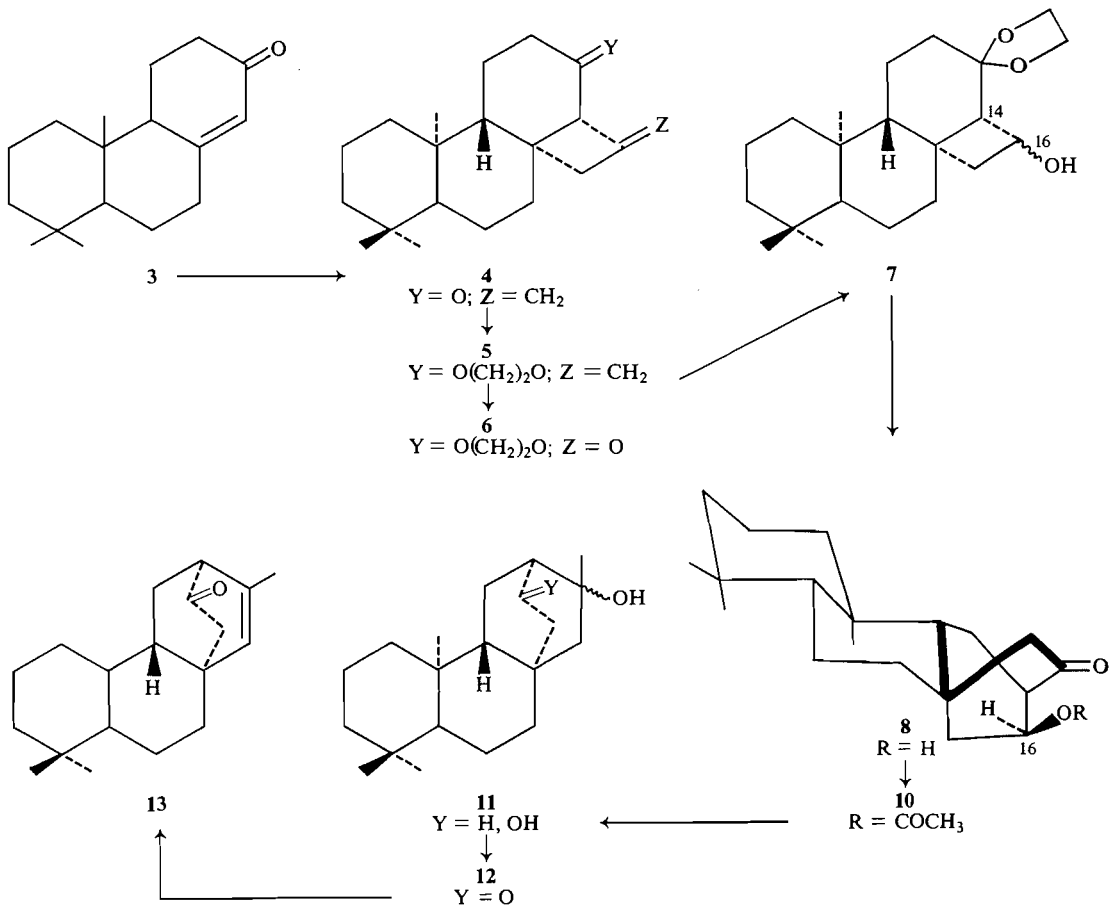

SCHEME 1

trachylobane skeleton is also found in the sesquiterpenoids ishwarone (6) and ishwarane (6) and we have recently described a total synthesis of the latter (7). We now wish to describe a total synthesis of trachylobane (**1**) which confirms the validity of the structure assigned to this diterpenoid and provides corroboration for the structures assigned to diterpenoids from which it has been derived as a conversion product (2, 3). The synthetic route is outlined in Schemes 1 and 2.

Stereo- and regiospecific photo-addition of allene (7 and refs. cited) to the totally synthetic (8) unsaturated ketone **3** afforded, in 70% yield, the crystalline adduct **4**. Consistent with structure **4**, the i.r. spectrum of the adduct showed carbonyl absorption at 1710 cm^{-1} and bands at 1675 and 875 cm^{-1} due to the exocyclic methylene and, in the n.m.r. spectrum, there was a multiplet at δ 4.95 (2H) attributable to the exocyclic methylene.[1]

Oxidation of the crystalline ketal **5** of **4** with osmic acid-periodate gave the crystalline cyclobutanone (**6**) in 93% yield (from **4**). The i.r. spectrum of **6** showed carbonyl absorption 1777 cm^{-1} due to the cyclobutanone and the n.m.r. spectrum was devoid of signals attributable to vinylic protons but showed a multiplet (4H) at δ 3.77 due to the ethylene group of the ketal function.

The cyclobutanone (**6**) was reduced to the crystalline cyclobutanol (**7**) in 97% yield with lithium aluminum hydride. The alcohol (**7**) had spectral properties consistent with the assigned structure. Thus, the i.r. spectrum showed

[1]Only spectral data pertinent to the discussion will be given in this section; for further details see Experimental.

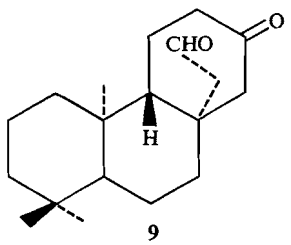
hydroxyl absorption at 3500 cm^{-1} and, in the n.m.r. spectrum, there was a doublet (1H) at δ 2.77 due to the methine at C-14 and a multiplet (1H) at δ 4.30 due to the C-16 proton.[2]

Treatment of **7** with aqueous hydrochloric acid in tetrahydrofuran resulted in deketalization followed by skeletal rearrangement to give, directly, the crystalline keto alcohol **8** in 97% yield. The conversion **7** → **8** involves deketalization followed by retro-aldolization to give the intermediate keto aldehyde **9** then aldol condensation to give **8** (*cf.* 7). The structure assigned



9

to the keto alcohol is supported by its i.r. spectrum which showed bands at 3370 (hydroxyl) and 1720 cm^{-1} (ketone) and by a multiplet (1H) in the n.m.r. spectrum at δ 4.17 due to the proton at C-16. In contrast with previous experience of this type of rearrangement (7), apparently only a single epimer was formed which has been assigned the stereostructure represented by **8** for reasons given in the sequel.

Conversion of **8** to the acetate **10** and treatment of the latter with methyl lithium followed by acid hydrolysis afforded the crystalline diol **11** in 85% yield. The i.r. spectrum of **11** was devoid of carbonyl absorption and the n.m.r. spectrum showed a singlet (3H) at δ 1.27 (CH_3—C—OH).

Jones oxidation (9) of the diol **11** gave, in 86% yield, the keto alcohol **12** (i.r. 3360 and 1710 cm^{-1}) as a crystalline compound. Dehydration of **12** with *p*-toluenesulfonic acid in boiling benzene gave the crystalline enone **13** in 78% yield. The spectral properties of the dehydration product were consistent with structure **13**. Thus, there were bands in the i.r. spectrum at 1725 (ketone) and 1647 cm^{-1} (double bond) and, in the n.m.r. spectrum, there was a doublet at δ 1.75 (vinylic methyl) and a multiplet at 5.77 (vinylic proton).

Reduction of the enone **13** with lithium aluminum hydride and chromatography of the product on silica gel afforded two epimeric enols **14***a* (m.p. 147–148°; yield 55%) and **14***b* (m.p. 135–136°; yield 42%). The i.r. spectra of the epimeric enols were similar, both displaying hydroxyl absorption at 3250–3300 cm^{-1} and a band at *ca.* 1650 due to the double bond. In the n.m.r. spectrum of the higher melting epimer there was a doublet (3H) at δ 1.68 (vinylic methyl), a multiplet (1H) at 3.87 (proton at C-16), and a multiplet (1H) at 5.48 (vinylic proton); in the case of the lower melting epimer the corresponding signals occurred at δ 1.76, 3.83, and 5.72 respectively.

The assigned stereoconfigurations at C-16 of the epimeric enols is based on the observation that, in the case of the higher melting epimer, the n.m.r. spectrum shows that the singlet (δ 1.08) for one of the tertiary methyl groups appears *ca.* 15 Hz downfield relative to the singlets (δ 0.80 and 0.85) for the other two tertiary methyl groups attached to C-4. No such pronounced deshielding effect is observed in the spectrum of the lower melting epimer in which the relevant singlets appear at δ 0.80 and 0.87 (superimposed singlets for two methyl groups). This effect was attributed to deshielding of the angular methyl group by the hydroxyl group. Consequently, the higher melting epimer was assigned structure **14***a*, in which the hydroxyl group is closer to the angular methyl group than in **14***b*. The latter structure must then be assigned to the lower melting epimer.

Unlike **14***b*, the enol **14***a* leads to a keto tosylate (**19**) in which the tosylate function is favorably aligned for an S_N2_i displacement by the carbanion at C-13 to form the cyclopropyl ketone **20**. For this reason, **14***a* rather than **14***b* was chosen for the continuation of the synthesis. However, based on experience gained during the synthesis of ishwarane (7) it seems likely that either epimer could have been chosen.

Reasoning similar to that applied to **14***a* (*vide supra*) can now be used to assign the configuration at C-16 of the keto alcohol **8**. Singlets for the three methyl groups appear at δ 0.83, 0.88, and 0.95. Thus, in contrast with **14***a*, no single methyl group is significantly deshielded relative to the other two by the hydroxyl group. In analogy with **14***b*, this requires that the configuration at C-16 be as shown in **8** in which the hydroxyl group is farther removed from the angular methyl group than it would be in the epimeric orientation. The fact that none of the

[2]The numbering system shown in **1** is adhered to throughout.

pertinent methyl groups in the diol **11**, which has the same configuration at C-16 as **8**, is deshielded relative to the others provides substantiation for this stereochemical assignment.

Conversion of **14***a* to the benzyl ether **15** followed by hydroboration afforded a single crystalline alcohol **16** in 55% yield (from **14***a*) the i.r. spectrum of which showed hydroxyl absorption at 3450 cm^{-1}. In addition to the signals due to the benzyl group, the n.m.r. spectrum exhibited a doublet (1H) at δ 2.75 (proton at C-14) and a multiplet (1H) at 3.68 (proton at C-16). The stereochemistry at C-13 and -14 is unknown but this is of no consequence so far as the synthetic route is concerned.

Oxidation of **16** with the Sarett reagent (10) gave, in 65% yield, the crystalline ketone **17** (i.r. 1710 cm^{-1}) which, on hydrogenolysis of the benzyl group gave the crystalline keto alcohol **18** in 76% yield (i.r., 3460 and 1690 cm^{-1}; n.m.r., devoid of signals for benzyl group).

The keto alcohol **18** was converted to the tosylate **19** and the latter was transformed in 52% yield into the crystalline cyclopropyl ketone **20** by heating at 60° for 2 h in dimethyl sulfoxide containing an excess of methylsulfinyl carbanion (11). The spectral properties of this key condensation product were consistent with structure **20**. Thus, the u.v. spectrum showed a maximum at 209 nm (ε 3800) due to absorption of the cyclopropyl ketone; the i.r. spectrum showed carbonyl absorption at 1720 cm^{-1} but was devoid of bands attributable to hydroxyl or tosylate absorption; the n.m.r. spectrum showed a partially obscured multiplet at *ca.* δ 0.60 due to protons on the cyclopropane ring and singlets for four tertiary methyl groups.

Finally, the cyclopropyl ketone **19** was reduced to the hydrocarbon **1** by the Barton modification (12) of the Wolff–Kishner reduction. After purification by t.l.c., the hydrocarbon was obtained as an oil in 56% yield. The spectral properties of the reduction product were consistent with structure **1**; the i.r. spectrum showed no carbonyl absorption and the n.m.r. spectrum showed a multiplet at δ 0.65 due to the protons on the cyclopropane ring and singlets for four tertiary methyl groups.

The identity of the synthetic hydrocarbon **1** with an authentic sample of trachylobane was established by the following criteria: identity of i.r. and n.m.r. spectra; identical retention times on v.p.c. (single peak on co-injection).

Experimental

Instrumentation, Methods, and Materials

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 237 B spectrophotometer and u.v. spectra were determined with a Perkin–Elmer Coleman model 124 instrument. The n.m.r. spectra were recorded with a Varian T-60 instrument; chemical shifts were expressed in p.p.m. (δ-values) downfield from the signal for tetramethylsilane which is used as an internal standard.

V.p.c. was performed on a Hewlett-Packard model 5750 instrument fitted with a stainless steel column (6 × 1/8 in) packed with 10% of UC-W98 (silicone gum-rubber) on diatoports (80–100 mesh). The t.l.c. was carried out on silica gel GF-254 procured from Brinkman Instruments (Canada) Ltd.

Reaction products were isolated by the following procedure. The product was extracted into the specified solvent and the extract was washed two or three times with appropriate aqueous solutions as indicated. The original aqueous layer (if any) and the aqueous washings were extracted three times with the solvent and the combined extracts were dried over anhydrous magnesium sulfate, filtered, and evaporated *in vacuo* on a rotary evaporator.

Petroleum ether refers to the fraction with boiling point range 30–60°.

Brine refers to a saturated solution of sodium chloride.

Photo-adduct 4

Photo-addition of allene to the unsaturated ketone **3** was carried out at −70° using a 450 W mercury vapor immersion lamp with a Corex sleeve. A solution of 8.0 g of **3** and 44.0 g of allene in 1500 ml of freshly distilled hexane was irradiated for 1 h then the reaction solution was left at room temperature overnight to allow excess allene to escape. The solvent was evaporated *in vacuo* and the residue was chromatographed on a column of 250 g of silica gel with benzene as solvent. Crystallization of the eluted material from ether afforded 6.56 g (70%) of **4**, m.p. 112°; ν_{max} (Nujol) 1710 (ketone), 1675, and 875 with overtone at 1750 cm^{-1} (exocyclic CH_2); n.m.r. ($CDCl_3$) δ 0.83 (s, 6H, superimposed singlets for two tertiary methyls), 0.90 (s, 3H, tertiary methyl), 4.95 (m, 2H, vinylic protons).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 84.21; H, 10.82.

Ketal 5

A solution of 5.47 g of **4**, 550 mg of *p*-toluenesulfonic acid monohydrate, and 16.5 ml of ethylene glycol in 550 ml of benzene was refluxed under a nitrogen atmosphere for 30 min. During reflux water was separated in a Dean–Stark adapter. The cooled reaction solution was worked-up in the usual manner with potassium bicarbonate solution and water. Crystallization of the resulting material from ether – petroleum ether gave 6.14 g (98%) of **5**, m.p. 116.5°; ν_{max} (Nujol) 1675 and 880 with overtone at 1760 cm^{-1} (exocyclic CH_2); n.m.r. ($CDCl_3$), δ 0.78, 0.82 and 0.87 (s, 3H each, tertiary methyls), 3.93 (br s, 4H, ethylene of ketal function), 4.94 (m, 2H, vinylic protons).

Anal. Calcd. for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37. Found: C, 80.31; H, 10.38.

Cyclobutanone 6

A solution of 600 mg of **5**, 5.1 ml of water, and 60 ml of dioxan was treated with a solution of 60 mg of osmic acid in 2.4 ml of pyridine. After stirring for 15 min in the dark, the reaction solution was treated over a period of 1 h, with 690 mg of sodium metaperiodate dissolved in 6.9 ml of water. The resulting mixture was stirred at room temperature in the dark for 2 days. Solid material was removed by filtration, the filtrate extracted with ether, and the extracts were worked-up in the usual manner with 10% sodium bisulfite solution and water. Crystallization of the product from ether – petroleum ether afforded 570 mg (95%) of **6**, m.p. 142–143°; ν_{max} (Nujol) 1777 cm^{-1} (ketone); n.m.r. (CCl_4), δ 0.78, 0.83, and 0.87 (s, 3H each, tertiary methyls), no signals for vinylic protons.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 76.06; H, 10.02.

Cyclobutanol 7

A solution of 153 mg of **6** in 10 ml of ether was added dropwise to a suspension of 200 mg of lithium aluminum hydride in 10 ml of ether over a period of 20 min. The reaction mixture was stirred at room temperature for 16 h then refluxed for 15 min. The cooled reaction mixture was treated with 0.3 ml of brine, stirred for 5 h, dried with anhydrous sodium sulfate, and filtered. The solid material was washed well with ether and the washings combined with the filtrate and evaporated *in vacuo*. Crystallization of the residue from ether afforded 151 mg (98%) of **7**, m.p. 142°; ν_{max} (Nujol) 3475 cm^{-1} (OH); n.m.r. (CCl_4), δ 0.77, 0.81 and 0.84 (s, 3H each, tertiary methyls). 2.77 (d, J = 3.5 Hz, 1H, methine at C-14), 3.87 (br s, 4H, ethylene of ketal function), 4.30 (m, 1H, H—C—OH).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.34; H, 10.48.

Keto Alcohol 8

A solution of 1.20 g of **7** in 90 ml of tetrahydrofuran was treated with 72 ml of 1 *M* aqueous hydrochloric acid and left under nitrogen at room temperature for 21 h. The reaction solution was extracted with chloroform and the extracts were worked-up in the usual manner with saturated sodium bicarbonate solution and water. Crystallization of the product from methylene chloride – petroleum ether afforded 1.04 g (97%) of **8**, m.p. 237°; ν_{max} 3370 (OH) and 1720 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.83, 0.88 and 0.95 (s, 3H each, tertiary methyls), 4.17 (m, 1H, H—C—OH).

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41. Found: C, 78.90; H, 10.50.

Keto Acetate 10

Conversion of 1.85 g of **8** in the usual manner with acetic anhydride in pyridine followed by crystallization of the product from methylene chloride – petroleum ether gave 1.94 g (92%) of **9**, m.p. 175°; ν_{max} 1740 cm^{-1} (broad band, acetate and ketone); n.m.r. ($CDCl_3$), δ 0.85, 0.88 and 0.99 (s, 3H each, tertiary methyls), 2.00 (s, 3H, acetate), 5.07 (H—O—Ac).

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70. Found: C, 76.00; H, 9.71.

Diol 11

A solution of 500 mg of **10** in 20 ml of tetrahydrofuran was added dropwise to 10 ml of a 1 *M* ether–tetrahydrofuran solution of methyl lithium under nitrogen; during the addition the methyl lithium solution was cooled on an ice bath. The reaction solution was stirred at room temperature for 1 h then treated dropwise with 24 ml of 0.5 *M* aqueous hydrochloric acid. The product was extracted with methylene chloride and the extracts were worked-up in the usual manner with sodium bicarbonate solution and brine. Crystallization of the product from methylene chloride – petroleum ether gave 393 mg (85%) of **11**, m.p. 182°; ν_{max} 3260 (OH); n.m.r. ($CDCl_3$), δ 0.82 (s, 3H, tertiary methyl), 0.87 (s, 6H, superimposed signals for two tertiary methyls), 1.27 (s, 3H, CH_3—C—OH), 3.97 (m, 1H, H—C—OH).

Anal. Calcd. for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18. Found: C, 78.34; H, 11.19.

Keto Alcohol 12

A solution of 210 mg of **11** in 25 ml of acetone was treated dropwise at room temperature with an 8 *N* solution of Jones' reagent (9) until a persistent orange color was observed. Excess oxidizing reagent was deactivated by the addition of 1 ml of methanol. The reaction mixture was poured into 100 ml of 5% sodium carbonate and the product was extracted into ether. The ether extracts were washed with brine, dried, and evaporated *in vacuo*. Crystallization of the residue from methylene chloride – petroleum ether gave 179 mg (86%) of **12**, m.p. 207–208°; ν_{max} (Nujol) 3360 (OH) and 1710 cm^{-1} (ketone); n.m.r. ($CDCl_3$), δ 0.77, 0.80 and 0.87 (s, 3H each, tertiary methyls), 1.40 (s, 3H, CH_3—C—OH).

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.90; H, 10.60 Found: C, 78.82; H, 10.58.

Enone 13

A solution of 1.09 g of **12** and 1.08 g of *p*-toluenesulfonic acid monohydrate in 1080 ml of benzene was refluxed for 5 h while water was separated in a Dean–Stark adapter. The cooled benzene solution was added to 600 ml of saturated sodium bicarbonate solution, the layers were separated, and the aqueous layer was extracted with ether. The benzene layer and the ether extracts were washed with brine, combined, dried, and evaporated *in vacuo*. Chromatography of the residue on a column of 135 g of silica gel impregnated with 20% silver nitrate with 2.5% of ether in petroleum ether as solvent followed by crystallization from petroleum ether afforded 800 mg (78%) of **13**, m.p. 94°; ν_{max} (Nujol) 1725 (ketone), 1647 and 805 cm^{-1} (olefin); n.m.r. ($CDCl_3$), δ 0.81 (s, 3H, tertiary methyl), 0.87 (s, 6H, superimposed signals for two tertiary methyls), 1.75 (d, J = 2 Hz, 3H, vinylic methyl), δ 5.77 (m, 1H, vinylic proton).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 84.01; H, 10.67.

Enols 14a and b

A solution of 426 mg of **13** in 10 ml of ether was added dropwise to a stirred mixture of 300 mg of lithium aluminum hydride and 10 ml of ether. The mixture was stirred at room temperature for 5 h then refluxed for 1 h, cooled, and treated with 0.3 ml of brine. After stirring overnight, anhydrous sodium sulfate was added and stirring was continued for 30 min. The solid material was collected by filtration and washed well with ether. The combined filtrate and washings were evaporated *in vacuo*. The residue was combined with similar material, resulting from the reduction of 800 mg of **13** as described above, and chromatographed on a column of 75 g of silica gel with 4–8% of ether in petroleum ether as solvent.

Cyclopropyl Ketone ***20***

A solution of 116 mg of **18** in 3.5 ml of pyridine was treated with 270 mg of *p*-toluenesulfonyl chloride and left at room temperature for 3 days. After the addition of 25 ml of ice-water, the reaction solution was stirred on an ice bath for 20 min. The product was extracted into ether and worked-up in the usual manner with cold 2 *M* hydrochloric acid and brine. The crystalline tosylate (**19**, 170 mg) was used without further purification for the next step.

The following reaction was carried out in a dry nitrogen atmosphere. The tosylate (170 mg), suspended in 5 ml of dry dimethyl sulfoxide, was treated with 1.1 ml of a 0.5 *M* dimethyl sulfoxide solution of methylsulfinyl carbanion (11). The mixture was heated, with stirring, at 60° whereupon the tosylate dissolved within a few minutes and heating was continued for 2 h. After cooling, the reaction solution was treated with 0.5 ml of water and diluted with ether. The ether solution was worked-up in the usual manner with brine and water. Purification of the product by t.l.c. on silica gel with ether – petroleum ether (1:3) as solvent followed by crystallization from petroleum ether afforded 54 mg (52%) of **20**, m.p. 85°; λ_{max} (EtOH) 209 nm (ε 3800); ν_{max} (Nujol) 1720 cm^{-1} (ketone); n.m.r. (CCl_4), *ca.* δ 0.60 (m, 2H, protons on cyclopropane ring), 0.81, 0.86, 1.03, and 1.06 (s, 3H each, tertiary methyls).

Mol. Wt. Calcd. for $C_{20}H_{30}O$: 286. Found (mass spectrum): 286.

(±)-Trachylobane ***1***

The reduction of **20** to trachylobane (**1**) was carried out in a dry nitrogen atmosphere as follows (*cf.* 12, 7). A solution of 52 mg of **20** in 6 ml of a stock solution prepared by dissolving 690 mg of sodium in 60 ml of diethylene glycol was treated with 0.4 ml of anhydrous hydrazine (12) and immersed in an oil bath at 210°. More anhydrous hydrazine (*ca.* 0.8 ml) was added until the reaction solution was refluxing freely and the temperature of the solution was 180°; the solution was allowed to reflux at this temperature for 14 h then an additional 1 ml of anhydrous hydrazine was added and reflux was continued for 1 h. Hydrazine was distilled from the reaction flask until the temperature of the solution reached 210°. After keeping the reaction solution at 210° for 24 h, it was cooled, diluted with ether and worked-up in the usual manner with cold 1 *M* hydrochloric acid, 1 *M* sodium carbonate, and brine. Purification of the product by t.l.c. on silica gel with pentane as solvent afforded 28 mg (56%) of **1** as an oil which gave rise to a single peak on v.p.c. with a retention time of 17.0 min (column temperature programmed from 94° to 250° at 10°/min), i.r., devoid of carbonyl absorption; n.m.r. ($CDCl_3$) δ 0.65 (m, 2H, protons on cyclopropane ring), 0.80, 0.83, 0.94, 1.13 (s, 3H each, tertiary methyls).

Anal. Calcd. for $C_{20}H_{32}$: C, 88.16; H, 11.84. Found: C, 88.35; H, 11.93.

The synthetic hydrocarbon **1** was identical with an authentic sample of trachylobane obtained from natural sources (i.r. and n.m.r. spectra, a single peak on v.p.c. when coinjected with the authentic sample).

We are grateful to the National Research Council of Canada for a grant in support of this work.

We are also grateful to Professors A. G. González and B. M. Fraga, Universidad de la Laguna, Tenerife, Spain, for a sample of trachylobane, to Professor J. St. Pyrek, Polska Akademia Nauk, Warsaw, for a sample of trachylobane and n.m.r. spectra of trachylobane and to Professor G. Ourisson, Université Louis Pasteur, Strasbourg, France, for an n.m.r. spectrum of trachylobane.

Determination of the Basicities of a Series of Substituted Benzyldimethylamines in 50% Aqueous Methanol

DONALD G. LEE AND R. SRINIVASAN

Department of Chemistry, University of Saskatchewan Regina Campus, Regina, Saskatchewan

Received June 28, 1972

The basicities of a series of substituted benzyldimethylamines have been determined potentiometrically in 50% (by weight) aqueous methanol. An excellent Hammett correlation ($\rho = -1.38$) is obtained. The larger value of ρ in aqueous methanol as compared to water (-1.14) is interpreted in terms of a greater capability of water to solvate ammonium ions, thus suppressing the stabilizing or destabilizing effect of ring substituents.

Les basicités d'une série de benzyldiméthylamines substituées ont été déterminées par potentiométrie dans le méthanol aqueux à 50% en poids. Une excellente corrélation de Hammett ($\rho = -1.38$) a été obtenue. La valeur plus élevée de ρ dans le méthanol aqueux comparée à celle déterminée dans l'eau (-1.14) a été interprétée par une capacité plus grande de solvatation des ions ammoniums par l'eau supprimant ainsi l'effet stabilisateur ou déstabilisateur des substituants du cycle. Can. J. Chem., **51**, 2542 (1973)

Introduction

A knowledge of the acid–base properties of a substrate is essential to a complete understanding of any reaction which is subject to acid catalysis or inhibition. Hence before undertaking a study of such a reaction it is necessary to first determine the basicity constants of the reactants. Consequently we have determined the pK_{BH^+} values (as defined by eq. 1) of several substituted benzyldimethylamines in connection with a study of the oxidation of tertiary amines by bromine (1).

[1] 
The recent development of standard buffers for aqueous alcohol solvents (2) permitted the use of potentiometric methods in 50% (by weight) aqueous methanol. This solvent was chosen because its *Y*-value (3) corresponds closely to that of the medium in which the oxidation reaction was studied (1).

Experimental

Reagents, Solvents, and Buffers

The solvent (50% aqueous methanol by weight) was prepared by mixing 63.3 ml of spectroquality methanol (MC/B) with 50 ml of water which had been purified by distillation from an all glass Corning AG-3 still.

Benzyldimethylamine, supplied by the Aldrich Chemical Co., was purified by distillation to give a colorless liquid, b.p. 74–75°/15 mm (lit. b.p. 73–74°/15 mm) (4). All other amines were purified by distillation just prior to use and the purity was checked by g.l.c. using a 30 ft column packed with the detergent, Tide.

Standardization of the p*H* meter was accomplished using the procedure of the National Bureau of Standards (5). For this purpose two buffer solutions were prepared as follows: (*i*) 0.2722 g of KH_2PO_4, 0.5359 g Na_2HPO_4-$7H_2O$, and 0.1169 g of NaCl in 1000 g of solvent (p*H* 8.232 at 25°); (*ii*) 0.3003 g of acetic acid, 0.6804 g of NaOAc $3H_2O$ and 0.2922 g of NaCl in 1000 g of solvent (p*H* 5.591 at 25 °C).

The p*H* meter, which utilized a glass and a calomel electrode, was standardized at a p*H* of 8.232 with the phosphate buffer thermostated at 25.0 ± 0.1° in a constant temperature cell. The p*H* of the acetate buffer solution was measured as 5.620, which is in reasonably good agreement with the reported value of 5.591 in this solvent (5).

Determination of pK_{BH^+} Values

The pK_{BH^+} values for the substituted benzyldimethylamines were determined at 25.0 ± 0.1° using a standard experimental procedure (6).

In a typical potentiometric titration, 20 ml of the amine solution in 50% aqueous methanol (*ca.* 0.01 *M*) was placed in a cell thermostated at 25.0 ± 0.1° and covered with aluminum foil to minimize evaporation of methanol. Portions ranging from 0.01 to 0.05 ml of perchloric acid in 50% aqueous methanol (*ca.* 0.20 *M*) were added from a microliter syringe, the solution being stirred well after each addition, and the p*H* was recorded. The titration was carried out over a p*H* range not less than two units on either side of the pK_{BH^+} value of the amine. The entire process of adding the titrant and recording the p*H* reading was repeated with a solution of KOH in 50% aqueous methanol (*ca.* 0.20 *M*) in a similar fashion. Corrections were made for the slight dilution involved in this

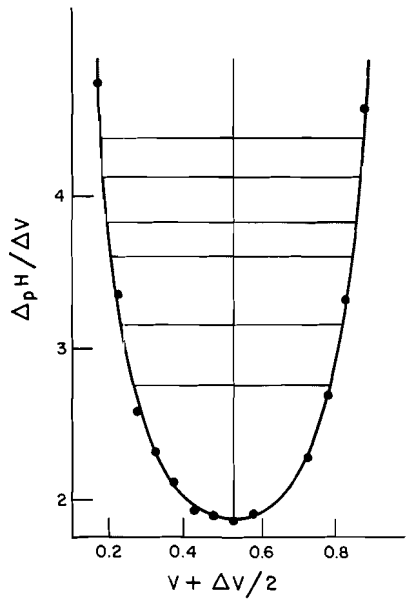

FIG. 2. Parabolic curve used for estimating the pK_{BH^+} of benzyldimethylamine.

process (6) and plots of titer (V) *vs.* pH for both acid and base titrations were found to give sigmoidal curves (Fig. 1). The pH value at the inflection point of each sigmoidal curve refers to the pK_{BH+} value of the amine. A differential method was adopted to estimate the inflection point. A plot of the ratio $\Delta pH/\Delta V$ *vs.* $V + \Delta V/2$ (the mid-point of the titer added) gave, as expected, a symmetric parabola (Fig. 2). The $V + \Delta V/2$ value through which the axis of symmetry of the parabola passes, would give the volume of titrant at which the amine is half protonated and the corresponding pH value, read from the sigmoidal curve, represents the approximate pH_{BH+} value of the amine. This value was then adjusted by use of a curve-fitting technique until the theoretical and experimental curves matched. The required adjustments were not great (usually about ± 0.02 pH units).

It was assumed that the pK_{BH+} values of the amines are insensitive to the small changes in ionic strength accompanying the titration. The activity coefficients of the species involved in the equilibrium were also assumed to be unity since the concentrations of the amines were small (*ca.* 0.01 M).

Syntheses of Substituted Benzyldimethylamines

The substituted benzyldimethylamines were prepared by a modification of the procedure described by Eliel *et al.* (7). As a typical example the synthesis of *p*-chlorobenzyldimethylamine is described in detail below and the results for other substituted benzyldimethylamines are summarized in Table 1.

Benzene (120 ml) was cooled in ice to the freezing point and gaseous dimethylamine was passed through it until 38.7 g (0.86 mol) had been absorbed. Gradual addition of a solution of *p*-chlorobenzyl chloride (33.81 g, 0.21 mol) in benzene (150 ml) to the stirred amine solution resulted in the precipitation of a white solid. This mixture was allowed to stand at room temperature for 4 days in a well stoppered flask. Then about 6 N hydrochloric acid (200 ml) was added gradually with constant stirring, whereupon two layers separated. The aqueous layer was washed with ether to remove traces of benzene and neutralized with a solution of KOH, the reaction flask being immersed in cold water during the addition of base. When the solution was distinctly basic, an oily layer separated. The latter was extracted into ether and the ethereal solution dried over anhydrous $MgSO_4$. Evaporation of the solvent then gave crude *p*-chlorobenzyldimethylamine which was purified by vacuum distillation (b.p. 87.5–88.5°/9 mm; lit. b.p. 90–95°/9–11 mm) (7) to give 26 g (73%) of colorless liquid which was shown to be a single pure compound by use of g.l.c.

For the purposes of analysis the amine was then converted to the solid hydrobromide derivative using the following procedure (8).

The amine (17 g, 0.1 mol) was dissolved in ether (250 ml) and HBr gas was passed through the solution at room temperature. The HBr gas was generated by dropwise addition of bromine to stirred dry tetrahydronaphthalene at 25° (9). The HBr gas was purified from traces of bromine by passing it through tetrahydronaphthalene and dried by passing it over silica gel. The colorless crystalline *p*-chlorobenzyldimethylamine hydrobromide, obtained in quantitative yields, was crystallized several times from ethanol–ether solutions (m.p. 198–199°) and identified from the analytical data reported in Table 2.

m-Methylbenzyl chloride was obtained from K & K Laboratories, Inc., while *p*-cyanobenzyl bromide and

p-methylbenzyl bromide were purchased from Pfaltz & Bauer, Inc. The remaining substituted benzyl halides used were supplied by Aldrich Chemical Co., Inc. Dimethylamine gas was obtained from Matheson of Canada Ltd.

Results and Discussion

The pK_{BH^+} values obtained as described above have been summarized in Table 2. For comparison purposes the values previously obtained in aqueous solutions have been included in Table 2. It should be noted, however, that the pK_{BH^+} values reported here refer to a particular standard state (50% aqueous methanol) and while they may be used to indicate relative basicities they cannot be extrapolated directly to any other standard state.

The Hammett plot shown in Fig. 3 gives a ρ value of -1.38 (11). It is of interest to compare this value with that reported by Rosenblatt *et al.* (12) for the same reaction in water, $\rho = -1.14$. The larger value of ρ obtained with the former solvent reflects the greater solvating abilities of water as compared to methanol. Since water is more capable of solvating ammonium ions the stabilizing or destabilizing influence of ring substituents is suppressed in an aqueous medium.

TABLE 2. pK_{BH^+} values of substituted benzyldimethylamines in 50% aqueous methanol at 25.0 ± 0.1 °C

Substituent	Acid titration	Base titration	Average	Value in* aqueous solutions
p-Me	8.31	8.35	8.33	9.22

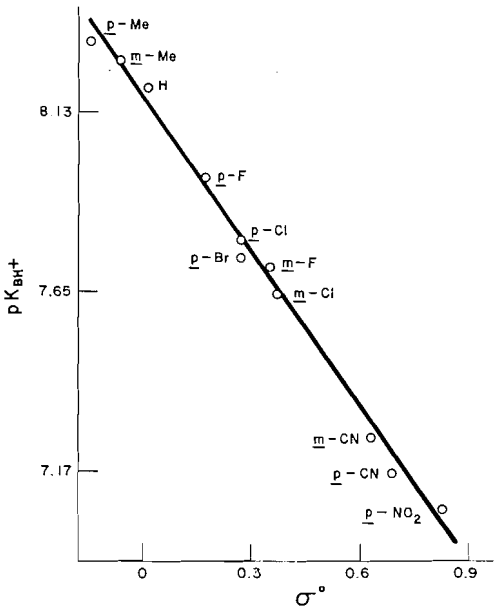

FIG. 3. Hammett plot correlating the pK_{BH^+} values of substituted benzyldimethylamines.

Good Hammett plots were obtained when either σ or σ° substituent constants were used; the correlation coefficients being 0.991 and 0.997 respectively (13). When attempts were made to use other substituent constants (*e.g.* σ^+ and σ^-) much lower correlation coefficients were obtained. Hence it would appear that the methylene group effectively isolates the ring from direct conjugation with the nitrogen.

The Oxidation of Benzyldimethylamine by Bromine

DONALD G. LEE AND R. SRINIVASAN

Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received June 28, 1972

The rates of oxidation of several substituted benzyldimethylamines by bromine in 50% aqueous acetic acid have been determined spectrophotometrically. Electron-withdrawing substituents decrease the rate of reaction with the Hammett ρ value being -0.95. The reaction is subject to general base catalysis and substitution of deuterium in the α-position decreases the rate of reaction by approximately 30%, thus indicating that the α-C—H bond is cleaved in the slow step of the reaction. All results are consistent with a mechanism which involves, in the rate determining step, loss of an α-hydrogen atom as a proton with concomitant transfer of electrons from nitrogen to the oxidant.

Les vitesses d'oxydation de plusieurs benzyldiméthylamines substituées par le brome dans l'acide acétique à 50% aqueux, ont été déterminées par spectrophotométrie. Les substituants électroattracteurs diminuent la vitesse de réactions avec une constante de Hammett de -0.95. La réaction est sujette à une catalyse basique généralisée et la substitution par le deutérium sur la position α diminue la vitesse de la réaction de 30% environ, indiquant ainsi que la liaison α-C—H est rompue dans l'étape lente de la réaction. Tous les résultats sont compatibles avec un mécanisme impliquant dans l'étape déterminante de vitesse la perte d'un atome d'hydrogène-α en tant que proton et le transfert compétitif d'électrons de l'azote à l'oxydant. [Traduit par le journal]

Can. J. Chem., 51, 2546 (1973)

Introduction

The oxidation of amines by halogens has a long history dating from 1900 when Wilstatter and Iglauer (1) treated *N*-methyl alkaloids with aqueous chlorine and found that tropidine, tropane, and *N*-methylpiperidine were demethylated. Later, when trimethylamine was cleaved by aqueous chlorine, *N*-chlorodimethylamine and formaldehyde were found to be the major products (2).

The oxidative cleavage of tertiary amines by aqueous bromine has recently been studied by Deno and Fruit (3) primarily to explore the synthetic potential of this reaction. From a limited study of the reaction mechanism they proposed that the slow step involved loss of an α-hydrogen as a proton and the abstraction of the lone pair of electrons on nitrogen by bromine. The synthetic utility and limitations of the oxidation of tertiary amines by aqueous bromine have also been discussed by these authors. This reaction has the advantage of simplicity of reagents and reaction conditions. In addition yields are generally very good and the reaction was also found to be rapid for those amines studied. Furthermore, the inertness of amides towards aqueous bromine affords a means of protecting and reforming primary and secondary amines. On the other hand the reaction suffers from the disadvantages of poor selectivity with unsymmetrical amines, competing bromination of aromatic rings, particularly the alkoxy-substituted aromatics so prevalent in alkaloids, and bromine addition to unsaturated systems.

In view of the synthetic usefulness of this oxidative process we have undertaken an investigation of the reaction mechanism. An understanding of the mechanism, apart from being interesting in its own right, often provides control and flexibility in its synthetic applications. Furthermore, it was anticipated that a study of the mechanism would complement the work of Deno and Fruit (3) and as a result, the reaction would become more attractive for synthetic and degradative purposes.

Experimental

Solvents and Reagents

Reagent grade acetic acid, supplied by the Fisher Scientific Company, was used without further purification since it was observed to be resistant to oxidation by bromine under the conditions of these experiments. Bromine (Mallinckrodt analytical reagent grade) was also used directly without prior purification. The preparation and purification of the substituted benzyldimethylamines have been described in the preceding paper (4). Benzyldimethylamine-α,α-d_2 was obtained from Merck, Sharp and Dohme of Canada Ltd. Its chemical purity was verified by g.l.c. and its isotopic composition was confirmed by n.m.r.

Kinetic Methods

The rates of bromine oxidations can be estimated by following the reduction of Br_2 either iodometrically (3, 5, 6) or spectrophotometrically (7–9). The iodometric method is preferable since it can be used to follow the rate of the reaction in aqueous buffered media similar to those used for synthetic purposes. However, it was found that this method did not give adequate reproducibility when attempts were made to study the rate over a significant portion of the reaction. Previous workers who have used this method have been content to follow the rate during the initial 10% of the reaction (3); however, it is apparent that the results would be more meaningful if the rate of the reaction was followed for at least one half life. Consequently, an attempt was made to use a spectrophotometric method similar to the procedure which has been described for monitoring the rate of bromine substitutions (7).

The primary difficulty with the spectrophotometric method is associated with the fact that Br_3^-, which forms as the reaction proceeds, has a very strong absorption in the same region as Br_2. Consequently, the absorption band of Br_2 becomes obscured by the greater absorption of Br_3^- in buffered aqueous solutions. However, in mixed solvents such as 50% aqueous acetic acid, the absorption bands of Br_2 and Br_3^- intersect at 449 nm and the total amount of unreduced bromine (Br_2 plus Br_3^-) can be monitored at that particular wavelength (10). Hence, although 50% aqueous acetic acid is not the most common solvent for synthetic purposes it was used since more precise kinetic data could be obtained in this medium.

The absorption spectra of solutions of bromine (3.50×10^{-3} *M*) in 50% aqueous acetic acid with and without addition of potassium bromide were recorded and the point of intersection of the absorption curves of Br_2 and Br_3^- was found to remain constant at 449 nm. Furthermore the Br_2–Br_3^- system was found to follow Beer's law closely ($\varepsilon = 125.3$) between 5.07×10^{-3} and 1.78×10^{-3} *M*, the working kinetic range.

In a typical kinetic experiment solutions of the amine and bromine (the amine concentration being at least five times that of the bromine concentration) in 50% aqueous acetic acid were thermostated at 25.0 ± 0.1°. Then 2 ml of the amine solution and 1 ml of the bromine solution were added to a teflon-stoppered glass cuvette and a timer was started. After thoroughly mixing the solution by inverting the cuvette several times it was placed in the thermostated cell compartment of a Unicam SP500 Series 2 spectrophotometer and the absorbance at 449 nm was recorded at intervals using the amine solution in 50% aqueous acetic acid as the reference. A plot of ln (absorbance) against time was then prepared and the pseudo first-order rate constant calculated from the slope of the resulting straight line. For the first 50% of the reaction the deviations of the experimental points from the statistically best fit straight line were generally random; however when data up to 75% completion were analyzed, the pseudo first-order plots showed curvatures toward slower rates. This observation could be accounted for quantitatively by the formation of Br_3^- which is a less vigorous oxidant than Br_2 (11). A typical rate plot has been reproduced in Fig. 1.

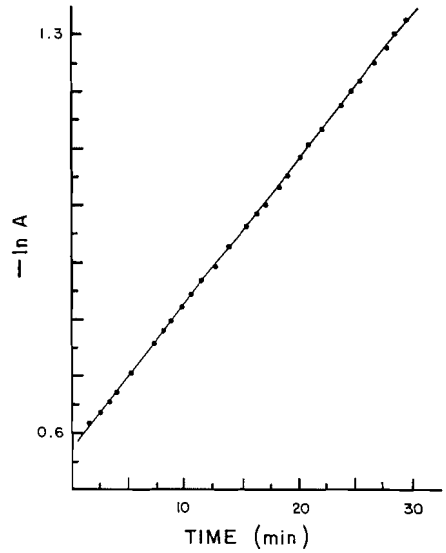

FIG. 1. Pseudo first-order rate plot.

Product Analysis

To a stirred solution of benzyldimethylamine (16.9 g, 0.125 mol) in 50% aqueous acetic acid (50 ml) at room temperature, bromine (4 g, 0.025 mol) in 50% aqueous acetic acid (75 ml) was added gradually. The solution was allowed to stand for about 3 h by which time the bromine had almost disappeared. The reaction mixture was added directly to 300 ml of 3 *M* hydrochloric acid containing 2,4-dinitrophenylhydrazine (9.90 g, 0.05 mol). The precipitated dinitrophenylhydrazone was filtered and dried to give 5.62 g (0.020 mol, 80%) of crude product (m.p. 228–232°). Crystallization from ethanol gave purified material (m.p. 235–236°; lit. m.p. 237° (12)), which was confirmed to be the 2,4-dinitrophenylhydrazone derivative of benzaldehyde from a mixed melting point measurement with an authentic sample.

Acidity Measurements

The acidities of solutions used in these experiments were measured by indicator procedures using *m*-nitroaniline and *p*-nitroaniline as indicators (13).

The pK_{BH^+} value for *m*-nitroaniline in 50% acetic acid was determined by use of eq. 1. The p*H* of the solution

$$[1] \qquad pK_{BH^+} = pH - \log([B]/[BH^+])$$

was changed by addition of variable amounts of 70% $HClO_4$ and the ratio $[B]/[BH^+]$ determined spectrophotometrically. The average pK_{BH^+} value calculated in this way was found to be 2.43 ± 0.03 in reasonable agreement with the value previously reported for this indicator in aqueous solutions of various mineral acids (13). Then by application of the indicator overlap technique (14) the pK_{BH^+} of *p*-nitroaniline was found to be 0.97, in excellent agreement with previous results (13). The H_0 values of 50% aqueous acetic acid solutions containing different concentrations of the amines which were used in kinetic experiments were then calculated from absorption measurements. The data obtained for the benzyldimethylamines are included in Table 1. From the data in this table it is quite apparent that the acidity of the medium is

dependent on the amount of amine present and that this fact must be taken into consideration in any quantitative treatment of the reaction kinetics.

Results

Since the oxidation of benzyldimethylamine was found to give benzaldehyde as the principal organic product (in agreement with the results obtained by Deno and Fruit (3) in an aqueous buffered medium) it is probable that the stoichiometry in both solvents can be represented by eq. 2. Furthermore it is to be expected that

$$[2]\quad RCH_2NR'R'' + Br_2 + H_2O \rightarrow RCHO + R'R''NH + 2HBr$$

the gross features of the reaction mechanism will be similar in the two solvent systems. However, it is not unlikely that some of the details may change significantly; for example, it is quite probable that the same rate law would pertain in both solvents, but it would be surprising if identical Hammett "ρ" and Brønsted "β" constants were obtained.

A logical starting point in the study of any reaction mechanism is to obtain the empirical rate law for the process. This was done by determining the order of the reaction with respect to each of the reactants. The results, obtained by varying the concentration of oxidant and reductant, indicated that the reaction was first order in bromine (Fig. 2) but that the order with respect to amine was slightly greater than unity (Fig. 3).

Consequently the rate law for the reaction can be expressed in the form of eq. 3, and the pseudo

$$[3]\quad -d[Br_2]/dt = k_2[\text{Amine}]^{1.1}[Br_2]$$

first-order rate constants obtained when the reaction was studied in the presence of excess amine would be given by eqs. 4 and 5.

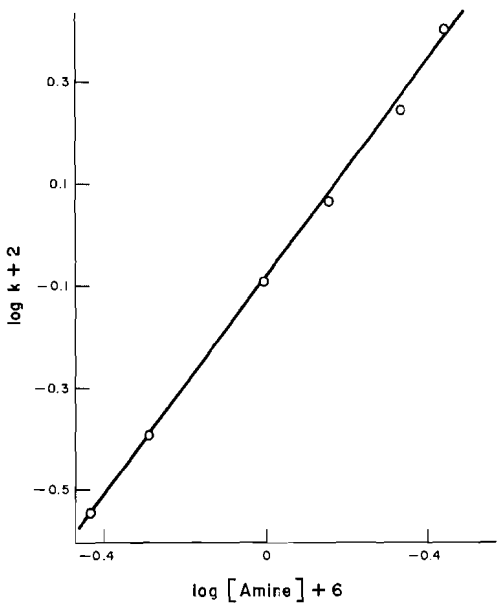

FIG. 3. Plot for determining the order with respect to benzyldimethylamine. Slope = 1.09 ± 0.02.

$$[4] \qquad -d[Br_2]/dt = k_1[Br_2]$$

$$[5] \qquad k_1 = k_2[\text{Amine}]^{1.1}$$

The decrease in rate of reaction associated with increasing acidity (Fig. 4) is undoubtedly due to a deactivating protonation of the amines which can be quantitatively accounted for if the pK_{BH^+} values for the amines are known. However because of the high acidity of 50% acetic

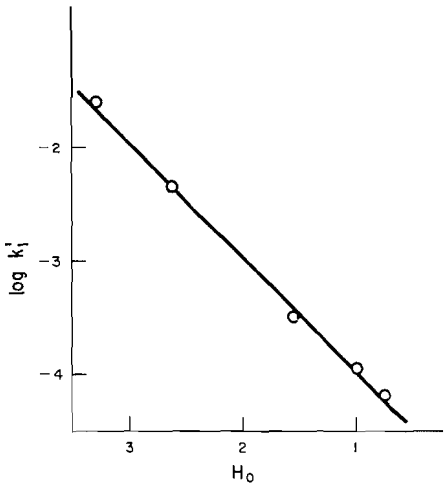

FIG. 4. Variation of rate with H_0.

acid accurate estimates of basicity constants cannot be obtained in this medium. Instead the pK_{BH^+} values were determined, as previously described (4), in 50% aqueous methanol. The necessity of changing to a different solvent system introduces the possibility of error in both the absolute and the relative rate constants for different amines. However an attempt to minimize such errors was made by using two solvents of similar *Y*-values (15), which can be expected to have similar solvating abilities. However, an understanding of the origin of *Y*-values makes it clear that two such solvent systems would have similar solvating properties with respect to carbonium ions, and not necessarily with respect to ammonium ions. Consequently this introduces a possible error into the ρ value that has been calculated by application of the Hammett equation (16) to the data in Table 1. However the error is not likely to be so large as to seriously affect the general conclusions that may be drawn.

The sign and magnitude of the ρ value and the correlation of rates with σ^0 substituent constants (and the lack of correlation with σ^+ constants) suggest that the amine fragment in the transition state is electron deficient compared to the ground state and that the electron deficiency is mostly on the nitrogen rather than on the benzylic carbon.

The reaction rate was found to be unaffected by light. No change in rate was observed when the reaction vessel was irradiated with a 250 W sunlamp. Hence, a free radical mechanism is probably not involved. Similar results were ob-

tained by Deno and Fruit (3) for the oxidation reaction in aqueous buffered medium.

That the reaction is subject to base catalysis was shown by studying the rates in the presence of several basic and non-basic salts. The results, which are presented in Table 2 and Fig. 5, clearly indicate that the rate is accelerated in the presence of sodium acetate and sodium benzoate, but slightly decreased in the presence of sodium chloride and sodium perchlorate. The acceleration caused by addition of acetate or benzoate ions is a clear indication of general base catalysis, whereas the decrease caused by the addition of chloride and perchlorate ions can be accounted for if one assumes that the transition state involves a significant participation by water. Addition of salts such as NaCl and $NaClO_4$ cause a decrease in the activity of water with the larger effect observed for chloride ion being in agreement with the known hydration properties of Cl^- and ClO_4^- (17). Similar trends attributed to the decrease in the activity of water accompanying the addition of these salts, have been reported in the literature (13, 18). For example, the effects of added salts on the kinetics of thallic ion oxidation of olefins in strongly acidic medium have also been explained in terms of the activity of water being altered by salts (19).

The addition of these salts to the solution alters its acidity. However, since the response of the rate to changes in acidity is known quantitatively it is possible to adjust all the rates to a common H_0 value. The adjusted rate constants are given in the last column of Table 2.

The observation of base catalysis also explains why the order with respect to amine is slightly greater than unity (Fig. 3). The amine in addition to being a reductant can also act as a base and thus increase the rate of reaction slightly.

The rate of oxidation of benzyldimethylamine-α,α-d_2 was found to be significantly slower than the rate of oxidation of the unlabelled compound under comparable conditions (Table 3). Rate decreases of this magnitude could be a reflection of either a secondary isotope effect (20) or a small primary isotope effect (21). A distinction between these two possibilities can be made by noting that the magnitude of the effect decreases by an amount well beyond the limits of experimental error when sodium acetate or sodium benzoate is added to the solution. Addition of these ions should cause no change in the magnitude of a secondary isotope effect, but could influence the primary effect if the rate determining step involved transfer of an α-proton to a base.

If the decrease in rate is due to a small primary isotope effect it follows from the theory elaborated by Westheimer (21) that the transition state must be extremely unsymmetrical with respect to transfer of the hydrogen to the base; *i.e.* either the carbon–hydrogen bond must be relatively intact *or* extensively cleaved in the transition state. If the former case were true adding more base would tend to make the transi-

†[Sodium benzoate] = 0.40 M.

tion state more symmetrical, and thus predict an increase in the magnitude of the isotope effect (in conflict with the experimental observations). On the other hand, if the proton was almost completely transferred to the base during the rate-limiting step, an increase in base concentration would tend to make the transition state even less symmetrical and thus reduce the magnitude of the isotope effect, in agreement with the data summarized in Table 3.

Hence the experimental results are most consistent with the suggestion that the diminution in rate which is observed on deuterium substitution is a consequence of a small primary isotope effect.

Discussion

The reaction mechanism is at least partially defined by the observations that the slow step involves cleavage of the α-carbon–hydrogen bond and that the transition state is electron deficient.

Carbon–hydrogen bond cleavage could be accomplished by either a homolytic or a heterolytic reaction. The possibility of a homolytic reaction is, however, eliminated by the observation that the rate is not changed on irradiation of the reaction vessel. Other free radical processes are known to be sensitive to light (22). Furthermore since the reaction rate correlates best with σ^0

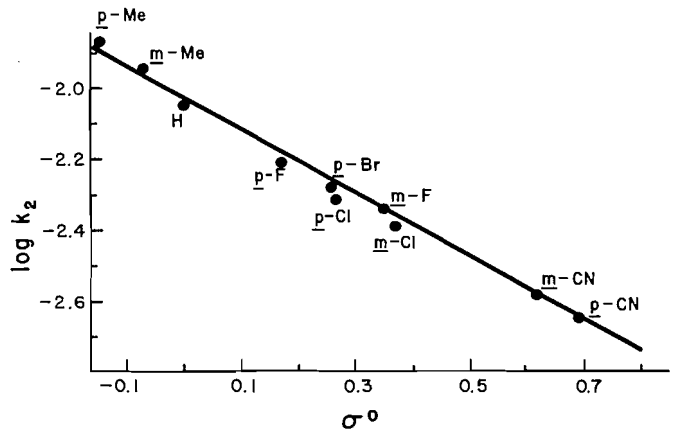

FIG. 6. Hammett plot for the oxidation of substituted benzyldimethylamines by bromine. [Amine] = 1.00×10^{-6}. Slope = -0.95 ± 0.04. Correlation coefficient = 0.99.

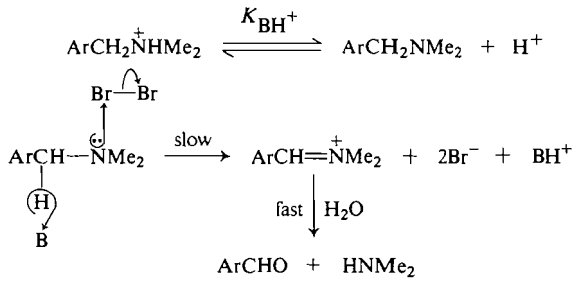
substituent constants affording a ρ value of −0.95, it also appears that a benzylic hydrogen is not abstracted as a hydride ion by bromine (Fig. 6). Such an abstraction would be expected to yield a much more negative ρ value. In reactions where considerable evidence for hydride transfer exists as in the oxidation of alcohols by bromine (23, 24) and the oxidation of amines by triphenylmethyl cation (3), ρ values of −2.29 and −2.0 were observed.

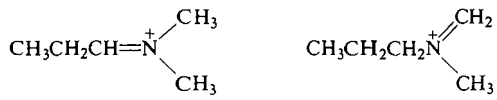
The negative ρ value also indicates that the rate determining step does not involve a simple loss of the α-hydrogen as a proton. Such a process would produce a negative charge on the transition state and the reaction would be expected to exhibit a positive ρ value. Loss of the α-hydrogen as a proton concomitant with electron transfer from the nitrogen to the oxidant is however, suggested by the experimental observations. In addition the small isotope effect is consistent with a transition state in which the α-carbon–hydrogen bond is extensively cleaved, and the observed base catalysis suggests that the hydrogen is transferred as a proton.

All of the results described herein are in quantitative agreement with the reaction sequence shown in Scheme 1.

This mechanism is also consistent with the previously reported product studies (3). For example, oxidation of dimethylpropylamine gave propanal as the main product, presumably because of the greater stability of intermediate **1** as compared to **2**. The former is a trisubstituted carbon–



SCHEME 1



1 2

nitrogen double bond whereas the latter is only disubstituted. Similarly the oxidation of dipropylbenzylamine gives mainly benzaldehyde because **3** allows for direct conjugation of the carbon–nitrogen double bond with the aromatic ring whereas **4** does not.

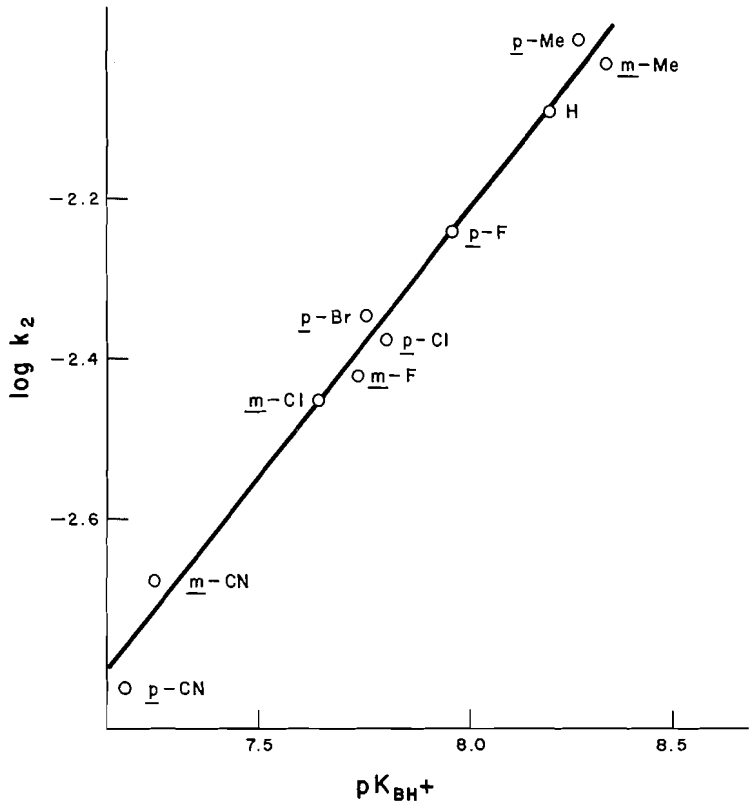

FIG. 7. Brønsted relationship between the rate of oxidation (in 50% aqueous acetic acid) and the basicity of substituted benzyldimethylamines (in 50% aqueous methanol). Slope = 0.67 ± 0.03. Correlation coefficient = 0.99.

The same reasoning also explains why the oxidation of benzyldimethylamine, which is described in this paper, gave benzaldehyde as the primary product, and it is significant to note that the yield of benzaldehyde increased from 52 to 70–80% on going from benzyldipropylamine to benzyldimethylamine.[1]

These observations also point out a difference between this reaction and the oxidation of the corresponding compounds by chlorine dioxide (25). The latter reaction, which is apparently initiated by a free radical abstraction results in preferential methyl cleavage during the oxidation of benzyldimethylamine.

Furthermore the Brønsted plot (Fig. 7) with $\alpha = +0.67$ indicates that there is a similarity between the transition state and the protonated amine (26). Had the substituent interactions on the protonation and oxidation reactions been identical a Brønsted slope of $\alpha = 1.00$ would have been expected. It is possible that the deviation from unity may be a solvent effect; however it should also be noted that an α of the magnitude observed in this work has been reported for other reactions where iminium ions have been proposed as intermediates (25).

The reaction also exhibits a steric effect; for example, oxidation diisopropyl – *n*-propylamine gives 50% propanal and only 21% acetone while benzylbis(1-methylbenzyl)amine gives 75% benzaldehyde and 5% acetophenone (3). It is possible

[1]It should be noted that the small primary isotope effect observed for this reaction may also be partially as a consequence of the fact that benzyldimethylamine can undergo cleavage of either the *N*-benzyl or the *N*-methyl bonds. Deuteration of the α-benzyl hydrogens would promote methyl cleavage and thus reduce the observed isotope effect.

to understand these results by noting that since the transition state also involves a base, which acts as a proton abstractor, disubstitution of the α-carbon would interfere with approach of base at that position.

N-Methylamino Acids in Peptide Synthesis. III. Racemization during Deprotection by Saponification and Acidolysis[1]

JOHN R. MCDERMOTT AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received March 5, 1973

The racemization of *N*-methylamino-acid derivatives in aqueous sodium hydroxide and hydrogen bromide in anhydrous acetic acid and other solvents has been investigated by determining the products of the reaction with an amino-acid analyzer after deprotection. Whereas MeIle-OMe, Z-MeIle, and the *N*-unmethylated derivatives were only slightly racemized (<2%), Z-MeIle-OMe (18–24%), Z-Ala-MeLeu-OMe (22%), and Z-Ala-MeLeu-OBu^t (7%) were appreciably racemized by aqueous sodium hydroxide. It is suggested that these derivatives racemize because of the absence of an >*N*—H or carboxyl group whose ionization would suppress ionization of the neighboring α-*C*—H bond. Z-MeIle and Z-Ala-MeLeu were substantially racemized (68% in 4 h and 34% in 1 h, respectively) by 5.6 *N* hydrogen bromide in acetic acid. The extent of racemization by acid varied with acid strength, polarity of solvent, and time. Incorporation of label into both isomers of Ala-MeLeu from a solution of the tritiated reagent established that ionization at the α-*C*—H bond had occurred. No racemization was caused by aqueous acid or by hydrogen chloride.

La racémisation des dérivés d'acide aminé *N*-méthylé dans la soude aqueuse et HBr dans l'acide acétique et autres solvants, a été étudiée par détermination des produits de réaction sur un analyseur d'acide aminé après déprotection. Tandis que le MeIle-OMe, Z-MeIle et les dérivés *N*-non méthylé subissent une racémisation légère (<2%), le Z-MeIle-OMe (18–24%), Z-Ala-MeLeu-OMe (22%) et Z-Ala-MeLeu-OBu^t (7%) se racémisent de façon notable dans la soude aqueuse. On pense que la racémisation de ces dérivés est due à l'absence d'un >N—H ou d'un groupe carboxyle dont l'ionisation empêcherait celle de la liaison voisine α-*C*—H. Z-MeIle et Z-Ala-MeLeu subissent une racémisation substantielle (68% en 4 h et 34% en 1 h respectivement) en présence d'acide bromhydrique 5.6 *N* dans l'acide acétique. L'étendue de la racémisation varie avec la force de l'acide, la polarité du solvant et la durée. Le marquage isotopique dans les deux isomère Ala-MeLeu à partir d'une solution de réactif tritié montre que l'ionisation se fait sur la liaison α-*C*—H. Il n'y a pas de racémisation par l'acide aqueux ou par l'acide chlorhydrique.

Protection of the amino function by the benzyloxycarbonyl group (2) and the carboxyl function as its methyl ester (3) is a widely used strategy in peptide synthesis. Selective deprotection of the *N*-terminus is accomplished by acidolysis, usually with hydrogen bromide in acetic acid (4), or by hydrogenation (2), and saponification is used to selectively remove the methyl ester (3). Racemization has generally been assumed to be negligible during these reactions, although a recent report (5) shows that saponification of a benzyloxycarbonyl-dipeptide methyl ester can cause a small degree of racemization.

Experience with derivatives of *N*-methylamino acids has been limited, and no one has investigated their susceptibility to racemization under conditions of saponification and acidolysis. Saponification has been used for the deprotection of several *N*-benzyloxycarbonyl- (6, 7) and *N*-*t*-butyloxycarbonyl-*N*-methylamino-acid (7) methyl esters, giving products in good yields with satisfactory optical rotations. An apparently stereochemically pure protected dipeptide, Z-Cys(Bzl)-MeTyr,[2] was obtained in excellent yield by saponification of the methyl ester (9). However, saponification of Ac-MePhe-OMe (6) and Z-MeAsp(OMe)-OMe (1) was attended by considerable racemization, and the seemingly curious observation that Ac-MeTyr-NHPh in ethanolic sodium hydroxide racemized more quickly than the corresponding unmethylated derivative is recorded in the literature (10).

TABLE 1. Racemization during the saponification of methyl esters*

Compound	Normality of NaOH	NaOH used (mol. equiv.)	Time (h)	Diastereomer formed (%)
Z-Ala-MeLeu-OMe	4	2	1/4	11
Z-MeIle-OMe	2	2	3	12
Z-MeIle-OMe	4	2	2	9
Z-MeIle-OMe	1	1.1	24	12
Z-Ala-Leu-OMe	1	1.1	1	<0.1
Boc-Ala-Pro-OMe	1	1.1	3	<0.1
Z-Ile-OMe	1	1.1	24	1.0
MeIle-OMe†	1	5	3	0.8
Z-MeIle-OH	2	2	3	0.8

*Two-three volumes of methanol added to the aqueous NaOH.
†No methanol added.

Products with high optical rotations were also obtained when *N*-benzyloxycarbonyl,*N*-methyl-amino-acid methyl esters were deprotected with 37% hydrogen bromide in acetic acid (6). However, measurement of optical activity is not a reliable test of stereochemical purity and small degrees of racemization may have been missed. We present here studies on the racemization attending the saponification and acidolysis of some *N*-methylated amino-acid and peptide derivatives by analysis with an amino-acid analyzer of the diastereomeric products of the reactions.[3] This work developed from the observation that two peaks corresponding to the L,L- and L,D-isomers were obtained on analysis with an amino-acid analyzer of Ala-MeLeu prepared by the saponification and hydrogenolysis of Z-Ala-MeLeu-OMe.

MeLeu-OMe.HBr was prepared by the hydrogenation of Z-MeLeu-OMe (6) in the presence of one molecular equivalent of hydrogen bromide, and coupled to Z-Ala by the mixed-anhydride method. The resulting oily protected dipeptide was saponified with 2 mol. equiv. of sodium hydroxide (1.25 *M* in 75% aqueous methanol), using the minimum reaction time required as determined by t.l.c. in a pilot experiment, and the product was converted to the free dipeptide by hydrogenation. Analysis showed it to contain 11% of the L,D-isomer. However, only 0.6% of the L,D-isomer was obtained on hydrogenation of Z-Ala-MeLeu-OBzl prepared by the same coupling technique (12). Thus considerable racemization had occurred during the saponification reaction—a surprising result in view of the general acceptance of this reaction in peptide synthesis.

Racemization was also detected when Z-MeIle-OMe was saponified under various conditions. The results together with data from other saponification experiments are shown in Table 1. Z-MeIle-OH underwent only slight racemization, as did Z-Ile-OMe, but no racemization was detected in the saponification of Z-Ala-Leu-OMe and Boc-Ala-Pro-OMe, thus emphasizing the different properties of the *N*-methyl derivatives.

It is difficult to compare the ease of racemization of esters of *N*-methylamino-acid derivatives with those of the corresponding amino-acid derivatives because the latter are hydrolyzed more readily than the former (15). It could be argued that since the amino-acid ester derivative is in contact with base for a shorter period of time, it would be expected to racemize less. To determine whether or not *N*-methylamino-acid derivatives are intrinsically more prone to racemize, the behavior of the *t*-butyl esters of Z-Ala-MeLeu and Z-Ala-Leu was investigated. As a precaution, only the neutral material was analyzed since unusual cases where *t*-butyl esters were saponified have been reported (16). The results in Table 2 show that both compounds racemized to some extent, and that there was a significant difference between the two compounds in the ease of racemization although it is less marked than the difference between the two methyl ester derivatives.

[3]A preliminary account of this work has appeared (11). The synthesis of the reference compounds and the chromatographic data for the various diastereomers are described in the accompanying paper (12). Analysis of diastereomeric products with an amino-acid analyzer has been used for determining amino-acid enantiomers (13), and as a test for racemization during peptide synthesis (14).

TABLE 2. Racemization of *t*-butyl esters by base*

Compound	Normality of NaOH	NaOH used (mol. equiv.)	Time (h)	Diastereomer formed† (%)
Z-Ala-MeLeu-OBu^t	1	1.1	1	3.3
Z-Ala-MeLeu-OBu^t	4	2	1/4	3.7
Z-Ala-Leu-OBu^t	1	1.1	1	0.3
Z-Ala-Leu-OBu^t	4	2	1/4	0.5

*Four volumes of methanol added to the aqueous NaOH.
†Corrected for the presence of a small amount of L,D-isomer in the starting material.

It is reasonable to assume that racemization occurred as a result of simple ionization at the α-carbon-hydrogen bond of the *N*-methylamino acid, although isoracemization in which the asymmetry is lost by ionization without dissociation (17, 18) cannot be ruled out. Why do *N*-methylamino-acid derivatives racemize more readily than the corresponding amino-acid derivatives? In an *N*-monosubstituted amino-acid ester, the $>N$—H will generally be more acidic than the α-*C*—H. Thus in base, this group will ionize first and so protect the neighboring *C*—H bond from ionization. In an *N*-substituted *N*-methylamino-acid ester, no such effect obtains, and the α-*C*—H will ionize more readily. Similarly, ionization of the free carboxyl group of an *N*-substituted *N*-methylamino acid will prevent further ionization at the α-carbon atom (19). Alternatively, Neuberger has proposed that the electron-donating methyl group favors the polar immonium form of the amide bond and that this encourages ionization of the neighboring *C*—H bond (19). From both these theories it would be predicted, however, that *N*-substituted proline derivatives should racemize as readily as *N*-methylamino-acid derivatives, but this is not the case. The reason for this is not clear.

Although the above results were obtained with only two systems (Ala-MeLeu and MeIle) there is nothing to suggest that they are not applicable to *N*-methylamino acids in general. It therefore appears that saponification should not be used during the synthesis of peptides containing *N*-methylamino-acid residues.

Racemization also occurred during the deprotection of *N*-methylamino-acid derivatives with hydrogen bromide in acetic acid. Z-Ala-MeLeu, prepared from the *t*-butyl ester, gave 0.4% L,D-isomer on hydrogenation, whereas treatment with 5.6 *N* hydrogen bromide in acetic acid gave 17% of the L,D-isomer. It was further discovered that Ala-MeLeu itself was racemized under these conditions. The effect of acid strength and duration of exposure on racemization was investigated (Table 3). Deprotection of Z-MeIle and Z-D-Me*a*lle was achieved with little racemization using 2.5 *N* hydrogen bromide, but stronger acid (5.6 *N*) over an extended period gave considerable racemization. An extended treatment of Z-Gly-Ala-MeLeu with the same acid also gave a partially racemized product. No racemization was detected for the derivatives of Ala-Leu and Ala-Pro, and only 0.3% for Z-Ile, even under drastic conditions.

During the above studies, it was found that the extent of racemization of Ala-MeLeu varied considerably, and not always in the predicted manner. Freshly prepared solutions of hydrogen bromide in acetic acid gave the highest values, and it was thought that accumulation of moisture in the reagent might be depressing the racemization. Indeed, when water was added deliberately to the reagent, no racemization took place.

Experiments with other solvents revealed that the extent of racemization increases with the polarity of the solvent (ether < dioxane < acetic acid). Various hydrogen chloride solutions did not cause racemization.

Thus concentrated hydrogen bromide in a dry, polar solvent can racemize *N*-methylamino-acid derivatives. Again, the presence of an $>N$—H group next to the α-*C*—H appears to inhibit racemization—contrast the values obtained for Z-MeIle (34%) and MeIle (3%) under the same conditions.[4] The difference between the values for Z-Ala-MeLeu and Z-Ala-Leu cannot be ascribed to different rates of cleavage of the benzyloxycarbonyl group, since the free peptide

[4]The results of Ikutani who showed that some *N*,*N*-dimethylamino acids, which lack the $>N$—H group, are unusually susceptible to racemization by hot dilute aqueous acid (20) are consistent with this view.
