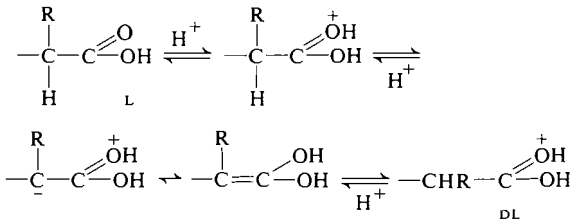
The acid-catalyzed racemization of amino acids in 6 *N* hydrochloric acid is well known (13, 19). Ionization of the α-*C*—H bond has been proposed as the mechanism (19), as follows:



Thus, heating amino acids in tritiated hydrochloric acid resulted in some incorporation of tritium into the α-position. The specific activity found for alanine was 3.5 times less than the value expected from the degree of racemization, however, and this has been attributed to an isotope effect (21).

Our results can be interpreted in these terms, since strong acid and polar solvent are essential requirements for racemization. To determine whether ionization and protonation were taking place, Ala-MeLeu was incubated in a tritiated solution of hydrogen bromide in acetic acid. The extent of racemization was determined on the analyzer as usual, and the amount of tritium incorporated into each diastereomer was determined by passing a second sample of the solution through the analyzer column, collecting the effluent in fractions, and determining their radioactivity with a liquid scintillation counter. The results are shown in Fig. 1. The peptide was found to contain 10% of the L,D-isomer, having a specific activity 6.5% of that of the original solution. The difference between these two values can be attributed to an isotope effect (21). The L,D-isomer also contained 2.6 times as much radioactivity as the L,L-isomer, a difference which can be attributed to asymmetric induction. A similar steric effect, although in an opposite sense, has been observed for isoleucine in tritiated hydrochloric acid, where the isoleucine had 1.4 times the radioactivity present in the *allo*-isoleucine formed by racemization (21). Ionization and protonation, therefore, unquestionably had taken place.

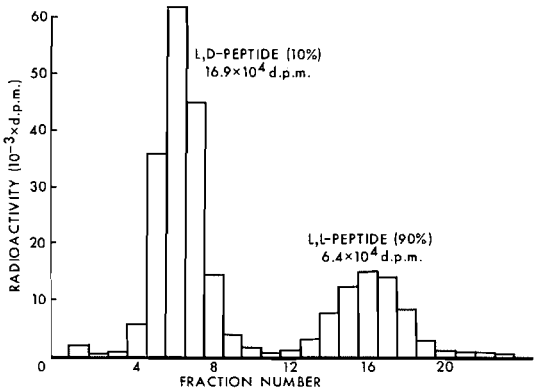

FIG. 1. Radioactivity incorporated into Ala-MeLeu after 4 h in tritiated HBr in acetic acid (saturated) at room temperature. The specific activity of the resulting L-Ala-DL-MeLeu was 1.17×10^6 d.p.m./mmol, corresponding to 9% of that of the original solution.

Again, the result for the proline dipeptide appears to be inconsistent with the theory that racemization is inhibited by the presence of an $>N$—H group next to the α-*C*—H, unless ionization of the derivative were followed by protonation solely at the "L"-position. A preliminary labelling experiment with Ala-Pro in tritiated hydrogen bromide in acetic acid gave an incorporation of less than 10% (the limit of detection with the system used) of that obtained for Ala-MeLeu, making this explanation unlikely.

It is evident that from a practical viewpoint, hydrogenation is to be preferred over acidolysis with hydrogen bromide for cleavage of benzyloxycarbonyl groups from *N*-methylamino-acid derivatives.

Experimental

Materials and Methods

L-Alanine, L-isoleucine, L-leucine, and L-proline were obtained from General Biochemicals, Chagrin Falls, Ohio, D-*allo*-isoleucine from ICN Nutritional Biochemicals, Cleveland, Ohio, and Boc-Ala from Pierce Chemical Company, Rockford, Illinois. Benzyloxycarbonyl-amino acids were prepared by the original procedure (2) as described by Greenstein and Winitz (22). Solvents were purified and dried by standard methods before use. Acetic acid was dried over $CaSO_4$, which was removed by filtration. Hydrogenations were done in the presence of 10% palladium on charcoal catalyst at atmospheric pressure. Solutions of hydrogen bromide were prepared by passing the gas (Matheson of Canada, Whitby, Ontario) into the solvent at 0 °C with the exclusion of moisture. Organic solvent extracts were dried with $MgSO_4$ and evaporated under reduced pressure using a rotary evaporator. Proton nuclear magnetic resonance (n.m.r.) (Varian T-60) and t.l.c. on silica gel GF_{254} in $CHCl_3$–MeOH (9:1) were used routinely to confirm the identity and purity of oils.

Analyses of diastereomeric amino acids and peptides were performed on a Beckman model 120B amino-acid analyzer using the long column (50 cm, AA-15 resin) and an intermediate length column (15 cm, Aminex A-5 resin) eluted with 0.20 *N* sodium citrate buffer, p*H* 4.25, at a flow rate of 68 ml/h (34 ml/h for MeIle (23)).[3] Benzyloxycarbonyl derivatives were deprotected by hydrogenation in 80% acetic acid for 4 h. *t*-Butyl-ester derivatives were treated with trifluoroacetic acid for 30 min before hydrogenation. The *t*-butyloxycarbonyl group was also removed with trifluoroacetic acid.

Z-Ala-MeLeu-OMe

Isobutyl chloroformate (2.6 ml; 20 mmol) was added to a solution of Z-Ala (4.66 g; 20 mmol) and triethylamine (2.8 ml; 20 mmol) in tetrahydrofuran (10 ml) at −10 °C, and the solution was stirred for 90 s. To this was added MeLeu-OMe.HBr (4.8 g; 20 mmol), prepared by the hydrogenation of Z-MeLeu-OMe (6) in the presence of 1 mol. equiv. of HBr, in tetrahydrofuran (15 ml) containing triethylamine (2.8 ml) and the suspension was stirred for 1 h at −10° and overnight at 0°. The reaction mixture was concentrated to an oil which was taken up in ethyl acetate (100 ml). The ethyl acetate was washed with water, *N* HCl, water, 5% aqueous $NaHCO_3$, and water (each 2 × 25 ml), dried, and evaporated. The residual oil was dried *in vacuo*. Yield 5.86 g (80%), homogeneous by t.l.c.; n.m.r. analysis consistent with the structure.

Z-Ala-Leu-OMe

This was obtained as an oil (88% yield) in the same manner from Z-Ala and Leu-OMe.HCl.

Z-Ala-Leu

Z-Ala-Leu-OMe (3 g) was dissolved in a mixture of methanol (9 ml) and 1 *N* NaOH (9 ml). After 1 h water (20 ml) was added, the solution was washed with ether (20 ml) and acidified to p*H* 1 with 4 *N* HCl. The resulting oil was extracted into ethyl acetate (2 × 30 ml), the extract was dried and evaporated to an oil. The oily Z-Ala-Leu was converted to the dicyclohexylammonium salt as described (24), recrystallized, m.p. 162–163°, lit. m.p. 163° (24), and regenerated as described (24). Yield 2.3 g, 80%.

Boc-Ala-Pro

Boc-Ala-Pro-OBzl was obtained as an oil (61%) by coupling Pro-OBzl.HCl (25) with the mixed anhydride of Boc-Ala. This was dissolved in ethyl acetate and hydrogenated for 8 h. Evaporation of the solvent gave an oil which was crystallized twice from ether – light petroleum b.p. 30–60°. Yield 94%, m.p. 154–155°, $(\alpha)_D^{28}$ −89.9° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{13}H_{22}N_2O_5.H_2O$: C, 51.3; H, 8.1; N, 9.2. Found: C, 50.8; H, 8.2; N, 9.1.

Z-MeIle, Z-D-MeAlle

These compounds were prepared from Z-Ile and Z-D-*a*lle by the room-temperature methylation procedure (1) using NaH (3 mol. equiv.) and methyl iodide (8 mol. equiv.) in tetrahydrofuran.

Boc-Ala-Pro-OMe, Z-MeIle-OMe, Z-Ile-OMe

The corresponding acid (1 mmol) was dissolved in ether (5 ml) and an ethereal solution of diazomethane was added dropwise until the first yellow color persisted. The excess reagent was destroyed with a drop of acetic acid, and the solution was evaporated to an oil. These oils were used without purification for the saponification experiments.

MeIle-OMe

Z-MeIle-OMe was hydrogenated in 80% aqueous acetic acid for 4 h, the solvent was removed by evaporation, and the resulting oil was dried *in vacuo* over KOH.

MeLeu-OBu^t

Z-MeLeu (8.0 g) (1) was *t*-butylated for 48 h using the method of Roeske (26). Yield 9.0 g (94%). The oil was hydrogenated in ethyl acetate (80 ml) for 4 h giving another oil upon evaporation of the solution (5.1 g, 98%). The n.m.r. analysis was consistent with the structure.

Z-Ala-MeLeu-OBu^t

This compound was prepared as an oil (R_f 0.78 on t.l.c.) in 87% yield by the mixed-anhydride coupling of Z-Ala (6.16 g) and MeLeu-OBu^t (5.10 g). Analysis after deprotection showed that it contained 0.4% of L,D-isomer.

Z-Ala-MeLeu

Z-Ala-MeLeu-OBu^t (6 g) was left in trifluoroacetic acid for 30 min at room temperature. The solution was evaporated and the product was partitioned between 5% aqueous $NaHCO_3$ and ether. The aqueous layer was brought to p*H* 1 with 4 *N* HCl, extracted with ethyl acetate (2 ×), and the extracts were dried and evaporated to give an oil. Yield 4.8 g (94%), R_f 0.7 on t.l.c.; n.m.r. analysis consistent with the structure.

Z-Ala-Leu-OBu^t

This was prepared by the mixed-anhydride coupling of Z-Ala with Leu-OBu^t (26) and recrystallized from ether – light petroleum. Yield 93%, m.p. 89–91°, lit. m.p. 90–92° (27). Analysis of a sample after deprotection showed that it contained 0.15% of the L,D-isomer.

Ala-MeLeu

Z-Ala-MeLeu (from the *t*-butyl ester) was hydrogenated in 80% aqueous acetic acid for 4 h. The solvent was evaporated and the crystalline product was dried *in vacuo* over KOH. Analysis showed that it contained 0.4% of the L,D-isomer. This compound was used for the acid-catalyzed racemization experiments.

Z-Gly-Ala-MeLeu

Z-Gly-Ala-MeLeu-OBu^t (0.1 g), prepared by coupling Z-Gly with Ala-MeLeu-OBu^t using *N*-hydroxysuccinimide–dicyclohexylcarbodiimide (12), was left in trifluoroacetic acid for 1 h at room temperature. The solution was evaporated and the residual oil was used directly.

Saponification

Methyl Esters

The methyl ester (0.5–2 mmol) was dissolved in methanol (2–3 times the volume of the NaOH solution used), and the aqueous NaOH was added. The mixture was shaken for the required time and water (20 ml) was added. Any neutral material was removed by extraction with ether (2 × 10 ml) and the aqueous layer was acidified to p*H* 1 with 4 *N* HCl (p*H* 3 with aqueous citric acid for Boc-Ala-Pro). The product was extracted into ethyl acetate (2 × 20 ml), the extracts were dried and evaporated, and the residue was deprotected and analyzed. The MeLeu-OMe reaction mixture was acidified to p*H* 2 and analyzed directly.

t-Butyl Esters

After the addition of water, the product was extracted into ethyl acetate (2 × 15 ml), the extracts were dried and evaporated.

Acid-catalyzed Racemization

The sample (0.1 mmol) was dissolved in the appropriate reagent (1 ml) in a flask protected from moisture. After the required time the solution was evaporated and the residue was dissolved in 0.2 *N* sodium citrate, p*H* 2.2, for analysis.

Tritium Exchange Experiments

Tritiated acetic acid was prepared by warming a mixture of ^3H_2O (25 mCi, 1 ml) and acetic anhydride (0.925 ml) at 60° for 24 h. Anhydrous $CaSO_4$ was added to remove the slight excess of water, the mixture was filtered, and hydrogen bromide was passed into the solution at 0 °C until saturation had occurred. Ala-MeLeu (43.6 mg; 0.2 mmol) was dissolved in the tritiated reagent (0.5 ml), and after 4 h the mixture was diluted to 10 ml with acetic acid. An aliquot (1.5 ml) was evaporated, the residue was taken up in 0.2 *N* sodium citrate, p*H* 2.2, and this was analyzed (Aminex A-5 resin, 15-cm column, p*H* 4.25 eluting buffer) for the peptide isomers and radioactivity with the amino-acid analyzer by incorporating a flow-cell scintillation counter assembly (Nuclear-Chicago model 4526) between the outlet of the column and the mixing coil. The two radioactive peaks coincided with the two ninhydrin-positive peaks. A second run was carried out, this time collecting the effluent from the column in 1.5 ml fractions, Each fraction was diluted with 15 ml of Aquasol (New England Nuclear, Boston, Massachusetts) and its radioactivity was measured with a Beckman LS-133 liquid scintillation counter. The values were corrected using a standard curve for tritium. The specific activity of the original solution was determined from the diluted solution, and found to be 1.28×10^7 d.p.m./mmol ^3H.[5]

Ala-Pro (36.8 mg; 0.2 mmol) was treated as described above, the radioactivity of the isomers being determined using the flow-cell assembly. Analysis showed 1% of the L,D-peptide, the labelled product having a specific activity 0.8% of that of the original solution.

We thank Dr. J. Rudinger and Dr. M. Goodman for helpful discussions.

[5]Assuming that the reaction mixture (1.54×10^8 d.p.m.) contained 12.2 mmol H^+: 0.6 mmol from the 0.2 mmol of peptide, 2.8 mmol of HBr, and 8.8 mmol (0.5 ml) of acetic acid. The increase in volume obtaining during the saturation of the acetic acid with HBr has not been taken into account. If a 25% increase had taken place, the specific activity of the solution would be 1.47×10^7 d.p.m./mmol.

N-Methylamino Acids in Peptide Synthesis. IV. Racemization and Yields in Peptide-bond Formation[1]

JOHN R. MCDERMOTT AND N. LEO BENOITON

Department of Biochemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received March 5, 1973

The racemization of an *N*-methylamino-acid residue during peptide-bond formation and mixed-anhydride activation has been investigated using Ala-MeLeu-Gly and Ala-MeLeu as model peptides. The results were compared with those for Ala-Leu-Gly, Ala-Leu, and Ala-Pro. The extents of racemization were determined by analysis of the diastereomeric products of the reactions after deprotection, using an amino-acid analyzer. Extensive racemization was detected after the hydrolysis of the mixed anhydrides of Bz-MeLeu, Z-Ala-MeLeu, and Z-Ala-Leu, but not of Boc-Ala-Pro and Z-MeIle. Significant racemization (2.8–39%) was observed when Z-Ala-MeLeu was coupled with Gly-OBzl by various methods in the presence of salts such as triethylamine hydrochloride or *p*-toluenesulfonate. Only coupling through the *N*-hydroxysuccinimide (HONSu) ester gave stereochemically pure product. In the absence of salt, less racemization was observed, but only couplings using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline and *N,N'*-dicyclohexylcarbodiimide–HONSu gave essentially pure products. Polar solvents promoted racemization, but excess base did not. Chemical evidence that the racemization intermediate is an oxazolium-5-oxide has been obtained by trapping the intermediate as an addition product (a pyrrole) in 85% yield.

The yields obtained by various coupling methods have been determined for several model peptides. Couplings at the carboxyl group of an *N*-methylamino acid gave high yields only in the absence of salt, except for coupling by the HONSu ester method. Couplings to an *N*-methylamino group gave high yields, except for coupling by the *p*-nitrophenyl ester method. Couplings to Ala-MeLeu-OBu^t gave higher yields than couplings to Ala-MeLeu-OBzl, presumably due to piperazine-dione formation by the latter.

La racémisation d'un reste acide aminé *N*-méthyle lors de la formation de la liaison peptidique et de l'activation par anhydride mixte, a été étudiée en utilisant les peptides modèles Ala-MeLeu-Gly et Ala-MeLeu. Les résultats ont été comparés à ceux obtenus pour Ala-Leu-Gly, Ala-Leu et Ala-Pro. L'étendue de racémisation a été déterminée par analyse des diastéréoisomères après déprotection et emploi d'un analyseur d'acide aminé. Une racémisation importante a été détectée après hydrolyse des anhydrides mixtes de Bz-MeLeu, Z-Ala-MeLeu et Z-Ala-Leu mais pas pour Boc-Ala-Pro et Z-MeIle. Une racémisation notables (2.8–39%) a été observée lors du couplage du Z-Ala-MeLeu sur le Gly-OBzl par les diverses méthodes en présence de sels tels que le chlorohydrate ou para toluène sulfonate de triéthylamine. Seul le couplage par l'ester de la *N*-hydroxy succinimide (HONSu) conduit à un produit de pureté stéréochimique. En l'absence de sel, la racémisation est plus faible mais seuls les couplages par le *N*-éthoxycarbonyl éthoxy-2 dihydro-1,2 quinoléine et le complexe *N,N'*-dicyclohexylcarbodiimide–HONSu donnent des produits essentiellement purs. Les solvants polaires favorisent la racémisation mais pas un excès de base. L'intermédiaire de racémisation oxyde-5 d'oxazolium a été mis en évidence par piegeage sous forme de produits d'addition (un pyrrole) avec un rendement de 85%.

Les rendements obtenus dans les divers couplages ont été déterminés sur différents peptides modèles. Les couplages sur le carboxyle d'un acide aminé *N*-méthylé se font avec des rendements élevés en l'absence de sel sauf pour la méthode de l'ester HONSu. Les couplages sur le groupe *N*-méthylamino se font avec des rendements élevés sauf pour la méthode de l'ester *p*-nitrophényle. Les couplages de l'Ala-MeLeu-OBu^t sont meilleurs que ceux de l'Ala-MeLeu-OBzl probablement à cause de la formation par ce dernier d'une pipérazine dione. [Traduit par le journal]

Can. J. Chem., 51, 2562 (1973)

Peptides containing *N*-methylamino acids form an important group of antibiotics (2) and are also of interest as analogs of peptide hormones (3). Many peptides of *N*-methylamino acids have been synthesized, but systematic studies in this area of peptide synthesis have not been carried out. The synthesis of these peptides is attended with the problems of the lack of crystallinity of intermediates, the tendency of intermediates to cyclize and the lesser reactivity of the methylamino group or steric hindrance (4), though the latter does not always manifest itself. Racemization has generally been assumed to be less of a problem than for ordinary peptides, because of the inability of *N*-acyl *N*-methylamino-acid de-

rivatives to form oxazolones (5), and because of their structural similarity to derivatives of proline whose resistance to racemization is well known. However, several observations are completely inconsistent with this assumption. Both *N*-methylphenylalanine and proline can be racemized by acetic anhydride in acetic acid (6), but only *N*-methyltryptophane and not proline was racemized by ketene at acid p*H* (7). Z-Gly-MePhe[2] was partially racemized as was Z-Gly-Phe during the formation of the *p*-nitrophenyl ester using tris-(*p*-nitrophenyl) phosphite but Z-Gly-Pro was not (9). And finally, a product with a lower specific rotation than that of the same product prepared by a different method was obtained from the DCCI-mediated coupling of Z-Cys(Bzl)-MeTyr with IleOMe (10). In the previous paper we have demonstrated the tendency of *N*-methylamino-acid derivatives to racemize during saponification and acidolysis (1). In this paper, we present a study on the racemization of *N*-methylamino-acid residues during peptide-bond formation, and a comparison of the yields obtainable by different methods for several model peptides.[3]

Our interest in racemization of *N*-methylamino acids during peptide synthesis arose from the observation that a mixed-anhydride coupling of Bz-MeLeu with *p*-nitroaniline gave a product devoid of optical activity (12). In preliminary experiments, it was then found that no optical activity remained after the mixed anhydride formed from Bz-MeLeu and ethyl chloroformate at 0° had been hydrolyzed. The extents of racemization for some other derivatives subjected to the same admittedly rather drastic activation conditions followed by hydrolysis are given in Table 1. Z-MeLeu racemized very little, but the extents of racemization of Z-Ala-MeLeu and Bz-MeLeu approached those of Z-Ala-Leu and Bz-Leu. Boc-Ala-Pro resisted racemization, as expected, but Bz-Pro racemized sufficiently to indicate that one should not disregard completely the possibility that proline residues might racemize during couplings.[4] The consistently low values observed for the two proline derivatives show that proline is atypical in not behaving like other imino acids, as has already been observed in the previous paper (1).

TABLE 1. Extent of racemization during the hydrolysis of mixed anhydrides*

Compound	Diastereomer or D isomer formed (%)
Bz-Leu	50†
Bz-MeLeu	45†
Bz-Pro	6.5†

Z-Ala-MeLeu	26.5‡
Z-Ala-Leu	38‡
Boc-Ala-Pro	0.1‡

*Mixed anhydride formed by reaction with ROCOCl–Et_3N in THF at 0° for 5 min. Water was then added.
†Determined by measurement of optical rotation. EtOCOCl used.
‡Determined by analysis after deprotection. Bu^tOCOCl used.

Further studies were then carried out on actual peptide synthesis using several standard coupling methods. The extents of racemization and the yields have been obtained throughout this work by determining the deprotected diastereomeric products of the reaction using an amino-acid analyzer. This method was chosen because the sensitivity and speed of this type of analysis have been demonstrated (14, 15) and because of our own experience with the analyzer (16). The elution conditions used and the elution times and ninhydrin color yields for the various diastereomeric pairs are given in Table 2.[5] The elution times and relative color yields for each pair were determined by analysis of the peptides prepared from the racemic amino acid, and the identity of the peaks and the absolute color yields for each isomer were established by analysis of the L,L-peptide. The standard instrument column and buffers,[6] plus the Aminex A-5 column which has been a standard part of our instrument for several years, sufficed for separating all the

[2]The abbreviations for the amino-acid and peptide derivatives are those recommended by the IUPAC–IUB Commission on Biochemical Nomenclature (8). When not indicated, the amino-acid symbols represent the L isomer, except for glycine. Other abbreviations used: DCCI, *N*,*N*′-dicyclohexylcarbodiimide; EEDQ, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline; HONSu, *N*-hydroxysuccinimide; NMM, *N*-methylmorpholine; NEPIS, *N*-ethyl-5-phenylisoxazolium-3′-sulfonate; THF, tetrahydrofuran.

[3]A preliminary account of this work has appeared (11).

[4]Partial racemization of a proline residue during coupling has in fact been reported (for the DCCI-mediated coupling of Bz(NO_2)-Pro with *p*-nitrophenol) (13).

[5]It is interesting to note the decrease in ninhydrin color constants in going from Ala-Leu-Gly (24.3), to Gly-Ala-MeLeu (13.6), Ala-MeLeu-Gly (5.7), Ala-MeLeu (1.1), and MeAla-Leu (<0.05).

[6]The concentrations given for the p*H* 4.25 buffer in refs. 11, 16, and 17 are in error. The correct concentration is 0.20 *N*.

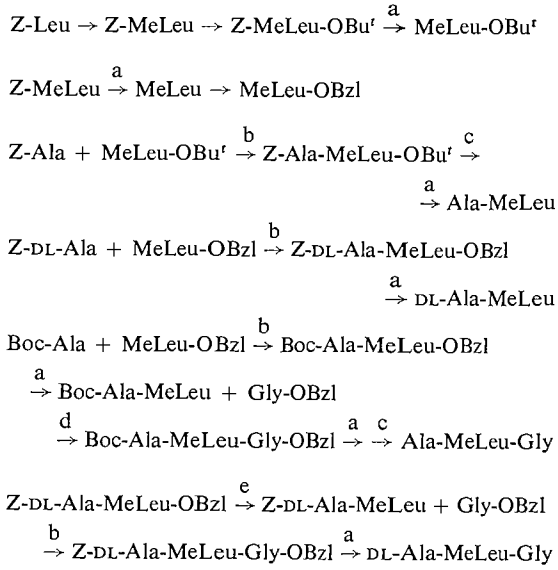
§Elution at 34 ml/h (16). Other constants at 34 ml/h: Ile, 39.1 (92 min); *a*lle, 39.3 (83 min); MeAla-Leu, 0.3 (82 min).

diastereomeric pairs. Though no experiments designed to test sensitivity were carried out, the peptide peaks were well enough separated to allow detection of about 1 part in 1000 of the other isomer, as has been reported by other workers (14, 15). The *N*-methylisoleucine–*N*-methyl-*allo*-isoleucine pair were less well separated, allowing detection of about 1 part in 200.

The methods used for the synthesis of the *N*-methylleucine peptides are shown in Scheme 1. Points to note are that the syntheses of the L,L-isomers had to be carried out without using saponification or acidolysis with hydrogen bromide, both of which cause racemization (1), and that the tripeptide was obtained by using DCCI–HONSu as the coupling agent for the reason which is apparent from Table 4.

The coupling of Z-Ala-MeLeu to Gly-OBzl was used to determine the extent of racemization during peptide-bond formation by various procedures. The crude product of the reaction was deprotected by hydrogenation, and the resulting tripeptide analyzed. The initial series of couplings were done in the presence of triethylamine *p*-toluenesulfonate or hydrochloride, derived from the salt of the appropriate Gly-OBzl. The results are shown in Table 3, together with those obtained for coupling Z-Ala-Leu to Gly-OBzl for comparison. Racemization occurred in varying degrees for all the coupling methods studied, except the HONSu ester method. Moreover, in



SCHEME 1. a, hydrogenation; b, mixed anhydride; c, trifluoroacetic acid; d, DCCI–HONSu; e, saponification.

all cases but one, the *N*-methylamino acid suffered more racemization than did the corresponding amino acid in the analogous peptide. The low extents of racemization obtained for Z-Ala-Leu-Gly-OBzl using DCCI–HONSu and EEDQ are in accord with the literature (15, 18, 19) except for the report of Kemp *et al.* (20). In the case of the DCCI–HONSu coupling, racemization clearly occurred during the formation of the active ester, since no diastereomer was formed when the HONSu ester was coupled. When *N*-methylmorpholine was used as base for the mixed-anhydride couplings, instead of depressing the degree of racemization as it normally does (21), it had the opposite effect.

In Table 4 are shown the results for couplings carried out using Gly-OBzl in the absence of salt of tertiary base. In this later work, crystalline Boc-Ala-MeLeu was used in preference to the oily benzyloxycarbonyl derivative. In a test case (DCCI), the yield and extent of racemization were, as expected, very similar for the two compounds. DCCI–HONSu and EEDQ caused much less racemization than in experiments with salt present, the former yielding a stereochemically pure product. The enhancement of racemization by salts (22, 23) has been attributed to the basicity of the anion (the chloride ion in particular) (13), the increased ionic strength of the medium (24),

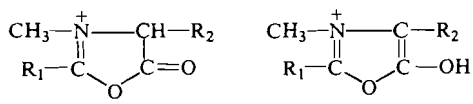
and more recently to both of these (25). We have shown that the addition of an equivalent amount of triethylamine to a DCCI coupling did not increase the percentage of L,D-isomer. Thus the racemization is not base-catalyzed, and only the increased ionic strength can be appropriate as an explanation here. The seemingly anomalous results obtained with *N*-methylmorpholine may be due to the higher solubility in THF of *N*-methylmorpholine hydrochloride compared to triethylamine hydrochloride, leading to an increased ionic strength of the solution. The mixed-anhydride coupling at −15° using a 30-s activation time (the conditions for minimum racemization) (21) gave less diastereomer but at the expense of a considerably reduced yield.

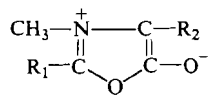
Racemization was considerably enhanced for both the mixed-anhydride and DCCI couplings when ethyl acetate was used instead of the less polar THF. This dependence on solvent polarity could explain why high extents of racemization were obtained for the NEPIS coupling where the solvent was acetonitrile. It is interesting to note that with this reagent under similar conditions (absence of chloride), Smart *et al.* were able to couple the racemization-prone Bz-Leu without diastereomer formation (22).

The absence of base catalysis indicates that the mechanism involved is not a simple α-hydrogen abstraction. *N*-Acyl *N*-methylamino acids cannot form oxazolones, and this has led to the oxazolonium salt **1** being proposed as the racemization intermediate (9, 13, 26). The oxazolonium (or more correctly the 5-oxo-Δ^2-oxazolinium) cation can racemize by loss of proton to give the mesoionic oxazolium-5-oxide **3** or by tautomerism to the 5-hydroxy-oxazolium cation **2**. The resonance stabilization of these two derivatives (the oxazolium ring is in fact pseudoaromatic (27)) could contribute to the ease with which *N*-methylamino-acid derivatives racemize.



1

2



3

Oxazolonium derivatives were thought to be extremely unstable, and evidence for their existence was derived from cryoscopic data obtained with Bz-MeGly in sulfuric acid (28) and from their implication in the mechanism of the Dakin–

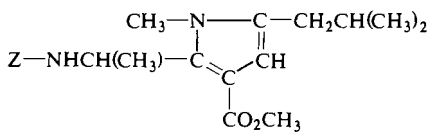
West reaction (29). Recently, however, several stable oxazolonium perchlorates have been prepared by treating *N*-substituted *N*-acylamino acids in acetic anhydride with perchloric acid (30).

The oxazolonium cation is a powerful acylating agent, giving a transient yellow color, ascribed to structure **3** when it is added to an amine (31, 32). We observed an immediate yellow color when we prepared the mixed anhydride of Bz-MeLeu or added DCCI to Bz-MeLeu. The oxazolium-5-oxides, prepared *in situ*, also undergo a 1,3-dipolar cycloaddition reaction with activated double and triple bonds (31), and we have made use of this reaction to show that oxazolonium-type intermediates can be formed under peptide coupling conditions. Z-Ala-MeLeu and DCCI were left in THF at room temperature for 10 min. Upon addition of methyl propiolate **4**, carbon dioxide was immediately evolved, and *N*,*N*′-dicyclohexylurea and the crystalline pyrrole **5** were obtained in about 85% yield. The plausible "classical" products of the

4



5

reaction would have been the *N*-acylurea derivative, which could not have been formed in large amounts, and the symmetrical anhydride of the protected peptide (33). But neither of these has the structural features required for a 1,3-dipolar cycloaddition reaction, therefore the pyrrole must have come from the oxazolium-5-oxide (**3**: R_1 = Z-NHCH(CH_3)—; R_2 = —$CH_2CH(CH_3)_2$), presumably formed in the reaction by cyclization to the oxazolonium cation followed by loss of a proton. This mechanism is consistent with the observations that the extent of racemization is (i) markedly dependent on solvent polarity and, seemingly, ionic strength which would be expected for a charged intermediate, and (ii) not affected by base, base catalysis being unnecessary for cyclization to an oxazolonium cation, the presumed rate-determining step.

The deprotonated mesoionic ring structure **3** is extremely unstable, and decomposes by dimerization (acylation at C-4) when unsubstituted at C-4(R_2 = H) (32). Treatment of Bz-MeGly with DCCI yielded the dimer resulting from α-*C*-acylation (34). It follows that if the oxazolonium cation is an intermediate in the coupling of *N*-methylamino-acid residues, the possibility that α-*C*-acylation might take place when sarcosyl is the coupling residue should be kept in mind. A practical implication of ignoring this danger might be that in the design of a synthesis, the decision to condense peptide fragments at sarcosyl residues in order to avoid racemization could prove to be more of a nuisance than an expedience.

It thus transpires that *N*-methylamino-acid residues seem to be just as prone to racemize during couplings as amino-acid residues, and even more so in the presence of salts. This is contrary to the generally accepted notions, which stem from their apparent structural similarity to prolyl residues, and could be attributed to the formation of the oxazolonium intermediate by the *N*-methylamino-acid derivative. The striking difference in behavior between the *N*-methylamino acid and proline could be due to the failure of the latter to form the oxazolonium intermediate. This in fact was proposed by Goodman and Stueben to account for the difference in behavior observed in the formation of the *p*-nitrophenyl esters (9). They suggested that the rigidity of the proline ring prevents the formation of a second contiguous ring. This appears to us a plausible explanation, but it must be borne in mind that under appropriate conditions, an oxazolonium intermediate can be formed even from a proline derivative. This had been suggested by Williams and Young (13) and has now been proved by Boyd and Wright who prepared the oxazolonium perchlorate from Bz(NO_2)-Pro (30).

The yields of tripeptide were determined in conjunction with the extents of racemization from the amino-acid analysis chromatogram (except as indicated in Table 3) for all the foregoing coupling reactions, and the results appear in Tables 3 and 4. They varied from 93% (DCCI–HONSu) to 52% (NEPIS) in the absence of triethylammonium salt and from 77% (DCCI–HONSu) to 45% (NEPIS) in the presence of salt. The yield was lowered by the presence of salt in all but the conventional mixed-anhydride case, where salt is always present. It is noticeable that

the two racemization-free coupling methods (DCCI–HONSu and EEDQ) gave the best yields. It is known that β-alanyl derivatives can be formed as side-products during DCCI–HONSu couplings when the formation of the intermediate HONSu ester is slow (35). A good correspondence was found between the yield of the tripeptide calculated from the amino acid analysis and the weight of the total neutral product, indicating that the amount of any such impurities in our case could not have been appreciable.

The yields for couplings between three other pairs of reactants were determined and the results are given in Table 5. Excellent yields of the dipeptide were obtained in all but the *p*-nitrophenyl-ester coupling. Allusions to the lesser reactivity of an *N*-methylamino group in couplings have been made (4, 36). From our findings it appears that couplings to an *N*-methylamino group proceed smoothly, with the exception of a classical activated-ester coupling, but that only moderate yields result when a *C*-terminal *N*-methylamino acid is activated for synthesis. More experiments with different peptides are needed to confirm this generalization.

The two tripeptides in Table 5 were used to investigate the importance of cyclization to the piperazine-2,5-dione, which is known to be a problem in synthesis with both proline and *N*-methylamino-acid derivatives (4). The dipeptide *t*-butyl ester gave very high yields indicating that the *t*-butyl ester provided adequate protection against this side reaction, whereas the dipeptide benzyl ester gave considerably lower yields, presumably because of the competing cyclization reaction (the piperazine-dione was not isolated). A high yield was nevertheless obtained with the benzyl ester when EEDQ was the coupling reagent. The explanation for this is not apparent to us.

Experimental

Materials and Methods

Amino acids were obtained from General Biochemicals, Chagrin Falls, Ohio; Boc-Ala and HONSu from Pierce Chemical Company, Rockford, Illinois; DCCI from Schwarz-Mann, Orangeburg, New York; EEDQ and NEPIS from Aldrich Chemical Company, Milwaukee, Wisconsin; methyl propiolate from K & K Laboratories Inc., Plainview, New York; Aminex A-5 resin from Bio-Rad Laboratories, Richmond, California. Benzyloxycarbonylamino acids were prepared by the original procedure as described by Greenstein and Winitz (ref. 37, p. 891). Solvents were purified and dried by standard methods before use. Light petroleum refers to the fraction boiling between 30–60°. Organic solvent extracts were dried with $MgSO_4$ and evaporated under reduced pressure using a rotary evaporator. When not specified, hydrogenations were carried out at atmospheric pressure in 80% aqueous acetic acid in the presence of 10% palladium on charcoal catalyst for 4 h. The catalyst was removed by filtration, the solution was evaporated, the evaporation was repeated several times after the addition of water, and the residue was dried *in vacuo* over KOH pellets. Optical rotations were determined with a Perkin Elmer model 141 polarimeter using a 1 dm tube. Proton nuclear magnetic resonance (n.m.r.) (Varian T-60) and t.l.c. on silica gel GF_{254} in chloroform–methanol (9:1) were used to confirm the identity and purity of oils. Diastereomeric amino acids and peptides were analyzed with a Beckman model 120B amino-acid analyzer according to Spackman *et al.* (38) using the conditions described in Table 2. Both the extent of racemization and the yield of a reaction were calculated from the same chromatogram of an aliquot of deprotected peptide using the data in Table 2.

The following compounds were prepared as indicated: Bz-Leu and Bz-Pro (ref. 37, p. 1266), Bz-MeLeu (40), Z-MeLeu (41), Boc-Ala-Pro (1), Z-Ala-Leu and Z-DL-Ala-Leu (42), Gly-OBzl.TosOH, Gly-OBzl.HCl, and Gly-OBzl (ref. 37, p. 928), Z-Ala-MeLeu (oil, containing 0.4% of the L,D-isomer) from the *t*-butyl ester (1).

MeLeu-OBzl.TosOH

A mixture of *N*-methyl-L-leucine (3.3 g, from the hydrogenation of Z-MeLeu in aqueous acetic acid), *p*-toluenesulfonic acid monohydrate (4.87 g), benzyl alcohol (20 ml), and benzene (60 ml) was heated under reflux for 36 h, the water formed being trapped in a Dean–Stark tube (44). The benzene was evaporated off,

ether (100 ml) and light petroleum (200 ml) were added, and the solution was left overnight at 0°. The crystals were collected, and recrystallized from ethyl acetate – methanol – light petroleum. Yield 7.0 g (72%), m.p. 116–117°, $[\alpha]_D^{25}$ −2.2° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{21}H_{23}NO_5S$: 61.9; H, 7.2; N, 3.4 Found: C, 61.5; H, 7.1; N, 3.4.

Boc-Ala-MeLeu

Boc-Ala (1.89 g) and MeLeu-OBzl.TosOH (4.04 g) were coupled by the mixed-anhydride method using Bu^{t}OCOCl (1.3 ml) and triethylamine (1.38 ml) in ethyl acetate (20 ml) at −10° as described below. The neutral product was an oil (3.6 g; 92%), giving a single spot on t.l.c., and whose n.m.r spectrum was consistent with the structure (Boc-Ala-MeLeu-OBzl). The oil was hydrogenated in ethyl acetate for 8 h. Removal of the solvent left an oil which crystallized upon trituration with light petroleum, and which was recrystallized from ether – light petroleum. Yield 2.0 g (75%), m.p. 107–109°, $[\alpha]_D^{28}$ −55.1° (*c*, 1 in ethanol).

Anal. Calcd. for $C_{12}H_{28}N_2O_5$: C, 56.9; H, 9.0; N, 8.9. Found: C, 56.4; H, 9.1; N, 8.4.

A sample (20 mg) was left in trifluoroacetic acid (0.5 ml) for 30 min and then analyzed. The product contained none (<0.1%) of the diastereomer.

Reference Compounds

The elution times and relative ninhydrin color yields for each diastereomeric pair of peptides were obtained by chromatography of the peptides synthesized from a racemic starting material. For convenience, in the case of the two *N*-methylamino acid peptides, one isomer of each diastereomeric pair was actually the enantiomorph of the L,D-isomer which was analyzed for. Moreover, some racemization undoubtedly occurred during the synthesis of these peptides at the mixed-anhydride coupling and saponification stages; however, the products would still be a mixture of diastereomers in equal amounts *i.e.*, L,L + D,D = D,L + L,D. The assignments of the two peaks obtained during chromatography and the absolute color yields of the isomers were then established by chromatography of a known amount of the stereochemically pure L,L-isomer.

N-methyl-L-isoleucine and *N*-methyl-D-*allo*-isoleucine were obtained by hydrogenation of Z-MeIle and Z-D-MeaIle prepared by the room-temperature methylation of Z-Ile and Z-D-*a*Ile (41). Ala-DL-Leu and Ala-DL-Pro were prepared from L-alanine *N*-carboxyanhydride and the free amino acid by the method of Manning and Moore (14), and used for analysis without purification. Ala-Leu was obtained by leaving Boc-Ala-Pro in trifluoroacetic acid for 30 min, evaporating the solution, and drying the residue *in vacuo* over KOH.

DL-Ala-Leu-Gly was obtained by hydrogenation (8 h) of Z-DL-Ala-Leu-Gly-OBzl, prepared by the mixed-anhydride (Bu^{t}OCOCl–Et_3N) coupling of Z-DL-Ala-Leu with Gly-OBzl.TosOH in THF. Ala-Leu-Gly was obtained by hydrogenation (8 h) of Z-Ala-Leu-Gly-OBzl prepared by the DCCI–HONSu-mediated coupling of Z-Ala-Leu with Gly-OBzl.TosOH as described below.

DL-Ala-MeLeu, as the hydrochloride, was obtained by a mixed-anhydride (Bu^{t}OCOCl–Et_3N) coupling of Z-DL-Ala (0.545 g) and MeLeu-OBzl.TosOH (1.06 g) in ethyl acetate (15 ml). The neutral product was isolated as an oil (1.07 g, 97%) which was hydrogenated in 80% aqueous acetic acid containing 2*N* HCl (1 mol. equiv.).[7] Ala-MeLeu was obtained by hydrogenation of Z-Ala-MeLeu.

DL-Ala-MeLeu-Gly was obtained by hydrogenation (8 h) of Z-DL-Ala-MeLeu-Gly-OBzl. The latter was the neutral product (oil, 0.55 g, 80%) obtained by the mixed-anhydride (Bu^{t}OCOCl–Et_3N) coupling of Z-DL-Ala-MeLeu (0.465 g) and Gly OBzl.TosOH (0.453 g) in THF as described below. The Z-DL-Ala-MeLeu (oil) was the acidic product (0.74 g, 77%) obtained by the saponification (2 h) of Z-DL-Ala-MeLeu-OBzl (0.97 g) in a mixture of methanol (8 ml) and 4 *N* NaOH (2.5 ml). Ala-MeLeu-Gly was the product obtained from the DCCI–HONSu-mediated coupling of Boc-Ala-MeLeu and Gly-OBzl described below. This was the first coupling to have given pure L,L-peptide.

Racemization during Hydrolysis of Mixed Anhydrides

The test compound (1–2 mmol) was dissolved in THF (5 ml) containing triethylamine (1 mol. equiv.) at 0°. Isobutyl chloroformate (1 mol. equiv.) was added with stirring, followed by water (2 ml) 5 min later. After 1 h at 0°, the THF was evaporated, and the residue was partitioned between ether (5 ml) and 5% aqueous $NaHCO_3$ (5 ml). The aqueous layer was acidified to p*H* 1 (p*H* 3 for Boc-Ala-Pro) with 3 *N* HCl, extracted with ethyl acetate, and the extract was dried and evaporated. Benzyloxycarbonyl derivatives were deprotected by hydrogenation, Boc-Ala-Pro by treatment with trifluoroacetic acid for 30 min, and the products were analyzed. The optical rotations of the benzoyl derivatives were measured, with the following results: Bz-Leu, $[\alpha]_D^{24}$ 0.0° (*c*, 1.8 in dimethylformamide); Bz-MeLeu, $[\alpha]_D^{24}$ −6.5° (*c*, 1 in dimethylformamide); Bz-Pro, $[\alpha]_D^{25}$ −83.3° (*c*, 4 in ethanol). Original values were, respectively: +7.0°, −54.0°, and −95.4°.

Coupling Methods for Racemization Experiments

The following methods were employed for coupling Z-Ala-Leu, Z-Ala-MeLeu, and Boc-Ala-MeLeu (0.5 mmol) with Gly-OBzl (0.5 mmol) (Tables 3 and 4). When salts of Gly-OBzl were used, triethylamine (0.5 mmol) was added to the ester salt. After the reaction, the solvent was removed by evaporation, the residual oil was taken up in ethyl acetate (10 ml), and the solution was washed with *N* HCl (2 × 5 ml), 5% aqueous $NaHCO_3$ (2 × 5 ml), and water (2 × 5 ml). The extract was dried and concentrated to an oil which was analyzed after deprotection by hydrogenation for 8 h. For couplings with Boc-Ala-MeLeu, aqueous citric acid was used instead of HCl for washing, and the hydrogenation was followed by treatment with trifluoroacetic acid (1 ml) for 30 min.

(i) DCCI (45)

DCCI (110 mg) was added to the reactants in the appropriate solvent (2 ml) and the mixture was stirred at room temperature for 18 h. The mixture was cooled, filtered, and the filtrate was evaporated.

---

[7]In the absence of HCl, only a small amount of ninhydrin-positive material was formed, presumably due to cyclization of the ester to the piperazine-dione after loss of the benzyloxycarbonyl group.

(ii) DCCI–HONSu (18)

As for the DCCI coupling except that HONSu (57 mg) was added to the reaction mixture before the DCCI.

(iii) HONSu Ester (46)

As for the DCCI–HONSu coupling except that the Gly-OBzl.HCl (0.101 g) in THF (1 ml) containing triethylamine (0.069 ml) was added 1 h after the DCCI and HONSu.

(iv) Mixed Anhydride (47)

The carboxy-containing component, base (0.069 ml of triethylamine or 0.056 ml of *N*-methylmorpholine), and isobutyl chloroformate (0.065 ml) were stirred in the solvent (2 ml) at −10° C for 90 s. The ester in THF (2 ml) was added, and the mixture was stirred at −10° for 1 h, and at room temperature for 1 h. One coupling was done under different conditions (Table 4).

(v) EEDQ (19)

A solution of the two reactants and EEDQ (129 mg; 5% excess) in THF (2 ml) was stirred at room temperature for 18 h. The neutral product was isolated as described above except that four washings with *N* HCl were carried out to remove the quinoline.

(vi) NEPIS (48)

The carboxy-containing component was stirred with NEPIS (127 mg) and triethylamine (0.069 ml) in acetonitrile (2.5 ml) at 0 °C for 1 h. The ester in cold acetonitrile (1 ml) was added, the mixture was stirred at 0° for 2 h, and then overnight at room temperature.

Couplings of Z-Ala + MeLeu-OBzl

Z-Ala (112 mg; 0.5 mmol) and MeLeu-OBzl.TosOH (202 mg) were coupled in THF (5 ml) using the methods described above. The neutral product was isolated and deprotected by hydrogenation in 80% aqueous acetic acid containing *N* HCl (0.5 ml) for 8 h. A solution of Z-Ala-ONp (39), MeLeu-OBzl.TosOH (202 mg), and triethylamine (0.069 ml) in dimethylformamide (2 ml) was kept at 37 °C for 36 h (43). The total neutral product was deprotected for analysis.

Couplings of Z-Gly + Ala-MeLeu-OR

Ala-MeLeu-OBzl.HCl (0.63 g; 91%; m.p. 157–160°; hygroscopic) was obtained by leaving Boc-Ala-MeLeu-OBzl (0.81 g) in dioxane containing hydrogen chloride (3.9 *N*, 10 ml) at room temperature for 1 h and evaporating the solution.

Ala-MeLeu-OBu^t.HCl (0.56 g; 70%; m.p. 176–178°) was prepared by hydrogenation of Z-Ala-MeLeu-OBu^t (1.1 g) (1) in *t*-butanol containing HCl (1 mol. equiv.) for 4 h. The product was obtained as a white solid by evaporating the solvent and drying the residual gel *in vacuo* over KOH.

Z-Gly (0.063 g) and Ala-MeLeu-OBzl.HCl (0.104 g) or Ala-MeLeu-OBu^t.HCl (0.092 g) were coupled in THF (2 ml) using the general methods described above, with triethylamine to neutralize the HCl. The nitrophenyl-ester coupling was carried out in dimethylformamide at 37° for 24 h. The neutral products were isolated to give Z-Gly-Ala-MeLeu-OBzl and Z-Gly-Ala-MeLeu-OBu^t as oils which were hydrogenated for 8 h. The *t*-butyl ester was treated with trifluoroacetic acid (1 ml) for 1 h before hydrogenation.

The color constant for Gly-Ala-MeLeu was determined from the deprotected product of the mixed-anhydride coupling of the benzyl ester. The product was washed with ether and dried *in vacuo* over KOH.

Trapping of Racemization Intermediate

Z-Ala-MeLeu (0.85 g) and DCCI (0.502 g) were stirred in THF (20 ml) at room temperature for 10 min. The mixture was cooled in ice, and methyl propiolate (0.50 ml) was added. There was an immediate evolution of carbon dioxide. The mixture was stirred at 0 °C for 2 h and then evaporated. The residue was suspended in acetone (20 ml), the mixture was kept at −10° for 3 h, and the *N,N'*-dicyclohexylurea (0.45 g; 83%) was filtered off. The filtrate was evaporated, the residue was taken up in ethyl acetate, and the solution was washed twice with aqueous $NaHCO_3$ and water, dried, and evaporated. The residual oil was crystallized (0.80 g) from ether – light petroleum and recrystallized from methanol–water. Yield 0.71 g (79%), m.p. 106–108°, n.m.r. δ($CDCl_3$–TMS): 7.31 (s, 5, $-C_6H_5$); 6.49 (s, 1, pyrrole); 5.11 (s, 2, $-CH_2O-$); 4.9 (b, 2, $-NHCH\langle$); 3.73 (s, 3, $-OCH_3$); 3.42 (s, 3, $\rangle NCH_3$); 2.84 (d, 2, $-CH_2-$, J = 7.0 Hz); 1.8 (m, 1, $\rangle CH-$); 1.52 (d, 3, CH_3-, J = 6.0 Hz); 0.92 (d, 6, $(CH_3)_2=$, J = 6.2 Hz).

Received January 15, 1973

Proton magnetic resonance data for uridine and uridine-5′-monophosphate, and the corresponding 6-azauracil analogs, are presented and discussed in terms of their overall three dimensional conformations in aqueous solution. The data reveal a destabilizing influence of the 6-aza base upon the gog and g′–g′ conformation of the ribose phosphate moiety.

Les données obtenues de la résonance magnétique du proton pour l'uridine, l'uridine-5′-monophosphate ainsi que les analogues correspondants aza-6 uracil, sont présentées et interprétées en termes de conformation totale tridimensionelle en solution aqueuse. Les données révèlent une influence déstabilisante de la base aza-6 sur la conformation g–g et g′–g′ de l'entité ribose-phosphate.

Can. J. Chem., **51**, 2571 (1973)

Introduction

There has been considerable interest in the antimetabolite behavior of 6-azauridine (azaU) which is known to have potent anti-leukemic properties (1). The nucleoside itself is not effective but is converted *in vivo* to 6-azauridine-5′-monophosphate (5′-azaUMP, Fig. 1) which inhibits the transformation of orotidine-5′-monophosphate (5′-OMP) to uridine-5′-monophosphate (5′-UMP) by the decarboxylating enzyme, orotidine-5′-monophosphate decarboxylase. Recently Saenger and Suck (2) have, by X-ray analyses, found that the *gauche–gauche* conformation about the $C_{4'}$—$C_{5'}$ bond which occurs exclusively in all previously-investigated nucleoside-5′-monophosphates is not assumed by 5′-azaUMP.

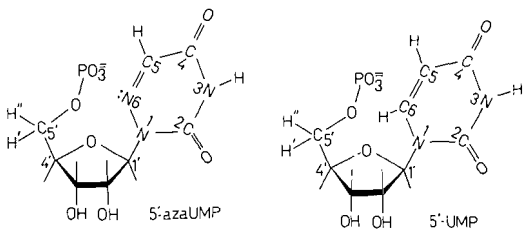

FIG. 1. Structural formula for 6-azauridine-5′-monophosphate (5′-azaUMP) and uridine-5′-monophosphate (5′-UMP).

[1]Postdoctoral Fellow.

The authors suggest that the presence of an unusual conformation (*gauche–trans*) might explain the inhibitory capacity of the aza derivative. In the present study we have obtained and analyzed the p.m.r. spectra of U(uridine), 5′-UMP, azaU, and 5′-azaUMP. Comparison of the p.m.r. data indicates that the presence of the 6-aza base has a marked destabilizing influence upon the *gauche–gauche* conformation of 5′-azaUMP and, therefore, that an unusual conformation of its ribose phosphate moiety is retained in aqueous solution.

Materials and Methods

Top grade azaU, 5′-azaUMP, and 5′-UMP were obtained from Calbio-Chem. The p.m.r. spectra of azaU (D_2O, 0.1 *M*, p*D* = 7.0, 30 °C, internal reference 3-trimethylsilylpropanesulfonic acid, DSS) were recorded at 220 MHz (Varian spectrometer, Canadian 220 Centre). Spectra for 5′-UMP and 5′-azaUMP (D_2O, 0.1 *M*, p*D* = 8.0, 30 °C, internal reference tetramethylammonium chloride, TMA) were obtained in the Fourier transform mode; details for obtaining FT spectra have been presented elsewhere (3). Both ^{31}P-decoupled and ^{31}P-coupled spectra were obtained and analyzed using LAME (4). Computer simulations of both the ^{31}P-decoupled and ^{31}P-coupled ^1H spectra were generated as a final test of the p.m.r. data. The experimental and simulated spectra for the mononucleotides are reproduced in Figs. 2–5. The experimental data are given in Table 1; the chemical shift and coupling constant data for U are taken from ref. 5. We would like to draw attention to, in particular, the 4′-region of 5′-UMP and 5′-azaUMP. In the case of 5′-UMP, a distinct sharpening of the

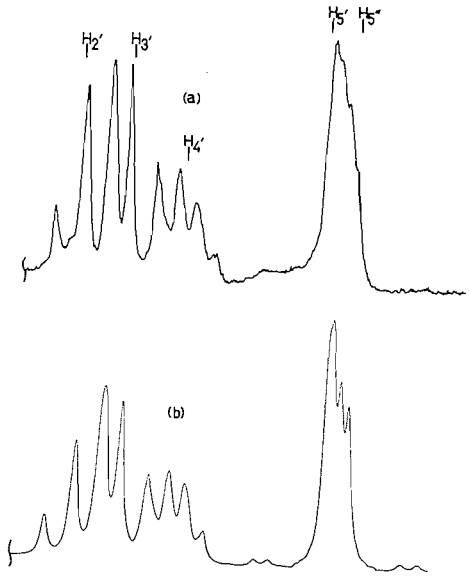

FIG. 2. (*a*) 100 MHz Fourier transformed spectrum of uridine-5′-monophosphate (5′-UMP) in D_2O, pD = 8.0, 0.10 *M*, with the phosphorus atom decoupled (2′ to 5″ region only). (*b*) Computer simulated spectrum.

4′-region is a consequence of P-decoupling (compare Figs. 2*a* and 3*a*). However, in the case of 5′-azaUMP, no difference is noted in the 4′-region of the ^{31}P-coupled and ^{31}P-decoupled spectra (Figs. 4*a* and 5*a*). LAME analysis generates a 1.8 Hz[2] P–$H_{4'}$ coupling for fitting of the experimental 4′-transitions of 5′-UMP, whereas no significant coupling (<0.1 Hz) was generated in the iterative fitting of the 4′-transitions of 5′-azaUMP. Thus, the presence of a long-range four-bond coupling between P and H-4′ is indicated for the uracil derivative but not for the 6-aza derivative.

Results and Discussion

It has been demonstrated that Karplus treatments of the vicinal 4′- to 5′-hydrogen coupling constants can yield information regarding the conformation about the $C_{4'}$—$C_{5'}$ bond of a nucleoside moiety (7–9). The main conclusion of these earlier studies was that the exocyclic CH_2OH group of a nucleoside interconverts, in solution, between the three principle staggered conformations (Fig. 6) with the relative populations of the conformational isomers dependent upon a number of factors including the nature of the base, furanose ring puckering, and solvent properties (9). In recent studies (8, 9), we have evaluated the $C_{4'}$—$C_{5'}$ conformational problem in terms of the experimental *sum* of $J_{4'5'} + J_{4'5''}$.

[2]A 2.2 Hz P–$H_{4'}$ coupling in 5′-UMP was reported by Smith *et al.* (6).

The use of this sum relies solely on the reasonable assumption that any vicinal *trans* H–H coupling (*ca.* 8–10 Hz) is larger than *all gauche* H-H couplings (*ca.* 2–4 Hz) experienced during the course of rotation about the $C_{4'}$—$C_{5'}$ bond. The sum allows for discussion of the relative contributions of the *gauche–gauche* (g–g) rotamer and the *combined* contribution from the *gauche–trans* (g–t) and *trans–gauche* (t–g) rotamers (Fig. 6). Evaluation of the individual contributions from the g–t and the t–g isomers requires, first of all, an absolute spectral assignment of the 5′-hydrogens which can be ultimately carried out only by selective deuteration at the 5′-position (a reasonable assignment for several molecules, based on phosphate field effects, has been presented by Remin and Shugar (10)). In addition corrections for the orientation-dependent effect of the electronegative furanose-ring oxygen (11) need be applied to, in particular, the *gauche* couplings. Until such time that these corrections can be estimated, it is our contention that the use of the sum $J_{4'5'} + J_{4'5''}$ provides a more than adequate guide for monitoring perturbations in time-averaged conformations about the $C_{4'}$—$C_{5'}$ bond in a nucleoside or nucleotide.

Assuming that these sums provide a meaningful basis for monitoring nucleoside (tide) structure, then a number of qualitative predictions

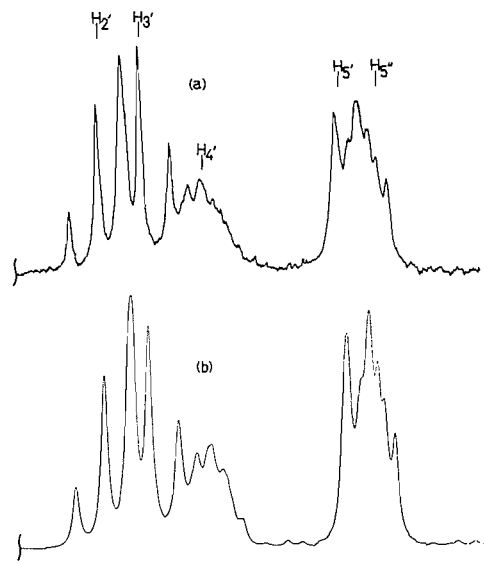

FIG. 3. (*a*) 100 MHz Fourier transformed spectrum of uridine-5′-monophosphate (5′-UMP) in D_2O, pD = 8.0, 0.10 *M*, without phosphorus decoupled (2′ to 5″ region). (*b*) Computer simulated spectrum.

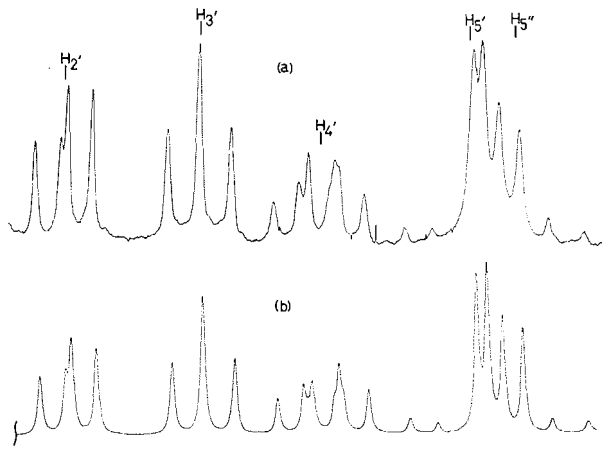

FIG. 4. (*a*) 100 MHz Fourier transformed spectrum of 6-azauridine-5′-monophosphate (5′-azaUMP) in D_2O, pD = 8.0, 0.10 *M*, with phosphorus decoupled (2′ to 5″ region). (*b*) Computer simulated spectrum.

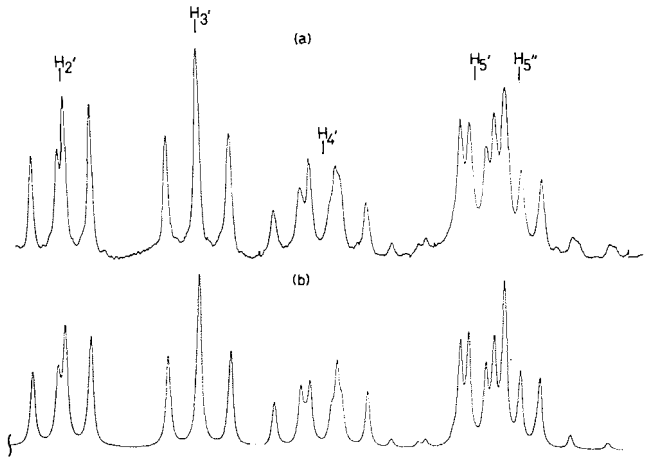

FIG. 5. (*a*) 100 MHz Fourier transformed spectrum of 6-azauridine-5′-monophosphate (5′-azaUMP) in D_2O, pD = 8.0, 0.10 *M*, without phosphorus decoupled (2′ to 5″ region).

can be made using Fig. 6. Clearly for the g–g conformation in which the 5′-O lies above the ring, the magnitudes of both $J_{4'5'}$ and $J_{4'5''}$ are predicted to be small (2–4 Hz) since the coupled nuclei are oriented *gauche*. However, if the 5′-O lies off the ring in either the g–t or t–g rotamer the 4′-hydrogen lies *trans* to one of the 5′-hydrogens and the corresponding vicinal coupling is expected to be large (*ca.* 8–10 Hz). Thus, any perturbation resulting in an *increase* in the g–g rotamer population should be manifest by a *decrease* in the experimental *sum* $J_{4'5'} + J_{4'5''}$ whereas an increase in the g–t and/or t–g populations, at the expense of the g–g conformer, should result in an *increase* in the observed sum (7, 8). Also, perturbations in molecular conformation about the $C_{5'}$—$O_{5'}$ bond can be monitored in an analogous fashion (12) (Fig. 7). In the g′–g′ rotamer, the P atom is *gauche* to each of the methylene hydrogens and therefore the *sum* $J_{P\text{-}H_{5'}} + J_{P\text{-}H_{5''}}$ is expected to be small (*ca.* 6 Hz) (13). In the g′–t′ and t′–g′ rotamers, however, the *sum* is expected to be large (*ca.* 24 Hz) since the P -atom is now *trans* to one of the 5′-hydrogens (13).

The experimental sums, $J_{4'5'} + J_{4'5''}$ (7.4 Hz for U; 8.8 Hz for azaU), indicate that the presence of the 6-azauracil base has a destabilizing influence, relative to uracil, upon the g–g orientation about the $C_{4'}$—$C_{5'}$ bond of a nucleoside.

†Taken from ref. 5.

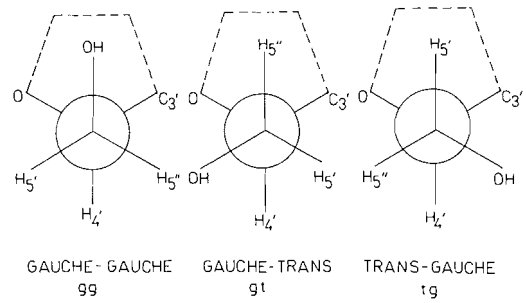

FIG. 6. Staggered conformations about the $C_{4'}$—$C_{5'}$ bond.

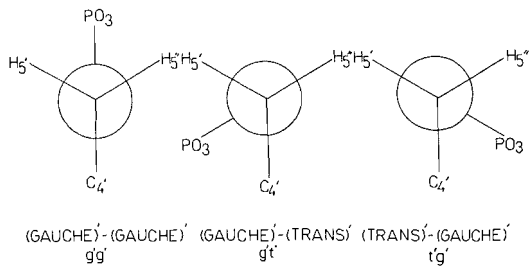

FIG. 7. Staggered conformations about the $C_{5'}$—O_5 bond.

The apparent destabilizing effect is even more pronounced for the monophosphate derivatives for which an *increase* of 5.2 Hz in the sum is evident when uracil is substituted by the 6-aza base (Table 1). Manipulation of eqs. 1–3 in ref. 7 allows for derivation of a simple relationship between P_{gg} (the fractional population of the g–g rotamer) and $\sum$(the observed sum of $J_{4'5'} + J_{4'5''}$):

$$[1] \qquad P_{gg} \simeq (12 - \textstyle\sum)/8$$

which provides rough estimates of g–g population. Substitution of the data into eq. 1 leads to P_{gg} values: U (60%); azaU (40%); 5′-UMP (80%); 5′-azaUMP (15%).

A similar expression may be derived for the $C_{5'}$—$O_{5'}$ bond of the monophosphates. Assuming $J_{P\text{-}H}$ (*gauche*) $\simeq$ 3 Hz and $J_{P\text{-}H}$ (*trans*) $\simeq$ 21 Hz (13), we can derive the relationship

$$[2] \qquad P_{g'g'} \simeq (24 - \textstyle\sum')/18$$

where $P_{g'g'}$ and $\sum'$ are the population of the g′–g′ rotamer and the observed sum $J_{P\text{-}5'} + J_{P\text{-}5''}$. The derived $P_{g'g'}$ values, 5′-UMP (90%), 5′-azaUMP (70%) suggest a but slight destabilizing influence of the 6-aza base upon the g′–g′ rotamer of a 5′-nucleotide.

Support for the above arguments is provided by the long-range four-bond $J_{P\text{-}4'}$ coupling in 5′-UMP (revealed by the decoupling experiments, Figs. 2, 3) but not in 5′-azaUMP (Figs. 4, 5). Four-bond H–H coupling constants are known to be strongly dependent upon the stereochemical arrangement of the intervening bonds

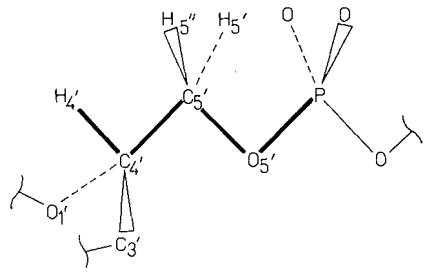

FIG. 8. The all *trans*, "W", spatial arrangement between the phosphorus atom and the 4′-proton.

and largest for the all-*trans* (W) conformation (14). Hall and coworkers (13, 15–17) have presented clear evidence that H–P coupling in H—C—C—O—P fragments follow a similar stereo-relationship. The "W" relationship between the phosphorus and 4′-hydrogen, of a 5′-mononucleotide, is encountered when the molecule is simultaneously oriented g–g and g′–g′ (Fig. 8) but is destroyed by rotation about *either* of the $C_{4'}$—$C_{5'}$ or $C_{5'}$—O bonds into one of the *trans* conformations. Thus, in view of the work by Hall *et al.* concerning the stereospecificity of four-bond H–P couplings in phosphate esters, we are inclined to present the $^4J_{P\text{-}4'}$ values for 5′-UMP (1.8 Hz) and 5′-azaUMP (<0.1 Hz) as further evidence for the suggested destabilizing influence of a 6-azauracil base upon the g–g and g′–g′ conformers.

The apparent destabilization of the g–g and g′–g′ rotamers in 5′-azaUMP is most reasonably interpreted in terms of a repulsive electrostatic interaction between the 6-aza nitrogen and the negatively charged 5′-phosphate.[3] This electrostatic interpretation, mentioned by Saenger and Suck (2) in their discussion of the crystal conformation of 5′-azaUMP, is supported by theoretical calculations (2, 23) which indicate that the C-6 position of the uracil base is a *positive* center whereas the 6-aza nitrogen is *negative*. These theoretical estimates of charge density at the 6-position and the negative charge on the phosphate, at neutral or basic p*H*, form a reasonable basis for discussion of *not only* the calculated *decrease* in the g–g rotamer in going from 5′-UMP to 5′-azaUMP *but also* of our calculated *increase* in g–g population of 5′-UMP relative to U (which suggests the presence of an attractive interaction between a uracil base and a 5′-phosphate) and our calculated *decrease* in g–g population of 5′-azaUMP relative to azaU. Furthermore our estimates of the rotamer populations at the nucleoside level point to a repulsion between the 6-azanitrogen and the 5′-hydroxyl of azaU but the interaction must certainly be attenuated relative to that involving a negatively charge phosphate in the 5′-nucleotide.

A consideration of space-filling molecular models leads us to suggest at this point a probable sequence of rotation of a g–g, g′–g′ oriented 5′-nucleotide into one of the *trans* conformations about the $C_{4'}$—$C_{5'}$ and $C_{5'}$—O bonds. In the g–g conformation steric interactions of the phosphate with the base and 2′,3′-hydrogens tends to restrict rotation about the $C_{5'}$—O bond to the g′–g′ conformation. However, after rotation of the molecule about the $C_{4'}$—$C_{5'}$ bond into the g–t, or t–g, form, rotation about $C_{5'}$—O becomes less sterically hindered. We suggest, therefore, that the appearance of the g′–t′ and t′–g′ rotamers of a 5′-mononucleotide is likely only after rotation of the molecule out of the g–g form, which in the case of 5′-azaUMP is most reasonably traced to the suggested base-phosphate repulsion.

The vicinal ribose H–H coupling constants $J_{1'2'}$, $J_{2'3'}$ and $J_{3'4'}$ can be discussed via the Karplus relation in terms of a favored mode of ring puckering. In a qualitative manner the similarity in corresponding *J* values indicates a similar ribose conformation for U, 5′-UMP, azaU, and 5′-azaUMP, which may be reasonably considered in terms of an equilibrium model involving interconversion between C-2′ *endo* and C-3′ *endo* mode[4] (7). Comparison of the

[3]This interpretation assumes an *anti* conformation for the uracil and 6-azauracil derivatives. In this conformation the 6-position of the base is located over the ribose and in close proximity to the 5′-O when the molecule is oriented g–g. Available spectroscopic evidence suggests that the *anti* range of conformers is favored, for these molecules, in both the crystal state and in aqueous solution (2, 18–22).

[4]The authors realize that furanose conformations have been discussed in terms of the 20 possible puckering modes (26). We also realize that use of p.m.r. data to confirm the presence of *one* particular mode is futile and consider the approach outlined recently (27) which discusses segments of the pseudorotational cycle thought to be significantly populated. By C-2′ *endo* we mean simply that conformation in which $H_{1'}$, $H_{2'}$ assume a quasi axial:axial (a:a) relationship and $H_{3'}$, $H_{4'}$ a quasi equatorial:equatorial (e:e) relationship and by C-3′ *endo* that conformation in $H_{1'}$, $H_{2'}$ are quasi e:e and $H_{3'}$, $H_{4'}$ are quasi a:a. In effect we mean by C-3′ *endo* and C-2′ *endo* terms the N and S conformations in the nomenclature recently presented (28) (see also ref. 3 for a useful discussion of furanose puckering).

relative magnitudes of $J_{1'2'}$ and $J_{3'4'}$ for the nucleotides suggests a slight preference for a C-2′ *endo* mode in 5′-UMP but a slight preference for a C-3′ *endo* mode in 5′-azaUMP. In the crystal state, the ribose moieties assume similar conformations; U (18) and azaU (19) are C-3′ *endo* while 5′-azaUMP (2) is C-3′ *endo* C-2′ *exo*. The crystal data for 5′-UMP are not available; however, in UpA the uridine fragment is found in the C-3′ *endo* C-2′ *exo* conformation (24, 25).

Conclusion

P.m.r. data for 6-azauridine and 6-azauridine-5′-monophosphate are presented and compared to those of the corresponding uracil derivatives. The data reveal a pronounced destabilizing effect of the 6-azauracil base upon the *gauche–gauche* conformation of the 5′-monophosphate. This effect is also noted at the nucleoside level but to a lesser extent. These observations are interpreted in terms of an electrostatic repulsion between the electronegative 6-azanitrogen of the base and the 5′-phosphate (or hydroxyl) group. Our evidence indicates a predominance of an unusual (*trans*) conformation about the $C_{4'}$—$C_{5'}$ bond of 5-azauridine-5′-monophosphate in aqueous solution in accord with observations of Saenger and Suck for the crystalline nucleotide, and lends support to their rationalization of the antimetabolite behavior of the molecule.

NOTE ADDED IN PROOF: A recent publication (29) has discussed the consequences of substitution by the aza nitrogen at the 6-position of uridine on the ribose chemical shifts and conformation. Also of interest is the X-ray study (30) of formycin, a C-ribosyl nucleoside with an aza nitrogen *ortho* to the glycosyl linkage; the structural features of this molecule also point to an electrostatic repulsion between this aza nitrogen and the sugar $O_{5'}$ atom.

This research was supported in part by grants from the National Research Council of Canada, The Research Corporation of New York, The National Cancer Institute of NIH, and the National Science Foundation. The Faculty of Graduate Studies of the University of Manitoba are gratefully acknowledged for a post-doctoral fellowship to D. J. Wood. The fast Fourier transform system was bought by funds furnished by the National Science Foundation and the State University of New York. The authors acknowledge illuminating discussions with Drs. B. Pullman, A. Saran, W. Saenger, and M. Sundaralingam. We also thank Dr. W. Saenger for forwarding to us a copy of his reprint (ref. 2), and Dr. Arthur A. Grey and Mrs. Valerie Robinson of the Canadian 220 MHz Centre, Sheridan Park, Ontario, Canada, for obtaining 220 MHz spectra.

Photo-additions of Naphthalene Derivatives with Substituted Ethylenes: Influence of Methoxy- and Cyano-substituents on the Products

TERENCE RICHARD CHAMBERLAIN AND JOHN JAMES MCCULLOUGH[1]

Department of Chemistry, McMaster University, Hamilton, Ontario

Received December 18, 1972

Irradiation of 2-methoxynaphthalene and acrylonitrile in ethanol affords *exo*- and *endo*-7-cyano-6-methoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene, in the ratio 30:70. The structures are assigned from the n.m.r. spectra. The *endo* compound is the more stable, and on base equilibration predominates (90%). These adducts eliminate a methoxy-group on treatment with *tert*-butoxide at 80°, to afford 2,3-naphthocyclobutene carboxamide. Irradiation of 2-cyanonaphthalene and methyl vinyl ether in ethanol gives a complicated mixture of adducts which includes the cyclobutane 7-methoxy-6-cyano-2,3-benzobicyclo-[4.2.0]octa-2,4-diene as a major product (35%). Also formed are 7-methoxy-2,3(8-cyanobenzo)bicyclo-[3.3.0]octa-2,7-diene (8%), 8-methoxy-10-cyano-1,2-benzocycloocta-1,3,5-triene (18%), and a dimer of the latter (7%), and 8-methylene-5-methoxy-2,3(10-cyanobenzo)bicyclo[2.2.1]heptene (35%). The structures of the latter adducts are assigned from spectroscopic data, including nuclear Overhauser effects. Possible mechanisms for formation of the latter adducts, and a rule for prediction of regiospecificity in cyclobutane formation, are proposed.

L'irradiation du méthoxy-2 naphtalène et de l'acrylonitrile dans l'éthanol conduit à l'*exo* et l'*endo* cyano-7 méthoxy-6 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 dans le rapport 30:70. Les structures ont été attribuées à partir des spectres r.m.n. Le composé *endo* est plus stable et prédomine par équilibration basique (90%). Ces adduits éliminent un groupe méthoxy par traitement au *tert*-butoxyde à 80° pour conduire au naphto-2,3 cyclobutène carboxamide. L'irradiation du cyano-2 naphtalène et du méthyl-vinyléther dans l'éthanol conduit à un mélange complexe d'adduits comprenant le cyclobutane méthoxy-7 cyano-6 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 comme produit majoritaire. Comme autres produits, on trouve le méthoxy-7 (cyano-8 benzo)-2,3 bicyclo[3.3.0] octadiène-2,7 (8%), le méthoxy-8 cyano-10 benzo-1,2 cyclooctatriène-1,3,5 (18%), le dimère de ce dernier (7%), et le méthylène-8 méthoxy-5 (cyano-10 benzo)-2,3 bicyclo[2.2.1] heptène (35%). Les structures des derniers adduits ont été attribuées à partir des données spectroscopiques, en particulier par des effets Overhauser nucléaires. Les mécanismes possibles de formation de ces derniers adduits et une règle pour prédire la régiospecificité de la formation du cyclobutane ont été proposés. [Traduit par le journal]

Can. J. Chem., **51**, 2578 (1973)

Previous work in our laboratory has shown that, in photo-additions of naphthalene with various substrates, the donor–acceptor properties of the reactants can determine the structures of products (1–4). For example, in the photoreaction of naphthalene with acrylonitrile (2), a protonation process has been discovered (3*a*), which is certainly dependent on the acceptor role of acrylonitrile. The reaction of naphthalene and pyrrole, however, is best explained by assuming the pyrrole to act as an electron donor (4).

The possible importance of charge-transfer in the photo-addition reactions of benzene and its derivatives with substituted ethylenes (5, 6) has been pointed out by Bryce-Smith (7). The light-induced additions of benzene with cyclobutene (8, 9), tetramethylethylene (10, 11), and 2-butene (11) have been reported. The tetramethylethylene reaction is influenced by an acid catalyst (10), suggesting that charge-transfer processes are important, *cf.* naphthalene–acrylonitrile addition (3).

Recently, photochemical additions of anthracene and 9-cyanoanthracene with dienes in the $4\pi + 4\pi$ and $4\pi + 2\pi$ modes have been described, and the authors have remarked on the effect of the electron-withdrawing, cyano-group on the products formed (12).

One approach we have taken in attempting to evaluate the importance of charge-transfer in photochemical additions was to study the reactions of naphthalene, substituted with an electron-donating or electron-withdrawing group with oppositely substituted ethylenes (1).

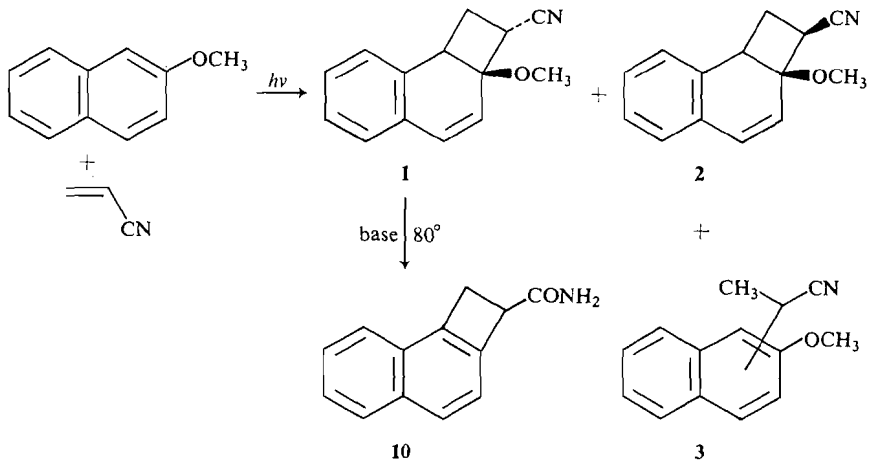
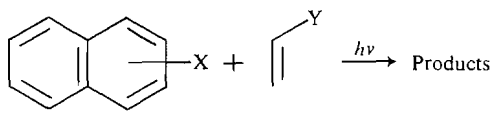


SCHEME 1



(X is electron-donating, Y is electron-withdrawing or vice versa)

In this paper, we are reporting the structures of the adducts formed on photolysis of methoxynaphthalene and acrylonitrile, and of 2-cyanonapthalene with methoxyethylene. The idea of studying these pairs of reactants followed the reports of Schulte-Frohlinde and co-workers (13), in which they describe the effect of donor–acceptor properties of a quencher and quenchee, on singlet and triplet quenching. The present study is a step in the continuation of our work with napthalene and acrylonitrile (2, 3, 14).

Results

2-Methoxynaphthalene and Acrylonitrile

The dimerization of 2-methoxynaphthalene in a $4\pi + 4\pi$ mode is apparently the only photochemical process known for this compound (15, 16). Irradiation of 2-methoxynaphthalene and acrylonitrile in ethanol using a pyrex filter causes a smooth addition to occur.[2] The reaction is shown in Scheme 1.

The product distribution was measured by v.p.c., which gave **1**, 70%; **2**, 25%, and **3** ~3%. The cycloadducts **1** and **2** were separated by column chromatography and fractional crystallization, and both were crystalline solids. Their structures were assigned as follows. Equilibration with *tert*-butoxide showed that **1** and **2** are epimers, with **1** the more stable (see below). The gross structures followed from this and their mass spectra, the latter showing weak parent ions of *m/e* 211, with the base peaks at *m/e* 158 corresponding to methoxynaphthalene cation, resulting from cyclobutane ring cleavage (14). Adduct **1** also decomposed on sensitized photolysis, giving 2-methoxynaphthalene, a known reaction of this ring system (2, 3). This evidence indicated that **1** and **2** were the epimeric 7-cyano-6-methoxy-2,3-benzobicyclo[4.2.0]octa-2,4-dienes.

The detailed structures were assigned from the n.m.r. spectra, which are shown in Fig. 1, and the data are collected in Table 1.

In adduct **1**, the doublet of doublets at 3.36 was removed by treatment with methoxide and D_2O in pyridine, which identifies the resonance with H-7, α to the nitrile. The doublet of triplets at 3.52 may then be assigned to H-1, and the splitting pattern, together with the result of decoupling experiments which show that coupling between H-1 and -7 is small, demands that H-1 and -7 cannot be vicinal, and the nitrile function must be at C-7.

The stereochemistry of the nitrile substituent is more difficult to assign. Equilibration of **1** with *tert*-butoxide gives a mixture of **1** and **2** in the ratio 9:1 (v.p.c.), showing that the minor photolysis product is also the less stable isomer. The latter is also quite labile, and was observed to revert to the equilibrium mixture on crystallization from hot petroleum. This was in part responsible for the difficulty experienced in isolating **2**.

[2]This contrasts with the reported lack of reaction between 2-methoxynaphthalene and maleic anhydride on irradiation (15*a*), a result which we have confirmed.

*Chemical shifts (p.p.m.), coupling constants (Hz), and multiplet structures of proton resonances in **1**, **2**, and **5**; s = singlet, d = doublet, t = triplet, m = multiplet, dd = doublet of doublets, etc.

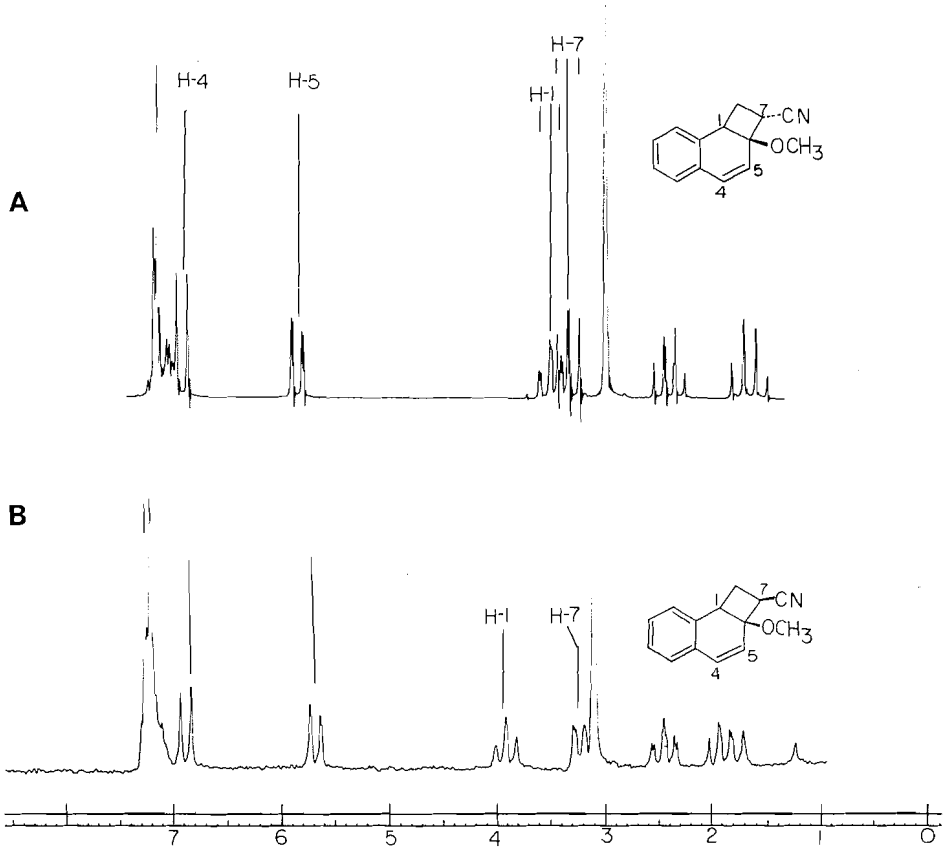

FIG. 1. 100 MHz n.m.r. spectra of **1** and **2**. A, spectrum of **1** (*endo*); B, spectrum of **2** (*exo*). The solvent was $CDCl_3$.

Noting that in the demethoxy series the *endo*-isomer **4** is the more stable (14), the above observation on the equilibration of **1** and **2** suggests **1** is *endo* and **2** is *exo*. This assignment is supported by the n.m.r. spectra at 100 MHz, which are shown in Fig. 1 and Table 1.

The important difference in the n.m.r. spectra appears in the resonances of H-7. In **1**, this resonance is a doublet of doublets, with J = 9.0 and 10.0 Hz. The resonance was positively identified with H-7 since it was removed by treatment with base and deuterium oxide, as already mentioned. The corresponding resonance in **2**, however, is a doublet with J = 9.0 Hz, further split with small coupling constants of 2.5 and 1.5 Hz. The magnitudes of these coupling constants point to the *endo* configuration for **1** and *exo* for **2**, if the four-membered ring has the same geometry in these adducts as in the demethoxy compound **4**, shown in Scheme 2. The shape of the latter is known from an X-ray study (14). In **1**, H-7 will be axial and should therefore be coupled strongly to the methylene group protons, since axial–axial and axial–equatorial vicinal coupling constants in cyclobutanes are large (17). In compound **2**, however, H-7 experiences one equatorial–equatorial coupling to the methylene group, and this is consistent with the coupling constant of 2.5 Hz (17). The large vicinal coupling (9.0 Hz) is, of course, due to the equatorial–axial splitting.

In both of the isomers, the H-1 resonance is basically a triplet with J = 9.0 and 10.0 Hz, which is consistent with the assigned structures shown in Scheme 2.

Spin decoupling experiments demonstrated that there are some small, long-range splittings in these compounds. For example, H-1 is coupled to H-5 in both isomers, with J = 1.0–1.5 Hz. In **2**, H-1 is also coupled to H-7 with J = 1.5 Hz, a splitting which appears to be absent from **1**, and, interestingly, is also absent

1 (90%) 2 (10%)

4

SCHEME 2

from the spectrum of **4** (14). This further strengthens the argument that **1** and **4** have essentially the same stereochemistry.

Treatment of a mixture of **1** and **2** with *tert*-butoxide in *tert*-butyl alcohol at reflux (80°), followed by aqueous acid work-up, resulted in expulsion of the methoxy group and aromatization to form the naphthalene derivative, 1,2-naphthocyclobutene-3-carboxamide (**10**). The structural evidence is given in the experimental. The above photo-addition is therefore a key to a convenient route to the 2,3-naphthocyclobutene system.

The substituted naphthalenes **3** were not purified on account of their oily nature and low yield. The n.m.r. spectrum of the fraction from chromatography of the photolysis mixture containing these products showed the characteristic methyl resonances (doublets) at high field, methine quartets, and the aromatic multiplet at low field (2). Thus, there is no doubt that substituted naphthalenes are formed, although their precise structures are unknown.

2-Cyanonaphthalene and Methoxyethylene

The photo-dimerization of 2-cyanonaphthalene has recently been reported (18). Irradiation of 2-cyanonaphthalene and methoxyethylene in ethanol, using a Pyrex filter, afforded five 1:1 adducts. These were separated by column chromatography and all were crystalline solids. The assigned structures are shown in Scheme 3.

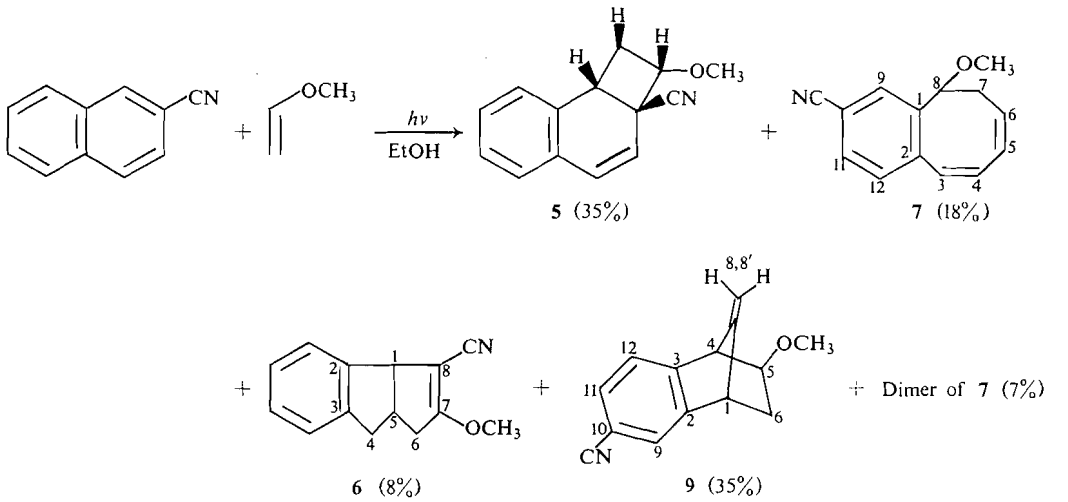
Since one of the products is particularly photolabile, the relative yields are variable, and the figures in Scheme 3 represent yields in a typical run. The product distribution was measured by v.p.c.

Structure **5** was easily assigned by comparison with cyclobutane structures obtained in other reactions (see above, and ref. 2). The compound decomposed on photolysis, consistent with the cyclobutane structure (2, 3). In the n.m.r. spectrum, which is described in Table 1, the significant features are the resonances (doublets) at 6.65 and 5.65 due to the vinylic protons, and the doublet of doublets at 4.35 with coupling constants of 8.5 and 7.0 Hz. The latter is assigned to H-7 (α to the methoxy-group), and since the resonance is a doublet of doublets, it shows that the methoxy-group is at C-7. We tentatively assign the *endo*-stereochemistry to the methoxy function, by analogy with **1**, **2**, and **4**; **5** is therefore *endo*-7-methoxy-6-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene.

The three other monomeric adducts were suspected not to be cyclobutane derivatives, since they were relatively stable to irradiation, and did not cleave in the fashion expected for cyclobutanes on electron impact (14). Their structures are derived mainly from the n.m.r. spectra, which are described below and in Fig. 2. The numbering used agrees with Scheme 3.

The n.m.r. spectrum of **6** (220 MHz, $CDCl_3$ solution) had the following resonances (number-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



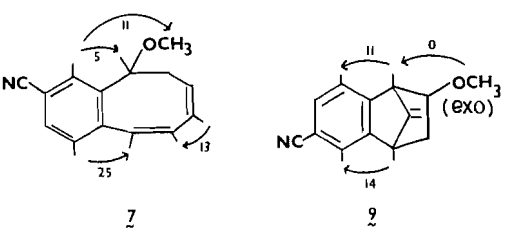
SCHEME 3

ing as in Scheme 3): 7.48 (area 1) and 7.23 (area 3) both multiplets, assigned to the aromatic ring; a complex multiplet at 3.15 (area 1), assigned to H-5; and a doublet at 4.34 (area 1), assigned to H-1. This doublet, which had $J = 7.0$ Hz, collapsed to a singlet when the multiplet at 3.15 (H-5) was irradiated. The remaining resonances, of the two methylene groups, occurred at 2.36 (doublet $J = 18.0$ Hz), 2.82 (multiplet), and 3.20 (multiplet). The resonance of the methoxy group was a singlet (area 3) at 4.02, which is consistent with a methyl vinyl ether (19). The downfield shift of one proton of the aromatic ring indicates that this proton is in the deshielding region of, and close to the cyano-group (20, 2*b*). The mass spectrum showed ions of *m/e* 211 (100) (parent and base peak) and 115 (46) (indenyl cation). In the i.r., the cyano-function absorbed at 2200 cm^{-1}, showing that it is conjugated with the double bond. The evidence all points to the structure 7-methoxy-8-cyano-2,3-benzobicyclo[3.3.0]octa-2,7-diene (**6**).

Compound **7** showed in the n.m.r. (100 MHz, $CDCl_3$ solvent) the protons of the aromatic ring at 7.80 (area 1) doublet, $J = 2$ Hz assigned to H-9; at 7.54 (area 1) doublet of doublets, $J = 2.0$ and 8.0 Hz due to H-11; at 7.24 (area 1) doublet, $J = 8.0$ Hz assigned to H-12. The diene system gave resonances at 6.53 (area 1) doublet, $J = 12.0$ Hz assigned to H-3; at 6.22 (area 1) doublet, $J = 12.0$ Hz assigned to H-4. The latter doublet was broadened by coupling to other protons, probably H-5 and -6. The resonance assigned to H-5 and -6 occurred at 5.66 (area 2) as overlapping singlets, and the protons of the methylene group (H-7) resonated at 2.54 and 3.02 (both areas 1). The methine proton H-8 resonated at 5.12 (area 1) doublet of doublets, $J = 11.0$ and 4.0 Hz. The methoxy group gave a singlet at 3.24 (area 3).

The above data show that the aromatic ring carried the cyano-group, that there are two ethylenic bonds, and that there is a methoxy-group and three aliphatic protons. These data allow the ring-expanded structure of **7** to be assigned. It does not, however, permit the location of the methoxy- or cyano-groups to be determined.

The latter structural details were determined by nuclear Overhauser effect (n.O.e.) measurements. These measurements were performed as described by Bell and Saunders (21). The increases in intensity in the observed signals, when various resonances were irradiated, are summarized in Fig. 2.



7 8

FIG. 2. Nuclear Overhauser effects in adducts **7** and **8**. Arrow tail indicates proton irradiated; arrow head indicates proton observed. Values give % increase in the observed signal intensity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The 20–25% enhancement of the H-12 signal intensity when H-3 resonance was irradiated, and the observed effects between H-9 and -8 and the methoxy-group, provide good evidence that the latter is at C-8, and the cyano-group at C-10. The enhancement of 13% in the H-4 resonance when that of H-5 is irradiated shows the double bonds are conjugated.

The u.v. spectrum had λ_{max} (EtOH) 280 mμ, log ε 3.87. The spectrum of 1-phenylbuta-1,3-diene has λ_{max} (EtOH) 280 mμ, log ε 4.50 (22).

Thus, the evidence points to the structure 8-methoxy-10-cyano-1,2-benzocycloocta-1,3,5-triene **7**.

A relatively insoluble, dimeric compound was also formed. Structure **8** is tentatively assigned to this compound, on the basis of n.m.r. (see experimental) data and on the assumption that the cyclization occurs via the most stable biradical intermediate.

The adduct which is assigned structure **9** is difficult to isolate in a pure form, and slowly crystallizes as waxy plates (from ethanol), which were sublimed, m.p. 50–52°.

The n.m.r. spectrum revealed the *exo*-methylene group resonances as a doublet, at 6.21 ($J_{8,8'}$ = 2.0 Hz) and a doublet of doublets at 5.91 ($J_{8,8'}$ = 2.0, $J_{1,8'}$ = 0.7 Hz); both had areas 1. The aromatic ring carried the cyano-group, and the resonances were at 7.89, doublet ($J_{9,11}$ = 2.0 Hz) assigned to H-9; at 7.70, doublet of doublets ($J_{9,11}$ = 2.0 and $J_{11,12}$ = 8.0 Hz) assigned to H-11; and at 7.26, doublet ($J_{11,12}$ = 8.0 Hz) assigned to H-12.

The resonances assigned to the bridgehead methine protons occurred at 4.03 as a broadened doublet with $J_{1,4}$ = 4.0 Hz attributed to H-4, and the H-1 resonance was at 3.48, but was partly obscured by the singlet of the methoxy-group which occurred at 3.56. The resonance of H-5 occurred at 4.27 and was coupled to the protons of the methylene group with J_{exo} = 3.5 and J_{endo} = 11.0 Hz. H-5 was not coupled to H-4, indicating that the methoxy group had the *exo*-stereochemistry (23*b*). The methylene group protons resonated at 1.46 (*endo*) and 2.44 (*exo*), and J_{gem} was 13.5 Hz.

The n.m.r. spectrum of **9**, particularly the coupling pattern, is consistent with the benzobicyclo[2.2.1]heptene system (23). To establish the relative positions of the methoxy and cyano-group, n.O.e. were measured. The results are shown in Fig. 2. Thus when the signal assigned to H-4 was irradiated, a 12% enhancement of the H-12 resonance was noted. Similarly, irradiation of H-1 caused a 11% enhancement of the H-9 signal. These results point to structure **9**, *exo*-5-methoxy-7-methylene-2,3-(2′-cyano) benzobicyclo[2.2.1]hept-2-ene.

NOTE ADDED IN PROOF: Recently, results of an independent study of 2-naphthonitrile and methyl vinyl ether photo-addition were described (41). Unfortunately, this paper did not include spectroscopic data or melting points, so that we are unable at present to compare the products described with those reported here. Some of our structural assignments differ from those of Mizuno *et al.* In particular, the benzonorbornene adduct **9** could in fact correspond to the cyclobutene adduct II in Mizuno's paper. The n.m.r. data which we obtained for **9** could well fit Mizuno's structure II. It is likely that the cyclobutene is the correct structure, and is probably formed by irradiation of the benzocycloctatriene, **7**.

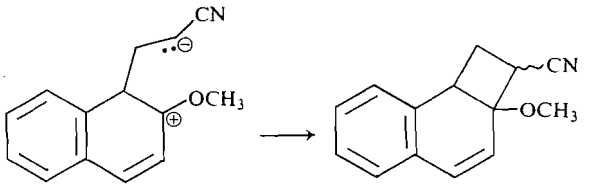
Discussion

Regiospecificity in Cyclobutane Formation

Mixed photo-additions of naphthalene with ethylenic substrates are known to afford cyclobutanes (2, 3). The present study has shown that this type of addition can also occur with 2-methoxy- and 2-cyanonaphthalene, if appropriate ethylenic substrates are used. It has also recently been reported that 2-cyanonaphthalene and tetramethylethylene add to form a cyclobutane on irradiation (24). Inspection of structures **1**, **2**, **4**, and **5** reveals that the following directive effects appear to be operating. First, addition occurs at the 1,2-bond of the naphthalene nucleus; if there is a substituent in the nucleus, addition occurs at the 1,2-bond carrying the substituent. Second, when mono-substituted naphthalenes and ethylenes react, the substituents are *vicinal* in the cyclobutane product, *e.g.*, **1**, **2**, and **5**.

While more than one specific interaction may be responsible for the observed directive effect, the following simple rule seems adequate for predictive purposes. That is, ring closure occurs from the most stable open-chain intermediate, which we represent as an ionic species. For example, closure of **11** would lead to **1** and **2**, as shown in Scheme 4.

The cation part of **11** consists of an allylic



11 1 and 2

SCHEME 4

For personal use only.

carbonium ion, stabilized by linear conjugation with a phenyl group, and with a methoxy group, all of which should contribute to stabilization.

This species **11** should be preferred over isomeric structures, in which bonding to the acrylonitrile moiety is at other positions of the substituted naphthalene ring, or at the unsubstituted ring. We also note that formation of the predominant cyclobutane **4** from naphthalene and acrylonitrile should involve the most stable intermediate, *i.e.* **11** without the methoxy group, since the cation center in that case is the relatively stable cinnamyl carbonium ion. The same rule accounts for formation of **5** from 2-cyanonaphthalene and methyl vinyl ether, and for the direction of addition of ethylenes to benzonitrile (6).

The intermediates such as **11** are represented as polar species, rather than biradicals because the excited states from which they are formed are singlets, and are best represented as spin-paired structures. Naphthalene and acrylonitrile add via S_1 (3*b*), and it is very likely that the additions of 2-methoxy- and 2-cyanonaphthalene are also singlet reactions (25).

The above rule for singlet additions of simple arene derivatives may be regarded as a counterpart of the "most stable biradical rule" which holds for many triplet additions (26, 27). In mentioning triplets, we note that the triplet states (T_1) of naphthalene and its non-carbonyl derivatives[3] appear to be photochemically quite inert, and this observation will be discussed elsewhere.

Isolation of substituted type products **3** from the 2-methoxynaphthalene-acrylonitrile reaction, albeit in low yield, is consistent with a donor–acceptor situation in which the acrylonitrile is the acceptor. The acrylonitrile should become electron-rich while bonded in an exciplex, and accept a proton from the solvent (3).

The formation of **10** on treatment of **1** and **2** with *tert*-butoxide at 80° is of synthetic interest. The photo-addition is thus the basis of a simple route to the naphthocyclobutene ring system of **10**, giving a compound with useful functionality in the four-membered ring. We are presently studying photo-additions of other substituted arenes, where the substituents is a potential leaving group, to attempt to extend this synthesis to other derivatives.

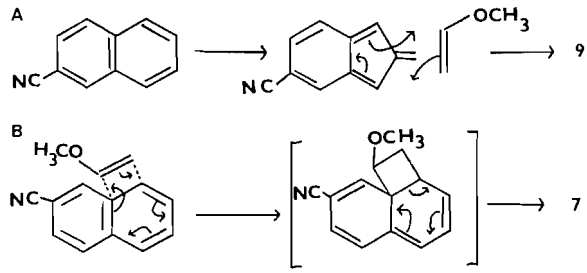
Possible Routes to Structures 6, 7, and 9

In contrast to the well-established $2\pi + 2\pi$ addition (28*a*) which can lead to adducts **1**, **2**, **4**, and **5**, the structures **6**, **7**, and **9** must be formed in a more complicated manner. However, although the latter adducts apparently have no precedent in arene photochemistry, it is possible to account for their formation without invoking any bizarre processes.

For example, it is known that on irradiation of benzene, fulvene is formed (29). Hence, the process shown in the first part of Scheme 5 is a suggested route for the formation of **9**.

In **7**, since the methoxy group is at C-8 (not C-7), as shown by the n.O.e., this compound cannot arise from **5**. It was also shown that **5** decomposes to 2-cyanonaphthalene on irradiation, and does not yield **7**. To account for the ring-expanded structure **7**, we propose that addition of methyl vinyl ether occurs not at the position of high bond order (the 1–2 bond of the naphthalene (30)) but on the bond from C-8 to the angular carbon, as shown in Scheme 5. Such an addition is formally a $2\pi + 6\pi$ addition, which is excited state symmetry allowed (28*b*), but is a rare process (31). This addition results in a temporary loss of aromaticity in the intermediate, which can be regained in one ring by the electrocyclic reaction in which the cyclo-

[3]2-Acetylnaphthalene adds to methyl cinnamate on irradiation (39), and this may be a triplet process.



SCHEME 5. Proposed mechanisms for formation of **7** and **9**

butane ring is ruptured and the eight-membered ring of **7** is formed.

Compound **6** is the minor product, but has an intriguing structure, which is supported by all the spectral data.[4] A mechanism leading to structure **6** can be envisioned, which comprises (*a*) $2\pi + 6\pi$ cycloaddition of methyl vinyl ether to the 2–3 bond of the 2-cyanonaphthalene, (*b*) ring opening of the intermediate to give a benzocyclooctatriene,[5] (*c*) 1,5-bonding followed by a 1,4-hydrogen shift to give the fused five-membered rings of **6**. These proposed steps all have precedent, either in ground or excited state chemistry (32–34).

In conclusion, photo-additions of simple naphthalenes with ethylene derivatives can afford substituted benzobicyclo[4.2.0]octa-2,4-dienes (2, 3, 14), which have been obtained in low yield by less direct routes (35). Also, the question of which reactant has which substituent in these mixed additions can be of the utmost importance, since the nature and complexity of the products may depend on the configuration of substituents. This dependence may result from an increased preference for $2\pi + 6\pi$ addition *vs.* $2\pi + 2\pi$, but a more precise explanation must await the results of further investigations.

Experimental

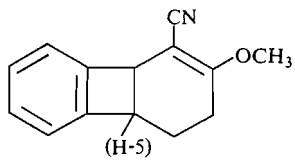
Materials and equipment used, unless stated otherwise, were as described elsewhere (2, 3, 14). 2-Cyanonaphthalene was from Eastman Kodak Co., and was recrystallized from light petroleum, b.p. 30–60°, and had m.p. 66–67°. 2-Methoxynaphthalene was from Aldrich and had m.p. 73–74°, from 95% ethanol. Methyl vinyl ether was from Matheson of Canada, Ltd. N.m.r. spectra were taken in $CDCl_3$ solution. Chemical shifts are given as p.p.m. (δ) downfield from tetramethylsilane, and coupling constants are in Hz.

Microanalyses were by the Spang Microanalytical Laboratory, Ann Arbor, Michigan.

Photo-reaction of 2-Methoxynaphthalene and Acrylonitrile

2-Methoxynaphthalene (6.0 g, 0.0379 mol) and acrylonitrile (30.0 g, 0.565 mol) in ethanol (1 l) were irradiated through Pyrex, in the usual apparatus for 12 h. A considerable amount of insoluble material was formed. The solution was evaporated and the residue was extracted with ether. The ether extracts were filtered and on evaporation gave 7.0 g of product mixture. Analysis of the latter by v.p.c. (5 ft × 1/8 in. SE-30 on Chromosorb Wat 190°) showed 2-methoxynaphthalene at 2 min, and product peaks at 6 and 6.5 min (ratio 80:20). Minor products (~2%) were noticed, retention times 7–9 min. The crude mixture was chromatographed on 500 g of silica gel in a 60 × 4.0 cm column, slurry-packed in benzene–hexane (4:1). This solvent was used for elution and 250 ml fractions were collected. Fractions 1–5 contained 2-methoxynaphthalene (2.066 g). Fractions 6–12 contained the minor components (total 0.1413 g) which were combined and chromatographed again (see below). Fractions 13–20 were mixtures of **1** and **2** (measured using the relative areas in the n.m.r. spectrum of the vinylic proton peaks), in a ratio of approximately 2:1. These fractions were crystalline, total 3.67 g. The yield of adducts was 71%, based on reacted 2-methoxynaphthalene. Fractional crystallization (3 times) of this mixture

[4]A referee has pointed out that the benzocyclobutene structure **I** is also consistent with our data. However, we favor structure **6** because **I** has both methine protons



I

benzylic, and in our experience, bridgehead, benzylic protons resonate at 3.5–4.0 δ (2), while the resonance of H-5, of **6** is at 3.15 δ. It is also known that the parent ring system of **I** rearranges under mild conditions to the isomeric benzobicyclo[4.2.0]octa-2,4-diene (35). It is therefore unlikely that **I** would have survived our isolation procedures, although it may be the primary photoproduct.

[5]A similar sequence can account for the formation of benzocyclooctatetraene derivatives, and possibly the dimethyl-3,4-benzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene-6,7-dicarboxylate, reported as products from irradiation of naphthalene and dimethyl acetylene dicarboxylate (40).

(3.20 g) from ether – light petroleum afforded 2.50 g of *endo*-7-cyano-6-methoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene (**1**), m.p. 85–86°. The n.m.r. and i.r. spectra are described in the text.

Anal. Calcd. for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63. Found: C, 79.50; H, 6.22; N, 6.69.

The mother-liquors of the crystallization of **1** were enriched in the second component **2** (n.m.r. monitoring). The combined liquors were evaporated, and further quantities of **1** mixed with **2** were separated by crystallization from ether – light petroleum, b.p. 30–60°. This process was repeated several times, and a gum residue was obtained from the final mother-liquors from two experiments, which n.m.r. analysis showed to be a mixture of **1** and **2**, in the ratio 1:3. The latter was chromatographed on a 52 × 3.0 cm column of silica gel for t.l.c., (Merck, A. G., grain size 10–40μ) slurry packed in benzene. Elution was with benzene, under 5 p.s.i. pressure of nitrogen and 20 ml fractions were collected. Fractions 62–80 contained 0.5960 g of a mixture of **1** and **2**, the earlier fractions being almost pure **1**. Fractions 80–90 contained **2**, the *exo*-isomer, (60 mg), m.p. 79–81° from hexane.

Anal. Calcd. for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63. Found: C, 79.74; H, 6.35; N, 6.60.

Base-catalyzed Epimerization of 1

To a solution of potassium (0.2748 g, 0.00703 g atom), purified according to Fieser and Fieser (36) in *tert*-butyl alcohol (50 ml) under nitrogen and at ambient temperature, was added 0.1034 g, 0.519 mmol of the methoxynitrile **1**, dissolved in *tert*-butyl alcohol (10 ml). The solution was stirred magnetically at ambient temperature for 21 h. The colorless solution was neutralized (5 ml in HCl), concentrated under vacuum, and extracted with ether. The ether extracts were washed with saturated NaCl solution, saturated $NaHCO_3$, and finally water. The ether solution was dried ($MgSO_4$) and evaporated. The residue (0.0946 g, 91.5%) was analyzed by n.m.r. on the T-60, and was shown to be a mixture of **1** and **2** in the ratio 9:1.

Base-catalyzed Aromatization of 1

The adducts of 2-methoxynaphthalene and acrylonitrile (**8** and **9**) (0.1049 g, 0.526 mmol) in *tert*-butyl alcohol (10 ml) were added to a solution of potassium *tert*-butoxide in *tert*-butyl alcohol (from 0.1780 g potassium and 50 ml *tert*-butyl alcohol). The mixture was stirred and heated under reflux in a nitrogen atmosphere for 2 h. The cool solution was neutralized with 5 ml of 1 *N* HCl, washed with aqueous NaCl–$NaHCO_3$, and dried ($MgSO_4$). Evaporation afforded a gum residue (0.18 g), which gave 0.09 g of white solid, m.p. 105–115° on trituration with ether. The latter was crystallized from ethyl alcohol giving crystals of **10**, 0.0214 g, 22% m.p. 202–204°.

Anal. Calcd. for $C_{13}H_{11}NO$: C, 79.21; H, 5.58; N, 7.10%. Found: C, 79.24; H, 5.56; N, 7.14%.

The compound is identified as 1,2-naphthocyclobutene-3-carboxamide from the following spectroscopic evidence. The i.r. spectrum (KBr disc) showed no nitrile band, but had absorption at 1665 (amide carbonyl) and 3400–3500 cm^{-1} (—NH_2 group). The u.v. spectrum (95% ethanol) had a band at 226 mμ, log ε = 4.95. Naphthalene has λ_{max} at 220 mμ, log ε 5.12 (37). The n.m.r. spectrum (CF_3COOH) using acetic acid as internal standard had a multiplet (area 6) centered at 7.3 (aromatic ring protons). The methylene and methine protons of the four-membered ring comprised an ABM system. The methine resonance was a doublet of doublets at 4.2 (J = 5.5 and 2.0 Hz), while the AB multiplet of the methylene group was centered at 3.4 and J_{AB} was 14.0 Hz. The spectrum was run on the T-60, and chemical shifts are only approximate.

Photo-reaction of 2-Cyanonaphthalene and Methoxyethylene

For this reaction, the Hanovia lamp immersion apparatus was fitted with a Dry-Ice condenser, and the solution was cooled in an ice–salt mixture. 2-Cyanonaphthalene (1.8857 g, 0.0123 mol) and methoxyethylene (38.6 g, 0.66 mol) in ethyl alcohol, 95% (320 ml), were irradiated in the usual way for 12 h. The solution was evaporated, and the residue triturated with ether. V.p.c. analysis of the ether solution (5 ft × 1/8 in. of 4% QF-1 on Diatoport at 180°) showed five components with retention times between 6 and 10 min. Retention times and fractional composition for each component are given below. The dimer **8**, 0.0924 g, which was insoluble, was filtered and had m.p. 270–280°. The dimeric adduct showed resonances between 7.0 and 8.0 (area 3) indicating that the cyano-group was in the aromatic ring; an AB quartet centered at 6.3, J = 12.0 Hz (area 2) is assigned to the vinylic protons; resonances at 4.5, 2.3, and 1.7 assigned to the methine and methylene protons. A singlet (area 3) at 3.2 is attributed to the methoxy-group. The u.v. spectrum had λ_{max} (EtOH–CH_2Cl_2) 270 mμ, log ε 4.54, and is similar to *p*-cyanostyrene, which has λ_{max} $CHCl_3$ 258 mμ, log ε 4.15 (38), if account is taken of the two chromophores, alkyl substitution, and cyclic structure in **8**. The assigned structure is the head-to-head cyclobutane dimer of **7**, with the 5,6 bonds of **7** forming the four-membered ring.

The ether solution was evaporated and the mixture (2.0907 g) chromatographed on a 59 × 2.0 cm column of silica gel for t.l.c. (240 g) (E. Merck, A. G., grain size 10–40μ), slurry-packed in and eluted with benzene. A pressure of 5 p.s.i. was used to give a flow rate of 2 drops/s, and 20 ml fractions were collected. 2-Cyanonaphthalene, m.p. 66–67° (1.1045 g), was found in fractions 13–17. Adduct **6** (0.0532 g), m.p. 80–96° (94–95° from hexane), was found in fractions 23–27. It was identified as 8-cyano-7-methoxy-2,3-benzobicyclo[3.3.0]-octa-2,7-diene. Fractions 29–31 were mainly compound **7** (0.1148 g), m.p. 70–106° (111–112° from hexane), which is assigned the structure 8-methoxy-1,2-(12-cyanobenzo)-cycloocta-1,3,5-triene. Fractions 32–36 contained the cyclobutane adduct **5** (0.1539 g), m.p. 73–74° from hexane, identified as 6-cyano-7-methoxy-2,3-benzobicyclo[4.2.0]-octa-2,4-diene. Fractions 38–42 were mixtures of compounds **11** and **9** (0.070 g), while the latter alone (0.0458 g) was found in fractions 43–50. This gave crystals, m.p. 50–51°, on slow crystallization from ethanol–water or on slow sublimation at 1 mm. Structure **9** was identified as 6-methoxy-7-methylene-2,3-(10-cyanobenzo)-bicyclo-[2.2.1]heptene. Elution with a further 2 l of benzene afforded intractable material (~0.150 g) which from the n.m.r. spectrum appeared to be a mixture of several compounds. The column was finally stripped with 0.5 l of ether, and 0.3988 g of mixture was obtained, which gave 0.0561 g of the above dimer **8** on trituration with ether. Total yield of **8** was 0.1485 g, m.p. 296–297° from ethanol. Recovery from the column was 2.0588 g, 98%.

Analytical figures for the isomeric photo-adducts **5–9**: Anal. Calcd. for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63. Found for **5**: C, 79.58; H, 6.25; N, 6.52. Found for **7**: C, 79.49; H, 6.16; N, 6.61. Found for **6**: C, 79.60; H, 6.35; N, 6.55. Found for **9**: C, 79.40; H, 6.20; N, 6.49. Found for **8**: C, 79.52; H, 6.18; N, 6.71.

V.p.c. analysis of the photolysis mixture gave the following composition: (**5**), 35.5% at 6.2 min; (**7**), 17.5% at 5.9 min; (**6**), 7.0% at 9.5 min; and (**9**), 35.5% at 6.7 min. There was in addition a minor peak appearing as a shoulder at 7.0 min, about 4%, corresponding to a compound which has not been identified.

Photo-sensitized Decomposition of the Cyclobutane Adducts

The cyclobutane from 2-methoxynaphthalene and acrylonitrile (**1**) (30 mg), 2-methoxynaphthalene (60 mg), and an internal standard (*cis*-7-cyano-2,3-benzobicyclo-[3.2.0]heptane (2*b*) (14 mg) in ethanol (13 ml) were irradiated at 313 mμ with a monochromator. Aliquots were withdrawn at known time intervals and were analyzed by v.p.c. on 5 ft × 1/8 in. of 4% QF-1 on Diatoport at 175°. The disappearance of adduct **1** was linear with time, and about 30% had decomposed in 2 h. The rate of decomposition was the same when 2-cyanonaphthalene was used as sensitizer.

A similar experiment with the adduct of 2-cyanonaphthalene and methyl vinyl ether (**5**), using 2-cyanonaphthalene as sensitizer showed that the adduct decomposed more rapidly, about 70% reacting in 2 h.

The major adduct of naphthalene and acrylonitrile (**4**) was checked for photostability in a similar way. It was found that naphthalene and benzophenone, but not fluorenone, would act as sensitizers for its decomposition.

Deuterium Exchange of Nitrile (1)

Treatment of nitrile (**1**) (50 mg) in dry pyridine (0.3 ml) and D_2O (0.1 ml) with sodium methoxide (15 mg) at 50° for 5 h resulted in exchange of one proton in the adducts for deuterium. The exchange was observed by n.m.r., and the experiment served to identify the methine proton α to the nitrile group.

We thank Dr. K. Saunders and Mr. B. Sawyer for measuring the nuclear Overhauser effects, Dr. R. F. Childs for the procedure for deuterium exchange of **1**, and Mr. B. R. Ramachandran for help with this experiment. We are grateful to the National Research Council of Canada for financial support.

High Temperature Aqueous Electrolyte Concentration Cells and the Ionization of Liquid Water to 200 °C

DIGBY D. MACDONALD,[1] P. BUTLER,[2] AND D. OWEN

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba R0E 1L0

Received December 1, 1972

High temperature aqueous electrolyte concentration cells with and without liquid junction are described. These cells were used to measure the ionization constant of water in 0.1, 0.25, 0.5, and 1.0 mol/kg KCl solutions at temperatures to 200 °C. Extrapolation to infinite dilution yielded the following functions for the temperature dependence of log K_w^0 and the thermodynamic parameters for ionization: log $K_w^0 = -4046.16/T + 3.537 - 0.01323T$; $\Delta G^0 = 77458.0 - 67.71T + 0.253187T^2$ J/mol; $\Delta H^0 = 77458.0 - 0.253187T^2$ J/mol; $\Delta S^0 = 67.71 - 0.5063T$ J/K mol; $\Delta C_p^0 = -0.5063T$ J/K mol.

Des cellules de concentration aqueuse d'électrolytes à haute température, avec ou sans jonction liquide, ont été décrites. Ces cellules ont été utilisées pour mesurer la constante d'ionisation de l'eau dans des solutions à 0.1, 0.25, 0.5, et 1.0 mol/kg de KCl, à des températures allant jusqu'à 200 °C. L'extrapolation à la dilution infinie a conduit aux fonctions suivantes pour l'influence de la température sur log K_w^0 et sur les paramètres thermodynamiques d'ionisation: log $K_w^0 = -4046.16/T + 3.537 - 0.01323T$; $\Delta G^0 = 77458.0 - 67.71T + 0.253187T^2$ J/mol; $\Delta H^0 = 77458.0 - 0.253187T^2$ J/mol; $\Delta S^0 = 67.71 - 0.5063T$ J/K mol; $\Delta C_p^0 = 0.5063T$ J/K mol. Introduction

An accurate method for determining ionic activities, pH, and equilibrium phenomena in solution is through the use of electrolyte concentration cells. This class of reversible cell may be divided into two types, *viz.* those with and without liquid junction, represented by cells I and II, respectively.

I $\quad Pt(H_2)/HCl(a_1)/HCl(a_2)/(H_2)Pt$

II $\quad Pt(H_2)/HCl(a_1),[AgCl]/Ag/[AgCl],HCl(a_2)/(H_2)Pt$

These cells have been investigated extensively at temperatures less than 100 °C (1, 2). Variations of cells I and II have been used to measure transport numbers, hydrogen ion activity and dissociation constants for weak acids and bases (1, 2). In two recent publications Mesmer *et al.* (3, 4) described an electrolyte concentration cell with liquid junction (*i.e.* cell I) which is capable of precise acidity measurements at elevated temperatures. This cell was used to determine the apparent ionization constant for water ($Q_w = m_{H^+} \cdot m_{OH^-}$) in 1 mol/kg KCl solution to 292 °C (3) and the hydrolysis of Al^{3+} in KCl solution to 150 °C (4).

In this paper we describe simple and reliable high temperature concentration cells with and without liquid junction. These cells were designed to provide accurate potentiometric acidity measurements at elevated temperatures as part of a program in this laboratory to study hydrolytic processes in high temperature water. The accuracy of these cells is demonstrated in the present work by measuring the ionization constant for water in 0.1, 0.25, 0.5, and 1.0 mol/kg KCl solutions at temperatures between 25 and 200 °C. Plots of log K_w *vs.* ionic strength, extrapolated to infinite dilution, yield log K_w^0 values which agree to within $\pm 0.2\%$ with the best data in the literature which have been derived from conductance techniques. This close agreement demonstrates that the apparatus described here is capable of yielding precise acidity measurements in high temperature water. These concentration cell techniques are being applied to the study of hydrothermal precipitation reactions and to the determination of transport numbers for ions in aqueous solution at elevated temperatures.

Experimental

Electrochemical Cells

The electrolyte concentration cells used in this study are shown in Fig. 1. The cell body consisted of a 300 ml titanium autoclave which was gold-plated on the inside surface to minimize contamination of the solution in the outer compartment. The inner compartment was ma-

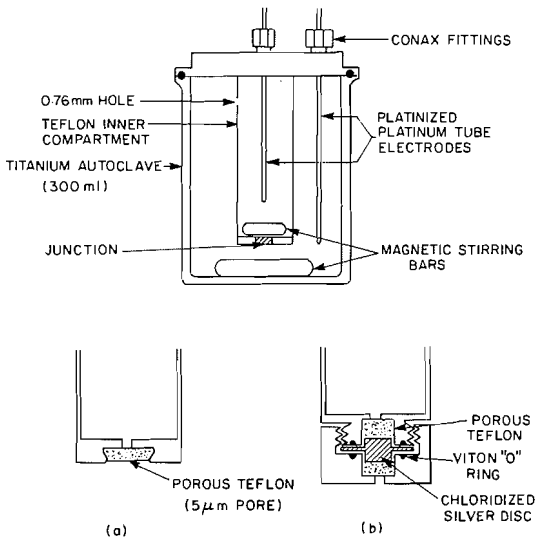

FIG. 1. High temperature aqueous electrolyte concentration cell.

chined from Teflon to a wall thickness of 1.5 mm. This wall thickness allowed rapid thermal equilibration of the two compartments after a sudden temperature change. Both compartments contained Teflon covered magnetic stirring bars to agitate the solutions. These stirring bars were activated by a rotating magnet located beneath the aluminum oil bath used to control temperature.

The reversible hydrogen electrodes consisted of pure platinum tubes (3 mm od., 1.5 mm i.d.) which were sealed at the lower ends. The tubes were insulated from the autoclave body by Conax fittings containing Teflon sheaths and cones. The electrodes were lightly platinized by electrolysis in a dilute solution of chloroplatinic acid immediately before use. Chromel–alumel thermocouples (0.8 mm diameter) were inserted into the platinum tubes to monitor the temperatures of the compartments.

The junctions used in cells I and II are shown in Figs. 1*a* and *b*, respectively. For cell I, the junction consisted of a porous Teflon disc (3 mm thick, 6.4 mm diameter, 10 μm pore size) which was pressed into the tapered cavity shown in Fig. 1*a*. Initial experiments showed that the porous Teflon did not always produce a satisfactory junction and electrolytic contact between the compartments was frequently interrupted. This resulted in erratic behavior of the potential difference between the two hydrogen electrodes. This phenomenon was attributed to the failure of expelling air from the pores because of the non-wettability of Teflon. Two techniques were used to overcome this problem. First, an electric discharge was passed through the Teflon disc in the presence of water vapor. This procedure produced a wettable surface presumably due to hydroxylation of the Teflon surface by hydroxyl radicals produced in the spark discharge. The second technique, and the one most often adopted, was to boil the Teflon disc in a saturated solution of KCl and then cool. During boiling, air was expelled from the pores in the Teflon disc and replaced by KCl solution when cooled. The boiling/cooling procedure was repeated over two or three cycles. Of the two techniques, the second one was found to produce the most reliable junctions.

The junction used in cell II consisted of a chloridized silver disc separated from the solutions by porous Teflon discs which were treated as described above. Direct contact between the two compartments was prevented by using Viton O rings. The silver disc was chloridized by anodizing in a slightly acidified 10% KCl solution for 30 min at a current density of 2 mA/cm². The silver discs were freshly chloridized before each run.

The autoclave was degassed by cyclic compression/decompression with pure hydrogen. This procedure was repeated at least five times to remove all traces of oxygen from the system and the pressure was finally adjusted to 0.6 MPa (6 bar) for cell I and 0.2 MPa (2 bar) for cell II. The lower pressure employed in cell II was required to reduce the rate at which AgCl was reduced by hydrogen at high temperature (5–8). The porous Teflon plugs also reduced the rate of reduction that occurred at the silver chloride surface, presumably by reducing the rate of diffusion of dissolved hydrogen to the surface. Even so, it was found that sufficient reduction occurred at 150 °C over 24 h to cause a change in color of the silver chloride surface from red-brown to silver. This probably reflects the formation of silver metal at the electrode surface. This color change was frequently accompanied by mV or tens of mV deviations in potential and experiments using cell II were restricted to a few hours duration at temperatures greater than 150 °C.

The entire autoclave was immersed in an oil bath which allowed temperatures (25–200 °C) to be controlled to ±0.1 °C. The system was brought to temperature in steps to ensure that the two compartments did not differ by more than 5° C. This procedure minimized distillation from the outer compartment to the inner compartment during heat-up and in the reverse direction during cool-down. Distillation was also minimized by maintaining a pressure of hydrogen in the system, and by having a hole of small diameter (0.76 mm) between the two compartments.

All potential measurements were made using a Beckman Research p*H* meter. This instrument was capable of detecting 0.1 mV changes in the potential difference between the two hydrogen electrodes. Potentials were recorded after they had become constant to within 0.1 mV for at least 15 min.

Solutions

Dilute solutions of HCl and KOH (0.010 mol/kg) in potassium chloride solutions (0.1–1.0 mol/kg) were prepared from reagent grade chemicals. The solutions were stored in tightly stoppered Teflon containers to minimize contamination due to atmospheric carbon dioxide.

Results

Cell I

Since the pressure of hydrogen is the same in both compartments the potential (E) of the inner compartment electrode with respect to the outer compartment electrode is given by eq. 1

$$[1] \qquad E = \frac{2.303RT}{F}\log\frac{(a_{H^+})_2}{(a_{H^+})_1} + E_j$$

where subscripts 1 and 2 designate the outer and inner compartments, respectively, and E_j is the

liquid junction potential. Since the inner compartment contained the KOH solution, we write

$$[2] \qquad (a_{H^+})_2 = a_{H_2O} K_w/(a_{OH^-})_2$$

where K_w is the ionization constant of water in the solution of interest, and a_i is the activity of species i in the system. Recognizing that

$$[3] \qquad a_i = \gamma_i m_i$$

where γ_i and m_i represent the activity coefficient and molal concentration, respectively, then substitution of eqs. 2 and 3 into eq. 1 results in the following expression for $-\log K_w$

$$[4] \quad -\log K_w = -\frac{F(E - E_j)}{2.30RT} - \log [(m_{H^+})_1(m_{OH^-})_2] - \log \frac{\gamma_{H^+}\gamma_{OH^-}}{a_{H_2O}}$$

Liquid junction potentials for cell I at high temperatures can be estimated using the Henderson equation (2, 3)

$$[5] \qquad E_j = -\sum D_i[(m_i)_2 - (m_i)_1]$$

where the D_i coefficients are given by

$$[6] \qquad D_i = RT|Z_i|\lambda_i/(Z_i F \sum(|Z_i|)\bar{m}_i\lambda_i)$$

The quantity $\bar{m}_i$ is the average concentration of species i in the two compartments, Z_i is the ionic charge, and λ_i is the equivalent conductance. Equivalent conductances for K^+, Cl^-, H^+, and OH^- at temperatures to 400 °C have been estimated by Quist and Marshall (9) and were used here to evaluate E_j. In the present study, the liquid junction potential rarely exceeded 1 mV which represents a minor correction to the measured potential (typically 500 mV).

The activity coefficient term in eq. 3 is equated to the analytical expression given by Harned and Cook. (10)

$$[7] \quad \log \frac{\gamma_{H^+}\gamma_{OH^-}}{a_{H_2O}} = -\frac{2S\sqrt{I}}{1 + A\sqrt{I}} + BI + CI^{3/2}$$

which has been used by Mesmer, Baes, and Sweeton (3) for cells of type I at elevated temperatures. The various coefficients in eq. 7 have the following values

$$[8] \qquad S = 1.814 \times 10^6/(\varepsilon T)^{3/2}$$

$$[9] \qquad A = 50.30\, a/(\varepsilon T)^{1/2}$$

$$[10] \qquad B = 0.266 + 5.2 \times 10^{-4} t$$

$$[11] \qquad C = -0.0350 - 4.88 \times 10^{-4} t$$

where a is a temperature independent parameter equal to 3.6 for KCl, ε is the dielectric constant for water (11), and I is the ionic strength of the solution. Since the ionic strengths of both compartments were kept nearly equal we equate I in eq. 7 to the average value. Equation 7 reproduces experimental data to better than 1% up to 3 mol/kg KCl and 60 °C, and the work of Mesmer *et al.* (3) indicates that these coefficients are acceptable to much higher temperatures.

Cell II

The potential of cell II for uniform hydrogen pressure is given by eq. 12

$$[12] \qquad E = \frac{2.303RT}{F} \log \frac{(a_{H^+,2})(a_{Cl^-,2})}{(a_{H^+,1})(a_{Cl^-,1})}$$

Expansion of this expression and substitution of eqs. 2 and 3 results in the following expression for $-\log K_w$

$$[13] \quad -\log K_w = -\frac{FE}{2.303RT} - \log (m_{H^+})_1(m_{OH^-})_2 - \log \frac{\gamma_{H^+}\gamma_{OH^-}}{a_{H_2O}} + \log \frac{(m_{Cl^-})_2}{(m_{Cl^-})_1} + \log \frac{(\gamma_{Cl^-})_2}{(\gamma_{Cl^-})_1}$$

where, as before, E is the potential difference between the inner and outer compartment platinum electrodes. We assume that, although the ionic strengths are well outside the Debye–Hückel range, the *ratio* of activity coefficients is given by eq. 14

$$[14] \quad \log \frac{(\gamma_i)_2}{(\gamma_i)_1} = -Z_i^2 S \frac{\sqrt{I_2} - \sqrt{I_1}}{(1 + \sqrt{I_2})(1 + \sqrt{I_1})}$$

It should be noted that, since $I_2 \approx I_1$, the contribution that the above term makes to $-\log K_w$ is small (usually $< 1\%$) and any error inherent in the above assumption is probably within the total experimental error.

Numerical values for $\log K_w$ in 0.1, 0.25, 0.5, and 1.0 mol/kg KCl solutions at temperatures between 25 and 200 °C are plotted in Figs. 2–5. Interpolated values at 25 °C intervals are plotted in Fig. 6 as a function of ionic strength. Extrapolation of $\log K_w$ to infinite dilution yields the numerical values for $\log K_w^0$ which are listed in Table 1.

Discussion

The values for $\log K_w^0$ listed in Table 1 are plotted in Fig. 7 together with similar data ob-

tained using both galvanic cell (8, 13) and conductance techniques (12). The present data agree to within $\pm 0.2\%$ with the values of Fisher and Barnes (12), which were derived from conductance measurements on the system acetic acid – ammonium acetate – ammonia. Good agreement is also obtained at 175 and 200 °C with the data of Dobson and Thirsk (8), which were derived from e.m.f. measurements on galvanic cells of the type H_2/HCl (or NaOH), NaCl [AgCl]/Ag. At lower temperatures (*i.e.* 100, 125, and 150 °C) the data of Dobson and Thirsk (8) are not in good agreement with either our values or the conductance measurements of Fisher and Barnes (12). However, the close agreement between the present e.m.f. data and the conductance values indicates that the data of Dobson and Thirsk at these lower temperatures are in error by approximately ± 0.1 in $\log K_w^0$ (*i.e.* $\pm 1\%$). At temperatures less than 100 °C, the data reported here are in excellent agreement with the very precise values of Harned and Robinson (13), which were also derived from galvanic cell measurements.

The present data were obtained over a sufficiently wide temperature range that meaningful values for the thermodynamic parameters of ionization at S.V.P. (ΔG^0, ΔH^0, ΔS^0, and ΔC_p^0) could be obtained. It was found that the experimental data are represented within experimental error (see Table 1) by eq. 15.

$$[15] \quad \log K_w^0 = -4046.16/T + 3.537 - 0.01323T$$

(standard deviation = 0.016)

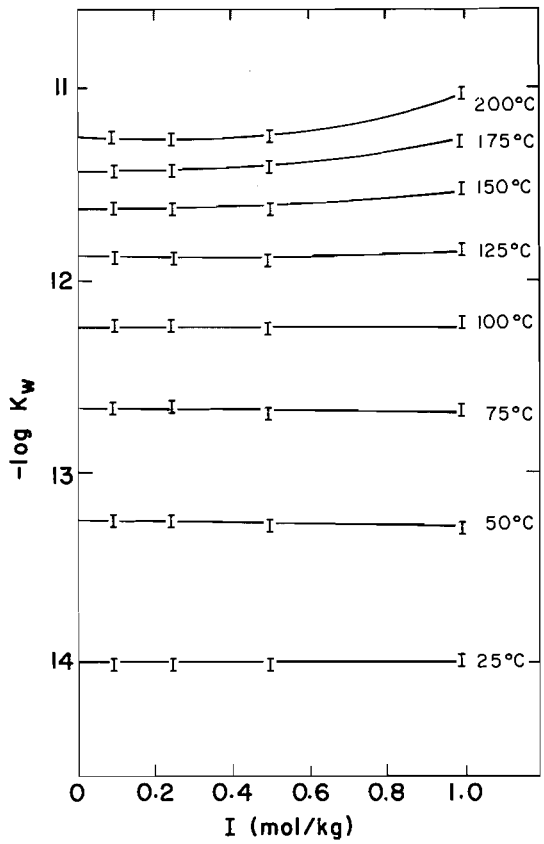

FIG. 6. The variation of $-\log K_w$ with ionic strength at various temperatures.

*Calculated using eq. 15.

and the standard free energy change by

[16] $\Delta G^0 = 77458 - 67.17T + 0.253187T^2$ J/mol

Differentiation of eq. 16 and application of standard relationships between free energy, entropy, enthalpy, and heat capacity resulted in the following expressions for ΔH^0, ΔS^0, and ΔC_p^0 at S.V.P.

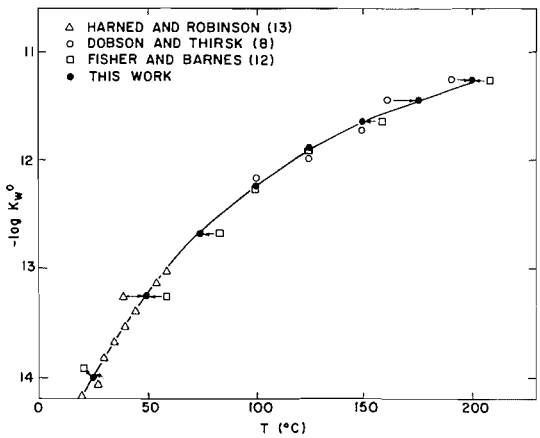

FIG. 7. The dependence of $-\log K_w^0$ on temperature for the ionization of water.

[17] $\Delta H^0 = 77458.0 - 0.253187T^2$ J/mol

[18] $\Delta S^0 = 67.71 - 0.5063T$ J mol

[19] $\Delta C_p^0 = -0.5063T$ J/K mol

Numerical values for ΔG^0, ΔH^0, ΔS^0 and ΔC_p^0 for the ionization of liquid water at 25 °C were calculated from eqs. 16 to 19 and found to be 77 458 J/mol, 54 951 J/mol, −83.2 J/K mol, and −151 J/K mol, respectively. Dobson and Thirsk (8) have analyzed log K_w^0/temperature data from previous studies in detail using a number of analytical functions to represent the temperature dependence of log K_w^0. The value obtained in the present study for ΔG^0 (25 °C) agrees within ±0.2% with the values derived by Dobson and Thirsk (8). The value derived here for ΔH^0 (25°) of 54 951 J/mol is 2–3% lower than calorimetric values of 56 576 J/mol (14) and 55 647 J/mol (15). However, Dobson and Thirsk (8) show that the value obtained for ΔH^0 (25 °C) from ionization data is sensitive to the function chosen to represent the temperature dependence of log K_w^0. Thus, for functions of the type

[20] $$RT \ln K_w^0 = \sum_{i=0}^{n} a_i T^i$$

ΔH^0 (25 °C) is found to vary from 43 036 J/mol for $n = 2$ to 57 739 J/mol for $n = 5$. For $n = 3$ they find ΔH^0 (25 °C) = 54 735 J/mol which is in good agreement with the present work. Similarly, the temperature dependence of ΔH^0 at 25 °C, *i.e.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ΔC_p^0 (25 °C), is highly sensitive to the value of n chosen for eq. 20 and varies from 0 J/K mol ($n = 2$) to −713 J/K mol for $n = 5$. The value obtained in the present study (−151 J/K mol) is in good agreement with the value of −150 J/K mol found by Dobson and Thirsk (8) for $n = 3$.

Differentiation of eq. 15 with respect to temperature, and putting $(d \log K_w^0/dT) = 0$, leads to values of 280 °C and −11.09 for T_{max} and $(\log K_w^0)_{max}$, respectively. These values are in excellent agreement with the experimental values of 275 °C and −11.01 as determined by Fisher and Barnes (12) from conductance measurements. Furthermore, values for $\log K_w^0$ extrapolated to the range 200 to 300 °C using eq. 15 agree to within 1% with the values determined from conductance data (12).

In the present work the dependence of the term $\gamma_{H^+}\gamma_{OH^-}/a_{H_2O}$ on ionic strength is represented by eq. 7. This expression has been found accurate to <1% in 0–3 mol/kg KCl at temperatures to 60 °C (10). The lack of dependence of $\log K_w$ on ionic strength, as shown in Fig. 6, demonstrates that eq. 7 is acceptable to temperatures as high as 125 °C. At higher temperatures, positive deviations occur, particularly in 1 mol/kg KCl. This deviation has also been noted by Mesmer, Baes, and Sweeton (3), and can be attributed to ion pairing to form (H^+Cl^-) and (K^+OH^-). Association of KOH has been suggested to occur at room temperature (16), and is expected to become increasingly important as temperature increases due to the decrease in the dielectric constant of water.

Previous investigations (5–8) of the H_2/H^+Cl^--[AgCl]/Ag system at elevated temperatures have shown that the reduction of AgCl occurs spontaneously,

$$AgCl + \tfrac{1}{2}H_2 = Ag + H^+ + Cl^-$$

This process results in a decrease in potential with time from the theoretical reversible value due to the establishment of local hydrogen cells at the silver/silver chloride electrode and due to the change in acidity of the solution. In the present study, we attribute the scatter in $\log K_w$ data at elevated temperatures, when measured with cell II (see Fig. 5), to the reduction of AgCl. Analysis of the solutions after a run showed that the change in H^+ concentration was sufficient to account for the observed scatter, and suggest that the existence of local hydrogen cells at the Ag/AgCl surface are of minor importance in the present system. It is possible that since the Ag/AgCl electrodes are opposed the interference from hydrogen cells at the surface tend to cancel. However, in view of the uncertainties associated with the behavior of silver/silver chloride electrodes in hydrogen rich systems, we recommend the use of cell I in the determination of acidities at elevated temperatures.

The Interaction of Organomercury Pollutants with Biologically Important Sites: An X-ray study of the 2:1 Complex between Methylmercury and Penicillamine

YAU SHING WONG, PETER C. CHIEH, AND ARTHUR J. CARTY[1]

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 24, 1973

The toxic pollutant methylmercurychloride forms 1:1 and 2:1 complexes with the sulfur amino acid DL-penicillamine. The mode of binding of the methylmercury by penicillamine has been established by a three-dimensional X-ray study of $[CH_3Hg]_2(SC(CH_3)_2CHNH_2COO)$.

Le polluant toxique méthylchlorure de mercure forme des complexes 1:1 et 2:1 avec le soufre de l'acide aminé DL-pénicillamine. Le mode de complexation du dérivé méthylmercure avec la pénicillamine a été établi grâce à une étude tridimensionnelle par rayon-X de $[CH_3Hg]_2(SC(CH_3)_2CHNH_2COO)$.

Can. J. Chem., 51, 2597 (1973)

Methylmercuric chloride is the extremely toxic form of the heavy metal which has caused numerous deaths and many cases of brain damage (1). Recent work has re-emphasized the inherent biological dangers in mercury pollution to human, animal, and plant life in view of the apparent ease of conversion of inorganic mercury to CH_3HgCl by biological methylation processes involving, for example, methyl group transfer from methylcorrinoids (2,3), present in microorganisms. In order to understand and combat the inhibitory effects of methylmercury it is essential to have detailed knowledge, currently lacking, of the mode of bonding between CH_3Hg— and the various sites (ligands) present in protein and enzyme molecules. We have carried out structural studies on model complexes of methylmercury with sulfur amino acids and we describe herein the characterization of complexes with DL-penicillamine $HSC(CH_3)_2CH(NH_2)COOH$.

Scheme 1 summarizes products obtained from CH_3HgCl and the zwitterionic form $[HSC(CH_3)_2CH(\overset{+}{N}H_3)COO^-]$ of DL-penicillamine.

Microanalysis indicated that crystals A and B were 2:1 complexes of methylmercury with penicillamine whereas C was a 1:1 complex. The i.r. spectra of complex B showed coordination of the deprotonated sulfhydryl group and the amino group but did not unequivocally establish bonding of the carboxylate group to methylmercury. An X-ray study was undertaken to unambiguously define the nature of the metal — amino acid linkage. Crystal data: $(CH_3Hg)_2[SC(CH_3)_2CH(NH_2)COO]$; orthorhombic crystals, space group *Pbcn*; $a = 19.70$ Å, $b = 10.48$ Å, $c = 11.97$ Å; $Z = 8$, ρ_{meas} (flotation) = 3.06 g cm^{-3}, $U = 2475.9$ Å^3, $\rho_{calcd} = 3.114$ g cm^{-3}. The intensities of 1047 independent reflections were measured on a GE XRD6 automatic diffractometer using MoK_α radiation; 935 reflections were considered observed and used in the analysis. The structure was solved by the heavy atom method and refined by least squares using anisotropic thermal parameters, to the present R value of 0.085.[2] The molecular structure is shown in Fig. 1. The binuclear molecule consists of a deprotonated penicillamine ligand in the form $^-SC(CH_3)_2CH(NH_2)COO^-$ bonded via the sulfur atom to one methylmercury unit and via the amino group to the other mercury atom. The coordination geometry around Hg(1) can best be described as linear, two coordinate with an S—Hg—C angle of 176.4° although a very weak interaction of Hg(1) with O(2) of a neighboring molecule may be indicated by a distance of 2.851

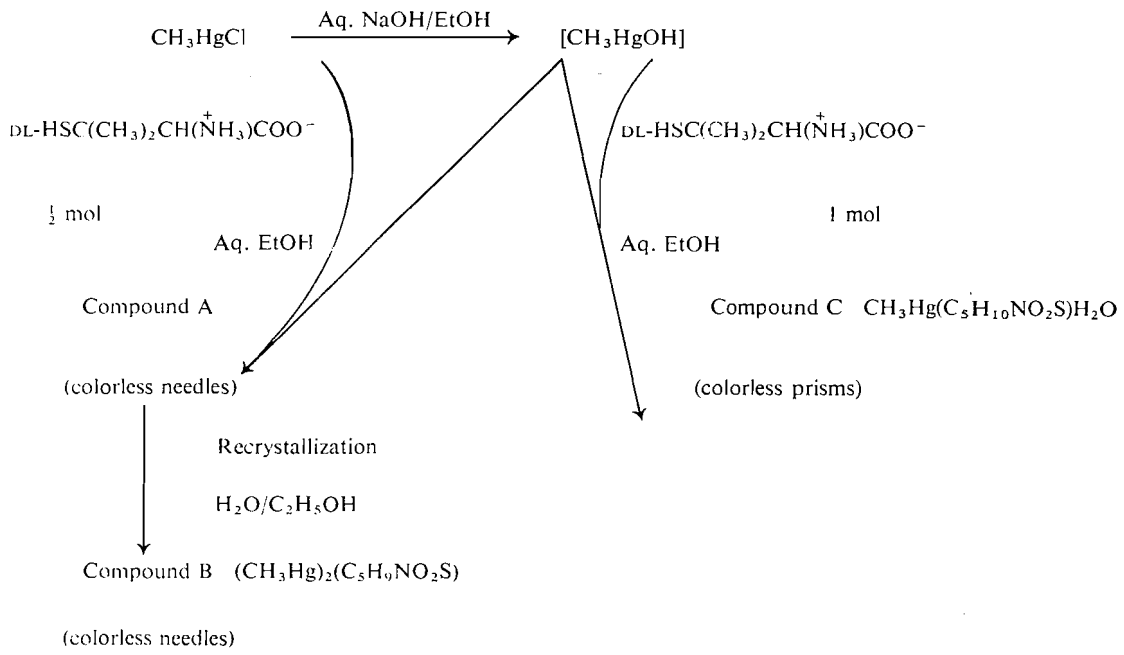

SCHEME 1

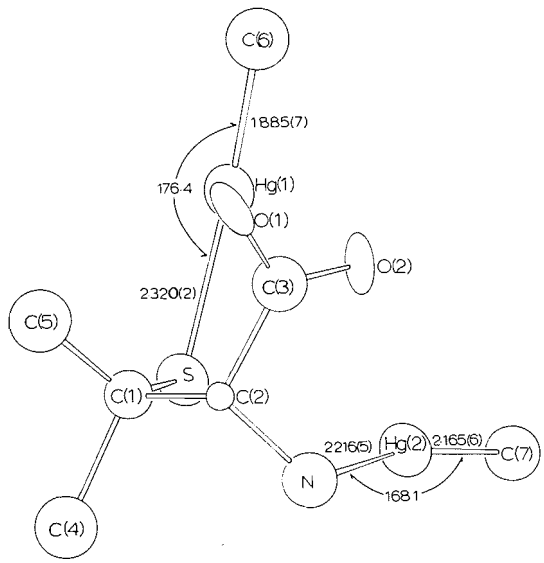

FIG. 1. A view of the molecular structure of the 2:1 complex between methylmercury and penicillamine, $(CH_3Hg)_2[SC(CH_3)_2CH(NH_2)COO]$, illustrating the atomic numbering and pertinent molecular parameters.

Å which is barely within the sum of Van der Waals radii for mercury (1.50 Å) (4) and oxygen (1.40 Å). In agreement with Hg(1) having a *characteristic* coordination number of two, the Hg(1)—S bond length of 2.320(2) Å is very similar to the Hg—S distances (average 2.330(7) Å) in $[C_6H_5N{=}C(OCH_3)S]_2Hg$ (5) where mercury is also two coordinate. By contrast, in $Hg(SCN)_2As(C_6H_5)_3$ where the characteristic coordination number is three the Hg—S distances average 2.54 Å (6) and in tetrahedrally coordinated mercury complexes Hg—S distances greater than 2.50 Å are usually observed (for a summary of X-ray data see ref. 7). Hg(2) is coordinated in approximately linear fashion to a methyl carbon atom and the nitrogen atom of the penicillamine amino group. The apparent deviation of the N—Hg(2)—C(7) angle from 180° may be attributable to the proximity of O(2) of the carboxylate group to Hg(2). The Hg(2)—O(2) distance of 2.708(4) Å is much longer than expected for covalent Hg—O bonds (2.00–2.30 Å) (8) but significantly shorter than the sum of the Van der Waals radii. The Hg(2)–O(2) interaction may be, in part, responsible for the significant difference in Hg(1)—C(6) (1.885(7) Å) and Hg(2)—C(7) (2.165(6) Å) distances although lack of accurate literature data for Hg—Csp^3 bond lengths preclude a detailed discussion. The Hg(2)—N bond length of 2.216(5) Å compares favorably with the Hg—N distance (2.10 Å) in H_2NHgCl (9) but is considerably shorter than in $Cl_3CHgCl{\cdot}C_{12}H_8N_2$ (10) (2.61 Å average) where the *o*-phenanthroline is only weakly

bound. The bonding of the $—NH_2$ group to Hg(2) implies that the complex is a zwitterion with the positive center localized in the $—NH_2—Hg—CH_3$ moiety and the negative center on the carboxylate group.

This structure determination demonstrates unequivocally that amino acids are capable of binding two methylmercury moieties. Previously it had been assumed that nitrogen containing bases would not form complexes with methylmercury (1*b*) and hence that arginine, lysine, and histidine would not be implicated in methylmercury poisoning. Preliminary work has shown that monoclinic crystals of complex A contain the amino acid bonded to mercury in similar fashion to B whereas in complex C only the sulfur atom of the deprotonated penicillamine molecule is implicated in bonding. A full X-ray study of complex C is in progress.

The results of this work can be compared with studies (11) of Hg^{2+} complexation by L-cysteine, *S*-methyl-L-cysteine, and DL-methionine. Whereas the Hg^{2+} ion has the ability to bind two amino acid sites simultaneously (11), the present work suggests that the CH_3Hg^+ species has little residual Lewis acidity after coordinating a sulfur or amino group. This is in agreement with studies which indicate a low complexing ability for organomercurials in general (12).

The Fluorescence of CS_2 Vapor

C. LAMBERT[1] AND G. H. KIMBELL

Defence Research Establishment, Valcartier and Centre de Recherches sur les Atomes et les Molecules, P.O. Box 880, Courcelette, Quebec

Received December 27, 1972

The fluorescence of carbon disulfide vapor was measured as a function of both wavelength of excitation and wavelength of fluorescence. It was found necessary to invoke a vibrational cascade model in order to account for the observations. Vibrational deactivation occurred on every collision, whereas electronic deactivation was found to require about ten collisions.

The quenching by the foreign gases Ar, N_2, O_2, CO_2, COS, SF_6, and C_3H_8 of CS_2 fluorescence excited by a wavelength of 320.0 nm was measured and the rate constants computed. The degree of efficiency could be correlated with the complexity of the molecule as determined by its polarizability.

La fluorescence des vapeurs de disulfure de carbone a été mesurée en fonction de la longueur d'onde d'excitation et aussi de la longueur d'onde de fluorescence. Il a été nécessaire, d'utiliser un modèle possédant des vibrations en cascade afin d'expliquer les résultats observés. Une désactivation en ce qui a trait aux vibrations, se produit pour chaque collision alors qu'une désactivation électronique semble nécessiter environ dix collisions. L'extinction par divers gaz étrangers Ar, N_2, O_2, CO_2, COS, SF_6, et C_3H_8, de la fluorescence du CS_2 provenant de l'excitation par une longueur d'onde de 320.0 nm a été mesurée et les constantes de vitesse calculées. Les degrés d'efficacité peuvent être reliés à la complexité de la molécule telle que déterminée selon sa polarisabilité. [Traduit par le journal]

Can. J. Chem., 51, 2601 (1973)

Introduction

Fluorescence of CS_2 vapor was first observed by Heicklen (1). He measured the total fluorescent emission between 420.0 and 650.0 nm, excited by different wavelengths varying between 280.0 and 350.0 nm. The quenching constant was calculated for pressures of CS_2 ranging from 10^{-2} to 10^2 Torr. Despite some large fluctuations in the data, a simple mechanism of a single state excitation (both vibrational and electronic) and collisional deactivation appeared to be obeyed. It appeared that electronic quenching occurred on every collision. CS_2 is not dissociated at these wavelengths and no evidence was obtained for any processes other than fluorescence quenching.

Herman, Herman, and Akriche (2) observed that an afterglow followed an electrical discharge through vapor of CS_2 but were unable to observe any structure in the spectra.

Arnold and Kimbell (3) studied the radiation emitted by shock-heated CS_2–Ar mixtures. Using a spectrophotometric technique they ascertained that the emitting state was likely to be the $^3A_2$ state observed by Kleman (4) in absorption. Following this work they attempted (5) to re-analyze the CS_2 afterglow. From their work it was possible to suggest that the state observed using the shock excitation technique was unlikely to be the same as produced in the afterglow (a result of CS + S recombination).

Very recently, during the course of the present work, Brus (6) measured the laser-excited fluorescence of CS_2 vapor and measured a double exponential decay suggestive of two emitting states. One of the lifetimes observed was in good agreement with that observed by Douglas (7).

Although a number of observations of emission from CS_2 vapor has been made, only suggestions have been made regarding spectral assignments. Also, in light of the recent work on NO_2 (8, 9) showing a vibrational cascade mechanism for the fluorescence deactivation process, further studies were made in an attempt to look for structure and to measure the quenching constants while varying the wavelengths of both excitation and observed fluorescence. Thus it was hoped that these studies would further clarify the mechanism of the quenching process and perhaps contribute further information towards a positive identification of some of the emitting levels.

The quenching of the fluorescence of triatomic molecules by foreign gases has been studied by many workers. The quenching of NO_2 fluorescence was studied recently by Myers, Silver, and Kaufman (11) in 1966. They obtained the quenching constants for thirteen inert gases. These values ranged from 1/25 to 1/2 of gas kinetic collision number and increased with increasing molecular complexity. These workers also observed that the quenching constant was dependent on the fluorescence wavelength. Mettee (12) in his studies of SO_2 fluorescence found quenching constants of a similar order of magnitude but no wavelength dependence. Brus has obtained some initial rate constants for the quenching of CS_2 fluorescence by several foreign gases. He employed a N_2 laser at 337.1 nm for excitation and observed the fluorescence decay. Prior to this report and the present work we are unaware of any additional work on the quenching of CS_2 fluorescence by foreign gases.

Measurements were made of the quenching constant for eight collision partners. The best empirical relation appears to exist between the probability of fluorescence quenching per gas kinetic collision and the polarizability of the molecule.

Experimental

The apparatus used is shown in Fig. 1. In general it is a standard method for exciting and observing fluorescence in the gas phase using a double monochromator system for excitation and detection. The detection system can use either a monochromator or narrow-band filter for selection of a narrow spectral band of the fluorescence. The fluorescence signal was amplified using phase sensitive techniques and an appropriate photomultiplier.

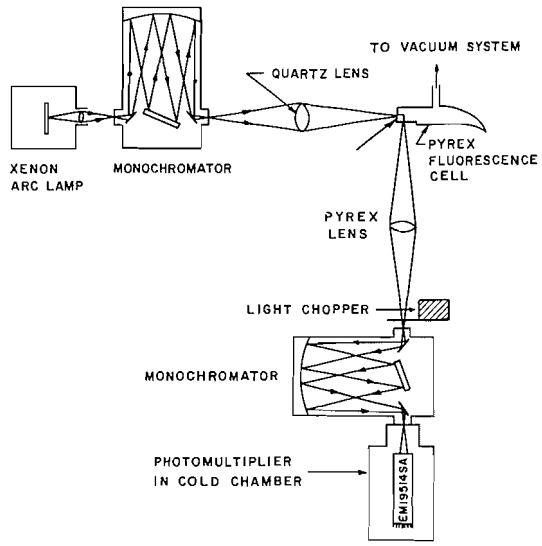

FIG. 1. Schematic of apparatus.

The excitation source was a Hanovia Model 901 C1 150 watt xenon lamp. Wavelength selection for excitation was made by a 0.25 m Jarrell-Ash monochromator equipped with a 2360 lines/mm grating blazed at 300.0 nm. With 2.3 nm slits at the entrance and exit, a nominal bandpass of 5.0 nm was maintained. Exciting radiation was concentrated in the cell using quartz optics. The Pyrex cell was equipped with "suprasil" quartz windows.

Fluorescence, perpendicular to the exciting radiation, was collected by a Pyrex lens and focussed onto the slit of an identical monochromator equipped with a 1180 lines/mm grating blazed at 600.0 nm. For experiments wherein the total radiation was captured, a Corning Sharp Cut, CS 3-72 filter was used to eliminate the scattered radiation below 420.0 nm. The photomultiplier used was an EMI 9514 SA and had an "S" response. Phase sensitive techniques using a PAR Model HR-8 lock-in amplifier were used and the output recorded using an Esterline-Angus recorder. Cooling of the photomultiplier was accomplished using a Products for Research Model TE 102 TS cooling chamber cooled to $-20\,^{\circ}C$.

The carbon disulfide used was Fisher Certified Reagent Grade, Infrared Spectranalyzed. The CS_2 was degassed several times prior to use by repeated freezing in a trap of liquid nitrogen. The pressure of CS_2 was measured using a Wallace and Tiernan gauge for the range 0.1 to 20 Torr (± 0.05 Torr) and an NRC Alphatron gauge for lower pressures.

All quenching experiments were carried out at a CS_2 pressure of 10^{-2} Torr. An average value of the fluorescence over a period of about 10 mins was recorded. The wavelength chosen for excitation was 320.0 nm and the bandpass 5.0 nm. All the gases used, except propane,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

were 99.99% pure as stated by Matheson and used without further purification. Propane was commercial grade. Pressures were measured using the Alphatron, precalibrated for the individual gas.

Results

Simple Stern–Volmer Model

For the simplest case where a molecule is excited to a single electronic energy level the following reaction sequence may be said to apply.

$$[1] \qquad CS_2 + h\nu \xrightarrow{I_x k_a} CS_2^*$$

$$[2] \qquad CS_2^* \xrightarrow{k_f} CS_2 + h\nu \qquad \tau = 1/k_f$$

$$[3] \qquad CS_2^* + CS_2 \xrightarrow{k_q} 2CS_2$$

From the stationary state approximation it is possible to obtain

$$[4] \qquad [CS_2^*] = \frac{I_x k_a [CS_2]}{k_f + k_q [CS_2]}$$

and if

$$[5] \qquad I = \alpha k_f [CS_2^*]$$

then

$$[6] \qquad I = \frac{\alpha I_x k_a k_f [CS_2]}{k_f + k_q [CS_2]}$$

where k_a represents the rate constant for light absorption; k_f, the rate constant for fluorescence; k_q, the rate constant for self-quenching; I, the fluorescence intensity measured in arbitrary units; and I_x, the intensity of the exciting radiation, or

$$[7] \qquad \frac{P}{I} = B[1 + QP]$$

where

$$Q = k_q/k_f,\ P = [CS_2] \text{ and } B = \frac{1}{\alpha I_x k_a}$$

This is the simple Stern–Volmer expression. Thus from measurements of the fluorescent radiation as a function of CS_2 pressure, the validity of this expression can be evaluated.

The spectral distribution of the fluorescent emission for an excitation wavelength (λ_E = 310.0 nm) and two different pressures of CS_2 is shown in Fig. 2. At the lowest pressure used (not shown) a shift in the intensity maximum towards shorter wavelengths was observed. No structure was observed under any of the conditions used. The long wavelength cut-off is not real as shown in view of the decreasing spectral sensitivity of the photomultiplier in this region.

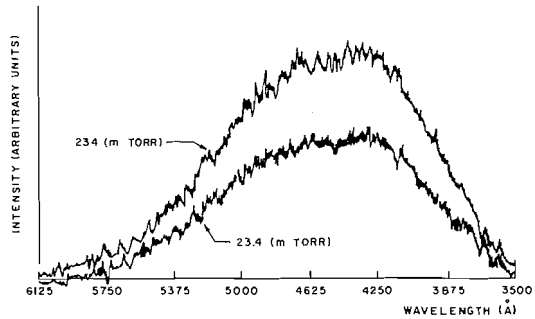

FIG. 2. Photomultiplier recordings of CS_2 fluorescence spectra at two pressures of CS_2.

Measurements of the total fluorescence intensity were made in two ways: (*1*) use of a Corning C.S. 3-72 filter permitted all wavelengths above 420.0 nm to reach the detector; (*2*) the entire fluorescence spectrum was measured using a monochromator and measurements made of the area under the curve.

When these data were plotted using eq. 7, the curves were linear in apparent agreement with the simple Stern–Volmer quenching relationship. Figure 3 shows two curves with λ_E = 310.0 and λ_E = 320.0 nm. Table 1 contains the data for four values of λ_E. These data were obtained using the sharp cut-off filter which gave the most precise measurements of the quenching. The error limits represent the standard deviation of the data points from the line such as shown in Fig. 3. Plots of the sort shown in Fig. 3 were obtained at pressures ranging from 3 to 300 mTorr.

Further studies were made of the fluorescence

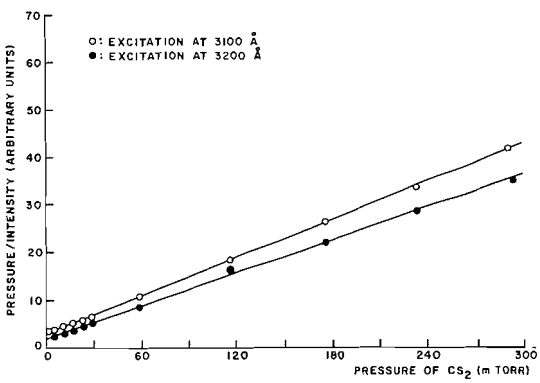

FIG. 3. Stern–Volmer quenching curves: observation of total fluorescence using Corning CS 3-72 filter.

	540.0	105	13.2±1.3	10

*Assuming $k_q = 8 \times 10^6$ $Torr^{-1}$ s^{-1}.

using five wavelengths of excitation and over the same pressure range. In this case, however, the fluorescence signal was recorded using a monochromator with slits set for 12.5nm. These data are shown in Table 2. A definite variation in the quenching constant Q is evident with both wavelength of excitation and fluorescent wavelength.

In addition to the above observations it was noted that at the lowest pressure of CS_2 used, a shift in the intensity maximum towards shorter wavelengths became apparent.

Vibrational Cascade Model

The results discussed above, therefore, suggest that the simple Stern–Volmer mechanism with only one excited level is insufficient as an explanation. A vibrational cascade model such as used to explain NO_2 fluorescence (8) may be described in the following way. This model assumes a vibrational deactivation of the primary excited level prior to re-emission of a photon. Although thoroughly developed by the authors of ref. 8, a brief summary will be included here for completeness.

$$[8] \quad -\frac{d[X_1]}{dt} = (k_{f_1} + k_{e_1}[X] + k_{v_1}[X])[X_1] - k_a I_x[X]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[9] \quad -\frac{d[X_2]}{dt} = (k_{f_2} + k_{e_2}[X] + k_{v_2}[X])[X_2] - k_{v_1}[X][X_1]$$

$$[10] \quad -\frac{d[X_i]}{dt} = (k_{f_i} + k_{e_i}[X] + k_{v_i}[X])[X_i] - k_{v_{i-1}}[X][X_{i-1}]$$

where [X] is the concentration of molecules in the ground electronic state, the $[X_i]$'s are the concentrations of the vibrational levels of the excited electronic state, k_f is the first order rate constant for radiation, k_V is the second order rate constant for vibrational quenching, k_e is the second order rate constant for electronic level quenching, k_a is the absorption coefficient, and I_x is the intensity of the incident radiation.

In order to simplify the analysis it is necessary to make some further assumptions:

(*a*) The rate constants are independent of the particular vibrational level of the upper emitting state. Although not strictly true in some cases, as recently proven (10), there is insufficient information to facilitate the development of such a detailed model.

(*b*) Only the energy transfer rates present in eqs. 8–10, are important. This ignores loss by diffusion, radiation of vibrational energy of the upper state, and collisionally-induced vibrational excitation.

Insertion of a diffusion dependent term $k_d[CS_2^*][CS_2]^{-1}$ in eq. 4 leads to

$$[11] \quad \frac{[CS_2]^2}{I} = \frac{1}{\alpha I_x k_a} \times \left[\frac{k_q}{k_f}[CS_2]^2 + [CS_2] + \frac{k_d}{k_f}\right]$$

A plot of $[CS_2]^2/I$ against $[CS_2]$ shows zero intercept; thus it appears adequate to neglect diffusive losses.

(*c*) All excited levels lying within $\Delta\nu$ of ν_E contribute to the fluorescence intensity in proportion to their concentration. $\Delta\nu = \nu_E - \nu_f$.

For the stationary state the populations of the excited states are given by

$$[12] \quad X_1 = \left(\frac{k_a I_x}{k_f}\right)\left[\frac{[X]}{1 + (Q_E + Q_V)[X]}\right]$$

$$[13] \quad X_i = \left[\frac{Q_V[X]}{1 + (Q_E + Q_V)[X]}\right][X_i - 1]$$

where $Q_E = k_e/k_f$ is the quenching constant for electronic energy; $Q_V = k_v/k_f$ is the quenching constant for vibrational energy. If the intensity is summed over all levels one can obtain

$$[14] \quad \frac{[X]}{I} = \frac{k_f}{k_a I_x}\left[1 - \left[\frac{1 + [X]Q_E}{1 + [X](Q_E + Q_V)}\right]^n\right]$$

where $[X] = P = [CS_2]$. Further, if $k_f/k_a I_x = B$ and $S = Q_E/Q_V = k_e/k_v$, this reduces to

$$[15] \quad \frac{P}{I} = \frac{B(1 + Q_V S P)}{1 - \left[\frac{Q_V P}{1 + Q_V(1 + S)P}\right]^n}$$

In this equation the exponent n represents the total number of excited levels contributing to the intensity of fluorescence; this number depends on the average value of the vibrational quantum transferred ($\Delta\nu_{vib}$) on each deactivating collision and on the difference in energy between the exciting radiation and the fluorescent radiation, *i.e.*

$$[16] \quad n = 1 + (\nu_E - \nu_f)/\Delta\nu_{vib}$$

where ν_E = wavelength of incident radiation; ν_f = wavelength of fluorescent radiation. For high pressures $P \gg 1/Q_V$ and eq. 15 reduces to

$$[17] \quad \frac{P}{I} = \frac{BQ_V PS(1 + S)^n}{[(1 + S)^n - 1]}$$

where from eq. 7

$$[18] \quad Q_{obs} = \frac{Q_V S(1 + S)^n}{[(1 + S)^n - 1]}$$

or $Q_{obs} = Q_V G(n,S)$. In order to check the applicability of this model it is necessary to calculate the function $G(n,S)$ for various values of n and S. Values are given in Table 2. An increase in n for fixed S corresponds to increasing $\Delta\nu$. Figure 4 shows the variation in Q_{obs} with $\Delta\nu$ for three values of S and differing values of $\Delta\nu_{vib}$. The best combination of S and $\Delta\nu_{vib}$ found to fit the data were $S = 0.1$ and $\Delta\nu_{vib} = 1000\ cm^{-1}$. For a value of τ radiative = 15 μs (see next section), $k_q = 7 \times 10^6\ Torr^{-1}\ s^{-1}$. (This assumes the molecular diameter of CS_2 to be 5 Å.) The value of Q_V can be obtained by eq. 18 and Table 3. It is then possible to calculate k_e and k_v. *e.g.* $k_e = 0.76 \times 10^{-10}\ cm^3\ molecule^{-1}\ s^{-1}$ and $k_v = 7.6 \times 10^{-10}\ cm^3 molecule^{-1}\ s^{-1}$.

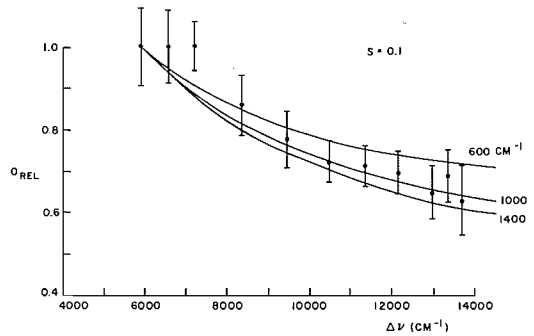

FIG. 4. Comparison of calculated and relative quenching constants as a function of $\Delta\nu = \nu_E - \nu_F$. Reference value is at 6000 cm^{-1}. $\Delta\nu_{vib}$ has been used as the parameter for the theoretical curves.

Radiative Lifetime

Heicklen measured the absorption coefficient of CS_2 and from this calculated a radiative lifetime for the fluorescing state of 3.2 μs. Douglas measured a value of 15 μs which in addition to those measured for SO_2 and NO_2 is abnormally long. This latter author proposed a mechanism whereby the lifetime is lengthened by the mixing of the levels of one electronic state with those of another from which there was no allowed transition to the ground state. This type of vibrational–electronic mixing can result in a situation where some molecules excited to the upper state can spend a portion of their lifetime in the state from which fluorescence is forbidden. This then could result in a lengthening of the lifetime.

Recently Brus has remeasured the lifetimes of CS_2 excited by an N_2 pulsed laser at 337.1 nm. He discovered a double exponential decay of the fluorescing radiation and attributed this to the presence of two excited states contributing to the fluorescence signal. The longer-lived of the two states was found to have a lifetime equal to 17 ± 2 μs in excellent agreement with Douglas. The shorter lived state was found to have a lifetime of 2.9 ± 0.3 μs. These emissions were tentatively assigned to the S and U states designated by Kleman. Recent work of Merer *et al.* (13) has aided greatly in the clarification. Merer *et al.* found that, at room temperature, hot bands of the V system extend to 340.0 nm and mask the weaker S and U bands. Thus Brus excited a hot band of the V system ($^1B_2$–$^1\Sigma_g^+$) in addition to an underlying triplet. The V system consists of the Renner–Teller mixed components of the $^1\Delta_u$ state. Thus it appears that Douglas using excitation at 320.0 nm also has measured the lifetime of the V state. It is thus possible and likely that more than one state has contributed to the fluorescence as measured in the present experiments.

It is therefore essential to consider whether or not the interpretation reported above could be in error. Reverting to the simple Stern–Volmer model (eq. 7) consider the contributions of both states. Let the two excited states be designated by 1 and 2. Then $I_{total} = I_1 + I_2$

$$[19]\quad I_{total} = \frac{\alpha_1 I_{x_1} k_{a_1} k_{f_1} P}{k_{f_1} + k_{q_1} P} + \frac{\alpha_2 I_{x_2} k_{a_2} k_{f_2} P}{k_{f_2} + k_{q_2} P}$$

and

$$[20]\quad \frac{I}{P} = \frac{1}{B_1}\left(\frac{1}{1 + k_{q_1}\tau_1 P}\right) + \frac{1}{B_2}\left(\frac{1}{1 + k_{q_2}\tau_2 P}\right)$$

therefore

$$[21]\quad \frac{P}{I} = \frac{B_1 B_2 (1 + k_{q_1}\tau_1 P)(1 + k_{q_2}\tau_2 P)}{B_1(1 + k_{q_1}\tau_1 P) + B_2(1 + k_{q_2}\tau_2 P)}$$

where $\tau_1 = 17$ μs, $k_{q_1} = 1.2 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}; $\tau_2 = 2.9$ μs, $k_{q_2} = 7.9 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} from Brus (6).

$$[22]\quad k_{q_1}\tau_1 \cong k_{q_2}\tau_2$$

hence

$$[23]\quad \frac{P}{I} = \frac{B_1 B_2}{B_1 + B_2}(1 + k_{q_1}\tau_1 P)$$

or

TABLE 4. Quenching of CS_2 fluorescence by foreign gases*

Collision partner	Q_M ($Torr^{-1}$)	% Error	k_M (cm^3 $molecule^{-1}$ s^{-1} $\times 10^{-10}$)	$\pi\sigma_q^2$ (cm^2 $molecule^{-1}$ $\times 10^{-16}$)	D (Å)	$\pi\sigma_c^2$ (cm^2 $molecule^{-1}$ $\times 10^{-16}$)	P
Ar	15.4	8.6	0.22±0.02 (0.17±0.03)	4.3±0.3 (3.5±0.6)	3.418	55.6	0.08
N_2	34.6	10	0.49±0.05 (0.20±0.05)	8.7±0.8 (3.6±0.9)	3.681	59.2	0.15
O_2	34.8	4.6	0.49±0.03 (0.32±0.05)	9.2±0.5 (6.0±1.0)	3.433	55.8	0.16
CO_2	73.0	6.4	1.0 ±0.04	21 ±1.2	3.996	63.5	0.34
COS	88.1	8	1.2 ±0.07	28 ±2.3	4.13	65.4	0.43
SO_2	104.	6.1	1.5 ±0.06	34 ±1.8	4.29	67.8	0.51
SF_6	114.0	5.4	1.6 ±0.06	44 ±2.0	5.01	78	0.57
C_3H_8	150.0	8.5	2.1 ±0.12	44 ±3.2	5.06	79.5	0.56

*Values obtained by Brus (6) are included in parentheses for comparison.

$$\frac{P}{I} = \frac{B_1 B_2}{B_1 + B_2}(1 + k_{q_2}\tau_2 P)$$

Thus it is concluded that in this particular case where coincidentally eq. 22 is valid the experimental results can only be interpreted in terms of a vibrational cascade in the upper state. It is, however, not possible to discriminate between the two states. So it appears that in this work, using broad band excitation, only the V was excited and thus vibrational relaxation within this state was observed. Brus also found that the relative proportions of the two components contributing to the double exponential decay were independent of pressure. This eliminates the possibility that one state is converted into the other.

Quenching of Fluorescence by Foreign Gases

In the presence of foreign gases the simple mechanism discussed earlier must be modified to include the following

$$[3a] \qquad CS_2^* + M \xrightarrow{k_M} CS_2 + M$$

It is possible to derive, following the stationary state approximation the expression

$$[24] \qquad \frac{I_0}{I} = 1 + \frac{k_M[M]}{k_f + k_q[CS_2]}$$

where I_0 is the fluorescence intensity in absence of foreign gas, M, and I is that measured in the presence of M. For constant $[CS_2]$ the slope of the plot of I_0/I *vs.* [M] is equal to

$$\frac{k_M}{k_f}\frac{1}{1 + \frac{k_q}{k_f}[CS_2]}$$

where k_M/k_f shall be called the quenching constant, Q_M. The factor

$$\frac{1}{1 + \frac{k_q}{k_f}[CS_2]}$$

was evaluated to be 0.75 using the value of the fluorescence lifetime equal 15 μs (7) and $k_q = 0.76 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}. This is in agreement with Heicklen who measured $(k_q/k_f)[CS_2] = 0.36 \pm 0.05$. Figure 5 shows the Stern–Volmer plots for the eight foreign gases used and Table 4 lists the values of k_M calculated from the slopes of these curves. Similarly, included are the values of $\pi\sigma^2$, the quenching cross-section, and the values of the steric factor obtained by dividing this cross-section by that calculated using the values of the gas viscosity collision diameters taken from Hirschfelder, Curtiss, and Bird (14). The % error was obtained from the 95% confidence interval on the slopes of the lines shown in Fig. 5. It can be seen from

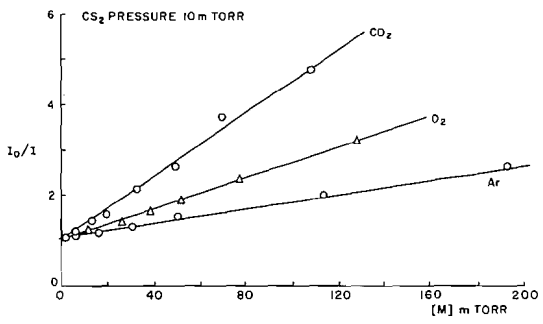

FIG. 5. Typical Stern–Volmer plots for M = Ar, O_2, CO_2.

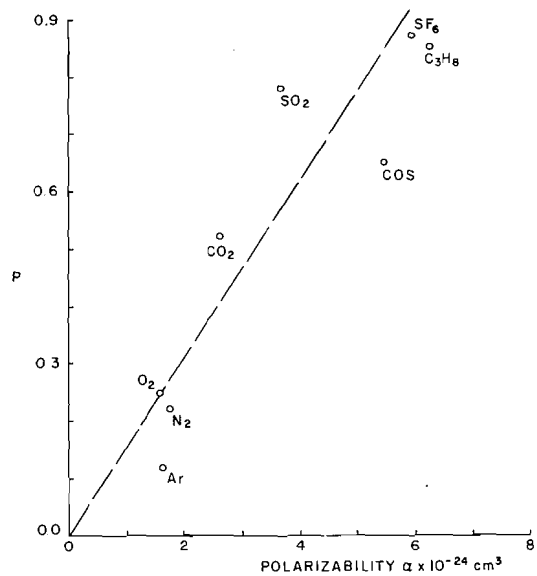

FIG. 6. Correlation of quenching probability per gas kinetic collision, P, with polarizability of the collision partner.

the table that there is excellent agreement with the recent data of Brus.

It has been stated by Mettee (12) that the quenching efficiencies for SO_2 fluorescence correlate well with the polarizability of the quenching partner. This appears also to be so for CS_2 as shown in Fig. 6, although with so few data points it is difficult to conclude a great deal. A similar graph plotting P *vs.* $1/\Delta E$ where ΔE is the energy discrepancy for nearest resonant energy transfer exhibits considerably more scatter. It would be very interesting to use these data to verify the recent theory of Thayer and Yardley (15), however, insufficient information with too few polar quenchers exists at present.

Conclusions

The simple Stern–Volmer model of fluorescence quenching is insufficient to explain the observed variation in quenching coefficient with exciting and fluorescing wavelength in CS_2 vapor. It is necessary to use a more complex model involving vibrational relaxation of an upper state prior to quenching. This relaxation has not been observed previously and, in fact, some authors have suggested that the high collision efficiencies for electronic deactivation suggest that it is not present (1, 6). Vibrational relaxation occurs with a rate constant equal to 7.6×10^{-10} cm^3 molecule^{-1} s^{-1}, approximately the gas kinetic rate of 2.3×10^{-10} cm^3 molecule^{-1} s^{-1}. Electronic quenching requires about 10 collisions or about 1/10 the gas kinetic rate. This is within the error of the observations of previous workers. The size of the vibrational quantum transferred is approximately 1000 cm^{-1}. This frequency is an approximate mean of the three normal vibrations of ground state CS_2 and thus is a reasonable value. The value of the rate of electronic quenching is in good agreement with the measurement of Brus on the longer-lived state (1.2×10^{-10} cm^3 molecule^{-1} s^{-1}) if the lifetime measured by Douglas is used. These results are in good agreement with those recently made on similar molecules, *i.e.* NO_2, SO_2.

The collision cross-sections for the quenching of CS_2 fluorescence by eight collision partners were measured and found to correlate adequately with the polarizability of the quencher.

Proton N.M.R. Spectra of some Cyclopentadienyltitanium Compounds

ALEXANDR GLIVICKY[1] AND JAMES DUNCAN MCCOWAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 26, 1973

N.m.r. spectra obtained preliminary to studies of compounds of the form Cp_2TiRCl and Cp_2TiR_2 raise questions about some previous interpretations of related spectra.

Les spectres r.m.n., obtenus antérieurement à l'étude des composés de la forme Cp_2TiRCl et Cp_2TiR_2, ont soulevé certaines questions quant aux interprétations précédantes des spectres se rattachant à ceux-ci.
[Traduit par le journal]

Can. J. Chem., **51**, 2609 (1973)

Introduction

Preliminary to a study of the stability and reactivity of cyclopentadienyl titanium, a catalogue of ^1H n.m.r. spectra was developed for reference. These spectra have been compared with those already reported (1–8) and any significant differences examined.

Procedures

Since many of the subject compounds are air sensitive, all manipulations were either within a nitrogen-filled glove box or within a vacuum line.

The glove box atmosphere was dry nitrogen (99.9% purity supplied by Matheson of Canada Limited and Canox Limited) which entered the box through a column packed with Linde molecular sieves No. 5A and was continually circulated, once within the box, through a Vac Corporation HE-493 Dri-Train. Glassware used within the box had been previously dried within high vacuum vessels that could be placed, sealed, within the interchange. The interchange itself could be evacuated to 6 Nm^{-2} before being flushed with nitrogen.

In the glove box, samples were prepared to known concentrations and component ratios in n.m.r. tubes fitted with tapers. They were degassed three times while frozen to liquid nitrogen temperatures on a vacuum line outside of the glove box and sealed at 10^{-2} Nm^{-2}. Spectra were obtained using frequency sweep on a Bruker HX-60 spectrometer. Tetramethyl silane was employed both as reference and as lock. All the samples were measured at 294 ± 1 °K. All shifts are reported relative to tetramethylsilane ($\tau = 10$). The accuracy of the reported τ values is better than $\pm 0.02\tau$.

$Cp_2Ti(C_6H_5)_2$ was prepared by the method of Summers *et al.* (9); $Cp_2Ti(C_6H_5CH_2)_2$ by the method of Razuvaev *et al.* (10); and $CpTi(C_6H_5CH_2)_3$ by the method of Cannell (11). Except for $Cp_2Ti(C_6H_5CH_2)Cl$, other organometallic materials were obtained from Alfa Inorganics.

The preparation of $Cp_2Ti(C_6H_5CH_2)Cl$ is based on a method by Dubsky and Jacot-Guillarmod (12), and is recommended for preparation of related compounds.

Dioxane (5.1 mmol) was added slowly with constant stirring to a 50 ml flask containing a 1.02 *M* solution of $C_6H_5CH_2MgCl$ (5.1 mmol) in tetrahydrofuran. After stirring for 15 min, the mixture was filtered and the filtrate evaporated to dryness. The white residue of $(C_6H_5CH_2)_2Mg$ was washed three times with pentane, dried for ½ h at reduced pressure, and finally dissolved in 15 ml of benzene.

$(C_6H_5CH_2)_2Mg$ (2.5 mmol) so prepared was added slowly, in benzene solution, to a 50 ml flask containing Cp_2TiCl_2 (1.54 g, 6.2 mmol), benzene (20 ml) and a magnetic stirring bar. After stirring for an additional 10 min, the resulting violet mixture was filtered through a fine frit. Addition of a two fold excess of *n*-pentane to the violet filtrate precipitated crystals. After approximately 20 h, the liquid was decanted and the remaining violet black crystals were dried at reduced pressure. Elemental analysis was by Alfred Bernhardt (Elbach).

Anal calcd. for $C_{17}H_{17}TiCl$: C, 67.02; H, 5.62; Cl, 11.64; Ti, 15.72. Found: C, 66.72; H, 5.61; C, 11.82; and Ti, 15.79.

It should be noted that the sample used in the above analysis was deliberately exposed to air for 6 h before being sealed in an evacuated tube and sent for analysis. The resulting analysis would tend to disprove the recent suggestion (6) that decomposition is rapid in air at room temperature.

The "melting point" was 365 °K with decomposition, as determined in an evacuated capillary. A value of 380 °K has been reported in an argon atmosphere (6).

Results and Discussion

N.m.r. data are presented in Tables 1 to 7. Chemical shifts are nearly independent of concentration. On the other hand, solvent influence is marked. The reported values can be explained in terms of the shielding contributions of the solvent (13, 14), as can most values reported in the literature (2–8), but some anomalies exist among the literature values. These are discussed below.

The Results of Waters and Mortimer

Waters and Mortimer (6) comment on the "abnormal" chemical shift observed for the cyclopentadienyl protons of $Cp_2Ti(C_6H_5CH_2)Cl$ in chloroform. However, in the present work, it was found that dissolving $Cp_2Ti(C_6H_5CH_2)Cl$ in $CDCl_3$ led rapidly to the formation of an intensely red solution by the following process:

[1] $2Cp_2Ti(C_6H_5CH_2)Cl + 2CDCl_3 \rightarrow$
$2Cp_2TiCl_2$ + bibenzyl
+ combination products of solvent radicals

Some $CpTiCl_3$ was also identified.

In order to verify that the reported spectra (6) were indeed those of the decomposition products, the chemical shifts of Cp_2TiCl_2 and of bibenzyl

in $CDCl_3$ were measured. They correspond exactly to those shifts reported (6) for the monobenzyl compound. Probably the same situation exists for the neopentyl compound. It seems certain that the reported values (6) are for the decomposition products, and that the subsequent discussion of "abnormal" behavior is without meaning.

The Results of Nesmeyanov et al.

The singlet resonance arising from the cyclopentadienyl protons of Cp_2TiCl_2 dissolved in tetrahydrofuran (Table 6) is inconsistent with the report of Nesmeyanov *et al.* (15) but agrees with reports from other investigators (1, 2, 16). Nesmeyanov observed two resonances, one close to that reported here and the other 0.25τ upfield, which coalesced into a singlet when the

system was heated to 408 °K. He interpreted the results in terms of nonequivalent protons.

A more plausible explanation is the presence of $(Cp_2TiCl)_2O$ in Nesmeyanov's sample. An n.m.r. spectrum of this material showed its resonance to be 0.25τ upfield from that of Cp_2TiCl_2 in tetrahydrofuran. Moreover, this material disproportionates (17) with polymerization of one of the products

[2] $2n(Cp_2TiCl)_2O \rightarrow nCp_2TiCl_2 + (Cp_2Ti{\cdot}O)_n$

This reaction, which proceeds visibly at room temperature, is very rapid at 408 °K. Since the fine yellow polymeric solid produces no observable proton resonance, all of Nesmeyanov's observations are explained.

The Results of Beachell and Butter

Beachell and Butter (2) have examined the influence of the electronegativity and electronic character of ligands R on the chemical shifts of the cyclopentadienyl protons in the compounds $(C_5H_5)_2TiR'R''$.

In one case, cyclopentadienyl proton chemical shifts of four compounds, $Cp_2Ti(CH_3)_2$, $Cp_2Ti(CH_3)Cl$, Cp_2TiCl_2, and $CpTiCl_3$ are plotted against the summed electronegativities of the "first atom" of the R groups and an excellent linear relationship is obtained. On this basis it is concluded that methyl, chlorine, and cyclopentadienyl ligands contribute an equal electronic effect. While the observation that the data for $Cp_2Ti(CH_3)Cl$ lie intermediate between those of the dimethyl and dichloro compounds is not unexpected, the apparent equivalence of the effects of the π bonded cyclopentadienyl and the methyl and chlorine is more surprising.

It is also fortuitous, since three of the values are in doubt. Both the value for $Cp_2Ti(CH_3)_2$ and that for $CpTiCl_3$ differ from those reported in Table 1 of the same paper, with the further difference that the $CpTiCl_3$ value was obtained in tetrahydrofuran (18). The $CpTiCl_3$ and Cp_2TiCl_2 values both differ from those reported here, the latter substantially.

Taking the tabulated values for $Cp_2Ti(CH_3)_2$ and $Cp_2Ti(CH_3)Cl$ and the value from Table 6 for Cp_2TiCl_2, a constant increment for ring proton chemical shift in the series $Cp_2Ti(CH_3)_nCl_{2-n}$ is still obtained, but with δ/n equal to 0.29. While these data could still be fitted to the correlation with electronegativity attempted by Beachell and Butter, the value for $CpTiCl_3$ could not. This fact, taken with the lack of linearity in some analogous series, suggests that there is little justification for simple correlations of cyclopentadienyl ring proton chemical shift with the electronegativity of the "first atom".

The authors thank the National Research Council of Canada, the Ontario Department of University Affairs, and Queen's University for financial support of this research. The award of fellowships to one of us (A.G.) by the Ontario Government and by Queen's University is gratefully acknowledged.

The Crystal Structure of $KAlP_2O_7$

HOK NAM NG AND CRISPIN CALVO

Institute of Materials Research, McMaster University, Hamilton, Ontario

Received December 22, 1972

$KAlP_2O_7$ crystallizes as monoclinic crystals with $a = 7.308(8)$, $b = 9.662(6)$, $c = 8.025(4)$ Å, $\beta = 106.69(7)°$, $z = 4$ and space group $P2_1/c$. The structure was refined from 1394 observed reflections by full-matrix least-squares method to a final R value of 0.032. The $P_2O_7^{4-}$ anion consists of a pair of corner-sharing PO_4 groups in a nearly staggered configuration. The mean bridging and terminal P—O bond lengths are 1.607 and 1.509 Å, respectively, and the P—O—P angle is 123.2°. The anions lie in planes parallel to (001). The Al ions are bonded to six oxygen atoms contributed by anions in three layers of P_2O_7 groups. The average Al—O bond length is 1.889 Å. The potassium ion is coordinated to ten oxygen atoms lying within a spherical shell with inner and outer radii of 2.739 and 3.185 Å.

$KAlP_2O_7$ crystallise sous forme monoclinique avec $a = 7.308(8)$, $b = 9.662(6)$, $c = 8.025(4)$ Å, $\beta = 106.69(7)°$, $z = 4$ et le groupe spatial est $P2_1/c$. La structure a été raffinée à partir des 1394 réflexions observées par la méthode des moindres carrés jusqu'à obtention d'une valeur finale pour R de 0.032. L'anion $P_2O_7^{4-}$ comprend une paire de groupes PO_4 ayant un côté commun, dans une configuration presque éclipsée. Les longueurs moyennes des liaisons P—O du pont et du bout sont respectivement de 1.607 et 1.509 Å et l'angle P—O—P est 123.2°. Les anions sont situés dans des plans parallèles à (001). Les ions Al sont liés à six atomes d'oxygène venant des anions des trois couches de groupes P_2O_7. La longueur moyenne de la liaison Al—O est de 1.889 Å. L'ion potassium est coordiné à dix atomes d'oxygène se trouvant à l'intérieur d'une enveloppe sphérique de rayons interne et externe de 2.739 et 3.185 Å.

Introduction

Although the structures of a number of divalent metal pyrophosphates are presently known, relatively little can be said about the structures of the $M^IM^{III}P_2O_7$ compounds, where M^I is a monovalent metal and M^{III} is a trivalent metal. The compound $KAlP_2O_7$ was first characterized by d'Yvoire (1) and later by Klyucharov and Skoblo (2). Gamondès, d'Yvoire, and Boule prepared two groups of $M^IM^{III}P_2O_7$ compounds (3). The first group consists of $KAlP_2O_7$ and $NaFeP_2O_7$-I and the second group consists of $NaAlP_2O_7$ and $NaFeP_2O_7$-II. An irreversible phase transformation from $NaFeP_2O_7$-I to $NaFeP_2O_7$-II was observed at 750 °C. From their X-ray powder patterns $NaFeP_2O_7$-II and $NaAlP_2O_7$ were considered to be isostructural and their structures to be related to that of α-$Cu_2P_2O_7$. The former two compounds belong to the space group $P2_1/c$ while α-$Cu_2P_2O_7$ belongs to the space group $C2/c$ (4); the lowering of symmetry results from the replacement of the symmetry equivalent Cu atoms in α-$Cu_2P_2O_7$, by Na and Fe or Na and Al atoms in an ordered manner. $KAlP_2O_7$ and $NaFeP_2O_7$-I, both with the space group $P2_1/c$, were also thought to be isostructural, but their structure was not known.

While attempting to grow crystals of $AlPO_4$ with the cristobalite structure by using KH_2PO_4 as a flux, we obtained some large colorless crystals which were identified as $KAlP_2O_7$. The structure investigation of $KAlP_2O_7$, as a representation of the group $M^IM^{III}P_2O_7$-I was deemed worthwhile in order to seek its relationship to that of the group $M^IM^{III}P_2O_7$-II compounds, and determine whether $KAlP_2O_7$ has polymorphic modifications analogous to $NaFeP_2O_7$.

Experiments

Crystals of $KAlP_2O_7$ were prepared by heating a mixture of 20% (mol) $AlPO_4$ and 80% KH_2PO_4 in a platinum crucible. The mixture was melted and the temperature was held at 1100 °C for 6 h. It was then cooled at a rate of 6 °C/h to 600 °C and quenched to room temperature. Clear and colorless parallelopipeds of $KAlP_2O_7$ could be separated from the powdery matrix by washing the product in boiling water.

Precession photographs showed that $0k0$ reflections with k odd and $h0l$ reflections with l odd were absent. The space group was confirmed to be $P2_1/c$. Accurate lattice parameters were determined by a least-squares fit to 15 2θ values measured with the Syntex PĪ automatic diffractometer. The values obtained are listed in Table 1 along with other crystal data. Also included in Table 1 are the lattice parameters determined from powder patterns by Gamondès *et al.*, who also determined the

density of $KAlP_2O_7$ to be 2.923 g/cm^3, corresponding to four formula units per unit cell.

A good quality single crystal of $KAlP_2O_7$, ground into spherical shape, with a radius of 0.012 cm was selected for intensity measurements. Intensity data were collected on a Syntex $P\bar{1}$ automatic diffractometer using graphite monochromatized MoKα radiation (λ = 0.71069 Å). The mode of scan used was θ/2θ at a variable rate. Reflections whose intensity corrected for background was less than three times the standard deviation were considered unobserved. A total of 2275 symmetry-independent reflections was collected, among which 1394 reflections were considered observable ($I > 3\sigma$). The data were corrected for Lorentz, polarization, and absorption effects ($\mu R = 0.28$).

The structure was determined from Patterson functions and subsequent electron density and difference electron density maps. The structure was refined by minimizing $\Sigma\omega(|F_o| - |F_c|)^2$ using a full-matrix least-squares program written by J. S. Stephens for the CDC 6400. Atomic scattering curves for K^+, Al^{3+}, P^{5+}, and O^{2-} were taken from Cromer and Waber (5) and those for the potassium and phosphorus atoms were corrected for anomalous dispersion (6). The atomic positions were refined together with individual isotropic temperature factors until the R value converged to 0.066. The anisotropic components of the temperature factors of K^+ and then of the other atoms were allowed to vary. A weighting function $\omega = (1.27 - 0.03F_o + 0.001F_o^2)^{-1}$ was chosen so that the square of the difference between the observed and calculated structure factors $\omega(\Delta F)^2$ would be independent of the local average value of $|F_o|$. Unobserved reflections were given zero weight if their calculated structure factor was less than the local minimum observable value; otherwise they were given a value 0.9 times the local minimum observable value. For a small number (seven) of intense reflections, all at low $\sin\theta/\lambda$, the calculated structure factor was substantially larger than the observed value. Correction was then applied for secondary extinction. The refinement terminated when the maximum shift in the parameters was less than one-third of the estimated standard deviation. The final R value is 0.032 and the residual

$$R_2 = \left[\frac{\sum \omega(|F_o|^2 - |F_c|^2)}{\sum \omega|F_o|^2}\right]^{1/2}$$

is 0.043. The final positional and thermal parameters are shown in Table 2. The calculated and observed structure factors are listed in Table 3.[1] The value of the mean deviation of a reflection of unit weight is 0.96.

Discussion

The pyrophosphate group in $KAlP_2O_7$ (Fig. 1) is formed from two slightly distorted PO_4 tetrahedra which share O(1). The plane containing the two phosphorus and the bridging oxygen atoms, or the plane of the anion, is approximately parallel to the *ac*-plane. The $P_2O_7^{4-}$ group nearly has C_s symmetry with the plane of the anion as the pseudo mirror plane. O(4) and O(5) deviate slightly from this plane since the dihedral angle between the O(4)—P(2)—O(1) plane and the O(5)—P(1)—O(1) plane is about 9°. The P—O—P bridge angle is 123°, which is smaller than any of the bridge angles in those pyrophosphates reported to date. The P(1)—O(1) bond (1.610 Å) is slightly longer than the P(2)—O(1) bond (1.604 Å). The terminal P—O bonds are also different. The shortest terminal P—O bonds are the P(1)—O(5) bond (1.502 Å) and the P(2)—O(4) bond (1.485 Å) which are the closest to the plane of the molecule. The average lengths of the terminal P—O bonds are 1.511 and 1.506 Å for the P(1) and P(2) tetrahedra, respectively. For both tetrahedra the O—P—O angles subtended by the terminal oxygen atoms are all larger than the ideal tetrahedral angle except O(2)—P(2)c—O(6), whereas those subtended by the central oxygen atom and the terminal oxygen atoms are all less than 109° 28′. These and other important bond lengths and bond angles are listed in Table 4.

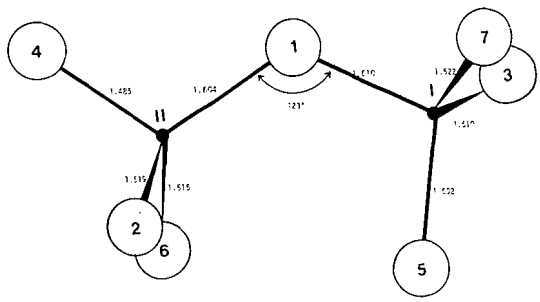

FIG. 1. Geometry of the $P_2O_7^{4-}$ anion in $KAlP_2O_7$. The phosphorus atoms are labelled I and II and the oxygen atoms are labelled 1 to 7. Bond lengths are in Å.

*Oxygen atom positions are derived from those listed in Table 2 by operations of the screw axis, *c*-glide plane and center of inversion designated by O(*n*)s, O(*n*)c, and O(*n*)i, respectively.

†Estimated standard deviations in parentheses include uncertainties in the unit cell dimension.

The $P_2O_4^{4-}$ group is propagated in the *ab* plane by the two-fold screw axes to form a sheet. Adjacent sheets are generated by the *c*-glide planes to form the network for the entire structure (Figs. 2 and 3). The distance between adjacent sheets is 3.84 Å as compared to 4.35 Å found in α-$Cu_2P_2O_7$ (4).

The aluminum ion is octahedrally coordinated with six oxygen atoms with an average Al—O bond length of 1.889 Å. Four of these oxygen

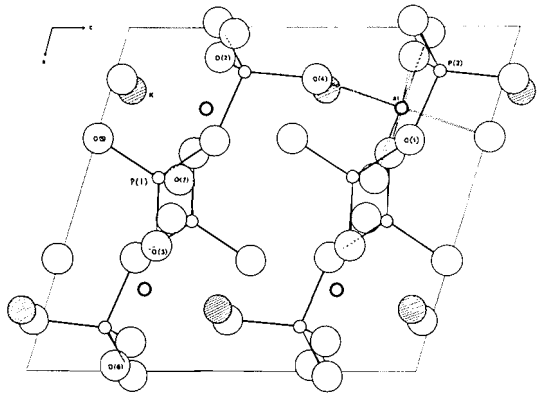

FIG. 2. Structure of $KAlP_2O_7$ projected onto the *ac*-plane. Small open circles are phosphorus atoms, large open circles are oxygen atoms, small double circles are aluminum atoms, and large shaded circles are potassium atoms.

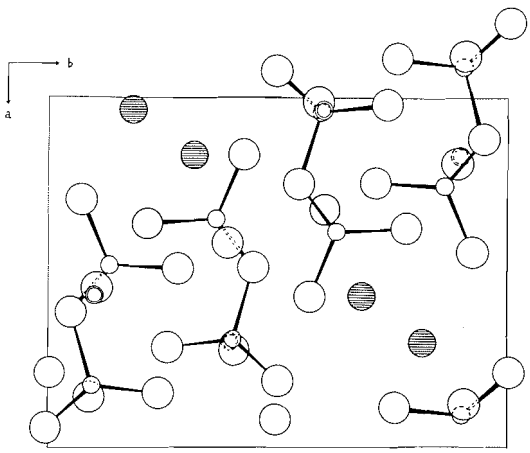

FIG. 3. Structure of $KAlP_2O_7$ projected onto the *ab*-plane. Same legends as in Fig. 2.

atoms (O(2)c, O(3)i, O(6)i, and O(7)c) from three different $P_2O_7^{4-}$ groups in the same sheet nearly lie on a plane while O(4) and O(5) from the adjacent sheets complete the octahedron. Thus the Al ion serves to link three pyrophosphate sheets (Fig. 2) and this may account for the small distance between sheets in $KAlP_2O_7$. The AlO_6 octahedron is distorted with the axial bonds (1.841 and 1.878 Å to O(4) and O(5)) considerably shorter than the equatorial bonds, which average 1.903 Å, and two O—Al—O angles in the equatorial plane significantly different from 90° (Table 4). It should be noted that O(4) is involved in the shortest Al—O and P—O bond, but forms the longest bond, among the nearest ten, with the other cation, K^+ (3.185 Å). Potassium shares oxygen atoms with two pyrophosphate sheets with bond lengths ranging from 2.739 to 3.185 Å.

The distortion of the $P_2O_7^{4-}$ ion from two regular corner-sharing tetrahedra (in $KAlP_2O_7$) is similar to that found in other pyrophosphate compounds. The difference between the terminal and the bridging P—O bond lengths, for a P—O—P bond angle near 109°, has been ascribed to the result of $d\pi$–$p\pi$ bonding by Cruickshank (8), who predicted bond lengths of 1.51 and 1.64 Å for the terminal and bridging bonds, respectively. Table 5 lists the average P—O bond lengths and bridge angles of the non-linear $P_2O_7^{4-}$ groups found in various pyrophosphate compounds. Experimentally this difference in terminal and bridging P—O bonds is always smaller than the predicted value of 0.13 Å. Cruickshank attributed this to the opening of the P—O—P bridge angle and as a result the bridging P—O bonds acquire some π-character from the orbitals in the P—O—P plane as well. It can be seen from Table 5 that a decrease in the P—O—P angle is indeed correlated with an increase in the difference between the bridging and terminal P—O bonds in a general way. In $KAlP_2O_7$ the P—O—P angle of 123° is the smallest among the pyrophosphate compounds listed in Table 5, and yet the difference of 0.10 Å in the P—O bonds is still less than the predicted 0.13 Å. The P_2O_7 group in the present compound has a staggered C_s symmetry while all the remaining staggered P_2O_7 groups have pseudo C_2 symmetry and show P—O—P angles larger than 130°. The anions showing eclipsed configurations all have angles lying in the range between 127 and 138°.

By way of contrast, the variation of individual bond length in a distorted coordination polyhedron AX_n was correlated by Baur with the bond strengths, p_x, received by the individual anions (9). That is, the anion is no longer considered to be isolated. This idea was quantitatively summarized by the equation

$$d(\text{A—X}) = \langle d(\text{A–X})\rangle + b\Delta p_x$$

where Δp_x is the difference between the p_x of one individual anion and the mean p_x of all anions in the coordination polyhedron. The mean cation–anion distance $\langle d(\text{A—X})\rangle$ and b are empirically derived constants, and the appro-

*$d_{calcd} = 1.537 + 0.109\Delta p_0$.

priate equation for the PO_4 tetrahedron was given by Baur as

$$d(\text{P—O}) = 1.537 + 0.109\Delta p_0$$

The predicted P—O distances for the two PO_4 tetrahedra in $KAlP_2O_7$ are compared with the observed values in Table 6. The results are generally satisfactory except for O(4).

Baur extended the idea of Δp_x correlation to the variation of Si—O—Si bridge angle in the disilicates (10). He showed a correlation between the bridge angle and $\Delta d_{(om)}$ which is the difference between the experimentally observed bridging Si—O bond length and the mean Si—O bond length $\langle d(\text{Si—O})\rangle$. Figure 4 shows the plot of $\Delta d_{(om)}$ versus the P—O—P bridge angle for 16 pyrophosphate compounds. The value for $\langle d(\text{P—O})\rangle$ chosen here is the actual mean P—O distance averaged over all the P—O bonds in the particular structure. The plot shows an inverse relationship between the bridge angle and $\Delta d_{(om)}$, but the correlation is rather poor.

The possibility of a phase transformation for $KAlP_2O_7$ was investigated by differential thermal analysis from 25 to 500 °C in air. A very small endothermic effect was observed at 455 °C.

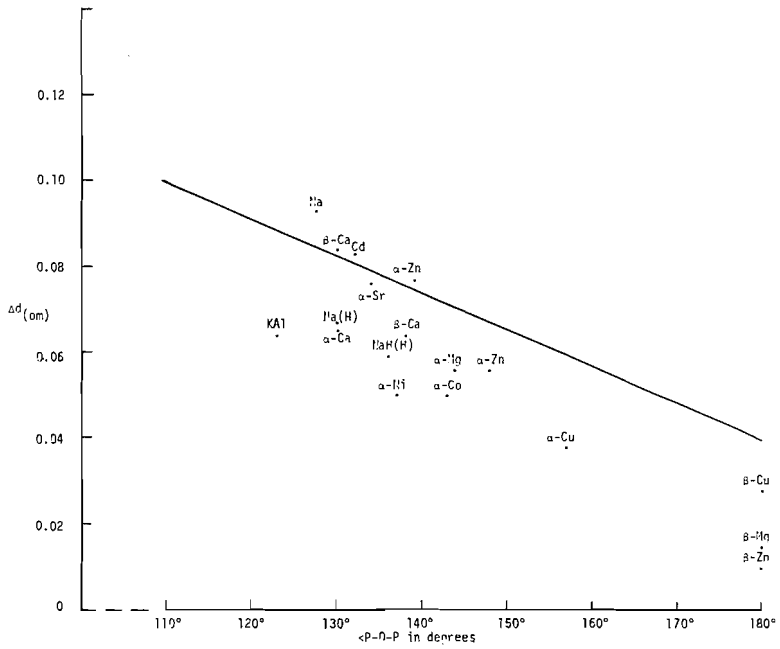

FIG. 4. Plot of $\Delta d_{(om)}$ *vs.* P—O—P bridge angle for 16 pyrophosphate compounds (for α-$Zn_2P_2O_7$ and β-$Ca_2P_2O_7$, the structure has two non-equivalent pyrophosphate groups). Na(H) and NaH(H) denote the compounds $Na_4P_2O_7 \cdot 10H_2O$ and $Na_2H_2P_2O_7 \cdot 6H_2O$, respectively. The solid line corresponds to Cruickshank's prediction.

However, precession photographs taken at 25, 430, and 500 °C on the same crystal showed no change in space group symmetry, and very little change in cell dimensions and intensity of the reflections.

If $NaFeP_2O_7$-I is isostructural with $KAlP_2O_7$ and $NaFeP_2O_7$-II is structurally related to α-$Cu_2P_2O_7$ as suggested by Gamondès *et al.* (3), a comparison between the structures of $KAlP_2O_7$ and α-$Cu_2P_2O_7$ should reveal some structural relationship between the two groups of $M^IM^{III}P_2O_7$ compounds and the nature of the phase transformation of $KAlP_2O_7$.

The space group of $NaFeP_2O_7$-II, $P2_1/n$, differs from the space group $C2/c$, to which α-$Cu_2P_2O_7$ belongs, by the absence of two-fold rotation axes through the bridging oxygen atom in the former in addition to a rotation of the a and c axes. In Fig. 5 the projection of the α-$Cu_2P_2O_7$ structure onto the $a'c'$ plane has been reproduced after applying the transformation $\boldsymbol{a}' = -\boldsymbol{a}$, $\boldsymbol{c}' = \boldsymbol{a} + \boldsymbol{c}$, so as to show space group symmetry $I2/n$. The dimension of this transformed unit cell for α-$Cu_2P_2O_7$ becomes $a' = 6.876$ Å, $b' = 8.113$ Å, $c' = 9.439$ Å, $\beta' = 113.8°$.

In both α-$Cu_2P_2O_7$ (Fig. 5) and $KAlP_2O_7$ (Fig. 2) the pyrophosphate anion, in a nearly staggered configuration, forms sheets parallel to the ab plane. In the former case the P—O—P plane contains the b axis and nearly lies in the ac plane in the present case. This change destroys the nearly hexagonally close-packed array of oxygen atoms which characterize the sheets in

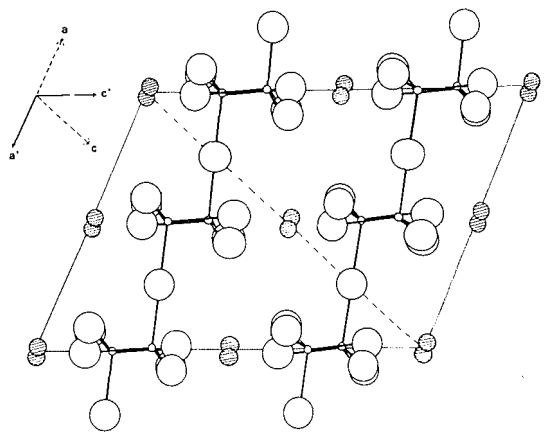

FIG. 5. Projection of the α-$Cu_2P_2O_7$ structure along the b-axis in the transformed space group $I2/n$. Small open circles are phosphorus atoms, large open circles are oxygen atoms, and shaded circles are copper atoms.

α-$Cu_2P_2O_7$. In addition the pyrophosphate groups are rotated so as to subtend an angle of $-11°$ with the sheet directions, rather than $+17°$, so as to accommodate the aluminum ion. This destroys the octahedral site between sheets creating the pseudo cubical sites occupied by K^+ in $KAlP_2O_7$. These changes suggest that gross rearrangements are involved in the change between $NaFeP_2O_7$-I and $NaFeP_2O_7$-II and that the analogous change is unlikely to account for the DTA anomaly seen in $KAlP_2O_7$.

The authors wish to thank Mrs. S. Leung for growing the crystals and the National Research Council of Canada for financial support in terms of a research grant and a Postdoctorate Fellowship (H.N.N.).

Crystal Structure of α-VPO_5

BYRON JORDAN AND CRISPIN CALVO

Department of Physics, McMaster University, Hamilton, Ontario

Received March 21, 1973

α-VPO_5 crystallizes in the tetragonal space group $P4/n$ with $a = 6.014(7)$ and $c = 4.434(2)$ Å. The structure, isotypic with that of α-VSO_5, was refined by full-matrix least-squares method to an R value of 0.089 using 239 independent reflections. The vanadium ion lies on a crystallographic four-fold axis, as does one of the oxygen atoms, and the P on a site of $\bar{4}$ symmetry. A second oxygen atom, as a result of disorder, occurs in two positions which are mirror reflected with respect to the *ac* plane. The structure consists of highly distorted VO_6 groups with bond lengths along the *c* axis of 1.580(11) and 2.853(11) Å while the remaining four V—O bond lengths are all 1.858(8) Å. The P—O bond lengths in the PO_4 tetrahedron are 1.541(8) Å with the PO_4 groups bridging across four chains of VO_6 groups.

L'αVPO_5 cristallise dans le groupe d'espace tétragonal $P4/n$ avec $a = 6.014(7)$ et $c = 4.434(2)$ Å. La structure, isotype de celle de l'αVSO_5, a été raffinée par les méthodes matricielles des moindres carrés jusqu'à une valeur R de 0.089 après 239 reflexions indépendantes. L'ion vanadium se trouve sur l'axe cristallographique d'ordre 4 de même que l'un des oxygènes, le P sur le site de symétrie $\bar{4}$. Un second atome d'oxygène résultant du désordre, se trouve dans deux positions qui sont images par rapport à un miroir du plan *ac*. La structure comprend des groupes VO_6 hautement distordus avec les longueur de liaison sur l'axe *c* de 1.580(11) et 2.853(11) Å tandis que les longueurs des quatres autres liaisons V—O sont toutes de 1.858(8) Å. Les longueurs des quatres autres liaisons P—O dans le tétraèdre PO_4 sont de 1.541(8) Å avec des groupes PO_4 traversant en pont quatre chaînes de groupes VO_6.

Can. J. Chem., **51**, 2621 (1973)

Introduction

The structures of a series of ABO_5 compounds with A in an octahedrally and B in a tetrahedrally coordinated site have been reported. Cations such as S^{6+}, P^{5+}, and Mo^{6+} occur in the B sites and V^{5+}, V^{4+}, Ta^{5+}, Nb^{5+}, and Mo^{5+} have been reported in the A site. Two crystalline forms are known for these substances; an orthorhombic form reported for β-VSO_5(1) and β-VPO_5(2) and a tetragonal form for $MoPO_5$(3), $VMoO_5$(4), $TaPO_5$(5), $NbPO_5$(6), α-VSO_5(7), and now α-VPO_5. Aside from VPO_5 only VSO_5 occurs in both phases, but unlike the present compound, single crystals of the α form of VSO_5 have not been obtained.

The preparation and unit cell parameters of both phases of VPO_5 have been reported by Bordes and Courtine (8) while the α form was prepared by Ladwig (9) and uncharacterized form by Brown and Hummel (10). Bordes and Courtine (8) found that the β-VPO_5 formed from a mixture of ammonium phosphate and ammonium metavanadate at 595 °C but the α phase appeared upon dehydration of $VPO_5 \cdot 2H_2O$ at 120 °C. Both substances were prepared under one atmosphere of O_2. Further, they found that, whereas the α form appeared to undergo reversible hydrolysis with the *c* axis length depending upon the value of X in $VPO_5 \cdot XH_2O$, the β form remained anhydrous under similar treatment. Since there is a great deal of interest in the optical (11) and electrical properties of V_2O_5–P_2O_5 glasses (12) and concern over the structural nature of these (13, 14), a detailed structure of this polymorph seems warranted.

Experiments

Crystals of α-VPO_5 were prepared from equal molar amounts of P_2O_5 (Fisher Scientific) and V_2O_5 (Fisher Scientific) weighed in stoppered bottles filled in a Dry Box. The components were well mixed and then transferred to a platinum crucible which was directly inserted into a furnace pre-heated to 200 °C. The temperature was then raised and kept at 850 °C over night, and then cooled at a rate of 10–15 °C/h to below 700 °C. At this point the power to the furnace was removed and the furnace plus sample allowed to cool to room temperature. Yellow-green dendritic crystalline plates formed on the surface of a darker green glass-matrix. α-VPO_5 will occur throughout the crucible when cooled more slowly, however. The crystals cleaved easily. All photographs indicated some disorder since the reflections were about 3 times longer parallel to *c* than in the *ab* plane. Prolonged heating in air up to 500 °C caused further disorder as indicated by an extension of the diffraction spot. However, crystals survived storage at room temperature and cooling to 150 °K. A very weak electron paramagnetic resonance signal arising from V^{4+}, whose maximum possible concentration was below 1%, was detected. The crystals are stable at least to 1140 °C without a loss of weight.

A small plate crystal with dimensions 1.5 × 1.5 × 0.1 mm was used to collect all the crystallographic data

using graphite monochromatized MoKα radiation. Accurate parameters were refined using least-squares from 2θ values obtained with a Syntex $P\bar{1}$ diffractometer. The crystal data are as follows:

α-VPO_5 f.w. = 161.91

Tetragonal, $a = 6.014(7)$, $c = 4.434(2)$ Å, $V = 160.37$ Å^3, (at 21 °C), $Z = 2$, $\rho_x = 3.353$ g/cm^3. Space group: $P4/n$ $F_{000} = 472$, $\lambda_\alpha = 0.71069$ Å. Extinct reflections are $hk0$ with $h + k =$ odd.

All the reflections in a hemisphere up to a 2θ angle of 60° were collected. The intensity was measured at variable scan rates from 2 to 24° per min, depending upon the peak intensity and backgrounds measured at 1° removed from the peak. Reflections whose intensity measure was less than 3σ were regarded as unobserved. The intensities were corrected for absorption using a linear absorption coefficient of $\mu = 36.2$ cm^{-1} and then symmetry equivalent reflections were averaged.

Refinement proceeded from the atomic coordinates reported for $VMoO_5$ (4) with P^{5+} in place of Mo^{5+}. Atomic scattering factors for V^{5+} were obtained from Cromer and Waber (15) and P and O were obtained from the International Table for X-ray crystallography (16). Dispersion corrections were applied. The structure was refined by a full-matrix least-squares program prepared for the CDC 6400 by J. S. Stephens. Weights, $\omega = [2.5 + 0.01F_o^2]^{-1}$, were chosen so that the difference between the observed and calculated structure factors would be independent of the magnitude of the observed structure factor. When convergence had been obtained with isotropic thermal parameters the components of the anisotropic thermal parameters were allowed to vary. As anticipated the U_{33} parameters were large and, in addition, the U_{11} parameter for O(2) indicated two disordered positions with a root-mean-squared displacement of about 0.5 Å. A model allowing for two separate positions for this oxygen atom, one at either end of this principal axis of this apparent thermal ellipsiod with variable occupancy, was tested. The R value changed from 0.12 to 0.10. Further refinement reduced the R value to 0.089 for 248 reflections of which 9, showing large deviations, were not included. The final value for the disorder parameter, the fractional occupancy of the O(2) site, is 0.67(2). The atomic parameters are in Table 1. The observed and calculated structure factors are in Table 2.[1] A final difference synthesis showed some residual peaks of about 0.03 of the vanadium peak at the vanadium site and peaks about half this height at 0, 1/2, 0.653 and 0, 1/2, 0.405.

Description of the Structure

The structure of α-VPO_5 is composed of chains of distorted VO_6 octahedra coincident with the four-fold axes as shown in Fig. 1. The four oxygen atoms in the *ab* plane are shared with four different PO_4 groups and each of the oxygen atoms of the PO_4 group is shared with a separate chain of VO_6 octahedra. The two disordered configuration for O(2) are derived from a structure where the V—O(2) and P—O(2) bonds coincide with either the

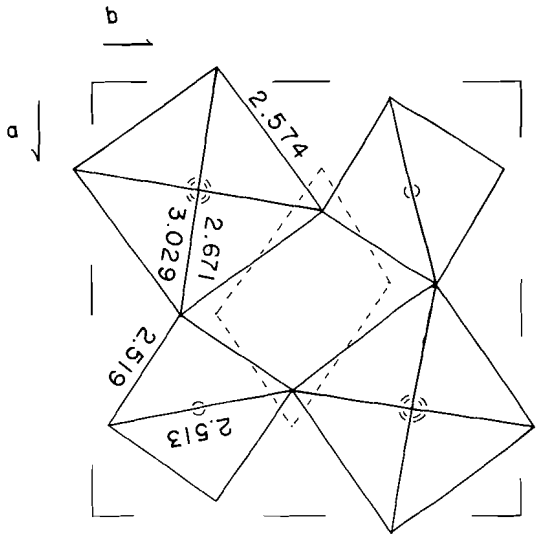

FIG. 1. The structure of α-VPO_5 projected onto the *ab* plane. Oxygen atoms lie at the corners of the polyhedra. The vanadium ions are represented by the double circle and phosphorus ions by the single circles. The corners of the dotted parallelogram represent the position of the oxygen atoms when disordered. The O—O lengths in Å are indicated.

ac or *bc* planes by a coupled rotation of the VO_6 groups in a given layer either all clockwise or all counterclockwise. At the present time it is not known whether this disorder is temperature dependent or results from errors in the stacking of mica-like sheets frozen in at the time of growth although significant intensity changes occur upon cooling.

The bond strength (S_i) – bond length (R) empirical curve (17) given by $S_i = (5/4)(1.714/R)^{5.1}$, suggests a regular VO_6 octahedral should have V—O bond lengths of 1.85 Å. The VO_6 groups are distorted from this regular VO_6 group by a displacement of the vanadium ion by about 0.37 Å along the *c* axis. Both oxygen atoms on the *c* axis move away from the displaced vanadium atom; the nearest by 0.1 Å and the furthest by 0.56 Å.

Discussion

Of all the structures isotypic with α-VPO_5 the present refinement is the only one which reports a disorder. Since the others were refined varying the individual thermal parameters isotropically only, it cannot be ascertained whether a similar phenomena occurs elsewhere in the series. Without a detailed resolution of these other structures it cannot be safely assumed that this disorder is characteristic of the structure rather than the compound. The possibility that these structures deviate slightly from stoichiometry cannot be discounted although the ease with which they form glasses suggests that the devia-

tions in the crystal are not likely to be the cause of the residual peaks. Twinning, with the twin plane through the phosphorus atom, does predict peaks near the positions found in the difference synthesis, but the agreement is by no means perfect.

In α-VSO_5(7) the vanadium ions are tetravalent and, as a result, the distortion of the VO_6 octahedron is less pronounced than in α-VPO_5. In particular the V—O(1) bond lengths are 1.63(3) and 2.47(3) Å while the remaining V—O bond lengths are 2.04 Å long in the former compound. As can be seen in Table 4, similar changes occur in this group between the α and β phases of the sulfate and the phosphate. It is common to ignore the long V—O bond and discuss only five orbitals for the vanadium oxygen system. However, if these bond orders, S_i, are taken as guides to the strength of the bonds it is just as serious an error to regard the short bonds as equivalent to the other five as it is to ignore the long one with regards to the V—O bonds of intermediate length. From the view of crystal packing, the distorted octahedron seems to be the basic unit in all these structures.

In this regard the discrepancy between the parameters presented here and those reported by Bordes and Courtine (8) ($a = 6.20$, $c = 4.11$ Å) should be noted. These values suggest that the V—O(1) *a* bond is about 0.22 Å shorter than that reported in Table 3 and the V—O(2) bond is about 0.10 Å longer. The relative direction of these changes is consistent with a redistribution of the bond about the vanadium ion but the magnitudes are not consistent with the predictions of the bond strength – bond length curve. These authors also report an expansion of the *c* axis by 0.16 Å between 130 and 700 °C. An expansion of this order of magnitude is unusual and substantially larger than the lattice expansion we could detect.

Caution should be exercised in deriving structural information concerning the V_2O_5–P_2O_5 glasses from the structures of α-VPO_5, β-VPO_5, and V_2O_5 alone. Structure sensitive data including electron spin resonance of V^{4+}, nuclear magnetic resonance of ^{51}V, and conductivity of the glasses have not provided a satisfactory resolution of this problem. Since the average tetrahedral P—O bond lengths differ by about 10% from that of V—O (1.71 Å) some replacement of P^{5+} by V^{5+} in the tetrahedral site would not be unexpected. Such a replacement has been proposed in $V_{1+x}Mo_{1-x}O_5$ when x deviates positively from zero. However, it is not possible to change continuously from either VPO_5

structure to that of V_2O_5. Each of these structures however, contain chains of octahedra involving alternately long and short V—O bonds nearly parallel to the axis of the chain. Thus, such chains, but of finite length, might be expected in the glasses on structural grounds. The replacement of a V—O—V interaction equatorial to the axis of the chain by V—O—P interaction will involve small changes in the bonding, and none in bond order, relative to the bond strength in the strong V—O bond and will preserve the approximately axial nature of the field gradient reported by Landsberger and Bray (14).

A General Method of Calculating the Water Activity of Supersaturated Aqueous Solutions from Ternary Data

J. SANGSTER, T. T. TENG, AND F. LENZI[1]

Département de Génie chimique, Ecole Polytechnique, Université de Montréal, Montréal, Québec

Received January 25, 1973

Recently developed methods of predicting water activities of multicomponent aqueous solutions use binary data. At high concentrations these methods are limited inasmuch as they require binary data beyond the solubility limit of individual solutes. A method is proposed whereby ternary water activity data may be used to calculate water activities of supersaturated binary solutions. The new method is compared with two extrapolation procedures on a known system and gives the best agreement. Values of the water activities for supersaturated solutions of KNO_3 (3.8 to 7.6 *m*) and K_2SO_4 (0.7 to 2.3 *m*) at 25 °C are obtained.

Des méthodes de prédiction de l'activité de l'eau de systèmes aqueux à composants multiples ont été récemment proposées. Ces méthodes demandent des données binaires, mais sont limitées par le manque de ces données au-delà de la limite de solubilité des solutés individuels. Une méthode de calcul des activités de l'eau des solutions binaires sursaturées est proposée à partir de données ternaires. Cette méthode est appliquée à un système connu et donne de meilleurs résultats que deux méthodes d'extrapolation. Les valeurs de l'activité de l'eau à 25 °C ont été établies pour des solutions sursaturées en K_2SO_4, de 0.7 à 2.3 *m*, et en KNO_3, de 3.8 à 7.6 *m*.

Can. J. Chem., **51**, 2626 (1973)

Introduction

The prediction of the water activity, a_w, of aqueous solutions is of both theoretical and practical interest (1, 8). This is especially true of solutions of moderate to high concentrations.

This paper describes a recently developed method that uses binary data to predict a_w values for multicomponent aqueous solutions, applicable to both electrolytes and non-electrolytes, up to total concentrations as high as 12 *m*. The reverse method is used herein to calculate "virtual" water activities, *i.e.*, a_w's for a solute beyond its solubility limit, from ternary a_w data. These are of definite thermodynamic interest. Robinson and co-workers (1), in calculating excess free energies of mixing for systems involving K_2SO_4, needed values for the osmotic coefficient of this salt $\varphi_{K_2SO_4}$, beyond its solubility limit. They estimated $\varphi_{K_2SO_4}$ from weighted averages of $\varphi_{Na_2SO_4}$ and $\varphi_{Rb_2SO_4}$. The predictive method of the present work is used to find virtual values of $\varphi_{K_2SO_4}$, in answer to Robinson's requirement, and also of KNO_3. It is a general method, applicable to both electrolytes and non-electrolytes.[2]

[1]To whom correspondence should be addressed.

[2]Stokes and Robinson (5) have used a similar method to obtain a_w values for supersaturated mannitol solutions.

The Zdanovskii Relation

A method of predicting a_w's which uses binary solution data has been found (4) to be equally applicable to electrolytes and non-electrolytes. It uses the linear molality relation for isopiestic solutions discovered empirically by Zdanovskii in 1936 (3). It is presented here in sketch form only, since it has been tested in detail elsewhere (4). If a ternary aqueous solution, of electrolytes 1 and 2 at molalities m_1 and m_2, respectively, is in isopiestic equilibrium with two binary solutions of molalities m_{01} and m_{02}, then

$$[1] \quad m_1/m_{01} + m_2/m_{02} = 1 \text{ at constant } a_w$$

Relation 1 was discovered independently in 1966 by Stokes and Robinson (5), where it was applicable to semi-ideal solutions of non-electrolytes at isopiestic equilibrium. In a survey of 117 ternary aqueous systems reported in the literature, it was found (4) that most of these obeyed Zdanovskii's rule (eq. 1) to a good approximation up to moderate concentrations. Equation 1 held well for a majority of electrolyte/electrolyte, electrolyte/non-electrolyte, and non-electrolyte/non-electrolyte ternary aqueous solutions.

To take account of deviations from Zdanovskii linearity, eq. 1 may be written (6) in the form

[2] $m_1/m_{01} + m_2/m_{02} + by_1y_2m = 1$

where

$$m = m_1 + m_2$$

$$y_1 = m_1/m$$

and

$$y_2 = m_2/m$$

Equation 2 defines b, an empirical deviation parameter. In the previous publication (4), the ternary systems were divided arbitrarily into groups A, B, and C, according to the magnitude of b, thus: group A, $0 < |b_{ave}| < 0.02$; group B, $0.02 < |b_{ave}| < 0.1$; group C, $|b_{ave}| > 0.1$. Zdanovskii plots of a system from each group are given in Figs. 1–3 of ref. 4.

The use of equation 1

[1] $m_1/m_{01} + m_2/m_{02} = 1$

to find a_w for a ternary aqueous solution of total molality $(m_1 + m_2)$ is essentially a determination of the equivalent isopiestic m_{01} or m_{02} (4). The given data are: m_1, m_2, and a_w *vs.* molality curves for each solute in its own solution. An estimate of the unknown a_w is made, the corresponding values of m_{01}' and m_{02}' are read off, and the sum S

$$m_1/m_{01}' + m_2/m_{02}' = S$$

is calculated. If $S \neq 1$, a second iteration can be performed, using $m_{01}'' = Sm_{01}'$ (or $m_{02}'' = Sm_{02}'$). The process is repeated until S is as close as desired to unity. The value of m_{01} or m_{02} at this point gives the a_w of the ternary solution. The a_w values calculated in this manner are usually within 0.5% of experimental values (4).

The use of eq. 1 in this method of calculation requires that the unknown a_w lie in the common range of a_w binary data available. This imposes a practical criterion for the reliability or feasibility of the calculation. The requirement is $(a_w)_{mixture} > a_w^*$ where a_w^* is the higher of the two limiting a_w's of the binary data. Exceeding the criterion implies extrapolating the a_w *vs.* m curve beyond a_w^*, with attendant uncertainty, since in practice an empirical polynomial is fitted to the a_w *vs.* molality data.

Finding "Virtual" Water Activities

It sometimes happens that ternary isopiestic solution data include solutions whose a_w's are smaller than the binary a_w^* defined above. If a_w^* represents the solubility limit of solute 2 then eq. 1 can be used in reverse to find a_w's of solute 2 beyond a_w^*, that is, "virtual" a_w's, or a_w's of supersaturated solutions.

The given data in this kind of calculation are: a_w of the ternary solution, m_1,m_2, and m_{01}, where m_{01} is the isopiestic molality of the more soluble solute. This a_w is the "virtual" water activity, and the isopiestic m_{02} is found by solving eq. 1 for this quantity. If greater accuracy is desired, eq. 2, which includes the correction factor b, may be used instead. Since b cannot be found at a_w's less than a_w^*, extrapolated values would have to be used.

Virtual water activities have previously been found by a weighted extrapolation procedure of the φ's of closely related electrolytes. Hidalgo and Orr (7) used this method to calculate φ's for supersaturated solutions of NaCl, KCl, RbCl, and CsCl up to 20 m; LiCl was the reference salt. The present paper will show that this procedure, while useful for extrapolation not far beyond the solubility limit, may not be reliable at concentrations much beyond this point.

Results

The corrected Zdanovskii relation 2 is used to calculate virtual a_w's for three salts: (*a*) $NaNO_3$ beyond 6 m (a check of the method on a "known" salt); (*b*) K_2SO_4 beyond its solubility limit, 0.7 m; and (*c*) KNO_3 beyond its solubility limit, 3.8 m.

(a) $NaNO_3$, the "Known" Salt

The Zdanovskii relation 2 may be rearranged to give

[4] $$m_{02} = \frac{m_2}{1 - \frac{m_1}{m_{01}} - \frac{bm_1m_2}{m}}$$

Equation 4 is used to find a_w's of $NaNO_3$ solutions beyond 6 m ($a_w = 0.845$) from data (9–12) of the ternary systems (*i*) $LiNO_3(1)$–$NaNO_3(2)$–H_2O; (*ii*) $NaCl(1)$–$NaNO_3(2)$–H_2O; and (*iii*) $UO_2(NO_3)_2(1)$–$NaNO_3(2)$–H_2O. The values for b used in equation 4 were found from: $LiNO_3/NaNO_3$, $b = -0.080 + 0.111a_w$; $NaCl/NaNO_3$, $b = -0.080 + 0.109a_w$; $UO_2(NO_3)_2/NaNO_3$, $b = 0.063 - 0.06a_w$. These relations are based on ternary isopiestic data at $a_w > 0.845$ (10,11,13). Table 1 presents calculated m_{02} and corresponding a_w values together with experimental m_{02} values interpolated from data in the

(2)–H_2O; (*ii*) KCl(1)–K_2SO_4(2)–H_2O; and (*iii*) NaCl(1)–K_2SO_4(2)–H_2O for $a_w < 0.975$. An average value for b for each system was used, calculated from the original data for $a_w > 0.975$: (*i*) $b_{ave} = -0.077$; (*ii*) $b_{ave} = +0.061$; and (*iii*) $b_{ave} = -0.027$.

The results are given in Table 3, and plotted in Fig. 2. Also included in this figure are a_w values at 0.8, 1.0, and 1.2 m calculated by Robinson (1) using the weighted comparison method.

(c) KNO_3 beyond 3.8 m ($a_w = 0.926$)

Virtual a_w's were found, using eq. 4, from data (12) of the ternary systems (*i*) $NaNO_3$(1)–KNO_3(2)–H_2O; (*ii*) KCl(1)–KNO_3(2)–H_2O; and (*iii*) NaCl(1)–KNO_3(2)–H_2O for $a_w < 0.926$. For systems (*i*) and (*ii*), the b_{ave} values used were +0.007 and +0.053, respectively (11, 12). In system (*iii*), b was a function of a_w, and an extrapolated value ($b = +0.14$ at $a_w = 0.8947$) was used; this is illustrated in Fig. 3. The results are given in Table 4.

For purposes of comparison, virtual a_w's of KNO_3 were calculated by the weighted extrapolation method described in section (*a*), using data for KNO_3, $NaNO_3$, and $LiNO_3$. The virtual a_w's for KNO_3 appear in Fig. 4.

Discussion

(a) Check of the Method Using the "Known" Salt, $NaNO_3$

Figure 1 shows that the a_w values calculated by our method follow quite closely the experimental line. The maximum value of the deviation $|m_{02}(\text{exptl.}) - m_{02}(\text{calcd.})| = \Delta m(\text{max})$ from Table 1 is 0.13 m, and the average deviation

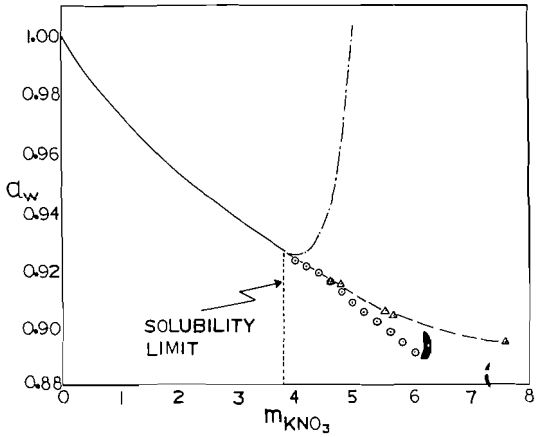

FIG. 4. Water activities of KNO_3 solutions at 25 °C. △ Zdanovskii method (average values); ⊙ weighted extrapolation; ----- extrapolation of polynomial fitted in the range 0–3.8 m.

Δm (ave) is 0.032 m. The corresponding values for Δa_w(max) and Δa_w(ave) are 0.0031 and 0.0007. This suggests that the Zdanovskii method can be used to find virtual a_w's with an expected average uncertainty of approximately 0.0007, or 0.1% at $a_w = 0.8$.

(b) Virtual Water Activities of K_2SO_4 Solutions

Figure 2 shows virtual water activities of this salt up to 2.25 m. The extrapolated values found by Robinson (1) coincide with those found from the Zdanovskii method; these are compared at round molalities as follows (the first of each pair is Robinson's value): 0.8 m: 0.9718, 0.9720; 1.0 m: 0.9656, 0.9655; 1.2 m: 0.9595, 0.9595. Thus weighted extrapolation not far beyond the solubility limit yields results in accord with the Zdanovskii method.

(c) Virtual Water Activities of KNO_3 Solutions

Figure 4 shows that there is a divergence between weighted extrapolation values and those of the Zdanovskii method, at concentrations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

much beyond the solubility limit. We believe the Zdanovskii method may be more reliable, for the following reasons. The weighted extrapolation method assumes a continuous uni-directional differential relation between the physical chemical properties of solutions of like salts. Though this may be justified in many examples, it is not necessarily true for all systems. The Zdanovskii method, when it uses group B and C systems, assumes a constant b_{ave} value (or, if b is strongly a_w-dependent, extrapolates an appropriate value) for a_w's beyond the solubility limit. This procedure, though it contains a residue of arbitrariness, does at least recognize a deviation parameter obtained from experiment. Insofar as it does so, the Zdanovskii method would seem to be inherently safer than simple weighted extrapolation.

The Zdanovskii method is strengthened if group A ternary systems are used, for then $b \simeq 0$, and no assumptions have to be made beyond the unlikelihood of a sudden large change in the value of b beyond the solubility limit. Both the weighted extrapolation and Zdanovskii methods are preferable to simple extrapolation of a_w–molality curves fitted by polynomials or other functions.

(d) The Use of "Virtual" Water Activities

Virtual water activities of single solutes are of great practical interest, since these would be required for prediction of a_w for concentrated multicomponent systems, either by the Zdanovskii method (4), or the more precise method of Reilly, Wood, and Robinson(2). These water activities can then be used to compute solubilities of salts in multicomponent systems, *i.e.*, to predict phase diagrams (16*a*, *b*).

The calculation of virtual a_w's by the present Zdanovskii method requires ternary solution data at water activities beyond the solubility limit of one of the solutes. Although the literature contains isopiestic data of a large number of ternary solutions, few of these data meet this requirement. Since virtual water activities are of definite practical importance, we hope that the necessary ternary data will soon be forthcoming.

Isotropic Nuclear Magnetic Resonance Shifts of Co(II) Complexes with Mixed Ligands

D. R. EATON AND K. L. CHUA

Department of Chemistry, McMaster University, Hamilton, Ontario

Received February 15, 1973

Isotropic n.m.r. shifts of several Co(II) complexes involving β-diketonate ligands are reported. A change of substituent on one β-diketonate ligand significantly affects the shifts of protons or fluorine atoms on the other β-diketonate ligand of the same compound. An argument is presented to suggest that these substituent shifts arise predominantly from contact rather than dipolar effects. The pattern of shifts is compared with that previously observed for β-diketone complexes of V(III) and a similar interpretation is proposed.

Les déplacements chimiques isotropes (en r.m.n.) de plusieurs complexes du Co(II) contenant des coordinats du type β-dicétonate ont été étudiés. Le changement d'un substituant sur un des coordinats β-dicétonate a modifié de manière significative les déplacements chimiques des protons ou des fluors sur l'autre coordinat β-dicétonate du même composé. On présente alors une hypothèse selon laquelle les déplacements chimiques des substituants proviennent principalement des effets de contact plutôt que des effets dipolaires. Le patron des déplacements chimiques est comparé à celui observé antérieurement pour des complexes de V(III) contenant des coordinats β-dicétone; une interprétation similaire est avancée.

Can. J. Chem., 51, 2632 (1973)

Introduction

The isotropic shifts observed in the n.m.r. spectra of paramagnetic transition metal complexes provide a sensitive method for the investigation of bonding in transition metal complexes. We have been interested of late in utilizing this method to study the transmission of substituent effects in complexes with mixed ligands. Such studies have been reported involving octahedral complexes of V(III) (1,2) and of Cr(II) (3) and tetrahedral complexes of Ni(II) (4). The detailed interpretation of the results has varied in the different cases but all show the common feature that the effects observed have been attributed to contact rather than dipolar interactions. In principle, the introduction of a substituent in a metal complex can induce a change in the magnetic anisotropy of a molecule and hence cause dipolar shifts. If large, such an effect could invalidate interpretations based on contact mechanisms. It seemed worthwhile to investigate the magnitude of such dipolar shifts by choosing to work with complexes in which they are expected to be present. Such a study would at least provide an indication of the errors which could arise from the neglect of dipolar interactions in other systems. The present paper reports some results obtained in this area.

Distorted octahedral complexes of Co(II) are known to possess large magnetic anisotropies and therefore to exhibit dipolar shifts (5). Complexes of the stoichiometry $Co(acac)_2L_2$ (acac = acetylacetonate, and L = a wide variety of monodentate ligands) have been extensively studied (6–10). Most of these studies have been concerned with the isotropic shifts of protons on the ligand, L. LaMar (11), however, has reported large differences in the acac shifts with changes in the ligand L. He concluded that these changes were dipolar in origin. Comparison of the shifts of the protons on L with those on the acac ligand lead to the conclusion that the species in solution had distorted octahedral geometry with the L ligands occupying *trans* positions. The shifts of the acac protons were interpreted as arising from a combination of dipolar and contact effects and a series of ligands L was presented in which the contact contribution becomes progressively more dominant. More recently Horrocks and Hall (12) have measured the anisotropy of the magnetic susceptibility of a single crystal of the compound in which L = pyridine and used this data to calculate the dipolar contribution to the isotropic n.m.r. shifts. Their conclusions are consistent with the interpretation presented by LaMar.

Results

In the present experiments the intent was to investigate the effect of making a substituent change on one of the β-diketone ligands on the

isotropic shifts of the other β-diketone ligand. By using different monodentate ligands L we hoped to vary the proportions of the dipolar and contact contributions to the isotropic shifts and hence deduce whether the substituent changes are predominantly dipolar or contact in origin. It was first necessary to measure the shifts for several symmetric chelates with different substituents on the β-diketone. Each chelate was examined with several different axial ligands L. These results are presented in Table 1. We then proceeded to examine the mixed chelates to ascertain the substituent effects. Results for mixed chelates are given in Table 2.

The β-diketone ligands involved have structures **1**–**4**. Co(II) chelates of β-diketone ligands tend to be polymeric in non-coordinating solvents such as chloroform. This is manifested by

4

the appearance of a complex n.m.r. spectrum. However in coordinating solvents a two line spectrum appears which is assigned to octahedral species such as $Co(acac)_2L_2$. With excess of ligand L this is the only species present. Excess can be assured by using L as the solvent. Since we are interested only in the β-diketone resonances deuterated solvents were used throughout. Addition of a second β-diketone ligand to such a solution leads to the formation of mixed chelates. Thus if ligand **4** is added to a solution of the Co(II) complex of ligand **1** in pyridine additional lines appear attributable to the mixed chelate. On continued addition the resonances attributable to the symmetric chelate with ligand **4** appear. The correctness of the assignments of the mixed ligand complex can then be checked by adding ligand **1** to the Co(II) chelate of ligand **4**. In simple systems such as these there are no assignment problems.

A number of difficulties restricted the systems available for study. For some of the complexes the lines are exceedingly broad. This is particularly true for compounds in which the β-diketone has trifluoromethyl substituents. LaMar (11) noted similar linewidth variations, though not so pronounced, and suggested that they arose from varying electron spin relaxation times due to spin–orbit interaction with low lying excited states. Relatively slow exchange with ligand L is also possible. Measurement of the temperature dependence of the shifts revealed some deviations from Curie law below −25 °C which could be due to slowing down of the fast exchange between free and complexed axial ligand. However we would not disagree with LaMar's explanation of the linewidth effects. Measurements in some solvents were also limited by oxidation of the complexes.

Discussion

Although the data available are limited we are able to arrive at a relatively unambiguous conclusion regarding the importance of dipolar effects. It is apparent from the results in Table 2 that significant substituent effects are observed in some, but not all, cases.

Mixed complexes involving the ligands **1** and **2**, **1** and **3**, **1** and **4**, and **2** and **3** have been examined with L = pyridine and L = dimethylsulfoxide. Significant substituent shifts are observed in all cases with L = pyridine and in the last two cases with L = dimethylsulfoxide. It is not certain whether the inability to observe shifts in the remaining two cases is due to the shifts being too small to observe, to the resonances of the mixed chelates being too broad to observe, or to the failure to form mixed complexes. In cases where the shifts of two or more resonances on the same mixed chelate are observed they are in the same direction relative to the symmetric chelate, *e.g.* both the CH_3 and the CH resonance of ligand **1** move to high field in the mixed complex with ligand **4**. The most significant observation though is that in each case resonances on one ligand are shifted in the opposite direction to those on the other ligand in a mixed complex. Thus in the series of mixed complexes with L = pyridine the CH resonance of ligand **1** is shifted +146, +200, and +360 Hz from its position in the symmetric $Co(acac)_2L_2$ for the cases in which the second ligand is **2**, **3**, and **4**, respectively. The CH resonance of the second ligand is concurrently shifted −284, −1102, and −1559 Hz when this ligand is **2**, **3**, or **4**, respectively. Examination of the data in Tables 1 and 2 reveals that this pattern holds throughout.

The pyridine ligands of $Co(acac)_2py_2$ are exchanging rapidly with free ligand in solution on the n.m.r. time scale. It is therefore permissible (12) to neglect the orientation of the pyridine molecule with respect to the metal–nitrogen bond when considering the geometry of the $Co(acac)_2py_2$ molecule. Given that the complex has a *trans* configuration (11) the symmetry of the molecule is therefore D_{2h}. The magnetic susceptibility tensor has three principal axes uniquely defined by the symmetry axes of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the molecule. If one of the acac ligands is replaced by hfac (ligand **4**) C_{2v} symmetry is retained. The elements of symmetry of the C_{2v} point group (a C_2 axis and two planes) suffice to define three principal axes for the magnetic susceptibility which are identical with those of $Co(acac)_2py_2$. The dipolar shift of a proton is given by the expression (12)

$$\frac{\Delta\nu}{\nu}\text{dip} = -\frac{1}{3N}\left[\chi_z - \frac{\chi_x}{2} - \frac{\chi_y}{2}\right]\left(\frac{3\cos 2\theta - 1}{r^3}\right)_{av} - \frac{1}{2N}[\chi_x - \chi_y]\left(\frac{\sin^2\theta\cos 2\Omega}{r^3}\right)_{av}$$

In this expression θ and Ω are angles relating the position of the proton in question to the principal axes of the magnetic susceptibility tensor. The angular functions in this expression have identical values for the two CH protons of $Co(acac)_2L_2$ since they are equivalent by symmetry. Since both the positions of the CH protons and the directions of the principal axes are unchanged on passing to Co(acac) (hfac)py_2 it follows that the angular functions for the two CH protons of this mixed complex are also identical. Any change in the dipolar shift of the two protons resulting from a change in the magnetic anisotropy of the mixed chelate compared with the symmetric chelate must therefore be identical in sign and magnitude for both protons. This is clearly not the case, in fact in every compound examined the two protons in question shift in opposite directions. We deduce therefore that the substituent shifts are predominantly contact in origin and that any dipolar component, if present, is relatively small.

Given this conclusion it becomes valid to compare the present results with those previously reported (1,2) for V(III) complexes which were also interpreted assuming a contact mechanism. Octahedral Co(II) complexes have a T_1 ground state which splits to A and E states on application of a tetragonal distortion.[1] In the present case the A state is lower and is separated from the excited E state by the tetragonal distortion energy ζ. The V(III) complexes also have a nondegenerate ground state. The type of effects predicted (13) for mixed complexes arising from an orbitally degenerate ground state and observed with Cr(II) compounds (3) are therefore not to be anticipated. Consider specifically the CH resonances which are common to all the ligands used. LaMar (11) suggested that the shift of this proton in the Co(II) complexes resulted from the combination of a downfield dipolar shift and an upfield contact shift with the dipolar shift becoming progressively less important as the tetragonal splitting ζ becomes larger. In the A ground state of the molecule the unpaired electrons occupy the d_{xy}, $d_{x^2-y^2}$ and d_{z^2} orbitals. The results in Table 1 show that the CH shifts of the symmetric complexes with ligands **2**, **3**, and **4** are all to high field of those for ligand **1** with the same axial ligand L^2 and hence we deduce that ζ is larger for these ligands and that mixing of the A state with excited states through spin–orbit coupling less important. If we consider only the ground state configuration direct delocalization of spin to the π orbitals of the β-diketonate ligand cannot occur since none of the spin containing orbitals d_{xy}, $d_{x^2-y^2}$ or d_{z^2} has the correct symmetry to mix with the π orbitals of ligands in the xy plane. If the spin is in the π system, as the most recent analyses has concluded (14), an indirect or polarization mechanism must be involved. According to the model originally proposed by Levy and Orgel (15) such a mechanism will lead to a preference for electrons of α spin in the d_{xz}, d_{yz} orbitals and a corresponding preponderance of β spin delocalized to the ligands. The situation in the V(III) complexes is exactly the opposite with the unpaired electrons being contained in d orbitals with the correct symmetry to interact with ligand π orbitals leading to α spin delocalization. In this manner the opposite signs of the contact shift in the two cases may be rationalized.

Consider now the results for the mixed complexes contained in Table 2. In the V(III) case in mixed complexes of acac (ligand **1**) and hfac (ligand **4**) the CH of the acac is shifted to low field and that of the hfac to high field (1). In the Co(II) case the acac resonance moves to high field and the hfac resonance to low field. If α spin delocalization is involved in the first case and β spin delocalization in the second case the results are clearly equivalent. Our analysis of the V(III) system involved two factors the first dependent on the populations of the various spin containing d orbitals and the second on the

[1]The further small splitting of the E state if the symmetry is D_{2h} rather than D_{4h} can be neglected in this discussion.

[2]The CH shift of ligand **1** in acetonitrile appears anomalous in this respect.

ability of a ligand oxygen to accept an electron, *i.e.*, on its charge. These factors usually acted in concert to enhance the shifts. In the Co(II) case the first factor is inapplicable since the interacting d orbitals are in all cases fully populated. The second factor, however, remains operative and reflects the movement of charge in the σ system brought about by substituent changes on other ligands. It may be significant that the substituent shifts are on the whole smaller in the Co(II) compounds than in the V(III) compounds. The implication is that they cannot be amplified by changes in orbital populations.

It would not be advisable to extend this analysis in a quantitative manner. It suffers from all the limitations discussed previously in the V(III) case plus the added complication that dipolar effects, although not predominant, may still be of some importance. The significant point is perhaps the observation of substituent effects of the same type as those previously observed in V(III) complexes in a system involving a different metal and a different delocalization mechanism. We would suggest that such effects may be of quite general importance in transition metal chemistry and that isotropic n.m.r. shifts may provide a very convenient probe. We also conclude that contact effects are more important than dipolar effects in determining changes in the isotropic shifts caused by ligand substitution. This is consistent with an earlier suggestion (16) regarding isotropic shifts in first row transition metal complexes but in no way disagrees with the results of Horrocks and Hall (12) showing that there is a substantial dipolar contribution to the absolute shifts in these Co(II) compounds.

Experimental

Source of Chemicals

Co(II) acetylacetonate and Ni(II) acetylacetonate were obtained from the Research Organic/Inorganic Chemical Co. and $CoCl_2 \cdot 6H_2O$ from D.B.D.H. Laboratory. Hexafluoroacetylacetone, 1,3-diphenyl-1,3-propanedione, and 2,2,6,6-tetramethyl-3,5-heptanedione were purchased from Eastman Kodak Co. and dimethylsulfoxide-d_6, pyridine-d_5, and acetonitrile-d_3 from Merck Sharp and Dohme Co.

Preparation of Compounds

The Co(II) β-diketone complexes were prepared as follows.

The appropriate ligand (0.02 mol) was dissolved in a small amount of methanol and added to about 30 ml of distilled water with stirring. The mixture was heated gently and 6 *N* ammonia solution added until the solution showed slightly basic to litmus paper. A second solution was prepared by dissolving 0.1 *M* $CoCl_2 \cdot 6H_2O$ in about 30 ml of distilled water. The two solutions were mixed with stirring. (If no precipitate appeared, more ammonia was added until a precipitate did appear, then 4 drops excess were added.) The precipitate was collected, washed with H_2O, and dried under vacuum.

Sample Preparation

Solution of di-adduct of Co(II) β-diketonate was prepared by adding the coordinating solvent to the corresponding β-diketonate in the mole-ratio of 320:1 so that the coordinating solvent was present in excess to ensure that all the Co(II) β-diketonate was coordinated and existed in a monomeric form. CCl_4 was then added to give a final concentration of 0.005 *N*.

Proton spectra were obtained using a Varian HA-100 instrument at 37 °C with TMS internal reference. ^{19}F spectra were obtained on a Varian DP 60 instrument using $CFCl_3$ internal reference, at 56.4 Mc/s and the shifts converted to 60 Mc/s.

We are indebted to the National Research Council of Canada for financial support of this research.

Received March 5, 1973

Crystals of the synthetic intermediate, 2-bromo-3-methoxy-5-hydroxy-5,6,7,8,9,10,13,14-octahydro-8-methyl-10,13-*N*-acetyl aminomethano-phenanthrene, $C_{19}H_{24}O_3NBr$, are monoclinic, space group $P2_1/n$, unit cell dimensions $a = 10.62(1)$, $b = 14.47(2)$, $c = 23.88(2)$ Å, $\beta = 99.4(2)°$, $z = 8$ with two molecules in the asymmetric unit. The structure was solved by the heavy atom method and refined by full matrix least squares to $R = 0.096$ for 2120 observed reflections. The conformation was found to be *cis* at the junction between rings A and B making further cyclization to obtain an A ring nitrogen bridge not possible.

Les cristaux de l'intermédiaire synthétique, bromo-2 méthoxy-3 hydroxy-5, octahydro-5,6,7,8,9,10,13,14 méthyl-8, *N*-acétylaminoéthano-10,13 phénanthène, $C_{19}H_{24}O_3NBr$, sont du type monoclinique appartenant au groupe $P2_1/n$ dont les dimensions de la maille unitaire sont $a = 10.62(1)$, $b = 14.47(2)$, $c = 23.88(2)$ Å, $\beta = 99.4(2)°$, $z = 8$ avec deux molécules par maille asymétrique. La structure a été élucidée par la méthode des atomes lourds et a été raffinée à l'aide de la méthode des moindres carrés (matrice complète) jusqu'à $R = 0.096$ et ce, pour 2120 réflections observées. On a trouvé que la conformation est du type *cis* à la jonction entre les cycles A et B ce qui entraîne l'impossibilité de former par cyclisation subséquente un anneau du type A contenant un azote qui forme un pont.

Introduction

In the light of a possible synthesis of the alkaloid songorine, $C_{21}H_{30}O_3N$ (**1**), a stereospecific synthesis of a prerequisite intermediate pentacyclic keto lactam, $C_{17}H_{19}O_4N$ (**2**), has been reported (1). Prior attempts to look for potential intermediates resulted in the synthesis of 2-bromo-3-methoxy-5-hydroxy-5,6,7,8,9,10,13,14-octahydro-8-methyl-10,13-*N*-acetylaminomethano-phenanthrene, $C_{19}H_{24}O_3NBr$ (**3**). As the stereochemistry of compound (**3**) could not be fully established from spectroscopic data, an X-ray structure analysis was undertaken.

Results

Crystal Data

$C_{19}H_{24}O_3NBr$ m.w. = 395.3 Monoclinic, $a = 10.62(1)$, $b = 14.47(2)$, $c = 23.88(2)$ Å, $\beta = 99.4(2)°$, $v = 3620$ Å^3, $\rho_0 = 1.42(1)$ gm cm^{-3}, $z = 8$, $\rho_c = 1.42$ gm cm^{-3} (20 °C, MoKα, $\lambda = 0.71069$ Å). The space group is $P2_1/n$ ($C^5{}_{2h}$) No. 14 in *International Tables for X-ray Crystallography Vol. 1* (2) with two molecules in the asymmetric unit.

X-Ray Data

The intensity data were collected on a Picker computer-controlled four angle diffractometer using a $\theta/2\theta$ scan with β-filtered MoKα radiation and a scintillation detector. A scan speed of 1°/min was used with a scan range of 1.5° corrected for dispersion. The background count was taken for 20 s at each end of the scan range. Data were corrected against a standard reflection taken at intervals of 20 readings. The *hkl* and $\bar{h}kl$ octants were explored to a maximum 2θ of 40°. There were 3380 accessible reflections in this region of which 2120 were considered observed. The threshold count was taken as 0.05 times the background count or 5 counts, whichever was the greater. The crystal was needle

For personal use only.

shaped with dimensions 0.40 × 0.24 × 0.20 mm^3. The needle axis *a*, was mounted parallel to the ϕ axis of the diffractometer. The linear absorption coefficient for MoKα radiation is μ = 17.8 cm^{-1}. No corrections were made for absorption or extinction.

Structure Analysis

A three-dimensional Patterson synthesis, and subsequent Fourier syntheses established all atoms other than hydrogen. All atoms are in general positions.

Refinement was carried out by minimizing the quantity $\sum\omega(|F_o| - |F_c|)^2$ for observed reflections only, using successive cycles of full-matrix least squares and anisotropic thermal parameters for all atoms. The weighting function used was $\omega = 1/1 + [(|F_o| - P_2)/P_1]^4$ with P_1 = 2 and P_2 = 11. Scattering factor curves used were those given in ref. 3, Table 3.3.1.A, with corrections for anomalous dispersion for bromine (ref. 3, Table 3.3.2.C.) The final agreement factor $R = \sum(||F_o| - |F_c||)/\sum|F_o|$ was 0.096. In the last cycle no parameter shift exceeded 0.1 times the established standard deviation. A difference synthesis showed residual peaks of height ranging from 0.3 to 0.9 e Å^{-3}. These were attributed to hydrogen atoms, although no attempt was made to establish their coordinates.

The table of final parameters and a set of structure factors based on these has been placed in the Depository of Unpublished Data.[1]

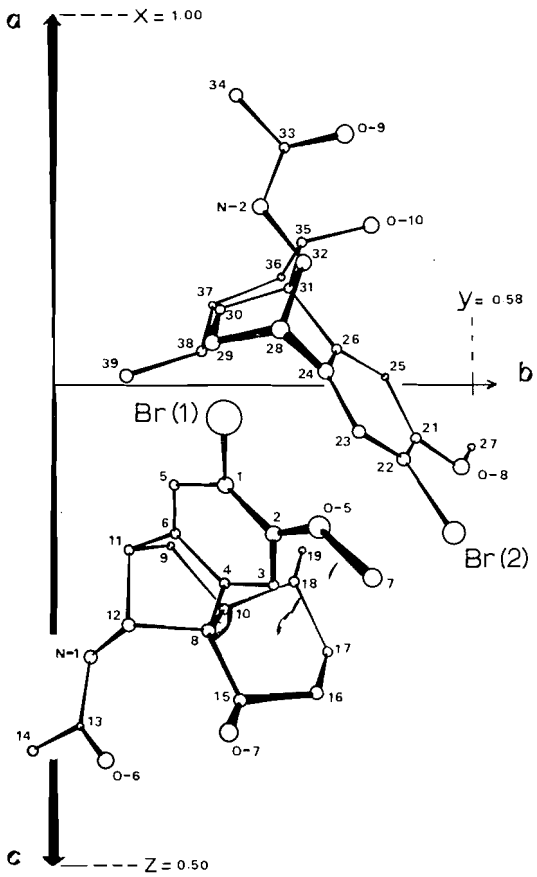

FIG. 1. Projection of the two molecule asymmetric unit (direction cosines of the normal to the plane of projection 0.707:0:0.707, refered to orthogonal axes X_o along *a*, Y_o along *b* and Z_o along *c**).

TABLE 1. Summary of bond distances for $C_{19}H_{24}O_3NBr$

Atoms		Distance (Å)
Ring system		
	C—C (aromatic)	1.38(3)–1.43(3)
	C—C	1.46(3)–1.63(3)
Side groups		
	C(ring)—O	1.37(2)
	C—O (alcohol)	1.42(3)–1.44(3)
	C—O (methoxy)	1.48(3)
	C=O	1.21(3)–1.25(3)
	C—N	1.43(2)–1.47(2)

Discussion

Figure 1 shows the relative orientation of the two molecules in the asymmetric unit. A brief summary of the bond distances is given in Table 1. The *cis* conformation between the A and B rings at C(8)[C(31)] and C(10)[C(30)] makes further cyclization of the A ring not possible between the nitrogen and the C(18)[C(38)] atom. As a consequence, this compound was considered to be of no further use as a possible intermediate in the alkaloid synthesis.

We wish to thank Dr. K. Wiesner for suggesting the problem, Dr. F. R. Ahmed of the National Research Council of Canada for use of his computer programs and the National Research Council of Canada for financial support.

Reversible Inhibition of the Esterase Activity of Carboxypeptidase A by Carboxylate Anions[1]

JOHN W. BUNTING AND CHESTER D. MYERS
Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received January 24, 1973

Reversible inhibition of the hydrolysis of *O*-(hippuryl)-L-3-phenyllactic acid by carboxypeptidase A has been studied for 26 carboxylate ion inhibitors at 25°, p*H* 7.5, and ionic strength 0.2 (NaCl). Competitive inhibition, partially competitive inhibition, and mixed inhibition kinetics were observed. Within homologous series, strictly competitive inhibition by the lower members gave way to partially competitive inhibition with higher members, while homologs having very large hydrocarbon moieties displayed mixed inhibition kinetics. Partially competitive inhibition in this system is not consistent with a scheme involving only 1:1 enzyme–inhibitor complexes; rather, higher order enzyme–inhibitor complexes will be necessary for a complete description of the inhibition mechanism.

Inhibition constants ($\log K_i$) for the aliphatic carboxylate ions which are strictly competitive inhibitors, are closely correlated linearly with Hansch's π-parameter for hydrophobicity. This *quantitatively* confirms the importance of hydrophobic interactions between carboxypeptidase A and inhibiting ions. Carboxylate ions containing aromatic rings are less effective inhibitors than expected on the basis of the π-parameters of their hydrocarbon moieties. The dependence of $\log K_i$ on π in this system is unusually strong for a binding phenomenon, and suggests that an inhibitor-dependent conformational change may also be involved.

L'inhibition réversible de l'hydrolyse de l'acide *O*-(hippuryl) phényl-3 L-lactique par la carboxypeptidase A a été étudiée par rapport à 26 inhibiteurs (ion carboxylate) à 25°; p*H* 7.5 et force ionique 0.2 (NaCl). On a observé des cinétiques d'inhibition compétitive, d'inhibition compétitive partielle et d'inhibition mixte. A l'intérieur d'une même série, l'inhibition seulement compétitive par des membres inférieurs a donné lieu à de l'inhibition compétitive partielle par les membres supérieurs alors que les homologues possédant des entités hydrocarbure très grandes possèdent un cinétique d'inhibition mixte. L'inhibition compétitive partielle dans ce système n'est pas en accord avec un processus impliquant des complexes inhibiteur–enzyme 1:1; au contraire, des complexes inhibiteur–enzyme d'ordre plus élevé seront nécessaires afin d'expliciter complètement le mécanisme d'inhibition.

Les constantes d'inhibition ($\log K_i$) pour les ions carboxylate aliphatique lesquels sont des inhibiteurs seulement de compétition, sont reliées intimement de façon linéaire avec le paramètre-π de Hansch en ce qui a trait à l'hydrophobie. Ce fait confirme *quantitativement* l'importance d'interactions hydrophobes entre la carboxypeptidase A et les ions responsables de l'inhibition beaucoup moins efficaces qu'il était prévisible en se basant sur les paramètres-π de leur entité hydrocarbure. La relation entre le $\log K_i$ et π dans ce système, est forte ce qui est inhabituel pour un phénomène de fixation et suggère ainsi qu'un changement conformationnel relié à l'inhibiteur peut ainsi être impliqué.

Can. J. Chem., **51**, 2639 (1973)

Both the peptidase and esterase activities of carboxypeptidase A are well-known to be reversibly inhibited by carboxylate anions (1–9). Systematic studies on the dependence of the nature and extent of this inhibition on the structure of the inhibiting anion are lacking, however. A systematic study is particularly important in the light of the variety of inhibition mechanisms that have been observed for various carboxylate anions. Thus, competitive, non-competitive, and mixed inhibitory modes[2] have all been observed for different anions with a common substrate, carbobenzoxyglycyl-L-phenylalanine (1). On the other hand, both competitive and non-competitive inhibition kinetics have been observed for the same inhibitor against different peptide substrates. Furthermore, inhibition of peptidase activity by 3-phenylpropanoate (hydrocinnamate) ion has been suggested to be a mixture of competitive, non-competitive, and mixed inhibitory modes (11). Other studies of individual carboxylate ion inhibitors and assignment of inhibition modes abound in the literature.

Much of this work is clouded by the fact that inhibition studies have often been carried out at substrate concentrations where substrate activation or inhibition is also important. Consequently, some measured inhibition constants can only be considered to be "apparent" con-

stants rather than true binding constants, since the inhibitor molecules may be competing for either or both of the substrate binding sites (12, 13). The only substantial attempt (2) at correlating inhibitor structure with inhibitory capacity is marred by the fact that the substrate which was used (carbobenzoxyglycyl-L-tryptophan), displays substrate inhibition at the substrate concentration (0.05 *M*) at which the inhibitors were evaluated (14).

Interference from these substrate activation and inhibition phenomena in the assignment of inhibitory modes of peptidase activity has been overcome by the choice of tripeptide substrates which are relatively free of these effects (6). Depending upon the inhibitor chosen, competitive, non-competitive and mixed inhibition kinetics may still be observed, however. In a recent elegant study using a stopped-flow fluorescence technique (15), mixed inhibition kinetics with peptide substrates were shown to arise through a combination of competitive and non-competitive inhibitory modes. A sufficiently comprehensive study to allow the rationalization of the dependence of inhibitory mode on inhibitor structure was not attempted, however.

We feel that a comprehensive systematic study is required of the reversible inhibition of both the esterase and peptidase activities of carboxypeptidase A by carboxylate anions. Such a study should clarify many of the apparently anomalous, and sometimes contradictory, inhibition data that are in the literature, and at the same time may throw some light on the interpretation of the profound differences in the activity of this enzyme towards peptide and ester substrates (16–20). We report herein, the first part of such a study, into the dependence of the inhibition of esterase activity on the structure of aliphatic and aromatic carboxylate anion inhibitors, since many of the present results are of interest in their own right. Comparison will be made at a later time with a similar study, which is currently underway in our laboratory, on the inhibition of peptidase activity.

Experimental

Materials

All carboxylic acids were obtained commercially. Solids were recrystallized to melting points in agreement with literature values. Liquids were distilled, and fractions having boiling points consistent with literature data were selected. The identity of each carboxylic acid was also checked by p.m.r. spectroscopy. Stock solutions of the sodium salts of each carboxylic acid were prepared by careful titration of a known weight of the acid in aqueous solution (or suspension) to p*H* 7.5 with standard sodium hydroxide solution.

O-(Hippuryl)-L-3-phenyllactic acid was purchased from Fox Chemical Co., Los Angeles. Bovine carboxypeptidase A was obtained as a suspension in toluene from Worthington Biochemical Corp. Enzyme stock solutions were prepared by dialysis of this suspension against 1 *M* sodium chloride in 0.05 *M* tris buffer, p*H* 7.5, containing 10^{-4} *M* zinc nitrate at 4°. Enzyme concentrations were estimated spectrophotometrically at 278 nm ($\varepsilon = 6.42 \times 10^4\ M^{-1}\ cm^{-1}$) (21).

Methods

All reactions were studied at 25°, ionic strength 0.2 (NaCl), p*H* 7.5. Hydrolysis of the ester was followed by titration with standard potassium hydroxide solution (0.0025 *M*) on a p*H*-stat which consisted of the following Radiometer Corp. components: Syringe Buret SBUla, Type TTTlc Titrator and Type SBR2c Titrigraph. Substrate concentrations were always less than 4×10^{-4} *M*, so that substrate inhibition which becomes important at higher concentrations of *O*-(hippuryl)-L-3-phenyllactic acid could be neglected (18, 22, 23). Enzyme concentrations were in the range $7.1 \times 10^{-10} - 2.8 \times 10^{-9}$ *M*.

For each inhibitor, inhibition constants were determined by measuring initial velocities of the enzymic hydrolysis at approximately ten different substrate concentrations for each of two or more different inhibitor concentrations. The set of data at each inhibitor concentration was inspected graphically (E/v_0 *vs.* $1/S$) for linearity, and fitted by computer according to the regression technique of Wilkinson (24). For the uninhibited enzyme, the parameters obtained were $K_m = 7.18 \times 10^{-5}$ *M* and $k_{cat} = 2.50 \times 10^4\ min^{-1}$. Literature values for this substrate at p*H* 7.5, 25°, but at different ionic strengths, are in the ranges $K_m = (5.1 - 8.8) \times 10^{-5}$ *M* and $k_{cat} = (2.80 - 3.47) \times 10^4\ min^{-1}$ (23).

For those carboxylate anions that exhibited competitive inhibition kinetics, the apparent Michaelis constant, K_m^{app}, at inhibitor concentration *I*, was used to calculate the inhibition constant K_i, from the relationship (10)

$$K_i = I/(K_m^{app}/K_m - 1)$$

Light-scattering measurements were made on a Brice-Phoenix Universal 1000-D Light Scattering Photometer in solution under the same experimental conditions as were used for the kinetic experiments, except that the enzyme and substrate were absent.

Results

For each of the straight chain alkanoate ions from acetate to octanoate, reciprocal plots (E/v_0 *vs.* $1/S$) typical of competitive inhibition were obtained at a number of inhibitor concentrations (examples in Fig. 1). Calculation of inhibition constants at each inhibitor concentration gave values which were independent of the inhibitor concentration in the series from acetate to hexanoate ions (Table 1). However, for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

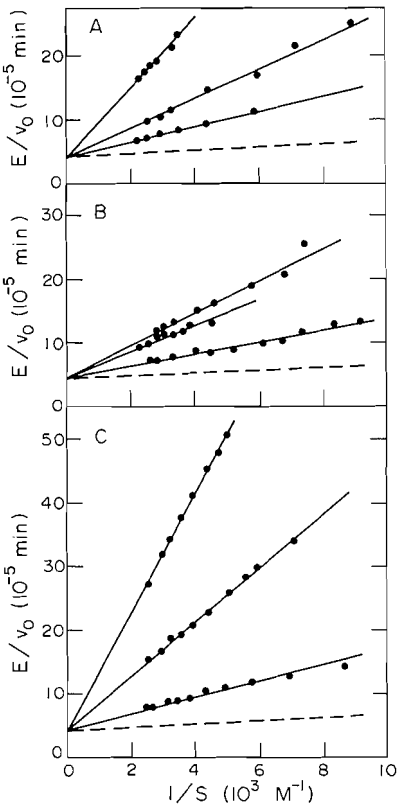

FIG. 1. Reciprocal plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A. A: propanoate, I = 21.3, 42.6, 63.9 mM; B: butanoate, I = 1.72, 2.58, 5.17 mM; C: octanoate, I = 2.02, 5.05, 8.07 mM. Dotted line indicates velocity in the absence of inhibitor.

the heptanoate and octanoate ions, the inhibition constants obtained were dependent on inhibitor concentration (Table 1), and in each case decreased with increasing inhibitor concentration. Such a phenomenon is typical of what has been termed partially competitive inhibition (10). With the nonanoate ion, the reciprocal plots are typical of mixed inhibition rather than competitive inhibition (Table 2).

Some branched chain alkanoate ions with small hydrocarbon moieties (up to five carbon atoms) also gave competitive inhibition constants that were independent of the inhibitor concentration (Table 1). Likewise, strictly competitive inhibition was also observed for the cyclopropane- and cyclobutanecarboxylate ions. However, cyclopentane- and cyclohexanecarboxylate ions displayed partially competitive inhibition, as was also the case for the cyclohexylacetate and 3-cyclohexylpropanoate ions (Table 1). With the 4-cyclohexylbutanoate ion, mixed inhibition kinetics were again observed (Table 2).

The benzoate and the ω-phenylalkanoate ions up to the 4-phenylbutanoate ion all displayed strictly competitive inhibition kinetics (Fig. 2 and Table 1). The slight trend in K_i apparent in Table 1 for the 5-phenylpentanoate ion may be due to partially competitive inhibition but experimental error cannot be completely ruled out. The 6-phenylhexanoate and also the 2-naphthalenecarboxylate ions gave mixed inhibition kinetics (Table 2).

The anionic inhibitors for carboxypeptidase A that were included in the present study display three characteristic types of reversible inhibition kinetics, *viz.* strictly competitive, partially competitive, and mixed inhibition. None of the carboxylate anions in the present study is a noncompetitive inhibitor for the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by this enzyme. Furthermore, a pattern to the dependence of the various types of inhibition on the size of the hydrocarbon moiety of the inhibiting ion is

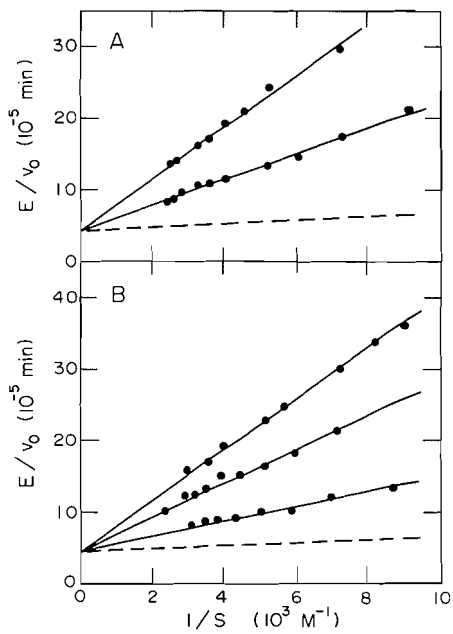

FIG. 2. Reciprocal plots for the inhibition of the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid by carboxypeptidase A. A: phenylacetate, I = 2.81, 4.23 mM; B: 5-phenylpentanoate, I = 0.696, 2.26, 3.38 mM. Dotted line indicates the velocity in the absence of inhibitor.

apparent. In all cases, the lower members of the series are strictly competitive inhibitors; the inhibition changes to partially competitive with higher members of a series, and eventually to mixed inhibition with very large hydrocarbon moieties. The large 2-naphthalenecarboxylate ion is also a mixed inhibitor, whereas the analogous smaller benzoate ion is a strictly competitive inhibitor.

Dixon and Webb (10) have shown that partially competitive inhibition kinetics will arise from Scheme 1, in which the catalytic activities

$$E + S \rightleftharpoons E.S \qquad \text{Dissociation constant: } K_s$$
$$E + I \rightleftharpoons E.I \qquad K_i$$
$$E.I + S \rightleftharpoons E.I.S \qquad K_{is}$$
$$E.S + I \rightleftharpoons E.I.S \qquad K_{si}$$
$$E.S \xrightarrow{k} E + P$$
$$E.I.S \xrightarrow{k} E.I + P$$

same. Scheme 1 gives rise to the dependence of initial velocity on inhibitor concentration in eq. 1. Equation 1 predicts that at constant sub-

$$[1] \qquad \frac{v_0}{E} = \frac{k}{1 + \frac{K_s}{S}\frac{(1 + I/K_i)}{(1 + I.K_s/K_i.K_{is})}}$$

strate concentration, a plot of E/v_0 *vs.* I should approach a maximum value at large inhibitor concentrations. However, the experimentally determined dependence of E/v_0 on inhibitor concentration for the cyclohexylacetate ion (a partially competitive inhibitor) in Fig. 3 shows no approach to a maximum over the experimentally accessible range of inhibitor concentration (up to 95% inhibition). Instead, the curve in Fig. 3 suggests a greater than first-power dependence on inhibitor concentration. Similar data for the cyclopropanecarboxylate ion is also included in Fig. 3. As expected for a strictly competitive inhibitor, the dependence of E/v_0 on I for this ion is linear (up to greater than 80% inhibition). From the slope of this plot we have estimated (10) a value of $K_i = 1.7 \times 10^{-3}$ M, which is in close agreement with the value obtained by varying the substrate concentration at constant inhibitor concentration (Table 1).

We therefore feel that the relatively simple scheme outlined above for partially competitive inhibition is not operative in the present cases. Reaction schemes involving complexes in which at least two inhibitor anions are bound to each enzyme molecule seem to be necessary in order to account for the observed dependence of K_i on inhibitor concentration for the anions with which we have observed partially competitive inhibition kinetics.

It is possible that the observation of partially competitive and mixed inhibition kinetics with some inhibitors in this study may perhaps be related to the tendency of the substrate, *O*-(hippuryl)-L-3-phenyllactic acid, to form higher order enzyme–substrate complexes (13, 22). We have attempted to minimize such effects by working only at substrate concentrations where substrate inhibition is minimal. However, the possibility exists that those anions that are not strictly competitive inhibitors, may be able to promote binding at one or both substrate binding sites via an initially formed enzyme–inhibitor complex. Kinetic schemes taking into account this possibility and also the higher order enzyme–inhibitor species noted above, would be relatively complex. At the present time, we do not have sufficient data to allow an analysis of the various kinetic schemes that are possible.

We thought that the occurrence of mixed inhibition kinetics with the largest anions may have been due to complications arising from the aggregation of these species to form micelles. However, a light scattering study of aqueous solutions of sodium 6-phenylhexanoate under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

the experimental conditions used in the kinetic studies gave no evidence of aggregation at the concentrations used in the inhibition studies. Furthermore, literature data suggest that the critical micelle concentration for the nonanoate ion is greater than 0.1 *M* at 25° (25, 26), which is a much higher concentration than was used for the observation of mixed inhibition kinetics with this ion (Table 2). We therefore feel that micelle formation is not an important factor in the present studies, and should not be implicated in the interpretation of the various forms of inhibition kinetics that are observed.

Carboxypeptidase A catalyzes the hydrolysis of the C-terminal amide bonds of peptides and analogous ester bonds, with a preference for C-terminal amino acids (or α-hydroxycarboxylic acids) that have hydrocarbon side-chains (27). In general, it has been found that carboxylate anions with similar types of hydrocarbon moieties are reversible inhibitors of the enzyme (1–9). X-ray crystallographic studies of this enzyme in the crystalline state have indicated that the active-site region does contain a convenient hydrophobic pocket for the acceptance of such entities (28–31). In an attempt to quantitatively describe the observed inhibitor specificity we investigated the possibility that the inhibition constants of the strictly competitive inhibitor anions were related to the Hansch π-parameters (32–34) for their hydrocarbon groups. This parameter, which is based upon the distribution coefficients of solutes between water and 1-octanol, has often been successfully used to reflect hydrophobic character in linear free energy correlations (33). From Fig. 4, it is clear that the log K_i values for the aliphatic carboxylate ions that are strictly competitive inhibitors of esterase activity (except hexanoate) are closely correlated with π (correlation coefficient = 0.966), with the straight chain, branched chain and cyclic alkyl groups all being accommodated by the same line:

$$[2] \qquad -\log K_i = 1.77\pi + 0.50$$

The inhibitors containing aromatic rings are not accommodated by this same equation. The plot for the strictly competitive inhibitors, $C_6H_5(CH_2)_nCO_2^-$ ($n = 0$–3), is not linear, although the first two members may be considered to lie on a line of similar slope to that of eq. 2 (broken line in Fig. 4). The larger anions

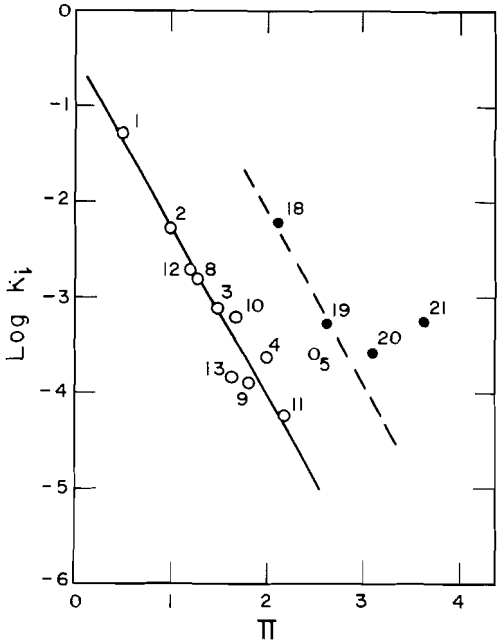

FIG. 4. Dependence of log K_i on π for strictly competitive inhibitor anions. Carboxylate ions are indicated by numbers which correspond to those in Table 1.

in this group ($n = 2$, 3) appear to be less effective inhibitors than the π values of their hydrocarbon groups would suggest, even allowing for an apparent inherent difference in inhibitory effectiveness between aliphatic and aromatic acids. Straight chain alkanoate ions larger than pentanoate, also are much less effective inhibitors than is consistent with their hydrophobic character. We feel that such hydrocarbon moieties are probably too large to fit into the hydrophobic pocket in their energetically most favorable conformations.

The pentanoate ion shows a slightly larger deviation from the correlation line in Fig. 4 than do any of the smaller aliphatic carboxylate ions. This suggests that the *n*-butyl group may be slightly longer than the maximum length that an *n*-alkyl group may be to fit into the hydrophobic pocket in its energetically most favorable conformation. Using Corey–Pauling–Koltun models, we have measured the distance from the carboxylate carbon atom to the end of the hydrocarbon chain in the pentanoate ion in its most extended conformation. This distance, 7.1 Å, should approximately reflect the length of the hydrophobic pocket that is accessible to an alkyl moiety.

Through eq. 2, one might predict that K_i for competitive inhibition of esterase activity by formate ion ($\pi = 0$) would be approximately 0.3 *M*. Thus, under our experimental conditions (ionic strength 0.2), the maximum concentration of formate ion (0.2 *M*) would lead to only 15% inhibition at substrate concentration 2×10^{-4} *M*.

Attempts to correlate the inhibition constant data with the steric parameter, E_s (35), or the electronic parameter, σ^* (35), rather than π, were unsuccessful. Thus, the 2,2-dimethylpropanoate ion and butanoate ions have similar K_i values (Table 1), although the E_s values of their alkyl groups are quite different (-1.54 for $(CH_3)_3C$; -0.36 for $CH_3CH_2CH_2$ (35)).

Discussion

In the past, the most extensively studied carboxylate ion inhibitors for carboxypeptidase A have been the phenylacetate and 3-phenylpropanoate ions. Literature values of K_i for these ions at p*H* 7.5 and 25° (but at various ionic strengths) lie in the range 0.39–0.73 m*M* for phenylacetate (1, 5, 6) and 0.062–0.19 m*M* for 3-phenylpropanoate (1, 5, 6, 7). Our inhibition constants for these two ions (Table 1) lie within these ranges. Our K_i value for the 4-phenylbutanoate ion (0.58 m*M*) is approximately half of two previously reported values (1.1 and 1.37 m*M* (1, 5)), although our data are consistent with previous reports that this ion is a less effective inhibitor than its next lower homolog, 3-phenylpropanoate (5). We have observed strictly competitive inhibition with each of these ions, which is in accord with studies on their inhibition of this enzyme towards *O*-hippuryl-L-mandelic acid (5) and carbobenzoxyglycyl-L-phenylalanine (1). However, a recent report (6) indicates that phenylacetate and 3-phenylpropanoate ions act as non-competitive inhibitors for the hydrolysis of carbobenzoxyglycylglycyl-L-phenylalanine and hippuryl-L-phenylalanine.

On several occasions (2, 4), acetate ion has been reported not to inhibit this enzyme, even in one case (2), in the presence of 1 *M* sodium acetate. Our data suggest that this ion is a significant inhibitor of esterase activity (K_i = 53 m*M*). Although an early report suggests that propanoate and butanoate ions display mixed inhibition kinetics towards carbobenzoxyglycyl-L-phenylalanine hydrolysis (1), we find that all the simple alkanoate ions are competitive inhibitors for the hydrolysis of *O*-hippuryl-L-3-phenyllactic acid. Similarly, benzoate ion is a strictly competitive inhibitor in our study, which was not the case in an earlier investigation (1).

Some of these apparently anomalous results may be due to the differences that have been observed between the peptidase and esterase activities of carboxypeptidase A (16–20), and also possibly to differences in experimental conditions. Furthermore, it has recently been demonstrated (15) that the phenylacetate, 3-phenylpropanoate, 3-iodopropanoate, and butanoate ions simultaneously display both competitive and non-competitive components in their inhibition of dansyl-glycyl-L-tryptophan hydrolysis by carboxypeptidase A. This requires at least two distinct binding sites for these carboxylate ions, and suggests that the predominant mode of inhibition observed for different substrates may be very dependent on substrate structure. It is possible that mixed inhibition kinetics for ester hydrolysis observed in the present study may arise in a similar manner. However, it should be noted that we have not observed any examples of purely non-competitive inhibition of ester hydrolysis, whereas this form of inhibition is well known for peptide hydrolysis (6).

Overall, our results are in qualitative agreement with an earlier more limited study (2) on the dependence of inhibitor effectiveness on structure, although as noted above, this earlier study was carried out under conditions where substrate inhibition has since been shown to be important.

It is clear from the X-ray crystallographic investigation (28–31) of carboxypeptidase A and carboxypeptidase–ligand complexes that there is a convenient hydrophobic pocket in the active-site region of the enzyme for the acceptance of apolar side chains of substrate and inhibitor molecules. It is also apparent that the negatively charged carboxylate group can be conveniently accommodated by an electrostatic interaction with the positively charged guanidinium group of arginine-145, or alternatively, coordinated to the active site zinc ion. Both types of electrostatic interaction have been observed in crystals of small molecule – carboxypeptidase complexes. The binding of a *p*-iodophenylpropanoate ion has been interpreted as involving a Zn^{2+} –

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

carboxylate interaction, whereas the binding of glycyl-L-tyrosine involves an ion pair between the tyrosine carboxylate group and the arginine-145 side-chain. It is possible that either (or both) of these interactions are important for the binding of carboxylate ion inhibitors in solution, and that some of the different inhibition modes that we have observed may result from different accommodations for the carboxylate groups of various inhibiting ions.

A p.m.r. spectroscopic investigation (36) of the binding of 3-phenylpropanoate ions to manganese – carboxypeptidase A in solution has indicated that a water molecule is displaced from the coordination sphere of the manganese ion upon inhibitor binding. This is consistent with the carboxylate group being coordinated to the metal ion in this case. Similarly, line-broadening in the p.m.r. spectrum of methoxyacetate ions in the presence of manganese–carboxypeptidase has been shown to be consistent with the coordination of this species to the active-site metal ion (37). It is clear, however, from the crystallographic investigation of *p*-iodophenylpropanoate–carboxypeptidase complexes, that there are at least four sites in the enzyme molecule at which these ions may be bound (28). Multiple binding of 3-phenylpropanoate ions to cobalt – carboxypeptidase A has also been observed by spectroscopic methods (38, 39). The observation of mixed inhibition kinetics with anions having large hydrocarbon entities may be a reflection of preferential binding at one or more of these other sites when the hydrocarbon group is no longer sufficiently small to be accommodated in the active-site hydrophobic pocket. The close correlation with π for the smaller carboxylate ions is strong evidence in support of these ions all being bound in a similar manner. The data in Fig. 3 for the cyclohexylacetate ion suggest that at least for this ion, and also presumably for the other ions that display partially competitive inhibition kinetics, multiple binding sites also exist in solution.

The slope of the log K_i *vs.* π correlation line (eq. 2) is considerably larger than has previously been observed for the binding of small molecules to macromolecules through "hydrophobic bonding". Typical pre-π factors in correlations of binding constants with π are in the range 0.46–0.84 (33, 40). Thus, the relationship in eq. 2 suggests an unusually strong dependence of binding on the hydrophobic character of the hydrocarbon moiety of the inhibiting anion. Consideration of homologous pairs of anions that fit eq. 2 allows the calculation of the contribution of a methylene unit to the binding of an inhibitor ion to the enzyme. The data in Table 3 suggest that the free energy change for binding per methylene unit in these reactions is 1.46 $\pm$ 0.05 kcal/mol. This value is considerably larger than expected for the free energy of transfer of a methylene unit between an aqueous and hydrocarbon environment. This latter value has been estimated to be approximately 0.8 kcal/mol in various studies (41, 42). Such a change would give rise to a pre-π factor of approximately 1.1 which is somewhat greater than is found in most correlations of hydrophobic character with ligand binding to macromolecules (33, 40), but considerably less than the value of 1.77 in eq. 2. Thus, if our observed $\Delta(\Delta F) = 1.46$ kcal/mol/methylene unit reflects the free energy change for the transfer of a methylene unit from bulk aqueous solution to the hydrophobic cavity at the active-site of the enzyme, one is forced to conclude that this cavity is more hydrophobic than a hydrocarbon solvent, a phenomenon that is of doubtful physical significance.

An alternative interpretation would be to suggest that, in addition to the transfer of a methylene unit from water to a less polar environment, the pre-π factor is also reflecting one or more other factors which are also dependent on the hydrophobic character of the binding ligand. The X-ray crystallographic studies indicate that considerable conformational changes occur in this enzyme in the vicinity of the active-site upon ligand binding (28–31). We suggest that the large pre-π factor of eq. 2 is the sum of the effects of the hydrophobic character of the inhibiting ion on both inhibitor binding (*i.e.*

TABLE 3. Differences in free energy of binding of homologous inhibitors to carboxypeptidase A

R_1	R_2	$\Delta(\Delta F)$* (kcal/mol)
CH_3	CH_3CH_2	1.40
CH_3CH_2	$CH_3(CH_2)_2$	1.11
$(CH_3)_2CH$	$(CH_3)_2CHCH_2$	1.52

hydrophobic bonding) and on producing a conformational change in the enzyme. This interpretation assumes that the conformational change upon formation of the enzyme–inhibitor complex is directly related to the hydrophobic character of the ligand. Such an assumption is not without precedent; Helmer *et al.* (43) have observed that the binding of small molecules to bovine serum albumin produces changes in optical rotation that correlate with the hydrophobic character of the ligand. These changes in optical rotation are believed to reflect conformational changes in the protein upon ligand binding. Furthermore, the changes in optical rotation are much more dependent on the hydrophobic character of the ligand (pre-π factor 2.23) than are the binding constants for these same ligands to this protein (pre-π factor 0.75).

The observed differences in the binding of strictly aliphatic carboxylate anions and those containing aromatic rings are puzzling. The differences cannot be due merely to the presence of a ring since both acyclic and cyclic aliphatic carboxylates seem to be reasonably well correlated by eq. 2. The lower ω-phenylalkanoic acid anions seem to lie on a line of similar slope to that for the aliphatic carboxylate ions (Fig. 4). The difference in inhibitory effectiveness for equally hydrophobic (*i.e.* equal π-values) hydrocarbon moieties between the two groups of inhibitors is

$$\log K_i(\text{aliphatic}) - \log K_i(\text{aromatic}) = -1.9$$

This relationship may be interpreted as meaning that carboxylate ions containing aromatic rings are inherently less potent inhibitors than strictly aliphatic carboxylate ions, but the reasons for this difference remain unclear at the present time. It is interesting to note that in a recent study (44) of the reversible inhibition of chymotrypsin by alkyl- and ω-phenylalkyl-boronic acids, a difference between aliphatic acids and phenyl substituted acids was observed. Here, however, based upon their hydrophobic character as expressed by π-values, the acids containing aromatic rings were *more* effective inhibitors than their aliphatic counterparts. For this system we have calculated

$$\log K_i(\text{aliphatic}) - \log K_i(\text{aromatic}) = 1.2$$

As is the case for carboxypeptidase A, the reasons for this inherent difference between aliphatic and aromatic inhibitors of chymotrypsin are not known.

Ring Opening of Dihydro-1,4-oxathiins

MAURICE ARMAND CORBEIL, MICHAEL CURCUMELLI-RODOSTAMO, ROBERT JAMES FANNING, BRUCE ALLAN GRAHAM, MARSHALL KULKA, AND JAMES BENJAMIN PIERCE

Uniroyal Limited, Research Laboratories, Guelph, Ontario

Received December 8, 1972

Acid hydrolysis of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide gives 2-(2-hydroxyethylthio)-acetoacetanilide enol. 3-Carbonyl-substituted 5,6-dihydro-1,4-oxathiins were found to undergo ring cleavage by nucleophilic nitrogen attack on C-2. Thus the following reactions were observed: 3-acetyl-5,6-dihydro-2-methyl-1,4-oxathiin on treatment with hydrazine gives 4-(2-hydroxyethylthio)-3,5-dimethylpyrazole, instead of the hydrazone. The 1,4-oxathiins, *N*-(5,6-dihydro-2-methyl-1,4-oxathiin-3-ylcarbonyl)-*N'*-phenylurea and 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid hydrazide rearrange to give 5-(2-hydroxyethylthio)-6-methyl-1-phenyluracil and 4-(2-hydroxyethylthio)-3-methyl-2-pyrazolin-5-one, respectively. Finally, treatment of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride with 2-aminopyridine and with 2-aminopyrimidine affords 4*H*-3-(2-hydroxyethylthio)-2-methylpyrido[1,2-*a*]pyrimidin-4-one and 4*H*-3-(2-hydroxyethylthio)-2-methylpyrimido[1,2-*a*]pyrimidin-4-one, respectively, as the predominant products.

L'hydrolyse acide du dihydro-5,6 méthyl-2 oxathiine-1,4 carboxanilide-3 a produit l'énol (hydroxy-2 éthylthio)-2 acétoacétanilide. Les composés dihydro-5,6 oxathiine-1,4 carboxyl-3 substitués ont subi un clivage du cycle consécutivement à l'attaque de la position C-2 par un azote nucléophile. Par suite, les réactions suivantes furent observées: l'acétyl-3 dihydro-5,6 méthyl-2 oxathiine-1,4 a produit lors d'une réaction avec l'hydrazine l'(hydroxy-2 éthylthio)-4 diméthyl-3,5 pyrazole au lieu de l'hydrazone. Les oxathiines-1,4 *N*-(dihydro-5,6 méthyl-2 oxathiine-1,4 carbonyl-3) *N'*-phénylurée et l'hydrazide de l'acide dihydro-5,6 méthyl-2 oxathiine-1,4 carboxylique-3 ont produit par réarrangement l'(hydroxy-2 éthylthio)-5 méthyl-6 phényl-1 uracile et l'(hydroxy-2 éthylthio)-4 méthyl-3 pyrazoline-2 one-5, respectivement. Finalement, la réaction du chlorure de dihydro-5,6 méthyl-2 oxathiine-1,4 carbonyle-3 avec l'amino-2 pyridine et avec l'amino-2 pyrimidine à conduit, comme produits principaux, à l'(hydroxy-2 éthylthio)-3-4*H* méthyl-2 pyridopyrimidine[1,2-*a*]one-4 et à l'(hydroxy-2 éthylthio-3-4*H* méthyl-2 pyrimido pyrimidine[1,2-*a*]one-4 respectivement. [Traduit par le journal]

Can. J. Chem., 51, 2650 (1973)

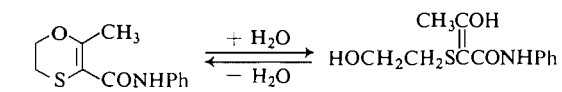
The discovery that 5,6-dihydro-1,4-oxathiins and more particularly 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (Vitavax®)[1] (**1**) and its sulfone (Plantvax®) possess systemic fungicidal properties (1) has stimulated interest in 1,4-oxathiin chemistry and has given impetus to the search for other systemic fungicides.

The purpose of this paper is to discuss the ring opening of several 3-carbonyl-substituted 5,6-dihydro-1,4-oxathiins by nucleophilic attack on C-2.

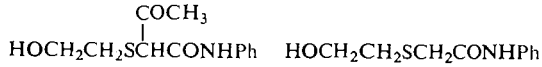
Recently Wilson demonstrated that 5,6-dihydro-2-methyl-1,4-oxathiin undergoes acid-catalyzed hydrolytic cleavage to form (2-hydroxyethylthio)-2-propanone (2). It has been found in this laboratory that 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (**1**) undergoes similar hydrolytic cleavage with formation of the enol form **2** of 2-(2-hydroxyethylthio)acetoacetanilide (**3**) (eq. 1). This compound was also prepared from 2-mercaptoethanol and 2-chloroacetoacetanilide.

That the hydrolysis product is the enol **2** and not the keto form **3** has been demonstrated by the purple color it gives in alcoholic ferric chloride, by its rapid dissolution in aqueous sodium and ammonium hydroxide, and by its i.r. and n.m.r. spectra. The ketone carbonyl band is absent in the i.r. spectrum and the singlet at 15.5 p.p.m. in the n.m.r. spectrum is indicative of an enolic proton. The enolization appears to be aided by the sulfur atom since unsubstituted β-ketoamides are largely ketonic. Similar enolization has been observed in 2-thio-1,3-diketones (3).

The cleavage product **2** was converted readily to **1** by heating in benzene with azeotropic water



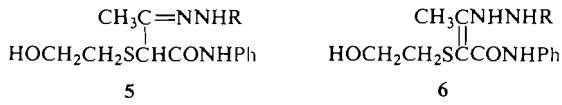
[1] **1** **2**



3 **4**

[1]®Uniroyal's registered trademark.

removal in the presence of an acid catalyst. As expected, it is sensitive to base, and in aqueous sodium hydroxide undergoes deacetylation to furnish 2-(2-hydroxyethylthio)acetanilide (**4**). Similar deacetylations have been previously observed (4–6). **2** forms a 2,4-dinitrophenylhydrazone (**5**) which is also obtained by treatment of the oxathiin **1** with 2,4-dinitrophenylhydrazine reagent. The n.m.r. spectrum of the hydrazone shows a singlet at 4.67 p.p.m. which is not affected on treatment of the sample with deuterium oxide. Assignment of this singlet to a proton at C-2 shows the hydrazone to have the imine structure **5**, rather than the alternative enamine structure **6**.

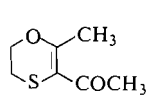


5 **6**

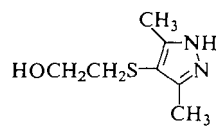
R = 2,4-dinitrophenyl

Mattsson and Bertilsson have shown that 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (**1**) can also be cleaved by amines (7). Thus a solution of **1** and pentylamine on standing at room temperature for several days affords 2-(2-hydroxyethylthio)-3-pentylaminocrotonanilide. A number of reactions of 3-carbonyl-substituted 5,6-dihydro-1,4-oxathiins involving nucleophilic attack on C-2 by nitrogen have been encountered in this laboratory.

One such reaction constitutes an example of the known conversion of β-alkoxy-α,β-unsaturated ketones to pyrazoles on treatment with hydrazine (8). Thus from 3-acetyl-5,6-dihydro-2-methyl-1,4-oxathiin (**7**) and hydrazine a product was obtained which was identified as 4-(2-hydroxyethylthio)-3,5-dimethylpyrazole (**8**). The n.m.r. spectrum (DMSO-d_6) of this product (**8**) shows a singlet at 2.23 p.p.m. attributed to two equivalent methyl groups and two triplets at 2.56 and 3.45 p.p.m. characteristic of the two methylenes of a 2-hydroxyethylthio group.

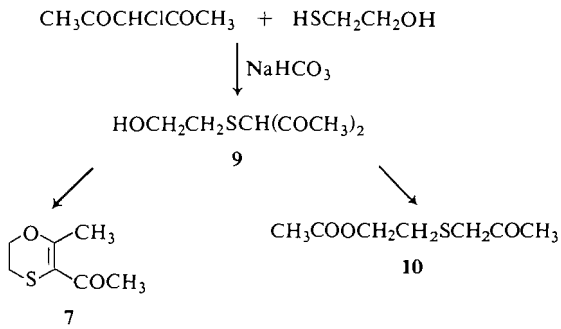


7

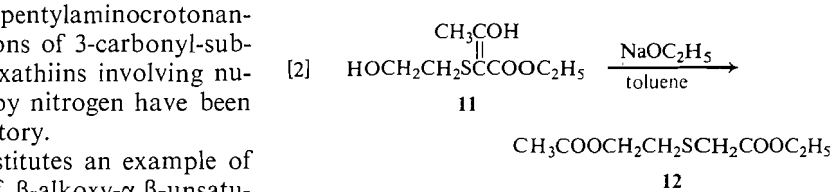


8

The preparation of the oxathiin **7** now warrants brief consideration. Reaction of 3-chloro-2,4-pentanedione with 2-mercaptoethanol in the presence of sodium bicarbonate gave a neutral and an acidic compound (Scheme 1). The acidic compound, presumably **9**, was converted to the desired oxathiin **7** by acid-catalyzed dehydration. The neutral product was identified as **10** by comparison of its i.r. and n.m.r. spectra with those of an authentic sample prepared by acetylation of (2-hydroxyethylthio)-2-propanone (2). It probably formed by rearrangement of **9**. A similar rearrangement, observed in this laboratory, consists in the conversion of ethyl 2-(2-hydroxyethylthio) acetoacetate (**11**) to ethyl (2-acetoxyethylthio)acetate (**12**) in the presence of sodium ethylate (eq. 2).



SCHEME 1



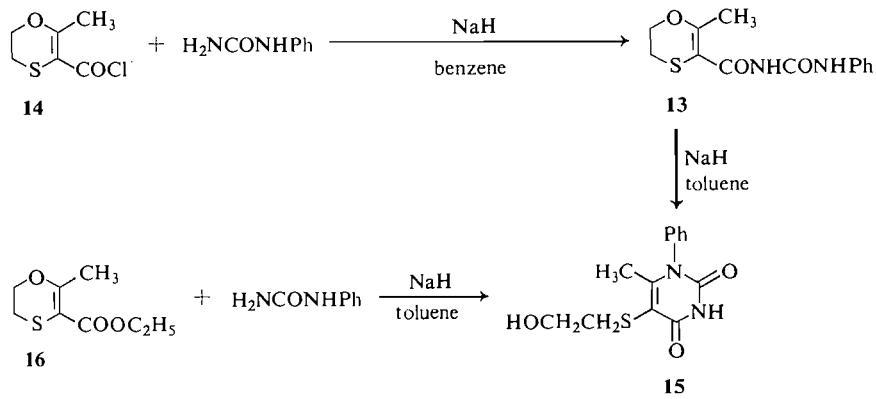
11

$CH_3COOCH_2CH_2SCH_2COOC_2H_5$

12

The identity of compound **12** was established by comparison of its i.r. and n.m.r. spectra with those of the compound obtained by acetylation of ethyl (2-hydroxyethylthio)acetate (9).

Another reaction involving nucleophilic attack by nitrogen on C-2 of a 1,4-oxathiin gave a 2-hydroxyethylthio-substituted uracil. Thus *N*-(5,6-dihydro-2-methyl-1,4-oxathiin-3-ylcarbonyl)-*N'*-phenylurea (**13**), prepared from 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride (**14**) and *N*-phenylurea, when heated in refluxing toluene in the presence of sodium hydride rearranged to 5-(2-hydroxyethylthio)-6-methyl-1-phenyluracil (**15**) in 57% yield (Scheme 2). Compound **15** was also obtained in an attempt to make **13** by the method of Wolfe and Trimitsis (10). Thus treatment of ethyl 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylate (**16**) (*1b*) with *N*-phenylurea and sodium hydride in toluene at reflux temperature gave **15** in 55% yield. Since, as shown above, compound **13** rearranges to

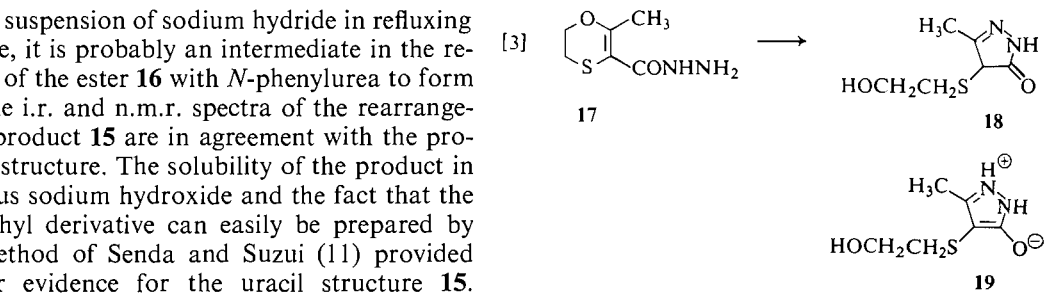


SCHEME 2

15 in a suspension of sodium hydride in refluxing toluene, it is probably an intermediate in the reaction of the ester **16** with *N*-phenylurea to form **15**. The i.r. and n.m.r. spectra of the rearrangement product **15** are in agreement with the proposed structure. The solubility of the product in aqueous sodium hydroxide and the fact that the *N*-methyl derivative can easily be prepared by the method of Senda and Suzui (11) provided further evidence for the uracil structure **15**. Confirmation of the presence of the alcoholic function came from the conversion of **15** to a chloride on treatment with thionyl chloride in chloroform. 1-(5-Chloro-2-methylphenyl)-5-(2-hydroxyethylthio)-6-methyluracil was obtained from ethyl 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylate **16** and *N*-(5-chloro-2-methylphenyl)-urea in the same manner as was **15**.

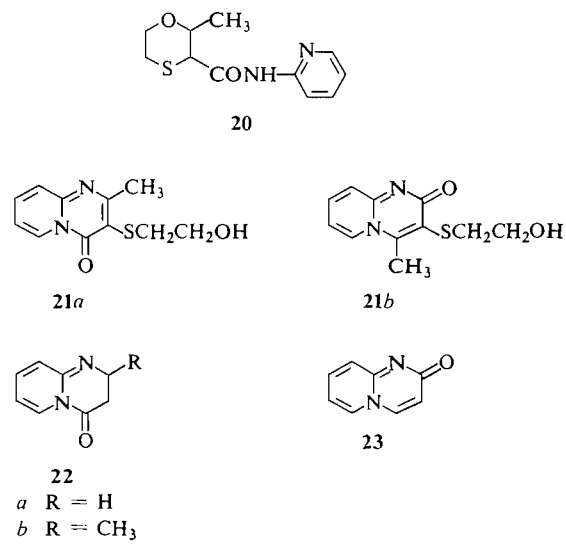
A further example of ring opening of a dihydro-1,4-oxathiin by intramolecular nitrogen attack was encountered when an *n*-butanol solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid hydrazide (**17**) was heated at reflux to give the rearranged isomer 4-(2-hydroxyethylthio)-3-methyl-2-pyrazolin-5-one (**18**) (eq. 3). The n.m.r. spectrum of **18** shows the two methylene triplets characteristic of a 2-hydroxyethylthio group. The solubility of **18** in aqueous sodium carbonate and its u.v. absorption at 242 nm are in accord with the assigned 2-pyrazolin-5-one structure. A strong band in the i.r. spectrum (KBr) between 2400 and 2900 cm^{-1}, ascribed by De Stevens and co-workers (12) to the pyrazolinone zwitterion, shows the important contribution of the tautomeric form **19**.

Cleavage of the dihydro-1,4-oxathiin ring was also demonstrated in the reaction of the acid chloride **14** with 2-aminopyridine in benzene in



the presence of triethylamine. This reaction gave the amide **20** in only 4% yield. The major reaction product **21**, isolated in 56% yield, was identified as 4*H*-3-(2-hydroxyethylthio)-2-methylpyrido[1,2-*a*]pyrimidin-4-one (**21***a*), an isomer of **20**.

The i.r. spectrum of compound **21** revealed the presence of a hydroxyl group. The n.m.r.



a R = H
b R = CH_3

spectrum shows two triplets (J = 6Hz), centered at 3.67 and 2.98 p.p.m., instead of the methylene multiplets present in the spectra of dihydro-1,4-oxathiins. The foregoing data indicated that cleavage of the dihydro-1,4-oxathiin ring had occurred resulting in the formation of a 2-hydroxyethylthio group. At this stage, structures **21***a* and **21***b* were considered for compound **21**.

The problem of distinguishing between a 2- and a 4-pyrido[1,2-*a*]pyrimidinone is not new and has been the subject of several investigations (13–19). In particular, it has been shown by Adams and Pachter (15) and by Allen *et al.* (19) that the u.v. spectra of 2- and 4-pyrido[1,2-*a*]-pyrimidinones are characteristically different in the relative values of the extinction coefficients of the maxima occurring in the regions of 240–270 nm (region *a*) and 300–400 nm (region *b*). Typically the 4-ones show a ratio of extinction coefficients $\varepsilon_b/\varepsilon_a$ greater than 1 whereas for 2-ones this ratio is less than $\frac{1}{3}$. Table 1 lists the u.v. data for compounds **22***a* and **23** (19) together with those we found for compound **21**. Comparison of the extinction-coefficient ratios ($\varepsilon_b/\varepsilon_a$) clearly indicates that **21** has the 4-one structure **21***a* rather than the alternative 2-one structure **21***b*.

Structure **21***a* received further spectroscopic support. The n.m.r. spectrum of compound **21** shows a single-proton doublet (8.93 p.p.m.) downfield from the bulk of aromatic absorption by 0.9 p.p.m. In structure **21***a* the low-field position of this doublet can be attributed to the deshielding of the 6-proton by the keto group whereas a similar effect is not possible in structure **21***b*. A comparable deshielding was found by Mendel for the 6-proton of compound **22***b* (20).

Confirmation of structure **21***a* rests on chemical evidence. Formation of the alternative structure **21***b* would be expected to involve the intermediacy of the minor reaction product **20**.

TABLE 1. Comparison of u.v. data of 2- and 4-pyrido[1,2-*a*]pyrimidinones*

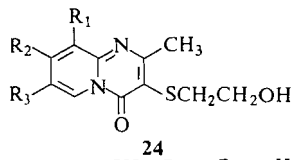
Compound	λ_a	ε_a	λ_b	ε_b	$\varepsilon_b/\varepsilon_a$
21*a*	248	11.5	352	14.3	1.24
22*a*†	248	10.0	348	10.0	1.00
	258	9.6			
23†	268	10.0	324	3.2	0.31

*The wavelength is given in nm and the extinction coefficient is expressed as $\varepsilon \times 10^{-3}$.
†U.v. data from ref. 19.

The latter, however, was shown not to be a reaction intermediate, since it was recovered quantitatively after being subjected to the reaction conditions.

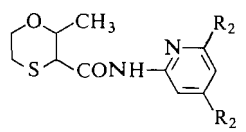
Reaction of the acid chloride **14** with 2-amino-3-, -4-, and -5-methylpyridine furnished the 4-pyrido[1,2-*a*]pyrimidinones **24***a*, **24***b*, and **24***c*, respectively. The dihydro-1,4-oxathiin carboxamides were shown by n.m.r. spectroscopy to form in low yield.

However, reaction of compound **14** with 2-amino-6-methylpyridine and with 2-amino-4,6-dimethylpyridine led exclusively to the amides **25***a* and **25***b*. Clearly, the 6-methyl group hinders attack of the electrophile on the ring nitrogen. Failure of the ring nitrogen of 2-amino-6-methylpyridine to participate in reactions with bifunctional electrophiles has been well documented (13, 21–23).



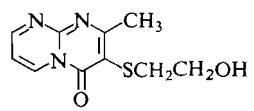
24

a $R_1 = CH_3$, $R_2 = R_3 = H$
b $R_1 = R_3 = H$, $R_2 = CH_3$
c $R_1 = R_2 = H$, $R_3 = CH_3$

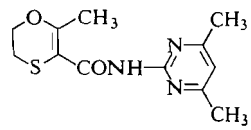


25

a $R_1 = CH_3$, $R_2 = H$
b $R_1 = R_2 = CH_3$



26



27

Treatment of the acid chloride **14** with 2-aminopyrimidine furnished the 4-pyrimido[1,2-*a*]pyrimidinone **26**. The structural assignment follows from the presence in the n.m.r. spectrum of a low-field absorption (centered at 9.2 p.p.m.) due to the C-6 and -8 protons (see above) and from analogy with the behavior of the 2-aminopyridines. As expected, reaction of compound **14** with 2-amino-4,6-dimethylpyrimidine yielded only the amide **27**.

Experimental

I.r. spectra were obtained on Perkin-Elmer 237B or 521 grating i.r. spectrometers. The n.m.r. spectra were recorded using an R-20 Hitachi Perkin-Elmer spectrometer and are expressed in p.p.m. (δ values) relative to tetramethylsilane as standard. Melting points were determined on a Gallenkamp melting point apparatus and are

uncorrected. Ultraviolet spectra were measured on a Perkin-Elmer 402 spectrometer and the analyses were performed on a Perkin-Elmer 240 elemental analyzer.

2-(2-Hydroxyethylthio)acetoacetanilide Enol (2)

To a solution of 2-chloroacetoacetanilide (53 g, 0.25 mol) in methanol (50 ml) and pyridine (25 g) was added 2-mercaptoethanol (20 g, 0.26 mol) and the solution stirred for 15 min with occasional cooling on a water bath maintaining the temperature at 35 to 40°. The reaction mixture was allowed to stand at room temperature for 2 h and then poured into water (200 ml). The material obtained by solidification of the precipitated oil was collected, washed well with cold water, and dried. Crystallization from toluene gave large white crystals (54.6 g or 87.5%) of m.p. 64–66°. Recrystallization from toluene yielded a pure product melting at 66–67°. N.m.r. ($CDCl_3$): 15.5 (1H, s, OH), 9.33 (1H, s, NH), 7.33 (5H, m, aromatic), 3.67 (2H, m, CH_2O), 2.63 (2H, t, CH_2S), 2.63 (1H, t, OH), 2.33 (3H, s, CH_3); i.r. ($CHCl_3$): 3680, 3620, 3325 cm^{-1}.

Anal. Calcd. for $C_{12}H_{15}NO_3S$: C, 56.89; H, 5.96; N, 5.52. Found: C, 56.80; H, 6.20; N, 5.61.

The enol **2** was converted in 65% yield to 2-(2-chloroethylthio)acetoacetanilide enol by treatment with thionyl chloride in benzene at room temperature, m.p. 83–85°.

Anal. Calcd. for $C_{12}H_{14}ClNO_2S$: C, 53.03; H, 5.19; N, 5.15; Cl, 13.04; S, 11.8. Found: C, 53.05; H, 5.61; N, 5.66; Cl, 12.8; S, 11.8.

Ring Opening of 5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxanilide with Aqueous Acid

A mixture of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (23.5 g, 0.10 mol), 10% aqueous hydrochloric acid (100 ml), and toluene (200 ml) was heated to 80° while stirred rapidly. The mixture was maintained at this temperature for 1 h, allowed to cool, and the aqueous and organic layers were then separated. The toluene phase was extracted with cold 10% aqueous sodium hydroxide (2 × 100 ml) and the aqueous extract acidified with dilute hydrochloric acid. The product immediately oiled out of the acidic solution. It was extracted with toluene (2 × 100 ml) and the toluene phase was reduced in volume (to about 75 ml) by distillation under reduced pressure. The product was crystallized from the remaining toluene by cooling to −20° and scratching to induce crystallization. Thus was obtained 2-(2-hydroxyethylthio)acetoacetanilide (14.5 g or 57%) of m.p. 63–67°. The i.r. spectrum of this material proved to be identical to that of the material isolated from reaction of 2-chloroacetoacetanilide with mercaptoethanol.

5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (1)

To a solution of 2-(2-hydroxyethylthio)acetoacetanilide enol (**2**) (23.5 g, 0.09 mol) in benzene (65 ml) was added *p*-toluenesulfonic acid (0.1 g) and the reaction mixture was heated under reflux for 2 h with azeotropic water removal in a Dean–Stark trap. The solution was diluted with benzene (100 ml) and then washed with cold 5% aqueous sodium hydroxide and with water. The solvent was distilled off *in vacuo* and the residue crystallized from toluene to yield white crystals (19.9 g or 90%) of m.p. 93–95°. N.m.r. ($CDCl_3$): 9.33 (1H, s, NH), 7.5 (5H, m, aromatic), 4.80 (2H, m, CH_2O), 3.52 (2H, m, CH_2S), 2.36 (3H, s, CH_3).

Anal. Calcd. for $C_{12}H_{13}NO_2S$: C, 61.28; H, 5.53; N, 5.96. Found: C, 61.29; H, 5.58; N, 5.87.

Deacetylation of 2-(2-Hydroxyethylthio)acetoacetanilide (2) to 2-(2-Hydroxyethylthio)acetanilide (4)

To a solution of 2-(2-hydroxyethylthio)acetoacetanilide (25 g, 0.1 mol) in benzene (100 ml) was added 10% aqueous sodium hydroxide (100 ml) and the reaction mixture stirred at 35 to 40° for 1.5 h. The reaction mixture was cooled and the precipitate collected, washed with water, and dried. The white solid thus obtained (15.5 g or 70%) melted at 80–81° and did not depress the m.p. of an authentic sample of 2-(2-hydroxyethylthio)acetanilide prepared from 2-mercaptoethanol and chloroacetanilide. The i.r. spectrum was identical with that of the authentic sample.

The treatment of 2-(2-hydroxyethylthio)acetanilide with thionyl chloride in chloroform yielded 2-(2-chloroethylthio)acetanilide in 65% yield, m.p. 91–93°.

Anal. Calcd. for $C_{10}H_{12}ClNOS$: C, 52.27; H, 5.26; N, 6.09. Found: C, 52.10; H, 5.20; N, 5.93.

2,4-Dinitrophenylhydrazone (5) of 2-(2-Hydroxyethylthio)acetoacetanilide (2)

To a solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide (10.5 g, 0.045 mol) in methanol (250 ml) was added a solution of 2,4-dinitrophenylhydrazine (9 g, 0.045 mol) in concentrated sulfuric acid (100 ml), water (400 ml), and methanol (100 ml). After allowing the reaction mixture to stand at room temperature for 2 days, the orange crystals were filtered, washed with water and with methanol, and dried. The yellow solid (18 g or 90%) melted at 188–190° and at 191–193° after recrystallization from acetonitrile. N.m.r. (DMSO-d_6): 10.86 (1H, s, NH), 10.31 (1H, s, NH), 6.8–8.9 (8H, m, aromatic), 4.9 (1H, t, J = 5.5 Hz, OH), 3.4–3.8 (2H, m, CH_2O), 2.72 (2H, t, J = 6.5 Hz, CH_2S), 2.29 (3H, s, CH_3); i.r. (KBr): 3240, 3310, 3590 cm^{-1}.

Anal. Calcd. for $C_{18}H_{19}N_5O_6S$: C, 49.87; H, 4.41. Found: C, 50.26; H, 4.52.

The same compound was obtained when 2-(2-hydroxyethylthio)acetoacetanilide (**2**) was treated similarly with 2,4-dinitrophenylhydrazine.

3-Acetyl-5,6-dihydro-2-methyl-1,4-oxathiin (7)

Sodium bicarbonate (92.4 g, 1.1 mol) was added to a stirred mixture of 3-chloro-2,4-pentanedione (24)(134.5 g, 1 mol), benzene (400 ml), 2-mercaptoethanol (78.1 g, 1 mol), and water (200 ml). After 0.5 h the organic layer was separated and extracted with 2 *N* sodium hydroxide (500 ml). The organic layer was washed with water (200 ml) and concentrated *in vacuo* to yield *(2-acetoxyethylthio)-2-propanone* (**10**) (5.9 g or 3.4%), a colorless liquid of b.p. 100° at 0.4 mm. N.m.r. ($CDCl_3$): 4.16 (2H, t, J = 6.5 Hz, CH_2O), 3.33 (2H, s, CH_2CO), 2.72 (2H, t, J = 6.5 Hz, CH_2S), 2.26 (3H, s, CH_3CO), 2.04 (3H, s, acetoxy); i.r. (film): 1730 (ester CO), 1700 cm^{-1} (ketone CO).

Anal. Calcd. for $C_7H_{12}O_3S$: C, 47.70; H, 6.86. Found: C, 47.52; H, 6.76.

The aqueous sodium hydroxide extract from above was acidified with hydrochloric acid and extracted with benzene (2 × 250 ml). The organic extracts were combined, added to *p*-toluenesulfonic acid (5 g), and heated to reflux with azeotropic removal of the water formed in the

reaction. When no further water was liberated the reaction mixture was cooled and washed successively with 1 *N* sodium hydroxide (200 ml) and water (200 ml). The organic layer was concentrated *in vacuo* to a syrup which was distilled through a vigreux column to give 3-acetyl-5,6-dihydro-2-methyl-1,4-oxathiin (**7**) (43 g or 27%), a yellow liquid of b.p. 89–90° at 0.5 mm. N.m.r. ($CDCl_3$): 4.31 (2H, m, CH_2O), 2.96 (2H, m, CH_2S), 2.26, 2.23 (each 3H, s, CH_3); i.r. (film): 1670 (CO), 1635 cm^{-1} (C=C).

*Rearrangement of Ethyl 2-(2-hydroxyethylthio)acetoacetate (**11**) to form Ethyl (2-acetoxyethylthio)-acetate (**12**)*

A sample of ethyl 2-(2-hydroxyethylthio)acetoacetate was prepared by the method given in ref. 1*b* and was not isolated. Thus to ethyl 2-chloroacetoacetate (25) (15.0 g, 0.089 mol) and 2-mercaptoethanol (6.8 g, 0.089 mol) in a mixture of toluene (200 ml) and water (50 ml) was added sodium bicarbonate (7.5 g, 0.089 mol). The reaction mixture was stirred for 18 h, the phases were separated, and some toluene (100 ml) distilled from the toluene phase to remove any residual water. To the resulting toluene solution of ethyl 2-(2-hydroxyethylthio)acetoacetate was added 6 drops of a 10% solution of sodium ethoxide in absolute ethanol. The mixture was heated on a steam bath for 2 h and the toluene was then removed under reduced pressure. The residue was distilled to give ethyl (2-acetoxyethylthio)acetate (10.2 g or 56%), b.p. 96–100° at 0.4 mm. This material proved to be identical in every respect to a sample made by acetylation of ethyl (2-hydroxyethylthio)acetate (9). N.m.r. ($CDCl_3$): 4.24 (2H, t, J = 6.5 Hz, OCH_2CH_2), 4.19 (2H, quartet, J = 7.2 Hz, OCH_2CH_3), 3.28 (2H, s, SCH_2CO), 2.86 (2H, t, J = 6.5 Hz, SCH_2CH_2), 2.05 (3H, s, CH_3CO), 1.27 (3H, t, J = 7.2 Hz, CH_3CH_2); i.r. (film): 1635, 1225, 1025 cm^{-1}.

*Reaction of 3-Acetyl-5,6-dihydro-2-methyl-1,4-oxathiin (**7**) with Hydrazine to form 4-(2-Hydroxyethylthio)-3,5-dimethylpyrazole (**8**)*

To a stirred solution of 3-acetyl-5,6-dihydro-2-methyl-1,4-oxathiin (3.16 g, 0.02 mol) in isopropanol (5 ml), cooled in an ice-water bath, was added dropwise a solution of aqueous hydrazine hydrate (85%, 1.3 g, 0.022 mol) in isopropanol (5 ml). After standing 12 h the reaction mixture was filtered to yield 4-(2-hydroxyethylthio)-3,5-dimethylpyrazole (**8**) (2.5 g or 73%) of m.p. 162–163°. Recrystallization from isopropanol gave colorless prisms: m.p. 162–163°. N.m.r. (DMSO-d_6): 3.45 (2H, t, J = 7 Hz, CH_2O), 2.56 (2H, t, J = 7 Hz, CH_2S), 2.23 (6H, s, $2CH_3$); i.r. (KBr): 1565, 1040 cm^{-1}; u.v.: λ_{max} (MeOH) 235 nm (1520).

Anal. Calcd. for $C_7H_{12}N_2OS$: C, 48.80; H, 7.02; N, 16.26. Found: C, 48.64; H, 7.16; N, 15.86.

*N-(5,6-Dihydro-2-methyl-1,4-oxathiin-3-ylcarbonyl)-N'-phenylurea (**13**)*

To a mixture of sodium hydride (7.2 g, 0.3 mol) and *N*-phenylurea (41 g, 0.3 mol) in dry benzene (270 ml) and dimethylformamide (30 ml), which had been warmed and stirred for 1.5 h, was added dropwise over 25 min a solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride (**14**) (1*b*) in benzene prepared from the corresponding acid (50 g, 0.33 mol) and thionyl chloride. The reaction mixture was then stirred and heated under reflux for 1 h and finally let stand at room temperature overnight. It was washed with 5% aqueous sodium hydroxide, dried over sodium sulfate, and the solvent removed. The residual oil solidified and the solid was recrystallized three times from ethanol (charcoal) to give white crystals (10.4 g or 12%) of m.p. 120–123°. N.m.r. ($CDCl_3$): 10.57 (1H, s, NH, D_2O exchangeable), 8.84 (1H, s, NH, D_2O exchangeable), 7.3 (5H, m, aromatic), 4.35 (2H, m, CH_2O), 2.86 (2H, m, CH_2S), 2.25 (3H, s, CH_3).

Anal. Calcd. for $C_{13}H_{14}N_2O_3S$: C, 56.09; H, 5.07; N, 10.06. Found: C, 56.27; H, 5.24; N, 9.81.

*5-(2-Hydroxyethylthio)-6-methyl-1-phenyluracil (**15**)*

*(a) From Ethyl 5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxylate (**16**) and N-Phenylurea*

To a mixture of sodium hydride (8.4 g, 0.35 mol), *N*-phenylurea (40 g, 0.29 mol), and dry toluene (300 ml), which had been allowed to stand for 1 h, was added ethyl 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylate (49.8 g, 0.27 mol) (1*b*). The mixture was heated under reflux. In about 45 min the solids dissolved almost completely and then precipitation began. The reaction mixture was stirred and heated under reflux for 2 h and subsequently let stand overnight; it was then treated with excess 5% aqueous sodium hydroxide and filtered. The aqueous phase was separated and acidified with concentrated hydrochloric acid. The precipitate was filtered, washed with water, dried, and washed with hot acetone and ethanol yielding a white solid (40.7 g or 55%) of m.p. 237–243°. Further purification by reprecipitation from aqueous sodium hydroxide followed by recrystallization from acetic acid yielded a product melting at 247.5–249°. N.m.r. (DMSO-d_6): 11.53 (1H, s, NH, D_2O exchangeable), 7.44 (5H, s, aromatic), 4.68 (1H, t, OH, D_2O exchangeable), 3.43 (2H, t, CH_2O), 2.73 (2H, t, CH_2S), 2.10 (3H, s, CH_3); i.r. (KBr): 3440, 1484, 1050, 760, 700 cm^{-1}.

Anal. Calcd. for $C_{13}H_{14}N_2O_3S$: C, 56.09; H, 5.07; N, 10.06. Found: C, 56.55; H, 5.27; N, 10.40.

*(b) From N-(5,6-Dihydro-2-methyl-1,4-oxathiin-3-ylcarbonyl)-N'-phenylurea (**13**)*

To a solution of *N*-(5,6-dihydro-2-methyl-1,4-oxathiin-3-ylcarbonyl)-*N'* phenylurea (**13**) (6.0 g, 0.022 mol) in dry toluene (40 ml) was added sodium hydride (0.6 g, 0.026 mol). The mixture was heated under reflux for 3 h, cooled to room temperature, and extracted with 5% aqueous sodium hydroxide (40 ml). The aqueous phase was separated after filtration and acidified with concentrated hydrochloric acid. The precipitate was collected, washed with water, and dried to yield a white solid (3.5 g or 57%) of m.p. 241–246°. The identity of this product with that obtained by method (*a*) was established by comparison of i.r. spectra and by m.m.p. determination.

5-(2-Hydroxyethylthio)-3,6-dimethyl-1-phenyluracil

5-(2-Hydroxyethylthio)-6-methyl-1-phenyluracil (**15**) was methylated in aqueous sodium hydroxide with dimethyl sulfate in the usual manner (11). The yield of the product after crystallization from toluene and from acetone – petroleum ether was 76%, m.p. 136–137.5°. N.m.r. ($CDCl_3$): 7.3 (5H, m, aromatic), 3.68 (3H, t, CH_2O + OH), 3.40 (3H, s, CH_3), 2.84 (2H, t, CH_2S), 2.28 (3H, s, CH_3).

Anal. Calcd. for $C_{14}H_{16}N_2O_3S$: C, 57.51; H, 5.51; N, 9.58. Found: C, 57.80; H, 5.76; N, 9.52.

5-(2-Chloroethylthio)-6-methyl-1-phenyluracil

To a stirred solution of 5-(2-hydroxyethylthio)-6-methyl-1-phenyluracil (**15**) (20 g, 0.068 mol) in chloroform (500 ml) was added over 40 min a solution of thionyl chloride (10 ml) in chloroform (50 ml). The reaction mixture was heated under reflux for 2 h, let stand overnight at room temperature, and filtered. The solvent and excess thionyl chloride were removed from the filtrate and the residue recrystallized from acetone and ethanol to yield a white solid (17.0 g or 84%) of m.p. 205–206.5°. N.m.r. (DMSO-d_6): 11.53 (1H, s, NH), 7.39 (5H, s, aromatic), 3.72 (2H, t, CH_2Cl) 2.99 (2H, t, CH_2S), 2.10 (3H, s, CH_3); i.r. (KBr): OH bands absent.

Anal. Calcd. for $C_{13}H_{13}ClN_2O_2S$: C, 52.60; H, 4.41; N, 9.44. Found: C, 52.99; H, 4.47; N, 9.03.

1-(5-Chloro-2-methylphenyl)-5-(2-hydroxyethylthio)-6-methyluracil

This was prepared from ethyl 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylate (**16**) and *N*-(5-chloro-2-methylphenyl)urea as above. The product melted at 242–244° and the yield was 31%. N.m.r. (DMSO-d_6): 11.6 (1H, s, NH), 7.40 (3H, m, aromatic), 4.65 (1H, s, OH), 3.52 (3H, t, CH_2O), 2.77 (2H, t, CH_2S), 2.11, 2.07 (each 3H, s, CH_3).

*5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxylic Acid Hydrazide (**17**)*

A suspension of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid (32 g, 0.2 mol) in thionyl chloride (20 ml, 0.28 mol) and benzene (200 ml) was heated at 70° until the solid dissolved. The reaction mixture was concentrated *in vacuo* to a syrup which was dissolved in chloroform (50 ml) and added dropwise to a stirred solution of hydrazine hydrate (85%, 100 ml) in chloroform (200 ml) cooled in an ice bath. After addition of the acid chloride was completed, the reaction mixture was kept at room temperature for 12 h before the chloroform layer was separated and extracted with cold 2.5 *N* hydrochloric acid (600 ml). The acidic aqueous extract was added to sodium bicarbonate (150 g) to give a weakly basic solution which was extracted with chloroform (2 × 200 ml). The chloroform extracts were combined and concentrated *in vacuo* to a syrup which was crystallized from ethanol to give the hydrazide (15.9 g or 46%) as colorless needles of m.p. 129.5–130.5°. N.m.r. (DMSO-d_6): 5.1 (3H, broad, NH), 4.2 (2H, m, CH_2O), 2.96 (2H, m, CH_2S), 1.97 (3H, s, CH_3); i.r. (KBr): 1650 cm^{-1} (CO).

Anal. Calcd. for $C_6H_{10}N_2O_2S$: C, 41.36; H, 5.79; N, 16.08. Found: C, 41.38; H, 5.80; N, 16.18.

*Rearrangement of 5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxylic Acid Hydrazide (**17**) to 4-(2-Hydroxyethylthio)-3-methyl-2-pyrazolin-5-one (**18**)*

A solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid hydrazide (3.48 g, 0.02 mol) in *n*-butanol (20 ml) was heated under reflux for 24 h. The crystals, which formed on cooling, were filtered and washed with isopropanol to yield 4-(2-hydroxyethylthio)-3-methyl-2-pyrazolin-5-one (**18**) (2.85 g or 82%) of m.p. 187–189°. Recrystallization from ethanol gave colorless needles: m.p. 188–190°. N.m.r. (DMSO-d_6): 8.5 (3H, broad, NH + OH), 3.48 (2H, t, J = 7 Hz, CH_2O), 2.55 (2H, t, J = 7 Hz, CH_2S), 2.18 (3H, s, CH_3); i.r. (KBr): 2900–2600 cm^{-1} (zwitterion), 3420, 1030 cm^{-1} (primary OH); u.v.: λ_{max} (MeOH) 242 nm (2650).

Anal. Calcd. for $C_6H_{10}N_2O_2S$: C, 41.36; H, 5.79; N, 16.08. Found: C, 41.54; H, 5.84; N, 16.12.

*5,6-Dihydro-2-methyl-N-(2-pyridyl)-1,4-oxathiin-3-carboxamide (**20**) and 4H-3-(2-Hydroxyethylthio)-2-methylpyrido[1,2-a]pyrimidin-4-one (**21a**)*

A solution of 5,6-dihydro-2-methyl-1,4-oxathiin-3-carbonyl chloride (**14**) (1*b*) in benzene (prepared from the corresponding acid (16 g, 0.125 mol) in benzene (250 ml) and thionyl chloride (18 g, 0.152 mol)) was added dropwise over 2 h to a stirred mixture of 2-aminopyridine (9.4 g, 0.1 mol), triethylamine (10.2 g), and benzene (300 ml). The reaction mixture was kept at 4–5° during the addition and then left to stand at room temperature overnight. The precipitate (mainly $Et_3N.HCl$) was collected and washed thoroughly with hot benzene. The solvent was removed from the filtrate under reduced pressure and the residue placed in a funnel, pressed, and washed with a little cold acetonitrile. Two crystallizations from acetonitrile afforded compound **21***a* (12.2 g or 56%) of m.p. 109–111.5°. N.m.r. ($CDCl_3$): 8.93 (1H, d, aromatic), 7.95–7.00 (3H, complex, aromatic), 4.15 (1H, s, OH), 3.67 (2H, t, J = 6 Hz, CH_2O), 2.98 (2H, t, J = 6 Hz, CH_2S), 2.72 (3H, s, CH_3); i.r. (KBr): 3270, 1670, 1625 cm^{-1}; u.v.: λ_{max} (EtOH) 248 (11 500), 352 nm (14 300).

Anal. Calcd. for $C_{11}H_{12}N_2O_2S$: C, 55.93; H, 5.12; N, 11.86. Found: C, 55.98; H, 5.12; N, 11.80.

The hydrobromide of **21***a* was prepared by addition of 60% HBr to a solution of the base in acetone. Recrystallization from acetonitrile containing a little water gave crystals of m.p. 235–236° (dec.).

Anal. Calcd. for $C_{11}H_{13}BrN_2O_2S$: C, 41.65; H, 4.13; N, 8.83. Found: C, 41.39; H, 4.22; N, 8.87.

The combined acetonitrile washings and mother liquors from the purification of **21***a* were evaporated under reduced pressure and the residue dissolved in chloroform. The chloroform solution was washed with aqueous sodium bicarbonate and warm water and then dried over sodium sulfate. A small amount of **21***a* (0.4 g, m.p. 110–112°) was obtained from the aqueous washings. The solid material isolated from the chloroform solution was recrystallized from 95% ethanol to give the amide **20** (0.9 g or 4%) of m.p. 108.5–110°. N.m.r. ($CDCl_3$): 8.76 (1H, s, NH), 8.34–6.85 (4H, complex, aromatic), 4.36 (2H, m, CH_2O), 2.93 (2H, m, CH_2S), 2.25 (3H, s, CH_3); i.r. (KBr): 3160, 1670, 1655, 1600 cm^{-1}.

Anal. Calcd. for $C_{11}H_{12}N_2O_2S$: C, 55.93; H, 5.12; N, 11.86. Found: C, 55.73; H, 5.11; N, 11.93.

From the ethanolic mother liquors an additional amount of compound **21***a* was obtained (0.6 g, m.p. 109–111°).

*Stability of Compound **20** under the Reaction Conditions*

A solution of 0.83 g of the amide **20** in benzene (40 ml) containing triethylamine (0.5 g) was kept for 3 h at 5° and an additional 3 h at room temperature. The solvent and triethylamine were removed under reduced pressure. The residue, 0.80 g, melted at 106–109°; it was identified as **20** by i.r., n.m.r., and m.m.p.

Compounds ***24a***, ***24b***, ***25a***, ***25b***, and ***27***

The following procedure was used for the preparation of these compounds. To a stirred slurry or solution of the aminopyridine or 2-amino-4,6-dimethylpyrimidine (0.10 mol) in benzene (300 ml) containing triethylamine (10.2 g) was added dropwise over 1.5 h a solution of the acid chloride **14** (0.12 mol) in benzene (100 ml). The reaction mixture was kept at about 5° during the addition and then left to stand at room temperature overnight. The reaction mixture was filtered and the precipitate washed with benzene. The benzene was removed from the filtrate under reduced pressure and the residue purified by crystallization.

*4H-3-(2-Hydroxyethylthio-2,9-dimethylpyrido[1,2-a]-pyrimidin-4-one (**24a**)*

Yield: 10.2 g or 41%; m.p. 92–92.5° (Me_2CHOH); n.m.r. ($CDCl_3$): 8.88 (1H, d, aromatic), 7.80–6.95 (2H, complex, aromatic), 4.32 (1H, t, J = 7 Hz, OH), 3.88–3.45 (2H, m, CH_2O), 2.97 (2H, t, CH_2S), 2.74, 2.56 (each 3H, s, CH_3); i.r. (KBr): 3410, 1653, 1620 cm^{-1}.

*4H-3-(2-Hydroxyethylthio)-2,7-dimethylpyrido[1,2-a]-pyrimidin-4-one (**24c**)*

To a stirred mixture of 2-amino-5-methylpyridine (10.8 g, 0.1 mol), triethylamine (10.5 g), and benzene (300 ml) was added dropwise over 2 h a solution of the acid chloride **14** (0.125 mol) in benzene (100 ml.). The reaction mixture was kept at 3–7° during the addition and then left to stand at room temperature overnight. The cooled reaction mixture was filtered and the precipitate treated with cold water (100 ml). The insoluble material was collected and dried in an oven under reduced pressure. Crystallization from ethanol–water (10:1) afforded crystals (8.8 g or 35%) of m.p. 122–123°. The benzene filtrate yielded an additional amount of product (1.5 g, m.p. 118–121°). N.m.r. ($CDCl_3$): 8.82 (1H, s, aromatic), 7.80–7.30 (2H, complex, aromatic), 3.65 (2H, t, CH_2O), 2.96 (2H, t, CH_2S), 2.73, 2.45 (each 3H, s, CH_3); i.r. (KBr): 3395, 1653, 1625 cm^{-1}.

Anal. Calcd. for $C_{12}H_{14}N_2O_2S$: C, 57.59; H, 5.64; N, 11.20. Found: C, 57.90; H, 5.40; N, 11.22.

The hydrobromide of **24***c* (prepared as that of **21***a*) was recrystallized from ethanol to give material of m.p. 239° (dec.).

Anal. Calcd. for $C_{12}H_{15}BrN_2O_2S$: C, 43.52; H, 4.56; N, 8.45. Found: C, 43.55; H, 4.54; N, 8.46.

The *O*-acetyl derivative of compound **24***c* (prepared as that of **24***a*) melts at 119–120° (petroleum ether).

Anal. Calcd. for $C_{14}H_{16}N_2O_3S$: C, 57.53; H, 5.52; N, 9.59. Found: C, 57.60; H, 5.61; N, 9.54.

*4H-3-(2-Hydroxyethylthio)-2-methylpyrimido[1,2-a]-pyrimidin-4-one (**26**)*

To a stirred mixture of 2-aminopyrimidine (9.5 g, 0.1 mol), triethylamine (10.2 g), and benzene (300 ml) was added dropwise over 1 h a solution of the acid chloride **14** (0.125 mol) in benzene (100 ml). The reaction mixture was kept at 3–5° during the first 2 h of the reaction and then left to stand at room temperature overnight. The precipitate was collected by filtration and washed with a little cold benzene. Then it was dissolved in water and the resulting solution basified with ammonia and extracted with chloroform. The extract was dried over sodium sulfate and the chloroform and triethylamine removed under reduced pressure. The crystalline residue (7.4 g) melted at 138–145°. Recrystallization from acetonitrile furnished crystals (5 g or 21%) of m.p. 150–152°. The

benzene filtrate and washings yielded an additional small amount of product (0.5 g, m.p. 147–150°). N.m.r. ($CDCl_3$): 9.37–8.99 (2H, complex, aromatic), 7.34–7.10 (1H, m, aromatic), 3.85–3.40 (3H, complex, CH_2O + OH); on addition of D_2O this absorption is replaced by a triplet, 2H, $J = 6$ Hz, CH_2O), 3.01 (2H, t, $J = 6$ Hz, CH_2S), 2.72 (3H, s, CH_3); i.r. (KBr): 3380, 1652, 1613 cm^{-1}.

Anal. Calcd. for $C_{10}H_{11}N_3O_2S$: C, 50.63; H, 4.67; N, 17.72. Found: C, 50.49; H, 4.63; N, 17.70.

The *O*-acetyl derivative of compound **26** (prepared as that of **24***a*) melts at 134–134.5° (petroleum ether – acetone).

Anal. Calcd. for $C_{12}H_{13}N_3O_3S$: C, 51.61; H, 4.69; N, 15.05. Found: C, 51.70; H, 4.72; N, 14.89.

Investigation of Factors Affecting Conformational Preference in Complex Haloethane Derivatives by Classical Energy Calculations[1]

WILLIAM F. REYNOLDS AND DONALD J. WOOD

Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received January 15, 1973

Classical energy calculations are used in combination with Abraham's electrostatic theory of solvation energy to estimate rotamer energy differences for haloethane derivatives. The calculations are tested by comparing experimental and calculated ΔE values for several di- and tetrahaloethanes. There is good agreement for chloro and bromo derivatives but poorer agreement for fluoro and iodo derivatives. ΔE values in solution are also estimated for 14 complex chloro- and bromoethanes which we have previously investigated by n.m.r. spectroscopy. The calculations generally parallel the experimental results as reflected by vicinal coupling constants. They are particularly useful for trends in conformational preference for closely related compounds and are used in conjunction with vicinal coupling constants to identify diastereomers produced by halogenation of alkenes. Steric interactions, dipole–dipole interactions and solvation energy are all important in determining conformational preference for complex haloethanes in solution.

Les calculs classiques d'énergie ont été utilisés combinés à la théorie électrostatique d'Abraham pour l'énergie des rotamères dans les dérivés d'haloéthane. Les calculs ont été testés en comparant les valeurs de ΔE expérimentale et théorique pour plusieurs di et tetrahaloéthanes. Pour les dérivés chloro et bromo, l'accord est bon mais faible dans le cas des dérivés fluoro et iodo. Les valeurs de ΔE en solution ont été aussi calculées pour quatorze chloro et bromoéthanes complexes que nous avons étudiés précédemment par spectroscopie r.m.n. Les calculs suivent généralement les résultats expérimentaux qui se reflètent dans les constantes de couplage vicinal. Les calculs ont été particulièrement utiles pour prévoir les tendances dans les conformations préférentielles des composés en étroite relation et ont été employés avec les constantes de couplage vicinal pour identifier les diastéréoisomères issus de l'halogénation des alcènes. Les interactions stériques, les interactions dipole–dipole et l'énergie de solvatation sont toutes importantes pour déterminer la conformation privilégiée des haloéthanes complexes en solution.

Introduction

While experimental energy differences have been determined for a large number of simple ethane derivatives (1), there is little information available for complex ethane derivatives (*i.e.* ethane derivatives with three non-equivalent rotational isomers (rotamers)). We have been interested in determining conformational preference of complex ethanes in solution by n.m.r. spectroscopy (2–5). By monitoring changes in vicinal coupling constants with solvent, it was possible to deduce orders of rotamer energy levels for a number of complex ethane derivatives (2, 4, 5), but no quantitative energy differences could be obtained.

Classical energy calculations have proved useful for determining conformational energy differences (6), even for macromolecules (7). This approach allows discussion of conformational preference in terms of non-bonded (steric) interactions, dipole–dipole interactions, etc. These calculations often do not include solvation effects. However, Abraham and co-workers have developed an electrostatic model for solvation effects (8) which has provided quantitative estimates of solvation energies for a number of simple polar ethane derivatives (9). Consequently, we decided to combine classical energy calculations with Abraham's electrostatic calculations in an attempt to obtain at least semi-quantitative estimates of energy differences for complex substituted ethanes as well as to determine factors affecting conformational preference in these derivatives. One additional possible application which we hoped to check was the use of these calculations for the identification of diastereomers produced by halogenation of alkenes.

Details of Calculations

Classical energy calculations can be performed with varying degrees of sophistication. We decided to keep our calculations as simple as possible

in the hope that reasonable energy levels could be estimated for a minimal expenditure of computer time.

While many classical energy calculations involve energy minimization techniques in which bond energies and bond lengths are varied to find the most stable geometry (6), this is a complex and time consuming procedure. Consequently, it was decided to use fixed bond angles and bond lengths to simplify the calculations. During the course of this investigation, Abraham and Parry reported results of similar calculations for simple substituted ethanes using fixed bond angles and bond lengths (10). However, they used different potential functions for non-bonded and dipolar interactions and restricted their calculations to the gas phase.

Bond lengths used in this investigation are given in Table 1. C—C—H and C—C—F angles in the ethyl group were taken as 109.5°. For other groups bonded to ethane (X = Cl, Br, I, CH_3, C_6H_5), X—C—C and X—C—X angles were fixed at 110.5° for di-substituted ethanes, 111.0° for tri-substituted ethanes, and 111.5° for tetra-substituted ethanes. A regular hexagonal geometry was assumed for the phenyl group.

The total energy, E_n, for rotamer **n** of a substituted ethane is assumed to be

$$[1] \quad E_n = E_{TOR} + E_{DIP} + E_{NB} + E_{SOLV}$$

where E_{TOR} represents the torsional barrier for rotation about a C—C bond, E_{DIP} represents the interaction between polar groups, E_{NB} represents steric or non-bonded interaction energies and E_{SOLV} represents the solvation energy. With this formulism, only energy differences between rotamers are significant.

The torsional contribution is given by

$$[2] \quad E_{TOR} = 0.5\ U_0(1 + \cos \beta\phi)$$

where U_0 is the barrier height for rotation about the unsubstituted carbon–carbon bond (the

For personal use only.

torsional term is assumed to be unaffected by substituents (11, 12), ϕ is the dihedral angle, and β defines the symmetry of the barrier. Values for these parameters are given in Table 1.

The effect of interactions between polar bonds was estimated by treating polar bonds as point dipoles acting at the center of the polar bond. This interaction is given by (13)

$$[3] \quad E_{DIP} = \sum^{i \neq j} \frac{1}{A} \frac{1}{|\boldsymbol{R}|^3} \times \left(\boldsymbol{U}_i \cdot \boldsymbol{U}_j - \frac{3(\boldsymbol{U}_i \cdot \boldsymbol{R})(\boldsymbol{U}_j \cdot \boldsymbol{R})}{|\boldsymbol{R}|^2} \right)$$

where $\boldsymbol{U}_i$ and $\boldsymbol{U}_j$ are the dipole moment vectors of the dipolar bonds i and j, $\boldsymbol{R}$ is the distance vector joining the two point dipoles, and A is the internal dielectric constant. Bishop and Craig estimated that $A = 1.5$ for a carbon framework, based upon the bond refraction of a C—C bond (14). Consequently this value was used. For reasons discussed in part *a* of the Discussion, calculations were normally performed using bond dipole moments (Table 1) although calculations for simple haloethanes were also carried out using group dipole moments (15).

The most commonly used non-bonded interaction potential functions are the exponential ("6-exp") and the Lennard-Jones ("6-12") functions (6). Scott and Scheraga recommended the use of the latter function since it contains only two adjustable parameters as opposed to three for the "6-exp" energies and because the "6-exp" function incorrectly predicts interaction energies at small internuclear separations (16). In addition, a variety of different parameters have been suggested for the "6-exp" functions (10). Consequently, we chose the "6-12" function to minimize parameterization.

With this function, for n non-bonded interactions,

$$[4] \quad E_{NB} = \sum_n^{i<j} [d_{ij}/r_{ij}^{12} - e_{ij}/r_{ij}^{6}]$$

where

$$[5] \quad e_{ij} = \frac{362.45\alpha_i\alpha_j}{(\alpha_i/N_i)^{1/2} + (\alpha_j/N_j)^{1/2}}, \quad d_{ij} = (e_{ij}r_{min}^{6})/2$$

and where r_{ij} is the separation between atoms i and j, α is the atomic polarizability, N is the "effective number of valence electrons" and r_{min} is the sum of the van der Waals' radii for i and j (16). Parameters used in the calculation are given in Table 1. The only parameter worthy of comment is α for phenyl carbons where α was increased by 0.29, corresponding to one-half the contribution from a C=C bond (17).

Solvation energy was calculated according to Abraham's electrostatic theory, using eq. 13 of ref. 8*a*. This divides the solvation energy into dipolar, E_{DISOL}, and quadrupolar, E_{QSOL}, reaction field terms (no corrections were made for solvent–solute dipole–dipole interactions (8*c*)). The quadrupolar term was calculated using the mid-point of the ethyl C—C bond as the origin to simplify the calculation. This may introduce a small error, since the calculation really should be carried using the geometric center of the molecule as the origin (8*b*).

The solute radius (assuming a spherical solute molecule) and the solute refractive index must be known for the solvation calculations. The solute radius, a, can be calculated from the molar volume $\overline{V}$:

$$[6] \quad \overline{V} = \text{M.W.}/d = 4/3(\pi a^3 N)$$

In cases where the density, d, was not known, $\overline{V}$ was estimated by assuming additivity of molar volumes, *e.g.*

$$\overline{V}_{C_6H_5CHClCH_2Cl} - \overline{V}_{C_6H_5CH_2CH_2Cl} = \overline{V}_{CH_2ClCH_2Cl} - \overline{V}_{CH_3CH_2Cl}$$

Unknown refractive indices were estimated from molar refractivities (18). A full listing of these parameters is available elsewhere (19).

A computer program, CONCAL, was written to carry out the calculation of the terms from eq. 1. The program as written can handle up to 30 atoms, 10 dipolar bonds, and one or two bond rotations. Calculation of non-bonded interactions between atoms whose relative positions are unchanged by rotation are suppressed to minimize the number of calculations. The program prints out all energy terms from eq. 1 and total energy for each conformation generated by incremental changes (usually 2°) of bond rotation angles. Thus, for example, in 1-phenyl-1,2-dibromoethane, calculations were performed for rotation about both the C_α—C_β bond and the C_α—C_6H_5 bond. In all compounds, energy minima corresponded (within 10°) to staggered conformations about the C_α—C_β bond. The phenyl groups were invariably calculated to have a conformation which minimized non-bonded

interactions with other groups. A full listing of the program is available elsewhere (19).

Experimental

Most experimental results have been previously reported (2–5). Spectra for 1,2-dichloro-1-phenylethane and *erythro*- and *threo*-1,2-dichloro-1-phenylpropane were obtained and analyzed using previously reported procedures (2). Dielectric constants, ε, used in the calculations corresponded to those measured experimentally for the solutions for which n.m.r. spectra were recorded. They were measured at 30 °C using a WTW DKO3 Dekameter.

Results and Discussion

The discussion is divided into four parts: (*a*) testing of the applicability of Abraham's theory of solvation energy to complex substituted ethanes, (*b*) testing of our particular model for classical energy calculations by comparing calculated and experimental energy differences for simple haloethanes, (*c*) discussion of CONCAL results for complex substituted ethanes, and (*d*) experimental confirmation of the tentative assignments of diastereomers provided by CONCAL plus vicinal coupling constants.

For all compounds, it is assumed that volume differences, ΔV, and entropy differences, ΔS, between rotamers are zero, *i.e.* it is assumed that $\Delta E = \Delta G$.

(a) Applicability of the Electrostatic Model of Solvation Energy to Complex Substituted Ethanes

Abraham's electrostatic theory of solvation energy (8) provides at least qualitative predictions of the change in rotamer energy with solvent for several complex haloethanes (2, 3, 5), although it breaks down for 1-phenyl-1,2,2-trihaloethanes (3). In an attempt to determine whether the theory gave quantitative answers for other complex ethane derivatives, solvation energy calculations were performed for three compounds for which experimental energy differences were either available or could be estimated; 1-bromo-2-phenylethane, 1,2-dibromo-1-phenylethane and 1,2-dibromo-3,3-dimethylbutane. Results are given in Table 2.

No experimental gas phase energy values are available to allow comparison of calculated and experimental changes in ΔE on going from the gas phase to various solvents. Consequently calculated and experimental energy differences in CCl_4 were assumed equal and calculated values in other solvents were expressed relative to this value. Experimental results for 1-bromo-2-phenyl ethane are those of Lin (20) while ΔE values for other compounds were estimated using the approach suggested by Snyder (21).

[a]Symbols are defined in text following eq. 1.
[b]Energy difference between *gauche*- and *anti*-rotamer (the *anti* rotamer for 1,1,2,2-tetrahaloethanes is defined as the rotamer in which each halogen atom is *anti* to another halogen. ΔE in kcal/mol.
[c]Dihedral angle of *gauche*-rotamer.
[d]Values in brackets calculated using group dipole moments.

This allows one to estimate ΔE values from vicinal coupling constants for compounds in which one of the rotamers has a negligible population (both compounds fulfil this requirement (2, 5)).

As can be seen in Table 2, there is very good agreement between experimental and calculated changes in ΔE, indicating that Abraham's theory can be applied to these compounds. The results for the two dibromo compounds are particularly informative. The calculations indicate a smaller change in ΔE for 1-phenyl-1,2-dibromoethane than for 1,2-dibromo-3,3-dimethylbutane, as observed experimentally. This arises from differences in both dipolar and quadrupolar solvation terms (Table 2). These differences are due to the polarity of the C_α—C_6H_5 bond (the C_α–*t*-butyl bond in the dibromoalkane is assumed to have $\mu = 0$). This also accounts for the solvent dependence of ΔE for 1-phenyl-2-bromoethane and points out the necessity of considering all neighboring polar bonds (*i.e.* using bond moments) in solvation energy calculations for complex substituted ethanes.

(b) Symmetrically Substituted Dihalo- and Tetrahaloethanes

Calculations were performed for these compounds, for which energy differences are available, to check the accuracy of the classical energy calculations. Abraham has pointed out that experimental solution energy differences generally have not been corrected for the variation of ΔE with temperature and really correspond to ΔE at 0 °K (8*a*). Consequently, experimental values have been corrected to 30 °C, using eq. 18 of ref. 8*a*. Results are given in Table 3.

There is generally satisfactory agreement between experimental and calculated results for the chloro and bromo derivatives. This is important since all of the complex ethanes which we have investigated are chloro and/or bromo derivatives. The calculations indicate that nonbonded (steric) interactions, dipolar interactions

and, in solution, solvation energy are all important in determining conformational stability. Results are similar for calculations using group and bond dipole moments.

The results for 1,1,2,2-tetrachloroethane in the gas phase are particularly interesting. The experimental ΔE value of zero is surprising since one might have expected both dipolar and non-bonded interactions to be greater in the *gauche* forms. However the calculations suggest a larger non-bonded interaction in the *anti* form, leading to the small ΔE value. This probably occurs because the "6-12" potential goes through a minimum at the sum of the van der Waals' radii. With the larger X—C—X and X—C—C angles, the separation of *gauche* chlorine atoms falls close to this distance, making *gauche* chlorines more stable than *anti* chlorines where the separation is larger.

The calculations overestimate the stability of the *anti* rotamer for 1,2-difluoroethane. Abraham and Parry noted even larger discrepancies for this compound (10), suggesting that both the "6-12" and "6-exp" potentials may be too hard. However, since in both this investigation and that of Abraham and Parry (10), better results were obtained for more highly substituted fluoro derivatives, this may not be the whole answer. Csizmadia and co-workers obtained better agreement for 1,2-difluoroethane using quantum mechanical calculations (22). Agreement for 1,2-diiodoethane is better using the "6-exp" potential (10), than the "6-12" potential. The latter potential may be too soft for iodine.

Tri-substituted ethanes and unsymmetrically di- and tetra-substituted ethanes show similar agreement between calculated and experimental results (19).

In summary, agreement between calculated and experimental results is generally satisfactory, with best results for bromo and chloro derivatives. Interestingly, the calculations show the same strengths and weaknesses of those of Abraham and Parry (10), even though entirely different steric and dipolar potentials were used.

(c) Complex Substituted Ethanes

There are no experimental ΔE values for the complex substituted ethanes which we have investigated. Consequently, calculated ΔE values are compared with vicinal coupling constants and, where possible, with the order of energy levels deduced from the variation of these coupling constants with solvent and temperature (2, 3). Results for complex substituted ethanes are given in Tables 4–6.

(i) 1,2-Dihalo-1-phenylethanes

The calculated energy levels for the 1,2-dibromo derivative (Table 4) are identical to those deduced experimentally (2, 21) and the changes in population with solvent parallel to the changes in coupling constants (assuming that an *anti* coupling constant is greater than a *gauche* coupling constant). Furthermore, the calculations suggest that n_3 is negligibly small, as deduced experimentally (2). Snyder's approximate method (21) (see above) gives $\Delta E_{2-1} = +0.73$ kcal/mol in CCl_4 while CONCAL gives $+0.70$ kcal/mol.

ethane indicate a smaller population of rotamer **1** than for the dibromo derivative and a significant population for **3** which increases with ε. The smaller value of $\langle J_{AB}\rangle$ is consistent with the smaller value of n_1 while the decrease in $\langle J_{AB}\rangle$ + $\langle J_{BC}\rangle$ with increasing ε is consistent with the calculated non-zero value of n_3 (since both coupling constants are *gauche* in **3**). Snyder's method cannot be applied since $n_3 \neq 0$.

As previously suggested (2), the preference

For personal use only.

for rotamer **1** in the 1,2-dihalo-1-phenylethanes is due to both steric and dipolar interactions. For example, for 1,2-dibromo-1-phenylethane in CCl_4, **1** is calculated to be more stable than **2** by 0.42 kcal/mol due to steric interactions and 0.28 kcal/mol due to dipolar interactions. The importance of dipolar interactions is consistent with our observation that even remote substituents can alter conformational preference due to dipolar interactions (4).

(ii) erythro and threo 1,2-Dihalo-1-phenylpropanes

Calculations for these compounds were carried out for only one solvent ($CDCl_3$) since they involve minimization of energy with respect to three independent rotations and take considerable computer time. $CDCl_3$ was chosen since the energy level for the *threo* derivative had been estimated in this solvent (2).

The calculated populations for these compounds are generally consistent with available evidence concerning conformational preference (2) although there are two minor discrepancies. From the temperature-independence of $\langle J_{AB} \rangle$ for the *threo* dibromo derivative in $CDCl_3$ and from the intermediate value of $\langle J_{AB} \rangle$, the energy order $E_5 < E_4 < E_6$ was deduced (2). However, these observations are also consistent with rotamers **4** and **5** of equal energy and **6** much less stable, as calculated. In the case of the *threo* derivatives, the larger value of $\langle J_{AB} \rangle$ for the dichloro compound is apparently inconsistent with the calculated values for n_4. While this could, in part, reflect electronegativity differences (29), it is probably due to inadequacies in the calculations. In this case, a difference of only 0.2 kcal for ΔE_{5-4} has a profound effect on calculated populations, since ΔE_{5-4} is very small.

The most important observation is that the calculations correctly predict the relative order of n_4 values for each *erythro–threo* pair (assuming that the magnitude of $\langle J_{AB} \rangle$ is approximately proportional to n_4). This suggests the possibility that the calculations could be used in conjunction with vicinal coupling constants to identify *erythro* and *threo* isomers produced by halogenation of alkenes. The identification of diastereomers from these reactions is important in view of the interest in mechanisms of halogen addition to alkenes (23, 24). There appears to be no general method for identifying diastereomers and previous attempts to use n.m.r. spectroscopy for this purpose have led to contradictory conclusions (25–28).

(iii) 1-Phenyl-1,2,2-trihaloethanes

These compounds were produced by halogenation of the appropriate β-halostyrenes (3). Since diastereomers were produced simultaneously and were extremely similar in physical properties (3), this seemed like a particularly rigorous test of the usefulness of classical energy calculations to identify isomer pairs. Results are given in Table 5.

There is a substantial difference in n_4 values for each pair of diastereomers. Fortunately, there is a correspondingly large difference in $\langle J_{AB} \rangle$ values for these compounds, making the assignment of diastereomers straightforward. In fact, for all of the 1-phenyl-1,2,2-trihaloethanes except for the two *threo* derivatives, calculated n_4 values parallel experimental $\langle J_{AB} \rangle$ values.

In view of the electronic similarities for these six compounds as well as for the 1,1,2-trihalopropanes (assuming phenyl and methyl groups both have small electronic effects), it was decided to attempt to estimate a self-consistent set of coupling constants for these derivatives:

$$[7] \qquad \langle J_{AB} \rangle = n_4 J_4 + n_5 J_5 + n_6 J_6$$

Experimental $\langle J_{AB} \rangle$ values and calculated n_4, n_5, and n_6 values for 1-phenyl-1,2,2-trihaloethanes in CCl_4[2] and 1,1,2-trihalopropanes in CCl_4 and $(CH_3)_2S{=}O$ were used to solve for J_4, J_5, and J_6, using the least-squares criterion. Best values were $J_4 = 9.3$, $J_5 = 1.8$, and $J_6 = 2.6$ Hz. The latter two values are reasonable for *gauche* coupling constants. While 9.3 Hz is smaller than many *anti* coupling constants, it is not unreasonably small. Extrapolation of variable temperature results for $\langle J_{AB} \rangle$ for 1-phenyl-1,2,2-tribromoethane to low temperatures gave a value of 9.7 Hz for the *anti* coupling constant (19), in good agreement with the above value.

There is good agreement between all experi-

[2]Results for other solvents were not used since these compounds apparently do not obey Abraham's solvation theory in polar solvents (3). No calculations were performed for the 1,2-dihalo-1-phenylethanes since in this system there are six coupling constants for the three rotamers. Consequently, a very large number of measurements would be necessary for an adequate least squares fit. Similarly, coupling constants were not estimated for 1,2-dihalo-1-phenylpropanes since there were only four data points to estimate three coupling constants.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

mental and calculated coupling constants for 1-phenyl-1,2,2-trihaloethanes except for the *threo* 1-chloro-1,2-dibromo derivative (with respective r.m.s. errors of 0.34 and 0.13 Hz with and without this derivative). The calculations appear to overestimate n_4 for the latter compound in CCl_4. This presumably accounts for the reversal of the *threo* derivatives in the comparison of n_4 and $\langle J_{AB} \rangle$. The agreement between calculated and experimental coupling constants was always significantly worse if J_4, J_5, and J_6 values were estimated with one or both assignments of *erythro–threo* pairs reversed (19). While this does not prove the assignments, it certainly supports them. Experimental evidence in support of the assignments is given in part *d*.

The calculations suggest that the differences in conformational preference for isomer pairs are primarily due to differences in steric interactions. For example, for the 2-bromo-1,2-dichloro derivatives the steric and dipolar energy values for **5** relative to **4** are respectively 0.02 and 0.25 kcal/mol for the *erythro* derivative and 0.53 and 0.23 kcal/mol for the *threo* derivative. This illustrates the sensitivity of the calculations since these differences in steric interactions are not apparent from an inspection of the rotamers (Table 5).

(iv) 1,1,2-Trihalopropanes

If one counts the total number of *gauche* steric interactions (involving Cl, Br, and CH_3 groups) and strong *gauche* dipolar interactions (Cl and Br), the predicted energy level order is: **4** (two steric, one dipolar interaction) $<$**5** (three steric, one dipolar interaction), $<$**6** (three steric, two dipolar interactions). This simplistic approach, which worked for several phenylethane and alkane derivatives (2, 5), obviously breaks down for this system since the small $\langle J_{AB} \rangle$ values (Table 6) strongly suggest small values for n_4.

The CONCAL calculations are clearly superior to first-order predictions of the type outlined above since CONCAL predicts that **4** is the least stable rotamer for both compounds in all solvents (Table 6). Furthermore, there is excellent agreement (r.m.s. error = 0.14 Hz) between experimental and calculated coupling constants, using the same values for J_4, J_5, and J_6 as given in *iii*.

The reason for the relative instability of **4** becomes apparent from a consideration of the individual energy terms. For example, for 1,1,2-trichloropropane, the difference in steric interactions, ΔE_{5-4} and ΔE_{6-4}, are respectively -0.44 and -0.40 kcal/mol. These are almost identical to the previously discussed (see part *b*) difference in steric interactions between *gauche* and *anti* rotamers of 1,1,2,2-tetrachloroethane (-0.47 kcal/mol). In addition, there is a slightly more favorable dipolar interaction for **5** ($\Delta E_{5-4} = -0.12$ kcal/mol). This arises from stabilizing interactions between proximate $\overset{\delta+}{C}—\overset{\delta-}{Cl}$ and $\overset{\delta\delta-}{C}—\overset{\delta\delta+}{H}$ bonds. By contrast, there is an unfavorable dipolar interaction in **6**, ($\Delta E_{6-4} = +0.74$ kcal/mol) due to *gauche* C—Cl bonds. However, this is compensated by the increased solvent stabilization of **6**, which has the greatest dipole moment. This leads to a predicted reversal of stability for **5** and **6** at high dielectric constant. In summary, the calculations suggest that a combination of stabilizing *gauche* interactions between CH_3 and Cl groups in both **5** and **6** and solvent stabilization of **6** lead to **4** being the least stable rotamer. Similar *gauche* interactions have been invoked to account for the stability of the *gauche* rotamers of 1-halopropanes (10, 30).

The close similarity between experimental and calculated coupling constants (even to the extent of predicting correct relative magnitudes of changes in $\langle J_{AB} \rangle$ with solvent for the two compounds), suggests that the electrostatic solvent theory is applicable for 1,1,2-trihalopropanes. By contrast, it did not work for 1-phenyl-1,2,2-trihaloethanes in polar solvents (3). This supports our suggestion that the latter breakdown was due to specific interactions involving the phenyl group (3).

(d) Chemical and Spectroscopic Identification of Erythro and Threo Pairs

It was decided to attempt to identify the *erythro* and *threo* isomers of 1-phenyl-1,2,2-trihaloethanes by carrying out a dehydrohalogenation reaction followed by spectroscopic identification of the halostyrene derivatives produced by this reaction.

Chlorination of *trans*-β-bromostyrene in CH_2Cl_2 at room temperature gave a mixture of two products (mixture A). The major product (81%) had the larger coupling constant in CCl_4 and corresponded to the isomer tentatively identified in part *c* as *threo*-2-bromo-1,2-dichloro-1-phenylethane. The reaction mixture was further

[c]Predicted shift equals shift for unsubstituted styrene plus effects of two substituents, *e.g.* Cl *trans* and Br *cis* to the phenyl group for 7.

reacted with 0.5 *M* potassium *t*-butoxide in *t*-butyl alcohol and worked-up according to the method of Fahey and Schubert (31). The n.m.r. spectrum of the reaction product showed six vinyl proton singlets, presumably corresponding to six different dihalostyrenes (see Table 7). This is the expected result (see Fig. 1), assuming only *trans*-dehydrohalogenation (32). The two peaks at lowest field are identified as peaks due to α-protons, both from the chemical shifts and because they were significantly broadened by long-range coupling to the phenyl protons (only α protons should show this coupling (33)).

The styrene with the vinyl peak at 7.03 δ is produced in such large yield that it clearly must be produced from the major isomer.[3] This styrene is either **7** or **10**. There has been considerable success in identifying vinyl derivatives by n.m.r. spectroscopy, assuming additivity of substituent effects (34, 35). Consequently, the chemical shifts of styrene and β-halostyrenes were measured in CCl_4. Chemical shifts of the β-dihalostyrenes were then predicted, assuming additive effects due to the β substituents. The results suggest that the predominant product is **10** (Table 7). Calculations based on three other sets of additive substituent parameters (34–36) gave the same prediction (19). **10** would be produced by *trans*-dehydrohalogenation of *threo*-1-phenyl-2-bromo-1,2-dichloroethane (see rotamer $\mathbf{6}_T$, X = Cl, Y = Br). Consequently, the *threo* product must be the major product and have the larger vicinal coupling constant, as predicted by CONCAL.

Bromination of a 50:50 mixture of *cis*- and *trans*-β-chlorostyrene in CCl_4 at 5 °C again gave two products (mixture B) with the major

[3]A β-dihalostyrene is the expected major product since the β hydrogen should be more acidic than the α hydrogen.

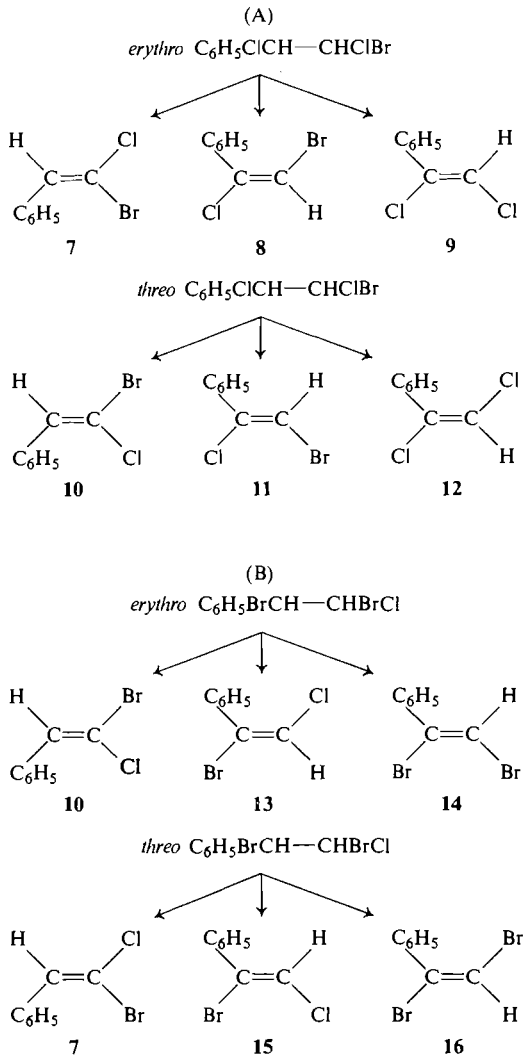

FIG. 1. Possible dihalostyrenes produced by dehydrohalogenation of mixtures of *erythro*- and *threo*-1-phenyl-1,2,2-trihaloethanes.

product (64%) having the larger coupling constant (bromination of the *trans*-styrene in CH_2Cl_2 gave a 50:50 mixture). Dehydrohalogenation of the mixture from CCl_4 again gave **10** as the major product. This indicates that in this case the major halogenation product with the larger coupling constant was *erythro*-1-phenyl-2-chloro-1,2-dibromoethane (assuming *trans*-dehydrohalogenation, see Table 5). This again confirms the prediction by CONCAL.

The first conclusion that can be drawn from the results in this part is that CONCAL can be used in conjunction with vicinal coupling constants to identify diastereomers produced by halogenation of alkenes. The results are also of interest from a mechanistic point of view. Chlorination of *trans*-β-bromostyrene yields 81% of the *threo* product, *i.e.* the *cis* product (see rotamer $\mathbf{6}_T$, Table 5). However, this does not necessarily imply *cis*-addition. As pointed out by Fahey (23, 31), the chlorination of phenylalkenes involves a linear carbonium ion and the product distribution depends upon the relative rates of rotation about the C—C bond and of ion pair collapse, as well as the conformational preference of the carbonium ion.

The results of the bromination of β-chlorostyrene indicate a greater fraction of the *trans*-product, consistent with the results of Fahey for halogenation of 1-phenylpropenes (31).

Summary and Conclusions

We have shown that Abraham's electrostatic theory of solvation energies can be applied to complex substituted ethanes while classical energy calculations reproduce the experimental rotamer energy differences for a number of simple chloro- and bromoethanes.

The two techniques used in conjunction reproduce the energy differences for complex ethanes (as reflected by vicinal coupling constants) with reasonable accuracy. The calculations appear to be most useful for detecting trends in conformational preference for related series of compounds. For example, the experimental coupling constants for 1-phenyl-1,2,2-trihaloethanes and 1,1,2-trihalopropanes are accurately reproduced using a single set of *gauche*- and *anti*-vicinal coupling constants in conjunction with the calculated rotamer populations. One important application of this ability to detect differences in conformational preference is the ability to use the CONCAL calculations to identify diastereomers produced by chlorination or bromination of alkenes.

By breaking down energy differences into differences in steric interactions, dipole–dipole interactions, solvation energies, etc., the calculations allow the rationalization of some unexpected results such as the stability of *gauche*-rotamers in 1,1,2,2-tetrachloroethane and 1,1,2-trichloropropane. The calculations indicate that all three of the above factors are important in determining conformational preference in complex substituted ethanes.

Dielectric Relaxation and Intramolecular Rotation in Aliphatic Ketones

JOHN CROSSLEY

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received April 2, 1973

Dielectric constants and losses have been obtained for a number of aliphatic and aromatic ketones in cycloexane, *n*-hexadecane, decalin and paraffin oil – cyclohexane mixtures at up to ten frequencies between 1 and 145 GHz at 25 °C. Static dielectric constants have also been measured at 2 MHz. The results for each system have been analyzed in terms of a Cole–Cole distribution. The relaxation times and their viscosity dependence are discussed in terms of dipole reorientation by intramolecular and whole molecule rotations.

Les constantes et les pertes diélectriques ont été obtenues pour un certain nombre de cétones aliphatiques et aromatiques dans le cyclohexane, *n*-hexadécane, décaline et dans des mélanges d'huile de parafinne – cyclohexane jusqu'à dix fréquences de 1 à 145 GHz à 25 °C. Les constantes diélectriques statiques ont été également mesurées à 2 MHz. Les résultats pour chaque système ont été analysés par rapport à la distribution Cole–Cole. Les temps de relaxation et leurs variations en fonction de la viscosité ont été discutés par rapport à la réorientation dipolaire par des rotations intramoléculaires et celles de la molécule entière.

Introduction

Dielectric relaxation times have been obtained for some carefully chosen aliphatic amines (1), bromides (2), ketones (3), and alkenes (4) as part of a systematic study of the factors governing the mechanisms of dipole reorientation in aliphatic chain compounds. For the straight chain 1-aminoalkanes and 2-alkanones, the mean relaxation times are virtually independent of the size of the *n*-alkyl group, and dipole reorientation apparently occurs by the intramolecular rotation of the terminal $-NH_2$ and $-COCH_3$ groups, respectively. The relaxation times for the primary amines are independent of the location of the $-NH_2$ group on the alkyl chain. In contrast, if the carbonyl group of a normal alkanone is removed from the chain end, the relaxation time detectably lengthens, probably because the intramolecular process is restricted and whole molecule rotation makes an increased contribution to the dielectric absorption. The intramolecular process is apparently restricted in secondary and tertiary amines, which have much longer relaxation times than the primary amines. Dipole reorientation in 1-alkenes and *n*-alkylbromides appears to involve the rotation of a variety of molecular segments from the polar end group to the whole molecule, and their relaxation times which lengthen with increased chain length are longer than those for analogous primary *n*-alkylamines and 2-alkanones.

In this paper the previous work on ketones is extended to include compounds in which intramolecular rotation may be restricted. Several of the previously examined ketones have been measured in more viscous solvents. The viscosity dependence of the mean dielectric relaxation time may be influenced by the degree to which whole molecule and intramolecular rotations contribute to the absorption, since intramolecular relaxation times have been considered to be relatively insensitive to the macroscopic viscosity (5) which is not the case for molecular relaxation times.

Experimental

The apparatus and procedure employed to determine dielectric constants, ε', and dielectric losses, ε'', at 1–145 GHz have been described previously (6–8). Static dielectric constants, ε_0, were measured at 2 MHz using a WTW Dipolmeter. All the chemicals were dried and distilled prior to use. The polar solute concentrations for all the solutions were generally about 0.03 mol fraction. The paraffin oil – cyclohexane mixtures contained about 30% by volume paraffin oil (Canlab). Viscosities (η) were measured using Ubbelhode type viscometers.

Results

The experimental η, ε' ($\pm 0.5\%$), and ε'' ($\pm 5\%$) values measured at 25 °C are given in Table 1 which has been placed in the Depository

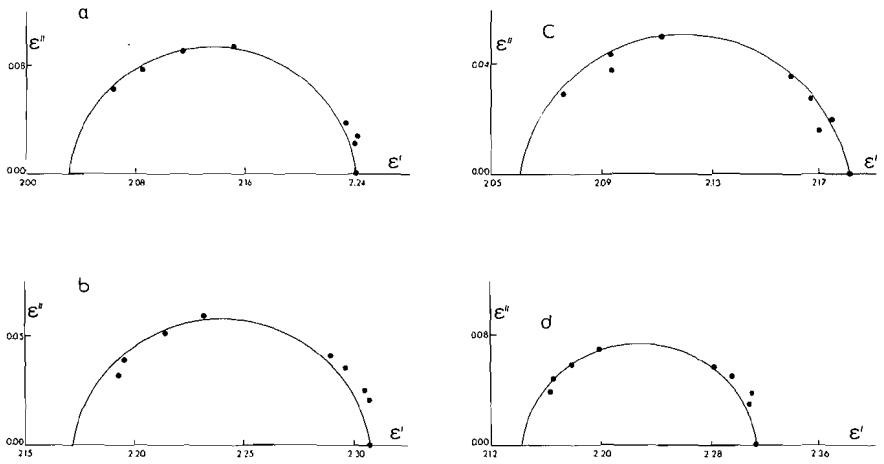

FIG. 1. Cole–Cole plots for 7-tridecanone in (*a*) cyclohexane, (*b*) decalin, (*c*) hexadecane, and (*d*) paraffin oil – cyclohexane at 25 °C. The experimental points were measured at 35.1, 24.0, 16.2, 9.32, 2.48, 1.93, 1.25, 0.97, and 0.002 GHz. The 2.48 GHz point is absent for the cyclohexane solution.

of Unpublished Data.[1] For all the systems it is possible to draw depressed center semicircular arcs through the experimental points, within the experimental error, when plotted in the complex plane and Fig. 1 shows some typical data. Consequently, the ε', ε'', and ε_0 values for each solute–solvent system were analyzed for a mean relaxation time, τ_0, a Cole–Cole distribution parameter, α, and a high frequency dielectric constant, ε_∞, using a computer fit to the Cole–Cole equations (9). Apparent dipole moments, μ, were calculated as before (3) from the ε_0 and ε_∞ values. The τ_0, α, and μ data are presented in Table 2. The errors involved in the above methods have been discussed (10).

[1]Copies of Table 1 are available at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Discussion

The mean relaxation times for 7-tridecanone and 11-heneicosanone in cyclohexane solution

are consistent with those previously obtained for 8-pentadecanone and 10-nonadecanone (3). These symmetrically substituted ketones have much longer relaxation times than any of the 2-alkanones and dipole reorientation, by twisting around the R—C and R′—C bonds, is apparently restricted when both R and R′ in

R—C—R′ have about five or more carbon atoms (the relaxation time for 5-nonanone, R = R′ = 4 carbon atoms, is not significantly longer than that for 2-nonanone). Similar results have been obtained for aliphatic ethers (11). The relaxation time for di-*t*-butyl ketone is quite short and very similar to that for acetone, 3.2 ps, in dilute solution (12). In addition, α is also quite small and it would appear that the *t*-butyl groups do not interfere with one another in the intramolecular twisting mechanism which is the major process of dipole reorientation. The relaxation time for 2,2-dimethyl-3-heptanone is quite similar to those for the nonanones (3), also in cyclohexane solution. Thus the two methyl groups adjacent to the carbonyl group of the former molecule are insufficient in size to hinder intramolecular rotation to any significant extent. In contrast, the *n*-butyl group in 3-*n*-butyl-2-heptanone appears to have a marked steric effect. The relaxation time for this molecule in cyclohexane is considerably longer than those for the 2-alkanones, and in the more viscous hexadecane, it is longer than that for 10-nonadecanone. It would appear that rotation of the whole molecule makes an important contribution to the dielectric absorption of this substituted heptanone. The Cole–Cole distribution parameter α is considerably greater than zero; however, the data could not be analyzed in terms of contribution from two reasonable relaxation times. The mean relaxation time for 1,3-diphenyl-2-propanone is much shorter than that for benzophenone (13), 19 ps in cyclohexane at 25 °C, which has a somewhat similar shape and size. Benzophenone is an essentially rigid molecule and thus intramolecular twisting about the benzyl – carbonyl group bonds must make a significant contribution to the dielectric absorption of 1,3-diphenyl-2-propanone. This is not unreasonable since the resonance effects thought to be responsible for the high barrier to intramolecular rotation in benzophenone are considerably reduced in the propanone. Unlike the aliphatic ketones, segmental rotations are largely unimportant for this aromatic ketone and the possibility of two overlapping Debye dispersions due to whole molecule and intramolecular rotations is more probable. Although the Cole–Cole plot for this compound in cyclohexane does not show any distinct separation, it is possible to obtain a good fit to the experimental ε' and ε'' data using $\tau_1 = 18$ ps, $\tau_2 = 5$ ps, and $C_1 = 0.7$, which are not unreasonable values for the above processes. The mean relaxation times for hexanophenone, benzophenone (13), and acetophenone (14) in cyclohexane at 25 °C are 18.8, 19, and 10.2 ps, respectively, and the respective values in decalin also at 25 °C are 39.3, 34.6 (15), and 17.5 ps. The resonance effects which restrict intramolecular rotation in benzophenone are not as important for acetophenone. The mean relaxation time for the latter is shorter than expected for molecular rotation and its dielectric absorption data may be analyzed in terms of two relaxation times which can be reasonably assigned to whole molecule and intramolecular rotation. Hexanophenone is similar in size to benzophenone and the mean relaxation times of these two ketones in both cyclohexane and decalin are quite close. For hexanophenone it would appear that the steric effect of the alkyl group, together with the resonance effect of the aromatic group, give rise to a high barrier to intramolecular rotation and dipole reorientation is dominated by rotation of the whole molecule.

The relaxation time of a rigid molecule lengthens with increased solvent viscosity, but experiments have shown (16) that the viscosity dependence of the relaxation time does not conform to a simple relationship and is considerably influenced by the shape of the solute molecule and the relative size of the solute and solvent molecules. However, the ketones under investigation are non-spherical in shape and although τ_0 will not be directly proportional to the macroscopic viscosity it should detectably lengthen if the rotation of the whole molecule makes any significant contribution to the dielectric absorption. Intramolecular rotation occurs with relatively little displacement of surrounding molecules and the relaxation times have generally been considered to be independent of viscosity. Thus for a system in which dipole reorientation is achieved by both whole molecule (τ_1) and intramolecular (τ_2) rotation the ratio τ_1/τ_2 would be expected to increase with increased viscosity

TABLE 3. Ratios of relaxation times in cyclohexane (τ_C), decalin (τ_D), hexadecane (τ_H), and paraffin oil – cyclohexane (τ_P), and reduced relaxation times in cyclohexane (τ_{RC}) and paraffin oil – cyclohexane (τ_{RP}) at 25 °C ($\eta_D/\eta_C = 3.5$; $\eta_H/\eta_C = 3.8$)

Solute	τ_D/τ_C	τ_H/τ_C	τ_P/τ_C	η_P/η_C	τ_{RP}/τ_{RC}
2-Hexanone	1.3	1.2	1.7	8.5	0.17
2-Nonanone	1.4	1.4	2.1	13.1	0.16
5-Nonanone	1.4	1.3	1.7	8.4	0.18
7-Tridecanone	1.5	1.4	1.9	10.5	0.17
8-Pentadecanone	1.5	1.4	1.9	11.6	0.16
2-Nonadecanone	1.4	1.5	1.9	11.6	0.16
10-Nonadecanone	1.5	1.5	1.8	11.7	0.15
11-Heneicosanone	1.6	—	—	—	—
3-*n*-Butyl-2-heptanone	—	1.9	—	—	—
Hexanophenone	2.1	2.2	3.0	12.1	0.43

and may give rise to a distortion of the Cole–Cole plot, which should facilitate an analysis in terms of two relaxation times. The Cole–Cole plots for the ketones in decalin, hexadecane, and paraffin oil – cyclohexane are as symmetrical as those obtained in the less viscous cyclohexane (Fig. 1). The relaxation times in Table 2 do lengthen with increased solvent viscosity, however; *i.e.* cyclohexane < decalin ≃ hexadecane < paraffin oil – cyclohexane.

A comparison of the effect of increased viscosity on the relaxation time of each ketone is given in Table 3, and, as expected even for rigid molecules, the viscosity ratios are much greater than the corresponding relaxation time ratios. The τ_P/τ_C value for 2-nonanone appears to be anomalously high when compared with the values for the other 2-alkanones; however, the viscosity of the 2-nonanone in paraffin oil – cyclohexane solution was greater than the others. In order to partially correct for the differences in viscosity of the paraffin oil – cyclohexane solvents, the reduced relaxation time (τ_0/η) ratios are presented in the last column of Table 3. Hexanophenone and 3-*n*-butyl-2-heptanone had previously been considered to be rigid molecules and the ratios for these compounds in Table 3 are greater than those for the other ketones in all the solvents. The values for the first seven ketones in Table 3 are very similar which is somewhat surprising in view of the earlier interpretation of the cyclohexane data (3). In addition, the small differences between the relaxation times of the 2-alkanones in cyclohexane are magnified in the more viscous solvents, and it would appear that whole molecule rotation does contribute to the absorption of the 2-alkanones, but the magnitude of this contribution is less than it is for the symmetrically substituted ketones. However, it was not possible to obtain sensible analyses in terms of two relaxation times, probably because segmental rotations, which are not possible for the analyzable aromatic ketones, also contribute to the absorption. In fact, for a majority of the ketones, the distribution parameters listed in Table 2 show no significant increase with increased solvent viscosity which might indicate that the intramolecular and whole molecule relaxation times are lengthened by the same factor. The effect of viscosity on these processes for aliphatic molecules has not been investigated in any systematic studies and consequently there is little with which to compare the values in Table 3. For *n*-octylbromide dipole reorientation is thought to occur by a variety of segmental rotations and τ_H/τ_C at 25 °C is 1.2 (17). The τ_D/τ_C value for anisole at 25 °C is about 1.2 and in solution the intramolecular relaxation process has a weight factor of about 0.65 (18, 5). The τ_D/τ_C value for both acetophenone and benzophenone is about 1.7 (14, 15).

In conclusion the results presented in Tables 2 and 3 indicate that the dielectric absorption of hexanophenone and 3-*n*-butyl-heptanone contains large contributions from the rotation of the molecule as a whole. Intramolecular and molecular rotation contribute to the absorption of the other alkanones, the relative magnitude of these contributions depends on the degree to which the intramolecular process is sterically restricted. Unfortunately, possibly because the viscosities were insufficient, detectable separation of the Cole–Cole arcs into regions which could be assigned to intramolecular and molecular relaxations were not obtained.

The author wishes to thank the National Research Council of Canada for a grant to support this work.

N.M.R. Studies of Anhydrous Hydrogen Fluoride Solutions[1]

JACOB SHAMIR AND AHARON NETZER[2]

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Israel

Received December 20, 1972

Solutions of anhydrous HF and SO_2 and electrolytes in anhydrous HF have been studied by n.m.r. Both ^1H and ^{19}F chemical shifts were studied as a function of concentration and temperature. The dimerization constant and the enthalpy of the reaction $2HF \rightleftarrows (HF)_2$ were calculated.

The results for electrolyte solutions were interpreted on the basis of two effects, ionization and the H-bond breaking effect. A linear relationship exists between δ_0, the molal chemical shft, and the ionic crystallographic radii. A temperature effect was also observed and interpreted. Solutions of salts of Lewis acids were also studied but results are less conclusive; it was shown, however, that their δ_0 values are smaller than those of alkali fluorides.

Les solutions anhydres de HF et SO_2 et d'électrolytes dans HF anhydre ont été étudiées par RMN. Les déplacements chimiques de ^1H et ^{19}F ont été étudiées en fonction de la concentration et de la température. La constante de dimérisation et l'enthalpie de la réaction $2HF \rightleftarrows (HF)_2$ ont été calculées.

Les résultats pour les solutions d'électrolytes ont été interprétés en fonction de deux effets: l'ionisation et la rupture de la liaison H. Une relation linéaire existe entre δ_0, déplacement chimique molal, et le rayon ionique cristallographique. Un effet de température a été aussi observé et interprété. Les solutions de sels d'acides de Lewis ont été également étudiées mais les résultats sont moins concluants; il a été montré cependant que les valeurs δ_0 correspondantes, sont plus petites que celles de fluorures alcalins.

Introduction

Anhydrous hydrogen fluoride is a highly polymerized liquid. There is no clear evidence for the extent of association or of the configuration of the polymeric molecules in the liquid state. The structure of the gaseous phase has indicated the existence of cyclic polymers. On the other hand, the heat of vaporization of the liquid is rather low for a highly associated liquid. It can therefore be concluded that not much of a change occurs in the average number of polymer units per mole of HF in the transition from liquid to gas.

Depolymerization of an associated compound can be achieved in either of two ways. One is to heat the associated substance, and especially to vaporize the liquid and lower the pressure of the vapor. The second is to dilute the associated liquid with a chemically inert liquid. In this study the second method was used.

On the basis of experimental data such as the Hammet function (H_0) of mixtures of HF and SO_2 and their i.r. and Raman spectra, Hyman (1) concluded that SO_2 behaves as an inert solvent with regard to HF, and it may therefore be assumed that dilution of HF with SO_2 would cause depolymerization of HF by breaking the H-bonds. More recently, Gillespie and Humphreys (2) have provided evidence for non-ionization/reaction of SO_2 in HF using a cryoscopic technique. Both anhydrous HF and SO_2 are liquid at room temperature when kept under their own pressure and are miscible in all proportions.

Many n.m.r. studies (3) have shown that when a polymerized liquid is depolymerized by dilution with an inert liquid, the ^1H resonance of the particular hydrogen involved in the H-bond is shifted to a higher field. A similar effect was therefore expected in the case of anhydrous HF. In every H-bond, another atom is involved, *e.g.*, F, O, or N. Very little is known about how the n.m.r. of these atoms is affected when they are involved in H-bonding.

In the system HF–SO_2 it is assumed that as the concentration of HF decreases, a depolymerization effect takes place:

$$(HF)_n \rightarrow (HF)_{n-k} + (HF)_k$$

It is probably more correct to assume that a

number of polymeric species of varying chain lengths exist simultaneously in solution. Only in very dilute solutions can it be assumed that the monomer and dimer are the dominant species.

The interpretation of the n.m.r. data becomes rather complicated as the various chemical shifts for the different species present in solution are unknown and only one weighted average signal can be measured.

The data obtained at low HF concentrations have been interpreted in terms of an equilibrium between monomeric and dimeric forms of HF. From the values of the dimerization constant, K_D, at different temperatures the enthalpy of dimerization was calculated. In addition, some measurements were made of the temperature dependence of ^1H and ^{19}F chemical shifts, which could also be interpreted as being a characteristic property of the H-bond itself rather than mainly a reflection of changes in the relative amounts of various H-bonded species in equilibrium.

In recent years various ionic solutions have been studied by n.m.r. spectroscopy. Some of these have recently been reviewed by Hinton and Amis (4). In most studies carried out in solution one observes only the weighted average signal. This is the result of fast chemical exchange on the n.m.r. time scale, among the various species present. This causes the interpretation to be rather difficult unless separate chemical shifts for the different species can be determined. The observed weighted-average signal could be formulated as:

$$[1] \qquad \delta_{obs} = \sum(p_i\delta_i)$$

where p_i is the fraction of the total number of nuclei with chemical shift δ_i.

In this paper we present some results obtained by studying electrolyte solutions of alkali fluorides and salts of the Lewis acids, BF_3, AsF_5, and SbF_5 in anhydrous HF. Anhydrous HF is a highly acidic non-aqueous solvent and most solutes in it behave as bases as they become protonated by the solvent. Only a few solutes act as acids in this strongly acidic medium and these are mainly fluoride acceptors such as BF_3, AsF_5, and SbF_5. Alkali fluorides act as bases and dissociate as follows

$$[2] \qquad MF \rightleftarrows M^+ + F^-$$

$$[3] \qquad F^- + (HF)_n \rightleftarrows [(HF)_nF]^-$$

The first step we will term the *ionizing effect*. The solute dissociates into ions and the fluoride ion attaches itself to a neutral molecule to become a larger anion. The second step, the *H-bond breaking step*, involves depolymerization

$$[4] \qquad (HF)_n \rightleftarrows (HF)_{n-k} + (HF)_k$$

Solutions of salts of the Lewis acids studied can be considered as 1 : 1 electrolytes and not as bases. The major process is the ionic dissociation

$$[5] \qquad MAF_x \rightleftarrows M^+ + AF_x^-$$

where M is an alkali metal, and A is boron, arsenic, or antimony; x is 4 or 6.

Experimental

Chemicals

Anhydrous Hydrogen Fluoride

Highly purified HF was obtained by fractional distillation of commercial anhydrous HF (Matheson). Its minimum specific conductivity was 2×10^{-6} ohm^{-1} cm^{-1} at room temperature. The details of the distillation column have been described elsewhere (5).

Sulfur Dioxide

Commercial sulfur dioxide (Matheson), reputed to be 99.99% pure, was condensed into a nickel vessel containing P_2O_5. The SO_2 was cooled to liquid N_2 temperature and all the non-condensable gases pumped off until a vacuum of the order of 10^{-6} Torr was achieved. The SO_2 was then allowed to warm-up to room temperature and stand overnight. The i.r. spectra of gaseous SO_2 samples showed no bands that could be attributed to water or other impurities. In addition, a high gain ^1H n.m.r. spectrum gave no indication of the presence of protons.

Metal Fluorides and Complex Fluorides

Commercial products were used and had the following purities: LiF, 99.6%; NaF, 99.6%; KF, 99%; RbF, 99.8%; CsF, 99%; $KSbF_6$, 95%; $NaBF_4$, 99.9%; KPF_6, 98%; $NaAsF_6$, 97%; $KAsF_6$, 98%.

The alkali fluorides were heated at 120 °C overnight, before being transferred in an inert atmosphere Dry Box to KEL-F vessels (0.75 in. o.d. × 6 in.). The complex fluorides were used without prior heating.

Preparation of Solutions

All the solutions were prepared and handled on the KEL-F section of the metal vacuum line. The concentrations of the HF-SO_2 solutions were determined by weight. The solutions were prepared either directly in KEL-F n.m.r. tubes, or, when a low concentration of one of the constituents was required, in a larger KEL-F vessel (0.75 in. o.d. × 6 in.) and some of it was then poured under vacuum into the n.m.r. tube.

The electrolyte solutions were prepared in (0.75 in. o.d. × 6 in.) KEL-F containers fitted with KEL-F valves. The concentrations were determined by weight. The tubes were charged with the appropriate dried salt in a Dry Box; they were then attached to the KEL-F section of the vacuum line evacuated, and the appropriate amount of

For personal use only.

anhydrous HF distilled in. The prepared solution was then poured, under vacuum, into the KEL-F n.m.r. tube using a Y-connection. The usual procedure was to start out by preparing the highest concentration and then diluting it further.

N.M.R. Measurements

N.M.R. Instrumentation

All measurements were performed on a Varian Analytical n.m.r. spectrometer, Model A-56/60 using KEL-F n.m.r. tubes. A Varian Automatic Voltage Regulator, Type 1581-A, was used to stabilize the voltage. The temperature was regulated by a Varian V-6040 temperature controller with a pressure switch modification for regulating the nitrogen flow.

The original instrument could detect fluorine resonances in the range from 8 000 Hz to low field to 11 000 Hz to high field of CCl_3F. For our purposes an extension of this region was needed, and this was achieved by the addition of extra crystals.

Reference Materials

TMS and CCl_3F were used as external references, respectively. The need for bulk diamagnetic susceptibility corrections was found to be negligible.

^1H Signals

All recordings were made with a 50 Hz sweep time of 250 s. For each sample 5–7 recordings were made, usually on the same chart, with a shift of 5 Hz in the sweep offset setting between one reading and the next. The numerical values of the chemical shifts, which never differed by more than ± 0.5 Hz, were then averaged. The reference calibration was done twice, once before the sample measurement and once after.

^{19}F Signals

In measurements of the fluorine resonance, a considerable broadening was observed as the solutions became dilute in anhydrous HF. This necessitated changing the sweep width, keeping it always as narrow as possible. As a result, the precision of the measurements was lower and the average error was about ± 1.0 Hz. In this case too, the reference calibration was done twice.

Results and Discussion

The HF–SO_2 System

In all the samples measured, only one resonance signal was observed for either ^1H or ^{19}F. This signal is therefore an average over all the HF molecules present in various degrees of polymerization. Apparently, the exchange rate is sufficiently fast for the signals to be completely collapsed.

The value of the chemical shift varies with the HF concentration. The lowest concentration at which signals could be observed and measured was at 0.639 *m* of HF (mole fraction = 0.0393): at this concentration the ^1H resonance has shifted by +2.78 p.p.m. (at 34 °C) and the ^{19}F resonance by −8.34 p.p.m. (at 38.5 °C), both with reference to pure anhydrous HF. The data are presented graphically in Figs. 1–3.

^1H Resonances and Concentration Dependence at Different Temperatures

The ^1H chemical shifts at 34° are presented as a function of the mole fraction of HF in Fig. 1. The data obtained at −31.5° is identical to the data presented in Fig. 1, except in the low concentration region (Fig. 2). The chemical shift, as seen in Figs. 1 and 2, moves towards higher field almost linearly with decreasing concentration. The degree of polymerization is higher at lower temperatures, and it is therefore to be expected that the change in chemical shift with concentration is more pronounced at lower temperatures. This is seen in Fig. 2, where the slope in the dilute region is steeper at lower temperatures. Assuming that in the region of low HF concentration (0.639–2.039 *m*) the dominant species are the monomer and the dimer, the

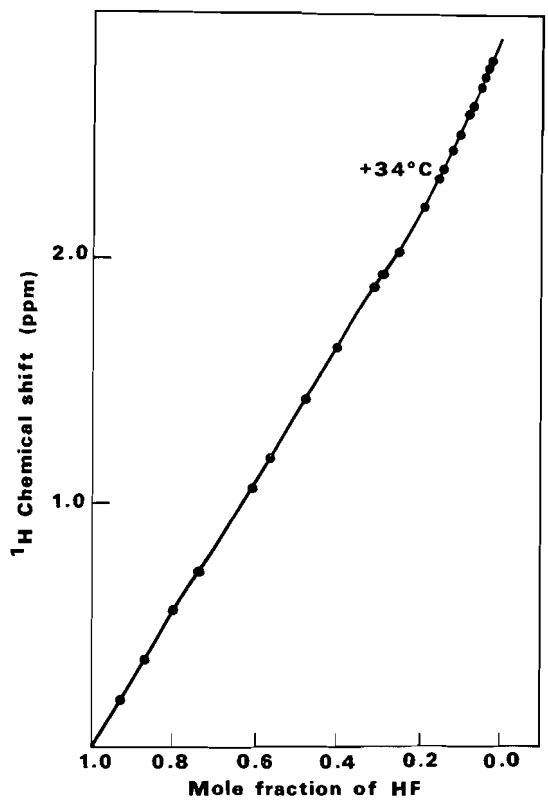

FIG. 1. Variation of proton chemical shift, expressed in p.p.m. with reference to pure anhydrous HF *vs.* concentration expressed in mole fraction in the HF–SO_2 system at 34 °C.

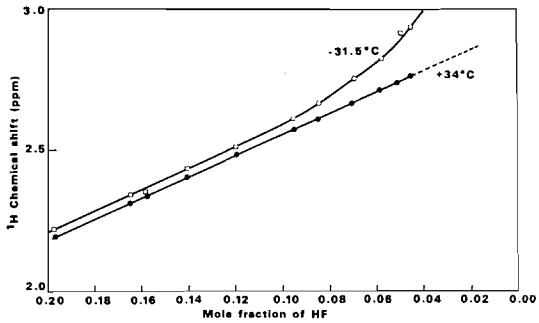

FIG. 2. Enlarged plot of the low HF concentration region: variation of proton chemical shift, expressed in p.p.m. with reference to pure anhydrous HF *vs.* concentration expressed in mole fraction in the HF–SO_2 system at 34 °C and −31.5 °C.

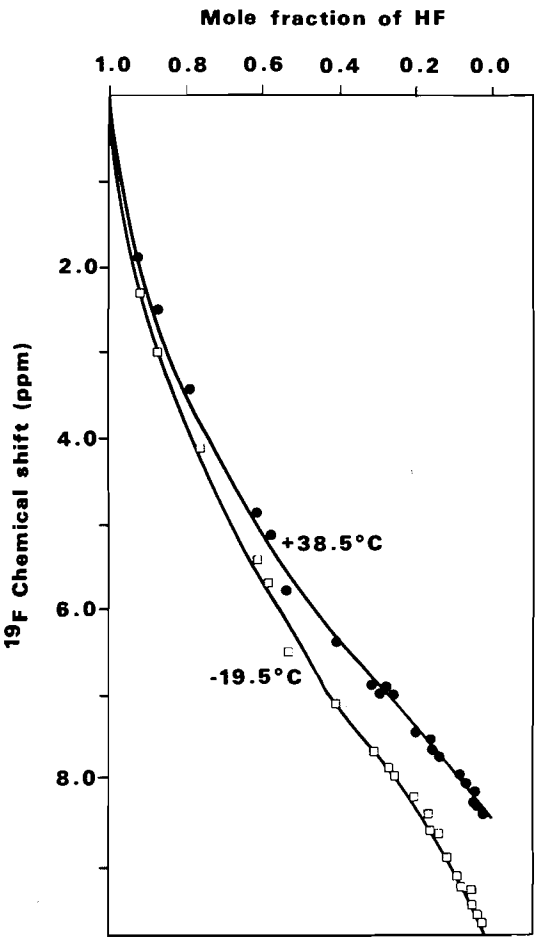

FIG. 3. Variation of fluorine chemical shift expressed in p.p.m. with reference to pure anhydrous HF *vs.* concentration expressed in mole fraction in the HF–SO_2 system at two temperatures.

observed chemical shift will be given by the following equations

$$[6] \qquad \delta_{obs} = (\delta_M P_M) + (\delta_D P_D)$$

$$[7] \qquad \delta_{obs} = \left(\delta_M \frac{X_M}{X_T}\right) + \left(\delta_D \frac{2X_D}{X_T}\right)$$

where $X_T = X_M + 2X_D$; and δ_M, δ_D are the chemical shifts of monomer and dimer, P_M, P_D are the fraction of the total number of nuclei in monomer or dimer form, X_M, X_D are the mole fractions of monomers and dimers, and X_T is the total mole fraction.

The dimerization constant is therefore given by

$$[8] \qquad K_D = \frac{[X_D]}{[X_T - 2X_D]^2}$$

From formula 7 we can derive

$$[9] \qquad \delta_{obs}\frac{X_T}{X_M} = \delta_M + \delta_D\frac{2X_D}{X_M}$$

or

$$[10] \qquad \delta_{obs} Y = \delta_M + \delta_D Z$$

where

$$Y = \frac{X_T}{X_M} \quad \text{and} \quad Z = \frac{2X_D}{X_M}$$

If one plots values for $\delta_{obs} Y$ *vs.* Z for the best value of K_D, a straight line should be obtained. From the slope of the line and its intersection both δ_M and δ_D can be calculated. Such a computation was done according to the method of Groves *et al.* (6) using a CDC 6400 computer. The results are tabulated below for two temperatures, the shifts being relative to pure anhydrous HF.

TABLE 1.

Temperature (°C)	δ_D(Hz)	δ_M(Hz)	K_D
+34	98.7	197.3	7.5
−31.5	106.1	379.3	123.0

In using these values the chemical shift was recalculated taking into account the K_D, δ_M, and δ_D values. The calculated values were compared to the δ_{obs} and were found to be in agreement within ±0.6%. In studying the chemical shifts as a function of pressure in the gas phase, Mackor *et al.* (7) obtained a value of 4.35 p.p.m. (261 Hz) for δ_M at room temperature.

From the values of K_D at different temperatures, the enthalpy of the dimerization was calculated

$$\Delta H = \frac{-\mathrm{d} \ln K}{\mathrm{d}(1/T)} R$$

The value found was

$$\Delta H = -6.29 \text{ kcal/mol}$$

In the cyclic hexamer – monomer equilibrium, one obtains $6\,HF \rightleftarrows (HF)_6$. This would mean that six H bonds are formed and accordingly this would result in a value of $-6.29 \times 6 = -37.74$ kcal/mol. This is in good agreement with other data of ΔH in the literature where different methods have been used. These data lie between -38.0 and -40.8 kcal/mol (8).

^{19}F Resonances

The results are presented in Fig. 3, which shows that the ^{19}F resonances shift towards lower field, as the HF concentration decreases. This is in contrast to the results obtained in n.m.r. studies of HF in the gas phase (7, 9). Our studies of the temperature effect in pure liquid anhydrous HF, as discussed later, also indicate that both ^1H and ^{19}F resonances shift towards higher field as the temperature increases. All these parameters, namely decreasing pressure in the gas phase, increasing the temperature of pure liquid anhydrous HF, and diluting HF solutions, result in depolymerization, and therefore, should be reflected by a shift towards higher field in the n.m.r. spectra. High field ^{19}F chemical shifts have been observed in the gas phase and in pure anhydrous HF, but not in $HF–SO_2$ solutions. This exception could be explained as the result of an enormous "solvent effect". This effect has been studied by Evans (10, 11) who compared the chemical shifts of CCl_4 solutions of various compounds containing fluorine with those of similar compounds containing hydrogen. For instance, CF_4 at infinite dilution in CCl_4 has a chemical shift of 9.24 p.p.m., compared to 0.5 p.p.m. in case of CH_4. In both cases, no interaction between solute and solvent is expected. The large "solvent effect" in the case of ^{19}F chemical shifts is a result of changes in the paramagnetic term, σ_{para}^{AA}, for the electrons localized on fluorine; whereas, for hydrogen, the dominant term is the diamagnetic term, σ_{AA}^{dia}, in the Ramsey equation (ref. 3, p. 130). The "solvent effect" observed in the ^{19}F n.m.r. of $HF–SO_2$ solution is large and in the opposite direction when compared to changes resulting from the breaking of H-bonds. Among the various factors responsible for the "solvent effect", Evans lists the extent to which the fluorine atom is protected from the influence of the solvent. In the case of HF, and especially when H-bonds are broken, the fluorine is under a greater influence from the solvent. In addition, this solvent has a large dipole moment, strongly polarizing the H-bonded fluorine. Observing such a large "solvent effect" and not being able to separate it from the H-bond breaking effect, did not enable us to interpret the ^{19}F n.m.r. data quantitatively.

Temperature Effect in Pure Anhydrous HF

The changes in the n.m.r. spectrum of pure liquid anhydrous HF were studied as a function of temperature. Raising the temperature causes a change in the chemical shift towards higher field, which is related to a depolymerization process. This is observed in both the ^1H and ^{19}F resonances and is in agreement with other studies (7). The data are presented graphically in Fig. 4.

The approximate linear dependence is given by

$$\delta_{^1H}(HF) = 7.70 + (t \times 1.20 \times 10^{-2}) \text{ p.p.m.}$$
(with respect to external TMS)

$$\delta_{^{19}F}(HF) = 198.65 + (t \times 4.0 \times 10^{-2}) \text{ p.p.m.}$$
(with respect to external CCl_3F)

where t is the temperature in °C.

It should be mentioned that the chemical shifts

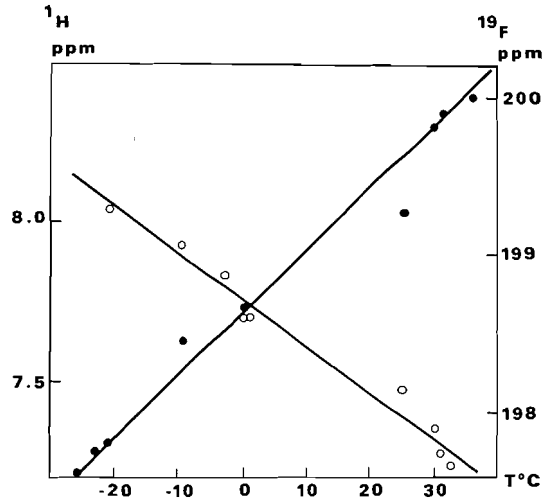

FIG. 4. ^1H and ^{19}F n.m.r. chemical shifts of anhydrous HF as a function of temperature.

TABLE 2. ^1H and ^{19}F molal chemical shifts (δ_0) for salts of Lewis acids in anhydrous HF, expressed in p.p.m./molal concentration

NaF	32	0.33	−3	0.30	31	2.30	−9	2.04

reported in the literature for both ^1H and ^{19}F in anhydrous HF vary slightly. For ^1H, the values lie between 7.8 and 8.85 p.p.m. (7, 9, 12, 13) and for ^{19}F, they range from 194.0 to 200.0 p.p.m. (7, 9, 14–16). These differences result from differences in the temperature at which the measurements were made and may also be due to the purity of the anhydrous HF.

Electrolyte Solutions

Alkali Fluorides

In all cases only one exchange averaged line was observed in both the ^1H and ^{19}F n.m.r. spectra. The data presented in Figs. 5–8, represent the chemical shifts of the ^1H and ^{19}F resonances with respect to anhydrous HF *vs.* the molality of the solutions at different temperatures. All the observed shifts are towards lower field. They all increase almost linearly as the concentration increases. In addition, the molal chemical shifts, δ_0, were calculated from the region of dilute concentrations.

$$\delta_0 = \left(\frac{d\delta}{dc}\right)_{c=0}$$

These values are summarized in Table 2 and will be discussed later.

An n.m.r. study of the $(HF_2)^-$ anion in various bifluoride salts of some butylamines has shown that ^1H resonances lie between 4.76 and 4.86 p.p.m., and ^{19}F resonances lie between 32.1 and 49.6 p.p.m. to low-field of pure anhydrous HF (17). The highest electrolyte concentration in this study was that of CsF which reached a value of 13.09 *m* (CsF:HF = 1:3.8). In this particular solution the ^1H chemical shift was 3.97 p.p.m. (238.4 Hz) and the ^{19}F chemical shift was 30.68 p.p.m. (1730.5 Hz) to low field of pure anhydrous HF. These values are rather close to those obtained for the $(HF_2)^-$ anion. As no levelling off is indicated in these curves, one is inclined to assume that the ionization process is a total one and therefore linear change is taking place.

If the ionic dissociation was the only process involved then one would expect that the chemical shift would only be dependent on the fluoride ion concentration and would not be influenced by the cation. But this is not the case, and a very pronounced relationship is noticed between the ionic crystal radii and the molal chemical shift (δ_0) as presented in Fig. 9. The second effect therefore to be considered is that of bond-breaking, *i.e.* depolymerization of the solvent molecules. The observed chemical shift is the sum of two contributions

$$\delta_{obs} = \delta_{ion} + \delta_{bb} \quad [11]$$

where δ_{obs} is the observed molal chemical shift, δ_{ion} is the molal ionization chemical shift, and δ_{bb} is the molal bond-breaking chemical shift.

The influence of depolymerization on the n.m.r. signals of HF has been reported earlier in this paper. It was established that the ^1H resonance shifts towards higher field as the degree of depolymerization increases. Since δ_{obs} is negative (towards lower field) and the δ_{bb} is positive, one has to conclude that δ_{ion} is negative and its absolute magnitude is greater than that of δ_{bb}.

$$|\delta_{ion}| > |\delta_{bb}|$$

Assuming that complete ionization occurs, δ_{ion} would be expected to be the same for all salts. Therefore the difference in δ_{obs} for the various salts has to be interpreted in terms of

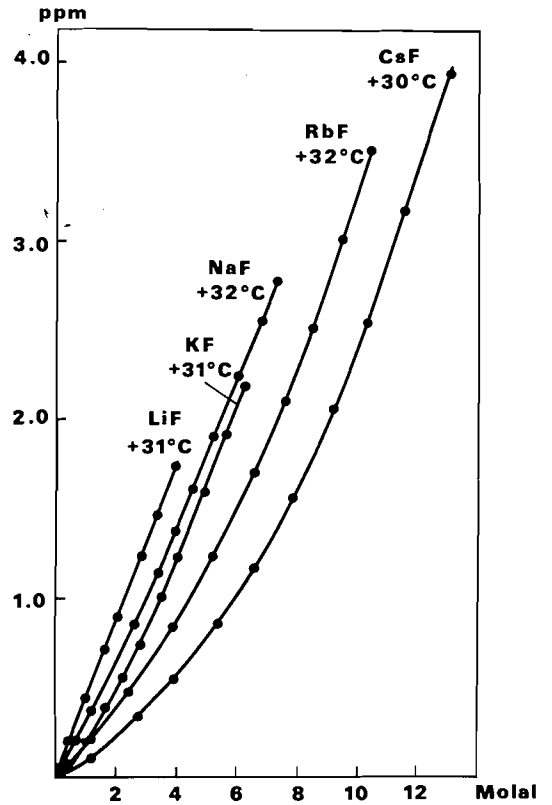

FIG. 5. Variation of proton chemical shifts expressed in p.p.m. with reference to pure anhydrous HF, *vs.* concentration, expressed in molality of various solutes.

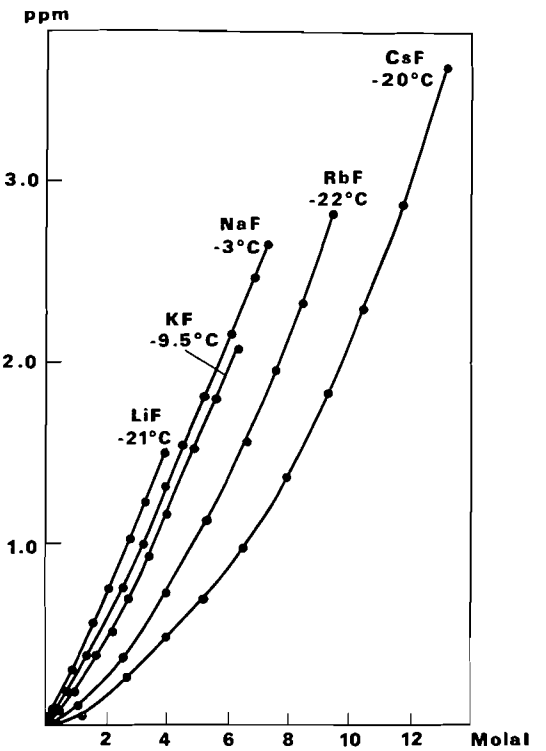

FIG. 6. Same as Fig. 5 for lower temperatures.

the depolymerization process. Since the signs of δ_{obs} and δ_{bb} are opposite, an increase in $|\delta_{obs}|$ reflects a decrease in δ_{bb} and vice versa.

From Fig. 9 it is seen that $|\delta_{obs}|$ is smallest for the Cs cation and largest for Li cation; in other words, δ_{bb} is largest for Cs and smallest for Li. An increase in the ionic crystallographic radius causes an increase in the degree of depolymerization.

Fabricand and Goldberg (18) studied the p.m.r. chemical shifts in alkali halide aqueous solutions. They too noticed that when plotting the crystal radii of cations and anions versus the relative to the molal proton chemical shifts, a straight line was obtained. They inferred that the average number of hydrogen bonds in water near an ion, is proportional to the ionic radius and that the number decreases with increasing radius. In aqueous solutions the two effects are δ_{bb} and δ_E, where δ_E is the polarization shift resulting from distortion of the electronic

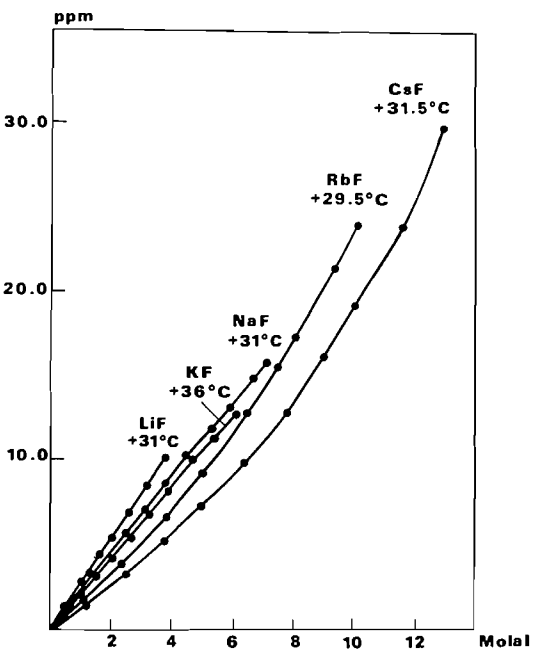

FIG. 7. Variation of fluorine chemical shifts expressed in p.p.m. with reference to pure anhydrous HF, *vs.* concentration, expressed in molality, of various solutes.

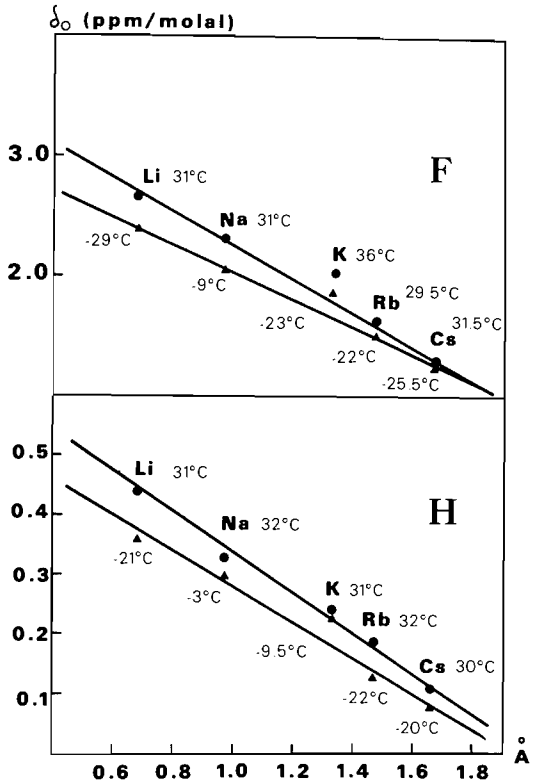

FIG. 9. δ_0 – molal chemical shifts of hydrogen and fluorine expressed in p.p.m./molality *vs.* crystallographic radii expressed in Å.

structure of water by the ionic electric field. In the case of HF, the polarization effect reaches an extreme situation when the solvent itself ionizes. Our observations are, therefore, very similar to previous findings for water, and we conclude that larger ions cause a larger bond-breaking effect, and as a result $|\delta_0|$ decreases as the ionic radius increases.

From Fig. 9 it is seen that a linear relationship exists between the ionic crystallographic radii and the observed molal chemical shifts. This similarity would not necessarily be predictable since water is a three dimensional system while HF is a two dimensional system.

Our results are also in agreement with those of Gillespie and Humphreys (2), who have shown that at low molarities (less than 0.15 *m*) the alkali metal fluorides act as simple 1 : 1 electrolytes. But at higher concentrations, there is substantial deviation from ideal behavior, which in our work we have attributed to ionization and H-bond breaking effects.

Temperature Effect

A comparison of the $|\delta_0|$ values at lower temperatures with values for the same salt at higher temperatures shows that $|\delta_0|$ is usually somewhat smaller at lower temperatures. The degree of polymerization in the pure solvent increases with decreasing temperature. Therefore, the number of H-bonds to be broken in order that a particular degree of depolymerization be attained with the same amount of solute will be greater at lower temperatures, and as a result $|\delta_{bb}|$ will be larger, and $|\delta_0|$ will therefore decrease, which is indeed observed.

Transverse Relaxation Times

From the width of the lines at their half height, the transverse relaxation times, T_2, were calculated. The ^1H resonances are observed to vary slightly, while in the case of the ^{19}F resonances, the width increases with increasing concentration. This change in line width varied from several Hz to several thousand Hz. This effect has already been observed by Solomon and Bloemberger (19), who studied the relaxation times of anhydrous HF and the changes caused by addition of water or potassium fluoride. We do not know of any explanation other than that given by these authors. Their explanation takes into account the effects of ionization, which presumably stabilizes the long ionized chains of $[(HF)_nF]^-$.

Salts of Lewis Acids

The solubilities of the alkali salts of Lewis acids studied were lower and the chemical shifts were also smaller than those of alkali fluorides, making these results less accurate. However, some general statements can be summarized. Both hydrogen and fluorine resonances shift towards lower field with respect to pure anhydrous HF, and this would indicate that in these cases too, the ionizing or polarizing effect is stronger than the bond-breaking effect. The observed molal chemical shifts, as summarized in Table 2, are smaller than the molal chemical shifts of alkali fluoride solutions. If one considers all the ionizing equilibria it seems that it really is a much more complicated system than the alkali fluoride solutions. The following equilibria can coexist

[12] $MAF_6 \rightleftarrows M^+ + AF_6^-$

[13] $AF_6^- \rightleftarrows AF_5 + F^-$

[14] $F^- + (HF)_n \rightleftarrows [(HF)_nF]^-$

[15] $2HF + AF_5 \rightleftarrows (H_2F)^+ + AF_6^-$

(A = P, As, Sb; M = Na, K). Steps 13 to 15 can be summarized by cancelling the ionization and dissociation of the complex AF_6^-. The net reaction can be written

$$(HF)_{n+2} \rightleftarrows (H_2F)^+ + [(HF)_nF]^-$$

which is really the self-dissociation of HF. It is possible that the dissociation of the salt MAF_6 would thus increase the self-dissociation of the solvent. One notices that the equilibria involved are rather complicated, and since no separate δ values for the various species involved are known, it is impossible to analyze the results quantitatively.

We would like to express our appreciation to the Ford Foundation for their financial support for this research.

1:2 Trimethylphosphine Complexes of the Group IV Tetrahalides, *trans*-$MX_4.2P(CH_3)_3$ and *trans*-$MX_4.2P(CD_3)_3$ (where M = Si, Ge, or Sn; X = Cl or Br); Assignment of Metal–Phosphorus modes

D. K. Frieson and G. A. Ozin[1]

Lash Miller Chemistry Laboratories and Erindale College, University of Toronto, Toronto, Ontario M5S 1A1

Received January 5, 1973

The vibrational spectra of some 1:2 trimethylphosphine adducts of the group IV tetrahalides, which contain ligands in a *trans* configuration, are examined in detail using perdeutero-trimethylphosphine to facilitate the assignment of all metal-halogen and metal–phosphorus stretching modes. Preparation of $SiCl_4.2PMe_3$ with a 1:1 mixture of $P(CH_3)_3$ and $P(CD_3)_3$ enables an almost unambiguous assignment of the spectrum of this adduct. Normal coordinate calculations for all adducts are reported.

Les spectres vibrationnels de certains composés d'addition 1:2 de la triméthylphosphine et de tétrahalogénures du groupe IV qui contiennent des coordinats dans une configuration *trans*, ont été étudiés en détail grâce à l'utilisation de la perdeutéro-triméthylphosphine afin de rendre plus facile l'attribution de tous les modes d'élongation des liaisons métal–halogène et métal–phosphore. La préparation du $SiCl_4.2PMe_3$ à partir d'un mélange 1:1 de $P(CH_3)_3$ et de $P(CD_3)_3$ a permis l'interprétation presque sans ambiguité du spectre de ce composé d'addition. On présente aussi pour tous les composés les calculs en coordonnées normales. [Traduit par le journal]

Introduction

The proliferation of adducts of the form $MX_4.nL$ reported in the literature is convincing evidence of the tendency of group IV tetrahalides to seek a maximum covalency of six through the formation of coordinate bonds with sufficiently strong electron donors (1). In the case where 1:2 adducts are formed, the possibility of *cis–trans* isomerism arises. The *trans* stereochemistry in group IV appears to be favored. X-Ray crystallography has established the *trans*-octahedral structures of several pyridine adducts of the type $MX_4.2py$ where MX_4 = SiF_4, $SiCl_4$, $GeCl_4$, $SnCl_4$, $SnBr_4$, $SeCl_4$, and $PbCl_4$ (2). In group IV, tin tetrahalide is unique in the formation of *cis* adducts (3); a *cis* adduct of a silicon or germanium tetrahalide involving monodentate ligands has yet to be demonstrated.

While crystallographic data must often be reverted to for conclusive proof of a given structure, vibrational spectroscopy can, in principle, be used to differentiate between a *cis* and a *trans* stereochemical configuration. Thus, a *trans* (D_{4h}) molecule should show two metal–halogen stretching frequencies in the Raman effect (the totally symmetric a_{1g} mode and the "antiphase" b_{1g} mode) and one in the infrared (the asymmetric e_u mode). In contrast, the *cis* (C_{2v}) molecule should show four such frequencies, two of which will be strong in the Raman spectrum but weak in the infrared (a_1 modes), and two of which will be strong in the infrared spectrum but weak in the Raman (b_1 and b_2 modes). (See Fig. 1.)

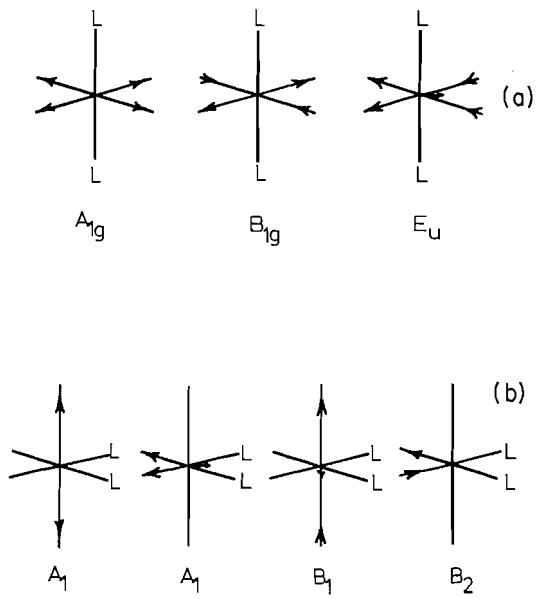

FIG. 1. (*a*) ν(M—X) modes of an $MX_4.2L$ complex having D_{4h} symmetry. (*b*) ν(M—X) modes of an $MX_4.2L$ complex having C_{2v} symmetry.

Trimethylphosphine has been shown to form 1:2 adducts with some group IV tetrahalides (4–6), and the vibrational spectra of these $MX_4.2PMe_3$(MX_4 = $SiCl_4$, $SiBr_4$, $GeCl_4$, and $SnCl_4$) compounds have been reported (5). The close similarity of the spectra and the observation of the typical D_{4h} spectral pattern of metal–halogen stretching frequencies (two Raman active and one infrared active) in the spectra have led Beattie and Ozin (5) to assign a *trans* stereochemistry to this system. Blayden and Webster (7) have recently confirmed this assignment with an X-ray study of $SiCl_4.2PMe_3$. In spite of the excellent vibrational data, the complexity of the spectra of molecules of this size precludes an unambiguous assignment of many fundamental modes.

The purpose of the present study is to investigate more thoroughly the spectra of these adducts using isotopic substitution as a means of conclusively identifying all skeletal stretching modes, particularly the metal–phosphorus vibrational frequencies.

Experimental

Silicon tetrachloride, silicon tetrabromide, germanium tetrachloride, and tin tetrachloride were purified by multiple distillation *in vacuo* in all-glass systems. Trimethylphosphine was dried over molecular sieve which had been heated to *ca* 300 °C under vacuum for at least 24 h. It was subsequently stored over calcium hydride in a break-seal ampoule. Perdeutero-trimethylphosphine was prepared by the method of Mann and Wells (8) substituting deuterated methyl iodide for methyl iodide (9) and isolating the ligand as the silver iodide derivative $[AgI.PMe_3]_4$ (10). The ligand was regenerated under vacuum by gentle heating, collected in a cold trap, and dried over molecular sieve as previously described.

Solvents (diethyl ether, benzene) were dried by reflux over calcium hydride for at least 24 h, followed by vacuum distillation onto more CaH_2 over which it was stored.

All reagents were thoroughly dried, outgassed, and vacuum distilled into break-seal ampoules prior to use. All glass apparatus was used throughout to avoid grease contamination.

The trimethylphosphine adducts (with the exception of $SnCl_4.2PMe_3$) were prepared at −78 °C under vacuum by distilling an excess of trimethylphosphine into a reaction flask containing an ether solution of the appropriate acceptor. The adduct precipitated immediately. After the reaction mixture had been allowed to come to room temperature and to interact for a period of time (at least 1 h), the ether solvent together with excess volatile reagent was removed by distillation. Bistrimethylphosphine tin tetrachloride was similarly prepared by direct interaction of tin tetrachloride with an excess of trimethylphosphine with subsequent removal of excess free ligand.

Solutions of $SiCl_4.2PMe_3$ and $SiBr_4.2PMe_3$ in benzene were prepared *in vacuo* for spectroscopic examination. Ampoules were then opened in a dry-box where the solutions were immediately transferred to infrared cells just before the spectrum was run. Nujol (Na dried) mulls were also prepared in the dry-box using standard techniques. $GeCl_4.2PMe_3$ and $SnCl_4.PMe_3$ were found to be insoluble in common covalent, noncoordinating solvents.

Raman spectra were recorded with a Spex 1401 double-spectrometer using argon-ion laser (4880 Å) excitation, while infrared spectra were obtained with a Perkin–Elmer 180 spectrometer with the use of high density polythene sample plates.

The computer programs used for the calculations of the vibrational spectra are based on those of Schactschneider's GMAT, FMAT, and EIGV and were run on an IBM 7094 computer system.

Results and Discussion

The total deuteration studies using $P(CD_3)_3$ remove any ambiguity in the assignment of the metal–halogen stretching frequencies of these adducts. Two low frequency Raman bands and one degenerate high frequency infrared band are readily recognized as the typical spectral pattern ($e_u + a_{1g} + b_{1g}$) of a formally D_{4h} *trans*-octahedral molecule (assuming free rotation of the ligands in solution). The frequencies of these bands are comparatively unaltered by isotopic substitution. The totally symmetric stretching mode generally gives the strongest line in the Raman spectrum and in solution it is polarized.

Metal–halogen stretching frequencies

Compound	ν(MX) anti	sym	asym	ν_1 (MX_4)*
$SiCl_4.2PMe_3-h_9$	234	295	416/387	429
$SiBr_4.2PMe_3-h_9$	140	204	323	249
$GeCl_4.2PMe_3-h_9$	225	267	285/251	397
$SnCl_4.2PMe_3-h_9$	235	269	291/272	368

*Reference 11.

For the tetrachloride adducts, this band is found to lie some 100–130 cm^{-1} below the ν_1 band of the parent compound. Qualitatively, this is indicative of a substantial weakening of the metal–halogen bond as a result of the increased electron density on the central metal atom when two donor ligands are coordinated. This is an expected trend which is also reflected in the increase in the length of the M—X bond (2.25 Å in $SiCl_4.2PMe_3$ (7) as compared to 2.02 Å in $SiCl_4$ (12), for instance).

It is interesting to note the relative constancy of position of the symmetric and antiphase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

modes through the tetrachloride series. The position of the asymmetric frequency on the other hand varies considerably since this mode involves movement of the central metal atom. The asymmetric stretching mode is doubly-degenerate (e_u symmetry) in a formal D_{4h} system but the degeneracy is removed in the solid state where the site symmetry (in the crystal) is C_{2h} (7). This explains the observation of a strong doublet for this e_u mode in the solid state spectra of all four adducts. Where spectra can be obtained from solution, this doublet collapses into a broad singlet which is the strongest absorption in the infrared spectrum.

Considerable difficulty arises when assigning the symmetric metal–phosphorus stretching vibration. This band is typically found at low frequencies in the region of the skeletal deformational modes which are subject to extensive coupling with ligand deformations of the same symmetry. (See calculations.) As a result, total deuteration produces a shift of all frequencies in this region. To circumvent this problem, mixed $P(CH_3)_3/P(CD_3)_3$ studies were undertaken in the case of $SiCl_4.2PMe_3$. When the adduct is prepared from a 1:1 mixture of non-deuterated- and per deutero-trimethylphosphine, the metal–phosphorus stretching modes split into 1:2:1 triplets whose components correspond to the three products possible from the reaction. (The Raman spectrum of the $P(CH_3)_3$ and $P(CD_3)_3$ mixture displays no evidence for methyl exchange over a period of time.) Identification of the mode is thus easily accomplished. Its position is relatively constant through the series and compares well with metal–phosphorus stretching frequencies of similar compounds in group III. For example, the ν_{sym}(In—P) band is assigned from single crystal Raman studies to the band at 135 cm^{-1} in $InCl_3.2PMe_3$ (13) and the ν_{sym} (Al—P) mode is probably the 133 cm^{-1} band in $AlCl_3.2PMe_3$ (14). The metal–nitrogen mode is also observed at low frequencies in similar nitrogen-donor adducts (15).

Metal-phosphorus stretching frequencies

Compound	ν(M—P)	
	sym	asym
$SiCl_4.2PMe_3-h_9$	158	478
$SiBr_4.2PMe_3-h_9$	156	462
$GeCl_4.2PMe_3-h_9$	146	380
$SnCl_4.2PMe_3-h_9$	157	354

Other workers have recognized the comparative invariance of the ligand modes in a variety of adducts as a means of separating them from skeletal modes (16). Deuteration of the ligand confirms previous assignments of these modes.

$GeCl_4.2PMe_3$	347 (306)	—†	279 (238)
$SnCl_4.2PMe_3$	338 (300)	—†	258 (223)

*Figures in parentheses refer to perdeutero-species.
†Hidden under $\nu(MCl)_{asym}$.

With two trimethylphosphine ligands *trans* to each other in a complex having C_{2h} symmetry, the representation of *ligand* stretching and deformational modes is

$$\Gamma^{C_{2h}}(l, \delta) = 2(2a_g + b_g + a_u + 2b_u)$$

where $l \equiv \Delta l \equiv$ P—Me bond stretching; $\delta \equiv \Delta\delta \equiv PMe_3$ deformation. If the ligands are considered to rotate freely about the metal–phosphorus bond, the adduct may be regarded as a formally D_{4h} symmetry type. The above representation then becomes

$$\Gamma^{D_{4h}}(l, \delta) = 2(a_{1g} + a_{2u} + e_g + e_u)$$

where correlation has been along a C_2' axis of the D_{4h} molecule. Thus, there are four fundamental modes of vibration, two Raman active and two infrared active, associated with both stretching and deformational motions of the ligands.

The four stretching modes which are typically found in the region of 670–760 cm^{-1} undergo spectral shifts of *ca.* 60–70 cm^{-1} on deuteration. In the deformation region, three of the four

possible modes can be identified. These typically shift 30–40 cm^{-1} with isotopic substitution of hydrogen. The e_g-type deformation appears to be split in both $SiCl_4.2PMe_3$ and $SiBr_4.2PMe_3$ and may conceivably be so in $GeCl_4.2PMe_3$ and $SnCl_4.2PMe_3$ also, with one-half of the doublet hidden in the $\nu(M—X)_{asym}$ band. Raman spectra of the former two in benzene solution indicate that here the degeneracy of the mode remains unperturbed. This supports the assignment of both solid state bands to this mode.

There are, in addition to the afore-cited modes, two ligand "rocking" vibrations. Since these normally occur in the range 220–180 cm^{-1} and are usually highly mixed with skeletal deformations, they will not be discussed at this point.

$SiCl_4.2PMe_3$

The spectra of this adduct, in the solid state and in benzene solution, are to be found in Tables 3 and 4, respectively. Table 5 contains the calculated and observed spectra together with the approximate description of each mode.

Three sets of experiments were performed including spectroscopic examination of $SiCl_4.2PMe_3$ which had been prepared from (*a*) nondeuterated-trimethylphosphine, (*b*) perdeuterotrimethylphosphine, and (*c*) a 1:1 mixture of nondeuterated- and perdeuterotrimethylphosphine. The total deuteration experiment enabled a complete separation of ligand and acceptor modes in the region above 200 cm^{-1}, although little information was obtained for modes below this range due to the high degree of mixing as previously described. The silicon–chlorine stretching frequencies are easily identified as those which are unperturbed by deuteration.

The Raman spectrum of bis(perdeutero-trimethylphosphine) silicon tetrachloride (Fig. 2) illustrates a classic case of Fermi resonance (17) and provides a rare example for a halide complex in which the strongest band in the spectrum is *not* the totally symmetric metal–halogen stretching vibration.

The mixed nondeuterated/perdeutero-trimethylphosphine experiment has been briefly described in the preceding section. Preparation of $SiCl_4.2PMe_3$ from a 1:1 mixture of PMe_3-h_9 and PMe_3-d_9 will yield a mixture of the adducts $SiCl_4.2(PMe_3\text{-}h_9)$, $SiCl_4.(PMe_3\text{-}h_9).(PMe_3\text{-}d_9)$, and $SiCl_4.2(PMe_3\text{-}d_9)$ in a statistical ratio of 1:2:1. The spectrum of this mixture (hereafter denoted as $SiCl_4.2PMe_3$-h_9/d_9) will thus be a summation of the spectra of $SiCl_4.2PMe_3$-h_9 and $SiCl_4.2PMe_3$-d_9 with additional bands which belong uniquely to $SiCl_4.(PMe_3\text{-}h_9).(PMe_3\text{-}d_9)$.

The Si—P stretching modes are very strongly coupled with the result that the symmetric and

asymmetric levels of the $SiCl_4.(PMe_3\text{-}h_9).(PMe_3\text{-}d_9)$ adduct lie between the respective levels of the $SiCl_4.2PMe_3\text{-}h_9$ and $SiCl_4.2PMe_3\text{-}d_9$ species. Thus, the asymmetric silicon–phosphorus stretching band is a *triplet* in the spectrum while the symmetric stretching band is most certainly an unresolved *triplet* centered midway between the corresponding bands of the h_9 and d_9 adducts. This is convincing evidence for the assignment of the band at 158 cm^{-1} to the symmetric silicon–phosphorus stretching frequency.

$SiBr_4.2PMe_3$

The vibrational spectra of nondeuterated- and bis(perdeutero-trimethylphosphine) silicon tetrabromide have been examined and are found in Tables 6 and 7. Calculated and observed spectra appear together in Table 8 with the most probable description of each mode. Considered in conjunction with the assigned spectrum of $SiCl_4.2PMe_3$, the assignment of the fundamental stretching frequencies is quite straightforward. The totally symmetric silicon–bromine stretching frequency is the polarized band at 204 cm^{-1}, the strongest in the Raman spectrum. The asymmetric mode is split in the solid state but coalesces to a singlet at 338 cm^{-1} in benzene solution. Four bands appear in close proximity in the lower region of the Raman spectrum of this adduct and all experience small shifts on deuteration. The strongest of these bands occurs at 156 cm^{-1}. In cognizance of the position of the silicon–phosphorus stretching frequency in $SiCl_4.2PMe_3$-h_9, this band is assigned to that mode in $SiBr_4.2PMe_3$-h_9.

$GeCl_4.2PMe_3$

The striking similarity of the spectrum of this adduct to that of $SiCl_4.2PMe_3$ strongly suggests that a *trans*-octahedral configuration is maintained. (See Tables 9 and 10.) The two strong peaks at 285 and 251 cm^{-1} in the infrared spectrum are assigned to the asymmetric germanium–chlorine stretching mode where the degeneracy has been removed in the solid state.

In the Raman spectrum, the totally symmetric germanium–chlorine stretching mode is the very intense band at 267 cm^{-1} while the antiphase mode is the medium intensity band at 225 cm^{-1}. Neither of these bands shift on deuteration. Conversely, the peak at 145 cm^{-1} shifts to 138 cm^{-1} in the perdeutero analog and is as-

signed to the symmetric germanium–phosphorus stretching frequency. An alternative assignment is the band at 172 cm^{-1}, but in light of the position of the corresponding mode in the silicon analogs, this is probably somewhat higher than expected.

$SnCl_4.2PMe_3$

The spectra of this adduct and its perdeutero-analog are found in Tables 11 and 12. The intense band at 269 cm^{-1} is assigned to the totally symmetric "breathing" mode of the assumed square planar $SnCl_4$ residue. As in the previous three adducts, the asymmetric mode appears to be split in the solid state, giving an intense doublet at 291 and 272 cm^{-1}, but the insoluble nature of the compound prevents confirmation of this assignment.

An examination of the Raman spectrum (Table 12) discloses bands at 157 and 123 cm^{-1}, either of which may be assigned to the symmetric tin–phosphorus stretching frequency. Although an unequivocal assignment is impossible, calculations support assignments to the 157 cm^{-1} band. The other band is preferably assigned to a deformational mode.

The asymmetric tin–phosphorus stretching mode is assigned to the infrared band at 354 cm^{-1} which shifts to 323 cm^{-1} on deuteration.

As in the case of the $GeCl_4.2PMe_3$ adduct, a correlation of calculated and observed frequencies has been made in Table 12.

Conclusion

We may summarize the vibrational data for the 1:2 trimethylphosphine complexes of the group IV tetrahalides, by stating that deuteration studies using $P(CD_3)_3$ and mixed ligand studies using $P(CH_3)_3/P(CD_3)_3$ have proven to be of considerable value in helping to distinguish internal ligand modes, halogen stretching modes, and metal–phosphorus stretching modes. In this way we have been able to assign with a reasonable degree of certainty, the symmetric and asymmetric metal–phosphorus stretching modes for most of the complexes studied and from the frequencies, calculate the respective k_{MP} band stretching force constants.

Normal Coordinate Analysis

Normal coordinate analysis of the $MX_4.2PMe_3$ adducts and their perdeutero-analogs were performed in C_{2v} symmetry using the Wilson **F–G** matrix method. Bond lengths and angles from the crystal structure were used for $SiCl_4.2PMe_3$ (7). Bond lengths of the square-planar MX_4 residue of the other adducts were obtained by multiplying the bond length in the parent molecule (18–20) by a factor corresponding to the increase in the Si—Cl distance upon complex formation. With the methyl group considered as a point mass, the coordinated PMe_3 structural parameters of $SiCl_4.2PMe_3$ were assumed in all cases. Likewise, the metal–phosphorus bond length was taken to be the sum of the appropriate covalent radii (21). This, in fact, corresponded exactly with the distance found in the crystal structure in the case of $SiCl_4.2PMe_3$ (see Table 1).

Internal coordinates are defined on the following pages. There are 33 normal modes of vibration if the methyl groups are considered as point masses where

$$\Gamma_{vib} = 11A_1 + 5A_2 + 8B_1 + 9B_2$$

Force fields of chemically and structurally related species were used where they existed. A scheme of 13/16 (PCl_6^-) was chosen for $SiCl_4.2PMe_3$ (22). Since a similar force field was not available for $SiBr_4.2PMe_3$, force constants were obtained from a (3/4) (PCl_6^-) scheme by multiplying the stretch and stretch–interaction constants by the factor $f_r(SnBr_6^{2-})/f_r(SnCl_6^{2-})$; and the bend and bending–interaction constants by the factor $f_\alpha(SnBr_6^{2-})/f_\alpha(SnCl_6^{2-})$ (23). The force fields of $GeCl_6^{2-}$ and $SnCl_6^{2-}$ (22) were transferred directly to $GeCl_4.2PMe_3$ and $SnCl_4.2PMe_3$, respectively. Only minor adjustments in some interaction constants of $SiBr_4.2PMe_4$ and

$GeCl_4.2PMe_3$ were necessary. Metal–phosphorus stretching force constants were chosen to reproduce observed frequencies and were found to be in the range 1.1–1.4 mdyn/Å (see Table 2). The excellent fits which these force fields produce exonerate the rather arbitrary nature of such a transference. Nevertheless one should not attach too much significance to the force fields *per se*.

The transference scheme and force constants are shown below.

Preparation, Infrared and Raman Spectra, and Stereochemistries of Pentacoordinate Trimethylphosphine Complexes, $MX_4.P(CH_3)_3$ and $MX_4.P(CD_3)_3$ where M = Ge or Sn and X = Cl or Br

D. K. FRIESON AND G. A. OZIN[1]

Lash Miller Chemistry Laboratories and Erindale College, University of Toronto, Toronto, Ontario

Received January 5, 1973

The 1:1 adducts $MX_4.PMe_3$ (M = Ge or Sn; X = Cl or Br) are prepared by recrystallization of the respective 1:2 complexes from excess MX_4 acceptor. Solid state infrared and Raman Spectra and X-ray powder photographs suggest that these adducts are all trigonal bipyramidal with the ligand in an axial position. Normal coordinate calculations in C_{3v} symmetry (axial ligand) and C_s symmetry (equatorial ligand) support this assignment. The rather high ν(MP) frequencies indicate unusually strong metal–phosphorus donor bonds in these compounds.

Les produits d'addition 1:1 $MX_4.PMe_3$ (M = Ge ou Sn; X = Cl ou Br) ont été préparés par recristallisation des complexes 1:2 correspondants à partir d'un excès de MX_4 accepteur. Les spectres infrarouge et Raman (état solide) et les photographies obtenues par rayons-X (poudre) suggèrent que ces composés d'addition possèdent tous une structure du type bipyramide trigonale avec le coordinat en position axiale. Des calculs en coordonnées normales pour une symétrie C_{3v} (coordinat axial) et une symétrie C_s (coordinat équatorial) sont en accord avec cette attribution. Les fréquences ν(MP) assez élevées sont généralement caractéristiques des liens forts donneurs métal–phosphore de ces composés.

Introduction

The vibrational spectra and stereochemistry of 1:2 adducts of trimethylphosphine with certain Group IV tetrahalide acceptor molecules have recently been discussed and their stability noted (1, 2). A number of other 1:2 triorganyl phosphine adducts with $SnCl_4$ have also been reported and their vibrational (2*a*, 2*b*) and Mössbauer (2*b*) spectra discussed. In all cases, *trans*-octahedral $MX_4.2L$ stereochemistries have been assigned to the 1:2 adducts. 1:1 Complexes of $SnCl_4$ with triphenylphosphine and tricyclohexylphosphine have been prepared (2*b*) but their vibrational spectra and structures as yet remain unassigned. Trimethylphosphine also tends to favor the formation of 1:2 complexes with the Group III (3) and the Group V trihalides (4, 5), the notable exception being $GaCl_3.PMe_3$ (3). The 1:2 trimethylphosphine complex of gallium trichloride is not known. These observations are to be compared with the tendency of trimethylamine to form stable 1:2 complexes in Group III (6) but unstable 1:2 and stable 1:1 complexes in Group IV (1, 7). Again gallium trichloride is the exception in Group III, the 1:2 adduct $GaCl_3.2NMe_3$ dissociating easily to $GaCl_3.NMe_3$ when the trimethylamine solvent is removed. $SiCl_4.NMe_3$ is also completely dissociated at room temperature. These trends suggest the possibility of producing the first examples of 1:1 PMe_3 complexes of the Group IV tetrahalides by introducing a small amount of the ligand into a large excess of acceptor solvent. Such experiments have yielded interesting results and are described in this paper.

Experimental

The Group IV tetrahalide reagents MX_4(M = Si, Ge, or Sn and X = Cl or Br) were purified by multiple trap-to-trap distillation *in vacuo*. The trimethylphosphine ligand was prepared and purified as described previously (1). The adducts were prepared *in vacuo* in thick-walled all glass reaction tubes by distilling a small quantity of ligand onto a large excess of the acceptor species at −78 °C. As the reagents warmed and the tetrahalide melted reaction occurred, this reaction tended to be quite sudden and violent and care had to be exercized to control the temperature of the mixture near the melting point of the acceptor.

In the reaction of excess $GeCl_4$ or $SnCl_4$ with PMe_3, the 1:2 product is initially formed. Recrystallization of these products from the excess acceptor at 140 and 100 °C respectively slowly yielded the 1:1 complexes. The Raman spectra of the mixtures was periodically examined and when no further change could be detected, the reaction was taken to be complete. In contrast, the 1:1 adducts of $GeBr_4$ and $SnBr_4$ are formed even in an excess of trimethylphosphine. (There was some evidence for the

formation of $GeBr_4.2PMe_3$ but the adduct proved very unstable and the results could not be reproduced.) For $SiCl_4$ and $SiBr_4$, only 1:2 adducts are formed despite prolonged recrystallization from excess acceptor (1, 2). The *per deutero*-trimethylphosphine analogs of all 1:1 adducts were also prepared. In addition, the known trimethylamine complexes $GeCl_4.NMe_3$ and $SnCl_4.NMe_3$ were made for the purposes of comparison and were identified by their vibrational spectra (8, 9).

The Raman spectra of the solids were obtained with a Spex 1401 Raman spectrometer and Carson argon or krypton ion laser excitation (4880 or 5682 Å) while far infrared spectra were recorded with a Perkin–Elmer 180 spectrometer. Solution data could not be obtained due to the insoluble nature of the compounds.

X-Ray powder photographs of $GeCl_4.NMe_3$, $GeCl_4.PMe_3$, $SnCl_4.NMe_3$, and $SnCl_4.PMe_3$ were obtained using a collimated beam type camera and the Straumanis method of film mounting. Monochromatic X-rays at $\lambda = 1.542$ Å from a copper source were used. Unfortunately these materials gave only low angle reflections so that it was necessary to calculate the Bragg angles on the assumption of uniform and negligible film shrinkage. These data are listed in Table 15.

The adducts were analyzed for total halide content by quantitatively hydrolyzing a known weight of the compound in 0.1 *M* HNO_3 followed by argentiometric titration. The results are shown in the table below. All manipulations were carried out under vacuum or in a dry box which was continuously purged with dried air.

Total halide analysis

	% X	
Adduct	Calculated	Found
$GeCl_4.PMe_3$	48.8	48.7
$SnCl_4.PMe_3$	42.1	42.0
$GeBr_4.PMe_3$	68.3	69.5
$SnBr_4.PMe_3$	62.1	61.6

Results and Discussion

The reaction of PMe_3 with an excess of $SiCl_4$, $SiBr_4$, $GeCl_4$, or $SnCl_4$ invariably produced the six-coordinate complex while the reaction with $GeBr_4$ or $SnBr_4$ always led to the formation of a 1:1 adduct even when the ligand was held in excess. (There was some indication for the formation of the 1:2 complex, $GeBr_4.2PMe_3$, but the results could not be reproduced.) However, when $GeCl_4.2PMe_3$ and $SnCl_4.2PMe_3$ were recrystallized from $GeCl_4$ and $SnCl_4$ at *ca.* 140 °C and *ca.* 110 °C respectively, compounds which analyzed correctly as 1:1 complexes resulted. In contrast 1:1 adducts of $SiCl_4$ and $SiBr_4$ could not be induced to form, despite prolonged recrystallization at temperatures above 150 °C. These latter results agree with observations by Beattie and Ozin (2).

Donor–acceptor compounds of the main groups now abound in the literature. Molecular weight determinations where possible have led most authors recently to favor a monomeric molecular formulation although the validity of such results is open to question due to the strong propensity of these adducts to dissociate in solution (10). Nevertheless, available crystal structure data generally support this contention. Among the known structures are $SiCl_4.2PMe_3$ (11), $GeCl_4.NMe_3$ (12), $SnCl_4.2POCl_3$ (13), and a host of *bis* pyridine adducts $MX_4.2py$ (14) where MX_4 is SiF_4, $SiCl_4$, $GeCl_4$, $SnBr_4$, $SeCl_4$, or $PbCl_4$. While the insoluble nature of the $MX_4.PMe_3$ adducts of this study in common inert solvents precludes accurate molecular weight determinations, the inherent simplicity of the spectra support the assumption that these species also are covalent monomers.

In five-coordinate complexes of this type, structures may be based on either of two possible geometries: the trigonal bipyramid or the square pyramid, each with various possible geometric isomers. Examples of square pyramidal (10 electron valence shell) configurations are extremely rare. (Indeed, to our knowledge, only two species are known to have this geometry: $InCl_5^{2-}$ (15) and $SbPh_5$ (16)). Most five-coordinate structures are based on the trigonal bipyramid and the structures of the $MX_4.PMe_3$ adducts will be discussed in terms of this configuration. Thus, for a 1:1 adduct, two possible isomers exist: the ligand may be in an axial, staggered conformation (5) in which case the adduct has C_{3v} symmetry (where it should be noted that intermediate rotameric conformations of the ligand would reduce the symmetry of the adduct below C_{3v}); or the ligand may occupy an equatorial site giving the molecule formally C_{2v} symmetry if free rotation about the metal–phosphorus bond is assumed and C_s if not (Table 1, Fig. 1).

As most five-coordinate molecules are found to be trigonal bipyramids, similarly most five-coordinate 1:1 adducts are C_{3v} symmetry types. The recent X-ray crystal structure proves this to be the case for $GeCl_4.NMe_3$ (12) while the vibrational spectra of $TiCl_4.PMe_3$ (9) and other $MX_4.NMe_3$ adducts (where MX_4 = SiF_4, $SiCl_4$, $TiCl_4$, or $SnCl_4$) (8, 9) strongly support an axial ligand. The only known exceptions are the $TiCl_4.PH_nMe_{3-n}$ complexes (where n = 1, 2, or 3) in which the vibrational

spectra suggest that the ligand is in an equatorial position (9).

As previously demonstrated (1) metal–halogen stretching vibrations can be identified as those bands which do not shift appreciably upon deuteration of the trimethylphosphine ligand, provided there is not severe coupling with ligand modes of the same symmetry. However, the narrow spectral region in which these bands tend to appear in the complexes studied here, and the appearance of ligand deformational modes in the same region can result in a certain amount of confusion as to which bands shift and which do not. There is also the problem of Raman and infrared coincidences (or near-coincidences) and there authenticity. Inspection of the spectra in Tables 7, 9, 11, and 13 reveals *at least three* bands which may be attributed to ν(MX) modes. These results are not unambiguous in their stereochemical implications although data supplied by X-ray powder photographs of $GeCl_4.NMe_3$, $SnCl_4.NMe_3$ and $SnCl_4.PMe_3$ (Table 15) lend strong support to the C_{3v} model. The recent X-ray crystal structure of $GeCl_4.NMe_3$ (12) has confirmed previous vibrational spectroscopic evidence (8) for an axial ligand (C_{3v} symmetry) and X-ray powder photographs (Table 15) prove $SnCl_4.NMe_3$ and $SnCl_4.PMe_3$ to be isomorphous with this adduct. While isomorphous crystals do not necessarily imply isostructural compounds, it is a highly probable event for chemically related species such as these. Numerous examples in the literature attest to this fact (see for example refs. 17, 18), as indeed does the isostructural pair $GeCl_4.NMe_3$ (12) and $SnCl_4.NMe_3$ (19). It is unfortunate and disquieting that $GeCl_4.PMe_3$ should yield the anomalous result in this respect. Nevertheless, the similarity of the spectra strongly suggest that the $MX_4.PMe_3$ compounds are isostructural and the isomorphicity of the $SnCl_4.PMe_3$ complex with the trimethylamine adducts is taken as evidence of an axial PMe_3 ligand in this series pending a more definitive study using single crystal X-ray techniques.

While metal–halogen stretching vibrations are relatively unperturbed by isotopic substitution, ν(MP) modes tend to shift 10–20 cm^{-1} due to the increased mass of the ligand when it is deuterated. For this reason the high frequency peaks at 536, 421, 537, and 423 cm^{-1} in the spectra of $GeCl_4.PMe_3$, $GeBr_4.PMe_3$, $SnCl_4.PMe_3$, and $SnBr_4.PMe_3$ respectively are assigned to metal–phosphorus stretches. The positions of these bands are indicative of unusually strong metal phosphorus bonds, and force constants of the order of 3.8–4.0 mdyn/Å for $MCl_4.PMe_3$ and 2.3–2.4 mdyn/Å for $MBr_4.PMe_3$ adducts were required to reproduce these frequencies in G.V.F.F. calculations (see later). However it would be dangerous to

attempt to relate these values quantitatively to bond strengths since the frequencies were found to be highly dependent upon interaction force constants in the force field. On the other hand, the effects of the strong donor bonds are reflected in the spectral position of stretching frequencies in the MX_4-residue since one would expect that the added electron density on the central atom should result in a weakening of the metal–halogen bonds. Thus, comparing the ν(GeCl) frequencies in $GeCl_4.PMe_3$ with those in $GeCl_4.NMe_3$ (8) where the *germanium–nitrogen* stretching frequency of 234 cm^{-1} typifies a much weaker dative bond, one finds the germanium–chlorine stretching modes at substantially higher frequencies in the latter complex (305–405 cm^{-1} as compared to 265–235 cm^{-1}).

Up to this point, the spectral analysis has been in terms of a covalent monomeric species. There are, however, two features in these spectra which deserve special mention. The first is the almost identical frequency of the ν(MP) modes in the respective germanium and tin tetrahalide analogs and the second is the magnitude of change in the ν(MP) frequency on passing from chloride to bromide analog. A plausible alternative explanation for this behavior, which seems to suggest a phosphorus–halogen bond, is formulation of the compounds as the products of the oxidative coupling reaction $[MX_3^-][Me_3PX^+]$ known to occur for certain adducts in Group V (5). However, the spectra rule out this possibility and the most reasonable chemical formulation for the Group IV complexes of this study remains the five-coordinate adduct and detailed interpretation of the spectra to follow will be in terms of this configuration.

$GeCl_4.PMe_3$

The solid state Raman and infrared spectra of $GeCl_4.PMe_3$ and its *per deutero*-analog are shown in Table 7. In order to identify the germanium–chlorine stretching frequencies it is necessary to correlate all spectral absorptions of $GeCl_4.P(CH_3)_3$ with those of $GeCl_4.P(CD_3)_3$. Table 7 shows the favored correlation but alternatives will be discussed below.

The most obvious coincidence is the strong Raman and infrared band at 267 cm^{-1}. Clearly unperturbed by deuteration, it is ascribed to a germanium–chlorine stretching mode. Similarly both the 323 cm^{-1} Raman band and the 319 cm^{-1} infrared band belong to ν(GeCl) vibrations. Although these bands are very close, the question arises as to whether they are indeed true coincidences. The 328 cm^{-1} component of the Raman doublet at 323/328 cm^{-1} does shift on deuteration of the ligand and the strong Raman peak at 278 cm^{-1} which appears to be in resonance with the 267 cm^{-1} band is found at 240 cm^{-1} in the spectrum of the deuterated adduct. However, the fate of the Raman band at 290 cm^{-1} is obscure: it could be unaffected by deuteration and appear in the 287 cm^{-1} band of the d_9-adduct in which case it would be a ν(GeCl) mode, or it could shift to 251 cm^{-1} in which case it is a deformation of the ligand. It is precisely the interpretation of this point which renders the spectra somewhat ambiguous for if it is accepted that this is a germanium–chlorine stretch, the spectra would imply the equatorial ligand site. Clearly more information is required.

Inspection of Table 8 will show that G.V.F.F. calculations in both C_{3v} and C_s (formally C_{2v}) symmetry give acceptable agreement with the observed spectrum. It must be noted, however, that an inordinately (and unacceptably) large axial stretch interaction force constant ($f_{dd} \sim 34\%$ of f_d) was required to fit the axial germanium–chlorine stretching frequencies of the C_s model. The C_{3v} force field seems to be more reasonable in this respect. Comparison of the spectrum of $GeCl_4.PMe_3$ with similar adducts (Table 2) also tends to favor an axial ligand. The spectra of the C_{2v} complexes $TiCl_4.PH_nMe_{3-n}$ $n = 1$ or 2, for example, clearly display *four* distinct and well-separated metal–halogen stretching vibrations while the spectrum of the C_{3v} complex $TiCl_4.PMe_3$ (9) resembles $GeCl_4.PMe_3$ with a set of *three* metal–halogen stretching modes in a narrow spectral range. It also displays a rather high frequency ν(TiP) mode. Owing to the substantial weakening of

the germanium–chlorine bonds as a result of the strong dative bond from phosphorus, comparison of the spectrum with $GeCl_4.NMe_3$ (8) is less enlightening but the foregoing considerations suggest $GeCl_4.PMe_3$ be assigned a C_{3v} stereochemistry.

$GeBr_4.PMe_3$

Unlike its tetrachloride analog, this adduct spontaneously forms in an excess of either reactant. The spectra of the deuterated and nondeuterated compounds are listed in Table 9. Germanium–bromine stretching modes characteristically appear at low frequencies and are unperturbed by isotopic substitution of the ligand. The strong Raman band at 295 cm^{-1} is quite obviously a ν(GeBr) mode. Although peaks at 233 cm^{-1} and 329 cm^{-1} are close to the ν_1 and ν_3 modes of free germanium tetrabromide (21), they are also assigned to germanium–bromine stretches in the adduct. The unchanging intensity of these peaks after extensive pumping on the complex by means of a liquid nitrogen trap and also after brief opening of the cell to the atmosphere justifies this assignment.

The infrared spectra are dominated by a very intense broad band centered at *ca.* 200 cm^{-1} which possibly contains two components. If this is so, four ν(GeBr) modes would imply the C_{2v} structure. Calculations in C_s symmetry however lend little support to this proposition for, in spite of an unacceptably large axial interaction force constant ($f_{dd} \approx 33\%$ of f_d), it was impossible to raise the calculated symmetric axial stretch and lower the asymmetric stretch sufficiently to fit observed values. G.V.F.F. calculations using reasonable values of force constants demonstrate that these spectra are best rationalized in terms of a C_{3v} stereochemistry (see Table 10).

Three bands in this region of the spectrum remain unassigned. The weak absorptions at *ca.* 270 cm^{-1} shift to lower frequencies on deuteration and are quite obviously ligand deformations. The strong Raman peak at 246 cm^{-1} appears to shift to 213 cm^{-1}. It is also attributed to a ligand deformational mode, while the medium shoulder at *ca.* 209 cm^{-1} is assigned to a ligand rocking vibration due to its appearance at *ca.* 182 cm^{-1} in the d_9-spectrum (this mode appears at 190 cm^{-1} in $InI_3.2PMe_3$ (3)). The unperturbed modes at 109 and 85 cm^{-1} are clearly skeletal deformations.

The germanium–phosphorus stretching mode in this adduct appears *ca.* 100 cm^{-1} below the analogous mode in $GeCl_4.PMe_3$. If the acceptor strengths of $GeCl_4$ and $GeBr_4$ were comparable one would of course expect to observe similar ν(GeP) frequencies in the two adducts. But clearly, the inability of $GeBr_4$ to form a 1:2 complex with PMe_3 and the comparative ease of formation of the *bis*trimethylphosphine adduct of $GeCl_4$ suggest much weaker Lewis acid properties toward PMe_3 in the tetrabromide. The effect of the weaker dative bond probably explains the lower germanium–phosphorus stretching frequency. The parallel change in the ν(SnP) frequency can be rationalized in a similar fashion.

$SnCl_4.PMe_3$

The spectrum of this adduct, particularly the nondeuterated complex, bears a close resemblance to the spectrum of $SnCl_4.NMe_3$ (19). X-Ray powder photographs show these two compounds to be isomorphous. This lends much support to the interpretation of the spectra on the basis of a C_{3v} stereochemistry, although G.V.F.F. calculations yield equally acceptable agreement with the observed spectrum for both models (see Table 12). As in the case of the C_s symmetry calculation of $GeCl_4.PMe_3$, this analysis however required a rather large (but in this case not unacceptable) axial interaction force constant ($f_{dd} \approx 14\%$ of f_d) to provide a reasonably close fit.

Inspection of the spectra in Table 11 reveals *three* medium to strong bands which do not shift when the ligand is deuterated. These are unequivocally tin chlorine stretching frequencies. There is, however, a fourth peak at *ca.* 350 cm^{-1} which is also relatively unperturbed by deuteration. *A priori*, the vibrational spectra would suggest that the ligand occupies an equatorial site but the fact that the X-ray powder

photographs of $SnCl_4.PMe_3$ and $SnCl_4.NMe_3$ are virtually superimposable and that the vibrational spectra are remarkably similar (see Table 3) favor the opposite conclusion. This band may then be due to splitting of the degenerate asymmetric ν(SnCl) mode, but unfortunately solution data could not be obtained to confirm this assignment.

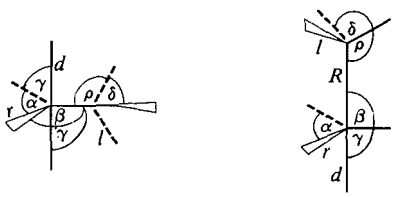
$SnBr_4.PMe_3$

The quality of the spectra of this adduct suffers due to the low frequencies at which the modes of interest appear. Below 200 cm^{-1} the shift of modes associated with motion of the ligand is proportionately less. The spectrum however, is very similar to that of $GeBr_4.PMe_3$.

The 245 cm^{-1} Raman band shifts to 201 cm^{-1} on deuteration and appears to be in resonance with the 180 cm^{-1} band because of the intensity changes observed (see Table 13). The infrared bands at 256 cm^{-1} and *ca.* 192 cm^{-1} are clearly tin–bromine stretching frequencies but the 165 cm^{-1} band is assigned to a skeletal deformation. The Raman band at 180 cm^{-1} is also attributed to a ν(SnBr) mode. Thus, three ν(SnBr) modes can be identified. The unshifted band at 139 cm^{-1} is unreasonably low to be a tin–bromine stretch although calculations in C_s symmetry would place the a'-type axial mode in this region. However, at the same time the a'' mode is calculated over 50 cm^{-1} too high and cannot be lowered without using an unacceptably large interaction force constant. G.V.F.F. calculations (Table 14) in C_{3v} symmetry suggest that this spectrum is best interpreted in terms of this stereochemistry. The band at 139 cm^{-1} is most probably a skeletal deformation mode.

Normal Coordinate Analysis

Normal coordinate analyses were performed on the two possible structures of a monomeric adduct based on a trigonal bipyramidal stereochemistry:



C_s (equatorial ligand) C_{3v} (axial ligand)

the C_{3v} model which contains the ligand in an axial position and the C_s model in which the ligand occupies an equatorial site. Equatorial metal-halogen bond lengths were taken directly from the parent molecules (22–24) while the axial bond lengths were multiplied by the ratio of the axial bond length to the equatorial bond length in molecular PCl_5 (25) to reflect the weaker axial bond known to exist in five coordinate species. The metal-phosphorus interatomic distance was taken as the sum of the covalent radii (26). Bond angles in both models were those of the idealized trigonal bipyramid: the structures were assumed to be undistorted. The structural parameters of the ligand were transferred unaltered from coordinated trimethylphosphine in $SiCl_4.2PMe_3$ whose crystal structure is known (11). These data are listed in Table 4. Internal coordinate definitions are shown below.

Force constants for both the C_s and the C_{3v} models were transferred from the tetrahedral and octahedral species $GaCl_4^-$ and $GeCl_6^{2-}$ for $GeCl_4.PMe_3$, and $InCl_4^-$ and $SnCl_6^{2-}$ for $SnCl_4.PMe_3$ according to the scheme adopted by Beattie and co-workers for the isoelectronic pentachloro-anions (27). For the tetrabromide adducts the tetrahedral force constants of $GaBr_4^-$ and $InBr_4^-$ (28) were initially chosen together with the octahedral force field of $SnBr_6^{2-}$ (29). Since $GeBr_6^{2-}$ is not known, an approximate force field was obtained by multiplying the appropriate $SnBr_6^{2-}$ force constants by the factor $f_{ij}(GeCl_6^{2-})/f_{ij}(SnCl_6^{2-})$. The transference schemes are delineated in Tables 1 and 6. Direct transference in general produced values which were in rather poor agreement with observed frequencies. For $GeCl_4.PMe_3$, a 3/4-scheme was somewhat more successful but, since the equatorial stretching modes were computed too high and the axial modes too low in both models, f_r and f_d were reduced and increased respectively. Interaction force constants were also adjusted to produce an acceptable fit. A satisfactory fit was also obtained for both

models of $SnCl_4.PMe_3$ by an upward adjustment of f_d to effect an increase in the symmetric axial tin–chlorine stretching frequency.

Particular difficulty was encountered in fitting the axial stretching frequencies of the tetrabromide complexes. In the C_s structure of $GeBr_4.PMe_3$, it was necessary to increase the interaction force constant f_{dd} substantially to accomplish a reduction in the asymmetric mode and an increase in the symmetric mode. Agreement is still rather poor, but further increase would make f_{dd} unreasonably large. Distortion of the axial bonds each 15° off the axis did not appreciably alter the frequencies. Similar adjustments were necessary for $SnBr_4.PMe_3$ and for the C_{3v} symmetry models.

Large f_{MP} force constants were required to approximately reproduce observed metal–phos-

Binary Transition Metal Dinitrogen Complexes. Part II. Matrix Infrared and Raman Spectra, Structure, and Bonding of $Pt(N_2)_n$ (where $n = 1$–3)

E. P. KÜNDIG, M. MOSKOVITS, AND G. A. OZIN

Lash Miller Chemical Laboratories, and Erindale College, University of Toronto, Toronto, Ontario

Received January 9, 1973

The products of the cocondensation reactions of Pt atoms with N_2 at 4.2–10 °K are investigated by matrix isolation infrared and Raman spectroscopy and are shown to be binary dinitrogen complexes of the form $Pt(N_2)_n$. Examination of the reaction products in pure $^{14}N_2$, in $^{14}N_2/^{15}N_2$, in dilute $^{14}N_2$/Ar, in $^{14}N_2/^{15}N_2$/Ar as well as $^{14}N_2/^{14}N^{15}N/^{15}N_2$/Ar matrices establishes the stoichiometries of the complexes to be $n = 1$–3. Structural assignments can be made for the complexes $Pt(N_2)$ and $Pt(N_2)_3$ which contain end-on bonded dinitrogen and are found to be similar to the corresponding dinitrogen and carbonyl complexes of nickel and palladium. $Pt(N_2)_2$ appears to be the exception in this series of complexes, for which side-on bonded dinitrogen is proposed.

On the basis of the Cotton–Kraihanzel force field of approximation and the isotope intensity sum rules, isotopic frequencies are computed for the NN stretching modes of the individual complexes and isotopic absorption intensities for $Pt(N_2)_3$ and are found to be in close agreement with the observed values. In the case of $Pt(N_2)$, the scrambled $^{14}N^{15}N$ isotope data establish that the dinitrogen ligand is bonded to the Pt atom in an end-on fashion. On the basis of its unusual spectroscopic behavior $Pt(N_2)_2$ is proposed to have sideways bonded dinitrogen ligands. $Pt(N_2)_3$ in solid α-N_2 is found to be slightly distorted from a regular triangular planar molecule but appears to be regular D_{3h} in solid argon. Calculations show that a substitutional site symmetry of C_2 for $Pt(N_2)_3$ satisfactorily accounts for all the spectral lines observed for the complex in nitrogen. Comparisons are made within the group of binary dinitrogen complexes $M(N_2)_n$ where $n = 1$–3 and with the corresponding binary carbonyl complexes $M(CO)_n$. The relationship between the dinitrogen complexes NiN_2, PdN_2, and PtN_2 and nitrogen chemisorbed on those same metals is discussed.

Les produits de cocondensation d'atomes de Pt avec du N_2 à 4.2–10 °K ont été étudiés à l'aide de la spectroscopie infrarouge et Raman (isolement de la matrice) et se sont révélés être des complexes binaires diazotés du type $Pt(N_2)_n$. L'examen des produits de la réaction dans les milieux $^{14}N_2$ pur, $^{14}N_2/^{15}N_2$, $^{14}N_2$/Ar dilué, $^{14}N_2/^{15}N_2$/Ar ainsi que $^{14}N_2/^{14}N^{15}N/^{15}N_2$/Ar, a fixé la stoechiométrie (n) des complexes égale à 1–3. Des attributions structurales peuvent être effectuées pour les complexes $Pt(N_2)$ et $Pt(N_2)_3$ qui contiennent les groupes diazotés liés aux extrémités et qui, par suite, ressemblent aux complexes correspondant du nickel et du palladium comportant des groupes diazote et carbonyle. Le $Pt(N_2)_2$ semble être l'exception dans cette série de complexes puisque l'on propose pour ceux-ci que les groupes diazotés sont liés de côté.

En se basant sur le champ de force Cotton–Kraihanzel et sur les règles d'additivité des intensités isotopiques, on a pu calculer les fréquences isotopiques pour les modes d'élongation NN des complexes individuellement ainsi que les intensités d'absorption isotopique par le $Pt(N_2)_3$; ces résultats sont en accord avec les valeurs observées. Dans le cas du $Pt(N_2)$, les données se rattachant aux isotopes $^{14}N^{15}N$ mélangés, ont montré que le coordinat diazoté est lié à l'atome de Pt par les extrémités. En se basant sur son comportement spectroscopique inhabituel le $Pt(N_2)_2$ semble posséder des coordinats diazotes liés de côté. Le $Pt(N_2)_3$ dans le N_2 solide semble ne pas correspondre à cause de torsions légères à une molécule planaire triangulaire mais par contre semble être un D_{3h} régulier dans l'argon solide. Des calculs ont montré qu'un site de symétrie C_2 pouvant être substitué, explique assez bien pour le $Pt(N_2)_3$ toutes les bandes spectrales observées pour le complexe dans l'azote. Des comparaisons sont faites à l'intérieur du groupe de complexes binaires diazotés $M(N_2)_n$ où $n = 1$–3 et avec les complexes binaires carbonylés correspondant $M(CO)_n$. On discute de la relation présente entre les complexes diazotés NiN_2, PdN_2, et PtN_2 et l'azote chemisorbé sur ces mêmes métaux. [Traduit par le journal]

Can. J. Chem., 51, 2710 (1973)

Introduction

We have recently shown that the products of the cocondensation reactions of monatomic Ni and Pd vapors with pure N_2 or dilute N_2/Ar mixtures at 4.2–10 °K are binary dinitrogen complexes of the form $Ni(N_2)_n$ and $Pd(N_2)_m$ where $n = 1$–4 and $m = 1$–3 (1). The bonding of the dinitrogen ligand in these complexes was shown to be similar in a number of respects to the coordinated dinitrogen molecule in dinitrogen complexes that are stable at room temperature as well as CO in carbonyls. For example, the

molecular structures of $Ni(N_2)_n$ and $Pd(N_2)_m$ were shown to be similar to the corresponding binary carbonyls $Ni(CO)_n$ and $Pd(CO)_m$. Also the Cotton–Kraihanzel force field approximation (2) and isotope intensity sum rules (3, 4) applied usually to CO in carbonyls, were shown to be equally successful for predicting the frequencies and intensities of infrared active NN stretching modes for coordinated N_2 in binary dinitrogen complexes and their mixed isotopic molecules (1).

As a continuation of our work on the Ni/N_2 and Pd/N_2 systems, we have now investigated the matrix cocondensation reactions of monatomic Pt vapors with N_2 and N_2/Ar at 4.2–10 °K and we find that by and large its behavior mirrors that of Pd in many respects. It nevertheless deviates from the behavior of both the Pd/N_2 and Ni/N_2 systems in some striking instances discussed below (5, 6).

A relationship between NiN_2 and that of N_2 chemisorbed on Ni has also been recently discussed (7) and it is of considerable interest therefore to try to obtain the analogous data for PtN_2 and to compare it with the available infrared data for N_2 chemisorbed on Pt metal (8).

Burdett, Graham, and Turner using similar metal atom – dinitrogen matrix cocondensation reactions, have reported that Ni, Cr, Pt, and Cu can *only* form monodinitrogen complexes of the form MN_2 (9). Our own data for the nickel–dinitrogen system differed markedly from theirs in several respects and necessitated a reappraisal of their data and an interpretation of our data in terms of the four complexes, $Ni(N_2)_n$ (where $n = 1$–4) (1).

For the platinum–dinitrogen system reported here, our matrix infrared data again differ with the corresponding data reported by Turner *et al.* Rather than forming a single complex PtN_2 as proposed by Turner *et al.*, we find that *three* dinitrogen complexes of platinum, $Pt(N_2)_m$ (where $m = 1$–3) are formed.

It is noteworthy that very few dinitrogen complexes of platinum, which are stable at room temperature, have been reported in the literature. The only available data refer to three closely related binuclear complexes of platinum containing dinitrogen, which were reported by Volkov and Volkova and were formulated as containing the linear Pt—N≡N—Pt grouping (10).

Briefly, our technique involves the cocondensation of Pt atoms with N_2 or N_2 in Ar at 4.2–10 °K followed by spectroscopic examination. Matrix infrared and matrix Raman were both used. The latter carries with it the possibility of performing matrix depolarization measurements thereby identifying the totally symmetric vibrational modes (11).

Mixed isotopic matrix gases were also used to help establish the coordination number of the reaction products under different degrees of matrix dilution. In the case of monodinitrogen complexes, the mode of attachment of the dinitrogen to the metal atom, that is, whether end-on or side-on, can be determined from the $^{14}N^{15}N$ isotope data. Finally, warmup experiments were performed which aid in the assignment of the spectral lines to the several species present in the matrix.

Experimental

Monatomic Pt vapor was generated by directly heating either a thin (0.008 in.) ribbon filament of Pt with AC or Pt wire (0.010 in.) wound around a tungsten rod (0.025 in.). The platinum (99.99%) was supplied by McKay Inc., New York, or Imperial Smelting, Toronto. Research grade $^{14}N_2$ (99.99%) and Ar (99.99%) were supplied by Matheson. Isotopically enriched $^{15}N_2$ (99.5%) was supplied by Prochem. A mixture of $^{14}N_2$, $^{15}N^{14}N$, and $^{15}N_2$ in the ratio 1:2:1 was prepared by the conventional technique and the relative concentrations of the isotopic molecules checked by gas phase Raman spectroscopy (Fig. 1).

The furnace used for the evaporation of the metals has been described previously (1). The rate of metal atom depositions was continuously monitored using a quartz crystal microbalance (12). The deposition rate was set such that the probability that a metal atom had another metal atom as a nearest neighbor in either the N_2 or Ar f.c.c.

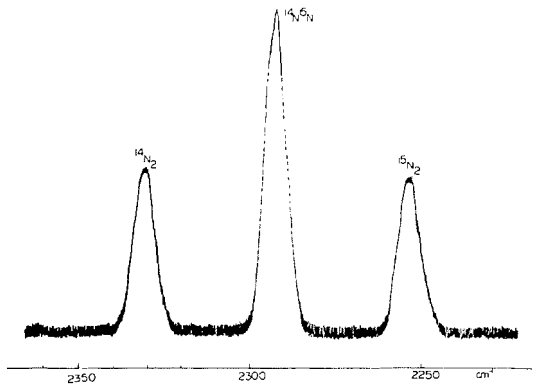

FIG. 1. The gas phase Raman spectrum of a statistical 1:2:1 mixture of $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$ at about 100 Torr pressure.

lattice was approximately 1 in 10^3. Matrix gas flows, controlled by a calibrated micrometer needle valve, were usually in the range 2–8 mmol/h. In the infrared experiments matrices were deposited on a cryotip cooled to either 4.2 or 10 °K by means of an Air Products liquid helium transfer system or a Displex closed cycle helium refrigerator. Spectra were recorded on a Perkin Elmer 180 spectrophotometer. In the Raman experiments the matrices were deposited on a liquid helium cooled (4.2 °K) cryotip. Spectra were recorded on a Spex model 1401 Raman spectrophotometer using Carson argon ion 4880 Å and 5145 Å laser excitation.

Results

Tris(dinitrogen)platinum(0),Pt(N_2)$_3$ in Solid N_2

When platinum atoms are cocondensed with pure $^{14}N_2$ at 10 °K the main feature of the matrix infrared spectrum is a doublet at 2217.1, 2206 cm^{-1} (the 2206 cm^{-1} line being the more intense) with two other very weak lines at about 2177 and 2148 cm^{-1} (Fig. 2*a*). The corresponding matrix Raman spectrum besides the lines belonging to $^{14}N_2$ and $^{14}N^{15}N$ (in natural abundance 0.3%) shows only one strong polarized line at 2258 cm^{-1} (Fig. 3).

When the matrix infrared experiment was repeated using a $^{14}N_2$:$^{15}N_2 \cong 1.33:1$ mixture,

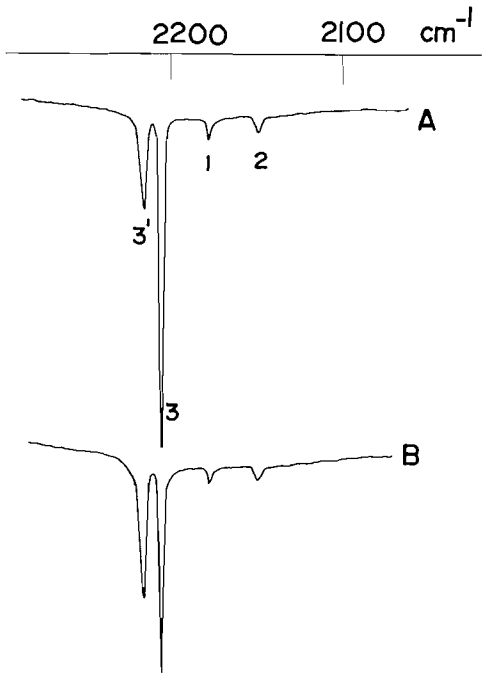

FIG. 2. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with pure $^{14}N_2$: (*A*) at 10 °K and (*B*) after warm-up to 35 °K.

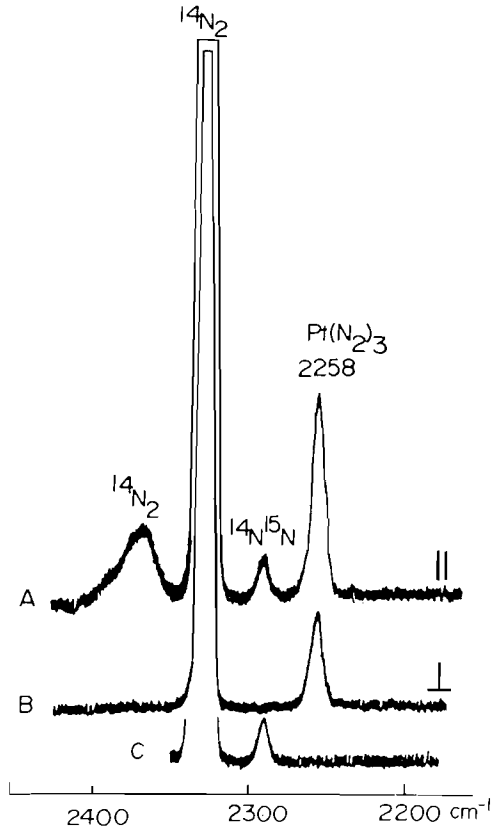

FIG. 3. The matrix Raman spectrum of the products of the cocondensation reaction of Pt atoms with pure $^{14}N_2$ at 4.2 °K: (*A*) parallel polarization, (*B*) crossed polarization and (*C*) after warm-up to 40 °K.

the spectrum shown in Fig. 4 was obtained. The main lines observed at 2217.1 and 2206 cm^{-1} in pure $^{14}N_2$ were replaced by *two* groups of lines at 2239.5, 2234, 2217.1, 2206, and 2151.5, 2145.8, 2141.0, 2132.5 cm^{-1}. In pure $^{15}N_2$ a doublet at 2141.0, 2132.5 cm^{-1} was observed.

The multiplet isotope structure for the Pt/$^{14}N_2$/$^{15}N_2$ reaction is very similar to that previously observed for the analogous Pd/$^{14}N_2$/$^{15}N_2$ reaction and a *prima facie* interpretation suggests the formation of a tris-dinitrogen platinum complex. A detailed analysis of the spectrum, to be described later, proves that the observation of only four new lines when going from $^{14}N_2$ to $^{14}N_2$/$^{15}N_2$ is *only* compatible with a tris-dinitrogen complex, Pt(N_2)$_3$ where the four new lines are associated with the mixed isotopic species Pt($^{14}N_2$)$_2$($^{15}N_2$) and Pt($^{14}N_2$)($^{15}N_2$)$_2$.

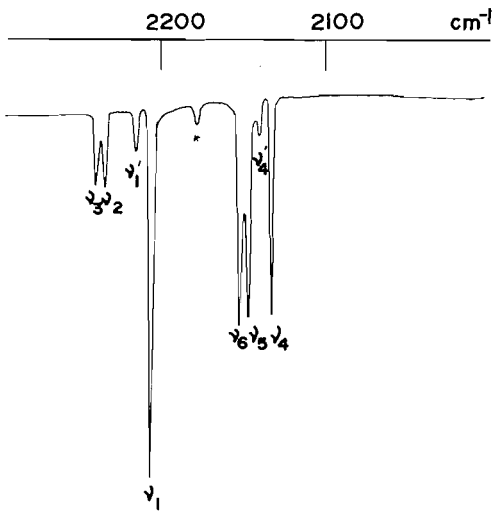

FIG. 4. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with a $^{14}N_2$:$^{15}N_2 \cong 1.33$:1 mixture at 10 °K. The asterisk shows a small amount of $Pt(N_2)$.

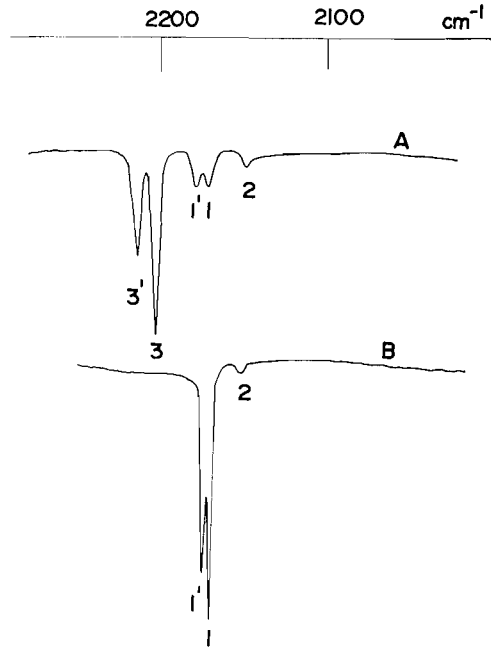

FIG. 5. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with (*A*) $^{14}N_2$:Ar = 1:3 mixture at 10 °K and (*B*) a $^{14}N_2$:Ar = 1:20 mixture at 10 °K.

Bis(dinitrogen)platinum(0),Pt(N_2)$_2$ and Mono(dinitrogen)platinum(0),Pt(N_2) in Solid Argon

When platinum atoms were cocondensed with dilute $^{14}N_2$:Ar = 1:20 mixtures at 10 °K, a strong doublet was observed at 2173, 2169 cm^{-1} in the infrared spectrum; together with a very weak line at about 2150 cm^{-1} (Fig. 5*b*). The corresponding lines observed in the $^{15}N_2$:Ar = 1:10 experiment were at 2104.5, 2095.5, and 2079 cm^{-1}. On warm-up to 35 °K, the absorption at 2150 cm^{-1} (in, for example, $^{14}N_2$:Ar = 1:10) grows in intensity while the doublet at 2173/2169 cm^{-1} gradually decays. Similar results were obtained in more dilute matrices ($^{14}N_2$:Ar = 1:1000) as shown in Fig. 6 which shows the intensity changes of the doublet at 2173/2168 cm^{-1} compared to the absorption at 2150 cm^{-1}, during warm-up to 30 °K. The intensity ratio of the 2173/2168 cm^{-1} components is observed to be approximately equal on deposition at 10 °K but changes during warm-up until at 30 °K, the 2168 cm^{-1} component predominates. The identity of the species giving rise to the new NN stretching modes at 2173/2168 and 2150 cm^{-1} in $^{14}N_2$/Ar matrices will be discussed below.

When the infrared experiment was repeated using a $^{14}N_2$:$^{15}N_2$:Ar = 1:1:100 mixture, the doublet at 2173/2168 cm^{-1} in $^{14}N_2$/Ar becomes a "doublet of doublets" at 2172.8/2168.3 and 2101.0/2096.5 cm^{-1} (Fig. 7*a*). This confirms the assignment of the 2173/2168 cm^{-1} doublet to a mono-dinitrogen complex, $Pt(N_2)$.

When Pt was evaporated into a 1:2:1:200 $^{14}N_2$/$^{14}N^{15}N$/$^{15}N_2$/Ar, aside from the two doublets at 2170/2166 and 2098/2094, a triplet of lines was observed at 2128/2132/2136 with absorbances roughly in the ratio 1:2:1. These are obviously associated with the molecule consisting of a Pt atom bonded to an atom of $^{15}N^{14}N$ and their significance will be discussed below.

Warmup experiments were carefully performed on the $^{14}N_2$:$^{15}N_2$:Ar = 1:1:100 matrix (Figs. 7*b*–7*e*) and show the initial disappearance of the absorptions assigned to $Pt(N_2)$ and the simultaneous growth of lines at 2150.0, 2140.9, and 2078.5, 2069.2 cm^{-1}. The line originally observed at 2150 cm^{-1} in $^{14}N_2$/Ar matrices (after warm-up to 35 °K) thus becomes a *quartet* isotope pattern in $^{14}N_2$/$^{15}N_2$/Ar and confirms its assignment to a bis-dinitrogen platinum complex, $Pt(N_2)_2$.

Prolonged warm-up of $Pt(N_2)_2$ at 35 °K

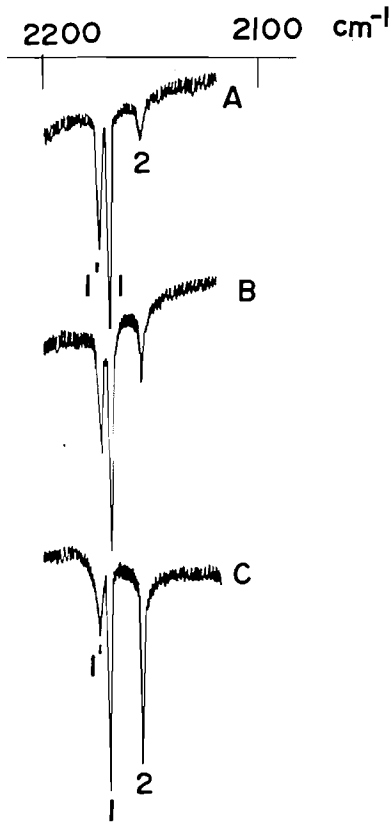

FIG. 6. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with a $^{14}N_2$:Ar = 1:1000 mixture at 10 °K: (*A*) before warm-up, (*B*) warm-up to 25 °K, (*C*) warm-up to 30 °K.

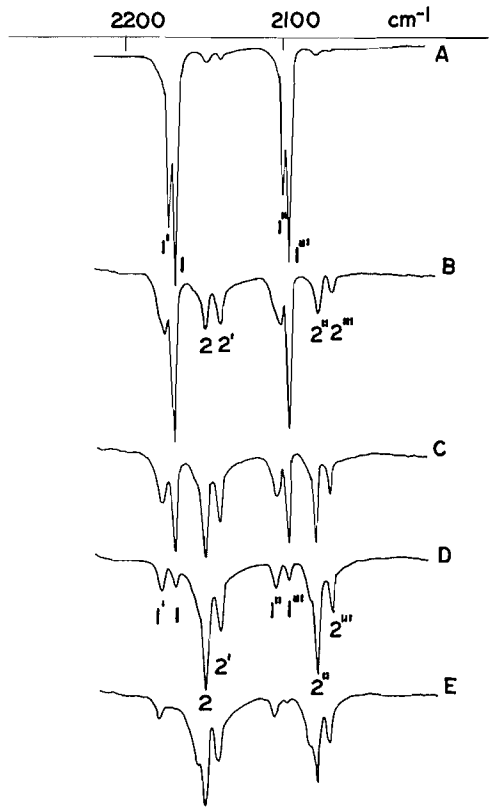

FIG. 7. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with a $^{14}N_2$:$^{15}N_2$:Ar = 1:1:100 at 10 °K: (*A*) before warm-up, (*B*)-(*E*) successive warm-up experiments at 20, 25, 30, and 35 °K.

produced a small splitting of the absorptions at 2150 and 2018.5 (Fig. 7*e*) which is assigned to a matrix splitting.

Discussion

Tris(dinitrogen)platinum(0),Pt(N_2)$_3$

The doublet structure at 2217.1, 2206 cm^{-1} observed for $Pt(N_2)_3$ in solid nitrogen (Fig. 2*a*) resembles in many respects the similar doublet at 2251, 2241 cm^{-1} for $Pd(N_2)_3$ also in solid nitrogen. For example, on allowing the $Pt/^{14}N_2$ cocondensate to warm up to 30–35 °K (Fig. 2*b*) the absorbance of the line at 2217.1 cm^{-1} grows while that of the 2206 cm^{-1} line diminishes, until they are approximately equal in absorbance. In dilute N_2/Ar matrices, which had been deposited at 25 °K and allowed to warm up to 35 °K, the doublet structures at 2217.1/2206 and 2141.1/2132.5 cm^{-1} assigned to $Pt(^{14}N_2)_3$ and $Pt(^{15}N_2)_3$, respectively, appear as single lines at about 2209 and 2138 cm^{-1}, respectively. In the $^{14}N_2/^{15}N_2$ mixed isotope experiment we noted that only *four* new lines appeared in addition to those at 2217.1, 2206 (in $^{14}N_2$) and 2141, 2132.5 (in $^{15}N_2$) cm^{-1}.

If the line at 2217.1 cm^{-1} were an independent species it would have to be a mono-dinitrogen species since it forms a doublet at 2217.1, 2141 cm^{-1} in the $^{14}N_2/^{15}N_2$ experiment. However, the mono-dinitrogen species has been identified at 2173/2168 cm^{-1} in the $^{14}N_2$:Ar = 1:1000 experiment in which *no* line is observed at 2217.1 cm^{-1}.

This behavior parallels very closely that observed for $Pd(N_2)_3$ and on the basis of similar reasoning, we prefer to assign both components

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

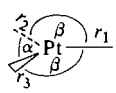
of the 2217.1, 2206 cm^{-1} doublet to the single species $Pt(^{14}N_2)_3$ rather than to two dinitrogen species in the matrix.

One must therefore conclude that the line at 2217.1 cm^{-1} (and its $^{15}N_2$ analog at 2141 cm^{-1}) belongs to $Pt(N_2)_3$, being one of the two components of the E' mode with its degeneracy removed and that, as with $Pd(N_2)_3$, the observed growth and decay behavior of the doublet is an annealing effect. In detail, when first deposited the matrix is irregular, hence the distortion of the $Pt(N_2)_3$ species from D_{3h} is at a minimum. When warmed the N_2 matrix anneals, thereby increasing the distortion of the $Pt(N_2)_3$ from D_{3h} to C_2, the substitutional site symmetry in α-N_2. However, it would appear that the distortion problem can be obviated by depositing Pt atoms into N_2/Ar matrices at 25 °K and then annealing at 35 °K. Under these conditions it is probable that $Pt(N_2)_3$ is a regular D_{3h} triangular planar molecule.

Frequency and Intensity Calculations for $Pt(N_2)_3$

We have recently shown that the method of Bor (3) and Haas and Sheline (4), used for calculating the effect of $^{13}C^{16}O/^{12}C^{18}O$ isotopic substitution on the relative intensities of the infrared bands of metal carbonyls, can also be applied successfully to $^{14}N_2/^{15}N_2$ isotopic substituted dinitrogen complexes of Ni and Pd (1) and that the Cotton–Kraihanzel force field approximation (2) usually applied to carbonyls is equally applicable to binary dinitrogen complexes. We therefore use an identical approach to that previously outlined for $Pd(N_2)_m$ where $m = 0$–3 to calculate the intensities and frequencies of the mixed isotopic species $Pt(N_2)_m$.

Using the notation outlined below:



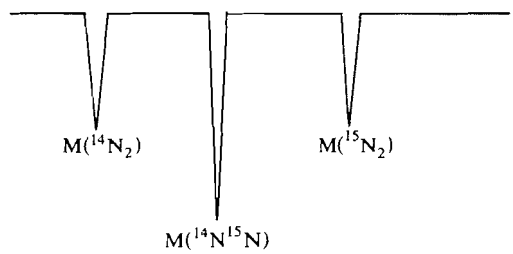
where f_{rr} is associated with α and f_{rr}' with β and the C_2 axis is taken collinear with r_1. The force constants for the $Pt(N_2)_3$ molecules were calculated by applying a least squares analysis to the observed frequencies assuming the Cotton–Kraihanzel force field simplification. The calculated and observed frequencies and force constants are shown in Table 1.

The intensity calculations were performed on the basis of a regular trigonal planar, rather than a C_2 molecule since it was felt that *before* warm-up the former structure represented the molecule more accurately than the latter. The results of the intensity calculations are also shown in Table 1. The agreement is quite good and when taken with the excellent correspondence of the observed and calculated NN stretching frequencies, provides convincing evidence for the structural and vibrational assignments and favors a C_2 substitutional site symmetry for $Pt(N_2)_3$ in solid α-N_2 (13). This rationale is given additional support by the close agreement between the observed and calculated intensity relationship of the split E' NN stretching modes of $Pt(^{14}N_2)_3$ as observed after warm-up when full C_2 symmetry is assumed (see Table 1).

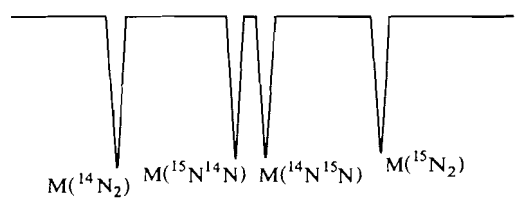
Mono(dinitrogen)platinum(0),$Pt(N_2)$

The Mode of Attachment of the Dinitrogen Ligand to Platinum and the Cause of the Doublet Splitting 2173/2168 cm^{-1}

The mode of attachment of N_2 to a metal atom in MN_2 can be shown to be either end-on or side-on by using metal atom cocondensation reactions with statistical mixtures of nitrogen isotopes $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$ = 1:2:1 diluted in Ar (7). The expected patterns of NN absorptions are shown below.



For side-on bonded N_2 three approximately equally spaced lines with absorption intensities in the ratio 1:2:1 are expected. This pattern has been observed for CoN_2 (14).



For end-on bonded dinitrogen four lines with a closely spaced central doublet are expected where

the absorption intensities of the four lines are equal. This pattern has been observed for NiN_2 (1, 7) and by Shilov and co-workers (15) for $[Ru(NH_3)_5N_2]^{2+}$.

The central doublet for end-on bonded N_2 arises from the non-equivalence of the mixed isotopic species $M—^{14}N\equiv^{15}N$ and $M—^{15}N\equiv^{14}N$.

In the case of Pt the interpretation of the scrambled isotopic results is complicated slightly by the matrix split of the NN absorption associated with the $Pt(N_2)$ species. Thus the type of bonding of the N_2 to the Pt does not immediately follow from the $^{14}N_2/^{14}N^{15}N/^{15}N_2$/Ar with Pt experiments. This necessitates the following analysis.

The two components of the doublet at 2173/2168 may in turn arise from two end-on bonded $Pt(N_2)$ species, two side-on bonded $Pt(N_2)$ species or one end- and one side-on bonded $Pt(N_2)$ species. The "difference" between the two $Pt(N_2)$ species is likely a multiple trapping site effect. Assuming these four possible causes for the 2173/2168 cm^{-1} doublet labeled below for convenience

(*iv*)	2173	(e)	A
	2168	(e′)	B

where e, e′ = end-on bonded dinitrogen, s, s′ = side-on bonded dinitrogen, the patterns that one would expect to observe in the $Pt/^{14}N^{15}N$ region (where the splitting of the $Pt^{14}N^{15}N/Pt^{15}N^{14}N$ is of the same order as the matrix splitting, that is, approximately 4 cm^{-1}) are shown in Fig. 8[1] for each of the four possible situations. Only the pattern corresponding to case (*iv*) matches that observed experimentally, hence both components 2173 and 2168 cm^{-1} are associated with end-on bonded dinitrogen in $Pt(N_2)$. If $Pt(N_2)$ may be assumed to be a linear triatomic molecule, one can in principle obtain from each of the two sets of four lines associated with each of the two $Pt(N_2)$ species (A and B) the three stretching force constants f_{NN}, f_{PtN} and $f_{PtN,NN}$. In practice one finds that the near linear dependance of the four equations relating the N—N stretching fundamental to the atomic masses and force constants together with the error in the position of the lines associated with the $Pt/^{14}N^{15}N$ molecules makes it impossible to determine the values of the three force constants unambiguously. The interdependance of f_{PtN} and $f_{PtN,NN}$ is especially marked and reasonable fits could be obtained with $f_{PtN,NN}$ anywhere in the range 0 to 0.5 mdyn/Å. Accordingly we report in Table 3 the force constants calculated on the basis of the simple valence force field approximation ($f_{PtN,NN} = 0$).

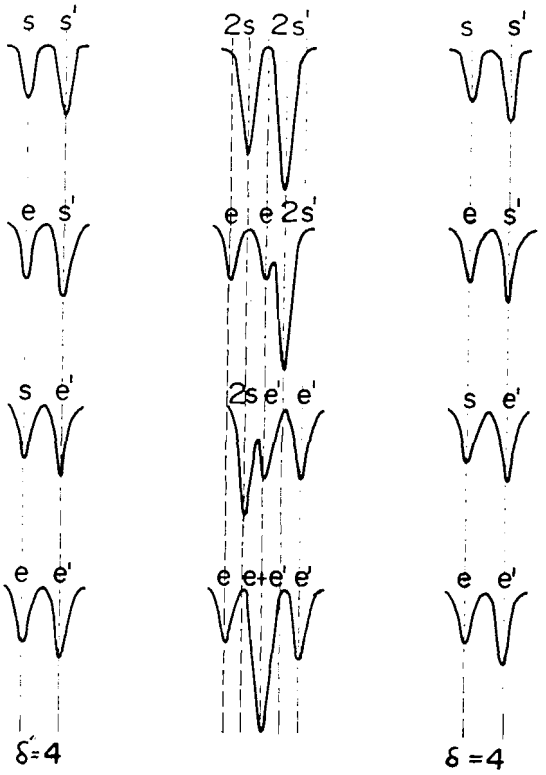

FIG. 8. Schematic representation of the isotope patterns expected for the $Pt(N_2)$ molecule when using statistical mixtures of nitrogen isotopes $^{14}N_2:{}^{14}N^{15}N:{}^{15}N_2 = 1:2:1$ in argon (s, s′ = side-on and e, e′ = end-on bonded dinitrogen; see text).

[1]The 2 in 2s and 2s′ of Fig. 8 is meant to indicate the expected overlap between the isotope lines of side-on (s or s′) bonded $Pt^{14}N^{15}N$ and $Pt^{15}N^{14}N$.

Bis(dinitrogen)platinum(0),Pt(N₂)₂

The characterization of $Pt(N_2)_2$ proved to be difficult in part because appreciable concentrations of the species could only be obtained by careful warmup experiments of $Pt(N_2)$ and in part due to its unusual character vis-à-vis bis-dinitrogen complexes of Pd and Ni. A number of approaches were used to try to maximize the absorptions assigned to $Pt(N_2)_2$. For example, Pt atom depositions with concentrated $^{14}N_2/Ar = 1/3$ mixtures were attempted. These gave mainly $Pt(N_2)_3$ (Fig. 5*a*); however, by changing to $N_2/Ar = 1/20$ the spectra showed

predominantly $Pt(N_2)$ (Fig. 5*b*). Depositions at higher temperatures (25 °K) gave predominantly $Pt(N_2)_3$.

It was noted that matrices which initially contained predominantly $Pt(N_2)$ or comparable amounts of $Pt(N_2)$ and $Pt(N_2)_2$, upon warmup, showed the growth of the absorption assigned to $Pt(N_2)_2$ and the gradual disappearance of $Pt(N_2)$. Using this approach, and $^{14}N_2/^{15}N_2/Ar = 1/1/100$ mixtures, a characteristic *quartet* pattern (Fig. 7) was observed which could be assigned to the NN stretching modes of the isotopic molecules $Pt(^{14}N_2)_n$ $(^{15}N_2)_{2-n}$ where $n = 0$–2.

The corresponding $^{14}N_2/^{14}N^{15}N/^{15}N_2/Ar = 1/2/1/100$ matrix was carefully warmed up to 35–40 °K. The infrared spectrum before warmup shows all of the lines assigned to the mono-dinitrogen isotopic molecules $Pt(^{14}N_2)$, $Pt(^{14}N^{15}N)$, $Pt(^{15}N^{14}N)$ and $Pt(^{15}N_2)$ which gradually decrease in intensity, with the appearance of new absorptions which can be associated with mixed isotopic bis-dinitrogen species, containing the $^{14}N^{15}N$ scrambled molecule (Table 2). Although some band overlaps of mixed isotopic $Pt(N_2)$ and $Pt(N_2)_2$ molecules can be anticipated, these new absorptions can be associated with the isotopic molecules $Pt(^{14}N^{15}N)(^{14}N_2)$[I], $Pt(^{14}N^{15}N)(^{15}N_2)$[II] and $Pt(^{14}N^{15}N)_2$[III].

Frequency and Force Constant Calculations for $Pt(N_2)_2$

The force constants and frequencies were calculated by applying a least squares analysis of the observed isotopic frequencies for the molecules $Pt(^{14}N_2)_n(^{15}N_2)_{2-n}$ assuming the Cotton–Kraihanzel approximation. The calculated and observed frequencies ν_1 to ν_4 for the three molecules $n = 0$–2 are compared in Table 2. The agreement is within 1.7 cm^{-1}. These calculations can apply equally well to a bis-dinitrogen complex containing end-on bonded N_2 (linear $D_{\infty h}$) or side-on bonded N_2 (pseudotetrahedral D_{2d} or square planar D_{2h}). Regardless of the geometry the calculations provide convincing evidence for our vibrational assignment of those lines to a Pt/N_2 complex containing two N_2 molecules.

Although in principle one can decide between the end-on and side-on structures on the basis of $^{14}N_2/^{14}N^{15}N/^{15}N_2/Ar$ mixed isotopic experiments, since one would expect 7 new lines to appear in the $^{14}N^{15}N$ stretching region for the linear molecule while only 3 new lines appear for the D_{2d} and square planar D_{2h} cases, the overlap of lines made the interpretation of the spectra difficult. Thus, although only three (2116, 2113, and 2103 cm^{-1}) new $^{14}N^{15}N$ absorptions with perhaps a fourth very weak feature at 2107 cm^{-1} were observed, we do not believe the data to be of sufficiently high quality to merit drawing any definite conclusions from it.

Concentration Behavior and Warm-up Characteristics of the Binary Dinitrogen Complexes of Platinum

From our experience with binary dinitrogen and carbonyl complexes it has proven possible to relate qualitatively the difference between the force constant of the free ligand and the respective C.K. force constant in a series of closely related compounds to their relative thermodynamic stabilities.

A justifiable assumption would appear to be that ΔH_{ML}, the average metal–ligand bond energy, is given by

$$\Delta H_{ML} \propto k^L - k_{C.K.}{}^L$$

where k^L and $k_{C.K.}{}^L$ are the free ligand and C.K. bond stretching force constants, respectively, and that ΔH_C, the enthalpy of decomposition of the compound to the metal atom and free ligand, is given by

$$\Delta H_C \propto n\Delta H_{ML}$$

where n is the coordination number with respect to the ligand.

This proposal receives support by examining the computed values of ΔH_C for the binary dinitrogen complexes of Ni, Pd, and Pt as a function of n (see Fig. 9 and Table 5). (Although decomposition to the metal atom and free nitrogen also involves the entropy of decomposition which in general would increase with increasing n, we make the assumption that its contribution to the free energy of decomposition is smaller than that of ΔH_C.) The results for Ni and Pd as expected parallel their warm-up behavior and confirm that the most stable complexes are those with the highest stoichiometry, $Ni(N_2)_4$ and $Pd(N_2)_3$. In the case of Pt, however, the data indicate that $Pt(N_2)_2$ is the most stable complex rather than $Pt(N_2)_3$ and one might anticipate some peculiar concentration and warm-up characteristics for the series $Pt(N_2)_n$. For example, upon warm-up, one might have expected the absorption assigned to $Pt(N_2)_2$ to grow at the expense of both $Pt(N_2)$ and $Pt(N_2)_3$.

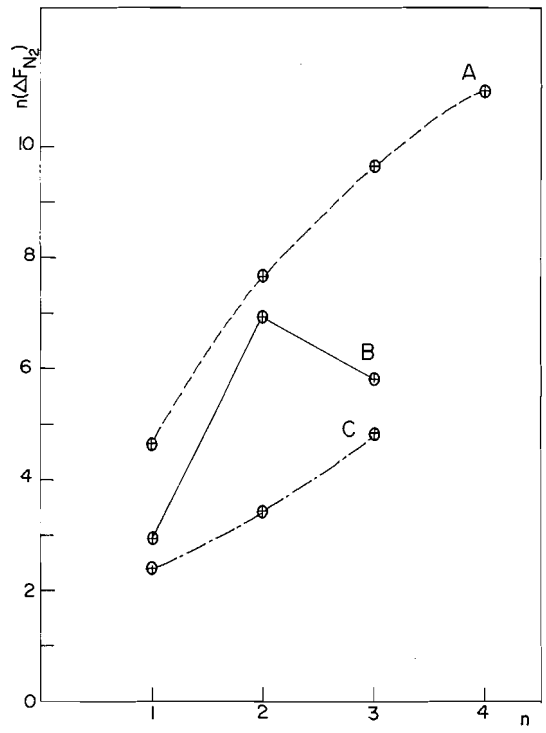

FIG. 9. Graphical representation of ΔH_C (in arbitrary units) as a function of the coordination number n: (*A*), $Ni(N_2)_n$; (*B*), $Pt(N_2)_n$; and (*C*), $Pd(N_2)_n$.

In fact we found that in warm-up experiments performed in $N_2/Ar = 1:10$–$1:100$ mixtures which initially show $Pt(N_2)$ and $Pt(N_2)_2$ but no $Pt(N_2)_3$, the $Pt(N_2)_2$ increased in intensity at the expense of $Pt(N_2)$. Under these conditions $Pt(N_2)_3$, however, was never observed to form by further reaction of $Pt(N_2)_2$ with N_2.

When Pt atoms were deposited into $N_2/Ar = 1:10$ mixtures at higher temperatures (25 °K), appreciable quantities of $Pt(N_2)_3$ and $Pt(N_2)$ were formed and smaller amounts of $Pt(N_2)_2$. Warm-up studies of these matrices at 35 °K show only the growth of $Pt(N_2)_2$ at the expense of $Pt(N_2)$, while the absorption intensity of $Pt(N_2)_3$ did *not* change. Similar results were obtained with more concentrated matrices $N_2/Ar = 1:3$ (Fig. 5*a*) when deposited at 10 °K.

In pure N_2 matrices (Fig. 2*a*) $Pt(N_2)_3$ was always the major product although some $Pt(N_2)$ and $Pt(N_2)_2$ were always formed. Such was not the case in the analogous Pd and Ni experiments.

One possible explanation for this peculiar warm-up behavior is that there is a high activation energy separating the $Pt(N_2)_2$ from the $Pt(N_2)_3$. This implies that in the experiments in which the N_2:Ar ratios are high or in the cases when the ratios were of intermediate values but deposition was carried out at higher temperatures, $Pt(N_2)_3$ forms via a one step tetramolecular reaction and does not decompose upon further warm-up to the $Pt(N_2)_2$. Thus, although $Pt(N_2)_3$ is thermodynamically less stable than $Pt(N_2)_2$, the former is prevented from decomposing to the latter because of the kinetic restraint.

Both of these effects would be in keeping with a $Pt(N_2)_2$ complex which is somehow structurally different from the other two complexes. For instance, by assuming a complex with sideways bonded dinitrogen ligands (either D_{2d} or square planar D_{2h}), both the inordinate thermodynamic stability and the kinetic effect are explained; the former being due to the saturation of the four coordination sites on the Pt while the latter is due to the structural rearrangement that would have to take place when going from a sideways bonded bis-dinitrogen to an end-on bonded tris-dinitrogen platinum complex.

This hypothesis is further strengthened by noting that the stretch–stretch interaction force constant for $Pt(N_2)_2$ is *negative* which makes it unique among the various Ni, Pd, and Pt binary dinitrogen species.

Jones (17) has shown that the CO stretch–stretch interaction force constant in carbonyls is positive. Assuming that his arguments may be carried over to binary dinitrogen complexes, one arrives at the same conclusion for the case of end-on bonded dinitrogen.

Jones' eq. 4 which reads

$$F_{kl} = -F_l(S_l)_k$$

in which F_{kl} is the interaction force constant linking internal coordinate k with l, F_l is the primary force constant associated with internal coordinate l and S_l is the change in internal coordinate l due to a unit positive change in internal coordinate k is almost generally valid and can therefore be used in determining the sign of F_{N_2,N_2} expected for sideways bonded dinitrogen in $Pt(N_2)_2$.

Consider a D_{2d} molecule as shown below (where the diagram is not meant to imply anything about the nature of the NN at PtN bonding).

*For the sake of consistency Cotton–Kraihanzel rather than exact force constants are listed for the mono-dinitrogen complexes.
†See text.

Stretching bond k reduces the π bonding within it and also decreases the π overlap with the metal. The π overlap between the metal and the other dinitrogen (l) is thereby increased, decreasing the π bonding within bond l and increasing internal coordinate l. Hence $(S_l)_k$ is positive and F_{kl} is negative.

Thus a negative N—N stretch–stretch interaction force constant is in keeping with a sideways bonded $Pt(N_2)_2$.

Summary of Structure and Bonding in Binary Dinitrogen Complexes of Ni, Pd, and Pt

Molecular dinitrogen complexes of Ni, Pd, and Pt of the form $Ni(N_2)_n$ (where n = 1–4), $Pd(N_2)_m$, and $Pt(N_2)_m$ (where m = 1–3) can be synthesized and stabilized by metal atom–nitrogen matrix cocondensation methods. These binary dinitrogen complexes have, with the exception of $Pt(N_2)_2$, been shown to be similar to the corresponding binary carbonyl complexes in a number of ways, some of which have been discussed previously (1). The behavior of Pt in the group deserves special attention. We note, for instance (Fig. 9), that the order of stability of the dinitrogen complexes as indicated by the quantity $n(\Delta F_{N_2})_n$ is in general Ni > Pt > Pd and, with the exception of $Pt(N_2)_2$, a monatomic increase in stability (Fig. 9) and C.K. force constants (Table 4) is observed with increasing coordination number. The inverse order observed for Pd and Pt is presumably a manifestation of the lanthanide contraction, and is in keeping with the Allred–Rochow electronegativities for the respective metals, X_{Ni} (1.75) > X_{Pt} (1.44) > X_{Pd} (1.35), concomitant with the synergic σ donor – π^* acceptance mechanism generally used to explain the bonding of dinitrogen to transition metals.

Relationship between PtN_2 and N_2 Chemisorbed on Pt

We have recently suggested that a connection exists between our earlier studies of NiN_2 and N_2 chemisorbed on Ni (7). In Table 6, van Hardeveld and van Montfoot's data (8) for N_2 chemisorbed on silica supported Ni, Pd, and Pt particles is compared with our own for the analogous MN_2 complexes. We note that the trend for ν_{NN} is Ni < Pt < Pd just as in the case of MN_2. We also observe that in all three cases ν_{NN} is *higher* for the chemisorbed N_2 than for the corresponding MN_2. This would indicate that, assuming one can extend our previously stated argument relating $n\Delta F_{N_2}$ with ΔH_C to the case of chemisorbed N_2, the metal–nitrogen bond strength is lower in chemisorbed N_2 than in the corresponding MN_2 complex. As discussed in ref. 7, this may arise from the fact that a surface metal atom releases some of its electrons into the conduction band of the metal. This formally raises the oxidation state of the metal, thereby decreasing the extent of backbonding below that which takes place when a single metal atom is bonded to a nitrogen molecule.

It is interesting to note in the last column of Table 6 that the extent of bond weakening is approximately the same for the three metals when going from MN_2 to the chemisorbed ligand. Thus a great deal of insight into the bonding of N_2 to surface metal atoms may be obtained by comparison with the parallel MN_2 molecules, vindicating the view that the forces which bind molecules to surfaces upon chemisorption are in

many ways similar to those operating in more conventional metal ligand coordination complexes (16).

NOTE ADDED IN PROOF: Recent data reported by D. Gruen *et al.* (J. Chem. Phys., in press) indicate the existence of an end-on bonded $Pt(N_2)_2$ complex. They report, however, their inability to produce a $Pt(N_2)_3$ complex. The source of this discrepancy has not yet been established.

Binary Dioxygen Complexes of Nickel, Palladium, and Platinum, $M(O_2)$ and $(O_2)M(O_2)$, in Low Temperature Matrices

H. HUBER, W. KLOTZBÜCHER, G. A. OZIN,[1] AND A. VANDER VOET

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario M5S 1A1

Received January 18, 1973

The cocondensation reactions of nickel, palladium, and platinum atoms with gaseous oxygen or dilute oxygen–argon mixtures at 4.2–10 °K give rise to binary transition metal dioxygen complexes. Variable concentration and diffusion controlled warm up studies, $^{16}O/^{18}O$ isotopic substitution studies, normal coordinate and isotope intensity calculations establish the complexes to be of the types $M(O_2)$ and $(O_2)M(O_2)$. Both the mono- and bisdioxygen complexes contain the dioxygen molecules coordinated to the metal atom in a side-on fashion, with a unique D_{2d} "spiro"-type structure favored for the bis-complexes. Frequency and bond stretching force constant trends within the series of complexes are examined and suggest that the O—O and M—O values increase with increasing coordination number, and thus with an increase in partial positive charge on the metal. This trend in O—O stretching frequencies is not in accord with the evaluation of metal–dioxygen bond strengths as based on the degree of reversibility of dioxygen coordination.

Les réactions de cocondensation des atomes de nickel, palladium et platine avec l'oxygène gazeux ou des mélanges dilués d'oxygène-argon à 4.2–10 °K, conduisent à des complexes binaires métal de transition – dioxygène. Les études sur la variation de concentration et sur la diffusion contrôlée par réchauffement, les effets de substitution isotopique $^{16}O/O^{18}$, les calculs de coordinat normal et de l'intensité isotopique, montrent que les complexes sont du type $M(O_2)$ et $(O_2)M(O_2)$. Les deux complexes mono et bis-dioxygène possèdent des molécules de dioxygène coordinées au métal d'une façon latérale conférant ainsi une structure unique de type D_{2d} "spiro" favorable dans le cas de bis complexes. L'évolution de la fréquence et de la constante de force d'élongation à l'intérieur d'une série de complexes a été examinée et laisse penser que l'accroissement des valeurs O—O et M—O va de pair avec le nombre de coordination ainsi que l'accroissement de la charge partielle positive sur le métal. Cette évolution dans les fréquences d'élongation O—O n'est pas en accord avec les valeurs des forces de liaison métal–dioxygène basées sur le degré de réversibilité de la coordination du dioxygène.

Introduction

As a continuation of our studies concerning the reactivity of monoatomic transition metal vapors with small gaseous molecules at cryogenic temperatures (1), it was decided to investigate the cocondensation reactions of nickel atoms with dioxygen. In a preliminary report (2) evidence was presented for the existence of binary dioxygen complexes, namely $Ni(O_2)$ and $(O_2)Ni(O_2)$. These experiments have now been extended to include all members of this group (Ni, Pd, Pt) and have been able to show that mono- and bisdioxygen complexes are capable of existence for all three metals.

Binary dioxygen complexes of this type can be considered to be simple "model sub-units" for more complicated synthetic and naturally occurring dioxygen complexes that are usually stable at normal temperatures and that make use of metal-activated molecular dioxygen. These binary dioxygen complexes can be thought of as having a fundamental relationship to any system in which the interaction between a metal and dioxygen is important, for example, the reactivity of coordinated dioxygen in synthetic and naturally occurring dioxygen carriers (3), oxidation reactions on metal based catalysts (4), etc.

This paper describes a series of cocondensation reactions between Ni, Pd, and Pt atoms and molecular oxygen at 4.2–10 °K in both pure O_2 and O_2/Ar matrices, as studied by matrix isolation infrared spectroscopy. The experiments include variable concentration studies of dioxygen in argon, diffusion controlled warm up studies, ^{18}O isotopic substitution (both $^{16}O^{18}O$ and $^{18}O_2$) and normal coordinate and isotope intensity calculations. The data for $M(O_2)$ and $(O_2)M(O_2)$ provide information regarding (*a*) the mode of dioxygen coordination, (*b*) the relative disposition of the dioxygen molecules in the bisdioxygen complexes and, (*c*) the force constants (and hence approximate strengths) of the metal–oxygen and oxygen–oxygen bonds in the mono- and biscomplexes.

Experimental

Monoatomic Ni and Pd vapors were generated by directly heating a 0.010 in. ribbon filament of the metal with a.c. in a furnace which has been described previously (1*c*). Platinum vapor was obtained by heating a 0.030 in. tungsten rod around the center of which were wound several turns of 0.010 in. Pt wire. The nickel, palladium, and platinum metal (99.99%) were supplied by McKay Inc., New York. Research grade $^{16}O_2$ (99.99%) and Ar (99.99%) were supplied by Matheson. Isotopically enriched $^{18}O_2$ (93%) was supplied by Miles Research Laboratories. Statistically scrambled mixtures of $^{16}O_2/^{16}O^{18}O/^{18}O_2$ were prepared by subjecting $^{16}O_2/^{18}O_2$ mixtures at about 200 Torr to a continuous tesla discharge. The scrambling process and concentration ratios were monitored by gas phase Raman measurements.

The rate of metal atom deposition was continuously followed and controlled using a quartz crystal microbalance (5). The deposition rate was set such that the probability of a metal atom having another metal atom as nearest neighbor in the argon lattice was approximately 1/1000. Matrix gas flows, controlled by a calibrated micrometer needlevalve, were maintained in the range 2–8 mmol per h. In the infrared experiments the matrices were deposited on a CsI window cooled to either 4.2 °K by an Air Products liquid helium cryotip transfer system or to 10 °K by means of an Air Products Displex closed cycle helium refrigerator. I.r. spectra were recorded using Perkin–Elmer 621 and Beckmann IR-12 spectrophotometers. Matrix Raman experiments were attempted but were generally unsuccessful due to laser diffusion and photodecomposition processes. Raman matrices were deposited on an aluminum tip and cooled to 4.2 °K. Spectra were recorded on a Spex 1401 Raman spectrophotometer using both Carson argon ion (4880 and 5145 Å) and krypton ion (6471 and 5682 Å) laser excitation. Normal coordinate calculations were performed using Schachtschneider's GMAT and EIGV programs for the M.V.F.F. analysis.

Results

As some of the details of the nickel dioxygen cocondensation reactions already have been described briefly (2), the approach to the matrix infrared experiments and the interpretation of the results can best be illustrated in detail by reference to the palladium dioxygen system. The similar procedure and interpretation of the data for Ni and Pt will only be referred to in tabular form.

The Palladium–Dioxygen Cocondensation Reaction

When Pd atoms were cocondensed with dilute $^{16}O_2$:Ar (1:200) mixtures at 4.2–10 °K, *two* sharp infrared absorptions are observed in the O—O stretching region at 1110.8 and 1023.5 cm^{-1} (see Fig. 1*B*), characteristic of coordinated dioxygen (3*a*, 3*b*). The intensities of these lines were shown to be directly proportional to the metal deposition time. The *relative* intensities of these lines were found to be very sensitive to the $^{16}O_2$:Ar ratio; and for example, at ratios less than 1:200 the absorption at 1023.5 cm^{-1} became dominant and at $^{16}O_2$:Ar = 1:1000 is the only band visible. In more concentrated matrices the band at 1110.8 cm^{-1} predominates and is the only line observed in pure $^{16}O_2$ (Fig. 1*A*) matrices (see later). Diffusion controlled warm up experiments on dilute matrices indicated that the higher frequency absorption increases in intensity with increase in temperature at the expense of that at lower frequency (Fig. 2).

When Pd atoms are cocondensed with a dilute argon matrix containing isotopically enriched oxygen ($^{18}O_2$:Ar = 1:200), *two* sharp absorptions are observed at 1048.5 and 966.5 cm^{-1}, which are shifted by 62.3 and 61.0 cm^{-1} from the $^{16}O_2$ counterpart lines (Fig. 1*C*). From this series of data, it is possible to deduce that *two*

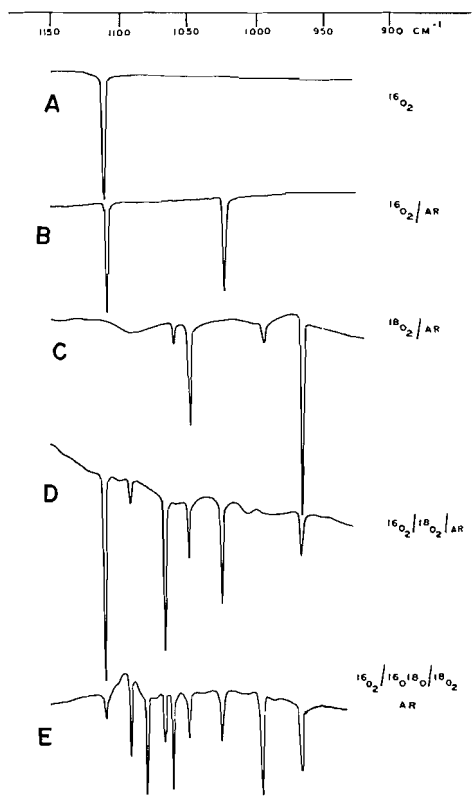

FIG. 1. The matrix infrared spectrum of the products of the cocondensation reaction of Pd atoms with (*A*) pure $^{16}O_2$, (*B*) $^{16}O_2$:Ar ≅ 1:200, (*C*) $^{18}O_2$:Ar ≅ 1:200, (*D*) $^{16}O_2$:$^{18}O_2$:Ar ≅ 2:1:600, and (*E*) $^{16}O_2$:$^{16}O^{18}O$:$^{18}O_2$:Ar ≅ 1:2:1:800, at 4.2 °K showing the characteristic isotope patterns of both $Pd(O_2)$ and $(O_2)Pd(O_2)$.

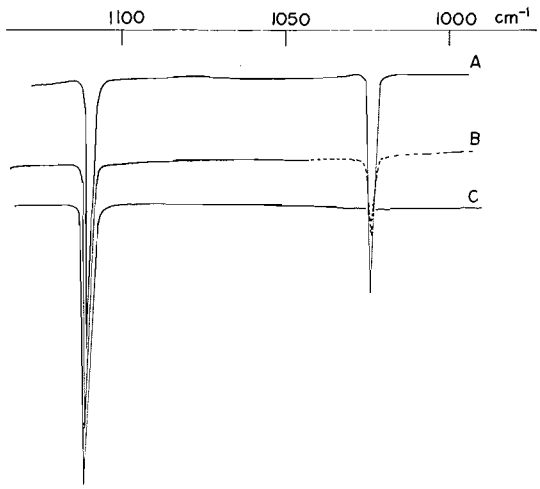

FIG. 2. Similar spectrum to that shown in Fig. 1*B* after successive warm-up experiments at 35 °K each for 10 min.

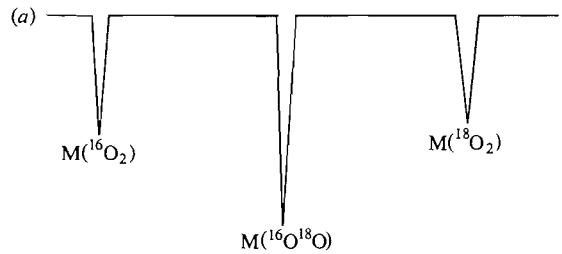
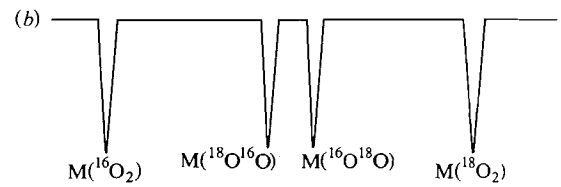
distinct palladium–oxygen species exist in dilute O_2/Ar matrices and a *single* species in pure $^{16}O_2$ and in O_2/Ar = 1:1000, where the higher frequency absorption (1110.8 ($^{16}O_2$)/1048.5 ($^{18}O_2$)) corresponds to a higher coordination complex than the lower. Fortunately the 1110.8 to 1023.5 cm^{-1} frequency separation is sufficiently large to permit meaningful mixed $^{16}O_2/^{16}O^{18}O/^{18}O_2$ isotope experiments on the two species without the complication of band overlap, which in principle should yield information concerning their stoichiometries, the nature of the metal–dioxygen bonding and the mode of attachment of the dioxygen molecule(s) to the metal atom (that is, whether end or side-on bonding). For the sake of clarity of presentation, each of these species will be discussed separately.

The 1023.5 Absorber, Monodioxygen Palladium, $Pd(O_2)$

When Pd atoms are cocondensed with a dilute $^{16}O_2:^{18}O_2$:Ar = 2:1:600 mixture at 4.2–10 °K (Fig. 1*D*) a doublet is observed at 1023.5 and 966.5 cm^{-1}. This 57 cm^{-1} splitting would indicate that the species responsible for the absorption at 1023.5 cm^{-1} contains a *single* dioxygen molecule. The mode of attachment of the dioxygen to the metal atom can be defined in principle by consideration of the intensity pattern and the number of lines observed when using a statistical mixture of dioxygen isotopes in dilute argon matrices (mixture used in this work: $^{16}O_2/^{16}O^{18}O/^{18}O_2$/Ar = 1:2:1:800). The spectrum obtained with this mixture is expected to be one of the two following patterns illustrated below:



A *three*-line spectrum, consisting of approximately equally spaced lines, with absorption intensities in the ratio 1:2:1. This multiplet pattern characterizes a single dioxygen molecule coordinated to the metal so as to form an isosceles triangle in which the oxygen atoms are equivalent (*i.e.*, side-on bonding). The central component shows the spectral equivalence of the mixed isotopic molecules $M(^{16}O^{18}O)/M(^{18}O^{16}O)$, and as it carries a statistical weighting factor of two as compared to the unscrambled species it is therefore expected to be twice as intense as the outer two components.



A *four*-line spectrum with a closely spaced central doublet with absorption intensities in the ratio 1:1:1:1, characteristic of a single dioxygen molecule coordinated in an "end-on" linear or non-linear fashion and having spectroscopically non-equivalent oxygen atoms. The inequivalence but equal weighting of $M(^{16}O^{18}O)$ and $M(^{18}O^{16}O)$ results in the small separation and equal intensities of the central doublet. Similar considerations have been able to distinguish between possible modes of attachment in transition metal – dinitrogen complexes (7, 8).

When Pd atoms were cocondensed with a dilute scrambled mixture ($^{16}O_2/^{16}O^{18}O/^{18}O_2$/Ar = 1:2:1:800) the matrix infrared spectrum showed a 1:2:1 *triplet* of approximately equally spaced lines at 1024.0, 995.5, and 967 cm^{-1} (Fig. 1*E*). The three-line spectrum was carefully examined under conditions of high resolution. All three were found to have *identical* band widths of 2 cm^{-1} at half height. The slit width used for the scan was 1 cm^{-1} with a scan speed of 2 cm^{-1}

per min. The central component remained unsplit under these conditions with an absorption intensity approximately twice that of the two outer components. It would thus appear that in dilute O_2/Ar matrices, Pd forms a monodioxygen species $Pd(O_2)$ in which the dioxygen molecule is acting as a ligand, bonding to the metal atom in a symmetrical side-on fashion.

Very similar results were obtained for both nickel (see, for example, Fig. 3) and platinum atoms with dilute O_2/Ar matrices. The data for all three monodioxygen complexes are presented in Tables 1–3. A matrix splitting effect of about 5 cm^{-1} was observed for platinum monodioxygen (see later).

The 1110.8 cm^{-1} Absorber, Bisdioxygen Palladium, $(O_2)Pd(O_2)$

When Pd atoms are cocondensed with a dilute $^{16}O_2/^{18}O_2$/Ar = 2:1:600 matrix at 4.2–10 °K, in addition to the doublet previously assigned to the monodioxygen species, four lines are observed at 1110.8, 1091.5, 1066.7, and 1048.0 cm^{-1} (Fig. 1*D*). This band pattern indicates that the absorbing species contains *two* equivalent dioxygen molecules and the lines are easily assigned to the isotopic species $(^{16}O_2)Pd(^{16}O_2)$, $(^{16}O_2)Pd(^{18}O_2)$, and $(^{18}O_2)Pd(^{18}O_2)$, as shown in Tables 2 and 5. A similar situation is observed in pure oxygen matrices as shown in Table 4 (see later).

In principle the mode of attachment of the dioxygen molecules to the metal in the bis-compound can be determined from $^{16}O^{18}O$ experiments, and indeed with a scrambled mixture (identical to that used in the monodioxygen experiments) the original absorption at 1110.8 in $^{16}O_2$/Ar was split into a *six*-line spectrum (Fig. 1*E*) which could be assigned to the possible isotopic combinations of a $(O_2)Pd(O_2)$ molecule as shown below:

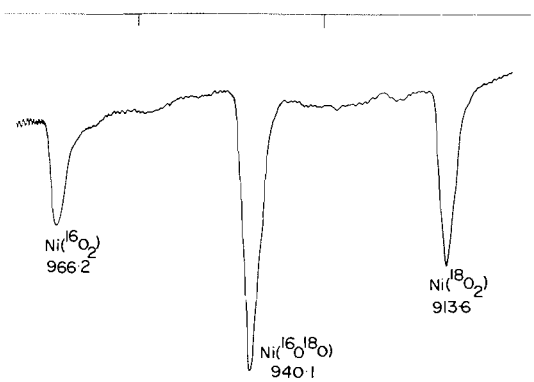

FIG. 3. The matrix infrared spectrum of the products of the cocondensation reaction of Ni atoms with $^{16}O_2$: $^{16}O^{18}O$:$^{18}O_2$:Ar ≅ 1:2:1:800 at 4.2 °K showing the characteristic oxygen isotope pattern for mono-dioxygen nickel containing sideways bonded dioxygen.

TABLE 1. Vibrational assignments of the oxygen stretching modes in binary dioxygen complexes $M(O_2)$ where M = Ni, Pd, or Pt

Molecule	Frequency (cm^{-1}) for M = Ni	Pd	Pt
$M(^{16}O_2)$	966.2	1024.0	926.6
$M(^{16}O^{18}O)$	940.1	995.5	901.4
$M(^{18}O_2)$	913.6	967.0	875.2

Molecule	Frequency (cm^{-1})
$(^{16}O_2)Pd(^{16}O_2)$	1111.5
$(^{16}O_2)Pd(^{16}O^{18}O)$	1092.2*
$(^{16}O^{18}O)Pd(^{16}O^{18}O)$	1080.5
$(^{16}O_2)Pd(^{18}O_2)$	1067.2
$(^{16}O^{18}O)Pd(^{18}O_2)$	1060.5
$(^{18}O_2)Pd(^{18}O_2)$	1048.5

*Note that owing to a 7% impurity of $^{16}O^{18}O$ in the commercially available $^{18}O_2$ gas, a very weak absorption at 1092.2 cm^{-1} belonging to $(^{16}O_2)Pd(^{16}O^{18}O)$ is also observed in the $^{16}O_2$/$^{18}O_2$ mixed isotope experiments.

This "sextet pattern" indicates a non-degenerate vibration of two equivalent dioxygen molecules each containing equivalent oxygen atoms. The second and fifth components of the multiplet indicate the equivalence of the oxygen atoms in each O_2 unit, since if the molecules were attached in an end-on fashion (non-equivalent), further splitting or line broadening of the lines due to the rearrangement of the $(^{16}O^{18}O)$ component would be expected. This broadening is not observed and all six components of the sextet are equally sharp. The absence of the lines assigned to the species $Pd(^{16}O^{18}O)_2$ in pure $^{16}O_2/^{18}O_2$ matrices, and the non-equivalence of the (16–16) (18–18) and (16–18)(16–18) species clearly indicated in the spectrum shows that the original oxygen molecules remain intact upon bonding to the metal atom.

Since a planar (D_{2h}) structure would have *cis*- and *trans*-isomers for the (16–18)(16–18) molecule and since no splitting is observed at the frequency assigned to the species (1080.5 cm^{-1}), the D_{2d} "spiro" structure is proposed (Fig. 4). This symmetry model is also favored from

Dewar–Chatt maximum π-bond overlap considerations (see later).

Very similar results were obtained for both nickel and platinum atoms (see for example Tables 3 and 5 and Fig. 5) and establish the existence of bisdioxygen complexes $(O_2)M(O_2)$ for all three metals. Only in the case of platinum atoms was a doublet structure with a small splitting (2–5 cm^{-1}) observed for each line (Fig. 5) in both pure dioxygen and dilute dioxygen–argon matrices (see later).

Observation and Assignment of Low Frequency Modes

Only in matrices in which the O—O stretching modes of $Pd(^{16}O_2)$ and $(^{16}O_2)Pd(^{16}O_2)$ were arranged to be *totally* absorbing, was it possible to observe weak lines at 504 and 427 cm^{-1} assignable to Pd—O stretching modes. On the basis of their concentration dependencies and warm-up behavior and similar νMO frequencies to stable synthetic dioxygen complexes (6), these two lines could be associated with the metal–oxygen

‡One-half of the doublet is hidden by the strong doublet at 1063.1, 1059.5.

§All infrared absorptions in these pure oxygen matrices observed as doublets with a splitting in the range 3.8–50. cm^{-1} (see text).

stretching modes of the bis- and monocomplexes, respectively. In the nickel atom – dioxygen reactions, similar weak lines were observed at 535 and 505 cm^{-1} assignable to the Ni—O modes of the bis- and monodioxygen compounds. Analogous low frequency modes in the Pt/O_2 system could not be observed, presumably because of their low intensity.

Bisdioxygen Complexes in Solid Oxygen

Having established that the highest stoichiometry complex formed in the Pd/O_2 reaction is $(O_2)Pd(O_2)$ which in argon matrices appears to have the spiro D_{2d} structure, it is interesting to consider the analogous data in pure oxygen matrices. The spectra obtained in argon and

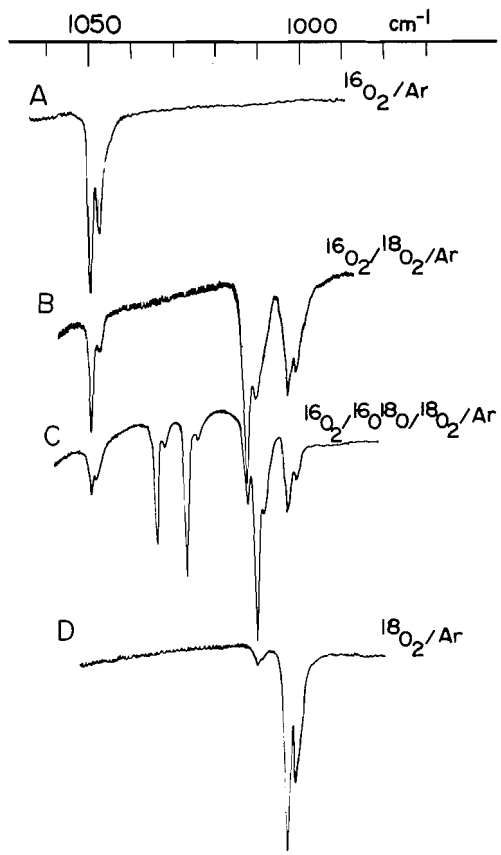

FIG. 5. The matrix infrared spectrum of the products of the cocondensation reaction of Pt atoms with (*A*) $^{16}O_2$:Ar ≅ 1:50, (*B*) $^{16}O_2$:$^{18}O_2$:Ar ≅ 1:1:100, (*C*) $^{16}O_2$:$^{16}O^{18}O$:$^{18}O_2$:Ar ≅ 1:2:1:200 and (*D*) $^{18}O_2$:Ar ≅ 1:50 showing the characteristic isotope pattern of $(O_2)Pt(O_2)$.

oxygen matrices show gross similarities in terms of the frequencies and intensities of the observed lines. However, the spectra in $^{16}O_2$, $^{16}O_2/^{18}O_2$, and $^{16}O_2/^{16}O^{18}O/^{18}O_2$ matrices show a doublet splitting of all the O—O stretching modes (see for example Fig. 6).

An examination of the reported crystal structures of solid oxygen is quite informative in terms of the possible sites of palladium atoms in the lattice. Solid oxygen exists in three crystalline modifications. The low, intermediate, and high temperature phases are referred to as α-, β-, and γ-oxygen respectively with phase transition temperatures α-O_2 (0–23.9 °K), β-O_2 (23.9–43.6 °K), and γ-O_2 (43.6–54.4 °K). The two low temperature phases have been studied extensively by diffraction methods (ref. 9 and references therein). α-O_2 is monoclinic with a $C2/m$ (C_{2h}^3) space group and has two molecules in the unit cell whose axis is perpendicular to the two-fold symmetry axis (see Fig. 7). The molecules are at positions having $2/m$ symmetry, that is, at a center of symmetry (C_{2h}) as suggested by Cairns and Pimentels' (10) tentative interpretation of the infrared spectra of solid α-oxygen. The β-phase has been assigned the space group $R\bar{3}m$ (D_{3d}^5) which can be described in terms of a primitive rhombohedral cell containing one molecule oriented parallel to the trigonal axis and occupying a site of D_{3d} symmetry.

From considerations of the bond length (1.18 Å) and van der Waals radius (1.4 Å) of oxygen and the atomic radius of palladium (1.38 Å), it appears unlikely that the palladium atom would reside in any of the interstitial sites of either the α or β oxygen lattices. The palladium

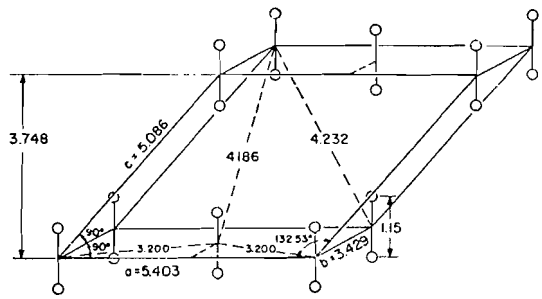

FIG. 7. The crystal structure of α-O_2 showing the monoclinic unit cell ($C2/m$). There are two molecules in the primitive unit cell centred at (000) and $(\frac{1}{2}\frac{1}{2}0)$ with the O—O bonds approximately normal to the *ab* plane.

atom must then reside in the more spacious C_{2h} substitutional site when in the α-O_2 lattice or the D_{3d} substitutional site when in the β-O_2 lattice about which there are four nearest O_2 neighbors. Preferential interaction of the palladium atom in a substitutional site with two nearest neighbor O_2 molecules (it is a matter of conjecture whether a fluxional situation exists) is then the most favored scheme for the formation of $(O_2)Pd(O_2)$ in solid oxygen.

When palladium atoms are deposited into a pure $^{16}O_2$ matrix at 4.2 °K, the infrared spectrum initially shows a *single* νO—O absorption at 1112.3 cm^{-1} (Fig. 8). However, on warming the matrix to 10–30 °K, this singlet absorption splits into a closely spaced doublet at 1114.7 and 1110.0 cm^{-1} (Fig. 8).

The warm up characteristics of the oxygen absorption of $(O_2)Pd(O_2)$ in solid oxygen would appear to indicate that when first deposited, at 4.2 °K the oxygen lattice can be considered to be in a disordered or glassy phase (evidence in favor of this stems from Pimentel's infrared data of O_2 when deposited at 4.2 °K, which shows significant lattice imperfections in the solid so prepared). The $(O_2)Pd(O_2)$ molecule experiences an averaged local field and thereby gives rise to a single oxygen absorption (1112.3 cm^{-1}). When the oxygen matrix is warmed, it is annealed (presumably in a somewhat non-uniform manner) thereby increasing the regularity of its α-O_2 and β-O_2 crystalline lattice portions. The $(O_2)Pd(O_2)$ molecule now feels the perturbing effect of the two different substitutional lattice sites (C_{2h} and D_{3d} in the α- and β-O_2 lattices, respectively) and gives rise to the observed closely spaced doublet structure or matrix splitting (Fig. 8).

In the case of Ni and Pt atoms deposited into

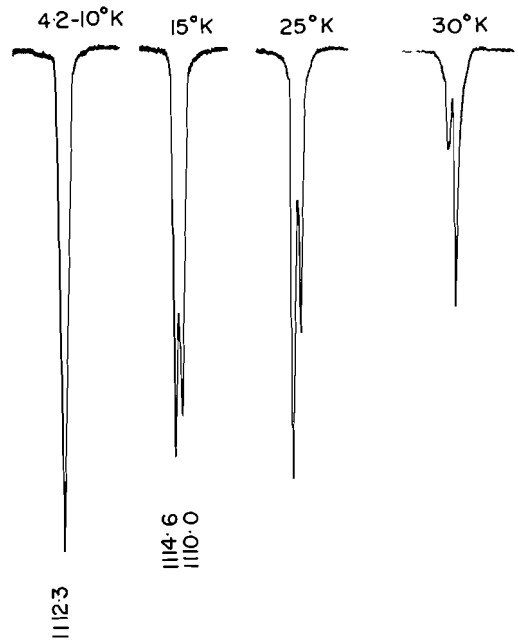

FIG. 8. The matrix infrared spectrum of $(^{16}O_2)Pd(^{16}O_2)$ formed in the cocondensation reaction of Pd atoms with pure $^{16}O_2$ on deposition at 4.2–10 °K, and after successive warm-up experiments at 15, 25, and 30 °K each for 10 min.

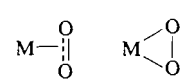
pure $^{16}O_2$ matrices, a similar matrix splitting effect is observed for the complexes $(O_2)Ni(O_2)$ and $(O_2)Pt(O_2)$ with components centered at 1064.0 and 1053.2 cm^{-1} and 1052.6 and 1049.6 cm^{-1}, respectively. The cause of these splittings is probably related to site effects similar to those described for $(O_2)Pd(O_2)$.

Normal Coordinate Calculations for Binary Mono- and Bisdioxygen Complexes of Nickel, Palladium, and Platinum

For synthetic dioxygen complexes that are stable at room temperature and which have been shown to contain the dioxygen ligand bonded to the metal in a side-on fashion, two limiting mechanical local models have been considered for the $M(O_2)$ residue of the complex. These two models have been referred to as monodentate and isosceles and are illustrated below:



As a significant reduction of the bond order of the oxygen molecule is observed for the binary

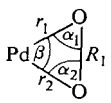
dioxygen complexes of the present study, indicating significant back bonding, the present analysis is best considered in terms of delocalized bonding of the isosceles type. (We note that insignificant lowering of the C=C bond order or bond stretching force constant for ethylene in Zeise's salt, points to the relevance of the monodentate model for this type of side-on bonded olefin complex (11).)

Normal Coordinate Analysis of $Pd(O_2)$ and $(O_2)Pd(O_2)$

$Pd(O_2)$

The palladium monodioxygen compound with side-on bonded O_2 is assumed to have the isosceles triangular structure of C_{2v} symmetry as shown below. Representative O—O and Pd—O bond lengths are taken at 1.4 and 2.1 Å, respectively.



The number and types of vibrational modes expected are $4A_1 + 2B_2$ and on the basis of the internal coordinates indicated in the diagram the symmetry coordinates are:

$$A_1 \quad S_1 = \Delta R_1$$
$$S_2 = 1/\sqrt{2}(\Delta r_1 + \Delta r_2)$$
$$S_3 = 1/\sqrt{2}(\Delta\alpha_1 + \Delta\alpha_2)$$
$$S_4 = \Delta\beta$$
$$B_2 \quad S_5 = 1/\sqrt{2}(\Delta r_1 - \Delta r_2)$$
$$S_6 = 1/\sqrt{2}(\Delta\alpha_1 - \Delta\alpha_2)$$

The approximation of a force field for the monodioxygen complex is fairly difficult since there is not a great deal of force constant data available in the literature for coordinated dioxygen. Some representative examples are listed in Table 6 for anionic, matrix isolated alkali metal peroxides and superoxides (12) as well as a number of synthetic dioxygen complexes (6*c*).

The Cotton–Kraihanzel force field approximation (13), which was applied successfully to binary dinitrogen and carbonyl compounds, is based on the ability to decouple the ligand stretching modes from the metal-ligand modes. Since, in the case of the isosceles model for dioxygen complexes, such coupling is expected to be *significant*, a more complete force field was desired. To obtain a reasonable frequency fit for $Pd(O_2)$, a M.V.F.F. and a least squares analysis of the data were employed. The dependence of the O—O and Pd—O frequencies on the values of k_{OO} and k_{PdO} and suitable interaction and angular force constants was thoroughly investigated and resulted in the force field listed in Table 7. The agreement between the observed and calculated frequencies also shown in Table 7 is excellent.

It should be noted here that the evaluation of this force field was made on the assumption that the observed Pd—O stretching frequency was of the A_1 type and that the B_2 mode was too weak to observe. It could be argued that the interaction force constant f_{PdOPdO} might be negative, as was assumed for the superoxide calculations (12), but reduction of this interaction force constant in the present analysis only increased the

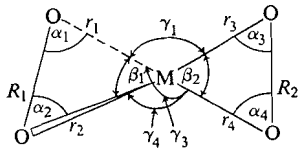
calculated value for the B_2 mode. Furthermore, the calculations indicated that to obtain a frequency fit compatible with a reversed assignment unreasonably low values of f_r or unreasonably high values of f_{rr} would be required. Hence the assignment to the symmetric metal–ligand mode was favored.[2] By similar iteration procedures, force fields were calculated for the nickel and platinum monodioxygen complexes and the results are also shown in Table 7.

$(O_2)Pd(O_2)$: The D_{2d} "Spiro" Configuration

On the basis of D_{2d} symmetry concluded from the observation of the six component multiplet pattern in the spectrum of $Pd/^{16}O_2/^{16}O^{18}O/^{18}O_2/Ar$, and using the same bond distances as used in the monodioxygen complex, the **G** matrix of the biscomplex could be evaluated. The internal and symmetry coordinates of the vibrational modes (including redundancies) are shown below:



(Eight torsional coordinates (τ) were included in the analysis.)

$$

These internal and symmetry coordinates are applicable to both pure $^{16}O_2$ and $^{18}O_2$ isotopic species, with appropriate changes in the mixed species where the symmetry is lowered C_{2v} in case of $(^{16}O_2)Pd(^{18}O_2)$, C_2 in case of $(^{16}O^{18}O)$-$Pd(^{16}O^{18}O)$, and C_s in the species $(^{16}O_2)Pd$-$(^{16}O^{18}O)$ and $(^{18}O_2)Pd(^{16}O^{18}O)$.

As in the case of the monodioxygen complexes, a M.V.F.F. was derived and the values of ν_{OO} and ν_{PdO} were calculated for the various $^{16}O/^{18}O$ isotopic combinations. Certain simplifying assumptions were made for these calculations, namely that the angle–stretch and angle–angle interaction force constants as well as the torsional force constants were equal to zero. After several iterations the final force field as shown in Table 8 was obtained. It should be mentioned that the calculations were based on the assignment of the Pd—O stretching frequency to the B_2 mode. The possibility of the assignment of this band to the E mode was tested, but a frequency fit could be made only with unreasonably low values of k_{PdO}. Similar calculations were done for $(O_2)Ni$-(O_2) (with the NiO stretching frequency (B_2) at 535 cm^{-1}) and the resulting force field is also

[2]NOTE ADDED IN PROOF: Assignment of the metal–oxygen stretching frequencies to the A_1 and B_2 modes for the mono and bisdioxygen complexes, respectively, was confirmed by intensity calculations. For $Pd(O_2)$ the ratio of relative intensities is approximately $I_{B_2}/I_{A_1} = \tan^2\theta$ where $\theta = \angle OPdO$. For the given bond lengths, θ is approximately equal to 40° and the ratio $I_{B_2}/I_{A_1} \sim 1/8$, therefore if only one MO stretching mode is observed for the monodioxygen complex it must be the A_1. For $(O_2)Pd(O_2)$ it can be shown that $I_E/I_B \sim \tan^2\theta$ and for $\theta \sim 40°$, $I_E/I_{B_2} \sim 1/8$. The MO mode is therefore assigned to the B_2 mode.

listed in Table 8. The calculated and observed frequencies for these $M(O_2)_2$ molecules are listed in Table 5 and the close agreement provides convincing evidence for the correctness of our vibrational and structural assignments.

It is significant that the force constants for the oxygen–oxygen stretching mode and for the metal–oxygen stretching mode both *increase* with increased coordination number.

Complete M.V.F.F. calculations were not performed for the platinum bisdioxygen molecule since the low frequency Pt—O mode was *not* observed in any of the experiments. However, it is not unreasonable to expect similar force constant trends upon going from $Pt(O_2)$ to $(O_2)Pt(O_2)$.

Although it was mentioned earlier that the expected coupling of the ligand and metal–ligand modes influenced the choice of a more complete force field, this does not mean that a Cotton–Kraihanzel force field cannot be established for dioxygen complexes. Indeed we performed such C.K. calculations for the high frequency O—O stretching modes (which may be referred to as the "monodentate" model) and obtained quite reasonable agreement between the observed and calculated frequencies of the bisdioxygen complexes of Ni, Pd, and Pt (Table 9). The best fit M.V.F.F. bond stretching force constants (listed in Table 8) are found to be slightly smaller than the corresponding C.K. values (listed in Table 9).

sity rules (for all coordinates of a given symmetry species) shown below (17):

$$\sum_k I_k = \sum_{k'k''} \frac{\partial \boldsymbol{\mu}}{\partial S_{k'}} \cdot \frac{\partial \boldsymbol{\mu}}{\partial S_{k''}} G_{k'k''}$$

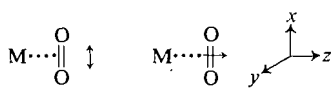
$$\sum_k \frac{I_k}{\lambda_k} = \sum_{k'k''} \frac{\partial \boldsymbol{\mu}}{\partial S_{k'}} \cdot \frac{\partial \boldsymbol{\mu}}{\partial S_{k''}} F_{k'k''}{}^{-1}$$

For example, in a number of binary dinitrogen and carbonyl complexes (18, 19) it was found that these intensity sum rules could be used in conjunction with the Cotton–Kraihanzel force field approximation, to predict relative absorption intensities for NN and CO infrared active stretching modes, respectively. Their application to these systems simply involves the determination of the components of the transition dipole moment vectors with respect to each symmetry coordinate S_k, where in the C.K. approximation $G_{k'k''}$ simply equals the reduced mass of the ligand and $F_{k'k''}{}^{-1}$ is an element of the matrix inverse to the force constant matrix $F_{k'k''}$.

Since homonuclear diatomic molecules do not undergo a net dipole change during bond stretching, the resultant mode is not infrared active. However, when the diatomic molecule is coordinated to a metal atom in an "end-on" fashion, ligand stretching is accompanied by a net dipole change as shown below

$$M{-}N\overrightarrow{\equiv}N \qquad \boldsymbol{\mu}' \neq 0$$

resulting in infrared activity of the mode. If one considers an oxygen molecule coordinated to a metal atom in a "side-on" fashion as postulated for $M(O_2)$ and $(O_2)M(O_2)$, it is apparent that the oxygen–oxygen stretching mode does not involve a dipole change and must gain its infrared activity from a transition dipole moment induced by coupling with the metal–oxygen stretching mode of the same symmetry. Therefore, it should be possible to define a transition dipole moment vector $\boldsymbol{\mu}'$ for the O—O stretching mode which is directionally dependent on the transition dipole moment vectors for the M—O stretching modes as shown below:



$\mu_x = \mu_y = 0$ $\qquad$ $\mu_z \neq 0$

It was felt that within the limits of the C.K. approximation, the non-zero components of the decoupled transition dipole moment vectors ($\boldsymbol{\mu}_z'$) could be used to predict relative absorption intensities for the O—O stretching modes of the isotopic bisdioxygen molecules. As an example, let us consider the schematic model for ($^{16}O_2$)M($^{16}O_2$) shown below.

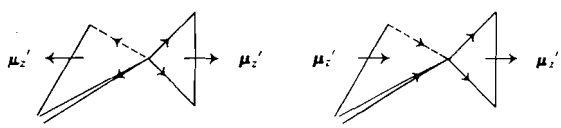
($^{16}O_2$)M($^{16}O^{18}O$)	8.51	7.81 (6.34)	6.92 (5.17)
($^{16}O^{18}O$)M($^{16}O^{18}O$)	9.39	9.29 (9.19)	9.21 (7.02)
($^{16}O_2$)M($^{18}O_2$)	4.40	3.97 (3.83)	3.04 (3.46)
($^{16}O^{18}O$)M($^{18}O_2$)	10.00	10.00 (10.00)	10.00 (10.00)
($^{18}O_2$)M($^{18}O_2$)	2.76	2.99 (3.69)	3.35 (3.16)

*The observed intensities were measured by assuming a triangular contour for the infrared band and using the expression $I = \Delta\nu_{1/2}[1 + \gamma \log \gamma/(1 - \gamma)]$ where $\Delta\nu_{1/2}$ = width of band at half height, γ = fractional transmittance, and $I = -\int \log \gamma \, d\nu$. Observed relative intensities presented in parentheses.

†Spectra of poor quality. See text.

It is possible to depict diagrammatically the two possible O—O stretching modes of symmetry type A_1 and B_2 with the corresponding M—O modes:



$$A_1$$

$$S_1 = 1/\sqrt{2}(\Delta R_1 + \Delta R_2)$$

$$S_2 = 1/2(\Delta r_1 + \Delta r_2 + \Delta r_3 + \Delta r_4)$$

$$B_2$$

$$S_1 = 1/\sqrt{2}(\Delta R_1 - \Delta R_2)$$

$$S_2 = 1/2(\Delta r_1 + \Delta r_2 - \Delta r_3 - \Delta r_4)$$

The vector sum of the transition dipole moment vectors for the A_1 mode is of course equal to zero, making this mode infrared inactive. However, the B_2 mode is expected to be infrared active and the intensity sum rules may be applied.[3]

Applying this method individually to each of the six isotopic molecules ($^nO^mO$)M($^nO^mO$) (where n, m = 16 or 18) and multiplying the intensity of each by its expected statistical abundance (and correcting for the true concentration ratio of $^{16}O_2$:$^{16}O^{18}O$:$^{18}O_2$) a set of expected relative intensities may be obtained as summarized in Table 10. Comparison of these calculated absorption intensities with those observed for $Pd(O_2)_2$ and $Pt(O_2)_2$ show remarkably close agreement and support the validity of the model and the frequency assignments used in the computations. Even though the $Ni(O_2)_2$ spectra were not of high quality the same general trends in the predicted and observed intensity pattern were quite apparent.

[3]C.K. force constants were used since they correspond more closely to the decoupled or monodentate model.

Discussion of Results

As found for $M(O_2)$ and $(O_2)M(O_2)$ (where M = Ni, Pd, or Pt) and many synthetic dioxygen carriers, the side-on mode of bonding appears to be the more common form (14), which is not unexpected for transition metals in relatively low oxidation states (15). The fact that $(O_2)M(O_2)$ is pseudotetrahedral (D_{2d}) rather than planar (D_{2h}) would tend to favor M(0) rather than M(II) complexes.

The addition of O_2 to Ni, Pd, and Pt atoms in these matrix cocondensation reactions can be discussed in terms of the π-bonding scheme of Chatt and Dewar (16). A delocalized three center molecular orbital scheme involving the symmetry allowed metal orbitals and an in-plane π^* of O_2 describes the situation more satisfactorily than a localized model in terms of O_2^{2-} or O_2^- (3*b*). The degree of back bonding which occurs will depend upon the relative energies and the amount of overlap between the orbitals.

It is interesting to try to relate briefly Ibers' (14*c*) rationale for the factors affecting reversible oxygen uptake in synthetic dioxygen carriers, to our data for binary dioxygen complexes. Ibers proposes that an increase in electron density at the metal accomplished by reducing the electronegativity of halide substituents or upon changing the metal in a complex (for example,

For personal use only.

Ir > Rh > Co in the series indicated below)

Complex	r(O—O)(Å)	r(M—O)(Å)	Oxygen uptake properties	Reference
$[Co(O_2)(2{=}phos)_2]BF_4$	1.420	1.902 1.871	Irreversible	14*a*
$[Rh(O_2)(diphos)_2]PF_6$	1.418	2.026 2.025	Reversible	14*c*
$[Ir(O_2)(diphos)_2]PF_6$	1.625	1.961 1.990	Irreversible	14*c*

will *enhance* O_2 uptake properties. This would appear to be borne out by the above crystallographic data and is in fact also reflected in the order of the O—O stretching frequencies and bond stretching k_{OO} force constants for the binary monodioxygen complexes $Ni(O_2)$, $Pd(O_2)$, and $Pt(O_2)$, which parallel (in an inverse fashion) the order of O—O bond lengths in the Co, Rh, and Ir complexes tabulated above, that is: r(O—O), Å, Rh $\simeq$ Co < Ir;[4] k(O—O), mdyn/Å, Pd > Ni > Pt; ν(O—O), cm^{-1}, Pd > Ni > Pt.

As mentioned earlier, the D_{2d} assignment for $(O_2)M(O_2)$, as well as being favored on spectroscopic grounds, is also preferred on a Dewar–Chatt π-bonding scheme (see Fig. 4). From maximum π-bonding overlap considerations, the use of the mutually orthogonal d_{xz}, d_{yz} orbitals is required and would necessitate that the dioxygen molecules adopt a "spiro" conformation about the metal atom. In this context it is important to note than on increasing the coordination number of the metal from one in $M(O_2)$ to two in $(O_2)M(O_2)$ where M = Ni, Pd, and Pt, the infrared active νOO stretching mode shifts to higher frequencies.

The degree of electron density transferred to π^* antibonding orbitals on the O_2 through the intermediary of the metal will depend on the other ligands on the complex. The νOO frequency order on passing from $M(O_2)$ to $(O_2)M(O_2)$ does follow the trend expected on the Chatt–Dewar concept of O_2 bonding, that is, $(O_2)M(O_2) > (M)O_2$. Thus, on increasing the dioxygen coordination number, the degree of charge transfer per O_2 molecule from the π metal orbitals would decrease as would the amount of π^* back bonding, resulting in a strengthening of the O—O bond upon passing from the mono- to biscomplex, as is observed. However, the order observed for the metal–oxygen stretching modes (and k_{MO} bond stretching force constants) is $(O_2)Pd(O_2)$ > $Pd(O_2)$ and $(O_2)Ni(O_2)$ > $Ni(O_2)$, which is *not* that expected from the rationalization of the reversible dioxygen uptake being related to those compounds containing dioxygen ligands with shorter O—O bond lengths (14*c*) (or high k_{OO} with higher M—O bond lengths and presumably lower k_{MO} force constants). This observation would seem to imply that the earlier descriptions of the bonding of O_2 to metals might be an oversimplification of the factors involved in the dioxygen carrying problem.

In our opinion, although the formal charge transfer to each dioxygen ligand in $(O_2)M(O_2)$ appears to be less than in $M(O_2)$, the "total" charge transfer from the metal, or the formal (fractional) oxidation state of M for the biscomplex, could conceivably be greater than that in the monocomplex. Furthermore, a shorter O—O bond for the dioxygen in $(O_2)M(O_2)$ as compared to $M(O_2)$ (deduced from νOO and k_{OO} values) would have the effect of shorten-

[4]As the difference in r(O—O) for the Co and Rh complexes is not significant when considered with the standard deviations, we have put the oxygen–oxygen bond length in $[Rh(O_2)(diphos)_2]PF_6$ approximately equal to that in $[Co(O_2)(2{=}phos)_2]BF_4$.

ing the PdO bond in the biscomplex compared to the monocomplex. If either of these effects were operative, one can then rationalize the stronger O—O and M—O bonds in the bisdioxygen complexes.

We wish to thank Dr. Martin Moskovits for many helpful discussions and the National Research Council of Canada and the Research Corporation for financial assistance.

Binary Mixed Dinitrogen–Carbonyl Complexes of Nickel(0), $Ni(N_2)_m(CO)_{4-m}$ (where $m = 1$–3)

E. P. KÜNDIG, M. MOSKOVITS, AND G. A. OZIN

Lash Miller Chemistry Laboratory, and Erindale College, University of Toronto, Toronto, Ontario

Received January 25, 1973

Nickel atoms have been cocondensed in various $^{12}C^{16}O/^{14}N_2$, $^{12}C^{16}O/^{14}N_2/Ar$, and $^{12}C^{18}O/^{14}N_2/^{15}N_2/Ar$ matrices and the infrared and Raman spectra of the products recorded at 4.2–10 °K. In addition to the infrared absorptions associated with the known compounds $Ni(N_2)_4$ and $Ni(CO)_4$, other NN and CO stretching modes are observed which can be ascribed to the mixed carbonyl–dinitrogen species $Ni(N_2)_m(CO)_{4-m}$ where $m = 1$–3. Confirmation of the molecular constitutions and vibrational assignments of the isolated species was obtained from (*a*) variable concentration experiments in which either N_2 or CO was arranged to be in excess, (*b*) diffusion controlled warm-up experiments in the range 10–35 °K, and (*c*) isotope substitution experiments using $^{14}N_2/^{15}N_2/^{12}C^{18}O/Ar$ matrices in which the total nitrogen to carbon monoxide ratio was varied. Cotton–Kraihanzel k_{CO} and k_{NN} force constants are computed for the mixed compounds $Ni(CO)_3(N_2)$, $Ni(CO)_2(N_2)_2$, and $Ni(CO)(N_2)_3$ and trends within the series are discussed in terms of the σ-donor and π-acceptor bonding properties of the N_2 and CO ligands. An analysis is presented in which the changes in the CO and N_2 bond stretching force constants in passing from $Ni(CO)_m$ to $Ni(CO)_m(N_2)_{4-m}$ and from $Ni(N_2)_{4-m}$ to $Ni(CO)_m(N_2)_{4-m}$ are related to the change in σ and π orbital populations. The results of that analysis indicate that CO is both a better σ donor and a better π acceptor than N_2. Integrated absorbances of the bands associated with the species $Ni(CO)_m(N_2)_{4-m}$ are measured and are used to compute ratios of the transition dipole moments $(\mu_{CO}')_m$ and $(\mu_{N_2}')_m$ for CO and N_2 respectively. The observed trends for $(\mu_{CO}')_m$ and $(\mu_{N_2}')_m$ as functions of m are found to be in keeping with the changes in the respective CO and N_2 π orbital populations.

On a étudié la cocondensation d'atomes de nickel dans plusieurs milieux $^{12}C^{16}O/^{14}N_2$, $^{12}C^{16}O/^{14}N_2/Ar$, et $^{12}C^{18}O/^{14}N_2/^{15}N_2/Ar$ et on a enregistré les spectres infrarouge et Raman des produits à 4.2–10 °K. En plus des absorptions infrarouges associées avec les composés connus $Ni(N_2)_4$ et $Ni(CO)_4$, d'autres modes d'élongation NN et CO, qui peuvent être associés aux espèces mixtes carbonyle-diazote $Ni(N_2)_m(CO)_{4-m}$ où $m = 1$–3, ont été observés. La confirmation des structures moléculaires ainsi que des attributions des vibrations pour les espèces isolées a été obtenue à partir des (*a*) expériences à concentration variable où soit N_2 soit CO était en excès (*b*) expériences de chauffage de 10–35 °K contrôlées par diffusion et (*c*) expérience de substitution isotopique en utilisant un milieu $^{14}N_2/^{15}N_2/^{12}C\ ^{18}O/Ar$ dans lequel on a changé le rapport entre l'azote total et le monoxyde de carbone. Les constantes de force Cotton–Kraihanzel K_{CO} et K_{NN} ont été calculées pour les composés mélangés $Ni(CO)_3(N_2)$, $Ni(CO)_2(N_2)_2$, et $Ni(CO)_2(N_2)_3$ et les tendances à l'intérieur de cette série sont discutées en termes des propriétés de liaisons, donneur et accepteur, des coordinats N_2 et CO. On présente une analyse dans laquelle les changements dans les constantes de force pour l'élongation des liens CO et N_2 lors du passage de $Ni(CO)_m$ à $Ni(CO)_m(N_2)_{4-m}$ et de $Ni(N_2)_{4-m}$ à $Ni(CO)_m(N_2)_{4-m}$ sont reliés au changement de population dans les orbitales σ et π. Les résultats de l'analyse ont montré que le CO est à la fois un meilleur σ-donneur et un meilleur π-accepteur que le N_2. Les absorbances intégrées des bandes associées aux espèces $Ni(CO)_m(N_2)_{4-m}$ ont été mesurées et ont été utilisées afin d'obtenir les rapports des moments dipolaires de transition $(\mu_{CO}')_m$ et $(\mu_{N_2}')_m$ pour CO et N_2 respectivement. La tendance observée pour $(\mu_{CO}')_m$ et $(\mu_{N_2}')_m$ en fonction de m sont, comme il est prouvé, en accord avec les changements des populations respectives de l'orbitale π du CO et du N_2. [Traduit par le journal]

Can. J. Chem., 51, 2737 (1973)

Introduction

Since the discovery that N_2 can form dinitrogen complexes which are isoelectronic and isostructural with CO in carbonyl complexes, there has been a great deal of literature written concerning the similarities and differences between N_2 and CO as neutral ligands (1–5). For example, despite the obvious greater stability of CO complexes over their N_2 analogs, one finds that the decrease in the former's force constant from that of free CO is always less than that of the latter. This has led some authors (6) to speculate that N_2 may be a better acceptor than CO. A variety of techniques has been used to determine the relative importance of σ and π bonding of coordinated CO and N_2 in analogous carbonyl and dinitrogen complexes.

For example, Chatt *et al.* (5) used ligand fre-

For personal use only.

quency and bond stretching force constant shifts, Darensbourg (4) used infrared frequencies and absorption intensities, Bancroft *et al.* (2) used Mössbauer partial isomer shifts and partial quadrupole splittings, while Purcell (1) and Fenske and co-workers (3) used approximate molecular orbital calculations. The general consensus reached by most of these authors was that N_2 is weaker in both its σ-donor and its π-acceptor function in bonding to the metal, than is CO. Only in the case of Bancroft's Mössbauer data (for a series of low spin iron(II) complexes) and Fenske's theoretical studies was it possible to separate quantitatively the relative σ-donor and π-acceptor characteristics of N_2 relative to CO.

Obviously, a unique insight into this problem may be gained by studying the properties of complexes, where CO and N_2 are in direct competition with each other for bonding electrons. In this paper we discuss such a situation.

Transition metal atom vapors in their monatomic form are extremely reactive and are proving to be convenient starting materials for a wide variety of inorganic syntheses at cryogenic temperatures. This type of "synthesis with metal atoms" has been reviewed recently (7).

In a matrix infrared study involving the cocondensation of nickel atoms with dilute $^{12}C^{16}O$/Ar matrices DeKock (8) was able to assign the four carbonyl stretching modes associated with the compounds $Ni(CO)_m$ where $m = 1$–4.

Recently, we reported matrix infrared and Raman data for the products of the cocondensation reaction of nickel atoms with dilute $^{14}N_2$/Ar matrices (9) in which we were able to identify the binary nickel dinitrogen compounds $Ni(N_2)_m$ where $m = 1$–4 with end-on bonded dinitrogen (10), which are isostructural and isoelectronic withDeKock's binary nickel carbonyls, $Ni(CO)_m$. More recently still, Rest (11) reported the matrix synthesis of $Ni(CO)_3N_2$, by matrix u.v.-photolysis of $Ni(CO)_4$ in dilute N_2/Ar mixtures.

In this paper we are reporting infrared and Raman spectroscopic data for $Ni(CO)_m(N_2)_{4-m}$ where $m = 1$–3, formed in the cocondensation reaction of nickel atoms with CO/N_2 and CO/N_2/Ar matrices at 4.2–10 °K.

Experimental

Monatomic Ni vapor was generated by directly heating a thin (0.010 in.) ribbon filament of the metal with AC. The nickel (99.99%) was supplied by McKay Inc, New York. Research grade $^{14}N_2$ (99.99%), $^{12}C^{16}O$ (99.99%), and Ar (99.99%) were supplied by Prochem. Gas mixtures were prepared by conventional vacuum line techniques.

The furnace used for the evaporation of the metals has been described previously (12). The rate of metal atom depositions was continuously monitored using a quartz crystal microbalance (13). The deposition rate was set such that the probability that a metal atom had another metal atom as a nearest neighbor in either the N_2 or Ar f.c.c. lattice was approximately 1 in 10^3 assuming equal sticking coefficients for all species. Matrix gas flows, controlled by a calibrated micrometer needle valve, were usually in the range 2–8 mmol/h. In the infrared experiments matrices were deposited on a CsI window cooled to 10 °K by means of an Air Products Displex closed cycle helium refrigerator. Spectra were recorded on a Perkin Elmer 180 spectrophotometer. In the Raman experiments the matrices were deposited on a liquid helium cooled (4.2 °K) aluminum tip. Spectra were recorded on a Spex model 1401 Raman spectrophotometer using Carson argon ion 4800 and 5145 Å laser excitation.

Two different approaches were used to achieve the desired mixed carbonyl–dinitrogen complexes: (*i*) cocondensation of Ni atoms with CO/N_2/Ar mixtures (total CO/N_2:Ar = 1:10) at 4.2–10 °K which yields all of the lower coordination number, mixed species $Ni(CO)_x(N_2)_y$ where $x + y \leqslant 4$ followed by matrix annealing at 30–35 °K to yield the tetracoordinate species $Ni(CO)_m(N_2)_{4-m}$ or (*ii*) cocondensation of Ni atoms with the same CO/N_2/Ar mixtures but at approximately 30 °K. Method (*ii*) apparently yielded a thermodynamically equilibrated mixture since little change could be induced by further annealing while method (*i*) required prolonged annealing to achieve the same results.

As well as runs containing 1:1 mixtures of N_2/CO in argon, experiments were carried out with gas mixtures containing excess N_2, for example, CO/N_2/Ar = 1/9/20 at 4.2–10 °K followed by annealing to 30 °K. Under these conditions the species containing the greatest number of N_2 ligands were favored. (The stability of these complexes apparently increases with increasing number of CO ligands.) Prolonged warming to 30–35 °K caused these species to decline gradually in relative abundance. Experiments of this sort helped in assigning the observed absorptions to the various species in the matrix.

Two main types of runs were performed. The first used mixtures of $^{12}C^{16}O$ with $^{14}N_2$ with various amounts of argon. The second used $^{12}C^{18}O$ with $^{14}N_2/^{15}N_2$/Ar mixtures of various ratios. The data from the latter set of experiments were used to aid in the assignment, determine the stoichiometries and calculate the C.K. force constants of the products formed. In the matrix–Raman experiments, metal atoms were deposited into pure $^{12}C^{16}O/^{14}N_2$ mixtures containing excess $^{14}N_2$ to maximize the formation of the less stable dinitrogen species.

Results and Discussion

When Ni atoms were cocondensed with $^{12}C^{16}O$:$^{14}N_2$:Ar = 1:1:20 mixtures at 10 °K and then annealed at 30 °K, apart from the strong infrared absorption assigned to $^{12}C^{16}O$ (2138 cm^{-1}) and its weak $^{12}C^{18}O/^{13}C^{16}O$ (2090 cm^{-1}) isotopic counterpart and $Ni(^{12}C^{16}O)_4$ at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2048 cm^{-1}, five new absorptions were observed in the NN stretching region at 2269.6, 2264.4, 2257.6, 2240.0, and 2210.3 cm^{-1}, and five absorptions in the CO stretching region at 2100.6, 2084.3, 2029.4, 2005.0, and 1991.3 cm^{-1} (Figs. 1, 2).

A number of features of this spectrum are worth noting. First, the spectroscopic *absence* of $Ni(N_2)_m$ and $Ni(CO)_m$ where m = 1–3 but the *presence* of the more stable tetracarbonyl $Ni(CO)_4$ at 2049.7 cm^{-1} (T_2). Second, the much larger infrared absorption intensities of the new CO stretching modes compared to their NN counterpart stretching modes. Third, *all* of the new NN stretching modes shift to *higher* frequencies compared to $Ni(N_2)_4$ whereas *four* CO stretching modes shift to *lower* and *two* to *higher* frequencies compared to $Ni(CO)_4$. In addition to the strong carbonyl stretching modes below 2048 cm^{-1}, the much weaker and very sharp absorptions observed at about 2100.6 and 2084.3 cm^{-1} are tentatively assignable to totally symmetric CO stretching modes (of which the stronger carbonyl modes mentioned above are their asymmetric counterparts).

These preliminary data are qualitatively what one would expect for the formation of *three* new molecules $Ni(CO)_3(N_2)$, $Ni(CO)_2(N_2)_2$, and $Ni(CO)(N_2)_3$.

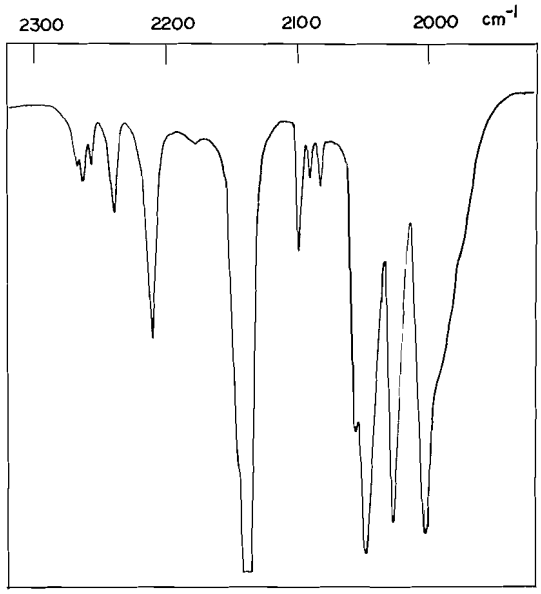

FIG. 1. The matrix infrared spectrum of the products of the cocondensation reaction of Ni atoms with $^{12}C^{16}O$: $^{14}N_2$:Ar = 1:1:20 mixture at 10 °K.

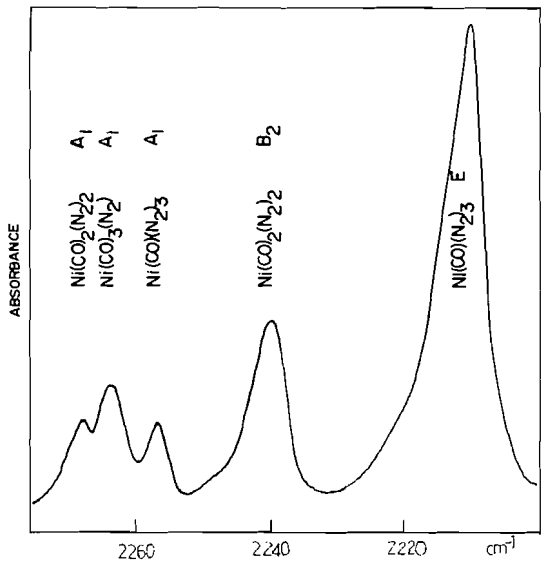

FIG. 2. The same as Fig. 1 but showing the νNN stretching region under conditions of high resolution with scale expansion.

Matrix Infrared Experiments

Monocarbonyl Trisdinitrogen Nickel(0), $Ni(CO)(N_2)_3$

When nickel atoms were cocondensed with $^{12}C^{16}O$:$^{14}N_2$:Ar = 1:9:20 at 10 °K and annealed at 30 °K, and the infrared spectrum compared to the 1:1:20 run described earlier (Fig. 1), it is apparent that higher dinitrogen species $Ni(N_2)_4$, $Ni(N_2)_3(CO)$ are being preferentially formed and one can assign the observed infrared lines shown below:

$Ni(N_2)_3(CO)$, (C_{3v}), ν_{A_1}CO, 2005.0 cm^{-1}; ν_ENN, 2210.3 cm^{-1}; ν_{A_1}NN, 2257.6 cm^{-1}.

$Ni(N_2)_4$, (T_d), ν_{T_2} NN 2173.0 cm^{-1} (9).

The observed $^{12}C^{18}O$ isotopic shift for $Ni(N_2)_3$-(CO) from 2005 to 1959 cm^{-1} is in excellent agreement with the calculated value (Tables 1, 2).

Using an isotopic mixture $^{12}C^{18}O$:$^{14}N_2$:$^{15}N_2$:Ar = 1:1:1:30 and experimental conditions similar to above, the multiplet structure of the NN stretching mode at 2210.3 cm^{-1} was carefully examined under conditions of high resolution (Fig. 3).

Four isotopic molecules for $Ni(N_2)_3(CO)$ are expected using $^{12}C^{18}O/^{14}N_2/^{15}N_2$/Ar isotopic mixtures as shown above. Because the ^{15}N isotopic shift for the E type infrared NN stretching mode of $Ni(N_2)_3(CO)$ is expected to be about

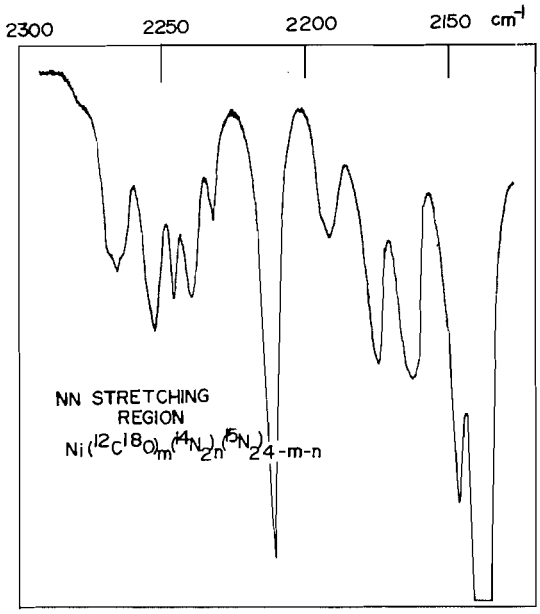

FIG. 3. The matrix infrared spectrum of the products of the cocondensation reaction of Ni atoms with $^{12}C^{18}O$: $^{14}N_2$:$^{15}N_2$:Ar = 1:1:1:30 showing the ^{14}N and ^{15}N isotope multiplet structure for the series of complexes $Ni(^{12}C^{18}O)_m(^{14}N_2)_n(^{15}N_2)_{4-n-m}$ (where m = 1–3 and n = 0–3).

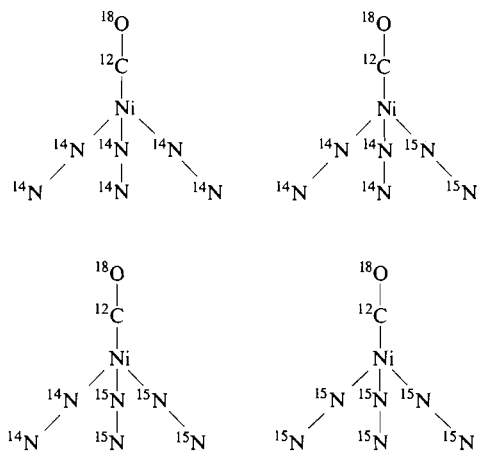


$^{12}C^{16}O$ in the isotopic $^{12}C^{18}O$ (see Table 2). These data serve to characterize $Ni(N_2)_3(CO)$ and place the ligand assignments on a firm basis.

It is interesting to note that prolonged warm-up of the species $Ni(N_2)_4$ and $Ni(N_2)_3CO$ in the presence of CO caused a decrease in intensity of the absorptions associated with these species, whereas the other absorptions presumably belonging to $Ni(CO)_2(N_2)_2$ and $Ni(CO)_3(N_2)$ were affected to only a minor extent. This would again indicate that the higher carbonyl species are more stable than the higher dinitrogen species.

Tricarbonyl Monodinitrogen Nickel(0) and Dicarbonyl Bisdinitrogen Nickel(0), $Ni(CO)_3(N_2)$ and $Ni(CO)_2(N_2)_2$

When Ni atoms were cocondensed with either $^{12}C^{16}O$:$^{14}N_2$:Ar = 1:1:20 or 9:1:20 at 10 °K and annealed at 30 °K, the absorptions associated with higher carbonyl species were always predominant compared to the analogous dinitrogen species. Examination of the infrared spectra shows the absence of $Ni(N_2)_4$ and very little $Ni(CO)(N_2)_3$ but the presence of considerable quantities of $Ni(CO)_4$, $Ni(CO)_3(N_2)$, and $Ni(CO)_2(N_2)_2$.

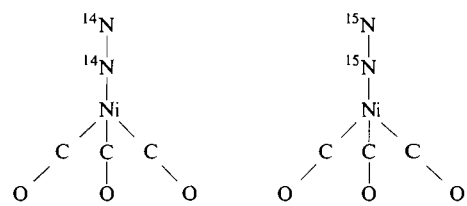
The distribution of absorption intensities under these conditions supports our initial tentative assignments of $Ni(CO)_3(N_2)$ and $Ni(CO)_2(N_2)_2$ as follows: $^{12}C^{16}O$:$^{14}N_2$:Ar = 1:1:20 or 9:1:20:

$Ni(^{12}C^{16}O)_3(^{14}N_2)$, (C_{3v}), ν_{A_1}NN, 2264.4 cm^{-1}; ν_{A_1}CO, 2100.6 cm^{-1}; ν_ECO, 2029.4 cm^{-1}.

$Ni(^{12}C^{16}O)_2(^{14}N_2)_2$, (C_{2v}), ν_{A_1}NN, 2269.6 cm^{-1}; ν_{B_2}NN, 2240.0 cm^{-1}; ν_{A_1}CO, 2084.3 cm^{-1}; ν_{B_1}CO, 1991.3 cm^{-1}.

The observed $^{12}C^{18}O$ isotopic shifts for $Ni(^{12}C^{18}O)_3(^{14}N_2)$ and $Ni(^{12}C^{18}O)_2(^{14}N_2)_2$ are in excellent agreement with the calculated values (see Tables 1, 2).

Using experimental conditions similar to the above, we cocondensed Ni atoms with $^{12}C^{18}O$: $^{14}N_2$:$^{15}N_2$:Ar = 1:1:1:30 mixtures in order to determine the multiplet structure of the NN stretching modes which we have assigned to $Ni(CO)_3(N_2)$ and $Ni(CO)_2(N_2)_2$. Two C_{3v} isotopic molecules are expected (shown below) for $Ni(CO)_3(N_2)$



using $^{14}N_2/^{15}N_2$ mixed isotopes which should yield a *single* NN stretching mode in the $^{14}N_2$ region and a *single* $^{15}N_2$ counterpart mode shifted by approximately 73 cm^{-1} to lower frequencies.

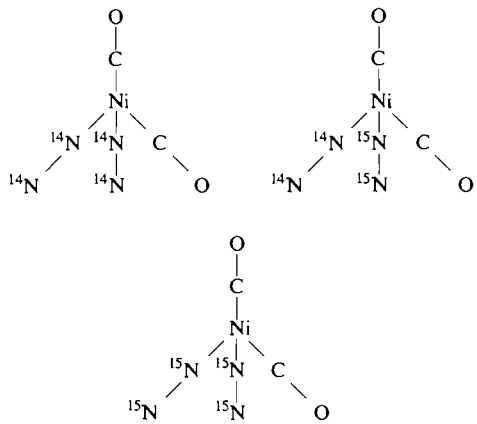
A doublet is observed at 2265 and 2191 cm^{-1} consistent with this prediction and serves to characterize the monodinitrogen-tricarbonyl molecule, $Ni(CO)_3(N_2)$. These vibrational assignments are in excellent agreement with those recently reported by Rest (11) for $Ni(CO)_3(N_2)$ produced in the matrix u.v. photolysis of $Ni(CO)_4$ isolated in dilute N_2/Ar matrices at 17 °K.

In this context, it seems reasonable to assign some disturbingly intense infrared absorptions in the 2100–2000 cm^{-1} region, which were not accounted for in DeKock's (8) $Ni(CO)_m$ study, to the mixed complex $Ni(CO)_3(N_2)$ presumably formed from "trace nitrogen impurities" in the CO/Ar mixtures or cryopumped onto the central cold plate during the matrix isolation experiment.

Having satisfactorily identified the NN and CO stretching modes belonging to $Ni(CO)_3(N_2)$ and $Ni(CO)(N_2)_3$, it remains to confirm that the observed infrared absorptions at 2269.6, 2240.0, 2084.3, and 1991.3 cm^{-1} belong to the dicarbonyl–bisdinitrogen complex $Ni(CO)_2(N_2)_2$.

Three isotopic molecules are expected for $Ni(CO)_2(N_2)_2$ using $^{12}C^{18}O$ and $^{14}N_2/^{15}N_2$ mixtures:



which should yield a *triplet* pattern in the $^{14}N_2$ region and a similar *triplet* pattern, shifted to lower frequencies by about 75 cm^{-1}, in the $^{15}N_2$ region.

This doublet of triplets multiplet structure was observed at 2265, 2253, 2240 and 2191, 2174, 2161 cm^{-1} (Tables 1, 2) and adequately serves to characterize the dicarbonyl-bisdinitrogen molecule, $Ni(CO)_2(N_2)_2$.

Matrix Isolation Laser Raman Experiments

Although we have been able to obtain high quality matrix Raman spectra for $Ni(N_2)_4$ in Ar (9), the analogous measurements for the mixed species $Ni(CO)_m(N_2)_{4-m}$ in Ar proved to be considerably more difficult primarily because of laser absorption throughout the visible range 4880–6471 Å and subsequent local heating of the matrix leading to decomposition.

This local heating effect by the laser beam was minimized by using extremely low power laser excitation. Reasonable quality Raman spectra could be obtained by cocondensing Ni atoms with $^{12}C^{16}O$:$^{14}N_2$ = 1:3 mixtures at 25–30 °K (see Fig. 3). The results showed that all of the molecules $Ni(CO)_m(N_2)_{4-m}$ were present under these conditions in comparable proportions. (In agreement with pure $^{12}C^{16}O$:$^{14}N_2$ = 1:1 matrix infrared experiments, our analogous 1:1 Raman experiments show predominantly $Ni(CO)_4$ and only minute quantities of the mixed carbonyl–dinitrogen species.)

The Raman data for the 1:3 mixture shown in Fig. 4, apart from the intense lines due to $^{12}C^{16}O$ (2138 cm^{-1}) and $^{14}N_2$ (2328 cm^{-1}) and much less intense lines due to natural abundance isotopes $^{12}C^{18}O$, $^{13}C^{16}O$ and $^{14}N^{15}N$, show weak lines at 2266, 2242, 2112, 2173 cm^{-1} assignable to NN stretching modes and 2098, 2076, 2048, 2026, 2002, 1996 cm^{-1} assignable to CO stretching modes of $Ni(CO)_m(N_2)_{4-m}$.

The correlation between the matrix Raman and matrix infrared data is excellent for the lines which are expected to show coincidences (that is, matrix shifts observed on passing from pure

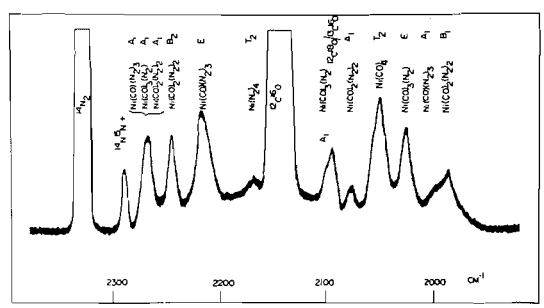


FIG. 4. The matrix Raman spectrum of the products of the cocondensation reaction of Ni atoms with $^{12}C^{16}O$:$^{14}N_2$ = 1:3 at 25–30 °K (spectrum recorded at 4.2 °K) showing all of the species $Ni(^{12}C^{16}O)_m(^{14}N_2)_{4-m}$ (where m = 0–4).

TABLE 3. Calculated Cotton–Kraihanzel force constants for $Ni(CO)_m(N_2)_{4-m}$ ($m = 1, 2, 3$)

Frequency and Cotton–Kraihanzel Force Constant Calculations for Isotopically Substituted $Ni(CO)_m(N_2)_{4-m}$

We have reported previously (9) that the Cotton–Kraihanzel force field approximation (15) applied usually to carbonyls is also successful in predicting NN stretch frequencies of binary dinitrogen complexes. We therefore use this approximation in calculating the force constants for the mixed carbonyl–dinitrogen complexes $Ni(CO)_m(N_2)_{4-m}$ assuming end-on bonded ligands and symmetries as shown below.

Molecule	Symmetry	ν_{NN}	ν_{CO}
$Ni(CO)(N_2)_3$	C_{3v}	A_1+E	A_1
$Ni(CO)_2(N_2)_2$	C_{2v}	A_1+B_2	A_1+B_1
$Ni(CO)_3(N_2)$	C_{3v}	A_1	A_1+E

The best values of the force constants for each of the three molecules $Ni(CO)_m(N_2)_{4-m}$ were obtained by a least squares fit. All reasonable assignments of the various lines among the three molecules were attempted. Those reported give by a substantial margin the best fit. It is gratifying that the assignment which gave the best fit is also that deemed most likely on the basis of matrix experiments containing either excess N_2 or CO. Calculated frequencies based on these force constants are listed in Tables 1 and 2. The values of the calculated force constants are listed in Table 3. These data are also plotted in Fig. 5 together with the corresponding data for $Ni(CO)_m$ and $Ni(N_2)_m$ where $m = 1 \rightarrow 4$.

The trends in the computed force constants illustrated in Fig. 5 are noteworthy. In particular one notes that the NN stretching force constant for $Ni(CO)_2(N_2)_2$ is larger than that of the other two mixed carbonyl dinitrogen species.

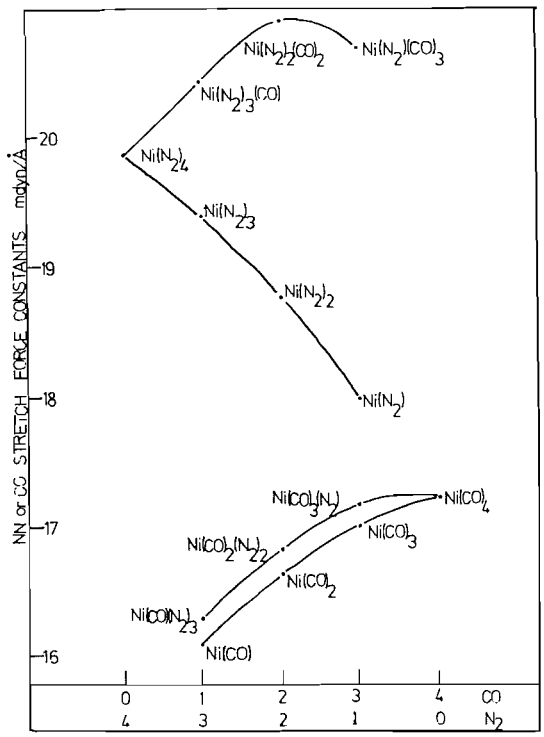

FIG. 5. Graphical plot of the NN and CO Cotton–Kraihanzel bond stretching force constants for the species $Ni(CO)_m(N_2)_{4-m}$, $Ni(CO)_m$ and $Ni(N_2)_m$ (where $m = 1$–4) as a function of m.

These observations are discussed in the next section.

The Relative Donor and Acceptor Properties of CO and N_2

Despite the fact that the relative donor and acceptor properties of ligands have been discussed widely in the current literature, these quantities are seldom rigorously defined. Accordingly for the purpose of the subsequent discussion we define the basicity and acidity of a ligand as follows.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

We assume that one can define a donor orbital and an acceptor orbital for the free ligand. For example, in CO the 5σ orbital of the free CO is the donor orbital and the 2π is the acceptor orbital; while in free N_2 the correct donor orbital is not $3\sigma_g$ but rather, following Fenske's notation (3), $\theta_5 = (1/\sqrt{2})(2\sigma_u + 3\sigma_g)$ which is centered on the N atom about to bond to the metal. Thus although more than one orbital is involved in the donation, one can form a linear combination of these, thereby defining a single "donor orbital". The proper acceptor orbital of N_2 is $1\pi_g$.

After the ligand bonds one can, in principle, express the ligand's charge distribution in a basis of the *free* ligand *molecular* orbitals; in this manner the σ donor ability of the ligand is defined by $n_\sigma^0 - n_\sigma$ where n_σ^0 is the σ-orbital occupation of the free ligand ($n_\sigma^0 = 2$ in the case of CO and N_2), while n_σ is the σ-orbital occupation of the bonded ligand.

Similarly the acceptor ability of the ligand is defined by $n_\pi - n_\pi^0$ where n_π^0 and n_π have analogous definitions ($n_\pi^0 = 0$ in CO and N_2). For simplicity we write

$$\sigma = n_\sigma^0 - n_\sigma$$

and

$$\pi = n_\pi - n_\pi^0$$

and we say that ligand L_1 is a better σ-donor (base) towards a particular metal atom or ion than ligand L_2 if $\sigma_1 > \sigma_2$ with a similar definition existing for relative π-acceptor ability (acidity).

Turning our attention specifically to the $Ni(CO)_m(N_2)_{4-m}$ case, we assume (in an analogous fashion to Fenske and co-worker (16)) that the CO bond stretching force constant in the above series of compounds may be written

$$f_m^{CO} = an_{\sigma m}^{CO} + bn_{\pi m}^{CO} + c$$

This equation can be rewritten as

$$[1] \qquad f_m^{CO} = d - a\sigma_m^{CO} + b\pi_m^{CO}$$

where $d = 2a + c$. We also assume that an identical equation holds for the CO stretch force constants K_m^{CO} of the series of binary carbonyls $Ni(CO)_m$, namely

$$[2] \qquad K_m^{CO} = d - a\sigma_m^{CO'} + b\pi_m^{CO'}$$

where the prime distinguishes the orbital populations in the $Ni(CO)_m$ case from that of $Ni(CO)_m(N_2)_{4-m}$. So that

$$[3] \quad f_{4-m}^{N_2} = d' - a'\sigma_{4-m}^{N_2} + b'\pi_{4-m}^{N_2}$$

and

$$[4] \quad K_{4-m}^{N_2} = d' - a'\sigma_{4-m}^{N_2'} + b'\pi_{4-m}^{N_2'}$$

Now if eq. 1 is assumed to hold for free CO and free CO^+, the quantity a would be given by

$$a = K_{CO} - K_{CO^+}$$

where K_{CO} and K_{CO^+} are, respectively, the bond stretching force constants of CO and CO^+. Similarly a' would be given by

$$a' = K_{N_2} - K_{N_2^+}$$

with analogous definitions for K_{N_2} and $K_{N_2^+}$. It is unlikely that this should be exactly the case; nevertheless one might at least expect the signs of a and a' to be correctly given by the above equations. Thus a is a negative quantity while a' is a positive quantity.[1] At the same time one expects both b and b' to be negative quantities implying the generally accepted fact that the ligand force constant decreases as the π overlap increases. Accordingly eqs. 1 and 3 will take the forms

$$[5] \qquad f_m^{CO} = d + |a|(\sigma_m^{CO} - \gamma\pi_m^{CO})$$

and

$$[6] \quad f_{4-m}^{N_2} = d' - a'(\sigma_{4-m}^{N_2} + \gamma'\pi_{4-m}^{N_2})$$

respectively, where γ and γ' are, respectively, $|b/a|$ and $|b'/a'|$. Similar equations hold for K_m^{CO} and $K_{4-m}^{N_2}$.

It is evident therefore that the force constants of bonded CO depend on a $(\sigma - \pi)$-like term while those of bonded N_2 on a $(\sigma + \pi)$-like term. This explains to some extent the greater decrease in the NN stretching frequencies (from that of the free ligand) observed in N_2 complexes than the corresponding decrease in the CO stretch force constant in the analogous carbonyls.

The data shown in Fig. 5 indicate that the CO stretch force constants for the species $Ni(CO)_m(N_2)_{4-m}$ are increased only *slightly* from those of the analogous $Ni(CO)_m$ complexes, while the NN stretch force constants are *markedly* in-

[1] $K_{CO} = 18.46$, $K_{CO^+} = 19.26$, $K_{N_2} = 22.37$, $K_{N_2^+} = 19.50$ mdyn/Å. These quantities were calculated from observed vibrational frequencies reported by Herzberg (17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

creased in the former species from those of the analogous $Ni(N_2)_{4-m}$ complexes. Furthermore, the NN stretch force constants for the $Ni(CO)_m(N_2)_{4-m}$ molecules are in every case *larger* than $K_4^{N_2}$, *i.e.*, that of $Ni(N_2)_4$, while the CO stretching force constant in the $Ni(CO)_m(N_2)_{4-m}$ molecules are in every case *smaller* than K_4^{CO}, *i.e.*, that of $Ni(CO)_4$. This implies (see eqs. 5 and 6) that the addition of $(4-m)$ N_2's to $Ni(CO)_m$ to form $Ni(CO)_m(N_2)_{4-m}$ causes the quantity $(\sigma^{CO} - \gamma\pi^{CO})$ to increase less than it does on adding $(4-m)$ CO's to form $Ni(CO)_4$; while on adding m CO's to $Ni(N_2)_{4-m}$ to form $Ni(CO)_m(N_2)_{4-m}$ the quantity $-(\sigma^{N_2} + \gamma'\pi^{N_2})$ increases more than it does on adding m N_2's to form $Ni(N_2)_4$. An analysis of the nine different possibilities[2] regarding the relative σ-donor, π-acceptor properties of the two ligands indicates that these trends are only consistent with CO's being a better acceptor than N_2. Furthermore, the fact that $f_{4-m}^{N_2} > K_{4-m}^{N_2}$ while $f_m^{CO} \simeq K_m^{CO}$ implies that in the former case there is both a large σ change and a large π change while in the latter case both σ and π changes are small. Hence CO is a better σ donor than N_2 or at least equal to it.

Turning our attention to the apparently anomalous value of $f_1^{N_2}$, we find that this too is a result of the better acceptor ability of CO over that of N_2. As one proceeds from $Ni(CO)_3N_2$ to $Ni(CO)(N_2)_3$ (*i.e.*, as $4-m$ increases), $\pi_{4-m}^{N_2}$ is expected to *increase* due to decrease in the number of CO's. (This is opposite to the trend one expects in $Ni(N_2)_m$ where there are no CO's to compete for the back donated electrons.) At the same time the presence of CO's on the Ni makes the metal more acidic, thereby increasing σ donation by the N_2's. Thus reducing the number of CO's *reduces* $\sigma_{4-m}^{N_2}$. The quantity $\sigma_{4-m}^{N_2} + \gamma'_{4-m}{}^{N_2}$ would therefore have a minimum, and $f_{4-m}^{N_2}$ a maximum, when the slope of $\sigma_{4-m}^{N_2}$ *vs.* $4-m$ is equal but opposite in sign to the slope of $\pi_{4-m}^{N_2}$ *vs.* $4-m$. A maximum is, in fact, observed for $f_2^{N_2}$ $(Ni(CO)_2(N_2)_2)$.

Infrared Intensities

Darensbourg (4) has attempted in several publications to relate the integrated infrared absorption intensities of bonded CO and N_2 to the π electronic charge transfer from the metal to the ligand. He has shown, for instance, that the absorbance due to the NN vibration correlates with its stretching frequency in a series of related dinitrogen complexes. This correlation indicates in fact that the transition dipole depends on both the σ as well as the π overlap.

We have measured the integrated absorbance of the bands associated with the species $Ni(CO)_m(N_2)_{4-m}$ (where bands overlapped, the individual components were obtained by means of a Lorentz line shape fit), but because the concentration of these species in the matrix is not known accurately, only ratios $(\mu_{CO}'/\mu_{N_2}')_m$, where μ_{CO}' and μ_{N_2}' are the transition dipole moments of the CO and N_2 ligand within the molecule $Ni(CO)_m(N_2)_{4-m}$, could be calculated.

The quantity μ_{CO}'/μ_{N_2}' was obtained from the relations

$$[7] \qquad \sum I_m = c_m \sum_{k'k''} \frac{\partial \boldsymbol{\mu}}{\partial S_{k'}} \cdot \frac{\partial \boldsymbol{\mu}}{\partial S_{k''}} G_{k'k''}$$

where c_m is an unknown constant proportional to the concentration of $Ni(CO)_m(N_2)_{4-m}$, and the other quantities are defined in ref. 4.

After obtaining μ_{CO}'/μ_{N_2}' one can substitute back into [7] and obtain $c_m\mu_{CO}'^2$ and $c_m\mu_{N_2}'^2$. All of these quantities are listed in Table 4. It is noteworthy that both $c_m\mu_{CO}'^2$ and $c_m\mu_{N_2}'^2$ *decrease* with *increasing m*.

Although the values c_m are not known one expects c_m to *decrease* as *m decreases*, thus, if anything μ_{CO}' and μ_{N_2}' both *increase* even more rapidly than indicated in Table 4 with decreasing number of CO's. This observation is in fact easily understandable. The decrease in μ_{CO}' with increasing number of CO ligands may be given the conventional explanation that the back-donated electrons must be shared by more CO's as the number of CO's increases, hence the π overlap population to an individual CO decreases, while the increase in μ_{N_2}' with increasing number of N_2's is explained by assuming that the number

TABLE 4. Calculated μ_{CO}'/μ_{N_2}' values for the molecules $Ni(CO)_m(N_2)_{4-m}$

m	Molecule	μ_{CO}'/μ_{N_2}'	$c_m\mu_{CO}'^2$	$c_m\mu_{N_2}'^2$
1	$NiCO(N_2)_3$	3.60	76.9	5.94
2	$Ni(CO)_2(N_2)_2$	3.97	55.7	3.53
3	$Ni(CO)_3N_2$	4.34	22.8	1.21

[2]These are: CO is an equal donor and an equal acceptor, an equal donor and a better acceptor, an equal donor and a worse acceptor, a better donor and an equal acceptor, a better donor and a better acceptor, a better donor and a worse acceptor, etc. than N_2.

of CO's present in the molecule determines the quantity of charge available for backbonding to the dinitrogens; this being a direct result of the fact that CO is a much better acceptor than N_2.

These observations are therefore in keeping with the view (4) that the transition dipole associated with the vibration of a ligand like CO or N_2 increases with increasing π overlap in a series of related compounds, here $Ni(CO)_m(N_2)_{4-m}$.

It should be pointed out that this observation does not preclude a dependence of μ_{CO}' or μ_{N_2}' on the σ-donor population as well as the π but rather it reflects the fact that in the $Ni(CO)_m(N_2)_{4-m}$ series, it is mainly the π overlap which changes as m varies.

Summary

Using the combined techniques of matrix infrared and Raman spectroscopy and isotope substitution we have been able to characterize for the first time the binary mixed dinitrogen–carbonyl complexes of nickel, $Ni(CO)_m(N_2)_{4-m}$ (where m = 1–3), formed in the cocondensation reaction of Ni atoms with $CO/N_2/Ar$ mixtures at 4.2–40 °K. The vibrational data for these complexes, when taken in conjunction with the data for the binary dinitrogen and carbonyl complexes $Ni(N_2)_m$ and $Ni(CO)_m$ (where m = 1–4) have proven to be of considerable value in shedding new light on the bonding properties of N_2 and CO in the unique situation, when bonded to the same metal atom and thereby competing for the same bonding electrons.

An analysis has been presented for the series of complexes $Ni(CO)_m(N_2)_{4-m}$ which attempts to correlate the changes in the C.K. CO and N_2 force constants with the respective changes in the σ and π orbital populations. With this type of approach, it has proven possible to effect a qualitative separation of the relative σ-donor and π-acceptor properties of the two ligands where the conclusions are found to be in agreement with those reported independently by Chatt *et al.* (5), Darensbourg (4), Bancroft *et al.* (2), and Fenske and co-workers (3), that is, CO is both a better σ-donor and a better π-acceptor than N_2.

We wish to thank Mr. Ted Huber for valuable technical assistance and the National Research Council of Canada, the Research Corporation, and Erindale College for financial assistance.

Transport Numbers for Hydrochloric Acid at Elevated Temperatures

DIGBY D. MACDONALD[1,2] AND D. OWEN

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba R0E 1L0

Received December 15, 1972

Transport numbers for H^+ and Cl^- have been measured as a function of concentration and temperature to 200 °C using electrolyte concentratio. ells. The infinite dilution transport number for H^+ decreases with temperature while that for Cl^- increases. This temperature dependence is discussed in terms of thermal destruction of the three dimensional structure of liquid water.

Les nombres de transport pour H^+ et Cl^- ont été déterminés en fonction de la concentration et de la température jusqu'à 200 °C en utilisant des cellules de concentration en électrolytes. Le nombre de transport à la dilution infinie pour H^+ décroît avec la température alors que celui de Cl^- croît. La discussion de cette dépendance vis à vis de la température a porté sur la destruction thermique de la structure tridimensionnelle de l'eau liquide. [Traduit par le journal]

A fundamental electrochemical property of an ion in solution is its transport number, *i.e.* the fraction of the total current carried by the ion under electrolysis. The experimental techniques used to derive transport numbers for ions at room temperature have been well reviewed by Robinson and Stokes (1), but little work has been reported on extending these techniques to higher temperatures. In this paper we describe the use of electrolyte concentration cells with and without liquid junction to determine the transport numbers of H^+ and Cl^- ions in hydrochloric acid at temperatures to 200 °C. Smith and Dismukes (2) have previously measured transport numbers in 0.1 mol/l KCl and NaCl solutions at temperatures to 125 °C using the moving boundary technique. Quist and Marshall (3) extrapolated these data to 400 °C to calculate limiting equivalent conductances for the single ions Na^+, H^+, K^+, NH_4^+, Li^+, Cl^-, and OH^- over the same temperature range.

The two compartment high temperature concentration cell with liquid junction [I] has been described elsewhere (4) and is similar in design to that used by Mesmer, Baes, and Sweeton (5) for high temperature acidity measurements in aqueous systems

$$[I] \qquad Pt,H_2 \left| \begin{matrix} H^+Cl^- \\ (m_1) \end{matrix} \right. \vdots \left. \begin{matrix} H^+Cl^- \\ (m_2) \end{matrix} \right| H_2,Pt$$

The concentric compartments contained lightly platinized platinum tube electrodes which also served as thermocouple wells for temperature measurement. The solutions in the two compartments were agitated by Teflon covered magnetic stirring bars which were activated by a rotating magnet located beneath the aluminum oil bath used for temperature control. Electrolytic contact between the two compartments was maintained through a porous (10 μm pore) Teflon disc. All potential measurements were made using a Beckman Research p*H* meter. A typical experiment consisted of loading cell I with the appropriate solutions ($m_1 = 0.10$, $m_2 = 1.00$, 0.50, 0.10, and 0.05 mol/kg), degassing followed by pressurization with hydrogen gas to 0.3 MN/m^2 and then heating the cell in steps of 10–15 °C up to 200 °C. Potentials (E_T) were measured after thermal equilibrium had been achieved and recorded after they had become sensibly constant (change <0.1 mV/h). The measured potentials are listed in Table 1 and were reproducible to about ± 0.2 mV as determined by triplicate experiments.

Potentials (E) for the concentration cell without liquid junction, [II],

$$[II] \qquad Pt,H_2 \left| \begin{matrix} H^+Cl^-, [AgCl] \\ (m_1) \end{matrix} \right| Ag \left| \begin{matrix} [AgCl], H^+Cl^- \\ (m_2) \end{matrix} \right| H_2,Pt$$

were calculated from the data of Greeley *et al.* (6) for the cell $Pt,H_2|H^+Cl^-$, [AgCl]|Ag at elevated temperatures and are listed in Table 1. The polynomial [1] was fitted to the potential data for cells I and II

$$[1] \qquad E_T = C_0 + C_1E + C_2E^2$$

*Interpolated from the data of Greeley *et al.* (6).

by a least squares technique at each temperature. The coefficients in eq. 1 and the associated standard deviations obtained by this procedure are listed in Table 2 for various temperatures between 25 and 200 °C.

Transport numbers for chloride ion, t_{Cl^-}, were calculated (1) from data listed in Table 1 using eq. 2

$$[2] \qquad t_{Cl^-} = (dE_T/dE)_{m_2}$$

where subscript m_2 designates the concentration of HCl at which the differential was evaluated. Transport numbers for hydrogen ion, t_{H^+}, were then evaluated using the relationship

$$[3] \qquad t_{H^+} = 1 - t_{Cl^-}$$

The above values were extrapolated by plots of t_{H^+} and t_{Cl^-} *vs.* $\sqrt{m_2}$ to $m_2 = 0$ to obtain the infinite dilution values listed in Table 2.

Plots of $t_{H^+}^\circ$ and $t_{Cl^-}^\circ$ *vs.* temperature to 200 °C are shown in Fig. 1. The values obtained in this work at 25 °C agree within experimental error (±0.005) with the accepted values listed by Robinson and Stokes (1) but differ by up to 5% from the values calculated from the limiting conductance data of Quist and Marshall (3) at higher temperatures. However, the data of Quist and Marshall were obtained by extrapolation of transport numbers for 0.1 mol/l KCl and NaCl solutions from $T < 125$ °C to higher temperatures together with conductance data for these and HCl solutions at elevated temperatures. In view of the errors inherent in extrapolations of this type, the differences found between the two sets of data are surprisingly small.

The data plotted in Fig. 1 shows that the infinite dilution transport numbers for H^+ and Cl^- exhibit "normal" variation with temperature, *i.e.* the cation and anion transport numbers approach equality with increasing temperature. Sodium chloride solutions exhibit similar be-

havior whereas in KCl solutions, the opposite has been observed to occur (1, 2).

It is generally recognized (1) that the abnormally high transport number for H^+ in aqueous solution is due to high mobility via a chain mechanism. In this mechanism the proton jumps from one water molecule to a neighboring one via the formation of a hydrogen bond. The rate at which this occurs is believed to be determined by the rate of rotation of water molecules into the hydration sheath of the H_3O^+ ion as the proton passes along the chain (7). This chain mechanism operates in parallel with the motion-in-a-viscous-fluid mechanism commonly used to describe the transport properties of ions other than H^+ or OH^-, *e.g.* Cl^-. At low temperatures this chain mechanism predominates and accounts for the large mobility observed for the proton in aqueous solution. However, it is likely that this process is highly cooperative in nature in that proton transfer cannot take place until a suitable orientation is attained by the rotating acceptor water molecule. Simple geometric considerations indicate that the required orientation is such that the molecule also satisfies the spatial requirements for tetrahedral bonding within the surrounding network of bonded water molecules. Accordingly, these orientations, on average, will be favored over the average orientation presented by a rotating non-bonded acceptor molecule. Thus, an increase in temperature, which results in destruction of the tetrahedral structure of water, will disfavor transport by the chain mechanism and the motion of hydrated H^+ in the field will be increasingly determined by the viscosity of the medium. In this manner, it is expected that the fractional increase in mobility of the proton for a given increase in temperature will be less than that for other small ions. The data of Quist and Marshall (3) show that this is indeed the case for ions such as Li^+, Na^+, K^+, NH_4^+, Cl^-, HSO_4^-, and SO_4^{2-}. Thus, for a hydrogen chloride solution the fraction of charge carried by H^+, and hence $t_{H^+}{}^0$, will decrease with rising temperature as observed.

Evidence for Reactive Intermediates Formed During Pyrolyses of α-Betaines: A Mass Spectrometric Investigation[1]

RUDOLPH A. CHAMPA[2] AND D. L. FISHEL[3]

Department of Chemistry, Kent State University, Kent, Ohio 44242

Received June 18, 1971[4]

Pyrolytic decomposition of glycine betaine, 2-(*N*-pyridyl)acetic acid betaine and 2-(*N*-pyridyl)propionic acid betaine were conducted in inlet systems of two mass spectrometers of differing geometries. Evidence was obtained for primary thermolysis with loss of carbon dioxide to give an ylid from each betaine. The ylids may react further by several alternate pathways involving either hydrogen abstraction, rearrangement and teleomerization, or by divalent carbon transfer by insertion reactions.

La décomposition pyrolytique des bétaines de la glycine, de l'acide (*N*-pyridyl)-2 acétique et de l'acide (*N*-pyridyl)-2 propionique, a été effectuée dans les systèmes d'introduction de deux spectromètres de masse de géométrie différente. La thermolyse primaire a été mise en évidence par perte de gaz carbonique et formation d'un ylure à partir de chaque bétaine. Les ylures peuvent réagir ensuite selon diverses voies: perte d'hydrogène, réarrangement et téléomérisation ou transfert de carbone divalent par réaction d'insertion.

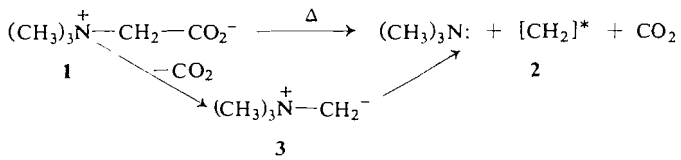
Can. J. Chem., 51, 2750 (1973)

Introduction

The structure usually presented for glycine betaine, **1**, suggests that this compound or derivatives might undergo a simple heterolytic thermal dissociation to give singlet methylene, **2**, either directly or via ylid, **3**



The analogous structure for pyridinium betaines, **4**, should be even more easily decarboxylated to an ylid, **5**, expected to readily undergo further transformation or serve as a methylenating agent

4 **5**

a, R=H
b, R=CH_3

We here report our investigations of these possibilities for genesis of products derived from α-betaine decompositions.

No recent work is reported on thermolytic reactions of glycine betaine, free of base or other reagents. Willstätter (2) reported interconversion with isomeric methyl *N*,*N*-dimethylaminoacetate at temperatures from 135° to 293°. Others have independently reported trimethylamine, dimethylamine, carbon dioxide, and nitrogen as products of pyrolytic distillation of glycine betaine as well as the rearrangement ester (3, 4). Volatile bases which reduced ammoniacal silver oxide or Fehling's solution but which gave no Schiff test nor hydrazone formation, were also obtained. The molecularity and other details of the rearrangement to methyl *N*,*N*-dimethylaminoacetate have not been established. The other reported products may result subsequent to formation of reactive intermediates by simple pyrolytic cleavage reactions such as **1** → **3**, **1** → **2**, or **3** → **2**.

Decarboxylation of α-haloacids on heating with pyridine to give ylids has been presumed to occur via initial formation of pyridinium

betaines (5). Evidence for ylids was isolation of *N*-alkylpyridinium halides supposed to arise from rapid protonation of the ylids. Attempts to isolate betaines by the reaction between 2,5-dimethylpyrazine and α-haloacids at room temperature are reported to give the analogous *N*-alkyl-2,5-dimethylpyrazinium salts (6).

Methylene (or carbene) and its substituted derivatives as well as a variety of ylids have been firmly established as reactive intermediates with finite lifetimes characterizable both chemically and spectroscopically. Much of the recent chemistry has been summarized in various monographs and reviews (7–10). Direct identification of these intermediates might be accomplished via electronic (11) or mass spectrometry. Carbenes are difficult to measure by the latter technique other than in specially designed apparatus (12) but ylids appear to have sufficient stability to be easily identified by either method.

As an alternative to direct detection of methylene, one might identify products which could be shown to result from either typical insertion and/or addition reactions or via transfer from an ylid. The least complicated array of products would be obtained if those initially produced were swept away or quenched before further attack by reactive species. Our approach to this technique of early product identification is to conduct pyrolysis reactions with small samples directly in the inlet system of a mass spectrometer. Expansion into the low pressure of the inlet system or spectrometer source effectively removes the initial products from the reaction zone and they are ionized and examined at once by mass spectrometry.

Results and Discussion

Mass spectra given as Tables 1–7 are typical of the data obtained. Peak intensities were reproducible to within 5% owing to care in maintaining nearly constant conditions from run to run, including temperatures and pressures, sampling times and sample size as well as instrument operating parameters. All the latter were routinely cycled and optimized for each analysis. We are confident that under these conditions, spectra obtained for betaine pyrolyses products may be directly compared with spectra for suspected pure stable components to unmask evidence for reactive intermediates.

Glycine Betaine

Glycine betaine is not directly ionized as such in a mass spectrometer since it is not volatile[5]. Ionization during introduction of betaine samples was not detectable at temperatures below 260° and then only weak spectra were realized until the sample temperature approached 300°. An *m/e* 117 peak (apparent molecular ion) observed at temperatures >260° must be associated with

[5]Attempts to sublime glycine betaine through a 3 mm distance at $\sim 10^{-5}$ Torr/200–300° produced samples which show no n.m.r. absorption characteristic of betaine. Peaks corresponding to methyl *N,N*-dimethylaminoacetate were easily recognizable, however.

†Peak doublets were resolved at these masses, footnoted values were higher in mass.

the rearrangement isomer, methyl *N,N*-dimethylaminoacetate for which good spectra can be easily obtained at lower temperatures. Betaine derivatives incapable of thermal rearrangement gave analogous results (2-(*N*-pyridyl)acetic acid and 2-(*N*-pyridyl)propionic acid betaines do not exhibit molecular ions at any temperature).

Flash pyrolyses of ≃0.1 mg samples of glycine betaine in the all glass inlet system produced the spectra of Table 1. Comparison with spectra obtained in an identical manner for methyl *N,N*-dimethylaminoacetate (Table 2) suggests two concurrent thermolysis reactions for betaine in addition to rearrangement to the ester. These are illustrated in Scheme 1 (processes which do *not* involve loss of radical to give cation). Clearly neither the *m/e* 73 nor the *m/e* 59 species arise by ion-fragmentation of the ester as they are absent in low voltage spectra of the latter but constitute the major ions for the betaine. High resolution mass measurements for the *m/e* 73, 72, 59, and 58 species confirm an atomic composition consistent with Scheme 1 (*m/e* 73 = $(CH_3)_3\overset{+}{N}CH_2^-$; *m/e* 59 = $(CH_3)_3N$:; *m/e* 72 and 58 are the fragment ions resulting from loss of H·). Reduction in relative ion intensity for both *m/e* 73 and 59 with increased ionization energy is also consistent with their identification as molecular species. On the other hand, *m/e* 72 and 58 represent an increased proportion of the total ion current with initial increases in ionization energy, consistent with formation by ion

fragmentation. The *m/e* 58 species likely is derived in part from all three molecular species present. It is clearly the principal fragment from the ester ($M^{\cdot +} = 117$) and is also the known principal fragment in trimethylamine spectra (1, 13). We also observed a metastable ion at *m/e* 46.1 in 70 eV spectra of glycine betaine consistent with the process: $73^+ \rightarrow 58^+ + CH_3$.

Carbon dioxide is a major volatile product from betaine pyrolyses at atmospheric pressure. Its absence in low voltage spectra is due to its high appearance potential ($\simeq$13.8 eV). In addi-

tion, this lowest molecular weight pyrolysis species is expected to diffuse more rapidly which may account for its low intensity in high voltage spectra.

The highly unstable ylid, *m/e* 73, would be expected to decompose or rearrange very rapidly. Thus it could further cleave to methylene plus trimethylamine as an alternate to formation of the latter directly from the betaine (dotted line, Scheme 1). The ylid might also undergo

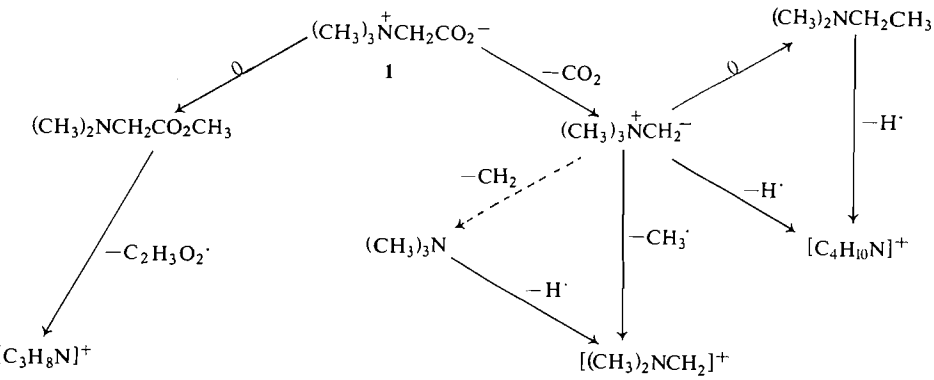
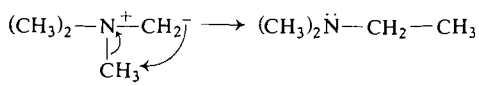


SCHEME 1. Proposed routes for pyrolyses and ion-fragmentation (bracketed ions) of glycine betaine at low ionizing energies.

Stevens rearrangement to ethyldimethylamine



The stable product resulting from such a rearrangement would account for the persistence of the *m/e* 73 contribution in low voltage spectra obtained via the glass inlet system in which products are "stored" for relatively long times, (Table 1).

Trimethylamine radical-ion might also result by ion fragmentation of the ylid radical-ion but this is less likely at low ionization energies. Attempts were made to establish formation of methylene during pyrolysis by observing *m/e* 14 during direct sample introduction. These experiments were conducted by pre-focussing the mass spectrometer on fragment-ion *m/e* 14 at high ionizing energies, then reducing the ionization energy just prior to sample pyrolysis. No signal was obtained under these conditions. This may be due to the difficulty inherent in optimizing tuning parameters, in particular the ion-repeller voltage in the absence of a signal at low voltages, or may indicate that this short life-time species is not present in sufficient concentrations in the gas phase to enable detection during betaine pyrolyses (12).

Evidence for a reactive intermediate that is a source of methylene is provided by the molecular ion species observed at *m/e* 131 which occurs in all low voltage as well as 70 eV spectra. This has a composition of $C_6H_{13}NO_2$ (high resolution mass measurement) and may result from C—H insertion of methylene (either directly or by transfer from the ylid) in either glycine betaine itself or in methyl *N,N*-dimethylaminoacetate. One may argue for insertion in the ester as more likely if attack is by free methylene, since methylene is an electrophile. Such insertion products would also contribute to the fragmentation spectrum observed for glycine betaine (*i.e.*, the stable products from thermolysis of glycine betaine).

Methylene insertion on the ester would be statistically favored at methyl. Extension of the ester alkyl chain to ethyl, for example, yields a product which has a mass spectrum identical to that for the methyl ester excepting the molecular ion region; *m/e* 131 and attendant isotope peaks replace *m/e* 117 and 118 peaks.

Higher molecular weight species would be expected if an appreciable concentration of the reactive intermediate was present in the condensed phase. The absence of peaks above *m/e* 131 in glycine betaine spectra suggests that thermolysis products are either rapidly volatilized or that the intermediate methylide is "quenched", via Stevens rearrangement, for example. Gas phase reactions between the 131 species and either methylene or methylide during direct insertion analysis is expected to be almost nil at the pressures of the mass spectrometer source ($\simeq 10^{-5}$ Torr).

Although the formation of methylene as an entity is not rigidly established here, there are few other realistic explanations for the origin of the *m/e* 131 ion. An alternate suggestion for its structure is that of the betaine (or its rearrangement products) which might result by nucleophilic attack of the ylid on glycine betaine with

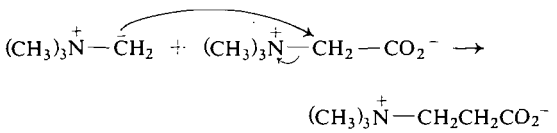
For personal use only.

displacement of trimethylamine



The latter betaine, however, is not stable at temperatures >140° but readily undergoes decomposition via Hoffman elimination to acrylic acid (2).

Thus, we feel the evidence supports the reactions presented in Scheme 1 when small amounts of glycine betaine are pyrolyzed at low pressures. In addition to molecular rearrangement, methylene is produced in a two step sequence via trimethylammonium methylide. The methylide may also abstract protons from any available source yielding a stable quaternary salt if suitable anions were available.

Pyridine Betaines

Coe (14) has observed that the pyridinium chlorides obtained for reactions between ethyl chloroacetate and various alkylpyridines are extremely hygroscopic; we confirm this and also wish to note that some small amount of water appears to be structurally bound to the betaines. Completely satisfactory elemental analyses could not be obtained for this reason. This tenaciously held water was identified by p.m.r. spectra taken in deuterium oxide as solvent, there being a signal for a singlet which intensifies on adding a small amount of water.

Mass spectra typical of those obtained for **4***a* and **4***b* are presented in Tables 4–7. Ionization characteristics similar to those for glycine betaine were observed. Ionization does not occur at temperatures below the thermal decomposition point (<150°); molecular ions are absent.[6]

A small sample of **4***a* decomposed at 295° and "stored" at 0.03 Torr then introduced via the all-glass inlet system led to intense ions at *m/e* 44, 52, 79, and 94 in low voltage spectra (Table 4). These ions provide evidence for decomposition involving initial C—C cleavage yielding the pyridine methylide, **5***a*, which abstracts a proton from any available source to give the *m/e* 94 species (Scheme 2). The most intense ion in low voltage spectra at *m/e* 79 is evidence for C—N cleavage. This could arise by subsequent fragmentation of the methylide, **5***a*, or the *m/e* 94 species. The absence of ions at *m/e* 58 suggests the latter path although the $C_2H_2O_2$ species which might give this ion may be too reactive to be observable as an ion in the mass spectrometer under these conditions. The *m/e* 52 ion is typical for pyridines that do not involve substitution at other than the nitrogen atom (16).

When a direct insertion sampling technique was employed (Table 5) the gross features of the spectrum from *m/e* 12–95 were much the same. Of greater interest was the appearance of new ions over the range from *m/e* 95–377; these higher mass ions were persistent even in low voltage spectra (8 eV, 20 μA) indicating they represent stable products derived from thermal decomposition of the pyridine betaine. In general ion–molecule reactions following electron impact require relatively high pressures and concomitant high ionizing energies (ref. 17, see particularly chapt. 11) and can thus be discarded as a source of these high molecular weight ions. The most intense ions in the high mass range are found at simple multiples of 94 less one, two, or three a.m.u. A logical explanation is that these higher molecular weight species are the result of dimerization, trimerization, etc., in the condensed phase, of pyridine methylide or a rearranged isomer of the ylid. In fact, exact mass measurements give the composition for the ions at *m/e* 93, 186, and 279 as C_6H_7N, $C_{12}H_{14}N_2$, and $C_{18}H_{21}N_3$, respectively. Recent work by Paquette, *et al.* (18) shows that certain 1H-azepine derivatives easily undergo thermochemical dimerization. Rearrangement of pyridine methylide to 2H-azepine is readily formulated and this isomer should no less easily dimerize than does 1H-azepine.[7] Although Paquette does not report evidence for trimers or higher oligomers of his compounds, the expected products of dimerization should be capable of continued cycloaddition reactions.

[6]Since our original submission, analogous behavior has been reported by Grønneberg and Undheim (15) for 3-hydroxypyridinium betaines; these workers report loss of CO_2 to give an apparent molecular ion. Intermolecular reactions involving the 3-hydroxy group are prominent in subsequent interpretation of their results.

[7]Since our work was completed, Grønneberg and Undheim (15) have independently suggested a 2H-azepine structure via rearrangement of ylids they presumed to arise from 3-hydroxypyridinium betaines. They do not report observation of teleomerization products from these systems, however.

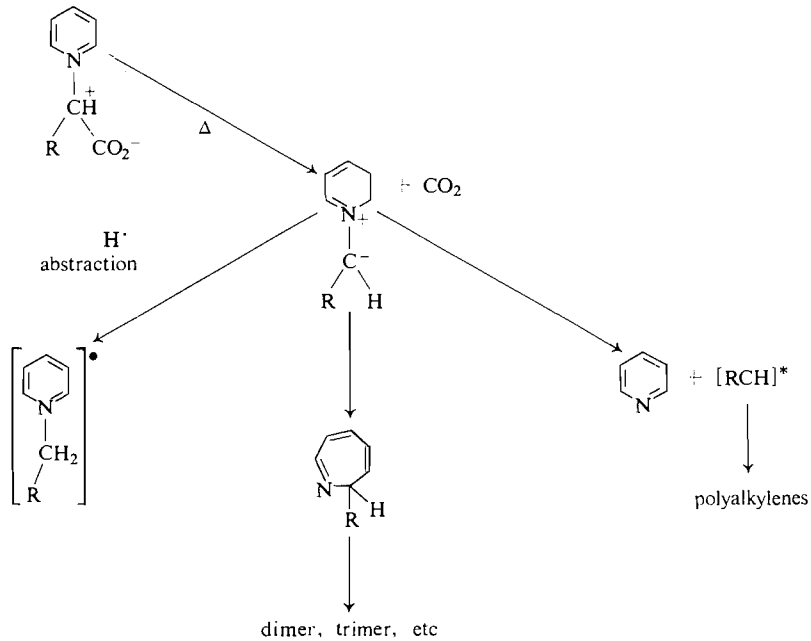

SCHEME 2. Proposed routes for pyrolyses of 2-(*N*-pyridyl)alkanoic acid betaines.

The direct insertion pyrolysis mass spectrum of methyl substituted derivative, **4***b*, shows features similar to the spectrum of **4***a*. This compound would be expected to decompose with loss of CO_2 to give the methyl pyridinium methylide, **5***b*, at *m/e* 107. Dimerization, etc. should give ions at *m/e* 214, 321, etc. Ions are observed at all expected *m/e* values and with relative intensities similar to their analogs in the spectrum of **4***a*.

In some spectra obtained by direct insertion pyrolysis of either the **4***a* or **4***b* derivatives, low intensity ions appeared as a group pattern of peaks 1 a.m.u. apart in approximate Gaussian distribution. This pattern was repeated at intervals of either 14 or 28 a.m.u. (respectively, for **4***a* and **4***b*) to the upper mass limit set for the scan. This pattern is analogous to that shown by a mixture of hydrocarbon homologues for the molecular ion region and it is suggestive of the formation of polyalkylenes by methylene polymerization or by methylene transfer from the ylid. An alternative for **4***b* is that the derived ylid may cleave with rearrangement to ethylene and pyridine, followed by subsequent polymerization of the ethylene. This would not, however, explain the analogous mass spectral results for **4***a*.

Scheme 2 presents a summary of reactions we believe to occur on thermolytic decomposition of *N*-pyridine betaines at low pressures.

Experimental

General

Melting points were determined in a capillary with a Hoover–Thomas melting point apparatus and are uncorrected; infrared spectra were determined with a Perkin–Elmer Model 337 spectrometer and p.m.r. spectra were determined with a Varian Associates A-60 spectrometer; data were consistent with structures assigned.

Materials

Betaine was obtained as the monohydrate (Eastman Kodak Company) which deliquesces if exposed to the atmosphere. It was freed from traces of atmospheric moisture in an oven at 100° for 10–15 min and stored in a desiccator over potassium hydroxide.

2-(N-pyridyl)acetic acid betaine was synthesized as follows:[8] Dry, reagent grade pyridine (7.9 g, 0.1 mol) was added to ethyl chloroacetate (12.3 g, 0.1 mol) and allowed to stand until completely solidified (about 24 h). The intermediate, ethyl 2-(*N*-pyridyl)acetate chloride salt was formed in almost quantitative yield. It was dissolved in absolute ethanol (50 ml) and added to a hot solution of potassium hydroxide (6.5 g, 0.1 mol) in ethanol (150 ml). There was an immediate precipitation of potassium

[8]The procedure for synthesis of pyridine betaine is adapted from a method reported to us by Dr. R. T. Myers of our department, who kindly provided us with the initial samples used in this study. See also ref. 14.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

chloride and the color of the solution turned dark orange. No further precipitation occurred after about 4 h and the potassium chloride was removed by filtration. Potassium chloride again precipitated from the filtrate and after 20 h was removed. This two-step precipitation and filtration always seemed to be necessary to obtain product free of potassium chloride. The second filtrate was stored at −5°; crude 2-(*N*-pyridyl)acetic acid betaine crystallized and was collected after 3 days. Concentration of the mother liquor afforded additional solid product on similar treatment. The combined crude product (12.2 g, 89%) was recrystallized from ethanol three times and gave faintly colored (yellow) product (5.48 g, 40%) m.p. 150–160° d. Further recrystallization merely removed the coloration; the melting behavior was identical. A dried sample gave the following analysis:

Anal. Calcd. for $C_7H_7NO_2$: C, 61.38; H, 5.11; N, 10.21.

Anal. Calcd. for $C_7H_7NO_2 \cdot \frac{1}{8}H_2O$: C, 60.03; H, 5.06; N, 10.00.

Found: C, 60.43; H, 5.23; N, 9.92.

N.m.r. (D_2O) τ = 5.65 (s, 2, —CH_2—), τ = 2–3 (m, 5, Ar—H), τ = 6.13 (s, H_2O).

2-(N-pyridyl)propionic acid betaine was synthesized by a procedure analogous to that above from pyridine and ethyl 2-bromopropionate. Overall yield of purified product was 17.8% m.p. 164–170°d. A dried sample was analyzed:

Anal. Calcd. for $C_8H_9NO_2$: C, 63.57; H, 5.96; N, 9.27.

Anal. Calcd. for $C_8H_9NO_2 \cdot 0.4\ H_2O$: C, 60.68; H, 6.19, N, 8.84.

Found: C, 60.56; H, 5.58; N, 8.62

N.m.r. (D_2O) τ = 1.00–2.15 (m, 5, Ar—H), τ = 4.66 (q, 1, —CH(CH_3)—, J = 7.4 c.p.s.), τ = 8.12 (d, 3, CH_3CH, J = 7.2 c.p.s.), τ = 5.4 (s, H_2O).

Mass Spectrometric Studies

Samples of the betaines were pyrolyzed in 0.1 to 1.0 mg amounts directly in the mass spectrometer inlet systems maintained at a fixed temperature. In the CEC Model 21-103C an all-glass heated inlet (temperature 295 ± 5°) with 3 l reservoir was used; volatiles were leaked into the source. In the AEI MS-12 a similar all-glass inlet system (1 l reservoir) or the source direct-insertion probe were used. Residual gas pressure above the decomposing samples varied from 10^{-2} to 0.2 Torr in the glass inlet systems and was ~4×10^{-7} Torr in the source.

Voltage scanning from *m/e* 25–250 required 15 min in the CEC 21-103C. Magnetic scanning from *m/e* 350–12 was done in ~30 s on the AEI MS-12. Other data are recorded in the tables; electron energies are nominal meter readings and are uncorrected.

We are indebted to the staff and director R. E. Farrell of the Broadway Laboratory of the Standard Oil Company of Ohio for mass spectra obtained early in this investigation with a CEC 21-103C. The A.E.I. MS-12 was purchased in part with funds provided under a National Science Foundation Matching Funds Grant.

The Reactions of Organometallic Compounds Involving Silicon. Reactions of Methyldiphenyl-, Triphenylsilyl-sodium, -potassium, -rubidium, and -caesium with 9-Methylfluorene in Tetrahydrofuran

MUHAMMAD ABDUL HAMID[1]

Department of Chemistry, The University of Manchester Institute of Science and Technology, Sackville Street, Manchester, M60 1QD, England

Received January 26, 1973

The reactions of triphenylsilyl-sodium (Ph_3SiNa), diphenylmethylsilyl-sodium ($Ph_2MeSiNa$), triphenylsilyl-potassium (Ph_3SiK), triphenylsilyl-rubidium (Ph_3SiRb), and triphenylsilyl-caesium (Ph_3SiCs) with 9-methylfluorene in tetrahydrofuran (THF) were studied using the stop-flow technique at low temperatures. The rate constant k ($l\ mol^{-1}\ s^{-1}$) depends on the nature of the cation; at $-50\,°C$ k is 11.5 for Ph_3SiNa, 29.5 for $Ph_2MeSiNa$, 26.8 for Ph_3SiK, 35.6 for Ph_3SiRb, and 47.9 for Ph_3SiCs. It seems that the organosilylalkali–metal compounds (R_3SiM) exist in the form of contact ion-pair and therefore the reactivity of an ion-pair is determined by the Coulombic binding energy of the pair. The thermodynamic constants of activation for these reactions were calculated for $-50\,°C$ and compared with the corresponding values of triphenylsilyl-lithium Ph_3SiLi reaction with 9-methylfluorene in THF. The plots of log k, ΔS^*, and ΔH^* against $1/(r_c + 2)$ and ΔS^* against ΔH^* were drawn to show that Li^+ due to its existence as solvent separated ion-pair behaves differently to its Na^+, K^+, Rb^+, and Cs^+ counterparts.

The electronic spectra of R_3SiM, 9-methyl-fluoren-9-yl-sodium, -potassium, -rubidium and -caesium were determined at temperatures varying from 20 to $-80\,°C$. A red shift was observed in spectra of R_3SiNa at low temperatures; this was attributed to the increase in dipole moment which occurs during the electronic transition. The spectra of 9-methylfluoren-9-yl-sodium, -potassium, -rubidium, and -caesium were compared with their lithium counterpart to explain the effects of gegenion on the solvation of these species.

On a étudié les réactions dans le tétrahydrofuranne du triphénylsilyl-sodium (Ph_3SiNa), du diphénylméthylsilyl-sodium ($Ph_2MeSiNa$), du triphénylsilyl-potassium (Ph_3SiK), du triphénylsilyl-rubidium (Ph_3SiRb) et du triphénylsilyl-caesium (Ph_3SiCs) avec le méthyl-9 fluorène en utilisant la technique d'interruption de débit pour des basses températures. La constante de vitesse K ($l\ mol^{-1}\ s^{-1}$) varie selon la nature du cation: à $-50\,°C$, K est égal à 11.5 pour Ph_3SiNa, 29.5 pour $Ph_2MeSiNa$, 26.8 pour Ph_3SiK, 35.6 pour Ph_3SiRb et 47.9 pour Ph_3SiCs. Il semble que les composés du type organosilylalcalino-métal (R_3SiM) existent sous la forme de paire d'ions intimes et que par conséquent la réactivité de cette paire d'ions est déterminée par l'énergie d'interactions coulombiennes de la paire. Les constantes thermodynamiques d'activation pour ces réactions ont été calculées à $-50\,°C$ et comparées avec les valeurs correspondantes de la réaction du triphénylsilyl-lithium (Ph_3SiLi) avec le méthyl-9 fluorène dans le THF. Les courbes du log k, ΔS^* et ΔH^* en fonction de $1/(r_c + 2)$ et de ΔS^* en fonction de ΔH^* ont été faites afin de montrer que le Li^+, à cause de son existence sous forme d'une paire d'ions solvatés, possède un comportement différent de celui des autres entités Na^+, K^+, Rb^+, et Cs^+.

Les spectres électroniques des R_3SiM, méthyl-9 fluorènyl-9-sodium, -potassium, -rubidium et -caesium ont été déterminés pour des températures allant de 20 à $-80\,°C$. Un déplacement vers le rouge à été observé dans les spectres du R_3SiNa à basses températures; ce fait a été relié à l'augmentation du moment dipolaire qui se produit lors de la transition électronique. Les spectres des méthyl-9 fluorènyl-9-sodium -potassium, -rubidium et -caesium ont été comparés avec ceux obtenus du dérivé lithié (Li) correspondant afin d'expliquer les effets de l'ion complémentaire sur la solvatation de ces espèces.

Can. J. Chem., **51**, 2759 (1973)

The dependence of the reactivity of organometallic compounds on the nature of the gegenion has been of significant interest in the anionic reactions. The reactivity of the ion pair of alkali metal salt of living polystyrene has been found to be increased with increasing the size of gegenion in the anionic polymerization of styrene in dioxane (1–4) while in THF (5–7) the order is reversed. The effect of changing the gegenion for the reactions of triphenylsilyl-alkali-metal compounds with 1,1-diphenylethylene in THF has been reported by Evans *et al.* (8). It has been found that when alkali metal was lithium, exceptional results were obtained both in the kinetics and in the spectroscopic experi-

ments. The reactions of substituted silyl-lithiums with 9-methylfluorene (9) have been reported previously; the results for the reactions of Ph_3SiNa, $Ph_2MeSiNa$, Ph_3SiK, Ph_3SiRb, and Ph_3SiCs with 9-methylfluorene in THF are now presented.

Experimental

Materials

9-Methylfluorene (9), hexaphenyldisilane (10), and THF (11) were purified and dried as described previously. Ph_3SiNa, $Ph_2MeSiNa$, Ph_3SiK, Ph_3SiRb, and Ph_3SiCs were prepared by the cleavage of corresponding symmetrical disilanes by the respective metal in THF using a method similar to that described for the organosilyllithium compounds (10). The rubidium and caesium films were prepared by heating the calcium turning with the respective metal chloride under high vacuum conditions.

Spectral Measurements

In order to determine the spectra and the extinction coefficients of the product for the reaction between R_3SiM and 9-methylfluorene in THF, the reactants were mixed under high vacuum conditions using the procedure similar to that described in the previous paper (12). The spectra of the R_3SiM and 9-methylfluoren-9-yl-alkali metal compounds were determined at temperatures varying from 20 to -80 °C using the same technique as described for 9-phenylfluoren-9-yl-lithium (12).

Kinetic Measurements

The reactions of Ph_3SiNa, $Ph_2MeSiNa$, Ph_3SiK, Ph_3SiRb, and Ph_3SiCs with 9-methylfluorene in THF were studied under high vacuum conditions at low temperatures using the stop-flow technique (13). The rate of formation of product 9-methylfluoren-9-yl-sodium, -potassium, -rubidium, and -caesium was most conveniently followed by observing the change of optical density at 510, 500, 510, and 500 nm, respectively, with time. The order of reaction in R_3SiM and 9-methylfluorene was determined using the procedure similar to that described in the previous paper (12).

Results

Spectra

The spectra of Ph_3SiK, Ph_3SiRb, and Ph_3SiCs in THF showed an absorption maxima at 363, 368, and 376 nm, respectively. The values obtained for extinction coefficients at maximum absorption were in agreement with those reported previously by Evans *et al.* (8) for Ph_3SiM reagents within the experimental error of $\pm 2\%$. The spectra of Ph_3SiM determined at low temperatures (20 to -80 °C) did not show any significant change in their maximum absorption. The slightly low values found for $\varepsilon\lambda_{max}$ at reduced temperatures could be due to the condensation of the water vapors on the surface of the sample cell. The spectra of Ph_3SiNa and $Ph_2MeSiNa$ determined in THF and 1,2-dimethoxyethane (DME) showed that the position of maximum absorption gradually changed at low temperatures in both the solvents, therefore the extinction coefficients were calculated at the respective λ_{max} (see Table 1 and Fig. 1).

TABLE 1. Spectral values for R_3SiNa

Compound	Solvent	Temperature (°C)	λ_{max} (nm)	$10^{-4}\ \varepsilon\lambda_{max}$
Ph_3SiNa	THF	20	340	1.41
	THF	−20	344	1.38
	THF	−80	346	1.31
	DME	20	343	1.42
	DME	−20	348	1.41
	DME	−80	356	1.40
$Ph_2MeSiNa$	THF	20	337	1.15
	THF	−20	348	1.15
	THF	−80	354	1.13
	DME	20	340	1.16
	DME	−20	350	1.16
	DME	−80	356	1.15

The red colored product of reaction between R_3SiNa and 9-methylfluorene in THF, 9-methylfluoren-9-yl-sodium showed one distinct absorption peak at 480 nm ($\varepsilon\lambda_{max} = 1.03 \times 10^3$) and a shoulder at 510 nm at 20 °C, which developed into a distinguishable absorption peak at low temperatures. The 510 nm absorption peak was used to study the chemical kinetics of R_3SiNa reactions with 9-methylfluorene in THF. The extinction coefficients calculated at 510 nm are 8.93, 9.27, and 9.7×10^2 at 20, −30, and −80 °C, respectively. The red colored product for the reaction of Ph_3SiK and Ph_3SiCs with 9-methylfluorene in THF, 9-methylfluoren-9-

yl-potassium and -caesium both gave typical broad spectra with maximum absorption at 500 nm (see Fig. 2). The values calculated for the $\varepsilon\lambda_{max}$ are 1.15×10^3 and 1.11×10^3 for 9-methylfluoren-9-yl-potassium and -caesium, respectively. No significant change was observed in the spectra of these compounds determined at reduced temperatures. The red colored product of reaction between Ph_3SiRb and 9-methylfluorene in THF, 9-methylfluoren-9-yl-rubidium showed three distinct absorption peaks at 532 ($\varepsilon\lambda_{max}$ 8.83×10^2), 500 ($\varepsilon\lambda_{max}$ 1.27×10^3), and at 476 nm ($\varepsilon\lambda_{max}$ 1.13×10^3) and a shoulder at 446 nm at 20 °C (see Fig. 2). The spectrum of 9-methylfluoren-9-yl-rubidium was slightly changed at reduced temperatures. For example, two new absorption peaks appeared at 510 and 538 nm overlapping the 500 and 532 nm absorption peaks, respectively. A shoulder at 550 nm was also observed at reduced temperatures.

Kinetics

The rate of reaction of Ph_3SiNa and $Ph_2MeSiNa$ with 9-methylfluorene in THF were measured at −30 °C to investigate the order of reaction whereas the corresponding reactions of Ph_3SiK, Ph_3SiRb, and Ph_3SiCs were most conveniently measured at −50 °C. The concentration of R_3SiM and 9-methylfluorene was varied from 2.25×10^{-3} to 1.611×10^{-2} *M* and from 2.06×10^{-3} to 1.611×10^{-2} *M*, respectively. To establish the order of reaction in the respective reactant, four experiments were carried out varying the concentration of one reactant and keeping the concentration of other one constant in the ratio of 1:2 to 2:1. At least ten repeat reaction curves were obtained to check the reproducibility of the system. It was observed that the reproducibility was very good. The order of reaction found from the dependence of the initial rate of reaction on the initial reagent concentration was 1.03 in Ph_3SiNa, Ph_3SiK and Ph_3SiRb, 1.01 in $Ph_2MeSiNa$, and 0.97 in Ph_3SiCs. For this sequence of R_3SiM the order in 9-methylfluorene was 0.96, 1.02, 1.01, 1.0, and 1.0. The analysis of the optical density *vs.* time curve for these reactions confirmed that the overall order of reaction was 2. These reactions may be considered as irreversible under the conditions of the experiments, since second order kinetics held for at least 90% of the reactions.

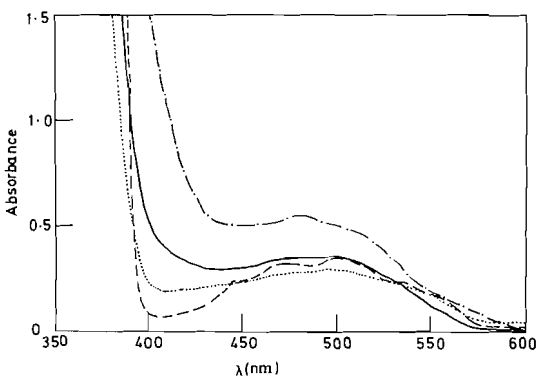

FIG. 2. Absorption spectra of 9-methylfluoren-9-yl-alkalimetal compounds in THF at 20 °C; path-length = 1 mm: ·····, 9-methylfluoren-9-yl-sodium (5.15×10^{-3} *M*);—, 9-methylfluoren-9-yl-potassium (3.28×10^{-3} *M*); ---, 9-methylfluoren-9-yl-rubidium (2.83×10^{-3} *M*); and ···, 9-methylfluoren-9-yl-caesium (3.16×10^{-3} *M*).

The activation energy (E_a) was found from the change in the rate constant of reaction over the temperature range of −10 to −56 °C (see Table 2). The values found for E_a from the Arrhenius

ΔS^* (cal mol^{-1} deg^{-1})	−31.5	−43.0	−30.1	−26.0	−18.0

plots were 2.7, 2.3, 5.2, 6.0, and 7.6 kcal mol^{-1} for Ph_3SiNa, $Ph_2MeSiNa$, Ph_3SiK, Ph_3SiRb, and Ph_3SiCs reactions with 9-methylfluorene respectively. The thermodynamic constants of activation calculated for $-50\,°C$ are given in Table 3. The results quoted have the following estimated systematic errors: k and A, $\pm 7\%$, ΔH^* and ΔG^*, $\pm 5\%$, and ΔS^*, $\pm 9\%$.

Products of Reactions

For product analysis the reactions of R_3SiM with 9-methylfluorene in THF were carried out at temperatures consistent to those used in the kinetic experiments under high vacuum conditions. The concentrations of the reactants were used similar to those described in the kinetics experiments. The reaction mixture was quenched with deuterium oxide, after complete reaction. The product formed when the reaction mixture was quenched was isolated by distilling off the THF. The residue material was dissolved in *n*-hexane, washed with water and then dried by storing over anhydrous magnesium sulfate. The solution was filtered and evaporated to dryness. The components of the product were isolated by fractional crystallization and preparative t.l.c. All the components were identified by their melting points, elemental analysis, and n.m.r. spectra.

It was found in all the cases that only 9-hydrogen atom of 9-methylfluorene was replaced by alkali metal atom of R_3SiM regardless of the concentration ratio of the reactants used in these reactions.

Discussion

The yellow-colored solution of R_3SiNa compounds in THF gives typical broad spectra as shown in Fig. 1. The values of λ_{max} and $\varepsilon\lambda_{max}$ of Ph_3SiNa spectrum are slightly different from those quoted by Evans *et al.* (8) (see Table 1). The broad absorption spectrum of a large molecule such as R_3SiNa is not unusual because the molecule has the choice of a variety of initial and final vibrational and rotational states all belonging to the same electronic transition. Furthermore, in solutions the vibrational-rotational fine structure is generally masked by solute–solvent interaction, and continuous absorption bands result in the spectrum. At low temperatures a well resolved spectrum of a molecule would be expected with an unaltered absorption maximum. However, in the spectra of R_3SiNa the absorption maximum is gradually changed to longer wavelength at low temperatures. This gradual red shift in absorption maximum at low temperatures could be explained by considering the fact that the R_3SiNa molecule experiences an increase in dipole moment on excitation which results in a gain in solvation energy for this state. Another factor which could be responsible for the red shift in the spectra of R_3SiNa is the promotion of ionization of these species at low temperatures. However, this latter factor should not be considered very important in this work because it does not explain the *gradual and reversible* red shift at low temperatures.

The spectra of R_3SiNa determined in DME were similar to those in THF. A small red shift caused in the spectra of R_3SiNa in DME could be explained using the arguments suggested by Hogen-Esch and Smid (14) in their studies of ion-pairs of carbanions, that DME because of its bidentate coordination behavior acts as a better solvating agent than that of THF for alkali metal ions.

The spectra of R_3SiM reagents in THF solution shifts toward longer wavelength as the ionic radius of the cation increases, but they do not overlap the spectra of 9-methylfluoren-9-yl-alkalimetal compounds. Hence the spectra of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

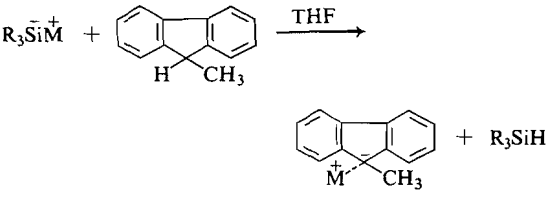
R_3SiM do not interfere with the wavelengths of the products selected to study the kinetics of these reactions. The red shift observed in the spectra of R_3SiM compounds with the increase in the radius of gegenion is consistent with the results reported for various anionic species (8, 14–18).

It has been reported in a previous paper (9) that the shape of 9-methylfluoren-9-yl-lithium spectra was unaltered whereas the values of $\varepsilon\lambda_{max}$ increase as the temperature was reduced from 20 to −88 °C. This increase in the $\varepsilon\lambda_{max}$ was attributed to the formation of solvent separated ion pairs at reduced temperatures from the contact ion pairs that exist at room temperature. The same phenomenon was observed in the case of 9-methylfluoren-9-yl-sodium, where a new absorption peak was developed at 510 nm at the expense of 480 nm peak when the temperature was reduced from 20 to −80 °C. The increase in $\varepsilon\lambda_{max}$ was relatively small in the case of 9-methylfluoren-9-yl-sodium as compared to its lithium counterpart, which could be an indication that the formation of solvent separated ion pairs was more difficult in the case of 9-methylfluoren-9-yl-sodium than -lithium at reduced temperatures. On the other hand no change in $\varepsilon\lambda_{max}$ was observed in the case of 9-methylfluoren-9-yl-potassium, -rubidium, and -caesium at reduced temperatures. Therefore, it could be concluded that these species exist as contact ion pairs in THF even at −80 °C. Similar results have also been reported by Smid and co-worker (14) in their studies of ion pairs of fluorenylalkali-metal compounds in THF.

The red shift of 6 to 10 nm observed in the absorption peaks of 500 and 532 nm at reduced temperatures in the spectrum of 9-methylfluoren-9-yl-rubidium is in marked contrast with its potassium and caesium counterparts. However, this behavior of 9-methylfluoren-9-yl-rubidium could not be explained at this stage.

It was quite easy to prepare Ph_3SiNa and $Ph_2MeSiNa$ in THF by the cleavage of the corresponding symmetrical disilanes using sodium metal, but it was not possible to prepare phenyldimethylsilyl-sodium using the same method. Furthermore, the cleavage of 1,2-diphenyl-1,1,2,2-tetramethyldisilane by sodium, sodium–mercury amalgam in DME at 50 °C also failed. Unsuccessful attempts to prepare $PhMe_2SiNa$ by the cleavage of 1,2-diphenyl-1,1,2,2-tetramethyldisilane have also been reported by Fearon and Gilman (19).

The reaction was first order in both reactants and the overall second order kinetics were retained to at least 90% of the total reaction. These kinetics results were further supported by the results obtained from product analysis that only 9-hydrogen atom of 9-methylfluorene was replaced by alkali metal atom of R_3SiM. In accordance with these results the reactions under investigation could be postulated as follows



The rate sequence for these reactions is as follows: Ph_3SiLi (9) < Ph_3SiNa < Ph_3SiK < Ph_3SiRb < Ph_3SiCs. This order is consistent with the results reported for various anionic reactions (1, 8) when the organometallic species exist as contact ion-pairs.

The plot of log k against $1/(r_c + 2)$, where r_c is the ionic radius of cation is an excellent straight line for the cation Na^+, K^+, Rb^+, and Cs^+ whereas Li^+ lies well below the line (see Fig. 3). Such a linear relation between log k and $1/(r_c + 2)$ signifies the importance of Coulombic attraction between the ion pair on the reactivity of Ph_3SiM reagents. A similar linear relation has also been reported for log k and $1/(r_c + 2)$ by Evans *et al.* (8) for the reactions of Ph_3SiM with 1,1-diphenylethylene in THF, with the only ex-

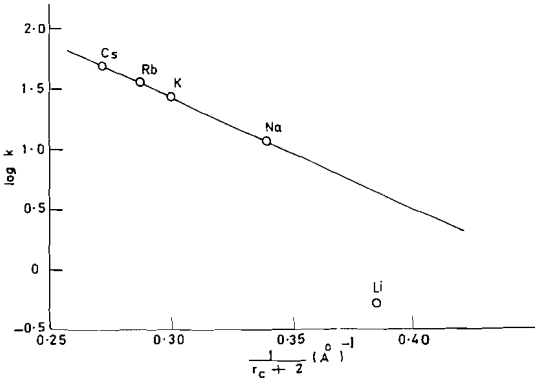


FIG. 3. Plot of log k against $1/(r_c + 2)$.

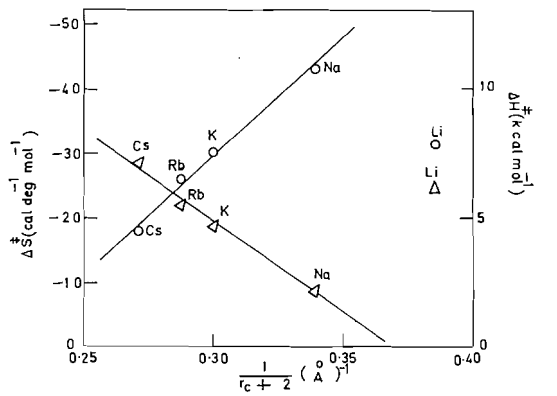

FIG. 4. △, Plot of $\Delta H^{\ddagger}$ against $1/(r_c + 2)$; ○, plot of $\Delta S^{\ddagger}$ against $1/(r_c + 2)$.

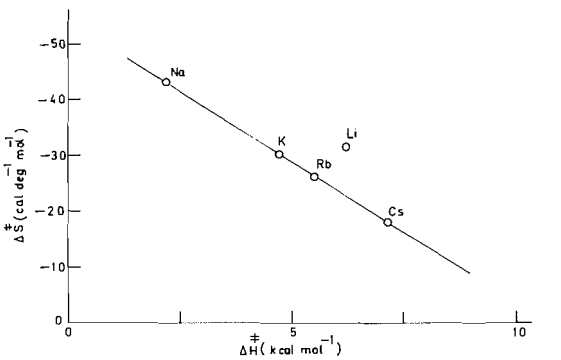

FIG. 5. Plot of $\Delta S^{\ddagger}$ against $\Delta H^{\ddagger}$.

ception that the Li^+ lay well above the line in their plot.

The plots of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ against $1/(r_c + 2)$ and $\Delta S^{\ddagger}$ against $\Delta H^{\ddagger}$ also show that Li^+ behaves differently to its Na^+, K^+, Rb^+, and Cs^+ counterparts (see Figs. 4 and 5). The analysis of these plots confirms the views already put forward that Ph_3SiNa, -K, -Rb, and -Cs all exist as contact ion pairs and therefore behave in a similar fashion while the exceptional behavior of Ph_3SiLi is due to its existence in the form of solvent separated ion pairs.

In the system involving Na^+, K^+, Rb^+, and Cs^+ the values of $\Delta H^{\ddagger}$ and A factor increase linearly from Na^+ to Cs^+, while the values of $\Delta S^{\ddagger}$ become more positive for the same sequence (see Table 3 and Fig. 5). In accordance with these results it could be suggested that both activation enthalpy and entropy are responsible in determining the rate of these reactions.

In the case of Li^+ the reactant (Ph_3SiLi) and the product (9-methylfluoren-9-yl-lithium) both exist as solvent separated ion pairs. Since the reaction involves equal solvation of the initial and the transition state, this deprives the system of some driving force. Furthermore, this accounts for the slower rate of reaction for Ph_3SiLi as compared to its Na^+, K^+, Rb^+, and Cs^+ counterparts, contrary to the fact that the solvent separated ion pairs should react more rapidly than the contact ion pairs.

Finally, the relative reactivity of Ph_3SiNa and $Ph_2MeSiNa$ is consistent with the fact that the replacement of a phenyl by a methyl group increases the electronegativity of the silyl anion.

The Anharmonicity Correction for Kinetic Isotope Effect Calculations

JAN BRON AND SYLVIA O. HACKER

Department of Chemistry, University of Natal, Durban, South Africa

Received March 12, 1973

The kinetic isotope effect, in the ring opening of a triatomic system, is corrected for anharmonicity in the vibrational ground state. For this system it is found that the correction is small and not larger than uncertainties caused by other assumptions made in kinetic isotope effect calculations.

L'effet isotopique sur la cinétique de l'ouverture de cycle d'un système triatomique a été corrigé en tenant compte de l'anharmonicité de l'état vibrationnel fondamental. Pour ce système, on a trouvé une petite correction de l'ordre des incertitudes issues des suppositions faites dans les calculs de l'effet isotopique sur la cinétique. [Traduit par le journal]

Introduction

The theoretical evaluation of kinetic isotope effects is usually carried out by application of transition state theory and statistical mechanics. By making many assumptions (1), the expression obtained is usually called the harmonic approximation. It has been discussed in great detail by Bigeleisen and co-worker (2) and Wolfsberg and co-worker (3).

One of the assumptions leading to the harmonic approximation is, as implied in the name, that the molecule vibrates harmonically. It has been shown (1) that for *equilibrium* isotope effects this assumption may lead to considerable error. Although equilibrium constants have been corrected for anharmonicity before (4), to give rather unexpected results, it was Wolfsberg *et al.* (5) who realized the importance of a constant term, G_0, in the expansion of the vibrational–rotational energy in powers of $(n_i + \frac{1}{2})$. This refers to the familiar (6) expression

$$[1] \quad E_v(n) = G_0 + \sum\omega_i(n_i + \tfrac{1}{2}) + \sum x_{ij}(n_i + \tfrac{1}{2})(n_j + \tfrac{1}{2})$$

in which the vibrational energy levels are assumed to be non-degenerate.

One of the first attempts to correct transition state calculations for anharmonicity has been made by Weston (7). However, the constant term, G_0, has been ignored. The anharmonicity correction for kinetic isotope effects has never been determined correctly. Because these calculations are carried out routinely now, it is worthwhile to determine the importance of this correction in kinetic isotope effect calculations.

General Considerations

If only the ground state is considered, the correction due to anharmonicity for the zero-point harmonic energy, $\frac{1}{2}\sum\omega_i$, is

$$[2] \quad \text{AZPE} = G_0 + \tfrac{1}{4}\sum x_{ij} = E_v(0) - \tfrac{1}{2}\sum\omega_i$$

The dimension of energy is wave numbers. Because the ground state is the most important accessible vibrational state at reasonable temperatures, only the correction due to AZPE will be considered. For some equilibria it has been shown that the correction for anharmonicity of the excited states is indeed small (1).

The expression for $E_v(0)$, referred to as ZPE has been given before (1) and shall not be reproduced. It should be noted, however, that it is only valid for a stable molecule. One of the terms in ZPE, $-\frac{1}{4}\sum B_e^{(\alpha\alpha)}$, is a simplification of the much more complicated term (8):

$$[3] \quad -\frac{1}{4}\sum B_e^{(\alpha\alpha)} = \frac{\hbar}{8\pi c}\sum_i \left[\sum_\alpha \frac{A_{ii}'^{(\alpha\alpha)}}{I_{\alpha\alpha}^{(e)}} + \sum_{\alpha<\beta} \frac{a_i^{(\alpha\alpha)}a_i^{(\beta\beta)} - (a_i^{(\alpha\beta)})^2}{I_{\alpha\alpha}^{(e)}I_{\beta\beta}^{(e)}} - \frac{3}{8}\left(\sum_\alpha \frac{a_i^{(\alpha\alpha)}}{I_{\alpha\alpha}^{(e)}}\right)^2\right]$$

All symbols used have been defined by Nielsen (6). Equation 3 should be used for transition states, because the relationships leading to its simplification break down. The running index i for a transition state has a maximum value of $(3N - 7)$ rather than $(3N - 6)$.

For the isotope effect (k_1/k_2) in the reactions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[4] $$\Delta_1 \overset{k_1}{\rightleftharpoons} \Delta_1^* \rightarrow P_1$$

$$\Delta_2 \overset{k_2}{\rightleftharpoons} \Delta_2^* \rightarrow P_2$$

in which the reactants Δ_1 and Δ_2 only differ in isotopic substitution and Δ^* stands for the transition state and P for the products, the anharmonicity correction is

[5] $$\text{ACOR} = \exp\,[-(\Delta\text{AZPE})hc/kT]$$

The quantity ΔAZPE is defined as

$$\Delta\text{AZPE} = \text{AZPE}(\Delta_2) - \text{AZPE}(\Delta_1) - \text{AZPE}(\Delta_2^*) + \text{AZPE}(\Delta_1^*)$$

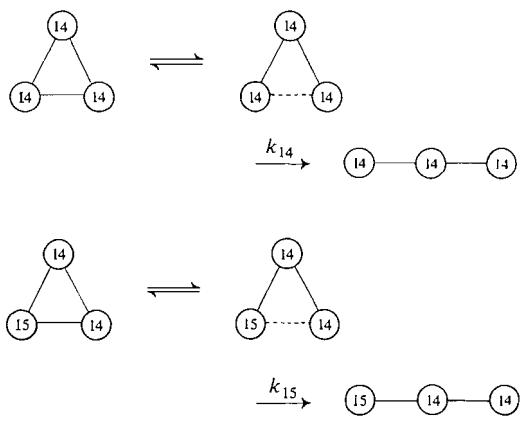
From a knowledge of geometry and force field of the species involved, ΔAZPE and hence ACOR can be evaluated.

The Model

The ring opening of an equilateral triangular, triatomic molecule, with each side equal to 1.524 Å (9) and leading to a bent transition state, may serve as the reaction for which the anharmonicity correction will be determined. All three atoms have an atomic weight of 14 in the species that is not isotopically substituted. The effect of isotopic substitution in the various positions can now be investigated. For example, the isotope effect and the corresponding anharmonicity correction can be evaluated if the rate of reaction of a species with isotope substitution at the position where the bond is being broken is compared with the unsubstituted case.

The reaction is supposed to take place in the ideal gas phase. The two reacting systems that will be compared are:

[6]



In these two reacting systems isotopic substitution takes place at the bond being broken. This bond will vary in length, while the other two remain unchanged. The kinetic isotope effect for the above reactions is then defined as k_{14}/k_{15}.

The Calculation of the Anharmonicity Correction and Isotope Effect

For the initial and transition states the changes in bond length have been chosen as the three internal coordinates. For symmetry reasons it is convenient to choose for the initial state a linear combination of internal coordinates. These are for all initial states, regardless of the fact that the symmetry may be changed on isotopic substitution, $S_1 = (r_1 + r_2 + r_3)/\sqrt{3}$, $S_2 = (2r_1 - r_2 - r_3)/\sqrt{6}$, and $S_3 = (r_2 - r_3)/\sqrt{2}$, in which, for example, r_1 means the change in bond distance between atoms 1 and 2.

From the choice of internal coordinates it follows that all diagonal force constants are the same for the initial state. This basically also holds for the transition state, except that the diagonal force constant which corresponds to the bond being broken (the reaction coordinate) has been taken as zero. The magnitudes of the non-zero diagonal quadratic, cubic, and quartic force constants for the *basic force field* (see below) are 4.37 mdyn/Å (9), −52.4 mdyn/Å^2, and 209.8 mdyn/Å^3, respectively. All off-diagonal force constants are taken as zero. The force constants strictly refer to the derivatives of the potential energy with respect to internal coordinates and exclude any multiplicative constant. The cubic force constant is −12 times and the quartic force constant 48 times the quadratic force constant, a trend *approximately* followed by most molecules (10, 11). There are other ways of estimating force constants (12), but the key data are lacking and the results obtained are not necessarily better in this case.

The transformation of force constants in internal coordinates to force constants in dimensionless normal coordinates (6) has been accomplished by the method of Pariseau *et al.* (13). Because the change in isotopic mass, the geometry of the transition state, and the force field are rather arbitrary, they have been varied in a systematic way to establish their importance in determining the magnitude of the anharmonicity correction of kinetic isotope effects. All quanti-

TABLE 1. The anharmonicity correction as a function of the geometry of the transition state

Geometry of t.s.*	AZPE (cm^{-1})†		200 °K		700 °K	
	t.s. (14)	t.s. (15)	k.i.e.‡	ACOR	k.i.e.	ACOR
1.0*h*	−38.09	−37.44	1.061	0.996	1.022	0.999
0.8*h*	−38.60	−37.96	1.059	0.996	1.020	0.999
0.6*h*	−37.74	−37.09	1.057	0.996	1.018	0.999
0.4*h*	−36.52	−35.85	1.053	0.996	1.015	0.999
0.2*h*	−35.62	−34.93	1.050	0.996	1.012	0.999

*h is the height of the triangle representing the initial state (i.s.). The number nh, (n = 1.0, . . . , 0.2), is the height of the transition state (t.s.) where only the reacting bond is changed with respect to i.s.

†t.s. (14) refers to the transition state without isotopic substitution, while t.s. (15) refers to the transition state where one of the atoms of weight 14, at the position where the bond is being broken, has been replaced by its isotope of weight 15. The corresponding initial states, i.s. (14) and i.s. (15), have an AZPE value of −56.64 and −55.38 cm^{-1}, respectively.

‡The kinetic isotope effect (k.i.e.) calculated by means of the harmonic approximation (2, 3) in which symmetry numbers have been ignored.

ties connected with the reaction coordinate in, for example, eq. 3 have been set equal to zero.

Results and Discussion

If the rates of reaction of the two systems [6] at 200 °K are compared, the kinetic isotope effect, as can be seen in the first line of Table 1, is about 1.06 (6%). The anharmonicity correction is quite small, only 0.996 (0.4%) at this temperature. At 700 °K the correction becomes 0.999, which is negligible. As is also true for the other results listed in Table 1, the basic force field has been used and the geometry of the initial and transition states is the same.

The remainder of Table 1 shows other interesting results. If only the reacting bond is allowed to stretch while leaving the remaining two unchanged, the small anharmonicity correction does not vary, contrary to the isotope effect which decreases slightly. It appears that AZPE for the transition state, similar to ACOR, is almost insensitive towards geometry of the transition state. Although the frequencies have not been listed, the magnitudes of AZPE for the initial and transition states are only 3–4% of the zero-point energies.

The anharmonicity correction as a function of the force field of the transition state is listed in Table 2. The force field for the initial state is the basic one and, as before, the geometry of both states is the same. Again the conclusion is simple; even for greatly differing cubic and quartic force constants the correction is smaller than 2.5% at temperatures higher than 200 °K. When the cubic and quartic force constants in internal coordinates are zero, the correction is very close to one (but not exactly). It can also be seen that the correction is more sensitive towards changes in the cubic force constants than to changes in the quartics.

TABLE 2. The anharmonicity correction as a function of the cubic and quartic force constants.

Force field of t.s.*	ACOR	
	200 °K	700 °K
coqo	1.000	1.000
cuqo	0.994	0.998
coqu	1.001	1.000
cuqh	0.995	0.999
cuqd	0.997	0.999
chqu	1.000	1.000
cdqu	0.978	0.994
chqh	0.999	1.000
cdqd	0.980	0.994

*Key to the code: c = cubic force constant; q = quartic force constant; o = zero; u = unchanged; h = halved; d = doubled. The letters cuqd, for example, mean the cubic force constants are unchanged and the quartic force constants doubled with respect to the basic force field (see text).

A spectacular increase in ACOR can be achieved decreasing the mass of the isotope to almost zero. Although without physical significance, the correction can be as large as 6537 at 200 °K, if an atom of mass 14 is replaced by one of 0.1. However, for any reasonable mass ratio the correction stays small. The results of the determination of the mass dependence of ACOR can be found in Table 3.

For the basic force field and geometry, isotopic substitution at the position away from the bond being broken reduces the isotope effect to 1.003 and ACOR to 1.000 at 200 °K. Double substitution at the bond being broken shows that

†Symmetry numbers are ignored.

the isotope effect and anharmonicity correction are roughly additive (1.117 and 0.991 at 200 °K, respectively).

Some other corrections have also been determined. The corrections for effective rotational constants (6), rotational stretching (14), and replacing the sum by an integral (15) in the rotational partition function are in all calculations less than 0.1% and can be safely ignored under normal conditions for the proposed reactions.

The authors would like to thank the South African Council for Scientific and Industrial Research for financial assistance and Miss S. E. Nieuwoudt for her help in computer programming.

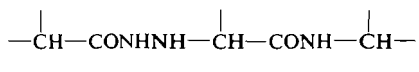
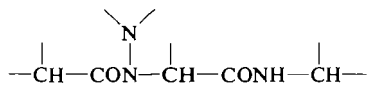
Introduction

Among natural products of pronounced physiological activity are numerous peptides. Typical examples are the kinins (1) and the recently discovered hypothalamic releasing hormones (2). The therapeutic application of peptides is, however, limited due to rapid enzymatic degradation in the alimentary tract after oral administration. Even on parenteral administration most of these compounds lose their potency much faster than desired. The elimination of this shortcoming is, therefore, a classical goal of peptide chemistry. A number of approaches have been explored in the past to improve the stability and to prolong the physiological lifetime of therapeutically interesting peptides, for instance: the use of alkylated aminoacids (3), the replacement of amide by ester groups (4), the substitution of D- for L-aminoacids (5), of the elongation of the peptide linkage by an additional —NH— to form a hydrazide of type I (6). These changes are in general accompanied by either considerable or total loss of activity. Some loss of activity, hopefully combined with increased pharmacological specificity, is frequently acceptable, since many natural products are effective at minimal concentrations (7).

Since modified peptides embodying a 1,1-disubstituted hydrazide (II) have not been described previously, model experiments were carried out to determine suitable reaction conditions for their preparation. The synthesis of model compounds of type II is the subject of this paper.



I



II

Methods

The versatile and elegant four-component condensation of Ugi (8) provided easy access to the desired peptide analogues. This reaction was modified so that the substituted hydrazones were prepared separately and then allowed to react with the isonitrile and the carboxylic acid as shown in Scheme 1. In the simplest case, the product is a dipeptide analogue in which one nitrogen atom carries a dialkylamino substituent.

Results

The addition of isonitriles to hydrazones was expected (8) to proceed with a rather low reaction rate in view of the reduced basicity of the hydrazones compared to the amine derivatives. Nevertheless Ugi products were obtained in acceptable yields, since the addition of the isonitrile and the carboxylic acid was followed by an irreversible rearrangement. Zinner and Bock (9) also succeeded in using hydrazines in the Ugi reaction in connection with the synthesis of substituted tetrazoles.

Tables 1–3 list the compounds prepared. Examples **1–4** (Table 1) represent reaction products of cyclohexanone dimethylhydrazone, ethyl

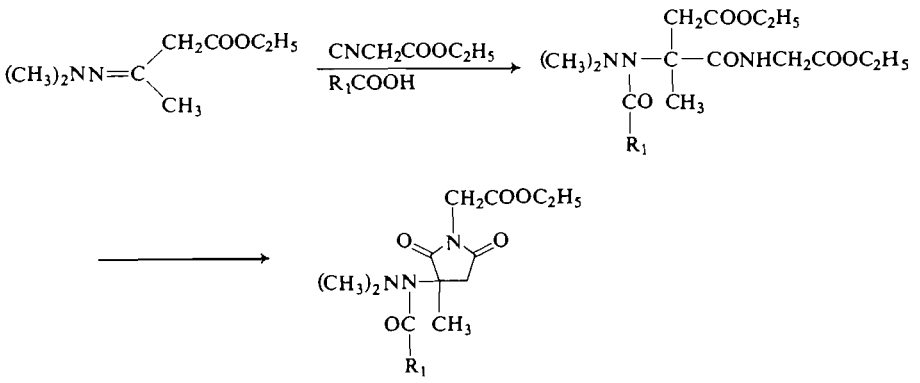

SCHEME 2

isocyanoacetate (10) and a carboxylic acid. It is evident that the reaction rate was considerably reduced with increasing bulk of the substituent R_1. This was also true for substances **5** and **6**, where the isonitrile derived from D,L-phenylalanine methylester was employed. Replacement of cyclohexanone by ethyl acetoacetate as carbonyl component led to Ugi products which underwent ring closure to 2,5-dioxopyrrolidines (Scheme 2), under mildly basic conditions. In some cases ring closure occurred spontaneously without base treatment (**7**, **8**, **12**).

Examples **9**, **10**, and **11** of Table 2 clearly demonstrate the influence of R_1 substituents on reaction rate. The latter depends on the conversion of A to B and is determined by the electrophilic character of the carbonyl group of the acid (Scheme 3).

Finally, the use of cyclohexylisonitrile and the

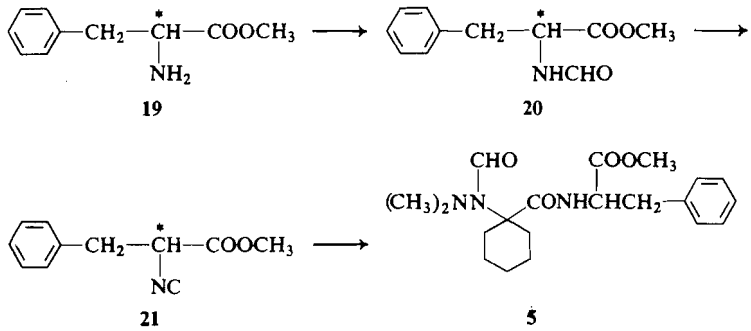

SCHEME 4

dimethylhydrazone of 4-ketopentanoic acid ethyl ester in the Ugi reaction was investigated. The reaction went smoothly and the reaction rate was again dependent on R_1 (structures **17**, **18**).

Whenever an asymmetric center is generated in the Ugi reaction a racemate is obtained (structures **7**–**18**), at least in the absence of inducing agents (11). It was now interesting to ascertain if isonitriles derived from optically active amino acid esters retain optical activity under the conditions employed. L-Phenylalanine methyl ester (**19**) (12) was converted into *N*-formyl-L-phenylalanine methyl ester (**20**) (12, 13) which was transformed into the isonitrile (**21**) with phosgene under mild conditions. The optically active isonitrile (**21**) was condensed with cyclohexanone-dimethylhydrazone in the presence of formic acid to yield **5** (Scheme 4) which showed no optical activity (14). The application of the Ugi reaction utilizing 1,1-dialkylated hydrazines to a peptide problem of pharmacological interest will be described separately (15).

Experimental

General Procedures[1]

(a) Synthesis of 1–8, 12, 17, 18

To a stirred, ice-cold solution of the isonitrile (0.1 mol) and the hydrazone (0.1 mol) in CH_2Cl_2 (50 ml) the solution of the carboxylic acid (0.1 mol) in CH_2Cl_2 (50 ml) was added dropwise. After the appropriate time the solution was diluted with 100 ml CH_2Cl_2 and washed with 4 *N* NH_4OH (100 ml), H_2O (100 ml), and saturated NaCl solution (100 ml). The organic phase was dried over Na_2SO_4, filtered, and evaporated to dryness *in vacuo*. The residue was crystallized.

(b) Synthesis of 9–11, 13–16

The residue obtained under (*a*) was dissolved in $CHCl_3$ (250 ml) and refluxed for 90 min in the presence of 40 g anhydrous K_2CO_3. The solids were filtered off, the solvent evaporated *in vacuo* and the residue crystallized.

L-*Phenylalanine methyl ester hydrochloride (19) (12)*

A solution of L-phenylalanine (25 g, 0.15 mol) in anhydrous methanol (250 ml), saturated with anhydrous hydrogen chloride, was heated to reflux for 5 min. The solvent was removed *in vacuo* and the residue crystallized from methanol – diisopropyl ether (16.0 g): m.p. 159–161° $[\alpha]_D$ + 38.7 (*c* 2.9 in EtOH).

Anal. Calcd. for $C_{10}H_{14}ClNO_2$: C, 55.68; H, 6.50; N, 6.50. Found: C, 55.79; H, 6.62; N, 6.59.

N-Formyl-L-phenylalanine methyl ester (20) (12, 13)

A hot solution of sodium formate (123 g, 0.18 mol) in 98% formic acid (14 ml) was added to a warm solution of L-phenylalanine methyl ester hydrochloride (22.0 g, 0.1 mol) in formic acid (15 ml). After 1 h the mixture was filtered, and acetic anhydride (29 ml, 0.245 mol) was added over a period of 20 min under ice cooling. After 1 h at room temperature the acids were removed *in vacuo*. The residual oil was dissolved in acetone (100 ml), filtered, and fractionally distilled. Yellow oil (19.7 g): b.p. 133–136°/0.88 mm; $[\alpha]_D$ + 32.5° (*c* 2.5 in EtOH).

Anal. Calcd. for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.75. Found: C, 63.51; H, 6.48; N, 6.74.

Methyl-2-isocyano-3-phenylpropionate (21)

A solution of phosgene (5.2 g, 0.052 mol) in dry CH_2Cl_2 (45 ml) was added dropwise to a stirred solution of *N*-formyl-L-phenylalanine methyl ester (10.0 g, 0.048 mol) and *N*-methylmorpholine (13 g, 0.125 mol) in dry CH_2Cl_2 (25 ml) at −30°. The solution was stirred at −30° for an additional 30 min, filtered, and the filtrate concentrated *in vacuo*. Benzene was added to the residue followed by filtration and concentration. The residue was distilled to afford a yellow oil (6.47 g): b.p. 97°/0.3 mm; γ_{max} ($CHCl_3$) 2150, 1746 cm^{-1}; n.m.r. ($CDCl_3$) 3.20 (d, *J* 7 Hz, 2H, —CH_2—), 3.77 (3H, $COOCH_3$), 4.48 (two doublets, *J* 7.5 and 5 Hz, 1H, —*CH*—), 7.30 p.p.m. (5H, aromatic); $[\alpha]_D$ −10.0° (*c* 1.0 in MeOH).

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86; N, 7.40. Found: C, 68.72; H, 5.97; N, 7.42.

N-[1-(N-Dimethylamino)formamido]cyclohexylcarbonyl phenylalanine methyl ester (5)

To a solution of cyclohexanone dimethylhydrazone (3.70 g, 0.026 mol) and L-methyl 2-isocyano-3-phenylpropionate (5.0 g, 0.026 mol) in dry CH_2Cl_2 (15 ml) a

The Direct Observation of a Stereospecific Pentadienyl – Cyclopentenyl Cation Cyclization

N. W. K. CHIU AND T. S. SORENSEN

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received February 20, 1973

Two isomeric 1,2,4,5-tetramethylpentadienyl cations (**4***a* and **4***b*) have been observed in FSO_3H–SO_2ClF at −125°. They undergo stereospecific thermal cyclizations to cyclopentenyl cations in accord with the Woodward–Hoffmann rules.

Les deux cations isomères (**4***a* et **5***a*) du tétraméthyl-1,2,4,5 cyclopentadiényle ont été observés dans un mélange de FSO_3H–SO_2ClF à −125°. Ils subissent des cyclisations thermiques stéréospécifiques qui les transforment en cations cyclopentènyles suivant les règles de Woodward–Hoffmann.

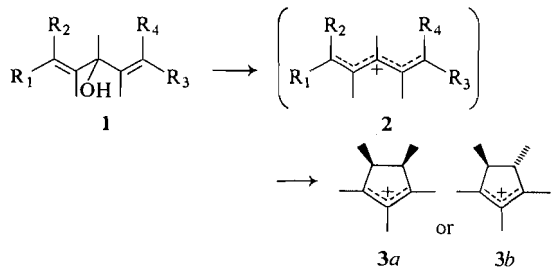
[Traduit par le journal]

Can. J. Chem., **51**, 2776 (1973)

Introduction

There are now many literature examples (1–7) in which a substituted dienylic cation undergoes a thermal cyclization reaction to yield a cyclopentenyl cation.

This reaction was one of the first to be treated by Woodward and Hoffmann (8). It can be described as an electrocyclic transformation and is predicted to proceed in a conrotatory manner.[1] In our previous paper relating to the stereochemistry of this transformation (9), we reported the thermal acid cyclization of the isomeric dienols **1***a–c* (via the presumed intermediacy of the dienylic cation **2**) to the cyclopentenyl cation **3***a* or **3***b*. The cyclization is nearly stereospecific and indeed proceeds in a conrotatory manner as predicted by the Woodward–Hoffmann rules (8).

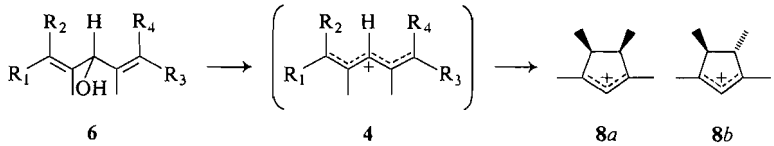


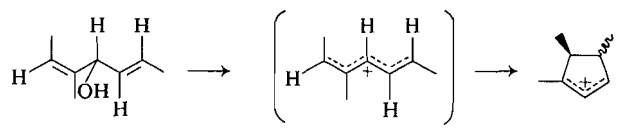
a $R_1=R_3=CH_3$, $R_2=R_4=H$
b $R_1=R_4=CH_3$, $R_2=R_3=H$
c $R_2=R_4=CH_3$, $R_1=R_3=H$

(In all cases — indicates a methyl group.)

However, the failure to directly observe the presumed dienylic cation intermediate **2** must inevitably lead to some doubt about the existence of **2** as an intermediate. Furthermore, the non-observation of **2** curtailed our original intention to examine the cyclization by both the thermal and photochemical processes.

In another attempt, we chose the homologous dienylic cation systems **4** and **5**, whose precursors are the dienols **6** and **7** respectively.





a $R_1=R_3=CH_3$, $R_2=R_4=H$
b $R_1=R_4=CH_3$, $R_2=R_3=H$
c $R_2=R_4=CH_3$, $R_1=R_3=H$

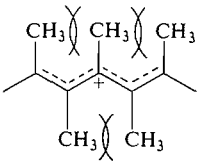
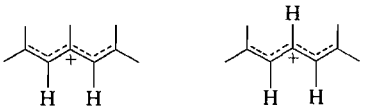
The steric interactions responsible for the instability (nonplanarity) of **2** are shown by molecular model studies to be mainly due to the following interaction.



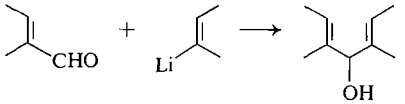
This interaction is reduced in **4** and even more so in **5**, at least in some of the geometric forms of these. An excellent precedent exists for the expectation that the removal of a C-3 methyl group in **2** will result in dienylic ion stability (to cyclization). The ion **10** has a half-life of 2.3×10^3 s at $-57°$ whereas ion **11** has a half-life of 4.6×10^4 s at 25° (6).



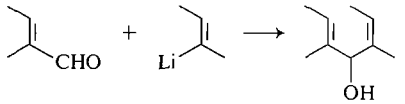
10 **11**

Results

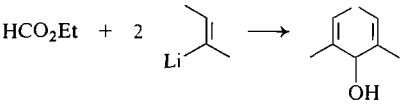
There are three geometric isomers of 3,5-dimethylhepta-2,5-dien-4-ol (**6**), *viz.*, 2E,5E (**6***a*), 2E,5Z (**6***b*) and 2Z,5Z (**6***c*). These isomeric alcohols were prepared as follows:



6*a*



6*b*



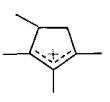
6*c*

In addition to the expected isomers, these preparations invariably yielded one of the other isomers as a minor by-product (geometric impurity). Thus alcohols **6***a*, **6***b*, and **6***c* contained **6***b*, **6***a*, and **6***b*, respectively, as an impurity. Fractional distillation at reduced pressure gave **6***a*, **6***b* and **6***c* in 88, 92, and 88% geometric purity, as determined by n.m.r. spectroscopy. The structure of these alcohols is shown by the method of synthesis and by the chemical shift values obtained for the C-2, -4, and -6 protons. The C-4 proton exhibits a broad singlet absorption at τ 5.80 in **6***a*, 5.20 in **6***b*, and 4.76 in **6***c*. The C-2 and -6 protons of the symmetrical isomers **6***a* and **6***c* show the expected quartet of quartets pattern (2H) centered at τ 4.52 and 4.76 respectively. The unsymmetrical alcohol **6***b* shows the expected double set of a quartet of quartets centered at τ 4.73 and 4.52. The C-4 proton peak was used for the analytical geometric purity determinations. This peak in **6***c* partially overlaps with that of the C-2 proton but fortunately **6***c* cannot be a significant impurity in **6***a* or **6***b* from the method of synthesis.

Similarly, the alcohol **7**, in predominantly (>85%) the geometry (2Z,5E) shown in the formula, was prepared from *trans*-crotonaldehyde and *trans*-2-butenyl-2-lithium.

Carbonium Ion Preparations

The isomeric alcohols **6***a*, **6***b*, and **6***c* were added to some or all of the following acids: H_2SO_4 (86–100%), $ClSO_3H$, CF_3SO_3H, FSO_3H, FSO_3H–SbF_5 (4:1), SbF_5–SO_2ClF (1:2), and FSO_3H–SO_2ClF (1:4). The temperature of addition ranged from -125 to 0°. In FSO_3H–SO_2ClF (1:4) at $-125°$, the dienol **6***a* gave mainly the dienylic ion **4***a*, dienol **6***b* gave **4***b* and a large amount of polymeric material, and dienol **6***c* gave only polymer. Invariably, the two cyclic ions **8***a* and **8***b* were also formed as by-products. At $-83°$, dienylic cations **4***a* and **4***b* both cyclized at about the same rate ($t_{1/2} \simeq 1$ h) to give mainly **8***b* and **8***a* respectively. With all other acid systems (temperature of addition $> -80°$) no dienylic cations were observed, only mixtures of cations **8***a* and **8***b* in varying ratios (Table 1). These results were actually obtained prior to the very low temperature studies and it subsequently became obvious from the cyclization rate of **4***a* and **4***b* why no dienylic cations were observed. In some cases, a third cyclic ion **8***c* was also formed as a component of the mixture.



8*c*

The structure of these ions was confirmed by n.m.r. spectroscopy. The n.m.r. spectral data for

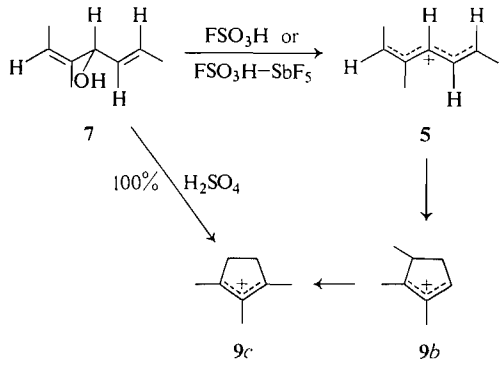
4*a*, **4***b*, **8***a*, and **8***b* are listed in Table 2, that for **8***c* has previously been reported (2). The chemical shifts observed for the dienylic cations **4***a* and **4***b* are similar to those observed for related systems (2, 6). The actual ground-state geometry of the ions (see ref. 1) cannot be determined by n.m.r. spectroscopy because of the lack of vicinal protons (and hence of vicinal coupling constants) on the cation framework. From previous results, the ground-state geometry is assumed to be the "W" or 2E,3E configuration (see ref. 3 for a proposed rational nomenclature for dienylic cations).

"W" or 2E, 3E

The assigment of the stereochemistry of **8***a* and **8***b* was based on their equilibrium ratio (K = **8***b*/**8***a* = 3.5 ± 0.1), obtained in H_2SO_4, which by analogy to ions **3***a* and **3***b*, should favor the *trans* ion **8***b* and by a comparison of their n.m.r. spectra with that found for **3***a* and **3***b* (9). For example, the C-4 and -5 methyl groups in **3***a* (*cis*) appear at a higher field than in **3***b* (*trans*) and a corresponding observation is consistent with the assignments for **8***a* and **8***b*.

For all acid systems other than SO_2ClF–FSO_3H (4:1) the relative amounts of the cyclized ions **8***a*, **8***b*, and **8***c*, in mixtures, were determined by peak area measurements using the C-2 proton n.m.r. peak at τ 2.42 in **8***a*, and 2.46 in **8***b*, and the C-2 methyl peak of **8***c* at τ 7.86. The details are given in the experimental section. The acid addition of alcohols **6***a* and **6***b* was in most cases quite smooth. In contrast, **6***c* reacted violently with all acids except H_2SO_4 to form large amounts of apparently polymeric material. When the aprotic SbF_5:SO_2ClF (1:2) acid solvent system was used, all three alcohols were at first poorly soluble and then reacted violently, only gummy residues being obtained.

The dienylic alcohol **7** was added to 100% H_2SO_4, FSO_3H, and FSO_3H–SbF_5 (4:1). In FSO_3H and FSO_3H–SbF_5, the dienylic ion **5** was observed at −70°. Ion **5** was found to rearrange slowly to give the cyclic ion **9***b* (FSO_3H, −40°, $t_{1/2} \simeq 1$ h) which in turn rearranges to **9***c* at higher temperature (FSO_3H, 20°, $t_{1/2} \simeq 10$ min). In 100% H_2SO_4 one is limited in the temperature of the preparation to 0° or slightly lower (supercooled solution) and in this solvent only **9***c* was obtained on addition of the alcohol.

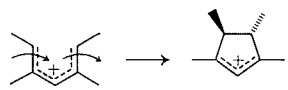


7 5 9*c* 9*b*

The structures of these ions were confirmed by n.m.r. spectroscopy (Table 3.)

Discussion

The observable dienylic cation **4***a* cyclizes to give predominantly the cyclopentyl cation **8***b* (the *trans* dimethyl configuration at C-4 and -5) while **4***b* gives predominantly **8***a*. As discussed in the earlier papers (6, 9), this is consistent with a conrotatory process in which the "U" or 2Z,3Z geometry of the dienylic cation cyclizes to a cyclopentenyl cation. The equilibrium involved



4*a* "U" or 2Z,3Z **8***b*

in getting from the ground-state 2E,3E configuration to the 2Z,3Z configuration has been discussed (6, 9). In the above results, a direct dienylic cation cyclization is involved and we therefore have excellent evidence for the existence of this species in those cases where only the cyclized ions are observed on dienol addition, *i.e.* the pentamethyl results (9) and the higher temperature results in this work (Table 1). The results for dienols **6***a* and **6***b*, *i.e.* showing considerable stereospecificity in the particular cyclopentenyl cation formed, are similar to the results obtained for the pentamethyl case and need be discussed no further.

The behavior of **6***c* presents a dilemma since a cyclization of the initially formed dienylic cation should have produced the *trans* ion **8***b*. However, in sulfuric acid (the only acid solvent not leading to considerable polymer formation or the production of considerable **8***c*), the *cis* ion **8***a* is formed in predominant amount (slightly higher stereospecificity than from even **6***b*). This is not

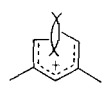
*Center of peak.

a thermodynamic result since we have already stated that the equilibrium **8***b*/**8***a* favors **8***b*. Rather than postulate a disrotatory closure in **4***c*, it seems more reasonable to postulate an isomerization at the dienylic ion stage **4***c* → **4***b*; the ring closure of **4***b* then yielding the observed *cis* cyclic ion **8***a*. There are several good reasons why this might happen:

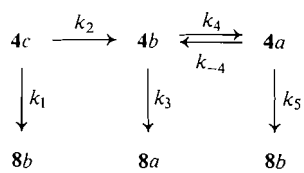
1. The transition state for the ring closure of **4***c* is particularly bad (large methyl–methyl repulsion).



4*c*

The alternative two stage process may then represent a lower energy pathway for reaction.

2. For steric reasons (9), the dienylic ion **4***c* (in any configuration) is not expected to be as stable as **4***b*; however, **4***a* is expected to be the most stable. The rate constants for possible isomerization and ring closure steps are shown schematically below.



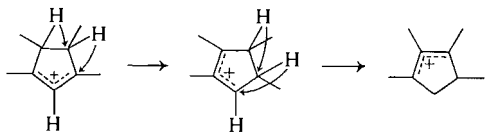
It seems possible that k_2 and k_4 may be competitive with k_1 and k_3 (and even a k_{-4} step and k_5 may be competitive). This would explain the lack of complete stereospecificity in **4***b* → **8***a* and **4***a* → **8***b*. In the case of **4***c*, the rate constant k_2 may actually be larger than k_1 so that cyclization occurs predominantly via **4***b*, leading to the *cis* ion **8***a*.

In the corresponding pentamethyl dienylic cations **2***a–c*, an analogous behavior, *i.e.* **2***c* → **3***a*, was not observed, the expected *trans* ion **3***b* always being the major product. This difference can be satisfactorily rationalized because, as pointed out in the Introduction, there is reason to expect the cyclization rate constants k_1, k_3, and k_5 to be smaller in the tetramethyl series, under investigation in this work. The isomerization rate constants k_2 and k_4 may not, however, be very different in the two cases. We believe therefore that in the pentamethyl series, k_1 is larger than k_2.

The formation of **8***c*, the rearranged cyclic ion, occurs mainly with alcohol **6***c* and only in certain acid solvents, in particular CF_3SO_3H and SbF_5–FSO_3H. This ion must be formed in the initial rather violent reaction sequence which takes place when the alcohol and acid are mixed since it can be shown that the rearrangement of **8***a* and **8***b* to **8***c*, while it does go to completion, is a very slow reaction on the time scale needed for the addition procedure. Also the formation of **8***c* can be correlated with the amount of polymer formed in the addition reaction. The virtual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

absence of **8***c* in some of the solvents studied indicates to us that these particular reactions are virtually free from hydride shifts occurring *after* the initial cyclization process since a hydride shift mechanism is the most obvious way of explaining the formation of **8***c*.



8*a* or **8***b* **8***c*

The trimethylpentadienyl cation system **5** could not be successfully used to study the pentadienyl → cyclopentenyl stereochemistry. Even in one of the strongest acid systems known (FSO_3H–SbF_5), the dienylic ion **5** does not give **9***a* as an observable product on cyclization. One has therefore no way of determing the stereochemistry of the cyclization process since the first observable product **9***b* has lost one asymmetric center.

In this work, we have shown for the first time an observable dienylic cation → cyclopentenyl cation cyclization which is nearly stereospecific. This complements the previous results (9) because in that study, dienylic cations were not actually observed, even though there was abundant presumptive evidence that they were involved as intermediates.

The thermal cyclization rates of **4***a* and **4***b* are extremely rapid and any photochemical studies will of necessity have to be carried out at extremely low temperatures.

Experimental

Boiling points are uncorrected. Distillations were done on either a stainless steel spinning band column or an auto annular Teflon spinning band column (Nester/Faust). The n.m.r. spectra of all neutral compounds were obtained as *ca.* 10% solutions in carbon tetrachloride with tetramethylsilane as internal standard using a Varian Associates A-60 or HA-100 spectrometer. The n.m.r. spectra of all ion solutions were obtained with tetramethylammonium cation as internal standard (τ 6.90) using the HA-100 spectrometer equipped with a variable temperature probe. Microanalyses were performed by the Microanalysis Lab., The University of Calgary.

3,5-Dimethyl-(2E,5Z)-heptadien-4-ol (6b)

A solution of 32.6 g (0.24 mol) of *trans*-2-bromobut-2-ene in 30 ml of ether was added slowly over 0.75 h to 3.5 g (0.5 mol) of lithium ribbon containing 1% sodium in 100 ml of ether at 0° under an argon atmosphere. To the resulting alkenyl lithium solution was added a solution of 21 g (0.25 mol) of tiglaldehyde in 25 ml of ether over 1 h, stirring being continued for a further hour at 20°. The reaction mixture was then filtered through glass wool into an ice cold solution of 30 g ammonium chloride in 150 ml of water with vigorous stirring. The ether layer was separated and the aqueous layer was extracted with three 75 ml portions of ether. The combined ether layers were washed with 10% carbonate solution and dried over potassium carbonate. Distillation of the residue at reduced pressure gave 16.0 g (46%) of colorless liquid, b.p. 85–85.5°/11 mm. During the course of distillation, five fractions were collected at this temperature and n.m.r. analyses showed that they had the same geometric purity (92% **6***b* and 8% **6***a*), n.m.r. peaks centered at τ 8.54 (12H, multiplet, two terminal methyls and C-3 and -5 methyls); 5.20 (1H, singlet, C-4 proton); 4.73 (1H, quartet of quartets, $J \simeq 6.0$ and 0.9 Hz, C-2 proton), and 4.52 (1H, quartet of quartets, $J \simeq 6.6$ and 1.3 Hz, C-6 proton). The OH peak is variable.

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 77.20; H, 11.58.

3,5-Dimethyl-(2Z,5Z)-heptadien-4-ol (6c)

To a solution of *trans*-2-butenyl-2-lithium prepared as above from 95 g (0.7 mol) of *trans*-2-bromobut-2-ene and 9.7 g (1.4 mol) of lithium in 200 ml of ether was added a solution of 26 g (0.35 mol) of ethyl acetate and worked up as usual to give 15.3 g (31%) of light yellow liquid, b.p. 52–6°/2 mm. Redistillation gave a very lightly yellow fraction, b.p. 81–2°/11 mm and a colorless fraction, b.p. 82°/11 mm. These two fractions had identical geometric purity (86% **6***c* and 14% **6***b*). The colorless fraction was found to dehydrate in about 2 days at 0° whereas the colored fraction was stable indefinitely and hence this was used for the study as reported in this paper. N.m.r. peaks centered at τ 8.31 (12H, multiplet, two terminal methyls and C-3 and -5 methyls); 4.76 (1H, singlet, C-4 protons), and 4.76 (2H, quartet of quartets, C-2 and -6 protons). The OH peak is variable.

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 76.98; H, 11.29.

3,5-Dimethyl-(2E,5E)-heptadien-4-ol (6a)

From 68 g (0.5 mol) of *cis*-2-bromobut-2-ene, 7 g (1 mol) of lithium, and 42 g (0.5 mol) of tiglaldehyde, there was obtained 35 g (50%) crude alcohol, b.p. 90–5°/14 mm. On redistillation, six fractions were collected, b.p. 83–4°/9 mm. They were shown by n.m.r. analyses to have identical geometric purity (88% **6***a* and 12% **6***b*). N.m.r. peaks centered at τ 8.39 (6H, doublet, $J \simeq 6.7$ Hz, each doublet split into quartets, $J \simeq 1.0$ Hz, two terminal methyls); 8.56 (6H, multiplet, C-3 and -5 methyls); 5.80 (1H, singlet, C-4 proton), and 4.52 (2H, quartet of quartets, $J \simeq 6.7$ Hz and 1.3 Hz, C-2 and -6 protons). The OH peak is variable.

Anal. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50. Found: C, 76.57; H, 11.70.

3-Methyl-(2Z,5E)-heptadien-4-ol (7)

The same procedure used for the preparation of **6** was used to prepare **7**. From 27 g (0.2 mol) of *trans*-2-bromobut-2-ene, 2.8 g (0.4 mol) of lithium, and 14 g (0.2 mol) of crotonaldehyde, there was obtained 11 g (44%) of a colorless liquid, b.p. 83–4°/13 mm. N.m.r. peaks centered at τ 8.36 (9H, multiplet, two terminal methyls and C-3 methyl); 5.06 (1H, multiplet, C-4 proton); 4.80 and 4.49 (3H, multiplet, C-2, -5, and -6 protons).

Preparation of the Ions

All ion solutions were made to *ca.* 8% weight of alcohol/volume of acid solvent by adding 50 mg of the alcohol to 0.6 ml of the acid. The concentrations of sulfuric acid were determined by titration. Chlorosulfonic acid (B.D.H.), fluorosulfonic acid (Diaprep. Inc., N.M.R. grade), and sulfuryl chloride fluoride (Research Organic/Inorganic Chemical Corp.) were used without further purification. Antimony pentafluoride and trifluoromethylsulfonic acid were purified by double distillation. When sulfuric acid was used as solvent, the hexane extraction method was followed. In all other acids, direct additions of the alcohol or a solution of alcohol in deuterochloroform or trichloromonofluoromethane (1:2 ratio) were used.

Equilibration of 8a and 8b

Mixtures of **8***a* and **8***b* in 88–93% H_2SO_4 were equilibrated at 0° until no appreciable changes occurred as indicated by n.m.r. spectroscopy. An equilibrium ratio of 3.53 ± 0.10 was obtained favoring the *trans* ion **8***b*.

The Observation of Two Different Base-catalyzed Processes Occurring in Directly Observable Carbonium Ion Rearrangements

N. W. K. CHIU AND T. S. SORENSEN

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received February 20, 1973

In aqueous sulfuric acid, *cis*-1,3,4,5-tetramethylcyclopentenyl cation (**1***a*) has been found to rearrange not only to the *trans* isomer (**1***b*) but also to 1,2,3,4-tetramethylcyclopentenyl cation (**1***c*). The **1***a* → **1***b* and **1***a*/**1***b* → **1***c* rearrangements follow H_0 with slopes of 0.94 and 0.45 respectively. The **1***a* → **1***b* rearrangement involves a neutral intermediate, 1,2,4,5-tetramethylcyclopentadiene, whereas the **1***a*/**1***b* → **1***c* rearrangement involves a termolecular or intramolecular push–pull process.

Dans l'acide sulfurique, le cation *cis* tétraméthyl-1,3,4,5 cyclopentenyle (**1***a*) se réarrange non seulement en isomère *trans* (**1***b*) mais aussi en cation tétraméthyl-1,2,3,4 cyclopentenyle (**1***c*). Les réarrangements **1***a* → **1***b* et **1***a*/**1***b* →**1***c* se font suivant H_0 avec des pentes de 0.94 et 0.45 respectivement. Le passage **1***a* → **1***b* se fait par un intermédiaire neutre tétraméthyl-1,2,4,5 cyclopentadiène, tandis que les réarrangements **1***a*/**1***b* →**1***c* se font selon un processus push–pull termoléculaire et intramoléculaire.

[Traduit par le journal]

Can. J. Chem., 51, 2783 (1973)

Introduction

A number of directly observable carbonium ion rearrangements in sulfuric acid occur by a base-catalyzed mechanism (1). These appear, however, to fall into two distinct categories:

1. Those in which k_{rearr} appears to approximately follow the acidity function, H_0, of the solvent, with unit slope.

2. Those in which this slope is only about 0.5.

This differentiation has involved a comparison of different ion systems, but in this paper it is shown that it is possible to have the same starting ion rearranging to two different products, where one process belongs to category 1 and the other to category 2. This fortunate occurrence allows one to differentiate the two processes on mechanistic grounds and, therefore, to define them in other than the rather empirical H_0 correlation.

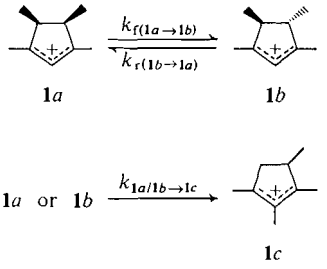
Results and Discussion

The two ion rearrangements studied were:

1. The interconversion of *cis*-1,3,4,5-tetramethylcyclopentenyl cation, **1***a*, and *trans*-1,3,4,5-tetramethylcyclopentenyl cation, **1***b*.

2. The rearrangement of either **1***a* or **1***b* into a third isomeric ion, the 1,2,3,4-tetramethylcyclopentenyl cation, **1***c*.

Ions **1***a* or **1***b* were prepared *in situ* in 84–100% H_2SO_4 and in pure FSO_3H, and could each be obtained in about 90% geometric purity. The n.m.r. spectra of **1***a*, **1***b*, and **1***c* are sufficiently different so that this tool can be used to quantitatively follow the reactions. The actual peaks used were the C-2 protons of **1***a* and **1***b* at τ 2.42 and 2.46 respectively and the C-2 methyl of **1***c* at τ 7.86. The n.m.r. data on these ions are reported in a separate paper (2).



(In all cases — indicates a methyl group.)

1*a* ⇌ **1***b* *Kinetics*

The equilibrium ratio of the two ions was determined to be $K_{1b/1a} = 3.5 \pm 0.2$ (2), favoring, as expected (1), the *trans* isomer. The most accurate kinetic data are obtained therefore by measuring the rate of the forward reaction $\mathbf{1a} \xrightarrow{k_{f(1a\rightarrow 1b)}} \mathbf{1b}$. The reaction was studied in sulfuric acid solvent concentrations ranging from 93.5 to 100.1% (concentrations corrected for dilution during the preparation (1)) at 0 °C and employing carbonium ion concentrations of 10% weight of alcohol per volume of acid. Under these conditions, the second reaction **1***a* or **1***b* → **1***c* is negligible.

The kinetic data gave good reversible first-

order plots and Table 1 lists the values of $k_{f(1a\rightarrow 1b)}$ for the various solvent concentrations. Except for the 100.1% acid data, log $k_{f(1a\rightarrow 1b)}$, when plotted against H_0 (Fig. 1), results in a reasonably linear correlation with a slope of about 0.94.

1*a* or **1***b* → **1***c* *Kinetics*

In this reaction, an equilibrium constant $K_{1c/1a+1b}$ was not observed; however, a minimum value is ⩾250 ($\Delta G \geqslant 3$ kcal/mol), based on the prevailing signal to noise ratio for the C-2 methyl group of **1***c* and correcting for the three proton size of this signal. The reaction was studied in 85.5 to 100.1% H_2SO_4 and in FSO_3H at 0 °C. The data gave good simple first-order plots once the **1***b*/**1***a* equilibrium was established and the resulting rate constants are reported in Table 2. A plot of log $k_{1a/1b\rightarrow 1c}$ *vs.* H_0 (Fig. 1), forcing a linear relationship, gives a slope of about 0.45 for the lower percent acid data. However, the plot appears to follow a curve which

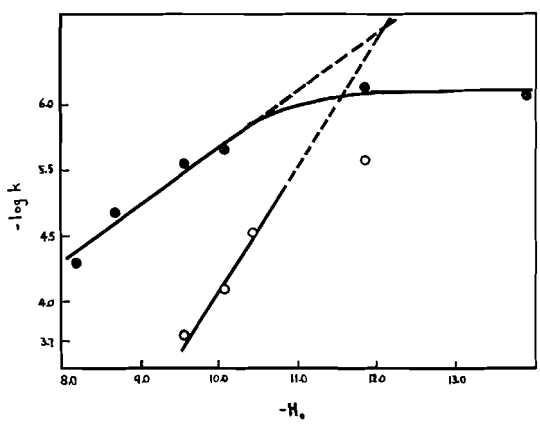

FIG. 1. (○) Plot of $-\log k_{f(1a\rightarrow 1b)}$ against $-H_0$, (●) plot of $-\log k_{1a/1b\rightarrow 1c}$ against $-H_0$, and (--) the extrapolation of both curves to higher H_0 values. The slope is 0.94 for the lower line and 0.45 for the higher, thereby showing the predicted changeover in the observed mechanism at higher H_0 values.

†Starting ion mainly **1***a*, **1***a*/**1***b* equilibrium not initially established.
‡Starting ion mainly **1***b*, **1***a*/**1***b* equilibrium not initially established.

levels off as H_0 gets bigger. One point which needs to be emphasized is that the slope at any point in this curve is much less than that observed for the **1***a* ⇌ **1***b* kinetics and it will be seen later that there is no particular mechanistic reason to expect any linearity of log $k_{1a/1b\rightarrow 1c}$ and H_0 in this reaction.

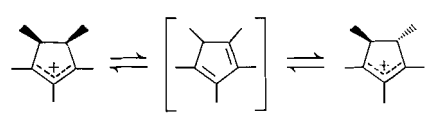
Comparison of $k_{f(1a\rightarrow 1b)}$ *and* $k_{1a/1b\rightarrow 1c}$

The **1***a* ⇌ **1***b* reaction at the lower sulfuric acid concentrations is much faster than the **1***a*/**1***b* → **1***c* reaction, *e.g.*, a factor of 20 in 93.5% H_2SO_4. However, a very rough extrapolation of both rates (Fig. 1) to very high H_0 solvents leads to the prediction of equal rates about $H_0 = -12$ to -13 and for the **1***a*/**1***b* → **1***c* reaction to be the faster above this. Fluorosulfonic acid is reported to have $H_0 = -13.9$ (3) and the above prediction is experimentally verified since the **1***a*/**1***b* equilibrium is not established in this solvent until the **1***a*/**1***b* → **1***c* reaction is well over 50% complete. The rates for **1***a* → **1***c* and for **1***b* → **1***c* are in fact different (Table 2).

Reaction Mechanisms

Category One

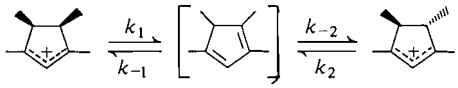
The **1***a* ⇌ **1***b* equilibrium constant and the acid dependence of the interconversion rates are very similar to those of the closely related *cis*- and *trans*-1,2,3,4,5-pentamethylcyclopentenyl cations, **2***a* ⇌ **2***b*, a slope of log k_{rearr} *vs.* H_0 of 0.99 (1) for the latter compared to 0.94 for the former.



2*a* **3** **2***b*

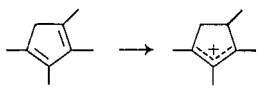
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The mechanism for the **2***a* ⇌ **2***b* interconversion has been shown previously to involve the intermediacy of the diene **3** and the same mechanism, therefore, appears very reasonable for **1***a* ⇌ **1***b*.



1*a* **4** **1***b*

In order to evaluate k_1 and k_2, the diene **4** was added to the strong acid solvents. Under the experimental conditions, where k_1 and k_2 are negligibly slow, the ratio of **1***a*/**1***b* observed is equal to k_{-1}/k_{-2}. This same procedure has previously been shown to yield reliable estimates of k_{-1}/k_{-2} for the **2***a* ⇌ **2***b* reaction. The ratio obtained from this study was 1.5 ± 0.2 favoring the thermodynamically less stable *cis* ion, **1***a*. Similar nonequilibrium protonation is also observed with **3** although the ratio is closer to unity. This ratio is *independent* of the strength of the acid and protonation occurs at C-4 since, within experimental error, only **1***a* and **1***b* are formed. However, the diene **4** was only *ca.* 94% pure and since the isomeric impurity **5** on protonation yields **1***c*, it is difficult to exclude the possibility



5 **1***c*

that up to 2 or 3% of **1***c* might have been formed in the protonation of diene **4**.

Assuming a steady-state concentration for **4**, then

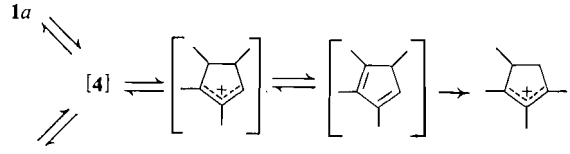
$$k_{f(1a\rightarrow 1b)} = \frac{k_1 k_{-2}}{k_{-1} + k_{-2}}$$

and since $k_{-1}/k_{-2} = 1.5$, therefore, $k_1 = 2.5\ k_{f(1a\rightarrow 1b)}$. Similarly, $k_2 = 0.5\ k_{f(1a\rightarrow 1b)}$.

It now seems reasonable to suppose that those base-catalyzed reactions belonging to category 1, with slope of about unity for log k_{rearr} *vs.* H_0, are always characterized by the intermediacy of the corresponding diene. This type of reaction is by no means limited to *cis–trans* interconversions but has as a general characteristic, the possibility of returning from the diene back to the starting cation so that in general $k_f \neq k_1$.

Category Two

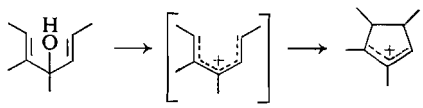
For the reaction **1***a*/**1***b* → **1***c*, we considered initially, as a working hypothesis, that it would



1*b* **6** **7** **1***c*

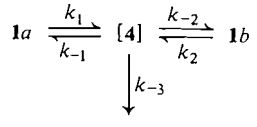
SCHEME 1

likely involve the sequence shown in Scheme 1. It seemed reasonable to suppose that a complex steady-state reaction of this type might show a different acid dependence from the **1***a* ⇌ **1***b* interconversion. In order to investigate some of the intermediate steps, the cyclopentenyl cation **6** was prepared by the addition of 3,4-dimethylhepta-2,5-dien-4-ol, **8**, to FSO_3H or FSO_3H–SbF_5 at −70°. A dienylic cation intermediate **9** is presumably formed initially which then cyclizes to give a mixture of the *cis* and *trans* isomers of **6** (for the cyclization of dienylic cations to cyclopentenyl cations, see refs. 2, 4–10).



8 **9** **6**

Ion **6** rearranges only to **1***c*; the rate constant $k_{6\rightarrow 1c}$ was determined and is reported in Table 3. Since the conversion of **6** to **1***c* is much faster than the conversion of **1***a*/**1***b* → **1***c*, steps subsequent to the formation of **6** cannot be rate determining. Projected experiments involving diene **7** thus became redundant. One can, therefore, substitute the following expression in place of Scheme 1.

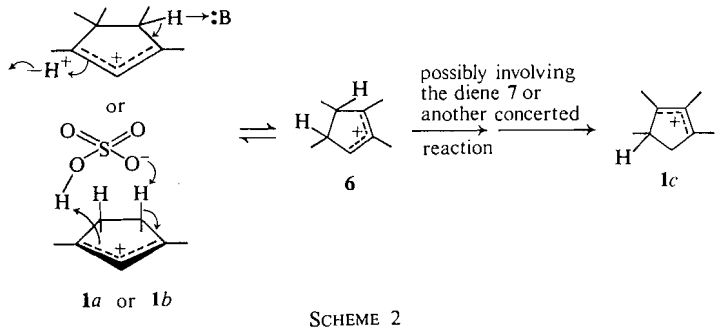


1*c*

TABLE 3. Kinetics for **6** → **1***c* in FSO_3H

Temp. (°C)*	$k_{6\rightarrow 1c}$ (s^{-1})†
−45	5.1×10^{-4}
−55	1.3×10^{-4}
−65	1.8×10^{-5}
0	1.7×10^{-1}‡

*±1°.
†Average of two runs at each temperature. The error is estimated at ±10%.
‡Extrapolated value.



SCHEME 2

Assuming a steady-rate concentration for **4**, the overall rate constant for the formation of **1***c* from an equilibrium **1***a*/**1***b* mixture is

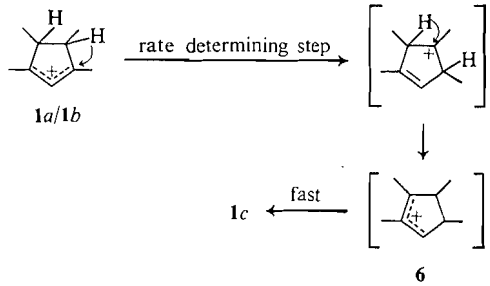
$$k_{1a/1b\rightarrow 1c} = k_{-3}\frac{k_1 + k_2K}{k_{-1} + k_{-2}}$$

and on substituting $k_{-1} = 1.5\ k_{-2}$, $K = 3.5$, and $k_2 = \frac{1}{5}k_1$, one obtains $k_{1a/1b\rightarrow 1c} = 0.7\ k_{-3}k_1/k_{-2}$. For comparison purposes, $k_f(\mathbf{1}a \rightarrow \mathbf{1}b)$ was equal to $k_1/2.5$. The only way $k_{1a/1b\rightarrow 1c}$ might have a different acid dependence from $k_f(\mathbf{1}a \rightarrow \mathbf{1}b)$ would be for the ratio k_{-3}/k_{-2} to vary, itself, as a function of the acid concentration. This certainly seems an acceptable possibility but experimental evidence is totally lacking, since protonation of **4**, even in very strong acids, does not yield **6** and hence **1***c*. We feel, therefore, that Scheme 1 does not represent the mechanism for **1***a*/**1***b* → **1***c* and, in particular, that the diene **4** is not an intermediate in the reaction.

About the only mechanism which has the required prerequisites, *i.e.*, base-catalyzed but no diene **4**, would be a termolecular[1] or intramolecular push–pull process (10) whereby a base species removes a proton and in a concerted process another proton comes on at the opposite end as shown in Scheme 2.

The acid dependence of such a process is unpredictable; however, the observed behavior is not inconsistent with such a mechanism, assuming the proton removal step is the more important. Also, one would not necessarily expect a linear H_0 correlation since no acid–base equilibria are involved.

In FSO_3H and 100.1% H_2SO_4 solvents, it is possible that a hydride shift mechanism operates since these are well-known in related cases (5, 7–11) (Scheme 3).



SCHEME 3

However, such a happening does not affect the central features of the **1***a*/**1***b* → **1***c* reaction, namely the solvent dependence and the observed slope of 0.45 in the weaker sulfuric acid solvents.

There are in the literature (10, 12) several other examples of base-catalyzed carbonium ion rearrangements where the k_{rearr} *vs.* H_0 slope is much less than unity. These, and the example described in this paper, have a unifying feature, *viz.* in each case a cation much less stable than either the reactant or the product is proposed as a key reaction intermediate. We suggest that this intermediate will always be formed by a concerted mechanism not involving diene. There are, therefore, two quite distinct classes of base-catalyzed carbonium ion rearrangements.

Experimental

Kinetics

The basic procedures used are similar to those reported for the pentamethyl case (1). Kinetic data are reported in Tables 1, 2, and 3.

Equilibrium of 1a/1b → 1c

Cation samples of **1***a* or **1***b* in 96% H_2SO_4 were kept at 0° for 120 h (minimum) and analyzed by n.m.r. spectroscopy. No peaks attributable to either **1***a* or **1***b* were observed. A minimum value of $K_{1c/1a+1b}$ was estimated to be $\geqslant 250$.

[1]The solvent is undoubtedly highly structured (polymeric) as a result of hydrogen bonding and the term termolecular is misleading in this sense.

Preparation of 1,2,4,5-Tetramethylcyclopentadiene (4)

A cation mixture of **1***a*/**1***b* (from 3 g of 2,4-dimethyl-2,5-heptadien-4-ol and 30 ml of concentrated H_2SO_4 at 0°) was injected slowly into the vortex of a vigorously stirred solution of 30% aqueous NaOH and ether at −5°. The ether layer was separated and the aqueous layer was extracted with ether (3 × 50 ml). The combined ether solution was washed with saturated brine and dried over anhydrous K_2CO_3. After removal of the ether under reduced pressure, micro distillation of the residue gave 1.7 g of colorless liquid, b.p. 40.5° at 12 Torr. V.p.c. (5 ft × 1/4 in. SE-30 on Chromosorb W at 65°) and n.m.r. analyses indicated 94% **4**, 3% of 1,2,3,4-tetramethylcyclopentadiene (**5**) (identified by co-injection with authentic sample), and 3% of an unidentified component.

Diene **4** shows n.m.r. peaks centered at τ 8.99 (C-5 methyl, doublet, J = 7.8 Hz); 8.24 (C-1 and -4 methyls, singlet); 8.13 (C-2 methyl, singlet); 7.53 (C-5 hydrogen, quartet, J = 7.8 Hz), and 4.30 (C-3 hydrogen, broad singlet).

Protonation of 4

Diene **4** was added to 98% and 100% H_2SO_4 at 0°. N.m.r. analysis of the resulting solution indicated 95% of **1***a* and **1***b* in the ratio of 1.5 ± 0.2 favoring **1***a* and 5% of **1***c*. In FSO_3H and 4:1 FSO_3H–SbF_5, the ratio **1***a*/**1***b* was 1.3 ± 0.2 with 15–25% of **1***c*.

Preparation of 3,4-Dimethylhepta-2,5-dien-4-ol (8)

Using the general preparative method for 3,5-dimethylhepta-2,5-dien-4-ol (2), from 9.8 g (0.1 mol) of 3-methylpent-3-en-2-one, 12.1 g (0.1 *m*) of 1-bromo-1-propene (*cis–trans* mixture), and 1.4 g (0.2 mol) of lithium, 7 g (60%) of **8** was obtained, b.p. 63–6° at 9 Torr.

N.m.r. analysis showed peaks at τ 4.25–4.75 (C-2, -5, and -6 protons); 8.20–8.55 (C-1, -3, and -7 methyls); 8.64 and 8.72 (C-4 methyl, two singlets due to the two isomers, *i.e.* (2E,5E) and (2E,5Z)). The OH peak is concentration dependent.

Preparation of 1,2,4,5-Tetramethylcyclopentenyl cation (6)

Dienol **8** (75 mg) was added to 0.5 ml of FSO_3H or FSO_3H–SbF_5 with stirring at −78°. N.m.r. analysis of the resulting solutions showed the presence of cation **6** (mixture of *cis* and *trans*). N.m.r. peaks were observed at τ 0.39 and 0.45 (C-3 proton); 6.38 and 6.82 (C-4 and -5 protons, broad), 6.99 (C-1 methyl, singlet), 7.74 (C-2 methyl, singlet), and 8.47–8.65 (C-4 and -5 methyl, multiplet). All peaks for the *cis* and *trans* isomers overlap except those for the C-3 proton.

Steric Effects in the Baeyer–Villiger Reaction of Simple Ketones

MITCHELL A. WINNIK AND VALERIE STOUTE

Erindale College and the Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario M5S 1A1

Received February 12, 1973

The reactions of simple alkyl ketones with peroxytrifluoroacetic acid (PTFA) and peroxymaleic acid (PMA) have been examined. Magnitudes of steric effects in the Baeyer–Villiger reaction have been determined, the largest being a factor of 13 in neopentyl to ethyl migration in 5,5-dimethyl-3-hexanone. PMA is consistently more selective toward electronic differences in migrating groups. PTFA shows the greater sensitivity to steric effects.

On a examiné les réactions de cétones alcoyles simples avec l'acide peroxytrifluoroacétique (PFTA) et l'acide peroxymaléique (PMA). On a déterminé les grandeurs des effets stériques dans la réaction de Baeyer–Villiger, le plus grand effet étant un facteur de 13 lors de la migration du néopentyle par rapport au groupement éthyle pour la diméthyl-5,5 hexanone-3. Le PMA est régulièrement plus sélectif vis-à-vis des différences électroniques dans les groupes migrateurs. PTFA possède une plus grande sensibilité pour ce qui est des effets stériques. Can. J. Chem., 51, 2788 (1973)

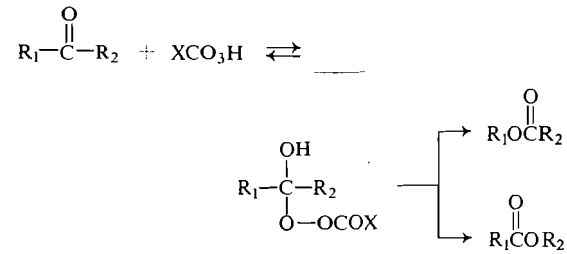
Introduction

While steric effects in the Baeyer–Villiger reaction (1) have received attention in bicyclic systems (2), ortho-substituted acetophenones (3), and benzaldehydes (4), simple aliphatic ketones have not been studied. Analytical difficulties abound and before the days of n.m.r. such study would have been impossible. While one might expect that migratory aptitudes of aliphatic groups, 3° > 2° ~ benzyl > 1° > Me, would have a steric component (the larger group always migrates in preference), Emmons and co-workers found almost no difference in the migratory aptitudes of ethyl and neopentyl when comparing the reaction of their respective phenyl ketones (5). Several years ago, one of us employed the Baeyer–Villiger reaction as a tool in the analysis of a mixture of long chain aliphatic ketones (6). It was necessary to assume indiscriminate migration of primary alkyl groups in the reaction of the ketones with peroxytrifluoroacetic acid. This seemed, in light of Emmons' results, to be a good approximation; but, as a control, 3-heptanone was subjected to these conditions. It was found that *n*-butyl migrated in preference to ethyl by 2 to 1. This paper presents the results of our study of the effect of steric bulk on the relative migratory aptitude of alkyl groups in the Baeyer–Villiger reaction.



Results

Methyl Ketones

The Baeyer–Villiger reaction was carried out at room temperature (23 ± 1°) on a series of methyl primary alkyl ketones in methylene chloride solution. The reactions were run to completion using twofold excess of peroxytrifluoroacetic acid (PTFA) in the presence of anhydrous disodium hydrogen phosphate or using fourfold excess of peroxymaleic acid (PMA) without added buffer. The reactions employing PTFA ordinarily were over in an hour, although, to ensure completion of the reaction, they were routinely stirred 90 min before working them up. Reactions employing PMA required 48 h stirring at room temperature to achieve complete reaction. No attempt was made to study the kinetics under these conditions. The former peracid requires a solid buffer in the reaction mixture, and, PMA reac-

tions deposit solid maleic acid during the course of the reaction. Both situations make it impossible to study the kinetics of the reaction under conditions identical to this product study.

Extent of methyl migration was assayed by n.m.r. The methyl resonance, in all cases, was well resolved and upfield of the methylene resonance of the corresponding isomeric ester. The small amounts of methyl esters produced required calibration of the attenuator. Calibration data, including correlation coefficients, are presented in detail in the experimental section. The methyl resonances were scanned at increased amplitude and the weight of the methyl peak was divided by its amplification factor. The very small values of methyl migration in methyl isobutyl ketone and methyl neopentyl ketone were calibrated by interpolating from known mixtures of the appropriate pure esters. We estimate the error in these measurements to be approximately $\pm 5\%$. The limit of our ability to detect methyl ester under these conditions is about 0.05%.

The extent of methyl migration for the ketones studied is collected in Table 1. The amount of methyl migration in methyl *n*-propyl ketone is half that observed in methyl ethyl ketone. Further homologation of the alkyl chain results in much smaller changes in extent of methyl migration. These differences are probably real, since they are outside of experimental error and are reflected in the amount of methyl migration found with both peracids. They may reflect conformational differences of the chains in methylene chloride solution. 2-Undecanone poses a peculiar problem here in that the product nonyl acetate is unusually sensitive to hydrolysis. Nonyl alcohol interferes with the assay procedure. The methylene protons adjacent to the OH fall on top of the ester O-methyl singlet. The product of the PMA oxidation underwent enough hydrolysis in 24 h reaction (3–10%) to obscure measurement of the extent of methyl migration in this case. Even with PTFA, when worked up in the usual way and allowed to stand at room temperature in CCl_4 in an n.m.r. tube, nonyl acetate underwent extensive hydrolysis.

[b]Ratio of migratory aptitude alkyl/methyl.
[c]Could not be measured due to partial ester exchange.

PMA is consistently more selective in the oxidation of methyl ketones. This difference of three- to fourfold increase in the selectivity probably reflects an increase in its sensitivity to electronic effects, when compared to PTFA. As the steric bulk of the alkyl group increases, this selectivity diminishes, suggesting that electronic and steric requirements lead to opposing effects.

Ethyl Ketones

The Baeyer–Villiger reaction of ethyl *n*-alkyl ketones was carried out under conditions identical to those described above. Both n.m.r. and mass spectral assays were employed. In the cases of 1-phenyl-2-butanone and neopentyl ethyl ketone, the CH_2—O protons of the respective esters were clearly resolved at 60 MHz. The esters from the reaction of isobutyl ethyl ketone could be resolved clearly only at 100 MHz. Partial resolution could be obtained at 60 MHz. The normal 3-alkanones did not lend themselves to an n.m.r. assay. Partial resolution was observed at 220 MHz for these reaction products. These partially resolved spectra were very useful since they allowed estimation of migratory aptitudes, which served as a convenient check on the more rigorous analyses.

Attempts to separate the product esters by g.l.c. failed, except in the case of 3-hexanone. Ethyl butanoate and propyl propanoate could be separated on a carefully packed 30 ft Carbowax 4000 column or on a 150 ft Carbowax 4000 coated capillary column. Our assay for 3-alkanones depended upon the propensity of ethyl alkanoates to give an intense ion in the mass spectrum at *m/e* 88, whereas propanate esters give peaks at *m/e* 57 and 75. The mass spectrometer was calibrated, in each instance, with known mixtures of the product esters and the composition of the Baeyer–Villiger product mixture was determined from the *m/e* 88/75 ratio by interpolation.

Table 2 lists the ratio of ethyl migration to

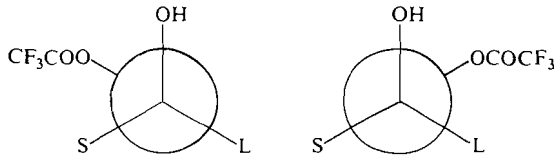
alkyl migration for both peracids. Also included in the table is the ratio of alkyl to ethyl migratory aptitudes, calculated from the methyl ketone data by comparing the ratio of alkyl/methyl migration to ethyl/methyl migration. It is interesting to note that, unlike the methyl ketones, the ethyl ketones show little change in selectivity in changing from PTFA to PMA as the peracid. Increasing the steric bulk of the alkyl group increases its tendency to migrate. *n*-Propyl acts as though it is larger than ethyl. Isobutyl contributes a factor of three over *n*-butyl to the relative migratory aptitude of the alkyl moiety, and neopentyl approximately another factor of three. The large migratory aptitude for benzyl indicates that electronic considerations are also important in the migration of this group.

Discussion

Steric Effects

Substitution of methyl groups on the β-carbon of 2- and 3-alkanones causes fairly small changes in the migratory aptitudes of the alkyl portion relative to methyl and ethyl. Extent of alkyl migration increases fairly regularly with the bulk of the alkyl group. Parallel effects are seen in the methyl and ethyl ketones and with both peracids. The largest difference is a factor of 13.3 seen in the reaction of ethyl neopentyl ketone with PTFA. This represents a difference in the free energy of activation ($\Delta\Delta G^{\ddagger}$) of neopentyl over ethyl migration of 1.5 kcal/mol.

We favor a steric origin for this change in migratory aptitude. One easily can visualize the origin of this steric effect in Newman projections of the Criegee intermediate by assuming that migration takes place *anti*-periplanar to the



departing carboxylate and that the product-determining transition state has similar steric demands. This argument has been advanced before (5). It is well to remember Curtin's admonition (8) that, if migration is slow with respect to rotation, the product ratio is determined solely by the ratio of the energies of the two transition states and not by the rotamer populations of the intermediate.

Comparison of the Peracids

Two papers by Emmons present examples of the change in relative migratory aptitude as a function of peracid. Emmons noted initially (5) that phenyl cyclohexyl ketone suffered 22% phenyl migration with PTFA and 11% phenyl migration with peroxyacetic acid in the presence of 1 *M* CF_3CO_2H. In later work (7), he observed that, in the reactions of desoxybenzoin, PMA gave a 7:1 ratio of benzyl to phenyl migration, whereas with PTFA, equal amounts were found. In both examples he concluded that migration was concerted with O—O bond cleavage and that the reaction involving the poorer leaving group was more selective.

Our results indicate that the situation is not so simple. PMA here is consistently more selective than PTFA when one is comparing two groups, which differ in the ability to stabilize positive charge by delocalization in the transition state. In the comparison of methyl with primary alkyl, PMA is about four times more selective. Comparing primary alkyl with benzyl, PMA is 1.4 times as selective. Where the comparison is between two primary alkyl groups (and one might expect a similar electronic demand) very small differences are observed between the two peracids.

Robertson and Swelin (9) visualize a homolytic pathway for O—O bond cleavage in the Criegee intermediate, derived from the reaction of peroxyacetic acid and benzophenones containing electron withdrawing groups. The normal Baeyer–Villiger products are produced by a 1,2 radical migration of one of the phenyl groups. A change in reaction mechanism, they assert, is responsible for the change in migratory apti-

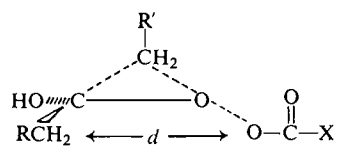
tudes of phenyl and *p*-nitrophenyl when peroxyacetic acid is used instead of PTFA. To our knowledge, alkyl migrations to radical centers are not known (10), and the absence of methyl migration in the *t*-butoxy radical argues against a radical pathway in our experiments. In addition, maleic acid is a much stronger acid than acetic acid (pK_a = 1.83 *vs.* 4.75, respectively, in water) (11) and a better leaving group from the Criegee intermediate.

We are well aware of the dangers of trying to present mechanistic conclusions based upon small differences in relative rate constants. With this in mind, we would like to comment on some of our more surprising data: in the reaction with methyl ketones, there is a pronounced decrease in the selectivity of PMA as the bulk of the alkyl groups increases. PMA is about fourfold more selective than PTFA in reaction with 2-butanone, three times as selective in the homologous 2-alkanones, and, in neopentyl methyl ketone, the selectivity drops to 20%. This suggests that PTFA, which carries out this Baeyer–Villiger reaction 50 times faster than PMA (as estimated from half-times for reaction), is more sensitive to steric effects.

This trend abates in the ethyl ketones where the two peroxyacids show very similar selectivity toward ethyl/alkyl migration. In one case, however, PTFA, is the more selective peroxyacid. It shows 11% increased selectivity over PMA in the oxidation of neopentyl ethyl ketone.

Likely sources of diminished steric sensitivity of PMA may be visualized in the drawing below. The assumption of *anti*-periplanar migration implies that the leaving group is in the staggered conformation with respect to the non-migrating group and the hydroxyl, which eventually becomes the ester carbonyl. Migration takes place with relief of steric interaction between the non-migrating and leaving groups.



A source of the smaller steric requirement for migration, when maleic acid is the leaving group, might be a later transition state in that reaction and hence a greater distance *d* between these groups. Another source, which is tempting to invoke, particularly in methylene chloride solution, involves specific hydrogen bonding requirements, for the second carboxyl function in PMA, which render the leaving group rigid and sterically remote from the non-migrating group. We have no specific evidence on either point. We have carried out a few experiments with trichloroperoxyacetic acid, which has a bulkier X group, but these reactions are not as clean as those with PMA and PTFA.

PMA asserts its more selective nature in the oxidation of 1-phenyl-2-butanone, suggesting that there is an electronic component to benzyl migration in the Baeyer–Villiger reaction. The electronic contribution to benzyl migration here, however, can be estimated to be less than 1 kcal per mol. If we assume the benzyl function to be approximately isosteric with the isobutyl group,[1] less than a factor of four need be explained by the ability of benzyl to stabilize a positive charge in the transition state for migration.

Experimental

Materials

All ketones, with the exception of 5,5-dimethyl-3-hexanone, were obtained commercially. All esters, excluding ethyl decanoate (K and K laboratories) and ethyl acetate (Fisher Scientific Co.), were prepared by standard methods. In each case, the compound was checked on a Varian T-60 n.m.r. spectrometer and a Perkin-Elmer 337 grating i.r. spectrophotometer. Purification was effected by careful distillation through a 10 in. Vigreux column or through a Nester–Faust spinning band column, depending on the nature of the impurities. Before use, each compound was assayed by gas chromatography using a Varian Aerograph Model 1440-2 gas chromatograph equipped with a flame ionization detector. No compound was used unless shown to be greater than 99% pure on two of the following columns: (1) 11 ft. × 1/8 in. 10% Carbowax 4000 on Chromasorb P 80/100 mesh; (2) 10 ft. × 1/8 in. 10% diethylene glycol succinate on Chromasorb W 100/120 mesh; (3) 150 ft × 0.02 in. capillary with SE-30 coating.

Hydrogen peroxide (98%) (FMC corporation) was standardized by permanganate titration. Trifluoroacetic anhydride (Eastman or Baker) and maleic anhydride (Fisher Scientific Co.) were used without further purification.

5,5-Dimethyl-3-hexanone

Dry, finely powdered cadmium chloride (16.5 g, 0.09 mol) was added to an ice-cold solution of ethyl magnesium bromide (0.18 mol) in 65 ml of dry ether.

[1]Benzyl is more closely isosteric with isoamyl. If benzyl is larger than isobutyl in the region of interest, the electronic enhancement of benzyl migration is even smaller than this value (Keith Yates, private communication).

TABLE 3. N.m.r. assay of methyl ketones[a]

Mixture	% methyl ester	Slope[b] (M)	Intercept[b] (C)	Correlation coefficient

[a]Measured by peak weights.
[b]Known composition = M (measured composition) + C.
[c]Percent ethyl ester.

The suspension was stirred at room temperature for 40 min before being cooled again to 5°. To this cold reaction mixture, 10 ml (0.106 mol) of *t*-butyl acetyl chloride in 30 ml of dry ether was added slowly, after which the mixture was refluxed with stirring for 90 min. Cooled to room temperature, the final product mixture was poured onto ice, leading to the formation of a white precipitate. Concentrated sulfuric acid was added dropwise until this precipitate just dissolved. The ethereal layer was separated, washed with successive portions of water, 10% sodium carbonate, and water, and then dried over magnesium sulfate. Distillation through a 10 in. Vigreux column gave the ketone (10.1 g or 79%), b.p. 136°.

Trifluoroperoxyacetic Acid

The peracid solution (*ca.* 1 *M*) was prepared fresh for each oxidation reaction. Trifluoroacetic anhydride (6.1 g, 0.029 mol) in methylene chloride was carefully added to 98% hydrogen peroxide (0.87 g, 0.025 mol) in 15 ml of methylene chloride at 0°. Once the addition was completed, the reactants were periodically agitated until a homogenous solution was observed. The solution was then diluted to 25 ml at room temperature and a 1 ml aliquot titrated iodometrically.

Peroxymaleic Acid

Maleic anhydride (2.45 g, 0.025 mol) was added to a suspension of 98% hydrogen peroxide (0.73 g, 0.021 mol) in 10 ml of methylene chloride at room temperature. Once the anhydride had dissolved, the methylene chloride was brought to reflux and maintained there for 30 min. The peroxymaleic acid solution thus formed was cooled and used directly in the oxidation reaction. This procedure was found to be superior to all other methods for producing this peracid.

Oxidations with Trifluoroperoxyacetic Acid

One procedure was found to give smooth, facile oxidation of all the ketones studied. The peracid solution (10 ml, *ca.* 0.010 mol) was added slowly from a pressure-equalizing dropping funnel to a mechanically stirred suspension of disodium hydrogen phosphate (4.25 g, 0.030 mol, previously dried over phosphorus pentoxide) in a solution of the ketone (*ca.* 0.005 mol) in 10 ml of methylene chloride, maintained at 23° ± 1°. Vigorous stirring was continued for 90 min to insure complete reaction. The reaction was quenched with water and the organic phase washed twice with water. The aqueous layers were combined and back-washed with 30 ml of methylene chloride. The combined organic layers were dried over magnesium sulfate and the solvent removed under reduced pressure. The reaction products were dissolved in carbon disulfide or carbon tetrachloride to be assayed by n.m.r., as described below.

Oxidations with Peroxymaleic Acid

To the entire solution of peroxymaleic acid (*ca.* 0.025 mol), prepared as above and maintained at 23° ± 1°, was added a solution of the ketone (*ca.* 0.005 mol) in 10 ml of methylene chloride. The contents of the reaction flask were stirred vigorously for 48 h after which they were mixed with 30 ml of water. This was enough to dissolve the white precipitate of maleic acid formed during the oxidation. The organic layer was separated, washed three times with 25 ml portions of phosphate buffer (0.5 *M*, p*H* 6.5) and once with a further 30 ml portion of water, dried over magnesium sulfate, and the solvent evaporated under reduced pressure. The reaction products were taken up in carbon disulfide or carbon tetrachloride before being assayed by n.m.r.

N.m.r. Analysis of Ester Mixtures

This assay was used for the product mixtures from oxidation of all the methyl ketones and of 5-methyl-3-hexanone, 5,5-dimethyl-3-hexanone, and phenyl-2-butanone. In every case, the two well-resolved signals, corresponding to the groups *alpha* to the ester oxygen in each of the two products, were scanned on a Varian T-60 n.m.r. spectrometer using a sweep width of 100 Hz and a sweep time of 50 s. The smaller of the two signals was then scanned 5 to 10 times at each of two increased amplitudes. Each scan was retraced several times to insure the reproducibility of the instrument and the phase was always carefully adjusted to make the base line of the peaks as straight as possible. The filter dial was always set at 2 so that, at the sweep width used, the peaks were smooth as well as broad. The areas under the peaks (in Xerox copies of these spectra) were then carefully cut out, weighed, corrected to the same amplitude, and the weight contribution, made by one hydrogen to each ester signal, calculated.

In the case of the products from 5-methyl-3-hexanone and 5,5-dimethyl-3-hexanone, similar spectra were run on a Varian HA 100 as well. Here the relative concentrations of the two esters were such that the signals could be compared at one amplitude.

The procedure was calibrated by subjecting series of known mixtures of esters to the same assay. For each series examined, plots were made of the known com-

positions versus the measured values. Slopes, intercepts, and correlation coefficients are collected in Table 3.

Mass Spectrometric Analysis of Ester Mixtures

This method was used for the product mixtures from the reaction of all ketones of the type $RCH_2CH_2\overset{O}{\overset{\|}{C}}CH_2CH_3$. All spectra were run on neat samples, using a Bell and Howell mass spectrometer model 21-490, at 70 eV and source temperature of 100° ± 10°. Four traces were collected for each sample. The m/e 75/88 values obtained for known mixtures were plotted against the alkyl/ethyl ester ratio as indicated in Table 4. Baeyer–Villiger product ratios were determined from their m/e 75/88 values by interpolation on these plots.

We wish to thank the National Research Council of Canada for financial support. Miss Stoute wishes in addition to thank the P.E.O. Sisterhood for a fellowship.

The Crystal and Molecular Structure of the Adduct Formed by the Reaction of Tributylphosphine and *p*-Chlorobenzylidenemalononitrile

GEORGE FERGUSON, COLIN ALAN FYFE, AND WAYNE CLIFFORD MARSH
Department of Chemistry, University of Guelph, Guelph, Ontario N1G 2W1

Received February 19, 1973

Crystals of the 1:1 adduct of tributylphosphine with *p*-chlorobenzylidenemalononitrile are monoclinic, $a = 13.719(2)$, $b = 12.557(5)$, $c = 14.229(3)$ Å, $\beta = 110.59(2)°$, $Z = 4$, space group $P2_1/c$. The structure was determined with diffractometer data by direct methods and refined by block-diagonal least-squares calculations to $R = 0.10$ for 1405 observed reflections. The structure is zwitterionic with the positive charge localized on the phosphorus atom and the negative charge mainly on the terminal $—C(CN)_2$ group.

Les cristaux de l'adduit 1:1 de la tributylphosphine avec le *p*-chlorobenzylidenemalononitrile sont monocliniques avec $a = 13.719(2)$, $b = 12.557(5)$, $c = 14.229(3)$ Å, $\beta = 110.59(2)°$, $Z = 4$, le groupe spatial est $P2_1/c$. La structure a été déterminée à partir des données du diffractomètre par les méthodes directes et les moindres carrés après raffinement juisqu'à un $R = 0.10$ pour 1405 réflexions observées. La structure est zwittérionique avec la charge positive localisée sur l'atome de phosphore et la charge négative principalement sur le groupe $—C(CN)_2$ terminal. [Traduit par le journal]

All the reactions involving the interaction of nucleophiles with electronegatively substituted alkenes can be rationalized in terms of an initial attack of the nucleophile on the β-carbon atom of the alkene to form the intermediate (**1**), whose further reaction can give rise to a variety of products depending on the conditions (eq. 1;

[1] $N^- + \text{X-substituted alkene} \rightleftharpoons \text{N-substituted intermediate} \longrightarrow \text{products}$

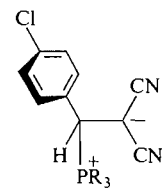
1

X is an electronegative sustituent) (1). The existence of species of type **1** has been verified in the case of substituted stilbenes for charged nucleophiles (2–4).

When the nucleophile is uncharged, a special case of eq. 1 arises and a zwitterion should be formed, eq. 2. One case where an adduct of 1:1

[2] $N + \text{X-substituted alkene} \rightleftharpoons \text{N}^+\text{-substituted intermediate}$

stoichiometry has been experimentally observed in such an attack by a neutral nucleophile is the interaction of tributylphosphines with benzylidenemalononitriles (5). Horner and Klupfel (5) originally formulated the structure as the zwitterion (**2**). Since then, several other possible structures have been considered (6, 7).



2

A recent n.m.r. investigation (7) has concluded that the zwitterionic structure (**2**) was correct. Because of the direct relevance of these compounds to the theory of nucleophilic alkene substitution reactions, the structure analysis of the 1:1 adduct of tributylphosphine with *p*-chlorobenzylidenemalononitrile was undertaken in an attempt to confirm the results of the n.m.r. investigation.

Experimental

The adduct crystallized from dioxan as yellowish irregular fragments. A small crystal was mounted and sealed in a thin-walled capillary (when left in the open the crystals showed evidence of decomposition and of being hydroscopic). Unit-cell and space group data were obtained from various rotation, Weissenberg, and precession photographs; accurate cell parameters were obtained by a least-squares procedure applied to the setting angles of 12 general reflections measured on a diffractometer.

Crystal Data

$C_{22}H_{32}ClN_2P$ (mol. wt. 390.9): monoclinic, $a =$

‡The estimated standard deviations in thermal parameters U lie in the range 0.002–0.014 Å^2.

13.719(2), b = 12.557(5), c = 14.229(3) Å, β = 110.59(2)°,[1] U = 2295 Å^3, Z = 4, D_c = 1.13 g cm^{-3}, $F(000)$ = 840. Cu K_α = 1.5418 Å, μ(Cu K_α) = 21 cm^{-1}. Space group $P2_1/c$ (C_{2h}^5) from systematic absences: $h0l$ when l is odd, $0k0$ when k is odd.

The intensities of all reflections with 2θ(Cu K_α) < 114° (minimum interplanar spacing 0.92 Å) were measured on a PDP 8-I controlled Hilger and Watts Y290 four-circle diffractometer, with a scintillation counter, approximately monochromatic Cu K_α radiation (nickel filter and pulse-height analyzer), and a θ/2θ step scan of 80 steps of 0.01° each. Background counts of 20 s were made at the beginning and end of each scan. No absorption corrections were applied. The crystal decomposed slowly in the X-ray beam as measured by the falloff of counts from standard reflections throughout the course of the data collection. The crystal did not appear to have moved from its original mounting, as going through the crystal alignment process after data collection yielded the same orientation parameters for the standard reflections as had been obtained initially. Allowance for the crystal decomposition was made by scaling the intensity data by means of the counts from the standard reflections. Lorentz and polarization factors were applied, and the structure factors were derived in the usual way. Reflections which had a net count of less than 3σ above background, where σ(I) is defined by $\sigma^2(I) = S + B + (0.05\,S)^2$ and S and B are the scan and background counts respectively, were taken as being unobserved. These reflections were assigned structure factors equal to the measured values but were excluded from the refinement. Of the 2764 possible reflections with 2θ < 114°, 1405 (51%) were classified as observed.

[1]Throughout this paper the estimated standard deviations are given in parentheses and refer to the last significant figure.

Structure Analysis

The data were placed on an absolute scale by Wilson's method (8), and normalized structure amplitudes E were derived. The 411 E's greater than 1.5 were used in the structure determination utilizing the PHASE (9) link of the X-ray 72 system. Initially the 100 largest E's were phased and these were then used to phase the remaining 311 E's greater than 1.5. An E map based on the 411 phased E's revealed the positions of 22 of the 26 non-hydrogen atoms, the missing atoms being in the n-butyl groups. A difference Fourier synthesis at this stage revealed the positions of the four missing atoms.

The structure was refined by block-diagonal least-squares methods, with the scattering curves of ref. 10, the function minimized being $\omega(|F_o| - |F_c|)^2$ with final weights, $\omega = 0$ for the unobserved reflections and $\omega = 1$ for $F_o < F^*$, and F^*/F_o for $F_o \geq F^*$. A value of 12.0 for F^* was found to be suitable from an analysis of $\omega(|F_o| - |F_c|)^2$ over ranges of $|F_o|$. Four cycles of refinement with isotropic temperature factors reduced R to 0.16. Six further cycles with all atoms allowed to vibrate anisotropically gave a final R of 0.10 for the 1405 observed data, and

$$Rw = [\Sigma\omega(F_o - F_c)^2/\Sigma\omega F_o^2]^{1/2} = 0.11$$

The maximum ratio of shift to e.s.d. on the final cycle was 0.5. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] A final difference synthesis showed maximum fluctuations of 0.7 eÅ^{-3}. Although a large number of peaks were in reasonable positions for hydrogen atoms, no attempt was made to include them in the analysis.

The positional and thermal parameters are listed in Table 1. Bond lengths and angles and their standard deviations are given in Table 2. Figure 1 is a stereoscopic view of the molecule produced by ORTEP (11). The molecular packing is shown in Fig. 2.

[2]A complete set of tabular data is available at a nominal charge from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

Discussion

The crystal structure (Fig. 2) contains discrete molecules. The two shortest contacts both involve the terminal N atoms of the cyano groups. Atom N(1) is only 3.34(2) Å from a neighboring C(7) atom (related by $-x, 1-y, -z$). Atom N(2) is 3.29(1) Å distant from an adjacent Cl atom (related by $1-x, \frac{1}{2}+y, \frac{1}{2}-z$). These and all other intermolecular distances correspond to, or are greater than, van der Waals contacts.

The molecular structure is shown in Fig. 1 and geometry details are in Table 2. Carbon (7) is clearly in a tetrahedral configuration (the bond angles at C(7) are between 108 and 114°); the C(7)—P bond is the same length as the P—C-

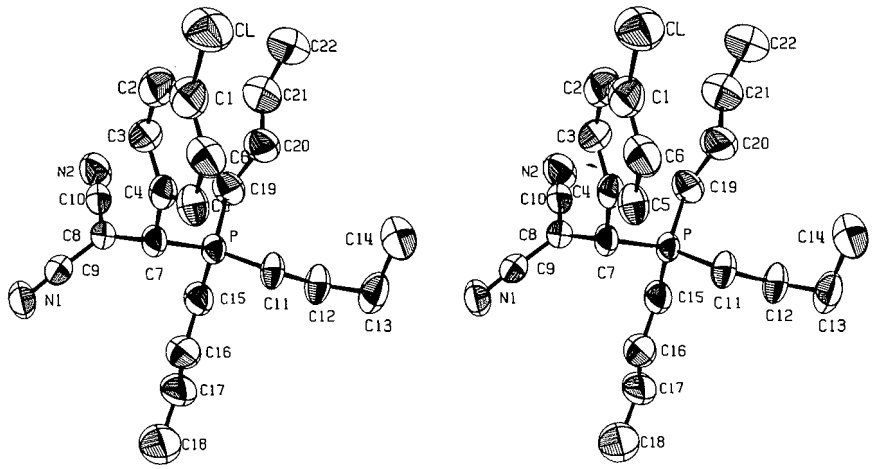

FIG. 1. Stereo view of the structure of the adduct, produced by ORTEP (11).

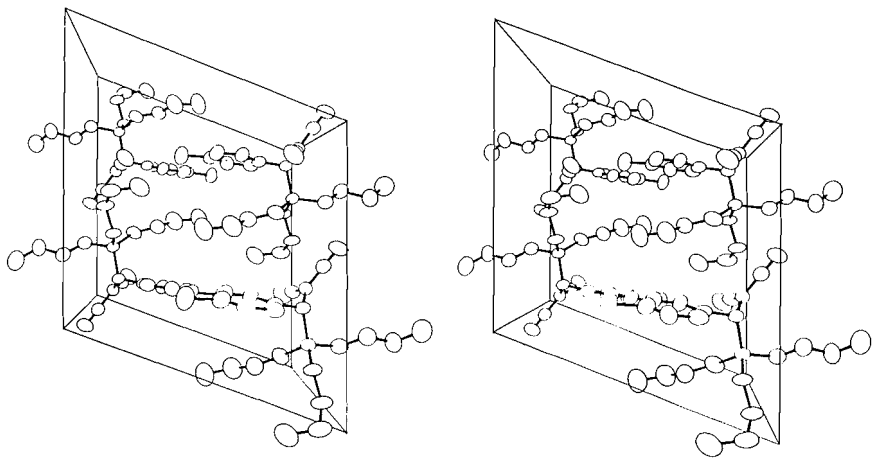

FIG. 2. Stereo view of the four molecules in the unit cell. The origin of the cell is at the lower left corner with $a \rightarrow$, $c \uparrow$, and b vertical.

(butyl) bonds; the coordination around the phosphorus is tetrahedral, and the configuration at C(8), the atom to which the cyano groups are bonded, is planar, implying sp^2 hybridization at C(8).

All the above features establish formulation (**2**) as the correct one with the positive charge localized on the phosphorus and the negative charge on the terminal $C(CN)_2$ group. The bond lengths found for the structure are not significantly different from expected values (12); the relatively high standard deviations obtaining from crystal decomposition preclude any really detailed discussion of fine structure. Mean molecular dimensions include P^+—$C(sp^3)$ 1.824(14), Csp^2—Csp^3 1.53(2), Csp^3—Csp^3 1.54(2), Csp^2—C(N) 1.40(1), and C≡N 1.15(1) Å.

The results presented thus substantiate fully the conclusions of the n.m.r. investigation, and it is considered that the characterization of the intermediate which ensues makes it suitable as a model for substitution reactions of this type. Further investigations using complete n.m.r. line shape analysis and stopped flow kinetics are currently in progress.

We are grateful to the National Research Council of Canada for operating grants A5975 (to G.F.) and A5876 (to C.A.F.) and for a computing grant C0357 (to G.F.).

We thank Dr. David F. Rendle for producing the ORTEP diagrams and assistance with the calculations.

Some Cobalt(II) Complexes in Non-aqueous Systems

K. E. JOHNSON AND J. L. MEYER

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan S4S 0A2

Received November 22, 1972

By following the variation of absorptivity and energy of the principal electronic transitions with addition of ligand it is shown that $CoCl_2$ gives rise to $CoCl_4^{2-}$ in γ-butyrolactone and $Co(NO_3)_2$ gives rise to dodecahedral $Co(NO_3)_4^{2-}$ in γ-butyrolactone, propylene carbonate, and acetone.

En suivant la variation de l'absorption et de l'énergie des transitions électroniques principales par addition de ligand, on a montré que le $CoCl_2$ conduit à $CoCl_4^{2-}$ dans la γ-butyrolactone et $Co(NO_3)_2$ au $Co(NO_3)_4^{2-}$ dodécahedral dans la γ-butyrolactone, le carbonate de propylène et l'acétone.

The interaction of simple salts with excess of ligand to form complexes is confused in several systems by the solvent's ability to complex appreciably with the metal ion. Thus, $[Co(H_2O)_6]^{2+}$ is the species produced by aqueous solution of several Co(II) salts. We have noted in previous work (1) that $Co(NO_3)_2$ dissolved in a molten alkali nitrate to give dodecahedral $[Co(NO_3)_4]^{2-}$ (2) and in dimethyl sulfone to give a dodecahedral species with apparently half the molar absorptivity of $[Co(NO_3)_4]^{2-}$ which reverted to $[Co(NO_3)_4]^{2-}$ on the addition of excess alkali nitrate. $Co(ClO_4)_2$ in dimethyl sulfone gave an octahedral Co(II) species with a spectrum very similar to that of $CoSO_4$ in 98% H_2SO_4 (3); addition of alkali nitrate to this dimethyl sulfone solution converted the Co(II) to $[Co(NO_3)_4]^{2-}$. It is well known that $CoCl_2$ in molten chlorides (4) and even in concentrated HCl exists as the tetrahedral $CoCl_4^{2-}$.

It is the purpose of this article to show that dodecahedral $[Co(NO_3)_4]^{2-}$ is readily produced in γ-butyrolactone, propylene carbonate, and acetone and that tetrahedral $CoCl_4^{2-}$ is obtained in γ-butyrolactone.

Experimental

Reagent-grade (99%) γ-butyrolactone, propylene carbonate, and acetone were used as supplied, lithium nitrate and lithium chloride were oven-dried at 150 °C, cobalt chloride dehydrated (5), cobalt nitrate prepared according to Addison and Logan (6), and cobalt nitrate trihydrate by heating the hexahydrate for 12 h at 90 °C. Spectra were recorded with a Beckman DK-2A spectrophotometer.

Results and Discussion

The spectrum of $CoCl_2$ in γ-butyrolactone with varying molar ratios of lithium chloride (n) showed two main peaks and a shoulder at 15 kK for $n > 2$. The shoulder became more pronounced at $n = 3$ but stayed constant in intensity at $n > 3$. If the molar absorptivity and peak energy are plotted as a function of n (Fig. 1), distinct changes of slope occur at $n = 2$. It appears that by $n = 2$ $CoCl_4^{2-}$ is the dominant cobalt species in solution. Furthermore, the intensity of the strongest peak varies roughly

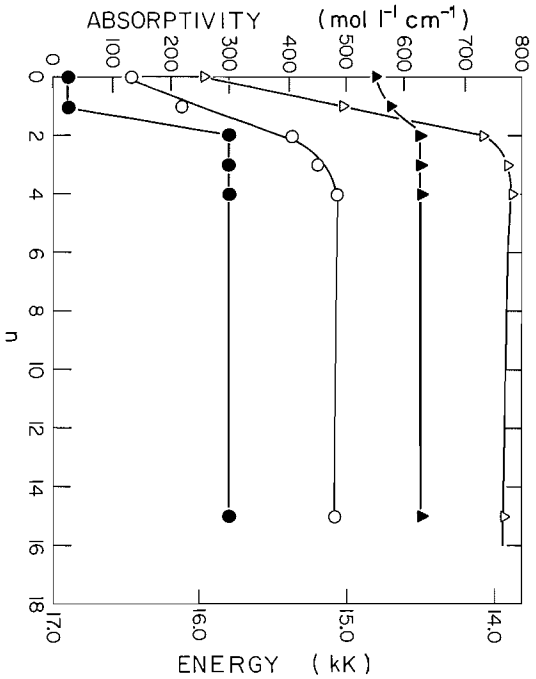

FIG. 1. Spectral maxima of $CoCl_2 + n$LiCl in γ-butyrolactone: △ absorptivity and ▲ energy of lower energy band *vs.* n; ○ absorptivity and ● energy of higher energy band *vs.* n; $CoCl_2$ concentration range 2.4–6.4 × 10^{-3} M.

as 1:2:3 for $n = 0$, 1, 2, suggesting that 1/3, 2/3, and 3/3 of the added $CoCl_2$ is converted to tetrahedral $CoCl_4^{2-}$ at these respective stages, the remainder being octahedrally bound as $CoCl(solvent)_5^+$ and therefore weakly absorbing. The alternative explanation that tetrahedral $CoCl_2(solvent)_2$, $CoCl_3(solvent)^-$, and $CoCl_4^{2-}$ are successively formed and that their absorptivities are in the ratio 1:2:3 is much less likely.

The spectra of $Co(NO_3)_2 + nLiNO_3$ solutions in γ-butyrolactone, propylene carbonate, and acetone were identical to those obtained from $Co(NO_3)_2 \cdot 3H_2O + nLiNO_3$. They all contain a band close to 19 kK with a molar absorptivity, in terms of added Co(II), ranging from 45–60 at $n = 0$ to 80–120 at $n = 9$. The plots (Fig. 2) of absorptivity *vs.* n are somewhat more curved than for the chloride with breaks at $n = 1$–2. The peak energy curves all drop from one energy at $n = 0$ to a virtually constant value for $n > 1$. In addition to the main band a broad absorption was noted for the propylene carbonate and acetone solutions with $\nu_{max} = 8.5$ and 8.8 kK, respectively, the $\varepsilon_{max} = 10$ and 8, respectively. This band shifted to higher energies as n increased and ε_{max} doubled over the range $n = 0$ to $n = 9$.

All the nitrate solution spectra compare closely with those of $Co(NO_3)_4^{2-}$ mentioned above. What is more the ratio of the final to initial absorptivities of approximately 2:1 suggests that we start with half the added cobalt dodecahedrally coordinated by nitrate and half of it coordinated, presumably octahedrally, by solvent molecules. The greater curvature of the nitrate plots is in accord with the lesser stability of the nitrate *vs.* the tetrahedral chloride complex, *i.e.* a large excess of nitrate is required to drive the formation of $Co(NO_3)_4^{2-}$ to completion. The intermediate formation of mixed nitrate–solvent complexes is also consistent with the data.

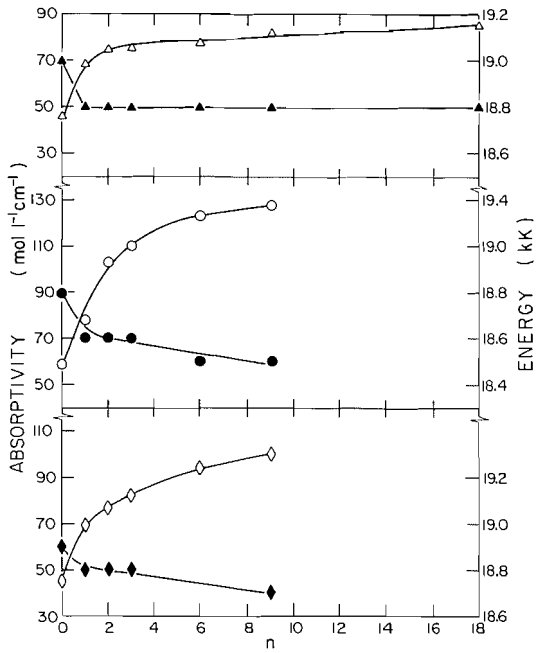

FIG. 2. Absorptivity (open points) and energy (closed points) of principal band of $Co(NO_3)_2 + nLiNO_3$ *vs.* n for butyrolactone (squares), propylene carbonate (circles), and acetone (triangles). $Co(NO_3)_2$ concentration ranges 1.3–17 × 10^{-2} M (butyrolactone), 0.9–1.0 × 10^{-2} M (propylene carbonate), and 1 × 10^{-2} M (acetone).

Effect of Dose on the Yield of Trapped Electrons in Aliphatic Amine Glasses

TOSHIYASU ITO, SHOJI NODA, KENJI FUEKI, AND ZEN-ICHIRO KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received January 29, 1973

An electron spin resonance (e.s.r.) and photoconductivity study has been made of the effect of dose on the yield of trapped electrons in γ-irradiated aliphatic amine glasses at 77 °K. It is shown that the effect of dose on the trapped electron yield can be correlated with matrix polarity.

Une étude par r.p.e. et photoconductivité a été effectuée sur l'effet de la dose sur le rendement en électrons piégés dans des verres d'amine aliphatique γ-irradiés à 77 °K. Une corrélation entre l'effet de la dose sur le rendement en électrons piégés et la polarité de la matrice a été ainsi établie.

Introduction

In a previous paper (1) we have reported the electron spin resonance (e.s.r.) and optical absorption characteristics of trapped electrons produced in γ-irradiated aliphatic amine glasses at 77 °K, demonstrating that there is a correlation between such spectroscopic characteristics and matrix polarity. Recently we have also made an optical bleaching study of trapped electrons in the same amine glasses (2), showing that there are bound excited states for trapped electrons in these matrices.

In this note we report the effect of dose on the yield of trapped electrons in aliphatic amine glasses at 77 °K, as studied by both e.s.r. and photoconductivity measurements. It is shown that the effect of dose on the trapped electron yield can be correlated with matrix polarity for a variety of matrices including the amines.

Experimental

Aliphatic amines (2-methyl-*n*-amylamine, diisopropylamine, and triethylamine) were purified as previously described (2). E.s.r. measurements were carried out on trapped electrons with a conventional X-band spectrometer using 100 kc.p.s. magnetic field modulation. In some experiments at high doses, optical absorption measurements were made on trapped electrons.

The photoconductivity cell was made from quartz and had a cylindrical shape with a diameter of 20 mm. Thin stainless steel mesh was used as electrodes. The spacing between the electrodes was 1 mm and their diameter was 10 mm. The electrodes were 3 mm from the cell window. The sample was distilled into the cell from a storage bulb on a vacuum line and was thoroughly degassed prior to γ-irradiation. In photoconductivity experiments on the γ-irradiated samples the light beam was directed through the semi-transparent electrodes. The light source was a Toshiba 500 W i.r. lamp. A Toshiba VR-68 filter was used to cut off light below about 680 nm. A d.c. electric field was 1.8 kV cm^{-1}. The photocurrent was amplified by a Kawaguchi Electric Works NA-16E electrometer and the output from the electrometer was recorded on a Toa Electronics EPR-2T recorder.

Results and Discussion

The experimental results are given in Figs.1–3, in which both the trapped electron concentration and the initial photocurrent are presented as a function of dose. Figure 1 shows the results for triethylamine. It can be seen from Fig. 1 that with increasing dose the concentration of trapped electrons increases initially, reaches a maximum and then decreases down to nearly zero. The photocurrent intensity behaves exactly in the same manner with dose. The curve of photocurrent *vs.* dose can be superimposed on that of trapped electron concentration *vs.* dose on a normalized scale. The agreement

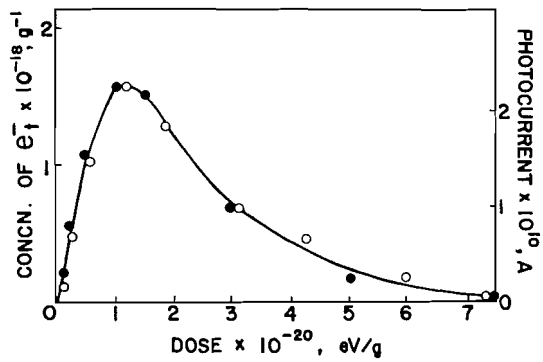

FIG. 1. Dose dependence of trapped electron concentration and of photocurrent for triethylamine at 77 °K: ○, trapped electron concentration; ●, photocurrent.

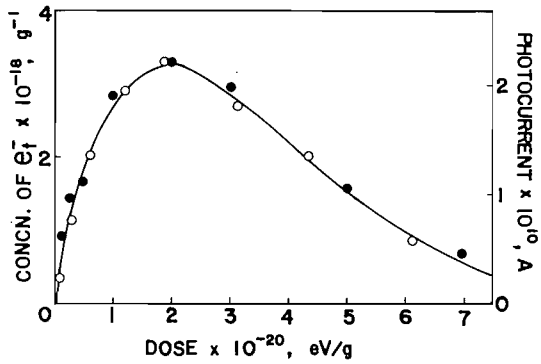

FIG. 2. Dose dependence of trapped electron concentration and of photocurrent for diisopropylamine at 77 °K: ○, trapped electron concentration; ●, photocurrent.

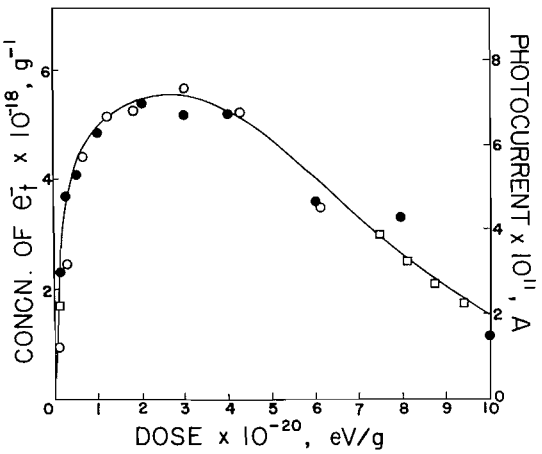

FIG. 3. Dose dependence of trapped electron concentration and of photocurrent for 2-methyl-*n*-amylamine at 77 °K: ○, trapped electron concentration (e.s.r.); □, trapped electron concentration (optical); ●, photocurrent.

between the two types of dose-dependence curves indicates that the photo-induced charge carriers are probably electrons. The maximum concentration of trapped electrons is $1.6 \times 10^{18}\ g^{-1}$ and the maximum photocurrent is 2.3×10^{-10} A. The dose at which the concentration of trapped electrons is maximum is 2.0 Mrad.

Figure 2 shows the results for diisopropylamine. The dose dependence of the trapped electron concentration and of the photocurrent is similar to that observed for the triethylamine. The maximum concentration of trapped electrons is $3.2 \times 10^{18}\ g^{-1}$ and the maximum photocurrent is 2.2×10^{-10} A at a dose of 3.1 Mrad.

Figure 3 shows the results for 2-methyl-*n*-amylamine. Again the dose dependence of the trapped electron concentration and of the photocurrent is similar to those observed for the triethylamine and the diisopropylamine. The maximum concentration of trapped electrons and the maximum photocurrent are $5.7 \times 10^{18}\ g^{-1}$ and 6.8×10^{-11} A, respectively, at a dose of about 4.8 Mrad. Since the e.s.r. spectrum of trapped electrons in 2-methyl-*n*-amylamine glass was broad (1), it was difficult to measure reliably the e.s.r. spectral intensity of trapped electrons at high doses where the trapped electron signal was partially masked by the radical spectrum. In these cases, the relative concentration of trapped electrons was measured by the optical absorption method and it was normalized to fit the dose–yield curve at a low dose.

The maximum concentration of trapped electrons and the dose yielding such a maximum are both in decreasing order for 2-methyl-*n*-amylamine, diisopropylamine, and triethylamine. This is in the order of decreasing matrix polarity, since the magnitude of permanent dipole moment of the matrix molecule is ~1.1 D for 2-methyl-*n*-amylamine, ~0.85 D for diisopropylamine, and 0.66 D for triethylamine. It is expected that the more polar the matrix, the higher is the yield of trapped electrons because stronger electron–solvent dipole interactions in the more polar matrix would make electron localization occur more efficiently in the matrix. It should be noted, however, that the more polar the matrix, the smaller is the maximum photocurrent. If it is assumed that the probability of optical transitions to the conduction band is about the same for trapped electrons in the three amines, the photocurrent should be proportional to the product of the trapped electron concentration, the electron mobility, μ, and the average lifetime, τ, of an electron in the conduction band in these amines. Using the observed values of the photocurrent and the trapped electron concentration, we can inversely estimate the relative magnitudes of $\mu\tau$ in these amines; $\mu\tau$(2-methyl-*n*-amylamine):$\mu\tau$(diisopropylamine):$\mu\tau$(triethylamine) = 1:6:12. We see that $\mu\tau$ decreases with increasing matrix polarity. This trend may be interpreted in terms of the charge transport mechanism in which mobile electrons are temporarily trapped in the matrix (3); and the

transient trapping time is presumably longer in the more polar matrix, making the electron mobility lower. Also, the permanent electron-trapping efficiency is expected to be higher in the more polar matrix, giving smaller τ.

We now consider the cause of decrease in trapped electron yield with increasing dose. This decrease arises probably from the reaction of mobile and trapped electrons with radiation-produced radicals and/or positive holes (4). The correlation between matrix polarity and the dose yielding the maximum concentration of trapped electrons suggests that the positive holes, which can migrate through the matrix, play a role in decreasing the trapped electron yield, since it is known that positive holes migrate through non-polar matrices such as hydrocarbon glasses while they are immediately trapped in polar matrices such as alcohol glasses (5). Also, it is conceivable that dielectron formation may play a part for the decrease in trapped electron yield at high doses. Experimental evidence has been reported for the existence of dielectrons trapped in polar liquids and solids (6–9). A recent theoretical study also indicates that the trapped dielectron is energetically stable relative to two single trapped electrons, suggesting the possible existence of dielectrons in polar matrices (10).

The correlation between matrix polarity and the dose yielding the maximum concentration of trapped electrons found for the amines can be observed more generally for a variety of matrices. Table 1 summarizes the relevant data available at present with remarks on the method of measurement: e.s.r., optical absorption, and photoconductivity. Table 1 includes various matrices covering a wide range of matrix polarity: alkaline ice (10 *M* NaOH), alcohols, ether, amines, and hydrocarbons. In Table 1 are also given the gas-phase values of permanent dipole moment, μ_d, of the matrix molecules and the static dielectric constants, ε_s, of the matrix compounds at room temperature. Matrix polarity is approximately in decreasing order from the top to the bottom. These data lend further support for the arguments put forward above.

Proton Transfer Reactions of Carbon Acids. III. Effect of Solvent Change on the Equilibrium and Kinetic Parameters of the Reaction of Di-(4-nitrophenyl)methane with Alkoxide Bases

JAE-HANG KIM[1] AND KENNETH T. LEFFEK

Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received March 22, 1973

The equilibrium constants, the second-order rate constants, and the activation parameters have been determined for the proton transfer from di-(4-nitrophenyl)methane to ethoxide ion in a series of mixed solvents containing various amounts of acetonitrile in ethanol. The quantities have been interpreted in terms of the general postulates of the Miller–Parker theory of solvation effects.

On a déterminé les constantes d'équilibre, les constantes de vitesse du second ordre ainsi que les paramètres d'activation pour le transfert d'un proton du di-(nitro-4 phényl) méthane à l'ion éthoxyde dans plusieurs mélanges de solvants contenant des quantités variables d'acétonitrile dans l'éthanol. Les données obtenues furent interprétées en fonction des postulats de la théorie de Miller–Parker traitant des effets de solvatation. [Traduit par le journal]

Can. J. Chem., **51**, 2805 (1973)

Introduction

Several proton transfer reactions between substituted methanes and bases in organic solvents have been studied kinetically with respect to the determination of the activation parameters and isotope effects (1–6). In the previous paper in this series (6) the reaction of di-(4-nitrophenyl)methane with alkoxide bases in the corresponding alcohol solvents was investigated. The variation of the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ with alkoxide–alcohol identity was interpreted in terms of solvation effects during the activation process. This paper presents a study of the effect of changing the solvating characteristics of the alcohol solvents by the addition of certain percentages of an aprotic co-solvent, acetonitrile, on the equilibrium constants and kinetic parameters of the same reaction 1 with two alkoxides,

[1] $(NO_2C_6H_4)_2CH_2 + \bar{O}AlK \rightleftharpoons [(NO_2C_6H_4)_2CH]^- + HOAlk$

ethoxide and *t*-butoxide. However, since the largest changes in these parameters take place when the alcohol content of the solvent is low, this work is actually an investigation of the reaction in acetonitrile solvent containing various concentrations of alcohol.

The objective of the study is to ascertain whether the reaction parameters change in a manner consistent with the previous interpretation (6) and with solvent effect theory in general.

Results and Discussion

Equilibrium Measurements

Optical density measurements on equilibrium mixtures of substrate and alkoxide may be used to determine the molar absorptivity (ε) of the colored anion of the substrate and also the equilibrium constant K for the reaction. From

[1]Post-doctoral Fellow 1971–1972.

TABLE 1. Equilibrium constants (25 °C) for the reaction of di-(4-nitrophenyl)methane with alkoxide ions and the molar absorptivity of the methane anion

$C_2H_5O^-$/20% ethanol	145	8 700
$C_2H_5O^-$/80% ethanol	20	2 600*
$C_4H_9O^-$/50% *t*-butanol	17 200	22 200

*At 560 nm wavelength.

the equilibrium expression 2

$$[2] \quad \frac{K}{[\mathrm{AlkOH}]} = K' = \frac{[\mathrm{A}^-]}{[\mathrm{AlkO}^-]([\mathrm{AH}] - [\mathrm{A}^-])}$$

which applies to reaction 1 when the alkoxide is in large excess but of only moderate concentration, and in which AH is the substrate carbon acid and A^- its anion, eq. 3 may be derived.

$$[3] \quad [\mathrm{AH}]/(\mathrm{o.d.}) = 1/K'\varepsilon\,[\bar{\mathrm{O}}\mathrm{Alk}] + 1/\varepsilon$$

where o.d. is the optical density.

A plot of [AH]/(o.d.) *vs.* $1/[\bar{\mathrm{O}}\mathrm{Alk}]$ gives a good straight line for all the solvent systems recorded in Table 1. Both ε and K are subject to large random errors since ε is quite large and is the reciprocal of the intercept of the graph. The error in ε also appears in K as this is calculated from the slope of the graph ($1/K'\varepsilon$). Thus, the values for K and ε collated in Table 1 are probably no better than ±20%, but may be interpreted with due regard to these limits.

The position of the absorption peak of the substrate anion changes from 560 nm in 80% v/v ethanol in acetonitrile to 770 nm in 20% v/v (or less) ethanol in acetonitrile, which must correspond to a change in the solvation shell from alcohol to a mixture of alcohol and acetonitrile. Large solvent shifts are quite common for carbanions; we recently reported a 40 nm shift for the sodium salt of diethyl 2,4-dinitrophenylmalonate between DMSO and methanol (7) and Bowden and Stewart (8) found a shift of 120 nm for the anion of tri-(4-nitrophenyl)methane between ethanol and 40 mol % ethanol in DMSO, although the anion of di-(4-nitrophenyl)methane showed a shift of less than 20 nm for the same solvent pair.

The data in Table 1 show that increasing the alcohol content of the solvent decreases both the equilibrium constant and the molar absorptivity of the anion.

Both the alkoxide ion and the carbanion are undoubtedly preferentially solvated by the alcohol molecules, since acetonitrile is a poor anion solvator (9). Moreover, the alkoxide ion, being smaller with a more concentrated charge, is the more strongly solvated of the two anions by alcohol–anion hydrogen bonding. Thus, increase in alcohol content stabilizes the alkoxide ion to a greater extent than it stabilizes the carbanion and causes a reduction in the equilibrium constant. Miller and Parker (10) and Parker (11) have postulated that in dipolar aprotic solvents, the polarizability of the anion causes the solvation to be greater the larger the anion. This effect again predicts the results observed in Table 1 with the large methane anion most stabilized in the acetonitrile-rich solvents.

Kinetic Measurements

First-order rate constants were measured for the reaction of eq. 1, using a large excess of alkoxide base and a rate equation derived for the equilibrium condition (1). A least-squares computation was carried out for a plot of k_1 *vs.* alkoxide concentration for each temperature studied and the slopes, equal to the second-order rate constants for the reactions, were obtained. These first- and second-order rate constants are shown in Table 2. The activation parameters derived from the k_2 values are given in Table 3.

The second-order rate constants decrease as the alcohol content of the solvent is increased, but the enthalpy of activation also decreases, which is more than compensated by an increasingly negative entropy of activation.

The variation of the rate constants with solvent composition are as expected for this type

of reaction in which the negative change is dispersed over a larger molecular entity on going from the initial state to the transition state. In terms of Miller–Parker theory (11), the alcohol is a much better anion solvator than acetonitrile and solvation by alcohol is stronger the smaller the anion. Thus, the initial state alkoxide is stabilized to a greater extent than the transition state as the alcohol content is increased, and this produces a smaller k_2 the greater the alcohol content. It is seen from Table 2 that most of the change in k_2 takes place between the alcohol contents of 5 and 20%, which indicates that there is a marked preferential solvation by alcohol molecules.

Another way of wording the same explanation is to say that the alkoxide ion is a stronger proton abstractor in acetonitrile-rich solvents since it is less strongly solvated by acetonitrile, than it is by alcohol in alcohol-rich solvents, with which it forms hydrogen bonds.

While the above arguments account readily for the free energy changes (*i.e.* the relative rates), the enthalpies of activation change in the opposite direction, decreasing with increasing alcohol content of the solvent. Since the Parker theory accounts for the rate changes with solvent variation of a large number of reactions, it seems reasonable to accept its general premises and develop a solvation theory for proton transfer reactions within its framework, but which at the same time is consistent with the observed enthalpies and entropies of activation.

In the previous paper in this series (6) it was postulated that in the initial state solvation shell there was a large amount of solvent–solute interaction, alcohol hydrogen-bonded to the alkoxide ion, whereas the transition state solvation shell featured solvent–solvent interaction, resulting from the lack of charge concentration in the much larger transition state. Thus, with increased alcohol content the solvation of the initial state would be stronger in free energy terms but the enthalpy of activation would be decreased because of the effect of having more alcohol molecules surrounding the inner solvation shell. The energy required to break one alcohol–alkoxide hydrogen bond would be offset by the formation of a new alcohol–alcohol hydrogen bond. That is, it requires less

For personal use only.

energy to break out one alcohol molecule from the solvation shell if the solvent molecule intermediately adjacent to it in the next solvent layer is another alcohol molecule, rather than an acetonitrile molecule.

A direct consequence of the formation of more solvent–solvent hydrogen bonds as the transition state is formed is that more alcohol molecules are tied down in the transition state than in the initial state giving rise to larger negative entropies of activation with increasing alcohol content.

Experimental

The preparation of materials and measurement of the equilibrium constants were carried out as previously described (6).

All the kinetic measurements were made with a Durrum-Gibson stopped-flow spectrophotometer with a Kel-F flow system and an optical cell of 2 mm light-pathlength. The technique used was essentially that already given (6), except that stock solutions of alkoxide in solvents containing 20% alcohol or less were prepared by making a suspension of solid alkoxide in acetonitrile in a dry-box and then adding the appropriate quantity of alcohol. Recently, Chattopadhyay and Coetzee (12) have pointed out a potential source of error in the use of the Durrum stopped-flow spectrophotometer. At temperatures other than ambient, the solutions in the valve block section of the flow system are not in thermal equilibrium with the thermostated reservoir which contains the drive syringes. Thus, it is possible that the temperature of the reacting solution in the cuvette is not that of the reservoir if insufficient solution is driven through the system to transfer solution from the drive syringes to the cuvette. We believe our experimental technique avoided this source of error. Fluid from an external constant temperature bath was pumped with a heavy duty pump through the drive syringe reservoir and also through the observation cuvette housing. To measure a rate constant the drive syringes were filled and allowed to equilibrate to the reservoir temperature which remained constant to ± 0.03 °C. Two or three trial runs were made and observed on the oscilloscope in nonstorage mode. If these appeared satisfactory and reproducible, the oscilloscope was switched to the storage mode and between four and six runs were made in rapid succession and superimposed on the oscilloscope screen. These runs nearly always superimposed exactly giving one slightly broadened trace and were carried out within a total time of less than 1 min. Using this technique, the actual temperature of the solution in the cuvette must be very close to that of the reservoir. The first-order rate constants were generally obtained from oscilloscope traces covering the range 50–100% transmittance, using a computer program which converted the transmittance values to absorbance before calculation of the rate constants. Examples of kinetic runs have been given previously (6).

The Structure of Thiobinupharidine

J. T. WRÓBEL AND B. BOBESZKO
Department of Chemistry, University of Warsaw, Warsaw, Poland
AND
T. I. MARTIN, D. B. MACLEAN, N. KRISHNAMACHARI, AND C. CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario
Received March 21, 1973

The spectroscopic properties of thiobinupharidine and its isomer, neothiobinupharidine, of established structure, have been examined and compared. From this study it was possible to deduce the structure and relative configuration of the alkaloid. The structure has been firmly established and the absolute configuration determined by the study of the crystal structure of thiobinupharidine dihydrobromide dihydrate, $C_{30}H_{42}O_2N_2S \cdot 2HBr \cdot 2H_2O$. The crystals are orthorhombic with space group $C222_1$, a = 25.128(6), b = 9.869(2), c = 26.380(6) Å, and Z = 8. The structure was refined, using full-matrix least-squares techniques with 1934 reflections, to a final R value of 0.097. The thiobinupharidine moiety hydrogen bonds to one of two types of H_2O–Br–H_2O spiral chains in the structure. The tetrahydrothiophene ring is distorted from planarity, and this together with the nonequivalence of the S and C atoms in the ring causes the molecule to deviate from C_2 symmetry.

Les propriétés spectroscopiques de la thiobinupharidine et de son isomère néothiobinupharidine de structure établie, ont été examinées et comparées. De cette étude, il a été possible de déduire la structure et la configuration relative de l'alcaloide. La structure et la configuration absolue ont été déterminées de façon sûre par l'étude de la structure cristalline du dibromhydrate de la thiobinupharidine dihydratée $C_{30}H_{42}O_2N_2S \cdot 2HBr \cdot 2H_2O$. Les cristaux sont orthorhombiques de groupe spatial $C222_1$, a = 25.128(6), b = 9.869(2), c = 26.380(6) Å et Z = 8. La structure a été raffinée par la technique matricielle des moindres carrés avec 1934 réflexions jusqu'à une valeur finale pour R de 0.097. Le groupe thiobinupharidine est lié par pont hydrogène à l'un des deux types de chaînes spirales H_2O—Br—H_2O dans la structure. Le cycle tétrahydrothiophène est distordu par rapport au plan; ce fait, en plus de la non équivalence des atomes S et C du cycle, cause une déviation a la symétrie C_2 pour la molécule.

Can. J. Chem., **51**, 2810 (1973)

Thiobinupharidine ($C_{30}H_{42}N_2O_2S$, (**1**)) was first reported in 1962 by Achmatowicz and Bellen (1) who described the properties of the base and some of its salts. The molecular formula assigned to this alkaloid, over which there was originally some question, was confirmed a few years later by mass spectrometry (2). In the original paper it was noted that this alkaloid had twice the number of carbon, nitrogen, and oxygen atoms present in the *Nuphar* alkaloid, deoxynupharidine ($C_{15}H_{23}NO$, (**2**)) of established structure (3) and the authors anticipated that there would be structural similarities between the new sulfur-containing alkaloid and **2**. A number of structures were considered in which two molecules of **2** were joined, but the exact nature of the union between the two molecules was not established. In later papers (2, 4) it was concluded from spectroscopic and other data that two molecules of **2** were joined through a new sulfur-containing ring.

The second sulfur-containing alkaloid to be isolated from *Nuphar* species was an isomer of **1** designated neothiobinupharidine (**3**) (4). From an examination of the spectroscopic properties of **1** and **3** (2, 4) it was concluded that they were stereoisomers. The i.r. spectra of the two bases were very similar, their p.m.r. spectra were distinctly different (see below), but their mass spectra (m.s.) were virtually identical. The structure of **3** was elucidated through an *X*-ray analysis of neothiobinupharidine dihydrobromide tetrahydrate (5, 6). The X-ray studies established the gross structure and the relative configuration at all chiral centers but not the absolute configuration of the molecule. The original supposition that two deoxynupharidine molecules were incorporated into **3** was substantiated. The two molecules were incorporated without alteration of relative configuration at any center other than C(7).

In the past several years other sulfur-contain-

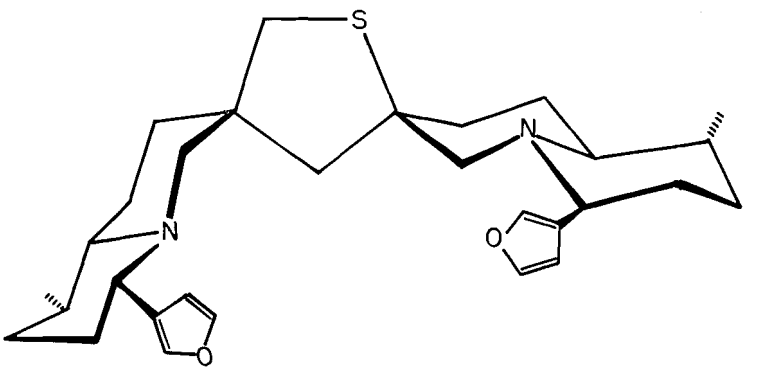
Ia THIOBINUPHARIDINE ($C_{30}H_{42}N_2O_2S$)



Ib

ing alkaloids of *Nuphar* have been reported. LaLonde *et al.* (7) have isolated two isomeric carbinolamines designated 6,6′-dihydroxythionuphlutine-A and -B and have reduced their immonium perchlorates to the apparently stereoisomeric thionuphlutines-A and -B ($C_{30}H_{42}N_2O_2S$). Thionuphlutine-A has very recently been shown to be identical with thiobinupharidine (8). It has been proposed (8) that nuphleine isolated some years ago (9) and 6,6′-dihydroxythionuphlutine-A are identical although a direct comparison has not been made. The isolation from *N. luteum* of a sulfoxide of neothiobinupharidine has also been reported (10). An alkaloid ($C_{30}H_{42}N_2O_3S$) named thionupharoline (11) has also been described and recent work in the authors' laboratories has shown it to be a hydroxyl derivative of **1**. Thus these sulfur alkaloids are all closely related and it seems that thiobinupharidine and thionuphlutine-B are stereoisomers of one another and of neothiobinupharidine. It was to examine the nature of the stereoisomerism between **1** and **3** that this work was undertaken.

We began our study by re-examining the spectra of **1** and **3** in the hope that we might clarify the stereochemical differences between the two molecules in this way. *trans*-Quinolizidines exhibit Bohlmann bands in their i.r. spectra and these bands are evident as expected in the spectrum of neothiobinupharidine (2, 4). When equimolar solutions of **1** and **3** were examined under the same conditions, it was observed that the Bohlmann bands in each spectrum were of nearly equal intensity although differing slightly in complexity. Thus it seems that **1** like **3** has two *trans*-quinolizidine rings.

The m.s. of **1** and **3** were reported some years

3 NEOTHIOBINUPHARIDINE
($C_{30}H_{42}N_2O_2S$)

ago (2) and that of **3** examined by high resolution very recently (10). We have confirmed the earlier observation that the spectra of **1** and **3** are very similar (Table 1) and have found by high resolution mass measurements that the compositions of the major ions in the two spectra are identical.

The p.m.r. spectra of the two alkaloids (Figs. 1 and 2) have now been examined at 220 MHz and the anomalies of the earlier studies (4) have been clarified. The interpretation of the spectra was aided greatly by referring to the studies of LaLonde and co-workers on the spectrum of deoxynupharidine (12) and on the spectra of model quinolizidines (13). Even so, the spectra

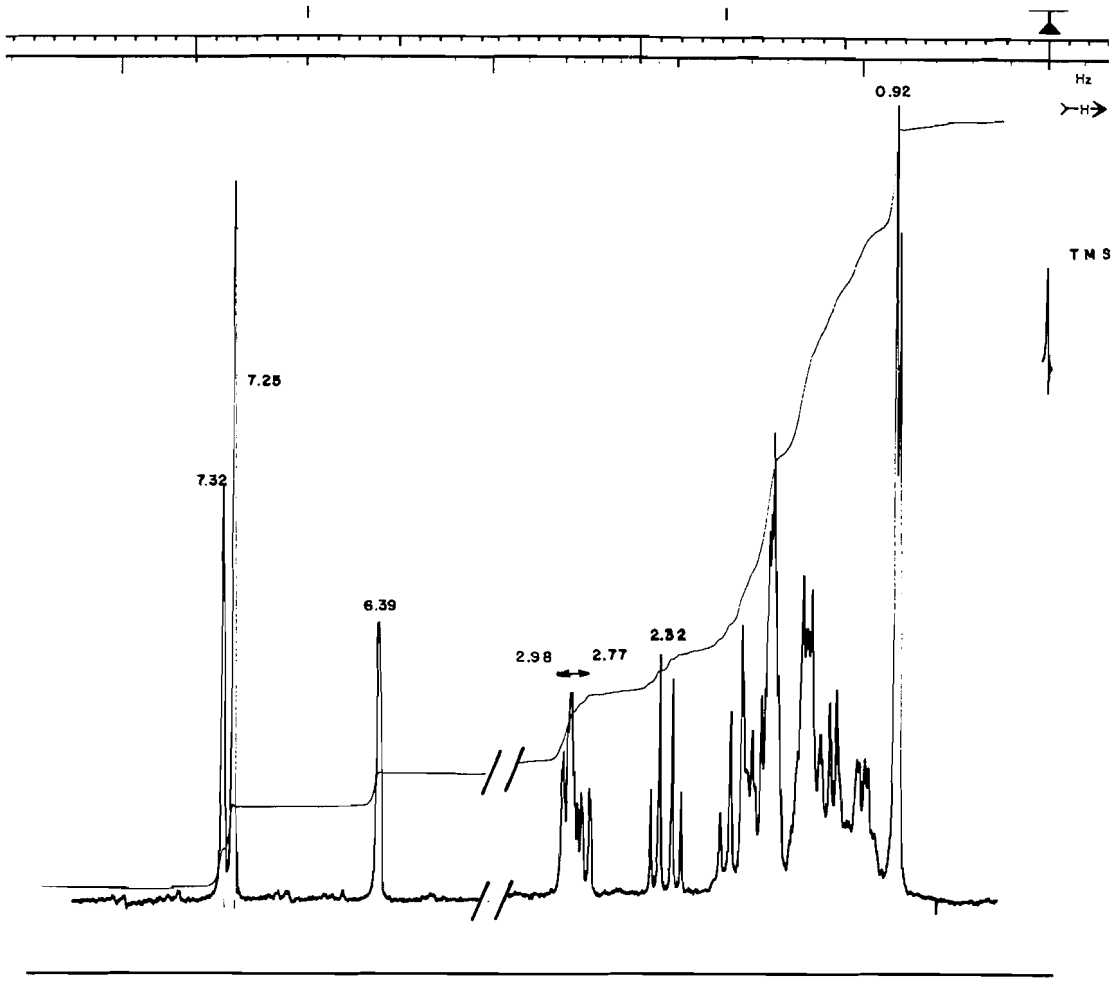

FIG. 1. The 220 MHz n.m.r. spectrum of thiobinupharidine.

are very complex and only a few of the protons of each were assignable.

In the spectrum of thiobinupharidine there is a signal of area 6 centered at δ 0.91 (J = 5 Hz) assignable to two CH—CH_3 groups. Similarly in **3** there is a signal of area 6 centered at δ 0.85 (J = 5.5 Hz). These resonances are very similar to the equatorial methyl resonance at C-1 of deoxynupharidine which is found at δ 0.92 (J = 5.6 Hz). Contrary to the earlier report there are no signals corresponding to methyl groups at quaternary carbon centers in either **1** or 3 nor are there any other signals attributable to CH_3 groups in the spectrum. The signals corresponding to the furan protons appear in **1** at δ 6.39 (2H, broad singlet, $w_{1/2}$ = 7 Hz) assigned to the β-protons of the two furan rings and at δ 7.25 (2H, singlet, $w_{1/2}$ = 4 Hz) and 7.32 (2H, singlet $w_{1/2}$ = 5 Hz) assigned to the α-protons. In the spectrum of **3** the furan signals are more complex appearing at δ 6.34 (1H, broad singlet $w_{1/2}$ = 3 Hz) and 6.52 (1H, broad singlet, $w_{1/2}$ = 3 Hz) attributable to the β-protons, and at 7.23 (1H, broad singlet, $w_{1/2}$ = 3 Hz) and 7.32 (3H, multiplet) assignable to the α-protons. These observations concerning the furan protons are in accord with those made earlier (4) which led originally to the incorrect conclusion that **1** must be a more symmetrical molecule than **3**. In the spectrum of **1** there are complex signals of area 4 in the region δ 2.77–2.98 attributed to the two protons α to the furan rings at C(4) and C(4′) and to the two equatorial protons at C(6) and C(6′). These assignments are made by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

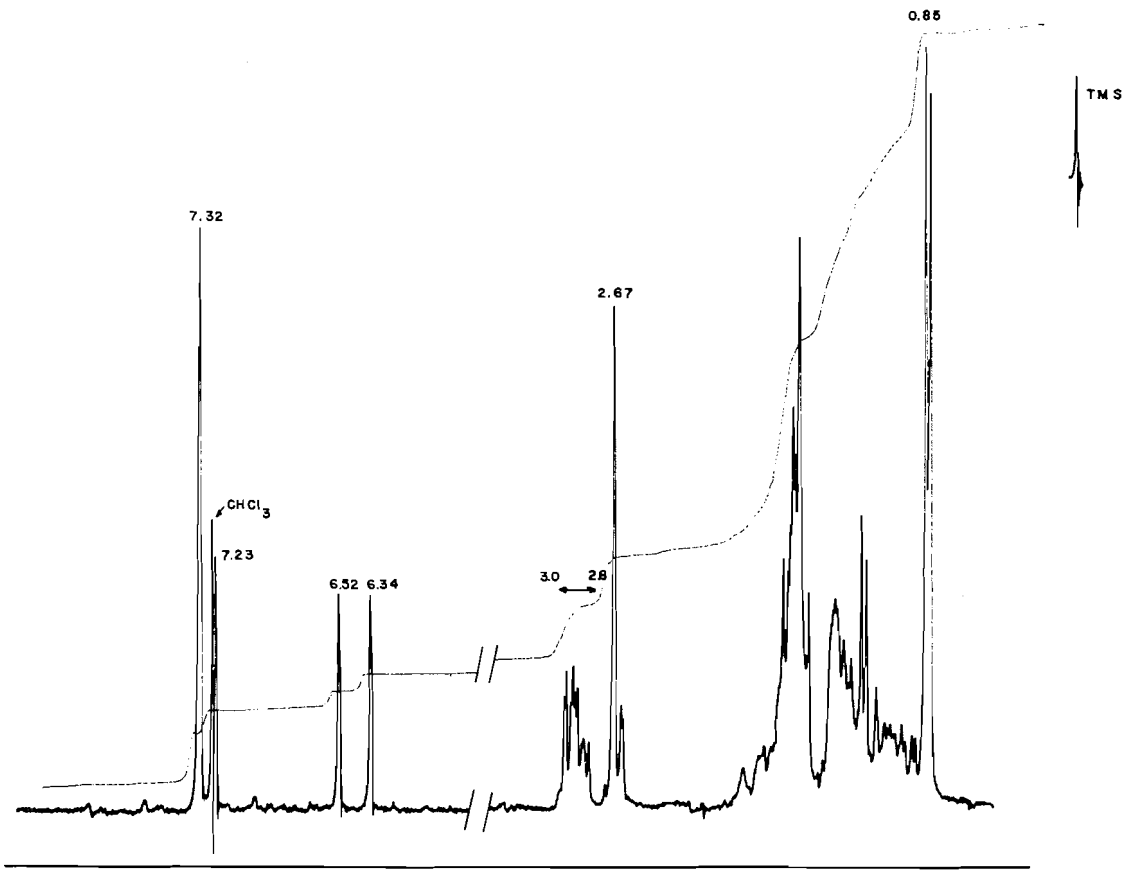

FIG. 2. The 220 MHz n.m.r. spectrum of neothiobinupharidine.

analogy with the chemical shifts of the corresponding protons in **2**. There is also in the spectrum of **1** a well-defined AB quartet centered at δ 2.32 (J = 11.5 Hz) attributed to the methylene adjacent to sulfur. In the spectrum of **3** the C(4) and C(4′) and the C(6) and C(6′) equatorial protons also appear in a complex pattern in the region δ 2.60–3.00. Superimposed on this complex pattern is a singlet at δ 2.67 (2H, $w_{1/2}$ = 3 Hz) attributed to the methylene adjacent to sulfur.

In recent studies on model compounds LaLonde *et al.* (13) have found that axial thiomethylene groups on quinolizidine systems absorb at δ 2.80 while equatorial thiomethylene groups absorb at 2.40. The thiomethylene group of **3** is known to be axial from the *X*-ray study and appears at δ 2.67. The much higher field absorption of the thiomethylene group of **1** at δ 2.32 would suggest by analogy that it is equatorial with respect to the quinolizidine ring. Therefore, this accounts for one of the stereochemical differences between the two molecules. Assuming that stereochemical differences between **1** and **3** reside in the tetrahydrothiophene ring and that the configuration at all other centers is the same, as the p.m.r. data suggest, there are two possible structures **1***a* and **1***b* for **1** in which the sulfur linkage to the second ring is equatorial and axial, respectively.

Until the finding that thiobinupharidine and thionuphlutine-A were identical there did not seem to be a method to differentiate between **1***a* and **1***b*. However, LaLonde (14) has presented evidence for the equatorial character of the C(7)—S linkage in thionuphlutine-A (thiobinupharidine) based on the formation of **1** by reduction of the immonium perchlorate derived from 6,6′-dihydroxythionuphlutine-A. In reduction experiments with borodeuteride and borohydride, he found evidence for sulfur participation, probably through an episulfonium ion, in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

directing the attack of D^- or H^- on the carbon–nitrogen double bond of the immonium salts. In the case where an equatorial sulfur was present deuteride attack was found to occur in a manner that introduced deuterium into an equatorial position, whereas when an axial sulfur was present the entering deuterium was introduced into an axial position. In the reduction cited above the entering deuterium occupied an equatorial position in the reduction product. Thus, the evidence favors structure **1***a* for thiobinupharidine.[1] (This structure has been confirmed through the X-ray crystal structure determination on thiobinupharidine dihydrobromide dihydrate discussed below.)

The structure found in the X-ray study for the hydrobromide is shown in Fig. 3. As concluded from the spectroscopy the structures of thiobinupharidine and neothiobinupharidine (6) are very similar particularly if it is assumed that **3** has the same absolute configuration as that determined for **1**. The major difference between thiobinupharidine and neothiobinupharidine lies in the fact that S and C(17′) (Fig. 3) are equatorial to the two quinolizidine systems in the former, whereas they are axial in the latter. Consequently C(17) is axial in thiobinupharidine and equatorial in neothiobinupharidine.[2] In both isomers the S, C(17′), C(7), and C(17) atoms lie in a plane and C(7′) is displaced from the plane by 0.28 Å in the present structure and 0.49 Å in neothiobinupharidine. Since the mean deviations of the atoms defining the plane is 0.004 Å in the former case and 0.006 Å in the latter these displacements are significant.

Pertinent bond distances and angles are found in Table 2. As in neothiobinupharidine, there are some unusually and significantly long bond lengths in the sulfur-containing ring. The S—C bond lengths lie on either side of the expected value of 1.81 Å (15), unlike those in neothiobinupharidine where both the C—S bond lengths are shorter than 1.81 Å. The thermal parameter for S is unusually large in both isomers (see Table 3) suggestive of disorder, but that of C(17′) is small in the present compound and large in neothiobinupharidine.

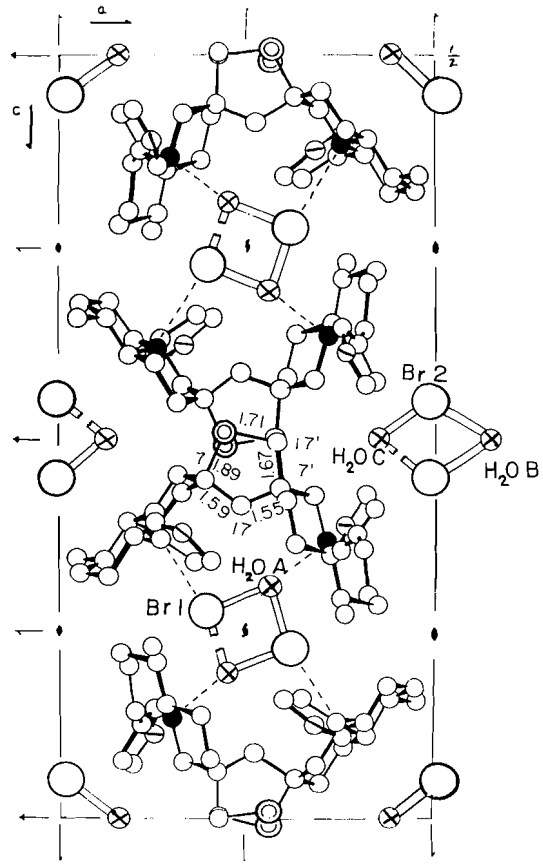

FIG. 3. The structure of thiobinupharidine dihydrobromide dihydrate projected down [010]. Only half the unit cell contents are shown. (○) Br; ◎ S; ⊗ H_2O; ● N; ⊘ O; (o) C.

The average $C(sp^3)$—$C(sp^3)$ bond length in the structure is 1.55 Å, in good agreement with the accepted value of 1.54 Å. The only bond of this type which exceeds the average value by as much as three standard deviations is that between C(17′) and C(7′) in the present structure. A similar anomaly in bond length is found in neothiobinupharidine. The mean C=C and C—O bond distances in the furan rings are both 1.39 Å compared with C=C, 1.361 and 1.351 Å, and C—O, 1.362 Å and 1.361 Å, found in furan (16) and furan-3,4-dicarboxylic acid (17), respectively. The average C—N bond length at

[1]In a recent personal communication Professor R. T. LaLonde has informed us that he has reached the same conclusion regarding the structure of thiobinupharidine and has found that the structure of thionuphlutine-B is that represented in **1***b*. His conclusions were reached as the result of more extensive chemical and spectroscopic studies on the alkaloids and on model systems. We thank Professor LaLonde for sending us a preprint of the paper he has prepared on his studies and which is in press in the Journal of the American Chemical Society.

[2]The same numbering system is used for both isomers and differs from that used by Birnbaum (6).

These values were obtained from

$$\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$$

where the β_{ij}'s appear in the structure factors as

$$\exp\left[-(\beta_{11}h^2 + 2\beta_{12}hk + \ldots)\right]$$

and the b_i's are reciprocal lattice vectors.

1.56 Å, is larger than expected from values reported in related structures (6).

The alkaloids in both isomers possess a pseudo twofold axis. The nonplanarity of the S-containing ring and the inequivalence of S and C(17′) destroy this element of symmetry. In the present structure S has a large thermal motion parameter while C(17′) has a very small one, suggestive of a disorder resulting in an unequal mixture of two orientations in which S and C(17′) interchange as a result of a rotation of 180° about the pseudo twofold axis. In neothiobinupharidine it is tempting to attribute the residual peak in the difference synthesis to a similar rotation of the molecule but with the axis of rotation substantially displaced from the

center of the C(17′)—S bond. In the structure at hand, however, this should cause an apparent shortening of the S—C(7) and S—C(17′) bonds, and a lengthening of the C(17′)—C(7′) bond. The S—C(17′) and C(17′)—C(7′) bond lengths of 1.71 and 1.67 Å are consistent with this, but not the S—C(7) bond, whose length is 1.89 Å and thus deviates by more than 4σ from the comparable distance in neothiobinupharidine. At present it is not possible to account for these features in this structure.

The packing in the structure is defined by the arrangement of the organic moiety between two types of spirals containing hydrogen-bonded water molecules and bromide ions. The first spiral contains Br(1) and H_2OA and is propagated by a 2_1 axis parallel to the *b* axis while the second contains Br(2), H_2OB, and H_2OC and is generated by the twofold axes parallel to *a* through the water molecules. The first spiral interacts with the thiobinupharidine through N(5) and N(5′) with Br(1) and H_2OA, respectively, and the stabilization of this interaction is reflected in the smaller thermal parameters for the atoms in the first spiral compared with the second. The interatomic interactions suggestive of hydrogen bonding are included in Table 2. The Br(1)—OA, Br(1)—OAa, Br(2)—OB, and Br(2)—OC distances at 3.36(2) Å for the first and 3.28(2) Å for the remainder are similar to the distances of 3.26 and 3.39 Å observed for similar interactions in quinuclidinylbenzilate hydrobromide (18) and capaurine hydrobromide (19), respectively. In these latter structures the bromide ion – quaternary nitrogen distances were 3.18 and 3.12 Å respectively. The corresponding distance in the present structure is 3.43 Å between Br(1) and N(5). It appears that given the configuration of the neothiobinupharidine moiety it is not possible to pack two bromide ions into this entity efficiently in the structure and that the water molecules permit the separation of the halide ions while allowing the organic framework to come into contact at the appropriate separations defined by the van der Waals' radii.

Experimental

Apparatus, Methods, and Materials

M.s. were determined on a C.E.C. 21-110B double-focusing mass spectrometer. Samples were introduced through a direct inlet system. Relative intensity data were obtained from low resolution m.s. recorded under identical conditions at 70 eV and at 140 μA and at a source temperature of 200 °C and a source pressure of 2×10^{-6} Torr. The high resolution mass spectra (h.r.m.s.) were recorded on Ilford Q-2 photographic plates which were developed in the usual manner. The spectra were then recorded on magnetic tape, using a Gaertner comparator-densitometer linked to a Datex system. They were processed on a CDC-6400 computer using a modified version of the HIRES program of Tunnicliff and Wadsworth (20). The compositions of all ions formed by electron impact and discussed in this paper were established by high resolution measurements and agreed with calculated values within the limits ±5 mmass units. A comparison of the intensities of the ions in the spectra of **1** and **3** is found in Table 1.

I.r. spectra of **1** and **3** were recorded on a Perkin-Elmer 521 spectrometer. Samples were made up at a concentration of 0.03 *M* (15 mg/ml) in carbon tetrachloride, using a solution cell with NaCl windows and a path length of 0.5 mm. The total area of the three absorption bands with maxima at 2740, 2760, and 2780 cm^{-1}, the Bohlmann bands, was estimated and found to be nearly equal.

P.m.r. spectra were recorded at 220 MHz on a Varian 220 HR spectrometer using a field sweep mode. Samples were dissolved in $CDCl_3$ using added TMS as internal locking signal. Chemical shifts are quoted relative to TMS = 0.0 δ.

In the X-ray experiments a crystal with dimensions 0.17 × 0.12 × 0.07 mm and a Syntex $P\bar{1}$ automatic diffractometer with graphite monochromatized MoKα radiation were used throughout this investigation. Unit cell parameters were obtained by least squares from 15 accurately centered reflections. The crystal data are as follows:

$C_{30}H_{42}O_2N_2S \cdot 2HBr \cdot 2H_2O$ FW = 692.68

$a = 25.128(6)$, $b = 9.869(2)$, $c = 26.380(6)$ Å, volume = 6545.6 Å^3, $D_m = 1.41$ g/cm^3, $Z = 8$, $D_x = 1.407$ g/cm^3, space group $C222_1$

The systematic absences are $h + k$ odd in general and $00l$ for l odd. Data were collected up to 2θ equal to 35°. Reflections were scanned at a rate between 2 and 24° per min depending upon the peak intensity. Backgrounds were measured at 1° removed from the peak. A total of 1934 unique reflections (consisting of hkl, $hk\bar{l}$ pairs) were observed of which 1452 had intensity greater than 3σ. The data were corrected for Lorentz and polarization effects but not for absorption. The linear absorption coefficient, μ, is 27.3 cm^{-1} and the average μR value is 0.19.

The atomic positions were determined from the Patterson function and subsequent electron density and difference electron density. The structure was refined using full-matrix least squares using a program written by J. S. Stephens for the CDC 6400. Atomic scattering factors were obtained from the International Tables for X-ray Crystallography (21) and corrected for anomalous dispersion. Weights, ω, were assigned such that ΔF would be locally independent of F_o by setting

$$\omega = [157\text{–}1.67F_o + 0.0103F_o^2]^{-1}.$$

The anisotropic components of the thermal parameters for Br and isotropic thermal parameters of the remaining atoms were varied resulting in a minimum R value of 0.091 with Friedel equivalent reflections averaged. These

Friedel equivalent pairs were then separated and the absolute configuration sought using about 200 pairs which showed greater than 20% difference in their measured intensities. Structure factor calculations for the two alternate configurations showed that the deviations were in the direction consistent with the proposed configuration in over 70% of the cases. This configuration was then refined using all 1934 reflections yielding a final R value of 0.085 for observed reflections only when all shifts were less than 0.3 of the calculated standard deviation. For all the reflections the final R value was 0.097. A final difference synthesis showed no peaks greater than 1/6 of a carbon peak. No attempt was made to locate hydrogen atoms. Table 3 contains the final atomic parameters. A list of selected bond distances and angles in the molecule appears in Table 2, and the observed and calculated structure factors are compared in Table 4.[3]

Thiobinupharidine Dihydrobromide Dihydrate

Thiobinupharidine (50 mg) was dissolved in hot methanol and a 1:1 mixture of methanol and concentrated hydrobromic acid was added dropwise to a pH of 3–4. The fine colorless needles that separated on cooling were recrystallized from a 1:1 mixture of acetone and water. The crystals melted at 245–247°.

Anal. Calcd. for $C_{30}H_{42}N_2O_2S \cdot 2HBr \cdot 2H_2O$: C, 52.02; H, 6.92; N, 4.04; Br, 23.09. Found: C, 52.06; H, 6.85; N, 4.08; Br, 23.11.

Conversion of the hydrobromide to the free base by treatment of an aqueous solution with ammonia followed by extraction with ether and subsequent workup gave thiobinupharidine identical with an authentic specimen.

Processus photophysiques dans la molécule de colchicine

H. ROIGT ET R. M. LEBLANC

Université du Québec à Trois-Rivières, Groupe de Biophysique, Département de Chimie-Biologie, C.P. 500, Trois-Rivières, Québec

Reçu le 6 mars 1973

Un diagramme de Jablonski est proposé pour la molécule de colchicine. A cette fin des résultats primordiaux ont été tirés de l'étude de l'absorption u.v.-visible, de la luminescence à 77 °K et de la photolyse. Ainsi le rendement de phosphorescence a été trouvé égal à 0.86 et un résultat important concerne la mise en évidence de l'établissement de pont hydrogène entre la colchicine et le solvant.

The photophysics of colchicine has been studied by absorption and luminescence spectroscopy. The quantum yield of phosphorescence has been found to be 0.86. The quantum yield measurements of colchicine photodegradation in different solvents are reported. The polarity and hydrogen bond character of the solvents are observed to play an important role in these measurements. The Jablonski diagram is proposed for the colchicine molecule.

Introduction

Une des principales caractéristiques de la colchicine réside dans son pouvoir antimitotique spécifique (1, 2). Un excellent résumé des propriétés apparaît dans l'article de Wallace et Ertel (3). Bien que possédant au point de vue médical des effets secondaires nocifs et imprévisibles, la colchicine est encore étudiée et utilisée fréquemment surtout dans les laboratoires de génétique cellulaire.

Or, un travail récent démontre que l'on peut inverser l'action biologique de la Colcemide (*N*-méthyl *N*-désacétyl colchicine) par irradiation du produit à 366 nm. Ce comportement est expliqué par la photodégradation de la substance (4). Pourtant, d'autres auteurs (5) observent des effets différents selon la région spectrale d'irradiation utilisée.

On s'aperçoit donc qu'une explication définitive ne pourra être formulée que lorsqu'une étude quantitative approfondie sur la photoinactivation de la colchicine aura été entreprise. Si l'on en juge par les travaux antérieurs (6–14) les résultats concernant la photodégradation quantique ne sont pas nombreux. Notre étude tente de combler cette lacune en examinant les processus photochimiques primaires et en établissant un bilan énergétique compte tenu d'un résultat préliminaire lié à la phosphorescence de la colchicine (15).

Partie expérimentale

Les solvants tels le tétrachlorure de carbone (spectranalyzed), le chloroforme (spectranalyzed, 0.75% C_2H_5OH), le dichlorométhane (spectranalyzed), le méthanol (99.9% pur), le *n*-propanol (certified normal), l'isopropanol (certified A.C.S.), le *n*-butanol (reagent A.C.S.), l'isobutanol (certified), le tertiobutanol (certified), le 1,4-dioxane (certified, 99% pur), le benzène (spectranalyzed), le formamide (certified), le *N*,*N*-diméthylformamide (certified A.C.S.), l'acétonitrile (certified A.C.S.) sont tous des produits Fisher et ont été employés sans autre purification. Il en est de même du mélange diéthyl éther, isopentane, éthanol, 5:5:2, (EPA mixed solvent, American Instrument Co. Inc.) et de l'éthanol à 95% (C.I.P., Gatineau, Québec). L'eau est distillée dans un système Barnsted.

Les standards de luminescence appartiennent à un ensemble de photosensibilisateurs (Organic Laboratory Chemicals, J. T. Baker Chemical Co., Phillipsburg, New Jersey, kit 4040).

L'oxalate de potassium et le chlorure ferrique (Fisher, reagent grade) ont servi à la préparation de l'actinomètre $K_3Fe(C_2O_4)_3.3H_2O$, lequel est recristallisé trois fois dans l'eau distillée tiède, à l'abri de la lumière.

Les cristaux verts obtenus sont séchés à l'air et récupérés dans un flacon teinté. Une solution sulfurique 0.006 *M* de ferrioxalate de potassium est ensuite préparée selon la technique élaborée par Hatchard et Parker (16).

L'acétate de sodium (reagent. Anachemia Chemicals Ltd.) et la 1,10-phénanthroline (certified A.C.S., Fisher) sont aussi utilisés tels quels dans la préparation des solutions nécessaires à l'obtention du complexe de couleur rouge avec les ions Fe^{2+}.

Les critères de pureté de la colchicine utilisée, ainsi que la description des caractéristiques du spectrophotomètre Unicam SP 1800 et du spectrofluorimètre Perkin-Elmer MPF 2A, ont déjà été mentionnés dans une publication antérieure (15). Cependant pour la détermination des rendements quantiques de phosphorescence, le photomultiplicateur HTV R106 a été remplacé par le HTV R136. Les spectres d'émission furent corrigés à l'aide de la réponse spectrale relative du photomultiplicateur au moyen d'une calculatrice électronique Hewlett-Packard 9820 A qui intégrait automatiquement les aires sous les courbes dans une unité commune. Les échantillons contenus dans des tubes en quartz ne présentaient aucune trace d'eau qui aurait eu pour effet de fendiller le verre

TABLEAU 1. Coefficients d'absorption de la colchine dans différents solvants

Solvant	λ_{max}(log ε) (±1 nm)			
Eau	354 (4.21)	246 (4.50)	234 (4.43)	199
Méthanol	352 (4.22)	243 (4.46)	234 (4.44)	206
Ethanol 95%	351 (4.22)	243 (4.47)	234 (4.43)	202 (4.40)
n-Propanol	351 (4.19)	244 (4.42)		202
2-Propanol	350 (4.23)	243 (4.60)	234 (4.44)	
n-Butanol	351 (4.21)	244 (4.45)		
t-Butanol	350 (4.20)	242 (4.40)		204
Tetrachlorure de carbone	347 (4.20)	260 (4.21)		
Chloroforme	350 (4.21)	242 (4.42)		
Dichlorométhane	343 (4.22)	248 (4.42)		
Benzène	344 (4.22)			
1,4-Dioxane	342 (4.19)	266 (4.11)		
Formamide	350 (4.22)	255 (4.29)		
N,*N*-Diméthyl formamide	344 (4.14)	262 (4.09)		
Acétonitrile	343 (4.19)	230 (4.45)		

(EPA solide) à 77 °K. Les tubes eux mêmes étaient maintenus en place par une garniture intérieure en Teflon, système qui avait pour effet d'obtenir des résultats reproductibles. Chacun des résultats est la moyenne d'une série de cinq ou six essais effectués dans des conditions expérimentales différentes.

Le système d'irradiation comporte les parties suivantes: une lampe au mercure General Electric AH4, 125 W, "pression moyenne"; un réflecteur cylindrique; une lentille convergente; un filtre de chaleur Chance No. HAI; un filtre optique 366 nm Chance No. 0.X.1; un diaphragme à iris ainsi qu'un bloc d'irradiation.

Le bloc d'irradiation comporte trois cellules de quartz, cylindriques, de 1 cm de trajet optique et de 2.75 cc de volume, calées dans des rainures à cet effet. Au milieu du bloc et placée perpendiculairement, avec un angle de 45° par rapport au faisceau incident, se trouve une lamelle de quartz de 1.5 mm d'épaisseur que répartit la lumière incidente en deux faisceaux perpendiculaires, dans le rapport: 7% réfléchie à angle droit et 93% traversant sans aucune déviation. Ce rapport est indépendant de l'intensité incidente.

La cellule latérale contient toujours de l'actinomètre et la densité optique mesurée à 5100 Å sert au calcul de l'intensité lumineuse émise par la lampe (éliminant ainsi les erreurs dues à une fluctuation possible de l'intensité durant l'irradiation).

La cellule arrière contient également de l'actinomètre et sert au calcul de la quantité de photons qui n'a pas été absorbée par la solution de colchicine: on peut ainsi corriger la valeur du rendement quantique de photodégradation obtenue.

Enfin la cellule frontale contient la solution dont on veut étudier la photolyse.

Les solutions de colchicine ayant servies à l'irradiation n'ont pas été dégazées à l'inverse de celles qui ont été utilisées pour la détermination des rendements de phosphorescence. En effet quelques expériences ont montré que le rendement quantique de dégradation de la colchicine demeurait dans les limites de l'erreur expérimentale quand on passait d'une solution non dégazée à une solution dégazée (pression inférieure à 10^{-5} Torr).

Résultats et discussion

Absorption

Certains résultats concernant l'absorption des molécules appartenant à la même famille que la colchicine ont déjà fait l'objet d'une importante étude de la part de Šantavý et coll. (17).

D'autres travaux portant sur les tropolones en particulier, prouvent la spécificité des bandes d'absorption dont l'une commune à tous ces composés et située vers 350 nm (arrangement du cycle tropolone) (18–20).

Quant à nous, nous nous sommes penchés plutôt sur l'effet de solvant, en restreignant notre champ d'investigation à la molécule de colchicine uniquement. Il va sans dire que les résultats concernant les coefficients d'absorption moléculaire sont absolument nécessaires pour le calcul des rendements quantiques de photoisomérisation de la colchicine.

Le tableau 1 concerne directement l'absorption en fonction du solvant, les coefficients d'absorption étant calculés par la méthode des moindres carrés. L'intervalle de concentrations se situe entre 10^{-3}–10^{-6} M, sauf le tétrachlorure de carbone (10^{-5}–10^{-6} M).

On note en premier lieu que la valeur de ces coefficients ε est relativement élevée ($\varepsilon \geqslant 12000$) ce qui implique des transitions $\pi\pi^*$ pour toutes ces bandes. Ceci est vérifié en outre par le déplacement bathochrome des maxima lorsque la polarité du solvant augmente.

On s'aperçoit aussi que le nombre des bandes d'absorption varie selon le solvant utilisé, mais celle entre 340 et 355 nm demeure toujours.

Un résultat important concerne l'absorption de la colchicine dans le formamide d'une part et dans son dérivé *N*,*N*-diméthylé d'autre part. Le maximum se déplace de 350–344 nm quand on passe du premier au second. Ce déplacement relativement important ne peut être expliqué uniquement par la variation du moment dipolaire du solvant. En effet, ici intervient un effet de liaison hydrogène c'est-à-dire que l'augmentation en intensité du ou des ponts hydrogènes entre la colchicine et le solvant conduit au même phénomène qu'une augmentation dans la polarité de ce dernier. Le doublet électronique libre sur l'azote du formamide est beaucoup plus disponible que dans le cas du *N*,*N*-diméthylformamide à cause d'un empêchement stérique provoqué par les groupements méthyle dans ce dernier cas. Il en découle donc une plus grande capacité à établir des liaisons hydrogène dans le cas du formamide et le déplacement de λ_{max} observé est tout à fait normal. Un tel effet a été commenté pour d'autres molécules (21).

Luminescence

Aucune fluorescence n'a été décelée, cependant une importante phosphorescence apparaît entre 380 et 600 nm, caractérisée par un spectre peu structuré avec un maximum d'intensité à 423 nm et une bande 0–0 à 402 nm dans l'*e.p.a.* La nature de cette luminescence a déjà fait l'objet d'un travail publié récemment (15).

Le choix des standards pour la mesure du rendement relatif de phosphorescence de la colchicine a été conditionné par l'énergie de son état triplet, $E_{T_1} = 71.5$ kcal mol^{-1}. A cette fin nous avons choisi la benzophénone (22), l'acétophénone (23) et le biphényle (24). Le rendement de phosphorescence ϕ_P(Colc.) a été déterminé à l'aide de la relation proposée par Parker et Rees (25):

$$[1] \qquad \phi_P(\text{Colc.}) = \phi_S(H/A)_S/(H/A)_{\text{Colc.}}$$

Colc. et S, indices se rapportant respectivement à la colchicine et au standard; H, hauteur maximum du spectre d'émission pour une même longueur d'onde d'excitation; A, aire sous le spectre, corrigée, d'après la réponse du photomultiplicateur.

Dans le cas des deux premiers standards la corrélation est excellente et indique une valeur moyenne ϕ_P(Colc.) = 0.86 (15 essais à différentes longueurs d'onde d'excitation), tandis qu'avec le biphényle on obtient une valeur de 0.18.

Cependant dans ce dernier cas, Parker et Hatchard (24) signalent que la valeur trouvée pour le biphényle n'est qu'approximative. Quant à nous, nous considérons qu'elle doit être erronée compte tenu des résultats obtenus avec les autres standards. Quoiqu'il en soit le calcul des rendements de photodégradation de la colchicine confirmera cette assertion.

Photolyse

En utilisant le dispositif d'irradiation décrit dans la partie expérimentale, on mesure par spectrophotométrie la décroissance de densité optique de la bande d'absorption $\pi\pi^*$ vers 350 nm, absorption due au cycle tropolone qui sera le siège d'un photoréarrangement. Cette bande est idéale pour une telle mesure puisqu'elle disparaît presque complètement dans le spectre des lumicolchicines β et γ dont le coefficient d'absorption à 350 nm, calculé à partir du graphique de Grewe et Wulf (12), est égal à: $\varepsilon = 1650$ l mol^{-1} cm^{-1}, soit une valeur équivalente au dixième de celle de la colchicine.

La figure 1 montre l'aspect spectral que revêt cette photodégradation dans l'eau. Des spectres semblables ont déjà été publiés mais ils concernaient la photoisomérisation de la lumicolchicine α (26) et celle de la *N*-méthyl, *N*-désacétyl colchicine (13).

Après un certain temps d'irradiation, il apparaît deux nouvelles bandes dont les maxima se situent respectivement à 223 et à 266 nm, absorptions caractéristiques des lumicolchicines β et γ. On note également la présence de quatre points isobestiques soit à 211, 228, 257 et 301 nm. La bande située à 350 nm diminue beaucoup d'intensité tout en se déplaçant vers les courtes longueurs d'onde (diminution de la conjugaison dans le cycle), tandis que les maxima à 199 et à 246 nm deviennent des minima.

Toujours sur la fig. 1, il est important de remarquer que la photodégradation de la colchicine n'est pas linéaire en fonction du temps, d'où l'obligation de recourir à une intensité d'irradiation plus faible et aussi à des intervalles d'irradiation plus courts. On a donc utilisé une intensité incidente corrigée, voisine de 10^{14} quanta s^{-1} cm^{-2} et dans ce cas on a noté une décroissance uniforme de la densité optique en fonction du temps, ce, durant 5 min à peu près, et pour deux séries de solvants, soient les chlorométhanes

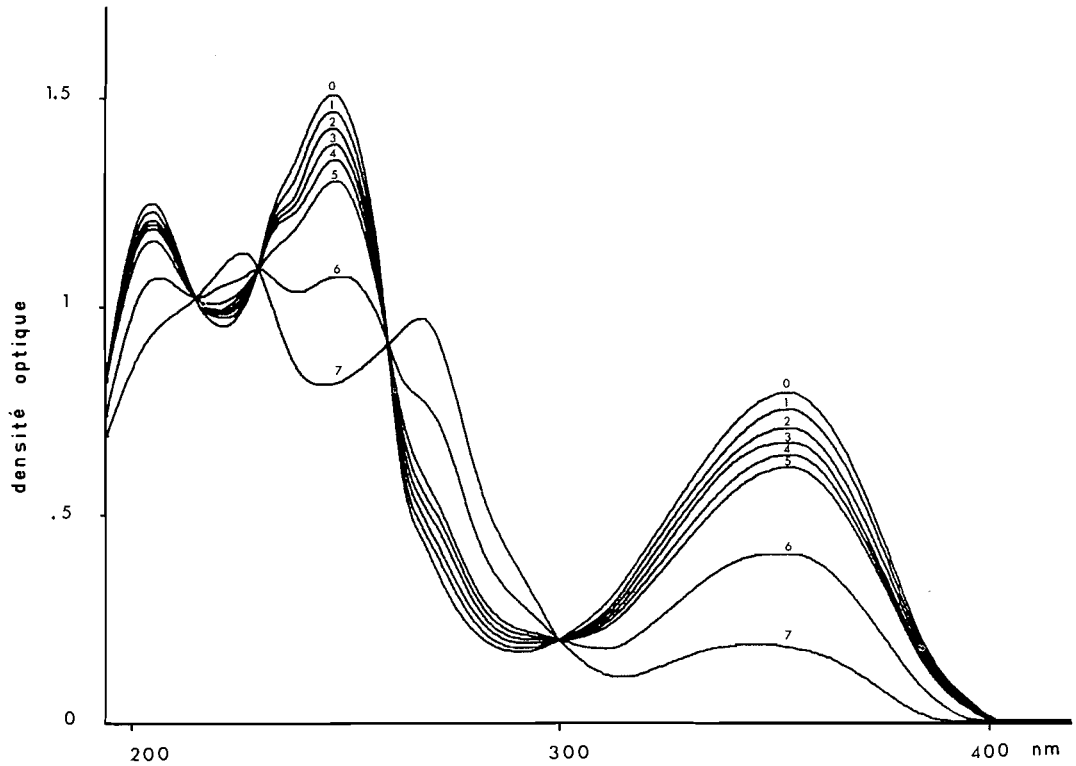

FIG. 1. Photodegradation de la colchicine en solution aqueuse. 4.9×10^{-5} *M*; p*H* = 5.8; $I_{abs} = 2 \times 10^{15}$ quanta s^{-1} cm^{-2}; temps d'irradiation 0: 0 min, 1: 10 min, 2: 20 min, 3: 30 min, 4: 40 min, 5: 50 min, 6: 120 min, 7: 240 min.

d'une part (fig. 2*a*), et les alcools d'autre part (fig. 2*b*). Le temps au bout duquel la linéarité disparaît, dépend du solvant: plus celui-ci est polaire, plus le temps est long. C'est la pente de ces droites qui sert à calculer le rendement quantique de photoisomérisation de la colchicine, selon l'équation:

$$[2] \quad \Phi(\text{Colc.}) = \frac{\Delta(\text{d.o.})_{350\,nm} \times N_0 \times V}{t \times \varepsilon_{max} \times I_{abs}}$$

Φ(Colc.): rendement quantique de photoisomérisation de la colchicine; $\Delta(\text{d.o.})_{350\,nm}$: diminution de densité optique du maximum vers 350 nm; N_0: 6.023×10^{20} molécules cm^{-3}; V: volume de la solution de colchicine irradiée en cm^3; t: temps d'irradiation en s; ε_{max}: coefficient d'absorption moléculaire vers 350 nm en 1 mol^{-1} cm^{-1}; I_{abs}: intensité absorbée par la colchicine en quanta s^{-1} cm^{-2}.

Effet de solvant

En plus des deux séries de solvants cités précédemment, ont été utilisés le benzène (faible probabilité de réaction d'abstraction d'hydrogène), le formamide et son dérivé *N*,*N*-diméthylé pour une comparaison possible quant à l'établissement de liaisons hydrogène. Les résultats apparaissent dans le tableau 2.

Dans l'une ou l'autre des séries de solvants étudiés, on remarque une diminution du rendement quantique de photodégradation en fonction du moment dipolaire du solvant.

Cet effet est expliqué par la formation d'un complexe de solvatation soluté – solvant, d'autant plus stable que le moment dipolaire est élevé.

Le cas du formamide et de son dérivé *N*,*N*-diméthylé, offre un aspect intéressant de l'intervention des ponts hydrogène et de leur importance dans les processus photophysiques. En effet, en passant du formamide à son dérivé, on assiste à une augmentation du simple au double du rendement de photodégradation et l'explication de ce phénomène ne peut résider uniquement dans la différence de moment dipolaire entre les deux molécules de solvant. Cette variation est

i-PrOH	"	1.14	0.037	16.7
C_6H_6	"	1.02	0.016	0
$HCONH_2$	"	0.32	0.016	
$HCON(Me)_2$	"	0.18	0.030	

*En ce qui a trait à la *N*-méthyl,*N*-désacétyl colchicine, Aronson et Inoué (4) avaient trouvé comme rendement quantique de dégradation: $\Phi = 3 \times 10^{-3}$ dans l'eau; $\Phi \simeq 36 \times 10^{-3}$ dans le *n*-butanol. Ces résultats sont très voisins des nôtres.

essentiellement due au fait que dans le formamide, le doublet électronique libre sur l'atome d'azote est beaucoup plus disponible donc du même coup, beaucoup plus apte à ériger un ou plusieurs ponts hydrogène avec la molécule de colchicine. Le complexe colchicine–formamide serait donc beaucoup plus stable à cause de ces liaisons hydrogène et inhiberait la photoisomérisation de la colchicine.

L'établissement de ponts hydrogène entre la colchicine et le solvant pourrait très bien expliquer l'action antimitotique de la substance.

Par contre, le cas du benzène est marginal: si l'on s'en tient à la valeur du moment dipolaire des molécules de solvant, le benzène devrait donner à peu près le même résultat que le tétrachlorure de carbone. Or il n'en est rien et il se pourrait bien que dans ce cas on assiste à un

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

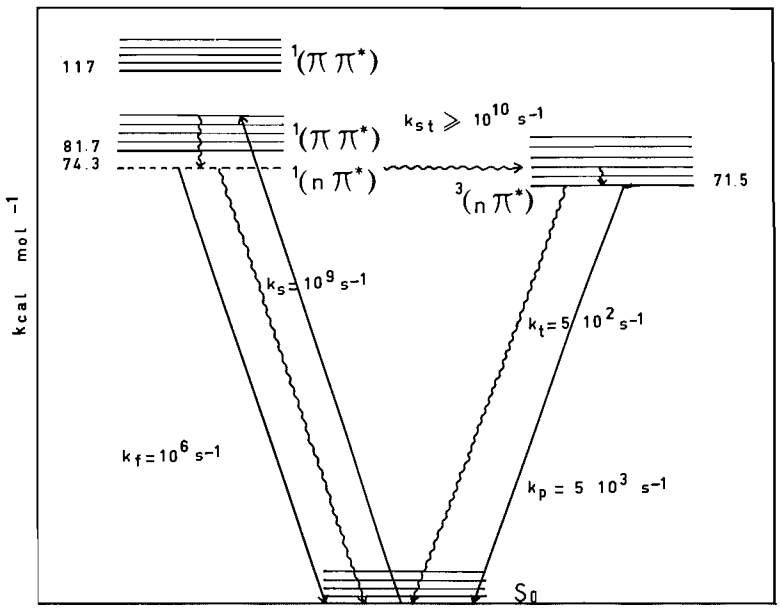

FIG. 3. Diagramme de Jablonski. (→) processus radiatif; (⇝) processus non radiatif.

transfert de charge qui diminuerait du même coup la photodégradation de la colchicine.

Autres effets

Des essais préliminaires sur quelques solutions portent à croire qu'un effet de concentration existe, surtout dans l'isopropanol. En effet le rendement quantique de photodégradation augmente proportionnellement avec la concentration. Or quand on sait que l'isopropanol est le solvant le plus apte à donner lieu à une réaction secondaire d'abstraction d'hydrogène en présence d'une fonction cétone (21), on conçoit donc qu'un tel effet soit tout à fait normal avec la colchicine qui possède aussi un groupement cétone sur le cycle tropolone.

Des études en ce sens sont actuellement en cours avec parallèlement des essais sur l'effet d'intensité, de la longueur d'onde d'irradiation, et aussi de p*H* (27).

Diagramme de Jablonski

Les processus photophysiques les plus importants que subit la colchicine, peuvent se résumer dans les étapes suivantes:

$$(\text{Colc.})_{S_0} + \text{solvant} \rightarrow (\text{complexe})_{S_0}$$

$$(\text{complexe})_{S_0} + h\nu \rightarrow (\text{complexe})^*_{S_n}$$

$$(\text{complexe})^*_{S_n} \rightarrow (\text{Colc.})_{S_0} + \text{solvant}$$

$$(\text{complexe})^*_{S_n} \rightarrow (\text{Colc.})^*_{S_1} + \text{solvant}$$

$$(\text{Colc.})^*_{S_1} \rightarrow (\text{Colc.})^*_{T_1}$$

$$(\text{Colc.})^*_{T_1} \rightarrow (\text{Colc.})_{S_0} + h\nu'$$

$$(\text{Colc.})^*_{S_1, T_1} \rightarrow \text{photoproduits}$$

Le complexe solvant–colchicine absorbe un photon, ce qui le conduit à un état excité S_n. Suite à cette absorption, le processus de conversion interne du complexe libère la molécule de colchicine qui demeure à l'état excité $^1(n\pi^*)$. A partir de S_1, aucune désactivation radiative n'est observée. Par contre la constante de conversion interne k_s, correspondant à une désactivation thermique $S_1 \rightarrow S_0$ est calculée théoriquement (28) $k_s = 10^9\ s^{-1}$.

Toujours à partir de S_1, on assiste à un croisement inter-système $S_1 \rightarrow T_1$ dont la constante de vitesse calculée théoriquement est égale à $k_{st} \geqslant 10^{10}\ s^{-1}$.

A partir de cet état triplet $^3(n\pi^*)$, il y a alors émission de phosphorescence (77 °K) avec $k_p = 5 \times 10^3\ s^{-1}$ (15).

Au sujet du processus photochimique qui conduit à l'isomérisation de la molécule, le mécanisme proposé par Chapman et coll. (29) relatif aux tropolones, ferait intervenir l'état triplet. Ceci reste cependant à vérifier dans le cas de la colchicine.

La transition la plus importante demeure le croisement inter-système $S_1 \rightarrow T_1$, ce qui signifie

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

que la plupart des molécules se retrouvent en T_1 après l'absorption d'un photon.

Tous ces processus sont schématisés sur le diagramme de la fig. 3.

En conclusion de cette étude photophysique de la colchicine, on peut affirmer que les résultats concernant le rendement quantique de photoisomérisation viennent corroborer ceux obtenus précédemment sur le rendement de phosphorescence. Ces deux processus primaires sont de loin les plus importants que subit la molécule et on s'aperçoit que la somme des deux rendements approche l'unité.

Nous tenons à exprimer notre gratitude au Conseil national de recherches du Canada ainsi qu'au Conseil de Recherches pour la Défense (# 9530-117) qui ont fourni l'apport financier à notre étude.

The Synthesis of Miserotoxin and Structural Analogs[1]

HANS H. BAER, SHUET-HING LEE CHIU, AND DOUGLAS C. SHIELDS
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received February 21, 1973

The condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide with a variety of nitro alcohols led to nitroalkyl β-D-glucopyranoside tetraacetates. The following nitro alcohols were employed: 3-nitro-1-propanol, 2-nitro-1-propanol, 1-nitro-2-propanol, 2-nitro-1-butanol, 2-nitro-3-pentanol, and 2-methyl-2-nitro-1-propanol. The free 3-nitropropyl and 2-methyl-2-nitropropyl glycosides were obtained from their tetraacetates by deacetylation with sodium methoxide, whereas methanolysis catalyzed by methyl *p*-toluenesulfonate was employed for deacetylation of the other tetraacetates. Evidence for the presence of epimers in glycosides having a chiral center in the aglycon was obtained. Physical data of synthetic 3-nitropropyl β-D-glucopyranoside agreed with those of miserotoxin, the poisonous principle recently isolated from *Astragalus miser* varieties.

La condensation du bromure de tétra-*O*-acétyl-2,3,4,6 α-D-glucopyranosyl avec plusieurs nitro alcools a conduit aux tétraacétates de nitroalcoyl du β-D-glucopyranosides. On a employé les nitro alcools qui suivent: nitro-3 propanol-1, nitro-2 propanol-1, nitro-1 propanol-2, nitro-2 butanol-1, nitro-2 pentanol-3, et méthyl-2 nitro-2 propanol-1. Les nitropropyl-3 et méthyl-2 nitropropyl-2 glycosides libres ont été obtenus à partir de leur tétraacétates par déacétylation par le méthylate de sodium, alors que la méthanolyse catalysée par le *p*-toluènesulfonate de méthyle a été utilisée pour la déacétylation des autres tétraacétates. On a mis en évidence la présence d'épimères dans les glycosides possédant un centre chiral dans l'aglycon. Des données physiques pour le nitropropyl-3 β-D-glucopyranoside sont en accord avec celles de la miserotoxine, l'entité toxique récemment isolée des variétés d'*Astragalus miser*.

Can. J. Chem., 51, 2828 (1973)

Certain varieties of timber milkvetch (*Astragalus miser*), a plant indigenous to the western regions of North America, contain a poison that may cause illness or death in livestock feeding in areas infested with the plant (1–7). The poisonous principle, which has been named miserotoxin, was isolated by Stermitz, Norris, and Williams (8) who adduced spectral and chemical evidence for its structure as 3-nitropropyl β-D-glucopyranoside (**1**). In continuation of our studies (9) on applications of the Koenigs–Knorr reaction to nitro glycoside syntheses, we decided to attempt a synthesis of **1**, which would corroborate the structural assignment of the natural product and, furthermore, we undertook to synthesize a number of β-D-glucopyranosides containing various other nitroalkyl groups as aglycons. It was thought that possession of such structural analogs might be valuable in biochemical and toxicological research bearing on the problem of miserotoxin. It is noteworthy that no simple nitroalkyl glycosides have thus far been reported in the literature, with the exception of 2-nitroethyl β-D-glucopyranoside tetraacetate (10). Attempted deacetylation of this compound led to cleavage of the glycosidic bond.

Condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (α-acetobromoglucose, (**7**)) with 3-nitro-1-propanol in chloroform in the presence of silver oxide afforded crystalline 3-nitropropyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**1***a*) in 46% yield. It is well known and

[1]Presented at the 8th International Symposium on the Chemistry of Natural Products, New Delhi, February, 1972. Miserotoxin was synthesized by D.C.S. (M.Sc. Thesis, University of Ottawa, 1970) and its analogs by S.H.L.C. (Ph.D. Thesis, University of Ottawa, 1971).

generally accepted that the Koenigs–Knorr reaction of **7**, when carried out in the normal manner, results in inversion of the anomeric configuration to give β-D-glucosides (11). The optical rotation and n.m.r. data of **1***a* were in full accord therewith (see Experimental). Deacetylation of **1***a* with sodium methoxide gave in 90% yield analytically pure but amorphous **1**. Its optical rotation and spectral data agreed with this structure and with data recorded (8) for natural miserotoxin.[2] Toxicity tests on chickens showed that synthetic **1** corresponded in its activity to milkvetch extracts.[3]

Next, we synthesized the nitroalkyl β-D-glucopyranosides **2**–**6**, where the 2-nitropropyl, 1-methyl-2-nitroethyl, 2-nitrobutyl, 1-ethyl-2-nitropropyl, and 2-methyl-2-nitropropyl groups served as aglycons. The selection of nitroalcohols to be condensed with α-acetobromoglucose thus represented primary and secondary alcohols as well as primary, secondary, and tertiary nitro compounds. It had to be considered that, with the exception of the tertiary nitro compound **6**, the glycosides to be synthesized would be sensitive towards base, a fact which had to be taken into account in the conduct of operations. Compounds **2**–**5** all are β-nitroalkyl acetals that are capable of anion formation at the nitro group and consequently are prone to eliminative cleavage of the glycoside bond (12, 13; see also later on). Performance of the Koenigs–Knorr condensation by use of the efficient, but strongly basic, condensing agent silver oxide therefore was deemed inadvisable. Silver carbonate appeared less objectionable in this respect, but due to its lower reactivity the condensations, especially those with secondary alcohols, were expected to require more time so that the advantage of reduced basicity was feared to be offset by a prolonged exposure of the product to the agent. In fact, exploratory experiments using either condensing agent proved unsatisfactory. However, good results were obtained when a combination of silver carbonate and silver perchlorate was used, an improved variant in the customary Koenigs–Knorr conditions first recommended by Wolfrom and co-workers (14) and occasionally employed by others (15). Its efficiency is based on the fact that the rate-determining dissociation of the glycosyl halide becomes a homogeneous-phase reaction in the presence of soluble silver perchlorate. Perchloric acid produced upon alcoholysis of intermediary glycosyl perchlorate is then neutralized by silver carbonate, thus regenerating silver perchlorate of which, for this reason, a catalytic amount only is needed (14). Nevertheless, in some of our cases, we observed smoother reaction when a stoichiometric amount was employed. Yields and physical constants of the nitroalkyl β-D-glucopyranoside tetraacetates **2***a*–**6***a* obtained are indicated in Table 1.

The 2-nitropropyl glycoside **2***a* theoretically is capable of existing in two diastereoisomeric forms due to epimerism at the nitromethine carbon. Since racemic 2-nitro-1-propanol was used in the synthesis, the formation of such epimers was expected and, indeed, the crystalline analytical sample (m.p. 135–137°) consisted of two components in approximately equal proportions as was revealed by its n.m.r. spectrum. Thus, the signal of the aglycon methyl group consisted of two doublets, δ 1.46 and 1.60, each having a spacing of 7 Hz. At low field, the signal attributable to the anomeric proton was also a pair of doublets (δ 4.48 and 4.53); each had a spacing of 7.5 Hz which indicated 1,2-diaxial proton orientation and hence the β-configuration for both components. The components were indistinguishable chromatographically, and no attempts at separation were made. Products having somewhat lower melting points (*e.g.*, 125–127°) were obtained in some runs, and these might have differed in epimer ratio. However, the problem was not investigated further in this case.

Similar observations were made in syntheses with 1-nitro-2-propanol. Preparations of 1-methyl-2-nitroethyl β-D-glucopyranoside tetraacetate (**3***a*) varying in their melting points were obtained, and in this instance, a more detailed study was made. From n.m.r. spectra it became evident that mixtures differing in epimer composition had arisen. One such (crystalline) mixture (**3***a*$_1$) was isolated in 35% yield when the condensation of **7** was performed as usual in chloroform solution in the presence of silver car-

[2]One minor discrepancy was in the asymmetric nitro vibration in the i.r., which we observed at ν_{max} 1545 cm^{-1}, that is, in the usual range for nitroalkane groups, whereas Stermitz and coworkers (8) reported ν_{max} 1520 cm^{-1}. The latter value probably is erroneous as it appears too low for a primary aliphatic nitro moiety.

In an attempt to prepare the tetraacetate **1***a* by acetylation of **1** with acetic anhydride and sodium acetate (reaction conditions not stated), the authors (8) obtained a hexaacetyl derivative whose aglycon they formulated as an *N,O*-diacetyl hydroxamic acid. We were unable to prepare such a product from synthetic **1**.

[3]Details to be published elsewhere.

TABLE 1. Nitroalkyl β-D-glucopyranosides

Tetraacetate	m.p. (°C)	$[\alpha]_D$ (in chloroform)	Yield (%) (based on alcohol)	Free glycoside	M.p. (°C)	$[\alpha]_D$ (in methanol)	Yield (%)
1*a*	116	− 4.8	42	**1**		−24.0 (H_2O)	90
2*a*	135–137	−18.4	43	**2**	115–117	−12.3	65
3*a*$_1$	128–129	−14.6	35	**3**		−18.3	56
3*a*$_2$	139–142	−17.2	18				
4*a*	86–88	−18.8	42	**4**	144–145	−22.0	81
5*a*$_1$	125–126	−19.6	50	**5**		−28.6	61
5*a*$_2$	136–139	−21.6	16				
6*a*	158–159	−20.1	40	**6**	141–142	−23.3	81

bonate and a relatively small amount of silver perchlorate. The epimeric components present showed a chemical shift difference in their aglycon methyl signals such that the two doublets overlapped to give a nearly symmetrical triplet (J = 6 Hz). In the region of δ 4.3–4.6 there occurred two quartets assignable to the nitromethyl group protons of two epimeric components, and two nearly coinciding doublets for the anomeric protons. Both of these doublets had a 7.5 Hz spacing, which precludes the contingency of α,β-anomerism. Condensation in the presence of an increased amount of perchlorate under otherwise unchanged conditions led to isolation of **3***a*$_1$ and, in addition, a higher-melting product **3***a*$_2$. The latter was the sole product isolated when the nitro alcohol was allowed to react with silver perchlorate as condensing agent but in the absence of silver carbonate. The yield was low (18%) under these conditions as might be expected in view of the absence of an acid scavenger.[4] The specific rotation of **3***a*$_2$ was very similar to that of **3***a*$_1$, and its n.m.r. spectrum suggested that aglycon epimers were present in a different ratio.

The n.m.r. spectrum of the 2-nitrobutyl glycoside tetraacetate **4***a* (m.p. 86–88°) showed no evidence for the existence of epimers although aglycon epimerism should be possible in this structure, too. However, samples varying somewhat in their melting points were obtained in different runs, and in one instance (which could not be reproduced) a crop melting at 99–103° was isolated; this might be an indication that epimers were present. Perhaps, in the analytical sample a single epimer had crystallized fortuitously, or else it contained epimers which were not differentiated spectroscopically.

With silver perchlorate and silver carbonate, the condensation of 2-methyl-3-pentanol led to a 1-ethyl-2-nitropropyl glycoside tetraacetate **5***a*$_1$ of m.p. 125–126°. Condensation promoted by mercuric cyanide in 1,2-dichloroethane solution was also tried with this alcohol, and a pure glycoside (**5***a*$_2$) of m.p. 136–139° was isolated. The mercuric cyanide method (17) is widely employed in glycoside synthesis (18) although it may entail complications due to incorporation of cyanide in the sugar (19).[5] As a consequence of the presence of two asymmetric centers in the aglycon of **5***a*, four diastereoisomers of this structure could have arisen. The n.m.r. spectra of the products **5***a*$_1$ and **5***a*$_2$ were difficult to analyze, especially since signals of sugar ring protons at C-1 and -6, and aglycon protons at C-1′ and -2′, were crowded together in the δ 4–5 region. However, in both spectra the signals at highest field (δ 0.9 approximately), which were due to the methyl part of the aglycon ethyl group, appeared as double triplets. Similarly, the anomeric proton signal, which at least in **5***a*$_2$ was clearly recognizable at δ 4.47, had the character of two (nearly coinciding) doublets with J = 7.5 Hz. These features suggested that the products were mixtures of diastereoisomeric β-D-glucosides.

No complications from aglycon epimerism were to be expected in the 2-methyl-2-nitropropyl derivative **6***a*. The n.m.r. spectrum of the product was readily interpretable in terms of the assigned structure.

[4]Silver perchlorate in nitromethane solution was introduced by Bredereck *et al.* (16) as a reagent capable of promoting glycosyl substitution on trityl ethers. In that case, insoluble trityl perchlorate is formed instead of perchloric acid, and acidity is not a problem.

[5]An unidentified by-product was present in our crude reaction mixture. When the condensation was carried out under the original Helferich conditions (17), namely in nitromethane as solvent, a substantial amount of what appeared to be an α-glycoside was formed along with **5***a*.

For the reason of alkali lability of the glycosidic bond referred to earlier, the customary de-*O*-acetylation procedure using sodium methoxide could be employed with **6***a* only, to which this limitation does not apply and which readily gave the deacetylated glycoside **6** in high yield. As far as the remaining tetraacetates were concerned, the facile cleavability by methoxide of β-nitroalkyl glycosides, earlier observed in 2-nitroethyl β-D-glucopyranoside (10), was confirmed on the example of **2***a*: deacetylation was accompanied by rapid cleavage of the glycosidic bond so that, after a few minutes, no **2** survived. Consequently, we had to resort to acid-catalyzed deacetylation as we had done in related cases (20) where the problem was deacetylation of hexopyranosides that possessed an activating nitro group at C-6 (*i.e.*, also in β-position to an acetal oxygen atom). The mild conditions of methanolysis in the presence of methyl *p*-toluenesulfonate permitted the removal of the acetyl groups with only a tolerable degree of concurrent transglycosylation. The minor by-product, methyl α-D-glucopyranoside, as well as traces of incompletely deacetylated materials, if present, were separated chromatographically, and the glycosides **2**–**5** were isolated in good yields (Table 1). They had retained the β-configuration as was indicated by spectral and polarimetric data.

No evidence was obtained for the isolated, crystalline product **2** to contain aglycon epimers although its acetate **2***a* had been found to be an epimeric mixture. One must assume either that the n.m.r. spectrum did not reveal epimers although they were present, or that in fact a single species had crystallized. The 1-methyl-2-nitroethyl glycoside **3**, which was obtained as a chromatographically pure syrup, was clearly demonstrated to consist of diastereoisomers. Its high-field signal, centered at δ 1.30 and attributable to the aglycon *C*—CH_3 group, was a pair of overlapping doublets (J = 6.5 Hz in each), and the same was true for the anomeric proton signal near δ 4.4 ($J_{1,2}$ = 7.5 Hz in each). In the spectrum of the crystalline 2-nitrobutyl glycoside **4**, on the other hand, no signal multiplicities that could be ascribed to different epimers were detected, and it is recalled that the tetraacetate **4***a* had appeared uniform also. The deacetylated glycoside **5** was a syrup. Its n.m.r. signal at highest field (centered near δ 1.0), which was assigned to the methyl portion of the aglycon ethyl group, consisted of two overlapping triplets indicating the presence of epimers.

The glycosides **2**–**6** were submitted to toxicological tests in chickens where, in comparison with miserotoxin, **3** and **5** showed similar and **2** and **4** showed enhanced toxicity while **6** had no effect.[3]

Experimental

General Methods

Melting points were taken in capillaries in an electrically heated aluminum block equipped with a calibrated thermometer. Evaporations were carried out under reduced pressure at about 35° (bath temperature). All reactions were monitored by t.l.c. on silica gel G; the spots were made visible by heating the plates sprayed with 1% ceric sulfate in 10% sulfuric acid. For column chromatography, silica gel 7734 (70–325 mesh) of E. Merck AG, Darmstadt, was used. In addition to solvent combinations mentioned in the text, the following systems (volume ratios) were frequently employed for chromatography: A, carbon tetrachloride – ethyl acetate (2:1); B, ethyl acetate – methanol (5:1); C, 10% acetone in benzene; D, 15% acetone in benzene; E, 20% acetone in benzene; F, 10% ethanol in benzene; G, 20% ethanol in benzene; H, 30% ethanol in benzene.

I.r. spectra were routinely taken from all starting materials and reaction products, and were in every respect compatible with the constitutions. All primary and secondary nitro compounds exhibited strong bands at 1550 ± 5 cm^{-1} (asymmetric NO_2 stretching vibration); in the tertiary nitro compounds **6**, **6***a*, and 2-methyl-2-nitro-1-propanol this band occurred at 1535 cm^{-1}.

Optical rotations were measured at room temperature in a Perkin-Elmer 141 automatic polarimeter.

N.m.r. data were obtained on a Varian HA-100 instrument except for those of the starting nitro alcohols which were recorded on a T-60 instrument. Unless otherwise stated, tetramethylsilane was used as internal standard.

Materials

3-Nitro-1-propanol

This compound was obtained in 71% yield from redistilled, commercial 3-bromo-1-propanol (Eastman Kodak Co., Rochester, N.Y.) and silver nitrite in anhydrous ether by the Victor Meyer reaction (21). The n.m.r. data (in $CDCl_3$) of the distilled, colorless liquid: δ 2.23 (2H, quintet); 2.52 (singlet, OH); 3.74 (2H, triplet); 4.53 (2H, triplet).

2-Nitro-1-propanol

This compound was prepared by Henry addition of formaldehyde (37% aqueous solution) to nitroethane in ethanol, in the presence of strongly basic anion exchange resin Amberlite IRA-401(OH^-), essentially according to the procedure of Astle and Abbot (22). The yield of distilled product was 61%. The n.m.r. data (in $CDCl_3$): δ 1.37 (3H, doublet, *C*—CH_3); 3.07 (1H, singlet, exchangeable with D_2O, OH); 3.95 (2H, doublet, O—CH_2—); 4.69 (1H, sextet, —$CH(NO_2)$—).

1-Nitro-2-propanol

This compound was obtained in similar manner from acetaldehyde and nitromethane in 45% yield (22). The

n.m.r. data (in $CDCl_3$); δ 1.35 (3H, doublet, *C*—CH_3); 3.20 (1H, doublet, exchangeable with D_2O, OH); 4.30–4.80 (3H, overlapping multiplets, O_2N—CH_2— and —*CH*(OH)—).

2-Nitro-1-butanol

The commercial product of J. T. Baker Chemical Co. was used after redistillation *in vacuo*.

2-Nitro-3-pentanol

This compound was prepared in 59% yield from propionaldehyde and nitroethane (22). The n.m.r. data (in $CDCl_3$): δ 1.00 (3H, triplet, C-5 methyl group), 1.50–1.70 (5H, overlapping multiplets, C-1 methyl and C-4 methylene groups); 2.90 (1H, broad doublet, exchangeable with D_2O, OH); 3.90 (1H, broad multiplet, C-3 proton); 4.60 (1H, multiplet, C-2 proton).

2-Methyl-2-nitro-1-propanol

Obtained in 24% yield from formaldehyde and 2-nitropropane (22), this nitro alcohol crystallized from benzene in colorless needles, m.p. 87–89.5°. The n.m.r. data (in $CDCl_3$): δ 1.58 (6H, singlet, $C(CH_3)_2$); 2.47 (1H, triplet, exchangeable with D_2O, OH); 3.90 (2H, doublet, collapsing to singlet upon D_2O addition, O—CH_2—).

2,3,4,6-Tetra-O-acetyl-α-D-glucopyranosyl Bromide (7)

The glycosyl halide 7, m.p. 88–89° and $[\alpha]_D$ +198°(*c*, 2, chloroform), was prepared according to the literature (23).

Other Reagents, and General Reaction Conditions

Chloroform used as solvent in Koenigs–Knorr reactions was freed from ethanol and dried shortly before use (24). Reactive silver oxide (25) and silver carbonate (26) were freshly prepared. Anhydrous calcium sulfate (Drierite) was powdered and activated by heating in the oven at 240° for 2 h. Anhydrous silver perchlorate was used as commercially supplied. Although no untoward incidents occurred in this laboratory, a note of caution regarding a potential explosion hazard of this chemical (14) is here repeated. The condensation reactions of **7** with nitro alcohols were carried out at about 25° with vigorous magnetic stirring. The reaction mixture was protected from light and from access of atmospheric moisture. In spite of the use of Drierite as an internal desiccant, a certain amount of **7** inevitably suffered hydrolysis to produce tetra-*O*-acetyl-D-glucose (TAG). The presence of this by-product (which is common in such syntheses) was revealed by the t.l.c. using an authentic sample for comparison. In one case, the identity of TAG was ascertained following its isolation. Similarly, methyl α-D-glucopyranoside, which arose as a side-product in the acid-catalyzed methanolyses of **2***a*–**5***a*, was detected by its mobility on t.l.c. and was identified in one example following its chromatographic isolation.

3-Nitropropyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (1a)

3-Nitropropanol (1.65 g), silver oxide (7.0 g), and Drierite (8 g) were first stirred in chloroform (50 ml) for 30 min under a pure nitrogen atmosphere, and a solution of **7** (5.84 g) in chloroform (30 ml) was then added dropwise during the course of 2 h. Stirring was continued for 1 h. The reaction mixture was filtered through sintered glass, the residue washed well with chloroform, and the filtrate evaporated to yield a pale-yellow oil (7.1 g). The oil, which showed two major spots (the slower one corresponding to TAG) as well as several minor spots on t.l.c. with solvent A, was applied to a silica gel column (500 g). Elution with carbon tetrachloride – ethyl acetate (7:4) and evaporation of the fractions that contained only the faster-moving main product furnished virtually pure **1***a* as a colorless substance (2.86 g, 46%, based on **7**). Crystallization from ethanol gave beautiful leaflets, m.p. 116°, $[\alpha]_D$ −4.8° (*c*, 0.5, chloroform). The n.m.r. data (in $CDCl_3$): δ 1.99, 2.01, 2.06, 2.08 (12H, singlets, *O*-acetyl); 2.26 (2H, quintet, aglycon C-2 methylene); 3.7 and 4.0 (2H and 1H multiplets due to H-5 and aglycon O—CH_2); 4.2 (2H, H-6,6′); 4.46 (2H, symmetric triplet, J = 6.5 Hz, aglycon C-3 methylene); 4.49 (1H, doublet, $J_{1,2}$ = 8 Hz, H-1. The lower-field line nearly coincided with the lower-field line of the nitromethylene triplet, and the higher-field line was 1.5 Hz beside the center line of the latter, as seen at 250 Hz sweep width); δ 5-region (3H, partially overlapping signals with large splittings, H-2, -3, -4).

Anal. Calcd. for $C_{17}H_{25}NO_{12}$ (435.4): C, 46.89; H, 5.79; N, 3.22. Found: C, 46.77; H, 5.93; N, 3.12.

3-Nitropropyl β-D-Glucopyranoside (1)

To **1***a* (1.63 g) in anhydrous methanol (25 ml) was added 0.1 *N* sodium methoxide solution (10 ml). After 5 h at room temperature the solution was deionized with cation exchanges and evaporated to give a slightly yellow gel (1.1 g) which on t.l.c. with solvent B showed one major spot (**1**) and a more slowly moving minor spot. Separation on a silica gel column (100 g) using solvent B furnished pure **1** which failed to crystallize. Upon drying *in vacuo* it was a cream-colored powder (900 mg, 90%); $[\alpha]_D$ −24.0° (*c*, 2, water). Reported for miserotoxin (8), $[\alpha]_D$ −22.0° (water). I.r. bands were at 3350 (broad, OH), 2880 (broad), 1545 and 1380 (strong, asymmetric and symmetric NO_2 vibrations), 1425, 1350, 1160, 1050, 890 cm^{-1}. The n.m.r. spectrum in acetone-d_6 showed at lowest field a 2-proton triplet (δ 4.65, J = 7 Hz) and at highest field (δ 2.27) a 2-proton quintet, which were due to the aglycon C-3 and -2 methylene groups, respectively. Upon addition of D_2O, these signals were slightly shifted (δ 4.68 and 2.32). The DOH peak, which partially obscured the anomeric proton signal, could be displaced downfield by addition of DCl, and the H-1 signal was then revealed as a clear doublet ($J_{1,2}$ = 7.5 Hz) at δ 4.44. The remaining protons all resonated in the range δ 3.1–4.2 and were not amenable to ready analysis. Data (60 MHz) reported for miserotoxin (8) were in essential agreement with those given here.

Anal. Calcd. for $C_9H_{17}NO_8$ (267.2): C, 40.45; H, 6.41; N, 5.24. Found: C, 40.50; H, 6.47; N, 5.25.

2-Nitropropyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (2a)

A mixture of 2-nitro-1-propanol (1.49 g), silver carbonate (3.26 g), silver perchlorate (2.46 g), powdered Drierite (8 g), and chloroform (50 ml) was stirred for 30 min, and solid **7** (8.7 g) was then introduced in 3 portions in 10 min intervals. After 30 min, further quantities of silver carbonate (0.4 g) and silver perchlorate (0.1 g) were added, and after another 30 min an extra amount of **7** (0.8 g) was added. The reaction mixture was worked up 2 h after the introduction of the first portion of **7**. T.l.c. with solvent E indicated the presence of **2***a* (R_f 0.70) and TAG (R_f 0.48) in the pale-yellow syrup (9.85 g) obtained upon evaporation of the solvent. Chromatography as

described for **1***a* but with benzene (100 ml), solvent C (200 ml), and solvent E (1500 ml) as eluants furnished **2***a* (2.65 g, 42.8%) as a syrup that crystallized (m.p. 124–127°) on trituration with absolute ethanol. Recrystallization from absolute ethanol – petroleum ether gave colorless prisms, m.p. 135–137°, $[\alpha]_D$ −18.4° (*c*, 1, chloroform), ν_{max} 1750 and 1550 cm^{-1}. The n.m.r. data (in $CDCl_3$): δ 1.46, 1.50 (3H, two overlapping doublets, J = 7 Hz, aglycon *C*—CH_3); 1.97, 1.99, 1.99, 2.06 (12H, s, *O*-acetyl); 3.7 (1H, m, H-5); 3.85–4.30 (4H, partially overlapping quartets of aglycon *O*—CH_2 and H-6,6′); 4.48, 4.53 (1H, two doublets, J = 7.5 Hz, H-1), 4.75 (1H, broad multiplet, aglycon —$CHNO_2$); δ 5-region (3H, m, H-2, -3, -4).

Anal. Calcd. for $C_{17}H_{25}NO_{12}$ (435.4): C, 46.89; H, 5.79; N, 3.22. Found: C, 47.03; H, 5.97; N, 3.03.

From subsequent fractions the less mobile product was isolated in crystalline form and identified as TAG by its m.p. (129–131°) and n.m.r. spectrum.

2-Nitropropyl β-D-*Glucopyranoside (2)*

Anhydrous methanol (30 ml) containing **2***a* (1.67 g) and freshly distilled methyl *p*-toluenesulfonate (55 mg) was refluxed with exclusion of atmospheric moisture. The progress of methanolysis was monitored by t.l.c. (solvent H), and the reaction was stopped after 29 h when the major product (R_f 0.35) gave a strong spot and the spot of a by-product (R_f 0.25) still was quite faint. (Pilot runs had shown that the latter tends to increase with time.) The syrup (1.15 g) obtained upon solvent evaporation was chromatographed on a silica gel column (60 g) by use of solvent G. Good separation was achieved, the fractions showing the spot of R_f 0.35 yielding a pure syrup of **2** (668 mg, 65%). Crystallization occurred from a minimal volume of dry methanol upon careful addition of ether and prolonged cooling. The rosette-shaped crystals exhibited m.p. 115–117°, $[\alpha]_D$ −12.3° (*c*, 1, methanol). The n.m.r. data (in acetone-d_6 + D_2O): δ 1.49 (3H, doublet, J = 7 Hz, aglycon *C*—CH_3); 3.2–4 (unresolved signals of sugar ring protons and DOH); 4.12 (center of 2H multiplet, aglycon OCH_2); 4.36 (1H, doublet, J = 7.5 Hz, H-1); 4.94 (1H, multiplet, aglycon $CHNO_2$).

Anal. Calcd. for $C_9H_{17}NO_8$ (267.2): C, 40.45; H, 6.41; N, 5.24. Found: C, 40.26; H, 6.58; N, 5.09.

From subsequent fractions of the column the minor product of R_f 0.25 was isolated. It crystallized readily (m.p. 163–165°) and was identified as methyl α-D-glucopyranoside by spectral and polarimetric comparison with an authentic sample.

*1-Methyl-2-nitroethyl 2,3,4,6-Tetra-O-acetyl-*β-D-*glucopyranoside (3a)*

Lower-melting Product (3a₁)

1-Nitro-2-propanol (1.01 g), silver carbonate (1.51 g), silver perchlorate (0.31 g), Drierite (14 g), and chloroform (50 ml) were stirred together for 30 min. A solution of **7** (3.76 g) in chloroform (50 ml) was then added dropwise in the course of 15 min, and another 0.50 g of **7** in chloroform was added after 2 h. The reaction was allowed to proceed for another 2 h. The inorganic material was filtered off and washed with chloroform, and the filtrate was evaporated to give a yellow syrup (4.8 g). Relatively rapid passage of this syrup through a silica gel column (150 g) with solvent E accomplished a partial separation of the nitro glycoside from more slowly moving TAG. The combined fractions containing the glycoside gave a syrup (3.93 g) which was still strongly contaminated by TAG. A second, similar chromatography was therefore performed, and this resulted in isolation of nearly pure **3***a*₁ (1.464 g, 35%) which crystallized on evaporation of the solvent, m.p. 123–129°. The m.p. was 127–128° after one, and 128–129° after a second, recrystallization from 99% ethanol. The melt was always turbid, clearing only above 130°. The specific rotation of the analytical sample was $[\alpha]_D$ −14.6° (*c*, 1, chloroform). The n.m.r. data (in $CDCl_3$): δ 1.27, 1.33 (3H, two doublets with J = 6 Hz (apparent triplet), aglycon *C*—CH_3); 1.96, 1.98, 1.98, 2.06 (12H, singlets, *O*-acetyl); 3.7 (1H, multiplet, H-5); 4.1–4.25 (2H, multiplet, H-6,6′); 4.34, 4.36 (two doublets, J = 7.5 Hz (apparent unsymmetric quartet), H-1; superimposed on broad multiplet of aglycon O—CH); 4.58 (midpoint of two quartets, aglycon CH_2NO_2); δ 5-region (3H, multiplets with large splittings, H-2, -3, -4).

Anal. Calcd. for $C_{17}H_{25}NO_{12}$ (435.4): C, 46.89; H, 5.79; N, 3.22. Found: C, 46.84; H, 5.73; N, 3.40.

A similar experiment was performed with 1-nitro-2-propanol (1.73 g), silver carbonate (3.5 g), silver perchlorate (2.73 g; note the relative increase), Drierite (15 g), and **7** (9.1 g) which was introduced as the solid in 5 portions in the course of 1.5 h. The total reaction time was 5.5 h. Chromatography on a 500-g silica gel column which was eluted with benzene (50 ml) followed by benzene–acetone – ethyl acetate (15:4:1) (1l) furnished a total of 3.78 g (52.7%) crude crystalline **3***a* in four fractions. Recrystallization from absolute ethanol gave 472 mg of **3***a*₂ (m.p. 137–140°; identified by n.m.r., see the next paragraph) from the first fraction and 1.47 g of **3***a*₁ (m.p. 123–130°) from the subsequent fractions (total 27%).

Higher-melting Product (3a₂)

1-Nitro-2-propanol (416 mg), silver perchlorate (810 mg), and Drierite (5 g) were stirred in dry nitromethane (35 ml) for 30 min, and **7** (1.63 g) was then added. After 3 h an additional 300 mg of silver perchlorate was added, and stirring was continued for 1 h. Solvent evaporation from the filtered reaction mixture gave a brown liquid (2.2 g) which was chromatographed on silica gel (115 g) with benzene (100 ml) and solvent E (600 ml). Early effluent fractions (35 ml) contained unreacted nitro alcohol (250 mg). Later fractions showing a single spot on t.l.c. were combined and gave syrupy **3***a*₂ which crystallized on trituration with ethanol. The yield was 307 mg (18%). Recrystallized from ethanol, the product showed m.p. 139–142° and $[\alpha]_D$ −17.2° (*c*, 0.7, chloroform). The n.m.r. data (in $CDCl_3$): similar to those of **3***a*₁ except that the aglycon *C*—CH_3 signal appeared as a strong doublet at δ 1.33 superimposed by a weak doublet at δ 1.27; furthermore, the multiplets in the δ 4.1–4.7 region contained fewer but broadened peaks.

Anal. Calcd. for $C_{17}H_{25}NO_{12}$ (435.4): C, 46.89; H, 5.79; N, 3.22. Found: C, 46.78; H, 5.78; N, 3.29.

1-Methyl-2-nitroethyl β-D-*Glucopyranoside (3)*

The tetraacetate **3***a*₁ (1.90 g) was refluxed for 20 h in anhydrous methanol (45 ml) containing methyl *p*-toluenesulfonate (65 mg). The reaction mixture was revealed by t.l.c. (solvent G) to contain a major product (R_f 0.35) as well as minor products that migrated faster (presumably incompletely deacetylated compounds) and more slowly (presumably methyl glucoside). Chromatographically

pure but syrupy **3** (0.49 g) was isolated by fractionation on a silica gel column (30 g) using solvents F, G, and H. Incompletely deacetylated material collected from fore-fractions was subjected to a second, similar methanolysis followed by chromatography, to give another crop of **3** (0.16 g). Thus, the total yield was 0.65 g (56%). The colorless syrup, $[\alpha]_D$ −18.3° (*c*, 1.1, methanol), could not be induced to crystallize. The n.m.r. data (in acetone-d_6): δ 1.3 (3H, overlapping doublets, J = 6.5 Hz, aglycon *C*—CH_3); 4.41, 4.44 (1H, two doublets, J = 7.5 Hz, H-1); 4.60 (2H, multiplet, aglycon CH_2NO_2).

Anal. Calcd. for $C_9H_{17}NO_8$ (267.2); C, 40.45; H, 6.41. Found: C, 40.84, H, 6.39.

2-Nitrobutyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (4a)

2-Nitro-1-butanol (1.15 g), silver carbonate (3.68 g), silver perchlorate (2.82 g), and Drierite (8 g) in chloroform (50 ml) were allowed to react with **7** (5.75 g) which was added in three portions in the course of 20 min. Stirring was then continued for another 90 min. The colorless oil (6.2 g) obtained on work-up was chromatographed on silica gel (250 g) by elution with benzene (100 ml) followed by benzene containing 8% acetone (100 ml), solvents C and D (100 ml each), and solvent E (500 ml). The fractions showing a single spot of the fastest moving product were combined and gave colorless **4***a* which solidified on trituration with absolute ethanol; yield, 1.852 g (42.6%). An analytical sample was recrystallized from ethanol, m.p. 86–88°, $[\alpha]_D$ −18.8° (*c*, 1.06, chloroform). The n.m.r. data (in $CDCl_3$): δ 0.97 (3H, triplet, J = 7 Hz, aglycon *C*—CH_3); 1.70 (2H, multiplet, aglycon C—CH_2—C); 1.97, 1.98, 2.02, 2.07 (12H, s, *O*-acetyl); 3.7 (1H, multiplet, H-5); 3.8–4.3 (4H, multiplets, aglycon *O*—CH_2 and H-6,6′); *ca.* 4.4 (1H, multiplet, aglycon $CHNO_2$); 4.53 (1H, doublet, J = 7.5 Hz, H-1); δ 5-region (3H, multiplets, H-2, -3, -4).

Anal. Calcd. for $C_{18}H_{27}NO_{12}$ (449.4): C, 48.10; H, 6.06; N, 3.12. Found: C, 48.05; H, 5.90; N, 3.04.

2-Nitrobutyl β-D-Glucopyranoside (4)

The tetraacetate **4***a* (1.30 g) was refluxed for 24 h in methanol (26 ml) containing methyl *p*-toluenesulfonate (52 mg). The solution, which then showed one major spot (R_f 0.35, compound **4**) and a faint spot (R_f 0.28 methyl glucoside) on t.l.c. with solvent H, was evaporated to give a colorless syrup. Purification of the syrup on a column of silica gel (80 g) by sequential elution with benzene (50 ml) and benzene containing increasing proportions (8–20%) of ethanol furnished chromatographically pure, partially crystalline **4** (660 mg, 81%). Recrystallization from a minimum volume of anhydrous methanol with addition of a few drops of ethyl acetate and ether gave colorless crystals of m.p. 130–132°, raised to 144–145° by further recrystallization; $[\alpha]_D$ −22° (*c*, 0.33, water). The n.m.r. data (in acetone-d_6 + D_2O): δ 0.91 (3H, triplet, aglycon *C*—CH_3); 1.86 (2H, quintet, aglycon C—CH_2—C); 4.1 (2H, multiplet, aglycon *O*—CH_2); 4.36 (1H, doublet J = 7.5 Hz, H-1); 4.80 (1H, multiplet, aglycon $CHNO_2$). The ring proton signals in the δ 3–4 region were not resolved.

Anal. Calcd. for $C_{10}H_{19}NO_8$ (281.3): C, 42.70; H, 6.81; N, 4.98. Found: C, 42.81; H, 6.63; N, 4.94.

1-Ethyl-2-nitropropyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (5a)

Lower-melting Product (5a$_1$)

2-Nitro-3-pentanol (2.03 g), silver carbonate (3.04 g), silver perchlorate (4.55 g), and Drierite (12 g) in chloroform (150 ml) were allowed to react with **7** (9.76 g) which was added to the mixture in 3 portions in 15 min intervals. After the addition, stirring was continued for 1 h. Work-up gave a pale-yellow oil (11 g) which was chromatographed on silica gel (500 g) using benzene (100 ml) and solvent G (1.6 l) as eluants. The fractions that showed a single spot (R_f 0.7) on t.l.c. were combined (250 ml) and afforded a pure syrup of **5***a*$_1$ that crystallized partially on drying (3.5 g, 50%). Additional nitro glycoside was contained along with TAG in subsequent fractions. Upon recrystallization from ethanol, **5***a*$_1$ melted at 125–126° and showed $[\alpha]_D$ −19.6° (*c*, 1, chloroform). The n.m.r. data (in $CDCl_3$): δ 0.92, 0.96 (3H, two overlapping triplets, J = 7 Hz, CH_3 of aglycon ethyl group); δ 1.5-region (5H, multiplet, CH_3 of aglycon nitropropyl and CH_2 of ethyl groups); 1.96–2.06 (12H, *O*-acetyl signals); 3.7 (1H, multiplet, H-5); 4.0–4.7 (5H, poorly resolved signals due to aglycon *O*—CH, H-6,6′ (δ 4.18), aglycon $CHNO_2$, H-1); δ 5-region (3H, multiplets, H-2, -3, -4).

Anal. Calcd. for $C_{19}H_{29}NO_{12}$ (463.4): C, 49.24; H, 6.31; N, 3.02. Found: C, 49.02; H, 6.20; N, 3.10.

Higher-melting Product (5a$_2$)

A mixture of 2-nitro-3-pentanol (0.55 g), powdered mercuric cyanide (2.07 g), Drierite (3 g), and **7** (3.38 g) in 1,2-dichloroethane (40 ml; dried by distillation from P_2O_5) was vigorously stirred for 30 h. The vessel was periodically flushed with nitrogen to remove accumulated hydrogen cyanide. The reaction mixture exhibited three spots on t.l.c. (benzene – ethyl acetate – ethanol, 15:4:1); the fastest and strongest spot (R_f 0.8) corresponded to **5***a*$_2$, the slowest to TAG, and the middle spot was not identified. The solution was diluted with chloroform and washed three times with water. The organic phase was dried (Na_2SO_4) and evaporated to give a yellow liquid (3.42 g). Column chromatography on silica gel (130 g) with the above solvent system, and rechromatography of mixed fractions on a smaller column, afforded about 0.80 g (42%) of nitro glycoside as a chromatographically uniform syrup of which 0.3 g crystallized from ethanol, m.p. 133–139°. An analytical sample was recrystallized from ethanol and then melted at 136–139°, the turbid melt clearing at 142°. $[\alpha]_D$ −21.6° (*c*, 1.2, chloroform). The i.r. spectrum was nearly identical with that of **5***a*$_1$. The n.m.r. data in $CDCl_3$ were very similar to those of **5***a*$_1$, with a pair of triplets at δ 0.92 and 0.95; *O*-acetyl signals at 1.95, 1.98, 2.02, and 2.03; and the H-1 signal as two nearly coinciding doublets centered at δ 4.47.

Anal. Calcd. for $C_{19}H_{29}NO_{12}$ (463.4): C, 49.24; H, 6.31; N, 3.02. Found: C, 49.08; H, 6.14; N, 3.28.

1-Ethyl-2-nitropropyl β-D-Glucopyranoside (5)

The tetraacetate **5***a*$_1$ (1.46 g) was refluxed for 45 h in methanol (30 ml) containing methyl *p*-toluenesulfonate (45 mg). The presence of one major spot (R_f 0.4) and 3 faint spots (R_f 0.7, 0.5, and 0.15) was then indicated by t.l.c. (solvent G). Upon removal of the methanol, the material was chromatographed on silica gel (60 g) with

solvent G. The fractions containing only main product, or main product contaminated by the less mobile by-product (methyl glucoside), were combined and rechromatographed in the same way. This resulted in isolation of **5** as a pure syrup (565 mg, 61%), $[\alpha]_D$ −28.6° (*c*, 1.9, methanol). The n.m.r. data (in acetone-d_6): δ 1.0 (3H, overlapping triplets, aglycon CH_3 of ethyl group); 1.4–1.7 (5H, multiplets, CH_3 of aglycon nitropropyl and CH_2 of ethyl groups); 4.8 (1H, multiplet, aglycon $CHNO_2$). The remaining protons resonated from δ 2.85–4.50 and their signals were not resolved.

Anal. Calcd. for $C_{11}H_{21}NO_8$ (295.3): C, 44.74; H, 7.17. Found: C, 44.51; H, 7.39.

2-Methyl-2-nitropropyl 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranoside (6a)

2-Methyl-2-nitro-1-propanol (2.38 g), silver carbonate (13.65 g), silver perchlorate (1.00 g), Drierite (20 g), and **7** (15.4 g) were stirred in chloroform (100 ml) for 15 h, with half of **7** being admitted 30 min after the start. The filtered reaction solution and chloroform washing of the inorganic residue were evaporated to give a yellow oil (14.6 g) which for chromatographic purification was divided in two parts. Each part was applied to a 500 g silica gel column to be eluted with solvent D. The fractions containing a single product spot (R_f 0.55 on t.l.c. with the same solvent system), or the same together with a trace of impurity (R_f 0.35; TAG), furnished syrups (total 4.85 g) from which crops of chromatographically pure prisms totalling 3.60 g (40%) were obtained upon trituration with 99% ethanol; m.p. 153–157°. A recrystallized sample showed m.p. 158–159° and $[\alpha]_D$ −20.1° (*c*, 1, chloroform). The n.m.r. data (in $CDCl_3$): δ 1.50, 1.56 (two 3H singlets, aglycon CH_3 groups); 1.96, 1.98, 1.98, 2.06 (12H, singlets, *O*-acetyl); 3.7 (1H, multiplet, H-5); 3.98 (2H, singlet, aglycon *O*—CH_2); 4.20 (2H, multiplet, H-6,6′); 4.49 (1H, doublet, J = 7.5 Hz, H-1); δ 5-region (3H, overlapping multiplets, H-2, -3, -4).

Anal. Calcd. for $C_{18}H_{27}NO_{12}$ (449.4): C, 48.10; H, 6.06; N, 3.12. Found: C, 48.03; H, 5.98; N, 3.30.

2-Methyl-2-nitropropyl β-D-Glucopyranoside (6)

To a vigorously stirred suspension of **6a** (1.00 g) in anhydrous methanol (12 ml) was added 3.5 ml of a sodium methoxide solution (containing 17.5 mg of Na). The suspension cleared within 5 min and, after 20 min, was deionized with cation exchanger and evaporated. The white residue (0.60 g, 96%) gave a single spot on t.l.c. (solvent G). By recrystallization from methanol–benzene–ether mixture, large colorless prisms of **6** (509 mg, 81%) were obtained; m.p. 141–142°, $[\alpha]_D$ −23.3° (*c*, 1.1, methanol). The n.m.r. spectrum (in D_2O, with acetone as lock signal): upfield, 0.60 (6H, singlet, aglycon CH_3 groups); downfield, 1.90 (midpoint of AB quartet, 2H, aglycon *O*—CH_2); 2.20 p.p.m. (1H, doublet, J = 7.5 Hz, H-1). The ring proton signals (0.9–1.7 p.p.m. downfield) were poorly resolved.

Anal. Calcd. for $C_{10}H_{19}NO_8$ (281.3): C, 42.70; H, 6.81; N, 4.98. Found: C, 42.89; H, 6.80; N, 5.10.

A Study on the Kinetically Controlled Cyclization of 6-Deoxy-3-*O*-methyl-6-nitro-D-glucose and -L-idose, and the Preparation of Optically Active Nitroinositol Derivatives[1]

JAN KOVÁŘ AND HANS H. BAER

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received March 12, 1973

The cyclization (internal Henry addition) of 6-deoxy-3-*O*-methyl-6-nitro-D-glucose (**1**) and -L-idose (**2**) was investigated with respect to the sequence in which stereoisomeric deoxynitroinositol methyl ethers are formed from each. It was found that, under conditions of kinetic control, the primary products generated from **1** are the nitronate **4'** (that corresponds to the epimeric deoxynitroinositols **4** and **5** having the *epi*-3 and *muco*-3 configurations, respectively) and the nitronate L-**6'** of optically active 1-deoxy-4-*O*-methyl-1-nitro-L-*myo*-inositol (L-**6**). They are formed in approximately equal proportions. Ensuing thermodynamically controlled processes lead to racemization of L-**6** and formation of the *scyllo* isomer **3** at a relatively slow rate. The cyclization of **2**, found to be faster than that of **1**, gave as primary products the enantiomeric nitronate D-**6'** and the nitronate **3'** in a ratio of about 4:1. The nitronate **4'** arose by subsequent epimerization. The optically active compounds D-**6** and L-**6** were isolated in pure, crystalline form.

La cyclisation (addition interne selon Henry) du déoxy-6 *O*-méthyl-3 nitro-6 D-glucose (**1**) et -L-idose (**2**) a été étudiée plus particulièrement du point de vue de la formation d'éthers méthyliques de déoxynitroinositols stéréoisomèrs à partir de chacun d'eux. Il a été prouvé que, dans des conditions de contrôle cinétique, les produits principaux obtenus à partir de **1** sont le nitronate **4'** (qui correspond aux déoxynitroinositols épimères **4** et **5** ayant les configurations *épi*-3 et *muco*-3, respectivement) et le nitronate L-**6'** du déoxy-1 *O*-méthyl-4 nitro-1 L-*myo*-inositol (L-**6**) optiquement actif. Ceux-ci sont formés dans des proportions approximativement égales. Le processus contrôlé thermodynamiquement qui suit, a conduit à la racémisation de L-**6** et à la formation de l'isomère *scyllo* **3** avec une vitesse relativement lente. La cyclisation de **2**, plus rapide que celle de **1**, a conduit, comme produits principaux, au nitronate énantiomère D-**6'** et au nitronate **3'** dans des proportions 4:1. Le nitronate **4'** est obtenu par épimérisation subséquente. Les composés optiquement actifs D-**6** et L-**6** ont été isolés pure, sous forme cristalline.

Can. J. Chem., **51**, 2836 (1973)

In the preceding article of this series (1) we described the synthesis of 6-deoxy-3-*O*-methyl-6-nitro-D-glucose (**1**) and -L-idose (**2**), and the cyclization of these sugars to deoxynitroinositol monomethyl ethers. Four crystalline cyclization products were obtained in that preparative work. They were three meso compounds, namely, 1-deoxy-4-*O*-methyl-1-nitro-*scyllo*-inositol (**3**), 3-deoxy-6-*O*-methyl-3-nitro-*epi*-inositol (**4**), and 3-deoxy-6-*O*-methyl-3-nitro-*muco*-inositol (**5**), and one racemic compound, 1-deoxy-4-*O*-methyl-1-nitro-DL-*myo*-inositol (DL-**6**). The results conformed to a fair degree to those recorded by Grosheintz and Fischer (2) for the cyclization of the analogous, nonmethylated nitro hexoses. There were, however, certain apparent incongruities calling for an explanation, and some questions regarding the stereochemical course of these reactions remained open, so that a more detailed investigation seemed indicated. Thus, we obtained different yields of four individual stereoisomers depending on whether pure **1** or mixtures of **1** and **2** served as starting materials,[2] whereas the earlier authors (2) had obtained, under a given set of conditions, identical mixtures of three (nonmethylated) deoxynitroinositols regardless of the configuration (D-*gluco* or L-*ido*) of the nitro hexose employed.[3] Evidently, thermodynamic equilibration of stereoisomers took place in the course of their operations. This was supported by experiments performed by the authors themselves (2) and later by Lichtenthaler (4), demonstrating that the three individual deoxynitroinositols do indeed epimerize readily in the presence of alkali; each of

[1]Cyclizations of dialdehydes with nitromethane. XVI. For part XV in this series see ref. 1.

[2]Pure **2** was not available (1).

[3]The products were later shown to possess the *scyllo*, DL-*myo*-1, and *muco*-3 configurations (3, 4). The *epi*-3 isomer corresponding to **4** was not encountered.

the compounds appeared to give a similar mixture of the *scyllo* and DL-*myo*-1 isomers. It was subsequently found (5) that 6-deoxy-6-nitro-D-glucose and -L-idose differ in the rates at which they cyclize at given p*H* values. This observation would seem to preclude significant epimerization at C-5 in the nitro hexoses themselves prior to cyclization, and one might infer that different kinetic products should be obtainable from the two sugars provided that subsequent epimerization on the inositol stage is slow enough. However, no attempts have thus far been made to determine whether this proviso does hold, and if so, what is the precise composition of the kinetically favored products arising from individual 6-nitro hexoses and what are the conditions best suited for isolation of such products. We herein report the results of an examination of these questions as regards the cyclization of the 3-*O*-methyl sugars **1** and **2**, and we expect to discuss the thermodynamically controlled epimerization of the products in a subsequent paper (6).

Methods

In order to identify, and possibly isolate, primary cyclization products arising from the nitro hexoses **1** and **2** it was necessary to provide conditions that were mild enough to minimize epimerization yet sufficiently effective to ensure reasonable reaction times. It was found that the course of the cyclization could be conveniently monitored when it was performed at 0° in aqueous barium hydroxide solution, with either an approximately equivalent amount (1.1 equiv) or a catalytic amount (0.1 equiv) of base present. The former conditions, resulting initially in a reaction medium of about p*H* 12, and the latter ones, where the p*H* was near 7, produced comparable inositol mixtures from a given sugar although, naturally, the reaction was faster in the strongly alkaline medium. The weakly basic conditions were advantageous for the isolation of kinetic products.

Analysis of the reaction mixtures at specified time intervals was performed by deionization followed by trimethylsilylation and v.p.c. of the products. To this end, compounds **1**–**6** were first trimethylsilylated and chromatographed singly and also as mixtures of known composition, and retention times (Table 1) and detector responses were determined. It was ascertained that the procedure gave reproducible results, reliably reflecting the composition of mixtures with sufficient accuracy (see Experimental). The crystalline β-anomer of **1** gave a main peak accompanied by a minor peak that was attributable to an admixture of the α-anomer. (The latter may have been present before, or arisen during, trimethylsilylation.) Brief exposure of the β-anomer to the weakly alkaline conditions referred to earlier (p*H* ~ 7) resulted in formation of these two peaks in approximately equal strength, due to anomeric equilibration, before any nitroinositol peaks were generated. The syrupy mixture of **1** and **2** gave rise to both of the peaks mentioned, and to two peaks attributed to anomers of the L-*ido* isomer **2**. The *scyllo* nitroinositol **3** produced a single peak requiring no further comment. The *epi*-3 and *muco*-3 isomers (**4** and **5**) gave one and the same peak upon trimethylsilylation and therefore could not be distinguished by this method. However, this fact was of no consequence for the present work since they both are derived from the same nitronate. Nitronates are the actual primary products in the cyclization, and the peak corresponding to **4** and (or) **5** could thus be taken as a direct measure for their common nitronate.[4] The DL-*myo*-1 isomer DL-**6** produced a strong peak that was always accompanied by a minor peak of 1/10 its intensity. In mixtures

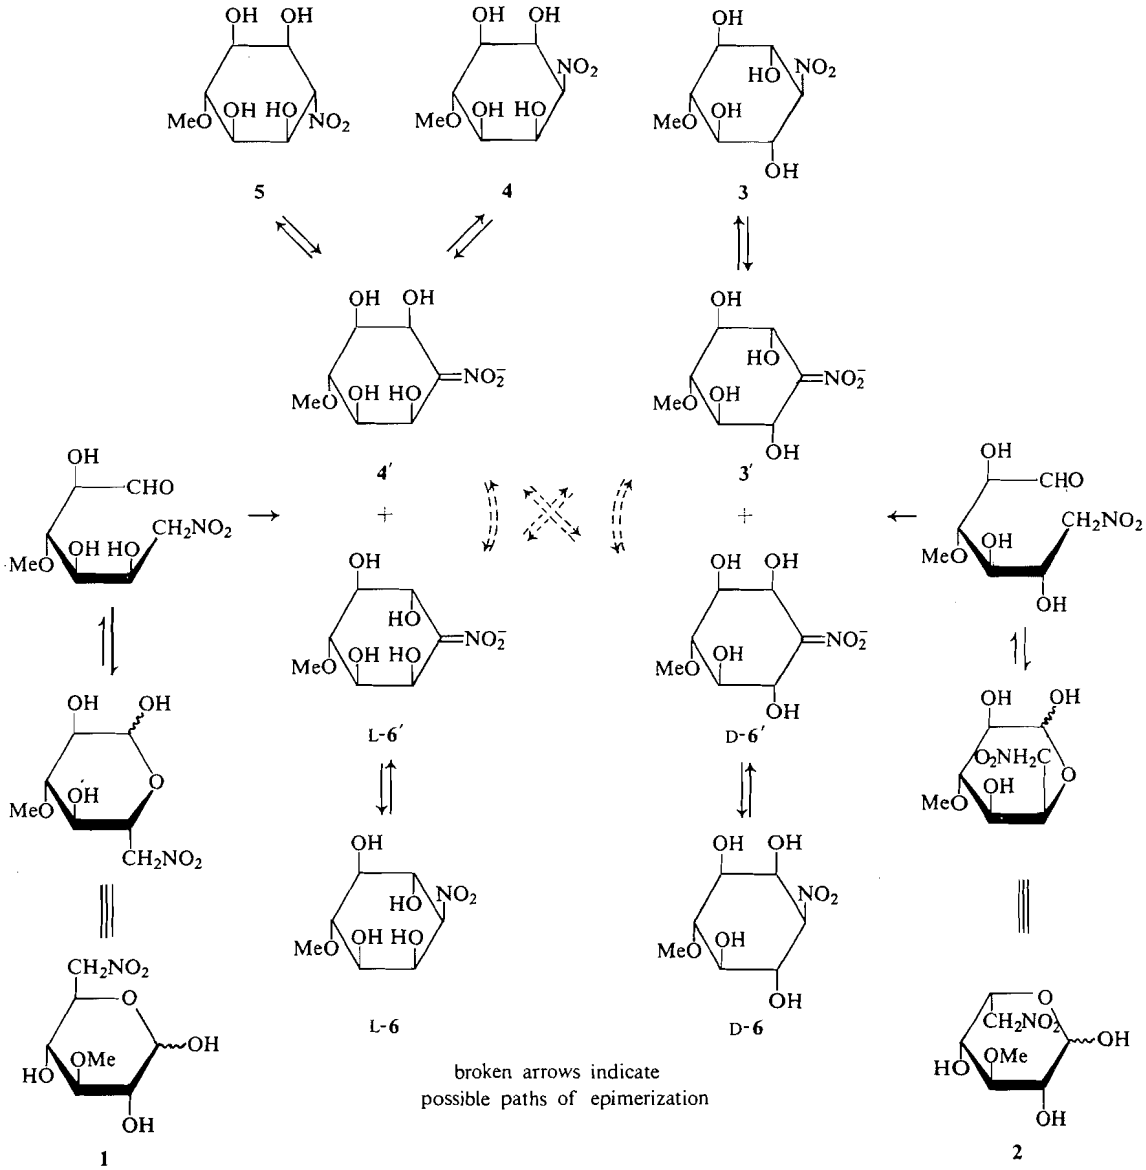
[4]In fact, if **4** and **5** had given separate peaks it would have been necessary to use the sum of these for the purpose at hand. Whether the trimethylsilyl derivatives fortuitously have an identical retention time or whether one of the isomers was converted into the other in the process cannot be stated. However it is recalled that **4**, upon acetonation, yielded the di-*O*-isopropylidene derivative of **5** (1).



of various kinds this minor peak was never seen unless the main peak corresponding to **6** was present also, and although its significance remained obscure it was considered to originate in some way from **6**; the sum of the two peaks was therefore taken as representing the proportion of this isomer. One difficulty to be faced in assays of mixtures containing both **2** and **6** was the fact that the major peak of **6** coincided with that of the lesser anomer of **2**. It will be seen in the discussion of results that this circumstance was relevant only to a few measurements and did not impair interpretations.

Results and Discussion

In the aldol-type addition reaction between a primary nitroalkane and an aldehyde, the nitro alcohol produced arises as its nitronate salt in the first instance. In the case of the cyclization of any given 6-deoxy-6-nitrohexose one can expect the formation of two diastereoisomeric deoxynitroinositol salts due to the creation of a new

chiral center at the carbon atom that was formerly C-1 in the hexose.[5] Thus, the D-*gluco* derivative **1** should give the nitronate **4′** (= **5′**), the salt common to the *epi*-3 (**4**) and *muco*-3 (**5**) nitroinositol derivatives, and secondly the nitronate L-**6′**, the salt of the L-*myo*-1 isomer L-**6**. The L-*ido* hexose **2** should form the nitronate **3′** derived from the *scyllo* isomer **3**, and the nitronate D-**6′** belonging to the D-*myo*-1 isomer D-**6**. If, under the prevailing reaction conditions, epimerization should occur at C-5 of the starting hexose before, during, or after the cyclization, all four nitronates would be formed from either hexose, with D-**6′** and L-**6′** emerging as the racemate. This is what has been observed in preparative work with these particular compounds (1) and their nonmethylated analogs (2, 4).

Table 2 summarizes the progress of the cyclization of **1** at 0°. It is seen that in the presence of a slight excess of base (A) the sugar anomerizes practically at once and disappears within 1 h. During this period of time two nitronates arise in a ratio of approximately 1:1, with the ratio remaining constant for about 1 day. Similarly, in the presence of a catalytic amount of base (B) there occurs instant anomerization followed by gradual disappearance of **1** with concomitant formation of the two nitro compounds in similar proportions, although the reaction expectedly is slower and complete consumption of **1** requires more than a day. V.p.c. of the products confirmed that one of the

[5]The reaction proceeds through the open-chain form of the sugar, in which C-1 is achiral, and the anomeric configuration of the cyclic form is therefore irrelevant.

[a]–[d]See footnotes to Table 2.

[e]At this time a strong deposit had occurred in the reaction mixture, and the aliquot that was withdrawn for analysis was a suspension of the solid in the supernatant.

[f]The values given in this column refer to the main anomer of 2. The minor anomer, whose percentage would have to be added for an estimate of the total proportion of 2 present, is chromatographically indistinguishable from 6 (see Table 1 and text) and is represented by (decreasing) fractions of the values listed for the latter. The starting material analyzed as follows: 1-β, 27%, 1-α, 7%, 2 (main peak), 54%, 2 (minor peak), 12%; α_{365} +0.050°.

[g]It follows from [f] that for the first hour or two, *i.e.* so long as there is still a large amount of 2 present, the actual proportion of 6 is represented by (increasing) fractions of the values in this column.

nitronates was **4′** and the other **6′**. Since the solution had retained optical activity at the time of complete disappearance of **1**, one of the enantiomers of **6** must have been present predominantly if not exclusively. Owing to its origin from the D-*gluco* compound **1** it must have been the enantiomer L-**6**. Further inspection of Table 2 shows that a third nitronate (**3′**) arises very slowly and only after the cyclization of **1** is complete. Consequently, **3′** cannot be a primary product but owes its formation to epimerization of **6′**.

In summary, then, the results discussed thus far prove clearly that the products of kinetic control in the cyclization of **1** are the nitronates **4′** and L-**6′** (with no significant preference for either), that cyclization is much faster than epimerization, and that epimerization leads relatively rapidly to racemic DL-**6′** and more slowly to **3′**. The ultimate thermodynamic equilibrium, which is not recorded in Table 2, will be the subject of a later communication (6).[6]

A like set of experiments was performed with a 2:1 mixture[2] of **2** and **1**. Naturally the data (Table 3) presented a more complex picture, but they nevertheless confirmed the results disclosed

[6]The reader will note in Table 2, B that the reaction was not monitored until equilibrium was reached, as the last entry shows optical activity still persisting. In the experiment recorded in Table 2, A, the p*H* value of the solution was found to decrease after some time (see the last three entries). It is to be discussed (6) in what way the p*H* influences the nitronate distribution at equilibrium.

above and revealed the behavior of **2**. First of all, it is seen that **2** cyclizes more rapidly than **1**. In the presence of excess base (Table 3, A), all of **2** was consumed after 1.6 min while nearly half of **1** remained at that time, in accordance with the data of Table 2, A. The nitronate **3′** was present at that time as one of the primary products expected to arise from **2**, and so was the nitronate **4′** that stemmed from **1**. The preponderant product at this point, however, was the nitronate **6′**. It must have contained the L-enantiomer (from **1**) and the D-enantiomer (from **2**), with the latter predominating because of the given ratio and observed relative reaction speeds of the precursors. That this was true was demonstrated by the dextrorotation that was recorded when a comparable point in the experiment listed in Table 3, B was reached (1 day). It is to be noted that **1**, which constituted 20% of the mixture at that point, is levorotatory (1) whereas D-**6** is dextrorotatory as was ascertained later on. A maximum of positive rotation is reached when all of **2** (also dextrorotatory but less strongly so than D-**6**) has reacted, and from then on the rotation decreases due to production of L-**6** by cyclization of **1** and, concurrently but more slowly, by racemization of D-**6′**. Further analysis of the data in Table 3, A and B, reveals that four times as much D-**6′** as **3′** is generated from **2** in the cyclization step, which contrasts with the 1:1 ratio of kinetic products arising from **1** (Table 2). With time progressing, the amount of **4′** in the mixture is seen to increase slowly at the expense of **6′** (Table 3, A), which must be ascribed to thermodynamically controlled epimerization.

An interesting difference exists in the behavior of **1** in the two sets of reaction conditions of Table 3. Under the strongly basic conditions (A), **1** begins to cyclize immediately albeit more slowly than **2**. In the absence of a stoichiometric amount of base (B), **1** does not appear to react appreciably until most of **2** is consumed after several hours. About half of **1** was still left after 24 h whereas in the cyclization of pure **1** (Table 2, B) the proportion surviving that period amounted to 13% only. The phenomenon may perhaps be explained by assuming that a greater nitromethylene acidity of **2** results in setting up buffer conditions which delay the cyclization of **1**.

In conclusion it can be stated that the products of kinetic control in the cyclization of **2** are the nitronates **3′** and D-**6′** (with the latter being favored about fourfold), and that **4′** is formed by ensuing epimerization. The reaction of **2** was found to be faster than that of **1** under both sets of conditions which were employed. A difference in nitromethylene acidity might partly be responsible for this. However, another factor is probably also important in this regard, namely, the conformational instability of idopyranose derivatives which facilitates reactions that require mutual approach of C-1 and -6. The same explanation has been suggested previously for the marked difference in rate of cyclization of 6-deoxy-6-nitro-D-glucose and -L-idose in the p*H* range 5–7 (5).

On the basis of the above results we were able to elaborate conditions under which maximum accumulation of kinetic products was obtained, and we succeeded in isolating the optically active L-*myo*-1 derivative L-**6** from the reaction mixture of **1**. A crystalline, crude product of 80% purity was obtained in 54% yield, and recrystallization furnished the optically pure enantiomer in 33% yield. The *muco*-3 isomer **5** was isolated in 28% yield from the mother liquor; it corresponded to the second kinetic nitronate (**4′**) produced in this reaction. The D-*myo*-1 enantiomer D-**6** was isolated in optically pure form in a yield of 19% upon cyclization of the mixture of **1** and **2**. Considering that the starting mixture contained only 60–65% of **2**, the yield of D-**6** based on **2** corresponded to about 30%.

Experimental

The preparation of the nitro sugars **1** and **2** and of the nitro inositol derivatives **3**, **4**, **5**, and DL-**6** has been described (1); the crystalline β-anomer of **1** and a syrupy mixture containing 60–65% of **2** were used for the present work. Optical rotations were measured in a 1 dm tube in a Perkin-Elmer 141 automatic polarimeter using a mercury lamp as the light source. V.p.c. was performed in a Varian Aerograph, Series 1200, with a hydrogen flame detector and a recorder equipped with a 224 Disc. Mod. integrator. The aluminum column (length, 5 ft; diameter, $\frac{1}{8}$ in.) was packed with 10% Carbowax 20M on Chromosorb W and was operated isothermally at 155–165°. The carrier gas was helium applied at a pressure of 80–90 p.s.i.

Analytical Procedure

The relative retention times (Table 1) and detector response values for the trimethylsilyl derivatives of **1–6** were determined as follows (7). The reagent for trimethylsilylation was prepared by mixing dry pyridine (2 ml), hexamethyldisilazane (1.8 ml), and trifluoroacetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

acid (0.2 ml). The reagent could be stored in a refrigerator for several weeks without deteriorating. An accurately weighed test sample (6.0 mg) was dissolved in 0.30 ml of the reagent by brief shaking, and the solution was then allowed to stand overnight at room temperature before 2–3 μl of it was injected into the chromatograph by means of a microsyringe. The solution was kept in a tightly stoppered vial in a refrigerator for later repeat analyses. Various test mixtures of known composition were assayed several times each, and the percentage values found deviated from the mean values no more than 2–3% and often less. The main peak of compound DL-**6** served as the retention time standard (1.00); its actual retention time under the conditions employed was approximately 10 min. As standard for calculating detector response values, the sum of the main and minor peaks given by DL-**6** was used. (see Discussion).

Cyclizations

A sample (100–200 mg) of the nitro hexose (mol. wt. 223) was dissolved in 0.0025 *N* acetic acid (0.45–0.9 ml) so that an *M* solution was obtained. (The purpose of the acid was to guard against premature commencement of cyclization, especially of **2**; compare ref. 5). The solution was cooled to 0°, and the calculated amount of 0.485 *N* barium hydroxide solution that would provide 1.1 equiv of base was added in the experiments of sections A, Tables 2 and 3. For example, 205.2 mg of **1** dissolved in 0.92 ml of said acid was rendered alkaline by the addition of 2.09 ml of hydroxide solution. For the experiments referred to in sections B of Tables 2 and 3, a 0.053 *N* barium hydroxide solution was used so as to provide 0.1 equiv of base. Samples of 0.10 ml were withdrawn from the reaction mixture at time intervals as stated (Tables 2 and 3), and the reaction was quenched by introducing the sample into 0.1 *N* acetic acid (1.0 ml). The solution was then passed through a bed (0.3 ml) of Dowex-1X2 (acetate form) and thereafter through a bed (0.6 ml) of Rexyn-101 (H^+) contained in a small column (disposable pipette) which was subsequently eluted with water (1.5–2.0 ml). The column could be re-used several times, after washing with more water. In cases where the optical rotation of the product was to be determined, the effluent volume was adjusted to 2.5 ml and the measurement was made in a 1 dm tube. The solution was then evaporated to dryness, and the residue was further dried in an oil pump vacuum at room temperature. It was subjected to trimethylsilylation and v.p.c. as described above.

*1-Deoxy-4-O-methyl-1-nitro-*L*-myo-inositol (*L*-**6**)*

A suspension of the crystalline nitro sugar **1** (583 mg, 2.61 mmol) in 0.0025 *N* acetic acid (2.61 ml) was stirred in an ice-water bath under a nitrogen atmosphere, and a chilled, 0.0533 *N* barium hydroxide solution (5.03 ml, 0.1 equiv) was added. The resulting solution was stored in a stoppered flask for 48 h at 0°. It was then poured into ice-cold 0.1 *N* acetic acid (10 ml), and the mixture was passed sequentially through 1 ml of Dowex-1X2 (acetate form) and 5 ml of Rexyn-101 (H^+) which were washed with water to give a total effluent volume of 24 ml. Evaporation of the effluent followed by coevaporation with added ethanol and drying *in vacuo* furnished a residue that was triturated with absolute ethanol and benzene (1 ml each). There was obtained a crystalline material (314 mg, 54%) showing m.p. 166–170° and $[\alpha]_{365}$ −147°. Recrystallization from 99% ethanol gave pure L-**6**, m.p. 178.5–179.5°; $[\alpha]_{578}$ +16.2°, $[\alpha]_{546}$ +15.0°, $[\alpha]_{436}$ +2.5°, $[\alpha]_{365}$ −184° (*c*, 0.4 in 0.0025 *N* CH_3CO_2H). M.p. and rotation remained unchanged on further recrystallization, and an n.m.r. spectrum in 2.1 *N* CF_3CO_2D in D_2O was identical with that described for DL-**6** (1).

Anal. Calcd. for $C_7H_{13}NO_7$ (223.2): C, 37.66; H, 5.87; N, 6.28. Found: C, 37.87; H, 6.01; N, 6.22.

The first mother liquor (from the trituration with ethanol–benzene) was evaporated and the residue crystallized from ethyl acetate to give an optically inactive material (164 mg) that melted at 151–152° and proved to be virtually pure *muco*-3 isomer (**5**).

*1-Deoxy-4-O-methyl-1-nitro-*D*-myo-inositol (*D*-**6**)*

A solution of the syrupy mixture of **2** and **1** (509 mg) in 0.0025 *N* acetic acid (2.28 ml) was treated with 0.0533 *N* barium hydroxide (4.38 ml) exactly as described above for **1**, except that the reaction time was 22 h only. Work-up as before afforded a partially crystalline syrup (536 mg) which upon trituration with 99% ethanol and benzene (1 ml each) and cooling overnight at 0° furnished crude D-**6** (213 mg), m.p. 172–174°, $[\alpha]_{365}$ +121°. Recrystallization from ethanol gave 97 mg (19%) of D-**6** melting at 176–177° and exhibiting $[\alpha]_{578}$ −15°, $[\alpha]_{546}$ −18°, $[\alpha]_{436}$ −4.7°, $[\alpha]_{365}$ +190° (*c*, 0.2 in 0.0025 *N* CH_3CO_2H). An n.m.r. spectrum of the product was identical with that of the enantiomer.

Anal. Calcd. for $C_7H_{13}NO_7$: N, 6.28. Found: N, 6.08.

The mother liquor was shown to contain unreacted **1**.

Support of this work by the National Research Council of Canada is gratefully acknowledged. Mrs. Ursula Williams is thanked for preparing the starting compounds.

Some Synthetic Interconversions in the Nitrocyclohexane System[1]

HANS H. BAER, DOUGLAS C. SHIELDS, AND GEOFFREY G. DAWSON[2]
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received April 2, 1973

Several transformations starting from *trans,trans*-2-nitrocyclohexane-1,3-diol (**1**) and its diacetate (**2**) were carried out as model reactions for synthetic work on nitro sugars. They included methylation with diazomethane, dehydration, dehydroacetylation, nucleophilic elimination–additions with alcohols, and bromination. The monomethyl ether of **1** (**3**), the monomethyl ether acetate (**5**), the dimethyl and dibenzyl ethers (**4** and **9**), bromonitro compounds derived from **1** and **4** (**13** and **14**), and four 3-substituted 2-nitrocyclohexenes with methoxyl, ethoxyl, acetoxyl, and hydroxyl groups as substituents (**6**, **8**, **7**, and **11**, respectively) were obtained in these studies. The nitronate formation of **1** and **4** and attendant production of nitroolefins was investigated by u.v. spectroscopy.

Plusieurs transformations portant sur le *trans,trans* nitro-2 cyclohexane diol-1,3 (**1**) et son diacétate (**2**) ont été effectuées pour servir de modèles de réaction à un travail de synthèse sur les nitrosucres. Elles comprennent des méthylations par le diazométhane, des déshydratations, des déshydroacétylations, des élimination–additions nucléophiles avec les alcools et des bromations. Au cours de cette étude, l'éther monométhylique de **1** (**3**), l'acétate de l'éther monométhylique (**5**), les éthers diméthylique et dibenzylique (**4** et **9**), les composés bromonitros dérivés de **1** et **4** (**13** et **14**) et quatre nitro-2 cyclohexènes substitués en 3 par les groupes méthoxyle, éthoxyle, acétoxyle et hydroxyle (respectivement **6**, **8**, **7** et **11**) ont été obtenus. La formation du nitronate de **1** et **4** et la production subséquente de nitrooléfines ont été étudiées par spectroscopie ultraviolette. [Traduit par le journal]

Can. J. Chem., 51, 2843 (1973)

2*t*-Nitrocyclohexane-1*r*,3*c*-diol (**1**), a compound that is readily prepared (1, 2) by cyclization of glutaraldehyde with nitromethane, represents a useful point of departure for model studies of synthetic and stereochemical problems which are relevant to the more complex chemistry of nitro sugars. For example, treatment of its diacetate **2** with ammonia afforded (3) in a single operation 1*r*,3*c*-diamino-2*t*-nitrocyclohexane, which was isolated upon *N*-acetylation. The diamination was explained (3) as a sequence of two elimination–addition reactions, and it has since been applied to acetylated deoxynitroinositols (3–6) and nitro glycosides including nucleosides (6–8). Treatment of **1** itself with various aliphatic amines furnished analogous, *N*,*N*′-disubstituted diaminonitrocyclohexanes (2), and similar reactions with thiols led to bisthioethers (9). A study (10) on the stereochemistry of protonation of the sodium nitronate of **1** was of interest in connection with related investigations in nitro glycosides (11). It was therefore considered worthwhile to perform, in the nitrocyclohexane system, a number of additional reactions that would complement current research in nitro carbohydrates.

The reactions that were carried out successfully are delineated in Scheme 1. Boron trifluoride-catalyzed methylation of **1** with diazomethane furnished the monomethyl ether **3** and the dimethyl ether **4**. So far as we know, this technique for methylation of aliphatic hydroxyl groups (12) had not previously been tried on nitro alcohols, and the question was whether the reagent is compatible with the nitro function in **1** and related nitro glycols. Diazomethane does not react with simple, weakly acidic nitroalkanes ($pK_a^{nitro} > ca.$ 8), but with negatively substituted nitroalkanes having a pK_a^{nitro} of less than *ca.* 8 it reacts, even without boron trifluoride catalysis, to give nitronic esters that may subsequently undergo various kinds of irreversible transformations (13*a*). For nitro sugars, pK_a values of 8–11 have been reported (11, 14), suggesting that some of them might be borderline cases in this respect. The selective methylation of hydroxyl groups in **1** placed confidence in possible applications of diazomethane to nitro sugars for which the customary base-promoted alkylation methods, although never actually tried, *prima facie* do not recommend themselves, both because they would

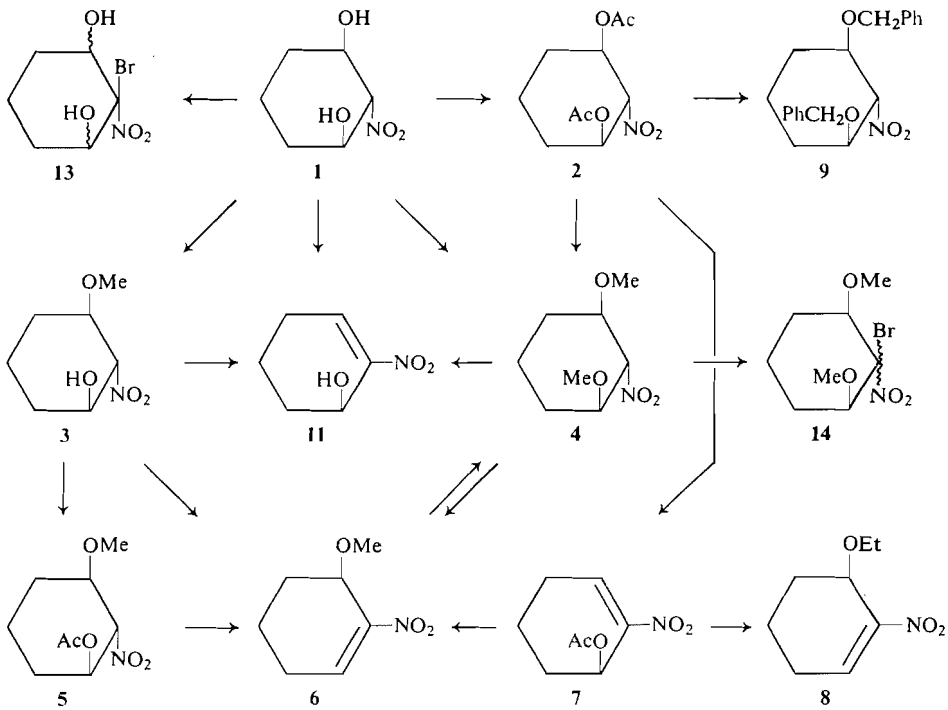

SCHEME 1

likely effect *O*- and (or) *C*-alkylation involving the nitro function (13*a*), and because of the proclivity of many nitro sugar derivatives to incur configurational and structural changes in basic media (11, 13*b*, 14–17). In the meantime, the diazomethane method has, in fact, been utilized in the synthesis of methyl 3,6-dideoxy-2,4-di-*O*-methyl-3-nitro-α-D-glucopyranoside (18).

Boron trifluoride-catalyzed acetylation (19), which is now routinely used in nitro sugars and has also served (3) for preparing the diacetate **2** from **1**, readily afforded the acetate **5** from **3**. Next, 3-methoxy-2-nitrocyclohexene (**6**) was made by dehydration of **3** as well as by dehydroacetylation of **5**. The former conversion was accomplished by treatment of the alcohol with aluminum oxide in toluene at 75°, following earlier observations (20) that certain nitro sugar derivatives can be dehydrated in a similar way.[3] The dehydroacetylation of **5** was carried out by Schmidt–Rutz reaction with sodium bicarbonate in refluxing benzene (13*b*); the yield was only moderate (22%). The same process proved more efficient with the diacetate **2**, giving 3-acetoxy-2-nitrocyclohexene (**7**) in 46% yield. There was no evidence for elimination of a second molecule of acetic acid, which would have resulted in a diene as was the case in the dehydroacetylation of methyl 3-deoxy-3-nitrohexopyranoside 2,4,6-triacetates (21).

Treatment of **2** with sodium methoxide in methanol at 0° led to the dimethyl ether **4**, no doubt by way of a double elimination–addition process through the steps **2** → **7** → **6** → **4** (Scheme 2). There is ample precedent in the literature for alkoxylation of α-nitroalkenes generated *in situ* from β-acyloxynitroalkanes (13*b*, 20, 22), and the twofold sequence clearly parallels the diaminations cited above. In agreement with this scheme, the methoxy olefin **6**, independently prepared as mentioned before, added methanol to give **4** under the same conditions of base catalysis. Furthermore, the acetoxy olefin **7**, obtained from **2** as stated in the preceding paragraph, was found to react with methanol to furnish **6** even in the absence of base; quantitative conversion took place at 65° within 12 h. Refluxing of **7** in ethanol quantitatively produced 3-ethoxy-2-nitrocyclohexene (**8**). It is proposed

[3]In the examples studied (20), the reaction temperature was 110°, and nitroolefinic derivatives were generated as intermediates that underwent further transformations in line with their particular structural features and by virtue of other reagents present.

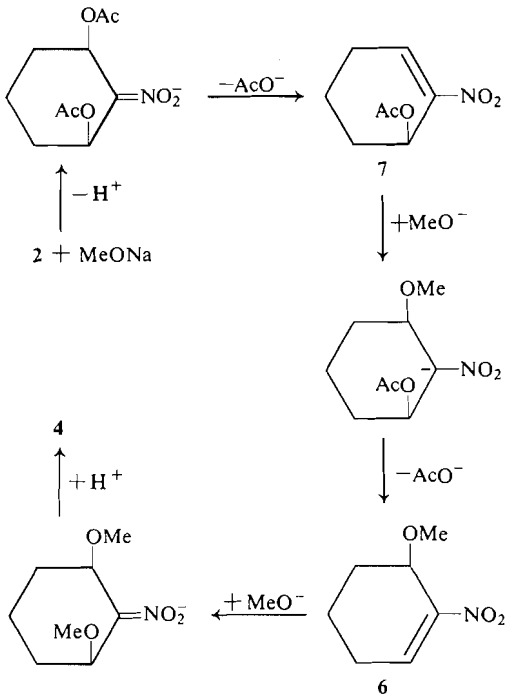
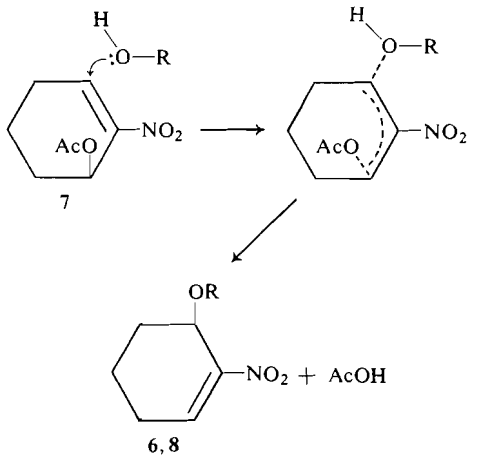


SCHEME 2

that these noncatalyzed substituent exchanges occur in a concerted manner, with the acetoxy bond breaking as the alkoxy bond is being formed (Scheme 3). For if one were to assume two distinct steps instead, namely (for **7** → **6**), methanol addition independent from subsequent elimination of acetic acid, then it would be difficult to explain why the product (**6**), in its turn, altogether resists adding methanol so that,

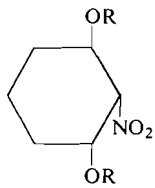


SCHEME 3

in the absence of base, the process stops at this stage instead of proceeding to **4**.

In order to explore further the synthetic utility of elimination–addition reactions of this kind, the diacetate **2** was allowed to react with benzyl alcohol and sodium benzoxide in tetrahydrofuran. Although the oily product that was isolated in 53% yield was not submitted to elemental analysis, spectral evidence showed it to be the dibenzoxy compound **9**. T.l.c. indicated that further products arise in the reaction (for which variously modified conditions were tried), and it seemed that olefins such as **7** and the benzoxy analog of **6** were among them. All attempts to react **2** with isopropoxide failed to give the corresponding bis-isopropyl ether, and a small amount of the olefin **7** was the only product that could be isolated.

Further studies were devoted to the behavior of the diol **1** and the dimethyl ether **4** towards alkali. It had previously been shown (10) that **1** undergoes partial epimerization when it is dissolved in *M* sodium borate solution; upon acidification after 20 h, mainly the starting diol **1** was recovered but small proportions of its *cis,trans* and *cis,cis* isomers were found to be present also. Undoubtedly the isomers also exist, as minor products, in the reaction mixture of the nitromethane cyclization of glutaral-



10 R = H
10*a* R = Ac

dehyde (2), and we have in fact been able to isolate the *cis,trans* isomer **10** by column chromatography in 15% yield besides the main product **1** which was obtained in 66% yield. However, a reaction hitherto apparently unrecognized, though not unexpected, was found to be brought about in **1** by strong base. Figure 1*a* shows u.v. spectra indicating the formation of nitronate in aqueous sodium hydroxide solutions of different normalities. In *N* and 0.1 *N* solutions, the characteristic anion peak at 246 nm is generated instantly and in full strength, or nearly so. The absorbance in *N* NaOH solution, corresponding to an ε value of 11 000 which is reasonable for

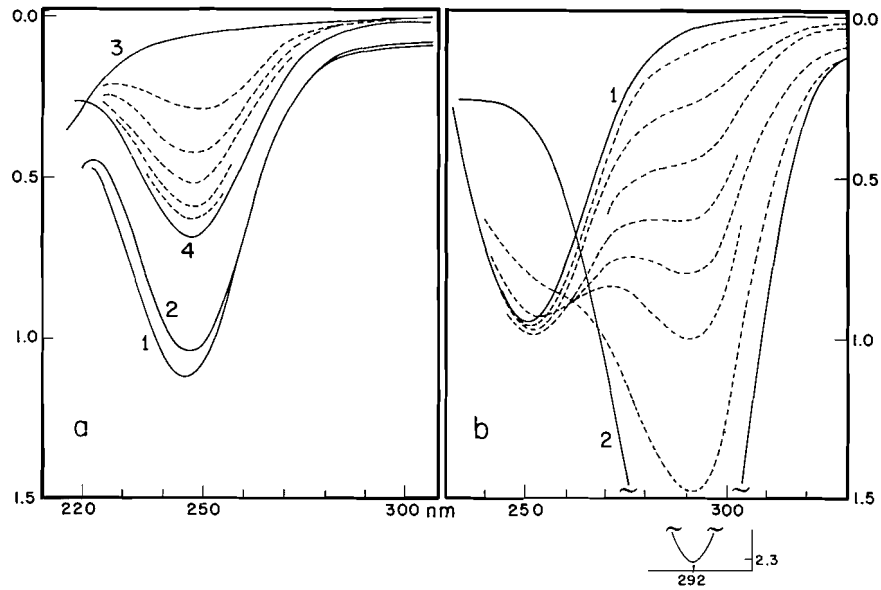


FIG. 1. (*a*) Nitronate u.v. absorption generated in 10^{-4} *M* solutions of **1** in aqueous sodium hydroxide. Curves 1 and 2, in 1 *N* and 0.1 *N* NaOH, respectively, after 1 min and essentially unchanged after 10 min. Curve 3, in 0.001 *N* NaOH (p*H ca.*10), constant for 1 h. Curve 4, in 0.01 *N* NaOH (p*H* 11.1) after 40 and 75 min; broken tracings, after 2, 4, 6, 12, and 24 min (increasing absorbance). (*b*) The same in 1 *N* ethanolic potassium hydroxide. Curve 1, after 4 min. Broken tracings, increasing absorbances after 0.25, 1, 1.5, 2, 2.5, 3, and 4.5 h. Curve 2, after 24 h.

such compounds, suggests that far-reaching ionization is attained. In 0.01 *N* NaOH, the nitro–nitronate equilibrium lies markedly less far on the nitronate side and is approached only after about 30 min, the half-time of equilibration being about 3 min at 26°. The nitronate proportion present in 0.001 *N* NaOH is too small to cause an absorption peak. Now it was observed that the anion peak of **1** in ethanolic, *N* potassium hydroxide solution (λ_{max} 250 nm) slowly decreased with time and completely disappeared within 20 h; concurrently a new, and more intense, peak arose at 292 nm (Fig. 1*b*). The dimethyl ether **4** behaved in a qualitatively similar manner although its nitronate was formed less rapidly. Even in 0.1 *N* sodium hydroxide solution, maximum absorption intensity at 248 nm was attained only after about 2 h (with a half-time of 22 min). This is depicted in Fig. 2*a* which also shows the beginning of the subsequent decline in the peak with concomitant appearance of long wavelength absorption. Figure 2*b* shows the change that occurred in ethanolic *N* potassium hydroxide solution where the new peak at 293 nm was fully established after 5 h.

The spectral phenomena just described are familiar from the chemistry of 3-deoxy-3-nitroaldopyranosides and need to be explained in the same terms as the analogous processes encountered there (15). The absorption in the 290 nm region is due to β,γ-unsaturated (allylic) nitronates (**12***a*, **12***b*) which arise by slow proton abstraction from intermediate α-nitroalkenes (Scheme 4). The latter are formed by β-elimination of a hydroxide (**11** from **1**) or methoxide ion (**6** from **4**) and are considered to be the same intermediates that are involved in the epimerizations and elimination–additions referred to before. Upon acidification of the allylic nitronates **12**, the nitronic acids liberated tautomerize rapidly.[4] *C*-Protonation in cyclohexene 3-nitronate (23) and other conjugated nitronates usually favors the terminal carbon atom of the system (13*a*), and in the present cases we were indeed able to isolate **6**, which was identified by i.r. and n.m.r. spectroscopic comparison, and **11**, which was characterized by its spectra and, further, by borohydride reduction giving known *trans*-

[4]In the analogous work in 3-nitro pyranosides (15), the corresponding nitronic acids incurred other transformations which were not elucidated in detail but were thought to involve hydrolysis of the enol ether linkage present in those structures.

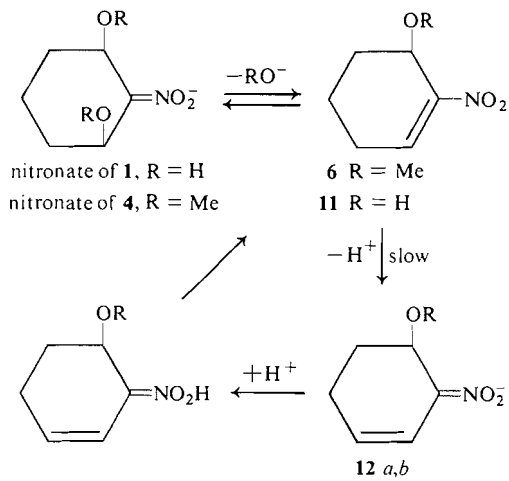

SCHEME 4

2-nitrocyclohexanol. Compound **11** arose not only from **1** but also, along with **6**, from **4**. The reaction was performed in an aqueous medium; it was therefore not surprising in light of the mechanism discussed, that part of the material underwent exchange of a methoxyl substituent. Conversely, exchange of hydroxyl for alkoxyl groups by the action of alcohols has been observed in nitro sugars and formulated as proceeding through intermediary α-nitroolefins (20, 24, 25).

Finally, compounds **1** and **4** were subjected to bromination by means of bromine and alkali according to the method concurrently applied to nitro sugars and published in detail (26). It had been found, in sugars, that formation of bromonitro derivatives is strongly dependent on stereochemical features. In rigid pyranosides where an equatorial nitro group was flanked by two equatorial substituents, bromination of the nitromethine carbon did not occur under standard conditions that afforded smooth bromination in sterically more favorable isomers. The conditions provided an equivalent amount of sodium hydroxide, in dilute solution at 0–20°, for the purpose of generating the requisite nitronate salt, and failure of bromination was attributed to sterically impeded nitronate formation. Under the conditions stated, **1** and **4** were resistant likewise, which is in harmony with their low acidity as reflected in Figs. 1 and 2 (absence of nitronate peak at p*H* 10). When nitronate formation was enforced by a strongly alkaline medium, bromination did proceed and bromonitro derivatives (**13** and **14**, respectively) were obtained in good yields. Each was accom-

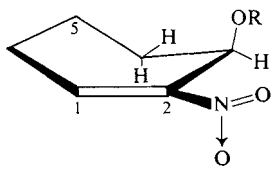
panied by a small amount of second product, presumably a stereoisomer.

The new trisubstituted cyclohexane derivatives **3**, **4**, **5**, and **9** were shown by n.m.r. spectroscopy to possess the *trans,trans* configuration like their known precursors **1** and **2**. Thus, in **3**, the signal at lowest field (δ 4.28) was a one-proton triplet attributable to the nitromethine proton, and its splitting of 9.5 Hz indicated a 1,2,3-triaxial proton arrangement and therefore equatorial orientation of the three substituents. Compounds **4**, **5**, and **9** exhibited the same kind of nitromethylene triplet, with splittings of 9–10 Hz. The symmetrically substituted compounds **4** and **9** showed single signals for their magnetically equivalent substituents, *i.e.*, one six-proton methoxyl singlet was given by **4**, and one 10-proton phenyl singlet as well as one four-proton benzylic methylene singlet was given by **9**. The spectrum of the bromonitro diol **13** was not readily interpretable in terms of configuration, but that of the dimethyl ether **14** revealed the methoxyl groups to be magnetically equivalent and therefore *cis*-oriented to each other. The configuration with respect to the bromonitro carbon remained unknown.

The n.m.r. spectra of the unsaturated derivatives **6**, **7**, **8**, and **11** all exhibited in mid-field (δ 4.42, 6.03, 4.53, and 4.85, respectively) a narrow quartet or triplet for H-3 containing couplings of 2–4 Hz. This indicated that the dihedral angles between H-3 and either proton at C-4 were both small, and on this basis the $^5H_4$ half-chair conformation, with pseudo-equatorial hydrogen and pseudo-axial substituent at C-3, could be assigned to these compounds. (The alternate $^4H_6$ conformation would call for a large and a small vicinal coupling in the H-3 signal). The conformation adopted is that which is predicted on grounds of the $A^{(1,2)}$ effect, the unfavorable nonbonded interaction between the nitro group, situated on an endocyclic double bond in a six-membered ring, and a neighboring pseudo-equatorial substituent (27). A case of precedence for the operation of this effect in an unsaturated nitro pyranose derivative has been reported (28).



$^5H_4$ conformation

6, 7, 8, 11

Experimental

T.l.c. was performed on silica gel G plates and routinely used for monitoring separations by column chromatography. Spots were made visible by heating the plates sprayed with ceric sulfate in 10% sulfuric acid. Unless otherwise indicated, the following combinations of carbon tetrachloride – ethyl acetate were used as chromatographic solvents: A, 1:1; B, 3:2; C, 2:1; D, 7:3; E, 3:1; F, 4:1; G, 6:1.

Unless specified otherwise, the n.m.r. data refer to 100 MHz spectra obtained from $CDCl_3$ solutions (lock signal, tetramethylsilane). I.r. spectra were obtained on a Beckman IR-20 instrument form Nujol mulls (or neat oils if so indicated). U.v. spectra were measured on a Perkin-Elmer 202 spectrophotometer.

2t-Nitrocyclohexane-1r,3c-diol (1) and Racemic 1r,2c,3t-Stereoisomer (10), and Their Diacetates 2 and 10a

Commercial glutaraldehyde (25% aqueous solution) was cyclized with nitromethane both by the original (1) and the modified (2) procedure. Yields of **1** (m.p. *ca.* 160°) were approximately 50–65%. Further recrystallization of **1** from benzene–ethanol (4:1) raised the melting point to 165–166°. Reported: m.p. 159–161° (1), 154° (2). Crude preparations, and especially the mother liquors thereof, showed a spot that moved slightly faster than that of **1** (t.l.c. with solvent A). A run starting from 9.5 g of dialdehyde (= 38 ml of solution) and performed according to the literature (2) gave a first crop of **1** (9.0 g). The remainder of the material was chromatographed on a column of silica gel (490 g) using solvent C as eluant. Initial fractions furnished a very small amount (74 mg) of an oil that appeared to be spectroscopically identical with the nitroolefin **11**. Subsequent fractions yielded an oil which solidified on standing (2.35 g, 15.3%). It showed only the faster t.l.c. spot and was judged to be identical with the *cis,trans* isomer of **1** (*i.e.* **10**, the racemic 1*r*,2*c*,3*t*-isomer) previously obtained (10) as an amorphous solid in 3% yield by base-catalyzed epimerization of **1**. Confirmation was obtained by acetylation with acetic anhydride and boron trifluoride (19) which gave the crystalline diacetate **10***a* in 63% yield; m.p. 87° after recrystallization from ethanol – petroleum ether. Reported: m.p. 88–89°. The n.m.r. spectrum of **10***a* in $CDCl_3$ was in agreement with the reported data (10) except that we noted slightly different chemical shifts for the acetoxy singlets (δ 1.99 and 2.02 rather than 2.05 and 2.08) and the H-2 quartet (δ 4.54 rather than 4.65); $J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 10.5 Hz.

Further elution of the column produced another 1.15 g of **1** (total yield, 66%). The diacetate **2**, m.p. 90–91.5°, was prepared as described (3) (lit. (1) m.p. 89–90°). N.m.r. data (in $CDCl_3$): δ 2.00 (s, 6H, OAc); 4.58 (t, 1H, $J_{1,2} = J_{2,3}$ = 10.5 Hz, H-2); 5.2 (sextet, 2H, H-1 and -3); 1.3–2.5 (m, 6H).

1-O-Methyl-2t-nitrocyclohexane-1r,3c-diol (3) and 1,3-Di-O-methyl-2t-nitrocyclohexane-1r,3c-diol (4)

From 1 by Diazomethane

An ethereal solution of diazomethane was prepared from nitrosomethylurea (50 g) and stored over Dry Ice. A suspension of the diol **1** (4.0 g) and freshly activated (150°) Drierite (3 g) in dry ether (40 ml) was stirred at 0°, and a few drops of boron trifluoride etherate followed by 3–4 ml of the diazomethane solution were added. As the yellow color of the reaction mixture began to fade, further small portions of diazomethane solutions were added, and when the color persisted for several minutes, additional small quantities of BF_3 were introduced. This alternating addition was continued for 3 h or longer, until the entire diazomethane solution and about 5 ml of catalyst had been consumed. Production of light, flocculent polymethylene was observed during the process. The reaction mixture was then treated briefly with some activated charcoal, filtered, and evaporated to give a colorless or faintly yellow oil. The oil contained **3** (R_f 0.6), **4** (R_f 0.4), and starting material **1** (R_f 0.3) according to t.l.c. with solvent **B**, in a visually estimated ratio of about 5:1:5. The components could be separated, and most of the unreacted **1** recovered, as is described below. Alternatively, the methylation was allowed to continue, using a correspondingly larger quantity of diazomethane, until t.l.c. revealed the presence of **3** (major product) and **4** (minor product) together with only a small proportion of **1**.

In order to remove the bulk of unreacted **1**, if present, the oily reaction product was triturated with chloroform (200 ml) whereby insoluble **1** (*e.g.* 1.5 g) separated as a white solid. The filtrate was evaporated to give a residue which was chromatographed on silica gel (300 g) by means of solvent **C**. The fractions (15 ml) were monitored by t.l.c. There was obtained, in turn, 420 mg of **4**, 1.62 g of **3**, and 230 mg of **1** (43% recovery, together with the 1.5 g, above). The yield of **3** was 37%, and that of **4** was 9% (65 and 15.5%, respectively, if the recovered **1** is taken into account). Similar chromatography of a reaction mixture from a more exhaustive methylation (see above) afforded 2.45 g (52%) of **3** and 890 mg (20%) of **4**.

The dimethyl ether **4** was found to be the major product when the reaction was carried out under cooling with Dry Ice, rather than at 0°, possibly because competing decomposition of diazomethane is less severe. Thus, from 2.0 g of **1** and diazomethane generated from 50 g of nitrosomethylurea there was obtained, upon eventual solvent evaporation, an oil that contained only a trace of **3** and that crystallized on cooling. Recrystallization from benzene – petroleum ether furnished **4** (2.03 g, 87%) as colorless platelets, m.p. 79–80°.

Compound **3** crystallized as colorless tablets from carbon tetrachloride, m.p. 80–81.5°; ν_{max} 3420 (sharp; OH), 1545 (NO_2), 1050–1075 cm^{-1} (strong; C—O—C). N.m.r. data: δ 4.28 (t, 1H, $J_{1,2} = J_{2,3} = 9.5$ Hz, H-2); 4.0 (broad peak, resolved to multiplet on adding D_2O, H-3); 3.6 (m, H-1); 3.32 (s, 3H, OCH_3); 2.35 (d, 1H, OH); 1.1–2.3 (unresolved signals, 6H, methylene groups).

Anal. Calcd. for $C_7H_{13}NO_4$ (175.2): C, 47.99; H, 7.48; N, 8.00. Found: C, 47.83; H, 7.59; N, 7.86.

Compound **4**, which after a second recrystallization also melted at 81° (compare **3**!), lacked hydroxyl absorption in the i.r.; ν_{max} 1550 (NO_2), 1090–1065 cm^{-1} (strong, C—O—C). N.m.r. data: δ 4.30 (t, 1H, $J_{1,2} = J_{2,3} = 10$ Hz, H-2); 3.6 (sextet, 2H, H-1 and -3); 3.31 (s, 6H, OCH_3); 1.0–2.5 (unresolved methylene signals, 6H).

Anal. Calcd. for $C_8H_{15}NO_4$ (189.2): C, 50.78; H, 7.99; N, 7.40. Found: C, 50.98; H, 7.83; N, 7.25.

Compound 4 from 2

To a chilled (0°) solution of **2** (40 mg) in anhydrous methanol (40 ml) was added, with stirring, a 0.037 *N* solution of sodium methoxide (1 ml; 0.23 mol equiv). After 7 min, carbon dioxide was passed through the solution for 0.5 h. (It had been found in numerous similar experiments that treatment of **2** with increased amounts of base and (or) for extended periods of time favored the formation of by-products and decreased the yield in **4**.) The reaction mixture was evaporated, and the residue was taken up in ethyl acetate which was treated with charcoal, filtered, and evaporated to yield a pale-yellow oil. The t.l.c. (solvent **C**) showed a trace of remnant **2**, a major spot of **4**, and a minor spot that had the mobility of **3**. (Presumably, some **3** could have arisen owing to de-*O*-acetylation competing with acetoxy elimination.) The oil was chromatographed on a small column of silica gel (4 g) with benzene–ether (4:1). The fractions containing pure **4** were treated with charcoal and then furnished a colorless oil that was crystallized from benzene – petroleum ether. The crystals (17 mg, 55%) melted at 79–80° and gave an i.r. spectrum identical with that of **4** obtained previously.

1-O-Methyl-2t-nitrocyclohexane-1r,3c-diol 3-Acetate (5)

Compound **3** (350 mg) was acetylated with acetic anhydride (6 ml) and boron trifluoride etherate (8 drops) at ambient temperature (40 min). The mixture was poured into ice water which was stirred until the excess anhydride was decomposed, and then extracted with several portions of ether. Evaporation of the dried ($MgSO_4$) extract with added toluene, and treatment of the residue with activated carbon, afforded **5** as a colorless oil that crystallized on cooling. Recrystallization from carbon tetrachloride – petroleum ether afforded 390 mg (90%) of white platelets, m.p. 92–93°; ν_{max} 1740 (C=O), 1550 (NO_2), 1235, 1200, 1100, 1040 cm^{-1} (all strong, C—O—C). N.m.r. data: δ 5.14 (m, 1H, H-3); 4.43 (t, 1H, $J_{1,2} = J_{2,3} = 10.3$ Hz, H-2); 3.68 (m, 1H, H-1); 3.32 (s, 3H, OCH_3); 1.99 (s, 3H, OAc); 1.3–2.4 (unresolved methylene signals).

Anal. Calcd. for $C_9H_{15}NO_5$ (217.2): C, 49.77; H, 6.96; N, 6.45. Found: C, 49.73; H, 7.04; N, 6.47.

3-Methoxy-2-nitrocyclohexene (6)

From 7

The acetoxy olefin **7** (47 mg) was refluxed in anhydrous methanol (4 ml) for 12 h, after which a single spot slightly faster moving than **7** was seen on t.l.c. (solvent **F**). Evaporation gave **6** in quantitative yield as a colorless oil. Crystals that formed on cooling to −10° melted at room temperature. I.r. data (neat oil): ν_{max} 2940, 2825 (C—H); 1670 (C=C); 1515 and 1340 (NO_2); 1450; 1090 and 1070 cm^{-1} (C—O—C). N.m.r. data: δ 7.40 (q, 1H, J = 3–4 Hz, H-1); 4.44 (q, 1H, half-height width *ca.* 5 Hz, H-3); 3.44 (s, 3H, OCH_3); 1.1–2.5 (methylene signals, 6H).

For personal use only.

Anal. Calcd. for $C_7H_{11}NO_3$ (157.2): C, 53.49; H, 7.05; N, 8.91. Found: C, 53.64; H, 7.23; N, 8.71.

From 5

Compound **5** (217 mg) and dry sodium bicarbonate (3.34 g) were heated with magnetic stirring in refluxing benzene (15 ml, dried over and distilled from sodium). After 10 h the reaction solution was cooled, filtered, and evaporated to give a yellow oil. Crystallization from carbon tetrachloride – petroleum ether returned 110 mg of unreacted **5**. The mother liquor showed two major t.l.c. spots corresponding to **5** and **6**. Separation on a silica gel column (10 g) using solvent G yielded another 20 mg of **5**, and 35 mg of **6** that was identified by its i.r. spectrum.

From 3

Compound **3** (183 mg) and dry, basic (20) aluminum oxide were stirred in toluene (15 ml, dried over sodium) at 70–75° for 90 min. The pale-yellow reaction mixture was treated with activated carbon, filtered, and evaporated to give a brown oil which, according to t.l.c. (solvent G), contained **6** as the major component. Chromatographic purification on silica gel (15 g) using solvent G yielded 69 mg (42%) of **6** whose i.r. spectrum was identical with that of the previous sample.

From 4

See later on.

3-Acetoxy-2-nitrocyclohexene (7)

The diacetate **2** (1.01 g) and sodium bicarbonate (6.8 g; dried at 120°) were stirred in refluxing dioxane (40 ml, dried over sodium) for 2.5 h. Work-up furnished a yellow oil that showed two major spots (7 and unreacted **2**) and several minor spots on t.l.c. (solvent G). Separation on silica gel (70 g) gave **7** (350 mg, 46%) and **2** (300 mg). The former crystallized from benzene – petroleum ether; m.p. 65–66°. I.r. data (neat oil before crystallization): ν_{max} 3000–2800 (C—H), 1730 (C=O), 1660 (C=C), 1515 and 1340 (NO_2), 1225 (C—O—C), 1155, 1005–900 cm^{-1}. N.m.r. data: δ 7.58 (q, 1H, J = 3 and 5 Hz, H-1); 6.03 (symm. t, 1H, J = 3 Hz, H-3); 2.00 (s, 3H, OAc); 1.6–2.6 (methylene multiplets).

Anal. Calcd. for $C_8H_{11}NO_4$ (185.2): C, 51.89; H, 5.99; N, 7.56. Found: C, 52.03; H, 5.79; N, 7.50.

3-Ethoxy-2-nitrocyclohexene (8)

The acetoxy olefin **7** (90 mg) was refluxed in 99% ethanol (5 ml) for 15 h, after which time t.l.c. (solvent F) showed essentially a single, new spot. Evaporation gave **8** as a nearly colorless oil; ν_{max} (neat): 3000–2800 (C—H), 1665 (C=C), 1510 and 1340 (NO_2), 1090 and 1070 cm^{-1} (C—O—C). N.m.r. data: δ 7.37 (q, 1H, J = 3-4 Hz, H-1); 4.53 (t, 1H, J *ca.* 3 Hz); 3.64 (q, 2H, ethyl CH_2); 1.16 (t, 3H, ethyl CH_3); 1.4–2.6 (methylene multiplets, 6H).

Anal. Calcd. for $C_8H_{13}NO_3$ (171.2): C, 56.12, H, 7.65; N, 8.18. Found: C, 56.06; H, 7.57; N, 8.32.

1,3-Di-O-benzyl-2t-nitrocyclohexane-1r,3c-diol (9)

A 2 *N* solution of sodium benzoxide in benzyl alcohol (0.60 ml, 4 mol equiv) was added dropwise, with stirring at room temperature, to a solution of **2** (70 mg) in anhydrous tetrahydrofuran (5 ml). A white precipitate was produced. Stirring was continued for 8 min, and carbon dioxide was then passed through the mixture for 30 min. Dilution of the mixture with ethyl acetate (20 ml), treatment with activated carbon, filtration, and evaporation gave an oil that contained benzyl alcohol and, according to t.l.c. in solvent E, a major reaction product (**9**), along with two minor, more slowly moving products. No **2** remained. Chromatography on a 50 g silica gel column with benzene–ether (4:1) furnished a total of 52 mg (53%) of a colorless oil from the fractions containing pure or nearly pure **9**. Crystallization could not be achieved. I.r. data of a chromatographically pure fraction (neat oil): 3100–3000 and 2940, 2860 (C—H); 2000–1670 (weak, aromatic combination bands); 1600, 1490, 1450 (arom. C=C); 1550, 1360 (NO_2); 1090 (broad; C—O—C); 1025, 730, 690 cm^{-1}. N.m.r. data: δ 7.35 (s, 10 H, phenyl), 4.67 (s, 4H, benzylic CH_2); 4.45 (t, 1H, $J_{1,2} = J_{2,3}$ = 9 Hz, H-2); 3.52 (m, 2H, H-1 and -3); 2.3–1.2 (methylene multiplets, 6H).

When less than the proportion of benzoxide specified above was used, *e.g.*, only 0.7–2 mol equiv, the crude products obtained after 5 min and even after a prolonged reaction time of 30 min apparently contained much nitroolefinic material, as suggested by i.r. bands occurring at 1660 and 1515 cm^{-1}.

Reaction of 2 with Sodium Isopropoxide

To a solution of **2** (245 mg) in dry benzene (50 ml) was added dropwise, with stirring at room temperature, a suspension of sodium isopropoxide (164 mg, 2 mol equiv) in benzene (20 ml). Stirring was continued for 1 h during which time a flocculent precipitate was formed. The mixture was treated with 5 ml of cation exchange resin, filtered, and evaporated to give a pale-yellow oil which t.l.c. (solvent B) showed to contain two major and several minor components. Of the former, one appeared to be starting **2**, and the other proved to be the acetoxy olefin **7** upon chromatographic isolation (yield, 42 mg) using solvent E, and identification by i.r. and n.m.r. spectra.

Similar experiments, in which tetrahydrofuran or isopropyl alcohol were employed as solvents and varying reaction times were tried, also seemed to produce chiefly **7** and (or) unidentified products as revealed by t.l.c.

Reaction of 1 with Sodium Hydroxide

Exploratory Experiments

Samples of **1** (20 mg) were dissolved in aqueous, 4 *N* sodium hydroxide (1 ml) at room temperature. After certain periods of time, the solutions were diluted with water and neutralized or acidified, by use of Amberlite IR-120 (H^+) or *N* hydrochloric acid (which did not appear to make a difference), and concentrated *in vacuo* for t.l.c. with solvent A. After alkali treatment for 10 min, 0.5, 1, 2, and 4 h there was seen a very strong spot (R_f 0.65) attributed to **11**, and a weak spot of starting **1** (R_f 0.3) together with a slightly faster trace spot (R_f 0.35–0.4). No significant change during 4 h was observed. On the other hand, use of 1 *N* NaOH produced, after 10 min, considerably less of the product R_f 0.65. An even slower reaction was observed with methanolic 1 *N* sodium methoxide which produced, however, *two* fast-moving spots (R_f 0.65 and 0.6; traces after 5 min, and fair spots after 1 h).

3-Hydroxy-2-nitrocyclohexene (11)

A solution of the diol **1** (0.50 g) in 4 *N* NaOH (50 ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was allowed to stand at 25° for 1 h and then diluted with water, cooled with ice, and deionized with Amberlite IR-120 (H^+). The resin was subsequently washed well with water followed by ethanol, and the combined solution was evaporated *in vacuo* to give a syrup. This was chromatographed on silica gel (40 g) with solvent A, fractions of 8 ml size being collected. Fraction Nos. 5–10 yielded 140 mg of the major reaction product **11** (R_f 0.65) in pure form. Fraction Nos. 11–19 (dry weight, 40 mg) were mixtures of **11** and the two slow-moving compounds. Fraction Nos. 20–40 contained small amounts of material presumed to be **1**.

Compound **11** was an oil that distilled at 0.2 mm Hg at *ca.* 140° (bath temperature), with partial decomposition. I.r. data (neat film of dried but undistilled substance): 3400 cm^{-1} (broad; OH); 2950, 2870 (C—H); 1660 (C=C); 1515 (strong; nitroalkene); 1340 (strong); 1250, 1180, 1165, 1085 (weak); 1060 and 985 (strong); 950–800 (6 weak bands); 750, 730 (medium). N.m.r. data (60 MHz): δ 7.45 (t, 1H, J = 4 Hz, H-1); 4.85 (narrow q, 1H, J = 2–3 Hz, H-3); 3.17 (s, 1H, removable by adding D_2O; OH); 1.6–2.6 (m, 6H, methylene).

In another experiment, the crude oil obtained on similar alkali treatment of **1** (400 mg) was dissolved in ethanol (15 ml), and $NaBH_4$ (250 mg) was added. After 20 min the mixture was deionized with cation exchange resin and evaporated. In the oil obtained, the t.l.c. spot corresponding to **11** was considerably weaker than previously, and a new and slightly faster spot was visible. Separation was achieved on a column of silica gel (40 g) using solvent D as eluant; the fraction size was 3 ml. Fraction Nos. 38–56 gave a single spot on t.l.c. and yielded 100 mg of an oil that did not show any olefinic signal (n.m.r.) or nitroalkene absorption (i.r.). It crystallized on cooling, and recrystallization from carbon tetrachloride – petroleum ether gave 40 mg of *trans-2-nitrocyclohexanol*, m.p. 46–47° (lit. (29) m.p. 47–48°). I.r. and n.m.r. spectra established identity with an authentic sample synthesized by oxidation (30) of *trans*-2-aminocyclohexanol.

Reactions of 3 and 4 with Sodium Hydroxide

Exploratory Experiments

These were carried out as described for **1** in the preceding section, except that, for **4**, small amounts of dioxane and methanol were added to the alkaline reaction mixture to assist in dissolving the compound. After 10–30 min in 4 N NaOH, compounds **3** (R_f 0.4) and **4** (R_f 0.6) both gave two product spots, apparently the same (R_f 0.5 and 0.7), on t.l.c. with solvent D. The R_f 0.5 spot corresponded to **11** (R_f 0.65 in solvent A), and the R_f 0.7 spot was attributed to **6**.

Isolation of 6 and 11

The diether **4** (0.40 g) was added to aqueous 4 N NaOH (20 ml). Stirring for 30 min at room temperature failed to effect complete solution. Dioxane was therefore added dropwise to dissolve all remnant **4**, and sufficient methanol was added to produce a homogeneous phase. Stirring was continued for 30 min. Work-up and column chromatography was performed as described for **11** in a preceding section, except that solvent D was employed and 6 ml fractions were collected. Fraction Nos. 13–20 gave **6** (40 mg) and fraction Nos. 24–40 gave **11** (50 mg). Both products were identified by their i.r. and n.m.r. spectra.

2-Bromo-2-nitrocyclohexane-1,3-diol (13)

The diol **1** (0.50 g) was dissolved in 1 N sodium hydroxide (3.1 ml, 1 mol equiv), and after 2 min bromine was added in small drops until its color persisted. A precipitate was formed. The mixture was evaporated, and added portions of ethanol followed by ethyl acetate were evaporated from the residue. The t.l.c. with benzene–ether (3:2) showed remnant **1** (R_f 0.3) and two products, R_f 0.4 and 0.5. Fractionation was achieved on silica gel (50 g) with the same solvent mixture. The product of R_f 0.4 was obtained as a colorless oil which crystallized on scratching. Recrystallization from benzene–ethanol gave **13** (310 mg, 41%), m.p. 188–189°. I.r. bands were at 3480, 3400 (OH), 1545 with shoulder at 1560 (NO_2), 1190, 1080, 1060, 945, 860, 735 cm^{-1}. N.m.r. data (in acetone-d_6): δ 4.15 (2H, complex multiplet, H-1 and -3); 1.5–2.0 (6H, methylene multiplets).

Anal. Calcd. for $C_6H_{10}BrNO_4$ (240.1): C, 30.02; H, 4.20; N, 5.84; Br, 33.29. Found: C, 30.07; H, 4.53; N, 5.64; Br, 33.44.

The faster-moving component was also isolated from the column as a solidifying oil, but only a small part (12 mg) was obtained crystalline, m.p. 132–134° (from carbon tetrachloride). The i.r. spectrum was very similar to that of the main product, with slight differences in band positions and relative intensities. Mass spectra were nearly identical, revealing the presence of bromine.

2-Bromo-1,3-di-O-methyl-2-nitrocyclohexane-1,3-diol (14)

To a mixture of the diether **4** (1.0 g) and 2.5 N sodium hydroxide (20 ml) was added some tetrahydrofuran followed by methanol as required to produce a homogeneous solution. Bromine was then added dropwise until the solution stayed yellow. The excess base was removed by means of cation exchange, and the solution was evaporated to dryness. The material contained a product (R_f 0.4) besides unreacted **4** (R_f 0.25) (t.l.c. with benzene–ether 3:2). Separation was achieved on a silica gel column (100 g) using the same solvent. The faster-moving product (**14**) was obtained as a solid that was recrystallized from carbon tetrachloride – petroleum ether; m.p. 92–93°. The yield was 0.68 g (48%). I.r. bands: 1555 (strong, NO_2); 1090 cm^{-1} (strong, C—O—C). N.m.r. data: δ 4.10 (m, 2H, H-1 and -3); 3.45 (s, 6H, OCH_3); δ 2.0 (m, 6H, methylene). The mass spectrum exhibited molecular ion peaks at *m/e* 269 and 267.

Anal. Calcd. for $C_8H_{14}BrNO_4$ (268.1): C, 35.84; H, 5.26; N, 5.22. Found: C, 35.76; H, 5.43; N, 5.02.

Starting **4** (185 mg) was recovered from later fractions.

Photolyse du butène-1 dans l'ultraviolet à vide

GUY J. COLLIN[1]

Radiation Chemistry Section, National Bureau of Standards, Washington, D.C. 20234

Reçu le 5 mars 1973

Le butène-1 est photolysé dans l'ultraviolet à vide (147–105 nm) et les produits principaux de la fragmentation de la molécule sont l'allène, les butadiènes, l'éthylène et l'acétylène. L'addition de l'atome d'hydrogène sur la double liaison forme le radical butyle secondaire et le radical butyle primaire (9% à 147 nm). Aux plus courtes longueurs d'onde, cette proportion passe à 18% à 123.6 nm montrant aussi que certains atomes d'hydrogène possèdent une énergie cinétique supérieure à l'énergie thermique tout au moins à 10 et à 11.6–11.8 eV.

The vacuum u.v. photolysis of 1-butene was studied in the 147–105 nm region. The main products formed from the fragmentation of excited molecules are allene, 1,3- and 1,2-butadienes, ethylene, and acetylene. The addition of a hydrogen atom to the double bond produces mainly secondary butyl radicals (91%) at 147 nm. At 123.6 nm, this proportion becomes 82%. Thus at shorter wavelengths (10 and 11.6–11.8 eV), hydrogen atoms are produced with a kinetic energy higher than the thermal energy.

Can. J. Chem., 51, 2853 (1973)

Introduction

La photolyse du butène-1 est bien connue en ce qui concerne le domaine de l'ultraviolet lointain: région de 185 nm et de 202–206 nm (1). Dans ce domaine de l'énergie, la principale réaction de décomposition de la molécule butène-1 est la réaction de scission de la liaison carbone–carbone située en position β de la double liaison. Nous avons étendu cette étude à la région comprise entre 147 et 104.8 nm. En outre, nous avons essayé de déterminer quelle peut-être l'importance de l'énergie cinétique que contiennent les atomes d'hydrogène libérés. Une étude semblable sur l'isobutène a déjà été publiée (2).

Procédure Expérimentale

La procédure expérimentale, ainsi que les lampes d'irradiation, ont déjà été décrites (3).

Le butène-1 a été purifié par c.p.g. puis dégasé avant d'être utilisé. Le butène-1,1-d_2 est un produit Merck, Sharp and Dohme of Canada et contient 1.2% de butène-1-d_1. Les résultats rapportés ont été corrigés pour cette impureté.

L'actinométrie a été faite en admettant que le rendement quantique M/N (nombre de molécules M produites par rapport au nombre N de molécules excitées formées par absorption d'un photon) de l'acétylène dans l'irradiation de l'éthylène est égale à l'unité entre 147 et 123.6 nm (4). Aux lignes d'argon, l'actinométrie est faite en mesurant le courant ionique libéré dans la cellule irradiée. Le rendement quantique d'ionisation du butène-1 est connu et est 0.32_1 (3).

Le taux de conversion est généralement inférieur à 0.1%, sauf dans de rares cas où il peut atteindre 0.5%.

Résultats

Ceux-ci sont rapportés dans les tableaux et figures de ce texte. Les rendements rapportés sont les rendements quantiques Φ ou les rendements par rapport au rendement des molécules excitées M/N(ex.); ces deux rendements étant liés par la relation $M/N(\text{ex.}) = \Phi/\Phi(\text{ex.})$. A ces résultats, il convient d'ajouter les résultats des analyses par spectrométrie de masse des produits formés dans l'irradiation du $CH_3CH_2CH{=}CD_2$.

La composition de l'éthylène varie de façon importante avec la pression de l'échantillon (tableau 1). La composition isotopique de l'acétylène est indépendante de la pression et de la lampe utilisée et de la présence ou de l'absence de l'oxygène. Il en est de même de l'allène et du propène:

$$C_2{-}D_2/{-}D_1/{-}D_0: 21.5 \pm 1.5/55 \pm 2/24 \pm 2$$

$$C_3H_2{-}D_2/{-}D_1/{-}D_0: 87 \pm 2/12 \pm 1/2 \pm 2$$

$$C_3H_3{-}D_3/{-}D_2: 15.5 \pm 1.5/84.5 \pm 1.5$$

En l'absence d'oxygène, l'éthane produit à 147 nm est

$$C_2H_4{-}D_2/{-}D_1/{-}D_0: 10/5/85$$

Discussion

Caractéristiques générales

Dans la région de l'ultraviolet à vide considérée ici, c'est-à-dire entre 104.8 et 147 nm, le spectre d'absorption du butène-1 est connu (5). A l'énergie émise par la raie de résonnance du xénon, 8.4 eV, l'absorption d'un photon conduit à une molécule neutre excitée. Aux raies de résonnance du krypton et de l'argon, 10.0 et 11.6–11.8 eV, une fraction des molécules ayant absorbé un photon sont ionisées:

[1] $C_4H_8\text{-}1 + h\nu \rightarrow (C_4H_8)^{**}$

[2] $C_4H_8\text{-}1 + h\nu \rightarrow [C_4H_8^+]^* + e^-$

L'importance relative des réactions 1 et 2 est connue (3, 6). Puisqu'à 8.4 eV, il n'y a pas d'ion formé (Φ(ion) = 0.00), le rendement M/N(ex.) est égal au rendement quantique. Au cours de ce qui suit, rien ne sera dit des réactions de l'ion excité $[C_4H_8^+]^*$. A 10.0 eV, cet ion ne contient pas assez d'énergie pour se fragmenter. Il ne contribue donc probablement pas aux produits analysés ici. En fait, il est connu que cet ion initie la polymérisation du monomère (7).

Toutes le valeurs des rendements sont donc rapportées au nombre de molécules excitées formées en phase gazeuse et seront donc de la forme M/N(ex.). On supposera donc que la formation de tous les produits mesurés ne proviennent que des réactions qui succèdent à la réaction 1.

Décomposition de la molécule excitée

La molécule excitée formée par absorption d'un photon contient au minimum 194.5 kcal mol^{-1}. C'est une énergie beaucoup plus grande que l'énergie requise pour briser l'une quelconque des liaisons de la molécule: environ 100 kcal mol^{-1}. Il est donc raisonnable d'admettre que l'espèce excitée a un temps de vie inférieur au temps disponible entre deux collisions dans le domaine de pression étudié ici:

[3] $(C_4H_8\text{-}1)^{**} \rightarrow H, R, R_1R_2$

où H et R sont respectivement l'atome d'hydrogène et un radical libre et R_1R_2 est un produit moléculaire stable. Le rendement de ces produits est donc, en principe, indépendant de la pression dans le présent domaine d'étude. Des résultats (voir plus loin), il ressort que plusieurs produits ont des rendements qui sont en première approximation indépendants de la pression (fig. 1). Il en est ainsi des rendements en allène et propyne (tableaux 2 et 3).

[4] $(C_4H_8\text{-}1)^{**} \rightarrow C_3H_4 + CH_4 \quad \Delta H =$ 27.7 kcal mol^{-1}

[5] $(C_4H_8\text{-}1)^{**} \rightarrow C_3H_4 + CH_3 + H \quad \Delta H =$ 132 kcal mol^{-1}

Cette réaction est précisée par l'analyse isotopique de l'allène formé dans l'irradiation du $CH_3CH_2CH{=}CD_2$:

[6] $(CH_3CH_2CH{=}CD_2)^{**} \rightarrow CH_3 + CH_2{=}C{=}CD_2 + H$

Puisque 87% de l'allène est de l'allène-d_2, cela est l'indication que la liaison carbone–carbone scindée se trouve en position β de la double liaison. Cependant, 12% de l'allène est de l'allène -d_1, indiquant ainsi qu'il peut y avoir une redistribution partielle des atomes d'hydrogène soit dans la molécule excitée, soit dans le radical C_3H_5 s'il est formé temporairement ou encore y avoir une mauvaise deutération partielle du butène-1 utilisé en ce qui regarde la situation des deux atomes de deutérium.

L'endothermicité des réactions 4 et 5 est compatible avec l'énergie des photons incidents. Etant donné le faible rendement en méthane "moléculaire", plus précisément de celui formé en présence d'oxygène, le rapport des constantes Φ_4/Φ_5 est inférieur ou égal à 0.04, 0.07, et 0.14 respectivement aux raies de résonnances du xénon, du krypton et de l'argon. Cette situation a déjà été remarquée dans la photolyse de l'isobutylène (2) et des *cis*- et *trans*-butènes-2 (8*a*). De la même manière, on peut admettre en l'absence de toute preuve que le radical CH_2—CH—CH_2 est formé temporairement et qu'il se décompose en perdant son atome d'hydrogène central pour former l'allène alors que la formation de propyne requiert la perte d'atome d'hydrogène terminal avec la migration de l'atome d'hydrogène central vers l'autre carbone terminal. Cette formation est donc peu favorable en accord avec les résultats expérimentaux.

La formation de l'acétylène est, elle aussi, en majorité issue d'une ou de plusieurs réactions de décomposition du monomère excité (fig. 1):

[7] $(C_4H_8\text{-}1)^{**} \rightarrow C_2H_2 + C_2H_6 \quad \Delta H =$ 34 kcal mol^{-1}

[8] $(C_4H_8\text{-}1)^{**} \rightarrow C_2H_2 +$ autres produits que C_2H_6

A partir des résultats obtenus, la valeur maximum du rapport Φ_7/Φ_8 est de 0.08 avec les trois

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

types de lampes utilisées. En fait, il serait plus judicieux de considérer la formation de l'éthylène et de l'acétylène dans le système suivant:

[9] $(C_4H_8\text{-}1)^{**} \rightarrow C_2H_5 + C_2H_3 \quad \Delta H =$ 89.5 kcal mol^{-1}

Les deux fragments radicalaires ont au minimum 105 kcal mol^{-1} d'énergie à se partager de telle sorte qu'au moins l'un des deux radicaux se décompose:

[10*a*] $(C_2H_5)^{*} \rightarrow C_2H_4 + H \quad \Delta H = 39$ kcal mol^{-1}

[10*b*] $(C_2H_3)^{*} \rightarrow C_2H_2 + H \quad \Delta H = 42$ kcal mol^{-1}

Il se peut même, thermodynamiquement cela est possible, que les deux radicaux éthyle et vinyle se décomposent, donnant lieu globalement à la réaction suivante:

[11] $(C_4H_8\text{-}1)^{**} \rightarrow C_2H_2 + C_2H_4 + 2H \quad \Delta H =$ 170 kcal mol^{-1}

Afin d'apprécier l'importance des réactions 9 + 10*a* et 9 + 10*b*, il faut pouvoir évaluer le rendement des radicaux éthyles et vinyles stables. Dans un système insaturé comme le butène-1 et en présence d'hydrogène sulfuré, les radicaux libres réagissent avec l'hydrogène sulfuré pour former le composé moléculaire supérieur (8*b*):

[12] $R + H_2S \rightarrow RH + HS$

Dans ces conditions, l'accroissement des rendements en éthylène et en éthane, en présence d'hydrogène sulfuré indique l'importance des rendements des radicaux vinyles et éthyles à la condition, bien sûr, que la réaction 12 soit bien la seule à être efficace dans le processus de capture des radicaux libres. On obtient ainsi les rendements maximum pour les réactions 9 + 10*a* et 9 + 10*b* (tableaux 3). Il en est de même pour les autres radicaux. Alors que les rendements en acétylène et allène sont inchangés, la présence de l'hydrogène sulfuré augmente aussi et considérablement les rendements en méthane et butane, montrant ainsi les rendements importants en radicaux méthyles et butyles.

L'analyse isotopique de l'acétylène produit dans l'irradiation du $CH_3CH_2CH{=}CD_2$ montre que 76% de l'acétylène est formé par décomposition de l'espèce $CH{=}CD_2$:

[13] $(CH{=}CD_2)^{*} \rightarrow C_2D_2(\text{ou } C_2HD) + H(\text{ou D})$

Cependant, 25% de l'acétylène est perhydrogéné montrant la possibilité d'au moins un autre processus de fragmentation conduisant à l'acétylène. Dans la photochimie des butènes-2, une réaction importante est la fragmentation en acétylène et deux radicaux méthyles (8*a*). Il est alors facile d'imaginer que cette fragmentation est précédée d'un transfert interne d'un atome d'hydrogène. Un tel transfert a été observé dans la photochimie de l'isobutène (2) (voir la composition isotopique de l'éthane). De la même

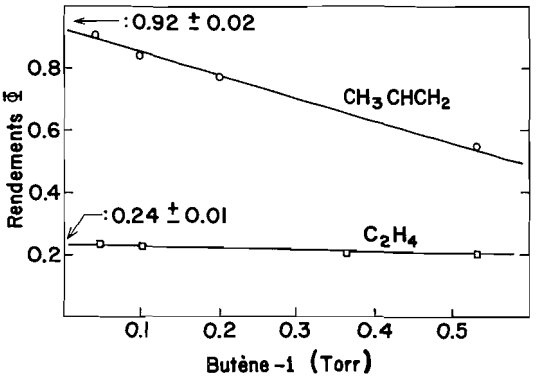

FIG. 2. Photolyse à 8.4 eV. Rendements à basse pression.

[14] $(CH_3CH_2CH{=}CD_2)^{**} \rightarrow$
$(CH_3CH{=}CHCD_2H)^{**} \rightarrow C_2H_2 + CH_3 + CD_2H$

façon, l'éthylène formé est en majorité perhydrogéné, démontrant ainsi la validité du mécanisme. A hautes pressions, 70% de l'éthylène est -d_0; cependant, 30% sont de l'éthylène-d_2. Là encore, il existe au moins un autre processus de formation de l'éthylène comme:

[15] $(C_4H_8\text{-}1)^{**} \rightarrow 2C_2H_4$

Etant donné les rendements des radicaux éthyles et vinyles, il s'en suit que la réaction 15 pourrait très bien rendre compte d'une part de la formation de l'éthylène. Cette éventualité rappelle un résultat déjà obtenu dans la photochimie du cyclobutane (9) et du méthylcyclopropane (10) qui se décomposent essentiellement dans une réaction similaire à la réaction 15. D'autres réactions de décomposition de la molécule butène-1 excitée sont responsables de la formation des butadiènes:

[16] $(C_4H_8\text{-}1)^{**} \rightarrow C_4H_6\text{-}1,3 + H_2(\text{ou } 2H)$

[17] $(C_4H_8\text{-}1)^{**} \rightarrow C_4H_6\text{-}1,2 + H_2(\text{ou } 2H)$

Enfin la formation du propène résiduel à haute pression est sans doute attribuable à la décomposition du monomère excité en radical méthylène et en propène comme cela a déjà été

démontré dans le cas de l'isobutène et des butènes-2 (2, 8*a*). Les rendements quantiques d'une telle réaction sont faibles: 0.03 et 0.05 aux raies de résonnance du xénon et du krypton.

Réactions radicalaires

Même en présence d'oxygène, les atomes d'hydrogène s'additionnent sur la double liaison pour former un radical butyle excité:

[18] $H + C_4H_8\text{-}1 \rightarrow (s\text{-}C_4H_9)^* \quad \Delta H = -41 \text{ kcal mol}^{-1}$

[19] $H + C_4H_8\text{-}1 \rightarrow (n\text{-}C_4H_9)^* \quad \Delta H = -37 \text{ kcal mol}^{-1}$

Le radical butyle formé contient plus d'énergie qu'il ne lui en faut pour se décomposer (11):

[20] $(s\text{-}C_4H_9)^* \rightarrow C_3H_6 + CH_3 \quad \Delta H = 26 \text{ kcal mol}^{-1}$

[21] $(n\text{-}C_4H_9)^* \rightarrow C_2H_4 + C_2H_5 \quad \Delta H = 23 \text{ kcal mol}^{-1}$

[22] $(s\text{- ou } n\text{-}C_4H_9)^* + M \rightarrow C_4H_9 + M$

Les réactions de décomposition des radicaux butyles sont en compétition avec la réaction de stabilisation par collision dans le domaine de pression étudié ici. Ces réactions sont en accord avec les analyses par spectrométrie de masse des propènes et éthylènes (figs. 1 et 2).

[23] $H(D) + C_2H_5CH{=}CD_2 \rightarrow (C_2H_5CHCD_2H(D))^* \rightarrow CH_3 + CH_2{=}CHCD_2H \text{ (ou } CH_2{=}CHCD_3)$

[24] $H(D) + C_2H_5CH{=}CD_2 \rightarrow (C_2H_5CH_2(D)CD_2)^* \rightarrow C_2H_5 + CH_2{=}CD_2 \text{ (ou } CHD{=}CD_2)$

Le propène formé est en majorité du propène-d_2 et un pourcentage relativement faible est du propène-d_3. Après déduction de l'éthylène formé par décomposition du monomère excité, l'analyse de l'éthylène par spectrométrie de masse montre une variété d'éthylène-d_2 et -d_3 dont la formation décroît avec la pression. Dans le cas de l'éthylène et du propène, le rapport des espèces -d_3/-d_2 est voisin de 0.18 aux trois longueurs d'ondes (voir résultats). Ce rapport est à comparer avec le rapport D/H contenu dans le monomère, rapport qui est égal à 0.33.

Il est intéressant de comparer ici les rendements des réactions 20 et 21 à basses pressions. La décroissance relative du rendement en éthylène comparée à celle du propène croît lorsque l'énergie incidente utilisée croît de 8.4 à 11.6–11.8 eV. Il apparaît que l'addition des atomes d'hydrogène sur la double liaison ne produit essentiellement que des radicaux butyles secondaires à 8.4 eV (91%). Récemment il a été démontré que 94.3% de l'addition des atomes d'hydrogènes thermiques se fait sur le carbone terminal (12). A la précision expérimentale près, les atomes d'hydrogène libérés dans la photolyse à 8.4 eV peuvent donc être assimilés à des atomes thermiques. A 10.0 eV, seulement 82% de l'addition conduit au radical butyle secondaire. Il faut donc conclure que les atomes d'hydrogène formés à 10.0 eV possèdent en moyenne une énergie cinétique supérieure à l'énergie thermique. L'addition de l'atome d'hydrogène sur la double liaison est alors moins sélective. A 11.6–11.8 eV, cette proportion n'est plus que de 63%.

Il existe enfin une autre possibilité de réaction de l'atome d'hydrogène:

[25] $H + C_4H_8\text{-}1 \rightarrow C_4H_7 + H_2$

L'importance de cette réaction est mineure.

TABLEAU 4. Photolyse du butène-1: rendements des produits en l'absence d'oxygène[a]

Butène-1	2.00	2.00	1.00

[a]Référence 1. [b]Formation de méthane moléculaire surtout.

Le rapport $k_{25}/k_{18} + k_{19}$ est de 1.6×10^{-2} (13). Cette faible participation de la réaction 25 est confirmée par le fait que les réactions de combinaison possible entre les radicaux C_4H_7 et le radical méthyle est faible (tableau 4). La somme des rendements des méthylbutènes et des pentènes correspondants est en effet inférieure à 0.03 ce qui, compte tenu de l'importance des radicaux méthyles, entraîne un rendement en radicaux butènyles de l'ordre de 0.12 à 8.4 eV. Ce rendement est cependant supérieur à celui attendu par la seule réaction 25. En conséquence, il se peut que d'autres radicaux réagissent avec le monomère dans une réaction similaire à la réaction 25. Il se peut également que l'absorption directe d'énergie conduise à la formation d'un radical C_4H_7. Cependant, étant donné l'énergie initiale de la molécule excitée, on peut en limiter le rendement quantique à 0.05 (8*a*). Tenant compte du rapport k_{18}/k_{19}, il est donc facile d'estimer le rendement en atomes d'hydrogène aux trois lampes utilisées (tableau 5). Il est en particulier intéressant de noter qu'à 8.4 eV, le rendement $\Phi(H)$ est de l'ordre de l'unité comme cela a déjà été démontré dans le cas des butènes-2 (8*a*).

Les autres radicaux les plus importants sont les radicaux méthyles, éthyles et vinyles. La formation de l'isopentane, du pentane normal et du méthyl-3-pentane est d'origine radicalaire et ceux-ci sont formés dans les réactions de combinaison des radicaux méthyles et éthyles avec les radicaux butyles. Il en est de même de l'éthane, du propane et du butane normal à partir des radicaux méthyles et éthyles alors que le méthane, les *trans*- et *cis*-butènes-2 le sont par dismutation des radicaux correspondants. En supposant que les radicaux libres réagissent entre eux de façon statistique et en connaissant les rapports des constantes de vitesse des réactions de dismutation et de combinaison des différentes paires de radicaux, on peut ainsi calculer les rendements des différents produits d'origine radicalaire (8*a*). Les résultats sont en accord avec ceux obtenus par l'utilisation de H_2S (tableau 5). Il faut enfin noter que les rendements des radicaux butyles secondaires et primaires sont connus à partir de la décroissance des rendements en propylène et éthylène en fonction de la pression.

Conclusion

Il est enfin possible d'établir de façon simplifiée l'importance relative des principaux processus de fragmentation de la molécule butène-1 excitée mis en évidence (tableau 6). Ces résultats sont comparés avec ceux obtenus à plus longue longueur d'onde (1). Il faut enfin dire que, dans la région de l'ultraviolet à vide et à des pressions relativement faibles, la fragmentation de la molécule photochimiquement excitée conduit essentiellement à un produit moléculaire stable et à deux fragments radicalaires.

Nous tenons à exprimer notre gratitude au professeur P. Ausloos qui, non seulement a bien voulu commenter ce travail, mais également nous a permis d'utiliser certains résultats inédits de son laboratoire.

Estimation of Phenols by the 4-Aminoantipyrine Method: Identification of the Colored Reaction Products by Proton Magnetic Resonance Spectroscopy

PETER F. JONES AND K. E. JOHNSON

Regina Water Research Institute, University of Saskatchewan, Regina, Saskatchewan S4S 0A2

Received April 10, 1973

The products from the oxidation of several phenols in the presence of 4-aminoantipyrine have been isolated and their p.m.r. spectra examined. The results confirm the proposed formation of *p*-quinoneimide adducts and the elimination of the para-group in the case of reactive *p*-substituted phenols. Data from ortho-substituted phenols reveal the formation of *syn* and *anti* geometrical isomers of the quinoneimide. In contrast, when the starting phenol has a meta-substituent, only a single isomer, the less hindered *anti* form, is obtained. An unusually large anisotropic effect of the antipyryl group, causing a deshielding of the closest proton on the quinoneimide ring, has been found. In the reaction between *p*-benzoquinone and 4-aminoantipyrine, the color obtained is due to the formation of the *p*-quinoneimide, and not to a charge-transfer complex.

Les produits d'oxydation de plusieurs phénols en présence d'amino-4 antipyrine ont été isolés et leurs spectres de r.m.n. examinés. Les résultats confirment la formation proposée d'adduits de la *p*-quinone imide et l'élimination du groupe para dans le cas des phénols *p*-substitués réactifs. Les données sur les phénols ortho substitués révèlent la formation d'isomères géométriques *syn* et *anti* de la quinoneimide. Au contraire, lorsque le phénol de départ possède un substituant méta, la forme *anti* la moins encombrée est le seul isomère obtenu. On a constaté un effet d'anisotropie inhabituellement fort du groupe antipyryle provoquant un déblindage du proton le plus proche sur le cycle quinone imide. Dans la réaction entre la *p*-benzoquinone et l'amino-4 antipyrine, la couleur observée est due à la formation de la *p*-quinoneimide et non au complexe de transfert de charge. [Traduit par le journal]

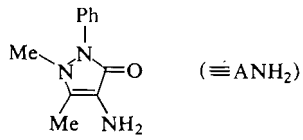
Introduction

The presence of phenols at very low (p.p.b.) concentrations in potable water supplies may cause taste and odor problems on chlorination. The standard procedure (1) for the estimation of phenols at such levels involves the photometric measurement of the dye formed on oxidation of the phenol-containing sample in the presence of excess 4-aminoantipyrine (4-amino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one), **1** (4-AAP). Our



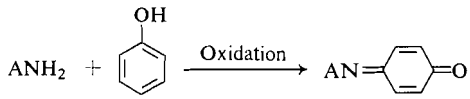
(≡ANH_2)

1

interest in and use of this method have led us to investigate the chemical basis of the test.

The method was introduced by Emerson (2) in 1943; he suggested on the basis of analogy with other aromatic amines that the reaction led to the formation of a *p*-quinoneimide adduct (see Scheme 1).

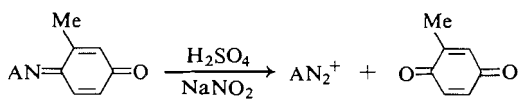
Para-coupling was proposed to explain the failure of the reaction with those phenols having



SCHEME 1

alkyl, aryl, nitroso, nitro, benzoyl, ester, and aldehyde groups in the para-position. However, certain *p*-substituted phenols did show a positive response and these groups (halo, carboxyl, alkoxyl, and sulfonic acid) were said to be expelled. No explanation of the nature of the "expulsion" was advanced.

Emerson and Sagal (3) later reported degradative evidence to support the proposed *p*-quinoneimide structure. *p*-Toluquinone was isolated following the hydrolysis, under diazotization conditions, of the dye obtained from *m*-cresol



SCHEME 2

Müller *et al.* (4) have since questioned the proposed expulsion of groups from the para-position. They were unable to detect the removal

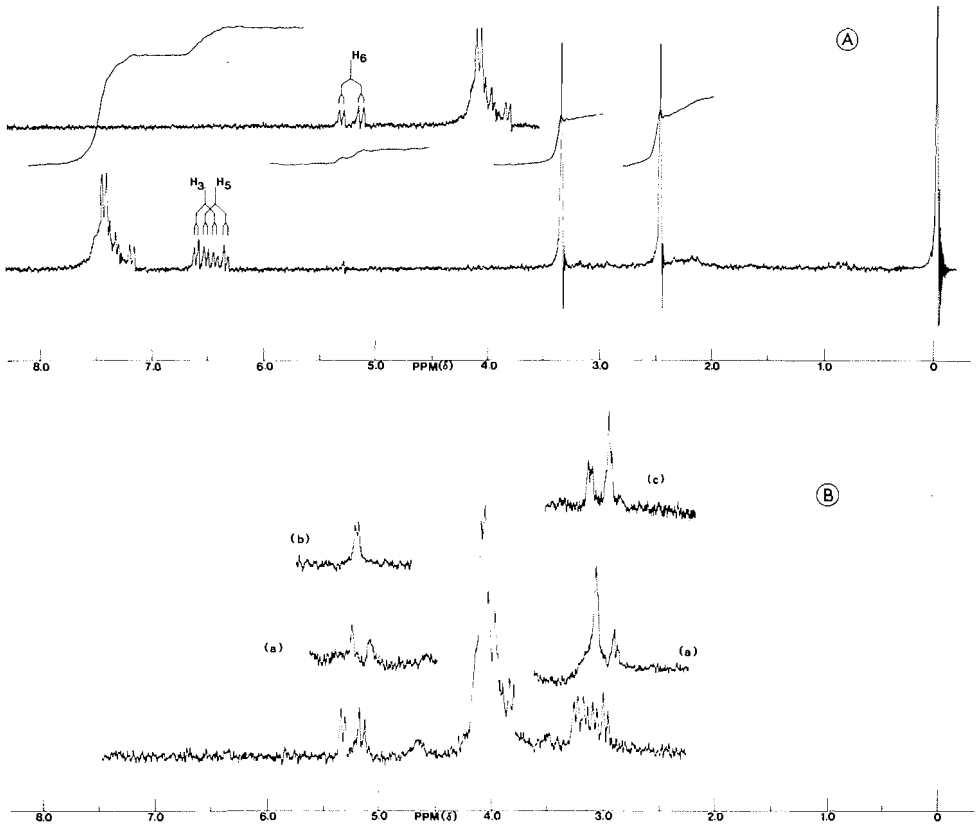


FIG. 1. (A) P.m.r. spectrum of phenol adduct, **2**. Upper trace offset 200 Hz. (B) Decoupled vinylic signals in **2**: (*a*) H_2 irradiated, (*b*) H_5 irradiated, (*c*) H_6 irradiated.

of carboxyl or alkoxyl substituents and consequently suggested that ortho-coupling had occurred. However, more recent studies (5–7) appear to confirm Emerson's original hypothesis. Dyes were isolated from the reactions of *p*-halophenols and the corresponding unsubstituted compounds. The products were found to be identical, confirming the elimination of the halogen atom. On the basis of visible spectra it was concluded that expulsion of *p*-alkoxyl and *p*-carboxyl groups also occurred. Elemental analyses on the isolated dyes gave empirical formulas corresponding to the structure of the expected *p*-quinoneimide adduct. Unfortunately, however, no other physical proof of structure was examined.

Thielemann (8) has recently shown that *p*-benzoquinone forms a dye with 4-AAP, which on chromatographic evidence is identical to that obtained from the oxidation of phenol. This might be taken as further proof of the *p*-quinoneimide structure. However, Okano and Uekama (9) reported that *p*-quinones gave colored products not only with 4-AAP, but also with other antipyrine derivatives where imide formation is impossible. They suggested that the formation of charge-transfer complexes was responsible for the color. Such complexes would, of course, also show the hydrolytic behavior quoted by Emerson as proof of the quinoneimide structure.

Thus there is no conclusive evidence for the structure of the dye products, and since such knowledge is essential for a fundamental understanding of the reaction pathway, we have consequently reinvestigated the Emerson reaction using modern spectroscopic techniques. The method chosen was to carry out the reaction with model phenols and to examine the p.m.r. spectra of the isolated dyes. As a result we have been able to assign the structure of the adducts unambiguously and further to reveal hitherto unobserved structural details.

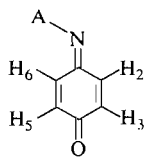
Results and Discussion

Phenol and Reactive Para-substituted Phenols

Phenol and its *p*-chloro, -carboxyl, and -methoxy derivatives were found to react to each give a dye having a similar m.p. and an identical p.m.r. spectrum. This confirms the elimination of the latter two groups, previously proposed (6) on the basis of visible spectroscopy. The p.m.r. spectrum, shown in Fig. 1A, confirms the *p*-quinoneimide structure of the product **2**.



2

Apart from the aromatic multiplet and the two methyl singlets arising from the antipyryl group, two vinylic multiplets can be seen. The doublet of doublets, which is at remarkably low field, is assigned (see later) to the proton H_6 which is *syn* to the antipyryl group and is coupled to both H_5 and H_2. The higher field signal, an eight line multiplet, must arise from the overlapping of the two doublets of doublets expected from the protons adjacent to the carbonyl group, H_3 and H_5. Integration of the spectrum suggested that the remaining signals due to H_2, the proton *anti* to the antipyryl group, are buried under the aromatic multiplet (in fact a portion of this signal appears to be visible).

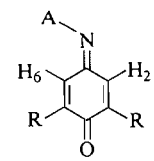
The position of H_2 was confirmed by spin-decoupling experiments, as shown in Fig. 1B. When the suspected H_2 region was irradiated, the signal due to H_6 collapsed to the expected doublet. Similarly the high field vinylic signal now appeared as a mixture of a doublet (one-half of the unchanged doublet of doublets due to H_5) and an unresolved multiplet (assumed to arise from superposition of the other half of the H_5 signal on the collapsed H_3 signal, predicted to be a doublet). A similar, but mirror image, situation was found in this region when H_6 was irradiated. Here H_5 is decoupled while H_3 is unchanged. Finally, the expected narrow doublet for H_6 was observed when H_5 was irradiated. These decoupling experiments reveal that the most deshielded of the protons adjacent to the imino group, H_6, is coupled to the most shielded of the protons adjacent to the carbonyl group, and the reverse. Thus, knowing the identity of H_6, it is possible to assign the identities of all the other ring protons.

The values observed for the vicinal coupling (J_{56}, $J_{23} \simeq 10$ Hz) and for the long-range cross-ring coupling (J_{26}, $J_{35} \simeq 2$ Hz) are of the magnitude reported for other quinone derivatives (10*a*). While the positions of the protons adjacent to the carbonyl group, H_3 and H_5, are very similar, those adjacent to the imino bond, H_2 and H_6, are separated by approximately 1.5 p.p.m., revealing that the antipyryl group has an extremely large anisotropic effect. A similar, but smaller, effect has been reported (11) in the spectra of quinonemonooximes and their anions.

The product from the reaction of *p*-benzoquinone with 4-AAP was identical to that obtained from the oxidation of phenol. Therefore the colors formed from *p*-quinones and 4-AAP are due to the formation of *p*-quinoneimides, and not to charge-transfer complexes, as previously suggested (9).

Symmetrical Ortho-disubstituted Phenols

Adducts **3** and **4** were obtained from 2,4,6-trichlorophenol and 2,6-dimethylphenol respectively. Their p.m.r. spectra are shown in Fig. 2.



3 R = Cl
4 R = Me

With the dichloro compound **3**, which provides a further example of the elimination of a *p*-chlorine atom, the low field doublet assigned to H_6, the proton *syn* to the antipyryl group, is the only visible vinylic signal. It is again assumed that the signal of the *anti* proton, H_2, is buried under the aromatic multiplet. Unfortunately, the low solubility of this compound prevented confirmation by accurate integration.

The p.m.r. spectrum of the dimethyl derivative **4** was unique among the compounds studied in that it revealed the signals of both the *syn* and *anti* proton. Both appeared as identical multiplets due to the additional long-range coupling with the allylic protons of the vicinal methyl group. This coupling, $J_{HCCMe} = 1.4$ Hz, of similar magnitude to those reported (10*b*) for analogous compounds, is also, as expected, shown in the six proton doublet due to these methyl groups.

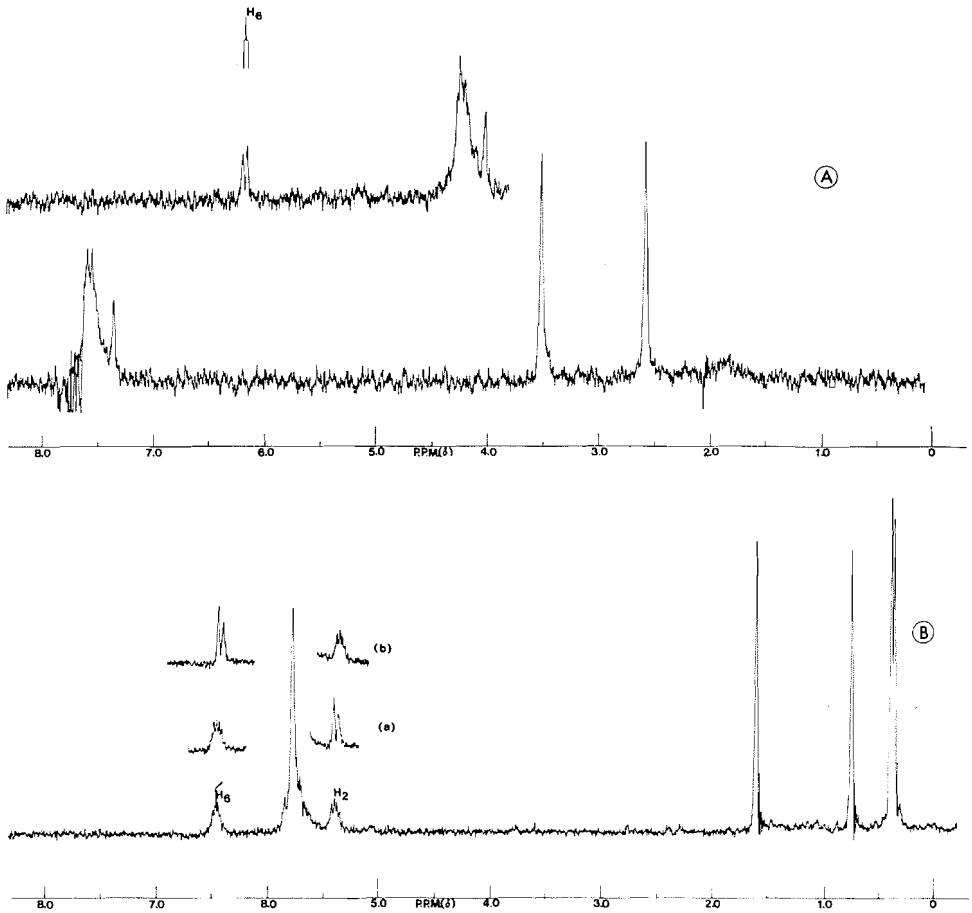

FIG. 2. (A) P.m.r. spectrum of 2,4,6-trichlorophenol adduct, **3**. Upper trace offset 200 Hz. (B) P.m.r. spectrum of 2,6-dimethylphenol adduct, **4**. Complete spectrum offset 100 Hz. Insert: (*a*) H_2 decoupled and (*b*) H_6 decoupled from vicinal methyl group.

When this doublet was irradiated and the H_2 and H_6 signals were examined, each was found to have collapsed to the expected doublet. Similarly, on irradiation of either H_2 or H_6 the methyl doublet collapsed to a broadened singlet.

The absence of signals in the δ 6.5 p.p.m. region in both compounds confirms the previous assignment of signals in this region of the phenol adduct **2** to the protons adjacent to the carbonyl group, H_3 and H_5.

Ortho-monosubstituted Phenols

The identical chloro compound **5** was obtained from both 2-chlorophenol and 2,4-dichlorophenol, confirming the report of Svobodova and Gasparic (6), while *o*-cresol gave the adduct **6**. Their p.m.r. spectra are shown in Fig. 3. Both compounds have a single proton H_5 adjacent to the carbonyl group and one might expect to find in each case a doublet for H_5, which is coupled only with H_6. However, both compounds show four lines in the appropriate region. This result suggests the formation of a mixture of *syn* and *anti* isomers in both cases, a doublet being obtained from each isomer. The presence of geometrical isomers is clearly shown in the appearance of the lowest field signals,

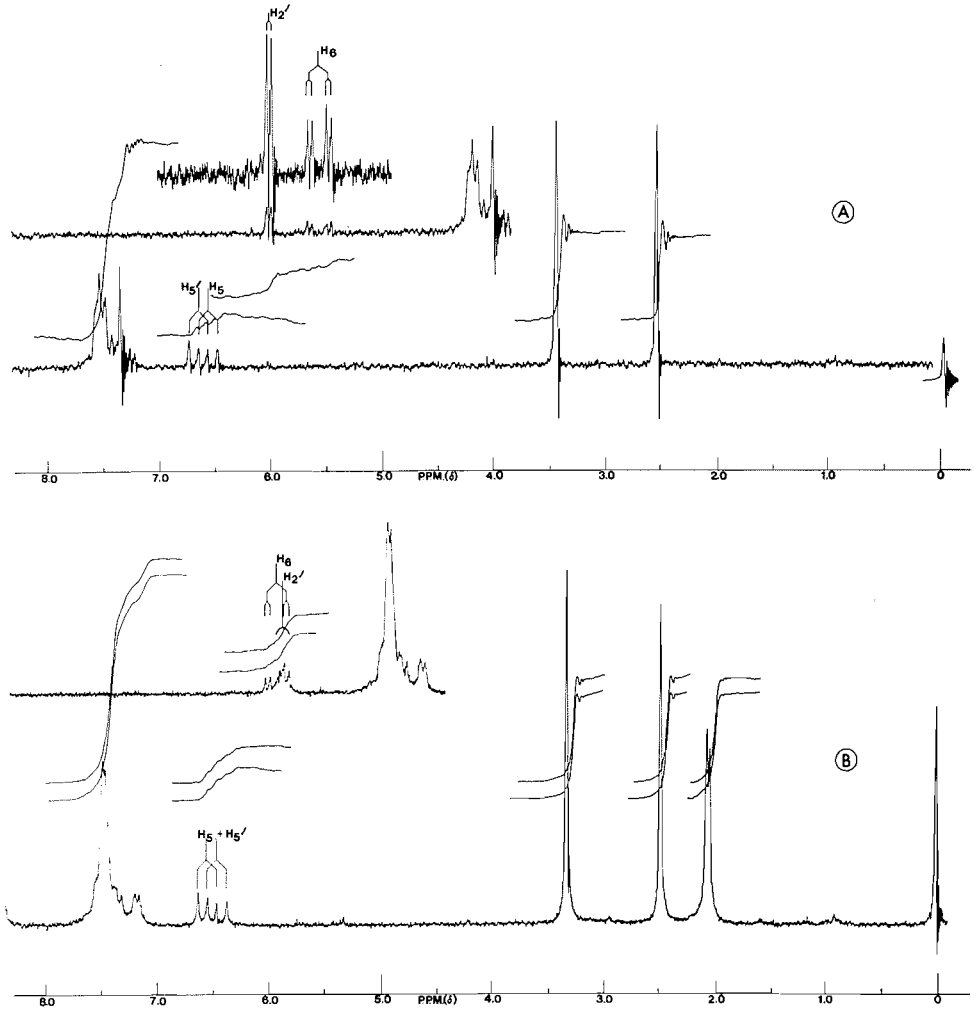

FIG. 3. (A) P.m.r. spectrum of 2-chlorophenol adducts, **5***a* and *b*. Upper trace offset 200 Hz. (B) P.m.r. spectrum of *o*-cresol adducts, **6***a* and *b*. Upper trace offset 150 Hz.

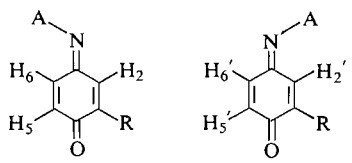


5 R = Cl
6 R = Me

which arise from a proton adjacent to the C=N bond and *syn* to the antipyryl group. Inspection of the chloro compounds, **5***a* and *b*, shows that these protons, H_6 and H_2', are not identical chemically. In the *anti* isomer **5***a* the proton H_6, coupled to both H_2 and H_5, should appear as a doublet of doublets, whereas in the *syn* isomer **5***b* this proton H_2' is only coupled to H_6' and should therefore be a doublet. Examination of Fig. 3A reveals the predicted splitting pattern. Spin-decoupling experiments confirm the proposed coupling assignments, and also reveal that in the four line high field vinylic signal due to H_5 and H_5', the former is the more shielded of the two protons. Again the protons adjacent to the C=N bond and *anti* to the antipyryl group, H_2 and H_6', appear to be hidden under the phenyl multiplet.

The lowest field signals of the *o*-cresol adducts, **6***a* and *b*, are more complex than those of the chloro analog, due to the additional long-range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

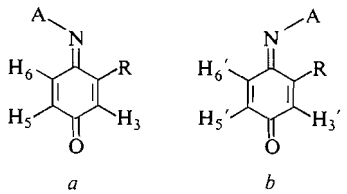
coupling of H_2' with the allylic protons of the vicinal methyl group. While one-half of the doublet of doublets due to H_6 is clearly visible, the other half is superimposed on the multiplet arising from H_2'. As with the chloro compounds the *anti* protons, H_2 and H_6', are not visible.

Comparison of the lowest field signals of **5** and **6** shows that in the chloro compound **5**, H_2' (adjacent to chlorine) is at lower field than H_6 (adjacent to hydrogen), while the reverse is true for the methyl analog **6**. Therefore the vinylic proton is deshielded by a vicinal chlorine atom and shielded by a vicinal methyl group. This follows the expected trend for substituted alkenes (10*c*).

In both cases approximately equal amounts of the *syn* and *anti* isomer appear to have been formed. This might have been anticipated, since there should be little interaction between the substituent and the remote antipyryl group, and consequently both isomers should be of similar energy.

Meta-monosubstituted Phenols

In all of the previous adducts **2**–**6**, the ring positions ortho to the C=N bond are unsubstituted. Although the signals of these protons, H_2 and H_6, are widely separated because of the anisotropy of the antipyryl group, it is not possible *a priori* to distinguish the identity of each signal. Accordingly the adducts **7** and **8** were prepared from 3-chlorophenol and *m*-cresol respectively. Here it might be anticipated



a *b*

7 R = Cl
8 R = Me

that unequal amounts of the *syn* and *anti* isomers would be produced, with the *anti* isomer *a* predominating in each case, because of unfavorable steric interaction between the substituent and antipyryl groups in the *syn* configuration. Examination of Fisher–Hirschfelder–Taylor models confirms that there is severe crowding in the *syn* isomer *b*.

The p.m.r. spectra illustrated in Fig. 4 clearly show in both cases a low field doublet. With the chloro compound **7**, integration of this doublet indicates that a single isomer, which from the above argument must be the *anti* isomer **7***a*, has been formed. Thus the lowest field signal must be due to H_6, the proton *syn* to the antipyryl group in the *anti* isomer. The presence of a single isomer appears to be confirmed by the high field vinylic signal, since only one doublet, due to coupling of H_3 with H_5, and one doublet of doublets, arising from the coupling of H_5 with both H_3 and H_6, are apparent.

A similar situation is found with the *m*-cresol adduct where again only a single isomer, **8***a*, appears to have been formed. The high field vinylic region is more complex than for the chloro compound due to additional long-range coupling of H_3 with the vicinal methyl group. The H_3 multiplet is superimposed upon one-half of the doublet of doublets due to H_5.

The formation of a single isomer, presumed to be *anti*, has also been noted (11) from the p.m.r. spectra of appropriately substituted quinone-oximes. The results allow us therefore to unambiguously assign signals for H_2 and H_6 in the previous compounds **2**–**6**.

The antipyryl group consequently can be seen to exert a substantial anisotropic effect, causing deshielding of a proton *syn* to it and adjacent to the C=N bond. While differences in the chemical shifts of *syn* and *anti* protons have been noted (10*d*) in the spectra of several classes of compounds having a C=N bond, the anisotropic effect of the antipyryl group is unusually large. The effect may be due to a conformation in which the *syn* proton may lie in the plane of the antipyryl carbonyl group and close to the oxygen atom, since large deshieldings have been noted (10*e*) in such cases. Examination of Fisher–Hirschfelder–Taylor models indicates that steric crowding may prevent free rotation of the antipyryl group around its external C—N bond and that in the resulting fixed conformation the *syn* hydrogen may in fact lie close to the antipyryl carbonyl oxygen.

In addition, the antipyryl group appears to have an opposite, but greatly reduced, effect on the *syn* proton meta to the C=N bond. Thus, in the phenol adduct **2** the *syn* proton H_5 is more shielded than the *anti* proton H_3. An identical result is found with the products from the ortho-substituted phenols **5** and **6**. In both cases, the *syn* proton H_5 in the *syn* isomer resonates at higher field than the corresponding *anti* proton H_5' of the *anti* isomer.

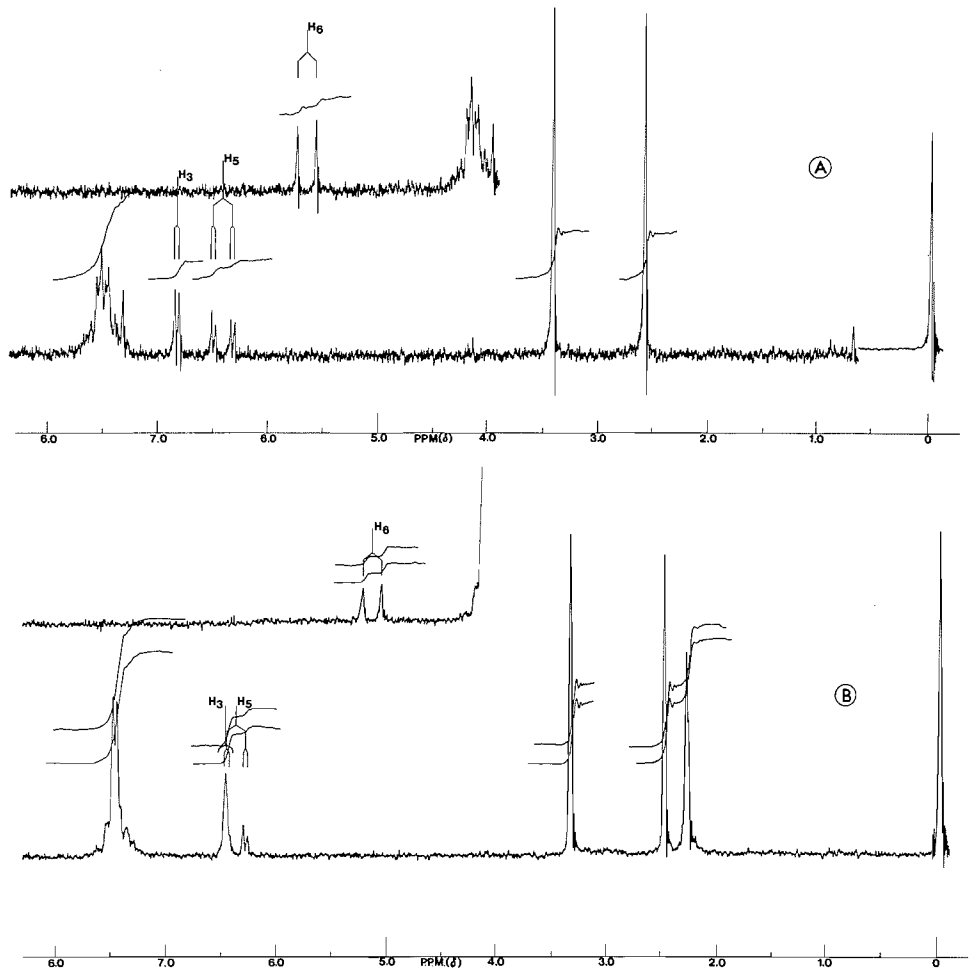


FIG. 4. (A) P.m.r. spectrum of 3-chlorophenol adduct, **7***a*. Upper trace offset 200 Hz. (B) P.m.r. spectrum of *m*-cresol adduct, **8***a*. Upper trace offset 200 Hz.

Experimental

P.m.r. spectra were recorded on a Varian A-60 spectrometer in deuterochloroform solvent and with tetramethylsilane as an internal standard. Spin-decoupling experiments were carried out using a Model V-6058 spin-decoupler.

Buffer solutions of p*H* 10.4 and 6.86 were prepared by dissolving dry buffer salt (Fisher) in distilled water. Buffer solutions for the p*H* 8 region were prepared by adjusting the latter, using a p*H* meter, to the appropriate p*H* by addition of dilute ammonia. 4-Aminoantipyrine (Aldrich) and the starting phenols were purchased from commercial suppliers and were used without further purification.

Melting points were taken on a hot stage apparatus and are uncorrected. Microanalyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

Preparation of Dyes

To a stirred mixture of 1 mmol of the given phenol and 0.35 g (1.5 mmol) of 4-aminoantipyrine in 75 ml of the appropriate buffer solution was added 2.7 g (10 mmol) of potassium persulfate dissolved in 50 ml of the same buffer solution. On mixing, a red color formed instantaneously and precipitation commenced rapidly. The reaction mixture was stirred for 30–60 min and the precipitate was then filtered off and washed several times with distilled water. The solid was then dried in air.

The yield and m.p. of purified samples are recorded in Table 1. P.m.r. spectral data are reported in Tables 2 and 3 (see text for interpretation). In those cases where formation of geometrical isomers was possible, comparison with the p.m.r. spectrum of the crude product indicated that recrystallization had not markedly effected the isomer ratio.

With potassium persulfate as oxidizing agent, only in the case of 2- and 3-chlorophenol was there any indication of the formation of significant amounts of any side-product(s). The unidentified side-product(s) showed several peaks in the δ 2.0–3.5 p.p.m. region. In the case of 3-chlorophenol it was not possible to obtain

TABLE 3. Spin–spin coupling constants (Hz) of *p*-quinoneimide adducts assuming first-order splitting

Compound	
2	$J_{26} = 2.5, J_{35} = 2.1, J_{23} = 10.5, J_{56} = 10.3$
3	$J_{26} \simeq 2$
4	$J_{26} = 2.5, J_{HCCMe} = 1.4$
5	$J_{26} = J_{2'6'} = 2.6, J_{56} = 10.4, J_{5'6'} = 10.0$
6	$J_{26} = 2.8, J_{56} = 10.4, J_{5'6'} = 10.1$
7	$J_{35} = 2.4, J_{56} = 10.3$
8	$J_{35} = 2.4, J_{56} = 10.2, J_{HCCMe} = 1.2$

a pure sample of **7** by recrystallization, although the p.m.r. spectrum showed that it was present and only in the *anti* form **7***a*. This difficulty was overcome by the substitution of 6.6 g (20 mmol) of potassium ferricyanide as oxidizing agent. In this case there was no impurity formation and **7***a* was the sole product. Similar difficulties with these and other halophenols have been noted (7).

Reaction Between p-Benzoquinone and 4-Aminoantipyrine

Addition of 0.108 g (1 mmol) of *p*-benzoquinone (yellow) and 0.203 g (1 mmol) of 4-aminoantipyrine (cream) to 10 ml of chloroform gave a red solution. This was allowed to stand in the dark for 70 h. Addition of 100–120° petroleum ether caused the precipitation of a reddish brown solid. This was filtered off to give 0.262 g (89%) of **2**, m.p. 162–167°. Recrystallization from benzene – 100–120° petroleum ether gave 0.215 g (73%) of red crystals, m.p 166–169°. The p.m.r. spectrum of the product was identical to that of the compound from the oxidation of phenol.

Grateful acknowledgment is made to the National Research Council of Canada for its generous support of this work.

Photoisomerization of Acylsilanes to Siloxycarbenes, and Their Reactions with Polar Reagents[1]

J. M. DUFF AND A. G. BROOK
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received February 1, 1973

The photolysis of acylsilanes in a variety of polar reagents (alcohols, acetic acid, HCN, pyrrole, etc.) is shown to involve formation of isomeric siloxycarbenes which act as nucleophiles and insert into the polar H—X bonds present in the reagents. With alcohols as solvents, mixed acetals of an aldehyde with 1 mol each of silanol and alcohol are formed, but these subsequently undergo dark, acid-catalyzed reactions, by one of two mechanisms which involve either carbon–oxygen or silicon–oxygen bond cleavage. The acid catalyst appears to be a by-product of the photolysis reaction. Kinetic and stereochemical evidence is presented in support of the proposed reaction pathways.

On a montré que la photolyse d'acylsilanes dans une série de réactifs polaires (alcools, acide acétique, HCN, pyrrole, etc.) implique la formation de siloxycarbènes isomériques qui agissent comme un nucléophile afin de s'insérer dans les liens polaires H—X que l'on trouve dans les réactifs. En se servant d'alcool comme solvant, des mélanges d'acétales d'une aldéhyde possédant 1 mol de silanol et 1 mol d'alcool sont formés bien que ces produits subissent par la suite des réactions (dans l'obscurité) catalysées par de l'acide, en suivant un des deux mécanismes impliquant soit un clivage du lien carbone–oxygène soit un clivage du lien silicium–oxygène. Le catalyseur acide a semblé être un produit secondaire de la réaction de photolyse. De même on apporte des preuves cinétiques et stéréochimiques afin d'appuyer le mécanisme réactionnel proposé. [Traduit par le journal]

Can. J. Chem., **51**, 2869 (1973)

Since their first synthesis in 1957 (1) acylsilanes (R_3SiCOR') have been of considerable interest to chemists because of their extremely long-wavelength carbonyl absorption both in the infrared ($R' = Me$, $\lambda_{max} = 6.08\ \mu$; $R' = Ph$, $\lambda_{max} = 6.18\ \mu$) and ultraviolet $n \rightarrow \pi^*$ region ($R' = Me$, $\lambda_{max} = 380$–390 nm (ε 100–400); $R' = Ph$, $\lambda_{max} = 415$–440 nm (ε 200–300)). Various explanations for these bathochromic shifts have been summarized (2). Following the early discoveries (3, 4) that acylsilanes, particularly in alcohol solution, were unstable to light (*i.e.* normal room illumination) the study of the photochemistry of acylsilanes has been a subject of continuing interest in these laboratories (5–11). A preliminary report (5) dealing with photolyses of a variety of acylsilanes in alcohol solution indicated that two types of processes appeared to be occurring depending on whether or not traces of base were present in the solvent. We describe here a mechanistic and stereochemical study of these processes and the results of photolyses in related protic solvents.

[1]From the Ph.D. Thesis of J. M. Duff, University of Toronto, 1970.

Photolyses in Protic Reagents in the Presence of Added Base

The photolyses of almost all acylsilanes in alcohols to which a trace of weak base (usually pyridine) has been added are relatively clean, rapid reactions giving as the single major product a mixed acetal of an aldehyde with silanol and the alcohol solvent.

These acetals are isolable as such only when base is present and, as will be described later, are very sensitive towards acid-catalyzed solvolysis. Typical results are shown in Table 1. The structures were established by normal spectroscopic methods and in some cases by alternative syntheses. For example, the product from the photolysis of acetyltriphenylsilane in ethanol was also readily synthesized by the addition of triphenylsilanol to ethyl vinyl ether using the procedure of Shostakovskii *et al.* (12). This product, like the other mixed acetals, showed an

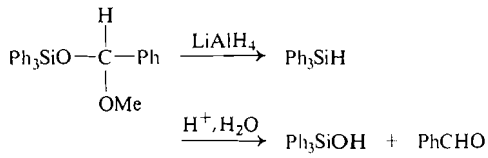
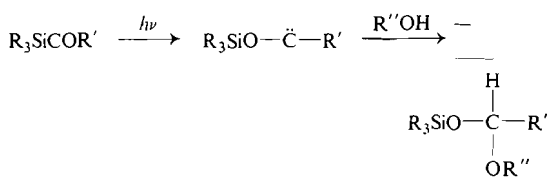
+ $CH_2{=}CHOEt$

Degradative studies also confirmed the mixed acetal structures. Thus reduction with lithium aluminum hydride under conditions known to reduce alkoxysilanes gave the corresponding silanes in good yield and acid- or base-catalyzed hydrolysis gave the expected silanol and aldehyde.

As has been proposed earlier (5) the formation of these mixed acetal products can be interpreted as arising from the insertion of a photochemically generated siloxycarbene into the polar O—H bond of the various alcohols.





In order to determine the scope of these insertion reactions the photolysis of benzoyltriphenylsilane in other polar solvents was investigated. Products corresponding to the

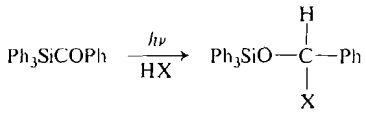
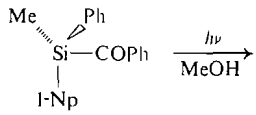
"insertion" of the siloxycarbene into the polar bonds of acetic acid hydrogen cyanide, hydrogen chloride, pyrrole, thiophenol, and malononitrile have been characterized. Though not essential in these reactions, the addition of base (pyridine for hydrogen cyanide and sodium acetate for acetic acid) sometimes afforded higher yields of the insertion products.



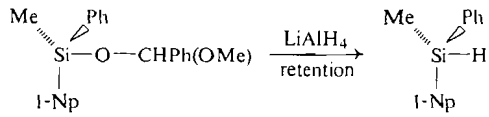
The acetic acid, pyrrole, and hydrogen cyanide products were relatively stable solids and could be crystallized in pure form. Others were too unstable to isolate analytically pure. Photolysis in aqueous dioxane gave triphenylsilanol and benzaldehyde, the products expected from decomposition of the intermediate H—OH insertion product (the hemiacetal $Ph_3SiOCHPh(OH)$). Related products were formed with acetyltriphenylsilane in acetic acid, hydrogen cyanide, or hydrogen chloride and with cyclic acylsilanes such as 1,1-diphenylsilacyclohexan-2-one in acetic acid, the other reagents not being tested. The above reagents, and alcohols, are related in that they possess reasonably acidic hydrogens ($pK_a < \sim 16$). However, no similar insertions were observed when acylsilanes were irradiated in the similarly acidic solvents, nitromethane or cyclopentadiene. The significance of these results will be discussed later.

The Stereochemistry of the Photolyses in Alcohol

When optically active benzoyl-1-naphthylphenylmethylsilane, $[\alpha]_D$ 6.2°, was photolyzed in methanol containing a trace of pyridine an optically active mixed acetal, $[\alpha]_D$ −8.2°, containing about 6% of 1-naphthylphenylmethylmethoxysilane was obtained. This mixture was reduced with lithium aluminum hydride under conditions known to reduce alkoxysilanes with retention of configuration (13), and the configuration (14) of the 1-naphthylphenylmethylsilane isolated ($[\alpha]_D$ −25°, *ca.* 75% optically pure) was identical to that of the starting benzoylsilane (15). Hence it is evident that the mixed acetal was formed from the acylsilane with at least 75% net retention of configuration.



6.2°

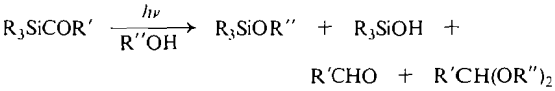


−8.2° −25°

Small amounts of methoxysilane, which probably arose from solvolysis of the mixed acetal, a reaction which occurs with inversion of configuration at silicon (13), would effectively reduce the optical purity of the hydride so the value of 75% represents a minimum optical purity for the mixed acetal.

Photolyses of Acylsilanes in Alcohols

When the acylsilanes were irradiated in purified methanol or ethanol the products usually obtained were "solvolysis" products, a mixture of alkoxysilane, silanol, aldehyde, and aldehyde dialkyl acetal. The products were identified and their yields determined by a combination of i.r., n.m.r., g.l.c. analyses and, in some cases, isolation. Some typical results are shown in Table 2.



One exception was benzoyl-1-naphthylphenylmethylsilane, which, when irradiated in purified methanol, gave the mixed acetal previously found in basic alcohol as the major reaction product. When the composition of this solution was subsequently followed with time, in the dark, using n.m.r. analysis of aliquots, it was observed that the mixed acetal concentration slowly fell while at the same time the concentration of methoxysilane, silanol, benzaldehyde, and benzaldehyde dimethyl acetal grew at a similar rate to eventually become the sole components in the system. This process could be inhibited by adding a few drops of pyridine which stabilized the mixed acetal. Hence it is evident that the solvolysis products were being

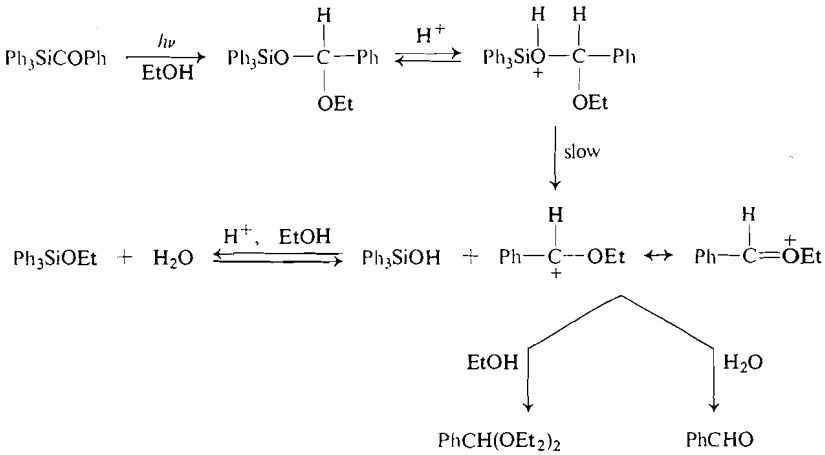

SCHEME 1

formed in the dark from the mixed acetal, a finding shown to be true for other acylsilanes under a variety of conditions.

By cooling the solution being photolyzed it was possible to slow down the rate of solvolysis while not significantly altering the rate of photolysis. A further differentiation in rates was effected by using two lamps, thereby doubling the rate of photolysis. Using these conditions and by removing aliquots of the photosolution and stabilizing these solutions by addition of pyridine it was possible, using a combination of n.m.r. and g.l.c. analysis, to determine with reasonable accuracy and reproducibility the concentrations of most of the species in the system.

The resulting kinetic data indicated that there were two different modes of acid-catalyzed decomposition of the mixed acetals, one predominating with benzoylsilanes and the other with acetyltriphenylsilane.

The behavior of benzoyltriphenylsilane in ethanol is illustrated in Scheme 1. Photolysis gives the mixed acetal initially but in the presence of acid (to be documented later) protonation on the siloxy-oxygen followed by slow, rate-determining dissociation gives silanol (which can be isolated in good yield) and a resonance-stabilized carbonium ion. The silanol, in the acidic alcohol, is fairly rapidly converted to ethoxysilane, this being a known reaction (16). The carbonium ion (which may never be truly free) suffers attack at carbon by ethanol to yield primarily benzaldehyde diethyl acetal but, with traces of water present, may also yield some free aldehyde via the hemiacetal.

This mechanism is supported by the kinetic data of Fig. 1. The benzoylsilane concentration rapidly fell to zero over about 20 min, at which time the light was shut off. While less obvious in this case, due to its instability, the concentra-

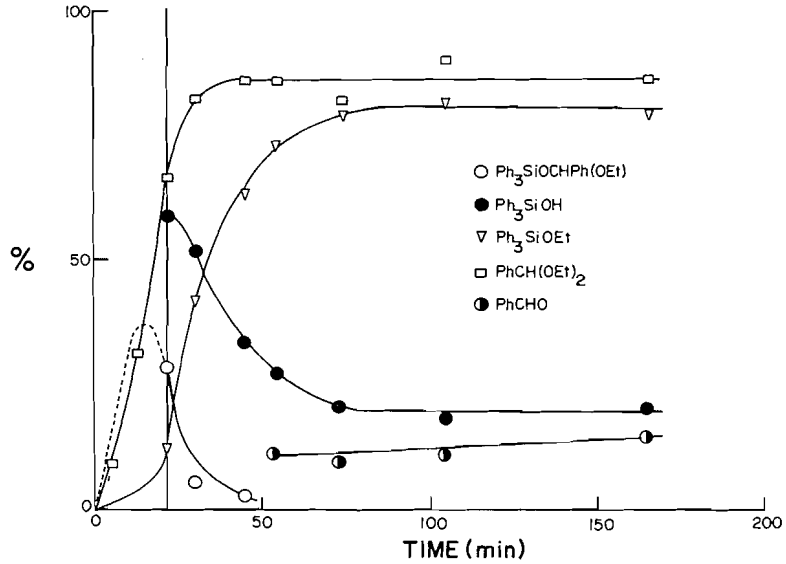

FIG. 1. Plot of the product yields *vs.* time for the photolysis of benzoyltriphenylsilane in ethanol at 0°.

tion of mixed acetal, shown by the dotted curve, initially rose rapidly, paralleling the decay of acylsilane, but it then began to decompose, giving rise to triphenylsilanol and benzaldehyde diethyl acetal. The silanol concentration also diminished as triphenylethoxysilane was formed, until an equilibrium mixture was reached.

The photolysis of benzoyltriphenylsilane in methanol was similar but in this case the rate of decomposition of the mixed acetal was relatively slow and the silanol concentration did not build up to the same extent, being present in about 30% yield at the most during the reaction.

Three additional pieces of information support this mechanism involving acid-catalyzed displacement at carbon. Firstly, the kinetics of decomposition of $Ph_3SiOCHPh(OMe)$ could be determined at 0° and the log concentration *vs.* time plot was a good straight line (Fig. 2) in accord with the *pseudo* first-order kinetics required by Scheme 1. Secondly, a series of para-substituted benzoyltriphenylsilanes were photolyzed in methanol and the rates of decomposition of the mixed acetals were followed by n.m.r. spectroscopy. The acetals derived from *p*-methoxy- and *p*-*t*-butyl-benzoyltriphenylsilane decomposed too rapidly to measure quantitatively and had disappeared by the time the photolyses were completed. The *p*-chloro and *p*-bromo mixed acetals were less reactive than the unsubstituted compound, the *pseudo* first-

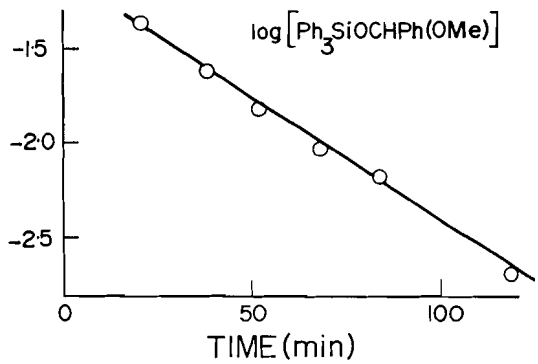

FIG. 2. Plot of log [$Ph_3SiOCHPh(OMe)$] *vs.* time for the photolysis of benzoyltriphenylsilane in methanol at 0°.

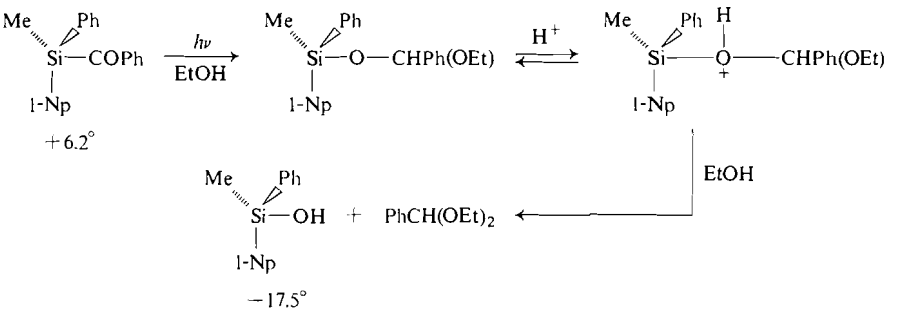
order rate constants being 4.56×10^{-2}, 3.07×10^{-2}, and 3.75×10^{-2} min^{-1} for the unsubstituted *p*-chloro and *p*-bromo compounds, respectively. This behavior is that expected from a reaction involving rate-determining formation of a benzyl-type carbonium ion stabilized by resonance interaction with a *p*-substituent.

Finally, the stereochemistry of the decomposition of the mixed acetal from (+)-benzoyl-1-naphthylphenylmethylsilane has been established. As shown above, the mixed acetal was formed in methanol with a high degree of retention of configuration. If the proposed mechanism were valid the silanol would also be formed with retention of configuration because the C—O bond breaking during solvolysis does not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



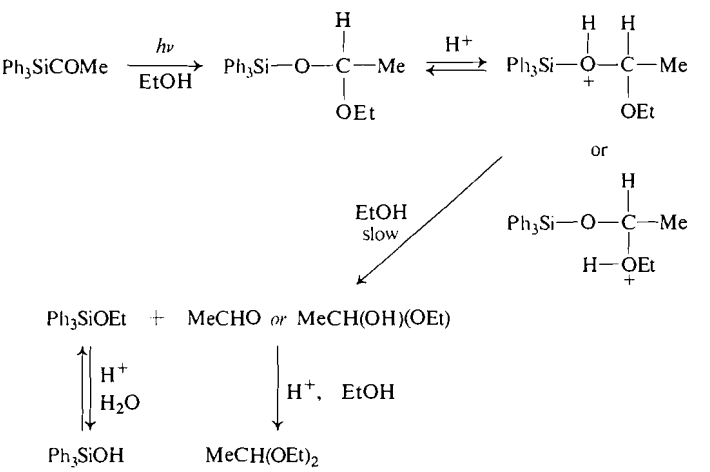
involve the asymmetric silicon center. The chiral benzoylsilane was photolyzed in ethanol at 0° and small amounts of the photolysis solution were removed and examined by infrared spectroscopy. When a maximum amount of silanol was indicated, the reaction mixture was worked up to give a 40% yield of (−)-1-napthylphenylmethylsilanol, $[\alpha]_D$ −17.5° (isolated by chromatography under conditions where the accompanying mixed acetal and methoxysilane were stable), which corresponds to an optical purity of at least 85% and to retention of configuration at silicon.

Hence it is clear that the decomposition of the mixed acetal from a benzoylsilane involves cleavage of the carbon–oxygen bond, the same process as is known to occur in general acid-catalyzed acetal formation or decomposition (17).

When the optically active (+)-benzoylsilane was irradiated in methanol the resultant methoxysilane, the major product present in the solution after *ca.* 1 h at room temperature (which arose through the acid-catalyzed methanolysis of the silanol), was found to be virtually racemic. This finding was not unexpected since it is known that the rate of racemization of 1-naphthylphenylmethylmethoxysilane in methanol is considerably accelerated by traces of acid (18). A previous report (5) that the methoxysilane thus obtained was significantly levorotatory is now believed to be erroneous (the product was levorotatory due to the presence of (−)-mixed acetal and (−)-silanol in the photolyzate).

A second mode of decomposition of the mixed acetals, believed to predominate in the photolysis of acetyltriphenylsilane in ethanol, is shown in Scheme 2. Here, protonation of the mixed acetal (either on the siloxy or ethoxy oxygen) followed by nucleophilic attack at silicon by ethanol yields ethoxysilane and the hemiacetal of acetaldehyde or, by what is essentially a β-elimination mechanism, acetaldehyde plus ethanol. These two alternatives have not been distinguished.

The data in Fig. 3 confirms the general features



SCHEME 2

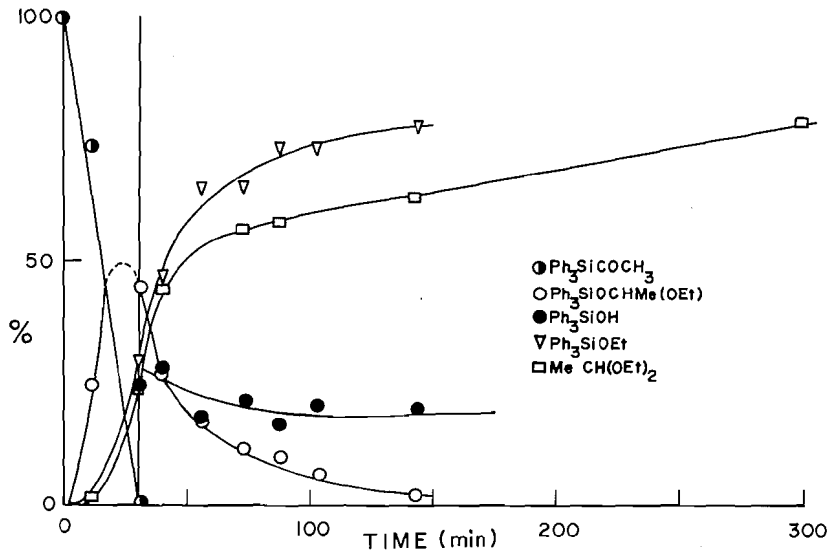

FIG. 3. Plot of the product yields *vs.* time for the photolysis of acetyltriphenylsilane in ethanol at 0°.

expected of this mechanism. Again acetylsilane rapidly decreased in concentration during the photolysis time (*ca.* 30 min) and the mixed acetal concentration rapidly increased initially and then fell off as it suffered solvolysis. The log concentration *vs.* time plot for the decomposition of $Ph_3SiOCHMe(OEt)$ was linear (Fig. 4) in accord with the proposed mechanism. Unlike the previous case, when silanol was formed initially, here ethoxysilane appears to be formed directly from the mixed acetal, there being no evidence for major amounts of silanol. (This was even more evident in the data for the solvolysis in methanol where by the time the acetylsilane concentration was down to 20% the methoxysilane concentration had reached 70%). What is equally important is that, as expected from the mechanism of Scheme 2, the amount of acetaldehyde diethyl acetal builds up at a rate which is much slower than the rate of decomposition of the mixed acetal; this is consistent with the independent formation of acetaldehyde diethyl acetal from acetaldehyde or its hemiacetal. The silanol could have arisen from hydrolysis of the mixed acetal or ethoxysilane due to the traces of water in the system.

In summary, it appears that there are two distinct mechanisms for the acid-catalyzed decomposition of the (photochemically formed) mixed acetals. The mixed acetals from benzoyltriphenylsilane preferentially undergo acetal carbon–oxygen bond cleavage (cf. conventional

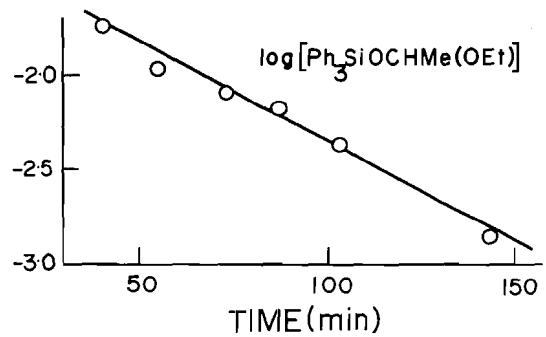

FIG. 4 Plot of log [$Ph_3SiOCHMe(OEt)$] *vs.* time for the photolysis of acetyltriphenylsilane in ethanol at 0°.

acetal hydrolysis), while those from acetylsilanes preferentially undergo silicon–oxygen bond cleavage (cf. solvolysis of alkoxysilanes or β-elimination).

Evidence for the Presence of Acid

It was indicated above that the solvolyses reaction were acid-catalyzed but we have deferred until now evidence that acids were involved and what their source was. It appears that the acid present is photochemically generated. Thus, solutions of benzoyltriphenylsilane in carefully purified methanol, on titration immediately after photolysis, shown an increased acid concentration of the order of 1/100 of a mole per mole of benzoylsilane photolyzed. Great precautions were taken to avoid the possibility that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the acid was introduced as an impurity on the surface of the glassware by using a variety of treatments of the glassware or by using polyethylene flasks, neither of which altered the observed phenomena.

Further evidence that acid was formed during the photolysis was provided by showing that although benzaldehyde was indefinitely stable in the methanol or ethanol used in the experiments or in solutions of acylsilane in the dark, if it was added to any photolysis solution it was relatively rapidly converted, in the dark, to benzaldehyde dialkyl acetal. Acid is the only effective catalyst known for this conversion (19, 20) and the rate of the process, under standard conditions, could be used to establish the relative acidity of various photosolutions. From observed rates it was deduced that the acetyltriphenylsilane–methanol photosolution was markedly more acidic than the photosolution from benzoyltriphenylsilane in methanol which in turn was slightly more acidic than that from benzoyl-1-napthylphenylmethylsilane in ethanol.

This acetal formation could be duplicated by adding comparable amounts (*ca.* 0.01 mol. equiv.) of relatively strong acids (sulfanilic, hydrochloric, oxalic) to solutions of benzaldehyde in alcohol but comparable rates of conversion could not be effected by addition of formic or acetic acid in similar (or even markedly greater) concentration. This suggests that the latter acids, which might conceivably have arisen from oxidation of the alcohols, cannot be the species responsible for the catalysis. Benzoic acid (conceivably formed by oxidation of benzaldehyde, although precautions were taken to avoid oxidation by working under nitrogen) was more effective as a catalyst than formic or acetic acid, but only at much higher concentrations than had been indicated by titration did it duplicate the rate of acetal formation in the photosolutions. The phenomenon of acid-catalyzed processes occurring during photolyses in alcohols is not unique to acylsilanes (21–23).

The Mechanism of Formation of the Mixed Acetals and Related Products

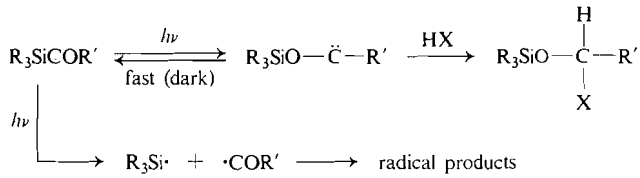
There is now compelling evidence in the literature that some ketones can be photoisomerized to oxacarbenes (21). The results described above are readily explained by similar photoisomerizations of acylsilanes to siloxycarbenes which

$$R_3SiCOR' \xrightarrow{h\nu} R_3SiO-\ddot{C}-R' \xrightarrow{HX} R_3SiO-\underset{X}{\overset{H}{C}}-R'$$

insert into polar bonds giving rise to mixed acetals and related products.

In principle the siloxycarbene could be nucleophilic or electrophilic in character, *i.e.* the effectiveness of trapping agents would depend either on their proton donating or electron donating ability. Evidence has already been published which demonstrated that cyclic siloxycarbenes from silacyclohexanones were strongly nucleophilic in nature, forming a cyclopropane adduct with the electron-deficient olefin, diethyl fumarate (9), or oxiranes via nucleophilic attack of the carbonyl group of aldehydes and ketones (10). The photochemistry of the acyclic acylsilanes (none of which were found to form related cyclopropanes or oxiranes in detectable amounts) is also most readily interpreted on the basis of the siloxycarbene being markedly nucleophilic. Thus the reagents which effectively trapped the siloxycarbene were in general acidic (ROH, HOAc, HCN, HCl, pyrrole, etc.). The fact that acetonitrile ($pK_a \sim 25$) failed to react with siloxycarbenes while malononitrile ($pK_a \sim 12$) did so readily demonstrates that it is the acidity of a substance rather than the availability of a site for electrophilic attack (*e.g.* the CN group) which governs whether reaction will occur. Furthermore pyrole ($pK_a \sim 15$) was the only amine of those investigated which was found to trap the carbene from benzoyltriphenylsilane; benzoyltriphenylsilane reacted slowly in the dark with diethylamine ($pK_a \sim 33$) but gave no evidence of undergoing photolysis in this solvent.

However, besides the noticeable nucleophilicity, there is a second property that must be ascribed to siloxycarbenes before the photochemistry of acylsilanes may be fully rationalized. It appears that siloxycarbene formation is a fast, reversible reaction and that if the siloxycarbene is not trapped by a suitable reagent it reverts to acylsilane. (An analogy of this process, involving isomerization of an alkoxycarbene to a ketone, has appeared recently (24).) Scheme 3 illustrates our preferred general mechanism for acylsilane photochemistry in which reversible carbene formation competes with an alternative radical cleavage process (11).



SCHEME 3. Proposed general mechanism for acylsilane photochemistry.

Of the acylsilanes studied to date, benzoyltriphenylsilane appears to undergo carbene formation almost exclusively since it reacts only very slowly when irradiated in nonpolar solvents (25), while phenylacetyltriphenylsilane (even in alcohol solutions) gives only radical-derived products (11). All other acylsilanes investigated show dual behavior, giving carbene products in the presence of suitable reagents, but otherwise forming radical products. In general the radical cleavage appears to be slower than the photoisomerization to siloxycarbene. The isolation of minor amounts of radical-derived product from the photolysis of acetyltriphenylsilane in methanol (11) is in accord with this scheme. This concept of the siloxycarbene as a short-lived nucleophilic intermediate also explains the relative inertness of benzoyltriphenylsilane to irradiation in nitromethane and cyclopentadiene.[2] Although these reagents are moderately acidic (pK_a's *ca.* 10 and 15, respectively) they are known to have a low kinetic acidity (26) (k_1 10^{-8} and 10^{-2}, respectively) in contrast to the reagents which did trap siloxycarbenes ($k_1 \sim 10^9$). With reagents of low kinetic acidity it is probable that the rate of isomerization of siloxycarbene back to acylsilane is more rapid than its rate of proton abstraction from the reagent to give the insertion product.

Finally, it is pertinent to comment on the demonstrated greater tendency of cyclic acylsilanes to react via siloxycarbenes relative to their acyclic analogs. It is apparent from a study of models that the approach of the carbene-carbon to the silicon atom, which is required for their isomerization back to acylsilane, is opposed by ring strain in the cyclic siloxycarbenes. Thus the apparently greater reactivity of the cyclic siloxycarbenes, relative to their acyclic analogs, may be due more to an increased lifetime than to real differences in their reactivities.

Further studies of a photophysical nature, designed to establish the validity of our proposed general mechanism for photolyses (Scheme 3), are in progress.

[2]Cyclopentadiene does not appear to quench the photolysis of benzoyltriphenylsilane in other solvents.

Experimental

General

All photolyses were carried out using a 100 W PAR 38 clear mercury lamp, ASA code H34-4GS (available from Westinghouse); the lamp has intense emission bands at 366, 405, and 436 mμ, reasonably matched with the u.v. absorption maxima of acetyl- and benzoyl-silanes at about 380 and 420 mμ, respectively. Irradiations were carried out in Pyrex flasks under nitrogen. In the case of benzoylsilanes, completion of a photolysis was indicated by the disappearance of the yellow color. For alkanoylsilanes the progress of the irradiation could be followed by observing the disappearance of the i.r. carbonyl band at *ca.* 6.08 μ in small, worked-up samples. Control experiments were carried out to ensure that the acylsilanes did not undergo dark reactions with the solvents and reagents used.

The instruments used in the experiments are as follows: Perkin-Elmer 237B Infrared Spectrophotometer; Varian A60, A56/60, T60 and, occasionally, HA100 n.m.r. spectrometers; AEI MS 902 mass spectrometer, operated at 70 eV.; Galileo-type MN 602 manual polarimeter, using a 1 dm micro-cell; Varian-Aerograph Series 200 dual column g.c. instrument with a thermal conductivity detector. Microanalyses were performed by A. B. Gygli of Toronto.

Photolyses in Alcohol Containing Pyridine

In the experiments described here commercial grade absolute ethanol or reagent grade methanol were used without further purification. Pyridine, 50 μl per 10 ml of solution, was generally used but similar amounts of piperidine or triethylamine gave the same results. Sodium carbonate could also be used for photolyses in ethanol. The standard conditions for an experiment involved irradiation of 0.00069 mol of acylsilane in 10 ml of solvent containing 50 μl of pyridine. The required reaction times and yields of the mixed acetals are given in Table 1. The major products from the acyclic acylsilanes all proved to be unstable oils which partially decomposed on standing at room temperature for several hours, or on attempted distillation. Although some mixed acetals were moderately stable to chromatography on silica gel, this procedure failed to separate them from accompanying alkoxysilane. All products had a characteristic i.r. spectral pattern from 9–10 μ; the n.m.r. spectra of the mixed acetals from the acyclic acylsilanes are given in Table 3.

Confirming evidence for the mixed acetal structures

[a]Carbon tetrachloride solution, internal tetramethylsilane standard.
[b]Nonequivalent methyl groups.
[c]Nonequivalent methylene protons.
[d]Buried in aromatic multiplet.

was obtained from the following mass spectra of crude photolyzates:

(*a*) Benzaldehyde methyl triphenylsilyl acetal (M = $Ph_3SiOCHPh(OMe)$); *m/e* (relative intensity, proposed origin): 396 (3, M), 365 (2, M—OMe), 319 (5, M—Ph), 290 (9, Ph_3SiOMe), 259 (18, Ph_3Si), 213 (29, Ph_2SiOMe), 161 (100, unidentified), 121 (81, PhCH(OMe)).

(*b*) Acetaldehyde ethyl triphenylsilyl acetal (M = $Ph_3SiOCHMe(OEt)$); *m/e* (relative intensity, proposed origin): 348 (5, M), 333 (4, M—Me), 319 (4, M—Et), 303 (10, M—OEt), 271 (21, M—Ph), 259 (100, Ph_3Si), 161 (75, unidentified), 77 (78, Ph), 73 (75, MeCH(OEt)).

(*c*) Benzaldehyde ethyl 1-naphthylphenylmethylsilyl acetal (M = 1-NpPhMeSiOCHPh(OEt)); *m/e* (relative intensity, proposed origin): 398 (1, M), 369 (0.5, M—Et), 292 (10, 1-NpPhMeSiOEt), 277 (13, 1-NpPhSiOEt), 264 (50, 1-NpPhMeSiOH), 249 (90, 1-NpPhSiOH), 135 (100, PhCH(OEt)), 127 (18, Np), 105 (43, PhCO), 77 (70, Ph).

Several cyclic mixed acetals were more stable than their acyclic counterparts and could be purified by distillation. These experiments are described in full.

1,1-Diphenyl-1-sila-2-oxa-3-methoxycycloheptane

A solution of 0.323 g of 1,1-diphenyl-1-silacyclohexanone-2 in magnesium-dried methanol (35 ml) containing 20 μl of pyridine was irradiated for 30 min. Removal of solvent at reduced pressure gave the mixed acetal as an oil contaminated with a small amount of what is believed to be the isomeric open chain aldehyde, 5-(diphenylhydroxysilyl)pentanal (4). The product was chromatographed on silica gel (eluting with benzene) and then was distilled to give the pure mixed acetal, b.p. 130–132°/0.04 mm; i.r. (CCl_4): 9–10 μ (complex, Si—O—C); n.m.r. (CCl_4): δ 7.10–7.75 (m, 10H, aryl-H), 4.90 (broad t, 1H, acetal H), 3.23 (s, 3H, O*Me*), 0.91–2.15 p.p.m. (m, 8H, $(CH_2)_4$).

Anal. Calcd. for $C_{18}H_{22}O_2Si$: C, 72.46; H, 7.43. Found: C, 72.93; H 7.48.

1,1-Dimethyl-1-sila-2-oxa-3-isopropoxycycloheptane

A solution of 1,1-dimethyl-1-silacyclohexanone-2 (1.0 g) in magnesium-dried 2-propanol containing 2 drops of pyridine, at 0°, was irradiated for 6 h. Removal of solvent at reduced pressure, followed by distillation, gave 0.9 g (80%) of the cyclic acetal as clear liquid, b.p. 44–46°/1.0 mm; n_D^{20} 1.4362; i.r. (CCl_4): 9–10 μ (complex, SiOC); n.m.r. (CCl_4): δ 4.83 (broad t, 1H, acetal *H*), 3.83 (septet, J = 6 Hz, 1H, OC*H*Me_2), 1.11, 1.04 (2d, J = 6 Hz, 6H, CH*Me*$_2$), 1.8–0.4 (complex, 8H, $(CH_2)_4$), 0.11, 0.03 p.p.m. (2s, each 3H, $SiMe_2$).

Anal. Calcd. for $C_{10}H_{22}O_2Si$: C, 59.35; H, 10.96. Found: C, 59.18; H, 11.42.

1,1-Dimethyl-1-sila-2-oxa-3-t-butoxycycloheptane

A solution of 2.0 g of 1,1-dimethyl-1-silacyclohexanone-2 in 20 ml of dry *t*-butanol containing 1 drop of pyridine was irradiated for 15 h. Removal of solvent on a rotary evaporator gave a yellow liquid which was distilled (44–45°/0.9 mm) to give 1.8 g (60%) of the cyclic acetal as a colorless liquid, n_D^{20} = 1.4376; i.r. (CCl_4): 9–10 μ (complex, Si—O—C); n.m.r. (CCl_4): δ 5.10 (broad t, 1H, acetal H), 1.15 (s, 9H, Bu^t), 1.8–0.4 (complex, 8H, $(CH_2)_4$), 0.07–0.03 (2s, each 3H, Me_2Si).

Anal. Calcd. for $C_{11}H_{24}O_2Si$: C, 61.16; H, 11.18. Found: C, 61.57; H, 11.51.

Hydrolysis of Benzaldehyde Ethyl Triphenylsilyl Acetal

The photolyzate obtained from 2.3 g of benzoyltriphenylsilane in ethanol (essentially pure mixed acetal), dissolved in 10% aqueous acetone, was treated with 4 drops of concentrated hydrochloric acid. After 30 min, workup using ether–water and distillation of the product

(200°; Kugelrohr) pure benzaldehyde (0.56 g, 84%), identified by its i.r. spectrum was obtained. Recrystallization of the solid residue from carbon tetrachloride – pentane gave pure triphenylsilanol (1.54 g, 88%), m.p. 154–156°, m.m.p. 154–156°. Similar degradations were carried out with other acyclic acetals.

Hydrolysis of 1,1-Diphenyl-1-sila-2-oxa-3-methoxycycloheptane

A sample of 0.41 g of the cyclic acetal in 20 ml of THF was treated with 2 ml of 1% potassium hydroxide. After 15 min the acidified solution was extracted with ether. The product was chromatographed on silica gel, eluting with 1:1 benzene–chloroform, to give 0.25 g (68%) of 5-(diphenylhydroxysilyl)pentanal (4).

Reduction with Lithium Aluminum Hydride

Qualitative degradative tests were carried out by stirring small samples of the triphenylsilyl mixed acetals with excess lithium aluminum hydride in diethyl ether solvent for about 24 h at room temperature. Spectra of the worked-up product showed that triphenylsilane (strong i.r. absorption at 4.70 μ and n.m.r. singlet at δ 5.45 p.p.m.) was the major product.

Alternative Synthesis of Acetaldehyde Triphenylsilyl Ethyl Acetal

A solution of 1.38 g (0.005 mol) of triphenylsilanol in 4.0 g (0.055 mol) of ethyl vinyl ether containing 4 μl of concentrated hydrochloric acid was sealed under nitrogen in a Pyrex tube and was heated at 67° for 21 h. After cooling, removal of the solvent gave a thick, clear, odorless oil, whose spectra were identical to those of the photochemically obtained acetal, $Ph_3SiOCHMe(OEt)$.

Reduction of Optically Active Benzaldehyde 1-Naphthylphenylmethylsilyl Methyl Acetal

The photolyzate from benzoyl-1-naphthylphenylmethylsilane (0.35 g, 0.001 mol), $[\alpha]_D$ +6.2°, in methanol containing pyridine was refluxed for 19 h in di-*n*-butyl ether (30 ml) containing 0.18 g (0.005 mol) of lithium aluminum hydride. Workup gave a thick oil (0.22 g) which was chromatographed on silica gel, eluting with 1:10 petroleum ether (60–70°) – carbon tetrachloride, to give pure 1-naphthylphenylmethylsilane, m.p. 40–51°, $[\alpha]_D$ −25.1° (*c*, 7.65, cyclohexane) (lit. (13) $[\alpha]_D$ 34°, cyclohexane).

Photolysis of Benzoyltriphenylsilane in Aqueous Dioxane

A solution of 0.50 g of benzoyltriphenylsilane in 10 ml of 20% aqueous dioxane was irradiated for 35 min until the color disappeared. Removal of solvent at the rotary evaporator gave an oil; an i.r. spectrum indicated that triphenylsilanol and benzaldehyde were the only products present. Crystallization from carbon tetrachloride – pentane gave 0.34 g (90%) of triphenylsilanol.

Photolysis of Benzoyltriphenylsilane in Acetic Acid

The photolysis of 1.0 g of benzoyltriphenylsilane in glacial acetic acid gave as the major product acetoxytriphenylsilane (along with about 5% of the expected carbene insertion product (see below)). Crystallization from dry hexane gave 0.76 g (91%) of acetoxytriphenylsilane (m.p. 95.5–97°; lit (27) m.p. 97°).

When the photolysis of 1.0 g of the benzoylsilane was carried out in a well-stirred suspension of 1.0 g of sodium acetate in glacial acetic acid (25 ml) it was completed in 25 min. Removal of solvent and extraction of the residue with dry ether gave a mixture of acetoxytriphenylsilane and α-triphenylsiloxybenzyl acetate (*ca.* 21:79 respectively by n.m.r.). After several recrystallizations from hexane had failed to yield pure siloxybenzyl acetate the product was rapidly chromatographed on silica gel, eluting with benzene. Early fractions (0.25 g) were recrystallized from pentane to give pure α-triphenylsiloxybenzyl acetate, m.p. 65–67°.

The results of similar photolyses of acyclic acylsilanes in polar solvents are summarized in Table 4.

Alternative Synthesis of (Triphenylsiloxy)phenylacetonitrile

Benzaldehyde cyanohydrin (29) (1.0 g, 0.0075 mol) was added to a solution of 1.47 g (0.005 mol) of triphenylchlorosilane in 80 ml of hexane–toluene (3:1) containing 0.79 g (0.01 mol) of pyridine. The solution was refluxed for 5 h and then the solvent was removed at reduced pressure. The residue was boiled with 60 ml of hexane and the solution, decanted from insoluble tar, was filtered over charcoal. The product (0.90 g, 46%) was obtained as large clear crystals, m.p. 87.5–89°, the spectra of which were identical to those of the photochemically prepared material (Table 4). Treatment of the nitrile with dilute hydrochloric acid in acetone gave triphenylsilanol (85%) and benzaldehyde cyanohydrin (spectroscopically identified). Concentrated hydrochloric acid (in dioxane) converted the nitrile to triphenylsilanol (80% after recrystallization) and *dl*-mandelic acid (62%), identified by m.m.p.

Degradation of α-Triphenylsiloxybenzylmalononitrile

A sample of 0.80 g of the benzoyltriphenylsilane–malononitrile photolyzate (containing about 15% of triphenylsilanol) was stirred in methanol at 20° for 26 h. Removal of the solvent followed by distillation (150°/10 mm; Kugelrohr) gave 0.18 g (63%) of benzalmalononitrile (i.r. 4.44 μ), m.p. 83–84°; lit. (30) 83.5–84°. The nonvolatile product was recrystallized from carbon tetrachloride – pentane to give 0.48 g (94%) of triphenylsilanol.

Photolysis of 1,1-Diphenyl-1-silacyclohexanone-2 in Acetic Acid

A solution of the acylsilane (0.132 g) in 10 ml of glacial acetic acid was irradiated for 20 min. The solvent was then removed and the residue was distilled to give a clear oil, b.p. *ca.* 170°/0.01 mm, which appeared to be almost pure 1,1-diphenyl-1-sila-2-oxa-3-acetoxycycloheptane; i.r. (CCl_4): 5.71 μ (C=O of acetate); n.m.r. (CCl_4): δ 7.1–7.7 (m, 10H, aromatic H), 6.28 (broad, 1H $OCHOAc$), 1.76 (s, 3H, $COMe$), 1.1–2.1 (complex, 8.2H, $(CH_2)_4$) p.p.m.

A small sample of the above material was hydrolyzed in dilute aqueous acidic acetone at room temperature for 20 h. Workup gave an oil, the spectra of which were identical to those of 5-(diphenylhydroxysilyl)pentanal (4).

Photolyses of Acylsilanes in Purified Alcohols

Pure dry methanol and ethanol were prepared by standard procedures. The glassware used was thoroughly cleaned and dried. Immediately prior to its use a flask was rinsed several times with the same purified alcohol to be used in the photolysis. Following the irradiation of

[d]Samples contained 5 μl pyridine/ml.
[e]Acetaldehyde not detectable.

samples of acylsilane in alcohol, the solvent was removed under reduced pressure and the residue was examined by n.m.r. spectroscopy. Peaks due to the nonvolatile products, silanol, alkoxysilane, and mixed acetal (if present), were generally sufficiently separated to allow determination of the yields by integration. The silanol peak, if it overlapped with any other peak, could generally be shifted to a clear region of the spectrum by diluting the solution.

The yields of the volatile photolysis products, aldehyde and dialkyl acetal, formed in alcohol solution, were determined by direct g.l.c. analysis of the photolysis solutions using a specially prepared 20 ft × 3/8 in. column of 30% SE-30 silicone gum on acid-washed dimethyldichlorosilane-treated Chromosorb W. This column was used in all the work described below. Unfortunately, conditions could not be found, using this or any other column, for the determination of small amounts of acetaldehyde in alcohol since its peak was buried under the solvent peak. Pyridine, which was also used in the kinetic runs to quench further acid-catalyzed reactions, was found to be a convenient internal standard for the yield determinations. The conditions used are shown in Table 5. Calibration curves were prepared for each compound determined.

Representative yields of the volatile products formed in irradiations at room temperature are given in Table 2.

Isolation of the Major Silicon-containing Photolysis Products: Benzoyltriphenylsilane–Ethanol; Isolation of Triphenylsilanol

The photolysis of 0.50 g (0.0014 mol) of benzoyltriphenylsilane in 10 ml of ethanol was complete in 24 min. Removal of the solvent followed by recrystallization of the residue from carbon tetrachloride – hexane gave 0.28 g (74%) of pure triphenylsilanol, m.p. 155–156°, identified by m.m.p.

Similar procedures gave triphenylmethoxysilane from the photolysis of actyltriphenylsilane in methanol and triphenylethoxysilane from acetyltriphenylsilane in ethanol, the products being isolated by crystallization and identified by m.m.p.

A Kinetic Study of the Photolyses in Ethanol and Methanol

In the kinetic runs 0.0069 mol of acylsilane was irradiated in 100 ml of purified alcohol at 0°. Samples were withdrawn using a 10 ml pipette and were mixed with an accurately measured volume of pyridine (50 or 100 μl depending on the run) which served to quench further reaction of the mixed acetal. Small samples of the resulting solution were used for determination of the volatile products by g.l.c., as previously described. The solvent was then removed and the resulting oil, in deuterochloroform, was analyzed by n.m.r. for mixed acetal, silanol, and alkoxysilane. The results of kinetic measurements for two representative runs are represented in Figs. 1 and 3. In most cases at least two runs were carried out; the results were found to be closely reproducible.

The Photolyses of p-Substituted Benzoyltriphenylsilanes in Methanol

The photolyses of *p*-methoxy-, *p*-*t*-butyl-, *p*-bromo-, and *p*-chloro-benzoyltriphenylsilane in methanol containing pyridine were found to proceed at about the same rate as that of benzoyltriphenylsilane and gave analogous products. Table 6 lists the yields of the mixed acetals and the important n.m.r. spectral features of the mixed acetals and solvolysis products (which were later observed in purified alcohol). The corresponding values for benzoyltriphenylsilane are included for comparison. Like the unsubstituted compounds the *p*-substituted mixed acetals were unstable and decomposed readily on standing to (spectroscopically identified) *p*-substituted benzaldehyde, triphenylmethoxysilane, and triphenylsilanol.

The procedure used for the kinetic investigations of the photolyses of *p*-bromo- and *p*-chloro-benzoylsilane was identical to that described above for the unsubstituted compound, but only nonvolatile products were determined.

Isolation of 1-Naphthylphenylmethylsilanol from the Photolysis of (+)-Benzoylsilane in Ethanol

A suspension of 2.43 g (0.0069) of (+)-benzoyl-1-naphthylphenylmethylsilane, $[\alpha]_D$ +6.2°, in 100 ml of purified ethanol at 0°, was irradiated with two lamps for 12 min. Small samples of the photosolution were withdrawn and investigated by i.r. spectroscopy. At the 95 min mark when silanol (2.70 μ) appeared to be at a maximum concentration, a 40 ml sample (equivalent to 0.00276 mol of the starting acylsilane) was withdrawn and was worked up. An n.m.r. spectrum of the resulting product showed that about 40% of 1-naphthylphenylmethylsilanol was present.

The oil was chromatographed on silica gel. Elution with 1:1 benzene – carbon tetrachloride gave, in the first five fractions, 0.51 g of a mixture of the mixed acetal and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

$C(Me)_3$	94	5.85	3.11	1.27	9.87	1.28	5.32	3.26	1.28
H	94	5.85	3.09	—	9.80	—	5.32	3.21	—
Cl	94	5.81	3.10	—	9.80	—	5.31	3.21	—
Br	94	5.79	3.09	—	9.81	—	5.30	3.21	—

[a]In deuterochloroform.
[b]The other products were triphenylmethoxysilane and free aldehyde.
[c]This mixed acetal was very unstable and decomposed in the solution used for n.m.r. spectroscopy.

1-naphthylphenylmethylethoxysilane along with traces of benzaldehyde and benzaldehyde diethyl acetal. The balance of the material eluted with this solvent mixture contained 1-naphthylphenylmethylsilanol along with benzaldehyde and benzaldehyde diethyl acetal. This fraction after being pumped on at 125°/0.1 mm to remove the volatile compounds gave 0.29 g (40%) of oil, $[\alpha]_D$ −17.5° (*c*, 14.3, diethyl ether), judged by n.m.r. to be pure 1-naphthylphenylmethylsilanol (lit. (13) $[\alpha]_D$ 20°, diethyl ether).

1-Naphthylphenylmethylmethoxysilane from the Photolysis of (+)-Benzoyl-1-naphthylphenylmethylsilane in Methanol

A suspension of 0.50 g (0.0014 mol) of (+)-benzoyl-1-naphthylphenylmethylsilane, $[\alpha]_D$ +5.7°, in 25 ml of methanol was irradiated for 26 min. The solution was held at room temperature for 1 h to allow conversion of mixed acetal to silanol and methoxysilane. Workup, followed by pumping on the resulting oil at 60°/0.5 mm for 5 min to remove volatile contaminants, gave 1-naphthylphenylmethylmethoxysilane along with a small amount of 1-naphthylphenylmethylsilanol. This material had $[\alpha]_D^{24}$ −1.5° (*c*, 10.0, cyclohexane).

A repetition of this procedure on a slightly larger scale (0.70 g of the benzoylsilane) gave a similar product having $[\alpha]_D$ −0.5°. In a third run, the crude product was optically inactive. The low negative rotation is not really meaningful since traces of silanol (maximum $[\alpha]_D$ −20°) may have been present in the samples.

Investigations of the Catalyst in the Photosolutions

Titration of the Benzoyltriphenylsilane–Methanol Photosolution (29)

A 10 ml sample of purified methanol containing 1 drop of a 1% solution of thymol blue indicator in methanol was titrated with a 0.102 *N* solution of sodium methoxide in methanol. In five separate titrations 0.05–0.07 ml was required to change the indicator color from red to yellow.

Following this, 0.25 g (0.00069 mol) samples of benzoyltriphenylsilane were irradiated in 10 ml of the same purified methanol until the solutions were bleached.

Similar titration of two such photosolutions required 0.14 and 0.13 ml of titrant corresponding to about 7×10^{-6} mol of acid.

Determination of the Rate of Conversion of Benzaldehyde to its Dialkyl Acetal in Various Photosolutions

The general procedure involved the photolysis of 0.00069 mol of acylsilane in 10 ml of purified alcohol under nitrogen. Benzaldehyde (0.00069 mol) was then added to the solution and 1 ml samples were withdrawn at various times and, following addition of 10.0 μl of pyridine, were analyzed by g.l.c. Results of a typical experiment are shown in Table 7. A similar procedure was used to determine the rate of conversion of benzaldehyde to its dimethyl acetal in methanol containing acetic, formic, benzoic, hydrochloric, oxalic, and sulfanilic acids. Details of a typical experiment may be found in Table 8.

Experiments which were carried out in duplicate gave

excellent reproducibility. In addition, it was found that the use of different samples of alcohol (Fisher Certified ACS methanol, unpurified, dried by distillation from magnesium or purified by conventional procedures) had little effect on the results. Also, in each of the three acylsilane–alcohol photosolutions studied it was shown that results did not depend on the glassware used for the photolyses. Thus the use of previously unused flasks, direct from the manufacturer, gave similar results and when the flask used for a run was immediately rinsed several times with pure alcohol and was then reused for the same experiment, identical results were obtained.

Aryl Carbanions. A ^{13}C Nuclear Magnetic Resonance Study of Deuterium Exchange in Acenaphthenes and Related Aromatic Hydrocarbons[1]

D. H. HUNTER AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ontario
Received March 9, 1973

The base-catalyzed hydrogen–deuterium exchange rates for the aromatic and benzylic centers in acenaphthene, 2,3-dihydrophenalene, 1,8-dimethylnaphthalene, 1,1,2,2,-tetramethylacenaphthene, and diphenylmethane have been determined using ^{13}C n.m.r. The exchange rates serve as a probe of carbanion stability and reactivity, clearly indicating the importance of ring strain effects on carbanion stability.

Les vitesses d'échange hydrogène–deutérium catalysé par une base pour les centres aromatiques et benzyliques de l'acénaphthène, dihydro-2,3 phénalène, diméthyl-1,8 naphtène, tétraméthyl-1,1,2,2 acénaphthène et diphényl méthane, ont été mesurées par la r.m.n. du ^{13}C. Ces vitesses d'échange qui apportent des informations sur la stabilité et la réactivité du carbanion, montrent de façon claire l'importance des effets de tension de cycle sur la stabilité du carbanion. Introduction

Base-catalyzed hydrogen, deuterium, or tritium exchange is a commonly used probe for kinetic acidity and perhaps then for thermodynamic acidity. Several experimental approaches have been used for determining the kinetic acidities of hydrogens in a molecule. Where a molecule has a single reactive site either by symmetry or by large differences in reactivity, kinetic acidities have been monitored by measuring the rate of appearance or disappearance of deuterium by proton n.m.r., mass spectrometry, and combustion analysis. Tritium exchange rates have been followed by scintillation techniques.

For molecules having several different hydrogens of similar kinetic acidity, the usual techniques become inappropriate and the synthesis of specifically labelled materials becomes essential. The use of ^{13}C n.m.r. to monitor deuterium incorporation (1) provides a satisfactory alternative solution to this problem. Provided the individual carbon signals are separate and assignable, the extent of deuterium incorporation at a given carbon can be determined directly by integration of the ^{13}C n.m.r. spectrum.

The kinetic acidities of the aryl protons in a series of specifically labelled aromatic hydrocarbons have been investigated using an amide–amine catalyst (2). These studies have allowed assessment of some of the factors which affect aryl anion stability. We wished to extend these studies to systems in which aryl proton exchange may occur through benzyl-like anionic intermediates to assess the importance of this exchange pathway. Thus the kinetic acidities of some 1,8-disubstituted naphthalenes have been determined by observing base-catalyzed deuterium incorporation from *t*-butyl alcohol-O-*d*–potassium *t*-butoxide.

[1]Part 30 in the series ^{13}C NMR Studies (Pt. 29, ref. 24).

Results and Discussion

Synthesis of Substrates

Of the substrates, acenaphthene (**1**), 1,8-dimethylnaphthalene (**3**), and diphenylmethane (**5**) were obtained commercially and 2,3-dihydrophenalene (**2**) (3) and 1,1,2,2-tetradeuterioacenaphthene (**1**-d_4) (4) were prepared by previously reported procedures. A new procedure was developed for 1,1,2,2-tetramethylacenaphthene (**4**) since the published method is long (5) and methylation of the anion from acenaphthene proved to be unexpectedly complicated (6). The synthetic scheme is summarized in Fig. 1.

The last step in the preparation of 1,1,2,2-tetramethylacenaphthene (**4**), the thermolysis of sulfone **9**, requires comment. First, significantly better yields of product were obtained by refluxing **9** as a neat liquid (~400°) rather than by using a flow system. The flow technique was only partially successful since the temperatures (650–1000°) required to convert **9** → **4** resulted in decomposition of **4**. Under such conditions **4** gave significant amounts of 1,2-dimethylacenaphthylene. Second, significantly higher temperatures

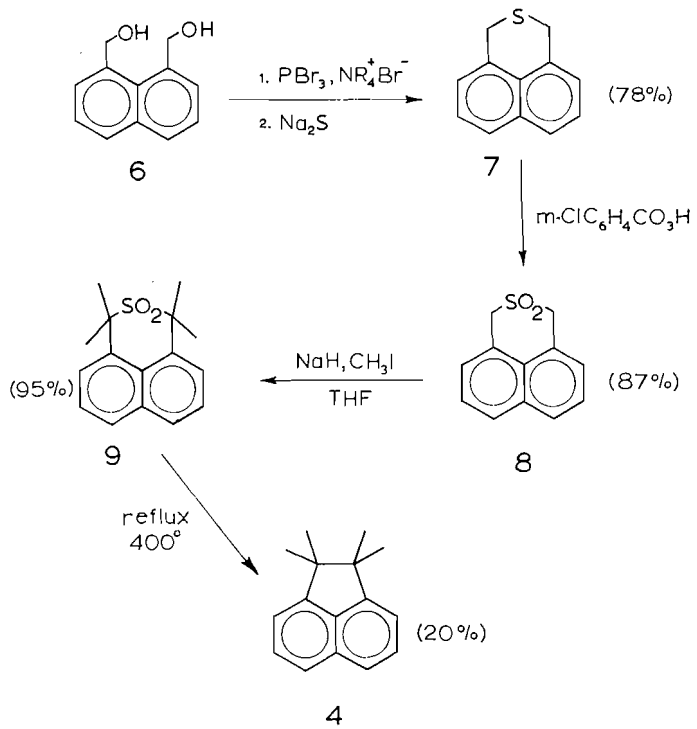

FIG. 1. Sequence employed for the preparation of **4**.

are needed for the conversion of **9** to **4** than for pyrolysis of allylsulfones and those sulfones which can yield orthoquinoidal methanes, but are somewhat milder than those necessary for simple alkyl sulfones (7). Thus it would appear that such intramolecular desulfonylation reactions can be synthetically useful even if a stepwise rather than concerted decomposition of the sulfone is likely.

^{13}C *Spectra*

The use of ^{13}C n.m.r. spectra seemed attractive for monitoring the incorporation of deuterium into these systems since the aryl carbons exhibit appreciably different chemical shifts and quantitative assessments of deuterium content at individual sites are readily accomplished by integration (8). The ^{13}C spectrum of acenaphthene has been described and unequivocal assignments established (9) as shown in Fig. 2*a*. Upon replacement of hydrogen by deuterium at a specific carbon, the shielding of that carbon is increased by the deuterium isotope effect and its absorption is a triplet since $I_D = 1$. Because the isotope shift is 0.3–0.5 p.p.m. (8–12 Hz at 25.2 MHz) and $J_{CD} \sim 25$ Hz, the C—H singlet (^{13}C bearing H) and C—D triplet (^{13}C bearing D) do not overlap; thus, the relative intensities of the ortho, meta, and para C—H signals can be determined readily by integration yielding the relative extents of deuteration. Since deuterium incorporation, however, occurs at all three positions, it was necessary to include an additional signal in the spectra for calibration purposes. We selected *p*-dichlorobenzene and a known amount was added to each sample for analysis. Thus, the deuterium content at each position was determined by careful integration of four signals, three for each substrate and the CH signal of *p*-ClC_6H_4Cl.

Since deuterium nuclei are unaffected by proton decoupling, the effects of ^{13}C–D coupling are manifest in these spectra; this feature is particularly helpful as an assignment aid because geminal and vicinal aryl ^{13}C–D coupling constants differ appreciably. From the data for benzene (10) and the fact that $J_{CD} = J_{CH}$ (6.51), the geminal couplings are ~ 0.2 Hz while $J_{CD}^{vic} \sim 1$ Hz. Thus, in the present systems, deuterium exchange at an ortho position is

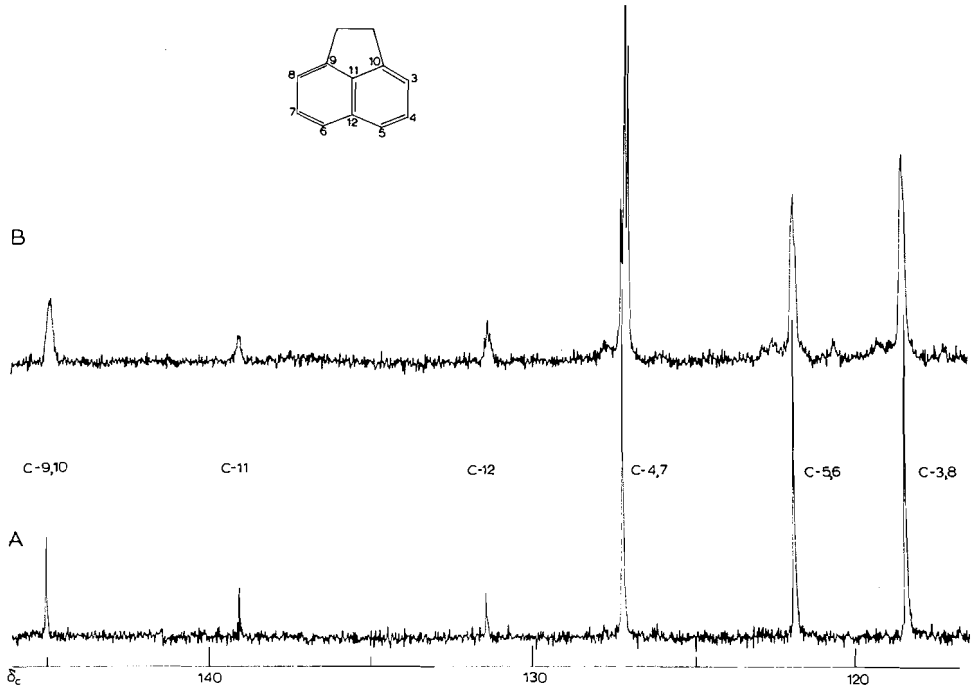

FIG. 2. Aromatic regions of the ^{13}C spectra of **1** (A) normal material, (B) after treatment with *t*-BuO$^-$ – *t*-BuOD at 204° (run 3).

evident from the marked broadening of the para carbon signal by coupling, while the meta signal is essentially unaffected by coupling but still exhibits characteristic changes because there are measurable geminal isotope shifts of 0.1 p.p.m. (2.5 Hz at 25 MHz). Consequently, a portion of the meta C—H absorption is shifted upfield, *i.e.* the meta band consists of two signals with the higher field component indicating the presence of deuterium at a geminal position. In these spectra, therefore, the ortho and para C—H signals are broadened by respective deuteration at the para and ortho positions, while the meta C—H absorption splits into two and then three signals upon mono- and di-deuteration at the ortho and para positions. These effects are illustrated in Fig. 2*b* for acenaphthene. Exclusive deuteration at the meta position would, of course, split the ortho and para C—H signals but this splitting is masked if deuteration also occurs at the other positions. Thus, as the extent of deuteration increases the meta band is readily distinguished from the ortho and para absorptions.

Although the ^{13}C assignments for acenaphthene have been unequivocally established by selective proton-decoupling experiments, the reported assignments (9) for 1,8-dimethylnaphthalene appeared to be incorrect on the basis of the spectra obtained in this study and the characteristic effects produced by deuteration. To confirm our suspicions, samples of partially deuterated 1,8-dimethylnaphthalene were converted to acenaphthene and the ^{13}C spectra of the latter recorded. From integrations of each pair of samples, unequivocal assignments for 1,8-dimethylnaphthalene follow directly. The spectra for one such pair are shown in Fig. 3. The ^{13}C shielding data for the hydrocarbons employed in this study are collected in Table 1.

Exchange Studies

The relative kinetic acidities of the various hydrogens in the aromatic hydrocarbons studied were determined from the rates of deuterium incorporation using 0.24 *M* potassium *t*-butoxide in *t*-butyl alcohol-O-*d* as the exchange medium. The exchange rates were followed at two temperatures, 120 and 204 °. At the lower temperature only exchange of benzylic hydrogens was observed whereas exchange of aromatic hydrogens required 204°. This temperature difference cor-

responds to a rate difference of about 10^3, assuming $\Delta H \approx 25$ kcal/mol (11).

Internal Return

The observed rates of deuterium incorporation can be related to kinetic acidities if internal return (carbanion formation without exchange) is minor or constant. As has been observed for some systems (*e.g.* fluorenyl, triphenylmethyl, and allyl derivatives), internal return contributes to varying extents (12).

$$\text{R—H} + {}^{-}\text{OR} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{R}^{-}\text{HOR}] \xrightarrow[k_2]{\text{DOR}} \text{exchange}$$

Using the extent of intramolecular isomerization (isomerization without exchange) in 1,3- and 1,5-proton shifts as a gauge for internal return, some generalizations are possible. With alkoxides in alcohol, potassium *t*-butoxide in *t*-butyl alcohol in particular, the intramolecular component is small and is usually less than 50%, suggesting that the rate of carbanion formation is at most a factor of two larger than the exchange rate. The contribution due to intramolecularity also seems to decrease with increasing temperature (13) and is not very sensitive to the structure of the carbon acid. Thus the observed exchange rates should be close to the actual rates of carbanion formation.

Although the ambiguity introduced by internal return remains for the molecules examined, the high temperature required (especially for aromatic exchange) and the structural similarity between the various carbanionic intermediates help to mollify the doubts.

Benzyl Exchange

The extent of base-catalyzed hydrogen–deuterium exchange at 120° as a function of time was determined using proton n.m.r. These data were converted to pseudo first-order rate constants for exchange on a per hydrogen basis. These rate constants for the substituted naphthalenes, shown in Fig. 4, cover a 20-fold range with acenaphthene the most acidic kinetically and 1,8-dimethylnaphthalene the least.

The similar kinetic acidities of 1,8-dimethylnaphthalene and 2,3-dihydrophenalene suggest that neither steric nor conformational effects are of major importance. The enhanced acidity of acenaphthene would thus appear to reflect hybridization changes at the benzyl carbon which becomes more electronegative towards the

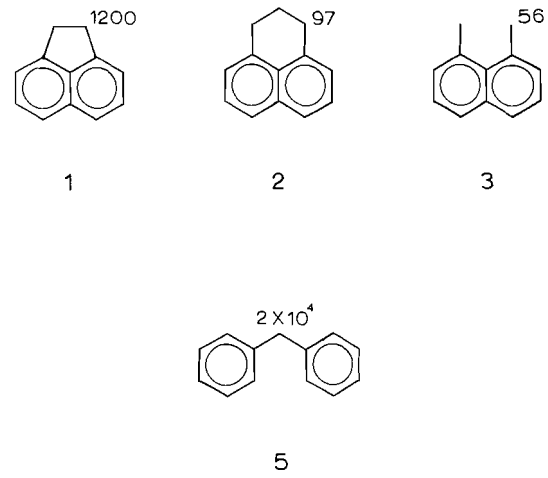

FIG. 4. Rate constants ($k_1 \times 10^7$ s^{-1}) for benzyl exchange at 120.4° for **1**, **2**, **3**, and **5**. For the latter the value was estimated from measurements at 60° assuming $\Delta H^{\ddagger} = 25$ kcal/mol.

bonded hydrogens as a result of the reduced C—C—C bond angle of 105° (14).

Aromatic Exchange

The extent and position of hydrogen–deuterium exchange at 204° at various times was determined using carbon-13 n.m.r. The results are reported in Table 2. This data has been used not only to interpret the mechanism of the exchange processes but also for ^{13}C signal assignments as discussed earlier.

Mechanism of Exchange

A qualitative picture of the relative kinetic acidities within any particular hydrocarbon can be obtained upon inspection of Table 2. To facilitate comparisons, these data were also converted to pseudo first-order rate constants for exchange on a per hydrogen basis. Reasonable plots were obtained from the rates of approach to equilibrium and rate constants were derived as given in Fig. 5.

The reactivity of the aromatic hydrogens varies by a factor of $\sim 10^2$ with the most acidic $\sim 10^4$ slower than the benzylic hydrogens. This should be compared with the results for toluene in cyclohexylamine–cyclohexylamide where the reactivity difference is about 10^2 (2*c*). For most of the compounds (except **4**) the benzyl anion is formed most frequently since, as mentioned earlier, the 84° temperature difference corresponds to a rate difference of about 10^3.

Except for acenaphthene and 1,1,2,2-tetra-

methylacenaphthene, the compounds studied show a very similar pattern of reactivity in the aromatic ring ($m > p > o$). This is the same pattern observed for toluene in which the meta[2] position is the most acidic (2*c*). Acenaphthene stands in marked contrast with the *meta* position, the *least* reactive. This unique behavior suggests either a change in mechanism or the presence of a significant perturbing influence on phenyl anion stabilities.

In the study of exchange of aromatic hydrocarbons in an amine–amide medium (2*b*) two mechanisms were considered: (*a*) direct exchange through aryl anions and (*b*) exchange via an addition–elimination process. The authors provided evidence favoring the aryl anion mechanism. With the introduction of benzyl hydrogens an additional mechanism is possible; aromatic

[2]The designation of ortho, meta, and para for monosubstituted benzenes will be used also for the naphthalene systems with 2,7 as ortho; 3,6 as meta; and 4,5 as para.

exchange at specific positions through deuteration in the ring of the preferentially formed benzyl anion followed by rearrangement. However, on the basis of the evidence obtained (2*c*), the aryl anion mechanism is favored for both toluene and benzene. The introduction of the methyl group on the benzene ring resulted in reduced reactivity at all ring positions with the meta position the least deactivated. Thus, rather than providing a more facile alternative route for ring exchange, the methyl group destabilizes the phenyl anions, presumably through a polar effect.

Similarly diphenylmethane, 1,8-dimethylnaphthalene, and 2,3-dihydrophenalene behave in a manner analogous to toluene in spite of the enhanced reactivity of the benzyl position. This suggests that aromatic exchange in these molecules is through the aryl anions rather than benzyl anions. This must certainly be so for exchange at the meta position.

The preferential exchange of acenaphthene in the para and ortho positions as well as the enhanced reactivity of the benzyl position are consistent with a change in mechanism to aromatic exchange through the benzyl anion or perhaps the dianion (6). However, the results obtained with 1,1,2,2-tetramethylacenaphthene mitigate against these possibilities; except for the ortho position, which should be susceptible to steric effects, both acenaphthenes show the same reactivity pattern. This suggests that some other structural features of acenaphthene are responsible for the changes in relative reactivity of the ring positions.

Ring strain in the aromatic ring and the concomitant changes in hybridization seem to provide a satisfactory alternative picture. An X-ray analysis of acenaphthene (14) has provided the bond angles shown in Fig. 6. From these, orbital hybridizations for the carbons at the ring fusions can be calculated (15) and are indicated in Fig. 6. The directed electronegativity of the carbons at the ring fusions should serve to enhance the acidity of the ortho and para positions more than the meta. Such effects have also been invoked to rationalize the kinetic acidities of the ring protons in biphenylene, benzcyclobutene, and triptycene (2*a*).

For the hydrocarbons examined in this study, ring protonation of benzyl anions does not seem to play a competitive role in aromatic exchange even though the benzyl anions form up to 10^6 times faster than aryl anions. This selectivity for

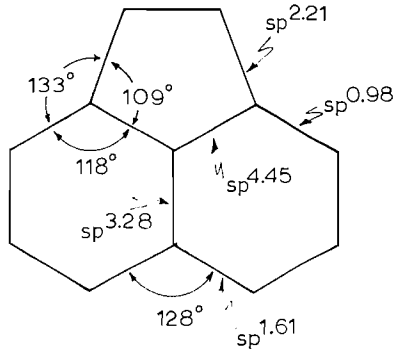

FIG. 6. Bond angles and calculated orbital hybridization in **1**.

the benzyl position establishes much higher limits for hydrocarbons than that previously estimated from the neutralization of 2-phenyl-2-propylpotassium (16). Apparently for the hydrocarbons the acidity of the benzyl proton must be further enhanced before selective ortho–para exchange will be observed. For example, both phenol (17) and aniline (18) exchange selectively at the ortho and para positions.

The ^{13}C shieldings of the ortho and para carbons in acenaphthene (**1**) are significantly shielded relative to these centers in 1,8-dimethylnaphthalene (**3**), perhaps because of ring strain. The corresponding ortho carbons in biphenylene absorb at essentially the same position as those in **1** (19). Ring strain effects have recently been observed in the e.s.r. spectra of anion radicals of substituted benzenes and naphthalenes (20). The basicities of some quinoxalines have also been interpreted in terms of ring strain (21).

Experimental

Bases and Solvents

The *t*-butyl alcohol-O-*d* was prepared by the procedure of Young and Guthrie (22) and analyzed for 0.98 atoms D/molecule. The base solution was prepared by adding freshly cut and cleaned potassium metal to the alcohol. The same base solution (0.24 *N*; <0.002 *M* in D_2O) was used for all reactions and reanalyzed after the final reaction was run. The pentane was distilled before use.

Substrates

The acenaphthene, 1,8-dimethylnaphthalene, and diphenylmethane were purified commercial samples. The sample of 1,1,2,2-tetradeuterioacenaphthene was prepared according to the procedure of Trost (4). The sample of 2,3-dihydrophenalene was obtained as a side product of the reaction of β-(1-naphthyl)-propionic acid in anhydrous hydrogen fluoride (3). The 1,1,2,2-tetramethylacenaphthene was prepared according to the following procedure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1,1,2,2-Tetramethylacenaphthene

(a) 1,8-Di(bromomethyl)naphthalene

To a well-stirred solution of 27.7 g (0.15 mol) of 1,8-di(hydroxymethyl)naphthalene (**6**) (4) and 25 g (0.074 mol) of tetrabutylammonium bromide in 500 ml of methylene chloride at 0° was added rapidly 90.7 g (0.33 mol) of phosphorus tribromide. The reaction mixture was stirred 24 h at ambient temperature and then poured into ice and water. The methylene chloride was washed once with water, once with saturated sodium bicarbonate, dried, and evaporated to yield 63.4 g of crude material.

The added ammonium bromide serves to eliminate the otherwise significant amounts of cyclic ether (1H,3H-naphtho[1,8-*c*-*d*]-pyran) that are formed.

(b) 1H,3H-Naphtho[1,8-c,d]-thiopyran (7)

To 40.8 g (0.17 mmol) of sodium sulfide (.9H_2O) in 150 ml of water and 300 ml of 95% ethanol was added dropwise the 63.4 g of previously prepared crude 1,8-di(bromomethyl)naphthalene in 120 ml of tetrahydrofuran. After refluxing for 12 h, the solvent was removed using a rotary evaporator and the residue was dissolved in ether and water. Both the layers were re-extracted. The organic layers were combined, dried, and evaporated. Recrystallization from methanol (carbon treatment) yielded 21.8 g of **7** (78% based upon **6**) of m.p. 95–96°, lit. 96–97° (23).

(c) 1H,3H-Naphtho[1,8-c,d]-thiopyran-2,2-dioxide (8)

To a stirred solution of *m*-chloroperbenzoic acid (51 g; 0.25 mol) in 400 ml of methylene chloride was added slowly a solution of **7** (21.8 g; 0.12 mol) in 50 ml of methylene chloride. After the initial exothermic reaction, the reaction solution was refluxed for 12 h, cooled, filtered, and washed with saturated sodium bicarbonate, dilute sodium sulfite, and then dried. Crystallization from 300 ml of methylene chloride yielded 9.8 g (37%) of material m.p. 235–236°. A second crop, 2.1 g (m.p. 234–236°), was obtained from 75 ml of methylene chloride.

The precipitate from the filtration proved to contain much **8**. It was treated with excess dilute sodium hydroxide and extracted twice with methylene chloride to dissolve all solids. The methylene chloride was washed, dried, and evaporated to yield an additional 9.0 g of material m.p. 236–239°. This raised the yield to 87%.

Anal. Calcd. for $C_{12}H_{10}SO_2$: C, 66.03; H, 4.62; S, 14.66. Found: C, 66.00; H, 4.50; S, 14.74.

The n.m.r. spectrum ($CDCl_3$) showed the methylene protons as a singlet (δ = 4.7; 4H) and the aromatics as a multiplet (δ = 7.4–8.1; 6H). The i.r. spectrum (chloroform) showed the characteristic sulfone absorptions at 1115 and 1320 cm^{-1}.

(d) 1,1,3,3-Tetramethylnaphtho[1,8-c,d]-thiopyran-2,2-dioxide (9)

To a cooled, stirred suspension of sodium hydride (27 g; 0.6 mol; 54% washed three times with pentane) and **8** (16.3 g; 75 mmol) in 175 ml of tetrahydrofuran was added a solution of 37.5 ml (0.6 mol) of methyl iodide in 50 ml of tetrahydrofuran. Bubbling occurred for 6 h as the reaction mixture warmed to room temperature and was then stirred for 50 h total. The excess sodium hydride was destroyed with water.

The reaction mixture was extracted using methylene chloride and water. After drying, the product was crystallized from methylene chloride – hexane to yield 14 g of material m.p. 258–260° and 5.7 g (m.p. 256–258°) with an overall yield of 95%.

Anal. Calcd. for $C_{16}H_{18}SO_2$: C, 70.04; H, 6.61; S, 11.66. Found: C, 70.20; H, 6.60; S, 11.62.

The n.m.r. spectrum ($CDCl_3$) showed the methyl singlet at δ = 1.9 (12H) and the aromatics as a multiplet at δ = 7.5–8.0 (6H).

(e) 1,1,2,2-Tetramethylacenaphthene (4)

A 10 g (36 mmol) sample of **9** was heated to reflux (~400°) under an argon atmosphere using a sand bath. The reflux temperature was maintained by collecting the lower boiling material (260–300°) as it formed. Heating was continued until reaction was nearly complete (~6 h) as judged by the pot residue and by monitoring the sulfur dioxide evolved. The distillate and pot residues were combined using methylene chloride to yield about 5 g of crude material.

The pentane soluble material was chromatographed on silica gel using pentane. The first major fraction (a complex mixture by v.p.c.) was distilled and the middle fraction (2.7 g; b.p. 71–73° at 0.05 mm) was recrystallized from ethanol to yield 1.1 g (15%) of material m.p. 53–55°, lit. 57–58° (5). Analysis by v.p.c. indicated 95% purity.

The pentane insolubles were sublimed at 0.05 mm to yield 1 g (10%) of unreacted **9**.

Procedures for the Exchange Reactions

(a) At 120.4°

Typically, a 30 mg sample of substrate in 1 ml of 0.24 *N* potassium *t*-butoxide – *t*-butyl alcohol-O-*d* was evacuated, degassed, and sealed in a 5 mm n.m.r. tube. The reaction was monitored by integrating the aromatic hydrogens, the benzyl hydrogens, and the hydroxyl hydrogens at selected times. After the final point the tube was opened and the sample isolated by extraction with pentane and water, followed by sublimation. N.m.r. analysis was then made on this material. In all cases there was good agreement between the two analyses.

At least five points were obtained to define the rate constant for each case. The enhanced reactivity of **5** required a lower temperature for exchange (60°) and the rate constant at 120° was estimated by assuming $\Delta H^{\ddagger}$ = 25 kcal/mol (11).

(b) At 204°

A 250–300 mg sample of substrate and 5 ml of 0.24 *N* potassium *t*-butoxide – *t*-butyl alcohol were twice degassed and sealed in a Carius tube. After heating for the specified time in a thermoregulated Wood's metal bath, the tube was opened and the substrate isolated using pentane and water for extraction. The substrate was normally chromatographed using silica gel and pentane and then sublimed or distilled. Recoveries were usually greater than 90%.

Samples for ^{13}C analysis were prepared by mixing weighed amounts of substrate and *p*-dichlorobenzene which was used as an internal standard for integration.

The individual analyses were converted to pseudo first-order rate constants from plots of the rate of approach to isotopic equilibrium. Runs 3, 4, 5, 11, and 17 provided estimates for isotopic equilibrium positions with **1**, **3**, and **5**. The corresponding equilibrium percentages were then estimated for **2** and **4** by taking account of the

substrate concentration and the number of exchangeable protons. The rate of approach to equilibrium provides the sum of the forward and reverse rate constants and the equilibrium constant provides the ratio, thus allowing calculation of each rate constant.

Conversion of 1,8-Dimethylnaphthalene (3) to Acenaphthene (1)

The sample of partially exchanged **3** (242 mg; 1.5 mmol) and *N*-bromosuccinimide (531 mg; 3.0 mmol) with 5 ml of carbon tetrachloride was refluxed for 90 min using a 275 W white sun lamp. After cooling and filtering, the filtrate was evaporated to dryness to yield 472 mg of crude material. This product was used without further purification. Following the procedure of Trost (4) the crude 1,8-di(bromomethyl)naphthalene was dissolved in 10 ml of benzene and 5 ml of ether and this solution was degassed and placed under an argon atmosphere. Commercial phenyllithium solution (1.25 ml; 2.25 mmol) was added dropwise to the reactant at −15°. After stirring and warming to ambient temperature over about 1 h, the solution was poured into water, which was extracted three times with an ether–pentane mixture. The organic layers were washed with water, dried, solvent evaporated, and the residue was chromatographed on silica gel using pentane. After sublimation the crystalline product (167 mg; 68%) was shown by ^{13}C n.m.r. and v.p.c. to contain considerable biphenyl which was removed by preparative v.p.c. to yield 101 mg (41%) of **1**.

^{13}C Spectra

Noise-decoupled ^{13}C spectra were obtained with a Varian XL-100-15 spectrometer operating in the Fourier transform mode. All samples were examined as 20–25% (w/v) solutions in CCl_4 containing a known amount of *p*-dichlorobenzene as a calibration standard for integrations. Initially, operating conditions were adjusted to give signals of equal intensity for the aryl C—H nuclei. Using these conditions, the partially deuterated samples were run, in duplicate or triplicate, and the C—H signals carefully integrated to determine the extent of deuteration for each center.

^{13}C Nuclear Magnetic Resonance Studies. 32. The ^{13}C Spectra of Several Norbornyl Derivatives[1]

J. B. STOTHERS, C. T. TAN, AND K. C. TEO

Department of Chemistry, University of Western Ontario, London, Ontario N6A 3K7

Received March 28, 1973

The ^{13}C n.m.r. spectra of several norbornyl derivatives have been recorded to examine the variation of ^{13}C shieldings with molecular geometry. Since it is well established that nonbonded interactions between vicinal carbon nuclei lead to pronounced upfield shifts, the so-called γ effects, series of methyl-substituted norbornanes, norbornenes, norbornan-2-ones (norcamphors), and norborn-5-en-2-ones were prepared as model systems having a variety of γ interactions between vicinal methyl groups. The observed shifts of these methyl carbons are considered in terms of the dihedral angle relating the vicinal nuclei. The use of specific deuteration for unequivocal signal assignments of carbons geminal and vicinal to the site of deuteration is illustrated.

Les spectres r.m.n. ^{13}C de plusieurs dérivés du norbornyle ont été enregistrés afin d'étudier la variation de l'effet de blindage du ^{13}C en fonction de la géométrie moléculaire. Puisqu'il est bien connu que des interactions non-liées entre des carbones vicinaux entraînent des déplacements du signal vers des champs élevés, relation connue sous le nom effets-γ plusieurs norbornanes, norbornènes, norbornanones-2 (norcamphres) et norbornène-5 ones-2 substitués par des groupes méthyles ont été préparés afin de servir de modèles possédant différentes interactions γ entre des groupes méthyles vicinaux. On a utilisé la deutération spécifique pour attribuer sans ambiguité les signaux se rattachant aux carbones géminés et vicinaux au site de deutération. [Traduit par le journal]

Can. J. Chem., 51, 2893 (1973)

Introduction

From the results of some of the earliest systematic studies of ^{13}C shielding trends within various families of compounds it was established that ^{13}C shieldings are remarkably sensitive to molecular geometry (1). In particular, the relative orientation of vicinal carbons, or of a carbon vicinal to a hetero atom, has a marked effect on their observed shieldings which has been attributed to 1,4-nonbonded interactions. These shifts, termed γ effects, are consistently to higher field with increased steric crowding and, consequently, provide a new method for the assignment of stereochemistry in a variety of systems. The relative magnitudes of the shifts are well characterized for cyclohexane derivatives (2, 3) in which, for example, an axial methyl carbon absorbs *ca.* 6 p.p.m. upfield from its equatorial counterpart. The axial methyl experiences γ *gauche* interactions with C-3 and -5 while the equatorial methyl is *anti* to these ring carbons. An even larger difference ($\sim$12 p.p.m.) is found (4) for the C-19 angular methyl carbons in 5α- and 5β-steroids for which there is also a difference of two γ *gauche* interactions (with C-2 and -4 in the 5α-series). Clearly the shielding of these methyl carbons depends strikingly on the dihedral angle relating the γ nuclei but these alicyclic derivatives provide examples for only two such angles, the *gauche* and *anti* arrangements. The relatively rigid and well-defined norbornyl skeleton, however, offers a framework with which a variety of dihedral angles between γ nuclei can be examined. We have prepared a series of methyl-substituted norbornyl derivatives primarily to investigate the effect of different vicinal orientations on the observed shieldings. While the ^{13}C spectra of a number of the compounds included in this series have been reported previously (5–9), these were reexamined to obtain data for the entire series under comparable conditions, namely 10–20% solutions in deuteriochloroform, for internal consistency. The earlier results were determined by steady-state operation which necessitated the use of highly concentrated solutions. Furthermore, a variety of referencing methods were employed which renders difficult detailed comparison of the results from different laboratories. In the present study, all data were measured relative to internal tetramethylsilane (TMS) which appears to be the reference of general choice.

In most instances the assignment of signals to specific carbons was straightforward on the basis

[1]Part 31, ref. 32; Part 30, ref. 33.

[a]In p.p.m. from internal TMS in $CDCl_3$ solutions.

of the earlier results, together with off-resonance decoupled spectra and the general additivity of substituent effects on shieldings. For four of the derivatives, however, an unambiguous assignment was only achieved through the examination of specifically deuterated materials. With Fourier transform operation and proton decoupling, the effects of a single deuterium atom are readily detected in the absorptions of the carbons geminal and vicinal to the deuterated center (10); consequently, the unequivocal identification of a few signals results from a single substitution. The utility of this technique is illustrated for the four 5,6-dimethylnorcamphors.

Results

The ^{13}C shieldings for the norbornanes and norbornenes examined in this study are listed in Table 1. Each of the parent compounds and their monomethyl derivatives had been examined previously (6, 7) and, in general, the agreement between the various sets of data is reasonable in view of the different referencing methods employed. For comparison with our results, those reported relative to CS_2 (6) were converted to the TMS scale using the factor 192.8 p.p.m. (*1b*). Although the present results tend toward higher field than the earlier data by approximately 0.5 p.p.m., the observed shieldings for the methyl carbons differ by only 0.0–0.2 p.p.m. in the three sets of results, indicating the existence of small but significant solvent effects rather than arising from calibration differences. With the single exception of the olefinic carbons in norbornene, the differences between our data and those of the Roberts' group (6) are <0.5 p.p.m. while comparisons with the results of Lippmaa *et al.* (7) reveal substantial differences (1.5–2.0 p.p.m.) for C-6 in *exo*-2-methylnorbornane, C-7 in *endo*-2-methylnorbornane, as well as C-4 and -6 in *endo*-5-methylnorborn-2-ene.

From the methyl results for the *exo*- and *endo*-monomethyl derivatives in each series it is apparent that the *endo*-methyl carbons are shielded relative to their *exo*- counterparts. On this basis the assignment of the methyl signals in the *trans*-dimethyl derivatives is straightforward. The remaining signals for the *trans*-dimethyl compounds were assigned by comparison of the observed shieldings with those expected on the basis of additivity of the individual substituent effects of each methyl group. Apart from the consistent upfield shift of each skeletal carbon (0.3–0.6 p.p.m.), our assignments agree well with those of Lippmaa *et al.* (7) except for the reversal of the C-5 and -6 signals for *trans*-5,6-dimethylnorbornene. The assignments for each of the four *cis*-dimethyl derivatives were readily accomplished, again by comparison of the observed shieldings with those predicted assuming additivity of methyl substituent effects. Major deviations occur only for the methine carbons bearing methyl groups as expected from the general behavior of carbon nuclei in fragments having appreciable γ interactions. In these cases, the methyl groups are eclipsed, or nearly so, and the pronounced upfield shifts found for the methyl and methine carbons seem unexceptional. These shifts are considered in more detail in the Discussion.

Our results for the norcamphors are collected in Table 2. The assignments for the carbonyl, bridgehead, α-carbon (C-3), and methyl signals presented no problems on the basis of the ob-

served shieldings and the off-resonance decoupled spectra. For the 5- and 6-methyl derivatives, the methine carbon bearing methyl was readily identified by off-resonance decoupling. The remaining methylene signals were assigned by comparison of the observed shieldings with those predicted assuming that introduction of a methyl group causes changes similar to those found for norbornane, using the values for norcamphor as the base. For an unequivocal assignment of the C-5 and -6 signals in norcamphor, the spectrum of norcamphor-3-*exo*-d_1 was recorded. The methylene signal at 27.1 p.p.m. showed the characteristic broadening caused by vicinal coupling with the *exo*-deuterium (10) while that at 24.2 p.p.m. was unaffected; thus these signals arise from C-5 and -6, respectively. The opposite assignment had been reported by one group (5). Although, from additivity, C-5 and -7 in *endo*-6-methylnorcamphor are predicted to be equivalent, the lower field signal of the two remaining methylene signals (38.7 and 35.8 p.p.m.) was assigned to C-7 since there is no precedent for an *endo*-methyl to shield C-7 by 2 p.p.m.; our assignment for these positions is reversed from that given earlier (6). Our assignments for C-5 and -6 are also reversed from those in an earlier report (6) but off-resonance decoupling supports the present identification.

Of the remaining ketones in Table 2, the 3,3- and 6,6-dimethyl as well as the 1,3,3- and 1,7,7-trimethyl derivatives have been reported previously (5–9) and the agreement between the various sets of results is satisfactory. It may be noted that our assignment for the 7-methyl carbons in camphor followed from the spectrum of the *endo*-3,9,9,9-tetradeuterio derivative (11).[2] An earlier report using a similar test surprisingly reached the opposite conclusion (5) while results of selective-decoupling experiments (7) agree with the present assignment.

While most of the assignments for the four 5,6-dimethylnorcamphors are straightforward, the C-4, -5, and -6 signals cannot be unambiguously assigned without additional information. For this purpose, the ketones were subjected to base-catalyzed deuterium exchange of the 3-proton and the spectra of the deuterated

[2]A sample of camphor-3,9,9,9-d_4 was kindly supplied by Prof. E. W. Warnhoff. It may be noted that the C-5 signal in its spectrum was essentially unchanged from its appearance in the spectrum of camphor indicating that the 3-deuterium is *endo* and, thus, only weakly coupled with C-5. Earlier results for camphor-3-*exo*-d_1 established that an *exo*-3-deuterium is strongly coupled with C-5 (10).

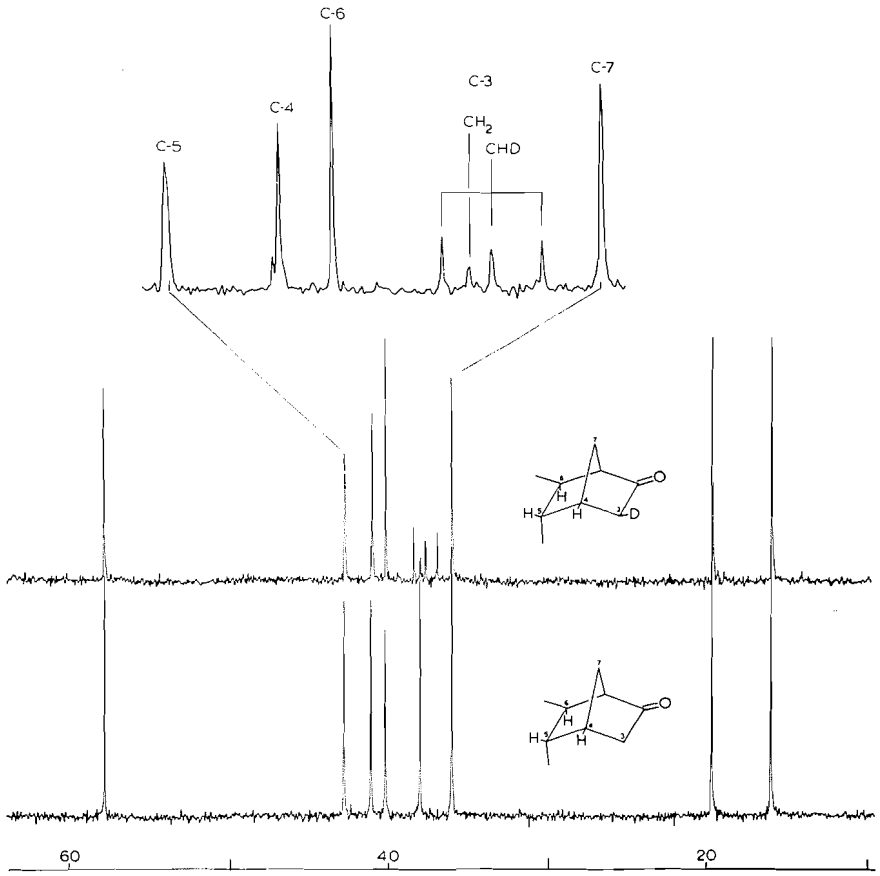

FIG. 1. High field region of the ^{13}C spectra of *endo*-5-*exo*-6-dimethylnorcamphor (lower spectrum) and its *exo*-3-d_1-derivative (upper spectrum). The upper inset is a fourfold expansion of the central portion to illustrate the effects of deuterium substitution.

ketones compared with those of the normal materials. In each case, the monodeuterated ketones exhibited a 0.1 p.p.m. upfield shift for one of the unassigned methine signals, a significantly broadened band for another, while the third was unaffected. Thus, the assignments for C-4, -5, and -6, respectively, were completed unequivocally. To illustrate these characteristic effects the spectra for *endo*-5-*exo*-6-dimethylnorcamphor and its *exo*-3-d_1-derivative are reproduced in Fig. 1. In the expanded spectrum shown at the top of this figure, the differences in the C-4, -5, and -6 absorptions are apparent. The small spike on the low field side of the main C-4 absorption corresponds exactly to the C-4 absorption in the normal material indicating that deuteration was not complete. Clearer evidence of this is given by the pattern for C-3 which consists of a triplet arising from ^{13}C–D coupling which is shifted upfield from the residual CH_2 signal by *ca.* 0.5 p.p.m. The marked broadening of the C-5 signal relative to the C-6 peak readily identifies each.

The assignments for the 1,7-dimethylnorcamphors follow directly from the available data for the corresponding hydrocarbons (7) and monomethyl ketones (6). Since the 1- and 7-methyl carbons are *gauche* the upfield shift relative to their positions in the monomethyl ketones is expected to be comparable for both. On this basis, the more shielded methyl signal was assigned to the 7-methyl carbon in each case. The methyl assignments for 7,7-dimethylnorcamphor were based on the relative shieldings for the corresponding carbons in camphor discussed above. The comparison of the data for *endo*-3-methylcamphor with those for camphor leads readily to the assignments listed.

[a]In p.p.m. from internal TMS in $CDCl_3$ solutions.

The 3,3,6-trimethylnorcamphors were isolated as the minor rearrangement products arising from homoenolization of fenchone (12). The assignments given in Table 2 were obtained by a comparison of the observed shieldings with those estimated by combining the data for the 6-methylnorcamphors and camphenilone. For each carbon in 3,3-*exo*-6-trimethylnorcamphor, the agreement is <0.2 p.p.m., while the deviations for the *endo*-isomer are larger, especially for the C-5, -6, and methyl carbons. An interpretation of these deviations is considered in the next section.

The shielding results for the norborn-5-en-2-ones are given in Table 3. Of these compounds, only the parent has been reported earlier (7) and the present data agree well with the published values. The olefinic carbons were distinguished by selective decoupling experiments and the remaining assignments were readily completed with off-resonance decoupling results. The methylnorbornenones similarly presented no assignment problems but the olefinic assignments were confirmed for the 3-methyl derivatives by selective decoupling. The expected variation in the olefinic shieldings upon methyl substitution of an olefinic hydrogen (1) gives these assignments directly for the last two entries in Table 3.

Of the norbornenones, 3,3-dimethylnorborn-5-en-2-one is the only previously unreported compound and its proton spectrum was analyzed completely by a variety of double resonance experiments. The parameters for the skeletal protons are listed in Table 4. The methyl groups absorb at δ 1.039 (*endo*) and 1.143 (*exo*) and simultaneous irradiation at the latter enhanced the intensity of the 7-proton at 2.227 p.p.m. by 7.9%, thereby distinguishing the *anti*-proton. The tabulated values seem unexceptional for this structure. The molecular weight was determined by high resolution mass spectrometry to be 136.0889; calculated for $C_9H_{12}O$: 136.0888.

Discussion

Since the shielding trends exhibited by the skeletal carbons in many of these compounds have been considered in detail previously (1, 6, 7), the following discussion is centered primarily on the methyl and carbonyl absorptions and their variation with structure and substituent orientation. As noted in the Introduction, the marked γ effects associated with 1,4-nonbonded interactions are particularly striking in ^{13}C spectra and the present series afford a number of comparisons of these interactions as a function of the dihedral angle relating the γ nuclei. The dihedral angle offers, at the least, a relative measure of the degree of steric crowding, the factor which is currently thought to dominate these γ effects (1, 13). Although a detailed analysis will require a more complete description of molecular geometry, relatively little geometric information is available for these systems but it has been shown that the norbornyl skeleton may be twisted from C_{2v} symmetry by as much as 14° (14). Because of this flexibility, albeit limited, complete force-field calculations are required to obtain the most probable geometry for each compound. While we have begun work in this direction, it seems reasonable, at present, to consider the ^{13}C shielding data qualitatively in terms of the estimated dihedral angles.

As a reference point for considering the methyl shieldings in these systems, the data for *exo*-2-methylnorbornane, *exo*-5-methylnorborn-2-ene, and *exo*-5-methylnorcamphor have been selected because the latter may be expected to be least affected by the carbonyl and olefinic functions. This gives a base value of 22.0 ± 0.4 p.p.m. It is interesting that this lies midway between the methyl shieldings for methylcyclohexane (2) and methylcyclopentane (15) but it is difficult to rationalize the trend. The *endo*-2-methylnorbornane and *endo*-5-methylnorcamphor have comparable methyl shieldings, 17.4 and 17.1 p.p.m., respectively. The upfield shift of *ca.* 4.7 p.p.m. is consistent with a decreased dihedral angle (ϕ) between these *endo*-methyl carbons and the γ-carbons (C-6 and -3, respectively). For the latter, $\phi \sim 45°$ whereas $\phi \sim 90°$ for the *exo*-methyl groups relative to C-7 since the *synchro* twist occurring in *exo*-2-methylnorbornane (14) tends to increase ϕ from the value of $\sim 85°$ for a symmetric skeleton. It is interesting that $\phi \sim 65°$ for a 7-methyl carbon relative to *both* carbons in the nearer ethano bridge and the observed shielding of 12.7 p.p.m. (6) represents a shift of 9.3 p.p.m. upfield from the base value which is essentially twice the shift exhibited by the *endo*-methyl as one would expect. These may be compared with the 1.3 ± 0.2 p.p.m. upfield shifts found for the 2- and 5-methyl carbons upon *trans*-vicinal methyl substitution, *i.e. trans*-2,3-dimethylnorbornane, and the *trans*-5,6-dimethylnorcamphors, for which $\phi \sim 120°$. Although the 6-methyl shieldings in the monomethylnorcamphors differ from those found for the 5-methyl derivatives the effect of a *trans*-vicinal methyl group is comparable for both. While the orientation of the *endo*-6-methyl group relative to C-2 is similar to that of the *endo*-5-methyl and C-3, the smaller shift of −2.1 p.p.m. for the former presumably results from the absence of an *endo*-2-hydrogen. Similarly, the methyl carbon in *endo*-5-methylnorborn-2-ene is only 2.3 p.p.m. more shielded than its *exo*-counterpart. The increased shielding for the *exo*-6-methyl relative to the *exo*-5-methyl may be due in part to a long-range shielding effect of the carbonyl group (C-4 in cyclohexanone is shielded relative to cyclohexane) or may result from a difference in the degree of twist of the skeleton. An indication that the latter feature may contribute is the fact that the 5- and 6-methyl carbons in the norbornenones are nearly equivalent (0.5 p.p.m.) and this skeleton is less flexible (14).

The 1-methyl shieldings for the α- and β-santenones (1,7-dimethylnorcamphors) compared with that for 1-methylnorcamphor show an upfield shift of 2.2 ± 0.2 p.p.m. Although this seems smaller than may have been anticipated since $\phi \sim 60°$, the methyl carbons in the santenones are further separated because of the small bridge angle of *ca.* 96° (16). A comparable shift is found for the 7-methyl carbons by comparison with the data for the 7-methylnorcamphors (6).

For the *cis*-vicinal dimethyl groups, ϕ lies in the range 0–15° and as expected the upfield shifts relative to the monomethyl derivatives are largest. For the norbornanes and norcamphors the *cis-exo*-methyls are shielded by −6.3 ± 0.3 p.p.m. while the *cis-endo*-methyls are shifted −5.3 ± 0.3 p.p.m. Perhaps the difference is indicative of different degrees of twisting since the shifts for both *exo*- and *endo*-dimethyl carbons in the less flexible 5,6-dimethylnorborn-2-enes are equal, −4.9 p.p.m.

The remaining monomethyl ketones are those with methyl carbons vicinal to the carbonyl oxygen and it is apparent that these are substantially shielded. Since the *exo*-3-methyl is shifted by −8.2 p.p.m. and the *endo*-3-methyl by −6.7 p.p.m., it can be suggested that the dihedral angle between the C—Me and C=O bonds is smaller for the former because of skeletal twist. Interestingly, the α-*endo*-methyl carbon in *endo*-3-methylnorborn-5-en-2-one is only shielded by −2.8 p.p.m. relative to the corresponding hydrocarbon while the α-*exo*-methyl is shifted −5.9 p.p.m. in the ketone. From these data one might anticipate a relatively large shielding difference for the methyl carbons in the 3,3-dimethyl derivative but the observed difference is 2.4 p.p.m. With one exception, the remaining 3,3-dimethyl derivatives exhibit comparable differences between the 3-methyl carbon shieldings, 1.8 ± 0.1 p.p.m., indicating presumably that the relative geometries of these carbons are similar in each case. Interestingly, the difference between the methyl carbons in 6,6-dimethylnorcamphor is comparable, 1.6 p.p.m. For 3,3-*endo*-6-trimethylnorcamphor, however, the 3-methyl carbons differ by 3.9 p.p.m. with the *endo*-carbon substantially shielded relative to the other 3,3-dimethyl derivatives. Since the *endo*-6-methyl is not nearly so greatly affected, it follows the difference for the α-methyls may arise from a change in their orientation relative to the carbonyl bond such that the *endo*-methyl is closer to the carbonyl oxygen and the *exo*-methyl

For personal use only.

farther from it than is the case for the other 3,3-dimethyl derivatives.

It is interesting that the nonequivalence of 0.8 ± 0.1 p.p.m. for the 7-methyl carbons in 7,7-dimethylnorcamphor and camphor is essentially the same as that for the 7-methylnorcamphors (6) while these carbons differ by 0.4 p.p.m. in the santenones and by only 0.1 p.p.m. in *endo*-3-methylcamphor. Perhaps these variations arise from slight differences in skeletal twist, a notion which is supported by the 1 p.p.m. downfield shift found for the 3-methyl group in the latter derivative relative to the methyl shielding in *endo*-3-methylnorcamphor.

As mentioned earlier, the shielding variations for the skeletal sp^3-hybridized carbons have been discussed in detail previously (6, 7) and the present data are entirely consistent with the expected trends. It may be noted that, while attention has been focussed on the methyl shieldings, each carbon nucleus in the four-carbon fragment involved in a *gauche* γ interaction, *e.g.* C-1, -2, and -6, and CH_3 in *endo*-2-methylnorbornane, etc., are shielded relative to their positions in an *anti* arrangement. Thus C-6 is shielded by an *endo*-2-methyl group, C-7 by an *exo*-methyl, etc. Thus, it is hardly surprising that the C-5 and -6 nuclei in the *cis*-5,6-dimethylnorcamphors and C-2 (C-3) in the *cis*-2,3-dimethylnorbornanes are upfield from their positions predicted by assuming that the substituent effects of each methyl group are additive, *i.e.* the eclipsing interaction of the vicinal methyls increases the shieldings of the ethano-bridge carbons.

Previously it had been pointed out (7, 17) that these 1,4-interactions are not reciprocal in that the skeletal carbons exhibit larger shifts with crowding than the methyl carbons. This comparison, however, may not be valid because different sorts of nuclei are affected. The present results permit comparisons of methyl with methyl and it is apparent that these are similarly affected. It seems hardly surprising that methyl, methylene, and methine nuclei exhibit different sensitivities to γ *gauche* interactions and it emphasizes one of the difficulties in developing a satisfactory theoretical basis for these shifts. The problems associated with deriving a simple prescription to account for the effects of steric crowding of γ nuclei have been discussed by Dalling and Grant (2).

In the spectra of the ketones, the most readily identified signal is undoubtedly the carbonyl peak and its variations with structure are interesting. In general, the present carbonyl data are approximately 2 p.p.m. downfield from the earlier results presumably because of hydrogen bonding with chloroform. It is established that hydrogen bonding tends to decrease carbonyl shieldings (18). An examination of Table 2 shows that in the absence of α-methyl substitution the carbonyl carbons in the norcamphors absorb at δ_c 217.0 ± 0.5 (standard deviation). As expected, α-methylation shifts the carbonyl absorption downfield but the magnitude of the shift depends on the position of substitution. The 3-methyl groups cause somewhat larger shifts (2.5 p.p.m.) than a 1-methyl group (~1 p.p.m.). Since methyl substitution of an α-hydrogen places the methyl carbon γ to the carbonyl oxygen it is conceivable that the normal β-effect of the methyl group at the carbonyl carbon (1) is reduced by the γ interaction with the oxygen. Since the dihedral angle between the C—Me and C=O bonds is less for a bridgehead methyl than for a 3-methyl group, the differences in the observed shifts may be rationalized. The effects of *exo*- and *endo*-3-methyl groups appear to be comparable in the monomethyl derivatives and additive in the 3,3-dimethyl compounds. For the norbornenones, however, an *exo*-3-methyl group has a substantially greater effect than its *endo*-counterpart (3.1 *vs.* 1.1 p.p.m.). The upfield shift exhibited by each of the norbornenones relative to the similarly substituted methylnorcamphor has been noted previously and attributed to homoconjugation (19). Support for this interpretation is given by the 12.3 p.p.m. difference observed for the olefinic carbons in norbornenone consistent with polarization of the double bond toward the carbonyl group. Although, as Lippmaa *et al.* (7) have pointed out C-2 (C-3) is shielded in norbornene relative to norbornane by 5.0 p.p.m. and, consequently, attributing the 2.7 p.p.m. shielding of the carbonyl carbon in norbornenone entirely to homoconjugation may be an oversimplification. It may be noted, however, that the downfield shift of C-3 in these ketones is more pronounced for norcamphor indicating a reduced inductive effect of the carbonyl bond in norbornenone which is consistent with some degree of homoconjugation in the latter compound.

Experimental

Materials

Apart from norbornane and norbornene, which are commercially available, the hydrocarbons were prepared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

by published procedures. The 5,6-dimethylnorbornenes, obtained by the methods of Miller and Greenlee (20) were hydrogenated over platinum oxide to yield the corresponding dimethylnorbornanes. The monomethyl derivatives were prepared by a similar sequence from the carboxylic acids formed by Diels–Alder addition of cyclopentadiene with acrylonitrile followed by hydrolysis (21). The *exo*- and *endo*-acids were separated by the iodolactonization procedure.

1-Methylnorcamphor (22), the santenones (23), and the 3-methylnorcamphors (24) were prepared from commercial norcamphor while the remaining monomethyl- and 5,6-dimethyl-norcamphors were obtained by hydroboration (25) of the olefins to the *exo*-alcohols followed by oxidation with CrO_3–pyridine in CH_2Cl_2 (26) to the required ketones. In those cases in which mixtures of two ketones were obtained, the individual isomers were isolated by gas chromatography (g.c.) using a 20% SE30 column. Camphenilone was prepared from camphene by ozonolysis (27) and 7,7-dimethylnorcamphor was obtained from 10-camphorsulfonic acid via ketopinic acid (28) which was decarboxylated by the silver salt degradation (29) and the ketone obtained by reduction of the bromoketone with sodium in alcohol followed by Jones oxidation. The 3,3,6-trimethylnorcamphors were isolated as the minor products in the homoenolization of fenchone (12). Professor N. H. Werstiuk and E. W. Warnhoff kindly provided samples of 6,6-dimethylnorcamphor and *endo*-3-methylcamphor, respectively.

The 5- and 6-methylnorborn-5-en-2-ones were obtained by the following sequence. The Diels–Alder addition of methylcyclopentadiene and vinyl acetate furnished a mixture of acetates from which 5- and 6-methylnorborn-5-enyl acetate were separated by g.c. Treatment of the individual esters with lithium aluminum hydride followed by oxidation with CrO_3–pyridine in CH_2Cl_2 gave the required ketones. This procedure is analogous to that recently reported by Krieger and Masar (30). The 3-methylnorborn-5-en-2-ones were prepared by the Diels–Alder reaction of cyclopentadiene and the enol acetate of propanal (31). The mixture of acetates was hydrolyzed and oxidized to afford a mixture of the *exo*- and *endo*-3-methylnorborn-5-en-2-ones which was separable by g.c. In a similar manner a small sample of the 3,3-dimethyl ketone was obtained from the enol acetate of isobutyraldehyde.

In all cases the i.r. and proton spectra of ketones were consistent with the expected structures and with those reported previously. The physical data for the new compounds encountered in these preparations are listed below.

exo,exo-5,6-Dimethylnorcamphor: ν_{max} ($CDCl_3$) 1725 cm^{-1}; δ_H ($CDCl_3$) 0.97 (d), methyl protons.

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.20. Found: C, 78.67; H, 10.30.

endo-5-*exo*-6-Dimethylnorcamphor: ν_{max} ($CDCl_3$) 1720 cm^{-1}; δ_H (CCl_4) 0.93 (d), 1.12 (d), methyl protons.

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.20. Found: C, 78.74; H, 10.45.

exo-5-*endo*-6-Dimethylnorcamphor: ν_{max} ($CDCl_3$) 1720 cm^{-1}; δ_H ($CDCl_3$) 1.30 (d), 1.34 (d), methyl protons.

Anal. Calcd. for $C_9H_{14}O$: C, 78.21; H, 10.20. Found: C, 78.44; H, 10.16.

N.m.r. Spectra

Proton spectral data were obtained with a Varian HA-100 instrument. ^{13}C spectra were recorded with a Varian XL-100-15 system operating in the Fourier transform mode. Solutions (10–15% w/v) in deuteriochloroform containing a few drops of TMS were examined in 5 mm tubes using a 5 mm receiver insert. With spectral widths of 2000 Hz, or less, and the available memory core (4K) all peak positions were determined to ± 1 Hz. In general, 2000 transients were accumulated for each sample. Off-resonance decoupling was employed to confirm the assignments for methyl, methylene, methine, and quaternary carbons, and specifically deuterated materials were examined in a few cases to distinguish between methine resonances as described in the Results section.

We wish to thank the National Research Council of Canada for financial support of this study. We are grateful to Professors E. W. Warnhoff and N. H. Werstiuk for kindly providing samples of *endo*-3-methylcamphor and 6,6-dimethylnorcamphor respectively, and to M. Gordon, J. L. Gough, S. H. Grover, and P. M. Pellitt for technical assistance.

In situ Generation and Electrophilic Addition Reactions of the Elements of 'XF'[1]

L. D. HALL AND D. L. JONES

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received November 1, 1971[2]

Addition of the elements of 'IF' and of 'BrF' to alkenes can be effected by the *in situ* generation of these electrophiles from the halogen-AgF. For cyclohexene, 3,3,6,6-tetradeuterocyclohexene, methylenecyclohexane, styrene, and indene, these reactions are simple. However, for acenaphthylene, halogen–fluorine exchange and other reactions make the overall reaction quite complex. Electrophilic addition reactions for 1-fluoro-acenaphthylene are also described. The n.m.r. spectra of many of the products are given and discussed in some detail.

L'addition des éléments 'IF' et 'BrF' aux alcènes peut être effectuée par réaction in situ de ces électrophiles à partir de AgF-halogène. Pour le cyclohexène, tétradeutero-3,3,6,6 cyclohexène, méthylcyclohexane, styrène et indène, les réactions sont simples. Cependant pour l'acénaphtylène, l'échange halogène–fluor et d'autres réactions rendent la réaction globale complexe. Les réactions d'addition électrophile pour le fluoro-1 acénaphtylène ont été également décrites. Les spectres r.m.n. de plusieurs de ces produits ont été donnés et discutés de façon détaillée. [Traduit par le journal]

Can. J. Chem., **51**, 2902 (1973)

A crucial aspect of our programme to develop fluorine as a structural probe has always been the synthesis of specifically fluorinated substrates. One of the methods which was found to be successful in the carbohydrate area involved the addition of the elements 'XF', where X = Cl, Br, or I, to an unsaturated sugar (2); the preferable source of the 'XF' electrophile was shown to be the generation *in situ* from halogen and silver monofluoride. In the present paper we describe the reaction of a variety of alkenes with the above source of the elements of 'XF'. As will be seen, the initial addition reaction may be followed by further halogen exchange reactions which are sometimes so fast that the initially formed adduct cannot be isolated.

It is appropriate to comment here that there had previously been some controversy in the literature concerning the efficacy of the X_2–AgF method for generating 'XF'. Schmidt and Meinert (3) reported that in acetonitrile solvent the elements of iodine monofluoride could be added across the double bond of cyclohexene, to form *trans*-1-fluoro-2-iodocyclohexane in 60% yield. However, Andreatta and Robertson (4), attempting to repeat this reaction, isolated only *N*-acetyl-2-iodocyclohexylamine in 17% yield; this work will show that the 'IF' addition reaction to cyclohexene is indeed a viable reaction, and can be extended to a variety of other alkenes, and also to 'BrF' additions.

Results and Discussion

The compounds described in the first section of the following discussion were for the most part isolable in pure form and were fully characterized. In constrast, the acenaphthyl fluorides discussed subsequently were generally unstable and hence could only be characterized by their ^1H and ^{19}F n.m.r. spectra.

The reactions summarized in Scheme 1 are typical of those of aliphatic alkenes. Slow addition of a dilute solution of iodine in benzene to a stirred suspension of AgF in cyclohexene and benzene afforded as sole product 1-fluoro-2-iodocyclohexane (**1**). The stereochemistry of the product was shown to be *trans* by examination of the ^1H n.m.r. spectrum of the product (**1**-d_4) obtained from 3,3,6,6-tetradeuterocyclohexene: it is noteworthy that neither the ^1H nor the ^{19}F n.m.r. spectra of the *crude* product arising from that reaction showed any detectable impurities.[3]

The addition of 'BrF' to cyclohexene was also successful, again producing a *trans*-product (2).

[1]For a preliminary communication see ref. 1. Presented in part at the 51st Canadian Chemical Conference of the Chemical Institute of Canada, Vancouver, British Columbia, June 3–5, 1968.

[2]Revision received February 23, 1973.

[3]The ^1H n.m.r. spectrum of this deuterated compound is shown in the accompanying paper (5).

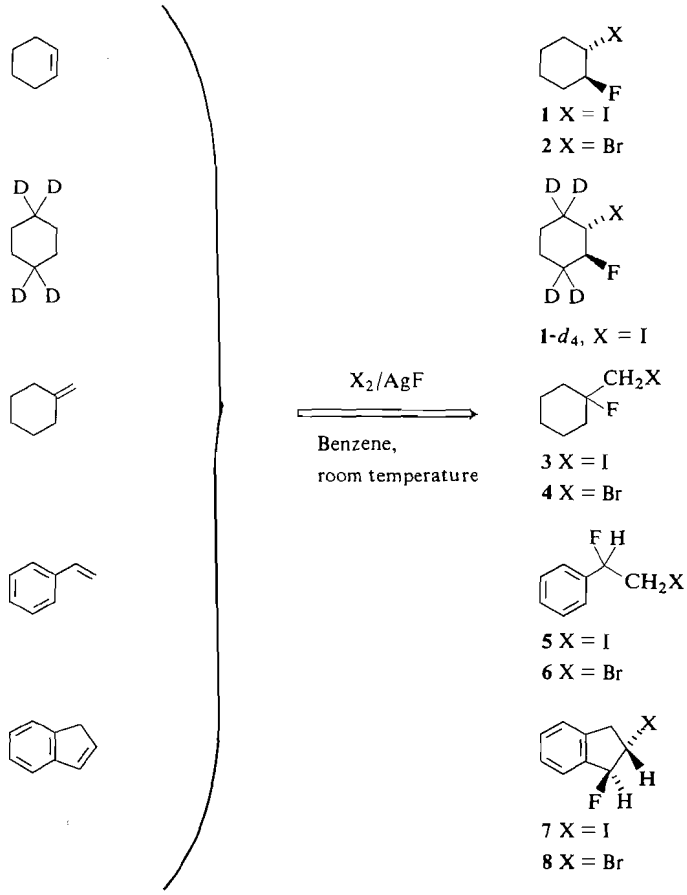

SCHEME 1

This reaction was more difficult to carry out and the AgF had to be absolutely dry, otherwise the 1,2-dibromide was formed.

Direct extension of the 'IF' and 'BrF' addition reactions to methylene-cyclohexane, styrene, and indene produced in each instance the reaction product having the structure anticipated for the reaction of X^+F^-.

In marked contrast to the ease of the above addition reactions, attempts with acenaphthylene were at first unsuccessful. 'BrF' addition in benzene solution produced no 'BrF' adduct, but gave instead a low yield of the *cis*- and *trans*-difluorides (**9**, **10**) (see Scheme 2). The major product of the reaction contained no fluorine and was high melting. In addition to these products, there were also two others, both in trace quantities, which were observed in the ^{19}F n.m.r. spectrum of the crude product; one was later shown to be 1-fluoro-acenaphthylene (**11**) and the other 1-bromo-2,2-difluoro-acenaphthene (**12**) designated hereafter as the 'BrF_2 adduct'.

If, however, the solvent was 50/50 benzene–acetonitrile,[4] the *trans*-'BrF' product (**13**) resulted. Increasing proportions of benzene in the solvent produced a mixture of all three products; *trans*-'BrF', *cis*- and *trans*-difluorides, as well as "polymeric" material; altering the time of the reaction seemed to have some effect on the relative amounts. Interestingly, it was not possible to convert the 'BrF' product to difluoride using AgF, with either benzene or acetonitrile as solvent. However, addition of Br_2 to acenaphthylene produced only *trans*-dibromide, confirming Cristols' result (6) and subsequent shaking with AgF yielded only *trans*-BrF (**13**).

[4]Acenaphthylene was dissolved in benzene–acetonitrile, but Br_2 added as a benzene solution.

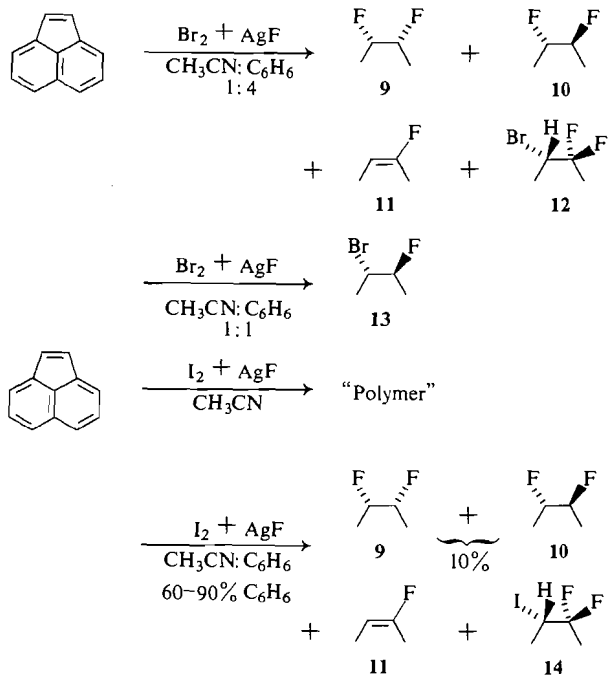

SCHEME 2

Reactions of I_2 + AgF with acenaphthylene were performed as for the Br_2 + AgF reactions; however the experimental results were significantly different. Any 'IF' product, if it ever existed, was too unstable to be isolated and led to further products. In benzene, the major fluorinated products were once again the *cis*- and *trans*-difluorides (**9**, **12**) but in low yield. Trace quantities of fluoro-acenaphthylene (**11**) and the 'IF_2' adduct (**14**) were also observed and isolated.

With increasing quantities of acetonitrile in the solvent, less of the above products were observed, and the best yields were obtained in 80–90% benzene.[5] Below 50% benzene none of these compounds were formed in substantial quantities but other fluorinated products were observed in the ^{19}F n.m.r. spectrum; however, they decomposed with every attempted isolation (such as column chromatography). From the chemical shift and multiplicity of the ^{19}F resonance it was evident that the unknown products could well contain a *trans*-'IF' adduct which would be expected to be very unstable indeed. The ratio of *cis*:*trans* difluorides was found to be close to 1:2, and essentially independent of solvent, in the range benzene–acetonitrile (40:60) to pure benzene. Finally it was observed that a number of other compounds were formed in trace quantities, and from the pattern of their ^{19}F resonances they appeared very similar in structure to the *trans*-difluoride.

The unexpected results obtained with 'XF' additions to acenaphthylene can be attributed to the increased reactivity of the halogen 'X' of the 'XF' adduct. This reactivity is well illustrated by the effect of AgF on 1-bromo-acenaphthene, 1-bromo-indan and bromo-cyclohexane respectively. The acenaphthene derivative is converted to the fluoride in minutes; in contrast, the indan compound requires 24 h for the same reaction, and bromo-cyclohexane is unreactive.

The products obtained from the 'XF' reactions with acenaphthylene suggested that many acenaphthyl fluorides might be obtained by a series of simple reactions, chiefly utilizing 1-fluoro-acenaphthylene (**11**); such compounds would provide the necessary data to determine the effect of electronegativity on $^3J_{HF}$ couplings.

1-fluoro-acenaphthylene (**11**) was prepared by the method described by Merritt and Johnson (7), *i.e.*, elimination of HF, using a refluxing

[5]Volume measurement.

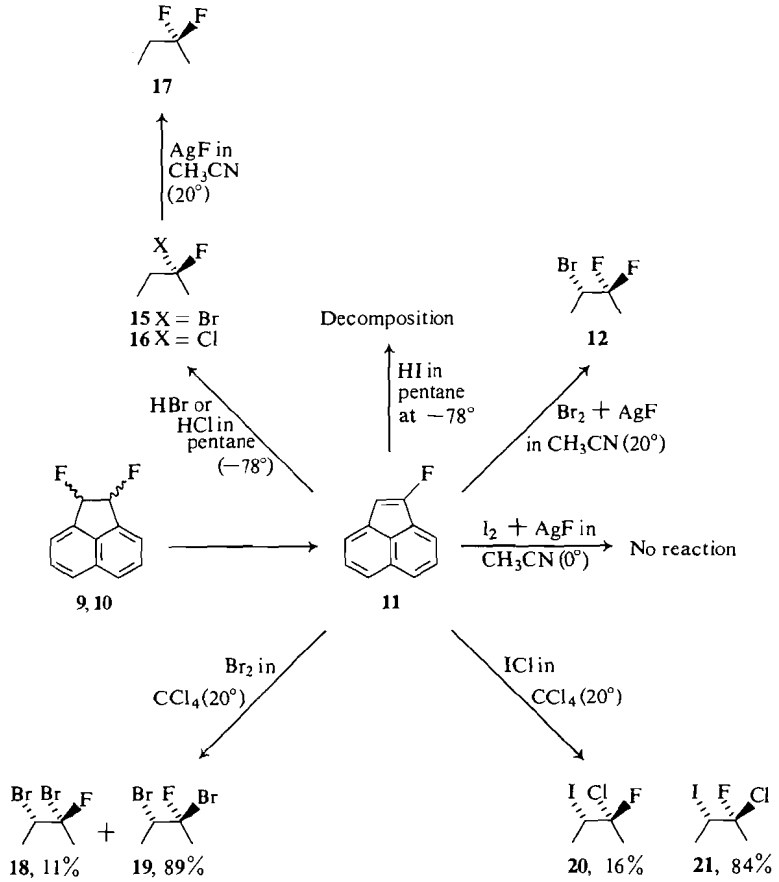

SCHEME 3

solution of KOH in ethanol, from either the *cis*- or the *trans*-1,2-difluoride of acenaphthene. The conversion obtained from this reaction was never quantitative, and it was necessary to recycle the recovered starting material. The reactions performed with **11** are summarized in Scheme 3. For convenience each of these reactions is listed separately below.

(a) Addition of HCl or HBr, Followed by AgF Exchange

Addition of HBr or HCl gas to a solution of 1-fluoro-acenaphthylene (at −78°) yielded the corresponding '*gem*-BrF' (**15**) and '*gem*-ClF' (**16**) adducts; in neither case was any vicinal product observed. Shaking either of these compounds with AgF powder in acetonitrile solution at room temperature produced the *gem*-difluoride (**17**). Addition of HI, instead of HCl or HBr, produced only decomposition even at −78°.

(b) 'BrF' Addition

Conditions identical with those used for acenaphthylene itself afforded as major product the expected 'BrF_2' adduct spectroscopically identical with the trace material found in the reaction of acenaphthylene; two minor components were also formed, but these were not identified.

(c) 'IF' Addition

The analogous reaction between I_2, AgF, and 1-fluoro-acenaphthylene did not proceed.

(d) Br_2 Addition

When elemental bromine was added to fluoro-acenaphthylene in either CCl_4 or CH_3CN solution, both *cis*- and *trans*-products (**18, 19**) were observed; the ratio of *cis*–*trans* was 1:8.

(e) ICl Addition

Analogous treatment of 1-fluoro-acenaphthylene with an ICl solution in CCl_4 gave similar

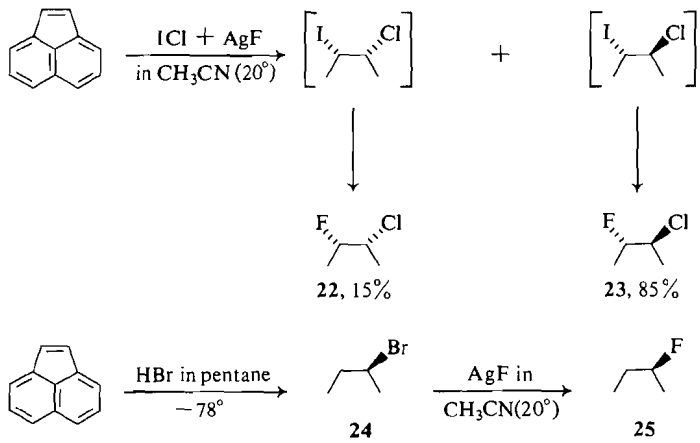
For personal use only.



SCHEME 4

results, *i.e. cis-* and *trans*-products (**20**, **21**) in the ratio 1:5.

Some apparently anomalous additions have been previously observed with acenaphthylene by several other workers; thus Cl_2 addition can be made to add *cis* or *trans*, depending on reagents whereas only a *trans*-dibromide is known (6). Furthermore, HBr and HCl addition has been shown to go 75–90% *cis* (8). However, it is possible that earlier workers (6) might have missed a small quantity of a minor product, such as a *cis*-dibromide, for example.

The *cis-* and *trans*-'ClF' adducts (**22**, **23**) shown in Scheme 4 were prepared by 'XF' addition to acenaphthylene using ICl and AgF in CH_3CN solution. Once again, the *trans*-adduct predominated (85%).

Following the procedure of Dewar and Fahey, 1-bromo-acenaphthene (**24**) was synthesized from acenaphthylene and HBr (8); this compound readily exchanged its bromine atom for a fluorine of AgF, in acetonitrile solution at room temperature. Unfortunately, this resulting fluoride was extremely unstable, and all attempts at purification or isolation resulted in decomposition; thus it was found impossible to run the compound on any available chromatographic apparatus (*i.e.* acid, neutral, or basic silica gel or alimina on either columns or plates). Additionally, it was decomposed by washing with a weakly basic aqueous solution, and also by warm chloroform.

Summary

The reactions discussed above indicate that electrophilic addition of the elements of 'IF' and 'BrF' to alkene can be accomplished using the halogen-AgF reagent. Addition of 'IF' is more facile than that of 'BrF' and for aliphatic alkenes both are simple reactions. However, if the 'XF'-product has the bromine or iodine substituent in a benzylic position then further reactions can follow the initial addition and the overall reaction sequence is then extremely complex.

The reactions discussed here afforded a range of interesting substrates for n.m.r. studies and these are described in three accompanying papers (5, 10, 11).

Experimental

All solutions were concentrated under reduced pressure. Benzene and acetonitrile were dried over calcium sulfate and light petroleum and dichloro-methane were fractionally distilled before use. Silver fluoride[6] was stored in a vacuum dessicator and ground to a fine powder just prior to a reaction. Cyclohexene was distilled before a reaction, but all other reagents were used as received.

Silica gel used for chromatographic columns was Mallinckrodt CC-7, a neutral high-purity grade.

trans-2-Iodocyclohexylfluoride (1)

Cyclohexene (3.1 ml, 2.5 g) and silver monofluoride (12 g) were added to benzene (50 ml) and the resulting mixture stirred vigorously and cooled in an ice–bath. A solution of iodine (8 g) in benzene (80 ml) was then added over 0.5 h with continued stirring.

The reaction mixture was filtered and the filtrate washed successively with aqueous sodium bicarbonate, sodium thiosulfate, sodium bicarbonate, and finally with water. The organic layer was separated, dried ($MgSO_4$), and concentrated to a clear liquid whose ^1H n.m.r. spectrum was virtually indistinguishable from the distilled material. Distillation under reduced pressure gave **1** (4.4 g, 63%), b.p. 50° (2 mm) (lit. (9), 64° (9 mm)), n_D^{23}

1.5310 (lit. (9), n_D^{20} 1.5318). The ^{19}F chemical shift in $CHCl_3$ solution was +159.9 p.p.m. with respect to $CFCl_3$ as a reference.

Anal. Calcd. for $C_6H_{10}IF$: C, 31.59; H, 4.42; I, 8.32. Found: C, 31.76; H, 4.63; I, 8.11.

trans-1-Bromo-2-fluoro-cyclohexane (2)

The same procedure as for preparation of **1** was used except that bromine was substituted for iodine, and no thiosulfate washing was necessary in the work-up. Bromine (6.0 g) in benzene (25 ml) was added dropwise, and all other procedures and quantities remained the same. The n.m.r. spectra of crude and distilled material again were very similar, and also matched that of the product of the Bowers reaction (9). The product had a b.p. 58° (9 mm) (lit. (9), 30° (13 mm)[7]), n_D^{25} 1.4825 (lit. (9) n_D^{20} 1.4830).

Anal. Calcd. for $C_6H_{10}BrF$: C, 39.78; H, 5.56; F, 10.49. Found: C, 39.90; H, 5.65; F, 10.61.

1-Iodomethyl-cyclohexyl Fluoride (3)

Prepared in a similar procedure as used for **1**. Quantities used were; AgF (10 g); methylene cyclohexane (2.5 g) dissolved in benzene (35 ml); iodine (8.5 g) dissolved in benzene (85 ml). Reaction time was 90 min. Crude yield 6.0 g; distilled yield 4.4 g (70%), b.p. 61° (1 mm), n_D^{25} 9.5175, ϕ_c 151.2 p.p.m.

Anal. Calcd. for $C_7H_{12}IF$: C, 34.73; H, 4.97. Found: C, 34.88; H, 5.02.

1-Bromomethyl-cyclohexyl Fluoride (4)

Similar procedure as for **2**; to methylene cyclohexane (2.5 g) and AgF (10 g) in benzene (40 ml) was added bromine (8 g) in benzene (40 ml) over 1 h at 0°. Distillation afforded 3.0 g of 4 (yield 59%), b.p. 47° (1 mm), n_D^{25} 1.4825, ϕ_c 156.3 p.p.m.

Anal. Calcd. for $C_7H_{12}BrF$: C, 43.12; H, 6.15. Found: C, 42.89; H, 6.25.

The position of the substituents is obtained from the n.m.r. spectrum; the lack of an identifiable $^2J_{HF}$ coupling (characteristically about 50 Hz) located the fluorine at the tertiary position.

2-Iodo-1-fluoro-1-phenylethane (5)

Identical procedure as for preparation of **1**, except that styrene (2.5 g) was used as starting material. Distillation *in vacuo*, however, resulted in decomposition. Crude yield (after work-up and removal of solvent), 4.7 g (78%). The n.m.r. spectrum showed that the product was substantially pure and its similarity to that of the bromo-derivative **6**, which is discussed below; ϕ_c +166.8 p.p.m.

2-Bromo-1-fluoro-1-phenylethane (6)

Same procedure as for **2**, except that styrene (2.5 g) and bromine (5.0 g) in benzene (40 ml) were used; time of addition was 105 min.

Distillation under reduced pressure produced a clear liquid, 3.5 g (71%), b.p. 69° (1 mm), n_D^{25} 1.5409, ϕ_c +174.5 p.p.m.

The n.m.r. spectra demonstrated the position of the substituents: the partial ^1H spectrum has two identifiable regions, an AB and M region of an ABMX spectra (where X = ^{19}F). The 50 Hz J_{MX} positions the fluorine in the secondary position.

2-Iodo-1-fluoro-indan (7)

Again, the same procedure was used as for **1**, (indene (2.8 g) was reacted with iodine (9.0 g) and AgF (13.0 g)). Although the product could not be distilled without decomposition, the crude product after work-up was a clear liquid, whose n.m.r. spectra showed no impurities. Crude yield was 4.8 g (66%), ϕ_c +155.2 p.p.m., $^2J_{HF}$ 5.6 Hz, $^3J_{HF}$ 18 Hz. The structure is derived from the n.m.r. spectra which are similar to those of the bromo-compound discussed below.

This compound was extremely unstable and the pure liquid, obtained by eluting off a neutral silica gel column with light petroleum at low temperatures, decomposed at room temperature in seconds. Elution down an alumina column produced indene. Solid $NaCO_3$ was effective in preventing decomposition.

2-Bromo-1-fluoro-indan (8)

Indene (2.8 g) was reacted with bromine (6.0 g) and AgF (13.0 g) over 90 min and worked-up in the usual way. Crude yield was 5.1 g (88%), ϕ_c 160.4 p.p.m., $^2J_{HF}$ 55 Hz, $^3J_{HF}$ 17 Hz. Distillation was not possible, but (in contrast to **7**) the material could be purified by elution down an alumina column with light petroleum.

In the ^1H spectra the proton next to the fluorine (identified by the characteristic $^2J_{HF}$ 55 Hz) has only one other coupling into it. Hence the fluorine must be in the 1-position. Furthermore, the proton to slightly higher field, which must be *geminal* to the bromine atom, is split into 16 lines (thus four couplings) and must be in the 2-position. The n.m.r. spectra and conformation of **8** are discussed more fully in the accompanying paper (10).

cis- and trans-1,2-Difluoro-acenaphthene (9, 10)

Acenaphthylene (2.0 g) was dissolved in a stirred mixture of benzene (40 ml), acetonitrile (10 ml), and AgF (10 g). Iodine (4.0 g) was also dissolved in the same solvent mixture (40 ml) and this solution was then added dropwise to the acenaphthylene–AgF mixture over 1 h, with cooling (ice-bath) and stirring. The mixture was then poured into a larger volume of a saturated $NaHCO_3$ aqueous solution, mixed thoroughly, filtered, and the organic layer separated from the filtrate and washed with more water. Drying over Na_2SO_4 and Na_2CO_3 and removal of solvent produced a dark red viscous liquid, whose ^{19}F n.m.r. spectrum revealed the presence of at least two compounds.

This crude product mixture was then separated chromatographically by eluting down a neutral silica gel column with light petroleum (b.p. 37°). The column fractions were monitored by t.l.c., ^1H and ^{19}F n.m.r. First off the column was a small amount of starting material, quickly followed by fluoro-acenaphthylene (**11**) and 1-iodo-2,2-difluoro-acenaphthene (**14**), both in trace quantities; then came a major product, *trans*-1,2-difluoro-acenaphthene (**10**). Further elution with 20% CH_2Cl_2 in light petroleum produced *cis*-1,2-difluoro-acenaphthene (**9**), contaminated with some highly colored material. The fractions containing **9** and **10** were then purified by twice eluting them down silica gel columns as above.

[7]The literature value of the boiling point of **2** appears to be in error; a sample of **2** prepared by the literature method (9) had a boiling point in agreement with that reported here.

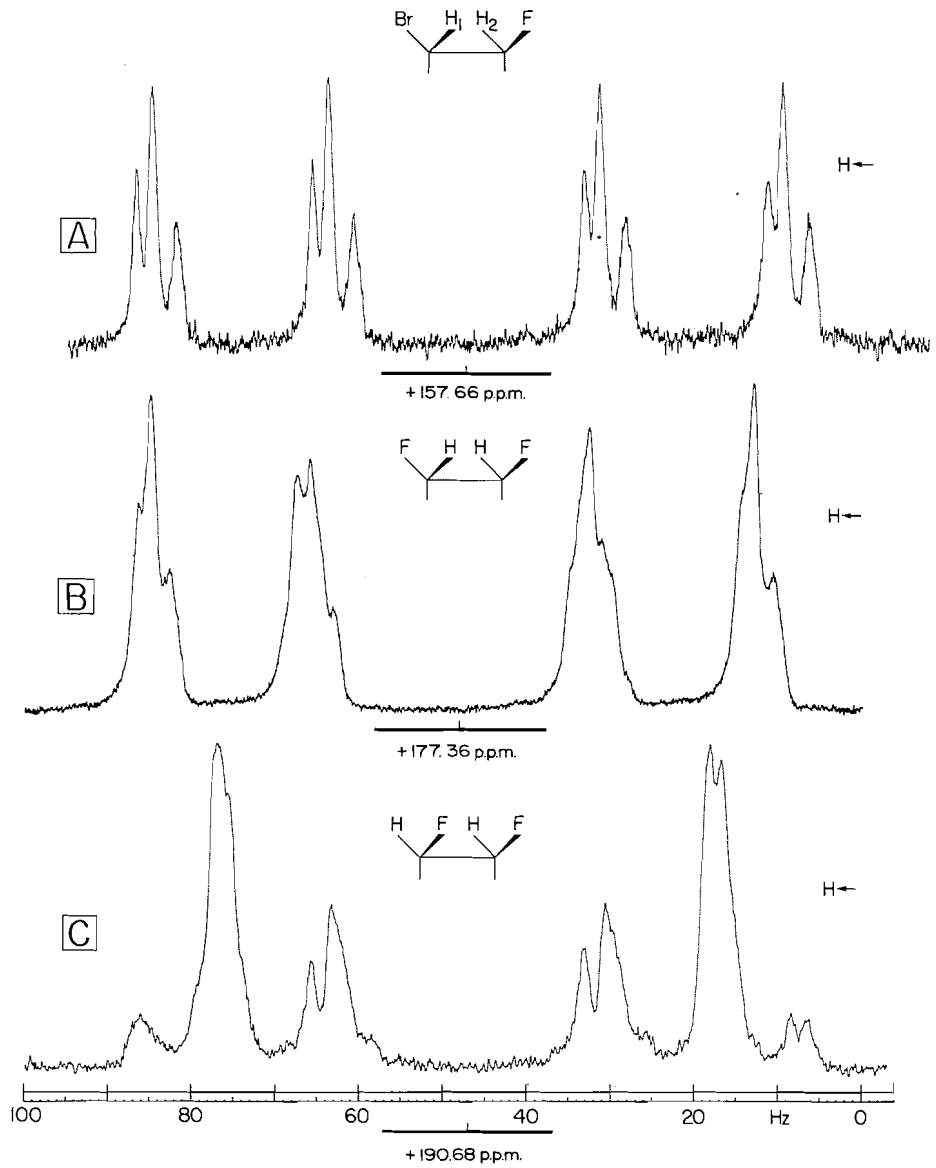

FIG. 1. ^{19}F n.m.r. (94.07 MHz) of the three major products of the 'XF' addition to acenaphthylene. A, *trans*-bromofluoride (**13**); B, *trans*-difluoride (**10**); C, *cis*-difluoride (**9**).

The ^1H spectrum of each is identical with its ^{19}F spectrum, which is a characteristic of A_2X_2 systems such as **9** and **10**; the ^{19}F spectra of each is shown in Figs. 1B and 1C and the ^1H spectra[8] in Figs. 2A and 2C. Decoupling of the aromatic protons of **10** produced a marked sharpening of the lines, as shown in Fig. 2B, but a similar decoupling experiment on **9** was a failure.

Crystalline samples of **9** and **10**, which were obtained by slow cooling of an ethanol–water solution, gave satisfactory elemental analyses.

Anal. Calcd. for $C_{12}H_{10}F_2$: C, 75.79; H, 4.21; F, 20.00. Found (*cis*): C, 75.95; H, 4.20; F, 19.80. Found (*trans*): C, 75.55; H, 4.00; F, 20.30.

Other physical data are:

	cis (**9**)	*trans* (**10**)
M.p. (°C)	113	47
$^3J_{HF}$ (Hz)	5.2	19.13
$^3J_{HH}$ (Hz)	5.1	1.23
$^3J_{FF}$ (Hz)	16.4	1.23
ϕ_c (p.p.m.)	190.68	177.36
τ_H	3.24	4.32

[8]Actually they are *partial* ^1H spectra, since the aromatic region is not shown.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

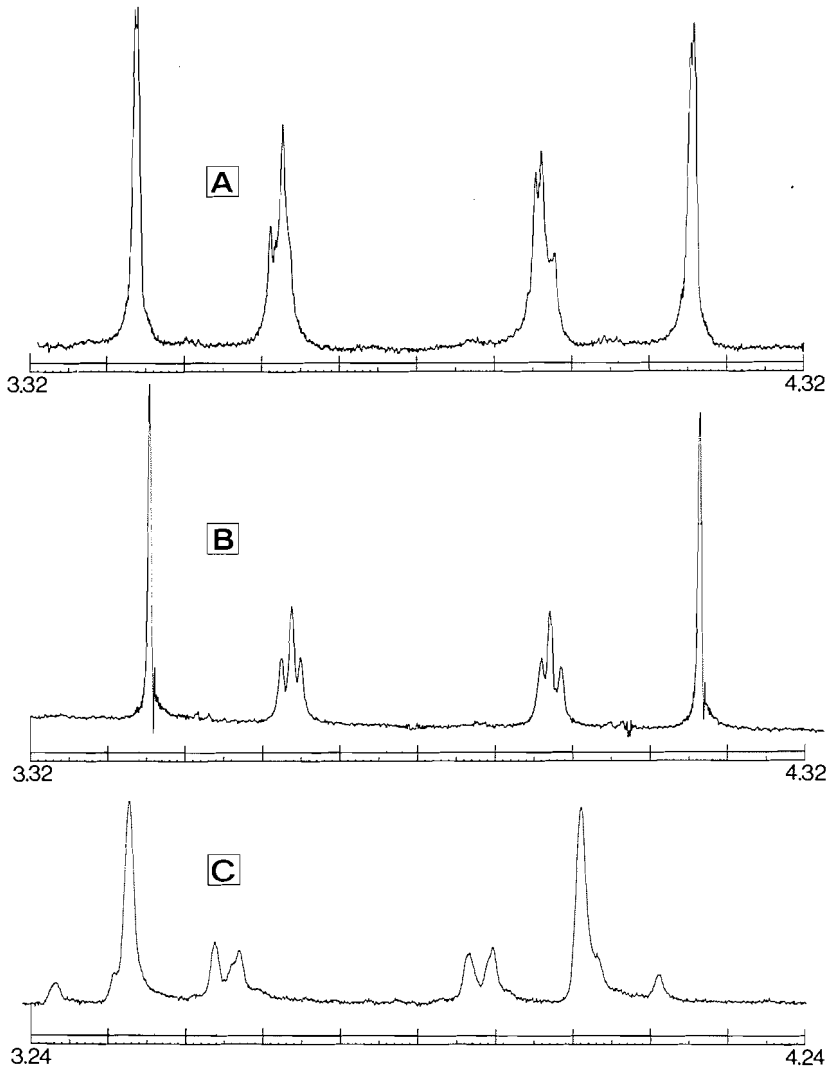

FIG. 2. Partial ^{1}H n.m.r. spectra (100 MHz) of the difluorides of acenaphthylene. A, the normal spectrum of the *trans*-difluoride (**10**); B, the same spectrum but measured with simultaneous irradiation of the aromatic protons; C, the normal spectrum of the *cis*-difluoride (**9**).

Although quantitative values for the yields could not be obtained, subjective estimates are 10% for the *trans*-isomer (**10**) and 5% for the *cis* (**9**). A series of experiments were carried out to optimize the yield; the percentage of benzene in the solvent was varied from 50–100% and an optimum yield was obtained in the range 80–90% benzene. However, the ratio of *trans*–*cis* was constant at 2:1. The analysis of the A_2X_2 n.m.r. spectra was done by hand;[9] agreement with Merritt and Johnsons' values (7) is good for the *cis*-isomer but rather poorer for the *trans*. This is understandable since the previous analysis would have been carried out on a spectrum such as Fig. 2A rather than 2B.

[9]A_2X_2 spectra consist of two unconnected sub-spectra and as such cannot be analyzed by an iterative computer procedure.

*trans-1-Bromo-2-fluoro-acenaphthene (**13**)*

A solution containing Br_2 (2.5 g) and benzene (25 ml) was added dropwise to a vigorously stirred suspension of finely powdered AgF in 50:50 benzene–acetonitrile at 0°. Simultaneously, another solution containing acenaphthylene (2.0 g) in benzene (25 ml) was also added.

This addition was carried out over a period of 20 min, after which the reaction mixture was immediately filtered, washed with $NaHCO_3$ solution, and then dried over Na_2SO_4–$CaSO_4$. The resulting light yellow solution was evaporated under vacuum to 5–10 ml[10] and then eluted down an alumina column with light petroleum. Apart from a small quantity of starting material (which runs very fast) the only product was **13**; the ^{19}F spectrum is

[10]Further concentration increases the possibility of decomposition.

shown in Fig. 1A and a partial ^1H spectrum in Fig. 3B. Decoupling of the aromatic protons revealed that this latter spectrum was the AB part of an ABX; this is shown above in Fig. 3A. Selective decoupling, not shown, of the left-hand doublet of H_2 collapsed the corresponding left-hand doublet in H_1. This confirms the analysis of spectra, and indicates that $^3J_{1F}$ has the same sign as $^2J_{2F}$. The small $^3J_{12}$, 1.0 Hz also indicates a *trans* relationship between Br and F.

The product **13** is very unstable and has to be kept well below 0° unless stabilized by solid $NaCO_3$. A concentrated pentane solution, cooled in Dry Ice deposited yellow crystals; however, they proved to have some solvent in them. A similar experiment with ethanol had the same result; however, the material deposited from this solution when warmed to −25° and pumped on for 4 h produced a crop of white–yellow crystals which had a sharp m.p. of 35° and whose ^1H n.m.r. showed no solvent present; they also gave satisfactory elemental analysis. The crystals were extremely unstable, being decomposed within minutes at room temperature.

Anal. Calcd. for $C_{12}H_{10}BrF$: C, 57.39; Br, 31.85; F, 7.57. Found: C, 57.16; Br, 31.59; F, 7.43.

τ_{H_1} 4.32; τ_{H_2} 3.52; ϕ_c 157.66 p.p.m.; $^3J_{HF}$ 21.4 Hz; $^3J_{HH}$ 1.0 Hz.

The product **13** could be distinguished from acenaphthylene with t.l.c.; the two compounds ran very close together (**13** last) but upon charring with concentrated H_2SO_4, acenaphthylene gives a green color whereas **13** turns brown.

1-Fluoro-acenaphthylene (11)

Following the procedure of Merritt and Johnson (7), *cis*-difluoroacenaphthene (**9**) (1.0 g) was heated under reflux with KOH (3 g) in ethanol (50 ml) for 5 h. The ^{19}F n.m.r. spectrum of the crude product indicated that most of the starting material had reacted. The product mixture was worked-up by removing most of the ethanol *in vacuo*, dissolving in petroleum ether and washing with water. The organic layer was dried, filtered, and concentrated again, prior to separation on a neutral silica gel column with pentane–benzene (70:30). The product **11** ran ahead of the starting material (**9**) and gave a characteristic yellow color to the solution.

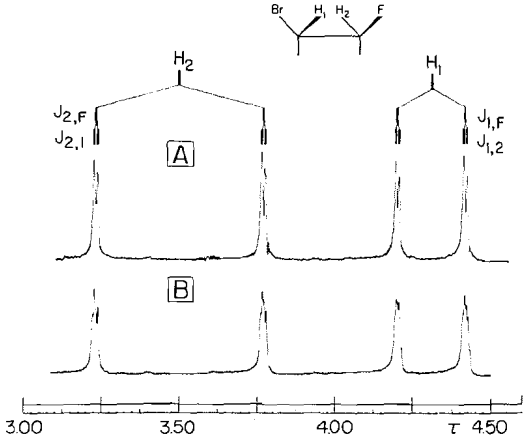

FIG. 3. Partial ^1H n.m.r. (100 Hz) of 1-bromo-2 fluoro-acenaphthene (**13**). A, the spectra measured with simultaneous irradiation of the aromatic protons; B, the normal spectrum.

Spectroscopically (^1H and ^{19}F n.m.r.), this material appeared to be free of impurities; however, small amounts of acenaphthylene itself which were undetected in the n.m.r. spectrum were picked out on a t.l.c. plate (very slightly ahead of **11**). Therefore the material was rerun down an extra long column (60 in.) of neutral silica gel with pentane; this removed the residual acenaphthylene. The two compounds could be distinguished on a t.l.c. plate by the fact that fluoro-acenaphthylene (**11**) fluoresces under u.v. light whereas acenaphthylene does not.

A crystalline sample of **11** was obtained by cooling a pentane solution to −78°; m.p. 37°, yellow plates (previously reported as oil). ^1H n.m.r. singlet at τ 4.00 (besides aromatic region), ^{19}F n.m.r. singlet at ϕ_c 99.4 p.p.m.; no impurity peaks were detected.

The reaction yield was high (from ^{19}F n.m.r.) but not quantitative. Significant amounts of starting material remained even with long reaction times (24 h) or high alkalinity of the solution. Use of *trans*-difluoro-acenaphthene (**10**) lowered the yield somewhat.

1-Bromo-2,2-difluoroacenaphthylene (12)

Bromine (0.4 g) in benzene (5 ml) was added over 20 min to a stirred solution of fluoro-acenaphthylene (**11**) (0.20 g) in acetonitrile (50 ml), containing powdered AgF (4.0 g). After the reaction, bicarbonate solution was added and the whole mixture filtered; the organic layer was separated, dried, filtered, and concentrated. ^{19}F n.m.r. of this material showed strong resonance which was evidently the AB-part of an ABX spectrum, and identified the main product as **12**; this was the same spectrum as that picked up weakly in the 'BrF' addition to acenaphthylene. This was analyzed (with TWOSUM) to give the following parameters: J_{AB} 253.65 Hz ($^2J_{H_1F_2}$ (*gem*)), J_{AX} 15.28 Hz ($^3J_{HF_1}$ (*cis*)), J_{BX} 3.72 Hz ($^3J_{HF_2}$ (*trans*)), ν_{AB} = 237.14 Hz (2.52 p.p.m.), τ_H 4.23, $\phi_c(F_1)$ 88.3 p.p.m.; $\phi_c(F_2)$ 85.8 p.p.m.

1-Iodo-2,2-difluoroacenaphthene (14)

'IF' did not react with 1-fluoro-acenaphthylene (**11**) under a variety of conditions, including as solvent acetonitrile, 60:40 benzene–acetonitrile, and benzene.

A small quantity of the desired product (**14**) was retrieved from the 'IF' reaction with acenaphthylene; after two chromatographic separations a spectroscopically pure sample was obtained, with a yield of only 0.2%. The large geminal F–F coupling (252 Hz) and the presence of only one other spin coupling into each ^{19}F resonance identified the product. The quartet in the ^1H spectrum confirmed this; $\phi_c(F_1)$ 75.8 p.p.m., $\phi_c(F_2)$ 87.5 p.p.m., τ_H = 4.24, $^2J_{FF}$ 252 Hz, $^3J_{HF_2}$ (*cis*) 16.26 Hz, $^3J_{HF_1}$ (*trans*) 4.24 Hz.

1-Bromo-1-fluoro-acenaphthene (15)

Fluoro-acenaphthylene (**11**) (0.30 g) was dissolved in dichloromethane and cooled to −78°; HBr gas was then bubbled in slowly until the characteristic yellow color of **11** had disappeared (15 min), leaving a cream-colored solution. The solvent and excess HBr were then removed *in vacuo*, leaving a light brown solid. All chromatographic treatment of this material ended in decomposition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The ^1H spectrum showed only a single ABX spectrum (AB-part) in the methylene region; the ^{19}F spectrum contained only a quartet at low field, with total width of 33 Hz, thus ruling out any *geminal* H–F coupling.The product must then be 15: τ_{H_1} 6.14, τ_{H_2} 6.00, ϕ_c 79.8 p.p.m., $^2J_{HH}$ 18.3 Hz, $^3J_{HF}$ (*cis*) 22.8 Hz, $^3J_{HF}$ (*trans*) 10.3 Hz.

1-Chloro-1-fluoro-acenaphthene (16)

The same reaction was performed as above, substituting HCl for HBr, with similar results; again no vicinal products were observed. Pentane was an equally good solvent for the reaction, which appeared (spectroscopically) to be quantitative: $\tau_{H_1} \simeq \tau_{H_2}$ 5.775, ϕ_c 81.3 p.p.m. ($^3J_{HF}$ (*cis*) + $^3J_{HF}$ (*trans*)) 32.8 Hz.

1,1-Difluoroacenaphthene (17)

A solution of **15** (40 mg) in acetonitrile was shaken with AgF (0.20 g) at 20° for 20 min. The solid matter was filtered off and the acetonitrile removed *in vacuo*; t.l.c. showed two compounds both running fast, on silica gel. ^{19}F n.m.r. of this material indicated two resonances; the weaker one was fluoro-acenaphthylene (**11**) and the other a triplet resonating at somewhat higher field than either **15** or **16**. ^1H n.m.r. again showed the singlet at low field, characteristic of **11** and also a triplet at lower field than that for either **15** or **16**. Integration of this region showed it to contain two protons (by comparison with aromatic region). Integration of the ^{19}F resonances gave the product ratio of 17:11 as 81%:19% (allowing for two fluorines in **17**).

Substituting **16** for **15** in this reaction and allowing 1 h reaction time gave substantially the same result, thus confirming that the new product **17** is the *gem*-difluoride. The identical triplets observed in both the ^1H and ^{19}F spectra are again characteristic of an AA′XX′ system; this time the large $J_{AA'}$ ($^2J_{FF}$ 250 Hz) effectively reduces the spectra to a true A_2X_2 (in which $J_{AX} = J_{A'X'}$ etc). This feature, which was verified by generating a theoretical spectrum using a reasonable set of parameters, is rather unfortunate since only the *sum* of the *vicinal* couplings may be extracted. The *geminal* couplings cannot be measured at all.

An attempt was made to get around this problem by selective deuteration; DBr was synthesized from PBr_3 (15 ml) according to the procedure in Shoemaker and Garland (12). This was then reacted with **11** in the same way as before to produce **15**-d_1, and exchanged with AgF to give **17**-d_1. This product was purified successfully by eluting down neutral silica gel with petroleum ether, but the ^1H spectrum again showed a broad[11] triplet with shoulders which could not be decoupled from the aromatic region; the latter region itself was very broad (> 75 Hz). The only parameters which can be extracted therefore are: ϕ_c 84.5 p.p.m.; τ_H 6.52, ($^3J_{HF}$ (*cis*) + $^3J_{HF}$(*trans*)) 26.4 Hz.

[11]The spectrum of a deuterated compound such as **17**-d_1 has been thoroughly investigated by Kanazawa and Baldeschewieler (13) and as such is capable of analysis, provided that a reasonably well-resolved spectrum can be obtained. However, the extreme broadness of the lines prevents one from observing the weak transitions which are necessary to obtain the full analysis of the spectrum.

cis-1,2-Dibromo-1-fluoro-acenaphthene (18) and trans-1,2-Dibromo-1-fluoro-acenaphthene (19)

To fluoro-acenaphthylene (**11**) (0.20 g) was added Br_2 (0.20 g) as a CCl_4 solution, over 15 min at 20°. ^1H and ^{19}F n.m.r. showed that there were two products, of which the predominant one (89%) had a small $^3J_{HF}$ and was therefore assigned as the *trans* adduct. *cis* (**18**) (11%) ϕ_c 83.8 p.p.m., τ_H 4.30, $^3J_{HF}$ (*cis*) 18.9 Hz. *trans* (**19**) (89%) ϕ_c 89.7 p.p.m., τ_H 3.94, $^3J_{HF}$ (*trans*) 3.1 Hz (all in benzene solution). The reaction was performed in CH_3CN with the same result.

cis-1,2-Iodochloro-1-fluoro-acenaphthene (20) and trans-1,2-Iodochloro-1-fluoro-acenaphthene (21)

ICl (220 mg) was added to fluoro-acenaphthylene (**11**) in the same way as above. ^1H and ^{19}F n.m.r. again revealed two products; the predominant one having the smallest $^3J_{HF}$ was assigned the configuration with iodine and chlorine *trans*. The product ratio was also similar, 5:1 in favor of the *trans* (ICl) adduct. *cis* (**20**) (16%) ϕ_c 82.2 p.p.m., τ_H 3.67, $^3J_{HF}$ 19.7 Hz. *trans* (**21**) (84%) ϕ_c 74.9 p.p.m., τ_H 3.68, $^3J_{HF}$ 6.0 Hz (both in CCl_4 solution).

cis-1-Chloro-2-fluoro-acenaphthene (22) and trans-1-Chloro-2-fluoro-acenaphthene (23)

Powdered AgF (8 g) was added to an acetonitrile solution (50 ml) of acenaphthylene (2.0 g) and the mixture cooled with an ice-bath. ICl (2.0 g), dissolved in acetonitrile (30 ml), was then added over 20 min to this mixture, with stirring. At the end of this period, the reaction was worked-up in the usual way. ^{19}F n.m.r. of this crude product revealed two resonances in the ratio 85:15, and it was immediately eluted down a neutral silica gel column with petroleum ether – benzene.

Three compounds were separated; the first and major component contained no fluorine and showed a sharp singlet at τ 4.45, indicating that it was the *trans*-dichloride of acenaphthene; the mass spectrum, melting point and elemental analysis confirmed this.

The second compound, running close behind, gave ^{19}F and ^1H n.m.r. spectra almost identical with that of **13** (see Figs. 1A and 3A) and was assigned as the *trans*-chlorofluoride (**23**). The last component, a minor one, was evidently the *cis*-chlorofluoride (**22**), since there were two low-field protons with a coupling between them of 6.0 Hz (expected for $^3J_{HH}$, $\phi = 0°$), which were coupled to fluorine. The n.m.r. parameters in benzene solution are:

	cis (**22**)	*trans* (**23**)
$^3J_{HF}$ (Hz)	10.0	21.0
$^2J_{HF}$ (Hz)	53.7	53.5
$^3J_{HH}$ (Hz)	6.0	1.0
τ_{H_1}	4.87	4.53
τ_{H_2}	4.36	3.77
ϕ_c (p.p.m.)	173.3	162.5

1-Fluoro-acenaphthene (25)

One gram of **24** was shaken with powdered AgF (2.0 g) for 20 min in acetonitrile at room temperature. The grey precipitate and excess AgF was filtered off and water and chloroform added to the solution. The organic layer was separated, dried, and concentrated down carefully without heating. The ^1H spectrum showed a set of broad lines

For personal use only.

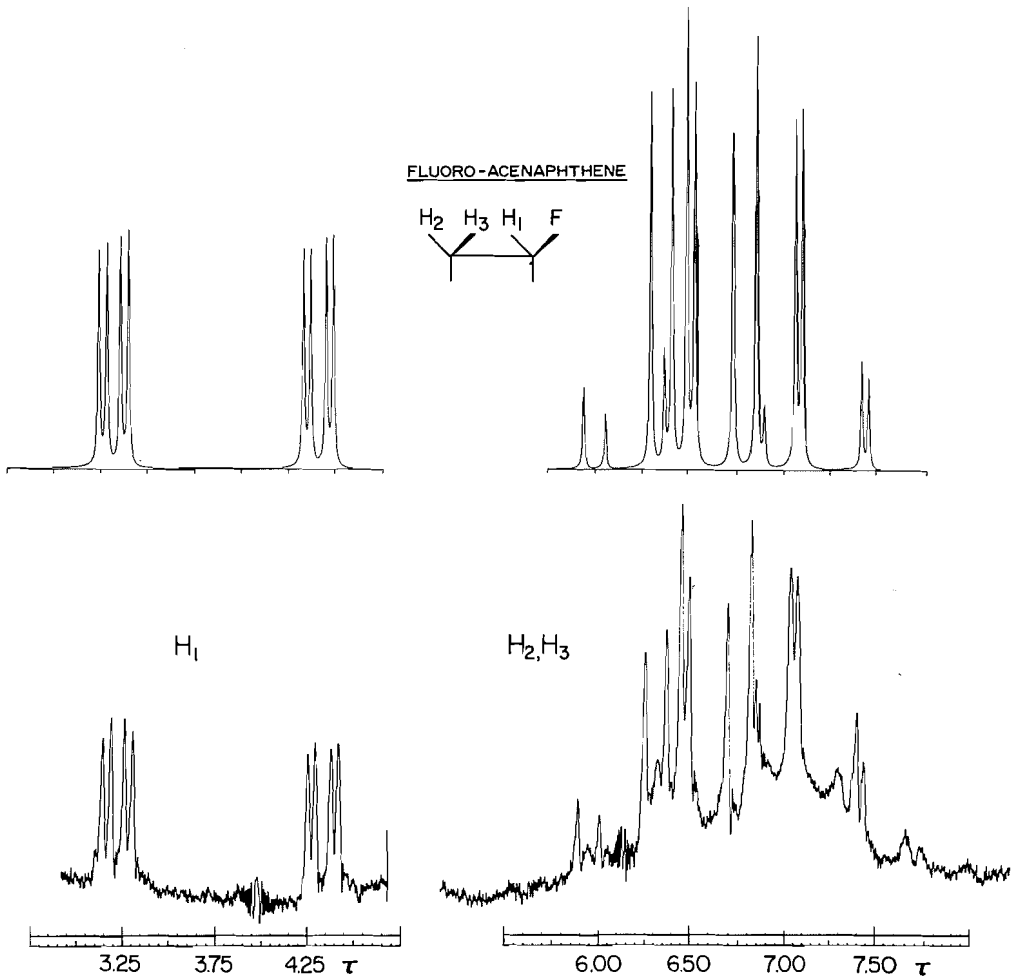

FIG. 4. Partial ^1H n.m.r. spectra of 1-fluoro-acenaphthene. The lower trace shows the spectrum measured with simultaneous irradiation of the aromatic protons. The upper trace is the computer simulation using the parameters listed in the text. The sample used could not be purified and hence contained some impurities.

in the methylene region and an octet at low field. By careful adjustment of the solvent, the complexity of the spectrum was reduced as much as possible (with 60% chloroform, 40% acetone). The lines were further sharpened by decoupling of the aromatic protons, and this double resonance (^1H) spectrum is shown in Fig. 4, bottom.

The spectrum was then analyzed by hand as an ABMX system; values from this analysis were used as the input numbers for an iterative computer analysis of the spectrum using TWOSUM. The final computer spectrum, which is shown above in Fig. 4, top, had an average deviation of only 0.028 Hz from the experimental.

Some impurity lines are visible in Fig. 4; it was found impossible to purify **25** in any way at all, since it decomposed on alumina and silica gel, and with gentle heat, weak acid or base. N.m.r. parameters: $^3J_{H_3F}$ (*cis*) 29.52 Hz, $^3J_{H_1H_2}$ (*cis*) 6.68 Hz, $^3J_{H_2F}$ (*trans*) 21.39 Hz, $^3J_{H_1H_3}$ (*trans*) 1.485 Hz, $^2J_{H_2H_3}$ (*gem*) 18.30 Hz, $^2J_{H_1F}$ (*gem*) 55.59 Hz, τ_{H_1} 3.665, τ_{H_2} 6.458, τ_{H_3} 6.661, ϕ_c 158.8 p.p.m.

Nuclear Magnetic Resonance Measurements

All n.m.r. measurements were made with a modified Varian HA-100 instrument (14) operating in the locked modes of operation, using appropriate reference substances; all proton chemical shifts are given with respect to tetramethylsilane and fluorine shifts (ϕ_c values) are with respect to fluorotrichloromethane (freon 11).

Spectra for analysis purposes were run on appropriate sweep widths, usually 100 Hz, and were fully calibrated.

Analyses of the n.m.r. spectra were often performed by long-hand methods. Computer based analyses used the programme TWOSUM, kindly provided by Dr. John Martin of the University of Alberta, Edmonton, and the

IBM 7040 computer at the University of British Columbia Computer Centre. A plotting routine SMASH was written by Mr. John Coulthard of the U.B.C. Computer Centre and was used in conjunction with a Calcomp plotter.

It is a pleasure to thank the National Research Council of Canada and Imperial Oil Ltd. for their financial support of this work.

Conformational Analysis of *trans*-1-Fluoro-2-iodocyclohexane: a Nuclear Magnetic Resonance Study[1]

L. D. HALL AND D. L. JONES

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received November 1, 1971[2]

The ^1H and ^{19}F n.m.r. spectra of the title compound and its 3,3,6,6-tetradeutero analog have been measured in a variety of solvents and over a wide range of temperatures. These measurements have been used as the basis of calculations of the thermodynamic and kinetic parameters for the chair–chair conformational equilibrium of this substance. The poor agreement between the different methods of evaluating ΔG is discussed.

Les spectres r.m.n. du proton et du fluor des composés-titres et de leurs analogues 3,3,6,6-tétradeutériés ont été mesurés dans plusieurs solvants et des températures très variés. Ces mesures ont été utilisées pour calculer les paramètres thermodynamiques et cinétiques de l'équilibre conformationel chaise–chaise de ces substances. La corrélation très faible qui existe entre les différentes méthodes d'évaluation du ΔG est discutée. [Traduit par le journal]

Can. J. Chem., **51**, 2914 (1973)

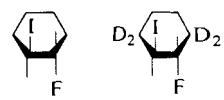
Introduction

We have been concerned for a number of years with the development of methods for synthesizing specifically fluorinated organic substances and with the evaluation of the stereospecific dependencies of ^{19}F n.m.r. parameters (2). An important stage of these continuing studies was to be an intercomparison of the effectiveness of different proton and fluorine n.m.r. parameters for studying chemical equilibria: the unsymmetrically fluorinated derivative, *trans*-1-fluoro-2-iodocyclohexane (1) which had become available as the result of work described in an accompanying paper (3) was ideally suited for this purpose.

Prior to this study Bovey and his coworkers (4) had made a detailed n.m.r. study of cyclohexyl fluoride and we shall refer to their work later in this paper. Roberts and his group (5) had extensively used fluorine as a conformational probe: their approach differs somewhat from our own insofar as they chose deliberately to retain the internal symmetry of the six-membered ring by using a CF_2 group and for this reason alone we shall make no further reference to their many excellent studies.

Results and Discussion

The derivatives chosen for this study were *trans*-1-fluoro-2-iodocyclohexane (**1**) and the corresponding 3,3,6,6-tetradeutero analog (**1**-d_4). Both substances were conveniently synthesized (3) by the stereospecific addition of the elements of "IF" (generated *in situ* from I_2 and AgF) to the corresponding cyclohexene. At room temperature, the ^1H spectrum of the IF adduct of cyclohexene (**1**) consists of two regions;



1 **1**-d_4

(*i*) 5–6 τ showing resolvable fine structure and assignable to the methine protons; and (*ii*) a high field region, of poorer resolution, which integrates to four times the area of *i*. This spectrum will not be considered further, owing to the greater simplicity of the spectrum of **1**-d_4.

Part of the ^1H n.m.r. spectrum of **1**-d_4 is shown in the lower trace of Fig. 1; the upper trace shows the same spectrum with irradiation of the deuterium nuclei. This spectrum is clearly the AB part of an ABX-system[3] and

[1]This paper forms Part IV of a series entitled, "The Conformations of Cyclic Compounds in Solution". For Part III see ref. 1. An account of this work was given at the 51st Canadian Chemical Conference of the Chemical Institute of Canada, Vancouver, British Columbia, June 3–5, 1968. Full details were published in the M.Sc. Thesis of D. L. Jones, University of British Columbia, 1970.

[2]Revision received February 23, 1973.

[3]Two small, long-range couplings are also present; their source is unknown.

For personal use only.

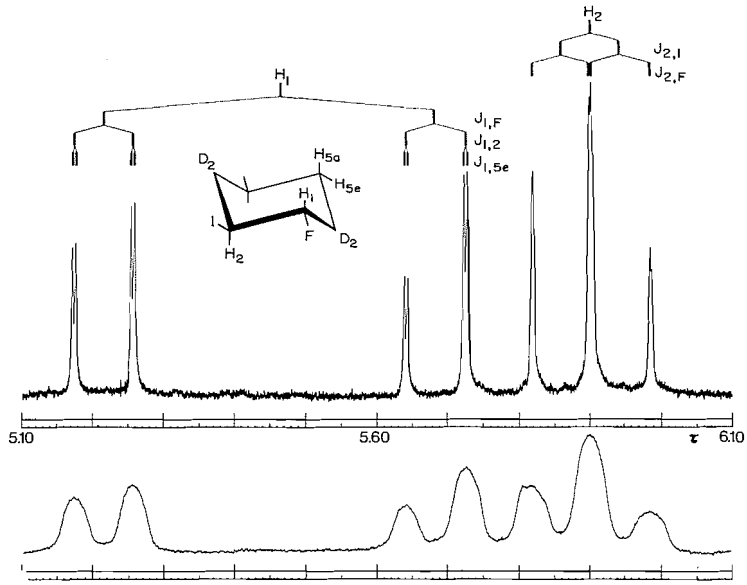

FIG. 1. Partial ^{1}H n.m.r. spectra (100 MHz) of 1-fluoro-2-iodo-cyclohexane-3,3,6,6-d_4 (**1**-d_4) in CS_2 solution at room temperature. The lower trace shows the normal resonances of the H_1 and H_2 protons. The upper trace shows the same resonances with simultaneous irradiation at the deuterium resonance frequency. The two traces were run at different gains. Note the additional long-range couplings in each of the resonances: that in H_1 is *ca.* 0.3 Hz.

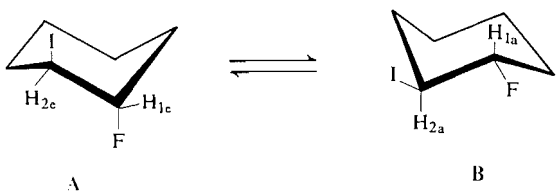
the 8 Hz coupling indicates that H_1 and H_2 are *diaxial*, and hence *trans* to one another. This identifies the primary conformation of the molecule as that having both the I and F substituents equatorially oriented, as in **B**, and also confirms the stereospecificity of the addition reaction.



A B

The room temperature ^{19}F spectra of both **1** and **1**-d_4 consist of broad doublets spacing approximately 50 Hz, corresponding to $^2J_{HF}$, and little information can be gained from them alone.

It is convenient to divide the remainder of the discussion into two separate sections. The first will deal with various evaluations of the free energy differences between the two conformers and the second with the determination of the activation parameters of the chair–chair equilibrium (**A** $\rightleftarrows$ **B**).

Evaluation of the Conformation Equilibrium

In this section we shall first describe the measurements which were made and then give a brief discussion of their significance.

(*a*) ^{1}*H Spectra*

The ^{1}H spectrum (with ^{2}H-decoupling) of **1**-d_4 in CS_2 solution at $-100°$ is shown in Fig. 2A; here the two chair conformations of the molecule (**A**, **B**) have been 'frozen out' and *two* ABX spectra are observed.

Each of these two ABX spectra were analyzed without using the X part;[4] this analysis yields the values of the various coupling constants in each conformer at $-100°$, in CS_2 solution. A calculated composite spectrum, based on this analysis is shown in Fig. 2B. Using these values, the position of the conformational equilibrium at room temperature may be calculated from

[4]It is possible to analyze an ABX spectrum purely from the AB part providing one has some prior knowledge of J_{AX} and J_{BX}. In this case, the geminal ^{1}H–^{19}F coupling, $^2J_{HF}$ (= J_{AX}), can be safely assumed to be of the same sign as $^2J_{HF}$, but considerably smaller (6).

All these partial ABX spectra were subjected to iterative computer analysis. In order to link up the energy levels, it is necessary to put in a 'false' X-transition, the frequency of which may be calculated from the AB part, with the above considerations in mind.

For personal use only.

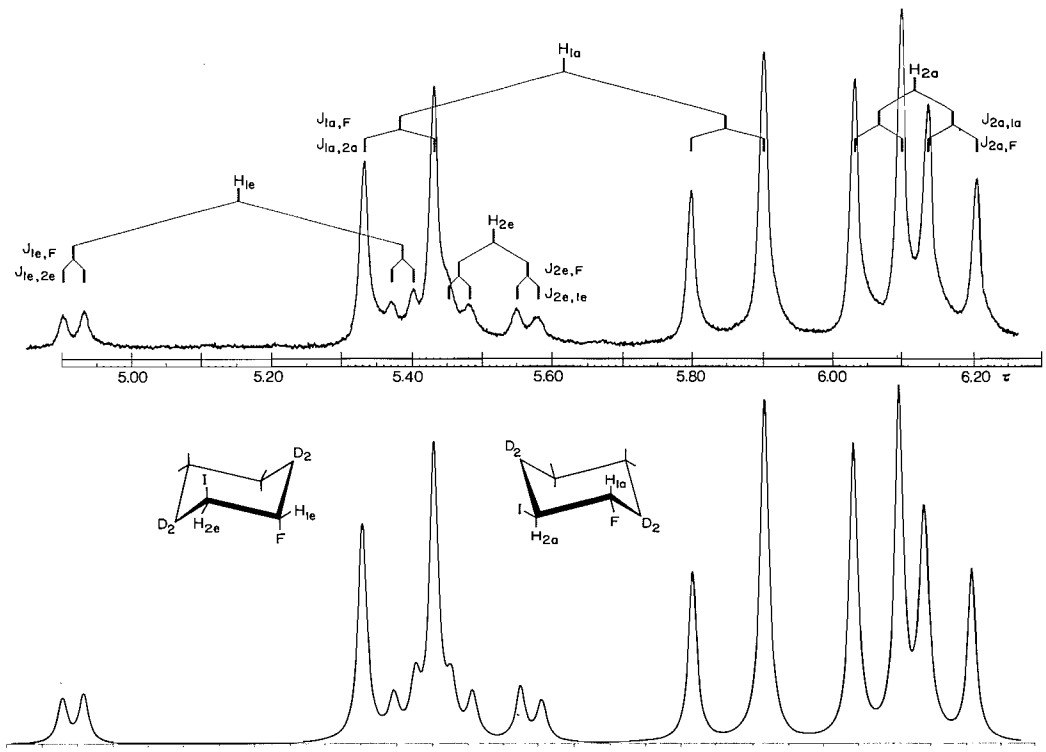

FIG. 2. Partial ^{1}H n.m.r. spectra (100 MHz) of 1-fluoro-2-iodo-cyclohexane-3,3,6,6-d_4 (**1**-d_4) in CS_2 solution at $-100°$ with deuterium decoupling. The upper trace shows the experimental spectrum and the lower a line-plot of the calculated spectrum.

the value of the coupling constants in the time-averaged spectrum (obtained at room temperature), Fig. 1.

Furthermore, the position of the equilibrium may also be determined[5] in other solvents by use of these low temperature values; the spectrum of **1**-d_4 in benzene, chloroform, acetone, and pentane were therefore obtained, and the results are summarized in Table 1. Also shown are equilibrium calculations based on the ^{1}H chemical shifts.

(b) ^{19}F Spectra

The ^{19}F spectrum of **1** in CS_2 solution at $-100°$ is shown in Fig. 3B; the expanded spectrum of the minor conformer (Fig. 3C) exhibits a second large splitting (*ca.* 43 Hz) which is conformatory evidence that the minor conformer is **A**.

Using ^{1}H-decoupling, the ^{19}F spectra of **1** was recorded in CS_2 solution at various temperatures between 0 and $-85°$. With ^{1}H couplings removed, the major contribution to the linewidth in this region is the exchange broadening. The widths and positions of various resonances from these spectra are given in Table 2A. It can be seen that at either end of the temperature scale, the peak positions are not static; since this was contrary to results already in the literature, the low temperature spectra were later retaken, but without ^{1}H-decoupling. These data are also included in Table 2A; there is a difference in the absolute value of the peak positions of the two sets of data (decoupled and normal spectra). This is because different samples were used, the original one having decomposed.

Calculation of the Free Energy Value

The experiments described above provide five different sets of parameters which were used as the basis of separate evaluations of the conformational free energy difference, ΔG^0.

[5]All of these calculations assume temperature independence of the respective parameters; this is discussed further later on.

*Parameters for diequatorial conformer **B**.
†Parameters for diaxial conformer **A**.

(a) Vicinal Coupling Constants ($^3J_{HH}$ and $^3J_{HF}$)

Using $^3J_{HH}$ from Table 1 the fraction of **1**-d_4 existing in the diaxial conformation is calculated to be 0.314; from values of $^3J_{HF}$ the fraction is 0.348. These values correspond to $\Delta G^0 =$ 0.478 and $= 0.397$ kcal/mol respectively. The difference between these numbers may represent a systematic error in the method, in particular a temperature dependence of the coupling constants, or it may just reflect the inaccuracy of experimental data; it is worth noting that an error of only 0.4 Hz in the value of $^3J_{HF}$ in either conformer would account for the difference, and the spectrum of the diaxial conformer is rather difficult to measure accurately (see Fig. 2A).

To be more specific, the first-order value of $^3J_{HF}$ taken from the low-temperature ^{19}F spectrum of **1** (Fig. 3C) is actually 11 Hz, 1.1 Hz more than the value calculated from the low temperature ^1H spectrum (Fig. 3A). Thus this inaccuracy of measurement appears to be a most likely source of error.

It is interesting at this point to consider some similar work by Anet (7) who used a specifically-deuterated cyclohexanol and its associated reference compounds (*cis*- and *trans*-4-*t*-butyl derivatives). From the various observed coupling constants, two independent calculations of the position of the equilibrium can be made; the fraction of the minor conformer is respectively calculated as 0.16 and 0.29. The reason for this discrepancy was not given; however, it seems possible that there is an appreciable *temperature dependence* of the coupling constants involved in both Anet's work and the present study.

Turning to solvents other than CS_2, the data in Table 1 indicate that for solvents which are non-polar like CS_2 (*i.e.* pentane, benzene) the agreement between $^3J_{HH}$ and $^3J_{HF}$ calculations is reasonable, whereas for the polar solvents acetone and chloroform, the agreement is quite poor. In fact, the gap between $^3J_{HH}$ and $^3J_{HF}$ calculations is too large to be attributable to experimental error (14% for chloroform) and this seems to indicate that the coupling constants are subject to a *solvent dependence* (8). There is certainly some precedent for this phenomenon; thus Stothers (9) determined the equilibria of 2-halocyclohexanones by comparison with the *cis*- and *trans*-4-*t*-butyl derivatives and used $J_{AX} + J_{BX}$ as well as chemical shifts. A variety of solvents were tried, and $J_{AX} + J_{BX}$ in the *cis* compound was found to vary from 5.7 (in cyclohexane) to 7.1 Hz (in acetonitrile).

(b) Areas

By integrating the individual peaks of the low temperature ^{19}F spectrum (*e.g.* Fig. 3B), the fraction of **1** in diaxial form was calculated as 0.153 at −90°; this corresponds to $\Delta G^0 =$ 0.625 kcal/mol.

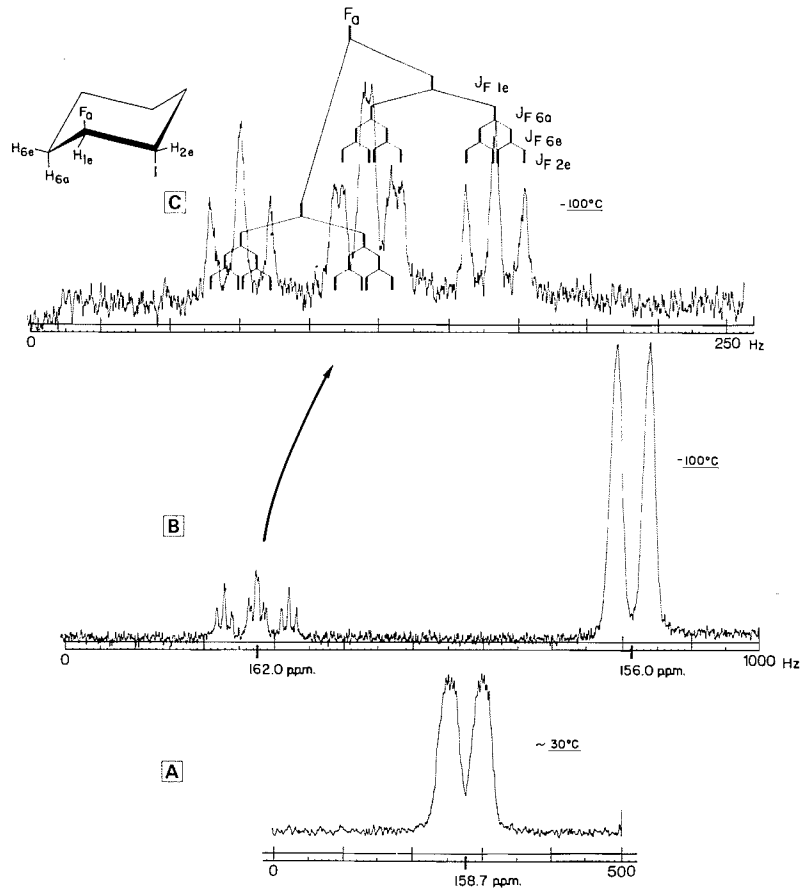

FIG. 3. ^{19}F n.m.r. spectra of 1-fluoro-2-iodo-cyclohexane (**1**) in CS_2 solution. A, shows the spectrum measured at room temperature; B, shows the spectrum measured at $-100°$, and C is an expansion of the low-field component of B. The first order assignment of this resonance, which corresponds to the axial fluorine substituent of conformer **A**, is also given. All chemical shifts are with respect to internal $CFCl_3$.

The areas of the equatorial and axial ^{19}F peaks were also measured under conditions of ^1H-decoupling. The intensities of both peaks were increased by about a factor of two, but the ratio stayed approximately constant (fraction diaxial = 0.150, Table 2B). Thus there appears to be a general (and favorable) *Overhauser effect* with ^1H-decoupling, but in this case it is not stereospecific.

(c) ^{19}F Chemical Shifts

The ^{19}F peak positions of **1** listed in Table 2A show that from $-65°$ to $-95°$ there is a fairly regular decrease[6] of 0.9 Hz per degree and from 0 to $-30°$ there is an average decrease of 1.2 Hz per degree. In the next section it will be shown that, from exchange considerations alone, the peak position is essentially invariant of temperature, approximately 20° on either side of the coalescence point; in this case the coalescence point can readily be seen to be approximately $-45°$. These calculations of when the peak positions are independent of temperature are not in accord with the statement in ref. 4: "Approximate calculations of the ^{19}F peak shift *versus* temperature ... showed that at temperatures of about 15–20° and above, the shift has become independent of the rate of conformational change ...." The input parameters for their calculation are of course different from the present one, but it can be shown that this does not significantly alter the conclusion. Examination of Table II in ref. 4

[6]This refers to the major, diequatorial, conformer.

183	85.0	15.0	84.7	15.3

*Two different samples were used, one for the data on the left hand side of Table 2A (*i.e.* ^1H-decoupled spectra) and the data in Table 2B, and the other for the data on the right-hand side of Table 2A (simple spectra). The first was approximately 20% in CS_2 solution (by volume), but the second one was more dilute, to permit more lengthy low-temperature measurements.
Peak positions are in Hz upfield of $CFCl_3$ resonance (internal).

shows the same kind of behavior as that described here, *i.e.* the peak positions continue to move to low field far away from the coalescence point. Evidently, either the individual chemical shifts of the two conformers are temperature dependent, or else the chemical shift of $CFCl_3$ is temperature dependent, or both.

The larger temperature dependence above the coalescence point is expected because the peak position now depends on the value of K, the equilibrium constant, which in turn depends on the temperature, ΔG^0 being constant. Thus supposing a ΔG^0 value of 0.625 kcal/mol[7] one may calculate the rate at which K is changing the temperature: at 273 °K, % (diaxial) = 24.1 and at 263 °K, % (diaxial) = 23.3.

If the chemical shift between conformers is 515 Hz (obtained by extrapolating low temperature data), then the time-averaged positions at 273 and 263 °K are 124.2 and 120.1 Hz respectively. Thus the peak position increases at a rate 0.4 Hz/°K in this temperature region, given the above assumptions.

Using the data in Table 2 to estimate the position of equilibrium requires a quantitative value for the temperature dependence of each conformer. For the diaxial conformer this quantity is not so well defined, because it is slower to recover from the exchange effects (hence the necessity for the extra data in Table 2). However, it does appear that the temperature dependence of the diaxial conformer is less than that of the diequatorial; from Table 2, value of 0.7 and 0.9 Hz/°K can be taken.

Extrapolating the peak positions of each conformer at −85 to 0° by these amounts then, the

[7]Fortunately this value is not critical.

For personal use only.

averaged peak position at 0° is 116 Hz from the diequatorial resonance and 400 Hz from the diaxial. This leads to values of 22.5% diaxial and $\Delta G^0 = 0.672$ kcal/mol (at 0°). Now combining this value for % diaxial along with temperature dependence of the individual conformers (0.9 and 0.7 Hz/°K), and the temperature dependence of K itself (0.4 Hz/°K, above) we may calculate the net change in the averaged peak position = ((0.775)0.9 + (0.225)0.7 + 0.4) = 1.25 Hz/°K; the observed increase with temperature is 1.2 Hz/°K, which is reasonable agreement.

(d) ^1H Chemical Shifts

Using the chemical shifts of H_1 and H_2 derived from the low temperature (−100°) spectra of **1**-d_4 yields values of 23.2 and 29.2% diaxial respectively at ambient temperature (*ca.* 35°). This corresponds to ΔG^0 values of 0.544 and 0.735 kcal/mol respectively (at 35°). Variable temperature ^1H spectra were not run, so no correction for temperature dependence of the chemical shifts could be made, as was done for the ^{19}F spectra; this undoubtedly introduces significant errors (10), and could well account for most of the difference in values from H_1 and H_2.

(e) ^{19}F Linewidths

Using the general lineshape expression of Gutowsky and Holm (11) a set of theoretical spectra may be generated, in which the residence time τ, and the equilibrium constant K may be varied. For any given value of K, there is a unique value of τ which gives rise to the largest linewidth; this is the coalescence point for that value of K. Thus the linewidth at the coalescence point is a function of K, and from the experimental linewidth, a value of K may be deduced.

The ^{19}F spectra of **1**, with ^1H-decoupling, were treated in this way and the maximum experimental linewidth was 114 Hz (at 228 °K, see Table 2); from the calculated spectra (*vide infra*), this implies that $K = 4.26$, which corresponds to $\Delta G^0 = 0.659$ kcal/mol.

A criticism of this method of deducing K might be that, in fact, the maximum may not be obtained, since the spectra were recorded at intervals of 5 °K, and the linewidth is a rapidly varying function of temperature. However, this criticism may be countered as follows: with a typical kinetic barrier to inversion (say 10 kcal/mol) a temperature increase of 5 °K decreases the residence time τ, by a factor of approximately 1.7 (see next part on rate calculations). Near coalescence, the linewidth is a more slowly varying function of temperature and a factor of 1.7 in τ is not enough to allow a significantly larger linewidth to come between 89 and 114 Hz (at 233 and 228 °K). This can be seen from the tables of calculated linewidths.

In the above discussions the value of ΔG^0 has been calculated in four different ways, and different values obtained. It seems sensible to adopt as the "best" values those derived from the methods having the fewest assumptions. On this basis, the coupling constant results and the ^1H chemical shift calculations must be classed as less reliable than the ^{19}F shift calculations, since no temperature dependence was accounted for. The preferred values are therefore: (20% solution in CS_2 solution). $\Delta G^0 = 0.625$ kcal/mol (−90°), areas of ^{19}F resonance; $\Delta G^0 = 0.672$ kcal/mol (0°), extrapolated ^{19}F shifts; $\Delta G^0 = 0.659$ kcal/mol (−45°), linewidth of ^{19}F resonance. The other values are: $\Delta G^0 = 0.397$ kcal/mol (35°) $^3J_{HF}$; $\Delta G^0 = 0.478$ kcal/mol (35°), $^3J_{HH}$; $\Delta G^0 = 0.735$ kcal/mol (35°), chemical shift of H_1; $\Delta G^0 = 0.544$ kcal/mol (35°), chemical shift of H_2.

Taking the three 'preferred' values together, it appears that ΔG^0 is nearly independent of temperature, if we state reasonable experimental limits, say ±0.025 kcal/mol. This implies a zero or significantly small entropy ($\Delta S^0 = -0.5$ e.u or lower).

Bovey *et al.* (4), examing cyclohexyl fluoride, arrived at ΔG^0 values of 0.242 (at 218 °K, from ^{19}F area measurements) and 0.153 kcal/mol (at 302 °K, from ^{19}F chemical shifts). This implies a positive entropy, $\Delta S^0 = 1.05$ e.u. However, there was no allowance made in that work for temperature dependence of ^{19}F chemical shifts, and it can be seen from the published data (Table II, ref. 4) that both the averaged resonance at high temperatures, and the equatorial resonance at low temperatures are strongly dependent on temperature; however, the axial resonance appears to be temperature independent. A quantitative estimate is hard to make because of the comparatively large amount of scatter in the points, but the equatorial resonance data is fitted quite well by 0.0095 p.p.m./°K (*i.e.* same as above for (1)). If a zero temperature dependence is assumed for the axial resonance, one can calculate that the ΔG^0 value is now 0.231

TABLE 3. Repulsion between substituents in the diequatorial form of some 1,2-dihalo-cyclohexanes*

Substituent(s)	*A* value† (kcal/mol)	Reference	Sum of *A* values† of substituents (kcal/mol)	Repulsion between halogens (kcal/mol)
F	0.276	10		
Cl	0.528	10		
Br	0.476	10		
I	0.468	10		
IF	0.650	This work	0.744	0.1
ICl	−0.250	12	0.996	1.2
Cl–Cl	0.200	13	1.056	0.8
Br–Br	−0.300	13	0.952	1.2
I–I	−1.000	14	0.936	1.9

*Measurements were all taken in CS_2 solution except for the last compound (di-iodide), for which benzene was used. This may be expected to make a significant difference to the *A* value of the di-iodide (see Table 1), and lower the calculated repulsion from 1.9 kcal/mol to approximately 1.6–1.7 kcal/mol.
†Free energy difference between the substituent(s) in the equatorial and axial orientation(s).

kcal/mol at 302 °K which is very close to the low temperature value given by Bovey. This would imply that ΔS^0 for this system is also close to zero. For **1**, the results are: (20% in CS_2) $\Delta G^0 = 0.650 \pm 0.025$ kcal/mol (183–273 °K); $\Delta H^0 = \Delta G^0$; $\Delta S = 0 \pm 0.5$ e.u.

This value of ΔG^0 is close to the sum of (0.744 kcal/mol) of the individual ΔG^0 values reported for iodine and fluorine in the literature (10). This sum is expected to be somewhat higher than the observed ΔG^0 for "cyclohexane IF", since the repulsions between the halogen atoms (in the diequatorial conformer) would be expected to reduce the latter value. The rather small reduction, 0.1 kcal/mol indicates, however, that this repulsion is quite small. This is in contrast to the case of "cyclohexane ICl" (12), in which the *diaxial* form predominates and $\Delta G^0 = 0.24$ kcal/mol. The sum of the *A* values for 'I' and 'Cl' in the diequatorial form must be contributing approximately 1.2 kcal/mol, or 12 times that between 'I' and 'F'. The repulsion between two bromine atoms or between two chlorine atoms can be similarly calculated, and both are found to be large (Table 3).

Rate Calculations

The activation free energy ΔF^f, enthalpy ΔH^f and entropy ΔS^f, associated with the chair-to-chair inversion of a cyclohexane derivative may readily be determined from a plot of rate, *k*, *vs.* inverse temperature, $1/T$ (4).

Using the Gutowsky–Holm equation (11) a computer programme GUTHO was written which calculates the width, height, and position of all resonances in a one-spin system undergoing chemical exchange. Input data required are the fractional population difference *PD*, the chemical shifts of both resonances in the slow exchange limit *SA* and *SB*, and the residence time *T*. This programme was then applied to the ^{19}F spectra of **1**, in which ^1H couplings had been removed by irradiation. *SA* and *SB* were fixed and then *PD* and *T* were varied in integral steps. Since, in our case, $(SA - SB)$ only varies about 4% (from 188 to 273 °K), this is not a bad approximation. However, *PD* varies considerably due to the temperature dependence of the equilibrium constant, throughout the range of experimental spectra.

Using the value $\Delta G^0 = 0.650$ kcal/mol, values of *PD* were calculated for each of the experimental spectra, and then the residence time *T* ($= \tau$) picked which most closely fitted the experimental peak width (4). The data are shown in Table 4. The plot of ln τ *vs.* $10^3/T$ is shown in Fig. 4, and has a slope which corresponds to an activation energy of 10.72 kcal/mol.

From this plot ΔF^f, ΔH^f, and ΔS^f may be calculated. However, these calculations contain the inherent assumption that the chair-to-chair inversion involves only one barrier; it has been pointed out (15), that in the event of there being *two* barriers to the process then the observed rate constant *k* is actually equal to one-half of the actual rate constant for passing over each barrier. For a cyclohexane derivative, it seems likely that a boat form is an intermediate in the process, and k_{cb}, the rate constant for the chair-to-boat process is equal to twice the observed rate constant. Hence the activation parameters for the chair-to-boat equilibrium are as follows:

198	5.05	0.677	5.6	1.2×10^{-2}

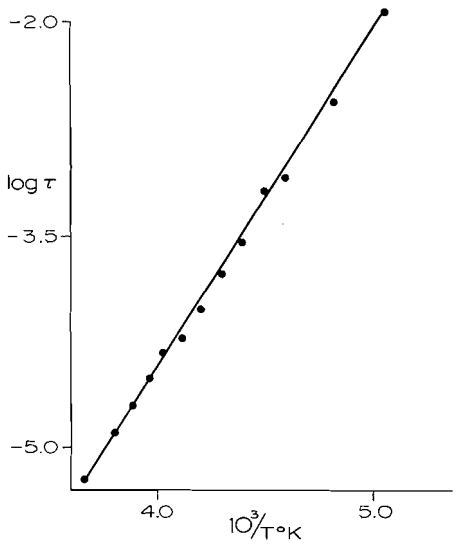

FIG. 4. Arrhenius plot for the conformational inversion of **1**.

At 216.5 °K (−56.5°): $\Delta F_{cb}^{f} = 9.65$ kcal/mol, $\Delta H^{f} = 10.27$ kcal/mol, $\Delta S_{cb}^{f} = 3.0$ e.u. At 266 °K (−7°): $\Delta F_{cb}^{f} = 9.45$ kcal/mol; $\Delta H^{f} = 9.99$ kcal/mol; $\Delta S^{f} = 2.0$ e.u.

Bovey *et al.* (4) have pointed out that activation parameters such as these are actually composite values of the forward and backward reactions, and they have given a set of equations to find the individual parameters. Using these parameters we obtain then the activation parameters for the chair–chair inversion process of **1** in CS_2 solution; these data are summarized in Table 5.

TABLE 5. Activation parameters for **1** in CS_2 solution

Parameter	Temperature (°K) 216.5	266
ΔF_{ca}^{f}(cb) (kcal/mol)	10.38	10.23
ΔF_{ac}^{f}(cb) (kcal/mol)	9.74	9.59
ΔH_{ca}^{f} (kcal/mol)	10.83	10.49
ΔH_{ac}^{f} (kcal/mol)	10.17	9.84
ΔS_{ca}^{f}(cb) (e.u.)	2.1	0.9
ΔS_{ca}^{f}(cb) (e.u.)	2.1	0.9

The most reliable work on the conformational inversion of cyclohexane systems appears to be that of Anet and Bourn (15), who studied cyclohexane-d_{11}. Their values for ΔF_{cb}, ΔH, and ΔS_{cb} are respectively 10.22 kcal/mol, 10.8 kcal/mol, and 2.8 e.u. (all at −67°). The comparable values in this study are (for diequatorial chair-to-boat process, since this has the lowest ground state) 10.38 kcal/mol, 10.83 kcal/mol, and 2.1 e.u. This is remarkably close agreement.

The small positive value of ΔS_{eq}^{f}(cb) is, as has been pointed out, (4, 15) exactly as expected, on the basis of symmetry grounds, *e.g.* for cyclohexane, there are six possible paths for reaching a cyclohexene-like transition state (16), and thus $\Delta S_{cb}^{f} = R \ln 6 = 3.6$ e.u. (neglecting vibrational and rotational entropy contributions).

Summary

The most interesting part of the above results appear not to be the final values obtained, but the appraisal of the various methods. Thus we conclude that the chemical shifts and vicinal coupling constants are *all* temperature dependent, those involving ^{19}F being particularly susceptible; there is no reason to suppose that this is a unique case, and instead it is likely that these phenomena are general.

It can be calculated that in order to bring the ΔG^0 values obtained from coupling constants into line with the above value, temperature coefficients of $+3 \times 10^{-3}$ Hz/°K (for $^3J_{HF}$) and -3×10^{-3} Hz/°K (for $^3J_{HH}$) are required. A recent review by Laszlo (17) presents some other evidence of temperature dependence of various coupling constants.

ΔG^0, calculated from the chemical shift of H_1 is 'high', whereas that from H_2 is 'low'; however, a shift of only 2.5 Hz in ν_{H_2}, of 1 Hz in ν_{H_1}, would account for the difference. Jensen and co-workers (10) have shown that this phenomenon is in fact general. Bovey *et al.* (4) noted that the conformer ratio of cyclohexyl fluoride as determined by ^1H chemical shifts differed from the value obtained from area measurements. This discrepancy is now explained.

Error limits on activation parameters have in most investigations apparently been determined by the authors' estimate of the accuracy of the measurement, rather than their evaluation of the validity of the method. This can be seen by considering the disagreement between workers using different methods. Anet and Bourn (15), in a refreshing departure, have taken the opposite view, *i.e.* systemmatic error is not so small as to allow the random error to become dominant, and this appears to be far more logical. Thus subjective estimates for errors in ΔH^f and ΔF_{cb}^f might be ± 0.2 kcal/mol, and ± 1.0 e.u. for ΔS_{cb}^f.

Experimental

*trans-1-Fluoro-2-iodo-cyclohexane-3,3,6,6-d_4 (**1**-d_4)*

The reaction described previously for cyclohexene (*3a*, *d*) was repeated on 3,3,6,6-tetradeutero-cyclohexene[8] on a somewhat smaller scale (0.25 g of deuterated material). To avoid possible decomposition on heating the product was not purified by distillation; the ^1H and ^{19}F n.m.r. spectra showed no detectable impurities.

All n.m.r. measurements were made with an extensively modified Varian HA-100 spectrometer operating in the locked, frequency-swept mode of operation. The equipment used for the heteronuclear decoupling experiments has since been described elsewhere (18).

Spectral analyses were performed using a slightly modified version of the programme TWOSUM,[9] and a plot-routine, SMASH, using an I.B.M. 7040 computer at the University of British Columbia Computing Centre.

The analysis of the chemical exchange spectra of **1** was carried out empirically; based on the Gutowsky–Holm equation (11) a simple programme GUTHO was written which calculated all the peak heights, widths, and positions for a two-site exchange, with certain parameters fixed. First the chemical shifts of each resonance were determined (from low temperature work) and the population ratio of the conformers calculated (from area measurements, etc.). Then the peak positions, etc. were calculated by Gutho for a given residence time, τ; τ was varied over a range of 10^6 and the calculated spectrum which most closely matched the experimental could then easily be selected. Thus a τ value was readily obtained for each experimental spectra, and allowed the calculation of activation parameters. This method, while not as rigorous as the line-fitting approach, has the important advantage of speed; the loss of accuracy is believed to be small, if at all, on the basis of the excellent Arrhenius plot obtained. Anet and Bourn (15), in a study of cyclohexane-d_{11}, came to the same conclusion.

It is a pleasure to thank the National Research Council of Canada for their generous financial assistance. This study was also supported by a grant from Imperial Oil Ltd.

Observations on the Electronegativity Dependence of Vicinal ^{19}F–^{1}H Coupling Constants

L. D. HALL AND D. L. JONES

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received November 1, 1971[1]

The *vicinal* ^{19}F–^{1}H couplings of 16 1,2-disubstituted derivatives of acenaphthene are reported. A plot of these couplings against substituent electronegativity shows a better agreement with an *exponential* relationship than with a conventional *linear* relationship.

Les constantes de couplage vicinal ^{19}F–^{1}H de 16 dérivés disubstitués-1,2 de l'acénaphtène sont rapportées. Une courbe reliant ces constantes avec l'électronégativité des substituants montre une meilleure relation si une fonction *exponentielle* est utilisée plutôt qu'une fonction *linéaire*.

[Traduit par le journal]

Can. J. Chem., **51**, 2925 (1973)

Introduction

It is well known that *vicinal* (^{3}J) ^{1}H–^{1}H couplings have a marked dependence on the dihedral angle separating the two C—H bonds (1) and also on the electronegativity (2) of nearby substituents: this latter variation also has a configurational dependence (3). Although *vicinal* ^{19}F–^{1}H couplings have received less attention it is clear that they also show all three of these dependencies (2*e*, 4). A fundamental assumption of all these studies of variations of coupling constants as a function of substituent electronegativity has been that a *linear* relationship should exist. In the present paper we shall question the validity of this tenet and shall demonstrate that for dihedral angles of *ca.* 0 and *ca.* 100° the relationship is non-linear, and *may* be exponential.

Any *experimental* evaluation of the effect of electronegativity changes on coupling constants requires a range of derivatives having essentially the same geometry but with substituents of differing electronegativity. The acenaphthene system was chosen as fulfilling this geometric requirement and fortunately it possessed the requisite chemical reactivity whereby a variety of halogen substituents could be introduced (5).

Results and Discussion

The syntheses of the specifically fluorinated derivatives **1**–**16** of the acenaphthene system were given in an accompanying paper (5), as also were full details of the analysis of their n.m.r. spectra: these were generally straightforward, and gave the data listed in Table 1. Included in that Table is the sum of the substituent electronegativities; Huggins' values (6) were used.

In assembling the data of Table 1 it has been assumed that an orientation effect of the type previously postulated (4*d*, *g*) for 60° dihedral angles is either very small or non-existent. That this assumption is reasonable is shown as follows: in compounds **3** and **2** (*trans-* and *gem*-acenaphthene BrF) $^{3}J_{HF}$ (0°) is 21.5 and 23.0 Hz respectively. In **4** (*gem*-acenaphthene ClF) the sum of the two couplings is 32.8, whereas in the *trans-* and *cis*-ClF compounds **6** and **5** the couplings are 21.0 and 10.0 respectively, a sum of 31.0. Similarly, in **11** (*gem*-difluoro-acenaphthene) the sum of the two couplings is 26.4, and from the individual *trans-* and *cis*-difluorides (**12**, **13**) the couplings are 18.8 and 5.2 respectively, a sum of 24.0.

Inspection of the data shown in Table 1 indicates that there is a monotonic relationship between the total electronegativity and the ^{19}F–^{1}H coupling: as the electronegativity increases so the coupling decreases.

All previous investigations of the relationship between electronegativity and coupling constants have concluded that it was a linear relationship.[2] This may seem logical at first sight, since a

[1]Revision received February 23, 1973

[2]A referee kindly drew our attention to a publication by Schaefer and Sutton (11) that had previously documented a non-linear electronegativity dependence for the ^{2}J and ^{3}J proton–proton couplings of a series of substituted ethylenes.

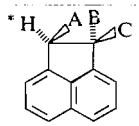
TABLE 1. Vicinal coupling constants for 1,2-substituted, fluoro-halo derivatives of acenaphthene

Derivative	Substituents* A	B	C	Sum of substituent electronegativities†	Coupling constant J_{cis}	J_{trans}
1	H	H	F	4.4	29.5	21.4
2	H	Br	F	5.15	23.0	10.0
3	Br	F	H	5.15	21.5	—
4	H	Cl	F	5.25	(Sum = 32.8)	
5	Cl	H	F	5.35	—	10.0
6	Cl	F	H	5.35	21.0	—
7	I	Cl	F	5.80	—	6.0
8	I	F	Cl	5.80	19.7	—
9	Br	Br	F	5.90	—	3.1
10	Br	F	Br	5.90	18.9	—
11	H	F	F	6.10	(Sum = 26.4)	
12	F	F	H	6.10	18.8	—
13	F	H	F	6.10	—	5.2
14	I	F	F	6.55	16.0	4.8
15	Br	F	F	6.85	15.3	3.7
16	F	F	F	7.80	12.8	1.2



†Huggins values (6) for the two additional substituents; *i.e.* not including one H and one F substituent.

strongly electronegative substituent, X, should 'pull' the electron density out of the neighboring bonds and thus decrease the coupling constants which are transmitted along them. This effect may reasonably be supposed to be proportional to the 'electronegative strength' of X. However, there is a basic fault with this reasoning, for it supposes that the source of electron density in the neighboring bonds is *infinite* and has no 'electronegative strength' of its own.

If one substituent X with electronegativity ε reduces the coupling constant J from J_0 to $(J_0 - Y)$, then a second (similar) substituent would not have the same effect (*i.e.* reduce J to $(J_0 - 2Y)$ as in the linear case), but rather it should reduce J *by the same fraction*, *i.e.* from $(J_0 - Y)$ to $(J_0 - Y)/J_0 \cdot (J_0 - Y)$. To put it another way, the rate of decrease with electronegativity is proportional to the remaining electron density and thus, coupling constant:

$$dJ/d\varepsilon = -kJ$$

or

$$dJ/J = kd\varepsilon$$

Hence:

$$lnJ = -k\varepsilon + \text{constant}$$

$$J = ae^{-k\varepsilon}$$

where 'a' is some constant.

Thus a negative exponential decay of coupling constant with electronegativity is a more logical relationship to expect than a linear one.[3] The data from Table 1 was fitted by a computer programme[4] to both exponential and linear relationships, and the results are shown in Table 2. It can be seen that the exponential fit is decidedly better especially for $J(trans)$ and a graph of the data is shown in Fig. 1. From this graph it is evident that the most important point is the size of $^3J_{HF}$ (*trans*) for the compound with the least electronegative substituents, *i.e.* acenaphthene fluoride itself (**1**). To further support this result the corresponding 1-fluoro-indan was synthesized.

The extremely complex ^{1}H n.m.r. spectrum of this compound (an ABCDMX with long range couplings) is not amenable to analysis within the lifetime of even a graduate student, but the ^{19}F spectrum is composed of two broad overlapping triplets, the bandwidth of which is the sum of the vicinal couplings into fluorine, *ca.*

[3]In both cases, coupling constants are assumed to be directly related to electron density.

[4]LQF, a library programme of the University of British Columbia Computing Centre, utilizes a least squares procedure.

TABLE 2. Vicinal ^{19}F–^{1}H coupling constant dependence on electronegativity; a comparison of exponential and linear fits to the data

	Exponential fit	Deviation*	Linear fit	Deviation*
$^3J_{HF}(cis)$	$J = 87.75e - 0.2522$	0.87	$J = -4.52 + 46.37$	1.32
$^3J_{HF}(trans)$	$J = 985.68e - 0.8749$	1.18	$J = -5.15 + 38.13$	3.35

*Deviation is the root mean square of the differences between calculated and experimental points.

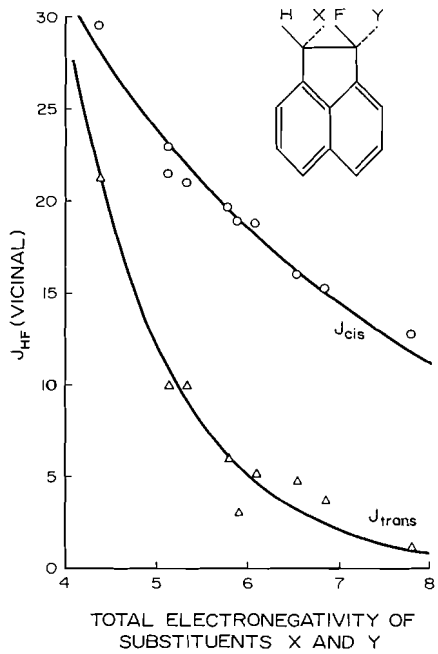

FIG. 1. Plot showing variation of vicinal ^{19}F–^{1}H couplings *vs.* total substituent electronegativity for 1,2-disubstituted-1-fluoro-acenaphthenes.

55 Hz. The largest $^3J_{HF}$ (*cis*) that may be expected is about 30 Hz, even if the five-membered ring is planar (4*f*), thus leaving a value of about 25 Hz for $^3J_{HF}$ (*trans*); this certainly supports the value obtained from acenaphthyl fluoride.

The reasons for the linear plots arrived at experimentally by previous workers can now be seen:

(*a*) The dependence of $^3J_{HH}$ on electronegativity is much less than for $^3J_{HF}$, thus leading to a shallower curve which is quite easily approximated by a straight line. A recalculation of some original data published for $^3J_{HH}$ couplings (2*h*, *i*) shows that they too give a slightly better fit for an exponential rather than a linear relationship.

(*b*) The ranges of electronegativity considered previously were not very wide, again leading to an effectively shallower curve.

(*c*) The $^3J_{HF}$ values considered previously had dihedral angles of 60 and 180°, which may well have less of an electronegativity dependence than at 100°, where it is really evident that a linear relationship is inadequate.

Since $^3J_{HF}$ couplings have such a large dependence on electronegativity, a general Karplus-type curve which is usually drawn, showing dihedral angle dependence, is not practical. However, one can plot several curves, each for a given electronegativity, and thus describe the three dimensional surface. In Table 3 there is listed a set of data collected from various references and this work; it can be seen that there are still some gaps to be filled but enough data are available for it to be useful, *i.e.* one should be able to make reasonable deductions concerning structure in most cases.

It is appropriate to comment here that the whole concept of substituent electronegativity, as applied to any molecule consisting of more than two atoms, is a nebulous one, and is essentially unsuitable for any incisive quantitation. With this in mind it is really questionable how far one can pursue the concept of electronegativity dependence of spin coupling constants: nevertheless, if one is to attempt to evaluate any such dependence it seems mandatory to recognize that it will be intrinsically non-linear, even if the experimental data *appear* to support a linear dependence.

Experimental

The syntheses of the compounds studied have been given elsewhere (5) together with details of the analyses of their n.m.r. spectra; the reader is referred to that paper for further details; all assignments and analyses were quite straightforward. Figures showing the spectra of some derivatives were included.

It was decided to determine the relative signs of a *cis*- and *trans*-pair of *vicinal* ^{19}F–^{1}H couplings. This was performed by the double resonance experiments described below, which were themselves confirmed by the use of a

computer programme[5] which simulates the *approximate* effect of such an experiment.

A plotting routine, SMASH, for n.m.r. spectra was written by John Coulthard of the University of British Columbia Computing Centre; it enabled the binary output of LAØCØØN, TWOSUM, or NMDRS to be matched directly with experimental spectra. This was particularly useful with NMDRS where the linewidths within a given spectrum are not constant.

The ^{19}F spectrum of 1-bromo-2,2-difluoroacenaphthene (**15**) is shown in Fig. 2 and is basically an ABX spectrum, with each fluorine further coupled to two of the ring hydrogens, yielding a triplet for each AB resonance (Fig. 3A, B). Irradiation of one triplet in the weak

[5]The original listing of the programme NMDRS (7) was obtained from the National Physical Laboratory, Teddington, U.K.; this programme was in ALGOL, and the necessary translation to FORTRAN was kindly carried out by Susan Boyd of the University of British Columbia Computing Centre.

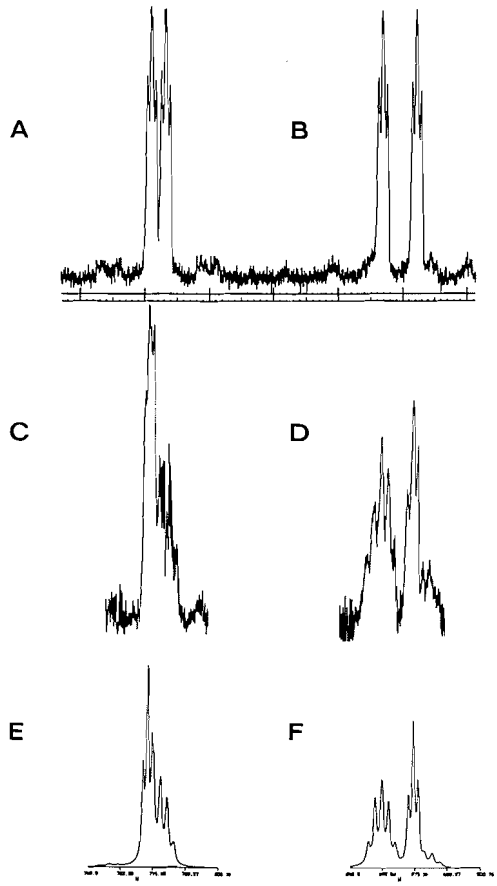

FIG. 3. Partial ^{19}F n.m.r. spectra of 2-bromo-1,1-difluoro-acenaphthene (**15**). The peaks shown in A and B are the normal resonances of the center components of the fluorine "quartet", A being the high field transitions of F_1 and B being the low field transitions of F_2 (see Fig. 2). The spectra shown in C and D are the same components measured in the presence of a second radiofrequency field; in C this has been centered on the highest field transitions of the fluorine "quartet" whereas for D it was centered on the lowest field transitions. The spectra given in E and F are the calculated spectra corresponding to C and D respectively.

resonance of F_2 affects the connected triplet in the strong resonance of F_1; had there been no extra 'tripletting' (*i.e.* if it had been a simple ABX, instead of ABM_2X), this 'spin tickling' would cause the two connected resonances to split into two new resonances, whose splitting equals the strength of the irradiating field (8).

However, the extra coupling into F_1 and F_2 causes the transfer of half the splitting of the irradiated resonance (F_2) to F_1; this new splitting, $\frac{1}{2}J_{MF_2}$, is added or subtracted from J_{MF_1} depending on how the resonances are connected (regressively or progressively) (9). The results of two such experiments are shown in Fig. 3C, D. It can be seen that in one case the triplet splitting has increased (from 1.7 to 2.5 Hz) and in the other it has decreased.

Shown below are the spectra calculated by NMDRS; the agreement is very satisfactory. These experiments confirm that the two *vicinal* ^{19}F–^{1}H couplings have the same *relative* signs; presumably both are *absolutely* positive (10).

It is a pleasure to thank the National Research Council of Canada and Imperial Oil Ltd. for their financial support of this work.

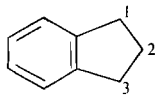
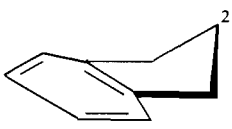
Introduction

Nuclear magnetic resonance spectroscopy has proven to be a powerful tool for studying configurational and conformational problems associated with six-membered ring systems: to a large degree, this success is associated with well-defined stereospecificities of *vicinal* ^1H–^1H (2) and ^{19}F–^1H (3) coupling constants for the ranges of dihedral angles found for chair conformations. Unfortunately the *vicinal* couplings of saturated five-membered rings do not fall into separate, well defined categories and as a result it is often difficult to use them to assign a configuration, let alone a conformation. Various subterfuges can be adopted whereby "selection-rules" may be used as the basis for more objective evaluations, but these are empirical as, for example in the CYCLOPS treatment (4), and may have their own particular limitations.

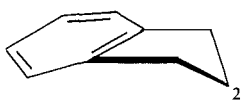
The conformational problems associated with the indan (**1**) system are simpler than those commonly encountered in saturated five-membered rings since the ring either exists in the envelope conformation having C-2 above (the ^2V-conformation in **A**) or below (as in the V_2-conformation in **B**) the plane defined by the rest of the ring.



1



A



B

The indane system has previously been the subject of several ^1H n.m.r. studies. Buys and Havinga (5) considered *trans*-1,2-dichloro-, *trans*-1,2-dibromo-, and *trans*-2-bromo-1-chloro-indan; combining dipole moment data with ^1H n.m.r. spectra they were able to arrive at the constant J_0 in the Karplus equation. To do this they needed to assume (*a*) that the pucker of the ring for all three molecules was 25° (in both conformations); (*b*) that the different molecules would have the same coupling constant in each conformer (*i.e.* the increased electronegativity of chlorine over bromine would have negligible effect); (*c*) that the Karplus equation could be strictly applied; and (*d*) some parameters for relating dipole moments and coupling constants (*e.g.* the partial moment along the C—X bond, the valency angle C—C—X, and others). From the observed *vicinal* ^1H–^1H couplings and the calculated value of J_0, the position of the conformational equilibrium could be calculated; the mole fraction of diaxial conformer increased from 0.67 in the dichloride to >0.95 in the dibromide.

In the second work, Austin and Lillya (6) measured the ^1H n.m.r. spectra of 22 1,2-disubstituted indans (both *cis* and *trans*) and extracted the three vicinal ^1H–^1H couplings from each. They assumed that these couplings were subject to a *linear* attenuation due to the electronegativity of the substituents which they allowed for by using reference data from the literature (7);

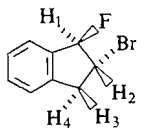
their own data show that this particular procedure was incorrect. No conclusions were drawn regarding the degree of pucker of the five-membered ring.

The synthesis (8) of *trans*-2-bromo-1-fluoroindan (**2**) provided an ideal model compound for a conformational study. With the known (9) dependence of $^3J_{HF}$ upon electronegativity and dihedral angle the degree of pucker was determined with fair accuracy. Values of $^3J_{HH}$ were then used to estimate the position of the conformational equilibrium.

Results and Discussion

The ^{1}H n.m.r. spectrum of **2**, run as the neat liquid, was reasonably straightforward to assign. Irradiation of the aromatic protons sharpened



2

the transitions due to H_1, H_3, and H_4 and enabled a far more accurate analysis to be made, as also did ^{1}H–[^{19}F] decoupling experiments. The resonances of H_3 and H_4 shown in Fig. 1A are typical; see also experimental section. The ^{19}F spectrum is a broad band; however, ^{19}F–[^{1}H] double resonance spectra helped confirm the spectral assignments.

The signs of the various coupling constants were determined by a series of spin-tickling experiments; since both the spectra and the experiments were reasonably complex, a computer programme (NMDRS, see Experimental) was used to check their outcome. Irradiation of the lowest field transition of the H_2 resonance (at τ 5.5263) produced the spectrum shown in Fig. 1B; the computer-simulated spectrum is shown in Fig. 1C. It can be seen that transitions 5 and 7 (counting from low field) of both H_3 and H_4 are split; this indicates that $^3J_{2F}$ has the same sign as both $^4J_{3F}$ and $^4J_{4F}$, but $^3J_{24}$ and $^3J_{23}$ have opposite signs to $^2J_{34}$. Since *vicinal* ^{1}H–^{19}F couplings ($^3J_{HF}$) are positive (10) this indicates that both long-range ^{1}H–^{19}F couplings in this molecule ($^4J_{3F}$ and $^4J_{4F}$) are positive. The agreement between theoretical and experimental spectra is reasonably good. Each transition is

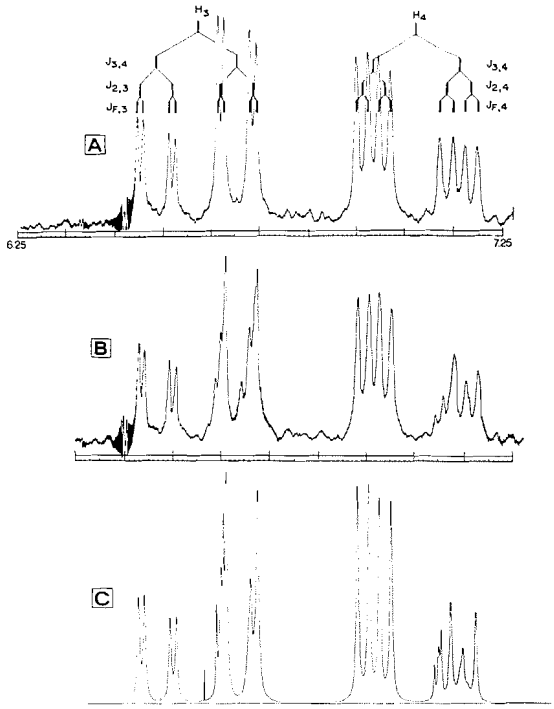


FIG. 1. The H_3 and H_4 resonances (100 MHz) of **2**. A, the spectrum measured with simultaneous irradiation of the aromatic protons; B, as for A, but with irradiation of the lowest field transition of the H_2 resonance; C, the computer simulation of the spectrum given in B.

now split into three lines rather than the usual two for spin-tickling, since the original transition in the H_3 (or H_4) spectrum is actually an unresolved doublet (due to the coupling of H_1) and only one line of each doublet is split in the spin-tickling experiment.

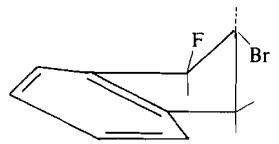
In a separate experiment a transition of the H_3 resonance was irradiated and the effect observed in the H_2 resonance; this indicated the $^4J_{3F}$ and $^3J_{2F}$ have the same sign, but $^2J_{24}$ and $^3J_{34}$ have opposite signs.

With the results of these experiments on hand, the normal spectra of **2** were subject to iterative computer analysis using TWOSUM (see Experimental section); the fit between the calculated and experimental spectra (^{1}H only) was satisfactory with an average deviation of only 0.049 Hz.[3] The final calculated coupling constants (Hz) are:

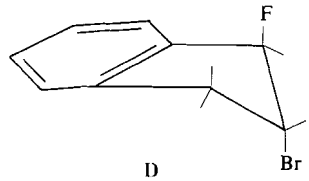
[3]One imaginary ^{19}F transition was put into the experimental set in order to link the energy levels together.

$^3J_{12} = 3.15$	$^3J_{23} = 6.74$	$^2J_{34} = -17.06$
$^4J_{13} = 0.0$	$^3J_{24} = 4.56$	$^4J_{3F} = 1.20$
$^4J_{14} = 0.0$	$^3J_{2F} = 17.27$	$^4J_{4F} = 2.45$
$^2J_{1F} = 55.73$		

It now remains to decide the shape adopted by the five-membered ring of **2**. Consideration of the size of $^3J_{2F}$ (17.3 Hz) in comparison with data for systems with similar electronegative (ε 5.15) substituents (9) indicates that the dihedral angle between H_2 and F is either 10–25° or about 110–125°. However, the second possibility is ruled out since the five-membered ring would have to bend an absurd amount to achieve such a large dihedral angle between *cis*-atoms. Hence the bend of the ring is determined to be in the region 10–25°, but this does not decide which way the ring is bent. Since $^3J_{24}$ and $^3J_{12}$ must be nearly equal, by symmetry, we can



C



D

assign the larger coupling (6.7 Hz) to $^3J_{23}$. For 1-bromo-acenapthene (11), with similar electronegativity, $^3J_{HH}$ (0°) = 6.8 Hz, and for the vinyl fluoride adduct of hexachlorocyclopentadiene (12), $^3J_{HH}$ (0°) = 7.0 Hz. Hence a small bend of the five-membered ring is also to be expected from this piece of information. However, $^3J_{23}$ also has approximately the same value with either conformation **C** or **D**.

The relative amounts of each conformer may, however, be deduced by comparison of $^3J_{12}$ with other data in this study. $^3J_{HH}$ ($\phi = 180°$) is obtained from the analysis of *trans*-1-bromo-2-fluoro-cyclohexane-3,3,6,6-d_4 (1) (10.1 Hz) and $^3J_{HH}$ ($\phi = 100°$) from *trans*-1-bromo-2-fluoro-acenapthene (9) (1.0 Hz). Thus for $\phi = 145°$ a value of 7.0 Hz is reasonable, and the experimental value of 3.15 Hz indicates that the *diaxial* conformer **D** predominates to the extent of *ca.* 60%.

The values of $^3J_{12}$ and $^3J_{24}$ may be compared with those in other *trans*-1,2-dihalides (5, 6).

	$^3J_{12}$	$^3J_{24}$
Br–F	3.15	4.56
Br–Br	1.2	1.3
Br–Cl	2.7	3.1
Cl–Cl	3.3	3.8
Cl–I	2.9	3.2

Since the bromo-fluoride has the highest electronegativity, there appears to be more diequatorial conformer present in this compound than in the other dihalides, once again indicating the small amount of halogen–halogen repulsion when fluoride is involved (1).

Experimental

The synthesis of *trans*-2-bromo-1-fluoro-indan (**2**) is described in an accompanying paper (8).

All n.m.r. measurements were made with an extensively modified (13) Varian HA-100 instrument operating in the locked frequency-sweep mode.

The computer-based analysis of the spectra of **2** used a version of the TWOSUM programme, kindly provided by Dr. J. Martin (University of Alberta, Edmonton) in conjunction with a plot-routine, SMASH, written by John Coulthard of the University of British Columbia Computing Centre.

The spin-tickling experiments used to determine the relative signs of the coupling constants were checked by using as double-resonance simulation programme, NMDRS[4] in conjunction with SMASH.

Although this programme is extraordinarily useful, it remains that *sometimes* the theoretical line shapes are rather poor reproductions of the experimental. This may reflect the inadequacy of the double resonance programme (NMDRS), which neglects all *relaxation effects* in calculating the line shapes; the programme frequently predicted extremely sharp lines which are virtually never observed in practice. Whether or not this was the fault of NMDRS as noted above or simply an instrumental problem (*e.g.* the saturation level of a very sharp line may be much lower than normal) was not determined.

Several figures have been submitted to the Depository for Unpublished Data.[5] Since we feel that some of these

[4]The original listing of the programme NMDRS (14) was obtained from the National Physical Laboratory, Teddington, U.K.; this programme was in ALGOL, and the necessary translation to FORTRAN was kindly carried out by Susan Boyd of the University of British Columbia Computing Centre.

The Kinetics of the Reaction $2C_3H_6 \rightarrow C_3H_5 + C_3H_7$

M. SIMON AND M. H. BACK
Chemistry Department, University of Ottawa, Ottawa, Canada, K1N 6N5

Received December 19, 1972

An attempt has been made to measure the rate constant for the bimolecular process

$$2C_3H_6 \rightarrow C_3H_5 + i\text{-}C_3H_7$$

using acetaldehyde as a radical scavenger. The rate constant obtained may be expressed as follows:

$$\log k \text{ (l mol}^{-1}\text{ s}^{-1}) = 10.4 - 43\,500/2.3RT$$

This activation energy corresponds to a value of 36 kcal/mol for ΔH_f(allyl).

On a essayé de mesurer la constante de vitesse du processus bimoléculaire

$$2C_3H_6 \rightarrow C_3H_5 + i\text{-}C_3H_7$$

en utilisant l'acétaldéhyde pour piéger le radical. La constante de vitesse obtenue peut être exprimée comme suit:

$$\log k \text{ (l mol}^{-1}\text{ s}^{-1}) = 10.4 - 43\,500/2.3RT$$

Cette énergie d'activation correspond à une valeur de 36 kcal/mol pour le ΔH_f(allyle).

Can. J. Chem., **51**, 2934 (1973)

Introduction

In a recent study of the kinetics of the decomposition of propylene in the region of 750 °K (1) it was suggested that the initiation step in the chain reaction was the bimolecular reaction of propylene to give an allyl and a propyl radical.

[1] $$2C_3H_6 \rightarrow C_3H_5 + i\text{-}C_3H_7$$

The present work describes an attempt to measure the rate constant for this process. The method involved the pyrolysis of propylene in the presence of a suitable scavenger to convert propyl radicals to propane. The scavenger chosen was acetaldehyde so that reaction 1 would be followed by

[2] $$C_3H_7 + CH_3CHO \rightarrow C_3H_8 + CH_3CO$$

If all the propyl radicals formed in reaction 1 react by reaction 2 the rate of formation of propane may be equated to the rate of reaction 1, provided other sources of propane are not important.

Experimental

Materials

Research grade propylene was obtained from Matheson of Canada, Whitby, Ontario. Analysis by gas chromatography showed a propane impurity of 0.007 mol%. This correction to the yield of propane was usually about 5% and never more than 10%. Acetaldehyde was prepared from research grade paraldehyde by distillation under nitrogen. Acetaldehyde was stored under vacuum at temperatures below 20 °C.

Apparatus and Procedure

The apparatus, a conventional static pyrolysis system, has been described (2). Two reaction vessels were used, each 200 cc, with S/V ratios of 1.0 and 8.5 cm^{-1}. The reactants were mixed in a one-liter flask with an internal cold finger. Various mixing procedures were tried; the most efficient involved inducing convection currents in the gases with a 100 W light bulb placed at one side of the flask. Whether the reactants were condensed together or not had no effect on the results. The reactants were introduced directly from the mixing flask into the reaction vessel through a Hoke diaphragm seal stainless steel valve. The products and reactant were condensed together and analyzed on an F and M temperature-programed gas chromatograph using a 3 ft column of silica gel and alumina. Rates of formation of products were measured at four temperatures, 743, 763, 783, and 803 °K, and over a range of pressures.

Results

The main products from the pyrolysis of propylene in the presence of acetaldehyde were methane, carbon monoxide, ethane, ethylene, butane, butene, and propane. Higher hydrocarbon products were not measured because their appearance on the gas chromatographic analysis was obscured by the large quantities of acetaldehyde. The present paper reports only the results of the measurement of the rate of formation of propane. Measurements of the other products are reported in the following paper. Initial rates of formation of propane were measured as a function of acetaldehyde pressure for several pressures of propylene at each temperature.

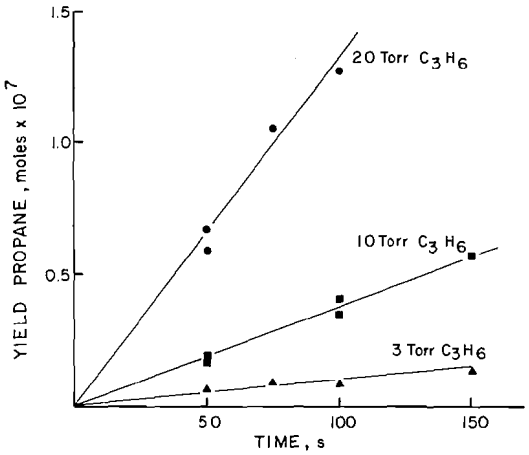

FIG. 1. Yield of propane as a function of time.

Typical results for the yield as a function of time are shown in Fig. 1.

There are two important kinetic features of the present system which enable the rate of formation of propane to be equated to the rate of reaction 1. As acetaldehyde is added to propylene, the rate of formation of propane should increase until a limiting value is obtained, which indicates that all the propyl radicals produced in reaction 1 are converted to propane by reaction with acetaldehyde. This behavior is illustrated in Figs. 2, 3, and 4. The yield of propane remained constant for ratios of propylene to acetaldehyde between 1:10 and 1:15 and most of the experiments were done with a ratio of about 1:14. Average values of the rate in the plateau region are given in Table 1. At 783 and 803 °K rates were measured in both the packed and unpacked reaction vessels. The rates were the same in each vessel and the values given in

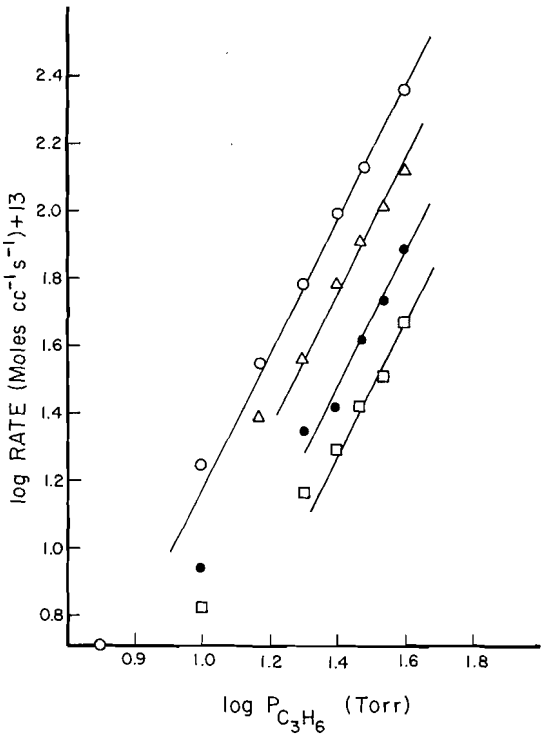

FIG. 5. Logarithm of the rate of formation of propane at the plateau against the logarithm of the propylene pressure. ○, 803 °K; △, 783 °K, ●, 763 °K; □, 743 °K.

Table 1 represent the average obtained from both sets of experiments.

The rate of formation of propane in the plateau region should be second order with respect to propylene. In Fig. 5 the log of the rate is plotted against the log of the propylene pressure. At each temperature, the line has been drawn to correspond to an order of 2.0. At pressures above 20 Torr the rate is second order with respect to propylene, but below about 20 Torr some propane appears to be formed by a lower order process, particularly at the lower temperatures.

A second-order rate constant was calculated from the relation

$$[3]\quad k_1 = \frac{\text{Rate of propane formation at plateau}}{[C_3H_6]^2}$$

where the rate was taken in the region of pressure where it was second order with respect to propylene. These values are shown in Table 1 as k_1 calculated from eq. 3.

In an attempt to correct k_1 for the occurrence of a lower order process giving propane, the data were analyzed according to the following equation:

$$\text{Rate of propane} = k_x[C_3H_6]^n + k_1[C_3H_6]^2$$

where k_x may be a composite rate constant. Linear plots of the following form were obtained only for $n = 1/2$.

$$[4]\quad \frac{\text{Rate}(C_3H_8)}{[C_3H_6]^{1/2}} = k_x + k_1[C_3H_6]^{3/2}$$

The data at 743 °K are shown in Fig. 6. The mechanism whereby propane is formed with a square-root dependence on the concentration of propylene is probably complex. In fact in these experiments this dependence represents an overall dependence of the rate on both reactants, since a constant ratio of acetaldehyde and propane was maintained. The separate dependence of the rate on each reactant cannot be determined. Furthermore, the value of k_x changed very little over the temperature range, indicating an activation energy of the order of 10 kcal/mol. Such a low value suggests the rate may be a complex sum of competing reactions or that surface reactions may be important.

Values of k_1 obtained from plots of eq. 4 are included in Table 1 as k_1 calculated from eq. 4. The two values of k_1 are essentially the same at the two higher temperatures where the rate was second order over a wide range of pressures. At

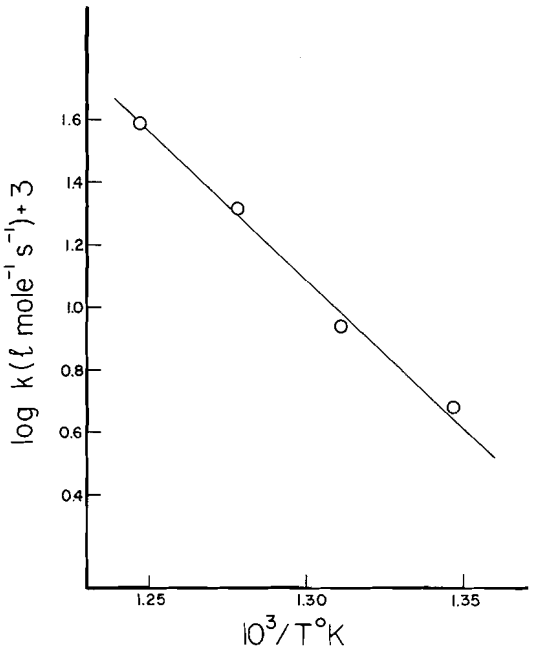

FIG. 7. Arrhenius plot of k_1.

the two lower temperatures, where more curvature in the order plot was observed the correction was as much as 30%.

An Arrhenius plot of the corrected values of k_1 is shown in Fig. 7. From this plot the following expression was obtained for k_1:

$$\log k_1(\text{l mol}^{-1}\ \text{s}^{-1}) = 10.4 - \frac{43\,500}{2.3RT}$$

The frequency factor for reaction 1 may be calculated from the entropy change of the reaction and the rate constant for the reverse disproportionation of allyl and propyl radicals. If the rate constant for combination of allyl and propyl radicals is assumed to be the same as that for two methyl radicals and the ratio of disproportionation to combination is taken as 0.20, the frequency factor for reaction 1 is 1.6×10^{10} l mol^{-1} s^{-1}. Although this ratio of disproportionation to combination has not been measured it may be estimated from the relation between k_d/k_c and $S_d^0 - S_c^0$ (3). The value of 0.20 obtained from this procedure is very similar to the value of 0.18 measured for the reaction of allyl and ethyl radicals (4). The calculated and measured values for the frequency factor are in excellent agreement.

The activation energy of k_1 represents the endothermicity of reaction 1 if the activation energy for the reverse process is assumed to be zero. Thus a value of 36 kcal/mol may be derived for ΔH_f(allyl) at temperatures in the region of 750 °K. The change in ΔH from 750 °K to 298 °K is less than 0.5 kcal/mol and this correction may be neglected. The limits of error are probably larger than indicated by the scatter of the data and a reasonable estimate is ± 2 kcal/mol.

An attempt was made to measure the rate of formation of propyl radicals using H_2S as scavenger. Although under some conditions, a plateau in the rate of formation of propane was observed as the concentration of H_2S was increased, the rate in the plateau region was approximately first order with respect to propylene, not second order. The rate was increased by about a factor of four in the packed reaction vessel and a given set of experiments was not reproducible over a period of time. The kinetics in this system were too complex to permit a straightforward measurement of the rate of reaction 1.

Discussion

The observed frequency factor for reaction 1 is in very good agreement with the value predicted from a simple consideration of the entropy change in the reaction and a comparison of the reverse disproportionation reaction with others of a similar type. The bimolecular reaction may therefore be described as a hydrogen atom transfer process similar to such reactions involving radicals but requiring a higher energy barrier. If excited electronic states of propylene were important, the frequency factor would likely be much lower.

Some recent measurements of ΔH_f(allyl) are summarized in Table 2. The low value obtained in the present experiments may be the result of an erroneously high rate of formation of propane. Several sources of propane, other than the sequence of reactions 1 and 2, might be suggested in the present system.

Hydrogen is a minor product in the pyrolysis of mixtures of acetaldehyde and propylene and is probably formed by the reaction of hydrogen atoms with acetaldehyde or propylene.

[5] $\quad H + CH_3CHO \rightarrow H_2 + CH_3CO$

[6] $\quad H + C_3H_6 \rightarrow H_2 + C_3H_5$

Addition of hydrogen atoms to propylene would

lead to formation of propyl radicals and hence to propane.

[7] $$H + C_3H_6 \rightarrow C_3H_7$$

Absolute values for k_5, k_6, and k_7 are not well established in the temperature range of 800 °K. Nevertheless if k_5 is taken as approximately equal to k_6 the following expression may be obtained (14):

$$\log \frac{k_7}{k_5} \approx + \frac{2000}{2.3RT} \approx 0.5$$

Under the present conditions the ratio of the rate of addition to propylene to the rate of abstraction from acetaldehyde in the plateau region will be about 0.2. These estimates are, however, not very reliable, and a better assessment of the importance of reaction 7 may be obtained from a consideration of the kinetics of hydrogen formation.

There are several possible sources of hydrogen atoms in the present system.

[8] $$CH_3CHO \rightarrow CH_3 + CHO$$

[9] $$CHO \rightarrow CO + H$$

[10] $$C_3H_6 \rightarrow C_3H_5 + H$$

[11] $$CH_3 + CH_3CHO \rightarrow CH_2CHO + CH_4$$

[12] $$C_3H_5 + CH_3CHO \rightarrow CH_2CHO + C_3H_6$$

[13] $$CH_2CHO \rightarrow CH_2CO + H$$

[14] $$CH_3 + C_3H_6 \rightarrow C_4H_9$$

[15] $$C_4H_9 \rightarrow C_4H_8 + H$$

[16] $$C_3H_5 + C_3H_6 \rightarrow C_6H_{11}$$

[17] $$C_6H_{11} \rightarrow C_6H_{10} + H$$

None of these reactions forming hydrogen atoms lead to a rate of formation of propane which is comparable to the rate observed or which is second order with respect to propylene and independent of the concentration of acetaldehyde. For example, the rate of reaction 10 is much slower than the rate of formation of propane in the present system. The rate of formation of hydrogen atoms by reactions 8 and 9 will be a function of the concentration of acetaldehyde and would not give the plateaus observed for the rate of formation of propane. The rates of reactions 11 and 14 depend on the concentration of methyl radicals and would likewise not be independent of the concentration of acetaldehyde. The concentration of allyl radicals may become independent of the concentration of acetaldehyde but in the present experiments, reactions 12 and 16 must be small relative to reactions 11 and 14, respectively. Furthermore, in the plateau region $k_5(CH_3CHO)$ should be greater than $(k_6 + k_7)(C_3H_6)$ and addition should not be an important process. Nevertheless, because the yield of hydrogen could not be measured with certainty and might be as much as five times the yield of propane under some conditions, the rate of formation of propane may be in error due to hydrogen atom addition to propylene by as much as a factor of two. Even this error has a small effect on the activation energy, provided the frequency factor for reaction 1 is not greater than the calculated value.

A second source of propane in this system might be the reaction, similar to reaction 1, of acetaldehyde and propylene.

[18] $$C_3H_6 + CH_3CHO \rightarrow C_3H_7 + CH_3CO$$

The rate of formation of propane from this reaction would be linearly dependent on the acetaldehyde concentration and a plateau would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

not be observed. Reaction 18 must not be important in this system. A corollary to this conclusion is that the rate of this process must be about fifty times slower than the measured rate of reaction 1 in order that a plateau be observed with the ratio of acetaldehyde to propylene in the present experiments. If the frequency factors for reactions 1 and 18 are the same, as appears likely from the similarity of the entropy change of the reactions, this restriction implies an activation energy of about 48 kcal/mol for reaction 18. Using the heats of formation of the radicals given in ref. 15 the endothermicity of reaction 18 is 47 kcal/mol. The restriction is thus well within the uncertainty of the estimation.

The kinetics of the formation of propane in the present system is consistent with its formation by the sequence of reactions 1 and 2. This interpretation, however, leads to a value for the heat of formation of the allyl radical lower than the most recent measurements but in agreement with values obtained from studies of the kinetics of pyrolysis reactions. Probably the most troublesome error in kinetic studies is the uncertainty in the mechanism of the reaction, which to a large extent determines the confidence with which the measured activation energy may be identified with the endothermicity of the reaction. Such errors have, however, not been identified in the present or the previous kinetic studies and it must be concluded that the reason for the range of values obtained for ΔH_f(allyl) remains uncertain.

The dissociation energy of the allyl radical was given an upper limit of 70 kcal/mol from measurements of the electronic absorption spectrum of the radical (16). This implies a lower limit of 28 kcal/mol for ΔH_f(allyl). The present results are well within this limitation.

The Co-Pyrolysis of Acetaldehyde and Propylene

M. SIMON AND M. H. BACK
Chemistry Department, University of Ottawa, Ottawa, Canada, K1N 6N5

Received December 19, 1972

Analysis of both major and minor products of the thermal reaction of mixtures of propylene and acetaldehyde over the temperature range 750–800 °K and at pressures below atmospheric show that both reactants initiate radical chains and that both addition and abstraction reactions of radicals with propylene are important. The relation to general mechanisms of the inhibiting effect of propylene in pyrolysis reactions is discussed.

L'analyse des produits mineurs et majeurs, issus de la réaction thermique d'un mélange propylène–acétaldéhyde entre 750 et 800 °K à des pressions inférieures à la pression atmosphérique, a montré premièrement que les deux réactifs sont capables d'initier des chaînes radicalaires et deuxièmement que les réactions d'addition et d'élimination, des radicaux avec le propylène, sont importantes. Dans le cas des réactions de pyrolyse, on discute de la relation entre l'effet inhibiteur du propylène et les mécanismes généraux de ces réactions. [Traduit par le journal]

Introduction

Propylene has long been known to inhibit the decomposition of many organic compounds (1–4). The inhibition has been explained by both addition and abstraction reactions of radicals with propylene. Both reactions reduce the apparent rate of reaction, the former by the formation of higher molecular weight products which lowers the rate of pressure increase, and the latter by the substitution of the relatively non-reactive allyl radical for the more reactive chain-carrying radical. A general mechanism has been formulated for such systems by Niclause *et al.* (5), who developed equations describing the rate of decomposition of an organic compound as a function of the concentration of additive for various types of chain mechanisms. With propylene they assumed that the predominant effect is the substitution of the allyl radical for the normal propagating radical, and for simplicity neglected addition reactions, as had been done by other authors (6, 7), although it was acknowledged that they could have some importance. Addition reactions were considered by Quinn (8) and by Marta *et al.* (9) in their studies of the effect of propylene on the pyrolysis of butane and of propionaldehyde, respectively, but their importance could not be assessed with any certainty because of incomplete product analysis. The relative importance of addition and abstraction reactions is a basic question in the mechanism of inhibition by propylene and in the related effect of self-inhibition of the pyrolysis of paraffins by the product olefins. The self-inhibition of neopentane, for example, has been explained by the ease of abstraction from the product isobutene (10), while the self-inhibition of propane (11) and isobutane (12) has been accounted for by addition processes.

Initiation of chains by unimolecular dissociation of propylene in propylene-inhibited reactions has been suggested (7) but it has generally been recognized that this dissociation would be slow compared to initiation by the original reactant. The bimolecular reaction of propylene to give radicals, either with itself or with the reactant, has not been considered in inhibition studies, but may under some conditions be faster than the unimolecular dissociation (13).

In spite of the considerable attention that has been given to the mechanism of inhibition by propylene the relative importance of abstraction, addition, and initiation reactions of propylene remains in some doubt. Previous studies have reported only the measurement of the rate of pressure change (14, 15) or of formation of major products (16–18), whereas a detailed examination of the products, both major and minor, is necessary to clarify these questions. In a recent study of the acetaldehyde–propylene system undertaken to measure the rate of bimolecular initiation by disproportionation of propylene (19) product data were obtained which showed the importance of addition to and initiation by propylene in this system. The present paper describes these results and their application to the mechanism of inhibition by propylene in general.

Experimental

Mixtures of propylene and acetaldehyde were pyrolyzed in a conventional static system which has been described (20). The purification of the reagents, the technique of mixing, and the analysis procedure for condensable products were given in the preceding paper. Methane and carbon monoxide were collected with a Toepler pump into a gas burette, where the total quantity was measured. The proportion of methane, carbon monoxide, and hydrogen was determined by combustion on a copper oxide furnace maintained at 420 °C. Because the yield of hydrogen was small (< 1% of CH_4 + CO), reliable values could not be obtained by this technique. The yield of hydrogen was estimated as roughly equivalent to the yield of propane.

Results and Discussion

Measurements were made at total pressures ranging from 20 to 600 Torr, usually with a ratio of propylene to acetaldehyde of 0.07, and at temperatures of 743, 763, 783, and 803 °K.

The main products were methane and carbon monoxide and their rates of formation were 100 times greater than the rates of formation of the other products. The decomposition was thus primarily that of acetaldehyde. The other products analyzed were, in order of importance, ethylene, ethane, butane, butene, propane, and hydrogen. Initial rates of formation of these products, except hydrogen, were measured, and, except for butane, yield–time plots were linear through the origin. Typical examples are shown in Fig. 1 and the measured rates, obtained from similar plots, are given in Table 1. At each temperature some experiments were done in the packed reaction vessel and in each case, no change in the rates of formation of products was observed. The rates in Table 1 are average values obtained using data from experiments in the packed and unpacked vessels.

In Table 2, the rates of formation of the main products from mixtures of propylene and acetaldehyde in the ratio 0.07 are compared with the rates of formation of each of these products from the pyrolysis of acetaldehyde (21) and propylene (13) separately. The rates of formation of products from the pyrolysis of 40 Torr of propylene were not measured directly, but were obtained by extrapolation of rates measured at higher pressures (100–600 Torr). They should therefore be regarded as approximate. In the two previous studies of the inhibition of acetaldehyde by propylene at 823 °K (14) and at 798 °K (16), where a minimum in the rate was observed at a ratio of propylene to acetaldehyde of 0.25, a ratio of 0.07 decreased the rate by a factor of 0.6, in good agreement with the present results.

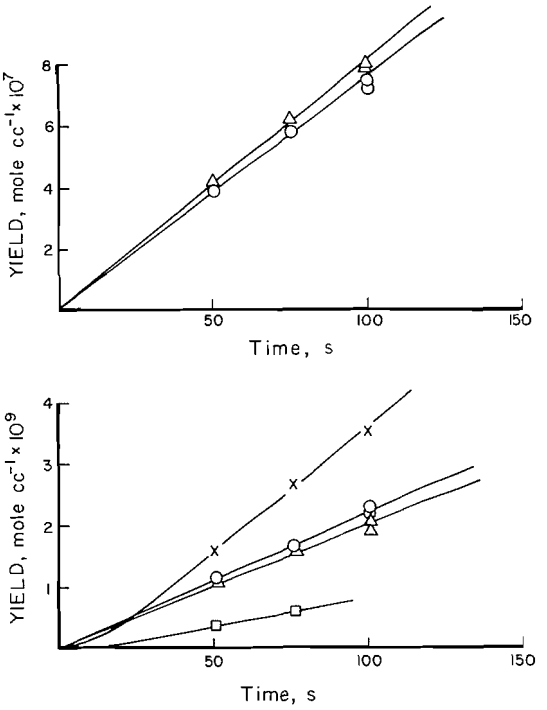

FIG. 1. Yields of products as a function of time. Temperature, 763 °K; pressure of propylene, 40 Torr; pressure of acetaldehyde, 550 Torr. Upper curve: △, CO; ○, CH_4. Lower curve: ×, butane; ○, ethylene; △, ethane; □, butene.

The product distribution from the mixture is quite different from that of either reactant by itself. In pure acetaldehyde, hydrocarbon products other than ethane were not observed. In pure propylene saturated hydrocarbon products other than methane were in very low yield, but higher molecular weight compounds, particularly C_6 hydrocarbons (not listed), were important products. In the pyrolysis of propylene addition to the double bond is a dominant feature of the mechanism, while in the pyrolysis of acetaldehyde abstraction of the aldehydic hydrogen is by far the most important chain-propagation process. In the mixture the availability of both types of reaction gives a new product distribution which illustrates the effect of the mutually interacting chain-propagation processes.

The following mechanism is a modification of the general mechanism proposed by Niclause *et al.* (5) to include initiation by propylene and addition of radicals to propylene.

TABLE 2. Comparison of rates of formation of products from acetaldehyde, propylene, and propylene + acetaldehyde mixtures at $T = 796$ °K

Product	Rate of formation (mol cc^{-1} s^{-1} × 10^{11})		
	Acetaldehyde (550 Torr)	Propylene (40 Torr)	Propylene (40 Torr) + acetaldehyde (550 Torr)
CO	3600	—	2140
CH_4	3600	0.115	1950
C_2H_6	0.307	—	4.90
C_2H_4	—	0.1	6.45
C_3H_8	—	0.024	1.82
C_4H_{10}	—	—	5.13
C_4H_8	—	0.008	4.07
H_2	5.55	0.02	<10

The importance of addition reactions is evident from the relative rates of formation of methane and carbon monoxide, (Fig. 1) and from the rates of formation of C_4 products. The yields of methane are 10–20% lower than the yields of carbon monoxide over the range of temperature and pressure studied, whereas in the pyrolysis of acetaldehyde itself the yields of methane and carbon monoxide are identical to within 0.5% (22). Methyl radicals therefore react by a process which does not give methane and which can only be reaction 7.

The relative importance of abstraction and addition reactions in the inhibition process may be roughly estimated by a comparison of the yields of carbon monoxide and methane. Assuming as a first approximation, that the chain-propagation process gives an acetyl radical and that all acetyl radicals decompose to give carbon monoxide, then the yield of carbon monoxide in the mixture is a measure of the inhibition caused by the substitution of the methyl radical by the allyl radical. The yield of methane from the mixture is reduced not only by this effect but also by addition of methyl radicals to propylene. From Table 2 it may be seen that in this study the addition of propylene reduced the rate of formation of carbon monoxide by a factor of 0.59 and the rate of formation of methane by 0.53. About 10% of the inhibition can therefore be attributed to addition of methyl radicals to propylene. The rate as measured by the pressure increase will be further reduced by subsequent addition of higher molecular weight radicals to propylene.

The formation of butane and butene may be accounted for by the sequence of reactions 7, 12, 13, and 14. Since the addition of methyl radical to propylene gives a secondary butyl radical, isomerization must occur either before or after decomposition. In either case the activation energies for reactions 14 and 15 may be expected to be similar. Alternatively, further addition of the butyl radical may occur, followed by isomerization and decomposition of the C_7 radical, giving C_2H_5, C_2H_4, or C_4H_8. Indeed, the sum of the yields of butane + butene + ethane or ethylene accounts for only about 10% of the difference between methane and carbon monoxide and suggests that higher molecular weight compounds, formed by successive addition of radicals to propylene and not detected by the analysis, may be important products. The rates of formation of butane, ethane, and ethylene as a function of acetaldehyde pressure are shown in Fig. 2.

The occurrence of the bimolecular initiation reaction of propylene, reaction 2, is demonstrated by the formation of propane as a primary product, reported in the preceding paper. The importance of this initiation compared to initiation by acetaldehyde may be estimated using the value for k_2 obtained in the preceding paper and the previously measured value of $k_1 = 10^{15.7}e^{80000/RT}$ (22). With a ratio of propylene to acetaldehyde of 0.07 and at a pressure of propylene of about 25 Torr at 783 °K,

$$\frac{\text{Rate [1]}}{\text{Rate [2]}} = \frac{k_1[CH_3CHO]}{k_2[C_3H_6]^2} = 0.3$$

Taking into account the uncertainty in these rate

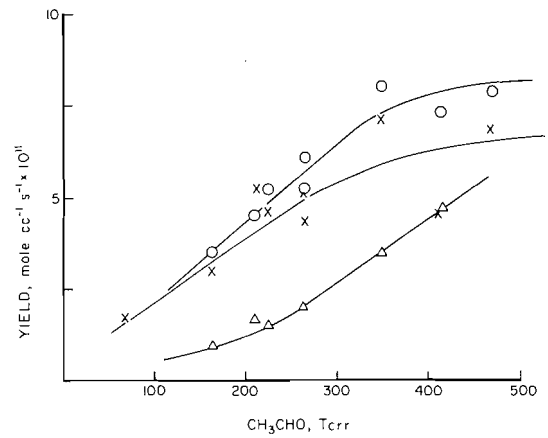

FIG. 2. Rate of formation of products as a function of acetaldehyde pressure. Temperature, 803 °K; pressure of propylene, 30 Torr. ○, ethylene; ×, ethane; △, butane.

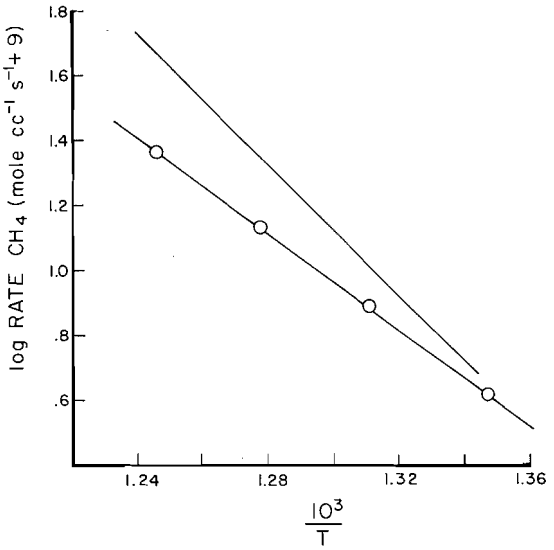

FIG. 3. Arrhenius plot of the rate of formation of methane. ○, 40 Torr C_3H_6 + 550 Torr CH_3CHO; solid line, 550 Torr CH_3CHO.

constants, the two rates may be considered to be roughly equal. With a ratio of propylene to acetaldehyde of 0.25, where the minimum in the rate was observed (14), initiation by reaction 2 would be at least three times as fast as by reaction 1 and would become increasingly important as the pressure of propylene was increased. The activation energy of the rate, obtained from the Arrhenius plot shown in Fig. 3, was 34 kcal/mol. This value is considerably lower than the value of 49 kcal/mol for the decomposition of acetaldehyde itself and is consistent with the occurrence of an additional initiation step of lower activation energy than the dissociation of acetaldehyde.

The analysis of inhibition mechanisms by Niclause *et al.* (5) showed that in the case where reaction with the additive forms a radical less reactive than the original chain-propagating radical, as is the case with propylene, the rate of reaction of the mixture will decrease with addition of inhibitor to a limit which represents the complete conversion of the original chain-propagating radical to the less reactive allyl radical. The rate of reaction of the mixture will increase only if propylene contributes to the initiation of radicals. Thus the subsequent increase in rate beyond the minimum value observed with mixtures of propylene and acetaldehyde (14) may quite reasonably be attributed to the initiation by propylene by the bimolecular disproportionation reaction. In mixtures of propylene with propionaldehyde (9) and with butane (23), where the rate was also observed to increase after passing through a minimum value, initiation by propylene may also be important. The ratio of propylene to reactant at which this secondary increase in rate is observed is a function of several competing rates, not only the rates of initiation, and cannot easily be predicted for any particular system.

Photolyse de l'ammoniac et de l'ammoniac perdeuterié à 185, 147, et 123.6 nm

JEANNINE MASANET, JANINE FOURNIER, ET CATHERINE VERMEIL

Equipe de Recherche du CNRS, associée à l'ESPCI, 10, rue Vauquelin, 75231 PARIS CEDEX 05 France

Reçu le 24 janvier 1973

La photolyse de l'ammoniac et de l'ammoniac perdeutérié a mis en évidence les faits suivants:

A 147 et à 123.6 nm, il existe un effet isotopique très important sur le rapport des rendements en hydrogène moléculaire et en hydrogène atomique $\phi_{H_2}/\phi_H > \phi_{D_2}/\phi_D$ tandis qu'à 185 nm $\phi_{H_2}/\phi_H = \phi_{D_2}/\phi_D$. La dissociation selon NH $(X^3\Sigma^-)$ + H + H apparaît à $\lambda = 147$ nm, ce qui implique $D_{NH-H} \leqslant 90$ kcal mol^{-1}.

On a pu évaluer la vitesse de la réaction D + $ND_3 \rightarrow D_2 + ND_2$, $k_{D+ND_3} = 3.5 \times 10^{13} \exp(-14400/RT)$ cm^3 mol^{-1} s^{-1}.

A very important isotopic effect for the ratio of molecular and atomic hydrogen yield in the photolysis of ammonia at 147 and 123.6 nm has been found $\phi_{H_2}/\phi_H > \phi_{D_2}/\phi_D$ while at 185 nm $\phi_{H_2}/\phi_H = \phi_{D_2}/\phi_D$.

The dissociation $NH_3 + h\nu \rightarrow$ NH $(X^3\Sigma^-)$ + H + H occurs for wavelengths as high as 147 nm which implies that $D_{NH-H} \leqslant 90$ kcal mol^{-1}.

The rate constant of the reaction D + $ND_3 \rightarrow D_2 + ND_2$ has been evaluated $k_{D+ND_3} = 3.5 \times 10^{13}$ exp $(-14\,400/RT)$ cm^3 mol^{-1} s^{-1}.

Can. J. Chem., 51, 2946 (1973)

Introduction

La photolyse de l'ammoniac dans son premier état excité $\tilde{A}\,^1A_2''$ est relativement bien connue (1,2); on considère généralement que la dissociation a lieu exclusivement en NH_2 + H. La photodissociation des autres états électroniques a été principalement suivie par spectroscopie d'absorption ou d'émission des radicaux NH et NH_2, formés soit par photolyse continue (3–5), soit par photolyse éclair (6). Ces travaux ne permettent pas de connaître les probabilités relatives des différents modes de dissociation. La présente étude a pour objet cette détermination dans trois régions différentes du spectre d'absorption en appliquant à l'ammoniac la méthode précédemment utilisée pour l'étude de la photolyse de l'eau (7,8), du méthane (9) et de leurs composés perdeutériés.

Principe de la methode

Selon l'état dissociatif atteint par absorption photonique, une molécule hydrogénée RH_2 peut en général se dissocier selon les trois modes suivants:

$$RH_2 + h\nu \rightarrow RH + H \quad \phi_a$$
$$\rightarrow R + H + H \quad \phi_b$$
$$\rightarrow R + H_2 \quad \phi_{H_2}$$
$$\phi_H = \phi_a + 2\phi_b$$

Si les atomes H sont interceptés par du deutérium, le schéma cinétique suivant rend compte des réactions secondaires des atomes H (en négligeant les réactions des radicaux R et RH et pour des taux de conversion faibles).

H (+M)	$\rightarrow \frac{1}{2}H_2$	k_d
H + RH_2	$\rightarrow H_2$ + RH	k_e
H + D_2	$\rightarrow$ HD + D	k_f
H + D (+M)	$\rightarrow$ HD	k_g
D (+ M)	$\rightarrow \frac{1}{2}D_2$	k_h
D + RH_2	$\rightarrow$ HD + RH	k_l

La mesure des concentrations relatives en H_2 et HD dans D_2 permet de déterminer pour des conditions d'irradiation variées, le rapport $[H_2]/[HD]$ en fonction du rapport $[RH_2]/[D_2]$. En appliquant le principe des états stationnaires et en négligeant k_g devant $k_f\,[D_2]$, on obtient:

$$\frac{[H_2]}{[HD]} = \frac{\phi_{H_2}}{\phi_H}\left(\frac{1}{1 + \frac{k_i[D][RH_2]}{\phi_H}\left(1 + \frac{k_d + k_e[RH_2]}{k_f[D_2]}\right)}\right) + \frac{k_d(\frac{1}{2} + \phi_{H_2}\phi_H^{-1}) + k_e[RH_2](1 + \phi_{H_2}\phi_H^{-1})}{k_f[D_2]\left[1 + \frac{k_i[D][RH_2]}{\phi_H}\left(1 + \frac{k_d + k_e[RH_2]}{k_f[D_2]}\right)\right]}$$

On obtient évidemment une expression analogue pour la photolyse de mélanges $RD_2 + H_2$.

Les rendements relatifs $[H_2]/[HD]$ (ou $[D_2]/[HD]$) sont exprimés graphiquement en fonction des rapports $[RH_2]/[D_2]$ (ou $[RD_2]/[H_2]$). Dans un domaine de concentration suffisante en RH_2, on obtient ainsi des droites qu'on peut extrapoler pour $[RH_2]/[D_2] \rightarrow 0$. *L'ordonnée à l'origine ainsi obtenue représente* $\phi_{H_2}/2\phi_H$, $(\phi_{D_2}/2\phi_D)$; on a alors en effet:

$$k_e\,[RH_2]/k_f[D_2] \ll 1$$

et

$$k_i[D][RH_2] \rightarrow \phi_H$$

Pour $[RH_2]$ constant, l'expression de $[H_2]/[HD]$ devient, avec une bonne approximation

$$\frac{[H_2]}{[HD]} - \left(\frac{[H_2]}{[HD]}\right)_{\text{limite}} = \frac{\alpha}{[D_2]} = \frac{1}{[D_2]}(A + B[RH_2])$$

avec

$$A \simeq (\phi_{H_2}/\phi_H + 0.5)k_{H+M}/k_{H+D_2}$$

et

$$B \simeq (\phi_{H_2}/\phi_H + 1)\,k_{H+RH_2}/k_{H+D_2}$$

Pour le système $RD_2 + H_2$, on a de même

$$A' \simeq (\phi_{D_2}/\phi_D + 0.5)k_{D+M}/k_{D+H_2}$$

$$B' \simeq (\phi_{D_2}/\phi_D + 1)k_{D+RD_2}/k_{D+H_2}$$

On a alors les rapports suivants

$$A/A' = (k_{D+H_2}/k_{H+D_2})(k_{H+M}/k_{D+M})(\phi_{H_2}/\phi_H + 0.5)(\phi_{D_2}/\phi_D + 1)^{-1}$$

$$B/B' = (k_{D+H_2}/k_{H+D_2})(k_{H+RH_2}/k_{D+RD_2}) \times (\phi_{H_2}/\phi_H + 1)(\phi_{D_2}/\phi_D + 1)^{-1}$$

Pour un composé RH_2 donné, on observe une variation importante des rapports ϕ_{H_2}/ϕ_H, ϕ_{D_2}/ϕ_D, A/A', B/B' en fonction de l'énergie du rayonnement photonique. *Les variations de* ϕ_{H_2}/ϕ_H, ϕ_{D_2}/ϕ_D, *tiennent à l'ouverture de nouvelles vallées dissociatives au fur et à mesure que l'on atteint de nouvelles hypersurfaces de potentiel; les variations de* A/A' *et* B/B' *sont essentiellement dues à celle du rapport* R *des constantes de vitesse d'échange isotopique* k_{D+H_2}/k_{H+D_2} *avec l'énergie cinétique des atomes H ou D.*

A partir des valeurs expérimentales de A/A', ϕ_{H_2}/ϕ_H, ϕ_{D_2}/ϕ_D et en prenant pour k_{H+M}/k_{D+M} la valeur de 1.35 (11,12) (atomes thermalisés), on peut calculer le rapport R. Par comparaison avec la valeur de R mesuré par Westenberg et de Haas (10) pour des mélanges en équilibre thermique $R = 0.9 \exp 900/T$, ($R = 18$ pour $T = 300$ K), on calcule une température fictive T_λ, variable avec $h\nu$, qui est reliée de façon statistique à l'énergie cinétique moyenne des atomes H ou D, de la même façon que leur concentration est supposée stationnaire. Tout se passe comme si le milieu réactionnel était porté à la température T_λ. Ce procédé de calcul n'a de sens que si les atomes H et D sont, pour une énergie photonique donnée, formés avec des énergies cinétiques voisines, hypothèse de travail vraisemblable étant donné l'identité des surfaces de potentiel de RH_2 et de RD_2 et la faible différence des énergies de dissociation de ces deux molécules.

En portant la valeur de R dans le rapport B/B', on obtient pour k_{H+RH_2}/k_{D+RD_2} une valeur expérimentale relative à des atomes "chauds". On ne dispose pas en général de mesures expérimentales de ces deux constantes de vitesse (pour des milieux en équilibre thermique) mais si k_{H+RH_2} est connue, on peut évaluer k_{D+RD_2} et, à l'aide de la température T_λ calculée plus haut, la valeur de $\Delta E^* = E^*_{H+RH_2} - E^*_{D+RD_2}$, différence des énergies d'activation de deux réactions e et e'. E^* doit en principe rester constant quand $h\nu$ varie. On peut ainsi contrôler la validité des résultats obtenus.

Les rapports ϕ_{H_2}/ϕ_H, ϕ_{D_2}/ϕ_D, ne dépendent pas de l'intensité de la source, qu'il n'est donc pas nécessaire de connaître. Cependant l'erreur due à l'extrapolation est loin d'être négligeable, de l'ordre de 20%. La connaissance de T_λ ne permet pas de connaître l'énergie cinétique des atomes H ou D au moment de leur formation. Cependant cette évaluation moyenne permet d'éliminer certains modes dissociatifs ou, au contraire, d'accorder une probabilité importante à d'autres.

C'est ainsi que pour H_2O, photolysé à 185, 147, 123.6 nm, le rapport R était toujours bien inférieur à 18, indiquant que les atomes d'hydrogène formés possédaient de l'énergie cinétique, cette énergie étant d'autant plus élevée que l'énergie des photons incidents était plus grande. Ce résultat a été attribué au fait qu'aux trois longueurs d'onde on observe la même dissociation en $H + OH(X^2\Pi)$ et que l'énergie excédentaire, croissant avec l'énergie incidente des photons, était emportée essentiellement sous forme d'énergie cinétique par les atomes d'hydrogène. Ce résultat est en accord avec les résultats de Welge et Stuhl (13) qui, à 147 nm, ont observé

TABLEAU 1. Tableau récapitulatif des résultats expérimentaux concernant la photolyse de $NH_3(ND_3)$, $H_2O(D_2O)$ et $CH_4(CD_4)$ à diverses longueurs d'onde

		$\lambda = 185$ nm	$\lambda = 147$ nm	$\lambda = 123.6$ nm

	ϕ_{D_2}/ϕ_D			1.5
	R			18
	T °K			300
	$E_{cin\ max}$ (kcal mol^{-1})			120–20–3

que le radical hydroxyle était en équilibre avec le milieu et que l'atome d'hydrogène emportait toute l'énergie excédentaire.

Dans le cas du méthane au contraire, à 123.6 nm, on a trouvé $R = 18$, indiquant que les atomes d'hydrogène sont dans leur quasi totalité thermiques. La probabilité de la photodissociation en CH_3 ($\tilde{X}^2A_2''$) + H, qui aurait laissé à l'atome d'hydrogène une énergie cinétique importante, est ainsi relativement faible, en accord avec les travaux théoriques de Lindholm (14).

Les résultats obtenus par cette méthode pour H_2O et CH_4 sont portés dans le tableau 1.

Données spectrales et thermodynamiques concernant la molécule d'ammoniac

Le spectre de l'ammoniac a été étudié par de nombreux auteurs (15–21). Il se compose principalement d'un continuum et de séries de bandes. Le premier continuum s'étend de 220 à 160 nm avec un maximum vers 187 nm. Les bandes ont été étudiées par Duncan pour NH_3 (18) et pour NH_2D, NHD_2, et ND_3 (19); il a mis en évidence quatre progressions dans le spectre de NH_3: 1ère de 168 à 217 nm; 2ème de 139 à 167 nm; 3ème de 122 à 144 nm; 4ème de 116 à 121 nm.

Les bandes de la première série sont diffuses, les trois autres, par contre, sont fines. L'étude approfondie de Douglas (22) révèle une prédissociation importante du premier état $\tilde{A}^1A_2$. Pour ND_3 l'état $\tilde{A}^1A_2$ possède une structure fine, ce qui le différencie de NH_3.

Les données thermodynamiques concernant la molécule d'ammoniac dans le domaine spectral considéré ont été récapitulées par Okabe et Lenzi (5); le tableau 2 est tiré de la référence (5) mais les seuils d'énergie correspondant aux réactions 2 et 8 ont été corrigés d'après les données de Stedman (23) relatives à la différence d'énergie entre les états X ($^3\Sigma^-$) et a ($^1\Delta$) de NH.

Conditions expérimentales

L'ammoniac de pureté 99.96%, l'hydrogène de pureté 99.995%, le deutérium de pureté 99.4% proviennent d'Air Liquide. L'ammoniac perdeutérié est un produit Merck, Sharp, and Dohm. Tous ces gaz ont été utilisés sans purification préalable. Le système d'irradiation lumineuse a été décrit précédemment (7). La cellule d'irradiation qui contient les mélanges $NH_3 + D_2$ et $ND_3 + H_2$ de concentrations connues, est un cylindre de pyrex de 160 cm^3 de volume, de 4 cm de diamètre recouvert intérieurement d'une couche d'or brillant de provenance Degussa 46 E/10%; elle est séparée du système d'irradiation par une fenêtre de fluorure de lithium Harshaw clivée.

Les pressions d'ammoniac ont varié entre 10 et 40

[8]	$\rightarrow NH$	$(a^1\Delta) + H + H$	9.07	126.7

*Les réactions 0, 5, 8 sont interdites par les règles de corrélation.

Torrs; celles de deutérium ou d'hydrogène entre 10 et 400 Torrs.

Les mesures de pression sont effectuées à l'aide d'une jauge de pression absolue à capsule AEI. Le rapport des concentrations des deux hydrogènes isotopiques H_2/HD (ou D_2/HD) formés par irradiation à la température ambiante dans un mélange de composition connue, est mesuré à l'aide d'un spectromètre de masse Thomson-Houston THN 205 (7–8). Dans le cas des irradiations de ND_3, la cellule était conditionnée pendant plusieurs jours afin d'éviter les échanges spontanés aux parois.

Resultats expérimentaux

Les résultats obtenus avec NH_3 et ND_3 sont portés dans le tableau 1, avec ceux obtenus précédemment pour l'eau et le méthane. A titre indicatif, on a calculé l'énergie cinétique maximum susceptible d'être emportée par l'atome d'hydrogène si, pour chaque type de dissociation, toute l'énergie excédentaire est transformée en énergie cinétique des fragments. Lorsque plusieurs modes de dissociation sont possibles, l'énergie cinétique de H peut avoir plusieurs valeurs pour une énergie photonique donnée; en conséquence on trouve dans certains cas plusieurs valeurs de l'énergie cinétique des atomes H.

On a porté sur la fig. 1 toutes les valeurs expérimentales de R dont on dispose en fonction de l'énergie cinétique maximum des atomes d'hydrogène. Si on veut bien considérer la courbe tracée comme un simple repère, on peut conclure qu'à 185 nm la production d'atomes d'hydrogène n'a lieu que selon la dissociation (1); qu'à 147 nm la production d'atomes d'hydrogène a lieu en grande partie selon la réaction 6, tandis qu'à 123.6 nm, les réactions 6 et 3 ont des probabilités vraisemblablement voisines.

Si on porte les diverses valeurs de T_λ calculées

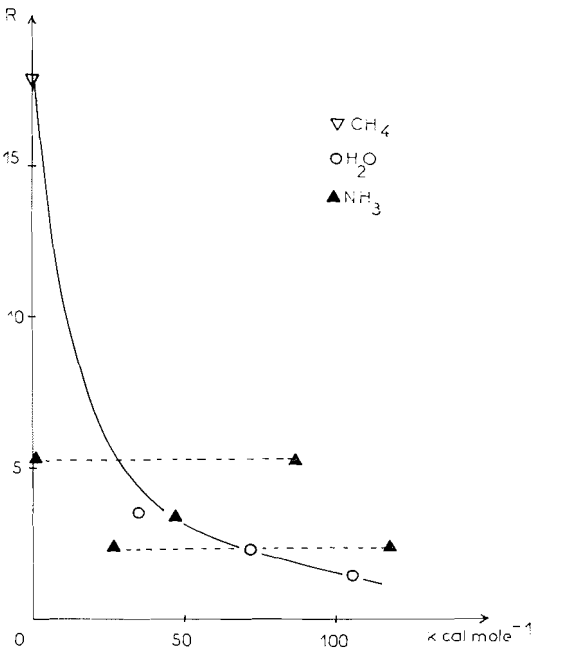

FIG. 1. Variation du rapport $R = k_{D+H_2}/k_{H+D_2}$ en fonction de l'énergie cinétique maximum des atomes d'hydrogène pour CH_4, H_2O, et NH_3.

pour NH_3 et ND_3 à partir des rapports A/A' dans les rapports B/B' on obtient: $E^*_{D+ND_3} - E^*_{H+NH_3} = 800 \pm 300$ cal/mol^{-1}. Cette valeur est en accord raisonnable avec la différence d'énergie de zéro des deux molécules, vraisemblablement comprise entre 500 et 1000 cal.

A partir de la constante de vitesse k_{H+NH_3} mesurée par Oganesyan et Nalbadayan (24):

$$k_{H+NH_3} = 5 \times 10^{13} \exp(-13610/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

et en admettant un rapport de 1.35 pour les

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

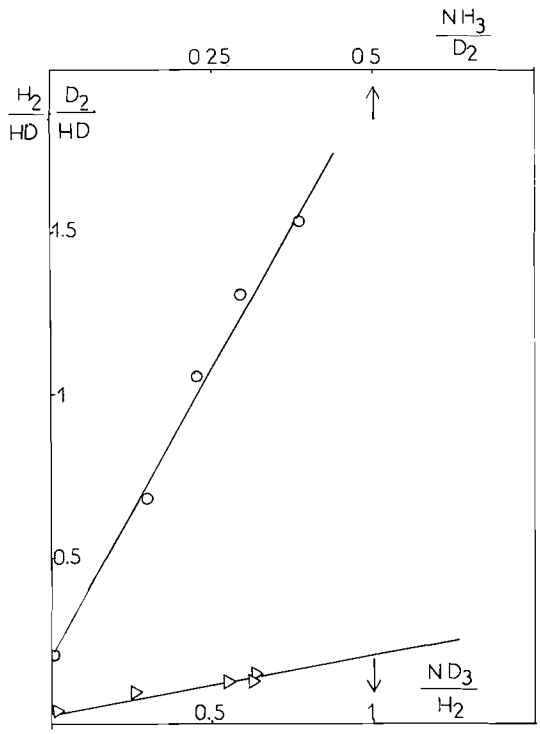

FIG. 2. Photolyse des mélanges $NH_3 + D_2$ et $ND_3 + H_2$ à 147 nm: ○, NH_3 6.4×10^{17} cm^3 mol^{-1}; △, ND_3 4.8×10^{17} cm^3 mol^{-1}.

facteurs préexponentiels, on obtient donc

$$k_{D+ND_3} = 3.5 \times 10^{13} \exp(-14\,400/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

A titre d'exemple, les résultats expérimentaux obtenus par photolyse de $NH_3 + D_2$ et de $ND_3 + H_2$ à 147 nm sont portés sur la fig. 2.

Discussion

L'examen des résultats de la photolyse de l'ammoniac et de l'ammoniac perdeutérié permet les remarques suivantes:

(1) A 185 nm

Seuls les processus 1, 2, 3, 4 sont possibles énergétiquement. On trouve $\phi_{H_2}/\phi_H = \phi_{D_2}/\phi_D = 0.04$; par conséquent, les processus 2 et 4 n'interviennent que très faiblement dans la décomposition. Dans le permier continuum Schurath, Tiedman, et Schindler (1) à 204.2 nm et Mc Nesby, Tanaka et Okabe (2) à 185 nm n'ont pas mis en évidence la formation d'hydrogène moléculaire; les rendements trouvés ici n'étant que de 4%, nos résultats ne sont pas incompatibles avec ceux des auteurs précédents.

L'émission de NH_2 ($\tilde{A}^2A_1 \rightarrow \tilde{X}^2B_1$) n'a été observée par Okabe et Lenzi que pour $\lambda \leqslant 164$ nm. A 185 nm, NH_2 est donc formé dans son état fondamental et la réaction 1 rend compte de la quasi totalité de la photodissociation. Le premier continuum $\tilde{A}^1A_2''$ peut donc être corrélé totalement ou presque totalement aux fragments NH_2 ($\tilde{X}^2B_1$) + H aussi bien dans le cas de NH_3 que dans le cas de ND_3, malgré l'aspect différent des spectres de ces deux molécules.

Puisque tous les atomes d'hydrogène proviennent de la dissociation 1, on peut évaluer à 47.5 kcal l'énergie maximale que possèderait ces atomes si toute l'énergie était transformée en énergie cinétique. Il est assez vraisemblable en conséquence que le radical NH_2 ($\tilde{X}^2B_1$) formé par ce processus n'a pas une énergie interne considérable.

(2) A 147 nm

Le rendement quantique en NH_2 ($\tilde{A}^2A_1$) a été estimé par Okabe et Lenzi (5) dans cette région spectrale à moins de 10^{-3}. De plus, Bayes, Becker, et Welge (6) observent NH ($X^3\Sigma^-$) produit par photolyse éclair de NH_3 dès $\lambda < 155$ nm et considèrent que NH ($X^3\Sigma^-$) est un produit primaire de la photolyse. Nous observons $T_{147} < T_{185}$, ce qui conduit à attribuer aux atomes d'hydrogène formés à 147 nm une énergie cinétique moyenne inférieure à celle qu'ils acquièrent à 185 nm. Deux interprétations peuvent rendre compte de cet ensemble de résultats: la dissociation 6 a lieu directement en trois fragments ou la formation de NH passe par une prédissociation de $NH_2(\tilde{A}^2A_1)$ en NH ($X^3\Sigma^-$) + H.

On observe un effet isotopique important ($\phi_{H_2}/\phi_H = 0.4$; $\phi_{D_2}/\phi_D = 0.06$). Si la dissociation 6 a lieu, l'effet observé serait dû au fait que NH_3 et ND_3 seraient portés par le rayonnement de 147 nm dans des états vibroniques différents. Si NH_2 ($\tilde{A}^2A_1$) est prédissocié, sa section efficace de prédissociation serait inférieure à celle de ND_2 ($\tilde{A}^2A_1$).

L'observation de la dissociation 6 (directe ou par prédissociation) à 147 nm implique pour l'énergie de liaison D_{NH-H} une valeur inférieure ou égale à 90 kcal/mol, en meilleur accord avec la détermination d'Altshuler (25) de 88 ± 4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

kcal/mol qu'avec une valeur plus récente donnée par Clyne et Thrush (26) de 95 ± 4 kcal/mol.

(3) A 123.6 nm

On obtient $T_{123.6} > T_{185} > T_{147}$; il s'ensuit que l'énergie cinétique des atomes H est plus élevée qu'aux autres longueurs d'onde. Ceci s'explique par l'absence de nouvelles vallées dissociatives susceptibles de former des atomes H.

Par ailleurs, outre un important effet isotopique, on note une augmentation du rapport ϕ_{H_2}/ϕ_H par rapport aux valeurs obtenues aux autres longueurs d'onde. Ceci peut correspondre à l'intervention de la réaction 7 en accord avec l'observation (3–5) de l'émission de NH $c^1\Pi \rightarrow a^1\Delta$. D'après Duncan l'absorption à 123.6 nm porte NH_3 (18) dans un niveau vibronique discret de la troisième série de bandes, tandis que ND_3 (19) est porté dans une zone diffuse. L'effet isotopique observé s'expliquerait par une prédissociation de ND_3 (et non de NH_3) conduisant aux réactions 1, 3 ou 6. Comme dans le cas précédent, l'effet isotopique peut aussi s'expliquer par une section efficace de prédissociation plus grande pour ND_2 ($\tilde{A}^2A_1$) que pour NH_2 ($\tilde{A}^2A_1$).

The Crystal and Molecular Structure of Penta-*p*-tolylantimony, $(p\text{-}CH_3C_6H_4)_5Sb$

C. BRABANT, J. HUBERT, AND A. L. BEAUCHAMP

Department of Chemistry, University of Montreal, Montreal, Quebec

Received March 12, 1973

Penta-*p*-tolylantimony crystals are monoclinic, space group $P2_1/c$, with a = 14.545(5), b = 4(6), c = 19.754(8) Å, β = 122.88(4)°, and Z = 4. The structure was solved by the standard heavy-atom method and anisotropic refinement on 1677 independent observed reflections led to a conventional R factor of 0.051. Unlike pentaphenylantimony, which is known to exist as square pyramidal molecules in the crystal, the corresponding penta-*p*-tolyl derivative exhibits the more common trigonal bipyramid structure. The Sb—C equatorial bond length average, 2.16 Å, is significantly shorter than the axial average, 2.26Å. Two of the C—Sb—C bond angles in the equatorial plane (113, 130°) differ considerably from 120°, but the other angles around antimony are normal. Packing forces appear to play a determining role in the structures observed for penta-aryl derivatives of antimony in the solid state.

Le penta-*p*-tolylantimoine cristallise dans le groupe monoclinique $P2_1/c$, a = 14.545(5), b = 12.134(6), c = 19.754(8) Å, β = 122.88(4)°, et Z = 4. L'affinement effectué sur 1677 réflexions observées indépendantes a conduit à un facteur résiduel R de 0.051. Contrairement au pentaphénylantimoine, dont la structure pyramidale carrée est connue, le dérivé penta-*p*-tolyl possède la structure d'une bipyramide triangulaire. La longueur moyenne des liaisons Sb—C équatoriales (2.16 Å) est significativement plus courte que celle des liaisons axiales (2.26 Å). On observe des écarts importants à la valeur prévue de 120° pour deux des angles C—Sb—C du plan équatorial (113 et 130°). Tous les autres angles impliquant l'antimoine sont normaux. Les interactions intermoléculaires dans le cristal jouent vraisemblablement un rôle déterminant dans la structure qu'adoptent les dérivés penta-arylés de l'antimoine à l'état solide.

Can. J. Chem., **51**, 2952 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It is known from X-ray work that in the solid state, $(C_6H_5)_5P$ and $(C_6H_5)_5As$ have the trigonal bipyramid structure (1), whereas $(C_6H_5)_5Sb$ exists as distorted square pyramidal molecules (2). This structure of pentaphenylantimony has recently been confirmed from three-dimensional X-ray data (3) and the pattern of Sb—C bond lengths (4 long, 1 short) observed in the latter study favors the view that the molecule is basically square pyramidal.

In order to determine the role played by intermolecular forces in this compound, a crystallographic study of some penta-aryl antimony compounds was undertaken. Penta-*p*-tolylantimony $(p\text{-}CH_3C_6H_4)_5Sb$ was selected first. It was felt that additional methyl groups on the rings would have little electronic effect on antimony, but would necessarily lead to a completely different molecular packing in the crystal.

Experimental Section

Crystal data

$C_{35}H_{35}Sb$ f.w. = 577.42

Monoclinic, $P2_1/c$, a = 14.545(5), b = 12.134(6), c = 19.754(8) Å, β = 122.88(4)°, V = 2927.8 Å^3, ρ_m = 1.30(1) g cm^{-3} (flotation in aqueous KI solution), Z = 4, ρ_c = 1.310 g cm^{-3}, t = 22 °C. λMoK$\bar{\alpha}$ = 0.71068 Å, λMoKβ = 0.63225 Å, μMoKα = 9.3 cm^{-1}.

Preparation

The starting stibine $(p\text{-}CH_3C_6H_4)_3Sb$ was obtained by reaction of $SbCl_3$ with $p\text{-}CH_3C_6H_4MgBr$ (4). It was dissolved in petroleum ether and converted to $(p\text{-}CH_3C_6H_4)_3SbCl_2$ by bubbling chlorine gas into the solution. Finally, the dichloride was reacted with an excess of $p\text{-}CH_3C_6H_4Li$ in ether, as described by Wittig and Clauss (5). The compound $(p\text{-}CH_3C_6H_4)_5Sb$ was isolated as a white powder and recrystallized from *n*-hexane (m.p. 189°).

The colorless crystals obtained from *n*-hexane are general parallelepipeds elongated along the *b* axis. The crystals, mounted on glass fibers, were left exposed to the atmosphere throughout this work. They are not affected by air, but decompose slowly in the X-ray beam.

Crystallographic Measurements

The cell parameters reported above with their e.s.d.'s were calculated by refinement (6) of the 2θ, ω, and χ angles for 12 independent MoKβ peaks centered on a Picker FACS-1 automatic diffractometer.

A fresh crystal with dimensions 0.10 × 0.37 × 0.15 mm^3 was used for data collection. A total of 4191 measurements within a sphere $2\theta \leqslant 45°$ were collected using Zr-filtered MoK$\bar{\alpha}$ radiation. The θ/2θ scan technique was used at a scan rate of 1°(2θ)/min. A scan range of 1.5° was selected and increased with 2θ to allow for the $\alpha_1\alpha_2$ doublet separation. Background counts B_1 and B_2 of 20 s were taken at each limit of the scan range. The three standard reflections all fell to 36% of their initial intensity during data collection.

The net intensities I were obtained from $I = P - T(B_1 + B_2)/40$, where T is the total scan time and P is the

For personal use only.

total scan count. A measurement was considered as statistically significant when $I \geqslant 300$ counts and $\geqslant 10\%$ of the total background count. By these criteria, approximately 2000 measurements (including the systematically absent reflections and most of the measurements in the 35–45° 2θ range) were rejected. After averaging the equivalent measurements, 1677 independent observed reflections remained. Absorption corrections based on the equations of the crystal faces was applied (NRC-3 program) and the data were finally corrected for the Lorentz and polarization effects.

Refinement

The scattering factors for carbon and antimony were those of Cromer and Waber (7); for hydrogen, those of Mason and Robertson (8) were used. The anomalous dispersion terms $\Delta f'$ (−0.75) and $\Delta f''$ (1.86) of antimony (7) were included in the calculations.

The structure was solved by the conventional heavy-atom method and refined by full-matrix least squares. The position of antimony was obvious from the three-dimensional Patterson map. Refinement of the coordinates and isotropic temperature factors of antimony led to $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.27$. A difference Fourier map phased on antimony revealed the positions of the 35 carbon atoms. The coordinates and isotropic temperature factors of the 36 non-hydrogen atoms converged to $R = 0.086$. At this point, anisotropic temperature factors were defined for each atom. Individual weights $w = 1/\sigma_F^2$ based on counting statistics (9) were applied. The resulting distribution of $w|\Delta F|^2$ *vs.* $|F_o|$ showed that the weights were too large for strong reflections and too small for weak ones. Subsequently, the weights for medium reflections were left unchanged, but those assigned to the remaining reflections were calculated from $w = 1/\sigma_F^2$ $(1 + 0.77(|F_o| - 15.6))$ for $|F_o| > 15.6$ or $w = 1/\sigma_F^2$ $(1 - 0.13\ (10.5 - |F_o|))$ for $|F_o| < 10.5$. The constants in the equations were adjusted to make the distribution of $w|\Delta F|^2$ practically constant with respect to $|F_o|$. A slight increase remained as a function of $\sin\theta/\lambda$.

The hydrogen atoms of the rings were fixed at the calculated positions (C—H distance of 1.08 Å) and assigned isotropic temperature factors of 6. The hydrogen parameters were not refined in subsequent cycles, but they were given the same shifts as the corresponding carbon atoms. Refinement of the coordinates and anisotropic temperature factors of the 36 non-hydrogen atoms converged to $R = 0.051$ and $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2\}^{1/2} = 0.054$. The final difference Fourier map did not show peaks higher than ± 0.4 e/Å^3. The surrounding of the methyl carbon atoms was carefully searched, but no hydrogens were found.

In addition to the conventional independent atom treatment described above, the structure was also refined with the six-membered rings defined as idealized hexagons (C—C distance fixed at 1.397 Å), according to the method described previously (3). For each carbon ring, the x, y, and z coordinates of the center, the three angles describing the orientation of the hexagon, and the six isotropic temperature factors of the carbon atoms were refined. Antimony and the methyl carbon atoms were treated as independent atoms and refined anisotropically. This treatment resulted in $R = 0.058$ and $R_w = 0.063$, a value slightly higher than for the independent atom model. On the basis of the Hamilton test (10), the independent atom model should be preferred, but the use of the idealized model to describe librating aromatic rings has already been justified (3).

The results reported here were those obtained with the independent atom model, except for the Sb—C bond lengths and angles, for which the values obtained with both models are given. The calculations were carried out with a CDC 6600 computer and the programs used are described elsewhere (3, 11)[1].

Results and Discussion

The atom parameters derived from the independent atom model are listed in Table 1. The carbon atoms are identified with labels of the type C(ij), where i is the ring number and j corresponds to sequential numbering of the ring vertices with $j = 1$ for the atom bound to antimony. Index $j = 7$ refers to the methyl group. Hydrogen atoms are referred to with the same pair of indices as the carbon atom to which they are attached.

Description of the Structure

The penta-*p*-tolylantimony molecule is shown in Fig. 1. The bond lengths and angles involving antimony are given in Table 2. Unlike pentaphenylantimony, the *p*-tolyl compound is trigonal bipyramidal. Rings 1 and 2 are axial, while rings 3, 4, and 5 occupy the equatorial positions. As usual, the axial Sb—C bonds are significantly longer (2.24–2.29 Å) than the equatorial (2.15–2.18 Å). The C(11)—Sb—C(21) segment is practically linear (177–178°), and the C_{ax}—Sb—C_{eq} angles are all in the 87–92° range. The equatorial Sb—C bonds are coplanar within experimental errors, but considerable departure from 120° is observed for two of the angles. The C(31)—Sb—C(51) angle is normal (117°), but the small C(31)—Sb—C(41) (113°) and the large C(41)—Sb—C(51) (130°) angles suggest a displacement of ring 4 towards ring 3. In spite of some distortion, a description of the molecule in terms of a trigonal bipyramid is fully justified.

The geometry of the *p*-tolyl groups is normal. The bond lengths and angles in the rings average 1.39 Å and 120° respectively.[1] The C(i4)—C(i7) distances involving methyl carbon atoms (1.54–1.60 Å) are all larger than normal, possibly due to neglect of hydrogen atoms. The six-membered rings are planar within 0.03 Å and the maximum distance of a methyl carbon atom from its ring

[1]The structure factor table and the list of bond lengths and angles in the tolyl rings are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

plane is 0.09 Å. For antimony, the distances to the same planes (0.10–0.14 Å) are of the same magnitude as observed in pentaphenylantimony (3), except for ring 2, where the distance is 0.27 Å. This corresponds to a relatively large angle of 6.7° between the Sb—C(21) bond and the plane of ring 2. This deformation will be discussed below.

Molecular Packing

All the intramolecular contacts are larger than the sum of the van der Waals radii (12). The shortest intermolecular contacts are listed in Table 3.

The strongest interaction (full line, Fig. 2) involves axial type 1 rings belonging to neighboring molecules. Values considerably less than normal are found for C(31)—C′(31) (3.25 Å) and for H(13)—C′(13) (or H′(13)—C(13)) (2.78 Å). Nevertheless, these short contacts do not result in any obvious distortions.

Some other intermolecular distances are less, though only slightly, than the sum of the van der Waals radii. For example, H′(32) and H′(33) on one molecule interact with several carbon atoms of ring 4 on another molecule (dotted line, Fig. 2). From their relative orientations, one would expect ring 3 and/or ring 4 to be displaced from the equatorial plane, but this is not the case.

There is little doubt that the abnormal C—Sb—C angles in the equatorial plane are the result of packing effects. A careful survey of the region between ring 4 and ring 5, where strain is expected, shows (Fig. 2) that the space is filled by ring 2′ from a centrosymmetrically related molecule. However, the H(43)—C′(25) contacts

(dashed lines) are normal (2.98 Å), although they would certainly become abnormally short if ring 4 were displaced towards ring 5 to restore the normal C(41)—Sb—C(51) angle of 120°.

In connection with the 10° distortion in the equatorial plane, a 7.6° angle is found between the Sb—C′(21) bond and the plane through ring 2′. This ring seems to be tilted in a suitable direction to avoid the approach of H(43) and H(42). The reason that steric strain shows up as bending at C′(21) appears to be the presence of H′(36) which would oppose any displacement of C′(21) in its own direction.

Structure of R_5Sb Molecules

Although by no means abundant, some structural information is now available on penta-organo derivatives of antimony. For instance, square pyramidal molecules are known to exist in crystals of pentaphenylantimony (2, 3) and it was concluded from the vibrational spectra (13) that the same structure is maintained in CH_2Cl_2 and CH_2Br_2 solutions. In the case of pentacyclopropylantimony, the vibrational spectra were also interpreted in terms of square pyramidal

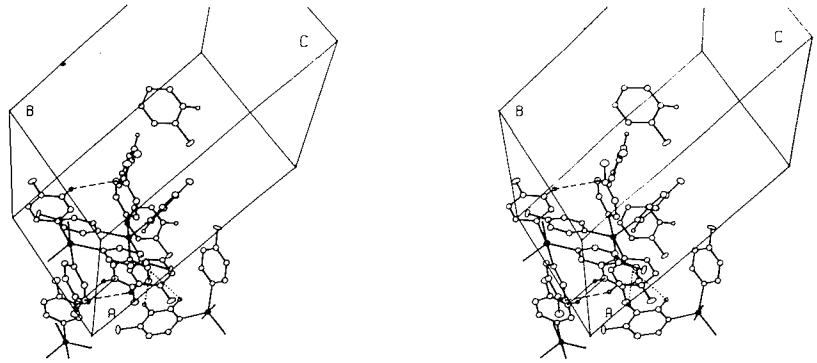

FIG. 2. Packing diagram for penta-*p*-tolylantimony. The antimony atoms are represented by dark spheres. The hydrogen atoms have been omitted, except for those discussed in the text. The complete molecule in the center of the diagram has the same orientation as in Fig. 1 and the rings can be identified by comparison.

molecules (14). On the other hand, a trigonal bipyramid structure has been established by infrared spectroscopy for pentamethylantimony (15) and by X-ray diffraction for phenylbis-2,2′-biphenyl-enylantimony (16) and penta-*p*-tolylantimony. Furthermore, preliminary results obtained in this laboratory on $(C_6H_5)_5Sb\cdot\frac{1}{2}C_6H_{12}$ indicate that the pentaphenylantimony molecule *in this crystal* has a trigonal bipyramid structure with virtually no distortion. Therefore, two examples of square pyramidal compounds are known, whereas a trigonal bipyramid structure has been observed in four cases. This suggests that antimony, like phosphorus and arsenic, shows a certain preference for a trigonal bipyramid structure, even in its organic derivatives.

Five-coordinate molecules frequently exhibit stereochemical non-rigidity and the intramolecular exchange of axial and equatorial positions in phosphorus compounds has been thoroughly investigated (17). Less is known on antimony compounds, but the room temperature n.m.r. spectrum of penta-*p*-tolylantimony in CS_2 has been interpreted in terms of trigonal bipyramid molecules undergoing fast intramolecular exchange (18). We have recorded the n.m.r. spectrum down to -100 °C in the same solvent and found that the exchange is fast even at that temperature.

In agreement with the above evidence for a low energy barrier in the exchange process, the crystal structures of $(C_6H_5)_5Sb$ and $(p\text{-}CH_3C_6H_4)_5Sb$ afford indications for highly flexible molecules. For example, in the *p*-tolyl derivative, two equatorial C—Sb—C angles show large (10°) distortions. In the case of pentaphenylantimony, departure from trigonal bipyramid geometry is so large that the resulting molecule must be considered as a distorted square pyramid. If extra energy is needed to stabilize the "distorted" structures in the crystals, it must be supplied by intermolecular interactions. The penta-aryl compounds discussed here are so similar in weight, size, bond polarity, chemical properties, etc., that the crystals are not expected to differ considerably in packing energy. Therefore, although the ground state structure of penta-arylantimony molecules appears to be the trigonal bipyramid, we may reasonably assume that the square pyramid or any similar structure would not be considerably higher in energy. This would explain that relatively small variations in packing energy result in important structural change.

We wish to thank the National Research Council of Canada for a research grant and scholarships.

Pseudo-thermodynamic Parameters and Isotope Effects for Hydrolysis of a Series of Benzyl Chlorides in Water

K. M. KOSHY, R. E. ROBERTSON, AND W. M. J. STRACHAN
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received February 12, 1973

The temperature coefficient of the enthalpy of activation ($\Delta C_p^{\ddagger}$) for the hydrolysis of *p*-methyl, *p*-chloro and *p*-nitro benzyl chlorides have been determined, as well as α-deuterium isotope effects and kinetic solvent isotope effects. These results are discussed in terms of probable mechanism of hydrolysis in water.

On a déterminé le coefficient de température de l'enthalpie d'activation ($\Delta C_p^{\ddagger}$) lors de l'hydrolyse des chlorures de *p*-méthyl, *p*-chloro et *p*-nitro benzyle. De même, les effets isotopiques de l'α-deutérium et les effets isotopiques du solvant, d'ordre cinétique, ont été déterminés. On discute de ces résultats en fonction d'un mécanisme possible de l'hydrolyse dans l'eau. [Traduit par le journal]

The extensive work on the effect of substitution on the rate of solvolysis in the benzyl series has been adequately summarized by several authors (1–7). A recurrent observation has been that the rates resulting from *p*-substitution through a series of such compounds fail to give a linear Hammett correlation (8–11). This less usual consequence of substitution has been attributed variously to a change in mechanism, mixed mechanism, or to the possible involvement of varying degrees of nucleophilic interaction, the weight of evidence appearing to favor the latter possibility (3, 6, 12). This would imply corresponding changes in charge development in the transition state. We were interested in correlating such changes with possible changes in the heat capacity of activation ($\Delta C_p^{\ddagger}$) and other indicators of mechanistic differences for hydrolysis of a series of *p*-substituted benzyl chlorides in water. No previous work of this kind existed save for the unsubstituted member (13) and some extrapolated data from work in alcohol-water mixtures by Hyne and co-workers (7).

In such a series *p*-methoxybenzyl chloride probably reacts by a limiting mechanism in water but the reaction is too fast to be studied by our methods. It is less certain that the *p*-methyl member approximates to a limiting mechanism though support for either possibility can be found. The other members were expected to provide examples of S_N2 behavior but the exact differentiation in terms of $\Delta C_p^{\ddagger}$-values and the α-deuterium isotope effect could only be guessed at.

Experimental

The kinetic rate data given here were obtained with the same equipment used in previous studies reported from this laboratory (14).

The *p*-methylbenzyl chloride was obtained after the lithium aluminum hydride reduction of the ethyl ester of a purified sample of toluic acid. Preliminary kinetic studies with reagent grade *p*-methylbenzyl chloride even after distillation, proved unsatisfactory. Fractional distillation of the product obtained from the reduced ester by treatment with $SOCl_2$ gave a pure compound as found by g.l.c.: b.p., 48° (1 mm), n.m.r.$_{TMS}^{CCl4}$ δ 7.15 (m,4,aryl), 4.45(s,2,methylene), 2.32(s,3,methyl). On hydrolysis this compound gave strictly first order rates. The corresponding α-deuterated compound was obtained by the same method but using lithium aluminum deuteride as the reducing agent.

p-Chlorobenzyl chloride, practical grade, was fractionally distilled through a glass bead column. The middle one-third was collected, b.p. 99–99.5 °C at 12 mm. *p*-Nitrobenzyl chloride, reagent grade, was recrystallized from petroleum ether, absolute ethanol, and dried in a vacuum pistol at 2 mm pressure, m.p. 72.5–73 °C.

In the kinetic studies, doubly distilled water or heavy water (better than 99.75% D_2O) was adjusted with KCl

to give a specific conductance of approximately 10^{-5} ohm^{-1} cm^{-1}. The solvent was degassed and 25–30 ml were added to each of four Queen-type stirred conductivity cells (15) (cell constants *ca.* 0.3). These, plus an additional 20 ml of the degassed solvent were placed in a stable thermostat. At each temperature, the substrate with the exception of *p*-nitrobenzyl chloride, was added from a Hamilton microsyringe (2–3 μl) to the 20 ml of solvent and 2–3 ml of the resulting solution was added to each of the cells yielding a reaction solution of approximately 10^{-4} *M* in substrate. In the case of *p*-nitrobenzyl chloride, the sample was added to the solvent as *ca.* 10 mg of a 3:1 Kieselguhr–chloride mixture (to aid rapid solution), and, after vigorous shaking, 2–3 ml of the solution filtered under nitrogen pressure directly into the stirred cells. Conductivity–time measurements obtained on the Auto-RAM and their computational treatment have been described elsewhere (14). Temperature control was maintained in the thermostats by Tronac controllers to ±0.005 °C or better and temperature measurements were made with a platinum resistance thermometer.

Results and Discussion

The kinetic rate constants so determined are recorded in Tables 1 to 3. The specific rate constant of hydrolysis for *p*-bromobenzyl chloride at 62.07 °C was 38.7 ± 0.3 × 10^{-5} s^{-1}. Since there was no reason to suspect that the $\Delta C_p^{\ddagger}$ value for this substituent would differ significantly from the *p*-chloro analogue, no extensive study was undertaken. The temperature dependence of the rate was expressed in the usual fashion by an empirical equation of the form $\log_{10} k = A_1 + A_2/T + A_3 \log_{10} T$ and values of the constants, A_1, A_2, and A_3 are given in Table 4. By applying transition state considerations, values of $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ can be derived. These values are collected in Table 5. Since the value of $\Delta C_p^{\ddagger}$ for *t*-butyl chloride hydrolyzing in water is about the same as the value found for the *p*-methylbenzyl chloride under similar conditions, it is easy to argue that the degree of charge development is similar and from this approximation draw mechanistic conclusions.

This is probably valid. For these weakly polar and relatively insoluble halides the uncertainties relating to differences in initial state solvation are probably small compared to the much larger differences relating to charge development and separation, at the transition state. Thus the fact

that $\Delta C_p^{\neq}$ values for the *p*-methylbenzyl and *t*-butyl chlorides are about the same points to a similarity in solvent reorganization. The fact that adamantyl nitrate (16) has a much larger temperature coefficient of $\Delta H^{\neq}$ probably indicates that none of the above halides hydrolyse in water by a limiting mechanism. That they tend to this limit is acceptable, but how close to the limit is difficult to estimate on the basis of $\Delta C_p^{\neq}$ values as a mechanistic criterion. In both the above examples, the ion-pair mechanism may be acceptable (17). By the same reasoning, it is doubtful whether the degree of charge development indicated by our $\Delta C_p^{\neq}$ values would justify a similar conclusion for the other members reported in Table 5, unless the term "ion-pair" is to include every degree of charge development. For example, the $\Delta C_p^{\neq}$ value calculated for the benzyl *p*-Cl and *p*-NO_2 compounds are seen to be of about the same magnitude as that found for the hydrolysis of other primary halides. In contrast to an earlier implication (17), Sneen now appears to accept such a broadening of the term "ion-pair intermediate" (18). When that term is taken to include any "extended covalent bond" it is, in our view, equivalent to saying that only activated molecules react. If such an all inclusive definition is needed, then the hypothesis has little additional value as a practical criterion on which to base mechanistic discussions.[1]

Two other sources of information relating to the transition state and thus indirectly to solvent disruption were explored: the kinetic solvent isotope effect and the α-deuterium isotope effect. Rate data for solvolysis in D_2O are summarized in Table 6 and it will be apparent that the value of k_{H_2O}/k_{D_2O} for the *p*-methyl and the *p*-nitro compounds are about the same. Since there is other evidence which suggests that it is unlikely that these two compounds react by the same mechanism, or more correctly, with the same

[1]For other criticism of the original claims see refs. 19–21. In citing these critical appreciations of this proposal, we do not overlook the value of a re-examination and elaboration of mechanistic concepts in S_N reactions.

degree of charge development, this similarity in k_{H_2O}/k_{D_2O} values is not helpful. We may go further and say that in general this rate ratio does not provide a basis for clear mechanistic distinction for S_N reactions in water even though reasonable expectations would seem to require an observable correlation. We have noted previously a failure of this ratio to correlate with values of $\Delta C_p^{\ddagger}$ in the halide series though the systematic differences which are found in the $\Delta C_p^{\ddagger}$ values between the sulfonates and the halides is paralleled by a systematic difference in k_{H_2O}/k_{D_2O} values. However where large differences exist in $\Delta C_p^{\ddagger}$ values in the displacement of halides which on the basis of other evidence point to mechanistic differences, no corresponding differences are found in the k.s.i.e. This failure to respond to mechanistic differences in the halide series has not been explained satisfactorily and we can only guess that because of the complexity of the effects which are incorporated into the ratio there is a compensation of opposed terms. By way of contrast, the α-deuterium isotope effect, though having about the same absolute values as the k.s.i.e. is less complex and can be correlated with the $\Delta C_p^{\ddagger}$ values and with mechanistic shifts.

Rate data for the α-deuterated benzyl chlorides and corresponding isotope effects are summarized in Table 7. Originally it was thought that a k_H/k_D values close to 1.15/D-atom at 25 °C was characteristic of an S_N1 mechanism. With the accumulation of further data it has been found that each leaving group has a characteristic maximum value of k_H/k_D. Thus 1.15 is the maximum for chloride as a leaving group while Br^- and I^- give smaller values. When the leaving group is a fluoride or groups such as tosylate, trifluromethanesulfonate or nitrate (groups which are attached to the α-carbon through an oxygen atom) values markedly higher than 1.15 are observed in the limit (15, 25). If allowance is made for these characteristic differences, the α-deuterium isotope effect can be used as a good indicator of the extent of bond breaking at the transition state. Where bond making is important the effect becomes small and may even be inverse (23). α-Deuterium isotope effects for three benzyl chlorides are compared with corresponding values for three other compounds in Table 7. The value of k_H/k_D for the *p*-methylbenzyl chloride is seen to be much higher than for the other compounds cited and is but slightly less than the postulated limiting value and in accord with the indications derived from the $\Delta C_p^{\ddagger}$ value. Since the k_H/k_D values reflect differences in bond breaking, solvolysis in other solvents would be expected to alter this ratio. This inference is illustrated by a comparison of our data (24) and that due to Shiner (25) (Table 8). A conclusion to be drawn from this comparison is that since k_H/k_D for the *p*-methyl compound is slightly higher for solvolysis in 70% and 97% trifluroethanol than we found in water, while the value in 50% ethanol is much lower, the mechanism in water for this compound is not limiting. In a strict sense (26) and in the absence of other data to the contrary this would imply an S_N2 mechanism. Further the similarity between the $\Delta C_p^{\ddagger}$ values for the *p*-methylbenzyl chloride and *t*-butyl chloride noted above and the "normal values" obtained for the other members of the series may be taken as strong evidence (27–29) against "mixed kinetics" for hydrolysis of members of this series (3). These conclusions are close to those of Kochi and Hammond for the solvolysis of a series of benzyl tosylates (1) while the more complex hypothesis advanced by Shiner (22) is unnecessary, at least for hydrolysis in water.

Etude du succinate de chrome(II) dihydraté, $[Cr(C_4H_4O_4).H_2O]_2.2H_2O$

PATRICK SHARROCK, THÉOPHILE THÉOPHANIDES, ET FRANÇOIS BRISSE
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 2 avril 1973

Le succinate de chrome(II) dihydraté, $[Cr(II)(C_4H_4O_4).H_2O]_2.2H_2O$ a été synthétisé pour la première fois. Ce sel a été caractérisé par son spectre infrarouge et par diffraction des rayons-X. Il cristallise dans le système triclinique et la maille a pour dimensions: $a = 6.522(10)$, $b = 7.596(3)$, $c = 8.154(4)$ Å, $\alpha = 103.2(1)$, $\beta = 73.4(1)$, et $\gamma = 98.7(1)°$. Il est isostructural du succinate de cuivre(II) dihydraté. Le succinate de chrome(II), rouge, s'oxyde très rapidement à l'air en un produit bleu-vert de composition $Cr(III)(C_4H_4O_4)(OH).H_2O$.

Chromium(II) succinate dihydrate $[Cr(II)(C_4H_4O_4).H_2O]_2.2H_2O$ has been synthesized for the first time. It has been characterized by its infrared spectrum and by X-ray diffraction. The triclinic unit cell has for dimensions: $a = 6.522(10)$, $b = 7.596(3)$, $c = 8.154(4)$ Å, $\alpha = 103.2(1)$, $\beta = 73.4(1)$, and $\gamma = 98.7(1)°$. This salt is isostructural with copper(II) succinate dihydrate. The red chromium(II) succinate is quickly oxidized in air and the blue oxidation product has composition $Cr(III)(C_4H_4O_4)(OH).H_2O$.

Can. J. Chem., 51, 2963 (1973)

Introduction

Les acides carboxyliques forment avec le cuivre des complexes de structures variées dans lesquels le ligand est mono-, bi- ou tridentate (1–5). Parmi tous ces complexes les carboxylates dinucléaires à structure cage ont été les plus étudiés, car pour ces composés il existe une possibilité de liaison métal–métal (6). Cependant, il semble que les structures cage soient imposées aux molécules dinucléaires par la géométrie particulière du groupement carboxylate plutôt que par la présence d'un lien métal–métal. Autrement dit, dans le cas des complexes cuivriques, l'interaction Cu–Cu est la conséquence et non pas le prérequis à la structure cage. Par contre, une étude récente (7) de l'acétate de chrome(II) révèle qu'une liaison multiple métal–métal est possible. En effet, l'acétate de chrome(II) est diamagnétique (8) et la distance Cr–Cr a pour longueur seulement 2.362(1) Å.

Les complexes du cuivre(II) avec les acides α,ω-dicarboxyliques ont aussi été étudiés (9–11). Le succinate de cuivre, à structure cage, est un exemple typique: son moment magnétique de 1.34 MB, à 16 °C, est en dessous de la valeur de 1.73 MB attendue en ne tenant compte que du spin (9). La distance Cu–Cu (12) est de 2.610(1) Å. Comme les acétates de Cu(II) et de Cr(II) sont isostructuraux (13) nous avons recherché si cette similitude se retrouvait entre les sels des acides dicarboxyliques et en particulier entre les succinates de Cu(II) et de Cr(II).

Partie expérimentale

Le succinate de chrome(II) a été synthétisé par une méthode analogue à celle utilisée pour la préparation de l'acétate de chrome(II) (14). Les manipulations ont été faites dans une boîte à gants, sous atmosphère d'azote purifié; les solvants utilisés ont été préalablement purgés à l'azote. On dissout 10 g de $CrCl_3.6H_2O$ (0.0376 mol) dans 30 ml d'eau. On ajoute 10 ml d'une solution aqueuse contenant 0.054 mole d'acide chlorhydrique. A cette solution verte on ajoute 3 g (0.05 mol) de poudre de zinc et on recouvre le bécher d'un verre de montre pour éviter les pertes par projection. Après une demi-heure la solution est devenue bleu-turquoise. Au bout de trois-quarts d'heure la réduction est terminée. La solution est filtrée pour enlever l'excès de poudre de zinc. Le filtrat est recueilli directement dans une solution de 6.5 g (0.0402 mol) de succinate de sodium anhydre dans 20 ml d'eau. Il se forme un précipité abondant de couleur rouge sienne-brûlée. Sept lavages, de 20 ml d'eau chacun, suffisent pour éliminer toutes traces d'ions chlorures de 2 g de précipité. Le produit est finalement lavé trois fois avec du méthanol puis est conservé sous éther pour le protéger des traces résiduelles d'oxygène dans la boîte à gants. Le succinate de chrome(II) s'oxyde très facilement à l'air en un produit bleu-gris.

Seule la forme oxydée du succinate de chrome a été analysée, après avoir été séchée à 100 °C. Le carbone et l'hydrogène ont été dosés par microanalyse élémentaire par Chemalytics Inc., Tempe, Arizona. Le chrome a été dosé par gravimétrie sous forme de chromate de baryum (15).

Les spectres infrarouges ont été enregistrés entre 4000 et 250 cm^{-1} sur un spectrophotomètre Perkin–Elmer 621. Les échantillons ont été broyés et comprimés sous forme de pastilles de bromure de potassium. Dans le cas du succinate de chrome(II) la pastille comprenait deux zones protectrices extérieures en KBr pur.

Tous les films de poudre ont été pris dans une caméra Debye–Scherrer de 114.5 mm de diamètre en utilisant les radiations filtrées du cuivre et du chrome (λ $CuK_{\bar{\alpha}}$ =

1.54178 Å et λ $CrK_{\bar{\alpha}}$ = 2.2909 Å). Les échantillons finement broyés dans la boîte à gants ont été introduits dans des capillaires de Lindemann (0.3 mm de diamètre) et scellés sous azote. Les intensités des raies ont été estimées visuellement.

Résultats et discussion

L'augmentation de poids au cours de l'oxydation du succinate de chrome(II) a été mesurée de la façon suivante: On renferme 2 g de succinate de chrome(II) rouge dans un tube de Schlenk (14) préalablement pesé et on place le tout sur une balance analytique. Dans une première expérience, on entrouvre les deux robinets pour laisser l'air pénétrer lentement dans le tube de Schlenk. On enregistre les changements de poids en fonction du temps. Le gain maximum de poids observé est de 3.99 %.[1] On déduit de cela que le produit de départ est bien le succinate de chrome(II) dihydraté car pour la réaction:

$$2\,[Cr(succinate).2H_2O] + \tfrac{1}{2}O_2 \rightarrow 2\,[Cr(succinate)(OH).H_2O] + H_2O$$

on s'attend à un gain de poids théorique de 3.95 % à condition que la molécule d'eau libérée reste emprisonnée dans le tube de Schlenk. On reprend cette expérience en faisant passer dans le tube de Schlenk un courant d'oxygène bien sec pendant 24 h. On note tout d'abord une augmentation de poids de 3.75%. Par la suite le poids de l'échantillon diminue régulièrement et très lentement. Au bout de 24 h, le poids reste constant. La diminution de poids est de 0.37% du poids initial. Cette baisse de poids s'explique bien par la perte lente d'une molécule d'eau entraînée hors du tube de Schlenk par le courant d'oxygène. En effet, le gain de poids dû à l'oxydation et la perte de poids due à l'élimination d'une molécule d'eau se combinent pour donner une diminution théorique de 0.49%, en accord avec la mesure expérimentale. Dans une troisième expérience on chauffe l'échantillon à 130 °C pendant 12 h. La perte de poids observée, 9.43%, coïncide avec le changement de poids théorique résultant de la perte de trois molécules d'eau, 9.37%.

Les résultats des analyses élémentaires confirment que la composition du succinate de chrome(III), forme oxydée, est bien: $Cr(III)(C_4H_4O_4)(OH).H_2O$.

Anal. calc. pour $CrC_4H_7O_6$: Cr, 25.61; C, 23.60; H, 3.45. Trouvé: Cr, 25.05; C, 23.09; H, 2.56.

Diffraction des rayons-X

Le diagramme de poudre du succinate de chrome(II) a été pris et comparé à celui du succinate de cuivre(II). Les diagrammes des deux succinates sont pratiquement identiques, tant du point de vue de la position des raies que de leurs intensités. Ces deux composés sont donc isostructuraux. Les diagrammes de poudre de ces deux composés ont été indexés par comparaison des distances réticulaires et des intensités observées aux valeurs correspondantes calculées[2] à partir des coordonnées fractionnaires et des facteurs thermiques des atomes et des paramètres de la maille élémentaire du succinate de cuivre(II) publiés par O'Connor et Maslen (12). Les paramètres de maille des succinates de cuivre(II) et de chrome(II) affinés selon la méthode de Cohen (16), sont présentés Tableau 1. En ce qui concerne les dimensions de la maille du succinate de cuivre(II), nos résultats sont en bon accord avec ceux publiés (12). Le volume de la maille du succinate de chrome(II) est légèrement, mais significativement, supérieur à celui du sel de cuivre. Les distances réticulaires et les intensités observées et calculées pour les deux succinates sont présentées Tableau 2. Les intensités du diagramme de poudre du succinate de chrome(II) ont été calculées en conservant les coordonnées atomiques fractionnaires du succinate de cuivre(II) mais en remplaçant l'atome de cuivre par un atome de chrome. Ce calcul des intensités permet de vérifier qu'aucune bande de forte

*Intensités calculées à partir des données de la réf. 12. Voir le texte pour les détails.

intensité n'a été omise de l'indexation. Les distances réticulaires groupées par une accolade étaient trop rapprochées pour être mesurables individuellement.

La distance Cr–Cr, obtenue à partir des coordonnées fractionnaires du succinate de Cu(II) et des dimensions de la maille du sel de Cr(II), est de 2.60 Å. La distance Cr–Cr ainsi calculée n'est pas significativement plus courte que la distance Cu–Cu dans le succinate de Cu(II) et reste bien loin de 2.362 Å observé dans le cas de l'acétate de Cr(II) monohydraté (7).

Pour tenter de confirmer "l'effet métal–métal *trans*" proposé par Cotton (17), les intensités qu'auraient les lignes de diffraction d'un diagramme de poudre de succinate de chrome(II) ont été calculées pour différentes valeurs de la distance Cr–Cr, de 2.60 Å jusqu'à un minimum de 2.36 Å. Seules les six premières raies présentaient des changements notables d'intensités. Ces variations étaient cependant insuffisamment marquées pour permettre un choix, compte tenu de la méthode d'évaluation des intensités observées. Seulement des données tridimensionnelles à partir d'un cristal unique de succinate de chrome(II) permettraient de calculer avec précision la distance Cr–Cr. Nous n'avons malheureusement pas encore réussi à obtenir un tel cristal.

Spectres infrarouges

Les spectres infrarouges de l'acide succinique et de divers succinates sont représentés fig. 1. Les attributions ont déjà été faites pour toutes les

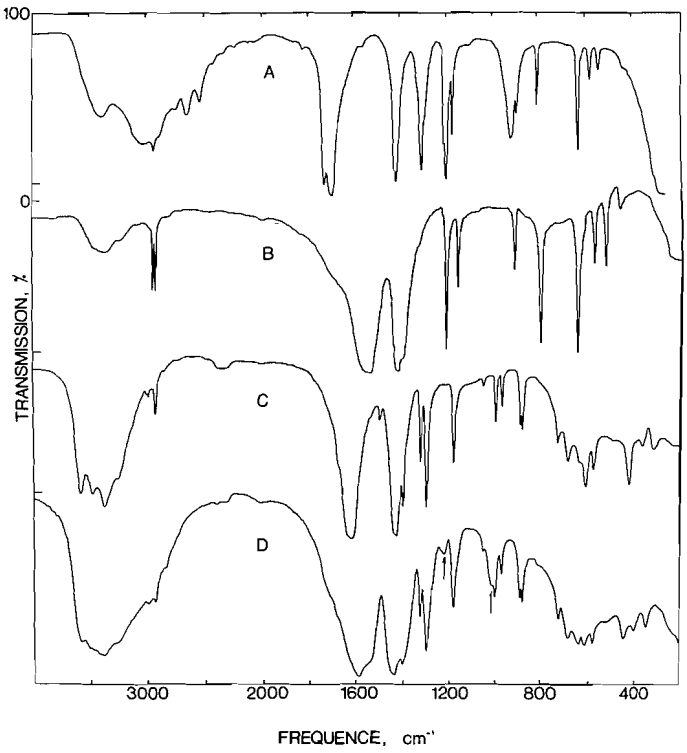

FIG. 1. Spectres infrarouges: *A*, acide succinique; *B*, succinate de sodium; *C*, succinate de cuivre(II) dihydraté; *D*, succinate de chrome(II) dihydraté. Les flèches indiquent des bandes dues à des traces résiduelles de méthanol.

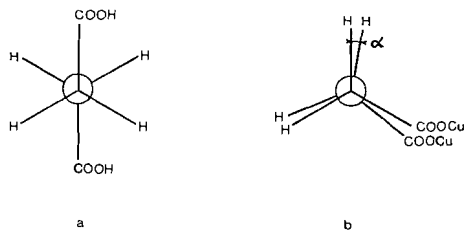

FIG. 2. Représentations de Newman: *a*, forme alternée *trans* dans l'acide succinique; *b*, forme éclipsée *cis* dans le succinate de cuivre(II) dihydraté. L'angle dièdre α est de 4.2°.

bandes observées (18, 19). Les spectres des succinates de cuivre(II) et de chrome(II) sont remarquablement identiques et ceci confirme l'isostructuralisme de ces deux complexes. Les spectres infrarouges des succinates de cuivre(II) et de chrome(II) sont distincts des spectres de la forme alternée *trans* trouvée dans l'acide succinique (18) ou dans les succinates des métaux alcalins (19). Il est reconnu que les différentes fréquences ν_{CH_2} sont sensibles à la conformation des chaînes linéaires (19). La fig. 2 représente les projections de Newman pour l'acide succinique et pour le succinate de cuivre(II); l'angle dièdre α de 4.2° a été calculé à partir des données de la réf. 12. Comme les spectres infrarouges des succinates de cuivre(II) et de chrome(II) sont identiques en dessous de 1400 cm^{-1}, il est raisonnable de conclure que les fréquences observées sont caractéristiques de la forme éclipsée *cis*.

En ce qui concerne la région du carbonyle, la validité de la spectroscopie vibrationnelle dans l'élucidation de la structure des carboxylates a déjà été mise en doute par de nombreux auteurs (20, 21). L'examen de la forme et de la position de la bande ν_{asym} CO seule permettrait de distinguer entre deux types de structures. En effet, les sels alcalins des acides carboxyliques ont une bande assez large vers 1550–1575 cm^{-1} tandis que les complexes à structure cage ont une bande fine à des fréquences généralement plus élevées (21, 22).

Cependant en ce qui concerne le succinate de chrome(II), la bande ν_{asym} CO à 1585 cm^{-1} est relativement large et présente un épaulement.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Une raison probable de cette différence serait due à une légère oxydation de l'échantillon, puisque la bande ν_{asym} CO de la forme oxydée du succinate de chrome coïncide avec l'épaulement observé à 1540 cm^{-1}.

Nous remercions le Conseil National des Recherches du Canada pour l'aide financière apportée à ce travail.

An Investigation into σ and π Contributions to Long Range ^1H–^1H Coupling Constants in Conjugated Dienes and Diynes Using CNDO and INDO Molecular Orbital Calculations[1]

IAN R. PEAT[2] AND WILLIAM F. REYNOLDS[3]

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A1

Received March 29, 1973

Molecular orbital calculations based on finite perturbation theory in the CNDO/2 and INDO approximations are carried out for fourteen conjugated dienes and diynes for which experimental results are available. There is generally very good agreement between experimental and calculated (INDO) coupling constants. Comparison of results of CNDO/2 and INDO calculations elucidates the relative importance of σ and π pathways for the various long-range coupling constants.

Des calculs d'orbitales moléculaires basés sur la théorie des perturbations dans les approximations CNDO/2 et INDO, ont été effectués sur quatorze dièns et diynes conjugués qui peuvent être reliés à des résultats expérimentaux. Dans la majorité des cas, un excellent accord fut noté entre les constantes de couplage (INDO) calculées et expérimentales. La comparaison des résultats obtenus par des calculs CNDO/2 et INDO a permis d'établir l'importance relative des contributions σ et π en ce qui a trait aux différentes constantes de couplage à longue-distance. [Traduit par le journal]

Can. J. Chem., 51, 2968 (1973)

Introduction

Molecular orbital calculations based on finite perturbation theory (1) in the INDO (2) and CNDO/2 (3) approximations have proved to be a powerful method for investigating mechanisms of transmission of long range ^1H–^1H coupling constants and, in particular, for determining the relative importance of σ and π contributions to these coupling constants (4–11).

While there have been a number of experimental investigations of coupling constants in conjugated dienes and diynes (4, 7, 12–21), there have been relatively few theoretical calculations of these coupling constants. Harris and coworkers calculated π contributions to coupling constants in 1,3-butadiene, 1,3-butadiyne, and 1,3,5-hexatriyne by several π molecular orbital methods (22). Bacon and Maciel calculated several of the coupling constants in 1,3-butadiene and a limited number of coupling constants in pentadiene and hexadiene isomers, using INDO finite perturbation calculations (4). They also investigated the effect of neglecting some of the one-center exchange integrals (to separate σ and π effects) and of distorting the molecular framework. Finally, Schaefer *et al.* have used both INDO and CNDO/2 calculations to estimate σ and π contributions to coupling constants in 1-penten-3-yne (7). Consequently it seemed appropriate to carry out a systematic theoretical investigation of coupling constants in conjugated dienes and diynes using CNDO/2 and INDO finite perturbation calculations. The results of this investigation are reported below.

Details of Calculations

CNDO/2 and INDO finite perturbation calculations were carried out using a modified version of the Quantum Chemistry Program Exchange Program 141. The modified program reproduced previously published results for several compounds (1). Standard bond lengths and angles (23) were used for the calculations on linear dienes and diynes. For cyclopentadiene, bond lengths and angles were taken from the microwave structure (24). Calculations were carried out on an IBM 370 computer.

Results and Discussion

Calculations were performed for s-*trans*- (**1***a*) and s-*cis*-1,3-butadiene (**2**), *trans*- and *cis*-1,3-pentadiene (respectively **1***b* and **1***c*) cyclopentadiene (**3**) and its 1-methyl and 2-methyl derivatives (for which experimental results have recently been reported (25)); acetylene and 1,3-butadiyne and their methyl and dimethyl derivatives. Results are summarized in Tables 1 to 3.

3

In cases where Bacon and Maciel (4) had also determined the coupling constants by INDO calculations, there is very close agreement between the two results.

(a) Conjugated Dienes

As a result of the neglect of one-center exchange integrals in the CNDO/2 approximation, these calculations do not predict the contribution from π coupling pathways arising from McConnell's spin polarization mechanism, *i.e.* they only measure σ coupling contributions (23). By comparison, the INDO calculations include one-center exchange integrals and consequently estimate both σ and π contributions. While it is tempting to take J(INDO) − J(CNDO) as a measure of π contributions (7), this is not strictly valid. A comparison of CNDO and INDO calculations of coupling constants in saturated systems (23) demonstrates that σ contributions are not equally estimated by the two methods. It appears that J(INDO) is alternately more positive, then more negative, than J(CNDO) as the number of intervening bonds increases. Consequently J(INDO) − J(CNDO) is not an exact measure of π contributions. However, for small J(CNDO), if J(INDO) − J(CNDO) is significantly different from zero, then this can be attributed to the presence of π contributions.

The results of the CNDO and INDO calculations for the butadienes (see Table 1) are in very good agreement with the available experimental data for these or closely related compounds (12, 16) although there is a persistent tendency to overestimate the magnitudes of the coupling constants. The agreement is generally significantly better than that noted by Harris *et al.* for π electron calculations (22). The calculations wholly support the conclusions of Bothner-By and Harris concerning the relative importance of σ and π contributions for these derivatives (14). For example, the INDO calculations correctly predict the relative magnitudes of the three non-equivalent ^5J values in **1***a*, $^5J_{16}(J_{tt}) > {}^5J_{15} = {}^5J_{26}(J_{ct}) \gtrsim {}^5J_{25}(J_{cc})$. Furthermore, the CNDO/2 calculations suggest small σ contributions to $^5J_{15}$, $^5J_{25}$, and $^5J_{26}$ but a significant σ contribution to $^5J_{16}$. The corresponding coupling constant for the s-*cis* isomer, $^5J_{1'6}$, is predicted to have a negligible σ contribution, confirming that $^5J_{16}$ is transmitted stereospecifically through the all-*trans* or zig-zag pathway. However, the calculations appear to overestimate the magnitude of this contribution. This appears to be a general problem associated with CN/INDO finite perturbation calculations. A similar overestimation of the stereospecific *meta–alpha* coupling constant was noted for styrene, with the error being greater for the INDO than for the CNDO calculations (5, 26).

The calculations are also in good agreement with all of the ^4J values for which experimental data are available. There are minor discrepancies for the values of $^4J_{14}$ and $^4J_{24}$ in the s-*trans* configuration (**1***a*). The calculations suggest $|J_{24}| > |J_{14}|$ when in fact they are equal in value (12, 16). The CNDO/2 calculations indicate that the calculated difference arises from a negative σ contribution to $^4J_{24}$. This is likely due to a direct interaction between H_2 and H_4 similar to that in *o*-xylene (9) and *cis*-2-butene (11). The failure to observe this experimentally may be a result of molecular distortions which increase the distance between H_2 and H_4 (17). The results for $^4J_{1'4}$ in the s-*cis* conformation (**2**) are partic-

ularly interesting. They reproduce the experimental change in sign from $^4J_{14}$ and confirm that this is due to a stereospecific σ contribution. They also provide a striking demonstration of the fallacy of taking J(INDO) − J(CNDO) as a measure of π contributions. In this case, J(INDO) − J(CNDO) ≈ 0. Since the corresponding value for $^4J_{14}$ is −1.2 Hz, this would imply a strongly stereospecific π coupling mechanism. However, there is no experimental evidence for strongly stereospecific π effects. In actual fact, the INDO calculations must overestimate the stereospecific σ contribution (relative to the CNDO/2 calculations) by an amount equal in magnitude but opposite in sign to the calculated π contributions.

It is probable that performing INDO calculations with and without one-center exchange integrals corresponding to σ–π exchange interactions (4) may provide a more reliable estimate of π contributions. For example, this approach does yield approximately equal π contributions for $^4J_{14}$ in **1***a* (−0.52 Hz) and $^4J_{1'4}$ in **2** (−0.29 Hz) (4). However, it is probably less reliable for estimating σ contributions since, as discussed above, the INDO calculations often overestimate these contributions. Thus it would appear that neither approach gives precise values for both σ and π contributions.

The ^2J and ^3J values are also in reasonable agreement with experiment. Probably the most significant result in this case is the correct prediction of the relative magnitudes of J_{34} and $J_{3'4}$ for the two derivatives with the difference again arising from a stereospecific σ effect.

It is instructive to compare the experimental and calculated ^4J and ^5J values for butadienes with the corresponding values for styrenes (see Table 2). The two sets of values show very similar patterns, with the values for styrene being consistently lower. This is the expected result since the C_1—C_2 π bond order in styrene is lower. The CNDO calculations for $^5J_{2'5}$ in both cases provide evidence for a direct interaction leading to a negative value for $^5J_{2'5}$. This has been observed experimentally for 2,5-dichlorostyrene (5). Support for the existence of this direct interaction follows from a comparison of the INDO and CNDO values for $J_{2'5}$ when the C_1—C_α—C_β bond angle is opened up to 130°, thus separating the proximate protons. $J_{2'5}$(CNDO) becomes less negative, approaching zero, while the INDO value becomes more positive, approaching the J_{25}(INDO) value (26).

The calculations for **1***b* demonstrate that the stereospecific σ effect for $^5J_{16}$ in s-*trans* 1,3-butadiene (**1***a*) has been almost completely removed by replacing H_1 by a methyl group. Experimental values for $^6J_{15}$ and $^6J_{16}$ in **1***b* and $^6J_{25}$ and $^6J_{26}$ in **1***c* are nearly identical and are equal in magnitude and opposite in sign to $^5J_{15}$, $^5J_{25}$, and $^5J_{26}$ in **1***a*. These observations are consistent with the predictions of the methyl group replacement technique (27) for a system with a dominant π electron coupling pathway.

The calculations closely reproduce these trends, even reproducing the relative magnitude of the six bond coupling constants.

By contrast, $^4J_{14}$ and $^4J_{24}$ in **1***a* are significantly larger than the corresponding 5-bond methyl proton coupling constants in **1***b* ($^5J_{14}$) and **1***c* ($^5J_{24}$). The INDO calculations reproduce both trends. In the former case, the apparent failure of the methyl group replacement technique could be due to a σ contribution to $^4J_{14}$ in **1***a* (4, 17), although the CNDO calculations do not support this assumption. In the latter case the difference may be due to both a direct interaction in **1***c*, since $^5J_{24}$ has a minimum positive value (maximum negative value by CNDO) when one of the methyl protons is proximate to H_4, and to a σ contribution in **1***a*. Finally, the difference could, in part, be due to in-plane distortions of the molecular framework of the pentadiene isomers (4, 17).

$^5J_{14}$ in **1***b* (as calculated by INDO) varies from 0.07 Hz for the C—H bond of the methyl group coplanar to the carbon skeleton to 1.42 Hz for a perpendicular C—H bond with an approximate $\sin^2\phi$ dependence (maximum deviation 0.09 Hz). A similar angular dependence is noted for other long range methyl proton coupling constants. This is analogous to the previously noted behavior of long range coupling constants to the α protons of styrene (5), toluene (9), and benzaldehyde (28). This type of behavior has been attributed to an allylic π mechanism (29).

There is a persistent tendency for couplings involving H_1 to increase on going from **1***a* to **1***c* but H_2 couplings remain essentially constant on going from **1***a* to **1***b* (17). These trends are reproduced almost quantitatively by the INDO calculations. Similarly, INDO calculations qualitatively reproduce the general increase in coupling constants on going from **1***a* to *cis,cis*-2,4-hexadiene (4). This suggests that the observed increases in coupling constants are due to electronic effects rather than molecular distortions, as previously suggested (17). However, the latter possibility cannot be totally ruled out, since INDO calculations predict that in-plane distortions will also cause increases in coupling constants (4). The observed increase in J_{56} for **1***b* and **1***c* relative to **1***a* is not predicted by our calculations, suggesting that it might arise from molecular distortions. Geminal coupling constants are particularly sensitive to small angle changes.

In general, our calculations for 1,3-butadiene and related compounds have provided more mechanistic information than the π electron calculations of Harris and co-workers (22) and have extended the conclusions of Bacon and Maciel (4) concerning the relative importance of σ and π mechanisms in these compounds.

In the case of cyclopentadiene (**3**), there is generally very good agreement between experimental and calculated (INDO) coupling constants. The worst agreement is for $^4J_{25}$ ($^4J_{35}$). Here the INDO calculations indicate a negative contribution, presumably due to an allylic coupling mechanism (29) while CNDO suggests a positive contribution, presumably a σ contribution through the pseudo zig-zag arrangement. It appears that the calculations again overestimate this contribution. All other coupling constants appear to be transmitted through the σ system. The calculations also appear to overestimate the stereospecific σ contribution to $^4J_{13}$.

The calculations closely reproduce the experimental trends on going from 1,3-cyclohexadiene (calculations for **2**) to cyclopentadiene (**3**), *i.e.* the large decrease for $J_{1'3}$ (J_{12}) and $J_{3'4}$ (J_{23}), the near constancy of $J_{1'4}$ (J_{13}) and the significant increase for $J_{1'6}$ (J_{14}). The latter increase is clearly due to the additional σ pathway through C_5.

The calculations also closely reproduce the experimental coupling constants for 1-methyl- and 2-methylcyclopentadiene. The CNDO calculations suggest that the coupling constants of the methyl group to the olefinic protons are dominated by a π mechanism, as previously suggested (25). $^4J_{15}$ for 1-methylcyclopentadiene is apparently transmitted through the σ system while $^5J_{25}$ for 2-methylcyclopentadiene is an example of homoallylic coupling (29) involving the π electron system. The CNDO calculations reproduce this coupling since, in this case, there is a direct interaction of both C—H bonds with the π bond.

(b) Acetylenes and Conjugated Diynes

The results of the calculations for these derivatives indicate that the coupling constant in acetylene is dominated by a σ mechanism but those for propyne and 1,3-butadiyne ("diacetylene") are dominated by π mechanisms. This should also hold for the more extended coupling paths for the other derivatives. The significant CNDO values in 2-butyne and 2,4-hexadiyne

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

can again be attributed to the direct interaction of the C—H bonds with the π electron system, *i.e.* a type of homoallylic interaction.

The overall agreement between experimental and calculated (INDO) results is good. The only surprising result is for 1,3-butadiyne. For the pairs propyne,2-butyne and 1,3-pentadiyne, 2,4-hexadiyne replacement of a proton by a methyl group is predicted and observed to leave the magnitude of the coupling constant almost unchanged. A similar theoretical prediction is made for the pair 1,3-butadiyne, 1,3-pentadiyne. Although the coupling constant for the former compound did not converge (after 100 iterations), its magnitude changed by less than 0.001 Hz over the last 60 iterations. Therefore, it is improbable that the failure to converge introduced any significant error. In the light of the above discussion, it is surprising to note that the magnitude of the experimental coupling constant for 1,3-butadiyne is almost twice that for its mono- and dimethyl derivatives. The origin of this discrepancy between experiment and calculation is unclear, particularly since the CNDO calculations suggest that there is no unexpected σ effect present.

Calculations were also performed for 2,4,6-octatriyne. There is again good agreement with experiment (30), supporting our earlier conclusions that INDO calculations give nearly quantitative predictions of coupling constants transmitted through extended π pathways (8).

Summary and Conclusions

This investigation has further demonstrated the great usefulness of molecular orbital calculations based upon finite perturbation theory in the CNDO/2 and INDO approximations for investigating mechanisms of transmission of long-range ^1H–^1H coupling constants and, in particular, for separating σ and π effects. In all cases the INDO calculations have reproduced the signs of the coupling constants and in most cases they have accurately predicted the magnitudes of the J values. Fortunately the CNDO calculations have largely fallen into two classes; those where the calculated coupling constants were nearly zero (negligible σ contribution) and those where the calculated coupling constants were similar to the experimental value. Except in systems where a homoallylic pathway is present, the latter results suggest dominant σ contributions.

The calculations for the 1,3-butadiene derivatives indicate that all long range coupling constants except $^5J_{16}$ in the s-*trans* conformation and $^4J_{14}$ in the s-*cis* isomer are dominated by π contributions. In the latter two cases, there is a significant σ contribution through the all-*trans* or zig-zag pathway. In the case of *cis*- and *trans*-1,3-pentadiene, all long-range coupling constants to the methyl group are dominated by π contributions. In the case of cyclopentadiene and its 1-methyl and 2-methyl derivatives, the couplings between olefin protons are dominated by σ interactions while the methyl proton – olefin proton couplings arise almost exclusively from π interactions. Finally all coupling constants in a series of acetylene and 1,3-butadiyne derivatives except that for acetylene are transmitted through the π system.

Pulse Radiolysis of Alkali Metal Solutions in Ethylamine[1]

J. W. FLETCHER, W. A. SEDDON, AND F. C. SOPCHYSHYN

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received March 21, 1973

Pulse radiolysis of solutions of alkali metal ethylamides in ethylamine shows the formation of three distinct species; the solvated electron e_s^-, the alkali metal anion M^-, and a species considered to be the cation–electron pair with stoichiometry M. The three species coexist in equilibrium in accord with the equations

$$e_s^- + M^+ \rightleftharpoons (M^+—e_s^-) \text{ or } M$$

$$M + e_s^- \rightleftharpoons M^-$$

Studies of these solutions as a function of temperature, alkali metal concentration, and added complexing agents ("crown" compounds) show that e_s^- and M have distinct absorption spectra with the former having a maximum $\geqslant$1800 nm. The latter exhibit maxima at 1400 nm for Na and K, ~1400 nm for Cs, and 1600–1700 nm for Li. The corresponding M^- species were observed in sodium, potassium, and cesium solutions with absorption maxima at 680, 890, and 1100 nm, respectively.

Rate and equilibrium constants for the formation of M and M^- vary markedly with the nature of the alkali metal. Estimates for these constants along with the extinction coefficients for the various species are summarized and compared with data obtained in alkali metal solutions.

La radiolyse pulsée de solutions d'éthylamidures de métaux alcalins dans l'éthylamine conduit à la formation de trois espèces distinctes: l'électron solvaté e_s^-, l'anion métallique M^- et une espèce considérée comme étant une paire de cation-électron de stoechiométrie M. Les trois espèces coexistent en équilibre selon:

$$e_s^- + M^+ \rightleftharpoons (M^+ - e_s^-) \text{ ou } M$$

$$M + e_s^- \rightleftharpoons M^-$$

Les études de ces solutions en fonction de la température, concentration en métal alcalin et addition d'agents complexants (composés "couronne") montrent que e_s^- et M possèdent des spectres d'absorption distincts, le premier avec un maximum $\geqslant$1800 nm et pour le second, un maximum à 1400 nm pour Na et K, ~1400 nm pour Cs et 1600–1700 nm pour Li. Les espèces M^- correspondantes ont été observées pour les solutions de sodium, potassium et césium avec respectivement un maximum d'absorption à 680, 890 et 1100 nm. Les constantes de vitesse et d'équilibre pour la formation de M et M^- varient de façon notable avec la nature du métal. Des valeurs sur ces constantes de même que celles des coefficients d'extinction pour les diverses espèces ont été rapportées et comparées aux données obtenues pour les solutions de métal alcalin. [Traduit par le journal]

Introduction

It is well known that alkali metals dissolve in liquid amines and liquid ammonia to give intensely colored solutions. Such solutions are generally very stable but can be catalytically decomposed to give the corresponding alkali metal alkylamides of general formula RCH_2NHM_s

$$RCH_2NH_2 + M_s \rightarrow RCH_2NHM_s + \tfrac{1}{2}H_2$$

Numerous investigations (refs. 1 and 2 and references therein) on the optical, magnetic, and conductance properties of alkali-metal solutions have indicated that intermediate species of stoichiometry e_s^-, M, and M^- are produced in equilibrium according to the equations

$$[1] \qquad e_s^- + M^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (M^+—e_s^-) \text{ or } M$$

$$[2] \qquad M + e_s^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} M^-$$

However, little is known about the equilibrium constants or the rate at which these equilibria are established. Interconversion of all three species has been observed in the flash photolysis of ethereal solutions (3–5) but prior to our earlier communication (6), no similar kinetic or optical evidence for the species M has been reported in amines.

With the development of fast infrared detectors pulse radiolysis can now be increasingly useful in the study of alkali metal solutions (7–9). This paper describes our results on the optical spectra and kinetics of the species, e_s^-, M, and M^- generated from the corresponding alkali metal ethylamides in Li, Na, K, and Cs solutions in ethylamine.

Experimental

Details of our pulse radiolysis facilities have been described elsewhere (10–12). Briefly, solutions were irradiated at room temperature with 0.5–2.0 μs pulses from a 2.5 MeV electron Van de Graaff accelerator. Rectangular quartz irradiation cells with an optical path length of 0.5–2.0 cm were mounted in a specially designed Pyrex or quartz flow system (Fig. 1). Samples were changed between pulses by a magnetically operated float valve which allows solution to flow from the reservoir B, through the cell C, to the drain D.

Ethylamine (Eastman Organic Chemicals) was dried and, to avoid cross contamination, purified under vacuum by fractional distillation from the appropriate alkali metal solutions. Alkali metals were stored and handled in a Dry Box. Metal ethylamide solutions were prepared in the following manner. Sodium (Baker reagent), potassium, and lithium (Fisher Chemicals) were pressed in the form of 0.1–1 mm diameter wire and transferred in calibrated weights per unit length to 2–3 mm diameter Pyrex or quartz tubing. These in turn were transferred, under vacuum, to the flow system, bulb D, via a modified (line of sight) greaseless stopcock, A (J. Young Ltd.). To aid dissolution it was found necessary to mirror the sodium samples. Aliquots of cesium (Alfa Inorganics Inc.) were "pipetted" in 0.5 mm diameter tubing and transferred to the flow system in a similar fashion. When necessary, analyses for Li, Na, or K were performed by absorption flame spectroscopy. Ethylamine was then fractionally distilled on to the metal and the resulting blue solutions catalytically bleached with electrolyzed Pt gauze to form the corresponding metal ethylamide (13). These solutions were then poured into bulb B to commence the experiment.

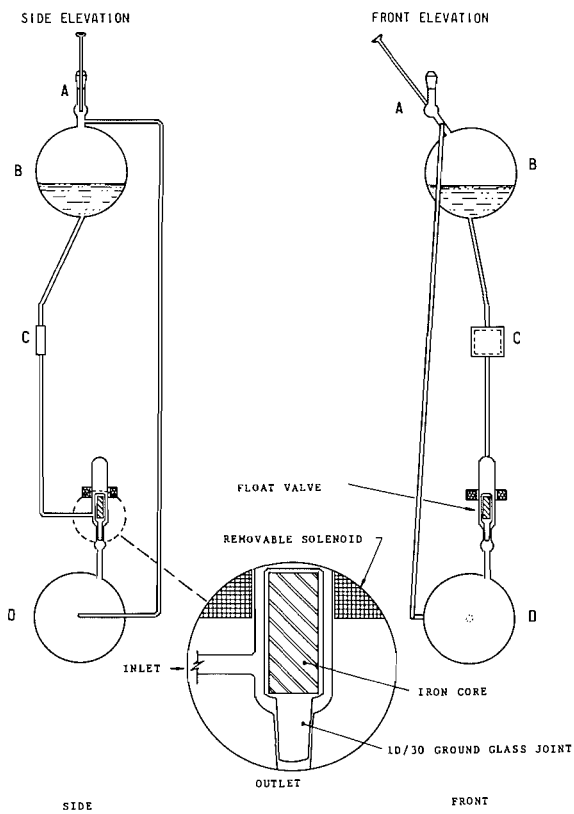

FIG. 1. Pulse radiolysis flow system. *A*, "line of sight" greaseless stopcock; *B*, 200 ml reservoir with solution under investigation; *C*, optical cell; *D*, drain (200 ml).

Fast infrared detection techniques were used throughout and great care taken to avoid misinterpretation of the data due to inherent features of the detector (14). A silicon photodiode SDG-100A, E.G. and G. Incorporated, covering the wavelength region 350–1100 nm and a liquid nitrogen cooled indium antimonide detector, Spectronics, SD-8721-2 with a nominal range of 1000–5500 nm were found to be excellent for our purposes. Under our operating conditions the former had a response time (0–98%) ≤80 ns and the latter (0–100%) ≤200 ns (14). A Corning 7-56 glass filter and long pass interference filters at 1500 and 1800 nm (Type LP sapphire substrate, Infrared Industries, Inc.) were used in conjunction with a Bausch and Lomb f 3.5 high intensity grating monochromator to eliminate second order wavelengths.

For most of the experiments three oscilloscope traces were recorded on a single Polaroid photograph. Examples are given in Figs. 3 to 9 where curve A shows the output profile of the analyzing light flash on a time scale of 500 μs/division. Curve B shows the transient signal recorded simultaneously with A, but at a higher gain, while curve C represents the analyzing light baseline on the

same amplification and time scale as B. The transient signal at lower gain is superimposed on curve A.

Results

Pure Ethylamine and Lithium Ethylamide Solutions

Figure 2 shows the absorption spectrum observed at room temperature immediately after a 0.5 μs pulse in pure ethylamine and in solutions containing $\sim 1 \times 10^{-3}$ *M* lithium ethylamide. In both cases the absorption maximum lies at $\geqslant 1800$ nm but no peak could be clearly resolved due to the large solvent absorption at the longer wavelengths. In pure ethylamine, the absorption decays completely with a half-life $t_{1/2} \leqslant 1$ μs, whereas in lithium ethylamide solutions a slow growth in absorption is observed after the pulse.

Figure 3 shows the spectrum observed in $\sim 1 \times 10^{-3}$ *M* lithium ethylamide solutions as a function of time, the maximum gradually shifting to 1600–1700 nm with a corresponding increase in intensity over a period of about 400 μs (inset Fig. 3). The overall transient signal is however markedly dose dependent and this is illustrated in Fig. 4. At large doses per pulse ($\geqslant 10^{20}$ eV/l) the initial absorption partially decays on a μs time scale, a feature not observed at lower pulse intensities. This effect can be seen by comparing the inset traces in Figs. 3 and 4.

Sodium and Potassium Ethylamide Solutions

Figure 5 shows the optical spectra obtained in

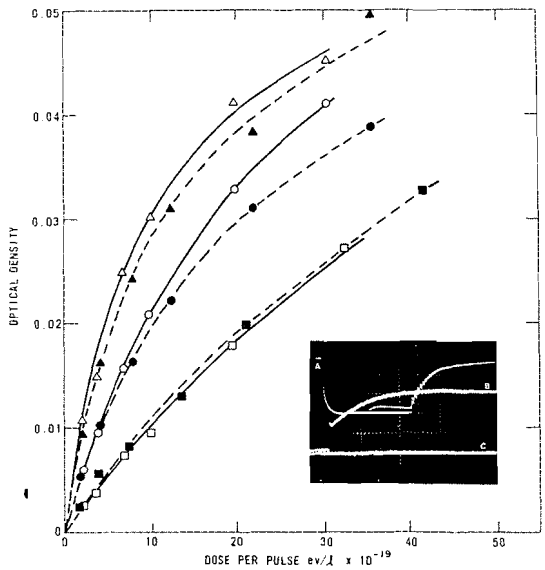

FIG. 4. Dose dependence of the transient absorption observed in $\sim 1 \times 10^{-3}$ *M* lithium ethylamide in a 1 cm cell. Open symbols, monitored at 1700 nm; closed symbols, 1900 nm. □, ■, 1 μs after the pulse; ○, ●, 150 μs after the pulse; △, ▲, 400 μs after the pulse. The inset curve *B* shows the transient absorption monitored at 1700 nm, dose 30.5×10^{19} eV/l, ordinate 3.3%/div., abscissa 50 μs/div. See Experimental section for relevance of traces *A* and *C*.

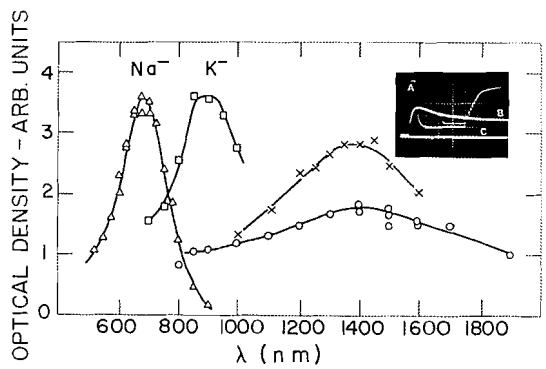

FIG. 5. Absorption spectra observed in 2.5×10^{-4} *M* sodium ethylamide and 4.5×10^{-4} *M* potassium ethylamide in ethylamine. ○, sodium solutions 5–14 μs after the pulse; △, sodium solutions 400 μs after the pulse; ×, potassium solutions 5–14 μs after the pulse; □, potassium solutions 400 μs after the pulse. For clarity the optical densities of the shorter time scale spectra are arbitrarily displaced with respect to each other and the long time scale spectra. The spectrum observed immediately after the pulse (not shown) is identical to that shown in Figs. 2 and 3. The inset curve *B* shows the transient absorption observed in 4.5×10^{-4} *M* potassium solutions at 1400 nm. Dose 15.3×10^{19} eV/l, ordinate 5.0%/div., abscissa 20 μs/div. Traces *A* and *C* are discussed in the Experimental section.

2.5×10^{-4} *M* solutions of sodium ethylamide and 4.5×10^{-4} *M* potassium ethylamide. Once again the spectrum observed immediately after the pulse (not shown) exhibits a maximum at $\geqslant$1800 nm and is very similar to those presented in Figs. 2 and 3. During the next 10–14 μs the absorption continues to increase in intensity and at the same time the spectrum shows a distinct change with the maximum shifted to 1400 nm. This absorption eventually decays to form a long-lived species with well characterized bands at 680 and 890 nm assigned to the metal–electron dimer species Na^- and K^-, respectively (1). The inset in Fig. 5 shows the formation and decay of the transient species in potassium solutions.

As in the case of lithium solutions the yield and rate of formation of the transient signals are a function of dose/pulse.

Studies at low dose ($\sim 1 \times 10^{19}$ eV/l) in 2.5×10^{-4} *M* solutions of sodium ethylamide and 4.5×10^{-4} *M* potassium ethylamide show the rate of formation of the absorption at

1400 nm to be first order and dependent on the nature of the alkali metal. Figure 6 shows an example of an oscilloscope trace and its kinetic analysis corresponding to the build up in the potassium solution. For both sodium and potassium solutions the 1400 nm band decays by a second order process with the concomitant formation of the 675 or 890 nm bands, respectively. Figures 7 and 8 illustrate this situation using examples chosen from the sodium solution.

Effect of Added "Crown" Compound

Previous studies (2, 15, 16) have shown that the addition of a cyclic polyether such as dicyclohexyl-18-crown-6[2], ("crown" compound) complexes alkali metal cations and enhances their solubility in a variety of amines and ethers. Figure 9 shows the optical spectra and transient signals observed from a solution prepared in a Pyrex flow system containing $\sim 2 \times 10^{-3}\ M$ potassium ethylamide, $\sim 2 \times 10^{-3}\ M$ lithium ethylamide, and $4 \times 10^{-3}\ M$ "crown" compound. At doses of about 2×10^{19} eV/l the transient absorption shows virtually no sign of decay or growth over a period of $\geqslant 500$ μs (upper inset). At higher doses per pulse the absorption consists of two parts; an initial rapid decay followed by a long lived residual component (lower inset). Both the initial and long lived absorptions have identical spectra with a maximum at >1800 nm. There is no evidence for the formation of either Na^- (via Na^+ contamination from the vessel) or K^-.

Cesium Ethylamide Solutions

Figure 10 shows the spectra obtained in $\sim 6 \times 10^{-5}\ M$ solutions of cesium ethylamide. The spectrum observed immediately after the pulse is relatively weak with an apparent maximum around 1800 nm. During the next 2–3 μs the intensity increases rapidly giving a strong absorption with a broad maximum from 1200–1500 nm. This spectrum changes again over the following 5 μs resulting in a final spectrum with a maximum at 1100 nm and a shoulder at ~ 1400 nm. Oscilloscope traces showing the formation of the transient species are presented in Fig. 11.

The rate of formation of the cesium species is significantly faster and, for equivalent concentrations, the least dose dependent, of the series Li, Na, and K. Figure 12 shows the effect of increasing the dose/pulse in a solution containing $2 \times 10^{-3}\ M$ cesium ethylamide.

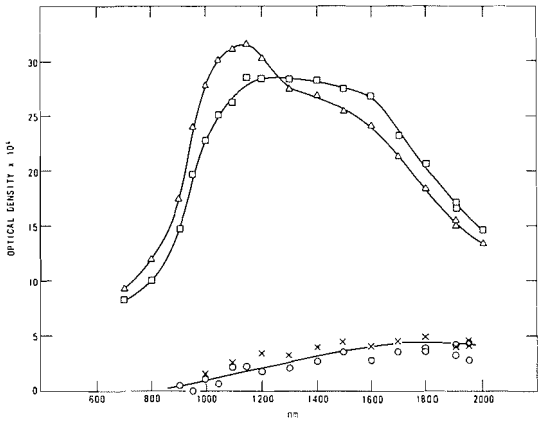

FIG. 10. Absorption spectra observed in $\sim 6 \times 10^{-5}\ M$ cesium ethylamide solutions in an 0.5 cm cell. ○, ×, spectrum observed in separate experiments at the end of an 0.5 μs pulse (dose per pulse $\sim 4.6 \times 10^{19}$ eV/l); □, spectrum observed 2.5 μs after the pulse; △, spectrum observed 7.0 μs after the pulse (dose per pulse $\sim 10^{20}$ eV/l). All spectra are normalized to a dose per pulse of $2.7_5 \times 10^{18}$ eV/l.

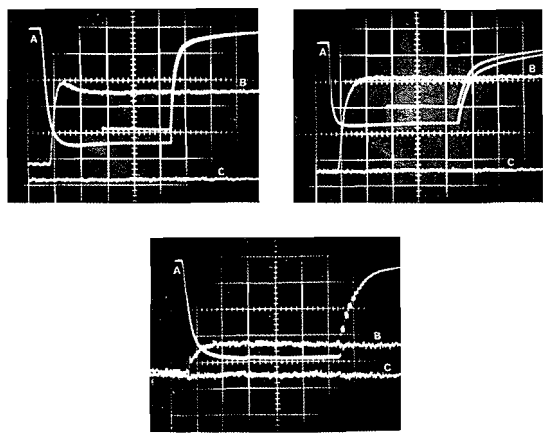

FIG. 11. Oscilloscope traces showing the formation of the transient species in $\sim 1.2 \times 10^{-5}\ M$ solutions of cesium ethylamide in an 0.5 cm cell. Upper left curve *B*, wavelength 1900 nm, dose 10.7×10^{19} eV/l, ordinate 4.5% absorption/div, abscissa 5 μs/div., Upper right curve *B*, wavelength 1000 nm, dose 10.2×10^{19} eV/l, ordinate 5.5% absorption/div., abscissa 5 μs/div.; Lower trace curve *B*, wavelength 1900 nm, dose 4.5×10^{19} eV/l, ordinate 2.6% absorption/div., abscissa 10 μs/div. Discussion

Spectral Assignments

Optical spectra of alkali metal solutions in amines and or ethers have been studied extensively (1, 2, 16). In general such spectra are composed of at least two absorption bands ascribed to metal-dependent and metal-independent species. The former band occurs at relatively short wavelengths, $\leqslant 1000$ nm, whereas the latter is often much broader and extends further into the infrared with a pronounced solvent dependence on both the maxima and band shape (2).

In sodium and potassium solutions in a variety of amine and ether solvents it is now generally accepted that the metal-dependent bands at 675 and 890 nm, can be assigned to a species of stoichiometry M^-, *i.e.* Na^- and K^-, respectively (1, 17, 18). Similarly, the band observed at 1050 nm in cesium solutions in tetrahydrofuran and ethylamine–ammonia is assigned to Cs^- (2, 16, 17).

Hitherto it has been common to assign the longer wavelength infrared absorptions to the solvated electron (19–21). This is supported in a number of amine and ether solvents where a good correlation exists between the absorption maxima (ranging from 1300–2200 nm) found by pulse radiolysis and flash photolysis and those observed in alkali metal solutions (2, 3, 7). However the agreement is not exact and Lok *et al.* (2), note that the metal solution bands are in general broader and at slightly higher energies than those found by pulse radiolysis. These authors suggest that such variations in band shape might arise from the interaction of e_s^- with the cation. It has also been pointed out for lithium solutions in ethylamine (1), that the single absorption band observed at 1400 nm at −17 °C, may be a composite of at least two paramagnetic species, namely e_s^- and possibly a neutral monomeric species (M or $M^+ - e_s^-$).

Cyclic polyethers ("crown" compounds) have been used by Dye and co-workers (2, 15, 16), to complex the alkali metal cation and, under the appropriate conditions, shift the equilibria 1 and 2, in favor of e_s^-. In ethylamine these workers observe a maximum at 1800 nm for e_s^- at room temperature (2). This peak position is consistent with our pulse radiolysis spectra observed immediately after the pulse in pure ethylamine, Li, Na, K, or Cs ethylamide solutions, and mixtures containing an excess of "crown" compound (Figs. 2, 3, 9, and 10). We suggest therefore that in ethylamine the true e_s^- absorption has a maximum at $\geqslant 1800$ nm, a wavelength significantly different from the infrared band maxima of 1400–1600 nm normally attributed to e_s^- in alkali metal solutions (19–21).

The rate of formation of the 1400 nm band is metal dependent (Table 1) and for 2.5×10^{-4} *M* sodium and 4.5×10^{-4} *M* potassium solutions the species is present in significant concentration 5 μs after the pulse (Fig. 5). In $\sim 1 \times 10^{-3}$ *M* lithium ethylamide solutions its formation is much slower and the shift in wavelength from 1800 nm is not as pronounced (Fig. 3).

We therefore propose that the bands formerly assigned to the solvated electron in ethylamine solutions are in fact due to a metal electron species of stoichiometry M. In sodium and potassium solutions at room temperature this species has a maximum at 1400 nm. In lithium solutions it is shifted towards 1600–1700 nm. It is conceivable that this latter absorption contains an appreciable equilibrium concentration of e_s^- which artificially displaces the maximum beyond

the 1400 nm obtained in sodium and potassium solutions. The 1600–1700 nm peak position correlates well with the band maxima of 1400 nm reported for lithium solutions at -17 °C and the temperature coefficient of ~ 6 nm per degree (1).

In $\sim 6 \times 10^{-5}$ *M* cesium ethylamide solutions (Fig. 10) the pulse radiolysis spectrum observed on a long time scale ($\geqslant 7$ μs) very closely resembles the steady state spectrum observed in cesium ethylamide solutions (1). However, the intermediate spectrum observed after 2.5 μs is clearly different and much more intense than the absorption obtained immediately after the pulse. Again our results show that in dilute cesium ethylamide solutions three species can clearly be distinguished. On the basis of the previous discussion we therefore conclude that (*a*) the initial species with a maxima at $\geqslant 1800$ nm is due to e_s^-; (*b*) the maxima at 1100 nm is due to Cs^-; and (*c*) the broad long wavelength shoulder with a maximum ~ 1400 nm is largely due to the monomer species, Cs, with equilibrium contributions from Cs^- and possibly e_s^-.

Kinetics and Dose Dependence

Formation of M

Studies of dilute solutions of Li, Na, K, and Cs ($\leqslant 1 \times 10^{-3}$ *M*) indicate that the rate of formation of M is first order and consistent with reaction 1, for example see Fig. 6. However we make no attempt in this paper to differentiate between reactions involving the cation M^+ and those possibly involving the undissociated metal

[3] $CH_3CH_2NHM + e_s^- \rightleftharpoons CH_3CH_2NH^- + M$

alkylamide CH_3CH_2NHM. Data from methylamine at -62.2 °C show that the potassium salt is only weakly dissociated (22), with $<2\%$ present as K^+ in 10^{-3} *M* solution. Even in liquid ammonia the corresponding sodium, potassium, and cesium amides are $<10\%$ dissociated (23). It is likely therefore that 10^{-3} *M* ethylamides are largely associated in ethylamine at room temperature. For simplicity our ensuing discussion assumes that the total concentration of the metal ethylamide is relevant to the overall rate of reaction involving M^+. Observed differences in the series lithium–cesium may in part be due to different degrees of dissociation of the alkyl ethylamides but such conjecture is outside the scope of this work.

Experimentally the dose per pulse and/or solute concentration must be chosen to minimize side reactions arising from radiolysis. For example, we believe the initial rapid decay illustrated in the oscilloscope trace in Fig. 4 is due to the reaction of e_s^- with other radical species produced during the pulse. The analysis is complicated further in that the decay of M to produce M^- is a second order process (Figs. 7 and 8), the rate of which becomes relatively more significant at higher doses. Any such contribution increases the error in determining OD_{max}, the optical density corresponding to the complete formation of M, although corrections can be made in the computer analysis of such build-ups (24). Furthermore, since the absorption spectra of e_s^- and M overlap, the buildup of M should strictly be corrected for equilibrium concentrations of e_s^-. However, in view of the much lower extinction coefficient for e_s^- (see below) and with equilibrium 1 clearly in favor of M, such corrections ($\leqslant 5\%$) were not considered significant. At low doses where the rate of decay of M is minimized we estimate from plots such as shown in Fig. 6 that $k_1 = 4 \times 10^6$, 1.6×10^8, 1.2×10^9, and 2.0×10^{10} M^{-1} s^{-1} for Li^+, K^+, Na^+, and Cs^+, respectively (Table 1).

Formation of M^-

In sodium and potassium solutions the spectrum of M^- is well established and distinctly separated from that of e_s^- and M. Sodium solutions represent the simplest case and here the decay of e_s^- and M to M^- is virtually complete indicating that the overall equilibria is largely in favor of Na^-.

The formation of M^- is second order, dependent on the nature of the alkali metal, and consistent with an overall pseudo-second order reaction 4,

[4] $$e_s^- + e_s^- \overset{M^+}{\rightleftharpoons} M^-$$

The overall rate of formation of M^- can be measured either by observing the decay of M at 1400 nm or via the build up of M^- at 675, or 890 nm, for Na^- and K^-, respectively. Figure 7 shows a kinetic plot corresponding to the formation of Na^- with a pseudo second order rate constant $4k_4 \sim 0.3 \times 10^6 \varepsilon_{M^-}$ $M^{-1}s^{-1}$. Since the equilibrium for reaction 1 appears to lie well to the right we can simplify the overall kinetics by neglecting reaction 2 and assume that M^- is formed by reaction 5

TABLE 2. Relative extinction coefficient data, expressed as $G\varepsilon$, for e_s^-, M, and M^- in Li, Na, K, and Cs solutions in ethylamine*

Metal	Ethylamide concentration ($\times 10^4$ M)	λ (nm)	$G\varepsilon(\times 10^{-5})$ e_s^-	M	M^-
Li (Pyrex)	5	1400	0.17	0.70†	—

	0.08	1900	0.23		
	0.01	1500	0.23	1.3	
	21	1500		1.6	

*Values obtained from dose studies. Extinction coefficients can be estimated assuming $G_{e_s^-} = 2$, $G_M = 2$, and $G_{M^-} = 1$.
†Solution contains Na^+ contamination from the Pyrex, value probably high.
‡Corrected assuming $K_{-5}[M^+] \sim 2 \times 10^{-7}$.

[5] $$M + M \rightleftharpoons M^- + M^+$$

On this basis we deduce $2k_5$ is equivalent to $2k_4 = 6 \times 10^5 \varepsilon_M M^{-1} s^{-1}$ (Fig. 8). Since Na^- is the final species, errors in OD_{max} are not as significant as those discussed previously concerning the formation of M. Combination of the above "k_4" values with the appropriate extinction coefficients (see Table 2 below) for Na and Na^- gives $k_4 = 2.0 \pm 0.4 \times 10^{10} M^{-1} s^{-1}$. However, this rate constant is strictly a measure of the overall stoichiometry composed in detail of the equilibria 1–3 and probably equilibrium 5. Consequently k_4 represents the value in $2.5 \times 10^{-4} M$ sodium ethylamide and will be concentration dependent as M^+ changes the equilibrium concentrations of e_s^-, M, and M^-.

It should be noted here that from similar studies in ethylenediamine, Dye *et al.* (8), suggest the formation of Na^- occurs via the intermediate e_2^{2-}

[6] $$e_s^- + e_s^- \rightleftharpoons e_2^{2-}$$

[7] $$e_2^{2-} + Na^+ \rightarrow Na^-$$

Further kinetic studies in methylamine (25) indicate that a mechanism consisting of reactions 1, 2, and 5 fits Dye's data on the effect of cation concentration, equally as well as reactions 6 and 7.

In potassium solutions similar kinetic treatment to that described for sodium gives the corresponding value $k_4 = 1.1 \pm 0.5 \times 10^{10} M^{-1} s^{-1}$. However, only the initial portions of the build-up and decay curves can be utilized since there is an additional complication in that the decay of M to M^- does not go to completion. On a long time scale the concentration of M reaches a finite steady state indicating that the equilibrium constant for the dissociation of M^- is greater than the analogous case for sodium solutions. As such, the equilibrium concentrations of M and M^- can be estimated from the residual optical densities observed after ~200 μs at 1400 (OD_{1400}), and 890 nm (OD_{890}), respectively. Figure 13 shows such steady state values for $4.5 \times 10^{-4} M$ solutions of potassium ethylamide as a function of dose per pulse.

On the basis of reaction 5, the equilibrium constant for the potassium solution $K_{-5} = [M]^2/[M^-][M^+]$. As a first approximation $K_{-5}[M^+] \propto OD^2_{1400}/OD_{890} = 7 \times 10^{-3}$. Using the appropriate extinction coefficients, deduced from Table 2, $K_{-5}[M^+]$ is then estimated as $\sim 2 \times 10^{-7} M$. The curve (Fig. 13) drawn through the OD_{1400} points represents the calculated fit to these data on the basis of K_{-5} and the best line drawn through points at 890 nm. The agreement is quite good and supports the second order formation of M^- in equilibrium with M. However in $2.3 \times 10^{-3} M$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

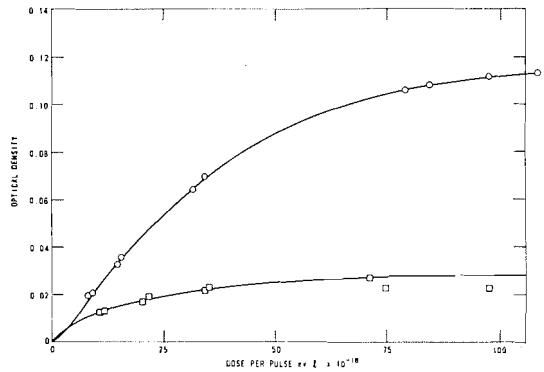

FIG. 13. Optical density of the transient species observed ~200 μs after the pulse in 4.5×10^{-4} *M* potassium ethylamide solutions as a function of dose per pulse in a 1.0 cm cell. □, 1400 nm; ○, 890 nm. Curves are calculated as described in the text.

potassium ethylamide solutions the relationship is not as satisfactory since to fit the data

$$K_{-5} \propto \frac{OD_{1400}{}^{1.6}}{OD_{890}}$$

implying the overall formation of M^- is of mixed order. Whether this is real, due to changes in the degree of dissociation of the ethylamide (22), or simply experimental error, is not known.

As mentioned earlier, Na^- is the predominant stable species in sodium solutions. From a similar analysis we estimate $K_{-5}[Na^+] < 1 \times 10^{-9}$ M. In cesium solutions the spectra of M and M^- overlap considerably so a reliable estimate for $K_{-5}(Cs^+)$ is not possible. However since both Cs^- and Cs are observed as stable species this indicates that $K_{-5}(Cs^+) > K_{-5}(Na^+) \leqslant K_{-5}(K^+)$. In common with the chemistry of alkali metal solutions no evidence was obtained in this work for Li^-.

Table 1 summarizes our rate and equilibrium constant data.

Decay Characteristics in the Presence of "Crown"

As mentioned previously, the addition of "crown" compound to ethylamine solutions containing K^+, Li^+, and presumably Na^+ from the vessel walls, displaces the equilibria 1 and 2 and prevents the formation of the M and M^- species. The solvated electron thus becomes the predominant reactive species and such solutions might be expected to be more characteristic of liquid ammonia than of amines. Although we have not attempted any detailed kinetic study of the "crown" mixtures the decay characteristics of e_s^- are qualitatively very similar to those observed on the pulse radiolysis of alkali metal amide solutions in liquid ammonia. The latter are characterized by an initial rapid reaction, principally between e_s^- and NH_2 radicals, followed by a long-lived residual absorption attributed to a stable e_s^- species (26 and 9 for earlier references).

In "crown" solutions, at low doses/pulse, the initial e_s^- absorption is stable for $\geqslant 500$ μs and shows no sign of an additional build up due to the formation of an M species. At higher doses the e_s^- absorption partially decays leaving a long lived residual component, again due to e_s^- (Fig. 9 and text). By analogy with ammonia we attribute the partial decay to the reaction of e_s^- with other radical species produced during the pulse. The addition of "crown" does therefore impart more "ammonia-like" properties to the ethylamine solutions.

Yields and Extinction Coefficients

Figures 4 and 12 show the formation of the various species as a function of dose per pulse in lithium and cesium solutions. It should be noted that at fixed times, but different wavelengths, there is a difference in relative intensity as a function of dose per pulse. This provides additional evidence that the overall absorption is a composite of more than one species. Similar plots (not shown), intermediate in character, were obtained for sodium and potassium solutions. These dose effects can be correlated with the measured values of k_1 (Table 1) where it might be expected that competing processes for e_s^- would be less significant with Cs^+ than for Li^+.

In view of this dose dependence we have estimated the initial yield for the various species from the linear portion of such curves and then in turn calculated the corresponding $G\varepsilon$ values.

Comparison with extinction coefficients measured in alkali metal solutions is difficult for two reasons. First, there is some uncertainty in the radiolytic yield of e_s^- in liquid amines and as an extension of this work we are attempting to deduce better values. Steady state data from γ radiolysis of liquid methylamine (27), and ethylamine (28), give $G_{e^-} = 3.2 \pm 0.2$ and 2.1 ± 0.1 molecules/100 eV, respectively. This large difference between very similar amines may or may not be real. Secondly, with the possible exception of e_s^- and Na^- our $G\varepsilon$

determinations represent minimum values since all three species are in equilibrium with each other. Since the respective equilibrium constants are as yet poorly defined, no attempt has been made to correct the basic experimental data. However, in sodium solutions the equilibria appear to be predominantly in favour of Na^-. The value for ε_{Na^-} ought then to provide some check on the consistency of our pulse radiolysis data with results obtained previously.

Assuming that $G_{e_s^-} = 2.1$ (28), then from Table 2 we deduce an extinction coefficient for e_s^- of $\sim 10^4\ M^{-1}\ cm^{-1}$ at 1800 nm. This is less than the value of 2×10^4 established for e_s^- in ethylenediamine (8, 29). In ethylenediamine it is possible that the e_s^- absorption contains a contribution from the sodium ion-pair species M, since our results indicate this reaction to be extremely fast. Unfortunately, in recent work using "crown" compounds (2), no estimates were made for the extinction coefficients of e_s^- and therefore we cannot ascertain the significance, if any, of our lower value.

On the other hand, again assuming $G_{e_s^-} = 2.1$, we find $\varepsilon_{Na^-} = 2 \pm 0.2 \times 10^5\ M^{-1}\ cm^{-1}$, based on a stoichiometry of two solvated electrons per Na^-. This extinction coefficient is some 3–4 times greater than previous estimates of 4.9 ± 0.7 to $6 \pm 2 \times 10^4\ M^{-1}\ cm^{-1}$, deduced from flash photolysis experiments in potassium ethylamide solutions (13). However, the latter work was done before it was realized that the species in question was in fact Na^- (due to Na^+ contamination from the glass) with the equivalent of two, and not one, electrons per mole. The quoted extinction coefficients should therefore be doubled to have the correct stoichiometry and hence give a value $\varepsilon_{Na^-} = 1.2 \pm 0.4 \times 10^5\ M^{-1}\ cm^{-1}$. In ethylenediamine the corresponding extinction coefficient is $8.2 \pm 0.3 \times 10^4\ M^{-1}\ cm^{-1}$ giving a calculated oscillator strength of 1.9 ± 0.2 consistent with the stoichiometry Na^- (29). Assuming $\varepsilon_{Na^-} = 2 \times 10^5\ M^{-1}\ cm^{-1}$ our spectra indicate an oscillator strength of at least four. This suggests that $G_{Na^-} \sim 2$ and hence in basic solutions $G_{e_s^-} \sim 4$, a factor of two higher than in pure ethylamine (28). Further studies on this point are in progress.

Finally Fig. 14 represents a reproduction of the various oscilloscope traces at doses $\leqslant 2 \times 10^{19}\ eV\ l^{-1}$, showing the comparative rate of increase and magnitude of $G\varepsilon$ (corresponding to the formation of M) as a function of time for different Li, Na, K, and Cs solutions. An interesting comparison is the apparent difference between two similar lithium solutions contained in Pyrex and quartz flow systems. In the Pyrex system both the $G\varepsilon$ value and the rate of formation of M appear greater than in quartz. This we believe is a further illustration of sodium contamination from the Pyrex (1, 29, 30) since the sodium species has a much faster rate of formation (Table 1). This, coupled with its higher extinction coefficient (Table 2), results in an apparently enhanced rate and growth of the "lithium" species.

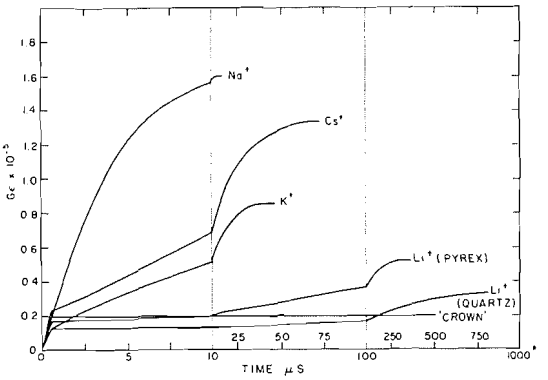

FIG. 14. Rate of formation of the species monitored at 1400–1500 nm in solutions of Li, Na, K, and Cs ethylamide. Dose per pulse $\leqslant 2 \times 10^{19}$ eV/l. Li (Pyrex), $5 \times 10^{-4}\ M$, Li (quartz), $\sim 1 \times 10^{-3}\ M$; Na, $2.5 \times 10^{-4}\ M$; K, $4.5 \times 10^{-4}\ M$; Cs, $1 \times 10^{-6}\ M$; "crown", $4 \times 10^{-3}\ M$ plus $\sim 2 \times 10^{-3}\ M$ K ethylamide and $\sim 2 \times 10^{-3}\ M$ Li ethylamide.

Conclusion

Pulse radiolysis of alkali metal ethylamide solutions demonstrates the existence of three distinct optical bands corresponding to the species of stoichiometry e_s^-, M, and M^-. Both e_s^- and M absorb in the infrared region of the spectrum but with a significant difference in the absorption maximum and magnitude of the extinction coefficient. The rate and equilibrium constants for the formation of the species M and M^- are markedly dependent on the nature of the alkali metal.

Synthesis and Structural Studies of the Metal(II) Mercury Tetrathiocyanate Complexes with Lewis Bases[1]

R. MAKHIJA,[2] L. PAZDERNIK,[3] AND R. RIVEST

Département de chimie, Université de Montréal, Montréal, Québec

Received January 8, 1973

Complexes of the type $MHg(SCN)_4.2L$, where M = Mn^{2+} to Zn^{2+} and Cd^{2+} and L = THF or Py, have been synthesized and characterized by spectroscopic methods. The thiocyanato groups are bridging between M^{2+} and Hg^{2+} whereas the donor atom of the ligand is coordinated to M^{2+} which now attains octahedral configuration. Definite shifts in certain absorption bands of the ligands upon coordination to M^{2+} are correlated to the formation constant of the metal atom involved in coordination. Electronic spectral data as well as magnetic measurements show that the M^{2+} is a high spin species in an octahedral environment. The X-ray powder photographs indicate that Co^{2+} and Zn^{2+} complexes are isostructural and also most probably are Mn^{2+} and Fe^{2+}. Tentative assignments for metal–NCS, M–ligand, Hg—S, and L—M—L absorption bands are discussed.

Les complexes du type $MHg(SCN)_4.2L$ où M = Mn^{2+} à Zn^{2+}, Cd^{2+}, et L = THF ou Py, ont été synthétisés et caractérisés à l'aide de méthodes spectroscopiques. Les groupes thiocyanato forment un pont entre le M^{2+} et le Hg^{2+} alors que l'atome donneur du coordinat est relié au Mn^{2+} qui possède alors une configuration octaédrique. Les déplacements obtenus pour certaines bandes d'absorption des coordinats lors de la coordination au M^{2+} ont été reliés à la constante de formation des complexes impliqués lors de la coordination. Des données obtenues des spectres électroniques aussi bien que magnétiques ont montré que le M^{2+} a un spin élevé et est dans un environnement octaédrique. Les photographies tirées des rayons-X (poudre) ont montré que les complexes du Co^{2+} et du Zn^{2+} sont isostructuraux de même que, fort probablement, ceux du Mn^{2+} et Fe^{2+}. Des attributions hypothétiques pour les bandes d'absorption métal—NCS, M—coordinat, Hg—S et L—M—L sont discutées. [Traduit par le journal]

Can. J. Chem., **51**, 2987 (1973)

Introduction

In our previous paper (1) we have reported the syntheses and structures of cobalt(II) mercury tetrathiocyanate complexes with Lewis bases. Related compounds like $MHg(SCN)_4$ with M = Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} have been known to be quite stable and their infrared, reflectance spectra, and X-ray powder patterns for some salts are reported (2–7). The X-ray structure (8) shows that the blue salt $HgCo(NCS)_4$ contains Co(II) in almost regular tetrahedral sites surrounded by four nitrogen atoms, while there is essentially tetrahedral coordination of the mercury by sulfur atoms. The corresponding zinc salt is isomorphous with cobalt salt (9). In the green salt $CuHg(SCN)_4$, the Cu atom is surrounded by an approximate square plane of nitrogen atoms, with bridging sulfur atoms above and below the plane (10). To understand the coordinating ability of the acidic metal site, we have prepared complexes $MHg(SCN)_4 \cdot 2L$, with M = Mn^{2+} to Zn^{2+} or Cd^{2+}, L = THF or py and have characterized them by an elemental analysis infrared, electronic, magnetic, and X-ray powder photographs. The probable structures are discussed.

Experimental

Materials and Manipulations

Anhydrous metal(II) chlorides from Alfa Inorganics Inc., and mercuric thiocyanate from B.D.H. were used without further purification.

Tetrahydrofuran and pyridine Fisher analytical grade were purified by standard methods (11) and stored on molecular sieves (4A B.D.H.). Absolute alcohol was distilled and dried over molecular sieves (4A B.D.H.). All these chemicals were stored in a Dry Box flushed with dry nitrogen.

The physical measurements, *e.g.*, infrared, ultraviolet, visible spectra, magnetic susceptibility, and X-ray powder patterns were made as discussed in our earlier paper (1).

The microanalyses were done by Galbraith Laboratories, Inc., Knoxville, Tenn., U.S.A..

Synthesis of the THF Complexes

Metal(II) chlorides were dissolved in dry tetrahydro-

furan and to this added ~2% solution of mercuric thiocyanate in tetrahydrofuran slowly with constant stirring. The solutions added were exactly in the mole ratio of 1:2. The reactants were stirred for 3 d, the resulting precipitates were filtered, washed with the solvent, and dried in vacuum at room temperature. The following reaction took place

$$2Hg(SCN)_2 + MCl_2 \xrightarrow{THF} MHg(SCN)_4 \cdot 2THF + HgCl_2$$

From the filtrate mercuric chloride was obtained along with small amounts of thiocyanates. $ZnCl_2$ or even $Zn(SCN)_2$ failed to form an adduct with THF, but only gave $ZnHg(SCN)_4$.

Synthesis of the Pyridine Complexes

The THF complexes of the type $MHg(SCN)_4 \cdot 2THF$ except for the zinc complex were treated with approximately 2% solution of pyridine in absolute alcohol. The reactants were stirred for 2–3 d, the resulting solids were filtered, washed and dried in vacuum. An alternate method for preparing the pyridine complexes was by reacting 1 mol of metal thiocyanate with 1 mol of mercuric thiocyanate in 2% pyridine solution either in absolute alcohol or tetrahydrofuran. Using this method, the pyridine adduct of $ZnHg(SCN)_4$ was isolated.

These complexes are insoluble in water and in most of the organic solvents except for the pyridine complexes which are slightly soluble in pyridine. Solution spectra, molar conductance or molecular weight measurements could not be made on them. They are non-melting but do decompose above 250 °C. The analytical results are given in Table 1.

Results and Discussion

Near Infrared Spectra

The infrared frequencies of the fundamental vibrations of the complexes studied are given in Tables 2 and 3.[4] The infrared absorption bands related to the pyridine and the THF vibrations of bis-pyridine and bis-tetrahydrofuran complexes of $MHg(SCN)_4$ can easily be assigned except the very weak overtone bands. The assignment of the absorption bands due to the C—N, C—S, Hg—S stretching and S—C≡N deformation are also made by comparing the spectra of complexes with those of the simple salts, KSCN(12) and $MHg(SCN)_4$ (13). For those bands which do not occur in the free ligand, namely, M—L stretching and L—M—L bending modes which occur in the far infrared region, tentative assignments have been made using the available literature (6, 14, 15).

[4]Complete set of tables and figures (Tables 2, 3, 6, 7; Figs. 1 and 2) is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

The bis-Pyridine Complexes

The lowest ring vibrations of pyridine (16) at 405 cm^{-1} and 604 cm^{-1}, due to out-of-plane and in-plane vibrations, respectively, are significantly shifted to higher frequencies 420–38 cm^{-1} and 625–45 cm^{-1} in our complexes, which is due to coordination of pyridine to a metal. Similar shifts have been observed by other workers also (17–19). In our complexes they both follow the Irving–Williams order of Mn^{2+} (420, 625), Fe^{2+} (420, 625), Co^{2+} (425, 631), Ni^{2+} (435, 632), Cu^{2+} (438, 640), Zn^{2+} (427, 645) which is directly related to the equilibrium constants for the formation of complexes with nitrogen donating ligands (20). We can conclude that these bands shift to higher frequencies as much as 35 cm^{-1} on coordination to a transition metal of the first row. In addition to these, we do find small shifts of other pyridine bands.

The THF Complexes

In THF complexes, the strong band associated with the C—O—C antisymmetric stretching shows the expected frequency decrease (21, 22), the strong 1070 cm^{-1} band in tetrahydrofuran moves to 1035–1040 cm^{-1}, similarly, the 908 cm^{-1} C—O—C symmetric stretching band moves to 876–890 cm^{-1}. These are typical features of tetrahydrofuran being coordinated to a metal atom, which are observed in our complexes. The infrared spectrum of $CoHg(SCN)_4$ shows a carbon–nitrogen and carbon–sulfur stretching frequencies at 2137 cm^{-1} and 793 cm^{-1} respectively. In the analogous compounds in which cobalt(II) is replaced by other divalent metals, these vibrations occur at approximately the same frequencies with the same intensities indicating no effect of changing M^{2+} on ν(C≡N) and ν(C—S) bands. The position of these bands in our complexes is comparable to the position of the same bands in $MHg(SCN)_4$ (13) since they appear at 2116–60 cm^{-1} and 716–70 cm^{-1}, respectively.

The S—C≡N deformation bands occur as a pair at *ca.* 465 cm^{-1} and *ca.* 445 cm^{-1} in our complexes, which are in good agreement with the values of 461 cm^{-1} and 448 cm^{-1} for $MHg(SCN)_4$ (15).

Far Infrared Spectra

The far infrared spectra of the complexes are shown in Figs. 1 and 2 and assignments of the important bands in the region 300–33 cm^{-1} are

†The missing M—NCS or M—L stretching bands are most probably hidden under the assigned bands.

summarized in Table 4.[4] In this region we should expect stretching vibrations of M—NCS, M—Ligand and Hg—S. We have assigned the strong absorption bands at 250–280 cm^{-1} as shown in Table 4, to M—NCS stretching. Clark and Williams (19) have shown that M—NCS stretching frequency decreases approximately by 65 cm^{-1} when changing the environment from tetrahedral to polymeric octahedral around metal atom. Since M—NCS stretching vibrations in tetrahedral complexes $MHg(SCN)_4$ appear *ca.* 320–278 as reported by Forster and Goodgame (6). Our results show a decrease in frequency, and are in good agreement with available data.

The metal—ligand and Hg—S stretching vibrations are assigned on the assumption that for a series of compounds $MHg(SCN)_4 \cdot 2L$, of the same stereochemistry, the ν(M—L) and ν(Hg—S) vibrations will have approximately the same frequencies. In some cases, overlapping can take place, hance making it difficult to assign a particular band with certainty. We have assigned absorption bands located at 220–240 cm^{-1} to asymmetric ν(M—O) (THF) or ν(M—N) (pyridine) stretching vibrations (23). ν(M—N) asymmetric vibrations are strongly dependent on the ligand to which the nitrogen atom is attached and their frequencies fall off in the order metal—ammonia(24) (420–500 cm^{-1}) metal—hydrazine(25) (306–440 cm^{-1}), metal—glycine (26) (275–423 cm^{-1}), metal—pyridine (200–287 cm^{-1}) (27), metal—α′α′-dipyridyl(23), metal—*o*-phenanthroline(1, 27), *i.e.*, among other factors, they are function of the mass of the ligand.

Hg—S stretching bands have been assigned by many workers (13) around 200 cm^{-1}. We have assigned the strong absorption bands in the 198–220 cm^{-1} region to Hg—S stretching modes as shown in Figs. 1 and 2. We do observe a number of bands below 200 cm^{-1} which may be due to symmetric M—L stretching, and L—M—L bending modes. These are not assigned due to uncertainty.

Electronic Spectra and Magnetic Susceptibilities

The corrected magnetic moments of our complexes at room temperatures are shown in Table 5, which are indicative of M^{2+} being in a weak crystal field, hence high spin state. The extensive orbital contribution (*i.e.* ~0.9 for Co^{2+}, 0.6 for Fe^{2+}, and 0.5 for Ni^{2+}) over spin only moment also implies an octahedral environment around M^{2+}. The values of the electronic absorption in the u.v.–visible region are in good agreement with those reported for M^{2+} in an octahedral configuration.

The electronic, the magnetic spectra, and the internal consistency of the infrared results lead us to conclude that in these complexes: (*i*) THF and pyridine are coordinated to a transition metal, (*ii*) the bridged structure M—SCN—M is

maintained, (*iii*) M^{2+} is in a high spin state within octahedral environment.

X-Ray Powder Patterns and Probable Space Group

Compounds of the type $MHg(SCN)_4$ (1–3) are known for many years. The X-ray single crystal studies of $CoHg(SCN)_4$ (28) have shown that both cobalt and mercury are tetrahedrally attached by thiocyanato bridging, and $ZnHg(SCN)_4$ is isomorphous with the cobalt compound (1).

The strong lines in the powder photograph of our compounds (THF series) are identical, but because of the large number of lines it is hard to conclude that they are isomorphous. The powder patterns of Co-pyridine and Zn-pyridine complexes are superimposable, which demonstrates their isomorphic structure.[4]

Financial support from the National Research Council of Canada is greatly appreciated. We thank Professor A. L. Beauchamp for helpful discussions. Authors are very thankful to Dr. R. N. Jones, National Research Council of Canada for running the far infrared spectra in his laboratory.

Apparent Molal Heat Capacities and Volumes of Tetrabutylammonium Carboxylates and Related Solutes in Water at 25 °C

PAUL-ANDRÉ LEDUC AND JACQUES E. DESNOYERS
Department of Chemistry, Université de Sherbrooke, Sherbrooke, Quebec
Received March 6, 1973

The apparent molal volumes and heat capacities were measured in water at 25 °C with a flow digital densimeter and a flow microcalorimeter for the following salts: tetrabutylammonium octanoate, tetrabutylammonium butanoate, tetrabutylammonium bromide, ammonium acetate, ammonium chloride, ammonium bromide, sodium octanoate, and sodium acetate. The tetrabutylammonium octanoate and butanoate and sodium octanoate form micelles at 0.13, 0.6, and 0.35 *M*, respectively. The concentration dependence of the apparent molal volumes of the carboxylate salts is similar to that of typical hydrophobic or hydrophilic electrolytes. On the other hand, in the submicellar region, the concentration dependence of their apparent molal heat capacities is abnormal when compared with model electrolytes. It seems that the heat capacities may be reflecting interactions involving a hydrogen bonding of the carboxylate group with water.

Les capacités calorifiques et les volumes apparents molaires ont été mesurés dans l'eau à 25 °C au moyen d'un microcalorimètre dynamique et d'un densimètre digital à écoulement pour les sels suivants: les octanoate, butanoate et bromure de tétrabutylammonium, les octanoate et acétate de sodium et les acétate, chlorure et bromure d'ammonium. Les octanoate et butanoate de tétrabutylammonium et l'octanoate de sodium forment des micelles aux concentrations suivantes: 0.13, 0.6, et 0.35 *M*. La dépendance sur la concentration des volumes apparents molaires des carboxylates est semblable à celle des électrolytes hydrophobes ou hydrophiles typiques. Par contre, dans la région sous-micellaire, la dépendance sur la concentration des capacités calorifiques apparentes molaires est anormale par rapport aux électrolytes modèles. Il semble que les capacités calorifiques font ressortir des interactions du type pont hydrogène entre les groupements carboxylate et les molécules d'eau.

Can. J. Chem., **51**, 2993 (1973)

Introduction

Recently, Lindenbaum (1) has measured the enthalpies of dilution of some tetrabutylammonium carboxylates in water. These salts formed by two hydrophobic ions, one symmetrical and one linear, are quite soluble in water and are characterized by very large exothermic enthalpies of dilution. The nature of the interactions giving rise to these large solubilities and enthalpies are still somewhat obscure, but they are of fundamental importance to the understanding of structural interactions and hydrophobic bonding in water. We have felt that the knowledge of the apparent molal volumes, ϕ_v, and heat capacities, ϕ_c, of tetrabutylammonium butanoate (TBABu) and octanoate (TBAOc) in water at 25 °C would be useful in this respect since these properties have proven to be very informative on hydrophobic interactions (2, 3). The negative concentration dependence of ϕ_v and ϕ_c has been attributed to hydrophobic interactions (non-contact ion pairing). It was also shown that micelle formation causes a large increase in ϕ_v and a large decrease in ϕ_c. We were also led in this study to measure ϕ_v and ϕ_c of ammonium acetate (NH_4Ac), NH_4Cl, NH_4Br, sodium acetate (NaAc), and sodium octanoate (NaOc). The ϕ_c of n-Bu_4NBr (TBABr) (4) have also been extended to higher concentrations.

Experimental

The preparation and purification of TBABu and TBAOc were essentially the same as was described by Lindenbaum (1). The origin and purity of the required chemicals are: TBABr (Eastman Kodak) recrystallized twice from ethyl acetate (5), silver nitrate 99.98% (Engelhard), butanoic acid (Baker), and octanoic acid (Baker). Both acids were distilled under vacuum from a fractionating column and the distillates were shown to be chromatographically pure.

The salt NaOc was prepared as described by Campbell *et al.* (6) and dried under vacuum at 120 °C for 48 h. All other salts (ACS Fisher certified reagent) were used without further purification and, except for NH_4Ac which is highly hygroscopic, dried in the same manner. The latter salt was freeze-dried under vacuum in a rotating flask containing stainless steel balls which helped to remove traces of water by crushing the crystals. The finely powdered salt was then transferred and weighed, all under dry nitrogen atmosphere.

All solutions, except those of TBAOc and TBABu,

*Reference numbers in parentheses.

were freshly prepared by weight with water redistilled from an alkaline permanganate solution. TBABu and TBAOc solution were obtained from a weight dilution of a 2.110_7 and 1.020_8 m stock solution. The molalities were converted to molarities whenever necessary using the measured densities of the solutions.

The apparent molal volumes and heat capacities are obtained from the following equations

$$[1] \qquad \phi_v = \frac{M}{d_0} - 1000\frac{(d - d_0)}{cd_0}$$

$$[2] \qquad \phi_c = Mc_p + 1000\frac{(c_p - c_p^0)}{m}$$

or

$$[3] \qquad \phi_c = \phi_v\sigma_0 + 1000\frac{(\sigma - \sigma_0)}{c}$$

where M is the salt molecular weight, c the molarity, m the molality, d the density (in g cm^{-3}), c_p the weight specific heat (in J K^{-1} g^{-1}) and $\sigma(= c_p d)$ the volumetric specific heat (in J K^{-1} cm^{-3}). For pure water at 25 °C, d_0, c_p^0 and $\sigma_0 = c_p^0 d_0$ were taken respectively as 0.997047 g cm^{-3} (7), 4.1793 J K^{-1} g^{-1} (8) and 4.1670 J K^{-1} cm^{-3}.

The differences in densities were measured to $\pm 3 \times 10^{-6}$ g cm^{-3} with a flow digital densimeter (9) and $(\sigma - \sigma_0)/\sigma_0$ with a flow microcalorimeter (10). The $\Delta\sigma/\sigma_0$ is obtained to $\pm 0.3\%$ (11) up to the limit of the sensitivity on $\Delta\sigma$ which is 7×10^{-5} J K^{-1} cm^{-3}. The general procedures for the density and heat capacity measurements were described in the original references.

Results

The experimental densities and volumetric specific heats and derived ϕ_v and ϕ_c are available elsewhere.[1] The data at low concentrations were fitted to the equations

$$[4] \qquad \phi_v = \phi_v^0 + A_v c^{1/2} + B_v' c$$

$$[5] \qquad \phi_c = \phi_c^0 + A_c c^{1/2} + B_c' c$$

where ϕ_v^0 and ϕ_c^0 are the standard apparent molal quantities (infinite dilution), A_v and A_c are the limiting Debye–Hückel slopes (A_v = 1.867 and A_c = 28.99 for 1:1 electrolytes in water at 25 °C) and the parameters B_v' and B_c' give the deviations from the Debye–Hückel law (B_v' and B_c' should be distinguished from B_v and B_c which correspond to eqs. 4 and 5 expressed in m). These parameters are obtained by a weighted least-squares method and are given in Table 1; those for NaBr and NaCl are also included for comparison. The densities of TBABr (12) and NH_4Br (2) were taken from the literature.

The accuracy of the present measurements may best be checked from the additivity of ϕ_c^0 and ϕ_v^0 and, whenever possible, from a comparison with literature data.

[1a] ϕ_c^0(NaOc) + ϕ_c^0(TBABr) − ϕ_c^0(NaBr) = 1883 J K^{-1} mol^{-1}
ϕ_c^0(TBAOc) = 1906 J K^{-1} mol^{-1}

[1b] ϕ_v^0(NaOc) + ϕ_v^0(TBABr) − ϕ_v^0(NaBr) = 409.3 cm^3 mol^{-1}
ϕ_v^0(TBAOc) = 411.3 cm^3 mol^{-1}

[2a] $\phi_c^0(NH_4Br)$ + ϕ_c^0(NaAc) − ϕ_c^0(NaBr) = 93.4 J K^{-1} mol^{-1}
$\phi_c^0(NH_4Ac)$ = 105.4 J K^{-1} mol^{-1}

[2b] $\phi_v^0(NH_4Br)$ + ϕ_v^0(NaAc) − ϕ_v^0(NaBr) = 58.2 cm^3 mol^{-1}
$\phi_v^0(NH_4Ac)$ = 58.6 cm^3 mol^{-1}

[3a] $\phi_c^0(NH_4Br) - \phi_c^0(NH_4Cl) = -8\ J\ K^{-1}\ mol^{-1}$

$\phi_c^0(NaBr) - \phi_c^0(NaCl) = -3\ J\ K^{-1}\ mol^{-1}$

[3b] $\phi_v^0(NH_4Br) - \phi_v^0(NH_4Cl) = 6.7\ cm^3\ mol^{-1}$

$\phi_v^0(NaBr) - \phi_v^0(NaCl) = 6.8\ cm^3\ mol^{-1}$

[4a] $\phi_c^0(TBAOc) - \phi_c^0(TBABu) = 358\ J\ K^{-1}\ mol^{-1}$

$\phi_c^0(HeptNH_3Br) - \phi_c^0(PrNH_3Br) = 343\ J\ K^{-1}\ mol^{-1}$ (ref. 3)

[4b] $\phi_v^0(TBAOc) - \phi_v^0(TBABu) = 65.1\ cm^3\ mol^{-1}$

$\phi_v^0(HeptNH_3Br) - \phi_v^0(PrNH_3Br) = 63.8\ cm^3\ mol^{-1}$ (ref. 2)

For alkali halides, ϕ_c can usually be obtained to $\pm 0.5\ J\ K^{-1}\ mol^{-1}$ above 0.1 *m* (8). Since eq. 5 is usually obeyed over a fairly wide concentration range, ϕ_c^0 can often be determined to better than $1\ J\ K^{-1}\ mol^{-1}$ with alkali halides (11). With the carboxylate salts, the limited concentration regions where eq. 5 can be used, errors in the determination of the initial stock solutions (with TBAOc and TBABu) and the possibility of a small degree of hydrolysis probably increase the uncertainty on ϕ_c^0 to about $\pm 10\ J\ K^{-1}\ mol^{-1}$. The only ϕ_c^0 of carboxylate salts that can be compared with literature data is NaOc; KOc was studied in 0.04 *N* KOH by Goddard *et al.* (15) and their ϕ_c^0, after correction for the difference between Na^+ and K^+, is $621\ J\ K^{-1}\ mol^{-1}$, compared with our $594\ J\ K^{-1}\ mol^{-1}$.

The ϕ_v^0 all appear to be precise to better than $1\ cm^3\ mol^{-1}$ from the additivity tests. Also ϕ_v^0 of NaAc ($39.18\ cm^3\ mol^{-1}$) can be compared with Millero's recommended value ($39.25\ cm^3\ mol^{-1}$) (16) and ϕ_v of NaOc, derived from Campbell's densities (6), agree inside the experimental uncertainty with ours.

The accuracy on ϕ_v and ϕ_c is sufficiently good to insure that any trends we will observe when comparing B_v' and B_c' for different electrolytes could not be due to experimental uncertainty.

Discussion

Ion–Solvent Interactions

The standard ϕ_v^0 of hydrophobic solutes are rather insensitive to ion–solvent interactions due to the compensation between the cavity effect and the increase in ice-likeness (2, 17). On the other hand, ϕ_c^0 of structure makers are usually much larger than their intrinsic heat capacities (18), *i.e.* the molar heat capacity of the solute itself. These latter values are not known for the present organic ions but their order of magnitude can be estimated from the specific heats of related organic liquids or solids (1.8 to $2\ J\ K^{-1}\ g^{-1}$ in general) and the solute molecular weight. With this test, TBAOc, TBABu, TBABr, and NaOc all appear as strong hydrophobic structure makers, while all the other salts are structure breakers ($\phi_c^0 < C_p(in)$). This is in agreement with the B_η viscosity coefficients which indicate that NH_4Br is a structure breaker (19) and with the enthalpies of transfer from H_2O to D_2O which suggest that sodium acetate is a structure breaker (20). Finally, ϕ_c^0 and ϕ_v^0 of NaOc are comparable with those of octylamine hydrobromide (2, 3), if allowance is made for the difference between Na^+ and Br^-. Therefore, the ϕ_v^0 and ϕ_c^0 of the present salts are all normal when compared with other similar solutes, or at least the anomalies are not obvious from their signs and orders of magnitude.

Solute–Solute Interactions

The concentration dependence of ϕ_v of the long chain carboxylate salts are compared with TBABr on Fig. 1. The excess apparent molal volumes, $\phi_v^{EX} = \phi_v - \phi_v^0 - A_v c^{1/2}$,[2] all show

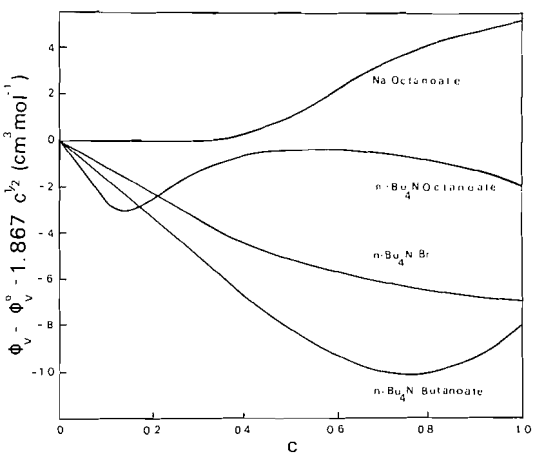

FIG. 1. Excess apparent molal volumes of carboxylate salts and tetrabutylammonium bromide in water at 25 °C.

[2]In defining these excess functions, we have assumed the Debye–Hückel limiting law to be part of the ideal function.

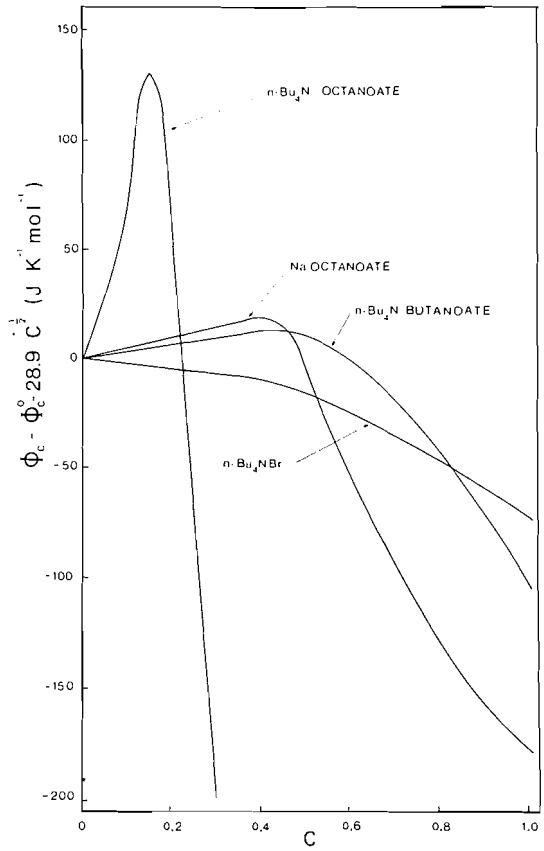

FIG. 2. Excess apparent molal heat capacities of carboxylate salts and tetrabutylammonium bromide in water at 25 °C.

an initial decrease and, with the carboxylate salts, eventually an increase with concentration. Micelle formation has been shown to be accompanied by a sharp increase in ϕ_v (2, 21). Therefore some hydrophobic association occurs with the carboxylate salts, but the lack of sharpness in the increase suggests that micelles are formed over a wide range of concentration. The critical micelle concentration (CMC) was taken as the minimum in ϕ_v^{EX} which probably corresponds to the region where micelles begin to form. The estimated critical micelle concentrations of these systems are summarized in Table 2. There are also signs of hydrophobic bonding with TBABr beyond 0.3 *M* although this association cannot really be qualified as micelle formation. The most interesting feature of Fig. 1 is probably the large decrease in the CMC when Na^+ is substituted for TBA^+. This is a general observation that

TABLE 2. CMC of carboxylate salts in water at 25 °C

	CMC (mol l^{-1})		
Electrolyte	from ϕ_v*	from ϕ_c†	Average
TBAOc	0.13	0.14	0.13
NaOc	0.32	0.38	0.35
TBABu	0.7	0.4	0.6

*CMC taken as the minima in Fig. 1.
†CMC taken as the maxima in Fig. 2.

larger counter ions reduce the CMC of surfactants (22). The explanation often given is that adsorption of the counter ions increases with their size.

A negative B_v' is usually interpreted through the overlap of hydrophobic co-spheres (5, 12, 23, 24) with typical hydrophobic salts such as the tetraalkylammonium halides (5, 12, 13) and long-chain alkylamine hydrobromides (2) in the sub-micellar region. Corresponding to the large positive apparent molal relative enthalpies ϕ_L of TBABu and TBAOc (1), a large negative B_v' is observed, and B_v' of TBAOc is more negative than either TBABr or NaOc. This suggests strong hydrophobic–hydrophobic structural interactions either of the cation–cation or cation–anion type. The only unexpected result is with NaOc, which has a slightly positive B_v' while a negative one would have been predicted. No explanation for this can be given.

With the present surfactants we can assume some kind of cooperative effect between the cationic–anionic and anionic–anionic hydrophobic interactions leading to stronger overall attractive forces (lower ΔG and CMC). This can be considered a triplet interaction; the attractive forces between two hydrophobic anions is larger in the presence of TBA^+. Therefore, the ϕ_v data, in agreement with the heats of dilution (1), seem to indicate that hydrophobic pair or triplet interactions increase in the order TBABr < TBABu < TBAOc, which is what we would expect.

The excess heat capacities, $\phi_c^{EX} = \phi_c - \phi_c^0 - A_c c^{1/2}$ (see footnote 2), for the carboxylate salts and TBABr are compared in Fig. 2. The large decrease in ϕ_c usually accompanying micelle formation (3, 15) is again observed for the long-chain carboxylate salts. The CMC, taken as the maximum in ϕ_c^{EX}, are given in

Table 2 and appear in reasonable agreement with those obtained from ϕ_v.

The parameters B_c' of most tetraalkylammonium halides (4, 25) and alkylamine hydrobromides (3) are all negative at 25 °C. This negative excess heat capacity has been attributed to hydrophobic–hydrophobic interactions (4); if hydrophobic hydration is responsible for the large positive $\phi_c^0 - C_p$ (in), then overlap of the hydrophobic co-spheres should decrease the structural effect per mole of solute. If this explanation is correct we would expect the excess ϕ_c in the submicellar region, or B_c' to become more negative in the order TBABr < TBABu < TBAOc. The exact opposite is observed. This apparent contradiction either means that the interpretation of B_c' previously given was wrong or that extra solute–solute interactions occur with the hydrophobic carboxylate salts.

Studies presently underway in this laboratory on the temperature dependence of B_c' of hydrophobic solutes indicate that dB_c'/dT is quite often positive. This means that B_c' of salts such as TBABr become less negative as the temperature decreases. As a matter of fact, with nonyl trimethyl ammonium bromide, B_c' actually becomes positive at 5 °C. Therefore, the previous interpretation of B_c' (4) might well have been wrong and the long-chain carboxylate salts might be behaving like typical hydrophobic solutes at very low temperatures. This explanation might account for ϕ_c^{EX} of TBABu and TBAOc, but the positive ϕ_c^{EX} of NaOc in the submicellar region is still intriguing since B_c' of octylamine hydrobromide (2) is negative and that of sodium octylsulfate (26) is approximately zero. The carboxylate group could therefore be partially responsible for the positive B_c'. It has been shown (27) that the addition of an —OH or —COONa group on a benzene ring causes a negative contribution to ϕ_c^0 and a positive ϕ_c^{EX}. The decrease in ϕ_c^0 was attributed to solute–solvent hydrogen bonding which was a weak interaction compared with the $H_2O...H_2O$ hydrogen bond but which increased in relative strength as the temperature was raised. This small but very temperature-dependent hydrogen-bonding interaction could account for the large contribution of these groups to ϕ_c^0. With the present solutes, it is not possible to compare ϕ_c^0 of the ions with the corresponding alkanes to determine the effect of the —COONa group since the data on these alkanes are not available. On the other hand, the ϕ_c^{EX} may very well be related to the hydrogen-bonding capacity of these electrolytes.

If hydrogen bonding interactions are involved with ϕ_c^{EX} of hydrophobic solutes, they should also show up with hydrophilic electrolytes such as NH_4Ac and NaAc. Alkali halides have small positive or negative B_v' and B_c' parameters. An examination of Table 1 indicates that B_v' of NH_4Ac and NaAc are normal when compared with NaCl and NaBr. For B_c' NaAc seems normal but NH_4Ac is more negative than expected. However, a systematic study of simple protic solutes in water would be necessary to establish the importance of hydrogen-bonding interactions on ϕ_c^{EX}.

We are grateful to Dr. S. Lindenbaum for making available to us, prior to publication, the preparation and purification procedure of the tetrabutylammonium carboxylates and to G. Perron and J. P. Savard for their assistance with some of the measurements. Grateful acknowledgment is also made to the National Research Council of Canada and to Environment Canada for financial assistance.

Mass Spectral Studies of Binuclear Metal Complexes: Copper(I) Carboxylates

DENIS C. K. LIN AND JOHN B. WESTMORE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2
Received March 22, 1973

The thermal decomposition of twenty-five cupric carboxylates was studied by mass spectrometry. In eleven cases volatile cuprous carboxylates (many of which have not been previously reported) were detected amongst the decomposition products. The cuprous carboxylates from acetic, propionic, *n*-butyric, isobutyric, difluoroacetic, trifluoroacetic, benzoic, *p*-fluorobenzoic, *p*-chlorobenzoic, *o*-chlorobenzoic, and pentafluorobenzoic acids were all found to be dimeric in the vapor phase. Two basically different fragmentation pathways can be proposed depending upon whether the copper salt is formed from an alkyl- or aryl-carboxylic acid. For the former, the spectra are dominated by even-electron fragment ions formed by initial loss of $RCO_2\cdot$ from the molecular ion. For the latter, a parallel fragmentation pathway initiated by loss of CO_2 from the molecular ion and migration of the aryl group to the metal is also present.

La décomposition thermique de 25 carboxylates cupriques a été étudiée à l'aide de la spectrométrie de masse. Dans 11 cas, on a pu détecter la présence de carboxylates cuivreux volatils (plusieurs de ceux-ci n'ont pas déjà été décrits) parmi les produits de décomposition. Les carboxylates cuivreux des acides acétique, propionique, *n*-butyrique, iso-butyrique, difluoroacétique, trifluoroacétique, benzoïque, *p*-fluorobenzoïque, *p*-chlorobenzoïque, *o*-chlorobenzoïque et pentafluorobenzoïque, se présentent tous sous forme dimérique en phase vapeur. Deux processus fondamentalement différents de fragmentation peuvent être proposés selon que le sel de cuivre est formé à partir d'un acide carboxylique alcoyle ou aryle. Pour le premier cas, les spectres se composent surtout de fragments ioniques comportant un nombre pair d'électrons qui proviennent de la perte initiale de $RCO_2\cdot$ de l'ion moléculaire. Pour le second cas, un processus de fragmentation parallèle issu de la perte de CO_2 de l'ion moléculaire et de la migration du groupe aryle au métal est aussi présent. [Traduit par le journal]

Can. J. Chem., 51, 2999 (1973)

Introduction

Since the reports of the synthesis of copper(I) formate and acetate near the beginning of this century (1–3) the structures and chemistry of copper(I) carboxylates have, until recently, been largely ignored. It is now apparent that compounds of this class may be useful reagents, particularly for organic synthesis. For example, synthesis of thiolbenzoate esters can be achieved with copper(I) thiobenzoate (4). Some copper(I) carboxylates can be decarboxylated giving organocopper intermediates which may then be coupled with aryl halides to give unsymmetrical biaryls, oxidized or pyrolyzed to give symmetrical biaryls, or hydrolyzed to arenes (5–8). Knowledge as to the relative stabilities and properties of copper(I) carboxylates would be useful in their synthesis and characterization.

Our primary interest in these complexes was to study the competing effects of metal and ligand in the mass spectra of metal-containing compounds, an area of theoretical and practical importance. Only a few copper(I) carboxylates have been prepared by simple methods (9, 10). However, our initial observations (11) that copper(I) acetate and benzoate could be produced thermally from the corresponding copper(II) complexes prompted a search for other copper(I) carboxylates that could be detected in a similar way. Consequently, we prepared twenty-five copper(II) carboxylates and in eleven cases were able to detect volatile copper(I) carboxylates among the products of decomposition of a sample of the copper(II) compound heated on the sample probe of a mass spectrometer.

Of importance in an interpretation of the mass spectra of the copper-containing compounds is a knowledge of their probable structure. Important conclusions can be drawn from structural information obtained for the solid state. Copper(II) carboxylates have been widely studied. Of particular interest have been measurements of antiferromagnetic interactions between neighboring copper(II) ions in the dimeric or polymeric systems by structural and magnetic susceptibility determinations, and by optical, infrared, or electron paramagnetic resonance spectroscopy. Much of this work has been reviewed (12–14). Usually the carboxylate anions serve as bridging groups between copper ions. On the other hand, for copper(I) only the structure of copper(I) acetate has been reported (15, 16). It contained chains of

TABLE 1. Decomposition of copper(II) carboxylates, $Cu(CO_2R)_2$, on the mass spectrometer sample probe indicating the major decomposition products identified, for those compounds which did not give detectable amounts of volatile copper(I) carboxylates

Copper(II) carboxylate	R	Major decomposition products identified*
Formate†	H	RCO_2H (100°)
Chloroacetate	CH_2Cl	RCO_2H (95°), HCl, CH_3Cl, followed at ~300° by Cu_3Cl_3, Cu_4Cl_4
Dichloroacetate	$CHCl_2$	RCO_2H (120°), HCl, CH_2Cl_2, followed at ~300° by Cu_3Cl_3, Cu_4Cl_4
Phenylacetate	$CH_2C_6H_5$	RCO_2H (110°), $C_6H_5CO_2H$
o-Toluate	*o*-$CH_3C_6H_4$	RCO_2H (115°)
p-Toluate	*p*-$CH_3C_6H_4$	RCO_2H (115°), $(RCO)_2O$ (195°)
o-Fluorobenzoate	*o*-FC_6H_4	RCO_2H (160°), $(RCO)_2O$ (190°), RCO_2R, R_2CO
o-Methoxybenzoate	*o*-$CH_3OC_6H_4$	RCO_2H (105°), C_2H_6, HCO_2H, H_2CO?
p-Ethoxybenzoate	*p*-$C_2H_5OC_6H_4$	RCO_2H (75°), $(RCO)_2O$ (245°), RCO_2R, R_2CO, R_2O, R_2
o-Hydroxybenzoate	*o*-HOC_6H_4	RCO_2H (100°), RH (220°), HCO_2H, H_2CO
p-Hydroxybenzoate	*p*-HOC_6H_4	RCO_2H (90°)
o-Nitrobenzoate	*o*-$NO_2C_6H_4$	RCO_2H (165°)
p-Nitrobenzoate	*p*-$NO_2C_6H_4$	RCO_2H (175°), $(RCO)_2O$ (300°)
β-Naphthoate	β-$C_{10}H_7$	RCO_2H (130°), $(RCO)_2O$ (225°), RCO_2R

*H_2O, CO_2, and possibly CO were always detected. In some cases positive identification was not obtained because a significant ion could arise either from the suspected compound or as a fragment ion from a compound of higher mass. The sample temperature (± 10°) at which the acid and anhydride were first detected is given in parentheses.

†Other workers (18) obtained a mass spectrum, but with considerable difficulty, containing the copper(I) salt.

dimeric units linked together by copper(I)–oxygen interactions. In the dimeric units each carboxylate group bridges the two cuprous ions to form an eight-membered ring in which, although the copper–copper separation was identical to that in copper metal, there was believed to be only a small interaction between the copper ions. The dimeric units bear a formal resemblance to the dimeric silver(I) perfluorobutyrate complex (17). This structure supports our original claim (11) that the major copper-containing species in the vapor was dimeric since, in view of the long separations between the dimeric units in the solid, the interactions between them would be quite weak. Nevertheless, very low intensity ions containing three or four copper atoms have been detected in the mass spectra of subliming copper(I) formate, acetate, trifluoroacetate, and benzoate (18) indicating that small quantities of a more highly associated species, probably the tetramer, also sublime, in addition to large quantities of dimer. (A similar observation has been made for metal acetylacetonates. Although the major subliming species was the monomer, more highly associated species were observed at low intensity (19).)

Experimental

The mass spectra were obtained on a Hitachi Perkin–Elmer RMU-6D single focussing mass spectrometer. About 0.5 mg of the copper(II) carboxylate sample was packed into a sample tube and inserted into the mass spectrometer via the solids inlet system. While monitoring the mass spectra at frequent intervals the sample temperature was raised slowly from ~40° until copper-containing species could be detected in the spectra or until a maximum temperature of~ 300° had been reached. The ionization chamber temperature was ~200° and the electron energy was 50 V.

The copper(II) carboxylates were prepared using published procedures (12, 20, 21) and were dried under a diffusion pump vacuum for 24 h before use.

Results and Discussion

Thermal Decompositions

The compounds studied are listed in Tables 1 and 2. In all cases, as the temperature of the sample was raised, the first decomposition products detected were CO_2, H_2O, and the carboxylic acid. Many of the aromatic carboxylates also gave the acid anhydride, but at higher temperatures. The compounds which did not give detectable amounts of copper(I) carboxylates are given in Table 1, while those that did are listed in Table 2. Apart from this difference, the nature of the decomposition products in the two tables seems very similar and we have not been able to find any simple parameter upon which to make a distinction between the compounds in the two tables. In fact, the differences between the decompositions of the isomers *o*- and *p*- CH_3, OH, NO_2, and Cl benzoates indicates that if electronic and steric factors control the course of decomposition they must be very subtle.

Thermogravimetric analysis of all compounds in air, and in vacuo, also failed to establish a classification for the compounds of Tables 1 and

p-Chlorobenzoate	*p*-ClC_6H_4	RCO_2H (75°), $(RCO)_2O$ (130°), ROH?
o-Chlorobenzoate	*o*-ClC_6H_4	RCO_2H (175°), $(RCO)_2O$ (250°)
Pentafluorobenzoate	C_6F_5	RCO_2H (145°), R_2

*See footnote to Table 1.

(22). We obtained residues in all cases (except for the chloroacetates for which volatile copper(I) chlorides can be formed (Table 1)) indicating, at best, only partial conversion to copper(I) carboxylates for the compounds of Table 2. Residues of metal or metal oxide were reported in the thermogravimetric analysis of copper(II) acetate (23, 24), trifluoroacetate (25), *n*-butyrate (26), and halobenzoates (27), and metal bromide from copper(II) bromoacetate (28), though some differences in reported decomposition products probably reflect different experimental conditions and procedures. In Angel's early study (2) the yield of cuprous acetate was 3–4%. These observations are all in direct contrast to a recent report that copper(II) acetate can be sublimed unchanged in vacuo (29).

The Mass Spectra

Two basic types of fragmentation can be identified in the mass spectra of the copper-containing vapor species depending upon whether the carboxylate is derived from an aliphatic or an aromatic carboxylic acid. It is thus convenient to separate the data into Tables 3 and 4, where ion assignments, and the odd or even character of the ions, are also indicated in the conventional way. Only the relative intensities of copper-containing ions are shown since the origin (*i.e.* copper complex or other decomposition product) of other ions is ambiguous. The decompositions of the copper(II) carboxylates were apparently quite smooth since reproducible spectra could readily be obtained. We contend that only the dimer is present in significant amounts. Appreciable concentrations of monomer are considered unlikely since the relative intensities of mono-copper containing ions remained sensibly constant with variations of sample temperature indicating that mono- and di- copper-containing ions have a common parent molecular ion. This is to be expected if the copper(I) carboxylates have similar structures to the previously discussed structure for the acetate.

The atomic compositions of the ions in the spectra can be unambiguously assigned. Observed peak intensities within a given ion type agreed well with calculated intensities based on relative abundances of copper and chlorine isotopes (Cu_1, 63:65, 0.691:0.309; Cu_2, 126:128:130, 0.477:0.427:0.096; Cu_2Cl, 161:163:165:167, 0.362:0.439:0.176:0.013; Cu_2Cl_2, 196:198:200:202, 0.274:0.421:0.235:0.060). So that, in future investigations, spectra can more readily be compared, the relative intensities presented in Tables 3 and 4 are for the highest peak in the group of peaks, but if desired, the relative intensities for each ion type can be calculated by using the multipliers given in the footnote to Table 4.

Our previously reported (11) mass spectra of copper(I) acetate and benzoate have subsequently been confirmed by others (18, 29). Our mass spectrum of copper(I) trifluoroacetate is in substantial agreement with a reported spectrum (18).

In view of the structural information cited earlier, the only acceptable structure for the dimers is **1** in which the C—O bonds are of equal length and normal for a carboxyl group, the copper–copper separation is similar to that in the metal, and the O—Cu—O bond angle is

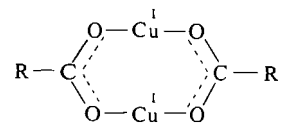
**m/e* values given are based on ^{63}Cu and ^{35}Cl. Except for R = C_6H_4Cl this gives the most abundant ion in the group. Relative intensities are given for the most abundant isotopic combination in the ion type and are not corrected to give relative total ion currents for the ion type. If desired these could be calculated by using the multipliers: Cu_1, ×1.45; Cu_2, ×2.10; Cu_2Cl, ×2.28; Cu_2Cl_2, ×2.38. (See text.) Sample temperatures in parentheses.
†Copper-containing ions were detected only at very low intensities and only the molecular ion and Cu_2R^+ could be measured.

only slightly smaller than 180°. This structure is in accord with the known preference for Cu(I) to form digonal bonds, a preference which has been interpreted in terms of formation of copper $d_{z^2}s$ hybrid orbitals (30).

The molecular ions are of high abundance in most of the spectra, indicating high stability. This can be understood from the following considerations. The molecular ions can be formally



1

represented by either of the canonical structures **2** or **3**. In **2** one of the copper ions is formally in its +2 oxidation state, a state known to be stable

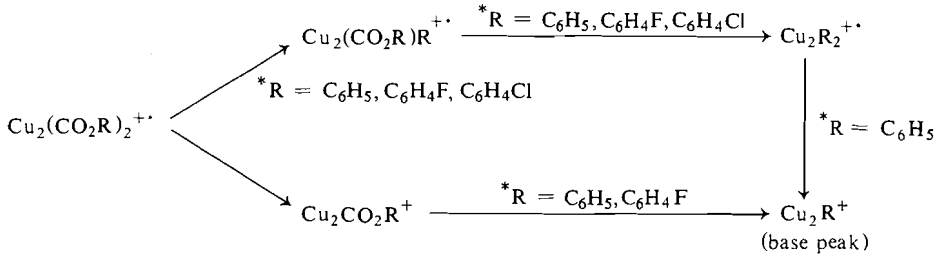
in the aqueous solution chemistry of copper. Since the pioneering work of Shannon and coworkers (19, 31), many correlations between mass spectral fragmentation patterns and the relative stabilities of metal oxidation states have been made (ref. 32 and references therein). In molecular orbital terms the relative stability of Cu(II) can be regarded as a ready donation of copper d_π electron density into ligand π orbitals (there is a vacancy in the bonding π orbital of **3**) and it seems preferable to regard the molecular ion by **4** in which the positive charge and unpaired electron are delocalized over π orbitals of both ligands and both copper atoms. Thus **4** should have high stability. Assignment of formal oxidation states in **4** is not useful since extensive mixing of the metal and ligand π orbitals is implied.

It has been possible to obtain a number of copper(I) carboxylate dimers to study the effect of the R group on the mass spectra. It is to be expected that electron withdrawing R groups would destabilize, while electron releasing R groups would stabilize the molecular ion. Thus, the relative intensities of the molecular ions are lowest when R = CF_3 and CHF_2.

Important fragment ions derived from the molecular ion can be represented by **5** and, when R is an aryl group, by **6**. **5** is formed from M^+ by elimination of $RCO_2^{\cdot}$, likely as $R^{\cdot}$ and CO_2. Whether these latter are lost sequentially or simultaneously cannot be determined unequivocally though intensities of the intermediate **7** are low, or not detectable, and when R = n-C_3H_7 a metastable peak was detected for the fragmentation $M^+ \rightarrow$ **5**. Certainly, if **7** was formed, elimination of CO_2 should occur readily. The ion $Cu_2(CO_2R)^+$ is evidently a very stable species since it is the base peak when R is an alkyl group. It is to explain this high stability that the structure **5** is suggested. The structure shown involves bonding interactions between the copper atoms (to be discussed later). Additional evidence for bond formation between the copper atoms is given by the presence in the spectra of other di-copper containing ions and in which copper–copper bonds cannot be denied. Furthermore, except when R = CF_3 or CHF_2, the total intensities of monocopper containing ions are relatively low. The lowered stability of **5** for these latter two cases can be understood by lower copper–oxygen bond strengths caused by the electronegative CF_3 or CHF_2 groups, an effect which is well-known. (For example, compare the stability constants of the copper(II) β-diketonate complexes: $Cu(acac)_2$, log $\beta_2 = 22.6$; $Cu(tfacac)_2$, log $\beta_2 = 17.2$; $Cu(hfacac)_2$, log $\beta_2 = 8$ (estimated), all in 75 volume % dioxane (33).) In addition, copper–fluorine bond formation can occur readily, a process which reflects the greater stability of these bonds compared with copper–hydrogen or copper–alkyl bonds.

When R is an aryl group, fragment ions which involve loss of CO_2 and rearrangement of R to the metal are prominent. The fragmentations are supported by metastable peaks as indicated below in the conventional way:

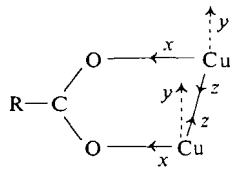


It can be noted that $Cu_2(CO_2R)R^{+\cdot}$ and $Cu_2R_2^{+\cdot}$ are radical ions (normally of lower stability than even-electron ions) and the only analogous rearrangement observed when R is an alkyl group gives the even-electron Cu_2R^+. Their presence reflects the higher stability of copper–aryl compared to copper–alkyl bonds, as evidenced by the relatively greater stability of arylcopper(I) (6, 7, 34) to alkylcopper(I) compounds (ref. 35 and references therein). Phenyl migration to copper in the mass spectra of other copper compounds (36, 37) and to other metals (37) has also been reported. The enhanced stability of the aryl-containing ions and radical ions evidently arises from π-electron delocalization between copper and aryl moieties, but we make no suggestion as to whether the aryl group occupies terminal or bridging sites with respect to the copper atoms. Bridging groups may not be essential for stability since copper(I) has a marked tendency to form copper clusters. Thus, some organocopper(I) compounds are polynuclear with octamers and tetramers apparently preferred (6, 7, ref. 35 and references therein). Copper clusters based on the cube and tetrahedron respectively were believed present (6, 7) in *m*-(trifluoromethyl)phenylcopper and *o*-(trifluoromethyl)phenylcopper.

Other noteworthy ions in the spectra include the even-electron species Cu_2F^+ and Cu_2H^+. Their precursor is probably $Cu_2(CO_2R)^+$ though only when R = CHF_2 was a metastable peak detected for the formation of Cu_2F^+ from this ion. Whenever fluorine is present in the ligand, Cu_2F^+ is formed, to the exclusion of Cu_2H^+, probably reflecting the greater strength of fluorine–copper compared to hydrogen–copper bonds. The Cu_2H^+ ion was observed in all other cases except for the acetate, reflecting the high energy required for formation of $CO_2 + CH_2$ compared to CO_2 + olefin (or aryne?) for the other complexes.

The major points of the spectra have been discussed. Further details of the fragmentations are obscured by absence of metastable transitions. Ions containing two copper atoms are noticeably persistent in the spectra and the only monocopper ion of consistently significant intensity is Cu^+.

The stability of the $Cu_2(CO_2R)^+$ ion is of interest. Assuming its point group to be C_{2v} and with axes as represented in **8** it is readily shown that the ligand σ orbitals transform as $A_1 + B_1$



8

and the out-of-plane π orbitals as $A_2 + B_2$. Pairs of equivalent copper orbitals transform as follows: $A_1 + B_1$, s, p_x, p_z, d_{z^2}, d_{xz}, $d_{x^2-y^2}$; $A_2 + B_2$, p_y, d_{xy}, d_{yz}. If **8** is regarded as formed from RCO_2^- and two d^{10} Cu(I) ions, hybrid orbitals on each copper atom, having substantial p_x character would act as acceptors for the ligand σ electrons. However, if in-plane bonds between the copper atoms are to be formed then mixing of $4p_z$, 4s, $3d_{z^2}$, and $3d_{xz}$ orbitals (as major contributors) and promotion of a d electron are required. A σ bond (d_{z^2}, p_z major contributors) and/or π bond (d_{xz}) *might* be formed in this way but we are unable to estimate their importance.

The metal orbitals which could contribute to out-of-plane π-bonding are the p_y, d_{xy}, and d_{yz} orbitals. If mixing of these orbitals and d electron promotion occur then π and/or δ bond formation between the copper atoms is possible. Furthermore, delocalization of charge between ligand and metal out-of-plane orbitals is possible. This may account possibly for the stability of the ion, $Cu_2(CO_2R)^+$.

Our rationalization of the stability of $Cu_2(CO_2R)^+$ is regarded as speculative. On the one hand, the existence of the organocopper(I) cluster compounds suggests the possibility of direct copper–copper bonding. Furthermore, weak copper–copper δ bonding interactions have been postulated in some copper(II) carboxylates (38). On the other hand, on the basis of promotion energy considerations, direct copper–copper bonding was not considered likely in (4-methyl-2-cupriobenzyl)dimethylamine in spite of the short Cu—Cu distances of 2.377 and 2.389 Å (39). In a positive ion, however, this latter objection may well be outweighed by the opportunity provided to delocalize the positive charge.

Conclusions

Two basic types of fragmentation pathway can be identified in the mass spectra of dimeric cuprous carboxylates. For aliphatic carboxylates the spectra are dominated by even-electron ions formed by initial loss of $RCO_2\cdot$ from the molecular ion. For aromatic carboxylates a parallel fragmentation pathway initiated by loss of CO_2 from the molecular ion and migration of the aryl group to the metal is also present.

We thank the National Research Council of Canada for financial support of this work.

The Limiting Conductance of $^1/_3In^{3+}$ Ion and the Conductances of Aqueous Solutions of Indium Trichloride

A. N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received March 19, 1973

The direct determination of the limiting conductance of $^1/_3In^{3+}$ ion is not possible because of hydrolysis. This figure has been obtained by a method which may be open to criticism as 56.3 mhos, at 25°. If anything, this figure is too high.

La détermination directe de la conductance limite de l'ion $^1/_3In^{3+}$ n'est pas possible à cause de l'hydrolyse. Le chiffre de 56.3 mhos à 25° a été obtenu par une méthode qui peut être ouverte à la critique. Quoiqu'il en soit, cette valeur est trop élevée. [Traduit par le journal]

Can. J. Chem., **51**, 3006 (1973)

The only investigation to be found in the literature of the conductances of aqueous solutions of indium trichloride is that of Thiel (1), who found a rapid increase in conductance, with dilution, in the dilute range ($\Lambda = 225$ mhos, for $c = 0.0003$ equiv/l), which he correctly attributed to hydrolysis. It occurred to me that it might be possible to measure the limiting conductance of $\frac{1}{3}In^{3+}$ experimentally, if the hydrolysis were suppressed by having excess of HCl present.

Some rough work with a p*H* meter gave the impression that 0.001 *N* HCl would be sufficiently strong to suppress the hydrolysis. Work was therefore undertaken on the conductance of indium trichloride in (*a*) conductance water, (*b*) HCl of strength 0.001 *N*. When pure water is the solvent, it is sufficient to subtract from the specific conductance of the solution that of the solvent by way of correction, but this is not sufficient when HCl solution is the solvent, because the ionic strength has a fixed minimum value, even when no indium salt is present. I know no way of calculating this effect theoretically, and therefore I made the assumption that the effect would be the same in an electrolyte of similar type, *viz.* lanthanum trichloride, a salt which does not undergo hydrolysis. The method I have adopted, therefore, was to determine the specific conductances of the solution in HCl and of the HCl solvent, and subtract one from the other. The final step was to plot the equivalent conductance against the square root of the ionic strength ($\sqrt{6c + 0.001}$), and to extrapolate the straight line plots which resulted to $\sqrt{6c + 0.001} = 0.0316$ ($c = 0$). This value of the limiting conductance ($\Lambda^{0\prime}$) when subtracted from the value of Λ^0 in pure water (known for lanthanum chloride) gave, it is to be hoped, the correction factor to be added to the limiting conductance of indium trichloride in 0.001 *N* HCl. The argument assumes that because La^{3+} and In^{3+} have the same charge, this is the only factor affecting the speed of the ion, at comparable ionic strength. The argument assumes, for instance, that the hydration of the ions is the same. As for the formation of complex ions, which undoubtedly occurs with In^{3+}, this is hardly likely to affect the conductance at limiting dilution. For the sake of completeness, I also determined the conductances of KCl and of $BaCl_2$ in 0.001 *N* HCl, since the conductances of these salts in water are well known. As expected, the differences between $\Lambda^{0\prime}$ and Λ^0 became less with decreasing valence (3:1, 2:1, 1:1).

All measurements were made at 25°. The conductances of barium chloride and of potassium chloride were plotted against $\sqrt{3c + 0.001}$ and $\sqrt{c + 0.001}$ respectively.

Experimental

Solid indium trichloride trihydrate was purchased from British Drug Houses but no attempt was made to obtain the anhydrous salt.[1] Lanthanum chloride heptahydrate was obtained from the Kerr-McGee Chemical Corporation. It was generally used in this form but was occasionally dehydrated by heating at 150°. Analysis of the solutions in the transport number work was done by precipitation as the hydrate and ignition to the oxide. Conductance water was obtained from a Haereus quartz still, using

[1]The author is indebted to Cominco Ltd. of Trail, British Columbia, for a concentrated solution (13.37 *N*) of pure indium chloride and a supply of indium metal.

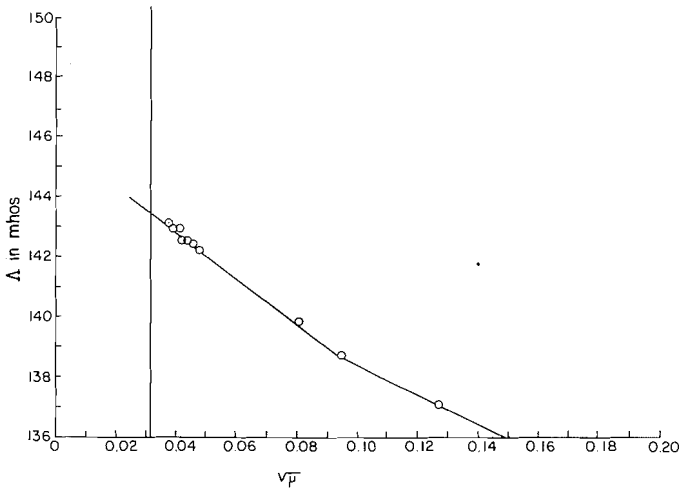

FIG. 1. Equivalent conductance of KCl in the presence of 0.001 *N* HCl, *vs.* (ionic strength)$^{1/2}$ ($\sqrt{c}$).

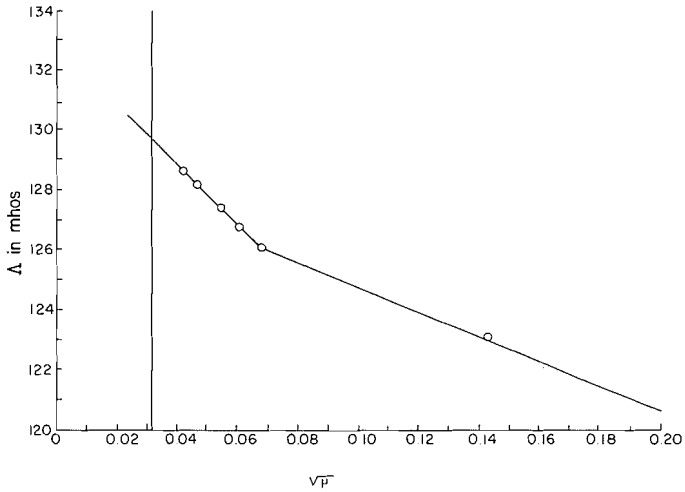

FIG. 2. Equivalent conductance of $BaCl_2$ in the presence of 0.001 *N* HCl *vs.* (ionic strength)$^{1/2}$ ($\sqrt{3c}$).

water which had previously been passed through an ion exchange column. No attempt was made to remove carbon dioxide from the water, so the specific conductance usually ran about 1×10^{-6} mho.

Conductance measurements were made on a Beckmann conductance bridge, model RC—18A, using, when necessary, a Shedlovsky quartz cell. In short, the technique was modern and accurate. The transference number was measured by the Hittorf method, using a silver anode and a silver/silver chloride cathode. In order to avoid passivity, the current was kept low, sometimes as low as 1.5 mA, with a correspondingly long run time, on one occasion as long as 72 h. Despite popular belief, this does not cause any change in the concentration of the intermediate compartment. Quantity of electricity was measured as the product of current by time. Absolutely constant current was supplied from an apparatus built by the National Research Council of Canada.

The results varied rather widely between 0.426 and 0.485 for the transport number of the cation. On the supposition that these limits are valid, the limiting conductance of $\frac{1}{3}In^{3+}$ ion must lie between 57 and 72 mho.

The numerical data are to be found in the Depository of Unpublished Data.[2] Figure 1 gives the equivalent conductance of potassium chloride in 0.001 *N* HCl, versus $\sqrt{c + 0.001}$. Extrapolated to $\sqrt{0.001} = 0.0316$, the limiting conductance appears to be 143.50, against a

[2]Photocopies may be obtained at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

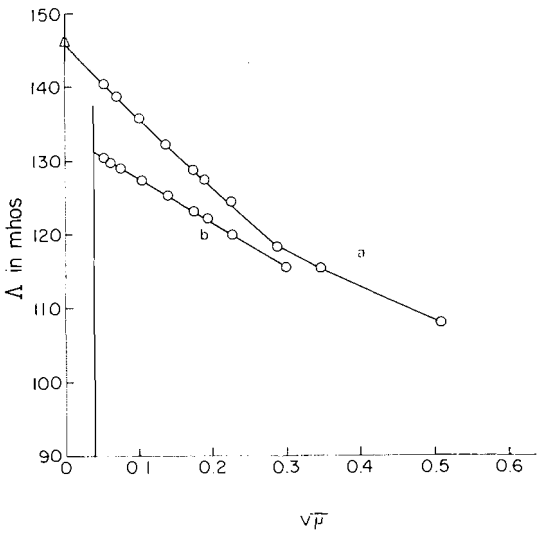

FIG. 3. Equivalent conductance of $LaCl_3$ in water (a) and in 0.001 *N* HCl (b) *vs.* $\sqrt{6c}$ and $\sqrt{6c + 0.001}$.

limiting conductance in pure water of 149.86. This indicates that the limiting conductance of a 1:1 electrolyte is reduced by 6.36 mhos, in the presence of 0.001 *N* HCl.

To show the effect of valence on the reduction in Λ^0, the conductance of $BaCl_2$ in 0.001 N HCl was measured.

Figure 2 shows the results for barium chloride; Λ is plotted *vs.* $\sqrt{3c + 0.001}$. The limiting conductance in acid appears to be 129.7 against a water value of 139.98. For a 2:1 electrolyte, the limiting conductance is reduced by 10.3 mhos.

Figure 3 gives the corresponding data for lanthanum trichloride, plotting Λ *vs.* $\sqrt{6c + 0.001}$. The limiting conductance appears to be 131.7, as against a value in pure water of 146.0. This would imply that the limiting conductance is reduced by 14.3 mhos, for a 1:3 electrolyte.

It appears that the effect of 0.001 *N* HCl in reducing conductance increases with the valence of the ion.

The corresponding data for indium chloride are given in Fig. 4.

Conclusion

The figures for the most dilute solutions of indium chloride in water are not shown, but the steep ascent of the curve is sufficiently obvious, indicating the hydrolysis of indium chloride in water. The sudden rise of the curve appears to commence at $\sqrt{6c + 0.001} = 0.3$, *i.e.* at $c = 0.015$ *N*, suggesting that hydrolysis is not appreciable above this concentration. The (large scale) extrapolation of Λ in the presence of acid gives a limiting value of 118.3 mhos. If to this is added 14.3 for a 1:3 electrolyte, the figure of 132.6 is arrived at for the limiting conductance of indium trichloride in water. From this the limiting transference number of indium in indium trichloride would appear to be 0.425 and the limiting conductance of $\frac{1}{3}In^{3+}$ ion, 56.3. This figure is lower than those of most ternary ions but higher than those of many binary ions. Since the effective diameter of an ion is largely a question of the degree of solvation, this would imply that the In^{3+} ion is more highly hydrated than say, the Al^{3+} ion.

The form of the curve expressing the conductance of indium chloride against the ionic strength in the presence of an acid shows that the limiting

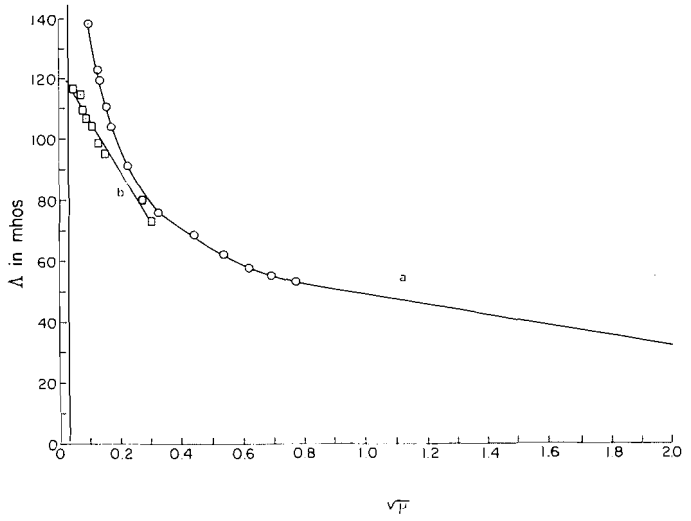

FIG. 4. Equivalent conductance of $InCl_3$ in water (a) and in the presence of 0.001 *N* HCl (b) *vs.* $\sqrt{6c}$ and $\sqrt{6c + 0.001}$.

For personal use only.

slope is greater than the Onsager slope. The obvious conclusion is that hydrochloric acid of strength 0.001 *N* is not sufficient entirely to suppress hydrolysis. Incidentally, if this were the case, my figure for the limiting conductance of $\frac{1}{3}In^{3+}$ would be still lower and this seems, on the face of it, improbable. Against this explanation of incomplete suppression of hydrolysis, I advance the following facts. (*1*) The conductance of a strong (13.37 *N*) solution of indium chloride in pure water is almost negligible ($\Lambda = 1.04$ mhos) and (*2*) the transport number indicates a lowest possible value of 56.6 for the ionic conductance. To explain the anomalous slope, I suggest that the ionization of indium trichloride takes place in stages

$$\rightarrow InCl_2 \rightleftarrows InCl_2 + Cl'$$
$$\rightleftarrows InCl^{2+} + 2\ Cl' \rightleftarrows In^{3+} + 3\ Cl'$$

The actual mechanism may be much more complicated, but the scheme is sufficient for its purpose. The final stage of the ionization, preponderating only in very dilute solutions would account for the steep slope of the graph.

^{13}C–H Coupling Constants in Cyclic Systems; a Probe for Hyperconjugation and Homoconjugation?

NICK H. WERSTIUK, ROLAND TAILLEFER, RUSSELL A. BELL, AND BRIAN SAYER

Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 25, 1972[1]

^{13}C–H coupling constants have been determined for bicyclic and tricyclic carbonyl compounds. In comparison to acyclic and monocyclic ketones these systems show an increase in the coupling constant at the bridgehead alpha to the carbonyl group.

Les constantes de couplage ^{13}C–H ont été déterminées dans le cas de composés bicycliques et tricycliques comportant une fonction carbonyle. Par comparaison avec des cétones acycliques ou monocycliques, ces systèmes ont montré une augmentation de la constante de couplage pour la position en tête de pont alpha du groupe carbonyle. [Traduit par le journal]

Can. J. Chem., **51**, 3010 (1973)

For personal use only.

Introduction

The correlation between hybridization and coupling constant for directly bonded ^{13}C—H and ^{13}C—^{13}C nuclei has provided an experimental tool for the estimation of s character in a carbon–hydrogen or carbon–carbon bond (1–10). In this area experimental and theoretical studies (11–13) have centered mainly on alicyclic hydrocarbons to avoid substituent effect problems.

Our study of the chemistry of bicyclic diones (14) has necessitated that we obtain hybridizational and conformational information on these systems. To that end a study of ^{13}C–H and ^{13}C–^{13}C coupling constants in bicyclic and tricyclic systems has been undertaken to ascertain whether or not the coupling constants are hybridizational probes in the presence of polar groups.

Results and Discussion

This communication reports the coupling constants for C_1—H, C_3—H, and C_4—H in **1**–**16**. The data are listed in Table 1.

That the difference between J_{C_1-H} and J_{C_4-H} in ketones **2** and **8**, and the thione **11** as well as J_{C_4-H} in **8** and **9** is not accountable directly in terms of an inductive effect is established by the following facts. The J_{C-H} values (CH_3-) for ethane, acetone, and acetophenone are 126, 127, and 127 Hz, respectively (12). Also, Ellis and Maciel (8) have shown that J_{C-H} alpha to the carbonyl group in 2,2-dimethylcyclopropanone (160), cyclobutanone (134.8), and cyclopentanone (129.5), respectively, is identical to J_{C-H} for the corresponding precursor hydrocarbon (cyclopropane, 161; cyclobutane, 134.6; cyclopentane, 128.5). Interestingly, a correlation, which utilizes the Swain–Lupton F (field effect) values (18) for $-I^+$ and $-I^-$ groups (12), provides information about the influence of inductive effects on J_{C-H}. The plot of J_{C-H} *vs.* the F values (Fig. 1) for a series of substituted methanes CH_3—X, where X is a $-I^+$ or $-I^-$ group, establishes that distinct correlations exist for the two types of substituents. The plot for the latter is located at a constant 15–20 Hz below the $-I^+$ plot. Thus, although the same sensitivity to $-I^+$ and $-I^-$ substituents is indicated, there must be either an attenuation of the inductive effect or there are

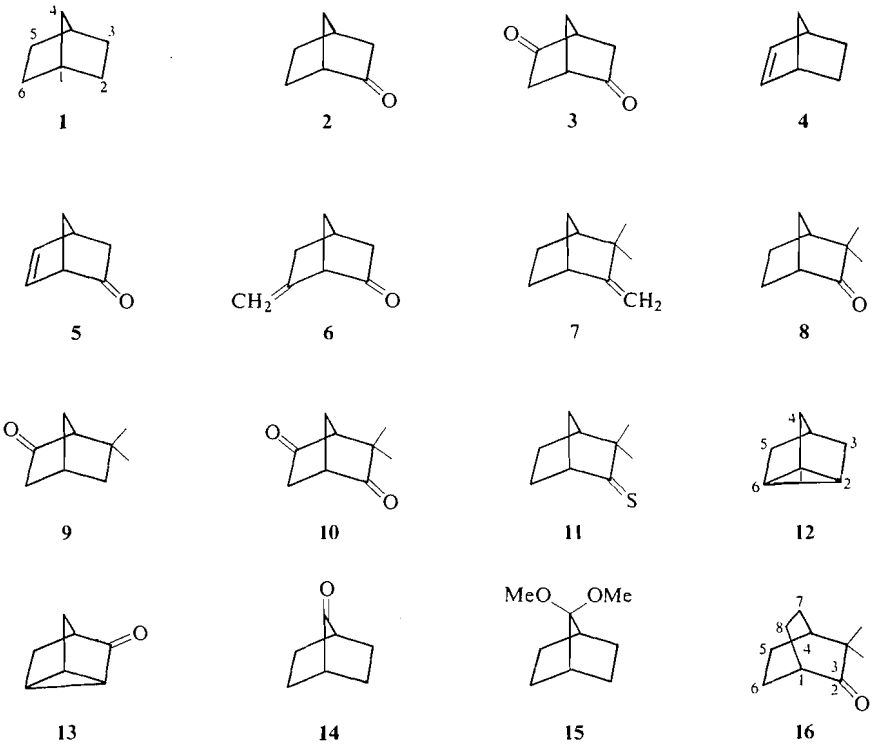

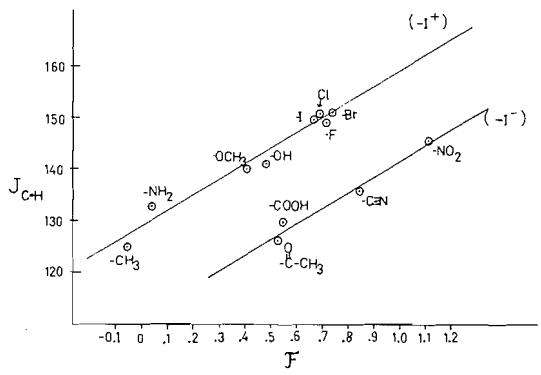

FIG. 1. Plot of J_{C-H} (H—CH_2—X) *vs.* the field effect values *F*.

other unknown factors which operate by a constant factor to decrease J_{C-H}. Conceivably, hyperconjugative interaction between C—H bonds and the π system of the $-I^-$ substituent (19) could contribute to the attenuation constant. Nevertheless, the correlations support the contention that $-I^+$ and $-I^-$ substituents interact differently with C—H bonds.

Strain effects also do not account adequately for the increase in J_{C-H} at the bridgehead since J_{C_4-H} and J_{C_3-H} in the [2.2.1]-system are insensitive to the total strain energy.[2] That is, while the strain energy (20) increases through the series **1**, **4**, and **12** (18.4, 22.8, 42.9 kcal/mol, respectively) the change in J_{C_4-H} is minimal. Compare also J_{C_3-H} for **1** and **12**. Furthermore, a comparison of the C–H coupling constants (alpha to the carbonyl) and strain energies (SE) (21) for cyclobutanone, cyclopentanone, and norcamphor with those of the parent hydrocarbons establishes that there is no correlation between ΔJ and Δ(SE).

Several factors may contribute to the unexpected increase in J_{C_1-H} in **2**, **3**, **8**, **9**, **10**, **11**, and **14** and J_{C_4-H} in **13**. Conceivably, hyperconjugative interaction between the appropriate strained σ bond and the carbonyl or thiocarbonyl is important and alters the hybridization at C-1 and C-4. Interestingly, Olah *et al.* (22) have reported a J_{C_1-H} value of 152 ± 5 Hz for the 2-phenylnorbornyl cation. Also, while the effect of a benzoyl group on J_{C-H} in a methyl group is minimal (*vide supra*) there is an increase of 11 Hz

[2]It is understood that not all the "strain" in each case is located in the bridgehead bonds.

TABLE 2. Coupling constant and strain energy differences

Nortricyclanone		1.80			
Norbornene	2.81	2.81	5.93	5.93	27
Norbornenone	2.87	3.14	6.54	6.09	27

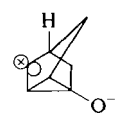
in $J_{\alpha C-H}$ and $J_{\beta C-H}$ in the conjugated system benzoylcyclopropane (173 Hz) over cyclopropane (162 Hz) (23). Possibly, the attenuating hyperconjugation component (*vide supra*) is removed in the [2.2.1]-systems because the bridgehead C—H bond is aligned perpendicular to the π system, thereby unmasking the inductive effect of the carbonyl group. Conceivably, the alignment of the lone pairs on the oxygen or sulfur with respect to the C—H bond is critical in the norbornyl systems and in benzoylcyclopropane.

Nevertheless, the J_{C-H} values for 7-norbornanone (152 ± 1), nortricyclanone (159 ± 1), and the ketal **15** (144 ± 1) account for the reactivity order observed in the KO-*t*-Bu-catalyzed exchange studies carried out by Gassman and Zalar (24). While 25% of C-1,C-4 hydrogen in 7-norbornanone is exchanged for deuterium after 48 h at 200°, exchange is 75% complete at C-4 in nortricyclanone after only 29 h. The dimethyl ketal of nortricyclanone does not exchange at C-4.

Therefore, since J_{C_1-H} for camphenilone (**8**) is 152 ± 1 Hz, it is likely that some of the deuterium incorporated into **8** at C-1 and -6 via homoenolization (25) is actually introduced through exchange at the bridgehead. We are currently studying base-catalyzed exchange in 6,6-dimethylcamphenilone to check this.

We propose therefore that the upfield shift of C_1—H over C_4—H in norcamphor and C_4—H in nortricyclanone (Table 3) over nortricyclane, is in each case primarily a consequence of "sp-like" hybridization rather than shielding by the carbonyl in the former and the cyclopropyl ring in the latter (23). ^{13}C chemical shift data for nortricyclanone and nortricyclane (Table 4) further support this proposal. That is, while C-1 experiences a downfield shift of 12.1 p.p.m. in norcamphor over norbornane the downfield shift of C-4 in nortricyclanone relative to nortricyclane is only 6.8 p.p.m. and is consistent with more "sp-like" hybridization at C-4, as established by J_{C_4-H}.

The data for norbornenone (**5**) are of interest. While the effect of the introduction of a double bond into norcamphor on J_{C_1-H} is minimal, J_{C_3-H} and J_{C_4-H} (155 ± 1) show dramatic increases. Therefore, in a valence bond description, **17** contributes significantly to the ground state of norbornenone and affects J_{C_4-H}. That **17** must be considered is further supported by ^{1}H and ^{13}C chemical shift data listed in Tables 3 and 4 respectively.



17

Possibly, cyclic conjugation, resulting from conjugation (through space) between C-6 and the carbonyl group at C-2 and hyperconjugation through three σ bonds (28, 29, 30, 31), operates

*Downfield from TMS.

in **5**. The cyclic conjugation could alter J_{C-H} by changing the molecular orbital description of the carbon framework and ΔE for the C—H bond. Several σ-coupled systems, namely diazabicyclooctane (29, 32), *exo*- and *endo*-dicyclopentadienones (28), diazaadamantone (28), tricyclo[4.4.2.0^{1,6}]dodeca-3,8-diene-11,12-dione (33), and *exo*- and *endo*-polycyclic cyclobutanones (34) warrant study to determine whether or not the C–H coupling constants on the σ framework are influenced by this hyperconjugation. The bridgehead coupling constants in diones **3** and **10** are 157–159 Hz. The unexpected increase in J_{C-H} over norcamphor may be due to improved hyperconjugative alignment of the C_1—C_6 and C_4—C_5 bonds as a result of a synchro-twist (35) as indicated by models and/or the interaction of the carbonyl groups via three σ-bond conjugation.

Although the contribution of each of the factors which determines the magnitude of J_{C-H} cannot be described precisely at present, the bridgehead coupling constants for the diones **3** (C-1, C-4; 157 ± 1) and **11** (C-1, C-4; 159 ± 1) and norbornenone (**5**) (C-4; 155 ± 1) establish that enhanced rates of base-catalyzed exchange should be expected at these sites. Studies on 3,3-dimethylnorbornenone and 3,3,6,6-tetramethylnorbornane-2,5-dione are presently underway.

Experimental

The ^{13}C–H spin–spin coupling constants were obtained on a Varian HA-100 spectrometer at 23.5 kG and 25.1 MHz. The operating probe temperature was +55 °C. Field frequency stabilization was achieved by use of an external (1.5 mm capillary) $^{13}CS_2$ lock and chemical shift measurements required for the location of appropriate carbons were made initially relative to internal dioxane and then to tetramethylsilane. A sample volume of 0.2–0.3 ml was used in a 5 mm o.d. sample tube with dioxane or CCl_4 as solvent where necessary. A signal accumulation of 300–500 scans on a Varian Associates C-1024 time averaging computer was required. J_{C-H} was obtained from the doublets and triplets by drawing an envelope for each absorption (broadened by long range coupling) and using the center (at half the peak width at half height) of the Gaussian curves. Each value quoted is the mean of 3–4 determinations. Our value of 142 ± 1 for J_{C_1-H} in norbornane is identical to that obtained from satellite studies (36). Furthermore, our value of J_{C_1-H} for **6** was identical to that obtained on an XL-100 FT system.[3] The comparisons provide a calibration for our values.

The ketones and diones used in this study were prepared in conjunction with base-catalyzed exchange studies (14) and the syntheses will be described in subsequent publications.

*Thiocamphenilone (**11**)*

Camphenilone (1.0 g, > 98% purity) was dissolved in absolute ethanol (25 ml), and HCl and H_2S were bubbled through the reaction mixture (37) for 2h. The reaction was monitored by withdrawing and quenching aliquots with solid sodium bicarbonate under pentane and analyzing the pentane solutions by g.l.p.c. on a 10 ft × ¼ in. 10% Carbowax on a Chromosorb W column maintained at 150° with He as the carrier gas. When the reaction was 85–95% complete the mixture was quenched by adding it to a slurry of solid $NaHCO_3$ and purified pentane that was cooled in ice. The pentane solution that was obtained after filtration was concentrated by distillation through a 6 in. helix-packed column until two layers separated. The pentane layer was removed, dried, and concentrated further (2–3 ml). The thione (0.30 g), an orange glassy solid, was isolated by preparative g.l.p.c. utilizing the conditions described above.

Financial support by the National Research Council of Canada is gratefully acknowledged. We thank Professor Warkentin for generous samples of **14** and **15** and Professor Stothers for a generous sample of **16**.

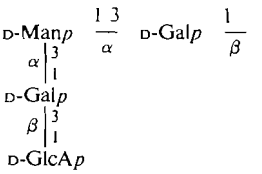
Structure of the Capsular Polysaccharide of *Klebsiella* K-type 20[1]

YUEN-MIN CHOY AND GUY G. S. DUTTON

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

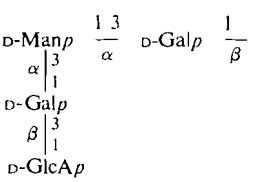
Received March 5, 1973

Methylation, periodate oxidation, and partial hydrolysis studies on the capsular polysaccharide, and on the carboxyl reduced polymer, of *Klebsiella* K20 show the structure to consist of a repeating unit



The anomeric linkages were determined by p.m.r. spectroscopy of the carboxyl reduced polysaccharide, and periodate degraded polysaccharides. The p.m.r. spectroscopy of the original polysaccharide also showed the presence in the polysaccharide of one *O*-acetyl group per eight sugar residues.

Des réactions de méthylation, d'oxydation au périodate et d'hydrolyse partielle, sur le polysaccharide capsulaire ainsi que sur le polymère avec le groupe carboxyle réduit, de *Klebsiella* K20 ont démontré que la structure se compose d'une unité fondamentale qui se répète à savoir:



On a donc démontré que la chaîne principale comporte un acide aldobiouronique comme ramification latérale. La *Klebsiella K20* est le premier exemple de ce type de structure.

Les liaisons anomériques ont été identifiées à l'aide de la spectroscopie r.m.n. en ce qui a trait au polysaccharide avec le groupe carboxyle réduit et aux polyosides apparentés obtenus par dégradations successives selon la méthode de Smith.

Le spectre r.m.n. du polysaccharide original a aussi révélé la présence d'un groupe *O*-acétyle par rapport à huit sucres. Cependant la position de liaison de ce groupe n'a pu être déterminée.

[Traduit par le journal]

Can. J. Chem., **51**, 3015 (1973)

Qualitative analyses of the capsular polysaccharides of the 80 serotypes of *Klebsiella* bacteria have been provided by Nimmich (1, 2) who has shown that the great majority contain D-glucuronic acid in combination with hexose and deoxyhexose sugars. Despite the amount of qualitative information available on *Klebsiella* polysaccharides at the start of our work detailed structures were only known for types K2, K8, and K54, (3, and references therein) to which

[1]Presented in part at the 56th Canadian Chemical Conference of the Chemical Institute of Canada, Montreal, Quebec, June, 1973.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

must now be added K9 (4), K21 (5), and K24 (6). Each of these structures is composed of a repeat unit involving a single sugar side chain. In addition, the type K5 is distinguished by the lack of carbohydrate side chain (7) and K56 by the lack of uronic acid (8). The structure of K-type 20 is the first of these capsular polysaccharides to be encountered with an aldobiouronic acid side chain. A preliminary report has appeared (9) which showed that the aldobiouronic acid is 3-*O*-(β-D-glucopyranosyluronic acid)-D-galactose and the nature of the repeat unit is now discussed.

The polysaccharide after purification by Cetavlon, deionization, and freeze drying had $[\alpha]_D^{20}$ +94° and a neutralization equivalent (by titration) of 701. The p.m.r. spectrum, run at room temperature, of a 2% solution of the sodium salt of the polysaccharide in D_2O showed a singlet at τ 7.8 characteristic of *O*-acetyl and the absence of pyruvate. Determination of the acetyl:sugar ratio was hampered by the presence of the large HOD peak which overlapped the region associated with the signals due to the anomeric protons. However, integration of the ring protons and the acetate signal indicated one acetyl group to approximately eight sugar units. The presence of the *O*-acetyl group was also confirmed by formation of the hydroxamic ester. An attempt to locate the position of the *O*-acetyl group using the procedure of de Belder and Norrman (10) was unsuccessful due to the very low yield, probably because of the high molecular weight (5–9 × 10^5) of the *Klebsiella* capsular polysaccharide. Similar difficulties have been encountered in other cases (6, 7).

Acid hydrolysis of the polysaccharide showed the rapid liberation of an aldobiouronic acid and complete hydrolysis gave D-mannose, D-galactose, and the aldobiouronic acid in equal amounts (9). Partial hydrolysis using the apparatus of Galanos *et al.* (11) gave a dialyzate containing an aldobiouronic acid as the major component together with an aldotetrauronic acid in addition to neutral sugars. The acidic compounds were separated on paper and partial hydrolysis of the aldotetrauronic acid, after borohydride reduction, gave galactitol, mannose, and aldotri- and aldobiouronic acids. The last named and the aldobiouronic acid isolated from the total hydrolysis were identical with that already described (9).

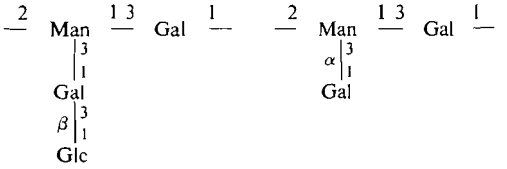
On methylation and hydrolysis, the original capsular polysaccharide gave the neutral sugars shown in Table 1A and when the uronic acid in the methylated polymer was reduced before hydrolysis the compounds in Table 1B were obtained. Methylation of the residual polysaccharide recovered from the partial hydrolysis gave the results shown in Table 1C which show that 4,6-di-*O*-methyl-D-mannose has largely been replaced by 3,4,6-tri-*O*-methyl-D-mannose thus demonstrating that the aldobiouronic acid is joined to position 3 of the mannose unit which in turn is linked through position 2. The small quantities of tetramethyl sugar arose from some fragmentation of the main chain.

TABLE 1. Methyl ethers from the hydrolyzates of methylated *Klebsiella* K20 polysaccharides

Sugars	Sample* A†	B	C	D	E
2,3,4,6-Tetra-*O*-methyl-D-mannose			2		
2,3,4,6-Tetra-*O*-methyl-D-galactose			3	1	
3,4,6-Tri-*O*-methyl-D-mannose			9		1
2,4,6-Tri-*O*-methyl-D-galactose	+	2	12	1	1
2,3,4-Tri-*O*-methyl-D-glucose		1			
4,6-Di-*O*-methyl-D-mannose	+	1	1	1	

*A, neutral sugars from methylated original K20 polysaccharide; B, reduced methylated K20 polysaccharide; C, methylated residual polysaccharide after partial hydrolysis; D, methylated polysaccharide (S1) recovered from first Smith degradation; E, methylated S2.
†Approximate molar ratios; (+) signifies present.

The methylation results in conjunction with the oligosaccharides isolated indicate the general nature of the polysaccharide. Confirmation of the proposed structure and definitive assignment of each anomeric configuration were obtained by successive Smith periodate degradations (12, 13), conveniently carried out on the carboxyl reduced polymer.



Carboxyl reduced K20 Polysaccharide S1

Polysaccharide S2

Carboxyl reduced polysaccharide (5, 14, 15) on hydrolysis gave D-galactose, D-glucose, and D-mannose in the ratio 2:1:1. The p.m.r. spectrum run in D_2O at 95° indicated the presence of two α-D- and two β-D-linkages (Table 2).

*Spectra run in D_2O with external tetramethylsilane (τ = 10 at 100 MHz).
†All sugars have D-configuration and are pyranose.

These signals may be assigned as a result of the periodate oxidations described below.

On the basis of the proposed structure the terminal D-glucose unit (from D-glucuronic acid) is the only periodate susceptible residue in the carboxyl reduced polysaccharide and it was found that 0.57 mol of periodate per hexose was reduced. Smith degradation gave glycerol and a degraded polysaccharide (S1) with $[\alpha]_D$ +129° and in the p.m.r. spectrum of which the signal at τ 5.00 had disappeared (Table 2). This is consistent with the loss of one sugar residue with a β-D-glycosidic bond. The signal at τ 5.00 had a width of about 6 Hz but no clearly distinguishable doublet. Hydrolysis of methylated S1 gave the compounds shown in Table 1D.

In S1 the terminal galactose may now be oxidized by periodate (consumption 0.8 mol/hexose) and degradation gave glycerol and a new polysaccharide (S2). This polymer had $[\alpha]_D$ +57° and the p.m.r. spectrum showed the presence of one α-D- and one β-D-linkage, in contrast to two α-D- and one β-D-linkages in S1, thus demonstrating that the lateral D-galactose is joined to the main chain by an α-glycosidic bond. Furthermore, since the signal at τ 5.48 exhibited a splitting of 6 Hz this must be due to the galactose unit in the main chain which therefore has a β-D-linkage. The methylation results on S2 are given in Table 1E.

All the evidence so far adduced is consistent with the proposed structure but the results do not exclude the possibility that the main chain is composed of blocks of D-mannose and of D-galactose units. That this is not the case is clearly demonstrated by subjecting polysaccharide S2 to one further Smith degradation. Examination on paper of the hydrolysis products, after reduction with borohydride, showed only glycerol and a compound with R_{Gal} 1.05; no slower moving compounds were observed. Hydrolysis of the latter compound gave only glycerol and D-galactose. This experiment thus provides convincing proof that the main chain, and hence the side chains, have a regular alternating structure. The structure of the capsular polysaccharide of *Klebsiella* K-type 20 may therefore be written

$$\frac{2}{-}\ \text{D-Man}p\ \frac{1\ 3}{\alpha}\ \text{D-Gal}p\ \frac{1}{\beta}$$
$$\alpha\vert^{3}_{1}\ \text{D-Gal}p$$
$$\beta\vert^{3}_{1}\ \text{D-GlcA}p$$

Experimental

General methods are as previously described (5).

Isolation and Properties of Capsular Polysaccharide

A culture of *Klebsiella* K-type 20 (889/50) was grown as for K21 (5) and after 3 days the cells were diluted with 1% phenol and centrifuged for 30 min at 60 000 × gravity. The clear supernatant was poured into ethanol and the product was redissolved in water. The acidic polysaccharide was precipitated with Cetavlon, redissolved in the minimum volume of 4 *M* sodium chloride, and isolated by precipitation into ethanol. The yield of pure polysaccharide was approximately 3 g per 4 l of medium and two such batches were pooled for the structure investigations.

The purified polysaccharide was dissolved in distilled water, deionized with Amberlite IR 120 resin, dialyzed, and freeze-dried. The product had $[\alpha]_D^{20}$ +94° (*c* 0.21, water), N, 0%. The equivalent weight of the polysaccharide was found to be 701 (theory 680) by titration with 0.03 *M* sodium hydroxide.

The above neutralized polysaccharide was lyophilized. The residue was dissolved in D_2O and exchanged twice by lyophilization. The p.m.r. spectrum of a 2% solution of D_2O showed a peak at τ 7.8 indicating the presence of *O*-acetyl. Due to the high viscosity of this solution, the magnitude of the HOD peak was so great that difficulty was encountered in obtaining quantitative information between the anomeric protons and the acetyl group. However, integration of the ring protons and the acetyl group showed there is approximately one acetyl per eight sugar units (5).

The presence of acetate was also confirmed by methanolysis of the polysaccharide and identification of the methyl acetate using the hydroxylamine – ferric chloride reagent (7). Attempted location of the *O*-acetyl group using the procedure of de Belder and Norrman (10) was unsuccessful due to the extremely low yield in the reaction with methyl vinyl ether.

Hydrolysis of the Polysaccharide

Polysaccharide (150 mg) was hydrolyzed with 2 *M* trifluoroacetic acid (TFA) at 100° for 2 h. After evaporation, the hydrolyzate was found by paper chromatography in solvent A to contain D-mannose, D-galactose, and a component with the mobility of an aldobiouronic acid (R_{Gal} 0.26). The hydrolyzate was separated into neutral and acidic fractions using ion-exchange resins (Amberlite IR 120 and Duolite A-4). The neutral fraction contained D-mannose and D-galactose in a 1 : 1 ratio as determined by the g.l.c. of the alditol acetates (column a) which permitted recovery of the individual compounds and identification of D-mannitol hexaacetate, m.p. 118–120°, and galactitol hexaacetate, m.p. 162–164°.

The D-configuration of galactose was shown by a positive reaction on part of the hydrolyzate with D-Galactostat reagent and of mannose by the positive circular dichroism (c.d.) curve of mannitol hexaacetate (16). The acidic component (60 mg, R_f 0.16, solvent C) was found to have $[\alpha]_D^{20}$ +17° (*c* 0.75, water) and an equivalent weight of 349 when titrated with 0.03 *M* sodium hydroxide ($C_{12}H_{20}O_{12}$ requires 356). A portion (20 mg) of the aldobiouronic acid was dissolved in 3 ml of 0.3 *M* acetate buffer (p*H* 4.8), 3 mg of β-D-glucosidase was added, and the solution was incubated at 38° for 6 h. D-Galactose was found by paper chromatography in solvent B to be the only neutral sugar present, whereas the presence of D-galactose, D-glucuronic acid, and D-glucuronolactone was demonstrated in solvent A. The same results were obtained by hydrolysis of the aldobiouronic acid (10 mg) using 3.5 *M* hydrochloric acid at 100° for 2.5 h.

The aldobiouronic acid (20 mg) was methylated and hydrolyzed with 3 *M* hydrochloric acid at 95° for 3.5 h. Paper chromatography in solvent E showed the presence of 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.66) and 2,3,4-tri-*O*-methyl-D-glucuronic acid (R_f 0.22). The identity of 2,4,6-tri-*O*-methyl-D-galactose was confirmed by g.l.c.–m.s. of the alditol acetate. Another portion of the capsular polysaccharide (20 mg) was hydrolyzed (0.4 *M* TFA, 95°, 2 h) and the aldobiouronic acid was found as the only mobile component on paper chromatography in solvent A.

Partial Hydrolysis of Polysaccharide

K20 polysaccharide (1 g) was partially hydrolyzed (0.4 *M* TFA, 30 h, 95°) using the apparatus described by Galanos, Lüderitz, and Himmelspach (11). The degraded polysaccharide in the dialysis sac was kept for subsequent methylation. The dialyzate was evaporated and separated into neutral and acidic fractions by ion-exchange resin. On paper chromatography (solvent C) the acidic fraction was shown to contain an aldobiouronic acid (R_{Gal} 0.45) as the major component together with aldotetrauronic acid (R_{Gal} 0.08) and trace amounts of aldotriuronic acid (R_{Gal} 0.30). The acids were separated by paper chromatography (solvent C) and analyzed as follows.

The aldobiouronic acid (80 mg) was found to have identical characteristics as the aldobiouronic acid isolated previously. P.m.r. data: τ 4.75 (0.5H); 5.4, J = 7 Hz (1.4H).

The aldotetrauronic acid (50 mg) had an equivalent weight of 650. The acid (10 mg) was partially hydrolyzed (1 *M* TFA, 95°, 1 h) and paper chromatography (solvent A) showed the presence of D-galactose as the principal monosaccharide with traces of D-mannose and a series of aldobiouronic, aldotriuronic, and aldotetrauronic acids which had the same mobilities as the components of the original mixtures. The aldotetrauronic acid (10 mg) was reduced with sodium borohydride and, after removal of the borate, the product was hydrolyzed with 2 *M* TFA for 1/2 h. On paper chromatography (solvents A and B), the neutral compound found was galactitol, which was confirmed by g.l.c. of the alditol acetate, m.p. 162–164°. Also produced were the same aldobio-, aldotrio-, and aldotetrauronic acids (solvent C) described above.

Methylation Analysis of the Polysaccharide

Capsular polysaccharide (90 mg) was methylated by the method of Hakomori to give a product which showed no absorption at 3600 cm^{-1}. A portion (20 mg) was hydrolyzed (2 *M* TFA, 100°, 2 h). Analysis of hydrolyzate by paper chromatography (solvent E) showed the presence of 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.66), 4,6-di-*O*-methyl-D-mannose (R_f 0.59), a methylated aldobiouronic acid (R_f 0.35), and a small quantity of 2,3,4-tri-O-methyl-D-glucuronic acid. The hydrolyzate was separated into neutral and acidic fractions using ion-exchange resin (Duolite A-4). On paper chromatography, the neutral

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

fraction was shown to contain 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.4, solvent D) and 4,6-di-*O*-methyl-D-mannose (R_f 0.29, solvent D). Reduction ($NaBH_4$), removal of borate, acetylation in a sealed tube (pyridine and acetic anhydride 1:1, 1 ml, 95°, 15 min), and injection (in ethyl acetate) onto column b at 200° showed two peaks.

The component eluted first had a retention time (6.9 min) and mass spectrum identical to authentic 2,4,6-tri-*O*-methyl-D-galactitol triacetate. The second component was similarly identical in retention time (9.9 min) and mass spectrum to authentic 4,6-di-*O*-methyl-D-mannitol tetraacetate (Table 1A). Demethylation and reacetylation of the partially methylated alditol acetate gave the corresponding galactitol hexaacetate, m.p. 166–169° and D-mannitol hexaacetate, m.p. 119–122°.

A portion (4 mg) of the acidic fraction was hydrolyzed (3.5 *M* HCl, 100°, 2 h) and the hydrolyzate was found to contain 2,4,6-tri-*O*-methyl-D-galactose (analyzed by g.l.c.–m.s. of the alditol acetate) as the only neutral sugar, and 2,3,4-tri-*O*-methyl-D-glucuronic acid (R_f 0.22, solvent E). Another portion (5 mg) was methanolyzed with 2% methanolic – hydrogen chloride and reduced with lithium borohydride. After removal of the borate the product was hydrolyzed (0.5 *M* H_2SO_4, 4 h). Paper chromatography showed the presence of 2,3,4-tri-*O*-methyl-D-glucose (R_f 0.62, solvent D) and 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.40, solvent D). G.l.c. of the alditol acetates showed two peaks at 9.5 and 8.7 min (column b, 200°, flow rate 60 ml/min) which were identical in retention time and mass spectrum to the corresponding authentic alditol acetates.

Another sample of methylated polysaccharide (20 mg) was reduced with lithium borohydride and hydrolyzed. Quantitative analysis of the derived alditol acetates by g.l.c. (column a, 180–217° at 2°/min) showed the presence of 2,4,6-tri-*O*-methyl-D-galactose (24.5 min), 2,3,4-tri-*O*-methyl-D-glucose (26 min), and 4,6-tri-*O*-methyl-D-mannose (29.8 min) in a molar ratio of 2:1:1 (Table 1B). The identity of the methylated sugars was again confirmed by m.s. of the derived alditol acetates.

Methylation of Degraded Polysaccharide

A portion of the degraded polysaccharide (120 mg) recovered from the partial hydrolysis was methylated and the product was hydrolyzed (2 *M* TFA, 100°, 4 h) to give (paper chromatography) 3,4,6-tri-*O*-methyl-D-mannose (R_f 0.58, solvent D) and 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.38, solvent D) as the major components, together with minor components of 2,3,4,6-tetra-*O*-methyl-D-galactose and D-mannose, and faint traces of methylated aldobiouronic acid (solvent E). The hydrolyzate was reduced with sodium borohydride, acetylated, and injected onto column b at 190°. 2,3,4,6-Tetra-*O*-methyl-D-mannose (6.5 min), 2,3,4,6-tetra-*O*-methyl-D-galactose (8.0), 3,4,6-tri-*O*-methyl-D-mannose (12.0), 2,4,6-tri-*O*-methyl-D-galactose (16.0), and 4,6-di-*O*-methyl-D-mannose (18.0) were found in a ratio of 2:3:9:12:1 (Table 1C). The mass spectrum of 3,4,6-tri-*O*-methyl-D-mannose was identical to an authentic sample.

Reduction of the Capsular Polysaccharide

Capsular polysaccharide (0.5 g) was converted into the methyl ester propionate and reduced with lithium borohydride to give the reduced polysaccharide (0.4 g), $[\alpha]_D^{24}$ +95.5° (*c* 2, water). The reduced polysaccharide (20 mg) was hydrolyzed (2 *M* TFA, 100°, 4 h) and analysis of the hydrolyzate by paper chromatography and g.l.c. showed D-galactose, D-glucose, and D-mannose in a ratio of 2:1:1.

Galactitol hexaacetate had m.p. 166–169°, D-glucitol hexaacetate had m.p. 96–98°, and D-mannitol hexaacetate had m.p. 119–122°. The hydrolyzate gave a positive test with D-Glucostat reagent, thus confirming the D-configuration of glucuronic acid. The p.m.r. spectrum of the reduced K20 polysaccharide was run in D_2O at 95° and was shown to give anomeric signals at τ (4.78 + 4.86), 5.00, and 5.45 in the ratio of 2:1:1 (Table 1). The signals at τ 5.45 showed a distinct doublet with a coupling constant of 7 Hz.

Smith Periodate Degradations and Methylation Studies of the Degraded Polysaccharides

The carboxyl reduced polysaccharide (66 mg) was dissolved in 10 ml water and 20 ml 0.05 *M* sodium metaperiodate was added. After 66 h, 0.57 mol of periodate per hexose unit was consumed. Ethylene glycol (1.5 ml) was added and the product was then dialyzed overnight against running water. Sodium borohydride (0.5 g) was added and the solution was left overnight. The solution was deionized with Amberlite IR 120, freeze-dried, and the product was distilled with several portions of methanol. The derived polyalcohol was dissolved in 5 ml 0.5 *M* TFA and left at room temperature overnight. On paper chromatography (solvent A) only glycerol was identified (R_f 0.45). The product was dialyzed against 2 l of distilled water. The dialyzate when evaporated was found to contain glycerol by paper chromatography and g.l.c. (glycerol triacetate 6.4 min, column b at 150°). The degraded polysaccharide (S1) remaining in the dialysis sac was freeze-dried. It has $[\alpha]_D^{20}$ +129°. P.m.r. spectrum of the degraded polysaccharide in D_2O showed signals at τ 4.6, 4.78, and 5.4 in a ratio of 1:1:1. The signals at τ 5.4 showed a doublet with coupling constant of 7 Hz, all other coupling constants being small. The degraded polysaccharide was then methylated by the Hakomori method and hydrolyzed. Paper chromatography showed the presence of 2,3,4,6-tetra-*O*-methyl-D-galactose (R_f 0.70, solvent D), 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.38, solvent D), and 4,6-di-*O*-methyl-D-mannose (R_f 0.29, solvent D). The ratio was found to be 1.05:0.9:1 by g.l.c. of the alditol acetates (Table 1D). 2,3,4,6-Tetra-*O*-methyl-D-galactitol acetate had a retention time of 13 min (column b, 160–200° at 2°/min) and had a mass spectrum identical to an authentic sample.

Another portion of the carboxyl reduced polysaccharide (0.3 g) was oxidized by periodate as described previously to yield 0.2 g of the degraded polysaccharide (S1). To this degraded polysaccharide S1 (0.2 g) 50 ml of 0.04 *M* sodium periodate was added. Periodate consumption was found to be 0.8 mol per hexose unit after 2 days. The derived polyaldehyde after reduction with sodium borohydride was partially hydrolyzed with 0.4 *M* TFA at room temperature overnight. Glycerol was found to be the only component mobile on paper chromatography in solvent A (R_f 0.44). The product was dissolved in 5 ml of water and dialyzed against 1 l of distilled water. The substance that remained in the dialyzing sac was freeze-dried to yield 0.1 g of a new degraded polysaccharide (S2). The degraded polysaccharide S2

had $[\alpha]_D^{20}$ +57° (*c* 0.35, water). P.m.r. of this polysaccharide was run in D_2O at 95° and showed signals at τ 4.8 and 5.48 in a ratio of 1:1. The signals at τ 5.48 consisted of a doublet with coupling constant of 6 Hz while that at τ 4.8 had a very small coupling constant.

A portion (27 mg) of the degraded polysaccharide S2 was methylated by the Hakomori method and hydrolyzed (2 *M* TFA, 100°, 4 h). Paper chromatography (solvent D) showed the presence of 3,4,6-tri-*O*-methyl-D-mannose (R_f 0.57) and 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.38). The ratio was found to be 1:1 by g.l.c. of the alditol acetate when 3,4,6-tri-*O*-methyl-D-mannose had a retention time (22 min, column b, 180–200° at 2°/min) and a mass spectrum identical to an authentic sample.

The degraded polysaccharide (S2, 43 mg) was further degraded by periodate. After the usual work-up the derived polyalcohol was hydrolyzed with 0.5 *M* TFA at room temperature for 6 h. The product was then reduced with sodium borohydride. After removal of the borate, paper chromatography in solvents B and C showed the presence of glycerol (R_{Gal} 4.3, solvent B; R_{Gal} 2.1, solvent C) and an unknown component (R_{Gal} 1.05, solvent B; R_{Gal} 1.2, solvent C).

The unknown component was separated by paper chromatography in solvent B, and then hydrolyzed with 2 *M* TFA for 2 h. On paper chromatography in solvents A and B, D-galactose and glycerol (R_{Gal} 4.6, solvent A; R_{Gal} 2.4, solvent B) were identified. The product was reduced with sodium borohydride and acetylated. On g.l.c., glycerol triacetate (retention time 8 min, column a, 140–200°) and galactitol hexaacetate (retention time 58 min) were found in equimolar amounts.

We are grateful to Dr. I. Ørskov for a culture of *Klebsiella* K20 (889/50), to Dr. P. J. Salisbury for growing the bacteria and to Dr. J. J. R. Campbell and Dr. J. B. Hudson for the use of their centrifuges.

We appreciate the continued financial support of the National Research Council and Y.M.C. acknowledges with thanks the award of a Killam Fellowship.

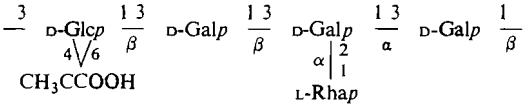
Structure of the Capsular Polysaccharide of *Klebsiella* K-type 56[1]

YUEN-MIN CHOY AND GUY G. S. DUTTON
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 5, 1973

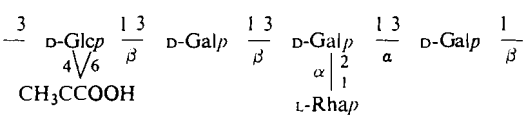
Methylation, periodate oxidation, and partial hydrolysis studies on the capsular polysaccharide of *Klebsiella* K-type 56 show the structure to be a repeating unit consisting of



The nature of the anomeric linkages was determined by p.m.r. spectroscopy of isolated oligosaccharides. The position of the L-rhamnose side chain was defined by characterization of the di- and tetrasaccharides obtained by partial hydrolysis of the fully methylated polysaccharide.

This structure represents the first capsular polysaccharide lacking uronic acid to be studied in the genus *Klebsiella*.

Les méthodes de méthylation, oxydation périodique et hydrolyse partielle ont démontré que la structure de *Klebsiella* K-type 56 se compose d'une unité qui se répète:



Les liaisons anomères ont été distinguées par la spectroscopie r.m.n. des oligosaccharides isolés. La position de la chaîne latérale du L-rhamnose était décidée par la caractérisation des di- et tetrasaccharides obtenus par l'hydrolyse partielle du polysaccharide complètement méthylé.

Cette capsule de *Klebsiella* est la première d'être trouvée sans un reste de l'acide uronique.

Can. J. Chem., **51**, 3021 (1973)

The majority of the capsular polysaccharides of *Klebsiella* owe their acidic properties to the presence of D-glucuronic acid but in a few instances the acidity is due entirely to the presence of pyruvic acid (1, 2) in a ketal linkage (3). We now report the structure of the capsular polysaccharide from *Klebsiella* K-type 56 which represents the first example to be investigated of those *Klebsiella* capsules lacking uronic acid.

The capsular polysaccharide, after purification through Cetavlon precipitation, had $[\alpha]_D^{24}$ $+79°$ and an equivalent weight of 908. The p.m.r. spectrum of the polysaccharide, run in D_2O at 95° on the sodium salt, indicated the presence of one pyruvic acid ketal and one 6-deoxyhexose to five anomeric protons the chemical shifts of which (Table 1) corresponded to two α-glycosidic linkages and three β-links (4, 5).

Reaction of the polysaccharide with acid rapidly liberated L-rhamnose and total hydrolysis gave L-rhamnose, D-galactose, and D-glucose in the ratio of 1.1:3:1. The configurations of the first- and last-named were determined by measurements of the circular dichroism (c.d.) of the alditol acetates; that of D-galactose was proved by measurement of the c.d. spectrum of a methylated derivative isolated subsequently (6). Since L-rhamnitol acetate does not crystallize readily this sugar was identified as methyl α-L-rhamnopyranoside.

Partial hydrolysis of the polysaccharide gave a series of neutral oligosaccharides which were separated from monosaccharides by charcoal column chromatography and individual components were obtained by gel filtration on Sephadex G-15. These were shown to be a glucosyl-galactose disaccharide together with related tri- and tetrasaccharides. The structures of these oligosaccharides are given in Table 1 together with the chemical shift of the anomeric protons which enables the nature of the gly-

*A, methylated original K56 polysaccharide; B, polysaccharide recovered from elimination of L-rhamnose by Smith degradation; C, partial hydrolysis with formic acid of sample A; D, reduced fraction 1; E, fraction 2; F, component 2b. The numbers indicate approximate molar amounts (see Experimental for details); (+) signifies present, no quantitative implication.
†T.l.c. silica gel, solvent D.

tose units are linked through position 3 and that the third carries a terminal L-rhamnose residue linked at position 2 or 3. Isolation of 2-*O*-methyl-D-glucose is consistent with the presence of a 4,6-*O*-(1-carboxyethylidene)-D-glucose unit linked in the chain through position 3.

The single unit side chain of L-rhamnose was most conveniently removed by Smith degradation (7) and the p.m.r. spectrum of the recovered polysaccharide demonstrated the retention of the pyruvic acid, the elimination of the deoxy sugar unit, and the loss of one α-glycosidic linkage per repeat unit. This is in agreement with the change in optical rotation ($[\alpha]_D$ $+79° \rightarrow +97°$) in the initial stages of the acid hydrolysis of the original polysaccharide on the assumption that L-rhamnose is the most acid labile residue. Hydrolysis of the recovered, methylated polysaccharide gave 2,4,6-tri-*O*-methyl-D-galactose in place of the 4,6-dimethyl ether (Table 2B) indicating that the L-rhamnose unit is joined to position 2.

The methylation data in conjunction with the analysis of the oligosaccharides enable the repeat unit of *Klebsiella* K56 capsular polysaccharide to be written thus

$$\text{—}\ ^{3}\text{Glc}\ ^{1\,3}\text{—}\ \text{Gal}\ ^{1\,3}\text{—}\ \text{Gal}\ ^{1\,3}\text{—Gal—}\quad \text{and}\quad \begin{matrix}{}^{2}\\ {}^{1}\\ \text{Rha}\end{matrix}$$

but they provide no information as to which D-galactose unit carries the L-rhamnose substituent. Partial hydrolysis of the original polysaccharide is not applicable here since the L-rhamnose is preferentially eliminated and each of the D-galactose units is similarly linked ($1 \rightarrow 3$). Partial hydrolysis of the methylated polysaccharide using formic acid, however, enabled this problem to be solved in the following manner.

Examination of the hydrolyzate (C) by t.l.c. showed the formation of products in addition to the expected methylated sugars. One of these (fraction 1) moved faster than 2,3,4-tri-*O*-methyl-L-rhamnose and the other (fraction 2) had a mobility between this sugar and 2,4,6-tri-*O*-methyl-D-galactose (Table 2C). Fractions 1 and 2 were separated from a portion of the hydrolyzate (C) and the former, after reduction and hydrolysis, gave the methylated sugars shown in Table 2D together with an alditol assumed to be 2,4,6-tri-*O*-methyl-D-galactitol. This fraction presumably corresponds to one complete pentasaccharide repeating unit.

Fraction 2 was obtained in greater amount and was investigated as follows. The p.m.r. spectrum showed the presence of pyruvate and the ratio of the sugars obtained on total hydrolysis of this fraction suggested it was a mixture (Table 2E). When this fraction was reduced with sodium borohydride and examined by t.l.c. there was a marked reduction in mobility and two components were observed with R_f values 0.14 (component 2a) and 0.07 (component 2b). Complete hydrolysis of component 2b gave the sugars shown in Table 2F together with 2,4,6-tri-*O*-methyl-D-galactitol, thus demonstrating that this component is a tetrasaccharide terminated by a 2,4,6-tri-*O*-methyl-D-galactose unit. Therefore, the rhamnose side chain cannot be attached to this terminal galactose residue. When component 2b was methylated and hydrolyzed 2,3-di-*O*-methyl-D-glucose was obtained but no 2,3,4,6-tetra- or 2-*O*-methylglucoses thus confirming the position of attachment of the pyruvate ketal and showing the glucose unit to be the nonreducing end. Component 2a was obtained in small quantity and hydrolysis gave 2-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-galactitol in approximately equal amounts.

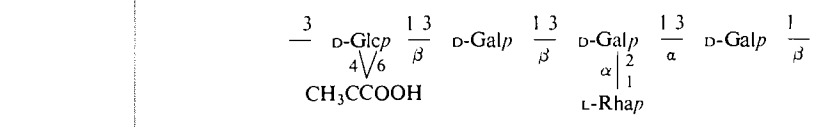
The free disaccharide corresponding to component 2a was more readily obtained when the remainder of the formic acid hydrolyzate (C) was further hydrolyzed with trifluoroacetic acid at 95° for 4 h. Separation by t.l.c. of this hydrolyzate gave the disaccharide (R_f 0.60) in addition to methylated monosaccharides. Total hydrolysis of the disaccharide gave 2-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-galactose and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hydrolysis of the reduced disaccharide gave the same products as component 2a. These results demonstrate that the rhamnose side chain is not joined to the galactose which is linked directly to glucose and hence, by elimination, must be joined to the central galactose unit.

Partially methylated disaccharides have been obtained fortuitously through incomplete hydrolysis (*e.g.* 8,9) and use has been made of the acid lability of furanosidic linkages in fully methylated polysaccharides to study acetate distribution (10), but we believe this is the first occasion that methylated oligosaccharides have been deliberately isolated as part of a structural investigation. The success of this approach in the present instance is no doubt aided by the known acid lability of 1 → 3-linked D-galactose units (11). The inability to isolate a methylated trisaccharide terminated by the 4,6-di-*O*-methyl-D-galactose residue is presumably due to the greater stability of the α-D- compared to the β-D-galactosidic linkage (12). In using this method clearly care must be exercised since methylated pentasaccharides may have very high mobilities and di- and tetrasaccharide units may migrate at the same rate.

The structure of the capsular polysaccharide of *Klebsiella* K56, the first representative of the type where pyruvic acid is the only acidic constituent, may thus be written



Experimental

General methods are as previously described (3).

Isolation and Properties of Klebsiella K56 Capsular Polysaccharide

Klebsiella K56 was grown on the medium as for K21 and the harvested capsular polysaccharide and cells (~2 l) were diluted two-fold with water and centrifuged at 27 000 r.p.m. at 4° for 30 min. The supernatant was collected and poured with stirring into ethanol (5 vol). The polysaccharide was collected, dissolved in distilled water, and purified through precipitation with Cetavlon giving 8 g of pure acidic polysaccharide having $[\alpha]_D^{24}$ +79° (*c* 0.43, water) as Na^+ salt. After deionization with Amberlite IR120 and dialysis, the equivalent weight was found by titration with 0.01 *M* sodium hydroxide (phenolphthalein) to be 908.

A sample of the Na^+ salt of the polysaccharide was dissolved in D_2O and exchanged twice by lyophilization. The p.m.r. spectrum of the solution (2% in D_2O) was run at 95° and showed a sharp singlet at τ 8.57, a doublet at 8.73, and five protons in the range 4.6–5.3 (Table 1). Integration showed the ratio between the singlet at τ 8.57 and the doublet at 8.73 to be 1:1 and the presence of five anomeric protons.

The existence of pyruvic acid was also confirmed by hydrolysis of the polysaccharide and identification of the pyruvic acid by paper chromatography (solvent A) using *o*-phenylenediamine spray which gave a characteristic fluorescence when examined by u.v. (13).

Hydrolysis of the Polysaccharide

Polysaccharide (50 mg) was hydrolyzed with 2 *M* trifluoroacetic acid at 95° for periods of 0.5, 1, 2, and 4 h. The liberation of L-rhamnose was found (paper chromatography) to be maximum at 0.5 h with no increase on longer hydrolysis. After 4 h, the hydrolyzate was evaporated and the ratio of L-rhamnose, D-galactose, and D-glucose was found to be 1.1:3:1 by g.l.c. of the alditol acetates (column a). Galactitol hexaacetate had m.p. and mixed m.p. 162–164° and D-glucitol hexaacetate had m.p. and mixed m.p. 98–99°. The configuration of L-rhamnose and D-glucose was determined by measuring the c.d. curves of the alditol acetates (6).

A sample of the polysaccharide was methanolyzed (3% MeOH–HCl, 2 h) and the methyl glycosides separated by t.l.c. using solvent D. Only the component having R_f 0.4 was extracted and after recrystallization from ethyl acetate it was identified as methyl α-L-rhamnopyranoside m.p. and mixed m.p. 108–109°.

Partial Hydrolysis of the Polysaccharide

K56 polysaccharide (1 g) was dissolved in trifluoroacetic acid (50 ml, 0.5 *M*) and the solution was heated on a steam bath for 1 h. The solution was evaporated and fractionated using a charcoal column (Darco G60, 10 × 3 cm). Monosaccharides were eluted by distilled water (2 l) and a series of oligosaccharides (mainly di-, tri-, and tetrasaccharides) was eluted with 20% aqueous ethanol (1 l); yield of oligosaccharides about 0.3 g. The mixture of oligosaccharides (100 mg) was applied to a Sephadex G15 column (110 × 2 cm) which was irrigated with water at a flow rate of 4–6 ml/h. The oligosaccharides (R_{Gal} values 0.52, 0.23, 0.16, solvent C) were separated into di- (40 mg), tri- (20 mg), and tetrasaccharides (25 mg) and analyzed as follows.

Analysis of Disaccharide

The p.m.r. spectrum (Table 1) of the disaccharide, run in D_2O at 95°, showed it to be β-linked. Hydrolysis (10 mg, 2 *M* TFA, 4 h, 95°) showed D-galactose and D-glucose as the only two sugars present in the ratio of approximately 1:1 (g.l.c. of the alditol acetates). The same ratio was obtained when another portion (10 mg) was dissolved in 5 ml 0.3 *M* acetate buffer (p*H* 5.5) to which β-D-glucosidase (10 mg) was added and the solution was incubated at 38° for 16 h. The disaccharide (10 mg) was methylated and hydrolyzed to give 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-galactose (paper chromatography, solvent D, R_f 0.80 and 0.40 respectively) together with small amounts of tri-*O*-methyl-D-galactofuranose (R_f 0.59, solvent D). The ratio of 2,3,4,6-tetra-*O*-methyl-D-glucose to 2,4,6-tri-*O*-methyl-D-galactose was found to be approximately 1:0.9 as determined by g.l.c. of the alditol acetates.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Trisaccharide

The p.m.r. spectrum showed both anomeric protons to be at τ 5.29. Partial hydrolysis (5 mg, 0.5 *M* TFA, 95°, 30 min) showed (solvent C) the formation of D-galactose and the disaccharide described above. Partial hydrolysis of a reduced sample gave the same disaccharide and galactitol (R_G 0.88, solvent B), hexaacetate m.p. 164–166° (isolated by g.l.c.).

Tetrasaccharide

The p.m.r. spectrum showed the anomeric protons at τ 4.75 (1H) and 5.28 (2H). Partial hydrolysis gave D-galactose and the above di- and trisaccharides. A portion (10 mg) was methylated and hydrolyzed to give a minor component corresponding to 2,3,4,6-tetra-*O*-methyl-D-glucose (R_f 0.79) and a major component equivalent to 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.37, solvent D). Lack of material precluded further identification.

Methylation of the Polysaccharide

Capsular polysaccharide (1 g) was methylated by the Hakomori procedure and, after dialysis and chloroform extraction, the product was fractionated by extraction with petroleum ether – chloroform. The fraction soluble in the 70:30 mixture showed no hydroxyl absorption in the i.r. and was used for analysis.

The fully methylated polysaccharide (85 mg) was hydrolyzed with 2 *M* trifluoroacetic acid at 100° for 2 h and then at 95° for 16 h. The acid was evaporated and the syrup was shown by paper chromatography (solvent D) to contain the four components (R_f values 0.88, 0.42, 0.16, 0.07) given in Table 2A. The ratio was found to be 0.85:2.2:1:1 as determined by g.l.c. of the alditol acetates which permitted isolation of 2-*O*-methyl-D-glucitol pentaacetate as a crystalline derivative having m.p. and mixed m.p. 54–56° (13). The identity of the other three components was confirmed by m.s. of the individual alditol acetates, demethylation (BCl_3), and reacetylation to the parent alditol acetate, m.p. of galactitol hexaacetate 164–167°, m.p. of D-glucitol hexaacetate 99°.

The c.d. spectrum of 2,4,6-tri-*O*-methyl-D-galactitol acetate was identical to that of a standard sample thus confirming the configuration of D-galactose.

Smith Degradation

Capsular polysaccharide (220 mg) was dissolved in sodium metaperiodate (100 ml, 0.025 *M*). After 64 h in the dark at 4°, 0.45 mol of periodate had been consumed per sugar unit. Following the addition of ethylene glycol, dialysis, reduction with sodium borohydride, dialysis, deionization, lyophilization, and removal of borate, the product was hydrolyzed (TFA, 0.5 *M*) at room temperature for 8 h. Paper chromatography in solvent A showed the presence of one mobile compound identified, by comparison with a standard, as 1-deoxyglycerol (1,2-propanediol) having R_f 0.80 and retention time 4.2 min on column a at 90°.

The polymeric product in 5 ml of water was dialyzed against 2 l of distilled water and the residue was freeze dried to yield a degraded polymer (150 mg). The degraded polysaccharide (70 mg) was methylated (Hakomori procedure) and then hydrolyzed. Paper chromatography (solvents D and E) showed only the presence of 2,4,6-tri-*O*-methyl-D-galactose and 2-*O*-methyl-D-glucose in the ratio of 3:1 (g.l.c. of the alditol acetates). The identity of the two compounds was again confirmed by m.s. of the alditol acetates and by the isolation of crystalline 2-*O*-methyl-D-glucitol pentaacetate, m.p. 54–56°.

The degraded polysaccharide had $[\alpha]_D^{20}$ +97° (*c* 1.0, water) and a portion (40 mg) of the sodium salt was exchanged twice with D_2O by lyophilization. The p.m.r. spectrum was run at 95° in D_2O (100%) and showed a singlet at τ 8.57 while the doublet at 8.73 was completely absent. The anomeric signals (Table 1) at τ 4.75, 5.09, and 5.21 were found to be in a ratio of 1:1:2. Integration showed one pyruvic acid per four sugar units. The anomeric signal at τ 5.09 was shifted upfield to 5.24 when the pyruvate ketal group was removed by hydrolysis with 0.1 *M* trifluoroacetic acid at 95° for 1 h.

Partial Hydrolysis of Methylated Capsular Polysaccharide

Methylated polysaccharide (200 mg) was hydrolyzed with 90% formic acid at 70° for 45 min. The hydrolyzate (C) was shown to contain products in addition to the expected methylated monosaccharides (Table 2C). The majority (150 mg) of the hydrolyzate (C) was resolved by t.l.c. (solvent D) and fraction 1 (R_f 0.78), obtained in only small quantity, on borohydride reduction and hydrolysis gave the sugars shown in Table 2D and an alditol assumed to be 2,4.6-tri-*O*-methyl-D-galactitol acetate.

Fraction 2 (R_f 0.66) was obtained in larger amount (40 mg) and total hydrolysis of a portion (7 mg) gave the results shown in Table 2E. Reduction of fraction 2 with sodium borohydride gave (t.l.c., solvent D) two components with R_f values 0.14 (component 2a) and 0.07 (component 2b). Isolation and hydrolysis of component 2a (12 mg) showed, on paper, only 2-*O*-methyl-D-glucose and on acetylation and g.l.c. 2-*O*-methyl-D-glucose acetates and 2,4,6-tri-*O*-methyl-D-galactitol acetate in a ratio of 1:1.25 (column a 170–220° at 2°/min, retention times 36 and 38 min and 22 min respectively).

When component 2b was isolated and hydrolyzed (10 mg) paper chromatography showed the presence of 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.39, solvent D; 0.61, solvent E), 4,6-di-*O*-methyl-D-galactose (0.14, 0.46) and 2-*O*-methyl-D-glucose (0.06, 0.35). Acetylation of the hydrolyzate and g.l.c. showed these components (retention times 18, 23; 26, 32; 37, 38 min) and 2,4,6-tri-*O*-methyl-D-galactitol (25 min) in the ratio 1.1:1:1:1.3. Methylation and hydrolysis of component 2b (5 mg) gave only 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.38, solvent D) and 2,3-di-*O*-methyl-D-glucose (0.27). The identity of the latter was confirmed by g.l.c.–m.s. of the derived alditol acetate.

The smaller part (50 mg) of the original hydrolyzate (C) was further hydrolyzed (0.5 *M* TFA, 95°, 4 h) and paper chromatography showed the presence of a compound (R_f 0.79, solvent E) moving slower than 2,3,4-tri-*O*-methyl-L-rhamnose (R_f 0.88). This compound (15 mg) was isolated by t.l.c. (R_f 0.6, solvent D). Complete hydrolysis (2 *M* TFA, 95°, 16 h) of a portion (5 mg) gave 2,4,6-tri-*O*-methyl-D-galactose and 2-*O*-methyl-D-glucose in the ratio of 1:1. Reduction and hydrolysis of the remainder showed on paper only 2-*O*-methyl-D-glucose and, after acetylation, 2,4,6-tri-*O*-methyl-D-galactitol acetate (22 min, column a 170–220° at 2°/min) and 2-*O*-methyl-D-glucose acetates (36 and 38 min) in the ratio of 1.2:1.

We are grateful to Dr. I. Ørskov for a culture of *Klebsiella* K56 (3534/51), to Dr. P. J. Salisbury for growing the bacteria, and to Dr. J. J. R. Campbell and Dr. J. B. Hudson for the use of their centrifuges.

We appreciate the continued financial support of the National Research Council and Y.M.C. acknowledges with thanks the award of a Killam Fellowship.

Structure cristalline et moléculaire du cyclopentadiényle dicarbonyle triphénylphosphine manganèse, $MnC_5H_5(CO)_2P(C_6H_5)_3$

CLAUDE BARBEAU, KLAUS SORRENTO DICHMANN ET LOUIS RICARD

Département de Chimie, Université Laval, Québec, Québec

Reçu le 14 juin 1972[1]

La structure cristalline du cyclopentadiényle dicarbonyle triphénylphosphine manganèse a été déterminée à partir de données tridimentionnelles obtenues de clichés de chambre à précession de Buerger. 2931 intensités indépendantes ont été utilisées dans l'affinement de la structure effectuée selon la méthode des moindres carrés. Le facteur de désaccord final est 0.11. $MnC_5H_5(CO)_2P(C_6H_5)_3$ cristallise dans le groupe spatial triclinique

$P\bar{1}$, $a = 9.41(2)$, $b = 10.60(2)$, $c = 11.36(2)$ Å,

$\alpha = 103.47(16)$, $\beta = 79.47(16)$, $\gamma = 101.72(16)°$, $V = 1068$ Å^3

La molécule présente des paramètres atomiques presque identiques à ceux de la molécule $MnC_5H_5(CO)_3$ sauf pour les distances des liaisons Mn—C qui passent de 1.80 Å à 1.75 Å. La distance Mn—P (2.236 Å) et les paramètres inchangés du groupement Mn—C_5H_5 confirment le pouvoir donneur élevé du cyclopentadiényle.

The crystalano molecular structure of cyclopentadienyl manganese dicarbonyl-triphenyl phosphine has been determined by means of three dimensional data obtained by a Buerger precession camera. 2931 independent intensities were utilized in the refinement of the structure using the least-squares method. The final disagreement factor is 0.11. $MnC_5H_5(CO)_2P(C_6H_5)_3$ crystallizes in the triclinic space group.

$p\bar{1}$, $a = 9.41(2)$, $b = 10.60(2)$, $c = 11.36(2)$ Å,

$\alpha = 103.47(16)$, $\beta = 79.47(16)$, $\gamma = 101.72(16)°$, $V = 1078$ Å^3

The molecule shows atomic parameter almost identical to those of $MnC_5H_5(CO)_3$ except for the Mn—C bond lengths which change from 1.80 to 1.73 Å. The Mn—P distance (2.236 Å) and the unchanged parameters for the Mn—C_5H_5 group confirm the strong donating power of the cyclopentadienyl group. [Journal translation]

Introduction

Dans le but de mieux connaître les effets du remplacement d'un groupe CO d'un métal carbonyle par un donneur D sur les paramètres structuraux tel que longueurs de liaison métal–ligand et angles de liaison, nous présentons le premier d'une série d'articles traitant de la structure cristalline et moléculaire de dérivés substitués de métaux carbonyle. $MnC_5H_5(CO)_3$ présente l'avantage de contenir un petit nombre de groupements carbonyles et de former des composés substitués stables. Puisque le remplacement d'un groupement CO entraîne ordinairement des changements importants, tant dans les fréquences de vibration C—O que dans les moments dipolaires (1), les composés $MnC_5H_5(CO)_2P(C_6H_5)_3$ et $MnC_5H_5(CO)(P(C_6H_5)_3)_2$ pourraient présenter des modifications structurales. Nous présentons ici la structure cristalline et moléculaire du composé monosubstitué $MnC_5H_5(CO)_2P(C_6H_5)_3$.

[1]Revision recue le 2 mai 1973.

Partie expérimentale

$MnC_5H_5(CO)_2P(C_6H_5)_3$ précipite sous la forme de poudre lors de l'illumination, par une lampe à vapeur de mercure du type General Electric H-100 A4/T, d'une solution de 1 mmol de $MnC_5H_5(CO)_3$ de 3 mmol de $P(C_6H_5)_3$ dans 70 ml de méthanol (2). Le solide jaunâtre est dissous dans une solution (1:1) benzène–éthanol d'où on obtient, par lent refroidissement, des cristaux de taille moyenne de 0.5 × 0.3 × 0.1 mm.

[a]Les écarts-types sont donnés entre parenthèses.
[b]Le facteur de température de chacun de ces atomes est de la forme

$$\exp\{-2\pi^2(a^{*2}h^2U_{11} + b^{*2}k^2U_{22} + c^{*2}l^2U_{33} + 2a^*b^*hkU_{12} + 2a^*c^*hlU_{13} + 2b^*c^*klU_{23})\}$$

Chaque coefficient U est multiplié par 10^3.

des intensités mesurait 0.40 × 0.30 × 0.20 mm. Trois expositions de durée variable (5 min – 16 h) ont été prises pour chacune des 19 strates (4 le long de b, 4 le long de c, 6 le long de [011] et 5 le long de [01$\bar{1}$]) en utilisant la chambre à précession de Buerger. Les intensités ont été mesurées à l'aide d'un microdensitomètre du type Wooster Mark IV. Le coefficient d'absorption linéaire ayant comme valeur $\mu = 7.4$ cm^{-1}, aucune correction d'absorption n'a été apportée sur les intensités qui ont cependant été corrigées pour les facteurs de Lorentz et ceux de polarisation. La mise sur échelle absolue a été réalisée en utilisant la méthode statistique de Wilson (4). Un total de 2931 réflexions indépendantes ont été mesurées et ont servi aux calculs. Les programmes utilisés ont été tirés du système X-RAY-70 de Stewart et coll. (5).

Determination de la structure

Les coordonnées des atomes Mn et P ont été obtenues à partir de la fonction de Patterson tridimensionnelle. Deux synthèses de Fourier ont permis de localiser 27 autres atomes de la molécule et d'abaisser l'indice résiduel

$$R = \frac{\Sigma(\big||F_o| - |F_c|\big|)}{\Sigma|F_o|} \text{ à } 0.27$$

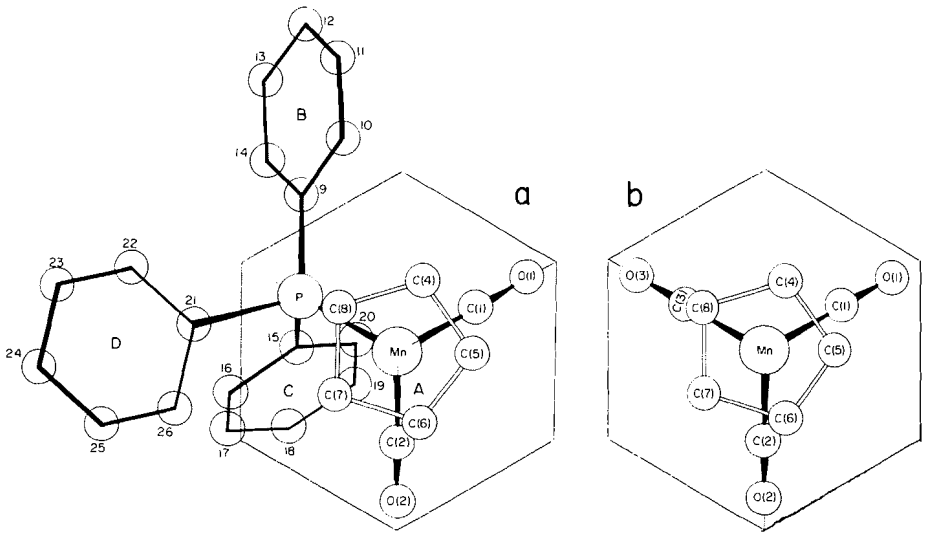

FIG. 1. Projection orthogonale dans un plan parallèle à celui du cycle C_5H_5 des composés: (*a*) $MnC_5H_5(CO)_2P(C_6H_5)_3$; (*b*) $MnC_5H_5(CO)_3$.

L'affinement des paramètres atomiques et des coefficients d'agitation thermique a été réalisé par la méthode des moindres carrés (matrice complète) en minimisant la fonction $S = \Sigma w(|F_o| - |F_c|)^2$. Quatre cycles en isotropie thermique avec des poids w unitaires ont réduit R à 0.17. Deux itérations subséquentes en anisotropie thermique pour les atomes directement reliés au manganèse et en isotropie pour les carbones des phényles ont abaissé R à 0.12. L'introduction à ce stade de poids w ($=1/\sigma^2$), exprimés en termes de $\sigma = 0.120F_o + 0.255 + 3.114/F_o$, et le rejet de 33 réflexions montrant des écarts ΔF supérieurs à 3σ, ont amené le facteur de désaccord à 0.108 en deux itérations.

Ni les coefficients d'agitation thermique ni les coordonnées atomiques n'ont subi de déplacement supérieur à 0.1σ lors de ces deux derniers cycles. Une synthèse de Fourier-différence n'a dévoilé aucun pic significatif (<0.9 $e/Å^3$).

Les facteurs de forme atomique utilisés sont tirés de la référence 6. Les valeurs définitives des coordonnées atomiques, des coefficients d'agitation thermique et de leurs écarts-types sont consignés dans le tableau 1. L'ensemble des facteurs de structure observés et calculés a été versé au dépôt des données non publiées.[3]

Description de la structure

La fig. 1*a* schématise une molécule de $MnC_5H_5(CO)_2P(C_6H_5)_3$ dans une projection orthogonale sur un plan parallèle à celui du cycle C_5H_5. La numérotation utilisée est celle employée pour la molécule non-substituée $MnC_5H_5(CO)_3$ (7) présentée à la fig. 1*b* selon la même projection. Les positions relatives des atomes communs des deux composés sont demeurés inchangés.

Les distances et les angles de valence sont présentés dans le tableau 2. Le tableau 3 donne les coefficients des plans moyens des cycles phényles et du cycle cyclopentadiényle ainsi que les écarts à ces plans. L'empilement des deux molécules dans la maille laisse une distance minimale de 2.5 Å de contact intermoléculaire tandis que les distances de contact intramoléculaire sont supérieures à 3.5 Å (incluant les atomes H).

Le groupement $P(C_6H_5)_3$ présente des paramètres semblables à ceux de la triphénylphosphine libre (8) et sa position dans la molécule, relative aux autres groupements, indique que le remplacement d'un groupe CO par un donneur aussi volumineux n'introduit pas de contrainte stérique ou des perturbations majeures dans le complexe. La distance Mn—P (2.236(3) Å) est plus courte que la somme des rayons covalents de Mn et P (2.48 Å) (9) et légèrement inférieure à la valeur moyenne de 2.30 Å observée dans les composés substitués de $Mn_2(CO)_{10}$ (10). La présence d'un donneur tel que cyclopentadiényle devrait contribuer à apporter une charge négative sur le métal, charge qui devrait être retournée en partie sur le groupement $P(C_6H_5)_3$ par l'intermédiaire d'un recouvrement d'orbitales de caractère π. Une liaison Mn—P à caractère

[a]Les écarts-types sont donnés entre parenthèses.

double se traduirait par cette "contraction" de l'ordre de 0.24 Å.

Le cycle cyclopentadiényle, considéré comme un donneur tridenté, présente les même caractéristiques dans les composés $MnC_5H_5(CO)_3$ et $MnC_5H_5(CO)_2P(C_6H_5)_3$ tant au point de vue des distances $Mn—C_{C_5H_5}$ et $C_{C_5H_5}—C_{C_5H_5}$ qu'au point de vue plan du cycle et agitation thermique des carbones. On retrouve aussi les mêmes paramètres structuraux dans $MnC_5H_5(CO)_2$-C_7H_8 (11). Ainsi $Mn—C_{C_5H_5}$ se situe à 2.16 ± 0.01 Å dans les trois composés tandis que $C_{C_5H_5}—C_{C_5H_5}$ présente une distance moyenne de 1.41 ± 0.02 Å. Il apparaît donc que le remplacement d'un CO par un ligand à caractère donneur n'affecte pas la liaison $Mn—C_5H_5$ de façon appréciable. De façon indirecte, il s'ensuit que C_5H_5 est un bon donneur dont le pouvoir accepteur est fort probablement assez faible pour que le groupement ne subisse pas de variations tant dans les paramètres atomiques que dans la fréquence de vibration de valence $Mn—C_5H_5$ (1).

L'introduction du donneur $P(C_6H_5)_3$ apporte des changements au niveau des liaisons Mn—CO.

C	−0.2787	0.9501	−0.1403	−0.4274	3.1
D	−0.2022	0.1357	−0.9699	3.1217	8.4

(*b*) Distances (Å) de chacun des atomes à leur plan

Plan A		Plan B		Plan C		Plan D	
C(4)	−0.0091	C(9)	0.0039	C(15)	0.0065	C(21)	0.0105
C(5)	0.0159	C(10)	−0.0138	C(16)	−0.0088	C(22)	−0.0030
C(6)	−0.0102	C(11)	0.0133	C(17)	−0.0041	C(23)	−0.0084
C(7)	0.0003	C(12)	0.0018	C(18)	0.0117	C(24)	0.0062
C(8)	0.0049	C(13)	−0.0074	C(19)	−0.0056	C(25)	0.0183
		C(14)	0.0013	C(20)	−0.0056	C(26)	−0.0244

NOTE: Le système orthonormé des axes de référence comprend X le long de a, Y dans le plan ab et Z le long de c^*.

Comparativement à $MnC_5H_5(CO)_3$ (1.80 ± 0.02 Å) et à $MnC_5H_5(CO)_2C_7H_8$ (1.79 ± 0.01 Å) la distance moyenne Mn—CO est plus courte de 0.04 Å (1.75 ± 0.01 Å). Lors du remplacement d'un groupe CO d'un métal carbonyle par la triphénylphosphine, la fréquence de vibration de valence M—C augmente alors que celle de vibration de valence C—O diminue (1). Le mécanisme accepté de transfert de la charge nette supplémentaire introduite par $P(C_6H_5)_3$ implique un renforcement de la liaison M—C et un affaiblissement du lien C—O par retour π dans l'orbitale moléculaire antiliante du monoxyde de carbone. On devrait donc observer, à la suite de la diminution de distance Mn—CO, un accroissement de la longueur de liaison C—O. Quoique l'écart ne soit pas statistiquement très significatif, on peut cependant noter que les valeurs moyennes de 1.14 et 1.17 Å pour les distances C—O dans les composés non-substitué et monosubstitué sont en accord avec un affaiblissement des liaisons C—O par suite de l'introduction de $P(C_6H_5)_3$.

Conclusion

Sauf pour une tendance marquée vers un changement des paramètres de liaison Mn—CO, le remplacement d'un groupe CO de $MnC_5H_5(CO)_3$ par le groupe donneur $P(C_6H_5)_3$ n'affecte ni la liaison Mn—C_5H_5 ni l'arrangement géométrique autour de l'atome central.

Photochemistry of Pivalaldehyde in Solution Studied by CIDNP

HOLGER E. C. CHEN, AREND GROEN, AND MICHAEL COCIVERA
Department of Chemistry, University of Guelph, Guelph, Ontario

Received April 18, 1973

The n.m.r. spectrum observed during irradiation of pivalaldehyde dissolved in perfluoromethylcyclohexane indicates the formation of several compounds whose hydrogens are spin polarized. These compounds are 2-methylpropane, 2-methylpropene, and pivalaldehyde. A mechanism involving radical reactions which is consistent with these results is presented. According to this mechanism, the primary photochemical step is cleavage of the bond between the carbonyl carbon and the tertiary carbon of the *t*-butyl group. In contrast, this step does not appear to be important for acetaldehyde. As a test of the proposed mechanism CCl_4 is added to trap free radicals. In this case, one of the products is CCl_3COH. A mechanism for the formation of this and the other products having nuclear spin polarization is presented.

Le spectre r.m.n. obtenu lors de l'irradiation de la pivalaldéhyde dissoute dans du perfluorométhylcyclohexane, a montré qu'il se formait plusieurs produits. Ces composés sont le méthyl-2 propane, le méthyl-2 propène et la pivalaldéhyde. On propose un mécanisme impliquant des réactions radicalaires qui serait en accord avec les résultats obtenus. Selon ce mécanisme, l'étape photochimique fondamentale est la clivage de la liaison entre le carbone du carbonyle et le carbone tertiaire du groupe *t*-butyle. Au contraire, cette étape ne semble pas importante en ce qui a trait à l'acétaldéhyde. Afin de prouver le mécanisme proposé, on ajouta du CCl_4 au mélange réactionnel pour isoler les radicaux libres; dans ce cas, l'un des produits isolés fut le CCl_3COH. Un mécanisme est proposé afin d'expliquer la formation de ce produit ainsi que des autres. [Traduit par le journal]

Can. J. Chem., 51, 3032 (1973)

Introduction

Chemically induced dynamic nuclear polarization (CIDNP) has proven to be very useful in the study of the mechanisms of radical reactions. In addition to providing information concerning the nature of the radicals involved, CIDNP has proven useful in the detection of compounds which are unstable under the experimental conditions employed. For example, while pivalaldehyde has been detected by CIDNP as one of the products arising from the photolysis of di-*t*-butyl ketone (*1*), this aldehyde was not detected by means of conventional product studies (2), presumably because the prolonged irradiation used for product studies decomposed the compound. More recently, CIDNP has been used to detect short-lived enols arising during the radiation-induced reaction of acetaldehyde (3) and acetophenone with phenol (4). The results of the acetaldehyde study are consistent with the conclusion that the main reaction path involves the transfer of the carbonyl hydrogen from one aldehyde molecule to a second one to give a radical pair consisting of an acetyl radical and an α-hydroxyethyl radical. A similar reaction has been observed for benzaldehyde (5, 6). Since in the di-*t*-butyl ketone study, we obtained no evidence that pivalaldehyde undergoes a similar reaction, we have undertaken a study of the photolysis of pivalaldehyde. In this paper we report the results of this study. Our results indicate that pivalaldehyde does not react in the same manner as acetaldehyde or benzaldehyde. Instead the photolysis appears to involve α-cleavage similar to that suggested for α-aryl aldehyde (7) to give a radical pair consisting of the *t*-butyl radical and the formyl radical. Analysis of the resulting n.m.r. spectra indicates that an excited triplet electronic state is the precursor for this radical pair.

Experimental

Pivalaldehyde (Canadian Laboratories) contained a small amount of impurity. This compound was purified by fraction distillation, checked by n.m.r. and g.l.c., and used in the photochemical studies. The distillation reduced the impurity to about 1% of pivalaldehyde. Carbon tetrachloride (Baker reagent, spectrograde), perfluoromethylcyclohexane (Pierce Chemical), and trichloroacetaldehyde (Aldrich) were checked by n.m.r. and used without purification.

Formyl chloride was synthesized by reaction of thionyl chloride with formic acid. It was trapped in CCl_4 and used without further purification.

The proton n.m.r. spectra at 100 MHz were obtained at 15 °C using a Varian HA-100-15 spectrometer which we have modified to operate on a time-sharing mode. In this mode, we are able to use a quartz probe which allowed direct irradiation of the sample while the

n.m.r. spectrum was being obtained. This probe was built in our laboratory and the details are given elsewhere (1). The n.m.r. spectra were obtained before, during, and after irradiation. The radiation source is a 1000 W Hanovia mercury xenon lamp. A filter was employed to allow transmission of radiation having wavelengths greater than 310 nm.

Results

A n.m.r. spectrum obtained during irradiation of a solution of 0.2 *M* pivalaldehyde in perfluoromethylcyclohexane is illustrated in Fig. 1*A*. As indicated in this figure, the spectra of three compounds are observed: pivalaldehyde **1**, methyl hydrogen singlet at 0.85 p.p.m., carbonyl hydrogen singlet at 9.22 p.p.m.; 2-methylpropane **2**, methyl hydrogen doublet at 0.73 p.p.m., and methine hydrogen decuplet at 1.56 p.p.m.; 2-methylpropene **3**, methyl hydrogen triplet at 1.53 p.p.m. and methylene hydrogen septet at 4.48 p.p.m. This spectrum was obtained using a 500 Hz sweep range, and the chemical shifts are given relative to the tetramethylsilane resonance. As illustrated in this figure, both absorption and emission resonances occur, indicating the CIDNP effect. Because the lines at 1.50 and 4.48 p.p.m. are rather weak at the gain used for Fig. 1*A*, these lines are illustrated at higher gain in Fig. 1*B*. In addition, the lines at 4.48 p.p.m. in *B* were obtained at half the sweep width used in *A*. The spectrum obtained after the sample has been irradiated for about 250 s consists of **1** and a small amount of **2** and what might be tetramethylbutane. Furthermore at higher gain the weak resonance of the methyl hydrogen of 2-methylpropene can be observed. In addition, the intensity of the methyl hydrogen line of **1** does not differ significantly during and after irradiation. Thus all of the lines in Fig. 1*A* except the methyl hydrogen line of **1** are enhanced absorption and/or emission lines.

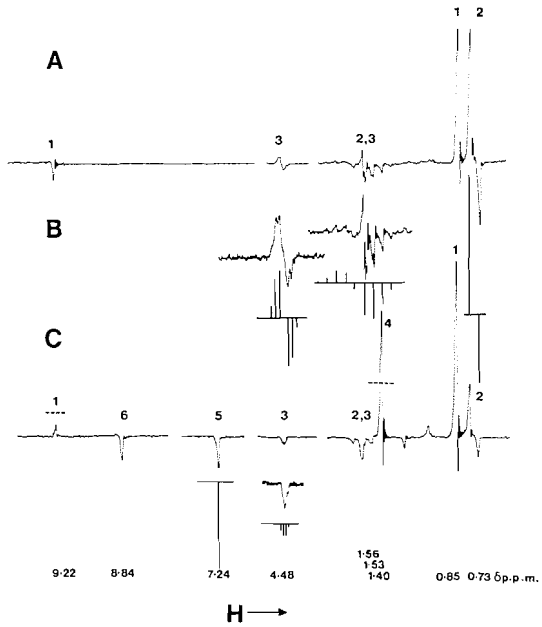

FIG. 1. 100 MHz n.m.r. spectra obtained during irradiation with wavelength greater than 310 nm. *A*, solution containing 0.2 *M* pivalaldehyde in perfluoromethylcyclohexane at 15 °C temperature. All resonance lines were obtained using 500 Hz sweepwidth. *B*, same solution at higher gain. In addition the lines at δ 4.48 p.p.m. were obtained using 250 Hz sweepwidth. *C*, solution containing 0.2 *M* pivalaldehyde and 0.2 *M* CCl_4 in perfluoromethylcyclohexane at 15 °C. All signals were obtained using 500 Hz sweepwidth. In addition, the resonance at δ 4.48 is illustrated at higher gain. The stick figures illustrate calculated relative intensities.

This experiment has been repeated for pivalaldehyde concentrations ranging from 0.1 to 1 mol/l. While the overall intensity of the spectrum depends on the concentration, the relative intensities of the individual lines do not appear to be altered significantly. Furthermore no new lines were observed at higher concentrations. When the experiment was repeated using a degassed sample, only a slight increase in the overall intensity of the spectrum was observed. Similar spectra were obtained when perfluorobenzene and deuteroacetonitrile were each used as the solvent. On the other hand, when a perfluoromethylcyclohexane solution containing 0.2 *M* pivalaldehyde and 0.2 *M* CCl_4 is irradiated under the same conditions, the spectrum (Fig. 1*C*) differs significantly from the one given in Fig. 1*A*. First, in addition to the lines observed in *A*, five new lines are observed. Three of these five have been definitely assigned to *t*-butyl chloride **4** at 1.40 p.p.m., chloroform **5** at 7.24 p.p.m., and trichloroacetaldehyde **6** at 8.94 p.p.m. We have ruled out the possibility that formyl chloride is responsible for any of these lines because we have determined its chemical shift as 8.04 p.p.m. The remaining two lines are unidentified. Second, the relative intensities and/or directions of lines in *C* differ from corresponding lines in *A*. These differences will be discussed in the next section.

Discussion

As in the case of di-*t*-butyl ketone (1), the observed spectra can be explained in terms of radical reactions occurring via radical pairs.

$$(CH_3)_3CCOH \xrightarrow{h\nu} [(CH_3)_3C\cdot\cdot COH]^T$$

1

[1] $\longrightarrow$ 1

[2] $[(CH_3)_3C\cdot\cdot COH]^{T,F} \longrightarrow (CH_3)_3CH + CO$ (2)

[3] $\longrightarrow (CH_3)_3C\cdot + \cdot COH$

[4] $(CH_3)_3C\cdot + \cdot COH \longrightarrow [(CH_3)_3C\cdot\cdot COH]^F$

[5] $2(CH_3)_3C\cdot \longrightarrow [(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$

[6] $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F \longrightarrow 2 + (CH_3)_2C = CH_2$ (3)

[7] $\longrightarrow$ tetramethylbutane

SCHEME 1

Before discussing the simulation of these spectra, it is convenient to present in Schemes 1 and 2 the mechanism proposed to explain our results.

According to Scheme 1, **1** absorbs a quantum of light and via intersystem crossing from an excited electronic singlet state eventually ends up in an electronic triplet state from which the $[(CH_3)_3C\cdot\cdot COH]^T$ radical pair is formed. The superscript T indicates that the radical pair precursor is a triplet state. This radical pair has several reaction paths available to it such as recombination (eq. 1), disproportionation (eq. 2), and dissociation (eq. 3). If the radical pair dissociates to free radicals (*i.e.* no spin correlation between the unpaired electrons), the *t*-butyl radical and the formyl radical may reassociate to form the radical pair $[(CH_3)_3C\cdot\cdot COH]^F$ which can react via eqs. 1 and 2 or dissociate according to eq. 3. Likewise two *t*-butyl radicals may associate to form the radical pair $[(CH_3)_3C\cdot\cdot C(CH_3)]^F$ which may react according to eqs. 6 and 7 or dissociate. Finally, two formyl radicals may associate to form the radical pair $[HOC\cdot\cdot COH]^F$; however, because Δg is zero, no net nuclear spin polarization would be observed for the products derived from this radical pair. Similarly, tetramethylbutane obtained according to eq. 8 would exhibit no nuclear spin polarization (1), and no enhanced resonance is observed for this compound.

The CIDNP spectrum observed in the presence of carbon tetrachloride supports this scheme and provides additional information. The mechanism proposed to explain the spectrum in Fig. 1*C* is given in Scheme 2.

In this scheme, the initial radical pair $[(CH_3)_3C\cdot\cdot COH]^T$ formed from the triplet precursor reacts to give **1** and **2** with nuclear spin polarization in the same manner as Scheme 1. However, once this radical pair dissociates to the free *t*-butyl radical and the free formyl radical, reassociation of these radicals is prevented by the reactions given by eqs. 8–12. That is, the presence of CCl_4 reduces the formation of $[(CH_3)_3C\cdot\cdot COH]^F$ and $[(CH_3)_3C\cdot\cdot C(CH_3)]^F$ to the point that nuclear spin polarization resulting from these radical pairs is minor compared to the reaction paths given in Scheme 2.

These conclusions are based on the calculation of the nuclear spin polarization which results from each radical pair given in Schemes 1 and 2. Details of the theory used to calculate the nuclear spin polarization have been given previously (1), and only the final equations are given here. The nuclear spin polarization in a diamagnetic product is proportional to $(\rho_{ss}^m - \rho_{ss}^j)$ where m and j indicate nuclear spin states and ρ_{ss}, which is the diagonal density matrix element for the singlet spin state of the radical pair, is given by the expression

$$[13] \quad \rho_{ss}^j = \frac{(\alpha_{ss} + \mu_j(2 + \gamma)\alpha_{TT})/k_{-2}}{1 + \gamma + \mu_j(2 + \gamma)}$$

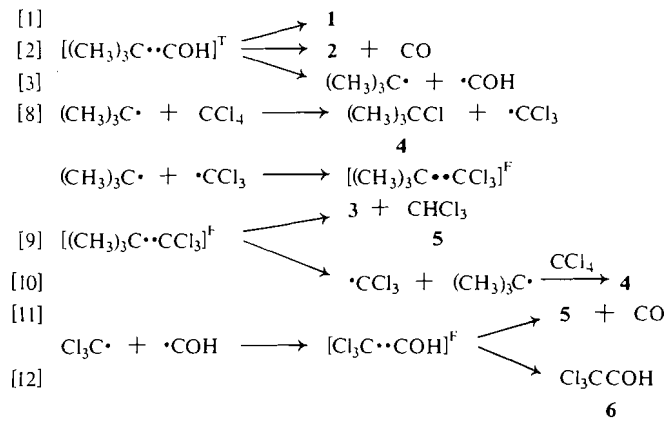
In this equation, α_{ss} and α_{TT} depend on the nature of precursor for the radical pair: for singlet precursor $\alpha_{ss} = r$ and $\alpha_{TT} = 0$; for triplet precursor $\alpha_{TT} = r'/3$ and $\alpha_{ss} = 0$; and if two separate free radicals combine to form the radical pair, $\alpha_{TT} = \alpha_{ss} = r''/4$ where r, r', and r'' are the rates for formation of the radical pair. In addition in eq. 13, $\gamma = k_1/k_{-2}$ where k_1 is the rate constant for product formation from the radical pair and k_{-2} is the rate constant for dissociation of the radical pair; and μ_j is given by the expression

$$[14] \quad \mu_j = \frac{H_{ST}^2/k_{-2}^2}{(1 + \gamma/2)^2 + 4J^2/k_{-2}^2 + (2 + \gamma)H_{ST}^2/k_{-2}^2}$$

In eq. 14, J is the electron exchange integral, and H_{ST} is the off-diagonal matrix element of the spin-Hamiltonian which mixes the singlet with the $M = 0$ state of the triplet manifold, and is obtained from the expression

$$[15] \quad H_{ST} = \tfrac{1}{2}\beta H_0(g_1 - g_2) + \tfrac{1}{2}\sum_l (A_1^l - A_2^l) < M_1|I_z^l|M_1>$$

In this expression β is the electron Bohr magneton, H_0 is the strength of the external magnetic



SCHEME 2

field, g is the isotropic electronic g factor, A is the electron-nuclear coupling constant, M_I is the nuclear spin state, I_z is z component of the nuclear spin operator, and the subscript and superscript label the electron and nucleus, respectively.

For the calculations, the g and A values for each radical are taken from e.s.r. data. The values used for J, k_{-2}, and γ are 10^8 Hz, 10^9 s^{-1}, and 0.2, respectively; and although they are reasonable (1), they are somewhat arbitrary. Consequently, absolute values for nuclear spin polarization could not be calculated. However, since the e.s.r. data are known, the calculated relative values are meaningful and very useful in understanding the photochemical reaction of pivalaldehyde.

Consider first the formation of **2** and its spectra in Figs. 1*A* and 1*C*. According to Scheme 1, this compound can be formed from three different radical pairs: $[(CH_3)_3C\cdot\cdot COH]^T$, $[(CH_3)_3C\cdot\cdot COH]^F$, and $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$. On the basis of the fit of calculated spectrum with the observed spectrum and the effect of CCl_4, one can determine that the polarization observed for **1** in Fig. 1*A* probably results from all three radical pairs. Furthermore, the radical pair $[(CH_3)_3C\cdot\cdot COH]^S$ derived from a singlet precursor cannot be responsible for the observed polarization because calculations show that it would give the opposite polarization. For the calculations based on these radical pairs, the values used for A and g are +22.7 G (1, 8) and 2.0025 for $(CH_3)_3C\cdot$, and +137 G (9) and 2.0009 (9) for ·COH. The value of g for $(CH_3)_3C\cdot$ is based on the values obtained for alkyl radicals (10). In addition, as was done previously, the following values were used for the indirect nuclear spin coupling constants: +6.4 Hz, vicinal coupling for **2**; and −1.1 Hz, allylic coupling for **3**.

As mentioned above, the spectrum of **2** can result from three different radical pairs. To arrive at this conclusion, it is necessary to compare Fig. 1*A* with 1*C* because Scheme 2 indicates that the formation of **2** is derived solely from $[(CH_3)_3C\cdot\cdot COH]^T$. Based on this radical pair, the calculated resonance lines for the methyl and methine hydrogens are given under Figs. 1*A* and 1*B*. Comparison of the calculated lines of the methyl hydrogens with the observed ones in Fig. 1*C* indicates a good fit. Unfortunately it is not possible to make the same comparison for the methine hydrogen because of the superposition of the *t*-butyl chloride and the methyl hydrogen lines of 2-methylpropene. We will return to the methine hydrogen below.

Thus, because of the fit between the calculated and observed intensities for the lines of the methyl hydrogen of **2**, we conclude that **2** is formed via the radical pair $[(CH_3)_3C\cdot\cdot COH]^T$ when **1** is irradiated in the presence of CCl_4. Furthermore, since the observed intensity pattern is similar in Fig. 1*A*, also, part of the polarization for **2** when CCl_4 is not present probably occurs via $[(CH_3)_3C\cdot\cdot COH]^T$. Reaction via the radical pair $[(CH_3)_3C\cdot\cdot COH]^S$ does not fit because the sign of the polarization calculated on this basis is opposite to the one observed. The importance of $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$ to the polarization observed in Fig. 1*A* is determined in the following manner. The intensity of the methyl absorption

line divided by the intensity of the methyl emission line is 2.6 in Fig. 1*A* and 3.2 in Fig. 1*B*. If only $[(CH_3)_3C\cdot\cdot COH]^T$ were responsible for the polarization, the ratio in Fig. 1*A* should be 3.2. If only $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$ were responsible for the polarization, the ratio based on a previous calculation (1) should be 1. Thus, $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$ contributes to part of the polarization of the methyl hydrogen of **2** observed in Fig. 1*A*. Additional evidence for this conclusion is obtained from the spectrum for 2-methylpropene as described below.

The contribution of $[(CH_3)C\cdot\cdot COH]^F$ to the polarization of **2** in the absence of CCl_4 cannot be determined with any degree of certainty. Although the intensity of the absorption and emission lines of the methyl hydrogen decrease in the presence of CCl_4 (Fig. 1*A vs.* Fig. 1*C*), we cannot rule out the possibility that the decrease is due mainly to the absence of any appreciable reaction via $[(CH_3)_3C..C(CH_3)_3]^F$ and to singlet or triplet energy transfer from pivalaldehyde to CCl_4.

For the methine hydrogen of **2**, the calculated intensities should be compared with intensities observed in the presence of CCl_4 since the intensities were calculated on the basis of $[(CH_3)_3C\cdot\cdot COH]^T$. Unfortunately, these lines are masked by the methyl hydrogen lines (emission) of **3** and the methyl hydrogen line (absorption) of **4**. For comparison with the methine lines in Figs. 1*A* and 1*B*, the calculated intensities should include the values based on $[(CH_3)_3C\cdot\cdot COH]^T$, $[(CH_3)_3C\cdot\cdot COH]^F$, and $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$. However, since the relative contributions of each of these radical pairs is not known, such a simulation would be arbitrary. Instead, the relative intensities calculated only on the basis of $[(CH_3)_3C\cdot\cdot COH]^F$ and $[(CH_3)_3C\cdot\cdot COH]^T$ (since they give identical results) have been included in Fig. 1 to illustrate that the polarization for **2** is consistent with F and T precursors rather than the S precursor.

As indicated earlier, while the carbonyl hydrogen line of **1** appears as emission during irradiation, the methyl hydrogen does not appear to be polarized. This result is consistent with the formation of **1** via $[(CH_3)_3C\cdot\cdot COH]^{T,F}$. The calculated relative intensity of the carbonyl hydrogen of **1** is about four times the value for the methyl hydrogen. Consequently, when the calculated intensity of the carbonyl hydrogen is normalized to the observed value in Fig. 1, the calculated intensity of the methyl hydrogen is a small fraction of the observed intensity, and no effect is expected.

In Fig. 1*C*, the carbonyl hydrogen line of **1** no longer appears as emission; however, its intensity is decreased compared to its intensity after irradiation (indicated by the dashed line). Thus, the polarization of this hydrogen in the presence of CCl_4 is decreased. A possible explanation for this decrease might be that polarization occurs via $[(CH_3)_3C..COH]^{T,F}$ in the absence of CCl_4 whereas it occurs only via $[(CH_3)_3C\cdot\cdot COH]^T$ in the presence of CCl_4 (Scheme 2). However, as mentioned above, we cannot rule out the possibility that the decrease is due to quenching of the excited state of pivalaldehyde by CCl_4.

As mentioned above, the spectrum for 2-methylpropene **3** provides additional evidence for the occurrence of the radical pair $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$ in the absence of CCl_4. As indicated in Scheme 1, **3** may be formed via a disproportionation reaction involving this radical pair. The calculated line intensities for the methylene hydrogens of **3** are illustrated under the observed intensities in Fig. 1*B*. Unfortunately, a similar comparison cannot be made for the methyl hydrogen of **3** because its lines are masked by the lines of the methine hydrogen of **2**. Another possible path for the formation of olefin is a disproportionation reaction involving $[(CH_3)_3C\cdot\cdot COH]^{T,F}$ to give olefin plus HCOH. However, no enhanced HCOH line is observed, and in this case the calculated intensity pattern for the methylene hydrogen differs from the observed one. Consequently, in the absence of CCl_4, our results are consistent with the formation of **3** mainly via $[(CH_3)_3C\cdot\cdot C(CH_3)_3]^F$.

In the presence of CCl_4, the intensity pattern for the lines of **3** change markedly as can be seen in Fig. 1*C*. The net emission observed for both the methylene and the methyl hydrogens of **3** is consistent with the formation of olefin via $[(CH_3)_3C\cdot\cdot CCl_3]^F$. The intensity pattern calculated for the methylene hydrogen lines is given under the corresponding observed lines in Fig. 1*C*. The calculated pattern for the methyl hydrogen is not presented since comparison with the observed pattern is not possible because of overlap with other lines. For this calculation, a value of 2.0091 was used for the *g* factor of $\cdot CCl_3$ (11).

The other product which results from this

radical pair is $CHCl_3$, and in agreement with observation, the calculation indicates emission for this line. Another source for this compound is the radical pair $[Cl_3C\cdot\cdot COH]^F$. As indicated in Scheme 2 this radical pair can give either $CHCl_3$ or Cl_3CCOH, both of which are observed. Again in agreement with observation, the calculation based on this radical pair indicates emission for the resonance lines for these compounds. The calculated intensity for Cl_3CCOH has not been included in Fig. 1 because it cannot be compared directly with the calculated intensities of the other products. Thus, both $[(CH_3)_3C\cdot\cdot CCl_3]^F$ and $[Cl_3C\cdot\cdot COH]^F$ can provide $CHCl_3$ having its hydrogen spin polarized. Our results do not allow us to determine the relative contribution of these two radical pairs to the formation of $CHCl_3$.

As indicated in Fig. 1*C*, the intensity of the *t*-butyl chloride line decreases to the dashed lines when the irradiation is stopped, indicating polarization of its hydrogens. This enhanced absorption can be rationalized as indicated in eq. 10 of Scheme 2. When the radical pair $[(CH_3)_3C\cdot\cdot CCl_3]^F$ dissociates, the hydrogens of $(CH_3)_3C\cdot$ are initially polarized. This radical then reacts with CCl_4 to form *t*-butyl chloride and $\cdot CCl_3$ at a rate fast enough to make the lifetime of $(CH_3)_3C\cdot$ shorter than the spin–lattice relaxation time of its hydrogens. Consequently, the polarization is retained in *t*-butyl chloride. Calculation of the polarization according to this mechanism gives the proper sign for the polarization. The calculated intensity of *t*-butyl chloride has not been included in Fig. 1 because it cannot be compared directly with the calculated intensities of the other product lines.

Finally, in addition to the reactions given by eqs. 8–12, it is probable that CCl_4 reacts with pivalaldehyde via a chain mechanism. A chain reaction between isovaleraldehyde and CCl_4 to give $CHCl_3$ and isovaleryl chloride as the main products has been reported (12). In the case of pivalaldehyde, we observe *t*-butyl chloride and $CHCl_3$ as the major products when pivalaldehyde is irradiated in the presence of CCl_4. A possible mechanism is

$$RCOH + \cdot CCl_3 \rightarrow RCO\cdot + CHCl_3$$

$$RCO\cdot \rightarrow R\cdot + CO$$

$$R\cdot + CCl_4 \rightarrow RCl + \cdot CCl_3$$

where R signifies the *t*-butyl group. This chain mechanism is similar to the one proposed earlier for isovaleraldehyde (12) except that a step for the loss of CO by $RCO\cdot$ is included and $R\cdot$ rather than $RCO\cdot$ reacts with CCl_4. While this chain mechanism can explain the formation of *t*-butyl chloride and $CHCl_3$, it cannot account for the nuclear spin polarization observed for these products during irradiation because it does not involve the formation of radical pairs. Consequently, Scheme 2 must also be included to explain the n.m.r. spectrum. Some idea of the importance of the chain mechanism compared with Scheme 2 can be obtained by comparing the intensities of the $CHCl_3$ and *t*-butyl chloride lines after irradiation. The ratio of *t*-butyl chloride intensity to the $CHCl_3$ intensity is about 25. This ratio is an average of runs on four identical samples. If only the chain mechanism suggested above were occurring, this ratio should be 9.

In summary, our CIDNP results are consistent with a mechanism in which the primary photochemical step in the photolysis of pivalaldehyde in perfluoromethylcyclohexane is the cleavage of the bond between the carbonyl carbon and the tertiary carbon of the *t*-butyl group. This step appears to occur predominantly via an excited electronic triplet state of pivalaldehyde. In contrast, this mechanism does not appear to be the main route responsible for the CIDNP effects observed in the photochemical reaction of acetaldehyde in solution (3). Finally, as indicated by the chain mechanism discussed above, the occurrence of CIDNP effects does not preclude the possibility of other reaction steps which may be more important in product formation (see also ref. 7).

The authors thank Dr. D. R. Arnold for indicating the possibility of a chain reaction. This research was supported in part by the Petroleum Research Fund administered by the American Chemical Society and by the National Research Council of Canada.

A Synthesis of 2-Acetamido-2,6-dideoxy-D-gulose, 2-Acetamido-2,6-dideoxy-D-idose, and 2,6-Dideoxy-D-*xylo*-hexose (Boivinose)[1]

MALCOLM B. PERRY AND VIRGINIA DAOUST

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received February 27, 1973

The base-catalyzed addition of nitromethane to 5-deoxy-D-xylose gave a mixture of 1,6-dideoxy-1-nitro-D-gulitol (**2**) and 1,6-dideoxy-1-nitro-D-iditol (**3**) (*ca.* 1 :1) which underwent the Nef reaction to give 6-deoxy-D-gulose and 6-deoxy-D-idose. Acetylation of mixed **2** and **3** afforded the corresponding 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-gulitol (**4**) and 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-iditol (**5**) derivatives which on treatment with methanolic ammonia yielded 2-acetamido-1,2,6-trideoxy-1-nitro-D-gulitol (**11**) and 2-acetamido-1,2,6-trideoxy-1-nitro-D-iditol (**12**) (*ca.* 6 :1). Compounds **11** and **12** underwent the modified Nef reaction to give 2-acetamido-2,6-dideoxy-D-gulose (**13**) and 2-acetamido-2,6-dideoxy-D-idose (**14**) which were separated by cellulose column chromatography.

Compound **4** was converted to 3,4,5-tri-*O*-acetyl-1,2,6-trideoxy-1-nitro-D-*xylo*-hex-1-enitol (**6**) which on catalytic reduction gave 3,4,5-tri-*O*-acetyl-1,2,6-trideoxy-1-nitro-D-*xylo*-hexitol (**7**). Compound **7** underwent the Nef reaction to yield 2,6-dideoxy-D-*xylo*-hexose (**8**) (D-boivinose).

L'addition, catalysée par une base, du nitrométhane au déoxy-5 D-xylose a conduit au mélange (*ca.* 1 :1) de didéoxy-1,6 nitro-1 D-gulitol (**2**) et de didéoxy-1,6 nitro-1 D-iditol (**3**) qui, soumis à la réaction de Nef, a conduit au déoxy-6 D-gulose et déoxy-6 D-idose. L'acétylation du mélange **2** et **3** a conduit aux dérivés correspondants tétra-*O*-acétyl-2,3,4,5 didéoxy-1,6 nitro-1 D-gulitol (**4**) et tétra-*O*-acétyl-2,3,4,5 didéoxy-1,6 nitro-1 D-iditol (**5**) qui, à l'aide d'un traitement avec une solution d'ammoniaque dans du méthanol, ont produit un mélange (*ca.* 6 :1) d'acétamido-2 tridéoxy-1,2,6 nitro-1 D-gulitol (**11**) et d'acétamido-2 tridéoxy-1,2,6 nitro-1 D-iditol (**12**). Les composés **11** et **12**, lorsque soumis à la réaction modifiée de Nef, ont conduit à l'acétamido-2 didéoxy-2,6 D-gulose (**13**) et à l'acétamido-2 didéoxy-2,6 D-idose (**14**) lesquels ont pu être séparés par chromatographie sur colonne de cellulose.

Le composé **4** a été transformé en tri-*O*-acétyl-3,4,5 tridéoxy-1,2,6 nitro-1 D-*xylo*-hexène-1 itol (**6**) qui, par réduction catalytique, a donné le tri-*O*-acétyl-3,4,5 tridéoxy-1,2,6 nitro-1 D-*xylo* hexitol (**7**). Le composé **7** soumis à la réaction de Nef a conduit au didéoxy-2,6 D-*xylo*-hexose (**8**) (D-boivinose).

[Traduit par le journal]

Can. J. Chem., **51**, 3039 (1973)

5-Deoxy-D-xylose (**1**) (1) underwent base-catalyzed addition of nitromethane to give approximately equal amounts of the expected 1,6-dideoxy-1-nitro-D-gulitol (**2**) and 1,6-dideoxy-1-nitro-D-iditol (**3**) derivatives. A portion of this product treated under the Nef reaction conditions (2, 3) gave 6-deoxy-D-gulose (**9**) and 6-deoxy-D-idose (**10**) which were separated by cellulose column chromatography. Both sugars had properties in agreement with those previously recorded and each on treatment with phenylhydrazine gave 6-deoxy-D-*xylo*-hexose phenylosazone. Kovár and Baer (4) and Baer (5) have shown that the nitromethane addition to aldoses is subject to kinetic control and that the epimeric product ratio is mainly influenced by the configuration at C-3 leading to the predominant production of the derivative with 2,4-*threo* hydroxyl groups. On these stereochemical considerations, hexitol **2** would have been expected as the major product. The equal yields of hexitols **2** and **3** may, however, represent thermodynamic products considering the extended reaction time (20 h) used.

Acetylation of mixed **2** and **3** afforded their corresponding 2,3,4,5-tetra-*O*-acetyl derivatives **4** and **5** from which 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-gulitol (**4**) (identified by Nef reaction product) was obtained crystalline. The compound **4** on treatment with sodium bicarbonate in boiling benzene solution gave 3,4,5-tri-*O*-acetyl-1,2,6-trideoxy-1-nitro-D-*xylo*-hex-1-enitol (**6**) and reduction of this compound with hydrogen in the presence of palladium black afforded 3,4,5-tri-*O*-acetyl-1,2,6-trideoxy-1-nitro-D-*xylo*-hexitol (**7**) which underwent the Nef reaction to yield 2,6-dideoxy-D-*xylo*-hexose (**8**) (D-boivinose). The 2,6-dideoxy-D-*xylo*-hexose

had physical properties in agreement with those recorded for the compounds isolated from natural glycosides (6) and with the compound synthesized from methyl 2,3-anhydro-α-D-alloside (7).

The mixed 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-hexitols **4** and **5** on treatment with methanolic ammonia afforded a mixture of 2-acetamido-1,2,6-trideoxy-1-nitro-D-gulitol (**11**) and 2-acetamido-1,2,6-trideoxy-1-nitro-D-iditol (**12**) which underwent the modified Nef reaction (3) to yield 2-acetamido-2,6-dideoxy-D-gulose (**13**) and 2-acetamido-2,6-dideoxy-D-idose (**14**) (*ca.* 6:1) which were separated by cellulose column chromatography. The 2-acetamido-2,6-dideoxy-D-idose was obtained crystalline but the 2-acetamido-2,6-dideoxy-D-gulose, which could not be induced to crystallize, was hydrolyzed with hydrochloric acid to give crystalline 2-amino-2,6-dideoxy-D-gulose hydrochloride which had physical properties in agreement with those recorded for the sugar synthesized from 2-amino-2-deoxy-D-gulose (8). It is interesting to note that the amination of 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-D-*xylo*-hex-1-enitol (9) followed by treatment of the products under the modified Nef reaction conditions afforded 2-acetamido-2-deoxy-D-gulose and 2-acetamido-2-deoxy-D-idose in the ratio 8.1 : 1.

Experimental

Paper chromatography was performed by the descending method (10) on Whatman No. 1 filter paper using either (A) pyridine – ethyl acetate – water (2 : 5 : 5 v/v, top layer) or (B) 1-butanol – ethanol – water (4 : 1 : 5 v/v, top layer) as the mobile phase. Glycoses were detected with either (a) 2% silver nitrate in acetone followed by 3% sodium hydroxide in ethanol (11), (b) 2% *p*-anisidine hydrochloride in ethanol (12) or 2% ninhydrin in acetone. The rates of movement of the glycoses are quoted relative to D-galactose (R_{Gal}) or to 2-amino-2-deoxy-D-glucose hydrochloride (R_{GN}).

G.l.p.c. was carried out using a Hewlett-Packard model 402 chromatograph with a hydrogen flame detector and fitted with glass U-tubes (4 ft × 6 mm × 3 mm internal diameter) packed with either (A) 10% neopentylglycol sebacate polyester on 80–100 mesh acid washed Chromosorb W or (B) 3% ECNSS-M on 100–120 mesh Gas-Chrom Q (Applied Science Labs., State College, Pa.). Retention times of the compounds are quoted relative to penta-*O*-acetyl-L-arabinitol (T_A) or 2-acetamido-1,3,4,5,6-penta-*O*-acetyl-2-deoxy-D-glucitol (T_{GNo1Ac}).

Melting points were determined on a Fisher-Johns apparatus and are corrected. Solutions were concentrated under reduced pressure and below 40 °C. Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter. I.r. spectra were obtained by the potassium bromide disc technique using a Perkin-Elmer 237B Infracord.

A. Addition of Nitromethane to 5-Deoxy-D-xylose

To a solution of 5-deoxy-D-xylose (**1**) (1) (10 g) in a mixture of methanol (120 ml) and nitromethane (50 ml) was added 1.7 *N* sodium methoxide in methanol (54 ml) and the stirred reaction mixture was kept at 20 °C for 20 h. Following the addition of ether (1 l), the precipitated product was collected by filtration, washed with a little cold methanol, ether, light petroleum (b.p. 30–60 °C), and dried *in vacuo* (12.9 g). The product (12.5 g) in water (200 ml) was passed down a column of Rexyn 101(H^+) ion-exchange resin (280 ml) and the eluate and water washings were concentrated to a syrup (10.3 g) containing 1,6-dideoxy-1-nitro-D-gulitol (**2**) and 1,6-dideoxy-1-nitro-D-iditol (**3**).

B. Synthesis of 6-Deoxy-D-gulose (9) and 6-Deoxy-D-idose (10)

A portion of mixed **2** and **3** (from experiment A) (1 g) dissolved in a solution of $Ba(OH)_2.8H_2O$ (1.23 g) in water (20 ml) was added dropwise with stirring to a solution of concentrated sulfuric acid (1.13 ml) in water (10 ml). After 16 h at room temperature, the reaction mixture was neutralized ($BaCO_3$), filtered, and the filtrate after deionization with mixed Rexyn 101(H^+) and RG6(OH^-) ion-exchange resins (10 ml) was concentrated to a syrup (0.52 g). Paper chromatographic examination of the syrup (solvent A) revealed two components having R_{Gal} 3.98 and 2.82 corresponding in mobility and color reactions with authentic **10** and **9** respectively.

A portion of the mixed **9** and **10** (5 mg) was reduced ($NaBH_4$) and acetylated (13) and g.l.p.c. (column B, 180 °C) of the product gave two peaks corresponding in retention times with 1,2,3,4,5-penta-*O*-acetyl-6-deoxy-D-gulitol (T_A 0.83, 51%) and 1,2,3,4,5-penta-*O*-acetyl-6-deoxy-D-iditol (T_A 1.08, 49%).

Separation of **9** and **10** by cellulose column (4 × 60 cm) chromatography using 1-butanol – water (10 : 1 v/v) as the mobile phase gave the following compounds.

(1) 6-Deoxy-D-idose (10)

10 (170 mg) was eluted first from the column and remained a chromatographically pure syrup having $[\alpha]_D$ +14.7° (*c*, 0.7 in water) and R_{Gal} 3.98 (solvent A). The reduced ($NaBH_4$) and acetylated sugar on g.l.p.c. examination (column B, 180 °C) gave a single peak with T_A 1.08, and treatment with phenylhydrazine afforded 6-deoxy-D-*xylo*-hexose phenylosazone having m.p. and mixture m.p. 175–177 °C (lit. (14) m.p. 168–172 °C, (15) 182–184 °C dec.) and giving an i.r. spectrum identical with an authentic derivative.

(2) 6-Deoxy-D-gulose (9)

9 (188 mg) had $[\alpha]_D$ −41° (*c*, 0.5 in water) (lit. 1, 16) $[\alpha]_D$ −38° (water), gave a single spot on paper chromatography (R_{Gal} 2.82 (solvent A)), and the reduced ($NaBH_4$) and acetylated derivative gave a single peak on g.l.p.c. (column B, 180 °C) with T_A 0.83. **9** on treatment with phenylhydrazine afforded 6-deoxy-D-*xylo*-hexose phenylosazone with m.p. and mixture m.p. 175–177 °C.

C. 2,6-Dideoxy-D-xylo-hexose (8)

(1) Acetylation of 1,6-Dideoxy-1-nitro-D-gulitol (2) and 1,6-Dideoxy-1-nitro-D-iditol (3)

The mixture of **2** and **3** (experiment *A*) (9 g) in acetic anhydride (80 ml) was treated with a drop of concentrated sulfuric acid and the mixture was heated on a boiling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

water bath for 30 min. The cooled mixture was poured into an ice–water mixture (700 ml) and after 1 h the acetylated derivatives, which had separated as an oil, were collected, taken up in chloroform (200 ml), washed with water (3 × 50 ml), dried (anhydrous Na_2SO_4), and concentrated to a syrup (13.4 g). An ethanol solution of the product afforded crystalline 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-gulitol (**4**) (4.2 g) which after two recrystallizations from ethanol had m.p. 158–159 °C and $[\alpha]_D$ +14.4° (*c*, 0.4 in chloroform).

Anal. Calcd. for $C_{14}H_{21}NO_{10}$: C, 46.28; H, 5.83; N, 3.86. Found: C, 46.47; H, 5.79; N, 3.70.

*(2) 3,4,5-Tri-O-acetyl-1,2,6-trideoxy-1-nitro-*D*-xylo-hex-1-enitol (6)*

Compound **4** (3.5 g) in dry benzene (45 ml) was boiled under reflux for 2.5 h with sodium bicarbonate (6 g). The cooled reaction mixture was filtered and the filtrate was concentrated to a syrup (3.3 g). An ethanol solution of the product kept at 2 °C afforded crystalline **6** (2.1 g) which had m.p. 126–127 °C and $[\alpha]_D$ +6.5° (*c*, 0.4 in chloroform).

Anal. Calcd. for $C_{12}H_{17}NO_8$: C, 47.52; H, 5.65; N, 4.62. Found: C, 47.45; H, 5.63; N, 4.59.

*(3) 3,4,5-Tri-O-acetyl-1,2,6-trideoxy-1-nitro-*D*-xylo-hexitol (7)*

Compound **6** (1.5 g) in ethanol (50 ml) was shaken with hydrogen at room temperature and pressure in the presence of palladium black (0.15 g). One mol equiv of hydrogen was absorbed in 30 min and the rate of reduction then became very slow. At this point, the reaction mixture was filtered and the filtrate was concentrated to a syrup (1.4 g). A methanol solution of the product gave crystalline **7** (0.92 g) which had m.p. 82–83 °C and $[\alpha]_D$ −16.6° (*c*, 0.3 in chloroform) unchanged on further recrystallization from methanol.

Anal. Calcd. for $C_{12}H_{19}NO_8$: C, 47.21; H, 6.27; N, 4.59. Found: C, 47.35; H, 6.40; N, 4.49.

*(4) 2,6-Dideoxy-*D*-xylo-hexose (8)*

Compound **7** (0.5 g) was dissolved in *N* sodium hydroxide solution (9 ml) at 37 °C and after 2 h the solution was added dropwise with stirring to a solution of concentrated sulfuric acid (3 ml) in water (20 ml) and the mixture was kept at 20 °C for 18 h. Following neutralization ($BaCO_3$) and filtration, the filtrate was passed down columns of Rexyn 101(H^+) (20 ml) and RG6(OH^-) (15 ml) ion-exchange resins and the eluate and washings were concentrated to a syrup (0.36 g). Crystalline **8** (0.27 g), obtained from acetone solution, gave a single spot on paper chromatography (R_{Gal} 5.22, solvent A) and had m.p. 98–99 °C and $[\alpha]_D$ −14° (*c*, 1 in acetone) (lit. (6, 7) m.p. 100–103 °C and $[\alpha]_D$ −15° (acetone)).

Anal. Calcd. for $C_6H_{12}O_4 \cdot \frac{1}{2}H_2O$: C, 45.85; H, 8.34. Found: C, 46.03; H, 8.47.

*D. 2-Acetamido-2,6-dideoxy-*D*-gulose (13) and 2-Acetamido-2,6-dideoxy-*D*-idose (14)*

The mixture of **4** and **5** (remaining from experiment C(1)) (9.2 g) in dry methanol (100 ml) was cooled to 0 °C and ammonia gas was passed into the solution over 30 min to saturation, and the mixture was kept at 20 °C for 18 h. The concentrated mixture was triturated with hot chloroform (3 × 60 ml) to remove acetamide and the residual syrup (4.6 g) dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (5.7 g) in water (90 ml) was added dropwise with stirring to a solution of concentrated sulfuric acid (5.3 ml) in water (50 ml). After 18 h at room temperature, the reaction mixture was neutralized ($BaCO_3$), filtered, and the filtrate was passed down a column of mixed Rexyn 101(H^+) and RG6(OH^-) ion-exchange resins (25 ml). Concentration of the column eluate and water washings afforded a syrup (1.94 g) which on paper chromatographic examination (solvent A) revealed two spots with R_{Gal} 4.74 and 4.04 (visual ratio 1 :10) corresponding in mobility with **14** and **13** respectively. A portion of the product (5 mg) after reduction ($NaBH_4$) and acetylation (17) on g.l.p.c. analysis (210 °C) gave two peaks corresponding in retention times with 2-acetamido-1,3,4,5-tetra-*O*-acetyl-2,6-dideoxy-D-iditol (T_{GNo1Ac} 0.37 (columns A and B), 15%) and 2-acetamido-1,3,4,5-tetra-*O*-acetyl-2,6-dideoxy-D-gulitol (T_{GNo1Ac}0.47 (column A), 0.43 (column B), 85%).

The mixture of **13** and **14** (1.75 g) was fractionated by cellulose column (4 × 60 cm) chromatography using 1-butanol–water (10 :1 v/v) as the mobile phase to give the following compounds.

*(1) 2-Acetamido-2,6-dideoxy-*D*-idose (14)*

The first pure fraction from the column was concentrated to a syrup (0.22 g) and the fraction, moistened with ethanol, afforded crystalline **14** which had m.p. 145–147 °C and $[\alpha]_D$ −11.5° (*c*, 0.6 in water) unchanged on further recrystallization.

Anal. Calcd. for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83. Found: C, 46.55; H, 7.40; N, 6.90.

14 gave a single spot on paper chromatography (R_{Gal} 4.74 (solvent A)) and following reduction ($NaBH_4$) and acetylation (17) the product gave a single peak on g.l.p.c. (210 °C) with T_{GNo1Ac}0.37 (columns A and B).

*(2) 2-Acetamido-2,6-dideoxy-*D*-gulose (13)*

The second fraction from the column was **13** (1.32 g) which remained a syrup and had $[\alpha]_D$ −75° (*c*, 0.5 in water). On paper chromatographic examination, **13** gave a single spot with R_{Gal} 4.04 (solvent A) and after reduction ($NaBH_4$) and acetylation (17) it gave 2-acetamido-1,3,4,5-tetra-*O*-acetyl 2,6-dideoxy-D-gulitol which on g.l.p.c. (210 °C) gave a single peak with T_{GNo1Ac}0.47 (column A) and 0.43 (column B).

*(3) 2-Amino-2,6-dideoxy-*D*-gulose Hydrochloride*

Compound **13** (from experiment *D*(2)) (1.1 g) was hydrolyzed with 3 *N* hydrochloric acid (25 ml) at 100 °C for 3 h and, following concentration, the resulting syrup was dissolved in a methanol–2-propanol mixture. On keeping at 2 °C, crystalline 2-amino-2,6-dideoxy-D-gulose hydrochloride (0.89 g) was obtained which had m.p. 171 °C (dec.) and $[\alpha]_D$ −36.4° (*c*, 1.2 in water) (lit. (8) m.p. >170 °C and $[\alpha]_D$ −35° (water)), and gave a single ninhydrin positive spot on paper chromatography (solvent B) with R_{GN} 1.67.

Anal. Calcd. for $C_6H_{14}NO_4Cl$: C, 36.10; H, 7.07; N, 7.02. Found: C, 36.05; H, 7.27; N, 6.84.

Organic Sulfur Mechanisms. 13. Sulfene Formation by a Reverse Diels–Alder Reaction

JAMES FREDERICK KING AND ERROL GEORGE LEWARS
Department of Chemistry, University of Western Ontario, London, Ontario

Received April 4, 1973

Dimethyl 2,2-dioxido-4-phenyl-2-thiabicyclo[2.2.2]octa-5,7-diene-5,6-dicarboxylate (**5**), a molecule purposely designed to undergo a thermal reverse Diels–Alder reaction to form sulfene and an aromatic co-fragment, has been synthesized. Thermolysis of **5** gave dimethyl biphenyl-2,3-dicarboxylate (7) and, in addition, (*a*) in the presence of an enamine (**6**) gave the appropriate sulfene–enamine adduct (**8**), and (*b*) with an excess of *p*-toluidine gave methanesulfon-*p*-toluidide (**10**), in agreement with the above expectation. In the absence of sulfene traps the only product identified, in addition to **7**, was sulfur dioxide; further experiments failed to determine the fate of the methylene group but serve to exclude certain possibilities, including fragmentation of sulfene to sulfur dioxide and a trappable carbenoid species.

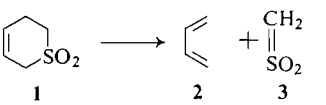
On a synthétisé le dioxydo-2,2 phényl-4 thia-2 bicyclo[2.2.2] octadiène-5,7 dicarboxylate-5,6 de diméthyle (**5**), afin d'étudier spécifiquement sa transformation thermique, selon une réaction inverse de Diels–Alder, en sulfène et en un fragment aromatique. La thermolyse de **5** a conduit au biphényl dicarboxylate-2,3 de diméthyle (**7**) et a conduit, en plus, (*a*) en présence d'une énamine (**6**) au composé d'addition prévu sulfène–énamine (**8**) et (*b*) en présence d'un excès de *p*-toluidine au méthanesulfon-*p*-toluidine (**10**) ce qui est en accord avec les prévisions énoncées antérieurement. En absence de sulfène, le seul produit identifié, en plus de **7**, a été l'anhydride sulfureux (SO_2); d'autres expériences n'ont pas réussi à montrer ce qu'il advient du groupe méthylène mais ont cependant permis de rejeter certaines hypothèses, en particulier celle qui impliquerait la fragmentation du sulfène en anhydride sulfureux et en une espèce carbènoide isolable. [Traduit par le journal]

Can. J. Chem., **51**, 3044 (1973)

Introduction

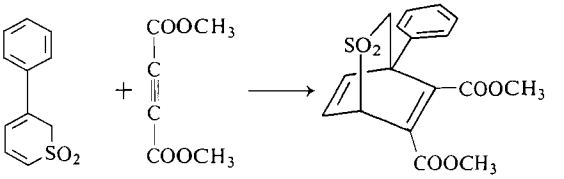
For some time we have been engaged in the study of the formation of sulfenes by thermolysis (1–3). Our goal in continuing this work has been to find a particularly mild, general route to sulfenes in which by-products or co-products would be either absent or unreactive toward the sulfene. This paper presents the details of one of our recent approaches to the problem which has employed the reverse Diels–Alder reaction (4); a preliminary report has already appeared (5).

The simplest reaction leading to formation of a sulfene by a reverse Diels–Alder reaction would be **1** → **2** + **3**. A rough thermochemical estimate indicates that the reaction **1** → **2** + **3** would be endothermic by about 40 to 50 kcal/mol,[1] but a molecule so constituted that the diene is part of an incipient aromatic system (*e.g.* **5**) would be



1 **2** **3**

expected to react more readily. Using essentially the method of Benson *et al.* (8), we estimate that for the fragmentation of bicyclo[2.2.2]octadiene into benzene and ethylene $\Delta H^0 \approx +1$ kcal/mol or lower,[2] whereas $\Delta H^0 = +39.7$ kcal/mol for the conversion of cyclohexene into butadiene and



4 **5**

[1]In simple average bond energy terms ΔH for the reaction **1** → **2** + **3** would be given by $E(C{-}C) + E(C{-}SO_2) - E_\pi(C{=}C) - E_\pi(C{=}SO_2)$, where $E_\pi(C{=}C) = E(C{=}C) - E(C{-}C)$ and $E_\pi(C{=}SO_2) = E(C{=}SO_2) - E(C{-}SO_2)$. We take $E(C{-}C) = 82.6$ kcal/mol and $E(C{=}C) = 145.8$ kcal/mol (6) (and so $E_\pi(C{=}C) = 63.2$ kcal/mol), $E(C{-}SO_2) = 62$ kcal/mol (average of the values deduced by Mackle (7)), and estimate (see Appendix) a value for $E_\pi(C{=}SO_2)$ of $\sim 35 \pm 5$ kcal/mol.

[2]Without correcting for steric strain we estimate $\Delta H^0 = +10.5$ kcal/mol. No estimate of the steric strain in the bicyclic diene itself is at hand but the corresponding correction for bicyclo[2.2.2]octane may be obtained by comparing the experimental $\Delta H_f = -24.09$ kcal/mol (9) with the value -33.5 kcal/mol derived by addition of Benson's group energies. The value so obtained, 9.4 kcal/mol, may be regarded as a lower limit for bicyclo[2.2.2]octadiene since the latter is almost certainly more strained than its saturated analog.

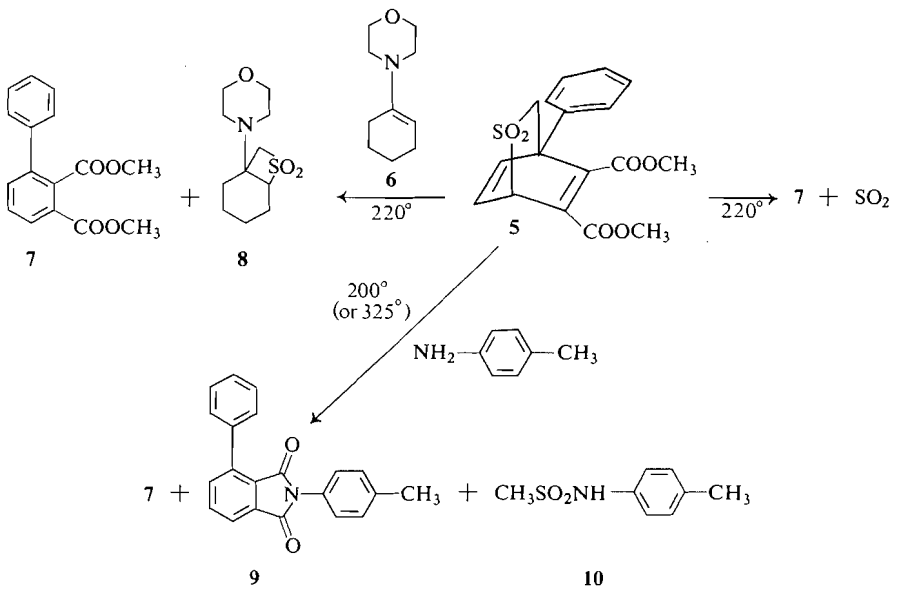

SCHEME 1

ethylene. In addition, as has been pointed out by Kwart and King (4), such a fragmentation process would be expected to be accompanied by an increase in entropy and hence be favored by an increase in temperature.

Results and Discussion

Synthesis of the Material to be Thermolyzed

The simplest bicyclic sulfone that would give sulfene and an aromatic co-product is 2-thiabicyclo[2.2.2]octa-5,7-diene 2,2-dioxide, but our attempts to obtain it from the monocyclic sulfide 1-thiacyclohexa-2,4-diene (10) having proved fruitless we explored the formation of the [2.2.2]bicyclo system using the substituted cyclohexadienic sulfone **4** (11). Dimethyl acetylenedicarboxylate with the sulfone **4** under mild conditions gave no reaction, but a 46% yield of **5** was obtained by heating the reagents at 140° for 68 h; small amounts of both starting material and thermolysis product were detectable in the reaction mixture. The product (**5**) was a solid melting at 210–211° for which the structure is established by the full agreement of the mode of synthesis and analytical and spectroscopic data. The n.m.r. spectrum is particularly indicative: in addition to phenyl hydrogens at 7.1 to 7.5 and two methyl groups 3.34 and 3.80, there is an AB quartet at 3.01 and 3.40 (J = 11.0) due to the methylene group and an ABX pattern, δ_A 6.84, δ_B 6.64, δ_X 5.30 p.p.m., J_{AB} 7.6, J_{AX} 6.6, and J_{BX} 1.6 Hz, arising from the olefinic plus bridgehead hydrogens.

Thermolysis of 5 in the Presence of Sulfene Traps

The thermolyses of **5** are summarized in Scheme 1. At 220° in the presence of the enamine **6** the biphenyldicarboxylic ester **7** and the enamine adduct **8** were obtained in 80% and 38% yields, respectively. The products were identical with authentic specimens synthesized essentially as described respectively by Heilbron and coworkers (12) and by Borowitz (13). An improvement in one step of the synthesis of the biphenyl diester (**7**) seems worth noting. Conventional esterification of 3-nitrophthalic acid stops at the monoester and whereas the earlier workers used a silver salt procedure to effect complete esterification, we found that sodium hydride in dimethylformamide followed by treatment with methyl iodide gave the diester in good yield.

The formation of **7** and **8** is clearly in agreement with a reverse Diels–Alder process as originally expected. Confirmation of this was obtained by the finding that methanesulfon-*p*-toluidide is the principal product (52% yield) when **5** is heated at 325° for 1.5 min with excess *p*-toluidine; a slightly lower yield of the sulfonamide (39%) was obtained when the reaction was carried out at 200° for 15 min. The biphenyl diester (**7**) was obtained in 49% yield at 325° (45% at 200°); some of the biphenyl portion ap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

peared as the imide **9** (17% yield at 325°, 30% at 200°). The imide (**9**) can be prepared by heating the biphenyl ester (**7**) with *p*-toluidine, and presumably some of the imide in the reaction product from **5** is so formed or else arises from a precursor derived from reaction of **5** with *p*-toluidine before the reverse Diels–Alder reaction takes place.

Thermolysis of 5 in the Absence of Sulfene Traps: The Fate of the Sulfene

One of the aims of this study, as pointed out in the Introduction, was to find a general method of making a sulfene in which neither the starting material nor the co-products would react with sulfene.[3] Such a reaction might make it possible to perform certain experiments on sulfenes not hitherto feasible, for example, performance of direct observations on sulfenes under conditions rather more convenient than the -196 to $< -160°$ range to which such experiments have been restricted to date (2). Since the results described above strongly indicated that sulfene was formed in at least 50% yield from **5**, it was felt that its thermolysis in the absence of the usual sulfene traps should be looked at.

An attempt at flash thermolysis (cf. refs. 2 and 3) at 700° and < 1 μ, carried out by Dr. R. A. Marty of this department, proved disappointing because the sulfone **5** proved almost involatile in the flash thermolysis apparatus and was induced to sublime into the hot tube only with great difficulty. The result is that it is unclear whether thermal decomposition actually takes place in the hot tube in the gas phase or merely during the heating of the material to induce sublimation. The infrared spectrum of the product on the cold finger at $-196°$ showed very weak bands of 1230 and 1330 cm^{-1} corresponding to the strongest bands previously observed for sulfene (2), but the weakness of the spectrum of the material from **5** precludes an unambiguous conclusion.

Simply heating **5** in the melt at 220° gave **7** in 95% yield. The only co-product that we have identified is sulfur dioxide which is formed in about 80% yield; the fate of the methylene carbon is unclear. The formation of sulfur dioxide would seem to point to the fragmentation of sulfene into methylene and sulfur dioxide, but when the thermolysis was carried out in the presence of a large excess of cyclooctene, there was no sign of the methylene adduct, bicyclo[6.1.0]nonane, even though an estimated 5% conversion to the methylene adduct would have been clearly detectable. It is noteworthy that a number of authors (one of us included) have suggested and looked for fragmentation of a sulfene to carbene and sulfur dioxide, and in no instance has any evidence for such a reaction been obtained (14). A simple estimate suggests that the reaction $CH_2{=}SO_2 \rightarrow CH_2 + SO_2$ is endothermic by 55 to 60 kcal/mol.[4]

Two other possibilities for the decomposition of the sulfene were explored and discarded. Under flash thermolysis conditions above 700—800°, sulfenes undergo desulfinylation, *i.e.* loss of sulfur monoxide with formation of the aldehyde or ketone (3). Even though the nearly quantitative conversion of sulfur monoxide to sulfur dioxide under these conditions seemed improbable, we made attempts to detect formation of formaldehyde. None was observed; control experiments indicated that a 10% yield would have been readily detectable. Another possibility was that the sulfene had dimerized to form Opitz' sulfene dimer, 1,3-dithietane 1,1,3,3-tetroxide. Under conditions of flash thermolysis this compound gives some sulfur dioxide, ethylene, and formaldehyde (16). No sign of ethylene was found in the gaseous products from **5**, thereby rendering it unlikely that the sulfur dioxide observed arises via Opitz' sulfene dimer.

Having excluded the above possibilities the question remains: where does the CH_2 go? With the comparatively modest supplies of **5** that were available the thermolyses were normally carried out on quantities of the order of 50 mg and the actual mass represented by the methylene group is thus only 2 mg. A small quantity of intractable, apparently polymeric material remained on the wall of the Carius tube after these reactions and

[3]It should perhaps be specifically pointed out that no such method was known at the outset of this study. The present work and the recently discovered sulfo-Cope rearrangement (1) come closest at present, and these are not ideal owing to the relatively high temperatures required.

[4]Using average bond energies $\Delta H = E_\pi(C{=}SO_2) + E(\dot{C}{-}\dot{S}O_2)$. We used for the former 35 kcal/mol (see Appendix) and for the latter the average of the estimated bond dissociation energies of a number of radicals of the type $R{-}\dot{S}O_2$, *viz.* 22 kcal/mol (7). Approximate similarity of $D(\dot{C}H_2{-}\dot{S}O_2)$ and $D(CH_3{-}\dot{S}O_2)$ is to be expected in view of the similarity of $D(CH_3{-}H)$ and $D(\dot{C}H_2{-}H)$, which are reported to be 104 and 106 kcal/mol, respectively (15).

For personal use only.

small amounts of unidentified materials were seen in the crude products; either (or both) of these materials could perhaps originate from the "lost" methylene. It would appear that **5**, though it has proved very useful in demonstrating the possibility of generating sulfenes by such a reverse Diels–Alder reaction, is not the ideal substrate either for flash thermolysis or determining what happens to the sulfene fragment in the absence of added traps. We intend to continue study of the latter points with another substrate when the opportunity presents itself.

Experimental

Melting points were taken in capillary tubes with a Gallenkamp apparatus and are uncorrected. Unless stated otherwise recrystallizations were effected from CH_2Cl_2–hexane, analytical t.l.c. was performed with microscope slides coated with silica gel, and preparative t.l.c. with 20 × 20 cm or 10 × 20 cm glass plates bearing 20 or 10 g of silica gel, respectively. T.l.c. plates were developed with CH_2Cl_2, analytical plates being visualized with iodine vapor and preparative plates by means of the u.v. phosphor in the silica gel; compounds were extracted from preparative plates using CH_2Cl_2–MeOH (100:15, v/v). In aqueous work-ups, dichloromethane solutions were run through a small plug of cotton wool (previously washed with dichloromethane to remove fats) before evaporation, which simultaneously removed the remaining trace of water azeotropically. I.r. spectra were measured with a Beckman IR20A, and n.m.r. spectra with Varian T-60 or HA-100 spectrometers.

Synthesis of Dimethyl 2,2-Dioxido-4-phenyl-2-thiabicyclo-[2.2.2]octa-5,7-diene-5,6-dicarboxylate (5)

A solution of sulfone **4** (11) (80 mg, 0.39 mmol) and dimethyl acetylenedicarboxylate (77 mg, 0.54 mmol) in xylene (5 ml) in a 10 ml round-bottomed flask was flushed with nitrogen for 10 min. The flask was then sealed with a wired-on serum cap and heated at 140° for 68 h. The bright-yellow solution was evaporated (rotary evaporator connected to an oil pump) to give a mixture of oil and crystalline solid, 153 mg. T.l.c. indicated that starting **4** was only a minor component of this reaction mixture. Recrystallization readily gave the adduct **5** as very pale-yellow, elongated prisms, m.p. 203–206°, 52 mg; a second crop of 10 mg was obtained (total yield 62 mg, 46%). Examination by n.m.r. of the material remaining in the mother liquors showed them to contain virtually no adduct. (The biphenyl **7** was a major component.) Similar results were obtained when the reaction was scaled up by a factor of about 10. Recrystallization gave an analytical sample as rosettes of colorless, elongated prisms, m.p. 210–211.5°, darkening right after melting.

I.r.: 1731, 1316, 1125 cm^{-1}; n.m.r.: 7.1–7.5 (m, 5H); an ABX pattern (3H, δ_A 6.84, δ_B 6.64, δ_X 5.30, J_{AB} 7.6, J_{AX} 6.6, J_{BX} 1.6), an AB quartet (2H, δ_A 3.40, δ_B 3.01, J 11.0 Hz), 3.34 (3H), 3.30 p.p.m. (3H).

Anal. Calcd. for $C_{17}H_{16}O_6S$: C, 58.60; H, 4.63; S, 9.20. Found: C, 58.83; H, 4.68; S, 9.06.

Thermolysis of 5

(a) In the Absence of Added Reagents

The adduct **5** (50 mg) was sealed under nitrogen in a 10 × 150 mm Pyrex tube, and the tube was immersed in an oil bath at 220° for 7 min; the compound melted, went brown, and effervesced. The tube was cooled under tapwater and opened; it was noted that the colorless gas in the tube smelled like sulfur dioxide and was acidic to moist p*H* test paper. The thermolyzate was an orange-brown gum, 48 mg, readily soluble in $CDCl_3$, the n.m.r. spectrum of which solution showed it to be essentially the biphenyl diester **7**; there was some absorption at δ 3.0–3.4. T.l.c. showed, besides the biphenyl **7**, a spot corresponding to less mobile material which was not further studied.

A dichloromethane solution of the thermolyzate was passed through a 5 × 15 mm column of neutral alumina (Woelm, activity I) and evaporated to give **7** as a clear, light-brown oil, 37 mg (95% yield), estimated by n.m.r. to be 95–99% pure. Two recrystallizations gave colorless rosettes, m.p. 95–95.5°; with authentic **7** (12) of m.p. 95–96°, the mixed m.p. was 95–96°. The two materials were indistinguishable by t.l.c., and their i.r. spectra were identical.

The yield of sulfur dioxide was found by thermolyzing the adduct **5** (50 mg) in a 12 × 100 mm Pyrex tube connected to a 45 × 110 mm gas cell, the apparatus having been previously evacuated and closed off. The thermolysis tube was almost completely immersed in an oil bath at 220° for 7 min; a little of the **5** appeared to distil rather than decompose. I.r. examination of the material in the gas cell showed it to be virtually only sulfur dioxide. The yield of sulfur dioxide and the upper limit to possible ethylene formation were found by comparing the i.r. spectrum of the gaseous thermolysis products with a series of spectra of known amounts of sulfur dioxide and of ethylene. These standard spectra were obtained by injecting through a serum cap from a syringe known volumes of the gases (at atmospheric pressure and room temperature) into the evacuated thermolysis tube – i.r. cell apparatus. The yield of sulfur dioxide was 82 ± 10%, and the yield of ethylene (of which there was no definite indication) was < 5%. The spectrum showed only very weak bands which might be ascribed to C—H or C=O groups. Sulfur dioxide was also identified by thermolyzing the adduct under a slow stream of nitrogen and sweeping the gaseous products into a trap cooled in Dry Ice. Dichloromethane was added and the u.v. spectrum of the solution was taken: there was no indication of anything besides sulfur dioxide (λ_{max} (CH_2Cl_2) 287 mμ).

Preparative t.l.c. of the thermolyzate residue (brownish solid) led to the recovery of 8% starting adduct **5** and the isolation of 81% of the biphenyl **7** (the yields of sulfur dioxide and the biphenyl were calculated taking into account the recovered adduct).

(b) Attempt to Detect a Carbenoid Species in the Thermolysis of 5

The adduct **5** (50 mg) and cyclooctene (1.0 ml) were heated under nitrogen in a sealed tube for *ca.* 10 min at 220°. The reaction mixture was filtered and the filtrate was distilled in an evacuated L-shaped tube (one arm heated in a waterbath, the other cooled in Dry Ice). The distillate was checked by v.p.c. (10% SE-30 on Chromo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sorp W, 6 ft × 1/4 in. copper column, 92°, helium flow *ca.* 60 ml/min); only a peak corresponding to cyclooctene was seen. By injecting known mixtures of cyclooctene and bicyclo[6.1.0]nonane it was shown that a 5% yield of bicyclo[6.1.0]nonane would have been detectable.

(c) Attempt to Detect Formaldehyde from the Thermolysis of 5

In one arm of an L-shaped tube was placed a solution of dimedone (20 mg) in about 0.5 ml of methanol, and a micro stirring bar. In the other arm was placed the adduct **5** (25 mg). The tube was sealed and the arm holding the adduct was heated at 220° for 7 min while the dimedone solution was stirred and cooled in ice. The whole length of the apparatus above the solution was then warmed with a flame to drive any formaldehyde (which might have condensed as paraformaldehyde) into the dimedone solution. The solution was then checked by t.l.c.: there was no trace of the dimedone adduct. A control experiment treating paraformaldehyde in the same way as the adduct **5** indicated that a 10% yield of formaldehyde would have been readily detectable.

Thermolysis of 5 in the Presence of Enamine 6

The adduct **5** (100 mg, 0.29 mmol) and the enamine (1.0 ml; 6.0 mmol) from cyclohexanone and morpholine (**6**) (24) were sealed under nitrogen in a 10 × 140 mm Pyrex tube holding a micro stirring bar. The mixture was stirred and heated at 200° for 25 min. The clear solution was evaporated and thoroughly evacuated to give an oil, 157 mg. The oil was dissolved in 10 ml of dichloromethane, extracted with 3 × 5 ml of 1 *N* HCl, and the HCl was then basified (*ca.* 25 ml of 10% NaOH) and extracted with 3 × 5 ml of dichloromethane, evaporation of which gave the sulfene–enamine adduct **8**, 32.6 mg (47%); this was estimated by n.m.r. to be *ca.* 80% pure, making the yield of adduct about 38%. A control experiment showed that this procedure for isolating the sulfene–enamine adduct led to its recovery in 97% yield. The crude **8** was recrystallized twice to give colorless prisms, m.p. 136–138°; with authentic **8** (11) of m.p. 138–140°, the mixed m.p. was 136–138°. The two materials were indistinguishable on t.l.c. (CH_2Cl_2–MeOH, 100:2 and 100:3, v/v) and showed identical i.r. spectra.

The acid-insoluble materials were obtained by evaporating the dichloromethane solution from which **8** had been removed as described. Preparative t.l.c. gave the biphenyl **7**, 62 mg (80%), identified by direct comparison with authentic material (mixed m.p., t.l.c., and i.r. spectra). In addition, a more polar material (19 mg), showing ν_{max} (CH_2Cl_2) 1729, 1315, 1128 cm^{-1}, was isolated but not further investigated.

Thermolysis of 5 in p-Toluidine

The adduct **5** (50 mg) and *p*-toluidine (200 mg) were sealed under nitrogen in a 10 × 150 mm Pyrex tube. The tube was briefly warmed on the steambath and agitated to produce a solution which was then allowed to cool and set to a solid mass. The reaction mixture was immersed for 1.5 min in an oil bath at 325°, then quickly cooled under the tap. The contents of the tube were dissolved in 10 ml of CH_2Cl_2, washed with 10 ml of 1 *N* HCl and then 4 × 10 ml of water and evaporated to give a yellow oil, 53 mg. This was dissolved in 10 ml of CH_2Cl_2 and extracted with 4 × 5 ml of 5% NaOH. The NaOH extracts were acidified (*ca.* 2 ml of concentrated HCl), extracted with 4 × 5 ml of CH_2Cl_2, and the CH_2Cl_2 was evaporated to give the sulfonamide **10** as a colorless solid, 12.5 mg (52%, taking into account recovered **5**). A control experiment showed that this procedure led to virtually quantitative recovery of the sulfonamide. Two recrystallizations gave colorless platelets, m.p. 100–101°; with authentic sulfonamide **10** (25) of m.p. 101–102.5°, the mixed m.p. was 101–102°. The two materials were indistinguishable on t.l.c. (CH_2Cl_2–MeOH, 100:2, v/v; both silica gel and neutral alumina), and their i.r. spectra were identical.

Evaporation of the CH_2Cl_2 solution from which the sulfonamide had been extracted gave the base-insoluble material as a yellow oil, 39.4 mg. Preparative t.l.c. (plate run three times) gave five bands. The two minor bands, 1.8 mg and 3.1 mg, were not investigated. The least mobile band (4.7 mg) was indistinguishable from starting adduct **5** on t.l.c. (analytical plate run four times). The next most mobile band (21.1 mg) was shown by n.m.r. to be *ca.* 90% pure biphenyl **7** (49% yield, if 90% pure). The most mobile band, 7.7 mg, was shown by n.m.r. to be *ca.* 95% pure biphenyl imide derivative **9** (17% yield, if 95% pure). The combined yield of biphenyl products was thus 66%.

That the material designated as the biphenyl 7 was in fact this compound was rigorously shown in another experiment in which the analogous band gave, after further purification (again subjected to preparative t.l.c., treated with decolorizing charcoal, and run through a 5 × 10 mm column of Woelm activity I neutral alumina with CH_2Cl_2, then recrystallized twice), colorless rosettes, m.p. 95–96°; with authentic biphenyl diester of m.p. 95–96°, the mixed m.p. was 95–96°. The two materials were indistinguishable on t.l.c., and their i.r. spectra were identical.

The material designated as the imide **9** was assigned this structure by comparison with authentic imide (*vide infra*) of the analogous band in another experiment: two recrystallizations (ethyl acetate – hexane) gave colorless needles, m.p. 175–176.5°; with authentic imide of m.p. 175–176°, the mixed m.p. was 175.5–176.5°. The two materials were indistinguishable on t.l.c., and their i.r. spectra were identical.

Thermolysis of the adduct **5** with *p*-toluidine at lower temperatures (200°/15 min) gave somewhat lower yields of sulfonamide (39%) and higher yields of the imide **9** (30%); the yield of biphenyl diester was about the same (45%).

Preparation of Dimethyl Biphenyl-2,3-dicarboxylate (7): a Simple Method for Esterification of 3-Nitrophthalic Acid

The synthesis of the biphenyl diester **7** by reaction of benzene with diazotized dimethyl 3-aminophthalate was carried out essentially as described by Heilbron and coworkers (12). One step in this synthesis, namely the formation of dimethyl 3-nitrophthalic acid, was modified as follows.

In a 100 ml round-bottomed flask was placed sodium hydride (57% dispersion in mineral oil, 406 mg, 9.7 mmol). The flask was flushed with nitrogen, fitted with a stirring bar and a serum cap, and the sodium hydride dispersion was washed twice with pentane by stirring briefly, letting the NaH settle, and removing the supernatant pentane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(syringe technique). Dimethylformamide (DMF, 50 ml) was then added, and a solution of 3-nitrophthalic acid (1.0 g, 4.17 mmol) in DMF (4.0 ml) was added fairly quickly (brisk effervescence, the H_2 was allowed to escape through a syringe needle); the syringe was rinsed with 2 × 2 ml of DMF. After stirring for 20 min at 25°, methyl iodide (2.0 ml, 4.55 g, 32 mmol) was added to the suspension over 30 s, and stirring was continued for 23 h. The light-yellow suspension was poured into 300 ml of water, extracted with 3 × 50 ml of CH_2Cl_2, and the CH_2Cl_2 extracts were washed with 4 × 150 ml of water and evaporated to give an oil which on evacuation overnight crystallized to a light-yellow solid, m.p. 66–68° (lit. (12) 67–68°), 0.92 g (81%); one spot on t.l.c. Recrystallization (CH_2Cl_2 : CCl_4 : hexane) gave colorless prisms, m.p. 69–70°. The structure was confirmed by the infrared (ν_{max} (CH_2Cl_2) *no* OH, 1737, 1538, 1350, 1280 cm^{-1}) and n.m.r. (δ 8.32, d, J=8.0 Hz, 2H; 7.67, t, J=8.0 Hz, 1H; 4.03, s, 3H; 3.97, s, 3H) spectra.

Attempts at esterification of 3-nitrophthalic acid using acidic catalysts (HCl, concentrated H_2SO_4, or BF_3-etherate (26)) gave the monoester alone or a mixture of the mono- and diesters.

Preparation of Authentic Biphenyl Imide **9**

The biphenyl diester **7** (51 mg) and *p*-toluidine (298 mg) were heated at 200° for 20 min under nitrogen in a sealed 10 × 150 mm Pyrex tube. The reaction mixture was dissolved in 10 ml of CH_2Cl_2, washed with 10 ml of 1 *N* HCl, then with 4 × 10 ml of water, and evaporated to give a pale-yellow oil, 50 mg. The n.m.r. spectrum showed this material to consist of diester : imide in the molar ratio 4.2 : 1.0. This reaction mixture was treated with *p*-toluidine (429 mg) and methanesulfonic acid (2.2 mg) at 200° for 20 min, as before. Workup gave a light-yellow oil, 47 mg, the n.m.r. spectrum of which showed it to consist of diester **7** and imide **9** in the molar ratio 1.3 : 1.0. Preparative t.l.c. led to the isolation of the biphenyl diester **7** (24 mg) and the imide **9** (white solid, m.p. 172–173°, 21 mg, 68% on the basis of reacted diester). The assigned structure **9** is supported by spectra and microanalysis. ν_{max} (CH_2Cl_2) 1778 w, 1721, 1515 m, 1381 cm^{-1}; this compares well with the i.r. spectrum of *N*-methyl phthalimide (prepared from phthalimide, sodium hydride, and methyl iodide in DMF), ν_{max} (CH_2Cl_2) 1773 w–m, 1713 cm^{-1}. The n.m.r. spectrum showed δ ($CDCl_3$) 8.1–7.2 (m, 12H), 2.38 (s, 3H). Recrystallization (ethyl acetate – hexane) gave colorless needles, m.p. 175–176°.

Appendix

Estimate of the "π-Bond Energy" of Sulfene

Our estimate of the "π-bond energy" of sulfene, $E_\pi(C{=}SO_2)$ (defined as $E(C{=}SO_2) - E(C{-}SO_2)$ was obtained by averaging an upper and a lower limit for $E_\pi(C{=}SO_2)$, each obtained by a slightly roundabout argument as follows.

It is evident from eqs. 1 to 3 that $\Delta H_1 + \Delta H_2 = \Delta H_3$ and $\Delta H_3 = E(C{-}H) + E(SO_2{-}Cl) - E_\pi(C{=}SO_2) - E(HCl)$, and so $E_\pi(C{=}SO_2) = E(C{-}H) + E(SO_2{-}Cl) - E(HCl) - \Delta H_1 - \Delta H_2$.

[1] CH_3SO_2Cl +  → $CH_2{=}SO_2$ +  Cl^- + ΔH_1

[2]  Cl^- → + HCl + ΔH_2

[3] $CH_3SO_2Cl \rightarrow CH_2{=}SO_2 + HCl + \Delta H_3$

E(C—H) and E(HCl), respectively 98.7 and 103.1 kcal/mol, are readily available (6) but $E(SO_2—Cl)$ is surprisingly uncertain; we use the value 58 ± 6 kcal/mol (17). An estimate of the heat of neutralization of pyridine with hydrogen chloride ($-\Delta H_2$) in acetonitrile of -19 kcal/mol may be made from data on the reaction of pyridine and hydrogen bromide taken with a comparison of the values of ΔH for the reactions of hydrogen bromide and hydrogen chloride with 1,3-diphenylguanidine (18). The corresponding data are not available for the reaction in 1,2-dimethoxyethane, the solvent for which we make an estimate of ΔH_1, but it seems probable that the variation in heat of neutralization on changing from one not very polar solvent to another is less than the uncertainties in the other parameters employed here. (With tributylamine and 2,4-dinitrophenol, for example, the variation in ΔH has been found to be <3 kcal/mol over a range of solvents including dibutyl ether, benzene, and fluorobenzene (19).)

The value of ΔH_1 is not known but a rough limit of <4 kcal/mol may be set as follows: (*a*) One may estimate $\Delta H_1^{\ddagger} = 8.7$ kcal/mol from the rate constants for reaction 1 in dimethoxyethane at 20.0 and 40.0° (20), and obviously ΔH_1 must be $<\Delta H_1^{\ddagger}$. (*b*) The magnitude of $\Delta H_1^{\ddagger} - \Delta H_1$ is unknown but a lower limit may be found from the following: (i) The amount of reversal of [1] in D_2O must be very small since the amount of $CH_2DSO_3^-$ that is formed is $<0.5\%$ (and that can be formed by other mechanisms than reversal of [1]) (21). (ii) In the reaction of methanesulfonyl chloride, piperidine, and water (molar ratio 1:2:30) in dimethoxyethane, a 98% yield of the piperidine was obtained (22). In order to account for the selectivities of water trapping *vs.* reversal of [1] and piperidine *vs.* water trapping, the activation barrier to reversal must be at least 5 kcal/mol greater than that for piperidine. Even if the latter barrier were zero (which is unlikely), ΔH_1 must therefore be <4 kcal/mol. Inserting all of these values in the expression above we obtain $E_\pi(C{=}SO_2) > 31$ kcal/mol.

An *upper* limit to $E_\pi(C{=}SO_2)$ may be deduced from the observation (23) that of the two ways of removing HCl from β-chloroethanesulfonyl chloride, that which gives the carbon–carbon double bond predominates, probably by a large amount, but at least by enough to lead to a 72% isolated yield of ethenesulfonyl chloride under one set of conditions (23); at the very least $\Delta G_5^{\ddagger} - \Delta G_4^{\ddagger} > 0$ kcal/mol.

[4] $ClCH_2CH_2SO_2Cl + R_3N \rightarrow CH_2{=}CHSO_2Cl + R_3\overset{+}{N}H\ Cl^- + \Delta H_4$

[5] $ClCH_2CH_2SO_2Cl + R_3N \rightarrow Cl—CH_2—CH{=}SO_2 + R_3\overset{+}{N}H\ Cl^- + \Delta H_5$

The two reactions involve a common attack of base on an α-hydrogen, and the (developing) charge in the α-carbon at some point proceeds to displace one of the chlorine atoms, either the one on the sulfur or the one on the carbon. In view of the probable similarity of the energy profiles it seems highly likely that the difference $\Delta G_5^{\ddagger} - \Delta G_4^{\ddagger}$ is a reflection of the difference $\Delta H_5 - \Delta H_4$, and also that $\Delta G_5^{\ddagger} - \Delta G_4^{\ddagger}$ is smaller than $\Delta H_5 - \Delta H_4$ because the bonds that lead to the energy difference are not fully formed and would not show the energy difference in full at the transition state stage. Since $\Delta H_5 - \Delta H_4 = E_\pi(C{=}C) + E(SO_2—Cl) - E_\pi(C{=}SO_2) - E(C—Cl)$, and $E_\pi(C{=}C) = E(C{=}C) - E(C—C) = 63.2$ kcal/mol (6), $E(C—Cl) = 81$ kcal/mol (6), and $E(SO_2—Cl) = 58$ kcal/mol (16), $\Delta H_5 - \Delta H_4 > \Delta G_5^{\ddagger} - \Delta G_4^{\ddagger} > 0$, then $E_\pi(C{=}SO_2) < 40$ kcal/mol.

Taking a number between the upper and lower limits, we obtain $E_\pi(C{=}SO_2) = 35 \pm 5$ kcal/mol. This number depends on a highly uncertain value for $E(SO_2—Cl)$ and a change in the latter would similarly change $E_\pi(C{=}SO_2)$. The value is clearly only rough but we believe that until a better one is obtained it can be useful in constructing energy diagrams for the reactions of sulfenes, and for the approximate thermochemical estimates of the kind made in this paper.

Thermodynamic Properties of Aqueous Organic Solutes in Relation to Their Structure. Part I. Free Energy of Transfer from H_2O to D_2O for a Series of Isomeric Ketones

CARMEL JOLICOEUR AND GHISLAIN LACROIX
Department of Chemistry, Université de Sherbrooke, Sherbrooke, Quebec

Received April 5, 1973

The solubilities of 18 decanones have been measured in H_2O and D_2O at 25 °C from their u.v. absorption spectra. The data were used to calculate ΔG_t^0, the standard free energy of transfer of these solutes from H_2O to D_2O. ΔG_t^0 was found negative for the saturated ketones, but positive for most of the unsaturated and polycyclic isomers. A rough correlation was observed between ΔG_t^0 and the degree of branching in the hydrocarbon chains of the ketones: ΔG_t^0 increases with the degree of branching. From the temperature dependence of ΔG_t^0 obtained at 10, 25, and 40 °C, heats of transfer ΔH_t^0 were determined for typical ketones, namely 2-decanone and adamantanone. ΔH_t^0 was found as -2.1 kcal mol^{-1} for 2-decanone and $\sim 0 \pm 0.5$ kcal mol^{-1} for adamantanone.

The results are discussed in terms of two main contributions: (1) an isotope effect in the free energy of cavity formation and (2) perturbation of solvent structure by the solutes, differing in H_2O and D_2O. Using the scaled-particle theory to evaluate the former, the variations in the observed ΔG_t^0 are assigned to the structural part of ΔG_t^0.

Nous avons mesuré, par spectroscopie d'absorbtion dans l'u.v., la solubilité d'une série de 18 décanones dans H_2O et D_2O à 25 °C. L'enthalpie libre standard pour le transfert ($H_2O \rightarrow D_2O$) des cétones, ΔG_t^0, s'avère négative pour les cétones saturées alors que pour la plupart des cétones insaturées on trouve des valeurs positives. Nous pouvons mettre en évidence une corrélation qualitative entre la grandeur de ΔG_t^0 et le degré d'embranchement des substituants alcoyles des cétones: ΔG_t^0 augmente avec le nombre d'embranchements dans les chaines alcoyles. Pour quelques systèmes types, notamment la décanone-2 et l'adamantanone, la chaleur du transfert $H_2O \rightarrow D_2O$, ΔH_t^0, a également été obtenue à partir des mesures de solubilité à 10, 25 et 40 °C. Pour la décanone-2, ΔH_t^0 est évaluée à -2.1 kcal mol^{-1} et à 0 ± 0.5 kcal mol^{-1} pour l'adamantanone.

L'interprétation des résultats est donnée selon deux contributions principales aux fonctions de transfert: (1) différence dans l'énergitique de la formation d'une cavité dans les deux solvants et (2) différence dans les effets que les solutés exercent sur la structure des solvants. La première contribution est évaluée à l'aide de la théorie "scaled-particle", et la spécificité observée dans le ΔG_t^0 des différents solutés est attribuée à la partie structurale de la fonction de transfert.

Can. J. Chem., 51, 3051 (1973)

Introduction

Studies on the properties of nonpolar or hydrophobic solutes in water commonly lead to the inference that the hydrogen-bonded structure of this solvent is stabilized in the neighborhood of the solute particle. The earlier evidence came from thermodynamic data, namely the observation of unusually large entropy losses upon dissolution of inert gases in water (1, 2). Confirmation of the concept of solvent structural enhancement was later found in other thermodynamic studies and kinetic investigations of large organic ions (*e.g.* tetraalkylammonium ions) for which anomalously large molar heat capacity and *B*-viscosity coefficients were found (3, 4). Further investigations of aqueous solutions of hydrophobic solutes using a variety of thermodynamic, kinetic, and spectral methods (5, these recent reviews deal with one or more aspects of this field) also helped to strengthen the idea that hydrocarbon-like solutes can promote *some* hydrogen-bonded structure in the surrounding solvent.

This concept is attractive, particularly in view of the formation of clathrate hydrates by hydrocarbon gases (see, for example, 6*b*) and several hydrophobic salts (6*a*), though it should be stressed that no long-lived (*i.e.* $> 10^{-10}$ s) clathrate structure has been observed in solutions of hydrophobic ions or molecules. Only indications of time-averaged structures have been assessed (5*a*, 7–9), often using the analogy between the effects produced by a hydrophobic solute and by a decrease in temperature. It should also be recognized that questions raised on some of the evidence for the structure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

promoting effects of hydrophobic solutes have not yet found satisfactory answers. In particular, Everett (10) judiciously pointed out that the large partial molal heat capacity $\bar{C}_p^0$ of inert molecules in water need not necessarily result from an increase of the amount or the stability of hydrogen-bonded structures in the solution. In fact, the explanation of $\bar{C}_p^0$ would only require that the water–water bonds which are perturbed by the hydrophobic particles become more sensitive towards temperature changes. Alternate explanations of other observations have been offered recently (11, 12), indicating that the molecular phenomena associated with the solvation of aqueous hydrophobic solutes have by no means found a unique or adequate description.

If, as we believe, some time-averaged structure is promoted around hydrophobic groups (at least near and below room temperature (13)), one might expect that the internal structure or geometry of the solute could play a role in determining the overall structural perturbation in the solvent. In other words, the solute geometry which is best accommodated in the solvent structure might have a feedback effect in inducing further stabilization of the water structure. The finding of such a correlation between the solute structure and its effect on the water structure could thus serve to confirm the initial concept of water structure stabilization by inert molecules.

Some attempts to relate the properties of aqueous solutes with their intrinsic structural features can be found, namely for acids (14), alcohols and sugars (15–18), and various other solutes (19–21). These investigations were concerned primarily with different arrangements of hydrophilic groups on solute molecules rather than with the structural features of their hydrophobic groups. In studies involving different isomers on the hydrophobic portion, noticeable differences are found among the properties of the isomers; for example the partial molal volumes of the isomeric butanols in water are measurably different (15, 16). Little can be gained from this information, however, since the solvation of the polar group of these small molecules could make an important contribution to their thermodynamic properties, and since similar differences are found in the thermodynamic properties of the isomeric butanols in methanol (22).

The purpose of this and following studies is to establish whether the geometry of hydrophobic solutes has a significant influence on their thermodynamic properties in water, and more specifically on the part of these properties which is commonly assigned to structural effects in the solvent. The work was initiated with a series of 18 decanones for which the free energy of transfer from $H_2O \rightarrow D_2O$ was measured at 25 °C. This transfer process is generally thought to emphasize the structural influences of the solutes (23–25) and therefore seems appropriate for the problem at hand.

Experimental

The origin and properties of the decanones used in the present work are summarized in Table 1. The specified purity was estimated from g.c. analysis carried out with a Hewlett Packard (Model HP-5750) chromatograph, using a Carbowax 20-M on Chromosorb-W column. The criteria for stating the purity as >99.5% was that no shoulder peak could be observed with a detector sensitivity such that the intensity of the main peak was ~5 full scales. The water used in preparing saturated solutions was doubly distilled over alkaline $KMnO_4$ in an all-glass still and equilibrated with atmospheric CO_2. D_2O (99.8%) was purchased from two different sources (Stohler Isotope Chemicals and Merck, Sharp and Dohme) and was used as such; the results of experiments carried out with both materials were identical. The cyclohexane used in some extraction experiments was Fisher Spectranalyzed grade.

Saturated solutions of the ketones in H_2O and D_2O were prepared by adding an excess of the ketone (~0.5 g) to ~15 cm^3 of solvent. The mixture was mechanically shaken in a constant temperature bath (±0.05 °C) for 3–4 h and allowed to equilibrate overnight. Aliquots were then sampled for absorbance measurements, using a transfer tube fitted with a small sintered glass filter and applying a light pressure over the solution. The mother solution was agitated again for several hours, allowed to equilibrate, and the absorbance of a second aliquot was recorded. If any discrepancy was found between the two results, the procedure was repeated a third time. For each ketone, at least three pairs of H_2O and D_2O saturated solutions were prepared, giving a minimum of six measurements for each compound.

The absorbance of the saturated solutions were recorded in the range (2200–4000 Å) using either a Perkin-Elmer (Model DB-G) or a Cary-14 Spectrophotometer, with stoppered cells of various path-lengths ranging between 5 and 50 mm. The absorbance of the saturated solution in water was first recorded directly. The absorbance of the solution in heavy water was then measured relative to that of the aqueous solution at the same λ_{max}, *i.e.*, H_2O (sat'd) in the reference compartment and D_2O (sat'd) in the sample compartment. The absolute solubility of the ketones in H_2O was calculated from their absorbance and that of dilute solutions prepared quantitatively. The latter measurements were, however, very difficult and only the magnitude of the saturation concentrations obtained is significant.

‡Position of peak at which absorbances were measured.

Throughout this work, thorough cleaning procedures of all laboratory glassware and spectrophotometer cells were followed. Also, great care was exercised to avoid evaporation of the organic solutes while handling the solutions. To assert the validity of this method in measuring relative solubilities, a number of tests were carried out, with respect to the following points.

(a) Keto–Enol Equilibrium and Partial Deuteration of the Ketone

While this known exchange could affect the solubility of the ketones in D_2O, it was verified that the solubilities of either 2-decanone or 4-phenyl-2-butanone in D_2O containing 0.01 *M* NaOD were time independent over a period of 48 h.

(b) By-products and Impurities in the Ketones

Impurities, particularly if they are water soluble, could significantly change the solubility of the ketones. To verify the possibility of solubilizing effects, each pair of saturated solutions of a given compound was prepared using different excess amounts of ketone (*e.g.* from 0.1 to 1 g). This produced no significant changes in the measured solubilities, except for 3-Me-2-nonanone and 3-decanone, of which the first was already known to be of lower purity (Table 1).

(c) Solvent Effects on Extinction Coefficients

In these experiments, the extinction coefficient of the ketones are assumed independent of the media, H_2O or D_2O. This was established by taking aliquots of D_2O saturated with 2-decanone and diluting 20-fold in H_2O and D_2O respectively. Both λ_{max} and the absorbance of the dilute solutions (95% D_2O and 95% H_2O) were found identical.

(d) Applicability of Beer's Law

The solubility measurements rely on the applicability of Beer's law to these mixtures. This could be demonstrated by showing that the relative absorbance of saturated solutions of 2-decanone in H_2O and D_2O was the same, whether the measurement was taken directly on these solutions or on cyclohexane extracts of the aqueous solutions. In the latter method an aliquot of each saturated solution was extracted quantitatively with cyclohexane and diluted 10-fold.

Results

The standard free energy of transfer from H_2O to D_2O was calculated from the usual equation (25):

$$[1] \quad \Delta G_t^0 \equiv \Delta G^0_{H_2O \rightarrow D_2O} = -RT \ln(X_{D_2O}/X_{H_2O})$$

where X is the mole fraction of the solute. As is commonly done for such dilute solutions, the solute activity coefficients are assumed to be identical in both solutions. Since the absorbance measurements are related to molar concentrations, M, these are converted to mole fractions (25):[1]

[1]In the molarity – mole fraction conversion it is assumed that the partial molal volume of the ketones is the same in H_2O and D_2O. For R_4N^+ ions, this is true within ~1% (26) and, thus, for the concentrations used here (<0.05 *M*) the error introduced is easily shown to be negligible.

*Estimated as described in Experimental.
†Standard deviation (see Results).
‡From measurements at 10, 25, and 40 °C; the uncertainty was estimated graphically.

[2] $$\frac{X_{D_2O}}{X_{H_2O}} = \frac{M_{D_2O}}{M_{H_2O}} \times F$$

The factor F includes molecular weights W and densities d of the two solvents:

$$F = \frac{W_{D_2O}}{W_{H_2O}} \times \frac{d_{H_2O}}{d_{D_2O}}$$

at 25 °C: $F = 1.00361$ (25). In terms of the measured absorbances, we then have

[3] $$\Delta G_t^0 = -RT \ln \left\{ \left[1 + \frac{\Delta A}{A(H_2O)} \right] \times F \right\}$$

where $A(H_2O)$ is the absorbance of the saturated solution in H_2O and ΔA is the differential absorbance of the saturated solutions in H_2O and D_2O (D_2O against H_2O). The heat of transfer $\Delta H^0_{H_2O \rightarrow D_2O} \equiv \Delta H_t^0$ obtained for a few ketones was determined graphically from van't Hoff plots:

[4] $$d(\Delta G_t^0/T)/d(1/T) = \Delta H_t^0$$

ΔG_t^0 values for all the ketones investigated are reported in Table 2, with the estimated solubility of the ketones in H_2O (*cf.* Experimental). ΔH_t^0 is also given in four cases which are believed to be representative of their structural categories. The uncertainty quoted on ΔG_t^0 values is the standard deviation on a minimum of five measurements. The accuracy of ΔH_t^0 was estimated graphically.

In attempts to establish a correlation between ΔG_t^0 and the structural features of the solutes, the results have been plotted against several parameters which relate to their molecular structures and properties. The parameters chosen were: the position of the carbonyl group on linear ketones (Fig. 1), the degree of unsaturation of the alkyl substituents (Fig. 2), and the number of branching centers on the alkyl groups (Fig. 3). In the evaluation of the latter, we counted the

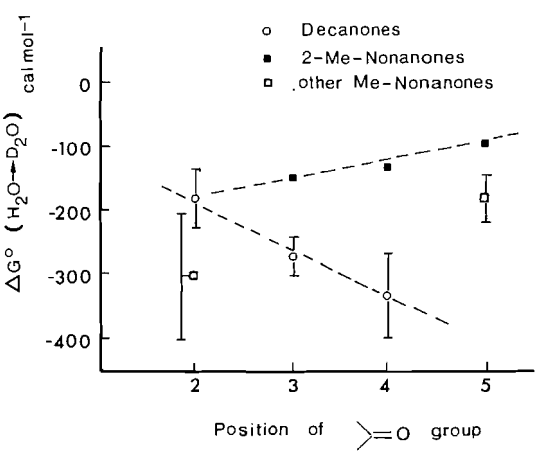

FIG. 1. Standard free energy of transfer from H_2O to D_2O of several decanones and methylnonanones at 25 °C (Table 2) correlated with position of the carbonyl on the linear alkyl chain.

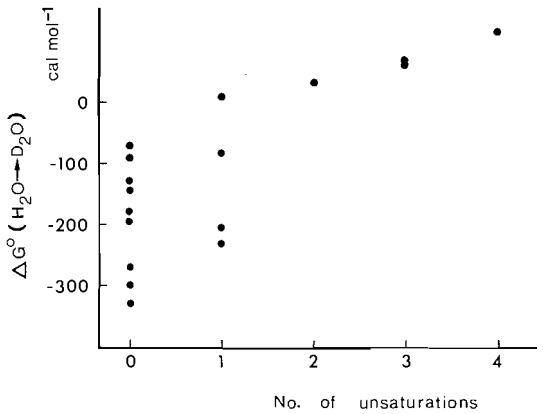

FIG. 2. ΔG_t^0 data from Table 2 correlated with the number of unsaturations in the hydrocarbon substituents.

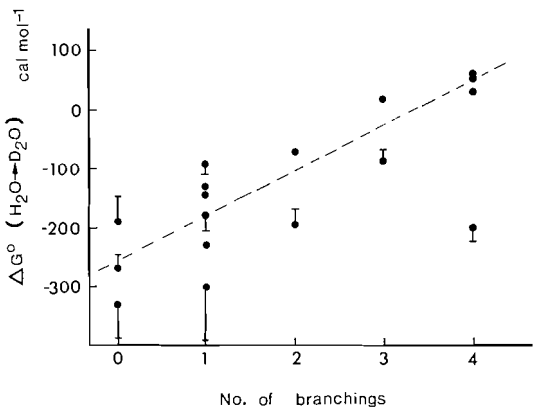

FIG. 3. ΔG_t^0 data from Table 2 correlated with the number of branching centers on the alkyl substituents: ΔG_t^0 for 4-phenyl-2-butanone was not included, and only one half of each error bar has been drawn.

number of carbon atoms bearing three substituents other than hydrogen, counting as two branchings a tetrasubstituted carbon. The best correlation, apparent from these data, is found with the degree of branching in the hydrocarbon chains of the solute.

Discussion

The results shown in Table 2 clearly indicate some specificity among the various isomeric ketones of same chemical composition. In addition, ΔG_t^0 which is negative for the linear saturated ketones becomes positive with most of the unsaturated homologs, particularly with the polycyclic compounds. ΔH_t^0 values apparently make a similar distinction between the two categories of ketones.

As is indicated by the larger solubilities of these ketones compared to similar hydrocarbons (27, 28), the solvation of the carbonyl group probably contributes to the thermodynamic properties of these solutes in aqueous media, and a solvent isotope effect on this contribution might be expected; in fact, this and two other contributions must be examined before the observed differences in ΔG_t^0 or ΔH_t^0 can be assigned to specific structural effects.

The free energy of transfer can conveniently be broken down into several contributions, by analogy with a similar procedure used in discussing heats of transfer (29):

$$[5]\quad \Delta G_t^0 = \Delta G_t^0(\mathrm{CAV}) + \Delta G_t^0(\mathrm{SOL}) + \Delta G_t^0(\mathrm{STR}) + \Delta G_t^{\mathrm{Ex}}(\mathrm{HI})$$

where the terms represent respectively the solvent isotope effect on the free energy, due to:

CAV: process of cavity formation in the solvent; SOL: solvation of the polar group of the molecule (dipole–dipole interactions, hydrogen bonding); STR: structural rearrangement of the solvent around the cavity enclosing the solute; (HI): solute–solute interactions (hydrophobic interaction) which must be considered since these measurements are carried out at finite concentrations. (This term obviously relates to the assumption of equal activity coefficients in H_2O and D_2O, *cf.* Results.)

Of course the contribution which would reflect specific influences due to different structures of hydrophobic groups would be ΔG_t^0(STR). The latter is intimately connected with ΔG_t^0(CAV), and it is by no means clear that these can be separated (29).

(a) ΔG_t^0(SOL)

Carbonyl groups are known to act as proton acceptors in hydrogen bonding with various donors (30). Because of the zero point energy difference (23), a solvent isotope effect can be expected on the free energy of solvation of the $\diagdown\!\!\diagup C{=}O$ group, probably in the direction of a lower chemical potential for the ketone in D_2O compared to H_2O. If the various ketones have different basicity or steric hindrance at the $\diagdown\!\!\diagup C{=}O$ group, the magnitude of ΔG_t^0(SOL) could differ for each of the compounds investigated here. Several experimental findings strongly indicate, however, that ΔG_t^0(SOL), and its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

variation throughout the series of ketones, must be small compared to the variations observed in ΔG_t^0.

This is first suggested by the fact that ΔG_t^0 of acetone is $\simeq 0 \pm 15$ cal mol^{-1} (31). Thus ΔG_t^0(SOL) could only be as large as the contribution from two methyl groups, and of opposite sign. Also, we see from Fig. 1 that changing the position of the $\rangle C{=}O$ group has a significant consequence on ΔG_t^0, but the effect is opposite in the two series of saturated ketones. This again indicates that the solvation of the $\rangle C{=}O$ group does not make a dominant contribution to ΔG_t^0.[2]

Evidence in support of the similar basicity of the various ketones is supplied by proton chemical shift measurements δ of protonated ketones (32). The observed δ for, *e.g.*, adamantanone and di-*t*-butylketone are large and very similar (respectively −13.85 and −13.51 p.p.m.) indicating similar basicity, in spite of drastically different molecular properties. As a further check of the similar proton accepting ability of the ketones studied here, we measured the shift induced in the fundamental —OH stretching frequency of CH_3OH upon hydrogen bonding to several ketones. The red shifts, measured in mixtures of 2 *M* ketones and 1 *M* CH_3OH in CCl_4, for compounds **1**, **10**, **16**, and **18** (See Table 1 or 2) were found respectively as 110, 160, 165, and 185 cm^{-1} relative to 1 *M* CH_3OH in CCl_4. These data indicate a noticeable degree of specificity, but at least for the last three compounds, the variations are small compared to the magnitude of the observed shifts. Since —OH stretching frequencies are very sensitive towards hydrogen bonding and usually well correlated with the hydrogen-bond energies (30), it appears that the basicity of the ketones studied here must be quite similar.

From the above considerations it thus seems justified to conclude that ΔG_t^0(SOL) is not the dominant contribution to ΔG_t^0, and that specific solvation effects cannot explain the variance observed in ΔG_t^0 for the ketones under investigation.

(b) ΔG_t^{Ex} *(HI)*

Some of the linear ketones studied here have the general structure of nonionic surfactants, hence hydrophobic interactions (perhaps even micelle formation) might occur in solutions of these compounds. The excess free energy arising from these interactions also exhibits a solvent isotope effect which was found as ~ -50 cal mol^{-1} for micellar *n*-dodecyltrimethylammonium bromide (34).

To demonstrate the absence of micellar aggregates in saturated solutions of 2-decanone and 4-decanone, we used a method based on changes in the e.s.r. spectrum of stable nitroxide radicals (13). This procedure was shown to be very effective in detecting the onset of aggregation of surfactant molecules with solutes bearing an alkyl chain longer than *n*-hexyl (13). In the present case, the e.s.r. spectra of di-tert-butylnitroxide (DTBNO) (5×10^{-5} *M*) in saturated solutions of either 2- or 4-decanone were identical to the DTBNO spectrum in water.[3] The presence of a significant concentration of micellar clusters in the solutions examined can thus be excluded. Remaining possible contributions from pairwise hydrophobic interactions are not expected to be significant for ΔG_t^0, on the basis of the following arguments.

(1) The isotope effect on the excess free energy of hydrophobic solutes such as Bu_4NBr is negative, but barely detectable up to concentrations of 2–3 *m* (35).

(2) Comparing the $(H_2O \rightarrow D_2O)$ transfer functions of small hydrocarbons, Ben-Naim (36) recently concluded that the solvent isotope effect on the hydrophobic interaction leads to a *positive* free energy contribution, *i.e.* ΔG_t^{Ex}(HI) > 0; the latter is less than 5% of the total free energy change due to the hydrophobic interaction (at 25 °C).

(c) ΔG_t^0*(CAV)*

As mentioned earlier, the solvent isotope effect on G^0(CAV) and G^0(STR) may not be truly separable. Still, it is interesting to inquire about the anticipated sign and magnitude of ΔG_t^0(CAV), using available means of estimating free energies of cavity formation.

The recent correlation established between the solubility of hydrocarbons and their estimated surface area (37) have been taken as evidence for the importance of the G^0(CAV) term in the free energy of solution. If the latter can be assumed

[2]In heats of transfer (33), the isotope effect due to hydrogen bonding is clearly evidenced only with such strong acceptors as F^-.

[3]For details on the experimental conditions see ref. 13.

For personal use only.

as (37)

$$G^0(\mathrm{CAV}) = 4\pi r^2\sigma_0$$

where r and σ_0 are respectively the radius of a spherical cavity and the bulk surface tension of the solvent, then one would expect small negative values of ΔG_t^0(CAV) because $\sigma_0(D_2O)$ is less than $\sigma_0(H_2O)$ by approximately 0.05% (25).[4] Since, for a given volume, the surface area of a cylindrical cavity is greater than that of a spherical cavity, we would predict ΔG_t^0 to be somewhat more negative for, *e.g.*, 2-decanone than for adamantanone.[5] Though for these two solutes, the relative order is correct, clearly, the free energy of cavity formation cannot be large enough to account for the magnitude of ΔG_t^0 on the basis of the surface tensions of H_2O and D_2O.

The free energy of cavity formation can also be computed from the scaled-particle theory which has been applied with remarkable results to solutions of nonpolar compounds in aqueous and nonaqueous solvents (38, 39). The theory envisages the solvent as a hard sphere fluid in which the reversible work required to create a cavity depends on particle density (number of particles per unit volume), pressure, temperature, and solvent and cavity diameters, a_1 and a_2. We used this theory to compute ΔG_t^0(CAV) assuming that the hard sphere diameters of H_2O and D_2O are identical (2.76 Å) and calculating the particle density from the molar volumes of H_2O and D_2O (40). ΔG_t^0(CAV) values were computed for several temperatures and cavity diameters, and the results are given in Fig. 4. The near linear dependence of ΔG_t^0(CAV) with a_2^2 shows that the theory emphasizes surface effects. Since the particle density is lower in D_2O than in H_2O, the prediction of a negative ΔG_t^0(CAV) is not surprising, but even the magnitude of the calculated ΔG_t^0(CAV) is in reasonable agreement. For example, for a spherical cavity having a volume equal to the partial molal volume of propane in H_2O (41), ΔG_t^0(CAV) is calculated as ~ -80 cal mol^{-1}, whereas ΔG_t^0 has been reported as -17.4 cal mol^{-1} (24). A similar estimate for *n*-decane[6] leads to ΔG_t^0(CAV) ~ -150 cal mol^{-1} which can be compared to our ΔG_t^0 for the *n*-decanones ~ -275 cal mol^{-1} (average). Thus the scaled-particle theory apparently accounts for much of the negative ΔG_t^0 without recourse to structural changes induced in the solvent by the solute.

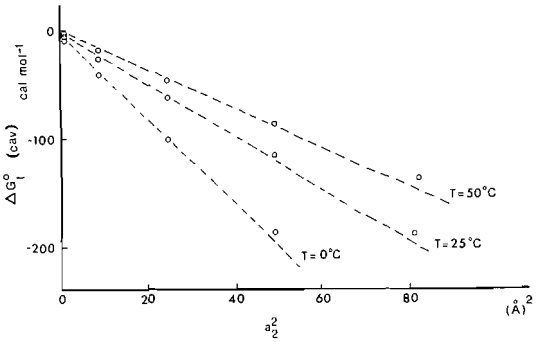

FIG. 4. Isotope effect on the free energy of cavity formation computed for several cavity diameters (a) and temperatures using the scaled-particle theory (see part c of Results). The hard sphere diameter of the water molecule was taken as 2.76 Å.

Calculations of ΔH_t^0(CAV) from the scaled-particle theory, with the assumptions given above, also lead to striking results: both ΔH_t^0-(CAV) and ΔS_t^0(CAV) are large and negative as is observed experimentally for a number of inert gases and hydrocarbons (24, 25, 36).[7] For a cavity the size of *n*-decane, we compute ΔH_t^0-(CAV) and ΔS_t^0(CAV) as respectively -0.9 kcal mol^{-1} and -2.4 e.u., which can be compared with -2.1 kcal mol^{-1} and -6.4 e.u. found for 2-decanone.

The observed positive ΔG_t^0 for a number of ketones, however, remains to be explained and require a more physical examination of the calculations of ΔG_t^0(CAV). The assumption that H_2O and D_2O only differ by their amount of free volume does not completely describe these peculiar liquids: while the particle density decreases in going from H_2O to D_2O, the cohesive energy density is greater in D_2O than in H_2O, *i.e.* zero point energy effect on the hydrogen bond (25). The intermolecular attraction potential, which is absent in the scaled-particle theory,

[4]More appropriate data for such a comparison would be hydrocarbon $-H_2O$ and hydrocarbon $-D_2O$ interfacial tensions, but there appear to be no data on the latter. On the other hand, scaling of these quantities for small curvature radii still remains a problem.

[5]The assumption on the relative surface area is contrary to other estimates (37) in which the surface area was calculated to increase with branching of a molecule.

[6]The partial molal volume ϕ_v of *n*-decane was estimated from ϕ_v(propane) assuming additive methylene group contributions (42).

[7]Other aspects of these calculations will be discussed in more detail elsewhere.

would thus lead to additional work required to expand a cavity in D_2O compared to H_2O. A simple explanation of some of our experimental results follows immediately. Since the amount of void space is greater in D_2O than in H_2O, solutes which can occupy this void space without excessive disruption of hydrogen bonds in the solvent will be best accommodated in D_2O (negative ΔG_t^0). This reasoning is a straightforward extension of Eley's proposition to account for the properties of inert gases in water (2), and possibly would apply to the linear ketones studied here.[8] On the other hand, bulky molecules such as adamantanone require cavities much larger than those existing in the solvent; for these, a significant number of hydrogen bonds must then be broken, a process which will require more work in D_2O than in H_2O. If the latter contribution is dominant, ΔG_t^0 would then be positive, with ΔH_t^0 and ΔS_t^0 also more positive.

The interpretation nicely accounts for the observed ΔG_t^0 which is negative for the linear ketones and increases with the degree of branching in the hydrocarbon groups, finally becoming positive for the bulky polycyclic molecules. Within the available ΔH_t^0 and ΔS_t^0 data, the explanation is consistent, except with a few cyclohexanone derivatives. In particular, tetramethylcyclohexanone stands out, as a bulky molecule, having a large *negative* ΔG_t^0 and ΔH_t^0. If these effects are real, they might, however, point out to other interesting specific behaviors which are presently being investigated through other thermodynamic measurements.

It may be added that the interpretation given here also accounts for other experimental findings, namely the positive ΔG_t^0 for benzene (36) and substituted benzenes (31). Likewise, the negative ΔH_t^0 for Bu_4N^+, compared to the positive ΔH_t^0 for Ph_4As^+ (33), may find a suitable explanation in the geometry of their respective hydrocarbon substituents.

(d) ΔG_t^0(STR)

As mentioned earlier, the thermodynamic quantities for the transfer of inert solutes from H_2O to D_2O are usually interpreted in terms of solvent structural perturbation by the solutes (24–26, 31, 33, 43). This follows from the assumption that molecular or liquid H_2O and D_2O are negligibly different (*e.g.* similar dipole moments, polarizabilities, and dielectric constants), except in the extent of hydrogen bonding responsible for the structure in the two liquids. Quantitatively, the extent of hydrogen bonding can only be defined as |(number of bonds) × (ΔH^0 per bond)|, but this quantity is larger for D_2O than for H_2O. The rationale underlying this postulate was well summarized by Arnett and McKelvey (25). A second widely used assumption is that whatever perturbation the solute exerts on the solvent structure (structure breaking or structure stabilizing), it will be more extensive in D_2O (25).

In a case of particular interest here, the $H_2O \rightarrow D_2O$ transfer of hydrocarbons, the negative ΔH_t^0 and ΔS_t^0 have been attributed to greater solvent ordering in the hydrocarbon solutions in D_2O compared to H_2O (24). However, if a significant part of the negative ΔG_t^0 (also of ΔH_t^0 and ΔS_t^0) can be explained from the hard sphere model, which invokes only the properties of the pure solvents, then only the difference between ΔG_t^0 and ΔG_t^0(CAV) can be assigned to structural effects. While relying on the scaled-particle theory for the (CAV) contribution to the transfer function may be questionable (44), it must be pointed out that ΔG_t^0(CAV) is much less dependent than G^0(CAV) on the choice of computation parameters (*e.g.* solvent hard sphere diameter). If we adopt ΔG_t^0(STR) as

$$\Delta G_t^0(\text{STR}) = \Delta G_t^0 - \Delta G_t^0(\text{CAV})$$

and again using the comparison between *n*-decane and 2-decanone, we find for the latter $\Delta G_t^0(\text{STR}) \simeq -30$ cal mol^{-1}, $\Delta H_t^0(\text{STR}) \simeq -1.2$ kcal mol^{-1}, and $\Delta S_t^0(\text{STR}) \simeq -4$. e.u. From the sign of these transfer functions we could then conclude, as in the earlier interpretation (24), that the linear 2-decanone induces more solvent ordering (structure) in D_2O than in H_2O. Presumably, the opposite would be true in cases where $\Delta G_t^0(\text{STR}) > 0$, *i.e.* adamantanone, but this could only be confirmed with more accurate data on ΔH_t^0.

The limited data on ΔH_t^0 preclude a more detailed interpretation of the ΔG_t^0. Still, within the validity of the present calculation of the cavity contribution, it can be concluded that the differences in the observed ΔG_t^0 for the different

[8]The effective diameter of the methylene group in water can be estimated from partial molal volume data (42) as 3.1 Å, somewhat less than for Ar (3.5 Å).

ketones originate in the structural part of ΔG_t^0.[9] From this and the present measurements, we can only infer that the linear ketones induce more structure in D_2O than in H_2O, while the reverse appears probable for the rigid polycyclic molecules. This is, in part, the connection we sought between the structure of a solute and the perturbation it exerts on the water structure. Now, if the structural part of the $H_2O \rightarrow D_2O$ transfer functions truly reflect the solvent structural perturbation by the solute, we must then ask: do the polycyclic molecules studied here exert *any* stabilizing influence on the water structure? The prominence of such solutes in natural chemical systems makes worthy further attempts to answer this question.

Conclusion

The magnitudes of the free energy and heat of transfer ($H_2O \rightarrow D_2O$) of large hydrophobic solutes are strongly influenced by the structure of these solutes. However, the solvent isotope effect on the thermodynamic quantities for the process of cavity formation in the solvent appears to be an important contribution to ΔG_t^0 and ΔH_t^0. Using the scaled-particle theory to compute the cavity contribution, the remainder is assigned to structural perturbations in the solvent, and is interpreted in terms of a better stabilization of the solvent structure by the linear molecules compared to those which are highly branched.

Financial support of this work by the National Research Council of Canada is gratefully acknowledged. We thank Dr. P. R. Philip for assistance with some of the calculations and Mr. Eric Firkins for i.r. spectral measurements. We also thank these people and Prof. J. E. Desnoyers for helpful discussions.

[9]Variations of ΔG_t^0(CAV) corresponding to differences in the intrinsic volumes should be small, particularly for the series of ketones of same chemical composition (*cf.* Table 2, compounds **1–10**). For instance, the molal volumes of the isomeric butanols differ by less than 2% (16).

La décomposition du tétraméthylgermane par les atomes Hg $6(^3P_1)$

JOCELYN DUVAL ET YVES ROUSSEAU
Université de Montréal, Département de Chimie, Montréal, Québec

Reçu le 14 mars 1973

Le seul processus primaire de la décomposition photosensibilisée au mercure à 2537 Å du tétraméthylgermane est la rupture d'une liaison C—H puisque le rendement quantique en hydrogène tend vers l'unité. Pour des conditions modérées, l'hydrogène moléculaire et le di(triméthylgermyl)-1,2 éthane sont les seuls produits de la réaction. La recombinaison des deux radicaux primaires conduit, surtout à basse pression, à des radicaux méthyles qui, par arrachement d'un atome d'hydrogène sur le substrat, produisent du méthane.

The primary process in the mercury photosensitized decomposition of tetramethylgermane is a C—H bond cleavage. The hydrogen quantum yield, extrapolated at infinite pressure, is close to unity. Under mild conditions, hydrogen and 1,2-di(trimethylgermyl)ethane are the only products observed. At high intensities and low substrate pressures, atomic cracking occurs yielding methyl radicals which lead to the formation of methane.

Can. J. Chem., 51, 3062 (1973)

Le parellélisme réactionnel entre les alcanes et les silanes ou germanes avec les atomes de mercure dans leur état $6(^3P_1)$ est apparent à la suite des travaux de Gunning et de ses collaborateurs (1). Même le tétraméthylsilane semble se comporter comme le néopentane vis-à-vis des atomes de mercure excités; sa décomposition est amorcée par le bris d'une liaison C—H. Cependant aucun travail n'a été effectué sur le tétraméthylgermane et, étant donné l'augmentation de dimensions en passant du silane au germane, on peut se demander si ce parallélisme sera conservé dans le cas des dérivés alkylés du germanium. On peut supposer que la liaison Ge—C est plus vulnérable et peut être plus facilement rompue qu'une liaison C—C ou Si—C. Nous avons donc entrepris d'étudier le comportement du tétraméthylgermane lors de sa réaction avec les atomes de mercure dans leur état excité $6(^3P_1)$. Puisqu'il n'y a pas de possibilité de formation de doubles liaisons entre deux atomes de germanium, on peut supposer que la cinétique de décomposition sera simple.

Section expérimentale

Le tétraméthylgermane (TMG) utilisé provient de la compagnie K + K et n'est pur qu'à 95%. On le purifie par chromatographie en phase gazeuse en utilisant une colonne de 24 pieds contenant de l'huile de silicone D C 200 à 30% sur chromosorb. La fraction collectée à la sortie du chromatographe est ensuite distillée pour y enlever les traces d'eau et de dioxyde de carbone. Le TMG ainsi purifié contient moins de 0.01% d'impuretés tel que déterminé par spectrométrie de masse et chromatographie. Le composé pur est gardé à une température de −64 °C. Les trois intensités lumineuses utilisées furent déterminées par la méthode de Hatchard et Parker (2) et confirmées par l'actinomètre N_2O–*n*-butane (3). Les produits sont analysés par chromatographie en phase gazeuse et par spectrométrie de masse. Les photolyses sont effectuées à température ambiante en utilisant une lampe au mercure à basse pression de Hanovia Lamp Division, type SC 2537. La radiation émise à 1849 Å est filtrée en se servant d'une cellule réactionnelle en Vycor 7910. Cette cellule est cylindrique. Son diamètre est de 5 cm et elle a 10 cm de longueur. Pour les études à 46.2 μeinstein/min une cellule de 3 cm de diamètre et de 22 cm de longueur est placée à l'intérieur de l'hélice de la lampe.

Resultats et discussion

Les principaux produits de la réaction sont: H_2, CH_4, et $[(CH_3)_3Ge—CH_2]_2$. A basse intensité lumineuse, le rendement en méthane est faible par rapport a celui des deux autres produits (~1%). Le di(triméthylgermyl)-1,2 éthane donne un spectre de masse caractéristique à cause des cinq isotopes stables du germanium. Les résultats rapportés au tableau 1 indiquent

TABLEAU 1. Rendements quantiques en hydrogène et en méthane en fonction de la pression de TMG*

P_{TMG} (Torr)	Φ_{H_2}	Φ_{CH_4}
10.5	0.17	0.003
51.5	0.38	0.004
150	0.60	0.005
250	0.76	0.008
295	0.76	0.008

*Intensité lumineuse: 0.02 μeinstein/min; temps de photolyse: 90 min.

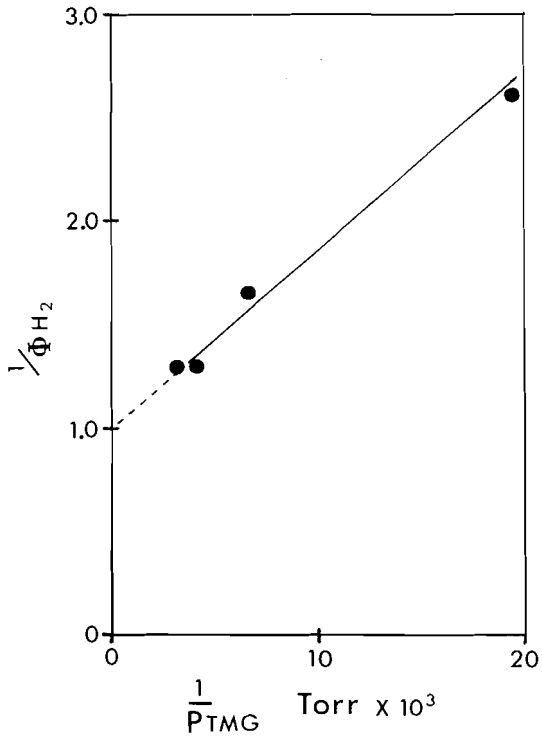

FIG. 1. Inverse du rendement quantique d'hydrogène en fonction de l'inverse de la pression de tétraméthylgermane.

une augmentation du rendement quantique en hydrogène en fonction de la pression de substrat. Il est donc peu probable que l'hydrogène soit formé par l'intermédiaire d'une molécule de tétraméthylgermane excitée à temps de vie assez long pour être désactivée par collisions. D'autre part on peut constater à la fig. 1, que la valeur de l'inverse du rendement quantique en hydrogène devient 1, lorsqu'extrapolée à pression infinie, ce qui est compatible avec un processus primaire impliquant une rupture C—H, *i.e.*

[1] $Hg\ 6(^3P_1) + TMG \rightarrow H^{\cdot} + H_2C{-}Ge(CH_3)_3 + Hg(^1S_0)$

[2] $Hg\ 6(^3P_1) + TMG \rightarrow HgH + H_2C{-}Ge(CH_3)_3$

L'intervention d'atomes métastables Hg $6(^3P_0)$, si elle a lieu, doit être suivie d'une réaction de décomposition du tétraméthylgermane afin d'être compatible avec le rendement quantique unitaire.

[3] $Hg\ 6(^3P_1) + TMG \rightarrow Hg\ 6(^3P_0) + TMG$

[4] $Hg\ 6(^3P_0) + TMG \rightarrow H^{\cdot} + H_2C{-}Ge(CH_3)_3 + Hg(^1S_0)$

La réaction 4 est peu probable, compte tenu du fait que le rendement quantique de décomposition du propane par les atomes Hg $6(^3P_0)$ est seulement de 0.57 à 63 °C. (4). L'hydrogène moléculaire et le di(triméthylgermyl)-1,2 éthane sont possiblement formés par les réactions suivantes:

[5] $H^{\cdot} + TMG \rightarrow H_2 + H_2C{-}Ge(CH_3)_3$

[6] $2\ H_2C{-}Ge(CH_3)_3 \rightarrow (CH_3)_3\ Ge{-}CH_2{-}CH_2{-}Ge(CH_3)_3$

Bien qu'un rendement quantique du di(triméthylgermyl)-1,2 éthane n'ait pu être mesuré à cause de l'absence de standard, ce produit est le seul produit lourd observé à faible intensité lumineuse et, dans tous les cas, constitue près de 99% de la fraction des produits plus lourd que le TMG. Les résultats obtenus à une pression de substrat de 250 Torr et mis en graphique à la fig. 2 sont compatibles avec le mécanisme proposé. En effet on peut y constater que l'hydrogène est un produit primaire alors que le méthane, dont le rendement augmente en fonction du temps de photolyse, est un produit secondaire.

Si on considère sous un autre angle les résultats du tableau 1, on peut attribuer l'augmentation observé dans les rendements quantiques à une désactivation incomplète des atomes Hg $6(^3P_1)$ à basse pression. Ceci n'est d'ailleurs pas particulier au TMG, mais a aussi été noté pour le tétraméthylsilane (1). D'autre part on peut voir au tableau 2 que, même à pression élevée, l'intensité lumineuse incidente a une influence mar-

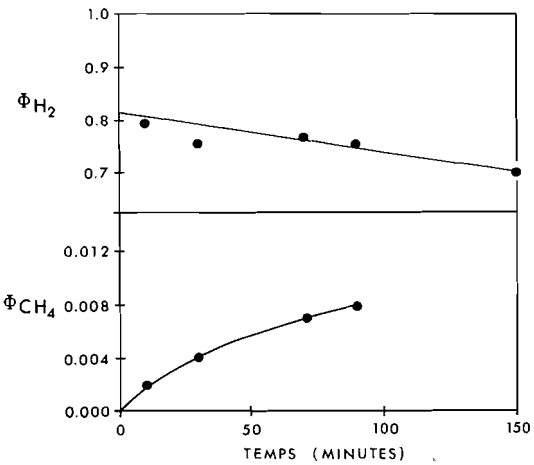

FIG. 2. Rendements quantiques de méthane et d'hydrogène en fonction du temps d'irradiation.

TABLEAU 2. Rendements quantiques en hydrogène en fonction de l'intensité lumineuse absorbée

I_a (μeinstein/min)	P_{TMG} (Torr)	Φ_{H_2}	% décomposition
46.2	100	0.002	0.6
10.1	100	0.058	0.8
0.02	100	0.48	0.2
46.2	225	0.003	0.2
10.1	230	0.13	0.5
0.02	230	0.73	0.1

quée sur le rendement quantique en hydrogène. Un certain nombre de réactions entre radicaux, en particulier celle impliquant les deux radicaux formés dans l'acte primaire, peuvent être responsable de ce phénomène:

[7*a*] $H^{\cdot} + {}^{\cdot}CH_2—Ge(CH_3)_3 \rightarrow (TMG)^*$

[7*b*] $(TMG)^* \rightarrow TMG$

L'intermédiaire (TMG)* peut être la principale source de radicaux méthyles.

[8] $(TMG)^* \rightarrow CH_3^{\cdot} + {}^{\cdot}Ge(CH_3)_3$

En effet, la formation d'une liaison C—H libère quelques 100 kcal/mol et la rupture du lien Ge—C n'en requiert que 65. Cependant puisque le nombre de degrés de liberté de la molécule TMG est grand, on peut supposer que 7*b* est prédominante. Toutefois si la réaction 8 est la principale source des radicaux méthyles, le méthane étant formé par 9,

TABLEAU 3. Rapport hydrogène/méthane en fonction de la pression de TMG*

P_{TMG} (Torr)	$[H_2]/[CH_4]$	% CH_4
7.0	4.5	18
13.5	8.5	10
45.5	24.5	4.5
90.0	27.0	3.8

*Intensité lumineuse absorbée: 46.2 μeinstein/min.

[9] $CH_3^{\cdot} + TMG \rightarrow CH_4 + {}^{\cdot}CH_2—Ge(CH_3)_3$

une augmentation de la pression doit être accompagnée d'un accroissement du rapport H_2/CH_4. Ceci est confirmé au tableau 3. A des taux de conversion plus élevés d'autres produits sont formés. Entre autres, on a pu identifier les produits suivants: C_2H_6, C_3H_8, C_2H_4, $(CH_3)_3Ge—CH_2—Ge(CH_3)_3$, et $(CH_3)_3Ge—Ge(CH_3)_3$.

Correlation of Ionization Potentials and the Sums of Substituent Constants for Substituted Benzenes

HARRY W. GIBSON

Xerox Corporation, Rochester Research Center, 800 Phillips Road, Webster, New York 14580

Received January 23, 1973

Previously reported experimentally determined ionization potentials of substituted benzenes are well correlated by the sum of the para substituent constants, regardless of the orientation of the substituents. σ^+ is better than σ for this purpose. Tri- through hexasubstituted benzenes are also correlated, but the slope and intercept are higher in accord with electrostatic theory. These results in support of recent MO calculations indicate that substituent constants are good measures of the energy of the highest occupied orbital.

Les potentiels d'ionisation expérimentaux précédemment rapportés pour les benzènes substitués sont en bonne corrélation avec la somme des constantes de substituant para. A cet effet, σ^+ est meilleur que σ. La corrélation pour les benzènes tri à hexa substitués a été également faite, la pente et l'ordonnée à l'origine sont plus élevées ce qui est en accord avec la théorie électrostatique. Ces résultats, qui concordent avec les récents calculs des OM, montrent que les constantes de substituants sont une bonne mesure de l'énergie de l'orbitale occupée la plus haute. The wide applicability of the Hammett and related equations to reaction kinetics and a variety of spectral and physical properties (1) has attracted the attention of molecular orbital theorists (2–6). These studies seem to place linear free energy equations of the Hammett type on a very sound theoretical basis.

Ionization potentials have long been recognized as absolute measures of energies of the highest occupied molecular orbitals (7). The ionization potential is defined as the energy necessary to remove an electron completely from a molecule or atom in the ground state to produce a positively charged ion and a free electron. In a few instances ionization potentials (IP) for homologous series, *e.g.*, *p*-substituted acetophenones (8), substituted toluenes (9) and monosubstituted benzenes (9), were correlated with the Hammett constants.

No one, however, appears to have correlated all values for substituted benzenes with the Hammett equation. Such a correlation would demonstrate on an experimental basis the link between orbital energies and substituent constants. For such a correlation to exist the electron being removed must be from a π orbital involved in the aromatic ring. If a substituent itself contains localized electrons of comparable or lower ionization potential, the compound will not fit the general correlation. On this basis the substituent is affecting the reactive site, *i.e.*, the π cloud, both by its resonance and inductive contributions. This would mean that σ_{para} values should be used since they include contributions from both effects, whereas σ_{meta} values do not include resonance contributions. To a first approximation the effect of the disposition of substituents with regard to one another is expected to be small.[1] Indeed, for disubstituted benzenes the difference in ionization potentials of the three isomers is less than 0.2 eV (9–11) (see Table 1), which is less than the deviation between the various methods used to obtain the data used herein.[2] As shown in Table 2, para substituent constants do give better fits of the data (10, 11). Brown's σ^+ values (12), which were derived for electrophilic reactions, *i.e.*, those involving generation of a positive charge on the aromatic nucleus as the result of attack by an electrophile, *e.g.*, NO_2^+, Br^+, seem to give slightly better correlations as previously noted (8, 9).

Figure 1 is a plot of ionization potential *vs.* $\sum\sigma^+_{para}$ for 49 mono- and disubstituted benzenes (10, 11) excluding phenols, bromides, and

[1]One rather obvious exception is the case where steric interference of the two (or more) substituents causes non-coplanarity of the substituent and ring, leading to loss of resonance contribution.

[2]All substituted benzenes for which ionization potentials were available from refs. 10 and 11 were used. The former are the "best" values from ref. 15. In many cases σ^+_{para} values are not available.

	2	1.47	8.88	0.981
	3	0.950	9.16	0.977

*Meta and para-disubstituted compounds only; ortho compounds are not considered in this table. Phenols, iodides, and bromides are excluded. Data from Table 1.

†*Method 1*: σ_{meta} for both substituents used for meta compounds; σ_{para} for both substituents used for para compounds, *e.g.*, for *m*-nitroacetophenone: $\Sigma\sigma = \sigma_{meta\,(COCH_3)} + \sigma_{meta\,(NO_2)} = 0.38 + 0.71 = 1.09$. *Method 2*: σ_{para} used regardless of substitution pattern, *e.g.*, for either *m*- or *p*-nitroacetophenone: $\Sigma\sigma = \sigma_{para\,(COCH_3)} + \sigma_{para\,(NO_2)} = 0.50 + 0.78 = 1.28$. *Method 3*: σ^+_{para} used regardless of substitution pattern.

‡Correlation coefficient $r = 1$ for perfect fit.

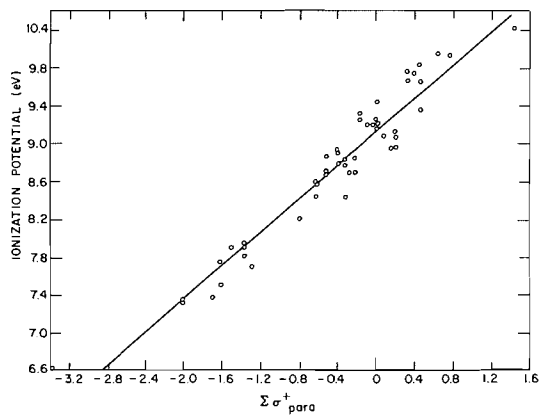

FIG. 1. Plot of experimental ionization potential *vs.* sum of para electrophilic substituent constants ($\Sigma\sigma^+_{para}$) for 49 mono and ortho-, meta- and para-disubstituted benzenes. Slope 0.885, intercept 9.11, correlation coefficient 0.967.

iodides. The correlation coefficient is 0.967. The standard deviation of the points from eq. 1 is 0.20 eV.

$$[1] \qquad IP = 0.885\Sigma\sigma^+ + 9.11$$

Use of 28 values from the same data set obtained by photoionization gives a correlation coefficient of 0.958; electron impact data gives a correlation coefficient of 0.890 for 18 points. While precisions of 0.05 eV or less are often quoted, inspection of literature data (10, 11) reveals that differences from laboratory to laboratory and method to method are at least 0.1 eV and quite often 0.2 eV. Therefore, this correlation is considered good in view of the fact that the ionization potentials were obtained by a variety of techniques and by a variety of investigators. No effort was made here to select "favorable" values.

It is significant that nine ortho-disubstituted compounds are well correlated by use of $\Sigma\sigma^+_{para}$. For the ten such compounds included in the correlation, the standard deviation is 0.16 eV. This upholds the original premise that orientation effects in disubstituted benzenes, at least, are within the scatter of points from eq. 1 (see below, however).

As one might anticipate bromo and iodo substituted aromatics do not always correlate; they have noticeably lower ionization potentials than expected from the Hammett constant values. If bromo and iodo compounds are included in the $\Sigma\sigma^+_{para}$ correlation (total of 58 points) the correlation coefficient drops to 0.953. The lower ionization potentials of the bromides and iodides may be due in part to their high polarizability, which could affect their electronic contribution more in solution than in the gas phase. The slopes are much lower than the other aromatics, that of the iodides being lower than bromides (slopes 0.495 *vs.* 0.816, respectively; intercepts 8.89 *vs.* 8.67, respectively).

Ionization potential *vs.* $\Sigma\sigma_{para}$ for 59 mono- and disubstituted benzenes (excluding phenols, thiophenol, acetophenones, bromides, and iodides), yields a correlation that can be expressed as eq. 2.

[2] $$IP = 1.45\sum\sigma + 8.80$$

The standard deviation of the 59 points from this line is 0.26 eV and the correlation coefficient is 0.943. Again the nine ortho-disubstituted benzenes correlate equally well with a standard deviation of 0.24 eV.

Use of all data except that for thiophenol, phenols, and acetophenones (71 points) gives a slope of 1.42 and an intercept of 8.77, an equation only slightly different from eq. 2, but the correlation coefficient drops to 0.933. Again this is partly due to the fact that bromides and iodides have lower than expected ionization potentials.

Phenols (from examination of nine examples) seem to ionize at higher potentials than anticipated (13). This could be related to the unusual problems involved in the assignment of substituent constants in these systems (1). Or it may be that the ionization occurs from either a π orbital of the benzene ring or a localized electron on the oxygen depending on the substituent, *i.e.*, that the ionization potentials of the two orbitals are close. In contrast phenolic ethers are well correlated.

Acetophenones seem to lose an electron from a different orbital than most of the aromatics since their ease of ionization (Table 1) is lower than expected from eq. 2 (8); the orbital involved could be on the carbonyl oxygen. We note, however, that the slope, *i.e.*, sensitivity to substituent effect, is the same for acetophenones as for the other aromatics. (Acetophenones were not correlated by $\sum\sigma^+$ since σ^+ for $COCH_3$ is not available (1).) The $NHCOCH_3$ group also appears to lead to lower ionization potentials. The sulfhydryl group also falls in this category.

A more rigorous test of the correlation of IP and $\sum\sigma$ is provided by data for more highly substituted benzenes, although a limited number of such data are available (Table 1). The σ^+_{para} correlation for tri-through hexasubstituted benzenes is given by eq. 3 and is shown in Fig. 2.

[3] $$IP = 1.10\sum\sigma^+ + 9.73$$

The standard deviation for the 13 points is 0.23 eV and the correlation coefficient is 0.951. The slope and intercept are appreciably higher than for the mono- and disubstituted benzenes (eq. 1). This is in accord with the electrostatic model (9, 14) which predicts that placing groups with the same sign of σ ortho to one another will result in a higher ionization potential than if

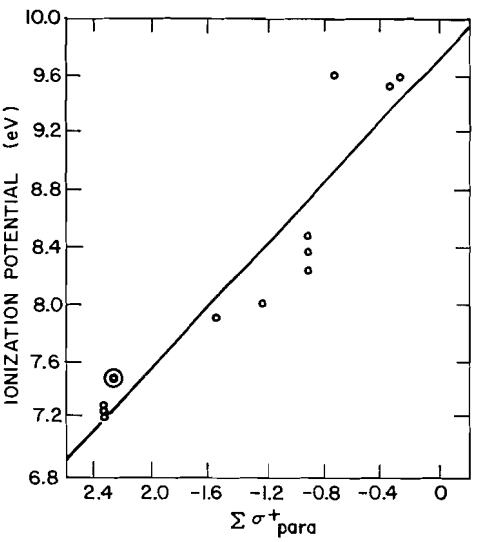

FIG. 2. Plot of experimental ionization potentials *vs.* sum of para electrophilic substituent constants ($\sum\sigma^+_{para}$) for tri- through hexasubstituted benzenes. Slope 1.10, intercept 9.73, correlation coefficient 0.951.

they are meta or para. Conversely, if the groups have oppositely signed σ's, the ionization potential of the ortho isomer will be lower. This leads to a greater slope and intercept. The tri- through hexasubstituted benzenes are better fit by $\sum\sigma_{para}$ giving eq. 4; the standard deviation is 0.23 eV and the correlation coefficient 0.966.

[4] $$IP = 1.73\sum\sigma + 9.19$$

These correlations of multi-substituted benzenes corroborate the linear relationship found in mono- and disubstituted benzenes, substantiate the general additivity of substituent effects even though the influence of dipolar effects modulates it and indicate a fundamental relationship between energies of highest occupied molecular orbitals and Hammett substituent constants.

This correlation offers the possibility of assigning σ and/or σ^+ values of substituents from the ionization potentials of a series of derivatives. For example σ^+ for CHO is not known (1); from 5 points it is estimated to be 0.50 ± 0.07. Preferably, all data would be gathered by the same technique on the same calibrated instrument.

In conclusion a good general correlation between ionization potential and the sum of substituent constants exists. This substantiates molecular orbital theory calculations which reveal the fundamental character of the Hammett

and related equations. Thus, substituent constants seem to provide a useful and convenient guide for prediction of ionization potentials for substituted aromatic systems. Conversely ionization potentials may be used to calculate substituent constants, especially σ^+, which may not otherwise be available.

Combinatorial Entropy of Mixing for Molecules Differing in Size and Shape

RÜDIGER N. LICHTENTHALER, DENIS S. ABRAMS, AND JOHN M. PRAUSNITZ
Chemical Engineering Department, University of California, Berkeley

Received March 6, 1973

In reducing experimental vapor–liquid equilibrium data it is common to calculate the Gibbs energy of mixing in excess of that for a solution whose entropy of mixing is given by one of two expressions: ideal entropy or Flory–Huggins entropy. The first of these is proper for a mixture of small molecules of similar size and the second one is proper for a mixture of monomer and chain polymer. This paper considers intermediate cases where there are significant differences in molecular shape as well as size. An expression is derived for the combinatorial entropy of mixing; this expression has Flory's result as the leading term but also contains corrections for molecular bulkiness. The combinatorial entropy of mixing depends on characteristic parameters reflecting both molecular size and shape. Methods are given for simple evaluation of these parameters and illustrations for representative mixtures are presented. In some case, the corrections for bulkiness can be very large.

En réduisant les données sur l'équilibre expérimental vapeur liquide, il est commun de calculer l'énergie de mélange de Gibbs en excès de celle d'une solution dont l'entropie de mélange est donnée par l'une des deux expressions: entropie idéale ou entropie Flory–Huggins. La première est propre au mélange de petites molécules aux dimensions semblables et la seconde est relative à un mélange de monomère ou polymère en chaine. Cette note traite des cas intermédiaires où il n'existe pas de différences significatives aussi bien dans la forme que dans la taille de la molécule. Une expression a été déduite pour l'entropie combinatoire de mélange cette expression contient le résultat de Flory comme terme dominant et aussi des termes correctifs pour l'encombrement moléculaire. L'entropie combinatoire de mélange dépend des paramètres caractéristiques reflétant à la fois la forme et la dimension de la molécule. Des méthodes simples d'évaluation de ces paramètres et des illustrations par des mélanges représentatifs ont été présentées. Dans certains cas les corrections apportées à l'encombrement peuvent être très élevées.

In recent years much effort has been devoted toward developing the statistical thermodynamics of liquid mixtures (1). While most of this effort has been directed at mixtures of simple fluids containing small, spherical molecules, considerable progress has also been achieved in mixtures containing both large and small molecules as in polymer solutions (2); this progress follows primarily from work by Flory (3) and by Patterson and Delmas (4) based on a partition function proposed by Prigogine (5). These recent developments, however, are concerned with residual thermodynamic properties, determined by differences in free volumes and in intermolecular forces. In the last twenty years very little attention has been given to the configurational properties of solutions as determined by the combinatorial factor. In this work we reconsider the problem of calculating the combinatorial entropy of mixing fluids whose molecules differ in size and shape. We have derived an expression similar to that of Tompa (6) using arguments different from those used previously. Our main concern, however, is directed at application of Tompa's result which appears to have been forgotten by contemporary workers in solution thermodynamics. We make some specific suggestions toward quantitative calculations of the combinatorial entropy of mixing which, in turn, are useful for reduction and subsequent interpretation of experimental data for real solutions.

We consider a binary mixture of two fluids indicated by subscripts 1 and 2. The entropy of mixing is defined as the change in entropy when N_1 molecules of 1 and N_2 molecules of 2 are mixed at constant temperature and pressure to form a homogeneous solution. It is convenient to write this entropy of mixing as the sum of two parts:

$$\Delta S = \Delta S^{C} + \Delta S^{R} \qquad [1]$$

where superscript C stands for combinatorial and superscript R stands for residual. While the recent work of Flory, Patterson and others has been directed at ΔS^{R}, we are here concerned only with ΔS^{C}. The mixing process considered here is one where the molecules of fluids 1 and 2 have finite size but no forces of attraction and where the isothermal, isobaric mixing process occurs also at constant volume.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Let molecule 1 consist of one segment and molecule 2 of r segments. As discussed in numerous textbooks, two expressions are commonly used for ΔS^C:

$$[2] \qquad \frac{\Delta S^C}{k} = -[N_1 \ln x_1 + N_2 \ln x_2]$$

$$[3] \qquad \frac{\Delta S^C}{k} = -[N_1 \ln \Phi_1 + N_2 \ln \Phi_2]$$

where x is the mole fraction

$$[x_1 = N_1/(N_1 + N_2) \quad x_2 = N_2/(N_1 + N_2)]$$

and Φ is the segment fraction

$$[\Phi_1 = N_1/(N_1 + rN_2) \quad \Phi_2 = rN_2/(N_1 + rN_2)].$$

Equation 2 gives the ideal entropy of mixing as used in the theory of regular solutions (7) and eq. 3, due to Flory, is used, almost without exception, in the polymer-solution literature. Equation 3 follows from well-defined assumptions (8) including the assumption that molecule 2 (the polymer) is a long, flexible chain; eq. 3, then, was not intended to apply to large bulky molecules. Using an approach different from Flory's, eq. 3 has also been derived by Longuet-Higgins (9) and by Silberberg (10).

In 1947 Hildebrand (11) presented a phenomenological, free-volume derivation of the combinatorial entropy of mixing. While that derivation is *ad hoc* and difficult to justify theoretically, it points to an important conclusion (later verified by Tompa (12)), *viz.*, the entropy of combinatorial mixing has a lower bound given by eq. 2 and an upper bound given by eq. 3; the "true" combinatorial entropy of mixing lies between these limits. Just where the "true" combinatorial entropy lies between these limits depends on the size and shape of the molecules. Tompa has shown that for mixtures of bulky molecules, eq. 2 provides a better approximation than eq. 3.

While eqs. 2 and 3 are quoted in all textbooks on liquid-mixture thermodynamics, it will be useful to have an expression which, taking molecular size and shape into consideration, is capable of covering the domain bounded by eqs. 2 and 3. We have derived such an expression here; it is

$$[4] \qquad \frac{\Delta S^C}{k} = -[N_1 \ln \Phi_1 + N_2 \ln \Phi_2] + \sum_{t=1}^{z} \alpha^{(t)} \left(1 - \left(\frac{q}{r}\right)^t\right) r \left\{\left[N_1 + \left(\frac{q}{r}\right)^t rN_2\right] \times \left[\ln\left(N_1 + \left(\frac{q}{r}\right)^t rN_2\right) - \ln(N_1 + N_2)\right] - rN_2\left(\frac{q}{r}\right)^t \ln\left(\frac{q}{t}\right)^t\right\}$$

A derivation of eq 4 is given in the Appendix. A similar equation, based on a different derivation, was given by Tompa (6).

In eq. 4, r is the number of segments of molecule 2 divided by that of molecule 1 and q is the surface (contact) area of molecule 2 divided by that of molecule 1. The coordination number z is the number of nearest neighbors of a molecular segment.

The parameters $\alpha^{(t)}$ depend on molecular size and shape. They obey the relations

$$[5] \qquad \sum_{t=1}^{z} \alpha^{(t)} = r - 1$$

$$[6] \qquad \sum_{t=1}^{z} t\alpha^{(t)} = \frac{z}{2}(r - q)$$

The quantity on the right side of eq. 6 is the number of contacts made by segments of molecule 2 with other segments in the same molecule.

Before discussing particular applications of eq. 4, it is instructive to point out some general properties of that equation.

(*a*) The first two terms in eq. 4 are identical to eq. 3; in other words, the summation term in eq. 4 is essentially a correction to Flory's equation.

(*b*) If molecules 1 and 2 are identical in shape and size, then $q = r = 1$. In that event, all $\alpha^{(t)}$'s are zero and eq. 4 reduces to eq. 2.

(*c*) If the coordination number z becomes very large, $q/r \to 1$ and it can be shown that the summation term in eq. 4 vanishes.

(*d*) The first two terms in eq. 4 are always positive and for $r > 1$, eq. 3 always gives an entropy of mixing that is larger than that given by eq. 2. Therefore, if eq. 4 is to give a result intermediate between eqs. 2 and 3, it is necessary that the summation term in eq. 4 be negative for $q/r < 1$ ($q/r > 1$ is physically impossible). The

summation term in eq. 4 is essentially always negative and increasingly so as $q/r \to 0$. For mixtures of bulky molecules of different size ($q/r \ll 1$), eq. 4 approaches eq. 2 as suggested by Monte Carlo studies of mixtures of different-sized spheres (1, 13). For mixtures where q/r is slightly less than unity, eq. 4 gives an entropy of mixing which is very slightly less than that given by eq. 2. In such a case therefore, eq. 4 is, strictly speaking, not valid although the error is negligibly small. For such mixtures and for mixtures where $r \approx 2$ or less, eq. 2 should be used.

(*e*) For mixtures of chain molecules, eq. 4 reduces to the result obtained by Huggins (14) and discussed by Guggenheim (15).

Determination of Parameters

To apply eq. 4, it is necessary to devise a consistent and physically reasonable method for evaluating the parameters r, q, and $\alpha^{(i)}$. We present such a method below.

To evaluate r, we use the van der Waals volumes calculated by Bondi (16). Using the group contributions of Chapt. 14 in Bondi's book it is simple to calculate the van der Waals volume v^* of a large variety of molecules. Then

$$[7] \qquad r = v_2^*/v_1^*$$

For typical mixtures, we find that r is nearly equal to the ratio of molar volumes.

To evaluate q, it is tempting to use Bondi's calculations of van der Waals surface areas. However, the surface areas given by Bondi are too large for our purposes; Bondi calculates the total surface area whereas we require that part of the total surface area which is available for interaction with neighboring molecules. Because of steric requirements, not all of the total surface area is available for interaction with nearest neighbors.

To establish a consistent method for evaluating both q and $\alpha^{(i)}$, we use a simple lattice model with $z = 6$. We assume that the dimensions of a molecule can be represented by three mutually perpendicular, characteristic lengths (l_x, l_y, l_z), whose product is equal to the van der Waals volume:

$$[8] \qquad v^* = l_x l_y l_z$$

As indicated in the Appendix for this simple lattice $\alpha^{(4)} = \alpha^{(5)} = \alpha^{(6)} = 0$. Therefore the three parameters $\alpha^{(1)}$, $\alpha^{(2)}$, and $\alpha^{(3)}$ suffice to describe the bulkiness of the molecule. It can then be shown that

$$[9] \qquad r = \frac{(l_x l_y l_z)_2}{(l_x l_y l_z)_1}$$

$$[10] \qquad q = \frac{(l_x l_y + l_x l_z + l_y l_z)_2}{(l_x l_y + l_x l_z + l_y l_z)_1}$$

$$[11] \qquad \alpha^{(1)} = 2(r - 1) - 3(r - q) + \alpha^{(3)}$$

$$[12] \qquad \alpha^{(2)} = 3(r - q) - (r - 1) - 2\alpha^{(3)}$$

$$[13] \qquad \alpha^{(3)} = (r - 1) - 3q + 3\frac{(l_x + l_y + l_z)_2}{(l_x + l_y + l_z)_1}$$

For a given molecule, the parameters l_x, l_y, l_z must be determined by the size and shape of that molecule, subject to the boundary condition given by eq. 8. To find these parameters, we utilize data for bond angles and bond lengths. To illustrate, Table 1 gives parameters for some representative molecules. These parameters were obtained primarily from van der Waals radii given by Bondi. For silicon-containing compounds Bondi's method of calculation was used with bond parameters taken from Handbook of Chemistry and Physics.

Combinatorial Entropies of Mixing for Some Representative Binary Mixtures

To illustrate the use of eqs. 4 and 9–13, we present calculations for a few typical binary mixtures. These are shown in Figs. 1–4. Parameters used to prepare these figures can easily be calculated with eqs. 9 to 13 using the numbers given in Table 1.

Our main interest is to compare results obtained from eq. 4 with those obtained from Flory's equation (eq. 3). The essential difference between these equations is related to the largest possible number of connections (bonds) which a segment, upon being placed in the lattice, may have with already placed segments of the same molecule. In Flory's equation, suitable for chain molecules, that maximum number is one. We therefore designate results obtained from Flory's equation by the letters SCSM which stand for Single-Connected Segment Model. By contrast, eq. 4 permits a segment of a large molecule to be connected to as many as $z - 1$ other segments of the same molecule which have already been placed on the lattice. Therefore we designate results obtained from eq. 4 by the letters MCSM

†For *n*-alkanes $C_{N_c}H_{2N_c}$($N_c > 1$) the following equations are valid: $l_x = 1.54N_c + 1.04$ Å; $l_y = l_z = 3.32$ Å. $v^* = 10.23N_c + 6.88$ cm³/mol $= 16.98N_c + 11.42$ Å³/molecule.

which stand for Multiple-Connected Segment Model.

Figures 1–4 give excess combinatorial entropies per mole of sites. The excess entropy is defined, as usual, as the entropy of mixing in excess of that found for an ideal system (eq. 2). While eqs. 2, 3, and 4 give entropies per mole of mixture, we can easily convert to entropies per mole of sites by writing

$$[14] \quad \frac{S^E(\text{per mole of sites})}{S^E(\text{per mole of mixture})} = 1 - \left(1 - \frac{1}{r}\right)\Phi_2$$

where Φ_2 is the site fraction of polymer.

Figure 1 gives results for the system *n*-hexane–*n*-hexadecane. Since both components are chain molecules, results from eq. 3 are essentially identical to those from eq. 4.

Figure 2 gives results for the system methane–*n*-hexadecane. Because of the larger size difference, entropies shown in Fig. 2 are appreciably larger than those shown in Fig. 1. Again, there is not much difference between SCSM and MCSM results. However, the relative difference in Fig. 2 is larger than that shown in Fig. 1 because the width of methane is smaller than that of hexadecane while the width of hexane is the same as that of hexadecane. The lower entropy for MCSM is in agreement with computer calculations reported by Bellemans (17).

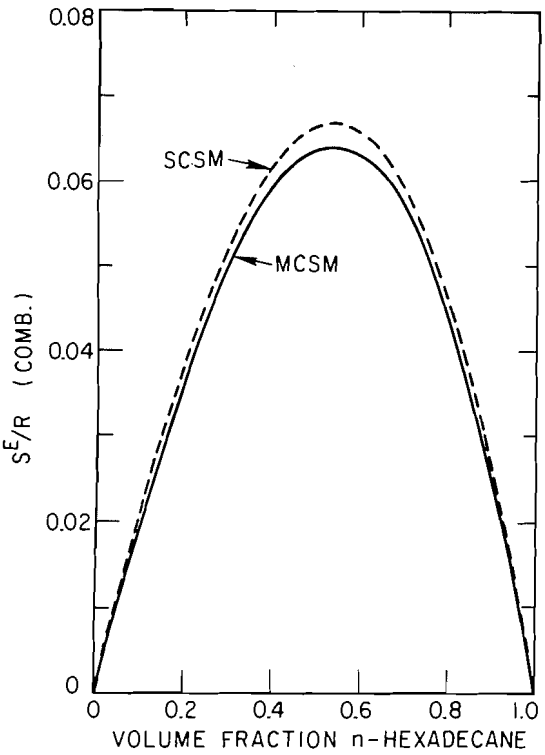

FIG. 1. Excess combinatorial entropy per mole of sites for *n*-hexane–*n*-hexadecane.

Figure 3 gives results for the system carbon tetrachloride – octamethylcyclotetrasiloxane (OMCTS). Both components consist of spherical molecules and therefore we expect a significant difference between SCSM and MCSM results. While the magnitude of the excess entropy is small, Fig. 3 shows that Flory's equation gives an excess entropy nearly twice as large as that found from eq. 4.

Figure 4 gives results for mixtures of benzene and polyethylene of carbon number 8022. All calculations shown are obtained from eq. 4 with parameters given in Table 1. The purpose of Fig. 4 is to show how the degree of bulkiness of the polyethylene affects the excess combinatorial entropy. Curve A refers to linear (straight-chain) polyethylene with $l_x = 12354$ and $l_y = l_z = 3.32$ (See Table 1 where all distances are given in Angstroms.) Curve B refers to a flat ribbon, *i.e.* to a double-strand linear polyethylene with $l_x = 6177$, $l_y = 6.64$, and $l_z = 3.32$. Curve C is also for a flat ribbon, but now the polyethylene is a quadruple-strand chain with $l_x = 3089$, $l_y = 13.28$, and $l_z = 3.32$. Curve D is for polyethylene in a rod-like shape with $l_x = 3089$, $l_y = l_z = 6.64$. Curve E is for a similar rod-shaped polyethylene but with shorter axis and larger cross-section; in this case $l_x = 154$, $l_y = 66.4$, and $l_z = 13.28$. Finally curve F is for polyethylene in the shape of a cube with $l_x = l_y = l_z = 51.4$.

Figure 4 clearly shows that the entropy is strongly affected by the bulkiness of the large molecule, *i.e.* by the extent to which the segments in the large molecule are multiple-connected rather than single-connected when placed onto the lattice. Flory's formula (eq. 3) cannot distinguish between the six cases shown in Fig. 4. Since Flory's formula depends only on the volume ratio, it gives results which are the same for all six cases, independent of molecular shape. Excess combinatorial entropies from eq. 3 are essentially identical to those shown by curve A.

Residual Excess Gibbs Energy

To interpret and correlate experimental data for liquid mixtures, it is desirable to calculate residual thermodynamic functions which, in turn, can be related to a suitable partition function. Following Flory (18), ΔG^R, the residual

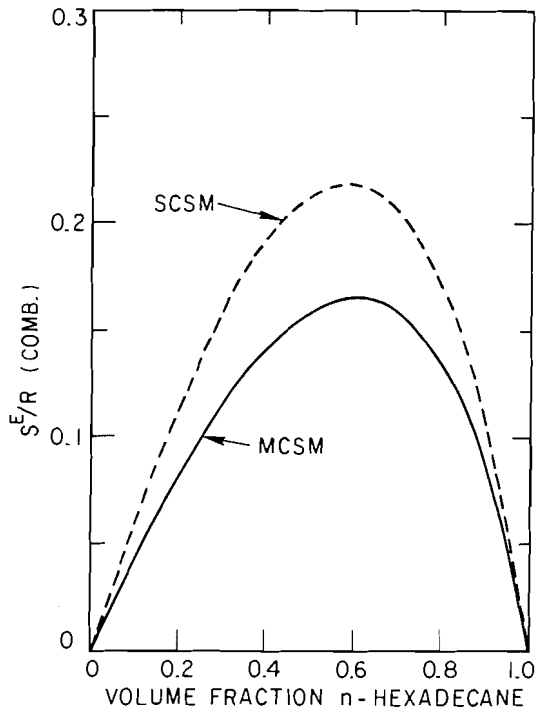

FIG. 2. Excess combinatorial entropy per mole of sites for methane–*n*-hexadecane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

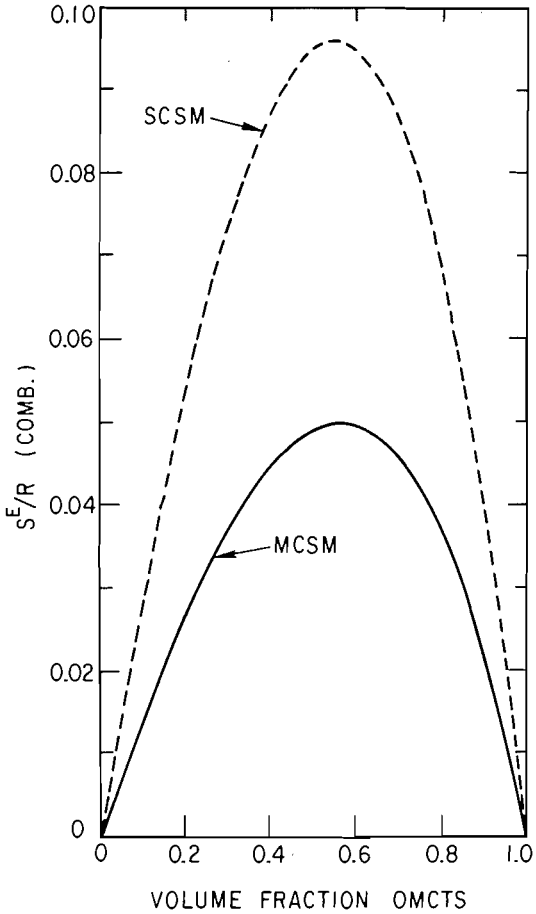

FIG. 3. Excess combinatorial entropy per mole of sites for carbon tetrachloride – OMCTS.

Gibbs energy of mixing is found from the experimental excess Gibbs energy of mixing by

$$[15]\quad \Delta G^R = G^E(\text{experimental}) - G^E(\text{combinatorial})$$

Since H^E(combinatorial) is zero, eq. 15 becomes

$$[16]\quad \Delta G^R = G^E(\text{experimental}) + TS^E(\text{combinatorial})$$

In some cases the residual Gibbs energy of mixing is sensitive to the model chosen for calculating S^E(combinatorial). To illustrate, Fig. 5 gives results for the system carbon tetrachloride – OMCTS and Fig. 6 for the system benzene – OMCTS; experimental data are from Marsh (19). For both systems the excess combinatorial entropy was calculated twice, once with eq. 3 and once with eq. 4. Since OMCTS is a large spherical molecule, many of its segments are multiple rather than single connected when placed onto the lattice. The excess combinatorial entropy calculated from Flory's equation is, therefore, too large and in both binary systems the residual Gibbs energy of mixing based on SCSM is more than twice that calculated from MCSM.

The results shown in Figs. 5 and 6 indicate that in some mixtures the residual Gibbs energy of mixing is a strong function of the method used to calculate the combinatorial entropy of mixing. Thus details in the calculation of the combinatorial entropy of mixing may affect interpretation and subsequent correlation of residual excess functions in mixtures.

Appendix

Derivation of Eq. 4

We consider a three-dimensional lattice with N sites. We want to fill the lattice with N_2 (large) solute molecules and N_1 (small) solvent molecules. Each solute molecule occupies r lattice sites and each solvent molecule occupies one site, such that $N = N_1 + rN_2$. We assume that all configurations have the same energy.

We proceed in the usual way by placing the N_2 solute molecules onto the lattice, one after another. The remaining sites are then filled with solvent molecules. Suppose j solute molecules have already been placed; we now want to compute $\gamma_{j+1,i}$ which is the number of ways we can place the ith segment of the $(j + 1)$th solute molecule.

Consider the first segment of a solute molecule and let Y_1 be the number of ways we can place that segment in the lattice if that lattice were empty. Now for the case where j solute molecules have already been placed previously, $\gamma_{j+1,1}$ is given by

$$[A1] \qquad \nu_{j+1,1} = \left(\frac{N - rj}{N}\right) Y_1$$

Equation $A1$ says that $\gamma_{j+1,1}$ is smaller than Y_1 by a factor which is the fraction of unoccupied sites.

It is tempting to generalize eq. $A1$ by assuming that the reducing factor, *viz.* the fraction of unoccupied sites, can also be used to calculate the number of ways of placing the ith segment, that is, to assume

$$[A2] \qquad \nu_{j+1,i} = \left(\frac{N - rj - (i - 1)}{N}\right) Y_i \approx \left(\frac{N - rj}{N}\right) Y_i$$

where Y_i is the number of ways of placing the ith segment of the $(j + 1)$th molecule when the lattice is nearly empty, containing only $i - 1$ segments of the $(j + 1)$th molecule. Since rj is generally much larger than $(i - 1)$, the equation can be simplified as shown.

Equation $A2$ was used by Flory. We do not use it here, however, because the reducing factor

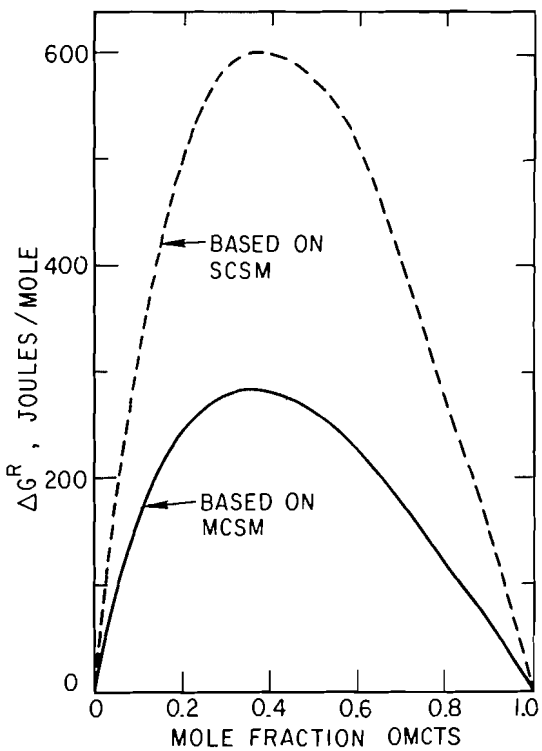

FIG. 6. Residual Gibbs energy of mixing for benzene–OMCTS at 25 °C.

For personal use only.

$(N - rj)/N$, while valid for the first segment, is too low for subsequent segments. Once the first segment of a solute molecule has been placed on a particular site, the probability that an adjacent site is empty, is larger than $(N - rj)/N$. Stated in more general terms, if $i - 1$ sites of a solute molecule have been placed on the lattice, the probability that a fixed site adjacent to the $(i - 1)$th segment is empty, is larger than $(N - rj)/N$. The probability is larger because if we know that $i - 1$ segments have already been placed in the region where we want now to place the ith segment, we know that this region is less concentrated in solute molecules than the lattice as a whole.

To obtain an improved expression for $\gamma_{j+1,i}$, we must first introduce the parameters z and q. The coordination number of the lattice is z; each solvent molecule has z nearest neighbors. Each solute molecule has a number of nearest neighbors equal to qz, which is less than rz, because some of the nearest neighbors of a segment within a solute molecule belong to the same molecule. Whereas the total number of segment–segment contacts for a molecule is rz, only qz contacts are external. For a bulky solute molecule, where many of the segments are internal (*i.e.* completely or primarily surrounded by segments of the same molecule), q/r is well below unity. For a linear chain molecule with no rings, q and r do not differ very much; they are related by

$$[A3] \qquad qz = rz - 2r + 2$$

Equation *A*3 is valid also for branched chain molecules. However, this equation assumes that a molecule does not bend back on itself, *i.e.* a segment of a molecule is never placed such that one of its immediate neighbors is a segment of that same molecule more than two links removed.

In Flory's equation (eq. *A*2) the reduction factor $(N - rj)/N$ is too low. If it is known that a given site (arbitrarily labeled A) is the neighbor of one site already occupied by a segment of the $(j + 1)$th molecule, then, the probability that site A is occupied by another segment of that same $(j + 1)$th molecule is $(1 - q/r)$, not zero as assumed in eq. *A*2. Further, if site A is such that t of its neighbors are occupied by segments of the $(j + 1)$th molecule, then the probability that site A is occupied by another segment of that same $(j + 1)$th molecule is even higher; it is $1 - (q/r)^t$. We therefore replace eq. *A*2 by writing

$$[A4] \quad \nu_{\substack{j+1,i \\ i>1}} = \left(\frac{N - rj}{N}\right) \times \left[1 - \left(1 - \left(\frac{q}{r}\right)^t\right)\frac{rj}{N}\right]^{-1} Y_i$$

The factor in parentheses in eq. *A*4 is always less than unity and since it is in the denominator, the number of ways of placing the ith segment of the $(j + 1)$th molecule as given by eq. *A*4 is larger than that given by eq. *A*2.

As the coordination number rises, the difference between r and q falls; when $z \to \infty$, $q/r \to 1$. In that case eq. *A*4 reduces to eq. *A*2.

Omitting symmetry numbers, we can now write the number of configurations, *i.e.* the number of ways of arranging N_1 solvent molecules and N_2 solute molecules

$$[A5] \quad \Omega(N_1,N_2) = \frac{1}{N_2!}\prod_{j=1}^{N_2}\prod_{i=1}^{r}\nu_{j,i}$$

$$= \frac{1}{N_2!}\prod_{j=1}^{N_2}\left\{[N - r(j-1)] \times \frac{[N - r(j-1)]^{r-1}\rho}{\prod_{t=1}^{z}\left[N - \left(1 - \left(\frac{q}{r}\right)^t\right)r(j-1)\right]^{\alpha^{(t)}}}\right\}$$

where ρ is the product of all Y_i values of one solute molecules (for $i > 1$) and $\alpha^{(t)}$ is the number of segments of a solute molecule which, when placed on the lattice, have already t neighbors occupied by segments of that same solute molecule. The sequence of placing segments on the lattice must be such that preference is always given to that segment which, when placed on the lattice, has the largest number of neighbors which are previously-placed segments. Two conservation equations relate the parameters $\alpha^{(t)}$ to the parameters q and t. These are eqs. 5 and 6 in the text.

We can now calculate the combinatorial entropy of mixing from

$$[A6] \qquad \frac{\Delta S^C}{k} = \ln\frac{\Omega(N_1,N_2)}{\Omega(0,N_2)\Omega(N_1,0)}$$

where k is Boltzmann's constant. To do so we first apply Stirling's approximation for large N to eq. *A*5 and obtain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[A7]\quad \ln\Omega(N_1,N_2) = N_2 \ln \rho - N_2 \ln N_2 - N_1 \ln N_1 + N \ln N + \sum_{t=1}^{z} \frac{\alpha^{(t)}}{\left(1 - \left(\frac{q}{r}\right)^t\right) r} \times \left\{ \left[N - \left(1 - \left(\frac{q}{r}\right)^t\right) r N_2 \right] \times \ln \left[N - \left(1 - \left(\frac{q}{r}\right)^t\right) r N_2 \right] - N \ln N \right\}$$

Substitution of *A*7 into eq. *A*6 gives eq. 4 in the text.

The parameter $\alpha^{(t)}$ represents the number of segments of a solute molecule which, upon being placed in the lattice, have t nearest neighbors occupied by other segments of the same molecule. The integer t varies from unity to z.

To illustrate the calculation of $\alpha^{(t)}$, we consider a two-dimensional example. Suppose we have a two-dimensional molecule of 20 sites; the molecule is a rectangle 4 sites wide and 5 sites long, as shown in Fig. 7. We assume that for a two-dimensional lattice $z = 4$; thus, for example, site 8 has four nearest neighbors (3, 7, 9, and 13). The rectangular molecule has $r = 20$ and qz, the number of nearest-neighbor external contacts, is 18 (one external contact each for sites 2, 3, 4, 10, 15, 19, 18, 17, 11, and 6; two external contacts for sites 1, 5, 20, and 16).

We place the segments on the lattice such that each segment placed must have the largest possible number of previously placed segments as neighbors. First we place segment 1. Then we place segments 2, 3, 4, and 5, and then segment 6. In each of these five placements, the segment placed has one nearest neighbor. Next we could place segment 11 or 10 or 7 or 8 or 9. We must choose segment 7 because it will be placed with two neighbors while the others would be placed with only one neighbor. After 7, comes 8, 9, and 10, each with two neighbors. Next comes 11 (with one neighbor) followed by 12, 13, 14, and 15 (with two neighbors). Finally, we place 16 (one neighbor) followed by 17, 18, 19, and 20 (two neighbors).

1	2	3	4	5
6	7	8	9	10
11	12	13	14	15
16	17	18	19	20

FIG. 7. Two dimensional molecule occupying 20 sites.

All placements (for $i > 1$) have either one or two neighbors. Thus $\alpha^{(3)} = \alpha^{(4)} = 0$. As indicated by the sequence of the previous paragraph

$\alpha^{(1)} = 7$ (Segments 2, 3, 4, 5, 6, 11, and 16)

$\alpha^{(2)} = 12$ (Segments 7, 8, 9, 10, 12, 13, 14, 15, 17, 18, 19, and 20)

It can readily be shown that these values for $\alpha^{(t)}$ satisfy eqs. 5 and 6 in the text:

$$\sum_{t=1}^{z} \alpha^{(t)} = r - 1 = 19$$

$$\sum_{t=1}^{z} t\alpha^{(t)} = \frac{z}{2}(r - q) = 31$$

Extension to Multicomponent Mixtures

Unfortunately there is no unambiguous way to generalize eq. 4 in the text to mixtures containing more than two components. For a mixture of n components the value of $\Omega(N_1,N_2,...N_n)$ depends upon the sequence 1, 2, ...n used for placing the molecules on the lattice, as pointed out long ago by Miller (20). Generalization can be achieved only in the special case where $\alpha^{(t)}r^{-1}[1 - (q/r)^{(t)}]^{-1}$ is the same for all molecules.

Nucleophilic Attack on Some Isothiazolium Salts

DAVID M. MCKINNON AND MOHAMED E. HASSAN
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received February 19, 1973

A variety of isothiazolium salts has been prepared and allowed to react with sodium benzoylacetate. 2-Benzoylthiophenes are obtained, suggesting that the position of initial nucleophilic attack is at the sulfur atom of the heterocyclic cation. Reaction with hydrogen sulfide gave acyclic reduction products, or 1,2-dithiole derivatives, depending on the type of substituent on nitrogen in the isothiazolium salts.

Une série de sels d'isothiazolium a été préparée et mise en réaction avec le benzoylacétate de sodium. Des benzoyl-2 thiophènes ont été obtenus laissant penser que l'attaque nucléophile initiale se faisait sur l'atome de soufre du cation hétérocyclique. La réaction avec l'hydrogène sulfuré conduit aux produits de réduction acyclique ou aux dérivés dithiole-1,2, en fonction du type de substituant sur l'azote dans les sels d'isothiazolium. While studies of nucleophilic attack on isothiazoles (1) and isothiazolones (2–5) indicate that the attack takes place at the ring sulfur atom, the situation with isothiazolium salts is by no means as clear. Various reactions of isothiazolium salts **1** with nucleophiles have been interpreted as occurring at carbon atom 3 (1, 6, 7), but in these reactions the products obtained could also have been formed by initial attack at sulfur. The reaction of certain 5-methylthioisothiazolium salts with hydrosulfide (8) has been suggested to occur at ring sulfur and recently (9) attack at carbon atom 3 by nitrogen nucleophiles, and at sulfur by hydrogen sulfide, has been demonstrated. In this work we wish to report some of our studies on the isothiazolium system which provide evidence on the position of nucleophilic attack.

A variety of isothiazolium salts **1**(*a–k*) was used in the investigation. Most of these except **1***h* had been made before. Compound **1***a* had been isolated as its iodide (10), but we found it simpler to alkylate isothiazole by dimethyl sulfate and isolate the salt as its perchlorate. **1***g* was prepared by alkylation of 2,4-diphenylisothiazoline-3-thione, the reverse of a reaction previously described (8). Compound **1***h*, which was new, was prepared by iodine oxidation of methyl 3-methylaminodithiocinnamate (**2***d*) similarly to known methods (8, 11). The dithioester was prepared by treatment of 3-methylthio-5-phenyl-1,2-

For personal use only.

dithiolium iodide with methylamine according to known methods (12). It is reported to be accompanied by 2-methyl-5-phenylisothiazoline-3-thione (**3***a*) and by 5-phenyl-1,2-dithiole-3-thione (**4***b*). In our investigation we found that the former compound was accompanied by greater or lesser amounts of *N*-methyl 3-methylaminothiocinnanamide (**2***f*), depending on the quantity of methylamine used, and in fact when a large excess of methylamine was used, the isothiazolinethione was not found and the amide was obtained instead. Treatment of the thione with methylamine gave no reaction, suggesting that the thione is not a precursor of the thioamide, and that the latter arises instead via some mechanistic change in the reaction of the dithiolium salt with the amine.

The isothiazoline-3-thione from the above reaction was smoothly converted by hydrogen peroxide in acetic acid into the 2-methyl-5-phenylisothiazolium cation, isolated as its perchlorate (**1***b*). Likewise, 2-methyl-4,5-diphenylisothiazoline-3-thione (**3***b*), prepared by reaction of 3-methylthio-4,5-diphenyl-1,2-dithiolium iodide with methylamine, was converted to 2-methyl-4,5-diphenylisothiazolium perchlorate (**1***d*). These oxidations by hydrogen peroxide in acetic acid are related to reactions of isothiazoline-5-thiones (8), and dithiolethiones (13, 14). Since *N*-alkylisothiazolium salts can be dealkylated to isothiazoles (15), the reaction represents another synthesis of these from dithiolium salts. These salts were identical to ones prepared (8) by methylation of isothiazoles, and by another method, the treatment of 1,2-dithiolium salts with methylamine to form β-methylaminopropenethiones **2** (16), which oxidized by iodine to form the *N*-methylisothiazolium salts **1***b* and *d*, isolated as the perchlorates. Yields by this method were rather poor, comparable to one such reaction previously studied (11), but it does at least represent a quick synthesis of *N*-alkylisothiazolium salts from the readily accessible (13, 14) 1,2-dithiolium salts.

Treatment of the isothiazolium salts **1** with sodium benzoylacetate yielded 2-benzoylthiophenes **5** in all cases. The formation of these can be explained by nucleophilic attack of a phenacyl ion (actual or potential) on ring sulfur, to give ring opening, followed by attack of the activated methylene group on the imine function to give recyclization to the thiophenes. The results from the 3- or 5-alkylthioisothiazolium salts **1***f*, *g*, and *h* are especially striking. By analogy with other related heterocyclic systems (16), had nucleophilic attack occurred at carbon, 3- or 5-acylmethleneisothiazoles would have been expected. For all cases except **1***f* cyclization occurs by loss of amine, but in that case, methanethiolate anion, a better leaving group, is lost instead, with formation of a 3-amino-2-benzoylthiophene (**5***e*). This reaction also afforded the acyclic reduction product **2***g*, which could have arisen by reaction of eliminated methanethiolate ion with another molecule of starting isothiazolium salt, either by reduction, or by nucleophilic attack. Similar results have been obtained for the attack of benzenethiol (**9**) or benzenethiolate anion (below) on isothiazolium salts. Likewise, the attack of hydrosulfide ion on two alkylthioisothiazolium salts in ethanol (8) may be rationalized as occurring by a similar route.
