Les spectres dans l'infrarouge lointain de 16 adduits entre la pyridine, quinoléine, urée, aniline, *o*- et *p*-toluidine et l'acétate, propionate, butyrate de cuivre et formiate de cuivre tétrahydraté ont été enregistrés à la température ambiante et à −196 °C. Une série de dérivés contenant du ^{65}Cu, de pureté isotopique, ont été préparés. Les spectres de ces dérivés ont été utilisés pour identifier de façon non équivoque, les fréquences d'élongation entre le cuivre et l'oxygène. Les complexes, qu'on pense être des polymères, exibent une vibration d'élongation oxygène–cuivre, entre 300 et 350 cm^{-1} (adduits de l'aniline et de la toluidine). Une seconde bande, entre 350 et 400 cm^{-1}, n'est pas sensible à l'effet isotopique. Les complexes dimères montrent une ou deux bandes dans la région 300–400 cm^{-1}, toutes sensibles à l'effet isotopique. Pour certains adduits avec les amines, on observe une bande proche de 240 cm^{-1} et sensible à l'effet isotopique, attribuée à la vibration Cu–N.

Can. J. Chem., **51**, 514 (1973)

The recent publication (1) of the X-ray structure of the *p*-toluidine adduct of copper propionate revealed that this complex has a polymeric structure (Fig. 1*a*) rather than the conventional binuclear arrangement (Fig. 1*b*) expected for most copper carboxylate derivatives (2, 3).

Magnetic studies (2, 3) had previously revealed that aniline adducts had markedly higher room temperature magnetic moments (*i.e.* lower exchange energies) than many other adducts and various proposals had been made to interpret this observation. It now seems credible that all aniline type adducts are in fact polymeric rather than dimeric. Since the electronic spectra of the aniline adducts do not differ in a significant fashion from, say, the dimeric pyridine adducts (2, 3), far infrared spectroscopy is used here to see whether a distinction might be made on the basis of the copper–oxygen stretching vibrations. Such a distinction should be possible in view of the observation (1) that the polymeric complex, copper propionate *p*-toluidine, contains at least three different types of Cu—O bond (Fig. 1*a*), whilst in the dimers the Cu—O bonds are probably all equivalent (Fig. 1*b*). Very recently, Mabbs and co-workers (4) showed that the trihydrate solvate of the *p*-toluidine adduct of copper acetate was not dimeric, but contained chains of copper atoms linked by bridging water molecules. They also suggested that the aniline type adducts may involve polymeric rather than dimeric structures and presented some magnetic and electron spin resonance data in support of this contention.

Experimental

Physical Measurements

The room temperature far infrared spectra were obtained as Nujol mulls between polythene plates utilizing a Beckman IR12 spectrophotometer. Low temperature spectra were obtained with the same instrument using a Beckman (Model VLT-2) Variable Tem-

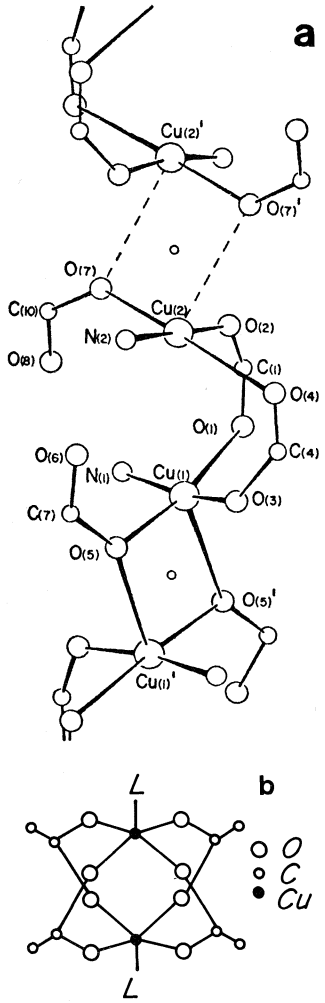

FIG. 1. (*a*) A view of a section of the one-dimensional polymeric structure of copper propionate *p*-toluidine. The copper oxygen distances are: Cu(1)—O(1) = Cu(1)—O(3) = 1.92 Å; Cu(1)—O(5) = 1.95 Å; Cu(1)—O(5)′ = 2.31 Å; Cu(2)—O(7)′ = 2.46 Å (reproduced by permission of the Authors, and of the American Chemical Society, from ref. (1)).

(*b*) Schematic structure of a dimeric copper carboxylate adduct.

perature Cell (with polythene windows), the sample having been ground intimately with regenerated polythene powder and compressed with a laboratory press into a thin opaque disc. These data were obtained with the instrument scanning at the rate of 8 cm^{-1}/min. The ^{65}Cu data and the natural copper data with which they were compared were scanned at the rate of about 1–2 cm^{-1}/min. For sharp absorption the accuracy will be ± 0.2 cm^{-1}, but for the more broad bands it was not possible to ascertain the centers of the band maxima with such accuracy. The data quoted are the average values from at least three scans.

Preparation of the Complexes

Previously described complexes were prepared by the literature route, recrystallized from an appropriate solvent and analyzed for copper. The copper analyses and bibliography are as follows: (calculated and found values for Cu (%)): copper acetate pyridine, (2, 3) 24.4, 24.4; copper acetate urea (5), 26.3, 26.1; copper acetate quinoline (6), 20.4, 20.3; copper propionate urea (5), 23.55, 23.1; copper propionate *p*-toluidine (1), 20.0, 19.8; copper propionate aniline (4), 21.0, 21.2; copper propionate pyridine (7) 22.0, 21.9; copper butyrate pyridine (3) 20.0, 19.4; copper butyrate *p*-toluidine (3), 18.4, 19.7; copper butyrate aniline (3), 18.4, 18.7; copper butyrate urea (5) 21.3, 21.1; copper formate tetrahydrate (8), 28.2, 28.1.

The isoquinoline derivatives were prepared by mixing the anhydrous copper alkanoate with isoquinoline in stoichiometric proportions in chloroform, and warming. The solid product was purified by soxhlet extraction with chloroform.

Copper Acetate Isoquinoline

Anal. Calcd. for $C_{13}H_{13}CuNO_4$: C, 50.2; H, 4.2; Cu, 20.4. Found: C, 50.35; H, 3.8; Cu, 20.5.

Copper Propionate Isoquinoline

Anal. Calcd. for $C_{15}H_{17}CuNO_4$: C, 53.2; H, 5.1; Cu, 18.75. Found: C, 52.9; H, 5.3; Cu, 18.6.

Copper Butyrate Isoquinoline

Anal. Calcd. for $C_{17}H_{21}CuNO_4$: C, 55.6; H, 5.8; Cu, 17.3. Found: C, 56.0; H, 6.0; Cu, 17.4.

Copper Propionate o-Toluidine

This compound was prepared by fusing anhydrous copper propionate with neat *o*-toluidine at 50–80° until a green product was obtained; this was then recrystallized from acetone.

Anal. Calcd. for $C_{13}H_{19}CuNO_4$: C, 49.3; H, 6.0; Cu, 20.1. Found: C, 49.2; H, 6.3; Cu, 20.4.

Results and Discussion

Despite the wealth of data which has appeared concerning copper carboxylates and their adducts, far infrared studies of the metal–ligand frequencies have, with the exception of some reports by Wasson *et al.* (9), Heyns (10), and Lorenzelli and Gesmundo (11), escaped attention. These authors assigned a series of bands between 400 and 250 cm^{-1} in copper acetate complexes to copper oxygen stretching vibrations. In order to confirm these assignments and to determine whether the far infrared region can be used to distinguish dimers from polymers, the far infrared data of a wide series of compounds were recorded and are presented in Table 1. Comparison of the spectra of the copper carboxylates with those of the corresponding alkali metal salts does indeed suggest that additional bands appearing in the copper spectra

below 400 cm^{-1} may reasonably be assigned to metal–oxygen modes.

The presence of a range of different axial ligands, some of which absorb in this region, does, however, complicate the issue. Comparison of the data in Table 1 reveals that the complexes may, with one or two exceptions and on the basis of their room temperature spectra, be subdivided into two groups. One group exhibits a *single* band between 300 and 400 cm^{-1} with an energy of about 350 cm^{-1} or more, and the other group exhibits *two* bands in this region, one usually below 350 and one above 350 cm^{-1}. Unfortunately this subdivision is not identical with the division into polymers and dimers suggested on the basis of the magnetic data (2, 3, 12), *i.e.* magnetic moments near 1.7 and 1.4 B.M., respectively.

The D_{4h} CuO_4 square planar chromophore should give rise to one infrared active (doubly degenerate) copper–oxygen stretching vibration, whilst the dimeric D_{4h} Cu_2O_8 unit would give rise to two ($A_{2u} + E_u$) active vibrations. Further additional active vibrations could arise through

factor group splitting since the data are obtained in the solid state. The polymeric structure (Fig. 1*a*) has very low symmetry (C_i) with four different Cu—O distances; considering a $Cu_4O_{12}N_3$ segment of the chain, up to six Cu—O stretching modes will be infrared active, though may not all be resolvable.

The isotopic substitution method (13) was used to unequivocally confirm that these bands are indeed copper–oxygen vibrations. A range of derivatives was obtained using isotopically pure (99.7%) ^{65}Cu and the spectra compared against those obtained with natural copper (69% ^{63}Cu, 31% ^{65}Cu). Isotopic substitution of the central metal is preferred to isotopic substitution with isotopes of oxygen (or nitrogen) since the former will reveal only vibrations whose potential distribution contains metal–ligand modes, whilst use of the latter provides shifts in all vibrations involving that oxygen (C—O as well as M—O). Because of the presence of some ^{65}Cu in the natural copper samples, the isotopic shifts recorded in Table 2 probably underestimate, slightly, a true isotopic shift upon replacement of ^{63}Cu by ^{65}Cu. Calculation (14) suggests that such replacement should lead to a frequency shift of some 3–5 cm^{-1} in a vibration whose potential distribution is predominantly Cu—O in origin. *The observation that certain absorption in the 300–400 cm^{-1} region exhibits isotopic shifts of this order of magnitude confirms that these bands may be considered to be dominantly copper–oxygen stretching (presumably) vibrations* (see Fig. 2). In particular all bands exhibited by the dimeric complexes in the 300–400 cm^{-1} region were isotopically sensitive whilst for the polymeric complexes only the lower of the two bands observed in this region exhibited isotopic

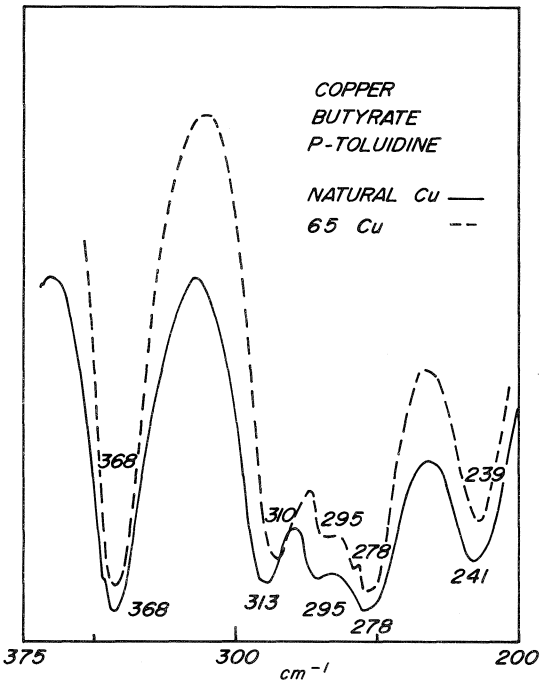

FIG. 2. The vibrational spectrum of copper butyrate *p*-toluidine containing natural copper, — and containing ^{65}Cu, ----.

sensitivity. Thus at least for those derivatives studied there is a distinction between the polymeric and dimeric species on the basis of the far infrared spectrum, albeit isotopic substitution experiments are needed to so demonstrate.

In those cases where bands shifted by less than 2.0 cm^{-1} some Cu—O contribution is indicated, but evidently the potential distribution contains some internal ligand modes. Thus those bands just above 400 cm^{-1} in the pyridine adducts and which show some slight sensitivity towards iso-

topic substitution may be assigned to a pyridine ring skeletal vibration (15, 16) coupled with a copper ligand mode (see Fig. 2).

Certain of the pyridine and toluidine adducts exhibit an isotopically sensitive band near 240 cm^{-1} assigned to the copper–nitrogen stretching vibration; such an energy is typical of a copper–nitrogen stretching mode involving such ligands (16 and references therein). However, the relatively small shifts observed suggest that this is not a very pure vibration.

In view of the broadness of the copper–oxygen modes in the room temperature spectra, the data were also taken at (or close to) −196 °C, when much more resolved spectra were obtained (see Fig. 3). Where two copper–oxygen modes were observed between 300 and 400 cm^{-1} the lower energy band was almost always resolved into two components, whilst the upper band generally shifted to higher energy. When one band was observed in this region in the room temperature spectrum, cooling led generally to a shift to high energy, and in one case to resolution into two components. One might certainly expect the polymeric complexes in particular to give a very complicated Cu—O spectrum since the crystal contains so many different kinds of Cu—O bond (1). Factor group splitting in the crystals of the dimeric molecule might also yield further bands at low temperature, so complexity in the 300–400 cm^{-1} region at low temperature, will not necessarily provide additional definitive information. Certainly splitting of the E_u modes by fields of less than four-fold symmetry might well be anticipated, such splitting being observable in the low temperature spectrum.

In comparing the room temperature data with those obtained at low temperature, problems arise because it is not always possible to draw a one to one correlation between the two spectra. Frequently a broad band will split into two components, one at lower and one at higher energy than the original band, whilst other bands will shift in energy, usually, though not always, to high energy. New features may arise in the low temperature spectrum, whilst others may disappear. Comparison is also complicated by the fact that different mulling techniques are employed to obtain the room temperature and low temperature data (see Experimental section); nevertheless there does seem to be the general trend that metal–ligand frequencies shift to higher energies on cooling as might be expected

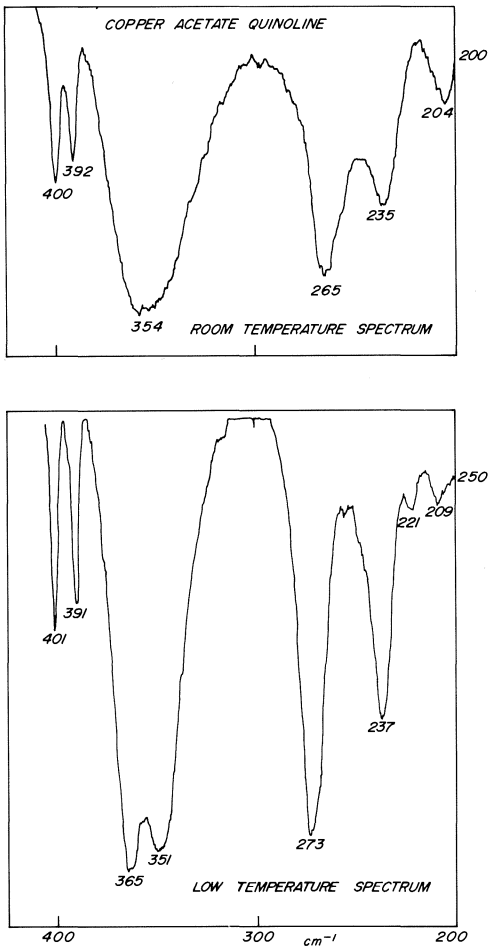

FIG. 3. The vibrational spectrum of copper acetate quinoline at room temperature (upper) and at liquid nitrogen temperature (lower).

(17, 18). Cooling frequently leads to a marked apparent increase in intensity which can aid the identification of features which are weak in the room temperature spectrum (10, 17, 18). Using the results of the low temperature studies, and the isotopic studies, as a basis, Cu—O (and in some cases Cu—N) stretching vibrations have been assigned in Table 1 for all the complexes under consideration. Although isotopic experiments were not carried out with all the complexes, it is considered that a sufficient pattern has been identified for the assignments to be secure.

NOTE ADDED IN PROOF

It is relevant that isotopic studies of the far infrared spectra of amino acid complexes of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 86.111.144.194 on 09/06/12
For personal use only.

copper(II) reveal γ(Cu—O) at *ca.* 330 cm^{-1} and γ(Cu—N) at *ca.* 380 cm^{-1} (19).

Summary

The polymeric complexes exhibit one or two bands in their room temperature infrared spectrum between 300 and 400 cm^{-1}, only the lower of which, from isotopic substitution experiments appears to be assignable to a Cu—O stretching mode. The dimeric complexes, on the other hand, have a potential distribution such that all bands between 300–400 cm^{-1} in the room temperature spectra involve copper–oxygen vibrations. Isotopic studies have also confirmed that the axial copper–nitrogen stretching vibration in certain amine adducts contributes to a band near 240 cm^{-1}.

Nitrilohexaphosphonitrilic Chloride: A Chemical and Spectroscopic Study

R. T. OAKLEY AND N. L. PADDOCK[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 16, 1972

The preparation of nitrilohexaphosphonitrilic chloride[2] $N_7P_6Cl_9$ is described; its infrared, Raman, mass and nuclear magnetic resonance spectra indicate a tricyclic condensed ring structure of C_{3v} symmetry. The molecule decomposes on attempted substitution of the chlorine atoms by fluorine and by methoxy-groups, but with dimethylamine both addition and substitution take place. One central bond is broken, and a bridged ring imide $N_6P_6(NH)(NMe_2)_8Cl_2$ is formed, in which the ring structure is sufficiently rigid for axial and equatorial groups to be distinguished. The detailed molecular structure of $N_7P_6Cl_9$ shows evidence of a compromise between the requirements for optimum σ- and π-bonding, the central N—P bonds being strained. Its substitution behavior, base strength, ultraviolet spectrum, mass spectrum, and molecular geometry are interpreted in these terms.

La préparation du chlorure de nitrilohexaphosphonitrilique[2] $N_7P_6Cl_9$ est décrite; ses spectres infrarouge, raman, résonance magnétique et son spectre de masse indiquent une structure tricyclique condensée de symétrie C_{3v}. La molécule se décompose lorsqu'une substitution des atomes de chlore par les groupes fluor ou méthoxy est tentée, avec la diméthylamine l'addition et la substitution ont lien toutes deux. Une liaison centrale se brise et un cycle imide ponté $N_6P_6(NH)(NMe_2)_8Cl_2$ se forme, dans lequel la structure cyclique est suffisamment rigide pour pouvoir distinguer les groupes axial et équatorial. La structure moléculaire détaillée de $N_7P_6Cl_9$ fournit la preuve d'un compromis entre un recouvrement optinal et nécessaire des liaisons σ et π et une tension des liaisons centrales N—P. Le comportement dans la substitution, la force basique, les spectres de masse et u.v., la géométrie moléculaire de ce composé ont été aussi interprétés en fonction de ce facteur. [Traduit par le journal]

Can. J. Chem., **51**, 520 (1973)

Introduction

In the course of his pioneer investigation of the preparation of the phosphonitrilic chlorides (2), Stokes obtained a small quantity of a compound of formula $N_7P_6Cl_9$, which he called nitrilohexaphosphonitrilic chloride. Much later, Krause (3) obtained the same compound by depolymerization of a phosphonitrilic chloride high polymer, determined some of its properties, and suggested for it a condensed ring structure (Fig. 1). Cationic fragments based on the N_7P_6 nucleus have since been detected in the mass spectra of the larger phosphonitrilic chlorides (4) and bromides (5), but there has been no detailed report of the general chemistry of this type of compound. In the present work, the condensed ring structure of $N_7P_6Cl_9$ has been established, and its reactions with typical nucleophiles investigated. The σ-bond requirements are important, causing the molecule to deviate strongly from planarity and straining the central bonds. The substitutional behavior is consequently less simple than that of monocyclic phosphonitriles, a rigid bicyclic derivative being produced on dimethylamination. The detailed structure and reactions can be understood in terms of theoretical concepts developed earlier.[3] A preliminary account of this work has been published (7).

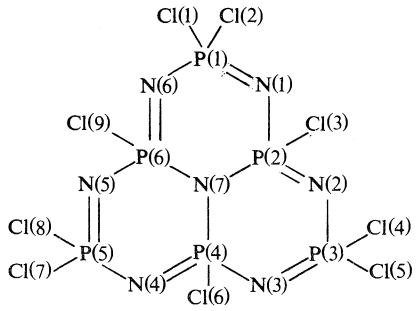

FIG. 1. Structure of $N_7P_6Cl_9$ as suggested by Krause.

Experimental

Mixtures of phosphonitrilic chlorides were prepared from phosphorus pentachloride and ammonium chloride by established methods (8). Potassium fluorosulfite was prepared by shaking finely ground dry potassium fluoride

with liquid sulfur dioxide for 3 days; its sulfur dioxide content was 98% of theoretical value. Activated potassium fluoride was obtained by heating it *in vacuo* (9). Benzene and methanol were dried by distillation from sodium; sodium methoxide was prepared from the metal and dry methanol. Silver(I) fluoride, lithium nitride, and dimethylamine were commercial products, and were used without further purification. Infrared spectra were obtained on a Perkin–Elmer 457 spectrometer, Raman spectra on a Cary 15 spectrometer with Spectra-Physics helium–neon laser excitation, and ultraviolet spectra on a Cary 14 spectrometer. A Varian HA100 spectrometer was used to obtain the ^{31}P and ^{1}H n.m.r. spectra (external 85% H_3PO_4 and internal tetramethylsilane, respectively), and an A.E.I. MS9 mass spectrograph (with conventional sampling techniques and an excitation potential of 70 V) for the mass spectra.

Preparation of Nitrilohexaphosphonitrilic Chloride

In a typical experiment, 200 g of a mixture of phosphonitrilic chlorides $(NPCl_2)_n$ (mean $n \sim 5$) was polymerized to a dark rubbery solid by heating it at 300 °C for several hours at atmospheric pressure. Extraction with benzene showed that no $N_7P_6Cl_9$ was formed at this stage. The product was depolymerized by heating it at 300 °C, <0.1 Torr, to give (mainly) a mixture (170 g) of $N_3P_3Cl_6$ and $N_4P_4Cl_8$ in the approximate weight ratio 1:2, and a residue of light flaky black ash, of unknown composition. The nitrilohexaphosphonitrilic chloride partly solidified in the condenser arm of the distillation apparatus, and partly distilled with the monocyclic chlorides, from which it was separated by taking advantage of its low solubility in petrol. The combined quantities of $N_7P_6Cl_9$ (0.5 g) were recrystallized from benzene and identified by m.p. (235°, lit. (2) 237.2°).

Anal. Calcd. for $N_7P_6Cl_9$: Cl, 52.9; N, 16.3; P, 30.8. Found: Cl, 52.8; N, 16.2; P, 30.7.

Its mass spectrum (Table 1) showed the compound to be monomeric. No improvement in yield was obtained by using the individual cyclic compounds instead of a mixture. Attempts at directed synthesis were unsuccessful; some reaction of hexaphosphonitrilic chloride $(NPCl_2)_6$ with lithium nitride took place in tetrahydrofuran, with formation of lithium chloride, but no $N_7P_6Cl_9$ was found in the product from this reaction or from those of tris-(trimethylsilyl)amine and tris(trimethylstannyl)amine with the hexameric chloride.

Reactions of Nitrilohexaphosphonitrilic Chloride

Fluorination

A slurry of $N_7P_6Cl_9$ (2.3 g, 3.85 mmol) and potassium fluorosulfite (6.5 g, 11.0 mmol) in 125 ml cyclohexane was heated under reflux in a dry atmosphere. No volatile products were trapped at −76 °C. After 16 h, the mixture was filtered and the solvent distilled off, leaving crystals of $N_7P_6Cl_9$ (1.4 g, 2.3 mmol); no $N_7P_6F_9$ or partially fluorinated derivatives were detected in the cyclohexane distillate. The insoluble residue contained chloride ion,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and, after mild hydrolysis, phosphate ion. It appeared that complete breakdown of 1.55 mmol $N_7P_6Cl_9$ had occurred, corresponding approximately to reaction of all the KSO_2F used, rather than partial fluorination of all the $N_7P_6Cl_9$. Similar results were obtained in a second experiment, in which an excess of activated potassium fluoride (3.6 g, 62 mmol) was stirred with $N_7P_6Cl_9$ (1.07 g, 1.78 mmol) at 150 °C for 48 h (a method found to give a good yield of $N_6P_6F_{12}$ from $N_6P_6Cl_{12}$). There was no visible evidence of reaction, no product was collected in the cold trap, and nothing was extracted from the reaction mixture by ethyl ether, benzene, or acetonitrile. The residue was soluble in water and gave a positive test for chloride ion, indicating that reaction of the P—Cl bonds and molecular breakdown had both occurred. In a third experiment, a finely ground mixture of $N_7P_6Cl_9$ (0.8 g, 1.34 mmol) and silver(I) fluoride (3.5 g, 27.5 mmol) was heated for 1 h at 180 °C, without obvious reaction. On further heating at 240 °C, a small quantity of an unidentified volatile product was obtained, of mean mol. wt. (vapor density) 114 (calcd. for $N_7P_6F_9$, 455). Again, breakdown of the ring evidently occurred.

Methoxylation

A solution of $N_7P_6Cl_9$ (0.3 g, 0.5 mmol) in 10 ml benzene was added slowly to a stirred suspension of sodium methoxide (0.35 g, 6.5 mmol) in 15 ml benzene. The reaction mixture was heated under reflux for 4 h, cooled, diluted with 20 ml ethyl ether and washed with water. Determination of the chloride ion showed substitution to have been quantitative. No phosphonitrilic derivative was detected either in the ethereal solution or in its aqueous extract, so that substitution was evidently accompanied by breakdown of the ring.

Amination

Dimethylamine (0.8 g, 17.9 mmol) in 12 ml benzene was added at 0 °C to a cold stirred solution of $N_7P_6Cl_9$ (0.5 g, 0.84 mmol) in 15 ml benzene. Precipitation of dimethylamine hydrochloride began at once. After 3 h, it was filtered off and the benzene evaporated from the filtrate, leaving a pale yellow oil. The oil was dissolved in petrol, filtered, and the solvent evaporated to yield 3,7,11-imino-3,11-dichlorooctadimethylamidocyclohexaphosphonitrile (0.46 g, 0.65 mmol, 77% theory) which was recrystallized from acetonitrile as colorless, flaky, triboelectric crystals, m.p. 161–163°.

Anal. Calcd. for $C_{16}H_{49}Cl_2N_{15}P_6$: C, 27.2; H, 6.9; Cl, 10.0; N, 29.8. Found: C, 27.2; H, 6.9; Cl, 10.0; N, 29.7.

Its mass spectrum showed the compound to be monomeric.

Solubility in Sulfuric Acid

A comparison of the basic behavior of the monocyclic and condensed ring compounds was made by measuring the partition coefficient P of $N_6P_6Cl_{12}$ and $N_7P_6Cl_9$ between cyclohexane and sulfuric acid of various concentrations. Solutions of the two compounds (0.001 *M*) were made in cyclohexane. The partition ratios were determined by mixing 30 ml of each solution with 30 ml of acid of known concentration, shaking the mixture for 2 min, and then finding the concentration of the chloride in the cyclohexane layer by evaporating a known volume of the solution to dryness and weighing the residue. The concentration in the acid layer was determined by difference. All measurements were made in triplicate over the range $H_0 = -8.4$ to -8.8, equal concentrations in the two layers being found for $H_0 = -8.57$ ($N_6P_6Cl_{12}$) and -8.67 ($N_7P_6Cl_9$).

Reaction with Aluminum Bromide

A solution of resublimed aluminum bromide (0.039 g, 0.145 mmol) in 9 ml carbon disulfide was added, under an atmosphere of dry nitrogen, to a stirred solution of $N_7P_6Cl_9$ (0.087 g, 0.145 mmol) in 10 ml carbon disulfide. There was no sign of a reaction after 30 min. The carbon disulfide was distilled off, and 0.083 g $N_7P_6Cl_9$ recovered from the residue by extraction with benzene.

Results

Molecular Structure of Nitrilohexaphosphonitrilic Chloride

The ^{31}P n.m.r. spectrum of $N_7P_6Cl_9$, determined in molten naphthalene, consists of two peaks of equal intensity, and is uniquely consistent with the presence of two sets of three equivalent phosphorus atoms, as implied in the structure of Fig. 1. Each peak exhibits unresolved structure. The lower chemical shift (−20.2 p.p.m.) is tentatively assigned to the PCl_2 groups by comparison with the shift (8) of $N_3P_3Cl_6$ (−20.0); the other line is at higher field (+3.5 p.p.m.), possibly because of electron release from the central nitrogen atom.

The indicated three-fold symmetry, which is independent of the detailed assignments, is confirmed by the vibrational spectra (Table 2). The symmetries D_{3h} and C_{3v} both require 33 active fundamentals, but in D_{3h} the horizontal plane of symmetry destroys the infrared activity of 14 out of 27 Raman active modes. In fact, although only 18 lines are observed, every Raman line is accompanied by an infrared counterpart. The inference of C_{3v} symmetry is supported by some detailed assignments. There have been many modifications to the vibrational assignments of the phosphonitrilic chlorides since the original work of Daasch (10), the most recent and detailed being that of Hisatsune (11, 12). In the present case, some assignments are tentative, because Raman polarization measurements were not available, owing to the compound's small solubility. The P—Cl stretching frequencies are the best established. The monocyclic phosphonitrilic chlorides, up to at least $N_6P_6Cl_{12}$, exhibit an infrared band near 600 cm^{-1} ($N_3P_3Cl_6$: 598 (11); 610 (13); 611 (14); 612 (15). $N_4P_4Cl_8$[4]: 596, 601 (15); 598, 610 (12). $N_5P_5Cl_{10}$: 601 (15); 607 (16). $N_6P_6Cl_{12}$: 603 (16); 602[5]). This is generally

*CsI plates. Frequencies obtained from solutions in CS_2, CCl_4, agreed within 5 cm^{-1}, except that the line at 870 cm^{-1} was resolved into two: 858 cm^{-1} (st), 880 cm^{-1} (m). st = strong, m = medium, w = weak, v = very.

attributed to $\nu_{as}(PCl_2)_{i.p.}$[6], and the i.r. band at 592 cm^{-1} in $N_7P_6Cl_9$ is so assigned. It is broadened, and could obscure $\nu_{as}(PCl_2)_{o.p.}$. The lower limit of $\nu(PCl_2)$ is assigned as $\nu_s(PCl_2)_{i.p.}$, usually on the basis of a strong polarized Raman line, as follows (cm^{-1}). $N_3P_3Cl_6$: 363 (13); 365 (14, 15, 17, 18). $N_4P_4Cl_8$[4,6]: 385, 413 (12); 387, 413 (15); 404 (13). $N_5P_5Cl_{10}$: 439 (15). $N_6P_6Cl_{12}$: 461 (16)[7]; 451[5]. We therefore assign the strong Raman lines at 442 cm^{-1} in $N_7P_6Cl_9$ to $\nu_s(PCl_2)_{i.p.}$, its infrared activity indicating the absence of a horizontal symmetry plane. $\nu_s(PCl_2)_{o.p.}$ is then either at 503 or 525 cm^{-1}; the latter seems more likely by comparison with the spectra of the trimeric chloride–fluorides (14), but a degenerate deformation mode of the N_3P_3 ring has been assigned near this frequency (10, 11, 13, 17), and these two assignments could be reversed. The two remaining frequencies in this region (557/548, 564 cm^{-1}) are characteristic of this particular compound, and are assigned to $\nu(PCl)_{i.p.}$ (A_1) and $\nu(PCl)_{o.p.}$ (E), in agreement with assignments of $\nu(PCl)$ at 563 (19) or 575 cm^{-1} (18) in $N_3P_3Br_5Cl$, 559 cm^{-1} in $N_3P_3Cl_5Br$ (19), and 568 cm^{-1} in $N_3P_3FCl_5$, $N_3P_3F_3Cl_3$ (14).

The higher frequencies are similar to those of other phosphonitrilic derivatives, especially those with 6-membered rings. The N_7P_6 framework has one more A_1 mode than the N_6P_6 ring of the same symmetry, involving essentially the symmetric stretching of the internal PN bonds. The Raman line at 807 cm^{-1} is assigned to this mode; there is no close line in the spectra of either $N_6P_6Cl_{12}$ (16) or $N_5P_5Cl_{10}$ (15, 16), and although there is a line at 782–785 cm^{-1} in the Raman spectrum of $N_4P_4Cl_8$ (12, 13, 15, 20), it is depolarized. However, in $N_3P_3Cl_6$ the totally symmetric ring breathing frequency is established at 783–785 cm^{-1} (10, 11, 14, 15, 17, 18), and the likelihood that $N_7P_6Cl_9$ contains 6-membered rings is reinforced by the occurrence of a Raman line at 661 cm^{-1}; a totally symmetric band, attributed to a trigonal ring deformation, appears as a strong polarized band in the Raman spectrum of $N_3P_3Cl_6$ at 669–671 cm^{-1} (11, 15, 17, 18). There is a further parallelism in the occurrence of an i.r. band at 870 cm^{-1} ($N_7P_6Cl_9$) and at 872–875 cm^{-1} ($N_3P_3Cl_6$). Although the symmetry species of this last band is still uncertain (11), the assignment of the 661, 807, 870, and 1188 cm^{-1} bands as ring vibrations allied to corresponding bands in $N_3P_3Cl_6$ is generally supported by the progressive variation of similar frequencies in the series $N_3P_3Cl_{6-n}Br_n$ (19). The strongest i.r. band, that of ν_{ar} (PNP) (1280 cm^{-1}), is intermediate between the corresponding frequencies of $N_3P_3Cl_6$ (1218 cm^{-1}) and $(NPCl_2)_{4-6}$ (1315 (10), 1354 (15), 1338 (16)).

[6]In view of the complexity of the molecule, Hisatsune (12) discusses only the symmetry assignments of $N_4P_4Cl_8$.

The low frequencies are assigned with less certainty. The two lowest may correspond to the 157, 172 cm^{-1} Raman lines in $N_3P_3Cl_6$ (13) which are there of species E'', characteristic of PCl_2 rocking and torsional vibrations. The line at 332 cm^{-1} seems the natural choice for $\delta(PCl_2)_{i.p.}$, but an out-of-plane ring deformation is also expected in this region. Changes of assignments in this region are unlikely to affect the general conclusion that the molecule has the condensed ring structure of Fig. 1, but with the rings bent away from the central P_3 plane, the overall symmetry being C_{3v}.

The mass spectrum of $N_7P_6Cl_9$ (Table 1) is consistent with this conclusion, and also shows many interesting points of comparison with those of the monocyclic chlorides. Besides the parent series $N_7P_6Cl_x^{n+}$, fragments of the series $N_6P_5Cl_x^{n+}$ have been detected, the latter for the first time. Loss of $NPCl_y$, either charged or neutral, evidently occurs, without loss of the central nitrogen atom. Monocyclic and linear fragments are also formed, and, in whatever type of fragment, even-electron fragments are more abundant than odd, for both singly and doubly charged species. It is a characteristic of the monocyclic phosphonitrilic chlorides that the parent series is stable to electron impact, and when breakdown occurs, high yields of smaller rings are obtained (4). The behavior of nitrilohexaphosphonitrilic chloride is different in that the condensed ring products are the least abundant type, and breakdown occurs mainly to small linear fragments, to a much greater extent than in the monocyclic chlorides, for which the linear products typically form 10–20% of the products (4). The condensed ring structure evidently destabilizes the molecule, although condensed ring carbocyclic aromatic compounds, such as naphthalene, are less fragmented (21) than benzene (22). A similar reduced stability of the skeletal structure is found in the chemical reactions of nitrilohexaphosphonitrilic chloride, and both phenomena find an explanation in the relation between molecular and electronic structure discussed below.

Structure of $N_6P_6(NH)(NMe_2)_8NHCl_2$

In the reaction of dimethylamine with $N_7P_6Cl_9$, one of the central bonds is broken, and two of the bridgehead chlorine atoms remain unsubstituted. The evidence for the structure of $N_6P_6(NH)(NMe_2)_8Cl_2$ (Fig. 2) is based on n.m.r. spectroscopy. Its ^{31}P n.m.r. spectrum consists of three peaks at −13.7, −3.7, +1.9 p.p.m., of relative areas 1, 2, 3, assigned respectively to P_1; P_2P_6; $P_3P_4P_5$. The peak at lowest field is a triplet (J_{PP} = 40 Hz; proton coupling incompletely resolved), and the other two are broad unresolved singlets. The direct and decoupled ^1H spectra are shown in Fig. 3, together with assignments which refer to Fig. 4. The molecular symmetry is low enough for a first order treatment to be applied, and derived chemical shifts and coupling constants are given in Table 3. The analysis has three points of direct structural interest. (*a*) The largest coupling constant is 12.7 Hz. In mononuclear phosphorus(V) compounds (23) and in the dimethylamino-derivatives of trimeric phosphonitrilic chloride (24), J_{PH} decreases with increasing aminolysis, and can be used to distinguish between $\equiv PClNMe_2$ and $\equiv P(NMe_2)_2$. For the former, J_{PH} is never less than 16.3 Hz. For the latter, J_{PH} is always less than 13.9 Hz, and is only slightly dependent on ring size, decreasing from 11.2 to 10.0 Hz in the series $[NP(NMe_2)_2]_n$, (n = 3–6) (25). We conclude that the dimethylamido-groups are paired, the remaining chlorine atoms being present in the bridgehead bonds P(2)Cl(3) and P(6)Cl(9). (*b*) The molecule is rigid. If each pair of dimethylamino-groups on each phosphorus atom were equivalent, three lines with relative intensities 2:4:2 would be found in the decoupled spectrum. The observed pattern (relative intensities 1:2:3:2) shows that the pairs of substituents on three phosphorus atoms are differentiated. The high-field resonance is assigned to the (undifferentiated) L_d protons, rather than L_b (Fig. 4) on the basis of its high J_{PH} and chemical shift (24). A complete assignment

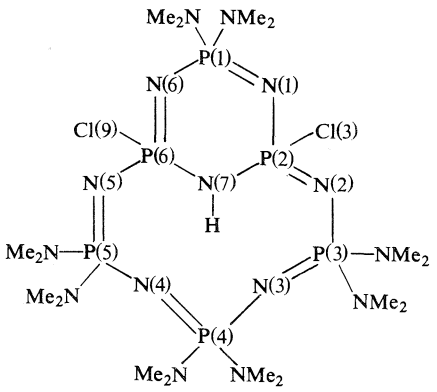

FIG. 2. Structure of $N_6P_6(NH)(NMe_2)_8Cl_2$.

TABLE 3. Proton chemical shifts and coupling constants* of $N_6P_6(NH)(NMe_2)_8Cl_2$

Type of proton†	Relative intensity	δ‡	J_{PH}(Hz)
H_a	1	2.626	10.7
H_b	2	2.606	10.7
H_c	3	2.576	10.7
H_d	2	2.551	12.7

*Dilute solution in $CDCl_3$, determined at 100 MHz. An additional proton signal, of intensity ~1/50th of the total of the high-field peaks tabulated, was found at δ = 6.15 p.p.m., and is attributed to the NH proton.
†See Fig. 4.
‡In p.p.m. downfield of internal tetramethylsilane.

of the other shifts is not possible, because the conformational structure is not unique. In terms of Fig. 4, which is based on the structure of $N_7P_6Cl_9$, the most likely interpretation is that the three equatorial dimethylamino-groups L_c have the same shift, and that one axial group L_a is differentiated from the other two, L_b, by its proximity to the central NH group. Irrespective of the exact correspondence, this is believed to be the first recorded instance of a purely conformational distinction in a phosphonitrilic derivative, the rigidity of the 10-membered ring presumably arising from the re-entrant P(6)N(7)P(2) section, and, possibly, hydrogen bonding from the NH group to the NMe_2 group L_a. (*c*) The chemical shift of the (NH) proton occurs at δ = 6.15 p.p.m., compared with δ ~ 1 for simple aliphatic secondary amines. The shift of the resonance to lower fields by electron-withdrawing groups ($C_6H_5NHCH_3$, 3.34 (26); $C_6H_5NHC_6H_5$, 5.42 (27); $C_6H_5CONHCH_3$, 8.18 (28)) is accompanied by a reduction in base strength, pK_{BH^+} for these three compounds being 4.85 (29), 0.77 (30), −0.46 (31). It is therefore likely that in the phosphonitrile the formal lone pair on the central nitrogen atom is largely delocalized into the ring system, the environment of the nitrogen atom being essentially planar, as it is in the phosphazane $N_3Me_3P_3O_3(OMe)_3$ (32). Both the infrared and mass spectra of $N_6P_6(NH)(NMe_2)_8Cl_2$ are consistent with the above structural conclusions, but are not given in detail because they are too complicated to be informative. ν_{as}(PNP) is represented by a broad complex series of bands (1150–1335 cm^{-1}) as expected for a molecule of low symmetry. The frequencies are lower than in the open ring $N_6P_6(NMe_2)_{12}$ (1340 cm^{-1}) (25). ν(NH) is present as a broad weak band centered near 3140 cm^{-1}, indicative of strong hydrogen bonding.

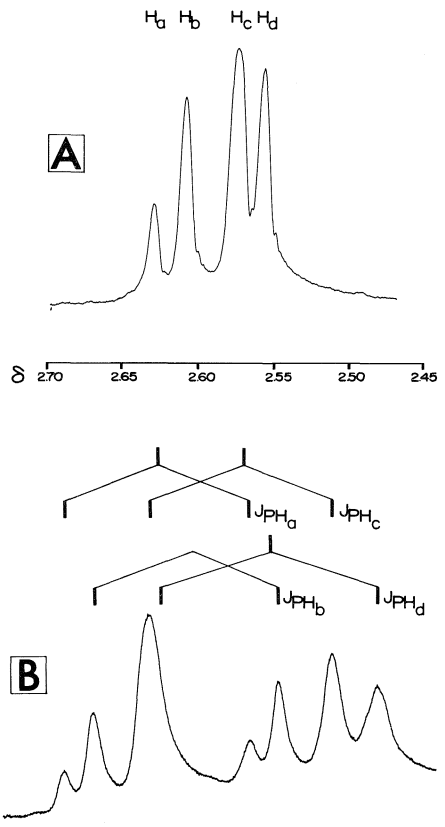

FIG. 3. The ^1H n.m.r. spectrum of $N_6P_6(NH)(NMe_2)_8Cl_2$, taken at 100 MHz. (*A*) ^{31}P–^1H decoupled, using a 2000 Hz noise band at 40.48100 MHz, (*B*) direct.

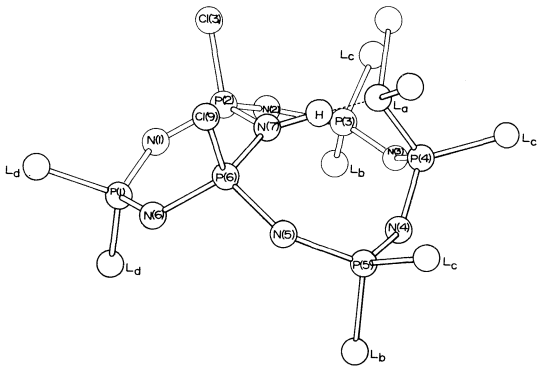

FIG. 4. Model of $N_6P_6(NH)(NMe_2)_8Cl_2$, constructed with equal bond lengths (except N–H), all ring angles at phosphorus 120°, nitrogen angles 120° in 6-membered ring, 135° elsewhere. Exocyclic groups shown as monatomic (∠ NPN = 104°) except L_a, where the angles are assumed tetrahedral. The dotted line represents the hydrogen bond referred to in the text.

Discussion

The structural features of $N_7P_6Cl_9$ deduced from its spectra have been confirmed by an X-ray determination of its crystal structure (1). The quantitative detail is important, because the nature of the bonding, the chemical reactions, and the molecular structure are inter-related. The structure is shown in Fig. 5. It consists of a central nearly planar section (the deviation of N(7) from the P(2)P(4)P(6) plane is 0.04 Å) and three 5-atom segments, typically P(6)N(6)P(1)N(1)P(2), each substantially planar, but making an angle of 25° with the central plane. It will later be more convenient to take the related angle θ_4 between the planes N(3)P(4)N(4) and P(2)P(4)P(6) as a measure of the deviation of the molecular framework from planarity. In the crystal, the small but crystallographically significant deviations from C_{3v} symmetry are believed to arise from lattice forces, and for this discussion the dimensions are averaged. The planar environment of the central nitrogen atom is consistent with complete delocalization of its unshared electrons into the ring π-system. In agreement, $N_7P_6Cl_9$ does not react with aluminum bromide, its base strength is no greater than that of the monocyclic $N_6P_6Cl_{12}$ itself, and its ultraviolet spectrum is also similar to those of the chlorides $(NPCl_2)_n$, in that there is no absorption above 210 nm, and λ_{max} is below 200 nm. In contrast, the localized n–σ* transition in dimethylamine is at 220 nm (33). Attempted interpretation of the structural information in terms of a π-system based on a planar molecule nevertheless reveals several discrepancies. The normals at N(7), P(4) to the planes P(2)P(4)P(6) and N(3)P(4)N(4) are taken as local Z_1, Z_2 axes, Y_1, Y_2, being in these planes and respectively along N(7)P(4) and the bisector of the angle N(3)P(4)N(4) (Fig. 5). If the molecule were actually planar ($\theta_4 = 0$), the two Z-axes would be parallel, and only d_{yz} would interact with p_z at N(7). For $\theta_4 > 0$, d_{z^2} and $d_{x^2-y^2}$ also participate, but since all three orbitals interact symmetrically with neighboring p_π-orbitals, to form, in monocyclic phosphonitriles, a homomorphic π-system, only a single d-orbital need be included in the simplest formal treatment. Figure 6 shows (for C_{3v} symmetry) how the scheme of levels of a P_6N_6 π-system is affected by the addition of a central p_π-orbital; the principal effect is to stabilize the two lowest A_1 orbitals.

Although this scheme makes clear how π-interactions stabilize the molecule, it is inadequate to explain the detailed properties of $N_7P_6Cl_9$, especially the length of the bonds to the central atom, which are comparatively long (1.723 Å). As a direct comparison, the mean lengths of the exocyclic PN bonds in $[NP(NMe_2)_2]_4$ (34) and $[NP(NMe_2)_2]_6$ (35) are smaller (1.68,

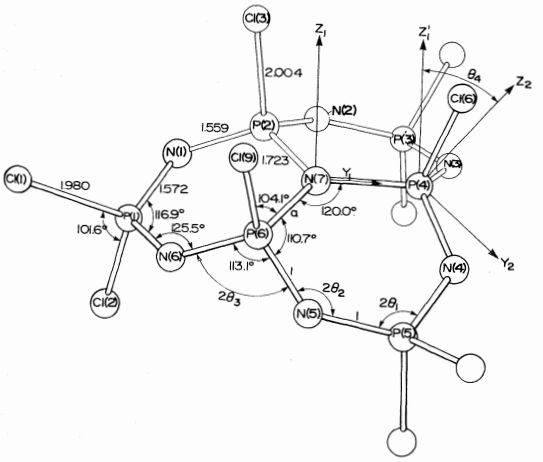

FIG. 5. Perspective view of $N_7P_6Cl_9$. Dimensions (in Å and degrees) (ref. 1) which are equivalent in C_{3v} are averaged, as are also the lengths of the equatorial and axial apical P—Cl bonds. Mean standard deviations of individual bond lengths: P—N, 0.006; P—Cl, 0.003 Å; angles: ClPCl, 0.1°; NPN, 0.3°; PNP, 0.4°; NPCl, 0.3°. The figure also shows the principal assumptions and coordinate axes used in the discussion of the structure.

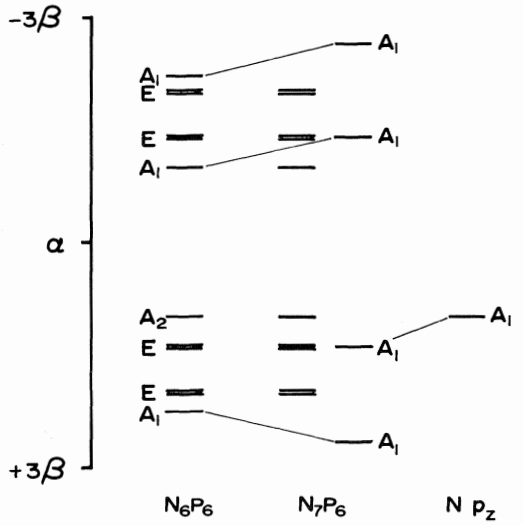

FIG. 6. π-electron levels of planar N_7P_6, related to those of N_6P_6 and a central Np_z orbital. Assumed symmetry C_{3v}. Hückel m.o.'s. $\alpha_N = \alpha_P + 2\beta$, $\alpha = (\alpha_N + \alpha_P)/2$.

1.67 Å), even though the mean sums of the angles round the nitrogen atoms are less (352°, 353°) than in $N_7P_6Cl_9$ (359.8°). The central bonds are therefore longer than expected by 0.05–0.06 Å, in spite of the apparently complete lone pair delocalization.

The paradox can be resolved if the σ-bond requirements are considered. This is not normally necessary for monocyclic derivatives because, although σ–π interaction has been recognized, the two bonding components are not mutually geometrically restrictive. In $N_7P_6Cl_9$, optimum use of both σ- and π-bonds is impossible, and the actual structure represents a compromise. The reason for the constraint can be seen if the bonds to the central atom are regarded as the equivalent of exocyclic bonds. In monocyclic derivatives, the local symmetry at phosphorus is close to C_{2v} if the two substituent groups are identical. If the σ-bonds are then formed from s–p hybrids, normalization and orthogonality require (36) that the internal and external angles 2α and 2β are related by

$$[1] \qquad C = \cot^2 \alpha + \cot^2 \beta = 1$$

Pairs of angles in phosphonitrilic derivatives often fit this relationship, values of C being for $N_3P_3Cl_6$, 1.024 (37); $N_4P_4Cl_8$ (mean), 0.955 (38); $N_5P_5Cl_{10}$ (mean), 1.011 (39). Use of d-orbitals in π-bonding need not affect the validity of this formula, so long as the electron distribution of the orbitals used is effectively spherical, but the dominant use of one d-orbital can cause the angles to vary in the same sense, rather than inversely. In $N_7P_6Cl_9$, C = 1.042 (apex), 1.112 (bridgehead), and while the angles are too small to fit the relationship accurately, they do so sufficiently closely to show the primary importance of the σ-bonds. The deviations depend on specific d-orbital interactions. Detailed consideration of the angular dependence of the overlaps of those d-orbitals which interact most strongly with the central p_π-orbital explains (1) the form and relative magnitude of the angular deviations, (2) the relative lengths of the apical and bridgehead PN ring bonds (wrongly ordered by simple "planar" m.o. theory) and (3) the relative lengths of the two types of P—Cl bond (which differ in the opposite sense to that expected on the basis of σ-hybridization).

The excessive length of the central PN bonds, crucial to the chemistry, can be interpreted with the help of a slight idealization of the real structure. The assumptions (right hand part of Fig. 5) are: symmetry C_{3v}, planarity of the central NP_3 group and the perimetric N_2P_3 segments, typically P(6)N(5)P(5)N(4)P(4), perimeter bonds of unit length, central bonds of length a. The molecular geometry is then characterized by the NPN angles $2\theta_1$ and $2\theta_3$, a PNP angle $2\theta_2$ and the dihedral angle θ_4 previously defined. The internal bond length is then

$$[2] \qquad a = (2/\sqrt{3}) \sin \theta_1 + (\sqrt{3}/3) \sin \theta_3 - \cos \theta_3 \cos \theta_4$$

It is convenient to define

$$[3] \qquad F = a - (2/\sqrt{3}) \sin \theta_1$$

a close approximation to the fractional excess bond length of central over perimeter bonds, which becomes exact for $\theta_1 = 60°$, close to the actual value. In Fig. 7, F is plotted as a function of θ_3 for typical values of θ_4. If the "pure" σ-requirement $\cot^2 \theta_3 + \cot^2 \theta_4 = 1$ is added, F is a unique function of θ_3 (dashed line), and the diagram becomes a useful basis for structural discussion. If $\theta_3 = 60°$, a normal value for the monocyclic chlorides in which the ring π-bonding is strong, a central bond length of 1.66 Å (F = 0.04) would be attained at $\theta_4 = 23°$, but only by strong violation of the σ-requirements (Fig. 7, *A*). On the other hand, if the structure is controlled entirely by the σ-bonds, the least elongation (F_{min} = 0.13) is found at $\theta_3 = 51.9°$ (*B*), an angle which corresponds to relatively weak π-bonding in the ring. The actual structure is a compromise ($\theta_4 = 49°$), but it is not accurately

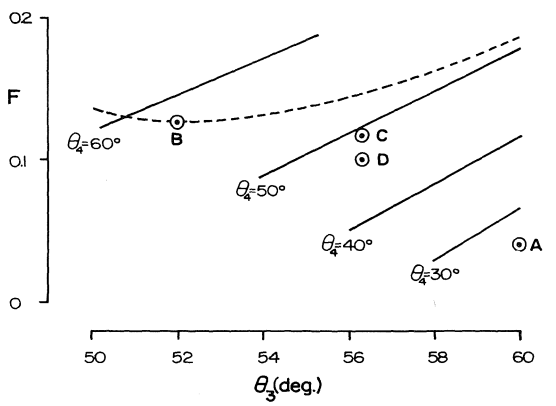

FIG. 7. Excess relative bond length F as a function of θ_3 (Fig. 5) for various θ_4. The dashed line corresponds to $\cot^2 \theta_3 + \cot^2 \theta_4 = 1$. For *A*, *B*, *C*, *D*, see text.

represented by *C*, because it does not comply with the assumptions of the model. The main inaccuracy is that the bisectors of the angles N(7)P(4)Cl(6) and N(3)P(4)N(4) are not collinear, but make a mean angle of 7.5°, in the sense that the bridgehead PN_3 groups are more nearly coplanar, and the central bonds shorter, than the σ-requirements would allow. Point *D* represents the actual values of *F* and θ_3 but not θ_4. We therefore interpret the observed fractional excess bond length of 0.1 as arising from a σ–π compromise, the bonds to the central atom being consequently strained.

It is possible to understand in this way the reduced stability of $N_7P_6Cl_9$, as compared to the monocyclic chlorides, the failure of directed syntheses from $N_6P_6Cl_{12}$, and, most important, the reactions of $N_7P_6Cl_9$ with nucleophiles. The substitution of chlorine by such electron withdrawing groups as fluorine or the methoxy-group would tend to remove electron density from the perimeter nitrogen atoms, so increasing θ_2 and θ_3 and lengthening the central bonds, and breakdown of the ring occurs with such attempted substitution. Dimethylamine would be expected to react less drastically, since the inductive effect of the nitrogen atom is offset by conjugative electron release to phosphorus. It seems most likely that the first step in the formation of $N_6P_6(NH)(NMe_2)_8Cl_2$ is the addition of Me_2NH across one central bond, sufficient strain being thereby relieved to allow normal substitution of the $P(Cl)NMe_2$ group and the remaining PCl_2 groups. If, as in phosphinate esters (40), substitution is accompanied by inversion, reaction at the bridgehead would be slow, and it is not surprising that two chlorine atoms remain.

We are grateful to the National Research Council of Canada for financial support and for an NRCC Scholarship (to R.T.O.), to Mr. P. Borda for the microanalyses, and to Dr. L. D. Hall and Mr. R. Burton for the n.m.r. spectroscopy.

Microwave Spectrum of Cyclohexene Sulfide

R. KEWLEY[1]

Department of Chemistry, Queen's University, Kingston, Ontario

Received August 15, 1972

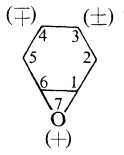
The microwave spectrum of cyclohexene sulfide (7-thiabicyclo[4,1,0]heptane) has been investigated in the 26.5–40 GHz region. R-branch lines due to both *a*- and *c*-type transitions have been assigned for the ground vibrational state and for the first excited states of the ring bending and ring twisting modes. From relative intensity measurements the frequencies of these two modes are estimated as: $\nu_{bend} = 115 \pm 20$ cm^{-1} and $\nu_{twist} = 200 \pm 60$ cm^{-1}. The rotational constants for the ground vibrational state are (in MHz): $A = 3512.086 \pm 0.010$, $B = 2057.969 \pm 0.003$, and $C = 1623.023 \pm 0.003$. These values are consistent with a twisted half chair structure for the heavy atom skeleton of cyclohexene sulfide, similar to that of cyclohexene oxide.

Le spectre en microondes du sulfure de cyclohexène (thia-7 bicyclo[4,1,0]heptane) a été examiné dans la région de 26.5 à 40 GHz. Les bandes de la branche R, causées à la fois par des transitions du type *a* et du type *c*, ont été attribuées à l'état vibrationnel fondamental et au premier état excité des modes de déformation ("bending") et de torsion ("twisting") du cycle. A partir des mesures d'intensité relative, les fréquences de ces deux modes sont évaluées comme suit: $\nu_{def} = 115 \pm 20$ cm^{-1} et $\nu_{tor} = 200 \pm 60$ cm^{-1}. Les constantes rotationnelles pour l'état vibrationnel fondamental sont (en MHz) $A = 3512.086 \pm 0.010$, $B = 2057.969 \pm 0.003$, et $C = 1623.023 \pm 0.003$. Ces valeurs sont compatibles avec une structure demi-chaise croisée pour le squelette d'atomes lourds du sulfure de cyclohexène, semblable à celui de l'oxyde de cyclohexène. [Traduit par le journal]

Can. J. Chem., **51**, 529 (1973)

Introduction

In a recent microwave study of cyclohexene oxide (1) it was found that the rotational constants and electric dipole moment components of that molecule are compatible with the twisted half chair structure determined by electron diffraction (2, 3):



where (+) and (−) designate the heavy atoms that lie above or below the $C_1C_2C_5C_6$ plane, respectively. Although the sulfur analog cyclohexene sulfide has been studied by infrared and ultraviolet spectroscopy (4, 5) and some of its sterol-like derivatives by nuclear magnetic resonance spectroscopy (6), there appears to be no structural data whatever for this molecule in the literature. It was therefore considered that a study of the rotational spectrum of cyclohexene sulfide and a comparison of the results with those for cyclohexene oxide would be of interest.

[1]On sabbatical leave 1971–1972 at Department of Chemistry, Rice University, Houston, Texas 77001.

Experimental

The cyclohexene sulfide sample was purchased from the Aldrich Chemical Company and used without further purification. It was stored at −20 °C when not in use. The rotational spectrum was observed in the 26.5–40 GHz region using a Hewlett–Packard model 8460A MRR spectrometer. Measurements were made at room temperature and at pressures in the range 5–20 μ. The frequency measurements were made with an accuracy of about ±0.05 MHz.

Results

Ground Vibrational State

The spectrum of cyclohexene sulfide is similar to that of cyclohexene oxide (1) in that the lines most easily assigned are those due to ${}^aR_{01}$ transitions originating from nearly degenerate pairs of levels J_{0J} and J_{1J}. For cyclohexene sulfide transitions of this type with $J = 7$, 8, 9, 10, and 11 fall within the 26.5–40 GHz range of the spectrometer. The interval between the transitions $10_{0,10} \rightarrow 11_{0,11}$ and $11_{0,11} \rightarrow 12_{0,12}$ gives $2C \simeq 3245$ MHz, which provides an estimate of C to within 1 MHz of the correct value, see Table 1. Other *a*-type R-branch lines were assigned, making a total of fifty-six such lines, as well as twenty-four somewhat weaker *c*-type R-branch lines with $J = 4$, 5, 6, and 7. A least squares fit, neglecting centrifugal distortion, was performed on these eighty lines of the ground vibrational

state giving the rotational constants in Table 1. The standard deviation of the least squares fit was 0.27 MHz. No lines of the ^{34}S isotopic form were assigned.

A careful search was undertaken for *b*-type R-branch lines even though, by analogy with cyclohexene oxide which has dipole moment $\mu_b = 0.18$ D, it was not expected that these lines would be strong enough to be observable. In fact no *b*-type lines were found. By comparing the noise level at the frequencies at which the transitions $8_{27} \rightarrow 9_{28}$, $8_{08} \rightarrow 9_{19}$, and $8_{18} \rightarrow 9_{09}$ were predicted to fall with the observed peak heights of the nearby a-type lines $8_{27} \rightarrow 9_{28}$, $8_{08} \rightarrow 9_{09}$, and $8_{18} \rightarrow 9_{19}$, respectively, it was concluded that $\mu_b \leq 0.15\,\mu_a$. Because of the fairly high J values involved and the weakness of the c-type transitions it was unfortunately not possible to measure the Stark shifts for more than two Stark lobes. A considerable amount of time and effort was spent in searching for other lobes. Attempts to find lobes for transitions falling below 26.5 GHz, using a conventional 100 kHz Stark modulation spectrometer, have not yet proved successful. The two measured lobes are:

[1] $7_{16} \rightarrow 8_{17}(M = 1)$ $\quad \Delta\nu/E^2 = (-2.10 \pm 0.05) \times 10^{-6}$ MHz cm^2 V^{-2}

[2] $7_{26} \rightarrow 8_{27}(M = 1)$ $\quad \Delta\nu/E^2 = (1.88 \pm 0.04) \times 10^{-6}$ MHz cm^2 V^{-2}

where $\Delta\nu$ = Stark shift.

The $\Delta\nu/E^2$ values for both lobes are very strongly dependent on the value of μ_c so that accurate determinations of μ_a and μ_b cannot be made from these data alone. However, an accurate value for μ_c can be obtained. Making the assumption that $\mu_b = 0.15\mu_a$ and then solving eqs. 1 and 2 for μ_a and μ_c yields $\mu_a = 1.92 \pm 0.40$ D, $\mu_c = 1.13 \pm 0.02$ D, and $\mu = 2.25 \pm 0.36$ D. If on the other hand μ_b is assumed to be zero, then the calculated dipole moment components are $\mu_a = 1.88 \pm 0.40$ D, $\mu_c = 1.13 \pm 0.02$ D, and $\mu = 2.19 \pm 0.36$ D. These values are based on $\mu_{OCS} = 0.7152$ D (7). Although the total dipole moment has large error limits, it is in quite good agreement with the solution dipole moment of cyclohexene sulfide (in CCl_4), which is 2.13 D (8). The same investigator also determined the (CCl_4 solution) dipole moment of cyclohexene oxide as 2.08 D, which is above the gas phase value of 1.91 D (1). Also the gas phase dipole moments of ethylene oxide and ethylene sulfide are, respectively, 2.00 and 1.84 D (9). This indicates that the gas phase dipole moment of cyclohexene sulfide is in the range 1.75–2.05 D and that the value of about 2.2 D in the present work is likely to be high. The μ_c component of 1.13 ± 0.02 D in cyclohexene sulfide is lower than that of cyclohexene oxide, 1.52 D, primarily because the *c*-axis makes a larger angle with the CSC angle bisector in the episulfide as compared with the angle made with the COC angle bisector in the epoxide. The increase in mass from oxygen to sulfur causes this effect.

Excited Vibrational States

In addition to the absorption lines of the ground vibrational state two sets of vibrational satellite transitions have been assigned. Intensities relative to the ground state were measured for thirteen transitions of one satellite set, yielding a vibrational frequency of 115 ± 20 cm^{-1}. Twelve

relative intensity measurements for the other weaker satellite set gave a frequency of 200 ± 65 cm^{-1}. As was the case for cyclohexene oxide the lower of the two frequencies may be attributed to the bending of the six-membered ring (about the direction C_2C_5, approximately) and the higher frequency to the twisting motion involving mainly C_3 and C_4. The corresponding frequencies for cyclohexene oxide are 156 cm^{-1} (bending) and 280 cm^{-1} (twisting) (1). The frequencies of fifty-nine rotational transitions for the first excited state of the bending mode and of fifty-five transitions of the first excited state of the twisting mode were measured. The rotational constants are given in Table 1. The standard deviations of the least squares fits were 0.35 MHz (bending mode, $v_{bend} = 1$) and 0.34 MHz (twisting mode, $v_{twist} = 1$).

Molecular Structure

As in the case of cyclohexene oxide the three measured rotational constants for the ground vibrational state of cyclohexene sulfide are insufficient to define a precise molecular structure. However, it is again possible to carry out a calculation based on reasonable assumptions for the other structural parameters in order to estimate the ring bending and twisting angles. Before doing so it may be noted that the planar moment of inertia $\sum_i m_i b_i^2 = 1/2(I_a + I_c - I_b)$ would be expected to remain about the same on going from cyclohexene oxide to cyclohexene sulfide provided that the structures are similar. The O or S atom should be very near the *a*–*c* plane. Also the C—C and C—H distances and the HCH and HCC bond angles do not change significantly between ethylene oxide and ethylene sulfide (9). Calculating from the observed moments of inertia it is found that $\sum_i m_i b_i^2 = 104.853$ a.m.u. Å^2 for cyclohexene sulfide and 104.940 a.m.u. Å^2 for cyclohexene oxide. These values give some support to the conclusion that the replacement of the oxygen atom of cyclohexene oxide by sulfur does not have a drastic effect on the rest of the structure. Therefore the procedure adopted below consists of assuming that the parameters of the epithio section are identical with those of ethylene sulfide while the other parameters are essentially the same as those assumed for cyclohexene oxide (1). The assumed $\angle C_6C_1C_2$ and the other CCC bond angles differ very slightly from the assumed cyclohexene oxide values because of the slightly different C_1C_6 distance. The angle between the H_1C_1 direction and the $C_1C_2C_5C_6$ plane in cyclohexene sulfide is assumed equal to the angle between the $H_{11}C_1$ direction and the $C_1H_{12}H_{22}C_2$ plane in ethylene sulfide (9) (Table 2).

TABLE 2. Initially assumed structure of cyclohexene sulfide*

Bond	Distance (Å)	Bonds†	Angles (deg)
C_1C_6	1.492	C_1SC_6	65.8
C_1S	1.819	$C_6C_1C_2$	121.7
C_1C_2	1.53	$C_1C_6C_5$	121.7
C_5C_6	1.53	$H_1C_1C_2$	116.8
C_2C_3	1.53	$H_6C_6C_5$	116.8
C_4C_5	1.53	All HCH	109.5
C_3C_4	1.53		
All CH	1.09		

*See Fig. 1.
†$\angle C_1C_2C_3 = \angle C_6C_5C_4$; $\angle C_2C_3C_4 = \angle C_5C_4C_3$. ∠HCH and ∠CCC have a common bisector at C_2, C_3, C_4, and C_5.

In addition there are the three ring angle parameters: the ring fusion angle θ, the twisting angle τ and the bending angle β, see Fig. 1. For cyclohexene oxide it was found that only for β close to zero could the residuals ($A_{obsd} - A_{calcd}$, etc.), in the least squares fit to the observed rotational constants, become very nearly zero. Starting from the cyclohexene sulfide structure assumed above, it is found that the residuals

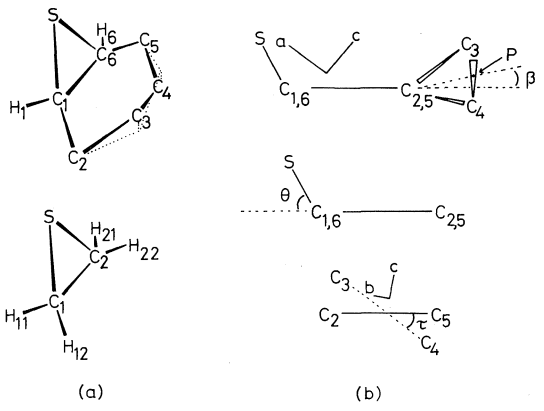

FIG. 1. (*a*) Structures of ethylene sulfide and cyclohexene sulfide. In the cyclohexene sulfide structure the hydrogen atoms attached to C_3, C_4, C_5, and C_6 have been omitted for clarity. (*b*) Definitions of the angles β (bending angle), θ (ring fusion angle), and τ (twisting angle). The point P is midway between carbon atoms C_3 and C_4. The approximate positions at the principal *a*, *b*, and *c* inertia axes are also indicated.

reach their minimum value (all less than 0.05 MHz) at $\beta = 25.7°$, $\theta = 57.2°$, and $\tau = 33.8°$. It does not seem reasonable that β should differ by as much as 25° between the two molecules. It was noticed that the value of β for minimized residuals was very sensitive to the initially assumed value of $\angle C_6C_1C_2$, which also determines the other CCC angles. A decrease of 1.1° in the value of this angle gives $\beta = 0°$, $\theta = 71.5°$ and $\tau = 27.6°$ for minimized residuals, all less than 0.05 MHz. These values appear to be quite reasonable when compared to the corresponding ones $\beta = 0°$, $\theta = 68.4°$, and $\tau = 34.4°$ obtained for cyclohexene oxide, with $\angle C_6C_1C_2 = 122°$ assumed. It should be borne in mind that these angles, for each molecule, do not represent a unique solution for the structure and that other values could be arrived at by varying $\angle C_6C_1C_2$ or the other assumed parameters.

Heterogeneous Interactions of Methylamines on Porous Adsorbents. Part III. The Adsorption Characteristics of Methylamines on γ-alumina and Types '3A' and '13X' 'Molecular Sieves'

WALTER GEORGE COOK AND ROBERT ANDERSON ROSS
Department of Chemistry, Lakehead University, Thunder Bay, Ontario
Received September 6, 1972

The adsorption characteristics of mono-, di-, and trimethylamine on γ-alumina have been investigated and adsorption isotherms in the regions of their boiling points determined, along with isothermal calorimetric heats of adsorption up to monolayer coverage ($\theta = 1$). From the initial heats of adsorption of 21.6 to 32.4 kcal/mol at $\theta = 0.05$, and the strong retention of the amines adsorbed at low pressures, chemisorption is considered to occur at $\theta < 0.20$. The maxima and minima displayed in the heat curves are discussed in terms of adsorbate–adsorbate interactions at sub-monolayer coverage levels. Adsorption isotherms for di- and tri-methylamine on Linde 'molecular sieves' '13X' and '3A' have been measured also, along with the trimethylamine heat curves for these materials.

Les caractéristiques d'adsorption des mono-, di-, et tri-méthylamines sur de l'alumine-γ ont été étudiées de même que les isothermes d'adsorption dans la région de leur point d'ébullition ont été déterminés en même temps que les chaleurs calorimétriques isothermales d'adsorption jusqu'à un recouvrement correspondant à une couche monomoléculaire ($\theta = 1$). A partir des chaleurs initiales d'adsorption qui correspondent à 21.6 jusqu'à 32.4 kcal/mol à $\theta = 0.05$, et de la rétention forte des amines adsorbées à basse pression, la chemisorption est prévisible pour des valeurs de $\theta < 0.20$. Les maxima et les minima observés dans les courbes de chaleur sont expliqués en terme d'interactions produit adsorbé – produit adsorbé à des niveaux de recouvrement inférieurs à la couche monomoléculaire. Les isothermes d'adsorption pour les di-, et tri-méthylamines sur de la sève moléculaire du type Linde '13X' et '3A', ont aussi été mesurés en même temps que les courbes de chaleur de la tri-méthylamine pour ces produits.

Introduction

In Parts I and II studies of the interactions of mono-, di-, and trimethylamine on silica gel and silica–alumina were reported (1, 2). The shapes of the heat curves obtained for the adsorption of these species on both materials were of particular interest as in many cases well-defined maxima and minima were observed. These phenomena were considered to arise mainly through adsorbate–adsorbate interactions. To obtain further information on the adsorption properties of the amines the work has been extended to include a study of their adsorption characteristics on γ-alumina and two types of synthetic zeolites, namely, Linde molecular sieves, '13X' and '3A'.

Experimental

The techniques of measurement, sorption balance, and calorimetry have been described (3, 4) and the physical properties of the γ-alumina adsorbent determined. Data supplied with the γ-alumina (Peter Spence and Sons Ltd.) stated it to be an aluminum trihydroxide with an X-ray structure showing 97% Gibbsite and 3% Bayerite, particle size 20 to 600 μ, and BET surface area 400 m^2/g after heat treatment at 420 °C. 'Molecular sieve' pellets were obtained from Union Carbide Corporation. A crystalline potassium aluminosilicate, type 3A, and a crystalline sodium alumino-silicate, type 13X, were used.

The purification procedures used for the amine adsorbates have been specified (1, 2).

Results

γ-*Alumina*

In all experiments alumina samples were activated at 420 °C for 3 h in air and then outgassed at 90 °C for 1 h under a vacuum of 10^{-5} Torr in the adsorption apparatus before use.

The complete adsorption–desorption isotherm for monomethylamine on γ-alumina at 266 °K is shown in Fig. 1, curve *B*. Equilibrium times were 45 min up to $p/p_0 = 0.50$ and 4 h above this pressure. The heat curve for monomethylamine adsorption on γ-alumina at 266 °K is shown in Fig. 3, curve *B*.

Figure 1 curve *A* shows the adsorption–desorption isotherm determined for dimethylamine on γ-alumina at 280 °K and Fig. 3 shows the heat curve *C* for this system. The corresponding data

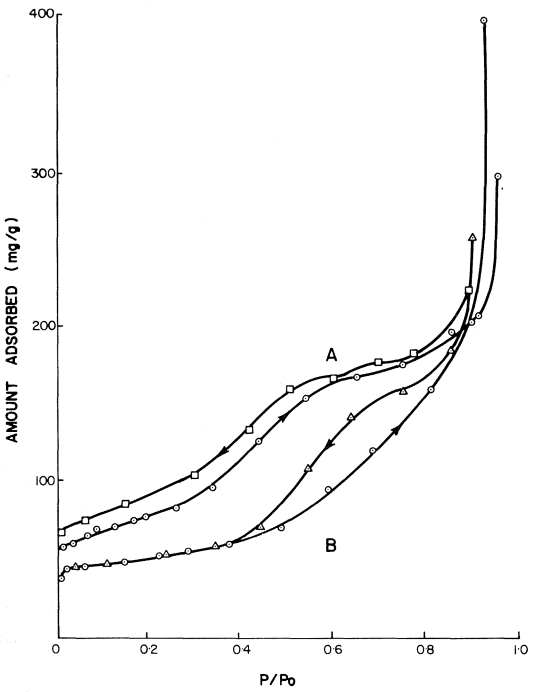

FIG. 1. Adsorption–desorption isotherms for *A*, dimethylamine at 280 °K and *B*, monomethylamine at 266 °K on γ-alumina.

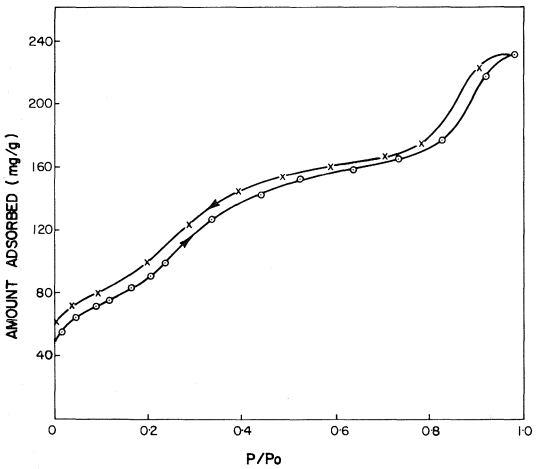

FIG. 2. Adsorption–desorption isotherm for trimethylamine at 276 °K on γ-alumina.

for trimethylamine adsorption at 276 °K are shown in Figs. 2 and 3, curves *A*.

The monolayer coverage values for mono-, di-, and tri-methylamine on γ-alumina were determined from BET plots to be 40.7, 65.0, and 72.7 mg/g, respectively, at the isotherm temperatures shown.

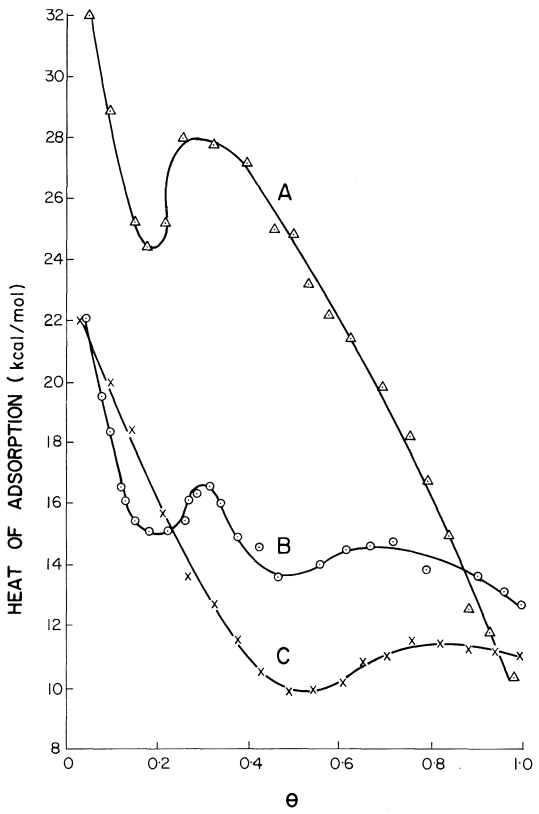

FIG. 3. Variation of isothermal calorimetric heats of adsorption with θ (fraction of surface covered) for *A*, trimethylamine at 276 °K, *B*, monomethylamine at 266 °K and *C*, dimethylamine at 280 °K on γ-alumina.

'*Molecular Sieves*'

The adsorption isotherms determined for dimethylamine adsorption on 'molecular sieves' '3A' and '13X' at 280 °K are shown in Figs. 4 and 5, curves *A*. Both materials had been activated in air at 316 °C (5) for 3 h and outgassed at 90 °C under a vacuum of 10^{-5} Torr for 1 h. In experiments with the '3A' 'molecular sieve', equilibrium was taken to be established when no measurable adsorption was detected over a 1 h period. This basis was used as an arbitrary standard since only on prolonged exposure of the 'molecular sieve' to the amine for 24 h was a further small uptake observed. The experimental error involved by adopting this procedure was estimated to be less than 0.5%. Equilibrium times for the '13X' molecular sieve' were 30 min below $p/p_0 = 0.90$ and 60 min at the highest pressures. Desorption times were consistently 60 min over the entire pressure range.

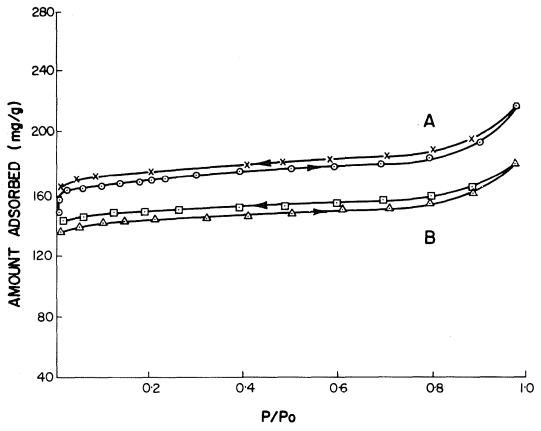

FIG. 4. Adsorption–desorption isotherms for *A*, dimethylamine at 280 °K and *B*, trimethylamine at 276 °K on 'molecular sieve' '13X'.

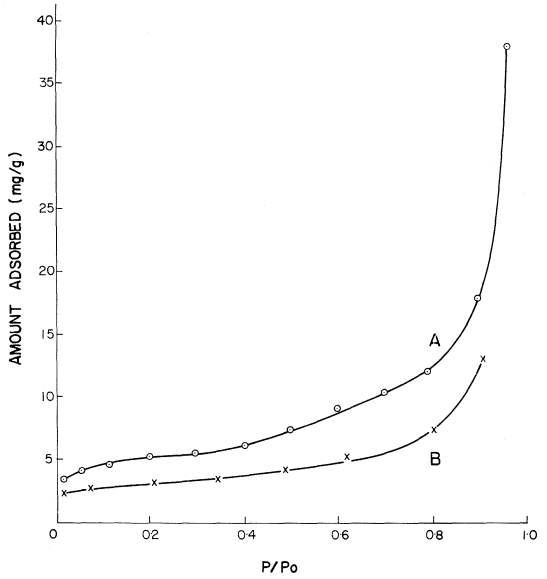

FIG. 5. Adsorption isotherms for *A*, dimethylamine at 280 °K and *B*, trimethylamine at 276 °K on 'molecular sieve' '3A'.

Trimethylamine adsorption isotherms at 276 °K on 'molecular sieves' '13X' and '3A', (Figs. 4 and 5), were of the same general form as the corresponding dimethylamine isotherms. The heat curves for trimethylamine on these materials are shown in Fig. 6.

Discussion

The adsorption of all amines on γ-alumina was initially strong, particularly in the region $p/p_0 < 0.02$. Samples of alumina equilibrated at 266

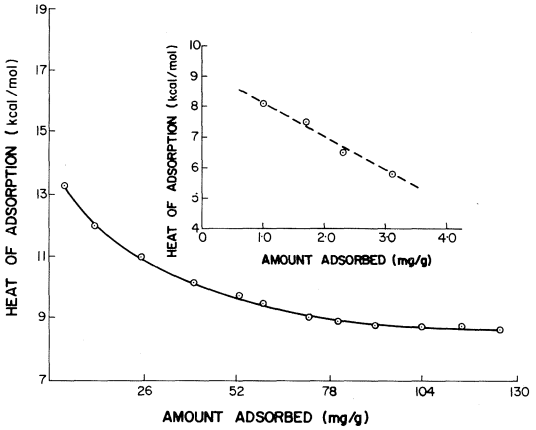

FIG. 6. Variation of isothermal calorimetric heats of adsorption with amount adsorbed for trimethylamine at 280 °K on 'molecular sieve' '13X' and 'molecular sieve' '3A' (inset).

°K in mono-methylamine vapor, $p/p_0 = 0.90$, when evacuated to 10^{-5} Torr for 1 h at this temperature retained 22.7 mg/g of the amine which corresponds to 55.7% of the monolayer coverage amount. On raising the temperature to 353 °K, the alumina still held 9.3% of the monolayer amount after being evacuated to 10^{-5} Torr for 1 h. This region of surface coverage therefore, is considered to involve strong adsorption which may involve chemisorption (6).

The adsorption isotherms of the amines on alumina show marked increases in the amounts adsorbed, after monolayer completion, beginning at $p/p_0 = 0.50$, 0.30 and 0.25 for mono-, di-, and trimethylamine, respectively. With mono- and dimethylamine, the amount adsorbed increased asymptotically above $p/p_0 = 0.90$ while trimethylamine adsorption showed a sharp increase between $p/p_0 = 0.83$ and 0.99. These effects are probably linked to the distribution of pore sizes of this adsorbent, which were determined (7) from low temperature nitrogen isotherms by the method of Cranston and Inkley (8), and which range from 20 to 300 Å in diameter with maxima occurring at 30 and 230 Å. The very steep increase in adsorption found for mono- and dimethylamine may be due to condensation of these adsorbates in the 230 Å diameter pores of the alumina. An analogous effect has been reported for the adsorption of methylamines on a "macroporous" silica gel which also showed a maximum in its pore size distribution in the range 200 to 230 Å diameter (1, 2).

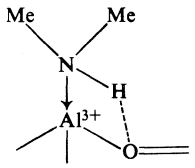
The initially-high heats of adsorption of the amines on alumina, Fig. 3, are compatible with the suggestion that chemisorption is involved at low surface coverages, $\theta < 0.2$. These heats, from 21.6 to 32.4 kcal/mol, probably arise through a chemisorptive process which may involve donation of the lone pair electrons of the amine nitrogen atom to empty sp^3 hybrid orbitals of surface aluminum ions (9). In this connection it is worth noting that nuclear magnetic resonance studies of the adsorption of monomethylamine on γ-alumina indicate that the hydrogens of the amino group are more restricted than the methyl hydrogens (10). Other modes of adsorption have been suggested for ammonia on γ-alumina, including adsorption on surface oxygen species with the formation of amide ions (11), and also adsorption through coordination of the nitrogen atom to a surface aluminum ion with concurrent hydrogen bonding to surface oxide ions (11). The absence of strong Brϕnsted acidity on alumina has been deduced from both pyridine (12) and ammonia adsorption studies (11). Thus the adsorption of methylamines may not only involve interaction between amine–nitrogen electrons and surface aluminum ions but also simultaneous hydrogen bonding of amino hydrogens to surface oxide species. Thus for dimethylamine



amine adsorption through interactions with surface hydroxyl groups and oxide ions may also occur.

The heats of adsorption on alumina for monomethylamine (Fig. 3, curve *B*) and trimethylamine (Fig. 3, curve *A*) fall to a minimum at $\theta = 0.20$ and 0.17, respectively, and then rise to a maximum at $\theta = 0.30$ and 0.28, respectively. The magnitude of these rises was 1.5 kcal/mol for monomethylamine and 3.6 kcal/mol for trimethylamine. This effect may result from lateral interactions between amine molecules which have been adsorbed at pressures corresponding to the minimum value of the heat curve in close proximity to amine molecules adsorbed earlier. Similar increases in the heat of adsorption to those displayed at low surface coverages with mono- and trimethylamine have been reported for ammonia adsorption on alumina (13).

The dimethylamine heats of adsorption on alumina do not show the rise which might be expected by analogy to occur at approximately $\theta = 0.29$. However, a noticeable similarity between the heat curves for mono- and dimethylamine is the occurrence of the minimum at $\theta = 0.50$ and 0.48, respectively. This fraction of monolayer coverage may correspond to the occupation of the "most active" adsorption sites by these adsorbates. Following these minima both curves show a gradual rise to a maximum at $\theta = 0.70$ and 0.81 and then a slight decrease to monolayer coverage. The increase in the heat of adsorption in this region is probably due to van der Waals interactions (14) amongst the adsorbed molecules while the subsequent decrease may occur as a result of repulsion between the partially-formed layer of polarized adsorbed molecules and molecules adsorbing subsequently in close proximity as the monolayer nears completion.

After the maximum shown at about $\theta = 0.28$ in the heat of adsorption of trimethylamine on alumina (Fig. 3), the heat evolved falls almost linearly from 28.0 to 9.9 kcal/mol at monolayer completion. The absence of a minimum at approximately $\theta = 0.5$ in this curve is difficult to explain but it may be that the large trimethylamine molecule, cross-sectional area about 30 $Å^2$ (1, 2), interacts with closely-adsorbed molecules over the entire range of surface coverage from from $\theta = 0.30$ to monolayer completion. This suggestion does not exclude any decrease in the heat of adsorption which would be expected to occur through surface heterogeneity.

The adsorption isotherms of di- and trimethylamine on 'molecular sieve' '13X', Fig. 4, are of the Langmuirian type. The effective pore diameter of this material is 10 Å (5) and these isotherms indicate that the internal cavities are almost filled by the amines at $p/p_0 = 0.01$ with little increase in adsorption below $p/p_0 = 0.70$. Between these pressures, the increase in amount adsorbed for dimethylamine was 17.0 and 13.0 mg/g for trimethylamine. Above $p/p_0 = 0.70$ both isotherms showed a considerably greater increase in the adsorbed amount, 37.0 mg/g for dimethylamine and 27.0 mg/g for trimethylamine while hysteresis occurred on desorption of both adsorbates over the entire pressure range.

In order to determine if the increased adsorption of di- and trimethylamine on 'molecular sieve' '13X' above $p/p_0 = 0.70$ could be explained by adsorption in surface discontinuities in the

pellets of the material, corresponding isotherms were determined on 'molecular sieve' '3A'. Since the effective pore diameter of this zeolite is 3 Å (5), the adsorption of di- and trimethylamine would be limited to the external surface. In both isotherms, Fig. 5, a distinct rise in the amount adsorbed took place at high pressures which seems to confirm that the final increase in adsorption on both molecular sieves did arise through intercalation and condensation of the adsorbates in the fissures and cracks in the surfaces of the pellets.

The heat of adsorption of trimethylamine on 'molecular sieve' '13X' is shown in Fig. 6. The curve falls smoothly from 13.3 kcal/mol at 5.2 mg/g adsorbed to 8.8 kcal/mol at 91.0 mg/g adsorbed and then remains constant. (It should be noted that the heats of adsorption for the 'molecular sieves' have been plotted against the amount of amine adsorbed since the basic assumptions of surface area determination do not hold for these materials (15).) A similarly-shaped heat of adsorption curve has been reported (16) for ammonia adsorption on synthetic Na faujasite. The '13X' 'molecular sieve' does not appear to contain any strong acidic adsorption sites as the initial heat evolved on trimethylamine adsorption is much lower than that observed with trimethylamine adsorption on alumina, silica–alumina or silica gel. The heats evolved on these materials were 32.4, 21.4, and 21.0 kcal/mol, respectively, at $\theta = 0.05$ (2). The fact that no irregularities are displayed in the '13X' heat curve may imply that a degree of surface heterogeniety is a factor in giving rise to increases in the heat of adsorption at low surface coverages on γ-alumina and the other siliceous adsorbents.

An attempt was made to estimate the heat evolved on trimethylamine adsorption on 'molecular sieve' '3A', Fig. 6 (inset). Extrapolation of the dotted line in this Figure gives a value of approximately 9.5 kcal/mol for initial adsorption compared with 14.0 kcal/mol for 'molecular sieve' '13X'.

Studies of Oxygen Exchange Between Trivalent Lanthanide – EDTA Complexes and Solvent Water: Evidence for a Structural Change Within the Series

R. H. Betts and R. H. Voss[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 30, 1972

Oxygen-18 labelled EDTA, dissolved in normal water, has been used to examine the kinetics of oxygen transfer between the solvent and a variety of metal–EDTA complexes, including most of the lanthanides, Ca and Th. The lability of the oxygens is profoundly affected by the ionic charge of the metal in the chelate. Thus oxygen exchange in the Th–EDTA–H_2O system shows a half-life of 10 min at 100 °C, while for comparable conditions, Ca–EDTA–H_2O shows a half-life in excess of 100 days. The lanthanides as a group show behavior intermediate between these extremes. Within the latter group the lability varies systematically with atomic number, Pr–EDTA (element 59) being the most reactive and Yb–EDTA (element 70) the least reactive. The maximum variation across the group is about 10-fold. Interpretation of these results is presented in terms of the polarizing effect of the metal ion on the electron density at the acetate groups. The variation in lability within the lanthanide group can be accounted for quantitatively by changes in coordination number of the central metal ion.

De l'EDTA marqué par de l'oxygène-18, dissous dans l'eau normale, a été utilisé pour examiner la cinétique du transfert d'oxygène entre le solvant et une série de complexes métal–EDTA, conprenant la plupart des lanthanides, Ca et Th. La labilité des oxygènes est profondément affectée par la charge ionique du métal dans le chélate. Par suite l'échange de l'oxygène dans le système Th–EDTA–H_2O possède une demi-vie de 10 min à 100 °C, alors que dans des conditions comparables, Ca–EDTA–H_2O possède une demi-vie supérieure à 100 jours. Les lanthanides, comme un groupe, possèdent un comportement intermédiaire entre ces 2 extrêmes. A l'intérieur de ce dernier groupe, la labilité varie systématiquement avec le numéro atomique, Pr–EDTA (élément no. 59) étant le plus réactif et Yb–EDTA (élément no. 70) le moins réactif. La variation maximum à travers le groupe se situe dans un intervalle de 10 environ. L'interprétation de ces résultats est présenté en terme d'effet polarisant de l'ion métallique sur la densité électrique des groupes acétales. La variation dans la labilité à l'intérieur du groupe des lanthanides peut être expliqué quantitativement par des changements dans le nombre de coordination de l'ion métallique central.

Can. J. Chem., **51**, 538 (1973)

Introduction

In recent years increasing emphasis has been placed on the study of the types of reaction undergone by coordinated ligands as opposed to the study of the behavior of the coordinated metal ions (1–3). A familiar example of this type of study is the metal ion catalyzed hydrolysis of amino acid esters (eq. 1) discovered by Kroll in 1951 (4). The most immediate consequence of ligand coordination is an electronic polarization of the substrate which facilitates the breaking of a bond or attack by a nucleophile. In this respect, the metal ion catalyst functions as a Lewis acid withdrawing electrons from the reaction center. The proton acts similarly in the corresponding acid-catalyzed reaction. However, unlike the hydrogen ion, metal ions may operate in neutral or weakly basic solution (thus the hydrolysis of

[1] 
amino acid esters complexed with Co^{2+}, Cu^{2+}, Mn^{2+}, Ca^{2+}, and Mg^{2+} ions is extremely rapid even at p*H* 7–8 where the amino acid ester itself is stable (4)).

If the stability constant may be regarded as a measure of the ability of the metal ion to accept electrons, then in the cases where the acidity of the central ion is of importance in catalysis, one might expect to find a correlation between com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

plex stability and catalytic power. Such a relationship is indeed frequently found in nonenzymatic reactions. Kroll (4), for example, established a correspondence between the catalytic effect of the metal ions and their increasing tendency to enter into complex formation. More relevant to the present study is the observation that in the lanthanide ion catalyzed decarboxylation of oxaloacetic acid, a correlation was established between the catalytic effect of the lanthanide ion and the stability of the chelate compounds of the lanthanide oxaloacetates (5).

The present work relates to the effect of complexation of a carboxylate on the lability of its oxygen atoms with respect to exchange with water, and in particular the lanthanide (Ln)–EDTA complexes (EDTA represents ethylenediaminetetraacetic acid). The filling of the 4f subshell of the lanthanides is accompanied by a decrease of the ionic radius ("lanthanide contraction") in a regular fashion from La^{3+} (1.16 Å) to Lu^{3+} (0.93 Å) (6). Another important property of the lanthanides is that their bonding with ligands is considered to be predominantly electrostatic (7–9) largely due to the identical noble gas configurations of their outer electronic shells.

The stability constants for complexation with EDTA in aqueous solution (reaction 2) are fairly

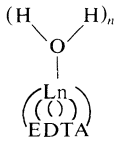
[2] $Ln^{3+}(OH_2)_m + EDTA^{4-} \rightarrow Ln(EDTA)(OH_2)_n^- + (m - n)H_2O$

sizeable; log K values range from 15.50 for La^{3+} to 19.83 for Lu^{3+} (10) (increasing in a regular manner as the ionic size decreases).

Inasmuch as the interaction of the Ln^{3+} ions with ligands is largely electrostatic, these ions are particularly suitable for a study of the influence of the size of the central ion on its behavior in chelate formation.

Choppin has pointed out in a recent review (7) that the nature of the lanthanide complex species present in aqueous solution is still uncertain. However, ample evidence now exists (7–9) to support the view that the coordination number (C.N.) of the lanthanides is greater than six and probably 8, 9, or 10; so that even the Ln–EDTA complexes are expected to be still partially hydrated in aqueous solution.

Hoard *et al.* (11) found from crystal structure determinations of some hydrated salts that La^{3+} is coordinated to one EDTA molecule and three water molecules (giving a net coordination number (C.N.) of 9); the entire arrangement is approximately that of two hemispheres, one containing the 3 water molecules and the other, the 6 ethylenediaminetetraacetate donor sites. Such work appears to be the most convincing evidence for an expanded C.N. for the lanthanides, and if we assume that a high C.N. is preserved in aqueous solution, then a reasonable representation of the Ln–EDTA complexes is:



EDTA utilizes all six of its donor atoms and, in addition, there are n water molecules within the primary coordination sphere giving a net C.N. of $(6 + n)$.

Various authors have expressed the opinion that owing to the "lanthanide contraction" partially hydrated complexes (12–14) and in particular the EDTA complexes (11, 15–17) are expected to undergo a change in coordination number somewhere in the middle of the lanthanide series. Such a change is also considered to be revealed in the irregular progression of the enthalpy (ΔH) and entropy (ΔS, see Fig. 1) changes associated with the complex formation reaction (eq. 2) (11, 15–17). The explanation offered proceeds somewhat as follows. As the radius of the Ln^{3+} ion decreases from La^{3+} to Lu^{3+} (and the polarizing ability of the ion increases) EDTA can reach further around the cation. The ultimate effect of this shrinkage of the "ligand envelope" is the ejection of another water molecule from the coordination sphere occurring within the series between Sm and Tb. Because of the additional release of water, the formation of the complex containing one water molecule less $Ln(EDTA)(H_2O)_{n-1}^-$ is entropically favored, and the observed entropy increase (Fig. 1) can be explained. In the region between Sm and Tb an equilibrium is proposed (17) between two types of EDTA complexes differing in their degree of hydration which in the series

[3] $Ln(EDTA)(OH_2)_n^- \rightleftharpoons Ln(EDTA)(OH_2)_{n-1}^- + H_2O$

$$K_s = \frac{[Ln(EDTA)(OH_2)_{n-1}^-]}{[Ln(EDTA)(OH_2)_n^-]}$$

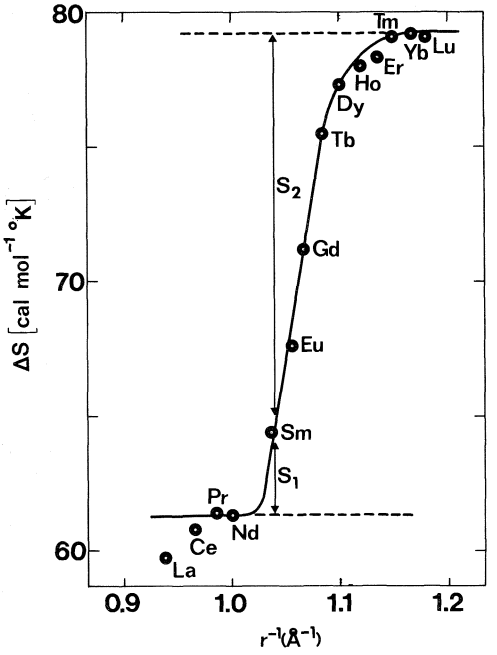


FIG. 1. Entropy change, ΔS, for Ln–EDTA complex formation reaction (eq. 2); for $\mu = 0.1$ *M*, 20 °C (33).

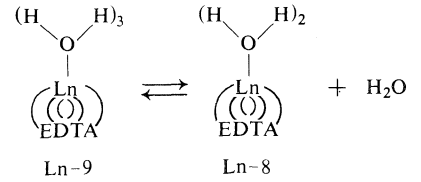
Sm, Eu, Gd, and Tb is gradually shifted towards the right. Geier and Karlen (17) were able to attach some quantitative significance to the above interpretation by evaluating the equilibrium constants for reaction 3. The relative amounts of the two complexes and therefore $K_s(= S_1/S_2)$ were determined from the distances S_1 and S_2 as indicated for Sm in Fig. 1. Additional evidence for the existence of an equilibrium such as [3] has been obtained at least for the europium complex from spectrophotometric (18–20) and polarographic studies (21) of aqueous solutions of the Eu–EDTA complex. The equilibrium constants, K_s, evaluated from spectrophotometric studies (18–20) were in good agreement with the values derived from thermodynamic data (17).

As regards the aquo ions, conflicting opinions have arisen. One group maintains that the C.N. of the aquo ions also changes across the series (7, 11, 22, 23) and is probably 9 for the ions from La^{3+} to Nd^{3+}, 8 for the ions from Tb^{3+} to Lu^{3+}, with the intermediate ions Sm^{3+}, Er^{3+}, and Gd^{3+} being mixtures of both types. Spedding's interpretation (22) is based on the observation that the apparent molal volumes of the Ln^{3+} ions show a non-monotonic development (becoming smaller from La to Nd, becoming larger from Nd to Tb, and then decreasing once more from Tb to Yb). On the other hand, Geier *et al.* (17–19) and Anderegg (14) are not convinced that the C.N. of the aquo ions changes. Geier considers it probable that the C.N. is 9, corresponding to a trigonal prismatic structure as found from an X-ray crystallographic study by Helmholz (24) for the $Nd(OH_2)_9^{3+}$ grouping in the solid compound $Nd(BrO_3)_3 \cdot 9H_2O$.

On the basis of (*a*) their interpretation of the thermodynamic data for EDTA complexation (as described earlier) and (*b*) the assumption that the C.N. of all the aquo lanthanide ions was constant across the series and equal to 9 (that is, $m = 9$ in eq. 2 and $n = 3$ in eq. 3), Geier and Karlen (17) investigated the thermodynamics for mixed complex formation (that is, the formation of complexes Ln(EDTA) (L) $(OH_2)_x$ where L = anions of OXS, IDA or NTA)[2] and found their data to be compatible with their original hypotheses (*a*) and (*b*). The two types of complexes in equilibrium [3] can then be represented schematically as follows



A recent study by Grenthe and Ots (25) on the lanthanide diglycolate complexes provides new evidence in support of Geier's proposed hydration equilibria [3]. A maximum in the plot of the heat capacity change (ΔC_{p_2}) for the formation of the 1:2 Ln–diglycolate complexes *vs.* atomic number was interpreted as due to the presence of hydration equilibria which (according to an expected similarity in the geometry of the Ln–EDTA complex (11) and the complex formed by the coordination of two (terdentate) diglycolate ligands to the Ln^{3+} ions) are expected to be similar to those proposed by Geier (17) for the EDTA complexes [3]. In addition, measured ΔC_p values for the corresponding EDTA complex formation (25) support Geier's claims of hydration equilibria existing among some lanthanide complexes in the middle of the series.

[2]OXS = 8-hydroxyquinoline-5-sulfonic acid, IDA = iminodiacetic acid, and NTA = nitrilotriacetic acid.

The studies of Geier and Karlen (17), Spedding *et al.* (22), Graffeo and Bear (23), and Grenthe and Ots (25) also serve to illustrate a favorite relationship employed by researchers in the field of lanthanide complexation, namely, that between some property of the individual complexes (*e.g.*, an apparent molal volume (22), enthalpy (ΔH) or entropy (ΔS) change for complex formation (17), rate constant for complex formation (23), heat capacity change (ΔC_p) for complex formation (25), or some other parameter) and the reciprocal of the cationic radius (or in some cases the atomic number). The point of view most often advanced by these (and other) researchers in the interpretation of their data is that a change in the continuity of a property as the ionic size decreases (or atomic number increases) is considered to be evidence for a change in the C.N. of the lanthanide ion. (This "discontinuity principle" has been explicitly stated by Karraker (8) and Anderegg (14)).

There is clearly a two-fold interest in examining the rate of oxygen exchange for the Ln–EDTA complexes. Such a study might provide evidence for metal ion promotion of oxygen exchange between a carboxylate group and water. In addition, an examination of the effect of the size of the Ln^{3+} ion on the rate of oxygen exchange (R) may be expected to provide further clues about variations in the structure of the group as a whole.

Experimental

Materials

Stock solutions ($\simeq$0.01 M) of the lanthanide nitrates were prepared by dissolving the respective oxides (99.99% purity; American Potash and Chemical Corp.) in a slight excess of nitric acid. The solution concentrations were determined by back titration of excess EDTA with a standard copper nitrate solution; the end point being determined potentiometrically using a mercury indicator electrode (26). Chloroacetic acid enriched in ^{18}O was prepared by dissolving 12 g of $ClCH_2COOH$ (Fisher Certified) in 36 ml of water enriched to about 1.6 atom % in ^{18}O (YEDA Research and Development Co. Ltd.) and equilibrating at 50 °C for 4–5 days. Labelled EDTA was prepared by condensation of the labelled chloroacetic acid with ethylenediamine (27). The ^{18}O-enriched EDTA (*ca.* 1.5 atom % ^{18}O as compared with *ca.* 0.2 % for natural abundance) was purified by dissolving the material in NaOH and reprecipitating it with HCl. The product was dried for several hours at 110 °C.

Sample Preparation and Isotopic Analysis

The experimental determination of the rate of oxygen exchange between Ln–EDTA complexes and solvent water involved adding weighed samples of ^{18}O-enriched EDTA to the various Ln nitrate stock solutions to give a solution $\simeq$0.01 M in the corresponding Ln–EDTA complex (generally $\simeq$5% excess of Ln^{3+} was added to ensure that the EDTA was completely complexed). For each individual run, the pH was adjusted, and six 3-ml aliquots were sealed in glass ampoules and placed in an oil bath thermostated at 104 °C. The ampoules were withdrawn at timed intervals and cooled rapidly in liquid air to "stop" the exchange reaction. To follow the progress of the exchange reaction, it was necessary to separate the EDTA from solution and analyze for its ^{18}O content. After addition of concentrated $HClO_4$ to give a medium *ca.* 1 M in acid, the separation was accomplished by passing each aliquot (generally six per run) through a cation exchange resin (Dowex AG 50 W-X8, hydrogen form). The Ln^{3+} cations were retained on the resin column and the effluent containing "free" (or uncomplexed) EDTA was brought to p$H \simeq 5$ (blue to bromocresol green indicator) by the addition of a dilute NaOH solution. (Exchange induced during this separation procedure was negligible since at room temperature and under drastic conditions ($\simeq$4 M $HClO_4$) the half-life of exchange for "free" EDTA was found to be of the order of 2 days). Approximately 1.5 ml of 0.5 M $AgNO_3$ solution was added, and the precipitate of Ag(I)–EDTA was filtered, washed with acetone, and vacuum dried. The silver salt was then pyrolyzed at 150 °C for ~5 min to give CO_2, which was collected and analyzed on a Varian-Mat GD 150 mass spectrometer for the 46/(44 + 45), ratio, $R(^{12}C^{16}O^{18}O/(^{12}C^{16}O^{16}O + {}^{13}C^{16}O^{16}O + {}^{12}C^{16}O^{17}O))$, which gave the relative abundance of ^{18}O in the CO_2 samples. The half-life of the exchange reaction ($t_{1/2}$) was derived graphically from the McKay plot (28) (for each run) of $-\log_{10}(1 - F)$ *vs.* time, where, F, the fraction exchanged at time t, was evaluated from the relationship

$$[5] \qquad F = (R_0 - R_t)/(R_0 - R_\infty)$$

where R_0, R_t, and R_∞ refer to the isotopic composition of the CO_2 samples at time zero, t, and isotopic equilibrium, respectively. The rate of oxygen exchange was then calculated using the equation

$$[6] \qquad R = \frac{ab0.693}{(a + b)t_{1/2}}$$

where a and b refer to the number of g-atoms of oxygen per l in the water and EDTA respectively.

Results and Discussion

Shown in Fig. 2 are the results for the dependence on pH of the rate of exchange for two Ln–EDTA complexes selected from opposite halves of the lanthanide series (note that the ordinate is a *negative* log plot of the rate such that the larger numbers correspond to a slower rate of exchange). Observe that beyond pH 4 the EDTA complexed by the lighter (larger) ion (Pr^{3+}) exchanges approximately ten times more rapidly than the EDTA complexed by the heavier (smaller) ion (Er^{3+}). Also shown for comparison

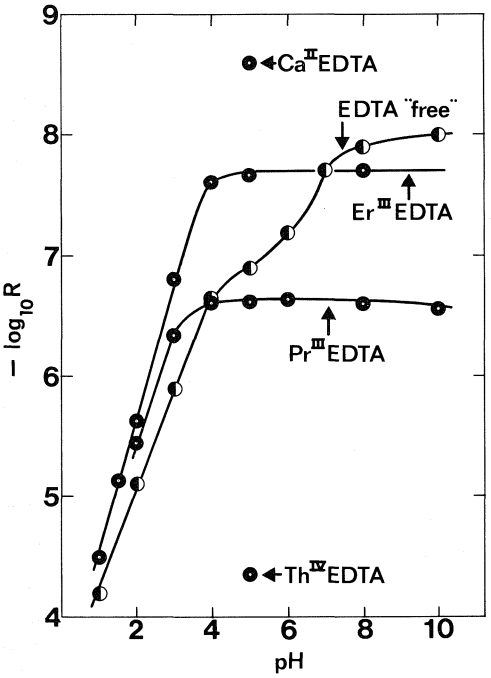

FIG. 2. pH dependence of the rate of oxygen exchange for complexed and uncomplexed ("free") EDTA at 104 °C; ≃0.01 M.

is the pH "profile" for the "free" EDTA at a comparable concentration (0.01 M) in the absence of Ln^{3+} ions. (A thorough investigation of the oxygen exchange reaction of EDTA with solvent water has been carried out by O'Connor (29) who postulated seven major mechanistic paths for this exchange. Our results (Fig. 2) are in reasonable agreement with those determined by O'Connor (29) at a comparable temperature (101 °C).)

Beyond pH 4, Pr appears to promote oxygen exchange with respect to the "free" EDTA. Er does not appear to become effective until beyond pH 7, and even then, the effect is small. In addition to the Ln complexes, preliminary investigations of a few other complexes have been made, results for two of which have been included here (Fig. 2). The tetravalent thorium ion has a very pronounced effect on the rate; EDTA complexed by this ion exchanges approximately 350 times more rapidly than the "free" EDTA (at pH 5 at least). The divalent Ca ion appears in fact to inhibit the rate of exchange.

A satisfactory explanation for the appearance of the pH "profile" for the Ln–EDTA complexes is that in the pH-independent region we have only one species, the "normal" EDTA complex (*i.e.*, EDTA 6-coordinated plus an additional "x" water molecules). At lower pH, formation of a protonated species, Ln(H EDTA) $(OH_2)_x$, must be taken into consideration (30).

We have reason to regard the eight oxygen atoms of the complexed EDTA to be equivalent although our evidence in support of this claim is not conclusive.

Figure 3 shows the effect of the size of the ionic radius on the rate of oxygen exchange for various Ln–EDTA complexes. On the basis of electrostatic arguments, one might expect the rate of exchange to increase in a regular fashion with decreasing ionic radius. The observed trend is in fact contrary to what would be expected according to our introductory remarks regarding the role of metal ions in catalysis. Perhaps a possible explanation for the observed trend in R resides in the very nature of the complex itself. The Ln–EDTA complex in aqueous solution can be classified as a mixed complex (*i.e.*, it contains two different ligands within the primary coordination sphere of the central metal ion; in this case EDTA and n water molecules). Various researchers concerned with reactions at coordinated ligands (1–3) have also stressed the im-

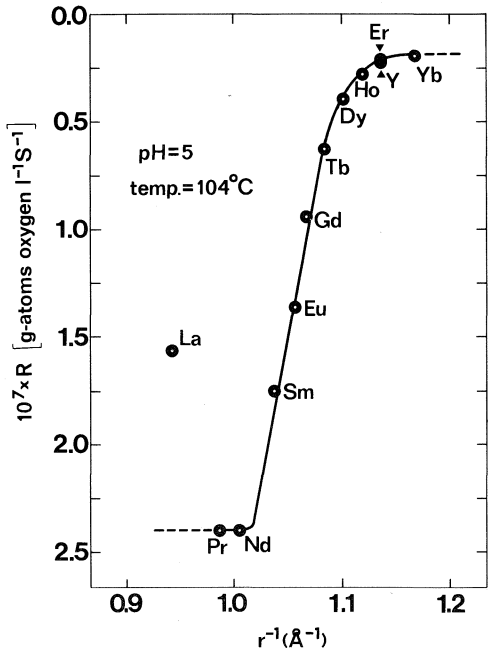

FIG. 3. Effect of the size of the central Ln^{3+} ion on the rate of oxygen exchange at pH 5 and 104 °C.

portance of mixed complexes wherein the metal ion contributes to the ease of reaction by bringing together both components of a bimolecular reaction within its coordination sphere as well as holding the reactants in position favorable for reaction. Although a large number of investigators have admitted to the possibility that the nucleophile which initiates the reaction is also attached to the metal ion (see, for example, ref. 31 and comments therein), good evidence for such a mechanism has only recently been provided by Buckingham's study (32) of the hydrolysis of glycine esters ($NH_2CH_2CO_2R$) in $Co(en)_2(Br)(NH_2CH_2CO_2R)^{2+}$. This reaction was explained in terms of two pathways, one involving external attack by a hydroxide ion and the other occurring by internal attack on the coordinated ester by a coordinated OH^- group. In the present study, then it is possible that the Ln^{3+} ions while rendering the carbonyl carbon more susceptible to attack may also provide the water molecule as the nucleophile. In this respect we also consider as significant the close resemblance between the progression of R (Fig. 3) and ΔS (Fig. 1) *vs.* $1/r$. Rather than to regard the close similarity of these two curves as fortuitous, we propose that they are complementary evidence for a coordination number change in the Ln–EDTA complexes due to the "lanthanide contraction" (*i.e.*, the "discontinuity principle" is applicable to our study). If we adopt an explanation comparable to that of Geier and Karlen (17), then both complex series (*i.e.*, Ln-8 and Ln-9 in eq. 4) can again be recognized in the "plateau" regions, and in the region between Sm and Er hydration equilibria occur between two types of complexes differing in the number of coordinated water molecules (3 and 2). To explain the observation that EDTA complexed by Pr exchanges about ten times more rapidly than the EDTA complexed by the smaller Er ion, we suggest that structural effects are important in determining the lability of the complexed EDTA, and that the structure of the 9-coordinated mixed complex is more favorable to reaction than that of the 8-coordinated complex. Equilibrium constants were also evaluated (following the method of Geier and Karlen) for the hydration equilibria [3] and are summarized in Table 1. The good agreement between the observed rates, R_{exp}, and those calculated on the basis of a varying contribution from 8- and 9-coordinated complexes demonstrates the adequacy of this type of analysis. Also included in Table 1 are the equilibrium constants, K_s, as determined by Geier and Karlen (17) and Kostromina and Tananaeva (20); our values are in reasonable agreement considering the differences in conditions (temperature, ionic strength) and methods of evaluation.

The behavior of yttrium in Fig. 3 is worth noting. Although Y is not a true lanthanide, the rate of exchange for EDTA complexed by the Y^{3+} ion falls in the position expected from a consideration of its radius. However, we were unable to reconcile the behavior of La within this scheme.

In conclusion, the rate of oxygen exchange of the Ln–EDTA complexes appears to be sensitive to changes in the primary coordination sphere with respect to hydration; and we interpret the observed trend (Fig. 3) as evidence (admit-

Dielectric Constants of a Binary Solution Near the Critical Solution Temperature

I. LUBEZKY[1] AND R. MCINTOSH
Department of Chemistry, Queen's University, Kingston, Ontario
Received August 31, 1972

The dielectric constants and dielectric losses of solutions of nitrobenzene and 2,2,4-trimethyl pentane have been measured near the critical solution temperature over a concentration range of 22–75% by weight and in the frequency regions of 5–60 and 1000 – 4000 kHz. It was found that below a critical concentration of 35% maxima existed in ϵ' and ϵ'' at a temperature of 0.3 °C above the critical solution temperature. At higher concentrations the maxima disappeared and phase separation was preceded only by changes in the thermal coefficients $d\epsilon'/dT$ and $d\epsilon''/dT$. The present study combined with others indicates that two regions of loss exist for the system near the critical temperature: low frequency losses of a conductive nature and high frequency losses of the Debye type. The published experimental knowledge of such systems remains insufficient to enable a thorough test of the theoretical studies published recently by Snider.

Les constantes diélectriques et les pertes diélectriques des solutions de nitrobenzène et de triméthyl-2,2,4 pentane ont été mesurées au voisinage de la température critique de la solution, dans l'intervalle de concentration en poids de 22–75% et dans les régions de fréquences de 5–60 et 1000–4000 kHz. Au dessous d'une concentration critique de 35% des maximums existent pour ϵ' et ϵ'' à une température de 0.3 °C au dessous de la température critique de la solution. Aux plus hautes concentrations les maximums disparaissent et la séparation de phase n'est précédée que par des changements dans les coefficients thermiques $d\epsilon'/dT$ et $d\epsilon''/dT$. Cette étude, ajoutée aux précédentes, montre l'existence de deux régions de perte pour le système au voisinage de la température critique: les pertes associées aux basses fréquences de nature conductive et les pertes de hautes fréquences de nature conductive et les pertes de hautes fréquences de type Debye. Les connaissances expérimentales sur de tels systèmes publiées à ce jour, restent insuffisantes pour vérifier selon un test sûr les études théoriques recemment publiées par Snider.

Introduction

A number of publications have appeared concerning the dielectric behavior of binary solutions in the critical region and interest has increased as a result of accumulating information of the physical properties of such systems (1). Quantities such as specific heat and viscosity show a maximum at a temperature close to the transition from a one-phase to a two-phase system. The critical solution point of a binary mixture may be characterized by the vanishing of its stability coefficients such as the second derivative of the molar Gibbs free energy with respect to the mole fraction. Since the inverse of the real part of the dielectric constant ($1/\varepsilon'$) is also such a stability constant, by investigating the behavior of ε' in transitions and phase equilibria between phases, one can relate the value of $1/\varepsilon'$ to the stability or instability of a phase.

Measurements of ε' and ε'' can be made as functions of concentration, temperature, frequency of the applied field, effect of impurities and other factors. For experimental convenience, in most cases systems having upper consolute temperatures close to room temperature have been investigated. These systems consisted of solutions of nitrobenzene in some hydrocarbon for which the consolute temperature is between 20–30 °C. The experimental results for such systems obtained in several laboratories have been gathered and interpreted by Arkhangelskii and Semenchenko (2). However, the studies show disagreement concerning the behavior of the dielectric constants in the vicinity of the critical temperature. Whereas in some cases a large maximum was found in ε' and ε'' near the separation temperature, in other instances no maxima were found, and transitions to two-phase systems were accompanied only by a change in the thermal coefficients $d\varepsilon'/dT$ and $d\varepsilon''/dT$.

The present study deals with the dielectric behavior of solutions of 22–75% by weight of nitrobenzene in 2,2,4-trimethyl pentane (iso-

For personal use only.

octane). This system had been investigated (3) using several concentrations and at a single frequency of 3300 MHz. It was found that the dielectric constant and loss tangent both approach a maximum at a temperature of 1.5 °C above the separation temperature. The maximum was sharpest in a concentration close to the consolute concentration, but the amplitude was higher in both ε' and tan δ with increasing concentration of nitrobenzene. Quinn and Smyth (4) tested the same system at a single solute concentration of 25% by weight and wavelengths of 575 m and 10, 3.22, and 1.26 cm (0.5, 3×10^3, 9.3×10^3, 2.4×10^4 MHz), respectively. A pronounced maximum was found in the real part of the dielectric constant at a temperature of about 2 °C above critical. It was also found that the dispersion could be characterized by a single relaxation time over much of the temperature range, meaning that a Debye absorption envelope existed for the system in the microwave range.

Experimental

Dielectric constants and losses were measured over a frequency range of 5–60 and 1000–4000 kHz. Two separate measuring circuits were employed for the two frequency ranges. A modified Schering bridge was used for the low frequency range and a resonance system served for the high frequencies. Circuit arrangements are described in an earlier work (5). The dielectric cell for the measurements consisted of a vertical coaxial capacitor which was constructed of aluminum and employed Teflon seals. The cell and lead capacitances were obtained by measuring the total capacitance with cell filled with air, benzene, ether, and chlorobenzene. The capacitance of the empty cell was found to be 20.6 pF. A careful assessment of lead capacitance and inductance was made for the frequencies employed. The overall scatter of ε' was approximately $\pm 0.05\%$ when using the bridge method, and approximately $\pm 0.2\%$ when using the resonance method. However, an uncertainty of 3% exists in the absolute value of ε'. The cell temperature was controlled in a water bath by means of a Haake thermoregulator with variable power output and cooling coils. The temperature of the thermostat was maintained to within 0.02 °C and temperature gradients along the cell were of the same order. It is believed that because of the high thermal conductivity of the cell's material the temperature gradients within it were even lower.

Nitrobenzene and 2,2,4-trimethyl pentane were obtained from Fisher Scientific Company. The certification of purity for both materials revealed less than 100 p.p.m. total impurities. Prior to measurements materials had been dried over freshly dehydrated calcium sulfate (B.D.H. analytical grade). After filling the cell with each mixture, the mother solution was placed in a sealed glass vessel beside the cell to allow observation of visual transition effects analogous to those presumably occurring in the dielectric cell under the same conditions.

Results and Discussion

In Fig. 1 the binodal curve for the system nitrobenzene–2,2,4-trimethyl pentane is shown. A review of the literature indicated that this curve had not been published previously. However, the consolute temperature deduced from the curve agrees with the value obtained by Woodburn *et al.* (6), namely, 30.4 °C. The curve was constructed from the temperatures at which the first signs of separation into two phases appeared as a sudden heavy turbidity.

In Fig. 2, ε' is described as a function of temperature for various concentrations and a frequency of 60 kHz at which the relative size of the maximum is most pronounced. It is obvious that a maximum exists in ε' and while its value increases with concentration of nitrobenzene, the amplitude of the maximum decreases until it disappears above 35% by weight of solute. Above this critical concentration the phase separation is preceded by a change in the thermal coefficient $d\varepsilon'/dT$. At a concentration of 75% of nitrobenzene it has become difficult to observe even the change of thermal coefficient. In all cases the maximum or break in the curves appeared at a temperature of 0.3 °C above separation which is indicated in the graphs by an arrow. This temperature gap does not agree with that reported in ref. 3 and the work of Quinn and Smyth (4) who found that the maximum in ε' was some 1.5–2.0 °C above separation temperature. It does agree, however, with Semenchenko's results on similar systems (7).

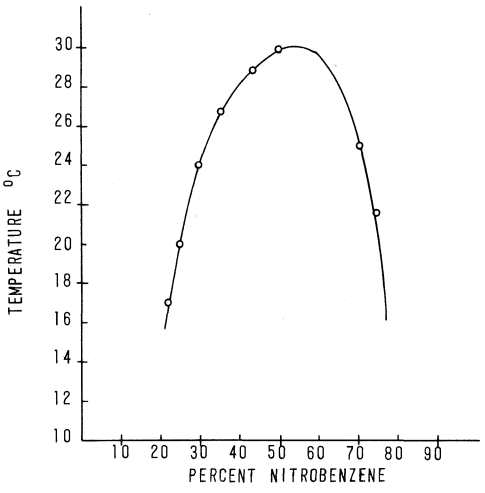

FIG. 1. Binodal curve for the system nitrobenzene-2,2,4-trimethyl pentane.

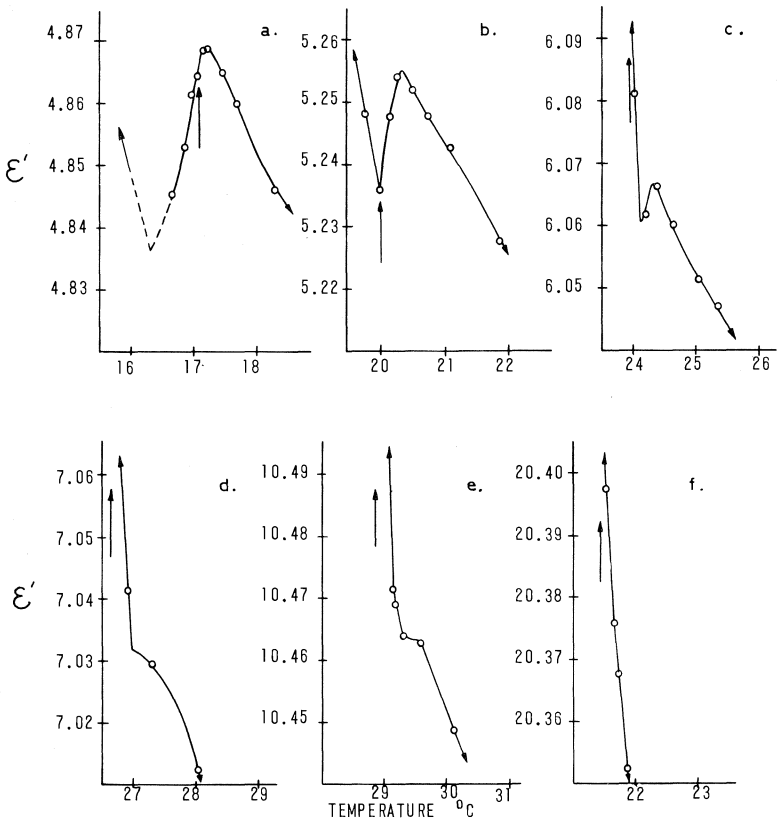

FIG. 2. ε′ as a function of temperature at a frequency of 60 kHz for the following concentrations: *a*, 22.3%; *b*, 25.0%; *c*, 30 0%; *d*, 35.3%; *e*, 50.0%; and *f*, 74.8%.

It should be noted that the frequency ranges employed by Semenchenko and in the present study were in the audio and lower radio frequencies, whereas the other two studies employed microwave frequencies. Therefore the differences could be attributed to conductance effects, which will be referred to below.

In Fig. 3, ε″ (loss factors) are plotted as a function of temperature for various concentrations and at a frequency of 5 kHz. Whereas it was found that the amplitude of the maximum in ε′ goes up, that of ε″ goes down with increasing frequency in the range of 5–60 kHz, in agreement with results of Semenchenko and co-worker (7, 8), while the frequency decreases ε′ and ε″ both increase. The effects are much more pronounced for ε″.

In Fig. 4 losses in the region of the maximum are represented for two concentrations as a function of frequency. The losses diminish with increasing frequency, and as the frequency reaches 1000 kHz, the losses are either zero or at a minimum. Beyond that frequency a new region of losses appears (note value at 4000 kHz). This region may correspond to the loss envelope in which Quinn and Smyth (4) found a single relaxation time for the system.

The audio frequency losses have the same frequency dependence even outside the critical region and indicate a contribution from conductivity effects. It seems, therefore, that in this case and others, where measurements have been made at audio frequencies, a contribution from conductivity is inherent in the losses. This effect could also account for the fact that at microwave frequencies the unusual dielectric effects were found at a temperature approximately 1° higher. In the 1000 kHz region where a smaller contribution from conductivity is expected, it is obvious from Fig. 4 that losses are either zero or at a minimum, depending upon concentration. On the other hand, ε′ retains its low frequency typical shape in the high frequency region, as seen in Fig. 5.

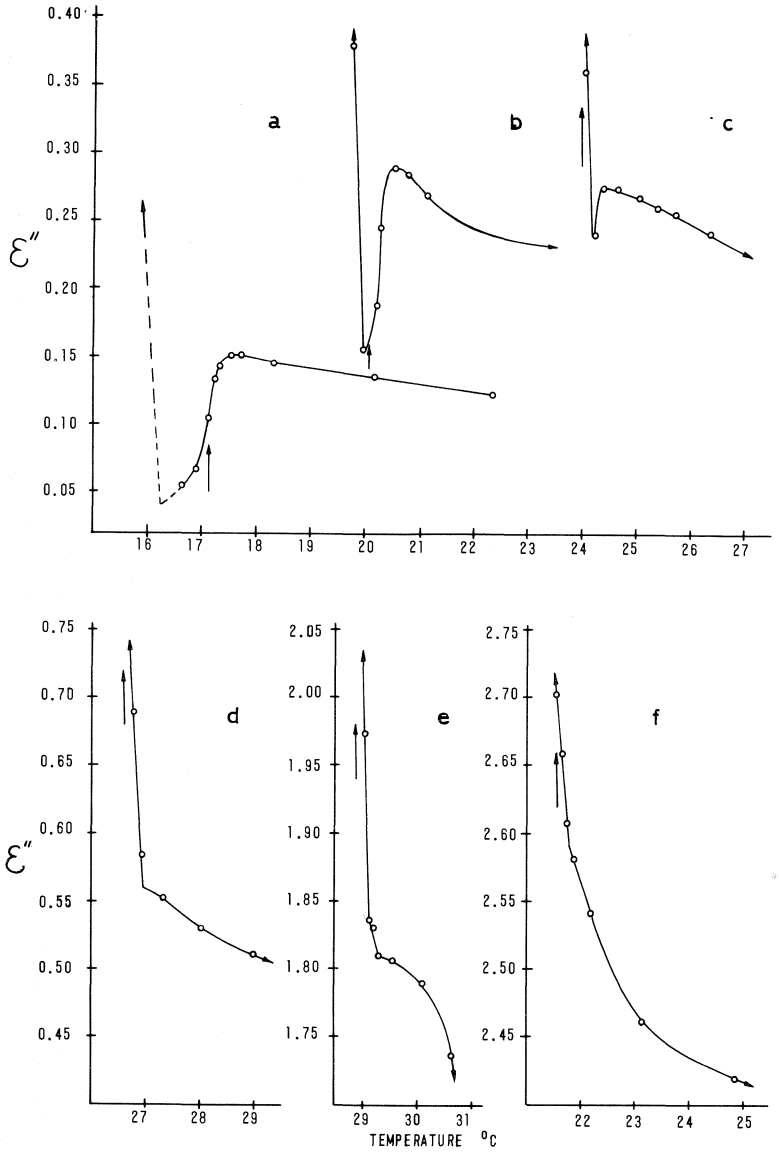

FIG. 3. ε″ as a function of temperature at a frequency of 5 kHz for the following concentrations: *a*, 22.3%; *b*, 25.0%; *c*, 30.0%; *d*, 35 3%; *e*, 50.0%; and *f*, 74.8%.

The disappearance of the maximum at a critical concentration (Figs. 2, 3, and 5) is contrary to the results given in ref. 3 as reported in the introduction. Semenchenko (2) found that for similar systems at a frequency of 1000 kHz the amplitude and sharpness of the dielectric plots reached maxima at the consolute temperature. Previous experiments of Piekara (9) and Lomova (10) showed that at the consolute temperature only a break occurred in ε′ *vs.* *T* curves and these results agree with the present findings.

Zamkov (11) tried to explain these discrepancies by showing that any value of ε′ between 0 and ∞ could be obtained at the critical temperature depending on the presence or absence of a free volume of solution outside the electric field. This explanation was adopted by Semenchenko (2).

Careful examination of Zamkov's analysis shows that it is incorrect. In the case of a cell with a free volume the expression for the free energy of the system is

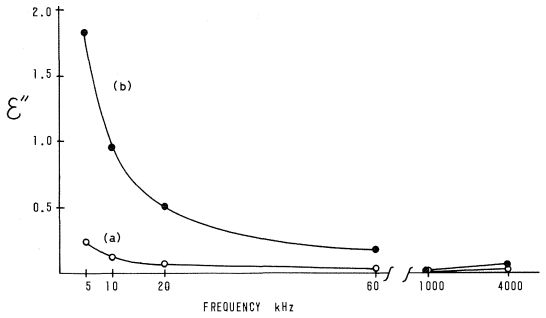

FIG. 4. ε″ at the maximum as a function of frequency: *a*, 25% solute; *b*, 50% solute.

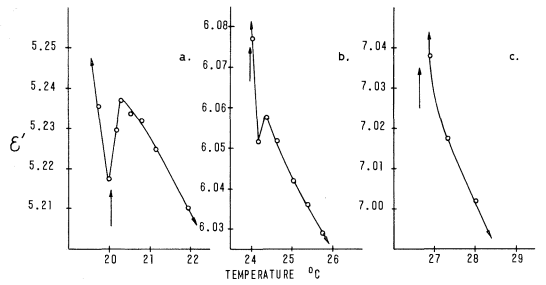

FIG. 5. ε′ as a function of temperature at a frequency of 1000 kHz for the following concentrations: *a*, 25%; *b*, 30%; *c*, 35.3%.

$$[1] \quad dG = -SdT + VdP - \frac{1}{4\pi} V_S D dE$$

where V_s is the volume confined between the electrodes, D and E are the dielectric displacement and electric field, respectively. Thus Zamkov obtains

$$[2] \quad \frac{\partial V}{\partial E} = -\frac{1}{4\pi} V_S \frac{\partial D}{\partial P}$$

and

$$[3] \quad V - V^* = -\frac{V_S}{4\pi} \int_0^E \frac{\partial D}{\partial P} dE$$

where he defines V and V^* as the volumes of material in the cell before and after applying the external field. Since there is a free volume from which to draw material, there will be no change of volume between the electrodes when the field is applied. Thus $V - V^*$ is said to be zero, which leads to the conclusion that $d\varepsilon'/dT$ is also zero.

This conclusion is incorrect as the following considerations show.

The energy of the system consists of two parts (12)

$$[4] \quad W = W_0 + W_E$$

where W_0 is the usual energy term of the system in the absence of any external perturbations and W_E is an additional term accounting for the work done by applying an external electric field.

$$[5] \quad W_E = -\frac{1}{4\pi} \int_0^V dV \int_0^E E dD$$

Therefore it is important to remember that eq. 1 applies to material both outside and inside the electric field. Consequently the integration of eq. 2 must cover the entire volume of the polarizable material. The integral of eq. 5 is evidently zero outside the cell, and this is the origin of V_s in eq. 1, but then $V - V^*$ is the change of the entire volume of the system and not necessarily equal to zero. Moreover, the electrostriction effect is well known and in polarizable materials $V - V^*$ has a definite positive value.

In the second part of Zamkov's paper in which he deals with a cell with no free volume, he again incorrectly assumes that $V - V^*$ equals zero, neglecting the electrostriction effect.

According to Zamkov's definitions the cell of the present study would be a cell with a partial free volume. Repeating the experiments and eliminating any free volume did not appreciably alter the results. With no free volume the critical concentration for the disappearance of the maxima was shifted to slightly higher values, but the differences were only of the order of the experimental error.

Conclusions

Consideration of the experiments reported here in conjunction with results already published, leads to the conclusion that apparent contradictions arise because sufficiently wide ranges of frequencies and concentrations have not been examined, even for a single system. There are now strong indications from earlier work (3, 4) and this study, that there exist at least two regions of loss for the nitrobenzene–isooctane system. The low frequency loss observed in this investigation resembles a conductive loss which is essentially eliminated as frequency is increased to 1000 kHz. However, the maximum in ε′ is still observed above the temperature of phase separation provided that solutions which contain less than 35% of nitrobenzene are examined (Fig. 5). The low frequency observations of this investigation differ from those made in the low microwave region (3, 4) in that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

low frequency effects diminish to zero with increasing concentration of nitrobenzene.

Recently Snider (13, 14) discussed the dielectric parameters of such systems theoretically on the assumption of density fluctuations in submicroscopic regions. Losses were attributed to diffusional phenomena as the critical systems change in response to the applied field. Large contributions to the dielectric constant were considered to arise from correlation effects between dipoles. Snider predicted losses at a frequency of about 500 kHz and contributions to the dielectric parameters which would be greatest at the critical composition, and which would shift to zero frequency at that composition, that is to say, at the consolute point.

Some support of these views was derived in a study of the dielectric behavior of four polar adsorbates (15). The evidence from the studies of a partially miscible liquid system has now been shown to be incomplete and no thorough test of Snider's views is as yet possible. Clearly, the intermediate frequency range from about 10 MHz to several hundred MHz must now be examined. In the meantime it is clear that results reported by Semenchenko and associates and by Smyth and associates, as well as those of Ripley and McIntosh (3), reveal anomalies in the dielectric parameters which are not due to experimental errors. Discrepancies among the experimental results are expected to disappear as further frequencies are employed. A thorough test of Snider's theoretical work will then be possible.

It is a pleasure to thank the National Research Council of Canada for financial support.

The Dissociation Constants and Conductivities of Mono-, Di- and Triethylamine in Aqueous Solution

ALAN NEWTON CAMPBELL AND SING-YEUNG LAM

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received September 22, 1972

The conductances of the mono-, di-, and triethylamines, and their hydrochlorides, in aqueous solution, have been determined. Corrections for the formation of amine carbonates and hydrolysis of the halides were made. By using the Kohlrausch law and the method of Shedlovsky and Kay, basic dissociation constants for the amines have been computed. The basic strength of this series has been found to conform to the usual trend for other series of aliphatic amines.

La conductivité des mono-, di-, et triethylamines et de leurs chlorhydrates a été déterminée en solution aqueuse. Des corrections pour la formation des carbonates d'amine et pour l'hydrolyse des dérivés halogénés ont été apportées. Utilisant la loi de Kohlrausch et la méthode de Shedlovsky et Kay, les constantes de dissociation basiques des amines ont été calculées. On a trouvé que la force des bases de cette série est conforme aux tendances observées pour d'autres séries d'amines aliphatiques.

Introduction

We have determined the conductivities of aqueous solutions of mono-, di-, and triethylamine, as well as those of dilute solutions of the amine hydrochlorides, so that the ionization constants of these weak bases might be known. The temperature chosen for the completely miscible systems monoethylamine–water and diethylamine–water was 25 °C. Since mixtures of monoethylamine and water containing more than about 70 mol% amine boil at 25 °C, measurements were not extended beyond this upper limit. For the system triethylamine–water the experimental temperature was 17 °C, since the system is completely miscible at this temperature.

Experimental

A. Materials

1. Conductivity water

See ref. 1.

2. Amines

See ref. 1.

3. Amine Hydrochlorides

The hydrochlorides were prepared from the amines by neutralizing chemically pure hydrochloric acid solutions with slight excess of amines. The excess quantities were expelled by gently boiling off the solutions until the condensate did not turn red litmus paper blue. The hydrochlorides were recrystallized twice from conductivity water, dried at 110 °C, then pulverized and kept in a desiccator over phosphorus pentoxide.

4. Potassium Chloride

Fisher certified A.C.S. potassium chloride was used without further purification, for the calibration of the conductance cells. It was dried at 115 °C. Standard potassium chloride solutions for calibration of the conductance cells were prepared by dissolving weighed quantities of the salt in known amounts of conductivity water.

B. Preparation and Analysis of Solutions

1. Amine Solutions

See ref. 1.

2. Amine hydrochloric solutions

Solutions for use in conductivity measurements were prepared by dissolving weighed quantities of the salts in conductivity water of known specific conductance. The weighings of the hydrochlorides were made with a microgramatic Mettler balance. Solutions of mass up to about 3 kg were weighed on a large balance having a sensitivity of 10 mg.

C. Conductance Measurements

A Leeds and Northrup conductivity bridge was used to measure the resistances of the solutions. Conductance cells of the type recommended by Jones and Bollinger (2) were used. A Shedlovsky quartz cell of the original design (3) was employed for very dilute solutions. Polarization errors were reduced by platinization.

Since the amine solutions had high vapor pressures even when chilled, rinsing the cells with amine solution might have caused a change in the original concentration of the solutions. To minimize this, dry conductance cells not rinsed by solution were used. Errors due to adsorption of amine on the platinum electrodes or to their possible attack on glass were compensated by plotting the measured resistance against time for 2 h and extrapolating the later portion, which appeared to be linear, back to zero time, when the cell was filled.

Treatment of Experimental Data and Results

The experiment equivalent conductances of the hydrochlorides of mono-, di-, and triethylamine, in which the hydrolysis effect has not been allowed for, as well as those of the free bases, as functions of their stoichiometric concentrations, are to be found in the Depository of Unpublished Data.[1] From these data, preliminary values of the basic dissociation constants were found. From these approximate values of the basic dissociation constants and the ionization constants of water at 25 °C (1.01×10^{-14}) and at 17 °C (5.33×10^{-15}), the effect of hydrolysis upon the conductivity was computed for each salt by the method of Campbell and Bock (4). The final limiting equivalent conductances computed for the substituted ammonium cations and the hydroxides are as follows:

Ion or compound	Temperature (°C)	λ^0 (cm² ohm^{-1} equiv^{-1})
Monoethylammonium ion	25	46.41
Diethylammonium ion	25	36.47
Triethylammonium ion	17	26.67
Monoethylammonium hydroxide	25	244.7
Diethylammonium hydroxide	25	234.8
Triethylammonium hydroxide	17	193.8

For ammonium ion and ammonium hydroxide, the limiting conductances at 25 °C are 73.55 and 271.9, respectively. The decrease in limiting conductance on passing from ammonia to triethylamine is no doubt due to the increase in size of the conducting species.

Our method of finding the dissociation constants of the amines is essentially that of Shedlovsky and Kay (5).

The mean activity coefficients of the free ionic species were calculated using the Davies equation (6)

$$\log y_{\pm}' = -A\left(\frac{|z_1 z_2|\sqrt{I}}{1+\sqrt{I}} - 0.3I\right)$$

with $A = 0.5115$ at 25 °C: 0.5045 at 17 °C. The ionic strength (I) was set equal to αc.

The molar activity coefficients of the free amine molecules were evaluated from the following equations

$$y_B' = \frac{kp_B}{c(1-\alpha)\cdot p_B^0}$$

and

$$k = \lim_{c\to 0} \frac{c(1-\alpha)p_B^0}{p_B}$$

where p_B and p_B^0 are the vapor pressures of B in solution and in the pure state. An example of how the limiting value of $c(1-\alpha)/a_B$ was obtained, is given for the case of monoethylamine, in Fig. 1, where $c(1-\alpha)/a_B$ is plotted against c. Since the vapor pressures of the amines in very dilute solutions were not determined we were obliged to use the data for higher concentrations, where α can only be calculated approximately ($\simeq\Lambda/\Lambda^0$). Although such an extrapolation from the plot may lead to an only approximate limiting value of k, the activity coefficient in any dilute solution is the ratio of k to the value read off from the curve at this particular concentration and it is fairly insensitive to the variation of k, provided the slope in the dilute region is not exceptionally large. In all cases, the activity coefficients of the amine molecules in dilute solutions are close to unity and this justifies the assumption often

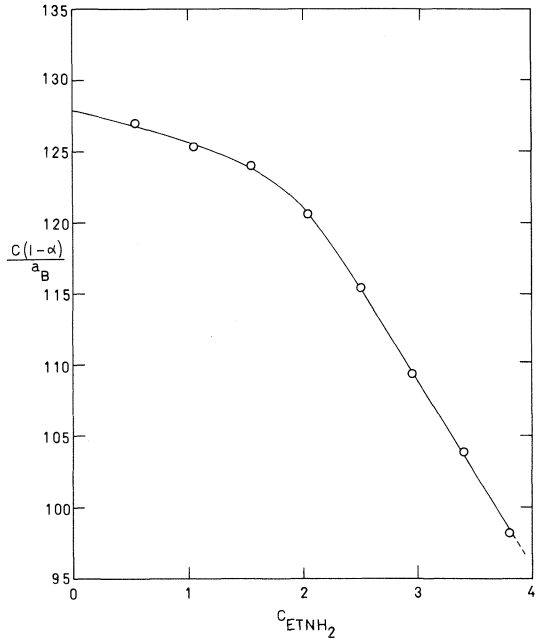

FIG. 1. Plot of $c(1-\alpha)/a_B$ *vs.* c for monoethylamine at 25 °C.

[1]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

made that they are unity. The activity coefficients of water in the aqueous amine solutions have been determined by us.

With these activity coefficients, water activities, and other quantities, values of

$$\frac{y_B'^{1/2} a_A^{1/2} c^{1/2}}{y_\pm' S(z)} \left[1 - \frac{\Lambda^*}{\Lambda^0} S(z)\right]^{1/2}$$

were calculated and plotted against the viscosity corrected specific conductances. The symbols, other than those well understood are: L,L_0 = specific conductance of solution and of solvent, respectively; y_B' = activity coefficient of free amine on molarity scale; a_A = activity of water; $S(z)$ = Shedlovsky function defined by

$$S(z) = 1 + z + z^2/2 + z^3/8 - z^5/12$$

$$z = \frac{(B_1\Lambda^0 + B_2)C^{1/2}\Lambda^{1/2}}{\Lambda^{0\,3/2}}$$

The intercepts of these plots give the solvent corrections, L_0, for the aqueous amine solutions. These are 4.5×10^{-6} for monoethylamine solutions, 3.5×10^{-6} for diethylamine solutions, and 4.0×10^{-6} for triethylamine solutions. These solvent corrections are several times larger than the original specific conductance of water, which contained some carbonic acid, because the amines converted the weak acid into the completely ionized salts.

The true specific conductances of the solutions were then computed. The stoichiometric concentrations of the amines were also corrected for those portions of the amines which had been converted into salt. We illustrate the method, using monoethylamine as the example. Using the limiting conductivity of monoethylammonium ion obtained above and those of the HCO_3^- and CO_3^{2-} ions at 25 °C, the concentrations of bicarbonate and of carbonate were estimated from the relation $L_0 \times 10^3/\Lambda_{salt}^0$, assuming that neutralization is complete to bicarbonate or carbonate. These concentrations are $c_{bicarbonate} = 4.9 \times 10^{-5}$; $c_{carbonate} = 2.0 \times 10^{-5}$. The concentration of monoethylammonium ion is αc. From the estimated dissociation constant of monoethylamine, $K = 4.8 \times 10^{-4}$, the ionic product of water, and the dissociation constants of carbonic acid, *viz.* $K_1 = 4.4 \times 10^{-7}$ and $K_2 = 4.7 \times 10^{-11}$, the following equilibria can be formulated

$$\frac{[\text{aminium}^+][HCO_3^-]}{[H_2CO_3][\text{aminium hydroxide}]} = \frac{\alpha}{1-\alpha} \times \frac{[HCO_3^-]}{[H_2CO_3]} = 2.1 \times 10^4$$

$$\frac{[\text{aminium}^+][CO_3^{2-}]}{[HCO_3^-][\text{aminium hydroxide}]} = \frac{\alpha}{1-\alpha} \times \frac{[CO_3^{2-}]}{[HCO_3^-]} = 2.3$$

Since the degree of dissociation is less than 0.4 for the most dilute monoethylamine solution, the ratio $[CO_3^{2-}]/[HCO_3^-]$ is larger than 3. For simplicity, we have assumed that that portion of the base was converted completely to dibasic salt. The correction for monoethylamine solutions is therefore 4.0×10^{-5} rather than 4.9×10^{-5}, and this was consequently subtracted from the concentrations of monoethylamine to obtain the corrected concentrations. In a similar manner the corrections found for diethylamine and triethylamine solutions were 3.3×10^{-5} and 4.7×10^{-5}, respectively.

From the corrected concentrations and specific conductances, new values of λ, z, $S(z)$, α and $y_\pm'$ for which the ionic strength included the contribution from the salt, were calculated. The relevant quantities are to be found in the Depository of Unpublished Data, and the final plots of corrected specific conductance against

$$\left[1 - \frac{\Lambda^*}{\Lambda^0} S(z)\left(1 - \frac{L_0}{L}\right)\right]^{1/2} \frac{y_B'^{1/2} a_A^{1/2} c^{1/2}}{S(z) y_\pm'}$$

are shown in Figs. 2, 3, and 4. Points in the low concentration regions lie on straight lines passing through the origin. The slopes were measured and, knowing the limiting conductances, the basic dissociation constants were calculated. They are 4.57×10^{-4} for monoethylamine at 25 °C, 1.02×10^{-3} for diethylamine at 25 °C, and 4.93×10^{-4} for triethylamine at 17 °C.

Separate calculations, neglecting the viscosity factor, were also made for the three systems. The results are given in the same figures, Figs. 2, 3, and 4. It is obvious that without viscosity corrections, the deviations from straight line behavior are much larger than those with viscosity correction, in the higher concentration regions. In less dilute solutions, for which values of αc are still less than 0.01, and therefore still within the working range of the Shedlovsky conductance equation, the deviations of the viscosity

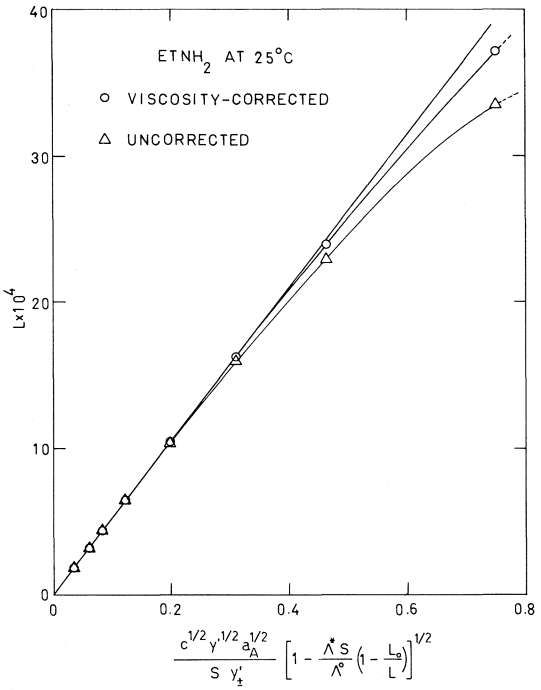

FIG. 2. Shedlovsky–Kay plot for aqueous monoethylamine solutions at 25 °C.

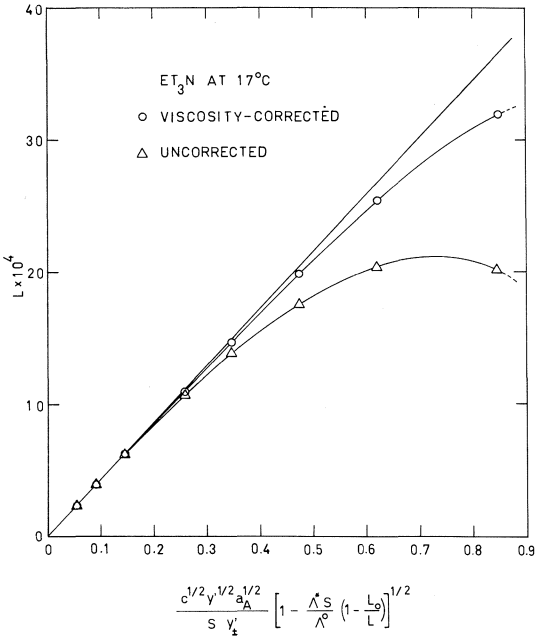

FIG. 4. Shedlovsky–Kay plot for aqueous triethylamine solutions at 17 °C.

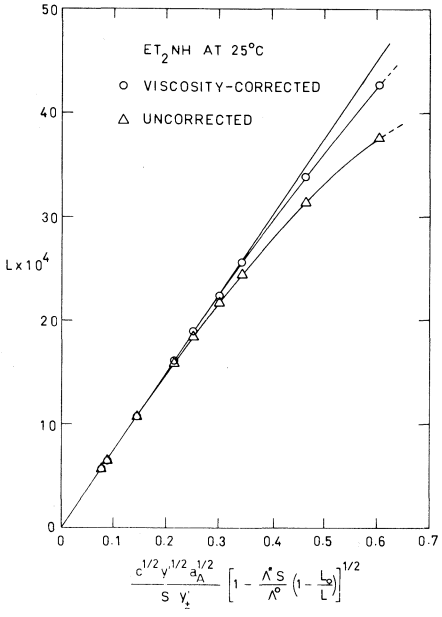

FIG. 3. Shedlovsky–Kay plot for aqueous diethylamine solutions at 25 °C.

corrected values from straight lines are presumably due mainly to the decrease of dielectric constant as the neutral amine molecules become more and more parts of the solvent media for the moving ions.

Our values of the dissociation constants agree well with the values obtained by Somerville (7), Ablard *et al.* (8), Everett and Wynne-Jones (9), Evans and Hamann (10), deLigny (11), van der Linde *et al.* (12), Moore (13), and Hansson (14). There is no doubt that for this series of substituted ammonias, diethylamine is the strongest base and ammonia the weakest ($K = 1.77 \times 10^{-5}$ mol l^{-1} at 25 °C).

The Mutarotation of Glucose in Dimethylsulfoxide and Water Mixtures

N. M. Ballash and E. B. Robertson

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received June 7, 1972

The mutarotation of glucose is a general acid – base-catalyzed reaction which involves two proton transfers. Whether these proton transfers are carried out in a stepwise or concerted manner, the latter alternative possibly incorporating several water molecules in a cyclic transition state, is not known with certainty.

This study was undertaken in an attempt to clarify the mechanism by determining directly the number of water molecules participating in the transition state. The method chosen was to determine rates for the acid-catalyzed mutarotation of glucose as a function of solvent composition in dimethylsulfoxide and water mixtures, particularly in the water poor region. The results show that for the acid-catalyzed reaction the order with respect to water is zero. For water catalysis, the results are less reliable but suggest that about three water molecules may be involved. These facts are interpreted to mean that a stepwise mechanism is operative in the proton-catalyzed reaction, but that the solvent-catalyzed process may involve a cyclic concerted mechanism.

Rate measurements were also carried out as a function of temperature for various solvent mixtures. The calculated activation parameters remain practically constant over the solvent composition region and attest to the constancy of the mechanism over this range. Thus the results which pertain strictly to solutions of high dimethylsulfoxide content should apply to aqueous solutions as well.

La mutarotation du glucose est une réaction de catalyse acidobasique généralisée engageant deux transferts de proton. La manière dont ces protons sont transférés (c'est-à-dire selon un mécanisme par étapes ou concerté, cette dernière possibilité faisant intervenir plusieurs molécules d'eau dans un état de transition cyclique) n'est pas connue avec certitude.

Cette étude a été tentée dans le but de clarifier le mécanisme par détermination directe du nombre de molécules d'eau engagées dans l'état de transition. La méthode adoptée est la mesure des vitesses de mutarotation acido catalysée du glucose, en fonction des compositions des divers mélanges diméthylsulfoxyde-eau, particulièrement dans la région pauvre en eau. Les résultats indiquent que l'ordre de la réaction acidocatalysée est de zéro par rapport à l'eau. Les résultats pour la catalyse par l'eau sont moins sûrs mais suggèrent que trois molécules d'eau environ peuvent être engagées. L'interprétation de ces faits peut être la suivante: dans la réaction catalysée par le proton, on a un mécanisme par étapes tandis qu'un mécanisme concerté explique le processus catalysé par le solvant.

Les mesures de vitesse ont été également effectuées en fonction de la température pour divers mélanges de solvants. Les paramètres d'activation calculés restent pratiquement constants dans la zone de composition du solvant et attestent de la constance de ce mécanisme dans cette zone. Ainsi les résultats qui appartiennent strictement aux solutions riches en diméthylsulfoxyde pourraient s'appliquer également aux solutions aqueuses. [Traduit par le journal]

Can. J. Chem., **51**, 556 (1973)

Introduction

Although the mutarotation of glucose has been studied by a large number of workers over a period of many years, there is still no agreement as to the mechanism by which the reaction occurs. There are at least three mechanisms possible, plus numerous minor modifications. The most widely accepted scheme involves the formation of the free aldehyde form (γ-glucose), as in eq. 1. According to the Pedersen version of this mechanism, acids can catalyze the reaction by protonation of the ring oxygen, thereby increasing the ease with which the carbon-oxygen bond can be broken (1).

[1] 
An alternative mechanism proposed by Schmid involves the removal of the proton from the C-1 hydroxyl group, as in eq. 2, and does not involve

[2] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the formation of the γ-glucose (2). According to this scheme, acid catalysis would result from the polarization of the water molecules in the hydration sheath of the proton, thus increasing the ease with which a water molecule could remove the hydroxyl proton (3).

Christiansen (4) has suggested that the reaction proceeds as the result of the removal of the C-1 hydrogen as depicted in eq. 3. Again, no aldehyde

[3] 
form is required. The proton may be removed from the glucose entirely, or be transferred to one of the two oxygens adjacent to the C-1 atom. Acid catalysis could presumably result from the prior protonation of the neighboring oxygen, in much the same way as in the Pedersen mechanism.

Of these three possibilities, the first seems most reasonable. It is not clear how reaction 2 can lead to mutarotation, that is, how the removal of a proton from the hydroxyl group makes easier the change in configuration of the C-1 atom involved in the transition from the second to the third species in eq. 2. The third possibility would lead to the desired reaction, but there is no reason to favor it over [1], especially since the two known equilibria of glucopyranose involve the loss of the proton from the C-1 hydroxyl (5) and the formation of the γ form. The existence of the free aldehyde form is confirmed both by the fact that D-glucose undergoes typical aldehyde reactions (6) and by its polarographic behavior (7–9).

Further, the observation that glucose -1-^{18}O undergoes oxygen exchange with water approximately 30 times more slowly than the mutarotation reaction (10) excludes other alternatives which do not proceed via ring opening.

Once reaction 1 has been accepted, the problem of the timing of the various steps remains. The Pedersen mechanism [1] considers the two proton transfers, protonation of the ring oxygen and deprotonation of the C-1 hydroxyl, to occur consecutively so that either the conjugate acid or conjugate base of glucose is an intermediate in the conversion of the sugar to the aldehyde. For the acid-catalyzed reaction, Pedersen's stepwise mechanism may be written as a fast pre-equilibrium protonation followed by a rate determining step involving simultaneous removal of the hydroxyl proton by the conjugate base of the acid and breaking of the ether linkage, eq. 4.

[4] 
Eigen has suggested that reactions such as mutarotation which require two proton transfers may in fact proceed via a concerted mechanism involving two or more water molecules in a cyclic hydrogen-bonded transition state (11). This mechanistic view is supported by studies of other reactions, particularly the dehydration of acetaldehyde hydrate (12, 13). Both of these reactions are general acid – base-catalyzed (14), exhibit linear Brönsted plots (11), and have almost identical primary isotope effects (15). In the case of the dehydration reaction, reducing the observed rate constant into contributions from the equilibrium constant for the prior protonation and the rate constant k_2 of the deprotonation step (in the Pedersen mechanism) leads to a value of k_2 which exceeds the diffusion-controlled limit (11).

However, the comparison with the reaction of acetaldehyde does have weaknesses. For glucose, the Brönsted plot is based on data over a range of only about two powers of ten in the acid ionization constants, plus data for proton and water catalysis. It is doubtful that these latter two acids should be considered in the same plot as, for example, acetic acid. Even if only water is excluded, the plot extends over only seven pK units, instead of 18, and hence the constancy of the Brönsted α is much less significant.

Further, there is at least one major difference between the mutarotation reaction and the hydration of acetaldehyde, in that the transition state for the latter must include at least one water molecule, a restriction which is not present for the mutarotation. Thus conclusions based on the hydration reaction may or may not be applicable to the mutarotation. In addition, the isotope effect for the acid-catalyzed hydration of acetaldehyde has been questioned recently (16).

Primary solvent isotope effects on the rates of mutarotation of glucose and tetramethylglucose have been observed in deuterium oxide (17) and in $H_2O + D_2O$ mixtures (18, 19). The

k_D/k_H ratio for the mutarotation in the pure solvents is consistent with the stepwise mechanism (17). Data from experiments carried out in mixtures of light and heavy water do not lead to a clear-cut mechanistic interpretation, seemingly because for this type of reaction, changes in the rates resulting from differences in solvent participation (*e.g.*, two or three water molecules in the transition state as opposed to no solvent participation) are very small. However, there is is a slight preference for a transition state containing no water for the proton-catalyzed reaction, and for the inclusion of three water molecules in the water-catalyzed reaction (18). For the base-catalyzed reaction, there is somewhat stronger evidence for a stepwise mechanism (19).

There is considerable evidence for a cyclic concerted mechanism in some other reactions (20–26). The present work in a mixed solvent system was undertaken in the hopes of finding direct evidence concerning the role of water in the mutarotation reaction. Dimethylsulfoxide (DMSO) was chosen as the co-solvent because it is a highly polar solvent, and should not therefore contribute too large a medium effect. The essential difference between DMSO and water is that the former, being aprotic, cannot form hydrogen-bonded cyclic structures such as those proposed for water.

Experimental

Materials

Reagent grade materials were used throughout, without further treatment except as noted. β-Glucose was dried *in vacuo* before use. Tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium bromide and sodium perchlorate, recrystallized twice from water, and dried at 60° over P_2O_5 *in vacuo*. Fisher Certified Reagent DMSO was used for most of the work at 25°; at the other temperatures and for high mole fractions of DMSO at 25°, practical grade DMSO was dried over calcium hydride for 12 h and then vacuum distilled (27).

Equilibrium Constants

The equilibrium constants were measured polarimetrically in thermostatted 20 cm tubes using the sodium D line. The initial specific rotations of α- and β-glucose were obtained by measuring the optical rotation, r, of unbuffered glucose solutions (approximately 5 wt. %). When the solvent-catalyzed reaction proceeded at a measurable rate, plots of log $(r_t - r_\infty)$ against time, using average r_∞ values obtained from rate experiments, were extrapolated to the time of mixing. For very slow reactions, a linear extrapolation of r_t as a function of time was used. In many cases, observations were made over a period of 1½ h, and the results of at least two trials were averaged in obtaining each initial value. The infinity values from the rate measurements were also used for the final, equilibrium readings required for the equilibrium constants.

Rate Constants

In order to determine the rate constant for the acid-catalyzed mutarotation of glucose, polarimetric experiments were carried out over a range of hydrochloric acid concentrations keeping the solvent composition, ionic strength, and temperature constant. At all temperatures a minimum of four runs was carried out at each mole fraction.

Mutarotation experiments were initiated by dissolving 1.25 g of α-glucose and a weighed amount of inert electrolyte (TEAP) in about 10 ml of the solvent in a 25 ml volumetric flask. An aliquot of hydrochloric acid was then added and the mixture made up to volume at the operating temperature. The temperature was checked and adjusted, if necessary, before the solution was poured into the pre-thermostatted cell.

The first optical reading could usually be taken from 3–6 min after addition of catalyst to the glucose solution. This time interval included a "settling down" time of 2 or 3 min while the solution came to thermal equilibrium.

A solution of hydrochloric acid in DMSO was obtained by slowly bubbling HCl gas into DMSO. Care was taken to cool the DMSO in an ice bath so that heat from the exothermic dissolution of HCl would not cause decomposition of the DMSO (28). Solutions of HCl in water and HCl in DMSO were standardized with a standard barium hydroxide solution which was protected from atmospheric carbon dioxide. Potentiometric titrations were carried out and equivalence points were obtained with the aid of a Gran plot (29). All DMSO and water mixtures were made up in approximately 100 ml portions by weighing on an analytical balance. The small volume changes attendant on mixing DMSO and water were taken into account when calculating the acid concentration in solvent mixtures.

Karl Fischer Reagent was used to determine the water content of solvent mixtures containing more than 0.9 mol fraction DMSO. The reagent was standardized with sodium tartrate dihydrate on the same day that it was used (30). Determination of the water content in this primary standard by drying gave the stoichiometric weight of water within 0.13%. Samples were titrated in approximately 25 ml of pre-titrated absolute methanol using the visual dead-stop end point (31). End points were reproducible to within about 0.030 ml.

[6] $$K = k^{\alpha}/k^{\beta} = \frac{(R_{\alpha} - R_{\infty})}{(R_{\infty} - R_{\beta})}$$

where the R's are the specific rotations of the pure α or β tautomers or of the equilibrium mixture. The results are summarized in Fig. 1. The average error is about 1.5%.

Rate Constants

The mutarotation of glucose strictly obeyed first-order kinetics under all conditions investigated (32). According to eq. 5, we are dealing with an opposing reaction scheme where k^{α} and k^{β} are pseudo-first-order rate constants. A system of this kind approaches equilibrium in a first-order fashion, with an observed rate constant $k_{obs} = k^{\alpha} + k^{\beta}$ (33).

The Guggenheim method for evaluating rate constants was employed (34) except for the fastest reactions in pure water at 35°. Here the total number of polarimetric observations was too few for the Guggenheim method to be used to advantage and rate constants were calculated using final rotation values. Slopes of Guggenheim plots were determined both graphically and by the method of averages (35). Excellent agreement was always obtained between the two methods. Except at 45° where errors are roughly doubled, estimated errors for the individual runs are less than 1%.

Under the acidic conditions used,

[7] $$k_{obs} = k_0 + k_{H^+}[H^+]$$

where H^+ represents the solvated proton. Kolthoff and Reddy have demonstrated that hydrochloric acid is completely dissociated in DMSO (28). The second-order catalytic constant, k_{H^+}, was evaluated by the method of least squares from plots of k_{obs} as a function of the molar concentration of hydrochloric acid. Extrapolation to zero acid concentration gave k_0, the solvent catalyzed rate constant. A representative plot is presented in Fig. 2.

The catalytic constants k_0, k_{H^+} and $(k_{H^+})^{\alpha}$ are listed in Table 1 along with values obtained in aqueous solutions by other workers. Acidic rate

coefficients for the forward reaction, $(k_{H^+})^\alpha$, have been calculated using the average equilibrium constants. Any variation of K with temperature is within experimental error at all mole fractions investigated. Plots of k_{H^+} and k_0 as a function of χ_{DMSO} are illustrated in Figs. 3 and 4 respectively. Figure 4 includes data for 25 and 35° only.

Activation Parameters

Table 2 summarizes the values of the enthalpy and entropy of activation as a function of solvent composition. At least three temperatures were used in the calculation at any given solvent composition.

Hill and Thumm obtained values of $\Delta H^\ddagger = 84.3$ kJ mol^{-1} and $\Delta S^\ddagger = -29$ J K^{-1} mol^{-1} for the acid-catalyzed reaction and $\Delta H^\ddagger = 71.5$ kJ mol^{-1} and $\Delta S^\ddagger = -113$ J K^{-1} mol^{-1} for the solvent-catalyzed reaction at 40° in pure water (39), in reasonable agreement with the present results.

Discussion

Entropy plays a very important role in determining the equilibrium properties of glucose solutions. Kendrew and Moelwyn–Hughes have measured the constant for the equilibrium between α- and β-glucose at temperatures ranging from 0–45° and have found it to be independent of temperature (40). Thus the equilibrium constant is entropy controlled.

The difference between the equilibrium constant values for glucose in water and in DMSO, 1.72 and 1.67 respectively, is just on the limits of experimental error. The plot of K against χ_{DMSO} (Fig. 1*d*) exhibits a small minimum at $\chi_{DMSO} = 0.35$. This is also the region where the viscosity and thermodynamic excess functions, including the considerable volume contraction on mixing (41), all show extremum behavior, indicative of a highly structured solvent mixture. It has been suggested that β-glucose fits into water structure more effectively than α-glucose (42, 43) possibly

because the anomeric hydroxyl group is more easily solvated in the equatorial position. In an ordered solvent system, such as the particular solvent mixture mentioned above, β-glucose might tend to disrupt the solvent structure more than α-glucose. This would result in a shift of the equilibrium in favor of the α-anomer.

Basicity of the solvent may also affect the position of equilibrium. Los and Simpson have

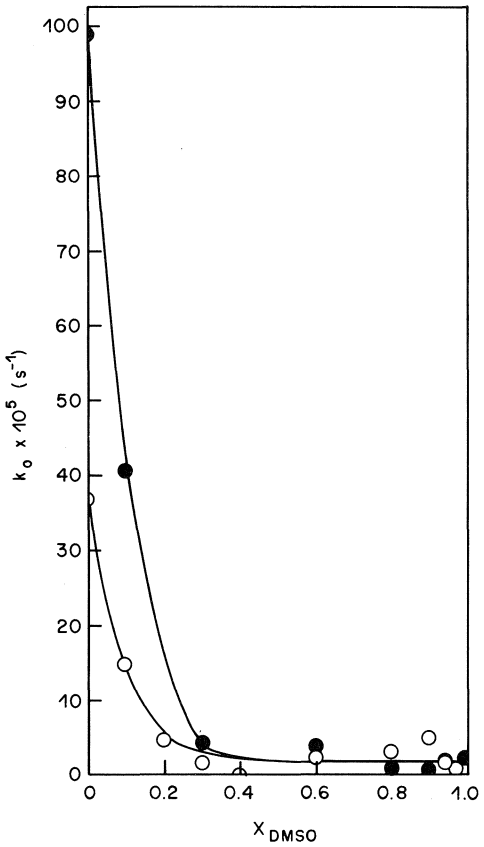

FIG. 4. k_0 as a function of χ_{DMSO} for the mutarotation of glucose in DMSO and water mixtures at 25° (○) and at 35° (●).

shown that α- and β-glucose differ in pK by about 0.3 unit (44) which is sufficient for the β-form to predominate almost exclusively in alkaline solution (45). On this basis, the equilibrium constant would be expected to remain essentially unchanged in water and in DMSO since these solvents are of comparable base strength (28). Changes in other solvent properties such as density, viscosity, and polarity may also affect the equilibrium, but the resulting solvation effects would be expected to be largely the same for both α- and β-glucose. In addition, these properties change by a relatively small amount over the entire mole fraction range.

Figure 3 shows that k_{H+} varies by less than a factor of two over the whole DMSO and water solvent composition region. Evidence that the mechanism for mutarotation remains constant over this solvent range exists in the fact that the thermodynamic activation parameters (Table 2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are nearly constant throughout. If the energetics of the reaction do not change appreciably, there is no reason to suspect any change in the mechanism.

The function k_{H^+} increases in going from pure water to about $\chi_{DMSO} = 0.8$ where it reaches a maximum. The value of k_{H^+} in DMSO is greater than in water by a factor of 1.3. The shape of this curve must depend to a large degree on the variation of acid strength with solvent composition but the extent of this variation cannot be determined unless activities for all of the species involved are known.

In contrast to the behavior of k_{H^+}, the "spontaneous" rate constant, k_0, decreases rapidly on adding DMSO to water (Fig. 4). At $\chi_{DMSO} = 0.3$, for example, k_0 is found to be 1.7×10^{-5} s^{-1} at 25° and 4.4×10^{-5} s^{-1} at 35°. These low rates are a consequence of the fact that at this mole fraction most of the water is presumably bound to DMSO in the form of 2:1 complexes (46). The rapid decline in k_0 with increasing DMSO content is in accord with the accepted view that the mutarotation reaction requires both an acid and a base. On the addition of DMSO to water, strongly hydrogen-bonded complexes are formed. This results in a reduction of the concentration of water, the only acidic species present, which is available to act as a catalyst for the reaction. As a result, k_0 decreases as does the amount of "free" water in solution.

The mutarotation of glucose in DMSO proceeds extremely slowly, if at all, in the absence of H^+. Any observed rate is likely due to the presence of traces of catalytic impurities which are extremely difficult to remove (28).

The water dependence of glucose mutarotation can be obtained by observing the rates of the acid catalyzed reaction in various DMSO and water mixtures where the concentration of water is small. The relationship between $(k_{H^+})^\alpha$ and molar concentration of water, $[H_2O]$, can be derived by considering, for example, the stepwise mechanism depicted in eqs. 8 and 9 where α-glucose is represented by α-G and n is a number. Reactions 8 and 9 are essentially the Pedersen

$$[8] \qquad \alpha\text{-G} + H^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \alpha\text{-GH}^+$$

$$[9] \qquad \alpha\text{-GH}^+ + nH_2O \xrightarrow{k_2} \text{Product}$$

mechanism adapted to show the water dependence of the rate determining step. The rate of reaction is

$$[10] \qquad \text{Rate} = k_2[GH^+][H_2O]^n$$

$$[11] \qquad = k_2 \frac{k_1}{k_{-1}}[G][H^+][H_2O]^n$$

assuming that $k_2 \ll k_{-1}$, *i.e.*, that the rate of removal of the hydrogen from the C-1 hydroxyl is much slower than the rate of removal of the hydrogen from the ring oxygen. The ratio k_{-1}/k_2 should be determined by the relative acidities of the two hydrogens. If the charge is localized on the ring oxygen, the ratio of acidities should be approximately the same as the ratio of the acidities of H_3O^+ as compared to H_2O.

Delocalization of the charge would involve weakening the carbon–oxygen bond, the breaking of which leads to aldehyde formation. Thus, the stability of the cyclic form as compared to the aldehyde form should indicate the extent of charge delocalization. Since the free aldehyde form is present to the extent of only 0.003% (9), very little charge delocalization occurs.[1]

The experimentally observed rate is given by

$$[12] \qquad \text{Rate} = k_{obs}{}^\alpha [G]$$

where

$$[13] \qquad k_{obs}{}^\alpha = k_0{}^\alpha + (k_{H^+})^\alpha [H^+]$$

In the solvent region under consideration ($\chi_{DMSO} = 0.8$–1.0) which is the region past the maximum in Fig. 3, $k_0{}^\alpha$ is negligible in comparison to $(k_{H^+})^\alpha$ and eq. 12 becomes

$$[14] \qquad \text{Rate} = (k_{H^+})^\alpha [G] [H^+]$$

A comparison of eqs. 11 and 14 gives

$$[15] \qquad (k_{H^+})^\alpha = k_2 \frac{k_1}{k_{-1}}[H_2O]^n$$

$$[16] \qquad \log (k_{H^+})^\alpha = n \log [H_2O] + \log k_2 \frac{k_1}{k_{-1}}$$

For the restricted solvent region mentioned above, a plot of log $(k_{H^+})^\alpha$ against log $[H_2O]$ should give a straight line with slope n. Figure 5 shows that for the mutarotation of glucose, the plot is not strictly linear, but does *not* correspond to first- or second-order kinetics and appears to approach zero order in solutions of low water

[1]We are indebted to one of the referees for suggesting this approach.

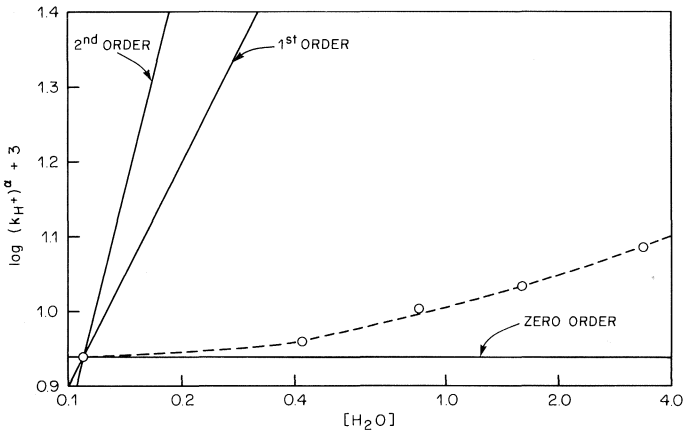

FIG. 5. Log $(k_{H+})^{\alpha}$ as a function of log [H_2O] for the mutarotation of glucose in DMSO and water mixtures at 24.66°. The solid lines represent the curves which would be obtained for various orders of reaction; the broken line connects the experimental points.

concentration. This indicates that there are *no* water molecules involved in the formation of the transition state, and excludes the possibility of a cyclic-concerted mechanism which requires a minimum of two water molecules. A stepwise mechanism on the other hand is consistent with this result and appears to be the only acceptable alternative. The fact that the plot is slightly curved is not surprising since there are many factors which may influence the slope of Fig. 5.

The solvent-catalyzed mutarotation reaction cannot be analyzed in the same way since, when $\chi_{DMSO} > 0.3$, uncatalyzed rates are exceedingly slow. For solutions containing water in concentrations of the order of 1 *M* or less, it is impossible to determine k_0 with any accuracy. However, for the region where k_0 could be measured ($\chi_{DMSO} < 0.3$), plots of log k_0^{α} against log [H_2O] were drawn up. Slopes of 3.3 ± 0.2 were obtained from data at both 25 and 35°. In aqueous solution without added catalyst, water molecules must act as an acid or base and it is possible that the mutarotation reaction does proceed *via* a cyclic-concerted mechanism involving about three water molecules. The alternative is that the solvent- and acid-catalyzed reactions proceed by way of analogous mechanisms with no solvent participation. The former possibility, based on the derived water dependence for the solvent-catalyzed reaction at high water concentrations, is certainly questionable although the amount of "free" water at $\chi_{DMSO} = 0.3$ is presumably very low (41, 47–49). This conclusion is very similar to the one drawn from a study of the solvent isotope effects (18, 19), and also agrees with the conclusions drawn by Stewart and Van Dyke from a study of the hydration of trifluoroacetophenones in aqueous sulfolane (26).

Patting and Strehlow have shown that pyruvic acid exists in aqueous solution as a "relatively stable trihydrate" (50), one water molecule being involved in the formation of the diol and the other two forming a hydrogen-bonded complex. They interpret the kinetics of the hydration and dehydration reactions as proceeding *via* a transition state similar to this trihydrate species. Inclusion of three water molecules in the kinetic expression for the hydration reaction leads to a nearly linear plot of rate as a function of HCl concentration up to levels as high as 5 *M* HCl. Their experimental conditions also involved 0.5 *M* pyruvic acid and 53 *M* water. Conclusions which are based on experimental results obtained under such extreme conditions must be treated with caution.

For the mutarotation of glucose, the enthalpies of activation were found to be practically constant over the entire range of solvent compositions. The values obtained in this study were in reasonable agreement with those reported previously (36, 40).

The entropy of activation is less negative for catalysis by proton than for catalysis by water. This order is difficult to explain since greater solvation should be observed with the charged complex resulting from an ionic catalyst unless factors other than solvation are important.

It is reasonable to propose again on the basis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of activation entropies that different mechanisms may be involved for different types of catalysis. The large negative activation entropy for water catalysis may represent the involvement of several water molecules in the transition state while the higher value for acid catalysis may simply be an expression of increased solvation of the transition state over the reacting species.

Summary

It has been demonstrated that the acid-catalyzed mutarotation of glucose proceeds by a stepwise mechanism in which there is no solvent participation in the transition state. On the other hand, conclusions regarding the mechanism for catalysis by water molecules are less definite. Both the kinetic and activation entropy results obtained in DMSO and water mixtures at high water concentrations indicate that the mechanism for solvent catalysis may be concerted involving three water molecules in a cyclic transition state.

The Conformational Equilibrium of 1,2,3-Tribromopropane in Solution

L. ERNST[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 3, 1972

The p.m.r. spectra of dilute solutions of 1,2,3-tribromopropane in carbon tetrachloride, acetonitrile, and dimethylsulfoxide as well as of the neat compound are examined. From the three- and four-bond spin–spin coupling constants and from a comparison between observed and calculated dipole moments it is concluded that in nonpolar solvents the title compound exists preferably in the enantiomeric conformations **a** and **i**. In polar solvents other rotamers contribute to the equilibrium but still seem to play only a minor role. Semiempirical calculations of conformational energies rule out contributions to the conformational equilibrium from rotamers having (1:3) bromine–bromine interactions, but otherwise are only in moderate agreement with experiment.

Les spectres r.m.p. de solutions diluées de tribromo-1,2,3 propane dans le tétrachlorure de carbone, l'acétonitrile, et le diméthylsulfoxide aussi bien que ceux du composé pur ont été étudiés. A partir des constantes de couplage spin–spin à trois et à quatre liaisons et à partir d'une comparaison entre les moments dipolaires calculés et observés, on a conclu au fait que dans des solvants non-polaires, le composé étudié existe préférentiellement dans les conformations énantiomériques **a** et **i**. Dans les solvants polaires, les autres rotamères contribuent à l'équilibre mais ne jouent, même là, qu'un rôle mineur. Des calculs semiempiriques des énergies conformationnelles refutent les contributions à l'équilibre conformationnel des rotamères possédant des interactions brome–brome (1:3), mais autrement ceux-ci ne sont qu'en accord partiel seulement avec l'expérience.

Introduction

There have been numerous studies in recent years on the rotational isomerism of ethane derivatives (1). 1,2-Disubstituted propanes, which can be regarded as trisubstituted ethanes, have also been investigated (2). In both types of compounds the maximum possible number of staggered conformations is three. An interesting and more complex problem is presented by the class of 1,2,3-trisubstituted propanes in which simultaneous rotation about the two C—C single bonds can occur, raising the maximum number of staggered conformations to nine. Dempster *et al.* studied the conformations of a number of polychlorinated propanes, among them 1,2,3-trichloropropane, by i.r. and n.m.r. methods (3).

We wish to report on the analyses of the p.m.r. spectra of 1,2,3-tribromopropane (**1**) in solvents of different polarity and on attempts to calculate conformational energies. The magnitudes of the three- and four-bond proton–proton coupling constants as well as the comparison between the observed (4) and calculated dipole moments allow some conclusions concerning the nature and the relative importance of the conformations involved in the rotational equilibrium.

Experimental

1,2,3-Tribromopropane, from Eastman Organic Chemicals, was used without further purification. Eight mole percent solutions in carbon tetrachloride, acetonitrile, and dimethylsulfoxide (DMSO) as well as a neat sample were prepared, all containing a small quantity of tetramethylsilane (TMS) as internal reference and locking substance. The samples were degassed by the usual freeze–pump–thaw technique. The p.m.r. spectra were recorded on a Varian HA-100 D spectrometer operating in the frequency sweep mode at a probe temperature of *ca.* 30 °C. Sweep rates were 0.02 or 0.05 Hz/s. To prevent errors arising from the nonlinearity of the spectrometer sweep, peak positions were calibrated at intervals of less than 5 Hz using a Hewlett–Packard 5323A frequency counter. The spectra which were of the AA′BB′C type were analyzed by means of the iterative computer program LAME (5).

Results and Discussion

(1) Analysis of Proton Magnetic Resonance Spectra

The spectral parameters for **1** and their standard deviations obtained in the iterative analysis are given in Table 1. In reporting the results we follow the recent recommendations of Abraham

[1]Postdoctoral Fellow 1971–1972. Present address: Badische Anilin- und Soda-Fabrik, Ludwigshafen, West Germany.

TABLE 1. Chemical shifts and coupling constants for 8 mol % solutions of 1,2,3-tribromopropane in different solvents

	Solvent			
Parameter*†‡	CCl_4	Neat	CH_3CN§	DMSO
ν_A	390.86 (1)		397.85 (1)

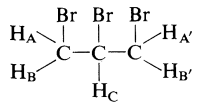
$^4J_{AA'}$	−0.40 (2)		−0.40 (2)	
$^4J_{BB'}$	−0.38 (1)		−0.34 (2)	
$^4J_{AB'}$	0.37 (1)		0.32 (1)	

*Chemical shifts in Hz at 100 MHz relative to internal TMS.
†Coupling constants in Hz.
‡Figures in brackets represent standard deviations as given by LAME and are to be applied to the last decimal figure.
§Chemical shifts in the CH_3CN solution were obtained relative to the solvent signal and were related to TMS by adding 196.4 Hz, the measured shift difference between CH_3CN and TMS in this solution.



1

(6). Complete analyses could only be obtained for the solutions in CCl_4 and CH_3CN. For the neat compound and for the solution in DMSO, line widths were larger than 0.2 Hz and the fine structure of the AA'BB' parts of the AA'BB'C spectra was not well enough resolved to allow assignment of a number of transitions sufficient for the extraction of the four-bond coupling constants. Therefore only the methine proton spectrum was analyzed to yield the vicinal couplings J_{AC} and J_{BC} and the chemical shift ν_C. Root mean square (r.m.s.) errors between calculated and observed frequencies were 0.036 Hz for the neat liquid and 0.024 Hz for the DMSO solution. Fifteen of the 16 calculated transitions in the methine region were assigned in both cases. The largest deviations between calculated and observed line positions were 0.07 (neat) and 0.05 Hz (DMSO). The larger errors for the neat sample were probably caused by line broadening from viscosity effects since the melting point of **1** is 16 °C.

The complete analysis of the spectra of the CCl_4 and CH_3CN solutions offered some difficulties. While good starting values for the iterative calculation could be obtained for the three chemical shifts and for the geminal and vicinal couplings, this was not the case for the four-bond couplings. It was not possible to extract ^4J values from the methylene spectrum using first-order rules (see Fig. 1 for the CCl_4 solution). Therefore J_{AC}, J_{BC} and ν_C were initially obtained from the analysis of the methine peaks. Reasonable estimates of ν_A, ν_B, and $^2J_{AB}$ could be found from the methylene spectrum. These values were then kept constant and about 40 noniterative spectra were calculated varying $J_{AA'}$, $J_{BB'}$ and $J_{AB'}$ independently between −0.6 and +0.6 Hz. The only spectra that bore a resemblance to the experimental ones, thereby permitting assignment of the transitions, were those with $J_{AA'}$ and $J_{BB'}$ lying in the vicinity of −0.4 Hz and with $J_{AB'}$ near +0.4 Hz. For the CCl_4 (CH_3CN) solution the signs and magnitudes of the four-bond couplings were then obtained by iteration on 61 (47) out of 64 (64) calculated transitions of sufficient intensity. The r.m.s. error was 0.024 (0.019) Hz and the largest deviation between calculated and observed frequencies was 0.05 (0.05) Hz. Spin tickling experiments were not useful because only very few lines of the AA'BB' part were nondegenerate. However, the relative signs of the coupling constants were safely determined by the distinctive second-order character of the spectra. In order to illustrate the analytical quality, the experimental and the calculated spectra of the methylene protons of **1** in CCl_4 are given in Fig. 1. The calculated spectrum uses a line width of 0.15 Hz and an asymmetric line shape to simulate spectrometer conditions (7).

(2) Vicinal Couplings

To facilitate the discussion, the nine possible staggered rotamers of **1** are shown together with

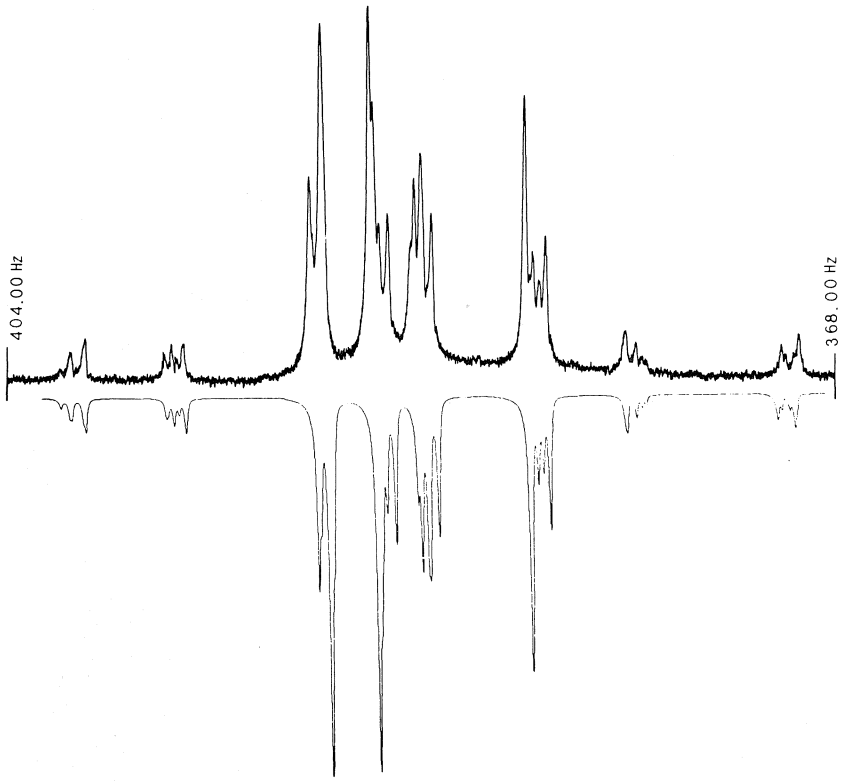

FIG. 1. Experimental (top) and calculated (bottom) p.m.r. spectra at 100 MHz of the methylene protons of an 8 mol % solution of 1,2,3-tribromopropane in CCl_4. Slight differences between the line positions of the two spectra arise from the nonlinearity of the spectrometer sweep.

the values of their dihedral angles ϕ_1 (Br^1—C^1—C^2—C^3) and ϕ_2 (C^1—C^2—C^3—Br^3). We arbitrarily define ϕ_1 as positive when Br^1 lies *in front* of the plane of the paper and ϕ_2 as positive when Br^3 lies *behind* the plane of the paper. This definition corresponds to looking along the bond from C^1 to C^2 (C^2 to C^3) with ϕ_1 (ϕ_2) being positive if an anticlockwise rotation of Br^1 (C^1) is required to cause eclipse with C^3 (Br^3). Not all nine conformations will differ in their physical properties because **a**/**i**, **b**/**f**, and **d**/**h** are pairs of enantiomers. Furthermore, conformations **c** and **g** have '(1:3) halogen–halogen interactions' and are not appreciably populated if other conformations are available to the molecule (3), a behavior well reproduced by calculations of conformational energies (see section 5). The discussion is thus limited to the four rotamers **a**, **b**, **d**, and **e** having statistical weights of 2, 2, 2, and 1, respectively. The fractional populations of **a**, **b**, **d**, and **e** are p_1, p_2, p_3, and p_4 and hence

$$[1] \qquad 2p_1 + 2p_2 + 2p_3 + p_4 = 1$$

The observed vicinal couplings J_{AC} and J_{BC} are the weighted averages of their values in the individual rotamers. It has been shown (8) that these individual couplings do not only depend on the relative orientation of the protons under consideration (*i.e.* if they are *gauche* or *trans* to each other) but also on the relative position of the substituents. Using the nomenclature of ref. 8 (subscripts to indicate the relative position of the bromine atoms and superscripts to give the relationship between the coupled protons) eqs. 2 and 3 can be written[2]

$$[2] \quad J_{AC} = p_1(J_t^g + J_g^{g'}) + p_2(J_t^g + J_g^t) + p_3(J_g^t + J_g^{g'}) + p_4 J_g^t$$

[2]See section 3 for the justification of labelling the protons A and B.

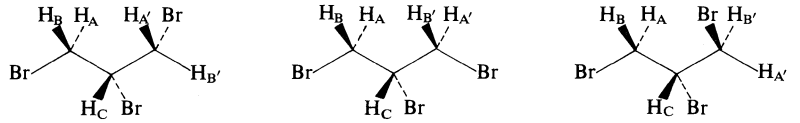
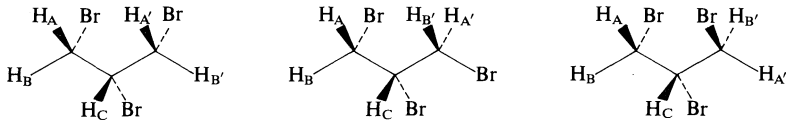
a: $\phi_1 = 60,\ \phi_2 = 60^\circ$ b: $\phi_1 = 60,\ \phi_2 = 180^\circ$ c: $\phi_1 = 60,\ \phi_2 = 300^\circ$



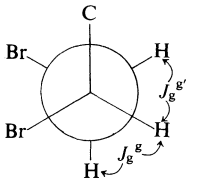
d: $\phi_1 = 180,\ \phi_2 = 60^\circ$ e: $\phi_1 = 180,\ \phi_2 = 180^\circ$ f: $\phi_1 = 180,\ \phi_2 = 300^\circ$



g: $\phi_1 = 300,\ \phi_2 = 60^\circ$ h: $\phi_1 = 300,\ \phi_2 = 180^\circ$ i: $\phi_1 = 300,\ \phi_2 = 300^\circ$

$$[3]\quad J_{BC} = p_1(J_t^t + J_g^g) + p_2(J_t^t + J_g^g) + p_3(J_g^g + J_g^g) + p_4 J_g^g$$

where the first entries in the brackets refer to the coupling constants across the C^1—C^2 bond, the second to the couplings across the C^2—C^3 bond. The meaning of J_g^g and $J_g^{g'}$ can be seen from formula **j**.



j

Abraham (8*a*) gives a set of equations describing the dependence of the coupling constants in the individual rotamers on the sum of the electronegativities of the substituents X and Y in molecules of the type X—CH_2—CH_2—Y, see eqs. 4*a–e*.

$$[4a]\quad J_t^g = 1.35 + 0.63\,(E_X + E_Y)$$

$$[4b]\quad J_t^t = 18.07 - 0.88\,(E_X + E_Y)$$

$$[4c]\quad J_g^g = 8.94 - 0.94\,(E_X + E_Y)$$

$$[4d]\quad J_g^{g'} = 10.45 - 1.43\,(E_X + E_Y)$$

$$[4e]\quad J_g^t = 16.47 - 0.60\,(E_X + E_Y)$$

For X = Y = Br, $E_X + E_Y = 5.9$ and the following values for J_t^g, J_t^t, J_g^g, $J_g^{g'}$, and J_g^t are obtained for Br—CH_2—CH_2—Br: 5.07, 12.87, 3.39, 2.01, 12.93 Hz. In the present case, Br—CH_2—$CH\langle^{C}_{Br}$, a third substituent is attached to the ethane framework and simple addition of the electronegativity of carbon to the term $E_X + E_Y$ yields values of 6.7 and −1.7 Hz for J_t^g and $J_g^{g'}$, respectively, outside the range of *gauche* couplings. As will be seen below, a compromise between these extremes proves to be most sensible.

Even if values for the individual couplings are available, there exist only three equations, 1–3, for the determination of four unknowns, p_1, p_2, p_3, and p_4. Fortunately the boundary conditions, that only solutions with positive values for the populations are possible and that p_1, p_2, and p_3 lie between 0 and 0.5 and p_4 between 0 and 1 (because of eq. 1), considerably simplify the problem. We varied p_1 in steps of 0.002 between the limits of 0 and 0.5 and calculated the remaining populations by means of eqs. 1–3. Using the individual couplings obtained directly from eqs. 4*a–e* there existed no solution for which all p's were positive. To account for the presence of the carbon substituent, the electronegativity term in eqs. 4*a–e* was augmented by 10% giving J_t^g, J_t^t, J_g^g, $J_g^{g'}$, and J_g^t as 5.44, 12.35, 2.84, 1.18 and 12.53 Hz, respectively. For this set of parameters, solutions to eqs. 1–3 could be found which satisfied the boundary conditions simultaneously for the values of J_{AC} and J_{BC} in the four different solvents.

Augmentation of $E_X + E_Y$ by 20% gave a

TABLE 2. Ranges of populations of the conformations of 1,2,3-tribromopropane in different solvents as obtained from the vicinal coupling constants

Solvent	ε*	J_{AC}	J_{BC}	p_1	p_2	p_3	p_4
CCl_4	2.45	4.25	7.04	0.40–0.44	0.05–0.00	0.06–0.01	0.00–0.09
Neat	6.40	4.57	6.81	0.36–0.42	0.06–0.00	0.08–0.02	0.00–0.12
CH_3CN	22.7	4.60	6.64	0.35–0.40	0.05–0.00	0.10–0.05	0.00–0.06
DMSO	29.2	4.78	6.34	0.32–0.37	0.05–0.00	0.13–0.09	0.00–0.09

*Calculated from eq. 5. for 8 mol % solutions.

$J_g{}^{g'}$ of 0.33 Hz, probably too small for the degree of substitution present in **1**. Nevertheless, solutions for all four solvent cases were still possible, although the vicinal couplings measured in CCl_4 allowed positive p_2, p_3, and p_4 values only in a very narrow range of p_1 (0.400–0.402). If the term $E_X + E_Y$ was made 30% larger no solutions were found with all p's positive. Consequently, if Abraham's eqs. 4*a–e* are to be applied to molecule **1**, the terms containing the sum of the electronegativities of the bromine atoms should be multiplied by a factor of 1.1 to 1.2 with 1.1 being more likely.[3]

Table 2 lists the ranges of populations which were obtained by the outlined procedure from the vicinal coupling constants in the different solvents. The dielectric constants were calculated by means of eq. 5 (ref. 9), where ε_1 ε_2, and ε_s are

$$[5]\quad \frac{\varepsilon_s - 1}{\varepsilon_s + 2} = \frac{\varepsilon_1 - 1}{\varepsilon_1 + 2}\cdot\frac{V_1}{V_1 + V_2} + \frac{\varepsilon_2 - 1}{\varepsilon_2 + 2}\cdot\frac{V_2}{V_1 + V_2}$$

the dielectric constants of solvent, solute, and solution, respectively, and V_1 and V_2 the volumes of solvent and solute. It is seen that with increasing polarity of the solution p_1 decreases from about 0.42 to 0.35, p_3 increases from 0.03 to 0.11, whereas p_2 and p_4 remain approximately constant over the solvent range at *ca.* 0.03 and 0.05, respectively. Conformations **a** and **i** are therefore the most important ones and together contribute 84% in CCl_4 and 70% in DMSO. The remaining conformations appear to be rather unimportant, except for the pair **d**/**h** which is present to the extent of about 20% in highly polar solvents.

(3) Four-bond Couplings

These couplings are less reliable as a tool in conformational analysis than are the vicinal couplings because most experimental data that are available refer either to more or less strained cyclic molecules or to molecules in which one of the protons belongs to a methyl group, thus yielding only an average over the staggered conformations. A number of INDO molecular orbital calculations (10) have been performed on propanic couplings and theoretical data are available for all possible staggered conformations. Barfield (10*a*) has shown that electronegative inductive substituents, whether bonded to the central or to the terminal carbon atoms, cause positive shifts in the coupling constants relative to propane. Comparing the theoretical coupling constants for propane and the monofluoropropanes (10*a*) and estimating the inductive effect of bromine to be about half as large as that of fluorine while assuming additivity of substituent effects, one arrives at some values for the long-range coupling constants of the individual rotamers of **1**. One can then write four equations (one for each of $J_{AA'}$, $J_{BB'}$, and $J_{AB'}$ plus eq. 1) to calculate the populations p_1 to p_4. However, this set of equations is very poorly defined and small changes in the parameters $J(\phi_1, \phi_2)$ or in the experimental coupling constants result in large variations of the calculated populations. This behavior arises because according to theory (10*a*) rather similar couplings have to be assumed for some conformations with different dihedral angles.

The long-range couplings are useful, however, in one respect. One of the experimental couplings, $J_{AB'}$, is positive and INDO (10*a*) predicts positive values only near the planar 'zig–zag' or 'W' arrangement of the coupled protons. This

[3]A referee pointed out that our treatment neglects the orientation factor for the extra carbon substituent in the fragment Br—CH_2—CH<(Br, C) as compared to Br—CH_2—CH_2—Br. Unfortunately, a decision on how to treat this factor cannot be made at the present time because of lack of evidence (experimental and theoretical) from similar compounds. We therefore emphasize that our conclusions can only be of a qualitative nature.

For personal use only.

arrangement occurs in **a** and its mirror image **i** (**c** and **g** being ruled out because of their (1:3) Br–Br interactions). As the contributions to J_{AB}, from all conformations but **a** are negative, **a** must be very appreciably populated in order to override the negative contributions from **b**, **d**, and **e**. This conclusion justifies the labelling of protons H_A and H_B in **a** to **i** since in the major pair of rotamers **a**/**i** the coupling $J_{AC} \simeq 4.5$ Hz is smaller than $J_{BC} \simeq 6.5$ Hz, in agreement with what is inferred from the formulae, *viz.* $J_{AC} = J^g$ and $J_{BC} = (J^g + J^t)/2$, *i.e.* $J_{AC} < J_{BC}$.

(4) Dipole Moment

The dipole moment of **1** at 20° is 1.58 D in benzene solution and 1.63 D in the neat liquid (4). Assuming the geometry described in section 5 and bond moments of $\mu_{C-H} = 0$ and $\mu_{C-Br} = 1.8$ D (1), one calculates a dipole moment of 1.68 D for **a**, 1.77 D for **b**, 2.88 D for **d**, and 3.19 D for **e**. This result constitutes another strong indication of the unimportance of rotamers **d** and **e** and suggests that **1** exists almost exclusively as **a** and/or **b**. Choosing C—Br bond moments of 1.6 D does not change this conclusion. Even $\mu_{C-Br} = 1.5$ D leads to $(2p_3 + p_4) < 0.23$.

(5) Calculation of Conformational Energies and Their Solvent Dependence

The method of classical mechanics was used in an attempt to calculate the energies and populations of all possible rotamers of **1**. We follow the approach of Abraham and Parry (11) in that the energy of a given conformation in the vapor phase consists of the torsional strain plus the sum of the interactions between the atoms not bonded to a common carbon atom, as given by eq. 6. The parameter $V_0 = 2.65$ kcal/mol and

$$[6] \quad E_v = 0.5\, V_0\,(2 + \cos 3\phi_1 + \cos 3\phi_2) + \sum \{a_{ij} \exp(-b_{ij}) - c_{ij}/r_{ij}^6 + d_{ij}/r_{ij}\}$$

the values for a, b, c, and d are taken from ref. 11. The first two terms in the summation of eq. 6 represent repulsive and attractive van der Waals interactions, respectively, and the third term gives the electrostatic interaction of the polar substituents. The present approach neglects the changes in geometry occurring during the internal rotation because it uses the same bond lengths and angles for all conformations and only takes into account the variation of the dihedral angles. Therefore the calculations are rather simple when compared to the method of adjusting the geometry of every rotamer for a minimum total energy (12).

The following geometry was used: C—H bond length 1.09 Å, C—Br 1.93 Å, and C—C 1.54 Å. The bond angles BrCC and HCH at the terminal carbon atoms were set at 113 and 106°, respectively. Assuming equal magnitudes of the BrCH and CCH angles, these were calculated to be 109.4°. For the central carbon the BrCC and CCC angles were taken as 111 and 113°, giving CCH and BrCH angles of 107.2° when the latter two were assumed equal. Other geometries were tried, *e.g.* the one given in ref. 11, but gave worse agreement between calculated and experimental populations.

Solvation energies E_s for the different solvents were included in the calculations following the principles laid down in ref. 13 and using a computer program described in ref. 14. This program and the subroutine which determines the vapor phase energies were tested by the recalculation of literature values (9, 11) and produced the same results. In the calculations of E_s for **1**, dipole moments of 1.8 D for the C—Br bonds (*1a*) entailed too high a sensitivity to changes in solvent polarity. A μ_{C-Br} value of 1.5 D appeared to be more appropriate.

The total energy $E = E_v + E_s$ was calculated for simultaneous rotation about both C—C bonds by varying ϕ_1 and ϕ_2 from 0 to 360° at intervals of 6°. A step size of 2° was chosen near the energy minima. The final potential energy surface for the CCl_4 solution is shown in the contour diagram of Fig. 2. The following points represent energy minima: **a** (62, 56), **b** (66, 190), **d** (166, 54), **e** (170, 190), **f** (170, 294), **h** (300, 194), and **i** (304, 298). The numbers in brackets give ϕ_1 and ϕ_2, respectively, in degrees. In the region of dihedral angles corresponding to conformations **c** and **g** only shallow high-energy troughs are found (see Fig. 2). Their minima lie at (81, 279) and (285, 75), considerably displaced from the 'ideal' dihedral angles of 60 and 300°. The destabilizing effect of the (1:3) bromine–bromine interactions is well reproduced. While the general appearance of the calculated energy surface seems reasonable there is no agreement between the calculated order of stability of the conformations and the order deduced from the experiments. For the CCl_4 solution $p_2 > p_1 \gg p_4 \sim p_3$

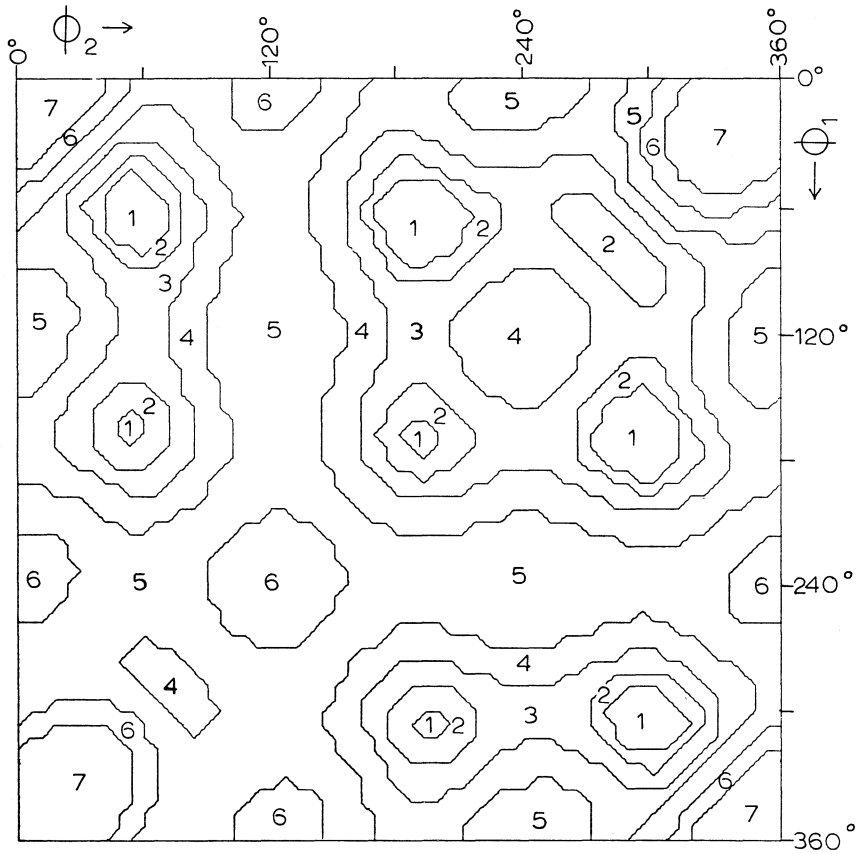

FIG. 2. Calculated energy diagram for the internal rotation of 1,2,3-tribromopropane in CCl_4. For the definition of ϕ_1 and ϕ_2 see text. The energy regions are defined as follows: 1: 0–1; 2: 1–2; 3: 2–4; 4: 4–8; 5: 8–16; 6: 16–32, and 7: >32 kcal/mol relative to the most stable conformation.

is calculated whereas the vicinal couplings lead to $p_1 \gg p_2 \sim p_3 \sim p_4$. Corresponding results for the DMSO solution are $p_2 > p_1 > p_4 > p_3$ (calculation) and $p_1 > p_3 > p_2 \sim p_4$ (experiment). These discrepancies may be due to the inadequacy of the method of calculation, *i.e.* assuming rigid bond lengths and angles over the whole range of dihedral angles. On the other hand, the functions describing the nonbonded interactions have so far only been used in calculations on ethane derivatives and on 1,2-disubstituted propanes. Perhaps they need modifications in order to describe the conformational behavior of the present, rather different, class of compounds.

We are grateful to the National Research Council of Canada for financial assistance. Dr. D. J. Wood kindly supplied the computer program for the calculation of solvation energies. Fruitful discussions with him are also appreciated.

Proton Magnetic Resonance Studies of Long-range Coupling Constants: Conformational Dependence of the ^4J Coupling Between Side Chain and Ring Protons in Formylheterocycles

BERNARD PIERRE ROQUES

Département de Chimie, Ecole Polytechnique, 17 rue Descartes, 75230 Paris Cedex 05, France

AND

SUZANNE COMBRISSON

Laboratoire de Chimie Organique, Ecole de Physique et Chimie, 10 rue Vauquelin, 75005 Paris, France

Received July 21, 1972

The ^4J coupling constant between side chain and ring protons is studied on particular models of planar heterocyclic aldehydes.

The preferential conformation of these molecules is established by use of the "zig–zag" rule for the ^5J coupling constant. This allows precise analysis of the ^4J coupling across *cc* and *ct* pathways.

The sign of some of these constants is determined and is found to be negative in either *cc* or *ct* pathways. The use of the "methyl replacement technique" shows a dominant σ electron contribution to the ^4J coupling constants. In all examples studied here, the ^4J coupling value is dependent on the pathway: $^4J^{ct}$ (−0.30 at −0.45 Hz) > $^4J^{cc}$ (−0.10 at −0.15 Hz). The existence of a stereospecificity for this coupling is in accordance with a preponderant σ electron mechanism and is useful in conformational analysis of planar aromatic aldehydes.

Le couplage ^4J entre la chaîne latérale et les protons du cycle est étudié sur différents modèles d'aldéhydes hétérocycliques de structure plane. La conformation préférentielle de ces modèles est établie par utilisation du couplage stéréospécifique ^5J. Ceci permet l'analyse détaillée des couplages ^4J au travers des enchaînements de liaisons *cc* et *ct*. Le signe de quelques-uns de ces couplages est déterminé. Il est négatif quelle que soit la disposition des liaisons. L'utilisation de la technique par remplacement d'un proton par un radical méthyle montre la prépondérance de la contribution électronique σ dans le mécanisme de ce couplage ^4J. Dans tous les exemples étudiés, le couplage ^4J est dépendant de la conformation de l'enchaînement: $^4J^{ct}$ (−0.30 à −0.45 Hz) > $^4J^{cc}$ (−0.10 à −0.15 Hz). L'existence d'une stéréospécificité de ce couplage est en accord avec la prépondérance du mécanisme de transmission σ, et peut être utilisée dans l'analyse des conformations planes d'aldéhydes aromatiques.

Can. J. Chem., **51**, 573 (1973)

Introduction

The spin–spin coupling constants over five bonds between ring and side chain protons in benzaldehydes and substituted derivatives have been studied extensively (1, 2). These couplings are stereospecific (zig-zag path) and are dominated by the σ contribution (3). In contrast, in benzaldehyde the sign of the coupling over four bonds is negative, and consequently its mechanism has been attributed to a π electron transmission. However, recently Danyluk *et al.* have shown that this coupling is dominated by a σ electron contribution (4). This conclusion is in accordance with theoretical calculations (5) which have shown negative values for ^4J coupling constants in particular conformations of saturated molecules.

In heterocyclic aldehydes (furan, thiophene, pyrrole), we have shown that the stereospecific rule for ^5J coupling is also valid (6, 7) and allows the determination of conformational preferences. In these structures, the ^4J couplings between formyl group and ring protons have not been systematically studied because of the weakness of these couplings. However, the asymetrical structures and conformational preferences of the heterocyclic aldehydes provide suitable models for a study of the ^4J coupling in two particular pathways: *cc* and *ct*. In this paper, we have

studied these couplings by the slow-passage technique in a number of α and β formylthiophenes, furans, and pyrroles. In some cases we have determined the sign of the coupling constants.

The results are discussed in terms of σ and π

electron contributions and the conformational dependence of the ^4J coupling.

Experimental

(1) Compounds

3-Formylthiophene (**6**), 2-formylpyrrole (**3**) and 1-methyl-2-formylpyrrole (**4**) were obtained from commercial sources. Other compounds were prepared by the methods quoted in references: **1** (8), **2** (9), **5** (10), **7** (11), **8** (12), **9** (13), **10** (14), and **11** (14).

(2) Nuclear Magnetic Resonance Spectra

Proton magnetic resonance spectra were recorded on a Varian HA 100 NMR spectrometer locked to HMDS at a sweep rate of 0.01 Hz/s. Double resonance experiments were accomplished using a Hewlett–Packard 200 AB oscillator. Solutions of the compounds were prepared in $CDCl_3$ that contained about 5% hexamethyldisiloxan (HMDS). All solutions were thoroughly degassed by several freeze–pump–thaw cycles. Chemical shifts are not included in this work because they are irrelevant for the present study. The coupling constants are measured directly on the spectrum and after selective irradiation. The accuracy is ± 0.05 Hz except for the compounds **1**, **2**, and **11** where the accuracy is ± 0.005 Hz. For these latter three compounds the coupling constants are computed by the "wiggle beat" technique (15).

(3) Signs

The relative signs of the coupling constants are usually obtained by the tickling technique described originally by Freeman and Anderson (16). We have determined the signs of the coupling constants in **1** and **2** by this method. However, tickling causes perturbations of any transition close ($\Delta\nu < 0.5$ Hz) to the irradiated transition and in the case of **11** the sign determination by this technique is unsuccessful. Instead, we have used the generalized Overhauser experiments described by Kaiser (17), and we have determined the sign of the coupling constants in **11** by the method of Bell *et al.* (3). In this technique, the amplitude of the second radiofrequency field is smaller than in the tickling experiments. As a consequence the connected transitions change in intensity instead of splitting into doublets.

The spin states of the nuclei coupled to other protons are given below the spectra with the convention that a positive sign under a lowfield peak of the proton denotes a positive coupling to the nucleus in question. The spin states are labelled in accordance with the signs found experimentally. The ring proton couplings are positive (18) and the signs are determined relative to them.

These experiments are illustrated by the results obtained for 4-bromo-2-formylthiophene (**2**) and 2,3-diformylthiophene (**11**).

(a) 4-Bromo-2-formylthiophene (2)

The spectrum of **2** is shown in Fig. 1. In Fig. 2, the single proton resonance spectrum of the H_3 proton is shown. The $^4J_{CHO-3}$ is clearly resolved. In Fig. 2*a* the intensity of transitions 2 and 4 of H_3 decrease by separation into unresolved doublets when transition 1 of H_5 in Fig. 1 is weakly irradiated. On the other hand no change is noted in the signal intensity of transitions 1 and 3. In Fig. 2*b* the irradiation of 4 of H_5 causes a decrease of transition 1 and 3 of H_3 while 2 and 4 remain unchanged. Hence $J_{3-5}/J_{CHO-3} < 0$. Because the couplings between ring protons and $^5J_{CHO-5}$ are positive (20), $^4J_{CHO-3}$ is negative.

(b) 2,3-Diformylthiophene (11)

We have determined by successive ticklings the signs

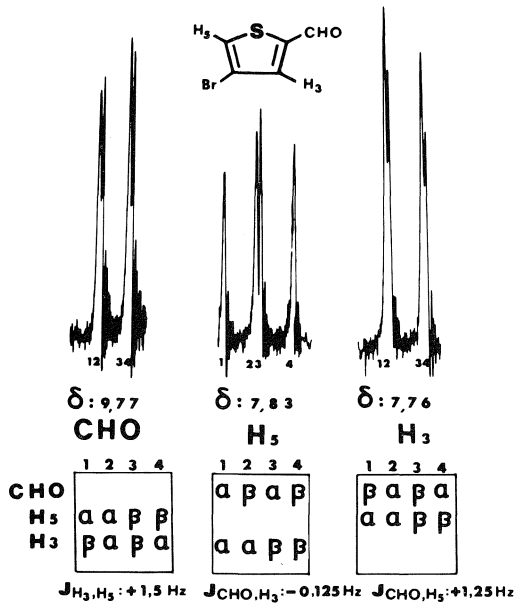

FIG. 1. Spectrum of 4-bromo-2-formylthiophene (**2**) ($\alpha = +$; $\beta = -$).

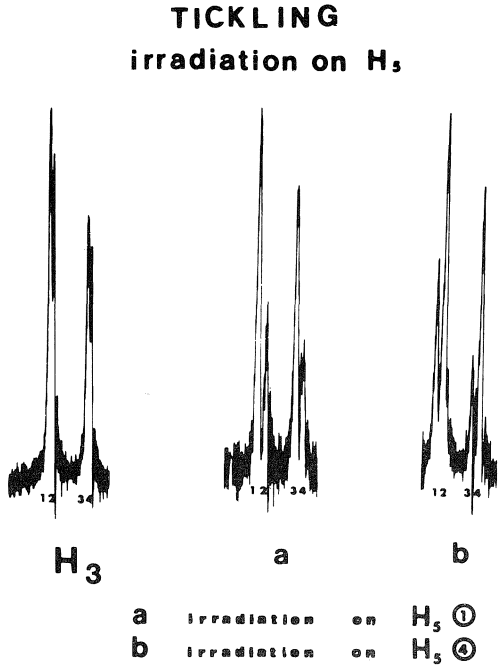

FIG. 2. Tickling on 4-bromo-2-formylthiophene (**2**).

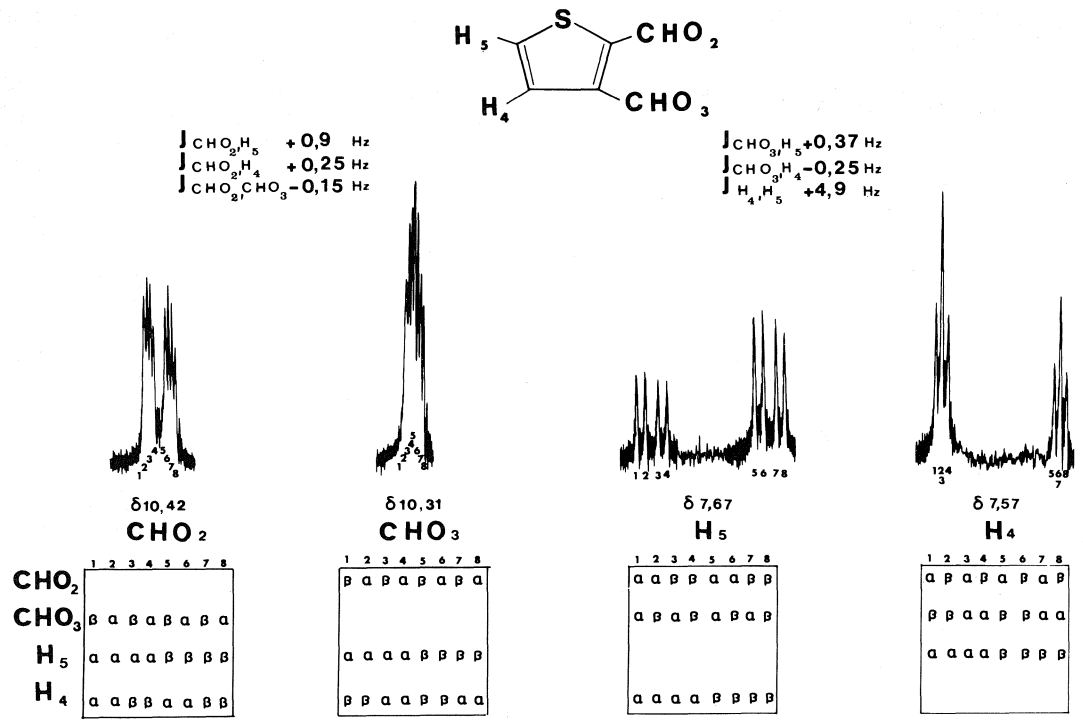

FIG. 3. Spectrum of 2,3-diformylthiophene (**11**) ($\alpha = +$; $\beta = -$).

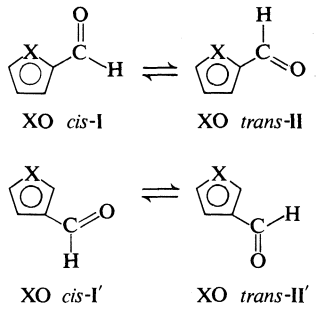
of $^5J_{CHO_2-5}$, $^5J_{CHO_2-4}$, $^5J_{CHO_3-5}$ which are all positive and $^4J_{CHO_3-4}$ which is negative in accordance with published data (19–21).

We have also determined directly $^5J_{CHO_2-CHO_3}$ by the generalized Overhauser experiment. Fig. 3 shows the spectrum of **11**. In Fig. 4*a*, the single proton resonance spectrum of the aldehydic proton CHO_2 is shown. Fig. 4*b* shows that very weak irradiation centered on peak 1 of H_5 (Fig. 3) causes a decrease in peak 2 (regressively connected transitions) and an increase in peak 6 (progressively connected transitions). Thus $^5J_{CHO_2-4}/^5J_{CHO_2-CHO_3} < 0$, and since $^5J_{CHO_2-4} > 0$, $^5J_{CHO_2-CHO_3}$ is negative.



Results

^5J Coupling Constants and Conformational Preferences

All spectra are interpreted at first order and the results are reported in Table 1.

Heterocyclic aldehydes must flip between two planar conformations XO *cis* **I** or **I'** and XO *trans* **II** or **II'**.

At room temperature, we had previously determined (22, 23), by application of the ^5J stereospecific rule, the preferential conformations of all the compounds described in Table 1 except **9**.

In unsubstituted derivatives, the formyl group in the β position is almost exclusively in the XO *trans* conformation **II'**. In contrast, furfural exists in roughly equal mixtures of O–O *cis*-**I** and O–O *trans*-**II** forms. This result has been interpreted by the attendance of three interactions (24). As in benzaldehyde the stereospecific ^5J coupling must be interpreted in terms of σ transmission. We have computed the percentage of π transmission in this ^5J coupling by the "methyl replacement technique" (25). The $W_{1/2}$ width of the H_5 signal before and during irradiation of the methyl group in 2-acetyl-4-bromothiophene is determined. The difference is about 0.10 Hz. Because the $^5J_{CHO-5}$ coupling constant in 2-formyl-4-bromothiophene is 1.20

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

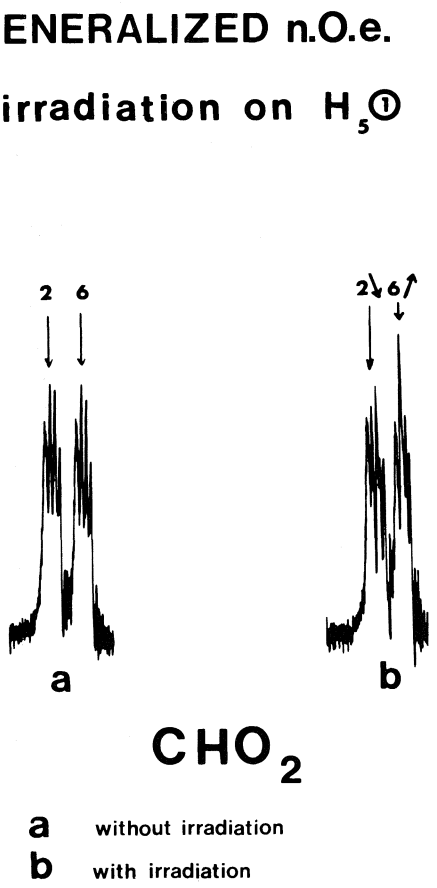

FIG. 4. Generalized Overhauser experiments on 2,3-diformylthiophene (**11**).

Hz, the percentage of π transmission is about $0.10/1.20 \times 100 \cong 8\%$.

For the present study on the ^4J coupling constants we have chosen models with conformations fixed by steric or electrostatic interactions.

Where fast inversion at room temperature occurs, the different forms are computed by application of the ^5J stereospecific rule: with the assumption that ^5J is maximum for the zig–zag pathway and ^5J is near zero for the antistereospecific pathway.

^4J Coupling Constants

There are two groups of heterocyclic compounds: α- and β-formylheterocycles. In each group two coupling pathways, *cc* and *ct*, are observed for some derivatives.

(1) α-Formylheterocycles

(a) 4-Bromo-2-formylfuran (1)

This compound shows a ^4J coupling constant $^4J_{CHO-3} = -0.085$ Hz (Fig. 5). This room temperature value is the average of the two coupling pathways: *cc* (60%) and *ct* (40%) (6). The same ^4J coupling has been measured in furfural itself by Fourier transform methods (26), $^4J_{CHO-3} = 0.06$ Hz. The introduction of a halogen in the 4 position suppresses the coupling J_{CHO-3} and allows a determination of the sign of $^4J_{CHO-3}$ as for 4-bromo-2-formylthiophene (see Experimental).

(b) 4-Bromo-2-formylthiophene (2)

This compound is entirely in the SO *cis* form **I** and the four bond coupling constant $^4J^{cc}_{CHO-3}$ is −0.125 Hz (Fig. 1).

(c) 2-Formylpyrrole (3)

As in **2**, the formyl group is completely in the *cis* conformation **I** and one observes a coupling $^4J^{ct}_{CHO-NH} = -0.32$ Hz. The sign of this coupling had been previously determined (27).

(d) 1-Methyl-2-formylpyrrole (4)

This derivative is almost exclusively in *cis* conformation **I** (28). $^4J^{cc}_{CHO-3}$ is nearly 0.12 Hz. This value is not directly measurable on the spectrum but is computed from line width measurements on the H_3 peak before and during irradiation of the CHO signal. The sign of $^4J^{cc}_{CHO-3}$ could not be determined, but on the basis of previous work, it is probably negative. Irradiation of the CH_3 signal shows no visible perturbation of the width of the CHO signal. Thus, we can assume a very weak π electron transmission for the $^4J^{ct}_{CHO-NH}$ in **3**.

(e) 1-Acetyl-2-formylpyrrole (5)

This compound is certainly planar for thermodynamic reasons, and the formyl group adopts a *trans* conformation **II** ($^5J_{CHO-4} = 0.70$, $^5J_{CHO-5} \cong 0$ Hz). The four bond coupling $^4J^{ct}_{CHO-3} = 0.37$ Hz (sign not determined but probably negative).

(2) β-Formylheterocycles

(a) 3-Formylthiophene (6), 3-Formylfuran (7), and 1-t-Butyl-3-formylpyrrole (8)

The preferential conformation of the formyl group in the β position is XO *trans*-**II**′ (22, 28). Consequently, in these derivatives the ^4J coupling constants adopt a *ct* pathway for $^4J_{CHO-4}$ and a *cc* pathway for $^4J_{CHO-2}$.

In **6**, **7**, and **8** the $^4J^{ct}_{CHO-4}$ coupling constants are in the range of −0.32 to −0.42 Hz. The signs of these couplings in β-formylthiophene and furan are known to be negative (21), and we can assume the same sign for **8**.

For personal use only.

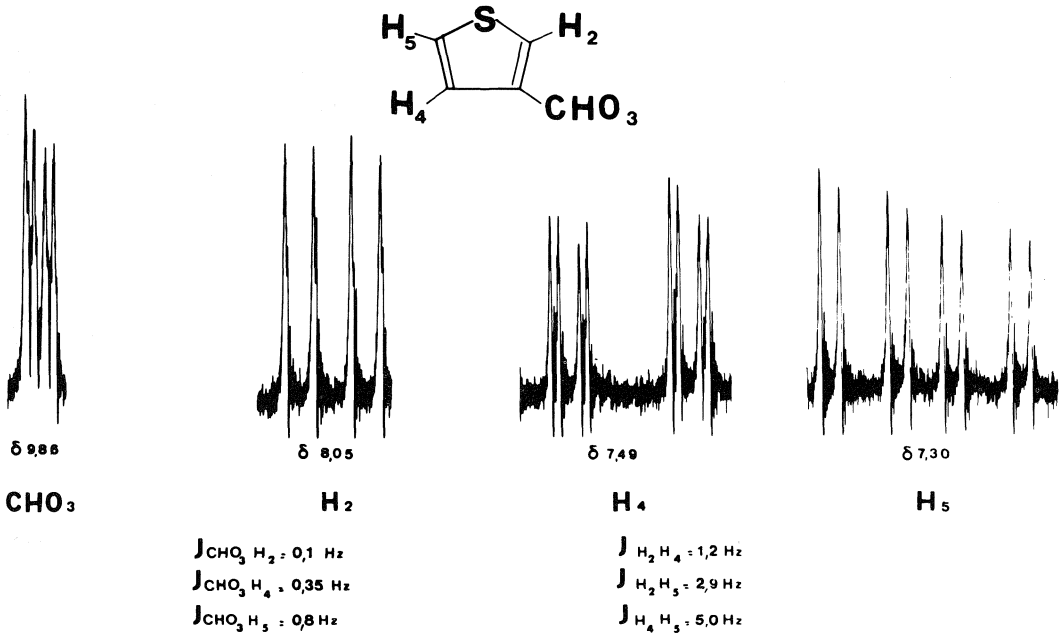

FIG. 6. Spectrum of 3-formylthiophene (**6**).

The $^4J^{cc}_{CHO-2}$ coupling has not been previously described in β-formylheterocycles. In 3-formylthiophene (**6**), $^4J^{cc}_{CHO-2} = -0.10$ Hz (Fig. 6). In the derivatives **7** and **8** this coupling is vanishingly small (<0.08 Hz) and cannot be seen in the spectrum. It is of interest to note that $^4J^{cc}_{CHO-2}$ can be observed in **6** where the formyl group is averaged at room temperature between the two forms SO *cis*-**I**′ (20%) and SO *trans*-**II**′ (80%) (22). Consequently, the value of 0.10 Hz accounts for a weak part of the $^4J^{ct}_{CHO-2}$ coupling constant.

(b) 4-Nitro-3-formylpyrrole (9)

Because of the existence of a repulsive potential between an oxygen of the nitro group and the oxygen of the formyl group, the conformation of **9** is almost exclusively HNO *cis*-**I**′. Indeed, for this compound the stereospecific $^5J_{CHO-5}$ coupling constant is undetectable. In contrast, $^4J^{ct}_{CHO-2}$ in DMSO-d_6[1] is 0.42 Hz, but the absence of $^5J_{CHO-5}$ hinders the determination of the sign of this coupling by tickling.

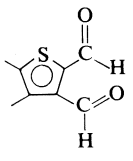
[1]The NH proton is exchanged by addition of a small amount of piperidine as described (13). The chemical shifts of the ring proton resonances are attributed in accordance with the additivity of the substituent effects (H_2 expt.: 7.64, calcd.: 7.77, H_5 expt.: 8 02, calcd.: 8.04 p.p.m.).

(3) 2-Acetyl-3-formylthiophene (10) and 2,3-Diformylthiophene (11)

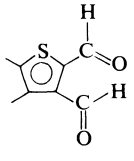
The above compounds permit the study of the ^4J coupling constants in all pathways except for the $^4J^{cc}_{CHO-4}$ in β-formylheterocycles. Unfortunately, compounds of fixed conformation such as 2-amino- or 2-hydroxy-3-formylthiophene are unknown. (In the latter, the hydroxy group is in ketoform.) However, we can calculate the value for $^4J^{cc}_{CHO-4}$ for the two models **10** and **11**. For the former, the conformation of the CHO group is exclusively SO *cis*-**I**′ for thermodynamic and steric requirements (24). The $^5J_{CHO-5}$ is 1.00 Hz, identical to the maximum value found in 4-hydroxy-3-formylthiophene (22). Thus, we can determine in this fixed conformation the maximum value for the $^4J^{cc}_{CHO-4}$ coupling constant : −0.42 Hz. The 2,3-diformylthiophene **11** has four possible conformations, but we have concluded (23) that only two forms, **III** and **IV**, are in important concentrations.

Application of the rule of stereospecific ^5J coupling constants gives the populations : $P_{III} \cong 65\%$, $P_{IV} \cong 35\%$. The signal of the β aldehydic proton is complicated by a small coupling between the two formyl groups $^5J_{CHO_2-CHO_3} = -0.15$ Hz (see Experimental). The sign of this ^5J coupling is negative and must be due either to a

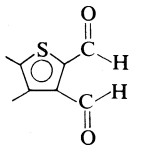
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



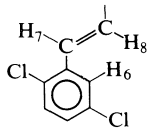
III



IV



V



12

relatively important $\sigma-\pi$ transmission in the averaged conformations (**III** and **IV**) or, as in 2,5-dichlorostyrene (**12**), to direct interactions (29) between the proximate C—H groups on a conformation like **V**, though the contribution of **V** is certainly small.

As for the stereospecific ^5J coupling constants, the value of $^4J^{cc}_{CHO_3-4}$ is averaged over the populations of P_{III} and P_{IV}. Thus we must calculate the maximum value for this coupling : $^4J_{obs} = [^4J^{ct}_{max} \times 0.35] + [^4J^{cc}_{max} \times 0.65]$ with $^4J_{obs} = -0.25$, and $^4J^{ct}_{max} = -0.42$ Hz found in **10**. Hence $^4J^{cc}_{max} \cong -0.15$ Hz in agreement with the maximum value found for similar couplings in the *cc* pathway.

Discussion

Except for **1** where J_{CHO-3} is smaller than expected, the data of Table 1 show clearly higher values for $^4J^{ct}$ than for $^4J^{cc}$. In para-substituted benzaldehydes, the $^4J_{CHO-H_o}$ depends upon the nature of the substituents, but this effect is always weak. In our work, we have not considered this effect because even in unsubstituted derivatives, $^4J^{ct}$ remains still higher than $^4J^{cc}$.

The signs for two ^4J coupling constants corresponding to *cc* conformations are determined and are negative. The negative sign of $^4J_{CHO_3-4}$ coupling constants on β-formylthiophene and furan had been previously determined. Thus, we can assume that in all the derivatives examined in this paper, the signs of the ^4J coupling constants are negative.

On the other hand, the "methyl replacement technique" indicates a dominant σ electron mechanism for this coupling, although for the very weak coupling constant $^4J^{cc}_{CHO_2-3}$ it may be difficult to evaluate the π contribution by this technique. The negative sign for ^4J appears surprising since ^4J σ is usually positive in norm. However Barfield (5) has shown by INDO (intermediate neglect of differential overlap) computations that the sign of ^4J σ is negative for particular planar conformations *cc* and *ct* in propanic fragments.

Likewise, in propene this author has computed (INDO) values of -0.76 Hz for $^4J^{ct}$ and -1.15 Hz for $^4J^{cc}$ in planar conformations (5). Thus we should expect $^4J^{cc} > {}^4J^{ct}$ in our compounds. However, this is not the case for some conjugated aldehydes and in aromatic rings. Indeed the experimental results for acrolein indicate a higher value for $^4J^{ct}$ than for $^4J^{cc}$ (30) and in 2,5-dichlorostyrene (**12**), Barfield *et al.* (29) calculate values of -0.27 Hz for $^4J^{cc}_{6-7}$ and -0.75 Hz for $^4J^{ct}_{6-7}$. Also in para-substituted benzaldehydes (4) and fluorobenzaldehydes (31) $^4J^{ct}_{CHO-H_o} > {}^4J^{cc}_{CHO-H_o}$. In the latter compounds $^4J^{ct}_{CHO-F_o} > {}^4J^{cc}_{CHO-F_o}$ and this result is in good agreement with INDO computed values.[2]

Our results are in accordance with these latter studies and clearly prove that the ^4J coupling between side chain and ring protons is dominated by a σ-electron contribution. Consequently, this coupling is dependent on the pathway and $^4J^{ct}$ is still higher than $^4J^{cc}$. These results are useful for the conformational analysis of planar structures. It allows us to corroborate the interpretation based on the stereospecific ^5J coupling constants and to prove the preferential conformation in cases where ^5J is not accessible. It is not known whether $^4J^{ct} > {}^4J^{cc}$. This may be caused by a small positive through-space coupling in $^4J^{cc}$. We are presently studying the dependence of ^4J on electronic effects of substituent and out-of-plane arrangement of the formyl group.

[2]Calculations on furfural by INDO are not satisfactory (32). INDO results are in good agreement with experimental values but predict $^4J^{cc} > {}^4J^{ct}$. Clearly, the agreement for the ^4J couplings is poor whereas it is good for ^5J couplings.

Studies on Horseradish Peroxidase. XI. On the Nature of Compounds I and II as Determined from the Kinetics of the Oxidation of Ferrocyanide

M. L. COTTON AND H. B. DUNFORD[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 31, 1972

In order to investigate the nature of compounds I and II of horseradish peroxidase, the kinetics were studied of ferrocyanide oxidation catalyzed by these compounds which were prepared from three different oxidizing agents. The p*H* dependence of the apparent second-order rate constant for ferrocyanide oxidation by compound I, prepared from ethyl hydroperoxide and *m*-chloroperbenzoic acid, was interpreted in terms of an ionization on the enzyme with a $pK_a = 5.3$, identical to that reported previously for hydrogen peroxide. The second-order rate constant for the compound II-ferrocyanide reaction also showed the same p*H* dependence for the three oxidizing substrates. However, with more accurate results, the compound II-ferrocyanide reaction was reinterpreted in terms of a single ionization with $pK_a = 8.5$. The same dependence of ferrocyanide oxidation on p*H* suggests structurally identical active sites for compounds I and II prepared from the three different oxidizing substrates.

Pour étudier la nature des composés I et II de la peroxydase de raifort, on a examiné les cinétiques de l'oxydation du ferrocyanure catalysée par ces composés, qui ont été préparés à partir de trois agents oxydants différents. L'influence du p*H* sur la constante de vitesse apparente du deuxième ordre pour l'oxydation du ferrocyanure par le composé I préparé à partir de l'hydropéroxyde d'éthyle et de l'acide *m*-chloroperbenzoique, a été interpretée en fonction de l'ionisation de l'enzyme à un $pK_a = 5.3$, identique à celle précédemment rapportée pour l'eau oxygénée. La constante de vitesse du second ordre pour la réaction entre le ferrocyanure et le composé II, montre aussi la même relation de p*H* pour les trois substrats oxydants. Cependant, avec des résultats plus précis, la réaction entre le ferrocyanure et le composé II a été reinterprétée par rapport à l'ionisation simple à $pK_a = 8.5$. La même relation entre l'oxydation du ferrocyanure et le p*H* laisse penser à des sites actifs de structure identique pour les composés I et II, préparés à partir de trois substrats oxydants différents.

Introduction

The intermediate compounds of horseradish peroxidase (HRP), that is, compound I (HRP-I) and compound II (HRP-II), have been known for many years (1, 2). Early investigations indicated that these compounds could be formed from alkyl (3, 4) and acyl hydroperoxides (5) as well as several inorganic oxidizing agents (6). A variety of possible structures has been proposed for these compounds (7–10). Recently, it has been shown that oxygen is incorporated into compound I of chloroperoxidase upon its formation from *m*-chloroperbenzoic acid (11, 12). Clearly, in addition to the electron transfer processes occurring, a portion of the peroxide must be retained at the active site upon HRP-I formation.

Although many techniques have been applied to the study of HRP compounds (13–17), the kinetic method, in principle, provides one of the better sources of information concerning the nature of the active site. The rather complex dependence of reaction rates upon p*H* observed for different reducing substrates in HRP-catalyzed oxidations (18–20) are indicative of proton transfer processes affecting the rate-determining step. These proton transfers are a direct result of ionizable groups present on the enzyme or reducing substrate. Formation of HRP compounds with hydroperoxides may result in small structural differences if the organic fragment is retained at, or near, the active site. This bulky fragment could conceivably interfere with, or block, one or more proton transfers that have been shown to occur during the reduction of HRP compounds prepared from hydrogen peroxide. A distinctly different p*H* dependence would then emerge. Therefore, in order to investigate these possible changes in the proton transfer mechanisms, two organic hydroperoxides were chosen to study the ferrocyanide oxidation, namely, ethyl hydroperoxide and *m*-chloroperbenzoic acid. Experiments were also

performed using hydrogen peroxide which supplemented a previous detailed investigation (18). The combined results of all of these experiments provide some incisive evidence concerning the nature of the enzyme's active site.

Experimental

Horseradish peroxidase was obtained from Boehringer-Mannheim as a highly purified ammonium sulfate suspension and prepared for experiments as described elsewhere (19, 20). Other experimental details are as described in the earlier study on ferrocyanide (18) except for the following.

The ethyl hydroperoxide was obtained from Polysciences Inc. as a 10% aqueous solution. A polarographic analysis of the reagent in dilute alkaline lithium sulfate solution (21) detected no hydrogen peroxide. The presence of other possible oxidizing agents known to form compounds with HRP was not observed by n.m.r. analysis. A 5×10^{-4} *M* aqueous solution of the alkyl hydroperoxide was stored at 5° and its concentration was analyzed periodically by spectrophotometry. In this method of analysis the amount of iodide oxidized was monitored quantitatively at 353 nm. A solution consisting of 0.05 *M* sodium iodide (Orion iodide standard) and 10^{-8} *M* HRP was prepared in an acetate buffer of p*H* 3.8 and $\mu = 0.01$. A 2 ml aliquot was pipetted into a cuvette, and the absorbance change observed upon the addition of 50 µl of the hydroperoxide solution. Using a molar absorptivity of $2.55 \times 10^4\ M^{-1}\ cm^{-1}$ (22), the hydroperoxide concentration was calculated. The solutions of hydrogen peroxide used to prepare the HRP compounds were also stored and analyzed in a similar manner. An independent analysis of hydrogen peroxide present in the ethyl hydroperoxide solution made use of the difference in the relative rates with which hydroperoxides and hydrogen peroxide react with iodide (23). Ammonium molybdate was used instead of HRP as a catalyst (24), and the rate of I_3^- formation was followed at 353 nm on the Cary 14 spectrophotometer. In the buffered iodide solution containing 0.005% by weight ammonium molybdate, the ethyl hydroperoxide solution was estimated to contain less than 2% hydrogen peroxide.

Technical grade *m*-chloroperbenzoic acid was obtained from the Aldrich Chemical Company. A 10% solution of the acyl hydroperoxide was made up in acetone and stored at −10°. Stock solutions of about 4×10^{-4} *M* *m*-chloroperbenzoic acid were prepared prior to each day's experimental work by adding 0.1 ml acetone solution to 100 ml of distilled water. The spectrophotometric technique described for hydroperoxide analysis was used to determine its concentration. Because of the rapid spontaneous oxidation of iodide with peracid, no HRP was required as a catalyst. Buffered iodide solutions to which HRP had been added were used to determine the total hydroperoxide and hydrogen peroxide concentration. Thus, it was estimated that slow hydrolysis (25) or contamination of the acyl hydroperoxide resulted in less than 5% of the total peroxide as hydrogen peroxide in the stock solution 8–10 h after its preparation.

All single-turnover kinetic experiments were carried out using a stopped-flow apparatus (18, 26) except at p*H* values between 9 and 10 where the Cary 14 spectrophotometer was used. The Cary 14 spectrophotometer was also used to obtain the steady-state results over the p*H* range 5–3.2 (18).

Results and Discussion

Over the p*H* range of the study HRP-I and HRP-II prepared from ethyl hydroperoxide or *m*-chloroperbenzoic acid showed identical kinetic behavior, within experimental error, to that observed for these compounds prepared from hydrogen peroxide. With excess ferrocyanide the reaction conditions become pseudo first-order and the differential rate expression for the HRP-II reaction is:

$$[1] \quad -\mathrm{d[HRP\text{-}II]}/\mathrm{d}t = k_{3,\mathrm{obs}}\,[\mathrm{HRP\text{-}II}]$$

where

$$[2] \quad k_{3,\mathrm{obs}} = k_{3,\mathrm{app}}\,[\mathrm{Fe(CN)_6}^{-4}]$$

Equation 1 was confirmed for both the alkyl and acyl hydroperoxides as oxidizing substrates by obtaining linear plots of log ΔV *vs.* time for reaction traces at many different p*H* values. Equation 2 was verified by obtaining linear relationships for k_{obs} with increasing ferrocyanide concentrations for each oxidizing substrate. Analogous results were obtained for the HRP-I reaction. Similar studies were performed at a number of other p*H* values on the stopped-flow apparatus for HRP-I, and both on the stopped-flow and spectrophotometer for HRP-II. Each stopped-flow study of k_{obs} *vs.* $[Fe(CN)_6^{-4}]$ represented 5–9 different concentrations over an order of magnitude range, and the analysis of 50–90 ΔV *vs.* time traces.

Kinetics of the HRP-II-Ferrocyanide Reaction

Values for $k_{3,app}$ were determined by the stopped-flow technique over the p*H* range 4–10.6. At high p*H* values, $k_{3,app}$ values also were determined on the Cary 14 spectrophotometer. The data appear in Table 1 and Fig. 1. Using the steady-state method, the HRP-catalyzed ferrocyanide reaction was studied in the acid p*H* region with ethyl hydroperoxide and hydrogen peroxide as oxidizing agents. The final results are presented in Table 2. Although the steady-state determinations are in good agreement with those published previously (18, 27), the second-order rate constants, $k_{3,app}$'s, determined by this method are consistently about 20% lower than those obtained by studying the HRP-

II-ferrocyanide reaction in isolation from other reactions involved in the steady-state cycle. Since the steady-state results are dependent on the total concentration of HRP whereas the stopped-flow results are not, the discrepancy may be caused by too small a value for the molar absorptivity of HRP at 403 nm (28). This is in agreement with recent spectral work (29, 30). However, since universal agreement has not yet been reached on the magnitude of ε_{403} for HRP, we have continued to use the previously accepted value.

In the stopped-flow experiments, a systematic deviation in reaction rates determined in successive experiments was observed in the acid pH region. Apparently, this was due to interference from an acid-catalyzed reaction which occurred in the stopped-flow apparatus and competed for ferrocyanide. The slow decay in ferrocyanide

concentration resulted in a gradual decline in the observed reaction rates. Interference from this competing reaction was partially overcome by preparing HRP-II in the low p*H* buffer. Therefore, for the experiments below p*H* 6, the ferrocyanide solution was unbuffered prior to the final mixing of the reactants in the stopped-flow apparatus. Under these conditions any enzyme denaturation in the acid solution was insignificant and did not affect the observed HRP-II-ferrocyanide rates. Greater precision was attained at a given p*H* by doing many experiments at different ferrocyanide concentrations. Several such studies were performed at low p*H*. Fresh ferrocyanide solutions of the correct concentration were insured by thorough flushing of the instrument with the reactant solutions prior to each experiment. Nevertheless, it was not possible to study this reaction successfully below p*H* 4 on the stopped-flow apparatus. Because these systematic errors were not detected in the previously reported work, the standard deviations for experiments performed in the earlier investigation at low p*H* were larger than originally estimated (18).

The resultant p*H* profile did not appear to justify the inclusion of an acid dissociation constant with a pK_a of 5.2 as previously reported (18). This was the case for HRP-II prepared from hydrogen peroxide, as well as the two hydroperoxides. The steady-state data confirmed this conclusion. There was no evidence for any acid dissociation constants present on the enzyme over the p*H* range 5.0–3.2. Below p*H* 3.2 the formation of HRP-I became rate-limiting so that k_3 could not be evaluated under steady-state conditions. The agreement is excellent among rate constants using all three oxidizing substrates at high p*H* for the HRP-II catalyzed oxidation of ferrocyanide (18).

For the HRP-II-ferrocyanide reaction the ionization of two acid groups, located on either the enzyme or substrate, has a major kinetic effect. Since the group having a pK_a of 8.5–8.6 cannot be associated with the ionization of any of the protonated forms of ferrocyanide, it must be assigned to the enzyme. This group also has been observed for the HRP-II-oxidation of *p*-cresol. The second group must remain largely deprotonated over the p*H* range investigated. Although substrate ionization cannot be excluded in making this group assignment, it has been shown conclusively that the enzyme has an ionizable group of p$K_a < 2$ influencing the HPR-II-iodide reaction (19). Therefore, it is not unreasonable to tentatively assign this second ionizable group to the enzyme. The simplest mechanism which adequately describes the data then becomes that depicted in eq. 3. The ground-state acid dissociation constant K_2 refers to the K_a observed at high p*H*, whereas K_1 is the ground-state acid dissociation constant of the second ionizable group. In the mechanism, $Fe(CN)_6^{-4}$ refers to all the unprotonated and protonated forms of ferrocyanide.

$$\begin{array}{ccc} & H_2P & \\ & K_1 \uparrow\downarrow & \\ HP & + \ Fe(CN)_6^{-4} \longrightarrow & \text{Products} \\ & K_2 \uparrow\downarrow & \\ & P & \end{array} \qquad [3]$$

Results from the nonlinear least-squares analysis of the data are to be found in Table 3 and a brief explanation in the Appendix. The K_2 value reported here is in good agreement with the acid dissociation constant in the alkaline p*H* region published earlier (18). The correlation shown in Fig. 2 was obtained from the steady-state data. At low p*H* values the regression line had a limiting slope of -1.0.

Kinetics of the HRP-I-Ferrocyanide Reaction

Values for $k_{2,app}$ are tabulated in Table 4 and plotted in Fig. 1 for both oxidizing substrates. Problems in the acid p*H* region were similar for HRP-I to those already discussed for HRP-II. Because of the faster rates of the HRP-I-ferrocyanide reaction, the data obtained below p*H* 5 have large experimental errors and the p*H* profile could not be precisely defined below p*H* 4.8 using the stopped-flow technique. The steady-state method is not amenable to an estimate of $k_{2,app}$. The best-fit parameters, presented in Table 5, were determined from a nonlinear least squares

TABLE 3. The parameters obtained from a nonlinear least squares analysis for the HRP-II-ferrocyanide reaction*

Parameter	Value
k_1'	$(1.8 \pm 0.1) \times 10^4$ (M^{-1} s^{-1})
K_1*	$(9.2 \pm 0.6) \times 10^{-7}$ (M)
K_1	$(3.3 \pm 0.2) \times 10^{-9}$ (M)

*The errors reported were the standard deviations obtained from the nonlinear computer analysis.

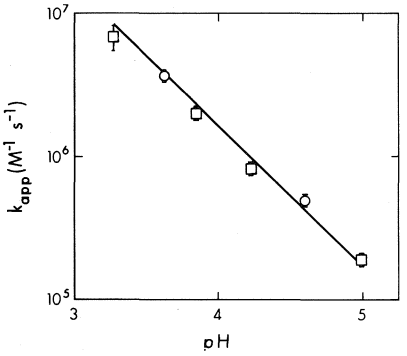

FIG. 2. Semilogarithmic plot of $k_{3,app}$ determined by steady-state kinetics *vs.* p*H* for the HRP-II-ferrocyanide reaction. Error limits were estimated as the 95% confidence limit from the linear least squares analysis at each p*H*. The correlation was obtained from a weighted nonlinear least squares analysis of the data using the $K_1{}^{\ddagger}$ and K_1 values appearing in Table 3 as fixed parameters. The variable k_1' had a calculated value of $(1.4\pm0.1) \times 10^4$ M^{-1} s^{-1}, 21% lower than that shown in Table 3. The limiting slope at the lowest p*H* was -1.0. Ethyl hydroperoxide and hydrogen peroxide were used in the preparation of HRP-II. Symbols are the same as for Fig. 1.

analysis of the data in Table 4. For comparative purposes the data reported earlier for HRP-I prepared from hydrogen peroxide (18), were reanalyzed in terms of transition-state parameters. These also appear in Table 5. The two sets of parameters are identical within the experimental errors.

Therefore, the evidence presented shows that in the reduction of each of HRP-I and HRP-II the proton transfer mechanisms are identical over a wide range of p*H* regardless of the hydroperoxide used as the substrate. This implies a structurally identical active site for each participating oxidizing agent.

Appendix

An interpretation of the p*H* dependence of the reaction based upon transition-state theory has been applied to this system and discussed in regard to experimental results obtained in deuterium oxide (27). Over the p*H* range of the combined stopped-flow and steady-state investigations of the HRP-II-ferrocyanide reaction, the data may be described in terms of one transition-state acid dissociation constant $K_1{}^{\ddagger}$, and one ground-state acid dissociation constant K_2. One may calculate $k_{3,app}$ from the relationship

$$[4] \qquad k_{3,app} = \frac{k_1'[H^+]([H^+]/K_1{}^{\ddagger} + 1)}{([H^+]/K_2 + 1)}$$

*The errors reported were estimated as in Table 3.
†From previously reported data for HRP-I prepared from hydrogen peroxide (18).

In this expression k_1' represents the limiting second-order rate constant at high p*H*. The ground-state acid dissociation constant, K_1, does not appear in eq. 4 because it lies outside the p*H* range of the study; therefore, it does not affect the rates above p*H* = 3.2.

For the HRP-I-ferrocyanide reaction the data may also be described in terms of one transition-state acid dissociation constant $K_2{}^{\ddagger}$ and one ground-state acid dissociation constant K_3. One may then calculate $k_{2,app}$ from a relationship similar to eq. 4:

$$[5] \qquad k_{2,app} = \frac{k_2'([H^+]/K_2{}^{\ddagger} + 1)}{([H^+]/K_3 + 1)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

In this expression, k_2' is the limiting second-order rate constant at high p*H*.

Studies on Horseradish Peroxidase. XII. A Kinetic Study of the Oxidation of Sulfite and Nitrite by Compounds I and II

R. ROMAN AND H. B. DUNFORD[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 31, 1972

The kinetics of the oxidation of sulfite and nitrite by horseradish peroxidase compounds I and II have been studied as a function of p*H* at 25° and ionic strength 0.11. The p*H* dependence of the rate of the reaction between compound I and sulfite over the p*H* range 2–7 is interpreted in terms of two ground state enzyme dissociations with pK_a values of 5.1 and 3.3, and that for the compound II reaction with sulfite in terms of a single ground state enzyme dissociation with a pK_a value of 3.9. Whereas the reaction between compound I and sulfite produces the native enzyme without the intermediate formation of compound II, the reaction of compound I with nitrite yields compound II. The second-order rate constants for the reactions of compounds I and II with nitrite increase linearly with increasing hydrogen ion concentration over the p*H* range 6–8.

Les cinétiques de l'oxydation du sulfite et nitrite par les composés I et II de la peroxydase du raifort, ont été étudiées en fonction du p*H* à 25° et à une force ionique de 0.11. L'influence du p*H* sur la vitesse de réaction entre le composé I et le sulfite, dans l'intervalle de p*H* 2–7, a été interprétée par deux dissociations enzymatiques à l'état fondamental, aux pK_a de 5.1 et 3.3; celle de la réaction entre le composé II et le sulfite a été expliquée par une dissociation enzymatique simple, à l'état fondamental, pour un pK_a de 3.9. Tandis que la réaction entre I et le sulfite conduit à l'enzyne native sans l'intermédiaire de II, la réaction de I sur le nitrite donne le composé II. Les constante de vitesse du second ordre pour les réactions de I et II sur le nitrite, croissent linéairement avec le concentration en ion hydrogène, dans l'intervalle de p*H* 6–8. [Traduit par le journal]

Introduction

Horseradish peroxidase (EC 1.11.1.7, donor-H_2O_2 oxido-reductase) catalyzes the oxidation of a wide variety of compounds by hydrogen peroxide. The early work of Chance (1) and George (2, 3) established that the reaction normally proceeds by the following general mechanism

[1] $$HRP + H_2O_2 \rightarrow HRP\text{-}I$$

[2] $$HRP\text{-}I + AH_2 \rightarrow HRP\text{-}II + AH\cdot$$

[3] $$HRP\text{-}II + AH_2 \rightarrow HRP + AH\cdot$$

[4] $$2AH\cdot \rightarrow \text{products}$$

where HRP represents the native enzyme, HRP-I and HRP-II are the oxidized forms of the enzyme referred to as compounds I and II, and AH_2 is the reducing substrate. Work on this enzyme up to 1966 has been reviewed by Brill (4).

Previous work in this laboratory (5–7) has included kinetic studies over a range of p*H* on the oxidation of ferrocyanide, iodide, and *p*-cresol by HRP-II and iodide by HRP-I (8). The latter reaction proved to be an exception to the general mechanism illustrated in eqs. 1–4 since there is a direct two-electron transfer from iodide to HRP-I thus forming HRP without the intermediate formation of HRP-II (8). This phenomenon is of potential relevance to the mechanism of iodide oxidation by the peroxidase present in mammalian thyroid glands (9). It is of interest to determine whether other substrates of HRP could also undergo direct two-electron oxidations and sulfite and nitrite were chosen as potential two-electron donors. HRP has been shown to catalyze the oxidation of sulfite both in the presence of hydrogen peroxide (10) and its absence (11, 12). However, no kinetic data on the separate reactions of HRP-I and HRP-II with sulfite have been published. The rate of the reactions of HRP-I and HRP-II with nitrite at a single p*H* have been reported by Chance (13).

Experimental

Materials

Horseradish peroxidase was obtained from Boehringer-Mannheim as a highly purified suspension in aqueous ammonium sulfate. The technique in handling it further has been described elsewhere (6–8).

Anhydrous sodium sulfite was obtained from Fisher

Scientific Co. (stated purity of 99.0%). Stock solutions of 0.1 M or greater were prepared fresh daily and were routinely analyzed using a molar absorptivity of $3.88 \times 10^2\ M^{-1}\ cm^{-1}$ at 276 nm for the sulfite in 0.1 F sulfuric acid (14). These sulfite solutions were found to undergo less than 1% decomposition over a period of 8 h. Sodium nitrite was obtained from the Baker Chemical Co. (stated purity 100.7%). Stock solutions of nitrite were prepared by weighing; their concentrations were checked at 355 nm using a molar absorptivity value of $23.0\ M^{-1}\ cm^{-1}$ (15). Solutions from 0.1 to $10^{-4}\ M$ were stable for several weeks when stored in the dark. Hydrogen peroxide, 30% by weight obtained from the Fisher Scientific Co., was stored in the dark as an approximately $5 \times 10^{-2}\ M$ solution, and diluted before use; its concentration was checked periodically by the HRP-catalyzed oxidation of iodide (16).

Kinetic Experiments

The majority of kinetic investigations were carried out using a stopped-flow apparatus described previously (5, 6). Kinetic experiments on the HRP-I sulfite reaction at pH values greater than 5.5 were performed on a Cary 14 spectrophotometer. Complete details of all experiments are recorded elsewhere (17). HRP-I was prepared immediately before use by adding hydrogen peroxide from a Hamilton microliter syringe to a concentration 0.8 times that of HRP. HRP-II was formed, when desired, by the addition of *p*-cresol to a concentration 0.5 times that of the enzyme, to the HRP-I solution just prior to its transfer to the stopped-flow apparatus. The reduction of HRP-I was monitored at 411 nm and that of HRP-II was usually monitored at 427 nm. In additional experiments, the HRP-II-sulfite reaction was also monitored at 411 and 403 nm.

All reactions were conducted at 25° at an ionic strength of 0.11 of which 0.01 was contributed by the buffer, and had half-lives ranging from about 10 ms to several seconds. Initial concentrations of HRP-I and HRP-II were typically about $10^{-6}\ M$. Pseudo first-order conditions were achieved by keeping the sulfite or nitrite in at least a ten-fold excess over the enzyme species.

Stoichiometric Experiments

The overall reaction stoichiometry for the HRP-catalyzed oxidation of nitrite by hydrogen peroxide was determined spectrophotometrically at pH 4.95 and 25.0°, by monitoring the decrease in nitrite concentration at 355 nm and the production of nitrate at 300 nm. Spectra of sodium nitrite and potassium nitrate were obtained from 400–270 nm on the Cary 14 spectrophotometer. The molar absorptivity of the nitrite maximum at 355 nm agreed with the published value to within 1% (15). Potassium nitrate had no observable absorbance at 355 nm. A maximum at 300 nm with a molar absorptivity of $7.3\ M^{-1}\ cm^{-1}$ was observed for the nitrate spectrum, whereas nitrite had a molar absorptivity of $8.9\ M^{-1}\ cm^{-1}$ at the same wavelength.

The stoichiometry of the reaction between HRP-I and nitrite was determined by a titration at 25.0° of HRP-I monitored at 411 nm. The initial rapid spontaneous decay of HRP-I was monitored until the rate of this reaction was slower than the reaction with nitrite (about 10% of the HRP-I was consumed), then solutions of sodium nitrite, from 2–10 μl, were added with a Hamilton microliter syringe and the changes in absorbance were measured.

Steady State Spectra

The spectra of the enzymatic species present in the steady state for the HRP-catalyzed oxidations of sulfite and nitrite were scanned on a Cary 14 spectrophotometer from 350–450 nm. Identical experiments were performed where the absorbance was monitored at a fixed wavelength (411 nm for sulfite, 431 nm for nitrite) to ensure that steady-state conditions did exist during the time taken to scan the spectrum and to estimate the number of enzymatic cycles taking place during this time.

Second Ionization Constant of Sulfurous Acid

The second ionization of sulfurous acid at an ionic strength 0.01 was measured spectrophotometrically, using a Gilford spectrophotometer with the cell-block maintained at 25.0°. Absorbance measurements were made at 212.5 nm, close to the maximum absorbance for sulfite ion, over the pH range 6.2–9.6 using phosphate or tetraborate buffers.

Results

Second Ionization Constant of Sulfurous Acid

The second ionization constant of sulfurous acid, K_s, under conditions of the present work may be defined in terms of concentrations and the operational pH scale by the relation

$$[5] \qquad pK_s = \log\frac{[HSO_3^-]}{[SO_3^{2-}]} + pH$$

The value of pK_s obtained from eq. 5 was 6.92 ± 0.02 in reasonable agreement with the published value, 6.91, obtained at unspecified ionic strength (18).

Kinetics of the HRP-I-Sulfite Reaction

With excess sulfite the observed differential rate expression is

$$[6] \qquad -d[\text{HRP-I}]/dt = k_{1,obs}[\text{HRP-I}]$$

as was verified by linear semilogarithmic plots of the change in photomultiplier output voltage *vs.* time. Values of the second-order rate constant, k_1, were obtained from the equation

$$[7] \qquad k_{1,obs} = k_1[\text{sulfite}]$$

where [sulfite] refers to the total concentrations of sodium sulfite without regard to its state of protonation. Plots of $k_{1,obs}$ *vs.* [sulfite] were linear as illustrated in Fig. 1 for the reaction at pH 3.81. Similar studies were carried out at 12 other pH values ranging from 2.7 to 7.2, in which the error in k_1 was equated to the standard deviation calculated from the linear analysis of the $k_{1,obs}$ *vs.*

*A, acetic acid – sodium acetate; C, citric acid – sodium citrate; G, glycine HNO_3 – glycine; P, potassium dihydrogen phosphate – disodium hydrogen phosphate.

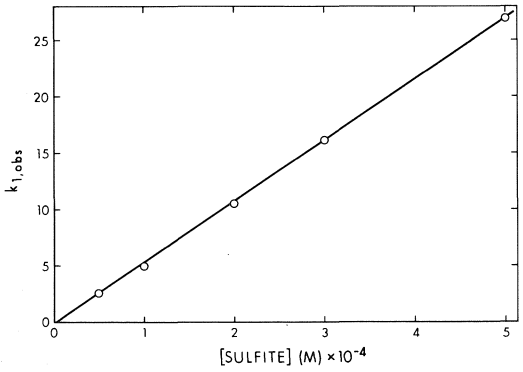

FIG. 1. Plot of $k_{1,obs}$ *vs.* [sulfite] for the reaction between HRP-I and sulfite at pH 3.81. The slope, k_1, with its standard error is $(5.4 \pm 0.1) \times 10^4$ M^{-1} s^{-1}.

[sulfite] data. The error in k_1 at the other pH values was estimated at $\pm 10\%$. Different buffers used at the same pH yielded the same kinetic results within experimental error, indicating that there were no detectable buffer effects.

Values of k_1 as a function of pH are listed in Table 1 along with the ranges of sulfite concentrations and buffers. The logarithm of k_1 is plotted *vs.* pH in Fig. 2. The pH dependence of k_1 was analyzed using the approach of Critchlow and Dunford (19) where negative and positive curvatures in the plot of log k_1 *vs.* pH are represented by ground state and transition state acid dissociation constants. The solid line in Fig. 2 illustrates the best fit to the phenomenological equation

$$[8] \quad k_1 = \frac{k_1'\left(1 + \frac{K_1^{\ddagger}}{[H^+]}\right)}{\left(1 + \frac{K_1}{[H^+]} + \frac{K_1K_2}{[H^+]^2}\right)\left(1 + \frac{K_s}{[H^+]}\right)}$$

where $K_1^{\ddagger}$ is a transition state dissociation constant associated with the positive curvature at pH 4, K_1 and K_2 are the ground state dissociation constants for acid groups of HRP-I associated with the negative curvatures at pH's 3 and 5, K_s is the sulfite dissociation constant, and k_1' is the pH independent second-order rate constant at low pH. The values of the parameters calculated from eq. 8 are listed in Table 2. The broken line in Fig. 2 is the best fit to the simpler equation

$$[9] \quad k_1 = \frac{k_1'}{\left(1 + \frac{K_2}{[H^+]}\right)\left(1 + \frac{K_s}{[H^+]}\right)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

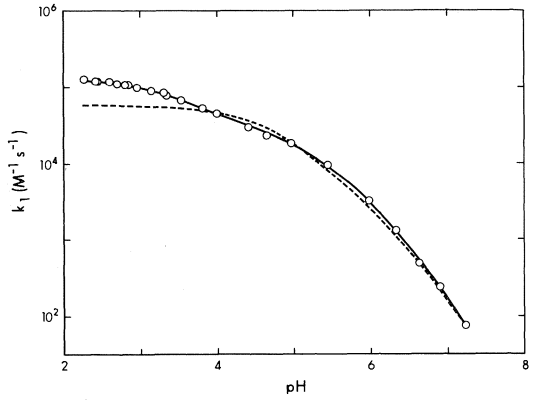

FIG. 2. Semilogarithmic plot of k_1, the second-order rate constant for the reaction of sulfite with HRP-I, *vs.* p*H*. The solid line was calculated by a weighted nonlinear least squares analysis of eq. 8 and the broken line by the comparable analysis of eq. 9.

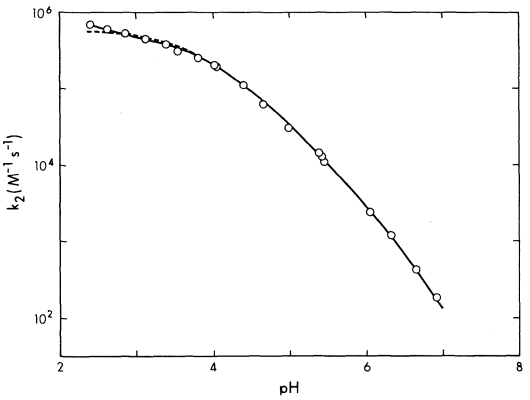

FIG. 3. Semilogarithmic plot of k_2, the second-order rate constant for the reaction of sulfite with HRP-II, *vs.* p*H*. The solid line was calculated by a weighted nonlinear least squares analysis of eq. 10 and the broken line by the comparable analysis of eq. 11.

At low p*H* there is substantial deviation between the calculated and experimental points which indicates that eq. 9 does not offer a satisfactory interpretation of the p*H* dependence of the reaction. In other words the inflections on the left side of Fig. 2 are outside the experimental error.

Kinetics of the HRP-II-Sulfite Reaction

The equations analogous to eqs. 6 and 7 were also verified for the HRP-II-sulfite reaction. The error in the second order rate constant, k_2, was equated to the standard deviation calculated from the linear analysis of the pseudo first-order rate constant *vs.* [sulfite] plots obtained at all values of p*H*. No buffer effects were observed.

Values of k_2 with their standard deviations are listed in Table 3 with the ranges of sulfite concentrations and buffers used at each p*H* and the logarithm of k_2 is plotted *vs.* p*H* in Fig. 3. The p*H* profile for the HRP-II reaction with sulfite resembles that for the analogous HRP-I reaction. At high p*H* the HRP-II rate is slightly smaller than that of HRP-I, the two rate constants are the same at p*H* 6 and at lower p*H* the HRP-II rate becomes larger than that of HRP-I. The solid line in Fig. 3 illustrates the best fit to the equation

$$[10] \quad k_2 = \frac{k_2'\left(1 + \frac{[H^+]}{K_2^{\ddagger}}\right)}{\left(1 + \frac{K_3}{[H^+]}\right)\left(1 + \frac{K_s}{[H^+]}\right)}$$

where $K_2^{\ddagger}$ is a transition state dissociation constant associated with the positive curvature at p*H* 2, K_3 is a ground state dissociation constant associated with the negative curvature at p*H* 4, K_s is the sulfite dissociation constant, and k_2' is the p*H* independent rate at p*H* 3. The broken line in Fig. 3 is the best fit to the equation

$$[11] \quad k_2 = \frac{k_2'}{\left(1 + \frac{K_3}{[H^+]}\right)\left(1 + \frac{K_s}{[H^+]}\right)}$$

which does not involve a transition state dissociation constant. Although the fit is better to eq. 10 than it is to eq. 11, this difference is small and it is not possible to distinguish between the two interpretations solely on the basis of our kinetic data. The values of the parameters calculated from eqs. 10 and 11 are listed in Table 4.

Two effects associated with the reduction of HRP-II by sulfite were observed when the reaction was monitored at 411 nm, the isosbestic point between HRP and HRP-II. If HRP-II was converted to HRP directly, as indicated in eq. 3, no change in absorbance would be expected at this wavelength, as has been observed for the reactions of iodide (6) and nitrite. For the HRP-

II-sulfite reaction however, an absorbance decrease was observed at 411 nm which corresponded to the decrease in absorbance observed for the reduction of HRP-II at 427 nm. Following this decrease in absorbance, the absorbance at 411 nm then returned exponentially to that of the native enzyme. It was found that measurements comparable to those made at 411 nm could be obtained at a variety of wavelengths from 360–420 nm. The first-order rate constants for the return of absorbance to that of the native enzyme, illustrated in Table 5, show that the reaction, measured at 411 and 403 nm, is independent of both pH and sulfite concentration. These results can be explained if the second-order process with rate constant k_2, observed at 427 nm corresponds to the formation of a spectrally distinct complex between HRP-II and sulfite and the first-order process observed at 411 nm to the decay of this complex. The spectrum of this enzymatic intermediate can be estimated from the total absorbance changes observed for the first-order reaction monitored at various wavelengths. Such experiments indicate that the molar absorptivity of the complex is about 40% of that for the native enzyme at the position of maximum absorbance by HRP (403 nm) and that the complex and native enzyme have an isosbestic point at approximately 425 nm. The similarity of the molar absorptivity values for the complex and HRP at 427 nm facilitated measurements of k_2, since no absorbance change for complex decomposition could be observed at this wavelength. At sufficiently high concentrations of sulfite, complex formation occurs more rapidly than

complex decomposition, thus the rate of the latter reaction could be measured at 411 and 403 nm without complication. The rate constants in Table 5 were all measured with the pseudo first-order rate constant for complex formation at least ten times larger than the rate constant for complex decomposition.

Attempts to study the HRP-II-sulfite reaction at higher pH on the Cary 14 spectrophotometer were abandoned due to the presence of a slow decrease in absorbance at 427 nm which complicated the kinetic analysis. This slow absorbance decrease appeared to be independent of both pH and sulfite concentration so that it did not interfere with measurements of reaction rates which were fast enough to be observed on the stopped-flow apparatus. The similarity in rates between the reactions of HRP-I and HRP-II with sulfite coupled with the complications resulting from the slow secondary process observed at 427 nm in the latter reaction, made impractical the titration of HRP-I and HRP-II with sulfite as performed for iodide (8) and nitrite.

Kinetics of the HRP-I- and HRP-II-Nitrite Reactions

The rate equations observed for the nitrite reactions are analogous to those for sulfite. Plots of pseudo first-order rate constants *vs.* total concentration of nitrite were found to be linear for up to a 100-fold change in nitrite concentration in reactions with both HRP-I and HRP-II. Second-order rate constants, k_3 for HRP-I and k_4 for HRP-II, are listed in Table 6 along with the ranges of nitrite concentrations and buffers used at each pH. Over the limited range of pH where the reactions of nitrite were studied, the logarithms of k_3 and k_4 decreased linearly with pH. The slope of the plots of both log k_3 and log k_4 *vs.* pH is -1.0 ± 0.01.

Reaction Sequence of the HRP-I-Sulfite Reaction

Figure 4 illustrates the spectrum of the steady-state concentration of the enzymatic intermediate present in a mixture of HRP, hydrogen peroxide, and sulfite. This spectrum was scanned using the technique devised to get accurate spectra of HRP-I (8) and HRP-II (20). From Figs. 2 and 3 it can be seen that the values of k_1 and k_2 at pH 6 are the same. Thus with an excess of hydrogen peroxide the steady-state intermediate would be expected to be a 1:1 mixture of HRP-I, HRP-II,

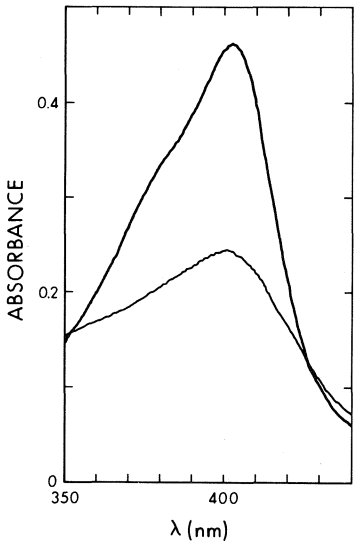

FIG. 4. Spectrum of the enzymatic species present in the steady state for the HRP reaction with sulfite (smaller maximum absorbance) compared to the spectrum of native HRP (larger maximum absorbance). The steady-state spectrum which corresponds closely to that of HRP-I, was scanned over a period of 40 s following the initiation of the reaction with hydrogen peroxide. By monitoring the same reaction at 411 nm it was estimated that the HRP had completed five reaction cycles during the time taken to scan the spectrum.

and the HRP-II-sulfite complex if HRP-I reacted to form HRP-II. The maximum in the spectrum in Fig. 4 agrees with that of the known spectrum of HRP-I within 8% and similar isosbestic points are observed (8) indicating that HRP-I is converted directly to HRP without the intermediate formation of HRP-II. The small deviation between Fig. 4 and the known spectrum of HRP-I is most probably a result of the slow spontaneous decay of HRP-I to HRP-II that was also observed for the reaction with iodide (8). The fact that HRP-II is not formed from the reaction between HRP-I and sulfite was also confirmed by studying the reaction of sulfite with a 1:1 mixture of HRP-I and HRP-II at 427 nm where the absorbance of the HRP-II-sulfite complex is negligible. If HRP-I reacted to produce HRP-II such a mixture would be expected to result in distinctly non-first-order kinetics for the HRP-II reaction, since HRP-II formation and decay would occur simultaneously. For such mixtures an exact first-order decay of HRP-II was always observed, with the same rate constant as obtained in experiments with no HRP-I present. This provides striking evidence that HRP-I is converted directly to native HRP.

Reaction Sequence of the HRP-I-Nitrite Reaction

As observed for similar experiments on the HRP-catalyzed oxidations of ferrocyanide and ascorbic acid, the spectrum of the enzymatic species present in the steady-state oxidation of nitrite closely resembles that of HRP-II (20). This steady-state spectrum reaffirms the observations of Chance (13), who reported that HRP-I reacts with nitrite in a one-electron transfer forming HRP-II.

The overall stoichiometry of the HRP-catalyzed reaction between hydrogen peroxide and nitrite is described by eq. 12 which was

$$[12] \qquad H_2O_2 + NO_2^- \xrightarrow{\text{HRP}} NO_3^- + H_2O$$

established by measuring the absorbance changes at 355 and 300 nm resulting from the steady-state oxidation of nitrite with various concentrations of hydrogen peroxide as illustrated in Fig. 5. The slope of the solid line in Fig. 5, 22.8 ± 0.4 M^{-1} cm^{-1} obtained from the linear analysis of the absorbance changes observed at 355 nm *vs.* the concentration of hydrogen peroxide is in good agreement with the value of the molar absorptivity difference between nitrite and nitrate,

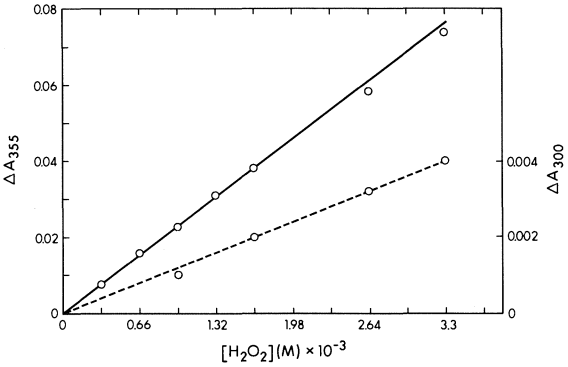

FIG. 5. Plot of the changes in absorbance at 355 and 300 nm *vs.* the concentration of hydrogen peroxide for the HRP catalyzed reaction between nitrite and hydrogen peroxide. The solid line was calculated by weighted linear least squares analysis of the observed absorbance changes at 355 and the broken line by weighted linear-least squares analysis of the observed absorbance changes at 300 nm. The slope of the solid line with its standard deviation is 22.8 ± 0.4 M^{-1} cm^{-1} and that for the broken line is 1.3 ± 0.5 M^{-1} cm^{-1}.

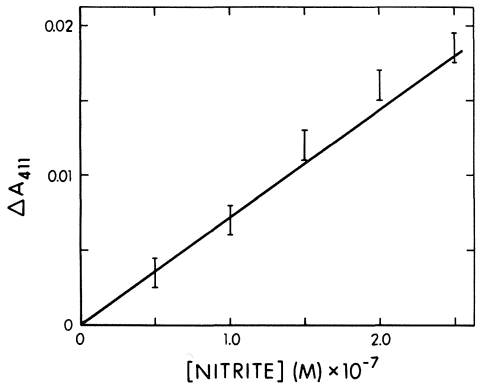

FIG. 6. Plot of the change in absorbance at 411 nm *vs.* the concentration of nitrite for the titration of HRP-I with nitrite. The solid line was calculated assuming a 2:1 ratio between HRP-I and nitrite using a difference in molar absorptivity of 3.6 × 10^4 M^{-1} cm^{-1}.

23.0 M^{-1} cm^{-1}, computed on the basis of 1 mol of nitrite being consumed for every mol of peroxide. A similar analysis at 300 nm led to a slope of 1.3 ± 0.5 M^{-1} cm^{-1} for the broken line in Fig. 5 in reasonable agreement with the difference in molar absorptivity expected if 1 mol of nitrate is formed for every mol of nitrite consumed (1.6 M^{-1} cm^{-1}).

A titration of HRP-I with nitrite was performed using the method employed for the titration of HRP-I with iodide (8). The results of the titration, as illustrated in Fig. 6, indicate that each mol of nitrite reacts with 2 mol of HRP-I.

Discussion

In general, sulfite oxidations by inorganic oxidizing agents capable of accepting two electrons always proceed via two-electron transfers producing sulfate as a product (21). The spectrum of the species present in the steady state illustrated in Fig. 4 along with the kinetic measurements made in a mixture of HRP-I and HRP-II indicate that the HRP-I-sulfite reaction involves a two-electron transfer to HRP-I without the observable formation of HRP-II. Although titrations of HRP-I and HRP-II with sulfite were not possible, it seems reasonable to assume that the stoichiometry observed for the reactions of HRP-I and HRP-II with iodide also apply to the reactions with sulfite. Thus the reaction of HRP-I with sulfite at any given pH could be described by eqs. 13 and 14 where the SO_3

$$\text{[13]}\quad \text{HRP-I} + \text{sulfite} \xrightarrow{k_1} \text{HRP} + SO_3$$

$$\text{[14]}\quad SO_3 + H_2O \xrightarrow{\text{fast}} SO_4^{2-} + 2H^+$$

does not necessarily have a discrete existence in aqueous solution.

The reaction of HRP-I with nitrite, unlike the corresponding reactions with sulfite and iodide, involves the transfer of a single electron from nitrite to HRP-I forming HRP-II. The 2:1 ratio of HRP-I to nitrite observed for the titration of HRP-I with nitrite and the 1:1 ratio between hydrogen peroxide and nitrite determined for the overall reaction indicates that the titration ratio between HRP-II and nitrite must also be 2:1. A simple mechanism for nitrite oxidation which incorporates the observed kinetics and stoichiometry for the reactions is

$$\text{[15]}\quad \text{HRP-I} + NO_2^- \xrightarrow{k_3} \text{HRP-II} + NO_2$$

$$\text{[16]}\quad \text{HRP-II} + NO_2^- \xrightarrow{k_4} \text{HRP} + NO_2$$

$$\text{[17]}\quad 2NO_2 + H_2O \xrightarrow{\text{fast}} NO_3^- + NO_2^- + 2H^+$$

where the NO_2 does not necessarily exist in aqueous solution.

It is somewhat surprising that nitrite reacts with HRP-I to produce HRP-II since it has been reported that compound I of catalase oxidizes nitrite in a direct two-electron transfer without the production of compound II (4). In addition the reaction between nitrite and hydrogen peroxide involves the transfer of two electrons and the formation of nitrate via a mechanism that is analogous to that for the reaction of sulfite with hydrogen peroxide (22). The following mechanism offers a simple rationale for the observed reactions of HRP-I with iodide, sulfite, and nitrite.

$$\text{[18]}\quad \text{HRP-I} + X \rightarrow \text{HRP-I}\overset{\delta^-\ \ \delta^+}{\ldots}X$$

$$\text{[19]}\quad \text{HRP-I}\overset{\delta^-\ \ \delta^+}{\ldots}X + H_2O \rightarrow \text{HRP-II} + \text{product}$$

$$\text{[20]}\quad \text{HRP-I}\overset{\delta^-\ \ \delta^+}{\ldots}X \rightarrow \text{HRP} + \text{product}$$

In the proposed mechanism the rate determining step is reaction 18 which is followed either by reaction 19 or 20. For the reactions of iodide and sulfite the products of single electron oxidation, atomic iodine (I·) and SO_3^-, do not react rapidly with water so that step 20 predominates. For the nitrite reaction however, the reaction between NO_2 and water is rapid (23) so that reaction 19 predominates. In the reaction of compound I of catalase, the two-electron transfer from nitrite could be due to the more transient nature of the initial enzymatic complex or perhaps to a more hydrophobic reaction site than HRP which could hinder the reaction analogous to 19.

The second-order rate constants for the reactions of HRP-I and HRP-II with the inorganic substrates iodide (6, 8), ferrocyanide (5), sulfite, and nitrite all show the same general trend of increasing values with increasing acidity. For the reactions of HRP-I and HRP-II with iodide it was possible to demonstrate that this trend resulted from the ionization of an enzyme group at low pH. For the reactions of sulfite and nitrite with HRP-I and HRP-II, the existence of substrate ionizations in the acid region (sulfite has a pK_a value of 1.8 and nitrite a pK_a of 3.4) does not allow the unambiguous establishment of the nature of the reactive protonated species, *i.e.* whether the rate influencing ionization is on the enzyme or substrate. If, however, it is assumed that the rate influencing ionizations observed for the reactions of HRP-I and HRP-II with iodide have a similar effect on the reactions with sulfite and nitrite, a good deal of consistency can be seen in the reactions of all three substrates.

For the HRP-II-sulfite reaction, the reaction of SO_3^{2-} can be shown to require a second-order rate constant of $3 \times 10^{10}\ M^{-1}\ s^{-1}$ to account for the observed rate at pH 2.4. Since the diffusion-controlled limit for a second-order rate constant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where one of the reactants is a large protein can have a maximum value of 10^{10} M^{-1} s^{-1} and is probably smaller (24), it would appear that the reactive form of the substrate is not SO_3^{2-}. If the ground state pK_a value of 3.3 and the transition state p$K_a^{\ddagger}$ value of 4.0 in Fig. 2 are considered to be paired together (a similar pairing of two inflections in close proximity was invoked for the p*H* dependence of the HRP-II-*p*-cresol reaction (20)) the reaction of HRP-I with SO_3^{2-} can also be shown to exceed the diffusion-controlled limit at low p*H*. Thus if the ionizations on HRP-I and HRP-II observed for the reactions with iodide have a similar effect on the reactions with sulfite and nitrite, then the reactive form is the singly charged anion for all three substrates.

The p*H* dependences of the second-order rate constants for the reactions of HRP-I with ferrocyanide (5), iodide (8), and sulfite all indicate enzyme ionizations with pK_a values of approximately 5. A self-consistent method for estimating the errors in these pK_a values has been developed and is reported in detail elsewhere (17). The results indicate that for the HRP-I reaction with ferrocyanide the pK_a is 5.3 ± 0.8, for reaction with iodide the pK_a is 4.6 ± 0.2 and for reaction with sulfite the pK_a is 5.1 ± 0.2. Since the difference in the pK_a values observed for the sulfite and iodide reactions is just outside the error limits on the two values, it appears reasonable to assume that the same ionizing group on HRP-I influences the reaction rate with all three substrates. The kinetics of the HRP-I-sulfite reaction indicate an enzyme pK_a of 3.3 which was not detected in the comparable reaction with iodide. Since the rapid rate of the iodide reaction prevented its study to as low a p*H* as was possible for the sulfite reaction, the influence of this enzyme ionization in the HRP-I-iodide reaction cannot be excluded. The reactions with ferrocyanide (5) and nitrite were not studied at sufficiently low p*H* to detect such a pK_a value.

The identity of the rate law and the similarity in the p*H* dependence of the second-order rate constant for the HRP-II-sulfite reaction monitored at 427 nm compared to the reactions of HRP-I and HRP-II with ferrocyanide (5), iodide (6, 8), and nitrite suggest that the former reaction is describing the same molecular process as the latter reactions. Critchlow and Dunford (20) have proposed a mechanism for the reactions of HRP-II in which this rate determining process involves (*i*) the slow displacement of a group coordinated to the iron followed by (*ii*) rapid electron transfer and (*iii*) rapid product departure. The HRP-II sulfite reaction appears to follow this three-step process but the observation of complex formation implies that one of the latter two steps is slow. The p*H* dependence of the second-order rate constant for the HRP-II sulfite reaction indicates a rate influencing ionization with pK_a of 3.9 that was not observed for the reactions of ferrocyanide (5) or iodide (6). The pK_a of this ionization suggests that the group might be a carboxylic acid residue and the electronegative character of the bisulfite ion makes plausible the postulate of a hydrogen bonding enzyme-substrate interaction.

The Hydrolysis of Disubstituted Alkyl Phosphorochloridates and *N,N,N',N'*-Tetra-substituted Phosphorodiamidic Chlorides in Water and Deuterium Oxide: Heat Capacity of Activation and Kinetic Solvent Isotope Effects

E. C. F. Ko[1] AND R. E. Robertson

Department of Chemistry, University of Calgary, Calgary, Alberta

Received August 3, 1972

The pseudo-thermodynamic parameters, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ and the kinetic solvent isotope effects have been determined for the three alkyl-phosphorochloridates, where the alkyl group is ethylisopropyl and *n*-propyl; for tetra-methyl and tetra-ethyl phosphorodiamidic chlorides; the di-*n*-propyl and di-isopropyl analog, the di(isopropylmethylcarbinyl)phosphorochloridate and the tetra-ethylthiophosphorodiamidic chloride. These compounds have a potential relationship to compounds used as insecticides and as polymers. The mechanism of reaction is discussed on the basis of these data.

Les paramètres pseudo-thermodynamiques, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, et $\Delta C_p^{\ddagger}$ ainsi que les effets isotopiques et cinétiques du solvant, ont été déterminés pour les trois phosphorochloridates d'alcoyles où le groupe alcoyle est l'isopropyle d'éthyle et le *n*-propyle; pour les chlorures de tétra-méthyl et de tétra-éthyl phosphorodiamique; l'analogue di-*n*-propyl et di-isopropyl, le di-isopropyl, méthyl, carbinyl phosphorochloridate et le chlorure de tétra-éthyl thiophosphorodiamique. Ces composés ont une relation possible avec d'autres produits utilisés comme insecticides et comme polymères. Le mécanisme réactionnel est discuté sur la base de ces résultats. Introduction

The significance of pseudothermodynamic parameters derived from the temperature dependence of the rates of reaction is uncertain. Whether this is indicative of some failure of transition state theory as some suspect (1) or due to a lack of proper identification and estimation of contributing factors is an open question which calls for solution if our knowledge in this area is to advance beyond free energy correlations. Among the limited areas where recent progress has been made, we may cite the general correlation between the magnitude of the negative temperature coefficient of the enthalpy of activation ($\Delta C_p^{\ddagger}$) and mechanism for ionogenic reactions in water. Under these conditions this parameter is sensitive not only to solvent reorganization but also can provide evidence for the intrusions of competing reactions with a change of temperature whether due to "mixed kinetics" or to other causes (2) and in certain cases gives evidence of changing solvent interaction with substituents (3). Judged by this latter criteria, mixed kinetics seems far less common for solvolysis in water than occasional reference would lead one to believe. Since the coefficient $\Delta C_p^{\ddagger}$ is essentially empirical,[2] however dignified by formal title, deductions with respect to mechanism depend in large degree on the establishment of "normal values". Thus the remarkable difference in $\Delta C_p^{\ddagger}$ for the hydrolysis of dimethylsulfamoyl chloride (**1**) ($\Delta C_p^{\ddagger} = -76$ cal deg^{-1} mol^{-1}, normal for an S_N1 mechanism (5)) and that for diethylsulfamoyl chloride (**2**) ($\Delta C_p^{\ddagger} = -38$ cal deg^{-1} mol^{-1}) (6) signalled a potential difference in solvent reorganization even though both would be considered to react by an S_N1 mechanism. Thus, a mechanistic distinction not previously suspected was revealed.

In this paper our aim is to determine the values of the $\Delta C_p^{\ddagger}$ for hydrolysis in water and associated values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for three alkyl phosphorochloridates which bear some resemblance to the alkyl chlorosulfates (7) and four *N,N,N',N'*-tetra-substituted phosphorodiamidic (see below) chlorides which have an obvious structural similarity to **1** and **2** and have been studied extensively (8–11) due to a potential

[1]Postdoctoral Fellow, 1970–1972.

[2]Granted the basic theory is a fair approximation, the value of $\Delta C_p^{\ddagger}$ as normally derived, involves the assumption that this term remains constant down to 0 °K, and is independent of temperature through the experimental range — useful but unlikely (4).

relationship to compounds used in the production of insecticides and polymers. Data for the hydrolysis of one thio-analog of the phosphorochlorides are reported as well as for di(isopropylmethylcarbinyl)phosphorochloridate.

$(R_1O)_2POCl$		$(R_1R_2N)_2POCl$	
3	R_1 = Ethyl	**7**	$R_1 = R_2$ = Methyl
4	R_1 = *i*-Pr	**8**	$R_1 = R_2$ = Ethyl
5	R_1 = *n*-Pr	**9**	R_1 = *n*-Pr; R_2 = H
6	$R_1 = R_2$ = 	**10**	R_1 = *i*-Pr; R_2 = H

The mechanism of hydrolysis for **3** and **4** appears to be well established as an S_N2 process (8, 9). While the mechanism for the hydrolysis of **7** and **8** is less well established, the basis for possible disagreement is not very persuasive to us (10, 11). The uncertainty here, as in the case of the sulfonyl chlorides (12) and of the sulfamoyl chlorides (5, 6) arises from that uncertainty which frequently attends mechanistic deductions based on small or no rate increases above the normal value for hydrolysis following the addition of a series of nucleophiles somewhat stronger than water (9, 13). Hall argued that since **7** exhibited virtually no rate enhancement on the addition of OH^-, F^-, and EtO^-, it hydrolyzed by an S_N1 mechanism. Subsequent results obtained by Crunden and Hudson (10) and by Traylor and Westheimer (11) on **8** and **9** show that under certain conditions the hydrolysis of **7**–**9** can be expected to show specific base catalysis and nucleophilic catalysis. There is a remarkable difference toward OH^- between the results for **7** and **8** and those for **9** and **10** and presumably other amidophosphoryl chlorides having a hydrogen attached to the amido nitrogen. Traylor and Westheimer estimate that for **9**, OH^- causes a rate enhancement of at least one million times over that for **7**.

This prior information on the probable mechanism of reaction for these phosphoryl compounds provided a useful background for correlation and examination of the corresponding values of $\Delta C_p^{\ddagger}$ derived from the temperature dependence of the rates of hydrolysis in water. An attempt was made to extend the series to the thio-analog $(Et_2N)_2PSCl$, but in spite of the fact that in each separate rate determination, good first-order kinetic behavior was found, some unknown factor was introduced, which resulted in a larger experimental error than was normally found in such studies. For this reason, we have less confidence in these data than in those for the phosphoryl chlorides. For the same reason the study was terminated with the first member studied.

Results and Discussion

The rates of hydrolysis of **3**–**10** in water were determined by a conductance method described previously (14). These react in water according to first-order kinetics and on the basis of neutral equivalent determination can be assumed to follow the overall equation:

[1] 
The pseudo first-order rate constants ($k < \pm 1\%$) were fitted to the three-constant equation

$$[2] \quad \log_{10} k_{obs} = A_1 + A_2/T + A_3 \log_{10} T$$

The corresponding empirical constants, A_1, A_2, A_3 are reported in Table 1 and provide a means for accurate interpolation of rates. The pseudo-thermodynamic parameters were calculated from these constants in the usual way (15) and are reported in Table 2. A sample of di(isopropylmethylcarbinyl)chlorophosphonate hydrolyzed under similar conditions to the above gave first-order rate constant of 25° and led to values of $\Delta H^{\ddagger}$ 12 735 ± 100 cal mol^{-1} and $\Delta S^{\ddagger}$ −27.44 ± 0.32 cal deg^{-1} mol^{-1} at 25°. Low solubility was considered to be the factor which prevented a more extended study.

The values of the constants corresponding to eq. 2 obtained for the hydrolysis of tetraethylthiophosphorodiamidic chloride[3] were A_1 = 54.86995, A_2 = −6264.362, and A_3 = −15.41276. The values of the derived terms were as follows: $\Delta H^{\ddagger}$ = 17 961 ± 11 cal mol^{-1}, $\Delta S^{\ddagger}$ = −17.21 ± 0.04, and $\Delta C_p^{\ddagger}$ = −32 ± 2 cal deg^{-1} mol^{-1}. The rate in D_2O at 60.20 °C was 1.216×10^{-3}. The corresponding value in H_2O is 1.561×10^{-3} giving a value of k_{H_2O}/k_{D_2O} = 1.28, a value significantly lower than found for the sulfonyl chlorides (16).

A considerable body of empirical data exists now to support the generalization that uncomplicated hydrolyses occurring by an S_N1 mechanism and leading to the creation of halide ions

[3]Rate data showing derivations >2% were discarded after a preliminary fit.

are characterized by a more negative value of $\Delta C_p{}^{\neq}$ than those reacting by an S_N2 mechanism (14). Such a generalization is consistent with the classical observation that the ionizing mechanism involved a greater degree of charge development at the transition state (17), and hence a greater degree of solvent reorganization. Thus halides assumed to react by an S_N1 mechanism generally have values of $\Delta C_p{}^{\neq}$ about -80 ± 5 cal mol^{-1} deg^{-1} while those reacting by an S_N2 mechanism have values in the range of -40 to -55 cal mol^{-1} deg^{-1}. Exceptions are known (19), hence this distinction by itself is not a sufficient mechanistic test. While the *p*-substituted benzyl nitrates show a wider range of values for $\Delta C_p{}^{\neq}$ (18), the corresponding values for the hydrolysis of the sulfonic esters, to date, all lie in the range of -35 to -41 cal deg^{-1} mol^{-1}.

As noted above (14), for an uncomplicated reaction mechanism, whether S_N1 or S_N2, involving the displacement of halides from carbon these differences could be correlated with charge development and solvent reorganization. A simple extension of this generalization led to the expectation (14) of a corresponding correlation between mechanism and the corresponding values of the kinetic solvent isotope effect (k_{H_2O}/k_{D_2O}, k.s.i.e.) but this was not observed. The hydrolyses of alkyl halides, sulfonates, sulfates, chlorosulfates, nitrates, and phosphates, irrespective of the mechanism of displacement from a carbon center show rather low k.s.i.e. values, in the order of 1.1–1.3 whether some degree of nucleophilic interaction is required or not (19). However, substituted alkyl phosphorochloridates, phosphorodiamidic chloride, and the sulfonyl chlorides with displacement occurring from either a phosphorus or sulfur atom have significantly higher values of k.s.i.e., in the range 1.3–1.9 (Table 3). Some part of this effect may be attributed to the greater degree of nucleophilic interaction required, a conclusion supported by Rossal and Robertson by showing that a linear correlation existed between the k_{H_2O}/k_{OH^-} ratio and the k.s.i.e. for a series of para-substituted sulfonyl chlorides (20). However, these authors overlooked a second potential contributor to the k.s.i.e. In each of the second series, there is at least one oxygen α to the reaction center. The k.s.i.e. seems to increase as the number of oxygen atoms adjacent to the reaction center increases, in contrast to the lack of such an effect where the oxygen atoms lie beyond the α-position as is the case with the sulfonates, sulfates, and phosphates (Table 4). Nucleophilic attack of water by the oxygen will place the hydrogens of that molecule

in the neighborhood of unshared electrons of the sulfonyl or phosphoryl oxygens and this interaction will tend both to polarize the bond and enhance the nominal k.s.i.e. Such an effect would be analogous to the "α effect" discussed by Edwards and Pearson (21) and others (22–25) in connection with the enhanced reactivity encountered in the reaction of nucleophiles with substrates bearing unshared electrons on adjacent atoms. A similar effect has been proposed by Murto in connection with the enhanced rate of hydrolysis of picryl fluoride compared with the chloride (27) and in a sense may be regarded as a kind of intramolecular general base catalysis (23). While the possibility of such an effect seems reasonable, it cannot be large since general base catalysis normally leads to values of k.s.i.e. of 2 or larger (19) and the measured values (Table 4) combine both the isotope effect arising from such interaction and that due to normal weakening of the O—H bond as a consequence of nucleophilic interaction plus about 0.1–0.3 attributed to solvent reorganization. In the sulfonyl chloride series Rossal and Robertson reported a value of k.s.i.e. = 1.82 for the *p*-nitro and 1.40 for the *p*-MeO compound. Were the above interaction important in the sulfonyl series, the opposite order of enhancement would be expected. In that comparison, one cannot exclude the possibility that the effect is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

present but is concealed by a larger opposing effect. With such an argument, any such effect could be explained and in the absence of independent supporting evidence we prefer to neglect it.

While the values of k.s.i.e. for **3** and **4** are about the same as found previously for methanesulfonyl chloride and *p*-bromobenzenesulfonyl chloride, the corresponding values of $\Delta C_p^{\ddagger}$ are significantly more positive. The latter provide two more examples of what appears to be a general phenomenon, first noted in connection with the value of $\Delta C_p^{\ddagger}$ found for the hydrolysis of *p*-methoxybenzenesulfonyl chloride (3) and supported by the corresponding value of ΔC_p derived from the ionization of benzoic acids substituted with a methoxy group (3). Further support is found in our results for the hydrolysis of β-methoxyethyl chlorosulfate (8). It was apparent from these examples that there was a temperature dependent solvent effect on the methoxy group which altered the effect of this group on $\Delta H^{\ddagger}$ and hence provided a positive component to $\Delta C_p^{\ddagger}$ which reduced the larger negative component due to solvent reorganization. Thus the less negative value of $\Delta C_p^{\ddagger}$ obtained for **3** and **4** compared to the values for **7** and **8** need not indicate a significant difference in charge development at the transition state. It follows that while it is probable that some degree of bond-making is required in the activation process for the hydrolysis of **7** and **8** as Crunden and Hudson maintain (10), the values of $\Delta C_p^{\ddagger}$ do not suggest any remarkable degree of charge development if that is implied by the term "looseness" which Traylor and Westheimer (11) introduce to account for the difference between their mechanistic conclusions and those of Hall (9) with regard to these compounds. Whether the unusually low value of $\Delta C_p^{\ddagger}$ found for the hydrolysis of **5** can be attributed to this same effect is uncertain. We see no structural reason why this should be so.

The values of $\Delta C_p^{\ddagger}$ for **9** and **10** are significantly more negative than those of **3**–**8** and hence may be taken as *prima facie* evidence of a greater degree of solvent reorganization accompanying the activation process as would be expected for an S_N1 mechanism. However, the values of k.s.i.e. are intermediate between those for **3** and **4** and those for **7** and **8**. These values are far smaller than would be expected were the amidic hydrogen (D in D_2O) strongly involved as is the case when the reaction is catalyzed by OH^- or in hydrogen participation such as occurred in the hydrolysis of **2** (6). Traylor and Westheimer report that when **9** is dissolved in D_2O, exchange of the amidic hydrogen takes place very rapidly, being essentially complete in less than 30 s. Since the rate of hydrolysis is much slower than this, the exchange process evidently does not trigger hydrolysis, after the fashion of the catalytic effect of OH^-.

An examination of Courtauld's space models for the seven phosphoryl chlorides suggests that no significant steric hindrance to nucleophilic approach exists, hence some factor other than steric hindrance (which seemed adequate in the case of the dimethylsulfamoyl chloride) (5) must determine the mechanism of hydrolysis. It seems possible that **9** and **10** can exist as a fast equilibrating mixture (eq. 3) in which a kind of hydrogen participation reduces the positive charge on

[3] 
P and at the same time, on activation, facilitates the ionization of the forming chloride ion. The effect cannot be large (or the k.s.i.e. would be much greater) but may be sufficient to favor an S_N1 mechanism over some alternative. No such tautomeric forms are possible in **7** and **8**, hence these will require some degree of nucleophilic interaction in the displacement of the chloride ion. The less negative value of $\Delta C_p^{\ddagger}$ and the smaller value of k.s.i.e. are both consistent with the conclusion that the transition state is reached for this compound with a lower degree of charge separation than for the corresponding tetraalkylphosphorodiamidic chlorides.

Conclusion

No claim is made here for a reversal of mechanistic proposals based on other evidence. Where an S_N2 type mechanism is to be expected this fact is reflected in the magnitude of the k.s.i.e. and in the corresponding values of $\Delta C_p^{\ddagger}$. Quantitative differences were noted and the trends in these two parameters were shown to parallel values already obtained in other systems.

*Solvent was CCl_4 except for **9** in which $CDCl_3$ was used.
†About 10° below that reported in ref. 4.

This was not too surprising but it does provide further support for the utility of k.s.i.e. and $\Delta C_p^{\ddagger}$ values. The tetra-substituted phosphorodiamidic chlorides bearing an amido-hydrogen introduced an unusual combination of a value of k.s.i.e., which nominally would indicate bond-making with a water molecule in the activation process, contrary to the conclusions reached on the basis of other data, while the $\Delta C_p^{\ddagger}$ values indicated that the activation processes were accompanied by a more extended degree of solvent reorganization and was in the approximate range for molecules reacting by an S_N1 mechanism. These two opposed mechanistic indications were rationalized by postulating an intra-molecular interaction between an amido-hydrogen and the phosphoryl oxygen.

Experimental

The phosphorochloridates **3–6** were made in a two-step process outlined in the literature (8). Phosphorus trichloride was reacted with three-fold excess of the corresponding alcohol to give a disubstituted hydrogen phosphite which was then chlorinated with gaseous chlorine to give the phosphorochloridate. Phosphorodiamidic chlorides **6–9** were synthesized, in general, from phosphoryl chloride with four-fold excess of the corresponding amine at low temperature as previously reported (11). These compounds, except **8**, were purified by vacuum distillation two or three times, until the distillates gave homogeneous peaks on v.p.c. using a 10% neopentyl glycol sebacate on chromosorb glass column. Compound **8** was recrystallized twice from methylene dichloride and then sublimated. Their physical properties and n.m.r. spectra are summarized in Table 5.

The reaction products, acid and chloride, were analyzed by hydroxide titrations and potentiometric silver nitrate titrations, respectively. No attempts had been made to isolate the substituted phosphorus acids in the form of salts. The purification of solvents and the kinetic measurements were similarly the same as outlined in previous papers (14).

Tetraethylthiophosphorodiamidic chloride was made from diethylamine and phosphorus thiochloride by a method similar to that outlined previously (26); b.p. 50/0.25 mm Hg; n.m.r. triplet at τ 8.73 and two sets of quartets centered at 6.63 and 6.33 respectively, integration of proton ratio being 6:4.

We acknowledge with gratitude the financial support received from the National Research Council of Canada which made this work possible.

We thank Miss Eileen Huang for permission to include her kinetic results obtained in an Honors Chemistry project.

The Crystal Structure of *cis*-Dichloro(2,2′-oxydi-3-butene)platinum(II), $PtCl_2((CH_2{=}CH{-}CH(CH_3))_2O)$[1]

J. HUBERT, A. L. BEAUCHAMP, AND T. THEOPHANIDES

Département de Chimie, Université de Montréal, Montréal, Québec

Received July 24, 1972

The reaction of K_2PtCl_4 with $CH_3{-}CH{=}CH{-}CH_2{-}OH$ yields the complex *cis*-[$PtCl_2((CH_2{=}CH{-}CH(CH_3))_2O$)]. The crystals are triclinic, space group $P\bar{1}$, a = 9.420(2) Å, b = 8.359(4) Å, c = 7.837(4) Å, α = 91.10(4)°, β = 62.13(4)°, γ = 80.80(5)°, and Z = 2. The structure, solved by standard methods, has been refined anisotropically by full matrix least-squares methods to a R factor of 0.052 by use of 2441 independent observed reflections. The complex is a monomer, where both double bonds of the diolefin ether are coordinated to the platinum atom as in Zeise's salt. The usual square planar coordination of platinum(II) is completed by two chlorine atoms. The ($=CH_2$) groups of both double bonds are found on the same side of the coordination plane. Various possible conformations of the coordinated ligand in the complex are discussed.

Le complexe *cis*-[$PtCl_2((CH_2{=}CH{-}CH(CH_3))_2O$)] a été préparé par réaction de K_2PtCl_4 avec l'alcool crotylique $CH_3{-}CH{=}CH{-}CH_2{-}OH$. Les cristaux obtenus sont triclinique ($P\bar{1}$) et les paramètres cristallographiques suivants ont été obtenus: a = 9.420(2) Å, b = 8.359(4) Å, c = 7.837(4) Å, α = 91.10(4)°, β = 62.13 (4)°, γ = 80.80(5)°, et Z = 2. La structure a été résolue par la méthode de l'atome lourd et un affinement anisotrope par moindres carrés à matrice entière a conduit à un facteur R de 0.052. Le complexe est un monomère. L'éther dioléfinique est coordonné au platine par l'intermédiaire des deux doubles liaisons. La liaison entre le platine et la double liaison est du même type que celle rencontrée dans le sel de Zeise. La coordination du platine est complétée à quatre par deux atomes de chlore. Les deux groupements ($=CH_2$) sont situés d'un même côté par rapport au plan de coordination. Diverses conformations possibles du ligand dans le complexe sont discutées.

Can. J. Chem., **51**, 604 (1973)

Introduction

In their studies of the metal–olefin complexes, Hartley and Venanzi (1) have observed several interesting reactions of substituted olefins with potassium tetrachloroplatinate(II). In the case of unsaturated alcohols, the authors have noticed the occurrence of side reactions during the formation of the alcohol complex $[PtCl_3(alcohol)]^-$.

During the investigation of the reactions of K_2PtCl_4 with crotyl alcohol ($CH_3{-}CH{=}CH{-}CH_2{-}OH$), we found that one of the products is an ether complex of the formula $C_8H_{14}Cl_2OPt$.

A $PtCl_2$(allylether) has been previously prepared by Jensen (2) and described as a monomeric *cis* species. More recently, the above conclusions were confirmed by Jones (3) and the structure on Fig. 1 was proposed on the basis of n.m.r. studies. The ether ligand occupies two coordination sites and is linked to the platinum atom through the double bonds.

The ether complex prepared from crotyl alcohol gave stable single crystals and an X-ray analysis was undertaken in order to determine the nature of bonding and the configuration of the ligand.

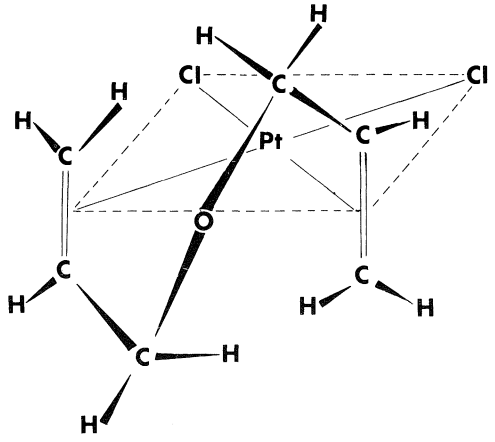

FIG. 1. Configuration proposed (3) for the *cis*-$PtCl_2$(allylether) complex.

*Coefficients β_{ij} are defined by the expression $T = \exp[-10^{-4}(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + \beta_{12}hk + \beta_{13}hl + \beta_{23}kl)]$.

80.80(5)°, $V = 535.3$ Å^3, $Z = 2$, $\rho_c = 2.43$, $\rho_o = 2.33$ (flotation) at 20 °C, $\lambda MoK_{\bar{\alpha}} = 0.71068$ Å, $\lambda MoK_\beta = 0.63225$ Å, $\mu MoK_\alpha = 136.7$ cm^{-1}.

The above cell was used throughout the calculations. A conventional reduced cell of type I (angles < 90°), $a' = 7.837$ Å, $b' = 8.359$ Å, $c' = 9.007$ Å, $\alpha' = 79.40°$, $\beta' = 67.60°$, $\gamma' = 88.90°$ may be obtained by the following transformations: $a' = -c$, $b' = b$, $c' = a - c$, where the primed symbols refer to the conventional cell and the unprimed symbols to the cell used in the present work.

Experimental

The compound was synthesized by the reaction of potassium tetrachloroplatinate(II) (3 g) with an excess of crotyl alcohol (Matheson, Coleman, and Bell) (b.p. 120–122 °C) (3 ml) in 30 ml distilled water. The mixture was heated (50 °C) until the solution turned yellow. After two days a white precipitate was deposited from the clear solution. The analysis was consistent with the formula $C_8H_{14}Cl_2OPt$.

Anal. Calcd. for $C_8H_{14}Cl_2OPt$: Pt, 49.74; Cl, 18.08; C, 24.48; H, 3.57. Found: Pt, 50.00; Cl, 17.96; C, 25.01; H, 3.45.

The complex is monomeric in chloroform and non electrolyte in nitromethane.

A colorless prism with dimensions 0.160 × 0.125 × 0.095 mm was found suitable for the X-ray work. The crystals are stable in air. From precession photographs, they were found to be triclinic ($P1$ or $P\bar{1}$). The measured density corresponds to two formula units per unit cell.

The intensity data were measured on an automatic Picker FACS-1 diffractometer by using Zr-filtered MoK_α radiation. The orientation matrix and the cell constants with their estimated standard deviations were obtained by a least-squares refinement on the χ, Φ, 2θ values for 12 independent reflections. The $\theta/2\theta$ scan method was used. Each peak was scanned at a 1°(2θ)/min rate over an average range of 1.75°. Stationary background counts of 20 s were taken at each limit of the scan. Periodic check of the 061, 510, and $\bar{1}14$ reflections indicated a slow decomposition of the crystal (total intensity decrease of 8%). This effect was taken into account when the reflections were scaled on the standards in the data reduction program. The integrated intensities of 3168 independent reflections within a sphere of $2\theta < 60°$ were measured. Reflections (727) with net intensities less than 3σ (total peak count + total background count) were considered as unobserved. An absorption correction based on the equations of the crystal faces (18) was applied and each intensity was corrected for Lorentz and polarization effects.

Structure Determination

The $P\bar{1}$ group was assumed and the coordinates of the platinum atom were obtained from the Patterson map. All other atoms except hydrogens were located by structure factor and Fourier map calculations. The parameters were refined by full-matrix least-squares. The scattering factors used were those of Cromer and Waber (4). The anomalous dispersion factors $\Delta f'$ and $\Delta f''$ of platinum and chlorine (5) were included in the calculations. Only the observed reflections were used in the calculations. Isotropic refinement with unit weights converged to an R factor of 0.088. The structure was then refined anisotropically and each reflection was assigned an individual weight w based on the eq. (6): $w = a + bF_o + cF_o^2$, where $a = 15.0$, $b = -0.794$, and $c = 0.0115$. This weighting scheme yielded minimum variations of the average weighted residual as a function of F_o and $\sin\theta/\lambda$. The refinement of the scale factor, the coordinates and the anisotropic temperature factors of all the atoms except the hydrogens resulted in a residual $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ of 0.052 and a weighted residual $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ of 0.065. On the final difference Fourier map, the residual electron density was less than 0.8 e/Å^3 (except for three peaks of 1.5 e/Å^3 near the platinum atom), the peak height of an average carbon atom in this analysis being 6 e/Å^3. The refined parameters are given in Table 1. The programs used are described elsewhere (7).[2]

[2]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

*Z(1–2) defines the midpoint of C(1)—C(2); Z(7–8) defines the midpoint of C(7)—C(8).

Results and Discussion

The crystal structure is made up from isolated *cis*-Pt(ether)Cl_2 molecules, where the diolefin acts as a bidentate ligand (Fig. 2). The diolefin ligand is not the expected dicrotylether (CH_3—CH=CH—$CH_2)_2O$. Instead, the organic moiety is the 2,2′-oxydi-3-butene, which was obtained by isomerization and condensation (whatever the actual mechanism might be) of the original alcohol. To our knowledge, it is the first time that such an isomerization is observed during complex formation.

The chlorine atoms and the midpoints of the double bonds are arranged in a nearly square planar geometry. The angles around platinum are all close to 90° or 180° (Table 2) and the midpoints Z(1–2) (of C(1)—C(2)) and Z(7–8) (of C(7)—C(8)) are less than 0.01 Å from the Pt—Cl(1)—Cl(2) plane.

The Pt—Cl distances (2.314, 2.316 Å) are identical. They fall within the range of normal platinum–chlorine bond lengths (2.30–2.34 Å) observed in similar complexes (8–10). The π-bonding olefin does not seem to exercise any *trans*-bond-lengthening effect. The same Pt—Cl distance has been recently reported for K_2PtCl_4 (11).

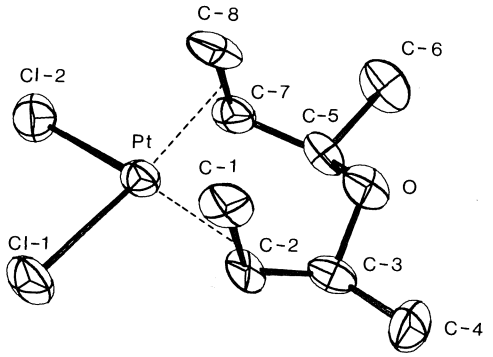

FIG. 2. Structure found for the *cis*-dichloro-(2,2′-oxydi-3-butene)platinum(II) complex.

The C(1)—C(2) (1.41(3) Å) and C(7)—C(8) (1.36(3) Å) distances are typical of those of olefins linked to platinum (8). They seem to be slightly larger than those of monosubstituted ethylene molecules (1.34–1.35 Å(12)), but these differences are not very significant. Both double bonds are nearly perpendicular to the Pt—Cl(1)—Cl(2)—Z(1–2)—Z(7–8) plane. The values obtained for ∠Pt—Z(1–2)—C(1) (89°) and ∠Pt—Z(7–8)—C(8) (88°) are very close to 90° and the dihedral angles between the Pt—Cl(1)—Cl(2) planes are 93° and 92°, respectively. The small

$PtCl_2(C_8H_{14}O)$	1.41(3) 1.36(3)	109 109	This work

distortions are probably due to packing effects and to steric constraints introduced by the rest of the ligand.

Normal values are observed for the other interatomic distances and bond angles in the coordinated ligand. The intermolecular contacts are all at least equal to the sum of the van der Waals radii.

Neutron diffraction work on Zeise's salt has shown that the hydrogen atoms are displaced away from the platinum atom and that the dihedral angles between the Pt—C—C plane and the four C—C—H planes average 101°. For an undistorted ethylene molecule in the complex, these angles would be 90°.

In the present work, dihedral angles of 109° were found between the platinum – double bond planes and the α-carbon – double bond planes (Pt—C(1)—C(2)/C(1)—C(2)—C(3) and Pt—C(7)—C(8)/C(7)—C(8)—C(5)). Although the hydrogen atoms of the double bonds could not be located, the latter dihedral angles are consistent with the structural changes taking place in the Zeise's salt. The dihedral angles and the "double bond" lengths for olefinic complexes are summarized in Table 3. It appears that these angles reflect better than the bond lengths the perturbation of the double bond on coordination.

In the *cis*-Pt(diolefin)Cl_2 molecule, the ether is the *meso* isomer and its two halves are related by an approximate mirror plane perpendicular to the coordination plane. The (=CH_2) groups of the ligand are both on the same side of the Pt—Cl(1)—Cl(2) plane. The "twisted" conformation (Fig. 1) with the two (=CH_2) groups on opposite sides of the coordination plane has been proposed by Jones (3) for the corresponding Pt(diallylether)Cl_2 complex. His conclusions were reached from solution n.m.r. spectra. Stuart molecular models of both conformations show that the present structure is favored by the following factors: (*i*) the nearly square planar geometry around the platinum atom is preserved, (*ii*) the bond angles in the ligand are not appreciably strained, and (*iii*) both "double bonds" are perpendicular to the Pt—Cl(1)—Cl(2) plane.

An interesting feature of the structure observed here is the possible existence of several isomers and conformers. Depending on the position of the oxygen with respect to the C(2)—C(3)—C(5)—C(7) plane two basic conformations are expected for the bridging ether in the complex, *i.e.*, a *boat* form (Fig. 3*a*) and a *chair* form (Fig. 3*b*). The distribution of the methyl groups on the axial (a_1,a_2) and equatorial (e_1,e_2) positions leads us to two *meso* isomers and a pair of optical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

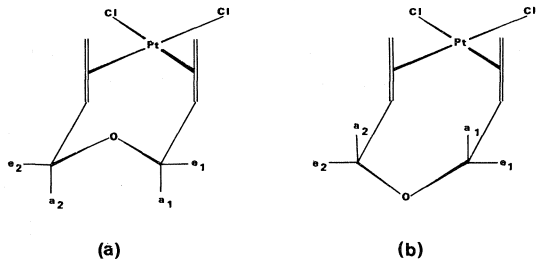

FIG. 3. Drawings of the two main conformers obtained by changing the position of the oxygen with respect to the C(2)—C(3)—C(5)—C(7) plane, in the *cis*-[$PtCl_2$(diolefinether)] complex.

TABLE 4. Possible isomers and conformers of the diolefin ether platinum(II) complex

Isomer	Conformer	a_1	a_2	e_1	e_2
meso I	Boat	H	H	CH_3	CH_3
	Chair	CH_3	CH_3	H	H
meso II	Boat	CH_3	CH_3	H	H
	Chair	H	H	CH_3	CH_3
d,l	Boat	CH_3	H	CH_3	H
		H	CH_3	H	CH_3
	Chair	CH_3	H	CH_3	H
		H	CH_3	H	CH_3

isomers, each of which might adopt both *boat* and *chair* conformations (Table 4).

For a given isomer the two conformations are not equally likely and a molecular model indicates that the interaction between the axial groups a_1,a_2 is a determining factor. On that basis, the *chair* form of meso I and the *boat* form of meso II are highly unlikely because of the close contact of the methyl groups in axial positions. An important interaction is also evident from the model between one methyl group and one hydrogen in axial positions for the boat and chair forms the *d* (or *l*) isomer. The least interaction is found in the cases of *boat* form of meso I and *chair* form of meso II. The *boat* form of meso I was found in this work, but there is no obvious reason for the non-existence of the *chair* form of meso II.

The n.m.r. spectra of the present diolefin complex are under study and our conclusions on the structures of the complex in solution and the reaction mechanisms will be published later.

The financial assistance of the National Research Council of Canada and the loan of platinum salts by the Johnson Matthey and Mallory Co. Ltd. is greatly appreciated.

Vibrational Spectra, Vibrational Analysis and Stereochemistries of the Pentacoordinate Molecules $SiCl_3X \cdot N(CH_3)_3$ and $SiCl_3X \cdot N(CD_3)_3$ where X = H, F, Br, or I

D. Boal and G. A. Ozin[1]

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario

Received June 27, 1972

The thermally unstable compounds $SiCl_3X.N(CH_3)_3$ and $SiCl_3X.N(CD_3)_3$ where X=H, F, Br, or I are studied at −196 °C by infrared and Raman spectroscopy. The data are compatible with molecular five coordinate compounds having a trigonal bipyramidal stereochemistry with the ligand trimethylamine always in the axial position. Using the vibrational data and normal coordinate analyses in both the C_s and C_{3v} configurations, X is suggested to be equatorial for H and F and axial for Br and I. The factors influencing the position of X in the compounds are discussed.

Les composés thermiquement instables $SiCl_3X.N(CH_3)_3$ et $SiCl_3X.N(CD_3)_3$ où X=H, F, Br, où I ont été étudiés à −190 °C par spectroscopie infrarouge et Raman. Les résultats peuvent être attribués à des composés moléculaires de coordination cinq (5) possédant une stéréochimie bipyramidale trigonale avec le coordinat triméthylamine toujours en position axiale. En utilisant les données vibrationnelles et les analyses en coordonnées normales pour les configurations C_s et C_{3v}, on peut supposer que X est équatorial pour H et F, axial pour Br et I. Les facteurs influençant la position de X dans les composés sont discutés.

Introduction

Stereochemical information for the compounds $SiCl_3X.NMe_3$ where X = H, F, Br, or I have not previously been reported although the existence of the hydride and fluoride has been known for some time (1, 2). The compounds are found to be stable at −196 °C, yet completely dissociated into free halide and amine at room temperature. Dissociation pressure measurements have been reported for the series $SiCl_nH_{4-n}.NMe_3$ and $SiCl_nF_{4-n}.NMe_3$ where the results indicated the influence of steric and electronegativity effects on the stability order of the molecules (3, 4). With recent improvements in low temperature infrared and Raman techniques, there has been renewed interest in vibrational and structural studies of unstable co-ordination compounds.

In an attempt to study these complexes, it was assumed that the basic shape at silicon was trigonal bipyramidal, with the trimethylamine ligand lying axially. Vibrational and single crystal Raman spectra and x-ray data (5, 6) for the complexes $MX_4.NMe_3$ (M = Si, Ge, or Sn and X = F or Cl), $MX_3.2NMe_3$ (M = Al, Ga, or In and X = H, Cl, or Br) and $MX_3.NMe_3$ (M = P or As and X = Cl or Br) have been reported and the evidence is overwhelmingly in favor of the amine lying axially. Assuming this, the question is then whether the X atom will reside in the equatorial or axial position for the series $SiCl_3X.NMe_3$. An argument has been put forward (7) that for trigonal bipyramidal molecules, the most electropositive atom will lie in the equatorial plane and hence one would expect to find Cl, F, Cl, and Cl in the axial positions for the series X = H, F, Br, and I. If the trimethylamine ligand were sterically bulky enough to crowd the atoms in the equatorial plane, then one might expect to find Cl, Cl, Br, and I for the same series. A third hypothesis based on molecular orbital theory is put forward in this paper, and leads to the same predictions as the steric argument. By examining the vibrational spectra of the complexes and their perdeutero analogs, it was found that the axial atoms were Cl, Cl, Br, and I for the series X = H, F, Br, and I.

Before going into detail, it is worthwhile to discuss the spectrum of the parent molecule $SiCl_4.NMe_3$ (8, 9), which has been reported to have C_{3v} symmetry with the trimethylamine ligand in the axial position. Its spectrum is very close to that of $GeCl_4.NMe_3$ which has been shown from single crystal Raman (9) and X-ray (10) data to have the above structure. The vibrational spectrum is easily divided into ligand and acceptor modes (9), the former experiencing

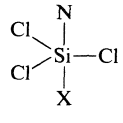
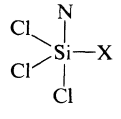
50–80 cm^{-1} shifts upon deuteration of the trimethylamine. The Si—Cl stretching modes are easily discernible because of their much smaller shifts upon deuteration. The asymmetric E mode of the equatorial chlorines is found at 582 cm^{-1} (high frequency), being strong in the infrared and weak in the Raman. The symmetrical A_1 of the equatorial chlorines comes at low frequency, 361 cm^{-1}, and is strong in the Raman. This low frequency (300–380 cm^{-1}) mode is common for light central metal atoms, for example, aluminum, silicon, and phosphorus. The other A_1 mode involves the axial silicon–chlorine stretch. This mode, because it contains motion of the silicon atom (whereas the other A_1 does not), is expected to come at higher frequencies, and indeed is observed at 385 cm^{-1}. It is significant to note that in the vibrational analysis of this complex, the axial stretching force constant was found to have one half the value of the equatorial one. In addition, the crystal structure of $AsCl_3.NMe_3$ (12) (which is based on a trigonal bipyramid with an equatorial lone pair) and $GeCl_4.NMe_3$ (10) shows the axial bond to be significantly longer than the equatorial one. The trimethylamine complex with $SiCl_3X$ can then have two possible stereochemistries

A (C_{3v})



$$\Gamma_{vib}^{\nu SiCl} = A_1 + E$$

B (C_s)



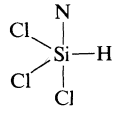
$$\Gamma_{vib}^{\nu SiCl} = 2A' + A$$

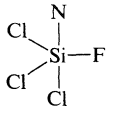
In configuration A, one would expect to find only one strong Raman peak in the Si—Cl stretching region due to the A_1 mode at about 370 cm^{-1}, as with monomeric $AlCl_3$ (11) (371 cm^{-1}). In B, however, there should be an A' mode due to the axial stretch above 380 cm^{-1}, and another A' mode having frequency greater than 400 cm^{-1} (the high frequency caused by both the motion of the silicon atom and the higher equatorial force constant compared to the axial one).

On the basis of the silicon–chlorine symmetric stretches, the stereochemistries were assigned. The perdeutero analogs were prepared to distinguish donor from acceptor modes, and normal coordinate calculations on each possible configuration were carried out.

$SiCl_3H.NMe_3$ and $SiCl_3F.NMe_3$

The spectra, observed and calculated, are tabulated in Tables 1 and 2. Both molecules show no silicon–chlorine stretching frequencies below 400 cm^{-1}, but rather two *high* frequency modes in the Raman. This strongly favors the hydrogen and fluorine atoms occupying the equatorial positions.





νSiCl	588 cm^{-1} A''	νSiCl	580 cm^{-1} A''
	517 cm^{-1} A'		460 cm^{-1} A'
	489 cm^{-1} A'		424 cm^{-1} A'

No serious attempt is made to assign the region under 300 cm^{-1} as the spectrum is far too complex (also indicating C_s symmetry). The low frequency calculated for the silicon–chlorine axial stretch in $SiCl_3H.NMe_3$ is due simply because of the very low force constant. If this force constant was raised to 3/4 of the equatorial, one obtains a frequency in the region observed. The calculations for a C_{3v} configuration are shown in Table 3. The Si—Cl stretching frequency calculated is significantly lower than that observed, and in order to raise this calculated value to even 470 cm^{-1}, a force constant of about double the $SiCl_4$ value must be employed. Clearly this is unacceptable since the $SiCl_4$ force constant should decrease, not increase, upon coordination. The C_{3v} model is also unable to explain the presence of two high frequency SiCl stretching modes; it predicts only one.

$SiCl_3Br.NMe_3$ and $SiCl_3I.NMe_3$

The spectra for these complexes are very different from the previous two (Tables 4 and 5). Both show only one strong band in the *low* frequency silicon–chlorine stretching region at about 370 cm^{-1}, and no acceptor modes between 400–550 cm^{-1}.

Evidence against an ionic formulation [$SiCl_3.NMe_3^+$] [X^-] for the bromide and iodide adducts stems from three observations: (*i*) the observed νSiBr and νSiI (382 and 332 cm^{-1} respectively) stretching modes are far too high and indicate normal covalently bonded halogen; (*ii*) the a_1 and e νSiCl frequencies for a "pyrami-

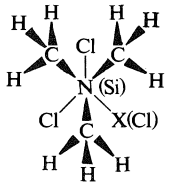
The calculations (Tables 4 and 5) give a very good match for C_{3v} symmetry, but a poor one for C_s. In the latter geometry, the bands were predicted to come at frequencies greater than 400 cm^{-1} as with the previous complexes, and very low force constants would have to be used to bring the frequencies down to 370 cm^{-1}.

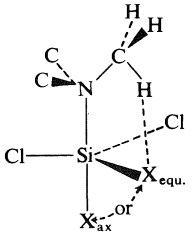
Discussion

Having defined the configurations of the molecules $SiCl_3X.NMe_3$, it is necessary to discuss the various factors which may influence the change in stereochemistry from C_s for X = H or F to C_{3v} for X = Br and I. It has been found that for trigonal bipyramidal trimethylamine complexes (5, 6, 10, 12), the bulky NMe_3 grouping adopts an axial staggered configuration with respect to the rest of the molecule. A staggered



configuration of the ligand would of course present the least amount of steric strain to the molecule.

An estimate of the degree of "ligand hydrogen – equatorial halogen" steric interaction (illustrated below) can be determined from a molecular model of $SiCl_3X.NMe_3$, based on a trigonal bipyramidal stereochemistry, having an axial staggered NMe_3 with respect to a coplanar arrangement of equatorial atoms. Placing the atom X = H, F, Cl, Br, or I in either the axial or equatorial sites, assuming tetrahedral angles at N and C and using single bond covalent radii, the maximum distances of H····X closest approach were calculated.



The computed H····X distances were all larger than a H—X single bond distance although the bromide H····Br (2.46 Å) and iodide H····I (2.56 Å) distances were considerably shorter than the corresponding Van der Waal's distances, 3.15 and 3.35 Å respectively.

From simple steric arguments one would tend to favor equatorial H and F atoms but axial Br and I atoms which is in agreement with our experimental observations. It is perhaps interesting to note that intramolecular ligand hydrogen – equatorial fluorine (H····F) hydrogen bonding would also probably favor an equatorial F atom in $SiCl_3F.NMe_3$.

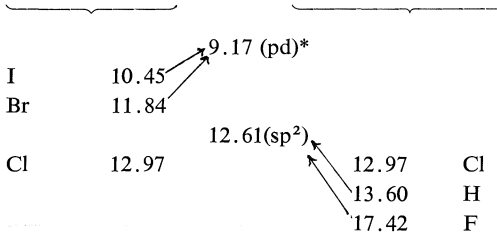
A semi-quantitative molecular orbital approach which can be considered when discussing the configurations of these trigonal bipyramidal molecules involves the energy gain on combining the orbitals of atom X and those of the central silicon atom. The sp^3d hybridized orbitals on the central atom of the trigonal bipyramidal molecule have been considered to be approximately divided into two orbital sets (7); axial linear pd hybrids and equatorial planar sp^2 hybrids. If the greatest energy to be gained by combining two orbitals occurs when the orbitals are evenly matched in energy, it is appropriate to consider as a first approximation the valence state ionization potentials (13) of the combining atom X = H, F, Br, and I and compare them with the values for the pd axial and sp^2 equatorial orbitals on silicon shown in Scheme 1. This



*In this approximation $E(pd) \simeq E(p_z)$.

SCHEME 1

simple scheme predicts that equatorial H and F atoms and an axial I atom are energetically favored in $SiCl_3X.NMe_3$, which agrees with our experimental observation and favors the geometries predicted from simple steric arguments. Although the fate of bromine is not clear cut on this scheme, perhaps the steric effect of Br predominates to favor the axial position.

Normal Coordinate Analysis For $SiCl_3X.NMe_3$ in C_s and C_{3v} Symmetry

The bond lengths used are listed in Table 6; the equatorial bond length is taken as the SiX_4 length while the axial one is taken as being 5% longer, in anticipation of the weakness of the axial bond, and in accordance with the $AsCl_3.NMe_3$ and $GeCl_4.NMe_3$ X-ray data (10, 12). The silicon–nitrogen length is set at 2.01 Å. The methyl groups were treated as point masses. The internal and symmetry coordinates are shown in the appendix.

The force field for the calculations on $SiCl_3X.NMe_3$ was assumed to be roughly the same as the previously published $SiCl_4.NMe_3$. The equatorial stretching force constants were set equal to the parent SiX_4 stretching constants while the axial stretching constants were given half this value. The f_β in the C_{3v} configuration was the average of the $SiCl_4$ and SiX_4 angle bending force constants and varied for each X. The f_α was given the same value as the parent SiX_4 molecule, in this case, $SiCl_4$. The f_γ was set at 3/4 of the f_α. The stretching

force constant for the Si–N bond was arbitrarily set at 1.20 mdyn/Å. The actual numbers used in the C_{3v} calculations are shown in Table 7. Only the stretching force constants changed in going to C_s symmetry, and the changes are shown in Table 8. Interaction constants not listed, as well as torsional force constants, were set equal to zero.

Experimental

Trichlorosilane (from Matheson Co.) was purified by trap-to-trap distillation and outgassed at −78 °C prior to use. Trichlorofluorosilane, trichlorobromosilane, and trichloroiodosilane were prepared by standard literature procedures (14–16) and purified by trap to trap distillation prior to use. The infrared and Raman spectra of the starting materials were found to be identical to those in the literature (17–18). Trimethylamine was dried and purified as described previously (19).

Dissociation pressure measurements have been reported for the systems $SiCl_3H/NMe_3$ and $SiCl_3F/NMe_3$ and clearly establish that only 1:1 complexes are capable of formation at low temperatures (1, 2). The $SiCl_3I.NMe_3$ adduct prepared for the first time in this study proved to be the most stable of the series and could be analyzed directly from a vacuum ampoule by hydrolysis followed by conventional argentrometric and pH titration techniques.

Anal. Calcd. for $SiCl_3I.NMe_3$: Cl, 33.2; I, 39.6; Me_3N: Si = 1. Found: Cl, 33; I, 38.7; Me_3N: Si = 1.10.

Vibrational spectra were recorded for thin films of the compounds formed by the slow deposition of a gaseous mixture of the appropriate halide with a slight excess of trimethylamine (approximately 1:1) onto the cold tip (−196 °C) of a low temperature infrared or Raman cell.

The infrared spectra were recorded on a Beckman IR 11 and Perkin–Elmer 180 and 221 spectrometers. Raman spectra were recorded on a Spex 1401 spectrometer using krypton and argon ion laser excitation.

We wish to thank the National Research Council of Canada for financial support and for an NRCC scholarship (D.B.).

Five Co-ordinate Complexes of Platinum(II) and Palladium(II)

K. R. Dixon and A. D. Rattray

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received August 10, 1972

Reactions of 1,10-phenanthroline with halogen bridged dinuclear species, $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$ and $[M_2X_2(PR_3)_4][BF_4]_2$, give the new five co-ordinate complexes, $[MX(PPh_2O)(PPh_2OH)(Phen)]$ and $[MX(PR_3)_2(Phen)][BF_4]$, where M = Pd or Pt, X = Cl or Br, Ph = phenyl, and R = ethyl (or phenyl when M = Pd). Decomposition of the $[MX(PR_3)_2(Phen)][BF_4]$ complexes in hot solvents gives the four co-ordinate species, $[MX(PR_3)(Phen)][BF_4]$. The complexes are characterized by elemental analyses, molecular weight, and conductance measurements and infrared and nuclear magnetic resonance spectroscopy. The spectroscopic data show that $[PtCl(PEt_3)_2(Phen)][BF_4]$ has a trigonal bipyramidal structure with the phenanthroline and one triethylphosphine in the equatorial plane and a chlorine and a triethylphosphine in the axial positions.

Les réactions de la phénantroline-1,10 avec des espèces halogénées pontées et binucléaires, $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$ et $[M_2X_2(PR_3)_4][BF_4]_2$ produisent de nouveaux complexes pentacoordinés, $[MX(PPh_2O)(PPh_2OH)(Phen)]$ et $[MX(PR_3)_2(Phen)][BF_4]$ où M = Pd ou Pt, X = Cl ou Br, Ph = phényle et R = éthyle (ou phényle si M = Pd). La décomposition des complexes du type $[MX(PR_3)_2(Phen)][BF_4]$ dans des solvants chauds produit des espèces tétracoordinées $[MX(PR_3)(Phen)][BF_4]$. Les complexes ont été identifiés et caractérisés à l'aide d'analyses élémentaires, de mesures de poids moléculaire, et de conductance, de la spectroscopie infrarouge ainsi que de la résonnance magnétique nucléaire. Les données spectroscopiques montrent que le complexe $[PtCl(PEt_3)_2(Phen)][BF_4]$ possède une structure du type bupyramidale trigonale avec la phénanthroline et un groupe triéthylphosphine dans le plan équatorial et un chlore ainsi qu'un triéthylphosphine en positions axiales.

Can. J. Chem., **51**, 618 (1973)

Introduction

The existence of five co-ordinate complexes of platinum(II) and palladium(II) is well established (1 and references therein). However, although some complexes of a flexible polydentate ligand (2) and some with two bidentate ligands (3–5) are known, most of the reported examples involve rather rigid polydentate ligands which may impose special constraints on the geometry of the complex. Five co-ordinate complexes of these metals involving mainly monodentate ligands are relatively rare, the principal examples being $[Pt(SnCl_3)_5]^{3-}$ (6) and $[PdBr_2(2\text{-phenyl-2-phosphaindane})_3]$ and its platinum analog (7). The present paper describes the synthesis and characterization of five co-ordinate complexes having three monodentate ligands and one bidentate ligand. One of these is of particular interest in that the nuclear magnetic resonance spectra of the ligands permit an assignment of the complex geometry.

Results and Discussion

All of the five co-ordinate complexes listed in Table 1 are prepared by cleavage reactions of halogen bridged complexes

$$[M_2X_2(PPh_2O)_2(PPh_2OH)_2] + 2\ Phen \rightarrow 2[MX(PPh_2O)(PPh_2OH)(Phen)]$$

or

$$[M_2X_2(PR_3)_4][BF_4]_2 + 2\ Phen \rightarrow 2[MX(PR_3)_2(Phen)][BF_4]$$

where M = Pd or Pt, X = Cl or Br, Phen = 1,10-phenanthroline, Ph = phenyl, and R = ethyl or phenyl. The reactions proceed rapidly in acetone solution at 25° and the products are generally stable to normal laboratory operations. However, it was noticed that in solution, particularly at elevated temperatures, the five co-ordinate $[MX(PR_3)_2(Phen)][BF_4]$ complexes tend to decompose to four co-ordinate $[MX(PR_3)(Phen)][BF_4]$ complexes. Presumably the reaction proceeds by dissociation followed by atmospheric oxidation of the tertiary phosphine and, in refluxing methanol, reaction is rapid enough to serve as a convenient preparation of the four co-ordinate species. The solid $[MX(PR_3)_2(Phen)][BF_4]$ complexes are air stable except that during melting point determinations, $[PdCl(PPh_3)_2(Phen)][BF_4]$ apparently decomposes at about 145° to form $[PdCl(PPh_3)(Phen)][BF_4]$ which finally melts close to the melting point of pure samples of the latter complex.

The phosphinato complexes, $[MX(PPh_2O)(PPh_2OH)(Phen)]$, are characterized by elemental analyses, molecular weight, and conductance measurements and by infrared spectroscopy. The infrared spectra are similar to those reported previously (8) for the corresponding $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$ complexes and in addition show the absorptions expected for co-ordinated phenanthroline (9). Absorptions due to ν(P—O) at 995 cm^{-1} accompanied by general broadening of the spectrum in the 1200–1600 and 700–800 cm^{-1} regions show the presence of the symmetrical hydrogen bonded system, M(P=O···H···O—P) (8), and we also find that a strong band at about 330 cm^{-1} is characteristic of this system.[1] Whether this group should be regarded as a bidentate ligand or as two monodentate ligands is a moot point. These complexes are similar to the phosphinato complexes reported previously (8) in that the ν(M—Cl) frequencies give very weak absorptions and are difficult to assign. However, clear differences in the spectra of the chloro and bromo complexes show that the halogen is co-ordinated in the solid state. In solution in dibromomethane, molecular weight measurements show no dissociation and in nitromethane solution the molar conductance values (11–34 ohm^{-1} cm^2) indicate only slight dissociation when compared with values of 75–95 ohm^{-1} cm^2 expected for 1 :1 electrolytes (10).

The $[MX(PEt_3)_{1\text{ or }2}(Phen)][BF_4]$ complexes are characterized by elemental analyses, conductance measurements and by infrared and nuclear magnetic resonance spectroscopy. We have not found molecular weight determinations useful for ionic compounds because of ion pairing effects. For both the four and five co-ordinate complexes the molar conductances in nitromethane are typical of 1 :1 electrolytes (10) and demonstrate that the halides are bound to the metal even in this polar solvent.

In the solid state infrared spectra show the expected ligand and anion absorptions but several interesting differences are observed between the five and the four co-ordinate complexes: (*a*) ν(M—Cl) frequencies[2] are higher for

[1] Re-examination of our previous spectra (8) has confirmed the presence of this band in all complexes having this ligand system.

[2] These were assigned by comparison of spectra with those of corresponding bromo complexes. The $[PdBr(PR_3)_{1\text{ or }2}(Phen)][BF_4]$ complexes are not included in Table 1 since attempted preparations yielded mixtures of four and five co-ordinate species, thus preventing complete characterization. However, their infrared spectra were clearly similar to those of corresponding chloro complexes except for the absence of the bands assigned to ν(Pd—Cl).

[a]Solvent: acetone-d_6, reference: tetramethylsilane.
[b]Solvent and reference: dichloromethane.
[c]Other coupling constants: $J_{P-2} = \sim 4$, $J_{P-CH_2} = 10$, $J_{P-CH_3} = 17.5$, $J_{CH_2-CH_3} = 7.5$ Hz.
[d]In these cases it is not possible to be certain which resonance belongs to the 3,4,5-ring and which to the 7,8,9-ring protons.
[e]Resolution was not sufficient to permit accurate determination.

tion of the three weak phenanthroline absorptions *ca.* 1600 cm^{-1} is in the range 1597–1602 cm^{-1} for the five co-ordinate complexes and 1610–1615 cm^{-1} for the four co-ordinate, (*c*) the separation of the two phenanthroline absorptions *ca.* 1500 cm^{-1} is in the range 12–20 cm^{-1} for the five co-ordinate complexes and 21–24 cm^{-1} for the four co-ordinate complexes, (*d*) the five co-ordinate triethylphosphine complexes show two absorptions (at ~440 m and 420 w) in the range 400–450 cm^{-1} whereas the four co-ordinate complexes show only one (at ~435 m).

The mean position of the *ca.* 1600 cm^{-1} absorptions and the separation of the *ca.* 1500 cm^{-1} absorptions have previously been correlated (9) with the radius of the metal ion bound to the phenanthroline[3] and we find values of 1592 and 10 cm^{-1} for the mean and separation, respectively, in 1,10-phenanthroline hydrate. A sample of $[PtCl_2(Phen)]$, prepared as previously described (11), gave corresponding values of 1611 and 20 cm^{-1}. Consequently items *a*, *b*, and *c* above are all consistent with a slightly larger radius for the five co-ordinate metals with slightly weaker metal–ligand bonding than in the four co-ordinate complexes. Although the infrared spectra of the phosphinato complexes are complicated in the 1600 cm^{-1} region by phenyl absorptions, they appear to follow the same pattern with means of 1599–1601 cm^{-1} and separations of 14–16 cm^{-1}.

Absorptions in the 400–450 cm^{-1} region of the spectra of triethylphosphine complexes were previously thought to be due to ν(M—P) vibrations. Although this has been recently shown to be incorrect (12), the available evidence (13) for planar four co-ordinate complexes still suggests that the presence of two absorption bands in this region is characteristic of two triethylphosphines in a mutually *cis* configuration whereas one band suggests a single phosphine or two phosphines in a mutually *trans* configuration. Assuming that similar considerations apply to our five co-ordinate complexes, item *d* above indicates that they have *cis* triethylphosphine ligands.

Data describing the proton nuclear magnetic resonance spectra of the triethylphosphine complexes are given in Table 2. The spectra confirm the ratios of ethyl:phenanthroline protons and for the $[MX(PEt_3)(Phen)][BF_4]$ complexes the methylene and methyl proton resonances show the expected doublet of quartets and doublet of triplets, respectively. At 60 MHz the methyl proton resonances of the $[MX(PEt_3)_2(Phen)][BF_4]$ complexes appear similar to the quintets normally observed (14) for two triethylphosphine ligands in a *trans* configuration. However, more detailed examination of the spectrum of $[PtCl(PEt_3)_2(Phen)][BF_4]$ shows this to be due to overlap of resonances from two chemically different triethylphosphines and at 220 MHz

[3]A correlation with the separation of absorptions *ca.* 850 and 725 cm^{-1} was also proposed but in our complexes the 725 cm^{-1} band is obscured by triethylphosphine absorption.

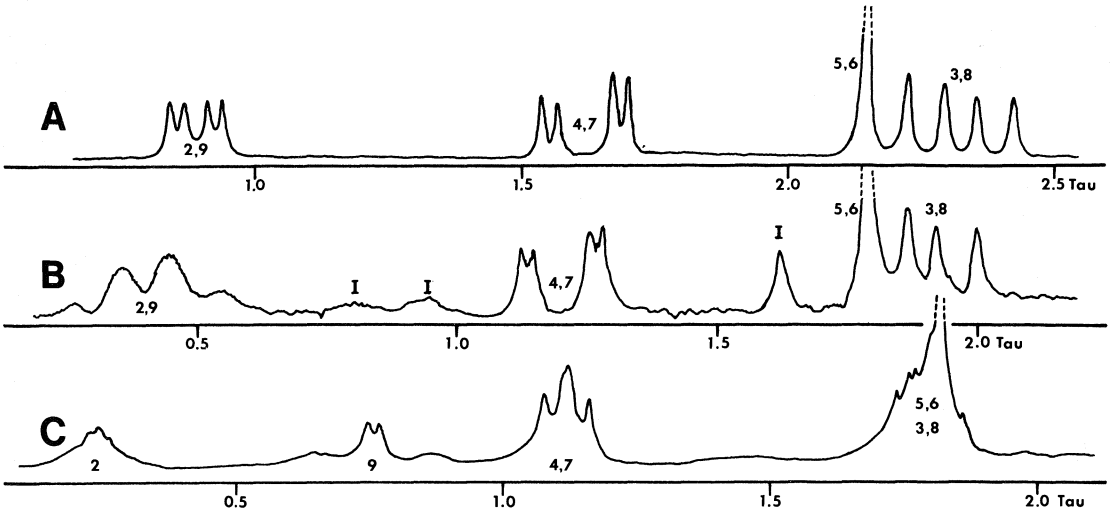

FIG. 1. Nuclear magnetic resonance spectra of phenanthroline ligands: *A*, 1,10-phenanthroline hydrate in acetone-d_6 at 60 MHz; *B*, $[PtCl(PEt_3)_2(Phen)][BF_4]$ in acetone-d_6 at 60 MHz; *C*, $[PtCl(PEt_3)(Phen)][BF_4]$ in dichloromethane at 220 MHz. Note: The 0.39 τ resonance in *B* was better resolved and more symmetrical at 220 MHz. Line width problems at 220 MHz and signal/noise problems at 60 MHz prevented the resolution of the expected 1.5 Hz couplings in *C*. *I* = Resonances due to compound *C*, present as impurity in compound *B*. Numbers adjacent to resonances refer to proton positions in the phenanthroline ring.

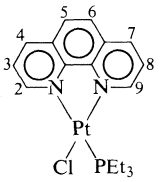
both methylene and methyl proton resonances show two separate multiplets. Resolution within the multiplets is poor and does not permit determination of coupling constants but the spectra are generally similar to those expected for ethyl groups coupled to one phosphorus atom, *i.e.* virtual coupling (14) between the two phosphorus atoms does not occur.

The nuclear magnetic resonance spectrum of the phenanthroline ligand in $[PtCl(PEt_3)_2(Phen)][BF_4]$ (see Table 2 and Fig. 1) is very similar to that of 1,10-phenanthroline hydrate except that (*a*) the 2/9 proton resonance in the complex has sidebands assigned to coupling with ^{195}Pt (33% abundant), (*b*) the 5/6 and 3/8 proton resonances overlap in the complex, and (*c*) the resonances shift to low field on co-ordination, in contrast to the high field shifts observed previously in octahedral complexes (15). The spectral data are generally very similar to those reported previously for phenanthroline and its complexes (15–17) and it is important to note that the simplicity of the $[PtCl(PEt_3)_2(Phen)][BF_4]$ spectrum indicates a very symmetrical environment for the co-ordinated phenanthroline. The phenanthroline spectrum in $[PtCl(PEt_3)(Phen)][BF_4]$ is more complex since the two nitrogen containing rings are *trans* to different groups:



Such an asymmetry is expected to make the 2, 3, 4, and 5 positions chemically different from the 6, 7, 8, and 9 positions and in our case the 220 MHz spectrum shows chemical shift differences between 2 and 9, 3 and 8, and 4 and 7, but not between 5 and 6. The asymmetry is thus smaller than that observed previously in octahedral complexes (16, 17) but in those cases ring current effects due to proximity of another phenanthroline may be involved. Although the expected 1.5 Hz couplings are not resolved, the 9 proton resonance is easily assigned to the doublet (with ^{195}Pt sidebands) at 0.76 τ. The resonance at 0.23 τ is more complex and is therefore assigned to the proton (position 2) *trans* to phosphorus. Coupling to ^{31}P combined with broad ^{195}Pt side-bands explains the complexity of the resonance and it is interesting that the coupling constants, $J_{Pt-9} > J_{Pt-2}$, are in the order expected (18) for weakening of the metal–ligand bond *trans* to phosphorus. Moreover,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

both J_{Pt-9} and J_{Pt-2} are larger than in $[PtCl(PEt_3)_2(Phen)][BF_4]$, which again indicates weaker metal–ligand bonding in the five co-ordinate complex. The assignment of the distorted triplet at ~1.1 τ as due to chemically shifted overlapping doublets (4 and 7 protons) is confirmed by the change in peak contour at 60 MHz. The 3,8 and 5,6 proton resonances are not resolved but their assignment is confirmed, together with all the other assignments, by computer simulation of the spectrum.

Nuclear magnetic resonance spectra of the other $[MX(PEt_3)_{1\text{ or }2}(Phen)][BF_4]$ complexes were recorded at 60 MHz and are generally similar to those described above except that for M = Pd resolution of the phenanthroline resonances is poor.

The nuclear magnetic resonance spectrum of $[PtCl(PEt_3)_2(Phen)][BF_4]$ was recorded in acetone-d_6. It is unlikely that the chloride would be co-ordinated in nitromethane (the solvent for our conductance measurements) and dissociated in acetone but as a check we recorded the molar conductance of the complex in acetone as 150 ohm^{-1} cm^2. Expected values for 1:1 electrolytes in acetone are not well established (10) but 150 ohm^{-1} cm^2 seems reasonable and is consistent with values obtained for other platinum complexes (19). Consequently, conductance shows the chloride to be co-ordinated, nuclear magnetic resonance shows two chemically shifted triethylphosphine resonances and a symmetrical phenanthroline and infrared shows that the chloride is co-ordinated and suggests a *cis* configuration for the triethylphosphine ligands. The only five co-ordinate structure which is consistent with these observations is a trigonal bipyramid with the phenanthroline and one triethylphosphine in the equatorial positions and a chlorine and a triethylphosphine in the axial positions. The data also exclude six co-ordinate solution species in which an acetone molecule occupies a co-ordination site. Presumably the other $[MX(PR_3)_2(Phen)][BF_4]$ complexes have similar structures and the same configuration is also possible for the $[MX(PPh_2O)(PPh_2OH)(Phen)]$ complexes. It is interesting that the bridge cleavage reaction has occurred essentially with "retention of configuration" just as observed previously (20) for cleavage by pyridine.

One aspect of these five co-ordinate complexes remains puzzling. The compounds are all pale yellow in color and their u.v./visible spectra in solution and in the solid state do not show the low energy bands previously considered characteristic of five co-ordination in platinum(II) and palladium(II) complexes (21, 22). It is possible that the high ligand field effects of phenanthroline and phosphine ligands (23) combine to move the low energy d–d bands under the charge transfer absorptions. In our complexes d–d bands at 28 000 cm^{-1} or higher energies would probably not be resolved and the previous report (21) of spectra of $[PtX\{(o\text{-}Ph_2As\cdot C_6H_4)_3\text{-}As\}][ClO_4]$ complexes gives band maxima from 21 900 cm^{-1} (X = I) to 29 200 cm^{-1} (X = CN) in dichloromethane solution. Consequently, although the required high field shifts are large, we believe this to be the most likely explanation especially since the other evidence so clearly favors five co-ordinate structures for our complexes.

Experimental

Data relating to the characterization of the complexes are given in Table 1. Microanalyses were by Schwartzkopf Microanalytical Laboratory, New York or by Chemalytics Inc., Tempe, Arizona. Molecular weights were determined in dibromomethane solution at 50° using a Hitachi–Perkin Elmer Model 115 Vapor Phase Osmometer. Conductance measurements were made on ~10^{-3} *M* solutions in nitromethane using a pipette-type cell connected to a Radiometer, Model CDM3 Conductivity Bridge. Infrared spectra were recorded from 4000–250 cm^{-1} with accuracy ±3 cm^{-1} on a Beckman IR 20 Spectrophotometer calibrated against polystyrene film and water vapor. Solid samples were examined as Nujol mulls between caesium iodide plates. Nuclear magnetic resonance spectra were recorded at 60 MHz on Perkin–Elmer R12A or Varian HA60 spectrometers and at 220 MHz by the Canadian 220 MHz NMR Centre, Sheridan Park, Ontario, using tetramethylsilane or dichloromethane as internal references. Computer simulation of spectra was achieved using the UEAITR programme (24). Ultraviolet/visible spectra were recorded on a Unicam SP700 spectrophotometer with diffuse reflectance attachment.

Analar 1,10-phenanthroline hydrate was obtained from British Drug Houses Ltd. and was used as received. The complexes, $[M_2X_2(PR_3)_4][BF_4]_2$ where X = Cl or Br and R = ethyl for M = Pt, and where X = Cl or Br and R = ethyl or phenyl for M = Pd, and $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$ where M = Pd or Pt and X = Cl or Br, were prepared as previously described (8, 20, 25). Cleavage reactions of these halogen bridged complexes by 1,10-phenanthroline were carried out in acetone solution under a nitrogen atmosphere and the preparation of $[PtCl(PEt_3)_2(Phen)][BF_4]$ is described below as an example. A representative preparation of a four co-ordinate complex, $[PtCl(PEt_3)(Phen)][BF_4]$, is also

described. Other preparations were similar and gave similar yields except for the variations noted below.

[$PtCl(PEt_3)_2(Phen)$][BF_4] and other Five Co-ordinate Complexes

[$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ (0.492 g, 0.444 mmol) in acetone (10 ml) was added dropwise to a stirred solution of 1,10-phenanthroline hydrate (0.176 g, 0.89 mmol) in acetone (10 ml) under a nitrogen atmosphere at 25°. The order of addition of reagents was chosen to minimize the reaction of the product with [$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ to produce [$PtCl(PEt_3)_3$][BF_4] and [$PtCl(PEt_3)$(Phen)]-[BF_4]. After stirring for 10 min, diethyl ether (100 ml) was added to yield [$PtCl(PEt_3)_2$(Phen)][BF_4] (0.552 g, 0.752 mmol) as a yellow oil which crystallized to a yellow powder. Samples for analysis were obtained by using insufficient diethyl ether to cause immediate precipitation and then cooling the reaction mixture to −15° to initiate crystallization.

The other cleavage reactions were similar except that the low solubility of the [$M_2X_2(PPh_2O)_2(PPh_2OH)_2$] complexes in acetone necessitated dropwise addition of phenanthroline solution to a stirred suspension of the appropriate starting complex. The resulting [$MX(PPh_2O)$-(PPh_2OH)(Phen)] complexes were recrystallized from dichloromethane by dropwise addition of diethyl ether.

[$PtCl(PEt_3)$(Phen)][BF_4] and other Four Co-ordinate Complexes

[$PtCl(PEt_3)_2$(Phen)][BF_4] (0.250 g, 0.341 mmol) was heated under reflux in methanol (2 ml) for 60 min in air. Ethyl acetate (5 ml) was added, followed by diethyl ether (20 ml) to yield [$PtCl(PEt_3)$(Phen)][BF_4] (0.085 g, 0.138 mmol) as a yellow precipitate which was recrystallized from methanol by dropwise addition of ethyl acetate followed by diethyl ether. The mother liquors contained mainly unreacted starting complex and higher yields could be obtained by recovering this material and re-peating the methanol reflux.

The [$PdX(PR_3)_2$(Phen)][BF_4] complexes decomposed rather more readily and brief reflux in dichloromethane was usually sufficient to yield the four co-ordinate complexes.

We thank the National Research Council of Canada and the University of Victoria for research grants and the University of Victoria for a postgraduate scholarship (to A.D.R.).

Low Energy Electron Impact Ionization and Fragmentation: Cyclobutanone

GRAHAM RICHARD BRANTON AND CLAUDIO KONG NAM PUA

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received September 6, 1972

Cyclobutanone is shown to yield both $C_3H_6^+$ and $C_2H_2O^+$ ions on fragmentation under electron impact in a mass spectrometer. Using the energy distribution difference (EDD) technique the ionization energy of cyclobutanone is found to be 9.58 eV and the appearance potentials of the $C_3H_6^+$ and $C_2H_2O^+$ ions are found to be 9.85 and 10.53 eV, respectively.

Dans un spectromètre de masse, on montre que la cyclobutanone lorsque soumis à un bombardement d'électrons, libère comme fragment à la fois des ions $C_3H_6^+$ et $C_2H_2O^+$. En utilisant la technique impliquant la différence de distribution énergétique (DDE), l'énergie d'ionisation de la cyclobutanone est donnée comme étant 9.58 eV et les potentiels d'apparition des ions $C_3H_6^+$ et $C_2H_2O^+$ comme étant respectivement 9.85 et 10.53 eV. [Traduit par le journal]

Can. J. Chem., **51**, 624 (1973)

Introduction

Cyclobutanone has previously been reported (1) as showing only one major fragmentation pathway, [*a*], upon ionization by electron impact. However, the methyl substituted cyclobutanones have shown (2) fragmentation according to both of the possible fragmentation pathways [*a*] and [*b*].

[*a*] $\rightarrow CH_2CO + C_2H_4$

[*b*] $\rightarrow CO + C_3H_6$

Both of these processes have been observed for the neutral species in its thermal (3) and photolytic (4) decomposition. There has been considerable recent interest in the photolytic decomposition of cyclobutanone, and the present investigation was undertaken to test the apparent lack of similarity between the decomposition pathways of the neutral and ionic species for the unsubstituted cyclobutanone (2).

Experimental

The cyclobutanone used in the study was obtained from Aldrich Chemical Company, Inc., (C-9600-1, Lot. No. 030607, Aldrich analyzed by i.r. and g.c.) and was used without further purification, after analysis by gas chromatography and mass spectrometry showed the sample to be better than 99.9% pure.

The xenon used as a calibration gas for the electron energy scale was research grade obtained from Airco Industrial Gases, Division of Air Reduction Co. Inc.

The argon used to check the experimental set up was research grade obtained from Union Carbide.

The mass spectra were determined on an Hitachi/Perkin–Elmer model RMU-7 mass spectrometer, modified as outlined below in order to allow ionization and appearance potentials to be determined. The electron energy was controlled via a 10 turn potentiometer which could be driven by a stepping motor (manufactured by the A. W. Haydon Company) directly connected to the potentiometer. The signal from the collector was fed to a Cary 401 vibrating reed electrometer from which it was stored in a Northern Scientific NS 560 signal averaging computer prior to plotting on an X–Y recorder or to conversion to paper tape for processing on an IBM 360/50 computer.

The ionization potential and appearance potentials were determined by observing the onset for the ion production after treating the data by the energy distribution difference (EDD) technique (5), using xenon as a calibrant for the energy scale. In all runs the xenon and cyclobutanone were present in the ionization chamber at the same time.

The EDD technique is based upon the application of the formula

$$\Delta I(V) = I(V) - B \times I(V + \Delta V)$$

where $I(V)$ = ion current at electron energy V, B = a constant, ΔV = voltage increment usually about 0.1 eV, and $\Delta I(V)$ represents the ion current which would result from an electron beam with a reduced thermal energy spread.

The data were first smoothed using a 15-point 5th degree smoothing routine (6) and the best value of B was found by adjusting the slope of the curve of $\Delta I(V)$ *vs.* electron energy to be zero just prior to the onset for the production of ions. In this way it was possible to reduce the effective thermal energy spread on the electron energy and thus observe the onset of ionization much more precisely.

Results

The low resolution mass spectrum was determined at an electron energy of 70 eV and found to be consistent with that reported previously (1).

Examination of the peak at $m/e = 42$ under higher resolution showed this to be a doublet indicating that fragmentation by both pathways [*a*] and [*b*] was occurring. The accurate masses of the peaks of the doublet were found to be 42.047 and 42.010, corresponding to $C_3H_6^+$ and $C_2H_2O^+$, respectively (the calculated masses being 42.0470 and 42.0106, respectively), the peak corresponding to $C_2H_2O^+$ being about thirteen times as intense as that corresponding to $C_3H_6^+$.

The relative intensities of the two peaks were examined at various electron energies and it was observed that just above the threshold for ion production the peak due to $C_3H_6^+$ was more intense than that due to $C_2H_2O^+$, but that as the electron energy was increased the latter rapidly grew in relative intensity to become the predominant fragment ion. The ions were of approximately equal intensity at an electron energy of 2–3 eV above the threshold of ion production. At higher electron energies peaks corresponding to CO^+ and $C_2H_4^+$ were also observed, as were peaks corresponding to further fragmentation of the $C_2H_2O^+$ and $C_3H_6^+$ ions. At all electron energies the peaks at $m/e = 42$ were much larger than any other fragment ion peaks.

The ionization potential of cyclobutanone, and the appearance potentials of the two ions at $m/e = 42$, were determined by examining the onset of the ionization efficiency curves of the ions after treatment of the data by the EDD (5) technique. The applicability of this technique to the equipment used was demonstrated (7) by a study of the ionization efficiency curves of xenon and argon, when the difference in the onset of ionization was found to be 3.6 eV (literature value 3.62 eV (5)). Breaks were also observed in the ionization efficiency curves of xenon and argon and these are compared with literature values in Table 1.

For the cyclobutanone, the ion at $m/e = 70$ and the two ions at $m/e = 42$ were studied using the EDD technique. Under the operating conditions the two peaks at $m/e = 42$ overlapped but were sufficiently well resolved that the ion current due to each could be recorded with minimal contribution from the other (less than 5%). Using xenon as a calibrant for the energy scale the ionization and appearance potentials found are shown in Table 2.

The value for $C_4H_6O^+$ was the average of seven runs and the others the average of five runs. The errors on the $m/e = 42$ peaks are slightly larger than for the parent ion due to the difficulty in completely resolving the peaks.

TABLE 2. Ionization and appearance potentials

Ion	*m/e*	I.P./A.P. (eV)
$C_4H_6O^+$	70	9.58±0.1
$C_3H_6^+$	42	9.85±0.15
$C_2H_2O^+$	42	10.53±0.15

Breaks were observed in the ionization efficiency curves for all of the ions in the first few volts above the onset of ionization. The reproducibility of these breaks was poor due to noise on the ionization efficiency curves, and they will not be discussed here.

Discussion

The investigation of the ionization efficiency curves of xenon and argon demonstrated that the EDD technique as applied in this study is reliable for the study of ionization efficiency curves and the measurement of the energy of the onset of ion production.

The ionization potential of cyclobutanone has been found to be 9.61 eV by the technique of photoelectron spectroscopy (8) and has been estimated to be 9.35 eV from optical spectroscopy (9). The photoelectron spectroscopy value and the value of 9.58 eV obtained in the present electron impact study correspond to the vertical

ionization potential, and the agreement between these values is remarkably good. The adiabatic ionization potential should be slightly lower than either of these values and the optical value of 9.35 eV is reasonable.

The detection of two ions at $m/e = 42$ and their identification as $C_3H_6^+$ and $C_2H_2O^+$ by accurate mass measurement clearly shows that the cyclobutanone undergoes fragmentation by the two pathways [*a*] and [*b*]. Whilst these results are in contrast to the results of Hofman (1) who observed no $C_3H_6^+$ ion, they are consistent with the mass spectral fragmentation observed for the methyl substituted cyclobutanones (2) and with the thermal and photolytic decomposition processes of neutral cyclobutanone (3, 4).

At high ionization energies the peak due to the $C_2H_2O^+$ ion was much more intense than that due to $C_3H_6^+$ and at 70 eV their relative intensities were approximately 13:1. The appearance potentials for the two ions were found to be 10.53 eV for $C_2H_2O^+$ and 9.85 eV for $C_3H_6^+$ showing that fragmentation via pathway [*b*] was occurring at lower energies than for pathway [*a*], and at ionizing energies just above the threshold of ion production the peak due to $C_3H_6^+$ ion was of greater intensity than that due to the $C_2H_2O^+$ ion. The latter peak increases much more rapidly than that due to the $C_3H_6^+$ ion and at only about 2 eV above the onset for the production of the $C_2H_2O^+$ ion it was found to be of greater intensity than the $C_3H_6^+$ ion. At higher energies further fragmentation of these ions was observed, but at the low energies these were the only fragment ions detectable.

If it is assumed that the $C_2H_2O^+$ ion is the ketene ion then the appearance potential for the production of this ion may be estimated from thermochemical data (10–12) to be 10.4 eV. The experimental data thus suggest that the $C_2H_2O^+$ ion observed is the ketene ion. Similarly the appearance potential of the $C_3H_6^+$ ion may be estimated to be either 10.4 eV, for a cyclopropane ion, or 9.7 eV for a propylene ion. The experimental data thus suggest that the observed $C_3H_6^+$ ion is the propylene ion. In each case the experimentally determined appearance potential is higher than the thermochemical estimate by about 0.15 eV; this is most likely caused by a "kinetic shift" (13).

Although such comparisons must be treated with care, it is interesting to compare the fragmentation of the ionic species with the decomposition processes observed for the neutral cyclobutanone. Thermal studies (3) have shown that although the neutral species decomposes via both processes [*a*] and [*b*], process [*a*] predominates. This correlates well with the mass spectral fragmentation at high electron energies. The photochemical processes involving neutral cyclobutanone have been recently studied in detail (4). Photochemical decomposition again occurs via both routes [*a*] and [*b*]. The relative contribution of each process depends on the energy of the exciting radiation, near to the absorption threshold, process [*b*] predominating at the lowest energies and process [*a*] predominating at energies a little higher than the absorption threshold.

The electron impact induced fragmentation of the ionic cyclobutanone is thus similar to the decomposition of the neutral species. The observation in the present study of a fragmentation process corresponding to pathway [*b*] has thus brought cyclobutanone into line with the methyl substituted cyclobutanones (2), which also show fragmentation, both of the ionic and neutral species, according to processes [*a*] and [*b*].

Grateful acknowledgment is made to the National Research Council of Canada for financial support.

Analysis of the Visual Spectrum of Methyl Orange in Solvents and in Hydrophobic Binding Sites

RICHARD L. REEVES AND ROBERT S. KAISER
Research Laboratories, Eastman Kodak Company, Rochester, New York 14650

AND

MARY S. MAGGIO, EDWARD A. SYLVESTRE, AND WILLIAM H. LAWTON
Management Systems Development Department, Eastman Kodak Company, Rochester, New York 14650

Received June 19, 1972

The absorption curves of methyl orange (MO) and analogous *p*-aminophenylazobenzenes in organic and aqueous organic solvents are shown to consist of two severely overlapping bands. The curves have been resolved into two skewed component bands using a regression method. The blue shift of the absorption maximum obtained when organic solvents are added to aqueous solutions of MO, or when MO is bound to bovine serum albumin or a surfactant micelle, is the result of a change in relative intensities of the component bands. The low-frequency component is assigned to a $\pi_1 \rightarrow \pi_1^*$ transition of a solvate in which there is specific hydrogen-bonding interaction between solvent and the azo nitrogens, and the high-frequency component to a $\pi_1 \rightarrow \pi_1^*$ transition of a solvate in which the interaction is absent. The low-frequency component is favored by aqueous solvent compositions and by low temperatures. The free energies of interconversion of the species in various hydrogen-bonding solvents are correlated by the solvent surface tension but not by the dielectric constant. The results show that the shift in absorption maximum accompanying binding to a protein or micelle should be interpreted as a shift in an equilibrium rather than as a shift in transition energy.

Les courbes d'absorption du méthylorange (MO) et des *p*-aminophénylazobenzènes analogues, en solvants organiques et organiques aqueux, comprennent deux bandes fortement enchevêtrées. La résolution de ces courbes en deux bandes gauches élémentaires a été faite par la méthode de régression. Le déplacement vers le bleu du maximum d'absorption, obtenu par addition de solvants organiques aux solutions aqueuses de MO ou lorsque le MO est lié à l'albumine du sérum bovin ou à une micelle surfactive, est le résultat du changement des intensités relatives des bandes composantes. La bande à basse fréquence est attribué à la transition $\pi_1 \rightarrow \pi_1^*$, d'un produit de solvatation dans lequel il y a interaction spécifique par liaison hydrogène entre le solvant et les azotes de l'azo; la bande à haute fréquence correspond à la transition $\pi_1 \rightarrow \pi_1^*$ du produit de solvatation sans interaction. La bande à basse fréquence est favorisée par la composition en eau des solvants et aux basses températures. Les énergies libres de l'interconversion des diverses espèces dans différents solvants à liaison hydrogène, ont été reliées à la tension superficielle du solvant et non à la constante diélectrique. Les résultats montrent que le déplacement du maximum d'absorption consécutif à une liaison à une protéine ou micelle devraient être interprétés plutôt comme un déplacement d'équilibre qu'un déplacement de l'énergie de transition. [Traduit par le journal]

Can. J. Chem., **51**, 628 (1973)

Methyl orange (MO, **1**) has been used as a probe for studying the interaction of organic anions with proteins (1–9), synthetic polymers (10, 11), polyelectrolytes (12), and surfactants (12–14) in aqueous solution. The interaction is usually accompanied by spectral changes that are not associated with the acid–base indicator properties of the dye. Binding to bovine serum albumin (BSA) (2, 3), to human serum albumin (HSA) at slightly acid p*H* values (3), and to surfactant micelles (13, 14) gives a shift of the absorption maximum to higher frequencies that can be duplicated by adding ethanol to aqueous solutions of MO (6, 15, 16). Binding to HSA in mildly alkaline solutions is anomalous in that the absorption curve is shifted to lower frequencies and increases in intensity (3, 7). A number of explanations have been offered for the blue shift of the absorption maximum. Forbes and Milligan (6) showed that an earlier proposal involving electrostatic interactions between protonated amino groups of the protein with the sulfonate group of MO (2) was incorrect. The importance of the *p*-dimethylamino group in giving the spectral changes was recognized (3, 6, 15) and hydrogen-bonded interactions between solvent and the amino group, azo nitrogens, and sulfonate group have

For personal use only.

been proposed (6, 15). Forbes and Milligan predicted correctly that hydrogen-bonding to the azo nitrogens should give a red shift (17–19), and out-of-plane twisting should give a blue shift, but were incorrect in their suggestion that hydrogen-bonding to the amino group should also give a red shift (19). Brode and co-workers alone have recognized that the absorption curve of MO could consist of two overlapping bands and interpreted the low-frequency component as arising from a solvate containing a hydrogen bond between water and the azo group (15).

The demonstration that the spectral changes associated with the binding of dyes to proteins can be used quantitatively as a tool for studying the binding (2) increases the importance of understanding the factors responsible for the changes. The high correlation between spectral changes in mixed aqueous solvents and in hydrophobic binding sites suggests that the dyes experience similar changes in environment in both cases. This correlation has led some investigators to interpret the "polarity" of protein binding sites in terms of empirical solvent polarity parameters (9, 14, 20). Our recent findings that some hydrophobic dyes undergo specific solvation changes in mixed aqueous solvents that are related to changes in solvent structure (21, 22) has led us to make a detailed spectral analysis of MO and similar dyes in pure hydrogen-bonding solvents, in aqueous binaries, in a surfactant micelle, and bound in albumin. Several facts support the idea that the visual spectrum of MO consists of two unresolved bands. The shape of the absorption curve changes in mixed aqueous solvents (Fig. 1) and is not that expected for a distribution function associated with a single band. The curves are too broad and are highly skewed toward high frequencies in an aqueous environment and toward low frequencies in organic compositions. The absorption curves of the related dyes, **5** and **6**, are narrower, more symmetric, and do not give a blue shift on transfer from water to ethanol. We have resolved the absorption curves of MO and a series of *p*-aminophenylazobenzenes (**2**–**4**) into the component bands using a nonlinear least-squares method, which puts no restriction on the nature of the function used in resolution (Gaussian, Lorentzian, etc). Our results give insight into the nature of the interaction of the dyes with hydrogen-bonding solvents and with binding sites.

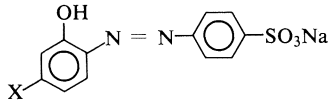
Experimental

Materials

The dyes used in the study are shown in Scheme 1.

1: X = Me_2N, Y = SO_3Na
2: X = Me_2N, Y = COONa
3: X = Me_2N, Y = H
4: X = H_2N, Y = H
5: X = HO, Y = SO_3H
6: X = MeO, Y = SO_3Na



7: X = OH
8: X = Me

SCHEME 1. Dye structures

Methyl orange was certified Eastman reagent grade and was recrystallized from water. Dyes **5** and **7** were Eastman reagent grade and were recrystallized from ethanol–water and water, respectively. Dyes **2**–**4** were Eastman reagent grade and were used without further purification. Dye **6** was a sample prepared previously (19) and **8** was prepared and purified by the standard method (23). Crystalline native bovine serum albumin was purchased from Nutritional Biochemicals. The ethanol, tert-butyl alcohol, and *N*-methylformamide were the solvents used previously (21). The formamide was the center cut from freshly distilled Eastman reagent grade material. Burdick and Jackson "Distilled in Glass" DMF and DMSO were redistilled immediately before use. An unopened bottle of B and J dioxane, distilled in glass and stored under nitrogen, was used without further purification. The preparation of solutions was described previously (21).

Spectral Measurements and Analysis

Absorption curves were obtained on a Beckman DK-2A recording spectrophotometer at dye concentrations of $2.0 \times 10^{-5} - 2.5 \times 10^{-5}$ *M*. No changes in the absorption curves were seen on a 10-fold dilution. The wavelength calibration of the spectrophotometer was checked at the beginning of the study against the 546 nm mercury line and was rechecked periodically during the study with a holmium oxide glass filter. Absorbance accuracy was checked against standard NBS potassium chromate solutions (24). Solutions were thermostated at 25° and the absorption curves were obtained in a thermostated cell block.

Curve Resolutions

We assumed that each of the *n* experimental absorption curves is a linear combination of two identical-shaped component functions. Although the basic shape of the components is the same for all solvent mixtures, the amplitudes, widths, and lateral displacements of *each* component are allowed to vary independently within the mixtures. The *i*th observed curve can be modeled by

$$[1] \quad y_i(x) = f(\boldsymbol{\theta}_i; x) + \text{error} \qquad i = 1, \ldots, n$$

where

$$[2] \quad f(\boldsymbol{\theta}_i; x) = \theta_{1i} g\left(\frac{x - \theta_{2i}}{\theta_{3i}}\right) + \theta_{4i} g\left(\frac{x - \theta_{5i}}{\theta_{6i}}\right)$$

θ_{1i} and θ_{4i} are the ε_{max} for the components, since g is normalized to unit height, θ_{2i} and θ_{5i} are the respective $\bar{\nu}_{max}$, and θ_{3i} and θ_{6i} are proportional to the bandwidths at half-peak height and $g(x)$ is the shape function of the components. Instead of specifying $g(x)$ as Gaussian or Lorentzian, we used regression analysis to determine simultaneously the best $g(x)$ and the best set of parameter vectors, $\boldsymbol{\theta}_i$, *i.e.*, the g and $\boldsymbol{\theta}_i$ which minimize

$$Q = \sum_{i=1}^{n} \sum_{j=1}^{p_i} [y_i(x_{ij}) - f(\boldsymbol{\theta}_i; x_{ij})]^2$$

where x_{ij}, $j = 1, \ldots, p_i$ are the points at which the *i*th curve has been read.

In the analysis we restrict ourselves to the selection of the best function g in the set of empirical functions G which are defined by a set of points (x_k^*, y_k^*), $k = 1, \ldots, m$. The function g is defined for all x by connecting the points (x_k^*, y_k^*) by straight lines within the region $x_1^* \leqslant x \leqslant x_m$ and setting it constant (and equal to the end points) outside this region. Since any function can be approximated arbitrarily well within a finite interval by this method, we have put no restrictions on the shape of g by restricting our attention to finding the best $g \in G$. The empirical approximating function is then given by

$$g(x) \begin{cases} \displaystyle\sum_{k=1}^{m-1} \left[\frac{y_{k+1}^* - y_k^*}{x_{k+1}^* - x_k^*}(x - x_k) + y_k^*\right] \Delta_k(x) & x_1^* < x \leqslant x_m^* \\ y_1^*, \; x \leqslant x_1^* \\ y_m^*, \; x > x_m^* \end{cases}$$

where

$$\Delta_k(x) = \begin{cases} 1 & \text{for } x_k^* < x \leqslant x_{k+1}^* \\ 0 & \text{otherwise} \end{cases}$$

The analysis proceeds by selecting the points $x_1^*, \ldots, x_m^*$ at which the optimal function $g(x)$ is to be determined. Initial estimates of the n parameter vectors $\boldsymbol{\theta}_i$ are made. Each iteration of the procedure uses a linear regression to determine an improved estimate of $g(x)$, *i.e.*, of the y_k^*'s. Then n nonlinear regressions are done to produce improved estimates of the $\boldsymbol{\theta}_i$. The iterations continue until the estimate of $g(x)$ has converged to a specified number of decimal places (in our case, to three). Details of the mathematical analysis are given elsewhere (25).

Absorbance values were read from the curves at 10 nm intervals from 600 nm, where the absorbance is zero, through 360 nm, where the absorbance from the tail of a slightly overlapping u.v. band is negligible. The x_k^* were initially selected by assuming that the $g(x)$ was Gaussian. These values were subsequently modified to yield a smooth representation of $g(x)$. In the early stages we obtained starting values for the parameter vectors, $\boldsymbol{\theta}_i$, by fitting the curves visually with linear combinations of two Gaussian functions on a DuPont curve analyzer. Later, however, initial estimates were obtained by making experienced guesses.

Results and Discussion

The absorption curves of the *p*-aminophenylazobenzenes (**1**–**4**) all showed similar spectral changes in aqueous ethanol mixtures. Representative curves of MO are shown in Fig. 1. Absorption curves of MO were also measured and resolved in mixtures of water with tert-butyl alcohol, dioxane, DMF, DMSO, in 50 vol% ethylene glycol, and in neat formamide, *N*-methylformamide, and ethylene glycol. We found that linear combinations of the same function served to reconstitute the experimental absorption curves of MO in all solvents, for MO in a micelle of hexadecyltrimethylammonium bromide (HTAB), and in the adsorbed state on BSA, and of **2**–**4** in all water–ethanol mixtures.

The second derivative spectra of solutions of MO in water and in 25 mol% ethanol showed minima at about 21 000 and 24 000 cm^{-1}, corresponding to the frequencies of the maxima of the components obtained by the resolution by regression analysis. It has been shown that higher-derivative spectra of multicomponent systems with overlapping bands facilitate the detection and location of the components (26, 27).

Because the band overlap is so severe and the spectral parameters are so highly correlated, the error surface for the resolution is shallow and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

rigorous criteria for convergence had to be applied to the regressions. Usually, iteration was continued until the root-mean-square differences between experimental and reconstituted absorption curves were nearly the experimental error for the spectrophotometry (about 0.016×10^4 extinction units). Using this criterion we found that replicate resolutions of four different solutions of MO in water gave standard errors for integrated intensities ($I = \int \varepsilon d\bar{\nu}$) of 1.03×10^6 cm mol^{-1} (1.65%) and 7×10^5 cm mol^{-1} (0.7%) for the low- and high-frequency components, respectively, and for ν_{max}, standard errors of 26 (0.12%) and 16 cm^{-1} (0.07%), respectively. In water the relative intensities of the low- to the high-frequency component are closest to unity (0.63), where one would expect the greatest difficulty in finding unique parameter values. The resolution should improve as one component becomes more predominant and then deteriorate as the minor component makes a relatively small contribution to the total curve. Figure 2 shows several typical resolutions.

We also attempted the resolution with two Gaussian functions on a frequency scale, but always obtained a much poorer fit than with the empirically determined skewed function. We likewise tried eq. 2 with a single component and found the fit to be inadequate. We have shown previously that an isolated band corresponding to the $\pi \rightarrow \pi^*$ transition for an azomethine dye is best described by a skewed function (22).

Absorption curves of MO in 47.8 mol% ethanol and in 50% (v/v) ethylene glycol – water were also measured at 45°, 0°, −30°, and −60°. The high-frequency component was predominant in the ethanol mixture at 25°, whereas the glycol mixture gave a curve typical of aqueous compositions. The absorption curves for the glycol – water mixture are shown in Fig. 3. In both cases, lowering the temperature increased the low-frequency component relative to the high-frequency component and gave the expected decrease in bandwidths. Both bands were shifted to slightly lower frequencies. If the experimental absorption curve were a single band, lowering the temperature should merely have decreased the width and increased the amplitude. The observed change confirms the presence of two bands, which are affected differentially by changing temperature. Further evidence for the presence of two bands comes from the fact that a clearly discernible shoulder

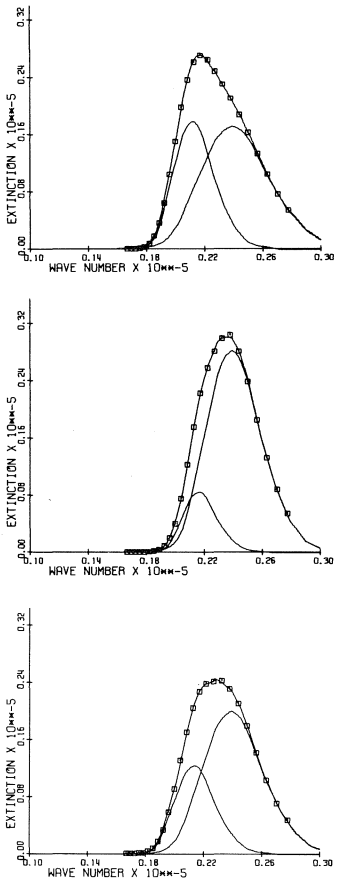

FIG. 2. Resolution of absorption curves of methyl orange. Upper curve, water; center curve, 0.677 mol fraction DMF; and lower curve, 9.0×10^{-5} *M* BSA, p*H* 7.0. The curves drawn through the data points are summations of the component curves.

is seen on the low-frequency side of the curve of **4** in 10% ethanol (15).

The principal long-wavelength absorption band of **5** and **6** and of the unsubstituted and *p*-chloro-substituted analogs are different from those of **1**–**4**, and appear to be single bands. They are nearly symmetric about the maximum on a wavelength plot and are narrower (69 nm at half-peak height for **6** in water compared to 114 nm for MO). Furthermore, transfer of **6** from water to ethanol does not give the blue shift seen with **1**–**4**, but a very small red shift (3 nm). The presence of two overlapping bands is characteristic only of the *p*-amino derivatives (15).

Hückel molecular orbital calculations on **3** show that the only electronic transition expected

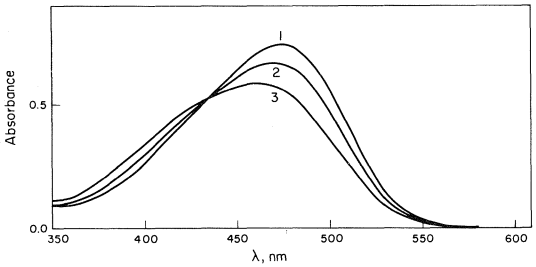

FIG. 3. The effect of temperature on the absorption curve of MO in 50% (v/v) ethylene glycol – water. Curve 1, −60°; curve 2, 0°; curve 3, 45°.

in the visual region is a single $\pi \rightarrow \pi^*$ transition (28). Using the ω-technique, Kroner and Bock calculated a transition energy that agreed with the experimental value obtained in nonpolar solvents. The low-energy band seen in aqueous solvents must be a $\pi \rightarrow \pi^*$ transition of a new absorbing species characteristic of an aqueous environment. The intensity of the low-frequency band is too great for an $n \rightarrow \pi^*$ transition. The possibility of *trans* → *cis* isomerism in the aqueous media has also been ruled out (15).

A unique solvent effect on the *p*-dimethylamino derivatives, arising from compressional forces in the structured solvents which twist this group out of coplanarity with the benzene ring, can also be ruled out. Such twisting results in a decrease in intensity of the $\pi \rightarrow \pi^*$ transition with either no frequency shift or a small blue shift (29). Furthermore, an explanation involving twisting cannot account for the fact that **4** shows the same spectral changes in the mixed solvents as **1**–**3**.

The most reasonable interpretation of the appearance of a low-frequency band in aqueous solutions of the *p*-amino derivatives is that of Brode and co-workers whereby the band is attributed to a hydrogen-bonded interaction between water and the azo nitrogens (15). The unique property of the *p*-amino group is the enhancement of the basicity of the azo nitrogens. We have calculated a pK_a of +3.6 for the azonium ion of MO, using the experimental pK_a and the azonium/ammonium tautomer ratio of the conjugate acid. The corresponding pK_a values of the next most basic derivatives, **5** and **6**, are estimated to be −1.45 and −1.49, respectively (19). The enhancement of basicity of —N=N by Me_2N— is demonstrated by the fact that an exhalted σ^+ substituent constant of −3.0 is required for Me_2N— to correlate the pK_a of MO azonium ion with the values of other ions in a homologous series. Covalent protonation of the azo nitrogens gives a pronounced red shift of the $\pi_1 \rightarrow \pi_1^*$ transition (17–19). It seems reasonable that weaker hydrogen-bonding interactions with solvent should give a smaller red shift.

Dyes **7** and **8** both have intramolecular hydrogen bonds (23). The absorption curves of both in alcohol – water mixtures showed low-frequency bands appearing either as a partially resolved shoulder or as a separate band. The relative intensities of the low-frequency components in the curves of **7** and **8** are in the same order as the relative strengths of the hydrogen bonds, as reflected in the differences in pK_a (23). Infrared (30) and electronic spectra (31) of 2- and 4-phenylazophenols show that these compounds exist as azophenols and not as quinone hydrazones in the solids and in solution.

Table 1 gives the intensities of the low-frequency (I_1) and high-frequency (I_2) components in the various neat solvents. Also listed are the solvent dielectric constants, surface tensions, and two empirical solvent "polarity" parameters, the *E* values of Reichardt and Dimroth, and δ values of Hildebrand (for a review of solvent polarity parameters for correlating spectroscopic data, see ref. 32). The *E* values are solvent-induced frequency shifts of a betaine probe and are thought to include the effect of hydrogen-bonding from solvent. The δ values are the square roots of the cohesive energy densities and are thought to be proportional to the energy required to form a solvent cavity. If we assume that the intensity ratio is equivalent to an equilibrium quotient, the logarithm of the ratio is proportional to the free energy for converting the non-hydrogen-bonded to the hydrogen-bonded solvate. Table 1 shows that the dielectric constant does not even predict the direction of change in the I_1/I_2 ratio. Figure 4 shows that there is an excellent correlation of log (I_1/I_2) with solvent surface tension (r = 0.997). A somewhat poorer correlation of log (I_1/I_2) is obtained with the *E* and δ values (r = 0.936 and 0.900, respectively). This result demonstrates the relationship between the spectral properties of the dye probe and the structural features of the hydrogen-bonding solvents. The correlation with γ suggests that the same forces that lead to high surface energies (solvent–solvent interactions) also promote sol-

vent–solute hydrogen-bonded interaction. The correlation with γ is for an interface with air of infinite radius of curvature, and not with the more appropriate (but inaccessible) interfacial tension corrected for a radius of curvature of molecular dimensions. It has been shown that the curvature correction is appreciable (33).

The effect of solvent composition on the intensity ratios and frequency maxima of the resolved bands in the aqueous binaries is shown in Figs. 5 and 6. In the frequency plots, the data point at $x_2 = 0$ (x_2 = mole fraction of organic component) is scaled to represent 95% confidence limits estimated from four replicates. The plots show that the spectral parameters in the alcohol–water mixtures do not vary in the same way as dielectric constant and empirical polarity scales such as the Kosower Z values (34) and the Y values of Grunwald and Winstein (35) since plots of these parameters against x_2 show no extrema or inflections. Most of the irregularities in the spectral parameters of MO occur in the highly aqueous solvent compositions, suggesting that this dye is inducing some solvent sorting in the mixed solvents. We have recently

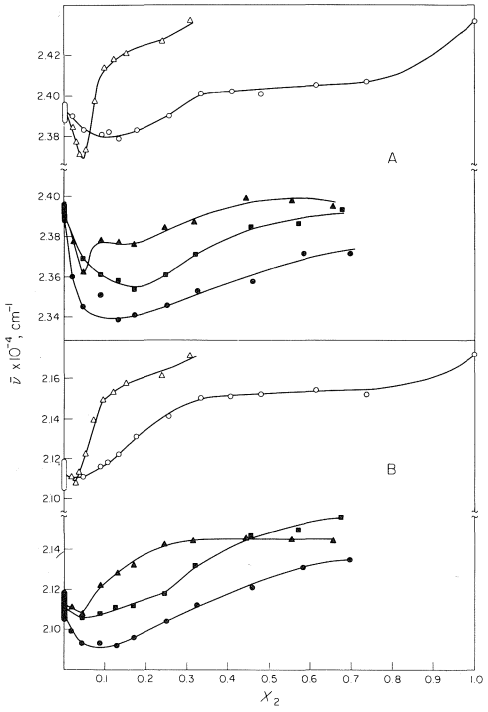

FIG. 6. Effect of solvent composition on the frequencies of maximum absorption of the resolved bands of MO in aqueous ethanol, ○; tert-butyl alcohol, △; dioxane, ▲; DMSO, ●; and DMF, ■. *A*, high-frequency component; *B*, low-frequency component.

presented evidence for induced solvent sorting from equilibrium (21), kinetic (22), and spectral studies (22) of other dyes. The effects of selective solvation on spectral properties have been treated theoretically (36).

There is a reciprocal relationship between the intensity of the low-frequency (I_1) and high-frequency (I_2) component bands that is responsible for the apparent blue shift in the experimental curves. The extrema and plateaus in the highly aqueous compositions suggest that in each case, the initial addition of the organic solvent reinforces the hydrogen-bonded interaction between solvent and dye. Similar extrema appear in the frequency plots and show that the initial addition of organic solvents shifts the resolved bands to lower frequencies. These shifts are small, but larger than experimental error. The large apparent shift of the composite curve is due primarily to the change in relative intensities.

The presence of extrema in the spectral properties of the resolved bands of MO in aqueous alcohol mixtures parallels closely the extrema that are found in many other properties of the mixtures both in the absence (37, 38) and presence of solutes (39). The generally accepted interpretation for such deviations from ideality is that the initial addition of the alcohol increases the long-range order of the solvent, and that the extrema occur at concentrations where the structure-promoting effect of the organic solvent is reversed. Our results indicate that the changes in the solvent–solvent interaction is reflected in changes in the solvent–solute interaction.

Figures 5 and 6 also show that the addition of aprotic solvents to aqueous solutions can give the same qualitative changes in the spectral parameters of MO as the two alcohols. This may not mean that similar changes in the solvent structure are induced by the protic and aprotic organic solvents. Extrema in excess thermodynamic functions of mixing (38), in viscosities (40) and in Walden product (40) occur in the water-rich dioxane–water mixtures, but these are not thought to result from enhancement of the long-range order. On the other hand, aqueous DMSO mixtures also show extrema in excess thermodynamic functions of mixing and in viscosity (41), and neutron inelastic scattering studies indicate that this solvent does increase the long-range order, with a maximum effect at $x_2 = 0.33$ (42).

The present results indicate that specific solute–solvent interactions occur in each of the binary mixtures. This fact and the failure of the spectral parameters of the resolved bands to parallel changes in solvent "polarity" scales show the difficulty in trying to conclude anything about the "polarity" of a binding site by comparing spectra of bound dye to spectra in aqueous organic solvent. By our interpretation, the spectral change accompanying the binding of MO to BSA or solubilization into a micelle is more the result of a diminution in a specific interaction with the aqueous solvent (hydrogen-bonding) than a change in polarity. The total change in the absorption curve of MO can be interpreted as a shift in the position of a ground-state equilibrium between solvation species, rather than as a change in transition energy of a single species as suggested by Williamson and Corwin (9, 14). Whereas a binding site may actually be less polar than the aqueous environment, we do not think that this is responsible for the spectral change. About all that can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

done is to compare the intensity ratios of the component bands of bound MO with the ratios in the solvent mixtures in order to find solvents showing similar spectral changes. Thus the ratio of the high-frequency to the low-frequency band in MO fully bound to BSA is 2.4, comparable to the ratio found in 30 mol% ethanol, 8 mol% tert-butyl alcohol, 15 mol% dioxane, and 40 mol% DMF and DMSO. Similarly, the intensity ratio in 0.002 *M* HTAB (cmc 9.1×10^{-4} *M* (43)) is 8.4, corresponding to the ratio found in about 84 mol% ethanol or 42 mol% dioxane. This shows that the environment of the dye in the micelle is less "waterlike" than the binding site on BSA, but we can make no numerical estimate of the "polarities" of either environment from comparison of spectral properties in the mixed solvents.

"Sideways" Bonded Dinitrogen in Matrix Isolated Cobalt Dinitrogen, CoN_2

G. A. OZIN AND A. VANDER VOET

Lash Miller Chemistry Laboratory and Erindale College, University of Toronto, Toronto, Ontario

Received October 16, 1972

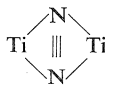
Infrared spectra are reported for matrix isolated cobalt dinitrogen isotopic species, $Co^{14}N_2$, $Co^{14}N^{15}N$ and $Co^{15}N_2$, formed in the cocondensation reaction of atomic cobalt with dilute nitrogen–argon matrices at 10 °K. The data provide the first unambiguous spectroscopic evidence for a dinitrogen molecule bonded in a "sideways" fashion to a transition metal atom.

Les spectres infrarouge sont rapportés pour les espèces isotopiques cobalt diazoté, $Co^{14}N_2$, $CO^{14}N^{15}N$ et $CO^{15}N_2$, isolées par matrice et formées par condensation du cobalt atomique avec des matrices diluées d'azote–argon à 10 °K. Ces données fournissent la première preuve spectroscopique et sans ambiguité de l'existence de la molécule d'azote liée de façon latérale à l'atome métallique de transition. [Traduit par le journal]

Can. J. Chem., **51**, 637 (1973)

With the increasing number of reports of stable and matrix isolated transition metal compounds containing coordinated dioxygen or dinitrogen molecules, there has also arisen considerable interest in the mode of bonding and nature of the interaction between the metal and the ligands. Although X-ray crystallography serves to determine unambiguously the type of bonding (end-on or sideways) in stable species, in such cases where diffraction studies are not possible (*i.e.*, matrix isolation systems) vibrational spectroscopic investigations using mixed isotopically substituted ligands, ^{14}N–^{15}N or ^{16}O–^{18}O, are able to distinguish the bonding types. This is due to the *nonequivalence* of the vibrational frequencies of, for example, M—^{15}N—^{14}N and M—^{14}N—^{15}N in both the M—N and N—N stretching regions and the expected splitting of these modes. X-ray crystallography has shown that in transition metal complexes with coordinated dioxygen molecules the bonding can be sideways (1) or end-on non-linear (2). Sideways bonding has been shown in i.r. spectroscopic studies of matrix isolated binary dioxygen complexes (3) $M(O_2)_n$ (where M = Ni, Pd, or Pt and n = 1 or 2). The dinitrogen ligand, on the other hand, has always been found to be bonded in an "end-on" fashion with a linear or near linear M—N—N skeleton (4). Unequivocal i.r. spectroscopic evidence for this bonding type has been shown for the stable cation $[Ru(NH_3)_5N_2]^{2+}$ and matrix isolated NiN_2 (5, 6). In both of these systems, 1:2:1 statistical mixtures of $^{14}N_2$:$^{15}N^{14}N$:$^{15}N_2$ were used and a four-line pattern of νNN stretching modes was observed corresponding to M—$^{14}N_2$, M—$^{14}N^{15}N$, M—$^{15}N^{14}N$, M—$^{15}N_2$. The splittings of the M—$^{14}N^{15}N$/M—$^{15}N^{14}N$ central components were 4.0 and 3.8 cm^{-1} for the ruthenium and nickel complexes respectively. It is also worth noting that the matrix i.r. and Raman spectra of $Ni(^{14}N_2)_4$ in solid argon were in agreement with that expected for a *regular* tetrahedral molecule containing "end-on" bonded dinitrogen (7).

Direct evidence for the existence of a compound containing the dinitrogen molecule bonded in a "sideways fashion" has not previously been reported in the literature. It was, however, postulated (8) as a transition state in the intramolecular $^{14}N^{15}N$ exchange of the anions $[Ru(NH_3)_5$-$^{14}N^{15}N]^{2+}$/$[Ru(NH_3)_5{}^{15}N^{14}N]^{2+}$ as evidenced in the time dependent intensity changes in the Ru—N_2 stretching region. It is noteworthy that Brintzinger's dinitrogen bridged binuclear titanocene complex $(C_5H_5)_2TiN_2Ti(C_5H_5)_2$ shows no absorption in the i.r. attributable to the NN stretching mode. Of the two suggested dinitrogen-bridged centrosymmetric structures, *i.e.* end-on Ti—N≡N—Ti and edge-on



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the latter was favored on the basis of chemical intuition (9).

In this communication we are reporting matrix i.r. spectroscopic evidence for the existence of cobalt dinitrogen, CoN_2, which we find to contain the dinitrogen ligand bonded in a "sideways" fashion to the cobalt atom. Our experiments consisted of cocondensing Co (McKay 99.99%) atoms with dilute nitrogen–argon matrices ($^{14}N_2$:Ar = 1:250; $^{14}N_2$:$^{15}N_2$:Ar = 1:1:2000; $^{14}N_2$:^{14}N-^{15}N:$^{15}N_2$:Ar = 1:2:1:2000 ($^{14}N_2$ Matheson 99.999%, $^{15}N_2$ Prochem 99.5%)) onto a cesium iodide plate cooled to 10 °K by an Air Products Displex closed cycle helium refrigerator. The furnace design and matrix set-up have been previously reported (10). The rate of metal atom deposition was monitored continuously throughout the experiment, using a quartz crystal microbalance as described previously (11). The probability of a Co atom having another Co atom as a nearest neighbor in the matrix was arranged to be less than 10^{-3}. Under these conditions one can be sure of producing mononuclear species. I.r. spectra were recorded on a Beckmann IR 12.

When Co atoms were cocondensed with $^{14}N_2$/Ar = 1:250 matrix gases a single sharp i.r. absorption was observed at 2101.0 cm^{-1} (Fig. 2). When the experiment was repeated with $^{14}N_2$/$^{15}N_2$/Ar = 1:1:2000, a *doublet* was observed at 2101.0 and 2029.5 cm^{-1}, which with $^{14}N_2$/$^{14}N^{15}N$/$^{15}N_2$/Ar = 1:2:1:2000 became a *triplet* at 2101.0, 2066.5, and 2029.5 cm^{-1}. These three i.r. absorptions are clearly assignable to νNN stretching modes of a binary dinitrogen complex of Co containing a *single* dinitrogen molecule, that is CoN_2 (Fig. 1).

The three-line spectrum was carefully examined under conditions of high resolution. All three absorptions were found to have *identical* band widths of 2.5 ± 0.2 cm^{-1} at half height. The slit width used for the highest resolution scan was 0.36 cm^{-1} with a scan speed of 0.4 cm^{-1}/min. At slit widths lower than 1.5 cm^{-1} intensity loss was observed, which indicates that a slit width of 0.36 cm^{-1} is below the 2.5 cm^{-1} band width at half height of the central νNN $Co^{14}N^{15}N$ component. If some splitting of the central component had remained undetected, it must be less than 0.4 cm^{-1}.

Unlike $Ni(N_2)$ (Fig. 2) the central νNN component of $Co^{14}N^{15}N$ is *not* split and has an absorption intensity approximately *twice* that

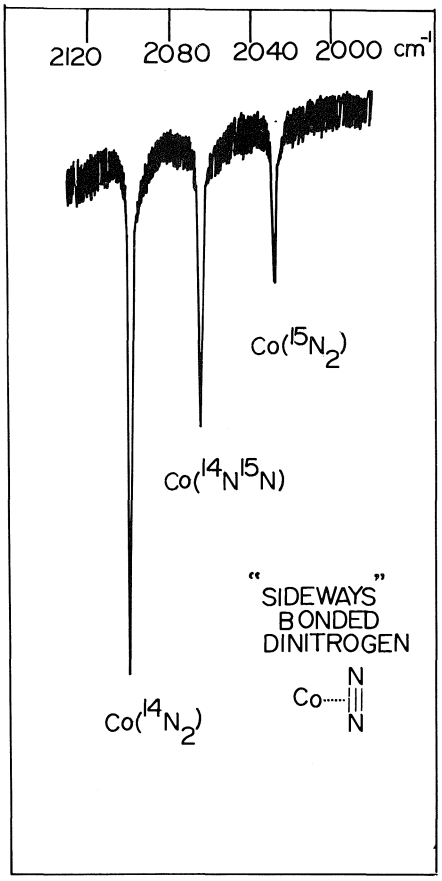


FIG. 1. The matrix i.r. spectrum of the products of the cocondensation reaction of Co atoms with $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$:Ar = 1:2:1:2000 at 10 °K. The intensity of the NN stretching mode assigned to $Co(^{14}N_2)$ is larger than expected because of trace quantities of residual $^{14}N_2$ gas either in the vacuum line or in the Ar matrix gas.

of the νNN component belonging to $Co^{15}N_2$. These two spectral observations, when taken in conjunction with the identical band widths at half height of νNN for $Co^{14}N_2$, $Co^{14}N^{15}N$ and $Co^{15}N_2$ and the 3.8–4.0 cm^{-1} doublet splitting of the central component for "end-on" bonded dinitrogen in the nickel and ruthenium complexes (5, 6), are overwhelmingly in favor of dinitrogen bonded in a "sideways" fashion to cobalt in CoN_2.

The dinitrogen ligand in CoN_2 is clearly bonding in a manner similar to that of olefins in transition metal olefin complexes (12). This is unlike dinitrogen in, for example, Andrews' matrix isolated lithium supernitride species (13) which shows an NN stretching mode characteristic of

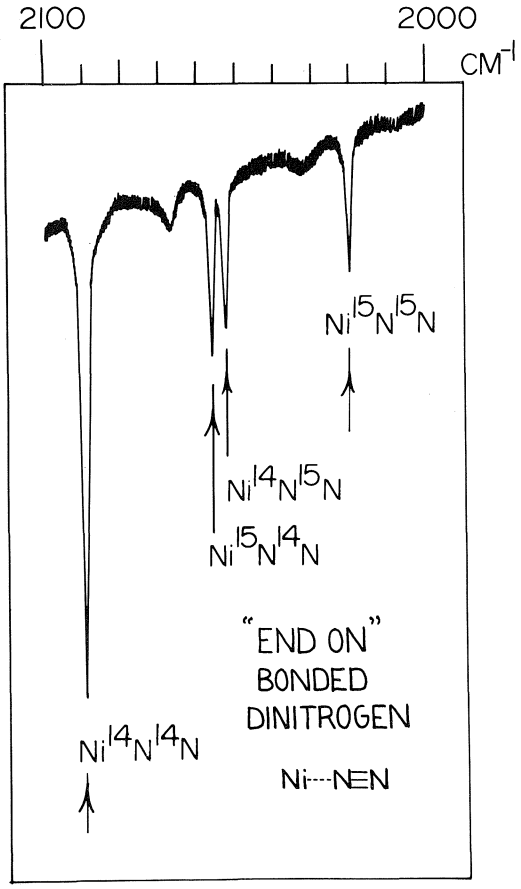

FIG. 2. The matrix i.r. spectrum of the products of the cocondensation reaction of Ni atoms with $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$:Ar = 1:2:1:2000 at 10 °K. The intensity of the NN stretching mode assigned to Ni($^{14}N_2$) is larger than expected because of trace quantities of residual $^{14}N_2$ gas either in the vacuum line or in the Ar matrix gas.

reduced dinitrogen at 1800 cm^{-1} (*cf.* 1836–1807 cm^{-1} from the Raman spectra of the supernitride ion N_2^- in potassium halide lattices (14)) and which is best described as an electrostatically bound ion pair $Li^+N_2^-$ (similar to matrix isolated lithium superoxide (15), $Li^+O_2^-$).

Orgel (16) was first to consider the stability of M—$\overset{\text{N}}{\underset{\text{N}}{\|}}$ relative to M—N≡N by invoking a two way charge-transfer process for the bonding picture of dinitrogen in terms of neutral excited states of the metal and ligand. This simple approach does not yield a clear distinction between side-on and end-on bonded N_2, as the n–π upper state of N_2 is 7.3 eV which is comparable to the π–π excited state of N_2 at 6–8 eV. However, extended Hückel molecular orbital calculations have recently been reported by Yatsimirskii *et al.* (17) for FeN_2 in both the side-on and end-on configurations. The calculated energies indicated that the sideways bonded species would be less stable than the end-on bonded. From considerations of the n_σ and n_π orbital populations for the N—N and N—Fe bonds and their relationships to bond strengths, one would have expected the ν_{NN} stretching frequency of sideways bonded N_2 to lie at a considerably lower frequency than end-on bonded N_2. In actual fact the NN stretching frequency for CoN_2 lies about 10 cm^{-1} *above* that of NiN_2.

The existence of side-on bonded N_2 in CoN_2 may give some clues as to possible new routes to stable complexes containing side-on N_2 and their relationship to the fixation of N_2. For example, synthesis might possibly be directed towards species isoelectronic with Co(0) in CoN_2, namely, Mn(−II), Fe(−I) or Ni(I). One finds in fact, that dinitrogen complexes of these low or negative valence state metals have not yet been investigated. Apparently the anticipated fixation of N_2 via "hydridic" dinitrogen complexes, such as $(Ph_3P)_3Co(H)N_2$ was unsuccessful. A breakthrough might possibly be realized with compounds of the type L_nM—$\overset{\text{N}}{\underset{\text{N}}{\|}}$ (where M = Mn(−II), Fe(−I), Co(0) or Ni(I)) using acidic rather than hydridic conditions.

We wish to thank Dr. Martin Moskovits for helpful discussion, the National Research Council of Canada and the Research Corporation for financial support.

X-Radiolysis Ion Yields and Electron Ranges in Liquid Xenon, Krypton, and Argon: Effect of Electric Field Strength

MAURICE G. ROBINSON AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alberta, T6G 2G2

Received July 21, 1972

X-Radiolysis ion yields were measured at electric fields between 1 and 60 kV/cm in argon at 87 °K, krypton at 148 °K, and xenon at 183 °K. The results were analyzed according to a theoretical model to obtain the total ion yields G_{tot}, the free ion yields at zero field strength G_{fi}^0 and the most probable penetration ranges b of the secondary electrons in the liquids. The respective values were: Ar, 7.3, 2.9, 1330 Å; Kr, 13.0, 5.8, 880 Å; Xe, 13.7, 7.0, 720 Å. The total ionization yields in these substances are greater in the liquid than in the gas phase, probably due to smaller ionization potentials in the condensed phase (polarization energy effect). Field dependent electron mobilities are also reported.

Les rendements en ions libres produits par les rayons X dans l'argon à 87 °K, le krypton à 148 °K, et le xenon à 183 °K ont été mesurés à des champs électriques allant de 1 à 60 kV/cm. Les resultats ont été analysés à l'aide d'un modèle théorique en vu d'obtenir pour chaque liquide le rendement total en ions, G_{tot}, le rendement en ions libres en l'absence de champ électrique, G_{fi}^0, et la distance de penetration la plus probable, b, pour les électrons secondaires. Les valeurs sont respectivement: Ar, 7.3, 2.9, 1330 Å; Kr, 13.0, 5.8, 880 Å; Xe, 13.7, 7.0, 720 Å. Le rendement total en ions pour ces substances est plus élevé en phase liquide qu'en phase condensée (effect de l'energie de polarisation). Les mobilités électroniques en fonction du champ électrique sont presentées.

Can. J. Chem., **51**, 641 (1973)

Introduction

Relationships between the ranges and mobilities of electrons in liquids and the properties of the liquids have aroused considerable interest recently (1–11). Ranges of radiolytically produced secondary electrons and mobilities of thermal electrons in liquid alkanes increase with increasing sphericity of the molecules (1). It has been suggested that anisotropy of molecular polarizability has a major influence on the electron behavior (1, 12).

In this respect the liquified rare gases are worthy of study, having isotropic polarizabilities. Electron behavior in liquid argon (7) is similar to that in methane (5, 7), which seems surprising in spite of the nearly isotropic polarizability of methane. Methane has a more complex structure and much lower molecular energy levels than does monatomic argon. One suspects that interactions of an electron with two or more argon atoms at once are important in the liquid (7). It is therefore of interest to do measurements in krypton and xenon.

Thermal electron mobilities in these liquids are limited by scattering interactions (13–18).

Experimental

Materials and Sample Preparation

Ultrapure grade, 99.999%, argon and Research Grade krypton (5 p.p.m. xenon, no other detectable impurities) were obtained from Matheson. The Research Grade, 99.995%, xenon from Linde contained < 1 p.p.m. oxygen.

The materials were handled in a vacuum rack that was initially evacuated to $< 10^{-6}$ Torr.

Traces of oxygen were removed from argon in the

§Reference 21.
‖Calculated from the polarizability α and density d, using the Clausius–Mosotti equation.

manner described previously (1, 7). Attempts to similarly purify xenon were unsuccessful. Purification of xenon and krypton was not pursued because it was found that the desired measurements could be made with the materials as supplied.

Physical Properties of the Liquids

These are summarized in Table 1. Values were taken or estimated from data in refs. 19–21.

Conductance Cells

A variety of cells were used, particularly in the case of argon. The large (25 cm^3) cell with a guard ring has already been described (5). Other cells had a much smaller capacity (5 cm^3) and were either of the simple two plate type (Fig. 1*a*) or the guard ring variety (Fig. 1*b*).

The cell constants were measured conductiometrically using standard KCl solutions.

Cooling Baths

The refrigerants were liquid argon 87 °K, *n*-pentane slush 148° K, and methanol slush 183 °K.

Determination of the Free Ion Yield

The free ion yields were measured using the charge clearing method (2, 5). A schematic diagram of the circuit is shown in Fig. 2. Signals were usually generated by 100 ns pulses of 1.70 MeV X-rays. Alternate signals and blanks (no pulse from the van de Graaff accelerator) were fed into a low drift high sensitivity integrator and averaged with the Fabritek model 1062 Instrument Computer. The clearing field was applied continuously and each current integration sweep, which normally lasted for 2 s, was begun about 100 ns before the X-ray pulse.

On two occasions 1 μs X-ray pulses were used for argon, and the results were within experimental error of those obtained with 0.1 μs pulses.

Electron Conductance Transient (ECT)

Measurement of the ECT was effected using the circuits shown schematically in Fig. 3. When the half life ($t_{1/2}$) of the ECT was greater than 1 μs circuit *a* was used. This circuit had a decay $t_{1/2} = 0.8$ μs and a gain of 10^6. For $t_{1/2} < 1$ μs circuit *b* was used. It had a decay $t_{1/2} = 50$ ns and a gain of 10^4.

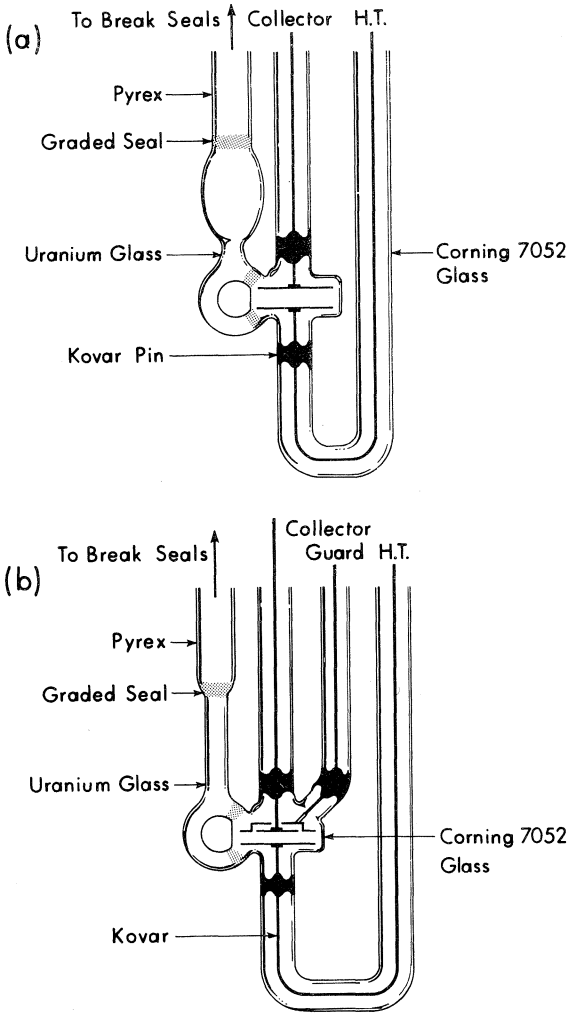

FIG. 1. Conductance cells: (*a*) electrode separation 0.50 cm, area 3.71 cm^2; (*b*) collecting electrode effective area 1.77 cm^2, separation 0.30 cm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

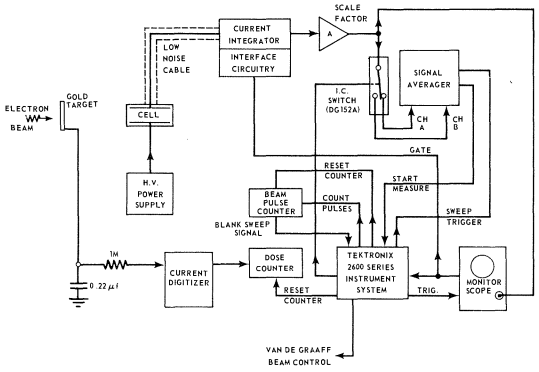

FIG. 2. Circuit for measuring free ion yields.

Dosimetry

The monitor used for every pulse was the charge collected on the gold target of the accelerator (5). The monitor was calibrated by thermoluminescence dosimetry with lithium fluoride crystals, which in turn were calibrated against the Fricke dosimeter in a low intensity (10–100 r/h) gamma source.

The amounts of photoelectric absorption in krypton and xenon had to be determined. To do this, several types of experiment were done: (*1*) apparent free ion yields were measured in each of the liquids with the normal 1.7 MeV beam, and with this beam filtered through 7 mm and 14 mm of lead; (*2*) apparent free ion yields were measured in xenon with the van de Graaff set at 0.75 MeV; (*3*) energy absorption calculations were done with X-ray spectra and absorption coefficients.

X-ray spectra were constructed from data in refs. 22

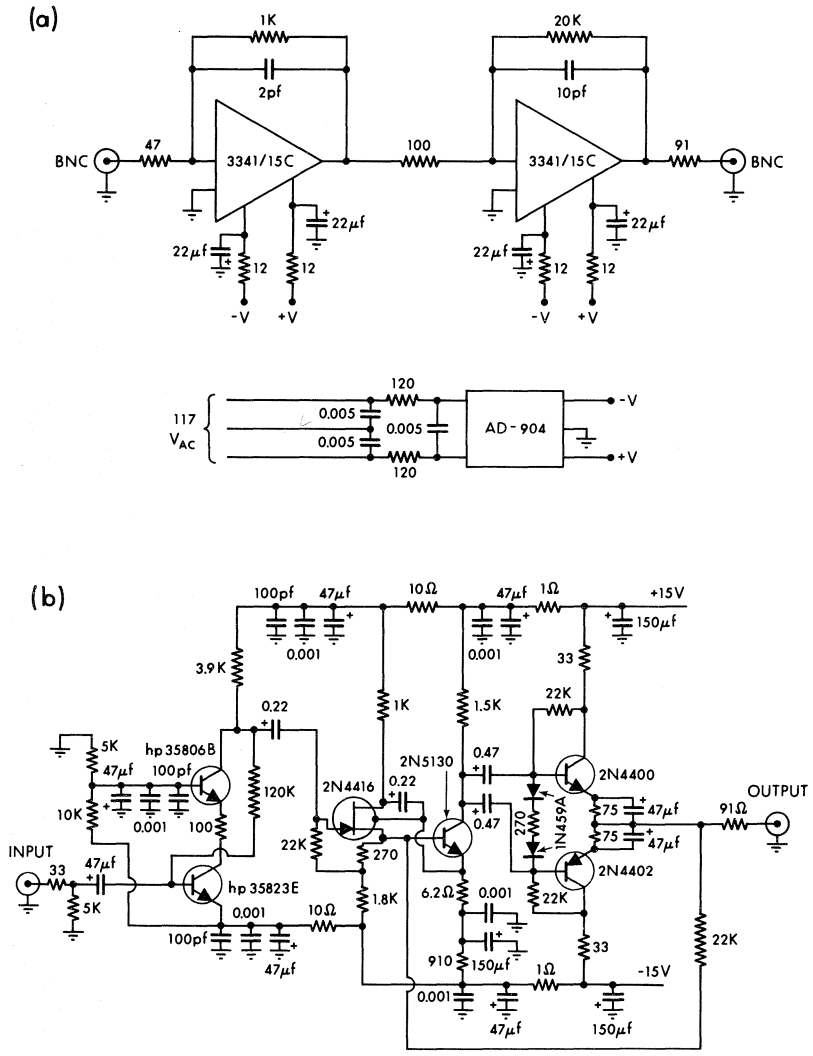

FIG. 3. Circuits for measuring the electron conductance transient. Response $t_{1/2}$ (*a*) 0.8 μs; (*b*) 50 ns.

TABLE 2. Dosimetry factors per electron of absorber M relative to that for LiF

M	Van de Graaff energy (MeV)	Pb filter (mm)	Factor* A†	Factor* B‡
LiF	1.70	0	1.00	1.00
	1.70	7	0.57 (0.54§)	1.00
	1.70	14	0.35 (0.33§)	1.00
Ar	1.70	0	1.03	1.03
	1.70	7	0.58	1.02
	1.70	14	0.36	1.02
Kr	1.70	0	1.16	1.16
	1.70	7	0.60	1.05
	1.70	14	0.37	1.04
Xe	0.75	0	2.14	2.14
	1.70	0	1.56	1.56
	1.70	7	0.70	1.24
	1.70	14	0.42	1.20

*Factor $= \int_0^{h\nu_{max}} {}_e\mu_a(M,h\nu)N(h\nu)h\nu dh\nu / \int_0^{h\nu_{max}} {}_e\mu_a(LiF,h\nu)N(h\nu)h\nu dh\nu$. The assumed fractional amount of gold K radiation in the normal beam (no Pb) was adjusted to give the correct ratio between the Xe ion yields with 0 and 7 mm Pb for the 1.7 MeV beam. The resulting fraction, 0.2% of the normal beam energy relative to 0.0% for the filtered beam, was assumed to be constant for all other absorbers. The same fraction gave good agreement for the 0.75 MeV beam results.
†Factor relative to LiF in normal (zero Pb) beam.
‡Factor relative to LiF in beam with same filter.
§Measured.

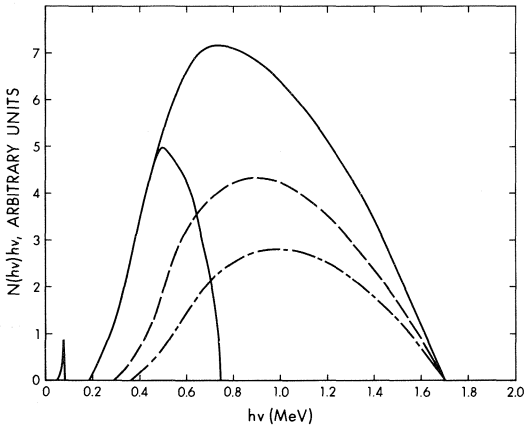

FIG. 4. X-ray spectra: $N(h\nu)$ is the number of photons of energy $h\nu$ per cm². —, normal beam; ---, filtered by 7 mm lead; -·-·-, filtered by 14 mm lead. The small peak at 0.08 MeV is gold K radiation; it contains 0.2% of the energy of the normal beam and corresponds to the difference between the amount of K radiation from Au in the normal beam and that from Pb in the filtered beam. The latter appears to be negligible.

and 23. The spectrum of an unfiltered X-ray beam with the desired $h\nu_{max}$ was simulated as in ref. 23. Attenuation by the gold target (effective thickness 2.8–2.9 mm) was estimated with the aid of absorption spectra constructed by interpolation between data in ref. 22.

The "normal" beam was the one emerging from the gold target. The shapes for 1.7 and 0.75 MeV peak energies are shown in Fig. 4 (full lines). Comparison of observed with calculated results indicates that the K radiation peak contains 0.2% of the beam energy in both cases.

Shapes of 1.7 MeV beams filtered by 7 mm and 14 mm of lead are also shown in Fig. 4 (broken lines). The calculated extent of beam attenuation agreed with that measured by LiF dosimetry when Pb absorption coefficient values lying between μ and μ_a were used (see eqs. 1 and 2 and discussion of build-up factors in ref. 24):

$$[1] \qquad \mu = \tau + \sigma_a + \sigma_s + \pi$$

$$[2] \qquad \mu_a = \tau + \sigma_a + \pi$$

where τ is the photoelectric absorption coefficient, σ_a and σ_s are the "actual" and "scatter" Compton coefficients, and π is the pair production coefficient (22).

The amount of dose D_M absorbed from the beam in material M relative to the amount absorbed in LiF is given by eq. 3.

$$[3] \qquad \frac{D_M}{D_{LiF}} = \frac{n_M \int_0^{h\nu_{max}} {}_e\mu_a(M,h\nu)N(h\nu)h\nu dh\nu}{n_{LiF} \int_0^{h\nu_{max}} {}_e\mu_a(LiF,h\nu)N(h\nu)h\nu dh\nu}$$

where n_M and n_{LiF} are the numbers of electrons/cm³ in M and LiF, respectively, ${}_e\mu_a(M,h\nu)$ is the "actual" absorption coefficient per electron of M for photons of energy $h\nu$, and $N(h\nu)$ is the relative number of photons of energy $h\nu$. The integrations were done numerically, using values of ${}_e\mu_a(M,h\nu)$ from Fig. 5 and the X-ray spectra in Fig. 4.

Values of the ratio of integrals in eq. 3 are listed in Table 2.

Normal doses were 1×10^{10} and 3×10^{10} eV/cm³ argon, for 0.1 and 1 μs pulses, respectively.

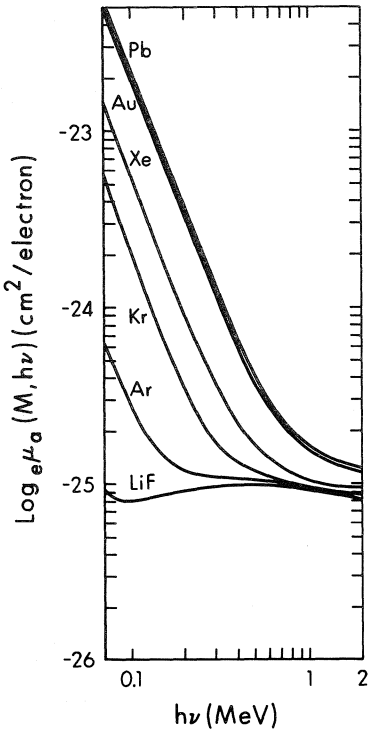

FIG. 5. Absorption coefficients per electron of material M, as functions of X-ray energy. ${}_e\mu_a = {}_e\tau + {}_e\sigma_a + {}_e\pi$. The values were interpolated and calculated from data in ref. 22.

Results

Free Ion Yields

Argon, 87 °K

Eleven series of experiments were done using different cells, different dosimeter crystals, different radiation pulse lengths (0.1 and 1 μs), and different preparations of argon. The measured values of $G_{fi}{}^{E}$, the free ion yield at applied electric field strength E, were reproducible to ±10%. The averaged results are shown in Fig. 6. The free ion yield increases rapidly from $G_{fi}{}^{E} = 4.6$ at 1.1 kV/cm to 7.0 at 12 kV/cm, then increases relatively slowly at higher fields.

Measurements were also done after placing lead filters between the X-ray target and the sample. Blocks of lead 7 mm and 14 mm thick reduced the beam strength, as measured by the LiF crystals, to 0.54 and 0.33, respectively, of the normal value. The amount of charge collected in argon per unit of dose measured with the LiF dosimeter was independent of whether the X-rays were filtered by lead. This agrees with the constancy of the dosimetry factors in Table 2.

Krypton, 148 °K

Free ion yields were higher in krypton than in argon, but the effect of field strength was similar in the two liquids (Figs. 6 and 7).

Filtering the X-rays through 7 mm of lead reduced by 12% the amount of charge collected in krypton per unit of dose measured with the LiF crystals. Increasing the filter thickness to 14 mm did not decrease this "apparent G value" further, thereby confirming the dosimetry factors in Table 2. The dosimetry factors account for the photoelectric absorption process, which is negligible in the LiF crystals but is appreciable in krypton. Filtration through lead reduces the fraction of lower energy photons in the X-ray beam and thereby decreases the importance of photoelectric absorption relative to the Compton process (22, 23).

The yields in Figs. 6–8 were calculated using the factors under B in Table 2, and are "true G

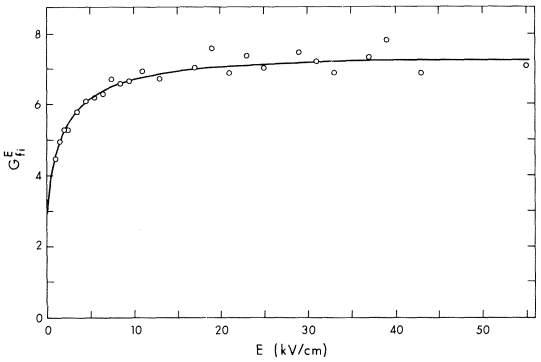

FIG. 6. Yields of ions collected at field strength E in argon at 87 °K. The points are the averages from eleven samples. The curve was calculated (see text).

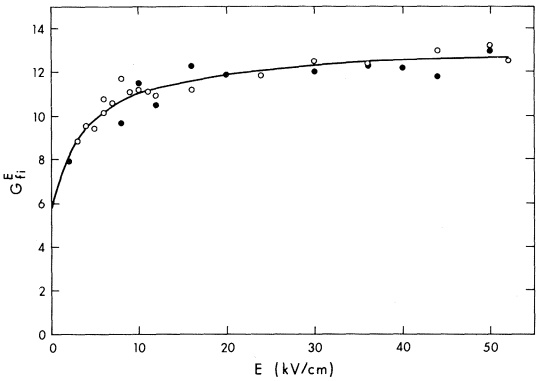

FIG. 7. Yields of ions collected at field strength E in krypton at 148 °K: ○, normal 1.7 MeV X-rays; ●, 1.7 MeV X-rays filtered by 14 mm Pb. The curve was calculated (see text).

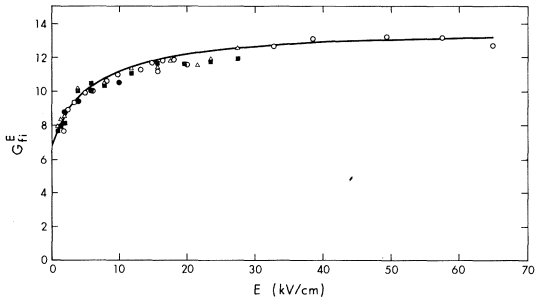

FIG. 8. Yields of ions collected at field strength E in xenon at 183 °K. 1.7 MeV rays: ○, normal beam; ■, 7 mm Pb filter; △, 14 mm Pb filter. 0.75 MeV X-rays, normal beam, ●. The curve was calculated (see text).

values", as distinguished from the "apparent G values" that were calculated directly from the LiF dosimetry.

Xenon, 183 °K

Xenon exhibits the highest ion yields measured thus far (Fig. 8). The field strength effect is similar to those in argon and krypton.

Filtering the 1.7 MeV X-rays through 7 mm of lead reduced the apparent G values by 25%; 14 mm of lead reduced the apparent G values an additional 2%. The effects of the lead filters are consistent with the dosimetry factors in Table 2.

Reducing the accelerator energy to 0.75 MeV increased the apparent G values by 35% over those at 1.7 MeV, with no lead filter. At the lower energy photoelectric absorption is more important, relative to the Compton process (22, 23), and the dosimetry factor is given in Table 2.

ECT and Electron Mobility

Argon, 87 °K

Argon that had been purified by the charcoal electrolysis technique (7) gave an ECT with a relatively long half life. The half life $t_{1/2}$ decreased with increasing field strength and pulse dose (Fig. 9). The decay of the ECT was first order at higher field strengths. The order increased at the lower field strengths but was still less than 2.0 at 4 V/cm with a pulse dose of 3×10^{10} eV/cm^3.

An idealized peak current i_0 at the end of the pulse was obtained by correcting the measured ECT for signal decay during the pulse and for circuit response characteristics (which varied from amplifier to amplifier). From i_0 one can obtain the electron mobility u through eq. 4 (7, 12, 25). The mobilities of the positive ions are negligible in these systems (26).

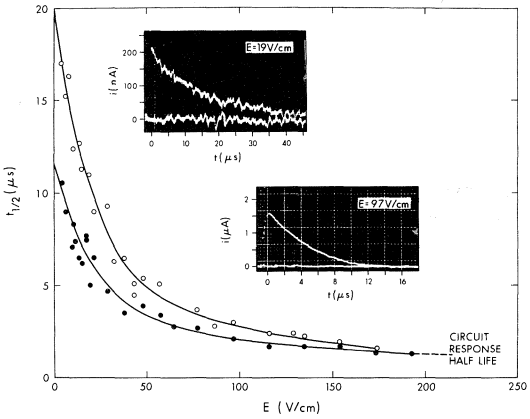

FIG. 9. Half life of ECT in argon as functions of applied field strength E and pulse dose: ○, 1.0×10^{10} eV/cm^3; ●, 3.6×10^{10} eV/cm^3. The inset pictures were obtained with 100 ns pulses of 1.3×10^{10} eV/cm^3.

$$[4] \qquad G_{fi}^{E}\, u = 6.24 \times 10^{20}\, i_0/\text{dose}\, AE$$

where i_0 is in A, the pulse dose is in eV/cm^3, A is the area of the collecting electrode in cm^2, E is the applied field strength (V/cm), G_{fi}^{E} is the free ion yield at E.

Values of u obtained from i_0 and G_{fi}^{E} (Fig. 6) are given in Fig. 10. Measurements were made at 1 and 6×10^{10} eV/cm^3 per pulse. The mobilities at $E > 80$ V/cm were independent of pulse dose and of field strength. The apparent decrease of u at low field strengths was somewhat more marked for the larger pulse dose and may be partly attributed to space charge effects.

Krypton, 148 °K

The half life of the ECT in krypton after a 100 ns pulse was 320 ns (amplifier response $t_{1/2} = 50$ ns) and was independent of field strength from 20 to 600 V/cm. A typical oscilloscope trace is shown in Fig. 11. The decay was first order and was attributed to reaction of the electrons with a trace of impurity, such as oxygen, in the liquid.

Values of i_0 and u were determined as described above, using a pulse dose of 1×10^{10} eV/cm^3. The electron mobility decreased steadily with increasing field strength, but was always much higher than that in argon (Fig. 10).

Xenon, 183 °K

The ECT had $t_{1/2} = 400$ ns, independent of field strength from 40 to 200 V/cm. The decay was first order, as in krypton.

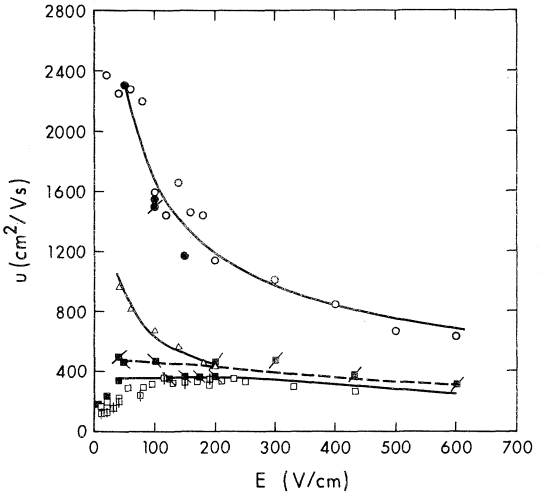

FIG. 10. Electron mobilities in liquids krypton, xenon, and argon. Krypton: ○, present results, 148 °K, v.p. = 6 atm, pulse dose 1×10^{10} eV/cm³; ◐, ref. 13, 148 °K, 6 atm; ●, ref. 13, 152 °K, v.p. = 15 atm; —, $u = 16{,}900\ E^{-1/2}$. Xenon: △, present results, 183 °K, v.p. = 3 atm, pulse dose 1×10^{10} eV/cm³; —, $u = 6{,}350\ E^{-1/2}$. Argon: present results, 87 °K, v.p. = 1 atm, □, pulse dose 1×10^{10} eV/cm³, ⊞, 6×10^{10} eV/cm³; ■, ref. 7, 87 °K, 1 atm, pulse dose 4×10^{10} eV/cm³; ◪, ref. 14, 85 °K, 0.7 atm; ▣, ref. 13, 90 °K, 6–7 atm; ---, Shockley theory, ref. 14; —, Cohen and Lekner theory, ref. 14.

The electron mobility decreased with increasing field strength (Fig. 10). The curve fell between those for krypton and argon.

Discussion

Yields and Ranges of Secondary Electrons

The results in Figs. 6–8 were analyzed to obtain values of the free ion yield at zero field $G_{fi}{}^0$, the total ionization yield G_{tot}, and the most probable penetration range b of the secondary electrons in the liquid. The computer method of analysis has been described in detail elsewhere (27, 28), so only illustrative equations are given.

The free ion yield $G_{fi}{}^E$ in the presence of an applied field E (V/cm) is given by eq. 5.

$$[5] \quad G_{fi}{}^E = G_{tot}\int_0^\infty F(y)e^{-r/y} \times [1 + \beta r + 0.375\beta^2 r^2 - 0.750\beta^2 ry + ...]dy$$

where $F(y)dy$ is the fraction of thermalized electron–ion pairs that have initial intrapair separation distances between y and $y + dy$, $r = \xi^2/\varepsilon kT$, $\xi = 4.80 \times 10^{-10}$ e.s.u., ε is the dielectric constant of the medium, k is Boltzmann's constant, T is the Absolute temperature, and $\beta = \xi E/600kT$. At zero field $\beta = 0$ and one obtains $G_{fi}{}^0$ from eq. 5.

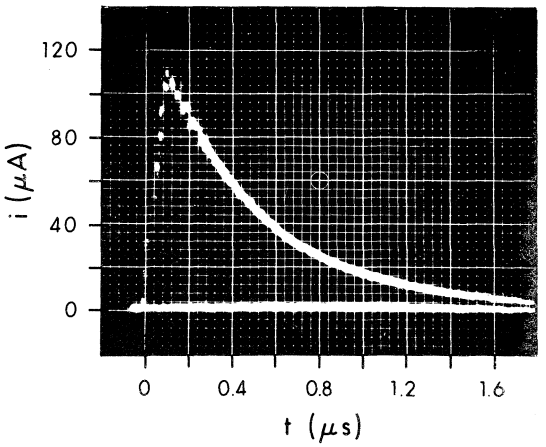

FIG. 11. Oscilloscope trace of ECT signal from krypton at 148 °K. $E = 140$ V/cm, pulse dose $= 1.3 \times 10^{10}$ eV/cm³, collecting electrode area = 3.65 cm².

For liquids in which the free ion yield is large, such as the present ones, the distribution $F(y)$ is well approximated by the Gaussian function, eq. 6 (28).

$$[6] \quad F(y) = (4y^2/\pi^{1/2}b^3)\exp(-y^2/b^2)$$

where b is the dispersion parameter. The separation distance y corresponds to the penetration range of the secondary electron into the liquid away from its parent ion, and b is the most probable value of y.

Values of b and G_{tot} were chosen to obtain the smallest mean deviation of the yields calculated by eq. 5 from the experimental yields for a given liquid. The best-fit values of b and G_{tot} are listed in Table 3 and the calculated curves are shown in Figs. 6–8. The resulting values of $G_{fi}{}^0$ are also given in Table 3.

One finds that the total ionization yield in liquid argon is nearly double the gas phase yield (29), whereas in krypton and xenon the ionization yields in the liquid are triple those in the gas phase (Table 3). Ionization in these liquids is evidently greatly facilitated by polarization energy, as it is in many solids (30, 31). For example, the ionization potential of anthracene is 7.2 eV in the gas phase (32) and $\leqslant$4.0 eV in the crystal (31). The lowering of the ionization potential is real. The generation of negative

charge carriers in the bulk crystal is linearly dependent on the light intensity (33), so it is not a two-quantum process (34).

The secondary electron ranges in krypton and xenon are smaller than those in argon (Table 3). This might be partly due to the decreasing size of the subelectronic-excitation energy region and partly due to an increase in $(-dT/dx)$ in the subelectronic region as one proceeds from argon to xenon.

The energy of the lowest excited state $^3P_2$ in the gas phase (Table 3) is probably higher than that of the lowest excited electronic state in the liquid, although the trends from argon to xenon should be the same.

Electrons in the subelectronic excitation region probably lose energy to intermolecular modes via transient M_2* states, where M is Ar, Kr, or Xe (35–43). Comparison with Brouilloin scattering of light (44) leads to the speculation that larger clusters M_n might also contribute to energy degradation of the electrons.

Thermal Electron Mobilities

The present values of the electron mobilities in krypton at 148 °K (Fig. 10) agree with those reported earlier for the same temperature (13). At the field strengths used the mobility decreases as $E^{-1/2}$, which has been attributed to an increase of electron "temperature" with E (13, 14, 45).

The electron mobility in xenon at 183 °K also decreases as $E^{-1/2}$ (Fig. 10). The mobilities are nearly a factor of two lower than those reported earlier for xenon at 163 °K (14). The temperature dependence of electron mobilities in these liquids is complex and is not understood (13–15, 18).

For argon at 87 °K the present mobility values are within experimental error of those in ref. 13 but are lower than those in ref. 14 (Fig. 10). The present results at $E > 100$ V/cm agree with the theory of Cohen and Lekner (14, 46) but not with that of Shockley (14, 45). The apparent decrease in mobility at $E < 100$ V/cm was previously attributed to space charge effects (7), but one would have expected a larger dependence upon pulse dose if space charge were the only cause. At 10 V/cm a six-fold increase in pulse dose decreased the apparent mobility by only 50% (Fig. 10). Ten different samples in four different cells gave the same results over the entire field range, within ±10%. The samples were given several radiation pulses at zero field before each field-on measurement, to remove polarization effects in the cell. The behavior at low fields is not understood, but the difference between the results from different laboratories (Fig. 10) indicates that experimental artifacts are important.

The study of electron mobilities will be continued.

We would like to thank J.-P. Dodelet for doing the calculations for Figs. 6–8 and the staff of the Radiation Research Center for aid with the electronics. This work was supported by the National Research Council of Canada. R. Schiller is thanked for a preprint of ref. 11.

Kinetics of Quasifree Electron Reactions in the Liquids Methane, Krypton, and Xenon

MAURICE G. ROBINSON AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alberta, T6G 2G2

Received July 21, 1972

The encounter efficiency of $e^- + N_2O \rightarrow N_2O^-$ in the liquids methane, krypton, and xenon at 183 °K is $f \approx 10^{-5}$. The parameter β, for the nonhomogeneous kinetics of reactions in γ radiolysis spurs in the liquids, has values similar to those (10^{13}–10^{14} V/cm²) obtained earlier for liquids such as cyclohexane, methanol, and water at 298 °K, in which f is approximately unity. Previous results for nitrous oxide in neopentane at 296 °K have been reinterpreted to obtain $f \approx 10^{-2}$. For solvents in which the electron mobility is very high (~10^3 cm²/Vs) the value of f is low. As the electron mobility decreases f increases to a maximum of unity.

La probabilité, f, de reaction par rencontre de $e^- + N_2O \rightarrow N_2O^-$ dans des liquides tels que le méthane, le krypton et le xenon à 183 °K est environ 10^{-5}. Le parametre β de cinetique nonhomogène (relatif aux reactions dans les grappes se produisant lors de l'irradiation γ) dans ces liquides a des valeurs comparables (10^{13}–10^{14} V/cm²) à celles déterminées précédemment à 298 °K pour des liquides tels que le cyclohexane, le méthanol, et l'eau pour lesquels f vaut pratiquement l'unité. Des resultats antérieurs concernant l'oxyde nitreux dans le néopentane à 296 °K ont été réinterprétés; ils donnent $f \approx 10^{-2}$. Pour des solvants à haute mobilité électronique (~10^3 cm²/Vs) la valeur de f est petite. Lorsque cette mobilité électronique décroît, f croît jusqu'à sa valeur maximum qui est l'unité.

Introduction

It has been demonstrated that the kinetics of the reaction of electrons with nitrous oxide in liquid hydrocarbons is influenced by the molecular structure of the solvent (1, 2). The efficiency of the reaction in neopentane (1) appears to be anomalously low. To determine whether the low efficiency correlates with the quasifree behavior of electrons (3, 4), the study has been extended to the liquids methane, krypton, and xenon. Electrons have a larger degree of freeness[1] in these liquids (5–8) than in neopentane (4, 6, 9), as indicated by the mobilities. The present work verifies that the encounter efficiency of the reaction between electrons and nitrous oxide decreases with increasing degree of freeness of the electrons.

Experimental

Materials and Apparatus

The vacuum system was grease free and was evacuated to $< 10^{-6}$ Torr, with baking of appropriate sections, before introducing the substances for sample preparation.

Matheson Ultrapure methane contained 5 p.p.m. oxygen and < 10 p.p.m. carbon dioxide. It was transferred from the cylinder to the vacuum system through a system of valves that was kept above atmospheric pressure and was thoroughly flushed with methane before a sample was collected. Each sample (several cm³) was condensed in a trap, subjected to several trap-to-trap distillations with occasional pumping on the receiver and retaining only the middle fraction each time, then pumped on until half of the remaining liquid evaporated.

Matheson Research Grade krypton (5 p.p.m. xenon, no other detectable impurities) and Linde 99.995% xenon (< 5 p.p.m. nitrogen, < 1 p.p.m. oxygen) were used as received, taking care to prevent the introduction of impurities.

Small samples (0.1–0.2 g) of each gas containing known amounts of nitrous oxide were condensed at 77 °K in 4 mm o.d. Pyrex tubes and sealed off (0.3 cm³). After equilibration at 193 °K for 30 min the colorless and homogeneous solutions were irradiated in a methanol slush bath at 183 °K to a dose of 4×10^{19} eV/g, in a ^{60}Co Gammacell-220. The dose rate was 5×10^{15} eV/g s in methane. Samples were frozen at 77 °K in a stainless steel "bomb" incorporated into the carrier gas flow line of a Hewlett–Packard 5750 gas chromatograph. The helium flow rate was 76 cm³/min. On warming, the sample tube exploded and its contents were swept by the carrier gas onto a 48 ft molecular sieve 5A column at 296 °K. Nitrogen and oxygen were measured by a thermal conductivity detector operated at 280 mA. Calibration of the system was effected using irradiated solutions of nitrous oxide in ethane and relating the nitrogen peak areas to the known $G(N_2)$ values determined by *P.V.T.* measurements and mass spectrometry (2).

[1]It has been customary to distinguish between "quasifree" and "localized" states of electrons in liquids. However, recent work (24) indicates that a continuous variation in electron behavior between "free" and "localized" is possible and one may speak of the "degree of freeness" of the electron.

The g.c. sensitivity of oxygen was shown to be 10% greater than that of nitrogen by injecting samples of air into the gas chromatograph.

Dosimetry

The Fricke dosimeter is suitable for use when the sample does not contain a large concentration of heavy elements ($Z > 16$). It was therefore used to determine the dose rate in methane and nitrous oxide; conversion from system to system was done on the basis of their relative electron densities. Energy absorption by light elements from the photons in a Gammacell occurs nearly exclusively by the Compton process.

In the krypton ($Z = 36$) and xenon ($Z = 54$) samples both photoelectric and Compton absorption were important. The relative contribution of the photoelectric process increases as Z^4 (10).

Gammacell radiation is comprised mainly of photons with energies 1.17 and 1.33 MeV, with a smaller amount of lower energy photons scattered from the shielding into the irradiation chamber. It is difficult to measure the actual energy spectrum of the radiation inside the chamber. The relative contributions of the low and high energy photons were estimated by comparing the induced electrical conductances in cyclohexane and xenon, with and without lead shielding. Similar measurements were made using a d.c. beam of 1.7 MeV peak energy X-rays from the van de Graaff, at a dose rate similar to that in the Gammacell. Dosimetry of the X-ray beam is reported in the adjoining article (11), and is used as the basis for the present calculations.

Measurement of the induced conductances in the unshielded cells was straightforward with both sources. When shielding was used with the van de Graaff, it was a 20 cm × 20 cm annulus of lead 1.4 cm thick. The geometry of the radiation field in the Gammacell and the awkward shape of the conductance cell prevented complete shielding to be accomplished in that source. However, the same shielding was used for xenon and cyclohexane in a given source.

About 0.1% of oxygen was added to the xenon to capture the electrons and reduce space charge effects. The cyclohexane was not deaerated.

The ratio of the unshielded/shielded conductances at low electric field strengths was measured for each substance with the two radiation sources. Only Compton absorption is important in the cyclohexane; both Compton and photoelectric absorption are important in the xenon. The cyclohexane ratio was therefore used as a standard to which the xenon ratio was compared: xenon/cyclohexane = 1.25 in the Gammacell and 1.28 with the van de Graaff. These values are the same within experimental error, which fortuitously allows the van de Graaff dosimetry factors (11) for xenon and krypton to be used for the Gammacell. The relative average absorption coefficients per electron of the medium are: 1.0 for C_6H_{12}, CH_4, N_2O, Fricke solution, LiF; 1.2 for Kr; 1.6 for Xe.

Accurate dosimetry for samples containing heavy elements is difficult to obtain. The total ion yields reported in this and the adjoining article agree within < 10%, which may be taken as the uncertainty in the dosimetry for xenon and krypton. That for methane and nitrous oxide is ~1%.

TABLE 1. Liquid and molecular (gas phase) properties

Liquid	T (°K)	ε	d (g/cm³)	α (Å³)	I.P. (eV)[h]

Liquid and Molecular (Gas Phase) Properties

The dielectric constants ε of the liquids were obtained from refs. 12 and 13 or calculated from the Clausius–Mosotti equation (12). Densities d were obtained from refs. 14–17. The values are listed in Table 1, along with those for the gas phase molecular polarizabilities α (15, 18) and ionization potentials I.P. (19).

Results

Nitrogen Yields

The yields of nitrogen from the γ radiolysis of solutions of nitrous oxide in methane, krypton, and xenon at 183 °K are shown in Fig. 1. Three xenon solutions were irradiated at 193 °K to be

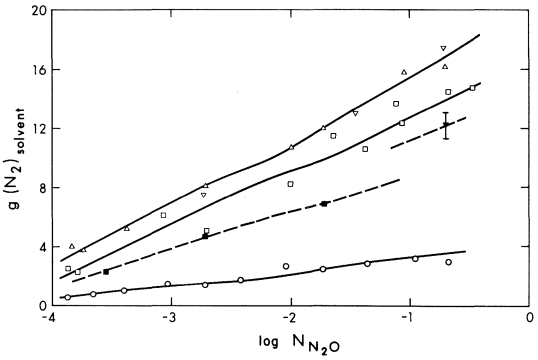

FIG. 1. Yields of nitrogen from nitrous oxide scavenging species in methane (○), krypton (□), and xenon (△) at 183 °K. N_{N_2O} is the mole fraction of N_2O. Other reaction conditions are xenon at 193 °K (▽); xenon containing 0.8–7 mol % propane at 193 °K (▼); krypton containing 2.7 mol % propane at 183 °K (■). All lines were calculated (see text); the broken lines refer to the samples containing propane and correspond simply 0.71 × the yields from samples without propane.

certain that nitrous oxide (triple point 182 °K) was all in solution; the results were the same within experimental error at the two temperatures (Fig. 1). The yields were corrected for the direct radiolysis of nitrous oxide and refer to the energy absorbed initially in the solvent. The nitrogen yield from the direct radiolysis of nitrous oxide in methane solutions was assumed to equal that from nitrous oxide containing propane, $g(N_2)_{N_2O} = 11$ (Table 2); that in krypton and xenon solutions was assumed to equal the yield in pure nitrous oxide, $g(N_2)_{N_2O} = 13$ (20, 21). The largest correction in the xenon solutions was 0.3 g units. The net yield $g(N_2)_{solvent}$ resulted from the scavenging by nitrous oxide of solvent radiolysis intermediates.

In all three liquids $g(N_2)_{solvent}$ increased steadily as the mole fraction of scavenger was increased from 10^{-4} to 0.2. The yields in xenon and krypton were much larger than those in methane.

Oxygen Yields

The oxygen yields from solutions of nitrous oxide in krypton and xenon are displayed in Fig. 2. The yields were corrected for the direct radiolysis of nitrous oxide and refer only to the scavenging of species generated by the radiolysis of the solvent. The shapes of the curves are similar to those in Fig. 1. The ratio of the oxygen to the nitrogen yield was constant over the entire concentration range, within experimental error, and equalled 0.17 ± 0.01 in both krypton and xenon; the corresponding ratio for pure nitrous oxide, averaged over the three studies reported in Table 2, is 0.21 ± 0.01.

Oxygen was not formed in the methane solutions.

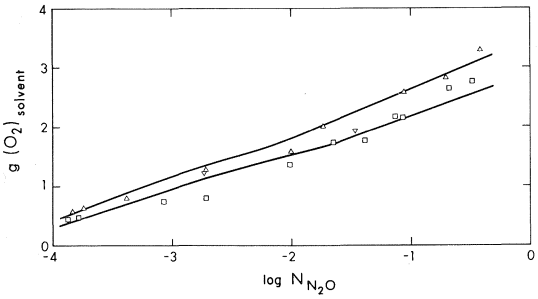

FIG. 2. Yields of oxygen from nitrous oxide scavenging species in krypton (□) and xenon (△) at 183 °K, plotted against the mol fraction N_{N_2O}. Xenon solutions were also measured at 193 °K (▽). The lines were calculated (see text).

Addition of Propane to Krypton and Xenon Solutions

The fact that the nitrogen and oxygen yields were so much greater from the xenon and krypton systems than from the methane solutions seemed to be related to the chemical reactivity of the hydrocarbon. Propane, which is more reactive than methane, was therefore added to the xenon and krypton systems to observe its effect.

To an initially 20% N_2O/80% Xe mixture was added 0.8, 2.4, and 6.7 mol% of propane. The three solutions gave the same results, within experimental error: $g(N_2)_{Xe} = 12.2 \pm 0.9$ and $g(O_2) = 0.0$. In the absence of propane the yields were $g(N_2)_{Xe} = 17$ and $g(O_2)_{Xe} = 3.0$. Thus a small amount of hydrocarbon eliminated the oxygen and reduced the nitrogen yield to a plateau value 0.7 times the original value.

Since 2% of propane was more than sufficient to reduce $g(N_2)$ and $g(O_2)$ to plateau values in a highly concentrated N_2O/Xe solution, 2.7% of propane was added to three low concentration N_2O/Kr solutions. As in xenon, the oxygen yield was eliminated and nitrogen was reduced to 0.7 of the yield at the corresponding N_2O concentration in the absence of propane.

Addition of propane to liquid nitrous oxide reduced the oxygen yield to zero but the nitrogen yield decreased only to 0.9 of the value for pure nitrous oxide (Table 2).

Discussion

Kinetic Analysis

The values of $g(N_2)_{max}$ in xenon and krypton containing propane were estimated to be 14 and 13, respectively (see later discussion), which agree with the total ionization yields estimated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by the charge clearing technique, 13.7 and 13.0, respectively (11). It therefore appears that one nitrogen molecule results from the scavenging of one electron in the hydrocarbon containing systems.

[1] $$e^- + N_2O \rightarrow N_2O^-$$

[2] $$N_2O^- + \ldots \rightarrow N_2 + \ldots$$

The nitrogen yields from the methane solutions are also consistent with the suggestion that one electron scavenged leads to the formation of one nitrogen molecule. It will be assumed that $g(N_2)_{max} = g(\text{ionization}) = 4$ in methane (5).

In the absence of hydrocarbon in xenon and krypton $g(N_2)_{solvent}/g(e^-\text{ scavenged}) = 1.4$. Speculation about the mechanism is not presented here.

Details of the kinetics model were published earlier (22, 23), but a brief outline is given here for convenience.

In pure liquid M the relevant reactions are:

[3] $$M \rightsquigarrow [M^+ + e^-]$$

[4] $$[M^+ + M] \rightarrow [N^+ + P]$$

[5] $$[N^+ + e^-] \rightarrow \text{geminate neutralization}$$

[6] $$[N^+ + e^-] \rightarrow N^+ + e^- \text{ (free ions)}$$

[7] $$N^+ + e^- \rightarrow \text{random neutralization}$$

Square brackets about reactants or products indicate that the enclosed species are in a spur. The ion N^+ is probably CH_5^+ in methane, Kr_2^+ in krypton, and Xe_2^+ in xenon.

In the presence of electron scavenger S:

[8] $$e^- + S \rightarrow S^-$$

[9] $$S^- + N^+ \rightarrow \text{products}$$

[10] $$[e^- + S] \rightarrow [S^-]$$

[11] $$[S^- + N^+] \rightarrow \text{products}$$

Reactions 7–9 involve only free ions and obey homogeneous kinetics: reactions 5, 6, and 10 are described by nonhomogeneous kinetics.

The free ion yield g_{fi} is given by

[12] $$g_{fi} = g(\text{ionization}) \times \int_0^\infty F(y) \exp(-\xi^2/\varepsilon kTy)\, dy$$

where $F(y)dy$ is the fraction of thermalized electron–ion pairs that have initial intrapair distances between y and $y + dy$, $\xi = 4.8 \times 10^{-10}$ e.s.u., ε is the dielectric constant of the medium, k is Boltzmann's constant, and T is the absolute temperature.

The distribution $F(y)$ in systems that have large free ion yields, such as the present ones, is suitably approximated by a Gaussian function (24)

[13] $$F(y) = (4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where b is the dispersion parameter. Furthermore, in such systems the product of b and the liquid density d has been found to be independent of temperature (24) and will be assumed to be so in the present solvents.

In methane at 120 °K $bd = 2.1 \times 10^{-6}$ g/cm^2 (5), so at 183 °K one obtains $b = 2.1 \times 10^{-6}/0.26 = 8.1 \times 10^{-6}$ cm. Using $g(\text{ionization}) = 4$ one obtains $g_{fi} = 1.8$ from eqs. 12 and 13. Thus the curve for methane in Fig. 1 should be governed by homogeneous kinetics between $g(N_2) = 0$ and 1.8; that at $g(N_2) > 1.8$ should be governed by nonhomogeneous kinetics.

Homogeneous Kinetics

A peculiarity is introduced into the kinetics by the fact that the mobility of electrons (6–8) is about six orders of magnitude greater than those of the positive and negative ions in these liquids (6, 25). Thus $k_7 \gg k_9$, and the steady state concentration of ions in the absence of scavenger ($\propto k_7^{-1/2}$) is about three orders of magnitude smaller than that when all the free ion electrons have been scavenged ($\propto k_9^{-1/2}$). At all practical scavenger concentrations greater than zero, one may write $[e^-] \ll [S^-] \approx [N^+]$. With this approximation steady state treatment gives:

[14] $$g(N_2)_{fi} = g_{fi}/[1 + ([N^+]/a)]$$

[15] $$[N^+]^3 + a[N^+]^2 = ab$$

[16] $$a = k_8[N_2O]/k_7$$

[17] $$b = Rg_{fi}/k_9$$

where R is the dose rate in units appropriate to those of g_{fi} and k_9. The cubic equation 15 was solved by trial and error at each nitrous oxide concentration, using a Hewlett–Packard HP-35 calculator.

In the present liquids the electron mobilities are $\sim 10^3$ cm^2/V s (6–8) and the positive and negative ion mobilities are $\sim 10^{-3}$ cm^2/V s (6, 25). Reactions 7 and 9 are both approximately diffusion controlled, so $k_7 \approx 10^{18}$ l/mol s and $k_9 \approx 10^{12}$ l/mol s (6). At the present dose rate in methane $Rg_{fi} = 4 \times 10^{-8}$ mol/l s. Fitting eq.

14 to the lower part of the methane curve in Fig. 1 gave $k_8 = 3 \times 10^{10}$ l/mol s, and the calculated curve is that shown between 1×10^{-4} and 4×10^{-3} mole fraction nitrous oxide.

The diffusion controlled value of k_8 would have been $\sim 4\pi(3 \times 10^{-8}$ cm) $(10^3$ cm^2/V s) (0.016 V) $(6 \times 10^{20}) \approx 3 \times 10^{15}$ l/mol s. Thus the encounter efficiency of reaction 8 is $\sim 10^{-5}$.

Nonhomogeneous Kinetics

The relevant equations are (23)

$$[18] \quad g(N_2) = g(N_2)_{fi} + g_{gn} \int_0^\infty F(y) \times [1 - \exp(-\xi^2/\varepsilon kTy)][1 - (1 - fN_s)^{\beta\nu}]\, dy$$

where $g_{gn} = [g(\text{ionization}) - g_{fi}]$, f is the encounter efficiency of reaction 10 and is taken equal to that of reaction 8, N_s is the mole fraction of scavenger, β is an adjustable parameter, and ν is given by

$$[19] \qquad \nu = 1.4 \times 10^7 \varepsilon y^3 \quad \text{cm}^2/\text{V}$$

where y is in cm.

The methane curve at $N_{N_2O} > 4 \times 10^{-3}$ in Fig. 1 was calculated from eq. 18 using $f = 10^{-5}$ and the best fit value of β was 2×10^{14} V/cm^2.

The krypton and xenon systems were similarly analyzed and the results are summarized in Table 3. The calculated curves are shown in Fig. 1.

In all three solvents the encounter efficiency of the electron reaction with nitrous oxide was very low, $\sim 10^{-5}$, and the values of β were in the vicinity of those that had been obtained for compounds such as cyclohexane and methanol (23, 26, and Table 3).

Attempts were also made to fit the methane results by arbitrarily taking $f = 10^{-6}, 10^{-5}, 10^{-4}$, etc., and varying β to get a best value in each case. A good fit could not be obtained with $f = 10^{-6}$, but for $f \geqslant 10^{-5}$ the same best-fit curve was obtained with values of β such that βf = constant. The same was true of the krypton and xenon systems. Thus, analysis of only the nonhomogeneous portion of the results furnishes only the value of βf. One needs separate information about either β or f. In the present three solvents the values of f were obtained from the homogeneous kinetics portion of the results.

It appears that $\beta \approx 10^{13}$–10^{14} V/cm^2 in a wide variety of systems, from krypton to methanol (Table 3). Earlier work on neopentane involved the assumption that $f = 1$ in that liquid, and the resulting low value $\beta = (5$–$8) \times 10^{11}$ V/cm^2 (1, 23) was not understood. One may now assume that β would be normal in neopentane, with $f \approx 10^{-2}$ (Table 3).

Values of β in the vicinity of 10^{14} V/cm^2 are readily understood in terms of the diffusion model (22).

The encounter efficiency of the reaction between electrons and nitrous oxide is very low in liquids in which the electron mobility is very high. As the mobility decreases f increases to its maximum value of unity (Table 3). This behavior is understandable in terms of the dependence of reaction probability on the electron–reactant interaction time per encounter.

Part of the decrease in f from 10^{-2} in neopen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tane at 296 °K to 10^{-5} in methane at 183 °K is probably due to a temperature dependence of $f(e^- + N_2O)$.

Oxygen Yields

Oxygen was not a product in the systems that contained an organic compound.

The curves in Fig. 2 were obtained by multiplying the upper two calculated curves in Fig. 1 by 0.17. Agreement between calculated and measured yields is satisfactory, which indicates that the mechanism following the scavenging of intermediates by nitrous oxide is constant over a wide concentration range.

We are grateful to J.-P. Dodelet for doing many of the calculations. This work was supported by the National National Research Council of Canada.

Reactions of Hot Hydrogen Atoms in Gaseous Hydrogen Chloride and Hydrogen Bromide

D. K. JARDINE,[1] N. M. BALLASH, AND D. A. ARMSTRONG
Department of Chemistry, The University of Calgary, Calgary, Alberta
Received August 18, 1972

Hydrogen atoms of initial kinetic energy $E_0 = 1.15$ or 2.1 eV were produced photolytically and their reactions with HCl were studied at 300 °K using bromine as a scavenger. The fraction, F_H, undergoing reaction 2 while hot was found to be 0.79 ± 0.02 and 0.55 ± 0.02 for $E_0 = 2.1$ and 1.15 eV, respectively.

[2] $$H + HCl \rightarrow H_2 + Cl$$

For 2.1 eV atoms a similar result was obtained at 200 °K with chlorine as scavenger. On the addition of carbon dioxide as a moderator F_H decreased in a manner consistent with the kinetic theory of hot atom reactions. Comparison of the present results with previous work on the D + DCl abstraction reaction showed that the cross section of the latter is probably 20 to 50% higher than that of H + HCl. The cross section of reaction 2 appears to increase with energy over most of the 0.1 to 1.1 eV range and possibly also above it. Its average magnitude over this energy region was estimated to be $\lesssim 0.35$ Å^2.

For atoms of $E_0 = 1.15$ eV reacting in HBr F_H is close to unity. The threshold of reaction 3′

[3′] $$H + Br_2 \rightarrow HBr + Br$$

is near zero energy and its cross section rises rapidly, becoming $\gtrsim 7$ Å^2 in the thermal region for 300 °K.

Des atomes d'hydrogène d'énergie cinétique initiale $E_0 = 1.15$ ou 2.1 eV ont été produits photolytiquement et leurs réactions avec HCl ont été étudiées à 300 °K en utilisant du brome comme fixateur. La fraction, F_H, impliquée dans la réaction 2 lorsque chaude s'est révélée être 0.79 ± 0.02 et 0.55 ± 0.02 pour $E_0 = 2.1$ et 1.15 eV, respectivement.

[2] $$H + HCl \rightarrow H_2 + Cl$$

Pour les atomes possédant $E_0 = 2.1$ eV, un résultat semblable a été obtenu à 200 °K avec du chlore comme fixateur. En additionnant du dioxyde de carbone comme modérateur, F_H a diminué en accordance avec la théorie cinétique des réactions impliquant des atomes chauds. La comparaison des résultats obtenus avec des travaux antérieurs sur la réaction d'abstraction D + DCl a montré que la coupe transversale de cette dernière est probablement plus élevé de 20 à 50 pour cent que celle de H + HCl. La coupe transversale de la réaction 2 semble s'accroître avec l'énergie tout au long de l'intervalle de 0.1 à 1.1 eV et probablement aussi au-dessus de celui-ci. Son amplitude moyenne pour cette région énergétique a été evaluée à $\lesssim 0.35$ Å^2.

Pour les atomes ayant $E_0 = 1.15$ eV et réagissant dans HBr, F_H est proche de l'unité. Le début de la réaction 3′ se situe

[3′] $$H + Br_2 \rightarrow HBr + Br$$

près de l'énergie nulle et sa coupe transversale augmente rapidement pour devenir $\gtrsim 7$ Å^2 dans la région thermique correspondant à 300 °K. [Traduit par le journal]

Can. J. Chem., **51**, 656 (1973)

Introduction

Atoms or radicals with excess translational energy are commonly referred to as "hot". They may be formed by nuclear recoil reactions, when their initial energy is in the 10^2 to 10^4 eV range (1, 2), or with lesser energy (0.5 to 5 eV) by the dissociation of molecules in repulsive excited states (3, 4). Since the cross sections for electronic transitions to repulsive states are often large in small molecules (5, 6), hot atoms and radicals are frequently encountered as primary species in photochemistry and radiation chemistry. However, in spite of this, the magnitudes and energy dependences of the cross sections for their reactions have only been studied in a relatively few systems. This publication is concerned with the reactions of hot *H* atoms with gaseous HCl and HBr. The experiments consisted of photolysing HCl, HBr, or HCl–HBr

mixtures in the presence of chlorine or bromine which competed very efficiently for thermalyzed atoms and less efficiently for hot atoms. By studying the hydrogen yields as a function of scavenger concentration, it was possible to determine the fraction of atoms which reacted hot and to estimate relative cross sections and some absolute cross sections. The effects of changing the initial energy of the atoms and of moderating them with carbon dioxide were also investigated. In addition to providing information which is vital for a more complete understanding of the mechanism of radiolysis of HCl, the results add to the present body of knowledge of hot hydrogen atom reactions and can be compared with those of other recent studies, including an investigation of the behavior of D atoms in DCl under similar conditions (7).

Experimental

Reagents

Hydrogen chloride, chlorine, and carbon dioxide were all obtained from the Matheson Company. Hydrogen chloride was purified as previously described to remove HBr, water, halogens, and other impurities (8, 9). After passage over KOH pellets to remove HCl and other acidic impurities, chlorine was carefully degassed and further purified by sublimation at −125 °C. Carbon dioxide was simply degassed and sublimed before use and reagent grade bromine was treated similarly.

Apparatus and Procedure

After purification the reagents were all stored at liquid nitrogen temperature in storage tubes attached to a mercury-free vacuum line. Samples were prepared for photolysis by measuring the desired pressure of each reagent in a standard volume using a diaphragm gauge. The photolysis cells were 6 cm long and 4.6 cm in diameter with the end windows of Suprasil and the cylindrical walls of quartz. Attached to the cells were a cold trap and a magnetically driven stirring vane which ensured complete mixing of the reagents. The Hanovia SC2537 low pressure mercury lamp for HCl photolyses was constructed with a Suprasil envelope. It was situated about 13 cm from the end window of the photolysis cell. Both were in a light proof box which could be purged with nitrogen, and the cell compartment could be thermostated at different temperatures. The lamp was allowed to stabilize for some 30 min before the shutter between it and the cell was removed to start a photolysis. In preliminary experiments the lamp was monitored continuously during each run, using a platinum photocell. Since the output was found to be constant over the short periods (1 to 10 min) involved, this procedure was abandoned and the lamp was simply checked for long term variations in intensity by measuring the hydrogen yield from HCl at a standard pressure. While a deterioration in the intensity of the 1849 Å line occurred over the lifetime of the lamps, examination of their emission spectra with a McPherson Model 218 vacuum u.v. spectrometer showed that this remained the only line of measurable intensity at wavelengths below that of the strong line at 2537 Å. For the photolysis of HCl–HBr mixtures a standard SC2537 lamp with a quartz envelope was used. This did not produce any hydrogen from HCl alone and showed no detectable emission at 1849 Å.

Photolyses with no scavenger in the cell were performed before and after each series of experiments with added scavenger. Yields in the presence of scavenger at a given concentration were determined relative to the yield from pure HCl at the same pressure as in the HCl–scavenger mixture. For 1849 Å photolyses HCl pressures were always such that over 99% of the incident light intensity was absorbed ($\varepsilon \simeq 80\ M^{-1}\ cm^{-1}$ at 1849 Å (10, 11)). For the 2537 Å photolysis the fraction of light absorbed by HBr is very small and proportional to the HBr concentration since $\varepsilon = 1.0\ M^{-1}\ cm^{-1}$ (12). A correction was made for absorption by bromine.

At the end of each photolysis the hydrogen halide, carbon dioxide, and halogen were condensed at liquid nitrogen temperature in the cold trap attached to the photolysis cell. The hydrogen was then pumped into an analysis line using an oil diffusion pump followed by a cold trap and toepler pump. The amount of hydrogen was determined by techniques already described (8).

Results

Since there is evidence for complex formation between HCl and polarizable molecules (13) we investigated the spectrum of bromine and HCl–bromine mixtures with a Cary Model 15 Spectrophotometer to determine whether such complexes were formed and if they absorbed between 1800 and 2000 Å, this being the region of absorption of the Br_4 complex (14). It was shown that any absorption at 1849 Å by an HCl–Br_2 complex or by Br_2 itself at the pressures used in this study was negligible compared to the absorption by HCl. The absorption by chlorine at this wavelength was also shown to be negligible. The extinction coefficient of bromine at 2537 Å was found to be $1.8\ M^{-1}\ cm^{-1}$ at the pressures used.

The upper line in Fig. 1 shows a plot of hydrogen concentration *vs.* photolysis time for a sample of initially pure hydrogen chloride. At sufficiently long photolysis times these plots tend to bend over toward a limiting hydrogen concentration. As illustrated by the lower curve this occurs at much shorter photolysis times at high chlorine concentrations. Since the small amount of chlorine formed during photolysis does not change $[Cl_2]$ significantly, the tendency to a limiting hydrogen concentration cannot be caused by an increasing consumption of H atoms in the reaction

$$H + Cl_2 \rightarrow HCl + Cl$$

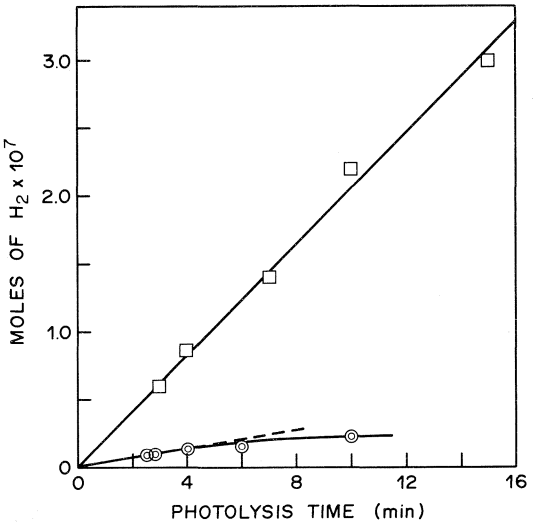

FIG. 1. Yield–time plots for the 1849 Å photolysis of HCl at 300 °K: □, initially pure HCl; ◎, HCl with added CO_2 and Cl_2 such that $[CO_2]/[HCl] = 5$, and $[Cl_2]/[HCl] = 0.05$.

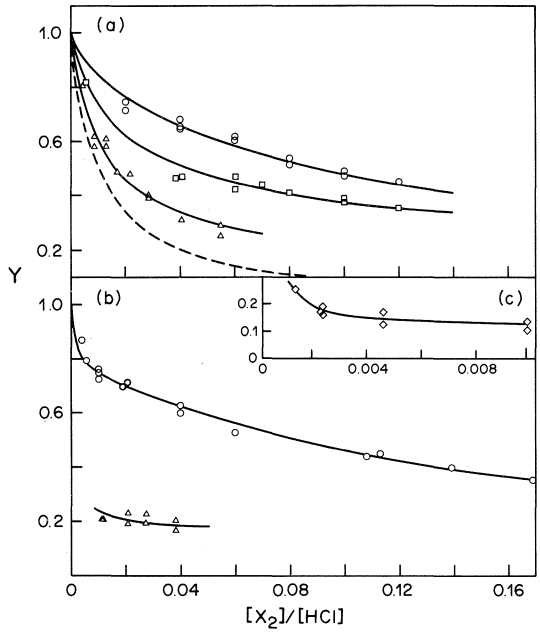

FIG. 2. Effect of scavengers on hydrogen yields from the 1849 Å photolysis of HCl in the presence and absence of carbon dioxide moderator: (*a*) chlorine as scavenger: ○, HCl only at 200 °K; □ and △, HCl + CO_2 at 300 °K with $[CO_2]/[HCl] = 1.00 \pm 0.04$ and 5.00 ± 0.05, respectively. The curves through these data are calculated (see text); the dashed line is calculated from ref. 23 and shows the yields expected for thermal atoms; (*b*) bromine as scavenger at 300 °K: ○, HCl only; △, $[HCl]/[CO_2] = 5.0 \pm 0.1$; (*c*) bromine as scavenger at 300 °K: $[HCl]/[CO_2] = 8.2 \pm 0.1$.

It must therefore be attributed to

$$Cl + H_2 \rightarrow HCl + Cl$$

which will increase in importance as $[H_2]$ builds up (9).

All hydrogen yields were obtained from the linear initial regions of plots such as those in Fig. 1. Hydrogen yields from hydrogen chloride – scavenger mixtures relative to those in standard runs with HCl alone (or HCl and CO_2, see below) are designated by the symbol Y and plotted as a function of scavenger concentration in Fig. 2(*a*) for chlorine and 2(*b*) for bromine. Results are shown for different moderator:HCl ratios. The relative yields were found to be reproducible to within $\pm 5\%$ or better. Figure 2(*c*) shows the effect of very low concentrations of bromine on hydrogen yields from an HCl–CO_2 mixture with a $[CO_2]/[HCl]$ ratio of 8.2.

Yields from the 2537 Å photolysis of HCl–HBr mixtures of fixed composition and of HBr were determined in the presence of varying concentrations of bromine. They were also expressed as relative yields, taking the yield in the absence of scavenger as a standard. They are plotted as a function of bromine concentration in Fig. 3 in accord with the mathematical analysis presented below.

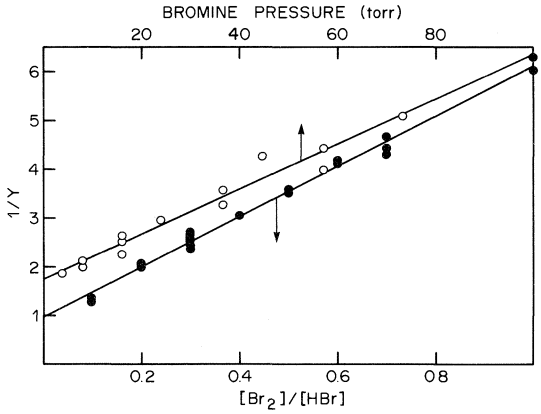

FIG. 3. Reciprocal plots of relative hydrogen yields from the 2537 Å photolysis of pure HBr (●), and a 0.98:0.02 HCl:HBr mixture (○). (Plotted in accord with expressions vi and vii, respectively; see text.)

Discussion

Mechanism

The vacuum u.v. spectrum of HCl has been studied by Romand (10) and Myer and Samson (11). Absorption begins at 2200 Å and only the 1849 Å line emitted by the SC2537 Å lamps with Suprasil windows will be absorbed. As explained elsewhere this leads to photodissociation with an excess kinetic energy of 2.1 eV going to the hydrogen atoms (7, 15)

[1] $$HCl + h\nu \rightarrow \underline{H}(^2S_{1/2}) + Cl(^2P_{3/2})$$

The photolysis of HBr with 2537 Å mercury radiation is similar, giving $\underline{H}$ atoms with an average kinetic energy of 1.15 eV (16, 17). Broadening of these energies by ~0.05 eV in both cases results from the distribution of rotational (and translational) energies of the dissociating molecules (16). The production of $X(^2P_{1/2})$ atoms is assumed to be negligible for both HCl and HBr (18).

The strong 2537 Å line from the SC2537 lamps will also be absorbed by chlorine and bromine when they are added as scavengers. This causes dissociation (5). Both of the resulting halogen atoms (X)

$$X_2 + h\nu \rightarrow X(^2P_{3/2}) + X(^2P_{1/2}) \text{ or } (^2P_{3/2})$$

are hot and the $^2P_{1/2}$ atom is also electronically excited, giving it a total excess energy of 1.26 and 1.69 eV for Cl_2 and Br_2, respectively. In both instances this is less than the threshold energy of the reaction

$$X + XH \rightarrow X_2 + H,$$

which must exceed the value of ΔE calculated from bond dissociation energies (ΔE = 1.95 eV for X = Cl and 1.80 eV for X = Br (19)). Hydrogen atom formation by this process should not therefore compete with the recombination of the halogen atoms (see below).

For the case of the HCl photolysis at 1849 Å the threshold energies for collisionally induced dissociation of HCl and Cl_2

$$\underline{H} + HCl \rightarrow 2H + Cl \qquad \Delta E = 4.43 \text{ eV}$$

$$\underline{H} + Cl_2 \rightarrow H + 2Cl \qquad \Delta E = 2.48 \text{ eV}$$

must each exceed the corresponding ΔE (19). They are both larger than the initial energy of the $\underline{H}$ atoms and these reactions may be neglected. Thus, as has been pointed out in previous publications dealing with the photolysis of deuterium chloride (7) and the radiolysis of hydrogen chloride (9, 15), the effect of chlorine may be interpreted in terms of the following reactions

[2] $$\underline{H} + HCl \rightarrow H_2 + Cl$$

[2] $$H + HCl \rightarrow H_2 + Cl$$

[3] $$\underline{H} + Cl_2 \rightarrow HCl + Cl$$

[3] $$H + Cl_2 \rightarrow HCl + Cl$$

[4] $$\underline{H} + M \rightarrow H + M$$

[5] $$Cl + H_2 \rightarrow HCl + H$$

[6] $$H + Cl + M \rightarrow HCl + M$$

[7] $$H + H + M \rightarrow H_2 + M$$

[8] $$Cl + Cl + M \rightarrow Cl_2 + M$$

Reaction 4 is composite in the sense that M can be hydrogen halide, carbon dioxide, or halogen. Unlike reactions 2 and 3 it occurs many times during the lifetime of an $\underline{H}$ atom, reducing the excess translational energy in small decrements until it falls below the minimum energy E_M for reaction 2. The atom is then designated as H. Shizgal and Karplus (20) have calculated a threshold energy of 0.113 eV for reaction 2 by fitting the experimental data of Westenberg and de Haas (21) for the thermal reaction to a line-of-centers model and this appears to be the best value available for E_M.[2]

In the presence of bromine as a scavenger reactions 3 and 3 will be replaced by the analogous reactions of Br_2. Also the ΔE (19) for reaction 9′

[9′] $$\underline{H} + Br_2 \rightarrow H + 2Br \qquad \Delta E = 1.97 \text{ eV}$$

shows that it may be possible with 2.1 eV $\underline{H}$ atoms. However, it would be manifested in terms of the efficiency of bromine as a moderator and would in fact be included in the bromine counterpart of reaction 4. Since reaction 10

[2]For reaction with a stationary HCl molecule momentum conservation actually requires that the minimum laboratory energy of $\underline{H}$ be ~2.8% higher than the reaction threshold energy (4). However, this is negligible when compared to the uncertainty in E_M arising from: (*a*) the fact that the cross section may rise more steeply than predicted by the line of centers model as has in fact been observed for the H + *n*-C_4D_{10} → HD + C_4D_9 abstraction, and (*b*) the contribution to the collision energy from the Maxwellian energy distribution of the target molecules. While (*a*) would raise the threshold energy, the effect of (*b*) would be compensatory, allowing atoms of lower energy to react. Though uncertain, E_M = 0.113 eV is therefore at present a reasonable choice.

[10] $Cl + Br_2 \rightarrow ClBr + Br$

will convert Cl atoms to Br atoms (22), reactions 5, 6, and 8 will therefore be almost entirely eliminated in favor of their bromine atom counterparts. To avoid an unnecessary proliferation of reaction numbers we shall use the same ones for analogous bromine and chlorine reactions, inserting a prime next to those which refer to bromine.

Since $[H_2]$ is always much smaller than [HCl], and $k_{5'} \ll k_{2'}$ and $k_5 \ll k_2$ (19), the concentration of H atoms will be much less than that of the halogen atoms. Hence, reactions 6 and 7 can be neglected. Under these circumstances the steady state approximation gives

[i] $$\frac{d[H_2]}{dt} = \phi I_{abs}(F_H + F_M f_t) - \text{rate of reaction 5} \times (1 - f_t)$$

The symbols F_H, F_M, and f_t are identified as follows, the rate constants being those for the case of chlorine as scavenger:

[ii] $$F_H = \left\{\begin{matrix}\text{fraction of } \underline{H} \\ \text{reacting with HCl} \\ \text{while hot}\end{matrix}\right\} = \left(1 + \frac{\sum_M \underline{k}_4[M]}{\underline{k}_2[HCl]} + \frac{\underline{k}_3[Cl_2]}{\underline{k}_2[HCl]}\right)^{-1}$$

[iii] $$F_M = \left\{\begin{matrix}\text{fraction of } \underline{H} \text{ moderated} \\ \text{to energies below the} \\ \text{threshold of reaction 2}\end{matrix}\right\} = \frac{\sum_M \underline{k}_4[M]}{\underline{k}_2[HCl]}\left(1 + \frac{\sum_M \underline{k}_4[M]}{\underline{k}_2[HCl]} + \frac{\underline{k}_3[Cl_2]}{\underline{k}_2[HCl]}\right)^{-1}$$

[iv] $$f_t = \left\{\begin{matrix}\text{fraction of} \\ \text{moderated H} \\ \text{reacting with HCl}\end{matrix}\right\} = \left(1 + \frac{k_3[Cl_2]}{k_2[HCl]}\right)^{-1}$$

For the case of the 2537 Å photolysis of HBr–HCl mixtures 1.15 eV atoms are produced in reaction 1′

[1′] $HBr + h\nu \rightarrow \underline{H} + Br(^2P_{3/2})$

and the following two reactions must be included in the mechanisms and accounted for in expressions *ii*, *iii*, and *iv*.

[2′] $\underline{H} + HBr \rightarrow H_2 + Br$

[2′] $H + HBr \rightarrow H_2 + Br$

Otherwise the mechanism and analysis of data are the same as for HCl.

Reaction 5 is the major reason for the approach to limiting hydrogen concentrations and it is clearly negligible in the linear initial region of the concentration:time plots (see Fig. 1) where our yields were measured. Thus, expression *i* becomes simply $d[H_2]/dt = \phi I_{abs}(F_H + F_M f_t)$ and the hydrogen yield in the presence of the scavenger relative to that in its absence may be written

[v] $$Y = F_H + F_M f_t$$

Expression v has a complex dependence on the halogen concentration and cannot be used without further simplification, the usual one being $F_M f_t = 0$.

Analysis

HCl and Scavengers Only

Assuming $F_M f_t = 0$ (*i.e.* k_3/k_2 equal to infinity), expression v simplifies to $Y = F_H$. Inverting and substituting proper terms for F_H from expression ii one has for the chlorine case

[vi] $$\frac{1}{Y} = 1 + \frac{k_4^{HCl}}{k_2} + \frac{(k_4^{Cl_2} + k_3)[Cl_2]}{k_2[HCl]}$$

where superscripts are used to identify the molecules to which each $\underline{k}_4$ refers. This is identical to the expression used in ref. 7 for the analysis of $\underline{D}$ atom reactions in DCl. Figure 4 shows plots of $1/Y$ *vs.* $[Br_2]/[HCl]$ and $[Cl_2]/[HCl]$. The slopes $((\underline{k}_4^{X_2} + \underline{k}_3)/\underline{k}_2$, X = Cl or Br) and intercepts $(1 + \underline{k}_4^{HCl}/\underline{k}_2)$ are presented in Table 1.

In practice k_3/k_2 (and $k_{3'}/k_2$) are not infinite. Their magnitudes will depend on the mean energy of the moderated atoms, reaching maximum values in completely thermalized systems. Figure 2(*c*) shows that for a carbon dioxide moderated

§Corrected from 1.76 for the effect of HBr.

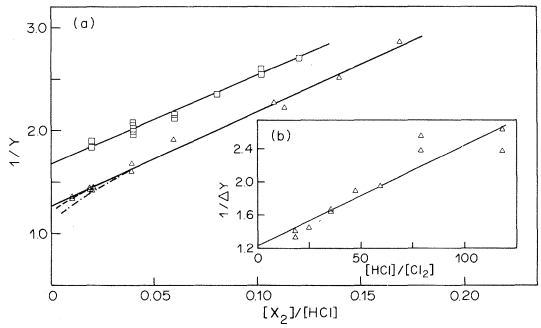

FIG. 4. Reciprocal plots of relative hydrogen yields from the 1849 Å photolysis of HCl: (*a*) □, HCl at 200 °K with Cl_2 as scavenger; △, HCl at 300 °K with Br_2 as scavenger; (*b*) $[CO_2]/[HCl] = 5.00 \pm 0.05$ mixture at 300 °K with Cl_2 as scavenger.

system with $[CO_2]/[HCl] = 8.2$, 80% of all hydrogen atoms were scavenged at $[Br_2]/[HCl] = 2.5 \times 10^{-3}$, whence it can be shown that $k_{3'}/k_2 \geq 1600$ for thermal H at 300 °K. To determine the effects of finite $k_{3'}/k_2$ ratios in the region of 1600 or less, values of $1/Y$ were calculated from expression v using the appropriate $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_2$ and $1 + \underline{k}_4^{HCl}/\underline{k}_2$ from bromine from Table 1. The dashed and dot-dashed curves in Fig. 4*a* demonstrate the curvature[3] obtained taking $k_{3'}/k_2 = 1600$ and 100, respectively. Over the $[Br_2]/[HCl]$ range 0.01 to 0.05 the experimental points show a better fit to the dashed curve (or the straight line) than to the dot-dashed curve, implying that $k_{3'}/k_2$ is much greater than 100 and probably close to 1600.

It is convenient to note here that for thermal H $k_2 = 1.11 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1} at 300 °K (21) and therefore with $k_{3'}/k_2 > 1600$, $k_{3'}$ must be $> 1.8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. Taking a value of zero for the activation energy it follows from the collision theory expression $k = \sigma_{AB}(8kT/\pi\mu)^{1/2} \exp(-E/RT)$ (19) that the cross section of reaction 3′ in the thermal region must be $\gtrsim 7$ Å^2.

The chlorine data, which are displaced upward by 0.5 on the ordinate scale in Fig. 4(*a*), are less extensive, but the linearity is good showing that, as for bromine, k_3/k_2 is at least an order of magnitude larger than $(\underline{k}_4^{Cl_2} + \underline{k}_3)/\underline{k}_2$. However, presently available data show that E_3 (= 1700 to 2200 cal mol^{-1} (15)) is much larger than $E_{3'}$ and the thermal rate constant ratio for k_3/k_2 at 200 °K is known (15, 23) to be only 340 ± 40. Thus the maximum value of k_3/k_2 is substantially smaller than $k_{3'}/k_2$ and chlorine will not be as effective a scavenger of H as bromine. The fact that the chlorine results give a smaller value of $1 + \underline{k}_4^{HCl}/\underline{k}_2$ than the bromine data (1.17 as opposed to 1.26, see Table 1) may in part be due to this.[3] However, the discrepancy lies within the combined experimental uncertainty of the two measurements. The mean value of F_H for 2.1 eV $\underline{H}$ in pure HCl calculated from the two results, 0.82 ± 0.04, is relatively large, confirming an earlier conclusion that reactions of hot hydrogen atoms would be important in the HCl system (9).

HBr and HCl–HBr Mixtures

The lower line in Fig. 3 shows hydrogen yields from the 2537 Å photolysis of HBr plotted as a function of $[Br_2]/[HBr]$ in accordance with

[3]Actually in addition to causing curvature at low $[X_2]/[HCl]$ values of $\underline{k}_3/\underline{k}_2$ less than 1600 cause a downward shift in the linear portion and this has not been shown. For $\underline{k}_3/\underline{k}_2 = 100$ it amounts to a shift of approximately 0.06 on the ordinate scale.

expression vi. In agreement with Fass' data (17) the intercept ($= 0.97 \pm 0.04$) is essentially unity, showing that in HBr the analysis cannot distinguish between atoms which react hot and after moderation. From Fass' results for complete moderation with carbon dioxide $k_{3'}/k_{2'}$ is 23 at 300 °K and $E_{2'} - E_{3'} = 0.8 \pm 0.3$ kcal mol^{-1}. Since $E_{3'} \simeq 0$ (see above) then $E_{2'}$ must be $\simeq 0.8$ kcal mol^{-1}. The threshold energy of reaction 2′ will be less than $E_{2'}$ and therefore lies in the region of $(3/2)RT$, where the average fractional energy loss of $\underline{H}$ per collision is reduced due to the thermal motion of the moderator molecules (see eq. 12 of ref. 24). This feature and the much smaller difference between $k_{3'}/k_{2'}$ and $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ (see below) than for the corresponding ratios in the HCl system may be partly responsible for the inability to detect any moderated atoms. However, it must be realized that F_H in HBr *should* be greater than in HCl and much closer to unity, since the cross section for reaction 2′ is about twice that of reaction 2 and moderation of $\underline{H}$ by HBr is probably less efficient than by HCl due to the greater molecular weight (see below). Assuming all $\underline{H}$ atoms react hot in HBr the slope of the lower line in Fig. 3 gives

$$\frac{\underline{k}_4^{Br_2} + \underline{k}_{3'}}{\underline{k}_{2'}} = 5.2 \pm 0.1$$

in good agreement with Fass' value of 5.3 ± 0.4.

The data in Fig. 3 for the 2537 Å photolysis of the 2% HBr in HCl mixture can be interpreted[4] in terms of expression vii

$$[\text{vii}] \qquad \frac{1}{Y} = 1 + \frac{\sum_M \underline{k}_4[M] + \underline{k}_{3'}[Br_2]}{\underline{k}_2[HCl] + \underline{k}_{2'}[HBr]}$$

The slope and intercept are then respectively

$$(\underline{k}_4^{Br_2} + \underline{k}_{3'})(\underline{k}_2[HCl] + \underline{k}_{2'}[HBr])^{-1}$$

and

$$\left[1 + \frac{\underline{k}_2}{\underline{k}_4^{HCl}[HCl]} + \frac{\underline{k}_{2'}[HBr]}{\underline{k}_4^{HCl}[HCl]}\right]$$

The values of $\underline{k}_4^{HCl}/\underline{k}_2$ and $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_2$ for $\underline{H}$ atoms of 1.15 eV initial energy in Table 1 were calculated with corrections for the HBr terms assuming the same value of $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ as in pure HBr and neglecting $\underline{k}_4^{HBr}$. The contributions of the HBr terms are in any case only about 10%, and errors resulting from the foregoing assumption should be small.

HCl–CO_2 Mixtures

Carbon dioxide is not entirely non-reactive toward $\underline{H}$. In fact in the present study the absolute hydrogen yields were consistently 3–4% lower when it was added to HCl in proportions of 1:1 or larger. This reduction in hydrogen yield should correspond to F_H for the reaction of 2.1 eV $\underline{H}$ atoms with CO_2: $\underline{H} + CO_2 \rightarrow HO + CO$, and it indeed compares very favorably with 2.8×10^{-2} measured by Oldershaw and Porter (25) for 2.02 eV $\underline{H}$ atoms in a region where F_H is rising steeply. It should be noted that in the present work an allowance for the small consumption of $\underline{H}$ by carbon dioxide was made by calculating the Y values in Fig. 2(*a*) and (*b*) with respect to standard runs containing the appropriate ratio of $[CO_2]$:[HCl].

Returning to expression v and assuming that $k_{3'}/k_2 \simeq 1600$ it can be shown that f_t should be negligible for $[Br_2]/[HCl] \geqslant 2 \times 10^{-2}$. Hence, it is apparent from the lower points in Fig. 2(*b*) that F_H is reduced to 0.20 ± 0.03 in the 5:1 CO_2–HCl mixture. For the case of chlorine at room temperature f_t is not negligible as is shown by the dashed line in Fig. 2(*a*), which gives values of Y calculated from the data of ref. 23 for the case of complete moderation and thermalization of all atoms (*i.e.* $F_H = 0$ and $Y = 1 \times f_t$). Thus the foregoing simple procedure cannot be used. However, with $F_H \simeq 0.20$ the reduction in Y caused by the scavenging or moderation of $\underline{H}$ by chlorine should be small below $[Cl_2]/[HCl] = 4 \times 10^{-2}$. Therefore, taking F_H as independent of $[Cl_2]$, the chlorine results for the 1:5 HCl–CO_2 mixture can be analyzed in terms of expression viii.

$$[\text{viii}] \qquad \frac{1}{1 - Y} = \frac{1}{F_M(1 - f_t)} = \frac{1}{\Delta Y} = \frac{1}{F_M}\left\{1 + \frac{k_3[HCl]}{k_2[Cl_2]}\right\}$$

Figure 4(*b*) shows the data plotted in accord with this expression. The intercept gives $F_M = 0.81 \pm 0.06$ and hence $F_H = 0.19 \pm 0.06$ which is consistent with the result obtained above from the bromine data.

From the ratio of the slope to the intercept of Fig. 4(*b*) k_3/k_2 is found to be 100 ± 10. The good agreement with the known rate constant ratio of 93 ± 14 for thermal H atoms at 300 °K

[4]It should be noted that $k_3/(k_2 + 0.02\ k_{2'})$ is 680 fulfilling the requirement that $F_M f_t$ is negligible for $[Br_2]/HX] > 2 \times 10^{-2}$ in the 2% HBr in HCl mixture.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

(23) implies that although F_M is not unity those atoms which fall below E_M approach a Maxwellian energy distribution before finally reacting with HCl or chlorine. This is expected to occur provided the distribution of thermal velocities of the target molecules is such that few of them can make a significant contribution to the relative velocity and energy of collision (26). For HCl molecules with a Maxwellian velocity distribution at 300 °K it can be shown that less than 20% of the collisions of a 0.10 eV H atom will have relative kinetic energy exceeding 0.113 eV.[5] Thus thermalization of a significant fraction of the moderated H atoms should be possible even in pure HCl. The present data suggest that it is the dominant fate of moderated atoms in the system with $[CO_2]/[HCl] = 5$. Other results not presented in detail provide evidence for a similar behavior in a system with $[CO_2]/[HCl] = 1.8$. They also give $F_M = 0.69 \pm 0.03$ (see Fig. 5 below).

Analysis of the chlorine scavenging results in Fig. 2(*a*) for $[CO_2]/[HCl] = 1.0$ at 300 °K by expression vi gave

$$(\underline{k}_4^{Cl_2} + \underline{k}_3)/\underline{k}_2 = 7.4 \pm 0.6$$

showing that this ratio is not markedly changed for the above carbon dioxide concentration. The intercept of the plot corresponded to $F_H = 0.53$ or $F_M = 0.47$, whence using expression iii $\underline{k}_4^{CO_2}/\underline{k}_2$ is 0.60. However, with $F_M \simeq 0.47$ the $F_M f_t$ term is again significant, though not as large as for the $[CO_2]:[HCl] = 5:1$ system. Thus the above values of both F_M and $\underline{k}_4^{CO_2}/\underline{k}_2$ must be regarded as lower limits. In fact it can be seen from Fig. 2(*a*) that the data for $[CO_2]/[HCl] = 1$ and 5 are all consistent with $\underline{k}_4^{CO_2}/\underline{k}_2 = 0.80$, the curves through the points having been drawn using $k_3/k_2 = 93$, $\underline{k}_4^{CO_2}/\underline{k}_2 = 0.80$, and $(\underline{k}_4^{Cl_2} + \underline{k}_3)/\underline{k}_2 = 8.6$.

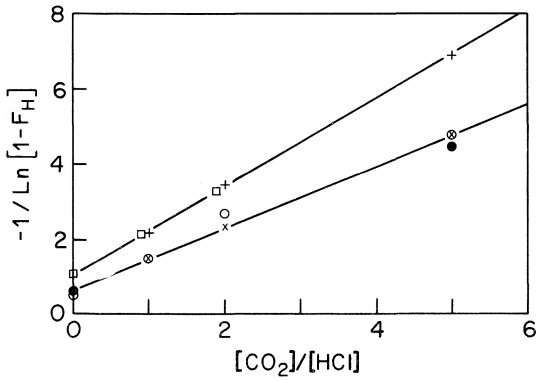

FIG. 5. Effect of CO_2 on the fraction of atoms reacting hot: □, experimental values of F_H for D + DCl from ref. 7; +, values of F_H calculated with expression *ii* taking $\underline{k}_4^{CO_2}/\underline{k}_2 = 1.15$ from ref. 7 for D + DCl; ●,○, experimental values of F_H for H + HCl from this study (open circle = chlorine, closed = bromine); ×, values of F_H calculated with expression *ii* taking $\underline{k}_4^{CO_2}/\underline{k}_2 = 0.80$ for H + HCl (see text).

[5]See expression (A4) of ref. 27.

Comparison with Other Systems

The purpose of this section is to examine the present results within the framework of the theory of hot atom reactions so that comparisons with data for related systems can be made. The basic equations for the analysis of hot atom reactions have been discussed by Wolfgang and his coworkers (see refs. 1 and 2 and citations therein). The fraction of atoms, F_M, moderated to energy E_M in pure reactant is given by

$$[ix] \qquad -\ln F_M = -\ln (1 - F_H) = \int_{E_M}^{E_0} \frac{P_r(E)}{F_r(E)} dE$$

where E_0 is the initial energy of the atoms. $P_r(E)$ is the probability of reaction per collision with reactant and $F_r(E)$ the reciprocal of the collision density for $\underline{H}$ atoms of energy E. For the case with moderator present, following Wolfgang's approach, we write

$$-\ln (1 - F_H) = \int_{E_M}^{E_0} \frac{f_r P_r(E)}{f_r F_r(E) + (1 - f_r) F_m(E)} dE,$$

where f_r is the collision fraction of the reactant. If the reciprocal collision densities $F_r(E)$ and $F_m(E)$ have the same functional dependence on E but differ by a constant factor, then:

$$[x] \qquad -\frac{1}{\ln (1 - F_H)} = \frac{\alpha_r}{I} + \frac{\alpha_m}{I} C \frac{[M]}{[R]}$$

C is the ratio of collision cross sections, $I = \int_{E_M}^{E_0} (P_r(E)/\phi(E))dE$, and the α terms are defined by $\phi(E) = F_r(E)/\alpha_r = F_m(E)/\alpha_m$. This form of expression is easily justified for systems with moderation by elastic hard sphere collisions, for which the kinetic theory model yields $\phi(E) = E$ and $\alpha = \ln \langle (E_{\text{before collision}}/E_{\text{after collision}}) \rangle$. De-

tailed theoretical calculations show that actual values of α for the inert gases are smaller than those calculated from the hard sphere model, because of the softness of the interaction potentials. For example, $\alpha_{Xe+\underline{H}} \simeq 0.005$ as opposed to the hard sphere value of 0.0153 (24). However, the *form* of expression x holds extremely well when applied to experimental data for inert gases as moderators (1, 2). In general it also holds well for polyatomic gases (1, 2, 28), and therefore provides a useful framework for the analysis of experimental data although its limitations for quantitative predictions must be recognized.

As shown in Fig. 5 the experimental determinations of F_H for 2.1 eV $\underline{H}$ atoms in Table 1 and values calculated from expression iii with $\underline{k}_3^{CO_2}/\underline{k}_2 = 0.8$ and $\underline{k}_3^{HCl}/\underline{k}_2 = 0.26$ obeyed expression x over the range $[CO_2]/[HCl] = 0$ to 5. This was also true of the corresponding data of Wood and White for the D atom – DCl – CO_2 system. Table 2 summarizes α_{HCl}/I and α_{CO_2}/I derived from the intercepts and slopes of plots of $\{-\ln(1 - F_H)\}^{-1}$ against $[CO_2]/[HCl]$. The constant C in expression x was calculated from the collision diameters $d_{DCl} = d_{HCl} = 3.3$, $d_{CO_2} = 3.9$, and $d_D = d_H = 2.5$ Å taken from viscosity data as in ref. 7. The kinetic theory model predicts $\alpha_{CO_2}/\alpha_{HCl} \simeq 0.85$ for both the H–HCl and D–DCl systems, and it is interesting to note that the experimental values are 1.04 and 0.85 respectively, showing a better agreement for the more massive D atoms. The absence of a marked discrepancy in favor of the halides implies that the displacement reaction

$$\underline{H}' + HCl \rightarrow H'Cl^v + H,$$

where $H'Cl^v$ has excess vibrational energy, does not play a major role in the moderation process for these molecules. There is no direct experimental information on this particular reaction, but the recent work of Wood (29) shows that at thermal energies the isotopic analog

$$H + DCl \rightarrow HCl + D$$

has an "A" factor ~850 times less than the abstraction process

$$H + DCl \rightarrow HD + Cl$$

although the latter has a higher activation energy. Thus the displacement reaction would not appear to be highly efficient.

The large fraction of atoms which cascade from the 1.15 to 2.1 eV energy range to the 0.113 to 1.15 eV range makes it difficult to state whether σ_2, the cross section of reaction 2, increases primarily below 1.15 eV or also above it. However, it appears from a comparison of α_{H+HCl}/I_{H+HCl} for $E_0 = 2.1$ and 1.15 eV in Table 2 that σ_2 is increasing with energy over most of the range between the threshold and 1.15 eV and possibly also above 1.15 eV. Substitution of the hard sphere value of $\alpha_{H+HCl} = 0.052$ into the α_{H+HCl}/I_{H+HCl} terms leads to average cross sections of ~0.35 and ~0.7 Å^2 over the energy ranges 0.113 to 1.15 and 0.113 to 2.1 eV, respectively. Although admittedly crude[6] these estimates show that at the energies used here σ_2 is only about 5% (or less) of the total collision cross section of 27.2 Å^2. The magnitude of the cross section for reaction 2 is thus comparable to that of reaction 11

[11] $\underline{H} + n\text{-}C_4D_{10} \rightarrow HD + C_4D_9$ (sec)

for which a maximum value of 0.35 Å^2 at 1.1 eV has recently been reported (30). If one accepts the kinetic theory prediction that the α values for $\underline{D}$ atoms colliding with DCl and CO_2 will be twice those for the corresponding collisions of $\underline{H}$ atoms, then the 2.1 eV data in Table 2 suggest that σ_2 may be significantly (20 to 50%) larger when H is replaced by D. This result is interesting since trajectory calculations (31) predict that mass effects, including isotopic substitution, are very important in determining the magnitude of cross sections for abstraction reactions. However, there are at present no detailed calculations for the H + HCl and D + DCl reactions.

The $(\underline{k}_4^{X_2} + \underline{k}_3)/\underline{k}_2$ ratios are complex functions of the reaction cross sections and collision densities in the hot atom region and cannot be eas-

TABLE 2. Kinetic theory parameters for the reactivity and moderation of hot atoms in DCl and HCl

Atom	E_0	Reactant (r)	α_r/I	$\frac{\alpha_{CO_2}}{I} C$
D	2.1	DCl	1.07	1.11
H	2.1	HCl	0.63	0.83
H	1.15	HCl	1.62	—

[6]Using $\alpha_{Xe+H} = 0.005$ as a standard the comparative data of ref. 25 show that α_{CO_2+H} should be ~0.024 as opposed to the hard sphere value of 0.044. α_{HCl+H} should be reduced by a similar proportion from the hard sphere value of 0.052 and the average cross sections reported in the text are therefore likely to be high.

ily related to physical parameters for individual processes. However, from certain comparisons a few interesting conclusions concerning the magnitudes of reaction cross sections for the HBr–Br_2 system can be drawn. As pointed out above Fass' value of $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'} = 5.3 \pm 0.4$ for $E_0 =$ 1.15 eV is in good agreement with ours. Fass also observed the same $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ for $E_0 =$ 2.9 eV. More recently White and Su (32) have reported $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'} = 5.48 \pm 0.22$ for $E_0 =$ 1.65 eV and 4.11 ± 0.16 at $E_0 = 2.9$ eV. Their value for $E_0 = 2.9$ eV does not agree with Fass'. However, the discrepancy is only about 20% and $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ is obviously not strongly dependent on E_0. Since few if any atoms are moderated before reaction it is reasonable as a first approximation to neglect $\underline{k}_4^{Br_2}$ and to associate the experimental values of $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ with $\underline{k}_{3'}/\underline{k}_{2'}$ or in fact with $\bar{\sigma}_{3'}/\bar{\sigma}_{2'}$, where the cross sections are averaged over the energy range of the reacting atoms.[7] Gann and Dubrin (33) have recently reported a mean cross section of 1.6 ± 0.3 Å^2 for reaction 2′ over the energy range 0.33 to 1.7 eV, based on the collision density distributed in xenon. From this and using our hot atom rate constant ratio of 5.2 as a measure of $\bar{\sigma}_{3'}/\bar{\sigma}_{2'}$, $\bar{\sigma}_{3'}$ is calculated to be $\simeq 8.5$ Å^2. Comparison with the estimate of > 7 Å^2 above (Analysis: HCl and Scavengers Only) for the thermal energy range confirms that $\sigma_{3'}$ must rise rapidly to its maximum value.[8] The constancy of $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_{2'}$ requires a similar rapid rise in $\sigma_{2'}$ which must be close to if not above its energy of maximum value at 1.15 eV.[8] The strong dependence of $(\underline{k}_4^{Br_2} + \underline{k}_{3'})/\underline{k}_2$ on energy (see Table 2) is in direct contrast implying, in support of earlier statements, that σ_2 is increasing more slowly with energy and may still be rising in the region above 1 eV.

[7]If one uses the average of $\bar{\sigma}_{2'} = 1.6$ Å^2 reported by Gann and Dubrin for the energy range 0.35 to 1.7 eV and a kinetic theory

$$\alpha \simeq \frac{2\mu_{H+HBr}}{m_H + m_{HBr}},$$

it can be shown that in pure HBr 70% of H are consumed between 0.6 eV and E_0 for $E_0 = 1.15$ eV and between 1.5 eV and E_0 for $E_0 = 2.9$ eV. Therefore, unless the real value of α is much larger than the kinetic theory prediction, Fass' two $\underline{k}_6^{Br_2}/\underline{k}_{2'}$ ratios correspond to average ratios of cross sections over these limited energy ranges. For the HCl competitions with bromine the lower reaction cross section and higher α would cause the energy range to be spread much more as indeed is indicated by the significant fraction of atoms moderated for $E_0 = 1.15$ and 2.1 eV.

[8]Trajectory calculations (32) actually show both $\sigma_{2'}$ and $\sigma_{3'}$ as decreasing in the region of 1.7 to 2.9 eV (32). Note, however, that $\sigma_{2'}$ may rise to a second maximum in the energy range where collisions with a large angle of approach relative to the molecular axis become important (31).

The Preparation and Properties of Complexes of Antimony and Bismuth Trifluorides with Strong Fluoride Acceptors

T. BIRCHALL, P. A. W. DEAN,[1] B. DELLA VALLE, and R. J. GILLESPIE

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 10, 1972

The reactions of antimony and bismuth trifluorides with the pentafluorides of antimony and arsenic in liquid sulfur dioxide yield the adducts $SbF_3 \cdot SbF_5$ (type A), $SbF_3 \cdot AsF_5$, $BiF_3 \cdot 3SbF_5$, and $BiF_3 \cdot AsF_5$; no adducts of the trifluorides with BF_3 were isolated. Antimony metal reacts with excess of antimony pentafluoride and arsenic pentafluoride in liquid sulfur dioxide giving a second form of $SbF_3 \cdot SbF_5$ (type B) and the same form of $SbF_3 \cdot AsF_5$ as produced from SbF_3, respectively. $BiF_3 \cdot 3SbF_5$ can be formulated as $Bi(SbF_6)_3$, but its Raman spectrum indicates the presence of extensive cation–anion fluorine-bridging. Their Raman spectra suggest that $BiF_3 \cdot AsF_5$, $SbF_3 \cdot AsF_5$, and $SbF_3 \cdot SbF_5$ (type B) have similar structures, possibly containing polymeric fluorine-bridged cations, but that $SbF_3 \cdot SbF_5$ (type A) has a different structure probably like that of $AsF_3 \cdot SbF_5$. The ^{121}Sb Mössbauer spectra of the SbF_3 adducts support the assignment of similar structures to $SbF_3 \cdot AsF_5$ and $SbF_3 \cdot SbF_5$ (type B), and the suggestion that $SbF_3 \cdot AsF_5$ and both forms of $SbF_3 \cdot SbF_5$ contain antimony (III) fluoro-cations. ^{19}F n.m.r. shows that SbF_3 has appreciable solubility in SO_2 solutions of SbF_5 and indicates the possible formation of "fluxional" SbF_2–Sb_nF_{5n+1} molecules in SbF_3–SbF_5 solutions.

Les réactions des trifluorures d'antimoine et de bismuth avec les pentafluorures d'antimoine et d'arsenic dans le dioxyde de soufre liquide donnent les produits d'addition, $SbF_3 \cdot SbF_5$ (type A), $SbF_3 \cdot AsF_5$, $BiF_3 \cdot 3SbF_5$ et $BiF_3 \cdot AsF_5$; aucun produit résultant de l'addition des trifluorures avec BF_3 n'a été isolé. Lorsque l'antimoine métallique réagit avec un excès de trifluorure d'antimoine et d'arsenic dans le dioxyde de soufre liquide, on obtient alors une seconde forme de $SbF_3 \cdot SbF_5$ (type B) ainsi que la forme identique de $SbF_3 \cdot AsF_5$ tel qu'obtenu à partir de SbF_3. On peut formuler la forme $BiF_3 \cdot 3SbF_5$ comme étant $Bi(SbF_6)_3$, cependant son spectre Raman indique un apport considérable de ponts fluorés entre les cations et les anions. Selon leurs spectres Raman, les composés $BiF_3 \cdot AsF_5$ et $SbF_3 \cdot SbF_5$ (type B) possèdent, semble-t-il, une structure similaire comportant vraisemblablement des cations liés par des ponts fluorés polymériques alors que $SbF_3 \cdot SbF_5$ (type A) possède une structure différente se comparant probablement à celle du $AsF_3 \cdot SbF_5$. Les spectres Mossbauer ^{121}Sb des produits d'addition du SbF_3 confirment l'attribution de structures semblables pour $SbF_3 \cdot AsF_5$ et $SbF_3 \cdot SbF_5$ (type B) et l'hypothèse selon laquelle le $SbF_3 \cdot AsF_5$ ainsi que les deux formes de $SbF_3 \cdot SbF_5$ contiennent des fluorocations (III). La spectroscopie r.m.n. du ^{19}F indique que SbF_3 possède une solubilité appréciable dans des solutions de SbF_5 dans le SO_2 et montre ainsi la formation possible de molécules "fluxionales" SbF_2–Sb_nF_{5n+1} dans des solutions de SbF_3–SbF_5. [Traduit par le journal]

Can. J. Chem., **51**, 667 (1973)

Introduction

Although PF_3 (1) and AsF_3 (2) form well-defined complexes with antimony pentafluoride, the situation with regard to similar complexes of SbF_3 is more confused. Ruff and Plato (3) reported an exothermic reaction between SbF_3 and SbF_5 which, on distillation of the reaction mixture, led to the compounds $SbF_5 \cdot nSbF_3$ (n = 2,5 and possibly 3,4). They found no evidence for a 1:1 compound. Woolf (4), however, found that SbF_3 was insoluble in SbF_5 and did not increase the conductivity of the pentafluoride. More recently, Davies and Moss (5) have been unable to repeat the work of Ruff and Plato. Nevertheless there is some indication that SbF_3–SbF_5 complexes are formed when carbonium ions (6) or hydrocarbons (7) are oxidized by SbF_5 in sulfur dioxide solution.

We have now reinvestigated the interaction between SbF_3 and fluoride-acceptors, and in addition have studied similar reactions of BiF_3, about the fluoro-basic character of which there has been no previous report.

Antimony metal reacts with excess arsenic or antimony pentafluoride in liquid sulfur dioxide to form Sb(III) containing fluorocomplexes and discussion of these complexes is also included in this report. It should be noted that if the pentafluorides are not in excess, antimony(I) salts can be produced in the reaction of antimony with SbF_5 or AsF_5 (8, 9).

Results and Discussion

Neither SbF_3 nor BiF_3 react with boron trifluoride under the experimental conditions reported here. However, BiF_3 reacts with excess AsF_5 or SbF_5 to give a 1:1 or 1:3 adduct, respectively, while SbF_3 gives 1:1 adducts with both pentafluorides. Inconclusive results were obtained while trying to prepare, from SbF_3,[2] SbF_3–SbF_5 complexes with other than a 1:1 stoichiometry. It is interesting that $SbF_3 \cdot AsF_5$ is an isomer of the known $AsF_3 \cdot SbF_5$ (2).

Antimony metal reacts with excess arsenic pentafluoride to give $SbF_3 \cdot AsF_5$ which is identical in all respects with the complex prepared directly from antimony trifluoride. In contrast, the reaction of antimony metal with excess antimony pentafluoride normally gives a form of $SbF_3 \cdot SbF_5$ quite different from that obtained starting with SbF_3. It was found that the two forms of $SbF_3 \cdot SbF_5$ could not be interconverted either thermally or by extended treatment with antimony pentafluoride in liquid sulfur dioxide. For the purposes of further discussion, the $SbF_3 \cdot SbF_5$ formed from SbF_3 will be called A, that formed from Sb, B.

Raman Spectra

The Raman spectra of the new metal trifluoride adducts are given in Table 1 together with the Raman spectra of $AsF_3 \cdot SbF_5$ and cesium hexafluoro-arsenate and antimonate for comparison.

The Raman spectra of $BiF_3 \cdot AsF_5$, $SbF_3 \cdot AsF_5$ and $SbF_3 \cdot SbF_5$ (B) are quite similar, but they differ from those expected for structures containing recognizable MF_2^+ cations and $M'F_6^-$ anions. Such basically ionic formulations might have been expected by analogy with the postulated structure of $PF_3 \cdot SbF_5$, *i.e.* $PF_2^+SbF_6^-$ (1) and in light of the partly ionic character of $AsF_3 \cdot SbF_5$ (11). An isolated MF_6^- anion of O_h symmetry has three Raman-active vibrations, $\nu_1(A_{1g})$, $\nu_2(E_g)$, and $\nu_5(T_{2g})$ while an isolated (bent) MF_2^+ ion with C_{2v} symmetry should also have three Raman-active modes, $\nu_1(A_1)$, $\nu_2(A_1)$, and $\nu_3(B_1)$. The majority of the bands observed in the Raman spectra of the above three compounds fall in the same regions as the bending and deformation modes of either AsF_6^- ($BiF_3 \cdot AsF_5$ and $SbF_3 \cdot AsF_5$) or SbF_6^- ($SbF_3 \cdot SbF_5$(B)), and, following accepted procedure, we have assigned these bands as being related to the normal modes of the MF_6^- with O_h symmetry. There are, however, many more bands than can be accounted for by assuming isolated octahedral MF_6^- anions to be present. We associate this complexity with the occurrence of a significant amount of cation–anion fluorine-bridging, a situation expected in these compounds which contain very acidic cations. Where fluorine-bridging is appreciable, both distortion of the anion and factor group splitting may contribute to the complexity of a spectrum (12).

Surprisingly the spectra of none of $BiF_3 \cdot AsF_5$, $SbF_3 \cdot AsF_5$, and $SbF_3 \cdot SbF_5$ (B) show bands which are obviously due to a cation, though clearly a cation must be present. This situation contrasts with that found for $PF_3 \cdot SbF_5$ (1) and $AsF_3 \cdot SbF_5$. The vibrational spectrum of the former shows two P—F stretches as expected for a bent PF_2^+ cation, and the Raman spectrum of the latter (see Table 1) has bands at 728 and 738 cm^{-1} which can reasonably be assigned to ν_1 of the AsF_2^+ cation (the doubling of ν_1 is probably a factor group splitting). The ν_1 frequency of AsF_2^+ is comparable to, but higher than, that found for gaseous GeF_2 (692 cm^{-1} (13)), as expected. Further comparison with the spectrum of GeF_2 suggests ν_3 for AsF_2^+ might be found at $\sim$700 cm^{-1}, a region obscured by the bands of the SbF_6^- anion. The situation with respect to ν_2 of AsF_2^+ is similar.

It is possible that the difference between the SbF_3 and BiF_3 adducts and the adducts of AsF_3 and PF_3 is related to the difference propensities for fluorine-bridging of the two heavy and two light elements. Both PF_3 and AsF_3 are monomolecular in the gas liquid phases (14) and presumably form molecular lattices, but SbF_3 (15) and BiF_3 (16) are extensively fluorine-bridged in the solid state. Therefore it is reasonable that any strong fluorine-bridging in $PF_2^+SbF_6^-$ and $AsF_2^+SbF_6^-$ should be between the cation and the anion. This is known to be the case for $AsF_3 \cdot SbF_5$ (11). For adducts of SbF_3 and BiF_3, on the other hand, two extreme possibilities can be envisaged: ether cation–anion fluorine-bridging is predominant (as in $AsF_2^+SbF_6^-$) or cation–cation bridging is stronger, *i.e.* a polymeric fluorine-bridged cation is formed. Provided all the fluorines in this cation are involved in strong fluorine-bridging no M(III)—F stretching vibrations will be seen. Thus it seems that the BiF_3 and SbF_3 adducts discussed above contain polymeric

[2]4 moles of antimony and 11 moles of SbF_5 react in liquid SO_2 giving Sb_3F_{11} but this is, in fact, an Sb(I) salt, $Sb(I)Sb_2F_{11}$ (10).

cations, *i.e.* they are $(SbF_2)_n^{n+}(MF_6^-)_n$ and $(BiF_2)_n^{n+}(AsF_6^-)_n$, and this suggestion receives support from the observation, in the spectra of all three adducts, of a broad band or bands in the region ~400–500 cm^{-1}, a region which appears characteristic of fluorine-bridged systems.

The Raman spectrum of $SbF_3 \cdot SbF_5$ (A) is markedly dissimilar to that of $SbF_3 \cdot SbF_5$ (B) showing that the two compounds must have different structures. The Raman spectrum of the former is more complicated than would be expected if it arose only from a distorted SbF_6^- anion; in particular, the quite strong band at 605 cm^{-1} is at too low a frequency to be due to an Sb(V)—F stretch and it seems clear that it must be assigned to a terminal Sb(III)—F stretch. This fact, together with the distinct similarity between the Sb(V)—F stretching regions of the spectra of $AsF_3 \cdot SbF_5$ and $SbF_3 \cdot SbF_5$ (A), allows the tentative conclusion that $SbF_3 \cdot SbF_5$ (A) has the $AsF_3 \cdot SbF_5$ structure or something quite similar to it, *i.e.* it is $SbF_2^+SbF_6^-$, and that the band at 605 cm^{-1} is, in fact, the ν_1 vibration of an SbF_2^+ cation. The proposed structure, involving fluorine-bridging only between Sb(V) and Sb(III), and not between Sb(III) and Sb(III) represents a second extreme type of fluorine-bridged structure as outlined above. If this is the correct structure, it is not unreasonable that a type A $SbF_3 \cdot AsF_5$ could not be prepared, since the AsF_6^- anion does not enter as readily into extensive fluorine-bridging as does SbF_6^-.

$BiF_3 \cdot 3SbF_5$ can presumably be formulated $Bi(SbF_6)_3$, and in agreement with this formulation its Raman spectrum (see Table 1) does exhibit bands in the stretching and deformation regions of the SbF_6^- anion. However, the large number of bands observed once more provides good evidence for strong cation–anion interactions, *i.e.* fluorine-bridging, a situation not unexpected in view of the anticipated very high acidity of Bi^{3+}.

^{121}Sb Mössbauer Spectra

Details of the Mössbauer data for the SbF_3 adducts are presented in Table 2 together with data for some related antimony fluorides. The chemical isomer shift, being a measure of "s" electron density at the antimony nucleus, can give valuable information about oxidation states. For example Sb^{3+} with a 5s electron pair would have a relatively high "s" electron density at the Sb nucleus, whereas Sb^{5+} with no 5s electrons would have a much lower "s" electron density. Since the nuclear term in the isomer shift expression is negative for the nucleus in question, compounds of Sb(III) will have less positive isomer shifts than compounds of Sb(V). This is clearly evident from Table 2 and ref. 19: antimony trifluoride has an isomer shift of −6.04 mm/s while SbF_5 and SbF_6^- salts have shifts of ~ +11 mm/s. One also notes the effect of the stereochemically active lone pair in SbF_3 which gives rise to a large quadrupole coupling constant. On the other hand, Sb(V) compounds have small or as yet undetected quadrupole coupling constants.

Both $SbF_3 \cdot SbF_5$ adducts gave Mössbauer spectra which contained two resonances of equal area, which immediately eliminates the possibility that these compounds are "$Sb(IV)F_4$". In both cases, the resonance absorption at the more positive velocity is typical of Sb(V) in a six coordinate environment, such as SbF_6^-. Note however that, in the adducts, the Sb(V) environment is much more distorted than that in the SbF_6^- salts. This confirms the Raman data discussed above where the deviations from O_h symmetry were postulated to arise from appreciable fluorine-bridging. The data would suggest that the Sb(V) environment in the (B) adduct is more symmetric than in the (A) adduct. Presumably the extent of bridging is less for (B) than for (A). However, attention should be drawn to the large error in the quadrupole splitting parameter.

The other resonance absorption in each of these spectra, and that in the spectrum of $SbF_3 \cdot AsF_5$, occurs at negative velocities with respect to InSb, is broad, and very asymmetric. This is typical of Sb(III) in a very distorted environment

TABLE 2. ^{121}Sb Mössbauer parameters for SbF_3 adducts and related compounds at 80 °K

Compound	Isomer shift* (± 0.2 mm/s)		Quadrupole coupling (± 2.0 mm/s)	
$SbF_3 \cdot SbF_5$(A)	−8.3	+11.3	+18.2	+8.0
$SbF_3 \cdot SbF_5$(B)	−7.5	+11.2	+18.3	+5.4
$SbF_3 \cdot AsF_5$	−7.3		+19.4	
SbF_3†	−6.04		+19.6	
SbF_5†		+10.8		
$NaSbF_6$‡		+10.4		
$KSbF_6$		+11.5		+3.1

such as that in SbF_3. The recently redetermined crystal structure of SbF_3 (15) shows a polymeric, rather than a molecular lattice, in which the antimony is at the center of a distorted octahedron of six fluorines, three at 1.93 Å and three at 2.61 Å. The gross distortion of the octahedron can be attributed to the influence of the 5s electron pair. Further, the magnitude of the isomer shift indicates that the 5s electron pair is participating to a considerable extent in the bonding scheme (21). Adduct formation with either SbF_5 or AsF_5 does not appear to result in drastic changes in the asymmetry about the Sb(III) since the quadrupole coupling is not significantly altered: the variations observed are within experimental error and a similar coordination number therefore seems probable for each compound.

The Sb(III) isomer shifts of these adducts are however appreciably different from SbF_3. The shift to more negative velocities on adduct formation can be rationalized in terms of placing at least some positive charge on the Sb(III): this would have the effect of contracting the orbitals, hence increasing the "s" electron density and causing a shift to more negative velocities. The isomer shifts for the $SbF_3{\cdot}AsF_5$ and $SbF_3{\cdot}SbF_5$ (B) adducts suggest that these are of the same structure type, again confirming the Raman data, but that $SbF_3{\cdot}SbF_5$ (A) has a different structure. A polymeric cation, as in $SbF_3{\cdot}SbF_5$ (B), having strong Sb(III)—F—Sb(III) bridge bonds and, presumably, two weak Sb(III)—F—Sb(V) bonds, would be expected to have a different isomer shift than the (A) adduct, where, by analogy to $AsF_3{\cdot}SbF_5$ (11), there are presumably two strong Sb(III)—F bonds and four weaker Sb(III)—F—Sb(V) bridge bonds. Since the more weakly bound fluorines would be less effective at removing electron density than strongly bound fluorines, a more negative isomer shift results for the $SbF_3{\cdot}SbF_5$ (A) adduct.

^{19}F *N.M.R. Spectra*

Because of its possible formation when carbonium ions (6) and hydrocarbons (7) are oxidized by SbF_5, it was of interest to measure the ^{19}F n.m.r. spectrum of $SbF_3{\cdot}SbF_5$ in SO_2. It was found however, that this complex, once isolated, was virtually insoluble in SO_2. Therefore the spectrum of the supernatant liquid over a mixture with $SbF_3/SbF_5/SO_2 = 1/4.0/17.8$ (a typical ratio for the preparation of $SbF_3{\cdot}SbF_5$) was measured and is shown in Fig. 1.

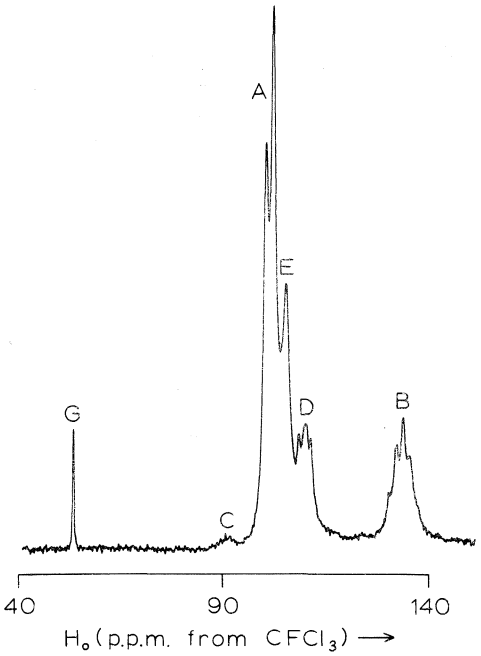

FIG. 1. The −85 °C 56.4 MHz ^{19}F n.m.r. spectrum of the supernatant liquid over a mixture of composition $SbF_5/SbF_3/SO_2 = 1/4.0/17.8$.

The resonance *G*, at ϕ 52.1, is almost certainly due to F-on-Sb(III) since the −90° ^{19}F n.m.r. spectrum of a saturated fluorosulfuric acid solution of $SbF_3{\cdot}SbF_5$ shows, in addition to signals from SbF_6^- and $SbF_5{\cdot}SO_3F^-$, a line at similarly low applied field, ϕ 65.9. The doublet *A* and quintet *B* (ϕ 100.5, 133.0; *J* 100 Hz) arise mainly from $SbF_5{\cdot}SO_2$ (6, 22), and the broad signal *C* (ϕ 90.5) and triplet-like resonance *D* (ϕ 109.8), which is, in fact, a double-doublet, from $Sb_2F_{11}^-$ (6, 23). The signal *E*, at ϕ 105.2, is in the same position as a resonance observed previously (6) in the spectrum of *t*-BuF/3.8SbF_5 in SO_2, which was thought to be due to a species involving Sb(III) and Sb(V). The position of *E* is consistent with its resulting from SbF_6^-. It appears therefore that SbF_3 has appreciable solubility in SO_2 in the presence of SbF_5 and that the SbF_6^- and $Sb_2F_{11}^-$ anions are formed together with an Sb(III) species which is presumably SbF_2^+. (Due to overlap of the somewhat broad signals in the region of F-on-Sb(V) we could not determine accurate intensities and hence the stoichiometries of the species involved.) However an earlier study (6) has shown that large amounts of SbF_6^- cannot coexist with $SbF_5{\cdot}SO_2$; the two combine to give $Sb_2F_{11}^-$. In the light of this earlier result,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the distribution of Sb(V) species in the present solution is somewhat anomalous. Recently, a similarly irregular distribution of species in NbF_5 (or TaF_5)–SbF_5–SO_2ClF has been interpreted (24) in terms of "fluxional" molecules, which, though they give n.m.r. spectra typical of ionic species are in fact covalent *i.e.* NbF_4–Sb_nF_{5n+1}. It seems possible that in SbF_3–SbF_5–SO_2 the III–V complexes formed are also "fluxional" and of the general form SbF_2-Sb_nF_{5n+1}.

To further determine the conditions under which the SbF_3–SbF_5 complexes exist in SO_2 solution, we prepared solutions similar to that above but also containing Et_4NSbF_6. When $SbF_6^-/SbF_5 > 1$, the only n.m.r. signals observed were from $Sb_2F_{11}^-$ or a mixture of $Sb_2F_{11}^-$ and SbF_6^-, no signal attributable to F-on-Sb(III) was seen. We conclude that SbF_3–SbF_5 complexes can only be formed in fluoride-containing SO_2 solution when $SbF_5/F^- > 2$.

Experimental

Reagents

Antimony pentafluoride (Ozark Mahoning Co.) and fluorosulfuric acid (Baker and Adamson Co.) were purified by standard procedures. Tetraethylammonium hexafluoroantimonate was prepared according to Bacon *et al.* (6). Boron trifluoride (Matheson of Canada Ltd.), arsenic pentafluoride (Ozark Mahoning Co.) and sulfur dioxide (Matheson of Canada Ltd., anhydrous grade), antimony trifluoride (K and K Laboratories, 99%) and bismuth trifluoride (Ozark Mahoning Co., 99%) were all used without further purification. The Raman spectra of the last two were:

SbF_3: 546 (mw.br.), 500 (s), 457 (ms), 275 (w), 249 (vw), 211 (vw), 117 (w), 90 (w) cm^{-1}.

BiF_3: 289 (m.br.), 270 (m), 245 (m), 198 (m.br.), 122 (m), 111 (ms), 80 (s), 65 (ms) cm^{-1}.

Reagents of Antimony and Bismuth Trifluorides with Boron Trifluoride, Arsenic Pentafluoride and Antimony Pentafluoride

The reactions were carried out in essentially the same manner previously reported (18) for complexes of stannous fluoride. As in the rest of this study, all manipulations, except those requiring use of a vacuum line, were carried out in a dry box. In typical preparations *ca.* 1 g of the trifluoride was treated with a large excess of Lewis acid (4 mol/mol). The reactions involving SbF_5 appeared complete after standing overnight at room temperature (without stirring), but to ensure completion, the reactions were normally allowed to stand for several days. An attempted stoichiometric preparation of $2SbF_3{\cdot}SbF_5$ gave an obviously inhomogeneous product even after a reaction time of several weeks. In the preparations of the AsF_5 adducts and the attempted preparations of the BF_3 adducts, the SO_2 suspension of the trifluoride and products was stirred for 1 week at room temperature. The solids isolated from the BF_3 reactions analyzed as the initial trifluorides.

Typical analyses are:

Anal. Calcd. for $SbF_3{\cdot}SbF_5$: F, 38.43; Sb, 61.57; Sb(III), 30.78. Found: F, 36.38; Sb, 61.5, 62.2, 62.4, 62.6; Sb(III), 33.0, 33.2, 31.6, 30.8.

Anal. Calcd. for $SbF_3{\cdot}AsF_5$: F, 43.59; Sb + As, 56.40. Found: F, 43.57; Sb + As, 55.99.

Anal. Calcd. for $BiF_3{\cdot}3SbF_5$: Bi, 22.81; F, 37.32; Sb, 39.87. Found: Bi, 22.70; F, 37.33; Sb, 38.50.

Anal. Calcd. for BiF_3AsF_5: As, 17.19; Bi, 47.95; F, 34.87. Found: As, 16.84; Bi, 47.19; F, 34.18.

Reactions of Antimony Metal with Arsenic and Antimony Pentafluorides

The apparatus and procedure were very similar to that used for the reactions of the trifluorides (above). Finely ground antimony (1 mol) was stirred, in liquid SO_2, with an excess of the pentafluoride (> 4 mol of SbF_5 or > 2.5 mol AsF_5). The reactions take place according to

$$2Sb + 8SbF_5 \rightarrow 5SbF_3{\cdot}SbF_5$$

or $$2Sb + 5AsF_5 \rightarrow 2SbF_3{\cdot}AsF_5 + 3AsF_3$$

The reaction involving SbF_5 is complete in *ca.* 24 h, that involving AsF_5 takes about 1 week at room temperature. The products were isolated after washing with liquid SO_2 and removal of volatiles. The Raman and Mössbauer spectra of the $SbF_3{\cdot}AsF_5$ prepared this way were identical with those of a sample prepared from SbF_3.

Anal. Calcd. for $SbF_3{\cdot}SbF_5$: F, 38.43; Sb, 61.57. Found: F, 38.69; Sb, 61.49.

$AsF_3{\cdot}SbF_5$

This was prepared according to ref. 2.

Analyses

Except for the determination of antimony in $SbF_3{\cdot}SbF_5$ which was achieved iodimetrically, analyses were performed by Alfred Bernhardt, West Germany.

Raman Spectra

The Raman spectra of the solids were obtained using a Spex Industries Model 1400 spectrometer with Ar^+ excitation (5145 or 4880 Å) from a Spectra Physics 140 laser. The 90° viewing technique of Gillespie and Pez (25) was used. Samples were contained in sealed Pyrex (melting point) capillary tubes.

Mössbauer Spectra

Mössbauer Spectra were recorded with an Austin Science Associates constant acceleration drive unit, used in conjunction with a Victoreen PIP 400A multichannel analyzer operating in multiscalar mode. The source was $Ba^{121m}SnO_3$ (0.5 mCi) obtained from New England Nuclear Ltd. All isomer shifts were reported relative to InSb at liquid nitrogen temperature. The detector was a Xe–CO_2 filled proportional counter with the window of the single channel analyzer set on the escape peak of the 37 keV ^{121}Sb gamma ray. The velocity scale was calibrated with a Pd(^{57}Co) source and a metallic iron foil. The $SbF_3{\cdot}SbF_5$ and $SbF_3{\cdot}AsF_5$ absorbers, which were mounted in the manner used for stannous fluoride complexes (18), were cooled to liquid nitrogen temperature; they contained 40 mg/cm² and 30 mg/cm² of antimony

respectively. The spectra were analyzed by means of the curve-fitting program previously described (26).

^{19}F N.M.R. Spectra

The n.m.r. spectra were obtained using a Varian DA-60 spectrometer modified as reported earlier (27). Samples were prepared by mixing the non-volatile components in an n.m.r. tube in the dry box and then condensing the requisite amount of SO_2 into the tube *in vacuo* prior to sealing. Chemical shifts were measured relative to $CFCl_3$ by sample interchange.

We thank the National Research Council of Canada for generous financial assistance. We are grateful to Mr. J. Ballard for preparing and obtaining the Raman spectrum of $AsF_3 \cdot SbF_5$.

Magnetic Susceptibilities of some Compounds of Sulfur

M. B. KENNEDY, M. W. LISTER, R. MARSON, AND R. B. POYNTZ
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received July 12, 1972

Magnetic susceptibilities are reported for a number of compounds containing sulfur–oxygen bonds; the sulfur may also be bonded to organic groups or to halogen. The results are compared with earlier measurements on the phosphorus–oxygen or halogen–oxygen systems, and with other data on the sulfur–oxygen compounds which give information on the bond order. Though some trends similar to those in phosphorus–oxygen or halogen oxygen systems are noted, it does not seem to be possible to correlate the magnetic susceptibilities with the bond orders in any simple way.

Les susceptibilités magnétiques ont été rapportées pour un certain nombre de composés contenant des liaisons soufre–oxygène, soufre-groupes organiques ou halogène. Les résultats ont été comparés aux mesures précedentes concernant les systèmes phosphore–oxygène, halogène–oxygène ainsi qu'aux autres données sur les composés soufre–oxygène; des informations sur l'ordre de liaison ont aussi été obtenues. Bien qu'on note une certaine similitude dans les tendances pour les systèmes phosphore–oxygène ou halogène oxygène, il ne semble pas possible de relier d'une façon simple les susceptibilités magnétiques aux ordres de liaison. [Traduit par le journal]

Can. J. Chem., **51**, 674 (1973)

For personal use only.

In an earlier paper (1), two of the present authors reported measurements on the diamagnetic susceptibilities of compounds containing oxygen linked to nitrogen or phosphorus. The results were considered in terms of the degree of double bonding of the oxygen, and possible delocalization of the π-electrons; and were related to the stretching force constants and bond lengths in some of the compounds. The results supported a singly bonded oxygen in amine oxides, R_3NO, but doubly bonded in phosphine oxides. Phosphate esters showed a large enhancement in susceptibility over the corresponding phosphite esters, $OP(OR)_3$ as compared with $P(OR)_3$, in spite of the apparent double bonding of the unique oxygen in phosphate esters. This was also true, but to a lesser extent in the oxyhalides as compared with the halides, OPX_3 as compared with PX_3, where X is chlorine or bromine.

Analogous measurements on sulfur compounds were made at the time of the above work, and amplified by other more recent measurements. The object of the present paper is to report the results, and to apply similar considerations to them. Some of the compounds have been measured by other workers, as mentioned in detail below, but it seemed worthwhile to report our results, as confirmation of values of diamagnetic susceptibilities have often proved useful.

Experimental

Apparatus

The susceptibility measurements were made as in the earlier paper (1). The standard substance was benzene, carefully freed from oxygen. It was assumed to have a volume susceptibility of -0.6187×10^{-6} e.m.u/ml at 25 °C, or -0.7081×10^{-6} e.m.u/g, as reported by Eggleston, Evans, and Richards (2). This was checked by measurements on water which gave a value of $-0.719 \pm 0.002 \times 10^{-6}$ e.m.u/ml, as a mean of eight determinations.

Densities of liquids were measured in a 10 ml pyknometer. Densities of solids were measured directly in the tube used for magnetic measurements, from the weight and length of the sample in the tube. These are, of course, apparent densities of the solids.

Chemicals

Thionyl and Sulfuryl Chlorides

Samples (500 ml) were distilled under nitrogen to give constant boiling middle fractions, boiling at 79.0 and 69.5 °C, respectively.

Dimethyl Sulfoxide

This was prepared by oxidation of dimethyl sulfide by 30% hydrogen peroxide. The product, after fractional distillation, melted at 18.5 °C, in agreement with Douglas' value (3), though Addison and Sheldon (4) report a melting point of 19 to 20 °C. A large sample, from the Crown Zellerbach corporation, after drying and fractionation, melted at 19 °C. Both samples had the same magnetic susceptibility within experimental error.

Diethyl Sulfoxide

This was prepared by oxidation of diethyl sulfide in acetone by 30% hydrogen peroxide (5). After repeated drying and distillation under vacuum, a sample melting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at 20.8 °C was obtained (20 °C in ref. (4)). The infrared spectrum showed no detectable diethyl sulfone.

Anal. Calcd. for $C_4H_{10}OS$: C, 45.24; H, 9.49; S, 30.20. Found: C, 45.23; H, 9.49; S, 30.11.

Dimethyl Sulfone

Dimethyl sulfone (200 g), from the Crown Zellerbach Corporation, was twice recrystallized from benzene, then fractionally sublimed under vacuum. It melted at 108.5 °C; Douglas (3) gives 108.1 to 108.5 °C.

Di (n-propyl) Sulfone

A sample from Distillation Products Industries Ltd. was fractionally distilled under vacuum. The melting point was 29.5 °C, as compared with the literature value (6) of 29 °C.

Dimethyl Sulfite

A sample from the Columbia Chemical Company was fractionally distilled, first under nitrogen and then under vacuum, to give a product boiling at 126 °C (7, 8).

Di(n-propyl) Sulfite

A sample was fractionally distilled under vacuum to give a middle fraction boiling at 192 °C; literature value (7) is 191 °C.

Methyl Sulfonyl Chloride

A sample from the Pennsalt Chemical Company was fractionally distilled to give a middle fraction boiling at 161 °C; literature values vary from 159 to 161.5 °C (9).

Sodium and Potassium Sulfite

Fisher Certified Reagent Grades were recrystallized twice under nitrogen, ground to a fine powder, and dried over phosphorus pentoxide. The products in both cases had a purity of 99.5%, by iodometric analysis.

Sodium Bisulfite

This was recrystallized from a mixture of water and ethanol under nitrogen. The product, after drying was 99.3% pure, by iodometric analysis.

Sodium and Potassium Bisulfate

Fisher Reagent Grade samples were recrystallized, ground to a fine powder, and dried over phosphorus pentoxide.

Fluorosulfuric Acid

A sample from the Allied Chemical Company was fractionally distilled; boiling point 162 °C, in agreement with the literature value (10).

Chlorosulfuric Acid

This was a reagent grade provided by the British Drug Houses.

Potassium and Cesium Fluorosulfites

These were prepared from the alkali metal fluoride and sulfur dioxide.

Anal. Calcd. for KSO_2F: K, 32.00; F, 15.55. Found: K, 32.28; F, 15.33.

Anal. Calcd. for $CsSO_2F$: Cs, 61.5; F, 8.79. Found: Cs, 61.0; F, 8.60.

Potassium Fluorosulfate

A sample from K and K Rare Chemicals Company analyzed as follows.

Anal. Calcd. for KSO_3F: K, 28.30; F, 13.75; S, 23.21. Found: K, 28.42; F, 13.46; S, 23.06.

Sodium and Potassium Chlorosulfates

These were prepared by the reaction of the alkali metal chloride with chlorosulfuric acid, the excess acid being then removed by distillation. The salts were analyzed for chlorine, and for the equivalents of acid produced on hydrolysis.

Anal. Calcd. for $NaSO_3Cl$: Cl, 25.60; weight to produce one equivalent of acid, 69.26. Found: Cl, 25.23; weight to produce one equivalent of acid, 70.13.

Anal. Calcd. for KSO_3Cl: Cl, 22.93; weight to produce one equivalent of acid, 77.3. Found: Cl, 22.06; weight to produce one equivalent of acid, 80.1.

The main impurity was the corresponding bisulfate.

Sodium Sulfide

A sample was recrystallized to give crystals of $Na_2S.9H_2O$. These were dehydrated by prolonged drying under vacuum over sulfuric acid. The product gave on analysis 97.0% Na_2S, and it was assumed that the rest was water.

Results

Table 1 gives the results for the molar diamagnetic susceptibilities for the various compounds. The units are -10^{-6} e.m.u/mol, and these units will be used throughout the discussion. Table 1 also contains values for the densities of the liquids; for solids only effective densities were obtained, or needed, and as these depend on the packing of the particular sample, they are not worth reporting. It might be added that dimethyl sulfone gave an effective density of 1.313 g/ml; as this was melted into the tube, and showed

TABLE 1. Density and molar susceptibility of various compounds

Compound	Density (g/ml at 25 °C)	Molar susceptibility (-10^{-6}e.m.u./mol)
$(CH_3)_2SO$	1.091	44.3
$(C_2H_5)_2SO$	1.001	67.3
$(CH_3)_2SO_2$	—	50.3
$(C_3H_7)_2SO_2$	1.112	97.1
$(CH_3)_2SO_3$	1.212	53.4_5

For personal use only.

little shrinkage on solidification, it is probably close to the true density. The susceptibilities are the means of at least three measurements, which agreed to 0.3%. The results for sodium and potassium chlorosulfates require comment, in that the samples, as analyzed, contained 2–3% of the alkali metal bisulfate. The susceptibilities per gram of these compounds are: $NaSO_3Cl$ 0.367, $NaHSO_4$ 0.364, KSO_3Cl 0.380, $KHSO_4$ 0.359. Therefore 3% of the bisulfates as impurity would change the g-susceptibility (and hence the molar susceptibility) of sodium chlorosulfate by 0.025% and of potassium chlorosulfate by 0.16%. These are less than other errors in measurement.

Discussion

A number of results on these, and related compounds, are available in the literature, some of them published after our own experimental work was completed. Relevant data on molar susceptibilities are: $(CH_3)_2SO$, 44.4 (11); $(C_2H_5)_2SO$, 67.0 (12); $(C_3H_7)_2SO$, 91.0 (11); $(C_4H_9)_2SO$, 112.5 (11); $(CH_3)_2SO_2$, 51.3 (11), 49.62 (13); $(C_3H_7)_2SO_2$, 97.3 (11), 96.7 (14); $(CH_3)_2SO_3$, 53.7 (11); $(C_3H_7)_2SO_3$, 100.6 (11).

Hameka (15) has shown that the diamagnetic susceptibility of a compound can be expressed as the sum of terms, firstly for each atom, secondly for each bond, and thirdly for the interactions of any two bonds with an atom in common. In general it is not possible to obtain a value for every term in such a sum from experimental data, but the terms can be grouped into a number of parameters, for which values can be found. In a homologous series containing only *n*-alkyl groups, the increment per CH_2 should be constant from the ethyl compound onwards. The methyl compound, or the hydrogen compound, might be expected to deviate from the constant increment, though the deviation in practice seems to be fairly small (16). O'Sullivan and Hameka (16) also suggest that the CH_2 increment is not constant from one series to another, but depends on the polar nature of the compounds.

If we apply their method to a compound RX, where R is an *n*-alkyl group, and X is any functional group, we obtain

$$\chi_M = a_0 + a_1 n$$

where n is the number of carbon atoms in R, provided n is two or more. The parameter a_1 is given by

$$a_1 = \chi_C + \chi_{CC} + 2\chi_{CH} + \chi_{CCC} + 4\chi_{CCH} + \chi_{HCH}$$

Here (and later), χ with one subscript is the contribution from the atom indicated by the subscript, χ with two subscripts is the contribution from the bonds between the two atoms indicated, and χ with three subscripts is the contribution from the interaction of two bonds starting from the central atom in the subscript and ending in the outside two. It can be seen that a_1 should be independent of the nature of the group X. It is assumed that χ_H is zero, as hydrogen has no inner electrons. If X is a single atom, a_0 is given by

$$a_0 = \chi_X - \chi_{CC} + \chi_{CH} + \chi_{CX} - 2\chi_{CCC} - 3\chi_{CCH} + 2\chi_{HCH} + \chi_{CCH} + 2\chi_{HCX}$$

This term depends on X; if X is polyatomic, a_1 is unchanged, but a_0 will contain other terms from bonds or interactions within X. For the methyl compound, CH_3X

$$\chi_M = a_0 + a_1 + \delta$$

where

$$\delta = \chi_{CCC} - \chi_{CCH} - \chi_{CCX} + \chi_{HCX}$$

Similarily for a compound R_2Y

$$\chi_M = a_0' + 2a_1 n$$

where each R contains n carbon atoms, provided n is two or more. a_1 has the same meaning as before, and a_0' if Y is monatomic, is given by

$$a_0' = \chi_Y - 2\chi_{CC} + 2\chi_{CH} + 2\chi_{CY} - 4\chi_{CCC} - 6\chi_{CCH} + 4\chi_{HCH} + 2\chi_{CCY} + 4\chi_{HCY} + \chi_{CYC}$$

The coefficients in most cases are double those of the corresponding term in a_0. For the methyl compound, $(CH_3)_2Y$, $\chi_M = a_0' + 2a_1 + 2\delta$, where δ is the same as before, with Y substituted for X.

For any series, a_0 (or a_0') and a_1 can be found by least squares. If this is done, the data in Table 1, refs. 11, 14, and 17, give the results in Table 2. In Table 2, the a_1 values, which are in fact the methylene increments, differ somewhat from Hameka's value of 11.26 for the alkanes. However it is not apparent that the a_1 values are related in any simple way to the structures of the series. The same applies to the values of δ in Table 2, though they are all rather small quantities, as has been found in other series (16).

If we look at the a_0 (or a_0') values in Table 2 we see firstly a very small increase in going from

For personal use only.

TABLE 2. a_0 or a_0', a_1, and δ values of a series of S compounds

Compound	a_0 or a_0'	a_1	δ
R_2S	22.42	11.50	−0.26
R_2SO	22.47	11.30	−0.39
R_2SO_2	24.97	11.80	+0.87
R_2SO_3	30.3	11.7	−0.13
R_2SO_4	39.2	11.7	−0.5
RSOCl	32.83	11.55	—
RSO_2Cl	40.76	11.06	1.87

the R_2S to the R_2SO series, similar to the change between R_3P and R_3PO, or between X^- and XO^-, where X is Cl or Br (18). This increase for the sulfur compounds equals

$$\chi_O + \chi_{SO} + 2\chi_{CSO}$$

and for the phosphorus compounds

$$\chi_O + \chi_{PO} + 3\chi_{CPO}$$

Hence, if the small increase in the phosphorus compounds is taken as evidence for a largely doubly bound oxygen, the same should be true of the sulfur series. The increase in a_0' from R_2SO to R_2SO_2 equals

$$\chi_O + \chi_{SO} + 2\chi_{CSO} + \chi_{OSO}$$

This is found to be appreciably larger than the increase from R_2S to R_2SO, and it is unlikely that this change can be ascribed to the extra χ_{OSO} term. Consequently the magnetic results suggest less double bonding in the sulfone, if it is assumed that doubly bound oxygen has a smaller diamagnetic contribution than singly bound, as is true of ketones and aldehydes, as compared with ethers and alcohols. However, the S—O distance is 1.47 ± 0.03 Å (19) in $(CH_3)_2SO$, and 1.43 ± 0.02 Å (20) in $(CH_3)_2SO_2$. The S—O stretching frequency is 1109 cm^{-1} in $(CH_3)_2SO$, which Gillespie and Robinson (21) interpret as a bond order of 1.56; the frequencies are $(CH_3)_2SO_2$ are $\nu_{sym} = 1143$, $\nu_{antisym} = 1310\ cm^{-1}$, which they interpret as a bond order of 1.77.

The best comparison for the sulfite is probably with the sulfoxide, where the increase in a_0' (sulfite–sulfoxide) is

$$2\chi_O - 2\chi_{CS} + 2\chi_{CO} + 2\chi_{SO} - 2\chi_{SCC} + 2\chi_{OCC} - 4\chi_{SCH} + 4\chi_{OCH} - 2\chi_{CSO} + 2\chi_{COS} - \chi_{CSC} + 3\chi_{OSO}$$

There will evidently be considerable cancellation in the bonding and interaction terms, but exactly how much is uncertain. The increase in a_0' is 7.8, or 3.9 per oxygen; somewhat smaller than for an ether oxygen, and considerably smaller than the increment of 7.5 per oxygen for the rather similar change from an alkyl phosphine oxide to an alkyl phosphate (1). If the sulfoxide contains a double bond, one can perhaps conclude that the sulfite does also. The increase in a_0' from sulfites to sulfates is

$$\chi_O + \chi_{SO} + 3\chi_{OSO}$$

which should not be very different from that from sulfoxide to sulfone. The actual increase is 8.9, which is large; but similar to that found in going from a ketone to an ester (about 8.6), or from a phosphite to a phosphate (about 9.4), this latter being a very similar structural change. The S—O distances in sulfuric acid (22) are fairly short (1.425 and 1.535 Å), with fairly high stretching frequencies (1368 and 968 cm^{-1}), which Gillespie and Robinson interpret as bond orders of 1.84 and 1.35. The relatively high magnetic susceptibility of both sulfuric acid and the sulfate esters presumably indicates considerable delocalization of the π-electrons.

In the acid halide series, it may first be noted as a basis for comparison that the average difference in magnetic susceptibility between a chlorine and a hydrogen atom is about 15.3 (data mostly from ref. 17). Consequently the difference of 15.8 between a_0 for R_2SO_2 and RSO_2Cl is in line with other covalent chlorides. However, the susceptibility of SO_2Cl_2 is only 9.9 higher than a_0 for RSO_2Cl. The S—O distances are much the same (about 1.43 Å) in all these compounds, but the S—O stretching frequencies increase along the series R_2SO_2, RSO_2Cl, SO_2Cl_2, being interpreted (21) as bond orders of 1.77, 1.82, and 1.87, respectively. This seems a somewhat small increase in double bond character to account for the considerable decrease in increment. The terms in these two increases should be

$$a_0(RSO_2Cl) - a_0'(R_2SO_2) = -\chi_H + \chi_{Cl} + \chi_{CC} - \chi_{CH} - \chi_{CS} + \chi_{SCl} + 2\chi_{CCC} + 3\chi_{CCH} - 2\chi_{HCH} - \chi_{SCC} - 2\chi_{SCH} - 2\chi_{SCO} + 2\chi_{OSO} - \chi_{CSC} + \chi_{CSCl}$$

$$\chi(SO_2Cl) - a_0(RSO_2Cl) = -\chi_H + \chi_{Cl} + \chi_{CC} - \chi_{CH} - \chi_{CS} + \chi_{SCl} + 2\chi_{CCC} + 3\chi_{CCH} - 2\chi_{HCH} - \chi_{SCC} - 2\chi_{SCH} - 2\chi_{CSO} + 2\chi_{OSO} - \chi_{CSCl} + \chi_{OSCl}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

These are sufficiently similar expressions, so that we can attribute differences in increment to differences in bonding.

The series: R_2SO, $a_0' = 22.5$; RSOCl, $a_0 = 32.8$; $SOCl_2$, $\chi = 45.2$ is more regular. The S—O distances are a little longer for R_2SO and the stretching frequency lower, as noted above; data for $SOCl_2$ are similar: S—O = 1.45 ± 0.02 Å (23), and 1229 cm^{-1} (24) which is interpreted as a bond order of 1.75. This agrees with the small increase in susceptibility along the series.

Turning now to the inorganic compounds, we must first consider what differences to expect from the different alkali metals used, or from the free acid. Selwood (25) gives as ionic susceptibilities: Na^+, 5; K^+, 13; Cs^+, 31; and similar values are quoted by Dorfman (26), though with a somewhat higher value of 36 for Cs^+. A comparison of salts of the same anion gives an average difference of 8.0 between Na^+ and K^+, and 20.6 between K^+ and Cs^+. Individual cases differ appreciably from these averages, since the susceptibilities are not strictly additive in terms of the ions they contain. If we accept the value of 5.0 for Na^+, and hence 13.0 for K^+ and 33.6 for Cs^+, the susceptibilities from the anions are as shown in Table 3, which also includes data by Trew *et al.* on sulfates (27), and on hydrogen sulfide (17).

The magnetic susceptibilities of HSO_3^- and SO_3^{2-}, or HSO_4^- and SO_4^{2-} are not very different, though HSO_4^- is somewhat less than SO_4^{2-}. These species differ only in a proton, and though the extent of delocalization of the π electrons must be somewhat different, this evidently has only a small effect on the susceptibility. Taking the average for each series we get: S^{2-}, 22.8; SO_3^{2-}, 28.6; SO_4^{2-}, 42.45; that is a rise of only 1.93 per oxygen in going from sulfide to sulfite, but a further rise of 11.85 in going to sulfate. In the latter increase, there is some resemblance to the phosphorus system. Gillespie and Robinson deduce bond orders 1.13 in sulfite and 1.50 in sulfate, so that it does not seem possible to correlate these with the magnetic susceptibilities in any simple fashion.

TABLE 3. Ionic susceptibilities

	Susceptibility				
Anion/cation	Na^+	K^+	Cs^+	Free acid	a_0
S^{2-}	22.8	—	—	25.5	22.4
SO_3^{2-}	31.0	26.2	—	—	30.3
HSO_3^-	27.95	—	—	—	—
SO_4^{2-}	42.45	41.2	43.7	39.8	39.2
HSO_4^-	38.8	36.0	—	—	—
SO_2F^-	28.2	28.0	—	—	—
SO_3F^-	—	38.65	—	37.4	—
SO_3Cl^-	45.75	45.65	—	46.2	—

As regards the halogen containing species, a comparison of the susceptibilities of a number of organic compounds, containing Cl, F, or OH (in alcohols), makes the average differences in susceptibility: Cl − OH, 10.3; Cl − F, 9.4; though with deviations from the average of up to 2.2. These are for covalent compounds; the differences for ions (mostly from alkali halides) are 13.6 for $Cl^- - F^-$, and, less certainly, 15.0 for $Cl^- - OH^-$. Selwood (25) gives values which make $Cl^- - F^-$ 15, and $Cl^- - OH^-$ 14. The differences observed for the ions in Table 3 are $SO_2F^- - HSO_3^-$ 0.25, and $SO_3F^- - HSO_4^-$ 1.25; both close to the average difference for covalent compounds of 0.9. Hence magnetically these behave as if the F and OH are similarly bound. The difference $SO_3Cl^- - HSO_4^-$ is 8.3; which is somewhat below the covalent average. This may indicate somewhat greater π-delocalization in HSO_4^- as compared with SO_3Cl^-, as might be expected from their formulae.

The Infrared and Raman Spectra of 3,4-Dichloro-1,2,5-thiadiazole

A. W. RICHARDSON

Department of Chemistry, Bishop's University, Lennoxville, Quebec

Received June 27, 1972

The i.r. and Raman spectra of 3,4-dichloro-1,2,5-thiadiazole have been recorded and assignments made for all 15 fundamental vibrations. Preliminary data from the vapor-phase u.v. absorption spectrum have been used to confirm some assignments.

Les spectres i.r. et Raman du dichloro-3,4 thiadiazole-1,2,5 ont été déterminés et les 15 vibrations fondamentales ont été assignées. Des données préliminaires dérivées des spectres d'absorption u.v. en phase vapeur ont été utilisées pour confirmer quelques-unes des attributions.

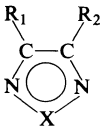
Introduction

We are currently investigating the vibrational and electronic spectra of compounds of the type



with the goal of determining the effects of the substituents R_1 and R_2 and heteroatom X on the ground and first excited states of these molecules. We have reported on the u.v. vapor-phase absorption spectra of 1,2,5-thiadiazole (**1**, $R_1 = R_2 = H$, X = S) (1) and furazan (or 1,2,5-oxadiazole) (**2**, $R_1 = R_2 = H$, X = O) (2). A report has also been given on the i.r. and Raman spectra of 3-chloro-1,2,5-thiadiazole (**3**, $R_1 = H$, $R_2 = Cl$, X = S) (3) in preparation for a study of its u.v. spectrum.

In the same way, we now present the results of a study of the i.r. and Raman spectra of 3,4-dichloro-1,2,5-thiadiazole (**4**, $R_1 = R_2 = Cl$, X = S). As in the study of **3**, the assignment of the fundamental vibrations is based primarily on the i.r. and Raman spectra, but some use of u.v. spectral data has been made to confirm the assignments of the totally symmetric vibrational modes.

Experimental

Compound **4** was prepared by the reaction of α-aminoacetonitrile bisulfate with sulfur dichloride in dimethylformamide followed by the addition of chlorine gas (4). After distillation through an 8 in. Vigreux column, the product was purified by g.l.c. using a 20 ft × 3/8 in. column of 30% SE30 on 45/60 Chrom W with a Varian Aerograph autoprep 700 gas chromatograph. Analytical g.l.c. on polar and non-polar columns showed the sample purity to be in excess of 99%.

The i.r. spectra were recorded on a Perkin–Elmer model 621 i.r. spectrophotometer. Spectra of the gas were recorded with the sample at its vapor pressure around room temperature in a 10 cm cell with KBr or CsI windows while those of the liquid were recorded for a capillary film between KBr plates or sheets of polyethylene. The Raman spectrum of the liquid sealed in a melting point tube was excited by an argon ion laser and recorded on a Spex double monochromator with a rotatable analyzer to measure depolarization ratios ρ.

Results

The measured wavenumbers of all bands observed for **4** in the i.r. and Raman spectra are listed in Table 1. Also included are other data such as estimated relative intensities, band types, depolarization ratios, etc. The accuracy of the measured wavenumbers is estimated to be about $\pm 2\ cm^{-1}$ for strong bands and somewhat worse for weaker bands. The i.r. spectrum of **4** in the gas phase is illustrated in Fig. 1.

Interpretation of Spectra

Compound **4** was assumed to be a planar molecule of C_{2v} symmetry like **1** (5). Thus, the 15 normal modes of vibration can be classified by symmetry as $6A_1 + 2A_2 + 2B_1 + 5B_2$.[1]

The A_1, B_1, and B_2 vibrations are allowed in the i.r., with types *A*, *C*, and *B* band contours, respectively, in the vapor phase. To facilitate making assignments for **4**, types *A*, *B*, and *C*

[1]The axis system used here has the *z* axis as the C_2 axis and the *x* axis perpendicular to the plane of the molecule. This recommended axis system was not used in earlier work on related molecules, thus leading to interchange of the B_1 and B_2 symmetry species as used here.

†b = broad.

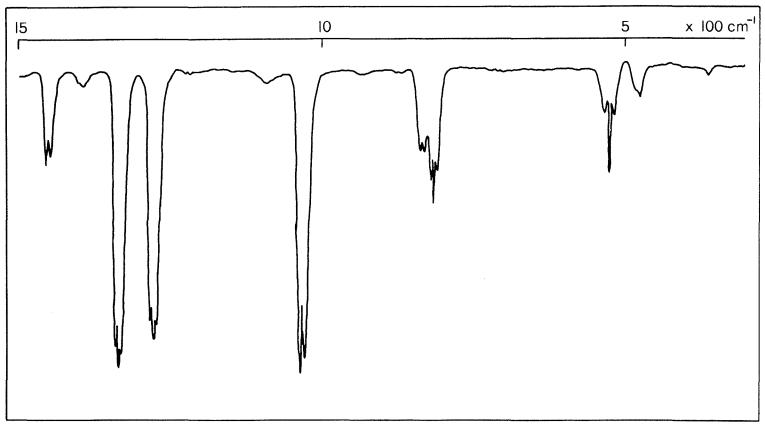

FIG. 1. The i.r. spectrum of 3,4-dichloro-1,2,5-thiadiazole in the vapor-phase.

band contours were calculated in the rigid asymmetric rotor approximation (6) using a computer program written by Pierce. Band contours calculated using the rotational constants $A = 0.06384$, $B = 0.04959$, and $C = 0.02791$ cm^{-1} for both the lower and upper states are shown in Fig. 2. These rotational constants were calculated by assuming the structure of **4** to be exactly the same as **1** (5) and r(C—Cl) = 1.70 Å (7).

All 15 fundamental vibrations are allowed in the Raman spectrum. The $6A_1$ fundamentals should be polarized ($\rho < 0.75$) while all others should be depolarized ($\rho = 0.75$). Because of experimental errors in measuring intensities, ρ values calculated from observed spectra may differ from the theoretical values. This was previously found to be particularly noticeable for low frequency bands in **3** recorded under the same conditions as used here (3).

Particular assignments for the fundamentals of **4** are based on assignments in related molecules. For the ring modes, the assignments made previously for **1** (8, 9) and **3** (3) were used as guides. Since it has been shown that **1** has aromatic character (5), it was felt that the effect of replacing two adjacent H atoms by Cl atoms might be similar to that in benzene. Thus, the X-sensitive modes of *o*-dichlorobenzene were used as guides in assigning the related modes of **3**.

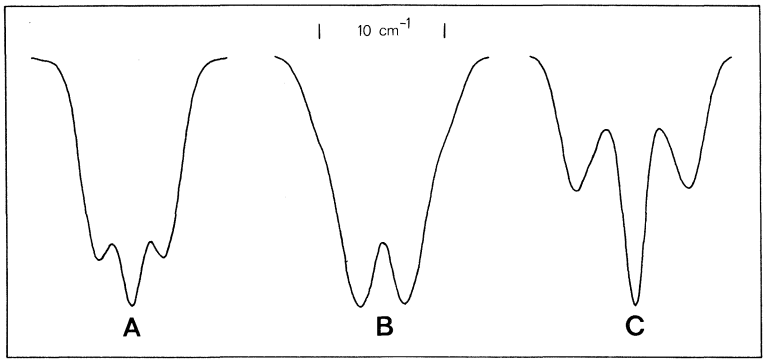

FIG. 2. Calculated type *A*, *B*, and *C* band contours for 3,4-dichloro-1,2,5-thiadiazole.

Normal coordinate calculations have shown that the vibrations involving the chlorine substituents are strongly coupled with the ring vibrations in *o*-dichlorobenzene (11). Therefore, it is to be expected that the same situation obtains in **3**. Since there are likely no "pure" vibrations, it is clear that definitive assignments of observed frequencies to particular atomic motions cannot be made and the safest procedure to follow at this point would be to label vibrations as ring modes or as X-sensitive modes as is done in *o*-dichlorobenzene (10). However it was thought useful to attempt to classify the X-sensitive vibrations further in terms of the principal components of the normal modes. Examination of the potential energy distribution calculated for *o*-dichlorobenzene (11) and the assignments made for other molecules having similar C—Cl bonds allowed reasonable conclusions as to which vibrational motion predominates in a particular normal mode to be reached and these are indicated below. These assignments are, of course, quite qualitative; more detailed assignments can be made only after a normal coordinate calculation.

A_1 Fundamental Vibrations

From consideration of the intensities of the observed bands plus the requirements that the band contours in the vapor-phase i.r. spectrum should be type *A* and the measured depolarization ratios in the Raman spectrum should be less than 0.75, it is clear that five of the A_1 fundamentals are 1334, 1278, 814, 738, and 471 cm^{-1}. For reasons detailed below, the sixth A_1 fundamental is chosen to be the band observed at 190 cm^{-1} in the Raman spectrum of the liquid.

By comparison with the assignments for **1** and **3**, it is clear that 1334 and 1278 cm^{-1} are ring stretching fundamentals and 814 cm^{-1} is a ring in-plane bending fundamental. That the bands at 738, 471, and 190 cm^{-1} are due to X-sensitive modes is clear from comparison to assignments for **1** and **3**. The band at 738 cm^{-1} may be assigned as largely due to the symmetric C—Cl stretching motion since it is the only strong A_1 band in the expected range. Similarly, the band at 471 cm^{-1} must be largely due to a ring in-plane bending motion. The remaining A_1 fundamental at 190 cm^{-1} is assigned as being largely due to C—Cl symmetric in-plane bending motion. This assignment was initially made by analogy to *o*-dichlorobenzene where an A_1 band largely due to the C—Cl symmetric in-plane bending motion is observed at 202 cm^{-1} (10, 11); this was done in spite of the fact that its measured depolarization ratio of 0.74 is greater than expected since there is confirmation of the assignment from the u.v. studies.

Preliminary analysis of the vapor-phase u.v. absorption spectrum of **4** in the 2900–2400 Å region (which undoubtedly is due to an allowed electronic transition) has shown the presence of hot bands at intervals of 1276 ± 3 (7), 814 ± 3 (9), 744 ± 2 (9), 471 ± 6 (10), and 202 ± 2 (9) cm^{-1} to long wavelengths of common bands in several places.[2] Obviously, the first four of these correspond to the A_1 fundamentals at 1278 (vapor), 814 (vapor), 738 (liquid), and 471 (vapor) cm^{-1}, previously assigned. The 202 cm^{-1} interval observed in the vapor must correspond to the 190 cm^{-1} band observed in the liquid and so provides conclusive evidence for its assignment as an A_1 fundamental.

[2]The figures given are the average value and standard deviation for the number of intervals given in parentheses observed in the vapor-phase u.v. absorption spectrum.

	ν_8	178‡	X-Sensitive (C—Cl out-of-plane bend)
B_1	ν_9	525	Ring out-of-plane bend
	ν_{10}	271†	X-Sensitive (C—Cl out-of-plane bend)
B_2	ν_{11}	1451	Ring stretch
	ν_{12}	1031	X-Sensitive (ring in-plane bend)
	ν_{13}	874	X-Sensitive (ring in-plane bend)
	ν_{14}	833	X-Sensitive (C—Cl stretch)
	ν_{15}	358	X-Sensitive (C—Cl in-plane bend)

*For the X-sensitive modes, the motion which most likely predominates in the normal mode is given in parentheses.
†Measured in i.r. of neat liquid.
‡Measured in Raman of neat liquid.

A_2 Fundamental Vibrations

Since these two vibrations are forbidden in the i.r. but allowed in the Raman, the assignments here should be straightforward. The band observed at 451 cm^{-1} in the Raman must therefore be an A_2 fundamental and is assigned as ν_7, an X-sensitive mode largely due to ring out-of-plane bending motion, by analogy to **1**. The fact that the measured depolarization ratio is less than the expected value of 0.75 must be caused by experimental errors in the intensity measurements which are probably due to the weakness of the band.

The remaining A_2 fundamental is expected to occur at low frequency, the analogous mode in *o*-dichlorobenzene occurring at 152 cm^{-1} (10). Therefore, ν_8 is assigned as the band observed at 178 cm^{-1} in the Raman; this mode is X-sensitive, but is expected to be largely due to C—Cl out-of-plane bending motion.

B_1 Fundamental Vibrations

These vibrations are allowed in the i.r., with a type *C* band contour in the vapor-phase, and in the Raman with a depolarization ratio of 0.75. From its observed type *C* band contour, the band at 525 cm^{-1} must be due to a B_1 vibration, and by analogy to **1** and **3** it is assigned as ν_9, a ring out-of-plane bending. ν_{10} is expected to be X-sensitive and to have a major contribution from C—Cl out-of-plane bending motion. Since the analogous vibration in *o*-dichlorobenzene is observed at 239 cm^{-1} (10), ν_{10} is assigned to the band at 271 cm^{-1}.

B_2 Fundamental Vibrations

These five vibrations are allowed in the i.r. with type B band contours in the vapor phase and in the Raman with depolarization ratios of 0.75. Examination of the observed spectra shows that the bands at 1451, 1051, and 833 cm^{-1} must be B_2 fundamentals. By comparison with **1** and **3**, 1451 cm^{-1} must be assigned as a ring in-plane stretching vibration. The 1031 and 833 cm^{-1} bands are clearly X-sensitive since there is no simple correlation with bands of **1** and **3**. The

	C—Cl antisymmetric in-plane bend	360	336

*The description gives the motion which most likely predominates in the particular normal mode (see text).
†Value in parentheses is for the vapor-phase as determined from the u.v. absorption spectrum.

most probable assignments would seem to be that 1031 cm^{-1} involves largely ring in-plane bending motion while 833 cm^{-1} involves mainly C—Cl antisymmetric stretching motion.

There now remain two B_2 fundamentals to be assigned; these will both likely be X-sensitive but one will consist largely of ring in-plane bending motion while the other will consist largely of C—Cl in-plane bending motion. There is only one band at low wavenumbers which is not assigned; this band at 358 cm^{-1} is easily assigned to an X-sensitive normal mode largely involving C—Cl in-plane bending motion since the corresponding vibration in *o*-dichlorobenzene occurs at 336 cm^{-1}. The assignment of the remaining fundamental presents more of a problem since there are no strong type *B* bands left. By reference to **1** and **3**, this X-sensitive vibration might be expected to fall in the 400–1000 cm^{-1} range. The only unassigned type *B* band in this range is at 874 cm^{-1} and so it must be assigned the X-sensitive mode largely involving the ring in-plane bending motion. This assignment is supported by the fact that this band cannot be assigned as a first overtone or binary combination band of B_2 symmetry.

Other Assignments

All except one of the other bands observed can be assigned as first overtones or binary combinations using the assignment of fundamentals given above; in a few cases more than one assignment is possible for a particular band. The details of these assignments are given in Table 1. In a few cases of weak bands, the assignments may be questioned (*e.g.* A_2 combination observed in the i.r. of the liquid), but in the absence of other suitable assignments these are left as indicated.

Conclusion

The assignments of the fundamental vibrations of 3,4-dichloro-1,2,5-thiadiazole are summarized in Table 2. These are consistent with the molecule being planar and having C_{2v} symmetry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The assignments for the ring modes can be correlated with those of the parent molecule 1,2,5-thiadiazole and 3-chloro-1,2,5-thiadiazole as shown in Table 3. The correlation is particularly good for the three ring stretching vibrations, the ring in-plane bend near 815 cm^{-1}, and the ring out-of-plane bend near 520 cm^{-1} but rather poorer for the four remaining vibrations due to their X-sensitive nature. The correlation obviously supports the assignments made and gives a better understanding of the form of these normal modes in these molecules.

A comparison of the frequencies of the remaining (X-sensitive) normal vibrations in 3,4-dichloro-1,2,5-thiadiazole with analogous vibrations of *o*-dichlorobenzene is given in Table 4 and shows that although the values for the former molecule are generally larger than for the latter molecule, the correlation is sufficiently good to give confidence in the assignments made.

The Kinetics of the Ethanolysis Reaction of Some 4-Nitro-substituted Triphenylmethyl Chlorides

ELEANOR L. KULIN AND K. T. LEFFEK
Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received July 31, 1972

The kinetics of the ethanolysis of three triphenylmethyl chlorides, the 4-nitro, 4,4′-dinitro, and 4,4′,4′′-trinitrophenylmethyl compounds, have been studied. The effect of change in substrate and solvent composition on the activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, has been determined. For these compounds, $\Delta H^{\ddagger}$ appears to be controlled by substrate structure while $\Delta S^{\ddagger}$ varies predominantly with solvent composition.

The attempted reaction of pyridine with 4,4′,4′′-trinitrophenylmethyl chloride to form the quaternary ammonium salt is also reported.

The reactions are interpreted to be proceeding via a carbonium ion-pair mechanism.

La cinétique de l'éthanolyse de trois chlorures de triphénylméthyl, le nitro-4, le dinitro-4,4′ et le trinitro-4,4′,4′′ phénylméthyl, a été étudiée. L'effet causé par le changement du substrat et par la composition des solvants sur les paramètres d'activation, $\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$, a été déterminé. Pour ces composés, il semble que le soit controlé par la structure du substrat alors que le $\Delta S^{\ddagger}$ varie essentiellement avec la composition du solvant.

La tentative pour réaliser la réaction entre la pyridine et le chlorure de trinitro-4,4′,4′′ phénylméthyl en vue de former le sel d'ammonium quaternaire est aussi relatée.

Un mécanisme impliquant une paire d'ions dont un ion carbonium est envisagé pour ces réactions.

Introduction

Nucleophilic substitution reactions on the central carbon atom of triphenylmethyl chloride have attracted a number of investigators because of the relative stability of the derived carbonium ion under a variety of conditions (1). This compound reacts via a carbonium ion mechanism even under conditions adverse to the ionization process. Thus in a benzene solution, which is colorless, the second-order reactions observed are in fact bimolecular attacks of the reagent on the triphenylmethyl chloride carbonium ion-pair (2–11). In order to observe an S_N2 reaction the substrate molecule must have its ionizing capability reduced by electron-withdrawing substituents on the phenyl rings. Patai and Zabicki (12) studied the acetolysis of 4,4′,4′′-trinitrophenylmethyl chloride, but found no reaction in glacial acetic acid at 30 °C, although solvolysis took place in aqueous acetic acid via a carbonium ion mechanism. However, Miotti and Fava (13) investigated the radiochloride exchange in acetone solvent between the same substrate and tetraethylammonium radiochloride and presented evidence that the reaction was a direct S_N2 attack on the covalent molecule.

In the present paper we report the rate constants and activation parameters for the 4-nitro, the 4,4′-dinitro, and the 4,4′,4′′-trinitrotriphenylmethyl chloride undergoing ethanolysis in two solvents.

Results and Discussion

Ethanolysis Reaction

First-order rate constants were obtained for the ethanolysis of each of the substituted triphenylmethyl chlorides at a minimum of seven different temperatures over a 35–40° range. At most temperatures, three or four runs were made, although with the very slow reactions only two runs were carried out. Since the 4-nitrotriphenylmethyl chloride was found to react with ethanol at about the same rate as it dissolves, the ethanolysis of this compound was measured in a solvent consisting of 30% v/v dioxane in ethanol. The 4,4′-dinitrotriphenylmethyl chloride was measured in both this mixed solvent and pure ethanol and the 4,4′,4′′-trinitrotriphenylmethyl chloride was studied only in ethanol. The results given in Table 1 were calculated by a least squares analysis of the data obtained by either the Guggenheim method (14) or from the

integrated first-order rate equation. The latter was used only for the runs which were too slow to follow over the three half-lives required by the Guggenheim method.

The rate constants of Table 1 were fitted to the transition state theory eq. 1 by a least squares computation. An example plot is shown

$$[1] \quad \log_{10}(k_1/T) = \log(k/h) + \Delta S^{\ddagger}/2.303R - \Delta H^{\ddagger}/2.303RT$$

in Fig. 1 from which it can be seen that, within the precision of the results there is no evidence of non-linearity in the dependence of $\log_{10}(k_1/T)$ on $1/T$. The derived activation parameters are shown in Table 2.

Since there was no discernible temperature dependence of the enthalpy of activation, the heat capacity of activation, $\Delta C_p^{\ddagger}$ seems to be indistinguishable from zero. This means it is less than about -30 cal deg^{-1}, which corresponds to a change of 0.1 kcal mol^{-1} in $\Delta H^{\ddagger}$ over a 30° temperature range.

The rate constants in Table 1 show that the order of solvolytic reactivity is trinitro < dinitro < mononitro derivative, which immediately suggests that we are dealing with a reaction, the mechanism of which involves an ionization as a rate determining step. This mechanism would be a classical S_N1 mechanism (15), which is at variance with the findings of Miotti and Fava

TABLE 2. Activation parameters for the ethanolysis of substituted triphenylmethyl chlorides

Substituents:	4-Nitro	4,4′-Dinitro		4,4′,4″-Trinitro
Solvent:	Dioxane/ethanol	Dioxane/ethanol	Ethanol	Ethanol
$\Delta H^{\ddagger}$ (kcal mol^{-1})	13.5±0.1	16.5±0.1	17.1±0.1	20.1±0.2
$\Delta S^{\ddagger}$ (cal deg^{-1} mol^{-1})	−23.9±0.2	−24.6±0.3	−18.6±0.4	−17.2±0.5

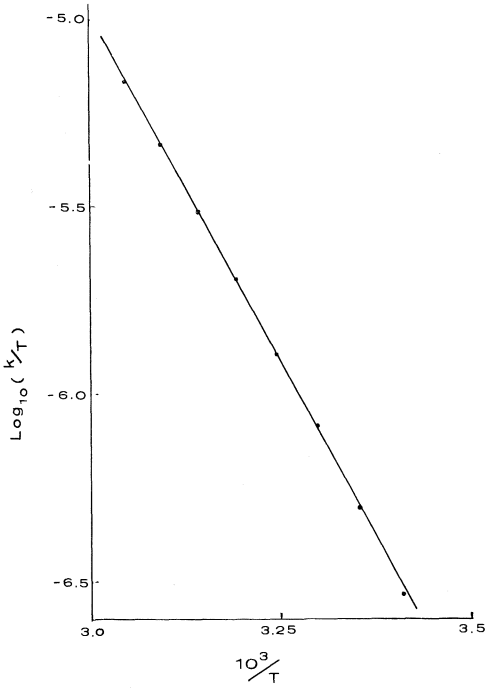

FIG. 1. Activation parameter plot for the solvolysis of 4,4′-dinitrotriphenylmethyl chloride in ethanol.

(13). However, the latter authors claimed a simple S_N2 reaction only for the radiochloride exchange of the trinitro-derivative in acetone solvent. They noted that in acetonitrile solvent the first-order component of the reaction increased and the second-order component decreased. Nevertheless, in both solvents, both the first- and second-order rate constants were greater for the dinitro than for the trinitro compounds, *i.e.* the same order as we observe. To explain this the authors suggested that "bond breaking may well be predominant in these bimolecular substitutions". It is very difficult philosophically and experimentally to distinguish between a simple S_N2 reaction with predominant bond breaking and a two-step mechanism with an ion-pair intermediate, although some erudite attempts have been made, particularly by Sneen and coworkers (16–20) and by Scott (21). Sneen *et al.* have suggested that S_N reactions go via ion-pair mechanisms and that direct attack on the covalent substrate seldom, if ever, occurs. This postulate is based on a detailed analysis of only a few S_N reactions, although Scott (21) has expanded the scope of the theory by applying it to solvolysis reactions of primary alkyl compounds. Sneen's theory is analogous to saying that there are no covalent or ionic bonds in chemistry but only bonds intermediate between the two. For S_N reactions he has cut back the range for the pure S_N1 and S_N2 mechanisms to practically nothing, and increased the range for intermediate mechanisms and at the same time described the intermediate mechanisms in more concrete terms. This is the direction in which the study of reaction mechanisms ought to be going, but this does not necessarily mean that Sneen's description of S_N reactions is, at this time, more useful than Ingold's S_N1 and S_N2. It seems clear that Miotti and Fava observed a reaction of trinitrotriphenylmethyl chloride in acetone, at least very close to a simple S_N2 displacement, whereas it seems most likely that in the more polar ethanol solvents, the solvolysis reactions probably proceed through a carbonium ion-pair, *i.e.* the present results are consistent with Sneen's theory, although the solvolysis of this substrate molecule is not a rigorous test of the theory.

A comparison of the rates in the two solvents for the dinitro compound also shows that this substrate reacts about seven times faster in the more polar ethanol than in the less polar mixed solvent, again indicating that the transition state of the rate determining step has more charge separation than the initial state.

The activation parameters in Table 2 exhibit an interesting pattern in that the enthalpy of activation, $\Delta H^{\ddagger}$, changes with substrate structure but not significantly with solvent change. On the other hand, the entropy of activation, $\Delta S^{\ddagger}$, remains constant when the alkyl group is changed but is distinctly different for the two solvents.

The enthalpies of activation increase with

increasing number of nitro substituents, qualitatively as would be expected for a rate determining ionization step, since each strongly electron-attracting nitro group would make it more difficult for the electrons of the carbon–chlorine bond to be transferred to the chlorine atom.

The fact that the entropies of activation do not change with substrate structure indicates, according to the criterion of Long and Schalager (22), that the mechanism of the reaction is the same for all three substrate molecules. However, the large negative values of $\Delta S^{\ddagger}$ would classify these reactions on Long's criterion as S_N2, although Long set up the $\Delta S^{\ddagger}$ test on the basis of hydrolysis reactions and cautioned that the complexity of the $\Delta S^{\ddagger}$ parameter precluded a too quantitative use of its size as an indicator of mechanism. Since it can be seen that about -6 cal mol^{-1} deg^{-1} can be added to this parameter by the introduction of the non-reacting co-solvent dioxane, the $\Delta S^{\ddagger}$ values cannot be considered evidence against an S_N1 mechanism but nevertheless may indicate non-typical behavior.

In a carbonium ion-pair mechanism either the first ionization step may be rate controlling (S_N1) or the second nucleophilic attack step may be rate controlling (S_N2 C^+). For solvolysis reactions, in particular, intermediate mechanisms may be envisaged in which neither step is completely rate controlling. The mechanism for the ethanolysis of 4-nitro substituted triphenylmethyl chlorides is most probably an intermediate mechanism but well over towards S_N1, *i.e.* the ionization step to yield a carbonium ion-pair is clearly the most important in controlling the rate but not necessarily exercising complete control. It is then easy to imagine that this mechanism changes to S_N2 with predominant bond breaking when the solvent is changed to acetone and the nucleophile to chloride ion, as found by Miotti and Fava (13).

Reaction of 4,4′,4′′-Trinitrophenylmethyl Chloride with Pyridine

Although the early literature contains many reports of the reaction of triphenylmethyl chloride itself with pyridine to form the quaternary ammonium salt, more recent work (4) shows that this reaction does not take place at atmospheric pressure, although Okamoto and Shimakawa (23) have prepared the salt at 4000–5000 atm pressure.

4,4′,4′′-Trinitrotriphenylmethyl chloride (10^{-3} *M*) in pyridine solution was maintained at 60–65 °C for 17 days, during which time the conductance of the solution increased by only a very small amount. If the quaternization reaction takes place it must be at least 500 times slower than the ethanolysis, or alternatively there is an equilibrium which overwhelmingly favors the reactants. Either of these alternatives is consistent with the proposition that an S_N2 reaction is not easily accomplished in the solvolysis of this type of substrate.

Experimental

4,4′,4′′-Trinitrotriphenylmethyl Chloride

This was prepared in a two-step process from triphenylmethane. The nitration was carried out according to the method of Shoesmith *et al.* (24) using a mixture of nitric and sulfuric acids at -5 to 0 °C. The nitrated methane was dried and recrystallized from chloroform – petroleum ether, m.p. 210–211 °C (lit. 212.5 °C (24)).

The chlorination of the trinitro derivative was carried out by the procedure given by Patai and Zabicky (12) using a similar apparatus. The reaction was carried out with 4 g of starting material and yielded 2.5 g of yellow crystals of 4,4′,4′′-trinitrotriphenylmethyl chloride, m.p. 199–204 °C (lit. 196–198 °C and 208 °C (12)). The n.m.r. spectrum ($CDCl_3$) gave δ 8.22, d, $J = 9$ Hz, 6H; 7.45, d, $J = 9$ Hz, 6H.

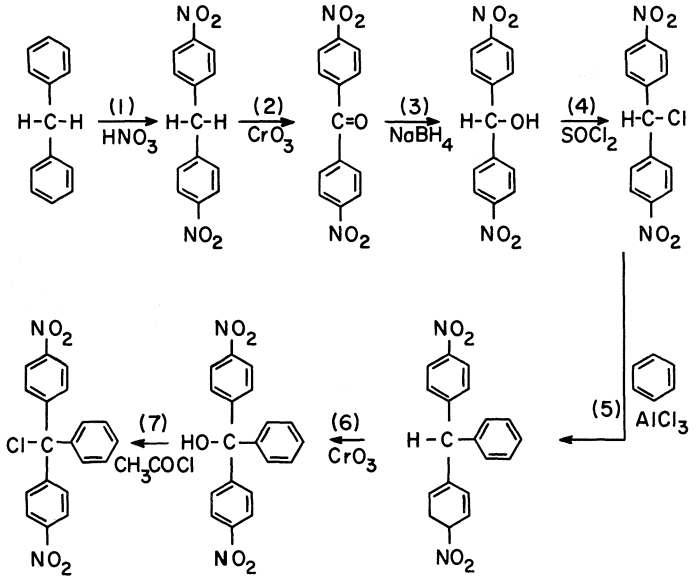
4,4′-Dinitrotriphenylmethyl Chloride

Ziegler and Mathes (25) described the preparation of this compound in 1930 using the method which Baeyer and Villiger (26) used for the preparation of 4-nitrotriphenylmethyl chloride in 1904 (see below). This method was found to work much more poorly for the dinitro derivative than for the mononitro derivation. Although on one attempt some product was obtained, it was not possible to purify it for kinetic measurements. The dinitro derivative was, therefore, prepared by the seven step procedure shown in Scheme 1.

Step 1. Diphenylmethane (75 g) was added in a fine stream to a vigorously stirred solution of nitric acid (390 g) and sulfuric acid (470 g) maintained at -10 to $-20°$. Stirring was continued for 45 min, the temperature not rising above -10 °C, then the solution was poured into an excess of ice water, the yellow precipitate filtered off, and washed with water, methanol, and hot diethyl ether. Yield of 4,4′-dinitrophenylmethane was 60 g, m.p. 186–189 °C (lit. 183 °C (27)).

Step 2. 4,4′-Dinitrophenylmethane (60 g) was dissolved in glacial acetic acid (700 ml) and the mixture refluxed. A solution of chromic anhydride (10 g) in water (110 ml) was slowly added through the top of the condenser and refluxing was continued for 2 h. The cooled solution was then added to an excess of ice-water, whereupon the crude 4,4′-dinitrobenzophenone precipitated. This was filtered, washed with water, $NaHCO_3$ solution, and water again, then dried at 90 °C. The i.r. spectrum contained a peak at 1675 cm^{-1} ($CHCl_3$). The yield was 68 g, m.p. 183–186 °C (lit. m.p. 189 °C (27)).

Step 3. 4,4′-Dinitrobenzophenone (68 g) was added to 95% ethanol (500 ml), followed by $NaBH_4$ (3 g) and the



SCHEME I

solution was allowed to stand 10 h, then poured into an excess of water. The yellow precipitate of 4,4′-dinitrodiphenylmethanol was collected and dried. The yield was 45 g, m.p. 160–162 °C. The i.r. spectrum showed a peak at 3570 cm^{-1} ($CHCl_3$), but none at 1675 cm^{-1}.

Step 4. 4,4′-Dinitrodiphenylmethanol (45 g) was dissolved in dry benzene (700 ml). Freshly distilled thionyl chloride (59 g) was slowly added and the solution refluxed 8 h. The benzene and excess thionyl chloride were distilled off under reduced pressure leaving a brown oil. This oil was dissolved in a minimum quantity of hot benzene, and warm petroleum ether (90–120 °C) was added until the solution became cloudy. On allowing to stand overnight, yellow crystals formed. The yield of the 4,4′-dinitrodiphenylmethyl chloride was 30 g, m.p. 109–111 °C. The i.r. spectrum showed no peak at 3570 cm^{-1}.

Step 5. 4,4′-Dinitrodiphenylmethyl chloride (30 g) was dissolved in dry benzene (800 ml). Freshly sublimed anhydrous aluminum chloride (30 g) was added slowly, and the solution refluxed for $3\frac{1}{2}$ h with vigorous stirring. On cooling, ice and dilute HCl were added to the stirred mixture. The whole mixture was poured into a separatory funnel and the aqueous layer drawn off. The benzene layer was washed twice with dilute HCl and the acid layers were collected and washed once with fresh benzene. The combined benzene layers were dried for at least 12 h over anhydrous $CaCl_2$, filtered, and the benzene was evaporated off at a rotary evaporator. The brown oil which remained was dissolved in the minimum quantity of benzene, and warm petroleum ether (b.p. 90–120 °C) was added until the solution became cloudy. Benzene was added to just clear the cloudiness and the mixture was allowed to cool slowly. After about 2 h, yellow crystals and a red oil formed. The residue was recrystallized several more times by the same procedure before a pure product, free from oily residue, could be separated. The yield of 4,4′-dinitrotriphenylmethane was 15 g, m.p. 160–165 °C.

Step 6. The methane (5 g) was dissolved in glacial acetic acid (150 ml) and heated under reflux, then a solution of chromic anhydride (7.5 g) dissolved in water (50 ml) was slowly added through the top of the condenser, after which refluxing was continued for 1 h. The reaction mixture was added to an excess of ice water, the yellow 4,4′-dinitrophenylmethanol which precipitated was collected, washed with water, $NaHCO_3$, and water again. The product was dried overnight, yield 4 g, m.p. 143–146 °C. The i.r. spectrum ($CHCl_3$) gave a peak at 3600 cm^{-1}.

Step 7. The alcohol (4 g) was added to freshly distilled acetyl chloride (50 ml) and refluxed 12 h. Dry benzene (20 ml) was added and the excess acetyl chloride distilled off under reduced pressure. The volume of the benzene was reduced to about 10 ml on a rotary evaporator, and petroleum ether (b.p. 90–120 °C) was added until the solution became cloudy. On standing overnight yellow crystals of 4,4′-dinitrotriphenylmethyl chloride formed and were recrystallized from benzene – petroleum ether. The n.m.r. spectrum ($CDCl_3$) gave δ 7.2–7.5, m, 5H; 8.17, d, $J = 9$ Hz, 4H; 7.53, d, $J = 9$ Hz, 4H. The i.r. spectrum ($CHCl_3$) gave no peak at 3600 cm^{-1}. Potentiometric titration indicated 97% purity, by chloride analysis. The yield was 3.5 g, m.p. 139–140 °C (lit. m.p. 141 °C (25)).

4-Nitrotriphenylmethyl Chloride

This was prepared in a two-step reaction from nitrobenzophenone by the method of Baeyer and Villiger (26). The latter material was converted to 4-nitrobenzophenone dichloride using PCl_5. The product was crystallized from hot petroleum ether (90–120 °C). Yellow crystals were obtained, m.p. 54–55 °C (lit. 56–57 °C (26)). The dichloride was reacted with $AlCl_3$ in dry benzene. The crude product was recrystallized several times from hot petroleum ether (90–120°) before oil-free yellow crystals were obtained. Two final recrystallizations were made from petroleum ether in the presence of acetyl chloride. The

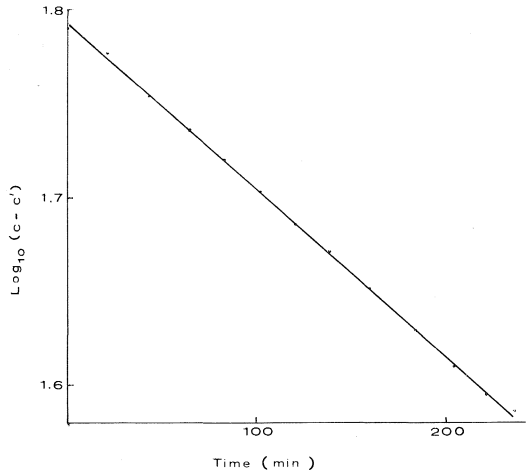

FIG. 2. Run No. 192. Guggenheim plot for the solvolysis of 4,4′-dinitrotriphenylmethyl chloride in ethanol–dioxane (70:30 v/v) at 29.9 °C.

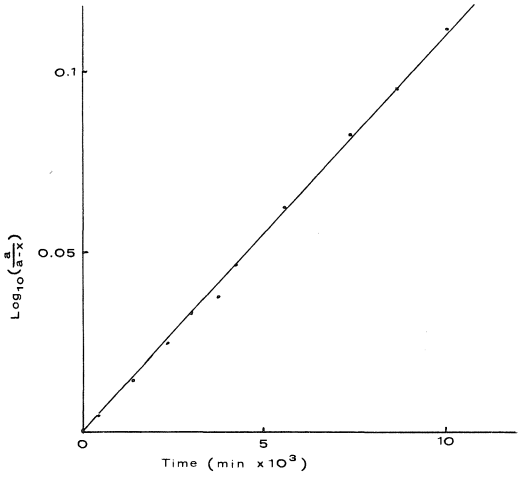

FIG. 3. Run No. 152. First-order plot for the solvolysis of 4,4′,4″-trinitrotriphenylmethyl chloride in ethanol at 25.0 °C.

yield of the second step was about 4%, m.p. 90–92 °C (lit. 92–93 °C (26)). The n.m.r. spectrum ($CDCl_3$) gave δ 7.25–7.35, m, 10H; 8.15, d, J = 9 Hz, 2H; 7.47, d, J = 9 Hz, 2H.

Solvents

Ethanol was dried with Mg turnings and fractionally distilled. Dioxane was dried with anhydrous $CaCl_2$ for 24 h, then sodium metal for another 24 h, followed by 6 h refluxing over sodium metal. The dioxane was then fractionally distilled.

Kinetic Procedure

The rates were determined by following the change in conductance with time, using cells of *ca.* 25 ml capacity, shiny platinum electrodes, and cell constants of about 0.01. The conductances were measured with a Wayne–Kerr bridge, type B221. The initial concentrations of the substrates were about 2×10^{-4} M or less and at such concentrations the relation between the produced HCl and measured conductance was found by experiment to be linear. Thus, most of the rate constants were calculated directly from the conductance readings using the Guggenheim method (14). However, the trinitro-derivative reacted too slowly below 50 °C to be followed over the minimum three half-lives, so the integrated first-order rate equation was used for these runs; the concentration of unreacted chloride being calculated from the HCl concentration read from a calibration plot. The calibration plots were set up using the precision burette described by Martin *et al.* (28). Two example runs are shown in Figs. 2 and 3.

The authors are grateful for financial support by the National Research Council of Canada, to Dr. R. E. Robertson for the loan of the precision burette, and to Dr. T. P. Forrest for helpful discussions on synthetic problems.

Biosynthesis of Mycophenolic Acid[1]

C. T. Bedford, P. Knittel, T. Money, G. T. Phillips, and P. Salisbury
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received May 8, 1972

Comparative incorporation experiments with (1′-^{14}C)-orsellinic acid (**2**) and (1′-^{14}C)-4,6-dihydroxy-2,3-dimethylbenzoic acid (**3**) suggest that only the latter compound is a specific precursor of mycophenolic acid; the implication of this result in terms of the early stages of the biosynthetic sequence is noted.

Des expériences comparatives d'incorporation avec l'acide orsellinique (1′-^{14}C) (**2**) et l'acide dihydroxy-4,6 diméthyl-2,3 benzoïque (1′-^{14}C) (**3**) suggèrent que seulement, le dernier composé nommé est un précurseur spécifique de l'acide mycophénolique; l'implication de ce résultat en ce qui a trait aux premières étapes de la séquence biosynthétique est aussi relatée.

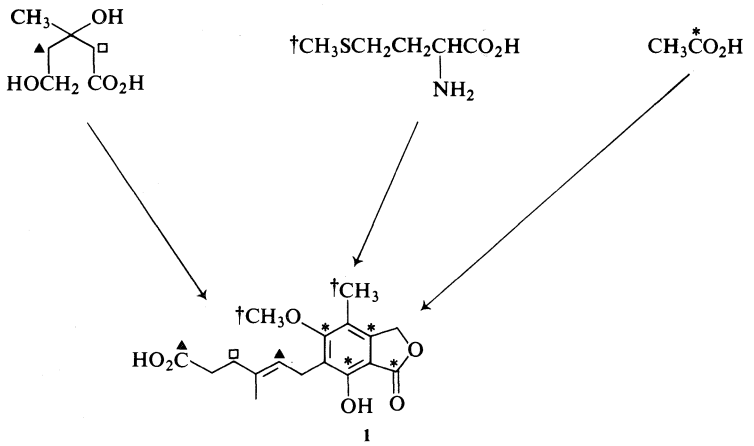
The structure (2, 3), synthesis (4), biosynthesis (1, 5–9), and biological activity (10) of mycophenolic acid (**1**), a metabolite of *P. brevicompactum*, have been the subject of considerable investigation. Current interest in the compound is centered primarily on its potential use in chemotherapy (10). At the outset of our investigations little was known of the sequence of reactions or intermediates involved in the biosynthesis of this important mold metabolite. Previous studies by Birch and co-workers (5) had shown (Scheme 1) that the basic carbocyclic skeleton of the molecule was acetate-derived and that methionine provided the *O*- and *C*-methyl groups attached to the aromatic nucleus (5, 7). In addition the terpenoid nature of the aliphatic side chain was established (5) by specific incorporation of mevalonic acid into this structural unit (Scheme 1). The combined results of previous research had therefore established the origin of every carbon atom in structure **1** but the order and nature of steps involved in the biosynthetic sequence remained unknown.[2]

Our initial studies were designed to determine the nature of the least complex polyketide intermediate in the biosynthetic route since this information would allow definite conclusions to be made regarding the nature of the β-tetraketo enzyme-bound precursor and exclude some of the possible operational sequences leading from basic units (acetate, mevalonate, etc.) to final product. For this purpose we decided to test the precursor activity of (1′-^{14}C)-orsellinic acid (**2**) and (1′-^{14}C)-4,6-dihydroxy-2,3-dimethylbenzoic acid (**3**). The synthesis of **2** and **3** followed procedures described by Thomas (11) and Pettersson (12), respectively. After purification, the acids **2** (2.5×10^{-3} mCi/mmol) and **3** (5.4×10^{-4} mCi/mmol) were separately administered to shake cultures of *P. brevicompactum* grown on Raulin–Thom medium.[3] The p*H* of the broth at the time of administration was 5.2–5.6 and when p*H* 7 had been reached (10–14 days later) mycophenolic acid was isolated from the parallel experiments and purified to constant radioactivity. Mycophenolic acid isolated from the orsellinic acid experiment was radioinactive while the sample from the experiment using acid **3** as precursor had specific activity of 6.3×10^{-5} mCi/mmol (specific incorporation 11.7%). To determine if the incorporation of radioactivity into mycophenolic acid was random or specific a variety of degradative methods were investigated. Ozonolysis of the dimethyl derivative **4** in dimethyl sulfide (13) or water (2) gave variable yields of fragmentation products **5** and **6** (see Scheme 2). Reductive cleavage of the intermediate ozonide with lithium aluminum hydride

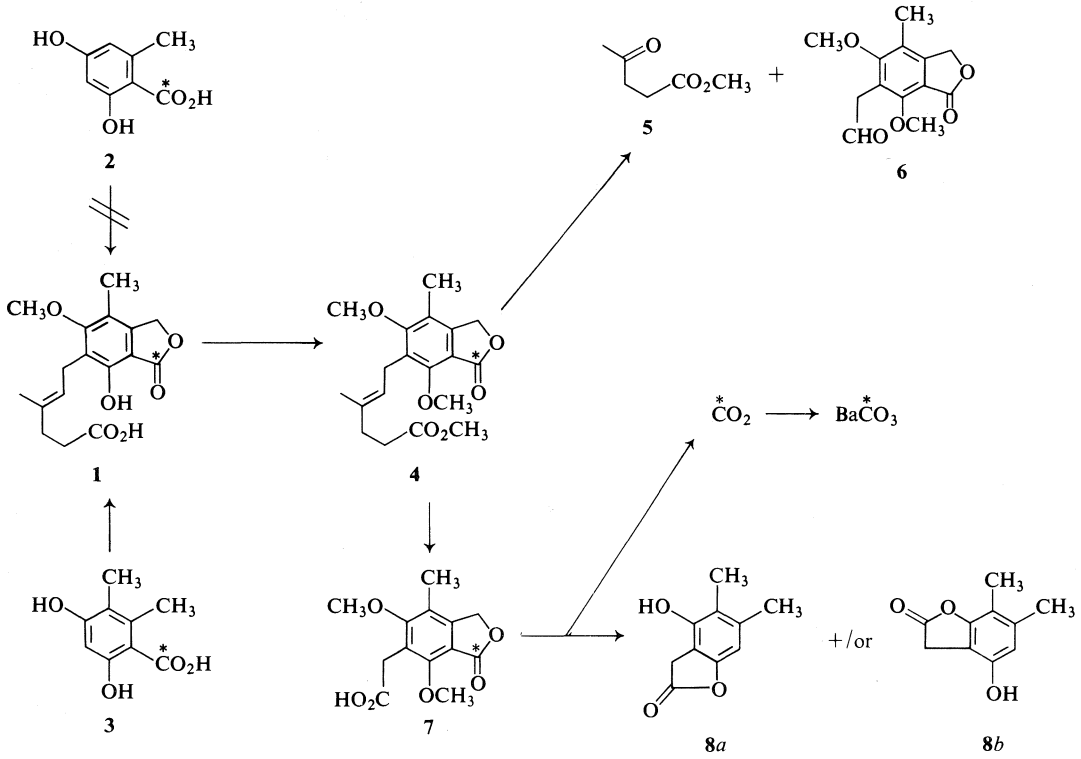
[1]Much of this work has been described in a preliminary communication (1).

[2]Preliminary investigations by Birch and his colleagues (6) indicated that radioactive orsellinic acid (**2**) was incorporated into mycophenolic acid (**1**) with partial randomization of the label. It was also suggested that the sequence from orsellinic acid to mycophenolic acid could involve acid **3** as an intermediate.

[3]It was found that if *P. brevicompactum* was grown on Czapek–Dox medium the correct p*H* was reached in shorter time but the recovered mycophenolic acid was much less pure.



SCHEME 1



SCHEME 2

also failed to give a satisfactory result. However, when ozonolysis of the dimethyl derivative **4** (after dilution, 1.78×10^{-5} mCi/mmol) was followed by treatment with 30% hydrogen peroxide – formic acid a good yield of 6-carboxymethyl-5,7-dimethoxy-4-methylphthalide (**7**) (1.77×10^{-5} mCi/mmol) was obtained with total retention of radioactivity. The specific location of the radioactive carbon atom in this compound was determined by further degradation. Treatment of **7** with red phosphorus and hydriodic acid (2) yielded radioinactive 4-hydroxy-6,7-dimethyl-2-oxocoumaran (**8***a*) and/or isomer (**8***b*) and 1 mol equiv of carbon dioxide (counted as

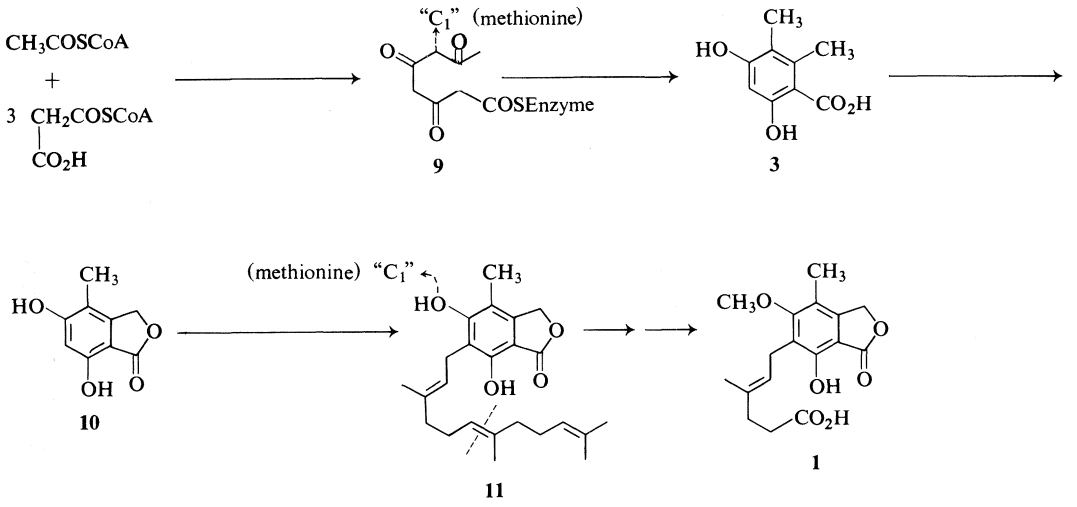

SCHEME 3

$BaCO_3$ (14); 1.71×10^{-5} mCi/mmol) which possessed 96% of the original activity. These results show that specific incorporation of radioactivity from (1′-^{14}C)-4,6-dihydroxy-2,3-dimethylbenzoic acid (**3**) into mycophenolic acid (**1**) had occurred and support the role of this acid[4] as the least complex aromatic precursor in the biosynthetic sequence[5] (1). In addition the contrasting results obtained with acids **2** and **3** lead to the exclusion of several possible biosynthetic sequences. Thus *C*-methylation is occurring before aromatization[6] of the β-tetraketo enzyme-bound thio-ester (**9**) (Scheme 3) and other secondary transformations (*O*-methylation, phthalide ring formation, and construction of the C_7 side-chain) are occurring after formation of acid **3**. The next step in the biosynthetic route seems to be the formation of the phthalide ring since Canonica and his colleagues have recently reported the specific incorporation of (7-^{14}C)-5,7-dihydroxy-4-methylphthalide (**10**) into mycophenolic acid (**1**) (8).

A solution to the problem presented by the construction of the C_7 terpenoid side-chain has been provided recently by the studies of Canonica and co-workers (9). 6-Farnesyl-5,7-dihydroxy-4-(methyl-^{14}C)-phthalide (**11**) was shown to be efficiently incorporated into mycophenolic acid and although degradation studies were not reported it seems certain that this compound is the next intermediate beyond phthalide **10** and that oxidative fission of the appropriate double bond in **11** (or its *O*-methyl ether) could produce the C_7 acidic side-chain present in mycophenolic acid. A biosynthetic scheme based on the cumulative efforts of several independent groups is depicted by Scheme 3.

Experimental

U.v spectra were recorded in methanol on a Unicam SP800 spectrophotometer. I.r. spectra were recorded on a Perkin–Elmer 137B spectrophotometer with sodium chloride cells using either Nujol mulls or chloroform solutions. N.m.r. spectra were recorded on Varian T-60, Varian A-60 or Jeolco C-60H instruments using tetramethylsilane as internal standard. Melting points (Kofler block) are uncorrected.

Radioactivity was measured with a Nuclear Chicago Mark 1 Liquid Scintillation System in counts per minute (c.p.m.). The radioactivity of the sample was subsequently calculated using the counting efficiency which was determined for each sample by the external standard technique utilizing a built in barium-133 gamma source.[7] The counting error[8] (% deviation) was 1.6% at a confi-

[4]It is interesting to note that we have detected 4,6-dihydroxy-2,3-dimethylbenzoic acid as a normal metabolite of *P. brevicompactum* (15). The acid has previously been isolated from *A. terreus* (16) and *G. roseum* (17).

[5]Low incorporation of **2** and high incorporation of **3** were simultaneously reported by Canonica and co-workers (9).

[6]*C*-Methylation before *and* after aromatization of polyketide precursors has previously been demonstrated (18, 19). Recent enzymic studies by Gatenbeck and co-workers have shown that the biosynthesis of **3** in *A. flaviceps* involves *C*-methylation at a pre-aromatic stage (20).

dence level of 90%. The organic scintillation solution used was made up of the following components: toluene (1 l), 2,5-diphenyloxazole (4 g), and 1,4-bis-[2-(5-phenyloxazole)]benzene (0.05 g). In practice the sample was dissolved in benzene (1 ml) or methanol (1 ml) in a counting vial and the volume made up to 15 ml with the above solution. For each sample counted, the background was determined using a vial filled with scintillator solution and solvent.

Administration of Radioactive Compounds to Penicillium brevicompactum

Cultures of *Penicillium brevicompactum* (1M1 17456) were grown on Raulin–Thom medium (100 ml) in 250 ml flasks until the p*H* of the broth was 5.2–5.6. Solutions of the radioactive compounds in ethanol or water (emulsified with Tween 20) were added directly to the broth. The time from inoculation until addition of radioactive substrates was 12–15 days and the optimum generation time (approximately 10 days) was measured by u.v. absorption at 303 nm and corresponded to a rise of approximately 1.6 p*H* units. In the case of (1′-^{14}C)-orsellinic acid 5.1 mg was administered to each of ten flasks (total radioactivity fed; 7.6×10^{-4} mCi) and for (1′-^{14}C)-4,6-dihydroxy-2,3-dimethylbenzoic acid 5.4 mg was administered to each of five flasks (total radioactivity fed; 8.0×10^{-5} mCi). The mycelium was filtered off and both the mycelium and the broth were extracted with large amounts of ether. Drying and removal of the ether yielded mycophenolic acid as a yellow gum. Purification was accomplished by crystallization from ethyl acetate to constant specific activity, m.p. 136–138 °C; mixed m.p. 137–139 °C.

*Ozonolysis of Mycophenolic Acid (**1**)*

Radioactive mycophenolic acid was diluted with radioinactive material and the mixture recrystallized from ethyl acetate. A typical degradative procedure is outlined below.

Mycophenolic acid (**1**) (75 mg, 0.23 mmol) was treated with ethereal diazomethane to give the dimethyl derivative **4**. The crude product was dissolved in methanol (10 ml), cooled to −78 °C, and ozone was passed through the solution until a permanent blue color was present. Excess ozone was removed in a stream of nitrogen and the solvent was removed under vacuum with very gentle heating. To the residual pungent yellow oil was added formic acid (0.38 ml) and 30% hydrogen peroxide (0.26 ml). The solution was heated at 100 °C for 30 min, excess formic acid was removed under vacuum, and saturated sodium bicarbonate solution was added to the residue. After extraction with ether, the aqueous layer was acidified. Extraction of the aqueous layer with ether followed by evaporation of the solvent provided a yellow solid which, on trituration with ether and crystallization from ether–petroleum ether (30–60°), gave 6-carboxymethyl-5,7-dimethoxy-4-methylphthalide (**7**) as white needles, m.p. 150–152 °C (lit. (2) m.p. 150–151 °C); ν_{max} (Nujol) 3300–2600, 1760, 1705, 1601 cm^{-1}; τ ($CDCl_3$) 1.59 (s, 1H), 4.83 (s, 2H), 5.90 (s, 3H), 6.21 (m, 5H), 7.82 (s, 3H).

*Reduction, Decarboxylation, and Demethylation of (**7**)*

A mixture of 6-carboxymethyl-5,7-dimethoxy-4-methylphthalide (**7**) (100 mg, 0.4 mmol), red phosphorus (0.3 g), and hydriodic acid (3 ml) was refluxed in an atmosphere of carbon dioxide–free nitrogen. The resulting carbon dioxide was converted to barium carbonate by bubbling through a barium hydroxide solution and after 19 h the filtered, dried barium carbonate was counted as a suspension (14). Excess phosphorus was removed by filtration, the filtrate extracted with ethyl acetate (4 × 15 ml), and the ethyl acetate extracts washed with water, and aqueous sodium thiosulfate. Drying and removal of the ethyl acetate yielded a gummy yellow solid. Sublimation at 120 °C/0.05 mm and subsequent crystallization from benzene gave 4-hydroxy-6,7-dimethyl-2-oxocoumaran (**8***a*) and/or isomer (**8***b*) as white needles, m.p. 179–183 °C (lit. (2) m.p. 184–185 °C); ν_{max} ($CHCl_3$) 3200–3500, 1801, 1745, 1650 cm^{-1}; τ ($CDCl_3$) 3.60 (s, 1H), 6.32 (s, 2H), 7.78 (s, 3H), 7.86 (s, 3H); *m/e* M^+ 178.

Vibrational Spectroscopic Studies of Aqueous Alkali Metal Bicarbonate and Carbonate Solutions[1]

BARRY G. OLIVER[2] AND ANTHONY R. DAVIS[3]

Water Quality Research Division, Department of the Environment, Ottawa, Canada

Received August 24, 1972

The laser Raman and infrared spectra of Li, Na, K, Rb, Cs bicarbonates and carbonates in H_2O and D_2O have been determined at 25 °C. The relative integrated intensities of the Raman bands have been measured for each salt from 0.01 *M* up to saturation. Changes observed in the carbonate spectrum with concentration have been interpreted in terms of solvation and ion-pairing of the carbonate ion. Based on the vibrational spectrum, there was no evidence for ionic interactions in the bicarbonate solutions. The hydrogen–deuterium exchange on the bicarbonate ion in H_2O–D_2O mixtures has been followed using Raman spectroscopy and the concentration quotients for the pertinent reactions have been calculated.

Les spectres en Raman laser et en infrarouge des bicarbonates de Li, Na, K, Rb, et Cs, ainsi que des carbonates dans l'H_2O et dans le D_2O ont été déterminés à 25 °C. Les intensités relatives intégrées des bandes du spectre Raman ont été mesurées pour chaque sel à partir de 0.01 *M* jusqu'à saturation. Les changements observés dans le spectre du carbonate par rapport à la concentration ont été interprétés en fonction de la solvatation et de la formation en paire d'ions de l'ion carbonate. En se basant sur le spectre vibrationnel, il n'y a aucune raison pour envisager des interactions ioniques dans les solutions de bicarbonate. L'échange hydrogène–deutérium sur l'ion bicarbonate dans des mélanges H_2O–D_2O a été suivi en utilisant la spectroscopie Raman et les quotiens de concentration pour les réactions correspondantes ont été calculés. [Traduit par le journal]

Introduction

An understanding of the bicarbonate–carbonate equilibrium is important in a study of natural waters, since it is largely responsible for controlling the water's p*H* and thus directly affects many of the chemical equilibria in the water (1). The Raman and infrared spectra of saturated aqueous potassium bicarbonate and carbonate solutions have been used to determine the structure of bicarbonate and carbonate ions in these concentrated solutions (2). It is of interest to extend these studies to lower concentrations approaching natural water levels to see whether the structure of the ions is changed by dilution.

Considerable information about ion–ion and ion–solvent interactions in aqueous nitrate systems has been obtained using vibrational spectroscopy (3–7). The relative importance of the ion-pairing and solvation effects can be assessed by varying the cation and by changing the solvent. In this study the laser Raman and infrared spectra of Li, Na, K, Rb, Cs bicarbonates and carbonates in H_2O and D_2O are reported.

Experimental

Raman and complementary infrared spectra were measured for aqueous solutions of each salt from about 0.01 *M* up to the solubility limit. The solutions were prepared using reagent grade salts and filtered through Solvinert Millipore filters (0.25 μ) prior to recording the spectra. The samples in precision Pyrex cells were placed in a holder thermostated at 25 °C and the Raman spectra measured with a Jarrell-Ash Model 25-300 Raman spectrometer (8). A Spectra Physics Model 125 Helium–Neon laser (632.8 nm, 50 mW) or a Coherent Radiation Model 54A Argon laser (488.0 nm, 200 mW) was used as the excitation source. Infrared spectra were obtained as smears between AgCl plates with a Perkin–Elmer Model 457 Grating Spectrometer. Band contours were resolved with a Dupont Curve Resolver using a Lorentz–Gaussian distribution function. All Raman band intensities were measured relative to the 459 cm^{-1} band of CCl_4. An accuracy of ±2% for band intensities is attainable with this instrumentation for strong well-resolved bands (*e.g.* 1069 cm^{-1} band of carbonate). Decomposition of the bicarbonate solutions results in larger errors for these solutions. In the case of weak or overlapping bands the accuracy of the intensity measurements is about ±10%.

Results and Discussion

A typical Raman spectrum observed for carbonate solutions is shown in Fig. 1. The relative intensities of the major Raman bands are graphed as a function of concentration in Fig. 2. The plots are linear over the whole concentration range. The bands in the 600 and 1400 cm^{-1} regions have much lower relative intensities than the band in the 1000 cm^{-1} region; so low in fact that feeble water bands in these regions have sufficient intensity to make curve resolving more difficult. Using D_2O as the solvent does alleviate this problem to some extent. The Raman and infrared band positions for potassium carbonate at different concentrations in H_2O and D_2O are shown in Table 1. The carbonate frequencies are virtually independent of alkali metal cation. The Raman band positions are seen to change by a few wave numbers with concentration.

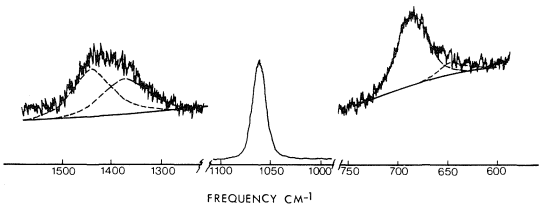

FIG. 1. Resolved Raman spectrum of 8 M Rb_2CO_3 in H_2O. Full scale equals 1×10^4 counts per s for the 100–1100 cm^{-1} region and 2×10^2 c.p.s. for the 600–750 cm^{-1} and the 1300–1500 cm^{-1} region. The weak Raman band at 880 cm^{-1} is observed only at high gain and is not shown in the figure.

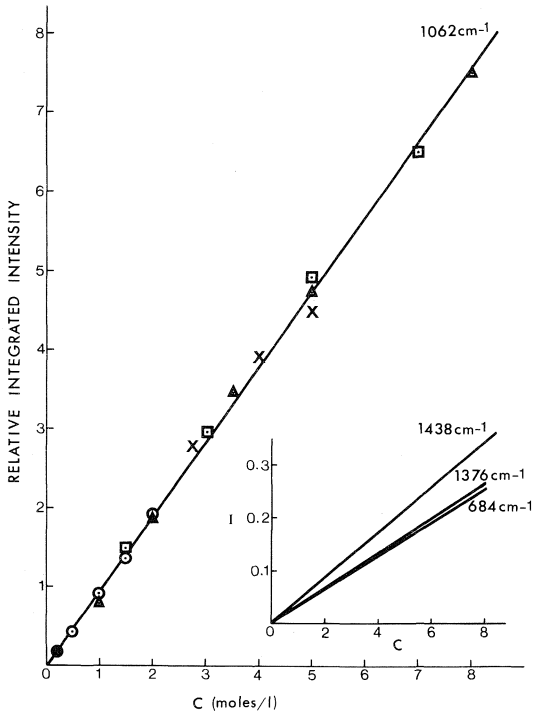

FIG. 2. A plot of relative integrated intensity *vs.* concentration for the major Raman bands of carbonate. ●, Li_2CO_3; ○, Na_2CO_3; △, K_2CO_3; □, Rb_2CO_3; ×, Cs_2CO_3. Only best fit lines shown for weaker bands for clarity.

The symmetry point group for an unperturbed carbonate ion is D_{3h} and the Raman and infrared activity of the expected vibrations are: $\nu_1(A_1')$ R ~1065 cm^{-1}, $\nu_2(A_2'')$ i.r. ~880 cm^{-1}, $\nu_3(E')$ i.r., R ~1400 cm^{-1}, and $\nu_4(E')$ i.r., R ~685 cm^{-1}. The vibrational spectrum of carbonate in aqueous solution is at variance with these selection rules. The infrared forbidden ν_1 band appears in the infrared spectrum of the concentrated solutions at 1052 cm^{-1}. Also the Raman forbidden ν_2 band appears in the Raman spectrum of the concentrated solutions at 880 cm^{-1}. In addition the $\nu_3(E')$ vibration appears to be split into two bands in both the infrared and Raman spectra at all concentrations.

These observations are in many ways similar to those made for alkali metal nitrates by Irish and Davis (3). They interpreted their data in terms of nitrate–water and nitrate–metal interactions. The persistent splitting of the $\nu_3(E')$ band in dilute carbonate solutions where interionic effects should be small, probably indicates that this splitting is due to carbonate–water interaction. This is supported by the fact that the splitting of the $\nu_3(E')$ band is different in the solvent D_2O. Also the band positions in the 1400 cm^{-1} and the 600 cm^{-1} region are different in the two solvents, another indication that the dilute solution spectrum is that of the solvated carbonate ion. The weak bands at 1052 cm^{-1} in the infrared and at 880 cm^{-1} in the Raman could also be features of the solvated carbonate ion spectrum. The weak band at 650 cm^{-1} which is present only in the ultraconcentrated solutions can be assigned to a carbonate ion–water restricted rotation or libration similar to modes found in pure water (9) and those observed for the solvated nitrate ion (3).

Lee and Wilmshurst (10) also observed that the $\nu_3(E')$ band of aqueous K_2CO_3 was split but attributed this to ion-pair formation. Previous studies of aqueous alkali metal nitrates (3, 5, 6)

have shown that the $\nu_4(E')$ band is split into two bands when contact ion-pairs are present. Only a single band was observed in the $\nu_4(E')$ region for the aqueous carbonate solutions. Bates, Brooker, Quist, and Boyd (11) have shown that the $\nu_4(E')$ band is not split even for molten alkali metal carbonates. Therefore, the spectral results indicate that contact ion-pairs may not be formed in this system. However, the results do not rule out the possibility of ion-pair formation. The $\nu_4(E')$ band is extremely weak in carbonates so recording and resolving the spectrum in this region is difficult. It could be that the $\nu_4(E')$ band for carbonate is split but to a much smaller extent than for nitrate. In any case, it is evident that in these solutions the carbonate ion symmetry has been altered by solvent and possibly cation interactions.

The Raman spectrum for bicarbonate in H_2O is shown in Fig. 3. The 1067 cm^{-1} Raman band is due to carbonate. About 10% of the bicarbonate decomposes to CO_2 and carbonate when it is dissolved in water at 25 °C.

[1] $$2HCO_3^- \rightarrow CO_2 + CO_3^{2-} + H_2O$$

Therefore, twice the carbonate concentration, determined from Raman relative intensity data

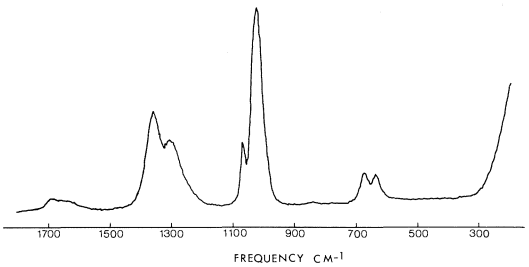

FIG. 3. Raman spectrum of 4 *M* $CsHCO_3$ in H_2O.

(Fig. 2), must be subtracted from the bicarbonate concentration, determined by weight, to obtain the correct concentration of bicarbonate in the aqueous solutions. The relative intensities of the major Raman spectral bands of potassium bicarbonate are plotted against this corrected concentration in Fig. 4. Three other fundamentals at 841, 1630, and 2650 cm^{-1} and one overtone band at 1684 cm^{-1} are also present in the Raman spectrum, but they are very weak. The plots are linear over the whole concentration range.

The Raman and infrared band positions for bicarbonate in H_2O and D_2O are compiled in Table 2. The structure of bicarbonate in a concentrated $KHCO_3$ solution and the assignment

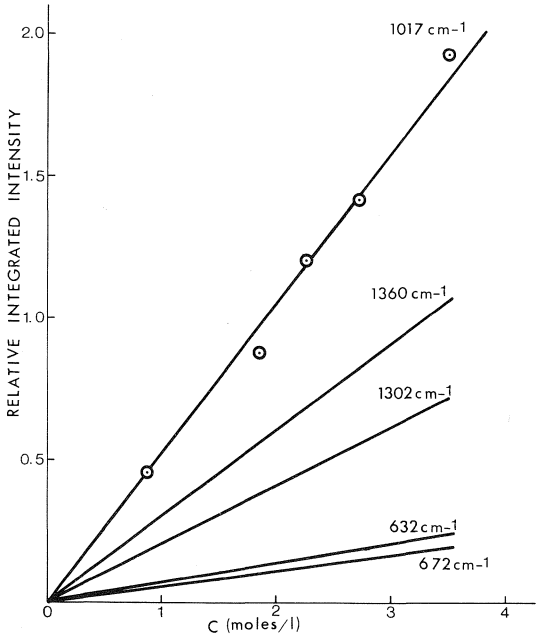

FIG. 4. A plot of relative integrated intensity *vs.* concentration for the major Raman band of potassium bicarbonate. Only best fit lines shown for weaker bands for clarity.

of frequencies to approximate modes of vibration has been deduced from the band positions, band shifts on deuteration, and Raman depolarization ratios (2). The replacement of $KHCO_3$ with Li, Na, Rb, or Cs bicarbonate proved to have little effect on the Raman or infrared band positions or the Raman relative intensities. Changing the bicarbonate molarity essentially has no effect on the spectra either. Thus it appears that the $C_s(\sigma_h)$ structure deduced for bicarbonate in concentrated $KHCO_3$ solutions holds for all concentrations and for all alkali metals. Certainly there is no evidence for ionic interactions from the vibrational spectrum.

The bicarbonate ion has an ionizable hydrogen atom which is replaceable by deuterium. This can occur when the bicarbonate ion is dissolved in D_2O and then the vibrations of the OH part of the ion will shift to lower frequencies due to the formation of OD. The 2650 cm^{-1} line shifts to 2030 cm^{-1} in D_2O, the 1302 cm^{-1} to 1030 cm^{-1}, the 1017 cm^{-1} to 980 cm^{-1}, and the 632 cm^{-1} to 600 cm^{-1}. Since the concentration of HCO_3^- in any solution can be found from the Raman intensity data (Fig. 4), it is possible to follow the hydrogen–deuterium exchange on the bicarbonate ion in H_2O–D_2O mixtures. The 900–1100 cm^{-1} region of the Raman spectrum of 2.9 *M* K_2CO_3 in H_2O–D_2O mixtures is shown in Fig. 5. The solution containing only DCO_3^- (spectrum (*d*)) was prepared by adding DCl to a D_2O solution of K_2CO_3 until no carbonate was detected in the Raman spectrum. Four bands appear in this region of the spectrum: the easily resolvable 1067 cm^{-1} carbonate band, the 1017 cm^{-1} HCO_3^- band, and the 980 and 1030 cm^{-1} DCO_3^- bands. The overlap of the latter three bands makes curve resolving difficult. But if it is kept in mind that both the 980 cm^{-1} and the 1030 cm^{-1} bands are generated by DCO_3^- and since it is possible to set the shapes of the two bands using the DCO_3^- spectrum, the total band contour for the two bands can be

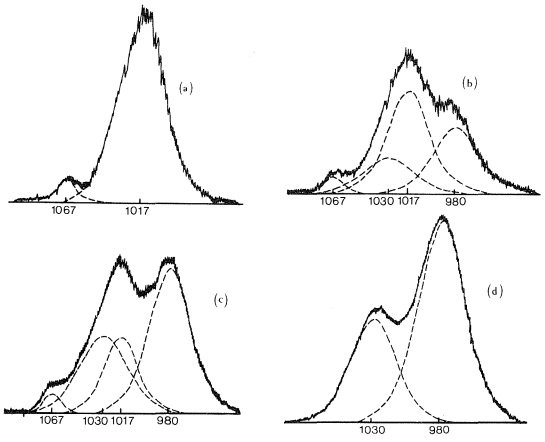

FIG. 5. Resolved Raman spectra of the 900–1100 cm^{-1} region for 2.9 *M* $KHCO_3$ in (*a*) H_2O, (*b*) 50 mol% H_2O – 50 mol% D_2O, (*c*) 25 mol% H_2O – 75 mol% D_2O, and (*d*) D_2O.

TABLE 3. Species concentrations and concentration quotients determined by Raman spectroscopy for the system $KHCO_3$–H_2O–D_2O*

Solution	$[HCO_3^-]$	$[DCO_3^-]$	$[H_2O]$	[HOD]	$[D_2O]$	Q_3	Q_4
2.9 *M* $KHCO_3$ in 50 mol% H_2O – 50 mol% D_2O	1.57	1.33	14.66	27.25	13.33	1.73	0.46
2.9 *M* $KHCO_3$ in 25 mol% H_2O – 75 mol% D_2O	0.96	1.94	4.06	21.42	29.72	1.46	0.38
2.9 *M* $KHCO_3$ in 10 mol% H_2O – 90 mol% D_2O	0.37	2.52	0.87	11.82	42.47	1.90	0.50

*Mean concentration quotients $Q_3 = 1.7 \pm 0.2$, $Q_4 = 0.45 \pm 0.05$.

treated as a single band and the missing gap filled with the 1017 cm^{-1} band. In this way it was possible to obtain excellent reproducible fits for the experimental spectrum. The concentration of HCO_3^- was then determined from the 1017 cm^{-1} band intensity and the concentration of DCO_3^- obtained by subtraction. A check on the accuracy of the determination was made using the 1302 cm^{-1} band intensity. The HCO_3^- concentrations from both regions of the spectrum were found to be in good agreement.

The important reactions for the exchange equilibrium are as follows

[2] $H_2O + D_2O \rightleftarrows 2HOD$

$$Q_2 = [HOD]^2/[H_2O][D_2O]$$

[3] $HCO_3^- + D_2O \rightleftarrows DCO_3^- + HOD$

$$Q_3 = [DCO_3^-][HOD]/[HCO_3^-][D_2O]$$

[4] $HCO_3^- + HOD \rightleftarrows DCO_3^- + H_2O$

$$Q_4 = [DCO_3^-][H_2O]/[HCO_3^-][HOD]$$

The value of the concentration quotient Q_2 for reaction 2 at 25 °C is 3.8 (12).

Since $[HCO_3^-]$ and $[DCO_3^-]$ have been obtained experimentally there are five unknowns in the equations: $[H_2O]$, $[D_2O]$, [HOD], Q_3, and Q_4. It is possible to write equations for the known total concentration of hydrogen and deuterium in the solutions.

[5] $[H]_{total} = 2[H_2O] + [HOD] + [HCO_3^-]$

[6] $[D]_{total} = 2[D_2O] + [HOD] + [DCO_3^-]$

From these five equations it is now possible to calculate the concentration quotients Q_3 and Q_4. The species concentrations obtained from Raman intensity data for three 2.9 *M* $KHCO_3$ solutions in H_2O–D_2O mixtures and the calculated concentration quotients are shown in Table 3. The experiment was repeated for 1 *M* $NaHCO_3$ solutions in two H_2O–D_2O mixtures and the quotients, $Q_3 = 1.9 \pm 0.2$, $Q_4 = 0.50 \pm 0.05$, are in close agreement with the $KHCO_3$ results. Therefore, the concentration quotients appear to be independent of cation and molarity.

The authors are grateful to Mrs. Jocelyn Larabie for technical assistance.

Bimolecular Reactions of Trapped Ions. V. Ionic Chemistry of Simple Oxygen-containing Molecules[1]

ALAN S. BLAIR AND ALEX. G. HARRISON

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received July 20, 1972

The ion-molecule reactions occurring in a number of one-component and two-component systems involving oxygen-containing compounds have been studied using an ion trapping technique. The variable reaction time possible (up to 3.2 ms) has permitted a study of the sequential ion–molecule reactions occurring. In one-component systems (M = CH_3CHO, $(CH_3)_2O$, or $(CH_3)_2CO$) the MH^+ ion formed initially reacts to produce M_2H^+ in a rapid third order reaction (k in the range 10^{-24} to 10^{-25} cm^6 $molecule^{-2}$ s^{-1}). No M_2H^+ was observed in ethylene oxide. In two-component systems a rapid proton transfer reaction $M_1H^+ + M_2 \rightarrow M_2H^+ + M_1$ occurs when the proton affinity of M_2 is greater than the proton affinity of M_1; consequently, the third order solvation reactions normally will involve only reactions of M_2H^+.

The reactions of isomeric $C_2H_5O^+$ ions have been studied. The $CH_3OCH_2^+$ ion reacts slowly by H^- abstraction and/or CH_3^+ transfer. The $CH_3CH{=}OH^+$ ion rapidly (and essentially completely) transfers a proton to $(CD_3)_2O$ and to $(CH_3)_2CO$. By contrast the $C_2H_5O^+$ ion obtained by protonation of ethylene oxide does not react completely with $(CD_3)_2O$ or $(CH_3)_2CO$. In the former case a quasi-equilibrium is reached while in the latter case there is evidence that the $C_2H_5O^+$ ions have rearranged to a $CH_3OCH_2^+$ structure by an unknown mechanism.

Considerable detail has been obtained concerning the primary ion–molecule reactions occurring, particularly for systems containing ethylene oxide.

Les réactions ion–molécule qui se produisent pour un certain nombre de systèmes à une ou deux composantes engageant des composés à oxygène, ont été étudiées par la technique du piègeage ionique. La possibilité de jouer sur la variable temps de la réaction (jusqu'à 3.2 ms) a permis une étude séquentielle des réactions ion–molécule. Dans les systèmes à une composante (M = CH_3CHO, $(CH_3)_2O$, ou $(CH_3)_2CO$), l'ion MH^+ initialement formé réagit et donne M_2H^+ selon une réaction rapide d'ordre trois (k de l'ordre de 10^{-24} à 10^{-25} cm^6 $molécule^{-2}$ s^{-1}). Pour l'oxyde d'éthylène, aucun M_2H^+ n'a été observé. Pour les systèmes à deux composantes, une réaction de transfert rapide de proton $M_1H^+ + M_2 \rightarrow M_2H^+ + M_1$, se produit lorsque l'affinité pour le proton de M_2 est supérieure à celle de M_1; en conséquence, les réactions de solvatation d'ordre trois n'engageront normalement que les réactions de M_2H^+.

Les réactions des ions isomères $C_2H_5O^+$ ont été étudiées. L'ion $CH_3OCH_2^+$ réagit lentement par abstraction de H^- et (ou) transfert de CH_3^+. L'ion $CH_3CH{=}OH^+$ transfère rapidement (et de façon pratiquement totale) son proton à $(CD_3)_2O$ et à $(CH_3)_2CO$. Au contraire l'ion $C_2H_5O^+$, obtenu par protonation de l'oxyde d'éthylène, ne réagit pas complètement sur $(CD_3)_2O$ ou $(CH_3)_2CO$. Dans le premier cas on atteint une quasi-équilibre tandis que pour le second, un réarrangement des ions $C_2H_5O^+$ en $CH_3OCH_2^+$ selon un mécanisme inconnu, a été mis en évidence.

Des informations détaillées ont été aussi obtenues pour les réactions primaires ion–molécules, surtout pour les systèmes contenant l'oxyde d'éthylène. [Traduit par le journal]

Can. J. Chem., **51**, 703 (1973)

Introduction

The ion–molecule reactions of a considerable number of oxygen-containing molecules have been studied by pressure variation at constant repeller field (1–7), by ion cyclotron resonance (i.c.r.) techniques (7–10), and by the zero-field pulsing technique (3, 11). It is well-established that the major reactions occuring involve formation of the protonated molecule (monosolvated proton) and in many cases more highly solvated protons are observed at higher pressures. Although rate constants for many of the reactions forming the monosolvated proton have been measured, there is little quantitative information available concerning the subsequent reactions of this species.

We have found (12–14) that the trapped ion technique (15) is particularly suited to the study of sequential ion–molecule reactions. The present work was undertaken, in part, to study the reactions of monosolvated protons in a number of one-component and two-component systems in-

[1]The work reported here will constitute part of the Ph.D. Thesis to be submitted by A. S. Blair to the University of Toronto.

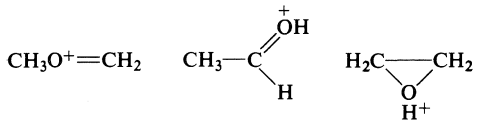
volving oxygen-containing molecules. The work necessarily involved a study of the reactions forming the monosolvated protons. This has, on the whole, confirmed the earlier work, but has provided additional details in several cases, particularly for systems containing ethylene oxide.

An additional objective of the present work was to study quantitatively the reactions of isomeric $C_2H_5O^+$ ions and the systems have been chosen with this objective in mind. Several structures (**I** to **III**) have been proposed for the



I II III

$C_2H_5O^+$ ions observed in the electron impact fragmentation of alcohols and ethers (16–19). While the present work was in progress Beauchamp and Dunbar (10) reported that $C_2H_5O^+$ ions derived from ethers (structure **I**) react by H^- abstraction and/or methyl cation transfer while $C_2H_5O^+$ ions of nominal structures **II** and **III** both react by proton transfer and therefore cannot be distinguished from each other by reaction type. However, this i.c.r. study reported no rate coefficients and the possibility remained that structures **II** and **III** might be distinguishable from the rate of reaction.

Experimental

The work was carried out using the mass spectrometer and ion-trapping techniques described previously (15). In this technique ions are produced during a short (1 μs) pulse of electrons of suitable energy and are trapped in the negative space charge of a continuous electron beam of energy insufficient to cause ionization. A positive voltage pulse applied to the repeller electrode a known and variable time after the ionizing pulse removes the ions for mass analysis. In the present work delay times between the ionizing and withdrawal pulses (and hence reaction times) of up to 3.2 ms were used. Rate coefficients were obtained from observations of the ion intensities (normalized as a fraction of the total recorded ion intensity) as a function of the reaction time.

Source concentrations were not measured directly but were related to the gas pressure in the inlet system. Tests showed that the source concentration was a linear function of sample inlet pressure and that the gas composition in the ion source was the same as that of the mixture in the inlet system. The relation between source concentration and inlet pressure was established by observation of the rate of the $CH_4^+ + CH_4$ reaction in pure methane; all rate constants are therefore relative to the value (11) of 1.20×10^{-9} cm^3 molecule^{-1} s^{-1} for this reaction. Gas mixtures were made up accurately by pressure and normally at least three different mixtures were used in establishing rate data. The error limits quoted represent the mean deviation of three or more determinations.

All unlabelled compounds were commercially available. Acetaldehyde-d_4, acetaldehyde-d_3, dimethyl-d_6 ether, methyl-d_3 ethyl ether, and ethylene oxide-d_4 were obtained from Merck, Sharp, and Dohme, Montreal. The unlabelled acetaldehyde contained a small diethyl ether impurity which was removed by gas chromatography. The remaining compounds showed no detectable impurities in their mass spectra and were used without purification.

Results and Discussion

Acetaldehyde

Figure 1 shows typical results obtained for this system at an ionizing electron energy such that CH_3CHO^+, CH_3CO^+, and CHO^+ were the only primary ions.[2] Although CH_3CO^+ shows an initial small decrease this was not observed at lower electron energies and we conclude that this ion is essentially unreactive with acetaldehyde, in agreement with the conclusions derived from earlier pressure studies (1, 2).

The reactions observed in the acetaldehyde system can be described by the scheme

[1] $CH_3CHO^+ + CH_3CHO \rightarrow CH_3CHOH^+ + C_2H_3O$

[2] $CHO^+ + CH_3CHO \rightarrow CH_3CHOH^+ + CO$

[3] $CH_3^+ + CH_3CHO \rightarrow C_2H_3O^+ + CH_4$

[4] $CH_3CHOH^+ + 2CH_3CHO \rightarrow (CH_3CHO)_2H^+ + CH_3CHO$

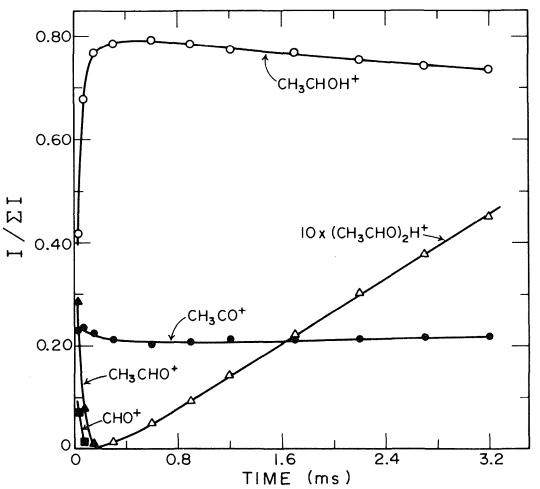


FIG. 1. Ion intensities *vs.* time, acetaldehyde [M] = 1.03×10^{13} molecules cm^{-3}.

[2]The mass spectrum of CD_3CHO indicates that the $(M - 1)^+$ ion of acetaldehyde is predominantly CH_3CO^+.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rate coefficients measured for reactions 1 to 3 are summarized in Table 1 and compared with previous literature values (2) obtained from pressure studies. The present value for k_1 is higher than the pressure study result; the lower value was obtained in the present work when unpurified acetaldehyde was used. Using CD_3CHO it was established that reaction 1 proceeds almost exclusively by transfer of the aldehydic hydrogen (as H or H^+), in agreement with the results of Meisels and co-workers (20).

The kinetic order of reaction 4 was not rigorously established but was assumed to be third order by analogy with the similar reactions in dimethyl ether and acetone (see below). The third order rate coefficient was found to be $k_4 = 1.2 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1} from the decrease in the CH_3CHOH^+ intensity with reaction time at long delay times.

Ethylene Oxide

Figure 2 shows typical results obtained at a source concentration of 1.17×10^{13} molecules cm^{-3}. The CHO^+ ion reacts rapidly by proton transfer, the rate coefficient (Table 1) being in good agreement with that obtained from the pressure studies (2). As in acetaldehyde the $C_2H_3O^+$ ion is unreactive.

The remaining reactions in ethylene oxide can be described by the scheme

[5] $C_2H_4O^+ + C_2H_4O \rightarrow C_2H_5O^+ + C_2H_3O$

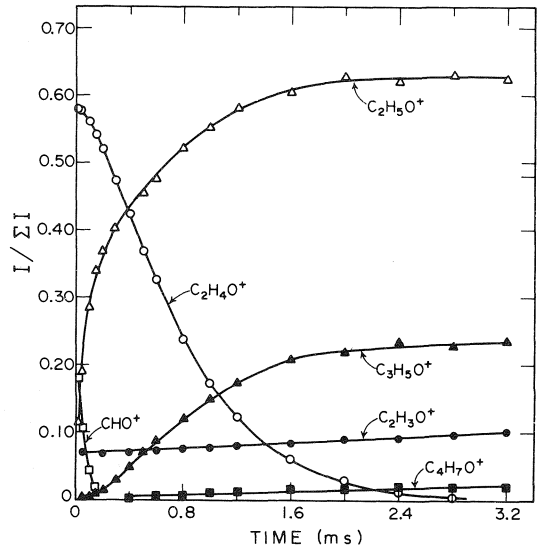

FIG. 2. Ion intensities *vs.* time, ethylene oxide [M] = 1.17×10^{13} molecules cm^{-3}.

[6] $C_2H_4O^+ + C_2H_4O \rightarrow C_2H_4O^{+*} + C_2H_4O$

[7*a*] $C_2H_4O^{+*} + C_2H_4O \rightarrow C_2H_5O^+ + C_2H_3O$

[7*b*] $\rightarrow C_3H_5O^+ + CH_2O$

[8] $C_2H_5O^+ + C_2H_4O \rightarrow C_2H_3O^+ + (H_2 + C_2H_4O)$

[9] $C_2H_5O^+ + C_2H_4O \rightarrow C_4H_7O^+ + H_2O$

The $C_2H_4O^+$ ion current does not decrease in the exponential fashion expected for a quasi-first order reaction but shows an initial sigmoidal shape. This behavior was also observed when $C_2H_4O^+$ was the only primary ion and therefore cannot be attributed to formation of $C_2H_4O^+$ by ion–molecule reactions. In addition the $C_3H_5O^+$ product species shows an initial induction period characteristic of the product of a sequence of bimolecular reactions. Both of these observations can be explained by assuming that the $C_2H_4O^+$ ions formed initially by electron impact react only slowly to form detectable products (reaction 5) but considerably more rapidly (reaction 6) to form a structurally or energetically modified ion, $C_2H_4O^{+*}$, which subsequently reacts to produce both $C_2H_5O^+$ and $C_3H_5O^+$ (reaction 7).[3] A similar type of reaction sequence has been observed in vinyl fluoride (12). It does not appear possible that the $C_2H_4O^{+*}$ can be formed by inelastic collisions between electrons and the trapped ions. Simple calculations show that the collision cross-section would have to be 10^{-10} to 10^{-12} cm^2 which does not appear possible for 5–8 eV electrons.

The proposed mechanism receives further support from the plot in Fig. 3 of $I_{C_3H_5O^+}$ and $\sum I_{C_2H_5O^+}$ *vs.* $\Delta I_{C_2H_4O^+}$, the *m/e* 44 which has reacted.[4] $\sum I_{C_2H_5O^+} = I_{C_2H_5O^+} + I_{CHO^+} + I_{C_2H_3O^+} + I_{C_4H_7O^+}$ and the increase in $\sum I_{C_2H_5O^+}$ with time thus represents the $C_2H_5O^+$ formed by reactions 5 and 7*a*. The plot of $\sum I_{C_2H_5O^+}$ *vs.* $\Delta I_{C_2H_4O^+}$ clearly shows two linear regions. The initial region, with a slope of 1.0, corresponds to formation of $C_2H_5O^+$ by reaction 5, and during this time no $C_3H_5O^+$ is formed. The second region has a slope of 0.52 ± 0.04 (average of several determinations) and corresponds to the fractional yield of $C_2H_5O^+$ by reaction 7. The $I_{C_3H_5O^+}$ plot has an onset corresponding to the

[3]In C_2D_4O the *m/e* 57 ($C_3H_5O^+$) ion moved to *m/e* 62 ($C_3D_5O^+$) confirming the ionic composition.

[4]The data of Fig. 3 were obtained at a lower ionizing electron energy than the data in Fig. 2.

TABLE 1. Rate constants for ion molecule reactions

Reaction	$k \times 10^9$ (cm^3 molecule^{-1} s^{-1}) This work	Literature (ref.)
$CH_3CHO^+ + CH_3CHO$	$2.4_9 \pm 0.1$	1.91(2)
$CHO^+ + CH_3CHO$	$2.5_3 \pm 0.1$	2.45(2)

$(CH_3)_2OH^+ + (CH_3)_2CO$	1.0 ± 0.1	
$CH_3CHOH^+ + (CD_3)_2O$	1.88 ± 0.05	
$CH_3CHOH^+ + (CH_3)_2CO$	2.25	
This Work		
$CH_3CHOH^+ + 2CH_3CHO \rightarrow (CH_3CHO)_2H^+ + CH_3CHO$	1.2×10^{-25} cm^6 molecule^{-2} s^{-1}	
$(CH_3)_2OH^+ + 2(CH_3)_2O \rightarrow ((CH_3)_2O)_2H^+ + (CH_3)_2O$	$1.0 \pm 0.2 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1}	
$(CH_3)_2COH^+ + 2(CH_3)_2CO \rightarrow ((CH_3)_2CO)_2H^+ + (CH_3)_2CO$	$6.5 \pm 0.5 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1}	

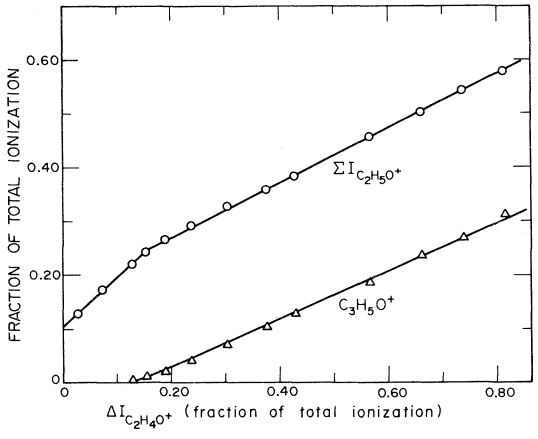

FIG. 3. Ethylene oxide, $\Sigma I_{C_3H_5O^+}$ and $I_{C_2H_4O^+}$ *vs.* $\Delta I_{C_2H_4O^+}$ (see text).

break in the $\sum I_{C_2H_5O^+}$ plot and a slope of 0.45 $\pm$ 0.04. Apparently $C_3H_5O^+$ is produced only by reactions of $C_2H_4O^+$ ions which have been modified by collision (reaction 6) and not by those formed initially by electron impact. From the position of the change in slope in Fig. 3 we estimate that k_6 is in the range 2–3 $\times$ 10^{-9} cm^3 molecule^{-1} s^{-1}. The total rate constant k_7 is given in Table 1.

The alternative explanation that $C_3H_5O^+$ is formed by reaction 10 is discarded as a major source of $C_3H_5O^+$ because

[10] $C_2H_5O^+ + C_2H_4O \rightarrow C_3H_5O^+ + CH_4O$

double resonance i.c.r. experiments (10) confirm *m/e* 44 as the precursor and because the $C_3H_5O^+$ yield does not increase significantly after the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

m/e 44 has disappeared even though $C_2H_5O^+$ is present in abundance. Experiments at higher source pressures did confirm that reaction 10 occurred but much too slowly to account for a significant fraction of the $C_3H_5O^+$ produced.

The $C_3H_5O^+$ product was not reported in the earlier pressure study (2) and a re-examination of the records shows that this region of the mass spectrum was not recorded. It was reported in the i.c.r. study (10) although neither the reaction order nor the fractional yield were established. Although the disolvated proton was reported in the i.c.r. study we did not observe this product even at our highest pressures ($\sim 4 \times 10^{13}$ molecule cm^{-3}) and longest reaction times. A small yield of a product of *m/e* 71 (probably $C_4H_7O^+$) corresponding to loss of H_2O from the $C_2H_5O^+ + C_2H_4O$ collision complex was observed (reaction 9).

Dimethyl Ether

Typical results are illustrated in Fig. 4. The results are consistent with the following reaction scheme which is in agreement with previous studies (1, 2, 10).

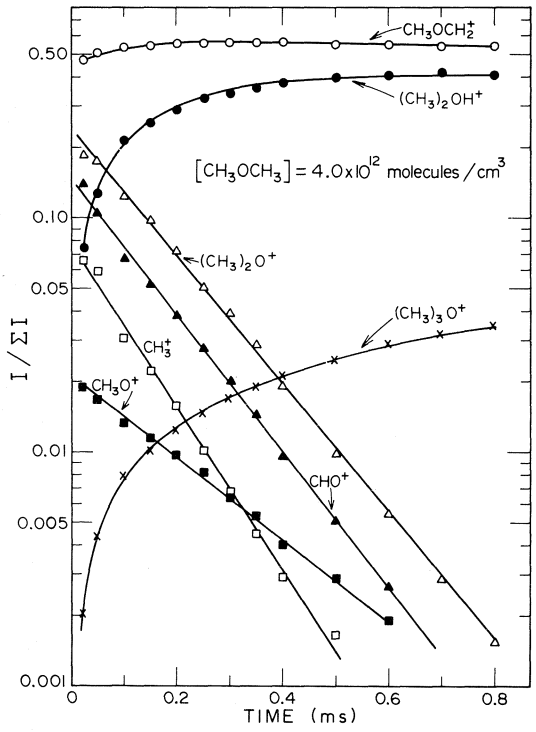

FIG. 4. Dimethyl ether, ion intensities *vs.* time [M] = 4.00×10^{12} molecules cm^{-3}.

[11] $(CH_3)_2O^+ + (CH_3)_2O \rightarrow (CH_3)_2OH^+ + CH_3OCH_2$

[12] $CHO^+ + (CH_3)_2O \rightarrow (CH_3)_2OH^+ + CO$

[13] $CH_3^+ + (CH_3)_2O \rightarrow CH_3OCH_2^+ + CH_4$

[14] $CH_3O^+ + (CH_3)_2O \rightarrow CH_3OCH_2^+ + CH_4O$

[15] $CH_3OCH_2^+ + (CH_3)_2O \rightarrow (CH_3)_3O^+ + CH_2O$

The rate coefficients measured are summarized in Table 1 and are in good general agreement with those obtained at 2.4 eV ion exit energy in the pressure studies (2). Reaction 15, methyl cation transfer, is one of the characteristic reactions of $C_2H_5O^+$ ions of structure **I** (10), however it is extremely slow ($k = 1.3 \pm 0.9 \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1}) and consequently it was difficult to obtain an accurate rate coefficient. The other reaction characteristic of structure **I** ions, H^- abstraction, is not observable in this system since it regenerates the reactant ion.

Figure 5 shows results obtained at a higher source pressure and an electron energy such that $(CH_3)_2O^+$ was the major primary ion. The monosolvated proton clearly reacts to form both $(CH_3)_3O^+$ and the disolvated proton $((CH_3)_2O)_2H^+$, presumably by the following reactions.

[16] $(CH_3)_2OH^+ + (CH_3)_2O \rightarrow (CH_3)_3O^+ + CH_3OH$

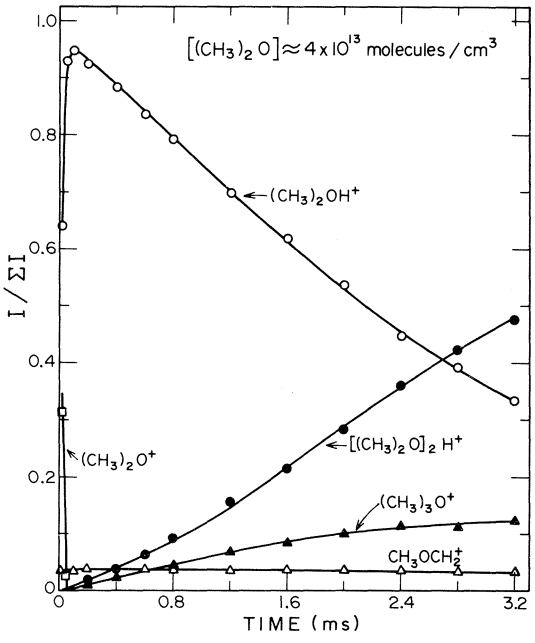

FIG. 5. Dimethyl ether system, [M] $\approx 4 \times 10^{13}$ molecules cm^{-3}.

[17] $(CH_3)_2OH^+ + 2(CH_3)_2O \rightarrow ((CH_3)_2O)_2H^+ + (CH_3)_2O$

Assuming these two reactions we may derive eq. 18 for reaction times greater than that necessary for complete reaction of $(CH_3)_2O^+$.

$$[18] \quad \log[(CH_3)_2OH^+] = \frac{-(k_{16}[(CH_3)_2O] + k_{17}[(CH_3)_2O]^2)t}{2.303} + \text{constant}$$

From eq. 18 we note that the slope of the plot of $\log[(CH_3)_2OH^+]$ *vs.* t when plotted in the form $2.303 \times \text{slope}/[(CH_3)_2O]$ *vs.* $[CH_3OCH_3]$ should yield a straight line with an intercept of k_{16} and a slope of k_{17}. A typical plot is shown in Fig. 6 covering a factor of two in $[CH_3OCH_3]$. A satisfactory least-squares straight line is observed leading from three separate determinations to the average values $k_{16} = 2.7 \pm 0.3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} and $k_{17} = 1.0 \pm 0.2 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1}.

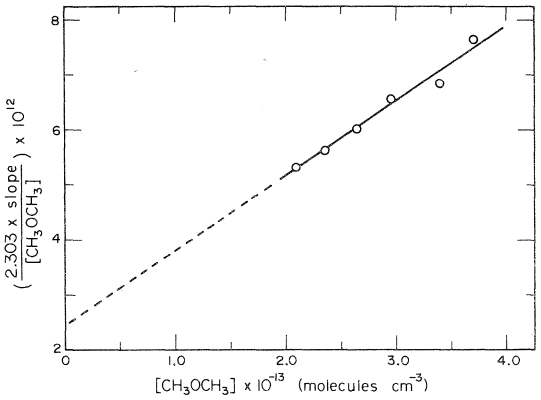

FIG. 6. Dimethyl ether, determination of k_{16} and k_{17} (see text).

Methyl-d_3 Ethyl Ether

Typical results for this system are shown in Fig. 7. The initial curvature in the $CD_3OCH_2^+$ plot is unexplained. The $CD_3OC_2H_5^+$ ion reacts to form $CD_3OC_2H_5{\cdot}H^+$ and $CD_3OC_2H_5{\cdot}D^+$ in the ratio 1.0:1.1 in excellent agreement with the ratio reported by Beauchamp and Dunbar (10) in the i.c.r. study. The $CD_3OCH_2^+$ ion reacts mainly by reactions 19 and 20 in the ratio $k_{19}:k_{20} = 0.05:0.95$.

[19] $CD_3OCH_2^+ + CD_3OC_2H_5 \rightarrow C_2H_5O(CD_3)_2^+ + CH_2O$

[20] $CD_3OCH_2^+ + CD_3OC_2H_5 \rightarrow CD_3OC_2H_4^+ + CD_3OCH_3$

This ratio is in good agreement with the thermal energy ratio of 0.04:0.96 obtained in the i.c.r. study (10). Although reaction 20, H^- abstraction, predominates over D^- abstraction from the methyl group of the neutral ether we do observe a low yield of $C_2H_5OCD_2^+$ which appears to react further, probably by H^- abstraction to yield $CD_3OC_2H_4^+$.

The total rate constants for reaction of $CD_3OC_2H_5^+$ and $CD_3OCH_2^+$ are recorded in Table 1. These rates have not been measured previously. The rate coefficient for reaction of $CD_3OCH_2^+$ with $CD_3OC_2H_5$ is approximately a factor of ten greater than that for reaction of

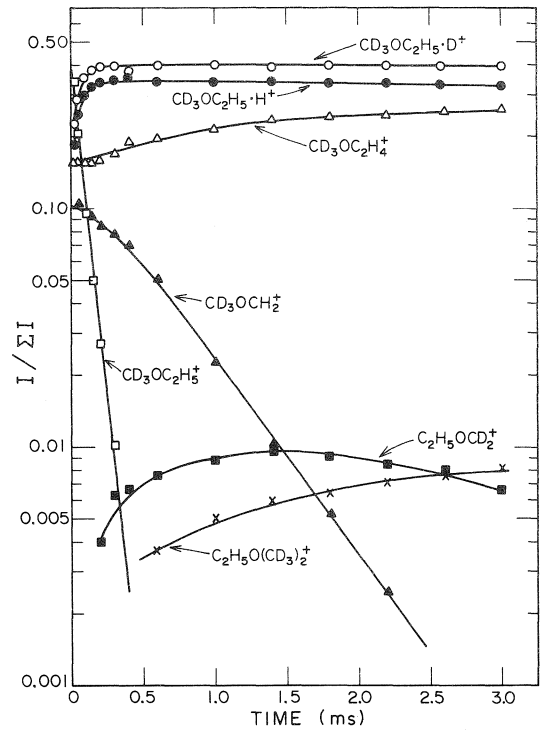

FIG. 7. Methyl-d_3 ethyl ether, intensities *vs.* time, $[M] = 1.02 \times 10^{13}$ molecules cm^{-3}.

$CH_3OCH_2^+$ with CH_3OCH_3, primarily because the H^- abstraction reaction is observable in the former system. However, the total rate constant is still much lower (at least a factor of ten) than the rate coefficient calculated from ion-induced dipole interactions (21) indicating that the majority of the collisions are non-reactive.

Acetone

Typical results for this sytem at an ionizing electron energy sufficient to produce only $(CH_3)_2CO^+$ and CH_3CO^+ as primary ions are shown in Fig. 8. The molecular ion reacts by two major channels, reactions 21 and 22, with the

[21] $(CH_3)_2CO^+ + (CH_3)_2CO \rightarrow (CH_3)_2COH^+ + CH_3COCH_2$

[22] $(CH_3)_2CO^+ + (CH_3)_2CO \rightarrow CH_3COCH_3 \cdot COCH_3^+ + CH_3$

relative rates $k_{21}:k_{22} = 0.78:0.22$ (average of seven determinations). Recently, MacNeil and Futrell (7) have reported a ratio 0.67:0.33, while Terry and Tiernan (6), from tandem experiments, have reported a ratio 0.48:0.52. Our results are in better agreement with those of MacNeil and Futrell. The slight increase and the curvature in the initial portion of the CH_3CO^+ plot indicate that this ion also is being produced to a minor extent by reaction of the molecular ion. Terry and Tiernan (6) have also reported a small yield of CH_3CO^+ when $(CH_3)_2CO^+$ is reacted with acetone in a tandem mass spectrometer.

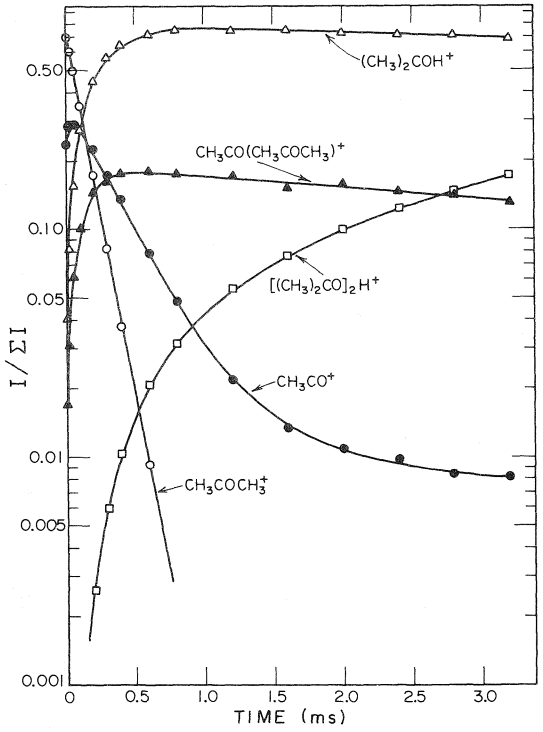

FIG. 8. Acetone, ion intensities *vs.* time, [M] = 1.14×10^{13} molecules cm^{-3}.

The total rate coefficient for reaction of $(CH_3)_2CO^+$, 6.5×10^{-10} cm^3 $molecule^{-1}$ s^{-1} (Table 1) is in satisfactory agreement with the thermal energy value of 5.4×10^{-10} cm^3 $molecule^{-1}$ s^{-1} and the pressure plot value of 5.1×10^{-10} cm^3 $molecule^{-1}$ s^{-1}, both reported by MacNeil and Futrell (7).

The major portion of the CH_3CO^+ ion is reactive, although the intensity levels off at approximately 0.4% of the total ionization indicating a possible non-reactive component. The only reaction detected was [23].

[23] $CH_3CO^+ + (CH_3)_2CO \rightarrow (CH_3)_2COH^+ + CH_2CO$

Terry and Tiernan (6) report that reaction 23 accounts for 99% of the reaction of CH_3CO^+, while MacNeil and Futrell report a 10% charge transfer to acetone at thermal energies. A small amount of charge transfer probably would not be detectable in our experiments. Values of $\Delta H_f((CH_3)_2COH^+)$ ranging from 110 kcal mol^{-1} (22) to 125 kcal mol^{-1} (23, 24) have been reported. The lower value makes reaction 23 6 kcal mol^{-1} exothermic while the higher value makes the reaction 9 kcal mol^{-1} endothermic for ground state reactants. It is possible that the reaction is indeed endothermic and that the unreactive component of the CH_3CO^+ signal represents that portion with insufficient energy to overcome the activation energy barrier for the reaction. The analogous reaction of CH_3CO^+ with acetaldehyde is 16 kcal mol^{-1} endothermic and CH_3CO^+ is completely unreactive with acetaldehyde (see above).

The $(CH_3)_2COH^+$ ion reacts further to form the disolvated proton $[(CH_3)_2CO]_2H^+$. To determine the order of this reaction the slopes of the log $[(CH_3)_2COH^+]$ *vs.* t plots at various concentrations of acetone were plotted in the manner 2.30 × slope/$[(CH_3)_2CO]$ *vs.* $[(CH_3)_2CO]$ (see eq. 18 and relevant discussion) as shown in Fig. 9. Within experimental error the intercept is zero indicating no second order contribution while the slope leads to a third order rate coefficient for the disappearance of $(CH_3)_2COH^+$ of $6.5 \pm 0.2 \times 10^{-25}$ cm^6 $molecule^{-2}$ s^{-1}. MacNeil and Futrell (7) have reported a second order rate coefficient for reaction of $(CH_3)_2COH^+$, however it is not clear that they have definitely established the reaction order.

As the results in Fig. 8 show the $CH_3COCH_3 \cdot COCH_3^+$ product reacts slowly at longer re-

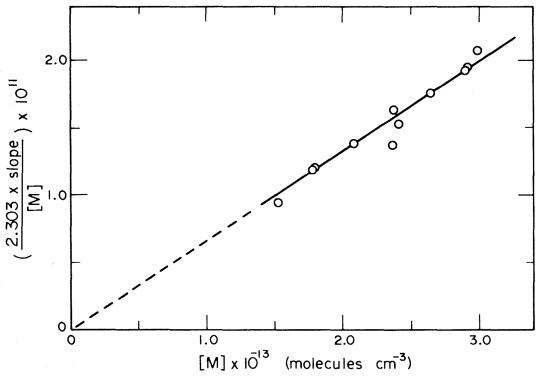

FIG. 9. Third-order plot for disappearance of $(CH_3)_2COH^+$, acetone.

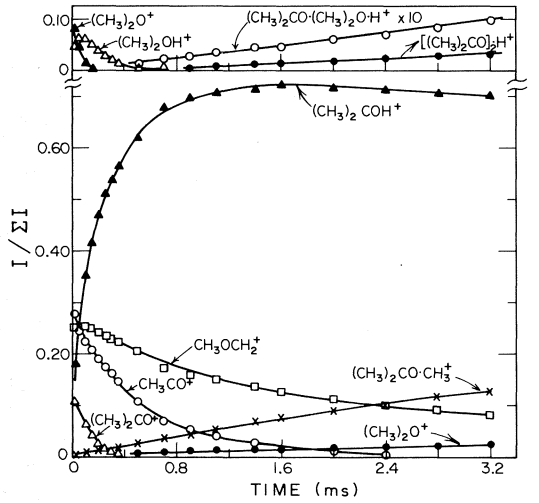

FIG. 10. Dimethyl ether – acetone system $[CH_3OCH_3] = [CH_3COCH_3] = 5.62 \times 10^{12}$ molecules cm^{-3}.

action times, probably to give the disolvated proton by reaction 24.

[24] $CH_3COCH_3{\cdot}COCH_3^+ + (CH_3)_2CO \rightarrow [(CH_3)_2CO]_2H^+ + CH_2CO$

Dimethyl Ether – Acetone

This system was studied to obtain quantitative information concerning the reaction of $CH_3OCH_2^+$ ions (structure **I**) with acetone. Typical results for a 1:1 mixture are shown in Fig. 10. Both the molecular ions react rapidly to give $(CH_3)_2OH^+$ and $(CH_3)_2COH^+$ and we estimate for the cross-sections $(CH_3)_2CO^+ + (CH_3)_2O$ and $(CH_3)_2O^+ + (CH_3)_2CO$ rate coefficients of $0.7 \pm 0.05 \times 10^{-9}$ and $2.8_5 \pm 0.05 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} respectively, although we cannot determine the relative importance of H atom abstraction and H^+ transfer in either case. The CH_3CO^+ ion reacts only with acetone yielding a rate coefficient of 2.4×10^{-10} cm^3 $molecule^{-1}$ s^{-1} in good agreement with the value obtained in pure acetone. Proton transfer from CH_3CO^+ to dimethyl ether would be 13 kcal mol^{-1} endothermic while H^- abstraction from the ether would be 7 kcal mol^{-1} endothermic.

The $(CH_3)_2OH^+$ reacts at longer delay times by proton transfer to acetone with a rate constant (Table 1) of $1.0 \pm 0.1 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. This reaction is consistent with the relative proton affinities (23), $PA((CH_3)_2O) =$ 186 kcal mol^{-1} and $PA((CH_3)_2CO) =$ 190 kcal mol^{-1}.

There appears to be an unidentified reaction forming $CH_3OCH_2^+$ at short reaction times. However, at longer times $CH_3OCH_2^+$ reacts slowly with $(CH_3)_2O$ to give $(CH_3)_3O^+$ and more rapidly by CH_3^+ transfer to acetone, reaction 25.

[25] $CH_3OCH_2^+ + (CH_3)_2CO \rightarrow (CH_3)_2CO{\cdot}CH_3^+ + CH_2O$

From the rate of disappearance of $CH_3OCH_2^+$ we estimate $k_{25} = 3.3 \pm 1.0 \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1} compared to the value of $1.3 \pm 0.9 \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1} for reaction of $CH_3OCH_2^+$ with dimethyl ether.

Acetaldehyde – Dimethyl-d_6 Ether

In pure acetaldehyde $C_2H_5O^+$ ions presumably of structure **II** are formed in abundance and react only slowly with acetaldehyde. The acetaldehyde – dimethyl-d_6 ether system was studied to elucidate the reactions of CH_3CHOH^+ ions with the ether.

Typical results are shown in Fig. 11. The primary CH_3CO^+ and $CD_3OCD_2^+$ ions are essentially unreactive[5] while CH_3CHO^+, CHO^+, and $(CD_3)_2O^+$ react rapidly to form the protonated and deuteronated forms of both neutral molecules. For the cross-reactions $CH_3CHO^+ + (CD_3)_2O$ and $(CD_3)_2O^+ + CH_3CHO$ we obtain rate coefficients of $1.6 \pm 0.4 \times 10^{-9}$ and $1.5 \pm 0.4 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} respectively. In neither case could the reaction channels

[5]At higher pressures and over longer reaction times a small yield of $CH_3CHO{\cdot}CD_3^+$ (*m/e* 62) was observed, presumably from the slow reaction of $CD_3OCD_2^+$ with CH_3CHO.

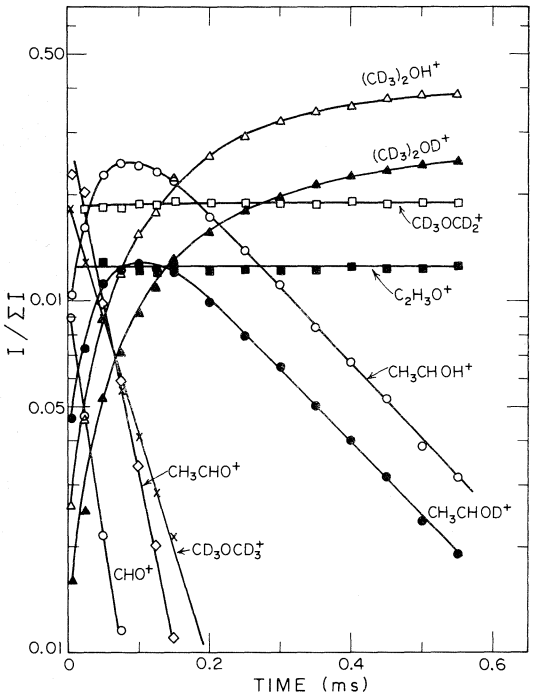

FIG. 11. Acetaldehyde – dimethyl-d_6 ether system $[CH_3CHO] = 7.22 \times 10^{12}$ molecules cm^{-3}, $[CD_3OCD_3] = 2.\overline{0} \times 10^{12}$ molecules cm^{-3}.

be clearly identified and probably both hydron transfer and atom abstraction occur.

At longer reaction times the semi-logarithmic plots for both CH_3CHOH^+ and CH_3CHOD^+ decrease linearly through occurrence of the reactions.

[26] $CH_3CHOH^+ + (CD_3)_2O \rightarrow (CD_3)_2OH^+ + CH_3CHO$

[27] $CH_3CHOD^+ + (CD_3)_2O \rightarrow (CD_3)_2OD^+ + CH_3CHO$

These reactions are anticipated since the proton affinity of dimethyl ether is greater than the proton affinity of acetaldehyde (23). The rate coefficients for the two reactions are identical within experimental error and several determinations led to the average value listed in Table 1.

Beyond 0.2 ms (*i.e.*, after the primary ions had reacted) the sums $CH_3CHOH^+ + (CD_3)_2OH^+$ and $CH_3CHOD^+ + (CD_3)_2OD^+$ remain constant indicating that reaction 27 occurs exclusively by D^+ transfer. Beauchamp and Dunbar (10) have noted that CD_3CHOH^+ ions produced by electron impact on $(CD_3)_2CHOH$ react with diisopropyl ether only by H^+ transfer below 12 eV ionizing electron energy. However, as the electron energy was increased above this value D^+ transfer was observed to increase rapidly in importance. Since $AP(CD_3CHOH^+) = 11.4$ eV they concluded that a maximum of 0.6 eV internal excitation was required to cause hydrogen randomization in the CD_3CHOH^+ ion. In our system the possible reactions forming CH_3CHOD^+ *i.e.*, $(CD_3)_2O^+ + CH_3CHO$ and $CH_3CHO^+ + (CD_3)_2O$, are 0.2 and 0.5 eV exothermic. Apparently either this excess energy is not retained by the product ion or it is insufficient to cause hydrogen randomization.[6]

One run was also carried out in a 10:1 CH_3CHO–$(CD_3)_2O$ mixture at approximately 2.5×10^{13} molecules cm^{-3} ion source concentration. The CH_3CHOH^+ signal peaked at ~0.05 ms (~47% of total ionization) and then decreased rapidly with a corresponding increase in the $(CD_3)_2OH^+$ signal. However, the CH_3CHOH^+ ion did not react completely but became constant at approximately 1.5% of the total ionization between 2 and 3 ms.

The origin of this apparent unreactive component is uncertain, however, it may indicate the attainment of a steady-state or quasi-equilibrium.[7] From the constant ionic concentrations and the relative neutral concentrations we calculate an apparent equilibrium constant for reaction 26 of ~400. This value is not inconsistent with the reported difference of 3 kcal mol^{-1} in the proton affinities of acetaldehyde and dimethyl ether (23). As discussed below a much larger non-reactive component is observed for $C_2H_5O^+$ in ethylene oxide – dimethyl-d_6 ether mixtures under similar conditions.

Ethylene Oxide – Dimethyl-d_6 Ether

These mixtures were studied in an attempt to obtain quantitative information concerning the reaction of $C_2H_5O^+$ ions of structure **III** with the ether. Because of the low reactivity of $C_2H_4O^+$ with C_2H_4O it was necessary to work

[6]In addition the reactant ions probably have an average kinetic energy of 0.4 eV (15). This does not appear to be converted to internal energy of the product ion to any significant extent since hydrogen randomization does not occur.

[7]Since the system is not at thermal equilibrium a true chemical equilibrium cannot be established. Hence we will refer to these steady-state conditions as quasi-equilibria.

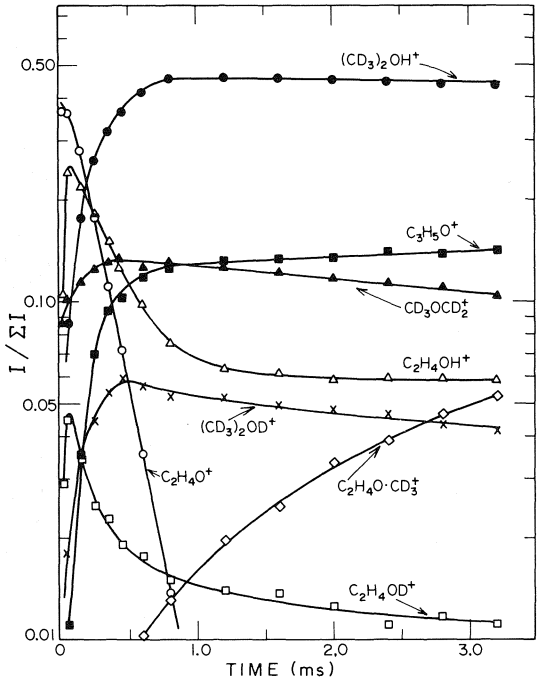

FIG. 12. Ethylene oxide – dimethyl-d_6 ether system, approximately 3.5×10^{13} molecules cm^{-3} $[C_2H_4O]$: $[CD_3OCD_3] = 10:1$.

at higher source pressures and with mixtures rich in ethylene oxide so that rapid conversion of $C_2H_4O^+$ to $C_2H_5O^+$ could be achieved.

Figure 12 shows results obtained in a 10:1 mixture at approximately 3.5×10^{13} molecules cm^{-3} total ion source concentration. At this concentration the ethylene oxide molecular ion disappears moderately rapidly not only by reactions 5 to 7 but also by reactions 28 to 30.[8]

[28] $C_2H_4O^+ + (CD_3)_2O \rightarrow (CD_3)_2OH^+ + C_2H_3O$

[29] $C_2H_4O^+ + (CD_3)_2O \rightarrow C_2H_4O{\cdot}D^+ + CD_3OCD_2$

[30] $C_2H_4O^+ + (CD_3)_2O \rightarrow CD_3OCD_2{}^+ + C_2H_4DO$

Reaction 30, D^- abstraction, is indicated by the initial significant increase in the $CD_3OCD_2{}^+$ ion current. The corresponding reaction is not observed in the acetaldehyde–ether system even though it is an exothermic reaction for both the acetaldehyde and ethylene oxide molecular ions. The reaction therefore appears to be characteristic of $C_2H_4O^+$ ion originating from ethylene oxide.

[8]It is probable that these reactions involve the $C_2H_4O^{+*}$ ion formed in reaction 6.

The rate of the proton transfer reaction 31

[31] $C_2H_4O{\cdot}H^+ + (CD_3)_2O \rightarrow (CD_3)_2OH^+ + C_2H_4O$

involving $C_2H_5O^+$ ions presumably of structure **III** could not be determined accurately. As shown in Fig. 12, the $C_2H_5O^+$ intensity, after reaching a maximum at ~0.1 ms, initially drops rapidly through the occurrence of reaction 31, but levels off at ~5.8% of the total ionization and no further reaction occurs. In a 120:1 ethylene oxide – $(CD_3)_2O$ mixture the $C_2H_5O^+$ intensity reached a maximum value of 52% of the total ionization at short delay times followed by a rapid decrease to a value of 32% which did not change between 2 and 3 ms.

The explanation of this apparent unreactive component of the $C_2H_5O^+$ signal may lie in the attainment of a quasi-equilibrium. From the experimental results we estimate apparent equilibrium constants for reaction 31 of 78 in the 10:1 mixture and 75 in the 120:1 mixture. The reported (23) proton affinities, $PA(C_2H_4O) = 183$ kcal mol^{-1} and $PA((CH_3)_2O) = 186$ kcal mol^{-1}, lead to a calculated equilibrium constant of 58 (for 373 °K, the approximate source temperature) assuming $\Delta S°$ is negligibly small.

Although this agreement supports the postulate of an equilibrium an alternative explanation is possible. The $C_2H_5O^+$ ion derived from ethylene oxide may have rearranged to structure **I** with the result that the experimental data really represent a steady-state achieved between reaction 26 and proton transfer from $(CD_3)_2OH^+$ to the oxide. These are two separate reactions which do not combine as a single reversible reaction and the steady-state conditions have no interpretation as a chemical equilibrium.

Although we are inclined to believe that the first explanation holds and that the different equilibrium constants for the ethylene oxide – ether and acetaldehyde ether systems indicate different structures for the $C_2H_5O^+$ ions, the results are not conclusive. More substantial evidence for the non-identity of the $C_2H_5O^+$ ions is obtained from the studies of the mixtures with acetone reported below.

In addition to the ions shown in Fig. 12 a small yield of the disolvated proton $((CD_3)_2O)(C_2H_4O)H^+$ was observed at high pressures and long reaction times in mixtures rich in ethylene oxide. This result is in contrast to the pure ethylene oxide system where no disolvated protons were observed even at the highest pressures used.

Acetaldehyde-d_4 – Acetone

This system was studied briefly to examine the reactions of CD_3CDOD^+ ions (structure **II**) with acetone. Results for a 3.9:1.0 mixture are shown in Fig. 13. Both CDO^+ and CD_3CDO^+ react with acetone to produce mainly $(CH_3)_2COD^+$. From the slope of the semi-logarithmic plot for CD_3CDO^+ we obtain, after correction for the $CD_3CDO^+ + CD_3CDO$ reaction, a rate coefficient of 3×10^{-10} cm^3 molecule^{-1} s^{-1} for the reaction of CD_3CDO^+ with acetone. Both CH_3CO^+ and CD_3CO^+ react with acetone only and we calculate rate coefficients of 3.0×10^{-10} and 2.6×10^{-10} cm^3 molecule^{-1} s^{-1}, respectively, in good agreement with the results obtained in pure acetone.

The CD_3CDOD^+ ion reacts rapidly and completely by D^+ transfer to acetone, the rate coefficient being 2.25×10^{-9} cm^3 molecule^{-1} s^{-1}. A complete reaction is to be expected since $PA((CH_3)_2CO)$ is at least 7 kcal mol^{-1} greater than $PA(CH_3CHO)$ (23). However, the result for this system is to be contrasted with the results obtained for the similar ethylene oxide – acetone system discussed below.

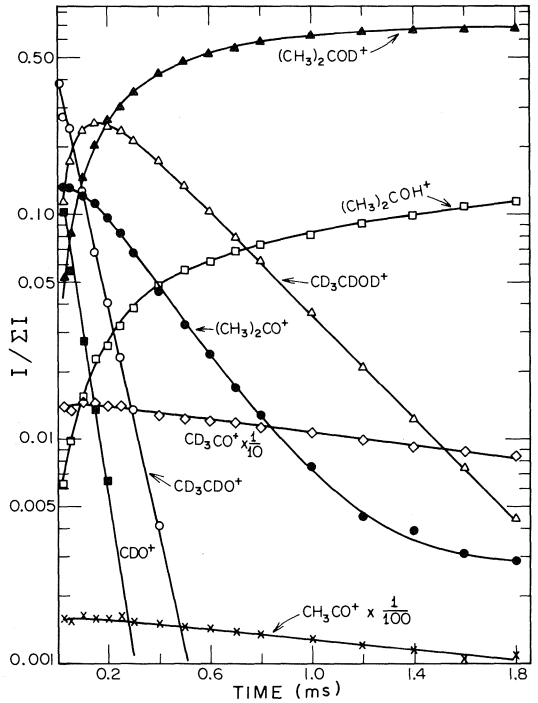

FIG. 13. Acetaldehyde-d_4 – acetone system, $[CD_3CDO] = 4.54 \times 10^{12}$ molecules cm^{-3}, $[CH_3COCH_3] = 1.16 \times 10^{12}$ molecules cm^{-3}.

Ethylene Oxide – Acetone

These mixtures were examined in an attempt to obtain quantitative information concerning the reaction of $C_2H_5O^+$ ions of structure **III** with acetone. Figures 14 and 15 present the results obtained in an 8:1 ethylene oxide – acetone mixture.

Several products are observed in this system which are not observed in acetaldehyde–acetone mixtures. A secondary ion is formed at *m/e* 72, shifting to *m/e* 74 in C_2D_4O–$(CH_3)_2CO$ mixtures, which corresponds to the addition of CH_2^+ to acetone (reaction 32).[9]

[32] $C_2H_4O^+ + (CH_3)_2CO \rightarrow C_4H_8O^+ + CH_2O$

A similar reaction between $C_2H_4O^+$ and acetaldehyde is also observed. A product ion is also observed at *m/e* 87, shifting to *m/e* 91 in C_2D_4O–$(CH_3)_2CO$ mixtures, which we attribute to the acetylation reactions 33 and 34.

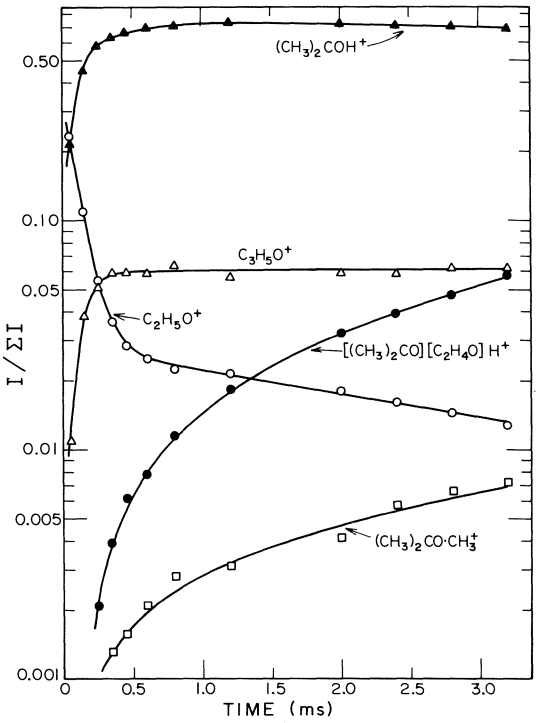

FIG. 14. Ethylene oxide – acetone system, $[C_2H_4O] = 4.96 \times 10^{13}$ molecules cm^{-3} $[CH_3COCH_3] = 0.63 \times 10^{13}$ molecules cm^{-3}.

[9] $C_4H_8O^+$ also appears to be formed by a further unidentified reaction since its intensity continues to rise slowly even after the $C_2H_4O^+$ ion has reacted completely.

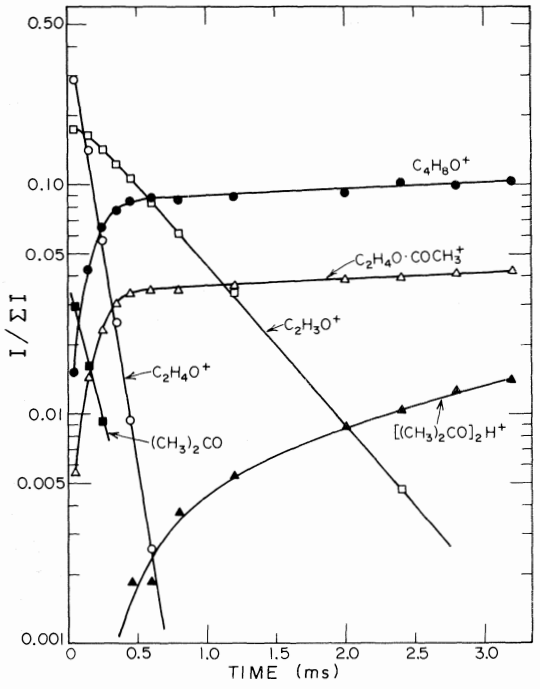

FIG. 15. Ethylene oxide – acetone system, conditions as for Fig. 14.

[33] $(CH_3)_2CO^+ + C_2H_4O \rightarrow C_2H_4O{\cdot}COCH_3^+ + CH_3$

[34] $(CH_3)_2COH^+ + C_2H_4O \rightarrow C_2H_4O{\cdot}COCH_3^+ + CH_4$

The latter reaction is included since the *m/e* 87 product intensity continues to increase after the $(CH_3)_2CO^+$ ion has reacted completely. Additional products are the disolvated proton $((CH_3)_2CO)(C_2H_4O)H^+$ (*m/e* 103) and $((CH_3)_2CO)_2H^+$ (*m/e* 117) observed in low yield at long reaction times.

As in the ethylene oxide – ether mixtures the rate of reaction of the $C_2H_5O^+$ ion could not be established accurately. As shown in Fig. 15 the $C_2H_5O^+$ intensity, which reached a maximum before 0.05 ms, initially decreases rapidly with a corresponding increase in $(CH_3)_2COH^+$. However, the reaction apparently does not go to completion and beyond 0.5 ms, the rate of decrease of the $C_2H_5O^+$ signal is much slower. Similar results were observed in 4:1 and 40:1 mixtures. The change in the rate of reaction cannot be due to the approach to a steady-state, as appears to be the case in the mixtures with $(CD_3)_2O$, since from the relative proton affinities (23) we calculate that the equilibrium in the proton transfer reaction should lie far to the side of protonated acetone ($K \approx 1 \times 10^4$).[10] Rather the change in rate of reaction appears to result from a change in structure of the $C_2H_5O^+$ ion.

There are two pieces of evidence which indicate that the slow reaction of $C_2H_5O^+$ at longer times represents reaction of structure **I** ions rather than structure **III** ions. In the region between 1.0 and 3.2 ms the linear semi-logarithmic plot for $C_2H_5O^+$ (Fig. 15) leads to a rate constant for the disappearance of $C_2H_5O^+$ of 4.2×10^{-11} cm^3 molecule^{-1} s^{-1} assuming reaction only with acetone.[11] An almost identical rate constant, 4.0×10^{-11} cm^3 molecule^{-1} s^{-1}, is obtained by a similar analysis of the results in a 4:1 mixture. Both these values are in good agreement with the value $k_{25} = 3.3 \pm 1.0 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} measured for the reaction in dimethyl ether – acetone mixtures. The occurrence of reaction 25

[25] $CH_3OCH_2^+ + (CH_3)_2CO \rightarrow (CH_3)_2CO{\cdot}CH_3^+ + CH_2O$

in the present system also is supported by the observation of a product species of *m/e* 73 ($(CH_3)_2CO{\cdot}CH_3^+$) which increases significantly over the time range from 1.0 to 3.2 ms (Fig. 14). In the 4:1 mixture where the decrease in $C_2H_5O^+$ over this time range is greater the *m/e* 73 intensity was considerably higher (maximum 2% of total ionization).

The mechanism by which $C_2H_5O^+$ ions of structure **I** are formed is not clear. It obviously must occur only in the mixtures with acetone since no reaction of $C_2H_5O^+$ by CH_3^+ addition was observed either in the pure ethylene oxide or ethylene oxide – $(CD_3)_2O$ systems.[12] A collision-induced isomerization is thermochemically permitted ($\Delta H_f(CH_3OCH_2^+)$) = 156 kcal mol^{-1} (26). $\Delta H_f(C_2H_4O{\cdot}H^+)$ = 170 kcal mol^{-1} (10), however, there is no apparent reason why it should be specific to the ethylene oxide – acetone

[10]Experimentally at long delay times we find that the ratio $[C_2H_4O]\,[(CH_3)_2COH^+]/[(CH_3)_2CO]\,[C_2H_5O^+]$ varies from 200 to 800 for the mixtures studied.

[11]The reaction of $C_2H_5O^+$ ions of either structure **I** or **III** with ethylene oxide is much slower.

[12]If the incomplete reaction of $C_2H_5O^+$ in ethylene oxide – $(CD_3)_2O$ mixtures was due to formation of $CH_3OCH_2^+$ ions the $C_2H_5O^+$ signal should not become constant but should continue to drop in Fig. 12 with the same slope as the $CD_3OCD_2^+$ signal.

mixture. Comparison with the results obtained in the acetaldehyde–acetone mixture shows once again differences for the $C_2H_5O^+$ ions formed in the two systems.

Ethylene Oxide – Acetaldehyde

The ionic reactions in the mixtures C_2H_4O–CH_3CHO, C_2D_4O–CH_3CHO, C_2H_4O–CD_3CDO, and C_2D_4O–CD_3CDO were examined. Figure 16, showing results for a 1:1 C_2D_4O:CH_3CHO mixture, is typical of the results obtained. In no case did we observe significant net proton transfer from one protonated form to the other neutral although the results from mixtures of each of the two components with $(CD_3)_2O$ do suggest that the proton affinity of ethylene oxide is slightly greater than the proton affinity of acetaldehyde.

From the rate of disappearance of CH_3CHO^+ we calculate that this ion reacts rapidly ($k = 1.9 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}) with C_2D_4O to produce both CH_3CHOD^+ and $C_2D_4OH^+$. This rapid rate of reaction rules out the possibility that the modified molecular ion $C_2H_4O^+$* produced in ethylene oxide (reaction 6) has the acetaldehyde structure since the rate of reaction 7 is much lower ($k_7 = 0.15 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}).

The plot of the $C_2D_4O^+$ ion current shows the characteristic sigmoid shape (compare Fig. 2) and it appears that $C_2D_4O^+$* is the major species reacting with acetaldehyde. From the linear region of the semi-logarithmic plot at longer reaction times we calculate $k \approx 6 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} for the reaction. The major product is $C_3H_4D_2O^+$ (*m/e* 60) whose graph of intensity *vs.* time shows an initial shape

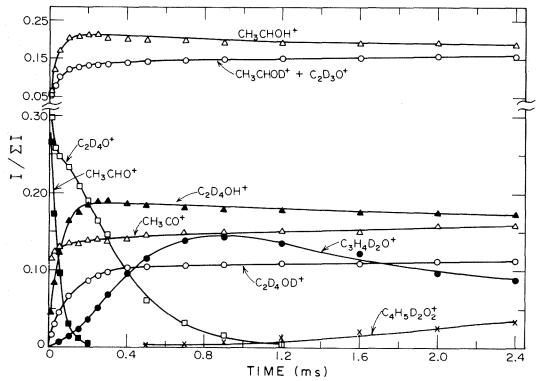

FIG. 16. Acetaldehyde – ethylene-d_4 oxide [CH_3CHO] = [C_2D_4O] = 5.49×10^{12} molecules cm^{-3}.

expected for the product of a sequential reaction series (compare $C_3H_5O^+$ in Fig. 2). The identity of the product was confirmed by the observation of the following reactions in the appropriate mixtures.

[35] $C_2H_4O^+ + CH_3CHO \rightarrow C_3H_6O^+$(*m/e* 58) $+ CH_2O$

[36] $C_2D_4O^+ + CH_3CHO \rightarrow C_3H_4D_2O^+$ (*m/e* 60) $+ CD_2O$

[37] $C_2H_4O^+ + CD_3CDO \rightarrow C_3H_2D_4O^+$ (*m/e* 62) $+ CH_2O$

[38] $C_2D_4O^+ + CD_3CDO \rightarrow C_3D_6O^+$ (*m/e* 64) $+ CD_2O$

The reaction clearly corresponds to $C(H,D)_2^+$ transfer from the reactant ion to the neutral acetaldehyde and occurs without isotopic mixing. The reaction is analogous to reaction 33 observed in ethylene oxide – acetone mixtures and thus appears to be typical of the reaction of ethylene oxide molecular ions with a carbonyl function.

The ions produced in reactions 35 to 38 react further in the isotopically specific reactions 39 to 42

[39] $C_3H_6O^+ + CH_3CHO \rightarrow C_4H_7O_2^+$ (*m/e* 87) $+ CH_3$

[40] $C_3H_4D_2O^+ + CH_3CHO \rightarrow C_4H_5D_2O_2^+$ (*m/e* 89) $+ CH_3$

[41] $C_3D_4H_2O^+ + CD_3CDO \rightarrow C_4D_5H_2O_2^+$ (*m/e* 92) $+ CD_3$

[42] $C_3D_6O^+ + CD_3CDO \rightarrow C_4D_7O_2^+$ (*m/e* 94) $+ CD_3$

which account for the major part of the $C_3(H,D)_6O^+$ ion which reacts. In each case the reaction corresponds to condensation of the ion with acetaldehyde and elimination of a methyl radical as the neutral fragment. Although the reactions are isotopically specific it cannot be determined from the present work whether the methyl radical is derived from the ionic or neutral reactant, however, it does not contain any of the hydrogens derived from the ethylene oxide precursor to the $C_3(H,D)_6O^+$ ion.

Conclusions

The present work has shown that in the one-component acetaldehyde, acetone, or dimethyl ether systems the monosolvated protons react

predominantly to form the disolvated proton. Under our conditions (up to 0.4 eV average ion kinetic energy) the reactions are third order with rate constants in the range 10^{-24} to 10^{-25} cm^6 molecule^{-2} s^{-1}. The rate coefficients for the thermal energy reactions should be even larger with the result that at moderate pressures in these systems extensive solvation of the proton should occur. The ethylene oxide system is unique in that no disolvated protons were observed, although in mixed systems solvates of the type $M(C_2H_4O)H^+$ ($M = (CD_3)_2O$ or $((CH_3)_2CO)$ were observed.

In two-component systems bimolecular reactions of the type

$$[43] \qquad M_1H^+ + M_2 \rightarrow M_2H^+ + M_1$$

occur rapidly if the proton affinity of M_2 is significantly greater than that of M_1 ($\sim$3 kcal mol^{-1}). The rate coefficients of several of these reactions have been measured and are in the range 1.0 to 2.2 $\times$ 10^{-9} cm^{-3} molecule^{-1} s^{-1}. Consequently in many of the mixed systems reaction 43 will be more rapid than the third order solvation reactions with the result that the latter reactions will involve mainly the M_2H^+ species.

In a number of systems the proton transfer reaction 43 did not go to completion but reached a steady-state or apparent equilibrium. Since there is little doubt that in our system the reactant species are not at thermal equilibrium the observation of a quasi-equilibrium situation illustrates the hazards of using such measurements to derive equilibrium constants and associated thermochemical data. Steady-state conditions appear to be relatively easy to attain, however, true equilibrium conditions may be much more difficult to attain.

The present work and i.c.r. work (10) both have shown that $C_2H_5O^+$ ions of structure **I** ($CH_3OCH_2^+$) undergo CH_3^+ transfer and, in some cases H^- abstraction reactions. However, in all cases studied a large fraction of the ion–molecule collisions are unreactive since the measured rate coefficients are in the 10^{-11} cm^3 molecule^{-1} s^{-1} range for CH_3^+ transfer and in the 10^{-10} cm^3 molecule^{-1} s^{-1} range for H^- abstraction. Neither in this work nor in the i.c.r. study (10) is there any evidence that $C_2H_5O^+$ ions of structure **I** undergo proton transfer reactions. Recently, Haney and Franklin (27) have proposed that ions of nominal structure **I** rearrange to structure **II** (CH_3CHOH^+) on formation from ethers by electron impact. The ion of structure **II** reacts rapidly by proton transfer and the failure of the $C_2H_5O^+$ ion from ethers to react similarly is strong evidence that the rearrangement has not occurred. Haney and Franklin's proposal was based on the measurement of the excess kinetic energy of the fragment ion at the appearance potential threshold. Assuming that the excess energy was randomized among all degrees of freedom they derived from the appearance potential, corrected for the excess energy involved, an ionic heat of formation for the $C_2H_5O^+$ ion of nominal structure **I** identical with the known value for ions of structure **II**. It is possible that in the work of Haney and Franklin (27) the assumption of complete randomization of the excess energy is not valid and that the fraction appearing as kinetic energy is correspondingly high.

The present work has revealed a number of unique features concerning the ionic reactions involving the molecular ion derived from ethylene oxide. The $C_2H_4O^+$ ion formed initially in the electron impact process is quite unreactive but apparently undergoes a rapid collisional modification to a more reactive species which reacts with neutral ethylene oxide to form $C_3H_5O^+$ and with carbonyl compounds by CH_2^+ addition. These reactions are not observed for $C_2H_4O^+$ (acetaldehyde) ions and the differences appear to provide a means of distinguishing between the two structures. However, one cannot rule out the possibility that these differences may arise from energy effects rather than structural effects since $\Delta H_f(\overline{CH_2—CH_2O^+}) =$ 231 kcal mol^{-1} while $\Delta H_f(CH_3CHO^+) = 196$ kcal mol^{-1} (25).

Computer-assisted Generation of IUPAC Names of Polycyclic Bridged Ring Systems

D. VAN BINNENDYK AND A. C. MACKAY

Canada Packers Limited, Research and Development Laboratories, 2211 St. Clair Avenue West, Toronto, Ontario

Received January 28, 1972[1]

A computer program for the generation of IUPAC names of polycyclic bridged ring systems has been devised. It enables the names of complex molecules to be arrived at easily from conventionally drawn structures.

On a mis au point un programme qui, à l'aide d'ordinateur peuvent dégénérer les noms systématiques (UICPA) de composés polycicliques. Ce programme permet de trouver facilement les noms de molécules complexes en faisant appel aux structures représentées d'une manière conventionnelle.

In 1966 it was pointed out by Meinwald and Crandall (1) that the IUPAC rules for the nomenclature of bridged polycyclic hydrocarbons (2) were not being complied with by all authors. More recently, Eckroth (3) has reported on a method intended to facilitate the generation of correct names for "von Bayer hydrocarbons". In spite of these papers, erroneous names for bridged ring compounds continue to appear in the literature (4, 5, 6) (see Table 1).

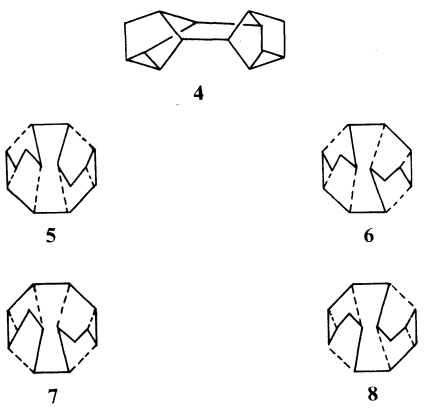
The IUPAC rules (2) may be summarized:

(*1*) Select as the *main ring* the ring that has the greatest number of atoms.

(*2*) Select as the *main bridge* the bridge spanning the main ring that has the greatest number of atoms; if there is a choice between two or more bridges of equal length select the bridge which divides the main ring most symmetrically.

(*3*) The system is now numbered along the longest arm of the main ring such that the superscripts describing the location of the other bridges are as low as possible.

Considering each of the rules in turn, while the first appears to be straightforward, it is not obvious that for a given compound there may be several ways in which the main ring may be generated. The possibilities for **4** (**5–8**) are illustrated and each of these must be considered in turn in arriving at the best name for the molecule. The second rule can result in several more possible names being generated, especially if two or more bridges fulfil the requirements of the rule. As far as the third rule is concerned, Eckroth (3) has already noted that there are three possible interpretations:



(*a*) The name selected will have, at the first difference in the first of the superscripts, the lower number. If this does not result in a discrimination between two different names, then the second superscripts are considered.

(*b*) Only the first superscripts are considered and if this does not enable a choice to be made, then selection is made on the basis of position of substituents or other features of the molecule such as a site of unsaturation.

(*c*) Chemical Abstracts uses the lower at the first possible difference of either of each pair of superscripts.

By following (*a*) above, which he suggests be adopted by IUPAC, a suggestion endorsed by the present authors, Eckroth gives **4** the name *endo,cis,endo*-heptacyclo[8.4.0.$0^{2,12}$.$0^{3,7}$.$0^{4,9}$.$0^{6,8}$.$0^{11,13}$]tetradecane. However, by selecting an

[1]Revision received August 23, 1972.

TABLE 1. Correct and erroneous names for some bridged ring compounds

Compound	Reference	Assigned name	Correct name
 1	4	Pentacyclo[7.2.1.$0^{2,8}$.$0^{3,11}$.$0^{6,10}$]-dodec-4-ene	Pentacyclo[5.5.0.$0^{2,6}$.$0^{3,10}$.$0^{4,8}$]-dodec-11-ene
 2	5	Tricyclo[6.1.0.$0^{5,9}$]nonane	Tricyclo[4.3.0.$0^{2,9}$]nonane
3	6	Tetracyclo[5.2.1.$0^{2,6}$.$0^{3,10}$]-deca-4,8-diene	Tetracyclo[4.4.0.$0^{2,8}$.$0^{3,7}$]-deca-4,9-diene

alternative main ring (**6** as opposed to **5**) a better name may be arrived at: *endo,cis,endo*-heptacyclo[8.4.0.0^{2,12}.0^{3,8}.0^{4,6}.0^{5,9}.0^{11,13}]tetradecane.

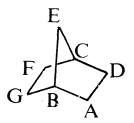
If no decision has been reached for the name by this stage, the position of hetero atoms and substituents may be taken into consideration.

With the synthesis of increasingly complex molecules, the generation of the correct name becomes correspondingly more difficult and time-consuming.

In light of the ever increasing use of automated systems for the retrieval of information, it is more than ever desirable that authors name their compounds correctly along the lines recommended by IUPAC. Without this, chemistry, and particularly the chemistry of bridged ring systems, will become hopelessly confused and information irretrievably buried; this should be self-evident since formula indices locate specific compounds, not members of a given system. Eckroth's paper only serves to emphasize the difficulties encountered in the manual generation of IUPAC names. Conversion of familiar three-dimensional representations into Schlegel diagrams (7) is not always easy and requires considerable practice. Furthermore, once the molecule is represented in this way, there is no assurance that the investigator will obtain the best possible name. However, conversion of the 3-D representation into a planar graph serves to change the point of view of the investigator and thus assists in a more objective analysis. Symmetrical molecules are particularly amenable to this method of name generation.

Conrow (8) reported in 1966 a Fortran program for the computer generation of IUPAC names for bridged bicyclic, tricyclic, and tetracyclic hydrocarbons. Its most severe limitation is that polycyclic compounds having more than four rings are excluded. Furthermore, in the case of a tetracyclic compound that is topologically twisted, absurd names are generated. The input required is in the form of a connection matrix; however, this limitation could be overcome by supplying simpler data together with a program for the generation of the connective matrix. Finally, quaternary atoms in the molecule under consideration result in no further processing of the name.

In noting the deficiencies of the above methods of name generation, it was felt that in order to consider exhaustively all possible names for a given system, a more comprehensive computer program would be necessary. A Fortran program[2] has now been written which will facilitate the generation of the correct IUPAC name for polycyclic bridged ring systems. The use of the program can be illustrated for a simple example. The molecule is drawn as usual. *e.g.*



9

[2]A listing of the program may be obtained on request from the authors.

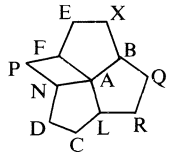
The carbon atoms forming the ring system are labelled alphabetically in any order. All of the bonds (with AB and BA regarded as separate bonds) are written down and counted. In preparing the list of atoms for the computer, the first atom in the list should be the tertiary or quarternary carbon dividing the longest chain of secondary carbon atoms incorporated in the bridged ring system. In cases of multiple choice, any one of the equivalents may be selected. (In Table 2 these atoms have been circled.) This ensures that the computer will determine the correct main ring. As described below, the computer starts its search for the best main ring from the first tertiary or quaternary carbon mentioned on the list. In the following example, listing from A, the best name will not be obtained. Starting the search from B, which fulfills the above condition, will give the correct name.



The above example is the only case encountered where the restriction on starting point has been found important. Other examples considered to date have given the correct IUPAC name in the list of names produced by random choice of starting point. On supplying these data, and the program, to the computer, the following output is obtained:

(*a*) The sequence of atoms in the main ring is printed and any atoms not part of the main ring are identified and printed.

(*b*) The bonds not used in the main ring are identified and printed.

(*c*) If two or more atoms are excluded from the main ring, the name has to be generated from the above data.

(*d*) If all, or all but one, atoms are involved in the main ring, the main bridge is selected by the computer and the name of the ring system is generated.

Some further elaboration of the above points is necessary, considering each in turn. Point (*a*) is the essential function of the computer program. The identification of the sequence of atoms in the main ring is accomplished by the complete enumeration of all possible rings. The first tertiary or quaternary atom given on the input list is selected as a starting point. There are then three or four possible starting routes, which are stored in computer memory. Proceeding to the second atom on the first route, it is determined (*i*) if secondary, the route is augmented with the third atom or (*ii*) if tertiary, a fourth route, from the original starting point, is enumerated or (*iii*) if quaternary, two additional routes must be enumerated. The program will continue in this way, enumerating all possible routes. If a route returns to the original starting point, thus becoming a ring, but other routes still continue, that ring is eliminated thus sparing computer storage. Similarly eliminated is any route which cannot proceed except by doubling back on itself. The storage of all possible routes takes up a large portion of the computer memory. For example, with the IBM 360 Model 40 computer used for this work, with a 100 k memory, it was found that a maximum of approximately 900 routes could be stored. This could be increased by using disk storage, or breaking down the analysis into parts, but the 900 routes were found to be sufficient for the analysis of some of the more complex polycyclic compounds given in the literature. The time taken on the computer also increases to a significant amount, that is, to 10 min and more, when analyzing nonacyclic compounds. When the program has run to completion, all routes are eliminated and those last to return to the original starting point are printed out as the longest. This method will generate twice the number of *different* possible rings fitting IUPAC rule no. 1 above; the factor 2 takes into account the necessity to discriminate between clockwise and anti-clockwise progression round the ring. Point (*b*) requires no further discussion. While (*c*) appears to be a definite limitation, most of the errors in naming bridged polycyclic ring systems seem to arise from the failure of the authors concerned to find the main ring in their molecules. It is a relatively simple matter to generate the name, given a complete list of the main rings (see example 1). For molecules fitting the criteria of (*d*), names are printed for each main ring generated. From the list of names printed, a selection may be made by inspection. Further refinement at this stage resulting in a single name being chosen by the computer does not seem advisable until one of the alternatives of IUPAC rule no. 3 is generally accepted.

As has been mentioned above, many of the wrong names found in the literature appear to

have arisen through incorrect choice of the main ring. The program may be divided, giving a sub-program which will generate with greatly reduced computer memory requirements, only the possible main rings. Thus smaller computers may be employed to overcome one of the major obstacles to correct nomenclature in bridged ring systems. For extremely complex cases, even with this reduced memory requirement, the number of possible routes being considered by the computer may exceed the space available.

A few ring systems subjected to this method of name generation are shown in Table 2.

Example 1: Manual Generation of the IUPAC Name from the Main Rings

Schleyer *et al.* (9) reported the synthesis of **I** to which they assigned the name nonacyclo-[11.7.1.1^{2,18}.$0^{3,16}$.$0^{4,13}$.$0^{5,10}$.$0^{6,14}$.$0^{7,11}$.$0^{15,20}$]-docosane. Computer print-out was in the form depicted in Chart 1. A total of 16 entries was

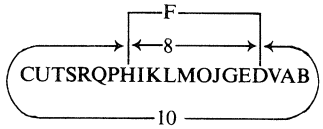
CHART 1

obtained; this represents eight pairs, thus after excluding one from each pair, eight rings have to be considered. The steps followed were:

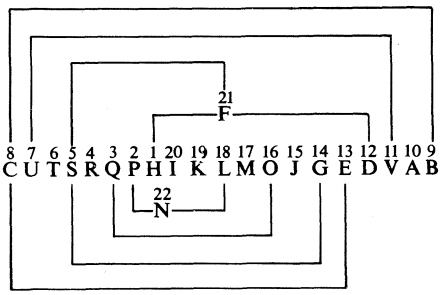
(*1*) Determine if any two atoms not in the main ring were joined; in this example they were not.

(*2*) For each of the eight rings, consider in turn each of the atoms as the main bridge in order to determine the most symmetrical bridge; in this example F forms the main bridge.



(*3*) Insert the remaining atom and the missing links then number the molecule in accordance with IUPAC rule 3 above:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



(4) The name of the compound, by inspection, is thus: nonacyclo[10.8.1.1^{2,18}.0^{3,16}.0^{5,14}.0^{5,21}-.0^{7,11}.0^{8,13}.0^{15,20}]docosane, which, according to the IUPAC rules is a more acceptable name than the one assigned by the authors.

In all the literature examples of bridged ring systems examined, in no case has the computer, controlled by this program, failed to make it possible to produce a name, as good as or better than the literature name.

In the case of the first compound in Table 2 only one main ring is found by the computer. Four names are generated since the main bridge divides the main ring equally and thus it is theoretically possible to start numbering from either bridgehead and to proceed in either direction. While programming the computer to produce a single name would be straightforward, the current confused situation with IUPAC rule 3 makes it expedient that all possible names be listed.

Dr. T. F. Massiah is cordially thanked for his interest and encouragement throughout the course of this work.

Photolyse du pentène-1 dans l'ultraviolet à vide

PATRICK M. PERRIN ET GUY J. COLLIN

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi, Québec

Reçu le 24 août 1972

La décomposition de la molécule pentène-1 excitée produite dans la photolyse aux raies de résonnance du xénon (8.4 eV) et du krypton (10.0 eV), a été étudiée. Les principaux produits de décomposition sont l'éthylène, l'allène, le butadiène-1,3, et l'acétylène ainsi que d'autres produits mineurs. Les atomes d'hydrogène s'additionnent sur la double liaison du monomère et forment ainsi un radical pentyle excité, qui se décompose en propène et radical éthyle à très basse pression ($P < 1$ Torr). Enfin l'isomérisation de la molécule excitée pentène-1 à ces énergies est de peu d'importance.

Photolysis of 1-pentene molecules at 8.4 eV (xenon photolysis) and 10.0 eV (krypton photolysis) was studied. Excited molecules decompose to produce mainly ethylene, propadiene, 1,3-butadiene, acetylene, and other minor products. Hydrogen atoms add to the double bond of the monomer and the resulting excited pentyl radical decomposes at low pressure ($P < 1$ Torr) into propene and ethyl radical. Isomerization of excited 1-pentene molecules is unimportant at these energies.

Can. J. Chem., **51**, 724 (1973)

Introduction

Nous avons récemment étudié la photolyse dans l'u.v. lointain des *cis*- et *trans*-butène-2 (1) et du butène-1 (2). L'étude du pentène-1 est un prolongement de ces travaux. Nous avons étudié l'importance des réactions de dégradation de la molécule de pentène-1 excitée, les réactions de recombinaisons radicalaires et la fragmentation des radicaux pentyles formés dans l'addition des atomes d'hydrogène sur la double liaison. L'effet de l'hydrogène sulfuré, comme intercepteur de radicaux vinyles en particulier, était au centre de nos préoccupations.

Procédés expérimentaux

Toutes les expériences de photolyse du pentène-1 ont été effectuées, en utilisant l'émission photonique dans l'u.v. lointain, produite par une lampe contenant du xénon ou du krypton sous faible pression, excitée à l'aide d'une antenne micro-onde. Ces lampes ont été décrites (3) et leurs caractéristiques ont été rappelées dans la littérature (1, 4). Au cours des irradiations du pentène-1 seul, ou en présence d'hélium ou d'oxygène, nous n'avons pas observé de baisse de rendement appréciable de la lampe. Par contre, dans les irradiations en présence d'hydrogène sulfuré, il se forme un dépôt de soufre sur la fenêtre cristalline que l'on nettoie périodiquement avec du disulfure de carbone. L'actinométrie a été faite comparativement à celle de l'isobutylène (5).

Le pentène-1 provient de Chemical Sample Co.; il a été purifié par chromatographie. Le pentène-1 perdeutéré a été fourni par Merck, Sharp and Dohme of Canada. L'hydrogène sulfuré et l'oxygène, fournis par les établissements Matheson, ont été utilisés après dégasage sur un système à haut vide. Les irradiations sont analysées par c.p.g. sur des colonnes de squalane et d'alumine. Les produits de l'irradiation des mélanges perdeutérés ont été piégés à la sortie du chromatographe à basse température et analysés séparément dans un spectromètre de masse CEC 21-104.

Résultats

L'irradiation du pentène-1 a été menée à des énergies de 8.4 eV (147 nm) et 10.0 eV (123.6 nm) dans les domaines de pression variant de 0.015–100 Torrs (tableaux 1 et 2).

Les figs. 1 et 2 montrent la variation du rendement de certains produits relativement au pentène en fonction du temps d'irradiation. La pente de ces courbes représente leur vitesse de formation et elle est constante. Il n'y a donc pas de réaction secondaire provenant de l'interaction des photons et des produits réactionnels. Cela reste valable tant que le temps d'irradiation reste inférieur à 100 min pour l'intensité utilisée. Le taux de conversion du pentène est alors de 1% environ. Au delà de ce délai, la pente des courbes diminue et le rendement quantique des produits décroît. Les autres résultats sont résumés dans les tableaux et figures qui suivent.

Discussion

Le potentiel d'ionisation du pentène normal est de 9.5 eV (6). Donc à 123.6 nm, soit 10.0 eV, une part importante des molécules excitées conduisent à l'ionisation et forment ainsi l'ion $C_5H_{10}^+$. Comme aucun effet de capteurs d'ions positifs ou d'électrons n'a été observé, il faut en conclure que les processus de réactions ioniques qui ont lieu à 123.6 nm ne participent pas à la formation des produits étudiés ici. Les seules

réactions retenues seront celles de la décomposition de la molécule de pentène excitée (éq. 1).

[1] $$C_5H_{10}\text{-}1 + h\nu \rightarrow (C_5H_{10})^{**}$$

L'énergie emmagasinée par la molécule est de 194 kcal mol^{-1} à 147.0 nm et 231 kcal mol^{-1} à 123.6 nm. Statistiquement, une importante partie de cette énergie peut se localiser au voisinage d'une liaison C—C ou d'une liaison C—H et en provoquer la rupture. Ces réactions sont très rapides et interviennent avant une collision moléculaire, du moins dans le domaine de pression étudié ici. Les rendements des produits ainsi obtenus sont indépendants de la pression et ne sont pas affectés par la présence de faibles proportions d'additifs (0, 10%). En général, les réactions de fragmentation sont donc de la forme de l'éq. 2. R_1 est un fragment radicalaire

[2] $$(C_5H_{10})^{**} \rightarrow R_1 + R_2^*$$

stable, et R_2 est un fragment radicalaire excité. Rompre une liaison C—H nécessite environ 100 kcal mol^{-1} et une liaison C—C, 90 kcal mol^{-1}. Il reste donc une quantité suffisante pour que l'un des deux fragments se scinde à son tour et globalement la molécule de pentène produira

[7*b*] $(C_5H_{10})^{**} \rightarrow H\cdot + \cdot C_3H_5 + C_2H_4$ ΔH = 100 kcal mol^{-1}

[7*c*] $(C_5H_{10})^{**} \rightarrow C_3H_6 + C_2H_4$ ΔH = 22.5 kcal mol^{-1}

[8] $(C_5H_{10})^{**} \rightarrow \cdot CH_3 + \cdot C_2H_3 + C_2H_4$ ΔH = 132 kcal mol^{-1}

Les tableaux 1 et 2 montrent que la plupart des produits analysés ont des rendements indépendants de la pression. Ils montrent aussi que les réactions de fragmentation, menant à la formation de deux composés moléculaires stables (réactions 3*b*–6*b* et 7*c*), sont beaucoup moins importantes que celles qui mènent à la formation de trois fragments stables: deux radicaux et une molécule neutre. Ainsi les rapports $k_{[4b]}/k_{[4a]}$ et $k_{[5b]}/k_{[5a]}$ sont inférieurs ou égaux à 0.05 à 147 nm et 0.10 à 123.6 nm. De plus ce schéma réactionnel se trouve en accord avec les analyses isotopiques de l'éthylène, de l'allène et du butadiène-1,3 (tableau 3). Ces produits sont tous perprotonés, ou perdeutérés. De plus l'irradiation du pentène-1,5d_1 (CH_2=$CHCH_2$-CH_2CH_2D) produit du butadiène-1,3 en majorité perhydrogéné.

Les pentynes n'ayant pas été mesurées, il en résulte que les rendements en pentadiènes donnent une valeur par défaut du rendement des réactions 3*a* et 3*b*. L'allène a été choisi comme composé de référence, car son rendement quantique reste constant quelle que soit la pression ou bien que l'on opère avec ou sans oxygène ou hydrogène sulfuré. Les processus donnant lieu à la formation du radical méthylène ne peuvent être importants (éq. 9). En effet ceux-ci,

[9] $(C_5H_{10})^{**} \rightarrow :CH_2 + R_1 + R_2$ (ou C_4H_8)

étant donné l'énergie utilisée, sont en majorité, des méthylènes singulets (7, 8). A basse pression, ils réagissent avec le pentène-1 (9) pour donner des composés d'insertion soit dans une liaison C—C, soit dans une liaison C—H pour donner les hexènes linéaires ou substitués, soit sur la double liaison pour donner alors le propyl-cyclopropane qui peut s'isomériser à basse pression et redonner des hexènes linéaires. Des expériences d'irradiation en présence d'oxygène, à 147.0 et 123.6 nm ont été menées à faible pression et l'analyse chromatographique n'a pas permis d'observer des composés hydrocarbonés en C_6. Sachant que l'oxygène ne gêne pas la réactivité des méthylènes singulets envers le pentène (7) et supprime tous les produits d'addition radicalaire, on en conclut que la quantité de radicaux méthylènes produite

est négligeable, ou que les produits d'insertion obtenus ne sont pas assez importants pour être observés. La quantité de C_4H_8 produite est, elle aussi, négligeable: de l'ordre de 0.01–147 nm.

Réactions radicalaires

Les réactions d'atomes d'hydrogène avec les oléfines sont bien connues (10–13) et le mécanisme réactionnel en est bien établi (éqs. 10–12).

[10] $H\cdot + C_5H_{10}\text{-}1 \rightarrow (\cdot C_5H_{11})^*$
$\Delta H = -33.5$ kcal mol^{-1}(11)

[11] $H\cdot + C_5H_{10}\text{-}1 \rightarrow \cdot C_5H_9 + H_2$

[12] $H\cdot + \cdot C_5H_{11} \rightarrow H_2 + C_5H_{10}$

La réaction 12 doit être négligée vis-à-vis de la réaction 11, étant donné la faible concentration des radicaux pentyles relativement à celle du pentène. Pour la même raison, on néglige les réactions d'addition de l'atome d'hydrogène sur les oléfines produites au cours de l'irradiation (pas de processus secondaire). Cvetanović et son équipe (10, 12) ont détermine le rapport $k_{[11]}/k_{[10]}$ pour le propène et le butène-1, soit 0.045 et 0.093. En l'absence de valeur pour le pentène normal, on peut estimer que la majorité des atomes d'hydrogène produits s'additionnent sur le pentène-1. Le radical pentyle formé est soit primaire, soit secondaire (éqs. 13 et 14).

[13*a*] $(s\text{-}C_5H_{11})^* \rightarrow \dot{C}_2H_5 + C_3H_6$
(D_s) $\Delta H = 15.5$ kcal mol^{-1}

[13*b*] $(s\text{-}C_5H_{11})^* + M \rightarrow s\text{-}\dot{C}_5H_{11} + M$ (S_s)

[14*a*] $(n\text{-}C_5H_{11})^* \rightarrow \dot{C}_3H_7 + C_2H_4$ (D_n)

[14*b*] $(n\text{-}C_5H_{11})^* + M \rightarrow n\text{-}\dot{C}_5H_{11} + M$ (S_n)

Ce mécanisme réactionnel est en accord avec la variation du rendement quantique du propène, en fonction de la pression: figs. 3 et 4. La variation du rendement en éthylène indique également une certaine quantité des radicaux pentyles primaires excités. Ce schéma est aussi en accord avec les données de la littérature (11) et la composition isotopique du propène exprimée dans le tableau 3. La variation du rapport S/D (stabilisation/décomposition), en fonction de la pression pour les deux énergies considérées, confirme également ce mécanisme:

$$\frac{S_s}{D_s} = \frac{(s\text{-}C_5H_{11})^* - (C_3H_6)_{[13a]}}{(C_3H_6)_{[13a]}} = \frac{k_{[13b]}M}{k_{[13a]}}$$

Les courbes S/D en fonction de la pression sont linéaires tant que le rapport S/D est

inférieur à 3 (fig. 5). Les pressions de demi-stabilisation à 8.4 et à 10.0 eV sont différentes, montrant ainsi qu'au moins à 10.0 eV, les atomes d'hydrogène ont une énergie cinétique supérieure à l'énergie thermique ordinaire. Bien que la pression la plus basse de travail (0.033 Torr) soit encore trop haute pour déterminer les rendements en propène et éthylène à pression "nulle" (figs. 3 et 4), les rendements en radicaux pentyles excités ont pu être estimés convenablement, en particulier à l'aide de l'effet de l'hydrogène sulfuré et des réactions radical–radical. A 147 nm, les résultats sont résumés dans le tableau 4. A 123.6 nm, la décroissance du rendement en éthylène est nette (fig. 5) et les rendements sont: $(s\text{-}\cdot C_5H_{11})^* = 0.9_5 \pm 0.1_5$ et $(n\text{-}\cdot C_5H_{11})^* = 0.18 \pm 0.04$. Alors qu'à 8.4 eV, 7% des radicaux pentyles sont primaires, ils sont de l'ordre de 17% à 10.0 eV, confirmant ainsi que les atomes d'hydrogène, au moins à 10.0 eV, ne peuvent plus être considérés comme thermiques. Ces résultats sont en accord avec ceux qu'on obtient avec les butènes (1, 2). La constante de vitesse de la réaction d'addition de l'atome d'hydrogène étant au moins de deux ordres de grandeur plus rapide sur pentène-1 que sur l'oxygène, la présence de 10% d'oxygène ne gêne donc pas la formation des radicaux pentyles (14).

L'irradiation du pentène-1 a été menée avec 5, 10 et 20% d'hydrogène sulfuré à deux pressions différentes, soit 1.5 et 100 Torrs et à différents temps d'irradiation. Les résultats concordent entre eux (tableau 1) (4*a*) (éq. 15). Même en

[15] $$R\cdot + H_2S \rightarrow RH + HS\cdot$$

opérant avec un maximum de 20% d'hydrogène sulfuré on peut en négliger la photolyse. La valeur du coefficient d'extinction de l'hydrogène sulfuré n'a pas été déterminé directement aux longueurs d'ondes utilisées. Toutefois il s'avère qu'il est très inférieur à celui du pentène-1 (15, 16). Le radical HS· produit dans la réaction 15 ne gêne pas le mécanisme réactionnel global. Il faut cependant noter la disparition presque totale du butadiène-1,3 lors des irradiations en présence d'hydrogène sulfuré en accord avec une observation déjà faite (4*b*). De plus on a noté que, sur la colonne de squalane, l'hydrogène sulfuré donne un signal correspondant au temps de passage du propène et, donc, empêche la détermination certaine du rendement quantique des radicaux allyles. En l'absence de tout intercepteur radicalaire, les réactions du type radical–radical étant athermiques, on a admis que chaque radical a autant de chance de réagir avec n'importe quel autre (12). Les valeurs des constantes de réaction de recombinaison–dismutation des principaux processus radicalaires ont été trouvés dans la littérature (14, 17, 18). Les principaux produits radicalaires sont le méthane, l'éthane, le propane, le butane, et le pentane dont les rendements quantiques varient avec la pression (figs. 4 et 6). Puisque la décomposition des radicaux pentyles est sensible à la pression, les rendements des radicaux éthyles et propyles sont aussi fonction de la pression. Donc le rendement des produits de combinaison du radical éthyle avec les radicaux propyle, méthyle ou lui-même décroît quand la pression croît. Cela se passera inversement pour le radical pentyle, dont la variation a été étudiée à travers celle du pentane. Il est alors possible de calculer en retour les rendements des radicaux libres (figs. 6 et 7). Il faut cependant noter que la majorité des produits formés par voies radicalaires sont des hydrocarbones saturés, mettant en évidence la formation intermédiaire de radicaux saturés. Il est cependant très probable que des radicaux insaturés, tels les radicaux vinyles et allyles, réagissent très vite avec le monomère et qu'ils ne participent pas aux ré-

actions radical–radical et ne sont pas interceptés par l'hydrogène sulfuré. Il est enfin difficile pour le moment d'expliquer l'effet de l'hydrogène sulfuré sur le rendement en éthylène, en fonction de la pression. Les rendements des radicaux libres sont ainsi rassemblés dans le tableau 4.

Conclusion

Dans le tableau 5 sont résumées les différentes réactions de décomposition de la molécule pentène-1 excitée. Conformément à un résultat déjà connu, le processus essentiel est celui de la fragmentation en deux radicaux et une molécule neutre stable (1), abstraction faite des ions $C_5H_{10}^+$ produits à 123.6 nm. Le rendement total des réactions de fragmentation est par défaut car d'autres réactions mineures peuvent s'ajouter à celles indiquées. Par exemple, l'importance de la réaction 16 est minime dans un travail

[16] $(C_5H_{10})^{**} \rightarrow H\cdot + \cdot C_5H_9$

similaire (1). Enfin il faut noter la faible importance des réactions d'isomérisation du pentène-1 excité à ces énergies en accord avec les résultats obtenus à ces longueurs d'onde avec les butènes (1, 2, 5) et contrairement à ceux obtenus avec des énergies plus faibles comme par exemple dans la photosensibilisation par le mercure (19, 20). Il est vrai que la pression des échantillons est ici trop faible pour permettre la stabilisation de la molécule surexcitée.

Nous remercions l'Université du Québec à Chicoutimi pour le traitement qu'elle a accordé à l'un de nous (P.M.P.) et le Conseil National de Recherches du Canada qui nous a assisté financièrement. Nous remercions

Fluorinated Alkoxides. Part VII. Complexes of 2-Acetamidohexafluoro-2-propanol with First-row Transition and Lanthanide Elements

CELIA MACDONALD AND C. J. WILLIS

Department of Chemistry, University of Western Ontario, London 72, Ontario

Received July 27, 1972

2-Acetamidohexafluoro-2-propanol (HAcfp), $CH_3CONHC(CF_3)_2OH$, may act as a bidentate, uninegative, ligand to give complexes of the type $M(Acfp)_2$ ($M = Co^{2+}$, Ni^{2+}, Cu^{2+}, Zn^{2+}); $M(Acfp)_3$ ($M = Fe^{3+}$); $M(Acfp)_4$ ($M = Ce^{4+}$); or $[M(Acfp)_4]^-$ (M = lanthanide(III)). Coordination is through the two oxygen atoms, except in the case of copper, where nitrogen also enters into coordination. In the complex $Cu(Acfp)_2$, the amido proton may be removed with NaH to give $Na_2[Cu(Acfp)_2]$, which undergoes addition reactions with carbonyl groups.

Formamide similarly undergoes reaction with hexafluoroacetone to give $HCONHC(CF_3)_2OH$, which chelates to copper in the same manner as HAcfp, while succinic acid diamide reacts with hexafluoroacetone to give the compound $[—CH_2CONHC(CF_3)_2OH]_2$, which acts as a tetradentate, dinegative, ligand.

Possible structures of the above complexes are discussed.

L'acétamido-2 hexafluoropropanol-2 (HAcfp) $CH_3CONHC(CF_3)_2OH$ réagit comme ligand bidentique, mononégatif pour conduire aux complexes du type $M(Acfp)_2$ ($M = Co^{2+}$, Ni^{2+}, Cu^{2+}, Zn^{2+}), $M(Acfp)_3$ ($M = Fe^{3+}$); $M(Acfp)_4$ ($M = Ce^{4+}$); ou $[M(Acfp)_4]^-$ (M = lanthanide(III)). La coordination se fait par les deux atomes d'oxygène excepté pour le cuivre où l'azote entre aussi en coordination. Dans le complexe $Cu(Acfp)_2$, le proton de l'amide peut être arraché par NaH pour conduire à $Na_2[Cu(Acfp)_2]$, qui donne des réactions d'addition sur les groupes carbonyles.

Le formamide donne des réactions semblables avec l'hexafluoroacétone et conduit à $HCONHC(CF_3)_2OH$ qui entre en chélation avec le cuivre de la même façon que HAcfp tandis que la diamide de l'acide succinique donne avec l'hexafluoroacétone, le composé $[—CH_2CONHC(CF_3)_2OH]_2$ réagissant en tant que ligand tétradentique[1] et binégatif.

Les structures possibles des complexes ci-dessus sont discutées.

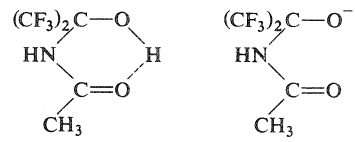
In previous investigations on fluorinated alkoxides, we have demonstrated that fluorinated tertiary alcohols are sufficiently acidic to act as donor ligands in an ionized form, *i.e.*, the hexafluoro-2-propanol group, $—C(CF_3)_2OH$, coordinates as $—C(CF_3)_2O^-$. We have thus prepared complexes of perfluoropinacol, $(CF_3)_2C(OH)C(OH)(CF_3)_2$, (PFP), with main group (1) and transition metals (2) and complexes of hydroxyhexafluoroisobutyric acid, $(CF_3)_2C(OH)COOH$ (3), both of these molecules acting as bidentate, dinegative, ligands.

Various compounds of the type $R—C(CF_3)_2OH$ may readily be made by the addition of hexafluoroacetone to suitable R—H bonds, and its reaction with acetamide is known to give 2-acetamidohexafluoro-2-propanol[1] (**1**) (4). This compound is of considerable interest as a potential ligand, as it has three possible donor sites; the hydroxyl group, the amido nitrogen atom, and the carbonyl group. We have therefore prepared a series of complexes of HAcfp with various transition metals and we have investigated the reactions of the ligand in both the free and coordinated states.

[1]Throughout this paper, the name of this compound is abbreviated to HAcfp, while its ionized forms are denoted as Acfp.

Ligands

The free ligand **1**, like most carbonyl-substituted alcohols, contains considerable intramolecular hydrogen-bonding. This would be



1 **2**

absent in the ionized form **2**, in contrast to perfluoropinacol, where the ion is stabilized by hydrogen-bonding (5), and, consistent with this, we find the pK_a of HAcfp to be 8.3, whereas that of perfluoropinacol is 5.95. However,

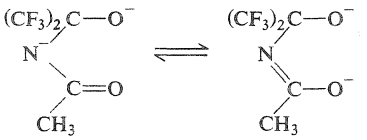
For personal use only.

HAcfp is still sufficiently acidic to give a detectable end-point on titration in aqueous solution, and in the formation of complexes it appears to react as structure **2**, that is, a bidentate, uninegative, ligand. Although this bears some structural resemblance to the familiar ligand acetylacetone (acac), the ligand lacks the delocalization of electron density present in acac.

As would be expected, the second proton in the HAcfp could not be removed by titration in aqueous medium, but reaction of the ligand with sodium hydride in tetrahydrofuran (THF) gave the stable disodium salt of the doubly ionized species **3**. In this case, delocalization of



3

the second negative charge between the nitrogen and the carbonyl oxygen atoms would lead to some increased stability, but, as before, complete delocalization around the ring of a chelated ion would not be possible. Although moisture-sensitive and intensely reactive, the disodium salt when kept *in vacuo* was more stable than the parent ligand. As described below, it proved possible to isolate complexes of the ligand in the doubly ionized form, but it was convenient to prepare these by deprotonation of complexes already formed from the singly ionized form. Hexafluoroacetone did not condense with trifluoroacetamide, nor with secondary amides, presumably because of steric hindrance (6).

With formamide, hexafluoroacetone underwent condensation readily to give 2-formamidohexafluoro-2-propanol, $HCONHC(CF_3)_2OH$. This product was similar in behavior to the acetamide adduct, but more stable with respect to decomposition into constituent amide and ketone. With amide, however, the adduct slowly decomposed at room temperature. Succinic acid diamide gave a stable 1:2 adduct with hexafluoroacetone.

Transition Metal Complexes

The reaction of HAcfp with the appropriate metal ion in methanol solution at a p*H* of approximately 8 gave a series of neutral complexes $M(Acfp)_2$ ($M = Co^{2+}$, Ni^{2+}, Cu^{2+}, Zn^{2+}) or $M(Acfp)_3$ ($M = Fe^{3+}$). Various other methods of complex preparation were attempted, without success, such as reacting the ligand with metal carbonyls or other low-valency metal compounds. With tetrakis(triphenylphosphine)-platinum(0), the ligand decomposed cleanly to give the product $[(C_6H_5)_3P]_2Pt(CF_3)_2CO$, known previously (7) from the reaction of that platinum compound with hexafluoroacetone.

Using tetramethylethylenediamine (TMED), the copper complex $[(TMED)Cu(Acfp)]^+$ was prepared, but HAcfp did not yield the extensive range of mixed ligand complexes which are readily formed with perfluoropinacol (8) and hydroxyhexafluoroisobutyric acid (3).

In assigning structures to the complexes of HAcfp, the main problem is concerned with the mode of attachment of the ligand, which, as mentioned earlier, has three possible donor sites. Based largely on i.r. spectral evidence, we suggest that the principle mode of attachment is through the two oxygen atoms of structure **2**, although the presence of both O—H and N—H frequencies, often hydrogen-bonded, makes a definite assignment difficult.

The ligand HAcfp in the solid state shows strong, broad, i.r. absorption at 3260 and 3090 cm^{-1}, associated with hydrogen-bonded O—H and N—H bonds, respectively. Unfortunately, the compound is not soluble in non-polar solvents, but in diethyl ether solution the intensity of absorptions in this region was much reduced, and positions of the peaks had moved to 3540 cm^{-1} (intramolecularly hydrogen-bonded O—H) and 3410 cm^{-1} (free N—H). Other characteristic absorption peaks were the "amide I" band (carbonyl absorption) at 1640 (solid) or 1675 cm^{-1} (solution) and the "amide II" band (N—H deformation) at 1560 (solid) or 1575 cm^{-1} (solution).

Positions of the amide I and II bands in the complexes $Fe(Acfp)_3$ and $M(Acfp)_2$ (M = Co, Ni, Cu, Zn) are shown in Table 1. The spectra are generally similar, with the amide II band at 1530–1540 cm^{-1}, somewhat lower than in the free ligand, while the amide I band varies over a slightly wider range from 1615–1680 cm^{-1}. In the region above 3000 cm^{-1}, however, there is a striking difference between the copper complex and the other four (Fig. 1). While complexes of Fe, Co, Ni, and Zn show a strong, extremely sharp absorption at 3440 cm^{-1}, the complex $Cu(Acfp)_2$ shows broad absorptions of medium intensity between 3200 and 3580 cm^{-1}. The

sharp absorption at 3440 cm^{-1} is clearly associated with a free N—H stretching frequency, confirming that the mode of attachment of the ligand in these compounds is through the two oxygen atoms. In the case of the copper complex, the shift to lower frequency and considerable broadening of the N—H absorption could be caused either by hydrogen-bonding or by coordination of the nitrogen atom to a metal atom. The former explanation is unlikely, since the amide II band (N—H deformation) is at the same frequency as in the other complexes. Furthermore, if hydrogen-bonding were present, it would presumably involve an oxygen or nitrogen atom on an adjacent ligand, and it seems unlikely that such interaction would occur in the copper complex, but not in the complexes of similar stoichiometry of other metals.

We therefore favor the explanation of coordination by the nitrogen atom, in view of the considerable body of evidence (9) that this causes a lowering of N—H stretching frequencies, although other workers (10) have questioned this theory as an over-simplification. Coordination of the nitrogen atom to copper could occur in either of two ways; by the ligand acting in a tridentate manner, or by the ligand coordinating through the alcoholic oxygen and amide nitrogen atoms, leaving the carbonyl oxygen uncoordinated. The latter possibility may be rejected in this case, since the carbonyl absorption frequency (amide I) of a free carbonyl group would be at higher frequency, whereas the amide I band in the copper complex is actually the lowest of those measured in this work. We suggest, therefore, that the Acfp ion is tridentate in the copper complex, but bidentate in the other four complexes studied. A mode of attachment in which the three donor atoms in the ligand coordinate to the same copper atom seems most unlikely, as the formation of the two required four-membered rings introduces an unreasonable degree of strain. Instead, it would seem probable that the copper atom is surrounded by four oxygen atoms in a plane from two ligands, with additional coordination perpendicular to the plane from nitrogen atoms in adjacent molecules of complex. In this way, the copper would achieve a basically square planar environment with weaker axial interactions, an arrangement frequently found for this element (11).

The mixed ligand complex, $[(TMED)Cu(Acfp)]^+$, was isolated as two salts, the sulfate and the fluorophosphate. Here again a difference in spectra in the N—H region was observed, the sulfate showing the broad absorption similar to $Cu(Acfp)_2$, while the fluorophosphate showed the very sharp band at 3440 cm^{-1} found in the complexes of other metals. Present evidence is insufficient to distinguish between hydrogen-bonding from anion to cation, or possible nitrogen coordination, as the cause of this difference.

The visible spectra and magnetic moments of the cobalt and nickel complexes suggest that the metal ion is octahedrally coordinated in both of them. Accepting that the appearance of the sharp N—H i.r. absorption precludes the possibility of coordination from the nitrogen atom in the ligand, such coordination could be achieved by polymerization through bridging oxygen atoms, a phenomenon well characterized in the trimeric $Ni(acac)_2$ (12) and the tetrameric $Co(acac)_2$ (13). Molecular weight measurements in methanol solution were of little assistance on this point, as most of the complexes were dissociated to a molecular weight of the monomer or less, but the cobalt complex did show some association as concentration was increased.

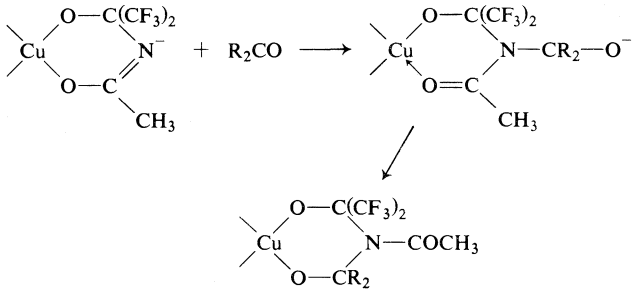

SCHEME 1

Reactions of the Coordinated Ligand

The isolation of the disodium salt of HAcfp suggested that the ligand might be capable of coordinating in a dinegative form. In practice, it was easier to form a complex of this type by deprotonation of the coordinated ligand using sodium hydride, but this reaction was only successful with the copper complex $Cu(Acfp)_2$. With complexes of other metals, reaction with sodium hydride led only to decomposition. The product, $Na_2[Cu(Acfp)_2]$ showed no O—H or N—H absorption in its i.r. spectrum, while the amide I band was at 1665 cm^{-1}. As would be expected, this complex was reactive and easily hydrolyzed, when the protonated complex $Cu(Acfp)_2$ was regenerated.

On attempted recrystallization of the salt $Na_2[Cu(Acfp)_2]$ from acetone, its properties changed markedly and it was no longer air-sensitive. Analysis showed that two molecules of acetone had been incorporated for each molecule of complex, and a similar reaction occurred with methyl ethyl ketone or ethyl acetate. The acetone was firmly held, being still present after keeping *in vacuo* at 70° for 24 h, but was lost when the adduct was dissolved in other solvents, unless they were scrupulously dry, $Cu(Acfp)_2$ being regenerated. In the formation of the acetone adduct, however, no particular precautions had to be taken to exclude moisture.

A similar adduct was formed with some difficulty from hexafluoroacetone by reacting excess of the ketone with $Na_2[Cu(Acfp)_2]$ in tetrahydrofuran (THF) in a sealed tube, then recrystallizing from solvents saturated with hexafluoroacetone.

The stability and ready formation of these adducts of carbonyl compounds makes it unlikely that they are simple 2:1 adducts in which donation is occurring from carbonyl oxygen to the copper atom. The i.r. spectrum of the acetone adduct showed no O—H or N—H bands, but the amide I band had split to give two peaks, at 1720 and 1600 cm^{-1}. Similarly, the methyl ethyl ketone adduct gave peaks at 1715 and 1600 cm^{-1}. It appears, therefore, that reaction of the ketone with the coordinated ligand has occurred, and Scheme 1 shows a possible sequence in which attack by the nucleophilic nitrogen atom on the carbonyl group is followed by a rotation of the ligand to displace the acetyl group. Such a structure for the products would account for the presence of two amide I bands in the i.r. spectrum, the higher frequency being that of the free acetyl group and the lower frequency that of the coordinated $—CR_2O$ group. With the hexafluoroacetone adduct, however, the higher frequency absorption of the free acetyl group was not seen, the strong amide I band being at 1680 cm^{-1}. The fluorinated ketone, with the basicity of the oxygen greatly reduced by the electronegative trifluoromethyl groups, would be even less likely than would acetone to coordinate as a simple donor molecule, so it must have reacted with the ligand. Although a definite decision cannot be made, we suggest that, in this case, reaction has stopped at the second stage of the above scheme, with one $—C(CF_3)_2O^-$ group coordinated to the sodium ion rather than the copper ion. The remarkable stability of fluorinated sodium alkoxides of this type has been demonstrated by the properties of the sodium derivative of perfluoro-*t*-butanol, $(CF_3)_3CONa$, which may be distilled without decomposition (14).

Lanthanide Complexes

Previous work on lanthanide complexes has shown that these elements form stable complexes with β-diketone ligands, and that bulky fluorine-substituted ligands give greatest stability, presumably through shielding the metal ion (15). In view of the resemblance of HAcfp to acac and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

similar ligands, it was thought probable that stable lanthanide–Acfp complexes could be prepared.

Reaction of a lanthanide 3^+ ion (typically, Er^{3+} or Dy^{3+}) with a considerable excess of HAcfp, neutralized with ammonium hydroxide, precipitated complexes with a 4:1 ligand–metal ratio, *e.g.* $NH_4[Er(Acfp)_4]$. The i.r. spectrum showed the strong, sharp, peak at 3440 cm^{-1} assigned to free N—H, and other bands (Table 1) typical of the coordinated ligand, and there is no reason to doubt that the lanthanide ion is eight-coordinate in these complexes. The ammonium salts could be sublimed unchanged, as can the analogous derivatives of hexafluoroacetylacetone (15).

The above complexes were, however, unstable in solution in the absence of excess ligand. When dissolved in organic solvent, or when a synthesis was attempted with a lower ligand–metal ratio, a product of different formulation was produced. Although this latter type of complex was prepared for ten different lanthanides (La, Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Yb), no definite decision on its formulation was possible. Analytical data (average of ten complexes) gave a F:C ratio of 1.10 ± 0.01, whereas HAcfp ($C_5F_6H_4NO_2$) requires a ratio of 1.20. The observed F:C ratio could be produced by a stoichiometry $C_{10}H_{11}$ (ratio 1.10) or $C_{11}F_{12}$ (ratio 1.09). The former ratio implies loss of a fluorine atom from a trifluoromethyl group, which was rejected as impossible under the mild conditions employed, so the complex appears to contain one extra carbon atom for each two molecules of ligand. Incorporation of a solvent molecule was ruled out, as the product obtained was independent of the solvent used, so the extra carbon appears to come from ligand decomposition.

The i.r. spectra of these complexes showed that the strong peak at 3440 cm^{-1} was still present, but an additional sharp absorption at 3660 cm^{-1} was also present. Partial deuteriation of the complex produced corresponding peaks at 2685 and 2520 cm^{-1} (Fig. 2), and they may be assigned to free N—H and O—H respectively. The usual amide bands were present at 1650 and 1535 cm^{-1}.

The position and sharpness of the O—H band in the i.r. spectrum suggests an hydroxide, rather than coordinated water. Taking into account the other evidence, the composition of these complexes corresponds to a formulation in which a molecule of acetamide, arising from ligand degradation, is incorporated for every two lanthanide atoms, giving the composition $M_2(Acfp)_4(OH)_2 \cdot CH_3CONH_2$. Direct evidence of the presence of acetamide is lacking, since its i.r. spectrum would be obscured by that of the Acfp ligand, so this conclusion rests mainly on analytical data and must be regarded as tentative.

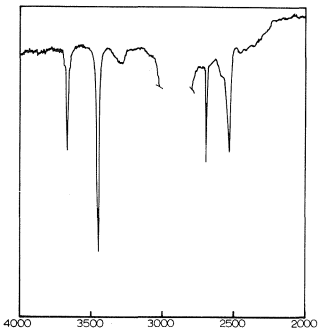

FIG. 2. I.r. spectra of partially deuteriated lanthanide complexes of Acfp.

When preparation of a complex of cerium(III) was attempted, using the same method as had been employed for the other lanthanides, the only product isolated was the neutral eight-coordinate Ce(IV) complex, $Ce(Acfp)_4$. This ready oxidation of cerium, apparently by air during the reaction, is surprising, but a similar effect has been noted in the preparation of a Ce(IV) complex of dipivaloylmethane using Ce(III) as starting material (16). The latter complex was red and relatively high-melting (276°), which the authors suggested as criteria for distinguishing Ce(IV) complexes, but our Acfp complex was pale yellow and melted at 118°.

Complexes of Other Ligands

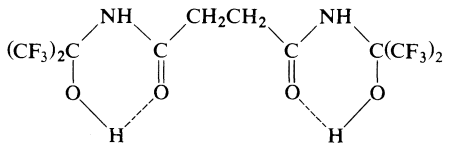
A brief investigation was made of the complexing ability of ligands formed by the condensation of hexafluoroacetone with other amides. The benzamide adduct, as described above, was of limited stability. It was hoped that it might be stabilized by incorporation into complexes, but although complex formation occurred, the products were unstable and satisfactory analytical data could not be obtained.

The formamide adduct, $HCONHC(CF_3)_2OH$, gave a stable copper complex similar to HAcfp. Its i.r. spectrum in the region above 3000 cm^{-1} showed the same broad N—H absorption as $Cu(Acfp)_2$. However, attempts to deprotonate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

it with sodium hydride led only to decomposition.

A preliminary investigation was made of the possibility of synthesizing multidentate ligands by the reaction of hexafluoroacetone with molecules containing several amide groups. Urea, the simplest diamide, was tried first, but the product was of limited stability and satisfactory characterization could not be achieved. With succinic acid diamide, however, a stable 1:2 adduct with hexafluoroacetone was prepared. The expected hydrogen-bonded structure for this product would be:



and examination of molecular models suggested that this should be capable of tetradentate coordination to a single metal ion, via the four oxygen atoms. This was confirmed by the isolation of a neutral, monomeric, complex of copper(II), very similar to the complex Cu(Acfp)$_2$. Studies on this and related multidentate ligands are continuing.

Experimental

General Techniques

Volatile materials were manipulated on a standard vacuum manifold. I.r. spectra were recorded on a Beckman model IR-10 instrument, visible spectra on a Beckman DK-1, n.m.r. spectra on a Varian HA-100 instrument at 100 or 94.1 MHz for ^{1}H and ^{19}F respectively (references: $(CH_3)_4Si$ and $CFCl_3$), and mass spectra on a Varian M-66 instrument. Magnetic moments were determined at room temperature by the Gouy method. Molecular weights were determined on a Hitachi–Coleman osmometer. Microanalyses were performed by Alfred Bernhardt Laboratories; all analytical data are in Table 2. Petroleum ether refers to 30–60° light petroleum spirit.

2-Acetamidohexafluoro-2-propanol (HAcfp)

The preparation followed the published procedure (4). Yield was virtually quantitative. The ^{19}F n.m.r. spectrum (acetone solution) showed a singlet at 82.5 p.p.m. The equivalent weight was determined by titration with standard base in 50% aqueous methanol: found, 226; calcd., 225.

Reaction of HAcfp with Sodium Hydride

Sodium hydride (1.0 g) was added to dry tetrahydrofuran (THF) (20 ml) under nitrogen, and HAcfp (4.0 g) in dry THF (30 ml) added slowly with stirring. After gas evolution had ceased (2 h), the solution was filtered and evaporated to dryness, the residue taken up in dry THF, filtered, and concentrated to precipitate the disodium salt, which was stored *in vacuo*. ^{19}F n.m.r. (THF solution) gave a singlet at 75.2 p.p.m.

Reaction of HAcfp with Cu(II), Ni(II),Co(II), and Zn(II)

Copper(II) sulfate (2.2 g) and HAcfp (4.0 g) were dissolved in methanol and methanolic potassium hydroxide added with stirring to p*H* 8. The solution was evaporated to dryness, and the residue dissolved in THF, filtered, and concentrated. Dropwise addition of petroleum ether precipitated light blue crystals of Cu(Acfp)$_2$, m.p. 180° (dec.), μ_{eff} = 1.73 B.M. The visible spectrum (acetone solution) gave a single peak at 15 600 cm^{-1} (ε 26) and two bands at 15 400 and 13 800 (sh) cm^{-1} by diffuse reflectance. The highest peak in the mass spectrum was at m/e = 444, corresponding to the parent molecule (protonated) less a trifluoromethyl group.

For nickel(II), the preparation was carried out in the same manner, using nickel nitrate. The product was noticeably less soluble in organic solvents than was the copper complex, and was recrystallized from methanol to give pale green crystals of Ni(Acfp)$_2$, m.p. 190° (dec.), μ_{eff} = 2.84 B.M. The visible spectrum (acetone solution) gave peaks at 8800 (ε 11), 14 100 (23), and 25 000 (61) cm^{-1} and peaks at 8200, 14 100, and 24 500 cm^{-1} by diffuse reflectance. The mass spectrum gave no peaks corresponding to nickel-containing fragments.

For cobalt(II), the preparation was carried out in the same manner, using cobalt(II) nitrate. The product was purified by washing with 2-propanol, followed by recrystallization from acetone – petroleum ether, m.p. 195° (dec.), μ_{eff} = 4.85 B.M. The visible spectrum (acetone solution) showed peaks at 17 000 (ε 13), 19 000 (17), and 20 400 (20) cm^{-1}, and poorly resolved peaks at 17 100, 19 000, and 23 000 cm^{-1} by diffuse reflectance. The highest peak in the mass spectrum was at m/e = 507, corresponding to the parent ion.

For zinc(II), the preparation was carried out in the same manner, using zinc sulfate. The crude product contained some oily impurity which was removed by heating *in vacuo* at 60°. The residue was then recrystallized from THF – petroleum ether. The ^{19}F n.m.r. spectrum showed a singlet at 81.6 Hz.

Molecular weight measurements on complexes in this group were attempted, but were not conclusive. The cobalt complex, Co(Acfp)$_2$, gave a value of 510 (calcd., 507) when extrapolated to zero concentration in methanol solution, but showed some association, rising to 700 at 3×10^{-2} *m*. The copper and zinc complexes both appeared to dissociate in dilute solution and gave low molecular weights. The nickel complex was not sufficiently soluble in methanol for reliable figures to be obtained, but appeared to be monomeric.

Reaction of HAcfp with Iron(III)

To a solution of ferric chloride (0.43 g) and HAcfp (2.0 g) in methanol (20 ml) was added ammonium hydroxide (6 *M* in 50% water–methanol) with stirring to p*H* 9. Diethyl ether (40 ml) was then added and the solution filtered to remove precipitated ammonium chloride. The filtrate was evaporated to dryness *in vacuo*, redissolved in diethyl ether, and filtered through anhydrous magnesium sulfate. Petroleum ether was added to the cloud point and green crystals of Fe(Acfp)$_3$ formed on

For personal use only.

standing, m.p. 130° (dec.), μ_{eff} = 5.68 B.M. The visible spectrum (methanol solution) showed one weak peak at 22 200 cm^{-1} (ε 6) before onset of a charge-transfer band. The highest peak in the mass spectrum was at m/e = 504, corresponding to the loss of one Acfp group from the parent molecule.

Reaction of HAcfp with Tetrakis(triphenylphosphine)-platinum(0)

The $[(C_6H_5)_3P]_4Pt$ (1.0 g) and HAcfp (4.0 g) were dissolved in dry THF (20 ml) under nitrogen, and the solution kept at 60° for 48 h, by which time the original yellow color had faded. After partial removal of solvent, petroleum ether was added and a white solid precipitated. This was recrystallized from benzene–pentane and identified as bis(triphenylphosphine)platinum(hexafluoroacetone), $[(C_6H_5)_3P]_2PtOC(CF_3)_2$, by analysis and by comparison of its ^{19}F n.m.r. spectrum with published data (7).

Attempted Reaction of HAcfp with Cr(III), Mn(III), and Fe(II)

The synthetic route described above for Cu(II) did not give complexes of Cr(III), Mn(III), or Fe(II). Standard methods for the preparation of acac complexes were therefore attempted, such as reaction of Cr(III) with aqueous HAcfp in the presence of urea, reaction of Fe(II) with HAcfp in acetate buffer solution, and reaction of permanganate with Mn(II) and HAcfp. No success was achieved. HAcfp also failed to give identifiable products on reaction with nickel carbonyl or chromium hexacarbonyl.

Reaction of HAcfp with Copper(II) and TMED

Copper sulfate (2.22 g) and HAcfp (2.0 g) were dissolved in methanol (60 ml) and TMED added dropwise with stirring to p*H* 8. The solution was filtered, evaporated to dryness, redissolved in methanol, filtered, and concentrated, then added dropwise to 200 ml of rapidly stirred dry acetone. The hygroscopic blue crystals precipitating were quickly filtered from the solution and dried *in vacuo* to give $[(TMED)Cu(Acfp)]_2SO_4$. The visible spectrum (methanol solution) showed a single peak at 16 000 cm^{-1} (ε 11). Reaction of a methanolic solution of the sulfate with potassium fluorophosphate precipitated potassium sulfate. Concentration of the remaining solution yielded dark purple crystals of $[(TMED)Cu(Acfp)]PF_6$, having the same visible spectrum as the sulfate.

Reaction of $Cu(Acfp)_2$ with Sodium Hydride

$Cu(Acfp)_2$ (10 g, 19.5 mmol) in dry THF (100 ml) was added slowly with stirring to a suspension of sodium hydride (1.0 g, 21.0 mmol) in THF (50 ml) under nitrogen. There was a vigorous initial evolution of gas which ceased after stirring for 2 h, by which time the blue color of the solution had faded and a dark blue precipitate formed. The solution was filtered and the solid washed with dry THF and dried immediately *in vacuo* to give the air-sensitive disodium salt, $Na_2[Cu(Acfp)_2]$. A similar reaction sequence with the nickel and zinc HAcfp complexes led only to decomposition products.

Reaction of $Na_2[Cu(Acfp)_2]$ with Carbonyl Compounds

The sodium salt was dissolved in acetone and the solution filtered and concentrated. Dropwise addition of petroleum ether caused precipitation of the acetone adduct as pale blue crystals, recrystallized from acetone, m.p. 147° (dec.). The same procedure was followed using methyl ethyl ketone or ethyl acetate in place of acetone. To prepare the hexafluoroacetone adduct, the sodium salt was suspended in dry THF in a glass reaction tube and excess hexafluoroacetone condensed in the tube. The tube was sealed and kept at 25° with shaking for 4 h, then the tube opened and the solution filtered. Addition of pentane saturated with hexafluoroacetone caused precipitation of the blue adduct, recrystallized from THF–pentane saturated with hexafluoroacetone, m.p. 114–115°.

Preparation of 2-Formamidohexafluoro-2-propanol

Formamide and hexafluoroacetone were reacted together under the same conditions as were used for the preparation of HAcfp, giving a virtually quantitative yield of 2-formamidohexafluoro-2-propanol, m.p. 120–121°, equivalent weight by titration, 215 (calcd., 211).

Reaction of 2-Formamidohexafluoro-2-propanol with Copper(II)

The procedure was the same as that followed for HAcfp, the product being recrystallized from methanol. The i.r. spectrum showed broad N—H absorptions at 3400 and 3190 cm^{-1}, while amide I and II bands were at 1640 and 1585 cm^{-1} respectively.

Reaction of Hexafluoroacetone with Succinic Acid Diamide

The diamide had only very limited solubility in suitable organic solvents, so reaction was much slower than with acetamide. In a typical preparation, succinic acid diamide (10 g) was suspended in dry THF (30 ml) in a Carius tube (100 ml) and excess hexafluoroacetone (30 g) condensed in. The tube was sealed and kept at 25° for 7 days, then opened and the solution filtered to remove unreacted diamide, then concentrated, when the adduct crystallized out. Recrystallization from THF gave *N,N'*-bis[1-hydroxyperfluoro-(1-methylethyl)] succinic acid diamide (H_2Fsda), m.p. 227° (dec.).

Reaction of H_2Fsda with Copper(II)

H_2Fsda (1.0 g) and copper(II) sulfate pentahydrate (0.56 g) were dissolved in methanol (20 ml) and methanolic potassium hydroxide added to p*H* 9. The solution was filtered and evaporated to dryness, the residue dissolved in THF, filtered, and petroleum ether added to the cloud point. The copper complex, Cu(Fsda), crystallized on standing. It had molecular weight in methanol of 516 (calcd., 524) and showed a single absorption at 15 400 cm^{-1} (ε 39) in methanol. The i.r. spectrum showed the same broad N—H absorption above 3000 cm^{-1} as was found for $Cu(Acfp)_2$, with the amide I and II bands at 1615 and 1580 cm^{-1} respectively.

Attempted Reaction of Hexafluoroacetone with Other Amides

No reaction could be detected between hexafluoroacetone and *N*-methylacetamide, trifluoroacetamide, or *N*-methyltrifluoroacetamide. Reaction of hexafluoroacetone with benzamide gave the expected adduct in 80% yield, but reversion to starting materials occurred slowly on standing and rapidly in solution when recrystallization was attempted. Satisfactory analytical data could not be obtained. Metal complexes (Cu, Co, Zn) were pre-

pared using the crude ligand, but these also decomposed on standing.

Reaction of HAcfp with Lanthanides

(*i*) As a typical example, erbium(III) chloride (1.0 g, 3.5 mmol) and HAcfp (1.8 g, 8.0 mmol) were dissolved in methanol (20 ml) and methanolic ammonium hydroxide added to p*H* 9. Diethyl ether was added to precipitate ammonium chloride, the solution filtered, evaporated to dryness, the residue taken up in ether, filtered, and benzene added to the cloud point. Subsequent slow evaporation gave pale pink needles of a complex whose analysis corresponded to the composition $Er_2(Acfp)_4(OH)_2 \cdot CH_3CONH_2$. By a similar reaction, analogous complexes were prepared for La, Pr, Nd, Sm, Eu, Tb, Dy, Ho, and Yb. Colors and magnetic moments were those usual to these lanthanides, and analytical data gave the respective F:C ratios of 1.08, 1.09, 1.09, 1.09, 1.09, 1.09, 1.12, 1.11, and 1.12 (average, 1.10). The lanthanum complex (the only one to be diamagnetic) showed two peaks in its ^{19}F n.m.r. spectrum, at 81.4 and 82.1 p.p.m.

(*ii*) The above procedure was repeated using cerium(III) nitrate. The product was the cerium(IV) complex $Ce(Acfp)_4$, pale yellow crystals, m.p. 118°. The complex was diamagnetic and the ^{19}F n.m.r. spectrum showed a singlet at 80.7 p.p.m. The proton n.m.r. spectrum showed a broad peak at 2.75 p.p.m., and the i.r. spectrum showed the sharp N—H peak at 3440 cm^{-1}.

(*iii*) A different procedure was adopted using a considerable excess of ligand. HAcfp (0.94 g, 4.2 mmol) was suspended in water (20 ml) and ammonium hydroxide added dropwise until solution was complete. The resulting solution was added slowly to aqueous erbium chloride (0.2 g, 0.7 mmol), giving a pale pink precipitate of $NH_4[Er(Acfp)_4]$, which could not be recrystallized without decomposition to give a complex of type (*i*). It had μ_{eff} = 9.80 B.M. and N—H absorptions in the i.r. spectrum at 3440 (sharp), 3380 (broad), and 3280 (broad) cm^{-1}. The similar dysprosium complex was white and had μ_{eff} = 10.6 B.M.

Interactions intramoleculaires. XIV.[1] Interactions *gauches* avec un groupement *t*-butyle (séries cyclohexanique et cyclohexénique)[2]

JEAN-PIERRE AYCARD ET HUBERT BODOT

Laboratoire de chimie organique structurale (Associé au CNRS n°109), Université de Provence, Centre de Saint-Jérôme, 13013 Marseille, France

Reçu le 8 décembre 1971[3]

Pour les 3-*t*-butyl cyclohexènes substitués en 4 (X = $COOC_2H_5$ ou C≡N) et disubstitués en 4,5 (X = $COOC_2H_5$), leurs homologues saturés et le 1,2-diméthyl 4-méthoxycarbonyl 5-*t*-butyl cyclohexène, les différences d'enthalpie libre entre stéréoisomères sont déterminées, et discutées en termes de différences d'interactions *gauches*.

Pour les composés cyclohexaniques disubstitués, les valeurs de ($I_{ae} - I_{ee}$) sont +0.2 (X = $COOC_2H_5$) et −1.7 kcal mol^{-1} (X = C≡N) pour les interactions avec un groupement *t*-butyle vicinal; dans le dernier cas, l'isomère à C≡N axial est nettement plus stable que celui à C≡N équatorial.

Pour les composés cyclohexéniques disubstitués, les valeurs ($I_{ae} - I_{ee}$) sont +2.1 (X = $COOC_2H_5$) et +0.6 kcal mol^{-1} (X = C≡N).

Pour les composés trisubstitués, les résultats s'expliquent par un renforcement des interactions I_{ee} pour les stéréoisomères ayant tous les substituants équatoriaux.

Les synthèses et les identifications des isomères sont rapportées.

For the 4-substituted (X = $COOC_2H_5$ or C≡N) and 4,5-disubstitued (X = $COOC_2H_5$) 3-*t*-butyl cyclohexenes, their saturated homologs and for 1,2-dimethyl 4-methoxycarbonyl 5-*t*-butyl cyclohexene, the free energy differences are determined and discussed in terms of *gauche* interaction differences.

For disubstitued cyclohexane compounds, ($I_{ae} - I_{ee}$) values are +0.2 (X = $COOC_2H_5$) and −1.7 kcal mol^{-1} (X = C≡N) for interactions with a vicinal *t*-butyl group; in the last case, the axial cyano isomer is clearly more stable than the equatorial cyano isomer.

For disubstitued cyclohexene compounds, ($I_{ae} - I_{ee}$) values are +2.1 (X = $COOC_2H_5$) and +0.6 kcal mol^{-1} (X = C≡N).

For trisubstitued compounds, the results can be explained by an increase of diequatorial interactions in all equatorial stereoisomers.

The synthesis and the isomer identifications are reported.

Can. J. Chem., **51**, 741 (1973)

Introduction

Dans le cadre d'une série d'études conformationnelles de composés cyclohexaniques et cyclohexéniques à contraintes stériques progressives (2, 3), nous avons évalué les interactions *gauches* (*I*) entre deux substituants éthoxycarbonyles (—$COOC_2H_5$) vicinaux (en position 4,5 en série cyclohexénique). Comme Sicher et Tichy (4, 5) l'avaient mis en évidence, nos résultats ont confirmé, en série cyclohexanique, l'inégalité des interactions I_{ae} (entre deux substituants *cis*) et I_{ee} (entre deux substituants *trans* diéquatoriaux): $I_{ae} > I_{ee}$. Par contre, nous avons montré, qu'en série cyclohexénique (positions 4,5), ces interactions sont peu différentes ($I_{ae} \simeq I_{ee}$); l'interprétation de ces résultats a montré qu'à côté du simple facteur stérique dû à l'inégalité des angles dièdres entre substituants vicinaux, il était nécessaire de tenir compte de la déformation des cycles, plus aisée quand les deux substituants sont en position *trans* diéquatoriale.

Nous abordons ici, dans chacune des deux séries (fig. 1), l'étude: (*a*) des interactions *gauches* entre le groupement *t*-butyle et les substituants cyano, méthoxycarbonyle, ou éthoxycarbonyle situés en positions 1,2 sur le cyclohexane, ou 3,4 et 4,5 sur le cyclohexène; (*b*) d'un groupe de quatre stéréoisomères impliquant simultanément une interaction *gauche* *t*-butyle-éthoxycarbonyle, et celle entre deux groupements éthoxycarbonyles.

Ce choix de structures fortement contraintes a pour but de mettre en évidence les limites des interprétations évoquées ci-dessus; ces limites

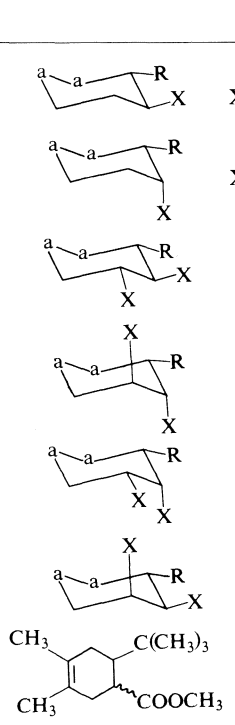

FIG. 1. Désignation des composés R = $(CH_3)_3C$; X = $COOC_2H_5$ (sauf pour **3** et **4**).

étaient prévisibles compte tenu de certains résultats récents de la littérature (6, 7).

Les synthèses, les séparations, et les identifications des différents stéréoisomères sont décrites en partie expérimentale, ainsi que leurs mises en équilibre; celles-ci conduisent aux valeurs des constantes d'équilibre et aux différences d'enthalpie libre du tableau 1.

Discussion

Pour les composés disubstitués **1**–**4**, les constantes d'équilibre varient de 10^{-2}–8. Dans chaque série, il intervient une forte diminution de la différence d'enthalpie libre en passant du groupement éthoxycarbonyle au groupement cyano (**1** → **3** et **2** → **4**); de l'ordre de 2.7 kcal mol^{-1}, ces variations sont beaucoup plus importantes que celles des enthalpies libres conformationnelles (ΔG_X^0) des groupements (environ 1 kcal mol^{-1}). D'autre part, pour les 2-*t*-butyl cyanocyclohexanes (**4**), l'isomère à cyano axial est nettement plus stable que celui à cyano équatorial ($\Delta G^0 = +1.47$ kcal mol^{-1}); ce renversement de la préférence conformationnelle est encore plus marqué qu'avec le substituant hydroxyle ($\Delta G^0 = +0.26$) (réf. 8).

Une analyse en termes d'interactions *gauches* peut être effectuée en admettant le blocage conformationnel du groupement *t*-butyle en position équatoriale ou pseudoéquatoriale (série cyclohexénique):

$$G^0_{cis} - G^0_{trans} = -\Delta G_X{}^0 + I_{ae} - I_{ee}$$

Les valeurs des enthalpies libres conformationnelles $\Delta G_X{}^0$ des groupements sont données dans le tableau 2.

Pour la série cyclohexanique, la différence des interactions *gauches* ($I_{ae} - I_{ee}$) diminue quand on passe du groupement méthyle au *t*-butyle (tableau 3), que le substituant vicinal soit un éthoxycarbonyle, un cyano, ou un hydroxyle; pour les deux derniers, qui ont un encombrement stérique faible ou modéré, l'inégalité $I_{ae} < I_{ee}$ est nettement marquée quand ils sont en interaction avec le groupement *t*-butyle. Ces résultats ne sont pas en accord avec l'interprétation élémentaire, évoquée dans l'introduction, qui ne considère que les modifications

†Solvant *t*-butanol; $((CH_3)_3CONa) = 3$ mol l^{-1}; $t = 82.0$ °C.
‡Solvant méthanol; $(CH_3ONa) = 0.8$ mol l^{-1}; $t = 65.0$ °C; pour ce couple de stéréoisomère, les fractions molaires ont été obtenues directement à partir des surfaces des pics chromatographiques sans correction (*cf.* partie expérimentale).
§Le rapport des fractions molaires des isomères **10** et **12** (non séparable en c.p.p.v.) à l'équilibre a été déterminé par r.m.n. (signaux des groupements *t*-butyles).

TABLEAU 2.

Série:	Cyclohexanique	Cyclohexénique (position 4 ou 5)
$X = COOC_2H_5$	−1.24(22)	−1.1(3, 17)
$X = C{\equiv}N$	−0.19(5)	0.0(3)

énergétiques associées à des variations d'angles dièdres. Les calculs semi-empiriques (modèle de Westheimer) réalisés sur les isomères *cis–trans* et *trans–cis* du 2,5-di-*t*-butyl cyclohexanol (9) montrent la difficulté d'une interprétation selon un modèle simple; la rotation du *t*-butyl semble jouer un rôle déterminant.

L'importance des interactions *gauches* diéquatoriales I_{ee} impliquant un groupement *t*-butyle, se manifeste également dans les deux résultats suivants: (*a*) l'isomère *trans–cis–trans* du 2-*t*-butyl 5-méthyl cyclohexane 1,4-diol est partiellement sous forme flexible (7); (*b*) la mise en équilibre des isomères *trans–cis* et *trans–trans* du 3-*t*-butyl 1,2-dibromo cyclohexane (10) est réalisée presque exclusivement au profit du dernier ($K > 99$), l'isomère *trans–cis* impliquant une interaction *gauche* $(CH_3)_3C \ldots Br$ diéquatoriale.

Pour la série cyclohexénique, lorsque les deux substituants sont en positions 4,5 (tableau 3, dernière ligne), le seul résultat dont nous disposons (composés **13**) nous conduit à une valeur de la différence $(I_{ae} - I_{ee})$ à peu près égale à celle de la série cyclohexanique, alors que pour l'interaction entre deux groupements éthoxycarbonyles vicinaux, la différence $(I_{ae} - I_{ee})$ était nettement plus importante en série cyclohexanique (2).

Pour les positions 3,4 de la série cyclohexénique (tableau 3, avant-dernière ligne), l'interaction I_{ae} est nettement plus importante que I_{ee}, même avec le groupement cyano. D'autre part, avec un groupement méthoxycarbonyle, cette interaction croit en passant du groupement méthyle au *t*-butyle.[4] Ces deux remarques s'expliquent bien sur la base de contraintes stériques importantes pour les isomères *cis*, l'angle dièdre entre les substituants étant nettement plus faible que celui de l'isomère *trans*; en effet, pour le 3,4-diméthyl cyclohexène, il a été calculé un angle dièdre de 47° (11).

Pour les composés trisubstitués **5–12**, les différences d'enthalpie libre entre stéréoisomères ont été évaluées (ΔG^0 calc. du tableau 1) en admettant l'additivité des enthalpies libres conformationnelles ΔG_X^0 et des différentes inter-

[4]Pour l'interaction avec le groupement méthyle, la différence $(I_{ae} - I_{ee})$ est estimée à environ 1 kcal mol^{-1}, d'après la différence d'enthalpie libre entre les isomères *cis* et *trans* du 3-méthyl 4-méthoxycarbonyl cyclohexène, et une analyse conformationnelle par r.m.n. des composés deutériés (travaux non publiés de R. Geuss et J. P. Aycard).

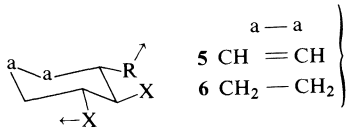
actions gauches R . . . X (tableau 3) et X . . . X,[5] ainsi que le blocage conformationnel du groupement *t*-butyle en position équatoriale ou pseudoéquatoriale. Par rapport aux valeurs expérimentales, les valeurs calculées sont toutes systématiquement surestimées d'environ 1 kcal mol^{-1} (2 kcal mol^{-1} pour le composé **12**). Ceci peut résulter d'une sous-estimation des interactions dans les stéréoisomères de référence (**5** et **6**). Ceux-ci adoptent vraisemblablement la conformation avec tous les substituants équatoriaux. Il peut être envisagé l'hypothèse d'un renforcement des interactions I_{ee} (*t*-Bu . . . $COOC_2H_5$) et I_{ee} ($COOC_2H_5$ . . . $COOC_2H_5$) résultant de l'impossibilité, pour le groupement éthoxycarbonyle central, de minimiser simultanément chacune de ces interactions par déplacement dans le plan équatorial de la molécule (effet de butoir des groupements vicinaux équatoriaux).[6]



Partie expérimentale

(i) Composés disubstitués ***1–4***

Les composés cyclohexéniques **1** et **3** ont été synthétisés par condensation diénique (13, 14) entre le 5,5-diméthyl 1,3-hexadiène (15, 16) et l'acrylate d'éthyle (14 h à 170 °C) ou l'acrylonitrile (24 h à 150 °C), respectivement. Dans le premier cas, le produit obtenu (eb_{10} = 78 °C; rendement 75%) est un mélange des 3-*t*-butyl 4-éthoxycarbonyl cyclohexène **1** *cis* (49%) et **1** *trans* (38%) et des 3-*t*-butyl 5-éthoxycarbonyl cyclohexène **14** *trans* (7%) et **14** *cis* (6%). Dans le second cas, le produit obtenu (eb_{20} = 100 °C; rendement 55%) est un mélange constitué des 3-*t*-butyl 4-cyano cyclohexène **3** *cis* (42%) et **3** *trans* (53%) et des 3-*t*-butyl 5-cyano cyclohexène **15** (5%).

Les séparations des différents stéréoisomères ont été effectuées par chromatographie de partage en phase vapeur (c.p.p.v.) (pour les temps de rétention, *cf.* tableau 4). Dans le premier cas, si le composé **14** *cis* a un temps de rétention plus grand que les autres isomères, il n'est pas possible de séparer **1** *cis* (88%) et **14** *trans* (12%) (pourcentages estimés par r.m.n.).

Chacune des fractions a été hydrogénée pour donner les composés cyclohexaniques **2** et **4** correspondants, en présence d'oxyde de platine dans l'acide acétique pour **1**, et en présence de palladium-sur-charbon (5%) dans l'alcool éthylique pour **2** (500 mg de produit sont traités dans 25 cm^3 de solvant avec 10 mg de catalyseur). Il a

[5]Pour les interactions $COOC_2H_5$ . . . $COOC_2H_5$, ($I_{ae} - I_{ee}$) = +1.0 et 0.2 kcal mol^{-1} respectivement en séries cyclohexanique et cyclohexénique (positions 4,5) (2).

[6]Le déplacement du groupement central dans le plan équatorial pourrait expliquer la diminution de ΔpK observée (12) à la fois pour les isomères *trans–trans* et *cis–trans* du 2-amino 6-*t*-butyl cyclohexanol.

été contrôlé, par c.p.p.v. et r.m.n., que l'hydrogénation est totale.

L'identification de ces différents composés a été assurée dans le cadre de l'hypothèse de conformations chaises (ou demi-chaises) et de la préférence conformationnelle du groupement *t*-butyle pour la position équatoriale (ou pseudo-équatoriale). Les arguments sont développés ci-dessous.

La mise en equilibre (par l'éthylate de sodium dans l'alcool éthylique) du composé **1** *trans* (temps de rétention: 8.0 min), conduit à un mélange de **1** *trans* (>99%) et de **1** *cis* (<1%) de temps de rétention 10.0 min; la mise en équilibre du mélange **1** *cis* (88%) + **11** *trans* (12%) conduit à un nouveau mélange: **1** *trans* (87%); **1** *cis* + **11** *trans* (4%); **11** *cis* (9%). Ces résultats montrent que le composé **1** *cis* correspond bien au second pic chromatographique (il se transforme essentiellement en son isomère **1** *trans*); d'autre part, la différence d'enthalpie libre associée à l'équilibre **1** *trans* ⇄ **1** *cis* ($\Delta G^0 = 3.2$ kcal mol^{-1}) (tableau 3) est très nettement différente de celle que l'on peut prévoir pour l'équilibre **11** *cis* ⇄ **11** *trans* ($\Delta G^0 \simeq 1.1$ kcal mol^{-1}) d'après l'enthalpie libre conformationnelle du groupement éthoxycarbonyle (3, 17, 18) situé en position 4 (ou 5) sur le cyclohexène[7]; dans ce cas, le groupement *t*-butyle, relativement éloigné, ne doit pas modifier sensiblement cette valeur. Enfin, l'épimérisation du 4-carboxyl 3-*t*-butyl cyclohexène (14) conduit à une proportion similaire des isomères *cis* et *trans* (5% et 95% respectivement).

La mise en équilibre (par le *t*-butylate de potassium dans l'alcool *t*-butylique) de **3** *cis* ou de **3** *trans* conduit à un mélange 28.9/71.1 de ces deux isomères.

En c.p.p.v., pour la série cyclohexanique, il a été remarqué (2, 19) que les composés à groupements éthoxycarbonyles équatoriaux ont des temps de rétention supérieurs à ceux de leurs isomères axiaux; cette inégalité est respectée pour les composés **2** *cis* et **2** *trans*. Par contre, en série cyclohexénique, les temps de rétention sont inversés (*cf.* tableau 4, composés **1** *cis* et **1** *trans*); cette observation est en accord avec les résultats d'Inukai et Kojima (20) concernant les 3-méthyl 4-méthoxycarbonyl cyclohexènes *cis* et *trans*, et avec nos propres résultats (*cf.* paragraphe (*ii*) concernant les isomères **5** et **7**. Les composés à groupement cyano ont des comportements analogues.

En r.m.n., les signaux d'un proton situé en α du groupement éthoxycarbonyle ou du groupement cyano se distinguent nettement, vers les champs faibles ($\delta \simeq 3.0 \times 10^{-6}$), quand ce groupement est axial; par contre, lorsqu'il est situé en position équatoriale, les signaux r.m.n. du proton axial correspondant sont situés dans le massif des autres protons du cycle (2, 19); pour chacun des isomères *cis* des composés **1**–**4**, il apparaît (tableau 4) un massif distinct entre 2.6 et 3.0×10^{-6} (et dont

[7]Le même argument a été utilisé pour identifier les composés **11** *cis* et **11** *trans*; toutefois, la précision expérimentale sur les pourcentages de ces isomères à l'équilibre n'est pas suffisante pour envisager une détermination quantitative de la différence d'enthalpie libre.

l'intégration correspond à un proton) confirmant la position axiale du substituant éthoxycarbonyle ou cyano.

Ainsi, les différentes remarques ci-dessus sont toutes en accord avec les identifications du tableau 4.

(ii) Composés trisubstitués à groupements éthoxycarbonyles trans ***5***, ***7***, ***6***, ***8***

La condensation diénique (18 h à 200 °C) entre le 5,5-diméthyl 1,3-hexadiène et le fumarate d'éthyle conduit à un mélange ($eb_{1.5}$ = 114–117 °C; rendement 70%) des 3-*t*-butyl 4,5-diéthoxycarbonylcyclohexène *trans–cis*[8] **5** (39%) et *cis–trans* **7** (61%); après séparation par c.p.p.v. préparative, chacun de ces isomères a été hydrogéné pour accéder aux composés cyclohexaniques correspondants (**6** et **8** respectivement).

L'identification des isomères a été réalisée grâce aux observations suivantes.

En r.m.n. (tableau 4), le composé **8** présente deux massifs centrés à 2.6×10^{-6} (intégration: 1 H) et à 3.3×10^{-6} (1 H) correspondant manifestement (*cf.* remarque ci-dessus) à deux protons équatoriaux en α des substituants éthoxycarbonyles diaxiaux; par contre, pour le composé **6**, les massifs correspondants ne se distinguent pas des signaux des protons du cycle.

En c.p.p.v. (tableau 4), le temps de rétention du composé **8** est inférieur à celui de son isomère **6**, en bon accord avec la remarque du paragraphe (*i*) ci-dessus.

Puisque les composés **6** et **8** résultent respectivement de l'hydrogénation des isomères **5** et **7**, l'identification de ces derniers est également assurée. Nous constatons d'autre part que: pour le composé **7**, les protons en α des groupements éthoxycarbonyles donnent lieu à une résonance à champ faible (massif entre 2.8 et 3.0×10^{-6}) confirmant la position diaxiale de ces deux groupements; et le temps de rétention de ce composé (27.2 mn) est supérieur à celui de l'isomère **5** à groupements éthoxycarbonyles diéquatoriaux (24.7 mn), soit un ordre inverse par rapport à celui de la série cyclohexanique.

(iii) Composés trisubstitués à groupements ethoxycarbonyles cis ***9***, ***11***, ***10***, ***12***

La condensation diénique (18 h à 200 °C) entre le 5,5-diméthyl 1,3-hexadiène et le maléate d'éthyle conduit à un mélange ($eb_{1.5}$ = 114–118 °C; rendement 60%) des 3-*t*-butyl 4,5-diéthoxycarbonylcyclohexène *cis–cis* **9** (46%) et *trans–trans* **11** (54%); après séparation par c.p.p.v. préparative, chacun de ces isomères a été hydrogéné pour accéder aux composés cyclohexaniques correspondants (**10** et **12** respectivement).

Pour chacun de ces quatre composés, le spectre r.m.n. fait apparaître un massif (intégration: 1H) pour des déplacements chimiques compris entre 2.7 et 3.2×10^{-6}; ce résultat confirme la présence d'un substituant éthoxycarbonyle axial pour chacun. D'autre part, en série cyclohexénique, pour le signal des protons du groupement *t*-butyle, le déplacement chimique est plus grand pour le composé dont le groupement éthoxycarbonyle vicinal est axial (*cf.* tableau 4; comparer les valeurs pour les couples **1** *cis*/**1** *trans* et **7**/**5**). Si l'on admet qu'il en est de même pour le couple des composés **9**/**11**, le composé ayant le plus faible temps de rétention (tableau 4) est identifié avec le composé **11**.

La mise en équilibre effectuée à partir de l'un de ces composés cyclohexéniques **5**, **7**, **9** ou **11** conduit à un mélange identique de ces composés dans les proportions suivantes: 55.7, 0.8, 1, et 42.6% respectivement. Le très faible pourcentage du composé **7** à l'équilibre est en accord avec la très forte interaction *gauche* (mise en évidence par l'équilibre **1** *trans* ⇄ **1** *cis*) entre le groupement *t*-butyle et un groupement éthoxycarbonyle vicinal situé en position axiale. Cet accord constitue une indication relativement nette en faveur de l'identification effectuée pour les isomères **9** et **11**; elle assure celle des composés **10** et **12**.

(iv) 1,2-Diméthyl 4-méthoxycarbonyl 5-t-butylcyclohexènes ***13***

Compte-tenu de l'impossibilité de condenser le 1,3-butadiène avec l'ester méthylique du 4,4-diméthyl 2-pentenoïque *trans*,[9] nous avons réalisé la synthèse diénique entre ce dernier et le 2,3-diméthyl 1,3-butadiène (48 h à 170 °C). Elle conduit, avec un rendement de 30% après séparation en c.p.p.v., à l'isomère **13** *trans*.

L'absence de signaux r.m.n. entre 2.5 et 3.2×10^{-6} est en accord avec la position équatoriale du groupement méthoxycarbonyle. La mise en équilibre, par le méthylate de sodium dans l'alcool méthylique, du composé **13** *trans* conduit à un mélange constitué de ce dernier et de son isomère **13** *cis* (10.6%). Celui-ci n'a pas été isolé, mais le spectre r.m.n. du mélange présente un signal de faible intensité à 2.9×10^{-6} correspondant au proton équatorial en α du groupement méthoxycarbonyle de **13** *cis*.

Il est à noter que le temps de rétention de l'isomère *cis* est inférieur à celui de l'isomère *trans* (tableau 4) comme pour les 1,2-diméthyl 4,5-diéthoxycarbonyl cyclohexènes (2), mais contrairement à ce que nous avons observé pour le couple **1** *cis*/**1** *trans* et pour les 4,5-diéthoxycarbonyl cyclohexènes (2).

(v) Mises en equilibre

Elles ont été réalisées dans les conditions décrites dans des publications antérieures (2, 5). Lorsque deux isomères ont des temps de rétention identiques (**1** *cis* et **14** *trans*; **10** et **12**), il a été considéré que le facteur correctif des aires des pics chromatographiques était le même pour ces deux isomères; leur proportion a été déterminée par r.m.n.

La mise en équilibre des isomères **13** a été effectuée dans le méthanol anhydre sous l'action du méthylate de sodium. Comme l'isomère *cis* n'a pas été isolé à l'état pur, un facteur correctif de 1.0 a été arbitrairement choisi.

---

[8]Ces deux suffixes se rapportent aux substituants éthoxycarbonyles (respectivement en positions 4 et 5) par rapport au groupement *t*-butyle.

[9]Ce diénophile a été préparé par la méthode de Brändström (21); sa structure *trans* a été confirmée par r.m.n. (δ × 10^6; s, singulet; d, doublet)

$$(CH_3)_3C\text{—}CH{=}CH\text{—}COOR$$
a b c e

R = H (solvant $CDCl_3$); a, 1.09 (s); b, 5.7 (d); c, 7.5 (d) (J = 16.5 Hz); e, 10.9 (s).

R = CH_3 (solvant (CCl_4); a, 1.09 (s); b, 5.8 (d); c, 6.8 (d) (J = 16.0 Hz); e, 3.6 (s).

Une partie de ces résultats a été exposée au cours de plusieurs conférences au Canada en juillet 1971; au cours des discussions qui ont suivi, des critiques et des suggestions ont été faites par de nombreux collègues Canadiens; nous les remercions pour leur contribution et pour leur accueil très chaleureux. Nous remercions également les deux rapporteurs pour leurs critiques constructives.

Capsidiol, an antifungal compound produced by the fruit of sweet peppers in response to inoculation with fungi, may have importance in the natural resistance of the plant to fungal disease (1). It can be assigned structure **1** on the basis of the chemical and spectral data reported here.

Capsidiol is optically active and has the molecular constitution $C_{15}H_{24}O_2$ as established by elemental analysis and high resolution mass spectrometry. The i.r. spectrum indicates the absence of carbonyl and the presence of hydroxyl functions. The latter are identifiable as two secondary alcohols by acetylation of **1** to an oily diacetate **2** which exhibits characteristic downfield shifts, relative to their resonance position in the proton spectrum of capsidiol, of two one-proton multiplets (Table 1). An isopropenyl group in capsidiol is responsible for a three-proton signal at δ 1.74 (vinylic methyl), two one-proton multiplets at δ 4.70 and 4.73, and i.r. absorption (in $CHCl_3$) at 888 cm^{-1} (1,1-disubstituted double bond). On hydrogenation of **1** to dihydrocapsidiol **3**, these bands vanish while two doublets appear at δ 0.88 and 0.90. The proton spectrum of **1** reveals, in addition, the presence of one other secondary and one tertiary methyl group as well as of a trisubstituted double bond (one-proton multiplet at δ 5.91); since capsidiol is transparent to light above 215 nm, this bond is not conjugated with the isopropenyl group.

The sum of these data accounts for all the functional groups of capsidiol and requires it to be bicyclic. Further information is available from a closer examination of the hydroxyl functions. Splitting patterns in the proton spectrum of **1** show that one of the alcoholic methine protons is vicinal to three other protons, while the second is flanked by only two protons. Their partly superimposed resonance signals appear as an eight-line pattern at δ 4.59 and as a triplet at δ 4.35, respectively. A decoupling experiment at 220 MHz demonstrated that the two protons are not vicinal to each other but suggested instead that both are coupled to the same methylene group; that is, that they are in a 1,3-relationship. This inference was confirmed and extended by chemical means.

Oxidation of capsidiol with dilute Jones' reagent furnished a mixture of capsenone (**4**) and the unconjugated ketone **5**. Both compounds were isolated in small amounts as oils.

Capsenone (**4**) became more readily available when it was discovered that the compound, identified by i.r., u.v., n.m.r., and mass spectra, was produced in pepper fruit after inoculation with certain fungi or on supplying capsidiol to cultures of these fungi in a synthetic medium (2). It is a conjugated ketone, ν_{max} 1692 cm^{-1}, whose u.v. absorption (λ_{max} 238 nm, ε 6300) recalls that of 3β-hydroxy-4-cholesten-6-one (λ_{max} 239 nm, ε 6300) (3*a*). The proton spectrum is in accord with the formulation of **4** as a six- or higher-membered cyclic ketone conjugated with an exocyclic double bond. The absorption of the lone olefinic proton (H-5) is shifted downfield from δ 5.91 in **1** to 6.71 in **4** with its splitting

pattern unchanged, indicating a β-*cis*-relation to the carbonyl at C-4; the intervening carbon atom must be a ring junction. Capsenone is stable to dilute base but on treatment with alkoxide in deuteriomethanol, two deuterium atoms are substituted for the two hydrogens on C-3. This collapses the eight-line pattern arising from H-2 into a doublet and confirms the 1,3-disposition of the two oxygen functions. On treatment of **4** with acid under mild conditions, the hydroxyl attached to C-2 is eliminated, with the formation of isocapsidienone which may be formulated as the cross-conjugated ketone **6**.

Compound **5** absorbs at 1718 cm^{-1} (unstrained nonconjugated ketone). Unlike capsenone, **5** is extremely labile to very dilute base which converts it instantaneously into capsidienone **7**. This compound exhibits carbonyl absorption at 1678 cm^{-1} but no hydroxyl absorption while its maximum at 290 nm (ε 12 200) corresponds to that reported for 3,5-cholestadien-2-one (λ_{max} 290 nm, ε 12 600) (3*b*).

Capsidienone is more conveniently accessible by manganese dioxide oxidation of capsidiol, in a slow reaction proceeding via **5** as an intermediate. Capsenone (**4**), the expected product of allylic oxidation, is generated in this reaction in only barely detectable traces. This evidently reflects severe steric hindrance of the C-4 hydroxyl group. The same inference may be drawn from the reaction of capsidiol with an excess of methanesulfonyl chloride, to form the 2-monomesylate **8** as the only major product. The mesylate was characterized unambiguously by its proton spectrum, having methanesulfonyl

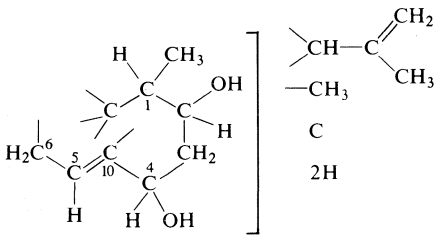
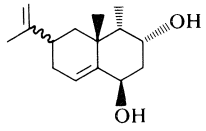
absorption at δ 3.01 and the eight-line pattern for H-2 at δ 5.49, well separated from the H-4 doublet of doublets at δ 4.39. The instability and pronounced tendency of **8** to yield intractable products precluded its use in further studies.

To account for the splitting pattern of H-2 in capsidiol and its derivatives, only one proton can be located at C-1. A ring junction at C-1 must be excluded because the ring cannot be smaller than six-membered and one junction has already been identified at C-10. Of the two remaining candidates for C-1 substitution, the isopropenyl group must also be excluded. Its presence at C-1 in compounds **5**, **6**, and **7** would provide extra deshielding of H-1, which would then be expected to absorb in the unobscured region of the proton spectra below δ 2.3. No such absorption can be observed. The substituent at C-1 is therefore the secondary methyl group, whose resonance does in fact undergo downfield shifts on oxidation of the hydroxyl functions. Further, irradiation of the secondary methyl in **7** simplifies part of the spectrum between δ 1.95 and 2.40 with the appearance of a singlet at 2.15. The singlet must represent the decoupled absorption of H-1 which cannot, therefore, be vicinal to protons other than those of the methyl group. This result implies that C-1 is situated between the carbonyl group and a fully substituted carbon atom.

The olefinic proton H-5 in capsidiol and its derivatives is characterized by splitting patterns which require it to be adjacent to an unsubstituted methylene group, thus excluding C-6 as a possible site for the isopropenyl group. A decoupling experiment showed that the latter is equatorially bonded to a carbon bearing at least one hydrogen atom. Irradiation at δ 2.22 (H-7) removed the 12.2 Hz coupling observed for the signal centered about δ 1.43 while the 14.4 Hz coupling, assigned to the geminal interaction, remained. These data lead to the following part structure for capsidiol.



The only biogenetically-plausible, bicyclic structure in which these fragments can be combined is that presented by **1**. The observed coupling constants and shielding effects indicate its stereochemistry to be as in **9** *if the B ring is a chair*. Deshielding effects on the angular methyl group and the coupling constants of H-4 indicate that the C-4 hydroxyl and angular



9

methyl groups are *syn*-diaxial. Since $J_{2,3a}$ is 12.0 Hz, H-2 is axial and since $J_{1,2} = 4.8$ Hz, it follows that H-1 is equatorial and consequently, the secondary methyl is axial. In the closely related eremophilanes, the corresponding methyl groups are *cis* (4). If this were the case for capsidiol, the B ring must exist in a boat conformation and from the presently available ^{1}H n.m.r. results, this possibility cannot be unequivocally excluded, although examination of models suggests that the boat conformation would not be as rigid as the 12.0 Hz coupling implies. Since preliminary ^{13}C n.m.r. data also appear to support the unexpected *trans*-diaxial disposition of the methyl groups, a detailed ^{13}C study is underway.

Experimental

Solvents were redistilled. Ethanol refers to 96% ethanol, light petroleum to the fraction boiling at 37–67°. T.l.c. was done on silica gel (Camag DF5) or alumina (Camag DSF5) in tanks saturated with solvent vapor, column chromatography on BDH silica gel (60–120 mesh). Melting points were determined on the Kofler block; i.r. spectra with a Unicam SP 1000 spectrophotometer; u.v. spectra on ethanolic solutions with a Beckman DK instrument. N.m.r. spectra were determined on deuteriochloroform solutions with tetramethylsilane as internal reference. The data given in Tables 1 and 2 were obtained with a Varian HA-100 spectrometer after the samples had been shaken with a drop of D_2O. Coupling constants (±0.05 Hz) were averaged from several scans at 100 or, more frequently, 50 Hz sweep-widths calibrated every 5 Hz. Decoupling experiments were carried out using stacked General Radio 1310 and 1310A oscillators and chemical shifts determined in this way were the measured difference frequencies when the appropriate maximum decoupling was achieved. Most of the chemical shifts, ±0.01 p.p.m., were determined from calibrated 250 or 100 Hz wide spectra. A 220 MHz spectrum and decoupling experiments on a degassed sample of **1** were

provided by the Canadian 220 MHz NMR Centre, Sheridan Park, Ontario. Other spectra were obtained with a Varian A60A instrument and their assignments were not confirmed by decoupling experiments. Molecular weights were obtained by Dr. D. B. MacLean and T. Martin by mass spectrometry. Specific rotations were determined on a Schmidt–Haensch polarimeter.

Capsidiol (1)

The isolation of capsidiol (**1**) from aqueous diffusates from fungus-inoculated fruit of *Capsicum frutescens* L. has been described (1). When other components of the crude ether extract are not required for study, it is advantageous to replace chromatography over silica gel (1) by chromatography over alumina (Woelm 200 neutral, grade III) with chloroform as eluant. Only the latter system was effective in the isolation of capsidiol from the more complex ether extracts obtained from tissue homogenates of inoculated fruit.

Pure capsidiol, m.p. 152–153°, is obtained by recrystallization from ether or ether – light petroleum. A form melting at 167–169° was obtained occasionally but reverted to the form, m.p. 152–153°, on recrystallization. Capsidiol is very soluble in methanol and ethanol, more sparingly in ether and chloroform, and almost insoluble in water. It has $[\alpha]_D^{22°}$ +21° (*c*, 2.1 in chloroform) and ν_{max} (KBr) 3430, 1651, 1472, 1455, 1382, 1217, 1060, 1022, 900, and 720 cm^{-1}.

Anal. Calcd. for $C_{15}H_{24}O_2$ (mol. wt. 236): C, 76.22; H, 10.24. Found (236): C, 76.07; H, 10.19.

Capsidiol diacetate (2)

Capsidiol (7 mg) was treated with acetic anhydride (0.3 ml) in pyridine (0.5 ml) at room temperature overnight. Evaporation gave the diacetate **2** as a syrup, homogeneous by t.l.c. and proton spectrum, and further characterized by ν_{max} (CCl_4) 1737, 1643, 1468, 1442, 1372, 1242, 1219, 1027, 1013, and 889 cm^{-1}.

Dihydrocapsidiol (3)

Capsidiol (125 mg) in isopropanol was hydrogenated by the standard procedure (5) in the Brown hydrogenator except that acetic acid was used instead of hydrochloric acid. Absorption of hydrogen ceased with 0.85 mol equiv. The product was filtered, the filter-cake washed with hot ethanol, and the combined filtrates evaporated to dryness. The residue was extracted with benzene, the extracts were re-evaporated, and the product refiltered in ether after addition of Celite. After concentration to *ca.* 1 ml and addition of light petroleum, dihydrocapsidiol (60 mg) crystallized out and was recrystallized from ether as needles, m.p. 153–155°, depressed on admixture with capsidiol, $[\alpha]_D^{23°}$ −3° (*c*, 1.00 in chloroform); ν_{max} (KBr) 3440, 1472, 1390, 1230, 1052, 1031, and 720 cm^{-1}.

Anal. Calcd. for $C_{15}H_{26}O_2$ (mol. wt. 238): C, 75.58; H, 11.00. Found (238): C, 75.55; H, 11.07.

Oxidation of Capsidiol

(*i*) Capsidiol (70.2 mg, 0.3 mmol) in acetone (18 ml) was chilled to ice-temperature, removed from the cooling bath, and treated dropwise and with vigorous shaking with 0.6 *N* chromic oxide in 0.6 *N* sulfuric acid (1.0 ml) during 15 min. After being shaken at room temperature for another 60 min, the product was diluted with water (20 ml) and extracted with ether (3 × 40 ml). The syrup obtained on evaporation of the washed and dried extracts was chromatographed over a column of silica gel (8 g; 105 fractions, 20 ml each; increasing concentrations of ether in light petroleum to ether). Suitably combined fractions were rechromatographed over silicic acid (Mallinckrodt) – Celite (4:1) with ether (15%) in light petroleum or by preparative t.l.c. (silica; 5% methanol in chloroform; also used to monitor the fractionation), and again over silica gel (25–30% ether in light petroleum).

The compounds isolated in essentially pure form were: (*a*) Unreacted capsidiol (16.5 mg). (*b*) Capsenone (**4**) (9.5 mg), viscous oil, ν_{max} ($CHCl_3$) 3780, 3460, 3030 (sh),

For personal use only.

2980, 2960, 1692, 1685 (sh), 1633, 1468, 1380, and 896 cm^{-1}.

Mol. Wt. Calcd. for $C_{15}H_{22}O_2$: 234. Found: 234.

(*c*) The ketone **5**, (4.4 mg), viscous oil, ν_{max} ($CHCl_3$) 3790, 3470, 3040 (sh), 2990, 2960, 1718, 1650, 1468, 1382, 990, and 900 cm^{-1}.

Mol. Wt. Calcd. for $C_{15}H_{22}O_2$: 234. Found: 234.

The u.v. spectrum showed end-absorption and a band (ε 300) near 286 nm, possibly attributable to an impurity. Addition of 0.10 *N* sodium hydroxide solution (0.10 ml) to the alcoholic solution (3.0 ml) containing **5** (6×10^{-3} mg) and immediate redetermination of the spectrum (< 30 s) gave an intense maximum at 290 nm (ε 11 400) stable during at least 0.5 h and to subsequent acidification.

(*ii*) The ether-soluble product from a similar oxidation of capsidiol (93.6 mg) was dissolved in ethanol (100 ml) and 1.0 *N* sodium hydroxide solution (1.0 ml) was added. After 2 min, the solution was acidified (10.0 ml 1.0 *N* hydrochloric acid), diluted with water, and extracted with ether. After washing, drying, and evaporating, the extract was chromatographed over silica gel (20 g). Fractions 11–28 (10–15% ether in light petroleum, 2.5 ml per fraction) furnished chromatographically homogeneous capsidienone (**7**) (15.4 mg) as a colorless oil, ν_{max} (liquid) 3100, 2990, 2950, 2890, 1678, 1635, 1589, 1465, 1455, 1398, 1373, 1250, 1209, 1060, 1009, 894, 875, and 842 cm^{-1}.

Mol. Wt. Calcd. for $C_{15}H_{20}O$: 216. Found: 216.

Fractions 44–49 (30% ether) gave capsenone (7.9 mg). More capsenone (6.8 mg) and capsidiol (14.3 mg) were obtained by preparative t.l.c. of fractions eluted subsequently (50%, 100% ether).

(*iii*) Capsidiol (104 mg) in benzene (10 ml) was stirred with active manganese dioxide (1 g) (6) at room temperature. T.l.c. indicated that slow conversion of **1** into **7** occurred with **5** as an intermediate accumulating only in traces. More oxidant was added after 6 and 10 days (0.60, 0.84 g respectively). After another day, the mixture was diluted with benzene, filtered, and the filter cake washed with ether. The residue (56 mg) from the combined filtrates was chromatographed over silica gel (5 g) in ether – light petroleum (1:4) to furnish pure **7** (n.m.r., u.v., i.r., t.l.c.; 49 mg).

Dideuteriocapsenone

To capsenone (16.6 mg) dissolved in methanol-d_4 (0.4 ml) was added potassium *tert*-butoxide (11.2 mg) in methanol-d_4 (0.6 ml). After 5 min, the yellow color of the solution was discharged by the dropwise addition of acetic acid-d_4 and deuterium oxide was added. The product was extracted with carbon tetrachloride, the extracts were washed with a little deuterium oxide, dried (sodium sulfate) and evaporated. Mass spectrometry was done on a sample further purified by t.l.c. (silica; *sec*-butanol – ethyl acetate – acetic acid 5:95:0.1) with substitution of hydrogen for the hydroxylic deuterium.

Mol. Wt. Calcd. for $C_{15}D_2H_{20}O_2$: 236. Found: 236.

Isocapsidienone (6)

To capsenone (15 mg) in ethanol (3 ml) was added concentrated hydrochloric acid (0.05 ml). Reaction was complete after about 8 h at room temperature. The solution was neutralized by addition of calcium carbonate and evaporated. The residue was extracted with chloroform, the extract washed with water, and freed from minor impurities by preparative t.l.c. on silica (methanol–chloroform 5:95). The resultant oil had ν_{max} (liquid) 3095, 3045, 2980, 2945, 2890, 1678, 1632, 1468, 1388, 1262, 892, and 808 cm^{-1} and λ_{max} 238 nm (ε 7800), λ_{sh} 267 nm (ε 4300).

Mol. Wt. Calcd. for $C_{15}H_{20}O$: 216. Found: 216.

Mesylation of Capsidiol

Capsidiol (121 mg) in pyridine (2.4 ml) at −5° was treated with freshly distilled methanesulfonyl chloride (0.10 ml; *ca.* 2.5 equiv). After 18 h at room temperature, the product was poured on ice (10 ml), acidified with concentrated hydrochloric acid (3.3 ml added dropwise), and extracted with chloroform. The oil obtained by evaporation of the washed and dried extract was chromatographed over silica gel (16.5 g). Fractions 45–50 (20 ml each; ether – light petroleum 1:1) and 51–60 (ether) contained material (94 mg) consisting predominantly of capsidiol-2-monomesylate (only traces of impurities detectable in the proton spectrum). On attempted remesylation at room temperature during 48 h, the material decomposed to an intractable product.

We are grateful to Prof. D. B. MacLean and Mr. T. Martin for providing us with mass spectrometric data and to the National Research Council of Canada for financial support of this study.

Some Electron Spin Resonance Observations in the Photoreduction of Nitrobenzenes

S. K. WONG AND J. K. S. WAN

Department of Chemistry, Queen's University, Kingston, Ontario

Received October 10, 1972

The photoreduction of some nitrobenzenes in various organic solvents was re-investigated by e.s.r. and the rapid scan e.s.r. method. The present study resolved the contradicting e.s.r. assignments of the radical observed in the photoreduction of nitrobenzene in tetrahydrofuran and confirmed the identification of the radical PhN(Ȯ)OR. All other radicals observed in various solvents were identified and their formation can be explained by secondary processes in the photoreduction.

La photoréduction de certains nitrobenzènes a été étudiée de nouveau dans plusieurs solvants organiques par r.s.e. (résonance de spin électronique) et par r.s.e. en balayage rapide. L'étude présente permet d'élucider les attributions contradictoires en r.s.e. du radical observé lors de la photoréduction du nitrobenzène dans le tétrahydrofuranne et confirme l'identification du radical PhN(Ȯ)OR. Tous les autres radicaux observés dans différents solvants ont été identifiés et leur formation peut s'expliquer par des processus secondaires dans la photoréduction. [Traduit par le journal]

Can. J. Chem., **51**, 753 (1973)

Introduction

Electron spin resonance spectroscopy has been widely used to identify paramagnetic intermediates in photochemical reactions; conversely photochemical reactions have provided convenient methods of generating radicals for e.s.r. study of their structures (1). The application of e.s.r. technique to investigate the photoreduction of nitro-compounds is one of the more controversial examples. In 1962 Lagercrantz and Yhland (2) first observed the e.s.r. spectra of a photoparamagnetic species in a tetrahydrofuran (THF) solution of *s*-trinitrobenzene. The authors (2) proposed the assignment of an *s*-trinitrobenzene radical anion, produced by a charge-transfer mechanism. Briegleb and Lind (3) later confirmed the charge-transfer process but the assignment of the e.s.r. spectra to the trinitrobenzene radical anion was challenged by Ward (4). Using deuterium-labelled THF as solvent in the photolysis of nitrobenzene, Ward (4) has observed a further hyperfine splitting due to a hydrogen atom from the solvent. Thus, he reassigned the spectra of the photoparamagnetic intermediate to the radical PhN(Ȯ)OH and suggested that the excited nitrobenzene abstracted a hydrogen atom from the solvent as the initial step in the photoreduction of aromatic nitro-compounds. This interpretation has gained general acceptance in the past (5–8). However, Cowley and Sutcliffe (9) have recently reported some good evidence that the photointermediate in the photolysis of nitrobenzene has the structure PhN(Ȯ)OR, in which R is the solvent radical.

Most of the e.s.r. studies of the photoreduction of aromatic nitro-compounds were carried out in ether or alcohol solvents, but many other studies involving product analysis of the photoreduction have been done using amines and hydrocarbons as solvents. We wish to report here a re-investigation of the photolysis of aromatic nitro-compounds in a variety of solvents by e.s.r. spectroscopy with the hope that some, if not all, of the previous contradicting assignments on the radical intermediates can be resolved.

Experimental

Nitrobenzene was purified by distillation, and *m*-dinitrobenzene and *s*-trinitrobenzene were recrystallized from ether. All solvents used were the highest grade available commercially.

Solutions of the nitro-compounds contained in 5 mm o.d. Pyrex tubings were degassed to 10^{-4} Torr before they were photolyzed at room temperature in the cavity of a Varian V4502 e.s.r. spectrometer with 100 kHz modulation. The light source was an unfiltered 200 W super pressure mercury lamp.

E.s.r. spectra simulation was performed on an IBM 360-50 computer using a modified programme made available by Bell Telephone Laboratory. The technique and the experimental assembly of the rapid scan e.s.r. method, using a Fabri-tek 1074 instrument computer, have been described elsewhere (10).

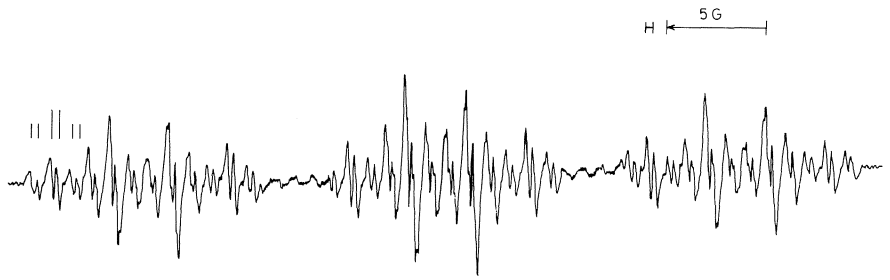

FIG. 1. E.s.r. spectrum observed during the photolysis of nitrobenzene in THF.

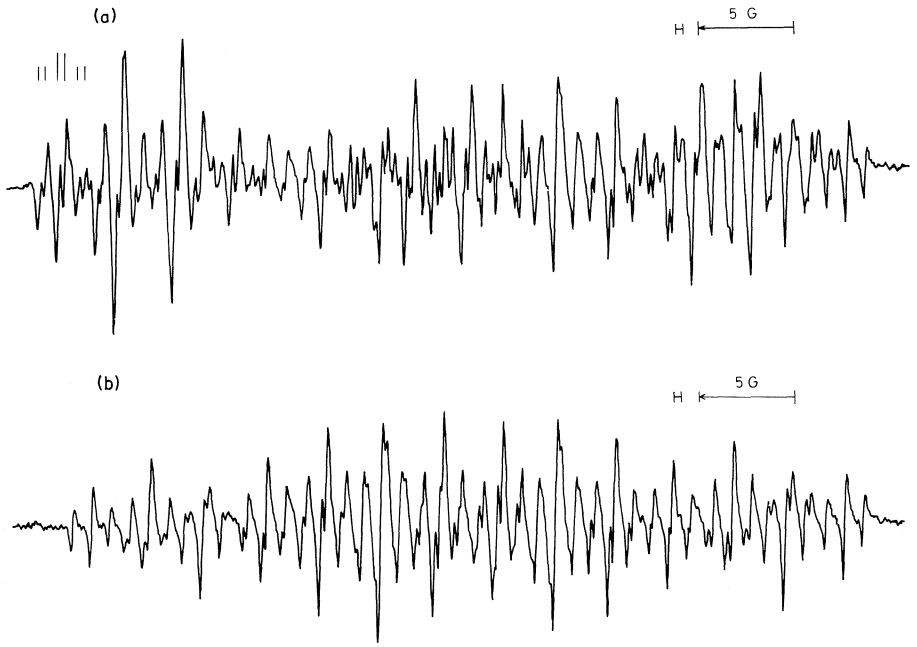

FIG. 2. E.s.r. spectra observed (*a*) during and (*b*) after the photolysis of nitrobenzene in THF + H_2O.

Results

Photolysis in Ethers

The photolysis of nitrobenzene in pure THF led to the observation of an e.s.r. spectrum given in Fig. 1. This spectrum is similar to that reported by Ward (4), except that the present spectrum was better resolved to show the small difference in the ortho and para proton splittings of the nitrobenzene ring. This spectrum is assigned to the radical PhN(Ȯ)OR (where R is the tetrahydrofuranyl radical) and its hyperfine coupling constants are given in Table 1. To support the assignment of the PhN(Ȯ)OR radical, further experiments were carried out in mixed solvents of THF and D_2O. It is reasonable to predict that radicals such as the PhN(Ȯ)OH would undergo proton exchange with water and therefore the doublet hydroxy proton splitting would collapse.

In a controlled experiment using THF and H_2O as solvent (9:1 in volume), the observed e.s.r. spectra *during* and *after* the photolysis were shown in Figs. 2*a* and *b*, respectively. Computer analysis revealed that the spectrum in Fig. 2*a* is the composite of the two spectra in Figs. 1 and 2*b*. When the experiment was carried out with 9:1 volume ratio of THF and D_2O, the observed e.s.r. spectra *during* and *after* the photolysis (Figs. 3*a* and *b*) again showed that the spectrum during photolysis (Fig. 3*a*) is the composite of Figs. 1 and 3*b*. Our interpretation is that the spectrum in Fig. 1 is correctly assigned

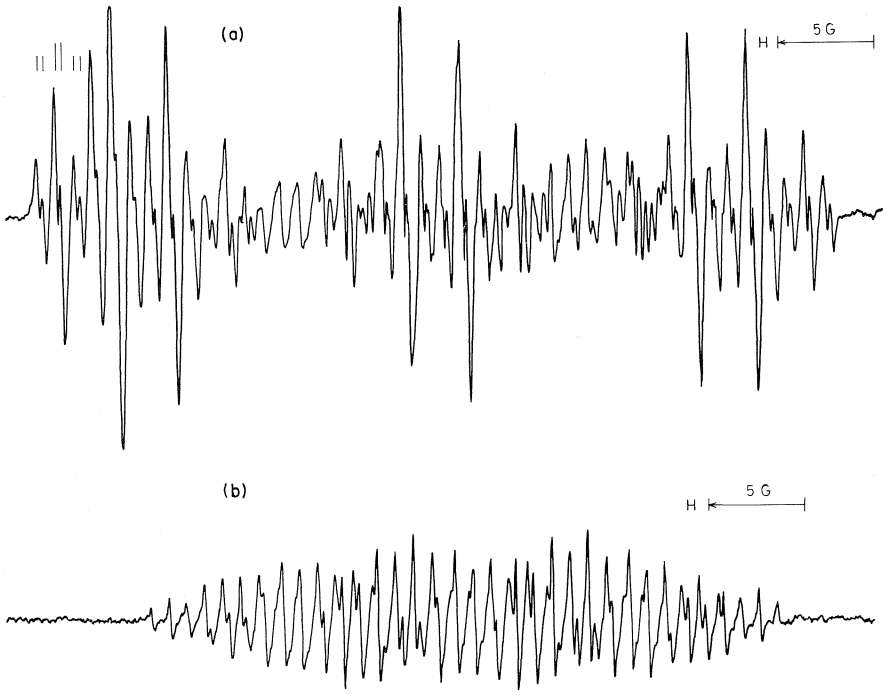

FIG. 3. E.s.r. spectra observed (*a*) during and (*b*) after the photolysis of nitrobenzene in THF + D_2O.

to the radical PhN(Ȯ)OR, which is not affected by the change of H_2O to D_2O in the mixed solvents. On the other hand, the additional species observed in the mixed solvent systems is assigned to the radical Ph(Ȯ)H, or the PhN(Ȯ)D, respectively. The latter radical probably resulted from proton–deuteron exchange between the PhN(Ȯ)H and D_2O. The hyperfine coupling constants of these radicals are reported in Table 1. We conclude that these experiments have demonstrated that the photoradical produced in the reduction of nitrobenzene in THF is indeed the radical PhN(Ȯ)OR as proposed by Cowley and Sutcliffe (9), and not the radical PhN(Ȯ)OH (4).

Photolysis of *s*-trinitrobenzene was also carried out in pure THF, in dioxane, and in perdeuteriated ethers. The spectra observed were substantially the same as those reported by Briegleb and Lind (3), and are given in Table 1.

Photolysis in Alcohols

Photolysis of nitrobenzene in methanol gave extremely weak e.s.r. signals which were difficult to detect. In isopropanol, however, a reasonable spectrum was observed which can be interpreted as due to PhN(Ȯ)$C(CH_3)_2OH$ (see Table 1). These results are quite different from those reported by Chachachaty and Forchioni (11). These authors claimed that they observed the radical PhN(Ȯ)CH_2OH in methanol and the radical PhN(Ȯ)H in isopropanol.

When the alcohols were made alkaline with ammonium hydroxide, the radicals observed were the nitrobenzene radical anion, during photolysis. Solutions of *m*-dinitrobenzene and *s*-trinitrobenzene in alkaline alcohol gave a deep red color probably due to the formation of the Meisenheimer σ-complexes (12). Photolysis of these solutions did not produce any observable e.s.r. spectra.

Photolysis in Amines

Photolyses of nitrobenzene in cyclopentamine, in morpholine, in tetrahydropyridine, in 40% aqueous dimethylamine, and in 40% aqueous diethylamine, all produced stable e.s.r. spectra which can be readily assigned to the nitrobenzene radical anion.

Solutions of *m*-dinitrobenzene and *s*-trinitro-

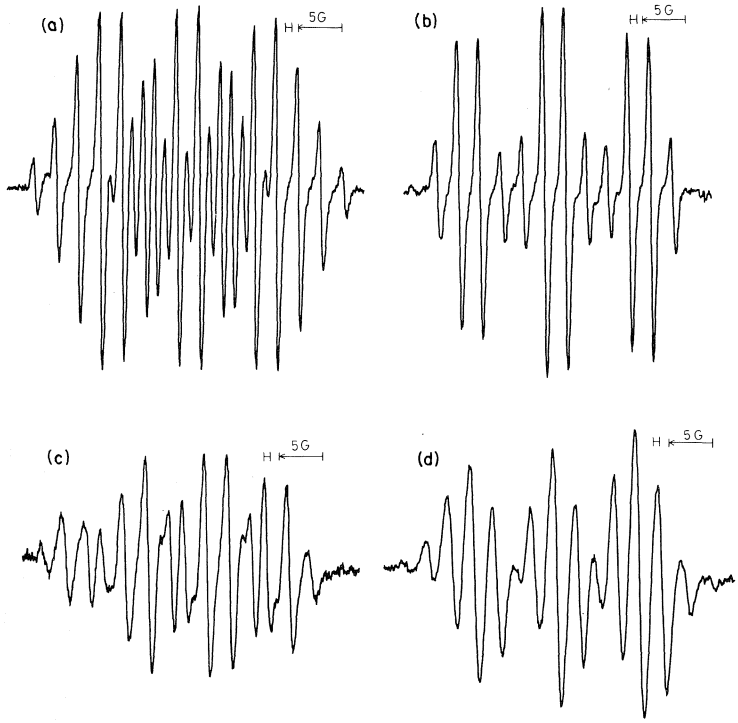

FIG. 4. E.s.r. spectra observed in the photolysis of trinitrobenzene in (*a*) toluene, (*b*) cumene, (*c*) diphenylmethane, and (*d*) indene.

benzene in various amine solvents also gave deep red or purple color and photolyses of these solutions produced no observable e.s.r. signal.

Photolysis in Hydrocarbons

In toluene, cumene, indene, diphenylmethane, and cyclohexane, the photolyses of *s*-trinitrobenzene gave fairly stable and well-resolved e.s.r. spectra (Fig. 4). These spectra are assigned to radicals of the type PhN(Ȯ)R, in which R is the hydrocarbon fragment after one of the α-hydrogens has been abstracted by the substrate. Their hyperfine parameters are reported in Table 1. These assignments were confirmed by experiments using 98% *s*-trinitrobenzene-d_3, generously supplied by E. Buncel of this Department.

When *m*-dinitrobenzene was photolyzed in these hydrocarbon solvents, the observed e.s.r. spectra were also due to the similar type of PhN(Ȯ)R radicals and were listed in Table 1.

Photolysis in Dimethylformamide

When nitrobenzene was photolyzed in dimethylformamide, the e.s.r. spectrum observed upon initial irradiation was very complex. After 10–20 min of continuous irradiation the spectrum changed gradually to a simple pattern which can be readily identified as the radical PhN(Ȯ)H. This simple spectrum can also be obtained directly by a pulse of light with observation appropriately delayed.

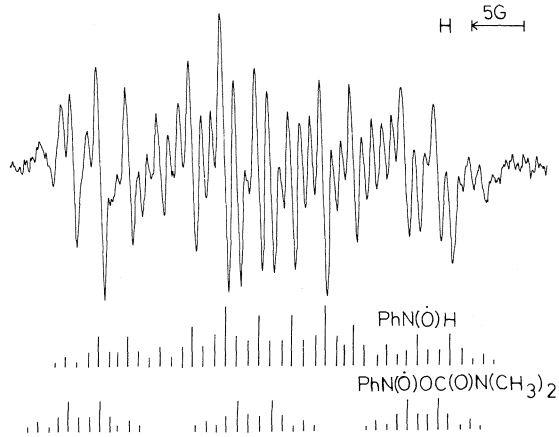

FIG. 5. Rapid scan e.s.r. spectrum observed in the photolysis of nitrobenzene in dimethylformamide.

For personal use only.

Because of the rapid changes in the initially observed e.s.r. spectra, it was hoped that the initial radical species could be captured before decay by the rapid scan e.s.r. method (10). About 3000 scans can be made within a minute during the short light exposure. The spectrum thus obtained is shown in Fig. 5. A careful analysis of this spectrum with the aid of computer simulation revealed that the initial spectrum was a composite of spectra due to both the PhN(Ȯ)H and the $PhN(\dot{O})OC(O)N(CH_3)_2$ radicals. The assignment of the latter radical (Table 1) must be treated as tentative, but its nitrogen splitting is similar to the type PhN(Ȯ)OR and quite different from that of the radicals PhN(Ȯ)R.

Discussion

The e.s.r. results in the present study confirmed the complexity of the solvent effect in the photoreduction of simple aromatic nitro-compounds as suggested by other studies (5, 13–15) involving product analysis. It is rather unfortunate that the presumably primary radical PhN(Ȯ)OH which would be expected from hydrogen abstraction of the excited nitrobenzene molecule, was not observed and identified in this study. However, analogous radicals resulting from photolyses of 2,3,5,6-tetrachloronitrobenzene and 2,3,6-trichloronitrobenzene have been claimed (9) to exist. While it is reasonable to postulate the role of the radical PhN(Ȯ)OH in the mechanism of the photoreduction of aromatic nitro-compounds, it must be recognized that direct e.s.r. evidence is still lacking. Nevertheless, we should discuss here the roles of those radicals detected by e.s.r. in the present investigation, in the mechanism of the photoreduction.

Radicals of the type PhN(Ȯ)OR, which have been observed in ethers, isopropanol, and dimethylformamide solvents, presumably are formed by addition of the solvent radical R to nitrobenzene. The solvent radicals R can be initially produced by losing a hydrogen atom to an excited triplet nitrobenzene. Indeed, the addition reaction 1 has been demonstrated by McMillan and Norman (16). Furthermore, the

[1] $$\dot{R} + RhNO_2 \rightarrow PhN(\dot{O})OR$$

intermediate tetrahydrofuranyl radical has also been trapped using phenyl-*t*-butyl nitrone (17). The decay kinetics of the 2,3,5,6-tetrachlorophenyl alkoxy nitroxide radical was found to follow the first-order rates under various conditions and was probably due to unimolecular decomposition (9*b*), as shown in reaction 2. The

[2] $$PhN(\dot{O})OR \rightarrow PhNO + R\dot{O}$$

radical RȮ produced in reaction 2 can further abstract a hydrogen atom from the solvent leading to a chain mechanism in the photoreduction. However, Hurley and Testa (5) have measured the quantum yield of the nitrobenzene in degassed isopropanol solution and their low value of $1.14 \pm 0.08 \times 10^{-2}$ seemed to be incompatible with a chain mechanism. Perhaps the low quantum yield could be due to a combination of factors, such as low efficiency in the intersystem crossing to the triplet state of the nitrobenzene and the rapid deactivation of the triplet nitrobenzene compared to the chemical abstraction reaction.

The phenyl nitroxide PhN(Ȯ)H, which was observed in aqueous THF and in dimethylformamide solvents, has been regarded as a possible precursor to one of the reduction products, phenylhydroxylamine (5). Ayscough and coworkers (18) proposed the step shown in reaction 3 for the formationof the phenyl nitroxide rad-

[3] $$PhNO + PhN(\dot{O})OH \rightarrow PhN(\dot{O})H + PhNO_2$$

ical. This, however, cannot be confirmed due to the illusiveness of the primary radical PhN(Ȯ)OH.

In amine or aqueous alkaline solutions, it has been demonstrated that the photolysis of nitrobenzene results in the observation of its radical anion. Barltrop and Bunce (14) have suggested that the anion radical is formed by loss of a proton from the primary PhN(Ȯ)OH radical (see eq. 4). While this again cannot be confirmed

[4] $$PhN(\dot{O})OH \rightleftharpoons Ph\dot{N}O_2^- + H^+$$

at present because of the lack of e.s.r. evidence for the primary PhN(Ȯ)OH radical, the subsequent decomposition of the nitrobenzene radical anion has been studied in detail in aqueous solutions by a variety of polarographic, e.s.r., pulsed radiolysis, and u.v. spectrometric methods (19–24). The result can be summarized and presented by reactions 5 and 6. Thus in these

[5] $$Ph\dot{N}O_2^- + PhN(\dot{O})OH \rightarrow PhNO_2 + PhN(O)OH^-$$

[6] $$PhN(O)OH^- \rightarrow PhNO + OH^-$$

aqueous solvents, nitrobenzene is photoreduced

by a different mechanism involving its radical anions as the major intermediate.

Another type of radical, PhN(Ȯ)R, which has been detected in hydrocarbon solvents, is likely to be a secondary radical formed by the addition of solvent radicals Ṙ to one of the intermediate product nitrosobenzene. The preference of the hydrocarbon radicals attacking the nitrosobenzene in presence of a higher concentration of nitrobenzene could partly be attributed to the fact that nitrosobenzene is a more powerful electron acceptor (9, 16).

Received July 20, 1972

Mentzeloside (**1**), *rel*-(1*R*,4*aR*,5*R*,6*R*,7*S*,7*aR*)-6,7-epoxy-1-*O*-β-D-glucosyl-5-hydroxy-1,4*a*,5,6,7,7*a*-hexahydro-4-methylcyclopenta(*c*)pyran, was isolated from flowers and seed pods of *Mentzelia decapetala*. The preparation of various chemical derivatives and the examination of spectral (i.r., u.v., and ^{1}H n.m.r.) data allowed a complete structure to be proposed for the title compound.

La mentzeloside (**1**), *rel*-(1*R*,4*aR*,5*R*,6*R*,7*S*,7*aR*) époxy-6,7-*O*-β-D-glucosyl-1 hydroxy-5, hexahydro-1,4*a*,5,6,7,7*a* méthyl-4 cyclopenta(*c*)pyranne, a été isolée à partir des fleurs ainsi que des cosses de la graine du *Mentzelia decapetala*. La préparation de plusieurs dérivés chimiques et l'examen de données spectrales (i.r., u.v., et r.m.n. ^{1}H) ont permis d'élaborer une structure complète pour le composé mentionné dans le titre. [Traduit par le journal]

Can. J. Chem., **51**, 760 (1973)

Mentzelia decapetala is the only member of the family Loasaceae found on the Canadian prairies. Previous work on the nature of the secondary constituents of the genus *Mentzelia* is limited to an investigation of their seed oil content (1). The present paper reports the structure elucidation of an iridoid glycoside, mentzeloside (**1**, Scheme 1) isolated from *M. decapetala*.

Compound **1** was isolated from a methanolic extract of the flowers and seed pods of *M. decapetala*. Separation on a Florisil column yielded an optically active white crystalline material. The empirical formula $C_{15}H_{22}O_9$ was established by elemental analysis and mass spectrometry. Preliminary examination of the i.r. (1665 cm^{-1}) and u.v. spectra (λ_{max} 204 nm) indicated the presence of an enol ether function (2). **1** gave black polymers on acid treatment, a property which has been shown to be characteristic of most iridoid compounds (3, 4). The latter designation gained further support by the presence of a one-proton signal at 6.13 p.p.m. in the ^{1}H n.m.r. spectrum (Fig. 1) assignable to the olefinic proton on C-3 of an iridoid skeleton.

A few other features of the n.m.r. spectrum were discernable. The 6.13 p.p.m. absorption displayed weak (J = 0.5 Hz) coupling to a high field (1.60 p.p.m.), three-proton signal, which was attributed to an allylic methyl function at C-4. Two upfield, one-proton signals centered at 2.31 and 1.91 p.p.m. were assigned to the two bridgehead protons, C-7*a* and -4*a* respectively. The 8 Hz interaction displayed between these protons was similar to the couplings observed in other *cis*-ring fused iridoids (5). Also the downfield tertiary proton (2.31 p.p.m.) was coupled (J = 10 Hz) with an ethereal proton signal at 4.68 p.p.m. The latter was assigned to the acetal proton at C-1. The large coupling was indicative of a dihedral angle approaching 180° and a *trans*-diaxial relationship between the protons on C-7*a* and -1.

Acetylation of **1** yielded a crystalline pentaacetate (**2**) of molecular formula $C_{25}H_{32}O_{14}$. Catalytic hydrogenation of **2**, or of **1** followed by acetylation, gave the dihydro-derivative (**3**). Comparison of the n.m.r. spectra of **2** and **3** showed loss of the C_3-olefinic proton at 6.07 p.p.m. and changes in the three-proton methyl resonance. This signal at 1.60 p.p.m. in **2** had undergone an upfield shift of 0.45 p.p.m. due to loss of the deshielding influence of the double bond. New protons appeared in the spectrum of **3** in the 2.12–1.47 and 3.79–3.41 p.p.m. regions. These were assigned to C-4 and -3 respectively. Irradiation at 1.70 p.p.m. affected collapse of the C-8 methyl from a broad doublet (J = 7 Hz)

[1]Presented in part at the American Society of Pharmacognosy, Iowa City, Iowa, July 1968.

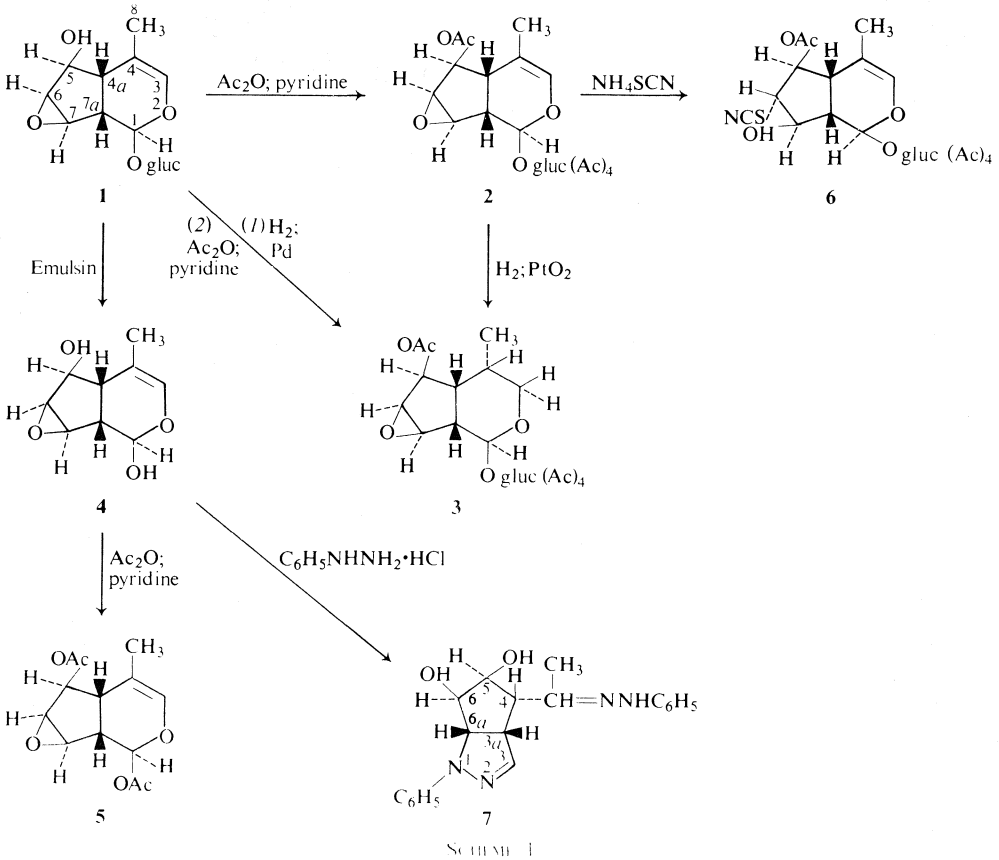


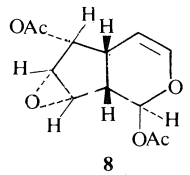
SCHEME 1

to a singlet. These changes in the spectrum of **3** served to prove the initial presence and subsequent saturation of an enol ether olefinic bond, and indicated a correct assignment for the C_4-methyl function in **1**.

The sharpness of the C-8 methyl resonance in the n.m.r. spectrum of **3** indicated that the reduction had been stereospecific. Approach to the catalyst surface from the least hindered β side of the molecule should give rise to a product in which the C-8 methyl group is α-orientated (2).

Enzymatic hydrolysis with emulsin of **1** yielded mentzelol (**4**) (a reducing aglycone) and glucose. The latter was confirmed by gas chromatography of the TMS–ether derivative. The glucose moiety must be at C-1 in **1**, due to the generation of reducing properties upon hydrolysis and by analogy with other iridoid glucosides. A β-configuration for glucose was indicated by the ease of hydrolysis with emulsin and by the signal of the glucose anomeric proton in the n.m.r. spectrum of **1** (4.54 p.p.m., $J = 7.5$ Hz) (6). There was no definite evidence for epimerization about C-1 in **4**. The n.m.r. spectrum did not show the C-1 axial proton epimer, which would be expected to occur as a narrowly split doublet at a somewhat higher field (7).

Acetylation of **4** produced a crystalline diacetate (**5**). The similarity of the n.m.r. (see Fig. 2) to that of unedol diacetate (**8**) (5) allowed tentative assignment of all structural features of **5** and by analogy **1** also. A low field signal at 6.10 p.p.m.



8

was assigned to the C-3 olefinic proton, while a high field three-proton doublet at 1.52 p.p.m. was attributed to the C-8 methyl function. A broad doublet at 5.51 p.p.m. which had undergone a downfield shift of 1.1 p.p.m. (relative to **4**) upon acetylation was shown by spin decoupling to be

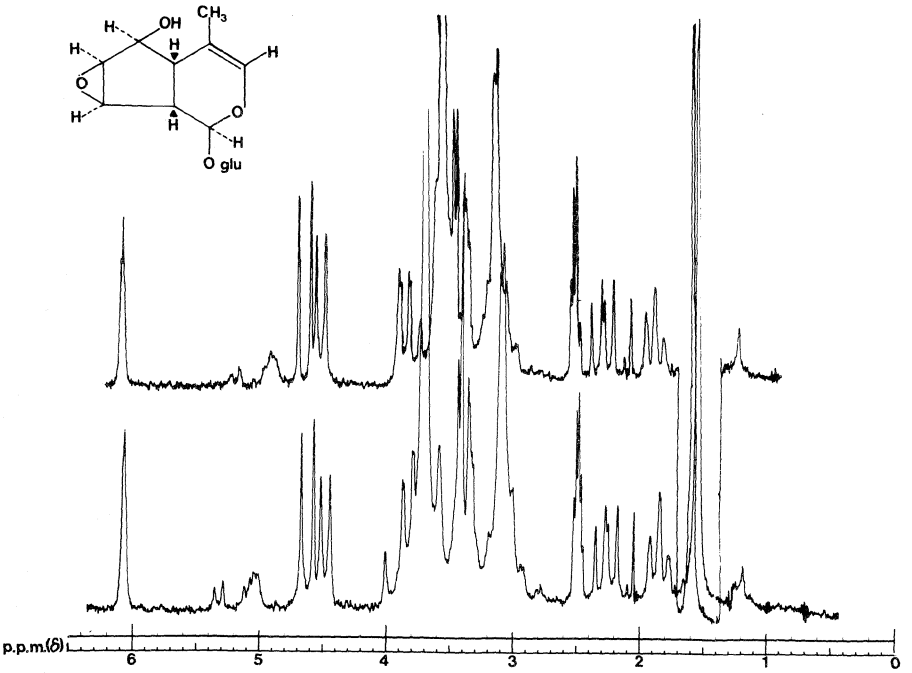

FIG. 1. The 100 MHz ^{1}H n.m.r. spectrum of mentzeloside; lower tracing, room temperature; upper tracing, 70°; solvent DMSO-d_6; DSS internal standard.

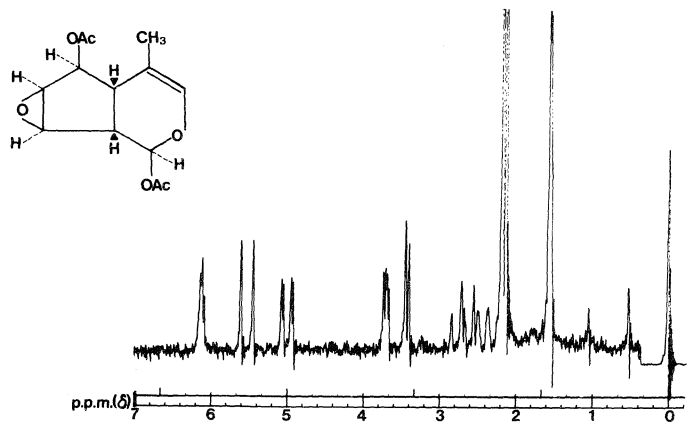

FIG. 2. The 60 MHz ^{1}H n.m.r. spectrum of mentzelol diacetate; solvent $CDCl_3$; TMS internal standard.

coupled with the C-7*a* bridgehead proton (J = 10 Hz). This signal was therefore the C-1 acetal proton and the retention of the large coupling indicated that the configuration at C-1 had not been affected by hydrolysis and acetylation. The C-7*a* bridgehead proton was coupled to a second bridgehead proton at 2.36 p.p.m. (J = 7.5 Hz), which was in turn coupled with a one-proton signal at 5.0 p.p.m. (J = 8 Hz). This latter signal had been shifted downfield 1.2 p.p.m. by acetylation and was assigned to a secondary acetate methine on C-5. Two coupled, one-proton, signals at 3.70 and 3.42 p.p.m. (J = 2.75 Hz) were the oxirane protons on C-6 and -7 of **5**. The magnitude of the coupling and the chemical shift of these signals were characteristic of the protons of an epoxide on a five-membered ring (5, 8). The downfield epoxide proton was coupled to the C-5 acetate methine (J = 1.5 Hz) and is thus positioned at C-6. The upfield epoxide proton is

Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

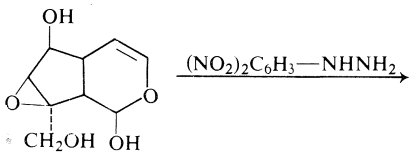
then attributed to C-7. Coupling between this proton and the C-7*a* bridgehead proton was absent. This lack of observable coupling is characteristic of a *trans*-interaction between vicinal protons in cyclic epoxides and thus the epoxide ring must be *trans* to the C_1—C_{7a} bond. The epoxide ring is then in a β-position, above the general plane of the iridoid nucleus. The configuration of the C-5 proton could also be deduced from the observed coupling of 1.5 Hz. This is characteristic of a *cis*-interaction and the C-5 proton must therefore be placed *cis* to the C-6 epoxide proton (8).

When mentzeloside pentaacetate (**2**) was allowed to react with the ammonium thiocyanate in *N*,*N*-dimethylformamide (DMF) under reflux a compound (**6**) incorporating CHNS was isolated ($C_{26}H_{33}O_{14}S$). The n.m.r. spectrum of **6**, as compared to that of **2**, showed loss of the epoxide protons centered at 3.68 p.p.m. and the appearance of three new signals. A low field multiplet at 4.08 p.p.m. and an upfield doublet of doublets at 3.30 p.p.m. were attributed to a secondary alcohol methine and a thiocyanate methine respectively. An intermediate signal at 3.55 p.p.m. was shown by deuterium exchange to be a hydroxyl proton. Spin decoupling experiments indicated that the thiocyanate methine was coupled to the C-5 acetate methine (5.12 p.p.m., J = 5 Hz) and to the 4.08 p.p.m. signal (J = 9.7 Hz), which allowed placement of the thiocyanate group at C-6. **6** thus resulted from S_N2 cleavage of the C_6—O bond by thiocyanate ion, accompanied by the appropriate inversion at C-6 and retention of configuration at C-7.

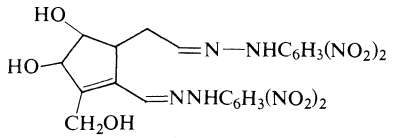
Epoxide cleavage with ammonium thiocyanate was also attempted in tetrahydrofuran under reflux, but resulted in the recovery of starting material. Goodman has reported that cleavage of vicinally substituted epoxides only under the vigorous DMF conditions was indicative of one *cis*- and one *trans*-vicinal substituent (9). This observation is in agreement with the steric assignment of a *cis*-relationship between the protons on C-5 and -6 in **5**.

An interesting feature in the n.m.r. spectrum of **6** was the collapse of the C-1 acetal proton signal in **2** from a broad doublet (J = 9 Hz) to a narrow doublet (J = 1 Hz), which was shifted downfield 0.79 p.p.m. This is interpreted as being due to a conformational inversion of the dihydropyran ring, resulting in an axial–equatorial inversion at C-1 and a change in dihedral angles from about 180 to about 90°. Although this ring inversion would cause the bulky tetra-*O*-acetylglucosyl group to assume an axial position, Drieding models show any 1,3- or 1,4-interactions to be minimal. This conformation should also be stabilized by the "anomeric effect" (10).

Unexpected confirmation of the presence of the epoxide function and its steric relationship to the C-5 hydroxyl group in **1** was obtained from the product (**7**) derived from the reaction of mentzelol (**4**) with phenylhydrazine hydrochloride. **7** was assigned the pyrazoline structure since the n.m.r. spectrum clearly lacked any signals assignable as epoxide protons, the u.v. spectrum did not contain a maximum near 320 nm characteristic of α,β-unsaturated phenylhydrazones (11), and exposure to bromine vapor produced an olive green color characteristic of pyrazolines (12). The product formed from the reaction of catalpol aglycone (**9**) with 2,4-dinitro-



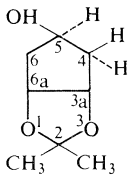
9



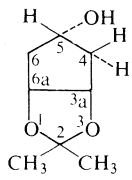
10

phenylhydrazine has been assigned as an α,β-unsaturated 2,4-dinitrophenylhydrazone (**10**) (13); however the use of phenylhydrazine would be expected to more readily yield a pyrazoline (14).

In the n.m.r. spectrum of **7** the bridgehead protons on C-3*a* and -6*a* appear as an octet at 3.92 and a doublet at 4.17 p.p.m. respectively. The latter signal displayed coupling only to the C-3*a* proton (J = 11 Hz), indicating that the dihedral angle to the proton on C-6 must approach 90°. Dreiding models show that this is only possible if these protons are *trans* and the cyclopentane ring has a "V_5 boat" conformation. This conformation is preferred in various rigidly fused bicyclic cyclopentane derivatives (8). Table 1 compares the observed couplings for the C-4, -5, and -6 protons of **7** to those recorded in the literature for the model compounds **11** and



11



12

TABLE 1. Observed couplings (Hz) in compounds **7**, **11**, and **12**.

Compound		$J_{4,5}$	$J_{5,6}$
7		10	4
11*	*cis*	6	
	trans	9.3	
12*	*cis*	4.7	
	trans	1.2	

*Reference 8.

12 (8). These latter structures have been shown to exist in the "V_5 boat" conformation, and the similarity of the coupling constants for **11** to those observed in **7** allows one to assign the hydroxyl of C-5 the same relative stereochemistry. Therefore, the C-5 hydroxyl group is indicated as being *cis* to the oxirane ring in **4** and **1** and the proton at this center must be α, thus completing all assignments of the relative stereochemistry of **1**.

Experimental

The n.m.r. spectra were run on Varian T-60 or HA-100 instruments. TMS was used as internal standard for $CDCl_3$ or acetone-d_6 solutions, while DSS was used for DMSO-d_6 solutions. Chemical shifts are recorded in p.p.m. (δ) units downfield from the internal standard. The i.r. spectra were recorded as potassium bromide discs on a Unicam SP200 spectrometer and the u.v. spectra on a Unicam SP800 recording spectrometer. Optical rotations were determined with a Bellingham and Stanley polarimeter. Melting points were determined with a Gallenkamp melting point apparatus and are uncorrected. Florisil (Floridin Company, 30–60 mesh or Fisher Scientific 60–100 mesh) or silica gel powder (Baker 3405, 60–200 mesh) were used for column chromatography. Microanalyses were carried out by Mr. R. M. Smith of the College of Pharmacy and Dr. Strauss, Oxford, England. Mass spectra were determined with an AEI-MS 12 single focusing mass spectrometer (70 eV) with a heated inlet system operating near or at the melting points of the compounds. Samples were introduced by direct probe.

Extraction and Isolation of Mentzeloside (1)

Flowers and seed pods of *Mentzelia decapetala* (fresh weight 12.2 kg) were immersed in methanol containing calcium carbonate immediately after collection. This plant material was further treated with boiling methanol, filtered, and air dried. The partially extracted dry plant material was then ground to a fine powder and exhaustively percolated with aqueous methanol (70%). The combined methanolic extracts were evaporated to an aqueous solution and washed with chloroform. The volume of the aqueous solution was then adjusted to 7 l with water.

An aliquot portion (500 ml) of the above aqueous solution was stirred with basic lead hydroxide (2 h) and filtered. Removal of solvent *in vacuo* yielded a brown syrup (39 g) which was successively extracted with hot absolute ethanol (400 ml), ethanol (500 ml), and methanol (300 ml). Concentration *in vacuo* of the combined extracts produced a brown syrup (30 g) which was redissolved in methanol, evaporated onto aluminum oxide (110 g), and placed in a soxhlet extractor. Exhaustive extraction with absolute ethanol yielded, after removal of solvent, a brown syrup (11 g) which was placed on a column of Florisil (400 g). Elution with benzene–methanol (3:1) yielded in the fraction between 1500 and 1900 ml of total eluate, **1**, which recrystallized from methanol as white crystals (0.240 g): m.p. 266–270° dec. $[\alpha]_D^{23}$ −100.88° (*c* 1.021 in H_2O); u.v. max 205 nm (log ε 3.53); i.r. 1665 (C=C—O) and 3420 cm^{-1} (O—H); n.m.r. (DMSO-d_6) δ 6.13 (m, 1, $J_{3,4a}$ = 0.5 and $J_{3,8}$ = 0.5 Hz, C_3-*H*), 4.68 (d, 1, $J_{1,7a}$ = 10 Hz, C_1-*H*), 4.54 (d, 1, $J_{1',2'}$ = 7.5 Hz, glucose), 3.89 (dd, 1, $J_{5,4a}$ = 8 and $J_{5,6}$ = 1.5 Hz, C_5-*H*), 3.83 (m, 2, glucose), 3.50 (d, 1, $J_{7,6}$ = 2.75 Hz, C_7-*H*), 3.39 (m, 1, C_6-*H*), 3.14 (m, 4, glucose), 2.31 (dd, 1, $J_{7a,1}$ = 10 and $J_{7a,4a}$ = 7.5 Hz, C_{7a}-*H*), 1.91 (m, 1, $J_{4a,5}$ = 8, $J_{7a,4a}$ = 7.5, and $J_{4a,3}$ = 0.5 Hz, C_{4a}-*H*), and 1.60 p.p.m. (d, 3, $J_{8,3}$ = 0.5 Hz, C_8-H_3); mass spectrum *m/e* (relative intensity) 184(80), 167(41), 166(4), 138(10), 137(60), 95(82), and 73(100).

Anal. Calcd. for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40. Found: C, 52.10; H, 6.45.

Mentzeloside Pentaacetate (2)

To a solution of mentzeloside (**1**, 0.310 g) in anhydrous pyridine (5 ml) was added acetic anhydride (1 ml). The solution was stirred on a steam bath (2 h). Cooling and addition of ice water yielded **2** which recrystallized from methanol as fine white needles (0.417 g, 85%): m.p. 199°; $[\alpha]_D^{26}$ −103.32° (*c* 0.974 in $CHCl_3$); i.r. 1665 (C=C—O) and 1740 cm^{-1} (ester C=O); n.m.r. ($CDCl_3$) δ 6.07 (m, 1, $J_{3,8}$ = 0.5 and $J_{3,4a}$ = 0.5 Hz, C_3-*H*), 4.77–5.33 (c, 5, C_5-*H* and glucose 4H), 4.57 (d, 1, $J_{1,7a}$ = 9 Hz, C_1-*H*), 4.13 (m, 2, glucose), 3.6–3.75 (c, 3, C_6-*H*, C_7-*H* and glucose), 2.50 (dd, 1, $J_{7a,1}$ = 10 and $J_{7a,4a}$ = 7.5 Hz, C_{7a}-*H*), 2.30 (ddd, 1, $J_{4a,5}$ = 8, $J_{4a,7a}$ = 7.5 and $J_{4a,3}$ = 0.5 Hz, C_{4a}-*H*), 2.0 (c, 15, 5 CH_3COO—), and 1.53 p.p.m. (d, 3, $J_{8,3}$ = 0.5 Hz, C_8-H_3).

Anal. Calcd. for $C_{25}H_{32}O_{14}$: C, 53.95; H, 5.80. Found: C, 53.89; H, 5.80.

Dihydromentzeloside Pentaacetate (3)

(*a*) Compound **1** (0.200 g) in water (15 ml) was added to a suspension of hydrogen saturated 10% palladium/charcoal (0.125 g) in ethyl alcohol (80%, 85 ml) and was stirred under a hydrogen atmosphere at room temperature for 16 h. Removal of the catalyst and evaporation of solvent yielded a glassy residue (0.190 g) which was pure to paper chromatography and lacked olefinic stretching in the i.r. spectrum.

To the above residue in pyridine (5 ml) was added acetic anhydride (1 ml). The solution was allowed to

stand at room temperature for 16 h and was poured into cold water (10 ml). Filtration and recrystallization from methanol yielded **3** (0.165 g, 55%): m.p. 184–185°; $[\alpha]_D^{26}$ −84.6° (*c* 0.654 in $CHCl_3$); n.m.r. ($CDCl_3$) δ 4.75–5.31 (c, 5, C_5-*H* and glucose 4H), 4.37 (d, 1, $J_{1,7a}$ = 9 Hz, C_1-*H*), 4.16 (m, 2, glucose), 3.79–3.41 (m, 5, C_3-H_2, C_6-*H*, C_7-*H*, and glucose 1H), 2.33 (dd, 1, $J_{7a,1}$ = 9 and $J_{7a,4a}$ = 8 Hz, C_{7a}-*H*), 2.12–1.47 (m, 17, C_4-*H*, C_{4a}-*H* and 5CH_3COO—), and 1.05 p.p.m. (d, 3, $J_{8,4}$ = 7 Hz, C_8-H_3).

(*b*) Compound **2** (0.250 g) in glacial acetic acid (10 ml) was added to a suspension of hydrogen-saturated platinum oxide (0.250 g) in ethyl alcohol – acetic acid (1:1, 50 ml) and was stirred at room temperature under a hydrogen atmosphere. After 3 h the catalyst was removed and the solvent evaporated yielding **3** which recrystallized from ethyl alcohol (0.180 g, 72%), and was identical to the product isolated above.

Mentzeloside Aglycone; Mentzelol (4)

To a solution of **1** (2 g) in water (350 ml) was added a suspension of emulsin (0.130 g) in water (50 ml). The resultant suspension was allowed to stand at room temperature (18 h), after which the solvent was removed *in vacuo* to yield a gummy residue. Extraction of this residue with hot chloroform–ethanol (4:1, 150 ml) yielded, after filtration and removal of solvent, crude aglycone (1.71 g). Crystallization from ethyl acetate yielded **4** as white crystals (0.654 g, 62%): m.p. 153–155°; $[\alpha]_D^{23}$ −122.35° (*c* 0.425 in CH_3OH); u.v. max 203 nm (log ε 3.56); n.m.r. (DMSO-d_6) δ 7.0 (d, 1, *J* = 7 Hz, O*H*, exchanges readily with D_2O), 6.05 (m, 1, C_3-*H*), 5.1 (d, 1, *J* = 7 Hz, O*H*, exchanges readily with D_2O), 4.4 (dd, 1, $J_{1,7a}$ = 9.5 and $J_{H,OH}$ = 7 Hz, D_2O exchange, d, $J_{1,7a}$ = 9.5 Hz, C_1-*H*), 3.8 (dd*, 1, $J_{5,4a}$ = 8 and $J_{H,OH}$ = 7 Hz, D_2O exchange, d, $J_{5,4a}$ = 8 Hz, C_5-*H*), 2.1 (dd, 1, $J_{7a,1}$ = 9.5 and $J_{7a,4a}$ = 7.5 Hz, C_{7a}-*H*), 1.8 (dd, $J_{4a,7a}$ = 7.5 and $J_{4a,5}$ = 8 Hz, C_{4a}-*H*), and 1.6 p.p.m. (d, 3, $J_{8,3}$ = 0.5 Hz, C_8-H_3); mass spectrum *m/e* (relative intensity) 184(100), 167(16), 166(3), 138(10), 137(54), and 95(75).

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.56. Found: C, 58.44; H, 6.38.

Mentzelol Diacetate (5)

To a solution of **4** (0.650 g) in anhydrous pyridine (7.5 ml) was added acetic anhydride (2.5 ml). This solution was heated on a steam bath (0.5 h), cooled, and poured into saturated aqueous sodium bicarbonate (150 ml). Extraction with chloroform (3 × 20 ml) yielded, after drying ($CaCl_2$) and evaporation, the diacetate (0.585 g, 62%). Vacuum sublimation (1 mm Hg, 114°) yielded **5** as white needle-like crystals: m.p. 109–111°; $[\alpha]_D^{23}$ −182.01° (*c* 0.467 in $CHCl_3$); n.m.r. ($CDCl_3$) δ 6.10 (m, 1, $J_{3,8}$ = 0.5 and $J_{3,4a}$ = 0.5 Hz, C_3-*H*), 5.51 (d, 1, $J_{1,7a}$ = 10 Hz, C_1-*H*), 5.0 (dd, 1, $J_{5,4a}$ = 8 and $J_{5,6}$ = 1.5 Hz, C_5-*H*), 3.70 (dd, 1, $J_{6,5}$ = 1.5 and $J_{6,7}$ = 2.75 Hz, C_6-*H*), 3.42 (d, 1, $J_{7,6}$ = 2.75 Hz, C_7-*H*), 2.68 (dd, 1, $J_{7a,1}$ = 10 and $J_{7a,4a}$ = 7.5 Hz, C_{7a}-*H*), 2.36 (ddd, 1, $J_{4a,5}$ = 8, $J_{4a,7a}$ = 7.5 and $J_{4a,3}$ = 0.5 Hz, C_{4a}-*H*), 2.18 (s, 3, CH_3COO—), 2.14 (s, 3, CH_3COO—), and 1.52 p.p.m. (d, 3, $J_{8,3}$ = 0.5 Hz, C_8-H_3).

Anal. Calcd. for $C_{13}H_{16}O_6$: C, 58.20; H, 6.01. Found: C, 58.43; H, 6.18.

Thiocyanate (6)

To a solution of mentzeloside pentaacetate (**2**, 0.420 g) in *N*,*N*-dimethylformamide (20 ml) was added ammonium thiocyanate (0.075 g, 1.3 equiv). The solution was heated under reflux (17 h) after which the solvent was removed *in vacuo*. The non-volatile residue was placed on a column of silica gel (30 g) and was developed with chloroform. Evaporation of the first 150 ml of solvent yielded starting material (**2**, 0.057 g). Further elution with chloroform (550 ml) and chloroform – ethyl acetate (19:1, 300 ml) yielded **6** as white crystals (0.068 g, 15%): m.p. 199.5–201.5°; i.r. 1670 (C=C—O), 2155 (—S—C≡N) and 3520 cm^{-1} (—OH); n.m.r. ($CDCl_3$) δ 6.0 (m, 1, C_3-*H*), 5.36 (d, 1, $J_{1,7a}$ = 1 Hz, C_1-*H*), 5.26–4.8 (m, 5, C_5-*H* and glucose 4H), 4.2 (m, 2, glucose), 4.08 (m, 1, C_7-*H*), 3.75 (m, 1, glucose), 3.55 (m, 1, exchanges readily with D_2O, O-*H*), 3.30 (dd, 1, $J_{6,5}$ = 5 and $J_{6,7}$ = 9.7 Hz, C_6-*H*), 2.55 (m, 2, C_{4a}-*H* and C_{7a}-*H*), 1.9–2.2 (c, 15, 5 CH_3COO—), and 1.65 p.p.m. (d, 3, $J_{8,3}$ = 0.5 Hz, C_8-H_3).

Anal. Calcd. for $C_{26}H_{33}NO_{14}S$: C, 50.72; H, 5.40; N, 2.28; S, 5.21. Found. C, 50.62; H, 5.34; N, 2.22; S, 5.50.

Mentzelol Phenylhydrazone Pyrazoline (7)

To a solution of mentzelol (**3**, 0.100 g) in water (5 ml) was added sodium acetate (0.200 g) and phenylhydrazine hydrochloride (0.230 g, 3 equiv). The reaction mixture was shaken until crystals began to appear and was then allowed to stand at room temperature overnight. Filtration yielded orange–brown crystals (0.196 g) which recrystallized from methanol–water to yield **7** (0.096 g, 50%): m.p. 209–210°; u.v. max 243 (log ε 4.11) and 276 nm (log ε 4.44); n.m.r. (acetone-d_6) δ 7.4–6.5 (c, 12, 10 aryl-*H*, C_3-*H*, and C_8-*H*), 4.17 (d, 1, $J_{6a,3a}$ = 11 Hz, C_{6a}-*H*), 3.92 (ddd, 1, $J_{3a,6a}$ = 11, $J_{3a,4}$ = 7, and $J_{3a,3}$ = 1.5 Hz, C_{3a}-*H*), 3.90 (d, 1, $J_{6,5}$ = 4 Hz, C_6-*H*), 3.68 (ddd, 1, $J_{5,6}$ = 4, $J_{5,4}$ = 10, and $J_{5,3}$ = 0.5 Hz, C_5-*H*), 2.90 (s, 3, exchange readily with D_2O, 2O*H*, N*H*), 2.55 (m, 2, C_4-*H* and C_7-*H*), and 1.30 p.p.m. (d, 3, $J_{9,7}$ = 6.5 Hz, C_9-H_3).

Anal. Calcd. for $C_{21}H_{24}N_4O_2$: C, 69.22; H, 6.62. Found: C, 69.23; H, 6.62.

^{13}C Nuclear Magnetic Resonance Spectra of Bridged 10π-Electron Systems. The Extent of Electron Delocalization

A. V. KEMP-JONES, ALAN J. JONES, M. SAKAI, C. P. BEEMAN, AND S. MASAMUNE

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received September 29, 1972

The ^{13}C n.m.r. spectrum of the cation **4** suggests the presence of considerable 1,7-bonding, indicating that it should be described as a substituted homotropylium cation rather than a monocyclic 10π-electron system. The intra-annular carbon atoms of **3** and **4** do not show a significant upfield shift due to the ring current. Explanations are offered.

Le spectre r.m.n. du ^{13}C du cation **4** suggère la présence d'une liaison importante entre 1 et 7; ce résultat indique que l'ion devrait être représenté sous forme d'ion homotropylium substitué plutôt que sous forme d'un système monocyclique contenant 10 électrons π. Les atomes de carbone intra-annulaires de **3** et **4** ne sont pas déplacés d'une façon significative vers les hauts champs à cause des courants de cycle. Des explications sont proposées. [Traduit par le journal]

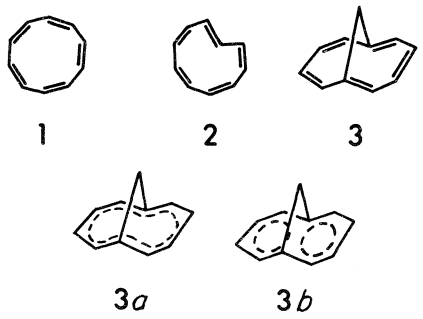
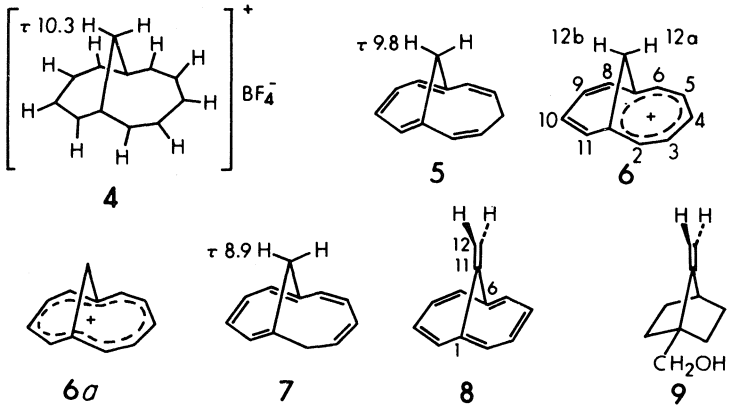
Our recent demonstration that both *cis*- and *trans*-[10]annulenes (**1** and **2**) are non-planar olefinic hydrocarbons (1) contrasts with the behavior of 1,6-methano[10]annulene (**3**), the p.m.r. spectrum of which indicates the presence of the diamagnetic ring current associated with



aromatic electron delocalization (2). The remarkable aromaticity of **3** might be partially caused by the possibility of some 1,6-bonding overlap; this interaction must be invoked in order to explain the u.v. spectrum of **3** (3). For this reason we investigated the ^{13}C n.m.r. spectrum of bicyclo[5.4.1]dodecapentaenylium fluoroborate (**4**) (4). ^{13}C n.m.r. shifts provide a sensitive probe for local charge and might, therefore, indicate to what extent the positive charge in **4** is delocalized over the π system. Estimation of the charge at the various carbon atoms of **4** requires a comparison of the chemical shifts with those in a neutral model compound having the same geometry, since ^{13}C shifts are also sensitive to changes in the geometry of the molecule (5); we have used bicyclo[5.4.1]dodecapenta-2,5,7,9,11-ene (**5**) (6) as the model compound. The ^{13}C n.m.r. spectra of **4** and **5** are shown in Fig. 1 and the chemical shifts relative to internal tetramethylsilane are given in Table 1. The choice of acetonitrile-d_3 as the solvent was determined by the solubility of the fluoroborate; no appreciable solvent-induced shifts were noted for a solution of **5** in dichloromethane-d_2. Analysis of the ^{13}C spectra of **4** and **5** first requires analysis of their proton spectra. The proton spectrum of **4** was previously recorded, but not analyzed (4). Four distinct multiplet patterns (H-α τ 0.7 (2H), H-β 1.15 (3H), H-γ 1.35 (2H), and H-δ 1.6 (2H)) appear in the aromatic region, in addition to two doublets of triplets (H-ε τ 10.3 (1H), H-ζ 11.8 (1H)) in the aliphatic region. Irradiation at H-α resulted in a general simplification of the H-β signal, but did not affect the signals of H-γ and -δ; the H-α, -β multiplets remained unchanged on irradiation at H-δ. Thus, the aromatic protons appeared to consist of two separate systems: H-α,β (5H) and -γ,δ (4H). Irradiation at H-ζ induced a significant change in the H-γ signal shape to give a typical, symmetrical AA'BB' pattern for H-γ and -δ, while H-α and -β remained unchanged. A reciprocal effect was noted on irradiation at H-γ and H-ζ became a doublet. Thus, it is now clear that H-γ,δ,ζ constitute an AA'BB'X system. In a similar manner, irradiation at H-ε resulted in a simplification of the H-α multiplet; irradiation at H-α caused the H-ε



signal to collapse to a doublet. Therefore the remaining group of six protons is safely concluded to be an AA'BB'CX system. If one applies the well-documented, long-range coupling (W-pattern) effect (7) to the present system, then the observation of the typical AA'BB' pattern on irradiation of H-ζ is consistent only with the assignment that H-γ,δ,ζ are H-8,11, -9,10 and -12a and that H-α,β,ε are H-2,6, -3,4,5 and -12b. The proton spectrum of **5** had been analyzed previously (6). The analysis of the proton spectra permitted assignment of the ^{13}C absorptions by means of the selective decoupling technique (8) as illustrated for **5** in Fig. 2. Because of the similar chemical shifts of some of the proton resonances of **4** (H-3,5 and -8,11) and **5** (H-2,6 and -8,11), complete assignment of the ^{13}C spectrum is not possible. However, when the proton resonances overlap, the corresponding ^{13}C absorptions are often close together, and in fact the resulting ambiguities in the chemical shifts are quite small and do not detract from the subsequent discussion. Strikingly, the downfield shifts of the carbon atoms C-8,11 and -9,10 are

‡In CD_3CN.

both in the range 9–15 p.p.m., whereas those of C-1,7, -2,6, and -3,5 are all substantially higher at 27–33 p.p.m. The latter range is remarkably similar to the 29.6 p.p.m. downfield shift observed between the tropylium cation and cycloheptatriene (9). The narrow range of the ^{13}C shifts in the seven-membered ring and their value suggests that **4** is best represented as a substituted homotropylium cation **6** rather than **6***a* (4).[1] The downfield shifts of C-8,11 and -9,10 can be attributed to the inductive effect of the homotropylium substituent. Representation of **4** as **6** rather than **6***a* is also consistent with the small shift of the bridge proton H-12b on converting **5** to **4**. Furthermore, this small shift of H-12b suggests that little change in the geometry of the framework occurs on converting **5** to **4**, since the chemical shift of H-12b is sensitive to changes in the geometry of the system, as is shown by comparing **5** and **7** (6). If the homoaromaticity (6π) of the C-7,8,9,10,11,1 system is more extensively attained in **4** than that implied by **6** (see footnote 1), then the degree of diamagnetic anisotropy due to the three double bonds of **5** may be approximately equated to that of the ring current effect of the same part of **4**. Obviously the representation of **4** as **6** implies that 1,7-homoconjugative overlap is important in stabilizing the cation **4**. This conclusion does not necessarily require that 1,6-overlap is important in stabilizing the ground state of **3**, but it does emphasize that the problem requires further investigation.

Another feature of the c.m.r. spectra of **4** and **5** which deserves comment is the small *downfield* shift of the bridge carbon C-12 on converting **5** to **4**; it might have been expected that C-12 would be shielded by the ring current of **4**. Similarly the bridge carbon (C-11) of 1,6-methano[10]annulene (**3**) resonates downfield from C-12 of **5** (see Table 1). No unequivocal shielding effects of ring currents on ^{13}C shifts have in fact been observed for any systems thus far, but this may be attributed to the positioning of the carbon atoms of all previously examined molecules in a 'null' shielding region between the shielding and deshielding regions (10). While this argument *might* still be applicable to **4**, especially when representation **6** is considered,[2] it seems less likely to apply to **3**. Not only the hydrogen atoms attached to C-11 are shielded, but also the methylene hydrogen atoms of **8** (11), which lie in the C-1, -11, -6 plane, resonate at τ 6.8, which represents a shielding of about 1.3 p.p.m.[3] The hydrogen atoms at C-12 of **8** should be in a much less favorable position than C-11 of **3** for shielding by the ring current. Therefore, C-11 of **3** appears to be in the shielding region regardless of whether we choose 1,6-methano[10]annulene

[1]The degree of homoaromaticity of the system involving C-1, -7, -8, -9, -10, and -11 is not certain at present. Therefore a highly electron-delocalized formula similar to **3***b* could possibly be more suitable as a structure. **6***a* means no electron overlap between C-1 and -7, whereas **6** is used to emphasize the presence of such an interaction, the degree of which of course remains to be determined.

[2]The substantial shielding of H-12a does not *necessarily* require that C-12 will be in a shielding region since the orientation of H-12a and C-12 with respect to the ring current is different.

[3]For comparison, methylene cyclohexane resonates at τ 5.18 and the 7-methylene-norbornane **9** (12) (a suggested model system (**11***b*)) absorbs at τ 5.38 and 5.48.

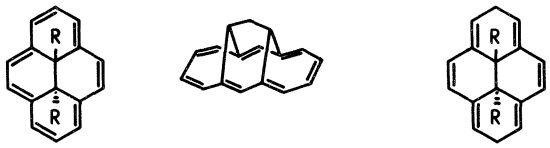
(**3***a*, monocyclic 10π) or 9,10-methanonaphthalene (**3***b*, bicyclic homoaromatic) as the model for the diamagnetic current induced in **3**. Although we still cannot rigorously exclude the possibility of a small null shielding region around C-11 as the reason for the lack of an upfield shift for C-11 in **3**, we feel that a much more likely explanation is that ^{13}C absorptions may be *relatively* insensitive to ring current effects. If the absolute value of the ring current effect (a few p.p.m. at most for ^1H) is independent of the nucleus involved then the effect in ^{13}C spectra would be outweighed by shifts due to changes in geometry and local charge.

The spectra of other molecules having intra-annular carbon atoms, such as **10** (13) and **11** (14), would be of interest in further examining this question, but the improbability of obtaining completely satisfactory model compounds (*e.g.* **12** for **10**) means that only a large shielding effect due to the ring current would be detectable (presumably 20 p.p.m. would be sufficient).



10 **11** **12**

Experimental

Compounds **3** (2), **4** (4), and **5** (6) were prepared by the literature procedures. The ^{13}C n.m.r. spectra were determined in the Fourier mode using a Bruker HFX-90 spectrometer operating at 22.63 MHz with deuterium lock.

Electrochemical Oxidation of Trifluoroacetic Acid in an Organic Medium. II. In Presence of Propionic Acid[1]

ROGER N. RENAUD AND DONALD E. SULLIVAN[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received September 5, 1972

Trifluoropropane could not be prepared by the "crossed" Kolbe reaction from a mixture of trifluoroacetic acid and propionic acid. Instead, a mixture consisting of 3,3,3-trifluoropropene, 1,2-bis(trifluoromethyl)ethane, 1,1,2-tris(trifluoromethyl)ethane, and 1,2,4-tris(trifluoromethyl)butane was obtained. The probable mechanism for the reaction is discussed.

Le trifluoropropane n'a pu être synthétisé par la réaction de Kolbe à partir d'un mélange d'acide trifluoroacétique et d'acide propionique. Au lieu du trifluoropropane, le trifluoro-3,3,3-propène, le bis-(trifluorométhyle)-1,2-éthane, le tris(trifluorométhyle)-1,1,2-éthane, et le tris(trifluorométhyle)-1,2,4-butane furent obtenus. Le mécanisme probable de la reaction est démontré.

Introduction

In the first part of this series (1), the preparation of deuterio-trifluoroethane and deuteriopentafluoropropane by the "crossed" Kolbe reaction of a mixture of the corresponding fluoroacids and acetic-d_3 acid was described. The series was continued using propionic acid instead of acetic acid in order to synthesize trifluoropropane.

It is known that the electro-oxidation of propionic acid anions gives ethane, ethylene, and, under certain conditions, butane (2). It is also reported in the literature that the electrolysis of a mixture of acetic acid and propionic acid gives some propane (3). Therefore, a series of electrolyses was carried out in order to optimize the experimental conditions for the preparation of trifluoropropane from trifluoroacetic acid and propionic acid. The results are shown in Table 1.

At high concentrations of sodium propionate (3) (run 1) or at high temperature (run 2), butane and esters were obtained, while at low current densities (run 3), practically no gaseous products were formed. However, under the conditions shown for run 4, a liquid with a low vapor pressure at −130 °C was obtained, which contained practically no butane, but consisted of a mixture of 3,3,3-trifluoropropene, 1,2-bis(trifluoromethyl)ethane, 1,1,2-tris(trifluoromethyl) ethane, and 1,2,4-tris(trifluoromethyl)butane as the major products.

[2]NRCC Summer Student 1971–1972.

Experimental

In run 4, a solution of trifluoroacetic acid (13.5 g) in water (25 ml) was added at a rate of one drop per 10 s to a solution of propionic acid (125 ml) and sodium propionate (15.7 g) in water (250 ml) at 20 °C in a 500 ml round-bottom flask equipped with a pressure equilibrated funnel, a thermometer, a reflux condenser, a magnetic bar stirrer, a salt bridge filled with a saturated KCl solution, and two pieces of smooth platinum foil (5 × 2.8 cm), 10 mm apart. The rest of the apparatus was essentially the same as described in the previous paper (1) except that a spiral side-arm trap at −78° was placed before the Stock trap. The electrolysis was carried out at a potential of 2.8 V *vs.* s.c.e. (current density: 0.20 A/cm^2) and continued for 1 h after the addition of the trifluoroacetic acid.

The trap in liquid nitrogen was attached to a vacuum line and the high vapor pressure fraction at −130 °C was discarded. The low vapor pressure residue proved on analysis by v.p.c. and mass spectrometry to be nearly pure 3,3,3-trifluoropropene when compared with an authentic sample. The yield was 23.7% (2.7 g).

The liquid collected in the trap at −78 °C (3.5 ml) was washed with 50 ml of a 20% sodium hydroxide solution at room temperature for 12 h under stirring, in a flask equipped with a Dry-Ice cold-finger, to remove any esters present. The supernatant oil (≈2.6 ml) was collected on the vacuum line, dried over $MgSO_4$, and fractionally distilled at atmospheric pressure through a semi-micro distilling column. Each fraction was analyzed by mass spectrometry, v.p.c., and elemental analysis.

The first fraction (b.p. ≈25 °C) was 1,2-bis(trifluoromethyl)ethane (1 g; yield 10%) identified by comparison with an authentic sample (4).

The second fraction (b.p. 52–53 °C) was 1,1,2-tris(trifluoromethyl)ethane (1.3 g; yield 14%); mass spectrum: *m/e* 215 $(M - F)^+$ and 195 $(M - HF_2)^+$.

Anal. Calcd. for $C_5H_3F_9$: C, 25.64; H, 1.28. Found: C, 25.47; H, 1.41.

The third fraction (b.p. 92–100 °C) and the residue (0.9 g; yield 8.7%) were most likely 1,2,4-tris(trifluoro-

Discussion

Goldschmidt *et al.* (5) identified a trace of butene-1, as its dibromoderivative, from the electrolysis of propionic acid, and postulated the mechanism depicted in Scheme 1 for its formation.

Therefore, in the presence of trifluoromethyl radicals, the formation of α-trifluoromethylpropionic acid is expected. This acid could be the precursor of trifluoropropene by oxidative decarboxylation followed by elimination or disproportionation. However, when the reaction was done with α,α-dideuteriopropionic acid, a 42/58 mixture of mono- and dideuterio-trifluoropropene was obtained, a result not explicable by the above mechanism. The result could be explained, however, by an attack of a trifluoromethyl radical on adsorbed ethylene which is always formed during the electrolysis of propionic acid. However, in no instance in the literature is it mentioned that ethylene functions as an adsorbed radical acceptor. Dienes and substituted ethylenes are generally good radical acceptors (6–11), to produce mainly the adjacent methyl acetoxy derivatives in acetic acid. The mechanism for these reactions is further complicated by the fact that the half-wave potentials of these olefinic compounds are all in the same range as the potential normally used for the Kolbe reaction. According to Fleischmann and Pletcher (12), the half-wave potential of ethylene is 3.3 V *vs.* s.c.e., a potential much higher than the potential used in this work. Therefore, ethylene can only react as a radical acceptor. To verify this statement, ethylene gas was bubbled between the two electrodes in a methanolic solution of sodium methylate to which trifluoroacetic acid was added. The products of this reaction were the same as when the reaction was done with propionic acid. No condensation products were obtained in an aqueous solution, probably due to the low solubility of ethylene in water. The electrolysis of acetic acid in the presence of ethylene gave no condensation products in a methanolic solution.

The fact that the electrolysis of propionic acid in the presence of acetic acid gives propane (3) and in the presence of trifluoroacetic acid, trifluoropropene, seems to follow the general trend of the relative reactivities of a methyl radical and a trifluoromethyl radical towards an ethyl radical and an ethylene molecule in the gas phase (13, 14) or in solution (15). However, it could be erroneous to compare free-radical reactions and adsorbed radical reactions. Moreover, the complete absence of trifluoropropane formation at

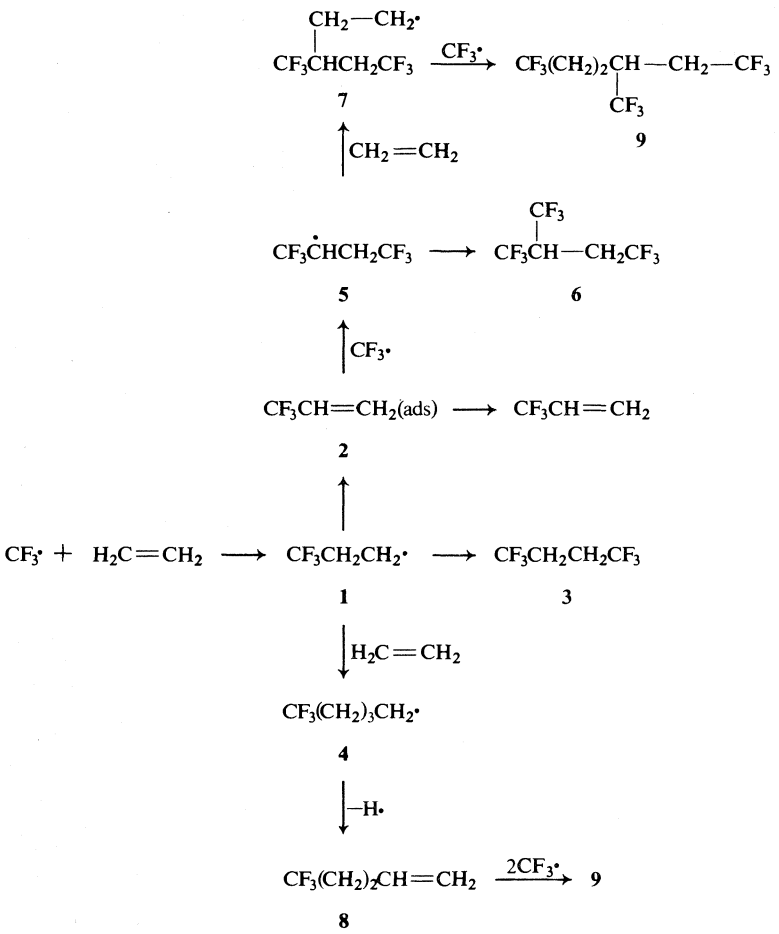

SCHEME 2

high ethyl radical concentration in the presence of trifluoromethyl radicals (Table 1, run 1) and the formation of polytrifluoromethylated compounds (run 4), a result which has no parallel in free-radical reactions, seems to indicate that an orientation effect and a strong adsorption effect of the fluorinated radicals at the anode surface might play an important role in the formation of the products observed. Orientation effects at the electrode surface were used by many authors to explain their observations in anodic (16–20) and in cathodic (21–23) processes. Even though no definite evidence has as yet been presented to support the control of product formation by the electrode surface, it often does point in this direction. More work is in progress in order to bring support to these effects on the course of the reaction.

It was found that at high propionate anion concentration (Table 1, run 1), butane was the major product, while at low anion concentration (run 4), the major product was trifluoropropene. At high anion concentration, the concentration of ethyl radicals at the surface of the anode, at any given time, is high and, consequently, the possibility of two radicals combining is also high. On the other hand, at low anion concentration, the chances of an isolated ethyl radical combining with another one are tremendously diminished and, therefore, the ethyl radical can lose a hydrogen radical to form ethylene. As the ethylene concentration in the medium increases, the formation of trifluoropropene also increases.

Assuming that the reasoning above is correct, then the mechanism for the formation of the other compounds isolated from the reaction can be illustrated as shown in Scheme 2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The adsorbed trifluoropropyl radical, **1**, can either lose a hydrogen radical to give an adsorbed trifluoropropene molecule, **2**, or have a long lifetime and react with another trifluoromethyl radical, which is kept in low concentration, to form 1,2-bis(trifluoromethyl)ethane (**3**), or react with another ethylene molecule to form trifluoropentyl radical, **4**. Compound **2** can either desorb or react with a trifluoromethyl radical to form 1,2-bis(trifluoromethyl)ethyl radical, **5**. 1,1,2-Tris(trifluoromethyl)ethane (**6**) can result from **5**. Two routes are possible for the formation of compound **9**. The first is via radical **5** by consecutive reactions with an ethylene molecule and a trifluoromethyl radical to give radical **8** and then **9**. The second route is via radical **4** to form **8** by the loss of a hydrogen radical and then to compound **9** in presence of a trifluoromethyl radical. Even though both routes are possible, the second is doubtful since neither hexafluorohexane nor trifluoropentene were isolated from the reaction mixture.

We are grateful to Dr. K. O. Kutschke for helpful discussions.

Robinson (1) in 1965 reported some p.m.r. data for adrenochrome (compound **1**, Table 1) which had previously been assigned a zwitterionic mesomeric structure by Harley-Mason (2). The spectrum was recorded in DMSO-d_6 solution and resonances at 5.47 and 6.50 δ were assigned to the hydrogens at C-4 and -7. However in a personal communication to one of us (R. A. Heacock) in 1966, Dr. Robinson stated that the assignments for these hydrogens should have been reversed. Since his original paper (1) no further p.m.r. data on adrenochrome or related aminochromes have been reported. To fill this gap in the literature we have recorded the p.m.r. spectra of some aminochromes and aminochrome monosemicarbazones (see structures listed in Table 1) in DMSO-d_6 at 60 MHz. All p.m.r. parameters in Table 2 were obtained by comparing the experimental spectra with those simulated with the Varian Spectro System 100. Because the spectra were comparatively simple it was not considered necessary to check the results at a second radiofrequency.

In all of the compounds examined, except **2**, **2***a*, and **4**, two resonances with chemical shifts characteristic of "aromatic" type hydrogens (3) were observed for H-4 and -7. Moreover H-7 could be assigned to the resonance at higher field (5.30–5.47 δ) because the low field signal for H-4 (6.42–6.80 δ) was absent from the spectra of **2** and **2***a* which are of known structure with $R_4 = CH_3$ (4). It follows, therefore, that the iodine atom in **4** must be located at C-7 since a characteristic resonance was observed for H-4 (6.56 δ) whereas no signal at higher field was observed for H-7. This work therefore confirms that the iodine atom in iodoaminochromes is at C-7 (5) rather than at C-2 as was originally suggested (6).

The "benzylic" type methylene hydrogens at C-3 in **8** were readily assigned (3) to the high field multiplet at 3.00 δ whereas the corresponding hydrogens at C-2, which also bears a nitrogen atom, occurred as expected at lower field at 3.80 δ (3). For those compounds in which there is an hydroxyl or methoxyl group at position 3, the hydrogen at C-3 exhibited a characteristic downfield shift appearing in the range 4.50–5.00 δ. On the other hand, replacement of one of the methylene hydrogens at C-2 with a methyl substituent as in **7** did not appreciably affect the chemical shift of the hydrogen at C-2 which appeared as expected at 3.76 δ. The remaining signals in all the spectra were readily identified on the basis of their chemical shifts, multiplicities, and/or intensities, or their ease of replacement with deuterium. Assignments were confirmed by decoupling experiments.

Compound **7** was synthesized from 1-(3,4-dihydroxyphenyl)-2-aminopropan-1-ol, the side chain of which has an *erythro* configuration, thus requiring that the methyl and hydroxyl substituents on C-2 and -3, and therefore H-2a

and -3a, have a *trans* relationship to one another. This follows because the experimental conditions for cyclization preclude epimerization at the two asymmetric carbons (see Experimental). From Table 2 it can be seen that, apart from the typical geminal coupling constants (7, 8), the spin–spin couplings between hydrogens on C-2 and -3 fall either in the range 1.8–4.0 or 6.2–7.0 Hz. The data for **7**, ($J_{trans} = J_{2a,3a} = 3.6$ Hz), together with known trends in the behavior of spin–spin couplings in other similar five-member ring systems (8), enabled the lower range of values discussed above to be assigned to *trans*, and the higher range of values to *cis*, spin–spin couplings for the compounds listed. It is also worth noting that for those compounds with a methylene group at position 2, the hydrogen (H-2a) *cis* to R_3 = OH or OCH_3, occurred at highest field and was *trans* coupled to H-3a. In the case of compound **8** which bore no electronegative substituent at C-3 the *trans* ($J_{2a,3a} = J_{2b,3b} = 4.0$ Hz) and *cis* ($J_{2a,3b} = J_{2b,3a} = 7.0$ Hz) couplings were the largest observed throughout the series of compounds investigated, as would be expected (8).

For those compounds in which R_4 = H long-range coupling ($1.5 \leqslant J_{3,4} \leqslant 2.3$ Hz) was observed between this hydrogen and all hydrogens directly bonded to C-3. When $R_4 = CH_3$, long-range coupling (8) was observed between H-3a and these methyl hydrogens in **2** but surprisingly not in **2***a*. The presence of long-range coupling between one of the aromatic hydrogens (H-4) and H-3a in the iodoaminochrome **4** is of course further evidence that the iodine atom must be attached to C-7 in this compound.

Experimental

Aminochromes

Methods described in the literature were used to prepare adrenochrome (9), adrenochrome methyl ether (10), 7-iodoadrenochrome methyl ether (10), 4-methyladrenochrome (4), 1-isopropylnoradrenochrome (10), noradrenochrome (11), and epinochrome (12).

2-*Methylnoradrenochrome* was prepared in a manner analogous to that for noradrenochrome (11). The free base 1-(3,4-dihydroxyphenyl)-2-aminopropan-1-ol (3,4-dihydroxynorephedrine; 2 g), prepared according to one of the standard procedures (*cf.* ref. 4) from the corresponding hydrochloride, was treated with silver oxide (8.3 g) in methanol (200 ml) for 8 min and the reaction mixture subsequently filtered through anhydrous sodium sulfate and then Dowex-1 × 8 (Cl^-). Crystallization was initiated by adding ethyl acetate (250 ml) and reducing the volume to ≈30 ml at <25° *in vacuo* followed by the further addition of ethyl acetate (30 ml) and once again reducing the volume of the solution to ≈25 ml. 2-Methylnoradrenochrome (515 mg; 26% yield) was obtained as dark red microcrystals which completely decomposed without melting by 115°; λ_{max} (H_2O) nm (ε): 216 (26 800), 295 (9600), 488 (3690); ν_{max} (Nujol): 3235, 3210, 1667, 1617, 1582, 1543 cm^{-1}.

Reactions of Thiyl Radicals. X. Photolysis of Ethyl Sulfide Vapor[1]

CONRAD S. SMITH AND ARTHUR R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

Received September 22, 1972

The photolysis of ethyl sulfide vapor at 2537 Å has been investigated as a function of substrate and CF_4 pressure, time, and temperature. Reaction products with quantum yields in parentheses are ethyl disulfide (0.178), ethane (0.138), butane (0.086), ethanethiol (0.096), 4-methyl-3-thiahexane (0.034) and 4-methyl-3,5-dithiaheptane.

Ethyl and ethylthiyl radicals are formed in the primary process and the product yields indicate a net primary decomposition quantum yield of 0.48. A reaction mechanism involving subsequent reactions of the primary fragments is proposed and explains the observed products and the observed variation in rates. Excited radicals and hot radical combination products play a minor role in this system, in contrast to the behavior of lower molecular weight sulfides. Secondary photolysis of the disulfide produced and consumption of ethanethiol are important factors in determining the time dependence of reaction rates in this system.

La photolyse de la vapeur de sulfure d'éthyle à 2537 Å a été étudiée en fonction de la nature du substrat et de la pression de CF_4 ainsi que du temps et de la température. Les produits de la réaction, dont les rendements quantiques sont donnés entre parenthèses, sont les suivants, disulfure d'éthyle (0.178) éthane (0.138), butane (0.086) éthanethiol (0.096), méthyl-4 thia-3 hexane (0.034), et méthyl-4 dithia-3,5 heptane.

Les radicaux éthyle et éthylthiyle sont formés dans la première phase et les rendements de produits indiquent fort nettement un rendement quantique de la décomposition primaire égal à 0.48. Un mécanisme réactionnel impliquant des réactions subséquentes des fragments primaires est proposé: celui-ci permet d'ailleurs d'expliquer la formation des produits observés ainsi que les fluctuations observées dans les vitesses de formation. Les radicaux excités et les produits de combinaison de radicaux chauds jouent, en réalité, un rôle négligeable dans ce système, ce qui va à l'encontre du comportement des sulfures ayant des poids moléculaires plus bas. La photolyse secondaire du composé disulfuré obtenue ainsi que la consommation d'éthanethiol sont des facteurs importants pour déterminer dans ce système la dépendance existant entre le temps et les vitesses de la réaction. [Traduit par le journal]

Can. J. Chem., **51**, 780 (1973)

Introduction

As part of a continuing series of investigations of the photochemical kinetics of sulfur compounds that are thiyl radical sources we have studied and report on here the vapor phase photolysis of $C_2H_5SC_2H_5$ at 254 nm. In comparison with the lower molecular weight sulfides, this substrate provides a relatively labile source of abstractable hydrogen atoms. In addition, the thiyl radical combination product $C_2H_5SSC_2H_5$ would be expected to be relatively stable to the unimolecular decomposition that would regenerate ethylthiyl radicals.

The photolysis of ethyl sulfide vapor has not been investigated previously. Methyl sulfide vapor has been studied in direct photolysis (1, 2) and in mercury photosensitization (3, 4). The direct photolysis of methyl ethyl sulfide has also been investigated (5). In each case the products of the reaction can be rationalized on the basis of a C—S bond cleavage in the primary process, followed by reactions of the alkyl and thiyl radicals formed thereby. It has been shown (4) that the thiyl radical disproportionation:combination ratio determined from thiol and disulfide yields is pressure sensitive and that only at high total pressures are the observed yields of these products indicative of the actual relative contribution of the two processes.

Experimental

The photolyses were conducted in a mercury-free system constructed of stainless steel and Pyrex glass. The vacuum line could be heated to 75 °C to facilitate the transfer of relatively non-volatile materials. The lamp was a Hanovia 30620 medium pressure mercury arc fitted with a Vycor 7910 filter. The filter, along with the absorption characteristics of the substrate (6) limited the effective wavelengths to between 2300 and 2600 Å; principally, the reversed Hg-line at 2537 Å. The reaction cell was a quartz

cylinder, 4.4 cm o.d. by 20 cm long fitted with a demountable furnace.

Ethyl sulfide (Eastman) and diethyl ketone (B.D.H.) were freed from impurities by preparative scale gas chromatography. In some experiments, A.P.I. standard sample ethyl sulfide, free from detectable impurities, was used without further purification. Carbon tetrafluoride (Matheson) was degassed and fractionated at low temperature in the line before use.

Reaction products were identified by comparison of g.c. retention times, confirmed by mass spectrometric analysis of the g.c. effluent.

For experiments involving the photolysis of the substrate alone, the reaction products and undecomposed substrate were fractionated by low temperature distillation at −160.5 °C. Products non-condensable at this temperature, C_2H_4 and C_2H_6, were analyzed on a 10 ft Poropac-Q column at 25 °C, while the substrate and other products were eluted with temperature programming on a 6 ft tricresyl phosphate column. In the experiments with CF_4 present, the addend was removed at −160.5 °C along with the C_2 fraction before analysis.

The absorbed intensity for the actinometry experiments was determined utilizing the photolysis of 12 Torr diethyl ketone at 170 °C, assuming a quantum yield of unity for CO production (7), with a Hanovia model 688A45 low pressure mercury lamp. The percent absorption at 2537 Å by both the actinometer, 19.1%, and the substrate, 18.4% at P = 30 Torr, were determined in the reaction cell using a Zeiss Model PMQ-II spectrophotometer. The emission spectrum of the lamp was determined and corrections made for the relative weak emission lines between 2655 and 3132 Å that are absorbed by the ketone but not by the sulfide. The carbon monoxide formed in the ketone photolysis was removed through a liquid nitrogen trap to an auxiliary system and determined in a gas burette. The absorbed light intensity was 0.134 μ einsteins min^{-1}. A comparison of the yields of products from the photolysis of 30 Torr sulfide in the actinometry experiments and in the experiments using the medium pressure Hg lamp indicated that the effective intensity of the latter light source is within 10% of the low pressure lamp. Thus the quantum yield determinations here were at effectively the same intensity as the other experiments.

Results

The photolysis of ethyl sulfide vapor at 30 °C and 20 Torr pressure gives the following reaction products listed in decreasing order of importance: C_2H_6, $C_2H_5SSC_2H_5$, C_4H_{10}, C_2H_4, C_2H_5SH, and 4-methyl-3-thiahexane (MTH), $C_2H_5CH(CH_3)$-SC_2H_5. In addition, a product too non-volatile to permit routine quantitative analysis was tentatively identified as 4-methyl-3,5-dithiaheptane (MDTH), $C_2H_5SC_2H_4SC_2H_5$. Thioacetaldehyde, if formed, would not have been detected.

A mass balance in carbon and sulfur may be estimated on the following basis. A rate for carbon-containing products can be determined from the observed product rates of products analyzed quantitatively via eq. 1. The analogous

$$[1]\quad R_c = 2R_{C_2H_4} + 2R_{C_2H_6} + 4R_{C_4H_{10}} + 2R_{C_2H_5SH} + 4R_{C_2H_5SSC_2H_5} + 6R_{MTH}$$

rate expression for sulfur-containing products is given by eq. 2. From the stoichiometry of the

$$[2]\quad R_s = R_{C_2H_5SH} + R_{MTH} + 2R_{C_2H_5SSC_2H_5}$$

$C_2H_5SC_2H_5$ decomposition R_c should be identical to $4R_s$. Although this kind of calculation is a valuable tool with respect to product accountability, it is insensitive to products with a c/s ratio of 4. The most likely such product would be the dimer of the "substrate radical", $CH_3\dot{C}HSC_2H_5$. A non-volatile product of that type and its isomers would not have been detected by the analytical techniques used here. If eqs. 1 and 2 are modified to include R_{MDTH}, the net effect would be the addition of a $2R_{MDTH}$ term to the right hand side of $R_c = 4R_s$. It is to be expected therefore that there would be a deficiency in sulfur products when the calculation excludes the MDTH whose rates were not determined.

Equations 1 and 2 do not include the possible yield of thioacetaldehyde that would result from the disproportionation between C_2H_5S radicals or between C_2H_5 and C_2H_5S radicals. The effect of incorporating this C_2H_4S yield would be to increase the $4R_s$ term more than R_c. Thus an apparent sulfur product deficiency indicated by eqs. 1 and 2 as written may be the result of not taking these disproportionation processes into account. However, the appearance of MTH and MDTH as products is evidence that abstraction reactions do occur in this system, since both products originate with the $C_2H_5S\dot{C}HCH_3$ radical. Thus at least some of the observed C_2H_6 and C_2H_5SH must be formed via H-atom abstraction from the substrate.

Figures 1 and 2 show the variation in rate of product formation as a function of ethyl sulfide pressure for an exposure time of 60 min. All rates show a continuous increase, indicating that absorption of the incident radiation is incomplete up to 50 Torr, the maximum pressure that can be examined at room temperature. This is consistent with the absorption measurements made in connection with the actinometry experiments.

Stoichiometric calculations utilizing eqs. 1 and 2 give $R_c = 0.133 \pm 0.004$ and $4R_s = 0.126 \pm 0.004$ μmol min^{-1} at 20 Torr sulfide pressure while at $P_{C_2H_5SC_2H_5} = 40$ Torr, $R_c = 0.220 \pm 0.007$ and $4R_s = 0.192 \pm 0.006$ μmol min^{-1}. The fact that the two rates are the same within experi-

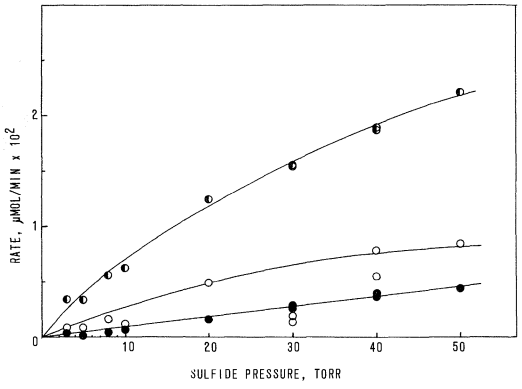

FIG. 1. Variation in rate of formation of ethyl disulfide, ◐; ethanethiol, ○; and MTH, ●, as a function of substrate pressure for the photolysis of ethyl sulfide at an exposure time of 60 min.

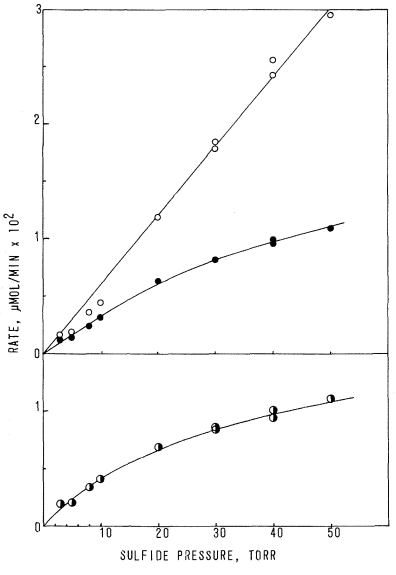

FIG. 2. Variation in rate of formation of ethane, ○; ethylene, ●; and butane, ◑; as a function of substrate pressure for the photolysis of ethyl sulfide at an exposure time of 60 min.

mental error is likely fortuitous since some sulfur deficiency should result from the exclusion of the MDTH yields, but is evidence against a very large contribution from C_2H_5S disproportionation. The sulfur product deficiency pointed to by the calculations from the rates at 40 Torr will be due in part to the MDTH yield. Because of its origin in abstraction from the substrate by primary radicals, the relative importance of this product would be expected to increase with substrate pressure.

The rate of consumption of the substrate is given by $R_c/4$, where R_c is defined by eq. 1. At an ethyl sulfide pressure of 50 Torr, the data in Figs. 1 and 2 indicate that for 60 min exposure there is 0.6% decomposition.

The variation in rates with exposure time for the photolysis of 20 Torr ethyl sulfide is shown in Fig. 3. The rates for C_2H_4 and MTH are time independent within experimental error. Ethyl disulfide and ethanethiol show rates that pass through a shallow maximum and decline at the longer exposure times. The C_2H_6 rate exhibits a pronounced increase while there is a concomitant decline in $R_{C_4H_{10}}$. The total rate of C_2H_5 radical consumption, however, calculated from eq. 3,

$$[3] \quad R_{-C_2H_5} = R_{C_2H_6} + R_{C_2H_4} + 2R_{C_4H_{10}} + R_{MTH}$$

remains essentially constant at $3.2 \pm 0.2 \times 10^{-2}$ μmol min^{-1} between 10 and 240 min.

The values, in μmol min^{-1} calculated from eq. 1 at 45 and 240 min for R_c are, respectively 0.124 ± 0.004 and 0.116 ± 0.004, while the corresponding $4R_s$ values computed using eq. 2 are 0.114 ± 0.004 and 0.099 ± 0.003. Although part of the increased S-product deficiency at longer times would be expected because of their greater susceptibility to secondary decomposition, the influence of MDTH formation is also significant. The effect of exposure time on the relative MTH and MDTH yields was estimated[2] to illustrate this point. For 60 min exposure of 20 Torr sulfide R_{MDTH}/R_{MTH} was 1.3 ± 0.2 while in an experiment corresponding to 480 min exposure, this ratio was 1.7 ± 0.1. If a $2R_{MDTH}$ term (see above) is included in eq. 2, the values of $4R_s$ at 45 and 240 min (assuming $R_{MDTH}/R_{MTH} = 1.5$) become 0.119 ± 0.004 and 0.104 ± 0.004 μmol min^{-1}, respectively. Thus there is a mass balance within experimental error at the short times while a sulfur deficiency, albeit somewhat reduced, remains in the observed rates at 240 min.

Table 1 lists the results of an investigation of

[2]The relative yields were approximated by comparing the g.c. peak areas for the two products assuming the same molar response. The longer experiment was carried out at a somewhat higher intensity and corresponded, on a percent decomposition basis, to 480 min exposure in the series described in Fig. 3. The retention time of the MDTH peak, even with temperature programming, was such that peak areas could not be determined accurately in the routine analysis of yields from experiments with exposure times up to 240 min where MDTH yields are on the order of 0.03 μmol or less.

100	8.3	1.5	3.5	5.7
165	8.4	1.8	4.6	5.2
250	8.4	1.7	4.6	5.3
500	7.8	1.6	5.3	5.2

*Exposure time = 60 min; T = 25 °C.

the effect of added CF_4 on the photolysis of 20 Torr $C_2H_5SC_2H_5$ for 60 min. As in previous investigations of addend effect with methyl sulfide (2) and methyl ethyl sulfide (5), there is some scatter in the observed rates but apart from a possible small increase in thiol yields, the rates appear to be essentially unaffected by inert addend.

A series of experiments was carried out to determine the effect of temperature on the reaction. Twenty Torr $C_2H_5SC_2H_5$ measured at 30 °C was photolyzed for 25 min at temperatures from 30–92.5 °C. The results are shown in Figs. 4 and 5. Application of eqs. 1 and 2 to the data at 80 °C gives R_c = 0.151 and $4R_s$ = 0.135 μmol min^{-1}. Comparison of these values with R_c and $4R_s$ for 20 Torr substrate at 30 °C indicates an apparent small increase in overall decomposition of 11% for carbon-containing products and 7% for S-compounds. Thus the principal effect of temperature is a redistribution of the products. Three products have rates that increase significantly with temperature, C_2H_6, C_2H_5SH, and

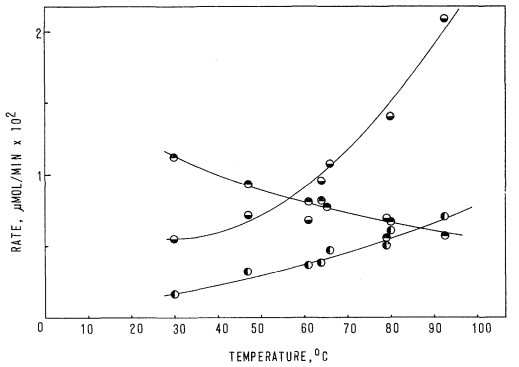

FIG. 4. Variation in rate of formation of ethanethiol, ◒; MTH, ◐; and ethyl disulfide, ◓; as a function of temperature for the photolysis of 20 Torr (measured at 30 °C) ethyl sulfide for 25 min.

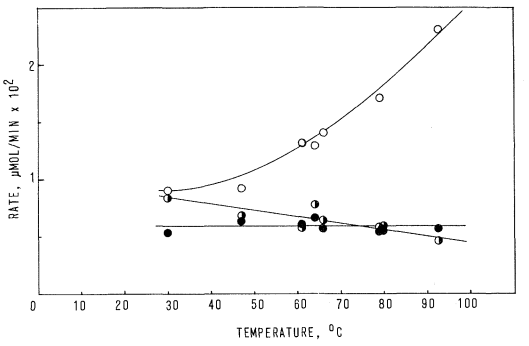

FIG. 5. Variation in the rate of formation of ethane, ○; ethylene, ●; and butane, ◑; as a function of temperature for the photolysis of 20 Torr (measured at 30 °C) ethyl sulfide for 25 min.

MTH. Arrhenius plots of $R_{C_2H_6}/R^{\frac{1}{2}}_{C_4H_{10}}$ and $R_{C_2H_5SH}/R^{\frac{1}{2}}_{C_2H_5SSC_2H_5}$ are linear between 30 and 80 °C (values at 92.5 being slightly higher than indicated by an extrapolation of the graph) and give apparent activation energies of 3.4 and 5.2 kcal mol^{-1} for C_2H_6 and C_2H_5SH, respectively. MTH is a secondary product and the variation with temperature of the concentration of radicals involved in its formation cannot be eliminated in a simple ratio. However, an Arrhenius plot of the MTH rates indicates an overall apparent activation energy of 5 kcal mol^{-1}.

Finally, utilizing the low pressure mercury lamp, the quantum yields of products were determined by photolysing 30 Torr ethyl sulfide for 30 min. The values are listed in Table 2. Comparison of the product ratios in this series with the data for 30 Torr at an exposure time of 60 min (Figs. 1 and 2) or 20 Torr at t = 30 min (Fig. 3)

TABLE 2. Quantum yields in the photolysis of ethyl sulfide at 2537 Å

Product	Φ (mol einstein^{-1})
C_2H_4	0.086
C_2H_6	0.138
C_4H_{10}	0.110
C_2H_5SH	0.096
MTH	0.034
$C_2H_5SSC_2H_5$	0.178

shows that there is no significant difference in product distribution between the two lamps. The primary decomposition quantum yield, Φ_p, can be computed from the yields of products that result from ethyl radicals using eq. 4, which gives

$$[4] \quad \Phi_p = \Phi_{C_2H_6} + \Phi_{C_2H_4} + 2\Phi_{C_4H_{10}} + \Phi_{MTH}$$

a value of 0.48, or from C_2H_5S radical products, via eq. 5. The thiol and disulfide yields alone

$$[5] \quad \Phi_p = \Phi_{C_2H_5SH} + \Phi_{C_2H_5SSC_2H_5} + \Phi_{MDTH}$$

give $\Phi_p = 0.43$ indicating a value of Φ_{MDTH} of *ca.* 0.05, consistent with the estimated value of 1.3 for R_{MDTH}/R_{MTH} and Φ_{MTH} (observed) of 0.034.

Discussion

The kind of reaction products observed in this system and their similarity to those that have been found previously to characterize the photodecomposition of other sulfides points to C—S bond cleavage in the primary process, reaction 6.

$$[6] \quad C_2H_5SC_2H_5 + h\nu \rightarrow C_2H_5S + C_2H_5$$

The fact that product yields are essentially unaffected by inert addend pressure rules out the possibility of the formation of a long-lived excited sulfide molecule in the primary process.

In attempting to explain product formation on the basis of subsequent reactions of the primary radicals, particularly with respect to the relative contributions of the several possibilities, a number of factors must be considered. As will become apparent, the lack of data on the kinetics of C_2H_5S radical reactions gives rise to some uncertainties in the interpretation of the results. The kinetic data that can be extracted from this study, however, provide useful information on the kinetics of this species, particularly indicating that its behavior is significantly different from that of CH_3S.

As with the lower molecular weight sulfides, there will be energy carry-over in the primary process. The S—C bond strength in $C_2H_5SC_2H_5$ is 71 kcal mol^{-1} (8). Therefore at 2537 Å, there is a 42 kcal mol^{-1} energy excess in reaction 6. If the carry-over is inversely proportional to mass, then $E_{C_2H_5} = 28$ and $E_{C_2H_5S} = 13$ kcal mol^{-1}. However, because of the larger number of degrees of freedom in the primary fragments, their excess energy, whether or not apportioned in that way, would be expected to be less important than in CH_3SCH_3.

The presence of relatively large amounts of thiol as a product in this system gives rise to the possibility, not a factor in CH_3SCH_3 or $C_2H_5SCH_3$ photolyses, that because of the lability of the sulfhydryl hydrogen the abstraction of hydrogen atoms from this molecule may be an important reaction. Radical attack on the S—H bond would be expected to have an appreciably lower activation energy than attack on the C—H bonds in the substrate.

Secondary photolysis of the ethyl disulfide produced would also be important. The absorption measurements carried out for the actinometry calculations give $\varepsilon_{C_2H_5SC_2H_5} = 5.3$ l/mol cm at 2537 Å while for $C_2H_5SSC_2H_5$, the molar extinction coefficient is 315 (6). Thus, for example, in the photolysis of 20 Torr ethyl sulfide, after 240 min exposure 25% of the absorbance is due to the 2.5 μmol of disulfide present.

On the basis of these considerations, the sequence of reactions depicted by eqs. 7–19 is suggested for the ethyl sulfide photolysis. The primary process, reaction 6, will be followed by [7], etc.

$$[7] \quad 2C_2H_5 \rightarrow C_2H_4 + C_2H_6$$

$$[8] \quad 2C_2H_5 \rightarrow C_4H_{10}$$

$$[9] \quad 2C_2H_5S \rightarrow C_2H_5SH + C_2H_4S$$

$$[10] \quad 2C_2H_5S \rightarrow C_2H_5SSC_2H_5$$

$$[11] \quad C_2H_5 + C_2H_5S \rightarrow C_2H_5SC_2H_5$$

$$[12] \quad C_2H_5 + C_2H_5S \rightarrow C_2H_4 + C_2H_5SH$$

$$[13] \quad C_2H_5 + C_2H_5S \rightarrow C_2H_6 + C_2H_4S$$

$$[14] \quad C_2H_5 + C_2H_5SC_2H_5 \rightarrow C_2H_6 + C_2H_5S\dot{C}HCH_3$$

$$[15] \quad C_2H_5S + C_2H_5SC_2H_5 \rightarrow C_2H_5SH + C_2H_5S\dot{C}HCH_3$$

$$[16] \quad C_2H_5 + C_2H_5S\dot{C}HCH_3 \rightarrow MTH$$

$$[17] \quad C_2H_5S + C_2H_5S\dot{C}HCH_3 \rightarrow MDTH$$

$$[18] \quad C_2H_5 + C_2H_5SH \rightarrow C_2H_6 + C_2H_5S$$

$$[19] \quad C_2H_5SC_2H_5 + h\nu \rightarrow 2C_2H_5S$$

The initial rates obtainable from Fig. 3 by extrapolation to zero exposure time are not influenced by reactions 18 and 19. Although the results at short exposure times are subjected to relatively large experimental errors because of the small amounts of products involved, some limiting values can be established that indicate the observed rates are consistent with the reactions proposed and with the kinetic information about these processes available from other systems.

The rate constant ratio $k_9/k_{10} = 0.07$, determined in the photolysis of methyl ethyl sulfide vapor (5) gives the initial rate of ethanethiol formation in reaction 9 from the observed value of $R^0_{C_2H_5SSC_2H_5} = 1.0 \times 10^{-2}$ μmol min^{-1} as 0.07 via eq. 20, where here, and in subsequent equa-

$$[20] \qquad R_9^0 = 0.07 R_{10}^0$$

tions and discussion, rates are quoted in μmol min$^{-1} \times 10^2$. The observed $R^0_{C_2H_5SH}$ value is 0.35 and thus from equation 21, the combined

$$[21] \qquad R^0_{C_2H_5SH} = R_9^0 + R_{12}^0 + R_{15}^0$$

rate of thiol production in reactions 12 and 15 is 0.28. This represents a *maximum* value for R_{12}^0, were reaction 15 to make a negligible contribution to C_2H_5SH formation. Proceeding on that assumption, since the initial ethylene rate can be expressed as in eq. 22, and $R^0_{C_2H_4} = 0.55$, the

$$[22] \qquad R^0_{C_2H_4} = R_7^0 + R_{12}^0$$

minimum value of R_7^0 is therefore 0.27. This value together with the observed $R^0_{C_4H_{10}}$ value of 1.05 gives $k_7/k_8 \geq 0.26$. Values of 0.1 (7), 0.2 (9), and 0.14 (10, 11) have been reported for this disproportionation:combination ratio of ethyl radicals. The fact that the minimum value estimated here from the stoichiometry is larger may be evidence that either the C_2H_5 radicals are "hot" or that C_2H_4 is formed in an additional primary process. Other aspects of the data, however, as indicated below, can be interpreted in terms of thermalized ethyl radicals and ethylene production solely via radical–radical reactions.

For ethane, the total initial yield is given by eq. 23. Figure 3 shows the initial rate to be 0.50,

$$[23] \qquad R^0_{C_2H_6} = R_7^0 + R_{13}^0 + R_{14}^0$$

and thus, using the R_7^0 minimum value of 0.27, $(R_{13}^0 + R_{14}^0) \leq 0.23$. On the basis of the known small contribution of the disproportionation mode to the total rate of thiyl radical reactions of the radical–radical type that has been rationalized principally on the basis of the tendency of organosulfur compounds not to undergo reactions in which C—S bonds are converted to C=S bonds (4, 12), it would be expected that R_{13}/R_{14} is quite minute and therefore that the 0.23 likely represents essentially the maximum value of R_{14}.

To complete the stoichiometric analysis, the rate of $C_2H_5S\dot{C}HCH_3$ radical formation is required. The very small yield of MTH and, more particularly of MDTH, precludes measurement of their rates at short exposure times. The rate for the dimer of the substrate radical, which product is likely formed to some extent, would also be required. Thus, although the data available do not permit definitive calculations, they nevertheless provide evidence for the main features of the proposed mechanism.

The observed variation in reaction rates that occurs within the framework of a constant calculated amount of decomposition as the exposure time is lengthened is evidence that the redistribution of reaction products arises from secondary reactions, of which processes 18 and 19 would be the most important. The reaction analogous to [18] involving C_2H_5S radicals amounts to an exchange process that would have no net effect on observed rates.

As the concentration of thiol increases in the system with time, reaction 18 will become progressively a more important source of ethane. Increased importance of this process has two effects. The rates of reactions 7 and 8 will decrease; the observed decline in $R_{C_4H_{10}}$ reflecting the reduction in the rate of the latter process. The second effect will be to regenerate ethylthiyl radicals whose most important reaction here is recombination forming ethyl disulfide. The secondary photolysis of this product, however, evidently limits the amount of disulfide that can accumulate with the result that $R_{C_2H_5SSC_2H_5}$ rises slightly with time but after longer periods shows a slight decline. The regeneration of thiyl radicals and the resultant increase in their steady state concentration is manifested in several ways. Ethanthiol declines only slightly with time; its consumption in reaction 18 evidently being compensated for by its secondary formation following C_2H_5S reformation from the disulfide photolysis. The relative amount of MDTH compared to MTH is found to increase. Finally, there is evidently an increase in the rate of reaction 12, giving additional ethylene that compensates for the decline in $R_{C_2H_4}$ from process 7, so that no net

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

change in the rate of C_2H_4 production is observed. Both reactions 7 and 12 are influenced by ethyl radical concentration but $R_7 \propto [C_2H_5]^2$ while $R_{12} \propto [C_2H_5]$. The increased sulfur product deficiency observed at the longer exposure times may reflect an increase in the rate of reaction 13, giving unanalyzable thioacetaldehyde, that parallels the rise in R_{12}.

The change in reaction rates with temperature is influenced by the same considerations, except that secondary disulfide photolysis will be essentially a constant factor. Because of the increases in the rate of abstraction processes with temperature, the recombination reaction involving ethylthiyl radicals cannot compete as effectively as at room temperature and the rate of disulfide formation is reduced. As more and more thiol is formed in primary radical–radical reactions, and in process 15 as reflected in the increase in rate for products coming from the $C_2H_5S\dot{C}HCH_3$ radical, its concentration will increase and again, through reaction 18, result in a higher C_2H_5S radical concentration. As with increasing exposure time, the latter alteration leads to an increase in the rate of reaction 12 counteracting the decline in R_7 that results from abstraction by C_2H_5 radicals becoming more important. This combination of effects then gives rise to the observed temperature independence of $R_{C_2H_4}$. Thus the observed rate can be explained on the basis of the interdependence of the proposed radical–radical reactions, but the arguments do not preclude the formation of ethylene and ethanethiol in an additional primary process.

These arguments also imply that some portion of the ethane yield comes from reaction 18 and thus the observed apparent activation energy of C_2H_6 formation represents the net effect of both reactions 14 and 18. Therefore the value of 3.4 kcal mol^{-1} for C_2H_6 does not necessarily indicate an important contribution from abstraction by hot ethyl radicals since the activation energy of reaction 18, even with thermalized radicals, would not be large. For example, Kerr and Trotman-Dickenson (13) report $E_a = 5.2$ kcal mol^{-1} for the abstractive attack of CH_3 radicals from the photolysis of acetone on C_2H_5SH. The observed yields of ethanethiol are less than those originating in the first instance from the radical reactions and process 15 (the former presumably being temperature independent) because of the secondary consumption of C_2H_5SH. If the latter reaction were not occurring, $R_{C_2H_5SH}$ would increase more rapidly with temperature. That would indicate an actual activation energy larger than the 5.2 kcal mol^{-1} observed, a prediction consistent with the suggestion that excess energy of the radicals in this system, although exerting some influence, is not as important as in the case of lower molecular weight sulfides.

The fact that the quantum yields in this system are less than unity may be an indication that some recombination of primary fragments is taking place, as indicated in reaction 11. In addition, the inefficiency of photodecomposition in this system may have the same origin as the more pronounced similar effect observed in methyl sulfide and methyl ethyl sulfide.

Further investigations to determine the rate of ethyl and ethylthiyl radical attack on the substrate will be required to elucidate further the relative importance of some of the processes that contribute to the decomposition. The examination of the triplet mercury sensitized decomposition will also be useful, as it has been shown to be in the case of methyl sulfide (4), in evaluating the role of the various reactions in the mechanism and the efficiency of the primary decomposition. An investigation of the latter system is currently underway in this laboratory.

Nuclear Magnetic Resonance Studies of Solute–Solvent Interactions. Improved Methods of Proton Chemical Shift Determinations for Completely Associated and Unassociated Solutes

R. E. KLINCK[1]

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

Received August 28, 1972

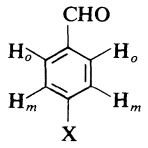
Previous data for the temperature dependence of the proton chemical shifts of two para-substituted benzaldehydes in toluene solution are re-investigated using improved methods for obtaining the proton chemical shifts in the associated and unassociated solutes. The calculations provide ΔH and ΔS values of -1.13 ± 0.07 kcal/mol and -4.0 ± 0.3 e.u., respectively. Attempts to determine the solute–solvent ratio gave inconclusive results.

Des données antérieures concernant l'influence de la température sur les déplacements chimiques des protons de deux benzaldéhydes substitués ont été réexaminées en solution dans le toluène en utilisant des méthodes améliorées pour obtenir les déplacements chimiques des molécules de soluté associées et non-associées. Les calculs ont permis d'évaluer que le ΔH et le ΔS sont respectivement de 1.13 ± 0.07 kcal/mol et -4.0 ± 0.3 u.e. Des essais en vue de déterminer le rapport soluté–solvant ont donné des résultats non concluants. [Traduit par le journal]

Can. J. Chem., **51**, 787 (1973)

Introduction

In a previous paper (1*a*), the thermodynamic parameters governing the postulated association (2) between *p*-substituted benzaldehydes (**1**) and toluene-d_8 were reported. To simplify analysis, it was assumed that the solute and solvent interact in a 1:1 ratio. The main disadvantages



1

in the method of analysis were the determinations of the chemical shifts of the unassociated aldehyde (ν_A) and the complex (ν_C). The present work was undertaken to try out improved methods for the determination of the above parameters as well as to obtain an estimate for the solute–solvent ratio which best fits the data.

Experimental

All experimental data used in this work are those obtained from the previous study (1). Chemical shift values are given in Hz relative to tetramethylsilane (TMS) as internal standard.

[1]Present address: Department of Chemistry, Urbana College, Urbana, Ohio 43078.

Treatment of Experimental Data and Results

For an unknown solute–solvent ratio, the association can be described by the dynamic equilibrium,

[1] aldehyde (A) + x solvent (S) $\rightleftharpoons$ complex (C)

where C is AS_x and x is the number of solvent molecules involved in the complex.[2] Letting p be the fraction of solute complexed at equilibrium, eq. 2 is obtained for the equilibrium con-

$$[2] \quad K = \exp(-\Delta H/RT)\exp(\Delta S/R) = \frac{p}{1-p} \times \left[\frac{1 - xpX_A^0}{X_S^0 - xpX_A^0}\right]^x$$

stant, where ΔH and ΔS are the enthalpy and entropy of formation of the complex, and X_A^0 and X_S^0 are the initial mole fractions of aldehyde and solvent. The fraction p is obtained as previously (1) from the observed proton shift (ν),

[2]To be completely general one should also include the possibility that more than one aldehyde molecule is involved in the complex. This was considered in a more general analysis of the data which provided a best value of one aldehyde molecule per complex molecule. It simplifies the treatment to use this result in the development above. The equations derived are satisfactory for describing all concentrations of solute provided that no self-association of the solute occurs.

such that

$$[3] \qquad p = (\nu - \nu_A)/(\nu_C - \nu_A)$$

A plot of ln K *vs.* $1/T$ should yield a straight line of slope $-\Delta H/R$ and intercept $\Delta S/R$. Note that for a given temperature the value of K must be the same for all concentrations. (An indication that the previous analysis is in need of improvement can be seen from Fig. 1*a*. Only one straight line should be obtained for all concentrations. Comparison with Fig. 1*b* shows the improvement from the present method of analysis.) The unknowns to be determined in eq. 2 are ν_A, ν_C, and x. The determination of these parameters will be discussed in detail for the *N*-methyl protons of *p*-*N*,*N*-dimethylaminobenzaldehyde.

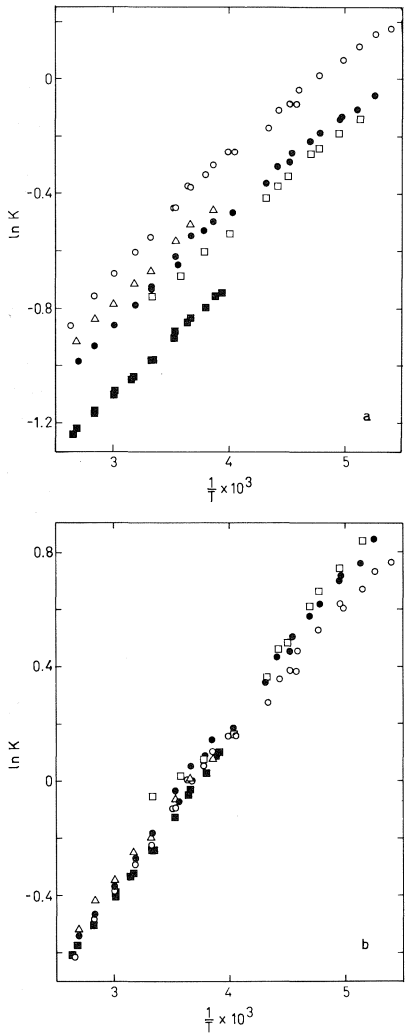

FIG. 1. Plots of ln K *vs.* $1/T$ for the methyl protons of *p*-*N*,*N*-dimethylaminobenzaldehyde in toluene-d_8: (*a*) from previous study (1); (*b*) from present treatment (solution concentrations in mol %: □, 0.5; ●, 1.0; ○, 2.5; ■, 5.0; △, 10.0).

Determination of ν_A

In the original treatment of the data (1), the value of the chemical shift of the unassociated solute was taken to be the value obtained in CCl_4 solution. However, in the complex, the solvent aromatic ring will have a different effect on each of the solute protons depending on its relative position (2). It has also been shown by Kotowycz and Schaefer that there can be a specific association between aromatic solutes and CCl_4 (3). Thus the values in CCl_4 are not a good approximation for ν_A. The present treatment provides more reliable values for the chemical shift of the unassociated solute.

As the temperature is increased, the equilibrium represented by eq. 1 will be shifted towards the unassociated solute. At infinite temperature, the aldehyde will be present only in the unassociated form. A plot of the observed chemical shift *vs.* reciprocal temperature gives a linear relationship at high temperatures. Therefore, extrapolation of the plot to $1/T = 0$ will give a value for ν_A. This is illustrated in Fig. 2 for four of the five concentrations (the 0.5 mol % solution was not studied above room tem-

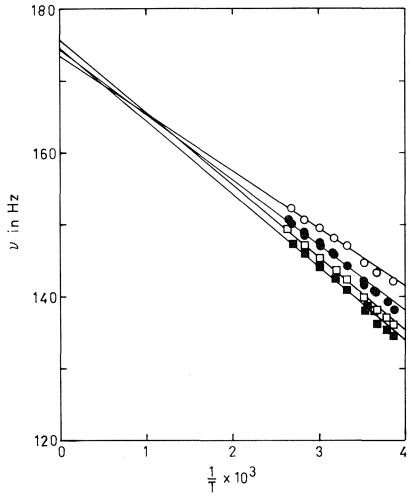

FIG. 2. Extrapolation of the ν *vs.* $1/T$ plot for the methyl protons of *p*-*N*,*N*-dimethylaminobenzaldehyde in toluene-d_8 to obtain ν_A (solution concentrations in mol %: ■, 1.0; □, 2.5; ●, 5.0; ○, 10.0).

perature) of *p-N,N*-dimethylaminobenzaldehyde using the chemical shift of the methyl protons. The straight lines represent the best least squares fit of the data above room temperature. A value for ν_A of 175 ± 2 Hz is obtained upon averaging the results for the four concentrations. Similar plots are obtained for the other protons of this solute and for the various protons of *p*-nitrobenzaldehyde. A check on the above values for ν_A can be made by conducting the same extrapolation on the chemical shift values obtained from deuterochloroform solution. Excellent agreement is found between the proton shifts in the two solvents as indicated in Table 1.

Determination of ν_C

In the previous calculations (1), the value of the chemical shift of the complex protons (ν_C) was obtained by extrapolating the ν *vs.* T plot to $T = 0$. Since the lowest temperature at which spectra were observed was 170 °K, there is considerable error involved with such an extrapolation. The present method uses a curve fitting procedure to obtain the best value of ν_C consistent with the experimental data. Taking the logarithm of eq. 2 yields eq. 4. For the proper

$$[4]\quad \ln\frac{p}{1-p} + x\ln\left[\frac{1 - xpX_A^0}{X_S^0 - xpX_A^0}\right] = \frac{-\Delta H}{RT} + \frac{\Delta S}{R}$$

values of x, ν_A, and ν_C a plot of the left hand side of eq. 4 *vs.* $1/T$ should give a linear relationship, with $-\Delta H/R$ as the slope and $\Delta S/R$ as the intercept. A computer program was written which allows a variation of the value of ν_C for a given value of x and performs a least squares fit of the data for each value of ν_C chosen. The value of ν_C which gives the maximum value of r (correlation coefficient) is taken as the best value (4). This analysis was carried out for each proton of the solute and each concentration studied. Initially the value of x was taken as unity to determine the general range of ν_C values and to determine if ν_C is concentration dependent. The randomness found for ν_C indicates there is no specific trend with concentration. The values of r ranged from 0.994–0.999 indicating very good fitting of the data points.

Estimation of x

As mentioned earlier for a given temperature, K must have the same value for all concentrations. Therefore, eq. 4 should yield only one straight line for all concentrations. The computer program also enables one to obtain the best fit of the data for all concentrations. The value of ν_C is varied as before and in addition the value of x is varied. Again, a maximum value for r is the criterion for a best fit. The best integer value for x in all cases is found to be 3, although the deviation is about ±0.4. Typical values of r found for integer values of x are shown in Table 2. The best values for ν_C, ΔH, and ΔS are 98 Hz, −1.07 kcal/mol, and −4.0 e.u., respectively. Using the values of ν_C and x obtained from this determination one can calculate the ΔH and ΔS values for each proton for all concentrations. These results are summarized in Tables 3 and 4.

Discussion

The present method of analysis provides a number of advantages. A much improved method of determining the chemical shift of the unassociated solute protons is employed. The validity of this method is shown by the good agreement obtained for all concentrations studied and for the two solvents used. Further studies of the applicability of the method to other systems are currently under way. The

chemical shift values obtained for the protons of the associated solute are also much more reliable than those obtained earlier. For these reasons the thermodynamic parameters obtained are more reliable and self-consistent. The agreement between the values obtained from different protons of the same solute is much better than that obtained earlier (1).

The best values of the thermodynamic parameters obtained from this treatment appear to be $\Delta H = -1.08 \pm 0.06$ kcal/mol, $\Delta S = -3.9 \pm 0.3$ e.u. for *p*-*N*,*N*-dimethylaminobenzaldehyde and $\Delta H = -1.18 \pm 0.07$ kcal/mol, $\Delta S = -4.1 \pm 0.3$ e.u. for *p*-nitrobenzaldehyde. These values for the enthalpy and entropy changes represent the statistical averages of the results obtained for all protons and all concentrations. The Chauvenet principle (4) was employed to eliminate widely divergent values. The error limits indicated represent the standard deviations (σ). The fact that the ΔH values are larger than those obtained with the previous treatment is due to the more reliable ν_A and ν_C values resulting from this analysis. The difference between the ΔH values from the meta protons and those from the ortho and formyl protons in the latter solute could be due to association taking place in the proximity of the nitro group as well as the formyl group as suggested by Ronayne and Williams (5).

Although the possibility of more than one solvent molecule being involved in the association has been accounted for in the present treatment, the conclusions regarding the nature of the

solute–solvent associations remain the same as reported earlier (1). The interactions are very weak. The present analysis substantiates this further when one considers the solute–solvent ratio found. From Table 2 it is apparent that the ratios of 1:2 or 1:4 would fit the data within the error limits for ΔH and ΔS. In addition there is no drastic change in the correlation coefficient r in going to these ratios. The specificity of the interaction is considerably obscured since it is difficult to envisage a reasonable physical model for a complex with a 1:3 solute–solvent ratio. These observations support the conclusions of recent reviewers of solvent effects (5, 6) in which the oversimplification of the 1:1 complex model and the inappropriateness of pictorial descriptions of such complexes are indicated.

The Wittig Reaction of Indole-2-methyltriphenylphosphonium Iodide with 4-Piperidone Derivatives and Aromatic Aldehydes[1]

JOHAN A. EENKHOORN, S. OSMUND DE SILVA, AND VICTOR SNIECKUS
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 17, 1972

2-(4-Piperidylidene)methylindole (**8***a–e*, **21**) and 2-(2-aryl)vinyl indole (**25***a–e*, **27**, **32**) derivatives have been obtained from the Wittig reaction of indole-2-methyltriphenylphosphonium iodides (**6**, **20**, **26**) with 4-piperidones (**7***a–e*) and aromatic aldehydes (**24***a–e*), respectively. Yields have been optimized by studying a variety of base-solvent combinations. The reaction failed in the case of **6** with 3-ethyl-4-piperidones (**10**); instead of compound **11**, 2-methylindole (**12**) was produced. The utility of phosphonium salts **9***a–c* and phosphonate ester **33***a* has been tested: compounds **9***a* and **33***a* showed some advantage in the preparation of Wittig adducts **8***e* and **25***c* respectively but the steric problems associated with hindered ketones (**10**) were not overcome even with the reactive phosphonium salts **9***b* and *c*. A mechanism is advanced for the formation of 2-methylindole analogous to that proposed for the base-promoted decomposition of benzylphosphonium salts (Scheme 2). Aromatic aldehydes yield mainly *trans*-Wittig adducts (**25**) with the exception of pyridine-2-aldehyde which produces exclusively *cis*-**25***c* in nonpolar solvent due to preferred formation of the hydrogen-bonded betaine **29**. Interconversion of *cis*-**25***c* ⇄ *trans*-**25***c* and their photochemical reaction to pyridocarbazole **28** are reported (Scheme 5). The chemistry of some 2-(4-piperidylidene)methylindoles has been briefly studied (Scheme 3).

Les dérivés du (piperidylidène-4 méthyl)-2 indole (**8***a–e*, **21**) et de l'(aryl-2 vinyl)-2 indole (**25***a–e*, **27**, **32**) ont été obtenus par la réaction de Wittig entre les iodures de méthylphosphonium-2 indoles (**6**, **20**, **26**) et les pipéridones-4 (**7***a–e*) et aldéhydes aromatiques (**24***a–e*) respectivement. Les rendements ont été optimalisés par l'étude de diverses combinaisons base-solvant. La réaction échoue dans le cas de **6** avec les éthyl-3 pipéridones-4 (**10**), on obtient le méthyl-2 indole (**12**) au lieu de **11**. L'utilité des sels de phosphoniums **9***a–c* et de l'ester phosphonique **33***a* a été testée: les composés **9***a* et **33***a* présentent un avantage certain dans la préparation respective des adduits **8***e* et **25***c* selon la réaction de Wittig mais les problèmes stériques des cétones encombrées (**10**) n'ont pas été résolus même avec les sels de phosphoniums réactifs **9***b* et *c*. Le mécanisme avancé pour la formation du méthyl-2 indole est analogue à celui proposé pour la décomposition basique des sels de benzylphosphoniums (schéma 2). Les aldéhydes aromatiques donnent surtout des adduits de Wittig *trans* **25** à l'exception de la pyridinealdéhyde-2 qui conduit exclusivement au *cis* **25***c*, en solvant non polaire, par la formation préférentielle de la bétaine 29 liée par pont hydrogène. L'interconversion du *cis*-**25***c* ⇄ *trans* **25***c* et leur réaction photochimique en pyrido-2 carbazole **28** sont rapportées (schéma 5). La chimie de quelques (piperidylidène-4 méthyl)-2 indoles a été brièvement étudiée (schéma 3). [Traduit par le journal]

Can. J. Chem., **51**, 792 (1973)

The most general reaction of indole compounds is manifest in their propensity to undergo facile electrophilic substitution at the 3-position (2). As a result, 3-functionalized indoles are readily available which may be modified to a variety of carbon chain-extended derivatives (3). On the contrary, direct electrophilic attack at the 2-position of the indole nucleus can be achieved only in special situations: (*a*) by inter- or intramolecular reaction of a 3-substituted derivative (**1**) (4); (*b*) via a 2-lithio derivative (**2**) (5); (*c*) in a 4-oxo-4,5,6,7-tetrahydroindole system (**3**) (6); (*d*) using activation at the 3-position, *i.e.* **4**, Y = CO_2Et, X = OH (*7a*); Y = H, X = OMe (*7b*) but not Y = H, X = NR_2 (8) for alkylation and Claisen rearrangement, *i.e.*, **4**, Y = CO_2Et, X = $OCH_2CH = CR_2$ (7); and (*e*) by reaction of π-allyl nickel dibromide with 2-bromoindole derivatives (9).[2] All of these possess certain synthetic limitations: in (*a*) further transformation at the 3-position is not possible while in (*b*) protection of the nitrogen by alkylation is required, a step which is not reversible. Cases (*c*) and (*d*) necessitate further steps to attain the indole oxidation state and both these as well as (*e*) may be limited to the preparation of 2-allyl derivatives. Alternate, although in some cases lengthy, routes to use-

[1]A portion of this work has appeared in preliminary form, see ref. 1.

[2]The mechanism of this reaction is not known although it most probably is not an electrophilic substitution.

fully functionalized 2-substituted indoles are available using benzenoid precursors. The most significant of these are: (*a*) the classical Reissert reaction (10); (*b*) the well-known Madelung reaction in which renewed interest has been expressed (11); (*c*) recently developed routes via *o*-azido- and *o*-nitrostyrenes (12); and finally (*d*) the Fischer synthesis which is only moderately useful for this purpose (13).

4

In spite of the above documentation, we observed that relatively few reports are available which deal with carbon chain extension or modification of 2-substituted indoles (14, 15, 16)[3,4] and that, in general, synthetic methodology in this area has been underdeveloped. In order to rectify this situation, we have explored the Wittig reaction of indole 2-methyltriphenylphosphonium iodide (**6**) and related compounds with 4-piperidone derivatives (**7**) and aromatic heterocyclic aldehydes (**24**) with the intent to develop a new '2-substituted indole' approach to complex indole alkaloids[5] and to establish new synthetic routes to certain heteroaromatic systems (15, 18). Specifically, we focused our attention initially on the uleine alkaloids[6] for which the key intermediate **11** was envisaged. While we have not succeeded in preparing the desired compound (**11**), we have developed a general Wittig synthesis of 2-alkylidene indoles[7] and we have delineated its scope and certain limitations insofar as both phosphorus and carbonyl components are concerned.

Indole 2-methyltriphenylphosphonium iodide (**6**) was prepared in high yield from the known 2-dimethylaminomethylindole methiodide (**5***a*) (21) or 2-diethylaminomethylindole methiodide (**5***b*) by treatment with triphenylphosphine in refluxing dimethyl formamide (DMF). The Wittig reaction (22) of **6** with 1-methyl-4-piperidones **7***a–d* in ethanol in the presence of metal (lithium, potassium, and sodium) ethoxides gave, with one exception, good yields of the adducts **8***a–d* (Scheme 1). Compound **8***e* was best obtained from the *p*-dimethylaminophosphonium salt (**9***a*) and **7***e* while **8***f* could not be prepared by this reaction due to its instability during isolation (*vide infra*).

The structures of the adducts are supported by spectral evidence, in particular the diagnostic u.v. absorption of a 2-vinyl indole chromophore (19). The n.m.r. spectra also agreed with the proposed structures in that they exhibited characteristic vinyl proton singlets and deshielded indole C_3-hydrogens (see Table 1). The low yield of **8***b* may be attributed in large part to attack of ethoxide ion on the carbophenoxy function resulting in the formation of phenol and **8***f*. Phenol was in fact obtained from the reaction mixture but **8***f* was not isolated. This was no doubt due to its inherent instability as evidenced from the observation that the reaction of **6** with 1-carbethoxy-4-piperidone (**7***f*) took place readily (u.v. evidence) but the expected product could not be isolated by the normal methods. In the case of compound **8***e* we experienced extreme difficulties in effecting clean separation of product from triphenylphosphine oxide. This problem was overcome by using the ylide derived from **9***a* which produces a phosphine oxide with a basic handle (22*b*, 23).[8] Separation was now readily achieved by extraction with dilute hydrochloric acid. Attempts to use **9***a* for the preparation of the *N*-carbethoxy Wittig product (**8***f*) only led to extensive decomposition.

Application of the most efficient set of condi-

[3]A heuristic principle not explicitly stated in texts dealing with indole chemistry is that attempts to modify a 2-substituent by electrophilic or oxidative reagents is inherently dangerous due to the presence of the exposed and highly reactive 3-position whereas the reverse is usually not true.

[4]For some indole 2-methyl functionalizations now widely used in indole alkaloid synthesis and transformations, see ref. 17.

[5]Such approaches are relatively rare, *cf.* refs. 5*b* and 16.

[6]For recent total syntheses, see ref. 19.

[7]A survey of the literature reveals very few examples of Wittig reactions involving simple indole derivatives, *cf.* refs. 5*b* and 20.

[8]We thank Dr. J. Muchowski for discussion regarding this method.

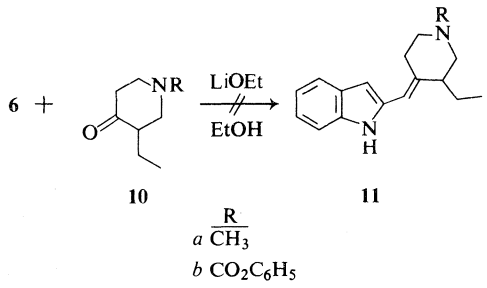
tions (lithium ethoxide in ethanol) for the formation of Wittig adducts **8***a–e* to the reaction of **6** with 3-ethyl-4-piperidone derivatives **10***a* and *b* gave disappointing results in that the expected products **11***a* and *b* were not detected even after prolonged reaction times and only substantial amounts of 2-methylindole were isolated.



In order to optimize yields of the Wittig adducts **8***a–e* and to overcome the problems associated with compounds **10***a* and *b*, we also studied the reaction of **6** with the representative ketones **7***a* and *b* under a variety of other conditions. Instead of the desired reaction, formation of 2-methylindole (**12**) was invariably observed irrespective of the nucleophilicity of the base (potassium *t*-butoxide, dimsyl sodium) or polarity of the solvent (DMF, DMSO, THF, benzene). Under some conditions, *e.g.*, dimsylsodium, DMSO, 70–80°, 70–80% yields of **12** were isolated. Although this type of side reaction in a Wittig synthesis has not been documented (22*b*), it may be likened to the well-known base-promoted decomposition of benzylophosphonium salts to toluene derivatives (24) and its mechanism may be analogously represented (Scheme 2). In support of this formulation, we found that prolonged treatment of **6** with sodium ethoxide in ethanol in the absence of carbonyl reagents gave compound **12** and triphenylphosphine oxide. If ylide **14** is a benzylic ylide and therefore classified as moderately stable (25), current mechanistic thought (22*a*) stipulates that **14** + $R_2CO \rightleftarrows$ **17** is fast and reversible and that **17** → **19** is the rate-determining step. This is in accord with its rather sluggish behavior in reactions with ketones **8***a–e* (22*b*) and its ready reactivity with aromatic aldehydes (*vide infra*). In cases (**10***a* and *b*) where the equilibrium to betaine **17** is not far advanced due to serious steric hindrance problems presented by the 3-ethyl group, the formation of 2-methylindole may be understood in terms of an escape route which proceeds via a small equilibrium con-

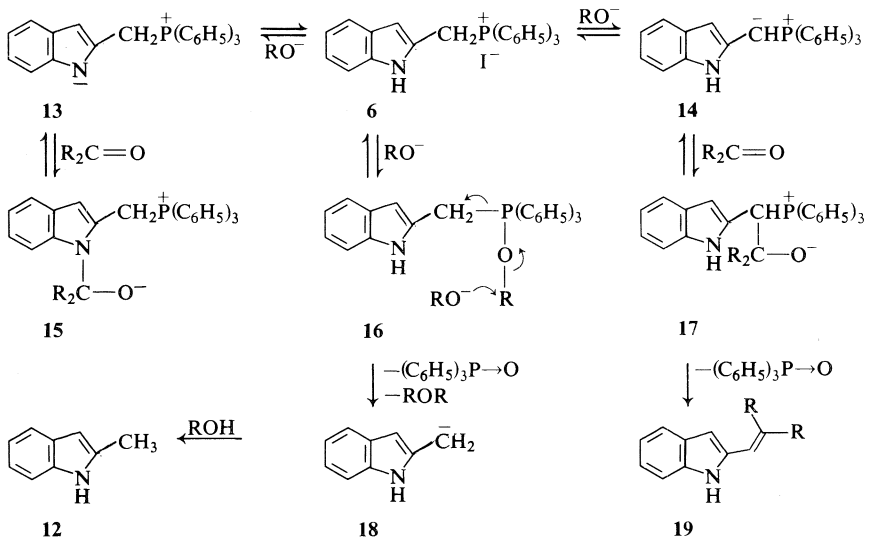
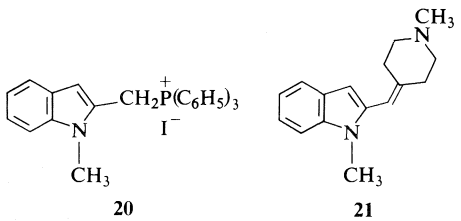


SCHEME 2

centration of the phosphonium salt **6** and thence through **16** → **18** → **12** and which becomes important under conditions of thermodynamic control.

We were also interested in determining if the potential formation of anion **13** and therefore of carbinol amine **15** had any influence on the yields in the Wittig reaction. That the anion **13** is in fact formed was shown by complete deuterium exchange of both the methylene and C_3-protons of **6** under comparable conditions using sodium ethoxide in ethanol-O-*d* (see Experimental).[9] However, since the Wittig reaction of the *N*-methyl analog, **20** with *N*-methyl-4-piperidone (**7***a*) gave olefin **21** in similar yield to that observed in the case of olefin **8***a* (Scheme 1), it would appear that the reversible formation of



15 has little if any effect on the overall outcome of the reaction.[10] Treatment of **20** with sodium ethoxide in ethanol for extended periods of time or with dimsylsodium in DMSO gave 1,2-dimethylindole, a result which indicates that the indole NH is not obligatory for the formation of 2-methylindole.[10,11]

In order to determine to what extent the steric interference can be relieved and ylide reactivity can be increased in the Wittig reaction, we undertook to study two other phosphonium salts **9***b* and *c*. Since previously it had been observed that replacement of phenyl groups by alkyl groups on phosphorus facilitates reaction in case of stabilized ylides but impedes it for unstabilized ylides (28), we prepared **9***b* and *c* by standard methods (see Experimental section) and subjected each of them first to reaction with **7***a* under the most favorable conditions (sodium ethoxide in absolute ethanol at reflux). In both cases, the product **8***a* was formed in high yield within minutes as evidenced by t.l.c. and u.v. spectroscopy (compared to hours needed in the

[9]Under these conditions, indole incorporated deuterium at the 3-position at a slower rate (50% by n.m.r.) (H. Waterman, these laboratories). This may be due to the comparatively greater NH acidity of **6** as a result of an inductive effect of the positively charged phosphorus.

[10]Other deuterium exchange studies of **20** are given in the Experimental section.

[11]An alternate mechanism involving reductive cleavage to produce 2-methylindole and triphenylphosphine has ample analogy in indole chemistry (26) and has been observed for benzyltriphenylphosphonium salts (27). The failure to detect triphenylphosphine in all experiments rules out this pathway.

case of **6**). In a preparative reaction of **9***c* with **7***a*, a yield of compound **8***a* comparable to that obtained by using phosphonium salt **6** was isolated. Nevertheless, when the identical conditions were applied to the reaction of either **9***b* or *c* with the 3-ethyl-4-piperidone **10***a*, slight development of the 2-vinylindole chromophore in the u.v. spectrum was noted over long reaction times and only 2-methylindole was isolated. Thus it would appear that the ylides derived from phosphonium salts **9***b* and *c* may be destablilized and more reactive than that formed from **6**. Nevertheless, since ketone **10***a* does not undergo reaction with either **9***b* or *c*, a combination of an unfavorable steric requirement for the formation of the betaine (**17**, Scheme 2) and/or olefin and possibly an enhanced facility for attack at the less encumbered phosphorus by alkoxide (29) must be responsible for the predominance of 2-methylindole formation in these two cases. Parenthetically, the ylide derived from the phosphonium salt **9***a* was also totally unreactive towards **10***a* even though an enhanced reactivity may have been expected on the basis of a $+I$ contribution from the *p*-dimethylamino group (22*a*).

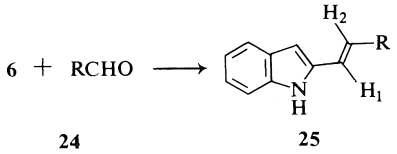
c $CO_2C_6H_5$

SCHEME 3

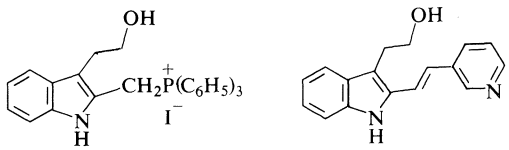
Several chemical interrelationships among the Wittig products and other potentially useful reactions were carried out (Scheme 3). The *N*-methyl derivative **8***a* was transformed into **8***b* by treatment with phenyl chloroformate according to the very useful procedure devised by Hobson and McCluskey (30). The reversal of this transformation could be achieved by lithium aluminum hydride reduction. The *N*-benzyl adduct **8***c* was obtained in overall 36% yield by direct lithium aluminum hydride reduction of the crude product **8***e* from the Wittig reaction of **6** with 1-benzoyl-4-piperidone (**7***e*). Deblocking of the trichlorocarboethoxy function in **8***d* was readily effected according to a known method (31) to yield compound **22**. Catalytic hydrogenation of both the *N*-methyl and N–H Wittig products **8***a* and **22** gave the dihydro compounds **23***a* and *b* respectively. Finally, as in the case of the *N*-methyl adduct **8***a*, compound **23***b* could be converted into the corresponding *N*-carbophenoxy derivative **23***c*.



a R = C_6H_5
b R = *p*-$NO_2C_6H_4$
c R = 2-pyridyl
d R = 3-pyridyl
e R = 4-pyridyl

SCHEME 4

For reasons discussed earlier, it was desirable to extend the Wittig reaction to benzaldehyde and pyridine aldehydes. As expected, the reaction of **6** with aldehydes **24***a–e* proceeded much more readily and gave high yields of adducts **25***a–e* (Scheme 4). Some indication of the scope of this reaction was given by the reaction of the readily available tryptophol 2-methylphosphonium salt **26** (see Experimental section) with pyridine 3-aldehyde to give a moderate yield of the adduct **27**, a potential precursor to Aspidosperma alkaloids (16).[12] In this series, isolation



26 **27**

[12]We have also recently prepared the analogous 4-pyridyl adduct in high yield.

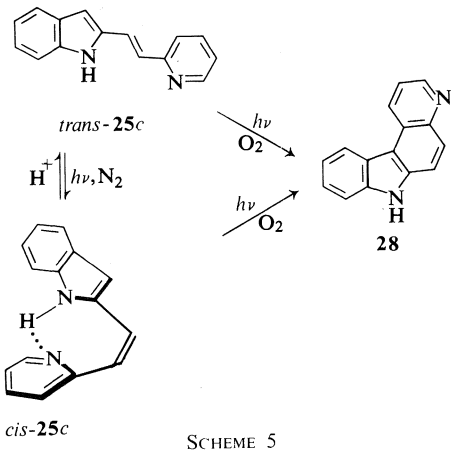
problems were again encountered. In some cases, an alternate method using 1,5-diazabicyclo(4,3,0)non-5-ene (DBN) (32) in DMSO or THF was adapted which gave better yields of products. Other variations from the general procedure are recorded in the Experimental section (Table 5).

The structures of adducts **25***a–e* and **27** are assigned on the basis of analytical and spectral evidence (Table 2). In our preliminary work (1), we assigned *trans* stereochemistry to the Wittig products **25***c* (m.p. 118°, prepared by method A) and **25***d* (prepared by methods A and B) by virtue of the observed large coupling constants (J = 14 Hz) for the vinyl protons. Although the complexity of the spectra for all other Wittig products precluded stereochemical assignment, it was nevertheless assumed to be *trans* by analogy and on the basis of previous experience with similar reaction conditions (22*a*). Further investigation of **25***c* presented inconsistencies between chemical and spectral data which have now led us to assign *cis* stereochemistry to the 118° m.p. product (**25***c*) on the basis of the following evidence. Its n.m.r. spectrum showed a broad absorption at τ −4.2 (1H, exchanged over several hours with D_2O), previously undetected (1), which is typical of strongly hydrogen bonded protons (33). Its i.r. spectrum in chloroform solution showed absorption at 3000 cm^{-1} whose position was unaffected by high dilution (34). Furthermore, it was converted to an isomeric compound, m.p. 210–211° by treatment with 1 *N* sulfuric acid. The latter was also obtained from the Wittig reaction carried out under a different set of conditions (Table 5, method B). Photolysis of the m.p. 210–211° compound in methylene chloride solution gave the m.p. 118° isomer and both were converted to the pyridocarbazole derivative **28** under the photolytic conditions described previously (18) (Scheme 5). These observations are consistent with the assignment of structure *cis*-**25***c* to the m.p. 118° isomer and *trans*-**25***c* to the m.p. 210–211° isomer.[13] The hydrogen-bonded structure, clearly seen by examination of models, must also be responsible for the lower energy transition observed in the u.v. spectrum of *cis*-**25***c* when compared to the *trans*-**25***c* structure (Table 2). The intensities of the high wavelength



SCHEME 5

absorptions of the two isomers are as expected for stilbene-like compounds (36).

In view of the above results, it was essential to obtain chemical evidence for the stereochemistry of all other Wittig products. Treatment of **25***a*, *b*, *d*, and *e* with 1 *N* sulfuric acid gave recovered starting material in greater than 80% yields. Compound **25***a* was stable to the photochemical conditions[14] which led to the isomerization of *trans*-**25***c* while *b* and *d* underwent extensive decomposition. Photolysis of *trans*-**25***e* gave a small amount of *cis*-**25***e* which rapidly reverted to the *trans* isomer in warm methanolic solution (see Experimental section). The *trans* stereochemistry of **27** is assured from the similarity of its u.v. spectrum to that of **25***d*. Clearly, with the exception of **25***c* which was isolated as the *cis* or a mixture of *cis* and *trans* isomers depending on reaction conditions, all Wittig products were obtained exclusively as the *trans* isomers. The exception was briefly investigated and the results obtained (Table 5) may be understood by a slight modification of the presently accepted formulation for the Wittig reaction of 'moderated' (moderately stable) ylides with reasonably reactive aldehydes (25, 37).

In an aprotic solvent (THF) with DBN as base, the slow irreversible formation of the *erythro* betaine **29** from **6** and the highly reactive pyridine 2-aldehyde (38) is expected to be strongly enhanced by the intramolecular hydrogen bonding between the indole NH and the pyridine

[13]The vinyl hydrogens in *trans*-**25***c* are deshielded in comparison with those of *cis*-**25***c* as expected (35).

[14]In one experiment, a small amount of a compound suspected to be *cis*-**25***a* was obtained. However, its rapid isomerization to the *trans* isomer during purification precluded characterization.

b C_6H_5

nitrogen and thus lead exclusively to the production of *cis*-**25***c* as observed. The change to a protic solvent (methanol) and sodium methoxide as base should favor the formation of the intermolecularly hydrogen-bonded *erythro* betaine **30**. However, the stability of betaines should now be greater and their decomposition to olefins and triphenylphosphine oxide should be slower. Therefore, the 'reversibility factor' (39) would be larger and there would be opportunity for leakage to the thermodynamically more stable *threo* betaine **31** which should lead to some *trans*-**25***c* product. In agreement with this rationale a 1:1 *cis–trans* ratio of **25***c* was obtained using sodium methoxide in refluxing methanol. A control experiment showed that no isomerization *cis*-**25***c* → *trans*-**25***c* was occurring under these conditions. No change in yields or *cis–trans*-**25***c* isomer composition was observed when the reaction was carried out in the presence of lithium methoxide and soluble lithium chloride in refluxing methanol solution. These results show that the enhanced stabilization of the *erythro* betaine **30** by coordination of the lithium ion with the oxygen function is not an important consideration and that the *cis–trans* isomer ratio is largely determined by the thermodynamic stability of the *erythro* (**30**) and *threo* (**31**) betaines (40). This contention is further supported by the observation that the *cis–trans* ratio remained the same when the reaction was carried out in the presence of lithium methoxide in methanol solution at *room temperature* (39). Finally, it is of interest to note that the Wittig reaction of the *N*-methyl phosphonium salt **20** with pyridine 2-aldehyde also produced a 1:1 mixture of *cis* and *trans* adducts (**32**) in refluxing methanol using sodium methoxide as the base, supporting the view that in a polar protic solvent *erythro* betaine **29** plays an insignificant role in determining the geometrical isomer ratio of the Wittig product.

In view of the results with pyridine 2-aldehyde (**24***c*), experiments were undertaken to vary the conditions of the reaction of **6** with the aldehydes **24***a*, *d*, and *e* in order to force the formation of the corresponding *cis* Wittig products. In all these cases, Wittig reaction in THF solution was very slow even at 80° (ylide **6** color persisted for 4 days), *cis* adducts were not detected, and decomposition of the ylide was eventually observed. The highly reactive *p*-nitrobenzaldehyde (**24***b*) gave exclusively *trans* product (**25***b*) (Table 5). If *cis* compound was formed in this case, then isomerization to *trans* product must be occurring rapidly even at room temperature. Therefore, from a stereochemical point of view it appears that two factors impart a special

position to pyridine 2-aldehyde in the reaction with ylide **6**: (1) its highly electrophilic carbonyl function (41) and, more importantly, (2) its ability to form a strong intramolecular hydrogen bonded *erythro* betaine **29**.

A recent demonstration of the successful Wadsworth–Emmons reaction (42) between triethylphosphonoacetate and hindered 3-ethyl-4-piperidone derivatives (43) led us to explore the reactivity of diethyl indole-2-methylphosphonate (**33***a*). Although this compound was readily prepared[15] from the methiodide **5***a*, it was found to be totally unreactive towards ketone **10***a* and, surprisingly, even **7***a* and **24***c* under several sets of previously mentioned conditions. We reasoned that perhaps the acidity of the indolic NH is much greater than that of the methylene protons in **33***a* and thus that the required carbanion for the Wittig reaction was not generated under these conditions. When **33***a* was treated with 2 equiv of each of sodium hydride and *N*-methyl-4-piperidone **7***a* in DMF solution, the adduct **8***a* was obtained, albeit in very low yield. However, application of these conditions to the reaction of **33***a* with pyridine-2-aldehyde (**24***c*) gave a *cis–trans* mixture of **25***c* in 44% overall yield offering some support for the above proposal. Although the yield is somewhat lower than that obtained using phosphonium salt **6** (Table 5), this method may be more convenient for the preparation of compounds **25***d* and *e* in that problems of separation of triphenylphosphine oxide encountered in the latter cases are circumvented.

Finally, an attempt was made to prepare indole-2-methyldiphenylphosphine oxide (**33***b*) since evidence in the literature indicated that this type of system was highly effective in reactions with hindered carbonyl compounds (46). Although the immediate precursor (**9***d*) for compound **33***b* was readily prepared, its hydrolysis with base by the prescribed method (47) gave 2-methylindole (**12**) instead of the expected product. This result may be explained by a mechanism analogous to that proposed for the production of **12** in the abortive Wittig reaction attempts (Scheme 2). Credibility for this proposal and thus for the behavior of 2-methylindole carbanion **18** as a good leaving group is further strengthened when it is realized that normally N—P bonds are broken more readily than C—P bonds in these systems (48).

[15]Our unambiguous synthesis of **33***a* corroborates the structural assignment for this compound which has caused some concern (44, 45).

Experimental

General Methods

Melting points were measured on a Fisher-Johns apparatus and are uncorrected. Microanalyses were performed by A. B. Gygil, Toronto; W. Boos, Uniroyal Laboratories, Guelph; Microtech Laboratories, Skokie, Illinois; Scandinavian Microtechnical Laboratory, Herlev, Denmark; and Microanalytical Laboratory, Bonn, Germany. I.r. spectra were determined with a Beckman IR-5A instrument in chloroform solution unless otherwise indicated. U.v. spectra were recorded on a Coleman-Hitachi EPS-3T spectrophotometer in methanol solution. N.m.r. spectra were obtained on Varian T-60, A-60A, and HA-100 spectrometers in deuteriochloroform solution unless otherwise stated. Mass spectra were determined with a Hitachi–Perkin–Elmer RMU-6E spectrometer at 70 eV. T.l.c. was carried out with Merck silica gel GF 254 and column chromatography with Merck silica gel (0.05–0.2 mm) obtained from Brinkmann (Canada) Ltd. unless otherwise stated. Benzene and THF were dried by refluxing over sodium and benzophenone until a deep blue color persisted in solution. DMF and DMSO were dried by allowing them to stand for several days over Linde molecular sieves (Type 4A) unless otherwise indicated.

The following compounds were purchased from Aldrich Chemical Co.: 1-methyl-4-piperidone (**7***a*), 2,2,2-trichloroethyl chloroformate, chlorodiphenylphosphine, dichlorophenylphosphine, diphenylphosphinic acid, and 1,5-diazabicyclo(4.3.0)nonene-5 (DBN). With the exception of **7***a* which was distilled, all of these were used without further purification.

Preparation of 4-Piperidone Derivatives

The following compounds were prepared by literature methods with minor modifications: 4-piperidone hydrochloride (49) (m.p. 145–150°; lit. (50) m.p. 147–149°); 1-benzyl-4-piperidone (**7***c*) (51) (b.p. 108–110°, 0.1 mm; lit. (50) b.p. 114–116°, 0.3 mm); 1-benzoyl-4-piperidone (**7***e*) (51) (b.p. 158–160°, 0.2 mm; lit. (50) b.p. 158–160°, 0.2 mm); 1-methyl-3-ethyl-4-piperidone (**10***a*) (51, 52) (b.p. 74–76°, 13 mm; lit. (52) b.p. 102°, 33 mm).

1-Carbophenoxy-4-piperidone (7b)

In an adaptation of a literature procedure (30), a solution of 15.7 g (0.10 mol) of phenyl chloroformate in 50 ml of methylene chloride was added dropwise to a stirred solution of 11.3 g (0.10 mol) of 1-methyl-4-piperidone (**7***a*) in 50 ml of methylene chloride. The mixture was refluxed for 18 h, cooled, and diluted with 50 ml of water. The methylene chloride layer was separated, washed with saturated salt solution, and dried (Na_2SO_4). After filtration, the solvent was removed *in vacuo* and the resulting oil was distilled to give 10.8 g (49%) of **7***b*, b.p. 150–160° (0.1 mm) which solidified upon standing. Two recrystallizations from carbon tetrachloride – petroleum ether (30–60°) gave an analytical sample, m.p. 76–78°; i.r. ν_{max} 1700 (C=O) cm^{-1}; n.m.r. (CCl_4) τ 2.3–3.0 (m, 5H, aromatic), 6.2 (t, 4H, J = 6 Hz, CH_2N), 7.64 (t, 4H, J = 6 Hz, CH_2CO).

1-(2,2,2-Trichlorocarboethoxy)-4-piperidone (7d)

To a stirred solution of 7.0 g (50 mmol) of 4-piperidone hydrochloride in 50 ml of water was added a solution of 10.5 g (50 mmol) of 2,2,2-trichloroethyl chloroformate in 100 ml of ether followed by a solution of 85 g (100 mmol) of sodium bicarbonate in 100 ml of water. An additional 100 ml of ether was added and the reaction mixture was stirred at room temperature for 17 h. The ether layer was separated and the aqueous layer was extracted with ether. The combined ether extract was washed consecutively with 2 *N* hydrochloric acid solution, water, and a saturated sodium chloride solution. The ether layer was dried (Na_2SO_4) and evaporated to dryness. The residue was distilled to give 13.3 g (97%) of a colorless liquid, b.p. 138–140°, 0.4 mm which solidified. Recrystallization from carbon tetrachloride – petroleum ether (30–60°) gave an analytical sample of **7d**, m.p. 47–48°, i.r. ν_{max} 1720 (C=O) cm^{-1}; n.m.r. (CCl_4) τ 5.20 (s, 2H, $CO_2CH_2CCl_3$), 6.20 (t, 4H, J = 6 Hz, CH_2N), 7.56 (t, 4H, J = 6 Hz, CH_2CO).

Anal. Calcd. for $C_8H_{10}Cl_3NO_3$: C, 35.00; H, 3.67; N, 5.10. Found: C, 35.34; H, 3.56; N, 5.12.

1-Carboethoxy-4-piperidone (7f)

This compound was prepared in 56% yield from **7a** and ethyl chloroformate by the procedure described for **7b**. It showed b.p. 99–100°, 0.3 mm (lit. (53) b.p. 93°, 1 mm) and required storage at 0° under nitrogen.

1-Carbophenoxy-3-ethyl-4-piperidone (10b)

The procedure was that used for the preparation of **7b**. From 7.0 g (0.05 mol) of **7a** and 7.8 g (0.05 mol) of phenyl chloroformate there was obtained 7.0 g (57%) of **10b** as a thick colorless oil, b.p. 152–154°, 0.03 mm; i.r. (neat) ν_{max} 1710 (C=O) cm^{-1}; n.m.r. (CCl_4) τ 2.5–3.1 (m, 5H, aromatic), 5.7–7.2 (m, 4H, CH_2N), 7.67 (t, 2H, J = 6 Hz, CH_2CO), 7.4–8.2 (m, 1H, CHCO), 8.2–9.0 (m, 2H, CH_2CH_3), 9.23 (t, 3H, J = 7 Hz, CH_3).

Anal. Calcd. for $C_{14}H_{17}NO_3$: C, 68.00; H, 6.93; N, 5.66. Found: C, 67.77; H, 7.06; N, 5.46.

*Preparation of Phosphonium Salts **6**, **9a–d**, **26** and Phosphonate Ester **33a** (Table 3)*

2-Diethylaminomethylindole Methiodide (5b)

This compound was prepared in 96% yield by lithium aluminum hydride reduction of indole-2(*N*,*N*-diethyl) carboxamide (m.p. 168–170°; lit. (54) m.p. 163–164°) followed by treatment with methyl iodide according to the method of Schindler (21). After recrystallization from methanol, it showed m.p. 167°.

Anal. Calcd. for $C_{14}H_{21}IN_2$: C, 48.83; H, 6.10; N, 8.14; I, 36.93. Found: C, 49.02; H, 6.14; N, 7.99; I, 37.01.

Indole-2-methyltriphenylphosphonium Iodide (6)

This compound was prepared by modification of a literature method (55). A stirred solution of 35 g (0.11 mol) of 2-dimethylaminomethylindole methiodide (**5a**) (21) and 45 g (0.17 mol) of triphenylphosphine in 350 ml of dry DMF was refluxed for 24 h. The solvent was removed *in vacuo* and the residue was triturated with 500 ml of benzene. The solid was collected and washed with benzene to yield 41 g (71%) of product. Recrystallization from ethanol provided an analytical sample of **6**, m.p. 254–255°.

Compound **6** was also prepared by treatment of 2-diethylaminomethylindole methiodide (**5b**) with 1.2 equiv of triphenylphosphine in DMF. In this case, however, the mixture was not refluxed; instead, diethylmethylamine was collected by distillation through a Vigreux column over a 1 h period. Isolation as described above afforded **6** in 90% yield.

Anal. Calcd. for $C_{27}H_{23}INP$: C, 62.44; H, 4.46; N, 2.70. Found: C, 62.42; H, 4.42; N, 2.66.

Indole-2-methyl(p-dimethylaminophenyl)diphenylphosphonium Iodide (9a)

This compound was prepared by the method outlined for **6**. From 12.6 g (0.04 mol) of **5a** and 18.3 g (0.06 mol) of *p*-dimethylaminophenyldiphenylphosphine (56) there was obtained 21.0 g (93%) of **9a** as a colorless solid, m.p. 275–277°.

Anal. Calcd. for $C_{29}H_{28}IN_2P$: C, 61.91; H, 5.02; N, 4.98. Found: C, 62.25; H, 5.09; N, 5.18.

Indole-2-methyldiphenylmethylphosphonium Iodide (9b)

A solution of 3.2 g (0.01 mol) of **5a** and 2.5 g (0.0125 mol) of diphenylmethylphosphine (57) in 50 ml of dry DMF was stirred and refluxed for 18 h in a carbon dioxide atmosphere. The solvent was removed *in vacuo* and the residue was triturated with a mixture of benzene and carbon tetrachloride to give a semisolid which was recrystallized twice from ethanol to yield 3.2 g (70%) of **9b** as a slightly pink, crystalline material, m.p. 231–233° (sinter 218°).

Anal. Calcd. for $C_{22}H_{21}INP$: C, 57.78; H, 4.63; N, 3.06. Found: C, 57.78; H, 4.68; N, 3.12.

Indole-2-methyldimethylphenylphosphonium Iodide (9c)

A stirred solution of 3.4 g (0.01 mol) of **5b** and 1.8 g (0.01 mol) of dimethylphenylphosphine (57) in 100 ml of dry DMF under a carbon dioxide blanket was brought to gentle reflux and diethylmethylamine was collected by distillation through an attached Vigreux column over a period of 1 h. The solvent was removed *in vacuo* and the resulting residue was dissolved in methylene chloride. This solution was successively washed with water and saturated salt solution, and dried (Na_2SO_4). The solvent was evaporated *in vacuo* to give a yellow resin which was recrystallized from acetone to yield 1.3 g (32%) of **9c**, m.p. 99–100° (sinter 95°).

Anal. Calcd. for $C_{17}H_{19}INP$: C, 51.66; H, 4.85; N, 3.54. Found: C, 51.69; H, 5.41; N, 3.41.

Indole-2-methyldiphenyl-N-t-butylaminophosphonium Iodide (9d)

In an adaptation of a literature method (47), a solution of 3.2 g (10 mmol) of **5a** and 5.2 g (20 mmol) of diphenyl-*t*-butylaminophosphine (47) in 50 ml of dry DMF was stirred and refluxed for 18 h. The solvent was removed *in vacuo* and the residue was triturated with carbon tetrachloride to give 5.5 g of yellow solid which, after two recrystallizations from ethanol at 0°, afforded 2.1 g (41%) of **9d**, m.p. 155–156°.

Anal. Calcd. for $C_{25}H_{28}IN_2P$: C, 58.38; H, 5.49; N, 5.45. Found: C, 58.39; H, 5.54; N, 5.43.

When compound **9d** was treated with aqueous potassium hydroxide according to Sisler and Smith (47), 2-methylindole (**12**) was obtained in 89% crude yield.

*Indole-1-methyl-2-methyltriphenylphosphonium Iodide (**20**)*

Sodium hydride (50% dispersion in mineral oil) (3.12 g, 65 mmol) placed in a flask under a slow stream of nitrogen was washed twice with dry petroleum ether (35–60°). The flask was immersed into a Dry Ice – carbon tetrachloride bath (−15°) and 150 ml of DMF (freshly distilled from calcium hydride) was added. To the stirred mixture was added dropwise a solution of 9.4 g (50 mmol) of indole-2(*N*,*N*-dimethyl)carboxamide (21) in 100 ml of dry DMF and stirring was continued for 45 min. Dried and freshly distilled methyl iodide (14.2 g, 100 mmol) in 50 ml of dry DMF was similarly added and the temperature of the mixture was allowed to rise to −10° over a 1 h period. After further periods of stirring at 0° (1 h) and room temperature (10 h), most of the solvent was removed *in vacuo* and the resulting residue was extracted with three 100 ml portions of ether. The combined extracts were evaporated to yield an oil which formed a solid upon addition of ice-water and vigorous agitation. Recrystallization from benzene – petroleum ether (60–80°) gave 9.1 g (91%) of *indole-1-methyl-2(N,N-dimethyl)carboxamide*, m.p. 95°, i.r. ν_{max} 1627 (C=O) cm^{-1}; u.v. λ_{max} 287 (11 700) mμ; n.m.r. τ 2.2–3.0 (m, 4H, aromatic), 3.37 (s, 1H, indole 3-H), 6.20 (s, 3H, indole 1-CH_3), 6.88 (s, 6H, $N(CH_3)_2$).

Anal. Calcd. for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85. Found: C, 71.22; H, 7.26; N, 13.88.

Lithium aluminum hydride reduction of indole-1-methyl-2(*N*,*N*-dimethyl)carboxamide according to the method of Schindler (21) gave a quantitative yield of *1-methyl-2-dimethylaminomethylindole*, b.p. 130°, 0.05 mm, n.m.r. τ 2.3–3.07 (m, 4H, aromatic), 3.85 (s, 1H, indole 3-H), 6.34 (s, 3H, indole 1-CH_3), 6.57 (s, 2H, CH_2N), 7.84 (s, 6H, $N(CH_3)_2$), which was converted into its methiodide also in quantitative yield. Recrystallization from benzene–methanol gave an analytical sample of *1-methyl-2-dimethylaminomethylindole methiodide*, m.p. 217–219° (dec.), λ_{max} 278 (10 000), 288 (sh, 7400), 300 (sh, 3900) mμ; n.m.r. (DMSO-d_6) τ 2.2–3.0 (m, 4H, aromatic), 3.1 (s, 1H, indole 3-H), 5.6 (br s, 2H, CH_2N^+), 6.12 (s, 3H, indole 1-CH_3), 6.82 (br s, 9H, $^+N(CH_3)_3$).

Anal. Calcd. for $C_{13}H_{19}N_2I$: C, 47.28; H, 5.77; N, 8.49; I, 38.49. Found: C, 47.58; H, 5.43; N, 8.54; I, 38.55.

The above compound was converted to *indole-1-methyl-2-methyltriphenylphosphonium iodide* (**20**) according to the method used for **6** except that the reflux time was abbreviated (3.5 h). Recrystallization from methanol gave a 60% yield of **20**, m.p. 240–241° (dec.). The compound was found to be very air sensitive.

Anal. Calcd. for $C_{28}H_{25}INP$: C, 63.05; H, 4.70; N, 2.63; I, 23.83; P, 5.82. Found: C, 62.70; H, 4.74; N, 2.65; I, 24.08; P, 5.44.

*Indole-2-[3-hydroxyethyl]-2-methyltriphenylphosphonium Iodide (**26**)*

Using the method for the preparation of **6**, 3.64 g (0.01 mol) of indole-3-[2-hydroxyethyl]-2-dimethylaminomethyl methiodide (58) was treated with 7.92 g (0.03 mol) of triphenylphosphine in 30 ml of dry DMF to give 5.60 g (99%) of compound **26**. Recrystallization from methanol gave a sample, m.p. 258–260° (dec.).

Anal. Calcd. for $C_{29}H_{27}INOP$: C, 61.82; H, 4.84; N, 2.49; I, 22.56; P, 5.51. Found: C, 61.49; H, 4.77; N, 2.52; I, 22.82; P, 5.49.

*Diethyl Indole-2-methylphosphonate (**33a**)*

The procedure of Harvey *et al.* (59) was adapted. To a stirred suspension of 0.46 g (9.6 mmol) of sodium hydride (50% suspension in mineral oil) in 25 ml of dry THF was added a solution of 1.6 g (11.6 mmol) of diethyl phosphite (59) in 25 ml of THF. The reaction mixture was refluxed until the solid had disappeared, cooled, and treated with a solution of 2.0 g (6.3 mmol) of **5***a* in 50 ml of DMF. The mixture was refluxed for 18 h and evaporated to dryness *in vacuo*. The residue was treated with water and the resulting solution was extracted with ether. The ether extract was washed with saturated sodium chloride solution and dried (Na_2SO_4). There was obtained 1.5 g of solid which was chromatographed (chloroform eluent) to yield 1.1 g (66%) of crystalline product. Recrystallization from methanol at −20° and repeatedly from ether gave a pure sample of **33***a* as colorless crystals, m.p. 105–107° (lit. (60) m.p. 119–120°), i.r. identical bands to those reported (60).

*Preparation of 2-(4-Piperidylidene)methylindole Derivatives (**8***a–e and **21**) (Table 4)*

*General Method 2-(1-Methyl-4-piperidylidene)-methylindole (**8***a)*

To a stirred solution of lithium ethoxide in ethanol under nitrogen (prepared from 125 mg (18 mmol) of lithium and 25 ml of absolute ethanol) were added consecutively 9.3 g (18 mmol) of indole-2-methyltriphenylphosphonium iodide (**6**), 50 ml of absolute ethanol, and a solution of 2.1 g (18 mmol) of 1-methyl-4-piperidone (**7***a*) in 40 ml of ethanol. An additional 50 ml of ethanol was added and the reaction mixture was stirred and refluxed for 21 h. The solvent was removed *in vacuo* and the residue was dissolved in ether. After removal of triphenylphosphine oxide by filtration, the solution was treated with an equimolar amount of citric acid monohydrate in benzene. The resulting precipitate was collected and washed with ether. It was then suspended in a mixture of water and methylene chloride and the mixture was basified with solid sodium bicarbonate. The organic layer was separated and the aqueous mixture was extracted further with methylene chloride. The combined extract was washed with saturated sodium chloride solution and dried (Na_2SO_4). There was obtained 3.4 g (84%) of product which was recrystallized from methanol to give 2.5 g of pure **8***a*.

*2-(1-Benzoyl-4-piperidylidine)methylindole (**8***e)*

To a stirred solution of lithium ethoxide in absolute ethanol under nitrogen (prepared from 24 mg (3.5 mmol) of lithium in 50 ml of ethanol) at reflux there was added 2.02 g (3.6 mmol) of **9***a* and 50 ml of ethanol, followed immediately by a solution of 0.72 g (3.6 mmol) of 1-benzoyl-4-piperidone (**7***e*) in 50 ml of ethanol. The reaction mixture was refluxed for 18 h and evaporated to dryness *in vacuo*. The residue was treated with 200 ml of benzene and the resulting precipitated phosphine oxide was removed by filtration. The filtrate was washed consecutively with water, four 50 ml portions of a 5% hydrochloric acid solution, and saturated salt solution. The benzene solution was dried (Na_2SO_4) and evaporated to dryness *in vacuo* to give 1.2 g of crude material which was recrystallized three times from ethanol to yield a pure sample of **8***e*.

[a]Compounds **8***a* and *c* were prepared by the Wittig reaction according to the general method described for **8***a*, Compounds **8***b*, **8***d*, and **21** were prepared by the same method except that the isolation procedure involved chromatography (**8***b*, neutral alumina; **8***d*, silica gel; **21**, basic alumina, grade III) with benzene as eluent. The preparation of **8***e* is described separately. The reactions were carried out on 1–9 mmol scale and the recrystallizations were effected at −20° to 0°.
[b]Reported yields are of crystallized material.
[c]The *p-N,N*-dimethylaminophenylphosphonium salt **9***a* was used in this preparation.
[d]This compound was obtained from **8***d*.

Interconversions and Transformations of Wittig Products (Scheme 3)

*Reaction of **8**a with Phenyl Chloroformate: Alternate Preparation of **8**b*

To a suspension of 450 mg (2 mmol) of **8***a* in 15 ml of dry benzene was added dropwise a solution of 320 mg (2 mmol) of phenyl chloroformate in 20 ml of benzene–chloroform (1:1). The thick mixture was stirred and refluxed for 4 h, cooled, and washed consecutively with water, dilute hydrochloric acid, water, sodium bicarbonate, and saturated salt solution. The benzene solution was taken to dryness to give a pale brown solid which was recrystallized from methanol to yield 255 mg (39%) of **8***b*, which was shown to be identical by m.p. and mixture m.p. comparison to an authentic sample prepared by the Wittig reaction.

*Lithium Aluminum Hydride Reduction of **8**b*

A solution of 68 mg (0.2 mmol) of **8***b* and 0.14 g (3.7 mmol) of lithium aluminum hydride in 5 ml of dry tetrahydrofuran was refluxed for 2.5 h. Normal isolation procedure yielded 23 mg (50%) of **8***a*, identical by i.r. and n.m.r. spectral comparison with an authentic sample prepared by the Wittig reaction.

*Lithium Aluminum Hydride Reduction of **8**e*

A sample of **8***e* prepared by the Wittig reaction of **6** with **7***e* was not purified but directly subjected to lithium aluminum hydride reduction (10-fold excess of LAH, reflux for 20 h in THF) as above to give **8***c* in 36% yield after purification via the citrate salt method as described for the preparation of **8***a*. The material was shown to be identical by m.p. and mixture m.p. comparison to an authentic sample of **8***c* prepared by the Wittig reaction.

*2-(4-Piperidylidene)methylindole (**22**)*

To a solution of 1.8 g (2.8 mmol) of **8***d* in 30 ml of methanol there was added 5 ml of glacial acetic acid and 1.1 g of zinc dust and the mixture was refluxed for 3 days (31). The inorganic material was removed by filtration and the filtrate was concentrated *in vacuo*. The residue was dissolved in water and the resulting solution was extracted with methylene chloride. The aqueous solution was basified with solid sodium bicarbonate and extracted with methylene chloride. The organic extract was washed with saturated salt solution and dried (Na_2SO_4). There was obtained 0.5 g of yellow solid which upon recrystallization from acetone at −20° gave 0.31 g (52%) of compound **22**.

*2-(4-Piperidyl)methylindole (**23**a)*

A solution of 0.7 g (3.3 mmol) of compound **22** in 140 ml of ethanol was hydrogenated over 0.4 g of 5% palladium-on-charcoal (50% water) at 3.5 atm and room temperature for 23 h. Normal isolation procedure and recrystallization from acetone at 0°, gave 0.5 g (73%) of **23***a*. An additional recrystallization from acetone afforded an analytical sample, m.p. 177–179° (sinter 168°); i.r. ν_{max} 3400 cm^{-1}; u.v. λ_{max} 275 (7700), 281 (7700), 291 (5900) mμ; n.m.r. τ 1.9 (br s, 1H, indole NH), 2.3–3.1 (m, 4H, aromatic), 3.8 (br s, 1H, indole 3-H), 6.7 (m, 4H, CH_2N), 7.35 (d, 2H, J = 6 Hz, indolyl-2-CH_2), 7.8–9.0 (m, 6H, $CHCH_2CH_2N$, NH).

Anal. Calcd. for $C_{14}H_{18}N_2$: C, 78.46; H, 8.47; N, 13.07. Found: C, 78.13; H, 8.43; N, 12.89.

*2-(1-Methyl-4-piperidyl)methylindole (**23**b)*

Compound **8***a* (1.49 g, 6.6 mmol) was reduced according to the procedure described for the preparation of **23***a*. There was obtained 0.81 g (54%) of **23***b* which was recrystallized from ethanol to give an analytical sample, m.p. 141–142°; i.r. ν_{max} 3400 (NH), 2780 (NCH_3) cm^{-1}; u.v. λ_{max} 275 (7500), 281 (7500), 291 (5800) mμ; n.m.r. τ 2.0 (br s, 1H, indole NH), 2.3–3.1 (m, 4H, aromatic), 3.7 (br s, 1H, indole 3-H), 7.3 (d, 2H, J = 6 Hz, indolyl-2-CH_2), 7.67 (s, 3H, NCH_3); 6.9–9.0 (m, 9H, piperidine).

Anal. Calcd. for $C_{15}H_{20}N_2$: C, 78.90; H, 8.83; N, 12.27. Found: C, 78.78; H, 8.80; N, 12.19.

*2-(1-Carbophenoxy-4-piperidyl)methylindole (**23**c)*

Compound **23***b* was treated with phenyl chloroformate according to the method used for the conversion **8***a* → **8***b*. Recrystallization from ethanol gave a 20% yield of **23***c*, m.p. 151–153° (sinter 148°); i.r. ν_{max} 3410 cm^{-1}; u.v. λ_{max} 275 (8100), 282 (8000), 291 (6400) mμ; n.m.r. τ 1.9 (br s, 1H, indole NH), 2.2–3.2 (m, 9H, aromatic), 3.7 (br s, 1H, indole 3-H), 5.75 (br d, 2H, J = 12 Hz,

piperidine α-CH_2), 7.08 (br d, 2H, J = 12 Hz, piperidine α-CH_2 shielded by —$CO_2C_6H_5$ function due to NCO_2-C_6H_5 hindered rotation), 7.31 (d, 2H, indolyl-2-CH_2), 7.8–9.1 (m, 5H, $CHCH_2CH_2N$).

Anal. Calcd. for $C_{21}H_{22}N_2O_2$: C, 75.42; H, 6.63; N, 8.38. Found: C, 75.56; H, 6.67; N, 8.27.

*Preparation of 2-(2-Aryl)vinylindole Derivatives (**25***a–e*, **27**, and **32**)*

Reactions were carried out with 1.93–3.85 mmol of **6** and equivalent amounts of base and aromatic aldehydes in 1:100 w/v of **6**:THF or DMSO (method A) or in 1:20 w/v of **6**:absolute methanol (method B). The preparation method, isolation procedure, and physical properties for compounds **25***a–e* and **32** are recorded in Table 5.

*2-(2-(p-Nitrophenyl)vinyl)indole (**25***b*)*

Method A. With DBN in THF or DMSO solution

To a stirred solution of 1.04 g (2 mmol) of **6** in 60 ml of dry THF at 40° (oil bath) under nitrogen there was added simultaneously and dropwise from two separatory funnels solutions of 0.30 g (2 mmol) of *p*-nitrobenzaldehyde in 10 ml of THF and 0.25 g (2 mmol) of DBN in 10 ml of THF. The reaction mixture was stirred at 40° for 1 h and then heated at 80° for 2 h. Heating was discontinued and the mixture was stirred for an additional 24 h. The solvent was removed *in vacuo* and the residue was chromatographed (methylene chloride) to give 0.52 g of **25***b*.

Method B. With sodium methoxide in methanol solution

To a stirred solution of 1.00 g (1.93 mmol) of **6** in 175 ml of absolute methanol at 40° (oil bath) under nitrogen there was added dropwise and simultaneously from two separatory funnels solutions of 0.29 g (1.93 mmol) of *p*-nitrobenzaldehyde in 25 ml of methanol and 0.08 g (1.93 mmol) of sodium methoxide in 25 ml of methanol. The reaction mixture was stirred at 40° for 2 h and then refluxed for 15 h. The solvent was removed *in vacuo* and the residue was stirred and refluxed with 200 ml of benzene for 10 h. The benzene extract was evaporated to dryness and the residue was chromatographed (methylene chloride) to give 0.42 g (81%) of **25***b* which was shown to be identical to the sample obtained by method A by m.p. and mixture m.p. determination.

*2-(2-(2-Pyridyl)vinyl)indole (cis-, trans-**25***c*) Using Diethyl Indole-2-methylphosphonate (**33***a*)*

A mixture of sodium hydride (0.288 g, 6 mmol) in dry DMF (75 ml) was prepared at −10° as in the experiment dealing with the synthesis of **20**. A solution of **33***a* (0.791 g, 3 mmol) in dry DMF (25 ml) was added dropwise to the stirred mixture over 30 min and stirring was continued for 1 h during which time the dark green reaction mixture was allowed to warm to room temperature. A solution of pyridine-2-aldehyde (0.642 g, 6 mmol) was added dropwise and the resulting yellow solution was stirred at room temperature for 16 h. The reaction mixture was concentrated and the brown gum was suspended in water. This suspension was extracted with ether (2 × 250 ml) and methylene chloride (250 ml) and the combined extracts were dried (Na_2SO_4) and evaporated to dryness. The residue was chromatographed over basic alumina (grade III, methylene chloride) to give 0.115 g (18%) of *cis*-**25***c* and 0.172 g (26%) of *trans*-**25***c* which were identified by m.p., mixture m.p., and spectral comparison with samples prepared by the Wittig reaction of **6** with **24***c*.

*Reaction of Indole-2-methyltriphenylphosphonium Iodide (**6**) with Sodium Methoxide. Formation of 2-Methylindole (**12**)*

To a stirred solution of 0.519 g (1.0 mmol) of **6** in 100 ml of anhydrous methanol under nitrogen was added dropwise a solution of 0.023 g (1.0 mmol) of sodium in 25 ml of anhydrous methanol. The mixture was refluxed for 48 h. The solvent was removed *in vacuo* and the residue was extracted with 100 ml of warm petroleum ether (60–80°). Concentration of the extract gave 0.081 g (62%) of 2-methylindole (**12**) shown to be identical to an authentic sample (50) by t.l.c. and u.v. and n.m.r. spectroscopy. The residue remaining from the petroleum ether extraction was extracted with 300 ml of hot ether. Concentration of this extract yielded 0.161 g (60%) of triphenylphosphine oxide. The remaining residue was recrystallized from methanol to give 0.175 g (33%) of starting material (**6**).

Deuterium Exchange Experiments

*(a) Phosphonium Salt **6***

A solution of 0.0046 g (0.2 mmol) of sodium metal in 3 ml of anhydrous ethanol-*O-d* (Stohler Isotope Chemicals, Montreal) was prepared under nitrogen. The mixture was allowed to cool to room temperature and 0.103 g (0.2 mmol) of **6** was added. The solution was stirred for 30 min and quenched with 5 ml of D_2O and excess Dry Ice. The solvent was removed *in vacuo*. The resulting residue showed m.p. 245–247° (dec.) and a u.v. spectrum identical to that of **6**. T.l.c. showed the absence of 2-methylindole. Its n.m.r. spectrum in DMSO-d_6 lacked absorption at τ −0.80, 4.20, and 4.82 indicating essentially complete deuterium exchange of NH, indole 3-H, and methylene protons in **6** (see Table 3).

*(b) Phosphonium Salt **20***

The procedure described above was performed using 0.0092 g (0.4 mmol) of sodium, 8 ml of ethanol-*O-d*, and 0.214 g (0.4 mmol) of **20**. After the normal work-up, t.l.c. examination of the solid showed the presence of triphenylphosphine oxide and a compound with an R_f value identical to that of 1,2-dimethylindole. Extraction of the solid with warm petroleum ether (60–80°) gave 0.037 g of 1-methyl-2-trideuteriomethylindole, m.p. 53–54°, which showed u.v. spectral and t.l.c. behavior in several solvent systems identical with those of an authentic sample of 1,2-dimethylindole (50). Its n.m.r. spectrum was superimposable on that of 1,2-dimethylindole except that it lacked a signal at τ 7.60 (2-CH_3). The residue remaining after the petroleum ether extract was treated with hot ether to give 0.071 g of triphenylphosphine oxide. The remaining residue was recrystallized from ethanol-*O-d* to give 0.635 g of deuterated starting material, m.p. 230–232° (dec.), which showed a u.v. spectrum identical to that of **20** and differed in the n.m.r. spectrum from the latter compound only in the absence of an absorption at τ 4.4 indicating that only the methylene protons had undergone deuterium exchange (see Table 3).

*cis–trans Isomerization of Compound **25***c*

*(a) Acid-catalyzed (cis-**25***c* → *trans-**25***c*)*

A solution of 0.100 g of *cis*-**25***c* in 25 ml of 1 *N* sulfuric

[a]Reported yields are of crystallized material except in the case of **32**.
[b]Isolation procedure: the reaction mixture was poured into ice-water and the resulting cloudy solution was exhaustively extracted with ether. The ether extract was dried (Na_2SO_4), concentrated and the residue was chromatographed (benzene).
[c]Poor results were obtained when THF was used as a solvent.
[d]The m.p. of **25***b* was incorrectly reported as 165–166° (dec.) and the yield of its formation has been improved from 74% to 99% (*cf.* ref. 1).
[e]Chromatography using chloroform as eluent.
[f]The reaction mixture was concentrated and extracted with cold petroleum ether (60–80°) to give *cis*-**25***c*. The residue was suspended in ether and repeatedly extracted with 5% hydrochloric acid solution. The combined acid extracts were basified with solid sodium carbonate and the solution was extracted with ether. The ether extract was dried (Na_2SO_4) and concentrated to yield *trans*-**25***c*.
[g]The reaction mixture was processed as in footnote [b] but the ether extract was treated with a saturated solution of citric acid in ether–ethanol (100:1). The resulting precipitate was washed with ether and then stirred with 10% sodium carbonate solution (200 ml) for 3 h. The aqueous solution was extracted with ether to yield reasonably pure product.
[h]Work-up as in footnote [f] followed by preparative t.l.c. on silica gel (Merck GF254, 9:1 MeOH:CH_2:Cl_2).
[i]Treatment of oily *cis*- or *trans*-**32** with methyl iodide in $CHCl_3$ at room temperature gave the same *trans*-**32** methiodide, m.p. 271 °C (MeOH) (identical i.r., u.v., mixture m.p. undepressed).
[j]Hygroscopic and unstable.

acid was stirred at room temperature for 36 h. The solution was basified with sodium carbonate and extracted with ether. Chromatography over basic alumina (grade III, methylene chloride) yielded 0.041 g of *trans*-**25***c* and 0.058 g of *cis*-**25***c*.

(b) Photochemical (trans-25c → cis-25c)

A solution of 0.100 g of *trans*-**25***c* in 200 ml of methylene chloride was irradiated under nitrogen at 3500 Å in a Rayonet Photochemical Reactor for 4 h. The solution was evaporated to dryness to give 0.0995 g of crystalline *cis*-**25***c*.

Photocyclization of trans-25c to 7H-Pyrido(2,3-c)-carbozole (28)

The photocyclization of *cis*-**25***c* (m.p. 118°) originally assumed to be the *trans* isomer (1) to **28** has been described (18). Under these conditions, *trans*-**25***c* (m.p. 210–211°) gave a 48% yield of **28** which was shown to be identical to an authentic sample (18).

We thank the National Research Council of Canada for financial support. Partial support from the University of Waterloo and the Ontario Mental Health Foundation is also gratefully acknowledged. We warmly thank Dr. D. B. MacLean, Mr. B. Sayer, Dr. L. W. Reeves, and Mr. R. Shaddick for some of the n.m.r. spectra, and Drs. R. H. F. Manske and J. Muchowski for suggestions and discussion. N. Burnett and E. R. Vrscay ably aided in large scale preparations. Dr. F. Grail of the Chemical Abstracts Service kindly solved some nomenclature problems.

Halogen Ring Monosubstituted Benzoic Acid Hydrazides as Ligands. II.[1] Ultraviolet Spectra and pK Determination

GEORGE MANOUSSAKIS, DEMETRIUS HARISTOS, AND CATHERINE YOURI
Laboratory of Inorganic Chemistry, University of Thessaloniki, Thessaloniki, Greece

Received September 14, 1972

The u.v. spectra of 12 halogen-substituted benzoic acid hydrazides are reported. A very intense band in the region 225–260 mμ and a second one of low intensity at 270–290 mμ are assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions, respectively.

The pK_1 and pK_2 of the mentioned hydrazides, corresponding to the Brönsted acids $XC_6H_4C(O)\overset{+}{N}H\overset{+}{N}H_3$ and $XC_6H_4C(OH)=NNH_2$ respectively, were obtained spectrophotometrically (X = F, Cl, Br, or I in *o*-, *m*-, and *p*-position). The influence of the nature and the position of the halogen atom on the pK values is discussed.

Les spectres u.v. de 12 hydrazides d'acides benzoïques substitués par des halogènes sont rapportés. Une bande très intense dans la région de 225–260 mμ et une autre de faible intensité à 270–290 mμ ont été assignées respectivement aux transitions $\pi \rightarrow \pi^*$ et $n \rightarrow \pi^*$.

Les pK_1 et pK_2 des hydrazides mentionnés, correspondant respectivement aux acides de Brönsted $XC_6H_4C(O)\overset{+}{N}H\overset{+}{N}H_3$ et $XC_6H_4C(OH)=NNH_2$ ont été obtenus spectrophotométriquement (X = F, Cl, Br, ou I en position *o*-, *m*-, ou *p*-). L'influence de la nature et de la position des atomes d'halogène sur les valeurs de pK est discutée. [Traduit par le journal]

Can. J. Chem., 51, 811 (1973)

Introduction

The present paper deals with the effect of substitution on the proton dissociation constants of halogen-substituted benzoic acid hydrazides (HBAH) and with their chelate-forming tendency. This investigation was undertaken because of our interest in the equilibria between these hydrazides and several metal ions in solution.

As far as we know, very limited attempts have been made to study spectrophotometrically and to elucidate the stabilities of halogen-substituted benzoic acid hydrazides. A notable work on this subject was that of Titov *et al.* (2, 3) who determined the pK of several ring-substituted hydrazides, including the *m*- and *p*-chloro-derivatives.

Results and Discussion

At lower pH values, the u.v. spectra of the studied hydrazides show two characteristic bands: a low intensity band at 270–290 mμ which is possibly due to an $n \rightarrow \pi^*$ transition, and a second one in the region 225–260 mμ that is possibly due to a $\pi \rightarrow \pi^*$ transition. The intensities of both these bands depend on pH values, as is shown in the representative spectra (Fig. 1). The intensity of the second band ($\pi \rightarrow \pi^*$) decreases markedly with an increase in pH while at the same time, the intensity of the first band ($n \rightarrow \pi^*$) increases, resulting in the appearance of two isosbestic points.

The presence of two isosbestic points is an indication that the equilibrium in question involves three absorbing species. This is more obvious from the diagram of Fig. 2, which shows the correlation between optical density (D) and pH values at 250 mμ, for the *o*-Cl derivative. In the analogous curves for the other 11 hydrazides, the inflection points are at almost the same place. The first section (A) of the curve in Fig. 2 corresponds to the equilibrium between the Brönsted acid $XC_6H_4C(O)\overset{+}{N}H\overset{+}{N}H_3$, designated LH^+, and the neutral form, $XC_6H_4C(O)NHNH_2$ (LH); the horizontal section (B) corresponds only to the neutral form; and the third section, at p$H > 10$, corresponds to equilibrium between the enolic $XC_6H_4C(\bar{O})=NNH_2$ (L^-) and neutral forms.

The wavelengths and molecular absorption coefficients of $\pi \rightarrow \pi^*$ bands of species LH and LH_2^+ of *p*-derivatives are tabulated in Table 1. *p*-Derivatives are specially selected, because their λ_{max} of $\pi \rightarrow \pi^*$ bands are in the accessible part of the spectrum (4). The $\pi \rightarrow \pi^*$ bands show considerable shifting to higher wavelengths and increase in ε_{max} from fluoro- to iodo-derivatives.

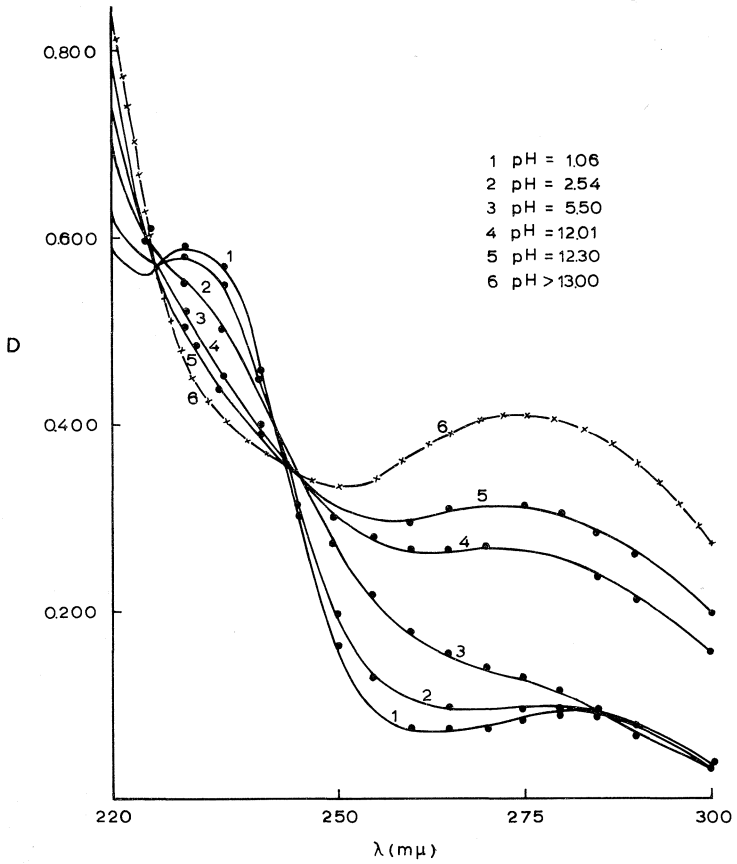

FIG. 1. Absorption spectra of *m*-Cl benzoic acid hydrazide in different p*H* values. Curve 6 is calculated.

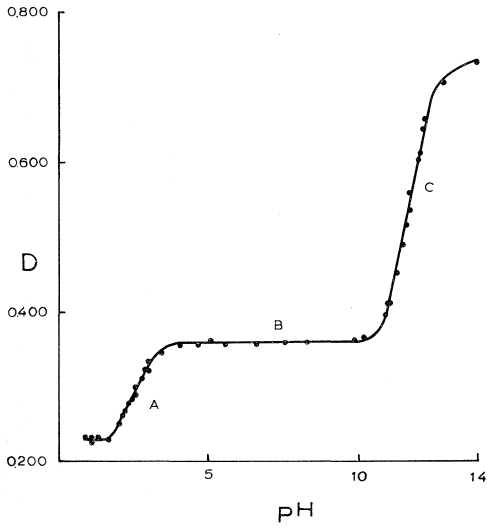

FIG. 2. Correlation between optical density and p*H* values at 250 mμ of *o*-Cl derivative.

TABLE 1. The λ_{max} and ε_{max} values of free benzoic acid hydrazide and HBAH in *p*-position

	LH		LH^{2+}	
Hydrazides	λ_{max} (mμ)	ε_{max}	λ_{max} (mμ)	ε_{max}
Free	226	8714	230	9620
p-F	229	8950	233	10150
p-Cl	237	13150	241	14700
p-Br	242	14050	247	15375
p-I	252	15025	257	14560

These variations are attributed mainly to the inductive effect ($-I$) and resonance effect ($+R$), which are introduced by the halogen substituent. These effects influence the polarity of the C—O bond; the first of them ($-I$) decreases the polarity and the second one ($+R$) increases it.

The increasing of ε_{max} values from fluoro- to iodo-derivatives (Table 1), could be explained by

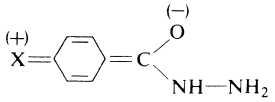
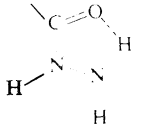
*The optical density of species L^- is calculated.
†Numbers in parentheses are references.

assuming that the chromophore action of HBAH is due to the following resonance form:



The value of ε_{max} will depend on the contribution of this form, which is favored by the polarization of the halogen atom and the strength of +R effect. The resonance effect varies according to series F < Br < Cl < I.

The values of λ_{max} and the corresponding ε values change slightly in going from neutral (LH) to ionic form (LH_2^+) of hydrazides (Table 1). This change is also attributed to the increased polarity of the C—O bond, which is affected as well by the form of the hydrazino group. The ionic form, $-NHNH_3^+$, makes the C—O bond more polar. The unique exception is the iodo-derivatives. This exception is possibly due to the greater tendency of the iodo-derivatives to form stronger intramolecular hydrogen bonding of the type,



because of the more pronounced resonance effect (+R). The increased tendency of the *p*-I derivatives to form strong intramolecular coupling of this type is obvious from the similarity of their i.r. spectra in the region of the amide I band, to those of the *o*-derivatives which also have a tendency to undergo intramolecular coupling (1).

The stability constants for the proton–ligand complexes have been determined spectrophotometrically (5). The method consists in determining the relative proportion of ions to molecules when a hydrazide is dissolved in a series of solutions of accurately known pH values. This has been done at the analytical wavelength, λ_{anal}, at which the greatest difference in optical densities between ion and molecule has been observed. For this purpose, the optical density of hydrazide solutions has been measured over the whole spectrum in a large range of pH values. Table 2 contains (*a*) the optical densities of the species LH_2^+, LH, and L^- at the corresponding region of the pH values, (*b*) the calculated pK values, and (*c*) the analytical wavelength used in each case. Since D_{L^-} values are not directly obtainable, they are calculated indirectly using a graphical method. The pK_1 and pK_2 values, in Table 2, which correspond to Brönsted acids $XC_6H_4C(O)NHNH_3^+$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and $XC_6H_4C(OH)=NNH_2$ respectively, were calculated from eqs. 1 and 2, where D_L is the observed optical density of species L^-, D_M that of a mixture of L^- and LH, and D_{LH} of LH respectively at the analytical wavelength in the proper region of pH.

$$[1] \qquad pK_1 = pH + \log \frac{D_{LH} - D_M}{D_M - D_{LH_2^+}}$$

$$[2] \qquad pK_2 = pH + \log \frac{D_{L^-} - D_M}{D_M - D_{LH}}$$

The obtained values agree well with those in the literature (2, 3, 6) for the non-substituted benzoic acid hydrazide thus confirming the reliability of the method used. Also in the cases of *m*- and *p*-chloro-derivatives, some data were available in the literature, but since these values were required as the basis of the present investigation, they were freshly collected under the conditions of this study. For these compounds our values, when converted into approximate thermodynamic constants, agree well with the values reported by Titov *et al.* (2, 3).

As it is shown from the calculated pK values (Table 2), *o*-derivatives are stronger acids than meta, and meta are stronger than *p*-derivatives. Such a change will be expected if we take into consideration that the strength of $-I$ inductive effect varies according to the series *o*-, *m*-, *p*-; this means a stronger withdrawal of electron charge by the substituent, according to the above-mentioned series.

The pK values of fluoro derivatives are higher than those of the corresponding chloro, bromo, and iodo compounds. This unusual phenomenon may be due to the possibility that fluoro-derivatives form stronger intra- or intermolecular hydrogen bonds.

Experimental

Preparation of Hydrazides

The hydrazides were prepared by the same method as described in an earlier communication (1).

Physical Measurements

A Zeiss PMQ II u.v. spectrophotometer was used. The pH values were measured by a Beckman pH meter (glass–calomel electrode). The ionic strength was 0.01 M with KCl.

Electrochemical Studies of Organotitanium Nitrogen Fixation Systems

T. CHIVERS AND E. D. IBRAHIM

Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received August 28, 1972

The electrochemical reduction of compounds of the type $(\pi\text{-Cp})_2\text{Ti(R)Cl}$ (R = Cl, CH_3, C_6H_5, C_5F_5, $OTiCl(\pi\text{-Cp})_2$) in ether solvents has been studied using the techniques of polarography, controlled potential electrolysis, and cyclic voltammetry. The one-electron reduction products, presumably $(\pi\text{-Cp})_2\text{TiR}$ (R = CH_3, C_6F_5), are initially green in tetrahydrofuran but, in a dinitrogen or argon atmosphere, they form intensely blue solutions which result from the reaction of $(\pi\text{-Cp})_2\text{TiR}$ with tetrahydrofuran solvent.

La réduction électrochimique des composés du type $(\pi\text{-Cp})_2\text{Ti(R)Cl}$ (R = Cl, CH_3, C_6H_5, C_6F_5, $OTiCl(\pi\text{-Cp})_2$) dans des solvants éthérés a été étudiée en utilisant les techniques de la polarographie, de l'électrolyse à potentiel contrôlé et de la voltamétrie cyclique. Les produits des réductions n'impliquant qu'un seul électron, probablement $(\pi\text{-Cp})_2\text{TiR}$ (R = CH_3, C_6F_5) sont initialement verts dans le tétrahydrofuranne mais, sous un atmosphère d'azote (N_2) ou d'argon, ceux-ci forment des solutions bleues très intenses qui sont les résultat de la réaction entre le produit $(\pi\text{-Cp})_2\text{TiR}$ et le solvant tétrahydrofuranne.
[Traduit par le journal]

Can J. Chem., **51**, 815 (1973)

Introduction

A number of systems which involve bis(π-cyclopentadienyl)titanium dichloride, $(\pi\text{-Cp})_2\text{TiCl}_2$, in the presence of an excess of a reducing agent are active in nitrogen fixation (1–11). The identity of the reduced titanium species responsible for nitrogen fixation has not been definitely established, however, although numerous suggestions have been made (Table 1). Brintzinger and co-workers (12, 13) have provided supporting evidence for the role of titanocene monomer in the coordination step, originally suggested by van Tamelen and co-workers (5–8), by isolation of the intensely blue complex $[(\pi\text{-Cp})_2\text{Ti}]_2\text{N}_2$ stable at room temperature. It is not certain, however, that the identity or even the oxidation state of the active titanium intermediate is the same for all the reducing systems described in Table 1. Indeed an intensely blue complex formed between dinitrogen and $(\pi\text{-Cp})_2\text{Ti}^{III}\text{Ph}$ of composition $[(\pi\text{-Cp})_2\text{TiPhN}]_n$ has been isolated, but is unstable above 0° (14).

The use of electrochemical techniques, whereby the extent of reduction of Ti(IV) can be controlled precisely, to study the reduction of $(\pi\text{-Cp})_2\text{TiCl}_2$ in the presence and absence of dinitrogen has been recognized (13, 15). Dessy and co-workers observed the formation of a deep blue species in the controlled potential reduction of $(\pi\text{-Cp})_2\text{TiCl}_2$ in dimethoxyethane after uptake of 2 electrons and attributed it to monomeric $(\pi\text{-Cp})_2\text{Ti}$ (16). More recently, Doisneau and Marchon (15) reported that the blue color appears under an atmosphere of dinitrogen, but not under helium, suggesting that the blue dinitrogen complex $[(\pi\text{-Cp})_2\text{Ti}]_2\text{N}_2$ might be generated in these electrolytic reductions. However, Brintzinger and co-workers have challenged this conclusion since they find that blue solutions are obtained under argon as well

TABLE 1. Nitrogen fixation systems based on $(\pi\text{-Cp})_2TiCl_2$

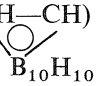
as in a dinitrogen atmosphere. They suggest the formation of the blue species is due to reaction of monomeric $(\pi\text{-Cp})_2Ti$ with either solvent or supporting electrolyte.

We have studied the electrochemical reduction of compounds of the type $(\pi\text{-Cp})_2Ti(R)Cl$ (R = Cl, CH_3, C_6H_5, C_6F_5, $OTiCl(\pi\text{-Cp})_2$) in ether solvents in order to determine the role of their one-electron reduction products $(\pi\text{-Cp})_2TiR$ in the coordination of dinitrogen. When this work was begun compounds of the type $(\pi\text{-Cp})_2TiR$ were unknown although $(\pi\text{-Cp})_2TiPh$ had been proposed as an intermediate in the $(\pi\text{-Cp})_2TiCl_2$/PhLi nitrogen fixation system (11) and in the thermal decompsition of $(\pi\text{-Cp})_2TiPh_2$ in hydrocarbon solvents (17) or in the presence of diphenylacetylene (18). $(\pi\text{-Cp})_2TiMe$ was presumed to be stable at room temperature from the persistence of its e.s.r. spectrum (10). During the course of this work brief reference has been made to the preparation of some $(\pi\text{-Cp})_2TiR$ derivatives (R = $\sigma\text{-}C_5H_5$, C_6F_5, $\sigma\text{-}CH_2C_6H_5$, $o\text{-}C_6H_4CH_2NMe_2$) (19). Previous electrochemical studies of organotitanium compounds in aprotic solvents have included the dihalides $(\pi\text{-Cp})_2TiX_2$ (X = F, Cl, Br, I) (24) and some $(\pi\text{-Cp})_2TiR_2$ derivatives (R = CH_3, C_6H_5, and $-CH_2-CH-CH)$ (25).



Experimental

Apparatus

Polarography

Polarographic measurements were carried out using a Metrohm Polarecord E261R in conjunction with an *iR* compensator E446. The dropping mercury electrode (d.m.e.) had the following characteristics: $m = 4.58$ mg/s and $t = 1.96$ s with open circuit and $h = 63.5$ cm. A saturated aqueous calomel electrode (s.c.e.) was used as a reference electrode. An agar salt bridge connected to a tube containing $(n\text{-Bu})_4NClO_4$ (10^{-1} *M*) in dimethoxyethane and a fine porosity frit was used to separate the s.c.e. from the solution under investigation. A two compartment cell in which the electrodes were separated by a 25 mm medium porosity frit was used and the auxiliary electrode was a platinum wire. Polarograms were recorded for solutions in both tetrahydrofuran and dimethoxyethane. Solutions were *ca.* 10^{-3} *M* in electroactive substance for polarography and 10^{-1} *M* in supporting electrolyte $(n\text{-Bu})_4NClO_4$ for all electrochemical work. These solutions were degassed for 15 min (N_2) or 40 min (Ar) and polarographic measurements were made at 25°.

Controlled Potential Electrolysis

Microcoulometric measurements were carried out in the same cell using a Heath Malmstadt-Enke EUW-401 polarography system in conjunction with a EUW-19A operational amplifier. The recorder of the Metrohm Polarecord was used for current–time curves, and *n* values were determined by measuring the area under these curves. The working electrode was a mercury pool, and electrical contact was made via a platinum wire pinch-sealed into glass. Stirring was achieved by bubbling inert gas into the solutions during electrolysis. Solutions were *ca.* 10^{-6} *M* in electroactive substance for microcoulometric measurements and the initial current was *ca.* 0.7–0.8 mA. Solutions were *ca.* 2×10^{-3} *M* for the formation of the blue species.

Cyclic Voltammetry

Cyclic potential sweeps were generated by a Hewlett–Packard 3300A function generator with trigger/phase lock plugin 3302A. The working electrode was a hanging mercury drop which could be adjusted by means of a micrometer screw. Read out devices were a Hewlett-Packard 7034A X–Y recorder (slow sweeps) and a Tektronix storage oscilloscope equipped with a Polaroid camera C12 (fast sweeps). Solutions were *ca.* 10^{-4} *M* in electroactive substance.

Materials

Argon and dinitrogen (prepurified 99.997% min.) were passed through a 30 cm column of freshly activated Ridox reagent (Fisher Scientific Co.) and a 30 cm column of phosphorus pentoxide and were then presaturated with ether solvent before passing into the solutions under electrochemical investigation. Ether solvents were predried (Na) and then freshly distilled from $LiAlH_4$ under argon before use. It was particularly important to ensure that dimethoxyethane was free of peroxide. Tetra-*n*-butylammonium perchlorate, prepared from tetra-*n*-butylammonium hydroxide and perchloric acid, was recrystallized from ethanol/water and dried overnight at 110°/0.01 mm in an Aberhalden pistol.

$(\pi\text{-Cp})_2TiCl_2$ was supplied by Strem Chemicals Inc. and was recrystallized from toluene before use. $(\pi\text{-Cp})_2Ti(C_6F_5)Cl$ was prepared from pentafluorophenyl-lithium and $(\pi\text{-Cp})_2TiCl_2$ (20) and after recrystallization from benzene/hexane had m.p. 201–203° (lit. m.p. 201–203° (20); 187–188° (21)).

Anal. Calcd. for $C_{16}H_{10}ClF_5Ti$: C, 50.5; H, 2.7. Found C, 49.9; H, 3.3.

$(\pi\text{-Cp})_2Ti(Cl)O(Cl)Ti(\pi\text{-Cp})_2$ was prepared by air oxidation of the green solution formed by reducing $(\pi\text{-Cp})_2TiCl_2$ with zinc dust in acetone and had m.p. 226–230° after recrystallization from acetone (lit. m.p. 230° dec. (22)).

Anal. Calcd. for $C_{20}H_{20}Ti_2Cl_2O$: C, 54.2; H, 4.6. Found: C, 54.2; H, 4.9.

$(\pi\text{-Cp})_2Ti(Me)Cl$ was prepared from $(\pi\text{-Cp})_2TiCl_2$ and methylmagnesium chloride in dry methylene chloride at −30° and recrystallized from hexane/toluene to give orange-yellow crystals of $(\pi\text{-Cp})_2Ti(CH_3)Cl$ which had an infrared spectrum identical to that reported in the literature (23). The ^1H n.m.r. spectrum in $CDCl_3$ showed two peaks at 3.72τ (π-C_5H_5) and 9.19τ (CH_3) with relative intensities 29:9.5 (lit. 3.66τ (π-C_5H_5); 9.28τ (CH_3) (23)). $(\pi\text{-Cp})_2Ti(C_6H_5)Cl$ was prepared according to the literature (23) but was not sufficiently stable as a dilute solution in dimethoxyethane for detailed electrochemical studies.

Spectroscopic Measurements

Solutions for spectroscopic investigations were removed from the electrochemical cell under vacuum and then transferred to a Vacuum Atmospheres dry-box. The following instruments were used: ^1H n.m.r. spectra (Varian A60), infrared spectra (Perkin–Elmer 337, and 621), ultraviolet/visible spectra Beckman DB-G. Analyses were carried out in this department by Mrs. S. Swaddle and by Alfred Bernhardt, W. Germany.

Results and Discussion

The data for the polarographic and controlled potential reduction of $(\pi\text{-Cp})_2Ti(R)Cl$ (R = CH_3, C_6H_5, C_6F_5, Cl, $OTiCl(\pi\text{-Cp})_2$) derivatives are summarized in Table 2.

$(\pi$-Cp$)_2$Ti(CH$_3$)Cl (1)

The polarogram of **1** shows one anodic and three cathodic waves. The anodic wave and first cathodic wave have very small diffusion currents which increase in intensity if the solution is stirred with mercury before imposition of potential indicating that these waves result from a reaction of **1** with mercury, as previously observed by Gubin and Smirnova (24) in their electrochemical studies of bis(π-cyclopentadienyl)titanium dihalides. The limiting currents of these two waves are independent of concentration and $\sqrt{h}$, suggesting kinetic behavior. The second cathodic wave shows absorption behavior up to a mercury height of 45 cm followed by a linear dependence on $\sqrt{h}$. A graph of potential against log $i/(i_d - i)$ for this wave had a slope of −0.096 V indicative of an irreversible electrode process, as expected for cleavage of a Ti—Cl bond. Controlled potential electrolysis on the plateau of the first wave (−1.80 V) gave an n value of 1.1, suggesting that this wave involves a one-electron reduction. The third cathodic wave at −2.32 V is very irreversible and c.p.e. on the plateau of this wave gave an n value of 2.2.[1] Since the limiting currents for the second and third cathodic waves are 4.0 and 0.5 μA, respectively, the following mechanism is postulated to explain the coulometric results,

TABLE 2. Polarographic and microcoulometric data for the reduction of $(\pi\text{-Cp})_2Ti(IV)$ derivatives in dimethoxyethane, 0.1 *M* Bu_4NClO_4

Compound	$-E_{1/2}$ (V)*	i_d (μA)	n†

§Reference 16.

[1]Gubin and Smirnova (24) reported only two waves for the polarographic reduction of **1** in dimethylformamide; an anodic wave at 0.14 V and a poorly defined cathodic wave at −1.17 V (*vs.* s.c.e.).

$$(\pi\text{-Cp})_2\text{Ti(CH}_3\text{)Cl} + e^- \rightarrow (\pi\text{-Cp})_2\text{TiCH}_3 + \text{Cl}^- \quad \text{(wave 2)}$$

$$(\pi\text{-Cp})_2\text{TiCH}_3 + \text{solvent} \xrightarrow{k_c} \text{Y}$$

$$\text{Y} + e^- \rightarrow \text{Z} \quad \text{(wave 3)}$$

where k_c has a value such that the chemical reaction occurs completely on the timescale for coulometry but not on that for polarography. The cyclic voltammogram of a 10^{-3} *M* solution of **1** with cathodic hold is shown in Fig. 1 and confirms the irreversible nature of the polarographic reduction at -1.26 V (peak A). The anodic sweep, however, reveals an oxidative wave (B) which, on reverse cathodic sweep, has associated with it a cathodic wave (C) with $E_{1/2}$ corresponding to the first cathodic polarographic wave. We are thus dealing with the process

$$(\pi\text{-Cp})_2\text{TiCH}_3 \underset{+e^-,\,(C)}{\overset{-e^-,\,(B)}{\rightleftharpoons}} (\pi\text{-Cp})_2\text{TiCH}_3^+$$

During electrochemical reduction (1 h) at -1.8 V, the orange solution of **1** in tetrahydrofuran turns green, consistent with the formation of $(\pi\text{-Cp})_2\text{TiCH}_3$ (26). After completion of the reduction the green solution becomes deep blue ($\frac{1}{2}$ h) either under a dinitrogen *or* an argon atmosphere. The appearance of the blue solution in the electrochemical reduction is not, therefore, due to the formation of a dinitrogen complex of the type $[(\pi\text{-Cp})_2\text{Ti(CH}_3\text{)N}]_n$ (14).

$(\pi$-Cp$)_2$Ti(C_6F_5)Cl (2)

The polarogram of **2** shows two cathodic waves at -0.84 V and -2.55 V. A very small pre-wave at -0.28 V results from the interaction of **1** with mercury before imposition of potential since its limiting current increases if the solution is stirred with mercury as indicated by polarograms recorded at regular time intervals. The first cathodic wave is well-defined and its limiting current is proportional to concentration and $\sqrt{h}$ indicating a diffusion-controlled process. The slope of the curve log $(i/i_d - i)/E$ is -0.120 V suggesting an irreversible reduction, as expected for cleavage of a Ti—Cl bond, and this is confirmed by the cyclic voltammogram which shows similar features to the cyclic voltammogram of **1** (Fig. 2). Controlled potential electrolysis at the first wave (-1.1 V) gives an *n* value of 1.1 suggesting a one-electron reduction. The orange solution of **2** in tetrahydrofuran turns green and then blue during electrochemical reduction (1 h) at the first wave under a dinitrogen *or* an argon atmosphere. As with **1** the appearance of the blue solution is not, therefore, due to the formation of a dinitrogen complex.

$(\pi$-Cp$)_2TiCl_2$ (4)

The polarographic reduction of **4** in dimethoxyethane proceeds via two one-electron steps (16) (Table 2). During the electrolysis of a 2×10^{-3} *M* solution of **4** in tetrahydrofuran (2 h) with *n*-Bu_4NClO_4 as supporting electrolyte at -2.4 V *vs.* s.c.e. (*i.e.* on the plateau of the *second* polarographic wave) we observed the following color changes: orange → yellow → green → blue *either* under a dinitrogen or under an argon atmosphere. These observations are consistent with the results of Brintzinger and co-workers (13) who used dimethoxyethane as solvent. Although monomeric $(\pi\text{-Cp})_2\text{Ti}$ is un-

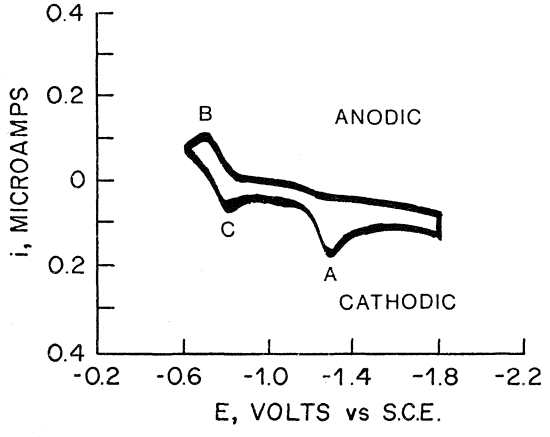

FIG. 1. Cyclic voltammogram of $(\pi\text{-Cp})_2\text{Ti(CH}_3\text{)Cl}$ in dimethoxyethane containing 0.1 *M* *n*-Bu_4NClO_4.

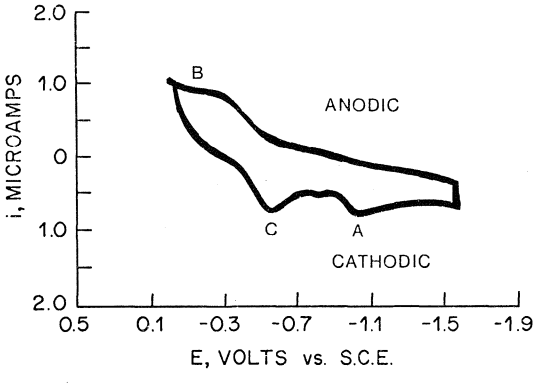

FIG. 2. Cyclic voltammogram of $(\pi\text{-Cp})_2\text{Ti}(C_6F_5)\text{Cl}$ in dimethoxyethane containing 0.1 *M* *n*-Bu_4NClO_4.

For personal use only.

doubtedly the primary product of electrolysis under these conditions, it is clear that the blue solutions do not result from dinitrogen uptake to give the known complex $[(\pi\text{-Cp})_2\text{Ti}]_2\text{N}_2$ (12, 13).

$[(\pi\text{-Cp})_2TiCl]_2O$ (5)

The polarogram of **5** shows one anodic wave and three cathodic waves.[2] The first two waves are kinetic in nature, their limiting currents being independent of $\sqrt{h}$. The cathodic wave at -0.77 V is diffusion controlled, as indicated by the linear dependence of the limiting current on concentration and $\sqrt{h}$. The slope of the curve $\log (i/i_d - i)/E$ is 0.154 V indicative of an irreversible electrochemical process. The irreversibility was confirmed by cyclic voltammetry. Controlled potential electrolysis (2 h) on the plateau of this wave (-1.45 V) gave an n value of 2, suggesting the following electrochemical reduction

$$(\pi\text{-Cp})_2\text{Ti(Cl)O(Cl)Ti}(\pi\text{-Cp})_2 + 2e^- \rightarrow (\pi\text{-Cp})_2\text{TiOTi}(\pi\text{-Cp})_2 + 2\text{Cl}^- \quad (6)$$

The color of the reduced solution, under dinitrogen, was green and remained green after completion of electrolysis, unlike the solutions containing the one-electron reduction products of **1** and **2**. The third cathodic wave of **5** at -2.38 V was poorly defined and clearly irreversible. Controlled potential electrolysis on the plateau of this wave gave an intensely blue solution consistent with the electrochemical cleavage of a Ti—O bond in **6** to give monomeric $(\pi\text{-Cp})_2\text{Ti}$ and an oxyanion *e.g.* $(\pi\text{-Cp})_2\text{TiO}^-$.

Conclusions

Nature of the Blue Solutions

The green, one-electron reduction products of $(\pi\text{-Cp})_2\text{Ti(R)Cl}$ (R = CH_3, C_6F_5), presumably $(\pi\text{-Cp})_2\text{TiR}$, in tetrahydrofuran turn blue under either a dinitrogen *or* an argon atmosphere. The blue species cannot, therefore, be a dinitrogen complex of the type $[(\pi\text{-Cp})_2\text{Ti(R)N}]_n$ but it may be a secondary product resulting from the interaction of electrochemically generated $(\pi\text{-Cp})_2\text{TiR}$ with either the solvent or the electrolyte. Although the blue solutions formed in the electrolytic reductions are thermally more stable than the blue dinitrogen complex $[(\pi\text{-Cp})_2\text{Ti}(C_6H_5)\text{N}]_n$ (14), they are extremely air-sensitive and it is not a practical proposition to separate the small amount of blue species from the large excess of electrolyte. Consequently we have prepared $(\pi\text{-Cp})_2\text{TiR}$ derivatives (R = CH_3, C_6F_5) by chemical reduction of $(\pi\text{-Cp})_2\text{Ti(R)Cl}$ (26) and we find that *ca.* 10^{-3} *M* solutions of the green $(\pi\text{-Cp})_2\text{TiR}$ compounds in tetrahydrofuran slowly become blue (λ_{max} 580 nm, R = CH_3; λ_{max} 582 nm, R = C_6F_5) either under a dinitrogen atmosphere or *in vacuo*. Furthermore green solutions of $[(\pi\text{-Cp})_2\text{TiCl}]_2$ (*ca.* 10^{-3} *M*) in tetrahydrofuran, but not in benzene, become an intense violet blue color (λ_{max} 575 nm) during the course of one week at room temperature either under dinitrogen or *in vacuo*.[3] Thus the blue solutions must be formed by interaction of $(\pi\text{-Cp})_2\text{Ti}^{III}$ derivatives with solvent tetrahydrofuran or by isomerization induced by the solvent. Removal of solvent from the blue solutions gives thermally stable, air-sensitive blue-black crystalline solids.

The characterization of these solids and the preparation of $(\pi\text{-Cp})_2\text{Ti}^{III}\text{R}$ derivatives by chemical reduction will be the subjects of future publications.

We are grateful to Dr. I. Drummond for help with the cyclic voltammetry experiments and to the National Research Council of Canada for financial support.

Pressure Effects upon the Rates of Aquation of Halopentaamminechromium(III) Ions: Evidence for an Associative Mechanism

G. GUASTALLA AND T. W. SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary, Alberta T2N 1N4

Received September 13, 1972

For the replacement of X^- by H_2O in $Cr(NH_3)_5X^{2+}$, ΔV_0^* (the value of the volume of activation ΔV^* at zero pressure) at 25.0° in 0.1 *m* NH_4ClO_4 is −10.8, −10.2, and −9.4 $cm^3\ mol^{-1}$ respectively for $X^- = Cl^-$, Br^-, and I^-, while ΔV, the molar volume of reaction, is −8.4, −7.2 and −6.0 $cm^3\ mol^{-1}$. The pressure-dependence of ΔV^* can be expressed in terms of the number x of water-molecules which are electrostricted as the systems go from ground-state to transition-state; for $X^- = Cl^-$, Br^-, and I^-, $x = 1.9$, 2.0, and 1.7. These data, combined with $\Delta V^* = -5.8\ cm^3\ mol^{-1}$ for the aquo-exchange of $Cr(NH_3)_5OH_2^{3+}$, indicate an associative mechanism for these reactions, as does the contrast with ΔV_0^* data for the formally analogous, but dissociatively-activated, reactions of $Co(NH_3)_5X^{(3-n)+}$.

Dans le remplacement de X^- par H_2O dans $Cr(NH_3)_5X^{2+}$, ΔV_0^* (valeur du volume d'activation ΔV^* à la pression zéro) à 25.0° dans NH_4ClO_4 0.1 *m* est de −10.8, −10.2, et −9.4 $cm^3\ mol^{-1}$ respectivement pour $X^- = Cl^-$, Br^-, et I^-, tandis que ΔV, volume molaire de la réaction, vaut −8.4, −7.2, et −6.0 $cm^3\ mol^{-1}$. L'influence de la pression sur ΔV^* peut être exprimée en fonction du nombre x de molécules d'eau, conditionné électrostatiquement lorsque le système passe de l'état fondamental à l'état de transition; pour $X^- = Cl^-$, Br^-, et I^-, $x = 1.9$, 2.0, et 1.7. Ces données, combinées à $\Delta V^* = -5.8\ cm^3\ mol^{-1}$ pour l'échange à l'eau de $Cr(NH_3)_5OH_2^{3+}$, indiquent un mécanisme associatif pour ces réactions, de même que les données contraires sur ΔV_0^* concernant les analogues formels, mais activés par dissociation, des réactions de $Co(NH_3)_5X^{(3-n)+}$. [Traduit par le journal]

Can. J. Chem., **51**, 821 (1973)

Introduction

We have recently shown (1–5) that the effect of pressure P upon the rates of substitution reactions of transition-metal complexes in aqueous solution can lead to useful mechanistic information if *either* the reaction is suitably simple *or* there is an independent criterion with which the derived parameters (the volume of activation, ΔV^*, and its pressure dependence, if significant) can be compared. Thus, for the ideally simple aquo-exchange reaction of $Co(NH_3)_5OH_2^{3+}$, ΔV^* is $+1.2\ cm^3\ mol^{-1}$ and is pressure-independent within the experimental uncertainty (6), which suggests a dissociative mechanism. This conclusion is reinforced by the observation that for $X^{n-} = SO_4^{2-}$, Cl^-, Br^-, NO_3^-, *and* H_2O in the reaction

[1] $$Co(NH_3)_5X^{(3-n)+} + H_2O \rightarrow Co(NH_3)_5OH_2^{3+} + X^{n-}$$

there is an excellent linear correlation of slope 1.0 between ΔV_0^* ($=\Delta V^*$ at zero pressure) and the molar volume of reaction ΔV, which indicates that the Co—X is completely broken, and the solvation of X^{n-} fully provided for, in the transition state (1–3).

On the other hand, the ΔV^* values for the aquo-exchange reactions of $Cr(H_2O)_6^{3+}$ and $Cr(NH_3)_5OH_2^{3+}$ are respectively −9.3 and $-5.8\ cm^3\ mol^{-1}$ and are apparently pressure-independent (2, 4, 5). It would be very difficult to rationalize these latter data except in terms of an associative interchange (I_a) mechanism (7) in which a water molecule from the second coordination sphere (solvation sheath) of the complex displaces an existing aquo-ligand from the first coordination sphere in a synchronous process on a time scale which is short compared with the time scale of the exchange of water molecules in the second coordination sphere with bulk solvent. In this mechanism, as in the dissociative mechanism proposed for the Co(III) system, only the water-molecules of the relatively incompressible first and second coordination spheres are involved, independently of bulk solvent, so that ΔV^* is not a function of pressure in either case (4, 5). Since it has become common practice to assume *dissociative* activation to be operative in octahedral substitutions in general, we have sought further evidence for an associ-

ative mechanism at cationic chromium(III) centers through high-pressure kinetic studies analogous to those which were successful with cobalt(III) complexes (1–3).

We have previously presented other evidence (8) favoring an I_a mechanism for substitutions in complexes of the type $Cr(H_2O)_5X^{(3-n)+}$, although Ferraris and King (9) have published data which appear to favor a D mechanism (7), *i.e.*, one in which a $Cr(H_2O)_5^{3+}$ intermediate with a lifetime greater than the relaxation time of the second coordination sphere is formed, for cases in which X^{n-} is a "good leaving group." The apparently contradictory evidence can be reconciled in favor of an associative mechanism for spontaneous $Cr(H_2O)_5X^{(3-n)+}$ substitutions (see below), but in any case these reactions involve uncertainties arising from the apparent activation of the aquo-ligand *trans* to X in the iodo-complex at least (10), as well as difficulties stemming from the incursion of inversely hydrogen-ion-dependent competitive reaction pathways, even in strongly acidic solutions. We have therefore turned our attention to the analogous reactions

$$[2]\quad Cr(NH_3)_5X^{(3-n)+} + H_2O \rightarrow Cr(NH_3)_5OH_2^{3+} + X^{n-}$$

which have the added advantage of being directly comparable with the $Co(NH_3)_5X^{(3-n)+}$ series previously examined (1–3).

Experimental

Materials

$[Cr(NH_3)_5OH_2](NO_3)_3.NH_4NO_3$ was prepared by the standard method (11) and converted to $[Cr(NH_3)_5OH_2](ClO_4)_3$ by precipitation with perchloric acid; the product was recrystallized from water containing $HClO_4$.

Anal. Calcd. for $[Cr(NH_3)_5OH_2](ClO_4)_3$: N, 15.5; H, 3.8. Found: N, 15.5; H, 4.0.

$[Cr(NH_3)_5Cl](ClO_4)_2.2H_2O$ was prepared from the chloride (12, 13).

Anal. Calcd. for $[Cr(NH_3)_5Cl](ClO_4)_2.2H_2O$: N, 17.1; H, 4.4. Found: N, 17.2; H, 4.6.

$[Cr(NH_3)_5Br](ClO_4)_2$ was made from the bromide (11) by precipitation from warm aqueous solution with perchloric acid; it was washed once with ice-cold water, then dried with alcohol and ether.

Anal. Calcd. for $[Cr(NH_3)_5Br](ClO_4)_2$: N, 16.8; H, 3.6. Found: N, 16.5; H, 3.9.

$[Cr(NH_3)_5I]I_2$ was prepared by heating solid $[Cr(NH_3)_5OH_2]I_3$ (made by precipitation with NaI from a solution of the double nitrate) at 120° for 1 h; the product was washed several times with water and dried with alcohol and ether. It could not be converted to the perchlorate salt because of its low solubility and rapid aquation.

The positions and molar absorbancy indices of the maxima in the visible spectra of all the above compounds were in excellent agreement with published values (14). All these compounds were stored in the dark over P_2O_5.

Fisher Certified NH_4ClO_4 was used without further purification.

Kinetic Measurements

These were made *in situ* in a Cary Model 15 spectrophotometer, using the high-pressure optical cell assembly previously described (15). The temperature of the high-pressure cell was maintained at 25.0 ± 0.1° by circulating water from a thermostat bath through the walls of the spectrophotometer sample compartment, thermal contact being made through an aluminum mounting-block, and the temperature was measured with a calibrated Atkins thermistor inserted in a narrow well drilled close to the solution cavity.

The solutions were about 3.0×10^{-3} *m* in chromium(III) complex and 0.1 *m* in NH_4ClO_4. For the chloro- and bromo-complexes, the decrease in optical absorbance was measured continuously as a function of time at 240 and 265 nm respectively over periods of at least 2–3 half-lives of the first-order aquation reaction. The "infinite time" absorbances had to be estimated from measurements on fresh solutions of $[Cr(NH_3)_5OH_2](ClO_4)_3$ and the appropriate halide ion, since some loss of the ammonia ligands was anticipated after several half-lives of the halo-aquation processes. In the case of the iodo-complex, however, the halide replacement was sufficiently rapid to be followed for fully ten half-lives at 360 nm.

Duplicate kinetic experiments conducted using various spectrophotometer slit-widths gave the same rate coefficients (within the experimental uncertainty) as did runs made in ordinary 2 cm quartz cells and runs carried out in the pressure assembly at atmospheric pressure. Thus, neither photo-effects nor interactions with the pressure vessel influenced the reaction rates under our experimental conditions.

Dilatometry

Volume changes accompanying the aquation of the various $Cr(NH_3)_5X^{2+}$ ions were measured at atmospheric pressure and 25.00 ± 0.01°, using a 50.0 ml vessel fitted with an upright capillary outlet tube of 0.0991 mm internal diameter. The procedure resembled that described by Spiro *et al.* (16). Typically, a weighed quantity ($\sim 2 \times 10^{-4}$ mol) of the powdered complex was dissolved rapidly at a selected "zero-time" in 60.0 ml of a 0.10 *m* NH_4ClO_4 solution which was already at 25.00°, and the dilatometer (also at 25.00°) was filled at once to overflowing with the solution, so that a drop remained standing on the level top of the capillary tube. When temperature perturbations caused by the filling process had subsided (10–15 min), the drop of excess solution was removed carefully, and the fall of the resulting meniscus in the tube was followed with a cathetometer as a function of time *t* elapsed since "zero-time."

For the bromo- and iodo-complexes the level (h_t) of the meniscus was recorded until it became stationary (h_∞) and the hypothetical level (h_0) corresponding to the start

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the aquation at "zero-time" was obtained by extrapolation of the function[2] log $(h_t - h_\infty)$, which was accurately linear with respect to t, back to "zero-time." First-order rate coefficients k, obtained from these data, were in good agreement with those measured spectrophotometrically. The molar volume of reaction ΔV was calculated from $(h_0 - h_\infty)$, the cross-sectional area of the capillary, and the number of moles of the halo-complex which would have been present at "zero-time" in the dilatometer.

For the chloro-complex, and for some runs involving the bromo-, the reaction was not followed beyond ~70% completion in the dilatometer; rather, the values of k obtained from the spectrophotometric measurements were used to calculate the amounts of unreacted halo-complex which would be present at times t_1, t_2, etc., whence ΔV could be calculated from measurements of the corresponding heights h_1, h_2, etc. These two procedures gave identical results, within the experimental uncertainty, for the bromo-complex.

Results

The spectrophotometric rate data were accurately first-order in halo-complex concentration up to at least 90% completion of reaction for $X^{n-} = I^-$ or Br^-, or 70% for Cl^-. Some slight deviations from strict first-order behavior after long reaction times in the latter case seemed to originate in minor degrees of ammonia loss from the aquo- or chloro-complexes. First-order rate coefficients k were reproducible to within 1% at worst, and were the same (within this limit) in both 0.1 m NH_4ClO_4 and 0.1 m $HClO_4$; the values of k measured at 1 bar pressure agreed satisfactorily with those reported by Levine, Jones, Harris, and Wallace (17). These data are summarized in Table 1.

The dependence of ln k upon P is non-linear for $X^{n-} = Cl^-$, Br^- and I^-, but the data can be represented to within the experimental uncertainty by the purely empirical equation

$$[3] \qquad \ln k_P = \ln k_0 + BP + CP^2$$

which assumes $(\partial \Delta V^*/\partial P)_T$ to be constant $(= -2RTC)$ and yields $\Delta V_0^* = -RTB$. Alternatively, if we assume instead that the pressure-dependence of ΔV^* is due exclusively to electrostriction of solvent (which is justified (3, 5), since ΔV^* is independent of P for the case $X^{n-} = H_2O$, in which there is no electrostrictional contribution) and acknowledge that electrostricted water is virtually incompressible as compared with bulk water, we can adapt the Tait equation for the compressibility of water to obtain the relationship

$$[4] \quad \ln k_P = \ln k_0 - P\Delta V_0^*/RT - (0.251x/RT) \times [(P + 3060) \ln (1 + P/3060) - P]$$

where P is in bars and x is the mean number (or at least a *lower limit* to the mean number) of water molecules added to the solvation sheath of the complex as it goes from the initial state to the transition state (3). These two equations represent the data equally well in this instance, and the respective parameters are listed in Table 2. In the following discussion, the parameters from eq. 4 are used, since the number x has a more obvious physical meaning than does $(\partial \Delta V^*/\partial P)_T$.

The volumes of reaction ΔV obtained from the dilatometric measurements were reliable to ± 0.3 cm^3 mol^{-1}, and are summarized in Table 3.

Discussion

If the ΔV_0^* values for reaction 2 are scaled against those for reaction 1 (1–3, 5), as in Fig. 1 (to which Gay and Nalepa's (18) ΔV^* value for the aquation of $Cr(NH_3)_5NCS^{2+}$ has been added), it is seen at once that ΔV_0^* varies only about *half* as rapidly with changing X^{n-} in the Cr series as in the Co series. If one accepts that the Co—X bond is essentially completely broken and the solvation of X^{n-} fully provided for in the transition state of reaction 1, then it must be

[2]It is easily shown that, for a first-order reaction in a dilatometer of the type described, ln $[h_0 - h_\infty)/(h_t - h_\infty)] = kt$, where k is the first-order rate coefficient.

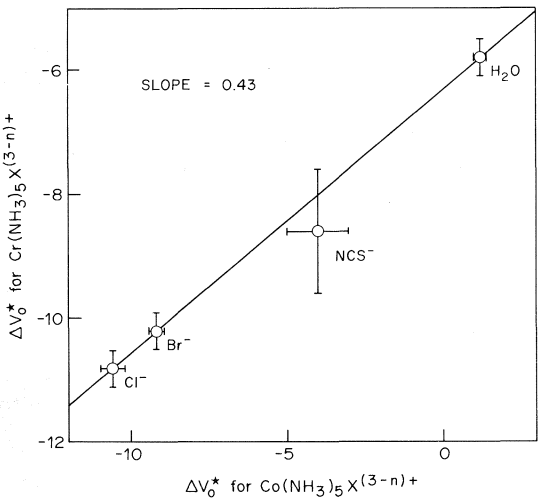

FIG. 1. ΔV_0* values for aquations of $Cr(NH_3)_5X^{(3-n)+}$ compared to those for $Co(NH_3)_5X^{(3-n)+}$.

acknowledged that these processes are only about *half* as far advanced in the transition state of reaction 2. This interpretation is supported by the observation that the mean numbers x of electrostricted water molecules in the transition state of reaction 1 for $X^{n-} = Cl^-$ and Br^- are 4.1 and 3.9 (5), as against *half* as many (Table 2) for the aquations of the analogous Cr(III) complexes.

An alternative approach (2, 3) is to divide ΔV_0* into a bond-making and -breaking part, ΔV_b*, which remains almost constant as X^{n-} is changed[3] and can be identified with ΔV* for the case $X^{n-} = H_2O$, and an electrostrictive part, ΔV_{el}*, which varies significantly with X^{n-} because of the markedly different solvational requirements of the various X^{n-}. We see that, for $X^{n-} = Cl^-$, Br^-, and NCS^-, ΔV_{el}* is −11.8, −10.4, and −5.0 $cm^3\ mol^{-1}$ for reaction 1, but only −5.0, −4.4, and −2.8 $cm^3\ mol^{-1}$ respectively for reaction 2; once again, electrostrictive effects are only about *half* as fully developed in the Cr(III) system as in the analogous Co(III) series.

However, the most convincing evidence to the effect that the separation of X^{n-} and provision for its solvation are only about half complete in the transition state of reaction 2 is the slope of 0.5_9 found for the linear relationship between ΔV_0* and ΔV (Fig. 2). This result stands in sharp contrast to that obtained for reaction 1, for which the slope of the ΔV_0* *vs.* ΔV plot is 1.0 (1–3) and which characterizes an I_d mechanism. Attempts to extend the correlation of Fig. 2 to include $X^{n-} = SO_4^{2-}$ and NO_3^- were thwarted by our failure to prepare and characterize $Cr(NH_3)_5SO_4^+$, and by the anomalous behavior of the nitrato complex, which aquates to yield *cis*-$Cr(NH_3)_4(OH_2)_2^{3+}$: these facts appear to be related mechanistically, and will be reported upon in detail in a forthcoming article. The *N*-thiocyanato complex could not be included because the loss of some coordinated ammonia, combined with the difficulty of adequate temperature control at the high tempera-

[3]The strongly negative value of ΔV* for the $Cr(NH_3)_5OH_2^{3+}$ aquo-exchange is considered (2, 4, 5) to originate in the "hole" left in the solvation sheath when the attacking water molecule moves to the first coordination sphere; this quantity will be virtually constant for a given type of solvation sheath, *i.e.*, for a given series of complexes such as $Cr(NH_3)_5X^{(3-n)+}$.

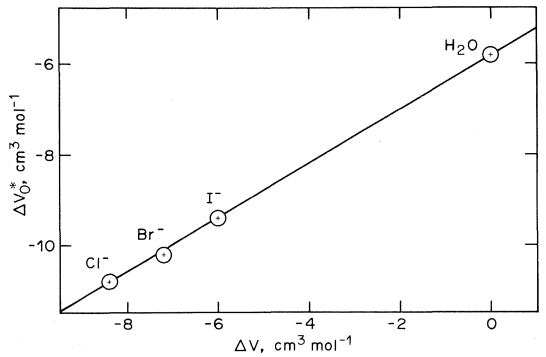

FIG. 2. Volume of activation ΔV_0^* (at zero pressure) *vs.* molar volume of reaction ΔV for the replacement of X^{n-} by H_2O in $Cr(NH_3)_5X^{(3-n)+}$ at 25.0° in 0.1 *m* NH_4ClO_4. Slope = 0.59.

tures necessary to study this hydrolysis, prevented our obtaining a meaningful ΔV value by dilatometry.

Clearly, the mechanism of substitution in the $Cr(NH_3)_5X^{(3-n)+}$ series is *not* the same as the I_d process which is considered to be operative in the analogous Co(III) systems. If we accept that the bond-breaking process is only about half as far advanced in the transition-state of reaction 2 as in the I_d mechanism of reaction 1, then consideration of the principle of microscopic reversibility requires that *either* bond-*making* (by incoming H_2O) must be as important as and synchronous with bond-breaking (an I_a mechanism), *or*, less plausibly, a long-lived[4] five-coordinated intermediate $[\{Cr(NH_3)_5\}(H_2O)_y]^{3+}$ is formed. In the latter case, bond-making and bond-breaking processes could be of comparable importance but would be *separate* in time; the bond-breaking transition state would lead to $Cr(NH_3)_5^{3+}$, and a bond-making transition state would lead onward from this intermediate toward the products.

However, the D mechanism can be discounted for at least three reasons. Firstly, it is in effect an extreme development of an I_d mechanism, and we have seen that the kinetic characteristics of reaction 2 do not correspond to those of reaction 1, which is considered to typify I_d behavior. Secondly, it is very hard to believe that a solvated, five-coordinate cationic species $[\{Cr(NH_3)_5\}(H_2O)_y]^{3+}$ would not collapse to the very stable $Cr(NH_3)_5OH_2^{3+}$ (aq) species in a time which would be somewhat less than the time-constant for the exchange of the yH_2O of the second coordination sphere with bulk solvent. Thirdly (and most importantly) the correlation of Fig. 2 very obviously includes the aquo-exchange reaction of $Cr(NH_3)_5OH_2^{3+}$, *which has a strongly negative volume of activation*; it would be exceedingly difficult to reconcile this observation with any kind of dissociative mechanism, and so we conclude that an associative mechanism is indeed operative in reaction 2 for the cases $X^{n-} = H_2O$, *N*CS^-, I^-, Br^-, and Cl^- at least. The mechanism is likely to be I_a rather than A (7), since steric compression (see below) would work against the survival of a long-lived seven-coordinate intermediate, and indeed no such Cr(III) species have been characterized to date.

Duffy and Earley (19) measured the anation rates and spectrophotometric ion-pair formation constants *K* for the reactions of $Cr(NH_3)_5OH_2^{3+}$ with Cl^- and NCS^-. Their data show that, if one assumes the reaction sequence

$$[5]\quad Cr(NH_3)_5OH_2^{3+} + X^- \overset{K}{\rightleftharpoons} \{Cr(NH_3)_5OH_2^{3+}, X^-\} \xrightarrow{k_i} \{Cr(NH_3)_5X^{2+}, OH_2\} \xrightarrow{\text{fast}} Cr(NH_3)_5X^{2+} + H_2O$$

then k_i is apparently significantly slower than the rate of aquo-exchange. This can be independently checked for the case $X^- = NCS^-$ (but not Cl^-) by plotting the reciprocals of Duffy and Earley's observed pseudo-first-order rate coefficients k_{obs} against $[NCS^-]^{-1}$; the intercept on the k_{obs}^{-1} axis gives $k_i = 3.7 \times 10^{-5}$ s^{-1} at 45°, while the slope ($= 1/k_iK$) gives $K \sim 12$ (which is close to the spectrophotometric value of 10). Our aquo-exchange rate data (5) show that NCS^- entry into the first coordination sphere from within the ion pair is thus about 18 times slower than aquo-replacement at 45°.

The latter observation is obviously consistent with an I_d mechanism, for which anation could only be consequent upon, and so not faster than, aquo-ligand separation. However, it is also

[4]"Long-lived" signifies that five-coordination persists longer than the average residence-time of molecules or ions in the second coordination sphere. An incoming ligand from bulk solution would have to enter the second coordination sphere of the intermediate complex before it could form a bond to the central metal ion; thus, the distinguishing feature of the intermediate of reduced coordination number in a D mechanism is that reduced coordination must persist longer than the time needed for exchange between the second coordination sphere and the solution at large.

entirely consistent with an I_a process in which NCS^- competes rather inefficiently with water as a nucleophile. Such is likely to be the case in a stereoretentive flanking replacement of the departing aquo-ligand, as seems to be usual for Cr(III) centers (14); the water molecules solvating the complex ion will tend to be concentrated around the acidic aquo-ligand, because of efficient hydrogen-bonding (5), while X^{n-} in an ion-pair will tend to be situated on the least heavily solvated side of the complex, remote from the replaceable aquo-group, where closest approach to the charged central metal-ion is possible. In any event, there is considerable disparity between the k_i values for Cl^- and NCS^- in Scheme 5 (19), whereas Langford and Muir (20) found the k_i values for the I_d anations of $Co(NH_3)_5OH_2^{3+}$ by Cl^-, NCS^-, and even SO_4^{2-} to be essentially equal; the obvious explanation of this difference in behavior between Cr and Co is that Cl^- and NCS^- are displaying their different nucleophilic powers against $Cr(NH_3)_5OH_2^{3+}$ in an I_a mechanism.

The assignment of an I_a mechanism to reaction 2 is supported by the observation (21) that the rate coefficients for the aquations of the pentaamine complexes $Cr(NH_2R)_5Cl^{2+}$ *decrease* 33-fold on going from R = H to R = CH_3, largely because of an increase of 4.0 kcal mol^{-1} in the activation enthalpy, ΔH^*. This is very likely due to increased steric hindrance to the entry of a seventh ligand in an I_a mechanism, since Foxman (22) has shown that there is severe steric congestion in the ground state of the analogous ion $Co(NH_2CH_3)_5Cl^{2+}$. It is particularly significant that the aquation rate of this last ion is 22 times *faster* than that of $Co(NH_3)_5Cl^{2+}$, in accordance with steric decompression on going to the transition state via an I_d mechanism (23). Solvational differences will also contribute to the rate differences, as pointed out by Parris and Wallace (21), and it is therefore not surprising that the aquation rates increase in *both* the $Cr(NH_2R)_5Cl^{2+}$ and $Co(NH_2R)_5Cl^{2+}$ series as the alkyl chain R is extended beyond methyl; alkyl chain lengthening will make the complexes increasingly "hydrophobic," without significantly increasing steric congestion, as the latter will originate almost entirely in the α carbon atoms.

The assignment of an I_a mechanism to acid-independent chromium(III) aquations and an I_d scheme to their cobalt(III) analogs provides an answer to the long-standing question (24) of why the ratio of base hydrolysis rates to aquation rates should be so much greater in cobalt(III) complexes than in their chromium(III) and rhodium(III) analogs. The hypothetical I_d process for Cr(III) aquations, which would be truly comparable with that operating at Co(III) centers, is evidently "undercut" by the more energetically accessible I_a path; thus, if both series of base hydrolyses proceed via a similar conjugate-base dissociative mechanism (as seems likely), the difference in rates between base hydrolysis and aquation for Cr(III) will seem anomalously small, and the relative importance of base hydrolysis in Cr(III) systems will be reduced as compared with Co(III). The same argument explains the apparent inertness (*vis-à-vis* aquation) of Rh(III) ammines toward base hydrolysis, since an I_a mechanism seems to be operative in the reactions of $Rh(NH_3)_5OH_2^{3+}$ at least (5, 25, 26). The point is then not that the base hydrolyses of Cr(III) and Rh(III) complexes are unusually *slow*, but rather that the corresponding aquations are unusually *fast*.

In the light of the above discussion and our previous arguments (2, 4, 8) in favor of an associative mechanism in substitution reactions of complexes of the type $Cr(H_2O)_5X^{(3-n)+}$, we consider it appropriate to make the general statement that *an I_a mechanism is operative in acid-independent substitution reactions of cationic chromium(III) complexes in aqueous solution.* This may appear to be inconsistent with Ferraris and King's observation (9) that the induced solvolysis of azido- and halo-pentaaquochromium(III) ions, and the spontaneous solvolysis of iodopentaaquochromium(III) ion extrapolated to zero extent of reaction, in aqueous methanol give essentially the same relative amounts of $Cr(H_2O)_6^{3+}$ and $Cr(H_2O)_5(CH_3OH)^{3+}$, for a given solvent composition. This observation *suggests* (but, as Ferraris and King emphasize (9), does not *prove*) that a common intermediate is produced, *i.e.*, that a D mechanism is operative in these solvolyses of various $Cr(H_2O)_5X^{(3-n)+}$ species.

However, it should be borne in mind that the two entering reagents $H_3C—OH$ and H—OH will both present essentially the same attacking group (—OH) to the Cr(III) center in an associative process, and consequently there will be very little *electronic* discrimination between the two nucleophiles by the Cr—X group. Accordingly, the CH_3OH/HOH ratio in the products is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

not likely to vary significantly from one X to another, especially since all the X^{n-} studied in this connection are "good leaving groups," so that the degree of bond-making in an I_a mechanism need not be great in order to provide the energetic assistance needed to facilitate the bond-breaking process. The greater "nucleophilic power" of water over methanol toward metal ion centers can be ascribed partly to steric factors (by analogy with Foxman's findings (22)).

On the other hand, when two competing nucleophiles *do* differ appreciably in their electronic structures, as for example H_2O *vs.* Cl^- (aq), the product ratios in a substitution reaction can be expected to vary with the nature of the departing ligand X^{n-} if the mode of activation is associative, but not if a D mechanism is operative. We have observed a significant variation in the yield of $Cr(H_2O)_5Cl^{2+}$ relative to $Cr(H_2O)_6^{3+}$ when various $Cr(H_2O)_5X^{2+}$ are aquated in 1.0 *M* HCl (8), and this, coupled with the strongly negative ΔV^* value for the $Cr(H_2O)_6^{3+}$ aquo-exchange (4) and a striking dependence of the anation rate of $Cr(H_2O)_6^{3+}$ upon the nature of the entering ligand X^{n-} (*e.g*, anation by NCS^- is $\sim 2 \times 10^3$ times faster than by I^-) (8), constitutes strong support for our view that an I_a mechanism is indeed operative in hydrogen-ion-independent substitutions in complexes of the $CrL_5X^{(3-n)+}$ type in aqueous solution. These considerations do not preclude the possibility that the *induced* solvolyses of $Cr(H_2O)_5X^{2+}$ species proceed by a D mechanism, as proposed by Ferraris and King (9); indeed, Birk and Ingerman (27) have recently presented evidence which suggests that the mechanisms of the spontaneous and induced aquation mechanisms differ in precisely this way.

We thank the National Research Council of Canada for financial assistance, Ms. S. J. Swaddle for microanalyses, and Drs. E. L. King and C. H. Langford for stimulating discussions.

Oxodichlororhenium(IV), $ReOCl_2$

P. W. Frais, H. E. Howard-Lock, and C. J. L. Lock[1]

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received August 22, 1972

The preparation and some physical and chemical properties of $ReOCl_2$ are described.

On décrit la préparation ainsi que quelques propriétés physiques et chimiques de $ReOCl_2$.

[Traduit par le journal]

Introduction

Until recently only two oxochlorides of rhenium have been clearly established, namely $ReOCl_4$ and ReO_3Cl (1). Very recently there have been reports of $ReOCl_3$ (2) and the mixed complexes $ReO_3Cl \cdot ReOCl_4$ (3) and $Re_2O_3Cl_6$-$(ReO_3Cl)_2$ (4). We now report the existence of yet another simple oxochloride, namely oxodichlororhenium(IV), $ReOCl_2$.

Experiments

Rhenium and chlorine analyses were performed by the neutron activation method described previously (5). Infrared spectra were recorded for solid samples ground into a mull with Nujol. The Nujol had been dried by refluxing with phosphorus pentoxide followed by vacuum distillation. The mull samples were mounted between potassium bromide plates and spectra were recorded on Perkin–Elmer 337, 521, and 301 spectrometers. Raman emission was excited by 10 mW of radiation from a He–Ne laser (λ6328 Å), and spectra were recorded with a Coderg PHO double monochromator with photoelectric detection. X-Ray diffraction photographs of powdered samples were recorded on a Debye–Scherrer camera. Samples were sealed inside fused quartz tubes and nickel-filtered CuKα radiation was used for recording the photographs. Line intensities were measured from the photographs with a Joyce–Loebl microdensitometer. $ReOCl_2$ was prepared by a number of different chemical reactions. Typical reaction conditions are described below unless changes in the conditions made significant differences in the distribution of products, in which case different runs are described.

Analysis and Identification of Products

For qualitative identification of products only infrared spectroscopy (volatile materials) or X-ray diffraction (involatile materials) was used. Combination of these techniques with quantitative analysis (see below) applied to pure and known "impure" samples (*i.e.* mixtures of known composition) has shown that infrared spectroscopy could identify as little as 5% of an impurity (and in many cases $< 1\%$) while X-ray diffraction could detect as little as 5% of impurity in a single substance and 10% in a mixture of two compounds. For X-ray diffraction it is possible that large quantities of an amorphous product were present but we have no other evidence for this in any of our experiments. For each type of reaction reported below many runs were made (typically 5–10) and in most runs attempts were made not only to separate volatile and involatile products, but to separate the products into individual components. This was hard to do for volatile products, but for involatile products was achieved by hand-picking crystals. Parts of both volatile and involatile samples were examined by X-ray and infrared techniques to confirm that only the expected products were present.

For quantitative analysis of a reaction, the nature of the products was established by a series of qualitative runs first. In the quantitative run the amounts of starting materials and volatile and involatile products were weighed on a microbalance. The remainder of the sample (which was weighed) was then analyzed by the neutron activation analysis technique described previously (5) to give (*1*) Re:Cl atom ratio, (*2*) percentage Re and Cl, (*3*) average oxidation state of rhenium. From the above data it was possible to calculate the amount of each individual product present, within the error limits we have given.

Reaction a: ReO_3 + $ReCl_5$

(*i*) ReO_3(1.0 g) and $ReCl_5$(1.55 g) were sealed in an evacuated Pyrex tube (25 mm diameter, approximate volume 40 ml) fitted with a break-seal, and heated at 350 °C for 17 h in a tube furnace. On cooling, the tube was sealed to a vacuum line, the seal was broken, and materials, volatile at room temperature, were distilled into a U-trap cooled by a Dry Ice/acetone bath. The volatile products were $ReOCl_4$ and ReO_3Cl (i.r. spectroscopy) and the residue was shown by X-ray powder diffraction to be a mixture of Re_3Cl_9, $ReOCl_2$, and ReO_3.

(*ii*) Experiment (*i*) was repeated except that the tube was heated to 400 °C for 5 days, care being taken to minimize the thermal gradient in the tube. In this case the involatile products were only $ReOCl_2$ and Re_3Cl_9. The $ReOCl_2$ was present as a cluster of metallic-purple acicular crystals and the Re_3Cl_9 was present as small compact crystals. The two types of crystals were readily identified under a microscope. Separation of the two components was accomplished by washing the mixture several times with dry acetonitrile, and in this way dissolving all the Re_3Cl_9. Thus far, this has been the only source of larger crystals of $ReOCl_2$, and these were used for all experiments performed with $ReOCl_2$.

TABLE 1. Analysis of $ReOCl_2$

Parameter	Value		
		Found	
	Calculated	Neutron activation	H_2 reduction
Cl/Re atom ratio	2.00	2.0(1)	—
%Re	68.1	65(3)	68(1)
%Cl	26.0	25(2)	—

Reaction b: ReO_3 + $ReOCl_4$

(*i*) ReO_3 (0.38 g) and $ReOCl_4$ (~0.4 g) were sealed in a tube (20 mm diameter, 20 cm long) fitted with a breakseal. The materials were placed in opposite ends of the tube and the tube was arranged in a furnace such that the ReO_3 was at ~235 °C and $ReOCl_4$ was at ~100 °C. No reaction occurred in 48 h and the temperatures were raised to ~280 °C and ~120 °C. After a further 72 h a coating of metallic-purple material had formed in the ~200 °C zone. The weight was not recorded, but X-ray powder photography showed the material was mostly $ReOCl_2$ with some Re_3Cl_9 impurity. An infrared spectrum of the residual volatile material showed it was a mixture of ReO_3Cl and $ReOCl_4$.

(*ii*) The experiment was repeated with 0.61 g ReO_3 and ~0.45 g $ReOCl_4$ placed in a tube with a constriction between the 285 and 200 °C zones. The reaction was allowed to proceed for ~7 days, and the products were separated. The products occurred as three groups in the tube, the two groups of involatiles occurring on either side of the constriction, and the volatile material condensed in the cool end. Examination of the three groups of products by suitable combination of weighing, infrared spectroscopy and X-ray powder photography showed the products were: product from 280 °C zone: > 90% ReO_3, trace of $ReOCl_2$, trace of Re_3Cl_9 (0.52 g); product from 200 °C zone: $ReOCl_2$ ~100%, trace of ReO_3 (probably from walls when filling tube), no Re_3Cl_9 (0.01 g); volatile products: mostly $ReOCl_4$ with some ReO_3Cl (0.54 g by difference).

Reaction c: Decomposition of $ReOCl_4(OH_2)$ (6)

When $ReOCl_4(OH_2)$ was distilled quickly under vacuum, at least partial decomposition occurred, giving a volatile mixture of $ReOCl_4$ and ReO_3Cl and a black residue remaining where the $ReOCl_4(OH_2)$ had been. Powder photography has shown this black residue was a mixture of $ReOCl_2$ and Re_3Cl_9.

Similarily, when $ReOCl_4(OH_2)$ crystals are allowed to sit exposed to a nitrogen atmosphere in a good dry box (Vacuum Atmospheres Corp., Calif. model HE493 DRI-TRAIN) a black surface layer formed, even in the short time required to mount a crystal in a capillary tube. This black material was also shown by powder photography to be a mixture of $ReOCl_2$ and Re_3Cl_9.

Reaction d: $ReOCl_4$ + $SnCl_2$

$ReOCl_4$ (~0.30 g) and $SnCl_2$ (0.15 g) were sealed in an evacuated Pyrex tube fitted with a breakseal at opposite ends of the tube. The tube was placed in a tube furnace such that the $SnCl_2$ was at ~210 °C and $ReOCl_4$ at ~70 °C. After 48 h the volatile colorless liquid (assumed to be $SnCl_4$) was removed through the breakseal, and the involatile products analyzed by powder photography. These were found to be a mixture of ReO_3 and Re_3Cl_9 with minor amounts of $ReOCl_2$ being present.

Reaction e: ReO_3 + $ReCl_3$

ReO_3 (0.10 g) and $ReCl_3$ (0.25 g) were reacted at 500 °C for ~72 h. The volatile component of the products were distilled through a breakseal and analyzed by infrared and neutron activation analysis. It was shown to be > 90% $ReOCl_4$ with ReO_3Cl as a minor impurity. The involatiles consisted of a mixture of Re metal and ReO_2 (identified by powder photography).

Analysis and Characterization of $ReOCl_2$

Neutron activation analysis was performed 12 times on six samples of crystalline $ReOCl_2$ prepared by preparation *a*. In addition a sample of $ReOCl_2$ weighing 14.2(1) mg was reduced in a gentle stream of hydrogen at ~250 °C for ~90 h. The $ReOCl_2$ was in a porcelain boat, and the apparatus was fitted with a U-trap cooled in a Dry Ice/acetone bath to trap any volatile rhenium products. The final weight of the reduced product was 9.6(1) mg, and neutron activation analysis showed only ~0.02 mg of Re in the U-trap. The results are summarized in Table 1.

Oxodichlororhenium(IV) was insoluble in dry acetonitrile, acetone or diethylether, but reacted with moisture present in the atmosphere or in these solvents to form a metallic-gold colored surface coating. With cold distilled water, immediate reaction occurred giving a fibrous black precipitate. The physical appearance of $ReOCl_2$ crystals was very similar to the published photographs of $MoOCl_2$ (7) and $WOCl_2$ (8), both of which were also described as possessing a metallic lustre.

Infrared spectra were recorded over the range 4000 cm^{-1} to 120 cm^{-1}, and Raman spectra were recorded in the range 20–1100 cm^{-1} from the exciting line. Infrared bands were observed at 906(w) and 128 cm^{-1}(m) and Raman bands were observed at 497, 460, and 370 cm^{-1} from the exciting line. Infrared bands were estimated to have a maximum error of ± 2 cm^{-1} in the 4000–400 cm^{-1} range and ± 5 cm^{-1} in the 400–100 cm^{-1} range. Errors in the Raman bands were estimated to be ± 2 cm^{-1} over the whole range.

Crystallography

Crystallographic examination was made on crystals of $ReOCl_2$. Without exception, needles of $ReOCl_2$ obtained from reaction *a*, examined with both precession and Weissenberg methods, yielded diffraction patterns indicating serious disorder in at least one direction. Attempts to obtain a full Weissenberg photograph rotating about the needle axis gave only streaks. It was possible to get

unit cell parameters from rotation and precession photographs. Data obtained were

Cl_2ORe f.w. = 273.1

Orthorhombic or monoclinic $a = 3.69(1)$, $b = 14.7(1)$, $c = 6.63(1)$ Å, $\beta = 90.0(1)°$, $V = 360$ Å^3, $\rho_c = 5.04$ g cm^{-3}, $Z = 4$, ρ_o, not determined, (22 °C, λMoKα = 0.71069 Å).

Powder photographs of $ReOCl_2$ were of mediocre quality, but were consistent in line position and intensity with precession photographs. Data are given in Table 2.

Reactions of $ReOCl_2$

(a) Thermal Decomposition

Accurately weighed amounts of $ReOCl_2$ (<60 mg) were sealed in evacuated 4 mm Pyrex tubes fitted with break-seals. The $ReOCl_2$ was heated in one end of the tube while the other end was at room temperature. At ~380 °C, $ReOCl_2$ began to decompose visibly. At 500 °C, decomposition occurred according to the equation

$$4ReOCl_2 \xrightarrow{500\ °C} Re + \tfrac{1}{3}Re_3Cl_9 + ReOCl_4 + ReO_3Cl$$

This was confirmed by a combination of X-ray powder photography, infrared spectroscopy and neutron activation analysis (3). The data obtained for two independent decompositions are shown in Table 3.

At lower temperatures, the decomposition of $ReOCl_2$ was incomplete and only $ReCl_3$, $ReOCl_4$, and ReO_3Cl were observed as products.

(b) Reaction of $ReOCl_2$ and $ReCl_5$

Equimolar amounts of $ReOCl_2$ and $ReCl_5$ were sealed in an evacuated reaction tube and reacted at 200 °C in such a way that separation of $ReCl_5$ was not possible. As expected, the much more thermodynamically stable products $ReOCl_4$ and Re_3Cl_9 are formed. The results are summarized in Table 4.

Results and Discussion

Analyses showed clearly that we had prepared a compound of the type $ReCl_2X$, where X was probably an amount of oxygen or OH group. Possible compounds were $ReOCl_2$, ReO_2Cl_2, $ReOCl_2 \cdot OH_2$, $ReOCl_2OH$. The analytical results suggested the first formulation but were not conclusive. However, we feel that by the determination of the weights of the reactants and products in various preparation and decomposition reactions we have shown unambiguously that we have prepared $ReOCl_2$.

The crystal structure studies of $ReOCl_2$ did not reveal the structure because of the presence of multiple crystals and possibly twinning or disordering. The unit cell is either orthorhombic or monoclinic with $\beta = 90°$. One distance is particularly short and suggests possible structures for the compound. They are shown in Figs. 1*a* and 1*b*. The short distance (3.69 Å = *a*) is very close to 3.73 Å observed for the linear Re—O—Re distance in ReO_3 (9). Two possible arrangements exist for the chlorine atoms and the layer arrangement shown in Fig. 1*a* seems more probable, considering the fibrous nature of the material. The *b* distance of 14.7 Å, which corresponds almost exactly to four $ReCl_2Re$ distances (as shown in Fig. 1) based on parameters for Re_2Cl_{10} (10), does not allow a choice between the two structures.

Reaction products				
Re_3Cl_9	17(1)	15(2)	46.1(5)	45.3(5)
$ReOCl_4$	17(1)	17(2)	52(1)	53.3(5)

*Calculations are based on 6.8 mg of unreacted $ReOCl_2$. The values are calculated from the equation $ReOCl_2 + ReCl_5 \rightarrow ReOCl_4 + \frac{1}{3}Re_3Cl_9$.

The vibrational spectra of $ReOCl_2$ are characterized by the absence of many significant features. Even for the most concentrated mulls or pellets, only two weak bands were observed in the infrared spectrum (906, 128 cm^{-1}) and for the solid (crystal or powder) only three bands were observed in the Raman spectrum (497, 460, 370 cm^{-1}).

Only two vibrations can be assigned with any confidence. The band at 906 cm^{-1} corresponds to a linear Re—O—Re asymmetric stretch (11) and is observed at the same frequency for ReO_3. Similarly a band at ~370 cm^{-1} has been assigned to an Re—Cl stretch for $ReOCl_4$ (12). The bands in the 460–497 cm^{-1} region are too high for transitions except those associated with the —O—Re—O—Re— system. For *bent* Re—O—Re systems the symmetric Re—O—Re stretch occurs in this region (11) but not, supposedly, for linear systems. Frequencies for the symmetric —O—Re—O— stretch and bend have not been reported. We have no explanation as to why we observed no infrared absorptions in the Re—Cl stretch region.

$ReOCl_2$ is one of the fourteen products which have now been identified as arising from the reaction of ReO_3 and $ReCl_5$ in the presence of small amounts of moisture (see refs. 2, 4, 6). $ReOCl_2$ is important in that our decomposition studies show clearly that it is the intermediate in the very unusual formation of rhenium metal from the reaction of two rhenium compounds in a high oxidation state.

Compared to the other oxochlorides of rhenium, $ReOCl_2$ is relatively stable with respect to reaction with air and moisture and one wonders why it has not been observed before. It is markedly thermally unstable, but it is found as a product in so many of the reactions tried. Perhaps one explanation is that it is relatively involatile and thus occurs with Re_3Cl_9 in most reactions. Unless one was looking for $ReOCl_2$

For personal use only.

it is possible not to recognize it in a sample of Re_3Cl_9, particularly if the $ReOCl_2$ is in the powder form. The presence of some $ReOCl_2$ in Re_3Cl_9 may explain some of the conflicting reports on the properties of different samples of Re_3Cl_9, such as solubility and magnetic properties (13 and references therein). Re_3Cl_9 is diamagnetic, but $ReOCl_2$ should be paramagnetic. Unfortunately we have been unable to prepare sufficient pure $ReOCl_2$ to perform magnetic measurements.

A Comparison of the Conformations of Uridine, β-Pseudouridine, and Dihydrouridine in Dimethyl Sulfoxide and Water. A ^{1}H Nuclear Magnetic Resonance Study[1]

ROXANNE DESLAURIERS AND IAN C. P. SMITH

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received July 6, 1972

The ^{1}H n.m.r. spectra of the nucleosides uridine (U), dihydrouridine (D), and β-pseudouridine (β-ψ) in deuterated dimethyl sulfoxide (DMSO-d_6) have been analyzed and the results compared with those obtained from analyses of spectra taken in deuterated water (D_2O). The conformations of the ribose rings in DMSO-d_6 and D_2O solutions are similar. The conformation about the exocyclic $C_{4'}$—$C_{5'}$ bond shows a greater preference for the *gauche–gauche* rotamer in DMSO-d_6 than in D_2O. No changes in the sugar–base torsion angle were detectable in the spectra taken with the two solvents. The resonances of the sugar ring hydroxyl protons were assigned and the spin–spin couplings measured. In the three nucleosides studied the hydroxyl groups are rotating rapidly with only slight preferences for the particular rotamers. When preferences are manifest, they are for the *gauche* rotamers at 2′ and 3′, and the symmetrical *gauche–gauche* rotamer at 5′.

On a analysé les spectres de r.m.n. ^{1}H des nucléosides uridine (U), dihydrouridine (D), et β-pseudouridine (β-ψ) dans le diméthylsulfoxide-d_6 (DMSO-d_6) et l'oxyde de deutérium (D_2O). On compare les conformations dans les deux solvants. Les cycles riboses sont semblables, mais les groupements exocycliques CH_2—OH manifestent une plus grande préférence pour l'isomère *gauche–gauche* dans le DMSO-d_6 que dans le D_2O. On ne trouve aucune différence conformationelle autour de la liaison glycosidique dans le DMSO-d_6 et dans le D_2O. Les groupements hydroxyles dans les trois composés sont en rotation rapide et montrent une faible préférence pour certains conformères, pour les rotamères *gauches* à 2′ et 3′, et pour le rotamère *gauche–gauche* à 5′.

Can. J. Chem., **51**, 833 (1973)

Introduction

In all transfer RNA sequenced to date, the modified nucleosides β-pseudouridine (β-ψ) and dihydrouridine (D) occupy special locations. However, no special structural role for them has yet been demonstrated. The conformations of uridine (U), β-ψ, and D have been compared in aqueous solution by ^{1}H n.m.r. and suggestions have been made for their structural roles in transfer RNA (1–3). One aspect of the conformations that could not be compared in aqueous solution is the preference for rotational isomers of the hydroxyl groups. We report here a study of this aspect in dry dimethyl sulfoxide. A study in this solvent is also of interest because so many biological compounds are studied in it for reasons of solubility, and a comparison of the overall conformations in each solvent is an indication of the usefulness of such data.

Experimental

Uridine (Sigma Chemicals), β-pseudouridine (Calbiochem, A grade), and dihydrouridine (Calbiochem, B grade) were used without further purification and revealed no impurities in the n.m.r. spectra. Deuterated dimethyl sulfoxide (Merck, Sharp and Dohme of Canada) was stored over molecular sieve (Linde 3A) to remove traces of water. Solutions (0.1 *M*) of nucleosides were prepared in the following manner. One sample of each was dissolved in D_2O, lyophilyzed, and then redissolved in DMSO-d_6 in order to exchange the protons of the hydroxyl groups, and gain a clearer spectrum of the ribose ring protons. Another was dissolved in DMSO, lyophilyzed, and redissolved in DMSO-d_6 to remove adsorbed water molecules. All manipulations were carried out in a dry box under dry nitrogen. Spectra were recorded using Varian XL-100 and HR-220 spectrometers (Canadian 220 MHz Centre, Sheridan Park, Ontario). Assignment of the hydroxyl protons was done by successively decoupling the 2′, 3′, and 5′ ribose ring protons. Spectral analysis was carried out using the computer program Hydra (4). Solutions were considered satisfactory only when the simulated spectra resembled the experimental spectra in every respect. The results of the analyses of the n.m.r. spectra of the three compounds are presented in Table 1. A typical spectrum of the hydroxyl protons is shown in Fig. 1.

Discussion

(a) Hydroxyl Group Conformation

H—C—O—H′ coupling constants are known to depend on the dihedral angle between the

*Chemical shifts of U and β-ψ in D_2O were reported with respect to internal 2-trimethyl-silyl-propanesulfonic acid, sodium salt (DSS), those of D in D_2O with respect to internal sodium-3-trimethyl-silyl-propionate-2,2,3,3-d_4 (TSP). Chemical shifts of the nucleosides in DMSO-d_6 are reported from internal TMS. The correction factors at 30 °C are: internal DSS – external TMS in D_2O = 0.41; internal DSS – internal TSP in D_2O = 0.02; internal TMS – external TMS in DMSO = 0.37 p.p.m. The corrections between the internal references used are less than 5 Hz at 30 °C.

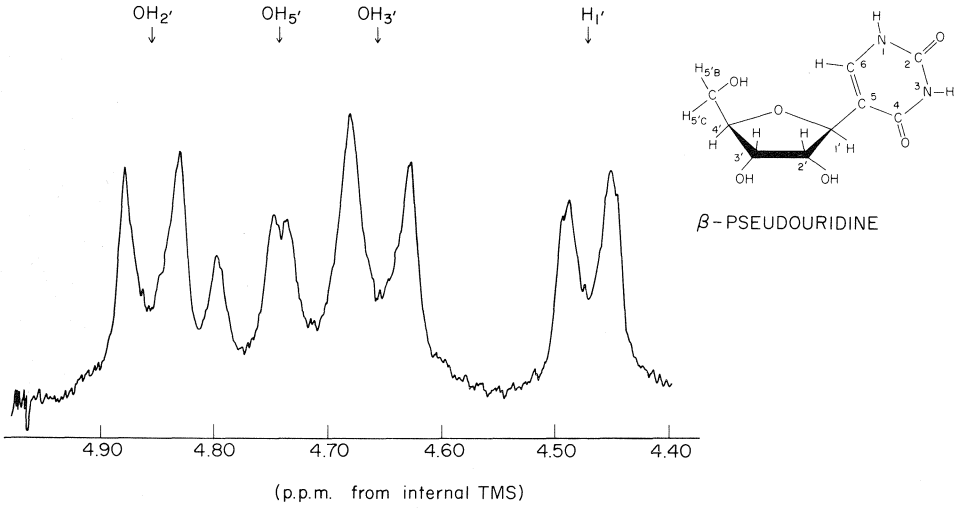

FIG. 1. The 100 MHz spectrum of the hydroxyl region of β-ψ in DMSO-d_6. Chemical shifts are reported in p.p.m. downfield from internal TMS.

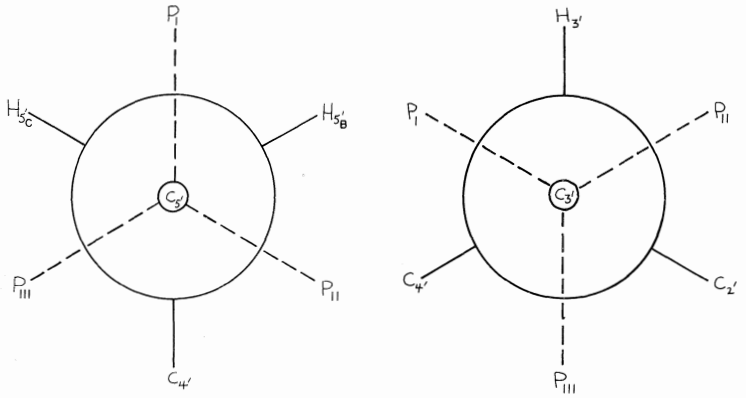

FIG. 2. Possible rotamers for the hydroxyl and phosphate groups at the 5′ and 3′ positions in nucleosides and nucleotides, respectively.

vicinal protons. A relationship similar to that proposed by Karplus (5) has been derived to account for this dependence (6),

$$[1]\quad J_{HCOH'} = 10.4\cos^2\phi - 1.5\cos\phi + 0.2$$

where ϕ is the dihedral angle formed between the H—C—O and C—O—H′ planes. This relationship has already been applied to the study of common nucleosides in mixtures of dimethyl sulfoxide and benzene (7). Our data for uridine, the only nucleoside common to both studies, demonstrate a significant difference in hydroxyl conformations in DMSO and in 40% benzene – 60% DMSO.

For a rapidly rotating hydroxyl group with equal lifetimes (populations) of the three possible rotamers an average coupling constant ($\bar{J}$) of 5.4 Hz would be observed. This arises from a weighted average of two *gauche* and one *trans* coupling.

$$[2]\quad \bar{J}_{observed} = P_I J_g + P_{II} J_g + P_{III} J_t$$

$$[3]\quad 1 = P_I + P_{II} + P_{III}$$

where J_g, using eq. 1, is 2.1 Hz and J_t is 12.1 Hz. P_i is the population of each rotamer; $P_I = P_{II} = P_{III} = 0.33$ for a freely rotating system. None of the measured couplings corresponds to that for either a *gauche* or a *trans* conformation. This indicates that the hydroxyl groups are interconverting rapidly between rotamers. It is possible that they may have a longer lifetime (larger population) in one rotamer state than the other.

Rotamer populations corresponding to the $H_{2'}$–$OH_{2'}$ and $H_{3'}$–$OH_{3'}$ couplings (Fig. 2) were calculated using eqs. 4 and 5.

$$[4]\quad \bar{J}_{observed} = 2.1\,P_g + 12.1\,P_t$$

$$[5]\quad 1 = P_g + P_t$$

There are two *gauche* conformers and the preceding set of equations measures only the total population.

For the 5′ hydroxyl group it is necessary to define the relationship between the OH-5′ proton and each of the H-5_B′ and -5_C′ protons (Fig. 2). In this case we call the rotamers *gauche–gauche* (I), *gauche–trans* (II), and *trans–gauche* (III). The relative populations of each rotamer can be estimated using eqs. 6–8

$$[6]\quad \bar{J}_{OH_{5'}-H_{5_B'}} = P_I J_g + P_{II} J_g + P_{III} J_t$$

$$[7]\quad \bar{J}_{OH_{5'}-H_{5C'}} = P_I J_g + P_{II} J_t + P_{III} J_g$$

$$[8]\quad 1 = P_I + P_{II} + P_{III}$$

where P_i is the mole fraction of each rotamer. J_g and J_t are the *gauche* and *trans* couplings determined from [1]. $\bar{J}_{OH_{5'}-H_{5_B'}}$ and $\bar{J}_{OH_{5'}-H_{5C'}}$ are the values obtained from the spectra. These are average values due to rapid rotation, on the n.m.r. time scale, about the exocyclic $C_{5'}$—$O_{5'}$ bond. We should emphasize here that the

		0.27			0.33			0.19	

*P_g, population of *gauche* rotamer (total population of two *gauche* rotamers at 2′ and 3′). P_t, population of *trans* rotamer. P_{t-g}, P_{g-t}, population of *trans–gauche* and *gauche–trans* rotamers at 5′. P_{g-g}, population of *gauche–gauche* rotamer at 5′.

method cannot distinguish the *gauche–trans* rotamer (II) from the *trans–gauche* rotamer (III) since absolute assignments of H-5_B′ and -5_C′ cannot be made.

The results of the rotamer calculations are shown in Table 2. At the 2′ position, D manifests no preference for any rotamer whereas both β-ψ and U have slight preferences for the *gauche* rotamers. At the 3′ position, β-ψ manifests no preference for any rotamer but D and U have slight preferences for the *gauche* rotamers. At the 5′ position, β-ψ slightly favors one of the unsymmetrical rotamers (II or III of Fig. 2), D has equal populations of all three, and U has a strong preference for the *gauche–gauche* rotamer.

Because the corresponding experiment cannot be done in water, comparison of the hydroxyl group conformations in DMSO-d_6 and D_2O cannot be made. However, recently it has been found that rotamer populations about C—O bonds can be estimated by means of the couplings between ^{13}C and ^{31}P in the group ^{13}C—C—O—^{31}P of nucleotides (8–11). The data for the 2′-, 3′-, and 5′-phosphates of U indicate that the 2′-phosphate group prefers the $C_{1'}$-*trans*, $C_{3'}$-*gauche* rotamer, the 3′-phosphate the $C_{2'}$-*gauche*, $C_{4'}$-*trans* rotamer, and the 5′-phosphate, the $C_{4'}$-*trans* rotamer (I of Fig. 2). No data are available for the phosphates of D and β-ψ. The bulkier phosphate groups have greater preferences for particular rotamers than do the hydroxyl groups of the compounds studied here. In the case of 2′-UMP, 3′-UMP, and 5′-UMP the preferences manifest by the phosphate group are similar to, although more pronounced than, those found for the corresponding hydroxyl groups of U.

(b) Ribose Ring Conformation

The expected angles and coupling constants for different ribofuranose ring conformations and the arguments used in the conformational analysis have been described in detail earlier (1, 2, 12), and justified by recent experimental (10) and theoretical (13) studies. The chemical shifts and coupling constants of the ribose ring protons are given in Table 1. The data indicate that within the reliability of the method there are no significant changes in the ribose ring conformation when changing the solvent from D_2O to DMSO-d_6.

(c) Conformation About the Exocyclic $C_{4'}$—$C_{5'}$ Bond

In DMSO-d_6, the vicinal (4′–5_B′ and 4′–5_C′) couplings for all three nucleosides are smaller and more alike than in D_2O. This indicates an even greater preference for the *gauche–gauche* rotamer in DMSO. The relative populations of each rotamer can be estimated using eqs. 3, 6, and 7 where J_g and J_t are determined using the Karplus relationship (5). The method, which assumes rapid interconversion between rotamers, has been described in detail elsewhere (1–3). Results of the calculations are presented in Table 3. Because an unambiguous assignment of H-5_B′ and -5_C′ cannot easily be made, the method cannot distinguish between the *gauche–trans* and *trans–gauche* rotamers. In the present case this is an insignificant limitation since the

TABLE 3. Limits for the relative populations of 60° staggered rotamers around the exocyclic $C_{4'}$—$C_{5'}$ bond of U, β-ψ, and D in DMSO-d_6 solutions

	Uridine		β-Pseudouridine		Dihydrouridine	
J_0 (0–90°)	9.4	9.4	9.4	9.4	9.4	9.4
J_0 (90–180°)	10.4	12.0	10.4	12.0	10.4	12.0
$J_{4'5_B'}$	2.8	2.8	3.0	3.0	3.8	3.8
$J_{4'5_C'}$	3.0	3.0	3.5	3.5	4.0	4.0
P_I	0.79	0.82	0.70	0.75	0.53	0.61
P_{II}	0.12	0.10	0.18	0.15	0.25	0.21
P_{III}	0.09	0.08	0.12	0.10	0.22	0.18

gauche–gauche rotamers are preferred. If we use the argument proposed recently by Remin and Shugar (14) the assignments represented by Fig. 3 of ref. 3 are correct, and states I, II, and III of Table 3 are the *gauche–gauche*, *gauche–trans*, and *trans–gauche* states, respectively.

(d) Chemical Shift Changes

In DMSO-d_6, most of the proton resonances shift upfield. The H-2′, -3′, -4′, -5_B′, and -5_C′ resonances do so by 24–35 Hz. This does not appear to be caused by any change in the sugar–base torsion angle. Such changes are usually measured by preferential shifts in the resonances of the ribose ring protons (15–17). The 2′ and 3′ protons should be deshielded and the 4′, 5_B′, and 5_C′ protons should be shielded if there is a change of base conformation from *anti* to *syn*. Such changes have not been observed, all proton resonances have shifted upfield by similar amounts.

The chemical shift changes induced in the base proton resonances by DMSO-d_6 are less uniform than the shifts induced in the ribose ring protons. In U, the H-5 resonance is shifted upfield 25 Hz but the H-6 resonance is shifted downfield 2 Hz. In β-ψ, the H-6 resonance is shifted upfield 11 Hz. In D, where the H-5_A, -5_B, -6_A, and -6_B resonances give rise to 'deceptively simple' spectra, the resonances appear shifted upfield 25–30 Hz. The anomalous behavior of U in this case may be due to specific solvent–base interactions, which have been invoked to explain abnormal temperature dependences of the base proton resonances of U and related oligonucleotides (18), and the solvent effects on the ^{13}C n.m.r. spectra of uridine (19).

Conclusion

Analyses of the n.m.r. spectra of U, D, and β-ψ in DMSO-d_6 do not show any large conformational differences in the ribose ring when compared with data taken in D_2O; the greatest difference is an increased preference by the exocyclic CH_2—OH group for the *gauche–gauche* rotamer. In the three nucleosides the hydroxyl groups are rotating rapidly and manifest only slight preferences for particular rotamers. When a preference is manifest, it is for the *gauche* rotamers at positions 2′ and 3′, and the *gauche–gauche* rotamer at position 5′. No changes were detected in the sugar–base torsion angle. The principal conformational difference observed in DMSO between uridine and the modified nucleosides dihydrouridine and β-pseudouridine is the strong preference of the 5′-hydroxyl group of uridine for the *gauche–gauche* rotamer.

6,8,8-Trimethyl-6-(*o*-methylthiobenzoyl)-4-thia-benzocyclooctenone. A Novel Product from the Attempted Base-catalyzed Methylation of 3-Methylthiochroman-4-one

IAN W. J. STILL, MOHINDER S. CHAUHAN, AND M. THOMAS THOMAS

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, 181, Ontario

Received October 6, 1972

The structure of the unusual eight-membered cyclic ketone **3** obtained on treatment of 3-methylthiochroman-4-one with methyl iodide in the presence of potassium *t*-butoxide has been assigned on the basis of n.m.r. (^{13}C and ^{1}H), i.r., and mass spectrometric evidence. A mechanism has been proposed to account for the formation of both abnormal and expected methylation products from 3-methylthiochroman-4-one under varying conditions.

La structure de la cétone inusitée **3**, cyclique à huit membres, obtenue en traitant le méthyl-3 thiochromanone-4 avec de l'iodure de méthyle en présence de *t*-butoxide de potassium, a été élucidée en se basant sur la r.m.n. (^{13}C et ^{1}H) l'i.r., et la spectrométrie de masse. Un mécanisme est proposé tenant compte de la formation des deux produits de méthylation, l'un anormal l'autre prévu, à partir du méthyl-3 thiochromanone-4, et ce sous différentes conditions.

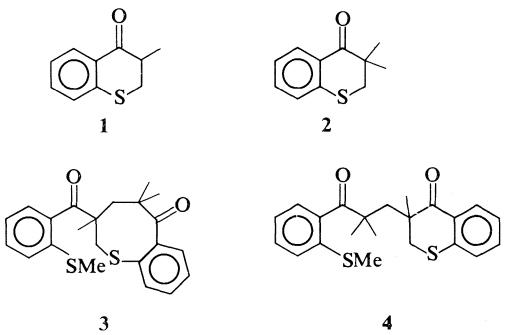
[Traduit par le journal]

Can. J. Chem., **51**, 839 (1973)

As part of a continuing investigation of the chemical and photochemical reactions of thiochromanone derivatives (1, 2) we wished to prepare 3,3-dimethylthiochroman-4-one (**2**) (3) from 3-methylthiochromanone (**1**) (4). In spite of some indication (5) that similar alkylation at the 3-position in the chromanones was likely to prove difficult, we have now succeeded in achieving the required conditions for the conversion of **1** into **2**. The details of an interesting rearrangement discovered during our search for the appropriate conditions have now been elucidated and will form the subject of the following discussion.

The treatment of 3-methylthiochroman-4-one with potassium *t*-butoxide and methyl iodide in refluxing *t*-butyl alcohol produced a solid product which was clearly not identical with the expected simple methylation product **2**. This ketone had i.r. bands at 1685 and 1655 cm^{-1} (C=O) and the presence of two carbonyl groups was further confirmed by the ^{13}C n.m.r. spectrum which showed signals at δ 210.6 and 198.5 p.p.m. The mass spectrum showed a molecular ion at *m/e* 384 with major fragments appearing at *m/e* 233 and 151. Chemical confirmation of the existence of two carbonyl groups was provided by sodium borohydride reduction which led to the formation of a diol.[1]

[1]Attempted desulfurization of the rearrangement product with Raney nickel led only to a complex mixture of products.



Two structures which might be expected to be compatible with the above evidence and the molecular formula of $C_{22}H_{24}O_2S_2$, and which can also be accounted for by reasonable mechanistic pathways are those of **3** and **4**. Our preference for structure **3** has been based on a thorough examination of the spectroscopic evidence not only from the rearrangement product but from model compounds such as **1**, **2**, and thiochroman-4-one itself. Our rejection of the thiochromanone structure **4** rests mainly on the following observations:

(*1*) The i.r. carbonyl stretching bands of **1**, **2**, and the parent thiochromanone are in the range 1665–1675, whereas the rearrangement product has carbonyl bands at 1685 and 1655 cm^{-1}.

(*2*) The ^{13}C chemical shifts of the carbonyl carbons of **1**, **2**, and thiochroman-4-one lie in the range δ 193.7–198.2, whereas the chemical shifts of the carbonyl carbons in the rearrange-

For personal use only.

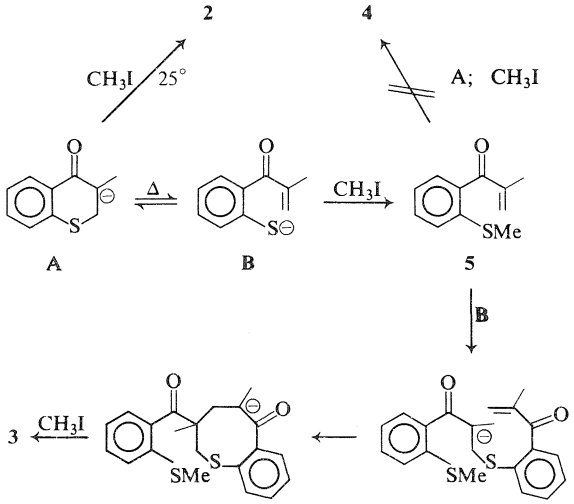
ment product are δ 210.6 (eight-membered ring) and 198.5 p.p.m. (acyclic carbonyl) (6). (Other assignments in the ^{13}C n.m.r. spectrum of **3** were made by examination of partially decoupled spectra and appear in the Experimental section.)

(*3*) The base peak in the mass spectra of four simple thiochromanones already examined, including **1** and the parent member of the series, corresponds to a retro-Diels–Alder fragmentation process (7). Occurrence of such a fragmentation in **4** would lead to a fragment of *m/e* 136. The spectrum of the rearrangement product indeed reveals a peak at *m/e* 136, but with an intensity less than 5% of that of the base peak (*m/e* 151). Structure **3** can better accommodate the fragmentations leading to peaks at *m/e* 233 ($C_{14}H_{17}OS$) and 151 (C_8H_7OS), whose constitution has been confirmed by accurate mass measurement, and also to a major peak at *m/e* 328, corresponding to loss of isobutylene from the molecular ion.

(*4*) Mechanistic arguments also favor formation of **3** rather than **4** and will be discussed in a later section.

It is of interest to point out one feature of interest in the ^1H n.m.r. spectrum of **3**, namely a well-marked distinction in the appearance of the two methylene group signals of the eight-membered ring. In the case of the —SCH_2— group, the expected doublet of doublets was evident, at δ 2.93 and 3.48 p.p.m., with a geminal coupling constant of 13.5 Hz. However, the non-equivalence of the protons of the —CCH_2— group was too small to be observable (8) on a 60 MHz spectrometer and was only just discernible on a 100 MHz spectrometer (slightly resolved peak centered at δ 2.50 p.p.m.). The addition of relatively small increments of the lanthanide shift reagent Eu(fod)$_3$ rapidly increased the non-equivalence of the —CCH_2— protons while affecting each diastereotopic proton of the —SCH_2— group almost equally, thus enabling us to obtain two well-resolved AB quartets and assign a geminal coupling constant of 14 Hz to the —CCH_2— hydrogens.

A series of methylation experiments on **1** using a variety of basic reagents (potassium *t*-butoxide, sodium amide, sodium hydride) in a variety of solvents (benzene, *t*-butyl alcohol, 1,2-dimethoxyethane) under nitrogen, for varying lengths of time and at different temperatures, has revealed that the product of the reaction is, in most cases, the expected 3,3-dimethylthiochroman-4-one (**2**). Only when potassium *t*-butoxide was employed as the base was any of the rearrangement product **3** obtained. Interestingly, **3** was the major product using potassium *t*-butoxide in refluxing solutions of benzene or *t*-butyl alcohol, although in each case minor amounts of **2** were also observed. In the former experiment we were able to isolate a small amount (*ca.* 5%) of 2-methyl-2′-methylthioacrylophenone (**5**), the structure of which has been established by n.m.r., i.r., and mass spectrometry, and also by catalytic reduction to the isobutyrophenone analog, and which we believe is involved in the formation of **3** as an intermediate (Scheme 1). However, even in the presence of potassium *t*-butoxide, **1** could be efficiently converted to **2** by carrying out the reaction in *t*-butyl alcohol at 25°.



SCHEME 1

Our view of the mechanistic route to **3** from **1**, summarized in Scheme 1, is based in part on the observation that higher temperatures appear to promote the formation of the 'abnormal' product in the base-catalyzed methylation reaction and in part on the isolation of compound **5** as a minor product from the potassium *t*-butoxide catalyzed reaction of **1** with methyl iodide in benzene. The equilibrium mixture of the anion **A** and the ring-opened thiolate ion **B** thus leads predominantly, if not exclusively, to **2** in the presence of methyl iodide at 25°, but predominantly to **5** at temperatures around 80°. The observed preferential attack on **5** by **B** rather than **A** is expected on steric grounds, while sub-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sequent cyclization (intramolecular Michael-type addition) and methylation account for the observed product **3**.

Our study has shown that while base-catalyzed alkylation at the 3-position in thiochroman-4-one derivatives is possible, it is markedly sensitive to the reaction conditions employed.

Experimental

General

The i.r. spectra (cm^{-1}) were recorded as specified on a Perkin–Elmer Model 337 grating spectrophotometer and the p.m.r. spectra (δ) on Varian A-60 and HA-100 spectrometers with tetramethylsilane as the internal standard.

The ^{13}C n.m.r. spectra were obtained on a Varian Associates XL-100-15 machine with tetramethylsilane as the internal standard. Mass spectra were recorded on a Bell and Howell 21-490 spectrometer and accurate mass measurements on the A.E.1. MS-902 instrument. The elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, Herlev, Denmark. V.p.c. was conducted on a Varian Aerograph Autoprep Model A-700 instrument using a Ucon column (12 ft × $\frac{3}{8}$ in.) containing 60–80 mesh Chromosorb W. Column chromatography was performed using silica gel (Davison Chemical, Grade 923, 100–200 mesh) or neutral alumina (Fisher Grade I, 80–200 mesh) and Fisher A.C.S. grade solvents. All melting points and boiling points are uncorrected.

3-Methylthiochroman-4-one

This compound was prepared by the method of Arndt (4).

Methylation of 3-Methylthiochroman-4-one

Method A

A solution of potassium *t*-butoxide prepared by refluxing potassium (1.17 g) in *t*-butyl alcohol (40 ml) under nitrogen was cooled to 40° and 3-methylthiochroman-4-one (1.78 g in 5 ml dry benzene) added with stirring. The mixture was immediately cooled in ice and methyl iodide (4 ml) was added. After stirring for 10–15 min, the reaction mixture was refluxed for a further 90 min. Water (40 ml) was added to the cooled reaction mixture and the *t*-butyl alcohol evaporated. The residual solution was extracted with ether and the combined ethereal extracts washed and dried ($MgSO_4$). The ether was evaporated and the residue chromatographed over alumina. Elution with benzene – petroleum ether mixture (40–50% benzene) gave 3,3-dimethylthiochroman-4-one (**2**) (70 mg). Further elution with benzene – petroleum ether mixtures (70% benzene), benzene, and finally benzene–ether mixtures (2–6% ether) gave the dimer **3** (1.2 g, 63%) which was crystallized from acetic acid and finally recrystallized from a mixture of benzene – petroleum ether, m.p. 112–113°. I.r. (KBr) 1685 and 1655 (C=O); n.m.r. ($CHCl_3$-d_1) 1.16 (3H, s), 1.26 (3H, s), 1.33 (3H, s), 2.31 (3H, s), 2.50 (2H, unresolved AB quartet), 2.93 (1H, d, J = 13.5 Hz), 3.48 (1H, d, J = 13.5 Hz), 6.90–7.40 (7H, m), 8.01 (1H, dd, J_1 = 8.5, J_2 = 2.0 Hz); ^{13}C n.m.r. 210.6 (s, cyclic C=O), 198.5 (s, acyclic C=O), 141.2, 140.2, 136.5, and 130.6 (each s, aromatic quaternary carbon), 133.7–123.5 (m, 8 aromatic carbon), 48.3, 44.9 (each s, quaternary carbon), 44.5 (t, C—CH_2), 38.6 (t, S—CH_2), 28.5, 26.3, and 24.2 (each q, C—CH_3), 17.5 (q, S—CH_3). The mass spectrum showed the expected molecular ion at *m/e* 384 (6), 328 (10), 233 (25), 194 (5), 177 (11), 151 (100), 136 (5), 108 (5). Mass measurements (*m/e* 233 and 151). Calculated for $C_{14}H_{17}OS$ and C_8H_7OS; 233.0999 and 151.0217. Found: 233.1013 and 151.0222.

Anal. Calcd. for $C_{22}H_{24}O_2S_2$: C, 68.75; H, 6.25; S, 16.66. Found: C, 68.61; H, 6.33; S, 16.43.

Method B

To a solution of potassium *t*-butoxide (1.17 g) in benzene (125 ml) was added 3-methylthiochroman-4-one (1.78 g in 10 ml benzene). Methyl iodide (4 ml) was then added to the brown solution at 25° and the temperature maintained at 25° for 15 min. The mixture was then refluxed for 1½ h and cooled. Water (40 ml) was added to the reaction mixture and the solution extracted thoroughly with ether, the combined extracts being washed and dried ($MgSO_4$). The ether was evaporated and the residue chromatographed over silica gel (100–200 mesh, 200 g). Elution with benzene – petroleum ether mixture (1:1) gave 3,3-dimethylthiochroman-4-one (**2**) (5 mg) and 2-methyl-2′-methylthioacrylophenone (**5**) (70 mg, 4%) which was purified by v.p.c. at 180°. I.r. (**5**) (neat liquid): 1650, 1580, 1430, 1350; n.m.r. ($CHCl_3$-d_1) 2.05 (3H, m, J < 1 Hz), 2.40 (3H, s), 5.50 (1H, m), 5.92 (1H, m), 7.10–7.60 (4H, m). The mass spectrum showed the expected molecular ion at *m/e* 192. Calculated for $C_{11}H_{12}OS$: 192.060874. Found: 192.061535.

Further elution with benzene and benzene methylene – chloride mixture (2% methylene chloride) gave the dimer **3** (1.3 g, 68%).

Method C

To a solution of 3-methylthiochroman-4-one (0.85 g) in dry benzene (10 ml) was added methyl iodide (1 ml in 5 ml of benzene). The mixture was cooled and sodium hydride (0.4 g) added with stirring during 30 min and the mixture refluxed for 5 h. Water (40 ml) was added, and the solution extracted with benzene. The combined benzene extracts were washed and dried ($MgSO_4$). The benzene was evaporated and the residue chromatographed over alumina. Elution with benzene – petroleum ether mixture (2:3) yielded 3,3-dimethylthiochroman-4-one (**2**) (0.3 g, 40%) and starting material (0.15 g).

Methylation of Thiochroman-4-one

To a solution of thiochroman-4-one (20.3 g) in freshly distilled 1,2-dimethoxyethane (50 ml) was added methyl iodide (20 ml) and the mixture cooled to −10°. A slurry of sodium hydride (12.5 g) in pentane was added in small amounts with vigorous stirring, keeping the temperature below 10°, and then the reaction mixture was maintained at room temperature for 4 h. During this period the red color gradually faded and finally the mixture was heated to 80° for 5 min by which time the red color had disappeared completely. The reaction mixture was cooled, water added, and the solution extracted with ether. Washing and drying ($MgSO_4$) of the combined extracts and evaporation of the solvent gave 3,3-dimethylthiochroman-4-one (**2**) (11.2 g, 46%) which was purified by distillation under reduced pressure, b.p. 120–122° (1.5 mm). I.r. (neat liquid) 1668, 1587, 1307, 1075, 985, and 892; n.m.r. ($CHCl_3$-d_1) 1.30 (6H, s), 3.00 (2H, s), 7.00–7.30 (3H, m), 8.05 (1H, dd, J_1 = 8.5, J_2 = 2.0 Hz).

Reduction of Dimeric Rearrangement Product **3** *with* $NaBH_4$

Compound **3** (200 mg) in dioxane (20 ml) was added to sodium borohydride (400 mg) in dioxane–water mixture (1:1) (16 ml) and the solution allowed to stand at room temperature for 1 h. The dioxane was removed under vacuum while keeping the bath temperature at 40–50°. The solution was acidified with dilute hydrochloric acid and the product (180 mg, 90%) collected as a white solid which was crystallized from a mixture of ethanol – petroleum ether, m.p. 172–174°. I.r. (Nujol) 3350, 3265, 1600, 1590. The mass spectrum showed the expected molecular ion at *m/e* 388 (4), 370 (7), 236 (19), 235 (24), 217 (17), 162 (100), 153 (57), 147 (45), 135 (24), 109 (16), 83 (16), 77 (17).

Hydrogenation of 2-Methyl-2′-methylthioacrylophenone (**5**)

2-Methyl-2′-methylthioacrylophenone (30 mg) was dissolved in ethyl acetate (15 ml) and hydrogenated over Pd (5% on C) (20 mg) at 25° and 760 Torr. After the uptake of 1 mol of hydrogen was complete the solution was filtered and the solvent evaporated. The residue was molecularly distilled to give *o*-methylthio-isobutyrophenone (25 mg). I.r. (neat liquid) 1655, 1580, 1550, 1450, 1425, 1260, 1220, 972, 730; n.m.r. ($CHCl_3$-d_1) 1.20 (6H, d, J = 7.0 Hz), 2.34 (3H, s), 3.41 (1H, m, J = 7.0 Hz) 7.00–7.80 (4H, m). The mass spectrum showed the expected molecular ion at *m/e* 194. Calculated for $C_{11}H_{14}OS$: 194.0765. Found: 194.0775.

We thank Mr. N. Plavac for recording the ^{13}C n.m.r. spectra and Mr. Ian Peat for helpful discussion regarding the use of the lanthanide shift reagent. Financial support of this work by the National Research Council of Canada is gratefully acknowledged.

The Alkylation of Cyclic Diketone Thallium(I) Salts

JOHN M. MCINTOSH[1] AND P. M. BEAUMIER
Department of Chemistry, University of Windsor, Windsor, Ontario

Received September 25, 1972

The *C*/*O* alkylation ratios of a series of alkyl halides and α-haloesters with the thallium(I) salts of 1,3-cyclohexanedione and 1,3-cyclopentanedione have been investigated. Unlike the alkylation of acyclic diketone salts, the predominant process in most cases is *O*-alkylation.

On a déterminé les pourcentages relatifs de *C* et de *O*-alkylation obtenus lors de la réaction des sels de thallium(I) de la cyclohexanedione-1,3 et de la cyclopentanedione-1,3 avec une série d'halogénures d'alkyle et d'esters halogénes en α. Contrairement aux résultats obtenus en séries acycliques, le processus prédominant dans la plupart des cas est la *O*-alkylation.

Much of the recent activity in organic synthesis has been focussed on the development of regiospecific reactions. The advances made in this area have allowed the synthesis of many compounds which would have been otherwise difficult if not impossible. Notable among these developments has been the regiospecific *C*-alkylation and -acylation of 1,3-diketones through the mediation of their thallium(I) salts in heterogeneous media (1). The problems involved in the alkylation of these compounds using more usual conditions are well known (for an excellent summary of these problems, see ref. 2).

Our interest in this procedure stemmed from the need to prepare 2-alkyl-1,3-cyclopentanediones and 2-alkyl-1,3-cyclohexanediones for other work. The alkylations of 1,3-cyclopentanedione and 1,3-cyclohexanedione are known to be unusually difficult (3, 4). When our investigation was initiated, no reports of the alkylation of *cyclic* 1,3-diketones via their thallium salts had appeared.[2] We, therefore, undertook a survey of these reactions with thallium salts **1** and **5** and a series of alkyl halides and α-haloesters in order to determine the *C*/*O* alkylation ratios.

Results and Discussion

Our initial attempts involved the reactions of **1** and **5** with methyl iodide (**2***a*) and ethyl bromide (**2***b*) (Scheme 1). The results in terms of *C*-alkylation, especially with **2***b*, were disappointing. However, it was felt that the use of a bifunctional alkylating agent, as well as affording more useful products, might well allow an increase in the amount of *C*-alkylation. Since most of the charge on the ambident ion will reside on the oxygen atom, an initial coordination of one of the two positively polarized atoms in **2** at this position might occur. The remaining electrophilic site in **2** might then orient itself towards the β-carbon atom of **1** or **5**, thus improving the chance for *C*-alkylation.

The results are summarized in Scheme 1 and Tables 1, 2, and 3. All reactions were run employing the salt as a suspension in the alkylating agent which also served as the solvent, conditions reported to maximize the yield of *C*-alkylated product (1*b*).

The regiospecificity of the alkylation of acyclic 1,3-diketone thallium salts has been attributed to the crystal structure of the salt. The metal and two oxygen atoms are inside the crystal, exposing only the carbon skeleton to the action of the alkylating agent (1*b*). The evidence for this has been summarized (1*a*). However, the data presented in Table 1 clearly indicate that this predilection of *acyclic* 1,3-diketone thallium salts for *C*-alkylation is not shared by their cyclic relatives. Although we have no evidence as to the crystal structure of **1** or **5**, we attribute our results to the steric prohibition of such a cyclic chelation and the shielding of the carbon atom of the ambident nucleophile by the ring methylene groups. Another proposal (ref. 2, p. 523) has suggested that the regiospecificity in the acyclic cases is due to the fact that the reactions are both heterogeneous and involve a cation which is tightly bound to oxygen, factors which are

‡Comprised of at least 4 compounds whose stability precluded further identification.

known to favor *C*-alkylation. Clearly our results do not support this postulate.

The isolation of a 13% yield of 4-oxo-2,3,4,5,6,7-hexahydrobenzofuran (**9**) from the reaction of **1** and ethylene dibromide (**2***c*) indicated the occurrence of some *C*-alkylation and gave some support to our hopes for improved yields of **3** from bifunctional alkylating agents. However, when **1** was treated with **2***d* or **2***f*, complex mixtures resulted, from which could be isolated the ethers **4***d* and **4***f*. The remainder of the products all showed strong carbonyl absorptions but their n.m.r. spectra were unintelligible in terms of simple alkylation procedures, and they decomposed rapidly on exposure to air and light.

The esters **3***d* and **3***f* have been prepared by

the action of α-haloesters on the potassium salts of 1,3-cyclohexanedione (6), but in our hands, none of these materials could be isolated. Since our interest was simply in the *C*/*O* alkylation ratios, we have not investigated these reactions further.

The data also indicate that *C*-alkylation is a more favorable process for **1** than for **5**. As proposed previously (3) this result may be ascribed to the fact that *O*-alkylation of **1** forces the product to assume the half chair conformation whereas *C*-alkylation allows the product to exist in the more stable chair conformation. In the case of **5**, both the *O*- and *C*-alkylation products are relatively rigid and therefore the stability gained by the formation of the conjugated ketone takes precedence. Similar reasoning has been used to rationalize the difference in the acidities of 1,3-cyclohexanedione and 1,3-cyclopentanedione (7).

One further point is of interest. When the enol ether **7***d* was allowed to stand at room temperature and exposed to the atmosphere, a clean conversion to **7***a* occurred over a period of some weeks. Although the enol ethers **7***a*, **4***a*, and **4***c* did decompose under analogous conditions, many products were produced. We have no further information on this rather novel decomposition.

NOTE ADDED IN PROOF: A recent paper (15) has presented results which also bring into doubt the ability of thallium enolate salts to promote exclusive *C*-alkylation in acyclic cases.

Experimental

Unless otherwise noted infrared spectra were recorded on a Beckmann IR12 spectrometer in chloroform solution and n.m.r. spectra were obtained on a JEOLCO C6OHL spectrometer in deuteriochloroform and are reported in δ units relative to TMS. The g.l.c. analyses were carried out on F and M Models 720 and 5750 gas chromatographs utilizing an 8 ft × 0.25 in. 20% SE-30 on Chromosorb W column. Preparative g.l.c. was performed using an 8 ft × 0.375 in. column packed as above. Composition of mixtures was determined using a disc integrator. Microanalyses were performed by A. B. Gygli, Microanalysis Laboratory, Toronto, Ontario.

*Preparation of Salts **1** and **5***

1,3-Cyclohexanedione or 1,3-cyclopentanedione (8) was dissolved in a mixture of benzene and ethanol (2:1) and thallium ethoxide (9) was added dropwise with stirring. The salt precipitated from solution, was collected by filtration, and recrystallized from ethanol. The yields were quantitative.

1,3-Cyclohexanedione thallium salt **1**; m.p. 191–192°; i.r.(KBr): 3410, 2940, 1655, 1540, 1415, 1375, 1320 cm^{-1}.

1,3-Cyclopentanedione thallium salt **5**; m.p. 205–206°; i.r.(KBr): 3380, 2920, 1635, 1560, 1360, 1280 cm^{-1}.

General Alkylation Procedure

The thallium(I) salt (**1** or **5**) was suspended in 15 ml of the alkylating agent and heated at constant temperature. The cooled reaction mixture was filtered and the residue was washed with 30 ml of benzene. The combined filtrates (fraction A) were evaporated to afford crude material which was immediately subjected to g.l.c. analysis. Preparative g.l.c. afforded samples of each of the components for spectral and elemental analysis. The residue from the filtration was then washed with absolute methanol to remove the thallium halide; the filtrate (fraction B) was evaporated and the crude material was analyzed. In each case, most of the unreacted **1** or **5** was recovered from this fraction. Only other products are mentioned below. The relative amounts of products are shown in Table 1 and the spectral data are summarized in Tables 2 and 3. Catalysis was accomplished by adding three drops of triethylamine to the reaction mixture.

*Methyl Iodide and **1***

Fraction A (0.5 g) containing 41% of **8** (10) and 59% of **4***a* (6) which were identical in all respects with authentic samples was obtained from 3.1 g of **1** (9.8 mmol). Fraction B afforded 0.7 g of **3***a* m.p. 198–200° (lit. (4) 204°).

*Methyl Iodide and **5***

Fraction A (0.7 g), identical in all respects with **7***a* (11), was obtained from 2.0 g (6.78 mmol) of **5**. Fraction B gave 0.3 g of **6***a*, m.p. 207–208° (lit. (12) 208–209°).

*Ethyl Bromide and **1***

Fraction A (0.1 g) was obtained from 1.5 g (4.92 mmol) of **1** and consisted entirely of **4***b*, identical with an authentic sample (6).

*Ethyl Bromide and **5***

Fraction A (0.1 g) identified as **7***b* was obtained from 1.3 g (4.45 mmol) of **5** in the usual manner.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.65; H, 7.99. Found: C, 66.61; H, 8.22.

Fraction B afforded **5** as the only isolable material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1,2-Dibromoethane and ***1***

Fraction A (0.4 g) was obtained from 3 g (9.85 mmol) of **1**. From this material **4***c* could be isolated by g.l.c.

Anal. Calcd. for $C_8H_{11}BrO_2$: C, 43.57; H, 5.04; Br, 36.47. Found: C, 43.86; H, 5.06; Br, 35.84.

Two other compounds were present, one of which presented spectral data consistent with **9**. Mass spectral analysis gave a molecular weight of 138 (P + 1 = 9%, P + 2 = 1%). $C_8H_{10}O_2$ requires P + 1 = 8.9%, P + 2 = 0.7% (13). Other prominent peaks in the mass spectrum occurred at *m/e* 111, 110 (base), 80, 68. The instability of the compound prevented our obtaining a satisfactory elemental analysis.

Again, fraction B afforded **1** as the only product.

1,2-Dibromoethane and ***5***

Fraction A (0.2 g) identified as **7***c* was obtained from 2.0 g (6.78 mmol) of **5**.

Anal. Calcd. for $C_7H_9BrO_2$: C, 40.98; H, 4.39. Found: C, 41.02; H, 4.34.

Fraction B afforded **5** as the only isolable material. Increasing the temperature to 100° raised the yield of **7***c* to 42% while adding three drops of triethylamine to the reaction afforded **7***c* in 85% yield.

Methyl Bromoacetate and ***1***

Fraction A (0.96 g) was obtained from 2.4 g (7.72 mmol) of **1**. From this material could be isolated 69% of **4***d*.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.49; H, 6.75.

The remainder of this fraction was comprised of four compounds in approximately equal amounts whose spectral characteristics indicated that they were not products of simple alkylation of **1** and which rapidly decomposed on standing.

Methyl Bromoacetate and ***5***

Fraction A (1.7 g) which consisted of 18% **7***a* and 77% of **7***d* was obtained from 2.0 g (6.78 mmol) of **5**.

Anal. Calcd. for $C_8H_{10}O_4$: C, 56.47; H, 5.92. Found: C, 56.44; H, 5.89.

That **7***a* was a product of decomposition of **7***d* was shown by analysis of a sample of **7***d* which had been allowed to stand at room temperature for a period of several days. It had been cleanly converted to **7***a*. No rearrangement took place when air was excluded.

Fraction B consisted entirely of unreacted **5**.

Ethyl Bromoacetate and ***5***

Fraction A (1.6 g) was obtained from 2.8 g (9.36 mmol) of **5**. The major (93%) component was identified as **7***e*. The remainder of the fraction was composed of several small impurities which were not investigated.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.77; H, 6.69.

Again, fraction B was entirely unreacted **5**.

Ethyl Chloroacetate and ***1***

Fraction A (0.47 g) was obtained from 3 g (9.85 mmol) of **1**. From this material **4***f* was isolated.

Anal. Calcd. for $C_9H_{14}O_4$; C, 60.50; H, 7.14. Found: C, 60.59; H, 7.12.

The remainder of the product was comprised of at least four compounds whose i.r. and n.m.r. spectra were not consistent with products of simple alkylation and which rapidly decomposed.

Fraction B afforded only unreacted **1**.

Ethyl Chloroacetate and ***5***

Fraction A (0.25 g) was obtained from 1.3 g (4.35 mmol) of **5** in the usual manner. This material consisted entirely of the *O*-alkylated product **7***e* (=**7***f*). Unreacted **5** was the only compound in fraction B.

The financial assistance of the National Research Council of Canada and the technical assistance of Mr. D. Hill are greatly appreciated. The assistance of Professor R. D. Bach (Wayne State University) in obtaining the mass spectrum is also gratefully acknowledged.

The reaction of 2,3-dimethyl-1,3-butadiene (**1**) with methyl acetoacetate in the presence of a catalyst composed of palladous chloride and *p*-phenyl-1-phospha-3-methyl-3-cyclopentene gave 3-carbomethoxy-5,6-dimethyl-5-hepten-2-one (**2**) (1:1 adduct). Alkali decomposition of **2** gave 5,6-dimethyl-5-hepten-2-one (**3**), which was a key intermediate for the preparation of α-irone. Similarly, isoprene gave a mixture of 5- and 6-methyl-5-hepten-2-one.

La réaction du diméthyl-2,3 butadiène-1,3 (**1**) avec l'acétoacétate de méthyle en présence d'un catalyseur composé de chlorure de palladium et de *p*-phénylphospha-1 méthyl-3 cyclopentène-3, conduit au carbométhoxy-3 diméthyl-5,6 heptène-5 one-2 (**2**) (adduit de type 1:1). La décomposition alcaline de **2** conduit à la diméthyl-5,6 heptène-5 one-2 (**3**) qui est l'intermédiaire clé dans la préparation de l'α-irone. De la même façon, l'isoprène donne un mélange de méthyl-5 et -6 heptène-5 one-2.

Can. J. Chem., **51**, 848 (1973)

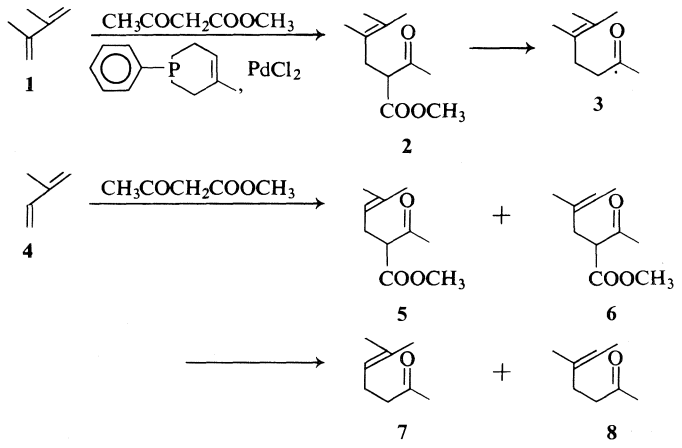
The ketone irone, found in oil of orris root, is used extensively in perfumery, because of its odor of violets. 5,6-Dimethyl-5-hepten-2-one (**3**) is an important key compound for the synthesis of α-irone. Ruzicka prepared 5,6-dimethyl-5-hepten-2-one (**3**) from 2,3-dimethyl-2-buten-1-bromide and ethyl acetoacetate (1). We have found the new preparative method for compound **3** from 2,3-dimethyl-1,3-butadiene and methyl acetoacetate using a new catalyst.

The reaction of active methylene compounds with 1,3-dienes has been reported (2). An active and easily available catalyst is prepared by mixing dichlorobis(triphenylphosphine)palladium and basic sodium compounds such as sodium phenoxide. The reaction of ethyl acetoacetate with 1,3-butadiene in the presence of $PdCl_2$-$(PPh_3)_2$–PhONa catalyst gives mixtures of 1:2 and 1:4 adducts (2). However, the reaction of 2,3-dimethyl-1,3-butadiene (**1**) with ethyl acetoacetate results in the exclusive formation of ethyl 2-acetyl-2,3,6,7-tetramethyl-2,7-decadienoate (1:2 adduct) in very low yields (7%). We have investigated the reaction of 2,3-dimethyl-1,3-butadiene (**1**) with methyl acetoacetate, and found that a new catalyst consisting of palladous chloride and *p*-phenyl-1-phospha-3-methyl-3-cyclopentene is very effective for the selective preparation of a 1:1 adduct. When a mixture of 2,3-dimethyl-1,3-butadiene (**1**) and methyl acetoacetate was heated for 10 h at 100 °C in the presence of a catalyst composed of palladous chloride, *p*-phenyl-1-phospha-3-methyl-3-cyclopentene, and sodium phenoxide, 3-carbomethoxy-5,6-dimethyl-5-hepten-2-one (**2**) (1:1 adduct) was selectively obtained in a yield of about 50% (see Scheme 1). This catalyst is a new special catalyst for the preparation of a 1:1 adduct (**2**). 5,6-Dimethyl-5-hepten-2-one (**3**) was prepared by the alkaline decomposition of **2**. Similarly, the reaction of isoprene (**4**) with methyl acetoacetate using this catalyst gave a mixture of methylheptenone (**7**), an important intermediate for the synthesis of terpene compounds, and 5-methyl-5-hepten-2-one (**8**), as shown in the Experimental. The method mentioned above is superior to the well-known method, the acetoacetate-rearrangement route (Carroll reaction) (4).

Experimental

Reaction of 2,3-Dimethyl-1,3-butadiene (1) with Methyl Acetoacetate

In a glass-sealed autoclave under nitrogen a mixture of 0.21 g (1 mmol) of palladous chloride, 0.29 g (2.5 mmol) of sodium phenoxide, 5 g (61 mmol) of 2,3-dimethyl-1,3-butadiene (**1**), and 0.35 g (2 mmol) of *p*-phenyl-1-phospha-3-methyl-3-cyclopentene was stirred at 25 °C for 5 min in an atmosphere of nitrogen. To this mixture, 10 g (122 mmol) of **1** was added. After 15 min, 22 g (190 mmol) of methyl acetoacetate was added. The mixture was heated at 100 °C for 10 h. The solution was directly distilled to give the following fractions: (A) b.p. ~85 °C/30 mm, yield 8 g; (B) b.p. 85–125 °C/30 mm, yield 2 g; and (C) b.p. 125–130 °C/30 mm, yield 16 g. Fraction A was a mixture of unchanged **1** and methyl acetoacetate. Fraction B was a mixture of 3-carbo-



SCHEME 1

methoxy-5,6-dimethyl-5-hepten-2-one (**2**) (yield 8%), **1**, and methyl acetoacetate. Fraction C was compound **2** (yield 44%); i.r.: 1745, 1720 cm^{-1}.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.67; H, 9.09. Found: C, 66.52; H, 9.06.

5,6-Dimethyl-5-hepten-2-one (3)

A mixture of 9.9 g (0.05 mol) of compound **2** and 5% sodium hydroxide solution was agitated for 4 h at room temperature. To this solution, 7.84 g of 50% sulfuric acid was added. The solution was directly distilled at atmospheric pressure. The distillate was extracted with isopropylether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and distilled to give the following fractions: (A) b.p. ~92 °C/31 mm, yield 0.5 g; (B) b.p. 92–93.5 °C/31 mm, yield 4.5 g (yield 70%). Fraction B was 5,6-dimethyl-5-hepten-2-one (**3**); i.r.: 1717 cm^{-1}; n.m.r. (δ, p.p.m.): 1.6 (s, CH_3—C, 9H), 2.0 (s, CH_3—C(=O)—, 3H), 2.3 (t, —CH_2—, 4H); mass spectrum (*m/e*): M^+ 140.

Anal. Calcd. for $C_9H_{16}O$: C, 77.64; H, 11.59. Found: C, 77.62; H, 11.56.

Synthesis of Methylheptenone (7) from Isoprene and Methyl Acetoacetate

In a glass-sealed autoclave, a mixture of 0.21 g (1 mmol) of palladous chloride, 0.29 g (2.5 mmol) of sodium phenoxide, 5 g (74 mmol) of isoprene, and 0.35 g (2 mmol) of *p*-phenyl-1-phospha-3-methyl-3-cyclopentene was stirred at 25 °C for 5 min in an atmosphere of nitrogen. To this mixture, 15 g (221 mmol) of isoprene was added. After 15 min, 22 g (190 mmol) of methyl acetoacetate was added. The mixture was heated at 50 °C for 13 h. The solution was directly distilled to give the following fractions: (A) b.p. ~85 °C/30 mm, yield 4 g; (B) b.p. 85–110 °C/30 mm, yield 2 g; (C) b.p. 110–115 °C/30 mm, yield 22 g; and (D) b.p. 103–104 °C/0.05 mm, yield 4 g. Fraction A was a mixture of unchanged isoprene and methyl acetoacetate. Fraction B was a mixture of 1:1 adduct (**5** and **6**, yield 4%), isoprene, and methyl acetoacetate. Fraction C was a mixture of 3-carbomethoxy-6-methyl-5-hepten-2-one (**5**) and 3-carbomethoxy-5-methyl-5-hepten-2-one (**6**) in yield of 37%. The mixture consisted of 85% of **5** and 15% of **6** by gas-chromatographic analysis; i.r.: 1680, 1745, 1720, 880 cm^{-1}.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.22; H, 8.70. Found: C, 65.20; H, 8.64.

Fraction D was an adduct of 2 mol isoprene with 1 mol methyl acetoacetate. Its structure was not determined.

Fraction C (9.2 g, 0.05 mol) was treated with sodium hydroxide solution in a manner similar to the preparation of **3** to give a mixture (7 g) of 6-methyl-5-hepten-2-one (**7**) and 5-methyl-5-hepten-2-one (**8**) in yield of 44%. The mixture consisted of **7** (85%) and **8** (15%) by gas-chromatographic analysis. Compounds **7** and **8** were separated by gas-chromatographic trapping using a column of Silicone DC 200 (20%) on Celite 545 (2 m). The structures of these compounds were confirmed by comparison of their authentic samples using g.l.c. and i.r. spectra.

Synthesis of p-Phenyl-1-phospha-3-methyl-3-cyclopentene

Dichlorophenylphosphine was prepared as reported previously (3), b.p. 90–92 °C/10 mm. In a dry glass equipment, a mixture of dichlorophenylphosphine (179 g), isoprene (89 g), and copper stearate (3.5 g) was left for 48 h to give a white solid, *p*-phenyldichloro-1-phospha-3-methyl-3-cyclopentene. This crude solid was washed with *n*-hexane several times. A mixture of the solid (124 g), tetrahydrofuran (300 ml), and Mg dust (18 g) activated by a small amount of ethyl bromide was refluxed for 1 h. The tetrahydrofuran solution was treated with water, made alkaline with diluted sodium hydroxide solution, and extracted with benzene. Distillation under nitrogen gave 69.7 g of *p*-phenyl-1-phospha-3-methyl-3-cyclopentene, b.p. 120–125 °C/5 mm.

Anal. Calcd. for $C_{11}H_{13}P$: C, 74.98; H, 7.43; P, 17.58%. Found: C, 74.93; H, 7.39; P, 17.42.

Marine Organic Chemistry. I. Isolation of 3β,6α-Dihydroxy-5α-pregn-9(11)-en-20-one from the Saponins of the Starfish *Asterias forbesi*. A Rapid Method for Extracting Starfish Saponins[1]

JOHN W. APSIMON, JOHN A. BUCCINI,[2] AND SATYANAND BADRIPERSAUD
Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received November 3, 1972

The major aglycone from the saponins of *Asterias forbesi* has been identified as 3β,6α-dihydroxy-5α-pregn-9(11)-en-20-one (**1**). A simplified procedure for extracting saponins from starfish is reported which reduces the required working time from 7–14 to 1–3 days.

L'aglycone majeur obtenu des saponosides de l'*Astérias forbesi* a été identifié comme étant le dihydroxy-3β,6α pregn-5α ène-9(11) one-20 (**1**). Une méthode simplifiée pour l'extraction des saponosides de l'étoile de mer est rapportée; celle-ci réduit le temps nécessaire requis par l'extraction de 7–14 jours à 1–3 jours. Can. J. Chem., **51**, 850 (1973)

Introduction

The phylum Echinodermata is comprised of some 6500 species of marine invertebrate animals, of which there are five classes (1): (*1*) Holothuridea (sea cucumbers), (*2*) Asteroidea (starfish), (*3*) Echinoidea (sea urchins and sand dollars), (*4*) Ophiuroidea (brittle stars and basket stars), and (*5*) Crinoidea (sea lilies and feather stars).

For many years, organic chemists have investigated the naphthaquinone and anthraquinone pigments (2), the carotenoids (2), and the sterols (3) produced by these animals. Chemically, the echinoderms are unique in that the holothuroids and asteroids produce saponins (4–6) while no other animals — including the echinoids, ophiuroids, and crinoids — have been shown to do so (7). Since the first reports of saponin in sea cucumbers (4, 5), several papers have appeared dealing with the physiological properties and chemical composition of the holothuroid saponins and aglycones (2, 8). Several workers have shown that starfish saponins are the active principles of starfish which induce the "avoidance" or "escape" responses in many species of mollusc, thereby reducing predation by starfish of susceptible species of mollusc (9, 10). The saponin mixture has recently been identified as the spawning inhibitor in the Japanese starfish *Asterias amurensis* (11). Despite extensive investigations of their biological properties, little attention has been paid to the chemical composition of the starfish saponins which are complex mixtures, incorporating steroidal and nortriterpenoid aglycones, several different sugars, and a sodium sulfate half-ester. Only within the last year have the results of chemical investigations of the starfish aglycones appeared in print (12–15). As part of a continuing investigation of biologically active marine organic compounds, we have examined the saponin mixture of a common North Atlantic starfish, *Asterias forbesi*, and wish to report here the results of our recent investigations.

(A) The Saponins of Asterias forbesi

Specimens of *A. forbesi* were collected at South Bristol, Maine in August, 1971 and immediately frozen with Dry Ice for shipment. Upon receipt the animals were thawed and extracted by the published procedure (6) to obtain the saponin mixture (Fig. 1). This material was hydrolyzed (2 *N* HCl, steam bath) and the precipitated aglycones obtained by chloroform extraction. Repeated t.l.c. on silica gel resolved the aglycone mixture into two bands, one being a mixture of compounds of molecular weight 414 and the other, crystallized from benzene to give pure **1**, m.p. 151–153 °C, $[\alpha]_D^{20}$ +60° (ethanol). The

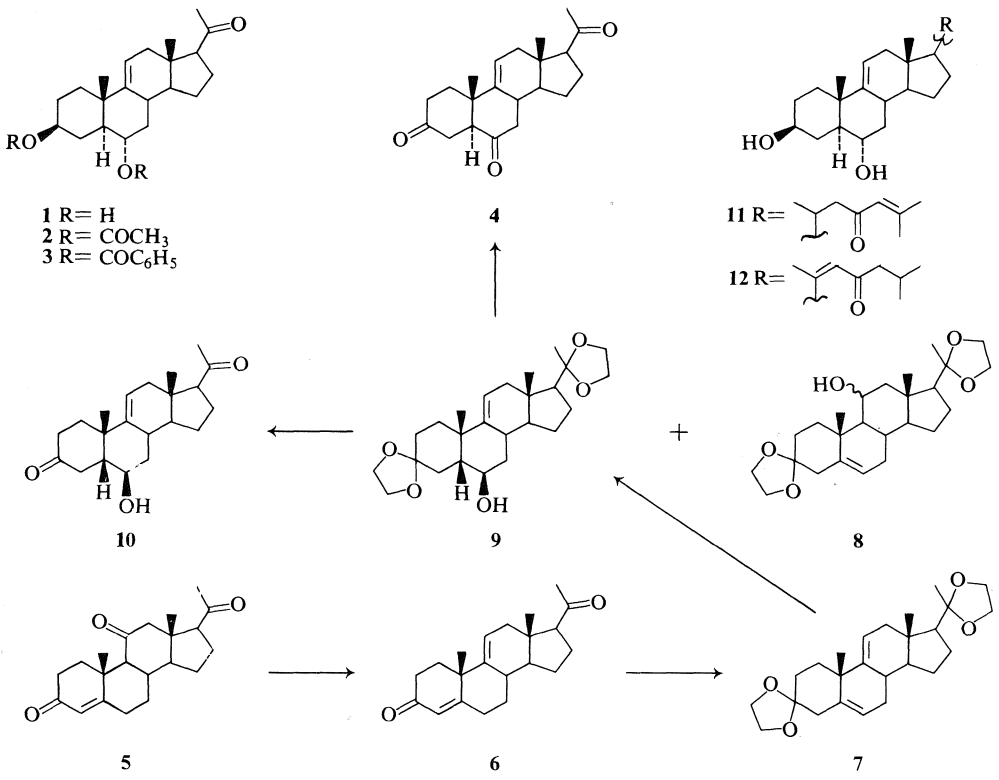

SCHEME 1

molecular formula was established as $C_{21}H_{32}O_3$ by high resolution mass spectrometry and the i.r. spectrum showed absorptions for hydroxy and carbonyl groups (3280, 1700 cm^{-1}, respectively). Aglycone (**1**) was shown to be a diol by conversion to the oily diacetate **2** [M^+ 416, ν_{max} (neat) 1735, 1700 cm^{-1}]. The n.m.r. spectrum of **1** indicated the presence of an acetyl group and from the general appearance of the spectrum, **1** was assumed to be a dihydroxy derivative of pregn-20-one. The n.m.r. spectrum of **1** exhibited an absorption at 5.36 δ corresponding to one olefinic proton indicating the presence of a trisubstituted olefinic bond.

Jones oxidation of **1** gave a crystalline triketone **4** whose molecular formula was established as $C_{21}H_{28}O_3$ by high resolution mass spectrometry. The u.v. spectrum of **4** in ethanol and NaOH/ethanol showed only end absorption, indicating that **4** did not possess an α,β-unsaturated ketone, a 1,2- or 1,3-diketone group. With these restrictions, there remained 72 possible structures for **4** *i.e.* for a pregn-20-one with one trisubstituted olefinic bond and two ketones in addition to the 17-acetyl group. Of this number, only two compounds had calculated (16, 17) angular methyl group chemical shifts which agreed with the experimental values for **4** (Table 1): these were pregn-5-en-2,11,20-trione and 5α-pregn-9(11)-en-3,6,20-trione. The former possibility was eliminated by a similar comparison of the calculated methyl group shifts of all possible 2,11-diols and -diacetates with the experimental methyl shifts of **1** and **2**. Thus, **4** was assumed to be 5α-pregn-9(11)-en-3,6,20-trione; this has been confirmed by the

*From tables in refs. 16 and 17.

synthesis of **4** from commercially available pregn-4-en-3,11,20-trione (**5**, Scheme 1).

Conversion of **5** to pregn-4,9(11)-dien-3,20-dione (**6**) was carried out following the published procedures (18, 19). Slow distillation of a mixture of **6**, benzene, ethylene glycol, and *p*-toluenesulfonic acid resulted in the formation of diketal **7**. Reaction of **7** with 1.3 equiv of BH_3/tetrahydrofuran was followed by oxidation with sodium hydroxide/hydrogen peroxide to give a mixture of two monohydroxy diketals (**8** and **9**) which were separated by t.l.c. on silica gel. Deketalization of the isomer of larger R_f (**8**) gave an enone, demonstrating that the olefinic bond in **8** was in the 5,6-position. The slower moving isomer was then assumed to be **9** and the stereochemistry at C-5 and -6 follows from a comparison of the experimental and calculated angular methyl group chemical shifts of **9** and of the diketone **10** obtained by deketalization of **9** (Table 1). Furthermore, in the n.m.r. spectra of **9** and **10**, the C-6 methine hydrogen signal appeared as a broad absorption with a half-intensity bandwidth of 8 Hz, clearly consistent with a C-6 equatorial proton (17). From precedents (20, 21) we had expected an α-attack in the hydroboration/oxidation of the 5,6-olefinic bond: the observed β-attack must reflect a severe steric effect on the α-face of the steroid system. Such steric hindrance would account for the results of our earlier attempts to reduce **7** in which we used up to 10 equiv of disiamylborane and still recovered **7** intact.

Collins oxidation of **9** followed by deketalization gave crystalline triketone **4**, shown to be identical to the sample obtained from **1** by comparison of i.r., n.m.r., and mass spectra and t.l.c. behavior on silica gel (chloroform, and ethyl acetate/benzene).

From the structure of **4**, it followed that the aglycone **1** must be one of the four possible isomers of 3,6-dihydroxy-5α-pregn-9(11)-en-20-one. Consideration of the methyl group chemical shifts led to the conclusion that **1** was either the 3α,6α- or 3β,6α-diol. The stereochemistry of the hydroxy groups was determined by obtaining the circular dichroism (c.d.) spectrum of the dibenzoate ester **3** and application of the dibenzoate chirality rule (22). The observed c.d. Cotton effects in methanol were +12.5 at 236 nm and −7.8 at 222 nm which are consistent only with a 3β,6α-stereochemistry: thus the complete structure of **1** is 3β,6α-dihydroxy-5α-pregn-9(11)-en-20-one.

Since completion of this work, three independent reports have appeared in which **1** has been proposed for the structure of the major aglycone from the saponins of *Asterias amurensis* (14), *A. forbesi* (15), and *Acanthaster planci* (13, 15). In these reports, the structure of **1** was postulated after hydrogenation of the olefinic bond (*presumed* to be in the 9(11)-position) and correlation with known saturated pregn-20-ones. Our synthesis of **4** firmly establishes the position of the olefinic bond and we report a novel demonstration of the hydroxy group stereochemistry of **1**.

In addition to **1**, two aglycones from starfish saponins have been identified: they are Marthasterone **11** from *Marthasterias glacialis* (12) and **12**, a minor aglycone from *Acanthaster planci* (13). It is striking that the three aglycones differ only in the composition of the C-17 side chain and would perhaps suggest a common biosynthetic route to these compounds. In view of the fact that starfish are characterized by Δ^7-sterols (3), it would be of interest to determine if the $\Delta^{9(11)}$-aglycones are biosynthetic or dietary in origin.

(B) A Simplified Extraction Procedure for Starfish Saponins

It is apparent from the recent literature that there is an increasing interest in the starfish saponins and we wish to report a simplified extraction procedure which we believe to be a significant improvement on the published procedure (6) shown schematically in Fig. 1. Working with 1–10 kg batches of starfish, we encountered several problems: (*a*) large volumes of alcohol/water were required to effectively extract the animals, (*b*) the rotary evaporation of large volumes of saponin extract was a tedious and time-consuming task, (*c*) defatting with benzene or ether gave emulsions which required 12–48 h to break, (*d*) using alcohol in the extracting solvent resulted in the extraction of large amounts of fats which were difficult to remove and contaminated the final sample of saponin. We have found that saponin may be successfully extracted merely by soaking live starfish in distilled water for 2-4 h at room temperature (Fig. 2). Removal of the animal bodies leaves an aqueous solution of saponin which contains but a minimal amount of fats and does not require defatting with ether or benzene. The aqueous solution can be immediately worked-up and the saponin extracted with *n*-butanol, etc.. It has

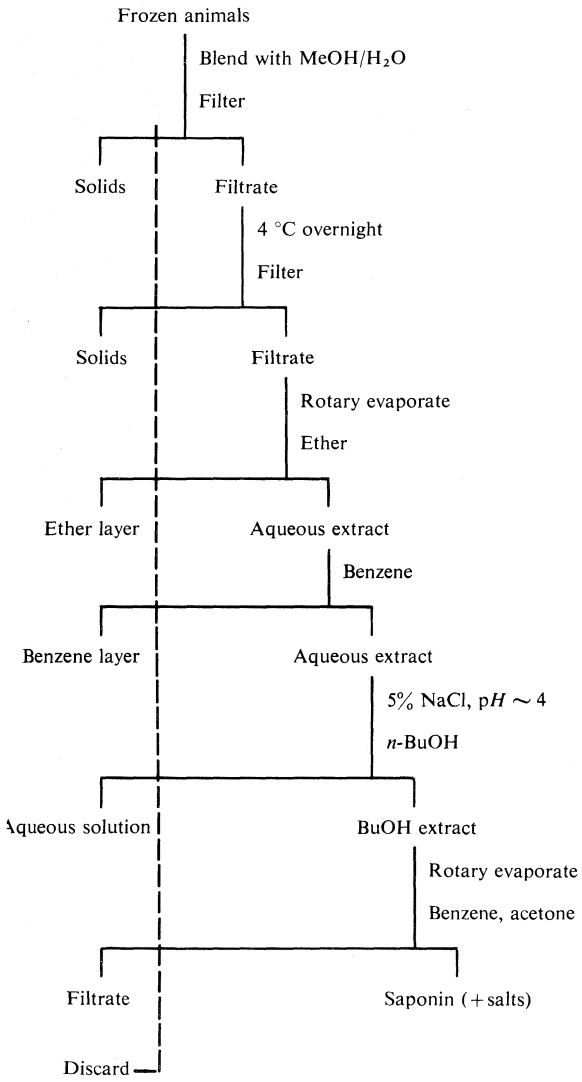

FIG. 1. Extraction procedure based on method in ref. 6.

been our experience that batches of 5–10 kg of starfish may be worked-up in 2–3 days to yield the saponin as compared with 10–14 days via the procedure in Fig. 1. The savings in time, solvents, and equipment are obvious.

Applying this technique to four species of starfish, we have succeeded in extracting from 33–94% of the saponin available in the animals, depending upon the species (Table 2). While the method would be of limited value in the 7- to 14-rayed *Solaster* species, it works very well with the 5-rayed *Asterias* and *Henricia* species. Further studies are currently underway to determine the generality of the extraction technique.

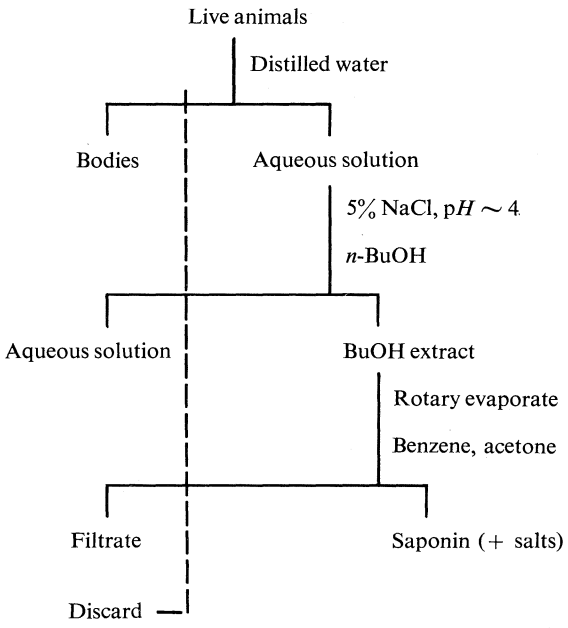

FIG. 2. Schematic representation of simplified extraction procedure.

TABLE 2. Extraction of starfish saponins via the simplified procedure (Fig. 2)

Species	Conditions	Saponin extracted (%)
Henricia sanguinolenta	1 × 2 h	60
	3 × 2 h	94
Asterias vulgaris	1 × 15 min	33
Crossaster papposus	3 × 2 h	33
Solaster endeca	3 × 1 h	37

Work on the constituents of a variety of echinoderms is also in progress in our laboratory.

Experimental

Melting points were determined on a Kofler hot stage and are corrected. The n.m.r. spectra were obtained on a Varian T-60 or Varian XL-100 spectrometer with tetramethylsilane as internal standard. Chemical shifts are expressed in the δ scale and the following abbreviations apply: s, singlet; d, doublet; t, triplet; m, multiplet. The i.r. spectra were determined on a Perkin–Elmer 237B grating spectrophotometer. Low resolution mass spectra were obtained on an AEI MS 12 instrument. The t.l.c. was performed using pre-coated plates obtained from E.M. Reagents (silica gel F-254, 0.25 or 2.0 mm).

Specimens of *Asterias forbesi* were collected in August, 1971 at South Bristol, Maine by representatives of the New England Aquarium, Boston, Mass. and immediately frozen with Dry Ice. The specimens of *Henricia sanguinolenta* (Feb./72), *Asterias vulgaris* (Aug./71), *Solaster endeca* (Oct./71), and *Crossaster papposus* (Dec./71) were collected at Deer Island in the Bay of Fundy by Marine

Research Associates, New Brunswick and were received live within 48 h of shipment.

Classical Extraction Procedure (Fig. 1)

Upon receipt, the frozen block of *A. forbesi* (5–10 kg) was divided into small pieces and thawed for 4–5 h under methanol/water (3/1) solution (15 l). The thawed mixture was homogenized using a Waring Commercial Blender and allowed to stand for 3 h. The animal pulp was separated by suction filtration and extracted twice more with methanol/water (10 l). The filtrates were stored in a cold room overnite at 4° and filtered once more. The filtrate was concentrated (to 4 l) by rotary evaporation, using bath temperatures of 45° or less to minimize thermal decomposition. The resulting mixture of oils and aqueous solution was diluted to 6 l with water and extracted with ether (3 l) and then benzene (3 l). In both extractions, emulsions were obtained: the ether emulsions separated in 2–4 h but those of benzene required 12–48 h for acceptable separation. The defatted aqueous solution was made up to 5% sodium chloride and the p*H* adjusted to 4 with dilute hydrochloric acid. The resulting mixture was extracted with water-saturated 1-butanol (3 × 2 l) and the water layer discarded. The butanol extract was suction-filtered through Whatman 1 filter paper and then gravity-filtered through a cotton plug to remove a sticky suspension. The butanol filtrate was concentrated (to 100–200 ml) by rotary evaporation and the saponin precipitated by the addition of benzene (1.5 l). The supernatant solution was decanted and the precipitate washed with acetone and collected by suction filtration. This precipitate contained large amounts of NaCl (silver nitrate test) and was freed of inorganic salts and small organic molecules (*e.g.* sugars) by dialysis in a cellophane bag against running tap water for 6–10 h. The clear solution in the cellophane bag was free of chloride (silver nitrate test) and lyophilization gave the saponin mixture (10 g).

Rapid Isolation Procedure (Fig. 2)

Live animals were completely immersed in distilled water at room temperature and allowed to soak for varying periods of time (Table 2). The animals were removed and the resulting solution gravity-filtered through a cotton plug, made up to 5% sodium chloride, and the p*H* adjusted to 4 with dilute hydrochloric acid. The saponin was then extracted with 1-butanol, etc. as in the classical procedure.

*3β,6α-Dihydroxy-5α-pregn-9(11)-en-20-one (**1**) from the Saponins of A. forbesi*

A solution of the saponin mixture from *A. forbesi* (4.3 g) in aqueous 2 *N* HCl (400 ml) was placed under a nitrogen atmosphere and warmed on a steam bath. Within 30 min, the clear solution became cloudy and after 2 h a clear supernatant and an oily deposit were observed. The mixture was cooled, extracted with chloroform (4 × 200 ml) and the aqueous solution discarded. Flash evaporation of the dried (Na_2SO_4) chloroform extract gave a gum (1.8 g) which was chromatographed on 2 mm silica gel plates, with the plates being developed twice (ethyl acetate, ethyl acetate/methanol = 20/1). Viewing the plates under u.v. light (360 nm), two dark bands were observed in the R_f range 0.5–0.8. The band of greater R_f was eluted and the spectral data indicated that it was probably a derivative of one of the sugars released during hydrolysis of the saponin. The second band visible under u.v. light was found to have a molecular weight of 414 and it is believed to be a mixture of several isomers (480 mg). This mixture is currently being investigated.

Elution of the area from R_f 0.1 to 0.5 gave a gum (180 mg) which was re-chromatographed to give pure aglycone **1** (120 mg). Crystallization from benzene gave **1** as a white solid, m.p. 151–153° (lit. m.p. 157–160 (14), 162–163 (13), 193–196° (15)); $[\alpha]_D^{20°}$ +60° (*c* 0.328, ethanol); $C_{21}H_{32}O_3$, M^+ 332.2350 (required 332.2351); ν_{max} (Nujol) 3280, 1700, 1040 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.55 (s, 3H, C-18 H_3), 0.95 (s, 3H, C-19 H_3), 2.13 (s, 3H, $COCH_3$), 3.3–3.8 (broad m, 2H, C-3 and -6 methine H), and 5.36 (broad m, 1H, C-11 H); *m/e* at 332, 317, 314, 299, 296, 281, 230.

*3β,6α-Diacetoxy-5α-pregn-9(11)-en-20-one (**2**)*

The aglycone **1** (8 mg) was acetylated (pyridine (0.1 ml) and acetic anhydride (3 ml) for 36 h) and the crude product purified by t.l.c. on silica gel (benzene/ethyl acetate = 20/1, then = 10/1). The diacetate **2** was obtained as a clear oil (6 mg) ν_{max} (film) 1735, 1700, 1250, 1035 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.55 (s, 3H, C-18 H_3), 1.03 (s, 3H, C-19 H_3), 2.03 (s, 6H, $OCOCH_3$), 2.12 (s, 3H, $COCH_3$), 4.4–5.1 (broad m, 2H, C-3 and -6 methine H), and 5.36 (broad m, 1H, C-11 H); *m/e* at 416, 356, 341, 296, 281, 226, 211.

*3β,6α-Dibenzoyloxy-5α-pregn-9(11)-en-20-one (**3**)*

The aglycone **1** (8 mg) was benzoylated (anhydrous pyridine (1 ml) and benzoyl chloride (0.5 ml), steam bath for 4 h) and routine work-up followed by t.l.c. on silica gel (benzene, then benzene/ethyl acetate = 20/1) gave the dibenzoate ester **3** as a clear gum (5 mg); ν_{max} (film) 1720–1700, 1600, 1580, 1490 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.60 (s, 3H, C-18 H_3), 1.15 (s, 3H, C-19 H_3), 2.16 (s, 3H, $COCH_3$), 4.84–5.33 (m, 2H, C-3 and -6 methine H), 5.40–5.60 (m, 1H, C-11 H), and 6.5–8.2 (m, 10H, ArH). The c.d. spectrum was run in methanol solution (*c* 5 mg/100 ml): maximum at 236 nm (+12.5), minimum at 222 nm (−7.8).

*5α-Pregn-9(11)-en-3,6,20-trione (**4**)*

An excess of Jones reagent (23) was added to a stirred, cooled (0°) solution of aglycone **1** (9 mg) in acetone (5 ml). After 15 min, the reaction mixture was diluted with water and extracted with chloroform (3 × 15 ml). Rotary evaporation of the dried (Na_2SO_4) chloroform extract gave an oil which was purified by t.l.c. on silica gel (benzene/ethyl acetate = 3/1, then = 1/1) to give the trione **4** (6 mg) which crystallized on standing, m.p. 180–182°; $C_{21}H_{28}O_3$, M^+ 328.2073 (required 328.2037); ν_{max} (Nujol) 1715–1700 cm^{-1}; n.m.r. ($CDCl_3$) δ 0.63 (s, 3H, C-18 H_3), 1.12 (s, 3H, C-19 H_3), 2.15 (s, 3H, $COCH_3$), and 5.64 (broad m, 1H, C-11 H).

*Conversion of Pregn-4-en-3,11,20-trione (**5**) to the Trione **4***

The synthesis of pregn-4,9(11)-dien-3,20-dione (**6**) from **5** was carried out following the published procedures (18, 19). A mixture of **6** (200 mg), benzene (100 ml), ethylene glycol (2 ml), and *p*-toluenesulfonic acid (5 mg) was slowly distilled over a 2 h period to leave a small volume (5–10 ml) of liquid remaining in the reaction

flask. The reaction mixture was cooled, washed with saturated aqueous sodium bicarbonate solution (15 ml), water (15 ml), and then dried (Na_2SO_4) and flash evaporated to give an oil. This material was chromatographed on silica gel plates (chloroform/methanol = 50/1) and the major band eluted to give the diketal **7** (130 mg); ν_{max} (film) 1675–1650 cm^{-1} (C=C); n.m.r. ($CDCl_3$) δ 0.77, 1.22, and 1.32 (3s, 3H each, C-18, -19, and -21 methyls), 3.99 (m, 8H, OCH_2CH_2O), and 5.37–5.60 (broad m, 2H, C-6 and -11 H).

A solution of diketal **7** (100 mg, 0.25 mmol) in anhydrous tetrahydrofuran (15 ml) was placed under a nitrogen atmosphere, cooled to 0° and reacted with 0.33 *M* BH_3/tetrahydrofuran (1 ml). After standing for 2 h at room temperature, the mixture was reacted with 3 *N* NaOH (3 ml) and 30% hydrogen peroxide (0.5 ml) and stirred for 1 h. Tetrahydrofuran was removed by vacuum evaporation and the resulting mixture extracted with ether. Flash evaporation of the dried (Na_2SO_4) organic extract gave an oily mixture which was chromatographed on silica gel plates to give two main bands. Elution of the band at R_f 0.5 gave crystalline material, m.p. 150–154°, assigned structure **9** on the basis of the following spectral data (see Table 1 and Discussion); ν_{max} (Nujol) 3475 cm^{-1} (OH); n.m.r. ($CDCl_3$) δ 0.72 (s, 3H, C-18 H_3), 1.28 (s, 3H, C-19 H_3), 1.32 (s, 3H, C-21 H_3), 3.7–3.9 (m, 1H, C-6 methine), 3.97 (m, 4H, OCH_2CH_2O), and 5.3–5.6 (m, 1H, C-11 H); *m/e* at 418, 403, 400, 358.

A mixture of acetone (20 ml), 2 N sulfuric acid (5 ml), and **9** (10 mg) was stirred at room temperature for 12 h, diluted with water, and extracted with chloroform to give the hydroxy-diketone **10** (6 mg); ν_{max} (film) 3450 (OH), 1700 (C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 0.62 (s, 3H, C-18 H_3), 1.36 (s, 3H, C-19 H_3), 2.16 (s, 3H, $COCH_3$), 3.7–3.9 (broad m, 1H, C-6 methine), and 5.5–5.8 (broad m, 1H, C-11 H).

Chromium trioxide (50 mg, 0.50 mmol) was dried in a vacuum dessicator over phosphorus pentoxide and then added to a stirred solution of anhydrous pyridine (83 mg, 1.05 mmol) in anhydrous methylene chloride (5 ml). After stirring this mixture for 30 min, a solution of hydroxy-diketal **9** (30 mg, 0.072 mmol) in methylene chloride (2 ml) was added dropwise and stirring continued for 1 h. The supernatant solution was decanted, leaving a black residue which was washed with ether (3 × 10 ml) and the combined ether and methylene chloride solutions were flash evaporated. The residue was taken up in ether and chromium salts removed by filtration. The ether filtrate was washed with 1 *N* sodium hydroxide (2 × 15 ml) and saturated sodium chloride solution. The ether was removed by flash evaporation and the residue refluxed for 1 h with acetone (5 ml) and 5% sulfuric acid (1 ml). Dilution with water and chloroform extraction gave crude trione **4**, purified by t.l.c. on silica gel to give crystalline material (11 mg), m.p. 175–177°. This sample of **4** was shown to be identical to that obtained by oxidation of **1** by comparison of i.r., n.m.r., and mass spectra and t.l.c. behavior on silica gel (chloroform, or ethyl acetate/benzene).

We wish to thank Mr. P. Montreuil (Montreal Aquarium, Montreal, Quebec) for valuable discussions, Mr. A. MacKay (Marine Research Associates, Lord's Cove, Deer Island, New Brunswick), and Mr. E. H. Taylor (Curator, New England Aquarium, Boston, Mass.) for providing the animals used in this work. Professor K. Nakanishi (Columbia University, New York, N.Y.) kindly determined the c.d. spectra and Professors D. B. MacLean (McMaster University, Hamilton, Ontario) and J. Holmes (University of Ottawa, Ottawa, Ontario) the high resolution mass spectra. The generous financial assistance of the National Research Council of Canada is gratefully acknowledged.

Studies Relating to Aziridine Antitumor Antibiotics. Part I. Asymmetric Syntheses. Part II.[1] Chiral Aziridines and their Conversion to α-Aminoacids

J. W. LOWN, T. ITOH,[2] AND N. ONO[3]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 18, 1972

Separable diastereomeric *cis-l*-menthyl 2-phenyl-3-aziridinecarboxylates (**4** and **5**) were prepared by the Gabriel reaction. *N*-Acylation with *p*-nitrobenzoyl chloride or *p*-anisoyl chloride of **4** and **5** gives **7** and **8**, and **23** and **24**, respectively. Sodium iodide-catalyzed rearrangement of the *N*-acylated aziridines is regiospecific with exclusive attack at C-2 and from **8** is obtained the chiral 2-oxazolines *cis*-**9** and *trans*-**10** in a ratio of 30:70 together with the unsaturated amide **11**. The structure of the latter was proven by independent synthesis. The intermediate *l*-menthyl *N-p*-nitrobenzoyl-3-iodophenyl-alaninate (**18**) was isolated at lower temperatures and shown to form the equilibrium mixture of **9** and **10** with triethylamine owing to partial racemization by a Finkelstein identity reaction. Use of an *N-p*-anisoyl substituent in the aziridine improves the yield of chiral 2-oxazolines by preventing the formation of **11**, and allows the separation of pure *cis*- and *trans*-oxazolines for characterization. The aziridines bearing *N-p*-anisoyl substituents display a greater sensitivity to attack by weaker nucleophiles than the *p-N*-nitrobenzoyl analogs.

Acid hydrolysis of **9** and **10** gives D-*allo*-β-phenylserine in an optical yield of about 17% from which **5** and **8** are tentatively assigned the 2R,3R configuration. Similar acid hydrolysis of the 2-*p*-anisyl-2-oxazoline (**26***b*) allowed the isolation of the intermediate *l*-menthyl *O*-anisoyl-*allo*-β-phenylserinate (**30***a*), hydrolysis of which gave D-*allo*-β-phenylserine in about 18% optical yield. The isolation of *allo*-β-phenylserine only from *cis*- and *trans*-2-oxazolines is attributed to acid-catalyzed inversion at the benzylic center to the conformationally more stable *allo* form.

Les diastéréoisomères séparables, *cis l*-menthyl, phényl-2 aziridine carboxylates-3 (**4** et **5**) ont été préparés à partir de la réaction de Gabriel. La réaction de *N*-acylation avec le chlorure de *p*-nitrobenzoyle ou avec le chlorure de *p*-anisoyle sur les produits **4** et **5** conduit aux produits **7** et **8**, et **23** et **24** respectivement. Le réarrangement catalysé par l'iodure de sodium des aziridines acylées est régiospécifique avec une attaque exclusivement sur le C-2; à partir de **8**, on obtient alors les formes optiquement actives oxazolines-2 *cis*-**9** et *trans*-**10** dans le rapport 30:70 ainsi que l'amide insaturée **11**. La structure de ce dernier produit fut d'ailleurs prouvée par synthèse indépendante. L'intermédiaire *l*-menthyl *N-p*-nitrobenzoyle iodo-3 phénylalaninate (**18**) a été isolée à des températures plus basses de même qu'il a été montré que celui-ci conduisait à un mélange en équilibre de **9** et **10** en présence de triethylamine à cause d'une racémisation partielle par une réaction du type Finkelstein. L'utilisation d'un substituant *N-p*-anisoyle sur l'aziridine conduit à une amélioration du rendement en oxazolines-2 optiquement actives en empêchant la formation de **11**, de même qu'il permet la séparation des oxazolines *cis* et *trans* pour des fins de caractérisation. De la même manière, les azirdines portant des substituants *p-N*-anisoyle deviennent plus susceptibles d'être attaquées par des nucléophiles plus faibles que les analogues de *p-N*-benzoyle.

L'hydrolyse acide de **9** et **10** conduit au D-*allo*-β-phénylserine avec un rendement optique d'environ 17% à partir duquel on a tenté d'assigner aux produits **5** et **8** les configurations 2R,3R. L'hydrolyse acide similaire de la *p*-anisyl-2 oxazoline-2 (**26***b*) a permis d'isoler l'intermédiaire *l*-menthyl *O*-anisoyl *allo*-β-phenylserinate (**30***a*) lequel hydrolysé, conduit au D-*allo*-β-phenyl serine avec un rendement optique d'environ 18%. L'isolation de l'*allo*-β-phenylserine à partir des oxazolines *cis* et *trans* seulement, est attribuée à une inversion catalysée par l'acide du centre benzylique de la forme *threo* pour donner la forme *erythro* représentant la conformation la plus stable.

Can. J. Chem., **51**, 856 (1973)

The Mitosane class of potent antitumor antibiotics **1** isolated in 1956 (1) from *Streptomyces caespitos* is in clinical use in Japan in the control of tumors (2). These compounds have yet to be synthesized and the mode of action is not fully understood, preventing rational structural modification to enhance antitumor properties (3, 4).

It has been established that the antitumor activity of the Mitosanes depends on their bifunctional alkylating ability through the carbamate side chain at C-10 and the chiral aziridine function at C-1 (5, 6). These initiate the introduction

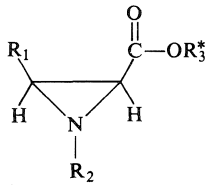
1



2

of covalent linkages and result in cross-linking of complementary strands in DNA (3). Irreversible loss of cross-linking activity upon opening of the aziridine ring attests to its role (6*b*). The principal intracellular consequences and lethal action of the administration of Mitomycin C lie in the inhibition of DNA synthesis resulting from this irreversible cross-linking (7–9). Despite the fact that Mitomycin C contains only one aziridine ring, it shows activity and specificity higher than all polyfunctional agents (8*a*). This suggests a highly specific mode of binding to the DNA and that the chirality of the aziridine may well be the determining factor.

Whereas studies on chiral aziridines hitherto have concentrated on chirality induced by restricted inversion of the 1-substituent in *N*-halo (10) and *N*-amino (11) aziridines, little or no attention has been paid to aziridines which owe their chirality to a 2-substituent such as exists in the aziridine moiety in the Mitosanes or in, *e.g.* **2**, where R_3* = *l*-menthyl, *l*-bornyl, 2-octanyl.

As part of a program designed to elucidate the mode of antitumor action of the Mitosanes and to develop more active analogs, we undertook to examine the chemistry of some chiral aziridines of type **2** especially with regard to configurational stability, preferred site of alkylation, and the stereochemistry of certain transformations.

In addition, chiral 2-carboalkoxyaziridines of type **2** contain the essential structural features for a possible asymmetric synthesis of α-aminoacids.

We report synthetic approaches that have been made via the Gabriel reaction. The reactions in the subsequent development to the α-aminoacids proved to be sensitive to steric hindrance effects with respect to stereospecificity and sensitive to substituent effects with regard to elimination and stereospecificity, but to exhibit the desired regiochemistry of ring opening (contrary to some literature precedents) and retention of configuration on nitrogen substitution and acid-catalyzed *trans*-esterification.

Just as the novel asymmetric synthesis of α-aminoacids from alkyl nitriles employing diisopinocampheylborane as a chiral agent described in Part 1 (27) is formally related to enzymatic transaminations (12), the synthesis described here, involving the formal addition of the elements of ammonia to a chiral olefin, resembles the aminations catalyzed by aspartase (13). A distinction is made, however, for while the former method qualifies as an asymmetric synthesis, in the latter a different approach is adopted in that the diastereomers are separated.

Bromination of *l*-menthyl cinnamate proceeded normally and treatment of the *l*-menthyl 2,3-dibromo-2,3-dihydrocinnamate (**3**) with methanolic ammonia proceeded stereoselectively to give a readily separable mixture of the diastereomeric and thermodynamically more stable *cis-l*-menthyl 2-phenyl-3-aziridinecarboxylates (**4** and **5**) as crystalline solids (see Scheme 1). This result is consistent with, but does not necessarily require (14) stereospecific *trans* addition of ammonia to the more stable intermediate *l*-menthyl 2-bromocinnamate (**6**) followed by *trans* internal S_N2 displacement of the *threo* intermediate. Treatment of **3** with triethylamine gives a single *l*-menthyl 2-bromocinnamate (**6**) which upon treatment with methanolic ammonia gives **4** and **5** (see Scheme 2). Both **4** and **5** were acylated with retention of configuration with *p*-nitrobenzoyl chloride in the presence of triethylamine to give the diastereomeric *cis-N-p*-nitrobenzoyl derivatives **7** and **8**.

When compound **8** was treated with a solution of sodium iodide (15) or potassium thiocyanate in refluxing acetone three products were obtained; the *cis*- and *trans*-2-oxazolines (**9** and **10**) and the unsaturated amide, **11** (see Scheme 3). Compounds **9** and **10** were produced in a ratio of 30:70. The assignments are based on comparison of the n.m.r. line positions and coupling constants of the methine protons with those of literature values (16). In this series, with both 2-*p*-nitrophenyl and 2-*p*-anisyloxazolines, the *cis* isomers had consistently larger coupling

constants and larger chemical shift difference than the *trans* isomers. The bulky *l*-menthyloxy group reduced the difference in the magnitude of the coupling constants compared with the methyl esters (16). However, the correlation which is possible between the analogous *cis*- and *trans*-5-methyl analogs and the corresponding α-aminoacids of known absolute configuration

places these assignments on a firm foundation (see ref. 28).

Rearrangement of compound **7** under similar conditions gave pure *trans*-**10** and compound **11**. The structure of **11** was proven by its independent synthesis from glycine by the route depicted in Scheme 4, a modification of a synthesis due

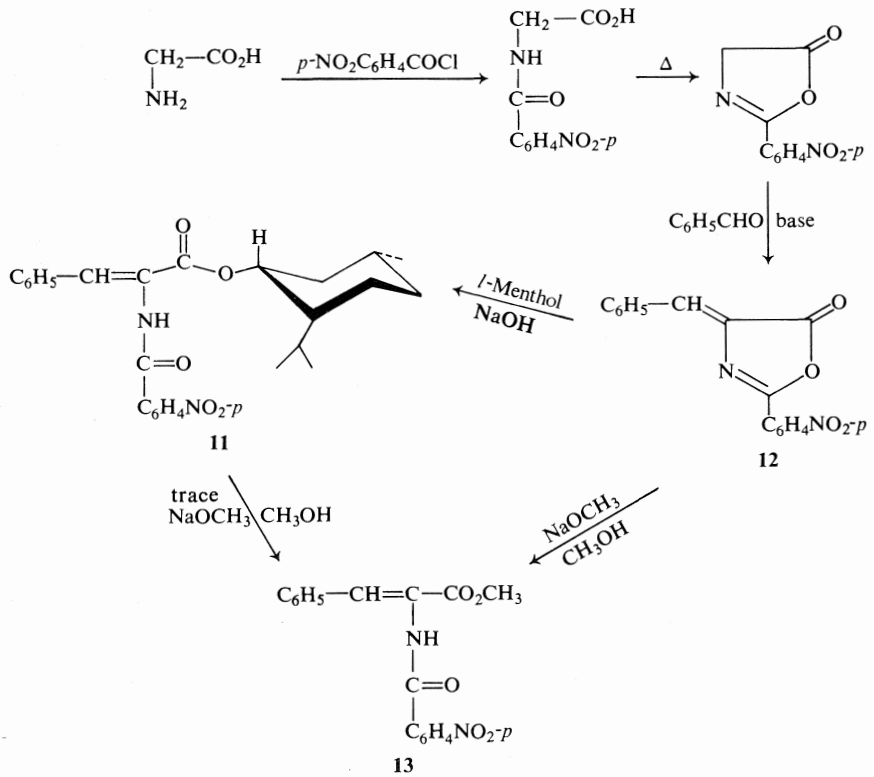

SCHEME 4

to Yamada and coworkers (17). Treatment of the benzaloxazoline **12** with methanol and sodium methoxide also afforded **13** which was identical with the product obtained by *trans*-esterification of **11** with sodium methoxide in methanol.

The iodide-catalyzed rearrangement of **7** and **8** is regiospecific in that nucleophilic attack occurs exclusively at the C-2 aziridine position to give **9** and **10**. The ultimate proof of the orientation of the groups in the oxazolines is the isolation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

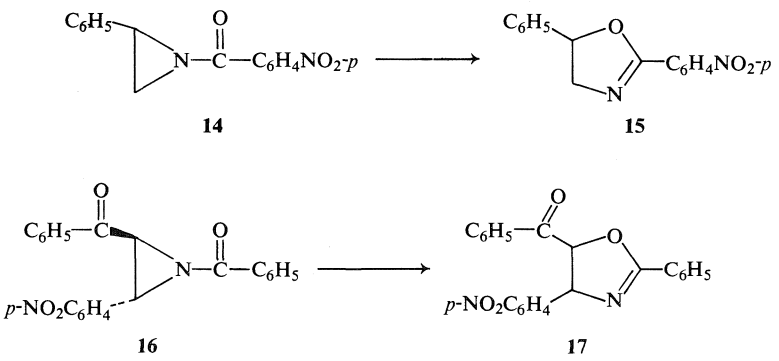

SCHEME 5

of *allo*-β-phenylserine by acid hydrolysis (see below). The regiochemistry observed, while desired from the viewpoint of α-aminoacid synthesis, was contrary to expectation based on some literature reports. Thus Heine and Kaplan (18) report the nucleophile-catalyzed rearrangement of 1-*p*-nitrobenzoyl-2-phenyl- and *trans*-1,2-dibenzoyl-3-*p*-nitrophenylaziridines (**14** and **16**) (see Scheme 5). In both cases the products **15** and **17** suggested that steric hindrance factors are not dominant in the opening, *i.e.* the nucleophile attacks the more positive and more hindered carbon in the case of **14** and **16**.

It seems plausible that in the case of **7** and **8**, however, the increased bulk offered by the carbomenthoxy group is sufficient to ensure exclusive attack at C-2. The *l*-menthyl group thus serves the several purposes in the synthesis of allowing the easy separation of diastereomers, controlling the regiochemistry of the rearrangement, and inducing asymmetry in the resulting α-aminoacid.

This dependence of the regiochemistry of nucleophilic ring opening in chiral aziridines on the steric bulk of the 2-substituent leads to the important conclusion, with regard to the mechanism of Mitomycin induced DNA cross-linking, that the site of alkylation in the antibiotic could be changed from C-1 to -2 provided W or the C-10 side chain in Mitomycin analogs were made sufficiently bulky. The "normal" Mitomycin bifunctional alkylation at C-1 and -10, *i.e.* across a four-carbon span, limits the alkylation sites on DNA effectively to guanine units on adjacent complementary strands (3). Shifting the alkylation site to C-2, *i.e.* across a five-carbon span, would increase the scope of cross-linking property.

Compounds **9**, **10**, and **11** arise from a common intermediate, the *l*-menthyl *N*-*p*-nitrobenzoyl-3-iodo-phenylalaninate (**18**) which could be isolated by a controlled room temperature iodide-catalyzed ring opening.

Compound **18** was identified by its spectral characteristics and in giving positive sodium fusion and Beilstein tests for iodine. Treatment of a solution of **18** with triethylamine at ambient temperature gave a mixture of **9** and **10** in a ratio of 25:75 in quantitative yield. Since this ratio is close to that obtained directly from *cis*-**8** it represents the equilibrium value for the Finkelstein reaction (see Scheme 6). Elimination of hydrogen iodide from **18** to give **11** is favored over ring closure by heating.

The isolation of the intermediate β-haloamide in the rearrangement of aziridines is comparatively rare and has been reported in only a few isolated instances (19). Presumably ring closure of **18** to **9** and **10** with triethylamine is favored over elimination to **11** because the NH proton in **18** is rendered more acidic by the *p*-nitrobenzoyl group.

Acid-catalyzed hydrolysis of the mixture of **9** and **10** obtained from *cis*-**8** gave D-*allo*-β-phenylserine containing a trace of phenylserine. The α-aminoacids were conveniently identified by the paper chromatographic procedure developed by Shaw and Fox (20) and by their characteristic i.r. spectra (21). The aminoacids have specific rotation of $[\alpha]_D^{25}$ −14.4 (*c*, 2, 6 *N* HCl) representing an approximate optical yield of 17.5%. This result in which the major product has the D-*erythro* configuration is closely comparable with that obtained from *l*-menthyl 2R,3R-2-methyl-1-*p*-nitrobenzoyl-3-aziridinecarboxylate (see ref. 28). On this basis we tentatively

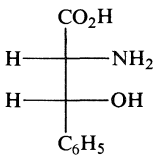
†When **18** was isolated in a room temperature reaction, treatment with Et_3N also gave *cis*-**9** *trans*-**10** quantitatively in a ratio of 25:75.

SCHEME 6



19

D-*allo*-β-Phenylserine

assign the configuration of the aziridine diastereomers **5** and **8** as 2R,3R as implied by their formulae given earlier in Schemes 1 and 3.

The fact that rearrangement of a diastereomerically pure *cis*-aziridine (**8**) leads to a mixture of *cis*- and *trans*-oxazolines which are subsequently hydrolyzed to D-*allo*-β-phenylserine with an optical yield of 17% implies that partial racemization occurs at both C-2 and -3 of **8** during the rearrangement and hydrolysis steps.

Similar behavior has been observed in the sodium iodide-catalyzed rearrangement of *cis*-1-*p*-nitrobenzoyl-2,3-diphenylaziridine (**20**) which in that case resulted in total inversion to give *trans*-2-*p*-nitrophenyl-4,5-diphenyl-2-oxazoline (**21**) (22) (Scheme 7). This was attributed to a Finkelstein identity reaction resulting in a Walden inversion of the intermediate promoted by the steric restrictions imposed upon formation of a *cis*-4,5-diphenyl-2-oxazoline. In the

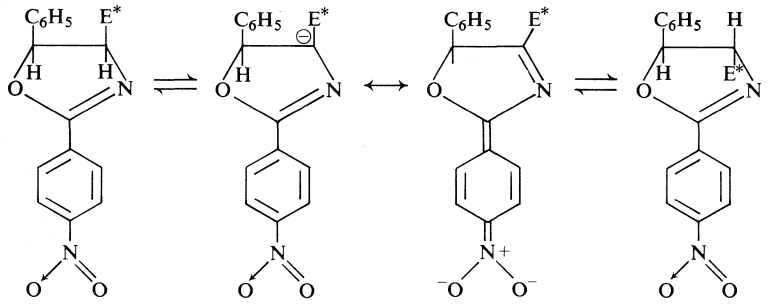
cis-**20** *trans*-**21**

SCHEME 7



22

$E^* = CO_2$-*l*-menthyl

SCHEME 8

present case the most plausible explanation for partial racemization at C-2 of the aziridine, in view of the isolation of **18**, is a Finkelstein reaction on the latter (accompanied by some irreversible loss of hydrogen iodide to form **11**) leading to an equilibrium ratio of **18**:*allo*-**18** of 25:75 (see Scheme 6). In addition, the vigorous acid conditions necessary to hydrolyze **9** and **10** to *allo*-β-phenylserine may also result in further racemization at C-3 of **19** in view of the benzylic nature of the latter position.

Thus the problems encountered in a projected asymmetric synthesis of α-aminoacids from chiral aziridines in using *N*-aroyl substituents in general and *N*-*p*-nitrobenzoyl group in particular are (*i*) facile elimination to give **11** which limits the yield of aminoacids; (*ii*) the non-separability of the *cis*- and *trans*-oxazolines (**9** and **10**); and (*iii*) Finkelstein inversion of the intermediate β-iodoamide promoted by the bulky aryl group at C-2 of the aziridine. In addition, the use of a nitro substituent increases the danger of racemization at C-4 of the oxazoline by nucleophiles or bases by the mechanism depicted in Scheme 8 (23).

These problems were obviated in part by employing a *N*-substituent (*p*-anisoyl) which bears an electron-releasing group. This resulted in prevention of elimination to **11**, allowed the separation of *cis*- and *trans*-oxazolines for characterization, and also resulted in a substantial change in the reactivity of the chiral aziridines towards regiospecific nucleophilic attack. While partial racemization due to the Finkelstein reaction was still encountered here, its total elimination by the use of a smaller C-2 substituent with the attendant dramatic increase in optical yield of α-aminoacids is described in ref. 28.

The pure diastereomeric aziridines **4** and **5** were acylated with *p*-anisoyl chloride in the presence of triethylamine to give **23** and **24**, respectively. Treatment of **24** with sodium

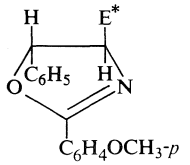
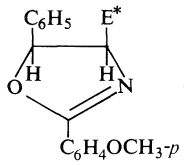
iodide in hot acetone gave geometrically pure *trans*-2-oxazoline (**25**) (*i.e.* retention) or geometrically pure *cis*-2-oxazoline (**26***a*) (*i.e.* overall inversion). In contrast to the rearrangement of the *p*-nitrobenzoyl analog, no concomitant elimination to form the analog of **11** occurred.



25



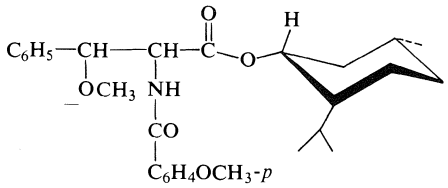
26

a $[\alpha]_D$ −20°
b $[\alpha]_D$ −80.5°

E* = CO_2-*l*-menthyl

The *cis* and *trans* configurations were assignable on the basis of their characteristic methine n.m.r. absorptions as explained earlier. Again the rearrangements were regiospecific in the required direction and involve the exclusive attack by the nucleophile at C-2 of the aziridine. This was proven subsequently by acid-catalyzed hydrolysis to *allo*-β-phenylserine.

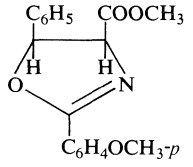
The *N*-*p*-anisoyl aziridines (**23** and **24**) displayed a greater sensitivity towards nucleophiles than the *p*-nitrobenzoyl analogs in that they are opened quantitatively under mild treatment with methanol to give **27***a* and *b*, respectively. Similar sodium iodide-catalyzed rearrangement of aziridine **23** gave only the *cis*-2-oxazoline (**26***b*) under all reaction conditions. The latter had a specific rotation quite different from that of **26***a*.



27

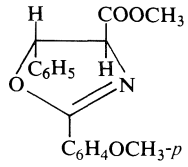
a $[\alpha]_D^{23}$ −11.0°
b $[\alpha]_D^{23}$ −10.5°

The fact that the observed rotations in **26***b* and **25** are not due merely to the presence of the *l*-menthyl residues and that they differ in diastereomeric composition is shown by the acid-catalyzed *trans*-esterification with methanol and anhydrous hydrogen chloride with retention of configuration at C-4 to form respectively the *cis*- and *trans*-methyl-2-oxazoline 4-carboxylates (**28** and **29**), both of which showed non-zero rotations. Thus the oxazolines **25**, **26***a*, and **26***b* retain chirality in the heterocyclic ring after the nucleophile-catalyzed rearrangement.



28

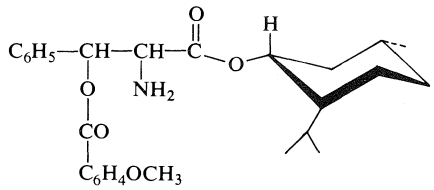
$[\alpha]_D^{23}$ −28°



29

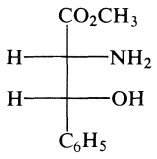
$[\alpha]_D^{23}$ +2.9°

Controlled hydrolysis of the *cis*-oxazoline (**26***b*) with 10% aqueous hydrochloric acid gave the *l*-menthyl *O*-anisoyl-*allo*-β-phenylserinate (**30***a*). Further acid hydrolysis of compound **30***a* afforded D-*allo*-β-phenylserine which exhibited a rotation of $[\alpha]_D^{23}$ (6 *N* HCl) −14.8°, representing 18% optical yield. The aminoacid was identified by paper chromatography (20) and also characterized by the preparation of the methyl ester **31** (24).



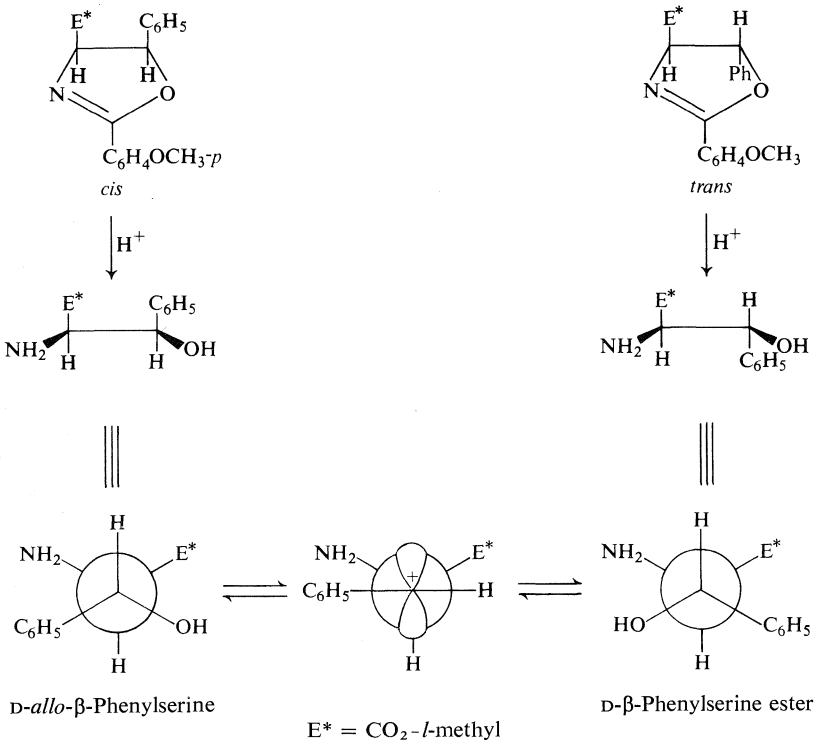
30

a m.p. 134–135°; $[\alpha]_D$ −27.3°
b m.p. 142–143°; $[\alpha]_D$ −33°



31

While the oxazoline yields have been improved by using a *p*-methoxy substituent in the synthesis, and regiospecificity is maintained in the rearrangement of **23** and **24**, stereoselectivity is obtained for **23** to **26***b* (retention) and **24** to **25** (inversion), and chirality is induced in both isomeric oxazolines (*cf.* **28** and **29**), nevertheless the optical yield obtained 18% is still low. Moreover only the *allo* isomer of the aminoacid is obtained. It seems likely that the relatively harsh acid conditions necessary to hydrolyse **25** and **26** results in partial racemization and equilibration to give the more stable *allo*-β-phenylserine (see Scheme 9).



SCHEME 9

In summary, chiral ester functions may be used in the Gabriel synthesis of aziridines to permit the separation of diastereomeric chiral aziridines and their derivatives and to induce asymmetry in the synthesis of α-aminoacids. The nucleophile-catalyzed rearrangements exhibit the required regiochemistry. The overall stereospecificity and hence the optical yield is limited by (*i*) racemization resulting from a Finkelstein identity reaction on the isolable β-iodoamide, although this is only partial in contrast to literature reports of the rearrangement of aryl substituted aziridines, (*ii*) racemization accompanying acid hydrolysis of benzylic derivatives, and (*iii*) elimination to an unsaturated amide in the case of the *p*-nitrobenzoyl derivatives. The observation on the regiospecificity of the nucleophilic attack on chiral aziridines is pertinent to the design of Mitomycin analogs.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

l-Menthyl Cinnamate

A solution of 99.96 g (0.6 mol) of cinnamoyl chloride in 50 ml of dry benzene was added dropwise to a stirred solution of 93.76 g (0.6 mol) of *l*-menthol in 150 ml of dry benzene. The mixture was stirred for 48 h at room temperature. Evaporation of the solvent afforded a yellow oil, fractionation of which gave 166 g (97% yield) of *l*-menthyl cinnamate, b.p. 175°/0.5 mm, as a colorless oil; $[\alpha]_D^{23}$ −76.14 (*c*, 1.06 EtOH).

Anal. Calcd. for $C_{19}H_{26}O_2$ (mol. wt. 286.1933): C, 79.68; H, 9.15. Found (286.1927 (mass spectrum)): C, 79.72; H, 9.03.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 0.7–2.5 (m, 18H, menthyl protons), 4.65–5.07 (m, 1H, menthyl methine); AB quartet centered at 6.43 and 7.68, J = 16 Hz (2H,

For personal use only.

trans-vinyl), and aryl absorption. The i.r. spectrum ν_{max}(film): 1700 cm^{-1} (conjugated ester C=O).

l-Menthyl 2,3-Dibromo-3-phenylpropionate (3)

The dibromo derivative **3** was prepared by bromination of the *l*-menthyl cinnamate in chloroform according to the usual procedure in 92% yield, m.p. 74–76° (CH_3OH); $[\alpha]_D^{23}$ −19.90 (*c*, 1.09 EtOH).

Anal. Calcd. for $C_{19}H_{26}Br_2O_2$: C, 51.45; H, 5.86; Br, 35.74. Found: C, 51.45; H, 5.72; Br, 35.56.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: AB quartet centered at 4.8 and 5.37, J = 12 Hz (CHBr—CHBr), and aryl and *l*-menthyl absorption. The i.r. spectrum $\nu_{max}(CHCl_3)$: 1730 cm^{-1} (saturated ester C=O).

l-Menthyl 2-Bromocinnamate (6)

To a solution of 26.7 g (0.6 mol) of *l*-menthyl 2,3-dibromo-3-phenylpropionate in 50 ml of dry benzene was added dropwise with stirring a sample of 6.50 g (0.65 mol) of triethylamine. The solution was stirred for 16 h at room temperature then washed with water and dried ($MgSO_4$). Removal of the solvent *in vacuo* gave a pale yellow oil which solidified on cooling. Crystallization from methanol gave *l*-menthyl 2-bromocinnamate (**6**) 21.59 g (98% yield), m.p. 93–95°.

Anal. Calcd. for $C_{19}H_{25}BrO_2$ (mol. wt. 364.1038): C, 62.05; H, 6.88; Br, 21.82. Found (364.1045 (mass spectrum)): C, 62.27; H, 6.70; Br, 21.53.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 8.23 (1H, s, vinyl proton) and menthyl and aryl absorption.

Preparation of Diastereomeric cis-l-Menthyl 2-Phenyl-3-aziridinecarboxylates (4 and 5)

Dry ammonia gas was introduced into a solution of 11.25 g (25 mmol) of *l*-menthyl 2,3-dibromocinnamate in 200 ml of methanol in a pressure bottle until the solution was saturated, the bottle stoppered, and the solution stirred for 3 days at room temperature. After removal of the solvent, the resulting residual oil was treated with 40 ml of dichloromethane and the solution was washed with water (2 × 20 ml) and dried ($MgSO_4$). Removal of the solvent and treatment of the residual oil with 40 ml of methanol precipitated 1.8 g (26% yield) of one of the diastereomeric *cis-l*-menthyl 2-phenyl-3-aziridinecarboxylates (**4**), m.p. 156–158°, as white crystals; $[\alpha]_D^{23}$ −18.78 (*c*, 0.74 benzene).

Anal. Calcd. for $C_{19}H_{27}O_2N$ (mol. wt. 301.2042): C, 75.71; H, 9.03; N, 4.05. Found (301.2038 (mass spectrum)): C, 75.75; H, 9.04; N, 4.12.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.3–2.2 (m, 18H, menthyl protons), AB quartet centered at 3.04 and 3.54, J = 6 Hz (*cis*-aziridine ring protons), 4.36–4.80 (m, 1H, menthyl methine), 7.4 (s, 5H, aryl). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1710 (C=O), 3325 and 3270 cm^{-1} (NH).

The filtrate was kept at 0° for 2 days when 1.5 g (22% yield) of the second diastereomeric *cis-l*-menthyl 2-phenyl-3-aziridinecarboxylate (**5**), m.p. 124° (MeOH), was obtained; $[\alpha]_D^{23}$ −51.75 (*c*, 0.80 benzene).

Anal. Calcd. for $C_{19}H_{27}NO_2$ (mol. wt. 301.2042): C, 75.71; H, 9.03; N, 4.05. Found (301.2041 (mass spectrum)): C, 75.75; H, 9.04; N, 4.12.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.3–2.2 (m, 18H, menthyl protons), AB quartet centered at 2.97 and 3.46, J = 6 Hz (*cis*-aziridine ring protons), 4.2–4.8 (m, 1H, menthyl methine), 7.30 (m, 5H aryl absorption).

Preparation of Diastereomeric cis-l-Menthyl 1-p-Nitrobenzoyl-2-phenyl-3-aziridinecarboxylates (7 and 8)

(*a*) To a solution of 1.5 g (5 mmol) of aziridine **4** and 0.5 g (5 mmol) of triethylamine in 20 ml of dry benzene was added with stirring a solution of 0.92 g (5 mmol) of *p*-nitrobenzoyl chloride in 10 ml of dry benzene and the mixture stirred for 18 h. The triethylamine hydrochloride which had precipitated, was collected and the filtrate washed with water (2 × 15 ml) and dried ($MgSO_4$). Removal of the solvent and recrystallization of the residual gum from a mixture of methanol, ethanol, and dichloromethane gave *cis-l*-menthyl 1-*p*-nitrobenzoyl-2-phenyl-3-aziridinecarboxylate (**7**) 1.3 g (58% yield), m.p. 157–158°; $[\alpha]_D^{23}$ −33.4° (*c*, 0.93 benzene).

Anal. Calcd. for $C_{26}H_{30}N_2O_5$ (mol. wt. 450.2155): C, 69.31; H, 6.71; N, 6.22. Found (450.2142 (mass spectrum)): C, 69.29; H, 6.53; N, 6.13.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.3–2.3 (m, 18H, menthyl protons), AB quartet centered at 3.66 and 4.05, J = 7 Hz (*cis*-aziridine ring protons), 4.3–4.8 (m, 1H, menthyl methine), 7.3–7.7 (m, 5H, phenyl), 8.30 (s, 4H, *p*-nitrophenyl).

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1780 (ester C=O), 1680 cm^{-1} (amide).

(*b*) Reaction of the diastereomeric aziridine **5**, 1.50 g (5 mmol), and 0.92 g (5 mmol) of *p*-nitrobenzoyl chloride by a similar procedure gave 2.23 g (99% yield) of *cis-l*-menthyl 1-*p*-nitrobenzoyl-2-phenyl-3-aziridinecarboxylate (**8**) which was purified by recrystallization from ethanol and dichloromethane, m.p. 176–177°; $[\alpha]_D^{23}$ −27.12 (*c*, 0.73 benzene).

Anal. Calcd. for $C_{26}H_{30}N_2O_5$ (mol. wt. 450.2155): C, 69.31; H, 6.71; N, 6.22. Found (450.2172, mass spectrum): C, 69.38; H, 6.69; N, 6.37.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.2–1.90 (m, 18H, menthyl protons), AB quartet centered at 3.66 and 4.06, J = 7 Hz (*cis*-aziridine ring protons), 4.3–4.90 (m, 1H, menthyl methine), 7.27–7.70 (m, 5H, phenyl), 8.30 (s, 4H, nitrophenyl).

Reaction of Diastereomeric cis-l-Menthyl 1-p-Nitrobenzoyl-2-phenyl-3-aziridinecarboxylates with Sodium Iodide in Acetone

While ordinarily treatment of **7** or **8** with a refluxing solution of sodium iodide in acetone gives both **10** and **11**, it was found that a molar ratio of aziridine:NaI of 1:4.6 favored formation of **9** and **10** and a ratio of 1:5 favored elimination to **11** as described below.

(i) Molar Ratio of Aziridine:NaI = 1:4.6

(a) Rearrangement of aziridine 8

A solution of 2.25 g (5 mmol) of aziridine **8** and 3.45 g (23 mmol) of sodium iodide in 30 ml of dry acetone was heated under reflux for 30 h. After removal of the solvent the residual oil was dissolved in 20 ml of dichloromethane and the solution washed with water (2 × 15 ml) and dried ($MgSO_4$). Removal of the solvent *in vacuo* gave a yellow solid and crystallization from methanol gave a 30:70 mixture of *cis*- and *trans-l*-menthyl 2-*p*-nitrophenyl-5-phenyl-2-oxazoline-4-carboxylate, 1.2 g (53% yield), m.p. 95–96°; $[\alpha]_D^{23}$ −32.6° (*c*, 1.03 benzene).

Anal. Calcd. for $C_{26}H_{30}N_2O_5$ (mol. wt. 450.2154): C, 69.31; H, 6.71; N, 6.22. Found (450.2154 (mass spectrum)): C, 69.18; H, 6.79; N, 6.27.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.6–2.35 (m, 18H, menthyl protons), 4.62–5.2 (m, 1H, menthyl methine), AB quartet centered at 4.97 and 5.50, $J = 6$ Hz (*trans*-oxazoline 4,5 methines); AB quartet centered at 4.90 and 5.92, $J = 8$ Hz (*cis*-oxazoline 4,5 methines) (ratio of *cis*:*trans* AB quartets by integration is 30:70) 7.40 (s, 5H, phenyl), 8.33 (s, 4H, nitrophenyl). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1732 (ester C=O), 1650 cm^{-1} (oxazoline C=N).

(b) Rearrangement of aziridine **7**

A solution of 2.25 g (5 mmol) of aziridine **7** and 3.45 g (23 mmol) of sodium iodide in a similar manner gave 1.8 g (80% yield) of *trans-l*-menthyl 2-*p*-nitrophenyl-5-phenyl-2-oxazoline-4-carboxylate, m.p. 96°; $[\alpha]_D^{23}$ −33.1° (*c*, 1.03 benzene).

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.6–2.3 (m, 18H, menthyl protons), 4.62–5.2 (m, 1H, menthyl methine), AB quartet centered at 4.97 and 5.52, $J = 6$ Hz (*trans*-oxazoline 4,5 methines), 7.46 (s, 5H, phenyl), 8.37 (s, 4H, nitrophenyl). The material was otherwise very similar to that obtained in section (*i·a*) above.

(ii) Molar Ratio of Aziridine:NaI = 1:5

A solution of 0.9 g (2 mmol) of aziridine **8** and 1.49 g (10 mmol) of sodium iodide in 15 ml of dry acetone was heated under reflux for 30 h. After removal of the solvent, the residual oil was taken up in 20 ml of dichloromethane and the solution washed with water (2 × 15 ml) and dried ($MgSO_4$). Removal of the solvent *in vacuo* gave *l*-menthyl 2-*p*-nitrobenzamidocinnamate (**11**), 0.80 g (88% yield) purified by recrystallization from methanol, m.p. 165°; $[\alpha]_D^{23}$ −23.56 (*c*, 1.18 benzene).

Anal. Calcd. for $C_{26}H_{30}N_2O_5$ (mol. wt. 450.2155): C, 69.31; H, 6.71; N, 6.22. Found (450.2166 (mass spectrum)): C, 69.30; H, 6.52; N, 6.16.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$ 0.6–2.3 (m, 18H, menthyl protons), 4.66–4.94 (1H, sextet, menthyl methine), 7.20–7.40 (6H, aryl and vinyl protons), AB quartet at 8.20 and 7.95, $J = 9$ Hz (4H, aryl and NH protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1690 (NHCO—), 1695 (ester), 3470 cm^{-1} (NH).

Similar treatment of 270 g (6 mmol) of aziridine **7** with 0.5 g (33 mmol) of sodium iodide in 10 ml of dry acetone afforded compound **11** identical with that obtained above.

*Isolation and Cyclization of l-Menthyl N-p-Nitrobenzoyl-3-iodophenylalaninate (**18**)*

A solution of 2.25 g (5 mmol) of aziridine **8** and 1.50 g (10 mmol) of sodium iodide in 70 ml of dry acetone was stirred at room temperature for 48 h. After removal of the solvent *in vacuo*, the residual oil was dissolved in 30 ml of chloroform and the solution washed with water (2 × 15 ml) and dried ($MgSO_4$). Removal of the solvent gave **18** as a pale yellow oil which gave strong positive Lassaigue and Beilstein tests for iodine.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.6–2.4 (m, 18H, menthyl protons) 3.50–4.0 (s, broad 1H, NH), 4.6–5.1 (m, 1H, menthyl methine), AB quartet centered at 4.94 and 5.46, $J = 7$ Hz (2H, methines), and aryl absorption. The i.r. spectrum ν_{max}(film): 1650 (amide C=O), 3360 cm^{-1} (broad NH).

A solution of 1.04 g (18 mmol) of **18** and 2.16 g (12 mmol) of triethylamine in 35 ml of dry acetone was stirred for 16 h at room temperature. After removal of the acetone *in vacuo* the residue was dissolved in 35 ml of chloroform and the solution washed with water (2 × 20 ml) and dried ($MgSO_4$). Removal of the solvent *in vacuo* afforded a mixture of *cis* and *trans* **9** and **10** in a ratio of 25:75 as shown by the integrals of the AB quartets in the n.m.r.

Independent Synthesis and Structure Proof of l-Menthyl 2-p-Nitrobenzamidocinnamate and Methyl 2-p-Nitrobenzamidocinnamate

*(a) 4-Benzal-2-p-nitrophenyl-5-oxazolone (**12**)*

This material was prepared from *p*-nitrohippuric acid and benzaldehyde in 60% yield by a literature procedure, m.p. 229° (lit. m.p. 225–228° (26)).

*(b) l-Menthyl 2-p-Nitrobenzamidocinnamate (**11**)*

This material was prepared from **12** and sodium *l*-menthylate according to a similar procedure described by Yamada and coworkers (17) in 75% yield, m.p. 165°. The spectral and physical data of this compound were identical with that obtained from aziridine **8** as described above.

*(c) Methyl 2-p-Nitrobenzamidocinnamate (**13**)*

A solution of 294 mg (1 mmol) of **12** in 50 ml of benzene was added to a solution of 63 mg (1.1 mmol) of sodium methoxide in 50 ml of methanol. The reaction mixture was stirred for 3 h at ambient temperature. Removal of the solvents *in vacuo* gave compound **13** as a white solid 264 mg (81% yield) which was purified by recrystallization, m.p. 189–190° (aqueous MeOH).

Anal. Calcd. for $C_{17}H_{14}N_2O_5$ (mol. wt. 326.0902): C, 62.57; H, 4.32; N, 8.59. Found (326.0902 (mass spectrum)); C, 62.34; H, 4.41; N, 8.93.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 3.85 (s, 3H, CO_2CH_3), 7.34 (m, 6H, phenyl and vinyl protons), 8.10 (s, 4H, nitrophenyl). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1688 (amide C=O), 1710 (ester C=O), 3420 cm^{-1} (NH). This material was identical with that obtained from **11** by *trans*-esterification with sodium methoxide in methanol.

Acid-catalyzed Hydrolysis of l-Menthyl 2-p-Nitrophenyl-5-phenyl-2-oxazoline-4-carboxylate

A solution of 0.9 g (2 mmol) of oxazolines **9** and **10** in 50 ml of concentrated hydrochloric acid and 30 ml of dioxane was heated under reflux for 3 days. The filtered solution was evaporated to dryness under reduced pressure and the residual solid subjected to chromatography on an ion exchange resin (J. T. Baker Chemical Co).

The main fraction afforded D-*allo*-β-phenylserine containing a little phenylserine as a white solid, 0.250 g (69% yield), m.p. 230°; $[\alpha]_D^{23}$ −14.4 (*c*, 2.0 6 *N* HCl) (lit. $[\alpha]_D^{25}$ 82.0 (*c*, 2.0 6 *N* HCl) (25)). The R_f values of D-*allo*-β-phenylserine and phenylserine on paper chromatography were 0.30 and 0.40 respectively by ninhydrin visualization.

Esterification of 0.226 g (1.25 mmol) of the amino acid with methanol according to the procedure described below gave methyl *allo*-β-phenylserinate, m.p. 78–80° (from ether) (lit. m.p. 110° (24)), $[\alpha]_D^{23}$ −3.0 (*c*, 2.0, EtOH). Mass spectrum calcd. for $C_8H_{10}NO$ fragment ion 136.0762; observed 136.0760.

*Preparation of Diastereomeric cis l-Menthyl 1-p-Anisoyl-2-phenyl-3-aziridinecarboxylates (**23** and **24**)*

(*a*) Aziridine **4** (1.50 g, 5 mmol) was acylated with 0.85 g (5 mmol) of *p*-anisoyl chloride in the presence of 0.5 g (5 mmol) of triethylamine according to the usual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

procedure affording the *N*-anisoylaziridine (**23**), 2.1 g (96% yield) as a white solid, m.p. 152–154°; $[\alpha]_D^{23}$ −33.8 (*c*, 1.05 benzene).

Anal. Calcd. for $C_{27}H_{33}NO_4$ (mol. wt. 435.2409): C, 74.45; H, 7.64; N, 3.22. Found (435.2400 (mass spectrum)): C, 74.36; H, 7.65; N, 3.32.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.2–2.0 (m, 18H, menthyl protons), AB quartet centered at 3.55 and 3.92, J = 7.0 Hz (*cis*-aziridine ring protons), 3.81 (s, 3H, OCH_3), 4.3–4.90 (m, 1H, menthyl methine), AB quartet centered at 6.84 and 8.03, J = 8.5 Hz (4H, anisoyl ring protons), 7.2–7.7 (m, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1680 (amide C=O), 1730 cm^{-1} (ester C=O).

(*b*) The diastereomeric aziridine (**5**) (1.50 g, 5 mmol) was acylated with 0.85 g (5 mmol) of *p*-anisoyl chloride in the presence of 0.5 g (5 mmol) of triethylamine according to the same procedure to give the *N*-anisoylaziridine (**24**), 2.13 g (98% yield), as a white solid purified by recrystallization from MeOH, m.p. 145–146°; $[\alpha]_D^{23}$ −42.8 (*c*, 0.75 benzene).

Anal. Calcd. for $C_{27}H_{33}NO_4$ (mol. wt. 435.2409): C, 74.45; H, 7.64; N, 3.22. Found (435.2405 (mass spectrum)): C, 74.34; H, 7.66; N, 3.44.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.3–2.2 (m, 18H, menthyl protons), AB quartet centered at 3.58 and 3.97, J = 7.0 Hz (*cis*-aziridine ring protons), 3.85 (s, 3H, OCH_3), 4.3–4.8 (m, 1H, menthyl methine), AB quartet centered at 6.90 and 8.10, J = 9.0 Hz (4H, anisoyl ring protons), 7.1–7.7 (m, 5H) phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1665 (amide C=O), 1730 cm^{-1} (ester C=O).

Reaction of Diastereomeric cis-l-Menthyl 1-p-Anisoyl-2-phenyl-3-aziridinecarboxylates with Methanol to Form 27a and b

(*a*) A solution of 217 mg (0.5 mmol) of aziridine **24** in 10 ml of methanol was heated under reflux for 30 min. The solvent was removed *in vacuo* and the residual solid purified by recrystallization from light petroleum giving **27***b* as a white solid, 210 mg (90% yield), m.p. 125–127°; $[\alpha]_D^{23}$ −10.5 (*c*, 1.34 benzene).

Anal. Calcd. for $C_{28}H_{37}NO_5$ (mol. wt. 467.2672): C, 71.92; H, 7.98; N, 3.00. Found (467.2681 (mass spectrum)): C, 71.84; H, 7.76; N, 3.02.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.7–2.3 (m, 18H, menthyl protons), 3.38 (s, 3H, OCH_3), 3.89 (s, 3H, aryl OCH_3), 4.8–5.2 (m, 4H, 3 methines and NH absorption), AB quartet centered at 6.94 and 7.72 (4H, anisoyl protons), 7.37 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1715 (ester C=O), 3440 cm^{-1} (amide NH).

(*b*) Similarly a reaction of 435 mg (1 mmol) of the diastereomeric aziridine **23** with refluxing methanol gave 430 mg (99% yield) of **27***a* as a white solid, m.p. 94–95° (from light petroleum); $[\alpha]_D^{23}$ −11.0 (*c*, 0.96 benzene).

Anal. Calcd. for $C_{28}H_{37}NO_5$ (mol. wt. 467.2672): C, 71.92; H, 7.98; N, 3.00. Found (467.2672); C, 71.87; H, 8.01; N, 2.95.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.7–2.3 (m, 18H, menthyl protons), 3.38 (s, 3H, OCH_3), 3.89 (s, 3H, aryl OCH_3), 4.8–5.2 (m, 4H, 3 methine peaks and NH), AB quartet centered at 6.94 and 7.72 (2H, anisoyl protons), 7.37 (s, 5H, phenyl protons). The i.r. spectrum ν_{max} ($CHCl_3$): 1740 (amide C=O), 1720 (ester C=O); 3440 cm^{-1} (amide NH).

Reaction of Diastereomeric cis-l-Menthyl 1-p-anisoyl-2-phenyl-3-aziridinecarboxylates with Sodium Iodide in Acetone

(*a*) A solution of 870 mg (2 mmol) of aziridine **23** and 1.20 g (8 mmol) of sodium iodide in 30 ml of dry acetone was heated under reflux for 15 h. After removal of the solvent the residual oil was taken up in 20 ml of chloroform and the solution washed with water (2 × 15 ml) and dried ($MgSO_4$). The solvent was removed *in vacuo* and crystallization of the resulting solid from light petroleum and methanol gave *cis-l*-menthyl 2-*p*-anisyl-5-phenyl-2-oxazoline-4-carboxylate (**26***b*), 0.635 g (73% yield), m.p. 89–90°. $[\alpha]_D^{23}$ −80.6 (*c*, 1.26 benzene).

Anal. Calcd. for $C_{27}H_{33}NO_4$ (mol. wt. 435.2409): C, 74.45; H, 7.64; N, 3.22. Found (435.2403 (mass spectrum)): C, 74.64; H, 7.70; N, 3.34.

The n.m.r. spectrum: $\delta_{TMS}(CDCl_3)$: 0.65–2.2 (m, 18H, menthyl protons); 3.80 (s, 3H, OCH_3); AB quartet centered at 4.74 and 5.77, J = 7.5 Hz (2H *cis*-oxazoline protons); 4.6–5.1 (m, 1H, menthyl methine); AB quartet centered at 6.90 and 7.99, J = 9.0 Hz (4H anisyl ring protons), 7.32 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1630 (oxazoline N=C), 1715 cm^{-1} (ester C=O).

(*b*) A reaction of 0.870 g (2 mmol) of the diastereomeric aziridine (**24**) with 1.20 g (8 mmol) of sodium iodide in acetone according to similar conditions gave *trans-l*-menthyl 2-*p*-anisyl-5-phenyl-oxazoline-4-carboxylate (**25**), 0.827 g (94% yield), as an oil. $[\alpha]_D^{23}$ −45.7 (*c*, 1.46 benzene).

Anal. Calcd. for $C_{27}H_{33}NO_4$ (mol. wt. 435.2409): C, 74.45; H, 7.64; N, 3.22. Found (435.2400 (mass spectrum)): C, 74.23; H, 7.51; N, 3.17.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.7–2.3 (m, 18H, menthyl protons), 3.85 (s, 3H, OCH_3), AB quartet centered at 4.83 and 5.38, J = 6.0 Hz (2H, *trans*-oxazoline protons), 4.6–5.1 (m, 1H, menthyl methine), AB quartet centered at 6.95 and 8.03 (4H, anisyl ring protons), 7.33 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1640 (C=N) 1725 cm^{-1} (ester C=O).

(*c*) A comparable reaction of 0.870 g (2 mmol) of the aziridine **24** with 1.20 g (8 mmol) of sodium iodide in acetone in a similar procedure gave 0.732 mg (84% yield) of *cis-l*-menthyl 2-*p*-anisyl-5-phenyl-oxazoline-4-carboxylate (**26***a*), m.p. 90°; $[\alpha]_D^{23}$ −20.0 (*c*, 1.65 benzene).

The spectral and physical data of this material were identical with that of the material obtained in the rearrangement of **23** described in section *a* above.

trans-Esterification of cis- and trans-l-Menthyl 2-p-Anisyl-5-phenyl-2-oxazoline-4-carboxylates

(*a*) A solution of 0.435 g (1 mmol) of **26***b* in 20 ml of methanol was saturated with dry hydrogen chloride at room temperature and the solution stirred at room temperature for 4 days. The solvent was removed *in vacuo* and the residue taken up in 10 ml of chloroform and the solution washed with (*i*) 5% sodium hydroxide (2 × 7 ml), and (*ii*) water (2 × 7 ml), then dried ($MgSO_4$). The solvent and displaced *l*-menthol were removed *in vacuo* at 50–60° in 20 h and the residual yellow oil decolorized by treatment with charcoal in benzene affording **28** as a colorless oil; $[\alpha]_D^{23}$ −28 (*c*, 1.83 benzene).

Anal. Calcd. for $C_{18}H_{17}NO_4$ (mol. wt. 311.1158): C, 69.44; H, 5.50; N, 4.50. Found (311.1154 (mass spectrum)): C, 69.32; H, 5.75; N, 4.78.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 3.86 (s, 6H, CO_2CH_3 and $—OCH_3$), AB quartet centered at 6.80 and 5.88, $J = 7.5$ Hz (2H, *cis* oxazoline 4,5 coupling), AB quartet centered at 6.94 and 8.0, $J = 9.0$ Hz (2H, anisyl ring protons), 7.38 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1635 (C=N), 1725 cm^{-1} (ester C=O).

(*b*) A similar *trans*-esterification was carried out with 0.435 g (1 mmol) of the diastereomeric *trans*-oxazoline **25** and 20 ml of methanol which was saturated with dry hydrogen chloride and worked-up as described above to give **29** as an oil 0.265 g (85% yield); $[\alpha]_D^{23}$ +2.9 (*c*, 1.0 benzene).

Anal. Calcd. for $C_{18}H_{17}NO_4$ (mol. wt. 311.1158): C, 69.44; H, 5.50, N, 4.50. Found (311.1154 (mass spectrum)): C, 69.26; H, 5.32; N, 4.41.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 3.85 (s, 6H, CO_2CH_3 and OCH_3), AB quartet centered at 4.90 and 5.42, $J = 6.5$ Hz (*trans*-oxazoline 4,5 protons, AB quartet centered at 6.97 and 8.06, $J = 9.0$ Hz (anisyl ring protons), 7.35 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1640 (C=N), 1730 cm^{-1} (ester C=O).

Acid Catalyzed Hydrolysis of cis- and trans-l-Menthyl 2-p-Anisyl-5-phenyl-2-oxazoline-4-carboxylates

(A) Hydrolysis to Intermediates O-Anisoyl-allo-β-phenylserinates

(*a*) A solution of 0.435 g (1 mmol) of oxazoline **26***b* in 20 ml of 10% aqueous hydrochloric acid was heated under reflux for 18 h. Upon cooling, a crystalline precipitate of *l*-menthyl-*O*-anisoyl-*allo*-β-phenylserinate hydrochloride had separated and was collected. A vigorous stream of dry ammonia was passed through a suspension of the crystalline solid in 70 ml of ether. The granular ammonium chloride was collected and washed with ether. Removal of the solvent from the filtrate and washings gave *l*-menthyl-*O*-anisoyl-*allo*-β-phenylserinate (**30***a*) 0.345 g (77% yield), m.p. 134–135° (CCl_4); $[\alpha]_D^{23}$ −27.3 (*c*, 1.9 hydrochloride salt in CH_3OH).

Anal. Calcd. for $C_{27}H_{35}NO_5$ (mol. wt. 453.2515): C, 71.49; H, 7.78; N, 3.09. Found (453.2508 (mass spectrum)): C, 71.21, H, 7.81; N, 3.06.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.6–2.1 (m, 18H, menthyl protons), 8.3–11 (bs, 2H, NH_2), 3.83 (s, 3H, OCH_3), 4.9–5.4 (m, 3H, 3 methines), AB quartet centered at 6.85 and 7.65, $J = 9.0$ Hz (4H, anisoyl protons), 7.33 (s, 5H, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1660 (anisoyl C=O); 1720 (ester C=O); 3460 cm^{-1} (NH_2).

(*b*) Acid-catalyzed hydrolysis of 0.43 g (1 mmol) of the isomeric *trans*-oxazoline **25** with 20 ml of 20% aqueous hydrochloric acid by a similar procedure gave 0.38 g (87% yield) of *l*-menthyl-*O*-anisoyl-*allo*-β-phenylserinate (**30***b*) which was purified by recrystallization from benzene, m.p. 142–143°; $[\alpha]_D^{23}$ −33 (c, 1.65, benzene).

Anal. Calcd. for $C_{27}H_{35}NO_5$ (mol. wt. 453.2515): C, 71.49; H, 7.78; N, 3.09. Found (453.2509); C, 71.25; H, 7.63; N, 3.02.

The n.m.r. spectrum was very similar to that obtained in the hydrolysis of **26***b*. Mixed m.p. of this material with **30***a* was depressed to 125–30°.

(B) Hydrolysis to α-Aminoacids. Preparation of allo-β-Phenylserine and Methyl allo-β-Phenylserinate

(*a*) A solution of 2.718 g (6 mmol) of compound **30** in 50 ml of concentrated hydrochloric acid and 30 ml of dioxane was heated under reflux for 5 days. The filtered solution was concentrated under reduced pressure and the residual solid was subjected to chromatography on ion exchange resin AGC-244 (J. T. Baker Chem. Co.). Removal of the solvents afforded allophenylserine **19**, 0.450 g, (45% yield), $[\alpha]_D^{25}$ (6 *N* HCl) −14.8 (*c*, 2.0), (lit. $[\alpha]_D^{25}$ (6 *N* HCl) −82.0 (*c*, 2.0) (25)). A stream of dry hydrogen chloride was passed through a suspension of 181 mg (1 mmol) of **31** in 20 ml of dry methanol for 45 min under reflux. The clear solution was concentrated almost to dryness and a stream of ammonia passed through a suspension of the residual oil in 60 ml of dry ether for 10 min. The precipitated ammonium chloride was collected and washed with ether (2 × 7 ml). Removal of the solvent *in vacuo* gave methyl *allo*-β-phenylserinate, 0.136 g (70% yield), m.p. 98–100° (from ether) (lit. m.p. 110° (20)); $[\alpha]_D^{23}$ −2.2 (*c*, 0.9 $CHCl_3$).

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18, Found: C, 61.63; H, 6.67; N, 7.13.

Mass spectrum Calcd. for fragment ion $C_8H_{10}NO$ ($C_6H_5CHOHCH{=}\overset{+}{N}H_2$): 136.0762). Found: 136.0760.

The α-aminoacid was identified by ascending paper chromatography according to the procedure by Shaw and Fox during 16 h. The respective R_f values of the spots visualized by the ninhydrin method were 0.30 (*allo*-β-phenylserine main product) and 0.44 (phenylserine present in trace amounts). The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 2.34 (2H, bs, D_2O exchangeable, NH_2 and OH), 3.74 (s, 3H, CO_2CH_3), 4.26 (s, 2H, 2 methines), 7.33 (s, sh, phenyl protons). The i.r. spectrum $\nu_{max}(CHCl_3)$: 1725 (ester C=O), 3390, 3520 cm^{-1} (NH_2,OH).

(*b*) Hydrolysis of 2.718 g (6 mmol) of **30***b* with concentrated hydrochloric acid under similar conditions gave allophenylserine, 0.75 g (76% yield), m.p. 225–257°; $[\alpha]_D^{23}$ −3.5 (*c* 1.0 CH_3OH as hydrochloride salt.)

Paper chromatography showed one spot with an R_f value of 0.30 (ninhydrin) identifying *allo*-β-phenylserine. Esterification of the *allo*-β-phenylserine with methanol and hydrogen chloride gave methyl *allo*-β-phenylserinate, m.p. 88–90° (from ether), in 87% yield. No m.p. depression with the product from section (*a*).

Anal. Calcd. for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.63; H, 6.83; N, 6.99.

Mass spectrum Calcd. for fragment ion $C_8H_{10}NO$ ($C_6H_5CHOHCH{=}\overset{+}{N}H_2$): 136.0762. Found: 136.0760.

This research was supported by a National Research Council of Canada grant to J.W.L. and by the Chemistry Department, University of Alberta, Edmonton, Alberta. We thank Mr. R. Swindlehurst and Dr. A. Hogg for the n.m.r. and mass spectra.

The Bimolecular Self-reactions of Secondary Peroxy Radicals. Product Studies[1]

D. LINDSAY, J. A. HOWARD, E. C. HORSWILL, L. ITON,[2] K. U. INGOLD, T. COBBLEY, AND A. LL

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received September 29, 1972

The principal products formed from 1-ethoxyethyl hydroperoxide and 1,2-diphenylethyl hydroperoxide on oxidation with reagents that are presumed to generate the corresponding *sec*-alkylperoxy radicals (Ce(IV), *tert*-butoxy, and Ag_2O) have been identified. The products formed when the corresponding alkoxy radicals are generated in pairs have also been identified. It is concluded that the Russell (1) concerted cyclic mechanism in which tetroxide decomposed to molecular products is not the exclusive route for the bimolecular self-reaction of *sec*-alkylperoxy radicals. It is suggested that there is also a second tetroxide decomposition process which yields radical products. The second process may yield "free" alkoxy radicals or it may, perhaps, yield the products of β-scission of the alkoxy radicals in a step concerted with O—O homolysis of the tetroxide. The relative importance of tetroxide decomposition to molecular and to radical products will depend on the structure of the alkyl groups, the temperature and, perhaps, the solvent.

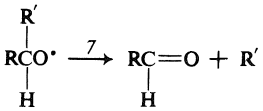
Les principaux produits formés dans l'oxydation de l'éthoxy-1 éthylhydroperoxyde et diphémyl-1,2 éthyl hydroperoxyde par des réactifs susceptibles d'engendrer les radicaux *sec*-alkylperoxy correspondants (Ce(IV), *ter*-butoxy, et Ag_2O) ont été identifiés. Les produits issus des radicaux alkoxy correspondants, lorsque ceux ci étaient formés par pairs, ont été également identifiés. Le mécanisme cyclique concerté de Russell (1) selon lequel le tétroxyde se décompose en produits moléculaires, n'est donc pas la voie exclusive dans l'autoréaction bimoléculaire des radicaux *sec*-alkylperoxy. Une seconde voie pour la décomposition du tétroxyde en produits radicalaires a été proposée. Ce second processus peut conduire aux radicaux alkoxy libres, ou aux produits de scission β des radicaux alkoxy selon une étape concertée avec homolyse O—O du tétroxyde. L'importance relative de la décomposition du tétroxyde en produits moléculaires ou radicalaires dépendra de la structure des groupes alkyles, de la température et peut être du solvant.

[Traduit par le journal]

Can. J. Chem., **51**, 870 (1973)

In 1957 Russell (1) suggested that the bimolecular self-reaction of secondary alkylperoxy radicals involved the concerted decomposition (reaction *2*) of an initially formed tetroxide (see Scheme 1).

The most frequently postulated alternative mechanism involves decomposition of the tetroxide to give two alkoxy radicals and oxygen (reaction *3*). According to the Russell mechanism the ketone, RR′CO, and the alcohol, RR′CHOH, will be formed in equimolar quantities. The same will be true of the non-concerted mechanism provided that all the alkoxy radicals that escape the cage (reaction *5*) undergo β-scission,



If, however, the free alkoxy radicals abstract a hydrogen atom there will be a preponderance of alcohol.

The Russell, or concerted, mechanism is supported by a considerable body of experimental evidence (2–5), most of which has been obtained at ambient temperatures (20–60°). The non-concerted decomposition will be favored at higher temperatures because it will have a higher activation energy than the concerted process. For example, it has been estimated (6) that with *s*-butylperoxy radicals k_3/k_2 is ~0.04 at 30° and ~0.3 at 100°.

Two experimental observations have prevented the unreserved acceptance of the Russell mechanism as the dominant process at ambient temperatures and below. Firstly, thermochemical calculations suggest that if the overall reaction proceeded by the concerted route it should have a negative activation energy of several kilocalories per mole (7). However, experimental measurements in the temperature range −16 to −90° indicate a positive activation energy of ~3 kcal/mol for a number of *sec*-alkylperoxy radicals (8, 9). Secondly, Diaper (10) has reported that 1-methoxy (**1***a*) and 1-*tert*-butoxynonane-1-hydroperoxide (**1***b*) were smoothly oxidized to di-(1-alkoxyalkyl)peroxides by 1 equiv of

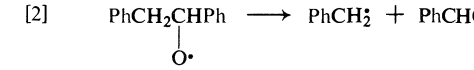
b R = $(CH_3)_3C$

Ce(IV) in methanol at 0° (eq. 1). Since Ce(IV) oxidizes alkyl hydroperoxides to the corresponding peroxy radicals in high yield (11, 12) it seems not unreasonable to suppose that 1-alkoxyalkylperoxy radicals react by the radical pathway and that the caged alkoxy radicals combine (reaction *6*, Scheme 1) rather than disproportionate.

Diaper's products contrast sharply with the products normally found in processes which are presumed to involve the bimolecular self-reaction of secondary alkylperoxy radicals. Numerous studies (1, 4, 6, 9, 13–16) attest to the fact that such products are the appropriate alcohol and ketone and that these are formed in high yield and in *approximately* equimolar amounts. Diaper's results prompted us, therefore, to investigate the products formed from an analogous peroxy radical, 1-ethoxyethylperoxy. Although little or no di-(1-ethoxyethyl)peroxide was formed, the other products suggested that alkoxy radicals played a significant role in the reaction. Our product studies were, therefore, extended to the 1,2-diphenylethylperoxy radical which was chosen because any free alkoxy radical should undergo a relatively rapid β-scission to yield benzaldehyde which could be easily detected in the reaction mixture (eq. 2). Attempts



were also made to study the behavior of caged pairs of 1-ethoxyethoxy and 1,2-diphenylethoxy radicals in order to avoid some of the assumptions otherwise necessary in interpreting the results of the peroxy radical studies (*cf.* refs. 3 and 4).

Results and Discussion

1-Ethoxyethylperoxy Radicals

These peroxy radicals were most conveniently prepared by oxidation of 1-ethoxyethyl hydroperoxide either by ceric ammonium nitrate, *tert*-butoxy radicals, or silver oxide. The principal reaction products expected from their self-reaction are shown in Scheme 2 while the yields of the products actually found are listed in Tables 1 and 2.

Ethanol was presumably formed by decomposition of the hemiacetal (eq. 3). The acetalde-

hyde formed in this process appeared as the appropriate dialkoxyethane in alcoholic solvents (eq. 4). The presence of methyl formate in

[4] $CH_3CHO + 2ROH \rightarrow CH_3CH(OR)_2 + H_2O$

methanol but not in ethanol, CCl_4 or benzene was probably the result of a *trans*-esterification of ethyl formate (eq. 5).

[5] $CH_3OH + CH_3CH_2OCHO \rightarrow CH_3CH_2OH + CH_3OCHO$

Diaper (10) obtained di-(1-*tert*-butoxynonyl)-peroxide in 45% yield by the oxidation of **1***b* with Ce(IV). In contrast, we could detect no di-(1-ethoxyethyl)peroxide among the products from the Ce(IV) oxidation of 1-ethoxyethyl hydroperoxide under similar experimental conditions. Although the product balances were not too good the sum of [formate] + [acetate] + ½([ethanol] + [dimethoxyethane]) for the Ce(IV) experiments with initial hydroperoxide concentrations of 0.18, 0.45, and 0.83 *M* were such that less than 10% of the hydroperoxide could have been converted to peroxide. This difference in products is surprising but is not necessarily inconsistent with the radical reaction playing an important role in the bimolecular self-reactions of these peroxy radicals. That is, high molecular weight alkoxy radicals will diffuse from the cage more slowly than low molecular weight radicals and so they will yield more peroxide if reaction *6* of Scheme 1 is the principal cage process. The cage lifetime may also be increased by hydrophobic bonding between the 1-*tert*-butoxynonoxy radical pair. That is, methanol is a hydrophilic solvent and as such will rather poorly solvate such large alkoxy radicals and so they will tend to remain in the cage for longer than the small, readily solvated, 1-ethoxyethoxy radicals. While the different peroxide yields can be rationalized in this way, it is by no means certain that the metal ion does not play a role in peroxide formation, the extent of this role depending on the hydroperoxide. An example of

the difficulties involved in interpreting products is provided by the observation that 3% di-*sec*-butyl peroxide is formed in the Co(II)-catalyzed decomposition of *sec*-butyl hydroperoxide (17) but none is produced in the *tert*-butoxy radical induced decomposition (4).

The yields of the products formed by the oxidation of 1-ethoxyethyl hydroperoxide in methanol by Ce(IV) and by *tert*-butoxy were quite similar. The average yields for the Ce(IV) oxidation of 0.18, 0.45, and 0.83 *M* hydroperoxide and the yield for the *tert*-butoxy oxidation of 0.33 *M* hydroperoxide (which gave a good product balance) are, respectively, methyl formate, 0.09 and 0.14; ethyl formate, 0.14 and 0.18; ethyl acetate, 0.39 and 0.18; ethanol, 0.54 and 0.76; dimethoxy ethane, 0.28 and 0.25. This similarity implies that both reactions involve similar intermediates, *i.e.* peroxy radicals (eqs. 6 and 7). Irrespective of the mechanism of the

[6] $ROOH + Ce(IV) \rightarrow ROO\cdot + Ce(III) + H^+$

[7] $ROOH + t\text{-}BuO\cdot \rightarrow ROO\cdot + t\text{-}BuOH$

subsequent reactions of the peroxy radicals the fact that the yield of ethanol was two or three times that of dimethoxyethane can only be accounted for if the latter compound was unstable under the reaction conditions. In separate experiments it was shown that dimethoxyethane was stable to Ce(IV) but was oxidized by *tert*-butoxy to form methyl acetate (among other products). Methyl acetate was one of the minor products identified in the *tert*-butoxy oxidations of the hydroperoxide (eq. 8). In the Ce(IV) reactions

[8] $(CH_3O)_2CHCH_3 \xrightarrow{(-H\cdot)} (CH_3O)_2\dot{C}CH_3 \longrightarrow CH_3OC(O)CH_3 + CH_3\cdot$

the dimethoxyethane may be oxidized by the radicals formed in this reaction.

The yields of ethanol and acetaldehyde were more nearly equal in CCl_4 and in benzene (both *t*-butoxy and Ag_2O oxidations). However, there is no obvious reason why [acetate] was so much less than $\frac{1}{2}$([ethanol] + [acetaldehyde(dimethoxy ethane)]) for the Ag_2O oxidation and for *t*-butoxy oxidation in methanol, whereas the reverse was the case for *t*-butoxy oxidation in CCl_4 and in benzene. For the Ce(IV) oxidation these quantities were equivalent as we would expect if they arose from tetroxide by way of reactions *2* or *3* + *4* of Scheme 1. Excess ethyl

[9] 
acetate might arise from abstraction of the tertiary hydrogen of the hydroperoxide (eq. 9), but a deficiency is difficult to account for.

With regard to the mechanism of the peroxy radical self-reaction, the most significant product is formate. In methanol it is conceivable that this could be formed by way of an oxidation of the solvent to formic acid. However, formate was also formed in CCl_4 and in benzene. It seems most likely that it was produced principally by β-scission of 1-ethoxyethoxy radicals (eq. 10). If

[10] 
this is correct, it implies that alkoxy radicals were present in these systems and hence that at least some tetroxide probably decomposed by reaction *3* of Scheme 1, with some of the alkoxy radicals escaping from the cage (reaction *5*). The relative importance of reactions *2* and *3* cannot be estimated without some knowledge of the behavior of caged ethoxyethoxy radical pairs (reactions *4*, *5*, and *6*).

Decomposition of Di-(1-ethoxyethyl)-peroxide

The principal products formed by thermal decomposition of di-(1-ethoxyethyl)peroxide in cumene at 130° are listed in Table 3. The production of hydrogen can probably be best explained by a non-radical concerted decomposition of the peroxide (eq. 11) (3, 18). This

[11] 
process accounts for about one quarter of the peroxide, *i.e.* ~0.25 mol H_2 and ~0.5 mol ethyl acetate. The remaining ethyl acetate and the

TABLE 3. Products from the thermal decomposition of di-(1-ethoxyethyl)peroxide in cumene at 130° (yields are mol/mol of peroxide)

other products are presumed to arise by processes involving free radicals.

The data can be interpreted in two extreme ways depending on the importance assigned to alkoxy radical disproportionation in the cage (reaction *4*, Scheme 1). If it is assumed that there is no cage disproportionation[3] then the approximately equal concentrations of ethanol and acetaldehyde (at the highest initial concentration of peroxide[4]) can be explained by hydrogen abstraction by free alkoxy radicals (eq. 12),

[12] $CH_3CH_2OCH(CH_3)O^{\bullet} + SH \longrightarrow S^{\bullet} + [CH_3CH_2OCH(CH_3)OH] \downarrow CH_3CH_2OH + CH_3CHO$

where SH is either cumene (hence the bicumyl) or peroxide (hence the remaining ethyl acetate[5]).

[13] $CH_3CH_2O\overset{\displaystyle CH_3}{\overset{|}{C}}OO\overset{\displaystyle CH_3}{\overset{|}{C}}OCH_2CH_3 \longrightarrow CH_3CH_2O\overset{\displaystyle CH_3}{\overset{|}{C}}O^{\bullet} + O{=}\overset{\displaystyle CH_3}{\overset{|}{C}}OCH_2CH_3$

(H on the first radical)

On the alternative assumption that cage disproportionation is very important, the ethanol, acetaldehyde, and remaining ethyl acetate are assumed to be formed in the cage (eq. 14).

[14] $[2CH_3CH_2OCH(CH_3)O^{\bullet}]_{cage} \longrightarrow CH_3CH_2OH + CH_3CHO + CH_3CH_2OC(O)CH_3$

Attempts to distinguish between these alternative mechanisms were unsuccessful.[6,7]

Ethyl formate and methane were formed in approximately equal amounts and constitute about one third of the products formed from alkoxy radical precursors. This presumes that these products arose by β-scission of free alkoxy radicals, the expelled methyl being converted to methane by solvent or peroxide (eq. 15). In

[15] $CH_3^{\bullet} + SH \rightarrow CH_4 + S^{\bullet}$

the hydroperoxide oxidations at 0–40°, formate constituted a rather similar fraction of the products (say 20 ± 10% for those experiments in which the product balance was reasonable). On the basis of the first assumption (*i.e.* all alkoxy radical pairs escape the cage with one third undergoing β-scission and two thirds abstracting H at 130°) it is difficult to predict what fraction of the product from a caged pair of alkoxy radicals would be formate at temperatures 100° lower. For *sec*-alkoxy radicals β-scission would

[3]Under similar conditions it has been reported both that "there is very little, if any, disproportionation of two *sec*-butoxy radicals in the solvent cage" (3), and that there is a significant amount of cage disproportionation of the *sec*-butoxy radicals (19).

[4]It is uncertain whether our failure to detect either of these compounds at lower peroxide concentrations was due to their further reaction under the experimental conditions or to poor resolution on the v.p.c.

[5]In this connection, it is worth noting that di-*sec*-butyl peroxide is not subject to induced decomposition under similar conditions (3). However, di-(1-ethoxyethyl)-peroxide should be a much better H donor than di-*sec*-butyl peroxide.

[6]Although the yield of acetate decreased with decreasing peroxide concentration (which argues in favor of an induced decomposition) the yield of formate also decreased rather than increasing as it should if the peroxide was the principal H donor to the alkoxy radicals.

[7]The product yield with 0.10 M peroxide initially was unaffected by the addition of 0.2 M 2,6-di-*tert*-butyl-4-methylphenol. This does not rule out induced decomposition of the peroxide since a sufficiently rapid attack of the alkoxy radicals on the solvent would prevent their interception by the phenol. If this is true, it must be cumyl radicals that induce decomposition of the peroxide.

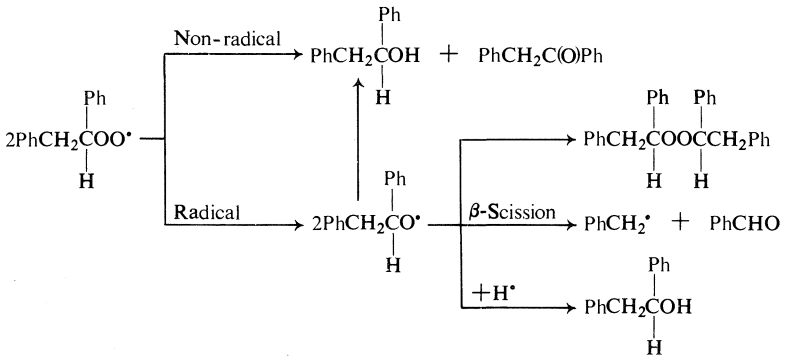


SCHEME 3

decrease in importance relative to hydrogen abstraction as the temperature was lowered. *If* this is also the case for *sec*-α-alkoxyalkoxy radicals then the high yields of formate in the hydroperoxide oxidations imply that most (say ≥80%) of the bimolecular self-reactions of the peroxy radicals yield alkoxy radicals and that the concerted process is relatively unimportant. On the other hand, if β-scission predominates over hydrogen abstraction as the temperature is decreased, then approximately 20% of the peroxy radicals react to give alkoxy radicals. On the basis of the second assumption (*i.e.* that one third of the alkoxy radical pairs escape the cage while two thirds disproportionate in the cage) one would predict that most peroxy radical pairs yield alkoxy radicals. This is because the ratio of alkoxy diffusion from the cage to disproportionation in the cage is not expected to be very dependent on the temperature.

The production of formate in the hydroperoxide oxidations argues in favor of some of the peroxy–peroxy reactions yielding free alkoxy radicals. Although far from definitive, the peroxide decomposition experiments suggest that the majority of such reactions yield alkoxy radicals and that the non-radical process is relatively unimportant (probably ≤20% of the total reaction).

1,2-Diphenylethylperoxy Radicals

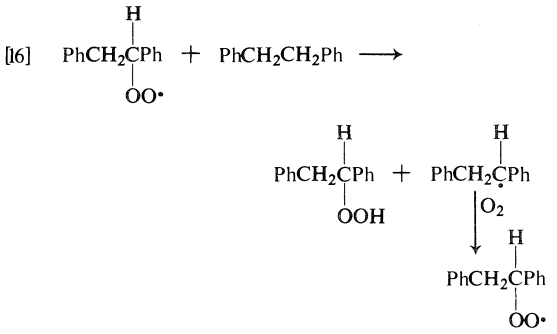
The possible self-reactions of these peroxy radicals are shown in Scheme 3. 1,2-Diphenylethylperoxy radicals were conveniently produced for product studies either by oxidation of 1,2-diphenylethyl hydroperoxide or by autoxidation of bibenzyl.

Oxidation of 1,2-Diphenylethyl Hydroperoxide

The products formed by the oxidation of this hydroperoxide with *tert*-butoxy radicals, with Ce(IV), and with silver oxide, are listed in Table 4. In the Ce(IV) oxidations the yield of 1,2-diphenylethanol was reduced and the yield of benzaldehyde enhanced by the facile and quantitative oxidation of this alcohol to the aldehyde (20). If some allowance is made for this side-reaction, then the yields of the four oxygen-containing compounds were reasonably similar in the different experiments. These products are, therefore, presumed to arise from 1,2-diphenylethylperoxy radicals.

Autoxidation of Bibenzyl

The major product formed during the autoxidation of bibenzyl was of course, 1,2-diphenylethyl hydroperoxide (eq. 16). Benzaldehyde and



benzoin were minor products (see Table 4) and were probably formed in the chain terminating step. It is uncertain whether or not 1,2-diphenylethanol was formed in termination since our analytical procedure (v.p.c.) required the rather large amount of hydroperoxide to be reduced to the alcohol (with Ph_3P) before the actual analysis. The error in the estimation of "termination" alcohol from the total yield of alcohol and the iodiometrically measured yield of hydroperoxide would be of similar magnitude to the

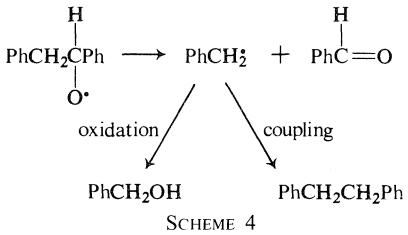
amount of alcohol expected to be formed in termination.

It seems likely that the bimolecular self-reactions of 1,2-diphenylethylperoxy radicals yield benzaldehyde, benzyl alcohol, 1,2-diphenylethanol, and benzoin. The last two compounds may be formed either by the non-radical or radical reactions.

The benzaldehyde and the benzyl alcohol and bibenzyl detected in the hydroperoxide oxidations were presumably formed via free 1,2-diphenylethoxy radicals (Scheme 4).



SCHEME 4

Bis-(1,2-diphenylethyl)hyponitrite

An attempt was made to study the chemistry of caged pairs of 1,2-diphenylethoxy radicals by the preparation and decomposition of bis-(1,2-diphenylethyl)hyponitrite. Unfortunately this hyponitrite could not be prepared with a purity better than 30% (see experimental). However, we feel confident that the four products listed in Table 5 resulted from the thermal decomposition of this hyponitrite according to Scheme 5.

The sum of the yields of benzaldehyde, diphenylethanol, and benzoin was 1.94 in the decomposition at 260° which is in good agreement with the expected value of 2.0. Product balances were less satisfactory for the decompositions in CCl_4 or cyclohexane.

The principal fate of 1,2-diphenylethoxy radical pairs is diffusion from the cage, followed in

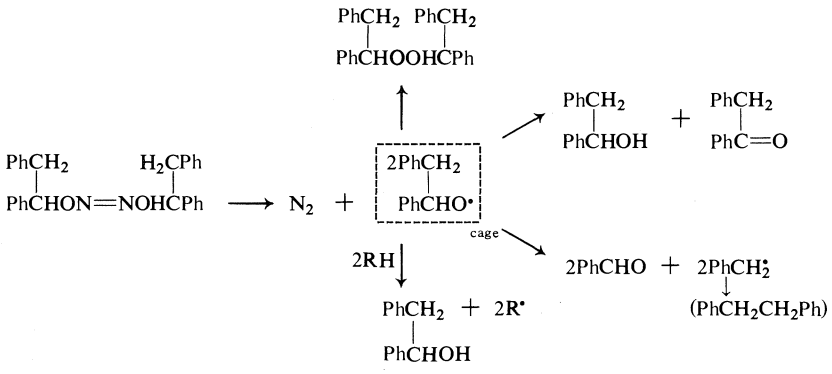


SCHEME 5

CCl_4 by β-scission, while in cyclohexane, at 80°, β-scission predominates but hydrogen abstraction from the solvent plays a significant role. Since there was relatively little benzoin or (in CCl_4) diphenylethanol, disproportionation in the cage cannot be important. However, carbonyl yields determined by i.r. spectroscopy were generally about 10–20% less than the yields of benzaldehyde and benzoin[8] measured by v.p.c. and recorded in Table 5. This suggests that some of the benzaldehyde found by v.p.c. arose from decomposition (in the injection port) of bis-(1,2-diphenylethyl)peroxide. In summary, the majority of the alkoxy radicals escape the cage and undergo β-scission or, in a suitable donor, abstract a hydrogen. About 10–20% of the caged pairs probably combine to yield peroxide but less than 10% of the pairs disproportionate in the cage. Hiatt's results (3, 4) suggest that caged *sec*-butoxy radical pairs behave rather similarly.

With regard to the bimolecular self-reactions of peroxy radicals, the data in Table 4 indicate that 1,2-diphenylethylperoxy radicals react together to give *approximately* equal quantities of benzaldehyde, diphenylethanol, and benzoin. The benzaldehyde is presumably formed from diphenylethoxy radicals. According to the data in Table 5 the other two compounds must be formed by a process *not* involving diphenylethoxy radicals. This latter process is, presumably, the concerted decomposition of the tetroxide. That is, approximately one third of the 1,2-diphenylethylperoxy radical pairs react via reactions *3* and *5* of Scheme 1 and two thirds via reaction *2*.

[8]I.r. spectroscopy only gives the sum of benzaldehyde and benzoin since the C=O fundamental stretching bands for these two compounds occur at almost the same frequency.

Conclusion

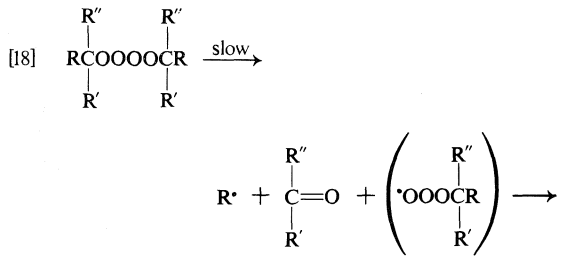
The present results provide evidence that not all secondary alkylperoxy radicals undergo their bimolecular self-reactions entirely by the concerted cyclic mechanism at ambient temperatures. A significant fraction of the overall reaction can apparently yield free alkoxy radicals. However, it is far from clear why, at similar temperatures, 1-ethoxyethylperoxy pairs yield alkoxy radicals in (probably) ≥80% yield, while 1,2-diphenylethylperoxy pairs yield alkoxy radicals in ~33% yield, and *sec*-butylperoxy pairs yield *sec*-butoxy radicals in only ~4% yield (4, 6). Possibly dialkyl tetroxides that can yield alkoxy radicals, that are very subject to β-scission, decompose by multiple bond scission, *i.e.* by a concerted but non-cyclic mechanism. Thus, although di-*tert*-butyl tetroxide probably undergoes one-bond scission (eq. 17) (21, 22), most

$$[17]\quad Me_3COOOOCMe_3 \xrightarrow{slow} Me_3CO^{\bullet} + (^{\bullet}OOOCMe_3) \xrightarrow{fast} O_2 + {}^{\bullet}OCMe_3$$

other di-*tert*-alkyl tetroxides are less stable than the *tert*-butyl compound (21–23) and their stability decreases as the derived alkoxy radicals become more unstable with respect to β-scission. This suggests that β-scission may be synchronized with (and therefore assist) O—O scission of the tetroxide. Suitably substituted tetroxides (both di-*tert*-alkyl and di-*sec*-alkyl) may therefore, perhaps, decompose by two-bond (or more) scission, *e.g.* as in eq. 18.

If this explanation of our analytical data is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



correct, it suggests that structural factors may have a profound effect not only on the rates of the bimolecular self-reactions of *sec*-alkylperoxy radicals, but also on their mechanism of reaction. Thus, for example, diphenylmethylperoxy radicals (24) should decompose principally by the concerted cyclic mechanism since neither phenyl nor hydrogen are readily cleaved from alkoxy radicals and since the hydrogen that must be transferred in the cyclic process will be quite labile. Evidence favoring the Russell mechanism for this peroxy radical has been presented previously (24). In contrast, peroxy radicals such as $(PhCH_2)_2CHOO^{\bullet}$ or $(Ph_3C)_2CHOO^{\bullet}$ are expected to react principally by the concerted non-cyclic route since they would yield unstable alkoxy radicals and since the central hydrogen is not particularly labile. It is expected that these two peroxy radicals would react more rapidly than, for example, $(CH_3CH_2)_2CHOO^{\bullet}$. For this radical the concerted non-cyclic process would be less favored so that reaction would be more likely to occur by the concerted cyclic process. Evidence favoring the cyclic process for $CH_3CH_2(CH_3)CHOO^{\bullet}$ has been obtained (25).

In conclusion, *sec*-alkylperoxy radicals can react both by the concerted cyclic (Russell) mechanism and by a process which yields either "free" alkoxy radicals or the products of β-scission of the alkoxy radicals in a step concerted with O—O homolysis of the tetroxide. The relative importance of these two processes will depend on the nature of the alkyl groups, the temperature and, perhaps, the solvent.

Experimental

Materials

1-Ethoxyethyl hydroperoxide was prepared from H_2O_2 and ethyl vinyl ether by the method of Milas *et al.* (26). Iodiometric titration indicated that the product was >90% pure. Reduction with a slight excess of triphenyl phosphine gave only acetaldehyde and ethanol. Ethyl formate was not formed in this reduction, nor was it present in the hydroperoxide.

Di-(1-ethoxyethyl)peroxide was prepared from H_2O_2 and ethyl vinyl ether in the presence of a small amount of thionyl chloride by the method of Lederer and Weissermel (27). Titration for peroxide indicated that the product was >90% pure.

1,2-Diphenylethyl hydroperoxide was prepared from H_2O_2 and 1,2-diphenylethanol (Aldrich, recrystallized from benzene:hexane, 1:20) by the method of Davies *et al.* (28). This hydroperoxide is a white crystalline material, m.p. 55°, purity >90% by iodiometric titration. Reduction of the hydroperoxide with Ph_3P gave only 1,2-diphenylethanol. Benzaldehyde was not formed in this reduction, nor was it present in the hydroperoxide. The hydroperoxide is stable at 56° yielding no benzaldehyde even after 8 days at this temperature.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.33; H, 6.64.

Bis-(1,2-diphenylethyl)hyponitrite was probably prepared in about 30% yield by reaction of 1,2-diphenylethyl bromide with silver hyponitrite according to the procedure of Partington and Shah (29). The bromide was prepared in 86% yield by reaction of 1,2-diphenylethanol with anhydrous HBr in benzene at its freezing point (30). The bromide was purified by dry column chromatography on silica using trichloroethylene as the solvent. The purified bromide, n_D^{20} 1.6019 (lit. (30) n_D^{20} 1.6019), showed no OH or C=O absorption bands in the i.r. V.p.c. confirmed that it contained no benzaldehyde, 1,2-diphenylethanol, benzoin, or bibenzyl.

The bromide (2.1 g) was dissolved in 20 ml of purified ether and cooled to −10°. Silver hyponitrite (2.2 g, 100% excess) was added in small portions with continuous stirring, the ether being kept under a blanket of dry argon. At the end of the addition all organic bromide was gone (copper wire test). The silver bromide and excess silver hyponitrite were removed by filtration. Removal of the ether in an air stream at 0° (or under vacuum) resulted in a vigorous evolution of nitrogen and the separation of oily white crystals. At this stage, the i.r. spectrum (mull) showed a large, hydrogen-bonded, OH band but little or no C=O band. On warming the crystalline mass, nitrogen evolution began again and became rapid at ~50°. The crystals remaining were *trans*-stilbene. The oily contaminant and/or some of the crystalline material is believed to be bis-(1,2-diphenylethyl)hyponitrite. Nitrogen evolution experiments indicated that the compound decomposing rapidly at 0° (compound A) was formed in ~10% yield based on starting bromide while that decomposing rapidly at 50° (the hyponitrite, compound B) was formed in ~30% yield. The balance of the material (~60%) was stilbene. All attempts to separate B from stilbene by fractional crystallization or by trituration from the stilbene crystals were frustrated by its low yield (relative to stilbene) and by its instability. However, we believe that B is the desired dialkyl hyponitrite and that compound A may be the mono-alkyl hyponitrite or, perhaps, hyponitrous acid. The raw product gave an intense i.r. absorption at 980 cm^{-1} which appears to be a characteristic of hyponitrites (31, 32). This band disappeared as B decomposed and the decomposition products and their yields were consistent with B being bis-(1,2-diphenylethyl)hyponitrite. Various modifications of the preparation described above such as changing the solvent, did not increase the yield of B.

The half-life for decomposition of B was ~6 h at 30°. This may be compared with half-lives of ~40 h at this temperature for di-*tert*-butyl hyponitrite (31) and ~4 h for dibenzyl hyponitrite (33) and for dicumyl hyponitrite (34).

tert-Butylhyponitrite was prepared by the method of Kiefer and Traylor (31). All other compounds were commercial materials that were purified by standard procedures before use.

Hydroperoxide Decompositions

Ceric ammonium nitrate (1.0 *M*) in methanol was added slowly with stirring to a 0.2 *M* solution of the hydroperoxide in methanol at 0°. Addition was continued until the color of the added ceric solution was not completely destroyed. The solution was stirred for a further 15 min at 0° and the reaction products were then analyzed by v.p.c. The products formed in the hydroperoxide oxidation were treated similarly. Only 1,2-diphenylethanol reacted, and that only slightly, under these conditions.

tert-Butyl hyponitrite (0.1 *M*) in benzene was heated with the hydroperoxide (0.18 *M*) in benzene, under vacuum, for ten half-lives of the hyponitrite before the samples were analyzed.

Silver oxide (freshly prepared) was reacted with the hydroperoxide (0.18 *M*) in benzene under vacuum until the hydroperoxide had been destroyed.

Peroxide Decomposition

Di-(1-ethoxyethyl)peroxide was decomposed for 8 h in undiluted cumene under vacuum at 130°.

Autoxidation of Bibenzyl

Bibenzyl (5.3 *M*) containing α,α′-azo-bis-isobutyronitrile (0.19 *M*) was shaken under 1 atm of oxygen at 56°. The oxygen absorption rate was $\sim 3 \times 10^{-6}\ M\ s^{-1}$, corresponding to a chain length of ~2. After 67 h the bibenzyl had absorbed 0.7 *M* of oxygen. The accumulated hydroperoxide was reduced with a slight excess of Ph_3P before v.p.c. analysis of the products.

Hyponitrite Decomposition

These experiments were carried out on the raw product obtained by reacting 1,2-diphenylethyl bromide with silver hyponitrite. After the preparation of each batch of hyponitrite the solvent was evaporated under reduced pressure and the raw product was divided into portions which were dissolved in CCl_4 or cyclohexane. I.r. spectra were recorded after the samples had stood at room temperature for 15–30 min (in order to destroy compound A). Only very small amounts of carbonyl- and hydroxyl-containing compounds were present at this time. One sample of B was decomposed at 50° in a system that allowed the nitrogen yield, and hence the purity of the hyponitrite, to be measured. A second sample was injected directly into the v.p.c. to determine the products of rapid thermal cracking (at 260°). The remaining samples were decomposed in refluxing CCl_4 or cyclohexane or at 30°, under a blanket of argon, and were analyzed by i.r. spectroscopy (for C=O) and by v.p.c.

The authors are grateful to Dr. T. Pearce. We also wish to thank Dr. K. F. Preston for analyzing the methane and hydrogen formed in the di-(1-ethoxyethyl)peroxide decompositions.

Condensation Reactions of 2-Amino-*N*-acylphenethylamines and 2-Amino-β-acylaminostyrenes

F. M. F. Chen and T. P. Forrest

Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received August 8, 1972

Molecular sieves have been used to catalyze the condensation reaction of *cis*-β-(*o*-acetotoluidino)-2-aminostyrene (**4**) to yield 2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine (**11**). A second major product from the reaction was 2-(*o*-toluidino)-*N*-acetylindole (**13**), an example of the type of compound presumed to be an intermediate in the Fischer indole synthesis. The formation of *N*-acetylindole from **13** occurred on treatment of **13** with silica or alumina.

The *trans* isomer, **5**, and the reduced analog, **6**, were unreactive with molecular sieves but **6** could be converted to 4,5-dihydro-2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine by reaction with phosphorous oxychloride.

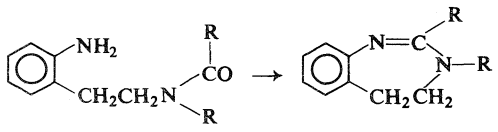
De la sève moléculaire a été utilisée pour catalyser la réaction de condensation du *cis*-β-(*o*-acetotoluidino) amino-2 styrène (**4**) pour produire la méthyl-2 (*o*-tolyl)-3-3*H* benzo-1,3 diazépine (**11**). Un second produit majeur de la réaction à été l'(*o*-toluidino)-2 *N*-acétylindole (**13**), un exemple du type de composé supposé être un intermédiaire dans la synthèse selon Fischer de l'indole. La formation du *N*-acétylindole à partir de **13** se produit lorsque l'on traite **13** avec de la silice ou de l'alumine.

L'isomère *trans*, **5**, et l'analogue réduit, **6**, ne réagissaient pas avec la sève moléculaire mais **6** pouvait être transformé en dihydro-4,5 méthyl-2 (*o*-tolyl)-3-3*H* benzo-1,3 diazepine par réaction avec l'oxychlorure de phosphore. [Traduit par le journal]

Can. J. Chem., **51**, 881 (1973)

Introduction

A potentially very useful method for the synthesis of 1,3-benzodiazepines by the internal condensation of 2-amino-*N*-acylphenethylamines is illustrated in Scheme 1. Although this type of



Scheme 1

condensation has been used in the synthesis of the six-membered quinazolines (1) and the five-membered benzimidazoles (2), attempts to employ it in the formation of the seven-membered 1,3-benzodiazepines have proven to be unsuccessful (3, 4). Treatment of 2-amino-*N*-benzoyl-4,5-dimethoxyphenethylamine (**1**) with the usual reagents employed in similar cyclizations led only to starting material or intractable tars (3). The acid-catalyzed rearrangement of ethyl-2-amino-α-benzamidocinnamate (**2**) yielded no 1,3-benzodiazepine derivatives (5). Thermal or acid-catalyzed condensations of 2-acetamido-3-(*o*-aminophenyl)-2-butene (**3**) led to excellent yields of 2,3-dimethylindole and no 1,3-benzodiazepines (6). We have investigated the reactivity of some 2-amino-*N*-acetylphenethylamine derivatives under various conditions and wish to report our findings.

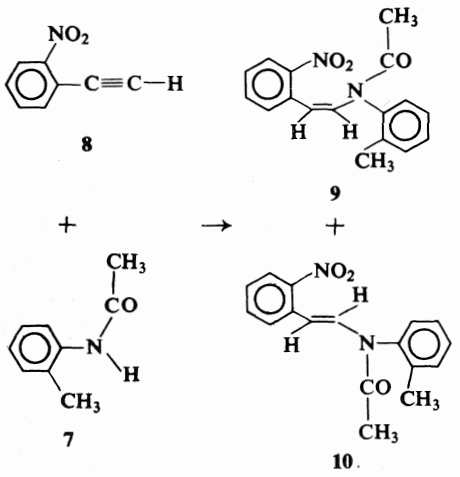
Results and Discussion

The compounds on which we chose to carry out our investigations were the *cis* and *trans* isomers of β-(*o*-acetotoluidino)-2-aminostyrene, **4** and **5**, and the dihydro analog, **6**. These were prepared by the addition of *o*-acetotoluidide (**7**) to *o*-nitrophenyl-acetylene (**8**) to form the β-(*o*-acetotoluidino)-2-nitrostyrenes, (**9** and **10**) (Scheme 2), which were then reduced. The addition reaction was catalyzed by sodium hydride and yielded a mixture of the *cis* and *trans* addition products. The spectral parameters which permitted the structural verification of these new compounds are presented in the Experimental.

The selective reduction of the nitro group of **9** and **10** was carried out by ferrous ammonium sulfate in a water–methanol mixture. Hydrogenation of **10** over palladium–charcoal reduced both the carbon–carbon double bond and the nitro group producing **6** in good yield.

No 1,3-benzodiazepines were obtained by treating the compounds with aqueous acid as was employed by Plieninger and Nogradi (7) in the cyclization of α-imino-β-(2-acetaminophenyl)-γ-butyrolactone; **4** and **5** yielded indole and *o*-acetotoluidine whereas **6** was recovered unchanged. The reaction of **6** with PCl_3 or $POCl_3$ was successful in producing the 4,5-dihydro-2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine, in contrast to the behavior of the similar compound **1**, which was reported (3) to give no 1,3-benzodiazepine under similar conditions. The reaction of **4** or **5** with $POCl_3$ or PCl_3 yielded only intractable tars.



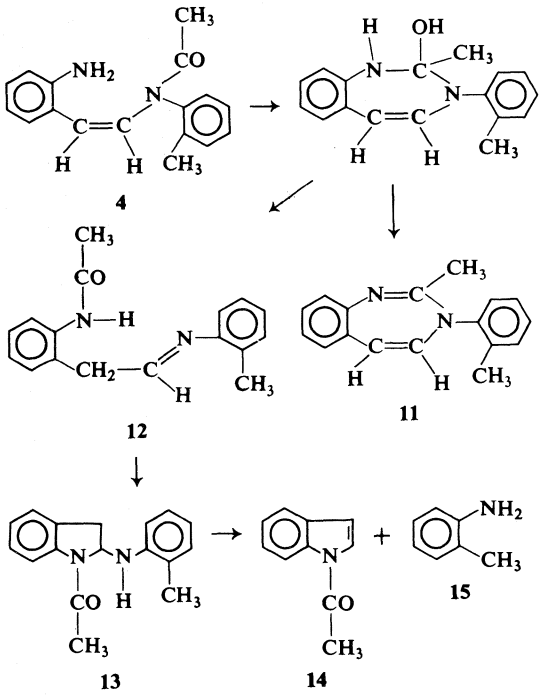
SCHEME 2

Heating **4** with molecular sieves provided a successful method for carrying out the condensation of the *cis* isomer to yield the corresponding 1,3-benzodiazepine. The best yield of 2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine (**11**) from **4** was obtained using molecular sieve 4A in benzene at reflux temperature. The *trans* isomer **5** and the saturated analog **6** yielded only starting materials when treated with molecular sieves.

The mass spectrum of **11** showed a molecular ion at *m/e* 248 and the n.m.r. spectrum exhibited peaks due to two singlet methyl groups at δ 1.63 and 2.40, eight aromatic protons between δ 6.60 and 7.40, and an AB system for the olefinic protons (δ 5.15, 5.67, J_{AB} = 8 Hz). Hydrolysis of **11** occurred on contact with water yielding **4**, thereby verifying the structure of **11**.

A second major product from the reaction of **4** with molecular sieves was 2-(*o*-toluidino)-*N*-acetylindoline (**13**). The mass spectrum of **13** exhibited a molecular ion at *m/e* 266 (6) and major fragment ions at 159 (5), 158 (10), 118 (60), 117 (55), 107 (100). The n.m.r. spectrum showed singlet methyl peaks at δ 2.06 and 2.14, a multiplet at 6.65–7.30 for seven aromatic protons, a broad doublet at 8.20 for the aromatic H-7 proton, a broad singlet at 4.0 for the NH and an ABX system for the heterocyclic ring protons (δ 3.07, d, H-3, A of ABX; 3.52, dd, H-3, B of ABX; 5.89, H-2, X of ABX; J_{AB} = 17, $J_{AX} < 1$, J_{BX} = 7 Hz). The structure was verified by the conversion of **13** to *N*-acetylindole and *o*-toluidine by chromatography on alumina or silica.

A plausible mechanism for the product formation is shown in Scheme 3. The latter part of this scheme has the same sequence of steps as the mechanism commonly accepted (8) for the Fischer indole synthesis. The formation of *N*-acetyl compounds **13** and **14** supports the conclusion of Yamamoto (9, 10, 13) that acyl derivatives of the Fischer indole intermediates do not require deacylation prior to closing the heterocyclic ring. It had been previously suggested (11) that the amide nitrogen had to be converted to the more basic amine nitrogen in order to add to the imine function of the indoline precursor (**12**). This isolation of 2-(*o*-toluidino)-*N*-acetylindoline (**13**) represents the first isolation of a 2-aminoindoline derivative which could eliminate the amino group to produce an indole as proposed for the last step of the Fischer indole synthesis. The feasibility of this step has been



SCHEME 3

demonstrated by the conversion of **13** to *N*-acetyl indole (**14**) and *o*-toluidine (**15**) by chromatography on alumina or silica. These products, **14** and **15**, were also isolated directly from the reaction of **4** on some molecular sieves.

Although molecular sieves have been commonly used as dehydrating agents, their use as catalysts in condensation reactions is not well established. A recent report (12) describes the marked catalytic effect of molecular sieves on the formation of ketimines and enamines. The molecular sieves are particularly useful catalysts in that relatively mild reaction conditions may be employed and simple isolation procedures permit their use where the products are sensitive to aqueous acid or base.

Experimental

N.m.r. spectra were recorded on a Varian T60 spectrometer using $CDCl_3$ as solvent and tetramethylsilane as internal standard. Mass spectra were recorded on a C.E.C. model 21-104 spectrometer. I.r. spectra were recorded in chloroform solution on Perkin–Elmer model 237 B spectrometer. Silica gel (silicar CC7 100 mesh) and alumina (neutral, activity 1, 80–200 mesh) were used as chromatographic stationary phases. Melting points are uncorrected.

*β-(o-Acetotoluidino)-2-nitrostyrenes (**9** and **10**)*

To a solution of *o*-acetotoluidide (1.65 g, 0.011 mol) in dry dimethylsulfoxide, under nitrogen, was added a 50% sodium hydride oil dispersion (0.1 g, 0.002 m). The mixture was stirred for 30 min followed by dropwise addition of a solution of *o*-nitrophenylacetylene (1.47 g, 0.01 m) in dimethylsulfoxide (10 ml). The mixture was stirred at room temperature for about 20 h and then made acidic with acetic acid. The solvent was removed under reduced pressure (35°/0.1 mm) and the residue transferred to a silica gel column (50 g) and eluted with 10% ether in hexane (0.85 g, 27% of *trans* product and 1.5 g, 52% of *cis* product). *trans*-β-(*o*-Acetotoluidino)-2-nitrostyrene (**10**), m.p. 80 °C; n.m.r. ($CDCl_3$): δ 1.88 (s, CH_3), 2.23 (s, CH_3), 5.70 (d, J = 14 Hz, 1H), 7.0–8.0. (m, 9H); i.r.: 1690 (C=O) 1635 cm^{-1} (C=C); mass spectrum: 296 (8), 251 (6), 236 (8), 149 (28), 132 (32), 120 (48), 118 (91), 107 (50), 91 (89), 43 (100). *cis*-β-(*o*-Acetotoluidino)-2-nitrostyrene (**9**), m.p. 100 °C; n.m.r.: δ 1.77 (s, CH_3), 2.08 (s, CH_3), 6.16 (d, J = 9, 1H), 6.7–7.7. (m, 9H); i.r.: 1680 (C=O), 1640 cm^{-1} (C=C); mass spectrum: 296 (4), 251 (8), 236 (10), 149 (27), 132 (30), 120 (49), 118 (90), 107 (49), 91 (88), 43 (100).

*β-(o-Acetotoluidino)-2-aminostyrenes (**4** and **5**)*

A solution of *cis*-β-(*o*-acetotoluidino)-2-nitrostyrene (**9**) (0.6 g, 0.002 mol) and $FeSO_4 \cdot 7H_2O$ (5 g, 0.018 mol) in 40 ml of a methanol–water mixture (1:1) was heated to reflux. Concentrated ammonium hydroxide (4 ml) was added and the mixture refluxed for 30 min. The mixture was cooled, filtered, and the filtrate concentrated under reduced pressure to one-half the original volume, then extracted with chloroform. The chloroform layer was then extracted with a 2 *N* HCl solution. The aqueous layer was basified with NH_4OH and extracted with chloroform. The chloroform layer, after drying and removal of solvent, yielded *cis*-β-(*o*-acetotoluidino)-2-aminostyrene (**4**) (0.3 g, 50% yield), m.p. 77 °C; n.m.r.: ($CDCl_3$): δ 1.77 (s, CH_3), 2.12 (s, CH_3), 3.50 (s, NH_2), 5.71; (d, J = 9 Hz, 1H), 6.2–7.0 (m, 8H), 7.21 (d, J = 9 Hz, 1H); i.r.: 3380, 3480. (NH_2), 1660 cm^{-1} (C=O); mass spectrum: 266 (16), 248 (8), 223 (10), 208 (19), 149 (30), 119 (36), 118 (100), 107 (45).

Anal. Calcd. for $C_{17}H_{18}N_2O$: C, 76.66; H, 6.81; N, 10.52. Found: C, 76.60; H, 6.86; N, 10.21.

trans-β-(*o*-Acetotoluidino)-2-nitrostyrene (**10**) (0.3 g, 0.001 mol) when reduced under the same conditions yielded *trans*-β-(*o*-acetotoluidino)-2-aminostyrene (**5**) (0.18 g, 61%), m.p. 155 °C; n.m.r. ($CDCl_3$): δ 1.83 (s, CH_3), 2.20. (s, CH_3), 3.37 (s, NH_2), 5.20 (d, J = 14 Hz, 1H), 6.44–7.37 (m, 8H), 8.00 (d, J = 14 Hz, 1H); i.r.: 3380, 3450 (NH_2), 1650 cm^{-1} (C=O); mass spectrum: 266 (7), 223 (5), 208 (5), 149 (17), 118 (34), 117 (100), 107 (50).

*N-2-(o-Aminophenyl)-ethyl-N-(o-tolyl)acetamide (**6**)*

trans-β-(*o*-Acetotoluidino)-2-nitrostyrene (**10**) (0.6 g, 0.002 mol) and 5% palladium-on-carbon (0.1 g) in ethanol (10 ml) was stirred under hydrogen at atmospheric pressure for 4 h. The solution was filtered and the solvent removed *in vacuo* to yield compound **6** (0.6 g, 95% yield), m.p. 113–115 °C; n.m.r. ($CDCl_3$): δ 1.8 (s, 3H), 2.3 (s, 3H), 2.7–4.2 (m, 4H) 4.5 (bs, 2H, D_2O exchangeable), 6.5–7.4 (m, 8H); i.r.: 1650, 3370, 3490 cm^{-1}; mass

spectrum: 268 (6), 149 (6), 120 (65), 119 (75), 106 (16), 84 (35), 56 (75), 43 (100).

4,5-Dihydro-2-methyl-3-(o-tolyl)-3H-1,3-benzodiazepine

Compound **6** (0.6 g, 0.002 mol) and phosphorous oxychloride (0.17 g, 0.0011 mol) in methylene chloride (20 ml) was heated under reflux for 16 h. After cooling, pyridine (0.4 g, 0.005 m) was added and the mixture stirred at room temperature for 30 min. The mixture was concentrated *in vacuo* to a small volume and the residue distributed between ether and an aqueous sodium carbonate solution (10%). The ether layer, after removal of the solvent and distillation (160 °C/0.1 mm), yielded 4,5-dihydro-2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine (0.4 g, 70%); n.m.r. ($CDCl_3$): δ 1.85 (s, CH_3), 2.24 (s, CH_3), 3.07–3.27 (m, 2H), 3.57–3.77 (m, 2H), 6.8–7.2 (m, 8H); i.r. 1620 cm^{-1} (C=N); mass spectrum: 250 (57), 235 (7), 132 (50), 131 (100), 130 (70), 119 (50), 91 (68), 90 (54), 77 (35), 65 (43), 43 (35).

*Reaction of **4** with Molecular Sieves*

cis-β-(*o*-Acetotoluidino)-2-aminostyrene (**4**) (1.1 g, 0.0045 mol) and freshly activated (by heating at 170° for 24 h) molecular sieve (Davison Chemical, 4A, 14–30 mesh granules) in dry benzene (50 ml) was heated under reflux for 16 h. The mixture was then filtered and the molecular sieve washed with fresh benzene. The solvent was removed *in vacuo* and an ether–hexane mixture (9:1, 10 ml) was added. The solid which formed was recrystallized from ether–hexane to yield compound **13** (0.36 g. 32%), m.p. 138–140 °C; i.r. 3400. (NH), 1660 cm^{-1} (C=O).

The mother liquors on distillation yielded 2-methyl-3-(*o*-tolyl)-3*H*-1,3-benzodiazepine (**11**), (b.p. 140 °C/0.05 mm) (0.15 g, 25%); i.r.: 1680 cm^{-1} (C=N); mass spectrum: 248 (20), 131 (100), 117 (35), 116 (30), 105 (40). A better yield of **13** (60%), could be obtained by using molecular sieve 3A in refluxing benzene for 72 h.

The Formation and Decay of the Paramagnetic Species Formed on the Surface of Al_2O_3–MoO_3 with Anthracene/Benzene Solution

HISASHI UEDA AND NAOYUKI TODO

National Chemical Laboratory for Industry, Meguro-ku, Tokyo, Japan

Received May 30, 1972

MoO_3 supported on alumina in a flow-through type sample tube was fixed in an e.s.r. cavity and anthracene solutions in benzene were passed through it at 20 °C. Three paramagnetic species were observed. One was Mo^{5+}, one was the anthracene cation R^+, and the remaining one was R^+O^{*2-} previously reported. Formation of R^+ and R^+O^{*2-} was complete within a few minutes after the contact of the solution after which the decay of R^+ became apparent. R^+ disappeared in a pseudo-first order reaction which actually was a second order reaction with the water dissolved in the solution. The rate constant for the reaction, $R^+ + H_2O \rightarrow$ diamagnetic products, was 0.34 l mol^{-1} s^{-1}. R^+O^{*2-} was completely stable during the measurement and even after draining the solvent or after drying the oxide particles with N_2 gas. It was concluded that Mo^{5+} was formed from two R^+ and H_2O molecules. The time dependence of the concentration of R^+ was found to be $[R^+] = [R^+]_0 \exp(-kt)$ and that of Mo^{5+}, $[Mo^{5+}] = [Mo^{5+}]_\infty (1 - \exp(-kt))$ where the subscripts zero and infinity indicate the time $t = 0$ and $t = \infty$ respectively. The present results seem to indicate that the more important paramagnetic species which influences the catalytic processes is not the cation R^+ but the complex ion R^+O^{2-}.

Le MoO_3 fixé sur alumine dans un tube à échantillon à flux continu, est placé dans la cavité d'un appareil RPE puis traversé par des solutions benzéniques d'anthracène à 20 °C. Trois espèces paramagnétiques ont été observées: Mo^{5+}, R^+ cation anthracène et R^+O^{*2-} précédemment rapporté. La formation de R^+ et R^+O^{*2-} est totale en quelques minutes, après contact de la solution, dès que la disparition de R^+ devient apparente. Cette disparition de R^+ se fait selon une réaction de pseudo-premier ordre qui est, en réalité, une réaction d'ordre deux avec l'eau dissoute dans la solution. La constante de vitesse de la réaction $R^+ + H_2O \rightarrow$ produits diamagnétiques, vaut 0.34 l mol^{-1} s^{-1}. R^+O^{*2-} est d'une stabilité complète durant la mesure et même après élimination de solvant ou sèchage des particules d'oxyde par N_2 gazeux. On a conclu à la formation de Mo^{5+} à partir de deux molécules de R^+ et H_2O. L'influence du temps sur la concentration de R^+ s'exprime en $[R^+] = [R^+]_0 \exp(-kt)$ et celle de Mo^{5+} en $[Mo^{5+}] = [Mo^{5+}]_\infty (1 - \exp(-kt))$ où les indices indiquent les temps $t = 0$ et $t = \infty$. Ces résultats semblent indiquer que les espèces paramagnétiques les plus importantes qui influent sur les processus catalytiques, ne sont pas le cation R^+ mais l'ion complexe R^+O^{*2-}. Introduction

The formation of charge transfer complexes and carbonium ions on the surface of silica–alumina particles was first established by visible absorption spectroscopy using 1,1-diphenylethylene and triphenylethylene (ref. 1, papers 62 and 65). Subsequently several attempts were made to detect these ionic molecular species by electron spin resonance (e.s.r.) method. The e.s.r. spectra of cations of hydrocarbons such as naphthalene, anthracene, and perylene (2–5) and the cations of 1,1-diphenylethylene, aniline, and diphenylamine (6, 7) were successfully observed by adsorbing the hydrocarbons on silica–alumina from a solution. These cations were considered to arise from the Lewis acid points on silica–alumina after charge transfer from these points to the added hydrocarbons, or as charge transfer complexes. As hydrocarbon cations are quickly decomposed by water, the removal of the last traces of water from these systems by a vacuum technique was essential in those experiments (2–7).

A different method to observe paramagnetic species on the surface of zinc oxide (8), alumina (9), and other oxides (10) was employed by Ueda and co-worker. The oxide powder was dipped in the benzene solution of an aromatic hydrocarbon or its derivative, the solution was then evaporated at room temperature. The paramagnetic species thus formed were stable and their e.s.r. spectra did not show any hyperfine structures. It was concluded that these species were complex ions R^+O^{*2-}, formed by an active O^{2-} surface ion(s), O^{*2-}, and the aromatic hydrocarbon, R.

Until now the relation between these two paramagnetic species, *viz.* the one formed on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

surface of silica–alumina in vacuum and the one formed on the surface of various oxides in air (with some humidity) was unknown. The rate constants for reactions by which the hydrocarbon cations are formed from hydrocarbon and Lewis acid points on the oxide surface have not been known. Nor have those for the disappearance of the hydrocarbon cations when reacted with water and other poisoning substances. In the present work the relation between these two paramagnetic species and the rate constants of their reactions with water have been studied and are reported.

Experimental

An anthracene solution was passed through a layer of the oxide particles supported on a fused silica filter in a silica sample tube placed inside the resonant cavity. Only a small portion of the solute in the solution was consumed and therefore the overall rate of formation of the paramagnetic species was only slightly affected by the flow rate. A JES-3BX type x-band e.s.r. spectrometer was used. The incident microwave power to the sample cavity was attenuated to 15 mW. A silica tube (5 mm o.d.) containing the filter section was inserted into the sample cavity. The benzene solution of anthracene was stored in a 500 ml reservoir and was delivered by a syringe pump into the top end of the silica sample tube through a flow meter. The solution which passed through the oxide layer was discarded from the lower end of the sample tube. The flow rate of the solution was 6.0 ml/min, therefore the measurement could be continued for 90 min. The anthracene used was purified by passing its solution through an activated alumina powder and then by recrystallization. The oxide particles used contained 8.5% MoO_3 supported on γ-alumina. Molybdenum was first supported as ammonium molybdate on γ-alumina from an aqueous solution and then was calcined at 550 °C for 1 h. Particle size was 10–20 mesh. The solvent benzene used contains 0.050% water, which is equivalent to 2.4×10^{-2} mol/l. This small amount of dissolved water was slowly adsorbed by the oxide and so that the "Q" of the resonant cavity was slowly reduced, which reduced the sensitivity of detection. To correct the variation in the sensitivity of the apparatus, one of the absorption lines of Mn^{2+} also present inside the cavity was repeatedly measured between the sample measurements. The time dependent intensity of the Mn^{2+} signal thus obtained was used for the sensitivity calibration. The spin concentration, c, was calculated as $c = c_0 I/I_0$ where c_0 is the concentration of the standard DPPH sample, I is the e.s.r. intensity of the unknown sample and I_0 is the e.s.r. intensity of the standard DPPH sample. $I = sh$ was used to determine the e.s.r. intensity, where s is the area enclosed by an integral e.s.r. absorption curve of a standard height and h is the height of the integral absorption curve of each spectrum.

Results

In Fig. 1 the e.s.r. absorption intensities of the Mn^{2+} line appearing at $g \simeq 2.14$ (or belonging

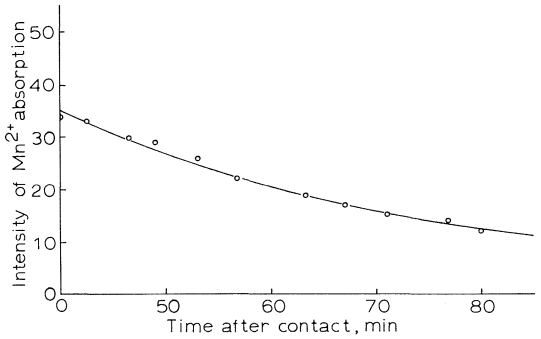

FIG. 1. Intensities of the experimental Mn^{2+} lines. The data in this figure were obtained from a 1 mmol/l solution of anthracene. The line measured belongs to $M_I = +5/2$ of the manganese nucleus.

to the nuclear spin quantum number of $+5/2$) are shown as a time dependent curve; the sensitivity calibration was made from this curve. Figure 1 was obtained when the anthracene concentration was 1 mmol/l, but similar results were observed at other anthracene concentrations. The approximately linear decrease with respect to time of the Mn^{2+} line at t, $m(t)$, will be proportional to the intensity of the sample absorption $I(t)$ with a proportionality factor $i(t)$

$$I(t) = i(t)m(t)$$

$m(0)$ is now used as a standard reference, where $t = 0$ means the moment at which the benzene solution was introduced. If $I'(t)$ is defined as

$$I'(t) = I(t)m(0)/m(t)$$

it represents the e.s.r. intensity compensated for the sensitivities of the e.s.r. detection system. As $I(t)$ is equal to $i(t)m(t)$, $I'(t)$ is equal to $i(t)m(0)$ and gives the relative e.s.r. intensity. Figure 2 shows the time dependence of $I'(t)$ obtained by the anthracene solution of 2 mmol/l. Two absorptions were observed, one at $g = 1.933$ and another at $g = 2.003$. The line at $g = 1.933$ is due to Mo^{5+} (11). The intensity of this line, y, as a function of time is given by

$$y = y_\infty(1 - \exp(-kt))$$

where k is the rate constant concerned. The initial dotted part of the curve means that no detection of the signal was made in this period because here the solution begins to flow into the cavity section of the sample tube and therefore adjustment of the microwave frequency must be done manually. Before the solution flowed in, the concentrations of both paramagnetic species were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

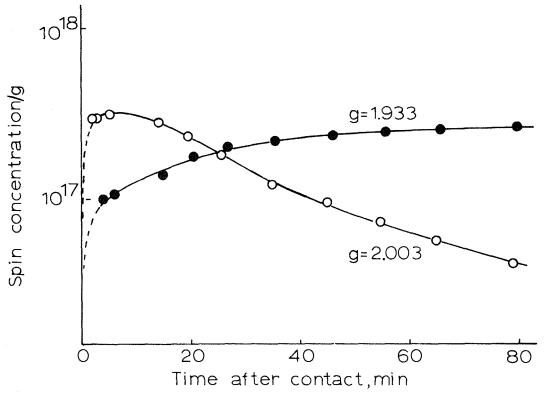

FIG. 2. Spin concentrations observed in Al_2O_3–MoO_3. The dotted initial parts of the curves were drawn as an extrapolation. The concentration of anthracene was 2 mmol/l.

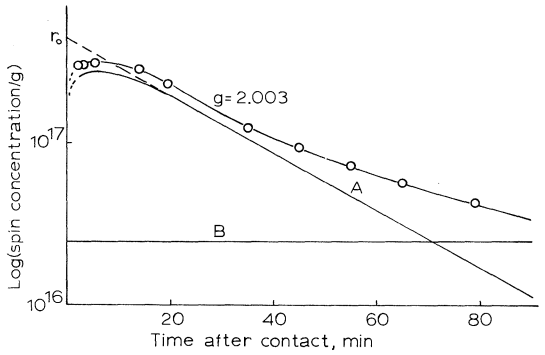

FIG. 3. The analysis of the intensity curve for $g = 2.003$ in Fig. 2, r_0 was obtained as an extrapolation of the component A to $t = 0$.

less than 1×10^{15} spins/ml ($g = 2.003$) and 5×10^{15} spins/ml ($g = 1.933$). The intensity curve of $g = 2.003$ in Fig. 2 can be separated into two components A and B as shown in Fig. 3. The component A can be written as

$$r = r_0 \exp(-kt)$$

except in the initial formation period, where r is the e.s.r. intensity, r_0 is the extrapolated value at $t = 0$, Fig. 3, and k is the rate constant already mentioned. The rate constant calculated from these data as

$$k = \log(r_1/r_2)/0.43294(t_2 - t_1)$$

is shown in Table 1, and is observed to be independent of anthracene concentration. The numerical values for the k calculated from y and those calculated from r are experimentally identical.

TABLE 1. The decay rate constant k and the concentrations of the paramagnetic species*

Anthracene (mmol/l)	k ($\times 10^{-4}$ s^{-1})†	b ($\times 10^{17}$ spins/g)	r_0 ($\times 10^{17}$ spins/g)
0.54	7.76	0.042	1.29
1.03	7.84	0.154	2.61
2.02	7.45	0.247	4.64
3.02	7.70	0.281	1.97
4.04	7.07	0.281	2.81
6.01	7.09	0.422	5.30
8.21	7.23	0.464	3.84

*The values obtained at 15 mW of incident microwave power.
†The average value is 7.45×10^{-4} s^{-1}.

The component B is a stable species and its concentration, b, is constant in the time scale of 90 min. However, the slope in Fig. 4 (2 h–20 h region) yield a decay rate constant of 5×10^{-6} s^{-1} for component B, *cf.* 7×10^{-4} s^{-1} for component A. The values b and r_0 are also shown in Table 1.

All the paramagnetic species have been thus far assumed to exist on the surface of Al_2O_3–MoO_3 particles, and not in the solution. In fact, as shown in Fig. 4, the change of e.s.r. intensities observed in the solution-flow-and-drainage, and N_2-purge treatments indicate that the assumption has been correct. Most of the unpaired electrons did not escape from the sample section by the drainage. As there is oxygen in the anthracene–benzene solution, one might suspect that the chemical species which destroys the paramagnetic species of the component A in Fig. 3 might be oxygen atoms or molecules.

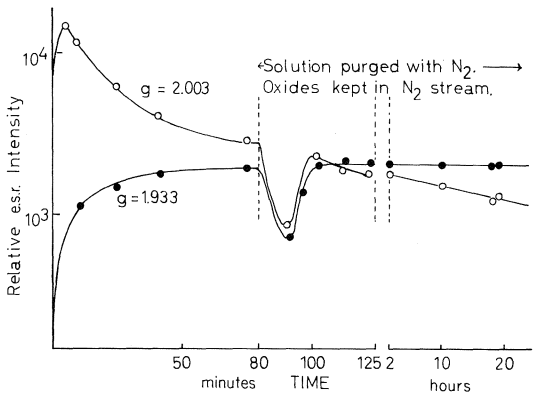

FIG. 4. The relative e.s.r. intensities observed during a solution-flow-N_2-purge period. The time axis after 125 min is in hours. The drop of both curves, after the N_2-purge was started, is due to cooling of the sample section in the cavity caused by the evaporation of benzene.

This is disproved by shaking the benzene solution with concentrated sulfuric acid and then distilling in a vacuum line three times. Well degassed Al_2O_3–MoO_3 particles and anthracene were added in vacuum, the anthracene cation thus formed was measured by e.s.r., again in vacuum. Oxygen was then introduced into the sample tube but it had no effect on the e.s.r. spectrum. Oxygen is thus not responsible for the decay of component A in Fig. 3.

Figure 5 indicates the e.s.r. spectra observed during 2–3 min period after contact of anthracene solution with the oxide layer. It is a composite of the e.s.r. spectra of component A and component B. The hyperfine component in the figure is ascribed to the component A because of its first order decay rate, $7.5 \times 10^{-4}\ s^{-1}$. As the spectral shape depends on the power of the incident microwave, the ratio of component A to component B in Fig. 5 is to be understood as that for 15 mW. At a lower incident microwave power such as 2 mW, a larger ratio of component A to component B was observed. Under the observed spectrum, an ideal e.s.r. spectrum, based upon the one obtained by the anthracene cation observed in concentrated H_2SO_4 but with zero line width, is shown with proton splittings of -6.53 G (9- and 10-positions), -3.06, and 1.38 G (1, 4, 5, 8- and 2, 3, 6, 7-positions, respectively) (12). The two spectra were compared by a simulation method. If one assumes the functional shape of each absorption line (*i.e.* $\exp(-aH^2)$) and a reasonable line width constant ($a = 50\ G^{-2}$ in the preceding formula) a simulated absorption curve in which the peak positions and the peak intensity is quite similar to the observed hyperfine structure is obtained. Only the positions of the major anion e.s.r. lines are shown at the bottom of Fig. 5. The corresponding cation e.s.r. lines (with the same relative intensities) are connected with the broken lines. Anion proton hyperfine splittings are -5.34, -2.74, and -1.51 G respectively (12). It was not found possible, with any simulation parameters tried, to fit the ideal anion spectrum to the experimentally observed hyperfine spectrum, although the cation ideal spectrum can be fitted to the experimental spectrum very easily. Therefore, the e.s.r. spectrum shown in Fig. 5 is from the anthracene cation and not from the anion.

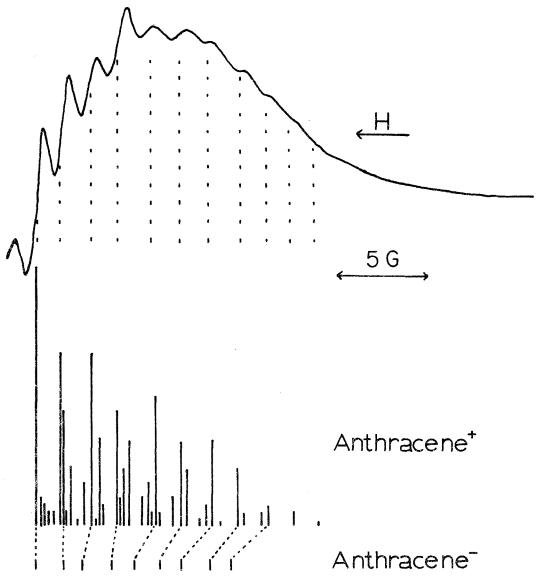

FIG. 5. The hyperfine structure of the species giving rise to the component A in Fig. 3. An ideal (width = 0) e.s.r. spectrum for anthracene cation is shown in the middle. The positions of the corresponding stronger lines of the anion spectrum are shown at the bottom of the figure.

The component B does not exhibit a hyperfine structure, and the shape of the spectrum is identical to that already reported for R^+O^{*2-} complex ion on alumina surface (10). In Fig. 6, the concentration of Mo^{5+}, y, is plotted against that of anthracene cation R^+, r; the equation

$$r + 2y = \text{constant}$$

fits these data approximately.

Figure 7 shows the effect of C_6H_6 and H_2O on the paramagnetic species formed on the sur-

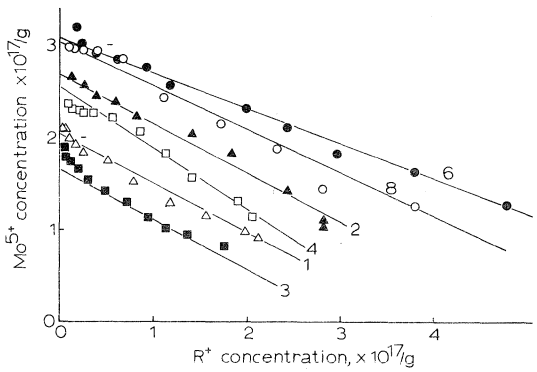

FIG. 6. The relation between the concentration of R^+ and Mo^{5+}. The figures shown at the end of each line indicate the concentration of anthracene in mmol/l.

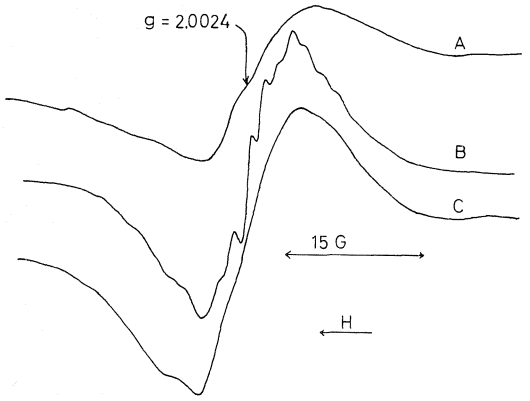

FIG. 7. The effects of benzene and water on the e.s.r. of anthracene–Al_2O_3–MoO_3 system. A: 0.07 g anthracene + 0.7 g Al_2O_3–MoO_3 evacuated. B: after 70 mm Hg of benzene introduced. C: after further addition of 20 mm Hg of water vapor. The overlapped hyperfine structure in B is due to anthracene cation.

face of Al_2O_3–MoO_3. A was obtained by 0.07 g of anthracene powder mixed with 0.7 g of Al_2O_3–MoO_3 after evacuation to 10^{-4} mm Hg for 10 min; B was obtained by introducing 70 mm Hg of benzene vapor into the sample which gave A; C was obtained by introducing 20 mm Hg of H_2O vapor into the sample which gave B.

Discussion

Two Paramagnetic Species

Figures 3 and 7 indicate the existence of two paramagnetic species. The reactive one has been shown to be anthracene cation in Fig. 5. The results in Fig. 4 indicate that the paramagnetic species giving rise to component B in Fig. 3 is identical to the stable paramagnetic species R^+O^{*2-} proposed by Ueda (9, 10). The concentration of B, *b*, does depend on the concentration of the solute, as shown in Table 1, but by Ueda's method of preparing R^+O^{*2-} the concentration of the solution immediately before the complete evaporation of the solvent reaches the solubility limit of the solute except in the case of a very dilute solution in which all the solute has been adsorbed by the oxide surface before complete evaporation of the solvent. Therefore, the concentration (per gram) of R^+O^{*2-} on the oxide surface depends only on the magnitude of the surface area and the surface properties of the oxide particle.

Some information on the relation between R^+ and R^+O^{*2-} are found in Figs. 3 and 7. As both species have cationic properties (if one considers O^{2-} in the lattice as an electronically neutral species in the sense that the ionization potential of O^{2-} in the lattice is not low), it may be anticipated that the two species are related in the following manner

$$R^+ \rightarrow X \rightarrow R^+O^{*2} \rightarrow Y \rightarrow \text{decay}$$

and so on. However, as shown in Fig. 7, the formation of anthracene cation requires the presence of benzene vapor while the formation of R^+O^{*2-} does not. Therefore, it should be concluded that the immediate origins of these two species are different and in that sense they exist independently. No perylene cation is formed when perylene solution is mixed with unsupported silica although perylene cation is formed on MoO_3-supported silica and mixed with perylene solution in the same way.[1] It is therefore concluded that R^+ is formed by a charge transfer reaction between anthracene and Mo^{6+}. R^+O^{*2-}, however, has been shown to be formed by anthracene and an active surface anion, O^{*2-} (9, 10).

Reaction of Anthracene Cation

The following shows that the apparent first order decay rate of R^+ is caused by the pseudo-first order reaction with water. The solution fed through the catalyst layer in the sample tube in the resonance cavity contains only benzene, anthracene, O_2, N_2, and H_2O. N_2 is known to be inactive with aromatic cations. In the present work, benzene and O_2 have been found to have no effect on the cation e.s.r. spectrum. On the other hand, H_2O destroyed the anthracene cation very effectively, as shown in Fig. 7. As the concentration of H_2O was always constant (2×10^{-2} mol/l), there is no way to interpret the apparent first order decay rate of R^+ other than by considering it to be a pseudo-first order reaction with H_2O. The average value of the pseudo-first order reaction rate constant in Table 1 is 7.45×10^{-4} s^{-1}. The reaction actually taking place is, therefore, a second order reaction,

$$[1] \qquad R^+ + H_2O \xrightarrow{k'} P + Q$$

where P and Q denote the reaction products. If the concentration of water is contained in *k*,

For personal use only.

k' can then be calculated and is 3.10×10^{-2} l mol^{-1} s^{-1}. It can be assumed that the reaction 1 is essentially the reaction between R^+ and OH^- existing in H_2O. If so,

$$[2] \qquad R^+ + OH^- \xrightarrow{k''} P' + Q'$$

As $[OH^-]$ is 10^{-7} mol/l, $k'' = 3.10 \times 10^5$ l mol^{-1} s^{-1} is obtained. This value is not far from the neutralization reaction rate constant between NH_4^+ and e_{aq}^- observed by pulse radiolysis, $\simeq 10^6$ l mol^{-1} s^{-1}, (13) so that the reaction scheme 2 is not unreasonable.

The formation of Mo^{5+}

It is shown in Fig. 6 that

$$r + 2y = \text{constant}$$

If y is differentiated with respect to r

$$dy/dr = -1/2.$$

This indicates that one Mo^{5+} is formed when two R^+ are lost. Therefore

$$[2'] \qquad 2R^+ + 2OH^- + Mo^{6+} \rightarrow Mo^{5+} + X$$

will be taking place. An electronically negative species, Mo^{5+} $(= Mo^{6+} + e^-)$ formed from R^+ is rather puzzling, but

$$[2''] \quad 2R^+ + 2OH^- \rightarrow 2RO + 2H$$

$$[3] \qquad 2H + Mo^{6+} \rightarrow Mo^{5+} + H^+ + 0.5H_2$$

will explain [2']. Only 50% of hydrogen atoms formed are assumed to reduce Mo^{6+} in [3]. As

$$y = \text{constant} - 0.5r$$

and

$$r = r_0 \exp(-kt)$$

$$y = \text{constant} - 0.5r_0 \exp(-kt)$$

is obtained. As

$$y = y_\infty (1 - \exp(-kt))$$

is observed experimentally, then

$$y = 0.5r_0 (1 - \exp(-kt))$$

should hold with

$$y_\infty = 0.5r_0$$

Some deviation from this last relation is found in Fig. 6, but, it is satisfied approximately.

Initial Reaction Rate

In Fig. 2, no measurements were made between $t = 0$ and $t = 2$, though the value at $t = 0$ was observed. Under the present experimental conditions, the linear flow rate of the solution was 1.41 cm/s and so the time required to wet all the oxide particles (filled length was 45 mm) was 3 s. This value is negligible when compared with 2 min. However, the space among oxide particles is filled with air which must be replaced with the solution. Not all the air among the particles is removed at the first contact of the solution and some bubbles are observed during the first minute. As the wave length of light in air and in benzene is considerably different, the automatic frequency control does not work during this period. Thus, the present experimental procedures cannot eliminate the 2 min period without measurement. One possible solution to this problem will be to fill the space among oxide particles with pure benzene and then switch to anthracene solution. But the initial anthracene concentration will then change greatly and this makes the analysis of the results complicated. A variation of this method is to inject anthracene solution into the flow path of pure benzene as a pulse. The analysis of this pulse method will also be complicated, and for this reason these experiments were not included in this work.

However, if a few assumptions are made, the initial rate of formation of anthracene cation can be estimated. The anthracene cation is formed by the reaction

$$R + L^+ \rightarrow R^+ + L$$

where R signifies anthracene molecule and L^+ signifies the Lewis acid point. If the concentration of L^+ is written as l, and its initial value as l_0, and the concentration of R^+ is written as r,

$$(dr/dt)_{\text{formation}} = k_i[R][L^+] = -dl/dt$$

By writing

$$k_i[R] = k_j$$

$$l = l_0 \exp(-k_j t)$$

is obtained. R^+ decays by reaction with H_2O with an apparent first order decay rate constant k_d. Therefore,

$$dr/dt = k_i[R][L^+] - k_d r = k_j l_0 \exp(-k_j t) - k_d r$$

is solved, and r thus obtained is

$$r = r_0 \exp(-k_d t) - k_j l_0 \exp(-k_j t)/(k_j - k_d)$$

The experimental results show that $k_j > k_d$.

When $t \to 0$, $r \to 0$, so that

$$r_0 - k_j l_0/(k_j - k_d) = 0$$

By approximating

$$k_j l_0/(k_j - k_d) \simeq l_0$$

$$r_0 = l_0$$

is obtained. The maximum point of the r–t curve is then given by

$$dr/dt = 0 = l_0(k_j \exp(-k_j t) - k_d \exp(-k_d t))$$

The time, t, obtained by solving this equation is

$$t = (\log_e (k_j/k_d))/(k_j - k_d)$$

The time for the maximum point observed in Fig. 3 is about 305 s. The k_d value observed is 7.45×10^{-4} s^{-1}, whence the value of k_j is estimated as 8.9×10^{-3} s^{-1}. As the value of [R] is 2×10^{-3} mol/l, $k_i = 4.5$ l mol^{-1} s^{-1} is obtained.

Implications for Catalyst Activity

Acid points on the surface of oxide catalysts are said to be the active point for isomerization reactions. The Lewis acid point, which makes the anthracene cation, has been deduced to be such a point. However, on the oxide surface another point exists at which paramagnetic species are formed, namely O^{*2-} sites. As shown in Fig. 3, the cation-forming points were destroyed in the earliest period of the flow of the anthracene solution containing water and were never regenerated again, at least at 20 °C. In other words, they are too sensitive to poisoning. Compared with it, R^+O^{*2-} was stable and resistant to poisoning. Therefore, repeated catalytic reactions seem to be possible with the O^{*2-} surface ions although not with the Lewis acid points at which the anthracene cation is formed. However, the results in Fig. 3 have been observed at 20 °C. At higher temperatures, poisoned acid points might be regenerated. These points will be investigated in future studies.

The authors wish to thank Mr. K. Ogawa for his assistance in the preparation of the mixed oxide.

The Barrier to Rotation in 2,2′-iminobis (acetamidoxime) and its Nickel(II) and Zinc(II) Complexes

ROGER E. CRAMER[1] AND ROBERT DERYKE

Department of Chemistry, University of Hawaii, 2545 The Mall, Honolulu, Hawaii 96822

Received July 19, 1972

The free energy of activation at the coalescence temperature was measured for the rotational barrier about the amide bond in 2,2′-iminobis(acetamidoxime) (IBO) and its Ni(II) and Zn(II) complexes. The barrier is 10.5 ± 0.3 kcal/mol and increases by about 1 kcal/mol upon coordination of Ni(II) and Zn(II). By means of INDO molecular orbital calculations it is shown that the amide proton *trans* to the donor nitrogen experiences the largest isotropic shift in $Ni(IBO)_2(NO_3)_2$ and that the major portion of spin delocalization takes place through the oxime nitrogen σ donor orbital, which is not the highest filled orbital of the ligand.

L'énergie libre d'activation à la température de coalescence a été mesurée pour la barrière de rotation autour de la liaison amide pour le 2,2′-iminobis(acétamidoxime) (IBO) et pour ses complexes avec le Ni(II) et Zn(II). Cette barrière vaut 10.5 ± 0.3 kcal/mol et augmente d'environ 1 kcal/mol par coordination avec le Ni(II) et Zn(II). Les calculs des orbitales moléculaires selon la méthodes INDO montrent que le proton amide *trans* par rapport à l'azote donneur subit le déplacement isotrope le plus grand dans $Ni(IBO)_2(NO_3)_2$ et que la majeure partie de la délocalisation de spin se produit à travers l'orbitale donneur de l'azote de l'oxime, qui n'est pas l'orbitale occupée du ligand la plus élevée.

[Traduit par le journal]

Can. J. Chem., **51**, 892 (1973)

Introduction

While the barrier to rotation about C—N bonds in amides has been an active area of research for some time (1), there have been no reports of such a barrier in an amidoxime. In addition while limited information is available about the change in the magnitude of the rotational barrier of amides upon coordination to the amido oxygen of such Lewis acids as H^+ (2) and BF_3 (3), apparently no similar information is available for transition metal Lewis acids. The recent synthesis of 2,2′-iminobis(acetamidoxime) (4), $HN[—CH_2—C(NH_2)NOH]_2$, has provided access to amidoximes, and the crystal structures (5) of the Ni(II) and Cu(II) complexes of this ligand have shown that the C—NH_2 bond length is comparable to that found in many amides. Accordingly we have estimated the barrier to rotation about this bond for 2,2′-iminobis(acetamidoxime) (abbreviation, IBO) and its complexes with Ni(II) and Zn(II) by approximate n.m.r. methods.

Experimental

IBO

IBO was synthesized by the method of Eddy *et al.* (4).

$Ni(IBO)_2(NO_3)_2$

This complex was prepared by the method of Eddy (4) substituting $Ni(H_2O)_6(NO_3)_2$ for $Ni(H_2O)_6Cl_2$. Since the nitrate complex is much more soluble in H_2O than is the Cl complex, it was necessary to isolate the complex by evaporation of the H_2O. The crystals were washed with MeOH and dried.

Anal. Calcd. for $Ni(IBO)_2(NO_3)_2$: C, 19.03; H, 4.39; N, 33.28. Found: C, 19.44; H, 4.32; N, 32.73.

$Zn(IBO)_2(NO_3)_2$

This complex was prepared in the same manner as was $Ni(IBO_2)(NO_3)_2$.

Anal. Calcd. for $Zn(IBO)_2(NO_3)_2$: C, 18.78; H, 4.33; N, 32.85. Found: C, 19.14; H, 4.38; N, 33.00.

N.M.R. Spectra

Spectra were obtained using a Varian Associates HA-100 spectrometer operating in the HA mode and chemical shifts are reported with respect to internal TMS. Temperature was controlled by means of Varian Variable Temperature Controller Model V-6040. The estimated error in the temperature measurements is ±2 °C.

Barrier Calculations

The free energy of activation at coalescence ($\Delta G^{\neq}_c$) for the rotation was calculated from the Eyring equation (1*a*)

$$[1] \qquad \Delta G^{\neq}_c = 4.57T(10.32 + \log T_c/K_r)$$

where T_c is the coalescence temperature, K_r is the rate constant for the exchange of the two amide protons at this temperature, and is given by

$$[2] \qquad K_r = \pi\Delta\nu/\sqrt{2}$$

where $\Delta\nu$ is the separation between the amide peaks in the absence of exchange. For IBO and for $Zn(IBO)_2(NO_3)_2$, $\Delta\nu$ was obtained from spectra recorded at temperatures in the slow exchange region. In the case

TABLE 2. The free energies of activation for amidoxime rotational barriers

Compound	Solvent	Δν (Hz)	T_c (C°)	$\Delta G^{\neq}$ (kcal/mol)
IBO	DMF	25±1	−60±2	10.5±0.3
Zn(IBO)$_2$(NO$_3$)$_2$	MeOH	15±1	−47±2	11.5±0.3
Ni(IBO)$_2$(NO$_3$)$_2$	DMSO	3000±300	+17±2	11.8±0.4

of IBO the DMF solution froze at −80 °C and Δν became constant below −70 °C while for Zn(IBO)$_2$-(NO$_3$)$_2$ the freezing point of the solution was far below the coalescence temperature. In the case of Ni(IBO)$_2$-(NO$_3$)$_2$, the separation of the nonexchanging amide peaks is temperature dependent due to the paramagnetism of the molecule (for a recent review of the n.m.r. of paramagnetic molecules, see ref. 6). In order to estimate Δν at the coalescence temperature the position of the two amide peaks for temperatures below T_c was plotted *vs.* 1/*T*. Straight lines were realized between +7 °C and the freezing point of the solution at −5 °C which indicates slow exchange in this temperature region. These straight lines were extrapolated to T_c where Δν was taken as the difference between the extrapolated chemical shifts, as suggested by Ho and Reilley (7). Although this method produces a rather large error in Δν (see Table 2) the resultant uncertainty in $\Delta G^{\neq}_c$ is acceptable due to the logarithmic nature of eq. 1.

Results

The chemical shifts for the compounds studied here at room temperature are reported in Table 1. The data necessary for the calculation of the barriers to rotation from eqs. 1 and 2, as well as values for $\Delta G^{\neq}_c$ are reported in Table 2. We place no significance on the small (0.3 kcal/mol) difference reported for the Ni^{2+} and Zn^{2+} complexes due to the difficulty in measuring the paramagnetically broadened peaks in the Ni^{2+} case, and due to possible errors in the extrapolation procedure (*vide supra*). Considering the wide differences in the parameters which characterize these two systems, we feel that the small difference in the reported barriers supports their validity.

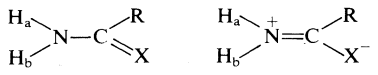
The p.m.r. spectrum of acetamide exhibits a broad featureless peak with a width at half-height of 70–80 Hz (8) due to relaxation caused by the quadrupolar ^{14}N (9). Roberts (10) has pointed out that the ^{14}N broadening is temperature sensitive, since slower molecular motion leads to more rapid relaxation of ^{14}N and thus sharper amide proton signals. It is found that larger amides have less broad proton peaks (10, 11) and that the peak width of any given proton decreases with decreasing temperature (8). The large size of the compounds reported here would lead us to expect narrow proton peaks at room temperature and the observed peak widths of 5–6 Hz for IBO and Zn(IBO)$_2$(NO$_3$)$_2$ are among the smallest reported for amido protons (10–12). The amide peaks also show a decrease in line width with decreasing temperature and at −10 °C both IBO and Zn(IBO)$_2$(NO$_3$)$_2$ exhibit line widths of 4 Hz. Attempts to decouple the ^{14}N from the protons at room temperature caused the line widths to decrease from 5–6 Hz to about 4 Hz, thus confirming that the ^{14}N is experiencing rapid relaxation and that its contribution to the proton line width is negligible at room temperature. Since the ^{14}N relaxation time decreases with decreasing temperature we conclude that quadrupolar broadening of the amido proton peaks will be negligible at the coalescence temperature, thus allowing the application of eqs. 1 and 2.

Discussion

Rotational Barrier of Amidoximes

The barrier to rotation about the C—NH$_2$ bond for IBO reported in Table 2 is among the lowest ever reported for an amide. It can be

compared to the value of 17.7 kcal/mol reported by Drakenberg and Forsin (13) for formamide. The lower barrier in the amidoximes compared to formamide is consistent with the trend in X groups pointed out by Kessler (1*a*) in that it closely resembles those found for other amides where X contains an imino nitrogen. Accordingly the barrier in IBO is quite similar to the values of 12 to 13 kcal/mol reported for some *N*-arylamidines (X = *N*—Aryl, R = $(CH_3)_2N$, H_a = H_b = Me) (14). The slightly higher barrier in this latter case may be due to the fact that the amido nitrogen substituents are methyl groups which are known to lead to barriers slightly higher than the corresponding protonic compounds (13). The low barrier reported here is also consistent with the failure of Neuman and Young (15) to observe two peaks for dimethylacetamidine (X = NH, R = H_a = H_b = Me) down to −40 °C. Thus we conclude that in amides containing the imino nitrogen, including the oxime group X = NOH, structure **1** is more favored than **2** for compounds containing nitrogen than oxygen, *i.e.*, there is more double bond character in the bond to an imino nitrogen than to a carbonyl oxygen.



1 **2**

Coordination of either Zn^{2+} or Ni^{2+} is seen to increase the barrier by about 1 kcal/mol or nearly 10%. This increase in the barrier of IBO upon coordination of Zn^{2+} and Ni^{2+} is comparable to that observed by other workers with similar systems. For example, Kessler (14) found that protonation of the imino nitrogen in *N*-arylamidines raised $\Delta G^{\neq}_c$ from 12.1 to 12.6 kcal/mol. Gore *et al.* (3) studied the effect of coordination of BF_3 upon the barrier in *N*,*N*-dimethylformamide, and treatment of their data by eqs. 1 and 2 shows that the barrier has increased to 21.9 kcal/mol (1*b*) from 20.9 kcal/mol for DMF. Although they had difficulty in measuring the coalescence temperature for the BCl_3 adduct, the approximate value given yields a $\Delta G^{\neq}_c$ of 22.1 kcal/mol. Due to the wide variations in these systems, detailed comparisons are not justified. Yet it does seem apparent that coordination of a Lewis acid at the X site does favor structure **2**, as expected, although the increase in barrier is only about 1 kcal/mol without regard to the details of the system.

Chemical Shifts

The chemical shifts of the protons of IBO and $Zn(IBO)_2(NO_3)_2$ are normal. The differences observed between IBO and $Zn(IBO)_2(NO_3)_2$ can be explained by the drain of electron density from the ligand upon coordination to the electrophilic Zn^{2+}. The NH_2 resonances of these compounds exhibit an interesting temperature dependence. In the case of IBO dissolved in MeOH this peak shifts from −5.43 p.p.m. at room temperature to −6.16 p.p.m. (average for two NH peaks observed at this temperature) at −75 °C, while in the case of the Zn^{2+} complex dissolved in DMF the shift is from −6.64 p.p.m. at 30 °C to −6.94 p.p.m. at −75 °C. Similar shifts as a function of temperature have been observed by Sunners *et al.* (16) for formamide in acetone and were attributed to a decrease in hydrogen bonding to the solvent at higher temperature. This explanation would also be expected to hold here, with the difference between the two systems being due to the greater acidity of the NH_2 protons in $Zn(IBO)_2^{2+}$ and the stronger Lewis base strength of DMF.

Isotropic Shifts

The chemical shifts of $Ni(IBO)_2(NO_3)_2$ are dominated by the isotropic shift resulting from the paramagnetism of the complex. The methylene shift is in close agreement with the values found for the methylene protons of $Ni(en)_3(Cl)_2$ (7). The only other report of a contact shifted hydroxyl proton of an oxime is by Baucom and Drago (17) who report a shift of −75 p.p.m. for this type of proton in *bis*(2,6-diacetylpyridine dioxime)nickel(II). Since the chemical shifts which we report here are the first to be reported for an amidoxime there is no other data with which to compare the NH_2 contact shift. The moderate downfield shift (18–19 p.p.m.) can however be contrasted with the large (≈100 p.p.m.) upfield shift found for the amino protons of $Ni(CH_3NH_2)_6^{2+}$ (18). Our inability to find the N—*H* proton is in accord with the very large line widths usually found for protons on amines coordinated to nickel(II) (7). The chemical shifts assignments reported here are supported by relative intensity and line width data as well as H–D exchange experiments.

Below the coalescence temperature, the chemical shifts of the two diasterotopic amido protons

of $Ni(IBO)_2(NO_3)_2$ are -10.0 p.p.m. and -40.0 p.p.m. respectively, at 0 °C. Subtracting the chemical shift of the amido protons of $Zn(IBO)_2(NO_3)_2$ to obtain isotropic shifts we have $\Delta\nu = -3.5$ p.p.m. and $\Delta\nu = -33.5$ p.p.m. From the spectra alone we have no way of assigning which of these two peaks is due to H_a and which is due to H_b of structure **1**. In a study of *N*-methyl lactams (19) coordinated to Ni(II), a larger isotropic shift was observed for the *N*-methylene group than for the *N*-methyl group. Thus the larger shift was found for the group *trans* to the carbonyl group. Since both the *N*-methyl lactams and IBO are amides with σ donor orbitals, and since all unpaired electrons of Ni(II) are in σ orbitals, we would expect a similar σ delocalization mechanism for the two ligands. Thus we might expect that H_a would experience the greatest isotropic shift.

In order to confirm these ideas we carried out INDO (20) molecular orbital calculations on the model compound acetamidoxime (R = CH_3, X = NOH). The highest filled molecular orbital in this compound is of π symmetry while the oxime nitrogen σ donor orbital, through which coordination to the Ni^{2+} ion takes place, is about 2.1 eV more stable than this π orbital. The usual method of estimating isotropic shifts from INDO calculations involves removing an electron from the highest filled molecular orbital (21), or replacing a nitrogen donor atom with a carbon atom (22). In the case of acetamidoxime both methods place unpaired spin in the highest filled orbital, which is of π symmetry. From our foregoing arguments we would not expect such a π mechanism to reproduce our experimental results for $Ni(IBO)_2^{2+}$, and this expectation is fulfilled. The radical cation predicts *upfield* shifts for both amido hydrogens, $R = A(H_a)/A(H_b) = -10.7G/-10.1G = 1.05$, while for the replacement by carbon we have $R = -7.8G/-8.7G = 0.89$. Experimentally, we find *downfield* shifts with an experimental ratio $R = -33.5$ (p.p.m.)/-3.5 (p.p.m.) = 9.6.

In order to test the σ mechanism we are faced with the problem of introducing spin into the oxime σ donor orbital. We could accomplish this by removing 3 electrons, *i.e.*, a 3+ cation, or by replacing the oxime nitrogen with a Be atom. It seems likely that both of these procedures would be so drastic as to render the results unreliable. We have therefore chosen to model the system in another way. We have placed a hydrogen atom in the position which would be occupied by the Ni(II) ion, *i.e.*, about 2.0 Å from the oxime nitrogen. Since the hydrogen atom has an unpaired electron, and is only capable of σ bonding with the ligand, it should be a reasonable qualitative, but not quantitative, probe for spin delocalization springing from a Ni(II) ion. The results of this calculation confirm our expectation that H_a has the larger coupling constant, and hence the larger contact shift. Thus this system is analogous to the *N*-methyl lactam system in that the greater shift is experienced by the amido nitrogen substituent *trans* to the donor atom. Comparison of the calculated ratios, $R = 0.508G/0.075G = 6.76$, with the experimental ratio 9.6 (*vide supra*) indicates reasonable agreement in view of the approximations necessary. The agreement is certainly much better than that discussed above for delocalization in a π orbital, and would indicate the primary spin delocalization is through the σ orbital. This is the first reported case where the delocalization is primarily found to be into the second highest filled orbital, rather than the highest filled.

We would like to thank Tom Bopp and John Gilje for useful discussions on this topic and to acknowledge the donors of the Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research.

Investigations of Substituent Effects by Nuclear Magnetic Resonance Spectroscopy and All-valence Electron Molecular Orbital Calculations. I. 4-Substituted Styrenes

GORDON K. HAMER,[1] IAN R. PEAT,[2] AND WILLIAM F. REYNOLDS

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received June 14, 1972

^1H and ^{13}C chemical shifts have been determined for over 20 4-substituted styrenes under conditions corresponding to infinite dilution in a non-polar medium. Correlations of the internal chemical shift difference for the β vinyl protons, $\Delta\delta(B - C)$ with electric field components estimated by a classical electrostatic calculation, with the field parameter *F*, and with hydrogen charge densities estimated by CNDO/2 MO calculations provide conclusive evidence for the existence of a through-space field effect. CNDO/2 calculations for 4-substituted 1-vinylbicyclo[2.2.2]octanes and ethylene–methylX pairs indicate that this through-space field effect has a geometric dependence similar to that predicted by the Buckingham equation.

Correlations of vinyl ^1H and ^{13}C chemical shifts and charge densities with field, *F*, and resonance, *R*, parameters provide a self-consistent picture of electronic effects in these compounds. ^1H chemical shifts for some derivatives are affected by magnetic effects but this does not obscure the overall pattern of electronic effects. This pattern of electronic effects can be completely accounted for by a model which assumes that substituent effects can be transmitted through space (field effects), via conjugative interactions (resonance effects) or by polarization of the styrene π electron system by the polar C—X bond (π polarization effects). The latter effect appears to be more important than previously realized.

^1H correlations with *F* and *R* are used to estimate self-consistent and apparently reasonable $\Delta\chi$ values for C≡N and C≡C—H groups and *F* and *R* values for carbonyl substituents and $(CH_3)_3M$ substituents (M = Si, Ge, Sn, and Pb). The halogens give anomalous results. A comparison of various correlations suggests that these anomalies are magnetic in origin.

Les déplacements chimiques de ^1H et ^{13}C ont été déterminés sur plus de vingt styrènes substitués en -4 dans des conditions de dilution infinie, en milieu non polaire. Les corrélations entre la différence de déplacement chimique interne pour les protons β vinyliques, $\Delta\delta(B - C)$ et les composantes du champ électrique évaluées par calcul classique d'électrostatique, le paramètre de champ *F*, et les densités de charge sur l'hydrogène obtenues par calcul CNDO/2 MO fournissent une preuve concluante de l'existence d'un effet de champ à travers l'espace. Les calculs CNDO/2 sur les vinyl-1 bicyclo[2.2.2]octanes substitués en 4 et sur les couples éthylène–méthyleX, montrent que cet effet spatial de champ dépend de la géométrie selon l'équation de Buckingham.

Les corrélations entre les déplacements chimiques du ^1H vinyle et ^{13}C, des densités de charge avec le champ *F* et les paramètres de résonance *R* fournissent une image cohérente des effets électroniques dans ces composés. Dans certains dérivés les déplacements chimiques du ^1H sont affectés par les effets magnétiques mais cela ne change pas l'allure générale des effets électroniques qui peut être totalement expliquée par un modèle qui suppose que les effets de substituants peuvent être transmis à travers l'espace (effets de champ), via des interactions de conjugaison (effets de résonance) ou par polarisation du système électronique π du styrène par la liaison C—X (effets de polarisation π). Ce dernier effet est plus important qu'on ne le pensait précédemmant.

Les corrélations entre ^1H avec *F* et *R* ont été utilisées pour apprécier les valeurs $\Delta\chi$ cohérentes et apparemment raisonnables pour les groupes C≡N et C≡C—H et les valeurs *F* et *R* pour les substituants du carbonyle et de $(CH_3)_3M$ (M = Si, Ge, Sn, et Pb). Les halogènes conduisent à des résultats anormaux. Une comparaison entre les diverses corrélations suggère que ces anomalies sont d'origine magnétique. [Traduit par le journal]

Can. J. Chem., **51**, 897 (1973)

Introduction

Zürcher (1) and Allinger and coworkers (2), have shown that the substituent dependence of proton chemical shifts for many aliphatic compounds can be accounted for in terms of the dipolar electric field effect and the anisotropic magnetic susceptibility of the substituent. The substituent dependence of proton chemical shifts (S.C.S.) for aromatic compounds is less certain. Miller and co-workers have summarized the results of approximately 100 correlations of S.C.S. for aromatic derivatives with Hammett

substituent constants (3):

$$[1] \qquad \delta^3 = \rho\sigma + \delta_0$$

However, many of the correlations were unsatisfactory (correlation coefficient, $r < 0.90$) and they concluded that the observed ρ values were not reliable measures of the efficiency of transmission of substituent effects (3). More recently, Wiley and Miller (4) have correlated S.C.S. with the divided field, F, and resonance, R, substituent constants of Swain and Lupton (5).

$$[2] \qquad \delta = fF + rR + \delta_0$$

While much better correlations were obtained, it was concluded that the correlations were physically meaningless since unrealistic values of the weighting factors, f and r, were found (4).

However, almost all of these investigations were carried out in interacting solvents (CCl_4 cannot be regarded as an inert solvent for p.m.r. measurements (6)) and often at finite solute concentrations. Consequently, the chemical shifts may reflect both solvent–solute and solute–solute interactions. In addition many investigations have involved a limited range of substituents, often including halogens or other substituents with uncertain magnetic anisotropy effects.

By contrast with ^1H chemical shifts, ^{13}C chemical shifts are relatively insensitive to magnetic anisotropy effects (due to the much greater chemical shift range (7)) and to solvent and concentration effects (8). Consequently ^{13}C chemical shift measurements have provided a considerable amount of information about electronic substituent effects in aromatic derivatives (9). ^{13}C chemical shifts primarily reflect substituent effects transmitted through the bonding network of the molecule.

An alternative approach for interpreting S.C.S. is to compare chemical shifts with electron densities determined by molecular orbital calculations. All-valence electron calculations of the CNDO/2 type (10) have proved to be particularly useful for investigations of ^1H (11, 12), ^{13}C (8, 13), and ^{19}F (14) chemical shifts of aromatic derivatives since they provide information about electronic effects transmitted through both π and σ electron systems. In addition, we have shown that they also reflect through space field effects (15).

In view of the uncertainties surrounding S.C.S. in aromatic derivatives, we decided to carry out a detailed investigation of a large family of closely related compounds, determining ^1H and ^{13}C chemical shifts under as inert conditions as possible and estimating electron densities by CNDO/2 (all-valence electron) molecular orbital calculations. The purpose of the investigation was threefold: to determine as completely as possible the electronic distributions in these compounds, to determine to what extent ^1H chemical shifts reflect this electronic distribution, and to interpret the three parameters listed above in terms of mechanisms of transmission of substituent effects. In order to fulfil this last aim it was decided to correlate chemical shifts with divided substituent constants. F and R were chosen since these are claimed to have the most complete division of field and resonance effects (5). However, since the use of F and R correlations has been severely criticized, we decided to use three criteria to test the validity of our correlations. First, ^1H and ^{13}C chemical shifts and charge densities should reveal similar patterns of substituent effects. Second, it should be possible to rationalize the f and r values for the correlations in terms of a reasonable model for mechanisms of transmission of substituent effects. Finally, the same model should account for variations in f and r between closely related series of compounds.

For our initial investigation, we chose 4-substituted styrenes as model compounds. The advantages of these compounds for investigations of S.C.S. has been previously discussed (16). While there have been several investigations of S.C.S. for these compounds (16–20), all of them suffered from one or more of the weaknesses outlined above. We report below the results of an investigation in which ^1H and ^{13}C chemical shifts of more than 20 4-substituted styrenes were measured in an inert medium and compared with charge densities determined by CNDO/2 molecular orbital calculations.

Experimental

(a) Preparation and Purification of Compounds

4-Methylstyrene and 4-vinylbiphenyl were obtained commercially from Aldrich Chemical Company, Inc. 4-Ethoxystyrene and 1,4-divinylbenzene were purchased from Pfaltz and Bauer, Inc. 4-*t*-Butylstyrene was ob-

[3]Chemical shifts in p.p.m. are defined according to the δ scale, *i.e.* with high frequency (low field) shifts positive.

tained from Professor K. Yates, University of Toronto. All of the remaining 4-substituted styrenes were known compounds and were synthesized using previously reported procedures. Physical constants were in good agreement with values from the literature. Full details of syntheses are reported elsewhere (21).

4-Vinylbiphenyl was sublimed at 80 °C and 0.1 mm immediately before use. Other styrenes were purified by vacuum distillation or recrystallization just before use. Purities were checked by n.m.r. spectroscopy and, in some cases, by v.p.c.

(b) Recording of Nuclear Magnetic Resonance Spectra

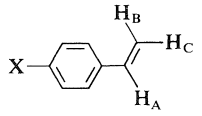
^{1}H spectra were recorded on a Varian HA-100 spectrometer operating in frequency sweep mode at a probe temperature of 30 ± 2 °C. Solvent cyclohexane was used as the lock and reference peak. Spectra were recorded and calibrated using previously reported procedures (16). The cyclohexane (Fisher A.C.S. grade) was fractionally distilled from sodium and stored over Linde 4A molecular sieve. Dissolved oxygen was purged by aeration with dry nitrogen immediately before sample preparation. Three styrene solutions were measured with concentrations in the range 1–5 mol %.

^{13}C spectra were obtained at 25.160 MHz using a Varian XL-100-15 spectrometer operating in pulsed Fourier transform mode with proton decoupling (probe temperature 32 ± 3 °C). Fourier transformations were performed using a Varian 620i computer (16K memory) and standard software. Spectra were recorded for 0.4 *M* solutions in CCl_4 with 8% C_6D_{12} as a lock signal and 1% tetramethylsilane as internal reference. ^{13}C spectra were not recorded for NH_2, CO_2CH_3, and $CO_2C_2H_5$ derivatives since these compounds were produced in very low yield.

Results

The vinyl proton spectra of 4-substituted styrenes were initially analyzed as ABC spectra by the exact method (22), using the computer program EXAN. The parameters from the exact method were further refined using the iterative computer programs LAOCN3 (23) or LACX (24). Computed r.m.s. errors between calculated and observed transition frequencies were <0.022 Hz.

No dilution shifts were observed for a number of compounds (OCH_2CH_3, SCH_3, CH_3, $C(CH_3)_3$, $Si(CH_3)_3$, $Ge(CH_3)_3$, $Sn(CH_3)_3$, and $Pb(CH_3)_3$) over the concentration range studied. The infinite dilution shifts were taken as the observed shifts at 2 mol % concentration. For other compounds, infinite dilution chemical shifts were estimated from least-squares plots of the dilution shifts. Dilution shifts were linear within experimental error. Standard deviations of the zero-concentration intercept were <0.0008 p.p.m. It is estimated that individual infinite dilution chemical shifts are accurate to 0.002 p.p.m. and that the internal chemical shift difference for the β protons, Δδ(B − C), is accurate to 0.001 p.p.m. Infinite dilution chemical shift data are reported in Table 1. Protons are labeled as shown in **1**. Although chemical



1

shifts were measured relative to cyclohexane they have been expressed relative to tetramethylsilane by adding 1.4457 p.p.m., the experimentally-determined chemical shift of cyclohexane, relative to tetramethylsilane at infinite dilution.[4] Coupling constant data are also given in Table 1.

^{13}C chemical shift data (relative to $^{13}CH_3Si(CH_3)_3$) are given in Table 2. Repeated runs for styrene with different frequency offsets, different spectral widths and concentrations from 0.1 to 0.4 *M* gave chemical shifts which were reproducible to 0.02 p.p.m. Consequently we believe that chemical shifts are accurate to at least 0.04 p.p.m. (1 Hz). Phenyl ^{13}C chemical shifts were assigned by assuming that S.C.S. for the styrene derivatives are very similar to those for phenyl derivatives (8, 25).

CNDO/2 calculations were performed using a standard program (26). Calculations were performed for two values of the styrene valence angle α (see Discussion) while standard parameters were used for other bond angles and bond lengths. For 4-aminostyrene, calculations were performed assuming both a planar NH_2 group and the previously reported pyramidal geometry (27). Full details of assumed geometrics for other substituents are tabulated elsewhere (21). Vinyl hydrogen and carbon charge densities and C-1 charge densities for α = 120° are given in Table 3 (other phenyl carbon charge densities and charge densities for α = 130° are on deposit in the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2).

Results of CNDO/2 calculations for 4-substituted 1-vinylbicyclo[2.2.2]octanes and methyl-X-ethylene pairs are summarized in Table 4.

Correlations of chemical shifts with *F* and *R*

[4]The previously reported value of 1.4438 (16) is in error. The data from ref. 16 have been corrected by adding 0.0019 p.p.m.

were performed using LMCL2, a linear least-squares multiple correlation program written by Unger and Swain (28) or the IBM SSP subroutine MULTR (29). A step-wise multiple regression subroutine, STPRG (29) was used for correlations with three independent variables (*i.e.* F, R, and $|R|$) in order to determine the relative significance of the variables entering the regression. All correlations and CNDO/2 calculations were performed on an IBM 360/65 computer.

Discussion

(a) Geometry of Styrene

The expected magnitudes of field and resonance effects in 4-substituted styrenes are very sensitive to the assumed geometry of styrene. While this is not precisely known, all available experimental data indicates that styrene is planar or nearly planar (30–32).

Calculated electric field effects upon the internal chemical shift of the β protons, $\Delta\delta(B - C)$, are particularly sensitive to the angle α between C-1, -α, and -β. Recently, it has been shown that α for *trans*-stilbene is accurately reproduced by CNDO/2 energy minimization calculations (33). Consequently, we attempted similar calculations for styrene.

Only the C_1—C_α bond length r, the C-α valence angle α, and the vinyl–phenyl dihedral angle ρ were treated as variables. A rigorous energy optimization was not attempted; instead r, α, and ρ were varied independently. Minima were found for r = 1.45–1.46 Å, α = 129–130°, and ρ = 90°. The values of r and α are consistent with experimental results for *trans*-stilbene (1.46 Å, 128°) (34) but the calculated value of ρ is completely inconsistent with available experimental evidence (30–32). The failure of CNDO/2 calculations to predict the most stable dihedral angle in conjugated aromatic molecules appears to be general since calculations for stilbene (31), benzaldehyde (35), and biphenyl (36) all give a minimum energy for ρ = 90°. Significantly, more sophisticated *ab initio* calculations for styrene give values of r and α similar to those for the CNDO/2 calculations (r = 1.46 Å, α = 128°) but predict minimum energy when ρ = 0° (37). In view of the above results, two geometries of the styrene molecule were employed in calculations: (*i*) standard (STD) geometry with α = 120°, r = 1.46 Å, and ρ = 0°, (*ii*) calculated (CNDO) geometry with α = 130°, r = 1.45 Å, and ρ = 0°. It is suspected that the correct value of α falls between these two extremes.

(b) Consideration of Possible Solute–Solute and Solvent–Solute Interactions

All of the styrene derivatives showed small dilution shifts which were linear, within experimental error, at low concentrations. Consequently, we are confident that the extrapolated infinite dilution ^1H chemical shifts are not affected by solute–solute interactions. Raynes and Raza have recently discussed the nature of cyclohexane solvent effects (38). They concluded that cyclohexane behaves as a magnetically isotropic molecule, does not show specific solvent effects, and that van der Waals' interactions should affect the different solute protons equally. However, their results suggest the presence of a reaction field effect. The reaction field should have a direction parallel to the solute electric dipole moment, μ (39):

$$[3] \qquad R = \tfrac{2}{3}\left(\frac{\varepsilon - 1}{2\varepsilon + n^2}\right)(n^2 - 1)\frac{\mu}{\alpha}$$

where n and α are respectively the refractive index and the polarizability of the solute and ε is the solution dielectric constant. According to this formula, the reaction field should, in many cases, cause shifts which are similar in sign and magnitude to those due to intramolecular field effects. However, Weiner and Malinowski concluded that eq. 3 should be modified by replacing ε by the effective dielectric constant, ε′ (40). For cyclohexane, ε′ = 1.0, *i.e.* it should not exert any reaction field effect. Our results support this viewpoint. If intramolecular field effects are dominant then $\Delta\delta(B - C)$ should depend upon the dipole moment of the C—X σ bond (16) while if reaction field effects are dominant, $\Delta\delta(B - C)$ will be determined by the molecular dipole moment. As shown below, $\Delta\delta(B - C)$ correlates very well with calculations based on C—X σ bond moments even for substituents such as OCH_3 where the C—X bond moment and the molecular dipole moment are grossly different (41). In addition, it has been shown that solvent shifts for 4-substituted styrenes are completely inconsistent with the reaction field model (16). Consequently, we believe that reaction field effects are much less important than intramolecular field effects for 4-substituted styrenes in cyclohexane and that cyclohexane

can be regarded as an inert solvent for investigations of ^1H S.C.S.

In order to confirm that CCl_4 was an inert solvent for ^{13}C chemical shift measurements, ^{13}C chemical shifts were determined for styrene and its 4-nitro and 4-*N*,*N*-dimethylamino derivatives in C_6D_{12}. S.C.S. for the latter two compounds were identical within 0.10 p.p.m. (0.05 p.p.m. for vinyl carbons) with those in CCl_4. Consequently, we believe that the ^{13}C chemical shifts in Table 2 are not affected by solvent effects.

(c) Predicted Nature of Substituent Effects in Styrene Derivatives

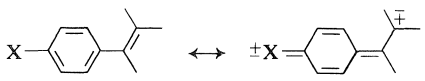
Three types of through-bond substituent effects will be considered: σ inductive effects, resonance effects, and π inductive effects. The latter two are respectively defined as involving (*i*) charge transfer between the substituent and the styrene π electron system and (*ii*) redistribution of π electron density without charge transfer. The σ inductive effect should contribute positively to *f*. Assuming that it depends on the number of intervening bonds, this effect should be greater for C-α than C-β. Similarly it should be greater for H_A and smaller and equal for H_B and H_C. By contrast, resonance effects should primarily affect π electron density at C-β (17*a*). Consequently, δ_{H_B} and δ_{H_C} correlations should have nearly identical *r* values with a smaller *r* value for δ_{H_A}. Similarly $\delta_{C\text{-}\beta}$ should show a greater *R* dependence than $\delta_{C\text{-}\alpha}$. π inductive effects should also affect δ_{H_B} and δ_{H_C} equally by altering electron density at C-β. However, the exact nature of these effects is controversial (42) and further comment will be reserved until section (*e*).

Through-space field effect contributions to individual protons can be estimated using the Buckingham equation which assumes that the field effect depends upon the electric field component acting along a C—H bond (43). Using STD geometry and assuming a dipole moment of 1.0 D located 0.9 Å along the C_4—X bond, calculated field components are: $E_z(A) = 7.5 \times 10^3$, $E_z(B) = -0.9 \times 10^3$, $E_z(C) = 7.0 \times 10^3$, and $\Delta E_z(B - C) = -7.9 \times 10^3$ e.s.u./cm^2. Through-space field contributions to *f* values for the individual proton correlations should be in approximately the same ratio. On the basis of the above discussion, δ_{H_B} and δ_{H_C} should be equally affected by through-bond effects and the only electronic substituent effect contributing to Δδ(B − C) should be the field effect.

S.C.S. for individual compounds may also be affected by the anisotropic magnetic susceptibility of the substituent. The contribution due to this term is given by:

$$[4] \qquad \delta_M = (1/3r^3) \sum_{i=1}^{3} \chi_i (3\cos^2\theta_i - 1)$$

where *r* is the distance between the centre of the induced magnetic dipole and the proton and θ_i is the angle between the *r* vector and the axis of one of three principal magnetic susceptibilities, χ_i (44). Finally, the substituent could alter the ring current effect of the phenyl group by resonance (45). The change in ring current depends upon the importance of quininoid structures:



Following Yamada *et al.* (46), this effect should depend upon |*R*|.

(d) Field Dependence of Δδ(B − C)

The internal chemical shift difference for the β protons, Δδ(B − C), should depend upon the difference in substituent-induced electric fields acting along the C_β—H_B and C_β—H_C bonds, $\Delta E_z(B - C)$ (16). Following Cumper's sugges-

tion of assigning $\mu = 0$ for the C—H bond moment (47), the field dependence of $\Delta\delta(B - C)$ should be given by:

$$[5] \quad \Delta\delta(B - C) = A\Delta E_z(B - C) + \Delta\delta_0(B - C)$$

where $\Delta\delta_0(B - C)$ is the chemical shift difference for styrene and A is the constant in the Buckingham equation (43). We have expanded our previous correlation of this type to include three additional groups, CH_3, $C(CH_3)_3$, and CF_3 which have dipole moments acting along the phenyl-substituent bond. Groups whose dipole moment axes are poorly defined were avoided as far as possible. Aliphatic group moments (47) were chosen to eliminate resonance effects from the calculations. Calculations were performed for STD geometry with E_z evaluated both at the proton and halfway along the C—H bond[5] and for CNDO geometry with fields evaluated at the same position (parameters used in the calculations are given elsewhere (21)). In each case, A was estimated from the slope of the best straight line for eq. 5. Excellent correlations were obtained when halogens were omitted (correlation coefficients, $r > 0.998$) with respective A values for the four correlations listed above of 4.6×10^{-12}, 3.1×10^{-12}, 6.5×10^{-12}, and 4.0×10^{-12}. The second correlation is illustrated in Fig. 1. While A is extremely sensitive to the chosen geometry, the observed values are reasonably consistent with previous values which have ranged from 2 to 4.2×10^{-12} (1, 43) (A is positive for the δ scale). Evidence is presented in the following paper (49) which suggests that the larger A values may be significant. When the halogens were included, the correlations were worse but the A values were almost unchanged (*e.g.*, $r = 0.968$, $A = 3.2 \times 10^{-12}$ for the correlation in Fig. 1). Thus inclusion of the halogens does not alter the conclusion that $\Delta\delta(B - C)$ primarily reflects the field effect of the substituent. It is well established that halogens show deviations in plots of S.C.S. which cannot be attributed to magnetic anisotropy effects (16, 50, 51). Possible origins for the deviations are discussed below.

Electrostatic calculations were also performed for 4-ethynyl and 4-cyanostyrene. After correction for the magnetic anisotropy effect of the triple bonds (see section (*f*)) these points lie close to the straight line in Fig. 2.

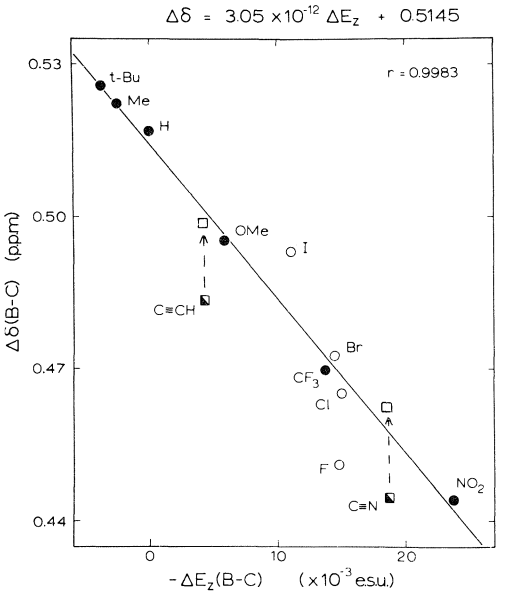

FIG. 1. Correlation of β proton chemical shift difference, $\Delta\delta(B - C)$ *vs.* difference in electric field along C_β—H_B and C_β—H_C bond, $\Delta E_z(B - C)$. Solid points are used for correlation. Uncorrected chemical shifts for the cyano and ethynyl groups (◪) and values corrected for magnetic anisotropy effects (□) (see section (*f*)) are also plotted.

An alternative approach for demonstrating the through-space field dependence of $\Delta\delta(B - C)$ is to correlate $\Delta\delta(B - C)$ with the field substituent parameter F. However, in view of the criticism of Wiley and Miller of the use of F and R for investigations of S.C.S. (4), F was first correlated with $\Delta E_z(B - C)$ to confirm that F was a measure of the electric field effect as calculated by the Buckingham equation. A very good correlation was obtained ($r = 0.989$) confirming that F is a valid measure of the through-space field effect. No deviations were noted for the halogens. Since F and $\Delta E_z(B - C)$ both measure only electronic effects, this suggests that the deviations for the halogens in the chemical shift plots are magnetic in origin.

The initial correlation of F *vs.* $\Delta\delta(B - C)$ was performed for 19 styrenes. F and R values were available for all substituents except the dimethylamino and ethynyl groups. F and R values can be calculated from σ_m and σ_p values (5). A variety of σ_p values have been reported for the dimethylamino group (52). $\sigma_p = -0.622$ (52) was chosen because it was determined for

[5]Buckingham suggested that E_z should be evaluated at the proton (43) while Musher argued that it should be evaluated halfway along the C—H bond (48).

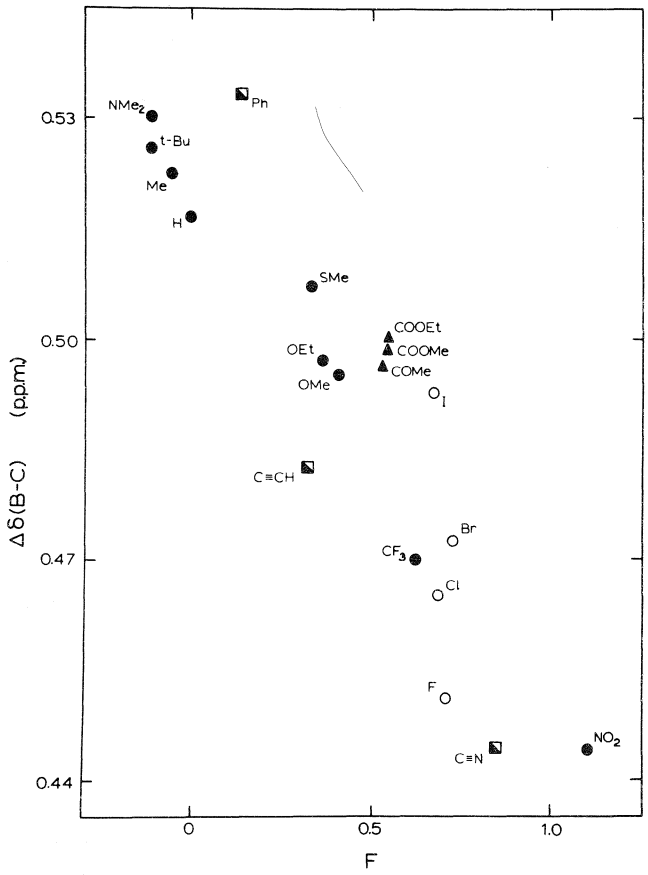

FIG. 2. Plot of β proton chemical shift difference *vs.* *F*. ◪ represents points for which anisotropic corrections are estimated while ▲ represents points for which revised *F* values are estimated (see section (*f*)).

reactants (*e.g.* $XC_6H_4CH{=}CHC_6H_5$ and $XC_6H_4CH{=}NOH$) which are electronically similar to styrene. *F* and *R* were then estimated as respectively −0.097 and −0.568. For the ethynyl group, σ_m and σ_p values from Landgrebe and Rynbrandt (53) were used to estimate $F = +0.317$, $R = +0.055$. Other *F* and *R* values were taken from the original tabulation (5).

A correlation of $\Delta\delta(B - C)$ *vs.* *F* for 19 4-substituted styrenes is shown in Fig. 2. A general relationship is apparent although the correlation coefficient is not very good ($r = 0.891$). A correlation with *F* and *R* gave a statistically insignificant *r* value, indicating that the scatter is not due to resonance contributions. However, closer inspection indicated that most of the larger deviations could be due to the expected magnetic anisotropy effect of the substituent. The cyano and ethynyl groups should shield all protons of the vinyl group while phenyl and carbonyl groups should deshield them (54, 55). Since H_B is closer to the substituent than H_C, this will decrease $\Delta\delta(B - C)$ for the first two groups and increase it for the other substituents, as noted in Fig. 2. The anomalous behavior of the halogens has been previously discussed.

Removal of the ten above-mentioned substituents left nine ($N(CH_3)_2$, $C(CH_3)_3$, CH_3, H, OCH_3, OC_2H_5, SCH_3, CF_3, and NO_2). All except NO_2 contain only single bonds and all except SCH_3 involve only first row elements. Consequently they would be expected to have small anisotropic effect. Available evidence (56, 57) indicates that the magnetic anisotropy effect of the NO_2 group should be small compared to S.C.S. (*e.g.* $\Delta\delta_M(B - C) = -0.005$ p.p.m. for $\Delta\chi$ values from ref. 56). Consequently no magnetic anisotropy corrections were applied for the NO_2 derivative. In the case of the 4-

phenyl derivative, it was found that the deviations between calculated and observed ^{1}H chemical shift both for $\Delta\delta$(B − C) and for the individual protons closely corresponded to the calculated ring current effect of the phenyl group as determined by the approach of Johnson and Bovey (58) (assuming a dihedral angle between the phenyl groups of 21° since ρ = 19–23° for biphenyl in cyclohexane (30)). Consequently ^{1}H chemical shifts for the phenyl derivative were corrected for ring current effects (see Table 5) and included in the correlation. Results of the ten point correlation are given in Table 6. $\Delta\delta$(B − C) still depends only upon F but with a much improved correlation coefficient. However, the most important observation is that the f value for the correlation in which groups with uncertain magnetic effects are eliminated is the same within experimental error as the f value for the original 19 point correlation. Consequently, we conclude that deviations of individual points due to magnetic contributions do not obscure overall trends in electronic effects upon ^{1}H S.C.S. *provided that enough points are included in the correlation.* Both the full correlation and the restricted correlation indicate that $\Delta\delta$(B − C) is dominated by field effects.

The dipolar electric field due to a substituent should polarize a C—H bond (48), altering the electron density in the hydrogen 1s orbital. Consequently, the difference in charge density between H_B and H_C of a 4-substituted styrene should reflect the field effect of the substituent.[6] We designate this difference, measured relative to styrene, as $\Delta(\Delta = (q_{H_B} - q_{H_C})_X - (q_{H_B} - q_{H_C})_H)$. A plot of Δ *vs.* $\Delta\delta$(B − C) (with anisotropic corrections for the cyano and ethynyl

groups) is shown in Fig. 3. For STD geometry (Fig. 3) the slope of the plot of Δδ(B − C) *vs.* Δ is 18.0 p.p.m./hydrogen 1s electron while for CNDO geometry (not shown) the slope is 23.2 p.p.m./hydrogen 1s electron. Both values are in excellent agreement with previously determined scaling factors which have ranged from 17.8 (59) to 26.6 (60) p.p.m./hydrogen 1s electron. However, deviations are again noted for some substituents. Field effects for CF_3 and NO_2 groups appear to be overestimated while the effect of the cyano group is underestimated. Similar deviations have been noted for dipole moments of $C_6H_5NO_2$ and $C_6H_5C{\equiv}N$ (14), indicating that CNDO/2 calculations do not precisely reproduce the charge distributions induced by these substituents.[7] However, this quantitative failure of the calculations for individual substituents does not obscure the overall trend shown in Fig. 3. This provides further evidence for the existence of a through-space electric field effect which affects ^1H chemical shifts by polarizing C—H bonds.

We have now shown that three independent measures of the electric field effect (classical electrostatic calculations, field substituent constants and charge densities estimated by MO calculations) indicate that Δδ(B − C) is dominated by field effects. In the first and third approaches, scaling factors relating field components and charge densities with chemical shifts are in good agreement with previously reported scaling factors (there is no *a priori* method for predicting a value of *f* for the second correlation). We believe that the results in this section represent the most convincing evidence yet presented for the existence of an intramolecular field effect upon proton chemical shifts.

[7]The correlation coefficient is significantly improved ($r = 0.967$) if charge densities for nitro and cyano derivatives are scaled to correctly reproduce the dipole moments.

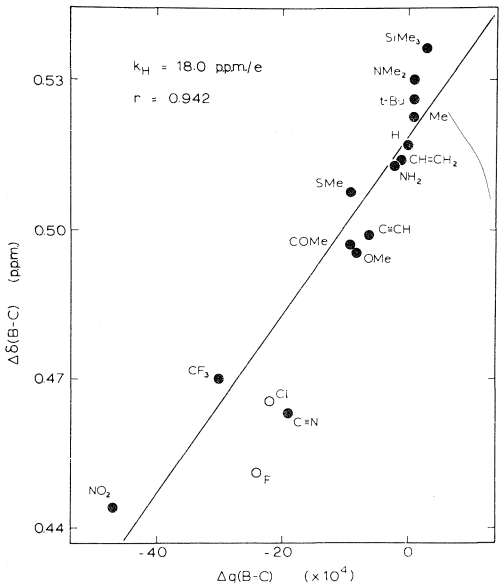

FIG. 3. Correlation of $\Delta\delta(B - C)$ with difference in calculated charge density for β protons of 4-substituted styrenes (halogens excluded).

(e) Substituent Effects upon Individual Vinyl Protons and Carbons

Correlations of vinyl proton chemical shifts with F and R were performed for the original 19 point set, for the restricted set of ten outlined in section (*d*) and for a further set in which two of the ten styrenes (CF_3 and SCH_3) were eliminated since they showed significantly larger deviations than the other eight. Results for the three sets of correlations are summarized in Table 6. The restricted set correlations were carried out in order to get the best possible lines to be used in evaluating magnetic anisotropy effects and unknown or uncertain F and R parameters (see section (*f*)). While the correlation coefficients are significantly improved for the ten and eight point correlations, it is most important to note that the pattern of f and r values is nearly identical for the three sets of correlations. This provides further evidence that magnetic effects upon individual protons do not obscure the overall pattern of electronic effects. Correlations were also performed against F, R and $|R|$. In each case the t test (61) indicated a less than 60% probability of a non-zero coefficient for $|R|$ with particularly small values in the case of δ_{H_A} ($\ll 50\%$) which should be most sensitive to variation in ring current. By contrast both f and r always exceeded 95% confidence limits and usually exceeded 99% confidence limits. Consequently, we conclude that there is a statistically insignificant contribution to S.C.S. for 4-substituted styrenes from the variation of ring current with substituent.

In addition to having similar values for the different sets of data points, the f and r values are consistent with the model of substituent effects outlined in section (*c*). For each set, r values for δ_{H_B} and δ_{H_C} are identical within the uncertainty in r and are much larger than the r values for δ_{H_A}. In all cases the correlation of $\Delta\delta(B - C)$ *vs.* F is insignificantly improved by a correlation with R, confirming that $\Delta\delta(B - C)$ is dominated by field effects. f is larger for δ_{H_C} than for δ_{H_B}, as predicted. However, f values for the individual proton correlations indicate that some additional effect is operative. Based on $f = -0.067_4$ for the correlation of $\Delta\delta(B - C)$ with F, predicted f values for δ_{H_A}, δ_{H_B}, and δ_{H_C} (using the values of E_z quoted in section (*c*)) are respectively $+0.064$, -0.007 and $+0.060$. The difference between predicted and observed values is $-(0.01 - 0.05)$ for δ_{H_A} and $+(0.09 - 0.11)$ for δ_{H_B} and δ_{H_C}. These residual f values are completely inconsistent with expected contributions due to σ inductive effects, indicating that these effects are insignificant in this system. However, ^{13}C chemical shifts and π charge densities for the vinyl group indicate that the residual field dependence can be attributed to a form of π inductive effect.

All available styrene derivatives were included in correlations of ^{13}C chemical shifts with F and R since magnetic effects should be negligible compared to the large ^{13}C S.C.S. (results presented in section (*f*) indicate $\delta_M < 0.10$ p.p.m. for vinyl carbons and protons). Interestingly, halogens fitted about as well as other points, providing further evidence that the deviations for these points in ^1H S.C.S. investigations are magnetic in origin. Results of the correlations are given by eqs. 6 and 7. One

$$[6]\quad \delta_{C\text{-}\alpha} = -(1.30 \pm 0.07)F - (0.35 \pm 0.13)R \quad (r = 0.974)$$

$$[7]\quad \delta_{C\text{-}\beta} = +(2.82 \pm 0.15)F + (7.14 \pm 0.27)R \quad (r = 0.991)$$

important observation is that the f values for C-α and C-β are very similar in pattern to the residual f values for the corresponding protons,

i.e. positive for C-β and smaller and negative for C-α.

The MO calculations indicate that substituent induced changes in vinyl charge density are dominated by changes in π electron density. This is particularly apparent for C-β where changes in σ charge density simply mirror changes in π charge density, as previously suggested (14):

$$[8] \qquad \text{C-}\beta_\sigma \approx -0.4\text{C-}\beta_\pi$$

Consequently, π charge densities were correlated with F and R:

$$[9] \quad \text{C-}\alpha_\pi = -(0.0075 \pm 0.0010)F - (0.0132 \pm 0.0014)R$$

$$[10] \quad \text{C-}\beta_\pi = +(0.0140 \pm 0.0022)F + (0.0314 \pm 0.0029)R$$

Again the f values are similar in pattern to those observed for the ^{1}H and ^{13}C chemical shift correlations. In addition, the ratios of f for chemical shift and charge densities are respectively 173 and 201 p.p.m./π electron for C-α and C-β, in excellent agreement with previously reported scaling factors for ^{13}C chemical shifts of 160–200 p.p.m./π electron (62, 63).[8] The charge densities indicate that the field dependence of the vinyl carbons and the residual field dependence of the vinyl protons (after subtraction of through-space field effects) arise from some mechanism which alters the π electron density but is proportional to F. We suggest that the mechanism is a polarization of the styrene π electron system by the polar C—X bond, leading to a polarization of the vinyl group. The exact nature of this π polarization effect is discussed in greater detail in the following paper (49). Further evidence for π polarization effects in phenyl derivatives has been obtained from ^{13}C spectra of phenylalkanes with α and β substituents (64). In addition, ^{13}C spectra of *trans*-1-substituted 1,3-butadienes also provide evidence of π polarization effects in these compounds (65). Consequently, we believe that π polarization effects are more important than previously realized (42).

The ^{13}C chemical shifts and charge densities also provide information about resonance effects. The C-β correlations indicate a substantial resonance effect at this carbon, as predicted in section (*c*) (with a reasonable ratio of r values of 228 p.p.m./π electron). However, the correlations suggest a negligible or slight negative resonance contribution for C-α (the calculations apparently overestimate this contribution since the ratio of r values is only 27 p.p.m./π electron). This is apparently anomalous since the proton correlations indicate a significant positive R dependence for δ_{H_A}. However, the vinyl proton charge densities indicate that this is not really an anomaly at all. For example, for 4-methoxystyrene, q_{H_A} is negative even though C-α_π is positive and through-space field effects should also make q_{H_A} positive. The negative charge for q_{H_A} apparently reflects the effect of the large negative π charge density at C-1 (see Table 3). C-1_π is primarily determined by resonance effects:

$$[11] \quad \text{C-}1_\pi = +(0.017 \pm 0.006)F + (0.086 \pm 0.007)R$$

This is confirmed by the ^{13}C chemical shift correlations:

$$[12] \quad \delta_{\text{C-1}} = +(2.98 \pm 0.37)F + (15.78 \pm 0.69)R \quad (r = 0.985)$$

(the ratio of f values is 175 p.p.m./π electron while the ratio of r values is 1.83 p.p.m./π electron, in good agreement with accepted values (62, 63)). We believe that the resonance dependence of δ_{H_A} arises from a through-space transmission of the effect of the large π charge density at C-1 (and to a lesser extent at C-β).

The above results indicate that a substantial fraction of the substituent effects in 4-substituted styrenes are transmitted through the π electron system. In an attempt to separate through-space field effects from effects transmitted through the π electron system and to confirm the validity of the Buckingham equation for field effects (43), calculations were performed for model compounds with no intervening π electron system. The compounds were 4-substituted 1-vinylbicyclo[2.2.2]octanes (VBCO) and pairs of molecules; ethylene and CH_3X molecules arranged so that the C—X bond and the ethylene molecule were in the same orientation as the C—X bond and the vinyl group in VBCO. Substituent-induced changes in vinyl charge densities (see Table 4) are in both cases consistent

[8]The validity of relating ^{13}C S.C.S. due to remote substituents with carbon charge densities is discussed elsewhere (64).

with the predictions of the Buckingham equation, *i.e.* $q_{H_A} \approx q_{H_C} \gg q_{H_B}$, confirming that the latter equation correctly predicts the geometric dependence of the electric field effect. However, the sensitivity of the vinyl protons to field effects (as measured by Δ) apparently depends upon the nature of the intervening molecular framework. This point is further discussed in the following paper (49).

In summary, correlations of ^1H chemical shifts (after correction for through-space field effects), ^{13}C chemical shifts, and carbon charge densities with F and R provide a consistent picture of electronic effects transmitted through the carbon framework of styrene. It is concluded that the two mechanisms of transmission of these through-bond effects are resonance and π polarization interactions. These two mechanisms plus a field effect similar to that predicted by the Buckingham equation can completely account for the f and r values for the ^1H and ^{13}C chemical shift correlations as well as the pattern of calculated charge densities.

(f) Estimation of Δχ Values or F and R Values for Individual Substituents

As pointed out in section (*d*), individual points showed deviations which might be due to magnetic anisotropy effects. We decided to use the individual ^1H correlations in conjunction with eq. 4 in an attempt to determine Δχ values. For substituents with axially symmetric magnetic susceptibilities, Δχ was estimated from the difference between the observed Δδ(B − C) value and the value calculated from the eight point correlation equation for Δδ(B − C) *vs.* F (see Fig. 4), using eq. 4. This Δχ value was then tested to see whether it could account for the deviations from the individual proton correlations. This is a rigorous test since the three individual proton correlations with F and R should be completely independent.

Results for C≡N, C≡C—H, F, Cl, Br, and I substituents are summarized in Table 5. The calculated correction factors for the first two groups are in good agreement with the differences between calculated and experimental chemical shifts. Assuming STD geometry, the correction factor for C≡N corresponds to $\Delta\chi = -29 \times 10^{-30}$ cm^3/molecule while for CNDO geometry it is $\Delta\chi = -39 \times 10^{-30}$ cm^3/molecule. Corresponding values for C≡C—H are respectively -25×10^{-30} and -34×10^{-30}

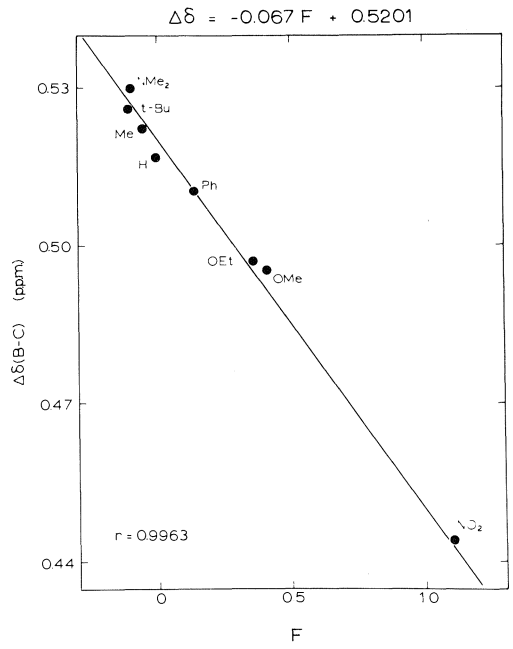

FIG. 4. Eight point correlation of Δδ(B − C) *vs.* F (phenyl corrected for ring current effects) used in section f to estimate Δχ and revised F values.

cm^3/molecule. All values are in good agreement with previously reported values which have ranged from -27×10^{-30} (66) to -34×10^{-30} cm^3/molecule (67) for both substituents. By contrast, deviations for the halogens are totally erratic and cannot be accounted for in terms of magnetic anisotropy effects. However, the correlation of F *vs.* ΔE_z(B − C) and the ^{13}C chemical shift correlations both indicate that the deviations are due to some type of magnetic effect, although the exact nature of the effect is unclear.

Since substituents containing the carbonyl group are characterized by two Δχ values (and two non-equivalent conformations of the vinyl group), correction factors cannot be estimated from the Δδ(B − C) correlation by itself. Instead, previously reported Δχ values for the C=O group (1, 68) were used to calculate correction factors. The calculated correction factors for the individual protons all have the wrong sign (Table 5). However, it was noted that the deviations parallel the signs and magnitudes of the f values for the four correlations, suggesting incorrect F values for carbonyl substituents. Consequently, we used the Δδ(B − C) correlation to estimate new F values (using an average deviation for the two esters). In

TABLE 7. Estimated F and R values for various substituents estimated from the 13 point correlations for δ(B) and δ(C)

Substituent	F	R	$\delta(A)_{exp.}$	$\delta(A)_{calcd.}$	Δ
$Si(CH_3)_3$	-0.26_6	$+0.09_5$	6.613	6.619	−0.006
$Ge(CH_3)_3$	-0.28_6	$+0.11_9$	6.629	6.622	+0.007
$Sn(CH_3)_3$	-0.35_2	$+0.07_9$	6.597	6.611	−0.014
$Pb(CH_3)_3$	-0.42_1	$+0.10_4$	6.613	6.612	+0.001
NH_2	$+0.14_5$	-0.58_6	6.494	6.516	−0.022
$CH{=}CH_2$	-0.00_4	-0.03_3	6.600	6.609	−0.009

each case, the agreement for all three protons is improved using the new, smaller F values. It is interesting to note that the corresponding σ_I values for carbonyl substituents determined from chemical shift measurements in aprotic solvents are approximately 50% smaller than those determined from reactivity measurements (69). This was the only type of substituent for which an effect of this type was noticed. Therefore, we believe it is reasonable that F for carbonyl substituents determined from chemical shifts in inert solvents appear to be significantly smaller than F values determined from reactivity measurements, even though this is contrary to the original assumption of Swain and Lupton that F and R are independent of the system (5). While this implies an insignificant magnetic anisotropy effect for the carbonyl group, anticipated δ_M values are small and might be difficult to detect by our approach. Deviations for CF_3 and SCH_3 groups could not be accounted for by any single correction involving F, R, or $\Delta\chi$. However, the deviations may be due to some combination of these effects.

Corrected δ values for C≡N and C≡C—H derivatives and corrected F values for carbonyl substituents were included in new 19 point, 15 point (halogen omitted), and 13 point (CF_3, SCH_3 omitted) correlations. Results are summarized in Table 6. With the corrected values, correlation coefficients are further improved but the f and r values are not significantly altered.

In view of the excellent correlations for the corrected 13 point set, it was decided to use these correlations to estimate F and R parameters for other substituents. Consequently, the 4-$(CH_3)_3$M-styrenes (M = Si, Ge, Sn, Pb) were synthesized. F and R were evaluated by simultaneously solving the 13 point correlations for δ_{H_B} and δ_{H_C}. The results are summarized in Table 7. The derived F and R values were checked by using them to evaluate δ_{H_A}. δ_{H_A} should be a sensitive probe for anisotropic effects since these effects should be relatively larger for δ_{H_A} than for δ_{H_B} and δ_{H_C} while field and resonance effects should be smaller. In fact, differences between calculated and observed δ_{H_A} values are small and show no evidence of persistent deviations due to anisotropic effects. Swain and Lupton (5) calculated $F = -0.047$ and $R = -0.044$ for the $(CH_3)_3Si$ group from measurements of benzoic acid dissociation constants. There have been several other determinations of σ constants for the $(CH_3)_3Si$ group (70). All of these give F negative and R positive with an average of $F = -0.23$ and $R = +0.15$, in good agreement with our results. The other $(CH_3)_3M$ substituents show increasingly negative F values on going from Si to Pb, consistent with previous conclusions concerning the inductive effects of these substituents (70). By contrast, the R values are essentially constant throughout the series. The $+R$ values could be taken as an indication of d(π)—p(π) bonding although we would not have anticipated that this effect should be constant throughout the series. The CNDO/2 calculations throw further light on the possibility of d(π)—p(π) bonding. The total change in π electron density, $\sum C_\pi$ is a measure of the resonance effect of the substituent (14). In the case of the $(CH_3)_3Si$ group (see Table 3), $\sum C_\pi$ is positive even when 3d orbitals are excluded from the calculation, indicating that it is not necessary to invoke d(π)—p(π) bonding to account for the $+R$ effect of the $(CH_3)_3Si$ group.

4-Aminostyrene was not included in the original correlations since it was not obtained in sufficient yield and purity until the correlations were completed. Consequently, it was decided to evaluate F and R from δ_{H_B} and δ_{H_C} and compare them with reported values. Results are given in Table 7. Calculated values of F and R are both more positive than those given by Swain and

Lupton (respectively +0.037 and −0.681) (5) although deviations are not much greater than the estimated probable error of ±0.05. It is interesting to compare the derived F and R values for NH_2 with those calculated for $N(CH_3)_2$ from σ constants estimated for electronically similar systems (see above). The R values are very similar but the F values are of opposite sign. By contrast, σ_I for NH_2 and $N(CH_3)_2$ are reported to have an identical value of +0.10 (69). However, both the values of Δδ (B − C) (Table 1) and the Δ values (Table 3) for the NH_2 and $N(CH_3)_2$ derivatives indicate that F has opposite signs for the two substituents. The CNDO/2 calculations also indicate the resonance effects of these groups are extremely sensitive to geometry. This may account for the sensitivity of σ_p values for amino groups to the nature of the reaction (52). F and R values for the vinyl group correlations are also given in Table 7. While it is possible that these values may not be very accurate due to magnetic anisotropy effects, they do suggest that the substituent effect of the vinyl group is small. This is confirmed by the charge densities for divinylbenzene (Table 3). This suggests that the vinyl group is a particularly useful probe for electronic effects since it is nearly electronically neutral. In summary, the correlations of δ *vs.* F and R have been used to obtain self-consistent Δχ values for several substituents which are in good agreement with previously reported values. They have also been used to estimate self-consistent and reasonable F and R values for other substituents. However, results for the halogens are anomalous and these substituents should be avoided in investigations of S.C.S., or at very least not included in limited data sets.

(g) Vinyl Proton Coupling Constants

The geminal coupling constants for 4-substituted styrenes are equally sensitive to field and resonance effects:

$$[13]\quad J_{BC} = (-0.38F - 0.37R + 1.07)\text{Hz} \qquad (r = 0.988)$$

By contrast, vicinal coupling constants are constant within experimental error. This is very surprising since both vicinal and geminal coupling constants vary with substituent in most vinyl compounds (71). At present we have no explanations for these observations.

Conclusions

Correlations of the chemical shift difference for the β protons, Δδ(B − C), with electrostatic calculations based on the Buckingham equation, with the field substituent parameter F, and with hydrogen charge densities estimated by CNDO/2 MO calculations demonstrate conclusively that Δδ(B − C) reflects a through-space electric field effect. In the absence of an intervening π electron system, calculated hydrogen charge densities for individual vinyl protons show a pattern similar to that predicted by the Buckingham equation.

Correlations of ^1H chemical shifts (corrected for through-space field effects), ^{13}C chemical shifts, and carbon charge densities with F and R provide a consistent picture of electronic effects transmitted through the carbon framework of styrene. While ^1H SCS for individual derivatives sometimes appear to reflect magnetic as well as electronic effects, the overall pattern of electronic effects deduced from f and r values is identical whether one includes all derivatives or if one removes derivatives with suspected magnetic effects. The through-bond electronic effects can be explained in terms of resonance and π polarization effects. These two effects plus through-space field effects can completely account for the f and r values for the ^1H and ^{13}C chemical shift correlations as well as the pattern of calculated charge densities. Since the three approaches give a self-consistent picture of electronic effects which can be rationalized in terms of field, resonance, and π polarization effects, we believe that we have fulfilled the primary aims of the project. We also have fulfilled two of the three criteria which we suggested for determining the validity of F and R correlations. The third criterion (comparison of f and r values for closely related compounds) is considered in the following paper. The combination of ^1H and ^{13}C chemical shifts measured under inert conditions with calculated charge densities appears to be a useful technique for investigating electronic distributions in molecules (provided that a sufficiently large set of substituents is investigated) since the check of self-consistency provides a basis for evaluating the reliability of the conclusions.

The ^1H chemical shift correlations have also been used to estimate self-consistent Δχ values for C≡N and C≡C—H groups which are in good agreement with previously reported values,

revised F values for carbonyl substituents which are consistent with σ_I values determined from chemical shift measurements, and apparently reasonable F and R values for several other substituents.

Investigations of Substituent Effects by Nuclear Magnetic Resonance Spectroscopy and All-valence Electron Molecular Orbital Calculations. II. 4-Substituted α-Methylstyrenes and α-*t*-Butylstyrenes

GORDON K. HAMER,[1] IAN R. PEAT[2] AND W. F. REYNOLDS

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received June 14, 1972

Substituent-induced ^1H chemical shifts (S.C.S.) for 19 4-substituted α-methyl- and α-*t*-butylstyrenes have been determined at infinite dilution in C_6H_{12} and ^{13}C S.C.S. have been determined for 0.4 *M* solutions in CCl_4. S.C.S. are correlated with field and resonance substituent parameters and compared with charge densities determined by CNDO/2 MO calculations. The variation of S.C.S. with the dihedral angle, ρ, between phenyl and vinyl groups and the overall pattern of S.C.S. can be largely accounted for by a model of substituent effects based on field, resonance, and π polarization effects, with conjugative interactions varying as $\cos^2\rho$. Both ^{13}C chemical shifts and charge densities indicate that the π polarization effect consists of two components: (*1*) a through-space polarization of the vinyl system by the polar C—X bond and (*2*) polarization of the entire conjugated styrene π electron system. However, significant deviations are noted for some of the ^1H S.C.S. correlations. The CNDO/2 calculations indicate that these deviations are primarily due to electronic effects not predicted by the model outlined above. CNDO/2 calculations for related compounds provide a partial explanation by indicating that the magnitude of the field effect depends upon the nature of the molecular framework.

Les déplacements chimiques en ^1H induits par des substituants (S.C.S.) pour 19 α-méthyl et α-*t*-butylstyrènes substitués en position 4 ont été déterminés à dilution infinie dans le C_6H_{12}; ceux-ci en ^{13}C ont été déterminés en solution 0.4 *M* dans le CCl_4. Les déplacements chimiques induits par des substituants sont reliés aux paramètres de champ et de résonance caractéristiques des substituants et comparés avec les densités de charge obtenues par des calculs CNDO/2 MO. La variation dans les déplacements chimiques avec l'angle dièdre, ρ, entre les groupes phényle et vinyl ainsi que le schéma général de ces déplacements chimiques peuvent très bien s'interpréter à partir d'un modèle des effets de substituants basé sur le champ, la résonance et des effets de polarisation π avec des interactions de conjugaison variant selon le $\cos^2\rho$. Les déplacements chimiques en ^{13}C et les densités de charge indiquent tous les deux, que l'effet de polarisation π possède deux composantes: (*1*) une polarisation à travers l'espace du système vinylique par la liaison polaire C—X et (*2*) une polarisation du système d'électrons π du styrène conjugué en entier. Cependant, des écarts notables ont été observés pour quelques-unes des correlations dans les déplacements chimiques en ^1H. Les calculs CNDO/2 montrent que ces écarts sont imputables principalement à des effets électroniques imprévisibles selon le modèle illustré précédemment. Les calculs CNDO/2 pour des composés voisins permettent une explication partielle en montrant que l'amplitude des effets de champ dépend de la nature du squelette moléculaire.

Can. J. Chem., **51**, 915 (1973)

Introduction

In the preceding paper (1), ^1H and ^{13}C chemical shifts for 4-substituted styrenes were correlated with field (*F*) and resonance (*R*) substituent parameters (2):

$$[1] \qquad \delta = fF + rR + \delta_0$$

These correlations of substituent-induced chemical shifts (S.C.S.) were used in conjunction with charge densities estimated by CNDO/2 molecular orbital calculations (3) to deduce mechanisms of transmission of substituent effects in these compounds. However, since the use of *F* and *R* correlations for this purpose has been severely criticized (4), several criteria were proposed to test the validity of the correlations (1). One of these criteria was that *f* and *r* values should vary in a regular and predictable fashion for related series of compounds. To test this criterion, a series of 4-substituted derivatives of 2-phenylpropene (**1**) and 2-phenyl-3,3-dimethylbutene (**2**) were synthesized. These compounds will hence-

forth be referred to as derivatives of α-methylstyrene (AMS) and α-*t*-butylstyrene (ATBS). These compounds were chosen on the assumption that through-bond electronic effects should vary as a function of the dihedral angle, ρ, between phenyl and vinyl groups.

Results of investigations of S.C.S. for AMS and ATBS derivatives are presented below.

Experimental

(a) Preparation and Purification of Compounds

α-Methylstyrene and its 4-fluoro and 4-chloro derivatives were obtained from Aldrich Chemicals, Inc. Other AMS derivatives were known compounds and were synthesized by previously reported methods. Full details are reported elsewhere (5).

Of the ATBS derivatives only the parent α-*t*-butylstyrene (6, 7) and its 4-methoxy derivative (7) have been previously described in the literature. The remaining compounds were synthesized by modifying known methods; in most cases, the olefin was obtained by catalytic dehydration of the appropriate 3,3-dimethyl-2-phenyl-2-butanol over activated alumina. Synthetic procedures and analytical data are outlined below.

3,3-Dimethyl-2-phenyl-1-butene

3,3-Dimethyl-2-phenyl-2-butanol, b.p. 108–109.5°/10 mm (lit. 128°/20 mm (6), 95.5°/4.5 mm (7)), was obtained from the reaction of 3,3-dimethyl-2-butanone and phenyllithium in refluxing ether (6). The alcohol was dehydrated over activated alumina and purified by v.p.c. An analytical sample had b.p. 56.5–57°/3.4 mm (lit. 75°/10 mm (6)).

Anal. Calcd. for $C_{12}H_{16}$: C, 89.93; H, 10.07. Found: C, 90.02; H, 10.13.

3,3-Dimethyl-2-(4′-methylphenyl)-1-butene

The required butanol, b.p. 93–97°/2 mm (lit. 98°/2.5 mm (7)), was prepared from 4-methylphenyllithium and 3,3-dimethyl-2-butanone and dehydrated over alumina. Purification by v.p.c. gave the styrene, b.p. 74.8–75°/2.6 mm.

Anal. Calcd. for $C_{13}H_{18}$: C, 89.59; H, 10.41. Found: C, 89.50; H, 10.39.

3,3-Dimethyl-2-(4′-t-butylphenyl)-1-butene

4-Bromo-*t*-butylbenzene, b.p. 82–84°/5 mm (lit. 113–114°/20 mm (8)), was obtained by addition of chlorosulphonic acid to an ice-cold solution of bromobenzene and *t*-butanol (9). The lithium reagent prepared from this product was treated with 3,3-dimethyl-2-butanone to give the required butanol, b.p. 99–102°/2 mm. Dehydration of the alcohol with alumina, followed by preparative v.p.c., gave a white crystalline solid, m.p. 46.5–47.5°, b.p. 86–86.3°/0.8 mm.

Anal. Calcd. for $C_{16}H_{24}$: C, 88.82; H, 11.18. Found: C, 88.64; H, 11.29.

3,3-Dimethyl-2-(4′-N,N-dimethylaminophenyl)-1-butene

The required butanol was prepared from 4-*N*,*N*-dimethylaminophenyllithium (10) and 3,3-dimethyl-2-butanone. The butanol did not readily dehydrate during distillation. Consequently the crude alcohol was refluxed with potassium hydrogen sulfate for 5 min at 140°, and vacuum distilled. An analytical sample of the olefin, recrystallized from methanol, had m.p. 26–27°.

Anal. Calcd. for $C_{14}H_{21}N$: C, 82.70; H, 10.41; N, 6.89. Found: C, 82.88; H, 10.31; N, 6.95.

3,3-Dimethyl-2-(4′-fluorophenyl)-1-butene

The reaction of 3,3-dimethyl-2-butanone with 4-fluorophenylmagnesium bromide gave the required alcohol, b.p. 90–97°/5 mm. The alcohol was dehydrated over alumina. The olefin, purified by v.p.c., had b.p. 58°/1.9 mm.

Anal. Calcd. for $C_{12}H_{15}F$: C, 80.86; H, 8.48; F, 10.66. Found: C, 80.72; H, 8.51; F, 10.48.

3,3-Dimethyl-2-(4′-chlorophenyl)-1-butene

4-Chlorophenylmagnesium chloride (11) was converted to 3,3-dimethyl-2-(4′-chlorophenyl)-2-butanol, b.p. 98–103°/2 mm, by treatment with 3,3-dimethyl-2-butanone. The alcohol was dehydrated over alumina; purification of the distillate by v.p.c. gave the styrene, b.p. 81–81.2°/1.9 mm.

Anal. Calcd. for $C_{12}H_{15}Cl$: C, 74.02; H, 7.77; Cl, 18.21. Found: C, 73.95; H, 8.04; Cl, 17.96.

3,3-Dimethyl-2-(4′-bromophenyl)-1-butene

The bromophenylbutanol, b.p. 110–115°/2 mm, was obtained from the reaction of 3,3-dimethyl-2-butanone with 4-bromophenylmagnesium bromide. Purification of the alumina catalyzed dehydration product by v.p.c. gave the desired olefin, b.p. 98–99°/2 mm.

Anal. Calcd. for $C_{12}H_{15}Br$: C, 60.26; H, 6.32; Br, 33.42. Found: C, 60.46; H, 6.27; Br, 33.24.

3,3-Dimethyl-2-(4′-methoxyphenyl)-1-butene

4-Methoxypivalophenone, b.p. 130–132°/5 mm (lit. 138–140°/8 mm (12)), was prepared by Friedel–Crafts acylation of anisole with pivaloyl chloride and aluminum chloride (12). The ketone was converted directly to the required styrene by the Wittig synthesis (13) and the crude reaction product purified by v.p.c. (column A; 160°, 200 ml/min helium). An analytical sample had b.p. 84°/1 mm (lit. 63°/0.6 mm (7)).

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 82.18; H, 9.33.

3,3-Dimethyl-2-(4′-nitrophenyl)-1-butene

3,3-Dimethyl-2-butanol was added to an ice-cold suspension of aluminum chloride in benzene while dry hydrogen chloride was bubbled into the mixture (14). The isolated product, 3,3-dimethyl-2-phenylbutane, b.p. 205–207°/756 mm (lit. 205–207°/760 mm (14)), was nitrated by the method of Stirling and Bogert (15). Distillation of the crude 3,3-dimethyl-2-(4′-nitrophenyl)-butane gave a fraction, b.p. 119–124°/2 mm (lit. 117–124°/2 mm (14)), which solidified on standing; m.p. 37.5–38.5°, recrystallized from methanol. Treatment of this material with *N*-bromosuccinimide and benzoyl peroxide (16) gave the benzyl bromide, m.p. 122–123°, recrystallized from methanol. The bromide was dehydrohalogenated with ethanolic potassium hydroxide (4 h at 60°) (16) to give 3,3-dimethyl-2-(4′-nitrophenyl)-1-butene, m.p. 42–43°, recrystallized from pentane.

Anal. Calcd. for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37; N, 6.83. Found: C, 70.16; H, 7.32; N, 6.94.

Catalytic dehydrations were carried out using activated alumina (Matheson Coleman and Bell; 8–14 mesh) which was washed with ammonium hydroxide and dried for 24 h at 100° before packing into the reaction tube. 3,3-Dimethyl-2-phenyl-2-butanols were passed through the heated (250°) reaction tube at a flow rate of 0.5 ml/min, using N_2 as a carrier gas and with the apparatus main-

tained at 130–150 mm pressure. Products were trapped in a receiver flask immersed in a Dry Ice – acetone slurry.

ATBS derivatives were dried over Linde 4A molecular sieve. They were then purified by preparative v.p.c., using a Varian Aerograph Autoprep 700 and a 20 ft × 3/8 in. column packed with 30% SE-30 on 45/60 mesh Chromosorb W. Melting points were determined on a Fisher–Johns hot-stage apparatus and are uncorrected. Elemental analyses were carried out by A. B. Gygli, Microanalyses Laboratories Limited, Toronto, Ontario.

(b) Sample Preparations and Recording of Spectra

All styrene derivatives were either used immediately after synthesis and purification or else were redistilled or recrystallized immediately before use. AMS derivatives were dissolved in cyclohexane which was used as a lock and reference signal. The cyclohexane (Fisher A.C.S. grade) was fractionally distilled from sodium and stored over Linde 4A molecular sieve. ATBS derivatives were dissolved in cyclohexane-d_{12} (Merck Sharp and Dhome Canada Ltd.) with 4% tetramethylsilane as lock and reference signal, to avoid interference between *t*-butyl and cyclohexane peaks. Measurements were made at three concentrations in the range of 1–5 mol %.

Proton spectra were obtained on a Varian HA-100 operating in frequency sweep mode at a probe temperature of 30°. Experimental conditions were identical to those previously described (17). Nuclear Overhauser effects for α-*t*-butylstyrene were determined according to the procedure of Bell and Saunders (18), using the electronic integrator of the HA-100 and a Hewlett–Packard 4204A digital oscillator. The sample (5 mol % in $CDCl_3$ containing 5 mol % tetramethylsilane as lock and reference) was filtered, degassed by five freeze–pump–thaw cycles on a high vacuum line and sealed at 0.01 mm.

^{13}C n.m.r. spectra were obtained in CCl_4 for 0.4 *M* solutions, using previously reported procedures (1).

Results

A complete A_3BC spectral analysis was carried out for the α-methyl and vinyl proton spectrum of α-methylstyrene, using the iterative computer program LAME (19) (protons are not labelled conventionally in order of increasing field but rather by analogy to styrene (1) to facilitate comparisons between different series).

TABLE 2. Vinyl proton chemical shifts (in p.p.m. relative to $(CH_3)_4Si$) and coupling constants (in Hz) for 4-substituted α-*t*-butylstyrenes at infinite dilution in cyclohexane-d_{12}

Substituent	δ_{H_B}	δ_{H_C}	$\Delta\delta$(B − C)	J_{BC}
H	4.7200	5.1367	−0.4167	1.79
CH_3	4.7256	5.1513	−0.4257	1.68
$C(CH_3)_3$	4.7247	5.1538	−0.4291	1.60
F	4.7247	5.1518	−0.4271	1.58
Cl	4.6958	5.1092	−0.4134	1.87

NO_2	4.7780	5.2399	−0.4619	1.19

However, it was found that all chemical shifts and coupling constants and also the chemical shift difference $\Delta\delta$(B − C) agreed within 0.05 Hz of those obtained from a first order A_3MX analysis. Consequently, all AMS spectra were analyzed by first order analysis. ATBS derivatives were analyzed as AB spectra (there was no resolvable coupling to the *t*-butyl group).

Infinite dilution proton chemical shifts were determined by least squares fitting of the linear dilution curves. Standard errors of intercepts never exceeded 0.0008 p.p.m. Proton chemical shifts and coupling constants for AMS derivatives are summarized in Table 1 with results for ATBS derivatives in Table 2. ^{13}C chemical shift data for both compounds are given in Table 3.

CNDO/2 calculations were carried out on an IBM 360-65 computer using a standard program (19). Most bond lengths and bond angles for styrene were identical to those previously reported (1) with the C_1—C_α—C_β valence angle α fixed at 120°. The C_1—C_α bond length was varied as a function of ρ

[2] $$r_{C_1—C_\alpha} = (1.52 - 0.06 \cos \rho)\text{Å}$$

to allow for decreased conjugation in the non-planar forms. Assumed geometries for other substituents are tabulated elsewhere (5). For reasons of computational economy, most calculations were carried out for 4-substituted styrenes with $\rho = 90°$ rather than for α-alkylstyrenes using the experimental ρ. Vinyl carbon and hydrogen charge densities are given in Table 4 (complete charge densities are on deposit in the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2). However, calculations were also performed for a limited number of styrene derivatives with $\rho = 30$ and 60° and AMS derivatives with the experimental ρ of 30°. These calculations showed that charge densities varied smoothly with ρ. In addition, nearly identical results were obtained for the substituent dependence of charge densities of styrene and AMS derivatives with $\rho = 30°$, demonstrating that no complications were introduced by the presence of the alkyl substituent.

Discussion

(a) Determination of Conformation of α-Alkylstyrenes

^1H and ^{13}C S.C.S. in 4-substituted α-alkylstyrenes are very sensitive to the dihedral angle, ρ, between the phenyl and vinyl groups. Consequently we attempted to determine this angle as accurately as possible. ρ was estimated from the

electronic absorption spectrum using two different techniques.

Experimentally determined λ_{max} values for the conjugation bands of styrene AMS and ATBS were respectively 248, 243 and 223 mμ while the corresponding extinction coefficients were 14 310, 10 900, and 2630. ρ can be estimated from the extinction coefficients using the approach of Braude and Sondheimer (20):

$$[3] \qquad \varepsilon/\varepsilon_{0^\circ} = \cos^2\rho$$

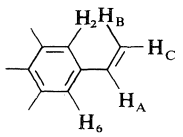
where ε_{0° is the extinction coefficient for styrene (assumed planar (1)). This approach gives ρ = 29° for AMS and ρ = 65° for ATBS. Alternatively one can determine ρ from conjugation band transition frequencies, using the method of Suzuki (21). This method yields ρ = 30° for AMS and ρ = 63° for ATBS (full details of the calculation are given elsewhere (5)). The two methods are in excellent agreement and average values of ρ = 30° for AMS and ρ = 64° for ATBS will be used in the following discussion.

(b) Assignment of H_B and H_C for AMS and ATBS and Discussion of Factors Determining $\Delta\delta_0$(B − C)

H_B and H_C for AMS have been previously assigned on the basis of specific deuteration experiments (22). It was found that $\delta_{H_B} > \delta_{H_C}$, as in styrene. However, $\Delta\delta_0$(B − C) is much smaller for AMS (+0.279 p.p.m.) than for styrene (+0.517 p.p.m.). H_B and H_C for ATBS have not been previously assigned. These were assigned by utilizing the nuclear Overhauser effect (n.O.e.) (23,24). Irradiation of the *t*-butyl group gave a positive n.O.e. of 11 ± 2% for the low field vinylidene proton and negative n.O.e. of 3 ± 2% for the high field proton. This allows unambiguous assignment of the low field peak as H_C and the high field peak as H_B. This means that $\Delta\delta_0$(B − C) has changed sign and now has a large negative value (−0.417 p.p.m.) for ATBS.

It is interesting to consider why this occurs. As shown in Table 5, δ_{H_C} is nearly constant while

δ_{H_B} moves continuously to low frequency (high field) on going from styrene to ATBS. It is known that the vinyl proton chemical shifts in styrene are not solely due to ring current effects (25). The CNDO/2 calculations indicate that differences in charge density for H_B and H_C contribute substantially to $\Delta\delta_0(B - C)$. Assuming an average scaling factor of 21 p.p.m./hydrogen 1s electron (1), then $\Delta\delta_0(B - C)$ for styrene and AMS are almost quantitatively predicted by a combination of ring current and charge density effects (Table 5). A somewhat larger error is found for ATBS although chemical shift trends are well reproduced, particularly for H_C. The large positive charge density for H_B in styrene (**3**) apparently is due to the steric interaction between H_B and H_2 since q_{H_B} decreases as ρ increases: Similarly, H_2 has a less



3

negative charge (-18×10^{-4}) than H_6 (-54×10^{-4}) with q_{H_2} becoming more negative as ρ increases. By contrast, q_{H_C} is much less sensitive to ρ. Thus, there are apparently two electronic contributions to the high field shift of H_B on going from styrene to ATBS: (*1*) relief of steric hindrance and (*2*) the electron-releasing effect of the alkyl substituent (as evidenced by the additional negative contribution to q_{H_B} for the alkylstyrenes as compared to styrene for the same ρ). This combines with the decreased ring current effect to give a large high field shift for H_B. By contrast, the near constancy of δ_{H_C} reflects a lesser sensitivity to both ring current and charge density effects. It is also possible that there is a van der Waals' or dispersion interaction (26) contributing to the low field shift of H_B in styrene. However, the results can be explained without invoking an effect of this kind.

One final conclusion can be drawn from the above discussion and the data in Table 5: for a given styrene derivative, δ_{H_B} should be much more sensitive than δ_{H_C} to small changes in ρ.

(c) Interpretation of Substituent-induced Chemical Shifts

π-Conjugative effects should vary as $\cos^2\rho$ (27). Consequently, the expected weighting factors, *r*, for correlations of S.C.S. with *F* and *R* can be estimated from the observed values for styrene (1):

$$[4] \qquad r_{H_B} = 0.414 \cos^2\rho$$

$$[5] \qquad r_{H_C} = 0.420 \cos^2\rho$$

$$[6] \qquad r_{C\text{-}\alpha} = -0.35 \cos^2\rho \approx 0$$

$$[7] \qquad r_{C\text{-}\beta} = 7.15 \cos^2\rho$$

It is more difficult to make predictions from the observed *f* values since they should reflect both through-space field effects and π polarization effects (1). As a first approximation it seemed reasonable to assume that the through-space field effect upon proton chemical shifts should be independent of ρ. To predict how π polarization effects vary with ρ it is necessary to determine the exact nature of these effects.

The $N(CH_3)_3^+$ group should have a large field effect and small resonance effect (zero according to Swain and Lupton (2)). Since σ inductive effects are unimportant (1), vinyl ^{13}C chemical shifts for $N(CH_3)_3^+$ derivatives should primarily reflect π inductive effects. Chemical shift data for $N(CH_3)_3^+$ derivatives of styrene and ATBS as well as charge densities for the styrene derivative at $\rho = 0$ and $\rho = 90°$ are given in Table 6. Comparison of π charge densities for $\rho = 90$ and $\rho = 0°$ suggests that there are two mechanisms of transmission of π inductive effects. For $\rho = 90°$, the phenyl and vinyl π electron systems appear to be independently polarized towards the positive group, leading to equal but opposite changes in π electron density for C-α and -β. This effect, which is probably transmitted through space, should be the only mechanism affecting the vinyl group for large values of ρ. For small values of ρ, the vinyl and phenyl groups are conjugated and the entire π electron system can be polarized. This additional polarization mechanism leads to electron transfer from the vinyl to the phenyl group with loss of electron density from C-β but little change in electron density for C-α. These two mechanisms can account for the *f* values obtained from the correlations of vinyl ^{13}C chemical shifts for 4-substituted styrenes with *F* and *R* (1). These correlations showed a small negative *f* value for C-α and a larger positive *f* value for C-β. The C-α and -β chemical shifts for $N(CH_3)_3^+$ derivatives of styrene and ATBS are also consistent with this interpretation of π

polarization effects. Assuming a $\cos^2\rho$ dependence for the conjugative π polarization mechanism, this indicates that the residual through-space π polarization effect upon $\delta_{C-\beta}$ at $\rho = 90°$ should be approximately 30% of the total π polarization effect at C-β for the planar styrene. By contrast, C-α is much less sensitive to ρ, as suggested by the calculations. Of the phenyl carbon chemical shifts, C-1 and -2,6 are consistent with the presence of a π polarization effect but C-3,5 and -4 apparently are not. However, the latter chemical shifts are likely to reflect structural effects similar to the α and β effects for linear hydrocarbons (28).[3] Since the $N(CH_3)_3^+$ group is isoelectronic with the $C(CH_3)_3$ group and similar in size, a comparison of chemical shifts for these pairs of styrene derivatives should minimize if not completely eliminate structural effects. The chemical shift differences should then reflect the effect of the positive charge on the $N(CH_3)_3^+$ group. As seen in Table 6, these chemical shift differences indicate a strong π polarization effect (the relatively small shift for C-4 may be due to the counteracting σ inductive effect of the $N(CH_3)_3^+$ group). This is a particularly interesting observation since π polarization effects are usually regarded as unimportant (32). However, we have obtained corroboratory evidence for π polarization effects from the ^{13}C chemical shifts of a large number of phenylalkane derivatives (31). In addition, ^{13}C chemical shift data and π charge densities for *trans*-1-substituted 1,3-butadienes indicate that π polarization effects are important in these derivatives (33).

The evidence presented above concerning the nature of π polarization effects can be used to predict *f* values for δ_{H_B}, δ_{H_C}, and $\delta_{C-\beta}$ as a function of ρ. Total *f* values for H_B and H_C of styrene are respectively 0.100 and 0.166 with estimated through-space field components of −0.007 and 0.060 and π polarization components of 0.107 and 0.106 (1). Assuming that 30% of the π polarization effect remains at $\rho = 90°$ (see above) and that the field effect is independent of ρ:

[3]The exact nature of these effects is still unclear (29) although it has been suggested that the α effect may be due to contributions to the diamagnetic and paramagnetic terms in the chemical shift equation arising from the electron distribution on the α substituent (29, 30). In any case, it appears improbable that the α and β effects will be totally reflected by changes in the ground state charge density at the carbon in question. γ-Effects were also noted for hydrocarbons (28). However, these effects apparently reflect *gauche* steric interactions (29) and should be insignificant in the case of C-2,6 S.C.S. since these carbons are *trans* to the substituent. The validity of correlating ^{13}C S.C.S. due to more remote substituents with ground state charge densities is discussed in detail elsewhere (31).

*Weighting coefficients for equation $\delta = fF + rR + \delta_0$.
†Standard deviation between calculated and observed chemical shifts (in p.p.m.).
‡Correlation coefficient.
§Values for f and r estimated from **eqs.** 4–10 (in brackets).

$$[8]\quad f_{H_B} = -0.007 + 0.107\,(0.30 + 0.70 \times \cos^2\rho) = +0.025 + 0.075\cos^2\rho$$

$$[9]\quad f_{H_C} = +0.060 + 0.106\,(0.30 + 0.70 \times \cos^2\rho) = +0.092 + 0.074\cos^2\rho$$

$\delta_{C\text{-}\beta}$ should only reflect π polarization effects and resonance effects. Since $f_{C\text{-}\beta}$ for styrene $= +2.82$;

$$[10]\quad f_{C\text{-}\beta} = +2.82\,(0.30 + 0.70\cos^2\rho) = +0.85 + 1.97\cos^2\rho$$

By contrast, both calculations and chemical shift data for $N(CH_3)_3^+$ derivatives suggest that $f_{C\text{-}\alpha}$ should be nearly independent of ρ. While eqs. 4–10 appear complex, they are based on a very simple model for mechanisms of transmission of substituent effects, *i.e.*, that any conjugative interaction should vary as $\cos^2\rho$.

Results of correlations of ^1H and ^{13}C chemical shifts with F and R are summarized in Table 7. Halogens were excluded from the ^1H correlations but included in the ^{13}C correlations for reasons discussed in the previous paper (1). Previously determined F and R values were used for the $N(CH_3)_2$, $Sn(CH_3)_3$, and $Si(CH_3)_3$ groups (1) with other values taken from the original tabulation (2).

The f and r values predicted from eqs. 4–8 are also given in Table 7. In the case of ^{13}C correlations, there is a generally good agreement between predicted and observed f and r values. In particular the f values are entirely consistent

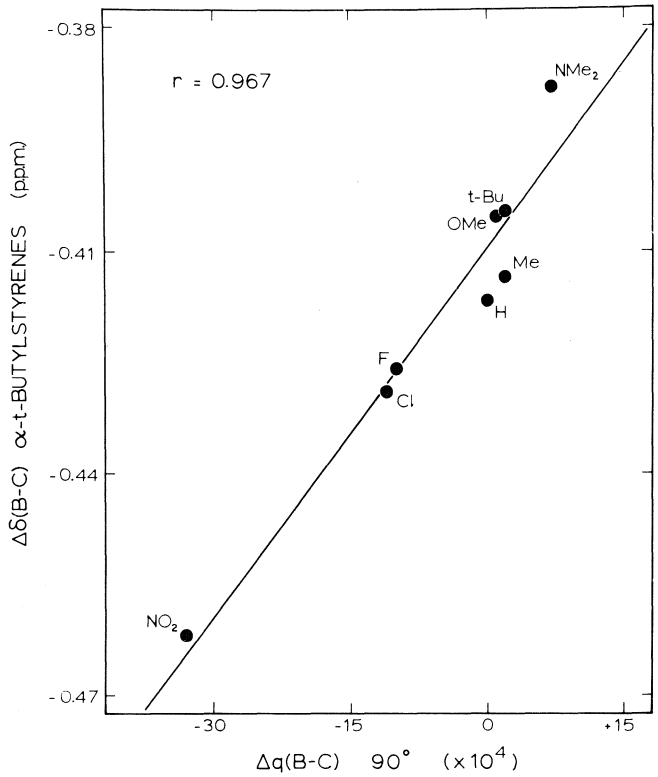

FIG. 1. Correlation of the β proton chemical shift difference, Δδ(B − C) of ATBS derivatives with the difference in charge density for the β protons of styrene derivatives (relative to styrene with ρ = 90°).

with the postulated nature of π polarization effects. The signs and magnitudes of the *f* values for C-2,6 and -1 are also consistent with phenyl group π polarization while the *r* values are consistent with normal pictures of resonance interactions (the increase in *r* with ρ for C-1 is logical since the resonance effect should be isolated in the phenyl group as conjugation between phenyl and vinyl groups decreases). No correlations were performed for C-3,5 and -4 because these chemical shifts are likely to be affected by structural effects. The ^{1}H chemical shift correlations also show good agreement between predicted *f* and *r* values. However, it appears that *f* for δ_{H_C} and *r* for δ_{H_B} both decrease more rapidly than predicted by eqs. 9 and 4. Consequently, Δδ(B − C) for AMS and ATBS derivatives depends upon both *F* and *R* with a smaller field dependence for Δδ(B − C) than in the case of styrene (1).

While the ^{1}H S.C.S. for H_B and H_C do not precisely follow the predictions based upon the model of electronic substituent effects outlined above, charge densities determined by the CNDO/2 calculations indicate a probable electronic origin for the deviations. For planar 4-substituted styrenes, $\Delta(\equiv q_{H_B} - q_{H_C}$, relative to styrene) is linearly related to *F*:

$$[11] \qquad \Delta(0°) = -(33 \pm 4) \times 10^{-4}F$$

with a statistically insignificant dependence on *R*. On the other hand, when ρ = 90°, Δ depends upon both *F* and *R*:

$$[12] \quad \Delta(90°) = -(20 \pm 3) \times 10^{-4}F - (17 \pm 4) \times 10^{-4}R$$

Thus it is seen that both the decreased field dependence and the negative resonance dependence of Δδ(B − C) on going from styrene to non-planar α-alkylstyrenes are reproduced by the CNDO/2 calculations. This has been further confirmed by plotting Δδ(B − C) for ATBS *vs.* Δ(90°) (Fig. 1). There is a good correlation (better than for styrene (1)) and the slope of 17 p.p.m./hydrogen 1s electron is consistent with previously suggested scaling factors for proton chemical shifts (34, 35). While the good

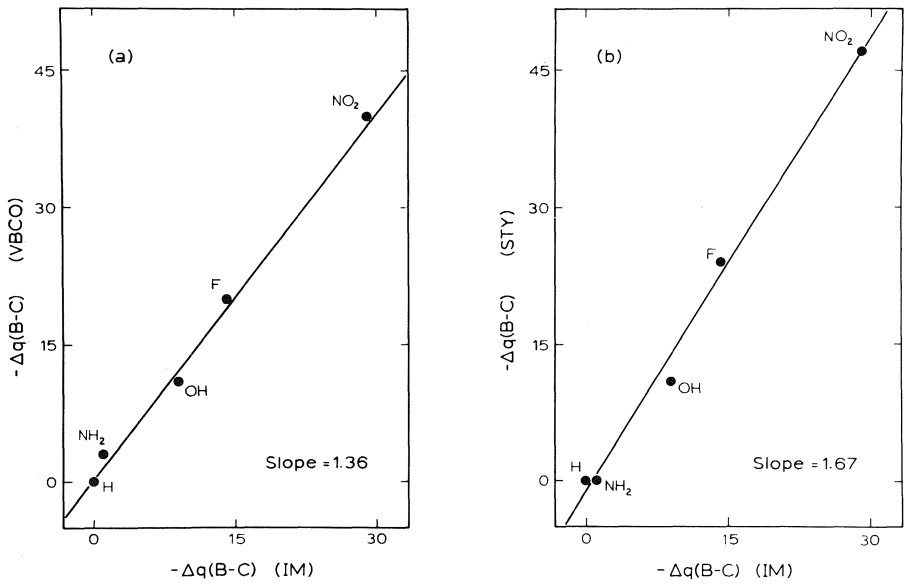

FIG. 2. Plots of differences in charge densities for H_B and H_C of (*a*) 4-substituted 1-vinylbicyclo[2.2.2]octanes (VBCO) and (*b*) 4-substituted styrenes (STY), both plotted against the corresponding difference in ethylene proton charge density for CH_3X—C_2H_4 pairs of molecules (IM).

correlation may be partly fortuitous since the calculations were carried out for styrene at 90° rather than ATBS at 64°, it is highly improbable that the agreement could be completely accidental. In addition, plots of $q_{H(90°)}$ *vs.* $q_{H(0°)}$ for each proton (not shown) revealed a linear plot for H_C while the plot for H_B was irregular, particularly for groups with large R values. This supports the conclusion from the F and R correlations that there is an unexpected resonance contribution to δ_{H_B}.

Thus the CNDO/2 calculations for 4-substituted styrenes with $\rho = 90°$ provide evidence for electronic effects which can apparently account for all deviations between predicted and observed f and r values for AMS and ATBS derivatives. In addition, CNDO/2 calculations for 4-substituted 1-vinylbicyclo[2.2.2]octanes (VBCO) and ethylene–CH_3X pairs (oriented so that the C—X bond and the ethylene group are in an identical orientation to the C—X bond and the vinyl group in VBCO) (1) provide a possible explanation for the reduced field dependence of δ_{H_B} and $\Delta\delta(B - C)$ on going from styrene to AMS to ATBS. These calculations indicate that the field effect of the substituent (as measured by Δ) strongly depends upon the nature of the intervening molecular framework (see Fig. 2). The field effect of the substituent should vary inversely as the effective dielectric constant within the cavity (36) where ε_{eff} is a function of both the molecule and the surrounding medium. Hermann (37) has calculated that ε_{eff} for 4-substituted bicyclo[2.2.2]octane carboxylic acids in vacuum is less than unity (0.73). This corresponds to an enhancement of the field effect by 1.37, in exact agreement with the calculated enhanced field effect for VBCO derivatives relative to CH_3X–ethylene pairs. The field effect is apparently even larger for styrene where the field acts in the nodal plane of the phenyl π system, *i.e.* in a cavity inside a polarizable system. It is entirely conceivable that ε_{eff} is increased by rotating the vinyl group so that the field no longer acts through the cavity formed by the phenyl π electron system. An increased ε_{eff} would lead to a decreased field effect. This would primarily effect the f coefficient for δ_{H_C}, as observed.

Previous experimental investigations (1, 38, 39) of field effects upon proton chemical shifts provide support for the suggestion that the A constant in the Buckingham equation (40) depends upon the system (see Table 8). Calculated A values are based upon Musher's calculated value of 3.1×10^{-12} for the effect of an isolated dipole upon a C—H bond (39) and the proportionality factors shown in Fig. 2. An experimental investigation of 1-vinylbicyclo[2.2.2]octane derivatives has been undertaken in an attempt to confirm this point.

TABLE 8. Comparison of observed and calculated values of A constant in the Buckingham equation for various systems

System	$A(\times 10^{12})$ Observed	Calculated

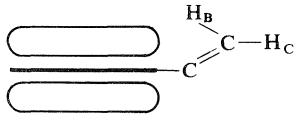
‡Estimated from S.C.S. for 4-substituted styrenes (1) (field evaluated at the proton).
§Calculated value for isolated C—H bond in gas phase (39).
‖Calculated values for 4-substituted 1-vinylbicyclo[2.2.2]octanes and styrenes, using $A = 3.1 \times 10^{-12}$ for a C—H bond in the gas phase and the slopes of the plots of Δ for these compounds *vs.* Δ for C_2H_4–CH_3X pairs (Fig. 2).

The CNDO/2 calculations strongly suggest that the smaller than predicted R dependence of δ_{H_B} for AMS and ATBS derivatives is, at least in part, due to electronic interactions. Since there is no apparent reason why conjugative interactions should affect δ_{H_B} and δ_{H_C} differently, the small r values apparently reflect some additional negative resonance contribution to δ_{H_B}, *i.e.* a contribution by which electron-withdrawing ($+R$) groups cause high field shifts while $-R$ groups cause low field shifts. This is unexpected and the nature of the electronic effect is unclear to us. However, it is possible that it may be associated with an interaction of the C_α—C_β—H_B σ bond system with the phenyl π electron system. C_β—H_C would be much less likely to interact with the π electron system.



4

While the CNDO/2 calculations indicate that S.C.S. for the vinyl protons of AMS and ATBS derivatives are primarily due to electronic effects, one substituent effect which is primarily magnetic in origin may also be present. This is associated with substituent-induced changes in the dihedral angle ρ. The vinyl group can either accept or donate electrons by resonance. Therefore any substituent with a significant resonance effect should increase the conjugation between phenyl and vinyl groups. This is supported by CNDO/2 calculations since the calculated C_1—C_α bond order is greater for both 4-*N*,*N*-dimethylaminostyrene (0.2949) and 4-nitrostyrene (0.2952) than for styrene (0.2919).

As shown in Table 5, δ_{H_B} is much more sensitive than δ_{H_C} to changes in ρ, primarily due to changes in ring current effect. Since δ_{H_B} increases with decreasing ρ, substituent-induced changes in ρ should be reflected by a positive dependence of δ_{H_B} and $\Delta\delta(B - C)$ on $|R|$ (since both $+R$ and $-R$ substituents should decrease ρ).[4] Since all substituents had either $-R$ effects or very small $+R$ effects, this is difficult to distinguish from the observed negative R dependence (*i.e.* $-R \approx +|R|$). Based on the data from Table 5, the predicted angular dependence of δ_{H_B} at $\rho = 30°$ is approximately -0.01 p.p.m./degree. Thus the additional resonance contribution to δ_{H_B} could arise from very small changes in ρ, probably not exceeding 5°. This does not appear unreasonable.

There is conflicting evidence for the existence of a magnetic effect due to changes in ρ. In support of an effect of this type is the observation that the negative R dependence for $\Delta\delta(B - C)$ is apparently greater for AMS than for ATBS, whereas a purely electronic effect might be expected to have a maximum for $\rho = 90°$. However, the CNDO/2 results provide strong evidence for the presence of an electronic effect. It is probable that both effects are present, but their relative importance is uncertain.

In conclusion, correlations of vinyl ^1H and ^{13}C S.C.S. for AMS and ATBS derivatives with F and R give f and r values which are in good agreement with values predicted from experimental results for styrenes and a model for transmission of substituent effects which assumes a $\cos^2\rho$ dependence for transmission of any conjugative interaction. In cases where discrepancies are observed between calculated and observed f and r values, CNDO/2 calculations indicate that the deviations are primarily due to unanticipated electronic interactions, although one possible magnetic effect is postulated. Since the ^1H and ^{13}C chemical shifts and CNDO/2 charge densities all reflect similar trends in substituent effects and since the variation of f and r with ρ is in overall good agreement with a simple model of substituent effects, we conclude that the F and R

[4]This effect is completely different from a substituent-induced decrease in the total ring current effect of the phenyl group (38). The latter effect, which should have a *negative* $|R|$ dependence, is not important in 4-substituted styrenes (1) and therefore is unlikely to be important here.

correlations reflect electronic effects for these compounds and can be used to deduce mechanisms of transmission of substituent effects. As in the case of 4-substituted styrenes (1), the three main mechanisms of transmission of substituent effects are through-space field effects, resonance or mesomeric effects and π polarization effects. The magnitude of the field effect appears to depend upon the nature of the intervening molecular framework. Both CNDO/2 calculations and vinyl and phenyl ^{13}C chemical shifts suggest that the π polarization effect can be divided into two effects. When there is no conjugation between phenyl and vinyl groups ($\rho = 90°$) the two groups are independently polarized by the substituent (presumably acting through space) but for $\rho < 90°$ an additional polarization of the entire conjugated styrene π electron system can occur. The observation of π polarization effects is particularly important since these effects have often been considered to be unimportant.

Our conclusion that the correlations of S.C.S. for styrene derivatives with F and R reflect intramolecular electronic effects in these compounds is contradictory to the conclusion of Miller and Wiley based on S.C.S. for other systems (4). We have reinvestigated some of the systems on which the latter conclusions were based. This is the subject of the following paper.

Stereochemical and Steric Effects in Nucleophilic Substitution of α-Halo Ketones

J. William Thorpe and John Warkentin

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 11, 1972

Bimolecular substitution reactions of α-halo ketones with acetate and azide ions are remarkably insensitive to steric hindrance. 1-Bromo-4,4-dimethyl-2-pentanone (bromomethyl neopentyl ketone) is only slightly less reactive than bromo acetone in spite of the fact that the carbonyl group in the former is neopentylic. The results are interpreted in terms of a normal S_N2 transition state, not involving either special alignment of entering and leaving group with the π-orbital of the carbonyl function (conjugation) or covalent interaction between nucleophile and carbonyl carbon (bridging) for reaction of conformationally-mobile systems. Conformationally-fixed systems, on the other hand, may be affected by such factors. *trans*-2-Chloro-4-*t*-butylcyclohexanone is 61-fold more reactive than the *cis*-isomer, in the S_N2 reaction with acetate. Activation parameters support the conclusion that only those α-halo ketones which are stereochemically set up for conjugation and bridging undergo substitution by a mechanism significantly different from that operating in corresponding reactions of alkyl halides.

Possible significance of the results to the mechanism of bimolecular elimination is discussed.

Les réactions de substitution bimoléculaire des α-halocétones avec les ions acétate et azoture sont remarquablement insensibles à l'empêchement stérique. La bromo-1 diméthyl-4,4 pentanone-2 (bromométhyl néopentyl cétone) n'est que légèrement moins réactive que la bromoacétone malgré un groupe carbonyle néopentylique. Les résultats sont interprétés par un état de transition normal S_N2 qui n'implique ni un alignement spécial du groupe entrant ou partant ave l'orbitale π du carbonyle (conjugaison) ni une interaction covalente entre le nucléophile et le carbone du carbonyle (pontage) pour la réaction des systèmes conformationnellement mobiles. Les systèmes de conformation rigide peuvent être affectés par de tels facteurs. La *trans* chloro-2 *t*-butyl-4 cyclohexanone est 61 fois plus réactive que le *cis* dans la réaction S_N2 avec l'acétate. Les paramètres d'activation permettent de conclure que seules ces α-halocétones, où la stéréochimie se prête à une conjugaison et à un pontage, subissent une substitution selon un mécanisme nettement différent de celui des halogénures d'alkyle.

L'apport possible de ces résultats au mécanisme de l'élimination bimoléculaire a été discuté.

[Traduit par le journal]

Can. J. Chem., **51**, 927 (1973)

Introduction

The enhanced reactivity of α-halo ketones, relative to alkyl halides, in bimolecular nucleophilic substitution has been known for many years. For example, phenacyl chloride and chloroacetone were reported to react 97 000 and 33 000 times as fast, respectively, as *n*-propyl chloride with iodide ion in acetone at 50° (1). Somewhat smaller rate factors, lying between 10^2 and 10^3, were reported for the same compounds reacting at 30° in methanol with acetate, azide, cyanate, and thiocyanate ions (2).

Many mechanisms have been proposed to account for the enhancement of reactivity conferred by the carbonyl group. Hughes (3) suggested that the inductive effect of the carbonyl group enhances the normal polarity of the carbon–halogen bond by increasing electron deficiency at the α-carbon. The more polar the C—X bond the faster would be the attack of nucleophiles in bimolecular displacement. Baker (4*a*) suggested that the first and rate-determining step is addition to the carbonyl carbon from which the addend is then transferred to the α-position, with displacement of halogen, in a fast step. A variant of that mechanism, which includes epoxide formation (eq. 1), has been considered by Pearson and coworkers (4*b*).

Other modes of interaction of the nucleophile

[1] $$RCOCH_2X + B \rightleftharpoons R-\underset{\displaystyle B^+}{\overset{\displaystyle O^-}{\underset{|}{\overset{|}{C}}}}-CH_2X \rightarrow$$

$$R-\overset{O}{\underset{\displaystyle B^+}{\overset{/\backslash}{C}}}-CH_2 + X^-$$

$$\downarrow B' \text{ fast}$$

$$RCOCH_2B' + B$$

with the carbonyl function have been suggested. Dewar (5) postulated that the C—X bond being broken and the new bond being formed at the transition state are aligned with the π-plane of the carbonyl group. Excess negative charge can then be accommodated in a molecular orbital encompassing the carbonyl group (conjugation) with consequent lowering of the activation free energy. A modification of that transition state picture, with partial covalent bonding of the nucleophile to both the carbonyl carbon and the α-carbon (bridging) has been suggested also (6). These last mechanisms have in common a strict geometric requirement but they differ with respect to the carbonyl-to-nucleophile[1] bond distance.

Another rationale for the enhanced S_N2 reactivity of α-halo carbonyl compounds does not invoke such a geometric restriction. Pearson and coworkers (4*b*) reached the conclusion that interaction between carbonyl group and nucleophile is largely electrostatic and that α-halo carbonyl compounds owe their high S_N2 reactivity to polarization interaction which is particularly important in those compounds because of the smaller steric requirement of RCO compared to RCH_2.

Finally, the possibility that α-halo ketones might give substitution products via the enolization–solvolysis mechanism, eq. 2, was considered in 1938 by Richard (7). Many cases have

[2]
$$RCH_2COCH_2X \rightleftharpoons RCH{=}C(OH){-}CH_2X \rightarrow RCH{=}C(OH)^{+}{=}CH_2X^{-} \xrightarrow{B^-} RCH_2COCH_2B + RCH(B)COCH_3$$

now been reported in which that mechanism is probably operative (8, 9). Possibly a given fast rate of substitution could result from fast enolization–solvolysis in which case comparison with S_N2 rates in corresponding alkyl halides would be meaningless.

For substitutions on α-halo ketones by weakly basic nucleophiles, many of the potential rationales (above) for fast rates are untenable or weak. The explanation of Hughes would require that electron-withdrawing α-substituents other than carbonyl should also enhance the rate of S_N2 reaction of a halide. However, what is found is that α-halogen, α-alkoxy, and α-sulfonyl substituents retard the rate of bimolecular substitution of alkyl halides. Baker's mechanism fails to fit the general observation that the rate of substitution of α-halo ketones is strongly dependent on the identity of the halogen (4*b*, 10); bromo ketones reacting faster than chloro ketones.

Epoxides have been isolated or shown to be intermediates in reactions of some α-halo ketones, particularly those containing the α-halo benzyl group, with bases (11–16). Alkoxide bases are the most common ones leading to epoxides and other products, such as ketals, derived from them. Whether or not epoxide intermediates lead to normal S_N2 products seems to depend on the system under investigation. Good kinetic evidence against epoxide intermediates in substitutions of α-halo ketones with nitrogen and sulfur bases was provided by Pearson and coworkers (4*b*). Lutz (17) used a stereochemical probe for the epoxide mechanism. He showed that optically active desyl chloride undergoes exchange and racemization, with radioactive Cl^-, at the same rate. For the epoxide mechanism exchange without racemization is predicted. On the other hand, Turro, Rappe, and coworkers (18) claim that the epoxide mechanism is a major route to α-methoxy ketones in reactions of several α-bromo ketones with methoxide in methanol.

The enolization–solvolysis mechanism should be easily recognized by examination of the products and of unreacted halo ketone. Unless high selectivity for capture of the allylic cation intermediate at the original halogen-bearing site is built in, the absence of rearranged substrate and rearranged product can be taken as evidence against ion-pair intermediates.

It is more difficult to rule out the remaining explanations; namely conjugation (5), bridging (6) and electrostatic/steric factors (4*b*). Evidence pointing to a definite geometric requirement as

[1]In the bridging mechanism, the leaving group as well as the nucleophile could bridge the two carbon atoms. Such bridging would have to be the same for both entering and leaving groups in cases of displacement on $RCOCH_2X$ by X^-.

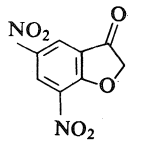
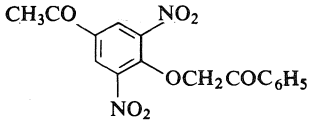
[a]In each group the bracketed numbers next to the rate constants are relative rates referred to the last entry for that group.
[b]At 0.2°, the ratio of rate constants (bromoacetone/bromopinacolone) is 5.98.
[c]For *n*-butyl bromide under the same conditions, $k^{AcO^-} = 2.06 \times 10^{-5}$ M^{-1} s^{-1}.
[d]This is a composite rate constant for the S_N2 reaction and the enolization/solvolysis mechanism, as indicated by the product composition: $(CH_3)_2CHCOCH_2OAc$, 72.5%; $(CH_3)_2CHCOCH_2OH$, 17.2%; $(CH_3)_2C(OAc)COCH_3$, 5.5%; $(CH_3)_2C(OH)COCH_3$, 4.8%. In reaction of the bromo ketone with azide, and in reaction of the chloro ketone with either nucleophile, solvolytic products were not detected.

demanded by the conjugation and bridging pictures was provided by Bartlett and Trachtenberg (19), who studied bimolecular substitution of pseudo halides **1** and **2**. In each case the leaving group is a dinitro phenoxide ion,



1



2

attached α to ketonic carbonyl. In **1**, however, the leaving group departs in a plane perpendicular to the carbonyl π-orbital, making bridging or conjugation impossible. Compound **2**, in which there is no such restriction, reacted 9000 times as fast with iodide in acetone at 0°; the net result of lower values of both $\Delta H^{\ddagger}$ (10 *vs.* 31 kcal mol^{-1} for **1**) and $\Delta S^{\ddagger}$ (−30 *vs.* +25 e.u. for **1**). Although these results were considered to be consistent with either the conjugation mechanism or the bridging mechanism (19), the authors cautioned that Pearson's electrostatic model might also suffice to explain the sluggishness of **1**, to which the nucleophile must approach along a line parallel to the C=O dipole but from the negative end. Sisti and Lowell (2) concluded, however, that the electrostatic model is insufficient. They found that highly-polarizable nucleophiles like cyanate and azide react faster with α-halo carbonyl compounds than with alkyl halides by factors no larger than those in corresponding reactions with less polarizable nucleophiles. If electrostatic interaction with the polar C=O group were a dominant source of stabilization, the extent of this interaction should depend critically on the polarizability of the nucleophile. Temnikova and coworkers (20) also favor a Dewar–Winstein transition state, with its geometric constraint, over one dominated by electrostatic factors.

The objectives of the work described in this paper were to find stronger evidence for or against the Dewar–Winstein transition states in substitution reactions of α-halo ketones and, if possible, to distinguish between them. The features on which probes were based are the strict geometric requirement common to both and the steric hindrance by R of $RCOCH_2X$ that should be appreciable if significant bonding to carbonyl carbon (bridging) were involved in displacements of the halogen.

Methods, Results, and Discussion

Rates of displacement of chloride or bromide ions from α-halo ketones by acetate or azide ions in homogeneous, dilute solutions of aqueous 1,2-dimethoxyethane (DME) were followed with appropriate ion-specific electrodes. Second order kinetics was established and products were isolated and identified. With two exceptions (see footnotes to Table 1) all the substrates gave unrearranged substitution products, without a trace of solvolytic products. Moreover, in those cases where stereochemistry could be demonstrated, substitution proceeded with inversion. Traces of α,β-unsaturated ketones, the expected products of E2 reactions, were looked for with u.v. spectroscopy in a few cases but none were

[a]In each group the bracketed numbers following the rate constants are relative rates referred to the east entry in that group.
[b]This rate constant, like that for reaction of the isomeric bromo ketone (Table 1, footnote *d*) is a composite value from competing S_N2 and enolization/solvolysis reactions. The value 2.28×10^{-5} M^{-1} s^{-1} is only an upper limit for the S_N2 rate constant and relative rates (26.8 and 64.0) in that column are nothing more than lower limits.

detected. It is therefore safe to conclude that the reactions followed, save for the exceptional cases, were purely bimolecular substitution processes.

Table 1 holds rate data for reaction of α-halo ketones in which the site of substitution is primary but in which the steric bulk of the other carbonyl substituent is varied, first by successive increases in the number of α-methyl groups (entries 1–4) and then by analogous changes in the extent of β-branching (entries 5–8). It is striking that in the first series the rate factors caused by substituting *t*-butyl for methyl at carbonyl carbon are only 3.4, 2.5, and 1.6 for displacement of Cl^- by AcO^-, Br^- by AcO^-, and Br^- by N_3^-, respectively, at 54.8°. For the second reaction run at 0.2°, the rate factor is increased to 6.0 (Table 1, footnote *b*). Steric hindrance to attack at neopentyl positions has been well documented. For example, saponification of ethyl acetate in 85% ethanol at 50° is 161 times as fast as the same reaction of ethyl trimethylacetate (21). In acid-catalyzed hydrolysis the same esters show a rate ratio of 35 at 25° (22). Other models for the steric effect in addition to neopentylic, sp^2-carbon include hydroboration of alkenes and carbene additions to alkenes. In hydroboration by disiamyl borane in THF at 0°, *cis*-2-butene is about 30 times as reactive as *cis*-4,4-dimethyl-2-pentene (23). Dichlorocarbene reacts 35 times faster with 1-butene than with 3,3-dimethyl-1-butene at −10° (24). These reactions are not equally good models for the steric effect to be expected for reaction of α-halo ketones via a three-membered transition state and differences in medium and in temperature compound the problem of choosing the best model. However, that choice is unnecessary because the steric effects found in this work (Table 1, entries 1–4) are considerably smaller than those in any of the above-mentioned model reactions and are therefore not compatible with appreciable bonding of the nucleophile to carbonyl carbon. This conclusion is supported by the activation parameter data, which are discussed below.

The larger rate factors resulting from β-branching of chloro ketones, but not of bromo ketones (Table 1), can be accounted for qualitatively. The neopentyl substituent at carbonyl carbon can hinder not only addition to that atom but also reaction at the remote α-site. Examination of molecular models reveals that the latter hindrance can be larger in the β- than in the α-branched series. Presumably chloro ketones are more sensitive than bromo ketones to steric hindrance at the halogen-bearing carbon because the nucleophile must bond more tightly to that site at the transition state for displacement of the poorer leaving group.

Table 2 shows the effects of steric hindrance resulting from branching in the halogen-bearing carbonyl substituent. As expected for a bimolecular substitution process, the rate factors are substantial. For substitution by acetate, changing CH_2X to $CHXC(CH_3)_3$ brings about a 20 000-fold rate reduction for X = Cl and a 1800-fold reduction for X = Br. Again the greater sensitivity of the chloro ketones to steric hindrance is in keeping with a tighter transition state for displacement of a poor leaving group.

The observed effects on rates, of changing the nucleophile from acetate to azide (Tables 1, 2), are similar to those reported by Sisti and Lowell (2) who found azide 126-fold and 46-fold faster than acetate in displacement of chloride from

$C_6H_5COCH_2Cl$ and CH_3COCH_2Cl, respectively, in methanol at 30°. Lower sensitivity of azide to steric factors is usually accounted for in terms of a more reactant-like transition state; the complementary rationale for the one accounting for leaving group effects (above).

Table 3 contains rate data and activation parameters for S_N2 reactions of some alkyl halides and halo ketones, including conformationally-locked systems. The *t*-butylcyclohexyl chlorides are nearly identical in both rate at 54.8° and parameters of activation. Two striking features emerge when these compounds are compared with the corresponding chloro cyclohexanones. First, both chloro ketones are more reactive than either cyclohexyl chloride. Even if the geometry precludes conjugative and bridging interactions between nucleophile and carbonyl group, the latter causes an appreciable rate enhancement. The second striking feature is that the origin of that enhancement is entirely entropic in the case of the *cis*-chloro ketone; the enthalpic effect of introducing the CO function is actually rate retarding. This feature is not peculiar to cyclohexyl systems nor to chloro compounds as the last two entries indicate. It is also not unique to the aqueous solvent system used here, or to acetate as nucleophile. Bordwell and Brannen (25) found that the faster rate of reaction of $C_6H_5COCH_2Cl$ (relative to that of *n*-BuCl) with I^- in acetone is largely the result of a more favorable entropy of activation. The third notable feature is that the reactivity of the *trans*-chloro ketone is quite different in origin. Here $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are both lowered relative to those parameters for the *trans*-cyclohexyl chloride.

Any interpretation of these results in terms of mechanism must recognize the similarity between the sets of data for *cis*-cyclohexyl chloride and *cis*-chlorocyclohexanone on the one hand and for 1-bromobutane and 1-bromo-2-butanone on the other. In both *cis*-cyclic, secondary chloro compounds and acyclic, primary bromo compounds, the result of changing $CH_2\underset{|}{C}HX$ to $\underset{|}{C}OCHX$ is to increase rate, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$. Since the geometry precludes conjugation and bridging in the conformationally-fixed systems, one must conclude that such factors are not important either in the S_N2 reactions of acyclic α-bromo ketones; a conclusion that is supported by the data in Table 1.

The data for *trans*-2-chloro-4-*t*-butylcyclo-

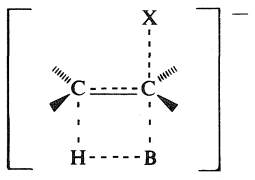
hexanone (Table 3) are consistent with either the Dewar or the Winstein picture. In the Dewar mechanism, activation enthalpy would be lowered by virtue of better charge redistribution (delocalized bonding) which is also achieved in the Winstein mechanism by more localized bonding. In either mechanism the enthalpic gain would be partly offset by entropic loss which follows from the reduction in degrees of freedom imposed by a strict geometric requirement.

In summary, we suggest that the Dewar–Winstein mechanisms of S_N2 reactions of α-halo ketones apply only in exceptional cases, where molecular geometry is already appropriately constrained in the substrate. Our present data are not extensive enough to permit selection of one of the two closely related mechanisms as the more likely in such cases.

For the S_N2 reactions of those acyclic α-halo ketones which were studied, electrostatic attraction between nucleophile and carbonyl carbon, coupled with a low steric requirement for RCO (4*b*, 25) appears to be adequate to explain both rates and activation parameters. To fit the results of Bartlett and Trachtenberg (19, see above) to this picture, one can invoke a substantial unfavorable electrostatic effect in reaction of **1**, rather than a large favorable conjugative or bridging effect in reaction of **2**. As was pointed out in the introduction, those authors considered such an alternative explanation.

Our results concerning substitutions may be relevant also to the mechanism of bimolecular elimination which, it has been suggested (26–28), proceeds through a bridged transition state having features of both elimination and substitution. This mechanism has been called



3

"E2C" and is pictured as having a transition state somewhat like **3**. Evidence against appreciable involvement of B^- at carbon, based on a probe of steric requirements similar to the one described in this paper, has been published (29). Our results also point to the low probability of E2C mechanisms, for it is unlikely that bridging to sp^3-carbon can be important if bridging to carbonyl carbon is not.

Experimental

Acyclic α-Halo Ketones

All halo ketones, except the 4-*t*-butyl chlorocyclohexanones, were purified by gas–liquid partition chromatography (g.l.p.c.) until samples were obtained which eluted as single peaks from analytical g.l.p.c. columns and which showed no evidence of extraneous signals in n.m.r. spectra run at high spectrum amplitudes. The bromo ketones listed in the tables were prepared either by bromination of the appropriate ketones (30) or by reacting a diazo ketone with hydrogen bromide. Chloro ketones were obtained by analogous reactions of ketones with chlorine (30). The following procedures are typical. Data for the purified products, all of which were known compounds, are listed in Table 4.

3-Bromo-4,4-dimethyl-2-pentanone and 1-Bromo-4,4-dimethyl-2-pentanone

Gradual addition of bromine (1.87 g, 0.0117 mol) to a well-stirred solution of 4,4-dimethyl-2-pentanone (2.40 g, 0.0211 mol) in water (100 ml) containing potassium chlorate (0.350 g, 2.87×10^{-3} mol) at 50–60° gave a mixture of bromo ketones as a dense layer on the bottom of the flask. Separation was followed by washing with water, shaking with magnesium oxide, further washing with water, and drying with calcium chloride. Preparative g.l.p.c. on a QF-1 column (10 ft × 3/8 in., 10% liquid phase) at 145° and 60 ml min^{-1} flow rate of helium gave, in order of their elution: 3-bromo-4,4-dimethyl-2-pentanone; 1-bromo-4,4-dimethyl-2-pentanone; 1,1-dibromo-4,4-dimethyl-2-pentanone; and 1,3-dibromo-4,4-dimethyl-2-pentanone.

1-Bromo-3-methyl-2-butanone

Isobutyryl chloride, b.p. 40° at 150 mm (24.5 g, 0.230 mol) was treated with diazomethane (19.3 g, 0.460 mol) in ether (31). The resulting diazo ketone was reacted with hydrogen bromide (31) to afford 1-bromo-3-methyl-2-butanone which was separated from minor impurities by preparative g.l.p.c. on the same column (above) at 150° and 24 ml min^{-1} flow rate of helium.

3-t-Butylcyclohexyl Chlorides

Following the procedure of Eliel and Martin (32), the chloroformate from *cis*-3-*t*-butylcyclohexanol (4.53 g, 2.90×10^{-2} mol) and phosgene (3.72, 3.71×10^{-2} mol) was converted to the *trans*-chloride by treatment with dry pyridine. After concentration with a rotary evaporator the solution was chromatographed on QF-1 (10 ft × 3/8 in. column, 10% liquid phase) at 135° and 50 ml/min. The first component to emerge was a cyclohexene; the second was *trans*-3-*t*-butylcyclohexyl chloride, as judged from the chemical shift of the equatorial CHCl proton (270 Hz) which is reported (32) to be 269.8 Hz from TMS. The *cis*-isomer (5% *trans*) was donated by Professor E. L. Eliel; its properties were the same as those reported in the literature (32). Gas chromatography removed the *trans*-isomer.

2-Chloro-4-t-butylcyclohexanones

These compounds were prepared and purified according to methods described by Teo (33).

Dry chlorine was passed into formic acid (340 ml) with stirring until the solution was 0.21 *M* in chlorine. The concentration was determined by adding 10 ml of 20% aqueous KI to 1 ml of the solution and titration of the resulting iodine with thiosulfate to the starch end point. This solution of chlorine in formic acid (7.14×10^{-2} mol of Cl_2) was added to 4-*t*-butylcyclohexanone (10.0 g, 6.50×10^{-2} mol) in 10 ml of formic acid. The solution was stirred for 1 h at 0–10° before water was added and the crude product was extracted into CH_2Cl_2. The latter solution was washed with saturated bicarbonate, water, and brine before it was dried with magnesium sulfate. Evaporation of the solvent left 11.0 g of a pale yellow oil; a mixture containing the isomeric chloro ketones.

Separation of the isomers was accomplished by column chromatography on silica gel, using 250 g of adsorbent in a 5 cm tube. The following solvents were used for elution, in the quantity and in the order given: (*1*) petroleum ether, b.p. 60–80°, 250 ml; (*2*) 99% petroleum ether/1% benzene, 250 ml; (*3*) 98% petroleum ether/2% benzene, 250 ml; (*4*) 95% petroleum ether/5% benzene, 250 ml; (*5*) 90% petroleum ether/10% benzene, 1000 ml; (*6*) 85% petroleum ether/15% benzene, 500 ml; (*7*) 80% petroleum ether/20% benzene, 4 l; (*8*) 70% petroleum ether/30% benzene, 750 ml; (*9*) 50% petroleum ether/50% benzene, 2 l; (*10*) benzene, 1750 ml; (*11*) 50% benzene/50% ether, 500 ml; and (*12*) ether, 500 ml.

Fraction *7* contained nearly pure *trans*-2-chloro-4-*t*-butylcyclohexanone (2.68 g) while fraction *8* was a mixture of that compound and a 2,6-dichloro ketone. Fraction *9* contained pure dichloroketone and fraction *10* held the desired *cis*-2-chloro-4-*t*-butylcyclohexanone (4.30 g). Fractions *11* and *12* were, respectively, a mixture of *cis*-2-chloro ketone with unreacted ketone and pure starting material. The *trans*-compound was purified by bulb-to-bulb distillation at low pressure and the *cis*-isomer was recrystallized from pentane to m.p. 58–59°. Spectra of both matched those supplied by Teo and Warnhoff (33).

Substitution Products

The isomeric 3-*t*-butylcyclohexyl chlorides were refluxed separately for several days in the acetate buffer used for kinetics (below). Extraction and chromatography on 10% QF-1 (10 ft × 1/8 in.) showed only starting material and one new component in each case. Preparative g.l.p.c. (10% QF-1, 10 ft × 3/8 in.) gave pure samples of the substitution products, which were shown by n.m.r. (32) and i.r. to be the isomeric 3-*t*-butylcyclohexyl acetates, formed by substitution with inversion of configuration.

Similarly, *cis*- and *trans*-2-chloro-4-*t*-butylcyclohexanone reacted with acetate ion to give, respectively, only *trans*- and *cis*-2-acetoxy-4-*t*-butylcyclohexanone. Of the latter, the *trans*-compound absorbed at 250 Hz ($AcOCH_{eq}$), compared to 255 Hz ($ClCH_{eq}$) in the *trans*-chloro ketone (33) and the *cis*-compound absorbed at 274 Hz ($AcOCH_{ax}$), compared to 270 Hz ($ClCH_{ax}$) in the *cis*-chloro ketone (33).

Substitution products from reaction of all acyclic halo ketones (Tables 1, 2) with acetate ion in aqueous DME were isolated by preparative g.l.p.c. and were identified by n.m.r. and i.r. spectroscopy. Because of the simplicity of these products and the ease with which they can be isolated and identified, details are not given. Some physical properties are gathered in Table 4.

α-Azido ketones were isolated from only a few reactions of azide ion with the halo ketones. 3-Bromo-4-methyl-2-pentanone, for example, gave only one product which was isolated by g.l.p.c. and identified from its spectra as the known (34) 3-azido-4-methyl-2-pentanone. Halo ketones which reacted solvolytically when acetate was the nucleophile (Tables 1, 2, footnotes) gave only one product (g.l.p.c.) from reaction with azide.

Ion-specific Electrodes

Bromide ion activity electrode, Model 94-35, and chloride ion activity electrode, Model 94-17, both by Orion, were used to measure halide ion concentrations. These electrodes develop potentials which are proportional to the logarithm of the activity of the ion in question (35). Potential *vs.* concentration curves were prepared for each electrode with standard solutions of the appropriate ion in the solvent used for kinetics (below). The bromide ion electrode was used in conjunction with a saturated calomel electrode (Fisher, Model 13-639-52) while the chloride electrode was used with a double junction reference electrode (Orion, Model 90-02). Potential

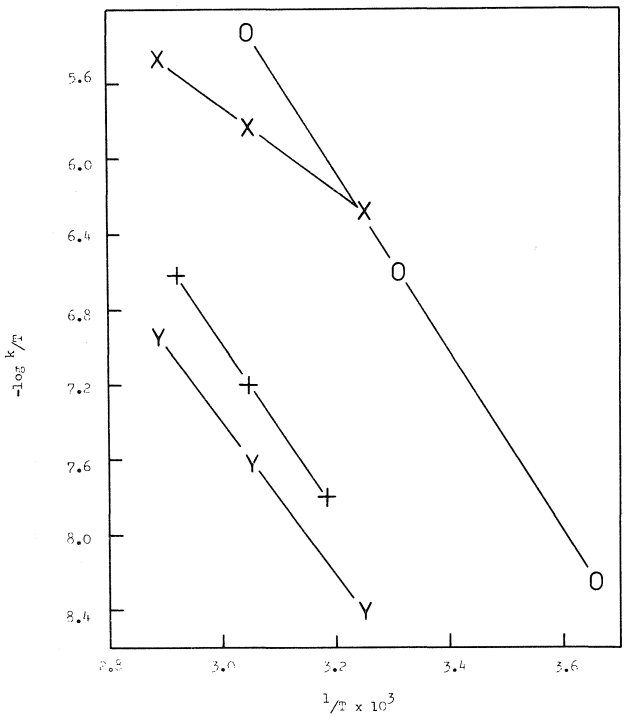

FIG. 1. Activation parameter plots for substitution by acetate: Y = *cis*-2-chloro-4-*t*-butylcyclohexanone; X = *trans*-2-chloro-4-*t*-butylcyclohexanone; + = *n*-butyl bromide; O = 1-bromo-2-butanone.

was measured with an expanded-scale p*H* meter (Fisher Accumet, Model 310), used in the expanded millivolt mode. A 1 mV recorder was used for following reactions with short (< 20 min) half-lives.

The bromide electrode was calibrated between 5.6×10^{-6} and 3.3×10^{-3} *M* in Br^-, readings being taken approximately every 10 mV. Log $[Br^-]$ *vs.* potential was linear in that range; the potential change being 120 mV. Its calibration was unchanged during 6 months of use. The chloride electrode was similarly calibrated. At the low end of its effective concentration range (5.0×10^{-5} *M*) that electrode's output was not proportional to log $[Cl^-]$. Gradual changes in the output of the chloride electrode required recalibration about once a month.

Kinetics

The reaction vessel, which was used for kinetics as well as for calibration, was a 125 ml three-necked flask of which the central neck was B-24/40 and the outer necks were B-19/40 ground joints. Electrodes were fitted snugly to these by means of machined Teflon rings, the halide electrode to the central neck and the reference electrode to an outer neck. This flask was supported in a water bath kept at 54.80 ± 0.04°, which contained an immersed magnetic stirrer (Tri-R Instruments) to drive the 1/2 in. Teflon-covered bar magnet in the flask.

For displacements by acetate the flask, mounted in the bath, was charged with 100 ml of a solution prepared from acetic acid (6.00 g, 0.100 mol), sodium acetate (8.20 g, 0.100 mol), 1,2-dimethoxyethane (24.0 ml) and water to make 100 ml. For substitution by azide, sodium azide (3.25 g, 0.050 mol) was added instead of acetate and the quantity of acetic acid was reduced to 3.00 g (0.050 mol). The necks were closed with glass stoppers during the time required for thermal equilibration. Electrodes were then inserted and, after about 20 min when the potential became steady, the halo ketone was injected from a syringe which was weighed before and after injection. Reaction was followed to two half-lives or more except for a few very slow reactions which were followed to 50% reaction only. In all cases where infinity values were taken, the agreement between the observed final halide concentration and that calculated from the quantity of halo ketone weighed in was within 3%. All halo ketones were run at least twice; the stoichiometric concentration of halo ketone being changed by factors between two and four. Agreement among the rate constants from these runs was to within 5% or better.

Pseudo first-order rate constants were obtained by plotting log $([X^-]_\infty - [X^-]_t)$ *vs.* time, where $[X^-]$ is the halide concentration. Values of $[X^-]_\infty$ were either measured or, in the case of slow reactions, obtained from the calculated initial concentration of organic halide. The slope of such a plot was set equal to $-k/2.303$. Division of such rate constants by the concentration of nucleophile gave the second order constants of Tables 1–3.

Activation parameters were obtained by fitting log k/T and $1/T$ data to a straight line (Fig. 1) with a linear least-squares computer program. The relationships (2.303 *R*) (slope) = $-\Delta H^{\ddagger}$ and (2.303 *R*) (intercept $-\log k/h$) = $\Delta S^{\ddagger}$ were applied to the computer values of the best slope and intercept. Errors were estimated from the maximum

and minimum slopes of lines fitting the extremes of the kinetic data.

The authors are indebted to Dr. K. E. Teo, Professor E. W. Warnhoff, and Professor E. L. Eliel for procedures, copies of spectra, and/or chemicals, as described in the manuscript. Financial support from the National Research Council of Canada, and an Ontario Graduate Fellowship to J. W. T., are also gratefully acknowledged.

Iron Carbonyl Complexes of the Diastereomers of *cis*-$(C_6H_5)(CH_3)AsC(CF_3)=C(CF_3)As(CH_3)(C_6H_5)$

W. R. CULLEN AND L. MIHICHUK

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received October 16, 1972

The reaction of $CF_3{\equiv}CCF_3$ with $(C_6H_5)(CH_3)As{-}As(CH_3)(C_6H_5)$ gave both *cis*- and *trans*-$(C_6H_5)(CH_3)AsC(CF_3){=}C(CF_3)As(CH_3)(C_6H_5)$, (L—L), in nearly equal amounts. When hexafluoroacetone is used as solvent the *cis*-isomer predominates (88%). The two diastereomers of the *cis*-adduct were isolated and reacted with $Fe(CO)_5$ to afford (L—L)$Fe(CO)_3$ and (L—L)$Fe_2(CO)_6$. Two of the three possible geometric isomers of the latter were obtained and their properties allowed assignment of the configuration of the starting ligands. Minor amounts of the symmetric and asymmetric forms of $[Fe(CO)_3As(CH_3)(C_6H_5)]_2$ were also obtained through loss of fluorocarbon.

La réaction du $CF_3{\equiv}CCF_3$ avec du $(C_6H_5)(CH_3)As{-}As(CH_3)(C_6H_5)$ donne à la fois les produits *cis* et *trans* $(C_6H_5)(CH_3)AsC(CF_3){=}C(CF_3)As(CH_3)(C_6H_5)$, (L—L) dans des proportions pratiquement égales. Quand l'hexafluoroacétone est utilisé comme solvant, l'isomère *cis* prédomine (88%). Les deux diastéréoisomères du produit d'addition *cis* ont été isolés et ont réagi avec le $Fe(CO)_5$ pour donner alors le (L—L)$Fe(CO)_3$ et le (L—L)$Fe_2(CO)_6$. Deux des trois isomères géométrique possibles de ce dernier produit ont été obtenus et leurs propriétés ont permis l'attribution de la configuration des coordinats de départ. Des quantités moindres des formes symétriques et asymétriques du $[Fe(CO)_3As(CH_3)(C_6H_5)]_2$ ont aussi été obtenus par la perte de carbones fluorés.

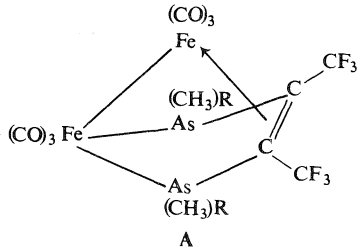
Can. J. Chem., **51**, 936 (1973)

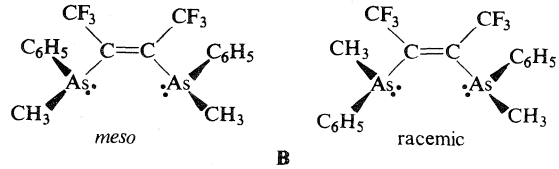
Introduction

Ligands of the type $RC{=}CR'(CF_2)_nCF_2$ (R = $As(CH_3)_2$, $P(C_6H_5)_2$; R′ = $As(CH_3)_2$, $P(C_6H_5)_2$; n = 1–4, but not all combinations) have been found to react with iron carbonyls giving a variety of products (1–4). The related acyclic ditertiary arsine *cis*-$(CH_3)_2AsC(CF_3){=}C(CF_3)As(CH_3)_2$, (L—L)′, seems to form only complexes of the type (L—L)′$Fe(CO)_3$ and (L—L)′$Fe_2(CO)_6$(2, 5). The former has a five-coordinate structure which is probably undergoing positional exchange in solution (4, 6). In the latter the double bond takes part in the bonding and the structure is as shown in **A** (R = CH_3). This triligate behavior is rare for acyclic ditertiary arsines (4) although the cyclic ligands $RC{=}CR'(CF_2)_nCF_2$ have a propensity to act in this way forming $Fe_2(CO)_6$ complexes



A

related to **A**. In order to investigate this phenomenon further it was decided to study another acyclic ditertiary arsine *cis*-2,3-bis(methylphenylarsino)hexafluorobutene-2 (**B**).



B

In this paper we report on the separation of **B** into its two diastereomers and describe the complexes formed by them.

Recently Bosnich and Wild (7) have prepared dichloropalladium complexes containg the *meso* and racemic isomers of $(C_6H_5)(CH_3)AsCH_2{-}CH_2As(CH_3)(C_6H_5)$ and have separated them using chromatography. Other platinum complexes of these same diastereomers have been studied by Cheney and Shaw (8).

Experimental

A standard vacuum system was used for the manipulation of volatile reactants. All reactions were carried out using degassed solvents in sealed evacuated Carius tubes. I.r. spectra were recorded on a Perkin–Elmer 457 spectrophotometer and calibrated using polystyrene and cyclohexane. N.m.r. spectra were run on a Varian T-60 spectrom-

eter. Chemical shifts are given in p.p.m. downfield from internal TMS for ^1H and upfield from internal $CFCl_3$ for ^{19}F spectra. Melting points were determined using a Gallenkamp melting point apparatus and are uncorrected.

U.v. irradiations were performed using a 200 W Hanovia lamp situated ~20 cm away from the reaction tube. The tube was continuously shaken, and cooled by an air stream. Microanalyses were made by Mr. Peter Borda of this department.

Hexafluorobutyne-2 and hexafluoroacetone were purchased from Peninsular Chemresearch Inc., iron pentacarbonyl from Alfa Inorganics Inc., and benzenearsonic acid from Eastman Organic Chemicals. All were used without further purification.

The experimental details reported have been selected from a number of related experiments and describe the conditions that have been found to result in the highest yields of the desired compounds.

*Preparation of cis-2,3-Bis(methylphenylarsino)-hexafluorobutene-2 (**B**)*

Methylphenylarsonic acid was prepared from benzene arsonic acid by the method of Cragoe *et al.* (9) and was reduced to 1,2-dimethyl-1,2-diphenyldiarsine as described by Reesor and Wright (10).

The diarsine (8 g, 24 mmol), dissolved in 25 ml of petroleum ether (b.p. 30–60°), and excess hexafluoroacetone (14 g, 84 mmol) were sealed together in a Pyrex tube and allowed to stand (with occasional shaking) for 4 h at 20°. The tube was then opened and hexafluorobutyne-2 was added (6 g, 36 mmol). The tube contents were allowed to react at 20° for 5 days. Excess volatile starting materials and solvent were taken into the vacuum system leaving a viscous yellow liquid to which hexane (50 ml) was added until the solution turned cloudy. Upon cooling in Dry Ice, white crystals of the racemic isomer of *cis*-2,3-bis(methylphenylarsino)hexafluorobutene-2 were isolated (m.p. 79–81°).

Anal. Calcd. for $C_{18}H_{16}F_6As_2$: C, 43.6; H, 3.2. Found: C, 43.6; H, 3.1.

The n.m.r. spectra (CCl_4 solution) consisted of a singlet at 1.20 (As—CH_3), a multiplet centered at 7.40 (As—C_6H_5), and a singlet at 53.2 p.p.m. (CF_3).

The solvent was removed under reduced pressure leaving a yellow liquid which was warmed to 34° at 10^{-3} mm to remove a small amount of impurity. The substantially pure *meso* isomer of *cis*-2,3-bis(methylphenylarsino)hexafluorobutene-2 remained. It was not possible to distill the product without decomposition.

Anal. Calcd. for $C_{18}H_{16}F_6As_2$: C, 43.6; H, 3.2. Found: C, 43.5; H, 3.1.

The n.m.r. spectra (CCl_4 solution) consisted of a singlet at 1.50 (As—CH_3), a multiplet centered at 7.20 (As—C_6H_5), and a singlet at 53.0 p.p.m. (CF_3). Traces of the *trans*-isomer were also present in this fraction, as evidenced by the presence of absorption at 50.0 and 50.8 p.p.m. (see Results and Discussion).

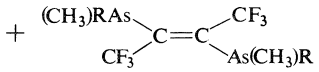
Reactions with Iron Pentacarbonyl

A number of reactions between iron pentacarbonyl and the ligands **B** are given in Table 1. Also included are some reactions of 1,2-dimethyl-1,2-diphenyldiarsine. In all cases the crude reaction mixture was evaporated to dryness and the residue was chromatographed on Florisil using nitrogen saturated solvents as indicated in Table 1. Analytical and spectroscopic data for the products of all these reactions are listed in Tables 2 and 3.

Results and Discussion

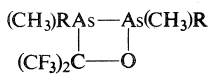
When tetramethyldiarsine reacts with hexafluorobutyne-2 at 20°, facile quantitative addition across the triple bond occurs with the formation of an approximate 1:1 mixture of the *cis*- and *trans*-isomers of 2,3-bis(dimethylarsino)-hexafluorobutene-2 (eq. 1, R = CH_3) (11). How-

[1] 
C



D

ever, when hexafluoroacetone is used as solvent and if the diarsine is first allowed to mix with the solvent before the acetylene is added then the product is predominantly the *cis*-adduct (~90%) (12). The stereospecificity is probably due to the initial formation of a complex between the diarsine and hexafluoroacetone such as **E** (R = CH_3) which allows attack of the acetylene on only one side of the arsenic–arsenic bond (12). Other workers have evidence for the existence of similar adducts (13).



E

We have now found that 1,2-dimethyl-1,2-diphenyldiarsine reacts similarly with hexafluorobutyne-2. Figure 1*a* shows the ^{19}F n.m.r. spectrum of the reaction product obtained in the absence of hexafluoroacetone. Figure 1*b* shows the spectrum of the product obtained when hexafluoroacetone is present.

The two lowfield peaks in the spectra can be assigned to the *meso* and racemic forms of the *trans*-adduct **D** (R = C_6H_5) and the two high field peaks to the *meso* and racemic forms of the *cis*-adduct **C** (R = C_6H_5). The latter are drawn explicitly as **B**. It can be seen that the

*N.m.r. spectra from $CDCl_3$ solutions; i.r. spectra from cyclohexane solutions.

effect of the hexafluoroacetone is to change the ratio from 55% *trans*:45% *cis* in its absence to 12% *trans*:88% *cis* in its presence.

Confirmation of this assignment comes from the result that the *meso* and racemic isomers **B** can be separated by virtue of their different solubility in hexane. One isomer which is obtained as a pure solid and which will be shown below to be the racemic one is responsible for the absorption at 53.2 p.p.m. The other isomer which will be shown to be the *meso* form of **B** is obtained as an oil, free of the racemic form, but contaminated with traces of the two forms of the *trans*-adduct **D** (R = C_6H_5).

The *cis*-diastereomers **B**, once separated, are stable. The *cis*-configuration allows them to act as monometallic bidentate (chelating) ligands or as bimetallic tridentate ligands as in **A**. The results given in Table 1 show that both the racemic and *meso* isomers give complexes (L—L)$Fe(CO)_3$ and (L—L)$Fe_2(CO)_6$ ((L—L) = $(CH_3)(C_6H_5)AsC(CF_3)=C(CF_3)As(CH_3)(C_6H_5)$) when reacted with iron pentacarbonyl. This confirms their *cis*-geometry.

The (L—L)$Fe(CO)_3$ complexes which as usual (2) are best prepared by u.v. irradiation show the expected three bands in the ν(CO) region of the i.r. spectrum. The slight differences in frequencies for the two isomers are probably not significant. The n.m.r. spectra show singlets for the CF_3 and CH_3 resonances indicating a symmetrical structure in solution. Thus, in solution, the ligand is either bound to two equatorial positions of a distorted trigonal bipyramidal structure, or, more likely, the molecule is undergoing positional exchange (6), possibly the turnstile mechanism (14). The spectroscopic results for these (L—L)-$Fe(CO)_3$ complexes do not allow a decision to be

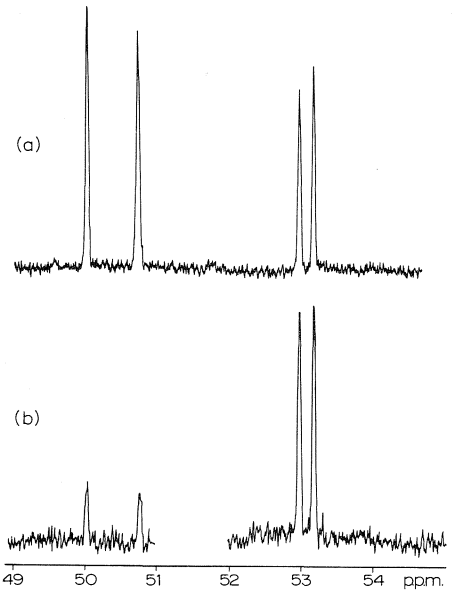

FIG. 1. The ^{19}F n.m.r. spectrum of the product of eq. 1 (R = C_6H_5) (*a*) in the absence of hexafluoroacetone and (*b*) in the presence of hexafluoroacetone.

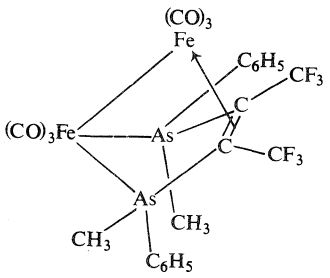
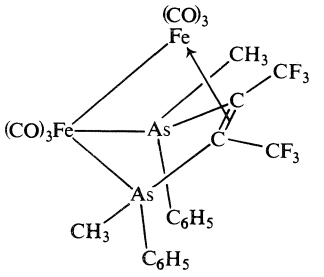
made regarding the structure of the initial ligand, *i.e.*, whether it is racemic or *meso*, since the complexes are too symmetrical; one having CH_3 groups *cis* with respect to the chelate ring (the *meso* complex) and the other *trans*.

The (L—L)$Fe_2(CO)_6$ complexes **A** (R = C_6H_5) are best prepared by heating the reagents (the (L—L)$Fe(CO)_3$ complexes are probably intermediates (Table 1) (2)). The i.r. spectra of these compounds in the ν(CO) region show the typical pattern (1), but in this case the differences in frequencies could be significant since three geometric isomers are possible. If it is assumed that no interconversion of the ligands **B** occurs during the reaction, the racemic isomer should give one complex **F** and the *meso* would give two isomers **G** and **H**.

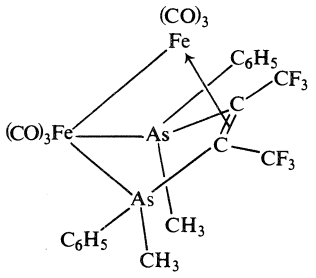
The crystalline ligand affords a $Fe_2(CO)_6$ complex whose n.m.r. spectrum shows two As—CH_3 and two CF_3 absorptions. The two CF_3 groups belong to the same molecule since there is spin–spin coupling between them ($J_{F,F}$ = 11.3 Hz). Such a spectrum would be expected only for **F** and thus the solid starting ligand is the racemic form of **B**. The n.m.r. spectrum of the $Fe_2(CO)_6$ complex obtained from the oily ligand showed only one type of As—CH_3 group to be present and only one CF_3 group. Such a spectrum would be possible for either **G** or **H**, but not from a mixture of both. Thus the oily product is the *meso* form of **B** and gives the same product, probably **G**, on heating and u.v. irradiation. The reason for preferring **G** is that phenyl–phenyl repulsions appear to be less than methyl–methyl in this sort of system (q.v.).



F



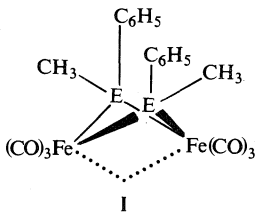
G



H

Also isolated from the thermal reactions of **B** with iron pentacarbonyl was a compound having the empirical formula $Fe(CO)_3As(CH_3)(C_6H_5)$. This proved to be identical with the product obtained by heating the iron carbonyl with 1,2-dimethyl-1,2-diphenyldiarsine: lower yields are obtained on irradiation.

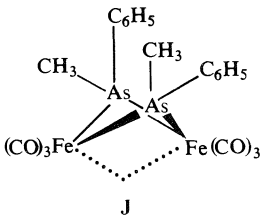
The major unfluorinated product has the structure **I** (E = As). The n.m.r. spectrum shows only one type of As—CH_3 group hence the structure is symmetrical. The ν(CO) bands are very similar to the phosphorus analog (15) which has the two phenyl groups axial as in **I** (E = P)



I

(16) and it is reasonable to believe the arsenic analog would be iso-structural.

The minor reaction product of the reactions of the diarsine with iron pentacarbonyl is an isomer of **I** which has the asymmetric structure **J**, since the ^1H n.m.r. spectrum shows two distinct singlets in the As—CH_3 region.



J

One of these resonances is at relatively high field (0.93 p.p.m.) and this can be assigned to the methyl group which is adjacent to the phenyl group on the other arsenic atom. The i.r. spectra of **I** and **J** in the ν(CO) region are identical (E = As) as is the case for the two phosphorus analogs (15).

More detailed study has shown that at 150° in benzene the symmetric and asymmetric forms **I** and **J** are in equilibrium with the ratio of **I** to **J** being 6:1. Thus n.m.r. spectrum of an initially pure sample of the asymmetric isomer when heated to 150° soon showed signals due to the symmetric form. A limiting spectrum was obtained after 15 h. Similarly a sample of the symmetric compound showed a comparable spectrum after heating at 150° for 90 h. The greater stability of the symmetric form **I** suggests that phenyl–phenyl repulsion is less than phenyl–methyl or methyl–methyl interactions. The symmetric isomer is 'rigid' in solution while the asymmetric one undergoes positional exchange (it 'flaps') (17). Considerations such as these form the basis for the choice made above that **G** would be more stable than **H**.

As mentioned above, the bridging arsenido compounds **I** and **J** are produced when the ligands **B** react with iron pentacarbonyl. Their yield is low after prolonged irradiation but heating to 150° for 3 days affords significant amounts. The *meso* isomer is a better source of the fluorocarbon-eliminated product. In fact the yield is almost that which is obtained by treating iron pentacarbonyl with the diarsine under identical conditions. The (L—L)$Fe_2(CO)_6$ complexes are stable by themselves in benzene solution at 150° for at least 5 days so they are not the unique source of the arsenido-bridged complexes.

The reaction mixture is very complex and it is difficult enough to establish when the fluorocarbon is lost, let alone rationalize the differences in behavior between the two ligands **B**. We have spectroscopic evidence for the existence of tetrakis(trifluoromethyl)cyclopentadienoneiron tricarbonyl in solution. This would be formed by reaction of the free acetylene with iron pentacarbonyl (18).

The Beckmann Rearrangement on Ketoximes Initiated by Hexamethylphosphoric Triamide

RICHARD S. MONSON AND BRUCE M. BROLINE
Department of Chemistry, California State University, Hayward, California 94542

Received August 24, 1972

Ketoximes are found to undergo the Beckmann rearrangement in hexamethylphosphoric triamide at 225–240°, affording the corresponding amides in good yield.

On a observé que les cétoximes subissent le réarrangement de Beckmann dans le HMPT à 225–240° en conduisant avec de bons rendements aux amides correspondantes. [Traduit par le journal]

Can. J. Chem., **51**, 942 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Hexamethylphosphoric triamide (HMPT), in addition to its well known uses as a reaction medium (1), shows promise of becoming a useful reagent in several dehydration and substitution reactions (2, 3). Continuing our studies on the uses of this versatile reagent, we now report that the Beckmann rearrangement of ketoximes can be successfully carried out in HMPT.

When aromatic ketoximes are heated in approximately a three-fold molar excess of HMPT (pot temperatures of 225–240°), a copious evolution of dimethylamine is observed. After a brief reflux, the solution is cooled and subjected to a water work-up. Good yields of the corresponding crude anilides are obtained as shown in Table 1.

TABLE 1. Amides by HMPT initiated Beckmann rearrangement on ketoximes

Oxime	Crude yield of corresponding amide (%)
Benzophenone oxime	54
Acetophenone oxime	52
p-Methoxyacetophenone oxime	71
p-Methylacetophenone oxime	85
p-Chloroacetophenone oxime	75
p-Bromoacetophenone oxime	89

Our prior work on reactions in refluxing HMPT (2) has suggested that dehydration reactions occur after initial formation of phosphorodiamidate derivatives. In the present case, these considerations lead to the reaction pathway shown in eqs. 1 and 2.

As in other reactions conducted in HMPT, the reaction products include a gummy precipitate which has previously been shown (4) to consist primarily of bis(dimethylammonium)dihydrogen pyrophosphate, $(Me_2NH_2)_2H_2P_2O_7$.

The yields of crude amides obtained by the reaction of ketoximes in HMPT compare favorably with those obtained by conventional reagents (5). Moreover, conventional reagents (for example H_2SO_4, H_3PO_4, or PCl_5) are frequently acidic and are usually extremely reactive towards many functional groups. On the other hand, HMPT is mildly basic and neither it nor its reaction products are highly reactive. This fact may offer a possible advantage in the preparation of sensitive amides.

Experimental

Oximes were prepared in the usual way from commercially available ketones, hydroxylamine hydrochloride, and aqueous sodium acetate. They were recrystallized from aqueous ethanol before use. HMPT was distilled before use, b.p. 120–122°/21 mm. Products were identified by their i.r. spectra and by comparison of their melting points with literature values.

Beckmann Rearrangement. General Procedure

The oxime (0.1 mol) is dissolved in 65 ml of HMPT and brought to reflux. The solution turns cloudy at 210–230°, and refluxing commences at 225–235°. When the pot temperature reaches approximately 240°, the reaction

[1] $$\mathrm{Ar{-}C(=NOH){-}CH_3} + (Me_2N)_3PO \rightarrow \mathrm{Ar{-}C(=N{-}O{-}P(O)(NMe_2)_2){-}CH_3} + Me_2NH$$

[2] $$\mathrm{Ar{-}C(=N{-}O{-}P(O)(NMe_2)_2){-}CH_3} \rightarrow \left[\mathrm{Ar{-}C(=N^{\oplus}){-}CH_3}\right] \rightarrow [\mathrm{Ar{-}N{=}\overset{\oplus}{C}{-}CH_3}] \rightarrow \mathrm{Ar{-}NH{-}C(=O){-}CH_3}$$

becomes noticeably exothermic. The total reflux time is 10 min, and the resulting solution is dark red.

The cooled reaction mixture is poured into 550 ml of ice water with rapid stirring. The solution is saturated with sodium chloride whereupon the crude amide separates. An additional portion of amide may be obtained by extracting the aqueous solution with ether – ethyl acetate (1:1), drying the organic solution (anhydrous Na_2SO_4), and evaporating the solvent. The crude amide may be purified by recrystallization from benzene or benzene–cyclohexane.

The Temperature Dependence of the Diffusion Coefficients of Ar, CO_2, CH_4, CH_3Cl, CH_3Br, and $CHCl_2F$ in Water

DOW M. MAHARAJH AND JOHN WALKLEY

Chemistry Department, Simon Fraser University, Burnaby 2, British Columbia

Received March 2, 1972[1]

Diffusion coefficient values are reported over a 0 to 35 °C temperature range for Ar, CO_2, CH_4, CH_3Br, CH_3Cl, and $CHCl_2F$ in water. Various empirical theories relating these diffusion coefficient values to the viscosity of water (η) and the size of the diffusing solute molecule are examined. None are found valid though a linear relationship is found to hold between log D and log η for all systems. McLaughlin's hard sphere theory is examined and found in surprisingly good agreement with experiment. It is seen, however, that this theory cannot adequately predict the temperature dependence of the diffusion coefficient of the solute.

Les valeurs des coefficients de diffusion pour Ar, CO_2, CH_4, CH_3Br, CH_3Cl, et $CHCl_2F$ dans l'eau, ont été rapportées dans l'intervalle de température de 0 à 35 °C. Diverses théories empiriques reliant les valeurs des coefficients de diffusion à la viscosité de l'eau (η) et à la taille de la molécule de soluté qui diffuse, ont été examinées. Aucune n'a été trouvée correcte bien qu'une relation linéaire existe entre le log D et le log η pour tous les systèmes. La théorie de la sphère dure de McLaughlin, en accord surprenant avec l'expérience, a été examinée. Cependant cette théorie ne peut prévoir de façon convenable la relation entre la température et le coefficient de diffusion du soluté.

Introduction

It is well established that a wide range of gases form solid water–gas clathrates in which the interaction between solute and water is of the van der Waals type (1). The range of stability of these clathrates varies considerably, the hydrate decomposition pressure of argon, at 0 °C, is 105 atm and for xenon is 1.5 atm. The hydrate decomposition temperature at 1 atm is −42.8 °C for argon and −3.4 °C for xenon. In general, these gases are only slightly soluble in water at 0 °C but have a "solubility" in the solid state often some powers of ten greater.

The development of an adequate theory for the equilibrium thermodynamic solubility properties of gases in water suffers because there is no adequate theory for pure water itself (2). The entropy and enthalpy of solution of gases in water are appreciably lower than those found in other solvents, their partial molal volumes far smaller (3). Early theories developed the concept that in water the gas molecule builds up an "iceberg" around it (4). More recent theories use the "two-structure" model of pure water and it is suggested that the dissolved gas solute stabilizes the large compact "clusters" already present (5). The early theory of Eley has been extended using recent developments in hard sphere theory (6). This theory predicts the observed thermodynamic properties with remarkable success and essentially treats both solute and water as hard sphere molecules (3, 6).

Hildebrand has recently suggested that the comparison of diffusion coefficient data for gases in water and in non-polar solvents may help to distinguish the role of the "water cage structure" (7). He argues that the diffusion coefficient for a solute is largely dependent upon the size of the solute. Thus the considerably greater size of a solute surrounded by a "water structure" cage should be revealed by a smaller diffusion coefficient. In a comparison of data for gases in water and in carbon tetrachloride solvent, no gross differences in the diffusion coefficient values are found.

In this paper we present diffusion coefficient data for argon, carbon dioxide, methane, methyl chloride, methylbromide, and dichlorofluoromethane in water over a temperature range of 0 to 35 °C. We describe the inverted tube method used for the measurement of the rates of dissolution of these gases into water. This method was devised in order to overcome the density gradient convection term often found operating in other methods.

In terms of the solid water clathrate, the gases

studied cover a hydrate decomposition pressure (at 0 °C) from 311 atm (CH_3Cl) to 12.3 atm (CO_2) and a decomposition temperature (at 1 atm pressure) from +11.1 °C (CH_3Br) to −42.8 °C (Ar). The gases span a molar volume (at boiling point V_b) range from 28 cc mol^{-1} (Ar) to 55 cc mol^{-1} (CH_3Br). The measured diffusion coefficient values (10^5 D cm^2 s^{-1}) range from 1.85 (CO_2) to 1.35 (CH_3Br). All gases give linear log D *vs.* $1/T$ plots, the slopes lying between 6.71×10^2 (CH_4) and 14.85×10^2 ($CHCl_2F$).

We discuss our data in terms of the accepted empirical relationships often proposed to correlate diffusion data and also in terms of the hard sphere diffusion model of McLaughlin (8). In terms of the former relationships, a generally uniform type of behavior is found for the range of gases examined. McLaughlin showed his extension of Thorne's hard sphere theory to the diffusion of hard sphere mixtures gave good comparison for a wide range of gases in water at 25 °C and for the diffusion of CO_2 in water over a wide temperature range. We find this theory disappointing in its prediction of the temperature dependence of the diffusion coefficient of the gases we ourselves have measured.

Experimental

Inverted Tube Method

The diffusion cell is made from precision bore tubing (1 mm diameter) and is some 15 cm long. A small bulb of about 1 ml capacity is blown 2 cm from one end and the other end is sealed. To load the cell, it is first placed in a desiccator vessel and evacuated thoroughly. The whole apparatus is then flushed with the gas under investigation and re-evacuated several times. It is finally filled with gas at 1 atm pressure and a few drops of the degassed solvent are transferred into the bulb of the diffusion cell through a serum cap, using a hypodermic syringe. The diffusion cell is then placed in a thermostat and after 30 min, more degassed solvent at the same temperature as the thermostat is quickly introduced into the capillary, displacing the gas, until a gas slug of some 5 mm in length is left at the end of the capillary. The change in position of the solvent meniscus accompanying the dissolution of the gas is followed with a microscope fitted with a calibrated filar eye piece (Gaertner Scientific Corp.). The magnification of the microscope is ×100 and the position of the meniscus can be measured as a function of time to within 0.005 mm. The whole apparatus is mounted on a concrete block to avoid mechanical vibration. A typical run lasts about 5000 s and during this time the meniscus moves some 1.5 mm. In preliminary runs, capillaries of 1, 2, and 3 mm in diameter were used for the cells. The rate of absorption of CO_2 into water is found to be independent of the diameter of the cell to within the accuracy of the experiment. The solvent, water, is purified by distillation in a Pyrex vessel and all gases were supplied by Matheson.

The whole system is kept at a constant pressure and the rate of absorption of the gas into the solvent is followed by measuring the position of the gas/solvent interface as a function of time. The moving boundary method for non-steady state diffusion has been treated extensively by Booth (9) and by Danckwerts (10). Experimental conditions with respect to the method of placing the gas below the solvent are suitable only for the measurements made at large t values and under these conditions the relationship between the volume of gas dissolved, V, and the time, t, is

$$V = \frac{2ARTX_2}{V_1}\sqrt{\frac{Dt}{\pi}}$$

where A is the area of the diffusion cell; X_2 is the saturation solubility mole fraction of the gas; R is the gas constant; T is absolute temperature; and V_1 is the molar volume of the solvent.

Results

Measurements have been made for the rate of absorption into water of Ar, CO_2, CH_4 over the temperature range 0 to 35 °C and of CH_3Cl, CH_3Br, and $CHCl_2F$ over the range 10 to 35 °C. Tables 1–6 give slope values of the V *vs.* $\sqrt{t}$ plots, estimated to be accurate to 2%. Diffusion coefficient values, (D_2 cm^2 s^{-1}) are also given in Tables 1–6. For all gases a linear ln D_2 *vs.* $1/T$ relationship was found, the coefficients of the equation $\ln D_2 = B/T + C$ are given in Table 7.

Diffusion coefficient values were calculated for argon using the solubility data of Ben-Naim *et al.* (11) for the range 0 to 30 °C and the value of Smith and co-workers (12) at 35 °C. We may compare our 25 °C value of $D_2 = 1.44 \times 10^{-5}$ cm^2 s^{-1} with that value obtained by Smith and co-workers using the "Ringboem" technique (13)

of 1.46×10^{-5} cm^2 s^{-1}. The experimental techniques are quite different, the agreement between the two values is excellent. The recent measurement of Boerboem and Kleyn (14) give values of 0.633×10^{-5} cm^2 s^{-1} at 0 °C and of 0.78×10^{-5} cm^2 s^{-1} at 25 °C. Wise and Houghton (15) using the collapsing bubble method, found D values higher than our own but this is expected from their method. For the CO_2/H_2O system the measured D_2 values agree well with those reported by Unver and Himmelblau (16) obtained using the laminar method. In obtaining D_2 values for methane we can use either the saturation solubility data of Lange or that of Claussen and Polgase (20). The data of Lange gave a linear $\ln D_2$ *vs.* $1/T$ plot, the data of Claussen and Polgase did not. Our data for methane using the Lange solubility values (17) agrees well with those values obtained by Witherspoon and Saraf (18) measured using the capillary cell method of Wang (19). Wise and Houghton using the collapsing bubble method report values again considerably higher than those of our own. For the remaining gases, we can make comparison only to the values obtained by Chiang and Toor (21) who, using the diaphragm method, obtained a value of $D_2 = 1.39 \times 10^{-5}$ cm^2 s^{-1} for CH_3Cl in water, agreeing well with our value of 1.40×10^{-5} cm^2 s^{-1} (at 25.0 °C).

Discussion

In a previous paper (22) we discussed the "open tube" method for measuring the diffusion of a gas into a solvent. In that method the gas is placed *above* the solvent and the rate of dissolution measured by finding the change in gas volume (at constant pressure) as a function of time. For benzene and carbon tetrachloride solvents, data were obtained in good agreement with values published by other workers. For the dissolution of gases into water this technique cannot be used. For these systems, the dissolution of the gas produces a layer of solvent of density greater than the bulk density. The simple diffusion controlled dissolution is enhanced by a density convection mechanism. This is a complex mechanical instability problem and has been discussed by several authors (23, 24). It is worth commenting that with this density induced convection term plus the natural diffusion term, the dissolution of the gas can be observed to follow a pseudo non-steady state mechanism (as in the case of argon into water) where volume uptake of gas is proportional to time$^{1/2}$ or to follow a

mechanism linear with time (as for CO_2 into water). The former mechanism gives rise to reproducible data and allows an "apparent" D_2 value to be obtained. Such D_2 values are far greater than the real D_2 (diffusion coefficient) value. For argon into water an apparent D_2 value of 10.3×10^{-5} cm^2 s^{-1} is found, a factor of 7 larger than the real value. Results for gases in water from our earlier "constant size bubble" method (25) were again found to give relatively higher D_2 values, presumably again due to the presence of the density convection term.

For the gases studied, the "inverted tube method" gives results in good agreement with those values obtained by other workers. It would seem that with the gas diffusing *upwards* into the solution, the dissolution process has no density convection term.

Over the temperature range studied, all gases exhibited good, linear, ln D_2 *vs.* $1/T$ plots (Fig. 1), suggesting there is no change in the immediate environment of the gas over this temperature range. If activation energies (ΔE) are meaningful, the values obtained from the ln D_2 *vs.* $1/T$ plots, given in Table 7, show reasonable constancy. The value for methane (3.06 kcal) is in good agreement with the 2.900 kcal value for the diffusion of a wide range of hydrocarbons in water as reported by Witherspoon and Saraf (18).

Various empirical relationships have been suggested for the diffusion coefficients of gases in liquids. The diffusion of a gas through a dense solvent is controlled mainly by the size of the diffusing solute molecule and by the viscosity of the solvent. Hildebrand has suggested that the product $D_2V_b^{2/3}$, where V_b is the solute molar volume at the boiling point, should be approximately constant (7). As seen in Table 7, a rough constancy is observed though the value of this product for argon is considerably less, and the value $D_2V_b^{2/3} = 53.9$ for $CHCl_2F$ is far higher, than the other gases. A linearity exists between $10^5D_2V_b^{2/3}$ and the activation energy ΔE for CH_4, CH_3Cl, and CH_3Br as might be expected from Hildebrand's arguments for the use of the $V_b^{2/3}$ term. The data of Witherspoon (18) give for CH_4, C_2H_6, and C_3H_8 a $D_2V_b^{2/3}$ value of 21.5 ($\pm$0.4).

Othmar and Thakar (26) have suggested that as both diffusion and viscosity are rate processes, both varying as an exponential function of temperature, a plot of log D *vs.* log η (the solvent viscosity) should give a straight line. We give such a plot in Fig. 2 and observe that all six gases give a good linear relationship over the temperature range measured. Wilke and Chang (27) have proposed an equation relating the diffusion coefficient of a solute to the physical properties of both solute and solvent, *viz.*

$$[1] \qquad D_2 = \frac{7.4 \times 10^{-13} \times (2.6\,M)^{1/2}T}{\eta V_b^{0.6}}$$

It is found that this equation is totally unable to represent our observed data; typical systems are plotted in Fig. 3. Neither do the various improvements of the Wilke–Chang equation show any better agreement with experiment. If we

examine the simple Stokes–Einstein relation

$$D_2\eta_1 = kT/3\pi\sigma_{22}$$

we find a reasonable consistency for the $D_2\eta_1/T$ term for all systems over the temperature range studied. If we plot the average value of $D_2\eta_1/T$ against $(1/\sigma_{22})$ we find that though a linear relationship exists for the CO_2, CH_4, Ar, and CH_3Cl, the slope of the line is of the wrong sign.

The McLaughlin (8) formulation of the diffusion equation, based upon the theory of Enskog (28), offers an alternative to the Stokes–Einstein equation and the many empirical relationships based upon it, some of which are discussed above. The resulting equation of the McLaughlin treatment for that case where X_1 (mole fraction of solvent) $\rightarrow 1$ and $X_2 \rightarrow 0$ is

$$[2]\quad \frac{D_2}{D_1^0} = \frac{(M_1 + M_2)^{1/2}}{2M_2}\left(\frac{\sigma_{11}}{\sigma_{22}}\right)^2 \times \left[\frac{(2 + b_{11}^0)}{(1 - b_{11}^0)^2 + 3b_{11}^0\sigma_{22}/\sigma_{12}}\right]$$

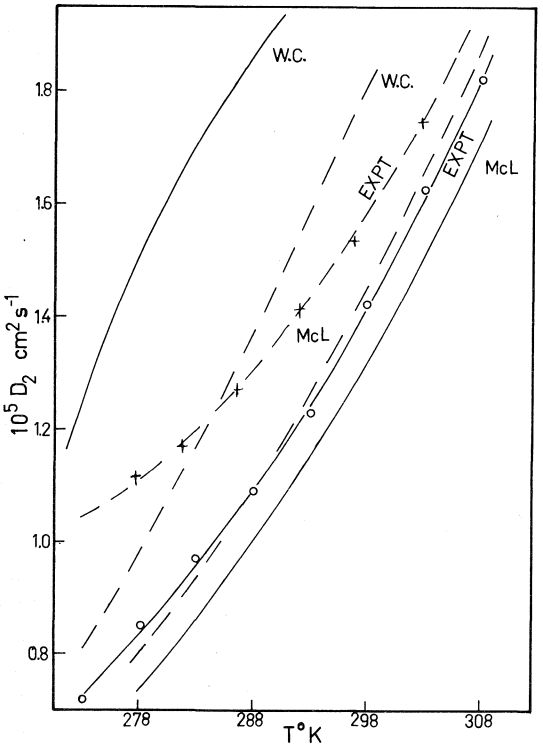

FIG. 3. Temperature dependence of diffusion coefficient of argon and of methane, with Wilke–Chang and McLaughlin approximations. Legend: argon data, full line; methane data, dashed line.

where D_2 is the coefficient of diffusion of the gas (solute) in the solvent, D_1^0 the self-diffusion coefficient of the solvent, M_i and σ_{ii} the molecular mass and hard-sphere diameter of solvent (*1*) and solute (*2*), and $b_{11}^0 = (\pi\eta_1\sigma_{11}^3/6)$. To obtain D values from this equation we need values of the self-diffusion coefficient D_1^0 of water over the temperature range of the experiment. We obtained these values from the data of Wang, Robinson, and Edelman (29). We also need hard-sphere diameter values (σ_{ii}) of the solvent and of the various solutes. For water we use a value $\sigma = 2.75$ Å (6). For the solutes we use the generally accepted 12–6 Lennard–Jones potential σ values (30).

As may be seen in Tables 1–6, a reasonable agreement of eq. 2 with experiment is observed. We have used D_1^0 data obtained with D_2O as the tracer molecule (29*b*) using $H_2{}^{18}O$ tracer data (29*a*) gives no overall better agreement. We compare data predicted by eqs. 1 and 2 with experimental data for argon and methane in Fig. 3. In general, the temperature dependence of D_2 is not well predicted by eq. 2. We note that we have not considered the hard-sphere diameter values to vary with temperature. We test the validity of this by plotting in Fig. 4 the diffusion coefficient of the solute (D_2) against the self-diffusion coefficient of water (D_1^0) at the same temperature. For all systems examined a good linear relationship exists. This suggests that the r.h.s. of eq. 1 can indeed be considered independent of temperature.

It is seen from Table 2 that for the CO_2–H_2O system the agreement between the theoretical eq. 2 values and experimental values is not only worse than the Wilke–Chang values but far worse than those values predicted from his theory, for this system, by McLaughlin (8). McLaughlin made two approximations when using eq. 2. He obtained the σ_{22}/σ_{11} ratio from data on the low density gas viscosities of water and of CO_2 over the temperature range of the D values. The ratio is obtained from the relationship (8)

$$(\eta_i)_{gas} = 1.015\,(5/16\sigma_{ii}^2)(M_i kT/\pi)^{1/2}$$

In this range, 0–55 °C, he found the σ_{22}/σ_{11} ratio to vary from 0.98 to 1.01. Having found this ratio close to unity he could then set the last term in eq. 2 equal to unity. The very small variations in σ_{22}/σ_{11} (from gas viscosity data)

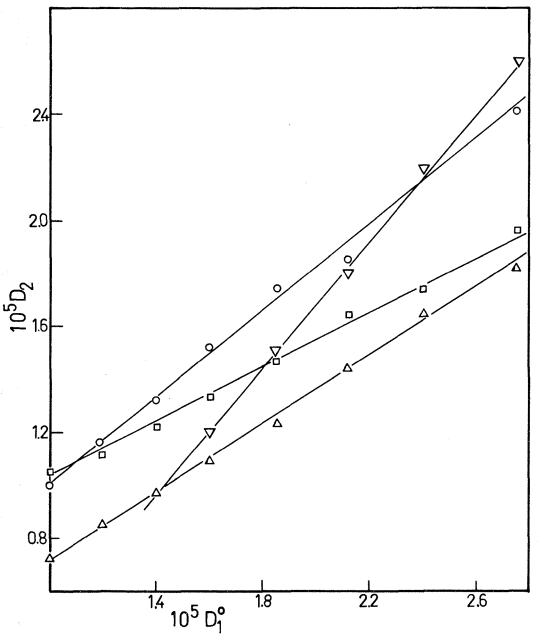

FIG. 4. Diffusion coefficient of gas (D_2) plotted against the self-diffusion coefficient of water (D_1°) at the same temperature. Legend: CO_2, ○; Ar, △; CH_4, □; $CHCl_2F$, ▽.

over the temperature range studied support our interpretation of the linearity of the D *vs.* D_1^0 plot. If we make the assumption that the final term in eq. 2 *is* unity, we can then obtain the σ_{22}/σ_{11} ratio from the slope of the D *vs.* D_1^0 plot. These are given in Table 7 and it is seen that for the CO_2–H_2O system the value of $\sigma_{22}/\sigma_{11} = 1.10$ is, in fact, self-consistent with the assumption that the final term in eq. 2 is approximately unity. It agrees with the σ_{22}/σ_{11} ratio obtained from the gas viscosity data for CO_2–H_2O but does not agree with the ratio obtained from accepted σ values. Using the σ_{22}/σ_{11} ratio obtained from the D_2 *vs.* D_1^0 plot, the D_2 values obtained from eq. 2 are in better agreement with the experimental values (see Table 2). For the CH_3Cl–H_2O and the CH_3Br–H_2O systems the D_2 *vs.* D_1^0 plot gives σ_{22}/σ_{11} ratios close to unity. As can be seen from Tables 4 and 5 using these σ ratios and making the assumption that the final term in eq. 2 is unity does *not* improve the agreement with experiment. We note, however, that for the latter two systems the σ_{22}/σ_{11} ratios from the D_2 *vs.* D_1^0 plot do not agree with the ratios obtained from gas viscosity data. For the $CHCl_2F$–H_2O system using a σ_{22} value of 4.45 Å (for source see Table 7), the diffusion values obtained are in rather poor agreement with the experimental values. From the D_2 *vs.* D_1^0 plot the σ ratio is found to be 0.60 but this ratio is not self-consistent with the assumption that the final term in eq. 2 is unity. We do not have dilute gas viscosity data for $CHCl_2F$ but it would appear that eq. 2 cannot predict the D_2 value for $CHCl_2F$ in water with any real success. In his examination of the CO_2–H_2O system McLaughlin (8), noting the difference in the reported D_1^0 values for water (obtained using different tracer molecules) (29*a*, *b*), showed that using $H_2{}^{18}O$ data better agreement could be obtained. Whilst this is so, an examination of the six systems here presented shows no overall improvement. For some systems a better agreement with experiment is observed, for others a worse agreement. We note, however, that D_1^0 data obtained using the $H_2{}^{18}O$ tracer give linear D_2 *vs.* D_1^0 plots just as were obtained using the D_2O tracer data.

As a final test of the McLaughlin equation we see that from eq. 2 we may obtain an expression for the ratio of the diffusion coefficients of two gas solutes in the same solvent, *viz.*

$$\frac{D_{2A}}{D_{2B}} = \frac{\left(\frac{M_1 + M_A}{M_A}\right)^{1/2}}{\left(\frac{M_1 + M_B}{M_B}\right)^{1/2}} \frac{(\sigma_{1B})^2}{(\sigma_{1A})^2} \times \frac{[(1 - b_{11}{}^0)^2 + 3b_{11}{}^0\sigma_{AA}/\sigma_{1A}]}{[(1 - b_{11}{}^0)^2 + 3b_{11}{}^0\sigma_{BB}/\sigma_{1B}]}$$

To a good approximation we may set the final term to unity, thus obtaining the expression

$$[3] \quad \frac{D_{2A}}{D_{2B}} = \left[\frac{M_B(M_1 + M_A)}{M_A(M_1 + M_B)}\right]^{1/2} \times \left[\frac{1 + \sigma_{BB}/\sigma_{11}}{1 + \sigma_{AA}/\sigma_{11}}\right]^{1/2}$$

Using argon as one of the two solutes (2A) we may compare the slope of the D_{2A} *vs.* D_{2B} plots (over the temperature range of the data) with the calculated slope as given by eq. 3. For all pairs of systems examined good linear plots are obtained but comparison of experimental and calculated slope values is very bad. We give a typical comparison in Table 8 in which the theoretical slope values are calculated using both the $(\sigma_{22}/\sigma_{11})^a$ and $(\sigma_{22}/\sigma_{11})^b$ values of Table 7.

Conclusion

The six gases studied cover a wide range of gas–hydrate stability. No outstanding differences in actual diffusion coefficient values nor in the temperature dependence of the D values is observed. Agreement of measured values and of various empirical theories is, in general, poor, but this is obviously a matter of the poverty of the empirical relationships. Huq and Wood (31) have examined a wide range of empirical and semi-empirical equations relating D values to the properties of solute and solvent and found a similar disparity between the experimental data and the expected correlation.

The McLaughlin diffusion equation, considering its simplicity (*i.e.* that it comes from hard sphere theory), its sensitivity to the σ_{ii} values used and even more so to the self-diffusion value of water (see ref. 8) gives reasonable agreement with experiment. We see, however, that even in the comparison of the D_2 value of one gas in water to the D_2 value of another gas in water the hard sphere theory lacks acceptable predictive success.

Experimental and Theoretical Estimates of Sigma and Pi Electron Contributions to Long-range Spin–Spin Coupling Constants in Coumarin and its Methyl Derivatives

J. B. ROWBOTHAM[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received July 17, 1972

A full analysis of the p.m.r. spectra of coumarin and five of its methyl derivatives allows the assignment of σ and π electron components to the inter-ring proton–proton spin–spin coupling constants. Magnitudes of up to 0.3 Hz are observed over a coupling path of eight bonds. The σ and π components can be combined on the basis of the appropriate valence bond structures to predict closely the observed parameters in naphthalene, suggesting only weak participation of the ether oxygen atom in the π electron system of coumarin. Calculations of the inter-ring coupling constants at the INDO and CNDO/2 levels of molecular orbital theory are helpful in the interpretation of the observed data, the agreement with experiment being quantitative in many instances. Comparison of the observed coupling constants in coumarin and styrene with the INDO results for an assumed planar form of the latter suggests that styrene exists in a nonplanar conformation.

Une étude complète des spectres r.m.n. du coumarin et de cinq de ses dérivés méthylés permet l'attribution des composantes σ et π aux constantes de couplages déduites spin–spin des interactions proton–proton. Des amplitudes allant jusqu'à 0.3 Hz sont observées pour une zone de couplage incluant huit liaisons. Les composantes σ et π peuvent être combinées en se basant sur les structures appropriées (obtenues par la théorie du lien de valence) pour prédire avec précision les paramètres observés pour le naphtalène suggérant une faible participation seulement de l'atome d'oxygène du groupe éther dans le système d'électrons π du coumarin. Les calculs des constantes de couplage déduites aux niveaux INDO et CNDO/2 de la théorie des orbitales moléculaires sont utiles dans l'interprétation des données obtenues, l'accord avec les données expérimentales étant très souvent quantitatif. La comparaison des constantes de couplage observées pour le coumarin et le styrène avec les résultats INDO pour une structure supposée planaire pour ce dernier suggère que le styrène existe dans une conformation non-planaire.

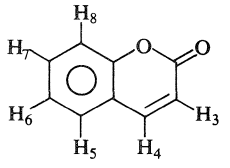
Introduction

The dependence on conformation and on bonding situation of the spin–spin coupling constants between protons on a side-chain and ring protons in benzene and pyridine derivatives has been extensively studied by experimental and theoretical methods (1–20). Less extensive investigations of inter-ring long-range proton coupling constants in fused aromatic systems (21, 22) have been reported for naphthalene (23), acridine (24), isoquinoline (25), and for several coumarin derivatives (26). The use of the 'methyl group replacement technique' (27–29) and of approximate molecular orbital theory at the INDO and CNDO/2 levels (30) is enlightening in the elucidation of the coupling mechanisms operating in the single ring compounds (7, 8, 14). In this paper we apply these methods to the inter-ring coupling constants in coumarin (**1**). Comparisons are made with experimental data for naphthalene, a fused aromatic molecule, and with theoretical data for styrene, a single ring compound.



1

Experimental

Coumarin and its 3- and 6-methyl derivatives were obtained from Aldrich Chemical Co. The 4-, 7-, and 8-methylcoumarins were prepared by standard procedures (31–33). Analytical samples contained tetramethylsilane (TMS) as internal reference and locking material and were degassed by the freeze–pump–thaw technique. The solvents and concentrations of solute (given in Table 1) were dictated by considerations of spectral complexity of the multispin systems. P.m.r. spectra were recorded in the frequency sweep mode on an HA-100D spectrometer

at a sweep width of 1 Hz/cm and a sweep rate of 0.02 Hz/s. They were repeatedly calibrated by reading sweep and manual oscillator frequencies at intervals of 5 Hz or less. Double irradiation experiments (34) employed an HP-4204A audio oscillator.

Results and Discussion

(1) Spectral Analysis

(a) Proton Assignments

In general the olefinic proton H_3 resonated at a higher field than the aromatic protons while H_4 resonated at lower field. However, the peaks from H_4 overlapped those from the aromatic protons in 3-methylcoumarin when dissolved in chloroform or benzene. But in acetone-d_6 solution these peaks were well separated. Variation of solute concentrations minimized the overlap of peaks belonging to different aromatic protons, those from H_5 and H_7 usually being centered 20–25 Hz to low field of those from H_6 and H_8.

(b) Computer Simulations

The program LAME (35), coupled to a plotting routine (36), was initially used in the non-iterative mode until the computed spectra closely resembled the experimental recordings. As many lines as practical were then assigned, followed by iterative computer runs. Typically about 300 of 800 transitions were assigned.[2] The r.m.s. error and the standard deviations in the derived parameters were better than 0.03 and 0.01 Hz, respectively. Two of the correlation coefficients involving the long-range coupling–coupling constants were sizeable. These were 0.45 for J_{35}–J_{37} in 6-methylcoumarin and 0.61 for ν_3–J_{36} in 8-methylcoumarin. Hence the sums of the indicated parameters in these two cases are rather more precise than the individual values. Often the smaller couplings were not reproduced as well as desired and consequently these were then adjusted by trial and error to yield the best simulations of the experimental spectra. Changes of a few hundredths of a Hz produced noticeable

[2]The presence of three magnetically equivalent methyl protons causes a large number of transitions so that the ratio of 3:8 is less severe than first appears.

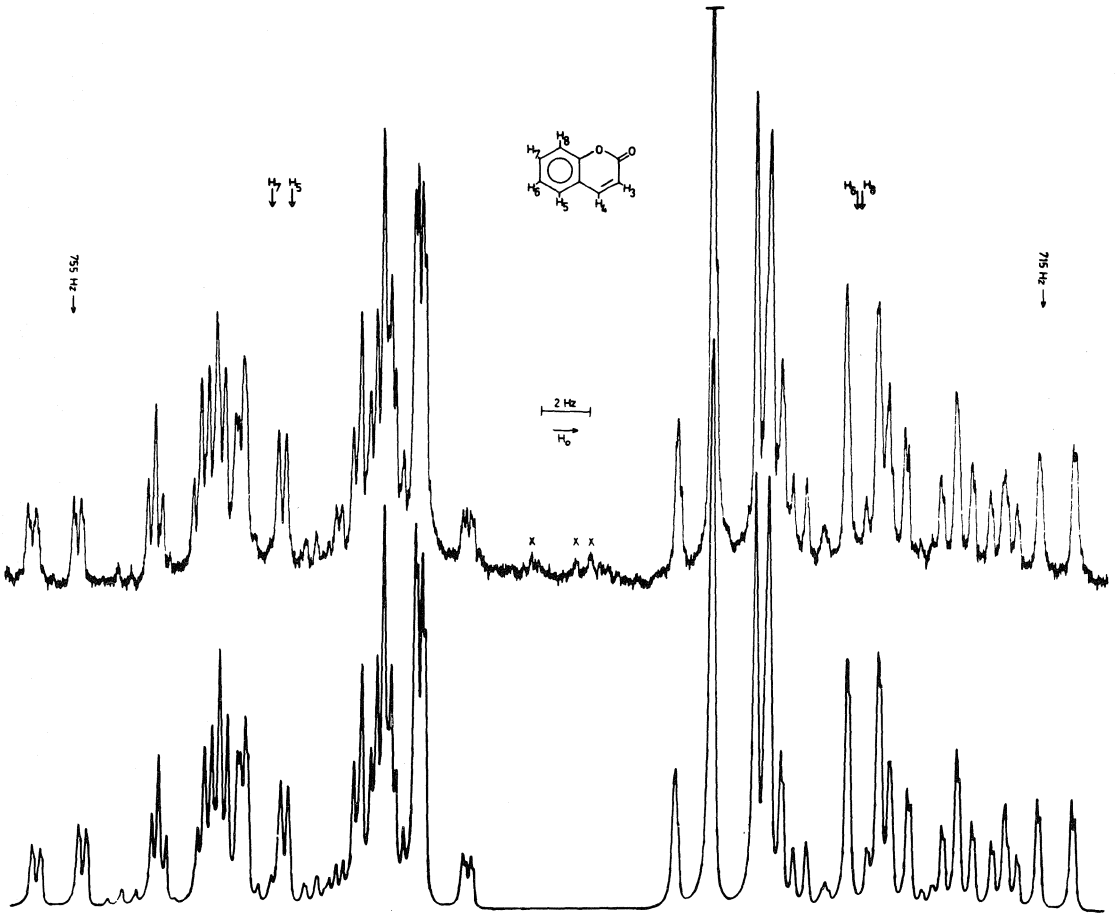

FIG. 1. The p.m.r. spectrum at 100 MHz of the ring protons in coumarin as a 20 mol % solution in chloroform-*d*. The shifts of the protons are indicated by vertical arrows. The calculated spectrum employs the parameters in Table 1 with $\Delta\nu_{1/2} = 0.15$ Hz and an asymmetry factor of 0.70 (see text). The peaks marked by crosses arise from impurities.

change in the spectra. Figure 1 displays the observed ring proton spectrum for coumarin together with the computed spectrum based on the parameters in Table 1 (assumed line width at half height of 0.15 Hz and an asymmetry parameter (36) of 0.70).

(c) 7-Methylcoumarin

The spectrum of this compound proved difficult to analyze accurately, as the chemical shifts of H_6 and H_8 are separated by only 0.3 Hz, and the coupling parameters are therefore less certain ($\pm$0.05 Hz) than for the other compounds in Table 1. Moreover, the peak positions of H_8 for this compound were not affected significantly by small variations of $^5J_{58}$, while the splittings in the H_5 region were not linearly dependent on the variations. As a result, equally good simulations were obtained when $^5J_{58}$ was set at 0.17 or 0.45 Hz. The former value was rejected as improbable.

(d) Determination of Signs of Couplings

In Table 1 the signs of the coupling constants[3] were determined by weak irradiation experiments (34) whenever possible and are given relative to the signs of the vicinal couplings, known to be positive. When the signs are not given or are enclosed in brackets they are not based on tickling experiments, these proving impossible or ambiguous because of difficulties in choosing

[3]In the nomenclature used here a left superscript on the coupling, *J*, indicates the number of bonds separating the coupled nuclei, their positions in **1** being given by right subscripts.

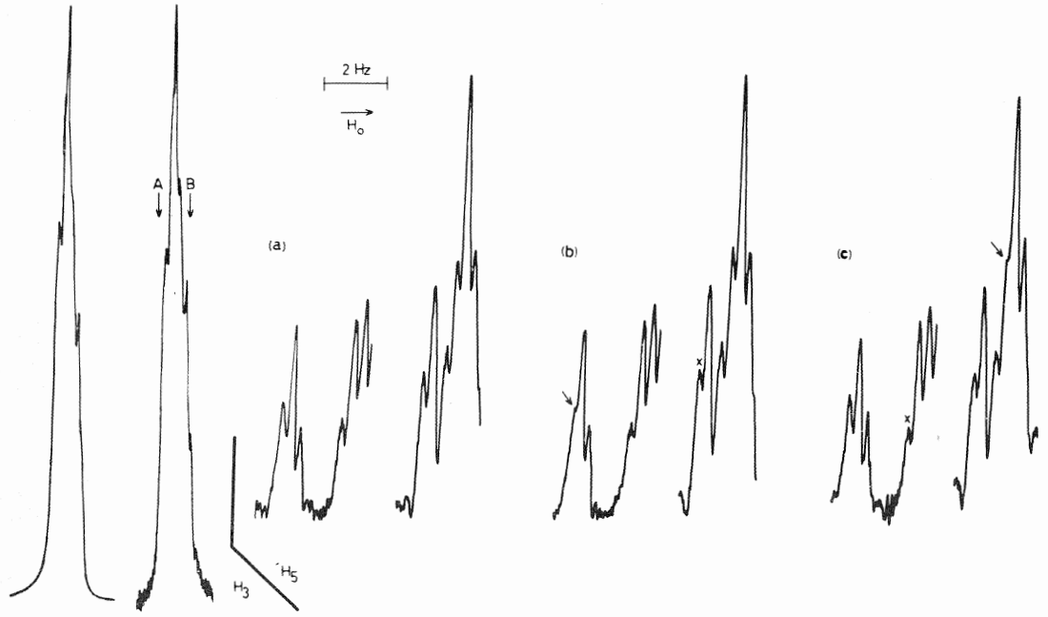

FIG. 2. On the left the high-field half of the p.m.r. spectrum of the olefinic proton H_3 in coumarin is shown together with the calculated spectrum; experimental and computational conditions as in Fig. 1. In the spectra of ring proton H_5 (easily matched to the left-hand part of Fig. 1) the conditions are (*a*) single resonance, (*b*) weak irradiation at the point marked A in resonance of H_3, (*c*) weak irradiation at point B in resonance of H_3. Arrows mark the peaks affected by the irradiation and crosses indicate those peaks which *would* have been affected had $^6J_{36}$ been negative; *i.e.*, of opposite sign to $^3J_{56}$.

the necessary triplets of couplings whose presence is reflected in well-resolved spectral splittings.

In only one case was a sign found opposite to expectation, that of $^6J_{36}$. When the high-field peaks from H_3 in coumarin are weakly irradiated at points marked A and B in Fig. 2, the peaks from H_5 are perturbed as shown. In brief, irradiation of a "low-field" H_3 peak perturbs a "low-field" H_5 peak and hence $^6J_{36}/^3J_{56} > 0$. It also follows from these experiments that $^3J_{34}/^4J_{45} < 0$ and $^7J_{37}/^4J_{57} > 0$.

(2) Intra-ring Coupling Constants

(a) Between Ring Protons

Most of these couplings are unexceptional (Table 1). Thus, the couplings in the aromatic ring of coumarin agree to within 0.2 Hz with the values calculated by assuming additivity (37–39) of the substituent effects from methoxyl and vinyl groups, as deduced from data on anisole (39), 3-bromostyrene (7), and bromobenzene (39), data for styrene itself being unavailable. The presence of a methyl group on the benzene ring alters the couplings in the manner expected from their values in benzene (37) and toluene (1). However, in 4-methylcoumarin $^3J_{56}$ is 0.3 Hz larger than in coumarin, possibly because of steric interference by the methyl group with the electron distribution in the C—H_5 bond. A similar situation is found in 9-methylacridine (24).

Again, the olefinic coupling $^3J_{34}$ in coumarin is smaller than in styrene derivatives (7) but by the amount expected from the difference observed in this coupling between methyl propenoate (40) and ethylene (41).

(b) Between Ring and Methyl Protons

The couplings between methyl and ring protons over five and six bonds, $^5J_m^{H,CH_3}$ and $^6J_p^{H,CH_3}$, lie within experimental error of those in toluene (1). The benzylic couplings over four bonds, $^4J_o^{H,CH_3}$, either lie near -0.80 Hz or near -0.60 Hz. A rationalization of these values depends on a contribution from structures **2** or **3**

because the magnitude of $^4J_o^{H,CH_3}$ is known (19, 42–45) to depend on the bond order of the intervening C···C bond. Indeed those couplings in Table 1 which involve bonds C_5—C_6 or C_7—C_8 in the coupling path have a magnitude near 0.8 Hz and those involving the C_6—C_7 bond are near 0.6 Hz in magnitude. Precisely similar arguments apply to, and magnitudes occur in, a series of benzene (19) and pyridine (6, 36) derivatives.

The allylic couplings, $^4J_{cis}^{H,CH_3}$, in 3- and 4-methylcoumarin are about 0.4 Hz smaller in magnitude than in propene (46), as is qualitatively expected if structure **2** (giving C_3—C_4 single bond character) is of importance. But substituent effects (—C═O linkage) may well occur in coumarin, although their prediction (47) is not easy.

(3) Long-range Inter-ring Coupling Constants

(a) The Methyl Group Replacement Results

As originally suggested by Hoffman (27, 28) the π electron contribution to a proton coupling constant $J^{H,H}$ can be estimated by substitution of one of the coupled protons by a methyl group. The negative of the ensuing coupling J^{H,CH_3} is a measure of the π contribution to $J^{H,H}$. When used with the realization that $^4J^{H,CH_3}$ (14, 47) and even $^5J^{H,CH_3}$ (14, 15) may contain residual σ electron contributions, the technique is of wide applicability (4, 6, 15, 19, 29).

In Table 2 the ranges of inter-ring proton–proton and proton – methyl proton coupling constants for the coumarins are abstracted from Table 1. Beginning with $^7J_{37} = 0.30 \pm 0.03$ Hz, one finds $^8J_{37}^{H,CH_3} = -0.28 \pm 0.02$ Hz. There exist no known proton coupling constants over seven bonds in saturated systems, so that this result is an excellent example of the methyl replacement technique.

Turning to ^6J, the technique implies that $^6J_{38}$ and $^6J_{47}$ are accounted for by a π electron contribution of −0.1 Hz. On the other hand, a value of +0.10 Hz for both $^6J_{36}$ and $^7J_{36}^{H,CH_3}$ indicates a σ electron contribution of +0.2 Hz to $^6J_{36}$. The three ^6J values are accounted for if there exists a π electron contribution of near −0.1 Hz to each but a σ contribution of +0.2 Hz to one of them only, $^6J_{36}$. It is interesting[4] that the bonds between H_3 and H_6 form a zig-zag or all-*trans* path (49), known to give rise to substantial magnitudes of ^5J.

The largest ^5J is $^5J_{48} = 0.67 \pm 0.03$ Hz. This ubiquitous coupling found, for example, in isoquinoline (21, 22, 25), acridine (24), indene (50), and benzofuran (50), occurs whenever a zig-zag configuration exists. Replacement of H_4 or H_8 in coumarin by a methyl group reduces $^6J_{48}^{H,CH_3}$ to almost zero; a σ mechanism therefore dominates. The other two five-bond couplings, $^5J_{46}$ and $^5J_{35}$ do not involve an all-*trans* pathway. $^5J_{35}$ is clearly π electron dominated ($^5J_{35} \simeq -^6J_{35}^{H,CH_3}$), while $^5J_{46}$ is very small, if not zero, and so is $^6J_{46}^{H,CH_3}$.

The methyl replacement method suggests that the *peri* coupling, $^4J_{45}$, arises from a σ electron mechanism. However, the methyl protons in 4-methylcoumarin can approach H_5 rather close-

[4]A coupling of ±1 Hz over six bonds in a saturated system occurs in the cyclopentadiene Diels–Alder adduct of bicyclo[2.1.0]pent-2-ene (48). The coupled protons are related via an all-*trans* or zig-zag bonding path.

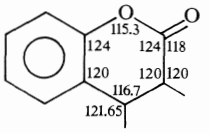
ly and a through-space (51, 52) and/or a direct (52) coupling interaction is possible and may well vitiate this suggestion.[5] Therefore, the question of mechanism cannot be settled by this method.

(b) INDO and CNDO/2 Molecular Orbital Calculations

The use of the finite perturbation technique with molecular orbitals at the INDO level of SCF MO theory (30, 53, 54) presents a useful guide to the interpretation of long-range coupling constants (7, 8, 14, 47, 55). Furthermore, the difference between coupling calculated at the INDO and CNDO/2 levels can be an *approximate* measure of the role of the π-electrons in the coupling mechanism (30).

In Table 2 the results of such computations on coumarin assume a planar form, **4**, the geometry of the molecule being unknown. Standard bond



4

lengths (30, 56) and trigonal angles very nearly closed the pyran ring but distorted the C—O—C angle by 11°. The chosen angles in **4** reduce the distortion of this angle to 5.9° (from tetrahedral). Up to 100 SCF cycles were performed (14, 57) on an IBM 360/65 computer, H_3 and H_4 being perturbed, and convergence to better than 0.01 Hz was obtained for the quoted numbers in Table 2.

(c) Comparison of INDO and CNDO/2 Results With Experiment

In Table 2 the INDO results for coumarin reproduce the observed signs of all the long-range inter-ring coupling constants but, in general, overestimate their magnitude. A similar situation was found in benzaldehyde and its derivatives (8).

The magnitude of $^7J_{37}$, a π-electron coupling, is correctly calculated by INDO while CNDO/2 calculates only 0.02 Hz: a good illustration of how INDO incorporates π electron effects.[6]

A comparison of INDO and CNDO/2 computations of ^6J is also instructive. INDO overestimates $^6J_{38}$ and $^6J_{47}$ by about −0.1 Hz and the vanishing values estimated by CNDO/2 confirm the π electron mechanism[7] for these couplings, as inferred from the methyl replacement technique. For $^6J_{36}$ this latter technique implied a π electron contribution of −0.1 Hz and a σ electron contribution of +0.2 Hz while CNDO/2 properly computes 0.24 Hz. This agreement is emphasized by the very small CNDO/2 estimates for $^7J_{37}$, $^6J_{38}$, and $^6J_{47}$: an all-*trans* configuration, as for H_3 and H_6 must exist for a σ electron involvement in ^6J. INDO overestimates $^6J_{36}$ by 0.1 Hz.

The all-*trans* or zig-zag configuration is also important for large σ electron contributions to ^5J (8, 49), as illustrated by $^5J_{48}$ in Table 2. CNDO/2 is in rather close agreement with observation for this constant but INDO overestimates its magnitude substantially, in much the same way as it does for $^5J^{H,CHO}$ in benzaldehyde and its derivatives (8). INDO also overestimates $^5J_{35}$ and $^5J_{46}$ by as much as 0.2 Hz. CNDO/2 gets $^5J_{46}$ right but disagrees with the methyl group replacement technique for $^5J_{35}$. However, the difference between the two theoretical estimates for $^5J_{35}$ is 0.29 Hz, in good agreement with the observed number. In this sense the theory could be said to be in agreement with experiment.

INDO computes $^4J_{45}$ correctly in sign and is close to experiment in magnitude. CNDO/2 disagrees in sign with experiment, the implication therefore being that $^4J_{45}$ is dominated by a π electron mechanism. The fact that $^5J_{45}{}^{H,CH_3}$ is only 0.06 Hz, instead of the 0.3 Hz expected for a π mechanism, may have its origin in the through-space (interaction of the hydrogen 1s orbitals on H_5 and CH_3) or direct (only the two C—H bond orbitals interacting) mechanism. These two mechanisms very likely produce negative coupling interactions (see footnote 5) and could reduce the π coupling of 0.3 Hz to the 0.06 Hz actually observed for $^5J_{45}{}^{H,CH_3}$.

(d) Comparison With INDO Calculations for Planar Styrene

In Table 2 the relevant long-range couplings between ring and olefinic protons, computed (7) by INDO methods for a planar styrene molecule,

[5]Some INDO MO calculations (14) in which a hydrogen molecule and a methane molecule, or two methane molecules, are brought to within van der Waals distances of each other predict *negative* couplings between protons in different molecules.

[6]For the vicinal coupling, $^3J_{34}$ in Table 2, the difference between INDO and CNDO/2 is 1.31 Hz, almost exactly equal to the magnitude of $^4J_{34}{}^{H,CH_3}$. The excellent agreement may be coincidental but is nevertheless encouraging.

[7]A referee emphasizes that the modification from CNDO/2 to INDO may introduce mechanisms which are neither σ nor π; *caveat emptor*.

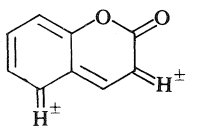
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

are very similar to those tabulated for the INDO calculations on coumarin. In fact, for many of the couplings the styrene calculations are in slightly better agreement with the observed data on coumarin than are the calculations for the latter, which also assume a planar molecule. Furthermore, the agreement is much better than that between the styrene calculations and the observations on a number of styrene derivatives (7). Therefore the O—C=O group in the pyran ring does not alter the computed couplings to a marked extent and probably the styrene molecule is not planar, in contrast to the benzaldehyde molecule (58).

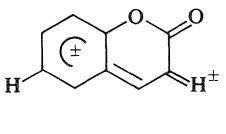
(e) Comparison With Long-range Couplings in Naphthalene

The inter-ring coupling constants in coumarin and naphthalene (Table 2) follow the same trends, the couplings lying within 0.2 Hz of each other in the two compounds while the algebraic sums of the eight couplings lie within 0.05 Hz. The ether linkage in coumarin redistributes the long-range interactions to some extent but does not radically alter them from their values in naphthalene.

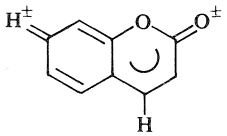
Another point from which to view this comparison invokes a valence bond picture. With reference to Table 2[8] it is likely that the π electron components of the long-range couplings fall into three groups. First, when a resonance structure connecting the coupled protons can be drawn, such as **5**, the π contribution is $+0.3$ Hz. Second, when it is possible to link only one



5



6



7

of the protons with the other ring, as in **6** or **7**, then the π component is -0.1 Hz. Third, if it is impossible to write a resonance structure linking a coupled hydrogen and involving both rings *without* including the p orbitals of the ether oxygen atom, then the π component of the coupling is zero (not detectable by our experiments). Again, the σ electron contribution is zero, except for an all-*trans* coupling path where it is 0.65 and 0.20 Hz respectively for five and six intervening bonds.

When these σ and π components are used to predict the coupling constants in naphthalene, using the appropriate resonance structures, the agreement with experiment is gratifying except for $^5J_{15}^{H,H}$, where the disagreement is as large as 0.1 Hz. Very probably, therefore, structure **3** and not **2** is an important one, the ether oxygen atom playing predominantly a "saturated" role in the pyran ring. The allylic coupling, $^4J_{34}^{H,CH_3}$, may after all be smaller than in propene because of the substituent effects discussed in detail by Barfield (47); hence **2** need not be important.

Conclusions

The inter-ring proton–proton coupling constants in coumarin may be separated into σ and π electron components by means of the methyl group replacement technique. By applying these components to the appropriate resonance structures of naphthalene, rather good agreement is found with the observed inter-ring coupling constants. Theoretical estimates at the INDO and CNDO/2 levels of molecular orbital theory are helpful in the interpretation of these couplings, although INDO somewhat overestimates the magnitudes of some of them. Comparison with the observed and calculated coupling constants in styrene suggests a nonplanar conformation for that molecule.

INDO Molecular Orbital Calculations of Nuclear Spin–Spin Coupling Constants Over Three Bonds Between ^{13}C and ^{1}H in Some Simple Molecules

R. WASYLISHEN[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 16, 1972

Molecular orbital calculations, at the INDO level, of the spin–spin coupling constants over three bonds between carbon-13 and protons are reported for a number of simple molecules. In propane the coupling depends on dihedral angle in the Karplus manner. Fluorine substituents cause changes in the computed coupling which are best described as alternating with the number of bonds intervening between the substituent and the coupled nuclei. Finer details of this phenomenon are discussed and calculations on propyllithium are performed. Replacement of a central carbon atom in propane by a heteroatom does not radically alter the computed couplings. The presence of a carbonyl group in the coupling path results in an overestimate of the magnitude of the coupling. In propene the coupling between ^{13}C in position 1 and a methyl proton displays a maximum when the C—H bond of the methyl group lies parallel to the π orbitals. In toluene the coupling to a methyl proton is insensitive to the dihedral angle over half its range, a result of importance to structural studies. Among other molecules under consideration are methylacetylene, propionaldehyde, and the strained bicyclobutane. It is suggested that in certain instances the mean of the predictions from the INDO and CNDO/2 procedures may agree better with experiment than will the prediction from either procedure alone. Calculations on fluorobenzene and 1,2-difluorobenzene suggest that the main experimental trends of the couplings between carbon and protons within the benzene ring are reproduced. Such is perhaps not true for the five-membered heterocycles.

Les calculs INDO appliqués aux orbitales moléculaires, des constantes de couplage spin–spin à travers trois liaisons entre le carbone-13 et les protons, sont rapportés pour un certain nombre de molécules simples. Dans le propane, le couplage dépend de l'angle dièdre selon la loi de Karplus. Les substituants fluorés provoquent des changements dans le couplage calculé qui alternent avec le nombre de liaisons séparant le substituant et le noyau couplé. Une analyse plus détaillé de ce phénomène et des calculs sur le propyl lithium sont donnés. La présence d'un groupe carbonyle sur le trajet du couplage a pour résultat une surestimation de l'amplitude du couplage. Dans le propène, le couplage entre le carbone-13 de la position 1 et un proton du méthyle passe par un maximum lorsque la liaison C—H du groupe méthyle est parallèle aux orbitales. Dans le toluène, le même couplage avec un proton du méthyle reste insensible à l'angle dièdre sur plus de la moitié de l'intervalle, résultat important dans les études de structure. Les autres molécules considérées sont le méthylacétylène, le propionaldéhyde et le bicyclobutane tendu. Pour certains exemples on pense que les prévisions selon les méthodes INDO et CNDO/2 donnent un meilleur accord avec l'expérience que ne le ferait chacune des méthodes seule. Les calculs sur les fluorobenzène et difluoro-1,2 benzène reproduisent les tendances expérimentales majeures pour les couplages entre carbone et protons du cycle benzènique. Cela n'est peut être plus valable pour les hétérocycles à cinq membres. [Traduit par le journal]

Can. J. Chem., **51**, 961 (1973)

Introduction

Approximate molecular orbital theory at the INDO level (1, 2) is relatively successful in reproducing the observed trends of nuclear spin–spin coupling constants for a variety of organic molecules (1–9). In particular, the calculated coupling constants over three bonds between protons (1, 4, 5) and between protons and other first-row elements (10, 11) display the Karplus relationship (12) with dihedral angles; and their dependence on substituent effects agrees fairly well with experiment (4, 5).

Recent advances in instrumentation facilitate the measurement of ^{13}C magnetic resonance spectra, and their use in structural and conformational studies is developing rapidly (13). The extraction of coupling constants over three bonds between ^{13}C and protons, $^{3}J(^{13}C,H)$, will therefore become common and their use in structural work (14) will likely be aided by theoretical predictions of their magnitudes for some model compounds.

In this paper we report the results of the

calculations of $^3J(^{13}C,H)$ in a number of common bonding situations. The computations are carried out by the finite perturbation technique (15*a*) at the INDO level of molecular orbital theory and yield the Fermi contact contribution to $^3J(^{13}C,H)$.

Computational Procedure

In the finite perturbation formalism, the Fermi contact contribution to nuclear spin–spin coupling between two nuclei A and B is given by eq. 1 (6–8), where h_B is the perturbation due

$$[1] \quad J_{AB} = \frac{\hbar}{2\pi}[(8\pi/3)\beta]^2\gamma_A\gamma_B S_A^2(0)S_B^2(0) \times [(\delta/\delta h_B)\rho^{spin}_{S_AS_A}(h_B)]_{(h_B=0)}$$

to the nuclear moment μ_B and has the form

$$h_B = \frac{8}{3}\pi\beta\mu_B S_B^2(0)$$

$\rho^{spin}_{S_AS_A}(h_B)$ is the diagonal element of the spin density matrix (in the presence of the contact perturbation h_B) corresponding to the valence s orbital of atom A, γ_A and γ_B are the magnetogyric ratios of nuclei A and B, β is the Bohr magneton, and $S_A^2(0)$ and $S_B^2(0)$ are the valence s-orbital electron densities of atom A and atom B at their respective nuclei. Using the method of finite differences Pople *et al.* (2, 15*a*) have shown that the derivative in eq. 1 can be approximated by $\rho^{spin}_{S_AS_A}(h_B)/h_B$. Thus the coupling constant (in Hz) is approximated by eq. 2. The error in the

$$[2] \quad J_{AB} = \frac{\hbar}{2\pi}[(8\pi/3)\beta]^2\gamma_A\gamma_B S_A^2(0)S_B^2(0) \times [\rho^{spin}_{S_AS_A}(h_B)/h_B]$$

approximation has a minimum when h_B is approximately 10^{-3} hartrees and $\rho^{spin}_{S_AS_A}(h_B)$ is calculated using open-shell semi-empirical molecular orbitals at the INDO level of approximation (1).

All coupling constants were calculated (15*b*) using eq. 2 with the same parameterization as used previously by Pople *et al.* (1, 15*a*). Because all other terms in eq. 2 are taken as constant, it is the sensitivity of the spin density in the orbital S_A to the presence of the perturbation h_B which determines the the spin-spin coupling constants. Because h_B is small, the spin densities are extremely small and therefore the spin density matrix must be known very accurately in the calculation of coupling constants. For carbon–proton coupling constants $J(^{13}C,H) = 285958.6283\ \rho^{spin}_{H_sH_s}$ Hz when $h_C = 10^{-3}$ hartrees. In order to obtain reasonably accurate coupling constants the usual energy criterion for convergence of the SCF iteration was changed to the requirement that

$$[3] \quad 10^{-4} \leq \frac{\rho_{ii}^{old} - \rho_{ii}^{new}}{\rho_{ii}^{old}}$$

for all *i*. By this criterion one can estimate the accuracy of the calculated coupling constants since J_{AB} is directly proportional to ρ^{spin}_{AA}/h or ρ^{spin}_{BB}/h depending on whether A or B is perturbed. For example, consider the accuracy of a calculated $J(^{13}C,H)$ with a magnitude of 28.60 Hz. If the convergence criterion given by eq. 3 is satisfied then the change in $J(^{13}C,H)$ in one SCF cycle is less than 0.00286 Hz. When coupling constants did not converge in 90 SCF cycles using the criterion given by eq. 3, 100 SCF cycles were carried out. If, after 100 SCF cycles the energy and the coupling constants did not converge, *e.g.* for $CH_3N{=}C{=}O$, the results of the calculations were discarded.

The input data for a calculation required the Cartesian coordinates of all atoms, the total charge, and the multiplicity of the molecule. Since the calculated coupling constants were sometimes sensitive to the molecular geometry, an attempt was made to use the best available structural parameters. The atomic coordinates were usually calculated from these structural parameters with the aid of the "Model-Builder" programme MBLD (15*c*). The sources of the structural parameters or atomic coordinates are given at appropriate places in the text.

All calculations were carried out on an IBM 360/65 computer.

Results and Discussion

(1) $^3J(^{13}C{-}C{-}C{-}H)$ in Propane, 1-Fluoropropane, 2-Fluoropropane, and 2,2-Difluoropropane

Standard geometries (1, 16) are assumed, yielding the results in Table 1. The dihedral angle and the conformations are depicted in **1**, **2**, **2***a*, **3**, and **4**. Note that staggered conformations about the C—C bonds are initially assumed and that one of the methyl groups (containing H_1) is then rotated so as to define a series of dihedral angles θ.

(i) Propane (1)

$^3J(^{13}C,H)$ was calculated at intervals of 15° or less between 0 and 180° and has been tabulated (17). The curve of $^3J(^{13}C,H)$ *vs.* θ is given for purposes of comparison in Fig. 1. It is represented by eq. 4 to within an average deviation of 0.013 Hz and a maximum deviation of 0.03 Hz. In eq. 4 the first coefficient, 4.26 Hz,

$$[4]\quad {}^3J(^{13}C,H) = 4.26 - 1.00\cos\theta + 3.56\cos 2\theta$$

corresponds to the average coupling constant for free rotation or, alternatively, to the average of $^3J(^{13}C,H)$ at angles of 60, 180, and 300° (the latter situation is realistic because the barrier to internal rotation of the methyl group is 3.575 kcal/mol (18)). The second coefficient, −1.00 Hz, is half the difference between the coupling constants at $\theta = 0°$ and $\theta = 180°$. The minimum in $^3J(^{13}C,H)$ occurs, not at $\theta = 90°$, but at $85° < \theta < 90°$. The shape of the curve is not surprising[2] in view of the work of Karplus (12) on ^3J(H—C—C—H) and in view of what is known for coupling over three bonds between other nuclei (17 and refs. therein).

(ii) 1-Fluoropropane (2 and 5)

The fluorine atom is attached to ^{13}C in **2** and lies *trans* to the methyl group containing the coupled proton. The computed coupling constants in Table 1 are plotted against θ in Fig. 1 and are reproduced by eq. 5 with an accuracy similar to that described for eq. 4. The computed

[2]Exact agreement with previous calculations (3, 4) of ^3J(H,H) and $^1J(^{13}C,^{13}C)$ in propane was found.

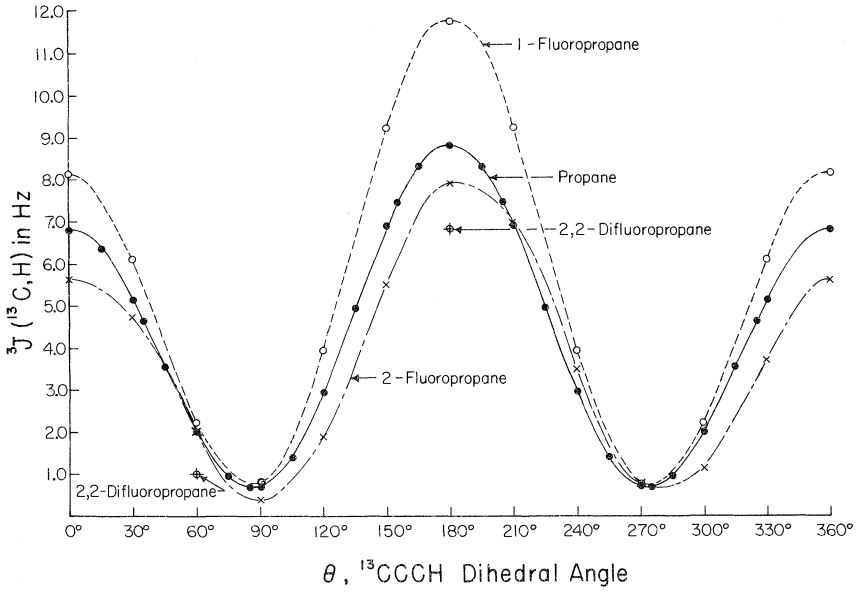

FIG. 1. The coupling constant (in Hz) over three bonds between ^{13}C and protons is plotted as a function of dihedral angle in propane, 1-fluoropropane, and 2-fluoropropane. The detailed conformations are depicted in the text. Note that J values are plotted for conformation **2** of 1-fluoropropane, in which fluorine lies *trans* to the methyl group containing the coupled proton.

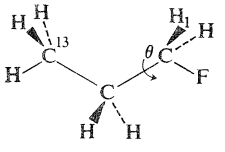
[5] $^3J(^{13}C,H) = 5.34 - 1.78 \cos\theta + 4.62 \cos 2\theta$

couplings are always larger than those for propane. On the other hand, when the fluorine atom is not attached to the ^{13}C site, as in **5**, one calculates $^3J(^{13}C,H) = 1.10$ Hz, *i.e.*, at $\theta = 60°$. The corresponding value for propane is 2.00 Hz and is 2.21 Hz for **2**.



$\theta = 60°$ for H_1

5

Subtraction of eq. 5 from eq. 4 yields the substituent effect, ΔJ, as represented by eq. 6. Clearly, the magnitude of ΔJ is minimal at

[6] $-\Delta J = 1.08 - 0.78 \cos\theta + 1.06 \cos 2\theta$

$\theta = 90°$, *i.e.*, when the C—H_1 bond lies perpendicular to the plane containing the carbon and fluorine atoms. The magnitude of ΔJ has a maximum at $\theta = 180°$. On the other hand, the relative substituent effect, $\Delta J/J$, where J is the value in propane, has a somewhat different dihedral angle dependence. For example, between $\theta = 120$ and 180° its value does not deviate appreciably from 1/3.

(iii) 1-Fluoropropane (2a)

In **2***a* the fluorine atom lies *gauche* to the methyl group containing the coupled proton. A plot *vs.* θ of the computed $^3J(^{13}C,H)$ values in Table 1 (not shown here) does not substantially deviate from that for propane. The two values in different quadrants generally bracket that for a given angle in propane, their mean falling within about 0.1 Hz of the coupling in propane (see Table 1). The average $^3J(^{13}C,H)$ for the staggered form (**2***a*) is 4.43 Hz (θ = 60, 180, and 300°), very near the corresponding value of 4.27 Hz for propane. In contrast, for **2** the average is 5.39 Hz.

Comparison of the results for **1**, **2**, and **2***a* in Table 1 suggests that when the C—H_1 bond lies perpendicular to the C—C—^{13}C plane, the values of ΔJ and $\Delta J/J$ will be small. If, in addition, the C—F bond also approaches perpendicularity to the C—C—^{13}C plane, the value of $\Delta J/J$ never becomes very large, no matter what the orientation of the C—H_1 bond. Although the experimental values may well turn out to differ somewhat from the computed values, the trends embodied by these rules should be of use in structural work.

The contrasting behavior of $^3J(^{13}C,H)$ in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12

For personal use only.

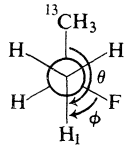
staggered conformations **2** and **2***a* can complicate the prediction of its magnitude in 1-fluoropropane and in analogous propane derivatives. If the two *gauche* forms, **2***a*, and the *trans* form, **2**, were equally populated, the predicted magnitude of $^3J(^{13}C,H)$ would be $(2 \times 4.43 + 5.39)/3 = 4.74$ Hz as compared to 5.39 Hz if only the *trans* form, **2**, were appreciably populated. We compute **2***a* as 1.8 kcal/mol less stable than **2**, in which the greater substituent dependence of $^3J(^{13}C,H)$ is predicted. Substituents larger than fluorine will no doubt increase the relative stability of the *trans* form.

(iv) 2-Fluoropropane (3 and 6)

In Table 1 the computed couplings are presented at 30° intervals between 0 and 360° of the dihedral angle θ and are plotted in Fig. 1. This curve in Fig. 1 is not symmetrical about θ = 180° and is represented to within an average deviation of 0.02 Hz by eq. 7. As implied by **6**, there exists an additional dependence of $^3J(^{13}C,H)$

$$[7]\quad {}^3J(^{13}C,H) = 3.69 - 1.16\cos\theta + 3.10\cos 2\theta - 0.19\sin\theta + 0.70\sin 2\theta$$

on the dihedral angle φ in the fragment H—C—C—F containing the coupled proton. In parti-



θ = 180° and φ = 60° for H_1

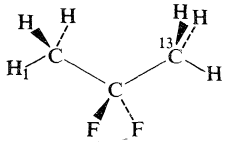
6

cular, when φ = 90°, corresponding to 210° for θ, the curves for propane and 2-fluoropropane coincide in Fig. 1. These curves also coincide at φ = 300° (or −60°), corresponding to θ = 60°. At φ = 270° (or −90°), corresponding to θ = 30°, the value for propane is decreased by less than 8%. To a good approximation, therefore, the substituent effect is small when the C—F bond is perpendicular to the C—H_1 bond. On the other hand, when φ = 180° (θ = 300°) the value for propane has been decreased by 44% and when φ = 0° (θ = 120°) the decrease is 37%. Again, to a good approximation, the substituent effect is relatively large when the C—F and C—H_1 bonds are near coplanarity.

Note, however, that between θ = 210° and about 270° the substituent causes an increase in $^3J(^{13}C,H)$ relative to propane, reaching a maximum of about 18% at θ = 240°. In practice, of course, the all-staggered conformation is the stable one and the angles 210 ≤ θ ≤ 270° do not occur. In fact the predicted value of $^3J(^{13}C,H)$ is 1/3(2.054 + 7.942 + 1.125) = 3.71 Hz, (as can also be deduced from the first term of eq. 7), about 0.55 Hz smaller than in propane.

(v) 2,2-Difluoropropane (7)

Only the staggered conformation, **7**, was considered. For θ = 180° (H_1 in **7**) one com-



7

putes $^3J(^{13}C,H)$ = 6.81 Hz and for θ = 60° the value is 1.00 Hz. These numbers are also entered in Fig. 1. The expense of the computations is such that calculations at other angles θ are hardly justified, the effect of a second fluorine substituent being as expected.

(vi) Propyllithium

The geometry of **2** was assumed, with lithium replacing fluorine and with a C—Li bond length of 2.10 Å. The computed values of $^3J(^{13}C,H)$ at intervals of 15° or less in the dihedral angle θ are to be found in Table 1. These values can be approximated by eq. 8 to within a maximum

$$[8]\quad {}^3J(^{13}C, H) = 2.25 + 0.93\cos\theta + 2.04\cos 2\theta$$

deviation of 0.15 Hz (at θ = 0 and 180°) and a mean deviation of 0.078 Hz. At a given angle the magnitude of $^3J(^{13}C, H)$ is smaller than in propane.

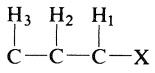
In addition, the maximum in $^3J(^{13}C,H)$ is smaller at 180° than at 0°, in contrast to propane or 1-fluoropropane, although the greatest substituent effect occurs at θ = 180°, as in form **2** of 1-fluoropropane. The positive coefficient of cos θ in eq. 8 describes the fact that $J(180°) < J(0°)$, the implication being that this happens whenever the substituent in a structure of type **2** is less electronegative than hydrogen.

The computed average $^3J(^{13}C,H)$ values for the staggered forms **1** (4.27 Hz), **2** (5.39 Hz), and propyllithium (2.25 Hz) imply a nonlinear dependence on the electronegativity of the substituent, different from the observed behavior of ^3J(H—C—C—H) in H—C—C—H. However,

the former situation is qualitatively different in that the substituent is bonded directly to one of the coupled nuclei, ^{13}C.

(vii) Calculated Substituent Effects

A decreasing, alternating substituent effect on ^3J(H—C—C—H) occurs (19, 20) and is qualitatively reproduced by INDO molecular orbital calculations (4, 5). In **8** a substituent X, more electronegative than the hydrogen which it replaces, causes a decrease in $^3J(H_1,H_2)$, an



8

increase in $^3J(H_2,H_3)$, and so forth. The magnitude of the effect decreases with the number of intervening bonds between the substituent and the coupled nuclei.

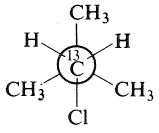
A natural extension of this scheme suggests that bonding of X to one of the coupled nuclei, as in **9**, will lead to an increase of $^3J(^{13}C,H)$ over that observed when X = H. The results in Table 1 and Fig. 1 confirm the suggestion for 1-fluoropropane. Then, when X is attached to C-2 in **9** a decrease in $^3J(^{13}C,H)$ is expected and is so calculated for 2-fluoropropane (with the qualifications noted in section 1.iv). Again, bonding of X to C-3 in **9** must also diminish $^3J(^{13}C,H)$, as calculated: at $\theta = 60°$ one has $^3J(^{13}C,H)$ as 1.10 Hz in **5** and as 2.00 Hz in propane (**1**).

9

These substituent effects must be considered when using $^3J(^{13}C,H)$ values in structural work. Note, however, that even the highly electronegative fluorine substituent is predicted to cause substantial changes in $^3J(^{13}C,H)$ only at certain angles θ (Fig. 1).

(viii) Comparison with an Experimental Datum

In 2,2-dimethyl-1-chloropropane (**10**), the observed value of $^3J(^{13}C,H)$ is 5.63 Hz (21), representing an average of the couplings to the



10

protons of the three methyl groups. The chlorine substituent lies *gauche* to two of the methyl groups, analogous to structure **2***a*, and *trans* to the third methyl group, analogous to structure **2**. If **2** and **2***a* can be used for purposes of comparison, one has a predicted value of $^3J(^{13}C,H)$ of $(2 \times 4.43 + 5.39)/3 = 4.75$ Hz (see section 1.iii). The agreement between observed and calculated values is not impressive, particularly as fluorine is more electronegative than chlorine.

(2) Cyclohexane

Standard geometries are assumed for the chair conformation and the calculated vicinal proton coupling constants agree exactly with literature values (4). The computations find that $^3J(^{13}C,H) = 1.70$ ($\theta = 60°$, axial proton) and $^3J(^{13}C,H) = 7.66$ Hz ($\theta = 180°$, equatorial proton). The corresponding values for propane are 2.00 and 8.81 Hz. At room temperature the rapid interchange of axial and equatorial proton positions entails an average $^3J(^{13}C,H)$ of 4.68 Hz (the different averaging procedure, over three angles, in propane yields 4.26 Hz).

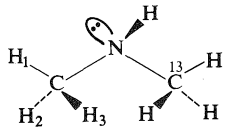
Experimental data for cyclohexane itself are unavailable but for rigid β-1,2,3,4,5,6-hexachlorocyclohexane, where the chlorine atoms take up equatorial positions (22), one has $^3J(^{13}C, H) = 1.08 \pm 0.04$ Hz ($\theta = 60°$). Each of the carbon atoms in the ^{13}C—C—C—H fragment carries a chlorine atom, the one on ^{13}C causing an increase in $^3J(^{13}C, H)$ and the other two causing a decrease (see Fig. 1 and Table 1); so that the observed value is in qualitative agreement with expectations based on the 1.70 Hz calculated for cyclohexane.

*(3) Dimethylamine (**11**) and Dimethylether*

(i) Dimethylamine

In this molecule a heteroatom replaces the central carbon atom in propane. Atomic coordinates were provided by a microwave study (23). The barrier to rotation of the methyl group is 3.2 kcal/mol (24) and calculations were done for the stable conformation, **11**, in which two C—H bonds lie in the C—N—C plane (23, 24*a*). The results were that $^3J(^{13}C,H_1) = 8.47$ ($\theta = 180°$), $^3J(^{13}C,H_2) = 0.955$ ($\theta = 300°$), $^3J(^{13}C, H_3) = 2.30$ Hz ($\theta = 60°$). Clearly, the coupling depends on the orientation of the lone-pair electrons but the conformational average is 1/3(2.30 + 8.47 + 0.96) or 3.91 Hz, not very different from the analogous average of 4.26 Hz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.



11

for propane, where the individual values are 8.81 (180°), 2.00 (300°), and 2.00 Hz (60°).

For the standard geometry of **11** the computations yield 8.39 ($\theta = 180°$), 1.34 ($\theta = 300°$), and 1.74 Hz ($\theta = 60°$) for $^3J(^{13}C,H)$. The individual values differ from those entailed by the microwave geometry above but the average of 3.82 Hz is close to the average for the latter geometry. Calculations at 15° intervals in θ for the standard geometry give an average of 3.90 Hz over 25 points on the period of 360° in θ.

(ii) Dimethylether

Calculations at 15° intervals between $\theta = 0°$ and 180° for dimethylether, assuming a standard geometry with a structure analogous to **11** (C—H bonds and lone-pairs staggered), resulted in an average value over 13 points of 3.24 Hz for $^3J(^{13}C,H)$. For the equilibrium conformation the mean of the values[3] at 180° (7.24 Hz) and at 60° (1.03 Hz twice) is 3.10 Hz.

A plot of $^3J(^{13}C,H)$ *vs.* θ for dimethylether can be represented by eq. 9 (the plot for dimethylamine is similar to that for 2-fluoropropane in Fig. 1) with an average deviation of 0.056 Hz. A comparison of eq. 9 with eq. 4 for propane

$$[9] \quad ^3J(^{13}C,H) = 3.10 - 1.14 \cos\theta + 3.05 \cos 2\theta$$

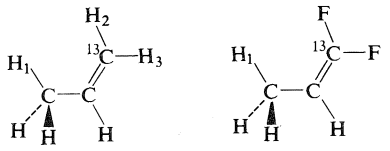
indicates the negative shift of the curve for the ether (a similar but smaller shift occurs for the amine).

Thus the computations predict that a heteroatom in the chain does not alter the calculated magnitudes by large amounts but that nitrogen and oxygen atoms act to decrease $^3J(^{13}C,H)$ relative to its value in a hydrocarbon fragment.

The observed value of $^3J(^{13}C,H)$ in dimethylether in solution is 5.7 ± 0.1 Hz (24*b*), much larger than the calculated 3.1 to 3.2 Hz. Observations are lacking on propane, so that the predicted negative shifts may be qualitatively correct. If so, the measured value in dimethylether suggests that $^3J(^{13}C,H)$ lies near 7 Hz in propane itself and should be easily observable in 2,2-dideuteropropane.

(4) Propene (12) and 1,1-Difluoropropene (13)

The geometry of propene was taken from the paper by Scarzafava and Allen (25*a*). In Table 2 the computed $^3J(^{13}C,H)$ magnitudes are given as a function of θ for propene. In contrast to its behavior in propane, $^3J(^{13}C,H)$ in propene displays a minimum at $\theta = 0°$ and a maximum



$\theta = 0°$ for H_1

12 13

near $\theta = 90°$ (see Fig. 2); indicating the importance of the π electrons in the transmission of spin information between the two nuclei. The predicted conformational average of $^3J(^{13}C,H)$ is 1/3(5.237 (0°) + 10.882 (120°) + 10.882 (120°)) = 9.00 Hz, more than twice as large as in propane.

The use of a standard geometry has the consequence that $^3J(^{13}C,H)$ is calculated as 5.277 Hz at $\theta = 0°$ and 10.199 Hz at $\theta = 120°$, giving a conformational average of 8.56 Hz.

The employment of a standard geometry for **13** yields 6.353 Hz for $^3J(^{13}C,H)$ at $\theta = 0°$ and 12.015 Hz at 120°. The average at the equilibrium conformation is 10.13 Hz, larger than in propene

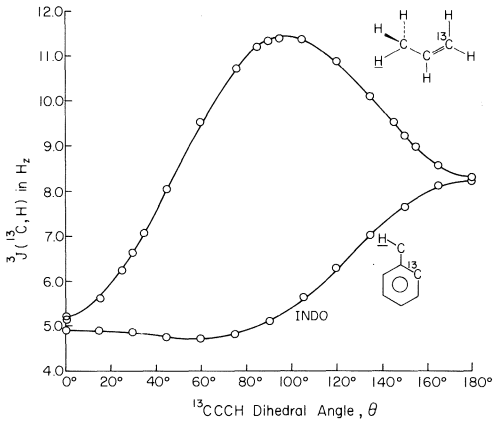


FIG. 2. The coupling constant (in Hz) over three bonds between ^{13}C and protons in propene and toluene is plotted against dihedral angle for the conformations shown in the text and sketched in the figure.

[3]The individual values at 15° intervals for dimethylether and dimethylamine are available from the authors.

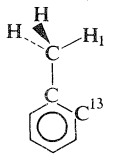
*Note that for meta and ortho fluorotoluene the two values are given for the appropriate angles θ. For example, when θ = 0° for C_1 it is 180° for C_2.

(a positive shift in J on substitution at ^{13}C by fluorine was also calculated above for propane). In 1,1-dichloropropene the observed value of $^3J(^{13}C,H)$ is ± 9.5 Hz (25*b*), in good agreement with theory if it is considered that chlorine is less electronegative than fluorine.

When ^{13}C in **12** is placed in the methyl group the calculations yield $^3J(^{13}C—C=C—H_2)$ = 5.96 (*cis* or θ = 0°) and $^3J(^{13}C—C=C—H_3)$ = 12.43 Hz (*trans* or θ = 180°).

(5) Toluene (14) and the Monofluorotoluenes

For toluene, **14**, and *p*-fluorotoluene standard geometries were assumed and the ensuing



θ = 0° for H_1

14

computations resulted in the angular dependence of $^3J(^{13}C\cdots C—C—H)$ in Table 2. In Fig. 2 the plotted dependence on angle of $^3J(^{13}C,H)$ contrasts strongly with that in propene, being largely independent of θ between 0 and 90°.

A comparison of the curves for propane, propene, and toluene (Figs. 1 and 2) allows the inference that in toluene, where the intervening $^{13}C—C$ bond possesses only a partially double bond character, the angular behavior of $^3J(^{13}C\cdots C—C—H)$ is a composition of that for propene and of one very similar to that for propane. The inference is strengthened by the near coincidence of the curves for propene and toluene at θ = 0 and 180°. At these angles the π electrons need not be significantly involved in the coupling mechanism, but between 0 and about 90° their increasing participation in toluene is roughly cancelled by the mechanism analogous to that represented for propane in Fig. 1. Then, between 90 and 180° the latter mechanism predominates.

This interpretation was examined by the calculation of $^3J(^{13}C,H)$ for **14** using the CNDO/2 molecular orbitals because these tend to reflect the contributions of the σ electrons to the transmission of spin information (1). In Table 2 the resultant values do indeed display a minimum of 0 Hz near θ = 90°, showing a Karplus-type

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

behavior as for propane. The interpretation above is evidently a reasonable one.

The curve for toluene should be remembered when the ^{13}C nucleus is bonded into a structure with delocalized electrons and a Karplus curve is being assumed. Note that between 90 and 180° such an assumption is qualitatively valid but is invalid between 0 and 90°.

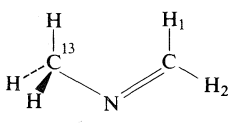
This somewhat unexpected behavior is confirmed by the computations given in Table 2 for the fluorotoluenes. The $^3J(^{13}C,H)$ values differ only slightly from those in toluene when fluorine is situated meta or para to the methyl group. When fluorine is bonded to ^{13}C the values are up to 0.5 Hz *smaller* than in toluene, in contrast to the behavior calculated for propane and 1-fluoropropane.

The average $^3J(^{13}C,H)$ values in toluene and *p*-fluorotoluene are found by taking the means of the numbers at 15° intervals between 0 and 180°. The averages are 5.82 Hz for toluene and 5.91 Hz for *p*-fluorotoluene, rather closer to that for propane (4.26 Hz) than that for propene (9.00 Hz). The averaging procedure for toluene is correct because the barrier to internal rotation of the methyl group is only 0.014 kcal/mol (26) whereas in propene, **12** is more stable than other conformations by 2 kcal/mol (27).

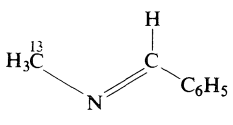
When ^{13}C occurs in the methyl group of toluene and a standard geometry is assumed with one C—H bond of the methyl group eclipsing a C—H bond on the ring, the computations yield $^3J(^{13}C,H)$ as 5.02 Hz for the proton in the eclipsing C—H bond and as 4.69 Hz for the other ortho proton in the ring. In principle this dependence on conformation could be applicable to the study of various alkyl derivatives of benzene.

(6) N-Methylmethylenimine (15)

In **15** a nitrogen atom replaces C-2 in propene. The calculation is performed for the molecule in which ^{13}C occurs in the methyl group because a measurement is available on **16**. The microwave geometry (28) of **15** is utilized to compute $^3J(^{13}C—N=C—H_1) = 9.09$ (*cis*) and $^3J(^{13}C—N=C—H_2) = 18.34$ Hz (*trans*) whereas a standard geometry yields 11.54 and 15.71 Hz, respectively. In *N*-benzylidenemethylamine (**16**), the observed value of *cis* $^3J(^{13}C—N=C—H)$ is 11.9 ± 0.6 Hz (29). The agreement between calculated and observed values is reasonable, particularly if the anticipated increase in $^3J(^{13}C,H)$ caused by the electronegative phenyl group in **16** is considered. Note also that replacement of C-2 in propene by a nitrogen atom leads to an increase in the calculated magnitude of the coupling, in contrast to the analogous situation for propane and dimethylamine (section 3).



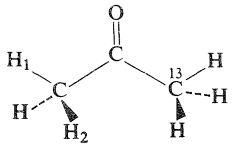
15



16

(7) Acetone (17)

In acetone (**17**), a trigonally hybridized carbon atom lies in the coupling path but the double



17

bond, in contrast to propene, is peripheral to the path. The atomic coordinates of the stable conformation **17** are known from a microwave investigation (30) and their use yields $^3J(^{13}C—C—C—H_1) = 7.29$ ($\theta = 180°$) and $^3J(^{13}C—C—C—H_2) = 3.08$ Hz ($\theta = 60°$). Corresponding numbers for propane are 8.81 and 2.00 Hz, respectively. When $\theta = 180°$ the oxygen substituent decreases $^3J(^{13}C,H)$ in a manner similar to fluorine in 2-fluoropropane (section 1). However, when the C—H bond containing the coupled proton does not lie in the nodal plane of the π electron cloud, the calculations predict an increase in $^3J(^{13}C,H)$ from its value in propane; indicating a positive contribution from the π electrons.

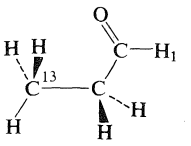
The barrier to internal rotation is only 0.778 ± 0.010 kcal/mol in the gas phase (31) so that conformations other than **17** are appreciably populated at room temperature. Nevertheless, a reasonable surmize from the above discussion is of a shallower curve for acetone than for propane (Fig. 1) and therefore the average $^3J(^{13}C,H)$ will hardly be smaller than 4 Hz. The experimental value is 1.46 Hz (32) and the conclusion that a substantial theoretical overestimate exists for this bonding situation is inescapable. The disagreement cannot be attributed to the use of a wrong or a standard geometry (the calculated

dipole moment of 2.90 D agrees exactly with the gas phase measurement (31)).

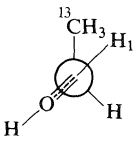
A more likely cause of the discrepancy resides in an overestimate of the π electron contribution to $^3J(^{13}C,H)$ in acetone.[4] For example, the INDO approximation finds $J(^{13}C—C—C—H)$ = 9.40 Hz in benzene while at the CNDO/2 level of calculation, which does not allow for nonzero π spin density inductions, yields 5.51 Hz (1). The experimental value is 7.4 Hz (33). It may well be, then, that for ketones the CNDO/2 prodecure will also be needed in order to arrive at better predictions for $^3J(^{13}C, H)$.

(8) Propionaldehyde-3-^{13}C and its Oxime

These compounds were chosen because experimental estimates of $^3J(^{13}C,H)$ are available and because they contain an aldehydic functional group. Standard geometries were assumed. In the gas phase the *cis* form, **18**, of the aldehyde is more stable than the *gauche* form, **19**, by 0.900 ± 0.100 kcal/mol (34) and the four heavy atoms are coplanar. In **18** the aldehyde proton,



18



19

H_1, and ^{13}C are *trans* to each other (θ = 180°) and the calculations predict $^3J(^{13}C—C—C—H_1)$ as 4.98 Hz whereas in the *gauche* form, **19**, they predict 1.40 Hz (θ = 60°). From the temperature dependence of $(^3J_g + {}^3J_t)/2$ in solution rough estimates of 3.5 Hz for J_t and 0.2 Hz for J_g were made (35*a*).

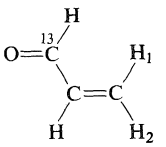
For the oximes of **18** and **19** standard geometries (C=N—O—H atoms in a plane and a CNO angle of 109.47°) give rise to predicted values

NOH
||

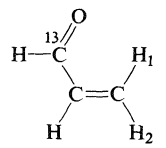
of $^3J(^{13}C—C—C—H_1)$ as 6.38 (θ = 180°) and 3.58 Hz when θ = 60°. When applied to the oxime O-methyl ether, $^{13}CH_3CH_2—CH=N—O—CH_3$, the experimental method above suggested 7.8 and 0.7 Hz for these two couplings (35*a*). It appears, therefore, that the theoretical overestimates may not be confined to the carbonyl compounds.

*(9) Acrolein (**20** and **20a**)*

In **20** and **20***a* one has a carbonyl group conjugated with the double bond in propene.



20



20*a*

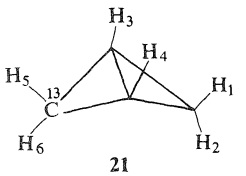
For the *s-trans* form, **20**, the standard geometry entails $^3J(^{13}C,H_1)$ = 11.14 and $^3J(^{13}C,H_2)$ = 20.24 Hz. The corresponding values for the *s-cis* form are 9.47 and 16.95 Hz. The observed values (35*b*) are 10.1 and 15.9 Hz, respectively. The *s-trans* form is the more stable and hence the theory is not in satisfactory agreement with experiment, substantially overestimating the magnitudes and their ratio for the two couplings.

(10) Methylacetylene

The microwave geometry (36) yields $^3J(^{13}C{\equiv}C—C—H)$ = 7.89 and $^3J(^{13}C—C{\equiv}C—H)$ = 4.87 Hz, both considerably larger than the observed (37) values of 4.8 and 3.6 Hz, respectively. Standard geometry entailed 7.43 and 4.80 Hz as the calculated values. From the CNDO/2 (6.55 Hz) and INDO (10.99 Hz) values of $^3J(H—C{\equiv}C—H)$ in acetylene (1), compared to the experimental measurement of 9.5 Hz (38), one may infer that the mean result from the two methods will also produce better agreement with experiment for $^3J(^{13}C{\equiv}C—C—H)$ and $^3J(^{13}C—C{\equiv}C—H)$.

*(11) Bicyclo [1.1.0] butane (**21**)*

As an example of a strained molecule, **21** was subject to the calculations based on the microwave structure (39). INDO predicts $^3J(^{13}C,H_1)$



21

= 11.33 and $^3J(^{13}C,H_2)$ = 2.72 Hz while the experiment (40) finds 16.0 ± 0.5 and 5.3 ± 0.2 Hz, respectively. The calculated quantities are too

[4]A referee suggests that for the carbonyl compounds the contact density at the carbon nucleus may differ from the optimum parameter determined by Pople and coworkers.

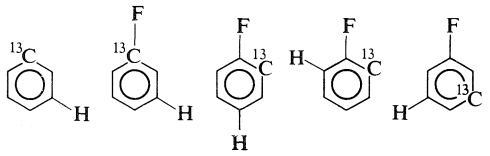
small,[5] a point to note when considering other strained molecules.

(12) Fluorobenzene (23) and 1,2-Difluorobenzene (24)

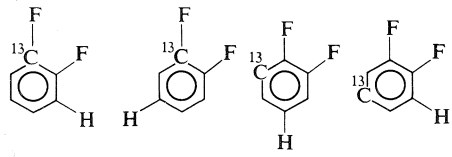
In this section the influence of electronegative substituents on $^3J(^{13}C,H)$ in the benzene ring is investigated. Standard geometries are assumed for both molecules. For ease of comparison, the diagrams display the calculated couplings in a serial fashion.



9.40 Hz	12.43	9.96	7.36	10.21
22	**23***a*	**23***b*	**23***c*	**23***d*

Relative to benzene the marked increase of $^3J(^{13}C,H)$ in **23***a* and the decrease in **23***c* is similar to that calculated respectively for 1-fluoropropane (**2**) and 2-fluoropropane relative to propane. No experimental data are available for compounds related to **23**.

Such data are available for 1,2-dichlorobenzene (41) and in the diagrams they are compared to the INDO calculations on 1,2-difluorobenzene. Noting that the observed value in benzene is 7.4 Hz (33), that the calculated value is 9.40 Hz (1) and that chlorine is less electronegative than fluorine, the calculations may be considered



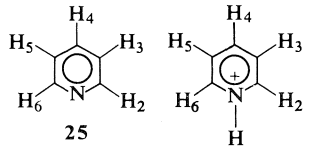
Calcd. 10.52 Hz	12.95	10.74	10.31
Obs. 7.92	11.57	8.41	8.63
(1,2-di Cl)			
24*a*	**24***b*	**24***c*	**24***d*

to reproduce the observed trends at least partially. It may well be helpful in disentangling the complex ^{13}C spectra of benzene derivatives (see ref. 41 and the last sentence of ref. 42).

[5]The vicinal proton coupling constants were calculated as $^3J_{3,4} = 5.67$ (10.4 ± 0.2), $^3J_{1,4} = 1.57$ (2.9 ± 0.2), $^3J_{2,3} = 2.08$ (1.2 ± 0.2) Hz, the experimental quantities being given in brackets.

(13) Pyridine (25) and Pyridinium Ion (26)

The atomic coordinates of pyridine were those of Bak *et al.* (43). The same coordinates were used for the ion but with an N—H bond length of 1.03 Å. It was calculated that $^3J(^{13}C_2,H_4) = 9.27$ (10.08) $^3J(^{13}C_2,H_6) = 13.53$ (5.40), $^3J(^{13}C_3,H_5) = 8.60$ (8.06), and $^3J(^{13}C_4,H_2) = 8.93$

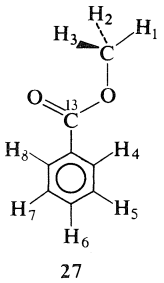


25 **26**

(7.48) Hz, where the values for the ion occur in the brackets. In **25** only $^3J(C_2,H_6)$ is calculated to be larger than in benzene (compare propane and dimethylether where the opposite shift is predicted) while in the ion, **26**, $^3J(C_2,H_4)$ is predicted as larger than in benzene.

(14) Methylbenzoate (27)

Couplings from the carbon nucleus in the carboxylate group to protons have recently been measured (44). A standard geometry was assumed in the calculation. The conformation of the methyl group, shown in **27**, was indicated by the known structure of methyl formate (45).



27

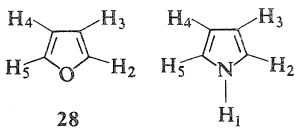
One computes $^3J(^{13}C,H_1) = 5.38$ and $^3J(^{13}C,H_2) = 0.75$ Hz, yielding an average of 2.29 Hz. The observed number is 3.73 Hz. Again, the computed values of $^3J(^{13}C,H_4)$ and $^3J(^{13}C,H_8)$ are 6.71 and 5.98 Hz, respectively, as compared to the observed mean value of 4.08 Hz. The relative magnitudes of the two calculated couplings are correctly reproduced, but one is too small and the other too large (compare dimethylether and acetone or acrolein above).[6] In planar benzaldehyde we compute

[6]One computes $^4J(^{13}C,H_5)$ as 0.47 and $^4J(^{13}C,H_7)$ as 0.83 Hz. The observed mean of $^4J(^{13}C,H)$ is 1.11 Hz. On the other hand, the calculated value of $^5J(^{13}C,H_6)$ is 1.53 Hz while the observed number is 0.48 Hz.

the analogous couplings as $^3J(^{13}C,H_4)$ equal to 7.53 Hz and $^3J(^{13}C,H_8)$ equal to 6.52 Hz. The stereospecificity displayed by the computed couplings of a carbonyl carbon to ring protons can probably be used as a probe in conformational work when it is combined with observation.

(15) Furan (28) and Pyrrole (29)

The atomic coordinates for **28** were taken from ref. 46, for **29** from ref. 47. The computations yield for **28**, $^3J(^{13}C_2,H_4) = 9.02$,



28

29

$^3J(^{13}C_2,H_5) = 6.64$, and $^3J(^{13}C_3,H_5) = 9.30$ Hz. The observed values are 10.8, 7.0, and 5.8 Hz, respectively (48). It is tempting to ascribe the disagreement between theory and experiment to a wrong assignment of the experimental spectrum (42, 48).

For **29** one calculates $^3J(^{13}C_2,H_4) = 9.69$, $^3J(^{13}C_2,H_5) = 6.04$, $^3J(^{13}C_3,H_5) = 9.55$, and $^3J(^{13}C_3,H_1) = 6.84$ Hz. Experiment suggests that both of the latter two couplings equal 7.8 Hz (48), while in 2,5-dimethylpyrrole $^3J(^{13}C_2,H_4)$ is 7.3 Hz (48). The theory is in difficulty in this respect with five-membered heterocycles.

Conclusions

In general the INDO MO computations of spin–spin coupling over three bonds between ^{13}C and protons may well be useful in conformational work when combined with experimental data. In particular, certain pitfalls connected with arguments based on analogies to H,H and H,^{19}F couplings over three bonds may be avoided by reference to the theory. However, the exploratory calculations reported here emphasize that the quantitative aspects of the theory must be treated with circumspection.

We are grateful to the National Research Council of Canada for financial support and to the staff of the Computing Center of the University of Manitoba for their cooperation. We thank the referees for some very helpful comments.

A Synthesis of 2-Amino-2,6-dideoxy-D-(and L-)galactose (Fucosamine) and 2-Amino-2,6-dideoxy-D-(and L-)talose (Pneumosamine)[1]

MALCOLM B. PERRY AND VIRGINIA DAOUST

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received October 10, 1972

5-Deoxy-D-lyxose underwent base-catalyzed addition with nitromethane to give a mixture of 1,6-dideoxy-1-nitro-D-galactitol and 1,6-dideoxy-1-nitro-D-talitol (*ca.* 2:1). Acetylation of the crystalline 1,6-dideoxy-1-nitro-D-galactitol gave 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol which on treatment with methanolic ammonia afforded 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol and 2-acetamido-1,2,6-trideoxy-1-nitro-D-galactitol (*ca.* 3:1) which under the modified Nef reaction conditions gave 2-acetamido-2,6-dideoxy-D-talose and 2-acetamido-2,6-dideoxy-D-galactose respectively. The glycoses were converted to 2-amino-2,6-dideoxy-D-talose hydrochloride and 2-amino-2,6-dideoxy-D-galactose hydrochloride on hydrolysis with hydrochloric acid.

A similar reaction sequence applied to 5-deoxy-L-lyxose afforded the L-enantiomorphic intermediates, and gave 2-amino-2,6-dideoxy-L-talose hydrochloride and 2-amino-2,6-dideoxy-L-galactose hydrochloride as final products.

Le déoxy-5-D-lyxose s'additionne sur du nitrométhane en milieu basique pour conduire au mélange de didéoxy-1,6-nitro-1-D-galactitol et de didéoxy-1,6 nitro-1-D-talitol (*ca.* 2:1). L'acétylation du didéoxy-1,6 nitro-1-D-galactitol cristallin fournit le tétra-*O*-acétyl-2,3,4,5 didéoxy-1,6 nitro-1-D-galactitol qui, en présence d'ammoniac méthanolique, conduit à l'acétamido-2 tridéoxy-1,2,6 nitro-1-D-talitol et à l'acétamido-2 tridéoxy-1,2,6 nitro-1-D-galactitol (*ca.* 3:1); dans les conditions de la réaction modifiée de Nef, ce mélange donne respectivement l'acétamido-2 didéoxy-2,6-D-talose et l'acétamido-2 didéoxy-2,6-D-galactose. Les glycoses sont convertis en chlorhydrates d'amino-2 didéoxy-2,6-D-talose et d'amino-2 didéoxy-2,6-D-galactose dans l'hydrolyse par l'acide chlorhydrique.

La même séquence réactionnelle sur le déoxy-5-L-lyxose conduit aux intermédiaires L-énantiomorphes puis aux chlorhydrates d'amino-2 didéoxy-2,6-L-talose et d'amino-2 didéoxy-2,6-L-galactose comme produits finals. [Traduit par le journal]

The following 2-amino-2,6-dideoxyhexoses have been identified as components of bacterial polysaccharides: 2-amino-2,6-dideoxy-D-glucose (quinovosamine) (1–5), 2-amino-2,6-dideoxy-L-mannose (rhamnosamine) (6, 7), 2-amino-2,6-dideoxy-D-galactose (fucosamine) (8–13), 2-amino-2,6-dideoxy-L-galactose (14–16), and 2-amino-2,6-dideoxy-L-talose (pneumosamine) (15, 17, 18). A survey of the carbohydrate components of *Pseudomonas* species made in this laboratory revealed many unusual aminoglycoses, including 2-amino-2,6-dideoxyhexoses. The synthesis of the series of these latter compounds was undertaken to provide glycoses for the development of analytical procedures and for the preparation of methyl ethers required in structural studies.

Although methods have been described for the synthesis of 2-amino-2,6-dideoxy-D-talose (18), 2-amino-2,6-dideoxy-L-talose (19, 20), 2-amino-2,6-dideoxy-L-galactose (20, 21), and 2-amino-2,6-dideoxy-D-galactose (13), it was considered that the series might be conveniently synthesized from available 5-deoxypentoses by the nitromethane method which has found general application in the synthesis of 2-amino-2-deoxyaldoses (22). This paper records the successful synthesis of 2-amino-2,6-dideoxy-D-talose and 2-amino-2,6-dideoxy-D-galactose from 5-deoxy-D-lyxose, and the corresponding L-enantiomorphs from 5-deoxy-L-lyxose, using the nitromethane method.

5-Deoxy-D-lyxose, prepared by the degradation of D-fucose diethyl dithioacetal (21, 23) underwent addition with nitromethane in the presence of sodium methoxide and the resulting precipitated sodium salts of 1,6-dideoxy-1-nitro-D-galactitol (66%) and 1,6-dideoxy-1-nitro-D-talitol (34%) were deionized with hydrogen form ion-exchange resin and the product afforded crystalline 1,6-dideoxy-1-nitro-D-galactitol which on acetylation gave 2,3,4,5-tetra-*O*-acetyl-1,6-

dideoxy-1-nitro-D-galactitol. Treatment of the 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol with saturated methanolic ammonia (24) afforded a mixture of 2-acetamido-1,2,6-trideoxy-1-nitro-D-galactitol (27%) and 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol (73%), the latter compound being obtained pure by crystallization from ethanol solution. The 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol on treatment under the mild modified Nef conditions (24) gave chromatographically pure 2-acetamido-2,6-dideoxy-D-talose. The crude 2-acetamido-1,2,6-trideoxy-1-nitro-D-galactitol remaining after the removal of crystalline 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol, underwent the modified Nef reaction to give a mixture of 2-acetamido-2,6-dideoxy-D-talose and 2-acetamido-2,6-dideoxy-D-galactose, the latter compound being separated by crystallization from the ethanol solution of the mixture.

The 2-acetamido-2,6-dideoxy-D-talose and 2-acetamido-2,6-dideoxy-D-galactose were each hydrolyzed with hot dilute hydrochloric acid to yield crystalline 2-amino-2,6-dideoxy-D-talose hydrochloride and 2-amino-2,6-dideoxy-D-galactose hydrochloride respectively which had physical properties in agreement with those recorded in the literature for these compounds.

The synthesis of the two 2-acetamido-2,6-dideoxy-hexoses performed without the isolation of the intermediates gave improved yields. The final products of 2-acetamido-2,6-dideoxy-D-talose and 2-acetamido-2,6-D-galactose were obtained in 44 and 17% yields respectively, based on 5-deoxy-D-lyxose used. The final mixture can be separated by preferential crystallization of the 2-acetamido-2,6-dideoxy-D-galactose leaving essentially pure 2-acetamido-2,6-dideoxy-D-talose which is readily purified by conversion to 2-amino-2,6-dideoxy-D-talose hydrochloride which is obtained pure in good yield. Alternatively, the two 2-acetamido-2,6-dideoxy-hexoses are easily separated by cellulose column chromatography using aqueous 1-butanol as the mobile phase.

5-Deoxy-L-lyxose, prepared either by the degradation of L-fucose diethyl dithioacetal (21) or from D-galactono-1,4-lactone (25), underwent the same synthetic reaction sequence as that described for 5-deoxy-D-lyxose to yield the corresponding L-enantiomorphic intermediates and to give, as final products, 2-amino-2,6-dideoxy-L-talose hydrochloride and 2-amino-2,6-dideoxy-L-galactose hydrochloride.

Experimental

Paper chromatography was performed by the descending method (26) on Whatman No. 1 filter paper using either (A) pyridine – ethyl acetate – water (2:5:5 v/v; top layer) or (B) 1-butanol–ethanol–water (4:1:5 v/v; top layer) as the mobile phase. Glycoses were detected with either (*i*) 2% silver nitrate in acetone followed by 3% sodium hydroxide in ethanol (27), (*ii*) 2% *p*-anisidine hydrochloride in ethanol (28), or (*iii*) 2% ninhydrin in acetone. The rates of movement of the glycoses are quoted relative to D-galactose (R_{Gal}) or to 2-amino-2-deoxy-D-glucose hydrochloride (R_{GN}).

Gas–liquid partition chromatography (g.l.p.c.) was carried out using a Hewlett-Packard model 402 gas chromatograph with a hydrogen flame detector and fitted with glass U-tubes (4 ft × 6 mm × 3 mm internal diameter) packed with 10% neopentyl-glycol sebacate polyester on 80–100 mesh acid washed Chromosorb W. Retention times of the compounds are quoted relative to penta-*O*-acetyl-L-arabinitol (T_A) or to 2-acetamido-2-deoxy-1,3,4,5,6-penta-*O*-(trimethylsilyl)-D-glucitol (T_{GN}).

Melting points were determined on a Fisher-Johns apparatus and are corrected. Solutions were concentrated under reduced pressure and below 40 °C. Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter.

(A) Synthesis of 2-Amino-2,6-dideoxy-D-talose Hydrochloride and 2-Amino-2,6-dideoxy-D-galactose Hydrochloride

(1) 1,6-Dideoxy-1-nitro-D-talitol and 1,6-Dideoxy-1-nitro-D-galactitol

To a solution of 5-deoxy-D-lyxose (21) (4.4 g) in a mixture of methanol (50 ml) and nitromethane (15 ml) was added 1.7 *N* sodium methoxide in methanol (23 ml) and the mixture was kept at 20 °C for 18 h. Following the addition of ether (140 ml), the precipitated product was collected by filtration, washed with cold methanol, ether, and light petroleum (b.p. 30–60 °C) and dried under vacuum. The product dissolved in cold water (70 ml) was passed down a column of Rexyn 101(H^+) ion-exchange resin (120 ml) and the eluate and water washings were concentrated to a syrup (5.5 g).

A portion of the product (20 mg) was dissolved in 2 *N* sodium hydroxide (0.2 ml) and the solution was added dropwise to 6 *N* sulfuric acid (0.3 ml) at 0 °C. After 2 h at room temperature the mixture was diluted with water (5 ml) and following neutralization ($BaCO_3$), filtration, and passage of the filtrate through a column of mixed Rexyn 101(H^+) and Rexyn RG6(OH^-) ion-exchange resins (2 ml), the solution was concentrated to a syrup (*ca.* 12 mg). Paper chromatographic examination of the syrup (solvent A) revealed two spots having R_{Gal} 2.37 and 4.26 corresponding in mobilities and color reaction, with authentic 6-deoxy-D-galactose and 6-deoxy-D-talose respectively (visual ratio 2:1). G.l.p.c. (180 °C) of a reduced ($NaBH_4$) and acetylated (29, 30) portion of the latter syrup gave two peaks corresponding with penta-*O*-acetyl-6-deoxy-D-talitol (T_A 0.72, 34%) and penta-*O*-acetyl-D-6-deoxy-D-galactitol(T_A 0.77, 66%).

On keeping, a methanolic solution of the mixed 1,6-dideoxy-1-nitro-hexitols (5.4 g) gave crystals (2.8 g), m.p. 170–176 °C (mixture of *talo*- and *galacto*-epimers, *ca.* 1:5 by Nef reaction) which after three recrystallizations from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ethanol afforded pure 1,6-dideoxy-1-nitro-D-galactitol (2 g) having m.p. 180 °C and $[\alpha]_D$ +6° (*c*, 0.3 in water).

Anal. Calcd. for $C_6H_{13}O_6N$: C, 36.92; H, 6.71; N, 7.18. Found: C, 37.10; H, 6.53; N, 6.99.

A small sample of the pure product on treatment under the Nef conditions (as above) gave only 6-deoxy-D-galactose.

(2) 2,3,4,5-Tetra-O-acetyl-1,6-dideoxy-1-nitro-D-galactitol

1,6-Dideoxy-1-nitro-D-galactitol (2 g) in acetic anhydride (20 ml) was treated with 1 drop of concentrated sulfuric acid and the mixture was heated on a boiling water bath for 30 min. The cooled reaction mixture was poured onto crushed ice (150 ml) and the precipitated derivative (3.9 g) was collected and washed with cold water. The product after two recrystallizations from ethanol gave crystalline 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol having m.p. 138–139 °C and $[\alpha]_D$ −18.5° (*c*, 0.7 in chloroform).

Anal. Calcd. for $C_{14}H_{21}O_{10}N$: C, 46.28; H, 5.83; N, 3.86. Found: C, 46.41; H, 5.86; N, 3.76.

Acetylation of the mixed 1,6-dideoxy-1-nitro-D-galactitol and -D-talitol (3.4 g) remaining after removal of the -D-galactitol component afforded further crystalline 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol (1.6 g) and a syrup mixture of 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol and 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-talitol (4.3 g).

(3) 2-Acetamido-1,2,6-trideoxy-1-nitro-D-galactitol and 2-Acetamido-1,2,3-trideoxy-1-nitro-D-talitol

2,3,4,5-Tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol (4.1 g) in dry methanol (45 ml) was cooled to 0 °C and ammonia gas was passed into the solution for 30 min and the saturated mixture was then kept for 18 h at 20 °C. The mixture was concentrated to a syrup which was triturated with warm chloroform (3 × 30 ml) to remove acetamide and the light brown syrup remaining was dissolved in hot ethanol, treated with charcoal (2 g), filtered, and, following concentration of the ethanol solution, crystalline 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol (1.2 g) was obtained, which had, after recrystallization from ethanol, m.p. 166–167 °C and $[\alpha]_D$ +20° (*c*, 0.4 in water).

Anal. Calcd. for $C_8H_{16}O_6N_2$: C, 40.67; H, 6.83; N, 11.86. Found: C, 40.83; H, 6.76; N, 11.69.

A portion of the product (10 mg) resulting from the action of ammonia on the 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol on treatment under the Nef conditions gave two 2-acetamido-2,6-dideoxy-hexoses which on paper chromatography gave two spots having R_{Gal} 3.02 and 4.10 corresponding in mobility and color reactions with 2-acetamido-2,6-dideoxy-D-galactose and 2-acetamido-2,6-dideoxy-D-talose respectively (visual ratio 1:2) while quantitative g.l.p.c. analysis (190 °C) of the trimethylsilylated product (31) indicated the mixture to be composed of 27% 2-acetamido-2,6-dideoxy-D-galactose and 73% 2-acetamido-2,6-dideoxy-D-talose.

(4) 2-Amino-2,6-dideoxy-D-talose Hydrochloride

2-Acetamido-1,2,6-trideoxy-1-nitro-D-talitol (0.96 g) was dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (1.18 g) in water (18 ml) and the mixture was added dropwise with stirring to a solution of concentrated sulfuric acid (1.2 ml) in water (11 ml) cooled in ice. The mixture was kept at 20 °C for 18 h and following neutralization ($BaCO_3$) and filtration, the filtrate was treated with Dowex-1 (CO_3^{2-}) ion-exchange resin (8 ml) and 4 drops of acetic anhydride and, after 20 min, the solution was passed down a column of mixed Rexyn 101(H^+) and Rexyn RG6(OH^-) ion-exchange resins and the eluate and washings were concentrated to dryness (0.62 g).

Paper chromatographic analysis of the product (solvent A) gave a single spot having R_{Gal} 4.10 corresponding with authentic 2-acetamido-2,6-dideoxy-D-talose and g.l.c. (190 °C) of the trimethylsilylated (31) equilibrated product showed four peaks having T_{GN} 0.53 (17%), 0.62 (46%), 0.98 (25%), and 1.07 (12%). The 2-acetamido-2,6-dideoxy-D-talose (0.6 g) which failed to crystallize was hydrolyzed with 3 *N* hydrochloric acid for 2 h at 100 °C and following concentration to dryness the product afforded pure 2-amino-2,6-dideoxy-D-talose hydrochloride (0.48 g) which gave a single ninhydrin positive spot on paper chromatography (solvent B) with R_{GN} 1.70 and had m.p. 164–165 °C and $[\alpha]_D$ +7 → −10° (*c*, 0.5 in water) (lit. (18) m.p. 161.5–163.5 °C and $[\alpha]_D$ +8 → −10° (water); L-enantiomorph (20) m.p. 162–163 °C and $[\alpha]_D$ −4 → +10° (water) and (19) m.p. 163–164 °C and $[\alpha]_D$ +9° (water)).

Anal. Calcd. for $C_6H_{14}O_4NCl$: C, 36.09; H, 7.07; N, 7.01; Cl, 17.75. Found: C, 36.12; H, 7.02; N, 7.15; Cl, 17.55.

(5) 2-Acetamido-2,6-dideoxy-D-galactose

The syrupy mixture of 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol and 2-acetamido-1,2,6-trideoxy-1-nitro-D-galactitol (1.42 g) remaining from the ammonia treatment of 2,3,4,5-tetra-*O*-acetyl-1,6-dideoxy-1-nitro-D-galactitol and removal of the crystalline 2-acetamido-1,2,6-trideoxy-1-nitro-D-talitol (section 3 above) was treated under the modified Nef conditions (as in section 4 above) to give a mixture of 2-acetamido-2,6-dideoxy-D-talose and 2-acetamido-2,6-dideoxy-D-galactose (1.1 g) which from concentrated ethanol solution gave crystalline 2-acetamido-2,6-dideoxy-D-galactose (0.48 g) which was removed leaving essentially pure 2-acetamido-2,6-dideoxy-D-talose as a syrup.

The 2-acetamido-2,6-dideoxy-D-galactose on paper chromatography (solvent A) gave a single spot R_{Gal} 3.02 and after recrystallization from ethanol the crystals (0.37 g) had m.p. 201–202 °C and $[\alpha]_D$ +109 → +87° (*c*, 0.4 in water) (lit. (13) m.p. 196–197 °C and $[\alpha]_D$ +129 → +92° (water); L-enantiomorph (21) m.p. 197–198 °C and $[\alpha]_D$ −119 → −82° (water)).

Anal. Calcd. for $C_8H_{15}O_5N$: C, 46.82; H, 7.37; N, 6.83. Found: C, 46.69; H, 7.44; N, 7.01.

G.l.c. (190 °C) of the trimethylsilylated (31) crystalline 2-acetamido-2,6-dideoxy-D-galactose gave a single peak T_{GN} 1.03 while the water equilibrated glycose gave two peaks having T_{GN} 1.03 (56%) and 1.75 (44%).

(6) 2-Amino-2,6-dideoxy-D-galactose Hydrochloride

2-Acetamido-2,6-dideoxy-D-galactose (0.2 g) after hydrolysis with 3 *N* hydrochloric acid for 2 h at 100 °C afforded crystalline 2-amino-2,6-dideoxy-D-galactose hydrochloride from methanol–acetone solution which gave a single ninhydrin positive spot on paper chromatography (solvent B) with R_{GN} 1.52 and had m.p. 192–193 °C and $[\alpha]_D$ +120 → +93° (*c*, 0.4 in water) (lit. (13) m.p. 192 °C and $[\alpha]_D$ +117 → +92° (water); L-enantiomorph (21) m.p. 192–193 °C and $[\alpha]_D$ −119 → −92° (water)).

Anal. Calcd. for $C_6H_{14}O_4NCl$: C, 36.09; H, 7.07; N, 7.01: Cl, 17.75. Found: C, 36.01; H, 6.98; N, 7.10; Cl, 17.60.

(B) 2-Amino-2,6-dideoxy-D-talose Hydrochloride and 2-Amino-2,6-dideoxy-D-galactose Hydrochloride

(1) 2-Acetamido-2,6-dideoxy-D-talose and 2-Acetamido-2,6-dideoxy-D-galactose

5-Deoxy-L-lyxose (21, 25) (5 g) was condensed with nitromethane (as in Section A.1) to yield the sodium salts of the 1,6-dideoxy-1-nitro-hexitols which were deionized (Rexyn 101(H^+)) and concentrated to a syrup (6.4 g). Acetylation of the syrup (as in Section A.2) gave the tetra-*O*-acetates of 1,6-dideoxy-1-nitro-L-talitol and 1,6-dideoxy-1-nitro-L-galactitol (11.3 g) which were treated with methanolic ammonia (as in Section A.3) and, following the removal of acetamide, the mixture of 2-acetamido-1,2,6-trideoxy-1-nitro-L-talitol and 2-acetamido-1,2,6-trideoxy-1-nitro-L-galactitol (7 g) was obtained as a syrup. The mixed 2-acetamido-1,2,6-trideoxy-1-nitro-hexitols were treated under the modified Nef reaction conditions (as in Section A.4) to yield 2-acetamido-2,6-dideoxy-L-talose and 2-acetamido-2,6-dideoxy-L-galactose (4.9 g). On keeping at room temperature, the concentrated ethanol solution of the product gave crystals of 2-acetamido-2,6-dideoxy-L-galactose (0.98 g) leaving essentially pure (*ca.* 90%) 2-acetamido-2,6-dideoxy-L-talose as a syrup (3.7 g).

The 2-acetamido-2,6-dideoxy-L-galactose after recrystallization from ethanol gave a single spot on paper chromatography (solvent A) R_{Gal} 3.02 and g.l.p.c. of the trimethylsilylated product gave a chromatogram identical with the D-enantiomorph. The crystals had m.p. 195–198 °C and $[\alpha]_D$ $-116 \rightarrow -83°$ (*c*, 0.2 in water).

Anal. Calcd. for $C_8H_{15}O_5N$: C, 46.82; H, 7.37; N, 6.83. Found: C, 46.59; H, 7.30; N, 7.02.

(2) 2-Amino-2,6-dideoxy-L-galactose Hydrochloride

2-Acetamido-2,6-dideoxy-L-galactose (0.3 g) was hydrolyzed with 3 *N* hydrochloric acid for 3 h at 100 °C and the concentrated product gave crystalline 2-amino-2,6-dideoxy-L-galactose (0.23 g) which gave a single ninhydrin positive spot on paper chromatography R_{GN} 1.52 (solvent B) and had m.p. 191–193 °C and $[\alpha]_D$ $-115 \rightarrow -95°$ (*c*, 0.5 in water).

Anal. Calcd. for $C_6H_{14}O_4NCl$: C, 36.09; H, 7.07; N, 7.01. Found: C, 36.00; H, 7.11; N, 7.07.

(3) 2-Amino-2,6-dideoxy-L-talose Hydrochloride

The impure 2-acetamido-2,6-dideoxy-L-talose (3.7 g) was hydrolyzed with 3 *N* hydrochloric acid (50 ml) for 3 h at 100 °C and following concentration, the methanol–acetone solution of the residue gave crystalline 2-amino-2,6-dideoxy-L-talose hydrochloride (2.3 g) which gave a single ninhydrin positive spot on paper chromatography R_{GN} 1.71 (solvent B) and had m.p. 163–164.5 °C and $[\alpha]_D$ $-5 \rightarrow +10°$ (*c*, 0.4 in water).

Anal. Calcd. for $C_6H_{14}O_4NCl$: C, 36.09; H, 7.07; N, 7.01. Found: C, 36.02; H, 7.11; N, 7.00.

Radical Intermediates in Chloramine and *N*-Chloroimide Reactions[1]

OLIVER EDWARD EDWARDS, DONALD H. PASKOVICH, AND ALLAN H. REDDOCH

Divisions of Chemistry and of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received October 10, 1972

Nitrogen-centered radicals produced by the action of Ag(0) or Ag(I)-amine systems on *N*-chloroazacyclononane, *N*-chloropiperidine, and *N*-chlorosuccinimide have been trapped using 2-methyl-2-nitrosopropane. The resulting nitroxides exhibited e.p.r. spectra consistent with structures **1**, **2**, and **3**. Hydrogen gas evolved during reaction of the chloramines with Ag(0) was shown to arise completely from the amine derivatives.

Excess Ag(0) reduced the succinamidyl radical to give the silver salt of succinimide.

Les radicaux centrés sur l'azote et obtenus par action des systèmes Ag(0) ou Ag(I)-amine sur le *N*-chloroazacyclononane, *N*-chloropipéridine, et *N*-chlorosuccinimide ont été piégés en utilisant du méthyl-2 nitroso-2 propane. Les nitroxydes qui en résultent, montrent des spectres r.p.e. compatibles avec les structures **1**, **2**, et **3**. Le dégagement gazeux obtenu dans la réaction des chloramines sur Ag(0) provient uniquement des dérivés aminés.

L'excès d'Ag(0) réduit le radical succinamidyle et conduit au sel d'argent du succinimide.

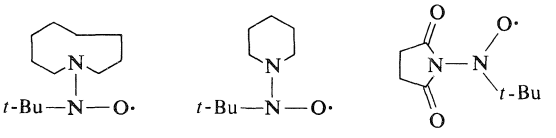
In connection with our studies of chloramine decomposition by silver ions or metallic silver (1) it seemed desirable to have independent evidence for the postulated nitrogen-centered radicals. The products from reaction of hypochlorites (2), hypobromites, and aliphatic chloramines (1) with finely divided silver were consistent with reduction to give the oxygen and nitrogen-centered radicals respectively. However the reaction of aliphatic chloramines with silver salts was more controversial. While considerable evidence has been provided by Gassman for heterolytic fission of the N—Cl bonds in a number of cases (3), our studies showed that this did not take place at room temperature with *N*-chloropiperidine or medium ring chloramines. The need for amine to initiate reaction, the formation of parent secondary amine, and the sensitivity of the reactions to oxygen led us to conclude that traces of metallic silver were initiating these reactions also. This conclusion is now supported by radical trapping evidence.

No radicals were detected when a degassed solution of *N*-chloroazacyclononane, indolizidine, and silver perchlorate in 90% aqueous acetonitrile was examined in the e.p.r. spectrometer. However if 2-methyl-2-nitrosopropane (4) was present during the reaction, a nitroxide with hyperfine splitting consistent with structure **1** was observed. The same nitroxide was formed when the chloramine was treated *in vacuo* with



1 **2** **3**

metallic silver in the presence of the nitroso compound. In a similar manner the radical **2** was identified in reaction of *N*-chloropiperidine with silver.

We conclude that silver induces homolytic fission of the chloramines as in eq. 1. A comparable reaction of *N*-chlorosuccinimide and *N*-bromosuccinimide takes place and the succinimidyl radical was trapped in the *N*-chloro case as nitroxide **3**. However preparative runs

[1] $$R_2NCl + Ag(0) \rightarrow R_2N\cdot + AgCl$$

with *N*-bromosuccinimide showed that the succinamidyl radical was rapidly reduced further to the anion (eq. 2). This provides a convenient

[2] 
high yield route to the silver salt of succinimide. The stability of the anion must contribute markedly to the ease of reduction of the imidyl radical. A comparable reduction of the medium ring amidyl radicals such as **4** probably accounts for the puzzlingly high yield of parent lactam

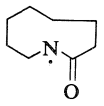
[1]NRCC No. 12976.

TABLE 1. Summary of e.p.r. spectra

System	Solvent	Coupling constants (G) a_N	$a_{N'}$	a_H*	$a_{N''}$†
N-Chloroazacyclononane	Dioxane–H_2O	16.1	1.24	0.78(4)	16.4
N-Chloroazacyclononane	2-MTHF–D_2O	15.4	1.26	0.56(4)	
N-Chloropiperidine	Dioxane–H_2O(80:20)	18.8	0.88	0.88(2)	16.2
N-Chloropiperidine	2-MTHF–H_2O	18.6			15.0
N-Chlorosuccinimide	2-MTHF–D_2O	16.4	1.80		7.7

*Numbers in brackets indicate the number of equivalent protons.
†The coupling constant $a_{N''}$ refers to a second nitrogen-containing radical coexisting with the first.

produced when the corresponding *N*-chlorolactam was treated with silver (5).



4

Aldimines were shown to be important products arising from cyclic nitrogen-centered radicals (1). These could arise by disproportionation (eq. 3) (6), radical attack

[3] $2RN\dot{-}CH_2R' \rightarrow RN(H)-CH_2R' + RN{=}CHR'$

on chloramine (eq. 4), or hydrogen atom loss from the nitrogen-centered radical (eq. 5).

[4] $X\cdot + RN(Cl)-CH_2R' \rightarrow$

$RN(Cl)-\dot{C}HR' \xrightarrow{Ag(0)} RN{=}CHR' + AgCl$

$RN(Cl)-\dot{C}HR' \rightarrow RN{=}CHR' + Cl\cdot$

[5] $RN\dot{-}CH_2R' \rightarrow RN{=}CHR' + H\cdot$

When *N*-chloroazacyclononane or *N*-chloropiperidine were treated with silver *in vacuo*, vigorous gas evolution was observed. We hence examined the nature of the gas produced when aqueous dioxane, aqueous dioxane-d_8, and dioxane-D_2O were the solvents. Pure hydrogen was produced in all cases. This observation seems to demand that hydrogen atoms are only formed on the silver surface (eq. 5) and that they either combine to give hydrogen gas before leaving the surface or selectively abstract hydrogen from other radicals on the surface (eq. 6).

[6] $RN\dot{-}CH_2R' + H\cdot \rightarrow RN{=}CHR' + H_2$

This may only be a minor reaction of the amine radicals, and it is not known what proportion of the aldimines arise by the routes shown in eqs. 3, 4, and 5.

Electron Paramagnetic Resonance Results

The coupling constants of the various e.p.r. spectra are summarized in Table 1. The spectra from *N*-chloroazacyclononane are consistent with a radical of structure **1**. The smaller coupling constants may be slightly uncertain because these splittings are not fully resolved. The two nitrogen couplings of 16.1 and 1.24 G are reasonable for a structure $\diagdown N\dot{-}NO-\diagup$ as shown by the radicals derived from *N*-chlorosuccinimide by Lagercrantz and Forschult (4*b*) (16.4 and 1.81 G) and from carbazole by Terabe and Konaka (8) (16.77 and 1.37 G). The four equivalent protons also support structure **1** if the radical is rapidly interconverting among various conformations.

Similarly the spectra support radical **2** as the product from *N*-chloropiperidine on the basis of magnitude and number of the coupling constants. The coupling with only two protons shows that the conformational inversion is slow relative to the e.p.r. time scale. The rather large a_N of 18.8 G may arise from such steric effects, as well as from solvent polarity (7).

The second radical found in both the above systems with a coupling constant of 16 G is probably di-*t*-butyl-nitroxide (7).

The *g* values of the radicals derived from *N*-chloroazacyclononane and *N*-chloropiperidine in aqueous dioxane are less by 0.00009 and 0.00032 respectively than that of the di-*t*-butyl-nitroxide in the corresponding solution. These values are within the range usually found for nitroxides.

N-Chlorosuccinimide yields the same spectrum as that obtained by Lagercrantz and Forschult (4*b*) on u.v. irradiation of that compound in chloroform in the presence of 2-methyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

2-nitrosopropane (a_N 16.4 and 1.81 G). This points to the presence of radical **3**. The second radical species with $a_N = 7.7$ G and a g value of 0.00098 greater than that of the first was also seen by these authors.

Experimental

The analysis for H_2, HD, and D_2 by g.l.c. was done using a 2 m column packed with alumina containing $MnCl_3$ at −196 °C (9).

The *in vacuo* experiments were done in two-compartment all-glass cells. The solution was separated from the silver by a fritted glass filter and a break seal. The liquid was degassed by three freeze–thaw cycles in high vacuum, and the silver was pumped free of volatile solvents and gases. Both arms were then sealed and the solution added to the silver via the break seal. For the e.p.r. study a 4 mm tube was provided on the solution arm and for the gas analysis a branch, with a standard taper joint and a break seal, was provided on the solution side. The gas samples were prepared by freezing all condensable components in liquid nitrogen. These were then sealed off from the gas-containing compartment.

Electron Spin Resonance Experiments

The dioxane used had been distilled over sodium and stored over sodium wire under nitrogen. It may still have contained traces of peroxides (5). The 2-methyltetrahydrofuran had been purified by drying over lithium aluminum hydride followed by distillation *in vacuo* into a high vacuum storage flask containing pyrene and sodium. It was distilled under high vacuum before use.

N-Chloropiperidine and N-Chloroazacyclononane

The typical experiment involved 1 ml of solvent, 2–3 mg of the dimer of 2-methyl-2-nitrosopropane, and Tollens' silver (1) from 0.75 g of silver nitrate. When D_2O was used as a co-solvent the silver was washed with the organic solvent to remove water prior to evacuation. The quantity of chloramine used was approximately 30 mg of *N*-chloropiperidine or *N*-chloroazacyclononane.

The experiments using *N*-chloroazacyclononane, indolizidine and silver perchlorate were performed in acetonitrile as follows:

To a solution of 5 ml of acetonitrile containing 90 mg of *N*-chloroazacyclononane, 7 mg of the dimer of 2-methyl-2-nitrosopropane and 121 mg of silver perchlorate was added 0.5 ml of acetonitrile containing 12 mg of indolizidine. A 1 ml aliquot was degassed twice and sealed *in vacuo*. The solution gave e.p.r. signals with the same parameters as those obtained from the silver-initiated reactions. Comparable runs without the nitroso compound gave no detectable e.p.r. signal.

N-Bromosuccinimide

A solution of 109 mg of *N*-bromosuccinimide and 3.3 mg of 2-methyl-2-nitrosopropane in 1 ml of acetonitrile was degassed. The deep yellow solution gave no e.p.r. signal. When mixed with Tollens' silver from 0.5 g of silver nitrate *in vacuo*, vigorous gas evolution resulted and the yellow color disappeared. Again no e.p.r. signal was detected.

N-Chlorosuccinimide

A solution of 51 mg of *N*-chlorosuccinimide (m.p 149°) and 3 mg of the dimer of 2-methyl-2-nitrosopropane was degassed and added *in vacuo* to approximately 300 mg of fresh Tollens' silver. The e.p.r. spectrum of a filtered solution is reported in Table 1.

Nature and Source of the Gas in Ag^0 Reactions

(*a*) A mixture of 189 mg of *N*-chloroazacyclononane in 1 ml of dioxane and 0.2 ml of deuterium oxide was degassed three times *in vacuo*, then added *in vacuo* to Tollens' silver from 0.7 g of silver nitrate. The gas evolved during 96 h was analyzed by g.l.c. and shown to be pure hydrogen free from HD or D_2.

(*b*) A repetition of (*a*) using 1 ml of dioxane-d_8 and 0.2 ml of water as solvent also gave pure hydrogen.

(*c*) Fresh Tollens' silver from 1 g of silver nitrate was added *in vacuo* to a degassed solution of 139 mg of *N*-chloropiperidine in 1 ml of dioxane and 0.1 ml of deuterium oxide. Vigorous gas evolution ensued. G.l.c. analysis showed this to be pure hydrogen.

(*d*) An identical experiment to (*c*) using dioxane-d_8 and deuterium oxide as solvents and dioxane-washed silver again gave pure hydrogen.

N-Bromosuccinimide With Tollens' Silver

A solution of 1.25 g of *N*-bromosuccinimide in 20 ml of acetonitrile was purged with nitrogen. After addition of freshly prepared Tollens' silver from 2.49 g of silver nitrate the mixture was stirred under nitrogen at 24 °C. The extent of reaction was 48% in 0.5 h, 63% in 1 h and 73.5% in 2 h. Silver from 1 g of silver nitrate was added to speed the reaction to completion. The mixture was filtered from solids (A) then the filtrate taken to small volume under reduced pressure. The residue was suspended in methylene chloride, then filtered. The soluble portion was fairly pure succinimide (60 mg). The insoluble white granular solid remaining (513 mg) proved to be the silver salt of succinimide. When suspended in dilute hydrochloric acid it gave silver chloride and succinimide.

The original solids (A) consisted of more silver salt of succinimide, unreacted silver, and silver bromide. This was treated with nitric acid to dissolve the silver and silver salt. The well-washed residue of silver bromide weighed 1.15 g. The calculated amount for 1 mol equiv from 18.5 ml of the original solution is 1.19 g.

The Synthesis of Trisubstituted Enol Ethers and of Methyl Ketones from Ketones

GILLES CARON AND JEAN LESSARD

Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received November 22, 1972

A reliable method for the synthesis of trisubstituted enol ethers (and of the corresponding methyl ketones) is described involving the condensation of the α-lithiated 2-methoxypropionic acid salt with a ketone to give a β-hydroxy acid, the cyclization to a β-lactone which is then decarboxylated (and mild acid hydrolysis of the enol ether).

On décrit une méthode efficace pour la synthèse d'éthers énoliques trisubstitués (et des méthyl cétones correspondantes). Les étapes de cette synthèse sont: la condensation du dérivé α-lithien du sel de l'acide méthoxy-2 propionique avec une cétone pour donner un β-hydroxy acide, sa cyclisation en β-lactone qui est ensuite décarboxylée (et l'hydrolyse acide de l'éther énolique dans des conditions douces).

Can. J. Chem., **51**, 981 (1973)

The Wittig reaction of α-methoxyethyl triphenyl phosphorane with ketones has been reported (1). However the trisubstituted enol ethers were not isolated as such but the crude reaction mixture was hydrolyzed to give the corresponding methyl ketones in low to moderate yields in the presence of the starting ketone. Furthermore, this Wittig reaction was not successful with cyclopentanone.

We wish to report a reliable and convenient method for the synthesis of trisubstituted enol ethers (and of the corresponding methyl ketones) from ketones. The reaction sequence of this synthesis is illustrated in Scheme 1. Although each step is well documented (2), the use of an α-lithio-α-alkoxycarboxylate is quite novel, and the usefulness and convenience of the method do make it of real interest to the synthetic chemist.[1] The yields of the different products[2] from four representative ketones are recorded in Table 1.

The 2-methoxypropionic acid (**1**) was prepared as described by Petrov *et al.* (3). The same experimental conditions as those described by Adam *et al.* (2) were used for the generation of the α-lithiocarboxylate salt **2**, its condensation with ketones as well as for the cyclization of the β-hydroxy acids **3** into the β-lactones **4**. The decarboxylation of the β-lactones **4** was carried out in the presence of solid anhydrous potassium carbonate (5–10% relative to the β-lactone) to prevent the isomerization of the trisubstituted enol ethers **5** into their monosubstituted isomers **7**.[3] The methyl ketones **6** were obtained by stirring, at room temperature, an ethereal solution of the enol ethers **5** with 0.2 *N* aqueous HCl (10–60 h) or more conveniently by saturating the ethereal solution with 70% aqueous $HClO_4$ (10 min) (4).

The synthesis of 2-methoxy-3-*n*-propyl-2-hexene (**5**, $R_1 = R_2 = n\text{-}C_3H_7$) is representative of the standard experimental procedure. Lithium α-lithio-2-methoxypropionate (**2**) was

[1]To our knowledge, this is the first reliable method for the synthesis of pure trisubstituted enol ethers from ketones.

[2]All compounds had spectral (i.r., n.m.r.) data compatible with their structures. All new compounds gave satisfactory compositional analyses and/or mass spectroscopic data. Known crystalline derivatives (semicarbazones or oximes) of the methyl ketones were prepared and their melting points compared with those of the literature.

[3]This isomerization occured quite extensively (40–70%) without the presence of base even with very pure samples of β-lactones. The less substituted isomers are more stable and the results of the equilibration studies will be reported later.

prepared by adding, under a nitrogen stream, 5.20 g (50 mmol) of 2-methoxypropionic acid (**1**) to a magnetically stirred ice-cold (freshly prepared (2)) solution of *t*-butylamide (100 mmol) in 100 ml tetrahydrofuran, then stirring at *ca.* 25° for 1 h. To this solution was added dropwise at *ca.* 25° 28.55 g (250 mmol) of 4-heptanone in 60 ml tetrahydrofuran and stirring was continued for 20 h. The usual working-up (2) gave 7.23 g (67%) of 3-hydroxy-2-methoxy-2-methyl-3-*n*-propylhexanoic acid (**3**, $R_1 = R_2 = n\text{-}C_3H_7$), 100–110° (0.8–1.0 mm).[4]

[4]The analytical sample was obtained by microdistillation.

Anal. Calcd. for $C_{11}H_{22}O_4$: C, 60.52; H, 10.16. Found: C, 60.46; H, 10.38.

To an ice-cold solution of 5.30 g (24 mmol) of the β-hydroxy acid in 120 ml anhydrous pyridine, 8.83 g (50 mmol) of benzenesulfonyl chloride was added. The mixture was shaken and placed in the refrigerator for 12 h. The usual working-up (2) gave 3.70 g (77%) of 3-methoxy-3-methyl-4,4-di-*n*-propyloxetan-2-one (**4**, $R_1 = R_2 = n\text{-}C_3H_7$), 70–72° (0.4 mm).[4]

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07. Found: C, 65.70; H, 10.33.

A mixture of 754 mg (3.76 mmol) of the β-lactone and 49 mg of K_2CO_3 was heated at 145° at atmospheric pressure for 55 min to yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

589 mg (100%) of 2-methoxy-3-*n*-propyl-2-hexene, 58–60° (20–25 mm).[4]

Anal. Calcd. for $C_{10}H_{20}O$: C, 76.86; H, 12.90. Found: C, 77.17; H, 13.03.

The condensation of the α-lithiocarboxylate salt **2** with a 17-ketosteroid, androst-5-en-3β-ol-17-one tetrahydropyranyl ether, gave none of the expected β-hydroxy acid and 93% of the starting ketone was recovered. Thus it appears that steric hindrance of the ketone is an important factor in this reaction, a fact that can be an advantage or a limitation.

Further studies are in progress to explore the possibility of a general synthesis of alkyl ketones from ketones and to extend this reaction to aldehydes.

A Low Temperature Infrared Study on the Association of Thiols with Pyridine and Triethylamine

R. BICCA DE ALENCASTRO[1] AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal, Québec

Received September 20, 1972

The infrared spectra of solutions containing propane-1-thiol or benzenethiol as proton donors, and pyridine or triethylamine as proton acceptors were measured down to about −100 °C. The dependence of hydrogen bond formation on concentration and temperature was studied at the fundamental and overtone region of the S—H stretching vibration. The predominant species is found to be a 1:1 S—H---N type complex. In addition, evidence was found for the existence of more highly associated species at low temperatures. Thiol–thiol S—H---π type hydrogen bonds are also present in the case of benzenethiol–pyridine mixtures.

Les spectres infrarouges de solutions contenant du propanethiol-1 ou du benzènethiol comme donneurs de proton et de la pyridine ou de la triethylamine comme accepteurs de proton ont été mesurés à des températures allant de 20 °C à −100 °C. Les effets de la concentration en base d'une part et de la température d'autre part sur la formation de la liaison hydrogène, ont été étudiés aux niveaux de la fondamentale et de la première harmonique de la vibration de valence du groupement S—H. L'espèce prédominante est un complexe 1:1 de type S—H---N. D'autre part, l'existence d'espèces plus associées a été mise en évidence aux températures les plus basses. Des liaisons hydrogène de type S—H---π auto-associées ont été trouvées dans les mélanges benzènethiol–pyridine.

Can. J. Chem., 51, 985 (1973)

Introduction

In a previous publication (1) we studied the self-association of both aliphatic and aromatic thiols in solution at low temperatures. Although the S—H---S hydrogen bonds formed are relatively weak, the existence of two or three differently associated species could be ascertained in most cases. As a second step in the study of the hydrogen bonds formed by S—H groups, we have examined some systems in which stronger bonds are expected. In the present paper we deal with S—H---N type bonds.

Solutions of mercaptans in organic nitrogen bases are known to undergo both self-association and association with the proton accepting solvent molecules. As early as in 1940, Gordy and Stanford (2) studied the variation of the infrared spectrum, in the region of the S—H stretching vibration, when mercaptans are dissolved in solvents such as pyridine, aniline, or benzylamine, and attributed these changes to association of the S—H---N type. Bulanin, Denisov, and Pushkina (3) observed association between propane-1-thiol and triethylamine. N.m.r. and u.v. studies (4, 5) confirmed this, and suggested that these complexes were of the 1:1 type.

We have studied the association of propane-1-thiol and benzenethiol with pyridine and triethylamine as proton acceptors over a wide temperature range, and have measured the fundamentals as well as the overtones of the S—H stretching vibration. The solvent used was

CCl_3F (Freon 11) which enabled us to work at temperatures down to -100 °C. We hoped to be able to follow the changing pattern of association with temperature, and to identify the bands due to the complexes formed between the thiols and the bases.

Experimental

The fundamentals were measured on a Perkin–Elmer Model 621 spectrometer and the overtones on a Cary 17 instrument. In the fundamental region, we used a 0.9 mm cell with silver bromide windows for low temperatures, and commercial 1.0 and 0.1 mm sodium chloride cells for room temperature spectra. A 1 cm quartz cell was used for the overtone region. More details of the experimental techniques are given elsewhere (6). Temperatures were measured with a copper–constantan thermocouple.

CCl_3F (Freon 11) obtained from the E.I. Dupont de Nemours of Canada Co., was distilled and kept over phosphorus pentoxide. Spectrograde quality carbon tetrachloride from Anachemia Chems. Ltd., Montreal, was dried on molecular sieves of the type 4A.

The mercaptans were the same as those used in our previous work (1). Pyridine, a spectroquality reagent from the Matheson, Coleman, and Bell Co., was treated with KOH pellets for at least 24 h before distillation. Triethylamine, from the same company, was dried over $CaSO_4$, and distilled. None of the i.r. spectra of these bases showed water absorption.

All solutions were prepared gravimetrically in a dry-box filled with nitrogen to avoid oxidation or moisture absorption. The concentrations were *not* corrected for solvent contraction since intensities measured at different temperatures were not compared. The correction should not exceed 15% at -100 °C in any case. All curves were corrected for solvent absorption. Figures 1 and 4 show the spectrum of the thiol in an inert solvent, the spectrum of the base in the same solvent, the spectrum of the thiol–base mixture, and the spectrum of the mixture, obtained by subtracting the absorption of the base. In the other figures only the first and the last are shown.

The solutions were used immediately after preparation. After 24 h, ternary solutions of mercaptans and triethylamine in CCl_3F, and solutions of mercaptans in triethylamine give a white crystalline precipitate. This solid shows (in Nujol) a band between 2650 and 2700 cm^{-1}, characteristic of the NH^+ absorption (for a discussion on quaternary ammonium salts see ref. 7). After being in contact with the silver bromide windows of the low temperature cells for several hours, the pyridine solutions gave a white solid deposit, soluble in acetone, which is probably a silver–pyridine complex. This deposit, however, showed no appreciable absorption in our spectral region.

Results and Discussion

Figures 1 and 2 show the effect of temperature and pyridine concentration on the spectrum of the complex between propane-1-thiol and pyridine. The maximum of the S—H---N band is near 2520 cm^{-1}, at room temperature, and at 2485 cm^{-1}, at -101 °C. The increased half-width seems to indicate that this band is actually due to more than one species. The band center must receive most of its intensity from the 1:1 complex, that is, from S—H---N type bonds. On the high frequency side, both free and S—H ---S bonds can contribute to the intensity. On

the low frequency side, S—H---N type bonds of more highly associated species of the type S—H---S—H---N come in. Of course, the S—H---S group of the latter may contribute to the intensity on the high frequency side. The breadth and the intensity increase of this band on its low frequency side as the temperature decreases, can be taken as an indication of the presence of such more highly associated complexes.

Figures 3 and 4 show that, at the first overtone, the free band is present up to a thiol–pyridine ratio of 1:7, (Fig. 3*a*) but is absent at higher pyridine concentrations. In all cases, however, the presence of pyridine decreases the intensity of the free band showing that S—H---N type association occurs. At lower temperatures and higher concentrations a broad band appears near 4900 cm^{-1}. This must be the S—H---N band of the 1:1 complex. As we are limited by the crystallization temperature of pyridine and by the stronger bands near 4800 cm^{-1} of pyridine (still strong enough in pyridine-d_5 to prevent concentration or temperature studies) we cannot observe the band of the more associated species at the overtone level. Studies in solution of inert solvents at lower temperatures are not possible because we are dealing with very weak bands.

Figures 5 and 6 show the results we obtained for the benzenethiol–pyridine complex. This is known to be a 1:1 complex at room temperature (4). The spectrum shows, at 20 °C, a broad and rather symmetrical band centered near 2430 cm^{-1}. This spectrum yields two interesting results. First, the band is very broad. Secondly, even with a 3:1 excess of pyridine to thiol the band near 2572 cm^{-1} still persists. The latter band is assigned to thiol–thiol S—H---π type hydrogen bonds. The free band is weaker and cannot be seen in the spectrum. However, it can be observed for similar concentrations at the overtone (see below). At low temperature (−101 °C) the broad band is asymmetrical on the lower frequency side. This is again probably

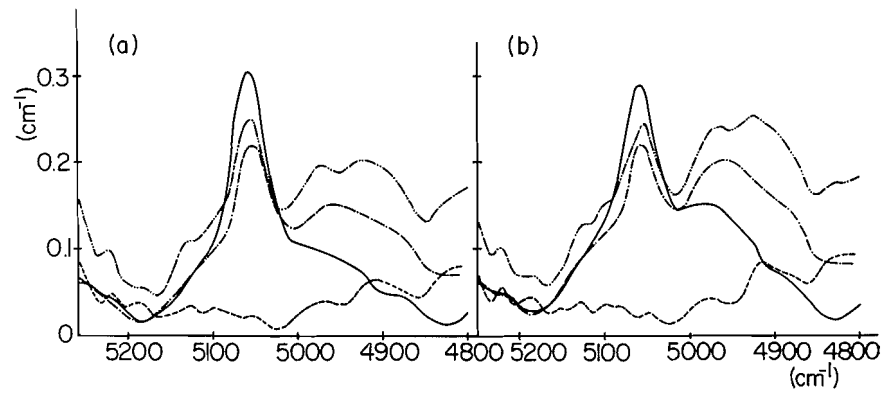

FIG. 4. The infrared spectrum (4800–5250 cm^{-1}) of (—), a 5.74 *M* solution of propane-1-thiol in CCl_3F; (---), a 5.54 *M* solution of pyridine in CCl_3F; (-·-·-), a mixture of 5.74 *M* propane-1-thiol and 5.54 *M* pyridine; (-·-), a mixture of 5.74 *M* propane-1-thiol and 5.54 *M* pyridine with the absorption due to pyridine subtracted. FIG. 5. The infrared spectrum (2350–2650 cm^{-1}) of (—), a 0.27 *M* solution of benzenethiol in CCl_3F; (···), a mixture of 0.27 *M* benzenethiol and 0.92 *M* pyridine in CCl_3F. (*a*) 20 °C; (*b*) −101 °C. The absorption due to pyridine is subtracted. Vertical axis: $1/I \log I_0/I$ in cm^{-1} units.

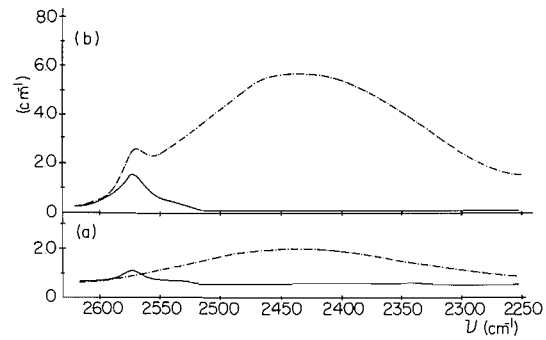

FIG. 6. The infrared spectrum (2250–2630 cm^{-1}) of (*a*) 0.68 *M* and (*b*) 2.54 *M* solutions of benzenethiol (—) in CCl_3F and (---) in pyridine, at 20 °C with the absorption due to pyridine subtracted. Vertical axis: $1/I \log I_0/I$ in cm^{-1} units divided by ten.

due to a more associated species. Another interesting observation is the breaking of some of the self-associated S—H---π bands at low temperatures. At the first overtone level (Fig. 7) the spectra are less conclusive due to the severe overlap with the much stronger bands of pyridine near 4800 cm^{-1}. Nevertheless some interesting remarks can be made. The "free" band loses intensity when the concentration of pyridine is raised and is shifted toward lower frequencies. A band, partially overlapped by pyridine absorption, can be seen at lower frequencies and should be ascribed to the S—H---N vibration of the 1:1 complex. As we showed in our previous work (1) the "free" band of benzenethiol is due, at the overtone level, to the actual free band and to the self-associated S—H---π type band. This is further confirmed in the present work by concentration studies at the overtone level (compare (*a*), (*b*), and (*c*) of Fig. 7). In the presence of pyridine we expect that the S—H---N complexes are formed by preferentially using the free S—H groups still present, rather than breaking existing weaker complexes. In a dilute solution of an inert solvent, the benzenethiol free band is expected to predominate over the S—H---π type band, but the reverse is true if the solvent is pyridine. Increasing the concentration of benzenethiol should favor the S—H---π bonds in both solvents. This is translated by two effects in the spectra of Fig. 7. First, the apparent maximum of the overlapping free S—H and S—H---π bands is at higher frequencies when pyridine is absent. Secondly, the difference between these two frequencies is greater for dilute solutions of benzenethiol. In addition, the S—H---π type band is seen to persist for similar concentrations (compare Figs. 6(*b*) and 7(*b*)) at the fundamentals. We therefore think that the band which remains at higher pyridine concentrations, near 5050 cm^{-1}, is not a free S—H band but the remaining S—H---π band of the self-associated benzenethiol.

The spectra obtained with the stronger base triethylamine are quite similar (Figs. 8 and 9). At the fundamentals the bands are again very broad and their maxima are, as expected, at lower frequencies than in the case of the pyridine complexes. As triethylamine has relatively strong bands in this part of the spectrum we had to use dilute solutions of propane-1-thiol and triethylamine in CCl_3F. The S—H---N band at room temperature is not well defined at these concentrations (it is located at 2420 cm^{-1} in a 5.72 *M* solution of propane-1-thiol in triethylamine, at 20 °C). However, it can be readily seen at lower temperatures. Its maximum is at 2360 cm^{-1}, at −101 °C, and it is clearly asymmetrical, indicating that at lower temperatures, as in the case of pyridine complexes, some more associated complex is also present. On the high frequency side of the 2360 cm^{-1} band, which corresponds to the S—H---S region, some increase of intensity is observed also. Since this spectrum is obtained by subtraction, this is somewhat doubtful (a strong band of triethylamine exists in this region). However, if this

(*a*) 20 °C; (*b*) −73 °C; (*c*) −101 °C. (---) region of comparatively strong bands of triethylamine. The absorption due to triethylamine is subtracted. Vertical axis: $1/l \log I_0/I$ in cm^{-1} units.

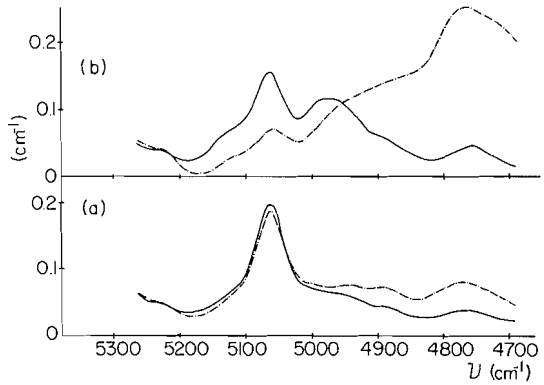

FIG. 9. The infrared spectrum (4700–5250 cm^{-1}) of a 3.23 *M* solution of propane-1-thiol (—) in CCl_3F and (---) in triethylamine. (*a*) 20 °C; (*b*) −98 °C. The absorption due to triethylamine is subtracted. Vertical axis: $1/l \log I_0/I$ in cm^{-1} units.

band really exists it would confirm the presence of a higher complex of the S—H---S—H---N type at lower temperatures. At the overtone (Fig. 9) the maximum is near 2480 cm^{-1} at −98 °C. This is probably due to the S—H---N type association of the 1:1 complex. Some S—H---S absorption remains and again we cannot say whether it is due to the remaining self-associated S—H---S bond, to some more associated S—H---N species, or to both.

Conclusions

The main associated species in solutions containing propane-1-thiol or benzenethiol as proton donors, and pyridine or triethylamine as proton acceptors, is a 1:1 complex with a hydrogen bond of the S—H---N type. The related band in the spectrum appears at distinctly lower frequencies than the S—H---S bands. At low temperatures we find evidence for the formation of a more highly associated species of the S—H---S—N type. The overtone of the 1:1 S—H---N complex has been identified.

Free S—H bands persist in these solutions at donor–acceptor ratios lower than 1:3. S—H---π type hydrogen bonds of the self-associated thiol are found for benzenethiol–pyridine mixtures even in the presence of a large excess of pyridine.

Charge Distributions and Chemical Effects. III.[1] A Comparison with PCILO and CNDO/2 Calculations

S. FLISZÁR AND J. SYGUSCH

Département de Chimie, Université de Montréal, Montréal, Québec

Received July 14, 1972

The PCILO charge distributions of a number of alkanes are in excellent agreement with charge distributions derived on the assumption that the inductive effects can be described in a Taft-like manner. This agreement with "quantitative chemical intuition" stresses the strong chemical character of the PCILO method. The CNDO/2 results are only in qualitative agreement with "chemical expectancy" and suffer apparently from the same difficulties as PCILO used with zero C—C and C—H polarities.

Pour une série d'alcanes, les distributions de charges calculées par la méthode PCILO sont en excellent accord avec celles dérivées de l'hypothèse que les effets inductifs puissent être décrits à la manière de Taft. Cet accord avec l'"intuition chimique quantitative" met en relief le fort caractère chimique de PCILO. Les résultats CNDO/2 ne sont qu'en accord qualitatif avec l'"intuition chimique" et connaissent les mêmes difficultés que PCILO, lorsque cette dernière méthode est utilisée avec des polarités C—C et C—H nulles.

The success of a quantum mechanical description of a molecule is usually evaluated by its ability of reproducing correctly some observable quantity, such as spectroscopic information, rotational barriers, conformations, etc. However, different quantum mechanical approaches though each one may be "successful" in its own right, are known to generate quite different information on charge distributions; quantities which are not, at present, subject to direct control. This is disturbing if one tends to consider molecular wave functions, or at least their densities, as part of the description of the molecular reality.

In this situation, one is thus restricted to express satisfaction with the fact that the different methods of calculation usually reproduce the same *trends* in charge distributions.[2] Although such an attitude is not free from difficulties, it may be justified, at least in part, on the grounds that the trends predicted by a variety of theoretical methods seem intuitively correct, *i.e.*, that they often agree with what one would expect from chemical evidence. In other words, theoretical trends are accepted when they make sense with the vague intuition derived from experimental facts.

The difficulty, arising from the fact that charge distributions are not measured, is that the "chemical intuition" had not been formulated in a sufficiently quantitative manner. Recently, however, charge distributions in simple hydrocarbons have been calculated on purely chemical grounds (2, 3). The object of the present study is a comparison of these charge distributions, based only on "chemical expectation", with those calculated by the PCILO ("Perturbative Configuration Interaction using Localized Orbitals" (4)) method and to discuss some aspects regarding the internal consistency of both these methods as far as electron populations are concerned. The interest in this bond orbital perturbation theory resides in its computational suitability for the conformational study of large molecules (5–7).

The "Chemical" Population Analysis

This calculation rests on the assumption[3] that the electron-withdrawing or -releasing ability of

[1]For parts I and II, see refs. 2 and 3.

[2]An interesting example is given in ref. 1

[3]The nature of the chemical information used in setting up this approach can best be described by the following examples. If it is assumed that the ethyl group is a better electron-donor than the methyl group, any H atom in ethane is expected to be electron-richer than a methane H atom. For similar reasons, the tertiary H atom in isobutane is expected to carry more electrons than an ethane H atom, because the tert-butyl group is a better electron-donor than the ethyl group. In a similar way, neopentane can be considered as a tert-butyl group attached to a methyl group. Since the tert-butyl group is, in common experience, a better electron-donor than methyl, a net positive charge should be carried by the

groups (inductive effects) can be evaluated and described by numbers in a Taft like manner (eqs. 1 and 2) and on eq. 3 which, crudely, expresses the idea of charge alternation: "a positive site is best favored when embedded in a negative surrounding, and conversely" (2, 3, 8). Equation 4 expresses the fact that the sum of the net atomic charges Q over the whole molecule is 0.

$$[1] \qquad Q_H = a\sigma^* + b$$

$$[2] \qquad Q(CH_3) = -a'\sigma^*$$

$$[3] \qquad Q_i = \sum(\alpha_j Q_j + \beta_j) \; (j \text{ adjacent to } i)$$

$$[4] \qquad \sum Q = 0$$

The request for the *simultaneous* validity of eqs. 1–4, which are individually verified by a variety of MO calculations (2), generates in a first approximation the charge distributions indicated in ref. 3. This approximation utilized the assumption that the parameters in eq. 3 are the same for primary to quaternary atoms. Although these calculated charge distributions were in satisfactory agreement with a variety of quantum-mechanical results, we now wish to remove this restriction, and calculate the charge distributions using only eqs. 1 and 2, inserting the appropriate Taft polar constants (9). For example, (average)Q_{Hprim}(propane) $= -0.115a + b$, with a and b as in Table 1, and $Q_{Cprim} = Q(CH_3) - 3Q_{Hprim}$.

It should be noted that the present calculation affects only the distributions within the CH_3 groups in propane, isobutane, and neopentane, the other results being those of ref. 3. For large n values[4] ($\gtrsim 10$), the difference between the two modes of evaluating the charges on the primary H atoms is small ($\lesssim 2\%$) and could therefore be neglected (3). For small n values, however, the differences between the two alternative solutions is considerable and, thus, useful in the discussion of the results.

TABLE 1. Parameters and net atomic charges, in relative units $Q_C(C_2H_6) = -1.000$

Compound	Charge*
	$a = -a' = 10/3n$
	$b = (n + 1)/3n$
Methane	$Q_C = -4(n + 1)/3n$
Ethane	$Q_C = -1.000$
Propane	$Q_{Cprim} = -(3n + 0.55)/3n$
	$Q_{Csec} = 2(2 - n)/3n$
	$Q_{Hprim} = (n - 0.15)/3n$
	$Q_{Hsec} = (n - 1)/3n$
Isobutane	$Q_{Cprim} = -(3n + 1.25)/3n$
	$Q_{Ctert} = (8 - n)/3n$
	$Q_{Hprim} = (n - 0.25)/3n$
	$Q_{Htert} = (n - 2)/3n$
Neopentane	$Q_{Cprim} = -(n + 0.35)/n$
	$Q_{Cquat} = 4/n$
	$Q_H = (n - 0.65)/3n$

*The usual Taft polar σ^* constants (9) were used *i.e.*, $\sigma^*(n\text{-}C_3H_7) = -0.115$, $\sigma^*(i\text{-}C_4H_9) = -0.125$, and $\sigma^*(neo\text{-}C_5H_{11}) = -0.165$.

Methods of Calculation

The PCILO semi-empirical all valence electrons method (4) considers, from a conceptual point of view, that the chemical formula is a good zeroth order approximation and looks at the molecule as an assembly of chemical bonds in interaction, the interaction being treated by perturbation theory. This method lies beyond the SCF approximation and uses the CNDO/2 hypotheses (10) for the integrals. Because of the inclusion of the CNDO/2 hypotheses on the atomic integrals in the PCILO calculations, the results obtained by a CNDO/2 calculation of charge distributions are also presented, for comparison. In PCILO, the hybrid atomic orbitals are constructed following Del Re's method (11), *i.e.*, hybrids with maximum overlap on the chemical bonds, adding to the strong chemical character of PCILO.

The PCILO program uses a polarity parameter δ for each bond, such that the coefficients c_{i1} and c_{i2} of the bonding orbitals are $c_{i1} = [(1 + \delta)/2]^{1/2}$ and $c_{i2} = [(1 - \delta)/2]^{1/2}$. These polarities may be determined empirically from bond dipole moments $\mu_i = 2\delta_i \times l_i$, where l_i = length of bond i. In the calculations reported below,

tert-butyl group and an equal net negative charge by the CH_3 group. Hence, a net positive charge is carried by the quaternary C atom, since the four methyl groups are equivalent. In isobutane, the net negative charge on the CH_3 groups is expected to be lower than in the case of neopentane, because isobutane is isopropy-methyl and the isopropyl group is less electron-donating than tert-butyl.

[4]This is the only parameter required for describing the charge distributions in simple alkanes (3) (Table 1). The meaning of n can be deduced from $a = 10/3n$, where a, in a way, measures the sensitivity of charge transfers to substituent effects (eqs. 1 and 2). Small n values indicate strong substituent effects; if, on the contrary, inductive effects were non-existent, the charge distributions would be those corresponding to $n = \infty$, *i.e.*, $a = 0$.

several choices for δ(CC) and δ(CH) have been considered, for comparison.

Results and Discussion

The PCILO results calculated assuming zero carbon–carbon polarity and two different carbon–hydrogen polarities are compared in Table 2 with the results obtained from Table 1, using in each case the best n value. The CNDO/2 results are also given, for comparison. In our "inductive" calculations, the net atomic charges are obtained in charge units by multiplying the expressions of Table 1 by a unity factor β, such that $-\beta = Q_C(C_2H_6)$.

The use of the carbon–hydrogen polarity $\delta = 0.035$ ($\delta(CC) = 0$) seems reasonable if a C—H bond dipole moment of ≈0.4 D is assumed. The agreement between the PCILO results and those calculated for $n = 1.3$ is reasonable, but the primary C atoms of propane, isobutane, and neopentane are somewhat more negative for the PCILO approach than in the "inductive" calculation.[5]

With $\delta(CH) = \delta(CC) = 0$, on the contrary, the net PCILO charges on the primary C atoms of propane, isobutane, and neopentane are *less* negative than those calculated with $n = 0.223$, using the "inductive" formulas. Of course, the previous approximation (3) would give rise to an even more pronounced disagreement with the PCILO results, because the relevant charges would be more negative than those given by the "inductive" calculation (*e.g.* −71 me for the primary C atom in neopentane, with $n = 0.223$). It is clear from these results that the chemical picture obtained with $\delta(CH) = 0$ is not satisfactory, even more so when the C atoms in ethane are found to carry a net positive charge. Indeed, the energies (Table 3) indicate that $\delta(CH) = 0.035$ should be preferred over $\delta(CH) = 0$.

The CNDO/2 charge distributions (2) (Table 2) for methane and neopentane are similar to those calculated by the PCILO method, using $\delta(CH) = 0.035$. For the other molecules between these extreme cases only erratic or at best qualitative agreement is obtained in comparison to the results using the best n value of 0.35. As in PCILO with zero polarities, the propane, isobutane, and neopentane primary C atoms are less negative in CNDO/2 than in the corresponding "inductive" calculation. However, although these CNDO/2 results apparently suffer from the zero C—H polarities, they still appear to be more acceptable in the chemical sense than those calculated by PCILO with $\delta(CH) = 0$. It must be noted that no attempt has been made here to improve the CNDO/2 results, although this could probably be done by an adequate choice of parameters.

The results presented in Table 2 clearly indicate that the PCILO charge distributions and their consistancy with the "chemical intuition" largely depends on the assumed C—H

[5]With this low n value, the difference between the present "inductive" results and those derived from the approximation described earlier (3) would be considerable. The latter approximation gives (with $n = 1.3$) the following results for the primary C atoms (in me): −35.5 (propane), −48.7 (isobutane), and −61.8 (neopentane), *i.e. more negative* values than the corresponding PCILO figures.

	C_{quat}	+82.0	+83.8
	H	+0.2	−0.9

polarity. The following results (Table 4) were obtained by an energy minimization with respect to both C—C and C—H polarity.[6,7]

The agreement between these "optimized" PCILO results and those obtained with $n = 0.525$ ($\beta = 11.0$ me) by means of the "inductive" formulas is far superior to what has been observed for the cases discussed above. Although these optimizations are probably not perfect, they are certainly close to the best values. Any further refinement would, however, lead only to small improvements. These would not become apparent in a comparison with the corresponding "inductive" results because the PCILO charges are not exactly normalized. In fact, at the level of the results of Table 4, the discrepancies between the two modes of calculation are not significant.

Conclusions

The PCILO method, properly optimized, reproduces the net atomic charges predicted on the assumption that the inductive effects of the alkyl groups can be described by numbers in a Taft-like manner. The best agreement is achieved by the charge distributions corresponding to the molecular energy minima. The CNDO/2 results, while of the order of magnitude of the PCILO net charges, are only in qualitative agreement with the "inductive" results and seem to suffer from the same difficulties as PCILO used with zero C—C and C—H polarities.

The close agreement between the "inductive" and selected LCAO results has been discussed earlier (3); the EHT, Del Re's method and the Pariser–Parr approach are characterized by their small inductive effects ($n \geqslant 9.5$) and large charge separations. In PCILO, on the contrary, the small n value, corresponding to important inductive effects, enables their discussion on a refined basis (inductive formulas). The fact that the PCILO and the "inductive" charge distributions agree so closely suggests that the usual interpretation of the inductive effects, in terms of net electron release, is appropriate and that the ordering of the electron releasing abilities, as described by Taft's polar σ^* constants, is adequate.

The use of the "inductive" formulas does not alter the spirit of "charge alternation" represented by eq. 3. This is indicated by the fact (Table 1) that in the methane-C, ethane-C, C_{sec}, C_{tert}, and C_{quat} atoms the net charge becomes more positive by the amount $\beta(4 + n)/3n$ for every substitution of H by a CH_3 group. Despite the restrictions on eq. 3, the concept of charge alternation can be used as a rule-of-thumb for the evaluation the effect of α-substitution of hydrogen atoms by methyl groups, as illustrated in the case of carbonium ions (3).

Finally, it may be considered that the close agreement between the PCILO charge distributions and their counterpart based on quantitative chemical intuition supports the claim, by the authors of PCILO, that "there is a lot of chemistry in PCILO".

[6]The polarities corresponding to this optimization are as follows: δ(CH) = 0.019 (CH_4), and 0.018 for all the other C—H_{prim} bonds. For secondary H atoms, δ(CH) = 0.017; for tertiary H atoms, δ(CH) = 0.015. The δ(CC) polarities are 0 (ethane), 0.002 (propane), 0.0025 (isobutane), and 0.003 (neopentane).

[7]The calculated rotational barriers were 2.1 kcal/mol (ethane), and 2.8 kcal/mol (propane), average obtained by taking one-half of the difference in energy between the completely staggered and eclipsed conformations. These results compare favorably with the observed barriers, *i.e.*, 2.8 kcal/mol (ethane) (12) and 3.4 kcal/mol (propane) (13).

A Field Ion Investigation of Oxygen on Tungsten

R. A. SHIGEISHI[1]

Inorganic Chemistry Laboratory, University of Oxford, Oxford, England

Received June 28, 1972

The adsorption of oxygen on tungsten was investigated with a field ion microscope. Two experimental procedures were followed. In the first, a tungsten tip previously annealed to 973 or 1173 °K was held at 78 °K while exposed to oxygen. Coverages ranged from less than a monolayer to saturation. After the ambient oxygen was removed, the tip was heated to the annealing temperature. In the second, oxygen adsorption occurred on a hot tip held at 973 °K. Estimated coverages were significantly less than a monolayer.

Results reveal a dramatic difference in the extent of surface diffusion, rearrangement, disruption, and oxygen penetration for the two procedures, the latter producing more extensive effects. Possible explanations for these differences are considered.

L'adsorption de l'oxygène sur le tungstène a été étudiée avec un miscroscope à champ ionique. Deux méthodes expérimentales furent suivies. Dans la première, un filament de tungstène recuit à 973 ou 1173 °K a été soumis à l'action de l'oxygène à 78 °K. On enregistre des recouvrements inférieurs à la couche monomoléculaire jusqu'à la saturation. Après avoir enlevé l'oxygène du milieu, le filament a été chauffé à la température de recuit. Dans la seconde, l'adsorption d'oxygène se passe sur un filament chaud maintenu à 973 °K. Les recouvrements estimés étaient de beaucoup inférieurs à la couche monomoléculaire.

Les résultats montrent alors des différences importantes en ce qui a trait à l'étendue de la diffusion en surface au réarrangement, à la rupture et à la pénétration de l'oxygène, pour les deux procédés; le dernier produisant des effets encore plus marqués. Des explications possibles pour ces différences sont présentées. [Traduit par le journal]

Introduction

The oxygen–tungsten system has been extensively studied for many years and recently, much new information has been obtained on surface structures, work function changes, surface diffusion, adsorption states, and kinetics of oxide formation by a variety of techniques including Leed, electron desorption spectrometry, flash desorption, and field emission microscopy. Recent reviews by McCarroll (1) and Musket (2) summarize these findings and hence need not be repeated here.

There are, however, comparatively few reports of the systematic investigation of the tungsten–oxygen system at elevated temperatures by means of field ion microscopy (3). It is now generally recognized that oxygen atoms on tungsten cannot be imaged since they are either field desorbed from the surface before imaging voltages are reached or else are buried within the surface (4). Nevertheless, it is also known that when oxygen is chemisorbed, tungsten–tungsten bonds are weakened with the result that in field desorption, both oxygen and an adjacent tungsten atom are stripped off together in the form of tungsten oxide molecular ions. Müller and co-workers' initial atom probe studies (5) have shown that these ions are WO^{3+}, WO_2^{3+}, and WO_3^{3+}. Thus the combination of chemisorption and field desorption results in an "etched" surface and from a comparison of the images of clean and etched surfaces the position of the oxygen can be inferred. Field ion microscopy should therefore be valuable in studying among other things, surface diffusion, preferential adsorption, and penetration of adsorbate into the substrate.

This paper is a report of the field ion investigation of the oxygen–tungsten system for coverages ranging from less than a monolayer to saturation, for the temperatures 973 °K and 1173 °K. This narrow temperature range is of particular interest since irreversibility as defined by Gomer and Hulm (6) occurs in this range. A preliminary report of this work has been presented by Anderson (7).

Two types of experiments were conducted. In the first, oxygen was adsorbed at 78 °K and following evacuation the tungsten tip was heated. In the second, oxygen was admitted to the tip

held at 973 °K. As will be shown, these procedures result in surfaces that are disrupted to substantially different degrees.

Experimental

The all glass field ion microscope was of conventional design (8) with an outer Dewar and a re-entrant cold finger to cool the tungsten tip and electrical leads.

The tip temperature could be altered by resistive heating via an electronic feedback circuit of a type designed by Klein (9). The temperature itself was calculated by measuring, potentiometrically, the resistance of a small central portion of the loop to which the tungsten tip was spot welded and using a temperature *vs.* resistance calibration curve (10). Approximately 5 s were required for the temperature to stabilize to within 5 °K for any chosen temperature between 900 and 1200 °K. While this method only measures the temperature at the central portion of the loop, van Oostrum (11) and Pichaud *et al.* (12) have shown that the temperature at the sharp tip is not significantly different.

Pure oxygen and helium could be admitted to the microscope by thermal diffusion through silver and Pyrex thimbles respectively.

Prior to beginning experiments, the tip was heated to temperatures greater than 2200 °K in 10^{-6} Torr oxygen for 24 h to rid the tungsten of internal carbon impurities. This was followed by outgassing the tip at greater than 2200 °K till a base pressure of 5×10^{-10} Torr was achieved. The re-entrant tube was then demounted, the tip re-etched and the unit sealed into the microscope. After a vacuum of 5×10^{-10} Torr was obtained, the tip was momentarily flashed to rid the shank of contaminants and then field evaporated to a perfect endform. Finally, the tip was heated to 973 or 1273 °K.

For the first set of experiments the tip was cooled to 78 °K and the oxygen leaked in to the desired pressure. After adsorption had occurred, the ambient oxygen was pumped out and the tip heated. The surface was then examined by controlled field desorption. In the second set, the tip was heated to 973 °K, the oxygen leaked in and after a set time pumped out. The surface was then examined as before. In both cases, in order to reduce the production of CO the leak thimbles had been previously calibrated so that the ion gauge was not in operation while oxygen or helium was being admitted.

Results

Low Temperature Adsorption

Figure 1 shows the sequence of micrographs for a tip at 78 °K exposed to 7×10^{-9} Torr oxygen for 40 min and heated to 973 °K for 2 min after the oxygen was pumped out. The first micrograph, that of a clean tip annealed to 973 °K reveals the usual structure described previously by Bassett (13). As compared to a field evaporated endform, the surface is disordered and the low index {211}, {110}, and {100} planes have grown in area and appear to be atomically flat. As well, multiple height steps are formed between the {211} and central (110) plane. The field emission micrograph subsequent to the oxygen and heat treatment shows prominent emission mainly from the low work function regions around and including the {111} and the viscinals of the {100}. While these might appear to be built up regions, the initial field ion micrographs indicate that the most prominent surface atoms are located at the edges of the {111} and in the {411} regions. Surprisingly, however, no atoms are to be seen in the triangular region centered on the (111) pole, which appears to be atomically flat. On the clean tip (Fig. 1*a*) atoms are visible in this area even though no crystallographic order is present. Furthermore, since little or no field desorption occurs from this area oxygen is not present here.

As the voltage is raised field desorption occurs predominantly from the viscinals of the {100}, especially {411}, and to a lesser extent from the edges of {211} planes. These areas are thus identified as being particularly rich in oxygen. However, after the initially bright atoms have been removed and most of the surface is imaged (Fig. 1*d*), it is apparent from a comparison of Figs. 1*d* and 1*a* that the surface is structurally similar to that of the clean annealed tip. The two exceptions are the {111} regions which have been remarked upon previously and the {211} planes. A color comparison of these same photographs leads to the observation that the {211} planes of the oxygenated surface have grown slightly in area.

As field evaporation voltage is approached and the rings of the central (110) become more visible, field desorption begins to occur in this region, but the comparatively low frequency of such events indicates only a light disruption of this plane.

Figures 1*e* and 1*f* are images of the surface just prior to and after the field evaporation of the top atom layer of the (110). The surface is almost atomically perfect except for the slight disorder around the {100} which is usually present in tips of large radius of curvature.

Comparison of voltages required to field evaporate the top atomic layer of the central (110) for the clean and treated tip (23.0 and 23.1 kV) indicates little or no thermal blunting of the tip.

Similar experiments at higher and lower oxygen exposures and at 1173 °K result in an almost identical surface disruption pattern as described

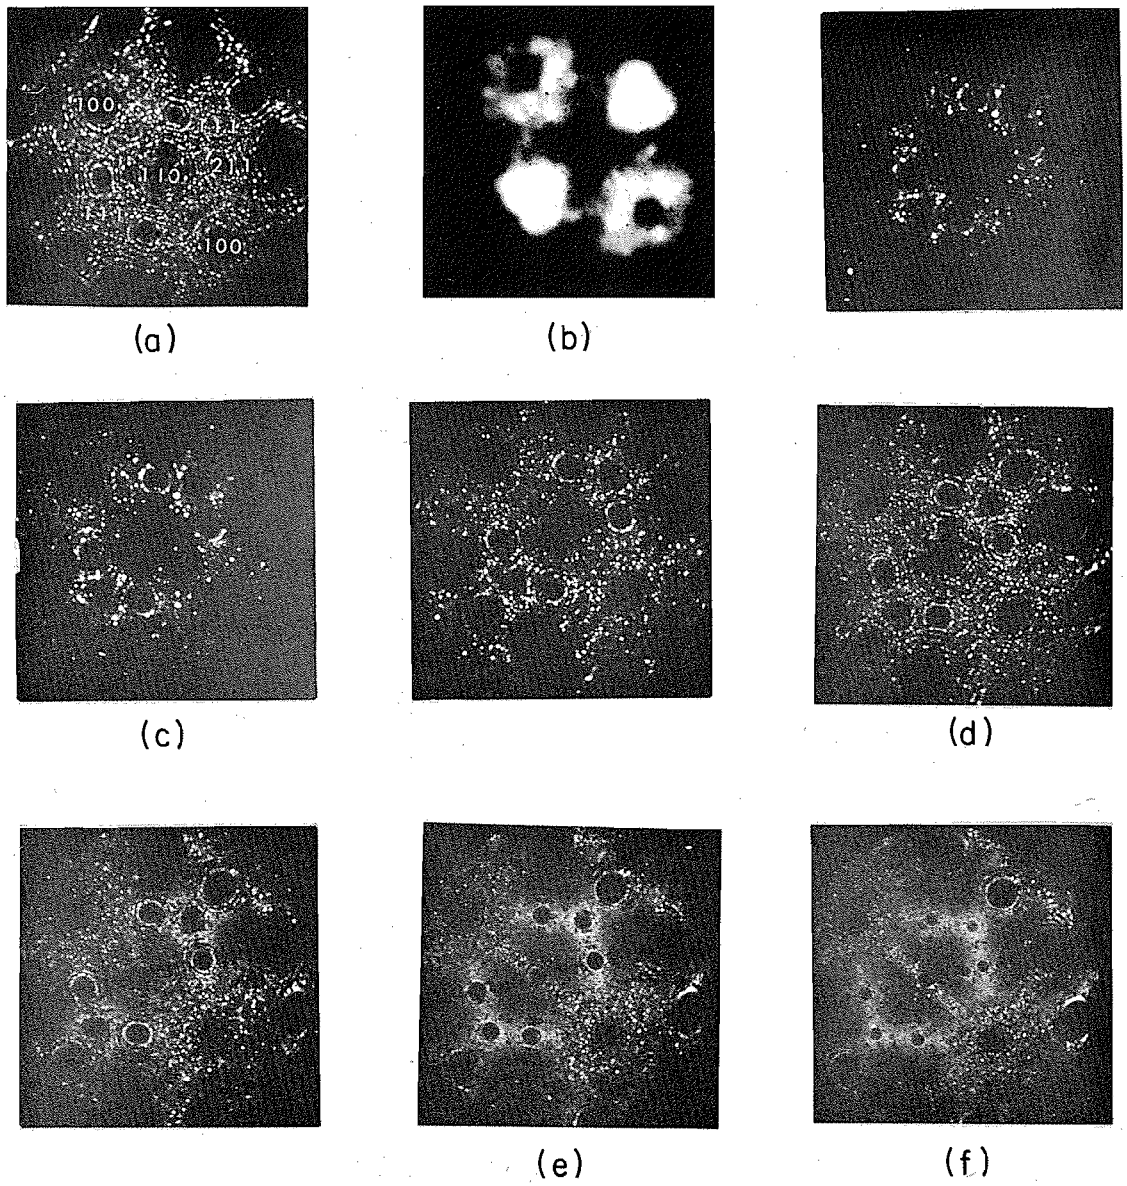

FIG. 1. (*a*) Clean tip annealed to 973 °K; 23.0 kV (20.0); (*b*) field emission; (*c*) 15.8 kV; (*d*) 18.5 kV; (*e*) 22.7 kV (19.4); (*f*) 23.1 kV (20.0). Figures in parentheses indicate best image voltage.

above, except that for very low coverages very little change in the surface is observed. Also the length of time the oxygenated surface was heated, whether 2 min or 1 h made little difference to the state of the surface. At 1173 °K the only change was a slight blunting of the tip. In all other respects, the flat {111} planes, the bright atoms at the periphery of the {111} and at the {411}, the slight growth of {211}, the high oxygen concentration at {411} and viscinals of {100} and the slight oxygen penetration, the results were the same.

Adsorption at 973 °K

Figure 2 shows the surface at progressively higher voltages of a tip that had been held at 973 °K for 3.5 min while the oxygen pressure built up to 5×10^{-9} Torr. For unit sticking

coefficient this corresponds to approximately 1/5 monolayer coverage. The characteristic square and trigon pattern in the field emission micrograph (Fig. 2*b*) implies prominent structures around the {100} and {111}. This is confirmed by the initial field ion micrographs which, unlike the previous case, reveal a narrow three pronged ridged structure centered on the (111) pole with each ridge pointing towards a (110) plane. After field desorption of the bright irregular clumps of atoms around the {111}, this region is atomically perfect and further field evaporation occurs very regularly. This implies that although the bright clumps may contain oxygen, once these are removed, oxygen is absent from the {111}. It would appear, then, in view of the subsequent perfection of the built-up ridge that the major diffusing species in this region is tungsten.

The other built-up structure which is located around the cube edges of the {100} is composed of clumps of bright atoms which show some order and which are comparatively stable with respect to field desorption, *i.e.*, as many as five to six (111) layers may be field evaporated before some of these bright atoms are removed. Unlike the ridge structure, however, the irregular manner of field evaporation from this built-up region implies the presence of oxygen in this structure. Diffusion to this region, therefore, must involve oxygen, whether as atoms or in the form of tungsten–oxygen complexes. It should be noted that the pattern of field desorption indicates only whether oxygen is present or not but gives no clue as to the structural or chemical relationship between the oxygen and tungsten. At the temperatures and pressures used here, an ordered bulk oxide phase seems unlikely. Rather, a solution of oxygen and tungsten (whether in the form of tungsten–oxygen complexes, reconstructed layers (19), or oxide nuclei (20)) reflecting the initial stages of oxidation seems probable.

Visual observation of the frequency of desorbing image points reveals, as in the previous case, that the regions of high oxygen concentration are viscinals of the {100}, and especially the {411} and the side of the {211} bordering {411} which is not imaged. The overall pattern of surface damage is seen in Fig. 2*e*. Comparison of this with Fig. 1*d* clearly reveals the dramatic difference in the effects of the two adsorption and heating procedures.

Figures 2*f* and 2*g* show the state of the surface after the removal of one and four layers of the central (110). Penetration of the oxygen is much more extensive in this case and even after the removal of four layers a small region near the {100} and {411} still shows some disorder.

Finally, while no overall blunting of the tip occurred, these micrographs indicate that the area of the {211} increased significantly due to facetting of the {111} and its viscinals.

Discussion

There is much documented evidence that adsorbed gases cause an enhanced surface diffusion of substrate metal atoms, the driving force being the resulting decrease in surface free energy (14, 16). That such a process occurs in these experiments is evident from the growth of {211} planes after the oxygen and heat treatment. Ehrlich and Hudda (15) have shown that surface diffusion of tungsten atoms on the {211} planes occurs most readily along the close packed rows in the [111] direction toward the {111} and {411}. As Anderson has pointed out (7), such an anisotropic diffusion of tungsten atoms from the top layer(s) of the {211} would explain the deposition of atoms at the {411} and the viscinals of the {111} and hence the bright atoms initially seen in these areas. However, in the case of low temperature adsorption, the micrographs indicate that some of these bright atoms diffused from the (111) plane itself. On the clean annealed surface the {111} is flat and structureless but it does contain atoms that are sufficiently prominent to be imaged. For the low temperature case these atoms have disappeared and the {111} planes are totally devoid of image spots. Either the {111} have become atomically flat as a result of diffusion or else the prominent atoms have been field desorbed in the form of tungsten–oxygen complexes. No desorptions are seen to occur from this area, however. While it is still possible that field desorption of these complexes may have occurred prior to the initial image formation this also seems unlikely, since in other regions of the surface field desorption of prominent atoms or complexes can be seen. It is only from regions like the center of a (211) plane which has become atomically flat by diffusion that no desorption is seen.

While surface diffusion of substrate metal atoms is assisted by the presence of oxygen (14), its extent in the instance of a chemisorbed layer rearranged at 973–1173 °K must be limited since no significant restructuring of the surface is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

evident in the micrographs. In particular, no prominent ridges are formed around the {111} and {100}. This is confirmed by Gomer and Hulm (6) and by Bell *et al.* (17). The latter workers measured work function changes and Fowler–Nordheim pre-exponential factors and concluded that no significant facetting or ridge formation occurs on the {100} and {111} regions when an oxygen layer adsorbed at 78 °K was heated to 1200 °K. However, it is significant that heating to 1600 °K did result in ridge formation and surface reconstruction in these areas. It seems, therefore, that the same surface endform may be achieved by heating a low temperature layer to 1600 °K as by adsorbing oxygen at 1000–1200 °K.

For high temperature adsorption, surface diffusion is much more extensive. Here, the three {211} planes around the (111) grow to such an extent at the expense of the (111) viscinals (facetting) that they tend to intersect each other and form a prominent three pronged ridge on top of which, a few bright atom clumps (probably these contain oxygen) are randomly distributed. Once these are removed gradual field evaporation reveals an atomically perfect (111) and viscinals with no trace of incorporated oxygen.

The pattern of field desorption indicates that the dramatic difference in the extent of diffusion facetting and surface restructuring for the low and high adsorption temperature procedures is due to the degree of oxygen–tungsten interaction in the formation of complexes or oxide nuclei. In this regard it is of interest to review the results of Ptushinskii and Chuikov (20) and Tracey and Blakely (25).

From a mass spectrometric analysis of flash desorption products of the O_2/W system, the former authors showed that oxide formation is much more extensive when oxygen is adsorbed on a hot (1050 °K) tungsten ribbon than when oxygen was adsorbed at 300 °K and subsequently heated to 1050 °K. Furthermore, they determined the rate law for oxide desorption and concluded that oxides are formed immediately when oxygen is adsorbed on a hot ribbon, but that they are only formed in the flashing process when the adsorption temperature is 300 °K. This implies for the latter case that oxide formation is a two step process, the first of which is probably governed by diffusion of oxygen atoms.

Tracey and Blakely observed the facetting of W(211) to W(110) under conditions similar to those used here. They found that the activation energy for facetting was 0.15 and 1.5 eV for high and low temperature adsorption. Since the activation energy for oxygen diffusion on tungsten is of the order of 1.5 eV it would appear that facetting following the latter procedure is hindered by diffusional barriers while in the former it is governed by the supply of gas phase oxygen to dissociation sites.

Thus the preceding evidence supports the results obtained here of the enhanced surface processes when the adsorption temperature is high. The more extensive formation of tungsten–oxygen complexes would naturally result in more damage to the surface since tungsten–tungsten bonds are being broken. Furthermore, these species should be relatively loosely bound to the surface compared to chemisorbed oxygen (*e.g.*, desorption energies of oxide and chemisorbed oxygen are 4.5 and 6.5 eV (20)) so that they should diffuse more easily. This results not only in a regeneration of adsorption sites for more complex formation but also in greater mass transport of tungsten to the appropriate areas (viscinals of {411} and {111}), hence resulting in greater facetting than in the case when chemisorbed oxygen must diffuse to the proper sites for complex formation. Although in the latter case complex formation is very limited at 1000 °K, heating to higher temperatures should enhance the reaction so that at some temperature ridge formation and facetting should occur. As mentioned previously, the results of Bell *et al.* show that this temperature is about 1600 °K.

A second major difference in the effects of the two procedures is the depth of oxygen penetration into the substrate. This is confined to the surface layer in the first case while in the second, it extends more than four layers. The micrographs indicate that the regions where greatest penetration occur coincide with those of greatest oxygen concentration, namely, the viscinals of the {100} planes and especially the {411}. While, previously, penetration of oxygen into tungsten had not been observed at low exposures of oxygen, more recent investigation by Singleton (21), Lee and Pethica (22), and Zingerman and Ishchuk (24) indicates a solution process confined to a few surface layers when oxygen is adsorbed on tungsten heated to 850–1050 °K. However, they were unable to indicate the crystal planes where the penetration was occurring. The difference in penetration depth can again be rationalized by the difference in complex formation and consequent surface diffusion, facetting,

and reconstruction involving incorporation of oxygen into the substrate lattice.

An alternative explanation for the differences in the results of the two procedures, involving the liberated heat of adsorption, is suggested by the work of both May (18) and Zingerman and Ishchuk (23, 24). May has suggested that for highly exothermic adsorption such as oxygen on tungsten, not all of the heat of adsorption is immediately dissipated by the substrate lattice at the moment of dissociative chemisorption but rather that part of this energy is available for the creation of a "hot" oxide molecule (or some tungsten–oxygen complex) which temporarily has a high kinetic energy parallel to the surface. The availability of part of the heat of adsorption combined with a high substrate temperature when adsorption occurs would help to rationalize the enhanced surface diffusion and restructuring which follows the second procedure. In the first procedure, the heat of adsorption is dissipated prior to heating the surface and hence is not available for overcoming surface diffusion.

With respect to penetration of oxygen into the lattice, the latter authors have suggested that this occurs only during the actual time of interaction between oxygen and tungsten with the liberated heat of adsorption providing the means of overcoming the activation barrier for the penetration process. If this suggestion regarding the availability of the heat of adsorption is correct it would account for the greater penetration when the adsorption temperature is high.

Summary and Conclusion

Heating a tungsten tip saturated with oxygen at 78 to 973 or 1173 °K produces relatively little change in the surface compared to a clean tip annealed to the same temperatures. Surface diffusion results in a slight growth of {211} planes and deposition of tungsten atoms at the periphery of {111} and {411}. The greatest concentration of oxygen is located in the atomically rough viscinals of the {100}. Penetration of oxygen beyond the first surface layer is not observed. For smaller oxygen coverages even less surface disruption occurs.

Adsorption on a tungsten surface at 973 °K of significantly less than a monolayer of oxygen causes much more extensive surface restructuring and build up around {111} and {100}. Growth of {211} planes occurs to such an extent that they intersect to form a ridge structure centered on the (111). Penetration of oxygen into the metal occurs to a depth of more than four atomic layers.

The extensive surface disruption for high temperature adsorption is tentatively explained in terms of the enhanced formation of oxygen–tungsten species although a second explanation in terms of the liberated heat of adsorption is also considered.

The author wishes to thank Professor J. S. Anderson who supervised this work and Dr. G. K. L. Cranstoun who gave freely of advice and assistance. The author also thanks the National Research Council of Canada for the award of a postdoctoral fellowship.

Crystal Structure of α-$Zn_2V_2O_7$

RAMANATHAN GOPAL[1] AND CRISPIN CALVO
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 19, 1972

α-$Zn_2V_2O_7$ is monoclinic with lattice parameters $a = 7.429(5)$, $b = 8.340(3)$, $c = 10.098(3)$ Å, $\beta = 111.37(5)°$, $Z = 4$ and space group $C2/c$. The structure was refined using a full matrix least-squares with 1034 reflections measured with a quarter-circle General Electric automatic X-ray diffractometer to a final R value of 0.066. The anion consists of a pair of VO_4 tetrahedra sharing an oxygen atom which lies on a two-fold axis. The bridging V—O bond length is 1.775(4) Å while the three independent terminal ones are 1.728(4), 1.704(7), and 1.658(8) Å long. These bond lengths are consistent with the charge character around the individual oxygen atoms. The Zn ions are coordinated to five oxygen atoms with Zn—O bonds ranging from 1.973 to 2.088 Å. The structure is similar to that of α-$Cu_2P_2O_7$ and transforms to the thortvietite structure at about 615 °C.

L'α-$Zn_2V_2O_7$ est monoclinique avec les paramètres de maille $a = 7.429(5)$, $b = 8.340(3)$, $c = 10.098(3)$ Å, $\beta = 111.37(5)°$, $Z = 4$ et le groupe est $C2/c$. La structure a été raffinée en utilisant une matrice des moindres carrés avec 1034 réflections mesurées avec un diffractomètre à rayons-X au quart de cercle automatique General Electric jusqu'à une valeur finale de R égale à 0.066. L'anion consiste en une paire de tétrahèdres VO_4 partageant un atome d'oxygène qui se trouve sur un axe binaire. La longueur de la liaison V—O faisant le pontage est de 1.775(4) Å alors que celle des trois autres liaisons terminales indépendantes, est de 1.728(4), 1.704(7) et 1.658(8) Å. Ces longueurs de liaisons sont compatibles avec le caractère de la charge autour des atomes individuels d'oxygène. Les ions Zn sont coordinés à cinq atomes d'oxygène avec les liens Zn—O s'échelonnant de 1.973 à 2.088 Å. La structure est semblable à celle de l'α-$Cu_2P_2O_7$ et adopte la structure de la thortvietite vers 615 °C.

Can. J. Chem., **51**, 1004 (1973)

Introduction

Recently determined structures containing pentavalent vanadium ions in tetrahedral coordination have shown that the V—O bond length is very sensitive to the environment of the oxygen atoms. For example, in the isotypic $Mg_3(VO_4)_2$ (1), $Co_3(VO_4)_2$ (2), and $Ni_3(VO_4)_2$ (3) the V—O bond lengths are 1.809, 1.813, and 1.815 Å respectively for that particular oxygen atom bonded to three divalent cations, while the remaining V—O bond lengths involving oxygen atoms bonded to only two divalent cations lie between 1.695 and 1.716 Å. α-$Zn_3(VO_4)_2$, which is also isotypic with these compounds, shows a similar but somewhat smaller effect (4).

$M_2X_2O_7$ compounds, when the radius of M is less than about 0.9 Å and X is tetrahedrally bonded to oxygen atoms, commonly crystallize in either the thortveitite structure or some modification of it. This seems universally true for X = P and As and for the two divanadate structures, that of $Mn_2V_2O_7$ (5) and $Cd_2V_2O_7$ (6), with cations in this range previously reported. In the thortvietite-like phase the coordination of M is six-fold, while in each of the various low-temperature α phases some fraction of the cations reduce their coordination to five oxygen atoms (7–10). Thus these phases are suitable for the study of environmental effects on bond lengths since in the α phases the terminal oxygen atoms will not all be bonded to the same number of cations.

Pollard (11), Brown and Hummel (12), Angenault (13) and Makarov, Foliev, and Serebryakova (14) have studied the phase diagram of the ZnO–V_2O_5 system. The general conclusion is that $Zn_2V_2O_7$ is polymorphic with a fast reversible phase transformation at 615 °C. Angenault concluded that α-$Zn_2V_2O_7$ is orthorhombic with lattice parameters of $a = 7.441$, $b = 8.337$, and $c = 18.84$ Å from powder diffractometry, contrary to the results reported here. A further point of interest is the thermochromic nature of $Zn_2V_2O_7$ which is light yellow in the α phase and changes to red in the β phase (12).

Experiments

Crystals of α-$Zn_2V_2O_7$ were prepared in a platinum crucible by the reaction of stoichiometric amounts of ZnO and V_2O_5 at 925 °C. The melt was slowly cooled

through the melting point (877 °C (12)) and quenched when the temperature was about 750 °C.

Accurate unit cell parameters were obtained from a least-squares refinement of sixteen 2θ values measured with a General Electric semi-automatic quarter-circle diffractometer utilizing filtered MoKα radiation (λ = 0.71069 Å) with standard errors 3X those obtained from the refinement. The crystal data are:

α-$Zn_2V_2O_7$ f.w. = 363.28

a = 7.429(3), b = 8.340(3), c = 10.098(3) Å, β = 111.37 (5)°, volume = 580.1 Å^3 space group: $C2/c$, Z = 4, ρ_o = 4.1 ± 0.1 g/cm^3, ρ_c = 3.93 g/cm^3.

The space group possibilities are Cc and $C2/c$ since preliminary photographic work showed that reflections were extinct in general when $h + k$ was odd and for $h0l$ when l was odd. The centric space group was chosen since electron paramagnetic resonance measurements on Mn^{2+} doped crystals showed only one unique cation site (15).

The structure was refined with data taken with a crystal whose size was 0.13 × 0.12 × 0.08 mm. Filtered MoKα radiation was used in conjunction with a General Electric quarter-circle semi-automatic diffractometer using a 2θ–θ scan. All the reflections in a hemisphere up to 2θ = 55° were scanned at a rate of 2° per min and an angular range dependent upon the value of 2θ. The background was determined under stationary conditions by a 20 s count at either side of the peak. Those reflections whose intensity measure, after correction for background, was less than zero were not considered in the refinement. The unobserved limit was set at 3σ with σ determined by the counting statistics. All the intensities were corrected for Lorentz and polarization effects and for absorption ($\langle \mu R \rangle$ = 0.7). The final data set contained 1034 unique reflections of which 653 were observed.

The structure was refined starting with the parameters reported for α-$Cu_2P_2O_7$ (7). A full-matrix least-squares program written by J. S. Stephens for the CDC 6400 was used. Atomic scattering factors, corrected for dispersion, were obtained from the International Tables for X-ray Crystallography (16). Weights were assigned according to the relationship $\omega = (7.00 + 0.097|F_o| + 0.0073|F_o|^2)^{-1}$ where the coefficients were determined so that $\omega|F_o - F_c|^2$ would be independent of the local average observed structure factor. Unobserved reflections whose calculated structure factors, F_{calc}, was less than the value derived from the 3σ limit were given zero weight in the refinement. The refinement was terminated when all the calculated shifts were less than 1/3 of the standard errors derived from the least-squares. The final R value was 0.066 while $\omega R = (\Sigma\omega||F_o| - |F_c||/\Sigma\omega|F_o|^2)^{1/2}$ was 0.086. The final parameters are in Table 1 and the calculated and observed structure factors are compared in Table 2.[2]

The phase transformation in $Zn_2V_2O_7$ was investigated by examining the diffraction pattern of a single crystal at elevated temperatures using a precession camera. The crystal was heated with a stream of hot air. All l odd reflections disappeared beyond the transition and no evidence of a stacking disorder, as had been found in $Cu_2P_2O_7$ (7), was detected. It is thus presumed that the high temperature phase has space group $C2/m$ and is isotypic with thortvietite (17).

Description of the Structure

The structure of α-$Zn_2V_2O_7$ is based upon a perturbed hexagonally packing of oxygen atoms with c as the stacking direction. The cations occupy sites with five oxygen atom neighbors under 3.0 Å. The sixth oxygen atom, O(4f), lies 3.35 Å away and the Zn—O(4f) bond corresponds to the one that is ruptured in transforming from a thortveitite-like high temperature phase to that of α-$Zn_2V_2O_7$ structure (Fig. 1). Because of the bent V—O—V moiety, showing an angle of 149.3°, the anion pulls away from the cation at each of its ends.

As Fig. 2 shows, the structure contains the layers of oxygen atoms stacked perpendicular to (001). Zn ions and V—O—V groups lie in octahedrally coordinated sites in alternate layers of oxygen atoms. These latter groups lie in sites, containing a crystallographic two-fold axis through the oxygen atom, elongated roughly along a with each vanadium ion sharing two oxygen atoms with one layer and one with the next.

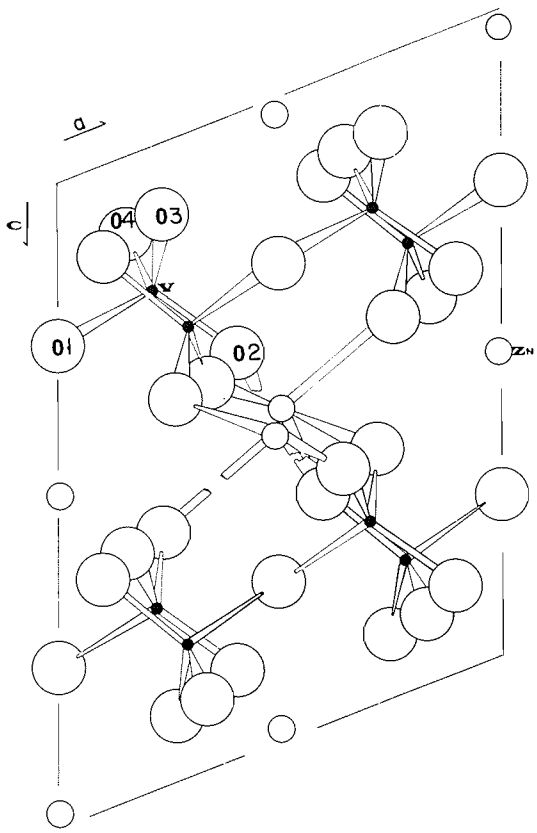

FIG. 2. The structure of α-$Zn_2V_2O_7$ showing the arrangement of the cations and their coordination environment.

The individual bond distances and angles are found in Table 3. The Zn—O bonds range from 1.973 Å (Zn—O(4*c*)) to 2.088 Å (Zn—O(3*a*)). O(4) is that oxygen atom bonded to only one Zn ion and V^{5+} ion while the remaining terminal oxygen atoms are bonded to two cations. The ZnO_5 polyhedra is a distorted trigonal bipyramid with the longer ZnO bonds in the axial direction.

The bridging V—O bond length at 1.775(4) Å is significantly longer than any involving terminal oxygen atoms. The V—O(4) bond length is the shortest, as one expects for that oxygen atom which is underbonded. The angular deviations from ideal tetrahedral values are small in comparison to comparable pyrophosphate systems (7–10). Two of the three O(1)—V—O bond angles are significantly smaller than ideal, while the remaining one does not differ significantly from the ideal value. The three O—V—O bond angles among terminal oxygen atoms are larger than ideal, but again one of them, O(3)—V—O(4), is not significantly larger.

Discussion

A comparison of the structure of α-$Zn_2V_2O_7$ with that of α-$Cu_2P_2O_7$ highlights many points of interest. α-$Cu_2P_2O_7$ has the largest P—O—P angle among those pyrophosphates with non-linear P—O—P bonds. By the same token α-$Zn_2V_2O_7$ also shows the largest V—O—V angle (149.3°) for the analogous divanadates. At the moment this group encompasses $Mg_2V_2O_7$ (17) (140.4°), $Co_2V_2O_7$ (2) (117.5°), β-$Sr_2V_2O_7$ (18) (123°), and $Pb_2V_2O_7$ (19) (122°).

The bridging oxygen atom in α-$Cu_2P_2O_7$ (7), as in $Zn_2V_2O_7$, shows enhanced disorder in the plane perpendicular to the vector connecting the centers of the tetrahedra forming the anion, as seen in Tables 4 and 5. It is not unexpected that the former compound would show a larger amplitude for this oxygen atom relative to the remaining ones as room temperature lies sub-

stantially closer to the transition temperature in the case of $Cu_2P_2O_7$. Further, the transformation is continuous leading to disorder streaks parallel to a^* in $Cu_2P_2O_7$; but no streaking was noted in $Zn_2V_2O_7$. Some indication of the effect of the disorder on the apparent geometry of the anion can be obtained by examining the difference in the maximum correction to the X—O bond lengths between the X—O bond involving the bridging oxygen atom and the average value in-

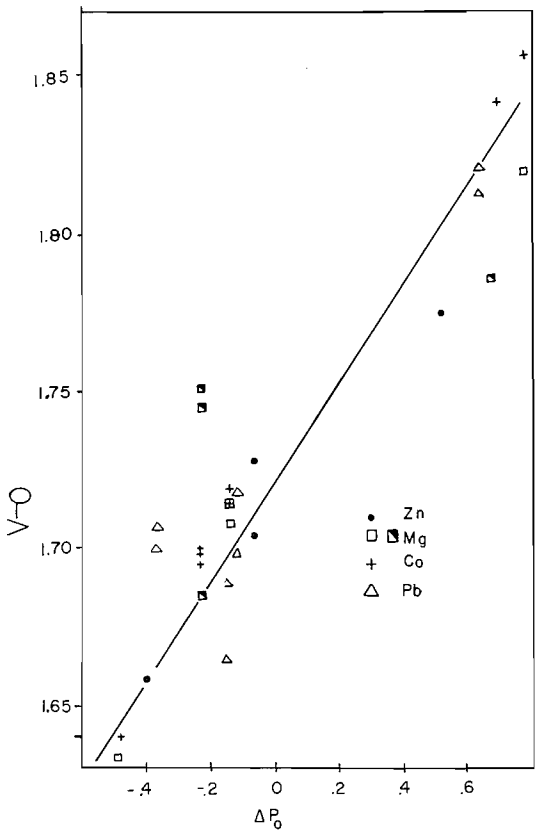

FIG. 3. V—O bond lengths in $M_2V_2O_7$ compounds *vs.* Δp_O. $Mg_2V_2O_7$ values indicated by ◥ represent the side of the anion with an additional weak V—O interaction.

volving the terminal oxygen atom. In $Zn_2V_2O_7$ this excess is 0.010 Å while in α-$Cu_2P_2O_7$ it is 0.024 Å, leading to maximum possible X—O—X angle decreases of 2 and 6°, respectively.

In $Zn_2V_2O_7$, as in α-$Cu_2P_2O_7$, the X—O bond involving the oxygen atom bonded strongly to only one cation, in addition to the pentavalent ion, is contracted. Baur has shown that for P—O bonds, the P—O bond length, d_{P-O}, is given by $d_{P-O} = 1.534 + 0.11\Delta p_O$ (20) and the analogous relationship for the vanadates is $d_{V-O} = 1.721 + 0.16\Delta p_O$ (19). The value of p_O is obtained by summing the ratios of the valency to the coordination number for each of the neighbors of the oxygen atom and Δp_O is the difference between p_O and its mean value in the specific compound. Figure 3 shows a plot of bond length versus Δp_O for the divanadates investigated in this laboratory. In $Mg_2V_2O_7$ one side of the V_2O_7 shows a fifth V—O interaction of about 2.4 Å and leads to large deviations as shown by the points in the plot. Generally the agreement with the linear correlation as shown in Fig. 3 is good. The predicted V—O(—V) bond length in $Zn_2V_2O_7$ lies substantially higher than the experimental ones, suggesting that the disorder indicated by the thermal parameters have significantly contracted this bond length.

Finally the question of the nature of the $Zn_2V_2O_7$ phase report by Angenault should be considered. His orthorhombic cell with space group *F*222, *Fmm*2, or *Fmmm* is somewhat reminiscent of the single crystal data that we have obtained on $Cu_2V_2O_7$ whose unit cell is orthorhombic with $a = 8.404$, $b = 20.670$, and $c = 6.442$ Å with space group *Fdd*2. The intensity distribution reported by Angenault is similar to that measured by us for $Cu_2V_2O_7$. It would appear that perhaps Angenault's $Zn_2V_2O_7$ is a high temperature modification from the manner in which it was prepared.

Radiolysis Free Ion Yields and Electron Ranges in Polar and Nonpolar Liquids: Fluoromethanes[1]

MAURICE G. ROBINSON AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alberta, T6G 2G2

Received October 23, 1972

The free ion yields at zero applied electric field strength in the liquid fluoromethanes are $G_{fi}^0 = 1.6$ in CH_3F, 1.9 in CH_2F_2 and 1.1 in CHF_3, all at 183 °K, and 0.07 in CF_4 at 143 °K. Median ranges y_{med} of the secondary electrons were estimated by fitting the electric field dependence of G_{fi} to a model equation: $y_{med} = 41$ Å in CH_3F, 39 Å in CH_2F_2 and CHF_3, and 132 Å in CF_4, at the above-mentioned temperatures. The average number of collisions, n, required to thermalize a secondary electron is about 64 000 in liquid Ar, 7 700 in CH_4, 660 in $C(CH_3)_4$, 360 in CF_4, 110 in C_3H_8, 44 in CH_3F, 39 in CH_2F_2, 35 in CHF_3, 17 in H_2O, and 12 in CH_3OH. The value of n with nonpolar molecules (up to neopentane in size) tends to decrease with increasing molecular complexity and with decreasing sphericity. Presence of a large dipole moment in the molecule decreases n further, and hydrogen bonds reduce n still more. Energy transfer between the electrons and rotational modes of the molecules appears to be important.

Le rendement en ions libres en l'absence de champ électrique, G_{fi}^0, est à 183 °K: 1.6 pour le CH_3F, 1.9 pour le CH_2F_2 et 1.1 pour le CHF_3; 0.07 pour le CF_4 à 143 °K. La distance médiane de pénétration, y_{med}, des électrons secondaires dans chaque liquide a été déduite de la meilleure distribution utilisée pour le calcul de l'effet du champ électrique sur le rendement en ions libres. Ces distances médianes sont aux températures mentionnées: $y_{med} = 41$ Å pour le CH_3F, 39 Å pour le CH_2F_2, 39 Å pour le CHF_3, et 132 Å pour le CF_4. Le nombre moyen de collisions, n, subies par un électron secondaire jusqu'à thermalisation est environ: 64 000 pour l'argon liquide, 7 700 pour le méthane, 660 pour le néopentane, 360 pour le CF_4, 110 pour le propane, 44 pour le CH_3F, 39 pour le CH_2F_2, 35 pour le CHF_3, 17 pour l'eau et 12 pour le méthanol. La valeur de n dans des liquides non polaires dont les molécules ont une taille ne dépassant pas celle du néopentane tend à diminuer avec l'accroissement de la complexité moléculaire et avec l'écart progressif de la forme sphérique. La présence dans la molécule d'un moment dipolaire élevé réduit n, et s'il y a liaisons hydrogènes n est réduit d'avantage. Le transfert d'énergie entre les électrons et les modes de rotation des molécules semble être important.

Can. J. Chem., **51**, 1010 (1973)

Introduction

Electron behavior in liquid hydrocarbons is affected by the structure of the molecules (1–5). The rate of energy loss by epithermal electrons in a liquid alkane correlates inversely with the sphericity of the molecules (3, 5). The electron–molecule energy transfer interaction apparently involves rotational modes of the molecules and may operate through the anisotropic polarizability of nonpolar molecules (5). Presence of a permanent electric dipole in a molecule should enhance the electron–molecule interaction (6). To obtain information about the effect of a permanent dipole moment, radiolysis free ion yields were measured and electron ranges estimated in CH_3F, CH_2F_2, CHF_3, and CF_4; the first three compounds have dipole moments $\mu > 1.6$ D, whereas that of CF_4 is zero (7). The results are reported below.

[1]This work received financial assistance from the National Research Council of Canada.

Experimental

Materials

The methyl fluoride and difluoromethane were obtained from Columbia Organic Chemicals and the fluoroform and tetrafluoromethane from Matheson.

Each gas was introduced into the high vacuum system via two purification columns at 298 °K. One contained sodium hydroxide pellets and the other silica gel; the latter was activated under vacuum for 4 h at 520 °K. After condensation at 77 °K the compounds were distilled repeatedly from trap to trap, the receiver being continually open to vacuum. Prior to use the compounds were electrolyzed as liquids at 143 °K and 1–2 kV/cm for 1 h. The samples were then distilled into the conductance cell at 77 °K and the cell unit sealed off with a flame.

The densities, dielectric constants, dipole moments, and mean polarizabilities of the four fluoromethanes are listed in Table 1.

Conductance Cell

The collecting electrode was guarded in a manner similar to that reported earlier (8), but the total cell volume was reduced to about 5 cm^3. The effective electrode area was 1.77 cm^2 and the separation 0.30 cm.

Determination of the Free Ion Yields

The free ion yields were measured as a function of

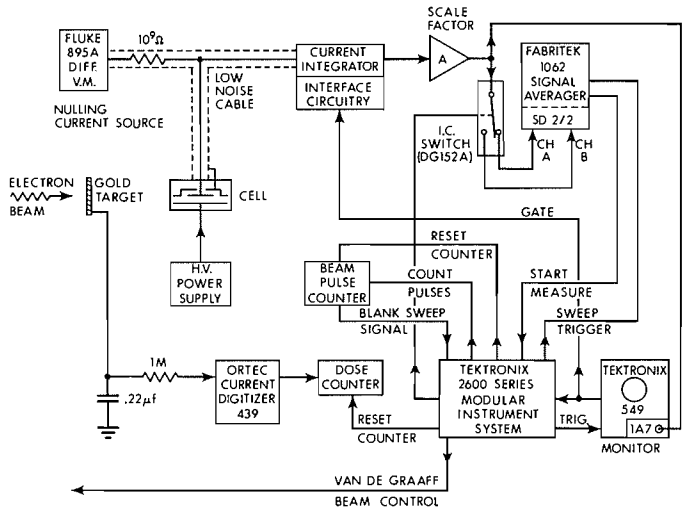

FIG. 1. Schematic diagram of circuit for measurement of free ion yields. Odd numbered sweeps of the integration system were blanks, in which no radiation pulse occurred. The nulling current source was used to cancel the background conductance of the sample. Details of the current integrator are in Fig. 3*b* of ref. 8.

applied voltage by the charge clearing method (2, 8–10). The circuit used was similar to that recently described (8) with the important exception that the clearing field was on continuously during an experiment. This eliminated the problems associated with a high voltage switch. A schematic diagram of the circuit used is shown in Fig. 1.

Signals were generated by 1 μs pulses of 1.7 MeV X-rays. At each field strength eight alternate signals and blanks (no radiation pulse) were fed into a low drift high sensitivity integrator and averaged with a Fabritek model 1062 Instrument Computer. The averaged signals and blanks were displayed on an oscilloscope and photographed (see Fig. 2). A Tektronix 549 B oscilloscope with a type 1A7 plug-in monitored the integrator output from each signal and blank. The integration time for each signal and blank was 2 s.

Despite the great care taken to purify these compounds the liquids CH_3F, CH_2F_2, and CHF_3 contained sufficient ionic impurities (ionic dissociation?) to give an appreciable background conductance. Additional treatment with sodium hydroxide or electrolysis had no effect. In order to take measurements of the radiation induced conductance the background conductance was nulled by an opposing voltage across a 10^9 ohm resistor. The nulling currents at the maximum field strengths used were 1.6 nA in CH_3F, 0.7 nA in CH_2F_2, and 0.1 nA in CHF_3.

Dosimetry

The absorbed dose per X-ray pulse was $\sim 3 \times 10^{10}$ eV/cm^3, measured by thermoluminescent dosimetry (8). The dose absorbed in the desired liquid was calculated from that absorbed in the thermoluminescent lithium chloride crystals, using the relative electron densities. Each pulse was monitored by the charge collected on the gold target.

Results and Discussion

Free Ion Yields and Their Field Dependence

The free ion yields increased in the order $CF_4 \ll CHF_3 < CH_3F < CH_2F_2$ (Fig. 3). The dielectric constants of the liquids increase in the same order (Table 1).

The free ion yield $G_{fi}{}^E$ increased with applied field strength E in all liquids, but the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

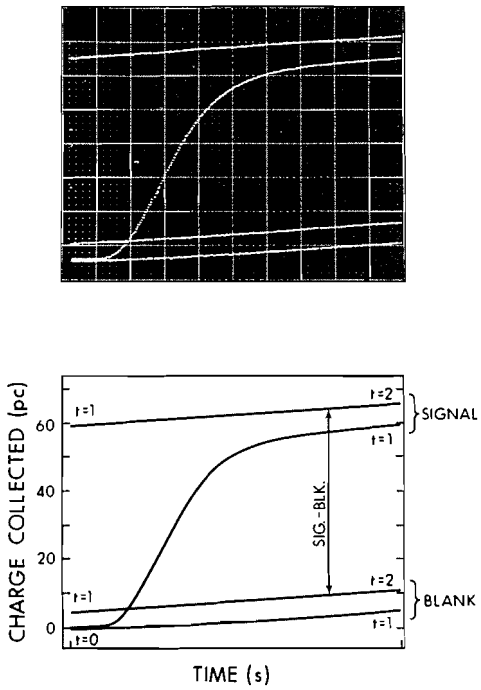

FIG. 2. Typical averages of four signals and four blanks from charge integrator output. Liquid methyl fluoride, 2.3 kV/cm, average pulse dose 3.8×10^{10} eV/cm^3, oscilloscope sweep time 1 s, total integration time 2 s.

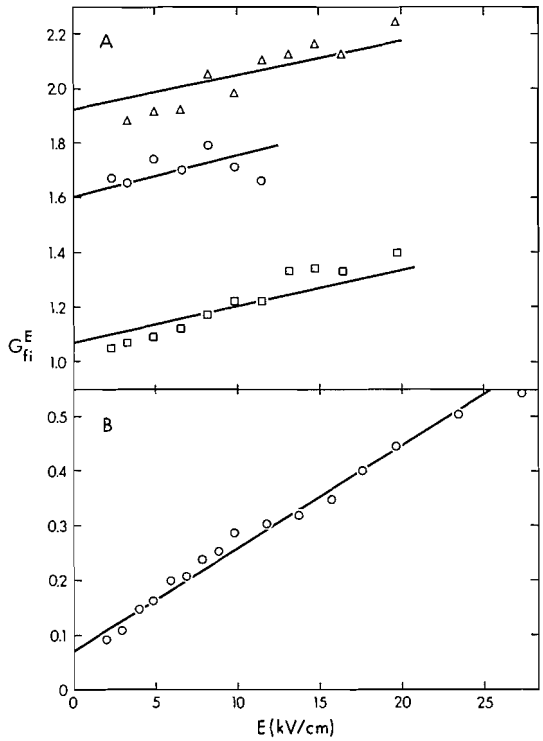

FIG. 3. Free ion yields $G_{fi}{}^E$ at applied electric field strength E. *A*, all liquids at 183 °K: ○, CH_3F; △, CH_2F_2; □, CHF_3. *B*, CF_4 at 143 °K. The curves were calculated from eq. 1, using the $F(y)$ distributions mentioned in the text.

increase was much greater in the nonpolar CF_4 than in the polar liquids CHF_3, CH_2F_2, and CH_3F (Fig. 3).

The influence of applied field strength on the free ion yield in a liquid irradiated by low LET radiation is approximately described by eq. 1 (11, 12).

$$[1] \quad G_{fi}{}^E = G_{tot} \int_0^\infty F(y)\, e^{-r/y} (1 + \beta r + 0.375\beta^2 r^2 - 0.750\beta^2 r y + \ldots)\, dy$$

where G_{tot} is the total number of ion–electron pairs generated per 100 eV absorbed by the liquid, $F(y)dy$ is the fraction of thermalized electron–ion pairs with initial intrapair separation distances between y and $y + dy$, $r = \xi^2/\varepsilon kT$, ξ is the electronic charge, ε is the dielectric constant of the liquid, k is Boltzmann's constant, T is the absolute temperature, and $\beta = \xi E/600kT$. At zero field strength $\beta = 0$ and

$$[2] \quad G_{fi}{}^0 = G_{tot} \int_0^\infty F(y)\, e^{-r/y}\, dy$$

By inserting the values of the appropriate constants one finds that $\beta r = 9.69E/\varepsilon T^2$. Furthermore

$$[3] \quad G_{fi}{}^E = G_{fi}{}^0 \left\{ 1 + \frac{9.69E}{\varepsilon T^2} + \frac{35.2E^2}{\varepsilon^2 T^4} - \frac{4.21 \times 10^4 E^2}{\varepsilon T^3} \frac{\int_0^\infty F(y) y\, e^{-r/y}\, dy}{\int_0^\infty F(y)\, e^{-r/y}\, dy} + \ldots \right\}$$

Under the conditions used in the present work the free ion yields increased approximately linearly with field strength. The fractional increase in yield with increasing field is given approximately by the second term in the brackets of the right hand side of eq. 3, $9.69E/\varepsilon T^2$. The relatively large field effect observed in CF_4 is due mainly to the low value of ε of that liquid compared to those of the other liquids (Table 1).

[d]Free ion yield extrapolated to zero field strength.
[e]Median range of the electrons.

Ranges of the Secondary Electrons

The observed values of G_{fi}^E were fitted to eq. 1, using the Gaussian range distribution [4] for CH_3F, CH_2F_2, and CHF_3.

$$[4] \qquad F(y) = (4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where b is the dispersion parameter, and is also the most probable value of y. The Gaussian function has been found to be suitable for liquids in which $G_{fi}^0 > 0.2$ (12). The value of b in each of the three liquids is listed in Table 2. The calculated values of G_{fi}^E are represented by the full curves for these compounds in Fig. 3.

The Gaussian form of $F(y)$ distribution did not allow satisfactory agreement to be obtained between calculated and observed values of G_{fi}^E in CF_4; the calculated field dependence was larger than that observed. It had been found earlier (12) that a power function [5] gave satisfactory results when G_{fi}^0 was <0.2.

$$[5] \quad \begin{cases} F(>y) = (y_{min}/y)^x & y \geq y_{min} \\ F(>y) = 1 & y \leq y_{min} \end{cases}$$

where

$$F(>y) = \int_y^\infty F(y)\,dy$$

This function worked well in eq. 1 for CF_4, and the best values of the parameters were found to be $y_{min} = 100$ Å and $x = 2.5$. The calculated yields are shown in Fig. 3.

The median range y_{med} can be used to compare typical range values in systems where different $F(y)$ distributions apply. The arithmetic-mean range is not appropriate for this purpose because it gives too much weight to the long-range tail in some distributions.

In the Gaussian function [4], $y_{med} = 1.09b$; in the power function [5] with $x = 2.5$, $y_{med} = 1.32\ y_{min}$. The values of y_{med} obtained for the fluorocarbons are listed in Table 2. Electron ranges are approximately equal in CH_3F, CH_2F_2, and CHF_3, while those in CF_4 are three times larger.

Comparison with Other Systems: Secondary Electron Energy Loss Rates

Medium ranges of secondary electrons in a number of liquids are listed in Table 3 (8, 12–14). The liquid density has been used successfully to normalize ranges in hydrocarbons (2, 5, 9, 12), but density is less suitable for the normalization of ranges in different kinds of compounds. A more meaningful comparison might be obtained by estimating the average number n of collisions required to thermalize the secondary electrons in the liquids.

The detailed shape of the electron path is determined by both elastic and inelastic scattering, but the length of the path is limited by inelastic scattering. The latter process is mainly responsible for the de-energization of the electron. The elastic (momentum transfer) scattering cross sections of all of the substances in Table 3 for 1 eV electrons are probably of the order of 10 Å^2(15*a*, 16, 17); the inelastic cross sections are in general smaller than elastic cross sections for electrons with energies less than 10 eV (16, 17).

The relation between the average number of collisions n undergone during thermalization and the median penetration range y_{med} is, assuming random scattering (15*b*):

$$[6] \qquad y_{med} = 1.09b = 1.09\sqrt{2n}\,\lambda$$

where λ is the mean free path. Therefore

$$[7] \qquad n = y^2{}_{med}/2.4\lambda^2$$

The secondary electrons in liquid hydrocarbons appear to interact with molecules or parts of molecules up to the size of neopentane (5), which is the largest molecule being considered

here. One might therefore take λ approximately equal to the molecular diameter for these small molecules, whence

$$\lambda \approx N^{-1/3} \quad [8]$$

and

$$n \approx y^2_{med} N^{2/3}/2.4 \quad [9]$$

where N is the number of molecules/cm^3.

Values of n are given in Table 3. The average number of collisions required to thermalize a secondary electron in liquid argon is an order of magnitude greater than that required in methane, which in turn is an order of magnitude greater than that in neopentane. The decrease in n corresponds to an increase in energy transfer per collision, $-dT/dn$, and correlates with the increasing molecular complexity in the series Ar, CH_4, $C(CH_3)_4$.

On going from $C(CH_3)_4$ to CF_4 n decreases by a factor of two. Thus CF_4 is somewhat more efficient than is $C(CH_3)_4$ at accepting energy from an epithermal electron. The difference might be due to a more accessible transient negative ion state in CF_4 than in $C(CH_3)_4$. Transient negative ion states are often invoked as intermediates in the vibrational excitation of molecules by electrons (18–22).

In the series CH_4, CH_3CH_3, $CH_2(CH_3)_2$, $CH(CH_3)_3$, $C(CH_3)_4$ n decreases 30-fold from methane to ethane, a further 2.5-fold to propane, then increases again 1.5-fold to isobutane and a further 4-fold to neopentane (Table 3). Two influences combine to give a minimum n value at propane: n tends to decrease with increasing molecular complexity and decreasing molecular sphericity. Molecular complexity increases throughout the series from methane to neopentane, but sphericity is at a minimum at propane. The less sphere-like alkanes have the greater anisotropies of polarizability α^a (Table 3). The magnitude of the rotational excitation cross section of a nonpolar molecule for slow electrons depends on the anisotropy (16). The selection rules for excitation by slow electrons (16) are similar to those for Raman excitation (23).

The value of n in CH_3F is 6-fold smaller than that in CH_3CH_3. This difference is presumably due to the large dipole moment in CH_3F (Table 3) and is consistent with the suggestion (5) that electrons lose their energy mainly to rotational modes of the molecules.

The small decrease in n from CH_3F to CHF_3 might be related to easier vibrational excitation of the latter, which presumably possesses a lower lying negative ion state and a lower vibrational excitation threshold (F—C—F bending) than does the former.

The 4-fold decrease in n on going from CH_3F

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to CH_3OH is not due to differences in the molecular dipole moments or anisotropies of polarizability (Table 3). These properties are similar for the two substances. It appears that hydrogen bonds are efficient energy sinks for low energy electrons. Hydrogen bonds have extremely high polarizabilities (24), and presumably large anisotropies. Furthermore, the strong solvating power of —OH groups for electrons might cause the electron to become localized before it has been completely "thermalized". The electron range would thereby be shortened.

Methanol appears to be a more efficient energy sink than is water for low energy electrons, n being smaller in the former than in the latter (Table 3). This difference is not understood, although it correlates with the relative optical absorption energies of solvated electrons in the two liquids: $E_{\lambda_{max}} = 1.9$ and 1.7 eV in methanol and water, respectively.

We would like to thank the staff of the Radiation Research Center for aid with the electronics and J.-P. Dodelet for calculating the curves in Fig. 2.

Reactivity of Substituted Benzenethiols Towards Chlorotris(triphenylphosphine)iridium(I) and Chlorotris(triphenylarsine)iridium(I)[1]

JOSEPH L. HERDÉ AND CAESAR V. SENOFF[2]

Department of Chemistry, University of Guelph, Guelph, Ontario

Received July 6, 1972

A series of substituted benzenethiols, HSC_6H_4Y (Y = 4-Br, 4-F, 4-H, 4-CH_3, or 4-CH_3O) have been shown to react with $IrCl(Ph_3M')_3$ (M′ = P or As) in benzene to form dimeric iridium(III) complexes of the type, $[IrHCl(SC_6H_4Y)(Ph_3M')_2]_2$, **1**. The thiol, 4-nitrobenzenethiol, reacts with $IrCl(Ph_3M')_3$ (M′ = P or As) to form complexes of the type $[IrCl_2(SC_6H_4NO_2)(Ph_3M')_2]_2$, **2**. Complexes **1** undergo reductive elimination with carbon monoxide to form *trans*-$[Ir(CO)_2(Ph_3M')_2]Cl$ whereas complexes **2** do not react with carbon monoxide. Spectroscopic properties (i.r. and n.m.r.) of these complexes are discussed in relation to their structure in the solid state and in solution.

Une série de benzènethiols substitués, HSC_6H_4Y (Y = Br-4, F-4, H-4, CH_3-4, ou CH_3O-4) réagit, comme il est montré, avec $IrCl(Ph_3M')_3$ (M′ = P ou As) dans le benzène pour former des complexes dimériques de l'iridium(III) du type $[IrHCl(SC_6H_4Y)(Ph_3M')_2]_2$, **1**. Le thiol, nitro-4 benzènethiol réagit avec $Ir(PH_3M')_3$ (M′ = P ou As) pour former des complexes du type $[IrCl_2(SC_6H_4NO_2)(Ph_3M')_2]_2$, **2**. Les complexes **1** subissent une élimination réductive avec du monoxide de carbone pour former le *trans*-$[Ir(CO)_2(Ph_3M')_2]Cl$ alors que les complexes **2** ne réagissent pas avec le monoxyde de carbone. Les caractéristiques spectroscopiques (i.r. et r.m.n.) de ces complexes sont discutées en fonction de leurs structures dans l'état solide de même qu'en solution. [Traduit par le journal]

Can. J. Chem., 51, 1016 (1973)

Chlorotris(triphenylphosphine)iridium(I) and related iridium(I) complexes have been investigated by several workers (1–7). The ability of these complexes to participate in oxidative addition reactions and their ability to function as homogeneous catalysts have also been of particular interest (2, 3). As part of a general investigation into the reactivity of substituted benzenethiols towards low valent transition metal complexes (8–10) we have undertaken a study of the reactivity of a series of 4-substituted benzenethiols, HSC_6H_4Y (Y = 4-NO_2, 4-Br, 4-F, 4-H, 4-CH_3, or 4-CH_3O) towards $IrCl(Ph_3M')_3$ (M′ = P or As). The results of this investigation are reported at this time.

Results and Discussion

At the outset of this study it was anticipated that the complexes, $IrCl(Ph_3M')_3$ (M′ = P or As) would oxidatively add HSC_6H_4Y (Y = an electron releasing or electron withdrawing substituent) to form $IrHCl(SC_6H_4Y)(Ph_3P)_3$ according to reaction 1. This expectation was not realized. The substituted benzenethiols do not simply oxidatively add to $IrCl(Ph_3M')_3$ but form dimeric complexes, the nature of which is markedly dependent upon the nature of the substituent, Y. Accordingly, it was found that HSC_6H_4Y (Y = 4-Br, 4-F, 4-H, 4-CH_3, or 4-CH_3O) reacted with $IrCl(Ph_3M')_3$ (M′ = P or As) to form cream-colored precipitates over a prolonged period of time according to reaction 2.

[1] $IrCl(Ph_3M')_3 + HSC_6H_4Y \rightarrow IrHCl(SC_6H_4Y)(Ph_3M')_3$

[2] $2IrCl(Ph_3M')_3 + 2HSC_6H_4Y \rightarrow [IrHCl(SC_6H_4Y)(Ph_3M')_2]_2 + 2Ph_3M'$

The time of reaction and yield of product are

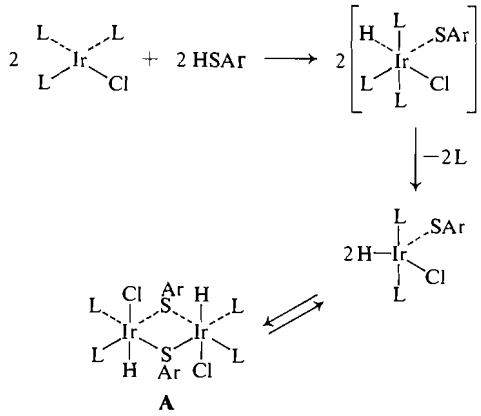
dependent on the nature of Y. These data are given in Table 1. The formation of these dimeric complexes may be *conceptually* rationalized by the following scheme where L = Ph_3P or Ph_3As, and Ar = YC_6H_4, *i.e.*,



A

The first step involves a simple *cis*-oxidative addition of the substituted benzenethiol to the iridium(I) substrate to form an octahedral iridium(III) "intermediate" followed by elimination of L to form a 5-coordinate iridium(III) derivative which then dimerizes to form the observed product, **A**. The triphenylphosphine complexes, $[IrHCl(SC_6H_4Y)(Ph_3P)_2]_2$, **1**, are air stable in the solid state and are sparingly soluble in common organic solvents (*e.g.*, acetone, benzene, chloroform, etc.) whereas the corresponding triphenylarsine complexes, $[IrHCl(SC_6H_4Y)(Ph_3As)_2]_2$, **2**, are also air stable in the solid state but are more soluble in organic solvents.

The complexes, **1**, are characterized by a strong, sharp band in the region 2231–2110 cm^{-1}, which may be assigned to the ν_{Ir-H} vibration. The corresponding iridium–hydrogen stretching vibration for the complexes, **2**, was observed between 2203–2184 cm^{-1}. Metal–chlorine stretching vibrations are expected to occur below 400 cm^{-1} (11). Complexes **1** and **2** exhibited a band of medium intensity in the regions 248–242 and 260–249 cm^{-1}, respectively, which has been assigned to the ν_{Ir-Cl} vibration. These infrared data are presented in Table 2.

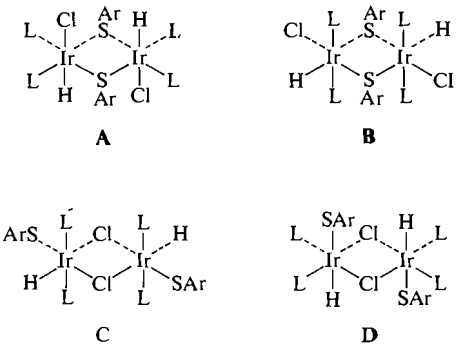
Complexes **1** were too insoluble to observe the high field resonance expected for a hydrido ligand bonded to iridium. However, the complexes **2** were sufficiently soluble to observe this resonance as a single peak at ~21 p.p.m. in $CDCl_3$. The n.m.r. data are given in Table 3.

Molecular weight measurements confirm that the complexes are indeed dimeric. Typical molecular weight data (osmometry in $CHCl_3$ or C_6H_6) are given in Table 4. These data indicate that the complexes dissociate in solution into two five coordinate species according to reaction 3. Unfortunately, the complexes **1** were too insoluble

[3] $[IrHCl(SC_6H_4Y)(Ph_3M')_2]_2 \rightleftharpoons 2[IrHCl(SC_6H_4Y)(Ph_3M')_2]$

to permit a measurement of their molecular weights. Presumably, these complexes are also dimeric in view of their similar properties (*vide supra et vide infra*) to the complexes **2**.

It is possible to visualize several different structures for the complexes **1** and **2**. The four most likely structures are shown below



A B C D

If one considers the propensity that an arenethiolato ligand has for functioning as a bridging group, then structures **C** and **D** may be eliminated from any further consideration. The fact that a single resonance due to the hydrido ligand bonded to iridium was observed in the ^1H n.m.r. spectra of complexes **2**, the fact that only one ν_{Ir-Cl} vibration and one ν_{Ir-H} vibration was observed in the infrared spectra of complexes **1** and **2** and the fact that molecular weight measurements for complexes **2** indicate that these complexes are dimeric are all consistent with structures A and **B** (C_{2h} local symmetry) having arenethiolato bridging groups. A δ value of ~21 p.p.m. in the ^1H n.m.r. spectra of complexes **2** (see Table 3) is consistent with the hydrido ligand being *trans* to a ligand of low *trans*-influence such as Cl^- or $YC_6H_4S^-$ (12 and references therein). Hence, the position of the highfield resonance of the hydrido ligand in complexes **2** does not unambiguously distinguish between structure **A** and structure **B**.

A plot of ν_{Ir-H} *vs.* the Hammett substituent parameter, σ_p, for the complexes **2** is shown in

†Not measured because of low solubility of complex.

Fig. 1. The non-linearity of this plot is interpreted as indicating that the *full* electronic effect of the para-substituent does not manifest itself in the position of the ν_{Ir-H} vibration as has been observed when a para-substituted benzenethiolato ligand is *trans* to a hydrido ligand (9). In this later situation a linear correlation was observed between ν_{Ir-H} and σ_p. The observed variation in ν_{Ir-H} for complexes **2** together with the fact that the high-field chemical shift of the hydrido ligand bonded to iridium(III) is invariant to the nature of the substituent, Y (see

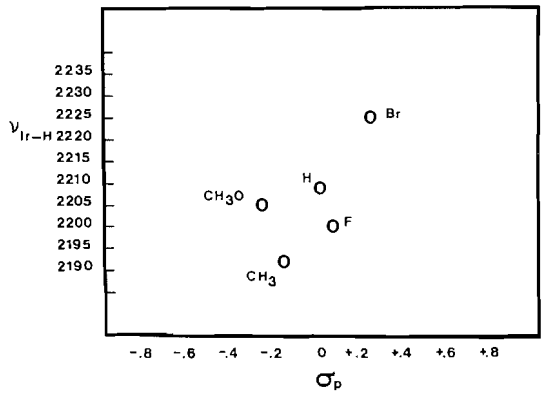

FIG. 1. Hammett plot for $[IrHCl(SC_6H_4Y)(Ph_3As)_2]_2$.

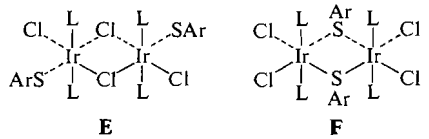
Table 3), are consistent with the arenethiolato moiety being *cis* to the hydrido ligand (8). These observations favor structure **A**.

Finally, for a large number of octahedral iridium(III) complexes it has been noted that ν_{Ir-Cl} appears at $\sim$250 cm^{-1} when Cl is *trans* to H (13). This particular vibration for complexes **1** and **2** has been observed between $\sim$240–260 cm^{-1} (see Table 2) and also lends support for structure **A**.

The product formed when 4-nitrobenzenethiol reacts with $IrCl(Ph_3M')_3$ is not of the type **1** or **2** but rather an iridium(III) complex which does not contain an iridium–hydrogen bond. These particular complexes have been formulated as $[IrCl_2(SC_6H_4NO_2)(Ph_3P)_2]_2$, **3**, and $[IrCl_2(SC_6H_4NO_2)(Ph_3As)_2]_2$, **4**, in the solid state. Molecular weight measurements (see Table 4) confirm that these complexes are indeed dimeric and also indicate that they are dissociated in solution according to reaction 4. The precise

[4] $[IrCl_2(SC_6H_4Y)(Ph_3M')_2]_2 \rightleftharpoons 2[IrCl_2(SC_6H_4Y)(Ph_3M')_2]$

reason for $HSC_6H_4NO_2$ behaving differently towards $IrCl(Ph_3M')_3$ is not clearly understood at present. The two most likely structures for **3** and **4** involve either Cl^- or $O_2NC_6H_4S^-$ bridging groups and are shown below where L = Ph_3P or Ph_3As and Ar = $C_6H_4NO_2$. Structure



E **F**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

E (C_{2h} local symmetry) would be expected to exhibit at least two ν_{Ir-Cl} vibrations ($2B_u$, bridging and terminal) whereas structure **F** (D_{2h} local symmetry) would be expected to show at least four ν_{Ir-Cl} vibrations ($2B_{2u}$ and $2B_{3u}$). Structure **F** appears to be more likely in view of the proposed structures for complexes **1** and **2** although structure **E** cannot be completely rejected on the basis of the available spectroscopic data (Table 2). Attempts to replace Cl by Br in the complexes **3** and **4** were not successful. Hence, the bands observed in the region 340–220 cm^{-1} could not be positively assigned to ν_{Ir-Cl} vibrations. Accordingly, the assignments for ν_{Ir-Cl} for **3** and **4** given in Table 2 must be regarded as tentative.

The reactivity of carbon monoxide with the complexes **1**–**4** has been investigated. Complexes of the type, **1** and **2** were found to readily undergo "reductive elimination" by reaction with CO at 1 atm and at room temperature to form *trans*-$[Ir(CO)_2(Ph_3M')_2]Cl$ where M′ = P or As, *i.e.*,

[5] $[IrHCl(SC_6H_4Y)(Ph_3M')_2]_2 + 4CO \rightarrow 2\ trans\text{-}[Ir(CO)_2(Ph_3M')_2]Cl + 2HSC_6H_4Y$

On the other hand, complexes **3** and **4** do not react with carbon monoxide and may be recovered unchanged after prolonged exposure to 1 atm carbon monoxide at room temperature, *i.e.*,

[6] $[IrCl_2(SC_6H_4NO_2)(Ph_3M')_2]_2 + 4\ CO \nrightarrow 2\ trans\text{-}[Ir(CO)_2(Ph_3M')_2]Cl + 2ClSC_6H_4NO_2$

Apparently, the hydrido ligand is necessary for reductive elimination of occur. The complexes *trans*-$[Ir(CO)_2(Ph_3P)_2]Cl$ and *trans*-$[Ir(CO)_2(Ph_2As)_2]Cl$ behave as 1:1 electrolytes in acetone and nitromethane (see Experimental section). The low molar conductivities associated with these complexes are similar to those reported recently by Collman and co-workers (14) for $[Ir(CO)_2(TDPME)]Cl$ where TDPME = 1,1,1-tris(diphenylphosphinomethyl)ethane. These low molar conductivities could be due to the loss of Ph_3M' in solution according to reaction 7.[3]

[7] $[Ir(CO)_2(Ph_3M')_2]Cl \rightleftharpoons [Ir(CO)_2(Ph_3M')Cl] + Ph_3M'$

These particular four coordinate iridium(I) complexes are similar to *trans*-$[Ir(CO)_2(Ph_3M')_2][ALCl_4]$ which have been reported by Hieber and Frey (15). The *trans*-arrangement of the CO ligands is supported by the fact that only one ν_{CO} vibration (D_{2h} local symmetry) was observed in the infrared at ~2000 cm^{-1}. The ν_{CO} vibration for *trans*-$[Ir(CO)_2(Ph_3P)_2]Cl$ was observed at 2025 cm^{-1} (Nujol), 2029 cm^{-1} ($CHCl_3$), and at 2020 cm^{-1} (Nujol), 2024 cm^{-1} ($CHCl_3$) for *trans*-$[Ir(CO)_2(Ph_3As)_2]Cl$. In order to eliminate the possibility that these dicarbonyl complexes were in fact not tricarbonyl derivatives of the type $[Ir(CO)_3(Ph_3M')_2]Cl$ (16, 17), the tetraphenylborate derivative, $[Ir(CO)_2(Ph_3P)_2](BPh_4)$ was prepared (see Experimental section) which also exhibited only one ν_{CO} band at 2024 cm^{-1} (Nujol).

Since the complexes **1** and **2** appear to be dissociated in solution (reaction 3), the observed reductive elimination (reaction 5) may be compared to the reaction of the five coordinate iridium(III) complexes, $[IrHCl_2(Ph_3P)_2]$ and $[IrHCl(O_2CCF_3)(Ph_3P)_2]$, with CO which undergo simple nucleophilic addition to form $[IrHCl_2(CO)(Ph_3P)_2]$ and $[IrHCl(O_2CCF_3)(CO)(Ph_3P)_2]$, respectively (18).

Experimental

Materials

Triphenylphosphine was purchased from Eastman Organic Chemicals, Inc. and was recrystallized from ethanol. A generous supply of cyclooctene was provided by the Columbian Carbon Co., Inc., Princeton, New Jersey. Other chemicals used were commercially available samples. All reactions were normally carried out under an atmosphere of nitrogen.

Di-μ-chlorotekrakis(cyclooctene)diiridium(I), $[IrCl(C_8H_{14})_2]_2$

This was prepared according to the method of Herdé and Senoff (19).

Chlorotris(triphenylphosphine)iridium(I), $IrCl(Ph_3P)_3$

This was prepared according to the method of Bennett and Milner (2) from the reaction of triphenylphosphine with $[IrCl(C_8H_{14})_2]_2$.

Chlorotris(triphenylarsine)iridium(I), $IrCl(Ph_3As)_3$

This complex was generated *in situ* from the reaction of triphenylarsine with $[IrCl(C_8H_{14})_2]_2$ according to the method of Bennett and Milner (2). The complex was not isolated because of its extreme reactivity with oxygen.

Di-μ-arenethiolatodihydridodichlorotetrakis(triphenylphosphine)diiridium(III), $[IrHCl(SC_6H_4Y)(Ph_3P)_2]_2$

The following general procedure was used to prepare these complexes. To a degassed benzene solution (20 ml) of chlorotris(triphenylphosphine)iridium(I) (0.50 g) was added an excess of the appropriate substituted benzenethiol (0.25 g or 0.5 ml). The solution immediately changed

[3]We thank a referee for bringing this point to our attention.

color from orange to green and was stirred for a prolonged period of time (see Table 1). The cream-yellow precipitate was then filtered, washed with benzene and dried *in vacuo* over boiling benzene overnight. Analytical data are presented in Table 5.

Di-μ-arenethiolatodihydridodichlorotetrakis(triphenylarsine)diiridium(III), $[IrHCl(SC_6H_4Y)(Ph_3As)_2]_2$

The following general procedure was used to prepare these complexes. To a degassed benzene solution (20 ml) of di-μ-chlorotetrakis(cyclooctene)diiridium(I) (0.50 g) was added an excess of triphenylarsine (1.25 g). This solution was stirred for 4–6 h whence an excess of appropriate substituted benzenethiol (1.0 g or 1.0 ml) was added. The reaction was allowed to proceed over a prolonged period of time (see Table 1). The cream-yellow product was then collected by filtration, washed with benzene, and dried *in vacuo* over boiling benzene overnight. Analytical data are given in Table 5.

Di-μ-arenethiolatotetrachlorotetrakis(triphenylphosphine)diiridium(III), $[IrCl_2(SC_6H_4NO_2)(Ph_3P)_2]_2$

To a degassed benzene solution (20 ml) containing chlorotris(triphenylphosphine)iridium(I) (0.50 g) was added 4-nitrobenzenethiol (0.25 g). The solution immediately changed color from orange to brick-red and was stirred for 12–24 h whence brick-red crystals precipitated upon the addition of ligroin (b.p. 63–75°; 50 ml). The crystals were then filtered, washed with ligroin and dried *in vacuo* at 25°. Yield = 0.33 g (71%). M.p. > 190° (dec.).

Anal. Calcd. for $C_{84}H_{68}Cl_4N_2O_8P_4S_2Ir_2$: C, 53.53; H, 3.62. Found: C, 52.91; H, 3.77.

Di-μ-arenethiolatotetrachlorotetrakis(triphenylarsine)diiridium(III), $[IrCl_2(SC_6H_4NO_2)(Ph_3As)_2]_2$

To a degassed benzene solution (20 ml) containing di-μ-chlorotetrakis(cyclooctene)diiridium(I) (0.50 g) was added an excess of triphenylarsine (1.25 g). This solution was then stirred for 4–6 h whence an excess of 4-nitrobenzenethiol (0.80 g) was added. The reaction was then allowed to proceed for 12–24 h after which time brick-red crystals precipitated upon the addition of ligroin (63–75°; 50 ml). The crystals were filtered, washed with ligroin, and dried *in vacuo* at 25°. Yield = 0.64 g (56%). M.p. > 145° (dec).

Anal. Calcd. for $C_{84}H_{68}Cl_4As_4N_2O_8S_2Ir_2$: C, 48.95, H, 3.30. Found: C, 49.82, H, 3.85.

trans-Dicarbonylbis(triphenylphosphine)iridium(I) Chloride, $[Ir(CO)_2(Ph_3P)_2]Cl$

This complex may be prepared starting with any complex **1**. A typical preparation is presented below.

Di-μ-(4-methoxybenzenethiolato)dihydridodichlorotetrakis(triphenylphosphine)diiridium(III) (0.50 g) was added to 100 ml of chloroform which was previously saturated with carbon monoxide. Carbon monoxide was then bubbled through the solution for 2–3 h. The volume of solution was then reduced to about 10–15 ml under reduced pressure at room temperature. Ligroin (b.p. 63–75°; 50 ml) was then added to precipitate the product as bright yellow crystals which were collected by filtration. The product was recrystallized from acetone–ligroin. Yield = 0.38 g (84%). M.p. 167–71° (dec.). Molar conductance of a 4.70×10^{-4} *M* solution in acetone at 25° was 54.7 ohm^{-1} cm^2 mol^{-1} and of a 3.47×10^{-4} *M* solution in nitromethane at 25° was 21.41 ohm^{-1} cm^2 mol^{-1}.

Anal. Calcd. for $C_{38}H_{30}ClP_2O_2Ir$: C, 56.45; H, 3.71; Cl, 4.38; Ir, 23.76. Found: C, 56.44; H, 4.60; Cl, 4.11; Ir, 24.65.

trans-Dicarbonylbis(triphenylarsine)iridium(I) Chloride, $[Ir(CO)_2(Ph_3As)_2]Cl$

This complex may be prepared using any complex **2** as starting material. The procedure followed to prepare this complex was essentially the same as that noted above for *trans*-$[Ir(CO)_2(Ph_3P)_2]Cl$. Yields were in the range 50–70%. M.p. 169–73° (dec.). Molar conductance of a 4.80×10^{-4} *M* solution in acetone at 25° was 46.9 ohm^{-1} cm^2 mol^{-1} and of a 4.69×10^{-4} *M* solution in nitromethane at 25° was 18.5 ohm^{-1} cm^2 mol^{-1}.

Anal. Calcd. for $C_{38}H_{30}As_2O_2Ir$: C, 50.89; H, 3.34; Cl, 4.02; Ir, 21.43. Found: C, 51.04; H, 3.72; Cl, 4.22; Ir, 22.50.

trans-Dicarbonylbis(triphenylphosphine)iridium(I)-tetraphenylborate, $[Ir(CO)_2(Ph_3P)_2](BPh_4).CH_2Cl_2$

A sample of *trans*-$[Ir(CO)_2(Ph_3P)_2]Cl$ (0.2 g) was dissolved in 10 ml of methylene chloride and 5 ml of methanol containing 0.1 g of sodium tetraphenylborate was added. The resulting solution was stirred at room tem-

For personal use only.

perature for 45 min whereupon it was filtered. The volume of filtrate was reduced under vacuum and an excess of methanol was added to precipitate the desired product as a yellow solid which was dried *in vacuo* at 25°.

Anal. Calcd. for $C_{63}H_{52}BCl_2O_2P_2Ir$: C, 64.27, H, 4.42. Found: C, 63.93, H, 4.64.

Physical Measurements

Infrared Spectra

These were recorded on a Beckman IR-12 spectrophotometer as Nujol mulls between NaCl or CsI plates in the region 4000–650 cm^{-1}. In the region 650–200 cm^{-1}, Nujol mulls between CsI or polyethylene plates were used. Solution spectra ($CHCl_3$) were recorded with 0.2 or 0.4 mm NaCl liquid cells. Sharp bands were scanned at 16 cm^{-1} min^{-1} and at about 25 cm^{-1} min^{-1} for all other bands.

^1H N.M.R. Spectra

These were recorded on a Varian HA100 spectrometer in $CDCl_3$ with tetramethylsilane as internal reference.

Conductivity Measurements

Electrical conductivities were measured at 25° with a Beckman Model RC-18H conductivity bridge using a glass cell with platinized electrodes (cell constant = 0.20 cm^{-1}).

Melting points were determined with a Fisher–Johns melting point apparatus and are uncorrected. Molecular weight measurements were performed on a Hitachi–Perkin Elmer 115 molecular weight apparatus, by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., or by the Alfred Bernhardt Microanalytical Laboratory, West Germany.

Raman Spectra of Hexagonal Ethylsulfates of Yttrium and of some Rare Earths[1]

G. SCHAACK[2] AND J. A. KONINGSTEIN

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received May 4, 1970[3]

The phonon Raman spectra of single crystals of $Y(C_2H_5SO_4)_3 \cdot 9H_2O$, $Ce(C_2H_5SO_4)_3 \cdot 9H_2O$, $Nd(C_2H_5SO_4)_3 \cdot 9H_2O$, $Sm(C_2H_5SO_4)_3 \cdot 9H_2O$ have been studied at low temperatures with laser excitation. Some information has also been obtained of the compounds of Ho^{3+} and Er^{3+}. The types of symmetry of the observed modes have been determined and compared with the results of a group theoretical calculation. The internal modes of the C_2H_5 and SO_4 groups and of the H_2O molecules can be completely attributed to observed transitions. There is some evidence to attribute the librational modes of the H_2O molecules to transitions which show a very pronounced temperature dependence of the line-widths. Reasons for this temperature dependence are discussed. No lines have been found that can be attributed uniquely to electronic transitions.

La spectrophonie Raman de monocristaux de $Y(C_2H_5SO_4)_3 \cdot 9H_2O$, $Ce(C_2H_5SO_4)_3 \cdot 9H_2O$, $Nd(C_2H_5SO_4)_3 \cdot 9H_2O$ et $Sm(C_2H_5SO_4)_3 \cdot 9H_2O$ a été étudiée à basse température par excitation laser. Des informations ont également été obtenues sur les composés de Ho^{3+} et Er^{3+}. Les types de symétrie des modes de vibration observés ont été déterminés et comparés avec les résultats du calcul théorique sur les groupes. Les modes de vibration internes des groupes C_2H_5, SO_4 et des molécules d'eau peuvent être complètement attribués aux transitions observées. L'attribution des modes de vibration des molécules d'eau a été prouvée d'une certaine façon par l'influence très prononcée de la température sur les largeurs des raies dont les causes ont été discutées. Il n'existe pas de raies qui ne soient uniquement attribuées aux transitions électroniques. [Traduit par le journal]

Can. J. Chem., 51, 1023 (1973)

Introduction

The rare-earth ethylsulfates $(M) \cdot (C_2H_5SO_4)_3 \cdot 9H_2O$, where M is one of the 14 rare-earth ions (R.E.) in the trivalent state or the yttrium ion, are an isomorphous series of crystals, which have attracted considerable interest for the studies of ions with an unfilled 4f shell in the crystalline matrix. In a series of investigations planned to study the electronic Raman scattering of low lying levels of the R.E. ions we have observed the Raman spectra due to the optical phonons of these crystals. The knowledge of these phonon levels is prerequisite for a study of electronic effects in these crystals, because both processes have scattering cross-sections of comparable magnitude and spectral lines between phonon or electronic levels have thus similar appearance (1). Information about the phonon levels is also needed for investigations on the 4f-electron–phonon interaction, especially for the interpretation of vibronic spectra (2).

In this paper we report on the Raman spectra of single crystals of yttrium ethylsulfate (Y-E.S.), Ce-E.S., Nd-E.S., Sm-E.S., Ho-E.S. and Er-E.S. Clear crystals (about $1.5 \times 1.0 \times 0.4$ cm^3) were grown from aqueous solutions at constant temperature. The well developed faces of the crystals were used to orient the cut and polished probes.

The Raman spectra of Nd-E.S., Sm-E.S., Ho-E.S., and Er-E.S. were excited with the 6328 Å radiation of a commercial He–Ne laser with a power of 80 mW, the spectra of Y-E.S. and of Ce-E.S. were studied with the 4880 or 5145 Å radiation of an Ar^+ laser (500 mW). The crystals were mounted on a cold-finger of a He research Dewar (3) or in the case of Ce-E.S. and Nd-E.S. immersed in superfluid helium at 2 K. A description of this second type of cryostat will be given elsewhere. Some samples were also studied at 77 and 300 K.

To discriminate between the three different types of Raman active transitions (see Structure), the plane of polarization of the incoming laser beam was rotated by means of half-wave plates and the scattered light analyzed in directions parallel and perpendicular to the Poynting vector of the laser beam under 90°-scattering geometry.
