The crystal structure of the R.E.-E.S. has been determined by X-ray methods (4, 5). The compounds crystallize in the space group C_{6h}^2 ($P6_3/m$) with 2 formula units per hexagonal unit cell. The R.E. ions have the site symmetry C_{3h} and 9 water molecules are the nearest neighbors. Six of them are situated above and below the mirror plane forming a trigonal prism and have a point symmetry C_1. The other three water molecules (C_s) are lying in this plane together with the three ethylsulfate groups (C_s), which fill the space between the metal-hydrate complexes.

In Table 1, results of the group theoretical calculations of the number and symmetry of

the optical phonons at zero wavevector are given. Here each molecule or molecular group is treated as a separate unit and the number and the symmetry of the internal and external (translational and librational) vibrations are tabulated together with the wavenumber region where the fundamental transitions are to be expected.

In the point group C_{6h} normal vibrations transforming according to the following irreducible representations are Raman-active: A_g ($\alpha_{xx} = \alpha_{yy},\alpha_{zz}$); $E_{1g}(\alpha_{xz},\alpha_{yz})$; $E_{2g}(\alpha_{xx} = \alpha_{yy},\alpha_{xy})$. The infrared active modes belong to $A_u(P_z)$ and $E_{1u}(P_x,P_y)$. The modes B_g, B_u, E_{2u} are optically inactive. In total, we should expect 35 A_g modes (20 + 15), 28 E_{1g} (13 + 15), 36 E_{1u} (20 + 16), 36 E_{2g} (20 + 16), and 28 E_{2u} (13 + 15) types of transitions including the two modes ($1A_u$, $1E_{1u}$) with zero frequency. The numbers in brackets give the internal and external modes, respectively. It must be emphasized, however, that the separation of the modes into internal and external motions of different molecules as in Table 1, is an enumeration of symmetry coordinates, the actual normal modes are a superposition of symmetry coordinates of equal species. The classification of the modes given in Table 1 is based on the following assumptions:

(*a*) The 6 water molecules with C_s symmetry are arranged in the unit cell with the plane of the molecules perpendicular to the mirror plane in the crystal. This arrangement gives plausible distances for H bonds to neighboring oxygen atoms (5) and is in agreement with intensity measurements of the Raman bands in the 3000 cm^{-1} region (6).

(*b*) The SO_4 and the C_2H_5 groups of the ethylsulfate complex can be treated as separate units, as far as their vibrational properties are concerned (6).

(*c*) The shell of 9 water molecules around a R.E. ion from a complex of coupled molecules. Accordingly, the translations and librations of the single H_2O molecules are coupled to form "internal" vibrations within this complex. The existence of such coupled modes in a tetrahedral arrangement of $4H_2O$ molecules has been demonstrated (7). In the present case, we can assume that the force constants acting on both the C_s and C_1 molecules are about the same. Values of the interatomic distances of the oxygen atoms in these complexes (5) indicate that the influence of ion–ion repulsion and alignment of the permanent dipole moment of the H_2O molecules in the central field of the R.E. ion and the strength of the H-bonds are very nearly the same for both types of molecules.

Spectra

Raman spectra of Y-E.S., Ce-E.S., and Nd-E.S. were studied in detail and the tensor components $z(xx)y$, $z(yx)y$, $z(xz)y$, and $x(zz)y$, $x(zx)y$, $x(yx)y$ were investigated (8). The A_g transitions can be observed in the (xx) and (zz) spectra, the E_{1g} modes in the (xz) spectra, the E_{2g} modes in the (xx) and (xy) spectra. In good samples, unique polarization properties were found, and a straightforward determination of the symmetry species was possible. Only the strong A_g transitions in the 700–1100 cm^{-1} region were present also in the (xy) and (xz) spectra (9), making the assignment of factor group split E_{2g} modes near the A_g modes somewhat uncertain. The region of the O—H and C—H stretching vibrations has been studied only for Y-E.S.

Similar experiments have been performed for Sm-E.S. However, due to electronic and vibronic transitions in this crystal, the scattered light was reabsorbed in broad wavenumber regions, leaving some unexplored gaps in the Raman spectrum. The same difficulties, on an extended scale, have been encountered for Ho-E.S. and Er-E.S. Symmetry species were not determined for phonons of these last two crystals. The symmetry of these observed phonons was found from a comparison of Raman lines of Y-E.S., Ce-E.S., and Nd-E.S. crystals of equal frequencies and similar shapes.

As an example of Raman spectra of R.E.-E.S. crystals, the spectrum of Ce-E.S. at 2 K is shown in Fig. 1. At room temperature (Fig. 2), the observed wavenumbers are shifted to lower values (2–5 cm^{-1}). A survey of the spectrum of Y-E.S. at 80 K between 2900 and 3500 cm^{-1}, the C—H— and O—H— valence region is depicted in Fig. 3. In Table 2, the wavenumbers observed at low temperatures and assignments are given. For completeness, the wavenumbers of the infrared active phonons of types A_u and E_{1u} are also included. The wavenumbers above 450 cm^{-1} were taken from ref. 6 (values of La-E.S.), the wavenumbers below 380 cm^{-1} are the values of Hill and Wheeler (10) for La-E.S., Sm-E.S., and Er-E.S., taken at helium temper-

*The wavenumbers in parentheses are infrared data on La-E.S. (in this table cited in the column of Nd-E.S.) and on Sm-E.S. and Er-E.S. (6, 10). For Ho-E.S. the following Raman shifts have been observed: 41, 66, 93, 115 cm^{-1}. s = strong, sh = shoulder, comb = combination. The horizontal lines in this table separate the wavenumber-regions according to the different origin of the modes: external modes, internal modes of the C_2H_5 and SO_4 groups and of the H_2O molecules.

ature. Assignments were not offered by these authors for the phonon spectrum.

It is seen from Tables 1 and 2 that good agreement exists between the numbers of expected and observed modes. There are $3A'$ and $2A''$ modes of the C_2H_5-group in the site-symmetry C_s in both the regions of C—H valence and deformation vibrations, although the factor group splitting is in some cases not fully resolved. In the region of the C—C vibrations, $3A'$ and $2A''$ modes are observed. Another mode $A_g + E_{2g}$ at 1114 cm^{-1} may be interpreted

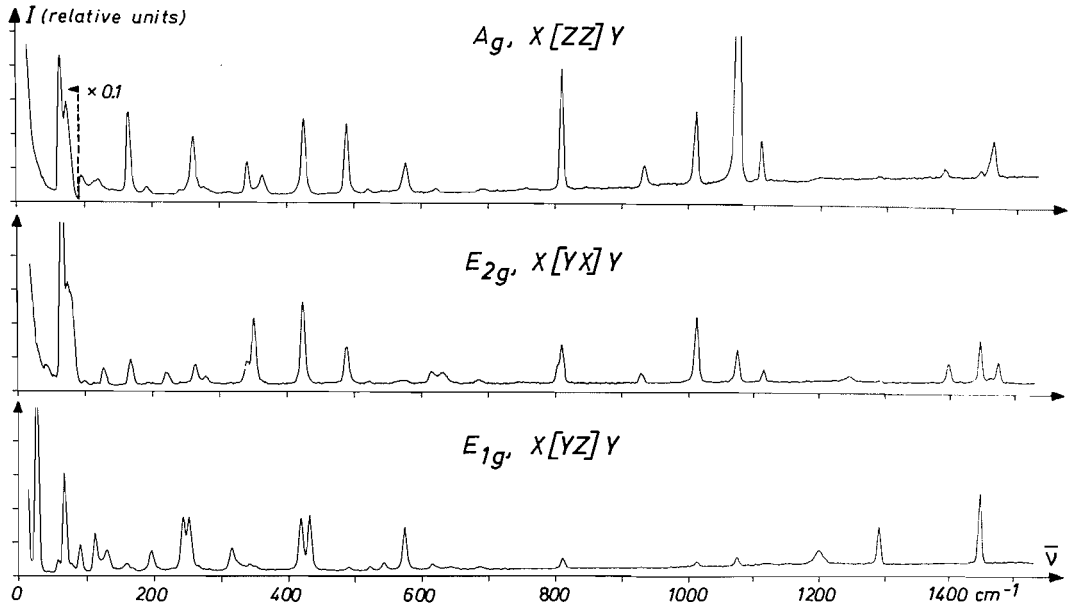

FIG. 1. Raman spectrum of Cerium-ethylsulfate at $T = 2$ K below 1500 cm^{-1}. Excitation wavelength $\lambda =$ 5145 Å, speed: 50 cm^{-1} min^{-1}, slits: 3.5 cm^{-1}. The spectrum has not been corrected for the wavelength dependent sensitivity of the photo-cathode (S 20) or the grating efficiency.

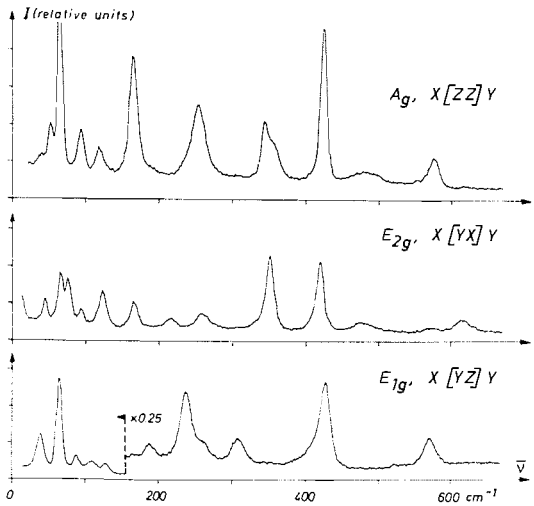

FIG. 2. Raman spectrum of Ce-E.S. below 600 cm^{-1} at $T = 300$ K. Other conditions same as in Fig. 1.

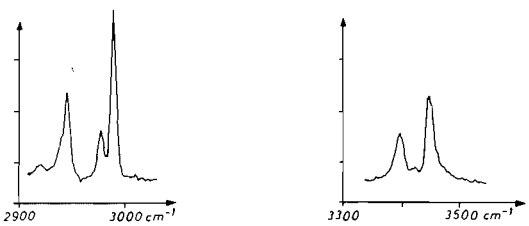

FIG. 3. Raman spectrum of Y.-E.S. at $T = 77$ K, region of O—H and C—H valence vibrations. The spectrum is a superposition of $z(yx)y$ and $z(yz)y$ ($E_{1g} + E_{2g}$).

as a combination of the very strong Raman active mode at 1073 cm^{-1} (ν_1 of SO_4) with the strong external (A_g,E_{2g}) mode at 43 cm^{-1}. In the region of the very broad O—H-transitions at 3000 cm^{-1}, reliable assignments of the observed bands to molecules with C_1 and C_s site symmetry cannot be given here. Transitions were not found in the region where O—H deformation vibrations are normally observed.

Below 800 cm^{-1} the external lattice modes are to be expected, together with the internal ν_2 and ν_3 modes of the SO_4 group. Not taking the latter into account, $15A_g$, $15E_{1g}$, and $16E_{2g}$ modes have been observed. From Table 1 we expect exactly these numbers. For this comparison, some weak and questionable bands which have been put into brackets in Table 2 have not been counted. Some may be due to electronic effects (see below), others may be due to second-order transitions or due to fluorescence from other rare-earth impurities. For the infrared active modes, the agreement between the calculated and observed number of modes is less satisfying. Twenty modes have been observed, while 32 were expected ($16A_u + 16E_{1u}$). However, the

infrared spectrum between 360 and 490 cm^{-1} is still unknown, and the wavenumber region above 500 cm^{-1} has been studied only in reflection where weak transitions were not detected.

There does not seem to be a direct correspondence between the phonon wavenumbers given here and the wavenumbers derived by Wong and Erath (2) from vibronic transitions of different R.E.-E.S. spectra. The frequencies of the latter were determined by the maxima of the density of phonon states at certain wavevectors ($\boldsymbol{k} > 0$) in the Brillouin zone. Due to the $\boldsymbol{k}$-dispersion of the external phonons, only in a few cases (determined by selection rules) will the wavenumbers of these maxima coincide with the values observed here for $\boldsymbol{k} = 0$. There is, however, some correspondence in both cases concerning the number of phonon frequencies within a certain interval. Both methods give a slowly decreasing "density of observed phonon levels" with increasing wavenumbers from 20 to 250 cm^{-1}.

Discussion

The internal vibrations of the C_2H_5-group, the SO_4-group and the water molecules have been discussed in ref. 6. Our present investigation fully supports the earlier assignments and conclusions. Here we treat the low frequency modes. Unfortunately, due to the complicated structure, only a few qualitative remarks can be made.

As a general experience in hydrated crystals, vibrations consisting predominantly of translations of the water molecules are found between 1000 and 350 cm^{-1}. In the ($Be \cdot 4H_2O$) complex (7) molecular motions of this type have been identified between 1014 and 488 cm^{-1}. If the same relative frequency spread is assumed for the ($R.E. \cdot 9H_2O$) system, corresponding modes should be expected between 750 and 350 cm^{-1}.[4] In this region $5A_g$, $4E_{1g}$, $4E_{2g}$ modes are observed, while $5A_g$, $4E_{1g}$, and $5E_{2g}$ modes are calculated (Table 1).[5] As a consequence, there is some reason to interpret the lines observed in this region as mainly due to translatory motions of the water molecules.

Enumerating these observed modes, the levels at 620 and 420 cm^{-1} (ν_2 and ν_4 of SO_4) have not been counted as well as the group of 3 levels at 490 cm^{-1}. This latter group we assign to librations of the H_2O molecules around the axis of the smallest moment of inertia (Fig. 4). There are several reasons for this assignment:

(*a*) Usually, because of the weak interaction of librating molecules within a metal hydrate complex, the correlation splitting is small (7). This is observed for the group at 490 cm^{-1} (LI), where the splitting between the 3 modes with different symmetry is within the precision of the measurements.

(*b*) There are two other groups of levels in the spectrum at 340 cm^{-1} (LII) and at 270 cm^{-1} (LIII) demonstrating the same features. These are assigned to the librations around axes II and III (Fig. 4).

The three frequencies ω_I, ω_{II}, and ω_{III} roughly obey the relation: $\omega_I^2 : \omega_{II}^2 : \omega_{III}^2 = \theta_I^{-1} : \theta_{II}^{-1} : \theta_{III}^{-1}$, where θ_I, θ_{II}, θ_{III} are the moments of inertia (e.g. ref. 11). Consequently, the potential well is about the same for the three librational motions.

(*c*) The H_2O molecule has a permanent intrinsic electric dipole moment parallel to the symmetry axis of the molecule. This dipole moment gives rise to strong infrared active transitions coupled with the librations around the axes I and III, while librations around axis

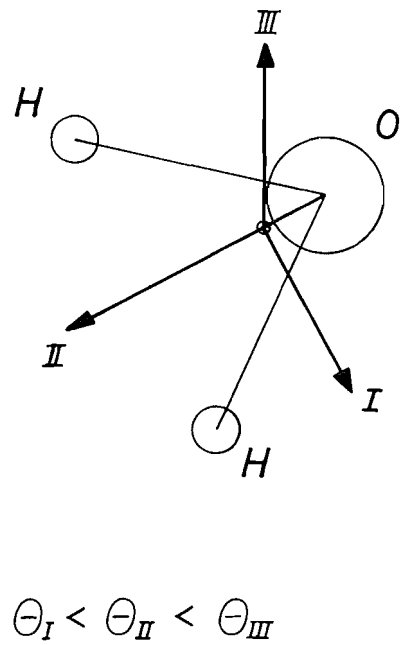

FIG. 4. Water molecule and the orientation of the axis of inertia. θ: moment of inertia.

[4]The region of the internal vibrations of the C_2H_5 group starts at 750 cm^{-1}.

[5]The missing E_{2g} mode might be the one at 804 cm^{-1} in Ce-E.S. This mode does not belong to the internal modes of the C_2H_5 group.

II remain infrared inactive in accordance with the observations.

(*d*) A strong temperature dependence of the line-width is generally encountered in low frequency levels of hydrated crystals. The two groups at 270 cm^{-1} (LIII) and at 490 cm^{-1} (LI) show an extraordinarily strong temperature dependence of the Raman line-width (Table 3) and Fig. 2. In the room temperature spectra, these groups are extremely broad and some components are barely visible. The group at 340 cm^{-1} (LII) has a smaller temperature dependence than the groups LI and LIII. The reason for this behavior of LII may be related to the fact that neither the O atom nor the electric dipole moment participate in this motion.

As is demonstrated in Table 3 and in Fig. 2, the temperature dependence of the line-widths is small in the region of the internal modes ($\nu > 800\ cm^{-1}$) and in the region of the modes at very low wavenumbers ($\nu < 100\ cm^{-1}$, translations of entire groups (SO_4, C_2H_5, R.E.)) (Table 3). In the region within these limits there is a considerable broadening with increasing temperature with a maximum effect occurring in the groups assigned to LI and LIII. In the case of the ($Be{\cdot}4H_2O$) complex (7), it was observed that translational motions of this complex are strongly coupled (mixed) with librations, while there exist pure librational modes with essentially no admixture of translations. There are good reasons to assume that this behavior is not a special property of the ($Be{\cdot}4H_2O$) tetrahedron, but is more generally encountered. Therefore, we can attribute the strong temperature effect for wavenumbers 100 $cm^{-1} < \nu < 800\ cm^{-1}$ to an admixture of librational motions of the water molecules with all the other modes of the crystal of appropriate symmetry in this region. The behavior of the librational modes can be understood by considering two possibilities:

(*1*) a potential of the librations that is more anharmonic than the potential of translational motions; or

(*2*) the potential energy of a librating H_2O molecule is strongly dependent on the metal–oxygen distance. Consequently, the thermal excitation of translatory motions at elevated temperatures will change, and in general reduce, this potential energy and lower the frequency of the librations of H_2O molecules in a thermally excited translatory state. Accordingly, the librational bands will spread with increasing temperature.

It is evident that more work has to be done to clarify this situation.

One of the motives of this investigation was to observe phonons that involve the translational motions of the R.E. ions. An assignment of these motions, which is of interest for crystal-field considerations, could be achieved in the case of the R.E. garnets (1) with the help of a mass dependent frequency shift. Such a shift can be expected in the Raman active irreducible representation containing these translations

(Table 1*b*). Unfortunately, this shift is completely masked by a frequency shift of all modes due to changes in the dimensions of the unit cell (5).

Electronic Effects

A search for electronic Raman transitions in the R.E.-E.S. crystals yielded no unique results even at temperatures of 2 K. There are weak bands observed in the expected wavenumber regions; however, the interpretation of these bands, mentioned above, is ambiguous. They are usually one or two orders of magnitude weaker in intensity than the neighboring phonon transitions. The application of a strong external magnetic field would be very helpful to identify these weak transitions. A careful search in the region of the excited multiplet components $2F_{7/2}$ of Ce^{3+} near 2200 cm^{-1} and $4I_{11/2}$ of Nd^{3+} near 2000 cm^{-1} also had only negative results. This finding is unexpected because in $CeCl_3$ (12, 13) most electronic transitions are easily detected. The density per unit volume of scattering R.E.-ions is higher by a factor of 5.8 in the hexagonal R.E.-chlorides than in the R.E.-E.S., but even this factor does not explain the extraordinary weak signals due to electronic effects. One has to consider however, the fact that the states of the 4f"-configuration have, on the average, larger widths in the R.E.-E.S. than in the chlorides due to the presence of phonons with much higher energy in the former crystal. The existence of such a direct coupling between the 4f electrons and the phonons has been demonstrated by the anomalous specific heat of Ce-E.S. near 3 K (14) which is found to be larger than the Schottky-type anomaly expected, due to the first excited Kramers-doublet at 4.7 cm^{-1} above the ground level of the Ce^{3+} ion. This anomaly was successfully calculated (15) by assuming an interaction between this excited electronic level and the acoustic phonons.

It will be the object of a further study to see if the surprising differences in frequencies and relative intensities of the low-lying optical phonons ($\nu < 100$ cm^{-1}) in Ce-E.S. between room temperature and 2 K (see Figs. 1 and 2) are due to a similar electron–phonon coupling mechanism. In Nd-E.S., where the first excited Kramers doublet is at 149.4 cm^{-1} (16), and in Y-E.S., the differences between room temperature and low temperature spectra are much less pronounced than in Ce-E.S.

Conclusions

The optically active phonon frequencies for this important crystalline matrix are now well known except for a small gap in the infrared spectrum. For a study of electronic Raman spectra, this matrix may offer some advantages: there are wavenumber regions free of phonon lines (1500 $cm^{-1} < \nu < 2900$ cm^{-1}; $\nu > 3500$ cm^{-1}) which are well suited for studies of $\Delta J = 1$ transitions of the Ce^{3+}, Pr^{3+}, Nd^{3+}, and Tb^{3+} ions. On the other hand, the large number of phonon levels may facilitate a study of an interaction between 4f electrons and resonant phonons.

Solid–Liquid Phase Equilibria for the Ternary Systems V_2O_5–Na_2O–Fe_2O_3, V_2O_5–Na_2O–Cr_2O_3, and V_2O_5–Na_2O–MgO

Received June 1, 1972

The phase equilibrium relationships of several vanadate systems have been studied by a combination of differential thermal analysis (DTA) and X-ray powder diffraction methods. All systems studied were eutectic in nature. The liquidus temperatures of the sodium vanadates were found to depend on the oxygen partial pressure for sodium oxide concentrations between 1.0 and 36 mol%. This effect was not observed for the ferric vanadate, chromic vanadate or magnesium vanadate systems. The solid–liquid phase equilibria for the ternary vanadate systems V_2O_5–Na_2O–Fe_2O_3, V_2O_5–Na_2O–Cr_2O_3, and V_2O_5–Na_2O–MgO were measured by determining the temperature–composition data for various quasi-binary systems within each ternary system. Liquidus temperatures between 500 and 700 °C were found for those compositional ranges containing greater than 40 mol% V_2O_5 and between 10 and 60 mol% Na_2O. The liquidus temperatures decreased with increasing oxygen partial pressure over much of the same compositional range.

Les relations d'équilibre de phases de plusieurs systèmes impliquant des vanadates ont été étudiées par combinaison de deux méthodes à savoir l'analyse thermale différentielle et la diffraction de rayons-X (poudre). Tous les systèmes qui furent étudiés, étaient du type eutectique. Les températures liquidus des vanadates de sodium se sont révélées dépendantes de la pression partielle de l'oxygène pour des concentrations d'oxyde de sodium dans l'intervalle compris entre 1.0 et 36 mol%. Cet effet ne fut pas observé pour les systèmes de vanadate ferrique, de vanadate chromique et de vanadate de magnésium. Les équilibres de phase solide–liquide pour les systèmes ternaires de vanadates, V_2O_5–Na_2O–Fe_2O_3, V_2O_5–Na_2O–Cn_2O_3 et V_2O_5–Na_2O–MgO, ont été mesurés en déterminant des données sur la température et la composition pour des systèmes presque binaires à l'intérieur de chacun des systèmes ternaires. Les températures liquidus entre 500 et 700 °C ont été trouvées pour les domaines de composition comprenant plus que 40 mol% en V_2O_5 et entre 10 et 60 mol% en Na_2O. Les températures liquidus diminuent si la pression partielle de l'oxygène augmente et ce, pour la plupart des domaines similaires de composition. [Traduit par le journal]

Introduction

The use of residual fuel oils of high vanadium and sodium contents (100 p.p.m.) as a low-cost fuel for power generation can often lead to severe corrosion problems (1). Particularly severe corrosion occurs on metal and refractory components which have been in direct contact with hot (>500 °C) fly ash deposits (2). This form of corrosion is often called "catastrophic" vanadate corrosion and is considered to be due to the presence of liquid vanadates in the fly ash deposits. The liquid vanadates are thought to increase the corrosion rate by fluxing or altering the normally protective oxide layers present on the surface of the alloys and by providing a source of oxide ion for the corrosion reaction (1).

Several vanadates are commonly found in the fly ash deposits which exhibit severe corrosion characteristics (3). The liquid sodium vanadates centering about the composition $Na_2O{\cdot}6V_2O_5$ are considered to be the most corrosive (4, 5). Ferric vanadates and chromic vanadates are often present in the fly ash deposits as corrosion products. The presence of magnesium vanadates is caused by magnesium-based additives in the fuel oil for controlling corrosion (6).

A number of phase studies have been made on the system V_2O_5–Na_2O. The solid–liquid phase equilibria have been examined by Canneri (7), Illarionov *et al.* (8), and Slobodin *et al.* (9). The meta-, pyro-, and ortho-vanadates were shown to be present, but there were some discrepencies in the reported melting points. Oxygen was evolved on freezing at compositions between 1 and 32 mol% sodium oxide, with the formation of vanadyl vanadates or sodium vanadium

"bronzes" (7, 10). These compounds have been the subject of a number of investigations because of their semiconducting properties (11, 12). Phases which have been identified include Na_x-V_2O_5, where $0.1 < x < 0.67$, and $Na_{1+y}V_3O_8$, where $0.0 < y < 0.8$ (13–15).

The systems V_2O_5–Fe_2O_3 and V_2O_5–Cr_2O_3 have been reported by Burdese (16) to exhibit eutectic melting together with the formation of the incongruently melting compounds $FeVO_4$ and $CrVO_4$. A miscibility gap has been reported for the system V_2O_5–Fe_2O_3 (17). The eutectic system V_2O_5–MgO was reported to contain the incongruently melting compounds: MgV_2O_6, $Mg_2V_2O_7$, $Mg_3(VO_4)_2$, and $Mg_3V_4O_{13}$ (18–20). The crystal structures of $FeVO_4$ (21), $CrVO_4$ (22), and $Mg_3(VO_4)_2$ (23) have been determined.

Because catastrophic vanadate corrosion is dependent on the presence of liquid vanadates in the fly ash deposits, it is important to have accurate data on the temperature–oxygen partial pressure–compositional ranges in which the liquid vanadates can occur. The solid–liquid phase equilibria of several vanadate systems have been determined.

Experimental

The liquidus and solidus lines of the vanadate systems were determined using differential thermal analysis (DTA). The samples were contained in 6 mm i.d. Vycor tubes open at one end. The sample tubes were contained in an Inconel 600 block, and chromel–alumel reference and sample thermocouples were placed next to the Vycor tubes. The melts were too corrosive to allow the thermocouples to be placed in the melts. A limited amount of attack of the Vycor tubes was observed when the melts contained more than 50 mol% sodium oxide (1). The samples and sample holder were enclosed in a gas-tight Vycor tube, allowing the oxygen partial pressures over the melt to be accurately controlled. High purity oxygen and argon were used to give controlled atmospheres above the melt. Reagent grade vanadium pentoxide, sodium carbonate, ferric oxide, chromic oxide, and magnesium oxide were used to prepare the vanadate mixtures. Johnson and Matthey "specpure" vanadium pentoxide was used to provide a temperature calibration standard.

A programmed rate of 10 deg per min was used for the DTA experiments. The sample was heated and cooled several times. The peak temperatures obtained from the heating DTA curves were used to plot the phase diagrams. Several temperature calibration experiments using high-purity lead and silver indicated that the temperature measurements were accurate to within ± 2 °C. "Specpure" vanadium pentoxide (m.p. 670 $\pm$ 2 °C) was used to provide a temperature calibration standard for every sample run. Powder diffraction spectra were made on selected air-quenched samples using a Norelco X-ray diffractiometer and zirconium-filtered molybdenum radiation.

Results

The System V_2O_5–Na_2O

The measured phase diagram of the system V_2O_5–Na_2O is shown in Fig. 1. The oxygen partial pressure was found to have a significant effect on the melting points for compositions between 1 and 36 mol% Na_2O; *i.e.*, for the sodium–vanadium bronzes. The sodium–vanadium bronzes lose oxygen on freezing (10):

$$[1]\quad Na_2O{\cdot}6V_2O_5(l) \rightleftharpoons Na_2O{\cdot}xV_2O_4{\cdot}(6-x)V_2O_5 + (x/2)O_2(g)$$

so that a change in oxygen partial pressure would be expected to change the composition of the solid. This was verified experimentally (Fig. 2) by measuring the weight change of the sodium vanadates as they were cooled under various oxygen partial pressures. As would be expected the V^{4+} ion concentration, as determined from the weight change, increased as the oxygen partial pressure was decreased. The melting points of these sodium vanadates increased initially as the oxygen partial pressure was decreased, but the melting point remained constant for oxygen partial pressures less than 0.2 atm (Fig. 3). The phase relationships shown in the quasi-binary phase diagram of Fig. 1 can also be represented as a portion of the ternary phase system V_2O_5–Na_2O–V_2O_4.

Five compounds, $Na_2O{\cdot}xV_2O_4{\cdot}(6-x)V_2O_5$, $5Na_2O{\cdot}xV_2O_4{\cdot}(12-x)V_2O_5$, $Na_2O{\cdot}V_2O_5$ or $NaVO_3$, $2Na_2O{\cdot}V_2O_5$, and $3Na_2O{\cdot}V_2O_5$ or Na_3VO_4, were identified by X-ray powder diffraction methods, using previously reported spectral data (24–26). No significant differences

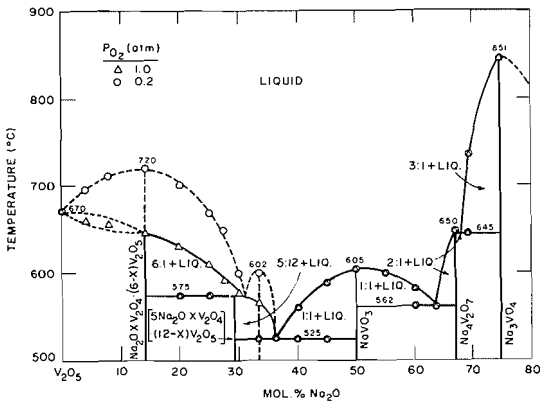

FIG. 1. The V_2O_5–Na_2O phase diagram at two oxygen partial pressures.

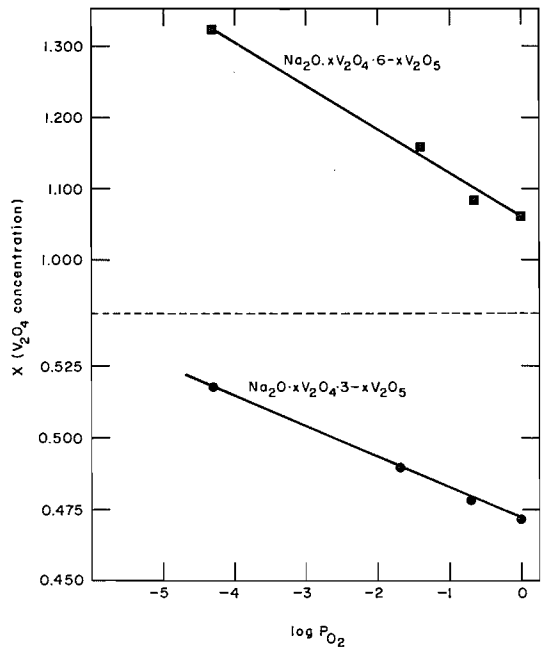

FIG. 2. Change in composition with oxygen partial pressure on freezing of the sodium vanadates $Na_2O \cdot xV_2O_4 \cdot (6 - x)V_2O_5$ and $Na_2O \cdot xV_2O_4 \cdot (3 - x)V_2O_5$.

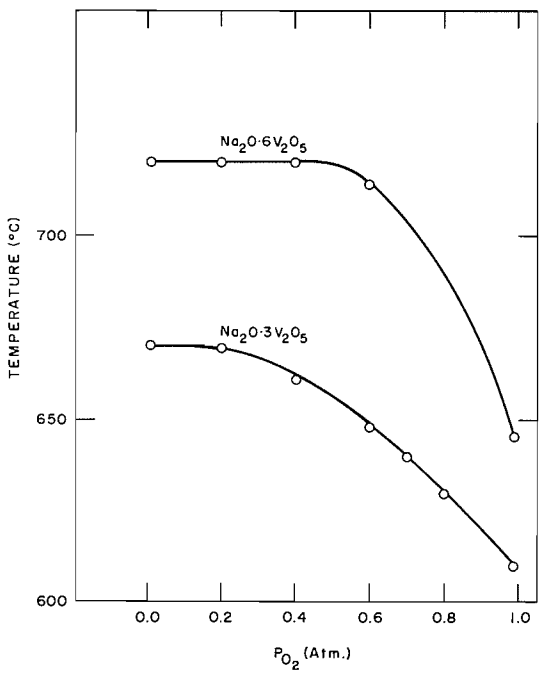

FIG. 3. The dependence of the melting point of the sodium vanadates $Na_2O \cdot xV_2O_4 \cdot (6 - x)V_2O_5$ and $Na_2O \cdot xV_2O_4 \cdot (3 - x)V_2O_5$ on the oxygen partial pressure.

in the X-ray diffraction spectra of the same vanadates frozen under various oxygen partial pressures were observed. The compositions and temperatures of the three eutectics and one peritectic are reported in Table 1. The differences in the previously reported phase diagrams (7–9) are at least partially due to the effect that oxygen partial pressure has on the liquidus points in the composition range of the sodium–vanadium bronzes. The lack of a clearly defined eutectic between the compounds V_2O_5 and $Na_2O \cdot xV_2O_4 \cdot (6 - x)V_2O_5$ probably indicates considerable solid solubility.

The System V_2O_5–Na_2O–Fe_2O_3

No effect of oxygen partial pressure on the melting temperatures was found for the system V_2O_5–Fe_2O_3 (Fig. 4). The orthovanadate, $Fe_2O_3 \cdot V_2O_5$ or $FeVO_4$, was identified by X-ray powder diffraction methods, using previously reported spectral data (27). No evidence was found for the existence of the metavanadate, $Fe_2O_3 \cdot 3V_2O_5$ or $Fe(VO_3)_3$, the pyrovanadate, $2Fe_2O_3 \cdot 3V_2O_5$ or $Fe_4(V_2O_7)_3$, or the previously reported compound $Fe_2O_3 \cdot 2V_2O_5$ (28). The compositions and temperatures of the two eutectics and the peritectic are reported in Table 1. Both the eutectic temperature (645 °C) and the peritectic temperature (870 °C) were higher than the eutectic temperature (635 °C) and peritectic temperature (840 °C) reported by Burdese (16). A liquid–liquid miscibility gap was found in the compositional region about $FeVO_4$, which is in agreement with data reported by Schlapfer *et al.* (17).

The liquidus phase diagram of the ternary system V_2O_5–Na_2O–Fe_2O_3 (Fig. 5) at an oxygen partial pressure of 1 atm was measured by deter-

mining the temperature–composition data for the following quasi-binary systems; V_2O_5–($Na_2O{\cdot}Fe_2O_3$), V_2O_5–($2Fe_2O_3{\cdot}Na_2O$), and Na_2O–($FeVO_4$). The data for these systems have been submitted to the Depository of Unpublished Data.[1] The temperatures and approximate compositions of three eutectic points and peritectic points found in the ternary system were determined separately and are reported in Table 1. A previous study of a portion of this ternary system has shown that the iron vanadate, $FeVO_4$, and sodium vanadium bronzes exist over a wide concentration range (29). The partial solution of V_2O_5 in Fe_2O_3 was also found.

The vanadium pentoxide-rich portion of the ternary system had melting points less than

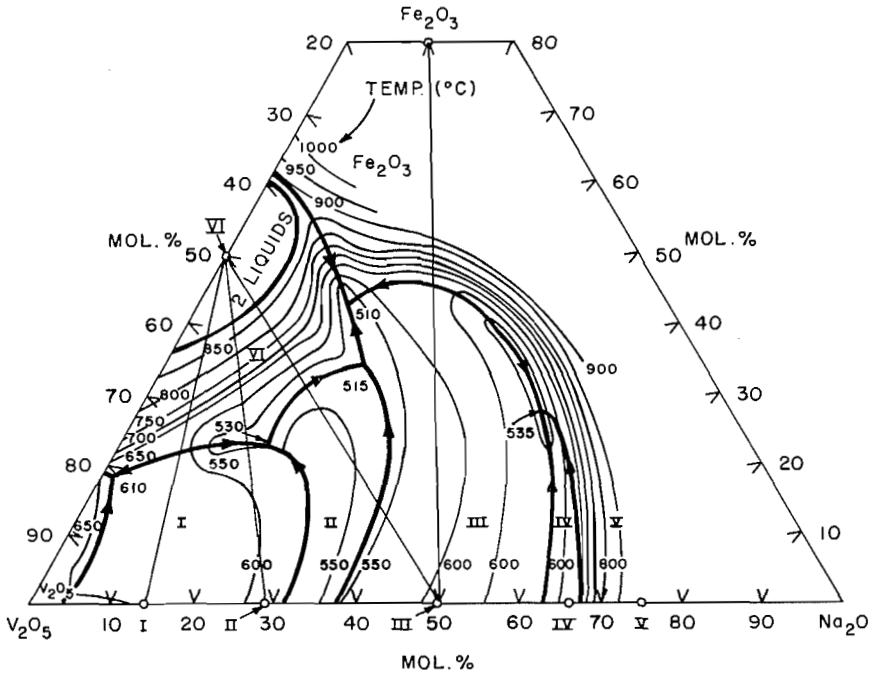

FIG. 5. Proposed ternary phase diagram V_2O_5–Na_2O–Fe_2O_3. Binary phase compositions: I = $Na_2O{\cdot}xV_2O_4{\cdot}(6 - x)V_2O_5$, II = $5Na_2O{\cdot}xV_2O_4{\cdot}(12 - x)V_2O_5$, III = $NaVO_3$, IV = $Na_4V_2O_7$, V = Na_3VO_4, VI = $FeVO_4$.

700 °C. Much of this same region also showed an increase in the temperature of the liquidus with a decrease in oxygen partial pressure, although the maximum liquidus points observed were still less than 720 °C (Fig. 6).

The System V_2O_5–Na_2O–Cr_2O_3

The phase diagram for the system V_2O_5–Cr_2O_3 is given in Fig. 7. The melting points were found to be independent of oxygen partial pressure. The compound $CrVO_4$ was identified from published X-ray diffraction data (30). No evidence was found for the existence of the metavanadate or the pyrovanadate (31, 32). The compositions and temperatures of the eutectic and peritectic are reported in Table 1. The peritectic temperature of 902 °C which was observed in the present work agrees more closely with the temperature 907 °C reported by Lucas *et al.* (33) than with the temperatures 810 °C and 886 °C reported by Burdese (16) and Amiel *et al.* (34), respectively. An eutectic temperature of 655 °C was found in this work. Amiel *et al.* (34) reported an eutectic temperature of 650 °C and Burdese (16) found the eutectic temperature to be 665 °C.

The liquidus phase diagram of the ternary system V_2O_5–Na_2O–Cr_2O_3 (Fig. 8) at an oxygen partial pressure of 1 atm was measured by determining the temperature–composition data for

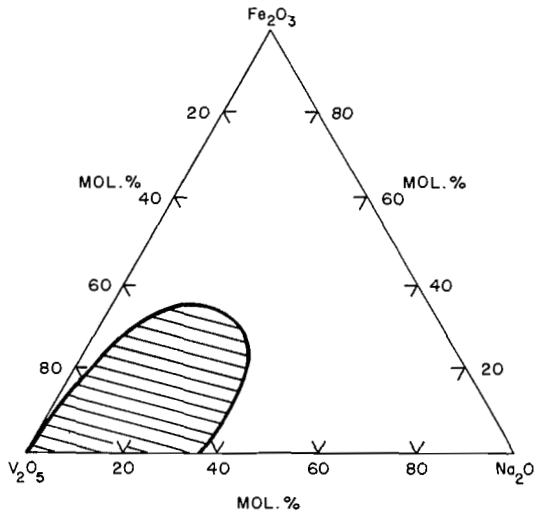

FIG. 6. Region of V_2O_5–Na_2O–Fe_2O_3 phase system which shows a change in melting point with oxygen partial pressure (shaded portion).

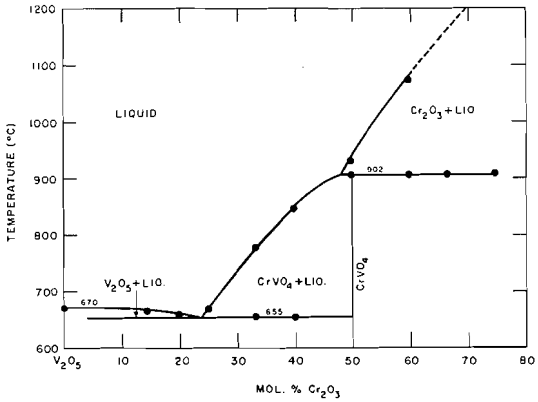

FIG. 7. The V_2O_5–Cr_2O_3 phase diagram.

the following quasi-binary systems: V_2O_5–($Cr_2O_3 \cdot 2Na_2O$), V_2O_5–($Cr_2O_3 \cdot Na_2O$), and V_2O_5–($2Cr_2O_3 \cdot Na_2O$). The data for these systems have been submitted to the Depository of Unpublished Data. The temperatures and approximate compositions of the four eutectic points and one peritectic point found in the ternary system were determined separately and are reported in Table 1.

Chromic oxide (Cr_2O_3) was found over a wider concentration range in this system than the other ternary systems. The portion of the vanadium pentoxide-rich section of the phase diagram in which the liquidus temperatures were less than 700 °C was less extensive than that found for the other ternary systems. However, the portion of the diagram in which the temperature of the liquidus was affected by the oxygen partial pressure was found to be much the same (Fig. 6).

The System V_2O_5–Na_2O–MgO

The phase diagram for the system V_2O_5–MgO is shown in Fig. 9. The oxygen partial pressures were found to have no effect on the liquidus temperatures. The metavanadate, $MgO \cdot V_2O$ or $MgVO_3$, the pyrovanadate, $2MgO \cdot V_2O_5$, and the orthovanadate, $3MgO \cdot V_2O_5$, were identified by X-ray powder diffraction methods, using previously reported spectral data (35–37).

A fourth compound, $2MgO \cdot 3V_2O_5$, was identified and the spectral data are reported in Table 2. This compound appears to be the stoichiometric equivalent of the oxygen-deficient compound α-MgV_3O_8 or $2MgO \cdot V_2O_4 \cdot 2V_2O_5$, which was prepared by Galy and Pouchard (35) under reducing conditions. The compound $3MgO \cdot 2V_2O_5$ has been reported (20, 38) but it was not identi-

fied in these studies. The eutectic nature of the magnesium vanadate system as shown in Fig. 6 agrees in general with that reported by Pollard (18), Kohlmuller and Perraud (19), and Speranskaya (20), although there are some discrepencies in the eutectic and peritectic temperatures. All of the magnesium vanadates except the orthovanadate, $Mg_3(VO_4)_2$, were found to melt incongruently.

The liquidus phase diagram of the ternary system V_2O_5–Na_2O–MgO (Fig. 10) at an oxygen partial pressure of 1 atm was measured by determining the temperature–composition data for the following quasi-binary systems: V_2O_5–$(2MgO{\cdot}Na_2O)$, V_2O_5–$(MgO{\cdot}Na_2O)$, and V_2O_5–$(2Na_2O{\cdot}MgO)$. The data for these systems have been submitted to the Depository of Unpublished Data. The temperatures and approximate compositions of the two eutectic points and six peritectic points found in the ternary system were determined separately and are reported in Table 1.

The vanadium pentoxide-rich portion of the phase diagram in which the liquidus temperature was less than 700 °C was more extensive than for either system previously shown. The portion of the phase diagram in which the temperature of the liquidus was affected by the oxygen partial pressure was much the same as that indicated for the two previous systems (Fig. 6).

Discussion

An interesting aspect of the vanadate systems examined in this report is the effect that oxygen partial pressure has on the liquidus temperatures when concentrations of 1 to 36 mol% sodium oxide are present. A number of vanadates containing 1 to 32 mol% of the univalent cation lose oxygen on freezing to form nonstoichiometric oxides (7), and can be represented as:

$$[2]\quad M_2O{\cdot}xV_2O_5(l) \rightleftharpoons M_2O{\cdot}yV_2O_4{\cdot}(x-y)V_2O_5 + (y/2)O_2$$

where $M_2O{\cdot}yV_2O_4{\cdot}(x-y)V_2O_5$ is often called a vanadate "bronze". These vanadate "bronzes" are frequently semiconducting and include the sodium, lithium, potassium (39), silver, and cuprous vanadates (40). The loss of oxygen is usually credited to the stabilizing influence of the lattice structure of solid V_2O_5, so that the compounds can often be formulated as $M_xV_2O_5$ (13–15). For example, the sodium ions in the sodium vanadates are considered to be situated in "tunnels" in the V_2O_5 lattice. Vanadate bronzes can also be formed with multivalent cations if highly reducing conditions are used (35, 41, 42).

As the oxygen partial pressure over the freezing sodium vanadates was reduced, there was an increase in the V^{4+} ion concentration, in the oxygen vacancy concentration of the solid sodium vanadates, and in the liquidus temperature. However, at still lower oxygen partial pressures (less than 0.2 atm), the V^{4+} ion concentration continued to increase, but the liquidus temperature remained constant. The eutectic points were not affected by the oxygen partial pressure. The increase in V^{4+} ion concentration apparently stabilized the compound $Na_2O{\cdot}xV_2O_4{\cdot}(6-x)$-$V_2O_5$, resulting in an increase in its melting point from 645 to 720 °C. The sodium vanadate

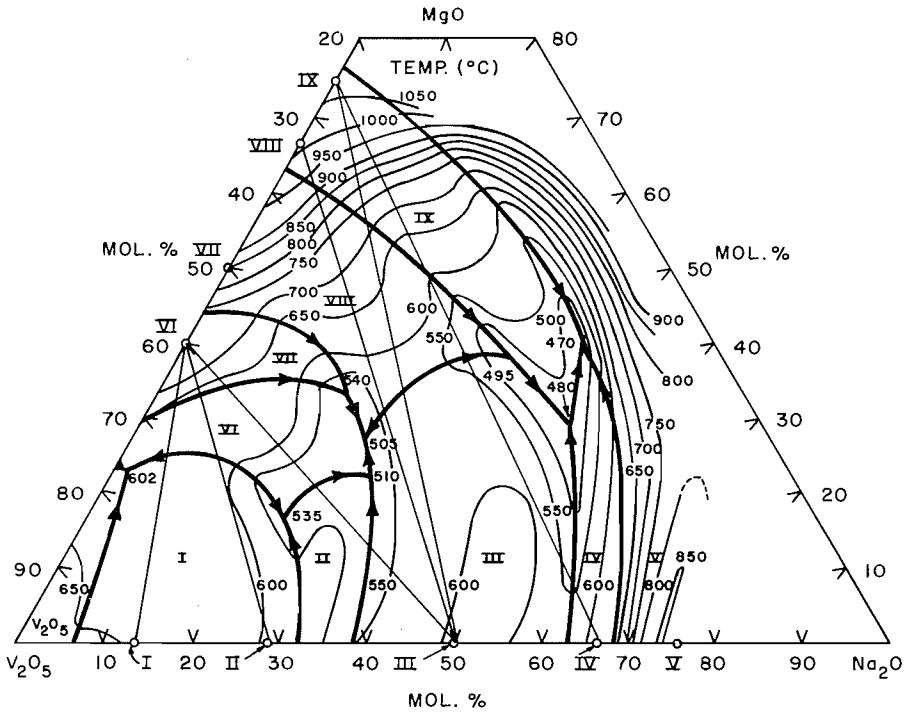

FIG. 10. Proposed ternary phase diagram V_2O_5–Na_2O–MgO. Binary phase compositions: I = $Na_2O{\cdot}xV_2O_4{\cdot}(6 - x)V_2O_5$, II = $5Na_2O{\cdot}xV_2O_4{\cdot}(12 - x)V_2O_5$, III = $NaVO_3$, IV = $Na_4V_2O_7$, V = Na_3VO_4, VI = $Mg_2V_6O_{17}$, VII = MgV_2O_6, VIII = $Mg_2V_2O_7$, IX = $Mg_3(VO_4)_2$.

phase diagram (Fig. 1) also appeared to indicate that the compound $Na_2O{\cdot}xV_2O_4{\cdot}(2 - x)V_2O_5$ may be stable at lower oxygen partial pressures, although X-ray powder diffraction analysis was unable to confirm this. Both of these oxygen-deficient compounds can be represented as ternary compounds in the system V_2O_5–Na_2O–V_2O_4.

The ferric vanadates, chromic vanadates, and magnesium vanadates did not show an increase in liquidus temperatures with decreasing oxygen partial pressures. The compounds evolved little, if any, oxygen on freezing. However, on the addition of sodium oxide to these vanadates, there was oxygen evolution on freezing in certain compositional ranges (Fig. 6), with a consequent increase in liquidus temperatures with decreasing oxygen partial pressures. The presence of a univalent cation appears necessary for the formation of oxygen-deficient vanadates under the conditions used in this study, *i.e.*, in an oxidizing atmosphere.

The large compositional ranges in the ternary vanadate systems in which the liquidus lies between 500 and 700 °C is of importance in relation to catastrophic vanadate corrosion because the corrosion mechanism is dependent on the presence of molten vanadates (1). For example, the operating temperatures of residual oil-fired boilers is at present limited to a maximum temperature of 500 °C, because of severe corrosion at higher temperatures (2). An examination of the ternary phase diagrams indicates that the sodium vanadates present in the fly ash deposits must dissolve at least their own weight in corrosion products or other oxides before the liquidus temperatures will rise above 700 °C. Therefore, it is difficult to control catastrophic vanadate corrosion by methods which raise the liquidus temperatures of the vanadates present in the fly ash, without accumulating large volumes of modified fly ash deposits.

Conclusions

The vanadate systems which were examined were predominately eutectic systems, although there may be some solid solubility of the metal oxides in vanadium pentoxide. The ternary sys-

tems V_2O_5–Na_2O–Fe_2O_3, V_2O_5–Na_2O–Cr_2O_3, and V_2O_5–Na_2O–MgO exhibited large compositional ranges between 40 and 100 mol% V_2O_5 and between 10 and 60 mol % Na_2O for which the liquidus temperatures were between 500 and 700 °C.

The liquidus temperatures of the sodium vanadates decreased with increasing oxygen partial pressure for compositions containing between 1 and 36 mol% sodium oxide. The same effect occurred in the case of the ternary systems examined in this study when more than 35 mol% of these same sodium vanadates were present. The effect appears to be related to the stabilization of the oxygen-deficient vanadyl vanadates at low oxygen partial pressures.

Received September 13, 1972

Partially oxidized tin(II) niobate and tantalate pyrochlores are homogeneous cubic phases. They have been shown by Mössbauer ^{119}Sn spectroscopy to contain both Sn(II) and Sn(IV). Each valency state is segregated on its own, crystallographically distinct sublattice as a consequence of the size disparity of Sn^{2+} and Sn^{4+} atoms. The strong temperature dependence of the Mössbauer Sn^{2+}:Sn^{4+} area ratios between room temperature and 4.2 °K indicates that the recoil-free fractions of the Sn^{2+} and Sn^{4+} atoms in these structures are noticeably different. The values of the recoil-free fractions at 0 °K, which were estimated from simple Einstein and Debye models, were used to obtain Sn^{2+}:Sn^{4+} population ratios from the Mössbauer area ratios extrapolated to 0 °K. The area ratios were shown to differ from the population ratios by 15–20% at 0 °K and by as much as 70% at room temperature. The formulae of the two nonstoichiometric pyrochlores based on the population ratios are $Sn_{2-2u}^{2+}(Sn_u^{4+}B_{2-u}^{5+})O_{7-(5/2)u}$ (B = Nb, Ta; u = 0.18–0.20). These formulae are consistent with chemical and other evidence. Mössbauer parameters and the limitations of using a Mössbauer area ratio to determine the Sn^{2+}:Sn^{4+} population ratio in Sn(II,IV) compounds are discussed.

Le niobate et le tantalate d'étain(II) partiellement oxydés sont des phases cubiques homogènes du type pyrochlore. Elles contiennent à la fois Sn(II) et Sn(IV) comme le prouvent les spectres Mössbauer de ^{119}Sn. Ces deux types d'atomes occupent chacun son sous-réseau cristallin à cause de la disparité dans la taille des atomes Sn^{2+} et Sn^{4+}. Les deux sous-réseaux sont cristallographiquement distincts. Les rapports des surfaces des pics d'absorption Mössbauer Sn^{2+}:Sn^{4+} varient fortement entre 4.2 et 290 °K, ce qui indique que, dans ces structures, les fractions d'effet Mössbauer sans recul des atoms Sn^{2+} diffèrent sensiblement de celles des atomes Sn^{4+}. On s'est servi de modèles simples d'Einstein et de Debye pour calculer les valeurs correspondantes à ces fractions à 0 °K. Ces valeurs ont été utilisées pour obtenir les rapports des populations atomiques Sn^{2+}:Sn^{4+} à partir des rapports des surfaces des pics Mössbauer extrapolés à 0 °K. On a démontré que l'écart de 15 à 20% qui existe, à 0 °K, entre les rapports de population et les rapports des surfaces, peut atteindre jusqu'à 70% à la température ambiante. Les deux pyrochlores non-stoechiométriques ont été formulés sur la base des rapports de population: $Sn_{2-2u}^{2+}(Sn_u^{4+}B_{2-u}^{5+})O_{7-(5/2)u}$ (B = Nb, Ta; u = 0.18–0.20); ces formules sont compatibles avec les preuves chimiques et autres. On discute des paramètres spectraux Mössbauer et des limites que pose la méthode pour déterminer le rapport de population Sn^{2+}:Sn^{4+} dans les composés Sn(II,IV) à partir du rapport des surfaces des pics d'absorption Mössbauer.

Can. J. Chem., **51**, 1041 (1973)

Previously we reported the preparation of cubic pyrochlores of the intended compositions $Sn_2^{2+}Nb_2^{5+}O_7$ and $Sn_2^{2+}Ta_2^{5+}O_7$ (1). The first attempt (samples *i*) resulted in products which were slightly inhomogeneous, but on repeating the preparations pyrochlores free from detectable foreign phases were obtained (samples *ii*, Table 1 of ref. 1). However, in refining the crystal structures of these two pyrochlores from powder diffractometer intensities, the discrepancy indices R could not be reduced below about 7%; the values of some of the parameters of refinement, as well as the measured densities, suggested that the niobate and tantalate might be nonstoichiometric. Since Bodiot (2), who also has described the preparation of such pyrochlores, considered his products as stoichiometric, we were curious to see whether the suspected lack of stoichiometry of our material could be traced to oxidation of some of the Sn(II) and therefore detected by Mössbauer ^{119}Sn spectroscopy. Preliminary spectra indeed indicated that both Sn(II) and Sn(IV) were present. This settled the problem of nonstoichiometry of our preparations quali-

tatively. However, the simultaneous presence of the two valencies of tin seemed to merit a detailed investigation by itself, as these pyrochlores are, to our knowledge, the first authenticated examples of oxidic mixed-valency tin compounds that have been reported. They afford an opportunity to study the recoil-free fractions of Sn atoms in different valency states and different coordinations but contained in the same crystal structure, and thus to assess the validity of the method of determining Sn(II):Sn(IV) ratios of such compounds from the area ratios of the two Mössbauer absorptions. We have carried out such a study and the results are described in the following.

Experimental

Details of preparation and the lattice parameters of the tin niobate and tantalate samples are given in ref. 1. Densities of the powders were determined as described in ref. 3.

Mössbauer spectra were recorded under conditions of constant geometry and for a fixed analyzer live time. Details of the apparatus are given in refs. 4 and 5. The source used was 5 mCi $BaSnO_3$ at room temperature. Absorbers were prepared by dispersing the sample powders in acrylic resin. Since the spectra were to be analyzed to give $Sn^{2+}:Sn^{4+}$ ratios, it was of particular importance to ensure that the areas and line widths of resonances were not distorted by the effects of nonlinear absorption in thick absorbers. The absorber thickness was therefore restricted to *ca.* 3 mg/cm^2 of natural Sn in each case. A check experiment using a thinner absorber showed no significant change in the relative intensities and line widths of the spectral features, and so it was concluded that the requirement of thin absorbers had been satisfied.

As discussed later, determination of $Sn^{2+}:Sn^{4+}$ population rations requires knowledge of the area of a spectral component as a function of temperature. Spectra were therefore obtained with the sample at 4.2, 77, 194.5 °K, and at room temperature. They were fitted to Lorentzian lines using the computer program developed by Clark (6), which provides for a variety of constraints. No correction for a curved baseline count was included, as at the source-to-detector distance used the curvature is known to be negligible and the spectra fitted to straight baselines all had acceptable χ^2 values. Isomer shifts are reported relative to $BaSnO_3$ at room temperature. To convert to β-Sn subtract 2.570 mm/s and to α-Sn, subtract 1.92 mm/s (7).

Results

Identification of the Mössbauer Absorption Peaks

Apart from varying relative intensities the same features were present in the Mössbauer spectra at all temperatures. These were a well-resolved doublet with isomer shift characteristic of Sn^{2+} and a singlet with isomer shift characteristic of Sn^{4+} (Fig. 1). Statistically acceptable fits were obtained by the use of Lorentzian line shapes assuming that the spectrum contained a total of three resonances and imposing no constraints on area or line width. The line widths were approximately 1 mm/s and were typical of thin-absorber ^{119m}Sn spectra obtained with the $BaSnO_3$ source. They are larger than the minimum (0.62 mm/s) calculated from the known lifetime of the ^{119m}Sn excited state. This increased line width may arise from resonant self-absorption in the source which may not be ideally thin, and from a fluctuating electric field gradient due to the presence of defects and distortions in source and absorber materials. The spectra of the

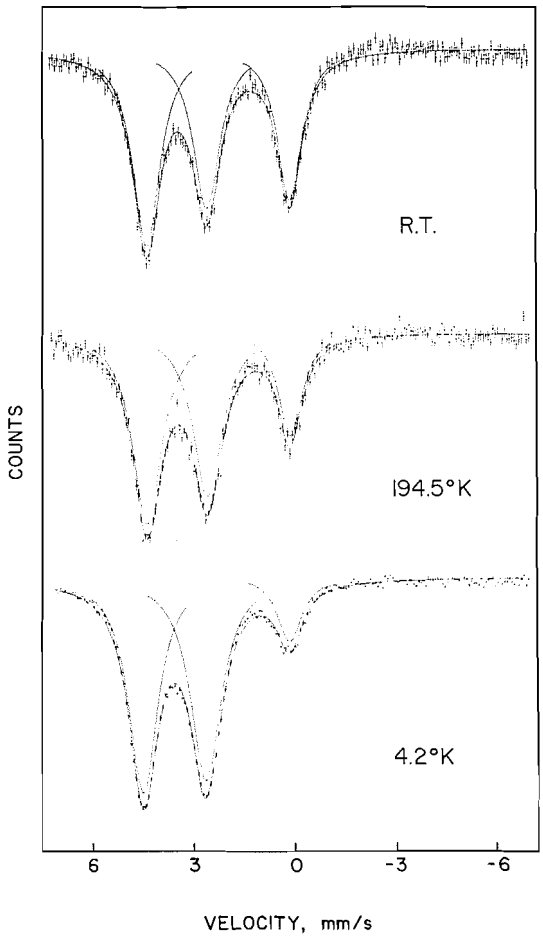

FIG. 1. Mössbauer spectra of tin tantalate (sample *ii*) at different temperatures. The zero of the velocity scale refers to the center of the $BaSnO_3$ calibration spectrum. The counts per channel (in thousands) for the spectra shown ranged from 5785 to 5875 (room temperature), 1660 to 1710 (194.5 °K), and 1535 to 1640 (4.2 °K).

*IS, isomer shift relative to $BaSnO_3$ at room temperature; QS, quadrupole splitting; Γ, line width (full width at half height). The standard deviations are quoted in units of the second decimal place.

niobate and the tantalate were very similar. They were reproducible on repeated cooling and warming up of the Mössbauer specimens between liquid–helium and room temperatures.

The Sn^{2+} absorption cannot correspond to free SnO as the isomer shift for the Sn^{2+} doublet is larger than would be expected for this oxide (*cf.* Table 1). Furthermore, no SnO lines were present in the X-ray powder patterns of the samples, and it is most unlikely that free SnO would have remained stable at the final firing temperatures of 750 °C or higher. The Sn^{2+} doublet must thus be due to Sn^{2+} within the *P* structure. The asymmetry of the doublet, which increases with temperature, arises from the Gol'danskii-Karyagin effect.

The well-defined Sn^{4+} resonance cannot be attributed to free SnO_2. If unreacted SnO_2 (formed by disproportionation of SnO) were present in an amount suggested by the relative intensity of the Sn^{4+} resonance, SnO_2 lines would have been observed in the powder patterns, which was not the case. Even if free SnO_2 were initially X-ray amorphous, it is unlikely to have remained in this state after heating to 750 °C.

Comparison of the Mössbauer spectra and parameters of samples *i* with those of samples *ii* shows little or no difference. There was no detectable resonance due to free tin in sample *i* of the niobate, and the interpretation of the Mössbauer results is therefore not affected by its presence. The results of measurements on samples *ii* are given in Table 1.

It seems clear that the spectra must arise from the presence of both Sn^{2+} and Sn^{4+} in a single homogeneous cubic *P* phase of mixed-valency character in both the niobate and the tantalate. Their Sn:*B* ratios must be 1:1 as intended, but allowance must be made for possible change in the oxygen content during firing or for the occurrence of an internal redox process (*vide infra*). In the first case the overall formula of the products can be written as $Sn_2B_2O_{7+z}$; in the second, $z = 0$ and formulae like $(Sn^{2+},Sn^{4+})_2(Nb^{5+},Nb^{4+})_2O_7$, for example, become a possibility.

The $Sn^{2+}:Sn^{4+}$ Ratio from the Mössbauer Spectrum

The relative areas of the Sn^{2+} and Sn^{4+} features of the Mössbauer spectra vary substantially with temperature (Fig. 1 and Table 1). This indicates that the recoil-free fractions of the two ionic species are unequal, implying a significantly different lattice vibrational spectrum for each. Moreover, the fractions will not be equal at 0 °K, owing to the effect of differences of zero-point motion. Hence considerable care must be exercised in interpreting the spectra in terms of relative ionic populations.

The following procedure was adopted for obtaining the $Sn^{2+}:Sn^{4+}$ ratio of each material. Assuming that the lattice vibrational spectrum of the solid is of the Einstein, single-frequency type, the recoil-free fraction f would be expected (21) to depend on temperature as

$$\ln f^E = -(\hbar^2/2\lambda^2 Mk\theta_E) \times \{1 + 2[\exp(\theta_E/T) - 1]^{-1}\}$$

where λ = γ-ray wavelength, M = mass of emitting nucleus, k = Boltzmann constant, and θ_E = the Einstein characteristic temperature. At

TABLE 2. Characteristic temperatures, recoil-free fractions and ionic populations for Sn^{2+} and Sn^{4+} (E, Einstein model; D, Debye model)

Parameter	Value	
	Niobate	Tantalate
$\theta_E(Sn^{2+})$	111 °K	100 °K
$\theta_D(Sn^{2+})$	192 °K	173 °K
$f_0^E(Sn^{2+})$	0.763	0.742
$f_0^D(Sn^{2+})$	0.792	0.772
$\theta_E(Sn^{4+})$	242 °K	170 °K
$\theta_D(Sn^{4+})$	424 °K	295 °K
$f_0^E(Sn^{4+})$	0.884	0.838
$f_0^D(Sn^{4+})$	0.900	0.859
$f_0^E(Sn^{2+}):f_0^E(Sn^{4+})$	0.863	0.884
$f_0^D(Sn^{2+}):f_0^D(Sn^{4+})$	0.880	0.899
Ionic population, %		
Sn^{2+}	90(2)	89(2)
Sn^{4+}	10(2)	11(2)

$T = 0$, $\ln f_0^E = -(\hbar^2/2\lambda^2 Mk\theta_E)$. If a Debye model is assumed, the corresponding results are

$$\ln f^D = -(3\hbar^2/4\lambda^2 Mk\theta_D) \times \left\{1 + 4(T/\theta_D)^2 \int_0^{\theta_D/T} x(e^x - 1)^{-1}\,dx\right\}$$

$$\ln f_0^D = -(3\hbar^2/4\lambda^2 Mk\theta_D)$$

The areas A^{2+} and A^{4+} (in arbitrary units) of the Sn^{2+} and Sn^{4+} components of the Mössbauer spectrum were obtained as a function of temperature from the constant-geometry, constant live time measurements. These were plotted as log A *vs.* T and fitted first to an Einstein and then to a Debye function. This procedure leads to values of θ_E and θ_D, and to values of f_0^E and f_0^D (Table 2). It was found that good fits were obtained to the data using either assumption.

The measured area ratio at 4.2 °K will not change significantly below this temperature. It may be corrected for the ratio of recoil-free fractions at $T = 0$ using the Einstein or the Debye value and leads then to a corrected population ratio $Sn^{2+}:Sn^{4+}$. The result is not particularly model sensitive. Taking a mean leads to the values for ionic populations given in Table 2, where due (and generous) allowance has been made in assessing the error for the dependence on model.

The $Sn^{2+}:Sn^{4+}$ Ratio from Total Oxidation

Assuming that the final oxidation states of Sn, Nb, and Ta in air are Sn^{4+}, Nb^{5+}, and Ta^{5+} respectively, firing the mixed-valency pyrochlores to constant weight at a sufficiently high temperature in air and noting the weight gain will give the total reducing power, *i.e.* the amount of oxygen required for complete oxidation of all the Sn^{2+} to Sn^{4+} and any B^{4+} to B^{5+}.

Typically, heating a 0.6 g sample each of the niobate and tantalate (preparations *ii*) for 24 h at 900 °C resulted in weight increases of 5.28 and 3.74% respectively. The color of both products was white. On the assumption that the weight gain was due solely to the oxidation of Sn^{2+}, the formula and the $Sn^{2+}:Sn^{4+}$ ratio are $Sn_2Nb_2O_{7.22(3)}$ and 8.1(12) for the niobate and $Sn_2Ta_2O_{7.32(4)}$ and 5.3(8) for the tantalate.[3] In the presence of Nb^{4+} or Ta^{4+} smaller $Sn^{2+}:Sn^{4+}$ ratios would be obtained, so the above values may be regarded as the upper limits of the ratios from the total oxidation experiments.

Lattice Parameter and Density

The values obtained for samples *ii* compare reasonably well with Bodiot's:

Compound	Parameter	Value	
		This work	Reference 2
Niobate	a_0 (Å)	10.588(1)	10.581(2)
	d (g/cm^3)	5.33(1)	5.64
Tantalate	a_0 (Å)	10.565(1)	10.550(2)
	d (g/cm^3)	6.58(5)	8.33

The exception is the density of the tantalate, which will be commented upon later.

The $a_0(P)$ values of the two $Sn_{1+x}B_2O_{6+x}$ phases increase with x (Fig. 2). Not all of the stated intended compositions represent the true stoichiometries; this uncertainty is undoubtedly responsible, at least in part, for the observed spread of the points for the tantalate.

Discussion

In the idealized P structure the cations are located in sites of two types, 16(*c*) and 16(*d*), both of symmetry $\bar{3}m$ (*cf.* ref. 8). A 16(*c*) site is coordinated by 6+2 oxygen atoms and accommodates the larger cation. A 16(*d*) site is coordinated by six oxygens and accommodates the smaller cation. The effective size of an Sn^{2+} atom for a particular coordination number is

[3]An arbitrary error of ±0.5 mg was assumed to be associated with the difference weighing and handling of the samples.

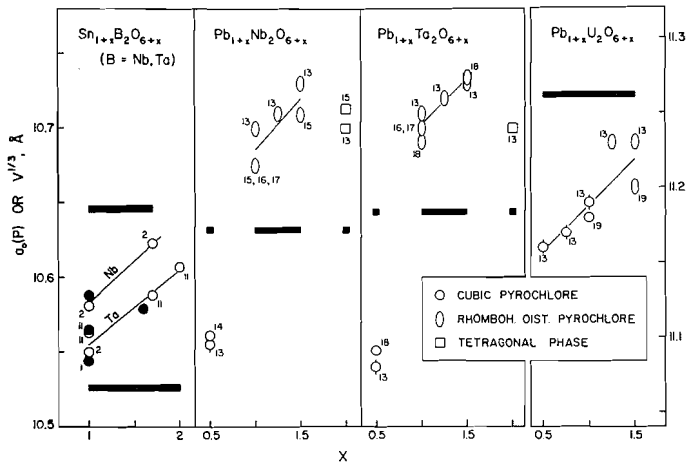

FIG. 2. Variation of the lattice parameter with composition for cubic $Sn_{1+x}B_2O_{6+x}$ (B = Nb, Ta) pyrochlore phases. Similar plots for $Pb_{1+x}B_2O_{6+x}$ (B = Nb, Ta, U) are shown for comparison (see text). Homogeneity ranges are indicated by black horizontal bars, references by numbers. Full circles, this work.

appreciably greater than that of an Sn^{4+} atom. Since A^{2+} ions in stoichiometric *2–5* pyrochlores, $A_2{}^{2+}B_2{}^{5+}O_7$, are located in 16(*c*) sites and B^{4+} ions in stoichiometric *3–4* pyrochlores, $A_2{}^{3+}B_2{}^{4+}O_7$, in 16(*d*) sites, it is plausible to assume that in the partially oxidized tin niobate and tantalate Sn^{2+} ions will be located in 16(*c*) and Sn^{4+} ions in 16(*d*). The separation of the valency states would then coincide with segregation into two crystallographically nonequivalent sets of sites, each having its own distinct coordination. The Mössbauer results are consistent with this view.

In general, the occurrence of markedly different recoil-free fractions for identical nuclei in ions of equal mass within the same crystal structure, is to be ascribed to (*i*) the dominance (in determining f) of modes of vibration characteristic for the ions of their bonding to immediate neighbors, and (*ii*) marked differences in the local bonding forces for the two ionic species. This latter would certainly be the case if the ions were located in different sites of unequal coordination.

Stoichiometry

The Sn^{2+}:Sn^{4+} ratios estimated from the corrected Mössbauer area ratios, 9.0(20) for the niobate and 8.1(18) for the tantalate, are indistinguishable within the stated errors, suggesting that the extent of oxidation to Sn^{4+} was much the same in all our preparations. The Mössbauer area ratio for the niobate leads to the formula $Sn_{1.64(4)}{}^{2+}Sn_{0.18(4)}{}^{4+}Nb_{1.82}{}^{5+}O_{6.55(9)}$. The maximum possible occupancy of the unit cell which is permitted for this composition by the experimental density is 97(2)%. The contents 16(*c*)|16(*d*)|48(*f*) + 8(*a*) of the unit cell can then be formulated as $12.8(3)\,Sn^{2+}|1.4(3)\,Sn^{4+} + 14.2\,Nb^{5+}|51.1(7)\,O^{2-}$. This agrees surprisingly well with the result obtained from the total oxidation experiment, $12.5(3)\,Sn^{2+}|1.5(3)\,Sn^{4+} + 14.0(1)\,Nb^{5+}|50.6(8)\,O^{2-}$, considering the so far unsupported assumption that all the niobium is present as Nb^{5+}.

The formula and unit-cell occupancy resulting from the Mössbauer area ratio and experimental density for the tantalate are

$$Sn_{1.60(4)}{}^{2+}Sn_{0.20(4)}{}^{4+}Ta_{1.80}{}^{5+}O_{6.50(9)}$$

and

$$11.7(4)Sn^{2+}|1.5(4)Sn^{4+} + 13.1Ta^{5+}|47.4(8)O^{2-}$$

the number of formula units calculated from d(exp) is only 7.27(14). The formula and unit-cell occupancy based on the total oxidation experiment

$$Sn_{1.45(4)}{}^{2+}Sn_{0.28(4)}{}^{4+}Ta_{1.72}{}^{5+}O_{6.30(4)}$$

and

$$11.0(4)Sn^{2+}|2.1(3)Sn^{4+} + 13.0(1)Ta^{5+}|47.8(4)O^{2-}$$

agree less well with those derived from the

For personal use only.

Mössbauer area ratio than in the case of the niobate. It should be realized, however, that an error $d\Delta w$ of 0.5 mg in a weight Δw of 0.025 g gained by a 0.5 g ($= w$) sample in a total oxidation experiment will produce a change of 0.8 in the Sn^{+2}:Sn^{4+} ratio Q of the niobate and 2.3 in that of the tantalate.[4]

The Q(Mössbauer) and Q(oxidation) values for the niobate are in reasonable agreement even though Q(oxidation) has been calculated on the assumption that Nb^{5+} is the only valency of niobium present. Since no attempt was made in this investigation to secure *direct* evidence of Nb^{4+} in the structure, the agreement of the Q values precludes the presence *or* the absence of Nb^{4+} being argued with any conviction. The bright orange-yellow color of the niobate *would* suggest the possibility that Nb^{4+} atoms are present: they would be expected to reside on the 16(d) sublattice in a statistical mixture with Nb^{5+} and Sn^{4+} atoms and thus be in a situation favorable for the existence of electronic exchange processes which are characteristic of many mixed-valency compounds and manifest by striking colors.[5] Unfortunately not enough is known about mixed Nb(IV,V) oxide compounds for the color to be used as evidence in support of Nb^{4+} in the niobate. Certain apparently stoichiometric oxygen compounds of Nb^{5+} which are colorless at room temperature turn characteristically bright orange when hot. If this reversible phenomenon has its analogy in the well-known color change in ZnO on heating in air, very small amounts of Nb^{4+}, of no consequence to bulk stoichiometry, would be responsible for the room-temperature color of the niobate. Those of Sleight's (9) $Hg_2B_2O_7$ (B = Nb, Ta) pyrochlores that were most nearly stoichiometric were yellow, while samples somewhat more deficient in mercury and oxygen were red to black and their unit-cell size was decreased. Similarly, the color of $Cd_2NbB^{IV}O_6F$ (B = Ti, Zr, Hf, Ge, Sn) pyrochlores (10) ranged from pale yellow to brick red; often there was a color variation from one preparation to another.

Inasmuch as the Sn^{4+} content of the tantalate, as estimated from the weight gain, is already somewhat greater than indicated by the Mössbauer area ratio, any Ta^{4+} assumed to be present would imply an even lower Sn^{2+} content and make the discrepancy worse. However, without an internal redox process involving lower valency states of Ta or Nb the question of the source of oxygen necessary to convert Sn^{2+} to Sn^{4+} in all our preparations becomes embarrassing. The Mössbauer spectrum of the black SnO used as a starting material did not show visible Sn^{4+} absorption; the pentoxides had been calcined before use; the quartz ampoules were kept under vacuum (better than 10^{-5} Torr) for several hours before sealing. Oxidation of the samples on storage in air would have increased the Mössbauer area ratio in the right direction; the initial Sn^{4+} content might therefore be even smaller than that estimated. A possible explanation might be oxygen adsorbed on the surface of the reactant powders. As for the correction factor applied to the Mössbauer area ratio, even *before* correcting for unequal recoil-free fractions the area ratio gives an Sn^{2+}:Sn^{4+} value higher than the "total oxidation" value. At present we cannot offer a satisfactory reason why the Sn^{2+} should have oxidized.

The question of whether strictly stoichiometric $Sn_2Nb_2O_7$ and $Sn_2Ta_2O_7$ can be prepared remains to be answered. Bodiot assumed that his preparations were stoichiometric, for his results gave him no reason to believe otherwise. However, the difference between the formula weights of $Sn_2B_2O_7$ and $Sn_2B_2O_{7.3}$ (a typical composition of our preparations) is only about 1% for Nb and about 0.7% for Ta, so that small departures from stoichiometry might escape attention in thermogravimetric experiments unless specifically looked for. Nonstoichiometry would not be much noticed in $a_0(P)$, as a decrease in $a_0(P)$ arising from deficient occupancy of

---

[4]For a composition $Sn_{2-y}^{2+}Sn_y^{4+}B_2^{5+}O_{7+y}$ the variation of Q is given by $dQ = -2y^{-2}dy = (K+1)wd\Delta w/(w - K\Delta w)^2$, where $K \sim 17$ for the niobate and ~ 22 for the tantalate. In the vicinity of the singularity at $w = K\Delta w$, dQ varies very steeply.

[5]In a P structure with fully occupied 16(d) and 48(f) sublattices the three-dimensional B—O_2 network forms $B_4(O_2)_6$ clusters of symmetry $\bar{4}3m$ about the empty 8(a) sites. These clusters are similar in shape to the P_4O_6 and As_4O_6 molecules in the vapor or to the As_4O_6 or Sb_4O_6 units in cubic As_2O_3 and Sb_2O_3 and may be described as tetrahedra with broken edges. The vertices of the tetrahedron are occupied by B and the points where the edges are broken are occupied by O_2. The unique BO_2B angle of the isosceles B—O_2—B triangle is about 135°, the B—O_2 distance is typically 1.96–2 Å, and the B—B distance is equal to $a_0\sqrt{2}/4$, *i.e.* typically about 3.6 Å. It is conceivable that such a compact local configuration of high symmetry is favorable for the occurrence of fast B^{4+},B^{5+} exchange interactions.

16(*c*) and 48(*f*) + 8(*a*) is partially compensated by the greater effective ionic radius of Sn^{4+} relative to Nb^{5+} and Ta^{5+}.[6] For a composition difference as large as $Sn_2Ta_2O_7$ and $Sn_3Ta_2O_8$ the difference in $a_0(P)$ is, according to ref. 11, 0.044(5) Å, *i.e.* only about 0.4%. This suggests that effects produced by differences in the oxygen stoichiometry of $Sn_2B_2O_{7+z}$ preparations would probably be small enough to pass for spread between different sets of measurements, especially since the spread in the values reported for $a_0(P)$ of "$Sn_2Ta_2O_7$" alone amounts to 0.021(2) Å (Fig. 2).

Bodiot's *d*(exp) value for the tantalate, 8.33 g/cm^3, yields $Z = 8.36$ for the formula $Sn_2Ta_2O_7$. However, a value of Z greater than 8 cannot be reconciled with the standard occupancy of a pyrochlore unit cell. If the discrepancy were to be attributed to experimental error, the error would have to be substantial, since density determinations on powders invariably tend to give values lower than *d*(X-ray).

For our preparations *ii* the fraction of 16(*c*) sites occupied by Sn^{2+} is only about 78% in the niobate and about 71% in the tantalate. The theoretical lower limit of the $Sn^{2+}:Sn^{4+}$ ratio consistent with $Sn:B^{5+} = 1$ and with full occupancy of the 16(*d*) and 48(*f*) sites is 3, corresponding to the unit-cell occupancy $Sn_{9.6}{}^{2+}|Sn_{3.2}{}^{4+}B_{12.8}{}^{5+}|O_{48}{}^{2-}|\square_8$.[7] In this case only 60% of the 16(*c*) sites are occupied, *i.e.* for every three Sn^{2+} atoms there are two vacancies, and the 8(*a*) sites are empty.

The site occupancy and unit-cell contents of the cubic phases deriving from $Sn_2B_2O_7$ with $Sn:B$ ratios greater than unity are not known at present. The composition ranges of these $Sn_{1+x}B_2O_{6+x}$ ($x \geqslant 1$) pyrochlores are substantial: Trunov *et al.* (11) have reported $x = 2$ as the upper limit for the tantalate (Fig. 2). For $x < 1$ the existence of only one phase has been ascertained in the SnO–Nb_2O_5 system (2). This is the congruently melting $SnNb_2O_6$; it has a complex powder pattern and a narrow, if any, homogeneity range. In the SnO–Ta_2O_5 system, in addition to $SnTa_2O_6$ (possibly related to the rhombohedral $PbTa_2O_6$) a tetragonal phase $SnTa_4O_{11}$ stable to at least 1400 °C has been found (2, 11).

These phase and structure relationships differ from those described for the systems PbO–Nb_2O_5, PbO–Ta_2O_5, and PbO–"U_2O_5" by Kemmler-Sack and Rüdorff (13) and by earlier authors (see Fig. 2). In the $Pb_{1+x}B_2O_{6+x}$ (B = Nb, Ta) compositions cubic P phases do exist but are restricted to $x = 0.5$, *i.e.* to unit-cell occupancies $Pb_{12}{}^{2+}|B_{16}{}^{5+}|O_{52}$; in this respect they are very similar to our Sn niobate and tantalate. The rhombohedrally distorted P phase which occurs from $x = 1$ to 1.5 is followed by a tetragonal phase of unknown structure at $x = 2$. The existence of the homogeneity range of the rhombohedral P phase is accounted for (13) from experimental evidence by a progressively smaller proportion of B^{5+} in 16(*d*) while 16(*c*) + 16(*d*) remain fully occupied, *i.e.* presumably (though this has not been demonstrated) $Pb_{16}{}^{2+}|Pb_{\delta}{}^{2+}B_{16-\delta}{}^{5+}|O_{56-(3/2)\delta}$. The size disparity of the Pb^{2+} and B^{5+} atoms occupying 16(*d*) and the simultaneous presence of oxygen vacancies are held responsible for the rhombohedral distortion and the eventual emergence of the tetragonal phase at $x = 2$. The alternative possibility of 16(*d*) being incompletely occupied and the excess Pb atoms being located elsewhere in the structure (presumably in 8(*a*) or 8(*b*)) has also been suggested (13).

In the $Pb_{1+x}U_2O_{6+x}$ pyrochlores the situation is reported to be different again (13). The cubic structure which exists at $x = 0.5$ is retained up to $x = 1$, after which a progressive rhombohedral distortion is observed to $x = 1.5$; a discrete $Pb_3U_2O_8$ phase could not be prepared. Experimental densities are consistent with unit-cell occupancies $Pb_{32(1+x)/(3+x)}{}^{2+}U_{64/(3+x)}{}^{5+}O_{32(6+x)/(3+x)}$ for $0 \leqslant x \leqslant 1$,[8] while interstitial

[6]The relative insensitivity of a_0 to variations of composition is responsible for the a_0 values of our and Bodiot's $Sn_2Nb_2O_7$ and $Sn_2Ta_2O_7$ samples being accommodated at $r^{VIII}(Sn^{2+}) = 1.22$ Å (12) on the straight line of Fig. 3, ref. 1, correlating $a_0(P)$ of $A_2{}^{2+}B_2{}^{5+}O_7$ (B = Nb, Ta) with $r^{VIII}(A^{2+})$. In this limited sense Shannon and Prewitt's value for the radius of Sn^{2+} in 8-coordination may be regarded as acceptable.

[7]This is apparently the limit of the oxygen content which the P structure can tolerate. It is, however, possible that in defect pyrochlores the oxygen atoms are distributed statistically over 48(*f*) + 8(*a*), leaving a small fraction of vacancies on the 48(*f*) sublattice.

[8]This occupancy requires some of the oxygen atoms to occur in interstitial positions and some of the U^{5+} atoms in the 8-coordinated 16(*c*) sites. Magnetic susceptibility measurements (20) seem to be consistent with this proposal. If the Pb and U atoms were distributed at random over 16(*c*) + 16(*d*) rather than 16(*d*) being occupied exclusively by U, the structure would approximate the defect fluorite structure.

For personal use only.

accommodation of lead and oxygen atoms is postulated for $x > 1$: $Pb_{8(1+x)}{}^{2+}U_{16}{}^{5+}O_{8(6+x)}$.

This variety of behavior shows the importance of the relative sizes of A^{2+}, B^{5+} and O^{2-} in determining the type of defect structure and rules out predictions for $Sn_{1+x}B_2O_{6+x}$ based on analogy with other $A_{1+x}B_2O_{6+x}$ compounds.

Mössbauer Parameters

The room-temperature isomer shifts of Sn^{2+} in the niobate and tantalate fall between the values reported by Lees and Flinn (7) for SnF_2 and SnC_2O_4, 3.46(4) and 3.59(4) mm/s respectively. The temperature dependence of the isomer shift is small. The quadrupole splitting is large and comparable with that of $Sn_3(PO_4)_2$, 1.90(3) mm/s (7). When our values are plotted in Fig. 4 of ref. 7, the points for the two pyrochlores are almost indistinguishable and lie considerably above the upper straight line. It is uncertain whether Lees and Flinn's interpretation of the Sn^{2+} isomer shift is applicable here. As pointed out above, the site symmetry at a 16(*c*) site is $\bar{3}m$, *i.e.* containing a center of symmetry. Sn^{2+} in these two pyrochlores is probably the first known case of a divalent tin atom in a centrosymmetric situation; or, more correctly, it would be if the two pyrochlores were stoichiometric.

The occupation of not more than about 78% of the 16(*c*) sites has several important consequences. Assuming that in an "essentially ionic" crystal only the immediate environment of a Mössbauer-active atom affects the spectrum, we shall consider the six 16(*c*), the six 16(*d*), and the two 8(*a*) sites adjacent to an Sn^{2+} atom. The sites of the first two types are arranged at the vertices of a cuboctahedron of edge length $a_0\sqrt{2}/4$ Å in such a way that the six corners of two opposing triangular faces are at the 16(*c*) sites and the remaining six, coplanar, vertices coincide with the 16(*d*) sites. All twelve sites are at a distance of $a_0\sqrt{2}/4$ Å from the Sn^{2+} atom. The two 8(*a*) sites are on a threefold rotation axis passing through the centers of the two opposing 16(*c*) triangles, at $a_0\sqrt{3}/8 = 2.28$ Å from the Sn^{2+} atom.

In a strictly stoichiometric $Sn_2{}^{2+}B_2{}^{5+}O_7$ pyrochlore all the Sn^{2+} atoms would be equivalent, at centers of coordination cuboctahedra of symmetry $\bar{3}m$, and only one, simple Sn^{2+} spectrum would be expected. This would very likely consist of a quadrupole doublet broadened only by crystal imperfections and by instrumental factors. However, the reduced occupancy of 16(*c*) in our preparations results, on the average, in a replacement of about 10% of the B^{5+} atoms in 16(*d*) by Sn^{4+} and about 5% by cation vacancies, and in the removal of about 83% of the O_1 atoms in 8(*a*) if 48(*f*) is assumed to be completely filled. As a consequence (assuming Bernoulli distribution, *i.e.* in the absence of preferential interactions) only about 5% of all the Sn^{2+} atoms have immediate environments of the type

$$Sn_6{}^{2+} \textit{ or } \square_6|B_6{}^{5+} \textit{ or } Sn_6{}^{4+} \textit{ or } \square_6|(O_1)_0 \textit{ or } (O_1)_2$$

i.e. of symmetry $\bar{3}m$. All the other Sn^{2+} atoms have environments of lower symmetries. Considering the very short Sn^{2+}—O_1 distance, one would expect the absence of one of the two nearest O_1 neighbors to have a substantial effect on the electric field gradient at Sn^{2+} and on the type of bond such as an Sn^{2+} atom engages in, and hence on the Mössbauer parameters. Moreover, there will be a variety of environments owing to the different configurations of the Sn^{2+}, Sn^{4+}, B^{5+} and $\square$ nearest neighbors at the vertices of the coordination cuboctahedra, corresponding to a range of point-group symmetries; the oxygen atoms may be distributed statistically over 48(*f*) + 8(*a*), leaving anion vacancies in 48(*f*) and consequently in the immediate O_2-environment of the Sn^{2+} (and Sn^{4+}) atoms; and there may be significant contributions from more distant neighbors in the defect pyrochlore structure. The observed Mössbauer Sn^{2+} spectrum is thus the resultant of a large number of spectra, each arising from an individual local situation and having its own isomer shift and quadrupole splitting. This is consistent with the observed line broadening. It is thus not strictly true that the values of the isomer shift and quadrupole splitting, as obtained by fitting the experimental spectrum to a Lorentzian quadrupole doublet, are those of Sn^{2+} in a centrosymmetric environment of the majority, $Sn_6{}^{2+}B_6{}^{5+}$ type, the contribution of such Sn^{2+} atoms to the overall spectrum being less than 5%. Otherwise it would be tempting to interpret the isomer shift in terms of Lees and Flinn's diagram (Fig. 4 of ref. 7) as corresponding to 0.5p electrons, which would be suggestive of linear $s^1(sp)^{\frac{1}{2}}$ or trigonal $s^{1\frac{1}{2}}(sp^2)^{\frac{1}{2}}$ orbital hybrids; the symmetries of both are compatible with the $\bar{3}m$ symmetry at 16(*c*).

For personal use only.

The vacancies in 8(*a*) may also be held responsible for the markedly different recoil-free fractions of the Sn^{2+} and Sn^{4+} atoms. The amplitude of thermal vibration of the Sn^{2+} atom must be, on the average, strongly anisotropic by virtue of the absence of one or both of the nearest-neighbor O_I atoms. Support for this is found in the occurrence of the Gol'danskii-Karyagin effect manifested by the asymmetry of the Sn^{2+} spectra.

Conclusions

(*1*) The partially oxidized cubic pyrochlores $Sn_2Nb_2O_7$ and $Sn_2Ta_2O_7$ were found to contain Sn^{2+} and Sn^{4+}, each valency being segregated in its own crystallographic equipoint and corresponding to a distinct characteristic (Einstein or Debye) temperature. The two oxides appear to be the first well-authenticated cases of oxidic Sn(II,IV) compounds.

(*2*) When Sn(II) and Sn(IV) are simultaneously present in a crystal structure, it is almost certain that the Sn(II) and Sn(IV) atoms will occupy crystallographically nonequivalent sites and hence have different environments. This difference will manifest itself in unequal recoil-free fractions. The Sn(II):Sn(IV) population ratio cannot then be obtained from the corresponding ^{119}Sn Mössbauer area ratio without first determining the temperature dependence of the latter and correcting for the dissimilarity of the recoil-free fractions at 0 °K. In the present case use of simple Einstein and Debye models has shown that without such corrections, the mean value of the Sn(II):Sn(IV) Mössbauer area ratio may differ from the Sn(II):Sn(IV) population ratio by as much as 20% even at 4.2 °K. The ultimate accuracy of the population ratio derived in this manner will depend significantly, even with spectra collected to high statistics, on the closeness with which the function assumed for the shape of the baseline represents the actual baseline.

(*3*) Using corrected Mössbauer area ratios, experimental densities and lattice parameters leads to the formula $Sn_{2-2u}{}^{2+}(Sn_u{}^{4+}B_{2-u}{}^{5+})O_{7-(5/2)u}$ (B = Nb, Ta; u = 0.18–0.20) for the two pyrochlore phases. This formula is consistent with the results of total oxidation experiments.

We wish to express our gratitude to Miss Rosemary Watkins for assistance in the calculation of population ratios from the Mössbauer data. Financial support of this investigation by the National Research Council of Canada is hereby acknowledged.

Matairesinol-4,4′-di-*O*-β-D-glucopyranoside from *Trachelospermum asiaticum* var. *intermedium*[1]

SANSEI NISHIBE, SUEO HISADA, AND ISAO INAGAKI

Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467, Japan

Received August 15, 1972

A new lignan diglucoside was isolated from the stems of *Trachelospermum asiaticum* Nakai var. *intermedium* Nakai (Apocynaceae) and the structure has been determined as matairesinol-4,4′-di-*O*-β-D-glucopyranoside (**1**).

Un nouveau diglucoside de la lignine a été isolé des tiges des *trachelospermum asiaticum* Nakai var. *intermedium* Nakai (Apocynaceae) et la structure a été identifié au matairesinol di-*O*-β-D-glycopyranoside-4,4′ (**1**). [Traduit par le journal]

Can. J. Chem., **51**, 1050 (1973)

In our previous papers (1–4), the structures of four lignan glucosides from the stems of *Trachelospermum asiaticum* Nakai var. *intermedium* Nakai were elucidated.

In this paper a new lignan diglucoside, matairesinol-4,4′-di-*O*-β-D-glucopyranoside (**1**) was isolated. The only other lignan diglucoside previously reported is liriodendrin (5). The co-occurrence of matairesinol-4,4′-di-*O*-β-D-glucopyranoside (**1**) and matairesinoside (matairesinol-4′-*O*-β-D-glucopyranoside) are subjects of interest from the biogenetic point of view and suggests the possibility of occurrence of another matairesinol monoglucoside possessing a glucose moiety linked with phenolic hydroxy group at C-4. Actually the isolation of matairesinol monoglucoside (matairesinol-4-*O*-β-D-glucopyranoside) from safflower meal has been reported (6–7).

The chloroform–methanol (2:1, v/v) extract described in the Experimental was subjected to a column chromatography on activated charcoal followed by chromatography on a silica gel column, chloroform–ethanol (3:2, v/v) being used as eluant.

Compound **1**, m.p. 104–106°, was obtained from the fraction showing R_f 0.16 spot on t.l.c. using chloroform–ethanol (3:1) as developer. The i.r. spectrum of **1** showed a γ-lactone band at 1765 cm^{-1}. The peaks at 225 and 279 nm in the u.v. spectrum were unchanged when adding sodium ethoxide, thus indicating the absence of free phenolic hydroxy group.

The acid hydrolysis of **1** yielded aglycone (**3**) and D-glucose. The i.r. spectrum of **3** showed a γ-lactone band at 1775 cm^{-1} and the u.v. spectrum showed the peaks at 231.5 and 283 nm, giving bathochromic shift to 250.5 and 298.5 nm with sodium ethoxide. The properties of **3** were identical with those of matairesinol. Compound **3** was identified with an authentic sample by a mixed melting point and i.r. spectra. The presence of D-glucose was proven by paper chromatography.

Compound **1** was treated with acetic anhydride and pyridine at room temperature to give the acetylated derivative (**2**). The n.m.r. spectral data of **2** are as described in the Experimental. The similar assignments of the protons of sugar and aglycone parts in the n.m.r. spectrum are reported in those of matairesinoside pentaacetate (8) and arctiin tetraacetate (9).

Compound **1** was suggested, therefore, to be a matairesinol derivative having two glucose moieties linked with phenolic hydroxy group at C-4 and -4′. The analytical data of **1** was satisfactory for $C_{32}H_{42}O_{16}\cdot H_2O$. The molecular weight determination of **2** by vapor pressure osmometry also agreed with the formula $C_{48}H_{58}O_{24}$. The proof of two glucosidic linkages rather than a glucosyl–glucosidic linkage was achieved as follows. The permethyl ether prepared by the methylation of **1** with sodium hydride, dimethyl sulfoxide, and methyl iodide (Hakomori's method (10)) afforded only methyl 2,3,4,6-tetra-*O*-methyl-D-glucopyranoside on methanolysis with 3% methanolic hydrogen chloride. The glucosyl–glucoside was omitted since it was not the only type of dissacharide moiety possible.

The stereochemistry of the glucosidic linkages could not be determined from the n.m.r. spectrum of **2** (11). The comparison of the experi-

1 R_1 = glucosyl; R_2 = glucosyl
2 R_1 = $(Ac)_4$ glucosyl; R_2 = $(Ac)_4$glucosyl
3 R_1 = H; R_2 = H

TABLE 1. Values of the specific molecular rotation

Calcd. $[M]_D^\circ$ in ethanol*		Found $[M]_D^\circ$ in ethanol
Lignans		Lignans
4′-β,4-β linkages	−250.7	**1** −168.2
4′-β,4-α or 4′-α,4-β linkages	+119.3	**3** −124.7
4′-α,4-α linkages	+489.3	

*The following $[M]_D$-values were used for the calculation: methyl-α-D-glucopyranoside, +307°, and methyl-β-D-glucopyranoside, −63°.

mental value of the specific molecular rotation ($[M]_D$) of **1** with those calculated with α- and β-glucose moieties are as shown in Table 1.

The $[M]_D$-value and the enzymatic hydrolysis of **1** with emulsin proved the β-linkage of glucose moieties with the aglycone. Thus the structure of **1** has been established as matairesinol-4,4′-di-*O*-β-D-glucopyranoside (4,4′-dihydroxy-3,3′-dimethoxy-lignan-olid(9,9′)-4,4′-di-β-D-glucopyranoside by the nomenclature of Freudenberg and Weinges (12)).

Experimental

All melting points were not corrected. The following equipment was used: i.r. spectra, infrared spectrophotometers IR-S, IR-E, and IRA-2 (Jasco); u.v. spectra, Hitachi recording spectrophotometer Model EPS-3T (ethanol); n.m.r. spectra, JNM-MH-60 (Jeol) with tetramethylsilane (δ = 0) as internal standard in deuteriochloroform; optical rotation, Yanagimoto OR-10; molecular weight, Hitachi Perkin–Elmer 115 molecular weight apparatus with benzil as reference compound; g.l.c., JGC-1100 (Jeol) with flame ionization detector.

The t.l.c. values were obtained with silica gel G (Merck) as adsorbent; the spots were detected by spraying with 10% sulfuric acid and heating. For paper chromatography Toyo filter paper No. 51 (2 cm × 40 cm) was used.

Extraction

The dried stems of *Trachelospermum asiaticum* Nakai var. *intermedium* Nakai (25 kg) were extracted with hot methanol (4 × 36 l) and the methanol solution was evaporated to a small volume, diluted with water, and filtered. The filtrate was extracted successively with light petroleum (4 × 1.5 l), ether (4 × 1.5 l), and chloroform (5 × 1.5 l). The aqueous layer was concentrated to a syrup and extracted with hot ethyl acetate (4 × 1.8 l). The residue was extracted with chloroform–methanol (2:1, v/v) (5 × 1.5 l). The chloroform–methanol extract (82 g) was chromatographed on a column of activated charcoal (Wako, 400 g, 9 cm × 32 cm). Fractions (1 l each) were eluted by methanol–water (1:99, v/v) (nos. 1–2), methanol–water (1:1, v/v) (nos. 3–7), and methanol alone (nos. 8–13), respectively.

Matairesinol-4,4′-di-O-β-D-glucopyranoside (1)

The eluate of fraction no. 10 (1.7 g) was chromatographed on a silica gel column (Mallinckrodt, 100 g, 4.5 cm × 26 cm) with chloroform–ethanol (3:2, v/v) as eluting solvent. Fractions (50 ml each) were monitored by t.l.c. using chloroform–ethanol (3:1, v/v) as developer. The R_f 0.16 fraction was evaporated and final purification was achieved by re-chromatography on a silica gel column to give colorless powder **1**, 51.4 mg, m.p. 104–106°, $[\alpha]_D^{14}$ −24.0 (*c*, 0.5 in ethanol).

Anal. Calcd. for $C_{32}H_{42}O_{16}\cdot H_2O$: C, 54.85; H, 6.33. Found: C, 54.52; H, 6.24.

Spectra: λ_{max} in nm (log ε) 225 (4.09), 279 (3.65); ν_{max} (KBr) 3560–3240 (hydroxyl), 1765 (γ-lactone), 1595, 1510 cm^{-1} (aromatic).

Acid Hydrolysis of Matairesinol-4,4′-di-O-β-D-glucopyranoside (1)

The solution of matairesinol-4,4′-di-*O*-β-D-glucopyranoside (45 mg) in 10% sulfuric acid (25 ml) was heated on a boiling water bath for 2 h. The oily product separated was extracted with ether and the ether solution was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue was chromatographed on a silica gel column (Mallinckrodt, 30 g, 2.5 cm × 12 cm) with chloroform–ethyl acetate (4:1, v/v) as eluting solvent. Fractions were monitored by t.l.c. using chloroform–ethyl acetate (1:1, v/v) as developer. The R_f 0.62 fraction was evaporated to dryness. The residue was recrystallized from 30% aqueous acetic acid to give colorless needles, 6 mg, m.p. 118.5–119.5°, $[\alpha]_D^{23}$ −34.8 (*c*, 0.3 in ethanol) an authentic sample $[\alpha]_D^{8}$ −40.0 (in ethanol) (9); lit. $[\alpha]_D^{25}$ −37.9, −35.7, −40.5 (in acetone) (6).

Spectra: λ_{max} in nm (log ε) 231.5 (4.10), 283 (3.79), shifting to 250.5 (4.33), 298.5 (4.03) in sodium ethoxide; ν_{max} ($CHCl_3$) 3560 (hydroxyl), 1775 (γ-lactone), 1610, 1510 cm^{-1} (aromatic).

The product was identified with an authentic sample of matairesinol by a mixed melting point and i.r. spectral comparison.

The water layer was neutralized with barium carbonate and evaporated to dryness. Paper chromatography of this

residue (solvent: butanol – acetic acid – water (4:1:1, v/v), color reagent: aniline hydrogen phthalate) showed only one spot of D-glucose.

Matairesinol-4,4′-di-O-β-D-glucopyranoside Octaacetate (2)

Matairesinol-4,4′-di-*O*-β-D-glucopyranoside (40 mg) was dissolved in pyridine (1 ml) and acetic anhydride (1 ml). The mixture was left standing overnight at room temperature. The reaction product was added to the ice water with stirring and then extracted with ether. The ether solution was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue was recrystallized from methanol to give colorless powder, 31.1 mg, m.p. 88–89°.

Anal. Calcd. for $C_{48}H_{58}O_{24}$ (mol. wt. 1018.98): C, 56.58; H, 5.74. Found ((vapor pressure osmometry in chloroform) 976.4): C, 56.77; H, 5.94.

Spectra: λ_{max} in nm (log ε) 227 sh (4.11), 279 (3.66); ν_{max} (KBr) 1760 (γ-lactone and acetyl), 1595, 1515 cm^{-1} (aromatic); n.m.r. 7.10–6.35 (6H, aromatic H, multiplet), 5.50–4.75 (8H, multiplet), 4.30–4.00 (6H, broad singlet), 4.00–3.80 (2H, C-9, multiplet), 3.75 (6H, methoxyl, singlet), 3.00–2.75 (2H, C-8, -8′, broad), 2.75–2.40 (4H, C-7, -7′, broad), 2.02 and 2.05 (24H, acetyl, two singlets).

Gas–Liquid Chromatography on Methanolysate of Permethyl Ether of Matairesinol-4,4′-di-O-β-D-glucopyranoside (1)

The carbanion prepared from sodium hydride (40 mg) and dimethyl sulfoxide (1 ml) was added to solution of matairesinol-4,4′-di-*O*-β-D-glucopyranoside (8 mg) in dimethyl sulfoxide (1 ml) under nitrogen gas and the mixture was stirred at room temperature. After 1 h, methyl iodide (0.2 ml) was added and the mixture was left standing overnight. The water was added to the reaction mixture, which was extracted with chloroform. The chloroform solution was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue (6.6 mg) was heated with 3% methanolic hydrogen chloride in a sealed tube placed in boiling water bath for 10 h. The reaction mixture was diluted with water and extracted with chloroform. The chloroform solution was washed with water, dried, and concentrated. The presence of methyl 2,3,4,6-tetra-*O*-methyl-D-glucopyranoside only in the concentrated solution was demonstrated by g.l.c. (condition: column, 15% poly-butanediol glycol succinate on Celite 545 (2 m × 3 mm); column temperature, 175°; carrier gas, N_2 (30 ml/min); t_R (min), 5.5 and 7.5).

Enzymatic Hydrolysis of Matairesinol-4,4′-di-O-β-D-glucopyranoside (1)

The emulsion (1 mg) (Tokyo Chemical Industry Co.), was added to matairesinol-4,4′-di-*O*-β-D-glucopyranoside (5 mg) in purified water (5 ml) and the mixture was left standing at room temperature for 2 weeks. The mixture was extracted with ether. The ether layer was dried and evaporated. The presence of matairesinol in the residue was proved by co-t.l.c. with an authentic sample. The water layer was evaporated to dryness. In the residue, only the presence of D-glucose was shown by the paper chromatography.

The authors are indebted to the Analytical Center of Nagoya City University for n.m.r. spectral measurements and elemental analyses.

Received October 6, 1972

The results of an investigation of the conformational properties of some benzophenones are reported. Carbon-13 n.m.r. spectra provide a generally applicable method to study the conformational preference of these compounds through the C=O shifts. Semi-empirical conformational energy calculations have been used to build contour maps of relative conformational energy as a function of the two internal rotation angles of these molecules. Conformations of minimum energy, as detected from the contour maps, have been assumed as the most stable. The phenyl torsional angles corresponding to these conformations, plotted against the C=O shifts, furnish linear relationships.

Les résultats d'une étude des propriétés conformationnelles de quelques benzophénones sont présentés. Les spectres r.m.n. du carbone-13 procure une méthode généralement applicable pour étudier la préférence conformationnelle de ces composés en se servant des déplacements du carbonyl C=O. Des calculs semi-empiriques de l'énergie conformationnelle ont été utilisés pour élaborer des diagrammes d'énergie conformationnelle relative en fonction des deux angles de rotation interne de ces molécules. Les conformations d'énergie minimum, obtenues à partir des diagrammes, ont été acceptées comme étant les plus stables. Les angles de torsion du phényl correspondant à ces conformations sont reliés linéairement avec les déplacements du C=O. [Traduit par le journal]

Can. J. Chem., **51**, 1053 (1973)

Introduction

The application of proton n.m.r. spectroscopy to the study of conformational preferences in ortho-substituted acetophenones and benzophenones has been recently reported (1). For acetophenones it has been shown that the carbon-13 carbonyl group shieldings can be employed effectively for the determination of the angle of twist between the C=O group and the benzene ring in these conjugated molecules (2). Potentially the carbon-13 n.m.r. (c.m.r.) method should have valuable application for the study of benzophenone conformation as well, however no c.m.r. data for benzophenones have been available in the literature to date.

We herein report results of a c.m.r. examination of nine benzophenones and detailed calculations of their preferred conformations.

In our approach, semi-empirical conformational energy calculations have been used to build contour maps of relative conformational energy as a function of the two internal rotation angles of these molecules.

Conformations of minimum energy, as detected from the contour maps, have been assumed the most stable.

The phenyl torsional angles corresponding to these conformations, plotted against the C=O shifts, furnish good linear relationships, thus providing a valuable method of conformational analysis.

Results

Table 1 contains the carbon-13 chemical shifts (downfield from internal TMS) for the benzophenones presently examined. To facilitate discussion the C=O shifts for related acetophenones are included in parentheses.

Assignments of the carbonyl resonances are straightforward, these carbons appearing at the lowest field position in the spectrum. Other carbons bearing no directly bonded hydrogens are easily recognized by their retention of singlet structure in the off resonance decoupling experi-

ment. In several compounds the ortho-aromatic carbons were assigned from specific ^1H decoupling since it is known (1) that aromatic protons ortho to the carbonyl group of acetophenones and benzophenones resonate at lower fields than those in meta- and para-positions. Remaining benzophenone ring carbon assignments were made by analogy with acetophenones (2) or by using well-established substituent effects on aromatic carbon shieldings (3).

Assignments of ring methyl and methoxy carbon resonances are unambiguous, the methyls appearing in the range $\delta = 18$–21 and methoxys near $\delta = 55$. It is clear that ortho-methyl groups resonate at *ca.* 2 p.p.m. higher field than their para counterparts, but the shieldings do not vary significantly with conformation.

Comparison of the ring-carbon shifts for benzophenones with the related acetophenones (2) reveals a striking similarity in the shieldings. Evidently there is no appreciable interaction between the two benzene rings in the diphenyl-ketones which affects these carbon shifts. In the proton spectra of these molecules, long range anisotropy effects are measurable (1); however, contributions to the carbon-13 shifts from anisotropic factors are of relatively minor importance (4). Accordingly, a detailed discussion of all ring-carbon shieldings seems unwarranted since the trends in acetophenones are well documented (2).

Carbonyl-carbon shieldings in these compounds, however, follow clear patterns. Interpretations are based on the well-established findings that conjugated carbonyl-carbon nuclei are shielded relative to their unconjugated counterparts (5). This effect is attributed to an increase in the electron density at the C=O in the conjugated systems. In the present series the C=O shifts for benzophenones are at higher field than for the corresponding acetophenones, an observation consistent with the presence of the second aromatic ring in the diphenyl-ketones. Also, within a series, as the degree of steric interference increases at the ortho-position, the carbonyl-carbon becomes deshielded, indicating the presence of steric inhibition of resonance. For acetophenones, Dhami and Stothers have correlated the torsional angle between the ring and the C=O group with the carbonyl shift and ob-

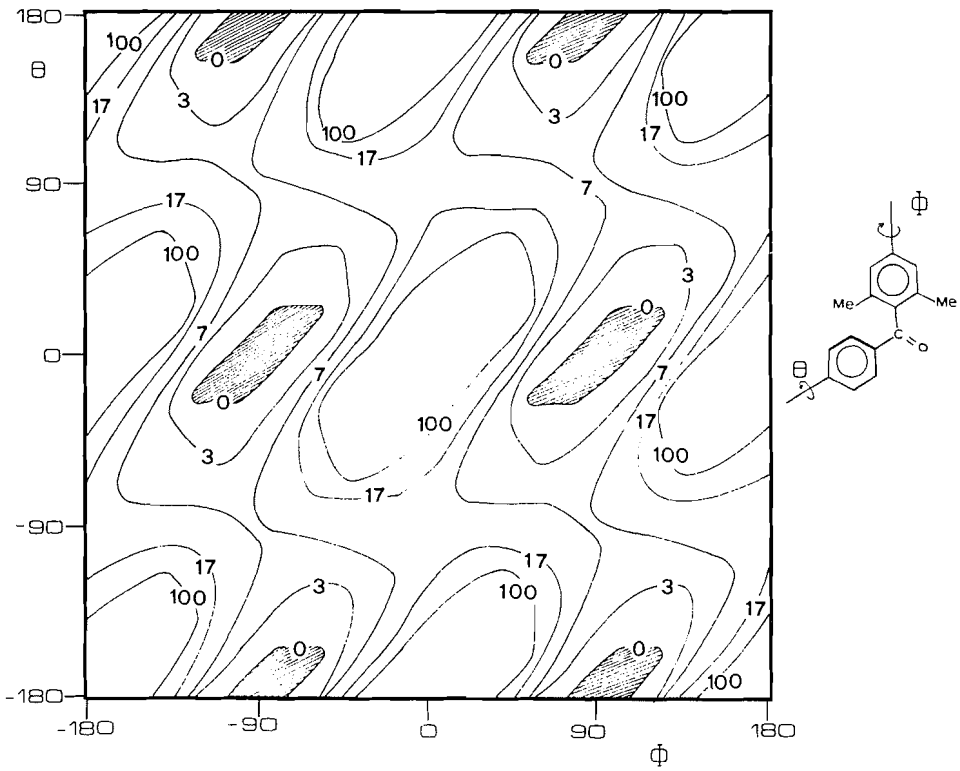

FIG. 1. Energy contour map of 2,6-dimethylbenzophenone. The planar starting conformation ($\phi = \theta = 0°$) is represented in the upper right side. The shaded area corresponds to the energetically "allowed" region. Numbers contained in the figure are energies in kcal/mol.

tained reasonable geometries (2). The situation in benzophenones is more complex since two torsional angles must be estimated.

Accordingly, we have calculated (see Experimental for details) the energy contour maps of some ortho-methyl substituted benzophenones as a function of the two internal rotation angles ϕ and θ. Relevant data are summarized in Table 2 and an example is given in Fig. 1.

The energy minimum for the unsubstituted benzophenone (Table 2) is found at $\phi = 30$, $\theta = -30°$.

This value compares favorably with that found (6) by Extended Huckel (EH) calculations for the same molecule ($\phi = 38$; $\theta = -38°$) and with a number of experimental figures from various techniques (7*b*, 7*c*, 8).

Also the position of the barrier to internal rotation (Table 2) is coincident with that found (6) by EH calculations, but its value (2.5 kcal/mol) is about twice as high.

As evidenced by the data in Table 2 the positions of the minima vary sensibly according to the substitution pattern. Molecular conformations identified by these energy minima have been assumed as the most stable and the corresponding phenyl torsional angles have been used in the correlations with spectral data.

Methyl Benzophenones

For the methyl benzophenones a plot of the observed ^{13}C carbonyl shift *vs.* $\cos^2 \phi + \cos^2 \theta$ is shown in Fig. 2. A correction factor for the presence of an ortho-methyl group has been suggested based on the finding that in ortho-xylenes, methyl carbons appear at slightly higher field (1 p.p.m.) than for cases where the methyls are further separated (9). Support for including this 1 p.p.m. per ortho-methyl correction in carbonyl compounds is gained from results for ortho-tolualdehyde, mesityaldehyde, and acetophenones (2). A plot which includes these corrections for ortho-methyl benzophenones is shown by the dotted line in Fig. 2.

Clearly, as the degree of steric hindrance at the ortho-position increases, the C=O group is

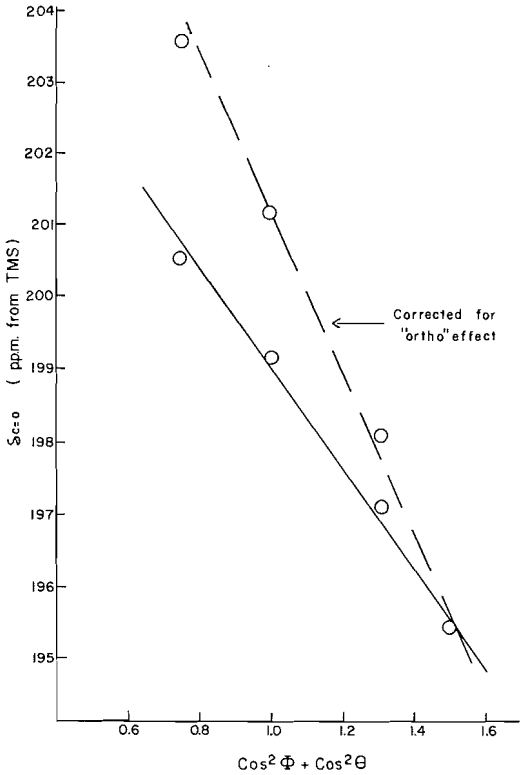

FIG. 2. Plot of carbonyl-carbon shielding *vs.* calculated phenyl torsional angles for benzophenone and ortho-methylbenzophenones.

less shielded, reflecting a decrease in the electron density at this carbon due to the attenuated conjugation with the benzene ring.

A check on the origin of the downfield C=O shifts with bulky ortho-substitution is provided by examination of the variation of the shielding of the aromatic carbon para to the C=O group. For both acetophenones and benzophenones the para-carbon is deshielded relative to benzene (δ = 128.7), due to the conjugative electron-withdrawing effect of the C=O group. In acetophenone where the torsional angle is 0°, the para-carbon resonates at 132.0 p.p.m. For benzophenone the calculated torsional angles are 30° and accordingly an upfield shift for the para-carbon is expected since the degree of resonance between *a single* aromatic ring and the C=O group should be decreased relative to the acetophenone. Indeed a small upfield shift to 131.6 p.p.m. is seen for the para-carbon of benzophenone. For ortho-methyl benzophenone the para-carbon is shifted upfield to 130.3 p.p.m. reflecting the decrease in resonance interaction on substitution of a bulky ortho-group. In the mesitylbenzophenones **3** and **4**, the trend is evident at the C-4′ position. Addition of the ortho-methyl group in **4** increases the calculated angle of twist to 30° and shifts the C-4′ resonance up to 130.9 p.p.m., whereas without this group a shielding of 132.5 p.p.m. is found. An apparent inconsistency in the C-4 shifts is present for compounds **6** and **7**. From the above argument the C-4 resonance in **7** is expected to be at higher field than in **6**, but a small effect (129.0 $\pm$ 0.1) *vs.* (129.4 $\pm$ 0.1) in the opposite direction is found. No ready explanation for this is available. In the following discussion, additional reasons for viewing the data for ortho-methoxy compounds with caution are presented.

Methoxy Benzophenones

Conformational calculations are not available for these compounds and thus only a qualitative discussion of trends is permitted. Addition of a para-methoxy group to benzophenone shields the C=O by 2.2 p.p.m., an effect which may be due to conjugative electron release by the para-oxygen atom. In the acetophenones (2) a similar albeit smaller effect is present. An ortho-methoxy function as in **6** deshields the carbonyl by 0.6 p.p.m. relative to **5** which may be indicative of some steric inhibition of resonance by this ortho-group. Direct comparison with benzophenone is not possible since a sample of ortho-methoxy benzophenone was not available. A comparison of acetophenones (2) however, shows a deshielding effect of 1.8 p.p.m. in the ortho-methoxy derivative.

In compounds **6**, **7**, and **8** it is clear that addition of ortho-methyl groups to the second aromatic ring increases the steric inhibition of resonance, causing the C=O shieldings to move to lower field. For compound **9** the low field C=O shift of 197.7 p.p.m. is puzzling. If indeed there is steric interference to resonance due to the ortho-methoxy group, the C=O shift in **7** should be at lower field than in **9**, which is not observed. A similar discrepancy occurs with the corresponding acetophenones (3).

It is apparent that successive addition of ortho-methyl groups gives rise to predictable changes in c.m.r. C=O shifts which are useful for estimating torsional angles in benzophenones. Results for molecules bearing ortho-methoxy groups, however, must be viewed with some caution.

It is of interest to compare the ^{13}C n.m.r. method with u.v. spectroscopy, which has been used extensively for studying steric inhibition of resonance. For methyl benzophenones with identically substituted rings, Rekker and Nauta (10) found that ortho-substitution causes a measurable decrease in the intensity of absorption of the K band (also termed the conjugative or C band). A value of 15° for the benzophenone torsional angle was obtained which is somewhat smaller than the present result of 30°.

The difficulties in obtaining accurate band intensity measurements from u.v. spectra are well known (11). In the benzophenone u.v. spectra (10) the B and K bands overlap partially further limiting the precision of the technique. At best one is employing an energy difference between an electronically excited state and ground state to evaluate a property of the ground electronic state.

^{13}C shifts, however, arise from the ground electronic state only, and the possibility of overlapping bands is remote, since the C=O resonances are at characteristically low field. Furthermore, contributions from non-steric effects can often be corrected as illustrated for the methyl group in Fig. 2.

We conclude that ^{13}C n.m.r. is a valuable technique for the examination of conformational preferences in Ar—X—Ar systems. Results for compounds having X = O, S, SO_2, and CH_2 will be reported in the near future.

Experimental

Spectra

The carbon n.m.r. spectra were obtained at 25.2 MHz using a Varian XL-100-12 n.m.r. spectrometer, most commonly under conditions of complete proton noise decoupling. Spectral accumulations were accomplished with a Varian C-1024 time-averaging computer. Samples were contained in 8 mm tubes and were examined as 0.5 *M* solutions in $CDCl_3$, containing 2% TMS as an internal standard. Off resonance decoupling experiments were carried out with the proton frequency offset approximately 500 Hz from the center of the proton spectral region. During the specific proton decoupling experiments the noise modulation was turned off.

Calculations

These were performed with help of a microcomputer Hewlett-Packard 9100 B. The starting conformation ($\phi = \theta = 0°$) for the compounds studied was taken with both rings planar, and the origin of the axes was placed at the bridge carbon atom. Interatomic distances and natural bond angles were taken from pertinent literature data (7).

Distances among interacting atoms were computed for each pair of ϕ and θ values calculating first (trigonometrically) the atomic coordinates for each interacting atom for a fixed conformation and then applying the usual rotation matrix methods (12). Non-bonded interactions were obtained from the calculated distances according to the Lennard-Jones potential (13). Torsional energies were not taken into account because they were found to be negligible (14).

Individual energy values for each one of the interacting pairs considered were added together obtaining the total strain energy (unminimized) for each pair of ϕ and θ values from 0–360°, with a 10° increment.

The strain energies found were minimized according to a procedure described in a previous paper (6).

The molecular-mechanical approach of computing the molecular energy does not normally include resonance interaction. In order to take into account this term we have subtracted, from the total strain energy of the methyl benzophenones studied, the theoretical conjugative energy (15) (E_0) of 6.0 kcal/mol which was assumed to vary (15, 17) as a function of the two internal rotation angles: $E = E_0 (\cos^2 \phi + \cos^2 \theta)$.

Compounds

Syntheses and physical properties of the benzophenones were reported previously (1).

The Photo-addition of Naphthalene and Acrylonitrile. An X-ray and Nuclear Magnetic Resonance Study of the Cycloadducts

R. M. BOWMAN, C. CALVO, J. J. MCCULLOUGH, R. C. MILLER, AND I. SINGH

Department of Chemistry, McMaster University, Hamilton, Ontario

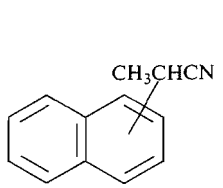
Received August 2, 1972

The photoaddition of naphthalene and acrylonitrile has been reinvestigated. It was found that the cyclobutane adduct described previously is *endo*-7-cyano-2,3-benzobicyclo[4.2.0]-octa-2,4-diene (**7**), and not the *exo*-8-cyano compound. The structure was determined from an X-ray diffraction study on the *p*-bromophenylurethane of the carbinol derived from the cyano-compound. The structural details are described. The crystallographic data are $a = 13.85(1)$, $b = 7.976(2)$, $c = 12.752(4)$ Å, $\alpha = 90.80(3)$, $\beta = 87.02(6)$, $\gamma = 90.99(5)°$ space group $P\bar{1}$, $Z = 2$ units of $C_{20}H_{18}O_2NBr$. The least-squares residual R was 0.085 for 651 X-ray reflections measured on a Syntex P1 diffractometer using graphite-monochromatized Mo radiation. The methine proton resonances in the 220 MHz n.m.r. spectrum of **7** were resolved using pyridine solvent, and the coupling constants are consistent with the structure and geometry, as derived from the X-ray work. A small fraction (7%) of 8-cyano-2,3-benzobicyclo[4.2.0.]octa-2,4-diene was also formed. This is tentatively assigned as the *endo* isomer, and on base treatment it isomerizes to a new compound, identified as the *exo* isomer. In contrast, the major cycloadduct **7** is recovered unchanged from base treatment. The folded geometry of the four-membered ring in these adducts apparently determines the stabilities of the epimers, and the proton–proton vicinal coupling constants.

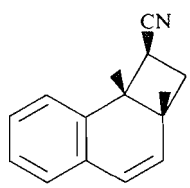
La photoaddition du naphtalène et de l'acrylonitrile a été réétudiée. On a trouvé que l'adduit cyclobutane précédemment décrit est l'*endo*-cyano-7 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 (**7**) et non l'*exo*-cyano-8. La structure a été déterminée par la diffraction de rayons X sur le *p*-bromophényluréthane du carbinol dérivé du composé cyano. Des détails sur la structure sont fournis. Les données cristallographiques sont: $a = 13.85(1)$ $b = 7.976(2)$, $c = 12.752(4)$ Å, $\alpha = 90.80(3)$, $\beta = 87.02(6)$, $\gamma = 90.99(5)°$, le groupe spatial est $P\bar{1}$ et $Z = 2$ unités de $C_{20}H_{18}O_2NBr$. La méthode des moindres carrés donne un R résiduel de 0.085 pour 651 réflexions de rayons X prises sur diffractomètre syntex P1, avec une radiation Mo rendue monochromatique par le graphite. Les résonances du proton méthine en r.m.n. à 220 MHz, ont été résolues avec la pyridine comme solvant; les constantes de couplage sont compatibles avec la structure et la géométrie fournies par les rayons X. Une petite fraction (7%) de cyano-8 benzo-2,3 bicyclo[4.2.0] octadiène-2,4 a été également formée. On a tenté de l'identifier à l'isomère *endo*, ce dernier s'isomérise par traitement basique en un nouveau composé identifié à l'isomère *exo*. Le cycloadduit **7** a été retrouvé inchangé après traitement basique. La géométrie plissée du cycle à quatre membres dans ces adduits détermine apparemment les stabilités des épimères et les constantes de couplage vicinal entre protons. [Traduit par le journal]

Can. J. Chem., **51**, 1060 (1973)

During the past few years, we have reported studies of products (1, 2) and mechanism (3, 4) of the photoaddition of naphthalene and acrylonitrile in hydroxylic solvents. The products were assigned the structures **1**, **2**, and **3**.



1, 2



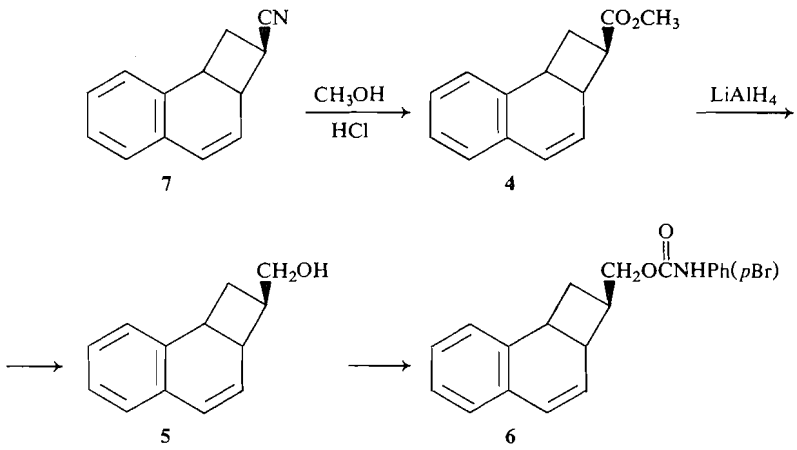
3

The cycloadduct was assigned the structure *exo*-8-cyano-2,3-benzobicyclo[4.2.0]-octa-2,4-diene (**3**) on the basis of n.m.r. evidence, equilibration behavior, and unit cell dimensions in the crystal (1, 2). However, in the course of the quantitative work on this reaction (3, 4) a second cycloadduct was found (7% yield) whose n.m.r. spectrum suggested that it was 8-cyano-2,3-benzobicyclo[4.2.0]-octa-2,4-diene. Since this minor adduct was not an epimer of the major one (see below), considerable doubt was cast on structure **3** for the latter. It was therefore decided to reinvestigate the structure of the major cycloadduct, and of the methods available, X-ray was chosen since this would reveal the position and stereochemistry of the cyano-group.

Results

Preparation of Derivative for X-ray Study

The major cycloadduct m.p. 98°, from photolysis of naphthalene and acrylonitrile (1, 2) was



SCHEME 1

converted to the methyl ester **4** by treatment with methanol and hydrogen chloride in ether (5). Reduction of the ester with $LiAlH_4$ gave the carbinol **5** as an oil. The latter reacted with *p*-bromophenylisocyanate in cyclohexane at reflux to give the *p*-bromophenylurethane **6**, m.p. 155–157°. This derivative gave single crystals from 95% ethanol, which were used in the X-ray work. The route from the photoadduct to the derivative **6** is shown in Scheme 1.

Structure of Photoadduct

The X-ray work on the *p*-bromophenylurethane **6** is described in detail in the Experimental. The structure of **6** is shown in Fig. 1, and the bond distances and angles in Table 1. It can be seen that the carbinol CH_2 group in **6** is bonded at C-7, and has the *endo*-configuration. The major photoadduct must therefore be *endo*-7-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene **7**, and not **3** as previously assigned.

Some interesting structural features of the benzobicyclo[4.2.0]octa-2,4-diene ring system follow from the X-ray structure. It is found, Table 2, that C-1, -2, -3, -4, -5 are coplanar, with C-6 0.16 Å out of this plane. The four-membered ring is *cis*-fused at C-1 and -6, and is non-planar, being folded about the C6–C8 diagonal by 21°. The dihedral angle in this compound is considerably smaller than in cyclobutane (33°), and somewhat smaller than in a number of substituted cyclobutanes (6, 7). The dihedral angle of 21° does allow the C-7 *endo*-substituent to adopt the more stable, equatorial conformation (7*d*, 8). The conformation of **7** is shown in Fig. 2.

It was reported previously (1, 2) and confirmed in more recent experiments that **7** did not epimerize on treatment with base, even though one proton was exchanged for deuterium under mild, basic conditions. We must conclude, therefore, that **7** is appreciably more stable than the (unknown) epimer. This is understandable

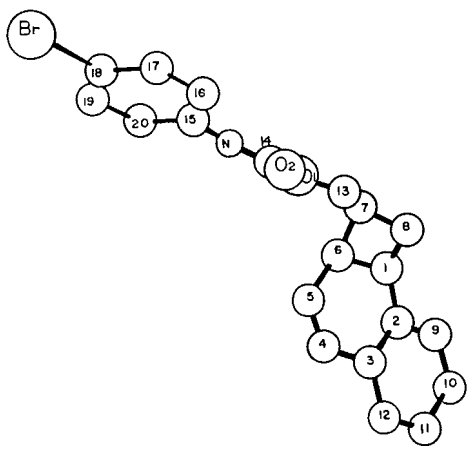


FIG. 1. Molecular structure of *p*-bromophenylurethane **6**; numbering agrees with that used in the Tables and in the text.

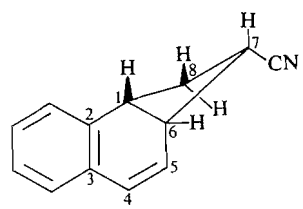

FIG. 2. Conformation of four-membered ring in photoadduct **7**.

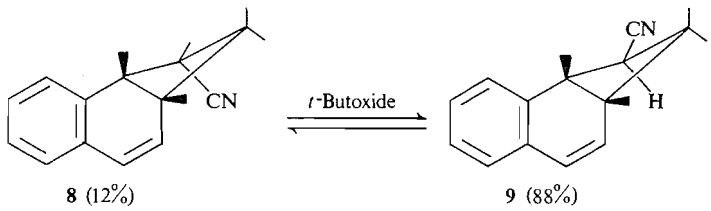
in terms of the geometry of **7**, since the epimer would have the cyano-group axial, if the cyclobutane ring is folded as shown.

Structure of the Minor Cycloadduct

The minor cycloadduct was present in about 7% of the total photoadduct yield, as estimated by v.p.c. analysis, and was isolated by column chromatography. The adduct **8** had m.p. 56–58° and isomerized on treatment with base to a compound **9**, m.p. 47–48°. Both **8** and **9** (and **7**) had mass spectra typical of cyclobutanes (9), in that the parent ion peaks at *m/e* 181 (3) were weak, and the base peaks at *m/e* 128 (100) corresponded to naphthalene cation. It is obvious that **8** and **9** must be the epimeric 8-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-dienes, but the question of which is which cannot be answered with certainty. However, if it is assumed that the four-membered ring is folded in the same way as in **7**, the structures of **8** and **9** can be assigned, as shown in Scheme 2.

The equilibrium composition is 88% of **9** and 12% of **8**. The cyano-group will be equatorial in the *exo*-compound, which should therefore correspond to the more stable isomer, **9**. The *endo*-isomer should therefore be the photoadduct, **8**.

This tentative assignment is supported by the n.m.r. spectra, which are described in Table 2. In the spectrum of **9**, H-8 (α to cyano-group) appears as a quartet, $J = 10.0$ Hz. That is, all



8 (12%) **9** (88%)

SCHEME 2

TABLE 2. Least-squares planes and out-of-plane distances*

Atom	Out-of-plane deviations (Å)
(a) Plane defined by C-1, -2, -3, -4, -5, -9, -10, -11, -12 is 9.18X − 3.65Y + 3.08Z = 11.04 with a standard of 0.05 Å	
C-6	0.16
C-7	−1.18
C-8	−1.58
C-13	−2.20
(b) Plane defined by C-6, -7, and -8 is −8.6X + 4.04Y + 7.31Z = 5.64	
C-1	−0.41
C-13	1.12
(c) Plane defined by C-1, -6, and -8 is 4.58X + 4.14Y + 5.62Z = 8.83	
C-2	1.17
C-3	2.44
C-4	2.43
C-5	1.39
C-7	−0.41
C-9	1.10
C-10	2.28
C-11	3.46
C-12	3.56
C-13	0.27

*The acute angle between planes (*a*) and (*c*) is 21.33° and that between (*b*) and (*c*) is 72.59°. The out-of-plane (*a*) distance of C-7 and -8 support the stereochemistry proposed as does the fact C-1 and -13 are on opposite sides of plane (*b*). Further support is provided by the fact that C-7 is on the opposite side of all the remaining atoms reported out-of-plane (*c*) and in particular C-13.

the vicinal coupling constants for H-8 are large. In **8** however, the H-8 resonance appears as a doublet of triplets, $J = 6.0$ and 8.5 Hz (a further splitting of $J = 2.0$ Hz is present, due to coupling with H-8). The coupling constant of 6.0 Hz may be due to a vicinal equatorial–equatorial coupling, since this is variable in magnitude (10). All the couplings in **9** however, should be axial–axial or axial–equatorial, and should therefore be large (10).

To check the above assignments, a spin decoupling experiment was performed on **8**. The multiplet at 3.20 δ (assigned to H-6) was irradiated, and the following changes were noted. The H-5 doublet of doublets became a doublet; the triplet at 3.92 δ (H-1) collapsed to a broad peak, and a small change was observed in the multiplet at 3.45 δ (H-8).

Interpretation of the Nuclear Magnetic Resonance Spectrum of the Major Cycloadduct

The n.m.r. spectrum of **7** ($CDCl_3$) at 100 MHz was described previously (1, 2). It was reported that the three methine protons gave rise to a complex multiplet at 3.54 δ, and the protons of the methylene group gave a multiplet at 2.65 δ, and this can be seen in Fig. 3A. No coupling constants could be measured from these multiplets. Since the geometry of the four-membered ring is known from our X-ray study, it seemed worthwhile to obtain values for the vicinal proton–proton coupling constants in this ring. Interpretation of cyclobutane p.m.r. spectra is difficult, in spite of the considerable amount of data which is available (11), and it was of interest to see if the spectrum of **7** could be interpreted by taking the shape of the cyclobutane ring into account (10).

During deuterium exchange experiments on **7**, using pyridine as solvent, it was noted that the methine multiplet was partially resolved at 100 MHz. By utilizing this solvent, which is known to shift protons near a polar functional group (12), and by use of a 220 MHz instrument, the three resonances in the methine multiplet were resolved. The coupling constants and chemical shifts are given in Table 3, and the spectra in pyridine (220 MHz) and in $CDCl_3$ (100 MHz) are shown in Fig. 3.

The vicinal coupling constants for H-1 and -7 (the latter assigned by deuterium exchange) are large (8.5–10.0 Hz), which is reasonable for structure **7**. There is no equatorial–equatorial splitting to these protons, and this apparently is the only vicinal coupling in cyclobutanes which can be small (10).

A repeat of the spin decoupling experiment

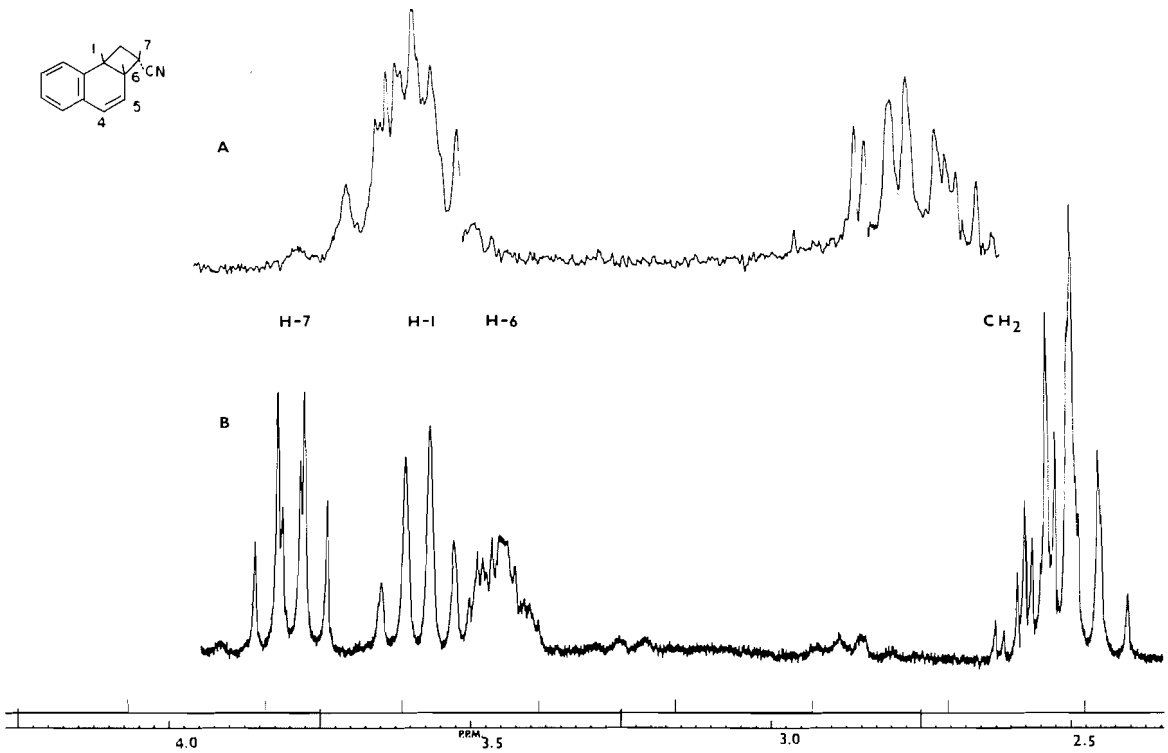


FIG. 3. N.m.r. spectra of cycloadduct **7**. (A) Spectrum at 100 MHz, $CDCl_3$ solvent; (B) spectrum at 220 MHz, pyridine solvent. The chemical shift scales for A and B are in approximate agreement, and chemical shifts should be taken from Table 2.

reported previously (2) revealed that the vinylic proton H-5 is coupled to the methine proton H-6, and not to the protons of the methylene group.

A discussion of the orientation in this photoaddition is included in the paper on substituent effects on the reaction (13).

Experimental

Materials

Reagents and solvents not listed here were obtained and purified as described previously (2). Acrylonitrile was Eastman Practical Grade, purified by the method of Bevington and Eaves (14).

Instrumentation

N.m.r. spectra were obtained with a Varian HA-100 instrument and chemical shifts are given in p.p.m. (δ) downfield from tetramethylsilane. I.r. spectra were run on a Beckman IR-5 or on a Perkin–Elmer 337 instrument. Mass spectra were normally measured on a Hitachi-Perkin–Elmer MRU 6 instrument. V.p.c. was carried out on a Varian 204B dual column instrument, using helium at 35 ml/min. Melting points were taken on a Kofler hot stage and are reported corrected. Microanalyses were by the Spang Microanalytical Laboratory, Ann Arbor, Michigan.

Photolysis of Naphthalene and Acrylonitrile

Naphthalene (1.025 g; 0.008 mol) and acrylonitrile (21.2 g, 0.4 mol) in 400 ml of 1:1 *tert*-butyl alcohol–*iso*-propyl alcohol were irradiated under argon, using the Hanovia 450 W lamp and a Pyrex filter, for 4 h. The solution was evaporated under vacuum, and the mixtures from seven identical runs were combined. The total crude yield was extracted with 250 ml of 5:1 hexane–ether mixture and filtered, and the filtrate was evaporated. The polymer-free mixture thus obtained was chromatographed on a 70 × 4.0 cm column of silica gel, slurry-packed in benzene, and eluted with this solvent. 200 ml fractions were collected. Fractions 1 and 2 contained naphthalene (2.15 g) and fractions 12–15 contained the substituted naphthalenes **1** and **2** (160 mg). The major cyclobutane **7** was found in fractions 16–29 (4.13 g, m.p. 97–98° from light petroleum). Fractions 30–40 contained the new cyclobutane, **8** mixed with **7** (total weight 750 mg). The latter fractions were combined and chromatographed on a 55 × 2.0 cm column of silica gel, again elution was with benzene, and 200 ml fractions were collected. Fractions 8–17 contained 500 mg of *8*, m.p. 55–60°, from light petroleum. The material was homogeneous by v.p.c. and t.l.c. Sublimation at 55–60°/0.1 mm, and further crystallization from light petroleum afforded *endo*-8-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene (**8**), m.p. 56–58°.

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.15; H, 6.12; N, 7.73. Found: C, 86.20; H, 6.12; N, 7.69.

*Measured at 100 MHz using $CDCl_3$ as solvent, except for 7 where H-1, -6, and -7 resonances were resolved at 220 MHz in pyridine solution; shifts given in p.p.m. downfield from tetramethylsilane.
†m = multiplet; d = doublet; dd = doublet of doublets; dt = doublet of triplets; ddt = doublet of doublets of triplets; q = quartet.
‡Coupling constants (*J*) given in Hz.

In the i.r. the CN stretch showed at 2265 cm^{-1} (CCl_4). The n.m.r. spectrum is described in Table 2 and in the text. Analysis of the photolysis mixture by v.p.c. (5 ft × 1/8 in. of 5% QF-1 on Chromosorb W, at 170°) showed the following ratios and retention times: **7**, 89%, 3.4 min; **8**, 7.0% 3.9 min; **1** and **2**, 4.0%, 2.6 min. The peaks of **7** and **8** overlapped and the ratio was measured using a Dupont Analog Curve Resolver.

Epimerization of endo-8-Cyano-2,3-benzobicyclo[4.2.0-]octa-2,4-diene (8)

Compound **8** (130 mg, 0.717 mmol) was dissolved in 15 ml of 0.1 *M* potassium *tert*-butoxide in *tert*-butyl alcohol. The mixture was stirred at ambient temperature in a nitrogen atmosphere, and the aliquots were withdrawn periodically and analyzed by v.p.c. on the above QF-1 column. A new peak of retention time 2.9 min appeared, and after 4 h of reaction, the area of this peak showed no further increase with time. This peak is identified as **9**, and the equilibrium mixture of **8** and **9** contained 88% of the latter. After 6 h, the mixture was poured into ether, and the solution was washed with 0.5 *N* HCl, then with saturated NaCl solution, and dried ($MgSO_4$). The oil obtained on evaporation of the solvent was chromatographed on a 2 × 65 cm column of silica gel. Elution was with benzene and 200 ml fractions were collected. Fractions 5–8 contained **9** (101 mg, m.p. 46–48°) and **8** (15 mg) was recovered in fractions 10–16. *exo*-8-Cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene had the CN band at 2265 cm^{-1}, and the n.m.r. spectrum is described above. Sublimation at 60°/0.1 mm, and crystallization from light petroleum gave colorless prisms, m.p. 47–48°.

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.15; H, 6.12; N, 7.73 Found: C, 86.26; H, 6.13; N, 7.67.

Since the retention times of **1**, **2** and **9** are very similar, it is difficult to know if **9** is formed in the photolysis. Since its presence was not noted during chromatography of the photolysis mixture, it can only be present in very minor amount.

Deuterium Exchange of endo-7-Cyano-2,3-benzobicyclo-[4.2.0]octa-2,4-diene (7)

To the cyano-compound **7** (20 mg) in dry pyridine (0.3 ml) was added 0.05 ml of 0.05 *M* NaOD, and the mixture was heated at 50° for 12 h. in an n.m.r. tube. Integration of the methine and methylene proton multiplets showed that one methine proton had been exchanged for deuterium. In this solution at 100 MHz the three methine proton resonances were partially resolved, and it was possible to identify the lowest field doublet of triplets with the proton removed by exchange.

Conversion of endo-7-Cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene (7) to endo-7-Carbomethoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene (4)

A mixture of methyl alcohol and anhydrous ether (7:20) (54 ml) at 0° was saturated with HCl from a tank by bubbling the gas through for 1 h. The cyano-compound **7** (1.0298 g, 0.00568 mol) was then added, and the solution was stirred (magnetic stirrer) for 8 h. Water (20 ml) was added dropwise at 0°, the mixture was warmed at 25°, and stirred 3 h. On pouring into water (500 ml) and extracting with ether, 144 mg of ester **4** was obtained. On allowing the aqueous layer from the extraction to stand 12 h, crystals of **4** (891 mg) m.p. 84–89° were deposited. The combined products were crystallized from ethanol–water to afford *endo*-7-carbomethoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene, 1.0200 g, 84%, m.p. 91–93°.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.44; H, 6.63.

$LiAlH_4$ Reduction of endo-7-Carbomethoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene

The ester **4** (700 mg, 3.267 mmol) in ether (20 ml) was added dropwise to a stirred slurry of lithium aluminum

hydride (2.0 g) in ether (100 ml). The mixture was stirred and heated under reflux for 12 h. Excess hydride was decomposed by the dropwise addition of water, and the ether was filtered and dried ($MgSO_4$). Evaporation gave an oil (524 mg, 85%) which declined to crystallize, but showed a broad i.r. absorption in the 3000–3500 cm^{-1} region (OH). This was assumed to be 2,3-benzobicyclo-[4.2.0]octa-2,4-dienyl-*endo*-7-carbinol (**5**) and was converted to the required derivative without further purification.

Preparation of the p-Bromophenylurethane of Carbinol (7)

The carbinol **5** (245 mg, 1.287 mmol) dried by azeotropic distillation of benzene, and *p*-bromophenylisocyanate (274 mg, 1.383 mmol) in cyclohexane (20 ml) were heated under reflux for 1 h. Crystals were deposited while the solution was still hot. The mixture was cooled and filtered to afford 272 mg (55%) of the *p*-bromophenylurethane of **5**, which gave needles, m.p. 155–157°, from 95% ethanol.

Anal. Calcd. for $C_{20}H_{18}O_2NBr$: C, 62.50; H, 4.72; N, 3.65; Br, 20.80. Found: C, 62.43; H, 4.64; N, 3.54; Br, 20.92.

These crystals were used in the X-ray study described below.

Description of X-ray Work on p-Bromophenylurethane (6)

Crystal Data

$C_{20}H_{18}O_2NBr$ f.w. = 384.26

Triclinic, space group $P\bar{1}$ with $a = 13.85(1)$, $b = 4.976(2)$, $c = 12.752(4)$ Å, $\alpha = 90.80(3)$, $\beta = 87.02(6)$, $\gamma = 90.99(5)°$, $V = 877.44$ Å³ $D_o = 1.39 \pm 0.08$ g/cm³, $Z = 2$, $D_c = 1.45$ g/cm³ (20 °C, λ(MoKα) = 0.71069 Å).

The derivative was crystallized from methanol–chloroform to obtain suitable plate-shaped crystals. The dimensions of the unit cell were obtained from a least-squares refinement of 15 values of 2θ measured with MoKα radiation using a Syntex automatic diffractometer. The calculated density assuming two molecules per unit cell agrees with the density measured using a solution of potassium iodide in water, and this leads to the space group $P\bar{1}$.

A crystal with dimensions 0.02 × 0.03 × 0.08 mm was used to collect data on the Syntex diffractometer. The MoKα used for intensity data collection was monochromatized using graphite. All the data are a hemisphere with a maximum radius defined by $2\theta \leq 35°$ were recorded using a θ–2θ scan with a scan rate determined by the intensity at the peak and scan range dependent upon the value of θ. Backgrounds were recorded on either side of the peak and used to determine the integrated

intensity together with an estimated standard deviation based upon counting statistics. The final reflections whose intensity were less than 36 were regarded as unobserved. Of the total 1113 reflections, 651 had observable intensities. The data were corrected for Lorentz and polarization but not absorption.

The bromine atom position was determined from the Patterson function. The signs determined from the subsequent structure factor calculation were used to calculate an electron density map from which the remaining atoms were found. The structure was further refined utilizing full matrix least squares programs. This and other calculations were done using 'X-ray 67' program system for X-ray crystallography published by the University of Maryland and adopted for use with the CDC 6400 by H. D. Grundy. The atomic scattering curves were taken from the International Tables for X-ray Crystallography (15). Weights, ω, were chosen so that $\omega|F_o - F_c|^2$ would locally be independent of the, F_o, observed structure factor and the function obtained was $\omega = [15 - 0.05|F_o|]^{-1/2}$. The unobserved reflections were weighted as the observed were and also included in the refinement. The final R value is 0.105 while the least-squares residual is 0.115.[1] The refinement was terminated when the calculated shifts were less than 1/3 of the estimated standard deviations. A final difference synthesis showed no missing structural features although peaks as 1/5 of a carbon atom were noted.

The final atomic parameters are recorded in Table 4, and the observed and calculated structure factors are compared in Table 5.[2] Table 1 contains a list of the pertinent bond lengths and angles with standard deviations calculated from the standard errors derived from the least-squares matrix. The structure is shown in Fig. 1.

We thank Mr. B. Sawyer for obtaining the 100 MHz n.m.r. spectra, and Dr. A. Grey and Mrs. V. Robinson of the Canadian 220 MHz n.m.r. center for the 220 MHz spectrum of 7. We are grateful to Dr. Grey for drawing our attention to ref. 10, and to Dr. R. F. Childs for suggesting the conditions for deuterium exchange of 7. We thank the National Research Council of Canada for financial support.

[1]The weighted $R = \left\{\frac{\Sigma\omega|F_o - F_c|^2}{\Sigma\omega|F_o^2}\right\}^{1/2}$

Oligoribonucleotide Synthesis. V.[1] Preparation of 2′-O-Tetrahydropyranyl Derivatives of Guanosine and Their Insertion into a General Stepwise Synthesis

THOMAS NEILSON, EDWARD V. WASTRODOWSKI, AND EVA S. WERSTIUK

Department of Biochemistry, McMaster University, Hamilton, Ontario

Received September 7, 1972

The syntheses of N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**5**) and its corresponding 5′-*O*-triphenylmethoxyacetyl derivative (**6**) are described. Compounds **5** and **6** are the protected derivatives of guanosine required for insertion into a phosphotriester synthesis for oligoribonucleotides. Syntheses of GpC and GpG were carried out to illustrate incorporation of **5** and **6** into a sequence.

Les synthèses de la *N*-benzoyl-2 *O*-tetrahydropyranyl-2′ guanosine (**5**) et de son dérivé *O*-triphénylmethoxyacétyl-5′ correspondant (**6**) ont été décrites. Les composés **5** et **6** sont des dérivés protégés de la guanosine requis pour l'insertion dans la synthèse d'un phosphotriester d'oligoribonucléotides. Les synthèses du GpC et GpG ont été realisées pour illustrer l'incorporation de **5** et **6** dans une séquence.
[Traduit par le journal]

Can. J. Chem., 51, 1068 (1973)

Oligoribonucleotides isolated from enzymic digestions of native RNAs vary in length and sequence. In order to synthesize any of these fragments or their modifications, for example, single base changes, a general synthesis for oligoribonucleotides of any length and sequence, is essential.

In one of our previous communications (2), a convenient stepwise synthesis for protected triribonucleotides of predetermined sequence containing adenine, cytosine, and uracil base residues, was described. Corresponding 2′-*O*-tetrahydropyranyl-nucleoside derivatives were coupled together using β,β,β-trichloroethyl 3′-5′-phosphotriester linkages to give protected triribonucleotide derivatives which on deblocking gave free trinucleoside diphosphates.

In this communication we report the syntheses of 2′-*O*-tetrahydropyranylguanosine derivatives and their incorporation into some sample diribonucleotides. This extension of our previous studies allows the assembly of sequences containing the guanine base residue at any position within the sequence and not just at the 3′-terminal position.

Since the *N*-benzamide grouping was used to protect adenine and cytosine bases in these current studies, it seemed the logical choice for protection of the 2′-amino group of guanosine. As well as giving better solubility to intermediates, the benzoyl group should provide more stable protection than would the acetyl group which has been used in earlier synthesis (3).

N^2-Benzoylguanosine (**1**) (4) was treated with excess trimethyl orthoacetate in the presence of *p*-toluenesulfonic acid to give the cyclic orthoacetate derivative **2** as the major product (see Scheme 1). Immediate benzoylation using benzoyl chloride in anhydrous pyridine converted **2** to its corresponding 5′-*O*-benzoate ester (**3**). Aqueous acetic acid cleaved the orthoacetate ring to give a mixture of the 2′- and 3′-acetates of N^2-5′-*O*-dibenzoyl guanosine in 67% overall yield. P.m.r. analysis of the acetate methyl signals revealed a 1:1 mixture. Fractional crystallization from ethanol gave pure 3′-*O*-acetyl-N^2-benzoylguanosine (**4**) in 40% yield. Routine reaction of **4** with dihydropyran followed by careful de-*O*-benzoylation gave a diastereoisomeric mixture of N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**5**). Silica gel chromatographic resolution of this mixture gave low R_F isomer **5***a* (50% yield) and high R_F isomer **5***b* (20% yield).

In accordance with normal practice, the less soluble low R_F isomer **5***a* was used exclusively for the 5′-terminal position of a short sequence to be assembled by stepwise synthesis, while the more soluble isomer **5***b* was "ear-marked" for guanosine insertion in positions other than the 5′-terminal slot. Before **5***a* could be incorporated into a sequence, conversion to its 5′-*O*-triphenylmethoxyacetate (**6**) was necessary to ensure phosphorylation only at the 3′-hydroxyl. This

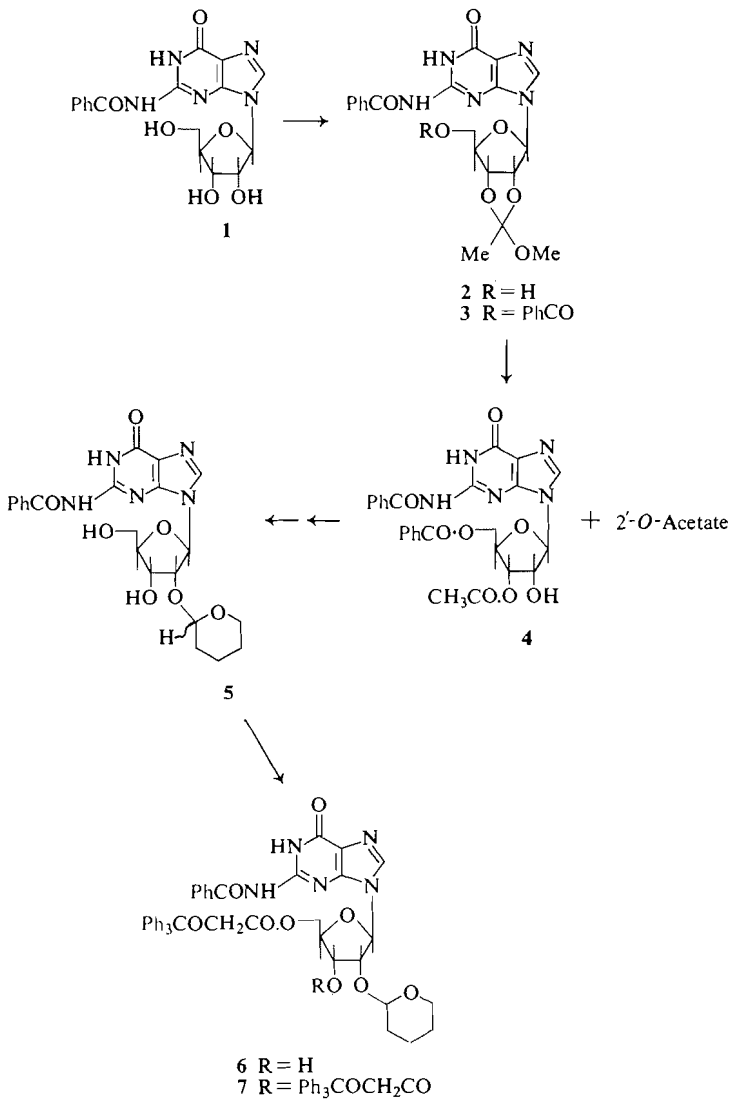

SCHEME 1

protecting group can be cleaved specifically using very dilute alkaline treatment (1). Once a protected di- or triribonucleotide has been prepared starting with **6** and coupling successive 2′-*O*-tetrapyranylnucleoside derivatives by means of 3′–5′-phosphotriester linkages, regeneration of its 5′-terminal hydroxyl would allow the partially deblocked di- or trinucleotides to participate in block synthesis, thus giving much longer oligoribonucleotides.

Treatment of **5***a* with sodium triphenylmethoxyacetate (1) and tri-isopropylbenzenesulfonyl chloride (TPS) in pyridine gave the desired product (**6**) in 52% yield accompanied by some disubstituted material (**7**) (16%) (see Scheme 2). Dilute aqueous ammonia treatment on **6** regenerated **5***a* completely within 2 h. Further treatment (>2.5 h) resulted in detectable hydrolysis of the benzamide grouping. This difference in hydrolysis rates will guarantee selective cleavage of the trityloxyacetyl group at the oligoribonucleotide level.

The bis-cyclohexylammonium salt of β,β,β-trichloroethyl phosphate (5) was converted to its corresponding pyridinium salt and activated in pyridine using 2 equiv of TPS. Phosphoryla-

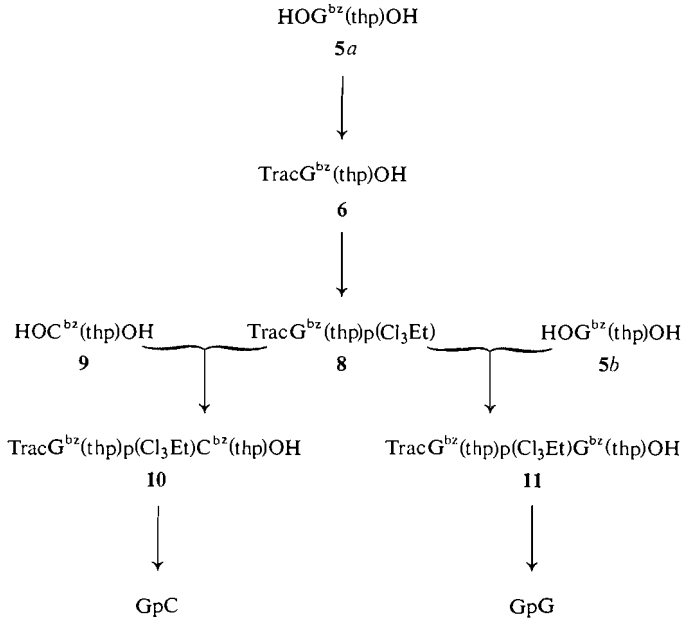

SCHEME 2

tion of **6** was carried out in pyridine to give protected Gp **8** as its pyridinium salt. Immediate activation with 1 equiv of TPS and coupling with the 5′-hydroxyl of the higher R_F diastereoisomer of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**9**) (6) gave protected GpC **10**[2] in 30% yield over two steps. In another experiment protected Gp **8** was coupled to the 5′-hydroxyl of the higher R_F diastereoisomer of N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**5***b*) to give protected GpG **11** in 28% yield over the two steps. These yields were lower than the previous protected dinucleotide preparations; however, in both couplings substantial percentages of protected Gp **8**, 35 and 38% respectively, were left unreacted and recovered. Apparently, reaction of TPS with the incoming nucleoside derivative competes with phosphotriester formation involving protected Gp **8**. Protected dinucleotide derivatives **10**[2] and **11** appeared as elongated spots on t.l.c. because each in reality is a diastereoisomeric pair resulting from the asymmetry of 3′–5′-phosphotriesters. No attempt was made to resolve these pairs as the chirality disappears on deblocking (1).

Complete deblocking of **10** and **11** using the three-step procedure described previously (2) gave the free dinucleoside phosphates, GpC and GpG, respectively, in *ca.* 80%.

Snake venom diesterase treatment on GpC gave G and pC in the correct ratio, similarly GpG gave G and pG. Complete digestions in each case confirmed the fidelity of the 3′–5′-diphosphate linkages (< 1% 2′–5′ linkage) thus confirming that specific 2′-*O*-tetrahydropyranyl protection exists in the guanosine derivatives, **5** and **6**.

Experimental

The p.m.r. spectra were recorded on a Varian T60 or Varian HA-100 spectrometer in 10–15% (w/v) DMSO-d_6 – D_2O solutions, and line positions are reported in p.p.m. from the reference (TMS).

Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were usually developed in 5 or 10% methanol in methylene chloride mixtures. The t.l.c. detection was carried out using a ceric sulfate spray (1 g $H_4Ce(SO_4)_4$ in 10% aqueous sulfuric acid solution) and followed by heating the plates at 300–400 °C. Compounds containing a trityl group develop as yellow spots, while others appear as brown colorations.

[2]To condense the large structural formulae necessary to describe protected dinucleotides shown in Scheme 2, a shorthand method suggested by the IUPAC–IUB commission on Biochemical Nomenclature is adopted (8).

For example, N^2-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanylyl (3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine can be written as TracG^{bz}(thp)p(Cl$_3$Et)C^{bz}(thp)OH where Trac is trityloxyacetyl.

TABLE 1. The R_{Up}'s of free dinucleotides and markers

Compound	Paper chromatography (Whatman No. 1) solvent A	Thin layer chromatography		
		Solvent A	Solvent B	Solvent C
GpC	0.95 (0.94)*	0.90	0.33	1.06
GpG	0.78 (0.80)*	0.67	0.23	
Up	1.0	1.0	1.0	1.0
G	1.81	4.9	1.52	3.5
pC	0.70	0.23	0.74	0.62
pG	0.50	0.21	0.48	

*Literature values ref. 7.

Paper chromatography was performed using the descending technique on Whatman No. 1 or 3 MM paper. Analtech pre-coated cellulose plates (Avicel F) were used for t.l.c. of deblocked nucleotides. The solvent systems employed for paper chromatography and t.l.c. on cellulose were (A) ethanol – 1 *M* ammonium acetate, p*H* 7.5 (7:3, v/v); (B) 1-BuOH – glacial HOAc – H_2O (5:3:2, v/v); (C) 2-PrOH – concentrated NH_4OH – H_2O (7:1:2, v/v). A short wave u.v. lamp was used for detection.

It was essential that moisture be excluded from all coupling reactions. After evaporation *in vacuo* of the pyridine solution, normal pressure was restored with dry nitrogen and *not* atmospheric air. All such evaporations were carried out in the temperature range of 30–40 °C.

Emulsion, frequently obtained during methylene chloride extractions of aqueous pyridine solutions, was broken by the addition of a few milliliters of saturated sodium chloride solution.

N^2-Benzoyl-2′,3′-O-methoxyethylideneguanosine (2)

Trimethyl orthoacetate (10.0 ml) was added to a stirred suspension of N^2-benzoylguanosine (4) (3.75 g, 9.70 mmol) and *p*-toluenesulfonic acid monohydrate (0.2 g, 1.05 mmol) in anhydrous dimethylformamide (7.5 ml). After 30 min, t.l.c. indicated *ca.* 50% conversion into a major product (R_F 0.06 → 0.5 in 10% CH_3OH–CH_2Cl_2). Further addition of *p*-toluenesulfonic acid monohydrate (0.2 g, 1.05 mmol) completed the reaction. The mixture was then cooled and neutralized with concentrated ammonia solution, then evaporated *in vacuo* to half volume. Pyridine (10 ml) was added and this solution was used for the next reaction without any further purification.

N^2-5′-O-Dibenzoyl-2′,3′-O-methoxyethylideneguanosine (3)

Benzoyl chloride (2.5 ml, 21 mmol) was added dropwise, with stirring to a cooled (ice) solution containing N^2-benzoyl-2′,3′-*O*-methoxyethylideneguanosine (**2**) prepared above. After 30 min, t.l.c. indicated complete conversion into a major product of R_F 0.85 in 10% CH_3OH–CH_2Cl_2. Ice (*ca.* 5 g) was then added, and after 30 min the reaction mixture was poured into ice-water (50 ml) and repeatedly extracted with methylene chloride (3 × 25 ml). The combined organic extracts were washed with saturated sodium bicarbonate solution (50 ml), followed by water (2 × 25 ml) and evaporated *in vacuo* to a yellow oil (R_F 0.85 in 10% CH_3OH–CH_2Cl_2) which was used in the next reaction without further purification.

3′-O-Acetyl-N^2-5′-O-dibenzoylguanosine (4)

A mixture of crude N^2-5′-*O*-dibenzoyl-2′,3′-*O*-methoxyethylideneguanosine (**3**) prepared above, and 10% acetic acid (25 ml) was stirred at room temperature. After 16 h t.l.c. indicated complete reaction (R_F 0.85 → 0.63 in 10% CH_3OH–CH_2Cl_2). The reaction mixture was then repeatedly extracted with methylene chloride (3 × 25 ml), the combined organic extracts were washed with saturated sodium bicarbonate solution (50 ml) and evaporated to dryness *in vacuo*. The yellow glass (4 g) was purified by chromatography on silica gel (100 g) in methylene chloride. Elution with 3.0 (1 l) and 3.5% (1 l) methanol – methylene chloride mixtures gave a mixture of 2′ and 3′-*O*-acetates (3.5 g, 67%; R_F 0.64 in 10% CH_3OH–CH_2Cl_2). The p.m.r. spectrum of the mixture showed signals (δ TMS) at 6.2 (1H, doublet; $J \simeq 4.5$ Hz; 1′-anomeric proton of 2′-*O*-acetate); 6.0 (1H doublet; $J \simeq 6.0$ Hz; 1′-anomeric proton of 3′-*O*-acetate); 2.20 (3H, sharp singlet; 3′-$COCH_3$ protons); and 2.15 (3H, sharp singlet; 2′-$COCH_3$ protons). The p.m.r. spectrum indicated a *ca.* 1:1 mixture of the two isomeric acetates. Pure 3′-*O*-acetyl-N^2-5′-*O*-dibenzoylguanosine (**4**), (2.10 g, 40%; m.p. 214–216°) was obtained by crystallization from absolute ethanol. The p.m.r. spectrum showed signals (δ TMS) at 8.25 (1H, singlet, 8 proton of G); 8.2–7.4 (10H, multiplet; two C_6H_5CO protons); 6.00 (1H, doublet; $J \simeq 6.0$ Hz; 2′-sugar proton) and at 2.20 p.p.m. (3H, sharp singlet; CH_3CO protons).

Anal. Calcd. for $C_{26}H_{23}N_5O_8$ (mol. wt. 533.30): C, 58.54; H, 4.35; N, 13.13. Found: C, 58.80; H, 4.27; N, 13.14.

Concentration of the mother liquor to a small volume yielded only varying mixtures of N^2-5′-*O*-dibenzoyl-2′,(3′)-*O*-acetates.

N^2-Benzoyl-2′-O-tetrahydropyranylguanosine (5)

A solution of *p*-toluenesulfonic acid monohydrate (0.20 g; 1.1 mmol) in dry dioxan (20 ml) containing molecular sieves (0.4 g) was cooled in ice until solidified. Dihydropyran (7.37 g, 8 ml; 88 mmol) was then added dropwise with stirring, followed by a suspension of 3′-*O*-acetyl-N^2-5′-*O*-dibenzoylguanosine (**4**) (2.13 g; 4.0 mmol; m.p. 215°, R_F 0.63 in 10% CH_3OH–CH_2Cl_2) in dry dioxan (20 ml). After 2 h the reaction was allowed to return to room temperature and t.l.c. indicated formation

of a major product (R_F 0.75 in 10% CH_3OH–CH_2Cl_2). This colorless solution was cooled in ice, and neutralized with concentrated ammonia. The precipitated ammonium tosylate was filtered off, washed well with methylene chloride, and the combined filtrate and washings evaporated *in vacuo* to give a yellow oil which was dissolved in a mixture of ethanol (20 ml) and pyridine (10 ml). Ethanolic sodium hydroxide (containing 10 ml 2 *N* NaOH and 10 ml absolute ethanol) was added with stirring. After 5 min t.l.c. indicated two products of R_F 0.35 and 0.30 in 10% CH_3OH–CH_2Cl_2 in the approximate proportion of 2:3. The p*H* of the solution was then adjusted to *ca.* 7.0 with Dowex 50W-X8 resin (pyridinium form). The resin was filtered off, washed well with ethanol, and the combined filtrate and washings evaporated *in vacuo*. The resulting mixture of diastereoisomers (**5**) was separated on silica gel (60 g) in methylene chloride. Elution with 2.5% methanol – methylene chloride mixture (500 ml) yielded the low m.p. diastereoisomer **5***b* (0.375*g*, 20%; R_F 0.35 in 10% CH_3OH–CH_2Cl_2). Continued elution with 3.0–3.5% methanol – methylene chloride mixtures (500 ml + 500 ml) gave a mixture of diastereoisomers (0.30 g, R_F 0.35 and 0.30 in 10% CH_3OH–CH_2Cl_2). Finally, the high m.p. diastereoisomer **5***a* (0.94 g, 50%; R_F 0.30 in 10% CH_3OH–CH_2Cl_2) was obtained on elution with 3.5–4.0% methanol – methylene chloride mixtures (500 ml + 500 ml). Total yield of **5***a* and *b* was 86%. An analytically pure sample of the high R_F diastereoisomer **5***b* of m.p. 152–154°, R_F 0.35 was obtained by crystallization from ethyl acetate containing a trace of methanol. Its p.m.r. spectrum showed signals (δ TMS) at 8.40 1H, singlet, 8 proton of G); 8.2–7.4 (5H, multiplet, C_6H_5CO protons); 6.18 (1H, doublet, $J \simeq 7.0$ Hz; 1′-anomeric proton); 5.00 (1H, multiplet, 2′-sugar proton); and a broad peak at 1.50 p.p.m. (6H, multiplet, thp protons).

Anal. Calcd. for $C_{22}H_{25}N_5O_7.H_2O$ (mol. wt. 489.49): C, 53.98; H, 5.56; N, 14.31. Found: C, 53.95; H, 5.58; N, 14.12.

Crystallization from ethyl acetate – methanol (2:1) provided an analytical sample of m.p. 192–194° of the other isomer (**5***a*) of R_F 0.30. Its p.m.r. spectrum showed signals (δ TMS) at 8.38 (1H, singlet, 8 proton of G); 8.2–7.4 (5H, multiplet, C_6H_5CO protons); 6.15 (1H, doublet, $J \simeq 8$Hz; 1′-anomeric proton); 5.20 (1H, multiplet, 2′-sugar proton); and a broad peak at 1.50 p.p.m. (6H, multiplet, thp protons).

Anal. Calcd. for $C_{22}H_{25}N_5O_7.H_2O$ (mol. wt. 489.49): C, 53.95; H, 5.56; N, 14.31. Found: C, 54.12; H, 5.54; N, 14.27.

N^2-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylguanosine (6)

Sodium triphenylmethoxyacetate (1) (550 mg, 1.72 mmol) was evaporated *in vacuo* from anhydrous pyridine (3 × 15 ml), and finally its volume reduced to *ca.* 5 ml. The solution was sealed under nitrogen, TPS (236 mg, 0.78 mmol) added, and the reaction mixture allowed to stand at room temperature for 2 h. The low R_F diastereoisomer of N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**5***a*) (0.336 g, 0.72 mmol; R_F 0.30 in 10% CH_3OH–CH_2Cl_2) was evaporated from anhydrous pyridine (3 × 15 ml) and finally its volume reduced to *ca.* 5 ml. This solution was then added to the triphenylmethoxyacetic acid – TPS complex (prepared above), and the reaction set aside at room temperature for 1–2 days in the dark. Further portions of TPS (2 × 50 mg) were added to ensure complete esterification. After 5 days t.l.c. indicated complete conversion into a product (R_F 0.30 → 0.65 in 10% CH_3OH–CH_2Cl_2). Ice (*ca.* 2 g) was then added, and the mixture stirred for a further hour. The reaction mixture was then poured into ice-water (40 ml) and repeatedly extracted with methylene chloride (3 × 10 ml). The combined organic extracts were washed, and evaporated to dryness *in vacuo*. The yellow glass obtained was purified by chromatography on silica gel (20 g) in methylene chloride. Elution with 1.0% methanol – methylene chloride mixture (500 ml) yielded N^2-benzoyl-3′,5′-*O*-di-triphenylmethoxyacetyl-2′-*O*-tetrahydropyranylguanosine (**7**) (120 mg, 16%; R_F 0.85 in 10% CH_3OH–CH_2Cl_2). The p.m.r. spectrum of **7** showed signals (δ TMS) at 8.20 (1H, singlet; 8 proton of G); 9.2–7.4 (35H, multiplet; C_6H_5CO and trityl aromatic protons); 6.00 (1H, doublet; $J \simeq 7$ Hz, 1′-anomeric proton); 5.5 (1H, multiplet; 2′-sugar proton); 5.1 (1H, multiplet; 3′-sugar proton); 3.8 (4H, singlet; —OCH_2CO protons); and a broad peak at 1.5 p.p.m. (6H, multiplet; thp protons). Pure N^2-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanosine (**6**) (0.282 g, 52% R_F 0.66 in 10% CH_3OH–CH_2Cl_2) was obtained on elution with 2.0–2.5% methanol – methylene chloride mixtures. An analytically pure sample of **6** of m.p. 110° (dec.) was prepared by crystallization from methylene chloride – hexane. The p.m.r. spectrum showed signals (δ TMS) at 8.25 (1H, singlet; 8 proton of G); 8.2–7.1 (20H, multiplet; C_6H_5CO and trityl aromatic protons); 6.14 (1H, doublet; $J \simeq 6$Hz, 1′-anomeric proton); 5.45 (1H, multiplet; 2′-sugar proton); 4.75 (1H, multiplet; 3′-sugar proton); 3.8 (2H, singlet; —OCH_2CO protons); and 1.5 p.p.m. (6H, multiplet; thp protons).

Anal. Calcd. for $C_{43}H_{41}N_5O_9$ (mol. wt. 771.83): C, 66.92; H, 5.35; N, 9.07. Found: C, 67.03; H, 5.46; N, 8.98.

N^2-Benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanosine (**6**) (3 mg, R_F 0.65 in 10% CH_3OH–CH_2Cl_2) was dissolved in dilute methanolic ammonia (0.3 ml, prepared by 100-fold dilution of concentrated ammonia with methanol) and stirred at room temperature. After 2 h, t.l.c. indicated complete regeneration of starting material (**5***a*) (R_F 0.31 in 10% CH_3OH–CH_2Cl_2). After 2.5 h, t.l.c. indicated the appearance of a further product (R_F 0.24 in 10% CH_3OH–CH_2Cl_2) obtained by hydrolysis of the benzamide group.

N^2-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylguanosine-3′-β,β,β-trichloroethyl phosphate (8)

Bis-cyclohexylamine salt (360 mg, 0.81 mmol; 3 equiv) of mono-β,β,β-trichloroethyl phosphate (5) was dissolved in anhydrous pyridine (20 ml) with warming, and converted to its pyridinium salt by repetitive evaporation *in vacuo* and solution in pyridine (5 × 20 ml). TPS (496 mg, 1.62 mmol; 6 equiv) was then added to the pyridinium salt in pyridine (10 ml). After 1 h, a pyridine solution of N^2-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanosine (**6**) (200 mg, 0.27 mmol; 1 equiv; R_F 0.65 in 10% CH_3OH–CH_2Cl_2) was added to the yellow solution and the reaction mixture sealed under nitrogen and set aside at room temperature in the dark. After 1.5 days, t.l.c. indicated complete conversion into a product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of R_F *ca.* 0.20 in 10% CH_3OH–CH_2Cl_2. Ice (*ca.* 2 g) was added and the quenched reaction left for 30 min, poured into ice-water (50 ml), and repeatedly extracted with methylene chloride (4 × 20 ml). The combined organic extracts were washed with distilled water (2 × 20 ml). Methylene chloride was removed by evaporation *in vacuo* and replaced by anhydrous pyridine (10 ml). This pyridine solution, containing the pyridinium salt **8** was used immediately to form blocked dinucleotide phosphate derivatives.

*N^2-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylguanylyl (3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-O-tetrahydropyranylcytidine (**10**)*

TPS (91 mg, 0.3 mmol; 1.1 equiv) was added to the pyridine solution of the blocked guanylate derivative (**8**), and activation allowed to proceed for 30 min at room temperature in the dark. The high R_F diastereoisomer of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**9**) (6) (173 mg, 0.4 mmol; 1.5 equiv; R_F 0.6 in 10% CH_3OH–CH_2Cl_2) dissolved in anhydrous pyridine (5 ml) was added and the reaction mixture sealed under nitrogen and set aside at room temperature for 7 days in the dark. Further portions of TPS (3 × 40 mg) were added till all the cytidine derivative (**9**) disappeared. T.l.c. indicated *ca.* 60% conversion into a product of R_F 0.60 in 10% CH_3OH–CH_2Cl_2. Ice (5 g) was then added, and after 30 min the aqueous pyridine solution was poured into ice-water (30 ml) and repeatedly extracted with methylene chloride (4 × 20 ml). The combined organic extracts were washed with water (2 × 20 ml) and evaporated *in vacuo*. The last traces of pyridine were removed by co-distillation with toluene (2 × 10 ml). Methylene chloride (100 ml) was then added and the solution mixture resolved by chromatography on silica gel (20 g) in methylene chloride. Elution with 1% methanol – methylene chloride mixture gave a fast moving material, tentatively identified as the TPS-derivative of **9**. Elution with 3.0% methanol – methylene chloride mixture yielded a mixture of the diastereoisomers of **10** (1) (60 mg, R_F 0.65–0.60 in 10% CH_3OH–CH_2Cl_2). An enriched sample of the lower R_F isomer **10** (50 mg) was obtained by eluting the column with 3.5% methanol – methylene chloride mixtures. Total yield of **10**, 30%. Further elution with 6.0–7.0% methanol – methylene chloride mixtures gave the uncoupled guanylate derivative **8** (97 mg; 35%). The p.m.r. spectrum of compound **10** showed signals (δ TMS) at 8.25 (1H, singlet; 8 proton of G); 8.2–7.15 (25H, multiplet; C_6H_5CO and trityl aromatic protons); 6.1 and 5.7 (2H, two doublets superimposed; 1′-anomeric protons); 3.75 (2H, singlet; —OCH_2CO protons); and a broad peak centered at 1.55 p.p.m. (12H, multiplet; thp protons).

Guanylyl(3′–5′)cytidine (GpC)

A solution of N^2-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanylyl (3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**10**) (10 mg, R_F 0.60 in 10% CH_3OH–CH_2Cl_2) in *N*,*N*-dimethylformamide (1.0 ml) was stirred at 50° with Cu–Zn couple (*ca.* 20 mg). After 1 day, t.l.c. indicated complete conversion of starting material into a product of R_F origin in 10% CH_3OH–CH_2Cl_2. Half saturated methanolic ammonia (1 ml) was then added, and the reaction mixture stirred at room temperature for 2 days. *N* Ammonia solution (1 ml) was added, and the Cu–Zn couple filtered off, and washed well with dilute ammonia. The combined filtrate and washings were carefully concentrated *in vacuo* and the solution p*H* brought to 8–10. Dowex 50 W (NH_4^+ form, *ca.* 1 g) was added, and the mixture stirred at room temperature for 15 min. The resin was filtered off, and washed well with water. The combined filtrate and washings were concentrated *in vacuo* to *ca.* 20 ml. The p*H* of the solution was then adjusted to 2.0 with 0.1 *N* hydrochloric acid solution, and the reaction mixture stirred at room temperature. After 2 days, t.l.c. on cellulose indicated that the hydrolysis was complete (R_{Up} 6.0 → 0.90). GpC (80 o.d.$_{260}$, 85%; R_{Up} 0.90 in solvent A) was isolated and purified by preparative paper chromatography in solvent A. Enzymic analysis of the ammonium salt of GpC (20 o.d.$_{260}$) in tris buffer (0.2 ml, 0.1 *M*; p*H* 8.0) with snake venom diesterase (100 λ) (Worthington, 1 mg/ml) at 35° for 16 h showed complete digestion. Paper chromatographic and t.l.c. analyses in various solvents showed the expected products (G + pC) in the correct ratio.

*N^2-Benzoyl-2′-O-tetrahydropyranyl-5′-O-triphenylmethoxyacetylguanylyl (3′-β,β,β-trichloroethyl-5′)N^2-benzoyl-2′-O-tetrahydropyranylguanosine (**11**)*

TPS (91 mg, 0.3 mmol; 1.1 equiv) was added to the pyridinium solution of the blocked guanylate derivative **8**, and activation allowed to proceed for 30 min at room temperature in the dark. The high R_F diastereoisomer of N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**5***b*) (170 mg, 0.35 mmol; 1.3 equiv; R_F 0.35 in 10% CH_3OH–CH_2Cl_2) dissolved in anhydrous pyridine (5 ml) was added and the reaction mixture sealed under nitrogen and set aside at room temperature for 7 days in the dark. Further portions of TPS (3 × 40 mg) were added till all of **5***b* had disappeared. T.l.c. indicated *ca.* 50% conversion into a product of R_F 0.60 in 10% CH_3OH–CH_2Cl_2. Ice (5g) was then added, and after 30 min the aqueous pyridine solution was poured into ice-water (30 ml) and repeatedly extracted with methylene chloride (4 × 20 ml). The combined organic extracts were washed with saturated sodium bicarbonate solution (2 × 20 ml) and then with water (2 × 20 ml) and evaporated *in vacuo*. The last traces of pyridine were removed by co-distillation with toluene (2 × 10 ml). Methylene chloride (100 ml) was then added, and the reaction mixture purified by chromatography on silica gel (20 g) in methylene chloride. Elution with 3.5% methanol – methylene chloride mixture gave a mixture of the diastereoisomers of **11** (107 mg; 28%). Further elution with 7% methanol – methylene chloride mixture gave uncoupled guanylate derivative **8** (105 mg; 38%). The p.m.r. spectrum of **11** showed signals (δ TMS) at 8.2 and 8.15 (2H, singlet; 8 protons of Gs); 8.15–7.10 (25H, multiplet; C_6H_5CO and trityl aromatic protons); 6.2 and 6.05 (2H, two doublets superimposed; 1′-anomeric protons of Gs); 3.75 (2H, singlet; —OCH_2CO protons); and a broad peak centered at 1.55 p.p.m. (12H, multiplet; thp protons of Gs).

Guanylyl(3′–5′)guanosine (GpG)

A solution of N^2-benzoyl-2′-*O*-tetrahydropyranyl-5′-*O*-triphenylmethoxyacetylguanylyl (3′-β,β,β-trichloroethyl-5′)N^2-benzoyl-2′-*O*-tetrahydropyranylguanosine (**11**) (5 mg, R_F 0.4 in 10% CH_3OH–CH_2Cl_2) in *N*,*N*-di-

methylformamide (1.0 ml) was stirred at 50° with Cu–Zn couple (*ca.* 20 mg). After 1 day t.l.c. indicated complete conversion of starting material into a product of R_F origin in 10% CH_3OH–CH_2Cl_2. Half saturated methanolic ammonia (1 ml) was then added, and the reaction mixture stirred at room temperature for 2 days. *N* ammonia solution (1 ml) was added, and the Cu–Zn couple filtered off, and washed well with dilute ammonia. The combined filtrate and washings were carefully concentrated *in vacuo* and the solution p*H* brought to 8–10. Dowex 50W (NH_4^+ form; *ca.* 1 g) was added, and the mixture stirred at room temperature for 15 min. The resin was filtered off, and washed well with water. The combined filtrate and washings were concentrated *in vacuo* to *ca.* 20 ml. The p*H* of the solution was then adjusted to 2.0 with 0.1 *N* hydrochloric acid solution, and the reaction mixture stirred at room temperature. After 2 days t.l.c. on cellulose indicated that the hydrolysis was complete. (R_{Up} 4.5 → 0.81). GpG (40 o.d.$_{260}$, 76%; R_{Up} 0.81 in solvent A) was isolated and purified by preparative paper chromatography in solvent A. Enzymic analysis of the ammonium salt of GpG (20 o.d.$_{260}$) in tris buffer (0.2 ml, 0.1 *M*; p*H* 8.0) with snake venom diesterase (100 λ) (Worthington, 1 mg/ml) at 37° for 16 h showed complete digestion. Paper chromatographic and t.l.c. analyses in various solvents showed the expected products (G + pG) in the correct ratio.

Low Temperature Infrared Study of Hydrogen Bonding in Dissolved Pyrrole and Indole

MARIE-CLAUDE BERNARD-HOUPLAIN AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal, Québec

Received September 21, 1972

Self-association by hydrogen bonding in the case of pyrrole was studied by i.r. spectroscopic methods. The fundamental first and second overtones of the NH stretching vibration were measured at different concentrations and at temperatures ranging from 22 to −190 °C. The existence of at least two associated species in solution has been ascertained. 2,5-Dimethylpyrrole and indole were also studied and gave similar results.

L'autoassociation du pyrrole par liaisons hydrogène a été étudiée par spectroscopie i.r. Les transitions fondamentales ainsi que les premières et deuxièmes transitions harmoniques de la vibration de valence NH ont été mesurées à différentes concentrations et à différentes températures allant de 22 à −190 °C. On a établi l'existence d'au moins deux espèces associées en solution.

Le 2,5 diméthylpyrrole et l'indole ont été étudiés dans les mêmes conditions et ont donné des résultats similaires.

Introduction

In an attempt to elucidate the nature of self-association by hydrogen bonding in the case of the NH group, we examined the i.r. spectra of three molecules taken as representatives of the different types of secondary amines, dimethylamine, *N*-methylaniline, and pyrrole. The technique used in this work consisted in measuring the fundamental, the first and, when possible, the second overtone of the N—H stretching vibration in mixed solvents which can be used down to liquid nitrogen temperature where these solvents become rigid glasses. Our work on dimethylamine and *N*-methylaniline was reported in two previous publications (1, 2).

In this paper we report our results on pyrrole (P). We have also studied indole (I) and 2,5-dimethylpyrrole (DMP).

The work done on the association of pyrrole with different bases has been reviewed by Bellamy (3). Self-association of pyrrole at room temperature has been studied by i.r. spectroscopy, as well as cryoscopic, calorimetric, dielectric, and n.m.r. methods (4–14).

Recently Lautié and Novak (15) measured the i.r. and Raman spectra of pyrrole in the solid state at −190 °C. They found that in the crystal, pyrrole forms long chains in which the individual molecules are associated by hydrogen bonds.

Neither low temperature nor overtone studies seem to have been reported on the self-association of pyrrole in solution up to the present time. We measured the i.r. spectra in both the fundamental, first and, when possible second overtone region of the N—H stretching vibration down to −190 °C in order to follow the pattern of molecular associations over a wide range of temperature.

Experimental

Pyrrole and 2,5-dimethylpyrrole were supplied by Aldrich Chem. Co. Inc. These products were distilled twice under vacuum; fresh samples were used for the preparation of the solutions. Indole was purchased from Fisher Scientific Co. Ltd. and was used without further purification; it was a "certified" Fisher product and its melting range was 51.0–51.7 °C.

Pyrrole-d_4 (minimum isotopic purity of about 99%) was supplied by Merck, Sharp and Dohme of Canada Ltd. and was used without further purification. Pyrrole-*N-d* was made by exchange between pyrrole and heavy water (16); we obtained a sample about 95% rich in pyrrole-*N-d*. The solvents were 1:1 mixtures of CCl_3F and CF_2Br–CF_2Br (FR) and of CCl_3F and methylcyclohexane (FM). These mixtures form rigid glasses near liquid nitrogen temperature (17–18). The freons were supplied by Dupont de Nemours Co. of Canada and the methylcyclohexane by Phillips Petroleum Company. Carbon tetrachloride was also used as a solvent and was purchased from Anachemia Chem. Ltd. All the solvents were distilled and kept over phosphorus pentoxide.

The preparation of solutions and filling of sample cells were done entirely in a dry box, under an inert atmosphere.

The NH fundamentals were measured on a Perkin–Elmer model 621 spectrometer and the overtones on a Cary 17 instrument.

Other experimental details were given in previous publications from this laboratory (17–18).

Results

Pyrrole

Figure 1 shows the results of a concentration study at 20 °C. In a dilute solution the free N—H band has its peak at 3498 cm^{-1}. A weak band appears at 3475 cm^{-1} on the side of the *free* band. This band was first assigned by Linnell (19) to a hot band involving the NH stretching vibration (ν_s) and the 565 cm^{-1} out-of-plane NH bending vibration (ν_i). The transition goes from ($\nu_{s,\,v=0} + \nu_{i,\,v=1}$) to ($\nu_{s,\,v=1} + \nu_{i,\,v=1}$) and the separation between ν_s and the hot band is equal to the anharmonic coupling constant between the two modes. As we shall see below our low temperature and overtone spectra confirm this assignment.

At higher concentrations a broad associated band appears whose center shifts to lower frequencies with increasing concentration. For the pure liquid the peak is at 3401 cm^{-1} with a shoulder near 3430 cm^{-1}. The half width of the free band is 14 cm^{-1} for the most dilute solution while it is 81 cm^{-1} for the associated band in the pure liquid. The hydrogen bond shift is of the order of 100 cm^{-1}.

At the same time in the first overtone region we find a free band at 6854 cm^{-1} for the most dilute solution (Fig. 2). The hot band is again observed and, as expected, its distance from the main peak is twice that in the fundamental region (42 and 23 cm^{-1}, respectively). The relative intensity of the associated band with respect to the free band is much less than in the fundamental region. It is not until about a 4 *M* concentration is reached that it is clearly distinguished as a shoulder. It becomes a band for the liquid with its maximum at 6757 cm^{-1}. This weakness of the overtone of the associated band is a general

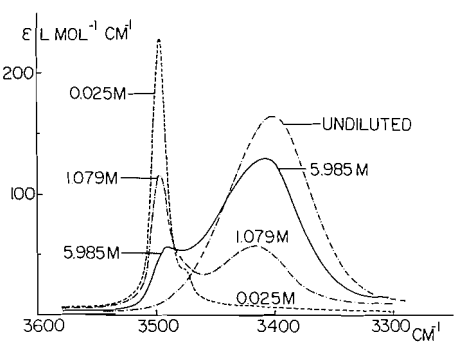

FIG. 1. The NH stretching fundamental of pyrrole at different concentrations, at 22 °C, in CCl_4.

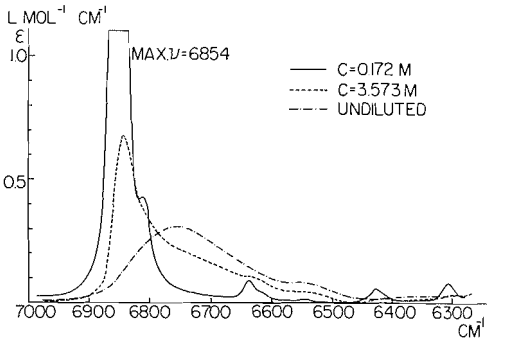

FIG. 2. The first overtone of the NH stretching vibration of pyrrole at different concentrations in CCl_4. Temperature: 22 °C.

phenomenon first observed by Luck and Ditter (20). An explanation for it was put forward recently by Di Paolo *et al.* (21).

In order to ascertain that CH + NH type combination tones make no significant contribution to the observed bands we measured the spectrum of C_4D_4NH (pyrrole-d_4). Only some weaker bands disappear below about 6640 cm^{-1}. The main band at 6757 cm^{-1} (or 6761 in C_4D_4NH) persists as well as a pronounced shoulder on its low frequency side (at about 6660 cm^{-1}).

Now, the question arises if the main maximum of the fundamental at 3401 cm^{-1} is due to the same associated species as the main peak at 6757 cm^{-1} of the overtone? The answer is that it is almost certainly not. Assigning the two apparent peaks to the same species would yield an anharmonicity constant ($\omega ex_e = \nu_{01} - \nu_{02}/2$) equal to only 23 cm^{-1} while the corresponding free bands give 71 cm^{-1}. A similar situation exists in the aliphatic amines and we were able to show previously that the apparent decrease in the value of the anharmonicity constant was due to an erroneous assignment. Since the less associated species are highly favored from the point of view of the intensity of their overtone bands it is reasonable to assume that the 6757 cm^{-1} peak corresponds to the shoulder at about 3430 cm^{-1} and the shoulder at about 6660 cm^{-1} to the peak at 3401 cm^{-1}.

The half width of the free overtone is 26 cm^{-1} and that of the broad associated band (in the liquid) is of the order of 190 cm^{-1}.

We also measured the second overtone for pyrrole. The free band is at 10 075 cm^{-1} (0.1 *M*), the hot band at 10 010 cm^{-1} and the associated band at 9883 cm^{-1} (pure liquid). The half widths

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are 42 cm^{-1} for the free band and about 340 cm^{-1} for the associated band. The anharmonicity constant computed from $\nu_{02}/2 - \nu_{03}/3$ is 69 cm^{-1} for the free band and about 80 cm^{-1} for the associated band.

Since the free:associated intensity ratios are similar in the first and second overtone region the correspondence between these bands is unambiguous and confirms our assignments of the first overtones.

These concentration studies were performed in a CCl_4 solution in which pyrrole has a very good solubility. Solute–solvent interaction between pyrrole and CCl_4 has only a weak influence on the spectra (9).

Figure 3 shows the spectra at a variety of temperatures in FM solution. The free band is slowly shifted to lower frequencies when temperature decreases. (The shift amounts to about 12 cm^{-1} from 20 to -140 °C for a 0.1 *M* solution). In a 0.1 *M* solution the free band is still present at -140 °C and at 0.014 *M* it is present even at -190 °C. Linnell's hot band appears as a shoulder at about 3475 cm^{-1} and fades away as temperature is lowered. The associated band shifts faster and very probably contains two bands, one at about 3425 which disappears rapidly when temperature is lowered and one, the main peak, at 3392 cm^{-1} (at -40 °C and 0.124 *M* in FM). The observed shift must be the result of a certain amount of real shift and of changing overlap conditions due to the varying intensities of the two bands. They can be assigned to two different associated species; we shall tentatively call them dimer and oligomer, respectively. At -190° practically only the oligomer is present. The free band has some asymmetry at its low frequency side but we do not see sufficient evidence for a different species there. It is probably due to Linnell's band and, perhaps, to the free end-NH group of associated species.

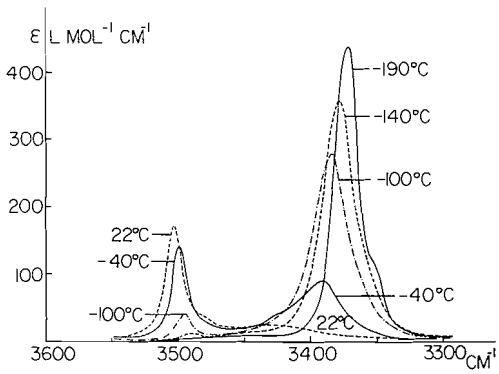

FIG. 3. The NH stretching fundamental of pyrrole at different temperatures in a 1:1 mixture of CCl_3F and methylcyclohexane. Concentration at 22 °C: 0.124 *M*.

The 3401 cm^{-1} peak found in the pure liquid at room temperature probably corresponds to the 3392 cm^{-1} peak (-40 °C) which shifts to 3375 cm^{-1} at -190 °C. However, the band of the liquid is broad and complex and does not reflect the same proportions of species as the low temperature spectrum of the dilute solution.

There is a shoulder becoming an almost separate narrow band at the low frequency side of the main peak, near 3355 cm^{-1} at -190 °C. It could correspond to a more highly associated species but its sharpness is surprising. Otherwise it could only be a ternary combination. Its persistance at low temperatures seems to rule out an assignment to a hot band. For the time being we shall consider it as a combination band.

These temperature variation studies lead to the same observations for initial concentrations varying from 0.01 to 0.4 *M*, which were the limits of our measurements.

The general appearance of these spectra places pyrrole somewhere between aliphatic secondary amines and alcohols. The relatively large shift from the free to the associated bands is reminiscent of alcohols. It amounts to about 80 cm^{-1} for our "dimer". The more moderate shift between "dimer" and "oligomer" is consistent with the assumption that in the case of alcohols where this latter shift is much larger, the change in anharmonicity upon hydrogen bond formation is responsible for a part of the shift (22). The half width of the 3375 cm^{-1} peak at -190 °C is only about 25 cm^{-1} so the band is quite sharp. This again may be due to relatively moderate anharmonicity (hardly higher than for the free band; see below) which does not favor strong environmental interactions (23) and to the existence of relatively well defined associated species.

In the bromine containing FR solvent the free band's relative strength is greater than in FM. This is another manifestation of the hydrogen bond weakening property of bromine containing solvents which we described previously (24). It slows down hydrogen bond formation which would otherwise occur more rapidly as temperature is decreased.

All the spectra given in Fig. 3 remain practically the same if we take C_4D_4NH instead of

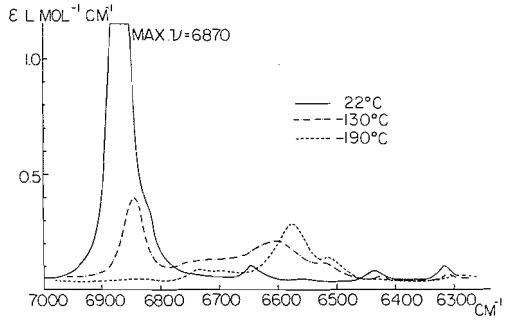

FIG. 4. The first overtone of the NH stretching vibration of pyrrole at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.127 *M*.

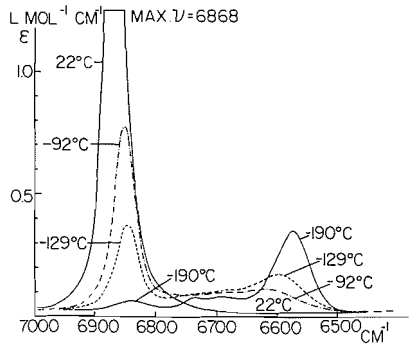

FIG. 5. The first overtone of the NH stretching vibration of pyrrole-d_4 at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.123 *M*.

C_4H_4NH. On the other hand all the above described bands "disappear" in C_4H_4ND.

In the region of the first overtone (Fig. 4) we observe the expected strong free band (6870 cm^{-1} at 20 °C in FR). At the lowest temperature, however, the free band is very weak (6840 in FR); it is followed by two weak associated bands at 6735 and 6690 cm^{-1} and a strong band at 6575 cm^{-1}. The weaker band at 6514 cm^{-1} is a CH + NH combination band as can be ascertained by comparing the spectrum of C_4H_4-NH to that of C_4D_4NH (Fig. 5). All other bands remain the same (CH + NH type combinations are much less disturbing than the analogous CH + OH bands of alcohols).

With the 3375 cm^{-1} main peak in the fundamental region the 6575 cm^{-1} band yields an anharmonicity constant of 88 cm^{-1}. We think that the moderate increase with respect to the corresponding value of the free NH vibration (69 cm^{-1}) is significant and illustrates the relative strength of this hydrogen bond. On the other hand, its "normal" value confirms the assignment of the 6575 cm^{-1} band to the overtone of the 3375 cm^{-1} fundamental.

Thus the observations made on the overtones underscore the important difference in the nature of the association between the pure liquid (room temperature) and the dilute solutions taken at low temperatures. As we have seen, in the pure liquid, the 6757 cm^{-1} band is predominant meaning that the most abundant species is a less associated species for the liquid than for the solutions at low temperatures. The weak and somewhat broad band at 3425 cm^{-1} (Fig. 3) is likely to contain the fundamentals of the weak bands at 6735 and 6690 cm^{-1}.

In the FR solvent we again see the delaying effect of the bromine containing solvent molecule and the greater relative strength of the free band.

In the region of the second overtone we see the free band at 10 101 cm^{-1} (0.133 *M* in FR) at 20 °C and Linnell's hot band at 10 020 cm^{-1}. At −190 °C the free band is reduced to a broad feature almost lost in the background. The associated species give a shoulder at 9740 and a band at 9615 cm^{-1}. The correspondence with the respective fundamentals and overtones seems to be straightforward (Table 1).

2,5 Dimethylpyrrole (DMP)

Self association of DMP was studied at 22 °C, in the region of the fundamental by Abraham *et al.* (25). They identified the bands of the free and one associated species; from the Δν(NH) value they concluded that the steric hindrance by the α-methyl group has no effect on the strength of the hydrogen bond.

We carried out similar studies on DMP as on pyrrole; the spectra can be interpreted on the same basis as previously and need not be discussed in detail.

Figures 6 and 7 show the spectra, at different temperatures, of a solution of DMP in FR. At 22 °C, the free band is observed at 3486 cm^{-1} and a hot band is found at about 3465 cm^{-1}. At the lowest temperature, at the fundamental level, we observe a strong associated band at 3337 cm^{-1} (half width 30 cm^{-1}) with a shoulder at approximatively 3370 cm^{-1} which is more pronounced than in the case of pyrrole. This indicates again the presence of at least two species at the lowest temperatures. At the overtone level,

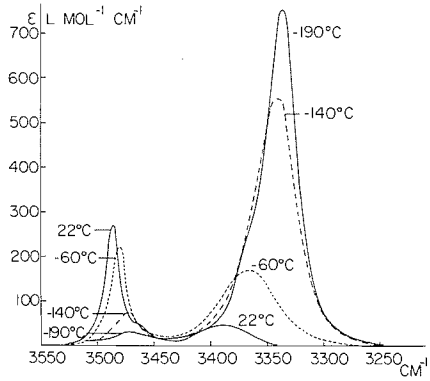

FIG. 6. The NH stretching fundamental of DMP at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.086 *M*.

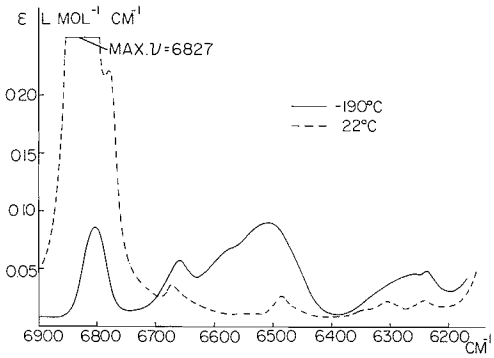

FIG. 7. The first overtone of the NH stretching vibration of DMP at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.091 *M*.

at −190 °C, the free band at 6803 cm^{-1} is still fairly strong; this can be taken as an indication of the lesser degree of association in DMP than in pyrrole, due to the steric hindrance by the α-methyl groups. (However, the HB are approximately of the same strength in the two amines as indicated by the values of the Δν(NH)).

The 6510 cm^{-1} band and a shoulder on its high frequency side are assigned to the overtones of the associated bands at 3337 and 3370 cm^{-1}, respectively. The band near 6660 cm^{-1} is present in dilute solution and does not change very much in frequency or in intensity when the temperature is gradually lowered and we assign it to a combination tone, not containing NH stretching motion; the same applies to the weak bands between 6300 and 6200 cm^{-1}.

The main point is that the existence of two associated species at low temperatures is confirmed by the observations made on DMP.

Indole

The effect of solvent and concentration on the n.m.r. spectra of several indoles has been investigated recently by Reinecke *et al.* (26) and by Saitô and Nukada (27). When the temperature of a 0.041 *M* solution of indole is gradually lowered, the intensity of the free band diminishes while its frequency is shifted from 3503 at 22 to 3490 cm^{-1} at −190 °C. The associated band located at 3435 cm^{-1} at room temperature is shifted to 3400 cm^{-1} with a strong shoulder appearing at its low frequency side. A comparison of the spectra of pyrrole and indole leads to the conclusion that the less associated species is favored in the case of indole; the more highly associated species comes in strongly at lower temperatures only. The coexistence of the two species in comparable proportions explains the greater width of the band measured at low temperatures (Fig. 8). Turning our attention to the first overtone

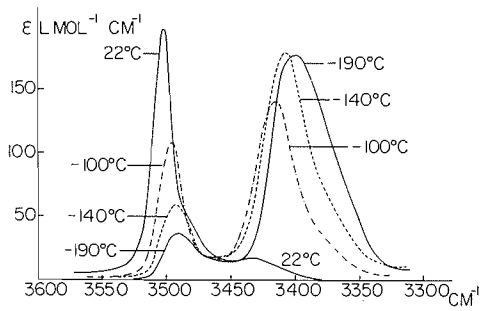

FIG. 8. The NH stretching fundamental of indole at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.041 *M*.

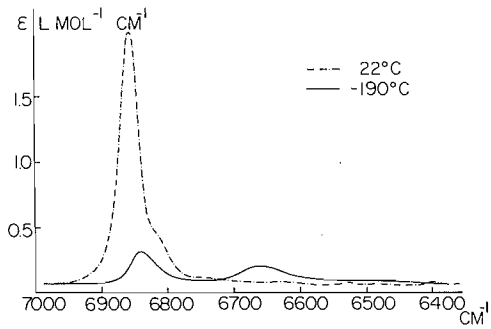

FIG. 9. The first overtone of the NH stretching vibration of indole at different temperatures in a 1:1 mixture of CCl_3F and CF_2Br–CF_2Br. Concentration at 22 °C: 0.041 *M*.

For personal use only.

region, at -190 °C, we still find a fairly strong free band at 6840 cm^{-1} (Fig. 9). Only one associated band can be distinguished at 6659 cm^{-1}, without any shoulder on its low frequency side. The main reason for this is probably that the overtone of the less associated band contributes most of the intensity of the observed band. We often encountered the fact that the relative intensities of two associated bands are different for the overtones from those for the fundamentals, so that the less associated species is favored at the overtone level.

Discussion and Conclusions

Dimethylamine, *N*-methylaniline, and pyrrole represent three different types of secondary amines and a comparison between their behavior from the point of view of molecular associations is instructive (Table 1 summarizes some of the main observations).

DMA consists essentially of monomers and dimers in solutions as well as in the pure liquid. Only at low temperatures, in solutions, did we find evidence for a more highly associated species. The shift that occurs upon hydrogen bond formation is of the order of $\Delta\nu = 67$ cm^{-1} for the dimer and about $\Delta\nu = 120$ cm^{-1} for the more highly associated species (at the fundamental level).

In the case of NMA we see the formation of three associated species as the temperature is lowered, with $\Delta\nu$ equal to 33, 69, and 156 cm^{-1}. The spectrum of the liquid gives a relatively well-defined band at about the same frequency as that of the dimer in solution with a low frequency tail containing the bands due to higher associated species. The case of NMA is closer to the case of weakly associating (sterically hindered) alcohols (28).

Pyrrole is even more associative. As in alcohols, in solutions of pyrrole the dimer located near 3425 cm^{-1} is difficult to find, it probably only exists in a narrow range of concentrations and temperatures.

The center of the broad associated band which we observe for pure pyrrole at room temperature is at a $\Delta\nu = 103$ cm^{-1} from the free band, indicating that the most abundant species in this case is no more a dimer but an oligomer even at room temperature. The breadth of this band must then be due to contributions from other associated species and a variety of solvent configurations. This situation is more like what we encounter for alcohols than that for DMA and NMA.

The sharp band which we find in the low temperature solution spectra of pyrrole at the fundamental level has a lower frequency than the center of the broad band of the liquid but remains relatively close to it. The sharpness of the band suggests that it belongs to well defined oligomer species with relatively little variation in their environments.

The anharmonicities for the oligomers are slightly higher than for the related free species, a fact that again emphasizes the resemblance of the hydrogen bonds formed by pyrrole to those of alcohols. The observed frequencies and shifts show, however, that the degree of association must be lower than in most alcohols.

It appears that in dilute solutions, at low temperatures we have a small number of relatively highly associated species while in the pure liquid, at room temperature, a greater variety of species exists which, on the average is less highly associated.

We express our thanks to the National Research Council of Canada for financial assistance.

The Influence of Coordinating Solvents on the Thermal Decomposition of Methyl Titanium Trichloride

JAMES D. MCCOWAN
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 2, 1972

The mechanism of decomposition of CH_3TiCl_3 in coordinating solvents is shown not to involve free radicals in some cases. An analysis of published work on the decomposition of titanium alkyls suggests mechanisms of decomposition similar to those postulated for alkyls of other transition metals.

On démontre que dans certain cas le mécanisme de décomposition du CH_3TiCl_3 dans des solvants coordinants n'implique pas de radicaux libres. Une analyse des résultats publiés sur la décomposition des alkyl titanium suggère que leurs mécanismes de décomposition sont similaires à ceux des dérivés alkylés des autres métaux de transition. A free radical mechanism of thermal decomposition is widely accepted for many alkyl–transition metal compounds (1, 2), particularly those involving methyl groups. In the particular case of CH_3TiCl_3, there is conclusive evidence (3) that free radicals do not form in non-coordinating solvents but it has become accepted (4) that a free radical mechanism is predominant in coordinating solvents. Such a mechanism was originally proposed (5) on the basis of mass balance considerations and of the relatively fast decompositions in coordinating solvents, and it was given substantial support by the observation (6) that the decomposition kinetics are first order, and that CH_3D is among the products, when the decomposition is carried out in a mixed solvent tetrahydrofuran and perdeuterotoluene. The observation of unambiguous first order kinetics is consistent with the postulate that the homolytic breaking of the carbon–metal bond is the rate determining step. Moreover, the existence of CH_3D among the products tended to confirm that a radical had formed, capable of attacking toluene-d_8 molecules which were, presumably, well beyond the coordination sphere.

The assumption of a free radical path as the general case in such systems, while plausible on the evidence, proves to be unjustified.

Experimental Methods

Materials

$(CH_3)_2Zn$ was Alfa Inorganics "Electronic Grade" and was used as received. $TiCl_4$ was reagent grade, once distilled under vacuum. $(C_2D_5)_2O$ (98% deuterated), $CD_3C_6D_5$ (99.5% deuterated), and C_8D_{18} (98% deuterated) were obtained from Merck, Sharp, and Dohme, from Stohler Inc., and from Wilmad Co. Inc., respectively, and were used as received. Non-deuterated solvents were purchased in reagent grade and were distilled under vacuum, the middle cut being used. Both ethers were first refluxed over sodium.

Preparation of CH_3TiCl_3

All steps of the preparation were carried out within a box of dry nitrogen.

$(CH_3)_2Zn$ (3.1×10^{-3} mol) was added slowly to a solution of 6.2×10^{-3} mol of $TiCl_4$ in 5 ml of CCl_3F at about 0 °C. After a few minutes shaking as the solution warmed to room temperature, the precipitated zinc chloride was filtered off. Three 1 ml amounts of CCl_3F were used to wash remaining CH_3TiCl_3 solution from the preparation vessel and the filter.

Using ungreased ground glass joints to prevent reaction, a vacuum trap-to-trap distillation at −35° separated the CH_3TiCl_3 from the more volatile CCl_3F. The purple crystals were then dissolved in the working solvent or transferred directly to the reaction vessel. Precipitation techniques of the sort usually employed (3, 4, 7) invariably result in the occlusion of some solvent (even heptane) in the CH_3TiCl_3 crystals and were therefore unsatisfactory for the work in this paper. Two or three distillations are required where complete solvent removal is obligatory.

Decomposition Studies and Results

A series of decompositions was carried out at room temperature in a variety of solvents, as shown in Table 1. Concentrations of CH_3TiCl_3 in the original solution were determined, for deuterated octane and toluene solutions, by comparison of ten or more integrals of the proton n.m.r. spectrum with those of a reference material, cyclohexane or trichloroethylene, added in known amount. Spectra were obtained on a Bruker HX-60 spectrometer.

In the case of solutions in heptane, or in diethyl ether, the amount was estimated from the known yield found in deuterated solvents.

In all samples except K, the non-coordinating solvent was measured into the distillation receiver, and the resulting CH_3TiCl_3 solution was then transferred to the decomposition vessels and, in some cases, to an n.m.r. tube. Coordinating solvents were then added as required

I	0.026	No	Trace	No	No	?
J	0.130	No	No	No	No	?
K	0.724	Yes	Yes	Yes	Yes	Trace

and the vessels sealed. In sample K, CH_3TiCl_3 was distilled into the decomposition vessel. The ether was added, and the vessel sealed.

Sample vessels have a total volume of approximately 3 ml. Each was stored, in darkness or in u.v. according to the experiment, until decomposition was near complete. Those products volatile at liquid nitrogen temperature were then released into the inlet system of the AEI MS10 mass spectrometer. In some cases, a second subsequent release at −80 °C was made in a search for the less volatile methyl chloride. Results are shown in Table 2.

Estimation of Errors

Quantities of liquid reagents were measured volumetrically using microliter syringes. Amounts are accurate to at least 3% in all cases.

In those samples where CH_3TiCl_3 concentration was determined by n.m.r., the concentration is known to within 10%. In all other cases, the estimate is very rough but the reproducibility of the preparation is such that estimates are probably within 30% of being correct and quite possibly better. In any event, exact knowledge of concentrations is not essential.

The relative amounts of CH_3D and CH_4 were established on the basis of measurements of mass 16 (corrected for contributions from CH_3D) and of mass 17 (corrected for contributions from CH_4 and from background water). Reproducibility in successive spectra was better than 10%. In most cases, an average of two spectra was used in calculating the relative amounts.

The presence or absence of H_2, HD, D_2, C_2H_6, and CH_3Cl was determined in some cases, but no quantitative estimates were attempted. Not only are there solubility differences at −195 °C but there is certain to be variable occlusion of gases in the crystals of frozen solvent. The relative amounts of CH_4 and CH_3D, however, are unaffected by these factors.

Discussion

Limited Occurrence of Free Radical Mechanism

D'yachkovskii's conclusion (6) that the mechanism of decomposition of $CH_3TiCl_3 \cdot 2THF$ in toluene-d_8 is a free radical one is borne out by the data from samples F and G. Moreover, these experiments show that the mechanism producing CH_3D does not require irradiation, removing any suspicion that the production of CH_3D arose from continuous irradiation in the u.v. spectrometer.

However, samples A to E show unequivocally that it is incorrect to apply this mechanism generally to other coordinating solvents, including the diethyl ether case of Beermann and Bestian (5). In the formation of methane by decomposition of CH_3TiCl_3 in noncoordinating solvents, the solvent is not the source of the fourth hydrogen (3, 7). In diethyl ether/alkane mixtures, the fourth hydrogen is to some extent obtained from the ether but never from the alkane. A free radical mechanism is therefore ruled out.

On the other hand, a free radical mechanism is supported by the evidence for the system $CH_3TiCl_3 \cdot 2THF$ in toluene-d_8, although an alternative explanation is available. Garnett has reviewed the mechanisms of transition metal catalysis of hydrogen exchange (8). His dissociative π-complex mechanism provides a route whereby a D atom from toluene-d_8 could find its way to subsequent elimination as CH_3D. Such exchanges are well established for alkyl benzenes and even for alkanes, and while one is reluctant to compare Garnett's acidic Pt(II) systems with those of the present work, it should be noted that there is evidence of catalysis of hydrogen exchange by reduced titanium. Coordination of aromatics to CH_3TiCl_3 has already

For personal use only.

been suggested on the basis of both decomposition (7) and n.m.r. (9) data. The possibility of catalyzed hydrogen exchange has also been suggested (7) as the explanation of the scrambling of hydrogens in the products of deuterolysis (7, 10, 11). The presence of traces of CH_3D among the products of decomposition of CH_3TiCl_3 in toluene-d_8 (sample J) and its complete absence in heptane and cyclohexane (3) support the suggestion that toluene coordinates to titanium and can transfer a hydrogen to the metal, thus providing an alternative explanation to the free radical one, at least for sample I.

While the balance of evidence supports a free radical mechanism in tetrahydrofuran, other alternatives should continue to be examined in all cases, and must be examined for solvents like diethyl ether where the free radical mechanism is invalid.

An Alternative Mechanism for Diethyl Ether

Alkane elimination involving abstraction of a hydrogen from an atom β to the metal by an alkyl attached to the same metal is well established as the mechanism of decomposition of many transition metal alkyls (1) including those of titanium (3). Moreover, such abstraction has been observed in molecules having atoms other than carbon in the α position (12, 13) although it is uncertain from the data in the cases cited if decomposition occurs in the liquid or solid. Related examples can be found elsewhere in transition metal chemistry, such as the formation of iridium hydrides from alcohols (14).

Abstraction from coordinated diethyl ether offers this pathway in samples A to E. Such a mechanism explains why deuterium is obtained from the ether but never from the alkane. Cyclic ethers have "β-hydrogens" further removed from the metal, and their complexes decompose markedly more slowly (4, 5). Ethers lacking a hydrogen on the atom β to the metal might be expected not to produce rapid decomposition. Preliminary experiments with diphenyl ether confirm this. Such a solvent has important possibilities both for fundamental studies and for the development of novel Ziegler catalysts.

Initiation of Autocatalysis

These experiments reveal a second point. In those systems involving deuterated ether (samples A, A′, E, and K), CH_4 and not CH_3D is the major product. Since this is true even in samples where other solvents are either deuterated (sample E) or absent (sample K), CH_3TiCl_3 itself must be the source of the fourth hydrogen. Thus while the presence of diethyl ether increases the rate of decomposition by several orders of magnitude, only a small part of the methane is formed through direct abstraction of a hydrogen from the ether.

Methane is formed in non-coordinating solvents without any contribution of hydrogen from the solvent (3) but at relatively slow rates (7). However the process is autocatalytic (5, 7), the solid decomposition products acting as the catalyst. If the solid produced in the ether systems catalyzed this reaction, as well as initiating the autocatalysis, a large amount of CH_4 would result.

Such an explanation gains additional support from samples H and H′. Here decomposition occurs in a non-polar but irradiated solvent. The rate of decomposition is at least two orders of magnitude greater than in the absence of irradiation, but we find relatively little CH_3D, the expected product of photodecomposition. Catalysis of decomposition by small nuclei of solid products, produced photolytically throughout the solution, is suggested, in analogy with the ether case where the "β-mechanism" serves to provide the initial catalyst.

Ethane is produced at accelerated rates when such decompositions occur in some coordinating solvents but it is much less abundant relative to methane than is the case for comparable concentrations and temperatures in non-coordinating solvents (7). While the production of ethane without solvent contribution must involve at least two CH_3TiCl_3 molecules, the complete absence of ethane among the products of $(CH_3)_2TiCl_2$ (7) strongly suggests that this latter species is not an intermediate. The mechanism is therefore likely to involve binuclear elimination. Strong coordination of tetrahydrofuran or toluene would interfere with this mechanism, as is observed in samples F, G, I, and J, providing further evidence of the active role of aromatic solvents.

Relationship to Thermal Decomposition of Other Transition Metal Alkyls

Recent work suggests that where the "β-mechanism" involves an alkyl group, there is a hydride/olefin intermediate (18–20). In the case

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of dialkyls, the reductive elimination of an alkane from such an intermediate would account for the observed product distribution.

In the decomposition of $(C_2H_5)_2Ti(C_5H_5)_2$, it has been shown that ethane is evolved more rapidly than ethylene, with both eventually appearing in equal quantities (15). Since titanium systems are efficient polymerization catalysts, the olefin predicted on the basis of this mechanism would be expected as polymer. Polyolefins have been reported by several investigators (5, 7). The proposed mechanism is also supported by the formation of CH_4 and C_2H_4 but never of C_2H_6 in mixed methyl and ethyl titanium systems (5); by the olefinic terminations of polyolefins produced on titanium based Ziegler catalysts (16, 17); and by the evidence of equilibria producing olefin/hydride species in related systems (18–20). Postulation of a slower, analogous α-elimination for methyl compounds, involving a carbene intermediate, is much more speculative, but such a route has been proposed (21, 22) for methyl chromium(III) compounds.

The hydride intermediate mechanism requires at least one vacant coordination site. Thus factors which lead to five or six coordinate configurations, providing that they do not block all sites, would enhance the rate of both eliminations. Absorptions of $(CH_3)_2TiCl_2$ on a β-$TiCl_3$ substrate would achieve this, as would coordination with suitable solvents. Strongly coordinating solvents, however, will retard the decomposition by blocking the vacancy necessary for the formation of the intermediate. This last point has already been put forward in a general way (23) and has been convincingly demonstrated for di-*n*-butylbis(triphenyl phosphine) platinum(II) (20). It explains why rates of CH_3TiCl_3 are slower in strongly coordinating tetrahydrofuran than in weakly coordinating diethyl ether, and are slower still with bidentate ligands (24), although, contrary to the last reference, solutions of uncoordinated CH_3TiCl_3 decompose more slowly still (7, 25).

Multiple Effects of Coordinating Species

Coordination may be expected to have at least two other influences on the rate and path of decomposition of CH_3TiCl_3 as well as other transition metal compounds.

Where the product solid catalyzes decomposition, the product species may itself be coordinated. This may alter its catalytic properties completely, even rendering it soluble.

Moreover, in certain cases where equilibria are involved, such as the proposed route (7) whereby CH_3TiCl_3 yields CH_4 through a disproportionation into $(CH_3)_2TiCl_2$ and $TiCl_4$, preferential coordination to one species could shift the equilibrium and increase or decrease the equilibrium concentration of the intermediate species. This particular effect has no analogy in many related cases, such as in the decomposition of $(CH_3)_4Ti$. Indeed, in this case, there is neither a catalyzing solid product nor an equilibrium, and the only effect of coordinating solvents is to block coordination sites needed for the decomposition path. Thus coordinating solvents invariably slow the decomposition, with the greatest effect from strongly coordinating bidentate ligands (26), and with those having a hydrogen on a β atom showing some decomposition by this route (27, 28).

The Similarities of Titanium Alkyls to the Alkyls of Other Transition Metals

The similarity of the mechanisms proposed to those proposed by other authors for other metal alkyls is worth emphasis. There has been a suggestion, sometimes explicit (2), that titanium alkyls are markedly different, and in particular that "promotional pathways . . . play a major role at the beginning of the transition metal series" whereas these pathways "do not operate at the end of the transition series" where "concerted pathways" are believed to dominate. The present work, and the accompanying analysis, suggest for titanium alkyls the same three mechanisms described by Braterman and Cross for the end of the series; β-elimination, reductive elimination, and binuclear elimination. These are all "concerted pathways" in the sense used by Braterman and Cross. It is "the availability of such pathways that controls the lability of the metal carbon bond" for titanium as for other metals.

Thanks are due to Queen's University for financial support of this research; to Dr. J. A. Stone for provision of the MS10 and for much kind advice on its use; and to Drs. M. C. Baird and B. K. Hunter for provocative discussions.

Pyrrole Chemistry. XV. The Chemistry of Some 3,4-Disubstituted Pyrroles[1]

JOHN KINGTON GROVES, NIVEN EDDY CUNDASAWMY, AND HUGH JOHN ANDERSON
Department of Chemistry, Memorial University, of Newfoundland, St. John's, Newfoundland

Received October 13, 1972

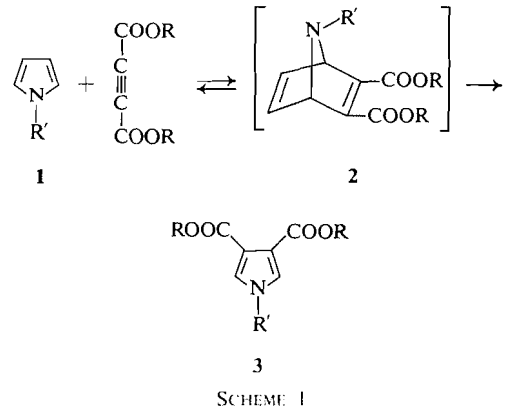
The syntheses of a variety of 3,4-disubstituted pyrroles including the antimitotic agent Verrucarin E are described. 3,4-Pyrroledicarboxylic esters were prepared through a Diels–Alder reaction. Partial hydrolysis of the diesters gave the 4-ester-3-acids which were modified to achieve the synthesis of a variety of unsymmetrically 3,4-disubstituted pyrroles. Raney nickel reduction of a thiolester gave hydroxymethyl under conditions which left acyl or carbalkoxy substituents unaffected. Pyrrole reactions involving carbanionic reagents are complicated by 1-proton abstraction. Therefore, when necessary, the nitrogen was protected by an *N*-benzyloxymethyl substituent which can be cleaved to the *N*-hydroxymethyl derivative by aluminum chloride or by hydrogenolysis. Subsequent treatment with benzyltrimethylammonium hydroxide gave back the pyrrole.

On a réalisé la synthèse de divers derivés bifonctionnels du pyrrole, y compris celle de l'agent antimitotique 'Verrucarin E', à partir des esters de l'acide pyrroledicarboxylique-3,4 qui furent préparés d'une réaction du type "Diels–Alder". L'hydrolyse partielle des esters a donné les ester-4-acides-3 qui furent alors transformés en de différents composés bifonctionnels et non-symmétriques. La réduction d'un thiolester en présence de nickel de Raney conduit à l'hydroxymethyl correspondant sous des conditions qui n'ont pas touché un groupe acyle ou carboalcoxy. Les réactions de pyrrole avec des réactifs carbanioniques sont compliquées par l'arrachement du proton-1. Alors, selon le besoin, l'azote fut protégé par un substituant benzyloxymethyl-*N* qui peut être scié par traitement avec le chlorure d'aluminium ou par l'hydrogenolyse pour amener a l'hydroxymethyl correspondant. Un traitement ultérieur par l'hydroxide de benzyltrimethylammonium ramène au pyrrole.

Can. J. Chem., **51**, 1089 (1973)

We have recently reported new syntheses of some 3-substituted pyrroles (1, 2) and in continuation of our efforts to devise viable routes to the less accessible pyrroles we have developed syntheses of a variety of 3,4-disubstituted pyrroles. These were of particular interest in view of the recent reassignment of the structure of the antimitotic agent Verrucarin E; originally thought to be 2-hydroxymethyl-4-acetylpyrrole (3), but later revised to 3-acetyl-4-hydroxymethylpyrrole (4). A synthesis of Verrucarin E starting from 2-carbethoxy-3-acetylpyrrole has been described (4), but the yield was very low and the method lacked flexibility.

The introduction of substituents into the two β-positions of the pyrrole nucleus may be accomplished by reaction with acetylenic dienophiles (5–8). Addition across the pyrrole "diene" system **1** gives 7-azanorbornadienes (**2**) which may undergo a retrodiene reaction to either reactants or the substituted pyrrole **3** (see Scheme 1). Although pyrrole itself is known to undergo cycloaddition reactions (9) the formation of 3,4-substituted pyrroles in reasonable yield requires the presence of an electron-withdrawing *N*-substituent. This is said to increase the diene character of the pyrrole system (*cf.* ref. 10) and inhibits attachment of a second molecule of dienophile (11, 12).



1 **2** **3**

SCHEME 1

Pyrrole *N*-esters have been converted to the triester **3** (R = Me or Et, R′ = COOMe or COOEt) and then selectively hydrolyzed to dialkyl 3,4-pyrroledicarboxylate (**4**, R = Me or Et) (6, 7). *N*-Benzoylpyrrole was found to give higher yields of the 3,4-diesters **3** (R = Me or

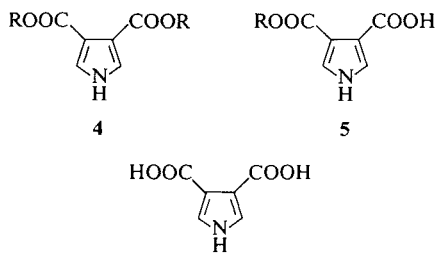
Et, R′ = COPh) with dimethyl and diethyl acetylenedicarboxylate than did the *N*-esters. Hydrolysis of the trisubstituted pyrroles may be controlled to afford either the diester **4** (R = Me or Et), the monoester **5** (R = Me or Et), or the diacid **6** in very high yield.



4 **5**

6

The monoester **5** is a potential starting material for the synthesis of 3,4-disubstituted pyrroles. The carboxylic acid group of the monoester **5** (R = Me) was readily converted into an aroyl ketone **8** by a Friedel–Crafts reaction of the acid chloride **7** with benzene or anisole. The anilide **9** and the mixed esters **10** and **11** were obtained by reaction of **7** with aniline, ethanol, and ethanethiol respectively. The conversion of

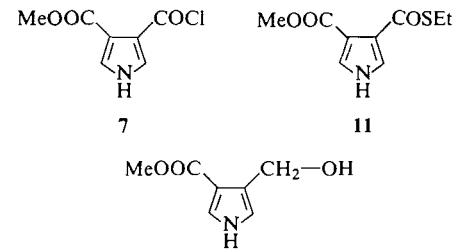
an acid derivative to a ketone generally requires a nucleophilic reagent and will be discussed later. 3,4-Pyrroledicarbonyl chloride was found to behave normally with ethanethiol, but Friedel-Crafts acylation using aluminum chloride in benzene was found to give 3,4-dibenzoylpyrrole. This contrasts with 1-*n*-butyl-2,5-dimethyl-3,4-pyrroledicarbonyl chloride which is reported to give an analog of **12** (13) (see Scheme 2).

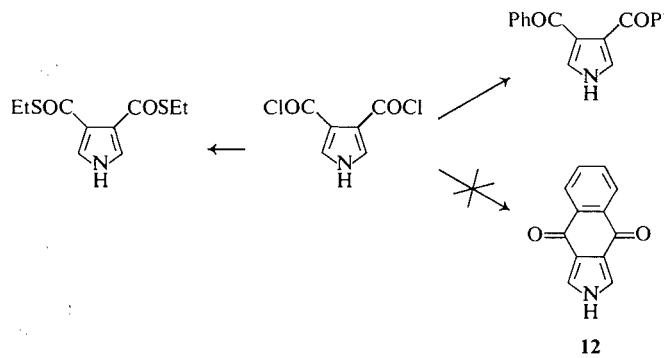
The reduction of an *N*-unsubstituted carboxylic acid derivative of pyrrole to the corresponding hydroxymethyl compound is often difficult since abstraction of the 1-proton initiates further reduction of the intermediate alcohol to the corresponding alkyl group (14) (Scheme 3). In the case of 3,4-disubstituted pyrroles the problem of reduction is further complicated by the presence of a second reducible group, either ketone or ester. Raney nickel was found to reduce selectively the corresponding ester thiolester **11** to the hydroxymethylpyrrole **13**.



7 **11**

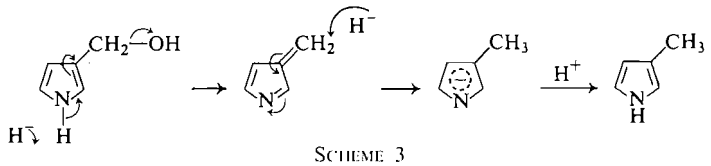
13

The synthesis of Verrucarin E requires the conversion of one of the β-carboxylate substituents into a methyl ketone. Reaction of the acid chloride **7** with excess methylmagnesium bromide or with dimethylcadmium gave only hydrolyzed starting material, while diethylcadmium gave a low yield of the corresponding ethyl ketone **14**. The use of the less basic methylmercuric iodide alone, or catalyzed with aluminum chloride, failed to effect any reaction. Condensation of **7** with sodium di-*tert*-butyl malonate gave only low yields of the ketomalo-



12

SCHEME 2



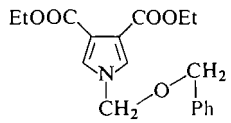
SCHEME 3

nate **15** although subsequent acid-catalyzed conversion to the ketone **16** was successful. Reaction of **7** with diazomethane resulted in *N*-methylation.

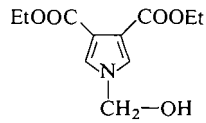
Abstraction of the acidic 1-proton by the carbanionic reagent and conjugative transfer of the resulting negative charge to the carbonyl substituents is probably the major factor accounting for the low reactivity of the chlorocarbonyl group in the above reactions.

At this point it was necessary to reconsider the synthetic approach to Verrucarin E. One problem was the very low solubility of pyrroles possessing electron-withdrawing groups in both 3- and 4-positions. This interfered with many of the reactions. For example, a potential ketone synthesis failed when it proved impossible to convert the 3,4-diacid to its cyclic anhydride because of the extreme insolubility of the diacid. The use of the di- and monoethyl esters rather than the methyl ones produced a considerable increase in solubilities and all further reactions involved these compounds.

The second major obstacle was the acidity of the *N*-hydrogen on these compounds as discussed above. This required that a base-stable, removable blocking group be found. Remers and co-workers (15) have examined 1-acetyl, 1-benzyol, 1-benzenesulfonyl, and 1-benzyl substituents for their suitability as protecting groups for the pyrrole nitrogen. Only the 1-benzyl substituent was found to be base-stable and since this is subsequently cleaved by sodium in liquid ammonia, its utility is restricted to compounds compatible with such vigorous reductive cleavage. Catalytic hydrogenolysis of the 1-benzyl substituent has previously been shown to be difficult for compounds in which the pyrrole nucleus bears electron-withdrawing substituents (16). After trials with several other reagents, diethyl 1-benzyloxymethyl-3,4-pyrroledicarboxylate (**17**) was prepared by reaction of the sodium salt of the diester **10** with benzyl chloromethyl ether. This provided an *N*-substituent stable to both acid and base but which could be cleaved by hydrogenolysis (17) or by aluminum chloride to the *N*-hydroxymethyl derivative **18**. On subsequent treatment of **18** with benzyltrimethylammonium hydroxide it rapidly lost formaldehyde to give back the pyrrole. As might be expected, it also increased the generally low solubility of the 3,4-disubstituted compounds.



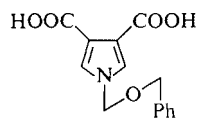
17



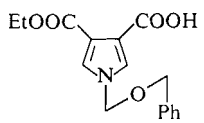
18

Basic hydrolysis of the protected diester **17** gave the corresponding 3,4-diacid **19**. On treatment with dicyclohexylcarbodiimide at 30° the diacid **19** gave an anhydride which was difficult to purify[2] and exhibited only a low reactivity towards dimethylcadmium, methylmagnesium iodide, and methyllithium.

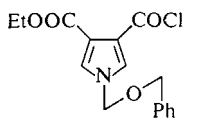
A more satisfactory route to the ketone involves controlled hydrolysis of the diester **17** to the monoester **20**. Subsequent reaction of the corresponding acid chloride **21** with dimethylcadmium afforded the *N*-protected ketone **22** in fair yield, together with some unreacted **21**.



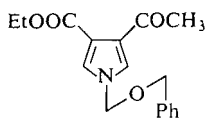
19



20



21



22

Conversion of **22** to Verrucarin E requires the removal of the *N*-protecting group and reduction of the remaining carboxylate substituent into hydroxymethyl via the thiolester. Although selective hydrogenolysis of a benzyl ether in the presence of an aromatic (including pyrrolic) ketone is usually possible (18–20) hydrogenation of **22** under various conditions resulted in either

[2]Physical properties suggested a mixture of monomeric and polymeric species.

no reaction or in preferential reduction of the ketone. Whilst cleavage of the benzyl ether occurred subsequent to reduction of the ketone, the p.m.r. of the product showed that concurrent hydrogenolysis of the hydroxyethyl group had occurred. It was then found that the benzyl ether in compound **22** could be readily cleaved to the corresponding 1-hydroxymethyl derivative with aluminum chloride. However, as the *N*-protecting group increased solubilities it was decided to retain it as long as possible. Conversion of the 3-carboxylate substituent to the 3-hydroxymethyl group is the other operation required to complete the synthesis. Hydrolysis of **22** to the acid **23** followed by conversion to the acid chloride and treatment with sodium ethanethioxide, gave an excellent yield of the corresponding thiolcarboxylate **24**. The benzyl ether in compound **24** was cleaved with aluminum chloride to the corresponding *N*-hydroxymethyl derivative **25** which on subsequent treatment with benzyltrimethylammonium hydroxide lost formaldehyde affording ethyl 3-acetyl-4-pyrrolethiolcarboxylate (**26**). The Raney nickel reduction of the thiolester group in compound **26** gave the hydroxymethyl derivative, Verrucarin E (**27**). The m.p. and i.r., u.v., and p.m.r. spectra of the synthetic compound were identical with those of natural Verrucarin E. The R_f values of the synthetic product were in agreement with those of the natural compound in various solvent systems.[3]

[3]The authors are indebted to Prof. Ch. Tamm who kindly provided an authentic specimen of Verrucarin E for comparison.

Confirmation of the proposed product structures is provided by their i.r., n.m.r., and mass spectral data. N.m.r. data for the trisubstituted pyrroles is given in Table 1.

Data for the 3,4-disubstituted pyrroles, given in Table 2, require further comment. Since many of the compounds were of low solubility their spectra were determined in dimethyl sulfoxide-d_6 solution. In this solvent spin–spin coupling between the 1-proton and the α-protons was not apparent, except in those cases where the pyrrole had a CO_2H substituent, because of rapid exchange of the acidic 1-proton with the basic solvent. As a consequence the symmetrical disubstituted compounds exhibited a singlet absorption for the α-protons whilst the unsymmetrical ones gave an AB type quartet. In deuterochloroform solution these absorptions appear as A_2X and ABX respectively.

I.r. data for the compounds are reported in the Experimental. In certain compounds the C=O stretching vibration occurs at an anomalously low frequency, a result which we attribute to intramolecular hydrogen bonding. Compare the values in the Experimental for **4** (R = Me or Et) **16**, **17**, and **22**.

*Stretching frequency of H-bonded carbonyl group

Most of the compounds reported exhibit an intense u.v. absorption in the 250 nm region. A further maximum below 215 nm was outside the useful range of the instrument used.

The major peaks in the mass spectra of some 2,4-disubstituted pyrroles are reported in Table 3. With the exception of the thiolesters the molecular ions are all of moderate abundance. The major fragmentation of each molecular ion

mixture was maintained at this temperature for a further 2 h prior to isolating the product.

Trimethyl 1,3,4-Pyrroletricarboxylate

Reaction of methyl 1-pyrrolecarboxylate (0.05 mol) and dimethyl acetylenedicarboxylate gave a dark oil which crystallized from methanol affording trimethyl 1,3,4-pyrroletricarboxylate, m.p. 67–68° (4.2 g, 35%) (lit. m.p. 69° (6)); ν_{max} 1775, 1745, and 1718 cm^{-1} (C=O); λ_{max} (MeOH) 247 nm (ε 7950).

Dimethyl 1-Benzoyl-3,4-pyrroledicarboxylate

1-Benzoylpyrrole (0.1 mol) and dimethyl acetylenedicarboxylate afforded an oil which was distilled to give recovered 1-benzoylpyrrole (4 g, 23%) and dimethyl 1-benzoyl-3,4-pyrroledicarboxylate (19.2 g, 67%), b.p. 210–212°/0.2 mm, which crystallized as needless, m.p. 115–116° (from MeOH); λ_{max} (MeOH) 229 (ε 17 600) and 253 nm (sh ε 9900).

Anal. Calcd. for $C_{15}H_{13}NO_5$: C, 62.7; H, 4.5. Found: C, 62.8; H, 4.4.

Diethyl 1-Benzoyl-3,4-pyrroledicarboxylate

Diethyl acetylenedicarboxylate similarly gave recovered 1-benzoylpyrrole (2.0 g, 25%) and diethyl 1-benzoyl-3,4-pyrroledicarboxylate b.p. 205–210°/0.2 mm, needles m.p. 65–66° (from petroleum (8.5 g, 54%); ν_{max} 1715 and 1732 sh cm^{-1} (C=O); λ_{max} (EtOH) 227 (ε 11 850) and 242 nm (sh ε 9750).

Anal. Calcd. for $C_{17}H_{17}NO_5$: C, 64.8; H, 5.4. Found: C, 64.9; H, 5.4.

Dimethyl 3,4-Pyrroledicarboxylate

Dimethyl 1-benzoyl-3,4-pyrroledicarboxylate (10.0 g) was added to KOH (1.5 g) in methanol (50 ml) and the mixture stirred at 5° for 3 h. The precipitated dimethyl 3,4-pyrroledicarboxylate was filtered and recrystallized from xylene to give needles (6.0 g, 94%), m.p. 242–243° (lit. m.p. 245° (6)); ν_{max} (Nujol mull) 1710 (C=O) and 3255 (N—H) cm^{-1}; λ_{max} (EtOH) 253 nm (ε 7900).

Diethyl 3,4-Pyrroledicarboxylate

Diethyl 1-benzoyl-3,4-pyrroledicarboxylate (3.15 g) was added to KOH (600 mg) in EtOH (65 ml) and the mixture was stirred at 20° for 2.5 h. The mixture was then cooled to 0° and the precipitated diethyl 3,4-pyrroledicarboxylate was collected by vacuum filtration. Recrystallization (from aqueous EtOH) gave plates, m.p. 151–152° (2.0 g, 95%) (lit. m.p. 153–154° (7)); λ_{max} (EtOH) 252 nm (ε 7500); ν_{max} 1730 and 1705 sh (C=O) and 3448 cm^{-1} (N—H).

3,4-Pyrroledicarboxylic Acid

Dimethyl 3,4-pyrroledicarboxylate (2.0 g), NaOH (20 g), and 50% aqueous MeOH (15 ml) were heated under reflux for 2 h. The resulting solution was poured onto ice and 3,4-pyrroledicarboxylic acid (1.55 g, 91%) was precipitated by addition of 2 *M* HCl. The acid had m.p. >300° (dec.) (lit. m.p. 290–292° dec. (6, 7)); ν_{max} (Nujol mull) 1590 (C=O), 2000–3000 (O—H), and 3160 cm^{-1} (N—H); λ_{max} (MeOH) 240 (ε 7900) and 259 nm (ε 7500).

3,4-Pyrroledicarbonyl Chloride

3,4-Pyrroledicarboxylic acid (155 mg), oxalyl chloride (1 ml), and dimethylformamide (1 drop) were heated under reflux in benzene (25 ml) for 30 min. Excess oxalyl chloride was distilled off leaving a homogenous, faintly yellow solution of pyrrole-3,4-dicarbonyl chloride.

Diethyl 3,4-Pyrroledithiolcarboxylate

The above diacid chloride solution, ethanethiol (1 ml), and pyridine (1 drop) were heated under reflux for 1 h. Cooling to 10° afforded diethyl pyrrole-3,4-dithiolcarboxylate as needles from benzene (160 mg, 66%), m.p. 179–180°; ν_{max} 1650 and 1640 cm^{-1} (C=O); λ_{max} (EtOH) 270 nm (ε 13 300).

Anal. Calcd. for $C_{10}H_{13}NO_2S_2$: C, 49.4; H, 5.4; N, 5.8. Found: C, 49.7; H, 5.2; N, 5.9.

3-Carbomethoxy-4-pyrrolecarboxylic Acid

Dimethyl 3,4-pyrroledicarboxylate (5.0 g) and methanolic KOH (1.53 g in 60 ml) were heated for 40 h on a steam bath. Water was added (10 ml) and the solution was filtered. Acidification of the filtrate afforded 3-carbomethoxy-4-pyrrolecarboxylic acid, m.p. 247–248° (from EtOH) (4.3 g, 93%); ν_{max} 1700 and 1625 (C=O) and 2500–3400 cm^{-1} (O—H); λ_{max} (EtOH) 245 (ε 8000) and 260 nm (ε 7350).

Anal. Calcd. for $C_7H_7NO_4$: C, 49.7; H, 4.2. Found: C, 49.9; H, 4.1.

3-Carbomethoxy-4-pyrrolecarbonyl Chloride

3-Carbomethoxy-4-pyrrolecarboxylic acid (1.0 g), oxalyl chloride (1.1 equiv), dimethylformamide (1 drop), and benzene (25 ml) were maintained at 50° for 2 h prior to cooling and filtering off the crude acid chloride (1.0 g, 90%); ν_{max} 1760 and 1715 cm^{-1} (C=O).

Ethyl 3-Carbomethoxy-4-pyrrolethiolcarboxylate

The above acid chloride (2.7 g), ethanethiol (1 ml), and benzene (30 ml) were heated under reflux for 2 h and then cooled to 10° to afford ethyl 3-carbomethoxy-4-pyrrolethiolcarboxylate, needles from benzene, m.p. 172.5–173° (2.3 g, 75%); ν_{max} 1710 and 1645 cm^{-1} (C=O); λ_{max} (EtOH) 255 (ε 9600) and 272 nm (7800).

Anal. Calcd. for $C_9H_{13}NO_3S$: C, 50.7; H, 5.2; N, 6.6. Found: C, 50.7; H, 5.0; N, 6.7.

3-Carbethoxy-4-carbomethoxypyrrole

The monoacid chloride (100 mg) and EtOH (5 ml) were heated under reflux for 1 h. Removal of excess EtOH afforded 3-carbethoxy-4-carbomethoxypyrrole, m.p. 159–160° (from $CHCl_3$) (97 mg, 92%); ν_{max} 1730 br cm^{-1} (C=O); λ_{max} (EtOH) 252 nm (ε 8500).

Anal. Calcd. for $C_9H_{11}NO_4$: C, 54.9; H, 5.6. Found: C, 54.9; H, 5.8.

3-Carbomethoxy-4-pyrrolecarboxanilide

3-Carbomethoxypyrrole-4-carbonyl chloride (100 mg), aniline (100 mg), and benzene (5 ml) were heated under reflux for 2 h. The mixture was cooled and filtered to afford 3-carbomethoxy-4-pyrrolecarboxanilide (105 mg, 85%). Sublimation (180°/0.1 mm) gave an analytical sample, m.p. 216–217°.

Anal. Calcd. for $C_{13}H_{12}N_2O_3$: C, 64.0; H, 4.9. Found: C, 63.9; H, 4.8.

3-Carbomethoxy-4-hydroxymethylpyrrole

Ethyl 3-carbomethoxy-4-pyrrolethiolcarboxylate (300 mg) in EtOH (75 ml) was cooled to 0° and W5 Raney nickel (2 g) was added. After 40 min in a Parr hydrogenator at 25° and 30 p.s.i. of hydrogen, the catalyst was removed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

by filtration through a Celite pad and washed with EtOH (200 ml). Concentration of the filtrate and washings yielded 3-carbomethoxy-4-hydroxymethylpyrrole, m.p. 94–95° (from EtOH) (148 mg, 68%); ν_{max} 1690 (C=O) and 3450 cm^{-1} (N—H).

Anal. Calcd. for $C_7H_9NO_3$: C, 54.2; H, 5.8. Found: C, 54.1; H, 5.9.

3-Propionyl-4-carbomethoxypyrrole

3-Carbomethoxypyrrole-4-carbonyl chloride (1.0 g) was added to a benzene solution of diethylcadmium (0.15 mol). The mixture was heated under reflux for 4 h and then poured onto ice – 6 *M* H_2SO_4. The benzene layer was separated and the aqueous layer was extracted with ethyl acetate. The organic solutions were washed with $NaHCO_3$ solution and then dried ($MgSO_4$). The solvent was removed and the product was chromatographed on basic alumina (Brockmann activity III). Elution with ethyl acetate gave 3-propionyl-4-carbomethoxypyrrole, m.p. 179–180° (from ethyl acetate) (0.38 g, 36%); ν_{max} 1720 and 1675 (C=O) and 3450 cm^{-1} (N—H); λ_{max} (EtOH) 253 nm (ε 7000).

Anal. Calcd. for $C_9H_{11}NO_3$: C, 59.7; H, 6.1. Found: C, 59.8; H, 6.0.

3-Benzoyl-4-carbomethoxypyrrole

3-Carbomethoxy-4-pyrrolecarboxylic acid (420 mg) was converted to the acid chloride in benzene solution. The flask was flushed with nitrogen, aluminum chloride (700 mg) was added, and the mixture was heated under reflux for 10 h. The product was poured onto ice–HCl, extracted into ethyl acetate, and washed with $NaHCO_3$ solution. Chromatography on neutral alumina (Brockmann activity I), eluting with ethyl acetate afforded 3-benzoyl-4-carbomethoxypyrrole, m.p. 163–164° (130 mg, 23%); ν_{max} 1717 and 1655 (C=O) and 3445 cm^{-1} (N—H).

Anal. Calcd. for $C_{13}H_{11}NO_3$: C, 68.1; H, 4.8. Found: C, 67.9; H, 5.0.

3-p-Anisoyl-4-carbomethoxypyrrole

3-Carbomethoxypyrrole-4-carboxylic acid (420 mg) similarly gave 3-*p*-anisoyl-4-carbomethoxypyrrole, m.p. 179–180° (from ethyl acetate) (306 mg, 47%); ν_{max} 1715, 1645 (C=O) and 3445 cm^{-1} (N—H); λ_{max} (EtOH) 218 (ε 8600) and 283 nm (ε 9000).

Anal. Calcd. for $C_{14}H_{13}NO_4$: C, 64.9; H, 5.0. Found: C, 64.6; H, 5.2.

3,4-Dibenzoylpyrrole

3,4-Pyrroledicarboxylic acid (155 mg) was converted to the diacid chloride in benzene solution (40 ml) as described earlier. Aluminum chloride (260 mg) was added and the mixture was stirred for 18 h at 50°. The product, 3,4-dibenzoylpyrrole m.p. 223–224° (from ethyl acetate) (94 mg, 34%), was isolated as above; ν_{max} 1650 (C=O) and 3445 cm^{-1} (N—H).

Anal. Calcd. for $C_{18}H_{13}NO_2$: C, 78.5; H, 4.7. Found: C, 78.6; H, 4.9.

Diethyl 1-Hydroxymethyl-3,4-pyrroledicarboxylate

Diethyl 3,4-pyrroledicarboxylate (211 mg), aqueous formaldehyde (5 ml of 37%), tetrahydrofuran (5 ml), and benzyltrimethylammonium hydroxide (0.2 ml) were heated under reflux for 5 h. The mixture was poured onto ice and extracted with ethyl acetate, washed with water, and dried ($MgSO_4$). Removal of the solvent afforded diethyl 1-hydroxymethyl-3,4-pyrroledicarboxylate, m.p. 85–86° (from $CHCl_3$–petroleum) (205 mg, 85%); ν_{max} 1725 br (C=O) 3350 br (O—H bonded), and 3560 cm^{-1} (O—H free); λ_{max} (EtOH) 250 nm (ε 6700).

Anal. Calcd. for $C_{11}H_{15}NO_5$: C, 54.7; H, 6.2. Found: C, 54.8; H, 6.1.

Elimination of Formaldehyde from Diethyl 1-Hydroxymethyl-3,4-pyrroledicarboxylate

Diethyl 1-hydroxymethyl-3,4-pyrroledicarboxylate (150 mg), tetrahydrofuran (3 ml), water (10 ml), and benzyltrimethylammonium hydroxide (0.1 ml) were heated under reflux for 3 h. The mixture was diluted with water and the organic material extracted into ethyl acetate and dried ($MgSO_4$). Removal of the solvent gave a product which was shown (i.r. and n.m.r.) to be diethyl 3,4-pyrroledicarboxylate.

Diethyl 1-Benzoyloxymethyl-3,4-pyrroledicarboxylate

Diethyl 3,4-pyrroledicarboxylate (1.05 g) in dry tetrahydrofuran (50 ml) was treated with 1 equiv of sodium hydride. The solution was heated under reflux for 2 h then cooled to 0° and benzyl chloromethyl ether (800 mg) in tetrahydrofuran (10 ml) was added over 15 min. The solution was allowed to reach 25°, stirred overnight, and then heated under reflux for 2 h prior to filtration. The filtrate was concentrated and, after chromatography on neutral alumina, gave diethyl 1-benzyloxymethyl-3,4-pyrroledicarboxylate as a viscous liquid (1.48 g, 90%); ν_{max} 1725 br cm^{-1}.

1-Benzyloxymethyl-3,4-pyrroledicarboxylic Acid

Diethyl 1-benzyloxymethyl-3,4-pyrroledicarboxylate (450 mg) was heated under reflux with aqueous alcoholic potassium hydroxide (12 ml of 10% solution) for 45 min. The mixture was allowed to stand for a further 1 h at 25° prior to acidification with 2 *M* HCl and subsequent extraction into ethyl acetate. Extraction of the organic acid into $NaHCO_3$ solution and re-precipitation afforded 1-benzyloxymethyl-3,4-pyrroledicarboxylic acid, m.p. 143–144° (from 5:1 aqueous-ethanol) (250 mg, 67%); ν_{max} 1720 and 1645 (C=O), 3200–2200 cm^{-1} (O—H); λ_{max} (EtOH) 257 nm (ε 7400).

Anal. Calcd. for $C_{14}H_{13}NO_5$: C, 61.0; H, 4.7; N, 5.1. Found: C, 61.0; H, 4.8; N, 5.2.

1-Benzyloxymethyl-3,4-pyrroledicarboxylic Anhydride

1-Benzyloxymethyl-3,4-pyrroledicarboxylic acid (125 mg) and dicyclohexylcarbodiimide (110 mg) were added to dichloroethane (25 ml). The mixture was heated under reflux for 90 min. The initial suspension became homogeneous prior to precipitation of the dicyclohexylurea. Filtration and concentration of the filtrate afforded a product (95 mg, 81%), m.p. 72–80°; ν_{max} 1785, 1835, and 1855 cm^{-1}, average molecular weight in dichloroethane: 308 (calcd. 257). Attempted recrystallization from various solvents failed to sharpen the melting point.

1-Benzyloxymethyl-3-carbethoxy-4-pyrrolecarboxylic Acid

Diethyl 1-benzyloxymethyl-3,4-pyrroledicarboxylate (6.5 g), potassium hydroxide (1.10 g), and EtOH (50 ml) were heated under reflux for 18 h. The product was poured into water and extracted with ether. The aqueous layer was separated, acidified, and filtered to afford 1-benzyloxymethyl-3-carbethoxy-4-pyrrolecarboxylic acid, m.p. 82–83° (from ether) (4.8 g, 81%); ν_{max} 1712 and

1635 cm^{-1} (C=O); λ_{max} (EtOH) 247 (ε 7650) and 260 nm (7300).

Anal. Calcd. for $C_{16}H_{17}NO_5$: C, 63.3; H, 5.6. Found: C, 63.5; H, 5.6.

Ethyl 1-Benzyloxymethyl-3-acetyl-4-pyrrolecarboxylate

The above half-acid (1.50 g) was heated under reflux with a benzene solution (80 ml) of oxalyl chloride (0.65 g) and dimethylformamide (1 drop). A solution of dimethylcadmium was prepared from magnesium (0.48 g) and methyl iodide (1.4 ml) to form a Grignard reagent in ether (50 ml), followed by the addition of cadmium chloride (1.83 g). This mixture was heated under reflux for 2 h prior to replacing the ether by benzene (50 ml). The above acid chloride was added to the dimethylcadmium solution over 15 min and the mixture was then heated under reflux for 3.5 h prior to pouring onto ice–HCl. The organic material was extracted into a large volume of ethyl acetate, washed with $NaHCO_3$ solution, dried ($MgSO_4$) and filtered through a short column of activity I basic alumina. Removal of the solvent afforded ethyl 1-benzyloxymethyl-3-acetylpyrrole-4-carboxylate as a viscous liquid (800 mg, 54%), ν_{max} 1710 and 1665 (C=O) cm^{-1}.

1-Benzyloxymethyl-3-acetyl-4-pyrrolecarboxylic Acid

The above keto-ester (200 mg) was heated under reflux for 2.5 h with a solution of KOH (500 mg) in aqueous ethanol (3 ml, 1:1). The solution was poured into water, acidified with 2 *M* HCl, and the resulting 1-benzyloxymethyl-3-acetyl-4-pyrrolecarboxylic acid was filtered off giving a solid m.p. 149–150° (from aqueous EtOH), (140 mg, 78%); ν_{max} 1710 and 1620 cm^{-1} (C=O); λ_{max} (EtOH) 262 nm (ε 10 300).

Anal. Calcd. for $C_{16}H_{17}NO_5$; C, 63.4; H, 5.6. Found: C, 63.5; H, 5.7.

Attempted Hydrogenolysis of the Benzyloxymethyl Substituent in **22**

Uncontrolled hydrogenolysis of ethyl 1-benzyloxymethyl-3-acetyl-4-pyrrolecarboxylate (**22**) (150 mg) in EtOH (20 ml) in the presence of 10% palladium-on-carbon (25 mg) resulted in complete hydrogenolysis of the benzyl group and complete reduction of the acetyl group as shown in the n.m.r. of the product. When hydrogenolysis under these conditions was stopped after the uptake of 1 mol equiv of hydrogen (2.5 h), the n.m.r. of the product showed the absence of acetyl group but retention of a benzyl group. The α-proton resonances occurred as doublets (J = 2.2 Hz) at τ 2.55 and 3.27.

Hydrogenolysis of **22** (100 mg) in tetrahydrofuran (40 ml) in the presence of 10% palladium-on-carbon (35 mg) and triethylamine (1 drop) for 4 h resulted in recovery of a product, the n.m.r. spectrum of which indicated that it was mainly **22** although a little reduction of the acetyl group was apparent in the spectrum.

Hydrogenolysis of **22** (50 mg) in EtOH (6 ml) in the presence of 10% palladium-on-carbon (20 mg) and sulfur–quinoline poison solution (0.1 ml) for 4 h resulted in complete reduction of the acetyl but retention of the benzyl as shown by the n.m.r. spectrum.

Hydrogenolysis of **22** (100 mg) in the presence of W5 Raney nickel (~200 mg) in EtOH (15 ml) under 30 p.s.i. for 1 h resulted in recovery of unchanged **22**.

Ethyl 1-Benzyloxymethyl-3-acetyl-4-pyrrolethiolcarboxylate

1-Benzyloxymethyl-3-acetyl-4-pyrrolecarboxylic acid (275 mg) was heated under reflux for 2 h in a benzene solution (25 ml) of oxalyl chloride (135 mg) and dimethylformamide (1 drop). A solution of sodium ethanthioxide was prepared by adding ethanethiol (65 mg) to 50 mg of 58% sodium hydroxide in 25 ml of benzene. The above acid chloride was then added to the sodium ethanthioxide solution and the mixture was refluxed for 1 h. The reaction mixture was then cooled and the precipitated inorganic salt was removed by filtration and washed with benzene (100 ml). The filtrate was then evaporated *in vacuo*, and the yellow viscous liquid thus obtained was filtered through a short column of neutral alumina (Brockmann activity I) using ether as eluant. Removal of solvent gave ethyl 1-benzyloxymethyl-3-acetyl-4-pyrrolethiolcarboxylate as a pale yellow viscous oil (225 mg, 71%); ν_{max} 1665 and 1660 cm^{-1} (C=O).

Anal. Calcd. for $C_{17}H_{19}NO_3S$: C, 64.4; H, 6.0; N, 4.4. Found: C, 64.2; H, 6.0; N, 4.5.

Ethyl 1-Hydroxymethyl-3-acetyl-4-pyrrolethiocarboxylate

Ethyl 1-benzyloxymethyl-3-acetyl-4-pyrrolethiolcarboxylate (160 mg) in anhydrous benzene (15 ml) was stirred at 40 °C for 30 min with aluminum chloride (140 mg). The solution was then cooled in ice and the excess aluminum chloride was slowly destroyed through addition of ice-cold water. The organic layer was separated, dried ($MgSO_4$) and evaporated *in vacuo*. The benzyl chloride formed was distilled under vacuum, the reddish gum obtained crystallized from ether–petroleum (92 mg, 81%), m.p. 89–91°; ν_{max} 3400 br (O—H), 1665, and 1660 cm^{-1} (C=O).

Anal. Calcd. for $C_{10}H_{13}NO_3S$: C, 52.9; H, 5.7. Found: C, 52.8; H, 5.9.

Ethyl 3-Acetyl-4-pyrrolethiolcarboxylate

Ethyl 1-hydroxymethyl-3-acetyl-4-pyrrolethiolcarboxylate (60 mg) in aqueous tetrahydrofuran (13 ml of 10:3) was heated under reflux with benzyltrimethylammonium hydroxide (0.2 ml). The mixture was then evaporated to half-bulk, diluted with water (20 ml), and extracted twice with ethyl acetate. The organic layer was separated, dried ($MgSO_4$), and evaporated *in vacuo* affording ethyl 3-acetyl-4-pyrrolethiolcarboxylate as a white powder, (44 mg, 85%). Recrystallization from ether – petroleum ether gave an analytical sample, m.p. 118–120°; ν_{max} 3440 (N—H free), 3250 (N—H bonded), 1665 and 1660 cm^{-1} (C=O).

Anal. Calcd. for $C_9H_{11}NO_2S$: C, 54.8; H, 5.8; N, 7.1. Found: C, 54.8; H, 5.6; N, 7.2.

3-Acetyl-4-hydroxymethylpyrrole

Ethyl 3-acetyl-4-pyrrolethiolcarboxylate (30 mg) in absolute methanol (20 ml) was cooled to 0° and W5 Raney nickel (about 800 mg) was added. The mixture was shaken in a Parr hydrogenator for 70 min at 25° and 30 p.s.i. of hydrogen. The catalyst was then removed by collection on a Celite pad and was washed with ethanol (250 ml). The filtrate and washings were combined and removed *in vacuo* affording a pink gum. Preparative t.l.c. (silica gel GF-254 chloroform–methanol, 97:3) of the crude product resulted in the isolation of pure 3-acetyl-4-hydroxymethylpyrrole (15 mg, 71%), m.p. 88–90°

(lit. (3, 4) 90.5–91°). The i.r., u.v., and p.m.r. spectra were identical with those of natural Verrucarin E. The R_f values of the synthetic product were in agreement with those reported for the natural compound using chloroform–methanol, 97:3; or 92:8; as well as ethyl acetate as eluants.

The continued financial support of the National Research Council of Canada and of the Memorial University of Newfoundland is gratefully acknowledged. The authors are indebted to Dr. C. E. Loader for many useful discussions.

Received August 28, 1972

The 100- and 220-MHz p.m.r. spectra of uridine, cytidine, and their 2′-*O*-methyl derivatives are obtained in aqueous solution at several temperatures. The experimental chemical shifts and coupling constants are discussed in terms of the overall molecular conformation. The conclusion is reached that 2′-*O*-methylation has little effect upon the three-dimensional structure of a nucleoside at the monomer level in an aqueous environment.

Les spectres r.m.n. à 100 et 220 MHz de l'uridine, de la cytidine, et de leur dérivé *O*-méthyl-2′ ont été obtenus dans des solutions aqueuses à différentes températures. Les déplacements chimiques expérimentaux ainsi que les constantes de couplage sont discutés en fonction de la conformation moléculaire totale. On a conclu que la *O*-méthylation en 2′ a peu d'effet sur la structure tridimentionnelle du nucléoside au niveau monomérique en milieu aqueux. [Traduit par le journal]

Can. J. Chem., **51**, 1099 (1973)

Introduction

It is well established that 2′-*O*-methylation of ribonucleosides is a highly specific enzymatic process which occurs at the polynucleotide level and leads to a characteristic distribution of these methylated residues in tRNA and rRNA of various organisms (1–6). The precise biological significance of this modification is not clear but, as might be anticipated the presence of the 2′-*O*-methyl substituent renders the phosphodiester linkage resistant to both alkali and ribonucleases (1, 2, 6, 7). A number of spectroscopic investigations of the methylated oligo- and polynucleotides have appeared in the literature and the possible role of the 2′-hydroxyl in stabilizing the three-dimensional structure of polyribonucleotides has been critically discussed (8–12). Studies on the various 2′-*O*-methyl polymers have demonstrated that the presence of the 2′-OH is not a prerequisite for the formation of helical structure of polynucleotides (13–15). We present here our initial p.m.r. studies of the effect of 2′-*O*-methylation on nucleoside conformation (16–19) at the monomer level (structural formulae in Fig. 1). Our data demonstrate that 2′-*O*-methylation has no significant effect upon the sugar–base torsion angle, the exocyclic $C_{4'}$—$C_{5'}$ conformation, or the furanose-ring puckering at the mononucleoside level.

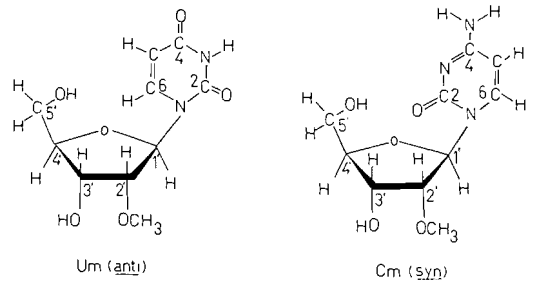

FIG. 1. Structural formulae of 2′-*O*-methyluridine (Um) and 2′-*O*-methylcytidine (Cm). Definition of the *anti*- and *syn*-rotations about the *N*-glycosyl bond of a pyrimidine nucleoside.

Experimental

Uridine (U) and cytidine (C) were obtained from Calbiochem and used without further purification. The 2′-*O*-methyl derivative of C (Cm) was prepared by dimethylsulfate treatment of cytidine in alkaline medium (20). 2′-*O*-methyluridine (Um) was then obtained by bisulfite

deamination of Cm.[1] Both compounds were recrystallized several times from ethanol to ensure elimination of traces of impurity, checked for at high concentrations by paper and thin-layer chromatography. 3-Trimethylsilylpropanesulfonic acid (DSS, E. Merck, Germany) was used as the internal p.m.r. reference. Solutions (0.1 *M*) of each nucleoside containing 0.1 *M* DSS were prepared in D_2O. The p*D* was adjusted to 7.0 ± 0.2 for the U derivatives and 8.0 ± 0.2 for the C derivatives. The samples were freeze-dried three times to reduce the intensity of the HDO resonance. Spectra were obtained on Varian HA-100 D and HR-220 spectrometers by conventional methods. Spectral analyses were carried out using LAME (21).

Results and Discussion

Spectral Assignment

The complete assignment and spectral analysis (for non-exchanging hydrogens) of the 100 and 220 MHz spectra of U in aqueous solution have been discussed in some detail elsewhere (17) and are used as a guide for interpreting the new data reported here for C, Um, and Cm. Recent studies by Narayanan and Iyer (22) of the shielding effect of methylation of the hydroxyl group of secondary alcohols upon the methine hydrogen proved useful for initial assignments of the spectral bonds of the methylated derivatives. The assignments were confirmed by some double resonance experiments and computer-simulated spectra were generated as final tests for the chemical shift and coupling constant data. In Fig. 2*a* we show a sample experimental spectrum (220 MHz) of the ribose region of Cm at 60 °C along with the calculated spectrum. In Fig. 2*b* is shown the 3′-portion of the 100 MHz spectrum of Cm (60 °C). Clearly, with the somewhat better resolution obtainable on 100 MHz spectrometers, additional spacings of 0.30–0.40 Hz become apparent in this region of the Cm (as well as Um) spectra. This spacing was attributed, by spin-decoupling, to a long-range four-bond coupling between $H_{1'}$ and $H_{3'}$ ($^4J_{1'3'}$). The methyl resonance of Um and Cm appeared as a sharp singlet at 3.51–3.54 p.p.m. downfield from DSS.

In Tables 1 and 2 are listed the observed chemical shift and vicinal coupling constant data for U, C, Um, and Cm as well as those for RCA (β-D-ribofuranosylcyanuric acid) taken from ref. 23 for comparison purposes (Fig. 3).

The Sugar–Base Torsion Angle

A conformational problem of considerable interest has been the elucidation of the orientation of the base and sugar moieties as defined by the sugar–base torsion angle about the *N*-glycosyl bond. X-ray diffraction studies are perhaps the most informative in this regard since the accurate bond lengths and bond angles establish unambiguously the favored conformation of the nucleoside in the crystalline state. For solutions o.r.d., c.d., and p.m.r. (24), and recently c.m.r. (25) have provided information, albeit qualitative, for the preference of either the *syn*- or *anti*-ranges of this torsion angle. However, recent applications of the theory of the nuclear Overhauser effect has demonstrated that more quantitative information of conformational distributions can be provided (26).

A preference for the *anti*-conformation of common pyrimidine nucleosides is apparent and generally agreed to be a consequence of unfavorable steric interactions between the 2-keto oxygen of the base and the substituents on the furanose ring which occur when the molecules assume a *syn*-conformation. Recent spectroscopic (27–29) studies point to a preference for the *syn*-conformation of pyrimidine derivatives possessing a bulky substituent (CH_3, COOH) at the 6-position of the base and lend support to the notion that non-bonding interactions between the base substituents at the ortho-positions and the ribose ring are the prime factors determining the favored range of the sugar–base torsion angle. Thus on the basis of purely steric arguments we predict that methylation of the 2′-hydroxyl will have no drastic effect upon the sugar–base torsion angle at the monomer level. In the ensuing discussion a qualitative comparison is made of the p.m.r. data of U, C, Um, and Cm which supports this prediction.

Prestegard and Chan (30) have argued that, because of the proximity of the uracil H_6 proton to the ribose moiety (particularly to the ethereal oxygen) in pyrimidine nucleosides exhibiting the *anti*-form, variations in the relative orientation of the base and sugar should be reflected in the chemical shift of this proton. From the data in Table 1 we see, however, only minor differences (<2 Hz) in the experimental resonant field values of H_6 for each N—Nm pair of nucleosides. These observations are in line with the prediction that no large perturbation of the average sugar–base torsion angle is a consequence of 2′-*O*-methylation.

Information about the favored range of sugar–

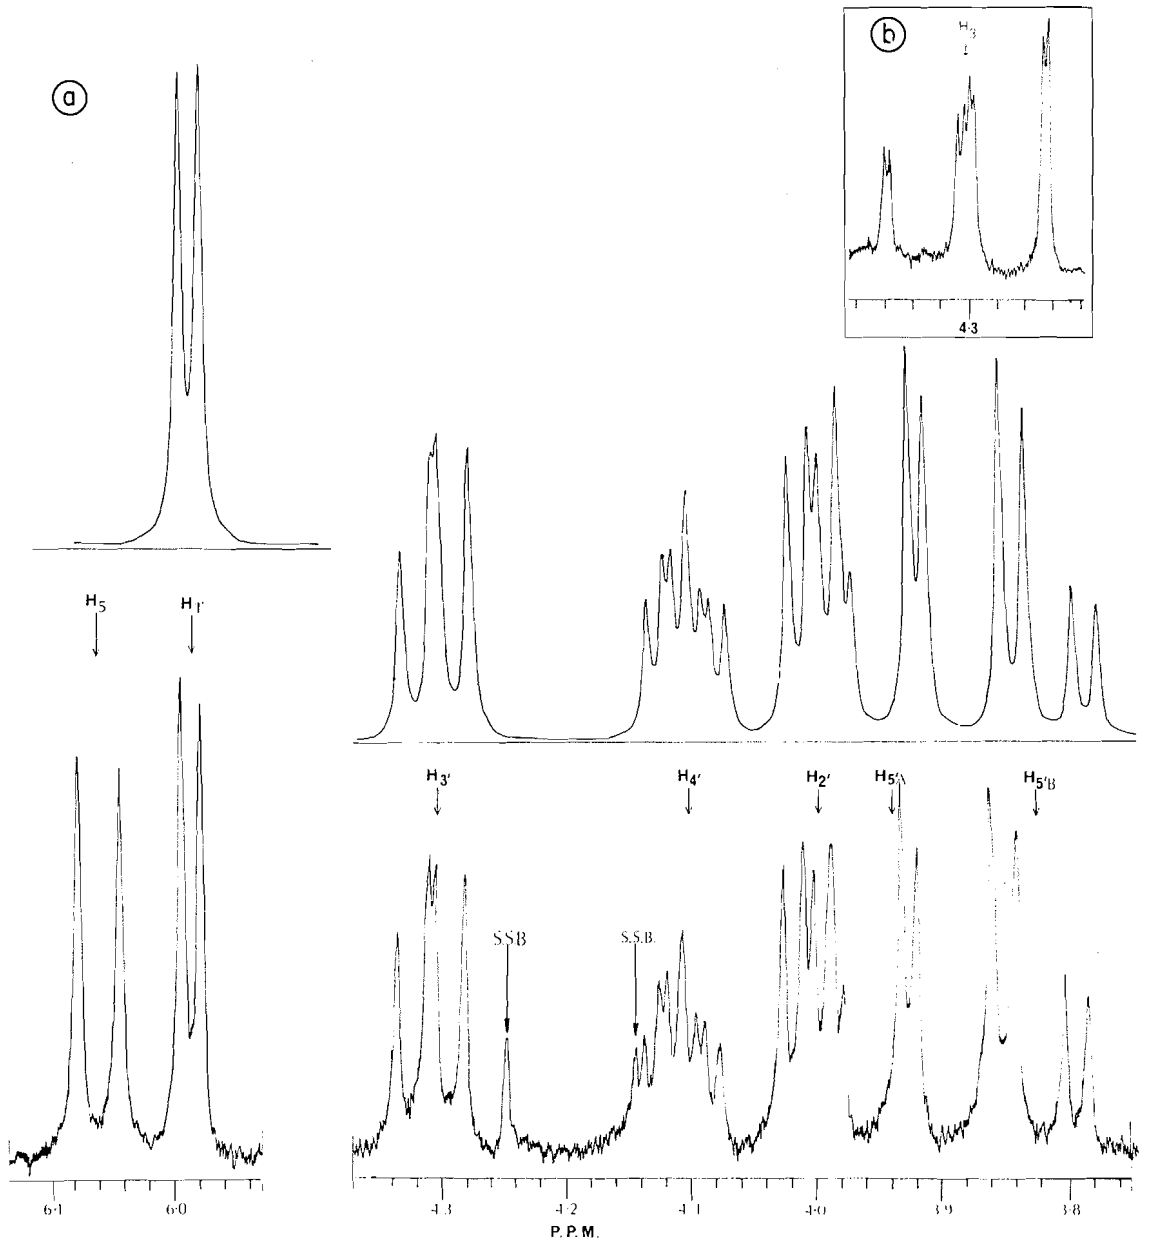

FIG. 2. (*a*) The 220 MHz spectrum of Cm (H_6 not included). Aqueous solution, 23 °C, p*D* 8.0. In p.p.m. relative to internal DSS. S.S.B. = spinning side-band. The computer-simulated spectrum is shown above the experimental. (*b*) 3′-Region of Cm obtained at 100 MHz. Aqueous solution, p*D* 8.0, 60 °C.

base torsion angle of pyrimidine nucleosides has also been obtained from observed long-range coupling ($^5J_{51'}$) interactions between the H_5 hydrogen (or 5-fluoro) of the base and the anomeric hydrogen (31, 32). The stereochemical dependence appears to be such that the largest $^5J_{51'}$ coupling is expected when $C_{1'}$—$H_{1'}$ and the base are coplanar with the molecule in the *anti*-conformation, that is, when $H_{1'}$ and H_5 are connected by an extended zig-zag path. Splittings attributable to $^5J_{51'}$ interactions were readily detected in the 5′ regions of U, Um, and Cm. We are inclined to present these as further evidence that their conformational distributions

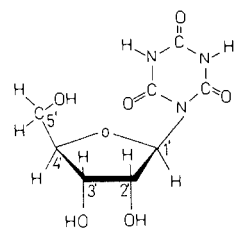

FIG. 3. Structural formula of β-D-ribofuranosylcyanuric acid (RCA).

about the N_1—C_1 bond are similar. However, we have not been able to detect an analogous splitting in the spectrum of C obtained under comparable solution and temperature conditions. For this molecule the H_5 resonances were relatively broad even at elevated temperatures, a feature which would obscure any small coupling. Double resonance experiments were employed to detect line narrowing and hidden spacings in the H_5 region but the experiments were inconclusive. No simple explanations for the H_5 bandwidth differences of C and Cm, other than the presence of paramagnetic impurities in the commercial preparation of C, are apparent.[2]

With recent p.m.r. measurements Schweizer *et al.* (28) and Dugas *et al.* (23) have presented a novel approach to evaluation of the *syn–anti* problem in pyrimidine nucleosides. These authors have noted that the presence of an ortho keto group on the base located over the ribose ring can lead to characteristic perturbations of the ribose hydrogen chemical shifts and coupling

[2]We have taken precautions to ensure that the solution p*H* is in the range where the line broadening effect, due to the presumed tautomeric equilibrium recently discussed by Lee *et al.* (33), should be unimportant.

constants. The most complete set of data, for RCA, are included in the tables for comparison purposes. We note that, relative to U, the $H_{2'}$ and $H_{3'}$ resonances in RCA are shifted downfield (by 0.34 and 0.14 p.p.m.) whereas $H_{4'}$, $H_{5'}$, and $H_{5''}$ are shifted upfield (by 0.16, 0.06, and 0.09 p.p.m. respectively), effects which were reasonably traced to the anisotropic shielding effects of the *keto* oxygen located above the furanose moiety. However, the effect of 2′-*O*-methylation is clearly seen to be diamagnetic ($\simeq$0.3 p.p.m.) for $H_{2'}$ (and in line with the work of Narayanan and Iyer (22) but paramagnetic ($\simeq$0.1 p.p.m.) for $H_{1'}$ and $H_{3'}$ and negligible ($<$0.05 p.p.m.) for $H_{4'}$, $H_{5'}$, and $H_{5''}$. The relative magnitudes of these methyl-induced shift changes suggest a (de)shielding mechanism related to separation from the methoxyl group and are not readily treated in terms of any significant *syn–anti* interconversion.

Conformation of the Furanose Ring

Detailed Karplus treatments have recently been carried out for a large number of nucleosides and qualitative models for the three dimensional structure of their furanose moieties have been put forth (16–19). The major conclusion arrived at from these solution studies was that the observed p.m.r. data could be accounted for not in terms of a single conventional puckered mode but if a rapid time-averaged pseudorotational (34) interconversion between several puckered modes was assumed. Suggested (16–17) as particularly attractive for U and β–ψ was a C_2 *endo*-$C_{3'}$ *endo*-equilibrium with significant contributions from each to the overall conformational blend. Rationalization of the *J* data in Table 2 in the manner outlined in ref. 16 leads us to conclude that the equilibrium model is reasonable for 2′-*O*-methyl derivatives and that methylation has no large effect upon either the barrier to the interconversion or upon the conformer weightings in the blend. A slight shift toward the $C_{3'}$ *endo*-mode of puckering may be inferred from the small changes in $J_{1'2'}$ and $J_{3'4'}$ of Um and Cm relative to U and C.

Karplus treatments have been extended (16–19) to the 4′- to 5′(5″)-vicinal couplings to yield estimates of the rotamer populations about the exocyclic $C_{4'}$—$C_{5'}$ bond. Consideration of the data for U in aqueous solution led to the conclusion (17) that the hydroxymethyl group interconverted between the *gauche–gauche*, *gauche–trans*, and *trans–gauche* rotamers with a preference for the *gauche–gauche* (Fig. 4). We may conclude from the similarity in the $J_{4'5'}$ and $J_{4'5''}$ values of U, C, Um, and Cm that 2′-*O*-methylation (or substitution of cytosine for uracil for that matter) has little effect upon rotamer population about the $C_{4'}$—$C_{5'}$ bond. Thus the hydrogen-donor properties of the 2′-hydroxyl seem to be unimportant in so far as mononucleoside conformation in aqueous solution is concerned.

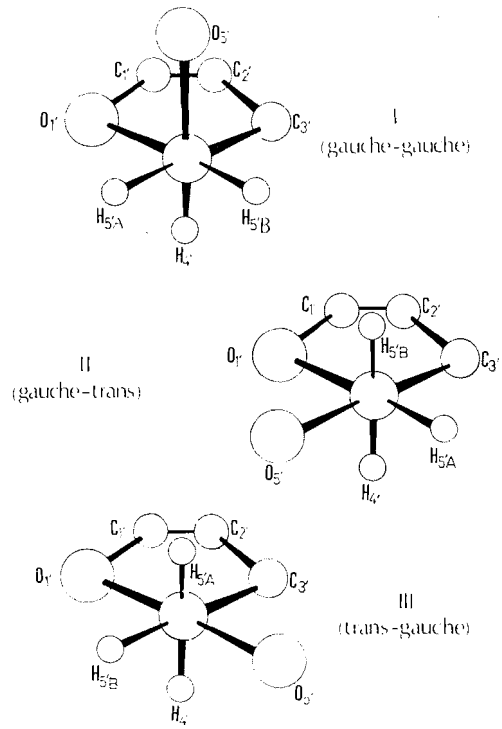

FIG. 4. Conformers about the $C_{4'}-C_{5'}$ bond of a nucleoside.

Mention should be made of the observed long-range coupling between $H_{1'}$ and $H_{3'}$ ($^4J_{1'3'}$) in Um and Cm in view of the strong steric dependence of four bond couplings in H—C—C—C—H propanic fragments and their value in structural problems (35). Splittings of 0.30–0.35 Hz in the 3′-regions, attributable by double resonance experiments to 1′–3′ interactions, were readily resolved in the pair of methyl derivatives (Fig. 2*b*). Analogous splittings were not resolved in either U or C which may indicate absence of $^4J_{1'3'}$ coupling but any 0.3–0.4 Hz splitting could be obscured by virtual coupling which is extensive in tightly-coupled ribose spectra. The presence of the 2′-*O*-methyl group, by virtue of its

shielding effect upon $H_{2'}$ and deshielding effect upon $H_{3'}$, has created a more loosely-coupled spin system in which small couplings have become resolvable, in the 3′-region at least. We are not surprised that the $^4J_{1'3'}$ splitting is not evident in the 1′ regions of Um and Cm in view of our (as well as other (36)) observations (37) that the 1′ hydrogen in furanoid derivatives can exhibit an extensive array of small, and generally unresolvable, long-range interactions which are seen only in the broadening of a proton signal.

It is now generally thought that the favored stereochemistry for four-bond coupling in saturated systems is a planar W path (35), approached, for instance, by 1,3 equatorial:equatorial hydrogens in pyranoid derivatives. $^4J_{e,e}$ couplings of up to 1.5 Hz have been observed in several pyranoses and shown to be positive in sign (38). In these molecules hydrogens connected by paths less favorable for four-bond interaction than the planar W (for instance the 1,3 equatorial:axial pairs of hydrogens), are found coupled with intermediate values of J (0.4–0.7) Hz and to be negative (28). There does not seem to be much evidence for coupling between 1,3 axial:axial hydrogens (37). Experimental data for flexible five-membered systems are scarce and thus far-reaching generalizations regarding the stereochemical dependence of four-bond coupling in furanoses are not permitted. A recent unpublished examination (37) of 2′,2′-anhydroarabinosyluracil (aU, Fig. 5) may be relevant in this regard. Examination of molecular models of aU indicate considerable rigidity in the molecule with the furanose ring locked in an extreme $C_{2'}$ *endo*-like conformation by the two point attachment of the base and arabinose moieties. We see further from models that $H_{2'}$ and $H_{4'}$ assume a quasi-equatorial:quasi-equatorial (qe:qe) relationship while the $H_{1'}$–$H_{3'}$ and $H_{1'}$–$H_{4'}$ pairs assumed a quasi-axial:quasi-equatorial (qa:qe) relationship. The observed values of the coupling constants for the three pairs of hydrogens connected by four-bonds were (aqueous solution, 30 °C): $^4J_{2'4'} = 0.54$, $^4J_{1'3'} = -0.75$, $^4J_{1'4'} = -0.46$ Hz. These data are suggestive of a parallel stereochemical dependence of ^4J in five- and six-membered carbohydrate rings.

The data for aU may seem encouraging in so far as the use of four-bond coupling for conformational assignments of nucleosides is concerned. However, we have obtained to date spectra for a large number of pyrimidine and purine nucleosides and note that resolvable ^4J couplings are the exception rather than the rule. The 2′-*O*-methyl ribosides seem to be special cases in so far as resolvable couplings are concerned, presumably for the reason given above. Even the $^4J_{1'3'}$ couplings of Um and Cm appear to us to be of limited value for conformational assignments. Since $H_{1'}$ and $H_{3'}$ assume a qa:qe orientation in both the $C_{2'}$ *endo*- and $C_{3'}$ *endo*-conformations, we do not expect the magnitude of $^4J_{1'3'}$ to be significantly altered by changes in ring puckering. Thus we do not expect these four-bond couplings to be of any particular value for assessing the position of our assumed equilibrium between $C_{2'}$ and $C_{3'}$ puckered modes.

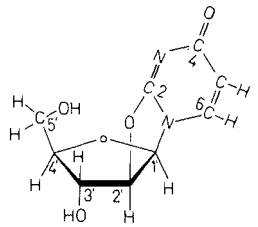

FIG. 5. Structural formula of 2,2′-anhydroarabinosyluracil (aU).

Orientation of the 2′-O-Methyl Group

One conformational problem peculiar to the 2′-*O*-methyl derivatives is the determination of the molecular conformation about the $C_{2'}$—$O_{2'}$ bond which fixes the orientation of the methyl group relative to the furanose ring. Evaluation of the favored orientation of this group is of considerable interest in view of its proximity to the adjacent phosphate and possible influence upon the ribose–phosphate backbone of a polynucleotide. In Fig. 6 are shown the three classically staggered conformations about the $C_{2'}$—$O_{2'}$ bond. In rotamer **I**, C(methyl) and $H_{2'}$ are situated *gauche* and we see in space-filling molecular models the close contact possible between the 2-keto oxygen of the base and the methyl hydrogens. In **II**, C(methyl) and $H_{2'}$ are oriented *gauche* but now close contact between the methyl and 3′-hydroxyl groups arises. In **III**, C(methyl) and $H_{2'}$ are *trans* across $C_{2'}$—$O_{2'}$. In this *trans*-orientation a number of intramolecular contacts are made which severely restrict the rotation of the methyl and the torsional motion of the furanose ring. For this reason we are inclined to think that the *gauche* rotamers will prevail in solution. As yet no spectroscopic evidence has

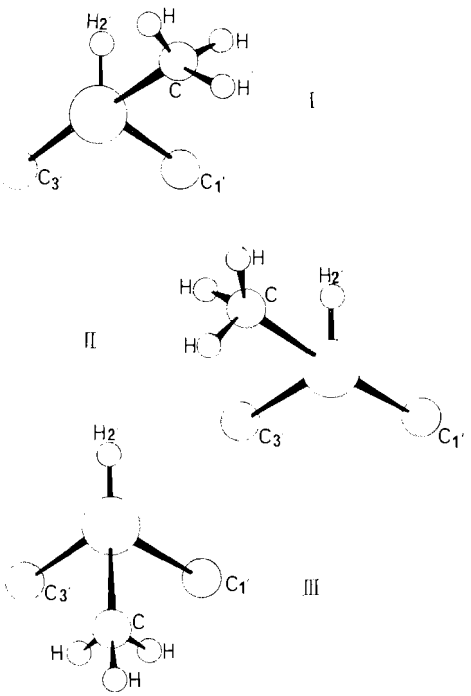

FIG. 6. Possible orientations of the 2′-*O*-methyl group.

appeared in support of either the *gauche* or *trans* possibilities.

Some very qualitative information regarding the methyl group orientation in Um and Cm may be derived from the data in the tables. Certainly the chemical shifts of the methyl hydrogens (which fall in the range observed for *O*-methyl groups in methylated hexoses (39)) are weighted for the relative $C_{2'}$—$O_{2'}$ rotamer populations but in the absence of data for molecules with known structure the favored rotamer cannot be predicted from the methyl–hydrogen shift values in Table 1. The similarity in their shifts, however, suggests that the methyl group experiences similar average environments in Um and Cm while the lack of any significant temperature dependence of the methyl shifts suggests that no large change in the $C_{2'}$—$O_{2'}$ rotamer populations occurs in the temperature interval examined.

The narrow line width (0.3 Hz) of the methyl resonance may give some information on the stereochemistry of the methoxyl group. In the *trans*-conformer **III** a planar zig-zag path between $H_{2'}$ and the methyl hydrogens is encountered during the course of rotation of the methyl group. For this reason a four-bond coupling across the $H_{2'}$—$C_{2'}$—O—C(methyl)—H is not unexpected. However, we may estimate from the line width that any $^4J_{2'm}$ coupling is less than 0.1 Hz. This absence of appreciable ^4J coupling could be a reflection of a low probability of the trans conformer.[3]

Conclusion

P.m.r. data are presented for 2′-*O*-methyl uridine and 2′-*O*-methyl cytidine in aqueous solution and compared with data for uridine and cytidine. The data demonstrate that methylation of the hydroxyl group has little effect on the conformational parameters of the mononucleosides in agreement with conclusion reached from c.d. studies (10). The hydrogen-donating potential of the 2′-hydroxyl group must therefore not be an important factor defining mononucleoside conformation in aqueous solution. The only slight variations in the shift and coupling constant data suggest that the molecular conformations of Um and Cm (as well as U and C) are independent of temperature in the interval from 30–60 °C. The effect, if any, of the 2′-*O*-methyl group on ribose conformation is consequently manifested only at the oligomer and polymer levels, so that its importance must be related to its effect on such properties as base stacking and/or base pairing, and in all probability via modifications in solvation of the molecules.

We are grateful for the financial support of the National Research Council of Canada, the Faculty of Graduate Studies of the University of Manitoba, and the Research Corporation of New York for a Cottrell Grant. We acknowledge Dr. A. A. Grey (Canadian 220 MHz Centre) for obtaining the 220 spectra and the members of the n.m.r. group of the University of Manitoba for valuable discussions. Special thanks are given to Dr. R. Wasylishen for communicating his INDO calculations prior to publication and to thank Dr. K.K. Ogilvie for a sample of aU. We thank Dr. M. Sundaralingam for pointing out a discussion of the effect of 2′-*O*-methylation in a recent work (S. T. Rao, M. Sundaralingam, S. K. Arora, and S. R. Hall. Biochem. Biophys. Res. Commun. **38**, 496 (1970).)

A Study of Thermal Motion of Ammine Groups in Carbonatotetramminecobalt(III) Sulfate

B. A. DUNELL, M. D. PACHAL, AND S. E. ULRICH

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received August 28, 1972

The results of spin–lattice relaxation measurements are reported for carbonatotetramminecobalt(III) sulfate. The observed T_1 minima and activation energies, 1.9 and 4.3 kcal, for the reorientation of ammine groups are interpreted on the basis of hydrogen bonding effects.

Les résultats obtenus des mesures de la relaxation spin–réseau sont présentés pour le sulfate de carbonatotétraminecobalt(III). Les minima observés T_1 et les énergies d'activation, 1.9 et 4.3 kcal, pour la réorientation des groupes amines sont interprétés en se basant sur les effets causés par les enchaînements par liaison hydrogène. [Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In previous studies (1, 2) of molecular motion in cobalt ammine complexes, two types of motion were observed between 77 and 400 °K. In most complexes studied the ammine groups were reorienting about their Co—N axes even at 77 °K, while whole molecule reorientation occurred for those cations having higher symmetry. In $[Co(NH_3)_4CO_3]Br$ the reorientation frequency of one of the ammine groups was found to become less than the value required to narrow the n.m.r. signal (some 10^4 Hz) at *ca.* 130 °K (3). This paper reports a broadline n.m.r. study of the solid complex $[Co(NH_3)_4CO_3]_2SO_4$ using both continuous wave and pulsed techniques.

Experimental

$[Co(NH_3)_4CO_3]_2SO_4 \cdot H_2O$ was prepared according to Glemser (4). The samples were evacuated at 70 °C for 48 h in order to remove the water of crystallization and to promote desorption of oxygen.

Proton continuous wave spectra were run at 16 MHz as described elsewhere (5). T_1 values were obtained as described previously (6). The free-induction decays were found to be exponential at all temperatures studied.

The calculated points shown in Fig. 1 were computed using a Non-Linear Least Squares program (BMD) written by the Health Sciences Computing Facility of UCLA. The program required a function subroutine, and one was written in which the functional line shape was assumed to be described by the sum of two BPP equations. The calculated curve was fit to the experimental curve by an iterative procedure where there were three variable parameters in each BPP term (6 total parameters). The variable parameters were $P(1)$, determined from the depth of the T_1 minimum, $P(2)$, the pre-exponential term in $A = A_0 \exp(E/RT)$ where $A = \omega_0 t_c = 0.6158$ at the minimum and $A_0 = \omega_0 t_0$, and $P(3)$, the activation energy, estimated from the slope of the experimental curves. The parameter estimates for the other component curve are made in a similar fashion. The calculated output included the computed function, shown in Fig. 1, are refined values of the 6 parameters.

Results and Discussion

The results of the second moment measurements for $[Co(NH_3)_4CO_3]_2SO_4$ are consistent with those found for $[Co(NH_3)_4CO_3]Br$ (3), namely 19 ± 1 G^2 at 77 °K and 10.2 ± 0.75 G^2 at 300 °K. The value at 77 °K corresponds to reorientation of three ammine groups and one rigid group, while the result at 300 °K corresponds to all four ammine groups reorientating.

Figure 1 shows the results of spin–lattice relaxation measurements. The crosses indicate the experimental points (±5%), and the circles are for the calculated values obtained as explained in the experimental section. Two minima are observed in the temperature range 120 to

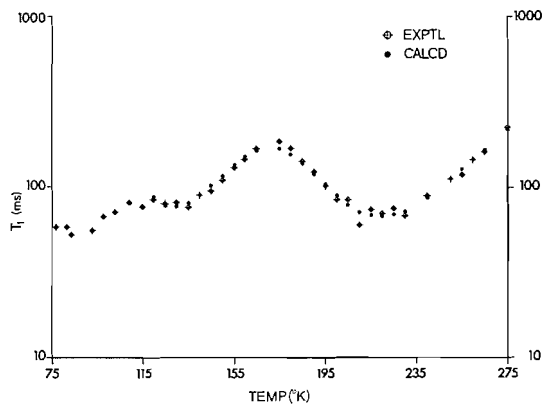

FIG. 1. Spin–lattice relaxation time as a function of temperature for $[Co(NH_3)_4CO_3]_2SO_4$.

300 °K, one at 125 °K and the other at 215 °K. The calculated depths are 76 and 72 ms, and the pre-exponentials ($\omega_0 t_0$) and activation energies are 2.9×10^{-4} and 3.4×10^{-5}, and 1.9 and 4.3 kcal, respectively. The standard deviation for both activation energies is 0.2 kcal. The magnitude of a T_1 minimum for a particular relaxation mechanism is proportional to the ratio of the total number of resonant spins to the number of spins whose motional correlation frequencies are suitable for producing spin–lattice relaxation, assuming that spin–spin interactions are strong enough to make $T_2 \ll T_1$, and allow spin diffusion to occur (7). Here, where there are two minima of equal magnitude and the expectation of another deeper minimum at a temperature below those accessible to us, we propose that one of the two observed minima represents the motion of one ammine group and the other observed minimum represents the motion of another ammine group. This is substantiated by a calculation, which, using the parameters for the 215 °K minimum, predicts that the midpoint of the second moment transition should occur at 121 °K. The observed midpoint is 120 °K and, as noted earlier, the change in second moment at the transition is appropriate to the motional effect of one ammine group reorienting about its C_3 axis. Below 100 °K the curve decreases toward what we believe to be a minimum representing two ammine groups, as the T_1 at 77 °K is substantially below 70 ms.

Since the second moment curve for $[Co(NH_3)_4CO_3]_2SO_4$ is virtually the same as that for $[Co(NH_3)_4CO_3]Br$ it seems reasonable to assume that the cations do not have greatly dissimilar structures. An X-ray investigation (8) of $[Co(NH_3)_4CO_3]Br$ indicated that there are three N—H···O distances significantly less than non-bonding distances for each cation. Okabe, *et al.* (3), have argued that this accounts for the 2.3 kcal activation energy they found for the rigid ammine group (at 77 °K) in $[Co(NH_3)_4CO_3]Br$. Of the eight hydrogen bonds per molecule reported for $[Co(NH_3)_4CO_3]Br$ five involved bromine atoms. Since hydrogen bonds are stronger to oxygen than to bromine this may account for our observed activation energy of 4.3 kcal in the sulfate as compared with 2.3 kcal for the bromide, assuming the two complexes have similar structures. Since the relative sizes of a sulfate group and a bromine ion are not terribly different, this may be a reasonable assumption.

The fact that there are two long and two short Co—N bonds probably accounts for the multiple minima in the T_1 curve. Two of the ammine groups are thought to have significant hydrogen bonding interactions, though different from one another, thus yielding activation energies of 4.3 and 1.9 kcal. The other two ammine groups have little hydrogen bonding interactions, and low apparent activation energies and they reorient with the same frequencies.

This work has been supported by a grant-in-aid from the National Research Council of Canada.

Substitution α to the Nitrogen in Dibenzylamine via Carbanion Intermediates

ROBERT R. FRASER, GUY BOUSSARD, I. DAN POSTESCU, JOSEPHINE J. WHITING, AND YUK Y. WIGFIELD

Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

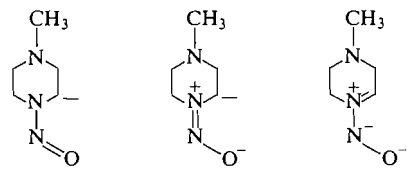
Received October 12, 1972

A method has been developed for introducing a variety of substituents into the position α to the nitrogen atom of dibenzylamine. Treatment of either the nitroso or the benzoyl derivative of dibenzylamine with lithium diisopropylamide generates a carbanion which reacts with alkyl halides or carbonyl compounds producing α-substitution products in yields of 66–99%. The method also gives good yields of derivatives of *N*-phenyl-*N'*-nitroso-piperazine. Attempts to form the carbanion of *N*-benzoylpiperidine failed.

Une méthode a été developpée pour introduire une série de substituants en position α à l'atome d'azote de la dibenzylamine. Le traitement soit du dérivé nitroso soit du dérivé benzoyle, de la dibenzylamine avec le diisopropylamide de lithium produit un carbanion qui réagit avec les halogénures d'alcoyle ou avec des composés possédant un groupe carbonyle pour produire des composés substitués en α avec des rendements d'environ 66–99% selon le cas. Cette méthode donne aussi de bons rendements en ce qui a trait à la formation de dérivés de la *N*-phényl *N'*-nitroso piperazine. Les tentatives afin de former le carbanion de la *N*-benzoylpiperidine ont échoué. [Traduit par le journal]

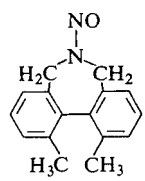
Can. J. Chem., **51**, 1109 (1973)

The report of Keefer and Fodor (1) that *N*-nitroso-*N'*-methylpiperazine, (**1**) undergoes base-catalyzed hydrogen–deuterium exchange in D_2O at 100 °C shows that the nitrosamino group exerts a potent stabilizing influence on an adjacent carbanion. The reason for its stabilizing effect was proposed to be the presence of a partial positive charge on the ring nitrogen due to the important resonance interaction **1***a*↔**1***b* in the anion. Subsequently, work in our laboratory (2)



1*a* **1***b* **1***c*

on the stereochemical course of hydrogen–deuterium exchange in the biaryl nitrosamine **2** provided evidence that resonance stabilization of the carbanion by the contributing structure **1***c* is likely of equal or greater importance. Most recently, a report (3) on the use of the α-nitrosamino carbanion for synthetic transformations of secondary amines[1] has appeared. Seebach and Enders showed that the carbanion of dimethylnitrosamine reacts with a variety of electrophiles, giving α derivatives in yields of 70–95%. We wish to describe an investigation of the reactivity of the carbanions derived from **2**, *N*-nitrosodibenzylamine, and *N*-nitroso-*N'*-phenylpiperazine. The results offer further evidence of the utility of this important new reaction In addition, we have discovered a new related type of carbanion, that derived by abstraction of the proton α to nitrogen in *N*-benzoyldibenzylamine. This carbanion appears to be comparable in ease of formation and reactivity to that derived from *N*-nitrosodibenzylamine.



2

Since nitrosamine **2** had been found to undergo proton exchange readily, direct conversion to its carbanion was first examined. Treatment of **2** in tetrahydrofuran (THF) at −78 °C with 1.1 equiv of methyl lithium, followed after 1 min by excess methyl iodide gave, after 30 min reaction

[1]Substitution in the α-position of secondary amines is a novel reaction. We have been informed that Professor Stork has recently described another new method of introducing functional groups into the α-position of secondary amines but the results have not been published (4). Several methods are known for obtaining α-derivatives of primary (5) and tertiary (6) amines.

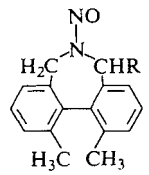
time and work-up, a 98% yield of crude methylated material (**3***a*). Its n.m.r. spectrum taken immediately thereafter indicated it to be solely one of the four possible stereoisomeric products, that in which H_4[2] had been replaced by a methyl group. Since H_4 was exchanged more than 30 times faster than any other proton in **2** the observation of a single methylation product



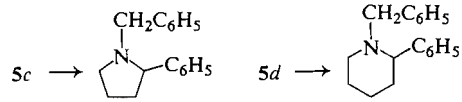
3

a R = CH_3
b R = D
c R = COOH

shows that the most stable carbanion in THF is the same as that observed by the kinetic method in *t*-butanol-*O*-*d*. Reaction of the carbanion derived from **2** with D_2O and with CO_2 gave high yields of **3***b* and *c* (R = D and COOH respectively). Isolation of **3***a–c* in pure form was complicated by the fact that slow but finite rotation about the N—NO bond occurs ($t_{1/2}$ = 0.5–10 h depending on solvent (2)). This caused difficulty in obtaining greater than 50% yields of a single analytically pure isomer.

Reactions of N-Nitrosodibenzylamine

Encouraged by the success in forming and reacting the carbanion of **2**, we then focused our attention on reactions of *N*-nitrosodibenzylamine (**4**). This amine was chosen for study since it is readily available, and it possesses only slight carcinogenicity whereas nitrosamines of lower molecular weight show very significant carcinogenic activity (7). Treatment of **4** in THF at −78° with either methyl lithium or lithium diisopropylamide (LDA) gave a relatively stable carbanion[3] which on reaction with methyl iodide gave, after chromatography, a 91% yield of pure benzyl α-phenethyl nitrosamine **5***a*. The results of the alkylation and condensation reactions of **4** are summarized in Scheme I and Table I. Compounds **5***a*, *b*, *e*, *f* were hydrolyzed to the parent amine and characterized as such. Compounds **5***c* and *d* had been prepared with the aim of achieving cyclization to give the substituted piperidine and azepine rings. Unfortunately the carbanions of **5***c* and *d* failed to cyclize. It would seem that cyclization of **5***c* is impeded by large steric effects. In the transition state leading to the six-membered ring the phenyl *syn* to the oxygen will encounter either $A^{1,3}$ strain if equatorial (8) or the normal 0.3 kcal destabilization if axial (9). Similar problems likely prevent ring closure of **5***d*. To prove their structures, **5***c* and *d* were cleaved to the secondary amines which spontaneously cyclized to the pyrrolidine **6** and the piperidine **7**. Such a sequence of

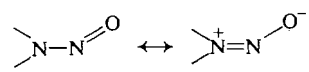


6 **7**

bromoalkylation and ring **6** closure provides a useful route for the synthesis of substituted nitrogen heterocycles.

*Reactions of N-Benzoyldibenzylamine (**8**)*

If the activating influence of the nitroso group results from the presence of a strong resonance interaction between the amine nitrogen and the nitroso group, *i.e.*



then other groups having the ability to accept the lone pair on nitrogen should similarly stabilize a carbanion α to the nitrogen. The strength of this resonance interaction is revealed by the activation energy for rotation about the partial double bond ($^{\delta+}N{=}N{=}O^{\delta-}$ or in general $^{\delta+}N{=}X{=}Y^{\delta-}$). These activation energies are readily available from n.m.r. studies of a variety of amine derivatives. The highest barriers to rotation are exhibited by nitrosamines, 23 kcal/mol (10, 11) and thioamides, 18–27 kcal/mol (12). Less hindrance to rotation is found in substituted benzamides (15–23 kcal/mol (12)) and aryl triazenes (13–16 kcal/mol (13)). Although the thiobenzoyl group would undoubtedly be of interest as an activating group it suffers from the disadvantage of being less easily introduced than the benzoyl or arylazo groups. We have

[2]The assignment of stereochemistry to the two pairs of diastereotopic protons is described in detail in ref. 2; H_4, the proton whose n.m.r. doublet appears at highest field, was shown to be *syn* to the oxygen atom and "quasi-axial". The n.m.r. of **3***a* lacks absorption in the region of H_4.

[3]The half-life of this carbanion at −78° in THF is approximately 30 min; the nature of the products of the decomposition were not investigated.

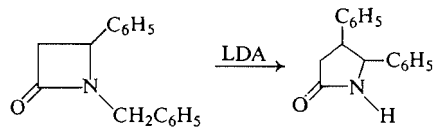
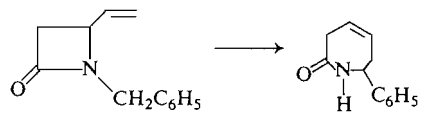
*These yields are of pure cyclized products 6 and 7.

examined the activating influence of these latter two groups. Attempts to prepare the carbanion derived from 1-*p*-nitrophenyl-3,3-dibenzyltriazene using methyllithium as base proved unsuccessful. Better results were obtained with *N*-benzoyldibenzylamine (**8**). A 30% yield of product was obtained from reaction of the carbanion generated by methyllithium with methyl iodide. When LDA was used as base, a stable anion was formed[4] which was reacted with four different electrophiles; in each instance the yields of product are listed in Table 1. As in the reactions of **4**, electrophilic substitutions α to the nitrogen of **8** proceed in high yields. There appears to be little to choose between the nitroso or benzoyl groups for the activation of dibenzylamine. Both groups can be introduced and later removed with comparable ease and efficiency. However, use of the benzoyl group is preferable because of the carcinogenicity of nitrosamines.

To our knowledge there is only one similar example of activation of a benzyl group towards carbanion formation. We have recently learned (14) that the *N*-benzyl-β-lactams **10** and **11** on treatment with LDA rearrange to pyrrolidones (12) or azepin-2-ones (13) presumably via carbanion intermediates.



10 **12**



11 **13**

Extension to Less Stable Carbanions

The phenyl groups in **4** and **9** undoubtedly provide appreciable stabilization of the benzylic carbanion. We have examined the reactivity of nitrosamines which lack this beneficial influence and have encountered considerable difficulty in obtaining high yields of substitution product. Alkylation of the carbanion of *N*-phenyl-*N*-nitrosopiperazine, (**14**), has been attempted under a variety of experimental conditions. The nature of the base, effects of added amines, the time for anion formation, and reaction with methyl iodide have all been studied. Under optimum

[4]There was no difference in yield when the interval between carbanion formation and addition of methyl iodide was varied from 2 to 6 min. A difference was found for the anion of **4**, the optimum interval being 4 min.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

conditions only a 46% yield of methylation product could be obtained.[5] Under the same conditions, carboxylation occurred in 73% yield. The poorer yields in the reactions of **14** likely indicate a competition between reaction and decomposition of the intermediate carbanion by the ring opening process **14** → **15**.

14 **15**

Seebach and Enders (15) have recently described the successful generation and reaction of the nitrosamino carbanions of *N*-nitrosopiperidine, *N*-nitrosopyrrolidine, and many other nitrosamines, including *N*-nitrosodiisopropyl amine. Their results show that nitrosamino carbanions offer great utility in organic synthesis. It would appear that the benzoyl group lacks the potent activating influence of the nitroso group, for we found that treatment of *N*-benzoyl piperidine with LDA followed by either CO_2 or CH_3I gave only unreacted starting material. We are currently investigating the potential activating influence of groups other than nitroso and benzoyl in the hope of finding ones with enhanced stabilizing effects but no adverse pharmacological properties.

Experimental

All melting and boiling points are uncorrected. The n.m.r. spectra were recorded on either a Varian T-60 or HA-100 spectrometer using deuteriochloroform as solvent unless otherwise noted. Chemical shifts are expressed in δ units (p.p.m. downfield from tetramethylsilane). Mass spectra were measured either on a Perkin–Elmer RMU-6D or an AEI, MS 9025, mass spectrometer.

All reactions involving methyllithium were carried out under an atmosphere of dry nitrogen using carefully dried equipment and reagents. Tetrahydrofuran was distilled from lithium aluminum hydride just prior to its use. Methyllithium obtained from Foote Chemical Company as a 5% solution in ether was injected by needle and syringe into the reaction vessel through a rubber septum. Work-up of a reaction refers to the standard operations of extraction, washing, drying, filtration, and removal of solvent by evaporation under vacuum. All chromatographic purifications were done using thin layers of silica gel on 20 × 20 cm glass plates.

Preparation and Nitrosation of N-Nitroso-6,7-dihydro-1,11-dimethyl-5H-dibenz(c,e)azepine, (2)

Reaction of 2,2′-bis-bromomethyl-6,6′-dimethyldiphenyl (16) with benzylamine and hydrogenolysis of the product according to the procedure of Wenner (17) gave the amine hydrochloride in 70% yield for the two steps. The product crystallized from methanol–water and melted from 272–273°; n.m.r.: 2.18 (6H, s), 3.62, and 4.11 (4H, AB q, J = 12 Hz), 7.40 (6H, s).

Anal. Calcd. for $C_{16}H_{18}NCl$: C, 72.91; H, 7.26; N, 5.61. Found: C, 72.69; H, 6.88; N, 5.24.

Nitrosation of this amine with nitrous acid (18) gave **2** in 82% yield. The product was recrystallized from hexane to give pale yellow needles, m.p. 123–123.5°. The n.m.r. spectrum of **2** has been described previously (2).

Anal. Calcd. for $C_{16}H_{16}N_2O$: C, 76.17; H, 6.39; N, 11.10. Found: C, 76.13, H, 6.49; N, 10.92.

Reactions of N-Nitroso-6,7-dihydro-1,11-dimethyl-5H-dibenz(c,e)azepine, (2)

(a) With Methyl Iodide

To a solution of 50 mg (0.2 mmol) of **2** in 15 ml THF at −78° was added with stirring 1.1 equiv of methyllithium and after 1 min, 0.1 ml of methyl iodide. After 30 min, work-up gave 50 mg of solid which was crystallized from *n*-hexane, then twice from methylene chloride – pentane to give a solid, m.p. 109–110°; n.m.r.: 0.70 (3H, d, J = 7 Hz), 2.17 (6H, s), 4.59, 5.45 (2H, ABq, J = 13.5 Hz), 5.69 (1H, q, J = 7 Hz), 7.00–7.40 (6H, m). No absorption due to a second isomer (CH_3 and NO *anti*) was seen until 1 h later.

Anal. Calcd. for $C_{17}H_{18}N_2O$: C, 76.67; H, 6.81; N, 10.52. Found: C, 76.44; H, 7.02; N, 10.48.

After dissolution, an equilibrium of 5:1 *syn*:*anti* was reached after 40 h.

(b) With Carbon Dioxide

Repetition of the above operation except that pieces of solid CO_2 were added in place of methyl iodide gave, after work-up, 58 mg of solid residue. After crystallization from carbon tetrachloride 26 mg, 45%, of a solid was obtained, whose n.m.r. indicated it to be a 2:1 mixture of *syn*:*anti* forms; *syn*-absorption at 2.10 (3H, s), 2.17 (3H, s), 4.51 (1H, d, J = 13 Hz), 5.58 (1H, d, J = 13 Hz), 6.37 (1H, s), 7.1–7.4 (6H, m).

Anal. Calcd. for $C_{17}H_{16}N_2O_3$: C, 68.81; H, 5.44; N, 9.45. Found: C, 68.43; H, 5.33; N, 9.29.

(c) With Deuterium Oxide

Repetition of formation of the carbanion of **2** followed by addition of 0.3 ml of heavy water (99.8%) gave after work-up a solid which was immediately dissolved in *t*-butanol-*O*-*d*: $CDCl_3$ (3:1) (to retard rotation about the N—NO bond (2)). The n.m.r. spectrum of this material was identical to that of **2** except that only 10% of the absorption at δ 3.41 (H_4) remained while 90% of the signal at δ 4.75 (H_3) was observed. The deuterium content at these positions caused the signals for the CH groups at δ 5.41 and 5.45 to appear as broad singlets. After standing for 48 h, the signals for H_3 and H_4 became equal in intensity. No isolation of this product was attempted.

N-Nitrosodibenzylamine, (4)

Nitrosation of dibenzylamine as previously described (19) gave *N*-nitrosodibenzylamine, m.p. 63–63.5° (lit. (19) m.p. 60–61°).

Reactions of N-Nitrosodibenzylamine (4)

(a) With Methyl Iodide

To a solution of 339 mg (1.5 mmol) of **4** in 30 ml of

[5]Details of these reactions are described in the M.Sc. thesis of I.D. Postescu, University of Ottawa, Ottawa, Canada, 1972.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

THF at −78° was added 0.24 ml (1.65 mmol) of diisopropylamine. When 1.65 mmol of methyllithium was added an immediate red coloration appeared. After 4 min, 0.46 ml (7.5 mmol) of methyl iodide was added and stirring was continued at −78° for 1.5 h. After the solution was warmed to 0°, addition of 15 ml water and work-up gave 417 mg of a yellow liquid. Chromatography using silica gel and elution with ether – petroleum ether (3:7) gave 345 mg (91% yield) of yellow liquid whose n.m.r. showed no significant impurities to be present. Absorptions for the *syn* and *anti* isomers (1:4) could be seen separately;[6] *syn*: 1.17, (3H, d, J = 7.5 Hz), 4.67, 5.25 (2H, ABq, J = 14.3 Hz), 6.18 (1H, q, J = 7.5 Hz), 6.8–7.4 (br m); *anti*: 1.73 (3H, d), 4.07, 4.98 (2H, ABq, J = 14 Hz), 5.35 (1H, q), 6.8–7.4 (br m).

This nitrosamine, **5***a*, was cleaved by the method of Stewart (21) as follows: dry hydrogen chloride was bubbled through a stirred solution of 345 mg **5***a* in 25 ml anhydrous benzene for 30 min. The solution changed from yellow to brown as the bubbling continued. A strong stream of nitrogen was finally passed through the solution for 10 min, during which time it became yellow again. The benzene was concentrated to 4–5 ml. The addition of ether precipitated white crystals (220 mg) on cooling. An additional 75 mg of solid was obtained from the mother liquor after standing overnight. The total yield was 285 mg (76%). Recrystallization from chloroform–ether mixture gave benzyl α-methylbenzylamine hydrochloride which melted at 179–180°, (lit. m.p. 179° (22)); n.m.r.: 1.80 (3H, d, J = 6.4 Hz), 3.40–4.40 (3H, m), 7.50 (10H m), 10.50 (2H, br m).

(b) Methylation of **4** *in Absence of Diisopropyl Amine*

To a solution of 339 mg (1.5 mmol) in 30 ml THF at −75° was added 1.1 equiv. of methyllithium. After 4 min, 0.46 ml methyl iodide was added. The reaction was worked-up as before. The yield, estimated from the n.m.r. spectrum of crude product, was 90%. Cleavage of this crude produce, in anhydrous benzene as above, gave 266 mg (72%) of **4**.

(c) With 1-Iodopropane

Dibenzylnitrosamine, 339 mg (1.5 mmol) was converted with LDA into its anion as in part (*a*). After 4 min, 0.74 ml (5 equiv) of 1-iodopropane was added. The solution was stirred at −75° for 2.5 h, then warmed up to room temperature. Work-up as in (*a*) gave 342 mg of crude **5***b* whose n.m.r. showed absorption for the *anti* isomer at 0.70–2.5 (7H, br m), 4.10, 5.07 (2H, AB q, J = 14 Hz), 5.12 (1H, t, J = 7.5 Hz), 6.80–7.50 (10H m). From the area of the small triplet at δ 6.25 assigned to the methine proton of the *syn* isomer it was found to constitute 15% of the mixture. Other absorptions of the *syn* form were not distinguishable from the predominant *anti* peaks. This material was cleaved as before in benzene (25 ml). After evaporation of solvent the residue was dissolved in ether and 320 mg (77%) of solid was precipitated by the addition of petroleum ether. Recrystallization from ether gave benzyl α-phenylbutylamine hydrochloride, (**5***b*), which melted from 139–140.5°.

Anal. Calcd. for $C_{17}H_{22}NCl$: C, 74.03; H, 8.04; N, 5.08, Cl, 12.85. Found: C, 73.66; H, 8.19; N, 5.47; Cl, 12.82.

This hydrochloride was converted to the free base and distilled (bulb-to-bulb) to produce a yellow oil.

Anal. Calcd. for $C_{17}H_{21}N$: C, 85.30; H, 8.84. Found: C, 85.31; H, 8.98.

(d) With 1,3-Dibromopropane

The same procedure as in (*a*) was followed with the exception that twice the amount of solvent was employed. The crude product after purification by chromatography was shown by n.m.r. to contain a small amount (< 10%) of the *syn* form. The *anti* form showed absorptions at 1.50–2.60 (4H, m), 3.20 (2H, t), 4.05 and 5.15 (2H, AB q, J = 14 Hz), 5.10 (1H, t), 6.85–7.60 (10H, m).

Cleavage of the nitrosamine gave 424 mg of solid amine hydrochloride which was dissolved in 40 ml water. The solution was made alkaline. After 5 min, extraction and work-up gave an oil which was purified by chromatography using petroleum ether – ether (7:3) as solvent. The first eluted material was 117 mg (33%) of solid 1-benzyl-2-phenylpyrrolidine which after recrystallization from acetone had m.p. 44.5–45° (lit. m.p. 43–44° (23)); n.m.r.: 1.50–2.50 (5H, m), 3.03 and 3.90 (2H, AB q, J = 13 Hz), 3.35 (2H m), 7.11–7.60 (10H m). The mass spectrum showed a peak for the molecular ion at m/e 237.

(e) With 1,4-Dibromobutane

As in (*c*) dibenzylnitrosamine was alkylated using a five-fold excess of 1,4-dibromobutane. Work-up and chromatography as above yielded an oil whose n.m.r. again showed the presence of < 10% *syn* isomer. The *anti* form showed peaks at 1.0–2.60 (6H, m), 3.23 (2H, t, J = 7 Hz), 4.08 and 5.10 (2H, AB q, J = 14 Hz), 6.90–7.67 (10H, m). Conversion of this nitrosamine gave the corresponding amine which then cyclized providing, after chromatography, 125 mg (33%) of 1-benzyl-2-phenylpiperidine. After recrystallization from ethanol–water the white solid melted at 90–91° (lit. m.p. 93–93.5° (24)); n.m.r.: 1.10–2.05 (8H, m), 2.76 and 3.78 (2H, AB q, J = 14 Hz), 3.05 (1H, br), 7.1–7.60 (10H, m); mass spectrum shows molecular ion at m/e 251.

(f) With Carbon Dioxide

A solution of 452 mg (2 mmol) of **4** was converted into its carbanion as in (*a*). Dry carbon dioxide gas was bubbled through the solution for 20 min. The temperature was then raised to 25° and the solution concentrated to dryness. Extraction of a solution of the residue in 5% Na_2CO_3 with chloroform yielded 40 mg of unreacted **4**. The aqueous solution was treated with 1 *N* HCl and the liberated acid (**5***e*), after extraction into ether, drying, and solvent removal, weighed 490 mg (99%). Its n.m.r. showed two isomers in the ratio 2:1 with the major one absorbing at 5.63 (1H, s), 4.95 and 5.48 (2H, AB q, J = 15 Hz), 6.75–7.40 (10H m), 12.9 (1H, s). The minor isomer (*syn*) showed absorption at 4.46 and 4.88 (2H, AB q, J = 15 Hz) and 6.30 (1H s). Cleavage as in (*a*) and concentration of the benzene solution gave a semisolid residue which was dissolved in hot acetonitrile. The amino acid, **5***c*, crystallized on cooling to a white solid. The solid was dissolved in hot water, the p*H* was adjusted to 6.8, and on cooling 400 mg of crystals, m.p. 225–227 (lit, m.p.

[6]The n.m.r. assignments for all the derivatives of **4** follow from the works of Karabatsos and Chow (20). In all cases the methine proton of the *syn*-isomer appears at lower field, while a methyl or methylene group in the α position shows the opposite order of shieldings.

225° (25)) was obtained. This yield is 87% for the two steps, 96% if based on recovery of unreacted **4**.

(g) With Benzaldehyde

Under the standard conditions of (*a*), reaction of the anion of **4** with 1 equiv of benzaldehyde gave a yellow oil which was purified by chromatography. Elution with chloroform developed a band ($R_f = 0.4$) from which a 62% yield of solid condensation product was obtained. Recrystallization gave white crystals, m.p. 120–121°. The n.m.r. spectrum reveals the presence of two isomers both of which likely possess the *anti* configuration. Isomer *a*; 3.80 and 5.06 (2H, AB q, $J = 15$ Hz), 4.84 and 5.64 (2H, AB q, $J = 7$ Hz), isomer *b*; 3.96 and 5.36 (2H, AB q, $J = 15$ Hz), 4.98 and 5.56 (2H, AB q, $J = 8$ Hz), also 2.50 (1H, s), and 6.65–7.4 (15H, m) for both isomers.

Anal. Calcd. for $C_{21}H_{20}N_2O_2$: C, 75.60; H, 6.02; N, 8.25. Found: C, 75.88; H, 6.07; N, 8.43.

N-Benzoyldibenzylamine, (8)

Reaction of benzoyl chloride with dibenzylamine produced **9** in 70% yield. Recrystallization from ethanol (99%) gave white crystals, m.p. 112–113° (lit. m.p. 112° (26)); n.m.r. (at 0° and 100 MHz), 4.40 (2H, s), 4.70 (2H, s), 7.0–7.8 (15H, m); at 37° the two CH_2 peaks coalesce indicating $\Delta G^{\ddagger}$ for rotation equal to 15.6 kcal/mol.

Reactions of N-Benzoyldibenzylamine, (8)

Generation of the Anion

A stirred solution of 300 mg (1 mmol) of *N*-benzoyldibenzylamine in 30 ml of dry THF cooled to −78° was treated with 0.15 ml (1.05 mmol) of diisopropylamine, then 0.7 ml (1.1 mmol) of methyllithium (5% in ether). A red–brown color developed immediately. After 4 min, the electrophile was added.

(a) Reaction with Methyl Iodide. Addition of 0.3 ml (5 mmol) of methyl iodide caused rapid disappearance of color. After 1 h the solution was warmed to room temperature, 15 ml water added, and the mixture was extracted with two 20 ml portions of methylene chloride. The methylene chloride extracts were washed with 5% sodium sulfite and water, then dried. Removal of solvent gave a liquid which crystallized on addition of ether. Recrystallization gave 234 mg of solid, m.p. 110–112°. Another 19 mg was obtained from mother liquors, total yield 253 mg (81%). In a separate experiment the crude product after chromatography on silica gel gave 284 mg (91%) of solid, m.p. 112.5–114 (lit. m.p. 109–111° (27)); n.m.r.: 1.46 (3H, d, $J = 7.5$ Hz), 3.96 and 4.90 (2H, AB q, $J = 16$ Hz), 5.47 (1H q, $J = 7.5$ Hz), 7.10–7.70 (15H m).

(b) With CO_2. A stream of dry CO_2 was bubbled through the solution of the carbanion derived from **8** for 10 min. The cooling was stopped, the solvent was distilled off and the residue dissolved in 5% Na_2CO_3 solution and washed with chloroform. Acidification and work-up gave 313 mg (98%) of a colorless oil which gradually crystallized. Recrystallization from ether gave a white solid, m.p. 124–125°; n.m.r.: 4.35 and 4.81 (2H, AB q, $J = 16$ Hz), 5.57 (1H, s), 7.0–7.5 (15H, m), 12.05 (1H, s).

Anal. Calcd. for $C_{22}H_{19}NO_3$: C, 76.79; H, 5.54; N, 4.05. Found: C, 77.16; H, 5.75; N, 3.79.

(c) With Acetone. After stirring with 0.1 ml (1.25 mmol) of acetone for 1 h, work-up gave 370 mg of a colorless oil which was purified by chromatography on silica gel using chloroform as eluent. The liquid obtained amounted to 320 mg (90%) and gave crystals m.p. 133–133.5° from hexane – ethyl acetate. N.m.r.: 1.0 (3H, s), 1.3 (3H, s), 4.2 (1H, s), 4.40 (2H, AB q, $J = 16$ Hz), 6.4 (1H, br), 7.2–7.4 (15H, m).

Anal. Calcd. for $C_{24}H_{25}NO_2$: C, 80.20; H, 7.01. Found: C, 79.85; H, 6.99.

(d) With Acetic Anhydride. After stirring the solution with 0.11 ml (1.1 mmol) of acetic anhydride for 1 h, work-up gave 365 mg of an oil which was purified by chromatography using chloroform as eluent. The product was an oil weighing 266 mg (66%) which showed n.m.r. 2.15 (3H, s), 4.5 (2H, AB q, $J = 16$ Hz), 5.5 (1H, s), 7.0–7.4 (15H, m); mass spectrum, weak molecular ion, strong peak at *m/e* 300.138 (P − 43). Calcd. for $C_{23}H_{21}NO_2$—CH_3CO: 300.139. This oil thus far has failed to crystallize.

Carboxylation of 1-Nitroso-4-phenylpiperazine

To a solution of 288 mg (1.5 mmol) 1-nitroso-4-phenylpiperazine (28) in 30 ml of THF was added 0.22 ml (1.5 mmol) of diisopropylamine. The mixture was cooled to −75° and 1.1 equiv of methyllithium was injected. After 4 min a stream of carbon dioxide was passed through the stirred solution for 15 min. The stirring was continued at −75° for 0.5 h and then at room temperature for 1 h. Work-up as in the previous carboxylation gave 162 mg (49%) of 1-nitroso-4-phenylpiperazine-2-carboxylic acid; n.m.r.: 2.50–3.80 (4H, m), 4.20 (1H, t), 4.85 (1H, d), 5.63 (1H, d, $J = 10$ Hz), 6.70–7.40 (5H, m), 11.40 (1H, s).

This nitrosamino acid was dissolved in 60 ml of dry benzene and the nitroso group was removed as described previously. The product was filtered to give 139 mg (38%) of pink crystals. Recrystallization from a water–acetone mixture afforded colorless crystals (m.p. 229–230°, dec.) of 4-phenylpiperazine-2-carboxylic acid hydrochloride.

Anal. Calcd. for $C_{11}H_{15}N_2O_2Cl$: C, 54.43; H, 6.23; N, 11.54; Cl, 14.61. Found: C, 54.05; H, 6.25; N, 11.05; Cl, 14.83.

Studies of Rhenium β-diketone Complexes. IV. The Synthesis, Properties, and Crystal Structure of Bis(μ-chlorotricarbonyl(1-phenyl-1-hydroxobut-1-ene-3-one)rhenium(I)), a Compound Containing a Monodentate Neutral β-Ketoenol

M. C. FREDETTE AND C. J. L. LOCK[1]

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received August 21, 1972

The title compound, $[Re(CO)_3Cl(C_6H_5 \cdot COH \cdot CH \cdot CO \cdot CH_3)]_2$, is one of a series of compounds obtained by the reaction of chloropentacarbonylrhenium(I) with β-diketones and has been characterized by n.m.r. and infrared spectroscopy and single crystal X-ray diffraction. The crystals are monoclinic with lattice parameters $a = 14.77(2)$, $b = 17.98(2)$, $c = 13.48(2)$ Å, $\beta = 124.34(9)°$; $C2/c$, $Z = 4$. A total of 1293 independent reflections were measured on a single crystal X-ray diffractometer and the structure was refined by full matrix least squares analysis to a weighted R_2 value of 0.0444. The dimeric halves of the molecules are held together by two chlorine atoms symmetrically bridging the rhenium atoms (Re—Cl = 2.511(5) Å). The structure is thus very like that of $[Re(CO)_4Cl]_2$, except that two neutral β-ketoenol molecules replace two carbon monoxide molecules (one on each rhenium) and are bonded through the ketone group (Re—O = 2.16(1) Å). The arrangement of the keto and enol groups is such that hydrogen bonding can occur between them.

Le composé mentionné dans le titre $[Re(CO)_3Cl(C_6H_5 \cdot COH \cdot CH \cdot CO \cdot CH_3)]_2$ appartient à une famille de produits obtenue par réaction du chloropentacarbonylrhénium(I) avec des β-dicétones. Ce produit a été caractérisé par r.m.n., par spectroscopie infrarouge et par diffraction de rayons-X (monocristal). Les cristaux sont du type monoclinique ave les paramètres de mailles qui suivent: $a = 14.77(2)$, $b = 17.98(2)$, $c = 13.48(2)$ Å, $\beta = 124.34(9)°$; $C2/c$, $Z = 4$. Un total de 1293 réflections indépendantes a été mesuré à partir d'un diffractomètre à rayons-X sur un monocristal et la structure a été raffinée par une matrice des moindres carrés jusqu'à une valeur R_2 pondérée de 0.0444. Les moitiés dimériques des molécules sont retenues ensemble par deux atomes de chlore impliquées symétriquement dans un pontage avec ceux de rhenium (Re—Cl = 2.511(5) Å). La structure, par suite, ressemble beaucoup à celle de $[Re(CO)_4Cl]_2$ à l'exception des deux molécules neutres β-cétoenol qui remplacent les deux molécules de monoxyde de carbone (une sur chaque rhénium) et qui sont reliées à l'aide du groupe cétonique (Re—O = 2.16(1) Å). L'arrangement spatial des groupes, cétone et énol, est tel que la formation de ponts hydrogènes peut se produire entre eux.

Can. J. Chem., **51**, 1116 (1973)

Introduction

We have investigated the reaction of $Re(CO)_5Cl$ with various β-diketones and have prepared two series of compounds with apparent stoichiometries $Re_2(CO)_6(dik)_2$ and $[Re(CO)_3Cl(dikH)]_2$.[2] The structure of $Re_2(CO)_6(dbm)_2$ has been reported elsewhere (1). The structure of $[Re(CO)_3Cl(bamH)]_2$ was examined by single crystal X-ray diffraction because spectroscopic and magnetic methods of examination gave no detailed information about the structure, and the physical properties (low solubility and general intractibility) were inconsistent with those we expected for a six-coordinate monomeric species. In this paper we discuss these studies and the single crystal X-ray structure determination.

Experiments

Analyses were performed on crystals of the compound for carbon, hydrogen, and chlorine by A.B. Gygli, Toronto, Canada and rhenium and chlorine were determined by neutron activation analysis (2). Infrared spectra were recorded for solid samples ground into a mull with Nujol. The Nujol had been dried by refluxing with phosphorus pentoxide followed by vacuum distillation. The mull samples were mounted between potassium bromide or polyethylene plates and spectra were recorded on Perkin-Elmer 337 and 301 spectrometers. Mass spectra were recorded on a Consolidated Electrodynamics Corp. Mass Spectrometer Model 21-110B. Measurements of magnetic susceptibility were made by the Gouy method. The apparatus used has been described elsewhere (3). Proton n.m.r. spectra were recorded on a Varian Associates HA 100 spectrometer using tetramethylsilane as a standard. All solvents and reagents

used were reagent grade and were not purified before use.

Bis(μ-chlorotricarbonyl(1-phenyl-1-hydroxobut-1-ene-3-one)rhenium(I))

Choropentacarbonylrhenium(I) (2 g) and benzoylacetone (1.5 g) were refluxed in benzene (~150 ml) for 1 day. The pale yellow solution gradually turned green. The solution was evaporated to near dryness, dichloromethane (20 ml) was added, the solution was filtered, and the filtrate was evaporated to near dryness. A mixture (1 :1 v/v) of dichloromethane and petroleum ether (40–60°) was added and the resulting solution was allowed to evaporate slowly over a few days to give the desired product as a yellow-green powder (yield 45%).

Anal. Calcd. for $C_{26}H_{20}Cl_2O_{10}Re_2$: C, 33.2; H, 2.2; Re, 40; Cl, 7.6. Found: C, 33.4; H, 1.9; Re, 40; Cl, 7.6.

The material was recrystallized from dichloromethane – petroleum ether to give crystals which were usually hexagonal plates or occasionally rhombic needles. The two forms have been shown by single crystal X-ray diffraction to be structurally identical. The product is slightly soluble in benzene, dichloromethane, diethyl ether, chloroform, and benzene and insoluble in petroleum ether (40–60°).

Crystallography

A piece of acicular crystal was sandpapered by hand to a sphere of 0.2 mm diameter. The crystal was shown by precession photographs to be monoclinic, and with proper choice of the *a* and *c* axes, the systematic absences hkl, $h + k = 2n + 1$, $h0l$, $l = 2n + 1$ revealed the space group was $C2/c$ or Cc. The former space group was suggested by the Patterson syntheses which showed rhenium atoms related by a center of symmetry and the choice was confirmed by the successful solution of the structure. Accurate unit cell parameters were obtained by least squares refinement of the output from a Syntex $P\bar{1}$ automatic diffractometer which centered on fifteen moderate angle reflections. The density of a few crystals was measured by flotation in a bromoform–chloroform mixture.

$C_{26}H_{20}Cl_2O_{10}Re_2$ f.w. = 935.2

Monoclinic, $a = 14.77(2)$, $b = 17.98(2)$, $c = 13.48(2)$ Å, $\beta = 124.34(9)°$, $V = 2956$ Å^3, $\rho_0 = 2.15(1)$, $Z = 4$ (dimer units), $\rho_c = 2.07$(20 °C, MoKα, $\lambda = 0.71069$ Å) $C2/c$ (No. 15, C_{2h}^6).

Data were recorded using zirconium-filtered MoKα radiation on a Syntex $P\bar{1}$ diffractometer. The radiation was made monochromatic by using the 002 reflection from highly oriented graphite. Intensities were measured by the θ/2θ scan technique up to a value of $2\theta = 45°$. 2° scans were made over θ, and the background was counted on both sides. Peaks less than 3σ above the background were called unobserved, and peaks less than background were rejected. The intensity of a standard reflection was measured every 50 reflections. It showed a deviation of ±2.6%. The linear absorption coefficient for the compound for MoKα radiation was 92.5 cm^{-1}. The data were corrected for Lorentz, polarization, and absorption errors. Absorption corrections were made assuming the crystal was a sphere of radius 0.1 mm. The data set consisted of 1293 independent reflections of which 1087 were observed.

Solution and Refinement of the Structure

Using Patterson maps for the (100), (010), and (001) zones it was possible to detect the rhenium atoms, which occurred as centrosymmetrically related pairs. Using all the data, refinement of the rhenium atom parameters gave $R_1 = 0.23$.[3] Electron density and difference maps located the chlorine atom and R_1 dropped to 0.18. Subsequent electron density and difference syntheses, with calculations based on known geometries for phenyl rings, revealed all the remaining atoms, except the hydrogen atoms. At this stage, temperature factors, which were isotropic for all atoms in the initial stages of refinement, were made anisotropic for the rhenium atom. Further refinement, using a Cruickshank weighting scheme (4) with the weights set equal to $(75 - 0.8F_o + 0.0029F_o^2 + 6100\ (\sigma/F_o)^2)^{-1}$ for observed reflections and zero weight for unobserved reflections, was terminated at $R_1 = 0.0445$ and $R_2 = 0.0444$.

Refinement of the diffractometer data was done using the full matrix least squares program CUDLS written for the CDC-6400 computer by J. S. Stephens. In all refinement cycles the rhenium and chlorine scattering curves of Cromer (5), including anomalous dispersion corrections (6), were used. The oxygen scattering curve was also that of Cromer and that for carbon was taken from the International Tables (7). No anomalous dispersion corrections were applied to carbon or oxygen.

In the final cycle of refinement no parameter shifted by more than 1/200 of its estimated standard deviation and a series of electron density difference maps through the unit cell showed no residual peaks outside ±0.8 e/Å^3. The final set of atom parameters is given in Table 1 and a comparison of $|F_o|$ and $|F_c|$ is given in Table 2.[4]

Results and Discussion

Selected bond distances and angles are given in Table 3, and the molecule is pictured in Fig. 1. The molecule is dimeric, based on the rhenium atoms, and the two halves are joined by two

[3] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$;
$R_2 = (\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega F_o^2)^{1/2}$

‡$U_{11} = 54.7(4)$, $U_{22} = 62.6(5)$, $U_{33} = 59.2(4)$, $U_{12} = 0(10)$, $U_{13} = 27.7(3)$, $U_{23} = 0(4)$.

chlorine bridges which are symmetric. The molecule is thus very like $[Re(CO)_4Cl]_2$ (8) in which two of the carbonyl groups are replaced by neutral β-ketoenol molecules bonded through the ketone groups. Surprisingly, both ketoenol groups are approximately at 90° to each of the Re—Cl bridges and are on the same side of the $ReCl_2Re$ plane. The β-ketoenol molecules are oriented such that the best planes through the two molecules lie roughly along the Re—Cl bonds. The Re—Cl distances are 2.511(5) Å each and are comparable to the distances of 2.465(13) Å found in Re_2Cl_{10} (9). The Re—O (ketone) distance of 2.16(2) Å is identical, within the errors, to the Re—O distances found in $Re_2(CO)_6(dbm)_2$ (2.15(1) Å) (1) but these distances are considerably shorter than the monodentate β-ketoenolate Cu—O distance in bis(1,1,1,5,5,5-hexafluoropentane-2,4-dionato)-bis(*N*,*N*-dimethylenediamine) copper (II) which is 2.76(1) Å (10). The steric requirements of the bridging chlorine atoms require the Cl—Re—Cl angle to be 80.4(1)° (Re_2Cl_{10} = 81.9(4), 80.8(4)°). The Cl—Re—O(1) angle is also less than 90° (84.9(4)°). The three mutually *cis* carbonyl groups are possibly slightly less than 90° apart from each other (87(1), 86(1), and 88.5(9)°) and thus the angles between the carbonyl group and the chlorine and oxygen atoms are opened up from 90° (92(1) to 95(1)°).

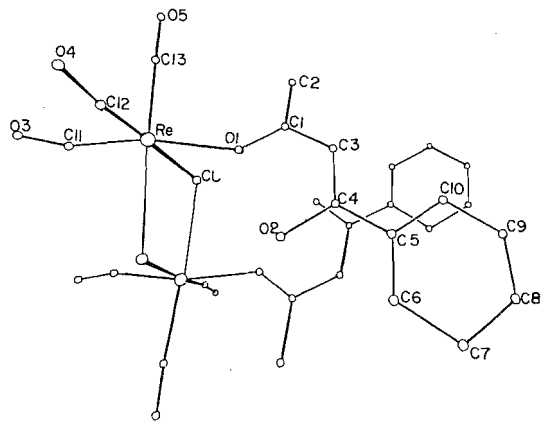

FIG. 1. The molecular structure of $Re_2Cl_2(CO)_6(bamH)_2$. The labelling of the atoms is as in Table 1.

The Re—C≡O systems are essentially linear and the Re—C and C≡O bond lengths are in good agreement with these found previously (1 and references therein). The β-diketone ring is essentially planar (see Table 4) and the two C—O distances in the ring are significantly different at the 95% confidence level and marginally different at the 99% confidence level as are the two ring C—C distances. This suggests that the ligand is in the ketoenol form with very little, if any, delocalization of electrons, in contrast to complexes of β-ketoenolate anions. The planarity

‡The double dagger refers to an atom generated by $(-x, y, 1/2 - z)$.

is probably maintained by hydrogen bonding from the enol oxygen atom to the ketone: the oxygen atoms are close enough (2.52(2) Å). The O(OH)—Cl distance of 3.52 Å is too long to allow any hydrogen bonding (11). The least squares planes data in Table 4 also show that the phenyl group is planar, as expected, and is almost coplanar with the β-ketoenol ring (dihedral angle 2.4°).

To our knowledge this is the first case in which it has been clearly shown by an X-ray structure determination that a neutral β-ketoenol molecule can act as a monodentate ligand, although a metal complex containing neutral acetylacetonimine has a very similar metal–ligand geometry (12). In addition, this type of structure has been postulated recently (13) for $Mn(acacH)_2Br_2$. The postulate by Kawaguchi and co-workers based on infrared spectra, that metal–ligand bonding to a neutral β-ketoenolate molecule will be weaker than to the β-ketoenolate anion, and the corresponding observation by Richardson *et al.* that M—O-(ketoenolate) distances are longer than M—O-(ketoenolate-hydrogen bonded) distances are not borne out for the two Re(I) compounds, $Re_2(CO)_6(dbm)_2$ and $Re_2Cl_2(CO)_6(bamH)_2$.

The packing of the molecules in the unit cell is shown in Fig. 2. The molecules are packed in rows in the *a* direction with overlap of the β-ketoenolate and phenyl rings from alternate molecules, which are arranged head to head, like a stack of knifes with blades overlapping, and the handle of each successive knife pointing in the opposite direction to the preceding one. Further contact in the *a* direction is between carbonyl groups in the $ReCl_2Re$ plane. In the *c* direction the chains of phenyl and methyl groups contact the carbonyl groups of the next chain related by the C-centering. In the *b* direction

*All planes are least squares planes determined by the program PALS written by P. G. Ashmore for the CDC 6400 computer and based on the work of Schomaker *et al.* (16). The program transforms the cell into an orthogonal cell corresponding to the crystallographic *a*, *b*, *c** axes.

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of $Re_2Cl_2(CO)_6(bamH)_2$. The *c* axis is parallel to the top of the page and the *b* axis to the side of the page. The view is approximately along *a**.

the contacts are primarily β-ketoenol–β-ketoenol and carbonyl–carbonyl.

Although the structural features revealed by the X-ray examination are consistent with a complex of rhenium(I) containing a neutral β-ketoenol bonded through the ketone group, it was impossible to find the hydrogen atoms and we have examined the compound by other physical methods to eliminate alternative structures, such as a neutral β-diketone complex of Re(I) or a β-ketoenolate complex of Re(II). Mass spectroscopy of the compound was not very helpful: the compound was relatively involatile and decomposed on heating. The major peak was at *m/e* 162 corresponding to $bamH^+$. The compound is diamagnetic and since there is a quasioctahedral arrangement of ligands around the rhenium atom a d^6 Re(I) system seems more likely than a d^5 Re(II) system. The Re—Re distance of 3.852(1) Å is too long to allow metal–metal bonding, although superexchange might take place through the chlorine atoms. As the compound was diamagnetic at both 23 and −180 °C, any superexchange would have to be very strong.

Chemical and physical evidence considered with the X-ray results shows clearly the presence of a neutral β-diketone or ketoenol: the pure neutral ligand was isolated when our compound was treated with dry CO at 50 atmospheres in the temperature range 90–150 °C. The reaction is

$$[Re(CO)_3Cl(bamH)]_2 + 2CO \rightarrow [Re(CO)_4Cl]_2 + 2bamH$$

At the higher temperature some $Re(CO)_5Cl$ was obtained, probably from the reaction

$$[Re(CO)_4Cl]_2 + 2CO \rightarrow 2Re(CO)_5Cl$$

Proton n.m.r. spectra gave the best evidence for the proposed structure and are consistent only with the ketoenol form. Although spectra showed that some decomposition took place with time, giving free β-ketoenol ligand, fresh solutions showed a peak at −13.8 p.p.m. from

*These figures are almost identical to the figures calculated by Hieber, but which he claimed applied to the compound given on the previous line.

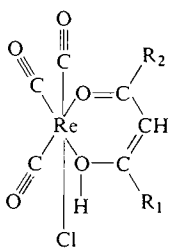
tetramethylsilane assignable to an enol OH group: this peak had the same area as a peak at −5.55 p.p.m. assignable to the γ C—H. (Similar peaks occur in the free ketoenol at −13.4 and −5.6 p.p.m. relative to tetramethylsilane).

Previously Hieber and Stanner (14) assigned a structure to a complex containing a neutral (but chelated) ketoenol on the basis of a δ-OH band at ~1610 cm^{-1} in the infrared spectrum. Our compound also shows a band at 1610 cm^{-1} as well as two others in the 1500–1600 cm^{-1} region, but we have observed (15) three infrared absorptions in this region for several β-ketoenolate compounds. The highest band for some of these compounds is near 1610 cm^{-1}. Thus, we do not regard this as a useful diagnostic test. We have not reported the infrared spectrum in detail since we have not assigned all the bands. A comparison of the infrared spectrum in the carbonyl stretch region with that of $(C_5H_5N)_2Re(CO)_3Cl$ (8) is interesting. Absorptions for $(C_5H_5N)_2Re(CO)_3Cl$ occur at 2041, 1934, and 1891 cm^{-1}. For $[Re(CO)_3(dikH)Cl]_2$ the absorptions are at 2040(m), 2030(s), 1930(m), 1910(m), 1910(s), and 1895(s) cm^{-1}. The *cis* arrangement of carbonyl groups postulated for the former compound is similar to that in one half of the second compound. The extra bands are consistent with a coupling of the vibrations of the two halves of the molecule to give rise to a doubling of the 2041 cm^{-1} (2040, 2030) and 1934 cm^{-1} (1930, 1910) bands.

The work of Hieber and Stanner (14), referred to above, reported the preparation of the monomeric form of our compound prepared by the reaction

$$[Re(CO)_3Cl]_x + dikH \xrightarrow{\text{heat}} Re(CO)_3Cl(dikH)$$

The structure proposed was



Very little physical evidence was given for this structure, and it seems very unlikely, as we have observed no tendency for our compound to form a monomer. If such a monomer exists, the structure of our compound, in which the enol group is relatively near the bridge position, would easily allow bridge breaking. Relatively little environmental change would take place at the rhenium atom, certainly not sufficient to give rise to a drastic colour change from the pale yellow-green of our compound to the deep red-brown of Hieber's. The final point against the structure proposed by Hieber is that, although the calculated and observed analytical results for Hieber's compounds agree very well, the calculated analyses are in error and fit better a formulation containing an extra carbon atom (see Table 5). Relatively little experimental detail is given of the preparations, but clearly

this work should be reinvestigated; so far we have been unable to repeat the preparations.

We thank the National Research Council of Canada for financial support of this work.

Pulse Radiolysis of Nitric Oxide in Aqueous Solution[1]

W. A. SEDDON, J. W. FLETCHER, AND F. C. SOPCHYSHYN

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received October 25, 1972

Transient spectra observed on the pulse radiolysis of aqueous solutions of nitric oxide at p*H* 7.0 have been assigned to the species NO^-, $N_2O_2^-$, and $N_3O_3^-$. In acid solution these species are protonated to form the corresponding acids, HNO, HN_2O_2, and HN_3O_3. Both the basic and acid forms undergo similar reactions, but at different rates, to form the products of radiolysis N_2O and NO_2^-.

$$N_3O_3^- \rightarrow N_2O + NO_2^-$$

$$HN_3O_3 \rightarrow N_2O + HNO_2$$

The basic species decays more slowly than the corresponding acid species but both processes have appreciable activation energies of 15 and 10 kcals/mol, respectively. Computer calculations have been used in conjunction with the experimental data over a wide range of p*H* and NO concentration to deduce a reaction mechanism consistent with the observed results. Reaction rate constants, acid dissociation constants and extinction coefficients for the various species are presented and compared with earlier work.

Les spectres temporaires observés lors de la radiolyse pulsée de solutions aqueuses d'oxyde nitrique à p*H* 7.0 ont été attribués aux espèces NO^-, $N_2O_2^-$, et $N_3O_3^-$. En solution acide ces espèces sont protonées, en formant les acides correspondants, HNO, HN_2O_2, et HN_3O_3. Les formes acides et basiques subissent toutes les deux des réactions similaires mais à des vitesses différentes, en formant des produits de radiolyse N_2O et NO_2^-.

$$N_3O_3^- \rightarrow N_2O + NO_2^-$$

$$HN_3O_3 \rightarrow N_2O + HNO_2$$

L'espèce basique disparait plus lentement que l'espèce acide correspondante mais les deux processus ont des énergies d'activation appréciables de 15 kcal/mol et 10 kcal/mol, respectivement. Des calculs par ordinateur ont été utilisés conjointement avec les données experimentales obtenues dans une grande gamme de pH et de concentration en NO pour en déduire un mécanisme de réaction en accord avec les resultats observés. Les constantes de vitesse des réactions, les constantes de l'equilibre de dissociation des acides, et les coefficients d'extinction pour les différentes espèces sont présentés et comparés avec des travaux antérieurs. [Traduit par le journal]

Can. J. Chem., **51**, 1123 (1973)

Introduction

Earlier studies (1–3), on the γ radiolysis of nitric oxide in aqueous solutions showed that the major products, HNO_2 and N_2O, were explicable by a simple mechanism:

$$H_2O \rightsquigarrow e_{aq}^-, H_3O_{aq}^+, H, OH, H_2, H_2O_2$$

$$e_{aq}^- + NO \rightarrow NO^- \xrightarrow{H^+} HNO$$

$$H + NO \rightarrow HNO$$

$$OH + NO \rightarrow HNO_2$$

$$HNO + 2NO \rightarrow N_2O + HNO_2$$

While the above reaction sequence is stoichiometrically correct a preliminary pulse radiolysis study (4) indicated the detailed mechanism to be much more complex involving the anionic species NO^- and $N_2O_2^-$ and their corresponding protonated forms HNO and HN_2O_2. Subsequent studies (5) confirmed the existence of NO^- and $N_2O_2^-$ together with the formation and eventual decay of a third polymeric anion $N_3O_3^-$. A detailed mechanism involving these species and their corresponding acid forms was proposed to explain the radiolytic reduction of NO in aqueous solutions (5).

Significant differences were noted, however, in acid and neutral solutions in the rates of decay of the species $N_3O_3^-$. For example at p*H* 7.0 the measured half life ranged from 2.1 ms (4) to 8 ms (5). In view of this and the complexity of the reaction kinetics we extended our earlier

[1]AECL No. 4417.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

studies to cover a wider range of NO concentration, pH, and temperature.

Computer calculations have been used in conjunction with the experimental data to check the proposed reaction mechanism, evaluate rate constants and determine pK values for the various equilibria. A large measure of agreement is obtained with the previous work (4, 5), but it is also found that the rate of decay of $N_3O_3^-$ is temperature dependent and additional reactions are required to explain the observations in detail.

Experimental

Nitric oxide solutions contained in 30 ml Pyrex syringes were prepared by the continuous bubbling and dilution techniques described previously (1, 3). Commercially available NO (Matheson Ltd. CP grade 99.8% min) was purified by passing over molecular sieve, type 4A, to remove N_2O and then through the NO flow system (1). The major impurity, NO_2^-, analyzed in the final product was always $< 10\ \mu M$. Triply distilled water was used throughout and glassware cleaned by baking in an air oven at 550 °C overnight.

Detailed descriptions of the pulse radiolysis facilities have been presented elsewhere (6), and only a brief outline is given here. A Van de Graaff accelerator operating at 2.25 MeV with pulse lengths 0.5–2 μs was used as the electron source. Experiments were generally conducted with a 1 μs pulse with currents in the range of 150 mA/pulse and a dose of about 3 krads. Rectangular quartz irradiation cells, having an optical path length of 2 cm, were filled and drained using the sample changer previously described (7). Fresh aliquots of solution were used for each pulse. For the variable temperature experiments the cell was either cooled with a stream of cold nitrogen gas or warmed with an infrared lamp. The temperature was read directly with a Comark electronic thermometer type 1604, using a Cr/Al thermocouple suspended in the solution.

A Hanovia 300 W high pressure xenon arc operated in the DC or pulsed mode, a General Electric 62 W quartz-iodine lamp or a 30/50 W deuterium lamp, were used as sources of analyzing light. Changes in light intensity were monitored with a Bausch and Lomb f 3.5 high intensity monochromator used together with RCA 1P28, or HTV R166 photomultipliers and a Tektronix 556 oscilloscope. Narrow band pass interference filters (Infrared Industries, Inc.) used below 300 nm in conjunction with the monochromator and R166 photomultiplier ensured spectral purity in this region. Using an automatic subtraction unit (8), a single Polaroid photograph (3000 ASA) recorded both the incident light level and the transient absorption signal in the DC coupled mode.

The dose delivered to the sample was determined using 2 mM aerated solutions of SCN^- as dosimeter taking the product of the G value (mol/100 eV) and extinction coefficient ε (M^{-1} cm^{-1}) $G\varepsilon = 2.10 \times 10^4$ for $(SCN)_2^-$ at 475 nm (9–11). Variations in dose/pulse were monitored by integrating the current striking a 1/4 in. aluminum collimating block placed in front of the cell.

Decay curves were digitized using a D-Mac pencil follower (type PF MKIB-Computer Equipment Co.) and analyzed by computer calculation (12).

Results and Discussion

Absorption Spectra

Transient and permanent spectra observed on the pulse radiolysis of aqueous solutions of NO buffered at pH 7.0 are shown in Fig. 1. These are in good agreement with those observed previously and have been assigned to the species NO^-, $N_2O_2^-$, $N_3O_3^-$, and NO_2^- (4, 5). At wavelengths $\leqslant 240$ nm we find, contrary to Grätzel *et al.* (5), that the absorption due to NO_2^- completely masks transient spectra in this region. The original literature should be consulted for additional details but spectral characteristics are summarized and compared with earlier results in Table 1.

The inset in Fig. 1 shows the build up and decay of the transient absorption (monitored at 380 nm) observed at 25 °C in 1.7 mM solutions of NO maintained at pH 7.0 with phosphate buffer (3). The initial absorption, complete on a μs time scale, is due to the formation of $N_2O_2^-$ (4), while the additional slow build up requiring some 250 μs to reach completion is a composite of the formation of $N_3O_3^-$ and concomitant

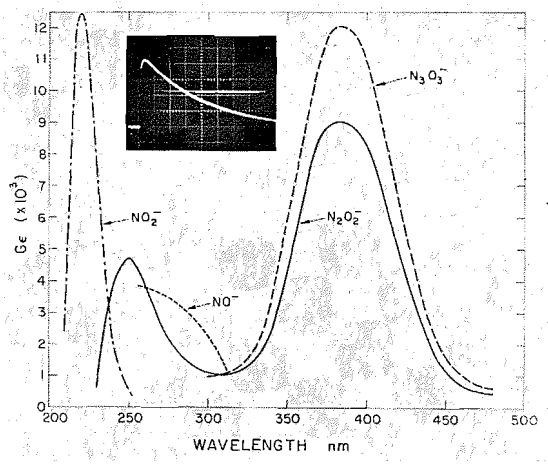

FIG. 1. Absorption spectra of species produced in the pulse radiolysis of NO in aqueous solution at pH 7.0. The NO^- spectrum was obtained in $\sim 10^{-4}$ M NO and the spectra for NO_2^-, $N_2O_2^-$, and $N_3O_3^-$ in $\sim 2 \times 10^{-3}$ M NO. The absorbance of NO^- and $N_2O_2^-$ was recorded immediately after the pulse while that for $N_3O_3^-$ was obtained by extrapolation back to the end of the pulse. The inset shows the formation and decay of the transient absorption at 380 nm and 25 °C in saturated solutions of NO; ordinate, 3.6% absorption/division; abscissa, 1 ms/division, dose/pulse 3.3 krads.

[11]	$N_3O_3^- + H^+ \underset{r}{\overset{f}{\rightleftharpoons}} HN_3O_3$		3.1	5
[12]	$HN_3O_3 \rightarrow N_2O + HNO_2$	$4600\ s^{-1}$		5
[13]	$OH + NO \rightarrow HNO_2$	$6.0\times10^9\ M^{-1}\ s^{-1}$		2
[14]	$HNO_2 \underset{r}{\overset{f}{\rightleftharpoons}} H^+ + NO_2^-$		3.5	13

decay of $N_2O_2^-$ (since both absorb at 380 nm but with $\varepsilon_{N_3O_3^-} > \varepsilon_{N_2O_2^-}$). The eventual decay is first order and corresponds to the disappearance of $N_3O_3^-$ (5). It should be noted here that we find the rate of decay of $N_3O_3^-$ to be temperature dependent. This feature will be discussed in more detail later but does explain the large discrepancy in rate constants previously reported for this process (4, 5).

The overall kinetics and yields of NO^-, $N_2O_2^-$, and $N_3O_3^-$ are dependent both on NO concentration and pH. Reactions 1–12 have been proposed to explain their formation and decay and these together with previously measured rate constants are summarized in Table 2. Also included is reaction 13, and the acid–base equilibria [14], since the permanent product HNO_2, pK = 3.5 (13), lowers the pH of unbuffered solutions.

Based on these reactions, we have utilized the

[9] $HNO + NO \underset{r}{\overset{f}{\rightleftharpoons}} HN_2O_2$	$k_f = 1.7\times10^9\ M^{-1}\ s^{-1}$ $k_r = 8.0\times10^6\ s^{-1}$	2.3_3
[10] $HN_2O_2 + NO \rightarrow HN_3O_3$	$8.0\times10^6\ M^{-1}\ s^{-1}$	
[12] $HN_3O_3 \rightarrow N_2O + HNO_2$	$1.6\times10^4\ s^{-1}$ at 23 °C	
[13] $OH + NO \rightarrow HNO_2$	$1.0\times10^{10}\ M^{-1}\ s^{-1}$	
[15] $N_2O_2^- \rightarrow N_2O + O^- (\rightarrow OH)$	$3.5\times10^2\ s^{-1}$	

*Other rate constants were found to be the same as in Table 2. Using these values and the extinction coefficients in Table 1, experimental traces such as shown in Figs. 2 and 4 can be accurately reproduced. For all the acid–base equilibria in this table and Table 2 it is assumed that $k_f = 1\times10^{10}\ M^{-1}\ s^{-1}$.

computer programs WR16 and WR20 (16), to calculate the concentrations of all the species taking part in the simultaneous first and second order chemical reactions occurring during and after the pulse. The programs require for input data a list of the species taking part in the chemical reactions, the reaction rate constants, radiation yields of the primary radiolysis products, the initial concentrations of NO and H^+, extinction coefficients of the absorbing species and the dose per pulse. We have therefore sought to check the proposed mechanism by comparing the computed concentrations of the transient species with our experimental data over a wide range of NO concentration and pH.

Solutions of NO Buffered at pH 7.0

The simplest sequence of reactions occurs in saturated ($\sim$2 mM), solutions of NO buffered at pH 7.0. Under these conditions the transient "NO" species exist entirely in their basic form and the equilibrium [5] lies predominantly in favor of $N_2O_2^-$. Preliminary calculations using the previously measured extinction coefficients and rate constants given in Tables 1 and 2 showed that the experimental observations relating to the formation and decay of $N_2O_2^-$ and $N_3O_3^-$ were explicable in terms of reactions 1 and 3 to 7. Note, however the discrepancy in the rate constants given for reaction 7. This we have now shown to be due simply to a temperature effect (see later) and hence for our calculations we chose to use our measured rate constant at 23 °C, *i.e.* $k_7 = 2.35\times10^2\ s^{-1}$.

In solutions of NO there is considerable disagreement with this simple mechanism at concentrations below $5\times10^{-4}\ M$. As a consequence of equilibrium [5], the mechanism predicts that the yield of $N_2O_2^-$ should decrease with decreasing NO concentration and at the same time the rate of formation of $N_3O_3^-$ produced in the pseudo first order reaction 6 should likewise decrease. While the former is observed, no slow build up attributable to $N_3O_3^-$ can be seen in $\sim2\times10^{-4}\ M$ solutions of NO. We suggest, therefore that the species $N_2O_2^-$ must itself decay

[15] $N_2O_2^- \rightarrow N_2O + O^- (\rightarrow OH)$

in competition with reaction 6.

It has been suggested previously that OH radicals might be produced as an intermediate species in the NO system, but competition experiments in the presence of CH_3OH did not support this proposal (2). However such experiments were all conducted in solutions saturated with NO at which concentration our rate constant data (see Table 3) indicate only about 5% of the $N_2O_2^-$ could disappear by [15] in competition

with [6]. Such a process would not have been detectable with any reliable accuracy by the standard competition methods employed in ref. 2.

Figure 2 curves A to C show the experimentally observed transient signals as a function of NO concentration. The computed curves (white lines), superimposed on the experimental traces represent the calculated best fit to the data using $G_{e_{aq}^-} = 2.6$, $G_H = 0.56$, $G_{OH} = 2.6$, $G_{H_3O^+} = 2.8$, $G_{OH^-} = 0.2$, $\varepsilon_{N_2O_2^-}$ and $\varepsilon_{N_3O_3^-} = 2850$ and 3750 M^{-1} cm^{-1}, respectively, The dose per pulse used in each case was within $\leqslant 5\%$ of the experimentally monitored dose. Rate constants, where they differ from those in Table 2, are given in Table 3. The overall agreement with previous values obtained at neutral pH is good with the rate constants $k_{5f} = 1.7 \times 10^9\ M^{-1}\ s^{-1}$ and $k_{13} = 1.0 \times 10^{10}\ M^{-1}\ s^{-1}$ being redetermined by observing the pseudo first order formation of $N_2O_2^-$ and NO_2^- at 380 and 220 nm, respectively.

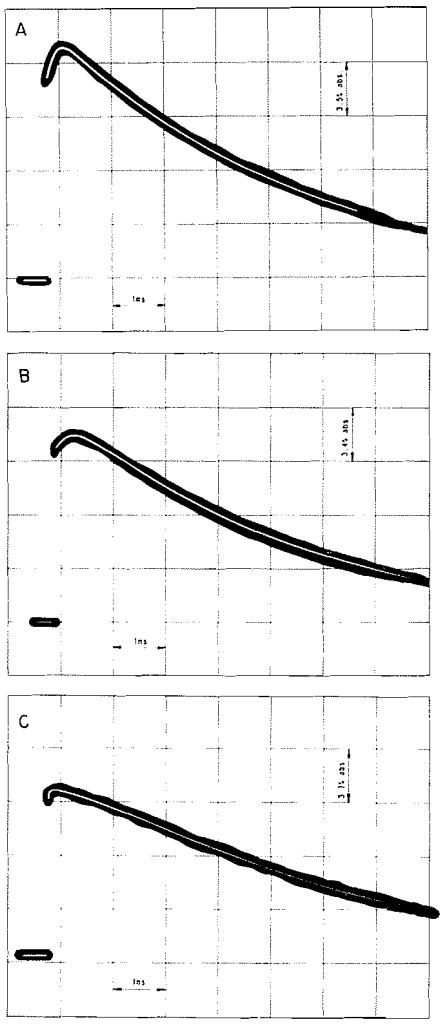

FIG. 2 Oscilloscope traces at 380 nm showing the formation and decay of the transient species $N_2O_2^-$ and $N_3O_3^-$ at pH 7.0 as a function of NO concentration. The computed curves (white lines) are shown superimposed on a reproduction of the experimental traces. Abscissa on all traces: 1 ms/division. Curve A: 2.01 mM NO, 3.4% absorption/division, 3.2 krads/pulse; curve B: 8.7×10^{-4} M NO, 3.4% absorption/division, 2.9 krads/pulse; curve C : 2.03×10^{-4} M NO, 3.6% absorption/division, 3.4 krads/pulse.

Figure 3 shows the change in $N_2O_2^-$ concentration as a function of NO concentration, the open circles being our values and the crosses the normalized results of Grätzel *et al.* (5). The curve drawn through the points represents an equilibrium constant $K_{-5} = 3.9 \times 10^{-5}$ M, *i.e.* $k_{5r} = 6.6 \times 10^4\ s^{-1}$ deduced by computer calculation. This can be compared with the previous value of 3.5×10^{-5} M (5).

Effect of pH

In acid solution the situation becomes much more complex with the yield and rates of formation and decay of NO^-, $N_2O_2^-$, and $N_3O_3^-$ being dependent on pH and NO concentration. Reducing the pH with H_2SO_4 or buffer solutions reduces (*a*) the overall intensity of the transient absorption, (*b*) the time taken to reach the maximum intensity (corresponding to the formation of $N_3O_3^-$), and (*c*) the half life, $t_{1/2}$, for the "first order" decay of $N_3O_3^-$ (Fig. 4*A*).

Reducing the NO concentration at a fixed acid

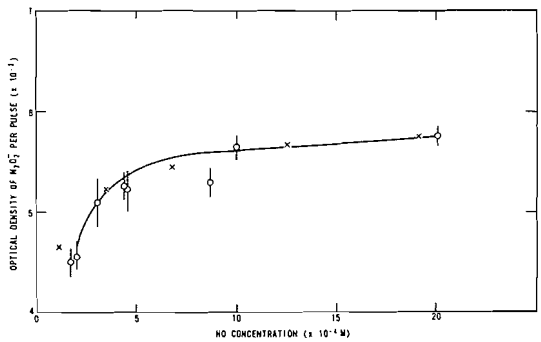

FIG. 3. Change in $N_2O_2^-$ concentration as a function of NO. Open circles, this work, crosses represent normalized data from ref. 5. Curve is calculated using $K_{-5} = 3.9 \times 10^{-5}$ M and the rate constants given in Tables 2 and 3. All data normalized to a dose/pulse of 3.2 krads.

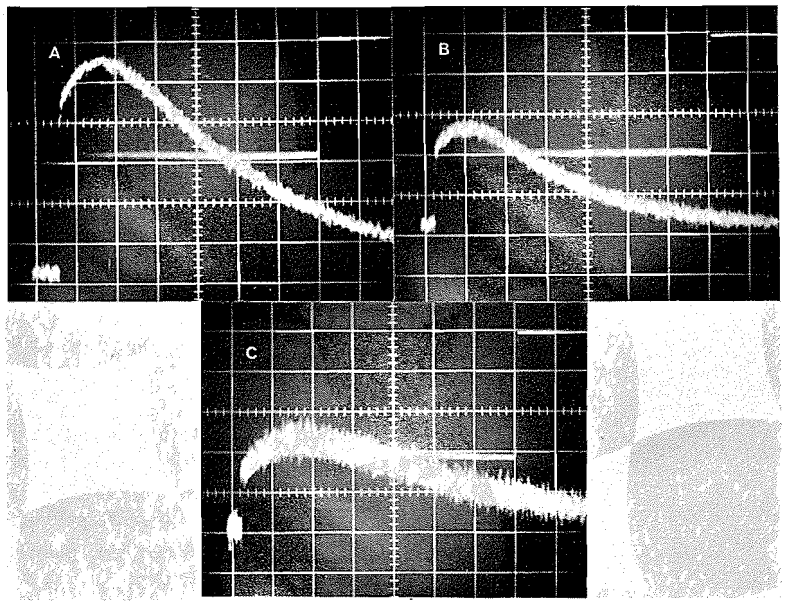

FIG. 4. Oscilloscope traces at 380 nm showing the formation and decay of the transient species $N_2O_2^-$ and $N_3O_3^-$ at pH 3.6_5 as a function of NO concentration. Curve A: 2.11 mM NO, ordinate 1.8% absorption/division, abscissa 100 μs/division, 3.7 krads/pulse; curve B: 1.13 mM NO, ordinate 1.7% absorption/division, abscissa 200 μs/cm, 2.9 krads/pulse; curve C: 4.76×10^{-4} M NO, ordinate 0.9% absorption/division, abscissa 200 μs/cm, 3.0 krads/pulse.

pH reduces the overall signal but increases the time taken to reach the maximum intensity (Fig. 4B and C). Unlike the results obtained at pH 7.0 (Fig. 2), the final rate of decay decreases significantly with decreasing concentration of NO (Fig. 4B and C).

These observations are all consistent with protonation of the basic species to form the corresponding acids HNO, HN_2O_2, and HN_3O_3, reactions 2, 4, 8, and 11 and the existence of equilibrium [9] (5). The extent to which these acids dissociate depends upon their relative acid strengths and since they do not absorb strongly at 380 nm (*i.e.* no transient absorptions are observed at p$H \leqslant 2$), their dissociation constants have been deduced by observing the decrease in concentration of their conjugate bases as a function of pH (5).

Initial computer calculations were again based on the rate constants presented in Table 2 assuming for the acid–base equilibria that the protonation reaction $k_f = 10^{10}\ M^{-1}\ s^{-1}$. Qualitatively, the original data predicted the general features observed in acid solution but, quantitatively, failed to reproduce the experimental traces such as shown in Fig. 4. Principal sources of disagreement were related to the pK for HN_2O_2 and the equilibrium constant for reaction 9 (see below). Having established "best fit" values for these two constants, k_9, k_{10}, and k_{12} were then deduced by matching the observed build up and decays as a function of pH and NO concentration.

Figure 5 shows the change in concentration of the species $N_2O_2^-$ and $N_3O_3^-$ as a function of pH in ~ 2 mM solutions of NO. The open and closed (buffered solution) circles represent our results and the crosses the normalized data of Grätzel *et al.* (5). The curve drawn through the points for $N_2O_2^-$ was calculated using $pK_{HN_2O_2} = 3.25$ and $pK_{HN_3O_3} = 3.1$. These values should be compared with the previous estimates of 3.5 and 3.1, respectively.

By inspection, the data for $N_2O_2^-$ (observed immediately after the pulse) indicate a pK for HN_2O_2 of about 3.7. This latter value is however above the real pK since the points are effectively displaced towards higher pH values as a consequence of equilibrium [9]. In other words the existence of [9] in conjunction with [8] suggests that HN_2O_2 is a weaker acid than is in fact the case.

Reaction 9 is the acid analog of equilibrium [5] and the inset in Fig. 5 shows the decrease in yield of $N_2O_2^-$ as a function of NO concentration at pH's 3.6_5 and 4.2. The curves drawn

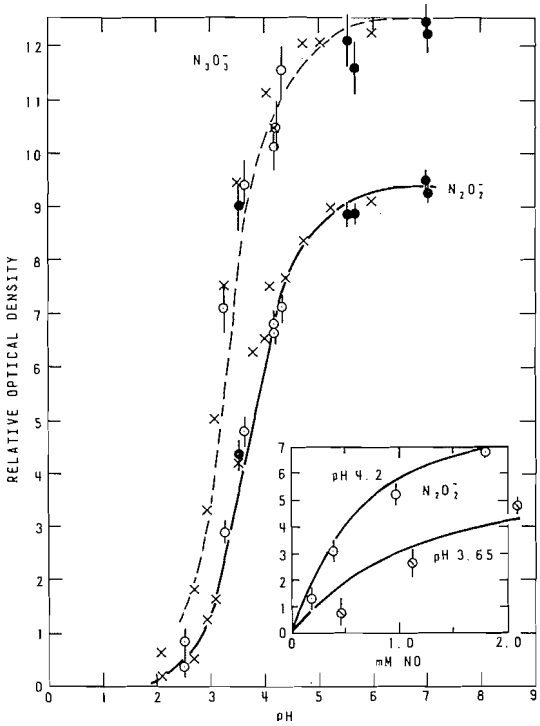

FIG. 5. Change in $N_2O_2^-$ and $N_3O_3^-$ concentration as a function of pH. Circles, this work (closed circles, buffered solution); crosses, normalized data from ref. 5. Inset shows decrease in $N_2O_2^-$ concentration as a function of NO concentration at two different pH's, 3.65 and 4.2. Curves are calculated in all cases (see text).

through the points represent an equilibrium constant $K_{-9} = 4.7 \times 10^{-3}$ M, *i.e.* $k_{9f} = 1.7 \times 10^9$ M^{-1} s^{-1}, and $k_{9r} = 8 \times 10^6$ s^{-1}, a value almost an order of magnitude greater than the previous estimate (5). The "fit" however is not as good as obtained in the analogous neutral case (Fig. 3). Attempts to match this particular aspect more closely were not considered justified in view of the weak absorptions coupled with experimental uncertainties in pH, NO concentration, dose, and temperature. Nevertheless it is clear that the acid species dissociates far more readily than does its conjugate base.

The results representing the change in concentration of $N_3O_3^-$ as a function of pH require further clarification. These points were all obtained by extrapolating the observed decays back to the end of the pulse, since seemingly excellent first order plots were obtained at all pH's. However computed formation and decay curves consistent with the raw data show that as the pH is lowered such extrapolations become a progressively less valid measure of the true $N_3O_3^-$ concentration but rather that of a mixture of $N_2O_2^-$ and $N_3O_3^-$. In the vicinity of the pK the overall decay becomes a composite of the disappearance of $N_2O_2^-$ and the concomitant formation and decay of $N_3O_3^-$. Thus below a pH of about 4.3, ($t_{1/2} \sim 700$ μs at 21 °C), the computed first order plots are in fact non-linear over the first two or three half lives. Since the curvature is within the analytical error such deviations from linearity were not detected experimentally.

The dashed curve in Fig. 5 therefore represents the computed concentrations of "$N_3O_3^-$" obtained by extrapolation to the end of the pulse on a time scale analogous to that of the experimental observations.

Effect of Temperature on the Decay of $N_3O_3^-$

As mentioned previously it was found that the first order decay of $N_3O_3^-$ to give the products of radiolysis N_2O and NO_2^-, reaction 7, was markedly temperature dependent. Figure 6 shows an Arrhenius plot for the decay of $N_3O_3^-$ at pH 5.0. The measured activation energy E_a[1] for this process decreases with pH as shown in Fig. 7. This decrease is due to the fact that the basic species $N_3O_3^-$ decays more slowly than the corresponding acid species HN_3O_3, reactions 7 and 12, but the two are interrelated by the acid–base equilibrium [11]. Based on these three

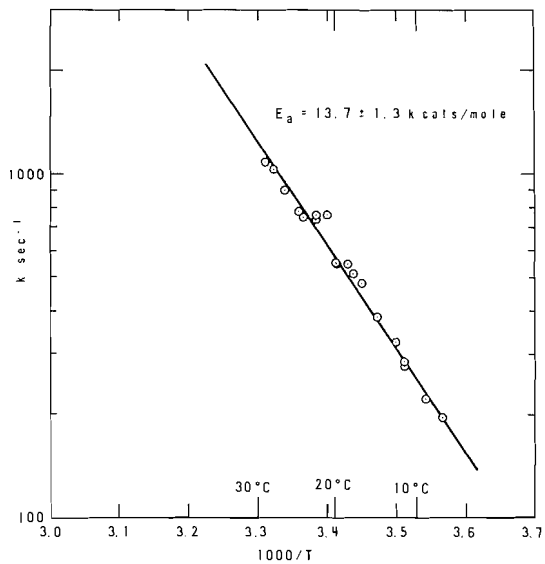

FIG. 6. Arrhenius plot for the first order decay of $N_3O_3^-$ at pH 5.0.

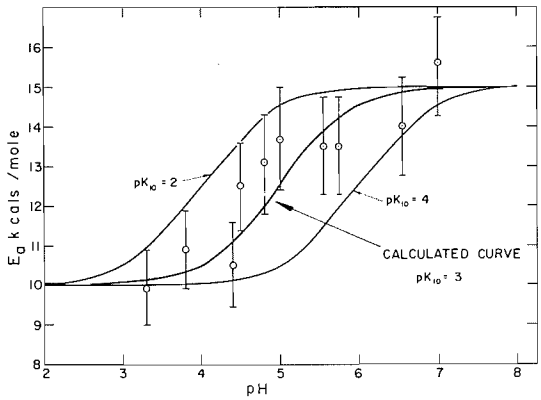

FIG. 7. Activation energy for the first order decay of $N_3O_3^-$ as a function of pH.

reactions one can show that at a given pH, E_a^1 is related to the measured rate constant k_{obs} via the rate constants k_7 and k_{12}, the dissociation constant K_{-11} and the activation energies for the decay of $N_3O_3^-$ and HN_3O_3, $E_a^{N_3O_3^-}$ and $E_a^{HN_3O_3}$, respectively.

The calculated curves in Fig. 7 are based on $E_a^{N_3O_3^-} = 15$ kcals/mol, $E_a^{HN_3O_3} = 10$ kcals/mol and the Arrhenius equation

$$-E_a^1/RT = \ln k_{obs} + C$$

where C is a constant and

$$k_{obs} = \frac{k_7[N_3O_3^-]}{[N_3O_3^-] + [HN_3O_3]} + \frac{k_{12}[HN_3O_3]}{[N_3O_3^-] + [HN_3O_3]}$$

substituting for $[N_3O_3^-]$ and $[HN_3O_3]$ from [11]

$$E_a^1 = \frac{2.303RT_1T_2}{(T_2 - T_1)} \times \log \frac{k_7^{T_2} + k_{12}^{T_2}[H^+]/K_{-11}}{k_7^{T_1} + k_{12}^{T_1}[H^+]/K_{-11}}$$

where $R = 1.987$ cal, T_1 and T_2 the absolute temperatures and $k_7^{296} = 2.35 \times 10^2$ s^{-1}, $k_7^{275} = 33.5$ s^{-1}, $k_{12}^{296} = 1.65 \times 10^4$ s^{-1}, $k_{12}^{275} = 4.5 \times 10^3$ s^{-1}, and pK (HN_3O_3) = 3.0. It is also assumed that both ε and K_{-11} remain independent of temperature over the range of study.

The curves to the left and right of the "best fit" are calculated using p$K_{-11} = 2$ and 4 respectively, showing indirectly the consistency of the rate constants in Table 3 and the value for p$K_{-11} = 3.1$.

In conclusion the results obtained in this work combined with those of Grätzel *et al.* (5), show that the reactions 1–15, and the rate constants presented in Tables 2 and 3 accurately reflect the transient changes observed on the pulse radiolysis of aqueous solutions of NO. In addition we find that the final decay process of $N_3O_3^-$ to form the products of radiolysis has a considerable activation energy which is also pH dependent. This accounts for previous discrepancies in the published rate constants for the decay of $N_3O_3^-$ and also introduces a change in the ratio k_{12}/k_7 with temperature from 135 at 2 °C to 70 at 23 °C.

The authors thank Mr. E. B. Selkirk for the design and construction of the electronics.

Comparisons between Orientation Polarizations and Atom Polarizations among Organomercurials

GEORGE F WRIGHT

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received September 26, 1972

Although a correlation between orientation and atom polarizations among simple aryl and alkyl mercurials is limited, a definite but inverse correlation is found for 2-oxyorganomercuric salts.

La corrélation qui existe entre l'orientation et la polarisation atomique chez les aryl et alkyl mercuriels simple est limitée; toutefois une corrélation bien définie mais inverse est observée avec les sels organomercuriques hydroxylés en position 2. [Traduit par le journal]

Can. J. Chem., 51, 1131 (1973)

For personal use only.

Because the phenomenon known as atom polarization is not clearly understood it must suffice in this report only to present and compare experimental data for a number of mercurials in which the polarity of the carbon–mercury linkage ought to accentuate structural differences.

The reactance of a substance in the gaseous phase, and to approximations in solution, may be expressed as follows:

$$P_T = P_E + P_A + P_O$$

where the total polarization (P_T) is a composite of the polarization at frequencies greater than $\sim 10^{14}$ Hz (P_E where the electrons can follow the alternating field) plus the polarization between $\sim 10^{12}$ and 10^{14} Hz (P_A) where the atom nuclei react with the field and finally P_O (orientation polarization where the entire molecule can follow the alternating field) at $\nu = \sim 10^6 - 10^8$ Hz if the system is not intrinsically too viscous.

At 10^6 Hz all three polarizations can react reversibly with the alternating electrostatic field to which they are subjected. In order to sort out these three effects we have earlier (1) devised a technique based on measurement of polarization in the solid state where orientation polarization cannot ordinarily occur. In this circumstance

$$P_{(solid)} = P_E + P_A = P_D$$

where P_D is called the distortion polarization.

It must be assumed that this experimentally-determined P_D will have the same magnitude for the substance in the gaseous state or in dilute solution as it displays in the solid state. This assumption is reasonable but it has not been proven. The most that has been shown is identity within experimental error of P_D for one substance in its crystalline and its amorphous state and for the polymorphs of two other substances (1).

Of course the magnitude of P_D will be much less than that of P_O for substances of appreciable dipole moment and P_A ordinarily is less than 20% of P_E. Consequently the magnitude of P_A is of small consequence for substances exceeding 2 D in moment unless high precision is required.

Orientation polarization (P_O) is assumed to be due to the alignment of a fixed dipole in the electric field. If disorientation due to thermal agitation is taken into account according to the Debye relationship (where l is 0.012812 and T is temperature in °K)

$$\mu = l\sqrt{P_O T}$$

then the dipole moment (μ) ought to be a temperature-independent constant for the substance under examination. It has been shown (2) that there are exceptions to this rule, which have been attributed to dipole distortion because of internal molecular energy. In turn it has been postulated (3) that in such instances P_O and P_A are interrelated in respect of temperature dependence. The temperature dependence of P_A has been evaluated theoretically (4) and has been found to be slight.

If there should be a relationship between P_A (due to charge dipole in the molecule) and P_O (orientation of the separated charge of a molecule) this relationship could be of use in evalua-

*When two values of dipole moment (μ) are given they have been determined at 20 and 40°, respectively.

tion of molecular structure. For example an abnormally high P_A has been found (Table 1) for 1,4-dichloromercuridurene (5) but the P_O and hence the dipole moment of this substance cannot yet be determined because it is non-volatile and is too insoluble in media of low dielectric constant. Consequently we have made a study of comparisons between P_A and P_O (the latter in terms of dipole moment) for a series of candidate substances.

The first series listed in Table 1 includes the arylmercuric halide group (6). There is little correlation between P_O and P_A even in respect of the halogeno–mercuri bond, although it is notable that P_A is unusually high. The values for P_A among the alkylmercuric chlorides is lower than those of the arylmercurials but it is of interest that the dipole moments increase regularly in the homologous series (expected because of the space swept out of the solvent by the alkyl group) whereas the atomic polarizations alternate upward in magnitude, remindful of alternate melting points in other crystalline homologous series among the alkenes. Thus there may be some dependence of P_A on the confinement of the crystal lattice when P_D is measured in the solid state.

More significant are the higher atomic polarizations (P_A) for the secondary alkylmercuric halides over those of the primary analogs.

However it is disturbing to find that substances of supposedly proven structure (7) like the 4-cyclohexylmercuric halides show atom polarizations more of the order of primary rather than secondary alkyl substituents. This discrepancy is consistent for the analogous 4-methylcyclohexylmercuric cyanides which, of course, may be expected to be more polar than the chlorides. In general it may be said that only a limited correlation is found among the items of Table 1.

By contrast we have found a definite correlation among the 2-oxyorganomercurials listed in Table 2, albeit an unexpected one. The so-called α-diastereomers which are obtained by addition (not acid-catalyzed) of the elements of methoxy-

mercuric acetate to α-Terpineol (8), cyclopentene, and cyclohexane (9) have lower dipole moments but higher atom polarizations than their epimerized β-diastereomers derived by radical-induced isomerization. Likewise the diastereomer which is formed predominately by acid-catalyzed hydroxymercuration of [2,2,1]-bicycloheptene (10) and which has the higher dipole moment (hence is designated as β) has the lower atom polarization by contrast to the less predominant α-diastereomer.

An apparent contradiction of this inverse correlation which is found for the methoxymercuration products of the geoisomeric stilbenes is only nominal. Firstly the apparently absurd (negative) values for P_A listed for these two oxymercurials should be adjusted upwards by 4–5 cc because of the previously demonstrated "phenyl effect" (11). Second, the nomenclature "α" and "β" refers for this pair of diastereomers to their derivation from *cis* and *trans* stilbene respectively (12, 13). With this interpretation it may be seen that the inverse correlation still applies, *i.e.* that the β-diastereomer from *trans*-stilbene has a lower dipole moment but a higher atom polarization (P_A) than does the α-diastereomer from *cis*-stilbene.

It may be of interest in respect of this inverse correlation that the α-diastereomer from *cis*-stilbene is more resistant to deoxymercuration by strong (molecular) hydrochloric acid than is the more slowly-formed β-diastereomer from *trans*-stilbene. This behavior whereby the diastereomer of higher dipole moment and lower atom polarization is more resistant to deoxymercuration by molecular hydrochloric acid also is consistent for the diastereomeric oxymercurials of α-terpineol, cyclopentene, and cyclohexene. It would appear that there is a conformational advantage in deoxymercuration which involves the pivot bond in the methoxydiphenylethane mercurials and which is related to dipole moment and to atom polarization of all these oxymercurials.

In this connection it is of interest to observe the minimal differences of P_A between the α and β diastereomers of 2-methoxycyclohexylmercuric chloride by contrast with those pairs of

oxyorganomercurials from cyclopentene and α-terpineol. In retrospect it would seem that the 2-methoxycyclohexylmercuric chlorides were the poorest candidates to choose for the single-crystal X-ray diffraction studies upon which their diastereomeric configurations were based (12). If heavy substituents can warp a cyclohexane ring out of its traditionally-regular hexagonal geometry then it is a pity that the methoxycyclopentylmercuric halides were not, instead, chosen for single-crystal analysis.

These observations have been made despite doubts about the meaning of atom polarization. It can only be said with reasonable assurance that the involvement of P_A with radiation frequencies above 10^{14} Hz is slight or inconsequential.

It must be realized that only during the past decade have measurements of precision been made for P_A. Previous measurements in the gaseous phase for extrapolation of P_T to infinite temperature are grossly imprecise. In liquids or solutions such extrapolations are absurd. Likewise evaluations of P_A from spectral absorptions lead to absurdities (14).

Indeed spectral absorption in the far infrared region seems to be singularly uniformative about the differences in P_A which have been determined by capacitance measurement. Some frequencies are listed in Table 3. The lack of correlation cannot be attributed to lattice forces in the solid state (in which state most of these spectra must be determined) because in one instance, isopropylmercuric chloride, the frequencies of absorption are similar in solid and solution states.

Perhaps a new conceptual model for P_A is needed. The data of Table 1 might then fall into some order and the inverse correlations of Table 2 might become meaningful.

Experimental

The dielectric constants and the densities of substances in the solid state were determined by methods previously described (1) (15). The orientation polarizations were calculated from the dielectric constants of solutions in benzene at 20° with apparatus previously described (16).

Spectral absorptions have been determined in a Beckman IR-11 Spectrometer using solid dispersions in polypropylene wax (1) except for isopropylmercuric chloride, which was examined both as a 15% solution in benzene (b) or as a very thin wafer of the pure crystalline substance (p). The findings are reported in Table 3.

The author thanks the Defence Research Board and the National Research Council of Canada for grants-in-aid which supported this research. The dielectric constants and densities of the solids were determined for the most part by Mr. H. Huber.

Alcohol to Ester Rearrangement. II. Diphenylphosphine and Hexafluoroacetone

ALEXANDER FRANK JANZEN AND OM CHAND VAIDYA

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 17, 1972

The reaction of diphenylphosphine with hexafluoroacetone gives $(C_6H_5)_2PC(OH)(CF_3)_2$ which is readily oxidized to $(C_6H_5)_2P(O)C(OH)(CF_3)_2$ and, in the presence of base catalyst, undergoes rearrangement to the isomeric $(C_6H_5)_2P(O)OCH(CF_3)_2$. Reaction of hexafluoroacetone with diphenylarsine gives $(C_6H_5)_2AsC(OH)(CF_3)_2$ while reaction with diphenyl phosphonate gives $(C_6H_5O)_2P(O)C(OH)(CF_3)_2$ which rearranges to $(C_6H_5O)_2P(O)OCH(CF_3)_2$.

La réaction de la diphénylphosphine sur l'hexafluoroacétone conduit à $(C_6H_5)_2PC(OH)(CF_3)_2$ qui s'oxyde facilement en $(C_6H_5)_2P(O)C(OH)(CF_3)_2$, ce dernier s'isomérise en $(C_6H_5)_2P(O)OCH(CF_3)_2$ selon un réarrangement catalysé par une base. La réaction de l'hexafluoroacétone sur la diphénylarsine conduit à $(C_6H_5)_2AsC(OH)(CF_3)_2$ et sur la diphénylphosphonate fournit $(C_6H_5O)_2P(O)C(OH)(CF_3)_2$ qui se réarrange en $(C_6H_5O)_2P(O)OCH(CF_3)_2$. [Traduit par le journal]

Can. J. Chem., 51, 1136 (1973)

Recently we reported the kinetics and mechanism of the base-catalyzed rearrangement of phosphorus(V) alcohols to the isomeric esters (eq. 1) (1). The alcohols were readily prepared

[1] $$(RO)_2\overset{\overset{OOH}{\|\ |}}{P}C(CF_3)_2 \xrightarrow{\text{Base}} (RO)_2\overset{\overset{O\ H}{\|\ |}}{P}OC(CF_3)_2$$

"Alcohol" "Ester"

$R = CH_3;\ C_2H_5;\ n\text{-}C_4H_9$

by the reaction of dialkyl phosphonates with hexafluoroacetone. Whether phosphorus(III) alcohols would behave similarly is of some interest in view of the report that reaction of diphenylphosphine and hexafluoroacetone gives a 1:1 adduct involving trivalent carbon (2). The reaction of hexafluoroacetone with diphenylphosphine was therefore repeated, as well as reaction with diphenylphosphine oxide, diphenyl phosphonate, and diphenylarsine.

Our results from the reaction of diphenylphosphine and hexafluoroacetone are entirely consistent with the initial formation of a phosphorus(III) alcohol of structure **1** (eq. 2).

[2] $$(C_6H_5)_2PH + (CF_3)_2CO \longrightarrow (C_6H_5)_2\overset{\overset{OH}{|}}{P}C(CF_3)_2$$

1

Compound **1** is a white solid, soluble in tetrahydrofuran (THF) and very susceptible to oxidation. Oxidation prevented satisfactory elemental analysis; however, the oxidized product **2** is stable in air and gave satisfactory elemental analysis.

Rearrangement of alcohol **2** to ester **3** occurred in the presence of a base catalyst such as THF or pyridine, consistent with the alcohol to ester rearrangement described previously (1).

[3] $$(C_6H_5)_2\overset{\overset{OOH}{\|\ |}}{P}C(CF_3)_2 \xrightarrow{\text{Base}} (C_6H_5)_2\overset{\overset{O\ H}{\|\ |}}{P}OC(CF_3)_2$$

2 **3**

The ^{19}F n.m.r. spectra were particularly useful in characterizing compounds **1**, **2**, and **3** and monitoring the rearrangement of **2** to **3**. Figure 1*a* shows a typical ^{19}F n.m.r. spectrum of a mixture of **1**, **2**, and **3** in THF in a sealed n.m.r. tube. The spectrum shown in Fig. 1*b* was recorded 5 h after that shown in Fig. 1*a* and it is evident that concentration of **2** has decreased whereas **3** increased, confirming the alcohol-to-ester rearrangement in THF (eq. 3). The rate of rearrangement may be increased by introducing a stronger base such as pyridine. During the rearrangement, the concentration of **1** remained unchanged, confirming that **1** is stable in THF provided that oxygen and moisture are excluded.

An alternate route to **3**, involving rearrangement of **1** to $(C_6H_5)_2POCH(CF_3)_2$ followed by oxidation to **3** was not observed in our study.

In a separate experiment it was shown that reaction of diphenylphosphine oxide with hexafluoroacetone gave **2** and addition of pyridine catalyzed the rearrangement to **3**. Similarly, reaction of diphenyl phosphonate with hexafluoroacetone gave alcohol **4** and addition of pyridine gave the isomeric ester **5** (eq. 4).

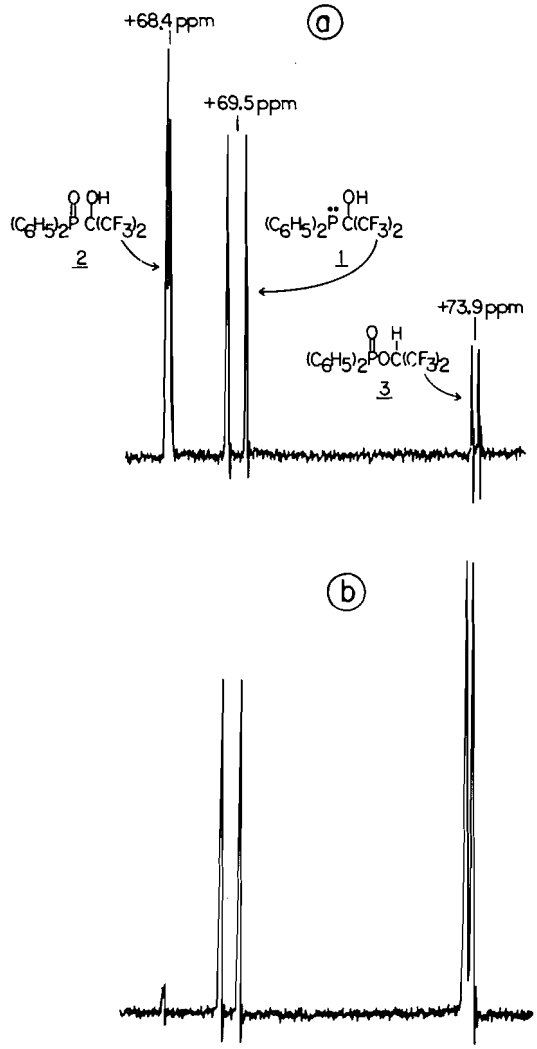

FIG. 1 (*a*) The ^{19}F n.m.r. spectrum of mixture of **1**, **2**, and **3** in tetrahydrofuran. (*b*) After 5 h at 25°. Concentration of **2** decreased, **3** increased while **1** remained unchanged.

[4] $(C_6H_5O)_2P(O)H + (CF_3)_2CO \longrightarrow$

$$(C_6H_5O)_2\overset{\overset{O}{\|}}{P}\overset{\overset{OH}{|}}{C}(CF_3)_2 \xrightarrow{\text{Base}} (C_6H_5O)_2\overset{\overset{O}{\|}}{P}O\overset{\overset{H}{|}}{C}(CF_3)_2$$

4 **5**

The reaction of diphenylarsine with hexafluoroacetone was carried out in an attempt to prepare a stable arsenic(III) alcohol analogous to **1** (eq. 5). Reaction occurred readily to give **6**,

[5] $(C_6H_5)_2AsH + (CF_3)_2CO \longrightarrow (C_6H_5)_2As\overset{\overset{OH}{|}}{C}(CF_3)_2$

6

an oily liquid which was more resistant to oxidation than **1** and gave satisfactory elemental analysis. The reaction of dimethylarsine with hexafluoroacetone to give an arsenic(III) alcohol has been reported by Cullen and Styan (4). Oxidation of **6** with gaseous oxygen gave bis (diphenylarsine) oxide.

Recent investigations have shown that phosphorus(III) derivatives may abstract fluorine attached to a carbon atom (5). During this study it was observed that if **1** was left in the presence of excess hexafluoroacetone, fluorine abstraction

[6] $$\mathbf{1} \xrightarrow[\text{or } XeF_2]{(CF_3)_2CO \text{ excess}} (C_6H_5)_2\overset{\overset{F}{|}}{P}\overset{\overset{OH}{|}}{C}(CF_3)_2$$

7

occurred to give **7** (eq. 6). Addition of a fluorinating agent such as XeF_2 (6) to **1** also gave **7**, which was identified on the basis of its ^{19}F n.m.r. and mass spectra. The ease of fluorination and oxidation is consistent with the structure proposed for **1**.

Experimental

Conventional vacuum line techniques were used for handling volatile materials. Hexafluoroacetone (Matheson of Canada), diphenylphosphine, diphenyl phosphonate (Eastman), diphenylarsine (Alfa), and xenon difluoride (PCR, Gainesville) were used as obtained. Diphenylphosphine oxide was prepared by oxidation of diphenylphosphine (7). The n.m.r. spectra were obtained on a Varian A-56/60A spectrometer using 60 and 56.4 MHz for proton and fluorine, respectively. Chemical shifts are relative to internal tetramethylsilane and trichlorofluoromethane. Mass spectra were obtained on a Finnigan 1015 quadrupole mass spectrometer. Elemental analyses were performed by Alfred Bernhardt, West Germany.

Reaction of Diphenylphosphine with Hexafluoroacetone

Diphenylphosphine (0.56 g, 3.0 mmol) was dissolved in $CFCl_3$ (3 ml) and hexafluoroacetone (0.73 g, 4.4 mmol) condensed onto the solution at −196°. The reaction mixture was allowed to warm to room temperature and stirred for 15 min. Removal of volatile products left a white solid identified as 2-hydroxy-1,1,1,3,3,3-hexafluoroisopropyldiphenylphosphine, $(C_6H_5)_2PC(OH)(CF_3)_2$ (**1**), on the basis of n.m.r., mass spectrometry, and chemical reactions.

The ^{19}F n.m.r. spectrum of **1** showed a doublet, $J_{FCCP} = 17.8$ Hz, at +69.5 p.p.m. and the ^1H n.m.r. showed a singlet (OH) at −3 p.p.m. and phenyl peaks.

1 was found to be very susceptible to oxidation to give **2**, described below, and the difficulty of excluding oxygen from solvents and reaction vessels prevented satisfactory elemental analysis. Rapid hydrolysis and oxidation occurred if **1** was exposed to the atmosphere, the end products being $(C_6H_5)_2P(O)OH$, identified by its mass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

spectrum and m.p. 193° (lit. 192° (8)) and hexafluoroacetone hydrate. A fresh sample of **1** was always prepared when needed.

The mass spectrum of **1** was contaminated by **2**; however, peaks (M = molecular ion) at *m/e* 352(M), 351(M − H), and 313(M − HF_2) may be assigned to **1** since they are not observed in the mass spectrum of purified **2**.

Oxidation of $(C_6H_5)_2PC(OH)(CF_3)_2$ to $(C_6H_5)_2P(O)C(OH)(CF_3)_2$

A slow stream of dry oxygen gas was passed through a suspension of **1** in $CFCl_3$ at −23° for 6 h. Removal of $CFCl_3$ under vacuum left a white solid identified as 2-hydroxy-1,1,1,3,3,3-hexafluoroisopropyldiphenylphosphine oxide $(C_6H_5)_2P(O)C(OH)(CF_3)_2$ (**2**). The ^{19}F n.m.r. spectrum showed a doublet, $J_{FCCP} = 1.5$ Hz, at +68.4 p.p.m. The mass spectrum showed highest mass ions at *m/e* 368(M), 367(M − H), and 348(M − HF).

Anal. Calcd. for $C_{15}H_{11}F_6O_2P$: C, 48.92; H, 3.01; F, 30.96. Found: C, 49.10; H, 3.04; F, 30.64.

Base-catalyzed Rearrangement of $(C_6H_5)_2P(O)C(OH)(CF_3)_2$ (2) to $(C_6H_5)_2P(O)OCH(CF_3)_2$ (3)

The preparation of **3** has been reported previously (2). In this study, a solution of **2** in THF was monitored and found to rearrange to **3**, with an approximate pseudo first-order rate constant $k_1' = 6 \times 10^{-5}$ s^{-1} at 25°. The rate of rearrangement increased on addition of a stronger base catalyst such as pyridine. Compound **2** could be prepared by an alternate route from diphenylphosphine oxide and hexafluoroacetone. Addition of pyridine again catalyzed the rearrangement to **3**.

The ^{19}F n.m.r. of **3** showed a doublet, $J_{FCCH} = 6$ Hz, at +73.9 p.p.m. (lit. +73.0 p.p.m. in dimethylformamide (2)).

Reaction of Diphenyl Phosphonate with Hexafluoroacetone

Diphenyl phosphonate (0.5 g, 2.1 mmol) and hexafluoroacetone (0.8 g, 4.8 mmol) was sealed in an n.m.r. tube and the ^{19}F n.m.r. spectrum recorded after 24 h. Only two doublets were observed. The doublet, $J_{FCCP} = 3$ Hz, at +71.3 p.p.m. is assigned to $(C_6H_5O)_2P(O)C(OH)(CF_3)_2$ (**4**) (46%) while the doublet, $J_{FCCH} = 6$ Hz, at +74.6 p.p.m. is assigned to $(C_6H_5O)_2P(O)OCH(CF_3)_2$ (**5**) (54%), by comparison with the chemical shifts and coupling constants found for $(RO)_2P(O)C(OH)(CF_3)_2$ and $(RO)_2P(O)OCH(CF_3)_2$ (3). Addition of base catalysts such as pyridine, diethylamine, or *n*-butyl lithium resulted in complete rearrangement of **4** to **5**, as monitored by ^{19}F n.m.r.

Reaction of $(C_6H_5)_2PC(OH)(CF_3)_2$ with Excess Hexafluoroacetone or XeF_2

Reaction of diphenylphosphine (0.21 g, 1.1 mmol) with excess hexafluoroacetone (0.71 g, 4.3 mmol) gave a white solid **1** as described above. On standing for 3 days at room temperature the solid dissolved to give a yellow solution. Excess hexafluoroacetone was removed under vacuum and an oily liquid remained, identified as $(C_6H_5)_2PF_2C(OH)(CF_3)_2$ (**7**) on the basis of n.m.r. and mass spectra.

The ^{19}F n.m.r. showed a doublet, $J_{FP} = 806$ Hz, at +38.5 p.p.m. assigned to the PF_2 group and a doublet, $J_{FCCP} = 5.9$ Hz, of triplets, $J_{FCCPF} = 1.5$ Hz, at +74.5 p.p.m. assigned to the trifluoromethyl groups. The mass spectrum showed characteristic ions at *m/e* 390(M), 389(M − H), 371(M − F), 294(M − C_6H_5F), 223($C_{12}H_{10}PF_2$), 204($C_{12}H_{10}PF$).

Compound **7** was also prepared by treating a solution of $(C_6H_5)_2PC(OH)(CF_3)_2$ in $CFCl_3$ with XeF_2 (8% in CH_3CN (6)) at −196°. The mixture was kept at −63° for 2 h and then warmed to −23° for 1 h. Removal of volatile products left behind an oily liquid which gave a ^{19}F n.m.r. spectrum identical to **7** above.

Reaction of Diphenylarsine with Hexafluoroacetone

Diphenylarsine (0.84 g, 3.7 mmol) and hexafluoroacetone (1.54 g, 9.3 mmol) were kept in a sealed tube at 25° for 4 h. Removal of volatile products left behind a viscous liquid, identified as 2-hydroxy-1,1,1,3,3,3-hexafluoroisopropyldiphenylarsine, $(C_6H_5)_2AsC(OH)(CF_3)_2$ (**6**). The ^{19}F n.m.r. spectrum showed a singlet at +69.6 p.p.m. and the ^1H n.m.r. a singlet (OH) at −2.3 p.p.m. and phenyl peaks.

Anal. Calcd. for $C_{15}H_{11}F_6AsO$: C, 45.47; H, 2.80; F, 28.78. Found: C, 45.30; H, 2.95; F, 28.47.

Vibrational Spectra and Rotational Isomerism in 2-Mercaptoethanol

S. K. NANDY, D. K. MUKHERJEE, S. B. ROY, AND G. S. KASTHA

Optics Department, Indian Association for the Cultivation of Science, Calcutta 32, India

Received September 18, 1972

From the Raman and i.r. spectra of 2-mercaptoethanol in the liquid state and the temperature variation of the intensity of the Raman lines, it has been concluded that both the *trans*- and *gauche*-isomers are present in the liquid. A tentative analysis of the vibrational frequencies of the isomers has been presented.

D'après les spectres Raman et i.r. du mercapto-2 éthanol à l'état liquide et aussi d'après la variation en fonction de la température de l'intensité des raies du spectre Raman, on peut conclure que les isomères *cis* et *gauche* existent tous les deux dans le liquide. Une analyse provisoire des fréquences de vibration des isomères est présentée. [Traduit par le journal]

Introduction

The rotational isomerism in 2-haloethanols was investigated by previous workers (1–4), but complete assignments of their vibrational frequencies were recently made by Buckley *et al.* (5). The molecule of 2-mercaptoethanol is similar to that of 2-haloethanols, so it is expected to show rotational isomerism, which, however, has not yet been reported. It would, therefore, be interesting to study the vibrational spectra of the molecule in relation to its rotational isomerism in the liquid state. With this object, the Raman and the i.r. studies of 2-mercaptoethanol were made in different states and the results of the investigations are discussed in the present paper.

Experimental

A pure sample of 2-mercaptoethanol obtained from Schuchardt (Germany) was distilled under reduced pressure just before use. The Raman spectrum of the compound and the polarization character of the Raman lines in the liquid state were obtained with a Fuess glass spectrograph. The Raman spectrum of the compound in the crystalline state could not be obtained despite numerous attempts, because the substance always yielded a glassy mass whose Raman spectrum was more or less the same as that of the liquid. The i.r. absorption spectrum of the liquid was recorded with a Perkin–Elmer Model 21 i.r. spectrophotometer with rock salt optics. The frequencies of the absorption bands were checked against the i.r. bands of a polystyrene film.

Results

The Raman spectra of the liquid and its glassy mass at -110 °C are shown in Fig. 1. The Raman wave numbers with visually estimated intensity and their polarization character, as well as the wave numbers of i.r. absorption bands are given in Table 1, which also includes the probable assignments of the vibrational frequencies of the molecule.

Discussion

As the Raman spectrum of 2-mercaptoethanol in the crystalline state could not be obtained as mentioned earlier and the Raman spectrum of the glassy mass was found to be more or less the same as that of the liquid, no simplification of the solid state spectrum was available for identification of the lines due to different isomers. However, from a study of the temperature dependence of the Raman spectrum in the liquid state, it was observed that the intensity of some of the prominent Raman lines, *viz.* 295, 668 cm^{-1} increase with increase of temperature, while those of some others such as 400, 763 cm^{-1} decrease with increase of temperature. Evidently, the former lines belong to the high energy form of the molecule, while the latter belong to the low energy form, indicating thereby the existence of at least two isomeric forms in the liquid state.

The assignments given in Table 1 are straightforward with regard to the stretching vibrations of OH, CH, and SH bonds, and the vibrations of the CH_2 group and were made by analogy with similar molecules of 2-haloethanols (5) and the alkanethiols (6, 7). The frequencies arising out of the C—X stretching (X = S or O), C—C stretching, and the skeletal bending vibrations are discussed below.

In alkanethiols (6, 7) the C—S stretching vi-

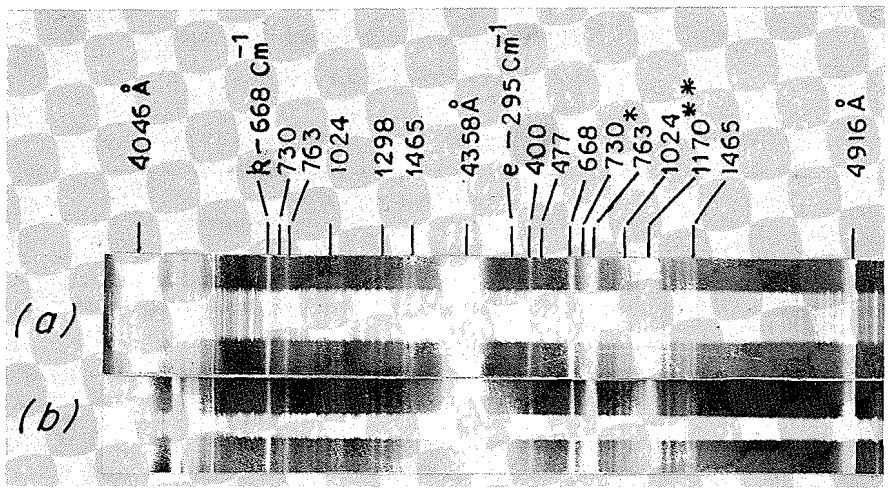

FIG. 1. Raman spectra of 2-mercatoethanol; (*a*) liquid, (*b*) glassy mass (−110 °C). *Overlapped by SH stretching frequency due to 4046 Å. **Overlapped by CH stretching frequency due to 4046 Å.

brations of the two isomers are found in the region 630–730 cm^{-1}. For example, in 1-propanethiol (6) and 2-propanethiol (7) the wave numbers 655 and 670 cm^{-1} respectively, are assigned to the C—S stretching vibration of the *gauche*-isomer, while the similar vibrations of the *trans*-isomer are at 710 cm^{-1} in both the molecules. In the case of 1,2-ethanedithiol (8) the pair of frequencies 639 and 665 cm^{-1} have been assigned to the C—S stretching vibrations of the *gauche*-isomer, while 690 and 718 cm^{-1} represent the similar vibrations of the *trans*-isomer of the molecule. In the present case, there are two Raman lines 668 and 730 cm^{-1} in this region. So in all probability the former line corresponds to a C—S stretching vibration of the *gauche*-isomer and the latter to a similar vibration of the *trans*-isomer. The corresponding i.r. bands are 665 and 735 cm^{-1}. It has already been pointed out that the Raman line 668 cm^{-1} belongs to the high energy form, so it is concluded that the *trans*-isomer of the present molecule in the liquid state is more stable than the *gauche*-isomer. This is unlike the case in 2-chloro- and 2-bromoethanols.

In the present molecule there is a depolarized Raman line of medium intensity at 763 cm^{-1} with a weak i.r. counterpart at 764 cm^{-1}. The C—SH bending vibration in alkanethiols (6–8) has been reported in the region 750–875 cm^{-1}. Therefore, the wave number 763 cm^{-1} probably represents such a vibration of the present molecule. Since this vibration, as already stated, belongs to the low energy form, it follows from the arguments given in the previous paragraph that this frequency arises from the *trans*-isomer. Similar vibration of the *gauche*-isomer is represented by the polarized Raman line 873 cm^{-1}. The corresponding i.r. band is at 875 cm^{-1}.

From Table 1, it can be seen that there are two Raman lines at 477 and 400 cm^{-1} in the spectrum of 2-mercaptoethanol. These lines have been assigned to the CCO bending vibrations of *gauche*- and *trans*-isomers respectively, following Buckley *et al.* (5) in 2-chloroethanol.

By analogy with alkanethiols (6–8) the broad and polarized Raman line, 295 cm^{-1} in the present case, is assigned to C—C—S stretching vibration of both the *trans*- and *gauche*-isomers.

The polarized Raman line 1024 cm^{-1} and the strong i.r. band at 1048 cm^{-1} are assigned to stretching vibration of the C—C bond in the two isomers as in 1,2-disubstituted ethanes.

Following the assignments of C—O stretching vibrations in the 2-haloethanols (5) the two prominent Raman lines 1055 and 1109 cm^{-1} are assigned to the *gauche*- and *trans*-isomers respectively in the present case. Similarly, the two strong i.r. bands 3200 and 3475 cm^{-1} have been assigned to OH stretching vibrations of the *gauche*- and *trans*-conformers respectively. Their low values correspond to free OH— stretching frequencies indicating the presence of intermolecular hydrogen bonding in the liquid state.

Synthesis and Nuclear Magnetic Resonance Spectroscopy of some Substituted Aryldiazoalkanephosphonates

N. GURUDATA

Department of Chemistry, Sir George Williams University, Montreal 107, Quebec

AND

C. BENEZRA AND H. COHEN

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received October 11, 1972

Six aryl diazoalkanephosphonates have been prepared and their proton and ^{13}C n.m.r. spectra analyzed. The results suggest that the carbon bearing phosphorus (and the diazo-group) is essentially sp^2 hybridized and that the dominant canonical form depends on the substitution of the aryl ring. Evidence is given for double bond character in the C—P bond.

Six diazoalcanephosphonates d'aryle ont été préparés et leurs spectres en r.m.n. du proton et du ^{13}C ont été analysés. Les résultats suggèrent que le carbone porteur du groupe phosphore (et du groupe diazo) possède exclusivement une structure sp^2 hybridée et que la forme canonique dominante dépend de la substitution sur le cycle aryle. Le caractère de double liaison dans le lien C—P a aussi été mis en évidence.

[Traduit par le journal]

Can. J. Chem., 51, 1142 (1973)

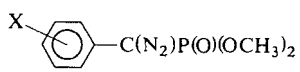
Introduction

Diazoalkanephosphonates are versatile reagents which undergo the usual diazoalkane reactions as well as exhibit carbenoid behavior (1,2). They are valuable intermediates in the synthesis of phosphorus substituted pyrazolines (1–3), and cycloalkyl, cycloalkenyl, and cycloalkylidene phosphonates (2). In the present study ^{13}C.m.r. is used to examine the ground state electron distribution of these reagents and its sensitivity to substitution effects.

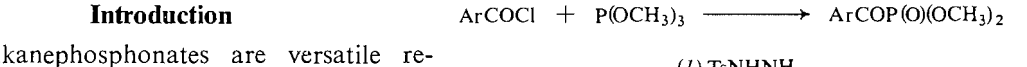
Materials and Methods

Synthesis of Dimethyl Aryldiazomethylphosphonates

Compounds **1–3** and **6** were prepared according to a general method developed by Seyferth and co-workers (1–3): (*a*) preparation of the corresponding α-ketophosphonate by an Arbuzov reaction between an acylchloride and trimethyl phosphite, (*b*) preparation of the tosylhydrazones, and (*c*) decomposition of those hydrazones with a base (Scheme 1).



1 X = *p*-CH_3O—
2 X = *p*-CH_3—
3 X = *p*-Br—
4 X = H
5 X = *p*-NO_2
6 X = *o*-CH_3O—



SCHEME 1

The *p*-nitrophenyldiazo compound, **5**, could not be prepared by this general route because $P(OCH_3)_3$ reacts with nitroaromatics to give a number of products (4). We used instead the approach of Regitz *et al.* (5), that is, nitration of dimethyl benzyl phosphonate followed by base exchange with tosyl azide. The reaction of trimethyl phosphite with *p*-nitrobenzoyl chloride is an interesting one, and details will be published elsewhere (6).

Compound **4** has already been prepared (3). All new compounds gave satisfactory elemental analysis and had i.r. data consistent with the proposed structures (see Experimental).

Experimental

General Synthetic Procedures

(a) Ketophosphonates

The starting acid chlorides, RCOCl, were prepared by addition of thionyl chloride (2.5 mol/mol of acid) to a solution of the acid in anhydrous benzene (20–30 ml) to which a few drops of pyridine had been added. Excess $SOCl_2$ was removed by distillation under vacuum (water

*All compounds recrystallized from methanol.

pump). The acid chloride was then distilled under 0.2–0.5 Torr pressure.

Two procedures were followed to prepare the ketophosphonates.

(*i*) *For solid acid chlorides*: Trimethyl phosphite (1.2 mol/mol of acyl halide) was added dropwise to a cooled solution (ice bath) of the acid chloride in anhydrous benzene (20–30 ml). The addition was completed in 1.0–1.5 h. The reaction mixture was allowed to stand for 24 h at room temperature under nitrogen, and then distilled under reduced pressure.

(*ii*) *For liquid or syrupy acid chlorides*: An analogous procedure was followed except that no benzene was used.

The data on the α-ketophosphonates are summarized in Table 1.

(b) Tosylhydrazones

A solution of the ketophonate in methanol (50 ml) was added in small portions to a solution of an equimolar amount of tosylhydrazide in methanol (50–70 ml). After standing for 24 h at room temperature, the resulting solution was reduced in volume under vacuum and the precipitated tosylhydrazone was filtered off and washed with methanol. Table 2 summarizes the results.

(c) Diazo Compounds

The tosylhydrazone was dissolved in 100–150 ml of water to which an equimolar amount of sodium carbonate had been added. The resulting solution was stirred vigorously for 24 h at room temperature and the diazo compound was then obtained by extraction with ether. (More diazo compound could be obtained if extraction from the same solution is repeated after 48h.) Purification was effected by column chromatography on silica gel (Silica Gel 60, Merck, 70-203 mesh ASTM) using ether as the only eluent. Data on the diazo compounds are given in Table 3.

Dimethyl p-nitrophenyldiazomethyl phosphonate (5)

This compound was prepared according to a procedure devised by Regitz and co-workers (5) for preparation of the diethyl analog.

Anal. Calcd. for $C_9H_{10}N_3O_5P$: N, 15.50; P, 11.42. Found: N, 15.80; P, 11.25.

I.r. ($CHCl_3$): 2100 (C=N_2), 1600 (aromatic), 1270 (P=O), 1050 cm^{-1} (P—O—C).

Nuclear Magnetic Resonance Studies

The p.m.r. spectra were obtained in dilute $CDCl_3$ solution on a Varian HA-100 Spectrometer operated in the "frequency sweep" mode. Proton decoupled ^{13}C.m.r. spectra were run at 25.15 MHz using the above spectrometer equipped with a VK-3512-1 Heternuclear Noise Decoupler and a V-3530 wide sweep accessory. A C-1024 Computer of Averaged Transients was used for accumulation. Both "noise decoupled" and "off-resonance decoupled" spectra were obtained from 1 *M* solutions in dioxan.

Results and Discussion

The p.m.r. parameters of the α-ketophosphonates are summarized in Table 1. Proton and C-13 chemical shifts and coupling constants of the aryldiazoalkanephosphonates are listed in Tables 4 and 5. No attempt has been made to analyze the aromatic region of the proton spectra. Both the proton chemical shift (3.80 ± 0.05 p.p.m.) of the methoxyl group bound to phosphorus and the phosphorus–proton coupling constant ($^3J_{POCH}$ = 12.0 ± 0.1 Hz) are insensitive to the substituent on the aromatic ring. These values are similar to

those obtained in Marmor and Seyferth (2) for alkyl and vinyl dimethyl-phosphono substituted diazoalkanes of general formula $RC(N_2)P(O)(OMe)_2$, and suggest that the substituents have little effect on the nature of the P—O—C—H bonding. This is supported by the constancy of $^1J_{CH}$ for the phosphono methoxyl groups (148.5 Hz for all the para-substituted compounds and 148.0 Hz for the ortho-substituted compound). The values of $^1J_{CH}$ were obtained from ^{13}C satellites in the p.m.r. spectra.

The resonance positions of the aromatic carbon atoms were determined from the multiplicity (in the off-resonance decoupled spectra) and the known substituent effects on the aromatic carbon chemical shifts (7). The signal due to C-7 is readily recognized by the C—P splitting while the methoxyl carbon atoms are at higher field and show a small coupling (5 Hz) to phosphorus.

The range of values for the chemical shift of the benzylic carbon (C-7, 56.9–77.2 p.p.m. from CS_2) is consistent with an sp^2 carbon atom: Feasible canonical forms include **7–10**.

If **9** is a dominant canonical form, the resonance of the benzylic carbon should be at a

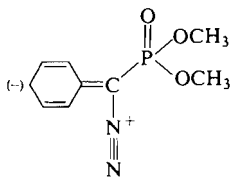
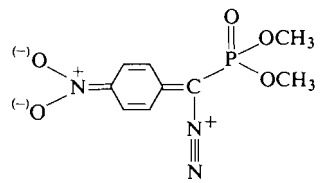
9



10

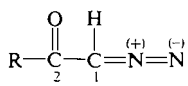
much higher field than observed. For example, in benzyl lithium ($C_6H_5CH_2Li$) the benzylic carbon absorbs at 163 p.p.m. upfield from CS_2 (8). The deshielding effect of the p-nitro group can be rationalized in terms of stabilization of **11**, in which the negative charge is distant from the benzylic carbon. The observed shielding effect of the p-methoxy group can be explained in terms of **12**, in which the center of positive charge is removed from the region of C-7. An analogous rationale holds for the shielding effect of the o-methoxy substituent.

Support for some double bond character in



11

the C–aryl bond can be found in the HMO calculations of Schuster and Polansky (9) on phenyl diazomethane. These authors reported (*i*) π-bond contribution to the C–aryl bond, (*ii*) negative charges at both the carbon and nitrogen termini of the diazomethane moiety, and (*iii*) appreciable charge delocalization into the aromatic ring. Further support may be derived from the J_{CH} coupling found by Kaplan and Meloy (10) in compounds **13**. The value of 199 Hz is consistent with an sp^2 carbon adjacent to an electron-withdrawing group. In these



13

cases, the double bond character in the C_1—C_2 bond is enough to account for a rotational barrier of 10 kcal mol^{-1}.

The Nature of the C—P Bond

The ^{13}C–^{31}P coupling constants range from 8.2 Hz for the p-OMe case to 12.3 Hz in the p-NO_2 compound. Although the small magnitude clearly indicates considerable π-character in the C—P bond (11), more detailed interpretations are not feasible. pπ–dπ carbon–phosphorus bonding in phosphonates has been proposed previously by Seyferth *et al.* (1) on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

basis of i.r. data while Berlin and Burpo (12) drew the same inference from u.v. spectral data of acylphosphonates.

Correlation with Reactivity

Various studies indicate that the behavior of diazoalkanes in cycloaddition to alkenes is predominantly nucleophilic (13) with electron-withdrawing groups reducing the reaction rates. In a recent study (14) the addition of compounds **1**–**6** to norbornadiene has been examined. After 24 h, reactions with **1**–**4** are 90% complete while that with **5** is 75% complete. The only member of the series to show appreciable difference in reaction rate (only 11% after 24 h) is **6**. It seems that, at least for this series of additions, steric factors are more significant than perturbations of electron density caused by substituents on the aromatic ring.

Radical Substitutions of Azo Compounds

HENRY LUI AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received December 20, 1972

Treatment of γ-(*p*-nitrophenylazo)-γ-valerolactone with benzoyl peroxide in benzene at 85°, yields *p*-nitroazobenzene and *p*-nitrobiphenyl. Similarly, α-methyl-α-phenylazotetrahydrofuran yields azobenzene. Radical substitution at azo nitrogen and at N-bearing benzenoid carbon are the suggested mechanisms. Such reactions of aryl azo compounds have not been reported previously.

Le traitement du γ-(*p*-nitrophénylazo)-γ-valérolactone par le peroxyde de benzoyle dans le benzène à 85° conduit au *p*-nitroazobenzène et *p*-nitrobiphényle. De la même manière, l'α-méthyl-α-phényl azotétrahydrofurane conduit à l'azobenzène. La substitution radicalaire sur l'azote de l'azo et sur l'azote porteur du carbone benzénoide a été le mécanisme suggéré. De telles réactions sur les composés azo aryles n'ont pas été rapportées jusqu'à présent.

[Traduit par le journal]

Can. J. Chem., **51**, 1148 (1973)

Reactions of radicals with organic, organometallic, and inorganic compounds include substitution at a wide variety of atoms representing many groups of the periodic table (1). Both one step (eq. 1) and two step substitutions (eq. 2) are well known mechanisms.

[1] $$A\cdot + D - E \rightarrow AD + E\cdot$$

[2] $$A\cdot + D - E \rightarrow ADE\cdot \rightarrow AD + E\cdot$$

The chemistry of nitrogen compounds does not include one step, radical substitution at that atom (1) (eq. 1, D = N), despite the attractive energetics for displacement at nitrogen of hydrazines (1). Examples of radical substitution at unsaturated nitrogen, by the addition–elimination mechanism (eq. 2), include vapor-phase nitration of methane with nitric acid (1, 2), formation of nitrosomethane dimer from reaction of methyl radicals with nitrites (1, 3–7), and reaction of alkoxy radicals with *C*-nitroso compounds to form alkyl nitrites (1, 8, 9). Some chain reactions of benzoyl azide (10) and phenyl azide (11) with stannanes and of phenyl azide with organosilicon hydrides (12) may also involve such substitution (1), *e.g.*, eq. 3.

[3] $$Bu_3Sn\cdot + C_6H_5CO-N=\overset{+}{N}=\overset{-}{N} \rightarrow$$

$$C_6H_5CO-\underset{\underset{SnBu_3}{|}}{N}-\overset{+}{N}=N \rightarrow C_6H_5CO-\dot{N}-SnBu_3 + N_2$$

Notably absent from the list is substitution at azo nitrogen[1] (eq. 4). Although hyponitrites, sulfonyl azo compounds, and azo thio ethers

[4] $$R\cdot + R'-N=N-R'' \rightarrow$$

$$\begin{matrix} R' \\ R \end{matrix}\!\!>\!N-\dot{N}-R'' \rightarrow R'\cdot + R-N=N-R''$$

react rapidly in radical chain processes with trialkyltin hydrides, they do so by radical addition at oxygen or sulfur, not at nitrogen (14–16). In the only reported case of probable radical substitution at azo nitrogen (17), that mechanism was invoked to account for a minor amount (4%) of an azo compound (eq. 4, R = R'' = CH_3, R' = $CH_2CH{=}CH_2$).

In aryl azo systems, radical aromatic substitution is an additional possibility. Although homolytic displacement of hydrogen and various other aromatic substituents (*e.g.* Cl, Br, I) is known (18), we have not found examples in which the leaving group is an azo function (eq. 5).

[5] $$R-N=N-C_6H_4Y + R'\cdot \rightarrow$$

$$R-N=N-\underset{\bullet}{\overset{R'}{\langle\bigcirc\rangle}}-Y \rightarrow R\cdot + N_2 + R'C_6H_4Y$$

[1]There is precedent for the first step of eq. 4. Both gas and liquid phase additions to azo compounds, forming substituted hydrazines, have been reported (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

We wish to report both types (eqs. 4, 5) of radical substitutions of aryl azo compounds. The experiments described below were undertaken when a minor product from thermolysis of γ-phenylazo-γ-valerolactone (**1**a) was identified as azobenzene (19).

A solution of **1**a (50 mg, 0.25 mmol) and benzoyl peroxide (**2**, 170 mg, 0.70 mmol) in benzene (4 ml) was degassed and heated at 85° in a sealed tube for 17 h. Analysis by g.l.p.c. (S.E. 30, 5%, 5 ft × 1/4 in., 155°) gave: **1**a, 40%; azobenzene, 37% (based on **1**a consumed); and biphenyl. From 1.48 g of **1**a and 5.09 g of **2** in benzene (50 ml) there was isolated, by column chromatography on neutral alumina, 0.41 g, (31%) of azobenzene.

Similarly **1**c (1.25 g, 7.0 mmol) and **2** (5.08 g, 21.0 mmol) in benzene (30 ml) gave, by g.l.p.c. following extraction with bicarbonate solution: **1**c, 57%; azobenzene, 14% (based on **1**c consumed); biphenyl; and phenylbenzoate. In a second run carried to 70% conversion of **1**c, the yield of azobenzene was 12%.

Analogous treatment of **1**b (400 mg, 1.60 mmol) with **2** (1.2 g, 5.0 mmol) in benzene (7 ml) left 10% **1**b unreacted and gave *p*-nitroazobenzene (80 mg, 24%), *p*-nitrobiphenyl (140 mg, 48%), and small amounts of compounds thought to be isomeric nitro terphenyls, on the basis of mass spectra. Qualitative experiments showed that *p*,*p*′-dinitroazobenzene also reacts with phenyl radicals in benzene to produce *p*-nitrobiphenyl.

Control experiments showed that compounds **1** are thermally stable in the reaction conditions. Therefore, the only plausible mechanisms which account for the observed products are those of eqs. 4 and 5. Biphenyl formation from **1**a and c, if it occurs, is obscured by biphenyl formation from benzoyl peroxide.

Recognition of these substitutions as mechanistic possibilities may be important in the further elucidation of the chemistry of azo compounds; the Gomberg–Bachmann reactions, for example. The reactions may be of synthetic value also, for the accessibility of aroyl peroxides and azo substrates (**1**) (20) and the absence of isomeric impurities may make up for the modest yields of unsymmetric diaryl azo compounds and biphenyls.

On the Bond Order between Atoms in Approximate SCF-MO Theory

R. J. BOYD[1]

Mathematical Institute, Oxford 0X1 3LB, England

Received September 12, 1972

The bond order between two atoms is discussed within the framework of all-valence-electron SCF-MO theories based on the Zero-Differential Overlap Approximation, and a definition of the bond order is proposed which is analogous to the procedure used to extract charge distributions from approximate SCF-MO calculations. Bond orders are calculated for a variety of small molecules and relationships similar to those found in π-electron theory between bond lengths and bond orders are observed. CNDO wave functions are used in this work, although the definition may also be used for calculations based on the INDO and NDDO approximations.

L'ordre de liaison entre deux atomes a été discuté dans le cadre des théories SCF-MO appliquées à tous les électrons de valence et basées sur l'approximation du recouvrement différentiel zéro; une définition de l'ordre de liaison a été proposée semblable au procédé utilisé dans l'extraction des distributions de charge à partir des calculs SCF-MO. Les ordres de liaison ont été calculés pour toute une variété de petites molécules et des relations, semblables à celles tirées de la théorie des électrons π, entre longueurs et ordres de liaisons, ont été observées. Les fonctions d'onde CNDO ont été utilisées dans ce travail bien que notre définition puisse être également appliquée dans les calculs basés sur les approximations INDO et NDDO.
[Traduit par le journal]

Can. J. Chem., 51, 1151 (1973)

The bond order concept has been studied in detail, at several levels of approximation, in the molecular orbital theory of π-electron systems (1). In general, the bond order associated with two atoms varies inversely with the interatomic distance and is regarded as a measure of the strength of a bond. The extensive development of the Hückel molecular orbital theory and the more sophisticated theories of conjugated molecules has established the bond order as a well-known concept of chemistry. Furthermore the formal bond order of the qualitative molecular orbital description of homonuclear diatomic molecules, defined as one half the excess of electrons in bonding orbitals over electrons in antibonding orbitals (2), is consistent with the chemist's view of single, double, and triple bonds. The purpose of this discussion is to propose a definition of the bond order between two atoms in all-valence-electron SCF-MO theories based on the neglect of differential overlap (3).

Definition

In MO theories which treat only the π-electrons explicitly, a single bond order is computed between two atoms which have valence-shell p orbitals available for bonding. Although the π-bond order may be defined in more than one way (4), the situation is much simpler than in all-valence-electron SCF theories. In the latter case, there may be more than a single atomic orbital in the basis set for each of the two atoms of interest, hence there may be many matrix elements in the charge-density and bond-order matrix **P** between the atomic orbitals of the two

[1]Present address: Department of Chemistry, University of British Columbia, Vancouver.

atoms. The **P**, or population, matrix is defined by

$$[1] \qquad P_{kl} = 2 \sum_{i}^{occ} C_{ki}{}^{*} C_{li}$$

where the summation is over occupied molecular orbitals only and C_{ki} is the coefficient of the kth atomic orbital in the ith molecular orbital. The conventional basis set consists of a 1s orbital for hydrogen and valence shell s and p orbitals for the other elements, and therefore if neither of the two atoms is hydrogen, a 4×4 submatrix of the **P** matrix is formed. It is perhaps reasonable to expect that the bond order between the two atoms should be related to the elements of this submatrix. It is not satisfactory, however, to simply sum the P_{kl} for all orbitals k on atom A and l on atom B because the P_{kl} are not necessarily invariant to rotations of the coordinate system. The electronic energy, orbital energies, and charge distributions are, of course, invariant (3) but only the P_{kl} between s orbitals and the trace of the submatrix are invariant.

In order to illustrate the invariance properties of the submatrices of the **P** matrix, it is convenient to consider some CNDO calculations (5) on carbon monoxide. Tables 1 and 2 list the submatrix for two of the many possible choices of coordinates. If the bond order were defined as the sum of the elements of the submatrix, the two orientations would give very different numerical values and, in fact, the bond order could even be negative (Table 2). Clearly the computed bond order should not depend on the orientation of the molecule with respect to the coordinate system. Nor is it reasonable to perform a Mulliken population analysis (6) to obtain the gross overlap population between the two atoms because the overlap of atomic orbitals is not included in the orthonormality condition for the molecular orbitals in SCF-MO theories which invoke the ZDO approximation (3). That is, the Mulliken population analysis is applicable to MO's which satisfy the condition

$$[2] \qquad \mathbf{C}\dagger\mathbf{S}\mathbf{C} = \mathbf{I}$$

but MO's based on the ZDO approximation satisfy the condition

$$[3] \qquad \mathbf{C}\dagger\mathbf{C} = \mathbf{I}$$

where **C**, **S**, and **I** are the coefficient, overlap, and unit matrices, respectively. Wiberg (7) has suggested that the sum of the squares of the P_{kl} for all orbitals k on atom A and l on atom B be used as an index for the character of a bond between atoms A and B. It is easily shown that Wiberg's index does not suffer from the invariance difficulty but it seems rather arbitrary to relate the bond order between two atoms to the squares of the bond orders between the orbitals of the two atoms.

*C at origin and O at (a,a,a), $3a^2 = r_{CO}{}^2$.

In view of the above discussion, the following definition is proposed for the bond order between two atoms, neither of which is hydrogen, in all-valence-electron SCF theories. It is suggested that the bond order be defined as the sum of the diagonal elements of the submatrix defined above, subject to the conditions that the submatrix has been block-diagonalized and that the sign of the matrix element between the p orbitals directed along the coordinate axis coincident with the line joining the atoms in the transformed orientation (corresponding to the block-diagonalized submatrix) is changed. The requirement that the submatrix be block-diagonalized eliminates the difficulty of deciding which orientation to choose. In the case of a linear molecule, the submatrix is block-diagonalized if the line joining the atoms lies along, or is parallel with, one of the axes of the coordinate system. Thus the submatrix of CO is block-diagonalized in Table 1 but not in Table 2. The second condition is necessary since the orbital bond order of interest is negative or positive depending on whether the net interaction is bonding or antibonding between the orbitals, as Pople and Segal (8) have noted. The importance of this condition for CO is illustrated by the submatrix in Table 1.

A similar situation is found for most molecules and usually the bond orders of σ-bonds are unrealistically small if the second condition of the above definition is ignored.

Calculation of Bond Orders

The submatrix cannot be block-diagonalized directly but rather it is necessary to operate on the entire population matrix. The block-diagonalization may be performed by an appropriate orthogonal transformation of the basis set. Thus if the original basis set is transformed to a new set, the new and original matrices, $\mathbf{P}'$ and $\mathbf{P}$, are related by

$$\mathbf{P}' = \mathbf{OPO}^{-1} \qquad [4]$$

where $\mathbf{O}$ is an orthogonal transformation matrix. Now if we rotate about the x axis by 45° and about the y axis by 54.7°, the $\mathbf{P}$ matrix for carbon monoxide which contains the submatrix of Table 2 will be transformed so that the new submatrix is identical with the one listed in Table 1. This procedure is easily programmed and provides a convenient method for calculating the bond order between two atoms. Complete details and a FORTRAN program are available upon request.

Bond orders calculated by means of the above definition are listed in Table 3 for a variety of molecules. The π and σ components of the bond order between two atoms are denoted by P_π and P_σ and their sum, the total bond order, by P_t. The results are based on some CNDO calculations (5), although it should be stressed that the conclusions of this discussion would not be altered if the INDO or NDDO approximations were used instead of the CNDO approximation. Furthermore the main points of this discussion would not be altered if a different set of parameters were used in the CNDO method, although, of course, the actual numerical values calculated for the bond order will depend on the parameters.

TABLE 3. Bond orders*

*Calculated with parameter set 1 of ref. 5.
†The bond orders for polyatomic molecules refer to the bonds in parentheses.

Discussion

The total bond orders of homonuclear diatomic molecules and their ions are identical with the values obtained by taking one half of the excess of electrons in bonding orbitals over electrons in antibonding orbitals. This is a consequence of the symmetry constraints imposed on the coefficients of the molecular orbitals in A_2 molecules. The bond orders of heteronuclear diatomic molecules are not constrained by symmetry so that the bond orders for AB molecules are not restricted to integral and half-integral values, although as in the case of the other molecules listed in Table 3 the calculated bond orders seem to be reasonable. Thus, the trends observed for the bond orders of the N_2, CO, and BF isoelectronic sequence and the C_2H_2, C_2H_4, and C_2H_6 hydrocarbon sequence correlate with the experimentally observed trends for bond lengths and force constants. These results are similar to the relationships between bond lengths and bond orders observed in π-electron theory (9). Similar observations can be made for the other bond orders listed in Table 3. As a consequence of such relationships, the bond order concept might be expected to provide a convenient means for the discussion of the lengths and strengths of bonds in large molecules where even with semi-empirical all-valence-electron methods it may not be practical to calculate equilibrium geometries and harmonic force constants.

It is worth noting that if the bond order is computed by means of Wiberg's index (7), the π-bond orders are 0.5, 2.0, 2.0, 0.5, and 0.0 and

the σ-bond orders are 1.15, 1.08, 1.00, 1.00, and 1.00 for B_2, C_2, N_2, O_2, and F_2, respectively. The Wiberg index appears to underestimate π-bonding in some situations and to overestimate σ-bonding in others with the result that the bond order of C_2 is predicted to be comparable to that of N_2. Similarly the Wiberg index suggests that the bond in the C_2 molecule is stronger than the C—C bond in acetylene contrary to the observed harmonic force constants of 12.2 and 16.3 mdyn/A for C_2 (10) and C_2H_2 (11) respectively, although the Wiberg index appears to give reasonable results for the C_2 hydrocarbons (2.94, 2.01, and 1.02 for C_2H_2, C_2H_4, and C_2H_6, see also ref. 12).

The definition of the bond order between two atoms, as proposed in this discussion, does not include the off-diagonal elements of the block-diagonalized submatrix. This may appear to be a serious omission because the interaction of an s orbital on one atom and a p orbital on a second atom can contribute to the formation of a bond between the two atoms provided the overlap of the two orbitals is not zero by symmetry. After allowing for the signs of the interactions, the inclusion of the off-diagonal elements would increase the σ-bond order by about 0.8 in CO (see Table 1) and by amounts ranging from 0.6 in F_2 to 1.5 in B_2 for the homonuclear diatomic molecules. Similarly the σ-bond order of the hydrocarbons in Table 3 would be approximately doubled. Clearly, the effect of including the off-diagonal elements can be quite large. However these terms are omitted here because the definition proposed above leads to bond orders which seem chemically reasonable in view of the preceding discussion. Furthermore the exclusion of the off-diagonal elements is analogous to the procedure commonly used for carving up the charge distribution in approximate SCF-MO theories based on the ZDO approximation. Thus atomic charges are normally obtained from the diagonal elements of the **P** matrix.

And finally it should be mentioned that the definition may be applied to bonds between two atoms where one of the atoms is hydrogen. In this case it is necessary to consider a 1×4 submatrix and the bond order is obtained by adding the elements of the submatrix once it has been reduced to the form $(a\ b\ 0\ 0)$ with the sign of the second element being taken into account. The bond order for through space H–H interactions is simply equal to the invariant P_{kl} matrix element between the 1s orbitals on the H atoms.

The author would like to thank Professor C. A. Coulson, F.R.S., Dr. James P. Snyder, and Dr. M. A. Whitehead for helpful discussions and their interest in this work. The award of a National Research Council of Canada Postdoctorate Fellowship is gratefully acknowledged.

On the Assignment of the Infrared Spectrum of Ethylene Oxide

JOHN E. BERTIE AND DAVID. A. OTHEN[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 18, 1972

In the infrared spectrum of gaseous ethylene oxide the A_1 C—H stretching and CH_2 wagging modes are assigned at 3018 and 1148 cm^{-1}, respectively. The previous assignment of the B_1 ring deformation mode at about 890 cm^{-1} is not consistent with the spectrum, but its correct assignment is not clear. The infrared spectrum of ethylene oxide liquid and the frequencies of the fundamental modes in the gas and liquid states are presented.

Dans le spectre infrarouge de l'oxyde d'éthylène gazeux, la bande d'élongation A_1 de C—H et les modes d'oscillation du CH_2 ont été attribués respectivement à 3018 et 1148 cm^{-1}. L'attribution précédente sur la déformation B_1 du cycle à environ 890 cm^{-1} n'est pas compatible avec le spectre mais son attribution exacte n'a été éclaircie. Le spectre infrarouge de l'oxyde d'éthylène liquide et les fréquences de vibrations fondamentales de l'état gazeux et liquide ont été présentés. [Traduit par le journal]

Can. J. Chem., **51**, 1155 (1973)

Introduction

The infrared spectrum of gaseous ethylene oxide has been assigned three times in recent years (1–3). If allowance is made for the unavoidably lower frequency accuracy and resolution of the earlier work (1), the three assignments agree for all modes except the A_1 C—H stretch, the A_1 CH_2 wag, and the B_1 ring deformation. The A_1 C—H stretch has not been identified in the spectrum of the gas and has been assigned by two (2, 3) groups as being coincident with the B_1 C—H stretch. The A_1 CH_2 wag has been assigned only from Raman or infrared spectra of the liquid, while the B_1 ring deformation has been assigned at about 890 cm^{-1} (1, 2) and at 876 cm^{-1} (3). In the course of a study of the infrared spectrum of ethylene oxide clathrate hydrate (4), the spectrum of gaseous ethylene oxide was obtained under higher resolution than appears to have been achieved before. This spectrum has enabled the A_1 C—H stretch and the A_1 CH_2 wag to be assigned, and has shown that the assignment of the B_1 ring deformation at 890 cm^{-1} is not consistent with the spectrum.

The infrared spectrum of liquid ethylene oxide has been partially tabulated in the literature (3) but no spectrum has been published. This paper therefore includes the infrared spectrum of liquid ethylene oxide at 210 ± 5 °K.

[1]Present address: Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia.

Experimental

Matheson 99.7% ethylene oxide was triply distilled in vacuum from −40 °C before use. Gaseous samples were held at ambient temperature in a 10 cm path length, glass, gas cell fitted with cesium iodide windows using glyptal cement. Liquid samples were condensed into an evacuable space between cesium iodide windows held in a metal cryostat of conventional design and were maintained at 210 ± 5 °K. The path length is uncertain but the cesium iodide windows were held apart by a brass or mylar spacer 0.002 or 0.010 in. thick. The spectra were recorded on a Beckman I.R. 12 spectrophotometer, which was calibrated to ±0.5 cm^{-1} below 2000 cm^{-1} and ±1 cm^{-1} above 2000 cm^{-1} using water vapor, ammonia, carbon dioxide, and hydrogen chloride (5). The gaseous samples were studied at 0.5 cm^{-1} resolution, and the liquid samples at 1.5 cm^{-1} resolution.

Results and Discussion

Ethylene oxide belongs (6) to Shimanouchi's (7) type 23, with 100 frequency divisions (7) equalling about 64 cm^{-1}. Thus an A_1 vibration yields a B type band with the two broad Q branches about 12 cm^{-1} apart, a B_1 vibration yields the PQR-structured A type band with the P–R separation equal to about 40 cm^{-1}, and a B_2 vibration yields the PQR-structured C type band with a P–R separation of about 54 cm^{-1} (6, 7). These predictions neglect the variation of the rotational constants with vibrational state, but this is not believed to significantly effect the conclusions drawn in this paper.

Figure 1 shows the infrared spectrum of gaseous ethylene oxide between 2960 and 3160 cm^{-1}. The assignment of the B_2 asymetric CH_2

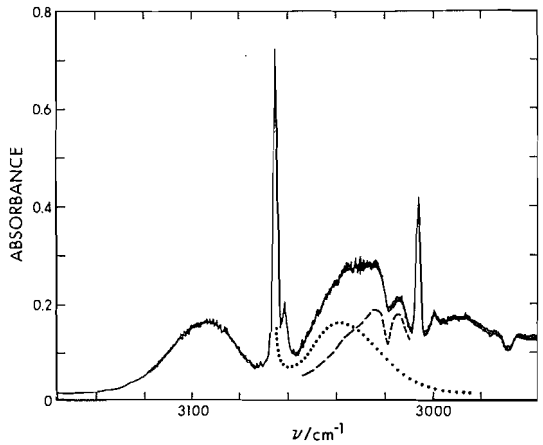

FIG. 1. Solid line, the infrared spectrum of gaseous C_2H_4O at 300 °K; 10 cm path length and 1.7 cm of mercury pressure. Dotted line, the mirror image of the R branch of the 3065.2 cm^{-1} band. Dashed line, the curve obtained by subtracting the dotted line from the observed spectrum, showing the presence of a *B* type band at 3018 cm^{-1}.

stretch at 3065.2 cm^{-1} and the B_1 symmetric CH_2 stretch at 3005.9 cm^{-1} is unambiguous. Subtraction of the P branch, indicated by the dotted line in Fig. 1, which is the mirror image of the R branch of the 3065.2 cm^{-1} band, from the observed spectrum leaves the dashed line shown in Fig. 1. The shape of the dashed line indicates the presence of a *B* type band at 3018 cm^{-1}, which can be immediately assigned to the A_1 symmetric CH_2 stretching mode. The deduction of the presence of this *B* type band does not depend upon the above subtraction. In the spectrum of gaseous ethylene oxide the only feature that causes an increase in absorbance such as is seen just above 3018 cm^{-1} in Fig. 1 is the rise to one of the Q branches of a *B* type band. Further support for this identification is that the two resulting Q branches are about 10 cm^{-1} apart, compared to the 12 cm^{-1} expected for a *B* type band.

The assignment of the A_1 symmetric CH_2 stretch at 3018 cm^{-1} and of the B_1 symmetric CH_2 stretch at 3005.9 cm^{-1} is consistent with the assignment of the corresponding modes in methylene cyclopropane (8) where the A_1 mode is at 2999.3 cm^{-1} and the B_1 is at 2996.0 cm^{-1}. Further support for this assignment comes from the infrared spectra of liquid (Fig. 2) and enclathrated ethylene oxide (4). The liquid shows a strong band at 3003 cm^{-1} which has a slight but definite shoulder at about 3014 cm^{-1} while in ethylene oxide clathrate hydrate at 100 °K distinct lines are resolved at 2998 and 3014 cm^{-1}.

The solid line in Fig. 3 shows the infrared spectrum of ethylene oxide gas in the region of 1150 cm^{-1}. This has been interpreted in terms of one *A* type band and one *C* type band only (1–3). The two features on the high frequency sides of the two strong Q branches strongly suggest the existence of a *B* type band in this region. The dotted line in Fig. 3 represents the *B* type band observed at 1270.3 cm^{-1} drawn with suitable intensity. Subtraction of this dotted curve from the observed spectrum yields the residual band shown as the dashed line in Fig. 3. This residual band can be readily interpreted in terms of an *A* type band at 1150.6 cm^{-1} and a *C* type band at 1142.0 cm^{-1}. The R branches of these two bands overlap to yield the peak at 1170 cm^{-1}, while the P branch of the *A* type band at 1150.6 cm^{-1} causes the peak at 1135 cm^{-1} and the P branch of the *C* type band at 1142.0 cm^{-1} causes the peak at 1117 cm^{-1}. Some distortion is evident in the residual bandshape, but this could well arise from imperfections in the bandshapes assumed. It seems clear that the A_1 CH_2 wag can be assigned to a *B* type band at 1148 cm^{-1} in the spectrum of ethylene oxide gas.

This assignment must rest on the merits of the arguments presented above and on the fact that no other band of significant intensity appears in the spectrum between 900 cm^{-1} and the ring breathing mode at 1270 cm^{-1}. In the Raman spectrum of the liquid this mode is clearly identified by the polarized line at 1122 ± 2 cm^{-1}, with the B_1 and B_2 modes at 1151 cm^{-1} (1, 3). The infrared spectrum of the liquid shows the same bands as the Raman spectrum, while the infrared spectrum of the clathrate shows ethylene oxide absorption at 1123 and 1147 cm^{-1}. Thus, an argument against the assignment of the A_1 CH_2 wag at 1148 cm^{-1} in the infrared spectrum of the gas is the gas-to-liquid frequency shift of about −25 cm^{-1} that it implies. This argument is not compelling, however, because the B_2 CH_2 rock appears to shift by −22 cm^{-1} from 821.2 cm^{-1} in the gas (refs. 1–3 and this work) to 799 cm^{-1} in the liquid (ref. 3 and this work).

Figure 4 shows the infrared spectrum of ethylene oxide gas in the region of 850 cm^{-1}. The A_1 ring deformation is unambiguously assigned to the *B* type band at 876.9 cm^{-1}, and the Q branch of an *A* or *C* type band clearly occurs at

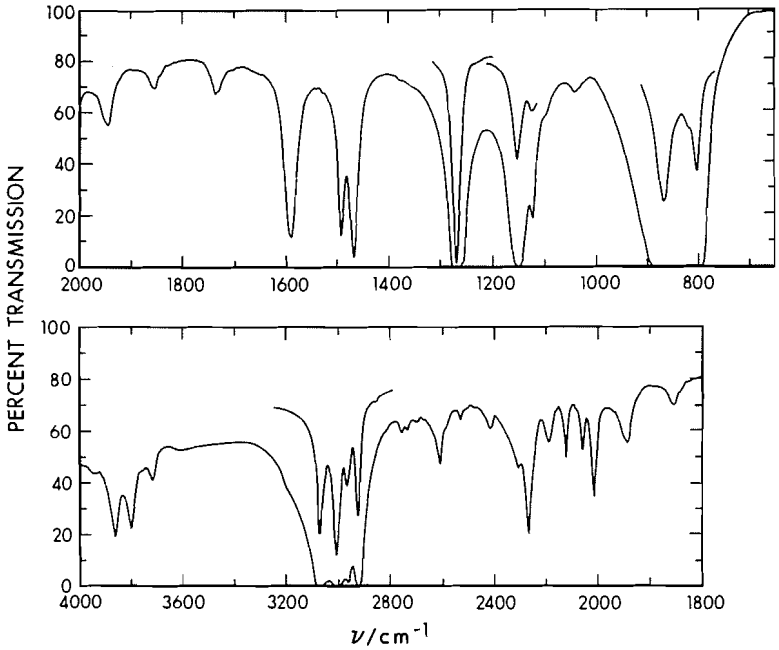

FIG. 2. The infrared spectrum of liquid ethylene oxide at 210 °K.

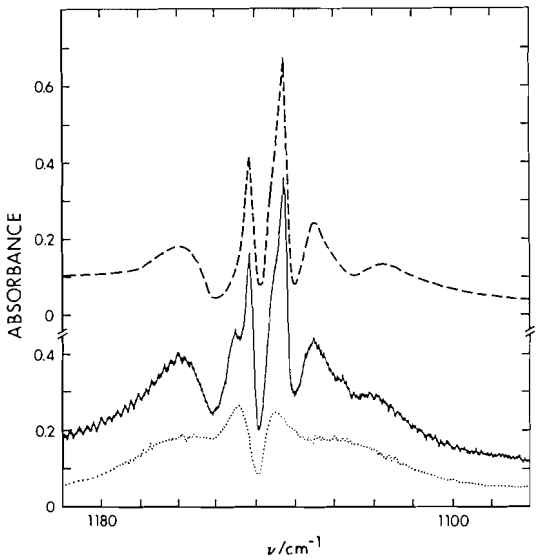

FIG. 3. Solid line, the infrared spectrum of gaseous C_2H_4O at 300 °K; 10 cm path length and 30 cm of mercury pressure. Dotted line, the *B* type band at 1270.3 cm^{-1} drawn with appropriate intensity. Dashed line, the curve obtained by subtracting the dotted curve from the observed spectrum.

821.2 cm^{-1} and has been assigned to the B_2 CH_2 rock (1–3). Earlier authors (1, 2) have assigned the B_1 ring deformation to a feature at about 890 cm^{-1}, but clearly this region contains only the *B* type band. Aleksanyan and co-workers (3) assigned the B_1 ring deformation at 876 cm^{-1} in the infrared spectrum of the solid, and the 867 cm^{-1} Raman line of the liquid is depolarized, suggesting that the B_1 ring deformation is indeed very close to the A_1 ring deformation at this frequency. On this basis the most reasonable assignment for the B_1 ring deformation in the infrared spectrum of the gas is to propose that the Q branch of its *A* type band coincides with the lower frequency Q branch of the *B* type band, at about 872 cm^{-1}. The broad peak at about 855 cm^{-1} is at about the right frequency for the P branch of the *A* type band, but its R branch is not detectable.

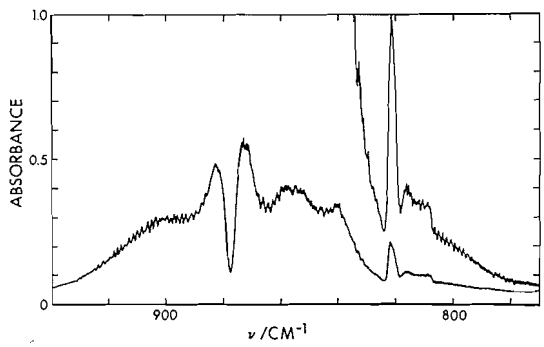

FIG. 4. The infrared spectrum of gaseous C_2H_4O at 300 °K; 10 cm path length and 1.7 and 8.7 cm of mercury pressure.

TABLE 1. The frequencies in cm^{-1} of the fundamental vibrations of ethylene oxide

Assignment			Frequency (cm^{-1}) Gas	Liquid
CH stretch	A_1	ν_1	3018	3014
	A_2	ν_6	—	—
	B_1	ν_9	3005.9	3003
	B_2	ν_{13}	3065.2	3072
CH_2 deformation	A_1	ν_2	1498.4	1492
	B_1	ν_{10}	1471.9	1468
Ring vibration	A_1	ν_3	1270.3	1268
	A_1	ν_5	876.9	864
	B_1	ν_{12}	872	864
CH_2 wag	A_1	ν_4	1148	1124
	B_1	ν_{11}	1150.6	1150
CH_2 rock	A_2	ν_8	—	815
	B_2	ν_{15}	821.2	799
CH_2 twist	A_2	ν_7	—	—
	B_2	ν_{14}	1142.0	1150

Many questions remain to be answered concerning this region of the spectrum. The lowest frequency fundamental is at 821.2 cm^{-1}. Therefore hot bands and difference bands should be exceedingly weak at 300 °K, and it is not at all obvious what transitions could contribute to the spectrum between 780 and 860 cm^{-1} apart from the fundamentals. Yet the spectrum in this region is unexpectedly complicated (Fig. 4), with sharp increases in absorption at about 808 and 818 cm^{-1}, and a weak but definite maximum at 840 cm^{-1}. Further, very weak Q branches occur at 1626, 1636, 1643.1, and 1648 cm^{-1} in the spectra of our samples. Even if the possible frequencies of the A_2 modes is considered no assignment of these frequencies is obvious from the present assignment of the fundamentals.

For convenience, the frequencies obtained in this work for the fundamental modes of ethylene oxide in the gas and liquid states are given in Table 1.

We thank the National Research Council of Canada for their support of this work and for a scholarship to one of us (D.A.O.).

The Infrared Spectrum of Ethylene Oxide Clathrate Hydrate at 100 °K between 4000 and 360 cm^{-1}

JOHN E. BERTIE AND DAVID. A. OTHEN[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 18, 1972

The infrared spectra of characterized samples of ethylene oxide hydrate made from 100% H_2O, 99.7% D_2O, and several dilute isotopic solutions, are presented between 4000 and 360 cm^{-1}. The similarity between the absorption by the water molecules in the hydrate and in ice I is discussed. The frequency and halfwidth of the OH and OD stretching modes of isolated HDO molecules in the hydrate are related to those in the disordered ice phases; the frequencies correlate rather well with the weighted-mean hydrogen bond lengths in these phases.

The ethylene oxide vibrations show sharp, single-line absorption. The only exceptions are the ring-breathing mode which appears as a doublet, separated by 2 cm^{-1}, with much weaker absorption about 13 cm^{-1} away on either side, and the ring deformation modes which interact with the $\nu_R(H_2O)$ modes. The possible causes of this behavior are discussed, but no firm conclusions can be drawn. The sharpness of the absorption by enclathrated ethylene oxide, compared to that by liquid ethylene oxide, is briefly discussed in the light of modern theories of bandshapes in liquids.

Les spectres infrarouge des échantillons caractérisés d'hydrate d'oxyde d'éthylène composé de 100% H_2O, 99.7% D_2O et de diverses solutions diluées isotopiques, sont rapportés entre 4000 et 360 cm^{-1}. La similitude de l'absorption par les molécules d'eau dans l'hydrate et dans la glace I a été discutée. La fréquence et la largeur à mi-hauteur des modes d'élongation du OH et OD des molécules isolées de HDO dans l'hydrate ont été reliées à celles des phases désordonnées de la glace ; la corrélation des fréquences est plutôt bonne avec la moyenne pondérée des liaisons hydrogène dans ces phases. Les vibrations de l'oxyde d'éthylène se présentent sous la forme d'une raie simple et fine. Les seules exceptions proviennent des modes d'élongation du cycle qui donnent un doublet séparé de 2 cm^{-1} en plus d'une absorption beaucoup plus faible de part et d'autre de ce doublet dont l'écart est d'environ 13 cm^{-1} ; et, les modes de distorsions qui entrent en interaction avec les modes $\nu_R(H_2O)$. Les causes possibles de ce phénomène ont été discutées mais aucune conclusion ferme n'a pu être tirée. La finesse de l'absorption du clathrate de l'oxyde d'éthylène, comparée à celle de l'oxyde d'éthylène liquide, a été brievement discutée en fonction des théories modernes sur les formes de bandes dans les liquides.

Introduction

The far infrared spectrum of ethylene oxide hydrate at 100 °K has recently been published (1). This paper presents the spectrum of the same compound between 4000 and 360 cm^{-1}. These two papers report the first extensive study of well-characterized samples of a clathrate hydrate. The relevant literature has been summarized previously (1).

Experimental

The experimental methods used in this work have been reported (1). For the present work some samples were prepared by condensing excess ethylene oxide into an evacuated flask containing de-gassed water, and allowing crystallization to proceed to completion at 5 °C, while the remaining samples were prepared by the methods described earlier (1). Method *ii* of ref. 1 was found to yield the purest hydrate samples.

Cesium iodide windows were used in the infrared cells, and the spectra were recorded using a Beckman I.R. 12 spectrophotometer fitted with a fiducial marker. The marks were calibrated to ± 0.4 cm^{-1} below 2000 cm^{-1} and ± 1.0 cm^{-1} above 2000 cm^{-1} using the standard gases (2). The resolution was generally 1.5 cm^{-1} but individual bands were studied at 0.5 cm^{-1} resolution. For many of the spectra the transmission scale was expanded using the Beckman variable scale expansion facility. Propane, propylene, and Freon 13 were used as mulling agents. The sample temperature was very close to the melting point of Freon 13, 92 °K, and is cited as 100 $\pm$ 10 °K to allow for slight heating which was applied to keep the Freon 13 in the liquid state. This temperature is consistent with that measured at the copper block which contained the sample and windows. The X-ray camera was calibrated using sodium chloride at room temperature (3).

Results and Assignment

The X-ray photographs clearly characterized the samples as the structure **1** clathrate hydrate,

and gave the unit cell parameter as 11.88 ± 0.03 Å for the hydrate and 11.90 ± 0.03 Å for the deuterate at about 120 °K. The presence of ice or solid ethylene oxide impurity was detected in some samples, enabling the spectral effect of these impurities to be determined, as discussed later.

The infrared spectra of ethylene oxide hydrate and deuterate in the three mulling agents at 100 °K are shown in Figs. 1 and 2, while, for convenience, Fig. 3 shows the spectra of the hydrate and deuterate deduced from these original spectra. The frequencies of the features in the spectra are listed in Table 1, along with their relative intensities and assignments. The frequency accuracy is about ±5 cm^{-1} for the bands due to water, except as noted in the table, ±1 cm^{-1} for the stronger, and ±2 cm^{-1} for the less intense, ethylene oxide bands. The assignment of the features to water or ethylene oxide absorption follows from the isotope shift of the water absorptions.

The detailed assignment of the H_2O and D_2O absorption follows immediately from that for ice I (4). The absorption by the water molecules in the clathrate is extremely similar to that in ice I, as illustrated by the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands, which resemble poorly resolved bands of ice I, and the $\nu_R(D_2O)$ band which is almost identical to that in ice I. The $\nu_R(H_2O)$ band in the clathrate is complicated by ethylene oxide absorption at 800 and 860 cm^{-1}. The presence of small amounts of ice I in the samples caused no detectable change in the absorption by H_2O or D_2O, and the same experimental techniques reproduced the published (4) spectra of ice I perfectly, so the similarity between the spectrum of the clathrate and that of ice I does not arise from error. The condensation of water vapor onto the cell windows during assembly is easily eliminated by proper technique, and does not influence the spectra presented. The peak at 3277 cm^{-1} in the spectra of the deuterate (Figs. 2 and 3) is due to $\nu_{OH}(HDO)$ and not to ice.

The detailed assignment of the ethylene oxide absorptions follows in general from that of pure ethylene oxide (5). In the first spectra recorded the only ethylene oxide absorptions clearly seen were the 1268 cm^{-1} band in the hydrate and those at 872, 1268, and about 3000 cm^{-1} in the deuterate. The remaining bands were only detected by repeated study using all three mulling agents and expansion of the transmission scale. Except for the combination bands between 2900 and 2980 cm^{-1} only the fundamental transitions were observed, and the corresponding absorption is shown in Fig. 4. Only the 1268 cm^{-1} band was clearly observable in the spectra of both the hydrate and the deuterate, the remainder being more or less masked by the water absorption in one of the two spectra. It is noteworthy that in spite of this overlap with either the H_2O or the D_2O absorption, only the absorption near to 870 cm^{-1} shows a significant frequency shift or change in shape between the spectra of the hydrate and deuterate. The greatest frequency shift for the other bands is 3 cm^{-1} at 3066 cm^{-1}, and this undoubtedly arises from the difficulty of measuring this band in the hydrate on the side of the intense water absorption.

The authenticity of the absorptions shown in Fig. 4 as bands due to enclathrated ethylene oxide is proved by comparison with the spectra of liquid and solid ethylene oxide (5–7) and of the clathrate hydrate containing solid ethylene oxide impurity. The absorption by the clathrate is sharper than that by liquid ethylene oxide, the halfwidths ranging from 2 to 5 cm^{-1} in general (Fig. 4), and does not show the factor group splitting seen in the spectrum of the solid (6, 7).

The band at 3069 cm^{-1} has a half-width of 10 cm^{-1}, much greater than that of any other ethylene oxide band. This band is assigned to the B_2 C—H stretching mode of ethylene oxide, and it seems probable that the breadth is due to the A_2 mode which is activated by the low site symmetry in this disordered solid. The 1260–1270 cm^{-1} region shows the only fine structure seen in the spectrum. Under 1.5 cm^{-1} resolution this band (Fig. 4) shows a peak and a weak shoulder, but under 0.4 cm^{-1} resolution the doublet shown in Fig. 4 is obtained. At this resolution the noise level is high and, for clarity, the curve presented has been smoothed to show only the reproducible features. Only one fundamental, the ring breathing mode, is expected in this region and, while the 1255 cm^{-1} feature can be assigned to the fundamental of ethylene oxide, $^{13}C^{12}CH_4O$, the origin of three other features, rather than the one expected, is unclear as discussed later. The relative intensities of the various bands in this region were studied for different samples, some of which had the uniform composition $6.7C_2H_4O.46H_2O$ and some of which had the average stoichiometry $6.4C_2H_4O$

The dotted lines indicate mulling agent absorption.

.46H_2O, judging from the conditions of preparation (1, 8). No changes in the relative intensities were observed for different samples, but the experimental difficulties made the sensitivity such that the possibility of observing an effect in the samples available was marginal.

The assignment of the ethylene oxide bands between 800 and 900 cm^{-1} requires some comment. The features at 881, 872, and 807 cm^{-1} are assigned to the B_1 and A_1 ring deformations and the B_2 CH_2 rock, respectively, by analogy with the assignment for gas and liquid ethylene oxide. The shoulder at 810 cm^{-1} appears to be real, although it is slightly masked by mulling agent absorption (Fig. 4), and it can be assigned to the A_2 CH_2 rock. This mode has been assigned at 818 cm^{-1} in the spectrum of the solid and the liquid (7).

The infrared spectra of ethylene oxide hydrate made from dilute solutions of H_2O in D_2O or vice versa are identical to those of the pure hydrate or deuterate, except for the appearance of the ν_{OH}(HDO) or ν_{OD}(HDO) absorption, due to the OH or OD stretching mode of HDO molecules surrounded by D_2O or H_2O molecules, respectively. These absorptions proved to yield the most sensitive test for ice as an impurity in the clathrate. Curve *a* of Fig. 5 shows the ν_{OD}(HDO) band in a sample of pure clathrate formed from 95% H_2O and 5% D_2O, and curve *b* of Fig. 5 shows the same band in a sample of the same isotopic composition but containing some ice, as shown by the X-ray photographs. Curve *a* shows a peak at 2427 ± 3 cm^{-1} with a halfwidth of 80 ± 10 cm^{-1}, while curve *b* shows a more pointed peak at 2419 cm^{-1} with a halfwidth of about 65 cm^{-1}. The assignment of these differences to the influence of ice as an impurity in the clathrate was confirmed by keeping the sample used to obtain curve *a* of Fig. 5 at −2 °C for 12 h in a closed vessel and then re-cooling it to −196 °C. This procedure should have caused some decomposition of the hydrate to ice I*h*. The X-ray pattern of the original sample showed no ice lines, and after the above treatment a very weak but definite indication of the ice lines was obtained. The sample after treatment yielded curve *c* of Fig. 5, clearly proving

the assignment. These differences in the $\nu_{OD}(HDO)$ peak shape are accompanied by measureable differences in the relative intensities of the $\nu_{OD}(HDO)$ peak for a 5 atom% D sample and the 1268 cm^{-1} ethylene oxide peak. The ratio of the intensities $\nu_{OD}(HDO)/EO.1268$ is 0.8 to 0.9 for a pure sample and 1.1 for a sample containing enough ice to show clearly on the X-ray pattern, such as that used for curve *b* of Fig. 5. The sample that yielded curve *c* of Fig. 5 showed a ratio of 1.0. Similar effects were noted for the $\nu_{OH}(HDO)$ peak. These peaks in the pure compound are rather flat-topped and broad, and the measurement of their frequency and halfwidth is difficult. From a large number of spectra of samples made from 1, 2, and 5% of D_2O in H_2O the best values of the frequency and halfwidth of the $\nu_{OD}(HDO)$ peak are 2427 $\pm$ 3 cm^{-1} and 80 $\pm$ 10 cm^{-1}, respectively, while from the spectra of samples containing from 0.3 to 5% of H_2O in D_2O the corresponding values for $\nu_{OH}(HDO)$ are 3272 $\pm$ 10 cm^{-1} and 125 $\pm$ 15 cm^{-1}. The samples with the lower percentages of the impurity isotope did not show significantly smaller halfwidths than the 5% samples. The relative intensities of the band in the different samples showed that this was not due to significant uncertainty in the isotopic composition.

Discussion

Absorption by the Water

The water molecules in ethylene oxide hydrate at 100 °K are orientationally disordered and reorient extremely slowly (ref. 1 and references therein). Thus, apart from the inclusion of ethylene oxide molecules in the structure, the clathrate system is similar to ice and the discussion of the vibrational spectrum of the water molecules must parallel that for ice. The comparison of the ethylene oxide absorption frequencies, and bandshapes in so far as they can be determined, in the spectra of the hydrate and deuterate shows that the vibrations of the water molecules do not couple with those of the ethylene oxide molecules, except for the $\nu_R(H_2O)$ band which appears to interact with the ring deformation modes of ethylene oxide at about 870 cm^{-1}.

The water molecule spectrum of the deuterate, and that of the hydrate apart from the $\nu_R(H_2O)$ band, is extremely similar to that of ice I. It is not straightforward to interpret this observation in terms of the structural differences and similarities between these phases, because the detailed assignment of the features in the mid-infrared spectrum of ice I is not known (4). It is clear (4) that all crystal vibrations based on the water molecule vibrations are infrared active, and that the spectra must be related to the density of vibrational states through an intensity distribution function. A comparison of the infrared (4) and Raman (9) spectra of ice I shows that the Raman intensity distribution function is extremely asymmetric with respect to the band of OH stretching frequencies in ice. Further the infrared intensity distribution function is extremely asymmetric with respect to the band of water rotational vibrations (4, 10, 11). However, the atomic displacements that occur at frequencies corresponding to the various peaks and shoulders in the spectrum of ice are quite unknown, other than that they involve OH stretching or rotational vibrations, etc. For the $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands there is the added complication that the first overtone, $2\nu_2$, of the HOH or DOD angle deformation modes may gain intensity from the stretching modes through Fermi resonance and influence the spectrum significantly. $2\nu_2$ does appear to influence the Raman spectrum of liquid water (12) and the infrared spectra of H_2O dissolved in various organic bases (13), and it seems possible that it also contributes to the spectrum of ice I. However the infrared (4) and Raman (9) spectra of ice I contain many features in the region of the OH or OD stretching modes, and it is clear that an assignment in terms of ν_1, ν_3, and $2\nu_2$ is a gross oversimplification, and that the correct assignment is unknown.

Because of these uncertainties the only discussion that can be given of the spectrum of the water molecules in the clathrate is to point out certain empirical relations between the structure and spectra of the clathrate and ice I. This discussion will be limited to the influence of the different hydrogen bond lengths in the two phases. Even with this simplification the conclusions are limited and there is, therefore, no justification for including a discussion of the influence of the O—O—O angles or the effect of non-nearest neighbors, except to point out that the angles around the oxygen in the hydrate are not all tetrahedral, as they are in ice I, although the weighed mean angle is 109.6° (14).

In ice I*h* all the hydrogen bond lengths are very close to 2.75 Å at 100 °K (ref. 1 and refer-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ences therein), while in the hydrate at 100 °K 52% of the hydrogen bonds are 2.75 Å long, 26% are 2.79 Å long, and the remainder are either 2.74 or 2.82 Å long (ref. 1 and references therein). The $\nu_{OH}(H_2O)$ and $\nu_{OD}(D_2O)$ bands in the hydrate and in ice I (4) are at the same frequencies and their shapes are very similar, with the band in the hydrate resembling a poorly resolved spectrum of ice I. It is, therefore, reasonable to conclude that the bandshapes and frequencies in the clathrate are primarily determined by the 2.75 Å bonds. The breadth of the features, which causes the appearance of a poorly resolved spectrum of ice I, can then be mainly attributed to the effect of the 2.79 Å bonds with smaller effects due to the 2.74 and 2.82 Å bonds. Phenomenologically the spectra and structure of the hydrate and ice I*h* can be understood in this way, as can the corresponding relations for ice I*h* and ice I*c* (4).

Theoretically this discussion is less satisfactory, because the conclusion must be drawn that the significant differences between the nearest-neighbor distances and long range packing in the hydrate and ice I are not great enough to greatly influence the density of states or the intensity distribution function. However, Shawyer and Dean (10) have shown that the OH stretching modes in ice I*h* are quite localized as a result of the disorder. Therefore, the density of states curve and the intensity distribution curve must represent some average of the effects of the disorder over the whole crystal. It is possible that this reduces the sensitivity of the spectrum to structural changes.

The discussion of the ν_R, ν_2, and the combination bands in the hydrate must follow the above discussion, with the added comment that the $\nu_R(D_2O)$ bands in the hydrate and ice I are almost identical, and therefore the structural differences have even less effect than for the OH and OD stretching bands.

The featureless breadth of the $\nu_{OH}(HDO)$ and $\nu_{OD}(HDO)$ bands in the hydrate provides further evidence of the orientational disorder in the clathrate structure. The ratio of their frequencies is 1.350, which is consistent with the corresponding ratio for the other ices (4, 15, 16) and shows that the anharmonicity of the OH stretching vibrations is similar in all of these phases. Kamb and Prakash (17) have shown that the hydrogen bond length and the $\nu_{OD}(HDO)$ frequency in ice I do not correlate well with the corresponding

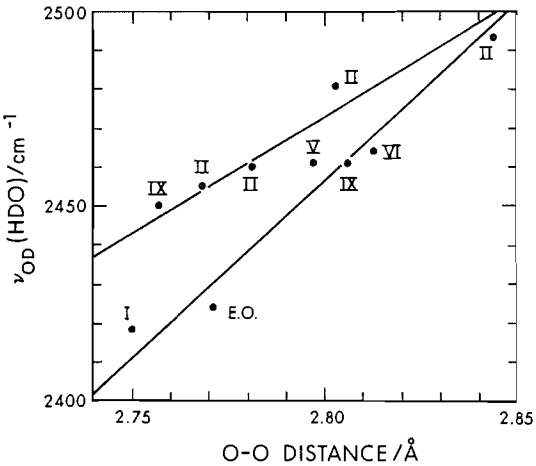

FIG. 6. Graph: $\nu_{OD}(HDO)$ *vs.* O—O distance for ordered phases or weighted-mean O—O distance for disordered phases. The Roman numerals refer to the ice phases and E.O. indicates ethylene oxide hydrate.

parameters in ices II and IX. In Fig. 6 Kamb's data (17, 18) is replotted along with the frequencies of $\nu_{OD}(HDO)$ in ethylene oxide hydrate, ice V (15) and ice VI (16) which are plotted against the weighted mean hydrogen bond length in these phases (1). As Kamb and Prakash showed (17) the four points for ice II and one of the points for ice IX lie close to a line with a slope of 510 cm^{-1} Å^{-1}. The data for ices I*h*, I*c*, V, and VI, and ethylene oxide hydrate, and one of the points for ice IX, lie further from this line, but all lie within 8 cm^{-1} of a second straight line with a slope of 910 cm^{-1} Å^{-1}. Hence a rough correlation does exist for all of the ices and the hydrate, and a rather precise correlation seems to exist for the phases that are predominantly orientationally disordered, but no exact correlation applies to both the ordered and the disordered phases.

The halfwidths of the $\nu_{OD}(HDO)$ absorptions should reflect the range of crystallographically non-equivalent bond lengths in the disordered phases. For ice I the halfwidth of about 20 cm^{-1} (19) has been related (4) to the range of O—O distances that actually exist because of the disorder in the structure, which has only one crystallographically determined hydrogen bond length (1 and references therein). If a similar width is taken to apply for each crystallographically determined bond length in the other disordered phases, then the range of such bond lengths present should be related

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to the observed halfwidth of ν_{OD}(HDO) minus 20 cm^{-1}. These residual halfwidths are 60, 50, and 60 cm^{-1} for ice V (15), ice VI (16), and the hydrate, respectively. Attempts to correlate these residual halfwidths with the actual range of hydrogen bond lengths were unsuccessful, even if the multiplicity of each bond length were taken into account. However, the residual halfwidths are roughly consistent with the weighted mean deviation of the hydrogen bond lengths, which are (1) 0.021, 0.022, and 0.025 Å for ice V, VI, and the hydrate, respectively, although the halfwidth for ice V is somewhat large.

Absorption by the Ethylene Oxide

It was pointed out above that the ethylene oxide vibrations do not appear to interact with those of the water molecules except for the $\nu_R(H_2O)$ modes and the ring deformation modes at 870 cm^{-1}. In the deuterate a strong peak and a shoulder are seen at 872 and 881 cm^{-1}, respectively, while in the hydrate this peak appears to have broadened and merged with the water absorption, indicating that interaction occurs between the two vibrations. The reasons for this interaction are obscure, because no other vibrations show it even though other ethylene oxide modes coincide with strong absorption by the water, which also absorbs quite strongly throughout the entire region of study. From the structural data (14) and the van der Waal's radii of the methylene group and the oxygen atoms (20), the methylene groups are within 0.3 Å and the oxygen atom of the ethylene oxide is within 0.4 Å of being in van der Waal's contact with the water molecules of the cage. Thus a mechanical interaction between the guest and host vibrations is possible, but it is not clear why it would not also affect the other modes, particularly the methylene rocking modes at 810 cm^{-1}. An alternative, and perhaps more likely, interaction mechanism is transition dipole – transition dipole coupling. The magnitude of such coupling is proportional to the magnitude of the transition dipole and, because the 870 cm^{-1} band is the strongest ethylene oxide absorption (Fig. 2) and the $\nu_R(H_2O)$ band is very intense, it is reasonable that these two modes should be the only ones to show such interaction.

The other ethylene oxide ring vibration, the ring breathing mode, also shows complicated behavior in the spectrum of the clathrate (Fig. 4). This is the only mode that shows fine structure, showing a doublet at 1268 and 1270 cm^{-1}, and much weaker side bands at 1255 and 1280 cm^{-1}. These side bands are roughly equidistant from the strongest peak at 1268 cm^{-1}, and the low-frequency band is the weaker of the two, so their assignment as sum and difference bands with a 13 cm^{-1} energy level is possible. The far infrared study (1) did not extend to 13 cm^{-1}, and thus yielded no evidence on this point. Alternatively, the 1255 cm^{-1} band can readily be assigned as the ring breathing mode of $^{13}C^{12}CH_4O$, so the correct assignment of these features is unclear. It seems unlikely that they arise from ethylene oxide molecules in different environments to the majority, because the ring breathing mode is quite insensitive to the molecule's environment, and occurs at 1270.3, 1268, and 1266 cm^{-1} in the spectra of the gas, liquid, and solid, respectively (5).

The main absorption in this region consists of bands at 1268 and 1270 cm^{-1}, each of which must have a halfwidth of less then 2 cm^{-1}. It is clear that they cannot arise from intermolecular coupling effects because the ethylene oxide molecules are far apart, rotate at about 10^{10} c.p.s. at 100 °K (21) and are, therefore, almost certainly disordered. It is possible that they arise from site effects, that is from molecules in non-equivalent positions or orientations in the structure. In discussing this possibility it must be borne in mind that the X-ray data has been interpreted (14) as indicating two non-equivalent orientations of the molecules in the tetrakaidecahedral cages, while the fast reorientation of the molecules at low temperatures (21, 22) and energy calculations (23) both argue that the barrier to reorientation is very low and that more than two orientations are likely to exist. The energy calculations further indicate that a range of different fields exist in the different cages, because of the random orientation of the water molecules, and that the most probable value of these fields is close to the mean value, and no other particularly probable values exist (23). Ethylene oxide molecules situated in these different fields should have different vibration frequencies and one would, thus, expect a single peak to arise from this source. The breadth due to the different fields is presumably included in the halfwidth of each component of the doublet. Then the doublet must indicate

either that two distinct orientations of the guest molecules do exist in the tetrakaidecahedral cages or that the 1268 cm^{-1} peak corresponds to molecules in these cages and the 1270 cm^{-1} peak corresponds to those in the dodecahedral cages. Only about 10% of the guest molecules are believed (8, 14) to be in the dodecahedral cages, and the apparent intensity of this peak appears to argue against this latter possibility, but the argument is not compelling. This interpretation, that site effects are responsible for the doublet, is the most probable one, but if it is correct it is not clear why similar splittings are not seen on other ethylene oxide absorptions, particularly when, for example, the 1491 and 1467 cm^{-1} peaks are extremely sharp (Fig. 4), and the ring breathing mode shows the smallest frequency shift of any mode between the spectra of the gas and the condensed phases of ethylene oxide (5).

It may be significant that only the ethylene oxide ring vibrations show unusual behavior in the spectrum of the clathrate at 100 °K but no clear interpretation of this exists at present.

The halfwidths of the bands due to enclathrated ethylene oxide are much smaller than those of corresponding bands in the liquid. This is shown in Fig. 4 for the C—H stretching region and the ring deformation and methylene rocking region. At 100 °K the ethylene oxide molecules in the clathrate reorient at about 10^{10} s^{-1} (21) which is of the same order as the reorientation rate in liquids. It has been argued that the bandwidths in liquids are due wholly (24) or at least in part (25) to the rapid reorientation of the molecules. It is clear from the present data that either the bandwidth is extremely sensitive to the reorientation rate, and in the hydrate the molecules rotate significantly more slowly than in the liquid, or that molecular reorientation without intermolecular vibrational coupling or collisions of like molecules is an ineffective source of broadening. In order to obtain more evidence on this point, and on the correct assignment of the peaks around 1270 cm^{-1}, studies of the temperature dependence of the spectrum are planned.

Received October 16, 1972

The n,π^* triplet energies of pyridine, 2-, 3-, 4-cyano, and 2,6-dimethylpyridines were found to correlate linearly with the corresponding half-wave potentials, $E_{1/2}$. Similar relationship was obtained for acetophenone, 2-, 3-, and 4-acetylpyridines as well as for benzophenone, 2-, 3-, and 4-benzoylpyridines. The latter relationships indicated that the n $\rightarrow \pi^*$ transition of the benzoyl and acetylpyridines must involve the n-electron of the carbonyl oxygen.

On montre que les énergies du triplet n,π^* de la pyridine et des cyano-2, -3, -4 diméthyl-2,6 pyridines sont reliées linéairement avec les potentiels de demi-vogue, $E_{1/2}$ correspondants. Une relation semblable a été obtenue pour l'acétophénone et les acétyl-2, -3, et -4 pyridines aussi bien que pour la benzophenone et les benzoyl-2, -3, et -4 pyridines. Cette dernière relation montre que la transition n $\rightarrow \pi^*$ du benzoyle et des acétylpyridines doit impliquer l'électron-n de l'oxygène du groupe carbonyle.

Can. J. Chem., 51, 1169 (1973)

Pyridine derivatives are the most fundamental heterocyclic aromatic hydrocarbons in which the —N= group replaces the methine group, —CH=, of the parent π-isoelectronic homocyclic compounds. Nevertheless, until rather recently there have been relatively few studies of the electronic properties of these compounds (1, 2). No correlations, however, between the electronic and physical properties have been investigated. We had previously correlated the n,π^* triplet energy ($^3E_{n,\pi^*}$) and the half-wave reduction potential ($E_{1/2}$) for some benzophenones and thiobenzophenones (3), aliphatic and aromatic ketones and aldehydes (4) and for some aza aromatic compounds (5).

In this report extension of the above relationship to include substituted pyridines is presented and discussed with respect to previous work.

The polarographic reduction of ten aza-heterocyclics, 2-, 3-, 4-cyano and 2,6-dimethylpyridine; 2-, 3- and 4-acetylpyridines; and 2-, 3-, and 4-benzoylpyridine, have been measured under similar condition, parallels to that of the corresponding parent aromatic hydrocarbons being: pyridine, acetophenone, and benzophenone respectively. The molecular structures are shown in Fig. 1. Reduction was carried out in 0.05 *M* TEAP – acetonitrile electrolyte and the experimental procedures were the same as described previously (3). Each of these heteromolecules gave a well characterized a.c. wave with a width at half-height of 90 ± 2 mV, corresponding to one electron process. In all cases, the reduction occurs at a more positive potential compared to the parent aromatic hydrocarbon. The rate of electron transfer, K_{ap}, *i.e.* the degree of reversibility of the reduction process will be discussed elsewhere. However, for this report it is sufficient to report that all reduction processes proceeded reversibly with K_{ap} much greater than 0.01 cm s^{-1}. The half-wave reduction potentials, $E_{1/2}$, are summarized in Table 1 together with the n,π^* triplet energies for compounds investigated.

Relationship between $E_{1/2}$'s and n,π^* Triplet Energies of Pyridine Derivatives

(a) Cyano and Methyl Substituted Pyridine

The activity of aza-heterocyclic compounds toward reduction can primarily be due to the heterocyclic ring, where substitution in the ring would affect the reduction through the σ or π donation of the substituents. The effect of sub-

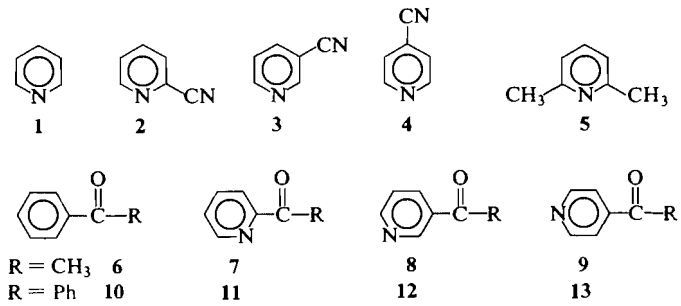

FIG. 1. Molecular structures of the substituted pyridines and the corresponding homocyclic analog and numbering systems.

stituents on the reduction potential of pyridine depends on the position of the substitution and the nature of the substituents. Replacing a hydrogen by cyano group in the pyridine ring, in general, eases the reduction process (reduction potential becomes more positive), while methyl substitution shifts $E_{1/2}$ toward a more negative potential (see Table 1). This behavior is due to the fact that electron-withdrawing substituents lower the energy of the π^*-level and electron-donating groups have the opposite effect. Since, during the reduction process the electron has to be placed in the lowest unoccupied π-molecular orbital, therefore, the $E_{1/2}$ should be related to the energy of this orbital (6). The positions in the pyridine ring are not equivalent, thus the 4-cyanopyridine reduces at a slightly more positive potential than the 2-cyano derivative and both are more positive than the 3-cyanopyridine. This behavior is in general agreement with Volke's concepts (7, 8).

TABLE 1. Electrochemical data and n,π^* triplet energies of the studied compounds

No.	Compound	$-E_{1/2}$ (V)	$^3E_{n,\pi^*}$ (kcal/mol)

*Reference 1.
†Reference 10.
‡$^3E_{\pi,\pi^*}$ (kcal/mol).

One basic feature of the aza-heterocyclics, which differs from the aromatic hydrocarbons, is the presence of nitrogen atom with a lone pair of electrons. Therefore, it should be possible to excite one of the electrons to the lowest unoccupied π^*-orbital, Indeed, many pyridine derivatives have lowest n,π^* triplet state. It is, therefore, anticipated that $E_{1/2}$ to correlate with the $^3E_{n,\pi^*}$ of substituted pyridine provided that the energy of the nitrogen lone pair (E_n) is not affected by the substituents. The latter is to be expected due to the orthogonality of the nitrogen n-orbital with respect to the π-system. The correlation between $E_{1/2}$ and $^3E_{n,\pi^*}$ for the cyanopyridines, pyridine, and 2,6-dimethylpyridine is shown in Fig. 2*a*.

(b) Acetyl and Benzoyl Pyridines

The 4-substituted derivative, in both series, reduces at a more positive potential than the 2-substituted pyridine and in turn they are reduced at a more positive potential than 3-substituted pyridine. This behavior is in agreement with the previous results. The acetyl and benzoyl pyridines were also reduced at a more positive potential than the corresponding homocyclic analog. This is because the nitrogen is more electronegative than carbon, therefore, it lowers all energy levels. This energy lowering is a consequence of two factors: (*1*) the $2P_\pi$ orbital of the nitrogen atom has a lower energy and hence, lowers the energy of the π-system in general; (*2*) the inductive effect of the nitrogen atom lowers the $2P_\pi$ energy levels of the carbon atoms, particularly, the vicinal ones and thus produces a smaller and more uniform lowering of all levels (9). The same applies to the π^*-levels. The acetyl and benzoylpyridines, similar to the corresponding homocyclic analog, acetophenone, and benzophenone, respectively, have

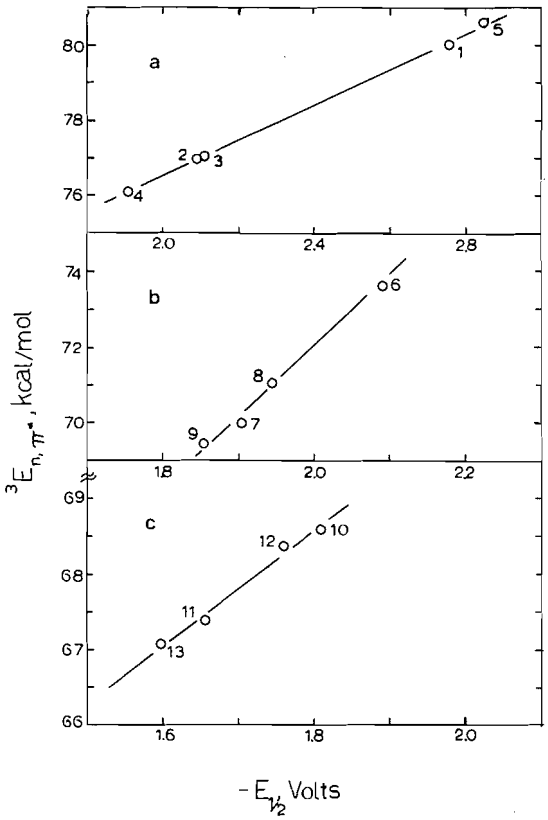

FIG. 2. Half-wave potentials *vs.* n,π* triplet energies of (*a*) cyanopyridines and pyridine; (*b*) acetylpyridines and acetophenone, and (*c*) benzoylpyridines and benzophenone.

triplet states which correspond to $n \rightarrow \pi^*$ transition. However, the energies of these triplet states (67–68 kcal/mol) are much lower than the pyridine (80 kcal/mol) and slightly lower than the corresponding homocyclic analog. Moreover, the $^3E_{n,\pi^*}$ of acetophenone and acetylpyridines correlate linearly with the corresponding $E_{1/2}$ (See Fig. 2*b*). Similar behavior was obtained for the benzophenone and the benzoylpyridines (Fig. 2*c*). The above results indicate that the $n \rightarrow \pi^*$ transition in the acetyl and benzoyl series must involve the n-electron of the carbonyl oxygen rather than that of the nitrogen atom. Arnold (10 and references therein) earlier showed that the triplet energies of acetophenone and acetylpyridines as well as benzophenone and benzoylpyridines correlate linearly with the Hammett's σ constant, which is in accordance with results obtained above.

The existence of a linear relationship between $^3E_{n,\pi^*}$ *vs.* $E_{1/2}$ for acetylpyridines including acetophenone and for benzoylpyridines including benzophenone indicates that the nitrogen in the ring acts as external substituent and changes the π*-level energy depending on its position with respect to the CO group, which is reflected on the $E_{1/2}$'s. It also indicates that the nitrogen in the ring exerts no or relatively small effect on the carbonyl oxygen n-level energy. According to the latter, it would be expected that the slope of the plots shown in Figs. 2*b* and 2*c* (0.54 and 0.33 respectively) to be identical to that of the acetophenones (11) and benzophenones (3) series, respectively. However, the results of comparison indicated that the pyridines series have larger slopes than the corresponding phenones series (0.42 and 0.19 respectively) and obviously they intercept at the parent homocyclic compound. Thus, deviation could be due to solvation energy differences, ΔE_{sol} between the various series (4, 12).

The authors wish to express their sincerest appreciation to Dr. W. R. Fawcett of the Chemistry Department, University of Guelph, Guelph, Ontario for making available the instrumentation used to determine the reduction potentials for all the compounds investigated.

Received April 21, 1972

The preparation and characterization of the ($Mttz_nX_2$) complexes (where M = Pd or Pt; *ttz* = thiazolidine-2-thione; n = 2, 3 or 4; X = Cl, Br, I) are reported. By i.r., p.m.r., and u.v.–visible spectra and by magnetic susceptibility and conductivity measurements it appears that in all complexes the ligand is *N*-bonded to the metal and that many equilibria are present in polar solvents. In particular, for ($Mttz_4I_2$)-derivatives there is an equilibrium between a square-planar and a penta-coordinate species. Furthermore, water is competing with the ligands and counterions in the coordination sphere. Our ligand is placed near water in the spectrochemical series. With copper(I) we have obtained complexes of the type ($Cuttz_3X$) (where X = Cl, Br, I, NO_3, ClO_4, and $\frac{1}{2}SO_4$), and in each case the anion is coordinated to the metal. The *ttz* molecule in these complexes behaves as a hard-base.

La préparation et la caractérisation des complexes ($Mttz_nX_2$) (où M = Pd ou Pt; *ttz* = thiazolidine thione-2, n = 2, 3 ou 4; X = Cl, Br, I) sont présentées. D'après les spectres i.r., r.m.n., u.v. et visible et d'après les mesures de la susceptibilité magnétique et de la conductivité, il apparait que dans tous ces complexes, le ligand est lié au métal par l'azote et que beaucoup d'équilibres existent dans les solvants polaires. Par exemple, pour les dérivés ($Mttz_4I_2$) un équilibre se produit entre les espèces carré-plane et penta-coordinée. De plus l'eau entre en compétition avec les ligands et les contre-ions dans la sphère de coordination. Notre ligand est situé près de l'eau dans la série spectrochimique. Avec le Cuivre (I), des complexes du type ($Cuttz_3X$) (où X = Cl, Br, NO_3, ClO_4 et $\frac{1}{2}SO_4$) sont obtenus et dans tous les cas, l'anion est coordiné au métal. Le comportement de la molécule de *ttz* dans ces complexes est celui d'une base dure. [Traduit par le journal]

Can. J. Chem., **51**, 1172 (1973)

Working on the problem of the competition between group VA and VIA donor atoms in the formation of a metal–ligand bond, we have reported in our previous papers (1–9) the characterization of many complexes with heterocyclic ligands. Particularly the thiazolidine-2-thione (*ttz*; $S{=}{}^{2}C{-}{}^{3}NH{-}{}^{4}CH_2{-}{}^{5}CH_2{-}{}^{1}S$) behaves as a soft (9) or a hard (8) base depending on the metal class. In order to extend the study of this ligand we have now prepared the palladium(II), platinum(II), and copper(I) complexes described below.

Palladium(II) and Platinum(II) Complexes

Results

All complexes were obtained from reactions in aqueous solution between K_2MCl_4 (where M = Pd or Pt) and *ttz* in the required stoichiometric ratio, in the presence of a small excess of HX (X = Cl, Br, I), as in the following scheme

$$K_2MCl_4 \xrightarrow[\text{(from 1:1 to 1:4)}ttz]{HX} Mttz_nX_2 \quad \begin{matrix} n = 2,3,4 \\ X = Cl, Br, I \end{matrix}$$

The $Pdttz_4(NO_3)_2$ derivative was obtained starting from $Pd(NO_3)_2$. With a metal:ligand molar ratio of 1:1 only a low yield of the 1:2 derivative was obtained. All compounds are diamagnetic; some of these are soluble in DMSO, DMF, or CH_3CN. Their colors change from yellow to brown, getting darker from chlorides to iodides and lighter from n = 2 to n = 4 (see Table 1). The conductivity values at 25 °C in DMF solutions are strongly concentration-dependent and show that, in very dilute solutions, all complexes seem to behave as 1:2 electrolytes (but the color of the solutions changes on diluting).

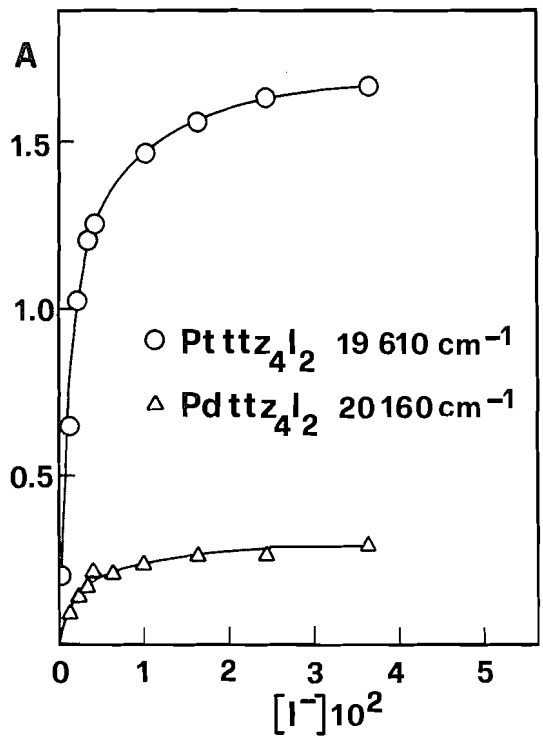

FIG. 1. Absorbance of palladium (7) and platinum (17) derivatives against iodide ion concentration: [7] = [17] = 2×10^{-4} *M*; [*ttz*] = 0.1 *M*; [KI] = $2 \times 10^{-3}/3.6 \times 10^{-2}$ *M*; 20 ± 0.1 °C.

molar ratio between the iodide and the complex.

As far as the i.r. spectra (Table 3) are concerned, the ν(Pd—Br) vibrations occur in the spectra of compounds **1** and **3** at 257 cm^{-1} as a very strong band while in those of compounds **2** and **5** the ν(Pd—Cl) vibrations are found at 368–367 cm^{-1} (medium) and near 303 cm^{-1} (weak), in very good agreement with literature data (3, 10). The ν(N—H) band shows an average shift of about −160 cm^{-1} if compared with the spectrum of a chloroform solution of the free ligand, while the thioamide I band and the absorption attributed to ν(C=S) + δ(NCS) (11) show positive shifts averaging 28 and 18 cm^{-1}, respectively. In the far i.r. region two halide-independent medium–strong bands in the range 370–350 cm^{-1} and near 230 cm^{-1} are present.

The p.m.r. of the free ligand spectrum shows a hyperfine structure in hexadeuterodimethylsulfoxide (DMSO-d_6) similar to that previously characterized (9) in $CDCl_3$ solution. The chemical shift values and the spectral patterns of CH_2(5)- and CH_2(4)-proton resonances of the free ligand in DMSO-d_6 (see Table 4) do not show noticeable modifications with respect to those obtained in $CDCl_3$ solutions (9) whereas the NH-proton resonance shifts by about 2 p.p.m. towards lower field. Further, all the chemical shift values are practically concentration-independent.

On going from the spectrum of the free ligand to those of the palladium derivatives in freshly-prepared DMSO solutions we observe: (*1*) the disappearance of the hyperfine structure of the resonances as a consequence of line broadening and (*2*), a general deshielding effect on the cited resonances increasing in the order $CH_2(5) < CH_2(4) \ll NH$.

In the p.m.r. spectra of the platinum-derivatives we observe a doubling of each ligand resonance, one component maintaining the hyperfine structure and showing the same chemical shift values as the respective free ligand resonance while the other one (assigned to the complexed ligand) showing instead a deshielding effect stronger than that observed for palladium complexes.

Furthermore, we observe that the deshielding effect on the NH-proton resonance decreases in the order chloride > bromide > iodide for both palladium and platinum compounds. In order to obtain a full characterization of these complexes additional p.m.r. experiments have been carried out changing *ttz* or KI concentrations or by adding water and/or by running several spectra many hours after the complexes solutions were prepared. The results of the measurements will be discussed below.

Discussion

The first problem to consider is the identification of the reaction center in the ligand molecule. The negative shift of ν(NH) of about 160 cm^{-1} accompanied by the positive shifts of the thioamide I band for ν(C=S) + δ(NCS) of about 28 and 18 cm^{-1}, respectively, clearly suggest that the nitrogen atom is involved in the coordination bond. In fact, in $Mttz_2X_2$ *N*-bonded compounds (where M = Zn, Cd, or Hg and X = Cl, Br, or I) (8) we have found a negative ν(N—H) shift of about 270 cm^{-1} and positive shifts for the thioamide I band for ν(C=S) + δ(NCS) of 36 and 19 cm^{-1}, respectively. The magnitude and sign of these shifts are typical of *N*-bonded derivatives (11). The hypothesis that the complexes studied here are *N*-bonded is strongly supported

15	$Pttz_4Cl_2$	3.50–3.63	3.88–4.15	10.05–11.42
16	$Pttz_4Br_2$	3.50–3.63	3.88–4.15	10.05–11.23
17	$Pttz_4I_2$	3.50–3.63	3.88–4.16	10.04–11.16

*Very broad lines.

by the noticeable deshielding effect on the NH-proton resonance observed in the spectra of all examined complexes. In fact, this deshielding effect is ascribed to electron withdrawal by the metal from the nitrogen atom. The electron withdrawal cannot be ascribed to hydrogen bond because in dilute DMSO solution the only possible hydrogen bond is with the solvent. The deshielding effect pointed out here results on comparing the spectra of complexes with those of the free ligand in DMSO solutions. On the other hand, in our previously studied *S*-bonded *ttz*-derivatives (9) the NH-proton resonances show a certain shielding effect. The examination of (CH_2) chemical shift values also leads to the same conclusion. In fact, the $CH_2(4)$ (the one directly bonded to the NH-group) is the most affected CH_2 resonance.

From this set of results we conclude that the ligand is *N*-bonded to the metal in all the complexes. The medium–strong i.r. band near 230 cm^{-1} may by attributed to the ν(M—N) vibration, in very good agreement with literature data (12–15).

According to the previously reported u.v. data (16), the shoulder near 32 000 cm^{-1} could be assigned to the first charge-transfer transition $L \rightarrow M$ while the shoulders near 29 000 cm^{-1} in the spectra of all the compounds could be due to the $\bar{\nu}_1$(d–d) transition of a square-planar chromophore species. In fact, the $\bar{\nu}_1$ transition in $[Pd(H_2O)_4]^{2+}$ occurs at 26 400 cm^{-1} while in thiourea derivatives it occurs at 27 700 cm^{-1}.

The absorption in the range between 25 000 and 19 600 cm^{-1} is generally absent in the spectra of the chloride derivatives but is almost always present in those of the other compounds (see Table 2). Further, on going from bromide to iodide complexes a red shift is also observed in the $Mttz_4X_2$ compounds. The magnitude of the deshielding effect on the NH-proton resonance is also shown to depend on the nature of the halide-atom both in $Mttz_3X_2$ and $Mttz_4X_2$ derivatives, being stronger in the order chloride > bromide > iodide (see Table 4). From both these findings it is clear that the halide atom is involved in the coordination sphere of the metal in $Mttz_4X_2$-type compounds too.

The systems $Mttz_4I_2$ (M = Pt or Pd) with KI have been further studied extensively both by u.v.–visible and p.m.r. techniques. The equilibria between the $Mttz_4^{2+}$ and I^- ions have been studied by the u.v. continuous variation method[1] and the results could be explained in terms of the two following reactions

$$[1] \qquad Mttz_4^{2+} + I^- \rightleftarrows Mttz_3I^+ + ttz$$

$$[2] \qquad Mttz_4^{2+} + I^- \rightleftarrows Mttz_4I^+$$

However, in our spectrophotometric experiments, the presence of a large excess of free-ligand (500:1 to the complex) should prevent reaction 1 occurring to a large extent. Furthermore, the absorptions near 20 000 cm^{-1}, which are a non-linear function of the $[I^-]$ values, cannot be attributed to $Mttz_3I^+$ (or $Mttz_2I_2$) species because these complexes do not absorb in this range, neither in the solid phase nor in DMF solution.[2] However, the shoulder at 20 160

[1]Obviously the method of continuous variations is insufficiently reliable when more than two species are present, as is likely here.

[2]Moreover, the yellow DMF solution obtained by thermal reaction between K_2MCl_4 and a large excess of KI does not absorb at 20 000 cm^{-1}. Thus the presence of this absorption cannot be due to a possible substitution of more than one iodide.

cm^{-1} and the peak at 19 610 cm^{-1} for palladium- and platinum-derivatives, respectively, could be assigned to a penta-coordinate species, of the type $Mttz_4I^+$, probably with a square-pyramidal geometry. This stereochemical hypothesis is supported by the high absorbance intensities ($\varepsilon \simeq 8\,300$ after 15 days at 19 160 cm^{-1} in the presence of $Pttz_4I_2$, KI, and *ttz* in 1:180:500 molar ratio), which would be expected to be much lower for trigonal-bipyramidal geometry (16, 17).[3]

On the other hand, it is very likely that the equilibrium reactions between $Mttz_4^{2+}$ and I^- ions above discussed are not the only ones present in polar-solvent solutions. In fact, the p.m.r. spectra of platinum derivatives indicate the presence of free ligand in the solution which might be formed by slow ligand exchange reactions, both in $Pttz_3X_2$ and $Pttz_4X_2$ complexes. In the palladium-derivatives these reactions also seem to occur but with a faster exchange rate. In fact, by adding an excess of *ttz* to the palladium complex solutions we do not obtain the free ligand spectrum but only a shift of all the resonances towards the respective resonance shift of the spectrum of the free ligand, so that the observed chemical shift values would be the weighted averages between those of the free ligand and those of the complexes.

By studying the OH-proton resonance, arising from the water traces present in our DMSO-d_6 solutions, we observe that this resonance moves towards lower fields with time[4] (for example: $Pttz_4Cl_2$: $t = 0$, $\delta_{OH} = 3.46$ p.p.m. from internal TMS; $t = 44$ h, $\delta_{OH} = 3.90$ p.p.m.; $Pttz_4Br_2$: $t = 0$, $\delta_{OH} = 3.51$ p.p.m.; $t = 44$ h, $\delta_{OH} = 3.79$ p.p.m.; $Pttz_4I_2$: $t = 0$, $\delta_{OH} = 3.99$ p.p.m.; $t = 44$ h, $\delta_{OH} = 4.08$ p.p.m.; $Pdttz_4I_2$: $t = 0$, $\delta_{OH} = 4.36$ p.p.m.; $t = 40$ h, $\delta_{OH} = 4.72$ p.p.m.; etc.).

Further, by adding small quantities of water the OH-resonances shift towards higher fields, *i.e.* towards the free water shift value, which may be interpreted as a fast proton exchange between free water and coordinated water.

Both these effects on the OH-resonance can be explained in terms of the water oxygen competing with the nitrogen atom of the ligand and the halide ions in coordinating the metal atom. This interpretation is further confirmed by the up field shift of the OH-resonance on adding a small amount of KI or *ttz*.

However, the complexity of these systems deriving from the possible existence of many ionic species in mutual equilibrium with very fast exchange processes does not allow a quantitative interpretation.

The DMF molar conductivities of dilute solutions tend to values typical of 1:2 electrolytes (Λ ranging between 180 and 200 $ohm^{-1}\,cm^2$). This could be a consequence of the existence in solutions of a number of equilibria involving variously coordinated complexes and complete halide-substitution in the coordination sphere in very dilute solutions. Finally the competition between water and ligand nitrogen atoms demonstrates that in these complexes our ligand should be placed near water in the spectrochemical series. In fact, in the u.v.–visible spectra the $\bar{\nu}_1$(d–d) bands occur in our complexes near 28 kK and in $[Pd(H_2O)_4]^{2+}$ ion at 26 400 cm^{-1}.

Copper Complexes

Pale-yellow, microcrystalline compounds with general formula ($Cuttz_3X$) (where X = Cl, Br, I, NO_3, ClO_4, and $\frac{1}{2}SO_4$) were prepared by various methods (see Experimental section). The conductivity measurements in DMF show that all derivatives behave as non-electrolytes. The magnetic susceptibility measurements demonstrate that the metal is present as copper(I). From the i.r. spectra it is clear that the NO_3^-, ClO_4^-, and SO_4^{2-} groups are always bonded. In fact, in the spectrum of compound **22** the strong band present at 1380 cm^{-1} (due to the ν_3 mode of NO_3) is accompanied by a medium absorption at 1420 cm^{-1} as a consequence of symmetry lowering in the nitrato-group (18). Furthermore, the ν_4 absorption is also split into two very weak bands at 760 and 740 cm^{-1} while a medium–strong band appears at 1580 cm^{-1}, where the ligand does not absorb. As far as the sulfato-derivative (**21**) is concerned, in its spectrum we observe a set of bands at 1140sh, 1120sh, 1110vs, 615s, 580w, and 460w cm^{-1} which could arise from bridging groups (19, 20). In the spectrum of the perchlorate derivative (**23**) the bands present at 630 and 620 cm^{-1} (due to ν_3 and ν_5 modes) and those at 1110 and 1085 cm^{-1} confirm that the group is present as the fragment

[3]No ε values are reported in Table 2 because many species are probably present in the solutions.

[4]The time independent chemical shift value of OH-resonance in the free ligand spectrum is $\delta_{OH} = 3.38$ p.p.m.

—O—ClO_3 of the complex (21, 22). These results are in agreement with those obtained by conductivity measurements. As far as the ligand–metal interaction is concerned, the remarkable shift of ν(NH) band towards lower frequencies (of about 280 cm^{-1}, having as reference the chloroform solution spectrum of the free ligand) clearly shows that the nitrogen atom is involved in the coordination bond. This hypothesis is confirmed by the strong band (independent of anion) present at 306–329 cm^{-1} which could, tentatively, be attributed to a ν(Cu—N) stretch, according to the values reported for morpholine- and imidazol-copper derivatives (23, 24).

Experimental

Preparation of the Compounds

The ligand (supplied by Fluka) was purified by recrystallization from hot water.

Method A: All the palladium(II) and the platinum(II) complexes were obtained by reaction in hot aqueous solution between K_2MCl_4 and *ttz* (in molar ratios from 1:1 to 1:4) in the presence of a small excess of HX; with the molar ratio of 1:1 only low yields of the ($Mttz_2X_2$)-type compounds were separated out. Compound $Cuttz_3I$ was obtained by reaction in hot aqueous solution between 1 mol of $CuSO_4$, 4 mol of *ttz* and an excess of KI in the presence of acetic acid. Compound $Cuttz_3ClO_4$ was obtained starting from $CuCO_3$ by reaction with 4 mol of *ttz* and $HClO_4$.

Method B: The compounds **8**, **18**, **19**, **21**, and **22** were obtained by reactions in aqueous solution between MX_2 and 4 mol of *ttz*.

Infrared Measurements

All compounds were examined in the region 4000–200 cm^{-1} with Perkin–Elmer Model 457 and 225 spectrophotometers on KBr discs and, in the far i.r. region, in Nujol mulls between thin polyethylene sheets.

Magnetic Susceptibility Measurements

These measurements were carried out by Gouy's method. All compounds were diamagnetic.

Conductivity Measurements

These measurements were carried out in 10^{-3} *M* DMF solutions (accuracy ±1%).

Ultraviolet–Visible Measurements

The spectra were recorded with Perkin–Elmer Model 402 and Beckman-DK2A spectrophotometers working in DMF solutions or in the solid phase respectively.

Nuclear Magnetic Resonance Measurements

All p.m.r. spectra were recorded on a Varian 100 MHz spectrometer at room temperature using TMS as internal standard. Only the DMSO-d_6 soluble compounds were studied.

Trends in the Spectrochemical Series and ^{31}P Chemical Shifts of Five-coordinated Cyclopentadienylnickel(II) Complexes

J. THOMSON AND M. C. BAIRD

Department of Chemistry, Queen's University, Kingston, Ontario

Received June 14, 1972[1]

The electronic spectra and ^{31}P n.m.r. spectra of the complexes π-$C_5H_5NiPPh_3X$ (X = Cl, Br, I, NCO, NCS, NO_2, CN, $SnCl_3$, $SnPh_3$, $PbPh_3$, alkyl, and aryl) have been obtained and interpreted. The "common" anions form a spectrochemical series which is identical with that reported for many octahedral systems, while the carbon, tin, and lead donors lie relatively high in the series. Currently accepted theory for the chemical shifts of ligand donor atoms fails to satisfactorily rationalize the ^{31}P chemical shifts.

Les spectres électroniques et les spectres de RMN du ^{31}P des complexes π-$C_5H_5NiPPh_3X$ (X = Cl, Br, I, NCO, NCS, NO_2, CN, $SnCl_3$, $SnPh_3$, $PbPh_3$, alkyle, et aryle) ont été obtenus et interprétés. Les anions "courants" forment une série spectrochimique identique à celles rapportées pour plusieurs systèmes octaèdraux tandis que les donneurs carbone, étain et plomb se trouvent à des valeurs relativement élevées dans la série. La théorie couramment acceptée sur les déplacements chimiques des atomes du ligand donneur ne rationalise pas de façon satisfaisante les déplacements chimiques du ^{31}P.

[Traduit par le journal]

Can. J. Chem., 51, 1179 (1973)

Introduction

During the current wave of interest in five-coordinated transition metal complexes (1–3), compounds of nickel(II) have played an important role (4). Both trigonal bipyramidal and square pyramidal complexes are known and have been intensively studied, and it seems to be generally assumed that all five-coordinated nickel(II) complexes are of one or both of these symmetries (or distortions thereof). It is the purpose of this paper to point out that the complexes π-C_5H_5NiLX (L = neutral ligand; X = monoanion) are 18-electron systems and thus may also be considered to be five-coordinated. They have a quite different symmetry from the other nickel(II) systems previously studied, and yet the relative energies of the d–d transitions in their electronic spectra agree very well with the well-known spectrochemical series for octahedral nickel(II) complexes (5).

We also report the ^{31}P chemical shifts for a variety of triphenylphosphine complexes. We have previously reported data for a few of these compounds in an attempt to correlate chemical shifts with electronic spectra in accord with the well-known equation describing the second order paramagnetic term (6). The correlation seemed promising, although the slope of the resulting linear plot had the wrong sign (7). We now realize that the theory of Buckingham and Stephens (8) for the chemical shifts of ligand donor atoms should be much more applicable to this system; unfortunately, in adding more compounds to the series, the linearity of the correlation is lost.

Experimental

The compounds π-$C_5H_5NiPPh_3X$ (X = Me, Et, *n*-Pr, *iso*-Pr, *n*-Bu, *iso*-Bu, *sec*-Bu, Ph, CH_2Ph, CH_2SiMe_3, $CHPhSiMe_3$, $SnPh_3$, $PbPh_3$, $SnCl_3$, CH_2CMe_3, CN, NCO, NO_2, NCS, Cl, Br, I) and $[\pi$-$C_5H_5Ni(PPh_3)_2]^+$-BF_4^- were prepared by the methods outlined previously (9–13).

Visible and Ultraviolet Spectra

The electronic spectra of the complexes were obtained on a Unicam SP800 spectrophotometer. Three absorptions with extinction coefficients of approximately 10^4, 10^3, and 10^2 cm^{-1} mol^{-1} were observed in most cases using 0.015 *M* solutions (prepared under nitrogen) of the complexes in cyclohexane and cells of pathlengths 0.1, 1.0, and 10 cm, respectively. The results are shown in Table 1.

^{31}P Nuclear Magnetic Resonance Spectra

The ^{31}P n.m.r. spectra were run on a Bruker HX60 spectrometer using approximately 0.5 *M* CS_2 solutions in 13 mm tubes. Hexafluorobenzene, which was used as lock, was contained in a coaxial tube, and complete proton decoupling was accomplished by broad-band decoupling at 60 MHz. The chemical shifts are listed in Table 1 referenced to 85% phosphoric acid (downfield shifts negative).

Discussion

Several crystal structure determinations have been carried out (13–16) for complexes of the type discussed here, and it has been shown that generally the PNiX plane is orthogonal to the C_5H_5 ring.

Considering the cyclopentadienyl group as a three-electron pair donor, the nickel is thus five-coordinated. Of the transitions listed in Table 1, the high energy band of extinction coefficient 4200 – 13 100 can generally be attributed to a charge transfer transition associated with the aromatic ligands and will not be considered further. In the cases of X = $CHPhSiMe_3$, $SnPh_3$, $PbPh_3$, and $SnCl_3$, this band is of unusually low energy and may be associated with

the anionic ligands; the relative energies of the charge transfer bands of the halide complexes are in the order expected for halide-to-metal charge transfer transitions (17).

The microsymmetry about the nickel in the complexes is very low (C_s, and then only for one orientation of the C_5H_5 ring), and thus there is no center of inversion and the parity selection rule may be expected to be relaxed. Making this assumption, we attribute the two low-energy bands in the spectrum of each compound to transitions between orbitals which are essentially nickel d orbitals in character. On this basis, a spectrochemical series for the "common" anions, X, can be established which parallels exactly that established for octahedral complexes (5), *i.e.*

$$I < Br < Cl < NCS < NO_2 < CN$$

This correlation, which holds for both series of the weaker bands, confirms that the bands can be attributed to d–d transitions. It may be noted also that trigonal bipyramidal and square pyramidal complexes of nickel(II) also often exhibit two d–d transitions in their spectra, although the relative intensities are often reversed (4).

The correlation between the two series is not very good for the IVa donors, although definite trends can be established. The complete spectrochemical series for the stronger and weaker d–d transitions, respectively are: $I < Br < Cl \ll NCO < NCS \ll CHPhSiMe_3 < NO_2 \ll SnCl_3 < CH_2Ph < PPh_3 \sim PbPh_3 \ll CH_2CMe_3 < CH_2SiMe_3 \sim$ *sec*-Bu $<$ *iso*-Pr $<$ *iso*-Bu $< Ph < SnPh_3 =$ *n*-Bu $= Et = CN \sim$ *n*-Pr $< CH_3$; $I < Br < Cl \ll NCO < NCS \ll CHPhSiMe_3 < NO_2 < SnCl_3 < CH_2SiMe_3 < CH_2Ph < CN < CH_2CMe_3 <$ *iso*-Bu $< CH_3 < Et =$ *n*-Pr $<$ *n*-Bu $\sim$ *sec*-Bu $< SnPh_3 = PbPh_3 <$ *iso*-Pr $\sim Ph < PPh_3$.

Although Ciampolini (18) successfully applied a crystal field model to explain the spectra of a number of trigonal bipyramidal and square pyramidal complexes of nickel(II), such an approach should be inappropriate for the complexes discussed here. Unfortunately, a semi-empirical molecular orbital calculation (19) has also proven inadequate to describe the spectra, and thus assignments of the d–d transitions cannot unambiguously be made at this time.

Although the differences in details of the two spectrochemical series cannot be explained, it would seem that some generalizations and comparisons with other systems can be made. First, the carbon donors in both series exhibit very high ligand field strengths, in some cases greater even than cyanide, and in most cases greater than the nitro or trichlorotin groups. These results are to some extent in contrast to the spectrochemical series found for the systems *trans*-$RuXY[C_2H_4(PMe_2)_2]_2$ (X = Y = Cl, Br, I, CN; X = H, Me, Ph, *p*-tolyl, Y = Cl) (20) and $[Rh(NH_3)_5X]^{2+}$ (X = I, Br, Cl, Et, *n*-Pr, *n*-Bu, NH_3, NO_2) (21). In the ruthenium system, the methyl group was found to exhibit a high ligand field strength, although less than that of cyanide. In the rhodium system on the other hand, the alkyl groups were placed below even ammonia and the nitro group. Thus it appears that relative ligand field strengths for strong field ligands may vary between different systems of transition metal complexes.

The triphenyltin and -lead groups are obviously strong field ligands, presumably because of their strong donor abilities, while the trichlorotin group may owe its position above, for instance, the nitro group to its pronounced π-acid properties (22, 23) (the σ-donor properties of this ligand have not yet been satisfactorily established (22, 23)).

The position of the isocyanate group in the spectrochemical series appears not to have been established in many metal systems; the ion lies between chloride and isothiocyanate in the nickel system. The position of triphenylphosphine is highly ambiguous, but this ligand does lie, as expected, high in the spectrochemical series.

The phosphorus chemical shifts were determined in an attempt to clarify some of the confusion in this area (6). By keeping the metal and the phosphine constant and varying only the relatively distant substituents on the nickel, it was hoped that we could avoid, for instance, the variations in the diamagnetic contribution and the substituent effects of the groups bonded to the phosphorus, and the deviations of symmetry about the phosphorus that have plagued other workers (6).

As expected, an attempted correlation of the phosphorus chemical shifts with the electronegativities of the anions was unsatisfactory, suggesting that inductive effects are not important. To test the theory of Buckingham and Stephens (8), we plotted the ^{31}P chemical shifts

vs. the wavelength of the stronger d–d transition, choosing this transition rather than the other on the grounds that its greater intensity suggests that it is probably not of "pure" d–d character, but may involve significant mixing of ligand character into the orbitals involved (24).

Assuming a constant metal–ligand distance and d-orbital exponent (Slater k), the theory, developed originally for transition metal hydrides, predicts that the shielding of the donor nucleus should decrease as the separation between the ground and excited state(s) of the metal increases. The theory appears to apply to about half of the compounds studied in this paper, to our knowledge the first time such a correlation has been made for tertiary phosphine coordination compounds.

Unfortunately the correlation does not hold for the bromo and iodo complexes, which have anomalously low chemical shifts, or for the phenyl, cyano, trichlorotin, nitro, isocyanato, isothiocyanato and triphenylphosphine complexes, which have anomalously high chemical shifts. Interestingly, Buckingham and Stephens (24) noted that the hydride chemical shifts of many hydrido–halide complexes also decrease in the order Cl > Br > I, *i.e.* the reverse of the order expected from the relative ligand field strengths. To explain this apparent anomaly, they suggested an increase in the covalency (change in k) in the order Cl < Br < I, as predicted by the relative positions of these ligands in the nephelauxetic series (25). Such covalency factors may dominate the chemical shifts in many other metal systems (26), and may be considered a result of the strong π-donor abilities of the halide ions, which are expected to increase in the order Cl < Br < I (21).

On this basis, the anomalously high chemical shifts of the phenyl, cyano, trichlorotin, triphenylphosphine and nitro groups may perhaps be a result of the π-acid properties of these ligands. We are aware of no evidence for π-acid properties of the isocyanate and isothiocyanate groups, but both at least have π-antibonding orbitals of the correct symmetry to π-bond to the nickel. At any rate, the presence of π-acidic ligands might be expected to raise the ^{31}P chemical shifts to higher fields.

The ^{31}P chemical shifts of the methyl, benzyl, and phenyltrimethylsilylmethyl derivatives remain anomalous.

The Ultracentrifuge as a Pressure-Densitometer

KENNETH S. ROGERS, ROSALIND BURKAT, AND ALFRED J. RICHARD

Departments of Biochemistry and Pharmaceutical Chemistry, Medical College of Virginia, Health Sciences Division of Virginia Commonwealth University, Richmond, Virginia 23219

Received September 18, 1972

The Spinco E analytical ultracentrifuge has been used to determine specific volumes or densities for organic liquids and water at pressure from 1 to 100 bars. Specific volumes calculated from experimental isothermal compressibilities (β_T) were in very close agreement with values from measurements recorded in literature. Bulk modulus ($1/\beta_T$) *vs.* pressure plots indicated that the Lennard–Jones 6-12 potential does not satisfactorily describe the molecular interactions for carbon tetrachloride, benzene, cyclohexane, or water. The organic liquids were reasonably approximated by a 7-28 potential or more exactly by a 6-24 potential. None of the two-term potentials could account for the interaction of water molecules.

L'ultracentrifuge analytique a été utilise pour déterminer le volume spécifique de certains liquides organiques et de l'eau, aux pressions de 1 à 100 bars. Nos résultats sont comparables aved les résultats obtenus par d'autres méthodes. Nos résultats ne sont pas in accord avec le potentiel 6-12 de Lennard-Jones pour les liquides que nous avons étudiés; tétrachlorure de carbone, benzène, cyclohexane, et eau. Les interactions entre les molécules des liquides organiques sont interprétées approximativement par un potentiel 7-28 ou mieux, par un potentiel 6-24. Un potentiel de deux termes n'est pas suffisant pour expliquer les interactions entre les molécules d'eau.

Introduction

Recently, we have reported additional evidence (1) that the ultracentrifuge may be used (2) to determine isothermal compressibilities

$$[1] \qquad \beta_T = -(1/V)(\mathrm{d}v/\mathrm{d}P)_T$$

for liquids at 1 bar and that β_T was inversely proportional to the cohesive energy of the liquid as measured by its bulk surface tension (1). In this study we wish to report the use of the ultracentrifuge as a pressure-densitometer in that specific volumes ($\bar{v}_p$) of liquids may be calculated directly from the definition (3) of β_T as a function of pressure, P, as follows:

$$[2] \qquad \int_{P=0}^{P=P} \beta_T \, \mathrm{d}P = -\int_{\bar{V}_0}^{\bar{V}_P} \frac{\mathrm{d}\bar{V}}{\bar{V}} = -\ln \frac{\bar{V}_p}{\bar{V}_0} = \ln \frac{\bar{V}_0}{\bar{V}_p}$$

The integral term may be evaluated graphically from a plot of β_T *vs.* P. $\bar{V}_0$ is the specific volume of liquid at 1 bar.

Other methods for determining β_T have required the direct measurement of liquid volume changes as a function of pressure (4, 5). Adiabatic compressibilities (6) have been calculated from the velocity of sound through a compressed liquid. These methods that do not use the ultracentrifuge may be open to some criticism in that (*a*) at low pressures, 0–200 bars, it is difficult to measure accurately the small changes which occur in the volume and (*b*) heat capacity data required for conversion of adiabatic compressibility to β_T may not be readily available. Therefore we have compared the specific volumes of several liquids at various pressures using the ultracentrifuge with those reported by other investigators.

In addition, we have calculated the tangent bulk modulus ($1/\beta_T$) directly from compressibility data. The pressure variation of $1/\beta_T$ is somewhat difficult to obtain from the experimentally observed volume changes of a liquid under pressure (7). Moelwyn-Hughes (3) has shown that $1/\beta_T$ can provide some insight into the molecular events that occur upon compression of a liquid from the following relationship

$$[3] \qquad \frac{\mathrm{d}(1/\beta_T)}{\mathrm{d}P} = (1/3)(y + z + 6)$$

where y and z are the attraction and repulsion exponents, respectively, of the Mie equation. Although it is quite common to assume that the Lennard–Jones potential, $y = 6$ and $z = 12$, may be used to approximate the interaction of organic molecules in the liquid state (3, 8), our data on the compressibility of liquids as a

For personal use only.

function of pressure strongly indicate that such a supposition of the 6-12 potential is in error.

Experimental

The modified (1, 2, 9) procedure of Dayantis for pressure studies was used throughout this work. In addition the camera lens and the cylinder lens were refocussed for each liquid since Richards *et al.* (10) indicated the need for refocussing every time a solution of different refractive index was used. The method of Wiener (11) was used[1] to establish a linear relation between the plane of focus for schlieren optics in the ultracentrifuge cell along the optic axis, and the refractive index of the liquid contained in the cell. Our compressibility experiments were performed with the camera lens focussed on a level of the cell along the optic axis such that the emerging light ray would be recorded on the photograph at its entrance coordinate along the centrifugal axis. The optic and centrifugal axes are at 90° to each other. The linear relationship between the plane of focus measured from the back of a 1.2 cm centrifuge cell, and n the refractive index at 5461 Å, and 25° was

$$[4] \qquad X_{(cm)} = 0.2726\, n + 0.3914$$

From this least squares equation (r, correlation coefficient = 0.999) and known refractive indices of various organic liquids, correct focussing values could be obtained.

An aluminum centerpiece and sapphire windows were used in the centrifuge cell. All organic liquids were purchased CP or of spectroanalyzed grade and were used after drying overnight with pellet KOH or $CaSO_4$. Gases were eliminated by vacuum distillation. Water was double distilled from glass and then vacuum distilled. To keep gas contaminants minimal, it was necessary to fill and to cap the centrifuge cell under a helium atmosphere. Pictures were taken 30 min after reaching the appropriate temperature and speed, *e.g.* 25°, 33 450 r.p.m. and then 25°, 3000 r.p.m. in that order. The base line photograph was taken second to account for slight base line shifts frequently observed due to rearrangements of the cell components subjected to high centrifuge speeds (1). The photographic plates were aligned on their reference lines in a Nikon two dimensional microcomparator and readings of the height of the schlieren pattern above the references were taken every 0.2 cm. Meniscus values were obtained by extrapolation. The height (h) of the schlieren pattern at any speed above the base line pattern (3000 r.p.m.) was proportional to isothermal compressibility, β_T, as demonstrated by the equation of Dayantis (2)

$$[5] \quad (1 + (\beta_T)_p P)(\beta_T)_p = \frac{(h)6n_p \tan\theta}{Lam_1m_2(n_p^2 + 2)(n_p^2 - 1)\rho_0 w^2 r_p}$$

where θ was the schlieren bar angle, 70°; L, the optical lever; a, the cell thickness; m_1m_2, the vertical magnification of the optical system; w, the angular velocity; and r_p, the distance from center of rotation. Densities, ρ_0, of the liquids were literature values (12) and n_p, the refractive index of the liquids under pressure, was calculated as previously reported (9).

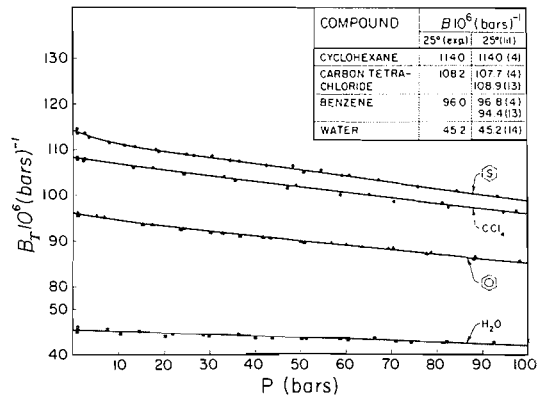

FIG. 1. Compressibilities (β_T) as a function of pressure for cyclohexane, carbon tetrachloride, benzene, and water at 25°.

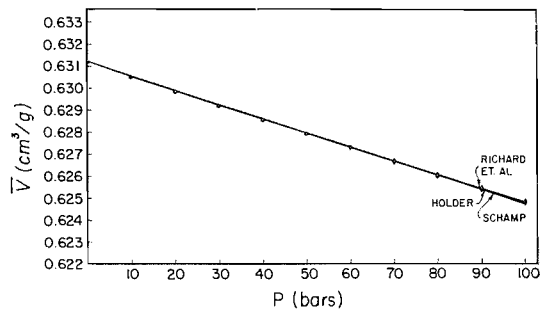

FIG. 2. The effect of pressure on specific volume ($\bar{v}$) of carbon tetrachloride.

Results and Discussion

In Fig. 1 are shown the plots of β_T *vs.* P for the liquids water, benzene, carbon tetrachloride, and cyclohexane at 25 °C. The *insert* compares our experimental β_T values with those in the literature at 1 bar. The specific volume of CCl_4 obtained at 25° from β_T values is plotted in Fig. 2 against pressure, together with curves given by Holder and Whalley (4) and by Schamp *et al.* (13). Excellent agreement may be seen between our work and that of Holder, since a difference at 100 bars of only 10 p.p.m. is observed (Table 1). An equation of state of the form

$$[6] \qquad \bar{V}_p = \bar{V}_0(1 - AP + BP^2 - CP^3)$$

may be used (4) to represent our data for liquids, *e.g.* carbon tetrachloride, benzene, cyclohexane,

and water at 25°. $\bar{V}_p$ is the specific volume at any pressure, and $\bar{V}_0$ is the specific volume at 1 bar. The constants were evaluated by multiple linear least squares regression analysis; and these constants, A, B, and C, are listed in Table 1. Also given in Table 1 are the $\bar{V}_p$ values at 25 °C and 100 bars for comparison with those from the literature. Thus, it is concluded that the ultracentrifuge may be used to advantage for determining specific volumes or densities of organic liquids as a function of pressure. Errors in such determinations are not greater than one or two parts in ten thousand. The major difficulty in extending the pressure range of the ultracentrifuge above about 100 bars results from bending of the sapphire cell windows (at about 35 000 r.p.m.) for which no corrections can be made at present time.

In addition, it should be noted that the approximation inherent in eq. 5 where the pressure average β of the $(1 + (\beta_T)P)$ term is assumed to be $(\beta_T)P$ will be less satisfactory as pressure increases.

In order to evaluate the repulsion (z) and attraction (y) exponents of the Lennard–Jones type from eq. 3, the tangent bulk modulus $(1/\beta_T)$ was plotted against pressure (Fig. 3). The slopes $d(1/\beta_T)/dP$ for the three organic liquids carbon tetrachloride, benzene, and cyclohexane, range from 11.7–12.0. The slope for water was 18.8. An unexplained downward curvature was noted at low pressures for the three organic liquids. Although the 6-12 potential was successful in representing molecular interactions of the inert gases and mercury (3), the work of Hamann and Lambert (15) and of Gupta and King (16) has shown that 7-28 potential functions were superior in representing the experimental properties of high density gases and fluids of somewhat spherical molecules, *e.g.* CCl_4. Application of 7-28 potential to eq. 3 permits calculations of a $d(1/\beta_T)/dP$ value of 13.6 whereas a 6-12 potential gave a $d(1/\beta_T)/dP$ value of 8. Thus, use of the 7-28 potential approximates our data (Fig. 3) much more closely than use of the 6-12 potential. A 6-24 potential would best describe

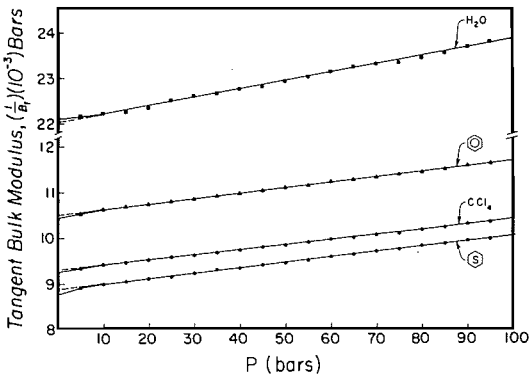

FIG. 3. The effect of pressure on the tangent bulk modulus ($1/\beta_T$) of several liquids.

our data. Water, because of its dipolar nature, behaves differently from the organic liquids and should require at least a three term potential such as the one presented by Rao and Keer (17). There is considerable evidence that liquid water also may contain ice-like clusters at 25° (18) and thus may not behave as a "pure" liquid. Unfortunately, the three term approach leads to an expression for $d(1/\beta_T)/dP$ which is dependent upon the distance between molecules at the potential energy minimum and on the distance between molecules when the potential energy equals zero. Neither of these distances are known experimentally.

Folded Conformations. IV. Intramolecular Shielding and Intramolecular Charge-Transfer Interaction in Benzyl Phenyl Sulfones and Sulfoxides

(MRS.) RENÉE VAN EST-STAMMER AND JAN B. F. N. ENGBERTS[1]

Department of Organic Chemistry, The University, Zernikelaan, Groningen, The Netherlands

Received September 18, 1972

Proton magnetic resonance spectra of the title compounds (A-SO_2CHR-D) were measured and compared with the spectra of appropriate reference systems containing an alkyl substituent instead of one of the aromatic rings. The observed upfield shifts of the aromatic proton resonances in the title compounds suggest that there is a significant population of folded conformations, which possess a *gauche* orientation of the aromatic rings. This conclusion is supported by the observation of an intramolecular charge-transfer band in the u.v. spectra of the compounds containing an A ring of high electron affinity and a D ring of low ionization potential. Stabilization of the folded forms may be obtained through minimizing the n–π repulsive forces between the sulfonyl oxygen lone pairs and the π-electron system of the D ring.

Les spectres de résonance magnétique nucléaire des composés cités (A-SO_2CHR-D) ont été enregistrés et comparés avec les spectres de référence de systèmes appropriés contenant un substituant alkyle au lieu d'un des cycles aromatiques. Les déplacements observés pour les protons aromatiques vers un champ élevé, laissent penser à l'existence d'une population importante en conformères plissés qui possèdent une orientation *gauche* pour les cycles aromatiques. Cette conclusion a été confirmée par l'observation en u.v. d'une bande de transfert de charge intramoléculaire pour les composés possédant un cycle A d'électroaffinité élevée et un cycle D à faible potentiel d'ionisation. La stabilisation des formes plissées peut être obtenue par minimisation des forces répulsives n–π entre les doublets libres de l'oxygène du groupe sulfonyle et le système électronique π du cycle D. [Traduit par le journal]

Can. J. Chem., **51**, 1187 (1973)

Introduction

During recent years it has been established that in solution a number of relatively simple molecules, possessing many degrees of internal rotational freedom, occur in preferred folded conformations (1–6). In suitably designed structures reliable probes for the detection of these folded conformations are: (*i*) intramolecular (de)shielding effects in n.m.r. spectra and (*ii*) intramolecular charge-transfer (CT) interaction between donor (D) and acceptor (A) groups which are positioned in the vicinity of each other as a result of the folding of the molecule (2, 7–13).

It has been shown by X-ray crystallography that the folded conformation of cyclo-glycyl-L-tyrosyl (14) and of ethyl *N*-methyl-*N*-*p*-tolylsulfonylmethylcarbamate (15) is retained in the solid state. In sharp contrast, 2-methyl-3-*N*-methylanilinomethyl-1,4-naphthoquinone, which shows intramolecular CT interaction in solution (10), adopts an unfolded conformation in the crystal (16).

The causes of the folding of the molecules in question have not been defined clearly. Intramolecular dipole–dipole interactions, dipole-induced dipole interactions, and dispersion forces have all been invoked to explain the conformational preferences (3–5).

Preliminary work (2) has demonstrated the occurrence of folded conformations for benzyl phenyl sulfones (A-SO_2CH_2-D). In continuing these studies, we have now obtained new data that shed some additional light on the factors that help to stabilize the folded forms.

Results and Discussion

In Table 1 chemical shifts are presented of the aromatic protons of systems of the type A-SO_2CHR-D (R = H and —CH_3). In order to check for n.m.r. spectral perturbations due to intramolecular proximity effects, the selection of proper reference compounds is of crucial importance. We have used systems related as closely as possible to the compounds under study, but lacking either the A or D aromatic ring (n.m.r. data also included in Table 1). Unfortunately, for the D part of **6** no reliable reference is available at the moment because of our inability to prepare the corresponding alkane sulfonyl derivative.

§Center of broad singlet.

The data given in Table 1 reveal that the aromatic proton resonances of **1**, **4**, **6**, and **7** are shifted to higher field by *ca.* 0.15–0.40 p.p.m. ("$\Delta\delta_H$-values"). Since the effect of dilution (0.1–1.0 *M*) on the chemical shifts is negligible (<0.05 p.p.m.), significant shifts due to intermolecular shielding can be excluded. Therefore, the upfield shifts suggest that these compounds possess significant populations of conformations in which the aromatic rings experience each other's magnetic anisotropy effect.

In the benzyl sulfones a conformation with eclipsed aryl rings will be sterically unfavorable owing to π–π repulsion. Conformations with S=O eclipsed with the D ring will be destabilized by n–π repulsion. However, two *gauche* conformations, which permit mutual shielding of the aromatic ring protons, are easily attainable (Fig. 1). The observed upfield shifts are only slightly smaller than those found for the phenyl

absorptions of 1,8-diphenylnaphthalene (17) where the phenyl rings assume a preferred face-to-face arrangement.

Additional evidence for folding of the sulfonyl systems is provided by u.v. spectroscopy. Those compounds that contain an A ring of high electron affinity together with a D ring of low ionization potential are colored and they exhibit a broad and structureless long-wavelength absorption band which cannot be attributed to either of the separate chromophores (Table 2 and Fig. 2). The new band obeys Beer's law in the concentration range between at least 10^{-5}–10^{-3} *M*. This strongly suggests that the band should be attributed to intramolecular CT interaction. Since it is reasonable to suppose that the σ and π electrons of the SO_2—CHR bridge are involved to only a minor extent in the CT interaction (18), the transition will be mainly

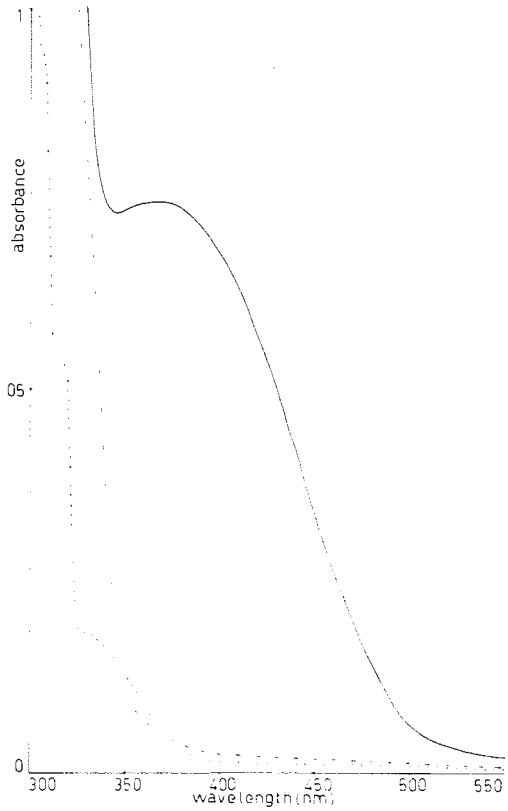

FIG. 2. U.v. spectra of 10^{-3} *M* solutions of **4** (—), **2** (···), and *p*-$CH_3C_6H_4CH_2C_6H_4N(CH_3)_2$-*p* (---) in $CHCl_3$.

the result of excitation of an electron from the highest occupied molecular orbital of the D ring to the lowest vacant orbital of the A ring in a folded conformation. However, there is a considerable difference in orientation of the A and D ring in the folded form of **1** as compared with that in the *inter*molecular complex between *N*,*N*-dimethyl-*p*-toluidine and methyl *p*-nitrophenyl sulfone because in the latter case a CT band is observed at much longer wavelength (2). It is of interest to note that sulfone **6**, which contains two potential donor–acceptor systems, shows a much larger ε_{max} (at 365 nm) than **1**. Apparently both benzyl phenyl sulfone systems are partially folded in solution.

For **1**, **4**, and **7** (and the corresponding reference compounds) the temperature dependence of the n.m.r. and u.v. spectra was examined in the hope of obtaining sufficiently large effects to allow the calculation of the thermodynamic parameters for the equilibrium between folded and unfolded forms. Although at higher temperatures deshielding of the aromatic proton resonances was observed, indicating partial unfolding, the differences were distressingly small (*i.e.* <3 Hz over the range -60 to $+60°$ in $CDCl_3$ or $+40$ to $+180°$ in DMSO-d_6).

However, the temperature effect suggests that there exists a (small) preference for the folded *gauche* conformations. This is in contrast to the situation for (substituted) 1,2-diphenylethanes where the *trans*-form is definitely favored, presumably owing to the repulsive π–π interaction in the *gauche* forms (19).

For **1** an increase in temperature is accompanied by a small hypsochromic shift of the CT maximum (17.8°, λ_{max} 368 nm, ε_{max} 526 l mol^{-1} cm^{-1}; 47.8°, λ_{max} 360 nm, ε_{max} 536 l mol^{-1} cm^{-1}), most likely attributable to a solvent-effect. The limited data presented in Table 3 also suggest that solute–solvent interactions play a role in determining the equilibrium between folded and unfolded forms. More polarizable solvents seem to destabilize the folded conformations of **7** in contrast to the minor effect of solvent polarizability on the folding tendency of some cyclic peptides (4).

The data obtained thus far do not allow definite conclusions regarding all possible mechanisms which may produce the folding tendency of the molecules. It is clear however, that CT interaction does not contribute significantly to the ground state stabilization as demonstrated by the approximately equal $\Delta\delta_H$ values for **1** and **7**.

In order to investigate whether dipolar interactions involving the strongly polarized sulfur–oxygen bonds of the sulfonyl function are effective in producing folded *gauche* conformations, we have prepared the sulfoxide and sulfide analogs of **7**. The data in Table 1 reveal that intramolecular shielding is decreased in the sulfoxide **10** and is negligible in the sulfide **13**, as compared with **7**. These results may be rationalized by assuming that the repulsive interaction between the lone pairs on the sulfonyl oxygen(s) and the π-electron cloud of the D ring (Fig. 1) will at least partially determine the favored dihedral angle defined by the bonds C_1^A—S—CHR—C_1^D and therefore the folding tendency. The known preference (20) of aryl sulfones to adopt conformations in which the ring C_1^A 2*p*-orbital is staggered between the two sulfonyl oxygen atoms ("case II conjugation")

*Chemical shifts in p.p.m. downfield from internal TMS (δ = 0). Concentration 0.2 *M* in $CDCl_3$.

will help to orient the A and D ring parallel to each other.

In an attempt to gain additional evidence for the proposed nonbonded interactions, the chemical shifts were measured of alkyl groups in some sulfones, sulfoxides, and sulfides containing either an aryl or an alkyl moiety in one of the β-positions (Table 4). In **16**, **18**, and **21**, the methyl and ethyl groups clearly experience upfield shifts as compared with **17**, **19**, and **22**, respectively, most likely due to the magnetic anisotropy effect of the β-aryl group.[2,3] Analysis of the intramolecular shielding of the methyl group in the *gauche* conformations of **16**, **21**, and **23** using Johnson and Bovey's isoshielding lines (21) and known bond angles and distances (22–24) reveals that the shielding should be approximately equal in **16** and **23** and appreciably less in **21** (Table 5).[4] The data in Table 4 show however, that intramolecular shielding decreases in the order sulfone > sulfoxide > sulfide, as in the case of the benzyl phenyl sulfones, thereby supporting the proposed n–π repulsive interactions.

TABLE 5. Calculated and observed intramolecular shielding in the *gauche* conformations of **16**, **21**, and **23**

Compound	Shielding (Hz)		Mole fraction of *gauche* conformation*
	Calcd.	Observed	
16	+18	+15	0.83
21	+13	+10	0.77
23	+18	+6	0.33

*These values are presumably slightly too low because of the inductive effect of the β-aryl ring (see text).

Experimental

N.m.r. spectra were recorded on a Varian A-60 D spectrometer equipped with a Varian V 6049 variable temperature controller. The recorder was calibrated with a side band technique using a Hewlett–Packard 200 AB audiooscillator and a Hewlett–Packard 5223 L electronic counter. Chemical shifts are given relative to TMS (δ = 0) as internal reference. If necessary, peak assignments were confirmed through the use of $Eu(DPM)_3$ as a paramagnetic shift reagent. U.v. spectra were taken with a Zeiss PMQ II spectrophotometer using 1 cm cells at

[2]A downfield shift would be expected solely on basis of the inductive effect of the β-aryl ring.

[3]In **20** only the methyl part of the ethyl moiety can be positioned in the shielding region of the aromatic ring.

[4]Calculation of the intramolecular shielding in benzyl phenyl sulfones is less straightforward but it is reasonable to expect that the preference for *gauche* conformations will be decreased due to π–π repulsions.

room temperature and 2 cm cells at variable temperatures in a temperature-controlled cell holder. I.r. spectra were measured on a Perkin–Elmer model 257 or model 125.

Melting points (uncorrected) were determined with a Mettler FP 1 melting point apparatus equipped with a Mettler FP 52 microscope attachment. Elemental analyses were carried out in the Microanalytical Section of our Department (supervisor: Mr. W. M. Hazenberg) and were satisfactory for the new compounds described.

Compounds **2** (25), **8** (26), **11** (27), **14** (28), **16**, **18**, **20**, **21**, and **23** were prepared by literature procedures. The new compounds were prepared as follows: sulfones **1** and **3–6** by condensation of aromatic amine with formaldehyde (or acetaldehyde) and the appropriate sulfinic acid (29); benzyl sulfides **13** and **15** from the corresponding thiols with *p*-methoxybenzylalcohol (29, 30); and sulfoxides **10** and **12** and sulfones **7** and **9** by oxidation of **13** and **15**, respectively, with 30% H_2O_2 in acetic acid (31). Yields and physical data of the new compounds are given in Table 6.

On the Mechanism of Ring Inversion in Cycloheptene and Its Derivatives

MAURICE ST-JACQUES AND CAMBYSE VAZIRI
Department of Chemistry, University of Montreal, Montreal, Quebec

Received October 6, 1972

Free energy barriers to ring inversion of 3,3-dimethyl-, 4,4-dimethyl-, and 5,5-dimethylcycloheptene were found to be much smaller than those of corresponding benzocycloheptene derivatives but show the same trend. This observation strongly suggests that the chair conformation of both types of molecules interconverts through the same mechanism. On the other hand, the $\Delta G^{\neq}$ value for 4,4,6,6-tetramethylcycloheptene is about 3 kcal/mol out of line from that expected from a consideration of the behavior of the corresponding benzocycloheptene derivative. An explanation is offered.

Les barrières d'énergie libre pour l'inversion des diméthyl-3,3, diméthyl-4,4 et diméthyl-5,5 cycloheptènes, tout en conservant la même tendance, sont plus faibles que celles qui caractérisent les dérivés correspondants du benzocycloheptène. Cette observation indique que la conformation chaise des deux classes de molécules s'inverse par le même mécanisme. Par contre, la valeur de $\Delta G^{\neq}$ pour le tétraméthyl-4,4,6,6 cycloheptène est environ 3 kcal/mol plus élevée que celle attendue après examen des benzocycloheptènes correspondants. Une explication est présentée.

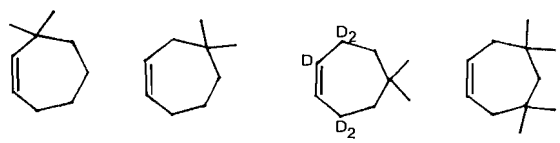
Attention has recently been given to the determination of the conformations and conformational mobility of cycloheptene and several of its derivatives (1–4). Most of the published experimental work has been concerned with n.m.r. investigations either of derivatives of benzocycloheptene (1*a*) or of cycloheptene with ring carbons replaced by heteroatoms (1*b*) as it was realized that constraints imposed by such modifications of cycloheptene raised the barrier to inversion sufficiently to enable a complete study of the p.m.r. spectral change occurring at readily accessible low temperatures. Because simple derivatives of the cycloheptene carbocycle have very low $\Delta G^{\neq}$ value (2), relatively few have been investigated until now.

Considerable efforts have also been oriented towards the theoretical prediction of the nature of the most stable conformations of cycloheptene and benzocycloheptene and their interconversion mechanisms. In fact, calculations by force field methods (1*a*, 4) suggest that the chair form is of lowest energy in both cases although there appears to be some disagreement on the nature of the conformation of the transition state for the most likely interconversion pathway. The earlier work (1*a*) on benzocycloheptene predicted a transition state whose conformation contains five carbon atoms essentially coplanar whereas the most recent work (4) predicts a conformation with six coplanar carbon atoms for cycloheptene.

A valuable step towards understanding the effect of the benzo group consists in demonstrating experimentally whether or not the cycloheptene and benzocycloheptene chairs interconvert through the same mechanism, especially since there is a possibility that the large difference in the free energies of activation ($\Delta G^{\neq}$) of 5.7 kcal/mol (1*a*, 2) might be the result of dual mechanisms.

Our approach to this question has been through the study of a particular substituent effect on $\Delta G^{\neq}$ for both systems. For this purpose we prepared the following compounds: 3,3-dimethylcycloheptene (**1**), 4,4-dimethylcycloheptene (**2**), 5,5-dimethyl-1,3,3,7,7-pentadeuteriocycloheptene (**3**), and 4,4,6,6-tetramethylcycloheptene (**4**).



1 **2** **3** **4**

Results

Compounds **1** and **2** were prepared from the same starting material, 2,2-dimethylcyclohexanone, through ring expansion with diazomethane in the presence of boron trifluoride (5) to give a mixture of 2,2-dimethylcycloheptanone and 3,3-

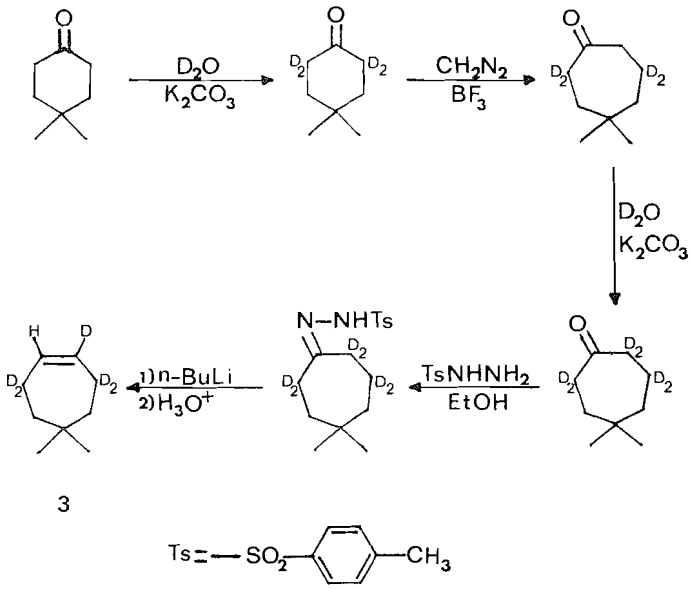


CHART 1

dimethylcycloheptanone (6). Each ketone was obtained pure by preparative v.p.c. and then transformed into the desired cycloheptene derivatives, **1** and **2** respectively, by a procedure utilizing tosylhydrazine and *n*-butyl lithium as recently described (7).

The derivative **4** was prepared from 3,3,5,5-tetramethylcyclohexanone by an analogous route. Compound **3** was also synthesized similarly from 4,4-dimethylcyclohexanone, but since the sequence of reactions involved several deuteration steps, it is illustrated on Chart 1.

The 100 MHz p.m.r. spectrum of **1** at room temperature contains a methyl singlet at δ 1.04 and broad methylene multiplets over the range δ 1.3–2.5. A gradual decrease in temperature down to −170° revealed no spectral change which could be attributed to a slowing down of ring inversion on the n.m.r. time scale. A very slight change in appearance was observed, however; it is due to increased viscosity and small variations in chemical shifts with temperature as indicated clearly from spectra above −120°.

On the other hand, lowering the temperature of a sample of **2** led to a splitting of the methyl singlet (δ 0.91 at +25°) into a doublet separated by 6.5 Hz below −153°, the coalescence temperature (T_c). The free energy of activation characteristic of the underlying process was calculated to be 6.0 ± 0.3 kcal/mol, at T_c, by standard procedures (8) using a transmission coefficient of one half. Consideration of the absence of a spectral change for **1** down to −170° suggests that its corresponding $\Delta G^{\neq}$ must be less than 5 kcal/mol (2, 9).

A preliminary investigation of 5,5-dimethylcycloheptene revealed that its methyl signal remains a singlet down to −170° whereas the broad methylene multiplet centered at δ 1.47 shows an ill-defined spectral change between −130 and −160°. In order to simplify the spectrum and its change, the deuterated derivative **3** was prepared. Figure 1 illustrates the spectral change in the region of the methylene protons (δ 1.47, singlet at +25°) as the temperature is decreased. This behavior is characteristic of the change of an A_2 singlet into an AB pattern. A careful examination of the spectrum at −162° shows a certain degree of asymmetry whereby the right side of the AB pattern is more intense. This deformation appears to be due in part to an overlap with the broad methyl signal. In addition, the small impurity peak, identified with a star in Fig. 1 adds to the asymmetry of the peak in the intermediate region of the spectral change. The analysis of the low temperature AB quartet gives a chemical shift difference of 29.6 Hz and a coupling constant of −13.7 Hz.

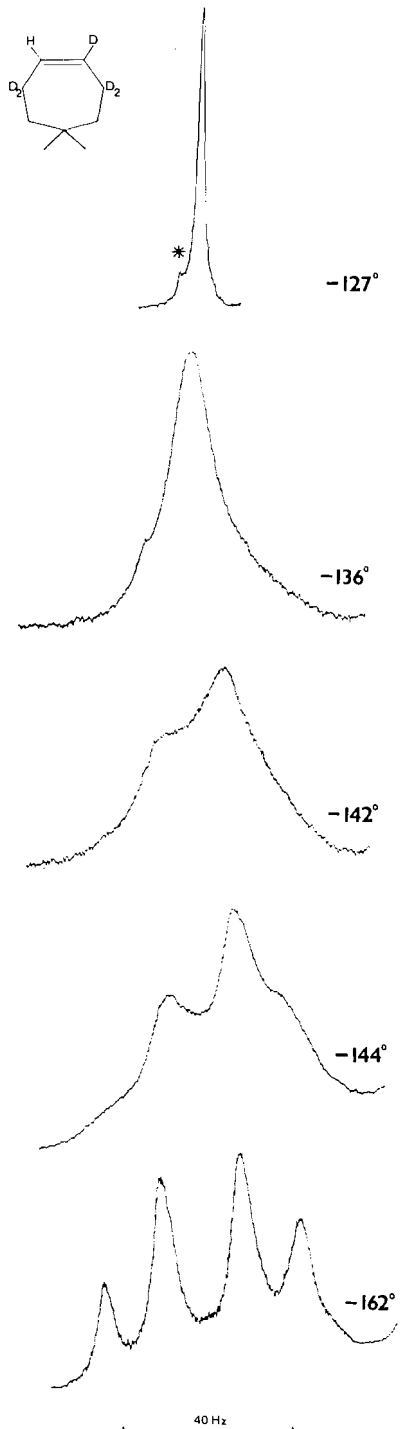

FIG. 1. The 100 MHz p.m.r. deuterium decoupled spectra of the C-4 and -6 methylene protons of **3** at several temperatures.

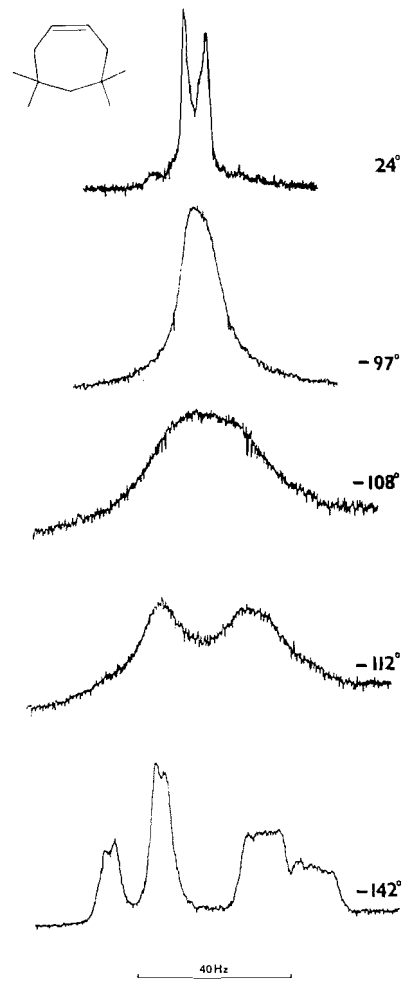

FIG. 2. The 100 MHz p.m.r. spectra of the C-3 and -7 methylene protons of **4** at several temperatures.

T_c is estimated at $-140°$ and a $\Delta G^{\neq}$ value of 6.2 kcal/mol is calculated at this temperature (8).

The 100 MHz, room temperature, p.m.r. spectrum of **4** contains three peaks characteristic of the non-olefinic protons: a singlet at δ 0.94 (four methyl groups), a singlet at 1.48 (C-5 methylene protons), and a doublet at 2.02 (J = 5.5 Hz; C-3 and -7 methylene protons). At low temperature the methyl signal splits into a doublet separated by 10.3 Hz below $-117°$ (T_c) whereas the C-5 methylene peak remains a singlet down to $-170°$. Figure 2 illustrates the change taking place for the signal of the allylic protons. The spectrum at $-142°$ is easily

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

recognized as an AB pattern for which the A and B protons are coupled differently to the olefinic protons. Approximate values for these vicinal coupling constants are 2.5 and 8.5 Hz for the low and high field components respectively; the average of these values agrees quite well with the separation of the high temperature doublet.

From the spectral change of the methyl signal of **4**, $\Delta G^{\neq}$ was calculated to be 7.7 kcal/mol at $-117°$. Table 1 contains a summary of the pertinent n.m.r. and thermodynamic parameters for the derivatives of cycloheptene investigated as well as for corresponding derivatives of benzocycloheptene (1*a*) which are identified by adding the letter *a* to the number of the corresponding cycloheptene derivative.

TABLE 1. N.m.r. and thermodynamic parameters for derivatives of cycloheptene and benzocycloheptene

Compounds	Δν (p.p.m.)	T_c (°C)	$\Delta G^{\neq}$
Cycloheptene	0.56[a]	−165	5.0
Benzocycloheptene	0.41[a]	− 57	10.7
1	—	—	<5
1*a*[b]	0.20[c]	− 73	10.3
2	0.065	−153	6.0
2*a*	0.47	− 45	11.3
3	0.296[d]	−140	6.2
3*a*	0.21	− 52	11.8
4	0.103	−117	7.7
4*a*	0.33	− 63	10.4

[a]For these compounds Δν refers to the C-5 protons whereas it refers to the methyl protons for all other compounds except 3; data taken from refs. 1*a* and 2.
[b]The label a in **1a** means that it is the benzo derivative of **1**. Data for these derivatives taken from ref. 1*a*.
[c]The spectra were taken at 60 MHz.
[d]The Δν refers to the C-4 protons.

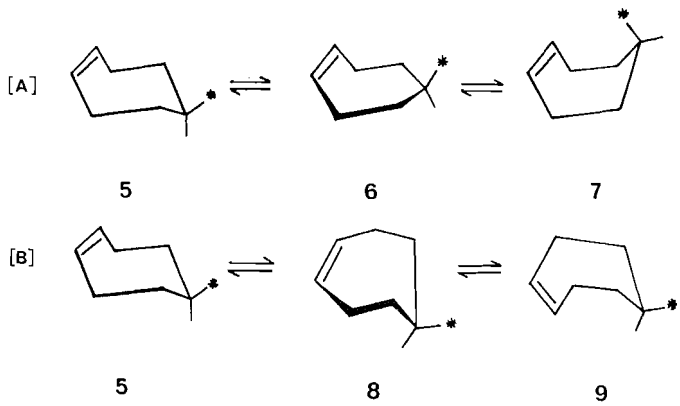
Discussion

It has recently been demonstrated that benzocycloheptene (3) and some of its methyl derivatives (1*a*) exist in the chair conformation and cycloheptene undoubtedly also does (2, 4, 10). While the low temperature spectra of compounds **1**, **2**, **3** and **4** do not give direct information on the stable conformation, there is no reason to suspect a change in the geometry of the ground state and so we assume that all molecules considered in this work exist as chair conformations.

A careful examination of the results given in Table 1 shows that each class of dimethyl compounds exhibits a similar trend in the variation of $\Delta G^{\neq}$ with respect to the parent compound. The behavior of the tetramethyl derivatives, on the other hand, seems abnormal since the $\Delta G^{\neq}$ of **4** is 2.7 kcal/mol higher than that of cycloheptene whereas that of **4***a* is about 0.3 kcal/mol lower than the value of benzocycloheptene.

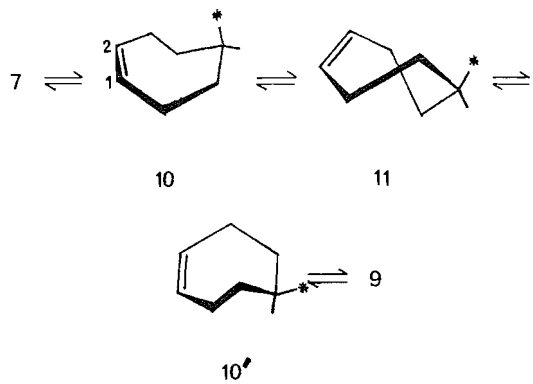
Experimental conditions (very low temperature, small Δν values, impossibility to get accurate T_2 in absence of exchange) make meaningful estimates of $\Delta S^{\neq}$ through computer simulation impossible. But since it is known that $\Delta S^{\neq}$ is close to zero for 5,5-difluorocycloheptene (10), symmetry arguments (2) suggest that it will be similar for the compounds of interest to us. It therefore appears that $\Delta H^{\neq} \approx \Delta G^{\neq}$ and that the differences in Table 1 ($\Delta\Delta G^{\neq}$) are fair approximations to $\Delta\Delta H^{\neq}$ for these compounds.

Ring inversion of the cycloheptene chair, responsible for the spectral changes of compounds **1** to **4**, must proceed through several steps (1*a*, 4). The first one consists of the change from the chair to a boat form; it is followed by



a pseudorotation among the boat forms and then by a conformational change to an inverted chair. While there is agreement on the mechanism for pseudorotation, two different pathways, [A] and [B], have been suggested for the chair to boat interconversion. One possibility [A] involves wagging C-5 of the chair (**5**), through an intermediate (**6**) having five carbon atoms in one plane, into the boat form (**7**) while the other [B] involves wagging the double bond, through a conformation (**8**) having six coplanar carbon atoms, into the boat form (**9**).

Pseudorotation which interconverts boat and twist-boat forms is illustrated below and shown to proceed through the high energy conformations **10** for which C-1, -2, -3, -4, and -7 lie essentially in one plane while C-4, -5, -6, and -7 lie in another (refered to as 1,2-biplanar form; **10′** is an inverted form of **10**).



Since the wagging of C-5 or C=C through transition states **6** or **8** involves deformations of different parts of the cycloheptene ring, it follows that substituent effects should depend on the actual mechanism of inversion. The observation (Table 1) of the same trend in $\Delta G^{\neq}$ for dimethyl derivatives of cycloheptene and benzocycloheptene therefore suggests strongly that the chair conformation of both classes of compounds interconverts through the same pathway.

Variations in $\Delta G^{\neq}$ with substitution are normally due to changes in energy of the ground state and/or transition state conformations provided all derivatives follow the same mechanism. It is often difficult to assess quantitatively the various contributions to each, although under favorable circumstances, when substituent effects are very large, it is usually possible to distinguish between two alternatives. Data in Table 1 show that differences are small within each class of dimethyl derivatives whereas the effect of the benzo group is quite large (~5 kcal/mol) for all substitution patterns. Since a unique mechanism is inferred from the results, it seems highly probable that the pathway which best explains the effect of the benzo group is the correct one.

Previous rationalizations of n.m.r. results (2, 10) in terms of transition state **6** were of limited success since they could not account adequately for the large effect of the benzo group. The theoretical prediction by Allinger and Sprague (4) that the cycloheptene conformation should invert through pathway B appears to go against a prediction based on model calculations (1*a*) but the remarkable agreement between the calculated energy barrier of 5.16 kcal/mol and the experimental value of 5.0 kcal/mol (2) supports the contention that models are indeed misleading here. The above agreement together with the results reported in Table 1 indicate that benzocycloheptene derivatives also invert through the same pathway B, the large effect of the benzo group being a consequence of the much lower torsional energy for rotation about the C_1—C_7 and C_2—C_3 bonds of benzocycloheptene than of cycloheptene (4, 11).

A detailed account of the various factors responsible for the trends in $\Delta G^{\neq}$ is virtually impossible since it would require the quantitative evaluation of several interactions both in the ground state and transition state. On the other hand, it is possible to point out some of the most important interactions and assess qualitatively their effect on $\Delta G^{\neq}$. For example, the eclipsing between the C-3 equatorial methyl group and the olefinic proton in structure **12** as well as transannular synaxial CH_3/H interactions between the C-3 axial methyl with the axial protons on C-5 and -7 should lead to a larger relief of torsional and repulsive strain for the inversion of **1** than of cycloheptene. Similar arguments are also valid for **1***a* so that it is not surprising to observe that $\Delta G^{\neq}$ for both **1** and **1***a* are lower than values for the parent compounds.

Methyl interaction with either an aromatic carbon or an olefinic proton should be absent in compounds **2**, **2***a*, **3** and **3***b* as seen in structures **13** and **14** which also reveal serious transannular

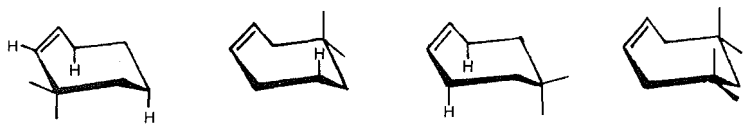
For personal use only.



12 13 14 15

syn-axial CH_3/H interactions. The inversion of **2** and **2***a* (4,4-dimethyl derivatives) is characterized by small changes of torsional strain about the C_3—C_4 and C_4—C_5 bonds and an increase in *syn*-axial CH_3/H repulsion since the distance between the groups concerned gets smaller in transition state **8**. The sum of the energies involved could easily account for a large fraction of the increase in $\Delta G^{\neq}$ of **2** and **2***a* over that of cycloheptene and benzocycloheptene. On the other hand, the inversion of **3** and **3***a* (5,5-dimethyl derivatives) is characterized by a relief of transannular interaction and an increase in torsional strain about the C_4—C_5 and C_5—C_6 bonds, the net effect being an increased barrier to ring inversion over that of the parent compounds.

Structure **15** illustrates the strong transannular methyl–methyl repulsion present in the chair form of **4** and **4***a* (4,4,6,6-tetramethyl derivatives). The energy of this interaction is probably comparable to that in 1,1,3,3-tetramethylcyclohexane (about 3.7 kcal/mol (12)) since the methyl–methyl distance is slightly less for the seven-membered ring. The change in torsional strain about the C_3—C_4, C_4—C_5, C_5—C_6, and C_6—C_7 bonds and the small increase in transannular *syn*-axial interaction during inversion through transition state **8** could add up to account for the small decrease in $\Delta G^{\neq}$ for **4***a*. Results for the dimethyl derivatives suggest that the same trend should carry over to **4** provided the energy profile for inversion was such that **8** is the rate determining transition state as is the case for **4***a*. Instead, a very significant departure in trend is observed.

Figure 3*a* illustrates the energy profile for the ring inversion of cycloheptene based on calculations (4) and recent p.m.r. results (2). The effect of the benzo group on the inversion profile of benzocycloheptene is shown qualitatively in Fig. 3*b* where the dominant feature is the large energy difference between the chair form and the transition state of geometry similar to **8**. While

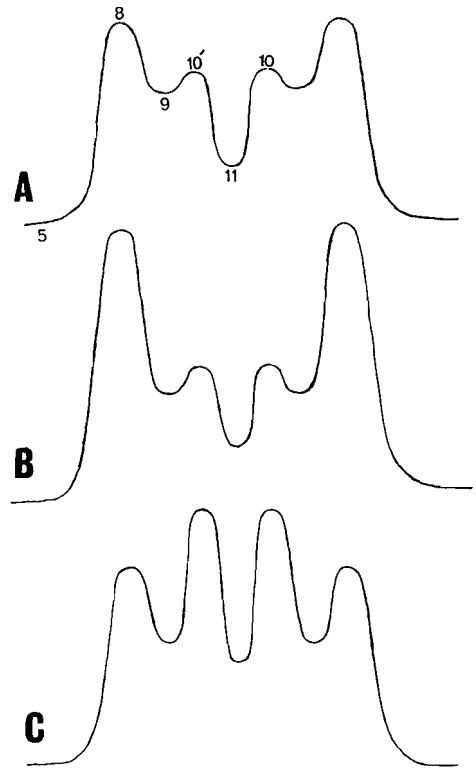


FIG. 3. Possible free energy profiles for the interconversion of chair conformations of (*a*) cycloheptene; (*b*) benzocycloheptene; (*c*) 4,4,6,6-tetramethylcycloheptene (**4**). The prime indicates the inverted form.

profile *b* is able to account for the substituent effect on $\Delta G^{\neq}$ for **1***a*, **2***a*, **3***a*, and **4***a*, profile *a* cannot explain the large increase in $\Delta G^{\neq}$ for 4,4,6,6-tetramethylcycloheptene (**4**).

It therefore appears that a different energy profile must exist for **4** and curve *c* in Fig. 3 is a possibility. This profile supposes that the stable conformation of **4** is a chair by analogy with **4***a* (1*a*) and suggests that the transition state **10** for pseudorotation becomes rate determining. This change is possible for **4** because the two maxima of profile *a* have very close conformational energies as suggested from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

calculations (4). The examination of a structure of geometry **10** for **4** reveals a large transannular C_4–methyl and C_7–proton interaction as well as increased torsional energy about the C_5—C_6 bond. These factors therefore could be responsible in large part for the very significant increase in the energy barrier to pseudorotation. Alternatively, if the stable conformation of **4** was a twist-boat, implying that the serious *syn*-axial methyl repulsion shown in structure **15** results in a change of conformation for **4** but not **4***a*, then an increased barrier to pseudorotation of twist-boat forms could also explain the $\Delta G^{\neq}$ value of **4**. The p.m.r. spectrum of **4**, unlike that of **4***a* (1*a*), is compatible with a twist-boat conformation since its C-5 methylene group remains a singlet down to lowest temperature attained.

In conclusion, we think that our study has provided sufficient experimental data to justify the comparison of the properties of the seven-membered ring of cycloheptene and benzocycloheptene. Our results strongly suggest that, in spite of the large difference in $\Delta G^{\neq}$ values for ring inversion, simple derivatives of both ring systems have similar conformational properties. For the more substituted derivatives, however, a careful consideration of possible change in energy profile for the cycloheptene derivative is necessary to predict substituent effects.

Experimental

The v.p.c. analyses and separations were carried out as previously reported (2, 3). Mass spectral analyses were performed on an Associated Electrical Industries MS-902 high resolution mass spectrometer operating at 70 and 12 eV. Mass determinations were made by comparison with perfluorotributylamine. Samples for low temperature studies consisted of 5% solutions in chlorodifluoromethane containing a small quantity of TMS, degassed and sealed.

Preparation of 3,3-Dimethylcycloheptene (1) and 4,4-Dimethylcycloheptene (2)

A solution of 1.0 g (0.007 mol) of 2,2-dimethylcyclohexanone in 20 ml of ether containing 1 ml of freshly distilled boron trifluoride etherate was reacted with diazomethane by a procedure described previously (6) until the amount of cycloheptanone was maximized as determined by v.p.c. analysis using a carbowax column at 200 °C. 2,2-Dimethylcycloheptanone (shorter retention time) and 3,3-dimethylcycloheptanone (longer retention time) were obtained in comparable amounts. The products of several reactions were separated and purified by preparative v.p.c. and found to have identical properties to those reported in the literature (13) and used in the next reactions.

3,3-Dimethylcycloheptene (1)

2,2-Dimethylcycloheptanone, 0.20 g (0.0014 mol), and 0.28 g of tosylhydrazine were dissolved in 10 ml of hot absolute ethanol. After 24 h of reflux, the reaction mixture is held at 0° for a few hours. The tosylhydrazone crystallized out and was collected by filtration. Elimination was carried out using a recently described procedure by Shapiro and Heath (7), whereby 10 ml of a 1.6 *M* solution of *n*-butyllithium in *n*-hexane was added dropwise at 0° to the above tosylhydrazone in 7 ml of ether; the reaction mixture was then stirred overnight. After work-up, v.p.c. analysis revealed a major product which was then collected using a silicon fluid DC550 column at 100°. The p.m.r. spectrum (60 MHz) of the product in carbon disulfide is in accord with that expected for 3,3-dimethylcycloheptene (**1**): singlet at δ 1.04 (6H); a broad signal centered at 1.6 (6H); a broad signal at 2.05 (2H), and a multiplet at 5.45 (2H).

Mol. Wt. Calcd. for C_9H_{16}: 124.1252. Found (mass spectrum at 70 eV): 124.1251.

4,4-Dimethylcycloheptene (2)

A quantity of 0.25 g (0.0018 mol) of 3,3-dimethylcycloheptanone from above was reacted similarly with tosylhydrazine followed by elimination with *n*-butyl lithium and purification by v.p.c. The product gave a p.m.r. spectrum in carbon disulfide (60 MHz) characteristic of 4,4-dimethylcycloheptene (**2**): singlet at δ 0.89 (6H); multiplet at 1.50 (4H); multiplet at 2.0 (4H), and a multiplet at 5.50 (2H).

Mol. Wt. Calcd. for C_9H_{16}: 124.1252. Found (mass spectrum at 70 eV): 124.1253.

Preparation of 5,5-Dimethyl-1,3,3,7,7-pentadeuteriocycloheptene (3)

4,4-Dimethylcyclohexanone (13) (6.5 g, 0.051 mol) was refluxed 16 h with 60 ml of deuterium oxide containing 6.0 g of potassium carbonate. The product was extracted with ether, dried, and condensed. A second exchange with 15 ml of deuterium oxide and 1.5 g of potassium carbonate followed by extraction and evaporation of the ether solvent gave 4,4-dimethyl-2,2,6,6-tetradeuteriocyclohexanone with a very high deuterium content as revealed from its p.m.r. spectrum in CCl_4: singlet at δ 1.10 (6H) and a broader singlet at 1.65 (4H).

Ring expansion of 5.0 g (0.038 mol) of the deuterated ketone as previously described gave a mixture of products from which 4,4-dimethyl-2,2,6,6-tetradeuteriocycloheptanone could be isolated by preparative v.p.c. using a UCW-98 column at 180°. A characteristic p.m.r. spectrum (60 MHz) in carbon tetrachloride showed the following peaks: a singlet at δ 0.97 (6H); two partially overlapping singlets at 1.48 and 1.55 (4H), and a singlet at 2.36 (2H).

A quantity of 1.2 g of the above tetradeuterated ketone was further exchanged with deuterium oxide as previously described to give 4,4-dimethyl-2,2,6,6,7,7-hexadeuteriocycloheptanone as revealed from the complete disappearance of the signal at δ 2.36 in the p.m.r. spectrum.

The hexadeuterated cycloheptanone derivative (0.75 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

0.0051 mol) was then reacted with tosylhydrazine followed by elimination with *n*-butyl lithium as previously described to give 5,5-dimethyl-1,3,3,7,7-pentadeuteriocycloheptene (**3**) as the predominant product which was purified by preparative v.p.c. using a silicone fluid SF-96 column at 125°. A p.m.r. spectrum (60 MHz) in carbon disulfide is in accord with the proposed structure: a singlet at δ 0.90 (6H); a singlet (4H) at 1.38, and a singlet (1H) at 5.54. A mass spectrum at 12 eV revealed the following isotopic distribution: $d_5 = 86$; $d_4 = 11$; $d_3 = 3\%$.

Preparation of 4,4,6,6-Tetramethylcycloheptene (4)

A solution of 5.0 g of 3,3,5,5-tetramethylcyclohexanone (14) in anhydrous ether containing some boron trifluoride etherate was submitted to a ring expansion reaction with diazomethane as previously described. A v.p.c. analysis using a carbowax column at 200° revealed a relative product distribution cyclohexanone–cycloheptanone–cyclooctanone and higher in the ratio (%) 27:27:46. The 3,3,5,5-tetramethylcycloheptanone was isolated by preparative v.p.c. and characterized by its p.m.r. spectrum in $CDCl_3$ (60 MHz): singlet (6H) at δ 1.00; singlet (6H) at 1.03; singlet (2H) at 1.43; a multiplet centered at 1.6 (2H); a multiplet centered at 2.5 (2H), and a singlet (2H) at 2.47.

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.58; H, 11.90. Found: C, 78.31; H, 11.91.

The above ketone (0.37 g, 0.0022 mol) was dissolved with 0.4 g of tosylhydrazine in 7 ml of hot ethanol. The solution was left standing at 0° overnight during which time the hydrazone crystallized out. The hydrazone (0.44 g) was filtered, dried, and then with 0.74 g of $LiAlH_4$ was refluxed in 30 ml of tetrahydrofuran for 24 h. After hydrolysis with 10% sulfuric acid, the organic product was extracted with petroleum ether, washed with a 5% NaOH solution, water, and then dried over magnesium sulfate. The main product was isolated and purified by v.p.c. using a β,β′-oxydipropionitrile column at 90°. It was then identified by its p.m.r. spectrum (60 MHz) in carbon disulfide to be 4,4,6,6-tetramethylcycloheptene (**4**): a singlet (12H) at δ 0.92; a singlet (2H) at 1.38; a doublet (4H) at 1.96, and a multiplet centered at 5.7 (2H).

Mol. Wt. Calcd. for $C_{11}H_{20}$: 152.1565. Found (mass spectrum at 70 eV): 152.1563.

Vicinal Electron Pairs and Conformation in Six-membered Rings. Some Evidence from the 1,3,2-Dioxathianes

GORDON WOOD, R. M. SRIVASTAVA, AND B. ADLAM
Department of Chemistry, University of Windsor, Windsor 11, Ontario
Received October 2, 1972

Barriers to ring reversal ($\Delta G^{\ddagger}$) at the n.m.r. coalescence temperature are reported for a series of 1,3,2-dioxathianes. The value for 1,3,2-dioxathiane-4,4,6,6-d_4 of 11.2 kcal/mol is compared with the corresponding values for cyclohexane and various six-membered rings with and without vicinal electron pairs. The 1,3,2-dioxathiane system is suggested as a model for trimethylene sulfites, where the strong preference of the exocyclic oxygen for the axial position interferes with barrier determination by n.m.r. techniques.

Les barrières d'inversion de cycle ($\Delta G^{\ddagger}$) à la température de coalescence r.m.n. sont rapportées pour une série de dioxathianes-1,3,2. La valeur obtenue, 11.2 kcal/mol pour le dioxathiane-1,3,2 d_4-4,4,6,6 est comparée avec les valeurs correspondantes pour le cyclohexane et divers systèmes cycliques à six membres avec ou sans paire d'électrons vicinale. Le système dioxathiane-1,3,2 est proposé comme modèle pour les sulfites de triméthylene, où la préférence marquée de l'oxygène exocyclique pour la position axiale gêne la détermination de la barrière par la technique du r.m.n. [Traduit par le journal]

Can. J. Chem., 51, 1200 (1973)

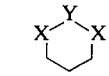
Introduction

There is now substantial evidence that the conformational properties of six-membered rings with two or more adjacent heteroatoms in the ring are significantly different from those of cyclohexane (1–3). This result is usually attributed to the presence of vicinal electron pairs which appear to increase the barrier to rotation about the connecting bond and at the same time displace, or even reverse (ref. 1*b*, p. 1205), the potential energy minima and maxima associated with rotation. Similar deviations exist in acyclic molecules (4) when ethane is considered the reference substance and their importance in six-membered ring behavior is a direct result of the importance of torsional barriers in determining conformational properties of rings.[1]

The work of Bushweller and co-workers (3) on the *s*-tetrathianes constitutes the most thorough study of this phenomenon to date. In addition to the expected high barriers to ring reversal, these workers have found changes in conformational energies dramatic enough to give rise to non-chair ground states and high barriers to pseudo-rotation between non-chair states.

[1]This relationship is generally accepted (5, 6). However, successful application of this principle to estimate ring reversal barriers requires careful choice of acyclic models, as we will show.

Compounds with three adjacent oxygen and/or sulfur atoms (**1**–**4**) might be expected to demonstrate similar interesting properties. Experimental work on systems of this type has been limited



1 X = S; Y = S
2 X = O; Y = S(=O)
3 X = O; Y = S
4 X = O; Y = S(=O)(=O)

so far to a determination of the ring reversal barrier of **1** and its 5,5-dimethyl derivative for which $\Delta G^{\ddagger} = 13.2$ and 14.7 kcal/mol, respectively (7), in addition to rather extensive data collection on trimethylene sulfites (**2**) by such diverse techniques as dipole moments (1*b*, 8, 9), i.r. (9*a*, 10), n.m.r. (1*a*, 2, 10, 11), osmometry (12), and ultrasonic absorption (13). Although all of the data point to some novel conformational properties, uncertainties in interpretation of the more derivative forms of data, especially from ultrasonic absorption (14, 15) and the present lack of a trimethylene sulfite suitably substituted for direct measurement of chair ⇄ chair ring reversal by the n.m.r. technique have thus far prevented the emergence of a generally accepted conformational description for this molecule.

This paper expands on our initial communication (16) of the magnitude of the barrier of ring reversal for some 1,3,2-dioxathianes (**3**). This system presents some synthetic difficulty, but its symmetry makes it ideal for n.m.r. study and its close structural resemblance to trimethylene sulfite confers on it some value as a model for the latter. Also, in this connection, **4** represents a closely related structure, the 5,5-dimethyl derivative of which has $\Delta G^{\ddagger} = 8.3$ kcal/mol (17). This result is in conformity with the fact that the ground state of this molecule has its energy increased by the location of a polar bond along the bisector of two electron pairs (4).

Results and Discussion

We here report the synthesis and low temperature n.m.r. data for several 1,3,2-dioxathianes, including the barrier to ring reversal for 1,3,2-dioxathiane-4,4,6,6-d_4, (**3***b*), which probably provides the most reliable value for comparison with cyclohexane and other six-membered ring compounds.

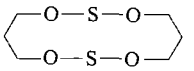
Synthesis and Spectra of 1,3,2-Dioxathianes

The compound **3***a* was synthesized from 1,3-propanediol and sulfur dichloride according to the method of Thompson (18). The isolated liquid showed two peaks which could be separated readily by preparative g.l.c. The peak with lower retention time was found to be **3***a*. The retention time of the other liquid was identical to that for authentic trimethylene sulfite.

The i.r. spectrum of **3***a* showed no hydroxyl absorption. The ^1H n.m.r. spectrum at room temperature consisted of a triplet at δ 4.38 and a quintet at 1.98. Had the compound possessed a macrocyclic structure such as **5**, the same n.m.r. spectrum would have been observed. The



5

mass spectrum showed a peak at *m/e* 106 which was assigned to the molecular ion. No peak at *m/e* 212 or higher was evident, nor was there any evidence of sulfite contamination (*m/e* 122).

In the low temperature n.m.r. experiment, the quintet at δ 1.98 broadened until at −70° two separate signals were obtained: δ 2.0–3.0 (multiplet) and 1.6 (broad doublet). These signals were assigned to axial and equatorial protons respectively. The C-5 proton signals sharpened at −85° and remained unchanged on further cooling. At −80° the doublet at δ 1.6 became a doublet of triplets ($J \simeq 2$ Hz).

These changes in the spectrum were shown to be reversible, and the coalescence temperature obtained was used to estimate the rate constant, k_c, for interconversion of the conformers from the equation

$$k_c = \Pi/\sqrt{2}\sqrt{(\nu_A - \nu_B)^2 + 6J_{AB}^2}$$

which reduces to

$$k_c = \Pi/\sqrt{2}(\nu_A - \nu_B)$$

when the signals are not coupled.[2] The value of $\Delta G^{\ddagger}$ was obtained from the Eyring equation,

$$k_c = k(K_B T/h)e^{-\Delta G^{\ddagger}/RT}$$

taking the transmission coefficient as unity. Both k_c and $\Delta G^{\ddagger}$ for the molecules studied are presented in Table 1.

The above procedure was repeated for 1,3,2-dioxathiane-4,4,6,6-d_4 (**3***b*) synthesized from labelled 1,3-propanediol and di-1-imidazolyl sulfide. The coalescence phenomenon of the simple AB spectrum provided a further check on the ring reversal barrier in this ring system and we consider the latter result of $\Delta G^{\ddagger} = 11.2$ kcal/mol at −42° to be the most reliable measure of ring reversal in 1,3,2-dioxathianes.

[2]A recent comparative study of n.m.r. methods of determining free energies of activation has indicated the conditions under which this approximate method gives satisfactory results (19).

For personal use only.

The 4,6-dimethyl derivatives were synthesized from 2,4-pentanediol (mixed isomers). G.l.c. of the product showed the presence of small amounts of all three 4,6-dimethyltrimethylene sulfites as well as racemic (**3***d*) and meso (**3***f*) 4,6-dimethyl-1,3,2-dioxathiane in a 56:44 ratio. I.r. and n.m.r. spectra for **3***f* were consistent with the assigned structure and the mass spectrum showed a peak at *m/e* 134 corresponding to the molecular ion. Proton n.m.r. spectra recorded in 1:1 CD_2Cl_2:C_2D_5Br showed no temperature dependence between +25 and −100°, a fact consistent with its expected adoption of a single chair conformation with both methyl groups equatorial.

Compound **3***d* produced a peak at *m/e* 134 which was assigned to the molecular ion. A small peak at *m/e* 150 was presumably due to contamination from a related sulfite. The ^1H n.m.r. spectrum consisted of a multiplet at δ 4.60, a triplet at 1.80, and a doublet at 1.43, in agreement with a fast equilibrium between conformations. On cooling, the spectrum underwent the expected broadening with two methyl doublets appearing at −90°. Below −100° these doublets are sharp and no further change occurred to −110°. The coalescence temperature for these signals was estimated to be −83° which gives $\Delta G^{\ddagger} = 9.4$ kcal/mol. The methylene and methine protons in this compound did not give definable coalescence. As a further check on the ring reversal barrier in racemic-4,6-dimethyl-1,3,2-dioxathiane, the labelled derivative **3***e* was found to give $\Delta G^{\ddagger} = 9.75$ kcal/mol based on coalescence of the methyl signal (δ 1.40) at −79.[3]

Interpretation of Nuclear Magnetic Resonance Results and Comparison with Related Systems

The barriers determined in the present work are presented in Fig. 1 along with a variety of other determinations on related molecules.[4] The 1,3,2-dioxathiane barriers, like those for other six-membered ring systems with vicinal electron pairs, are generally higher than the comparable cyclohexane or 1,3-dioxane structure. Generally, the substitution of oxygen for sulfur in the ring appears to lower the barrier (tetramethyldithiane and -dioxane are exceptions). Removal of the vicinal electron pair interaction in 1,3,2-dioxathiane by conversion to trimethylene sulfate lowers the barrier to a value comparable to the similarly substituted 2,2,5,5-tetramethyl-1,3-dioxane.

If the analysis presented here has any relevance for the case of trimethylene sulfite barriers which are not amenable to direct n.m.r. measurement, then these compounds should have ring reversal barriers near those for the 1,3,2-dioxathianes and certainly higher than the trimethylene sulfates. It is unfortunate that the ultrasonic absorption method which appears to detect a barrier to conformational change in the trimethylene sulfite system (13, 21) gives no evidence as to the structure of either the low energy or high energy state which the barrier separates.[5] Clarification of the nature of the ultrasonic process must await comparative n.m.r. and ultrasonic data on representatives of each of the ring systems under discussion. In the meantime, it should be noted that although no experimental value exists for S—O bond rotation, the ring reversal barrier for 1,3,2-dioxathiane is consistent with a high rotation barrier, as has been found for related bond types.[6]

The effect of exocyclic oxygen in the axial position on a trimethylene sulfite in the chair form has often been discussed in terms of interaction with the axial substituents on C-4 and -6. Values of n.m.r. shifts for several 1,3,2-dioxathianes which lack this exocyclic oxygen make it possible to check for evidence of this interaction. When allowance is made for the averaging of n.m.r. signals caused by conformational interconversion in the 1,3,2-dioxathianes,

[3]In spite of strenuous effort, complete purification of this compound was not achieved. Persistent n.m.r. signals appeared at δ 1.70, 1.50, and 1.18 p.p.m.

[4]These comparisons are presented in the format used by Kabuss and co-workers. References 20*a* and *c* contain additional data on six-membered ring reversal barriers.

[5]The difficulty with the low energy state is generally recognized (15) and in favorable cases this structure can be assigned from spectral data. The high energy state presents a much more formidable problem. Attempts to assign this structure and to attribute the measured barrier must of necessity rest on analogy with model compounds. In the case of trimethylene sulfites, lack of appreciation of the importance of vicinal electron pair effects led to inappropriate choice of acyclic models (13, 21) for estimation of the contribution of torsional barriers to the ring inversion barrier (1).

[6]Recent work has established a minimum value for S—S at 7.0 kcal/mol (22).

most of the shifts observed for these compounds are within 0.1 p.p.m. of the value for the corresponding trimethylene sulfite (ref. 1*a*, p. 522). The most clear-cut exception arises from the meso-4,6-dimethyl-1,3,2-dioxathiane which, like its sulfite analog, is assumed to be fixed in the chair conformation with methyl groups equatorial. The axial 4,6-protons in the former appear at δ 4.25 p.p.m. which is 0.7 p.p.m. upfield from the corresponding proton in the trimethylene

sulfite. This puts a quantitative estimate on the magnitude of S=O axial deshielding.

With the latter effect removed, the difference in chemical shift between axial and equatorial protons at C-4 and -6 in the dioxathianes (estimated from low temperature spectra) becomes smaller than typical cyclohexane values of 0.3–0.5 p.p.m. (*e.g.* $\Delta\nu = 8.7$ Hz for **3***c*, Table 1), but it is not possible from the present data to determine which proton appears at higher field.

The protons at C-5 generally show the same shifts as the corresponding sulfites. The axial proton of the parent compounds (δ 2.5 p.p.m.) is almost 1 p.p.m. toward lower field than the equatorial one, a phenomenon common to 1,3-dioxanes and other compounds with oxygens at positions 1 and 3.

Throughout this paper possible non-chair forms of 1,3,2-dioxathianes have been ignored. The data discussed here appear to be consistent with this assumption, but the evidence is in no sense compelling. The presence of vicinal electron pairs should at least reduce the energy of non-chair forms relative to cyclohexane, for reasons previously discussed (1*b*).

Summary and Conclusions

The synthesis and n.m.r. study of a series of 1,3,2-dioxathianes has extended the available data on six-membered ring compounds with vicinal electron pairs. In conformity with previous findings for systems of this general type, ring reversal barriers are found to be higher than for similar compounds lacking vicinal electron pairs. The results support the general conclusion that electron pairs on adjacent atoms in a ring increase the barrier to rotation about the bond joining them, and in this way increase the barrier to ring reversal.

When the considerable evidence now available to reinforce this generalization is applied to the relatively intractable trimethylene sulfite problem, it becomes apparent that the latter compounds must be in some sense anomalous. Perhaps the chair $\rightleftarrows$ chair interconversion in these molecules occurs across a barrier very much lower than that measured for any other similar ring (to accomodate one interpretation of ultrasonic absorption results). Alternately, the chair $\rightleftarrows$ chair interconversion may have a barrier which is comparable to that for structurally similar molecules, but which is not amenable to n.m.r. measurement because the sulfite ring system is strongly biased toward one chair form. Weighing these possibilities against each other, we find that uncertainties in conformational assignments for the higher energy state in ultrasonic absorption studies remove the necessity for the former interpretation. The latter situation appears to us particularly likely since it can readily incorporate the ultrasonic results on the basis of chair $\rightleftarrows$ non-chair interconversions.

Experimental

Elemental analyses were obtained from Midwest Microlab, Ltd., Indianapolis, Indiana.

Proton n.m.r. spectra were measured on a JEOL C60HL spectrometer using TMS as internal reference.

Mass spectra were taken by Dr. Larry Dusold, Chemistry Department, Wayne State University, Detroit, on an AEI MS902B spectrometer.

G.l.c. analyses were made with an F & M Model 720 instrument using columns packed with 10% diethyleneglycol succinate (LAC728) on chromosorb W and at a flow rate of carrier gas (helium) of 60 ml/min. Analytical work was done on a 1/4 in. × 5 1/2 ft column (70–90°) and collections on a 3/4 in. × 8 ft column (135°). Dioxathianes were prepared essentially by the method of Thompson (18). For the preparation of 4,6-dimethyl-1,3,2-dioxathianes, the reaction was carried out under a nitrogen atmosphere to reduce the formation of sulfites. The deuterated parent compound, **3***b* was prepared in better yield by substituting di-1-imidazolyl sulfide for sulfur dichloride.

1,3,2-Dioxathiane (3a)

From 38.0 g (0.5 mol) of 1,3-propanediol and 51.5 g (0.5 mol) of sulfur dichloride there was obtained an oil which after distillation afforded 4.5 g of light yellow liquid, b.p. 38–48° at 12–13 mm. G.l.c. of this liquid showed two peaks. The component of lower retention time was identified as 1,3,2-dioxathiane by spectral means although the index of refraction, $n_D^{25.5}$ 1.4750, differed from the reported value, n_D^{23} 1.4948 (18).

The i.r. spectrum of the pure liquid showed no hydroxyl absorption. The n.m.r. spectrum in CD_2Cl_2 consisted of a triplet at δ 4.38 p.p.m. ($J = 5.0$ Hz) and a quintet at 1.98 p.p.m. ($J = 5.0$ Hz). The low temperature n.m.r. results have been described. A peak at *m/e* 106 in the mass spectrum was assigned to the molecular ion.

Authentic trimethylene sulfite possessed the same retention time as the second product from the reaction.

1,1,3,3-Tetradeuterio-1,3-propanediol (23)

A solution of 5.0 g of $LiAlD_4$ in 200 ml of anhydrous tetrahydrofuran was placed under a nitrogen atmosphere in a 500 ml three-necked flask equipped with a reflux condenser, dropping funnel, and magnetic stirrer. Dimethyl malonate (13.2 g) diluted to 25 ml with anhydrous tetrahydrofuran was introduced with stirring at a rate sufficient to maintain gentle reflux. The mixture was then heated and stirred under reflux for 20 h. Decom-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

position was accomplished by the careful addition of water (50 ml), 15% NaOH (5.0 ml), and water (150 ml). The mixture was filtered and the precipitate washed with six 50-ml portions of boiling tetrahydrofuran. Evaporation of solvent from the dried ($MgSO_4$) filtrate and washings yielded 4.4 g of a clear, light yellow oil.

I.r. analysis showed the usual hydroxyl absorption as well as C—D stretching at 2100 and 2200 cm^{-1}. A singlet at 1.7 p.p.m. in the n.m.r. spectrum was assigned to C-2 protons and the hydroxyl protons appeared at 3.89 p.p.m.

Di-1-imidazolyl Sulfide

Following the procedure of Walter and Radke (24), 36.0 g of imidazole was reacted with sulfur dichloride (13.5 g) to yield 16.2 g of product, m.p. 78–83° (lit. (24) m.p. 80–85°).

4,4,6,6-Tetradeuterio-1,3,2-dioxathiane

Under a nitrogen atmosphere 8.58 g of di-1-imidazolyl sulfide was dissolved in 250 ml of anhydrous tetrahydrofuran in a 500 ml three-necked flask equipped with an addition funnel and a magnetic stirrer. 1,1,3,3-Tetradeuterio-1,3-propanediol (4.35 g diluted to 15 ml with anhydrous tetrahydrofuran) was introduced rapidly with stirring. After 15 min of stirring, the tetrahydrofuran was removed on the rotary evaporator and the residue vacuum distilled. The product was contained in a fraction (2.24 g) with b.p. 29–33°/0.25 mm.

The peak of lower retention time on preparative g.l.c. (17% of total) was found to be the desired product (**3***b*). The other major peak (83%) had a retention time corresponding to trimethylene sulfite.

*5,5-Dimethyl-1,3,2-dioxathiane (**3***c*)

Reaction of 52 g (0.5 mol) of 2,2-dimethyl-1,3-propanediol with sulfur dichloride gave a brown liquid which was separated by distillation into two fractions: (*i*) 1.65 g, b.p. 26–30°/2.0–2.2 mm and (*ii*). 14.7 g, b.p. 31–40°/1.2 mm. In addition to the desired product, these fractions contained 12 and 37%, respectively, of 5,5-dimethyltrimethylene sulfite.

Spectral results for this compound (**3***c*) have been reported (16).

Anal. Calcd. for $C_5H_{10}O_2S$: C, 44.75; H, 7.51; S, 23.89. Found: C, 45.0; H, 7.6; S, 23.6.

*4,6-Dimethyl-1,3,2-dioxathianes (**3***d and f)*

Sulfur dichloride (26.0 g, 0.25 mol) was reacted with 2,4-pentanediol (26.0 g, 0.25 mol, mixed isomers) under nitrogen to yield a crude oil. Distillation gave two fractions: (*i*) 13.8 g, b.p. 67–74°/13 mm and (*ii*). 4.23 g, b.p. 67–70°/1.25 mm. G.l.c. of fraction *i* showed five peaks, of which the two major peaks had the lowest retention times and n.m.r. spectra corresponding to the desired products.

The *trans*-4,6-dimethyl compound (**3***d*) showed a multiplet at δ 4.60 p.p.m., a triplet at 1.8 p.p.m. (J = 5.3 Hz), and a doublet at 1.43 p.p.m. (J = 6.8 Hz).

Anal. Calcd. for $C_5H_{10}O_2S$: C, 44.75; H, 7.51; S, 23.89. Found: C, 44.7; H, 7.5; S, 23.9.

The *cis*-compound (**3***f*) showed a multiplet at δ 4.25 p.p.m., a five-line signal at 1.5–1.83 p.p.m., and a doublet at 1.33 p.p.m. (J = 6 Hz) in $CDCl_3$ solution.

Anal. Found: C, 44.5; H, 7.6; S, 23.8.

2,3,3,4-Tetradeuterio-2,4-pentanediol

The procedure of Pritchard and Vollmer for synthesis of 2,4-pentanediol (25) was adapted to make the tetradeuterio derivative. Sodium borodeuteride (5.0 g, 0.12 mol) was added to a three-necked 300 ml flask containing 50 ml of D_2O and 0.3 ml of a 40% solution of NaOD in D_2O. The reaction flask was cooled to 10° and 20.0 g (0.20 mol) of 2,4-pentanedione in 60 g of CH_3OD was added during 2 h while the temperature was maintained at 10–15°. Following an additional 2 h of stirring at room temperature, the solvent was removed under vacuum and glycerine (100 ml) was added. Fractional distillation yielded 18.2 g (84.3%) of a colorless liquid, b.p. 50–55°/0.1 mm; n_D^{25} 1.4314.

*4,5,5,6-Tetradeuterio-4,6-dimethyl-1,3,2-dioxathianes (**3***e and g)*

The procedure described for **3***d* and *f* was followed using tetradeuteriodiol, and preparative g.l.c. which provided the dioxathianes as before. The peak of lowest retention time showed an n.m.r. singlet (δ 1.32 p.p.m.) which was unchanged on cooling to −100° and this compound was therefore assigned the *cis*-structure (**3***g*). The second g.l.c. peak also had as the most prominent feature of its n.m.r. spectrum a singlet (δ 1.40 p.p.m.), but cooling caused a broadening of the signal and separation into two singlets (δ 1.25, 1.55 p.p.m.) at −100°. This compound was assigned the *trans*-structure (**3***e*). Weak signals at δ 1.2, 1.5, and 1.7 p.p.m. were also present and are probably due to contamination from the corresponding sulfites, which are also represented by the three smaller peaks of higher retention time in the crude product as before.

The Mechanism of the HgH $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ Emission in the Hg(6^3P_0) Photosensitization of Hydrogen and the Alkanes

A. C. VIKIS AND D. J. LE ROY

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received November 10, 1972

The mechanism of the HgH $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ emission detected in the Hg(6^3P_0) photosensitized decomposition of H_2 and some of the lower alkanes, RH, was investigated. It was concluded that ground state HgH was formed in the primary process Hg(6^3P_0) + RH(or H_2) → HgH($X^2\Sigma^+$) + R(or H). The HgH $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ emission and presumably the $A_1{}^2\Pi_{1/2} \rightarrow X^2\Sigma^+$ and $B^2\Sigma^+ \rightarrow X^2\Sigma^+$ emission, also observed in the above systems, result from secondary excitation of ground state HgH on collision with Hg(6^3P_0). Studies of the emission made possible the estimation of relative quantum yields for the above primary process.

Le mécanisme de l'émission HgH $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ détectée dans la décomposition photosensibilisée par Hg(6^3P_0) de H_2 et de quelques un des alcanes inférieurs RH, a été étudie. On a conclu à la formation de HgH fondamental résultant du processus primaire Hg(6^3P_0) + RH (ou H_2) → HgH ($X^2\Sigma^+$) + R (ou H). L'émission de HgH $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ et probablement celles de $A_1{}^2\Pi_{1/2} \rightarrow X^2\Sigma^+$ et $B^2\Sigma^+ \rightarrow X^2\Sigma^+$ également observées pour les systèmes ci dessus, résultent d'une excitation secondaire de HgH fondamental par collision avec Hg(6^3P_0). Les études sur l'émission permettent d'évaluer les rendements quantiques relatifs aux processus primaires décrits ci dessus.

In a recent communication (1) we have reported the detection of HgH by its emission spectrum in the Hg(6^3P_0) photosensitized decomposition of H_2, CH_4, C_2H_6, C_3H_8, and n-C_4H_{10}. We had concluded that our finding was an indication of the long-sought (2–5) evidence for primary HgH formation in the Hg($6^3P_{1,0}$) photosensitized decomposition of

[1] $$Hg(6^3P_{1,0}) + RH \rightarrow HgH(X^2\Sigma^+) + R$$

the alkanes, RH, rather than, or in addition to the alternative primary process,

[2] $$Hg(6^3P_{1,0}) + RH \rightarrow Hg(6^1S_0) + H + R$$

Medium resolution spectra of the HgH emission are shown in Fig. 1, where the main emission bands are identified. The mechanism which we proposed (1) for HgH formation and excitation of the various bands was in accord with previous similar studies in the presence of hydrogen (2, 6, 7),

[3] $$Hg(6^3P_0) + RH \rightarrow HgH(X^2\Sigma^+) + R$$

[4] $$Hg(6^3P_0) + HgH(X^2\Sigma^+) \rightarrow HgH(A_1{}^2\Pi_{1/2}, A_2{}^2\Pi_{3/2}, B^2\Sigma^+) + Hg(6^1S_0)$$

[5] $$HgH(A_1{}^2\Pi_{1/2}, A_2{}^2\Pi_{3/2}, B^2\Sigma^+) \rightarrow HgH(X^2\Sigma^+) + h\nu$$

This mechanism was supported by qualitative evidence and the approximate light intensity dependence of the HgH fluorescence on the intensity of the primary lamps. It was felt necessary, however, to investigate the system in greater detail in order to support our claim that reaction 3 was responsible for the HgH formation and that reactions 4 and 5 were responsible for the emission. The present work supports this mechanism and also makes possible the calculation of relative HgH yields for reaction 3.

Experimental

The flow system used in the present work was described previously (8). Matheson prepurified grade nitrogen (99.997%) was used as the carrier gas at a flow rate of 20 std cc/min. The carrier gas was passed through a 1 ft long (12 mm i.d.) quartz tube packed with activated copper turnings at ~500 °C, in order to eliminate any oxygen impurity. Activation of the copper turnings was accomplished by a number of oxidation–reduction cycles using O_2 and H_2. Two Dry Ice – acetone traps followed the above treatment. The other reagents and their purity were as follows: H_2, Canox grade (99.9%), was passed before use through a catalytic Deoxo unit followed by two liquid nitrogen traps. The hydrocarbons were Phillips research grade; their purity in % by mole was stated by the manufacturer as follows: CH_4 (99.99), C_2H_6 (99.99), C_3H_8 (99.99), n-C_4H_{10} (99.8), i-C_4H_{10} (99.9). The most troublesome impurities in the alkanes were small amounts of olefins which were largely removed by adsorbing the gases on molecular sieve 13X at 77 °K and desorbing them at temperatures giving sufficient vapor pressure for transfer to a separate liquid nitrogen trap. The first fraction to transfer, which was

found to be purest with respect to olefins, was used after several freezing, pumping, and thawing cycles which served to remove condensibles.

The optical system used in the present work is shown in Fig. 2. Mercury(6^3P_0) is formed from Hg(6^3P_1) by collisions with N_2. The following elementary steps and their respective rate constants are well known (3).

$$Hg(6^1S_0) + h\nu\,(2537\text{ Å}) \rightarrow Hg(6^3P_1)$$

$$Hg(6^3P_1) \rightarrow Hg(6^1S_0) + h\nu\,(2537\text{ Å})$$

$$Hg(6^3P_1) + N_2 \leftrightarrows Hg(6^3P_0) + N_2$$

$$Hg(6^3P_0) \rightarrow Hg(6^1S_0)$$

The effective Hg(6^3P_1) lifetime with respect to emission, allowing for radiation imprisonment, is 2.06×10^{-7} s for the particular cell and Hg pressure (1.8×10^{-4} Torr) used (8). The overall lifetime of the Hg(6^3P_0) atoms at 20 Torr of N_2 is of the order of 10^{-3} s. The relative Hg(6^3P_0)/Hg(6^3P_1) steady state concentration is of the order of 10^3/l. Under these conditions and at the low partial pressures of H_2 and RH used (10^{-3} to 1 Torr, depending on the quenching efficiency of each gas) all reactions studied are to a good approximation initiated by Hg(6^3P_0).

The Hg(6^3P_0) population was followed by absorption of 4047 Å radiation emitted from a Pen-Ray mercury lamp, L_3, (Type 22 SC-3S). Light emitted from the Pen-Ray lamp was collimated and passed through a Pyrex filter before entering the reaction cell. The path length illuminated by the primary lamps was 18 cm. After passing through the reaction cell the analytical 4047 Å beam was focussed on the slit of a Bausch and Lomb grating monochromator, M (dispersion 33 Å/mm), and detected with an EMI 6255B photomultiplier, P. With the monochromator set at the peak of the 4047 Å line and the slits set at 0.10 mm the calibration graph of Fig. 3 was obtained by varying the intensity of the primary 2537 Å radiation emitted from the two U-shaped low pressure Hg lamps, L_1 and L_2. The absorption-concentration relationship was found to deviate significantly from Beer's law. Relative or absolute Hg(6^3P_0) concentrations were obtained from Fig. 3 according to the method of Ladenburg and Reiche (9, 10).

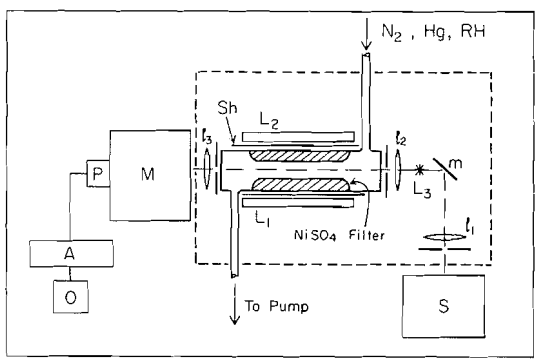

FIG. 2. Optical system and reaction cell assembly.

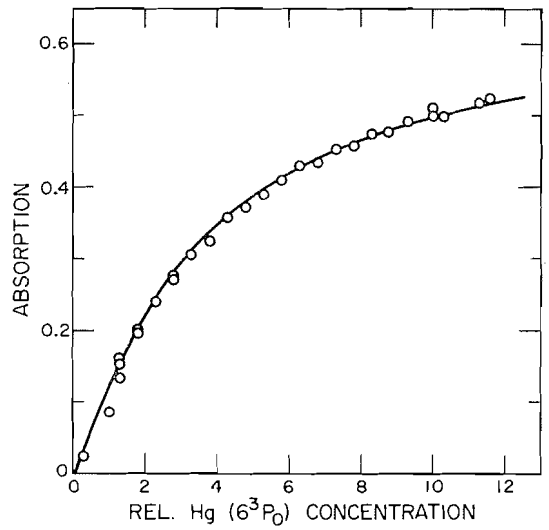

FIG. 3. Absorption of 4047 Å light *vs.* relative Hg(6^3P_0). (The solid line is the calculated absorption with $\alpha = 2.8$ (*cf.* ref. 9) and represents the best fit to the experimental absorption indicated by open circles. The product $k_0 l$[Hg(6^3P_0)] can be obtained by multiplying the abscissa by 0.458; k_0 is 5.90×10^{-12} cm^2/atom (11) and $l = 18.0$ cm.)

In order to eliminate problems associated with fast removal of Hg(6^3P_0) by olefins produced under steady irradiation the photomultiplier signal, after amplification by a Keithley Model 417 picoammeter, A, was displayed and photographed on a Phillips PM3230 oscilloscope, O. This made it possible to determine Hg(6^3P_0) populations at delay times of 0.2 s after exposing the reaction cell to the light from the 2537 Å lamps by the manual removal of a shutter, Sh. Typical oscillographs are shown in Fig. 4. It can be seen that olefin impurities, either initially present in the alkanes or formed during the reaction, are a serious problem and most likely account for the rather large discrepancies in Hg(6^3P_0) quenching cross sections reported by various groups (12–15).

The HgH emission spectra were obtained with the M-P-A-O arrangement, whenever low resolution was desired. For better resolution a Hilger and Watts model E-517 quartz spectrograph, S (82 Å/mm dispersion at 3500 Å) and Kodak 102-O plates were used. A few higher resolution spectra (Fig. 1) were obtained with a Hilger and Watts Model E-498 quartz spectrograph (24 Å/mm dispersion at 3500 Å).

In the kinetic studies the HgH emission, I^*, at the maximum of the $A_2{}^2\Pi_{3/2}$–$X^2\Sigma^+$ 0,0 band (340–350 mμ), was monitored, because this region was the most intense and also free of atomic mercury lines. To eliminate scattered radiation of other wavelengths a Bausch and Lomb 340 mμ (20 mμ half-width) interference filter was placed before the monochromator and the monochromator slits opened to 1.5 mm. This emission signal was displayed on the oscilloscope and monitored at short delay times whenever olefinic impurities were a problem. Typical oscillographs are shown in Fig. 4.

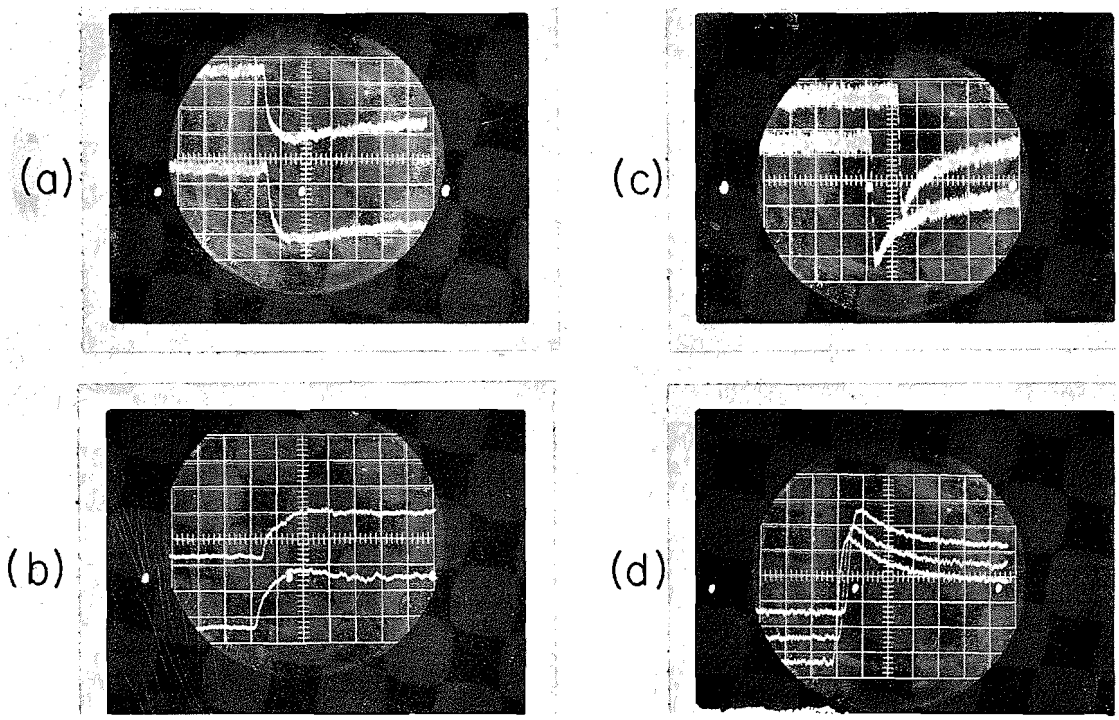

FIG. 4. The variation of $Hg(6^3P_0)$ absorption and HgH emission with irradiation time. The full time axis is 5 s. Oscillographs (*a*) and (*b*) were obtained with untreated research grade C_2H_6; (*c*) and (*d*) with treated C_2H_6. The absorption attenuation setting is the same in (*a*) and (*c*) (dumping control decreased in (*c*)); the same is true for the emission attenuation in (*b*) and (*d*). The C_2H_6 pressures in Torr are: (*a*) both 0.41; (*b*) 0.63 (upper) and 0.35 (lower); (*c*) 0.61 (upper) and 0.46 (lower); (*d*) 0.86 (upper), 0.66 (middle), and 0.42 (lower). The initial increase in absorption or emission in (*a*) and (*b*) occurring in the first second is probably due to removal of ethylene initially present. The subsequent decrease in absorption or emission is due to ethylene built-up as the system achieves steady state.

Results and Discussion

Besides the elementary steps associated with $Hg(6^3P_0)$ formation from $Hg(6^3P_1)$ and decay, already discussed in the experimental section, the reactions that follow were found necessary to explain the data. Other possible mechanisms are also discussed in this section and shown to be inadequate.

[6] $Hg^0 + RH \rightarrow HgH + R$

[7] $Hg^0 + HgH \rightarrow (HgH)^{**} + Hg$

[8] $(HgH)^{**} + M \rightarrow (HgH)^{*} + M$

[9] $(HgH)^{**}, (HgH)^{*} \rightarrow HgH + h\nu$

[10] $HgH\ (+M) \rightarrow Hg + H\ (+M)$

[11] $HgH + R\ (H) \rightarrow Hg + RH\ (H_2)$

where Hg^0 and Hg denote $Hg(6^3P_0)$ and $Hg(6^1S_0)$, respectively; $(HgH)^{**}$ and $(HgH)^{*}$ denote the initial and collisionally altered vibronic populations of the $A_1{}^2\Pi_{1/2}$, $A_2{}^2\Pi_{3/2}$, and $B^2\Sigma^+$ states, and HgH the ground electronic state; M denotes the bath gas, which is mainly N_2. The bimolecular reaction 10 is expected to be the dominant reaction of HgH decay in the absence of reaction 11. Callear and Hedges' (4) HgH decay curves indicate a HgH lifetime of $\sim 10^{-4}$ s at pressures roughly ten times ours. Thus at 20 Torr an upper limit for the HgH decay would be $\sim 10^{-3}$ s. This is approximately ten times higher than the simple collision theory prediction but could be feasible if the rotational degrees of freedom contribute to the dissociation according to the mechanism of Palmer and Hornig (16).

The variation of the peak intensity of the $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$, 0,0 band *vs.* the intensity of primary excitation (2537 Å light), is shown in Fig. 5 for various conditions. Earlier studies in this laboratory (1) and others (7), employing spectrographic methods, indicated that the HgH emission intensity was roughly dependent on

For personal use only.

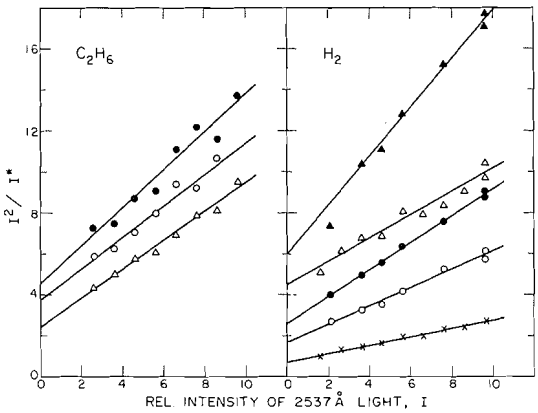

FIG. 5. Variation of HgH emission intensity, I^*, with the primary light intensity, I (C_2H_6: P_{N_2} = 20 Torr, $P_{Hg} = 1.8 \times 10^{-4}$ Torr; ●, 0.153 Torr; ○, 0.098 Torr; △, 0.048 Torr, the ordinate displaced by −3; H_2:P_{N_2} = 20 Torr, $P_{Hg} = 1.8 \times 10^{-4}$ Torr; ▲, 7.9×10^{-3} Torr; ●, 3.1×10^{-3} Torr; ○, 1.90×10^{-3} Torr; H_2:P_{Hg} = 1.8×10^{-3} Torr; △, P_{N_2} = 1 Torr; $P_{H_2} = 2.5 \times 10^{-3}$ Torr; X, P_{N_2} = 4.5 Torr, $P_{H_2} = 2.5 \times 10^{-3}$ Torr).

the second power of the primary radiation, I. This would indicate that two Hg^0 atoms are involved in the overall process, as expected. More precise photoelectric measurements obtained in the present work indicate that the above is true in the limit of low light intensities but that at higher intensities the exponent of I assumes lower values. Since the Hg^0 concentration, which was followed by absorption, was found to be directly proportional to I, it is concluded that, in addition to reaction 10, there must be a competitive process of removal of HgH due to reaction with H atoms and/or alkyl radicals present in the system. The possibility that in the case of the alkane reactions, HgH or $Hg(6^3P_0)$ are consumed in reactions with olefinic products is excluded since the above measurements refer to short delay times (0.2 s) when such products are not significant. The data in Fig. 5 indicate that at the primary light intensities used, corresponding to 9.5 in Fig. 5, reaction 11 is two to five times faster than the combined first and pseudo first order decay of HgH. Reaction 11 is expected to proceed with high efficiency with either H or R (4). The radical concentrations are expected to be of the order of 10^{-4} Torr in our system.

The variation of HgH emission, I^*, with H_2 and RH is shown in Figs. 6 and 7. An equation which describes this dependence and which is also in accord with the given mechanism is

$$[12] \qquad I^* = \frac{C\phi_{RH}k^{0g}_{RH}[RH][Hg^0_{RH}]^2}{k + C'_{RH}k^{0g}_{RH}[RH][Hg^0_{RH}]}$$

where C is a composite constant associated with the formation of Hg^0 and the efficiency of detecting the emission; C'_{RH}, is another composite rate constant associated with the rate constants of reaction 11 and the presumably pseudo-first order decay of H and R. That R decays by a first order process only, *e.g.* wall recombination, is not clear. It is possible, however, that gas phase recombination contributes but that the net rate can be approximated by a first order one; k, is a net first order HgH decay constant; ϕ_{RH} is the yield of HgH per quenching collision; k^{0g}_{RH}, is the $Hg(6^3P_0)$ quenching rate constant

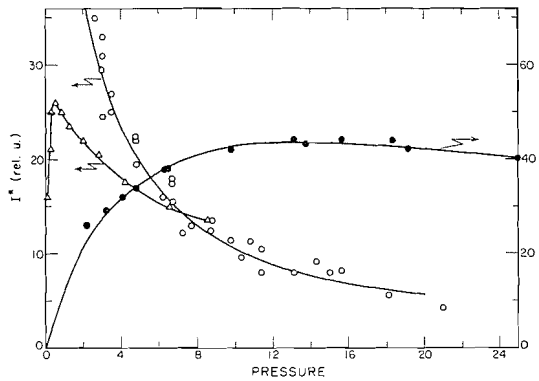

FIG. 6. Variation of HgH emission with quencher pressure (P_{N_2} = 20 Torr, $P_{Hg} = 1.8 \times 10^{-4}$ Torr; ○, H_2 in Torr × 10^3; △, C_2H_6 in Torr × 10; ●, CH_4 in Torr × 10; the solid lines are obtained from the least squares fit to eq. 12).

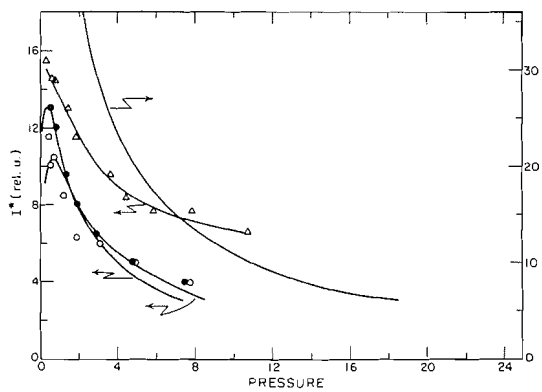

FIG. 7. Variation of HgH emission with quencher pressure. (P_{N_2} = 20 Torr, $P_{Hg} = 1.8 \times 10^{-4}$ Torr; ○, n-C_4H_{10}; ●, i-C_4H_{10}; △, C_3H_8 in Torr × 10^2; the solid lines are obtained from the least squares fit to eq. 12; the solid line with no points is for H_2, Fig. 6).

†Values for these molecules represent averages of more than one determination.

and $[Hg^0_{RH}]$ is the population of $Hg(6^3P_0)$ in the presence of RH. Quenching or reaction of HgH or any of its excited states by H_2 or RH is not included due to the relatively low partial pressures used.

Other Possible Mechanisms

Mercury hydride emission in the $Hg(6^3P_0)$ photosensitized decomposition of H_2 and alkanes could also arise through other mechanisms than the one proposed here. Three such mechanisms are discussed below and excluded on the basis of experimental evidence.

(a) Mercury hydride formation via the combination of Hg and H, followed by excitation with $Hg(6^3P_0)$

[13] $$Hg + H \rightleftarrows HgH$$

or most likely

[14] $$Hg + H + M \rightleftarrows HgH + M$$

Figure 8 shows the variation of I^* *vs.* $Hg(6^3P_0)$. The $Hg(6^3P_0)$ population was varied in two ways: (*i*) by varying the primary light intensity at fixed Hg pressure, and (*ii*) by varying the Hg pressure at fixed light intensity. All other conditions were kept constant. The variation of I^* in (*ii*) when compared to that in (*i*) shows no evidence of either reactions 13 or 14 occurring to any significant extent, despite the six-fold variation in the Hg pressure. This is due to the fact that at the conditions of our experiments the above equilibria favor the free atoms ($HgH/H \sim 10^{-3}$). Similar experiments were not performed with any of the alkanes but it can be shown that if such a mechanism were correct the quantum yields of HgH determined for the alkanes would be at least two orders of magnitude lower than that of H_2. This is not the case (see Table 1).

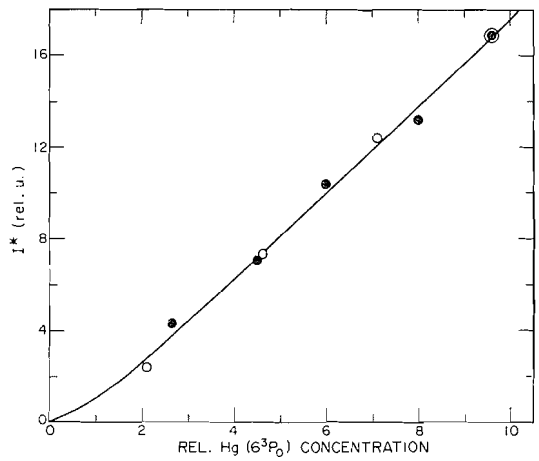

FIG. 8. Variation of HgH emission with $Hg(6^3P_0)$ concentration (○, method (*i*) in text, $P_{Hg} = 1.2 \times 10^{-3}$ Torr; ●, method (*ii*) in text, the Hg pressures in Torr × 10^4 are 1.8, 3.3, 4.9, 7.6, and 12, read on the graph from left to right).

(b) Direct formation of HgH in the excited states via the combination of Hg^0 with H

It is expected that such a combination would proceed on the $A_1{}^2\Pi_{1/2}$ surface because this is the only one that correlates with $Hg(6^3P_0)$ and $H(^2S_{1/2})$ (see Fig. 9). Population of the $A_2{}^2\Pi_{3/2}$ or $B^2\Sigma^+$ state could arise via inverse predissociation (17).

[15] $$Hg(6^3P_0) + H(^2S_{1/2}) \rightleftarrows HgH(A_1{}^2\Pi_{1/2}) \rightarrow HgH(X^2\Sigma^+) + h\nu(\text{continuous})$$

[16] $$HgH(A_1{}^2\Pi_{1/2}) \rightleftarrows HgH(A_2{}^2\Pi_{3/2}, B^2\Sigma^+) \rightarrow HgH(X^2\Sigma^+) + h\nu(\text{discrete})$$

This mechanism is excluded firstly because of the discrete spectra observed and secondly because the observed discrete spectra are due to transitions from much lower energy states than the ones

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

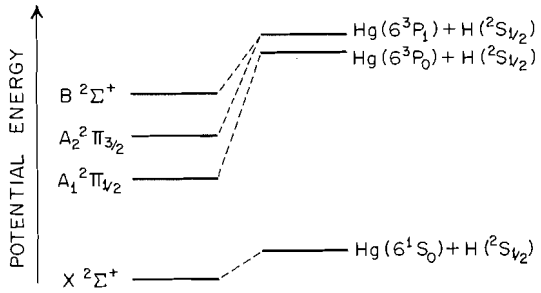

FIG. 9. Relevant energy states of HgH (schematic).

which could be populated by inverse predissociation.[1]

A more feasible mechanism would require a third body, such as

[17] $Hg(6^3P_0) + H(^2S_{1/2}) + M \rightarrow HgH(A_1{}^2\Pi_{1/2}) + M$

[18] $HgH(A_1{}^2\Pi_{1/2}) \rightarrow HgH(A_2{}^2\Pi_{3/2}, B^2\Sigma^+)$

This mechanism, however, can certainly be excluded on the basis of the rather high emission intensities observed. Relative intensity measurements of the $Hg(6^3P_1)$ emission at 2537 Å and the integrated intensity of the $A_2{}^2\Pi_{3/2} \rightarrow X^2\Sigma^+$ 0,0 band, indicate that the emission rate of the latter is $\sim 10^{12}$ quanta $cm^{-3}\ s^{-1}$. A maximum emission rate of 10^8 quanta $cm^{-3}\ s^{-1}$ can be calculated from the termolecular rate $k_r[N_2]\,[Hg^0]\,[H]$ using the fairly generous values of $k_r \sim 10^{10}$ $M^{-2}\ s^{-1}$ and $H \sim 10^{-4}$ Torr (the total H_2 pressure was 2×10^{-3} Torr). The N_2 pressure was 20 Torr and the Hg^0 pressure was 1.3×10^{-7} Torr (measured by absorption). The discrepancy of 10^4 between calculated and observed rates is beyond any uncertainty in estimating these quantities.

(c) Mercury hydride formation via reaction of Hg^0 with H_2 formed in the photosensitized decomposition of the alkanes

[19] $Hg^0 + RH \rightarrow Hg + H + R$

[20] $H \xrightarrow{\text{wall}} \frac{1}{2} H_2$

[21] $H + R\ (\text{or } RH) \rightarrow H_2 + R'(R)$

[22] $Hg^0 + H_2 \rightarrow HgH + H$

This possibility is particularly important in view of earlier failures to detect HgH in the alkanes (2–5). If such a mechanism were applicable, however, one would expect a higher order dependence of the HgH emission on the intensity of the primary radiation, *i.e.*, $2 \leqslant n \leqslant 3$ in the expression $I^* \propto I^n$ rather than $1 \leqslant n \leqslant 2$ as observed.

Furthermore, one should observe an induction period for I^* as the system approaches a steady state. The intensity profile of I^* with time would be characterized by the product $[Hg^0(t)]^n[H_2(t)]$. $Hg^0(t)$ is the variation of $Hg(6^3P_0)$ with reaction time due to olefin formation and can be determined from $Hg(6^3P_0)$ absorption *vs.* time. The variation of H_2 with time, $H_2(t)$, would be of the form $(H_2)_{s.s.}(1 - e^{-t/\tau})$, where τ is the lifetime of H_2 with respect to flowing out of the cell, and $[H_2]_{s.s.}$ is the steady state concentration of H_2. Such intensity profiles are shown in Fig. 10 for $n = 1$, 2, and 3 (curves *A*, *B*, and *C*, respectively) for 0.28 Torr of C_2H_6 and the standard conditions of 20 Torr of N_2 and a flow rate of 20 std cc/min. Curve *D* is the experimental one and should be compared to a curve calculated between *A* and *B*, since $1 \leqslant n \leqslant 2$. The two curves are in disagreement which would indicate that reaction of the

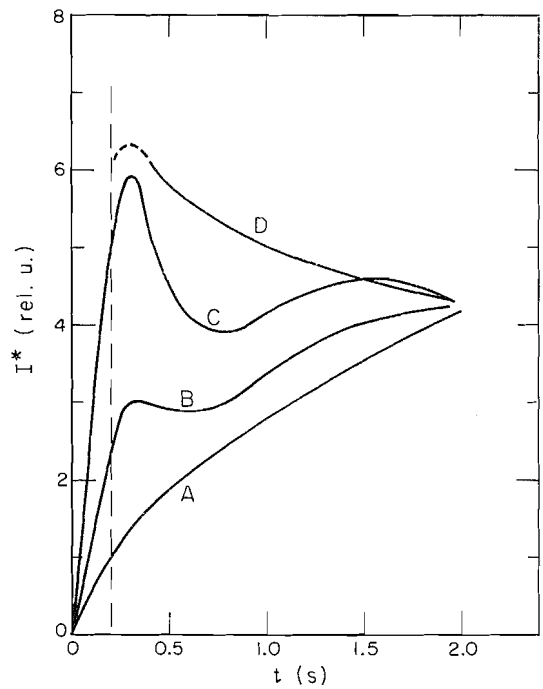

FIG. 10. The variation of HgH emission with reaction time. (The dotted vertical line at 0.25 s delineates the time required for complete removal of the shutter isolating the reaction cell from the lamps.)

[1]In the case of transitions from the upper states of $A_1{}^2\Pi_{1/2}$, $A_2{}^2\Pi_{3/2}$, $B^2\Sigma^+$ to the ground state, $X^2\Sigma^+$, the spectra would be continuous due to the instability of the lower surface.

product H_2 with $Hg(6^3P_0)$ cannot account for the observed emission.

Relative Quantum Yields of HgH

Relative quantum yields of HgH are obtained from graphs of $[RH][Hg^0_{RH}]^2/I^*$ *vs.* $[RH]$-$[Hg^0_{RH}]$, (*cf.* eq. 12). The intercepts of such plots give $k/C\phi_{RH}k^{0g}_{RH}$. These results are shown in Table 1, where ϕ_{RH}/ϕ_{H_2} is obtained from the ratio of intercepts for H_2 and RH, $\phi_{RH}k^{0g}_{RH}/\phi_{H_2}k^{0g}_{H_2}$, and the ratio of quenching rate constants determined in this work. The latter, with the exception of $k^{0g}_{H_2}/k^{0g}_{C_2H_6}$, compare very well with other literature values (12, 13), which are listed for comparison. The rather large probable errors in ϕ_{RH}/ϕ_{H_2} are the result of a combination of uncertainties in Hg^0_{RH} and k^{0g}_{RH}, as well as in the extrapolation to small intercepts. Callear and McGurk (5) have determined a HgH quantum yield of 1.0 for the reaction of $Hg(6^3P_0)$ with H_2, thus the ratios listed in Table 1 could also represent absolute values.

Conclusions

The present results indicate that the HgH emission in the $Hg(6^3P_0)$ photosensitization of hydrogen and the alkanes is due to direct formation of HgH in the primary quenching process followed by excitation of HgH on collision with another $Hg(6^3P_0)$. Earlier failures (2–5) to detect HgH in the presence of the alkanes may have been the result of rapid accumulation of olefins in these systems and the relatively fast reaction of HgH with H atoms and alkyl radicals.

The quantum yield data, when put on an absolute basis using the result of Callear and McGurk (5) on the $Hg(6^3P_0)$–H_2 system, show that quenching of $Hg(6^3P_0)$ by RH through formation of HgH is a significant process. It could possibly be the major process but, due to the higher exothermicity in the case of the alkanes, a higher proportion of vibrationally and/or rotationally excited HgH is formed and decays before detection.

The relatively high HgH yields detected in the alkanes could be interpreted as an indication that the exothermicity of the reaction does not appear entirely as localized repulsion between the H atom and the alkyl group, as suggested by the relative yields of HgH and HgD in the case of the $Hg(6^3P_{1,0})$–HD system studied by Callear and McGurk (5). Due to the high exothermicities (15 to 26 kcal/mol) and the heavy mass of the alkyl group such an energy release would result in vibrational and rotational excitation of HgH well beyond its dissociation limit ($D_0{}^0 = 8.67$ kcal/mol (17)).

A possible explanation of the observed high HgH yields is that a relatively long-lived complex is formed between $Hg(6^3P_0)$ and the alkane. This would allow equipartitioning of the exothermicity among the various degrees of freedom of the complex. From this point of view it would be desirable to have more precise quantum yield data in order to reveal any correlation between the yield, the exothermicity, and the structure of the alkane. Such correlations were shown to exist in the quenching of $Hg(6^3P_{1,0})$ and in the spin–orbit relaxation process induced by the same molecules (8, 18).

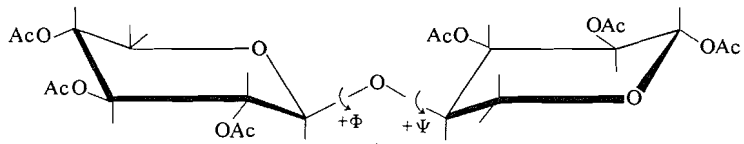
Crystal Structure of β-D, 1 → 4 Xylobiose Hexaacetate

F. LEUNG AND R. H. MARCHESSAULT

Department of Chemistry, University of Montreal, Montreal 101, Quebec

Received August 14, 1972

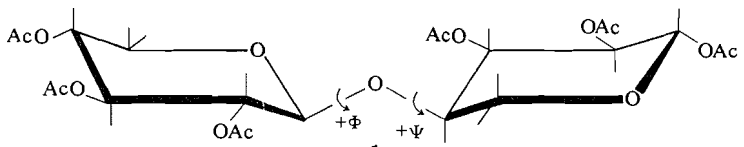
Three dimensional crystal structure analysis has been carried out on β-D, 1 → 4 xylobiose hexaacetate (**1**)



1

The crystal data are: orthorhombic, $P2_12_12_1$, $a = 10.938(2)$, $b = 8.377(4)$, $c = 29.976(7)$ Å. It was found that the bond lengths and angles of the Cl chairs are similar to other carbohydrate structures, the conformational angles $(\Phi,\Psi) = (20.4°, -15.2°)$ and the orientations of the acetate groups are in good agreement with those predicted by stereochemical calculations using Flory functions. The structural resemblance between this molecule and the polymer, xylan diacetate, is discussed.

L'analyse de la structure de la tridimensionelle d'un cristal a été effectué sur la β-D, 1 → 4 hexaacétate de xylobiose (**1**)



1

Les données cristallines sont: orthorhombique $P2_12_12_1$, $a = 10.938(2)$ $b = 8.377(4)$, $c = 29.976(7)$ Å. Il a été montré que la longueur des liens ainsi que les angles des chaises Cl sont semblables à ce que l'on trouve dans les structures des carbohydrates. Les angles conformationnels $(\Phi,\Psi) = (20.4°, -15.2°)$ et les orientations des groupes acétates sont en accord avec les valeurs prévues par des calculs stéréochimiques impliquant la fonction de Flory. La ressemblance structurale entre cette molécule et le polymère diacetate de xylane est discutée. [Traduit par le journal]

Can. J. Chem., **51**, 1215 (1973)

Introduction

The structure of xylan diacetate has been studied by Gabbay, Sundararajan, and Marchessault (1). By means of conformational analyses, the conformational angles[1] (Φ,Ψ) of the disaccharide unit (Fig. 1) were found to be $(42°, -21°)$ for $\tau = 117.5°$. Their findings were based on the assumption that xylan diacetate has a two-fold axis with a fiber repeat of 10.31 Å. Assuming these (Φ,Ψ) values, the preferred orientations of the acetate groups were established using energy minimization methods in an iterative manner (1). It was found in general that the acetate groups were approximately 20–30° off the positions where the C—H and C(A)—O bonds were eclipsed in the four-atom system H—C—O—C (A) (Fig. 2). Similar results were obtained when electrostatic interactions were considered (2).

Structurally, xylobiose hexaacetate (Fig. 3) closely resembles the xylobiose tetraacetate unit, which is the basis of the stereochemical calculations performed on xylan diacetate. The

[1]Angle Φ is the angle between the planes defined by the atoms C(1), O(1), C′(4) and O(4), C(1), O(1); Ψ is the angle between the planes defined by C(1), O(1), C′(4) and by O′(1), C′(4), O(1). The conformation corresponding to $(\Phi,\Psi) = (0°, 0°)$ has the C(1)—H(1) bond *cis* to O(1)—C′(4) and C′(4)—H′(4) is *cis* to C(1)—O(1). Keeping the unprimed ring fixed and looking along the directed bonds C(1) → O(1) and O(1) → C′(4), the clockwise rotation of the primed ring is considered to be positive. This is the convention adopted by Gabbay *et al.* which is the same as that used by Sundararajan and Rao (1).

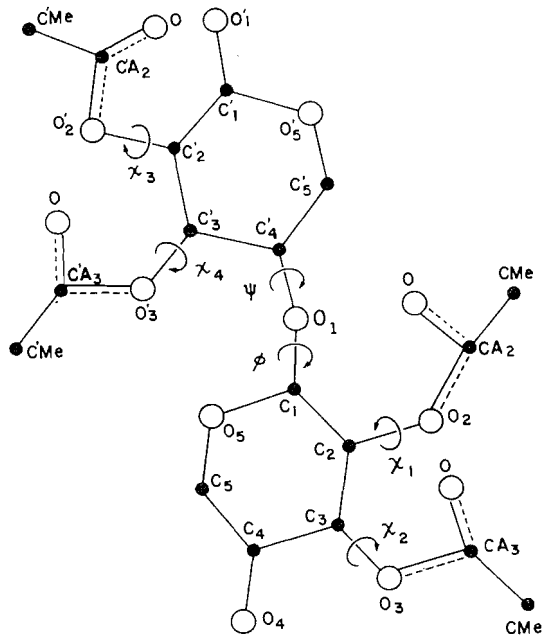

FIG. 1. A schematic diagram of the xylobiose tetraacetate unit. The direction of rotations Φ,Ψ are marked and χ measures the orientation of the acetate group. In this diagram the acetate groups are shown in their positions corresponding to $\chi = 0°$ (ref. 1*a* or Fig. 7).

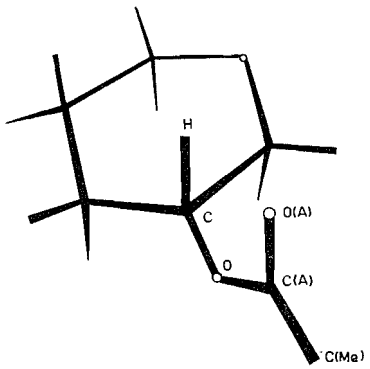

FIG. 2. A diagram showing the orientation of the acetate group with respect to the pyranose ring.

purpose of this work is to compare the structural details of xylobiose hexaacetate with some known carbohydrate structures, and with the structure of xylan diacetate deduced from X-ray and stereochemical studies. Such comparison will add to our understanding of stereochemical calculations which are of paramount importance in structural investigations of polysaccharides. In addition to the backbone conformation, particular interest is placed in comparing the acetate positions from X-ray data with those from the iterative stereochemical approach.

Experimental

Suitable crystals were obtained after recrystallization from 1:1 methanol–water solution of xylobiose hexaacetate. The compound was dissolved in methanol and water, the solution was allowed to stand at room temperature in a small (10 ml) conical flask which was loosely plugged with tissue paper. After a few days, clusters of minute crystals (fine needles) were formed. The clusters of crystals were dispersed by shaking the solution and after about one week, layers of plate-like crystals were obtained.

The unit cell dimensions were determined from diffractometer measurements and refined by a least-squares procedure. The crystal density was determined by flotation in a mixture of hexane and carbon tetrachloride. The crystal data are:

$C_{22}H_{30}O_{15}$ f.w. = 534.1

Orthorhombic, $a = 10.938(2)$, $b = 8.377(4)$, $c = 29.976(7)$, $V = 2746.6$ Å^3, $Z = 4$, $D_c = 1.29$ g/cc, $D_m = 1.30$ g/cc, space group $P_{2_12_12_1}$, $\mu = 9.7$ cm^{-1} (CuKα, $\lambda = 1.5418$ Å).

The intensity data were collected on the FACS-1 automatic diffractometer with 2θ-scan using CuKα (Ni-filtered) radiations. The crystal used for data collection had the dimensions of 0.6 × 0.4 × 0.1 mm and was mounted along the *b*-axis. A total of 2366 independent reflections were measured within the range $0 \leqslant 2\theta \leqslant 120°$, of which 491 have net counts less than 10% of the background. These reflections were considered to be unobserved and were not used in the structure refinement. No absorption correction was made in the data reduction procedure. Normalized structure factors were generated by the K-curve method.

Structure Determination and Refinement

The structure was solved using the multisolution TANFOR program[2] which involves direct application of the tangent formula (3):

$$\tan \phi_h \simeq \frac{\sum_k |E_k E_{h-k}| \sin(\phi_k + \phi_{h-k})}{\sum_k |E_k E_{h-k}| \cos(\phi_k + \phi_{h-k})}$$

Reflections with the initial phases are listed in Table 1. The symbol *b* must be either $-\pi/2$ or $+\pi/2$, but both *a* and *c* can have any value in the range of $-\pi$ to $+\pi$. In the course of tangent formula application, four initial values of $\pm\pi/4$, $\pm 3\pi/4$ were allocated to each of the

[2]A tangent formula program by M. Drew, Lawrence Radiation Laboratory, University of California, Berkeley, California, extensively modified by A. C. Larson and S. Motherwell at Cambridge University, England, K. Fawcett at the University of Toronto, Ontario, further modified and adapted to CDC 6600 computer by F. Leung at the Université de Montréal, Montreal, Quebec.

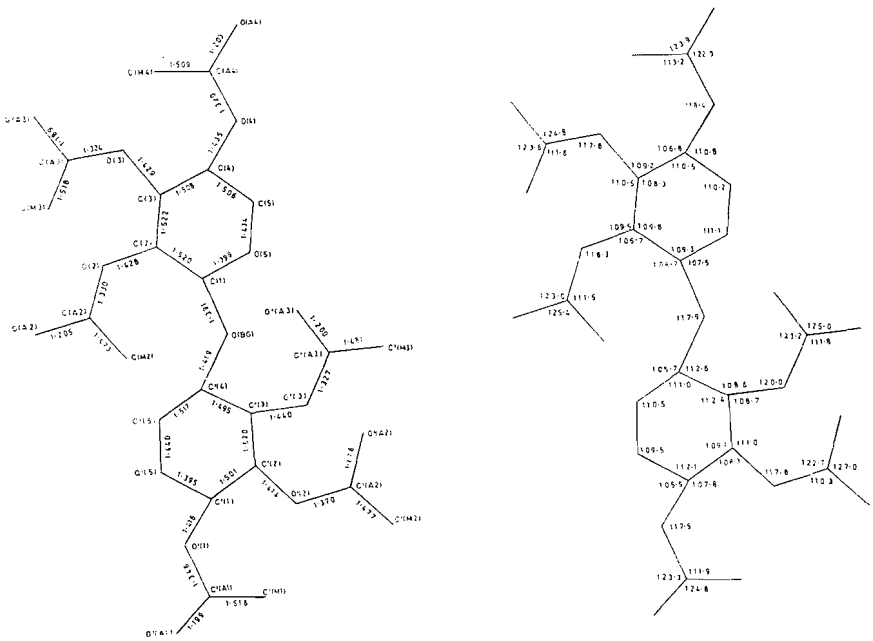

FIG. 3. A schematic diagram of xylobiose hexaacetate with bond lengths and angles.

TABLE 1. Starting phases for tangent formula

h	k	l	$\|E\|$	Phase
1	0	8	2.86	0.0
0	5	1	2.83	$\pi/2$
2	5	0	2.62	0.0
0	5	12	2.24	$\pi/2$
4	6	1	2.98	a
8	0	5	3.13	b
5	7	3	3.18	c

symbols a and c, while $\pm\pi/2$ were given to the symbol b. Consequently a total of 32 different sets of phases were obtained, corresponding to the 32 different combinations of initial phases allocated to the symbols. For the set with the lowest R_{Karle} (0.27), 201 phases ($|E| \geq 1.50$) were determined. R_{Karle} is defined by (3):

$$R_{\text{Karle}} = \sum_{k_r} | |E_h|_{\text{obs}} - |E_h|_{\text{calcd}}| / |\sum_{k_r} |E_h|_{\text{obs}}$$

By further applications of the tangent formula with 201 known phases, an additional 121 phases with $1.30 \leq |E| \leq 1.50$ were determined. The E-map computed using these 312 reflections revealed 31 non-hydrogen atoms. Successive Fourier syntheses revealed all the non-hydrogen atoms of the molecule.

The atomic coordinates estimated from the final Fourier synthesis were refined with individual isotropic thermal parameters by full-matrix least-squares employing unit weights. The refinement converged to an R-factor of 0.14.

$$R = \frac{\sum ||F_o| - |F_c||}{\sum |F_o|}$$

The refinement was continued with anisotropic thermal parameters using block-diagonal matrix. Upon the convergence of anisotropic refinement, all hydrogen atoms were located from successive difference Fourier syntheses. At this stage, the hydrogen atoms were included in the refinement with isotropic temperature factors, and the following weighting function was used

$$\omega = \frac{1}{(1.358 - 0.022|F_o| + 0.003|F_o|^2)^2}$$

This weighting function was deduced from a plot of $|\Delta F|$ *vs.* $|F_o|$. The atomic scattering factors used for the hydrogen and non-hydrogen atoms were taken from Stewart *et al.* (4*a*) and Cromer *et al.* (4*b*) respectively. The least-squares program used was NUCLS.[3] The hydrogen

[3]NUCLS a highly modified version of ORFLS, modified by Doedens at the University of Wisconsin, Madison, Wisconsin, and J. Ibers at Brookhaven National Laboratories, Brookhaven, Philadelphia, further modified for block-diagonal option by J. Sygusch at the Université de Montréal, Montreal, Quebec.

atoms and the non-hydrogen atoms were refined isotropically and anisotropically respectively. After several cycles of block-diagonal least-squares refinement, an ultimate R-factor of 0.058 was obtained. Structure factor calculations including the unobserved reflections showed an R-factor of 0.070. The difference Fourier computed subsequently revealed no residual electron density other than background fluctuations. The final positional and thermal parameters are listed in Tables 2 and 3. Final F_o and F_c values have been placed in the Depository for Unpublished Data.[4]

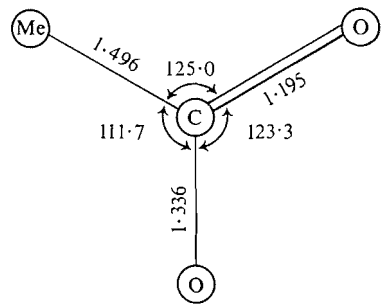

FIG. 4. The average bond-lengths and angles for the acetate groups.

Results and Discussion

As expected from experimental (5, 6) and theoretical (7) investigations, the β-D-xylose unit has a C1 chair conformation. The pyranose rings are joined through β, 1 → 4′ linkages. All acetate groups occupy equatorial positions and are planar within experimental error. The average bond lengths and angles for the acetate groups are shown in Fig. 4; the bond lengths and bond angles of the molecule are given in Fig. 3 and Fig. 5 is a stereoscopic view of the

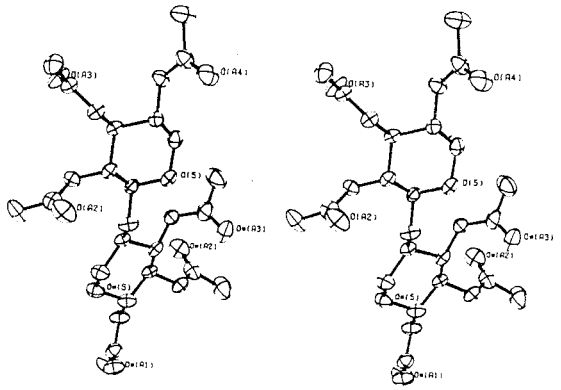

FIG. 5. A stereoscopic view of the molecule looking down the *a*-axis. Atoms in the contiguous residue are marked with an asterisk.

molecule. The average standard deviations of the bond lengths are shown in Table 4 while the average standard deviation for the bond angles is 0.7°. The average carbon–carbon bond-length (1.514 Å) in the unprimed ring is slightly shorter than the average in the primed ring (1.508 Å). Although the difference is less than a standard deviation, a similar difference was also observed for β-cellobioside–methanol and for cellobiose 8. The average ring carbon–O(Ac) bond length is 1.427 Å with a spread of 0.026 Å. In contrast to the case of β-cellobioside–methanol, the two ring carbon–oxygen bonds in both primed and unprimed rings are unequal: C(1)—O(5) = 1.399 Å *vs.* C(5)—O(5) = 1.434 Å, and C′(1)—O′(5) = 1.395 Å *vs.* C′(5)—O′(5) = 1.440 Å. According to Arnott and Scott (9), the average values for C(1)—O(5) and C(5)—O(5) are 1.429 and 1.436 Å respectively, thus the discrepancies here are much more pronounced: 3σ in the unprimed ring and 4σ in the primed ring. Kim and Jeffrey (10) pointed out that similar discrepancies were observed in the case of glycosidic substituted sugars.

The ring carbon–hydrogen bond lengths lie in the range of 0.89–1.07 Å and those of the methyl groups are in the range of 0.73–1.17 Å.

TABLE 4. Average standard deviations of the bond lengths for β-D, 1 → 4 xylobiose hexaacetate

	Length (Å)		
Bond	Rings	Equatorial bonds	Acetate groups
C—C	0.0092		0.0118
C—O	0.0086	0.0078	0.0088
C=O			0.0098

The average interior and exterior ring angles are 110.4° and 108.7°, respectively, similar values were observed in β-cellobioside–methanol. The average angle at the oxygen atom linked to the acetate group is 118.3° with a spread of 2.5°. The angles Me—C(A)—O(Ac) for all acetate groups are 111.7°, much less than 120° as one might expect; the spread was 2.9°. Similar distortion of this bond angle was also observed in 3′-*O*-acetyl-4-thiothymidine (11).

There is neither hydrogen bonding nor obviously short interatomic contacts throughout the crystal structure. The molecular packing is shown in Fig. 6.

Following the convention adopted by Sundararajan and Rao (1*b*) and used by Gabbay, Sundararajan, and Marchessault (1*a*), the conformational angles (Φ,Ψ) as shown in Fig. 1 were calculated to be (20.4°, −15.2°) for the structure in question. These values are somewhat different from those deduced for xylan (42°, −21°) but since the O′(1)...O(4) distance is 10.47 Å as compared with the fiber repeat in xylan diacetate which is reported (1*a*) as 10.31 Å the difference is in the expected direction.

For cellobiose, the conformational angles are (42°, −18°) (8).[5] These results are in excellent agreement with those deduced from conformational analysis of cellulose (40°, −20°) (12, 16). The reason that one gets better agreement between cellobiose and cellulose is perhaps due to the intramolecular hydrogen bonding between O′(3) and O(5) which is present in both compounds. (Polarized infrared spectroscopy provided the evidence for such intramolecular hydrogen bonding in cellulose (13). The O′(3)....O(5) distance in xylobiose hexaacetate is 3.03 Å while in cellobiose it is 2.767 Å (14). If the conformations of a polysaccharide and its chemically related disaccharide are mainly determined by the same factors, *e.g.* an intramolecular hydrogen bond in the case of cellulose and cellobiose, then one would expect that in xylan diacetate and xylobiose hexaacetate the O′(3)...O(5) distance would be the same. In the conformational study by Gabbay, Sundararajan,

[5]The (Φ,Ψ) reported by Ham *et al.* (8) were (−42°, +162°). To transform these values to our convention, the relationships $\Phi = -\Phi_{Rees}$, $\Psi = \Psi_{Rees} + 180$ were used (15).

and Marchessault (1*a*) the geometry chosen and the observed fiber repeat was such as to lead to a 2.7 Å distance between O'(3)...O(5) in xylan diacetate. The observed Φ,Ψ angles for xylobiose hexaacetate correspond to Φ,Ψ = (20.4°, −15.2°) which is near the helical parameters $n = 2$ and $h = 5.2$ Å, *i.e.*, a two-fold axis and a fiber repeat corresponding to 10.4 Å. The reported fiber repeat for cellulose triacetate is 10.43 Å (17) which is in keeping with this. It would seem that some adjustment either in molecular geometry or in the observed fiber repeat for xylan diacetate is required to bring about agreement between the conformational angles predicted (1*a*) for xylan diacetate and those observed for its disaccharide.

The observed orientations of the acetate groups together with those obtained from stereochemical calculations by Gabbay, Sundararajan, and Marchessault (1) are shown in Fig. 7. In all four cases, the predicted positions of the C(A)—O bonds, measured by the angle χ, are further away from the coplanar position with respect to the C—H bonds than those obtained from X-ray crystallography. It is also evident that the χ values computed using the Flory functions (18) give much better agreement with experiment than those calculated using the Kitaigorodsky functions (19). In spite of the fact that the calculated acetate orientations are based on the conformational angles (42°, −21°) instead of what were actually observed, the agreement between experimental and calculated values (Flory functions) is reasonably good. This seems to indicate that the orientations of the acetate groups are independent of Φ and Ψ. This is being further substantiated by investigating the structures of other acetylated sugars.

The authors wish to thank Dr. F. Brisse and Mr. J. Sygusch for their advice on computing and helpful discussions.

Fungal Steroids. A Stereoselective Synthesis of Isoantheridiol

C. R. POPPLESTONE AND A. M. UNRAU

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received October 11, 1972

The synthesis and characteristics of the 23-hydroxy-δ-lactone isomer of antheridiol and (22S,23R) 3β-hydroxy-24-carbethoxymethylene-cholest-5-en-22,23-epoxide are described. The synthesis of the latter compound follows from the highly stereoselective epoxidation of 3β-acetoxy-cholesta-5,22-diene-24-one followed by a Wittig reaction to give (22S,23R) 3β-acetoxy-24-carbethoxymethylene-cholest-5-en-22,23-epoxide which upon treatment with perchloric acid gave exclusively the δ-lactone. Hematoporphyrin-sensitized photooxygenation followed by cupric acetate oxidation gave the required α,β-unsaturated ketonic system in ring B. The 22R,23S stereochemical assignment of the final product is based on circular dichroism spectra.

La synthèse et la caractérisation de l'isomère hydroxy-23 δ-lactone de l'anthéridiol et du (22S,23R) hydroxy-3β carbethoxyméthylène-24 cholestène-5 époxyde-22,23 ont été données. La synthèse de ce dernier passe par l'époxydation hautement stéréosélective de l'acétoxy-3β cholestadiène-5,22 one-24 suivie d'une réaction de Wittig pour conduire au (22S,23R) acétoxy-3β carbethoxyméthylène-24 cholestène-5 époxyde-22,23 qui, après traitement à l'acide perchlorique donne la δ-lactone exclusivement. La photooxygénation sensibilisée de l'hématoporphyrine par l'acétate cuivrique conduit au système cétonique α,β-insaturé requis pour le cycle B. L'attribution stéréochimique 22R,23S du produit final est basée sur les spectres de dichroisme circulaire. [Traduit par le journal]

Can. J. Chem., **51**, 1223 (1973)

Continued refinement of analytical techniques has led to the discovery and characterization of a multitude of intermediate compounds involved in the biosynthetic pathways leading to major end products. Many postulated intermediates have been identified although present in only minute quantities. It is now quite obvious that in the course of the elaboration of the side chains of phytosterols, an extensive array of biogenetic intermediates is involved. The rather highly functionalized side chain of antheridiol (**1**), a mold sex hormone, is an example in which the hydrocarbon side chain of the most probable precursor, fucosterol, has been extensively modified. This steroidal hormone has been isolated, along with the biologically inactive 23-deoxyantheridiol (**2**), from culture liquids of the water mold, *Achlya bisexualis* (1, 2). Both antheridiol (**1**) (in its natural 22S,23R configuration), and 23-deoxyantheridiol (**2**) (in its unnatural 22S configuration) have been chemically synthesized (2, 3). In this communication we describe a relatively efficient synthesis of the 23-hydroxy-δ-lactonic isomer of antheridiol, **3***a*, having the 22R,23S configuration. We also describe the synthesis and characterization of 3β-hydroxy-24-carboxymethylene-cholest-5-en-22,23-epoxide (**7***a*).

Our recent identification of fucosterol as the major sterol in *Achlya bisexualis*, and the occur-

rence of both the γ- and δ-lactone derivatives in this fungal species, thus indicating a common biosynthetic precursor, prompted our attempts to synthesize the 23-hydroxy-δ-lactone isomer.

The starting material for our synthesis was the α,β-unsaturated ketone, **4**, derived from readily available stigmasterol, a sterol which has been extensively used in our laboratory as a chemical precursor for synthesis of biogenetic steroid precursors in yeast (4). Alkaline epoxidation with hydrogen peroxide in methanol gave a mixture of epoxy acetate **5***b* and alcohol **5***a*. This reaction is known to be highly stereoselective giving the 22S,23R isomer (5). Deacetylation of the mixture gave the epoxy alcohol **5***a* in 70% yield.

A Wittig reaction (6) of the carbanion of diethyl carbethoxymethyl phosphonate (**6**) with α,β-unsaturated ketone **5***a*, was used to generate the important intermediate **7***a* in 30% yield. When this reaction was carried out on **5***b*, a mixture of **7***a* and *b* was obtained due to alkaline hydrolysis of the 3β-acetoxy group. Compound **7** can have two possible side chain isomeric forms (7). The *E*-configuration was assigned to **7** based on the following evidence. The *Z*-configuration would require isomerization to *E* as a prerequisite to lactone formation. Such a step would involve protonation at C-28 to give the C-24 carbonium ion and allow free rotation about the C_{24}—C_{28} bond. In the presence of D_2O, the C-28 olefinic proton, in the case of the *Z*-isomer, would be expected to exchange. In the conversion of **7** to **8** in the presence of D_2O, no reduction in the intensity of the C-28 proton signal was observed. This would be expected for the *E*-configuration of **7** in which isomerization of the C_{24}—C_{28} double bond is not required for lactone formation.

Treatment of **7***a* with aqueous perchloric acid in methanol resulted in rapid formation of the highly insoluble δ-lactone **8***a* in quantitative yield. This substance (**8***a*) gave one spot on t.l.c. as did the monoacetate **8***b* and diacetate **8***c*. Since the 22S,23R and 22R,23S isomers of the corresponding γ-lactone have been separated by t.l.c. (3), this indicated the product **8***a* was a single epimer. No formation of the γ-lactone was detected in the reaction. The monoacetate, **8***b* was noticeably more soluble in organic solvents than the corresponding 3β-alcohol, **8***a*. For this reason the n.m.r. spectrum for the monoacetate is recorded in preference to that of **8***a*. It is significant to note that the coupling constant of the C-23 proton (J = 10 Hz) is strongly indicative of *trans* C-22 and -23 hydrogens thus further substantiating the assigned *E*-configuration of **7** and is also supportive of the suggested mechanism of δ-lactone formation.

Compound **8***a* was readily converted into the

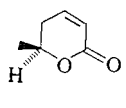
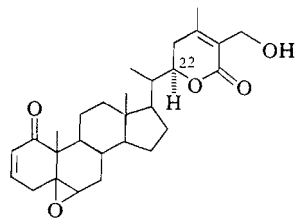
(22R,23S) 23-hydroxy δ-lactone isomer of antheridiol (**3***a*) by hematoporphyrin-sensitized photooxygenation (8) and oxidative rearrangement (9) in 50% yield.

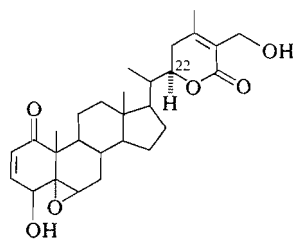
The stereochemical assignments at C-22 follow from a comparison of the circular dichroism (c.d.) spectra of the δ-lactones **3** and **8** and parasorbic acid **9** in which the methyl group is known from n.m.r. measurements to be equatorial (10). The c.d. curve of **3***a* (in methanol) revealed a strong negative peak at 255 nm ([θ] = −20 460°), as did **8***a* at 260 nm ([θ] = −8440°). Since parasorbic acid exhibits a positive CD curve at 260 nm (11) due to the chirality of the nonplanar enone system, it follows that both the δ-lactones (**3** and **8**) have the opposite stereochemistry to parasorbic acid. Since the C-22 stereochemistry of both jaborosalactone A (**10**) and withaferin A (**11**) have been determined by this method (the assignments were subsequently found to agree with those determined by X-ray measurements (12, 13)), we feel justified in assigning the 22R configuration to the δ-lactones **3** and **8**.



9



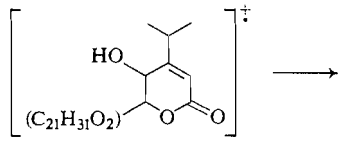
10



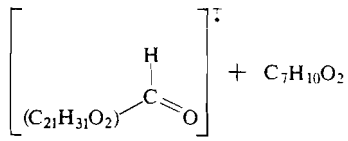
11

The assignment of the R configuration at C-22, and the fact that only the δ-lactone is formed, is based on the n.m.r. evidence for *trans* C-22 and -23 hydrogens (J = 10 Hz). We further interpreted these observations to indicate a relatively concerted epoxide ring opening resulting in the formation of the δ-lactone exclusively. Epoxide ring opening to yield a relatively free carbo-cation (C-22) would be expected to give an R,S configuration at C-22 of the eventual δ-lactone. A plausible route could involve hydrolysis of the α,β-unsaturated ester function with concomitant protonation of the epoxide followed by a concerted epoxide ring opening (nucleophilic attack at C-22) to give the δ-lactone.

The mass spectrum of the 23-hydroxy-δ-lactone (**3***a*) is similar to that reported for antheridiol (14). The molecular ion **a** undergoes a retro-Diels–Alder fragmentation (15) to furnish a very intense peak (*m/e* 344, **b**) and fragment **c**.



a



b c

The 23-hydroxy-δ-lactone, **3***a*, is characterized by its m.p. 240–243°, a broad absorption band in the u.v. at 230 nm (ε 16 500), and a strong absorption band in the i.r. at 1685 cm^{-1}. When the ethanolic solution which had been used for the u.v. spectrum was refluxed with hydrochloric acid the u.v. spectrum changed to λ_{max} 216, 279 nm resulting from extended conjugation of the $\Delta^{3,5}$-7-ketone.

The monoacetate **3***b* was also prepared with the expectancy that it would be more soluble in chloroform than the 3β-hydroxy compound **3***a*, but this was not the case. However, the n.m.r. of the monoacetate **3***b* has been included for comparison.

Experimental

Instruments and Materials

Melting points were obtained on a Fisher–Johns m.p. apparatus and are uncorrected. Spectra were obtained on the following instruments: Perkin–Elmer 457 (i.r.), Unicam SP 800 (u.v.), and Varian XL-100 n.m.r. spectrometer. N.m.r. results are reported as δ using TMS as internal standard (δ = 0). Ionizing voltage for mass spectrometry, Perkin–Elmer Hitachi RMU-7, was 80 eV if not specifically mentioned otherwise. Stigmasterol was generously supplied by the Upjohn Company, Kalamazoo, Michigan.

Preparation of 3β-Acetoxy-24-oxo-cholest-5-en-22, 23-epoxide (5b)

To a solution of **4** (3.0 g, 6.8 mol) in 100 ml acetone and 300 ml methanol, was added 20 ml of 38% hydrogen peroxide. The solution was stirred at room temperature and 4 *N* NaOH (3 ml) added at such a rate as to keep the solution alkaline over a period of 3 h, and the solution was then left to stand at 4 °C for 5 h. Most of the solvent was removed *in vacuo* and water added to the residue. The solution was extracted twice with ether and removal of the solvent *in vacuo* gave a non-crystalline residue, which was shown by t.l.c. (SiO_2, 2% MeOH–$CHCl_3$) to be a mixture of **5***a* and *b*. The mixture was refluxed for ½ h with 100 ml 2% K_2CO_3 in 10% H_2O–MeOH. The solvent was removed (*in vacuo*), water added to the residue, and the product extracted with ether. The ether layer was dried over $MgSO_4$ and removal of the solvent gave a crystalline solid. Recrystallization from methanol gave **5***a*, m.p. 180–181 °C, (70%).

Acetylation of **5***a* with acetic anhydride – pyridine gave **5***b*.

Recrystallization from methanol gave m.p. 125–126 °C; ν_{max} ($CHCl_3$): 2940, 1715, 1250, and 1030 cm^{-1}; n.m.r. ($CDCl_3$): δ 0.65 (CH_3—C_{18}, s), 1.01 (CH_3—C_{19}, s), 1.01, 1.06, (2 × d, J = 7 Hz, $2CH_3$—C_{25}), 2.01 (CH_3OCO—, s), 2.5–2.9 (2H; sept. centered at 2.69, H—C_{25}; m centered at 2.80, H—C_{22}), 3.25 (H—C_{23}, d, J = 2 Hz), 4.4–4.8 (H—C_3, broad m), 5.51 (H—C_6, narrow m).

Anal. Calcd. for $C_{29}H_{44}O_4$ (mol. wt. 456): C, 76.27; H, 9.71. Found (*m/e*, 456): C, 76.23; H, 9.64.

Preparation of (22S,23R) 3β-Acetoxy-24-carbethoxy-methylene-cholest-5-en-22,23-epoxide (7b)

A solution of **6** (2 g, 0.01 mol), prepared from ethyl bromoacetate and triethyl phosphite (16), in THF (10 ml) (distilled over $LiAlH_4$) was added dropwise with stirring to a suspension of sodium amide (0.4 g, 0.01 mol) in dry THF (10 ml) at 20 °C. The solution was then stirred at room temperature under a slow stream of N_2 to sweep out the evolved ammonia. To the resulting yellowish-green solution was added **5***a* (0.8 g, 2 mmol) in THF (10 ml) over a 1 h period at 20–25 °C after which the solution was left for a further period of 1 h. The solvent was removed *in vacuo*, and water added to the residue. The aqueous solution was extracted with ether, the extract dried over $MgSO_4$ and evaporated to give a colorless oil which was purified by chromatography (SiO_2, benzene) to give **7***a* which crystallized as needles from petroleum ether (30:60), m.p. 117–118° (40%).

Mol. Wt. Calcd. for $C_{31}H_{48}O_4$: 484. Found (mass spectrum): 484.

When this Wittig reaction was carried out with acetate (**5***b*) the product was found by t.l.c. (SiO_2, $CHCl_3$) to be a mixture consisting mainly of **7***a* and *b*. Acetylation of **7***a* with acetic anhydride – pyridine gave **7***b* as an oil which crystallized as needles from ethanol, m.p. 117–118°; ν_{max} (KBr) 2970, 1730, 1710, 1630, 1245, 1210, 1172, and 1030 cm^{-1}; λ_{max} (EtOH) 231 nm (ε 14 800); n.m.r. ($CDCl_3$): δ 0.68 (CH_3—C_{18}, s), 1.03 (CH_3—C_{19}, s), 1.06 (H—C_{21}, d, J = 7 Hz), 1.28 (C_2H_5OOC—, t, J = 7 Hz), 4.18 (C_2H_5OOC—, q, J = 7 Hz), 4.32 (H—C_{23}, broad s), 4.3–4.8 (H—C_3, broad m), 5.35 (H—C_6, narrow m), 5.78 (—OOC—CH=, s).

Anal. Calcd. for $C_{33}H_{50}O_5$ (mol. wt. 526): C, 75.29; H, 9.50. Found (*m/e*, 526): C, 75.41; H, 9.64.

Preparation of (22R,23S) 3β,23-Dihydroxy-24-carboxymethylene-cholest-5-en-19,22-lactone (8a)

To **7***a* (500 mg) dissolved in methanol (50 ml), 5 ml 30% perchloric acid was added. After 5 min the solution was concentrated to about half volume *in vacuo* then poured into water and extracted twice with ethyl acetate. The solvent layer was washed with saturated $NaHCO_3$ solution and water, and dried over $MgSO_4$. The ethyl acetate was concentrated *in vacuo* to small volume and left to stand at room temperature for crystallization to give **8***a*, m.p. 267–270° (>90%). ν_{max}(KBr): 3360, 2930, 1685, and 1380, cm^{-1}; λ_{max} EtOH 210 nm (ε 11 800); c.d. (*c*, 0.04, MeOH)$[\theta]_{300}$ ±0, $[\theta]_{285}$ −677, $[\theta]_{280}$ −1360, $[\theta]_{275}$ −2940, $[\theta]_{270}$ −4960, $[\theta]_{265}$ −7210, $[\theta]_{260}$ −8440, $[\theta]_{255}$ −7660, $[\theta]_{250}$ −3160, $[\theta]_{245}$ +3400, $[\theta]_{240}$ +12 000, $[\theta]_{323}$ −18 000, $[\theta]_{225}$ +10 200, $[\theta]_{220}$ −4520°.

Anal. Calcd. for $C_{29}H_{44}O_4$ (mol. wt. 456): C, 76.27: H, 9.71. Found (*m/e*, 456): C, 76.34; H, 9.73.

The monoacetate **8***b*, was prepared in a similar way from **7***b*. Recrystallization from benzene gave m.p. 249–252° (d); n.m.r. ($CDCl_3$): δ 0.72 (CH_3—C_{18}, s), 1.03 (CH_3—C_{19}, s), 1.04 (H—C_{21}, d, J = 6.5 Hz), 1.17 ($2CH_3$—C_{25}, d, J = 7 Hz), 2.02 (CH_3OCO—, s), 2.87 (H—C_{25}, sept., J = 7 Hz), 4.16 (H—C_{22}, d, J = 10 Hz), 4.2–4.8 (2H, m; addition of D_2O gives d at 4.37 J = 10 Hz, H—C_{23} and H—C_3), 5.36 (H—C_6, m), 5.72 (lactone olefinic-H, s).

Mol. wt. Calcd. for $C_{31}H_{46}O_5$: 498. Found (mass spectrum): 498.

Compound **8***b* was also prepared using 60% perchloric acid (2.5 ml) – D_2O (2.5 ml). The n.m.r. ($CDCl_3$) of the product was identical to that reported above, *i.e.* no exchange occurred at C-28.

Acetylation of **8***b* or *a* with acetic anhydride – pyridine gave diacetate **8***c*. Recrystallization from methanol gave m.p. 207–209°.

Mol. Wt. Calcd. for $C_{33}H_{48}O_6$: 540. Found (mass spectrum): 540.

T.l.c. of compounds **8***a*, *b*, and *c* on SiO_2 using 10% EtOAc–C_6H_6 as solvent showed each compound as a single spot.

Preparation of (22R,23S) 3β,23-Dihydroxy-24-carboxymethylene-5-en-7-one-29,22-lactone (3a)

A stirred solution of **8***a* (100 mg) in 20 ml pyridine containing 10 mg hematoporphyrin was irradiated in a water-cooled jacket with seven 15 W fluorescent lamps (General Electric F15T12), during which time O_2 was bubbled through the solution. The reaction was monitored by t.l.c. (SiO_2 – 4% MeOH in $CHCl_3$). After 24 h the mixture was diluted with ether, treated with 20 mg charcoal, filtered through Celite and the ether evaporated. Cupric acetate (70 mg) was added to the pyridine solution and the mixture was stirred for 5 h and diluted with ethyl acetate. The solution was washed with dilute phosphoric acid, dilute $NaHCO_3$ and H_2O, dried over $MgSO_4$, and evaporated to dryness to give **3***a*. Recrystallization twice from ethyl acetate gave m.p. 240–243° (50%); ν_{max}(KBr) 3390, 2940, 1685, 1380, 1270, and 1050 cm^{-1}; λ_{max} EtOH 230 nm (ε 16 500). The solution of **3***a* which had been used for the u.v. spectrum (2 mg in 50 ml EtOH) was treated with a few drops of 6 *N* HCl and refluxed for 4 h. The u.v. spectrum now gave maxima at 279 and 216 nm. Mass spectrum (inlet temperature

270°): *m/e* (relative intensity) 470 (45, M^+), 452 (18), 345 (42), 344 (41), 287 (29), 269 (26), 245 (41), 126 (62), 43 (100); c.d. (*c*, 0.0345, MeOH) $[\theta]_{310} \pm 0$, $[\theta]_{300} -538$, $[\theta]_{295} -1080$, $[\theta]_{290} -2160$, $[\theta]_{285} -2960$, $[\theta]_{280} -4300$, $[\theta]_{280} -4300$, $[\theta]_{275} -7000$, $[\theta]_{270} -10\,000$, $[\theta]_{265} -14\,800$, $[\theta]_{260} -18\,850$, $[\theta]_{255} -20\,460$, $[\theta]_{250} -18\,850$, $[\theta]_{245} -12\,120$, $[\theta]_{240} -4050$, $[\theta]_{235} +810$, $[\theta]_{230} -4050$, $[\theta]_{225} -18\,850$, $[\theta]_{220} -70\,000°$.

Anal. Calcd. for $C_{29}H_{42}O_5$: C, 74.01; H, 8.99. Found: C, 74.21; H, 9.00.

The monoacetate 3*b* was prepared in a similar manner from **8***b*. Recrystallization from benzene gave m.p. 290–295 °C; n.m.r. (pyridine): δ 0.68 (CH_3—C_{18}, s), 1.09 (CH_3—C_{19}, $2CH_3$—C_{25}, d, $J = 7$ Hz), 1.13 (H—C_{21}, d, $J = 6.5$ Hz), 2.03 (CH_3OCO—, s), 3.20 (H—C_{25}, sept., $J = 7$ Hz), 4.44 (H—C_{22}, d, $J = 10$ Hz), 4.5–4.8 (2H, m, 23-H and H—C_3), 5.74 (H—C_6, broad s), 5.90 (lactone olefinic-H, broad s).

Mol Wt. Calcd. for $C_{31}H_{44}O_6$: 512. Found (mass spectrum): 512.

Acetylation of 3*a* or *b* with acetic anhydride – pyridine gave diacetate 3*c*. Recrystallization from methanol gave m.p. 215–216 °C.

Mol. Wt. Calcd. for $C_{33}H_{46}O_7$: 554. Found (mass spectrum): 554.

The High Dose Rate Radiolysis of H_2S: Sulfur as an Electron Scavenger[1]

A. W. BOYD, C. WILLIS,[2] AND O. A. MILLER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received October 2, 1972

The radiolysis of gaseous hydrogen sulfide has been studied in the presence of added sulfur at 200–250 °C. At 2×10^{27} eV g^{-1} s^{-1} sulfur reduces the hydrogen yield from $G(H_2) = 12.0 \pm 0.3$ to $G(H_2) = 7.3 \pm 0.3$. This reduction in yield appears to be due to electron attachment by the sulfur thereby suppressing formation of hydrogen from dissociative neutralization. Assuming the sulfur is S_8 we estimate the attachment rate of electrons to sulfur to be about 1×10^{14} M^{-1} s^{-1}.

At 25 °C the reduction in the H_2 yield at 2×10^{27} eV g^{-1} s^{-1} with increasing dose appears to be due to polysulfanes rather than radiolytic sulfur.

Over the range of $10^{26} - 10^{28}$ eV g^{-1} s^{-1} the H_2 yield increases from $G(H_2) = 11$ to $G(H_2) = 13$. Mechanisms to account for this increase are discussed.

La radiolyse du sulfure d'hydrogène gazeux a été étudiée en présence de soufre additionné, à 200–250 °C. Pour des valeurs de 2×10^{27} eV g^{-1} s^{-1}, le soufre diminue le rendement en hydrogène de $G(H_2) = 12.0 \pm 0.3$ à $G(H_2) = 7.3 \pm 0.3$. Cette réduction dans le rendement est imputable, semble-t-il, à l'attachement par le soufre d'un électron ce qui empêche la formation de l'hydrogène à partir de la neutralisation dissociative. En supposant que le soufre est sous forme S_8, on estime que le taux d'attachement d'électrons par le soufre est d'environ 1×10^{14} M^{-1} s^{-1}.

A 25 °C, la réduction dans le rendement en H_2 pour des valeurs de 2×10^{27} eV g^{-1} s^{-1} avec augmentation des doses semble imputable aux polysulfanes plutôt qu'au soufre radiolytique.

Dans l'intervalle $10^{26} - 10^{28}$ eV g^{-1} s^{-1}, le rendement en H_2 augmente de $G(H_2) = 11$ jusqu'a $G(H_2) = 13$. Les mécanismes expliquant cette augmentation sont discutés.

[Traduit par le journal]

Can. J. Chem., 51, 1228 (1973)

Introduction

Rcently several studies of the radiolysis of hydrogen sulfide have been reported (1–14) and we have proposed a mechanism based on our measurements at high dose rates (13). While this mechanism is in general agreement with the observed yields there are problems which need further investigation.

The main experimental results all obtained at room temperature are as follows. At low dose rates ($10^{16} - 10^{18}$ eV g^{-1} s^{-1}) $G(H_2) = 7.0$–9.3 (1–11) with more recent data supporting values at the lower end of this range. Addition of compounds capable of electron attachment, N_2O or SF_6, does not reduce this hydrogen yield. At high dose rates ($10^{26} - 10^{28}$ eV g^{-1} s^{-1}) the yield is much higher $G(H_2) = 11.5$–13.0 (12–14) and appears to increase with dose rate over this range. At 2×10^{27} eV g^{-1} s^{-1} the hydrogen yield $G(H_2) = 12.0 \pm 0.3$ is reduced to $G(H_2) = 7.9 \pm 0.3$ by the addition of SF_6 (13). In multi-pulse irradiation experiments of pure H_2S at a dose rate of 2×10^{27} eV g^{-1} s^{-1} the hydrogen yield decreases with dose to $G(H_2) \approx 8$ above a total dose of ~ 10 Mrads. For H_2S–SF_6 mixtures no similar reduction with dose is observed (13), the hydrogen yield remaining constant at $G(H_2) = 7.9$.

We interpreted these results in terms of changing charge neutralization processes. At high dose rates for single pulse irradiations in pure H_2S, charge neutralization involves the free electron, reaction 1.[3]

[1] $$H_5S_2^+ + e \rightarrow H + 2H_2S$$

On the addition of SF_6, SF_6^- is involved in the neutralization step and the formation of hydrogen atoms, [1], is suppressed.

[2] $$e + SF_6 \rightarrow SF_6^-$$

[3] $$H_5S_2^+ + SF_6^- \rightarrow HF + 2H_2S + SF_5$$

[1] A.E.C.L. No. 4456.

[2] Present address: Chemistry Department, University of the West Indies, Kingston, Jamaica.

[3] As will be discussed, the predominant positive ion is more probably $H_5S_2^+$, rather than H_3S^+ which was assumed in ref. 13.

This correspondingly reduces the hydrogen yield from [4].

[4] $$H + H_2S \rightarrow H_2 + SH$$

The decrease in yield with increasing dose can be explained if elemental sulfur, which is formed in a yield equivalent to that of hydrogen, can act in a manner similar to SF_6, reactions 5 and 6.

[5] $$S_n + e \rightarrow S_n^-$$

[6] $$H_5S_2^+ + S_n^- \rightarrow 2H_2S + HS_n$$
or
$$2H_2S + SH + S_{n-1}$$

Clearly, if reactions 5 and 6 can occur, then at low dose rates, because of the much longer lifetime of the electron with respect to neutralization, only very low concentrations of sulfur and hence very low doses will be required to suppress completely production of hydrogen via neutralization.

To test our suggestion that sulfur is acting as an electron scavenger we have irradiated mixtures of H_2S and sulfur at 200 °C. This temperature is required to obtain a sufficient concentration of sulfur in the vapor phase.

There are other points which need further study.

The proposed mechanism does not predict any dose rate effect in the range $10^{27} - 10^{28}$ eV g^{-1} s^{-1}, yet we observed an increase from $G(H_2) = 12.0 \pm 0.5$ to $G(H_2) = 13.1 \pm 0.4$ over this range (13, 14). To study this further we have measured H_2 yields in both pure H_2S and H_2S–SF_6 mixtures from 1×10^{26} eV g^{-1} s^{-1} to 2×10^{28} eV g^{-1} s^{-1} at room temperature.

The equilibrium vapor pressure of sulfur at 25 °C is less than 10^{-5} Torr. If there is vapor–solid equilibrium for the sulfur, formed in multipulse irradiations at room temperature, then the concentration of sulfur in the gas phase is so low that k_5 would have to be improbably high for reaction 5 to compete with reaction 1 and there should be no effect of dose at high dose rates. To determine if the observed fall-off is due to supersaturation of sulfur vapor we have both varied the time between pulses and cooled the cells in liquid nitrogen between pulses.

Experimental

Radiation Sources and Dosimetry

Both Febetron 705 and Febetron 706 accelerators were used. In the 705 irradiations the gas samples were irradiated in quartz cells with a break-seal. These could be heated in a furnace (15) at temperatures up to 250 °C prior to irradiation. In the 706 irradiations the samples were irradiated in aluminum cells (14). The average dose in both types of cells was determined by nitrous oxide dosimetry taking $G(N_2) = 12.4$(14, 16–18). The maximum dose per pulse and average dose rate obtained with the 705 were 1×10^{20} eV g^{-1} and 2×10^{27} eV g^{-1} s^{-1}. These were reduced to 5×10^{18} eV g^{-1} and 1×10^{26} eV g^{-1} s^{-1} by the use of a scattering foil (19). The dose in the aluminum cells with the 706 was 5×10^{19} eV g^{-1} per pulse and the average dose rate 2×10^{28} eV g^{-1} s^{-1}.

Materials and Analyses

The H_2S and SF_6 (Matheson C.P. grade) were purified by eliminating gases non-condensible at 77 °K by several freeze–pump–thaw cycles. The sulfur (Fisher USP) was added to the irradiation cells in solution in CS_2. The CS_2 was removed by use of a vacuum oven followed by pumping on a vacuum line at room temperature. This was shown not to remove any appreciable amount of sulfur. As in ref. 13, the hydrogen was measured using a McLeod gauge and a calibrated mass spectrometer.

Results

H_2S–S Mixtures

The hydrogen yields from single pulse irradiations of H_2S–S mixtures at 200–250 °C are shown in Fig. 1. These yields have not been corrected for the slight increase in total dose due to the addition of sulfur. There appears to be no significant change in the initial yield of hydrogen $G(H_2) = 12.0 \pm 0.5$ (13) from H_2S on increasing the temperature from 25 °C to 200–250 °C.

Two other sets of data are plotted in Fig. 1. Cells containing pure H_2S were irradiated with 6 to 10 pulses at room temperature. These were cooled with liquid nitrogen and the hydrogen formed was removed. The cells were then irradiated at 200 °C. The amount of sulfur formed was calculated assuming the yield to equal that of hydrogen. The effect of the radiolytically produced sulfur appears to be the same

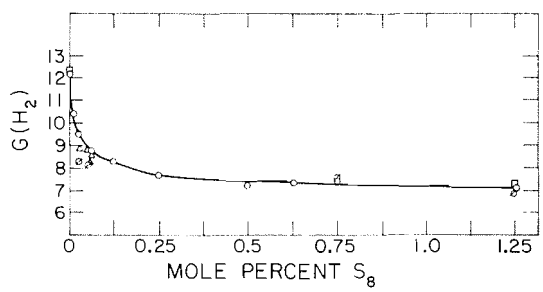

FIG. 1. Hydrogen yields in the radiolysis of H_2S–S mixtures, 2×10^{27} eV g^{-1} s^{-1}, 10^{20} eV g^{-1} 200 °C: ○, 800 Torr; □, 300 Torr; ∅, 800 Torr plus 2 mol % SF_6; △, 800 Torr sulfur formed radiolytically.

as that of the added sulfur. At room temperature however added sulfur did not significantly reduce the hydrogen yield.

In addition mixtures with H_2S containing 2 mol% SF_6 as well as sulfur were irradiated at 200 °C. The SF_6 has little or no effect on the hydrogen yield except at low sulfur concentrations.

To facilitate comparison between H_2S–SF_6 and H_2S–S mixtures the curve from Fig. 1 is plotted with data for H_2S–SF_6 mixtures in Fig. 2. For reasons of scale the sulfur is assumed to be S_4 rather than S_8 in this figure.

Dose Rate Effects

The hydrogen yields from single pulse irradiations of H_2S and H_2S–SF_6 mixtures at 25 °C at various dose rates are listed in Table 1.

Multipulse Irradiations

The hydrogen yields from H_2S samples following 8 or 10 pulses each at a dose rate of 2×10^{27} eV g^{-1} s^{-1} under different conditions are listed in Table 2.

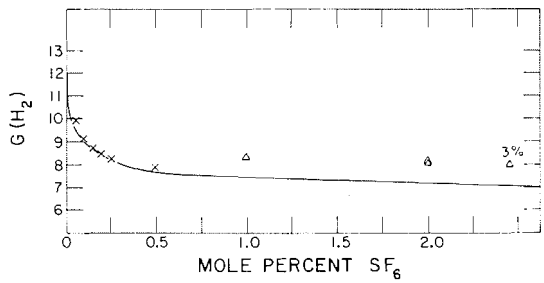

FIG. 2. Hydrogen yields in the radiolysis of H_2S–SF_6 mixtures 800–1000 Torr, 2×10^{27} eV g^{-1} s^{-1}, 10^{20} eV g^{-1} 25 °C: △, this work; ×, from ref. 13; —, from Fig. 1 but with scale doubled so that sulfur is as S_4.

Discussion

Comparison of H_2S–S and H_2S–SF_6 Mixtures

It is clear that the reduction in the hydrogen yield from H_2S radiolysis at Febetron dose rates by the addition of sulfur vapor is similar to the reduction by the addition of SF_6. It seems almost certain, then, that sulfur is a very efficient electron scavenger. Assuming this to be the case a rate constant for reaction 5 can be derived from the relative reduction in hydrogen yield. The major species in pure sulfur vapor at room temperature is S_8 (20). At 200–250 °C the composition is ~60% S_8, ~25% S_6, and ~15% S_7 but for the present discussion we shall assume that all the sulfur is S_8. Using the computer program of Schmidt (21) and our knowledge of the dose and duration and shape of the electron pulse the reduction in the hydrogen yield can be calculated for various values of k_1 and k_5. The rate of dissociative recombination of H_2S, reaction 1, has not been measured but the value for water vapor is in the range 6–18 × 10^{14} M^{-1} s^{-1} (22). Using these values for k_1 the rate constant for reaction 5 was calculated to be $k_5 = 8$–16×10^{13} M^{-1} s^{-1}. For comparison the rate constant for thermal electron attachment to SF_6 is 1.8×10^{14} M^{-1} s^{-1} (23, 24). As we have discussed (13) the rate constant for attachment of electrons to SF_6 under our conditions appears to be about 10 times smaller. Thus for Febetron conditions sulfur is a more effective electron scavenger than SF_6.

As can be seen in Fig. 2 the plateau values of the hydrogen yield in H_2S–SF_6 and H_2S–S

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mixtures are different. This difference is supported by comparing the reciprocal plot of the yields for H_2S–S and H_2S–SF_6 mixtures shown in Fig. 3. These plots are based on the expression

$$\frac{1}{G(H_2)_0 - G(H_2)_A} = \frac{1}{G(H_2)_0 - G(H_2)} \times \left[\frac{1 + \text{Constant} \times [H_2S]}{K[A]}\right]$$

where A may be S or SF_6. The intercepts at $[H_2S]/[A] = 0$ give values of $G(H_2)_0 - G(H_2) = 4.1$ and 4.7 for SF_6 and S_8, respectively. Obviously the H_2 yield with sulfur may be too low or the yield with SF_6 may be too high.

It is likely that the lower plateau yield of $G(H_2) = 7.3 \pm 0.3$ obtained with sulfur is closer to the true yield in the presence of an electron scavenger. Charge transfer to sulfur from $H_5S_2^+$ would reduce $G(H_2)$ and is exothermic but for this to compete with neutralization of these ions the rate constant would have to be two orders of magnitude greater than that of any observed charge transfer reactions. It is also unlikely that, at a concentration of 1 mol%, sulfur will compete with H_2S for H atoms. The rate constant for reaction 4 at 200 °C is $\sim 1 \times 10^9\ M^{-1}\ s^{-1}$ (25). On the other hand Huyton and Woodward (1) observed an increase in $G(H_2)$ on the addition of SF_6 in the low dose rate radiolysis of H_2S.

Dose Rate Effects at $10^{26} - 10^{28}\ eV\ g^{-1}\ s^{-1}$

The H_2S yields in the H_2S–SF_6 mixtures, Table 1, are the same at the three dose rates

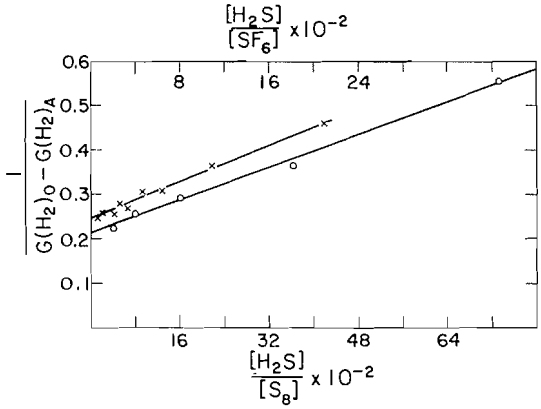

FIG. 3. Reciprocal plot of reduction in hydrogen yield, 2×10^{27} eV g^{-1} s^{-1}, 10^{20} eV g^{-1}; ○, 800 Torr H_2S–S mixtures sulfur 200 °C; ×, 1000 Torr H_2S–SF_6 mixtures 25 °C.

used, therefore the changes in the yields in pure H_2S are presumably due to dose rate dependent changes in ionic processes. The primary positive ions formed in H_2S in a mass spectrometer are H_2S^+ (52%), SH^+ (22%), S^+ (23%), and H^+ (3%) (26). Taking $G(e) = 4.0$ ($W_{H_2S} = 25.3$ eV/ion pair (2)) and assuming that the same relative concentration of primary ions are produced in radiolysis we have

[7] $H_2S \rightsquigarrow H_2S^+ + e$ $G = 2.08$

[8] $H_2S \rightsquigarrow HS^+ + H + e$ $G = 0.88$

[9] $H_2S \rightsquigarrow S^+ + H + H + e$ $G = 0.92$

[10] $H_2S \rightsquigarrow H^+ + SH + e$ $G = 0.12$

The reactions of these ions with H_2S are listed in Table 3. We shall assume that under our conditions the major ion is $H_5S_2^+$ with a yield of $G(H_5S_2^+) = 3.55$. The yields of the other positive ions are relatively small $G(H_2S_3^+) = 0.4$, $G(H_2S_2^+) = 0.04$. It is most unlikely that the yields of these three ions will be reduced by neutralization of the primary ions. To compete with reactions 11–20 the rate constants for neutralization would have to be greater than $10^{17}\ M^{-1}\ s^{-1}$. The highest reported neutralization rate constant is $1.5 \times 10^{16}\ M^{-1}\ s^{-1}$ for neutralization in NH_3 (31).

Neutralization of $H_2S_3^+$ is assumed not to produce H_2

[21] $H_2S_3^+ + e \rightarrow H_2S + S_2$

and the yield of hydrogen that can be affected by the addition of an electron scavenger then arises from the reactions of $H_5S_2^+$.

As discussed the plateau yield of radiolytic H_2 on the addition of an electron scavenger to H_2S corresponding to suppression of the dissociative neutralization of the positive ion is taken to be $G(H_2) = 7.3 \pm 0.3$. Thus the contribution of dissociative neutralization of the positive ion in H_2S to the H_2 yield increases from $G(H_2) = 3.8 \pm 0.3$ to $G(H_2) = 5.8 \pm 0.4$ as the dose rate increases from 10^{26} to 2×10^{28} eV g^{-1} s^{-1}. These values are consistent with a change in number of H atoms formed per neutralization as the dose rate is increased.

There does not appear to be a satisfactory mechanism to account for this change. We have considered mechanisms based on formation of H_2S^- and ion clustering beyond $H_5S_2^+$ but there are objections to each of these. In both cases it was assumed that neutralization of

TABLE 3. Ionic and radical reactions in H_2S

	Reaction	Rate constant ($l\ mol^{-1}\ s^{-1}$)	Reference
[11]	$H_2S^+ + H_2S \rightarrow H_3S^+ + SH$	3.5×10^{11} to 5.5×10^{11}	27, 28 29, 30
[12]	$HS^+ + H_2S \rightarrow H_3S^+ + S$	5.4×10^{11}	30
[13]	$HS^+ + H_2S \rightarrow HS_2^+ + H_2$	1.5×10^{11}	30
[14]	$HS^+ + H_2S \rightarrow H_2S_2^+ + H$	3.7×10^{10}	30
[15]	$HS_2^+ + H_2S \rightarrow S_2 + H_3S^+$	2.6×10^{11}	30
[16]	$S^+ + H_2S \rightarrow H_2S^+ + S$	2.6×10^{11}	30
[17]	$S^+ + H_2S \rightarrow H_2 + S_2^+$	2×10^{11}	30
[18]	$H_3S^+ + 2H_2S \rightarrow H_5S_2^+ + H_2S$	5.5×10^{11}	29, 30
[19]	$S_2^+ + 2H_2S \rightarrow H_2S_3^+ + H_2S$	1.1×10^{11}	29, 30
[20]	$H^+ + H_2S \rightarrow H_3S^+$	10^{11}	Assumed

$H_5S_2^+$ by an electron gives two H atoms as in reaction 22.

[22] $$H_5S_2^+ + e \rightarrow 2H + SH + H_2S$$

Decreasing the dose rate would favor formation of H_2S^- and further clustering of $H_5S_2^+$. The neutralization reactions could then be [23] and [24]

[23] $$H_5S_2^+ + H_2S^- \rightarrow H + 3H_2S$$

[24] $$H_7S_3^+ + e \rightarrow H + 3H_2S$$

The objections to the first of these are that nondissociative electron attachment to H_2S has not been observed and it has been estimated that the lifetime of H_2S^- is $\sim10^{-15}$ s (32). For the second mechanism to be valid clustering reactions subsequent to reaction 18 would have to have rate constants smaller than k_{18} by about two orders of magnitude. This is not likely in view of the rates of clustering reactions in water vapor (33) nor does it seem likely that there should be a difference in the number of H atoms produced in reactions 22 and 24.

A further possibility is that instead of competition between reaction 22 and reactions such as [23] or [24] the observed dose rate dependence is due to trace amounts of an electron scavenger in the H_2S. As will be discussed sulfanes appear to be very efficient electron scavengers.

It is important to note that whatever the reason for the observed dose rate dependence of the yields there must be neutralization reactions in the high dose rate radiolysis of H_2S that produce more than one H atom per ion pair.

Multipulse Irradiations

As stated in the introduction the vapor pressure of sulfur at room temperature is less than 10^{-5} Torr. Using the data tabulated by Yost and Russell (34) a ln p *vs.* $1/T$ plot gives a value of 1×10^{-6} Torr for the vapor pressure of rhombic sulfur at 25 °C. The mole ratio of sulfur to H_2S at this temperature is thus less than 10^{-8}. For sulfur at this concentration to effectively compete with the neutralization of electrons by $H_5S_2^+$ at Febetron dose rates would require a rate constant of electron attachment to sulfur of the order of $10^{18}\ M^{-1}\ s^{-1}$. This is 10^4 times the rate constant derived from the data at 200 °C.

The results in Table 2 show that the observed reductions in the hydrogen yield cannot be attributed to simple supersaturation in the vapor phase. Any supersaturation that does occur must be longer lived than 8–16 h and be capable of being reestablished in 8–16 h after cooling to 77 °K. The most likely explanation of these results and the lack of any effect of added sulfur in 25 °C irradiations is that radiolytically formed sulfur reacts with H_2S at room temperature to form polysulfanes of the form H_2S_n. These polysulfanes, which are sufficiently volatile, then act as very efficient electron scavengers as for example in reaction 25 and suppress dissociative neutralization.

[25] $$H_2S_n + e \rightarrow H_2S + S_{n-1}^-$$

The polysulfanes are thermodynamically unstable with respect to H_2S and S but are metastable at room temperature (35) and presumably are not decomposed by cooling to 77 °K. Clearly if we are to quantitatively explain the reduction

For personal use only.

of the H_2 yield as a function of dose a relatively large amount of radiolytic sulfur must be able to be vaporized as polysulfanes in 1 atm of H_2S.

It does not seem possible that the sulfanes can exist at 200 °C. For example the rate constant for the decomposition of H_2S_2 at 50 °C is 0.56 h^{-1} (35). The activation energy for decomposition is 25 kcal/mol (35) so that the rate constant for decomposition at 200 °C is 18 s^{-1}. Thus sulfur itself appears to be the electron scavenger at 200–250 °C. This is supported by the results of Febetron irradiations of N_2O–S mixtures at 200 °C (36). We have found that the dependence of the reduction of the N_2 yield in these irradiations on the sulfur concentration is similar to the dependence of $G(H_2)$ on the sulfur concentration in H_2S–S mixtures at 200 °C and to the dependence of $G(N_2)$ on the concentration of SF_6 in N_2O–SF_6 mixtures.

Conclusions

The results in this paper provide strong evidence for our suggestion that sulfur is a very efficient electron scavenger. Assuming that sulfur at 200–250 °C is S_8 the rate constant for electron attachment to sulfur is of the order 1×10^{14} M^{-1} s^{-1}. The limiting yield of hydrogen from Febetron irradiations of H_2S–S mixtures at 200–250 °C $G(H_2) = 7.3 \pm 0.3$ is in good agreement with the most precisely determined value of the hydrogen yield $G(H_2) = 7.0 \pm 0.2$ (2) at low dose rates.

It appears however that the reduction in the hydrogen yield at Febetron dose rates observed at high doses at room temperature is due to polysulfanes. Like sulfur these must be very efficient scavengers. We are unable to quantitatively examine the role of polysulfanes because of the lack of basic information. However for reasons which we have previously discussed (13) H_2S_2 is not an electron scavenger and n must be greater than two for the sulfane H_2S_n to be involved. It should be noted that it cannot be assumed that H_2S as an additive in radiation chemistry will act only as an H atom scavenger.

The reduction in the H_2 yield on the addition of SF_6 at dose rates in the range $10^{26} - 10^{28}$ eV g^{-1} s^{-1} shows that neutralization reactions occurring must give more than one H atom per ion pair.

We are indebted to Professor M. Forys for providing us with his preliminary results on the H_2S system with added sulfur and for much helpful correspondence.

Liquid Bismuth Calorimetry: Enthalpies of Solution of Copper, Indium, and Tellurium, and Enthalpies of Formation of Cuprous Selenides

KENNETH GORDON SKEOCH AND ROBERT DONALD HEYDING

Department of Chemistry, Queen's University, Kingston, Ontario

Received September 19, 1972

An isoperibol liquid metal solution calorimeter in which samples are introduced below the surface of the melt is described. Enthalpies of solution in liquid bismuth at *ca.* 625 °K in kcal mol^{-1} were found to be $+0.99 \pm 0.05$ for copper, -1.41 ± 0.08 for indium, and -1.16 ± 0.07 for tellurium.

Enthalpies of formation in kcal mol^{-1} at 625 °K of cubic cuprous selenides are -7.98 ± 0.20 for $Cu_{1.80}Se$; -7.80 ± 0.19 for $Cu_{1.85}Se$; -5.92 ± 0.20 for $Cu_{1.90}Se$; -5.29 ± 0.20 for $Cu_{1.95}Se$; and -5.21 ± 0.14 for $Cu_{2.00}Se$.

Un calorimètre constitué par une solution liquide métal isopéribol, dans lequel les échantillons sont introduits au dessous de la surface de fusion, est décrit. Les enthalpies de solution dans le bismuth liquide vers 625 °K, en kcal mol^{-1}, sont égales à $+0.99 \pm 0.05$ pour le cuivre, -1.41 ± 0.08 pour l'indium, et -1.16 ± 0.07 pour le tellurium.

Les enthalpies de formation à 625 °K, en kcal mol^{-1}, pour les séléniures de cuivre cubiques sont de -7.98 ± 0.20 pour $Cu_{1.80}Se$; -7.80 ± 0.19 pour $Cu_{1.85}Se$; -5.92 ± 0.20 pour $Cu_{1.90}Se$; -5.29 ± 0.20 pour $Cu_{1.95}Se$; et -5.21 ± 0.14 pour $Cu_{2.00}Se$. [Traduit par le journal]

Introduction

At 625 °K, a cubic phase exists in the Cu/Se system from *ca.* $Cu_{2.0}Se$ to $Cu_{1.8}Se$ (1). The structure is disordered, with Se forming a face centered cubic sublattice, Cu in half of the tetrahedral holes as in the zinc blende (*B*3) structure, and the remaining copper ions randomly distributed between sites slightly displaced from the centers of the remaining tetrahedral holes (pseudo trigonal sites) and the octahedral holes in the Se lattice (2). Stevels has found that ~2.6 of the 7.2 copper ions in the unit cell in $Cu_{1.8}Se$ occupy trigonal sites while ~0.6 occupy octahedral sites (3). The distribution at other compositions is not known.

Gattow and Schneider obtained enthalpies of formation by bomb (reaction) calorimetry for $Cu_{1.8}Se$ and $Cu_{2.0}Se$ of -13.23 ± 0.02 and -14.17 ± 0.03 kcal mol^{-1}, respectively (4). Rossini *et al.* listed a value of -5.5 kcal mol^{-1} for $Cu_{2.0}Se$ (5).

We have measured ΔH_f for $Cu_{2-x}Se$ in a liquid metal solution calorimeter using bismuth as the solvent. In this paper the calorimeter is described briefly, and enthalpies of solution of Cu, In, Te, and several $Cu_{2-x}Se$ specimens at *ca.* 625 °K are reported and discussed.

Experimental

The Calorimeter

An isoperibol liquid metal solution calorimeter was patterned after the calorimeter described by Orr, Goldberg, and Hultgren (6). In this calorimeter the temperature of the solution cell during the dissolution process is measured relative to a large "isothermal" heat sink in the form of a heavy metal block surrounding the cell. The unique feature of our calorimeter is in the design of the solution cell, in which sample ampoules are broken on demand beneath the surface of the molten metal. The advantage of such an arrangement over the more conventional design in which the sample is dropped into the solvent from a temperature controlled holding zone is significant if the specimen has an appreciable vapor pressure at the temperature of the solvent, or if the density of the specimen is such that it is likely to float on the surface of the solvent. One of the disadvantages is that the calorimeter cannot be calibrated by the addition of a specimen of the solvent itself at the temperature of the holding zone, a common practice in drop calorimeters.

Details of the solution cell are shown in Fig. 1. The cell was machined from a block of 310 stainless steel. The upper section contains six sample wells, in each of which an evacuated thin walled Pyrex sample ampoule is secured by a clip. The dome contains a filling hole by which the final portion of the solvent can be added to the cell following assembly. The upper section fits snugly into the lower. Its orientation is fixed by a small keyway in the rim of the lower section and by a small screw. The shaft of the stirrer enters the cell, from below, through a long housing. Assembled and in operation, this major passage between the cell and the rest of the calorimeter is sealed by the liquid metal between the shaft and the skirt of the stirrer. The lower section of the cell is tapped at six points on its circumference to accept six thermopile junction assemblies.

The cell is supported by three legs which are secured by adjustable feet to the bottom of the heat sink (Fig. 2). Heat transfer via the legs is minimized by mica spacers in the foot assemblies.

The stirrer has two paddles, one of which sweeps the

For personal use only.

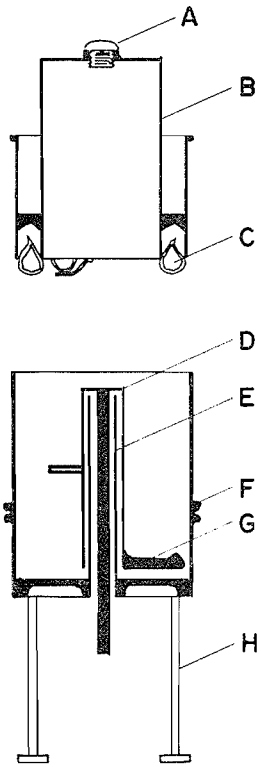

FIG. 1. Detail of calorimeter cell: *A*, filling port; *B*, dome; *C*, sample ampoule (6); *D*, stirrer; *E*, stirrer housing; *F* thermopile junction anchor (6); *G*, hammer/stirrer blade; *H*, leg (3).

surface while the second agitates the bulk of the solution. The second paddle also serves as the hammer which breaks the sample ampoules. This function is obtained by activating solenoids in the body of the calorimeter which lift the stirrer assembly and the stirrer at any one of six points corresponding to the positions of the ampoules in the cell. The position of the paddle is registered by a pointer on the stirring shaft between the rotary vacuum seal and the stirring motor on the bottom external face of the calorimeter.[1]

The cell is surrounded by a copper block weighing 52 kg; a heater with independent top, side, and bottom elements; three molybdenum radiation shields, and a vacuum jacket. In operation the calorimeter is pumped to $< 5.10^{-3}$ Torr. The cell is maintained at 360 °C by a heater input of *ca.* 290 W. The difference in temperature between the cell and the copper block is measured by a twelve junction thermopile, whose signal is amplified by a nanovoltmeter and fed to a strip-chart recorder.

[1]Detail sketches of the calorimeter, including the stirring/ampoule breaking mechanism, are available, at a nominal charge, from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Canada K1A 0S2.

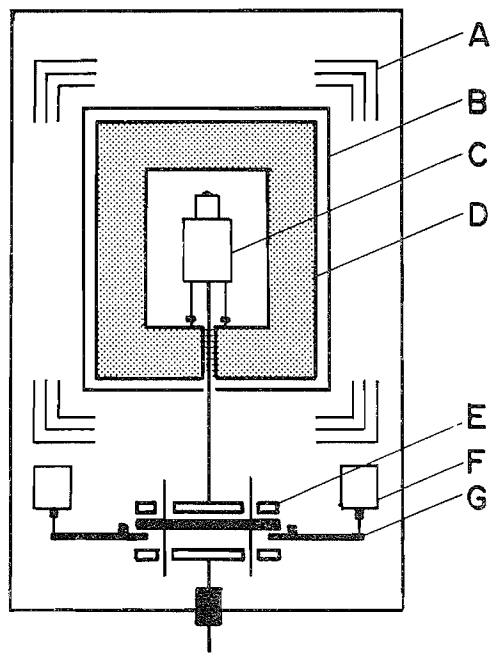

FIG. 2. Calorimeter schematic: *A*, radiation shields; *B*, heater shell; *C*, cell; *D*, heat sink; *E*, drive discs; *F*, solenoids; *G*, lift yoke.

Experimental Procedures

Specimens were prepared using Cominco 69 grade cadmium and zinc; Asarco 69 grade copper, selenium and tellurium; and 59 grade zinc supplied by Alfa Inorganic. The copper selenides $Cu_{2-x}Se$, $0 \leqslant x \leqslant 0.2$, were prepared by reaction between the elements in sealed Pyrex or silica ampoules in the usual manner. The products were identified by X-ray powder diffraction patterns. Diffraction patterns of the cuprous selenides were also obtained in a 19 cm Unicam high temperature camera at the temperature of the calorimeter to confirm the structure of the phase going into solution.

Approximately one-half of total charge of 410 g (1.96 mol) of bismuth (Cominco 59 grade) was premelted *in vacuo* in the lower section of the cell with the stirrer in position. The balance of the charge could then be accommodated in the dome of the upper section following assembly. Since the calorimeter was calibrated by the dissolution of selenium or of copper, at least one of these was included in each set of six solutes in the cell. Each ampoule contained between 2.5 and 5 mmol of solute. At these concentrations the energy associated with breaking the glass of the ampoule is negligible compared with the heat of solution.

Interpretation of Results

The form of the differential signal as a function of time from a calorimeter of this type has been discussed by Orr *et al.* (6) and by Morris and Pratt (7). The two equations used here in the interpretation of the recorder trace are

*Standard error limits are the standard deviations in the analysis of the experimental data using eq. 2.

[1] $$\ln \Delta T = -kt + \text{const}$$

and

[2] $$\Delta T^* = \frac{\Delta H}{C} = \Delta T_f + k\int_{t_0}^{t} \Delta T \mathrm{d}t$$

where ΔT is the difference in temperature between the cell and the heat sink at time t following addition of the solute, provided the solution process is complete; ΔH is the total heat effect due to the solution process and C is the heat capacity of the cell; and ΔT_f is the difference in temperature between cell and sink on completion of the solution process. ΔT^* is the difference in temperature which would have been observed had the solution process been instantaneous. The cooling constant k and ΔT_f are evaluated by plotting the logarithm of ΔT (*i.e.*, recorder pen deflection) against time. The value of the last term in eq. 2 is determined by successive graphical integrations at increasing values of t until a constant value for ΔT^* is obtained.

The calorimeter was calibrated with selenium as the primary standard, using the values for the enthalpy of solution of selenium in liquid bismuth reported by Chaudhari and Bever (8). In some experiments in which the selenium specimen was lost and in those experiments in which selenium was incompatible with the other solutes, copper was used as a secondary standard.

Results and Discussion

The enthalpies of solution of several elements in liquid bismuth at 625 °K are given in Table 1 together with literature values. Selenium is not a suitable calibration standard for experiments with cadmium and zinc, because cadmium and zinc selenides are not soluble in bismuth. Addition of either of these elements to a bismuth solution containing selenium produces a large exothermic signal from the calorimeter due to the formation of the selenides.

The enthalpies of solution of indium and tellurium agree well with values given in the literature.

A mean value for the enthalpy of solution of copper of +0.99 ± 0.05 kcal mol^{-1} was used in those experiments in which copper was the calibrating standard, and in the estimation of enthalpies of formation of the cuprous selenides.

Heats of solution of several $Cu_{2-x}Se$ specimens are given in Table 2. Enthalpies of formation at 625 °K calculated from these data are given in Table 3, assuming enthalpies of solution of copper and selenium of +0.99 ± 0.05 kcal mol^{-1} and −5.96 ± 0.17 kcal mol^{-1} (8), respectively. The Kopp–Neumann rule was assumed to hold in estimating the standard enthalpies of formation, ΔH_f^0, given in this table. With this assumption, the difference in the two enthalpies of formation are due to the fusion of selenium and the difference in heat capacities of solid and liquid selenium:

[3] $$\Delta H_f^0 = \Delta H_f^{625} + \Delta H_{\text{fusion}}^{\text{Se}} + \int_{491}^{625} (C_{p(l)}^{\text{Se}} - C_{p(s)}^{\text{Se}})\mathrm{d}T$$

The difference in heat capacities of liquid and solid selenium is 2.7 cal mol^{-1} deg^{-1} at 491 °K, and the enthalpy of fusion is 1.25 kcal mol^{-1} (11). Values of ΔH_f^0 for $Cu_{2.0}Se$ to $Cu_{1.9}Se$ are given in parentheses in Table 3 to emphasize that the cubic phase does not exist in this composition range at room temperature.

The data in Table 3 can be used to estimate the energy required to remove an electron/copper ion pair from the Cu_2Se lattice:

[4] $$Cu_2{}^{+}Se_{(s)}{}^{2-} \rightleftharpoons Cu_{(2-2x)}Cu_x{}^{2+}\square_x Se_{(s)}{}^{2-} + xe^- + xCu_{(g)}{}^{+} \quad \Delta H_4$$

using the cycle

[5] $$Cu_2{}^{+}Se_{(s)}{}^{2-} \rightleftharpoons Cu_{(2-2x)}Cu_x{}^{2+}\square_x Se_{(s)}{}^{2-} + xCu_{(s)} \quad \Delta H_5$$

$Cu_{2.00}Se$	−5.21±0.14	(−3.59±0.19)

[6] $$x\mathrm{Cu}_{(s)} \rightleftharpoons x\mathrm{Cu}_{(g)} \qquad \Delta H_6$$

[7] $$x\mathrm{Cu}_{(g)} \rightleftharpoons x\mathrm{Cu}_{(g)}^{+} + xe^{-} \qquad \Delta H_7$$

The enthalpy of sublimation of copper at 298 °K is *ca.* 85 kcal mol^{-1} and the first ionization energy is 178.0 kcal mol^{-1} (12). The enthalpy change ΔH_4 associated with the removal of 10% of the copper ions in the Cu_2Se lattice is therefore +50 kcal mol^{-1}, and the average energy required to form a vacancy in this way is +11 eV. The energy required to form a vacancy by removal of a neutral gaseous copper atom (eqs. 5 and 6) is *ca.* +3 eV per vacancy.

Solvent Effects on the Position of *cis–trans* Olefin Equilibrations and Additivity of Vicinal Group Pairs in Determining the Equilibrium Position for Trisubstituted Olefins[1]

DONALD EDWARD MCGREER, BRIAN DENIS PAGE, AND DHARAM PAUL KAUSHAL

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received October 10, 1972

The equilibrium positions reached by a photo-induced bromine-catalyzed reaction for eight disubstituted *cis–trans* isomer pairs have been determined in pentane and carbon tetrachloride at room temperature. Data were collected for these conditions due to the observation that equilibrium positions can be markedly solvent dependent. The data thus obtained were used to calculate the expected equilibrium position for 15 trisubstituted isomer pairs, and comparison between calculated and observed data for the six available isomer pairs was good.

Les positions d'équilibre atteintes par la réaction induite photochimiquement et catalysée par du brome pour huit paires d'isomères *cis–trans* disubstitués ont été déterminées dans le pentane et dans le tétrachlorure de carbone à température de la pièce. Des données furent recueillies pour ces conditions à cause de l'observation selon laquelle les positions d'équilibre peuvent être profondément dépendante du solvant. Les données ainsi obtenues ont été utilisées pour calculer la position d'équilibre prévue pour 15 paires d'isomères trisubstitués, et la comparaison entre les valeurs calculées et observées pour les six paires d'isomères disponibles est satisfaisante. In an earlier paper (1) we found evidence to suggest that the position of a *cis–trans* equilibrium for a trisubstituted olefin could be estimated by adding the contribution of the isolated vicinal pairs of substituents. Thus by using the fact that the equilibrium position recorded for 3-chloroacrylonitrile is 69% *cis* (2) and for 1-chloropropene is 75.5% *cis* (2) we can estimate that the percentage of the *E* form of 3-chloromethacrylonitrile should be 58% (1) (31/69 × 75.5/24.5 = 58/42). This estimate compares favorably with the 60% value found experimentally (1). The success of such calculations is encouraging; however, we recognized that most literature values of the equilibrium constants are made on neat samples at a variety of temperatures thus introducing unknown solvent and temperature effects on the data.

Our present paper has two objectives. Firstly, to determine when and by how much can solvents affect the position of equilibrium and secondly, to set up standard conditions under which equilibrium constants can be measured to further test the additivity relationship earlier encountered.

We have examined the photo-induced bromine-catalyzed equilibrium position for five *cis–trans* pairs of compounds, neat and as 10% solutions, in a variety of solvents at room temperature (25 °C). The compounds studied were crotononitrile (**1**), 3-bromoacrylonitrile (**2**), 2-bromocrotononitrile (**3**), 1,2-dibromoethene (**4**), and 1,2-dichloroethene (**5**). The measured values for these compounds appear in Table 1.

In order to discuss the trends in Table 1 we have included observed values of the dipole moments of the individual isomers or, where these were not available, calculated values from bond moments. There are many parameters for measuring solvent polarity. We have correlated our results with the E_T values of the pyridinium *N*-phenolbetaine of Reichardt (3).

The proportion of the more polar isomer is enhanced in all cases in the more polar solvent. This corresponds to an increase of the more dominant isomer found under non-polar conditions for **2**, **4**, and **5**, a decrease of the more dominant isomer for **1** and little change for **3** where the calculated dipole moments of the two isomers show little difference. The neat liquid in the case of **1**, **2**, and **3** is clearly a polar solvent whereas in the case of **4** and **5** is of intermediate polarity. The measured value of the equilibrium position for the neat liquid is consistent with this conclusion.

Clearly then solvents do affect the position of

the equilibrium and particularly when an isomer pair have a large difference in dipole moment. The presence of a dipole moment in at least one of the isomer pairs will also imply that the equilibrium measured on the neat sample will differ from that measured in a non-polar solvent.

Because of the above observations we have standardized our measurements of *cis–trans* equilibria, where possible; to measurements of 10% solutions in pentane or carbon tetrachloride at 25 °C. An investigation of the effect of concentration of 1,2-dibromoethylene (**4**) in pentane showed no significant change in the range 0.5–10%. In nearly all of our studies equilibrium was achieved by adding 0.5 μl (bout 2 mol %) of a bromine – carbon tetrachloride (1:9 by volume) solution to 100 μl of the olefin solution (10%) and followed by irradiation by sunlight or 310 nm light in a Rayonet apparatus. The bromine was found to be a true catalyst as it permitted equilibration from either isomer and equilibration did not occur in its absence. Data presented involve at least four measurements (two from each isomer) and frequently many more, and were reproducible to ±1%. The percent composition of equilibrium mixtures was determined by n.m.r. spectroscopy and/or v.p.c. for which it was found that no correction was necessary for differences in detector response.

For the present study we have only examined interactions between substituents having symmetric top symmetry Br, Cl, CH_3, and CN. There are ten possible pairings of these groups and the equilibrium positions for eight vicinal pairings are given in Table 2.

These same substituents can be used to form 24 trisubstituted olefins of which 15 make use of a combination of pairs of interactions listed in Table 2. We have experimentally measured many of these and have calculated most of them. These results are listed in Table 3.

It is significant that from Table 2 we can see that the *cis*- or *Z*-isomer is favored at equilibrium in all cases except 2-butene. We do not intend, in this paper, to determine the contributing interactions that lead to the value of a particular equilibrium position; however, if it is a single factor or a combination of factors it is of interest to see whether they might be separated and com-

bined in a linear free energy sense. Unfortunately we still lack sufficient raw data to properly test such a hypothesis; however, Table 3 shows the results of combining the free energy component of the vicinal pairs in Table 2 to calculate the expected equilibrium position in trisubstituted olefins and compares these with data obtained experimentally. We find this is done most conveniently by converting the percent-terms of Table 2 to free energy differences. Then by adding or subtracting these we find the free energy differences for the trisubstituted olefins and the equilibrium percent can thus be derived. Table 4 provides the conversion of isomer percent to free energy difference and back. The correspondence of isomer percent found *vs.* calculated in Table 3 falls in the range $\pm 7\%$ in all cases except one ($ClCHC(CH_3)CN$ in pentane). This is equivalent to an error in the calculated free energy difference of ± 0.21 kcal.

We feel therefore that the concept of additivity for free energy contributions in the cases listed is very useful and we welcome further experimental data to complete Tables 2 and 3.

Experimental

All of the compounds studied herein were obtained as mixtures of *E* and *Z* forms from commercial suppliers or by literature procedures. These were separated using standard conditions on an Aerograph A90P vapor phase chromatograph. Table 5 lists these compounds with an identifying physical constant to be compared with the literature value in brackets. Boiling points are at 1 atm unless otherwise stated. In addition, all stereochemical assignments were confirmed by n.m.r.

β-Bromoacrylic Acid

Propiolic acid (15.6 g, 0.22 mol) was added dropwise over 0.5 h to 91 ml of 48% hydrobromic acid with stirring at 0 °C. The reaction mixture was allowed to come slowly to room temperature and stirring was continued for 30 h. Filtration of the white solid which had separated gave 2.1 g of β-bromoacrylic acid (*E*), m.p. 115.5–116.5° (lit. (8), m.p. 121°). The filtrate was extracted with six portions of 50 ml of chloroform. The combined extracts were dried and solvent evaporated to yield 27.8 g of β-bromoacrylic acid (*Z*), m.p. 54.5–55° (lit. (8), m.p. 55°). The n.m.r. spectrum indicated that there was 12% of the *E*-isomer present in this sample, however, it was used as such for the next step.

β-Bromoacrylamide

Thionyl chloride (8.4 g) was added to 10.1 g of the β-bromoacrylic acid (*Z*) and the mixture was stirred at room temperature for 18 h. Removal of the thionyl chloride followed by distillation gave 9.05 g of β-bromoacryloyl chloride (*Z*), b.p. 63°/18 mm. The acid chloride thus obtained was added to 50 ml of anhydrous ether and cooled in an ice bath. Anhydrous ammonia was bubbled through the solution with stirring for 30 min. The ether and excess ammonia were evaporated and the solid residue was extracted with ether in a Soxhlet extractor for 66 h. On evaporation of the ether extract there was obtained 8 g of product which was crystallized from methanol–ether to give pure β-bromoacrylamide (*Z*), m.p. 90–90.5° with n.m.r. peaks in acetone at 3.18 and 3.24 τ, $J_{cis} = 8.1$ Hz.

Anal. Calcd. for C_3H_4BrN: C, 24.02; H, 2.69; N, 9.34. Found: C, 24.12; H, 2.90; N, 9.55.

A sample of the *Z*-isomer was converted by irradiation in carbon tetrachloride with a bromine catalyst to the *E*-isomer, m.p. 153–155° (lit. (9) m.p. 155–156°) which had n.m.r. peaks in acetone at 2.56 and 3.28 τ, $J_{trans} = 13.5$ Hz.

β-Bromoacrylonitrile

To 3.8 g of phosphorus pentoxide was added 3.0 g of β-bromoacrylamide (*Z*). From this mixture, which was heated in an oil bath at 75–90°, 2.25 g of β-bromoacrylonitrile (*Z*), b.p. 171/760 mm, was distilled at 40 mm; n_D^{20} 1.5006 with n.m.r. peaks in carbon tetrachloride at 2.72 and 3.68 τ, $J_{cis} = 8.4$ Hz.

Anal. Calcd. for C_3H_2BrN: C, 27.31; H, 1.53. Found: C, 26.96; H, 1.75.

As this product was very sensitive to moisture and light it was stored in a sealed ampoule at −78° in the dark. A sample was converted by irradiation in carbon tetrachloride with a bromine catalyst to a mixture containing

*The *Z*-isomer is newly prepared in this work. See Experimental.

†For this preparation we used potassium acetate in acetic acid for the dehydrobromination. The isomers were only partially separated on an FFAP column at 153°; however, n.m.r. peaks at 7.94 (CH_3) and 3.22 τ (H) could be assigned to the *E*-isomer having the lower retention time and peaks at 8.05 (CH_3) and 3.02 τ (H) to the *Z*-isomer having the longer retention time due to deshielding of the CH_3 or vinyl H by the CN when oriented *cis*.

‡Dehydration of the cyanohydrin of methyl ethyl ketone (16) using pyridine and thionyl chloride gave a mixture containing α-ethylacrylonitrile, angelonitrile and tiglonitrile in a ratio of 6 :80 :14 which was separated by v.p.c.

30% of the *E*-isomer. Separation by v.p.c. on a FFAP column gave β-bromoacrylonitrile (*E*), m.p. 58–59° (lit. (9), m.p. 56–58°) with n.m.r. peaks in carbon tetrachloride at 2.56 and 3.88 τ, J_{trans} = 14.9 Hz.

Support for this work from the National Research Council of Canada is gratefully acknowledged.

Studies of the Carbonyl Group in Some Five-membered Ring Compounds by Photoelectron Spectroscopy

A. D. BAIN AND D. C. FROST

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received October 12, 1972

A study has been made of the ionization potentials (IP) of the carbonyl lone pair orbitals in a series of five-membered carbonyl ring compounds. CNDO/2 and INDO calculations have been performed on these molecules, and correlation of IP shifts with changes in molecular bonding is obtained.

Une étude a porté sur les PI(s) de la paire d'électrons libres du groupe carbonyle dans une série de composés cycliques à cinq membres possédant une fonction carbonyle. Des calculs CNDO/2 et INDO ont été effectués sur ces molécules et la corrélation dans les déplacements des PI(s) en fonction des changements dans les liaisons moléculaires est obtenue. Introduction

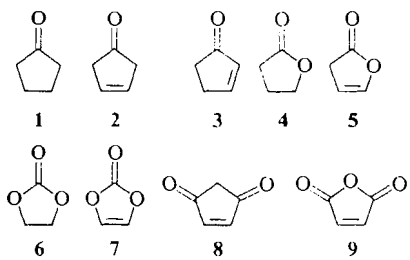
Lone pair orbitals have been amenable to study by photoelectron spectroscopy (PES) (1–3) because their ionization potentials (IP's) are usually lower than other types of orbitals and they can often be easily and unambiguously assigned to a peak in the PE spectrum. Through a series of molecules these lone pairs retain much of their atomic character and so the correlation of IP shifts with changes in bonding is a valid procedure.

An orbital that is well suited to this kind of study is the lone pair of the oxygen atom of the carbonyl group. Some simple carbonyl compounds have already been studied (4–8) but this paper extends this work by presenting the carbonyl oxygen lone pair IP's of a series of five-membered ring carbonyl compounds (**1**–**9**).



1 **2** **3** **4** **5**

6 **7** **8** **9**

The IP's for cyclopentanone (**1**), cyclopenten-2-one (**3**), and cyclopenten-3-one (**2**) were obtained from previous work (6), but for the rest of the compounds, PE spectra were taken on a spectrometer using a 584 Å light source and a $2\frac{1}{2}$ in. mean radius hemispherical analyzer, with a resolution of 20 meV (9). Also LCAO–MO–SCF calculations were performed, using the CNDO/2 and INDO methods, to help in assigning the spectra and elucidating the composition of the orbitals. The observed vertical IP's of the orbital corresponding to the carbonyl lone pair, along with the calculated IP's (the calculated orbital energy minus a 4 eV "scale factor" (10)) and the calculated charge on the carbonyl oxygen, are given in Table 1.

Discussion

All of these molecules are planar, or approximately so, and from this assumption of planarity there follows a rigorous separation of σ- and π-type orbitals. Since it is symmetric with respect to reflection in the plane of the molecule, the carbonyl oxygen lone pair orbital is of σ-symmetry. The rest of the σ-orbitals are similar in all the molecules in the series but the major difference between each of these molecules is in the π-orbitals.

However, since these π-orbitals are of different symmetry than the carbonyl lone pair, there can be no net overlap between them. This means that changes in the π-structure can only influence the carbonyl lone pair indirectly, for instance by changing the effective nuclear charge of the oxygen atom. Assuming that these indirect effects can be treated as perturbations it was thought that the results of several alterations should simply add together, since first-order perturbations are additive (11).

For example, this hypothesis states that the difference in the carbonyl lone pair IP between ethylene carbonate (**6**) (which has two oxygens

TABLE 1. Ionization potentials of the carbonyl lone pairs (eV)

Compound	Observed IP	ΔIP (relative to **1**)	ΔIP (calcd.)	Calculated IP		Charge on Oxygen	
				CNDO/2	INDO	CNDO/2	INDO
Cyclopentanone (**1**)	9.25	0	0				
Cyclopenten-2-one (**3**)	9.34	0.1	0.21				
Cyclopenten-3-one (**2**)	9.44	0.2	0.21				
α-Butyrolactone (**4**)	10.26	1.0	1.16	8.83	8.03	0.34	0.39
α-Crotonolactone (**5**)	10.70	1.5	1.37	9.74	8.72	0.31	0.36
Ethylene carbonate (**6**)	11.47	2.2	2.32	10.53	9.69	0.32	0.38
Vinylene carbonate (**7**)	11.91	2.7	2.53	10.24	9.35	0.37	0.43
Cyclopentene dione (**8**)	10.25	1.0	1.05	9.85	8.88	0.25	0.30
Maleic anhydride (**9**)	11.45	2.5	2.21	10.30	9.32	0.26	0.31

α to the carbonyl) and cyclopentanone (**1**) should be twice the difference between butyrolactone (**4**) (having only one oxygen α to the carbonyl) and cyclopentanone.

In this series of molecules there are three alterations to be considered. First, there is the substitution of an oxygen for a methylene group α to the carbonyl (the difference between butyrolactone and cyclopentanone). Second, there is the difference between the cyclopentenones (**2** and **3**) and cyclopentanone, a double bond in the ring. However, there are not enough data available here to really distinguish between the two possible positions of the double bond, because changing the position does not affect the carbonyl lone pair IP very much (the difference in this IP between the two cyclopentenones is only 0.1 eV (6)). Finally, there is the effect of a second carbonyl group at the β position in the ring. In the case of these dicarbonyl compounds there are, of course, two carbonyl lone pairs and for the purposes of assigning a shift, the mean of these two IP's was used. Because of this somewhat arbitrary use of the average IP, and also the fact that there are only two dicarbonyl compounds in the series, then the numerical parameter obtained for this case will not be very reliable.

The difference in the lone pair IP, ΔIP, between each compound and cyclopentanone was calculated and these numbers fitted to an equation of the form of eq. 1. The quantities $n_{C=C}$, n_O,

$$[1] \quad \Delta IP = n_{C=C}\,\delta_{C=C} + n_O\,\delta_O + n_{C=O}\,\delta_{C=O}$$

and $n_{C=O}$ are, respectively, the numbers of double bonds, oxygen atoms in the ring, and additional carbonyl groups (for example, vinylene carbonate has $n_{C=C} = 1$, $n_O = 2$, $n_{C=O} = 0$) and the δ's are the effects of each of these groups. The values of the δ's were obtained from a least squares fit and the results were as follows:

$$\delta_{C=C} = 0.21 \text{ eV}, \quad \delta_O = 1.16 \text{ eV}, \quad \delta_{C=O} = 0.84 \text{ eV}$$

In order to see if the dicarbonyl compounds' presence affected the other two parameters, a fit was done with just the six numbers from the monocarbonyl compounds, but the values of the parameter obtained were not significantly different.

Therefore, each of these groups stabilizes the carbonyl lone pair orbital, and for example, an oxygen atom next to the carbonyl group causes the lone pair IP to increase by about 1.2 eV. By inserting these values of the δ's back into eq. 1, calculated values for the ΔIP's were obtained and these are compared with experimental values in Table 1. It can be seen that these all agree within 0.2 eV.

Both the carbonyl group and the oxygen atom in the ring have a strong electron-withdrawing inductive effect, and the replacement of sp^3-hybridized carbons by sp^2-types, which occurs on the creation of a double bond in the ring, also has this kind of effect (6). Although these inductive effects play an important part in the observed stabilization of the carbonyl oxygen lone pair, the parameters obtained cannot be called true inductive parameters. The results of the MO calculations show that there are more subtle influences as well. For instance, the calculations predict that vinylene carbonate (**7**) will have a higher IP than crotonolactone (**5**), in agreement with experiment, but the calculations also show a greater negative charge on the carbonyl oxygen in vinylene carbonate. If the inductive effect were the only influence that caused the IP to shift, then vinylene carbonate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

should have a lower IP. However, the exact nature of these other effects is not well understood at present.

Thanks are due to Dr. L. Weiler for his helpful discussions and to Dr. F. G. Herring for his assistance with the MO calculations. A.D.B. would like to thank the National Research Council of Canada for the award of a scholarship, which body also supported this work with generous financial assistance. We thank Professor C. A. McDowell for his interest in the work.

Scandium(III) Complexes of 8-Hydroxyquinoline and Derivatives

A. CORSINI, F. TONEGUZZO, AND M. THOMPSON[1]

Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 20, 1972

Under the conditions specified, scandium(III) and 8-hydroxyquinoline react in aqueous solution to give $Sc(C_9H_6NO)_3 \cdot H_2O$ and not the adduct, $Sc(C_9H_6NO)_3 \cdot C_9H_7NO$, as previously reported. The adduct is formed by reaction of the aquo tris chelate in molten 8-hydroxyquinoline and the anyhdrous tris chelate is obtained by thermal decomposition of the adduct. The 2-chloro, 4-chloro, and 5-methyl and 5-nitro derivatives also yield aquo tris chelates from aqueous solution while the 2-methyl and 4-methyl derivatives give adducts.

Placé dans les conditions spécifiées le scandium(III) et l'hydroxy-8 quinoléine réagissent en solution aqueuse pour donner le $Sc(C_9H_6NO)_3 \cdot H_2O$ et non pas le produit d'addition $Sc(C_9H_6NO)_3 \cdot C_9H_7NO$ tel que rapporté antérieurement. Le produit d'addition est formé par réaction du chélate tris aquo dans l'hydroxy-8 quinoléine fondu alors que le chélate tris anhydre est obtenu par décomposition thermique du produit d'addition. Les dérivés, chloro-2, chloro-4, méthyl-5 et nitro-5 donnent aussi des chélates tris aquo à partir de solutions aqueuses alors que les dérivés méthyl-2 et méthyl-4 donnent des produits d'addition. [Traduit par le journal]

Can. J. Chem., 51, 1248 (1973)

Introduction

8-Hydroxyquinoline (QH) forms solid adducts with the general formula $MQ_n \cdot pQH$, where M is a metal ion or central group of charge n^+ (*e.g.*, $UO_2Q_2 \cdot QH$, $ThQ_4 \cdot QH$, $YQ_3 \cdot QH$, SbOQ·2QH, and NaQ·QH (1–5). In aqueous solution, the reaction between Sc(III) and QH has been reported by Pokras and Bernays to give a lemon-yellow precipitate with the formula $ScQ_3 \cdot QH$ (6, 7).

Several investigations have been made to determine the nature of the forces binding the QH molecule. On the basis of cryoscopic experiments in benzene and toluene (8), it was concluded that the QH molecule is bound in the solid merely by lattice forces. This view was favored by Van Tassel *et al.* (9) and is in contrast to recent findings regarding the adducts $UO_2Q_2 \cdot QH$ and $ThQ_4 \cdot QH$, in which X-ray, i.r., and carbon-14 techniques have shown that the QH molecule is a monodentate ligand coordinated to the metal ion through the oxygen atom, with the acidic proton being located on the nitrogen atom and strongly hydrogen-bonded (10–12). In a thermogravimetric and infrared study, Cardwell and Magee were unable to draw clear conclusions regarding the binding of QH in $ScQ_3 \cdot QH$ (13). These workers did report the preparation of two new compounds $[ScQ_3]_2 \cdot QH$ (prepared by precipitation from homogeneous solution using 8-acetoxyquinoline), and $[ScQ_3]_2 \cdot 3QH$ (prepared by a "solid-phase" reaction between $ScQ_3 \cdot QH$ and QH). Numerous attempts to thermally convert $ScQ_3 \cdot QH$ to ScQ_3 have failed (6, 7, 13–16), even though such conversions of the U(VI) and Th(IV) adducts are well-established (*e.g.*, ref. 17). In a careful study (18), Petronio and Ohnesorge reported that the complex prepared according to the procedure of Pokras and Bernays is not an adduct but simply ScQ_3, and that this composition is consistent with the failure of the thermal reaction. Petronio and Ohnesorge further reported that they could not obtain analytical data for % C and % H that were satisfactory for either ScQ_3 or $ScQ_3 \cdot QH$, using the procedure of Pokras and Bernays. Not only were the results for % C significantly lower and those for % H slightly higher than the theoretical values for the normal and adduct complexes, but the reproducibility was poor.

In view of the existing uncertainty regarding this compound, we undertook to re-examine its preparation and composition. In the present work, we confirm the view of Petronio and Ohnesorge that the compound precipitated from aqueous solution is not the adduct $ScQ_3 \cdot HQ$, but neither is it the simple normal chelate ScQ_3; it is $ScQ_3 \cdot H_2O$ (at least under the conditions described), and as discussed below, the presence of water could well account for the analytical

[1]Present address: Department of Chemistry, Loughborough University of Technology, U.K.

data obtained by Petronio and Ohnesorge. The adduct $ScQ_3 \cdot QH$ can be prepared by dissolving $ScQ_3 \cdot H_2O$ in molten QH, and ScQ_3 can be prepared by thermal treatment of $ScQ_3 \cdot QH$. Thermal dehydration of $ScQ_3 \cdot H_2O$ results in a slightly sub-stoichiometric ScQ_3 compound.

We also report the new scandium complexes of 2-chloro, 4-chloro, 4-methyl, and 5-methyl-8-hydroxyquinoline, and additional information on the previously known 2-methyl-8-hydroxyquinoline complex (14, 19–22).

Experimental

Materials

Stock solutions of scandium containing 1.57 mg/ml Sc (0.035 mmol/ml) were prepared from $ScCl_3 \cdot 6H_2O$ and standardized by EDTA titration before use (23). Hexachloro-1,3-butadiene for i.r. mulls was vacuum-distilled over BaO and then stored over molecular sieves (Type 4A). Acetic acid-d_4, ammonia-d_3, and D_2O (Stohler Isotope Chemicals) were used as supplied. 8-Hydroxyquinoline and the 2-methyl derivative (obtained commercially) were steam-distilled and recrystallized from aqueous ethanol. 2-Chloro- and 4-chloro-8-hydroxyquinoline were synthesized by the procedures of Rudolph *et al.* (24) and Pinnington (25), respectively. The 4-methyl and 5-methyl derivatives were prepared according to Phillips *et al.* (26) and Hollingshead (27), respectively.

Physical Measurements

I.r. spectra were recorded with a Beckman IR-5 spectrophotometer. Sample mulls were prepared in hexachloro-1,3-butadiene (in a dry-box, where appropriate). All spectra were recorded over the range 5000–630 cm^{-1} using NaCl windows. Thermograms were recorded in air at atmospheric pressure on a Stanton HT-D thermobalance at an initial heating rate of 1 °C/min to approximately 160 °C, and thereafter at 6 °C/min to about 600 °C, where the constant weight-level associated with Sc_2O_3 was attained. Thermal conversions *in vacuo* were done in the apparatus described previously (28). Proton magnetic resonance spectra were recorded with a Varian A-60 spectrometer. X-Ray powder photographs were obtained using CuK_α radiation emitted by a Philips PW1011 generator. Protonation (concentration) constants, $\log K_{NH}$ and $\log K_{OH}$, of the ligands were determined by potentiometric titration in 50% v/v aqueous dioxane, at 25 °C and ionic strength 0.1.

The scandium content of the complexes was determined by wet-oxidation of the sample (~0.1 g) with concentrated nitric acid (20 ml) and subsequently with hot perchloric acid (4 ml), dilution and adjustment of the p*H* to about 2.5, and titration of an aliquot of the resulting solution with EDTA, using xylenol-orange indicator (23). The accuracy was ±0.02 mg Sc. The ligand content of the complexes was determined bromometrically (29), with an accuracy of ±0.1–0.2 mg ligand. Microanalyses (C, H, and N) reported in this work were performed by Alfred Bernhardt, Elbach über Engelskirchen, West Germany.

Preparation of Complexes

$ScQ_3 \cdot H_2O$

From the stock Sc solution, 7.35 ml (0.26 mmol Sc) were diluted with 100 ml of water and warmed to 70–80 °C. Ten ml of QH solution (2.26% w/v in 2 *M* acetic acid) containing 1.56 mmol QH and 45 ml of a buffer solution (30 ml 2 *M* ammonium acetate and 15 ml 2 *M* ammonia) were added, the latter solution by dropwise addition with stirring. The resulting suspension was stirred for 1 h. The lemon-yellow precipitate was filtered hot (p*H* of the cooled filtrate was 7.8–8.0) and washed with 100 ml of water at 70–80 °C. The compound was dried *in vacuo* at 40 °C (overnight) and at 100 °C (14 h). For each drying condition, the analytical data indicated the same composition. The data for 40 °C precede that for 100 °C (in brackets) below.

Anal. Calcd. for $Sc(C_9H_6NO)_3 \cdot H_2O$: C, 65.46; H, 4.07; N, 8.48; Sc, 9.07, $C_9H_6NO^-(Q^-)$, 87.29. Found: C, 65.84 (65.24); H, 4.00 (4.17); N, 8.75 (8.59); Sc, 9.02 ± 0.01 (9.05 ± 0.01); Q^-, 86.8 ± 0.2 (87.2 ± 0.2); Q^-:Sc ratio, 3.00:1 (3.00:1).

The data for Sc and Q^- represent the average of three determinations on three seperate preparations for each drying condition.

The compound was also prepared as above using deuterated reagents and D_2O as solvent. Samples of the nondeuterated and deuterated compounds dried at 100 °C were retained for infrared analysis.

The effect of p*H* on the composition was studied over the p*H* range 5–8 by varying the amount of buffer solution added. The filtered compounds were dried overnight at 100 °C and samples taken for wet-chemical, molecular weight and p.m.r. analysis.

The effect of QH concentration on the composition of the precipitate was also investigated. The above procedure was used except that 10 ml of the Sc solution (0.35 mmol Sc) were taken and 10 ml of a 5.0, 3.5, 3.0, 2.5, and 2.0% w/v solution of QH in 2 *M* acetic acid were added (corresponding to 3.45, 2.41, 2.07, 1.72, and 1.38 mmol of QH, respectively). The procedure with 3.45 mmol of QH closely approximated that used by Pokras and Bernays (7). In a further study, this procedure was modified by precipitating the compound from a mixed aqueous organic solvent in which the final precipitation medium was 10% v/v aqueous acetone. In all cases, the filtered compound was dried overnight at 40 °C *in vacuo*. The analytical data are summarized in Table 1.

$ScQ_3 \cdot QH$

This complex was prepared from molten QH as follows. One hundred mg of $ScQ_3 \cdot H_2O$ (0.20 mmol) were thoroughly mixed with 145 mg of QH (1.00 mmol). The yellow mixture was ground to a fine powder and placed in an air-oven at 90 °C. Near the m.p. of QH (73 °C), the color turned orange. Above 80 °C, a homogeneous melt was obtained. Heating was continued for 30 min at 90 °C. On cooling, an orange glass was obtained which was ground to a fine powder and heated over night *in vacuo* at 100 °C to remove the excess (unbound) QH. The solid was reground and reheated to yield a bright-orange compound.

Anal. Calcd. for $ScQ_3 \cdot QH$: Sc, 7.22; Q^-, 92.62. Found: Sc, 7.05; Q^-, 92.3; Q^-:Sc ratio, 4.08:1.

Similarly, the compound was prepared from $ScQ_3 \cdot D_2O$

TABLE 1. Effect of QH concentration and solvent on the Sc(III)–QH complex

Solvent	QH added* (mmol)	% Q^- found†	% Sc found†	Sum (%)	Q^-:Sc ratio found

and molten QD. An atmosphere saturated with D_2O was used to minimize deuterium–hydrogen exchange due to moisture.

$Sc(2\text{-}Me\text{-}Q)_3 \cdot (2\text{-}Me\text{-}QH) \cdot 2H_2O$

The compound was prepared as described for $ScQ_3 \cdot H_2O$ except that 10 ml of Sc solution (0.35 mmol Sc) and 10 ml of a 3.3% w/v solution of 2-Me-QH in a 2 *M* acetic acid (2.07 mmol) were taken and the final p*H* was adjusted to 8.3–8.5 with the buffer solution. The bright yellow compound was dried *in vacuo* overnight at 40 °C and then at 95 °C for 1 h. At the latter temperature, the anhydrous compound $Sc(2\text{-}MeQ)_3 \cdot (2\text{-}Me\text{-}QH)$ was obtained. Analytical data are reported in Table 3, together with data for compounds obtained when 3.51 and 1.44 mmol of 2-Me-QH were used, and when the precipitation medium was 10% v/v aqueous acetone.

$Sc(4\text{-}Me\text{-}Q)_3 \cdot (4\text{-}Me\text{-}QH)$

The procedure was identical to that for the 2-Me-QH complex except that the yellow precipitate was dried overnight *in vacuo* at 95 °C. Analytical data are given in Table 4.

$Sc(2\text{-}Cl\text{-}Q)_3 \cdot H_2O$, $Sc(4\text{-}Cl\text{-}Q)_3 \cdot H_2O$, and $Sc(5\text{-}Me\text{-}Q)_3 \cdot H_2O$

To 10 ml of the Sc solution were added 2.79 mmol of 2-Cl-QH (or 3.50 mmol of 4-Cl-QH or 5-Me-QH) dissolved in 18 ml of acetone, 80 ml of water, and 10 ml of 2 *M* acetic acid. The mixture was heated to 60–70 °C and 50 ml of the buffer solution were added dropwise with stirring (p*H* ~ 8.5). After 15 min, the yellow precipitate was filtered hot, washed with 150 ml of warm water and dried for 4–12 h at 95 °C *in vacuo*. Analytical data are given in Table 4.

Determination of Water Content

The water content in all complexes sufficiently soluble in anhydrous methanol was determined by titration with stabilized Karl Fischer reagent. The necessary precautions to exclude atmospheric moisture from the titration assembly and the reaction vessel were taken (30). The KF reagent was standardized prior to each series of titrations with a methanol solution containing a known amount of water (2 mg H_2O/ml CH_3OH). The water content of the essentially anhydrous methanol solvent was determined in a blank titration. The amount of the complexes taken for analysis (150–250 mg) was limited by their solubility in methanol and provided only about 5–8 mg H_2O for determination. The volume of methanol solvent was kept small (usually 25 ml) to limit the magnitude of the blank correction. Each result below is the average of at least two titrations.

% H_2O calculated for $ScQ_3 \cdot H_2O$: 3.64. Found: 3.97.

% H_2O calculated for $Sc(2\text{-}Me\text{-}Q)_3 \cdot (2\text{-}Me\text{-}QH) \cdot 2H_2O$: 5.03. Found: 5.32.

No water was found in the compounds $Sc(2\text{-}Me\text{-}Q)_3 \cdot (2\text{-}Me\text{-}QH)$ and $Sc(4\text{-}Me\text{-}Q)_3 \cdot (4\text{-}Me\text{-}QH)$ prepared and dried as described above. The solubility of $Sc(2\text{-}Cl\text{-}Q)_3 \cdot H_2O$, $Sc(4\text{-}Cl\text{-}Q)_3 \cdot H_2O$ and of $Sc(5\text{-}Me\text{-}Q)_3 \cdot H_2O$ was too low to allow a meaningful titration.

Results and Discussion

The procedure described by Pokras and Bernays for the preparation of $ScQ_3 \cdot QH$ is not clear. In particular, it is uncertain whether 0.03 mmol of scandium were taken as stated (7), or whether ~0.3 mmol were taken as calculated from the amounts of Sc_2O_3 given in Tables 2 and 3 of ref. 7. In an additional report (6), the amount of Sc_2O_3 taken (Table 1) corresponds to ~0.3 mmol. Depending on which figure is used, the molar ratio of QH:Sc taken for the preparation was either 100:1 or 10:1. Since 10:1 is considered more likely, ~0.3 mmol of scandium were used in the present study. The analytical data for the compound obtained by the assumed procedure of Pokras and Bernays are given in Table 1 (first row), together with data for compounds prepared by using smaller amounts of QH or prepared from an aqueous acetone medium. At first glance, the Q^-:Sc ratio (4.06:1) found for Pokras and Bernays' compound suggests support for their proposed composition, $ScQ_3 \cdot QH$. It is noteworthy, however, that the % Q^- and % Sc values are in poor agreement with this composition (compare with last line of Table 2) and that their sum is only 97%. Indeed, when smaller amounts of QH were used, the Q^-:Sc ratio decreased to nearly 3.00:1, and the % Q^- and % Sc values approached good agreement with the composition $ScQ_3 \cdot H_2O$ (compare with the second line of Table 2). Furthermore, when acetone was present in the precipitation medium, the Q^-:Sc ratio was reduced to 3.4:1 and the sum of % Q^- and % Sc was only about 96%. These results suggest that the compound reported by Pokras and Bernays is not $ScQ_3 \cdot QH$ but $ScQ_3 \cdot X$ (where X is a moiety of molecular weight such that the sum of % Sc and Q^- is ~96%) contaminated by QH. This compound could not be heated to constant weight at 105 °C (in air) but continued to lose weight slowly for several days, probably because of slow volatilization of the contaminant.

To reduce the risk of contamination by QH, which has only limited solubility in weakly basic aqueous solution, Pokras and Bernays' procedure was altered by lowering the amount of QH used from 3.45 to 1.56 mmol. The amount of Sc was slightly lowered (to 0.26 mmol) to give a QH:Sc ratio of 6:1. Because the presence of the moiety X was suspected, the drying temperature was lowered from 110 °C to 40 °C. As shown in the Experimental, elemental analysis yielded data that agreed well with the composition $ScQ_3 \cdot H_2O$; furthermore the compound could be safely dried at 100 °C. The presence of H_2O

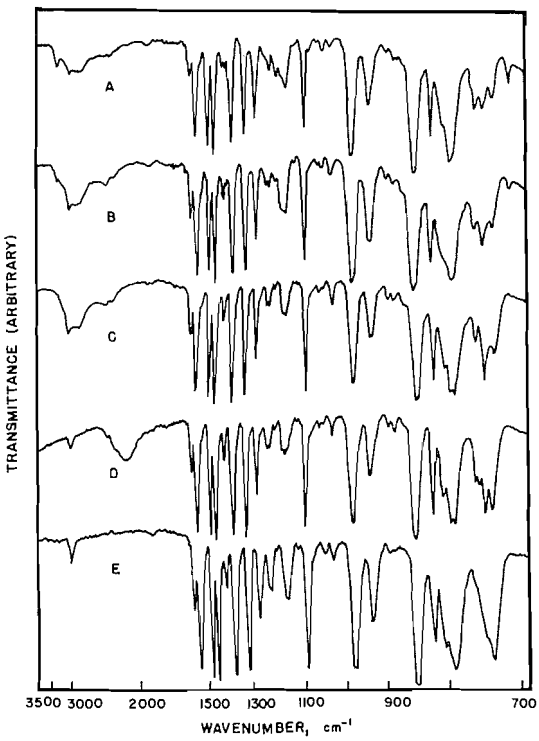

FIG. 1. Infrared spectra of Sc(III) complexes of 8-hydroxyquinoline: (*A*) Pokras and Bernays' compound, (*B*) compound precipitated from 10% v/v aqueous acetone, (*C*) $ScQ_3 \cdot H_2O$, (*D*) $ScQ_3 \cdot D_2O$, and (*E*) thermal product, ScQ_3.

was confirmed by infrared spectra (below) and by heating the complex *in vacuo* at 160 °C and trapping the evolved water in a U-tube. Titration with Karl Fischer reagent confirmed the presence of one water molecule in the complex.

The 3.00:1 ratio found for Q^-:Sc confirms the finding of Petronio and Ohnesorge (18) that the compound is not $ScQ_3 \cdot QH$. These workers reported the compound to be ScQ_3 but pointed out that the results of carbon determinations were appreciably lower and those for hydrogen slightly higher than the calculated values for ScQ_3. However, it is noteworthy that their average values for % C (65.63) and % H (4.16) are in good agreement with the calculated values based on $ScQ_3 \cdot H_2O$ (65.46, 4.07), although this observation may be fortuitous in view of the poor precision of the data. Petronio and Ohnesorge suggested that the poor precision of the data (not only from different samples but also from the same sample) could be reconciled if the compound ScQ_3 is hygroscopic after drying at 110–120 °C. This suggestion is reasonable since we observed that loss of water from $ScQ_3 \cdot H_2O$ begins at about 120 °C. The milder drying conditions used in the present work minimized the loss of water and afforded reproducible data.

The i.r. spectra of Pokras and Bernays' compound, the compound prepared from 10% v/v aqueous acetone, and the proposed complex $ScQ_3 \cdot H_2O$ are shown in Fig. 1, spectra *A*, *B*, and *C* respectively. Two significant features are apparent. Firstly, the three spectra are very similar except that the weak bands at 3330, 1410, and 710 cm^{-1} in spectrum *A* are reduced in intensity in spectrum *B* (relative to other bands in the spectrum), and are absent in spectrum *C*. The bands at 1410 and 710 cm^{-1} are present in the spectrum of pure QH (not shown). The band at 3300 cm^{-1} (ν_{OH}) is shifted from the center (3100 cm^{-1}) of the very broad OH band in the spectrum of QH, probably because of a lower order of intermolecular hydrogen bonding. The decrease in intensity of the three bands is consistent with a decrease in the Q^-:Sc molar ratio from 4.06:1 to 3.00:1. Thus, the bands are likely due to contaminating reagent. Secondly a broad band centered at 2900 cm^{-1} is present in all three spectra. The spectrum *D*, Fig. 1, of the complex precipitated from D_2O solution shows the 2900 cm^{-1} band shifted to 2150 cm^{-1}, proving that the absorption is protonic ($\nu_H/\nu_D = 1.34$). This band is absent (*E*, Fig. 1) after the compound has been heated at 160 °C *in vacuo* to remove the water. (The band at about 3000 cm^{-1} in spectra *D* and *E* is ν_{CH}.) Similar broad bands have been found in the i.r. spectra of the complexes $MgQ_2 \cdot 2H_2O$, $BiQ_3 \cdot H_2O$, $ZnQ_2 \cdot 2H_2O$, $NiQ_2 \cdot 2H_2O$, and $Be_2OQ_2 \cdot 2H_2O$ (31–33). The OH stretching modes of these compounds occur in the range 3300–3600 cm^{-1}. The 2900 cm^{-1} frequency is unusually low by comparison; this is likely the result of stronger hydrogen-bonding (34) and/or stronger coordination of the water molecule to the scandium atom (35).

From the results above, it appears that the extra reagent in Pokras and Bernays' compound is due to contamination of $ScQ_3 \cdot H_2O$ by coprecipitation. The powder diffraction lines of the compound do not contain lines from QH or $ScQ_3 \cdot H_2O$. Therefore, the compound is not a bi-crystalline mixture of the latter two components, and the extra reagent is likely incorporated into the $ScQ_3 \cdot H_2O$ crystal by occlusion.

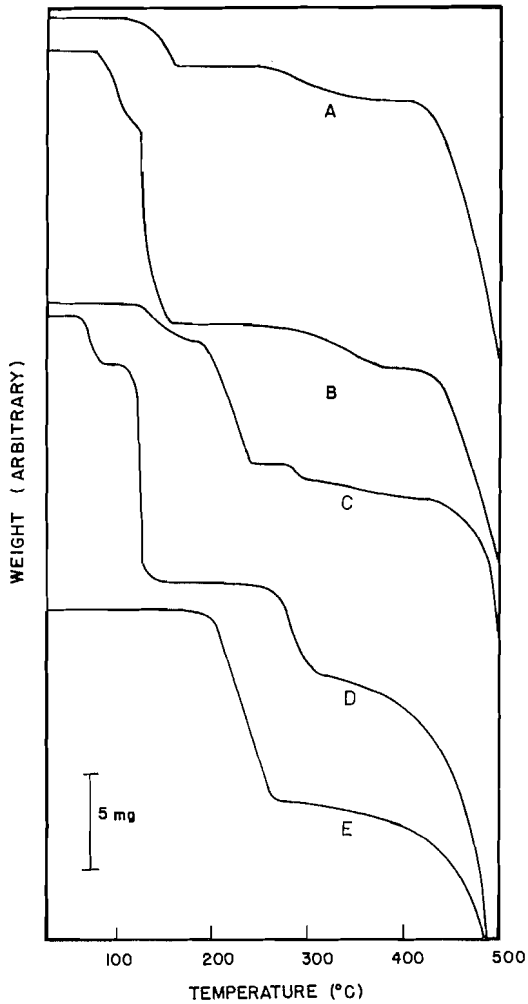

FIG. 2. Thermograms of (*A*) $ScQ_3 \cdot H_2O$ (initial weight, 58.9 mg), (*B*) Pokras and Bernays' compound (58.6 mg), (*C*) melt product $ScQ_3 \cdot QH$ (32.9 mg), (*D*) $Sc(2\text{-Me-Q})_3 \cdot (2\text{-Me-QH}) \cdot 2H_2O$ (55.1 mg), and (*E*) $Sc(4\text{-Me-Q})_3 \cdot (4\text{-Me-QH})$ (45.6 mg).

The thermogram (*A*, Fig. 2) of $ScQ_3 \cdot H_2O$ shows that loss of H_2O occurs over the range 120–160 °C. The constant-weight level associated with ScQ_3 occurs in the range 160–240 °C. Ultimately, the compound decomposes to Sc_2O_3 at approximately 600 °C. Pokras and Bernays' compound (*B*, Fig. 2) loses both the bound water and extra reagent in the range 75–160 °C to yield ScQ_3. Analysis of several samples of $ScQ_3 \cdot H_2O$ heated in the temperature range 160–240 °C *in vacuo* revealed that removal of water results in a slightly substoichiometric compound. In all experiments, a small amount of QH was evolved (1–3 mg from 100 mg of hydrate), and a residue deficient in Q^- (Q^-:Sc ratios in the range 2.86–2.92) remained. The ligand deficiency is likely the result of solid-phase hydrolysis of the hydrate according to the following thermal reactions:

$$ScQ_3 \cdot H_2O \rightarrow ScQ_2 \cdot OH + QH$$

$$ScQ_2 \cdot OH \rightarrow ScQ \cdot O + QH$$

The reaction occurs only to a small extent, the major process being the total removal of water from the hydrate. Similar behavior has been observed for other QH complexes such as $MgQ_2 \cdot 2H_2O$, $BaQ_2 \cdot 4H_2O$, and $Be_2OQ_2 \cdot 2H_2O$ (33, 36), and for the rare-earth acetylacetonates $Ln(acac)_3 \cdot nH_2O$ (37) and dibenzoyl-methides $Ln(dby)_2 \cdot H_2O$ (38). Muetterties and Wright (39) have suggested that the hydrolysis of the rare-earth complexes indicates a significant bonding interaction between the metal atoms and the oxygen atom of the water molecule. The monohydrate phases may well contain hepta-coordinate metal atoms. Therefore, in $ScQ_3 \cdot H_2O$, the water molecule is likely coordinated to the scandium atom, but an X-ray or neutron diffraction structural determination is required to decide this point.

In the preparation of $ScQ_3 \cdot H_2O$, the effect of p*H* on the composition of the precipitate was examined over the p*H* range 5–8, and a marked effect was noted. The compound $ScQ_3 \cdot H_2O$ was obtained only between p*H* 7–8. Between p*H* 5–6.8, the composition could be formulated as $Sc(Q)_{3-x}(OAc)_x$, where OAc^- is acetate and $x = 0.4$ at p*H* 5.0 and 0.2 at p*H* 6.8. The Q^-:Sc ratio of the compounds varied from 2.59:1 to 2.78:1 from p*H* 5.0 to 6.8, respectively. The compound precipitated at p*H* 6.2 (Q^-:Sc = 2.70:1) was taken to be representative and studied in more detail. The p.m.r. spectrum in DMSO exhibited a sharp singlet at 1.72 p.p.m. characteristic of the acetate methyl group; this band is not present in the spectrum of $ScQ_3 \cdot H_2O$. Integration of the spectrum gave 17:1 for the 8-hydroxyquinoline–anion and acetate – anion proton ratio. This ratio compares favorably with the ratio 18:1 for the formula $Sc(Q)_{2.7}(OAc)_{0.3}$ arrived at from the analytical data. These acetate complexes are most likely associated or polymerized in the solid phase. A molecular weight determination of $Sc(Q)_{2.7}(OAc)_{0.3}$ (calculated molecular weight, 452) by vapor-phase osmom-

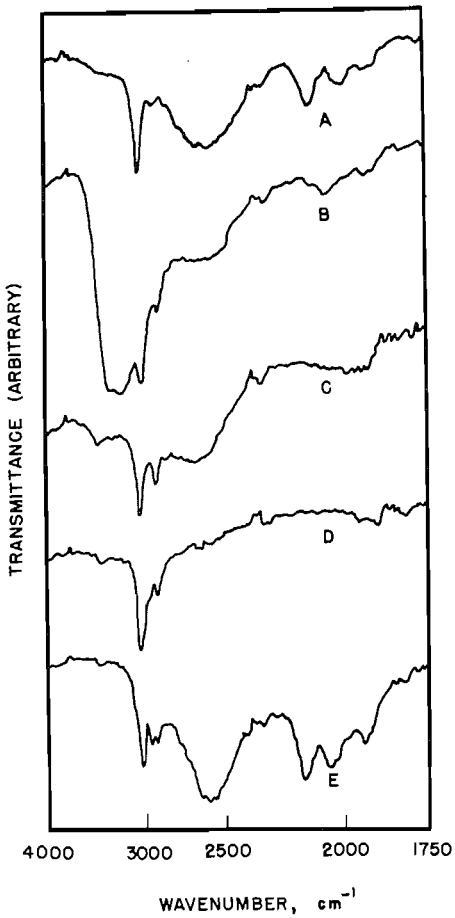

FIG. 3. Infrared spectra of (*A*) melt product $ScQ_3 \cdot QH$, (*B*) $Sc(2\text{-Me-Q})_3 \cdot (2\text{-Me-QH}) \cdot 2H_2O$, (*C*) $Sc(2\text{-Me-Q})_3 \cdot (2\text{-Me-QH})$, (*D*) $Sc(2\text{-Me-Q})_3$, and (*E*) $Sc(4\text{-Me-Q})_3 \cdot (4\text{-Me-QH})$.

etry gave a value of 760, suggestive of some degree of association in benzene solution.

The product, $[ScQ_3]_2 \cdot 3QH$, from the "solid-phase" reaction between $ScQ_3 \cdot QH$ and QH described by Cardwell and Magee (13) was re-examined. It was presumed that $ScQ_3 \cdot H_2O$ was the reactant rather than $ScQ_3 \cdot QH$. The color change from yellow to bright-orange upon formation of the melt suggests that the reaction does not occur in the solid-phase but in molten QH in which $ScQ_3 \cdot H_2O$ dissolves. Analysis showed the bright-orange product to be $ScQ_3 \cdot QH$, replacement of H_2O by QH having occurred.

The i.r. spectrum (*A*, Fig. 3) of $ScQ_3 \cdot QH$ shows bands centered at 2600 and 2100 cm^{-1} that are characteristic of hydrogen-bonded $\overset{+}{\diagdown}\!\!\diagup NH$ (11, 12, 40); the broad water band at 2900 cm^{-1} is absent. The spectrum (not shown) of the product obtained from molten QD showed a significant reduction in intensity at 2600 cm^{-1} and a broadening of the band intensity at 2100 cm^{-1} ($\nu_H/\nu_D = 1.25$), confirming that the vibrations are protonic. The bands are identical to those observed for the QH adducts of U(VI) and Th(IV) (11, 12, 40). As with the U(VI) and Th(IV) adducts, the additional molecule of reagent in the Sc(III) adduct is likely monodentate and bound to the metal atom through the oxygen atom. (The disposition of the water molecule in $ScQ_3 \cdot H_2O$ may well be similar.) If it is assumed that the complex exists as a monomer in the solid-phase, the result suggests that the scandium is hepta-coordinate in the complex. No examples of hepta-coordinate scandium have been reported in the literature, although several examples of hexa-coordination and a few of octa-coordination are documented (41).

The thermogram (*C*, Fig. 2) of $ScQ_3 \cdot QH$ shows the loss of the extra HQ molecule over the temperature range 130–240 °C. The constant weight level associated with lime-green ScQ_3 occurs in the range 240–280 °C. As expected, the i.r. spectrum (not shown) of ScQ_3 shows the disappearance of the $\overset{+}{\diagdown}\!\!\diagup NH$ bands.

Interestingly, and unlike QH, the compound precipitated from aqueous solution by 2-Me-QH is the adduct (Table 3): this result confirms the finding of Phillips *et al.* (19). If the amount of reagent used is too large, contamination occurs, resulting in too high a 2-Me-Q^-:Sc ratio (Table 3). Contamination can be overcome by the presence of acetone in the solvent medium. Too low a concentration of the ligand leads to a substoichiometric product. The composition of the compound is $Sc(2\text{-Me-Q})_3 \cdot (2\text{-Me-QH}) \cdot 2H_2O$ when dried at 40 °C and $Sc(2\text{-Me-Q})_3 \cdot (2\text{-Me-QH})$ when dried at 95 °C (see Table 3 and Karl Fischer titration data in Experimental). Phillips *et al.* (19) reported the composition of the precipitated complex as the anhydrous adduct but the drying temperature used (100 °C) was adequate for the removal of water from the complex.

The infrared spectrum (*B*, Fig. 3) of the compound dried at 40 °C features an intense broad band at 3200 cm^{-1}, which confirms the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

presence of water. The breadth and position of the band indicate water of hydration rather than contaminating moisture. Moisture bands in the i.r. spectra of complexes usually occur at higher frequency (~3400 cm^{-1}) and are considerably less broad and intense. The spectrum also shows broad bands at 2650 and 2070 cm^{-1} characteristic of hydrogen-bonded $\rangle\overset{+}{N}H$, although the band at 2650 cm^{-1} is somewhat overlapped with the broad water band at 3200 cm^{-1}. The sharp peaks at about 3000 and 2900 cm^{-1} represent ν_{CH} (aromatic and aliphatic, respectively).

The thermogram (*D*, Fig. 2) of Sc(2-Me-Q)$_3$·(2-Me-QH)·2H_2O shows a weight loss at 70 °C and then a constant-weight level over the range 80–100 °C. Chemical analysis showed this level to correspond closely to the yellow anhydrous compound Sc(2-Me-Q)$_3$·(2-Me-QH). A further weight loss occurs at 105 °C followed by a constant-weight level over the range 150–240 °C; analysis of the Sc and ligand content (see Experimental) showed this level to be associated with the lime-green complex Sc(2-Me-Q)$_3$. The i.r. spectrum of Sc(2-Me-Q)$_3$·(2-Me-QH) (*C*, Fig. 3) shows the removal of the water band, and that of Sc(2-Me-Q)$_3$ (*D*, Fig. 3) the disappearance of the $\rangle\overset{+}{N}H$ bands. As suggested above from infrared data, X-ray powder diffraction studies indicated that the water in the complex is not likely present as moisture; Sc(2-Me-Q)$_3$·(2-Me-QH) has a different powder pattern (and therefore crystal structure) from that of Sc(2-Me-Q)$_3$·(2-Me-QH)·2H_2O. The thermal removal of moisture would not affect the powder pattern in this manner. The low temperature required for removal of the water suggests, however, that it is not coordinated to the scandium.

The ligand 4-Me-QH also forms an adduct with Sc(III) (Table 4). The adduct is anhydrous (confirmed by Karl Fischer titration) although the higher drying temperature could conceivably have removed water of hydration. The i.r. spectrum (*E*, Fig. 3) of Sc(4-Me-Q)$_3$·(4-Me-QH) shows $\rangle\overset{+}{N}H$ bands at 2650, 2150, and 2050 cm^{-1}. The thermogram of the adduct (*E*, Fig. 2) shows a weight-loss occurring initially at 190 °C, with a discontinuity at 270 °C corresponding to the composition of the lime-green complex Sc(4-Me-Q)$_3$, as shown by elemental analysis of the residue. In the i.r. spectrum of the latter

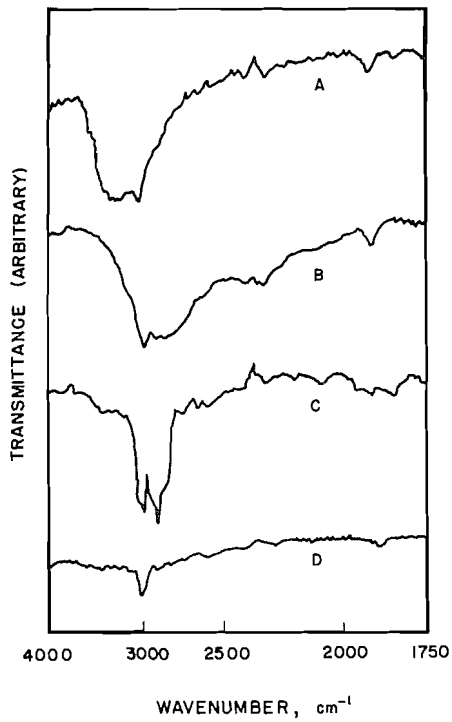

FIG. 4. Infrared spectra of (*A*) Sc(2-Cl-Q)$_3$·H_2O, (*B*) Sc(4-Cl-Q)$_3$·H_2O, (*C*) Sc(5-Me-Q)$_3$·H_2O, and (*D*) Sc(4-Cl-Q)$_3$.

(not shown), the $\rangle\overset{+}{N}H$ bands are not present.

The i.r. spectra of the 2-Cl-QH, 4-Cl-QH, and 5-Me-QH complexes (Fig. 4; *A*, *B*, and *C*, respectively) do not show the presence of $\rangle\overset{+}{N}H$ bands. Broad bands in the region 2900–3200 cm^{-1} suggest the presence of water. Limited analytical data (Table 4) indicate the compositions Sc(2-Cl-Q)$_3$·H_2O, Sc(4-Cl-Q)$_3$·H_2O, and Sc(5-Me-Q)$_3$·H_2O, but the amount of water present could not be confirmed by Karl Fischer titration because of the low solubility of these complexes in methanol. The water could be readily removed from Sc(4-Cl-Q)$_3$·H_2O by heating at 170 °C *in vacuo* to yield Sc(4-Cl-Q)$_3$, as shown by elemental analysis. The water band is absent in the i.r. spectrum (*D*, Fig. 4). Presumably, the other complexes behave similarly. The very low solubility of the ligands in aqueous media increased the risk of contamination of the complexes. In view of this and the limited amount of data, the composition reported for these complexes should be regarded as tentative.

In summary, two main classes of compounds

are formed by reaction between Sc(III) and 8-hydroxyquinoline and derivatives in aqueous solution: aquated tris chelates and adduct complexes. The parent ligand QH, and the 2-chloro, 4-chloro, and 5-methyl derivatives precipitate Sc(III) as the aquo tris chelates, while the 2-methyl and 4-methyl derivatives yield the adducts in which the extra ligand is coordinated as a monodentate (zwitterion) ligand, as in the U(VI) and Th(IV) complexes of QH (12, 40). It appears that there is a competition between the monodentate ligand and water for a coordination site. The competition is well illustrated by the displacement of water in $ScQ_3 \cdot H_2O$ by QH on dissolution of the compound in molten QH. The reason for the difference in behavior between these two groups of ligands in not obvious. Of the properties considered (solubility of the reagents, steric properties of the substituents, and basicity of the ligand nitrogen and oxygen atoms), the only apparent correlation is with nitrogen basicity. The nitrogen protonation constants (log K_{NH}) of 2-Me-QH and 4-Me-QH (4.75 and 4.85, respectively) are appreciably higher, on the whole, than those of the ligands forming tris complexes (2-Cl-QH, 2.0; 4-Cl-QH, 2.83; QH, 4.12; 5-Me-QH, 4.27). Since the tendency for zwitterion formation both in solution and in the complex is increased with increasing nitrogen basicity, it is possible that the formation of the aquo or adduct complex is determined, at least in part, by nitrogen basicity. If this is so, then the pK_{NH} value for QH and 5-Me-QH must be very close to the threshhold pK_{NH} value at which adduct formation is favored.

We wish to thank the National Research Council of Canada for the financial support of this study. One of us (M.T.) is indebted to the International Nickel Company of Canada for a Fellowship.

The Rate Constants for the Reactions of Ozone with Triphenylphosphite and Triphenylphosphine[1]

STANISLAV DMITRIEVICH RAZUMOVSKII[2] AND GEORGE DAVID MENDENHALL[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received May 29, 1972

The stoichiometry and rate constants for the reaction of triphenylphosphite and triphenylphosphine with ozone were measured at several temperatures. The rate was first order in each reactant, with $k = (3 \pm 1) \times 10^4$ and $(5 \pm 2) \times 10^3$ M^{-1} s^{-1}, respectively, for the reaction of ozone with triphenylphosphine and triphenylphosphite (2,4-dimethylhexane, $-90°$). The reaction of ozone with triphenylphosphite has a low activation energy in carbon tetrachloride. The stoichiometry was 1:1 for both compounds under these conditions.

La stoechiométrie et les constantes de vitesse de la réaction entre le triphénylphosphite et la triphénylphosphine avec l'ozone ont été mesurées à diverses températures. La vitesse est du premier ordre pour chaque réactant avec $k = (3 \pm 1) \times 10^4$ et $(5 \pm 2) \times 10^3$ M^{-1} s^{-1} respectivement pour la triphénylphosphine et le triphénylphosphite (diméthyl-2,4-hexane, $-90°$). La réaction de l'ozone sur le triphénylphosphite possède une faible énergie d'activation dans le tétrachlorure de carbone. La stoechiométrie est de 1:1 pour les deux composés dans ces conditions.

Can. J. Chem., 51, 1257 (1973)

The reaction of ozone with heteroatom compounds containing free electron pairs or *d* orbitals has come under increasing study in recent years (1–5). In most cases the final products do not incorporate all three oxygen atoms of the ozone and variously formulated intermediates have been proposed. The relatively stable adduct from triphenylphosphite and ozone (2) has aroused particular interest because it oxidizes organic substrates by at least two mechanisms, one involving singlet molecular oxygen (6).

The reaction of trivalent phosphorus compounds with ozone to give the corresponding R_3PO species [2] may be described by the scheme shown below.

$$[1] \qquad R_3P + O_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R_3PO_3$$

$$[2] \qquad R_3PO_3 \xrightarrow{k_2} R_3PO + {}^1O_2$$

$$[3] \qquad {}^1O_2 + R_3P \xrightarrow{k_3} \text{products}$$

$$[4] \qquad R_3PO_3 + R_3P \xrightarrow{k_4} \text{products}$$

$$[5] \qquad {}^1O_2 \xrightarrow{k_5} {}^3O_2$$

The initial product **1** from triphenylphosphite contains pentacovalent phosphorus (^{31}P n.m.r.) (2) and decomposes slowly at $-70°$, although triphenylphosphine in contrast does not give a stable adduct (2).

We studied the reactions of triphenylphosphine and triphenylphosphite at several temperatures in a flow system described by one of us earlier (7). A 6% O_3–O_2 mixture is bubbled through a dilute solution (isopentane or CCl_4) of the reactant and the appearance of ozone is monitored in the effluent. As the reaction proceeds, the concentration of ozone observed increases and reaches a constant value when the reaction is complete and the solution is saturated with ozone (see Fig. 1). From the shape of the O_3 *vs.* time curve compared to that for pure solvent both rate constants and the stoichiometry of the reaction may be calculated.

As the ozone–oxygen is passed through the solution, equilibrium is rapidly established:

$$[O_3]_g \rightleftharpoons [O_3]_l$$

where α is the solubility coefficient. The dissolved ozone reacts with the substrate:

$$[O_3]_l + s \xrightarrow{k_r} \text{products}$$

Provided that the rate of solution is not the limiting stage, at any time the following equality must hold

$$k_r = w([O_3]_0 - [O_3]_g)/\alpha[RH][O_3]_g \text{ l mol}^{-1} \text{ s}^{-1}$$

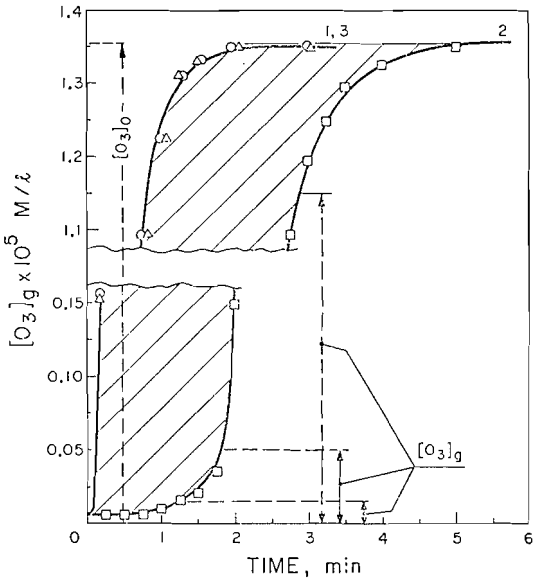

FIG. 1. The dependence of the ozone concentration after the reactor, $[O_3]_g$, on the time of reaction between ozone and triphenylphosphite. Initial concentration $[O_3]_0 = 1.36 \times 10^{-5}$ mol/l. Curve *1*, pure solvent (○); *2*, solution $[(PhO)_3P]_0 = 1.42 \times 10^{-4}$ mol/l (□); *3*, after complete reaction and removing excess of ozone (△).

where w is the specific rate of feed of the gas mixture in s^{-1}; $[O_3]_0$ and $[O_3]_g$ are the ozone concentrations at the reactor inlet and outlet, respectively. The numerator of the equation express the amount of reacted ozone per unit time, the denominator the product of the concentrations of the reactants.

Dilute solutions of both substrates examined showed 1:1 stoichiometry and the reaction was first-order in each component. The stoichiometry observed indicates that the reactions 3 and 4 are not important under these conditions, though Thompson (2) found up to 2.5 atoms of oxygen per ozone molecule appeared in the products at higher concentrations. A spent reaction mixture, flushed free of ozone, showed the same curve on readmitting ozone as did pure solvent, indicating the absence of side reactions with oxidation products. This also follows from the slow rates of reaction of ozone with benzene and with anisole, which roughly simulate the organic portions of our phosphorus compounds. Finally, no ozone reappeared in the effluent when the solution was flushed with O_2 4 h after the initial reaction, indicating that $k_{-1} \ll k_1 + k_2$.

The rate constants derived are listed in Table 1. The constants for both compounds are high (10^4 M^{-1} s^{-1}) and nearly temperature-invariant. If the rate in 2,4-dimethylhexane is included with those in CCl_4, an activation energy of 2 ± 1 kcal can be estimated for the reaction of ozone with triphenylphosphite. Both the high rate and low E_a are consistent with the strength of the P—O bond (84 kcal) (8) presumably formed in the process. It is expected that the phosphine reacts faster with ozone than triphenylphosphite, though the difference is not large. The observed order is common; for instance triphenylphosphine reacts 26 times faster than triethylphosphite toward ethyl iodide (acetonitrile, 60°) (9). The rates of reaction of *t*-butylperoxy radical toward triphenylphosphine and triphenylphosphite are 200 and 260 M^{-1} s^{-1}, respectively (*i*-pentane, −95°) (11). The lower P—O bond order in the species formed from *t*-butylperoxy radical in the latter reactions is consistent with the fact that their rates are orders of magnitude slower than the corresponding ozone reactions.

Our results do not bear directly on the question why triphenyl phosphine ozonide (**1**, R = Ph) is

TABLE 1. Rate constants for the reaction of ozone with triphenylphosphite, triphenylphosphine, and related compounds

Compound	Temperature (°C)	Solvent	$10^5[O_3]_0$* (*M*)	10^5[Substrate]$_0$ (*M*)	10^{-4} k_1 (M^{-1} s^{-1})

not stable, except to show it is not due to a reverse reaction. If the instability results from an enhanced value of k_2 (unimolecular decomposition), we might not detect this process by a change in stoichiometry due to the subsequent reaction 3, because deactivation of $^1O_2$ probably competes effectively at our concentrations.[4]

The large rate constants observed here suggest that phosphites may be a useful class of antiozonants.

Some Oxime and Amide Complexes of $NiCl_2$

M. E. STONE[1] AND K. E. JOHNSON[2]

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

Received November 23, 1971[3]

$[Ni(Aox)_4Cl_2]$ (Aox = acetaldoxime), $[Ni(Acm)_4(H_2O)_2]Cl_2$ (Acm = acetamide), $Ni(Cy)_3Cl_2$-(Cy = cyclohexanone oxime), and $[Ni(cap)_6]Cl_2$(Cap = caprolactam) have been prepared. Their solution electronic spectra indicate approximately octahedral environments for Ni(II) while solid $Ni(Aox)_4Cl_2$ shows a small tetragonal distortion. The i.r. spectra can be accounted for by oxime bonding to Ni via nitrogen and amide bonding to Ni via oxygen alone.

Les produits, $[Ni(Aox)_4Cl_2]$ (Aox = Acetaldoxime), $[Ni(Acm)_4(H_2O)_2]Cl_2$ (Acm = acétamide), $[Ni(Cy)_3Cl_2]$ (Cy = oxime de cyclohexanone) et $[Ni(Cap)_6]Cl_2$ (Cap = caprolactame) ont été préparés. Leurs spectres électroniques en solution montrent approximativement un environnement octaédrique pour le Ni(II) alors que le $Ni(Aox)_4Cl_2$ solide possède une légère déformation tétragonale. Les spectres i.r. peuvent s'expliquer par la liaison de l'oxime au Ni par l'intermédiaire de l'azote et par la liaison de l'amide au Ni par l'intermédiaire de l'oxygène seulement.

[Traduit par le journal]

Can. J. Chem., **51**, 1260 (1973)

Oxime and amide complexes of nickel(II) are of interest as possible intermediates in Beckman rearrangements catalyzed by Raney nickel or nickel(II) salts (1–3). Acetaldoxime has been reported (4, 5) to form $Ni(Aox)_4Cl_2$ and Ni—N bonding was postulated in this complex. Acetamide, the rearrangement product of acetaldoxime, forms several complexes with Ni(II), *viz.*, $(NiCl_2)_2(Acm)$ (6), $Ni(Acm)_4Cl_2\cdot(H_2O)$ (7), $Ni(Acm)_4Cl_2\cdot 2H_2O$ (8) and $Ni(Acm)_6Cl_2$ (9). Ni—O bonding was suggested for the latter (9) but the one of interest to us, $Ni(Acm)_4Cl_2\cdot 2$-(H_2O) was not studied in detail. In concurrent work (10) we have determined the crystal structures of $Ni(Aox)_4Cl_2$ and $Ni(Acm)_4Cl_2\cdot 2(H_2O)$ and find that Ni(II) is essentially octahedrally coordinated in both: in the former by 4 N at 2.114 Å and 2 Cl at 2.441 Å, and in the latter by 2 amide O at 2.044 Å, 2 amide O at 2.102 Å, and 2 water O at 2.063 Å.

In this paper we wish to compare the i.r. spectra of $[Ni(Aox)_4Cl_2]$ and $[Ni(Acm)_4(H_2O)_2]Cl_2$ with those of the free ligands and to report the electronic spectra of solid $Ni(Aox)_4Cl_2$ and ethanolic solutions of both complexes. In addition, we include i.r. and electronic spectra for the cyclohexanone oxime complex $Ni(Cy)_3Cl_2$ and the caprolactam complex $Ni(Cap)_6Cl_2$, noting that Pd and Pt complexes of cyclohexanone oxime are known (11, 12) and that Madan and Denk (13) have prepared and studied in some detail $Ni(Cap)_6(ClO_4)_2$, $Ni(Cap)_6I_2$, and $Ni(Cap)_2Cl_2$. We were unable to obtain crystals of $Ni(Cy_3)Cl_2$ and $Ni(Cap)_6Cl_2$ suitable for X-ray structure work.

Experimental

Anhydrous $NiCl_2$ (Alfa Inorganics, 99.9% pure) was dissolved in absolute ethanol and excess ligand (Baker Chemical Co.) alone (in the case of Aox) or dissolved in absolute ethanol, was added. The solid products formed after standing for several days were recrystallized from ethanol–methanol (50% v/v). All of them were hygroscopic.

Analyses were carried out by both Chemalytics, Inc., and Galbraith Laboratories, Ltd., as follows:

Anal. Calcd. for $[Ni(Aox)_4Cl_2]$: C, 26.26; H, 5.52; N, 15.31; Cl, 19.38. Found: C, 26.1, 26.2; H, 5.6, 5.4; N, 15.4, 15.3; Cl, 19.1, 19.5.

Anal. Calcd. for $[Ni(Acm)_4(H_2O)_2]Cl_2$: C, 23.91; H, 6.03; N, 13.94; Cl, 17.64. Found: C, 23.8, 23.7; H, 6.1, 6.0; N, 14.0, 13.6; Cl, 17.5, 18.7.

Anal. Calcd. for $Ni(Cy)_3Cl_2$: C, 46.09; H, 7.09; N, 8.96; Cl, 15.12. Found: C, 45.7, 45.9; H, 7.2, 7.3; N, 8.9, 8.9; Cl, 14.9, 15.4.

Anal. Calcd. for $Ni(Cap)_6Cl_2$: C, 53.48; H, 8.28; N, 10.39; Cl, 8.77. Found: C, 54.9, 54.4; H, 8.6, 8.9; N, 10.9, 10.2; Cl, 7.8, 8.4.

It is interesting to note that the acetamide complex was a hydrate, although superficially dry conditions were maintained.

Electronic spectra of 0.02 to 0.3 *M* solutions of the complexes in absolute ethanol in the range 5–33 kK were obtained with a Beckman DK 2A recording spectrophotometer. The spectra were analyzed into their Gaussian

components by the method of Chatt (14). The spectrum of a single crystal of $Ni(Aox)_4Cl_2$ was measured by Dr. J. R. Dickinson at the University of Virginia. A Beckman IR 12 spectrometer was used to record infrared spectra of the complexes and pure ligands in the range 200–4000 cm^{-1}; KBr pellets were used for solid compounds while a KBr cell was used for liquid acetaldoxime. Conductances of solutions were measured with a Beckman Model RC-18A bridge and a conventional cell by Dr. J. L. Meyer.

Results and Discussion

The conductances of ethanolic solutions of $[Ni(Aox)_4Cl_2]$ and $[Ni(Acm)_4(H_2O)_2]Cl_2$ indicate that both complexes yield weak electrolytes. The Λ *vs.* $\sqrt{C}$ plots (Λ = equivalent conductance in $ohm^{-1}\,cm^{-1}\,l^{-1}$ equivalents, C = concentration in equivalent l^{-1}) are curved, Λ rising from 1.82 to 35.4 for an acetaldoxime complex concentration change from 0.0385 to 0.00010 and rising from 15.0 to 49.3 for an acetamide complex concentration change from 0.0139 to 0.000028. Calculated maximum values of the degree of dissociation of the most dilute ethanolic solutions used in the spectral studies are 5% for the acetaldoxime complex and 15% for the acetamide complex.

The infrared spectra of $Ni(Aox)_4Cl_2$ and $[Ni(Acm)_4(H_2O)_2]Cl_2$ are consistent with the X-ray results for these compounds. In particular, on complexing the oxime the C=N band shifted from 1675 to 1630 cm^{-1} and decreased in intensity and the 1200–1500 cm^{-1} region was radically changed since only the *syn*-configuration is preserved and the OH is H-bonded to Cl. The amide I band, the C=O stretching frequency, was lowered from 1690 to 1672 cm^{-1} in the acetamide complex and the amide II band, the NH stretch, shifted from 1605 to 1586 cm^{-1}, in line with Ni—O bonding (15) and H-bonding between the NH_2 and Cl (10). The new bands appearing at 504 cm^{-1} in the oxime complex and 385 cm^{-1} in the amide complex might be due to Ni—N and Ni—OH_2 stretches, respectively (*cf.* ν_{Ni-N} at 515 and 480 cm^{-1} in $[Ni(NH_2CH{=}CHNH_2)_2][PtCl_4]$ (16) and ν_{Ni-O} at 405 cm^{-1} in $[Ni(H_2O)_6]SO_4$ (17)) but new bands at 637 cm^{-1} in the oxime complex and 531 cm^{-1} in the amide complex are not readily assigned.

Complexing of cyclohexanone oxime lowered the C=N frequency from 1676 to 1664 cm^{-1} with a shoulder at 1640 cm^{-1} and produced new bands at 607 and 550 cm^{-1} while the C=O stretch of caprolactam changed from 1668 cm^{-1} to bands at 1661 and 1638 cm^{-1} and a new band occurred at 535 cm^{-1}.[4] One can speculate that Ni—O frequencies are at $\sim$535 cm^{-1} for both amides but these bands could easily be combination modes.

The details of the electronic spectra of ethanolic solutions of the complex are given in Table 1 and the peak positions of the unresolved reflectance spectrum of $[Ni(Aox)_4Cl_2]$ are listed in Table 2. The only previously published spectrum for comparison is that by Bright *et al.* (18) of $Ni(Cap)_6(ClO_4)_2$ but although the assignments are the same the details do not agree very well with our results for $Ni(Cap)_6Cl_2$ (Table 3), perhaps because different solvents were used, the ethanol displacing the lactam to some extent for example.

The electronic spectra of all four complexes in solution correspond to octahedrally coordinated Ni(II). This is no surprise for the caprolactam complex. The X-ray data indicate that the 6 coordinating oxygens in $[Ni(Acm)_4(H_2O)_2]Cl_2$ are at virtually equal distances and if we compare the spectrum with that of $[Ni(H_2O)_6]^{2+}$ we see that there is little change beyond a shift of 0.6 to 1.6 kK to lower energy. For $[Ni(Acm)_6]^{2+}$ we can predict a further shift of 0.3 to 0.8 kK in the spectrum. The octahedral coordination in $Ni(Cy)_3Cl_2$ is not easy to rationalize without Cl bridges but apart from the fit of the transition energies to an octahedral structure the intensities of the bands are low for D_{3h} symmetry (19).[5]

Since the solution process involves little dissociation of the entity $[Ni(Aox)_4Cl_2]$ and no rupture of molecular bonds, the Cl atoms being H-bonded to ligands within the same group, it is surprising to find a typical octahedral Ni^{2+} spectrum for the blue solution of this complex in ethanol. However, the spectrum of the solid does exhibit a small tetragonal distortion, resembling that of $[Ni(pyridine)_4Cl_2]$ (20) (Table 2). We note that the solution spectrum of $[Ni(py)_4Cl_2]$ also showed no tetragonal splitting (20).

From the solution spectra, the ligand field strength (Δ), Racah parameters (B and C) and nephelauxetic coefficient (β) were calculated to give the best fit to the observed values using a program described elsewhere (21, 22) based on the Tanabe–Sugano energies for pure octahedral

[4]Ni—N and Ni—O bonding are thereby inferred, respectively, for these two complexes.

[5]The absorption spectrum of Ni(II) in several symmetries is discussed and Fig. 48, ref. 19, in particular is cogent to these arguments.

symmetry (23). Comparison of the Δ and β values for the complexes indicates that acetaldoxime gives rise to the strongest field and the greatest covalency and in fact Δ/β is such in $[Ni(Aox)_4Cl_2]$ that the $^3T_1(F)$ state has higher energy than the $^1E(D)$ state and therefore results in a different order of transitions. This is quite consistent with mainly nitrogen coordination as opposed to oxygen coordination in the amides.

A crystal field treatment of solid $Ni(Aox)_4Cl_2$ including configuration interaction between T_{1g} states (24) gave the very reasonable parameters $\Delta_{Aox} = 8.6$ kK, $\Delta_{Cl} = 8.3$ kK, $Dt = 0.31$ kK, and $Ds = 0.38$ kK. Thus the distortion is com-

parable to that found in $Ni(py)_4Cl_2$.

The Tanabe–Sugano expressions for the energies of the ligand field transitions are based on the assumption that there is no spin–orbital coupling. In practice we find not only spin-allowed, parity-forbidden transitions but also spin-forbidden, parity-forbidden transitions. The spin-forbidden transitions involve excited states close in energy to states of the same spin as the ground state (23) and, thus, are a consequence of spin–orbital coupling (25). Fortunately, although it is large enough to make the spin-forbidden transitions observable, it is insufficient to invalidate the Tansabe–Sugano energy expressions and, indeed, an approximate value for the spin–orbital coupling constant is given by (26):

$$\lambda = 2.7 \frac{B^2}{\Delta}$$

It is interesting to note the reasonable values derived for the series of complexes studied here (Table 4): in particular, the value for $Ni(Aox)_4Cl_2$ is distinctly lower than the rest following the trend for β.

The Reaction of CH_3^+ with D_2

ALEX. G. HARRISON AND BERNARD G. KEYES
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 12, 1972

The exchange reaction between CH_3^+ and D_2 leading to CH_2D^+ and CHD_2^+ is shown to proceed through a collision complex in which the hydrogens and deuteriums become equivalent. The rate coefficient for reaction of CH_3^+ with D_2 is $6.1 \pm 0.1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}.

On démontre que la réaction d'échange entre CH_3^+ et D_2 conduisant à CH_2D^+ et CHD_2^+ procède par l'intermédiaire d'un complexe de collision dans lequel les hydrogènes et les deutériums deviennent équivalents. Le coefficient de vitesse pour la réaction de CH_3^+ avec D_2 est de $6.1 \pm 0.1 \times 10^{-10}$ cm^3 molécule^{-1} s^{-1}. [Traduit par le journal]

Can. J. Chem., 51, 1265 (1973)

Two recent ion cyclotron resonance (i.c.r.) studies (1, 2) of isotopic methane–hydrogen systems have shown conclusively that the reaction between methyl ions and D_2 is responsible for at least part of the isotopic exchange observed when methane–deuterium mixture are subjected to high energy irradiation (3). However in the $CH_4(CD_4) - D_2(H_2)$ systems studied a number of other reactions occur which produce the various deuterated methyl ions and consequently these i.c.r. studies have not provided much detail concerning the exchange reaction nor have they established the rate coefficient for the reaction.

In connection with other studies we have examined the reaction of CH_3^+, produced by electron impact ionization of CH_3Cl, with D_2 by the pressure variation technique. This system has proven to be much simpler and permits a more detailed study of the exchange reaction.

The mass spectrometer and experimental techniques employed have been described previously (4, 5). Runs were carried out varying the D_2 pressure at a constant CH_3Cl pressure of 1 μ and repeller fields corresponding to ~1.1 eV ion exit energy. Nominal ionizing electron energies of 16.0 and 17.0 eV were employed, giving D_2^+/CH_3^+ ratios at 1 μ pressure of each component of 0.036 and 0.16, respectively. Identical results were obtained at the two electron energies indicating that reactions originating with D_2^+ did not play a significant role.

Typical results obtained at 16.0 eV electron energy are shown in Fig. 1 as a plot of the relative abundance of the $C(H,D)_3$ ions (% total methyl ions) *vs.* the D_2 pressure. The sequential conversion of CH_3^+ to CD_3^+ by reactions 1 to 3 is clearly established.

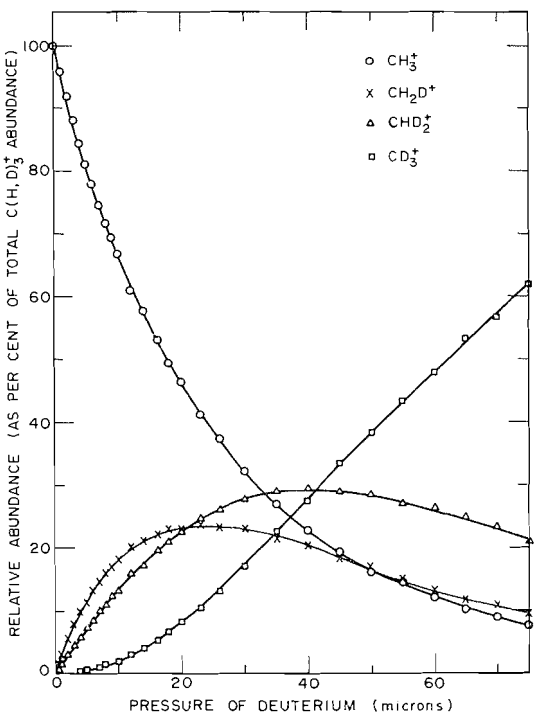

FIG. 1. Normalized $C(H,D)_3^+$ intensities as a function of D_2 pressure.

[1*a*] $CH_3^+ + D_2 \rightarrow CH_2D^+ + HD$

[1*b*] $\rightarrow CHD_2^+ + H_2$

[2*a*] $CH_2D^+ + D_2 \rightarrow CHD_2^+ + HD$

For personal use only.

At low D_2 pressures (<2 μ), before any CD_3^+ was observed, the ratio CH_2D^+/CHD_2^+ was found to be 2.0 ± 0.4. This value is in excellent agreement with the ratio of 2.0 predicted if the hydrogens and deuteriums in a $CH_3D_2^+$ collision complex become equivalent. This provides strong evidence that a collision complex is formed which has a lifetime sufficient for equilibration of the hydrogens and deuteriums to occur. Presumably the complex has the protonated methane structure which has long been known from ion–molecule reactions (6, 7).

From the semi-logarithmic plot of the normalized CH_3^+ intensity as a function of the D_2 pressure we obtain $k = 5.5 \pm 0.1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. Since the loss of H_2 and HD from the $CH_3D_2^+$ collision complex is statistical, we can assume that ~10% of the complexes will lose D_2 to regenerate CH_3^+. Correcting for this experimentally unobservable reaction, we derive a rate coefficient of 6.1×10^{-10} cm^3 molecule^{-1} s^{-1} for the reaction of CH_3^+ with D_2. This value is approximately one-half the collision rate coefficient of 1.2×10^{-9} cm^3 molecule^{-1} s^{-1} calculated using the ion-induced dipole model (8) indicating that a significant fraction of the collisions do not lead to a complex which survives for a time long enough for isotopic exchange to occur. The present experimental rate coefficient is considerably higher than the value $k_1 = 1.7 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} reported some years ago (9). However this earlier value was obtained from studies of CH_4–D_2 mixtures and recent work has shown that in these mixtures many reactions occur. It is possible that the earlier work is in error because of unrecognized reactions.

Regiospecificity and Stereoselectivity in the Photodimerization of 2,3-Dihydro-2,6-dimethyl-4-pyrone[1]

PETER YATES AND DONALD J. MACGREGOR
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario
Received October 6, 1972

Ultraviolet irradiation of 2,3-dihydro-2,6-dimethyl-4-pyrone in aqueous solution leads to the regiospecific and stereoselective formation of three *cis–anti–cis* photodimers of the cyclobutane type, *i.e.*, octahydro-2,7-8*a*,8*b*-tetramethylcyclobuta[1,2-*b*:4,3-*b*']dipyran-4,5-diones, whose structures have been established by chemical and spectroscopic methods, including studies of nuclear Overhauser effects in the proton magnetic spectrum of one of them. The dimers undergo photointerconversion, and it is proposed that this process involves photoreversion to monomer and that the reversibility of the dimerization reaction may be a factor in determining the regiochemistry and stereochemistry of the photodimers. A bisdehydro product prepared from the dimers of the dihydropyrone has been shown to undergo photocleavage to 2,6-dimethyl-4-pyrone, and it is proposed that reversibility may also be a factor affecting the course of the photodimerization of this pyrone.

Si l'on irradie la dihydro-2,3 diméthyl-2,6 pyrone-4 avec de l'ultraviolet en phase aqueuse, on observe la formation régiospécifique et stéréosélective de trois photodimères *cis–anti–cis* du type cyclobutane *i.e* octahydro tétraméthyl-2,7,8*a*, 8*b* cyclobutadipyranne-[1,2-*b*:4,3-*b*'] diones-4,5. Ces structures ont été élucidées à l'aide de méthodes chimiques et spectroscopiques qui incluent des études de l'effet Overhauser nucléaire dans le spectre de résonance magnétique nucléaire du proton pour l'une de ces structures. Les dimères subissent une photointerconversion dont le processus semble impliquer une photoréversion au monomère et que la réversibilité de la dimérisation peut être un facteur déterminant dans la régiochimie et dans la stéréochimie des photodimères. Un produit bisdehydro préparé à partir de dimères de la dihydropyrone semble subir un photoclivage pour donner la diméthyl-2,6 pyrone-4; il est proposé que la réversibilité peut aussi être un facteur influencant le processus de photodimérisation de cette pyrone.

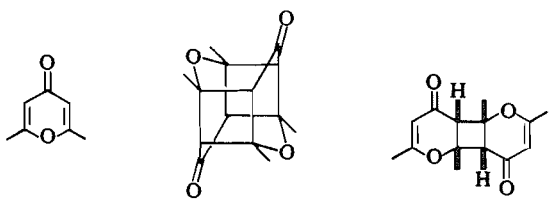
Can. J. Chem., **51**, 1267 (1973)

Introduction

The photodimerization of 2,6-dimethyl-4-pyrone (**1**) in the solid state and in solution has been found to give the cage compound **2** (2); an analogous photodimer is formed from 2,6-diethyl-4-pyrone when irradiated as the neat liquid or in solution (3). The formation of **2** from **1** must proceed via the intermediate formation of the head-to-tail *cis–syn–cis seco*-dimer **3** or by a concerted process involving the corresponding orientation of the monomer units. Compound **3** was prepared by pyrolysis of **2** and shown to undergo facile photocyclization to **2**.



1 **2** **3**

[1]A preliminary report on part of this work has appeared (1).

The apparent regiospecific and stereospecific formation of **2** was of considerable interest in that it contrasted with the photodimerization of 2-cyclohexenones, which either give mixtures of regioisomers or stereoisomers (*e.g.*, 2-cyclohexenone (4), 3-methyl-2-cyclohexenone (5), piperitone (6), isophorone (7)), or proceed regiospecifically and stereospecifically to give *cis–anti–cis* products (*e.g.*, 3-phenyl-2-cyclohexenone (8)). Since **1** differs from 2-cyclohexenones both in the presence of the annular oxygen atom and of a second ethylenic bond, it was considered to be of importance to determine whether the unusual course of the photodimerization of the pyrone could be attributed to one of these structural features individually. To this end, the photodimerization of 2,3-dihydro-2,6-dimethyl-4-pyrone (**4**) has been investigated.

Preparation of 2,3-Dihydro-2,6-dimethyl-4-pyrone and Determination of the Structure of its Photodimers

The dihydropyrone **4** was prepared by hydrogenation of the pyrone **1** over 10% pal-

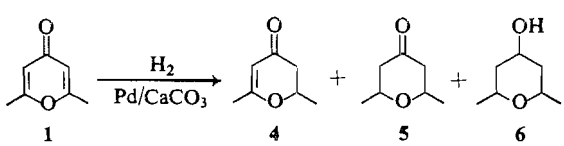
ladium – calcium carbonate (9, 10) (see Scheme 1); this gave the tetrahydropyranol **6**[2] in addition to **4** and the tetrahydropyrone **5** (9). Most of the **6** could be removed from the product mixture by extraction of its chloroform solution with 6 *N* hydrochloric acid; fractional distillation then gave **4** in 10–12% yield, contaminated with 1–10% of **6**, which has the same boiling point; the latter could be removed by chromatography on alumina.[3] The u.v. spectrum of **4** showed λ_{max} (EtOH) 263 nm (ε 14 000); while the position of this maximum corresponds with that



SCHEME 1

[2]This is most probably identical with the product obtained earlier (9) by hydrogenation of **1** over Raney nickel.

[3]It was shown that the presence of **6** did not affect the photochemistry of **4**, and thus the photodimers of **4** could be prepared from samples of **4** that had not been chromatographed.

observed by de Vrieze (9), its intensity is twice that previously reported, and it appears most probable that the product previously obtained in 25% yield was only 50% pure.[4]

Irradiation of a 12% aqueous solution of **4** under nitrogen in Pyrex with a Hanovia 450 W medium pressure lamp for 4 weeks led to the deposition of a crystalline mixture of photodimers. An additional amount of this mixture could be obtained by extraction of the aqueous solution with chloroform; the total yield was 97%. The p.m.r. spectra of the product mixtures in benzene or pyridine (but not in deuteriochloroform) showed that they were composed of three closely related compounds and provided an analytical method for following the difficult fractionation of the product mixture (*cf.* Table 1).

Crystallization of this mixture from polar solvents gave dimer **A**, m.p. 163–164°, and an

[4]An alternative method of formation of **4** by acid treatment of 5,6-dihydrodehydroacetic acid (11) gave a product with λ_{max} (EtOH) 263 nm (ε 10 500); exploratory experiments indicated that the yield of pure **4**, based on dehydroacetic acid, obtained by this route was *ca.* 5%.

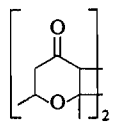
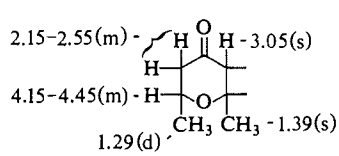
*Spectra of a 1 : 2.5 : 6.5 mixture of **A**, **B**, and **C**.

eutectic mixture of dimers **A** and **B**, m.p. 130–133°, in a 1:4 ratio. Repeated crystallization of this mixture from hexane gave dimer **B**, m.p. 133–134°. From the combined mother liquors was obtained a crystalline mixture of **A**, **B**, and a third product, dimer **C**. The last was not isolated in pure form, but the mixture was enriched in **C** by countercurrent distribution between water and cyclohexane to give a mixture of **A**, **B**, and **C** in the ratio of 1:2.5:6.5. The ratio of these dimers in the original reaction product mixture was *ca.* 9:15:1.

The gross structure of **A** can be assigned on the basis of its elemental composition, molecular weight, and spectra as a cyclobutane type dimer, **7**. Its i.r. and u.v. spectra (Table 2) are in accord



7

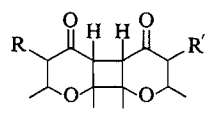


8

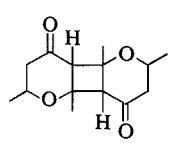
with the presence of two carbonyl groups in six-membered rings (*cf.* the cyclobutane-type photodimers of piperitone, whose u.v. spectra show maxima at 302 nm (ε 85) (6)). Its p.m.r. spectrum can readily be interpreted, as shown in **8**, if each of the five types of protons associated with one six-membered ring are chemically equivalent to the corresponding types of protons associated with the other six-membered ring. The p.m.r. spectrum of **A** excludes the possibility that this dimer is of the oxetane type (12).

The relationship of the spectra of **B** to those of **A** shows that it also has the gross structure **7**; its p.m.r. spectrum reveals that in this case the environment of the five types of protons associated with one six-membered ring is different from that of the corresponding types of proton associated with the other six-membered ring. Although **C** was not obtained pure, the spectra of a mixture of **A**, **B**, and **C** containing 70% of **C** showed that it also has the gross structure **7** and that it resembles **A** in having five types of chemically equivalent protons.

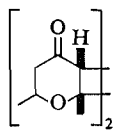
The conclusion that **A**, **B**, and **C** all have the gross structure **7** leads to the formulation of each of them as one of the regioisomers **9** or **10**. In the case of **B**, the head-to-head structure **9** can be chosen immediately since the coupling constant, $J = 6$ Hz, of its cyclobutyl protons shows that these must be adjacent (13). In the case of **A** and **C**, because of the chemical equivalence of the cyclobutyl protons, a direct choice between **9** and **10** cannot be made. However, examination of the low field ^{13}C—H satellite of the cyclobutyl proton signal in the 100 MHz p.m.r. spectrum of **A** showed it to be a doublet, $J = 7$ Hz, demonstrating that **A** also has structure **9** (14). This was confirmed by the preparation of the monobromo derivative, **11**, which was not obtained pure, but whose p.m.r. spectrum clearly showed that the cyclobutyl protons have a coupling constant, $J = 7$ Hz, characteristic of vicinal cyclobutyl protons. Dimer **C** was also shown to have structure **9** by its interrelation with **A** and **B** (*vide infra*).



9 R = R′ = H
11 R = Br; R′ = H
15 R = R′ = Br



10

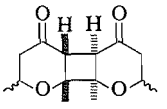


12

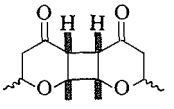
That both ring fusions in **A**, **B**, and **C** are *cis*, as in **12**, was shown by the fact that individual treatment of **A**, **B**, and a mixture of **A**, **B**, and **C** with boiling pyridine caused no change in these compounds as shown by their p.m.r. spectra (15). This was confirmed by the observation that chromatography on alumina of a mixture of **A** and **B** or the heating of such a mixture at 200° for 1 h led to no change of its p.m.r. spectrum (15). The possibility that one or both of the ring fusions is *trans*, and that conversion to the *cis* fusion does not occur because of failure of the adjacent carbonyl group(s) to enolize,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was excluded by the demonstration that treatment of **A** with boiling 10% D_2O – pyridine led to the exchange of six deuterium for hydrogen atoms. The p.m.r. spectrum of the hexadeutero derivative (see Experimental) confirmed the assignments made previously in the p.m.r. spectrum of **A**. The three dimers must therefore have stereostructure **13** or **14**.

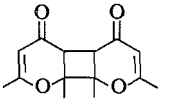


13

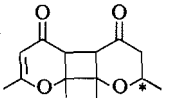


14

Distinction between the *anti* structure **13** and the *syn* structure **14** cannot be made directly on the basis of p.m.r. spectroscopy because of the similarity of the coupling constants between *cis* and *trans* vicinal cyclobutyl protons (13). The choice was made on the following basis. Bromination of **A** with two molar equivalents of bromine gave a dibromo derivative **15**, which on dehydrobromination with boiling pyridine gave **16**; compound **16** could also be obtained directly from **A** by treatment with *N*-bromosuccinimide in carbon tetrachloride. The gross structure of the dibromo compound **15** followed from the relationship of its spectra (see Experimental) to those of **A**; that of the dehydrobromination product **16** was assigned on the basis of a comparison of its spectra with those of **3**, the *seco*-photodimer of **1** (Table 3). Reaction of **B** with *N*-bromosuccinimide under the same conditions also gave **16**, confirming that **A** and **B** are both in the head-to-head series.



16



17

The reaction of **A** and **B** with *N*-bromosuccinimide gave in addition to the common bisdehydro product **16** an individual monodehydro side product in each case; these were not fully characterized, but their spectra showed that they are stereoisomeric forms of **17**. Since a single bisdehydro product is formed from both **A** and **B**, the stereoisomers of **17** must differ in relative configuration only at the asterisked carbon atom.

The bisdehydro product **16** from **A** and **B** will have the stereostructure **18** or **19** depending on whether **A** and **B** have the *anti* or *syn* structure, **13** or **14**. U.v. irradiation of the *seco*-photodimer **3**, which has perforce a *syn* disposition of the six-membered rings with respect to the cyclobutane ring, analogous to **19**, has been shown to result in facile reclosure to the cage photodimer **2** (2). Compound **16** was therefore subjected to irradiation to determine whether it underwent a corresponding ring closure. The formation of a cycloaddition reaction product analogous to **2** was not observed, the only product obtained was 2,6-dimethyl-4-pyrone (**1**), formed by fission of the cyclobutane ring.[5] It is therefore concluded that the bisdehydro product from **A** and **B** has the *anti* structure **18** and that **A** and **B** have the *anti* structure **13**. The possibility that the bisdehydro product has the *syn* structure **19**, but that ring closure does not occur because of unfavorable dipolar interaction between the carbonyl groups in the transition state, is contraindicated by the fact that analogous interactions do not inhibit the formation of cage photodimers from *p*-quinones (12). The assignment of the *anti* structure in the case of **B** has been confirmed by a study of nuclear Overhauser effects (n.O.e.) in its p.m.r. spectrum (*vide infra*).

The assignment of structure **13** to **A** and **B** restricts their full stereostructures to **20**, **21**, or **22** (or their respective enantiomorphs). Only in

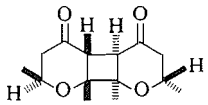
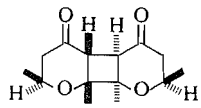
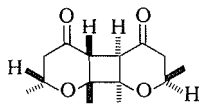
the case of **21** is the environment of the five types of protons associated with one six-membered ring different from that of the corresponding types of protons associated with the other six-membered ring. This permits the immediate assignment of this structure to **B**.



20

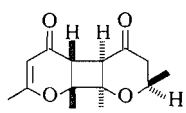


21

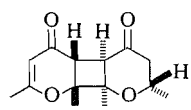


22

Hydrogenation of **18** over palladium–calcium carbonate gave a crystalline product mixture whose p.m.r. spectra in deuteriochloroform and in benzene showed that it consists of **C** and a dihydro product **17**, identical with the dehydro product obtained previously from **B**. The presence of **A** or **B** could not be detected. Examination of molecular models of **18** shows that the less hindered side of each of the six-membered rings is the side remote from the other six-membered ring. Thus hydrogenation is expected to lead to **22**, and this structure can be assigned to **C**; likewise, the dihydro product from **18** can be formulated as **23**. Finally, structure **20** can be assigned to **A** by exclusion of **21** and **22**. The last assignment leads to the assignment of structure **24** to the dehydro product from **A** (**17**); the dehydro product from **B** is then **23**, identical with dihydro **18** as observed.

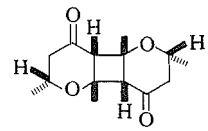


23



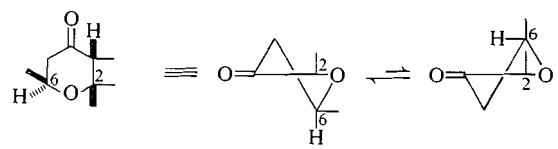
24

The hydrogenation of the *seco*-photodimer **3** was examined as a model for the hydrogenation of **18**. A single tetrahydro product was obtained. Its structure is considered to be **25**, since molecular models of **3** indicate that in this case, too, hydrogen addition will occur from the side of each six-membered ring remote from the other six-membered ring. As expected, the p.m.r. spectrum of this product shows signals attributable to five sets of equivalent protons.

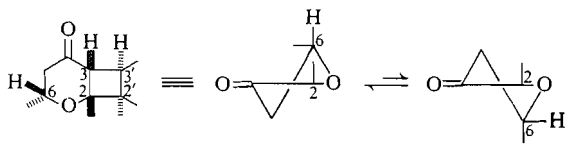


25

A consideration of the conformations of **A** (**20**), **B** (**21**), **C** (**22**) and their dehydro products, **23** and **24**, corroborates the conclusions reached above in respect to the relative configurations of the carbon atoms bearing methyl groups. The cyclobutane rings of these compounds may have planar or puckered conformations (16); however, this does not affect the gross conformations of the six-membered rings, which in either case may be expected to adopt half-chair conformations analogous to the stable conformation of cyclohexene.[6] Methyl groups at C-6 that are *cis* to a methyl group at C-2 (*cf.* **26**) will lead to a strong preference for the conformation **26***a* in which they are equatorial because of the 1,3-diaxial interaction with the C-2 methyl group in the alternative conformation **26***b* (see Scheme 2). The same preference is expected for methyl groups at C-6 that are *trans* to a methyl group at C-2 (*cf.* **27**) in the case of the head-to-head *anti* dimers and their derivatives, because of severe interaction of a C-6 axial methyl group with the C-2′ methyl group of the other six-membered ring, *i.e.*, conformation **27***a* is strongly favored over **27***b*. Thus, the preferred conformations of the three head-to-head *anti*



26 **26***a* **26***b*



27 **27***a* **27***b*

SCHEME 2

[6]The possibility exists that the six-membered rings may exist in boat conformations, which in the present instance are anticipated to have only slightly higher energies than the half-chair conformations; however, the following considerations are applicable to both types of conformation.

TABLE 4. Chemical shifts of C-6(6′) protons in the p.m.r. spectra of **A**, **B** and **C** and related compounds

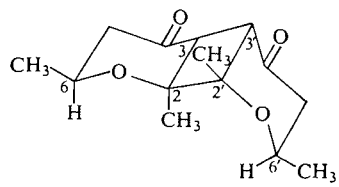
	δ (C_6H_6)*	
A (**20**)	3.8–4.1	—
B (**21**)	3.8–4.2	3.4–3.7
C (**22**)	—	3.4–3.8
Dehydro-**A** (**24**)	3.8–4.1	—
Dehydro-**B** (**23**)	—	3.3–3.8

*Parallel results were obtained in deuteriochloroform.

dimers **A**, **B**, and **C** will correspond to the three possible different combinations of part-structures **26***a* and **27***a*.

The chemical shift values for the C-6(6′) methine protons for compounds **A**, **B**, **C**, dehydro-**A**, and dehydro-**B** fall into two distinct ranges (Table 4). This can be interpreted as due to a shielding of the C-6(6′) proton by the carbon–carbon bond (17) of the methyl group at C-2(2′) in part structure **27***a*, an effect absent in part structure **26***a*. In these terms **A** can be assigned a structure with two part-structures **26***a*, *i.e.*, structure **20** in agreement with the earlier conclusions. The structures previously assigned to **B**, **C**, dehydro-**A**, and dehydro-**B** are similarly corroborated.

The *anti* stereochemistry assigned to the three dimers was also substantiated by studies of n.O.e.'s in the p.m.r. spectra of **B** (**28** = **21**). The maximum n.O.e. enhancements observed on irradiation of the C-2 and -2′ methyl signals are shown in Table 5. The observation of a n.O.e. in only one cyclobutyl proton (H-3(3′)) signal on saturation of an individual CH_3-2(2′) group is consistent with the *anti* stereochemistry: if **B** were *syn*, individual saturation of these methyl signals should give n.O.e.'s in both of the cyclobutyl proton signals. Furthermore, the n.O.e.'s observed for both methine protons at C-6(6′) on irradiation of one but not the other of the CH_3-2(2′) proton signals is in accord only with the assignment to **B** of the structure and stereochemistry depicted in **28**. It may be noted that these n.O.e.'s are the source of the H-3(3′) signal assignments given in Table 5[7]; the assignments of the H-6(6′) signals follow from the conformational analysis above.



28

It remains to record a further important experimental observation concerning the three photodimers of **4**, *viz.* their photointerconversion. Individual irradiations (Pyrex filter) of dimers **A** and **B** in solution led to mixtures of all three dimers; similar irradiation of a dimer mixture enriched in dimer **C** led to a change in the composition of the dimer mixture (Table 6).

TABLE 5. N.O.e. in the p.m.r. spectrum of **B** (**28**)

Signal irradiated (δ)	Signal integrated (δ)	Maximum n.O.e. (%)
1.16 (Me-2)	2.85 (H-3′)	0 ± 2
	3.04 (H-3)	8 ± 1
	3.55 (H-6)	10 ± 2
	3.95 (H-6′)	9 ± 1
1.29 (Me-2′)	2.85 (H-3′)	8 ± 1
	3.04 (H-3)	0 ± 2
	3.55 (H-6)	0 ± 2
	3.95 (H-6′)	0 ± 2

Discussion

Considerable attention has been paid recently to the photodimerization of α,β-unsaturated carbonyl compounds and to the related photoaddition of such compounds to olefins (18), but the interplay of the factors that influence the regiochemistry and stereochemistry of these reactions remains far from elucidation. Although the present work has not provided a solution to this general problem, it has led to results

TABLE 6. Photochemical interconversion of dimers **A**, **B**, and **C**

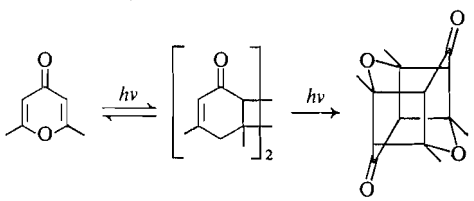
[7]The measurement of n.O.e.'s in conjunction with monosubstitution of one of the terminal rings promises to be a general method for distinguishing between *syn* and *anti* dimers of the cyclobutane type.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that should contribute to an eventual clarification.

The investigation had its inception in our interest in the photodimerization of 2,6-dimethyl-4-pyrone (**1**), which gives the cage compound **2**, an unusual *cis–syn–cis* head-to-tail product (see Introduction), and we discuss this process before proceeding to discuss the photodimerization of 2,3-dihydro-2,6-dimethyl-4-pyrone (**4**). The work has shown that it is the second ethylenic bond of **1** in relation to **4** that is the structural factor associated with the unusual stereochemistry of this dimerization. It has also revealed that photoreversibility may well play a crucial role, as suggested earlier (2). This conclusion stems from the observation that the bisdehydrodimer **18** of **4** undergoes photoreversion to the monomeric pyrone **1**. Thus it can be proposed that irradiation of **1** leads initially to a mixture of regioisomeric and stereoisomeric dimers of type **29**, of which only the *cis–syn–cis* head-to-tail compound undergoes photocycloaddition to give the cage compound **2**, which precipitates from solution, and that photoreversion of the other dimers of type **29** followed by redimerization leads to eventual formation of **2** as essentially the only photodimeric product. This view receives considerable support from recent observations of Hammond and MacGregor (19), who have found that irradiation of the pyrone **1** in acetonitrile leads to initial formation of two dimers of type **29**, *viz.* **3** and **18**, in addition to the cage dimer **2** (see Scheme 3).[8]



1 **29** **2**

SCHEME 3

The dimerization of **4** proceeds regiospecifically in a variety of solvents to give head-to-head dimers only. Further, although the reaction is stereoselective rather than stereospecific in that three stereoisomers are formed, these isomers differ only in the relative configurations of the C-6(6′) carbon atoms and the reaction is stereospecific with respect to cyclobutane ring formation, giving only *cis–anti–cis* dimers. This combined regiospecificity and stereospecificity is in marked contrast to the cases of the photodimerization of 2-cyclopentenone, 2-cyclohexenone, and alkyl-2-cyclohexenones (4–7, 20). It finds analogy, however, in the cases of 3-phenyl-2-cyclohexenone and 3-*p*-anisyl-2-cyclohexenone, which give only *cis–anti–cis* head-to-head photodimers (8, 21). It is therefore important to consider what features these 3-aryl-2-cyclohexenones possess in common with **4** that distinguish them from 2-cyclopentenone, 2-cyclohexenone, and alkyl-2-cyclohexenones. In terms of factors that have previously been adumbrated (18) as having importance in determining the course of photodimerization reactions, the possibility exists that the substitution of an aryl group or an ether oxygen atom at the β carbon of the α,β-unsaturated carbonyl system leads to a change in the nature of the excited state involved in the dimerization or that these substituents exert their influence by virtue of their stabilizing effect on an intermediate complex or diradical.

More intriguing is a third factor, *viz.*, again the reversibility of the photodimerization reaction (21). The photodimerization of the two 3-aryl-2-cyclohexenones has been shown to be reversible (8, 21), while, as far as we are aware, a similar observation has not been made in the cases of 2-cyclopentenone, 2-cyclohexenone, or alkyl-2-cyclohexenones. We now find that the photodimerization of **4** also is reversible. This conclusion stems from the observation of the photointerconversion of the photodimers of **4**, which can readily be interpreted as involving reversion to the monomer followed by redimerization.[9] Although we cannot offer a rationale to relate reversibility with the formation of *cis–anti–cis* head-to-head dimers[10] nor can we rule

[8]A very minor product from this reaction is considered to be the head-to-head analog of **2**; it cannot be excluded that traces of this compound accompanied **2** in the final reaction product in our original photodimerization experiments.

[9]Other routes for the photointerconversion could involve cleavage and reformation of $C_{6(6')}$—O bonds or exchange of monomer units among dimer molecules, initiated by a small amount of monomer. We know of no analogies for these processes and consider them to be considerably less probable than a process involving reversion to monomer and recombination.

[10]An interpretation in terms of preferential product precipitation cannot be made in the case of **4**, as was made for **1**, since no precipitation occurred during the photointerconversion of its dimers in solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

out the possibility that the other photodimerization reactions may in fact also be reversible,[11] we consider that the present results make consideration of this factor important in the eventual formulation of any comprehensive mechanistic scheme.

Finally, we refer to the composition of the mixture of stereoisomeric dimers obtained from **4**, which, as emphasized previously, differ only in the relative configurations at the C-6(6′) carbon atoms. Random regiospecific dimerization of racemic **4** to give *cis*-fused products would lead to a mixture of racemic dimers **A**, **B**, and **C** in a 1:2:1 ratio. The observed ratio from the preparative experiments in water was 9:15:1. This distribution must reflect the interplay of differing rates of formation, differing rates of interconversion, and differing solubilities of the dimers. Although the last factor was inoperative in the photointerconversion studies, where no precipitation occurred, another factor now intervened, the occurrence of side-reactions, and thus no quantitative conclusions can be drawn from the data in Table 6. It is of interest to note that dimerization of a single enantiomorph of **4** should lead to a mixture of single enantiomorphs of dimers **A** and **C**, but no dimer **B**.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover apparatus and are uncorrected. Unless otherwise stated, i.r. spectra were recorded in chloroform, u.v. spectra were recorded in 95% ethanol, and p.m.r. spectra were recorded at 60 MHz in deuteriochloroform containing tetramethylsilane (TMS) as internal reference. Mass spectra were recorded at 70 e.V. with an A.E.I. MS-9 spectrometer. Preparative t.l.c. was carried out on 20 × 20 cm glass plates coated with a 0.5 mm thickness of fluorescent silica gel G. Solutions of products in organic solvents were dried over anhydrous magnesium sulfate before removal of the solvent with a rotatory evaporator in conjunction with a water aspirator.

2,3-Dihydro-2,6-dimethyl-4-pyrone (4)

A modification of the method of de Vrieze (9) and Yates and Hand (10) was employed. 2,6-Dimethyl-4-pyrone (**1**) (50 g, 0.40 mol) in 95% ethanol (250 ml) was hydrogenated over 10% palladium – calcium carbonate (Engelhard Type 1, 13 g) at an initial pressure of 28 p.s.i. in a calibrated Parr apparatus; the hydrogen uptake was 0.42 mol during 90 min. The pyrophoric catalyst was removed by filtration (sintered glass), and the combined filtrates from four successive hydrogenations were concentrated to *ca.* 125 ml and cooled to give crude **1** (72 g, 36%), which was collected by filtration and washed with a small amount of petroleum ether (b.p. 90–100°). Analytical g.l.p.c. (6 ft × 1/4 in. 10% DIDP – Chromosorb P, 60 ml He/min, 150°) of the combined filtrate and washings showed the presence of **4**, **5**, and **6**. These were concentrated to an oil which was dissolved in chloroform (100 ml) and washed in turn with 6 *N* hydrochloric acid (2 × 50 ml) and water (4 × 50 ml); removal of the chloroform gave a brown oil (52 g). Fractional distillation (10 mm) of the oil gave crude tetrahydropyrone **5** (b.p. 25–70°; 23 g), a 1:1 mixture of **4** and **5** (b.p. 70–83°; 5.3 g), and **4** (b.p. 83–85°; 20 g (10%)) contaminated with 1–10% of the tetrahydropyranol **6**. The dihydropyrone (**4**) had λ_{max} 6.04 and 6.21 μ; λ_{max} 263 nm (log ε 4.15) (*cf.* de Vrieze (9) λ_{max} 263 nm (log ε 3.84)); δ 1.45 (d, J = 7 Hz, 3H), 1.98 (s, 3H), 2.1–2.5 (m, 2H), 4.5 (m, 1H), 5.28 (s, 1H); *m/e* (relative abundance) 126 (51), 111 (4), 85 (99), 84 (10), 69 (43), 43 (100), 42 (19), 41 (18), 39 (19). The dihydropyrone decomposed slowly on standing, but could be stored for long periods in the frozen state at −20°.

Redistillation of the first fraction above gave pure **5**, b.p. 80–82° (30 mm); $\lambda_{max}(CCl_4)$ 5.81 μ; δ (CCl_4) 1.27 (d, J = 6 Hz, 6H), 2.0–2.2 (m, 4H), 3.6 (m, 2H).

A small amount of tetrahydropyranol **6** was isolated from the crude hydrogenation product by g.l.p.c. and had λ_{max} (CCl_4) 2.75 (m), 2.8–3.0 (w) μ, and no bands in the carbonyl region. In other experiments in which the extraction with hydrochloric acid was omitted, the distillates with b.p. > 70° (10 mm) were chromatographed on alumina (B.D.H. chromatographic grade). Elution with chloroform gave a mixture of **4** and **5**; elution with acetone gave pure **6**, b.p. 102–103° (27 mm); $\lambda_{max}(CCl_4)$ as above; δ (CCl_4) 1.15 (d, J = 6 Hz, 6H), 1.8 (m, 4H), 3.5 (m, 3H), 4.08 (s, 1H).

Irradiation of 2,3-Dihydro-2,6-dimethyl-4-pyrone (4): Preparation of Dimers A (20), B (21), and C (22)

A solution of **4** (18.83 g, 96% pure by g.l.p.c.) in water (150 ml) was purged with a slow stream of nitrogen for 30 min in a Pyrex tube; the stoppered tube was placed 3 in. from the cooling well of a 450 W medium-pressure Hanovia lamp and irradiated for 2 weeks. The precipitated crystalline product (9.15 g) was collected, and the filtrate was irradiated as above to give a second crystalline crop (4.48 g). Extraction of the filtrate with chloroform and evaporation of the extracts gave a resinous yellow solid (4.50 g) which showed in its p.m.r. spectrum in addition to bands attributable to dimers of **4** weak bands due to the tetrahydropyranol **6**. P.m.r. analysis of the total product (18.13 g; 96% yield based on 100% pure **4**) in pyridine showed the presence of dimer **A** (**20**) (36%), dimer **B** (**21**) (60%), and dimer **C** (**22**) (4%). Preliminary qualitative experiments showed that similar product mixtures were obtained by irradiation of neat **4** or its ethanol, benzene, cyclohexane, and aqueous solutions in quartz (254 nm).

The total photoproduct was crystallized from ethanol to give a white crystalline fraction, m.p. 144–150°. Six recrystallizations of this material from polar solvents (ethanol, isopropyl alcohol, 50% aqueous isopropyl

[11]It may be noted that the asymmetric centers at C-6(6′) in the dimers of **4** serve to make evident the photoreversion of these dimers; it is possible that in cases lacking such a marker photoreversion followed by redimerization has gone undetected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

alcohol) gave dimer **A** (**20**),[12] m.p. 163–164°; molecular weight 244 (osmometric determination in benzene; calcd. 252); *m/e* 127 (56), 126 (26), 85 (100), 84 (8), 82 (8), 69 (13), 56 (4), 43 (38), 42 (16), 41 (8). The p.m.r. spectrum (100 MHz) of **A** in deuteriochloroform showed a doublet (J = 7 Hz) for the low-field satellite of the cyclobutyl protons ($J_{C^{13}-H}$ = 126 Hz).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.67; H, 7.94. Found: C, 66.40; H, 7.94.

Recrystallization (ethanol) of the combined residues obtained from the above mother liquors gave a large fraction, m.p. 130–133°. P.m.r. analysis (pyridine) of this material showed it to be a 1:4 mixture of dimers **A** and ***B***; subsequent construction of an m.p. *vs.* composition diagram for **A** and ***B*** showed a single eutectic point at 20% **A**. Attempts to fractionate this mixture by column chromatography on alumina or silica gel, by analytical t.l.c. on silica gel G or alumina, by preparative t.l.c. (silica gel G), by analytical g.l.p.c. (10% SE-30/Diatoport S, 180°; 10% Fluorosilicone – Diatoport S, temperature programmed from 175° at 3°/min), by zone refining, and by fractional sublimation were all unsuccessful.

Four recrystallizations of the eutectic mixture of dimers **A** and ***B*** (the first two from 100 vol/wt.) from hexane gave pure dimer ***B***[12] (**21**), m.p. 133–134°; *m/e* 127 (67), 126 (40), 85 (100), 84 (11), 82 (15), 69 (18), 56 (7), 43 (59), 42 (10), 41 (13).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.67; H, 7.94. Found: C, 66.93; H, 7.96.

A crystalline mixture (*ca.* 1 g) of dimers **A** (15%), **B** (50%), and **C** (35%), obtained from unsuccessful attempts to isolate dimer **C** by fractional crystallization of the lowest-melting fractions (m.p. *ca.* 115–123°), was dissolved in cyclohexane (100 ml) and subjected to 24 liquid–liquid extractions in a 10-funnel distribution train with 100 ml portions of cyclohexane and water as the stationary and mobile phases, respectively. Small amounts of crystalline material were obtained from all but the first aqueous fraction; the proportion of dimer *C* increased from 35% in the second fraction to 60% in the sixteenth fraction and remained at 60–65% in the next eight fractions. A fraction containing dimer **A** (10%), dimer **B** (25%), and dimer C (65%) was used to record spectra[12]; this fraction had *m/e* 127 (62), 126 (33), 85 (100), 84 (6), 82 (14), 69 (13), 56 (3), 43 (40), 42 (7), 41 (9).

Attempted Isomerization of the Photodimers

The eutectic mixture of dimers **A** and **B** (*ca.* 100 mg) was sealed in a Pyrex tube under a nitrogen atmosphere and heated for 1 h at 200°. No change was observed in the p.m.r. spectra of the mixture.

A solution of dimer *A* (55 mg) in dry pyridine (15 ml) was refluxed for 1 h under a nitrogen atmosphere; no change was observed in the p.m.r. spectra of the residue. Parallel results were obtained on reflux of pyridine solutions of dimer **B** and of a dimer C-enriched fraction of the mixture of photodimers.

Base-catalyzed Deuteriation of Dimer A

A solution of dimer **A** (50 mg) in deuterium oxide (2 ml) and dry pyridine (20 ml) was refluxed for 1 h under a nitrogen atmosphere; removal of the solvent gave a residue whose p.m.r. spectrum showed partial deuteration. This was treated overnight under the same conditions to give crystalline hexadeutero-**A**; λ_{max} 5.84 μ; δ 1.22 (d, J = 6 Hz, 6H), 1.39 (s, 6H), 4.34 (q, J = 6 Hz, 2H); *m/e* 130 (40), 129 (18), 86 (100), 70 (13), 56 (8), 44 (11), 43 (80), 42 (8), 41 (8), 40 (8).

Bromination of Dimer A

*(i) Formation of α-Bromo Ketone **11***

A stirred solution of dimer **A** (109 mg, 0.43 mmol) in chloroform (25 ml) was treated dropwise with a solution of bromine (32 mg, 0.20 mmol) in chloroform (10 ml) at a rate such that the reaction mixture became colorless before each new addition of bromine. The chloroform layer was washed with aqueous 5% sodium carbonate (15 ml) and evaporated to give a crystalline residue (124 mg), which was chromatographed (4% ethanol–benzene) on two t.l.c. plates to give dimer **A** (70 mg) and crude **11** as white crystals (45 mg). The major contaminant in the product was *ca.* 25% of dimer **A**. The crude ketone **11** had λ_{max} 5.82 μ; δ 1.31 (d, J = 6 Hz, 3H), 1.34 (d, J = 6 Hz, 3H), 1.43 (s, 3H), 1.51 (s, 3H), 2.31–2.45 (m, 2H), 3.07 (d, J = 5 Hz, 1H), 3.78 (d, J = 5 Hz, 1H), 4.08 (d, J = 2 Hz, 1H), 4.0–4.5 (m, 2H). It decomposed on standing.

*(ii) Preparation of α,α′-Dibromo Ketone **15***

A stirred solution of dimer **A** (75 mg, 0.30 mmol) in chloroform (3 ml) was treated as above with a solution of bromine (96 mg, 0.60 mmol) in chloroform (5 ml). The chloroform layer was washed with 5% aqueous sodium bicarbonate (10 ml) and evaporated. Recrystallization of the white crystalline residue (123 mg; *ca.* 90% pure by p.m.r. analysis) from hexane (12 ml) gave pure **15** as fine white needles, m.p. 168–170° (dec.); λ_{max} (CCl_4) 5.79 μ; λ_{max} 304 nm (log ε 2.20); δ 1.33 (d, J = 6 Hz, 6H), 1.53 (s, 6H), 3.80 (s, 2H), 4.05 (d, J = 2 Hz, 2H), 4.23 (q of d J_q = 6 Hz, J_d = 2 Hz, 2H); *m/e* 208 (10), 207 (5), 206 (10), 205 (5), 127 (13), 126 (20), 86 (100), 70 (20), 43 (54), 41 (26).

Anal. Calcd. for $C_{14}H_{18}Br_2O_4$: C, 40.99; H, 4.22; Br, 38.97. Found: C, 41.02; H, 4.47; Br. 39.15.

*Preparation of the Bis-enone **18***

*(i) By Dehydrobromination of **15***

Crude α,α′-dibromo ketone **15** (210 mg; *ca.* 90% pure by p.m.r. analysis) was dissolved in dry pyridine (40 ml), and the solution was refluxed with stirring in a nitrogen atmosphere for 5 h and then stirred overnight at ambient temperature. The dark red solution was diluted with ether (75 ml) and water (50 ml) and extracted with chloroform (3 × 10 ml). A black tar (129 mg) was obtained after prolonged drying of the residue from the chloroform extracts over concentrated sulfuric acid *in vacuo*. P.m.r. analysis of the tar showed the presence of the bis-enone **18** with *ca.* 15% of the monomeric pyrone **1** as the only major impurity; the latter was removed by chromatography on silica gel; elution with 2–4% ethanol–chloroform gave spectroscopically pure, but yellow, **18** (106 mg). This was purified by crystallizing it once from 70% aqueous isopropyl alcohol, followed by chromatography on silica gel. The column was developed by slowly changing the mobile phase from 20% chloroform–benzene to 15% benzene–chloroform; the colorless product was eluted with 10–0% benzene–chloroform. After one

[12]The p.m.r. spectra of this dimer are recorded in Table 1 and its u.v. and i.r. spectra in Table 2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

recrystallization from ethanol, **18** (22 mg, 17%) had m.p. 179–181°; *m/e* 248 (6), 163 (10), 125 (100), 124 (43), 96 (43), 95 (10), 80 (4), 69 (16), 53 (9), 43 (63).[13]

(ii) By Treatment of Dimer A with N-Bromosuccinimide

A mixture of *N*-bromosuccinimide (NBS; 144 mg, 0.81 mmol) and a solution of dimer **A** (102 mg, 0.41 mmol) in carbon tetrachloride (35 ml) was heated to boiling in a flask equipped with a pressure-equalizing addition funnel, a gas delivery tube, and a condenser. A slow stream of nitrogen was passed through the mixture until the first appearance of a pink coloration due to bromine (2–3 min after the commencement of boiling); nitrogen flow was then continued very briskly during the ensuing reaction to assist the rapid removal of bromine by codistillation with carbon tetrachloride. The volume was kept approximately constant by adding carbon tetrachloride from the addition funnel during the distillation (*ca.* 5 min). The rapid distillation cooled the reaction mixture, and the heating – rapid distillation process was continued until no further bromine evolution occurred on reheating the mixture to its boiling point. The precipitated succinimide was removed by filtration after refrigeration, and the yellowish crystalline residue obtained by removal of the solvent was fractionated by preparative t.l.c. on two plates (10% methanol – carbon tetrachloride). In order of increasing R_F values, five fractions were obtained and identified by i.r. spectroscopy: succinimide (8 mg); two mixtures of succinimide and the bis-enone **18** (19 and 4 mg); the enone **24** (47 mg); and dimer **A** (36 mg). The mixtures of succinimide and **18** were separated by extraction of their solutions in carbon tetrachloride with water or by chromatography on silica gel with 50–60% chloroform–benzene. After one recrystallization (−20°) from isopropyl alcohol, bis-enone **18**, m.p. 172–173°, spectroscopically identical with the product obtained in (*i*) above, was obtained.

The crude enone **24** obtained above had λ_{max} 5.83, 6.07, 6.23 μ; δ 1.32 (d, J = 6 Hz, 3H), 1.48 (s, 3H), 1.52 (s, 3H), 1.98 (s, 3H), 2.30–2.45 (m, 2H), 3.07 (d, J = 5 Hz, 1H), 3.17 (d, J = 5 Hz, 1H), 4.05–4.50 (m, 1H), 5.22 (s, 1H).

(iii) By Treatment of Dimer B with N-Bromosuccinimide

Several experiments similar to that described in (*ii*) above were performed with dimer **B**. After aqueous extraction of succinimide, the combined crude products were chromatographed as described in (*i*) above; elution with 0–5% ethanol–chloroform gave the bis-enone **18** (25 mg). One recrystallization (−20°) from ethanol gave an analytical sample, m.p. 181–182°, unchanged on recrystallization from ethanol and spectroscopically identical with the two samples of **18** prepared above. The product had mixed m.p. 179–181° with the product obtained in (*i*) above.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 67.75; H, 6.43.

Preparative t.l.c. of other reaction products of dimer **B** with NBS, as described in (*ii*) above, gave the crude enone **23**: λ_{max} 5.83, 6.04, 6.24 μ; δ 1.28 (d, J = 6 Hz, 3H), 1.38 (s, 3H), 1.47 (s, 3H), 2.02 (s, 3H), 2.32–2.47 (m, 2H), 2.92 (d, J = 5Hz, 1H), 3.15 (d, J = 5 Hz, 1H), 3.9–4.3 (m, 1H), 5.27 (s, 1H).

Acid-catalyzed Cleavage of Cage Photodimer 2: Preparation of the seco-Dimer 3

A suspension of the cage photodimer **2** (5.01 g) in a solution of 2 *N* hydrochloric acid (1.85 l) in methanol (2.5 l) was stirred for 2 days in a nitrogen atmosphere at room temperature. Unconsumed **2** (0.33 g) was removed by filtration, and the filtrate was neutralized with potassium carbonate and distilled (35°/15 mm) to remove the methanol. The concentrated aqueous solution was extracted with chloroform. Evaporation of the combined extracts left an orange paste (3.37 g) from which a white crystalline fraction (1.24 g) was obtained by trituration with ether. This material was chromatographed on silica gel (100 g); prolonged development of the column with chloroform (which was recycled), slowly displaced unconsumed **2** as a turbid band which was subsequently eluted with 0–2% acetone–chloroform. Continued elution of the column with 3–5% acetone–chloroform gave the *seco*-dimer **3** (0.96 g, 21%). One recrystallization from ethanol gave pure **3**, m.p. 223–224° (sealed capillary); *m/e* 248 (3), 126 (9), 125 (100), 124 (45), 96 (31), 80 (29), 79 (9), 69 (12), 43 (37), 39 (7).[13]

Photolysis of the Bis-enone 18

Spectroscopically pure bis-enone **18** (33 mg) dissolved in absolute ethanol (2.5 ml) in a tightly corked Pyrex semi-micro test tube was irradiated for 1 day with the 254 nm light source of a Rayonet Photochemical Reactor. After removal of the solvent, the residue was identified as crude **1** by its i.r., p.m.r., and mass spectra. In a control experiment under identical conditions, most of the *seco*-dimer **3** was converted to cage photodimer **2** in 6 h; a separate control irradiation of the pyrone **1** showed it to be photochemically unreactive under the above conditions for 2 days.

Catalytic Hydrogenation of Bis-enone 18: Formation of Dimer C

Analytically pure bis-enone **18** (28 mg) was dissolved in 95% ethanol (2.5 ml) and hydrogenated at atmospheric pressure in the presence of 10% palladium – calcium carbonate (*ca.* 5 mg) for 4 days.[14] Removal of the catalyst and solvent left a crystalline residue, whose p.m.r. spectra in deuteriochloroform and in benzene identified it as a *ca.* 2:1 mixture of dimer **C** and the enone **23**.

Catalytic Hydrogenation of seco-Dimer 3: Formation of 25

A solution of *seco*-dimer **3** (126 mg) in 95% ethanol (25 ml) containing a suspension of 10% palladium – calcium carbonate (14 mg) was hydrogenated at atmospheric pressure for 10 h. The crystalline residue was chromatographed on silica gel; elution with 25% benzene–chloroform gave a fraction (89 mg) which showed no bands due to **3** in its i.r. spectrum. Two recrystallizations of this product from petroleum ether (b.p. 90–100°) gave a sample, m.p. 113–115°, with a satisfactory microanalysis for **25**, but whose p.m.r. spectrum indicated the presence

[13]Other spectral data for this compound are given in Table 3.

[14]Hydrogenation of **3** on the same scale was also very slow.

of impurity; the major component had δ 1.26 (d, J = 6 Hz, 6H), 1.43 (s, 6H), 2.28–2.44 (m, 4H), 2.58 (s, 2H), 3.7–4.0 (m, 2H); *m/e* 127 (39), 126 (30), 111 (9), 85 (100), 69 (22), 55 (7), 44 (9), 43 (63), 42 (13), 41 (20).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.67; H, 7.94. Found: C, 66.92; H, 8.17.

Intramolecular Nuclear Overhauser Effect Measurements on Dimer B

Measurements were performed with a Varian HA-100 spectrometer operated in the frequency sweep mode at an r.f. attenuation of 20 dB. The saturating r.f. field was provided by a Muirhead-Wigan D-890-A decade oscillator. The instrument was tuned to maximum deflection of an A.C. voltmeter connected to the oscilloscope; in this way field stability could be monitored during the n.O.e. measurements. The effects cited in Table 5 were measured as percentage area increases obtained during irradiation of a given resonance at predetermined optimum external frequency, power level, and phase settings, compared with integrals obtained under identical conditions except for a 100 Hz offset in the position of the saturating field. All integrals were measured at a sweep rate of 2 Hz/s; the pen output was set to give integrals > 50 mm. The results quoted are the average of at least four separate determinations and are precise to at least ±2%.

The samples employed were filtered 5–6% solutions of dimer **B** in hexadeuteriobenzene containing 10% of benzene for a frequency lock signal. Oxygen was removed by passing oxygen-free nitrogen through the solutions (22). A 10% solution of β,β-dimethylacrylic acid in deuteriochloroform containing 10% TMS, prepared by the above method, gave an optimum n.O.e. of 15 ± 2%, in good agreement with the result of Anet and Bourn (23).

Irradiation of Dimers A, B, and C

Solutions of dimers **A**, **B**, and a fraction enriched in dimer C (*ca.* 50 mg each) in absolute ethanol (3 ml) were irradiated simultaneously in Pyrex tubes with the 300 nm source of the Rayonet apparatus for 1 day. Analysis (p.m.r.) of the residues obtained after evaporation of the solvent showed that interconversion of the dimers had occurred concomitant with the formation of an oily, uncharacterized product. The approximate compositions of the dimeric fractions (*ca.* 75% of the product mixtures) are shown in Table 6.

We thank the National Research Council of Canada for support of this work and Dr. S. N. Eğe for preliminary experiments. D.J.M. thanks the Province of Ontario and the Canadian Kodak Co. for financial assistance. The n.O.e. measurements were carried out at the School of Chemistry, University of Bristol, England, by D.J.M. during the tenure of a National Research Council of Canada postdoctoral fellowship; grateful acknowledgement is made to Professor M. C. Whiting for his hospitality and to Dr. R. J. Goodfellow for technical advice.

Mechanism of Ozonolysis. The Initial Ozonide. Lack of Evidence for "Unified Concept" Involving Staudinger Molozonide

PHILIP S. BAILEY, THOMAS P. CARTER, JR., CHARLES M. FISCHER, AND JAMES A. THOMPSON

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

Received October 30, 1972

Contrary to previous reports cyclohexanone and pinacolone are not oxidized to the corresponding Baeyer–Villiger oxidation products during ozonolysis of ethylidenecyclohexane in their presence. Addition of propionaldehyde to a solution of the 1,2,3-trioxolane initial ozonide of *trans*-1,2-di-*t*-butylethylene resulted in oxidation of the aldehyde to propionic acid and reduction of the 1,2,3-trioxolane to pivaldehyde. Thus, there is no necessity for the four-membered Staudinger molozonide as an ozonolysis intermediate, as recently proposed by Story.

Contrairement aux publications antérieures, la cyclohexanone et la pinacolone ne sont pas oxydées selon un Baeyer–Villiger pendant l'ozonolyse de l'éthylidènecyclohexane en leur présence. L'addition du propionaldéhyde à une solution de trioxolane-1,2,3, ozonide dérivé initial du *trans*-di-*t*-butyl-1,2 éthylène, a pour résultat l'oxydation de l'aldéhyde en acide propionique et la réduction du trioxolane-1,2,3 en pivalaldéhyde. Ainsi, il n'est plus nécessaire d'avoir le monozonide à quatre membres de Staudinger comme intermédiaire d'ozonolyse, comme cela a été proposé recemment par Story.

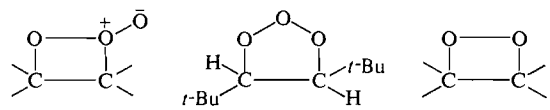
Story and coworkers (1–3) recently have proposed a so-called "unified concept" (2) for the mechanism of the ozonolysis reaction, in which they invoke the initial formation of a four-membered ring system (**1**, a Staudinger "molozonide") as a precursor to the accepted 1,2,3-trioxolane (*e.g.* **2**) initial ozonide and/or peroxidic and nonperoxidic ozonolysis products. The experimental basis for this proposal is their reported finding that ozonolysis of several olefins in a large excess of propionaldehyde (1), cyclohexanone (1), or pinacolone (3) resulted in reduction of the initial ozonide (to aldehydes and/or ketones) and Baeyer–Villiger oxidation of the added aldehyde or ketone (to propionic acid, 6-hexanolactone, and *t*-butyl acetate, from the above three, respectively). Since it had previously been shown that ozonolysis of an olefin in the presence of only 1 mol of added aldehyde gave cross ozonides (4, 5) and since the earlier Story–Murray mechanism (4) accounts for this via attack of the aldehyde on a 1,2,3-trioxolane (*e.g.* **2**) intermediate, Story (2, 3) felt that some other species, a precursor to the trioxolane and/or ozonolysis products, was the oxidant which was reduced by the excess aldehyde or ketone. As further evidence that this species was the Staudinger molozonide (**1**), Story (3) reported that several olefins yielded the corresponding dioxetane (**3**) upon ozonation in the presence of pinacolone; the dioxetane, of course,



1 **2** **3**

would readily break down to aldehyde and/or ketone moieties.

Because ozone is considered to be one of the most typical 1,3-dipoles (6), it seemed highly unlikely to us that it would react initially with an alkene to form a strained four-membered ring adduct, especially as a precursor to the five-membered 1,2,3-trioxolane ring which has been established in several cases as an ozonolysis intermediate (7, 8).

The purpose of the present paper is to give additional experimental details concerning our earlier low temperature n.m.r. proof of the 1,2,3-trioxolane structure for the initial ozonide (**2**) of *trans*-1,2-di-*t*-butylethylene (7) and to show that there is no experimental basis for the "unified" ozonolysis mechanism of Story and coworkers (1–3). Just as we were finishing this work, Professor K. R. Kopecky kindly sent us a preprint of the paper describing his work (9) which also refutes the Story mechanism.

Our first approach to testing the "unified concept" of Story (2) was to determine whether or not a known 1,2,3-trioxolane would oxidize propionaldehyde, cyclohexanone, etc., to their

[a]Ratio of approximately 1:9 for methine to *t*-butyl protons.
[b]The acetone was acetone-d_6.
[c]A water peak was also present, varying from around δ 4.3 at low temperatures to 2.8 at room temperature.
[d]Minor peaks due to slight decomposition also were observed, along with a small peak due to H^1 content of acetone-d_6 (2.11).
[e]Addition of pivaldehyde increased these peaks. Also some minor peaks due to ozonides or polymeric peroxides were observed.
[f]Di-*t*-butylethylene.
[g]Addition of *cis*- and *trans*-ozonides increased these peaks.

Baeyer–Villiger oxidation products; if so, there would be no need to invoke the Staudinger molozonide structure (**1**). Such a substance is the initial ozonide (**2**) of *trans*-1,2-di-*t*-butylethylene, which we showed in 1966 by low temperature n.m.r. to have a symmetrical structure and, therefore, to possess a five- (**2**) rather than a four- (**1**) membered ring. Both in acetone-d_6 at −95° and in Freon 11 ($CFCl_3$) at −95° or below only two singlet peaks were observed, one for the *t*-butyl protons and one for the methine protons (Table 1) in the ratio 9:1.

In his first paper on the "unified" mechanism, Story (1) reported that he ozonized *trans*-1,2-di-*t*-butylethylene in pentane, added propionaldehyde to the cold reaction mixture, and found that oxidation of propionaldehyde to propionic acid occurred. However, the initial ozonide is insoluble in pentane and Story (1) assumed that the precipitate was the Staudinger molozonide (**1**) and that the symmetrical trioxolane structure was present only in solution. We, therefore, used very dilute (0.5%) solutions of *trans*-1,2-di-*t*-butylethylene in acetone in order to insure that all of the initial ozonide stayed in solution after the ozonation. The ozonation was carried out at −78° (the initial ozonide does not decompose until −60° or above, see Table 1) in a special two-chambered ozonation vessel (Fig. 1) after which a precooled solution of a large excess of freshly distilled propionaldehyde or cyclohexanone was added as described in the Experimental. The results are shown in Table 2. The propionaldehyde was oxidized to propionic acid and the initial ozonide (**2**) was partially reduced to pivaldehyde. However, no oxidation of cyclohexanone to 6-hexanolactone was observed.

The propionaldehyde experiment shows that it is unnecessary to invoke a Staudinger molozonide (**1**) precursor to account for the oxidation to propionic acid; the oxidation must have been brought about by the trioxolane (**2**), the Criegee carbonyl oxide zwitterion, or some species in between. If it involved the trioxolane or an initial

decomposition product thereof, the difference in the action of propionaldehyde when present to the extent of 1 mol per mole of olefin (to give a cross ozonide) (1) and in large excess (to reduce the initial ozonide) could be explained on the basis that the first reaction is first order with respect to the propionaldehyde whereas the second reaction probably is second order or higher. A possible mechanism is shown in Scheme 1. A similar Baeyer–Villiger oxidation could also be invoked for the carbonyl oxide zwitterion as the oxidant.

In order to determine whether or not the cyclohexanone results favored the Story mechanism, in that some species other than the 1,2,3-trioxolane was needed to oxidize the cyclohexanone to the 6-hexanolactone, *trans*-1,2-di-*t*-butylethylene was ozonized in cyclohexanone as a solvent. Gas chromatographic analysis revealed no 6-hexanolactone. Next, the very experiment reported by Story (1) was performed, namely the ozonation of ethylidenecyclohexane in cyclohexanone solvent. Whereas Story (1) reported a 50% yield of 6-hexanolactone, we found either none or only a trace. This experiment was performed several times, independently, by two different people in our laboratory. It was shown that under our v.p.c. conditions, 6-hexanolactone could easily be determined if present. Similar results were obtained using *trans*-3-hexene. Finally, again following Story's procedure (3), ethylidenecyclohexane was ozonized in pinacolone solvent; no *t*-butyl acetate was observed as a product. This experiment also was performed many times, independently, by three different people in our laboratory, by Kopecky and coworkers (9), in Criegee's laboratory in Karlsruhe,[1] and Fliszar's laboratory in Montreal.[2] Table 3 compares the results of ozonation of ethylidenecyclohexane in pentane and in pinacolone. Ethyli-

TABLE 3. Ozonation of ethylidenecyclohexane[a]

Solvent	O_3[b] (mmol)	Recovered starting material (mmol)	Cyclohexanone		Active oxygen (mmol)	
			mmol	% yield	KI[c]	HI[c]
Pentane	1.8	0.42	0.71	45	0.22	1.21
Pentane	1.9	0.19	0.88	49	0.02	1.17
Pinacolone	1.8	0.43	1.17[d]	75	1.30	1.63
Pinacolone	1.9	0.37	1.17[d]	72	1.22	1.78

[a]2 mmol in 10 ml of solvent was employed.
[b]An ozone–nitrogen stream was used.
[c]The low KI and high HI values in the first two experiments indicate the ozonide which was shown to react only slightly with KI, probably because it was trisubstituted. In the last two experiments the peroxide seems to be polymeric.
[d]The greater than 1 mol equiv of cyclohexanone obtained is probably due to decomposition of polymeric peroxides on the v.p.c. column.

denecyclohexane ozonide was isolated from the pentane experiments, but not from the pinacolone experiments, which appeared to give largely polymeric peroxides. Ozonation of ethylidenecyclohexane in acetone gave dimeric cyclohexanone peroxide and polymeric peroxides.

It is of interest that with the experiments in which cyclohexanone was added to a cold solution of the initial ozonide of *trans*-1,2-di-*t*-butylethylene (Table 2) more than 1 mol of pivaldehyde was obtained per mole of olefin. Likewise, in the ethylidenecyclohexane ozonations, considerably more cyclohexanone was obtained using pinacolone solvent than pentane solvent. This could be interpreted as indicating that reduction of some form of an initial ozonide or some other peroxidic species occurred, as reported by Story (1, 3). However, no oxidation of the solvent or added ketone occurred and only minor amounts of pivalic acid (from di-*t*-butylethylene) and acetic acid (from ethylidenecyclohexane) were obtained. We believe that the excess aldehyde or ketone product in these experiments comes from decomposition on the v.p.c. of polymeric peroxides or polymeric ozonides. There appears to be a solvent effect of cyclohexanone and pinacolone upon the fate of the initial ozonide, causing polymeric peroxidic ozonolysis products rather that ozonides to be produced (Tables 2 and 3).

Like Kopecky and coworkers (9) we found no evidence for the production of a dioxetane upon ozonolysis of ethylidenecyclohexane in pinacolone. Since our work parallels Kopecky's in this respect, we will relegate our results to the Experimental. We also found no evidence for the formation of a dioxetane upon ozonolysis of 2-methyl-2-butene in pinacolone.

These results, therefore, make the recent proposals of Story and coworkers (1–3) both unnecessary and untenable. The best description of the ozonolysis reaction at the present time is that a π complex is initially formed (10) which then is converted to a 1,2,3-trioxolane via 1,3-dipolar cycloaddition. There undoubtedly are several fates possible for the initial ozonide, including that described by the SMY mechanism (4) when a small excess of aldehyde is present. However, the Criegee mechanism, as refined recently (11), still provides the best description of the fate of the initial ozonide under normal conditions.

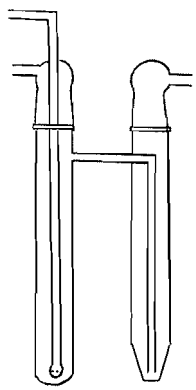

FIG. 1. Two-chambered ozonation vessel.

Experimental

The ozonation equipment and procedures using ozone–oxygen or ozone–nitrogen are described in earlier papers (12). For ozonations involving the addition of a cold solution of a substrate to an ozonized solution, without warming or introduction of oxygen occurring, a special two-chambered vessel shown in Fig. 1 was used. Different sizes were employed, varying from 10 to 125 ml volume in the ozonation chamber. V.p.c. determinations were made either with a Varian Aerograph 1520 B chromatograph or with an F and M 500 chromatograph. The low temperature n.m.r. spectra were recorded with a Varian DP-60 spectrometer using TMS as an internal standard. Other n.m.r. spectra were recorded either with

a Varian A-60 or HA-100 spectrometer. *Ethylidenecyclohexane* and *trans-1,2-di-t-butylethylene* were obtained from Chemical Samples Co. and were 99% pure. Other reagents and solvents also were obtained commercially and were checked for purity by v.p.c. The propionaldehyde was redistilled under nitrogen before each use.

Ozonation of trans-1,2-Di-t-butylethylene. N.m.r. Proof of 1,2,3-Trioxolane Structure of the Initial Ozonide

The ozonations were on 1% by weight solutions of *trans*-1,2-di-*t*-butylethylene in 5 ml of acetone-d_6 or Freon 11 ($CFCl_3$) at -95 to $-110°$. In earlier work 2.5–5% solutions were used, but the initial ozonide did not remain completely in solution. The solutions were ozonized with ozone in a nitrogen stream until pale blue, after which the excess ozone was swept out with nitrogen. An aliquot of the reaction mixture was then transferred to a precooled n.m.r. tube by means of a precooled disposable pipette. Tetramethylsilane was added and the n.m.r. spectrum taken in the low temperature probe of the spectrometer. In some cases the temperature was allowed to rise and new spectra taken. Where mixed solvents were employed, cold acetone-d_6 was added to a cold aliquot of the Freon 11 ozonation mixture. The results are shown in Table 1. It can be seen that decomposition of the initial ozonide begins somewhere between -63 and $-48°$ (experiments 6–8). The unusually large shift to lower field for the methine protons of the initial ozonide in going from the less polar Freon 11 to the more polar solvent appears to be only a solvent effect, rather than a difference in structure of the initial ozonide in the two solvents (*cf.* ref. 7), since the change gradually occurs as acetone is added to the Freon 11 solution (experiments 1–4). Ozonation of *cis*-1,2-di-*t*-butylethylene under the same conditions gave only ozonides (experiments 19–21).

Addition of Propionaldehyde or Cyclohexanone to Solution of Initial Ozonide (2) of trans-Di-t-butylethylene

A solution of approximately 0.5% by weight of *trans*-1,2-di-*t*-butylethylene in spectro-quality acetone was placed in the ozonation chamber of a large two-chamber ozonation vessel (Fig. 1). The appropriate amount of propionaldehyde or cyclohexanone in acetone was placed in the other compartment and the entire reaction vessel was cooled to $-78°$ in a Dry Ice – isopropanol bath. An equivalent of ozone in a nitrogen stream was then passed into the olefin solution, after which the reaction mixture was swept with nitrogen for 15 min. At this point the propionaldehyde or cyclohexanone solution was blown over into the ozonation solution with a nitrogen stream, the two solutions were mixed well by means of a nitrogen stream, and the reaction mixture was allowed to interact at $-78°$ for 1 h. Next, it was kept at $-60°$ for $\frac{1}{2}$ h, at $-30°$ for $\frac{1}{2}$ h, and then allowed to warm to room temperature. Benzene was added as an internal standard and pivaldehyde was determined on a 20 ft diisodecyl phthalate on Chromosorb G column at 80° (Aerograph 1520 B). Acetone and other volatiles were removed at room temperature by means of a water aspirator (6-hexanolactone boils at 118–119° at 15 mm) and the residue was taken up in carbon tetrachloride and analyzed by v.p.c. for pivalic acid and propionic acid or 6-hexanolactone. Propionic acid was identified by comparison with an authentic sample on a 5% DEGS, 2% phosphoric acid column (Aerograph 1520 B) and determined on a 5% Dimer Acid – Silicone Oil on Haloport F column at 90° (F and M 500) using the standard solution method. Pivalic acid was then determined on the DEGS–H_3PO_4 column at 90° (Aerograph 1520 B) using propionic acid as the internal standard. In the cyclohexanone experiments, pivalic acid was determined by n.m.r. (singlet at δ 1.22). No evidence for the 6-hexanolactone was obtained by v.p.c. using a 10 ft 30% Silicone Gum Rubber SE-30 on Chromosorb P column at 150° and comparing with an authentic sample. Likewise n.m.r. failed to show any lactone: multiplets at δ 4.20 (2H), 2.65 (2H), and 1.80 (6H). Other identifications also were made by n.m.r.: pivaldehyde, δ 9.42 (singlet), 1.07 (singlet); propionic acid, 1.16 (triplet), 2.35 (quartet); ozonide, 4.80, 4.74, 0.97 (singlets); polymeric peroxide, 5.2–5.0 (multiplet).

Ozonations of trans-Di-t-butylethylene, trans-3-Hexene, and Ethylidenecyclohexane in Cyclohexanone Solvent

These were carried out as described by Story (1). The reaction mixtures were evaporated and analyzed for 6-hexanolactone as described above. In some cases (concentrated solutions, 0.2–3.0 *M*) the undistilled reaction mixture was analyzed for the lactone. In no case was more than a trace (1–3% yield) of lactone obtained. It was shown that significant quantities of 6-hexanolactone could be detected under these conditions.

Ozonation of Ethylidenecyclohexane in Pinacolone Solvent

A solution of 2.5 mmol of ethylidenecyclohexane in 10 ml of pinacolone was ozonized to completion (blue color) at $-45°$ with ozone–nitrogen. The solvent was stripped off in *vacuo* (oil pump) at 0° and collected in a cold trap at $-78°$. V.p.c. analyses for *t*-butyl acetate were made on the original solution, the stripped solvent, and the residue using a 10 ft diethyleneglycol adipate on acid-washed Chromosorb P column at 70° (F and M 500) and a 10 ft 10% Silicone Fluid XF-1150 on Chromosorb P column at 100° (Aerograph 1520 B). No *t*-butyl acetate was found, as shown by comparison to the retention time of an authentic sample. The residue and stripped solvent also were analyzed for acetic acid and cyclohexanone by v.p.c. using a 10 ft 5% Dimer Acid – Silicone Oil on Haloport F column at 70° (F and M 500). Considerable cyclohexanone but only a trace of acetic acid was found.

A small amount of the residue from the above experiment was dissolved in 2 ml of *cis*-decalin and to this solution 50 mg of rubrene was added. The mixture was heated rapidly to boiling (195°). An orange glow which lasted for about 1 min was readily visible in the dark. In a similar experiment without rubrene, no luminescence was observed. In another experiment the ethylidenecyclohexane was ozonized in methylene chloride rather than pinacolone and the solvent was stripped. The rubrene experiment was performed on the residue and luminescence was similarly noted. This, therefore, can not be used as evidence for a dioxetane, as reported by Story (3). Kopecky *et al.* (9) discusses this further.

In another experiment, a sample of the freshly stripped, cold (0°) residue was transferred by means of a precooled pipette to a precooled n.m.r. tube and an n.m.r. spectrum was taken in a low temperature probe at 0°. Of particular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

interest was the methine proton absorption which was a featureless multiplet at δ 4.8, characteristic of polymeric peroxide methine protons. The dioxetane methine absorption is in the form of a quartet at δ 5.09 (9). A similar experiment was carried out with 2-methyl-2-butene; a broad structureless multiplet was observed at δ 4.8 (*cf.* ref. 3).

Lithium aluminum hydride reductions of the residue from the ethylidenecyclohexane ozonation were carried out in the standard fashion. Like Kopecky and coworkers (9) and contrary to the report of Story (3) none of the glycol expected from the dioxetane was obtained. Similar results were obtained with the 2-methyl-2-butene ozonation mixture.

In certain other ozonations, slightly less than 1 equiv of ozone was employed. Analyses for unreacted ethylidenecyclohexane and cyclohexanone were carried out as described in the next experiment. The results are shown in Table 3. The peroxidic residue after the removal of the solvent gave a positive lead tetraacetate test for a hydroperoxide group. Potassium iodide and hydriodic acid determinations for active oxygen were made as described in the following experiment. The nearly identical results (Table 3) appear to indicate a polymeric peroxide. T.l.c. indicated a mixture of products. N.m.r. showed that no ozonide was present (*cf.* following experiment).

Ozonation of Ethylidenecyclohexane in Pentane

A solution similar to the one above, except using pentane rather than pinacolone solvent, was ozonized with slightly less than 1 equiv of ozone at −45°. Determinations of unreacted ethylidenecyclohexane and cyclohexanone were made on a 5% Dimer Acid – Silicone Oil on Haloport F column at 120° (F and M 500). The solvent was evaporated as in the preceding experiment and KI (room temperature) and HI (56% at 60°) determinations for active oxygen were made (titration of released iodine with standard thiosulfate). The results are shown in Table 3. In another experiment the residue was distilled and a fraction collected at 39–40° (5 mm). This was shown to be ethylidenecyclohexane ozonide; n.m.r. in CCl_4: δ 1.33 (doublet, J = 5.3 Hz); 1.62 (broad singlet); 5.20 (quartet, J = 5.3 Hz); ratio of upfield protons to quartet was 13:1. The material gave a strong HI, but weak KI, test.

Anal. Calcd. for $C_8H_{14}O_3$ (mol. wt. 158): C, 60.74; H, 8.93. Found (158 (mass spectra)): C, 59.57; H, 8.96.

Ozonation of Ethylidenecyclohexane in Acetone

This experiment at −78° resulted in the appearance of a white precipitate which was shown to be the dimeric cyclohexanone peroxide by comparison with an authentic sample (13).

Use of *N*-Carboxyanhydrides in the Synthesis of Dipeptides. Factors Affecting the Yields of Several Alanine and Valine-containing Dipeptides[1]

ERIC M. GROVESTINE,[2] JEAN R. LANGLOIS,[3] AND ROSS E. WILLIAMS[4]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received November 20, 1972

A series of dipeptides having aliphatic side chains have been prepared in aqueous solution from alanine and valine NCA. An organic base was used to establish and maintain the p*H*. After the reaction the amounts of unreacted amino acid nucleophile and the overall yields in the reaction were determined. Our observations have led us to propose that NCA stability, the pK_a of the amino acid nucleophile and the stability of the carbamate all can play an important role in determining synthetic yields during these preparations.

Une série des dipeptides qui possédent les chaînes latérales aliphatiques a été preparée en phase aqueuse avec alanine et valine NCA. Pour établir et maintenir le p*H* on a employé une base organique. Après la réaction nous avons déterminé la quantite du nucléophile non-reagie et le rendement totale du dipeptide. Nous proposons donc que la stabilité du NCA, le pK_a de l'acide aminé et la stabilité du carbamate peut jouer un rôle important dans la détermination de la synthèse du dipeptide.

Introduction

Use of *N*-carboxyanhydrides (NCA's) for the synthesis of racemization-free dipeptides under controlled conditions has received attention in recent times (1–4). The original method (1), *i.e.* borate buffer (p*H* 10.2), rapid stirring, has been modified in several ways including the use of 0.2 *M* sodium carbonate solutions containing acetonitrile (no p*H* control exercised) (2) or the use of organic buffers (p*H* control exercized) (3). A further simplifying modification of this latter type involved the use of only a liquid organic base to establish and maintain the p*H* during the reaction (4). In view of the demonstrated utility of this procedure for the large scale preparation of dipeptides we have studied the effect of p*H* on the yields of several peptides derived from the reaction of alanine and valine NCA with amino acids having various sized aliphatic side chains. These studies have allowed us to delineate the factors which control the synthetic yields of this reaction.

Methods and Materials

Amino acids were obtained from Bion Biochemicals. Toronto, Ontario. They were all of the L-configuration. Water was doubly distilled from glass. All other chemicals were of reagent grade and were used as received.

N-Carboxyanhydrides were prepared, using suitable precautions, according to established procedures (5). They were twice precipitated from ethyl acetate with petroleum ether (30–60°) and gave decomposition temperatures in accord with those reported.

A Beckman amino acid analyzer, model 120C, using a standard elution programme on a 69 × 0.9 cm column (resin UR 30, sodium citrate buffers, 0.2 *N* in sodium ion, p*H* 3.25 and 4.30, temperature 55 °C) was employed for determination of the extent of reaction. In order to ensure quantitative conversion of all valine-containing peptides to ninhydrin-positive materials a buffer flow rate of 50 ml/h was used. Amino acid standards were those supplied by Beckman. Dipeptide standards were obtained from commercial sources (Schwarz-Mann, Sigma Chemical, and Fox Chemical. They were dried overnight under vacuum at 60 °C and all gave satisfactory elemental analyses. They contained less than 1% ninhydrin-positive impurities when subjected to amino acid analysis.

Dipeptide syntheses were carried out on an analytical scale (1 m*M* amino acid nucleophile per 10 ml) as previously described (4). In general, a solution (40 ml) containing a known amount of the amino acid to be used as nucleophile was cooled to 2 °C in a jacketed Waring blendor (125 ml capacity). A few drops of cetyl alcohol was added to prevent foaming and the p*H* was adjusted to the desired value with triethylamine. A slight excess of the solid NCA (1.1 mol equiv) was added under conditions of rapid stirring. More triethylamine was added to maintain the p*H*. At cessation of base uptake, as evidenced by stability in the p*H*, the solution was rapidly acidified with formic acid to p*H* 3. The blendor contents were decanted, washed through a glass filter, and made up to 100.0 ml with water. An aliquot (0.100 ml) was applied to the amino acid analyzer to determine the amount of amino acid nucleophile remaining in the solution and the amount of product formed during the reaction.

All yields were calculated on the basis of the amount of input nucleophile used. Percentages of amino acid nucleophile reacting were calculated as follows:

$$(N_0 - N_f)/N_0 \times 100$$

Overall yields, in percent, were calculated as follows:

$$D_f/N_0 \times 100$$

where N_0 is initial molar concentration of amino acid nucleophile, N_f is final molar concentration of amino acid nucleophile, and D_f is final molar concentration of dipeptide. The yields, presented in graphical form in Figs. 1–4, are based upon the average of triplicate runs at p*H*'s 9.2, 9.8, 10.3, and 11.0. Experimental variation amounted to approximately ±8% in each one of the calculated yields. This variability can be attributed in part to the purity of the NCA used, the rate at which it was added, the variation of the p*H* from that desired during the reaction, as well as the time elapsed before acidification in order to terminate the reaction.

Results and Discussion

In a previous communication (4) it was shown that the use of an organic base to establish and maintain the p*H* during the reaction of an amino acid NCA with another amino acid is adequate for the preparation of dipeptides in yields which are synthetically useful. Product isolation was aided since all the buffer components could be removed prior to isolation of the dipeptide via conventional procedures, such as crystallization or chromatography.

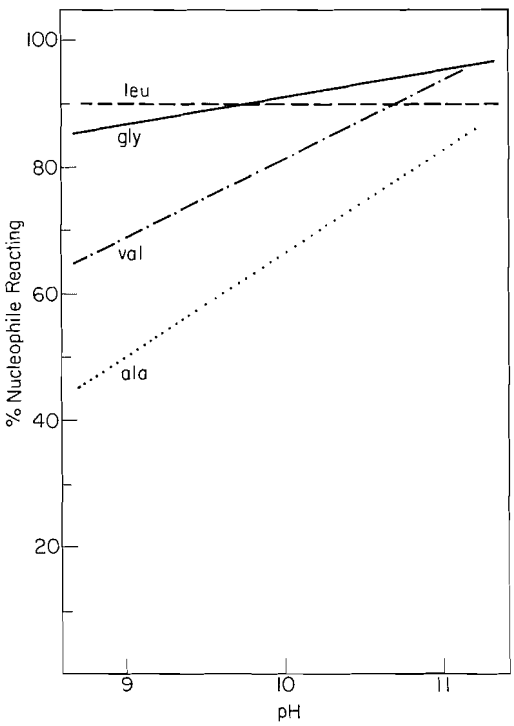

FIG. 1. NCA preparation of alanyl dipeptides from alanine NCA. Variation with p*H* of the percentage of amino acid nucleophile reacted. Glycine (———); alanine (···); valine (-·-·-); and leucine (---).

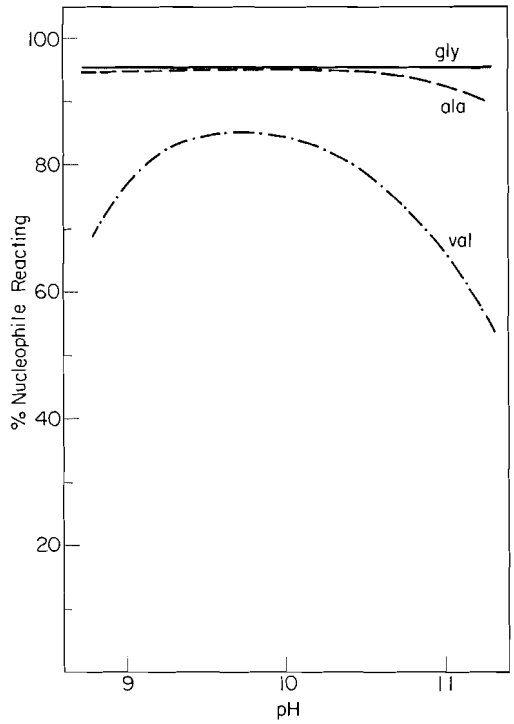

FIG. 2. NCA preparation of valyl dipeptides from valine NCA. Variation with p*H* of the percentage of amino acid nucleophile reacted. Glycine (———); alanine (---); and valine (-·-·-).

Because of the obvious preparative utility of the method we wished to investigate the effects which might control yields in the reaction. By determining both the overall reaction yield and the amount of nucleophile consumed in the reaction of various amino acid nucleophiles with an NCA at different p*H*'s we have been able to investigate the effects that NCA stability, steric interference of the side chains, the amino acid nucleophilicity (related to the amino function's pK_a), and the stability of the intermediate carbamate, have upon the synthesis of a representative group of dipeptides: alanyl-X and valyl-X, where X is an aliphatic amino acid.

Steric control of the nucleophilic attack on the NCA by the amino acid (see Scheme 1) might be important in limiting the synthetic

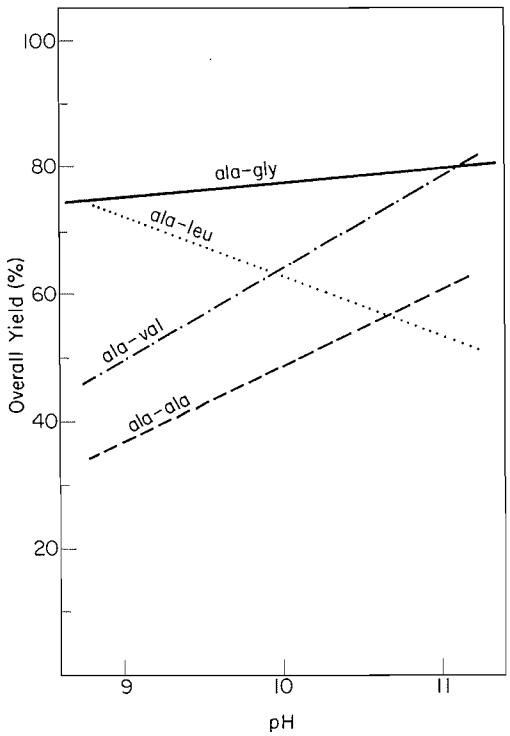

FIG. 3. NCA preparation of alanyl dipeptides from alanine NCA. Variation of the overall yield with p*H*. Alanyl–glycine (———); alanyl–alanine (---); alanyl–valine (-·-·-) and alanyl–leucine (···).

yields. This effect would be primarily reflected in the amount of amino acid nucleophile removed from solution during the reaction since a slower reacting species would allow destruction of the NCA by base hydrolysis. Both alanine NCA and valine NCA were reacted with a series of amino acid nucleophiles to form the respective dipeptides. The percentage of the amino acid nucleophile removed from solution during the reaction is given in Figs. 1 and 2. When alanine NCA was used (Fig. 1) glycine was nearly totally consumed and showed a very slight p*H* dependency (rising at p*H* 11). With leucine as nucleophile, percentages paralleled those observed with glycine. With either alanine or valine as nucleophile the percentages consumed were very much reduced. However, they were in an order opposite to that expected for steric control of attack. The valine being more hindered would be expected to give lower yields. The p*H* effects on the reactions with alanine and valine as nucleophiles show the result of having a larger portion of unprotonated amine as nucleophile in the solution, that is, the amount of unprotonated amine in the solution at the beginning of the reaction controls the extent of the reaction. This is, thus, an effect related to the pK_a of the amino acid involved and shows the ability of hydroxide ion to compete with bulky amino acid nucleophiles for the alanine NCA. This effect seems to be important with these two compounds but nothing of this sort is observed with glycine or leucine.

When valine NCA was used to prepare a similar series of dipeptides, the order of consumption of glycine, alanine, and valine gave a definite indication of steric control (Fig. 2). p*K* effects were only noticeable in the preparation of valyl–valine and did not seem to be as important as those seen with alanyl NCA. This would indicate that the hindered valine NCA is more stable towards hydrolysis than alanine NCA, allowing the nucleophile ample time to attack before the NCA is destroyed. The decreasing consumption seen at high p*H*'s with valine NCA may reflect a decrease in the NCA stability due to attack by hydroxide ion.

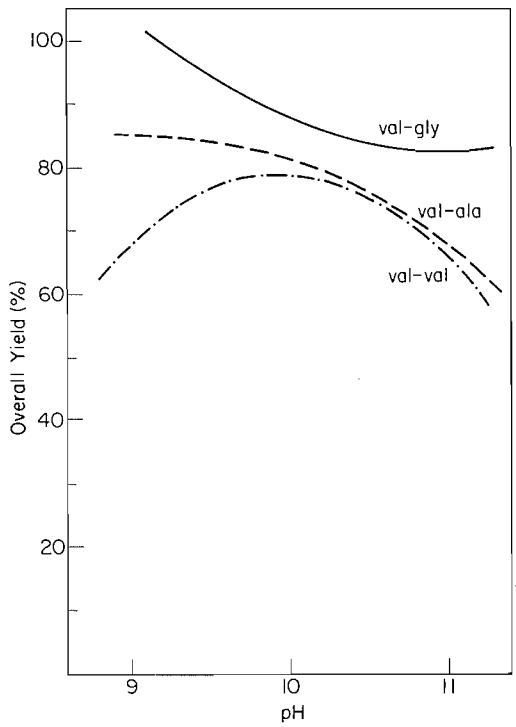

FIG. 4. NCA preparation of valyl dipeptides from valine NCA. Variation of the overall yield with p*H*. Valyl–glycine (———); valyl–alanine (---); and valyl–valine (-·-·-).

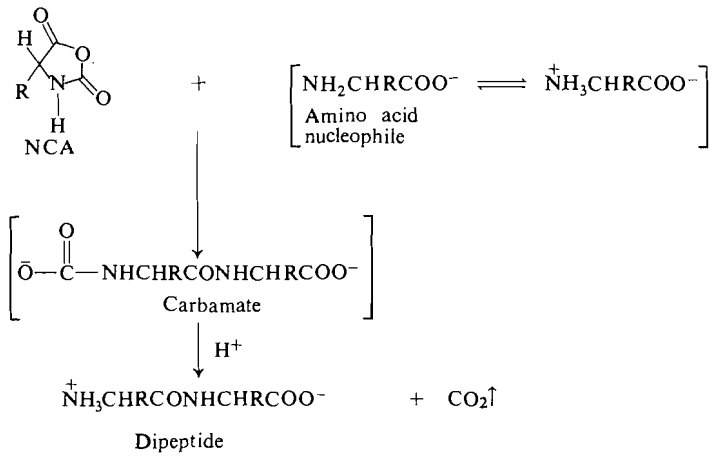

SCHEME I

The overall yields in the alanine series (Fig. 3) present p*H* dependency profiles paralleling that seen for the nucleophile consumption except for one case, that of alanyl–leucine. This parallelism indicates that the stability of the intermediate carbamate is not playing an important role in determining the overall yield of most of the reactions. If carbamate stability were important no such parallelism would be noted since destruction of the carbamate by hydroxide ion would result in overreaction to higher peptides and a lowering of yields at higher p*H*'s. In the case of alanyl–leucine we see a definite case of the carbamate instability affecting the reaction yields. Between the point at which the leucine is removed from the solution and the product formation begins, a reaction occurs, perhaps controlled by the intermediate's conformation, in which the carbamate is destroyed either by hydrolysis yielding a product capable of further reaction to tri- and tetra-peptides, or to ninhydrin-negative materials.

Examination of overall yields in the valine series (Fig. 4), on the other hand, shows the order expected for steric control, *i.e.* the more bulky alanine and valine nucleophiles form product to less of an extent than the less bulky glycine nucleophile. Carbamate stability, in this series, does not seem to play an important role in controlling the synthetic yields.

As can be seen from the above results not only steric effects (the valine series) but also amino acid pK_a's (the alanine series) play an important role in controlling the yields of dipeptides synthesized by this method. Steric effects seem to dominate when the NCA is relatively stable to hydrolysis by hydroxide ion. The pK_a effects become relevant when hydroxide ion can effectively compete with the nucleophile for the NCA. The results with alanyl–leucine suggest that carbamate stability can also play an important role in determining the overall yields in the reaction.

While no definite conclusions may be drawn regarding the interplay of all the various factors influencing the reaction yields our results do provide the necessary information for the successful large scale synthesis of these aliphatic dipeptides. These results also support our previous contention (4) that all large scale syntheses must be preceded by a series of analytical runs in order that the optimum conditions for any new preparation might be determined.

We wish to thank H. Seguin for the elemental analyses and A. E. Castagne for the amino acid analyses. Our thanks are also due to Dr. D. R. Lauren for discussions and reading the manuscript.

Crystal and Molecular Structure of *B,B*-Diphenylboroxazolidine (2-Aminoethyl Diphenylborinate), $Ph_2BO(CH_2)_2NH_2$

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 18, 1972

Crystals of the title compound are monoclinic, $a = 13.840(1)$, $b = 8.9169(5)$, $c = 10.170(1)$ Å, $\beta = 98.85(1)°$, $Z = 4$, space group $P2_1/n$. The structure was determined by direct methods, and refined by electron-density and full-matrix least-squares procedures to R 0.041 for 1458 observed reflections. The five-membered boroxazolidine ring is in the half-chair conformation. Bond angles in the ring range from 99.7° for OBN to 110.1° for BOC. Bond lengths are as follows: mean B—C, 1.611(2), B—N, 1.653(3), B—O, 1.484(3), C—N, 1.485(3), C—O, 1.413(3), mean C—C (aromatic), 1.383(11), and C—C, 1.505(4) Å. The structure consists of discrete molecules linked by O...H—N hydrogen bonds (2.874(2) Å) to form continuous spirals about the 2_1 axes.

Le composé du titre cristallise dans le système monoclinique, $a = 13.840(1)$, $b = 8.9169(5)$, $c = 10.170(1)$ Å, $\beta = 98.85°$, $Z = 4$, groupe d'espace $P2_1/n$. La structure a été déterminée à partir des methodes directes, et a été affinée par les procédés de la densité électronique et de moindres carrés (matrice complète) jusqu'à un facteur résidual R 0.041 pour 1458 reflexions observées. Le cycle de cinq chaînons est dans la conformation demi-chaise. Les angles des liaisons dans le cycle s'etendent de 99.7° pour OBN à 110.1° pour BOC. Les longuers des liaisons sont: B—C (moyenne), 1.611(2), B—N, 1.653(3), B—O, 1.484(3), C—N, 1.485(3), C—O, 1.413(3), C—C (moyenne aromatique), 1.383 (11), et C—C, 1.505(4) Å. La structure est constituée par les molecules discrètes liées par liaisons hydrogènes (2.874(2) Å) qui forment les spirales continues autour des axes 2_1.

Can. J. Chem., **51**, 1288 (1973)

Introduction

In recent years the boroxazolidines have been extensively studied, the primary concern being the unusual stability of the amino alcohol esters with respect to boron esters of ordinary alcohols. *B,B*-Diphenylboroxazolidine (**1**) was originally

1

prepared by Letsinger and Skoog (1), who correctly proposed the cyclic structure of the ester. The possibility of the N—B dative bond was first proposed by Brown and Fletcher (2) for triethanolamine borate (triptych boroxazolidine) in 1951. The first substantial evidence for the existence of the N—B dative bond in boroxazolidines was the result of detailed kinetic studies of the acid hydrolysis of these compounds by Zimmerman and co-workers, the details of which are the subject of a review article by Zimmerman (3). The X-ray crystallographic study of *B,B*-diphenylboroxazolidine was undertaken to provide conclusive proof of the existence of the boroxazolidine ring.

Experimental

B,B-Diphenylboroxazolidine was prepared as previously described (1, 4). Recrystallization from 1:1 ethanol – carbon tetrachloride gave colorless needles, elongated along *b*, with (100), (001), and (101) variously developed. The crystal chosen for study was mounted with *b* parallel to the goniostat axis and was *ca.* 0.5 mm in length with a cross section of 0.3 × 0.3 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 22 reflections measured on a diffractometer with Cu-Kα radiation. Crystal data are:

$C_{14}H_{16}BNO$ f.w. = 225.1

Monoclinic, $a = 13.840(1)$, $b = 8.9169(5)$, $c = 10.170(1)$ Å, $\beta = 98.85(1)°$, $V = 1240.1(2)$ Å^3, $\rho_o = 1.201(5)$, $Z = 4$, $\rho_c = 1.2055(3)$, $F(000) = 480$ (20 °C, CuKα, $\lambda = 1.5418$ Å, $\mu = 5.9$ cm^{-1}). Absent spectra: $0k0$, $k \neq 2n$ and $h0l$, $h + l \neq 2n$ define uniquely the space group $P2_1/n$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuKα radiation (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of $(1.80 + 0.86 \tan\theta)$ degrees in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 120°$ (minimum interplanar spacing 0.89 Å). A check reflection was monitored every 40 reflections throughout the data collection. The intensity of the check reflexion remained within ±2.5% of its initial value during the data collection, the final

value being equal to the initial value. Lorentz and polarization corrections were applied, and the structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 1837 independent reflections measured, 369 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.05\ S)^2$ with S = scan count and B = background count, corrected to time of scan. These reflections were classified as unobserved.

Structure Analysis

The structure was solved by direct methods. Sixteen sets of signs for 254 reflections with normalized structure factor $|E| \geqslant 1.50$ were determined by a computer program which uses Sayre relationships in an iterative procedure (5). The starting set of reflections is given in Table 1. One set of signs was outstanding in that it converged in 5 cycles to a set having the highest consistency index (5) (0.85) with 130 positive signs and 124 negative signs. An E-map was computed using the 254 signed values of E from this set. The 17 non-hydrogen atoms accounted for the highest 17 peaks on the map. A structure factor calculation based on the positions from the E-map gave R 0.211. Two cycles of full-matrix least-squares refinement of the positions and isotropic temperature factors of the boron, nitrogen, oxygen, and carbon atoms reduced R to 0.151. All 16 hydrogen atoms were then located from a difference Fourier. One cycle with the non-hydrogen atoms having anisotropic temperature factors and the hydrogen atoms isotropic resulted in $R = 0.058$. Convergence was reached after two more cycles at $R = 0.041$, for 1458 observed reflections (10 reflections were given zero weight in the final stages of refinement due to suspected extinction errors: 002, 10$\bar{1}$, 200, 111, 31$\bar{1}$, 310, 020, 021, 22$\bar{1}$, and 130).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The scattering factors of ref. 6(*a*) were used for the boron, nitrogen, oxygen, and carbon atoms and those of ref. 6(*b*) for the hydrogen atoms. The anisotropic temperature factors employed in the refinement are U_{ij} in the expression:

$$f = f^0 \exp\,[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where f^0 is the tabulated scattering factor and f is that corrected for thermal motion. The weighting scheme: $\sqrt{w} = 1$ if $|F_o| \leqslant 10$; $\sqrt{w} = 10/|F_o|$ if $|F_o| > 10$, and $\sqrt{w} = 0.7$ for the unobserved reflections gave constant average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$, and was employed in the final stages of refinement.

On the final cycle of refinement, no parameter shift was greater than 0.33 σ. The final positional and thermal parameters are given in Tables 2 and 3, respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[1]The structure factor table is available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Results and Discussion

The X-ray analysis confirms the cyclic structure first proposed for this compound by Letsinger and Skoog (1). Figure 1 shows the molecule viewed down the b axis. Individual bond lengths with their standard deviations are shown in Fig. 2 and mean bond lengths are given in Table 4. Bond angles are in Table 5.

C—H(ar)	10	0.974(25)
N—H	2	0.92(7)

*For single value parameters, the least-squares standard deviation is given in parentheses.

The five-membered boroxazolidine ring is in the half-chair conformation, with C(2) displaced 0.08 Å from the BON plane and C(1) lying 0.50 Å on the opposite side of the BON plane. The dihedral angle C(2)N—BO is 3°. There is considerable strain in the ring as evidenced by the sum of interior angles, 524°, which is 23.5° less than the ideal 547.5° (5 × 109.5). The BOC(1) angle (110.1°) is close to the expected value. The high angular strain at the remaining ring atoms is partially relieved by a shortening of the C(1)—C(2) bond to 1.505 Å from the expected value of 1.537 Å (7) for a C(sp^3)—C(sp^3) bond and a lengthening of the B—N bond to 1.653 Å from the mean value of 1.55 Å (7) for B(sp^3)—N(sp^3) bonds. The iso-

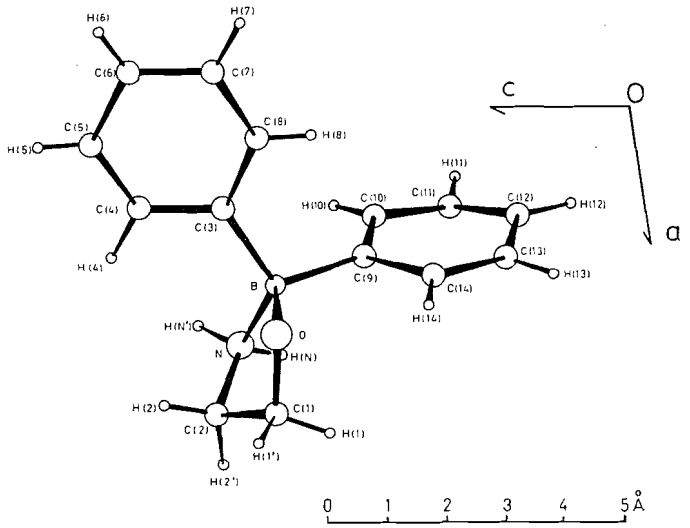

FIG. 1. The molecule viewed down *b*, showing crystallographic numbering scheme.

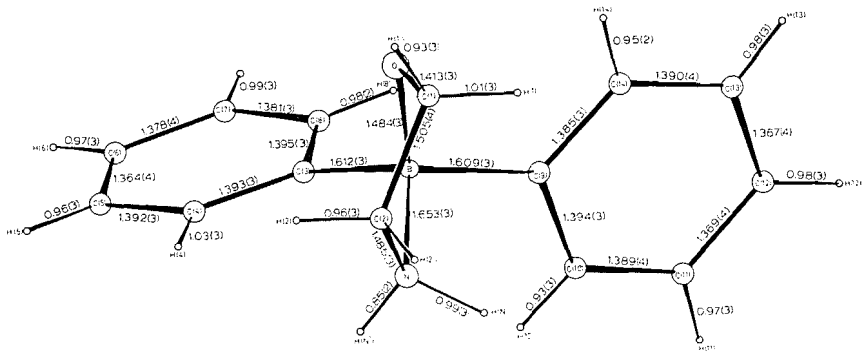

FIG. 2. A general view of the molecule with bond distances (Å) and their standard deviations in parentheses. The C(2)—H(2′) distance is 0.94(3) Å.

electronic N—C (1.485 Å) and O—B (1.484 Å) bonds as well as the C—O bond (1.413 Å) are normal (7).

The two phenyl groups are planar within experimental error (see Table 6). All of the phenyl hydrogen atoms lie in the respective phenyl planes with the exception of H(10) which lies 0.08 Å (3 σ) below the C(9)—C(14) plane. The boron atom deviates significantly from both phenyl planes, being displaced 0.15 Å from the C(3)—C(8) plane and −0.02 Å from the C(9)—C(14) plane representing a slight folding of the two planes away from each other. The angle between phenyl plane normals is 100°. The two rings are not equivalent as the C(3)—C(8) ring is twisted 21° with respect to the BNC(3) plane while the C(9)—C(14) ring lies nearly in the BOC(9) plane, dihedral angle 7°. The C—C (ar) distances range from 1.364 to 1.395 Å with a mean value of 1.383(11) Å. The mean value agrees with the literature mean of 1.394 Å(7). There are, however, significant differences between the individual C—C distances in the phenyl rings. There is a noticeable trend toward shortening of the C—C distances as they are removed from the boron substituent. This is probably due to a combination of electron delocalization, steric, and thermal libration effects (these distances have not been corrected for thermal motion). The boron–carbon distances, mean 1.611(2) Å, are significantly shorter than the B—C distances of 1.631(9)–1.646(8) Å found in the tetraphenyl borate anion (8), in accord with electron delocalization.

The mean bond angles at tetrahedrally and trigonally coordinated atoms are 109.4 and

H(4)—C(4)—C(5)	119.7(14)		

120.0°, respectively. There are a number of significant deviations from these values, resulting from steric and charge delocalization effects. Intramolecular contacts between atom pairs N and C(4), N and C(10), and O and C(14) are responsible for angular distortions at the boron atom, and at carbon atoms C(3) and C(9). Expansion of the angles NBC(3), OBC(9), BC(3)C(4), BC(9)C(4), and BC(9)C(10) (112.9, 113.7, 124.1, 122.4, and 122.0 respectively) allows the distances C(4)...N (3.143 Å), O...C(14) (2.955 Å), and N...C(10) (3.210 Å) to be equal to or slightly greater than the sum of the van der Waals radii. The expansion of OBC(9) and NBC(3) causes a contraction of NBC(9) to 106.8° which is balanced by an expansion of BC(9)C(10) (as above) to allow the N...C(10) contact to be normal. The phenyl C—C—C angles at C(3) and C(9) are both contracted to 115.6° as a result of expansion of B—C—C angles. This, in turn, makes angular adjustments at the remaining phenyl carbon atoms necessary in order to retain the planarity of the phenyl rings. The magnitude of these distortions is also dependent on the electron delocalization in as much as the C—C distances are not all equal.

The angle opposite the small OBN angle (99.7°) is opened to 114.0° and is normal for the angle between two bulky substituents. The interior angles in the boroxazolidine ring, as previously mentioned, are all contracted as are the H—N—H and H—C—H angles opposite them, all of which are less than, but not significantly different from the tetrahedral angle. The remaining angles involving the ring hydrogen atoms are generally greater than the tetrahedral angle. The angles H(N′)—N—C(2) (113.9°) and H(N′)—N—B (116.9°) represent bending of H(N′) toward the oxygen atom to which it is hydrogen bonded.

Bond angles involving the phenyl hydrogen atoms show a trend that when the adjacent C—C distances are different, so are the corresponding H—C—C angles. The H—C—C angle which

Crystal and Molecular Structure of Hexakis(dimethylamino)cyclotriphosphazene, $[NP(NMe_2)_2]_3$

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 18, 1972

Crystals of the title compound are monoclinic, $a = 15.539(4)$, $b = 9.061(1)$, $c = 16.707(6)$ Å, $\beta = 107.19(5)°$, $Z = 4$, space group $P2_1/c$. The measured and calculated densities are 1.19 and 1.180(1) g cm^{-3}, respectively. The structure was determined by direct methods and refined by electron-density and full-matrix least-squares procedures to $R = 0.047$ for 2503 observed reflections. The six-membered phosphazene ring is slightly, but significantly, non-planar, the conformation being that of a distorted boat. The molecule has approximate D_3 symmetry. The ring P—N bonds are all equal, mean P—N = 1.588(3) Å, and the relatively short exocyclic P—N bonds, mean 1.652(4) Å, indicate the presence of exocyclic π-bonding in the molecule. The N—C bonds range from 1.417(7) to 1.471(5) with a mean of 1.45(2) Å. The mean endocyclic N—P—N and P—N—P angles are 116.7(4) and 123.0(4)°, respectively, while the exocyclic N—P—N angles average 101.5(8)°.

Les cristaux du composé cité dans le titre crystallise dans le système monoclinique, $a = 15.539(4)$, $b = 9.061(1)$, $c = 16.707(6)$ Å, $\beta = 107.19(5)°$, $Z = 4$, groupe spatial $P2_1/c$. Les densités mesurées et calculées sont respectivement 1.19 et 1.180(1) g cm^{-3}. La structure a été déterminée à l'aide de la procédure directe et a été affinée par un calcul de densité électronique et par la méthode de moindres carrés (matrice complète) jusqu'à un indice $R = 0.047$ pour 2503 réflexions observées. Le cycle hexagonal du phosphazène est légèrement, mais d'une manière significative, gauche, sa conformation étant celle d'un bateau déformé. La molécule s'écarte à peine de la symétrie D_3. Les longueurs des liaisons P—N du cycle sont toutes égales à 1.588(3) Å, et les liaisons P—N exocycliques courtes, 1.652(4) Å en moyenne, indiquent la présence de liaisons π exocycliques dans la molécule. Les longueurs des liaisons N—C s'eténdent de 1.417(7) à 1.471(5) Å, ayant la valeur moyenne de 1.45(2) Å. Les angles N—P—N et P—N—P endocycliques sont égaux respectivement à 116.7(4) et 123.0(4)° en moyenne, tandis que les angles N—P—N exocycliques sont égaux à 101.5(8)° en moyenne.

Can. J. Chem., 51, 1295 (1973)

Introduction

The crystal structures of six homogeneously substituted cyclotriphosphazenes have been reported, $[NPX_2]_3$ (X = F, Cl, Br, Ph, $\frac{1}{2}[O_2C_6H_4]$, and OPh) (1–8). The P—N bonding mechanism in cyclophosphazenes (9, 10) is a topic of current interest. The crystal and molecular structure of $[NP(NMe_2)_2]_3$ has now been determined to enhance the understanding of the bonding in this class of compounds, to provide additional information on exocyclic π-bonding between phosphorus and nitrogen atoms (already established by the structures of $[NP(NMe_2)_2]_4$ (11) and $[NP(NMe_2)_2]_6$ (12)), and to provide a starting point for the analysis of the structure of $[(P_3N_3(NMe_2)_6H]_2CoCl_4$ (13).

Experimental

Crystals of $[NP(NMe_2)_2]_3$ are colorless plates elongated along *b*. The specimen chosen for study had dimensions of *ca.* 0.4 × 0.6 × 0.4 mm and was mounted with *b* parallel to the goniostat axis. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by a least-squares treatment of $\sin^2\theta$ values for 30 reflections measured on a diffractometer with CuKα radiation. Crystal data are:

$C_{12}H_{36}N_9P_3$ f.w. = 399.40

monoclinic, $a = 15.539(4)$, $b = 9.061(1)$, $c = 16.707(6)$ Å, $\beta = 107.19(5)°$, $V = 2247(1)$ Å^3, $\rho_{exp} = 1.19$ (by flotation in KI solution), $Z = 4$, $\rho_{calc} = 1.180(1)$, $F(000) = 864$, (20 °C, CuKα, $\lambda = 1.5418$ Å, $\mu = 24$ cm^{-1}). Absent spectra: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured on a Datex-automated General Electric XRD 6 diffractometer, with a scintillation counter, CuKα radiation (nickel filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 120°$ (minimum interplanar spacing 0.89 Å). A check reflection was monitored every 50 reflections throughout the data collection. The intensity of the check reflection had fallen off by 24% of its starting value by the end of the data collection. Lorentz and polarization corrections were applied, and the structure amplitudes derived. No absorption correction was made. Of the 3299 independent reflections measured, 794 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.03S)^2$ with S = scan count and B = background count. These reflections were classified as unobserved.

Structure Analysis

The structure was solved by direct methods. Sixteen sets of signs for 432 reflections with normalized structure factor $|E| \geqslant 1.50$ were determined by a computer program which uses Sayre relationships in an iterative procedure (14). The starting set of reflections is given in Table 1. One set of signs converged in the least number of cycles, 4, and had the highest consistency index (14), 0.97, with 212 positive signs and 220 negative signs. An *E*-map was computed using the 432 signed values of *E* from this set. The three phosphorus atoms accounted for the three highest peaks on the map and the nine nitrogen and eight of the twelve carbons were among the 40 highest peaks. One cycle of isotropic full-matrix least-squares refinement gave *R* 0.213. The four remaining carbon atoms were then located from a difference Fourier. One cycle with the phosphorus and nitrogen atoms anisotropic and the carbon atoms isotropic reduced *R* to 0.109. The carbon atoms were then refined anisotropically for one cycle, giving *R* 0.088. A difference Fourier revealed possible locations for all 36 hydrogen atoms which were then refined isotropically for one cycle, resulting in *R* 0.061. It was noted at this point that two of the hydrogen atoms, one associated with C(3) and the other with C(12), would not refine. Large thermal vibrations of these carbon atoms along *b* indicated possible disorder. An attempt to refine a split-atom disordered model failed. It should be noted that geometrical data involving the C(3) and C(12) methyl groups may be subject to errors arising from a possible slight disordering of the atoms involved. The two bad hydrogen atoms were removed from the list of atoms and a difference Fourier was calculated which revealed the locations of the two hydrogen atoms. All the non-hydrogen atoms were then treated anisotropically and the hydrogen atoms isotropically for four cycles of refinement. Convergence was reached at *R* 0.047 for 2503 observed reflections (2 reflections were given zero weight in the final stages of refinement due to suspected extinction errors: 002 and $20\bar{2}$).

The least-squares refinement was based on the minimization of $\Sigma w(F_o - F_c)^2$. The anisotropic thermal parameters are U_{ij} in the expression:

$$f = f_o \exp[-2\pi^2(U_{11}a^{*2}h^2 + U_{22}b^{*2}k^2 + U_{33}c^{*2}l^2 + 2U_{12}a^*b^*hk + 2U_{13}a^*c^*hl + 2U_{23}b^*c^*kl)]$$

The scattering factors, f_o, of ref. 15 were used for the non-hydrogen atoms and those of ref. 16 for the hydrogen atoms. A standard errors weighting scheme: $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave constant average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement.

A final difference Fourier was calculated and showed maximum fluctuations of 1.0 e Å^{-3} near the P_3N_3 ring and 0.2 e Å^{-3} elsewhere. On the final cycle of refinement, no parameter shift was greater than 0.6 σ for all non-hydrogen atoms except C(3) and C(12). These carbon atoms, as well as some of the hydrogen atoms, had parameter shifts of up to 1.7 σ. Final atomic positions are given in Table 2 and thermal parameters in Table 3. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Results and Discussion

A view of the molecule down *c* is shown in Fig. 1. Individual bond lengths and angles, with standard deviations, are given in Tables 4 and 5 respectively. Some weighted least-squares mean planes appear in Table 6.

The six-membered phosphazene ring is slightly but significantly non-planar, all atoms lying between −0.099 and 0.097 Å from the mean plane (see Table 6). The NP—NP dihedral angles in the ring, given in Table 7, range from −9.5

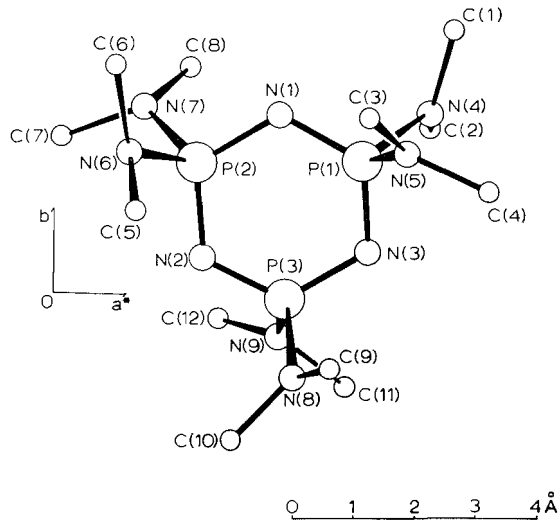

FIG. 1. A view of the molecule down *c* showing crystallographic numbering scheme. Hydrogen atoms have been omitted for clarity.

to 11.4° with a mean amplitude of 6.3°. Atoms P(1) and N(2) lie on one side of the mean plane while the remaining atoms lie on the opposite side so that the conformation of the P_3N_3 ring is that of a distorted boat. Of the other $[NPX_2]_3$ molecules whose structures have been studied, the fluoride (1) has a planar ring, the chloro- (2–4), bromo- (5), and phenyl (6) derivatives have slightly non-planar rings in the chair conformation, and the phenoxy derivative (8) has a slightly folded ring with approximate C_2 symmetry. In $P_3N_3Cl_3(NMe_2)_3$ (17) the P_3N_3 ring also has a distorted boat conformation. These small deviations from planarity have been ascribed to intra- and intermolecular steric effects (2, 5, 6).

The molecule has approximate D_3 symmetry. Bond lengths and angles averaged assuming D_3 symmetry appear in Table 8. The ring nitrogen atoms will be designated N_R and the exocyclic nitrogen atoms N_E. There are two classes of carbon atoms: one set [C(2), C(3), C(5), C(8), C(9), and C(12)], rotated toward the center of the P_3N_3 ring, are designated C_I (for inner) and the other set [C(1), C(4), C(6), C(7), C(10), and C(11)] C_O (for outer).

The P—N_R distances are equal within experimental error. They range from 1.583 to 1.592 Å (σ = 0.002–0.003 Å) with a mean value of 1.588(3) Å which is essentially equal to the mean P—N_R distances of 1.581(13) Å in $P_3N_3Cl_6$ (4) and 1.576(10) Å in $P_3N_3Br_6$ (5). The ring P—N distances in other $[NPX_2]_3$ molecules are: X = F (1), 1.560(10), Ph (6), 1.597(6), $\frac{1}{2}[O_2C_6H_4]$ (7), 1.575(2), and OPh (8), 1.575(2) Å. In $[NP(NMe_2)_2]_n$, where n = 4 (11) and 6 (12), the P—N_R distances average 1.578(10) and 1.563(10) Å, respectively. The close agreement of P—N_R distances in this structure with those in the chloro derivative (4) is in accord with the conclusion that the mean P—N bond length of a P—N—P segment is dependent primarily on the mean electronegativity of the two pairs of substituents on the bordering P atoms of the segment (6). On this basis the P—N_R bonds in the Cl and NMe_2 derivatives are expected to be of equal length since both substituents have an electronegativity of 3.0.

The exocyclic P—N_E bonds are also equal within experimental error. They range from

1.645 to 1.656 Å (σ = 0.003 Å) and the mean value of 1.652(4) Å is comparable to the mean P—N_E bond lengths of 1.678 (10) Å in $N_4P_4(NMe_2)_8$ (11), 1.669(10) Å in $N_6P_6(NMe_2)_{12}$ (12), and 1.636 Å in $N_3P_3Cl_3(NMe_2)_3$ (17). The P—N_E distances are considerably shorter than the 1.77 Å expected for a normal P(sp^3)—N(sp^3) bond (18). The shortening of P—N_R and P—N_E bonds in phosphazenes is indicative of some π-character in the bond but is also contributed to by a σ-hybridization effect (10), and can only be discussed in terms of π-bonding after σ-effects have been considered. Using the methods outlined by Craig and Paddock (10), the σ-hybridization adjustments have been made and corrected π-contractions estimated for all the P—N bonds. The observed and σ-adjusted π-contractions appear in Table 9, and show that the π-character of the P—N_R bonds is somewhat greater than in the P—N_E bonds.

The mean N—C distance (corrected for thermal motion) of 1.482(10) Å is close to the expected value of 1.472(5) Å (19). The uncorrected N—C bonds average 1.447(21) Å, 1.453(12) Å

if C(3) and C(12) are excluded, compared to the value of 1.455 Å for $N_4P_4(NMe_2)_8$ (11), $N_3P_3Cl_3(NMe_2)_3$ (17), and $HNMe_2$ (20). The mean $N—C_I$ bond is shorter than the mean $N—C_O$ bond for both the corrected and uncorrected distances (see Table 8). Table 4 shows that at each N_E the two N—C distances differ by at least 2 σ (for the uncorrected distances). This is due to steric and electronic effects which will be discussed later.

The individual bond angles and dihedral angles (Table 7) show some small but significant deviations from D_3 symmetry. The most notable of these distortions is the inequivalence of the two NMe_2 groups bonded to each P atom. (In view of the possible disorder in C(3) and C(12), associated geometrical parameters may be in error. It is felt, however, that the errors are small enough to retain the validity of the ensuing discussion, supported by data in refs. 11, 12, and 17 and the location of C(3) and C(12) H atoms.) This is due to interaction of the two N_E lone electron

pairs with different d orbitals of the phosphorus atom (10). This causes no noticeable difference between the two P—N_E bond lengths at each phosphorus atom, but manifests itself primarily in the bond angles at the N_E atoms. The sum of bond angles at N_E atoms ranges from 347.7 to 359.9° with a mean value of 353.3° (mean angle at N_E = 117.8°), some 25° greater than expected (3 × 109.45). This is indicative of delocalization of the N_E lone pairs into the ring system in agreement with the estimated π-contractions calculated for the P—N_E bonds. Data in Table 6 show that for each phosphorus atom one of the NMe_2 groups is significantly more planar than the other; in fact the group P(1)N(5)C(3)C(4) is planar within experimental error. Moreover, the more planar NMe_2 groups, N(5), N(7), and N(9), are not all on the same side of the P_3N_3 ring. N(5) which is attached to P(1), the unique P atom in the boat conformation, lies on the opposite side of the ring from the two other more planar NMe_2 groups. The bond angle sums at the various N_E atoms are: N(4), 347.7, N(5), 359.9, N(6), 349.4, N(7), 353.0, N(8), 350.7, and N(9), 359.0°. The mean value for the more planar groups is 357.3° and for the less planar groups 349.3°. Comparable differences between two NMe_2 groups attached to the same phosphorus atom have been noted for other phosphazene derivatives, for example, sums of bond angles about the two classes of N_E atoms average 358.5 and 349.5° in $N_4P_4(NMe_2)_8$ (11), 357.5 and 348.7° in $N_6P_6(NMe_2)_{12}$ (12), and 351.1 and 347.9° in $N_3P_3Cl_3(NMe_2)_3$ (17). Averaged bond lengths and angles treating the more and less planar N_E atoms separately also appear in Table 8. These parameters have better r.m.s. deviations than those calculated assuming D_3 symmetry.

The mean C—N—C angle is 113.9(12)°, each individual value being significantly larger than the 111.8° in $HNMe_2$ (20). Again we note a difference between the more and less planar N_E atoms, the C—N—C angles average 114.8(9) for the former and 112.9(3)° for the latter. Steric interactions between the ring nitrogen atoms and C_I hydrogen atoms are responsible for significant differences between the two PN_EC angles at each N_E atom and the two N_RPN_E angles at each phosphorus atom. Expansion of the PN_EC_I angles to a mean value of 121.3(27), and the corresponding N_EPN_R to a mean of 112.7(8)° combined with corresponding contractions of PN_EC_O to a mean

*Both observed and σ-adjusted π-contractions are tabulated (π-contractions are estimated with reference to a P—N single bond length of 1.77 Å). The last value in each column is an average value.

of 118.1(3)° (from an expected 119.7° assuming equality of the two PN_EC angles) and of N_RPN_E to a mean of 106.1(5)° ease the intramolecular contacts $N_R...H(C_I)$ and $N_R...C_I$ which are compiled in Table 10. Each of the listed N...H contacts is less than the van der Waals distance of 2.7 Å, and the N...C contacts are less than the corresponding 3.2 Å. There are again small differences in these angles for the more and less planar N_E atoms listed in Table 8.

The mean angle at each phosphorus atom is 109.3°; the ring angles N_RPN_R average 116.7(4)°, comparable to the $[NPX_2]_3$ molecules (1–8) where the endocyclic NPN angles have mean values ranging from 116.6 to 120.0°. There are

TABLE 10. Selected nonbonded contacts less than 3.5 Å

Intramolecular		Intermolecular	
Atoms	Distance (Å)	Atoms	Distance (Å)
N(1)...H(31)	2.48(4)	N(1)...H(112^{I})	2.96(6)

*Roman numeral superscripts refer to atoms at positions: I, x, 1 + y, z; II, $-x$, $y - \frac{1}{2}$, $\frac{1}{2} - z$; III, 1 − x, $y - \frac{1}{2}$, $\frac{1}{2} - z$; IV, x, $\frac{1}{2} - y$, $z - \frac{1}{2}$; V, x, $\frac{1}{2} - y$, $\frac{1}{2} + z$.

small but significant deviations between the individual values which range from 116.3(1) to 117.0(1)°, a range of 5σ. The mean P—N_R—P angle is 123.0(4)° which is slightly, but not significantly larger than in the other $[NPX_2]_3$ molecules (1–8), where mean P—N_R—P angles range from 121.3° in the bromo-derivative (5) to 122.5° for $X = \frac{1}{2}[O_2C_6H_4]$ (7). Again there are small but significant differences between the individual values due to inter- and intramolecular steric effects as mentioned earlier.

The angles made by the planes of the ligands (PN_EN_E) with the mean plane of the phosphazene ring are inequivalent, being 87, 88, and 99° at P(1), P(2), and P(3), respectively. The rotations of the NMe_2 groups about the P—N_E bonds (measured by the N_RP—N_EC_O dihedral angles listed in Table 7) range from −49.5 to −58.6°, mean −53(3)°, the angles being smaller (mean −50.7°) at the more planar N_E atoms than at the less planar (mean −55.1°). These values are similar to the values of 50 and 53 in the $\diagdown P(NMe_2)_2 \diagup$ segment of $P_3N_3Cl_3(NMe_2)_3$ (17).

The geometry involving the hydrogen atoms is as expected; C—H bonds range from 0.65 to 1.14 Å, mean 0.96(11) Å. The mean angle at carbon is 109.2°, the N—C—H angles average 110.5° and the H—C—H angles 108.0°, as expected on steric grounds.

The structure viewed down *b* is shown in Fig. 2. There are no N...C or C...C intermolecular contacts less than 3.5 Å. The shortest intermolecular contacts involve hydrogen atoms and are given in Table 10. All of these correspond to normal van der Waals contacts.

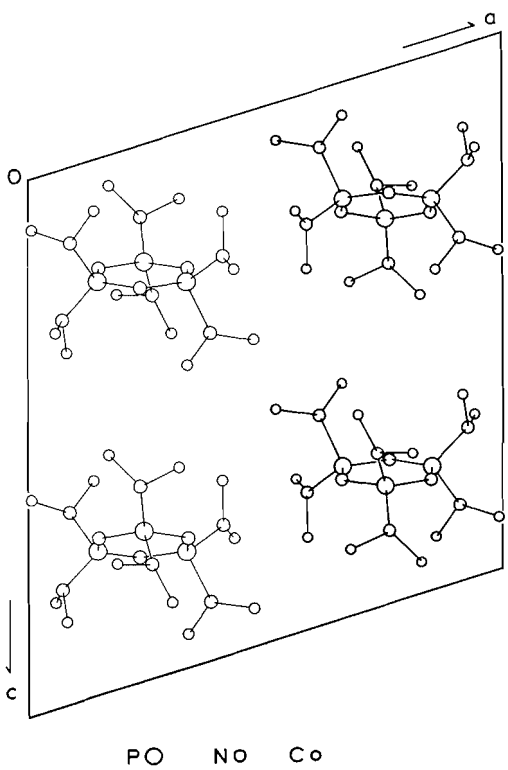

FIG. 2. Projection of the structure down *b*. Hydrogen atoms have been omitted for clarity.

We thank Professor N. L. Paddock and Dr. J. N. Wingfield for the crystals and discussion, the National Research Council of Canada for financial support, and the University of British Columbia Computing Centre for assistance.

Crystal and Molecular Structure of Potassium *trans*-1,2-Diaminocyclohexane-*N*,*N*′-tetraacetatomanganate(III) Monohydrate, K[Mn(DCTA)]·H_2O[1]

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 18, 1972

Crystals of the title compound are triclinic, $a = 15.60(3)$, $b = 8.66(2)$, $c = 7.36(1)$ Å, $\alpha = 103.8(1)$, $\beta = 95.7(1)$, $\gamma = 70.7(3)°$, $Z = 2$, space group $P\bar{1}$. The measured and calculated densities are 1.69(2) and 1.656(6) g cm^{-3}, respectively. The structure was determined by Patterson and Fourier synthesis and refined by full-matrix least-squares procedures to a final R of 0.067 for 2333 observed reflections. The structure is composed of layers of oxygen bridged potassium ions situated between two layers of $[Mn(DCTA)]^-$ anions, thus forming the basic structural unit which repeats along a. The manganese(III) is six-coordinated to the two nitrogen and four oxygen atoms of the hexadentate ligand, the coordination polyhedron being a very distorted octahedron with N—Mn—O and O—Mn—O angles of 77.1(2) and 128.5(2)°, respectively. The anion has approximate C_2 symmetry with two classes of Mn—O bonds, mean bond lengths 1.887(7) and 2.015(22) Å; the mean Mn—N distance is 2.263(5) Å. The water molecule is twofold disordered and is coordinated to the potassium ion in both positions. The potassium ion is eight or nine coordinated to oxygen atoms depending on the position taken by the water molecule. Weak hydrogen bonds involving the water molecule are probably present, O...O distances range from 2.71(3) to 3.18(3) Å, as well as possible C—H...O hydrogen bonds with C...O distances ranging from 3.300(9) to 3.388(8) Å.

Le composé cité dans le titre cristallise dans le système triclinique, $a = 15.60(3)$, $b = 8.662(2)$, $c = 7.36(1)$ Å, $\alpha = 103.8(1)$, $\beta = 95.7(1)$, $\gamma = 70.7(3)°$, $Z = 2$, groupe spatial $P\bar{1}$. Les densités mesurées et calculées valent respectivement 1.69(2) et 1.656(6) g cm^{-3}. La structure a été déterminée à l'aide des synthèses de Patterson et de Fourier, et a été affinée par la méthode de moindres carrés (matrice complète) jusqu'à un indice $R = 0.067$ pour 2333 réflexions observées. L'unité fondamentale de la structure se compose d'une couche d'ions de potassium reliés par des ions d'oxygène, située entre deux couches d'anions $[Mn(DCTA)]^-$, et cette unité se répète le long de l'axe a. L'ion manganese(III) est coordonné aux deux atomes d'azote et aux quatre atomes d'oxygène du ligand hexadenté, le polyèdre de coordination étant un octaèdre très déformé dont les angles N—Mn—O et O—Mn—O sont égaux respectivement à 77.1(2) et 128.5(2)°. L'anion, qui s'écarte à peine de la symétrie C_2, possède deux classes de liaisons Mn—O, dont les longueurs moyennes sont égales à 1.887(7) et 2.015(22) Å, et la longueur moyenne de la liaison Mn—N est égale à 2.263(5) Å. La molécule d'eau est doublement désordonnée et dans chaque position elle est coordonnée à un ion de potassium. L'ion de potassium est coordonné à huit ou neuf atomes d'oxygène selon les positions des molécules d'eau. Il est probable que la molécule d'eau s'engage dans de faibles liaisons hydrogène ; les distances O...O s'étendent de 2.71(3) à 3.18(3) Å. Des liaisons hydrogène C—H...O sont possibles ; les distances C...O s'eténdent de 3.300(9) à 3.388(8) Å.

Can. J. Chem., 51, 1303 (1973)

Introduction

The structure analysis of K[Mn(DCTA)]·H_2O has been undertaken to investigate the possibility of a seven-coordinate Mn(III) complex. Parallel chemical investigations (1 and references therein; 2, 3) have suggested a strong association between the water molecule and the complex ion in solution, and seven-coordination has been found in related complexes (4 and references therein). The present analysis however shows that in the solid state the Mn(III) ion is six-coordinated to the hexadentate ligand. It has been pointed out (4) that the ring constraints are incompatible with a quasi-octahedral configuration except for a relatively small central cation. The apparently strong interaction in solution and the large angular distortions from octahedral geometry in the six-coordinated anion found in the solid state for the present compound imply that the size of the manganese(III) ion is near the upper limit for six-coordination to DCTA.

Experimental

Single crystals of K[Mn(DCTA)]·H_2O, suitable for X-ray analysis were prepared by Poh (2). The recrystallization solvent was a 3:2 mixture of water and methanol.

[1]Here, and elsewhere in this paper, EDTA and DCTA refer to the ethylenediaminetetraacetate and *trans*-1,2-diaminocyclohexane-*N*,*N*′-tetraacetate anions.

*See ref. 5.

The crystals were dark and irregularly developed. The specimen chosen for study was elongated along c and was mounted with c^* along the goniostat axis. The crystal dimensions were *ca.* 0.3 × 0.3 × 0.45 mm. Unit cell and space group data were obtained from film and diffractometer measurements. The unit cell was refined by a least-squares treatment of $\sin^2\theta$ values for 30 reflections measured on a diffractometer with MoKα radiation. The density was measured by flotation in benzene–chloroform. Crystal data are:

$C_{14}H_{20}KMnN_2O_9$ f.w. = 454.0

Triclinic, $a = 15.60(3)$, $b = 8.66(2)$, $c = 7.36(1)$ Å, $\alpha = 103.8(1)$, $\beta = 95.7(1)$, $\gamma = 70.7(3)°$, $V = 910(3)$ Å^3, $\rho_o = 1.69(2)$, $Z = 2$, $\rho_c = 1.656(6)$, $F(000) = 468$ (20 °C, MoKα, $\lambda = 0.71069$ Å, $\mu = 10$ cm^{-1}). Space group $P\bar{1}$(C_i^1, No. 2) from structure analysis.

Intensities were measured on a General Electric XRD 6 diffractometer, with a scintillation counter, MoKα radiation (zirconium filter and pulse height analyzer), and a θ–2θ scan at 2° min^{-1} over a range of (1.80 + 0.86 tan θ) degrees in 2θ, with 20 s background counts being measured at each end of the scan. Data were measured to $2\theta = 52°$ (minimum interplanar spacing 0.81 Å). A check reflection was monitored every 40 reflections throughout the data collection. The intensity of the check reflection had dropped to 63% of its original intensity by the end of the data collection. The intensities of 20 strong reflections which had been measured early in the data collection were remeasured at the end and were found to have the same relative intensities as before. Lorentz and polarization corrections were applied, and structure amplitudes were derived. No absorption correction was made in view of the low value of μ. Of the 3560 independent reflections measured, 1227 had intensities less than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.03\ S)^2$ with S = scan count and B = background count. These reflections were classified as unobserved.

Structure Analysis and Refinement

The $|E|$ statistics are compared with theoretical values (5) for centrosymmetric and noncentrosymmetric structures in Table 1; the former distribution is strongly indicated, confirming the space group as $P\bar{1}$.

The positions of the manganese and potassium atoms were determined from the three-dimensional Patterson function. One cycle of full-matrix least-squares refinement of the positional and isotropic thermal parameters of the heavy atoms gave R 0.320. A difference Fourier synthesis revealed the positions of all the non-hydrogen atoms with the exception of O(9), the water oxygen. The atoms located were refined as follows; two cycles of isotropic refinement of all the atoms followed by one cycle with the carbon atoms isotropic and all the remaining atoms anisotropic, reducing R to 0.109. A second difference Fourier was calculated which revealed a possible location for O(9) as well as 17 of the 20 hydrogen atoms. The carbon atoms were refined anisotropically and O(9) isotropically for one cycle followed by one cycle of isotropic refinement of the hydrogen atoms and O(9), resulting in R 0.074. It was noted that the temperature factor for O(9) was not refining and a difference Fourier was calculated revealing a peak greatly elongated along z for O(9). The remaining non-water hydrogen atom was also located. Positions and site-occupancies were estimated for the twofold disordered O(9) from the difference Fourier and the positional, thermal, and then occupational parameters for the split O(9) were refined over two cycles resulting in R 0.069. Finally the entire structure was refined, all non-hydrogen atoms anisotropically and the hydrogen atoms isotropically for two cycles. Convergence was reached at R 0.067 for 2333 observed reflections.

The least-squares refinement was based on the minimization of $\Sigma w\ (F_o - F_c)^2$. The scattering factors of ref. 6(*a*) were used for the non-hydrogen atoms and those of ref. 6(*b*) for the hydrogens. The weighting scheme: $\sqrt{w} = 1$ if $|F_o| \leqslant 15$, $\sqrt{w} = 15/|F_o|$ if $|F_o| > 15$, and $\sqrt{w} = 0.50$ for the unobserved reflections gave constant average values of $w(F_o - F_c)^2$ over ranges of $|F_o|$, and was employed in the final stages of refinement.

On the final cycle of refinement, no parameter shift was greater than 0.45σ. A final difference Fourier was calculated and showed maximum fluctuations of 0.8 e Å^{-3} in the proximity of the heavy atoms and 0.4 e Å^{-3} elsewhere. The final positional and thermal parameters are given in Tables 2 and 3, respectively. Measured and calculated structure factor amplitudes have been placed in the Depository of Unpublished Data.[2]

[2]The structure factor table is available at a nominal charge from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

*Multiplicities for the positions of the disordered water molecule are O(9), 0.62 and O(9′), 0.38.

Results and Discussion

The Complex Anion $[Mn(DCTA)]^-$

Individual bond lengths and angles in the anion are given in Tables 4 and 5, respectively. The manganese(III) ion is six-coordinated to the two nitrogen and four oxygen atoms of the hexadentate ligand DCTA. The coordination polyhedron of the manganese(III) ion is a very distorted octahedron with N—Mn—O and O—Mn—O angles of 77.1(2) and 128.5(2)°, respectively. The mean Mn—N distance is 2.263 Å and the Mn—O bonds fall into two classes with mean bond lengths of 1.887 and 2.015 Å. The anion, illustrated in Fig. 1, has approximate C_2 symmetry despite its asymmetric environment. The quasi-twofold axis, common in this type of structure (see *e.g.* refs. 4, 7–9), passes through the Mn atom and the midpoints of the C(1)—C(2) and C(4)—C(5) bonds of the cyclohexane ring. The geometrical parameters for the anion, averaged assuming twofold symmetry, appear in Table 6.

Using the terminology of ref. 4, the less strained glycinate rings, MnO(3)C(10)C(9)N(1) and MnO(5)C(12)C(11)N(2), are designated as L, and the more strained, MnO(1)C(8)C(7)N(1) and MnO(7)C(14)C(13)N(2), as M. The cyclohexane and pseudoethylenediamine (MnN(1)-

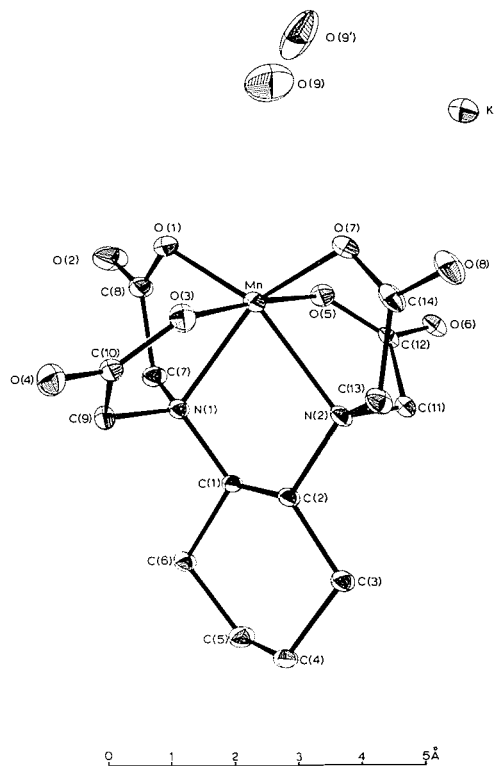

FIG. 1. A view of the anion and the neighboring potassium and disordered water molecule, 50% probability ellipsoids are shown. Hydrogen atoms are omitted for clarity.

*Anisotropic temperature factors are U_{ij} in: $f = f^0 \exp(-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*))$.

C(1)C(2)N(2)) rings are designated as CH and E, respectively. The carboxylate oxygen atoms are classified as O_c or O_u depending on whether or not they are complexed to the manganese atom. The O_c are the odd numbered carboxylate oxygens and the O_u the even numbered. The hydrogen atoms are identified by the number of the carbon atom to which they are bonded followed by a 1 or 2. For the cyclohexane ring hydrogen atoms, the 1 denotes axial and the 2 equatorial positions; the glycinate hydrogens were arbitrarily numbered 1 or 2.

The cyclohexane ring is in the "chair" form, showing only minor angular strain. The CC—CC dihedral angles range from 47 to 64° in absolute value with a mean magnitude of 55°. The C—C bond lengths in the CH ring range from 1.537–1.551 Å with a mean value of 1.541(7) Å in excellent agreement with the standard 1.54 Å for a C(sp^3)—C(sp^3) bond (10). The C—C—C

*R.m.s. deviation from the mean given when more than one value has been used, for single values the least-squares standard deviation is quoted.
†Angle at the junction of two rings.

equal to those in the M rings. Ring strain in the L, M, and E rings is indicated by the sum of the interior angles in the rings, and by the dihedral angles. The ideal L and M rings should be nearly planar (7), the sum of interior angles then should be 540° and the dihedral angles 0°. The ideal E ring should have a 528° sum of interior angles (90 + 4(109.5)) (7). The sums of interior angles for the L, M, and E rings, respectively, are 538.1(6), 526.2(18), and 513.1°, and the mean magnitudes of the dihedral angles in the L and M rings are 9 and 25°. The larger OCC angle in the M ring (compared to that in the L ring) is compatible with closing the O(1)—Mn—O(7) angle and is a notable difference between this structure and the similar seven-coordinate $[Fe(OH_2)DCTA]^-$ in which the corresponding O—Fe—O angle is 148.9°, and the OCC angle is equal to 115.7° in both L and M rings (4).

The mean C—N bond length of 1.488(16) Å is close to the expected value of 1.479 Å for a N(sp^3)—C(sp^3) bond (10). The C—C(glycinate) distances, mean 1.527(8) Å, are somewhat longer than the 1.510 Å expected for C(sp^3)—C(sp^2) bonds (10), but agree with the values found in similar structures, *e.g.* 1.523 Å in $[Fe(OH_2)DCTA]^-$ (4), 1.523 Å in $[Ni(H_2EDTA)\cdot H_2O]$ (11), and 1.53 Å in $[Co(EDTA)]^-$ (7), all

For personal use only.

of which have relatively strong M—O interactions. The difference in C—O_u and C—O_c bond lengths is an indication of the strength of the metal–oxygen interaction. In this structure, unlike that of [Fe(OH_2)DCTA]$^-$, there is a difference between the C—O distances for the L and M rings. The C—O_u and C—O_c bond lengths are 1.233 and 1.315 Å for the L rings, and 1.245 and 1.286 Å for the M rings. These can be compared to the mean values for the above structures: C—O_u and C—O_c are 1.233 and 1.273 Å for the Fe compound, and 1.22 and 1.30 Å for the Co compound.

The geometry involving the hydrogen atoms is normal; the C—H bond lengths range from 0.86 to 1.18 Å, mean 1.00(9) Å. The N—C—H, C—C—H and H—C—H bond angles do not differ significantly from the tetrahedral value, ranging from 99–119°, mean 108(5)°.

The two Mn—N bonds are equal, within experimental error, to the mean value of 2.263 Å. These distances are significantly longer than the 2.019 and 2.020 Å "short" and the 2.153 Å "long" Mn—N bonds in (acac)Mn(III)(pati)$_2$ (acetylacetonatobis-(*N*-phenylaminotroponiminato)manganese(III)) (12). The shorter Mn—O distances in the L rings are equal, and their mean, 1.887 Å, agrees well with the mean Mn—O distance of 1.894 Å found for (acac)$_3$Mn(III)-(trisacetylacetonatomanganese(III)) (13 and a refinement of the data given by Davis *et al.*). The Mn—O distances in the M rings, however, differ by a statistically significant 0.042 Å (7σ). These distances, Mn—O(1), 2.036 Å and Mn—O(7), 1.993 Å, are intermediate between the short (1.959 Å) and long (2.134 Å) Mn—O bonds found for (acac)Mn(pati)$_2$ (12). This difference can be ascribed to the effects of the asymmetric environment. The difference between the two sets of Mn—O distances (*ca.* 0.12 Å), the long Mn—N distances, and angular distortions at the manganese atom are due primarily to the stereochemical constraints imposed by the ligand and by the size of the manganese(III) ion. In the similar [Fe(OH_2)DCTA]$^-$ anion (4), the metal–nitrogen bonds were also found to be relatively long. If the Mn—N distances were reduced, the C—N—C angles between the E ring and both the L and M rings would need to be expanded further from their already strained values (E–L, 115.1, E–M, 113.0°) in order to maintain the same Mn—O bond lengths. It is of interest to note that the mean bond distance (of M—O and M—N bonds) in this complex is 2.055 Å, nearly equal to that of (acac)Mn(pati)$_2$, 2.051 Å (12). It is also greater than that of six-coordinate [Co(EDTA)]$^-$, 1.908 Å (7), and shorter than found in the seven-coordinate complexes [Fe(OH_2)DCTA]$^-$ (4), [Fe(OH_2)-EDTA]$^-$ (9), 2.127 and 2.120 Å, respectively. The range of bond distances in [Mn(DCTA)]$^-$ is 0.38 Å (including the Mn—N distances). This is much larger than observed in other six coordinate EDTA complexes, *e.g.* 0.04 Å in [Co(EDTA)]$^-$ (7) and 0.15 Å in [Ni(H_2EDTA) H_2O] (11). The possibility that the pattern of two short and four long bonds is to some degree due to a "Jahn–Teller distortion" for this high-spin Mn(III) complex should not be ruled out. Distortions of both distances and angles are present in (acac)Mn(pati)$_2$ (12).

Statistically significant deviations from C_2 symmetry occur in the inner coordination group. In addition to the difference between the Mn—O bond distances in the M rings, the bond angles at the manganese atom all show small but significant deviations from C_2 symmetry, except the pair O(1)—Mn—O(5) and O(7)—Mn—O(3). The largest of these differences is 3.7° between the angles O(1)—Mn—O(3) and O(7)—Mn—O(5). The edges of the coordination polyhedron show considerable deviation from C_2 symmetry, the significant differences being: 0.109 Å between O(1)—O(3) and O(7)—O(5), 0.040 Å between O(3)—N(2) and O(5)—N(1), and 0.035 Å between O(1)—O(5) and O(7)—O(3). As has been pointed out (8, 9), the strains produced by the asymmetric environment accumulate in the coordination group.

The four carboxylate groups are all planar within experimental error. The carbon atoms of the E ring (C(1), C(2)) lie on opposite sides of the MnNN plane, being displaced 0.34 and 0.42 Å from the plane, respectively. The two L rings are roughly perpendicular to the MnNN plane, the angles between the mean planes of the L rings and the MnNN plane averaging 80.6(8)°. The angle between the C.COO reference planes in the two L rings is 91°. The deviations of the manganese and nitrogen atoms, respectively, from C.COO reference planes in the L rings are −0.18 and 0.17 Å for the ring containing O(5), and 0.32 and 0.05 Å for the ring containing O(3).

The methylene carbon atoms of the M rings (C(7), C(13)) lie 1.0 Å on opposite sides of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

MnNN plane, as in $[Co(EDTA)]^-$ (7). The Mn—O bonds in the M rings should ideally lie in the MnNN plane, but due to angular strain in the ligand, this is not the case. The M ring oxygen atoms [O(1)1,O(7)] lie 0.46 and 0.38 Å on opposite sides of the MnNN plane. The angle between the reference C.COO planes of the M rings is 12°. All the atoms in the M rings lie to one side of the Mn—O bond, the manganese and nitrogen atoms lie on opposite sides of the C.COO planes, being displaced 0.60 and 0.30 Å in the M ring containing O(1), and 0.32 and 0.46 Å in the ring containing O(7). The C.COO planes make angles of 34 (O(1) ring) and 26° (O(7) ring) with the MnNN plane.

It is apparent from the previous data that the individual L and M rings are not equivalent. The reason for these deviations from C_2 symmetry is asymmetric interaction of the oxygen atoms with the potassium ion and the water molecule. The O_u atoms of both glycinate rings containing N(2) bridge two potassium ions, while for their counterparts O(2) (M ring) is coordinated to a potassium ion and O(4) is involved in, at best, a very weak CH...O hydrogen bond. Both O_c atoms in the M rings interact with potassium ions, but O(7) is more strongly coordinated than is O(1). The L ring O_c atoms (O(3), O(5)) are also different in that O(3) coordinates only the manganese while O(5) is probably hydrogen bonded to the water molecule

Crystal Packing Arrangement

Projections of the structure along *c* and *b* are shown in Figs. 2 and 3, respectively. The structure consists of layers of oxygen bridged potassium ions which form dimers when O(9) is present and polymers with O(9′). The potassium atoms form zig-zag arrays along *b* which lie approximately in the *bc* plane as shown in Fig. 4. The layers of potassium ions are situated between two layers of $[Mn(DCTA)]^-$ anions. These three layers form a basic unit as each potassium ion coordinates oxygen atoms from five different $[Mn(DCTA)]^-$ anions. This basic structural unit repeats along *a*, layers are staggered, thereby minimizing contacts between the cyclohexane rings.

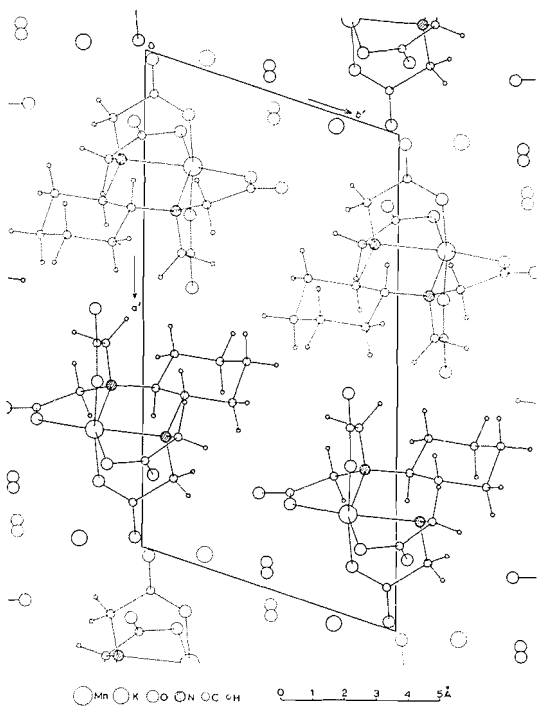

FIG. 2. Projection of the structure down the *c* axis.

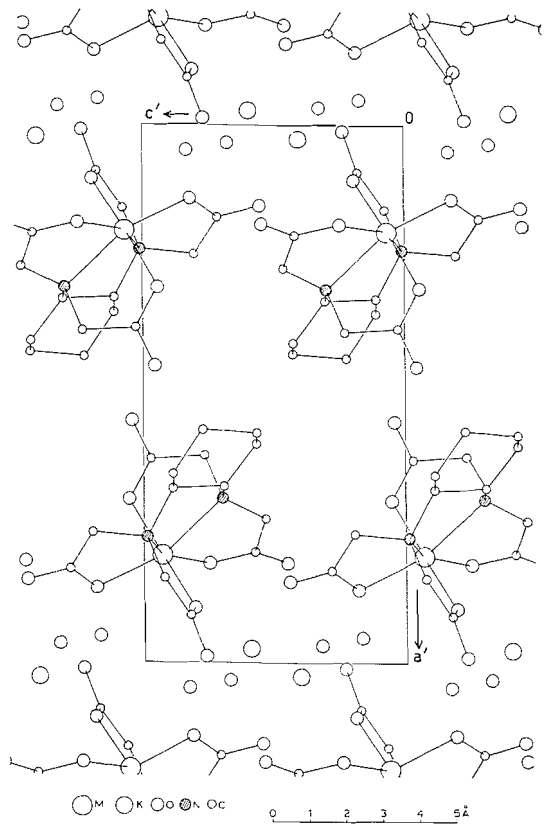

FIG. 3. Projection of the structure down the *b* axis; hydrogen atoms are omitted for clarity.

TABLE 7. Possible hydrogen bonds

	Lengths (Å)		Angles (deg)
A.....H—B	A...H	A...B	A...H—B
O(5)...(H)O(9)	—	2.94(2)	—
O(2)...(H)O(9)	—	3.18(3)	—
O(5)...(H)O(9′)	—	2.83(2)	—
O(2)...(H)O(9′)	—	2.72(3)	—
O(2)...H(132)—C(13)	2.46(7)	3.300(9)	156
O(4)...H(92)—C(9)	2.48(8)	3.388(8)	150
O(8)...H(11)—C(1)	2.38(6)	3.383(8)	151

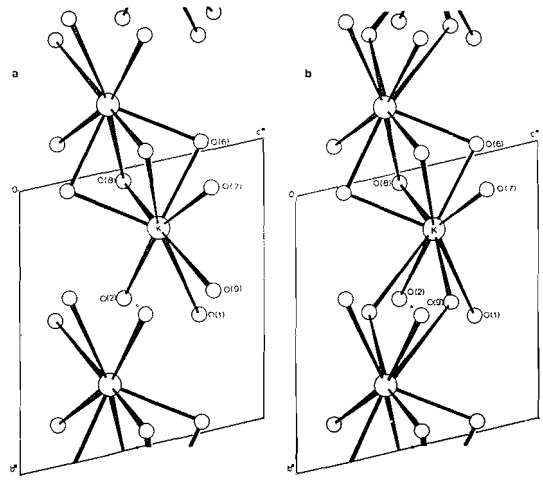

FIG. 4. Views of the arrangement of the potassium and oxygen atoms down *a*; (*a*) water molecule in position O(9), (*b*) water molecule in position O(9′).

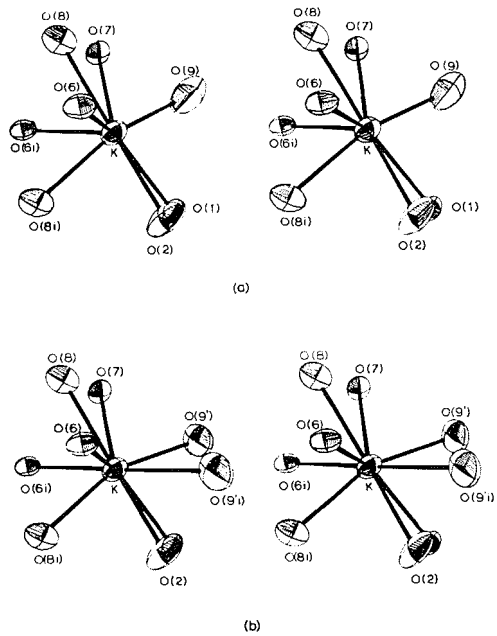

FIG. 5. Stereo views of the coordination group of the potassium ion; (*a*) the eight coordinate structure resulting from occupation of position O(9) by the water molecule, (*b*) the nine coordinate structure resulting from occupation of the position O(9′) by the water molecule.

The nearest neighbors of the potassium ion are eight or nine oxygen atoms from the water molecules and the anions at distances ranging from 2.71 to 3.21 Å. Distances observed in similar structures range from 2.6 to 3.2 Å (14–26). The next nearest neighbor to the potassium atom is C(14) at 3.275 Å. The potassium atoms lie astride centers of symmetry at (0,0,1/2) and (0,1/2,1/2). Oxygen atoms O(6) and O(8) bridge between two potassium atoms related by the center at (0,0,1/2), the water oxygen O(9′) bridges potassium atoms related by the center at (0,1/2,1/2). Oxygen atoms O(1) and O(7) are coordinated to the potassium and form bridges between Mn and K atoms. The coordination sphere is completed by oxygen atoms O(2) and O(9). Stereo views of two of the possible coordination groups of the potassium atom, those involving either O(9) or O(9′) but not both, are shown in Fig. 5. The bridging arrangement involving O(6) and O(8) is quite similar to that found in the structure of K[PhC(O)CH:NOHON:CHC(O)Ph] (14). The coordination polyhedra formed were not found to have any obvious simple geometry (27).

The water molecule is probably involved in hydrogen bonds to O(2) and O(5) (see Table 7 for relevant geometrical data). O(9′) is the more favorable of the two disordered positions for hydrogen bonding; the distances to O(2) and O(5) are 2.72(3) and 2.83(2) Å. O(9) forms weak hydrogen bonds with the same atoms at distances of 3.18(2) and 2.94(2) Å. The distance O(7)...O(9)

is 3.04 Å, but a hydrogen bond between these atoms was rejected on the basis of geometrical data.

It has been remarked that a good criterion for the existence of the hydrogen bond is that at least two heavy atom – hydrogen distances less than the sum of the van der Waals radii be present (28). There are three independent O...H separations less than the 2.6 Å sum of van der Waals radii present in this structure. The O...H distances range from 2.38–2.48 Å (see Table 7), and involve O_u atoms O(2), O(4), and O(8), and methylene hydrogen atoms H(132), H(92), and H(11). There is a good possibility that these are weak C—H...O hydrogen bonds. The full geometrical data in Table 7 are quite reasonable for hydrogen bonding schemes. The O...C distances, ranging from 3.300 to 3.388 Å, are somewhat longer than the 2.95–3.22 Å reported previously for postulated C—H...O hydrogen bonds (ref. 28, p. 182; 29). All other intermolecular contacts correspond to van der Waals interactions.

We thank Professor R. Stewart and Dr. B.L. Poh for crystals and discussion, the National Research Council of Canada for financial support, and the University of British Columbia Computing Centre for assistance.

Nucleic Acid Related Compounds. 5. The Transformation of Formycin and Tubercidin into 2′- and 3′-Deoxynucleosides[1,2]

MORRIS J. ROBINS,[3] JAMES R. MCCARTHY, JR.,[4] ROGER A. JONES,[3,5] AND RUDOLF MENGEL[3,6]

Department of Chemistry, The University of Alberta, Edmonton, Alberta T6G 2G2 and Department of Chemistry, University of Utah, Salt Lake City, Utah

Received November 7, 1972

Reaction of tubercidin (4-amino-7-β-D-ribofuranosylpyrrolo[2,3-*d*]pyrimidine) (**1**) with α-acetoxyisobutyryl chloride in the presence of excess sodium iodide in acetonitrile gave an acylated iodo intermediate (**2**) which was converted into 3′-deoxytubercidin (**4**) by hydrogenolysis and subsequent saponification.

Analogous treatment of formycin (7-amino-3-β-D-ribofuranosylpyrazolo[4,3-*d*]pyrimidine) (**5**) gave 3′-deoxyformycin (**6**) and 2′-deoxyformycin (**7**) in an approximate ratio of 3:2. These purified nucleosides, **6** and **7** were individually deaminated enzymatically to give 3′-deoxyformycin B (**8**) and 2′-deoxyformycin B (**9**).

Biological rationale, n.m.r., and mass spectra of these antibiotic-derived deoxynucleosides are discussed.

La réaction de la tubercidine (amino-4 β-D-ribofuranosyl-7 pyrrolo pyrimidine [2,3-*d*]) (**1**) avec le chlorure d'α-acétoxyisobutyryle en présence d'un excès d'iodure de sodium dans l'acétonitrile donne un intermédiaire iodo acylé (**2**) qui a été transformé en déoxy-3′ tubercidine (**4**) par hydrogénolyse suivie d'une saponification.

Le traitement identique de la formycine (amino-7 β-D-ribofuranosyl-3 pyrazolo pyrimidine [4,3-*d*]) (**5**) donne la déoxy-3′ formycine (**6**) et la déoxy-2′ formicyne (**7**) dans un rapport approximativement égal à 3:2. Les nucléosides purifiés, **6** et **7**, donnent respectivement la déoxy-3′ formycine B(**8**) et la déoxy-2′ formycine B(**9**) lorsque l'on enlève leur groupement aminé par action enzymatique.

Les caractéristiques biologiques ainsi que les spectres de masse et r.m.n. de ces déoxynucléosides dérivés d'antibiotiques sont discutés. [Traduit par le journal]

Can. J. Chem., **51**, 1313 (1973)

We wish to report the synthesis of 3′-deoxytubercidin (**4**), 3′-deoxyformycin (**6**), and 2′-deoxyformycin (**7**) using the "abnormal" reaction of α-acetoxyisobutyryl halides with diols discovered by Mattocks (1) and first applied to nucleosides by Moffatt and coworkers (2).

The nucleoside antibiotics tubercidin (**1**) and formycin (**5**) have been studied in considerable detail in biological systems and a comprehensive review is available (3). Formycin (**5**) is currently undergoing investigation in molecular biology

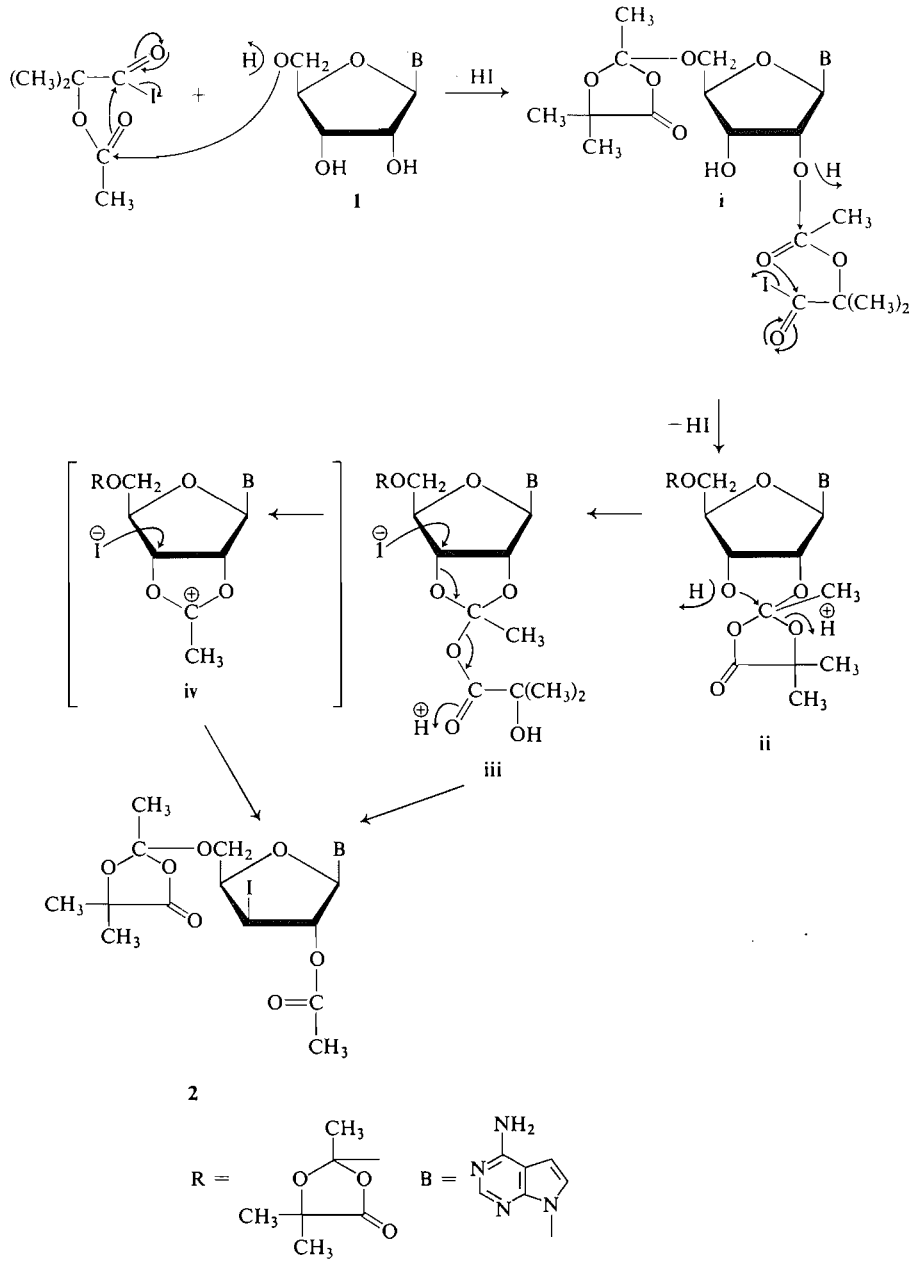

SCHEME I

due to its fluorescent properties which make its observation in polynucleotide and coenzyme systems unique (4), and also due to its *syn*-sugar–base conformation (5). The synthesis and study of deoxypolynucleotides containing 2′-deoxyformycin as well as enzyme-monomer studies of various deoxyformycin phosphates would be of considerable interest. Enzymatic systems can reduce tubercidin (**1**) to a 2′-deoxy derivative in microgram quantities 6), but no chemical syntheses of deoxy analogs of these antibiotics have been reported.

Reaction of tubercidin (**1**) with α-acetoxyisobutyryl chloride (7) in the presence of a threefold molar excess of sodium iodide in acetonitrile (*in situ* formation of α-acetoxyisobutyryl iodide

with sodium chloride precipitation from solution) gave the acylated iodo intermediate (**2**) which could arise by the mechanism depicted in Scheme 1. Attack of the 5′-oxygen on the less sterically hindered acetyl carbonyl carbon of α-acetoxyisobutyryl iodide with concurrent attack of the acetyl carbonyl oxygen on the carbonyl iodide and subsequent deprotonation of 5′-*O* would lead to **i** as analogously proposed by Mattocks (1). Corresponding attack of either the 2′- or 3′-hydroxyl oxygen of **i** (illustrated in Scheme 1 with the 2′-isomer) would lead to the 2′,5′-bis-*O*-(2,5,5-trimethyl-1,3-dioxolan-4-on-2-yl)tubercidin intermediate (**ii**). Protonation of the ether-type oxygen of **ii** and attack of the 3′-oxygen on the orthoacetate carbon would lead to the mixed orthoester-anhydride **iii**. This intermediate (**iii**) could be protonated at the carbonyl function of the mixed anhydride and suffer S_N2 attack by iodide concurrently at the 3′-carbon to give 4-amino-7-(2-*O*-acetyl-5-*O*-[2,5,5-trimethyl-1,3-dioxolan-4-on-2-yl]-3-iodo-3-deoxy-β-D-xylofuranosyl)pyrrolo[2,3-*d*]pyrimidine (**2**) directly or lose α-hydroxyisobutyric acid to give the 2′,3′-acetoxonium ion intermediate (**iv**) (2) which could then undergo S_N2 attack by iodide at the 3′-carbon to give **2**.

The *trans*-orientation of substituents at the 2′- and 3′-positions was proven by conversion of **2** to the *ribo*-epoxide by base. The u.v. spectra of **2** indicated no modification of the heterocyclic base since acylation of the amino function causes significant bathochromic shifts.[7] The i.r. spectra of **2** show bands corresponding to the dioxolanone carbonyl at 1796 cm^{-1} (1) and the acetyl carbonyl at 1746 cm^{-1}. The n.m.r. spectrum of **2** is also consistent with the proposed diastereomeric structure with *gem*-dimethyl peaks at δ 1.52 and 1.59, orthoacetate methyl at 1.79, and 2′-*O*-acetyl methyl at 2.12.

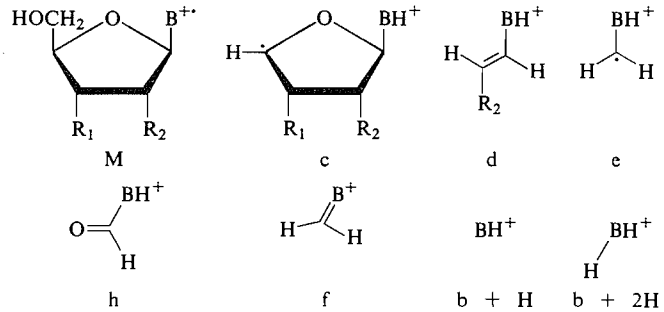
Compound **2** was catalytically hydrogenated to give the blocked 3′-deoxy intermediate **3** (see Scheme 2). Treatment of **3** with methanolic ammonia gave 3′-deoxytubercidin (**4**) in 38% overall yield, which was purified by ion-exchange chromatography. The n.m.r. spectrum of **4** exhibited an anomeric proton doublet at δ 5.95, $J_{1'-2'}$ = 2.7 Hz and a two-proton multiplet at δ 1.98 as expected (8, 9) from the 3′-deoxy structure **4**. The mass spectrum of this product was consistent with the assigned structure **4** with peaks at *m/e* 250 (M), 220 (c), 177 (d), 163 (h), 147 (f), 134 (b + H; 100%), and 135 (b + 2H) (peaks are assigned letters as discussed by McCloskey and coworkers (10)). Indeed, the fragmentation pattern down to ion "k" (B + H − HCN, *m/e* 107) was completely parallel to that (11) of 3′-deoxyadenosine (cordycepin) except at one lower mass unit (^{12}C—^{1}H *vs.* ^{14}N at the 7-position — purine numbering).

The same reaction procedure was applied to formycin (**5**). However, it is of considerable interest that in this case 3′-deoxyformycin (**6**) and 2′-deoxyformycin (**7**) were formed in an approximate ratio of 3:2 as estimated by n.m.r. spectroscopy. Since the supply of formycin was limited and the diastereomeric mixtures of 2′- and 3′-acylated intermediates were not resolved in numerous chromatographic systems, the total mixture of intermediates was purified, catalytically hydrogenated, and then deblocked to give **6** and **7** (as the hydrochlorides) in 30% overall yield from **5**.

The separation of **6** and **7** was extremely challenging. The useful Dekker column (12) is, of course, precluded by the acidic pyrazole proton. Of some 15 solvent systems investigated with five types of thin-layer and paper chromatography supports and adsorbants, only the system described in the Experimental gave effective resolution for analytical observation after three developing/drying cycles. Preparative t.l.c. using this system failed to resolve the isomers, however. A clean separation of **6** and **7** was achieved on a Dowex 1-X2 (Cl^-) column using an ammonium chloride – ammonium hydroxide buffer. The 3′-deoxy isomer **6** was eluted before the 2′-deoxy isomer **7**, which is opposite to the behavior of the corresponding deoxy adenosine isomers on an (OH^-) column (12).

The n.m.r. spectrum of **6** exhibited a doublet for the anomeric proton at δ 5.06, $J_{1'-2'}$ = 3.6 Hz and a two-proton multiplet at δ 1.98 for the 3′-protons whereas that of **7** had an ABX "triplet" for the anomeric proton at δ 5.43, $J_{1'-2',2''}$ = 8.1 Hz and a two-proton multiplet at δ 2.24 for the 2′-protons as expected from the respective structures (8, 9, 13). The mass spectral patterns of **6** and **7** were also consistent with the assigned structures. The 3′-deoxy isomer **6** had peaks at *m/e* 251 (M), 221 (c), 178 (d), 164 (h), 148 (f), 135 (b + H), and 136 (b + 2H) whereas 2′-deoxyformycin (**7**) had peaks at *m/e* 251 (M),

[7]M. J. Robins, R. Mengel, and R. A. Jones. To be published.



Mass spectral ions (see ref. 10)

221 (c), 162 (d), 164 (h), 148 (f), 135 (b + H), and 136 (b + 2H) with peaks identified as discussed by McCloskey and co-workers (10). In the case of **6**, the mass spectral base peak was at *m/e* 164 (ion "h") as was observed by Townsend and Robins (14) with formycin and other *C*-linked nucleosides. However, the mass spectral base peak for **7** occurred at *m/e* 162 which corresponds to cleavage of the $C_{1'}$—$O_{4'}$ and $C_{2'}$—$C_{3'}$ bonds to give the "2′-substituent-identifying" ion "d" (10). The corresponding ion "h" at *m/e* 164 was of 40.4% relative intensity whereas the heterocycle peak (base + H) at *m/e* 135 was of 12.4% relative intensity. Therefore a *C*-linked nucleoside will *not always* exhibit a mass spectral base peak at heterocyclic base + 30 as suggested earlier by Townsend and Robins (14) on the basis of their studies on unmodified ribosides. Ions "e" and "f" at *m/e* 149 and 148 are 18.8 and 4.8% relative intensity for **7** and 26.6 and 16.5% for **6** which is in accord with observations on nucleosides having a 2′-OH absent or present respectively (10).

Previous studies (15) have shown that formycin is deaminated by adenosine deaminase and it is well-known (16) that 2′- and 3′-deoxyadenosines are effective substrates for this enzyme. Treatment of the anomerically pure deoxyformycins **6** and **7** with calf intestinal adenosine deaminase gave rapid and quantitative conversion to 3′-deoxyformycin B (3-(3-deoxy-β-D-*erythro*-pentofuranosyl)pyrazolo[4,3-*d*]pyrimidin-7-one) (**8**) and 2′-deoxyformycin B (3-(2-deoxy-β-D-*erythro*-pentofuranosyl)pyrazolo[4,3-*d*]pyrimidin-7-one) (**9**) as evaluated by t.l.c.

Again the isomers had n.m.r. spectral properties in agreement with the assigned structures. The 3′-deoxy compound **8** had a peak at δ 4.87, $J_{1'-2'}$ = 3.9 Hz for the 1′-proton and a two-proton multiplet centered at δ 1.97 corresponding to the 3′-protons whereas the 2′-deoxy isomer **9** had the anomeric peak at δ 5.27 as an ABX "quartet" with $J_{1'-2',2''}$ = 6.1 and 10.1 Hz. The large coupling observed is indicative of a quasi *trans* diaxial relation between $H_{1'}$ and $H_{2'}$ and suggests a 1′-*exo*-2′-*endo* sugar conformation. Although the anomeric peak width (16 Hz) is much wider than observed for α-anomers, the ABX "quartet" pattern is not common for β-anomers (13, 17) and again emphasizes the empirical nature of this means of anomeric assignment. A *syn* orientation of the base over the sugar ring of **9** could contribute to an unusual sugar ring pucker.

The 3′-deoxy isomer **8** had characteristic mass spectral peaks at *m/e* 252 (M), 222 (c), 179 (d), 165 (h), 149 (f), 136 (b + H), and 137 (b + 2H) and the 2′-deoxy isomer **9** at *m/e* 252 (M), 222 (c), 163 (d), 165 (h), 149 (f), 136 (b + H) and 137 (b + 2H). Again as in the case of the 7-amino analogs **6** and **7**, the mass spectral base peak (100% relative intensity) for **8** is ion "h" at *m/e* 165 whereas the mass spectral base peak of the 2′-deoxy isomer **9** is ion "d" at *m/e* 163; and ion "f" at *m/e* 149 is about four-fold more intense in the isomer **8** (2′-OH present).

The chemical shifts observed for the 1′- (anomeric) and 4′-protons of these deoxynucleosides are of interest. The anomeric proton peak for 2′-deoxyformycin (**7**) is at δ 5.43 whereas that for the 3′-deoxy isomer **6** occurs at 5.06. The corresponding peak positions for the 2′- and 3′-deoxyformycin B isomers are at δ 5.27 and 4.87, respectively. These Δδ shifts of 0.37 p.p.m. for the formycins and 0.40 p.p.m. for the formycin B isomers are of comparable magnitude to shifts observed between α and β pairs of anomeric nucleosides (18). The peaks arising from

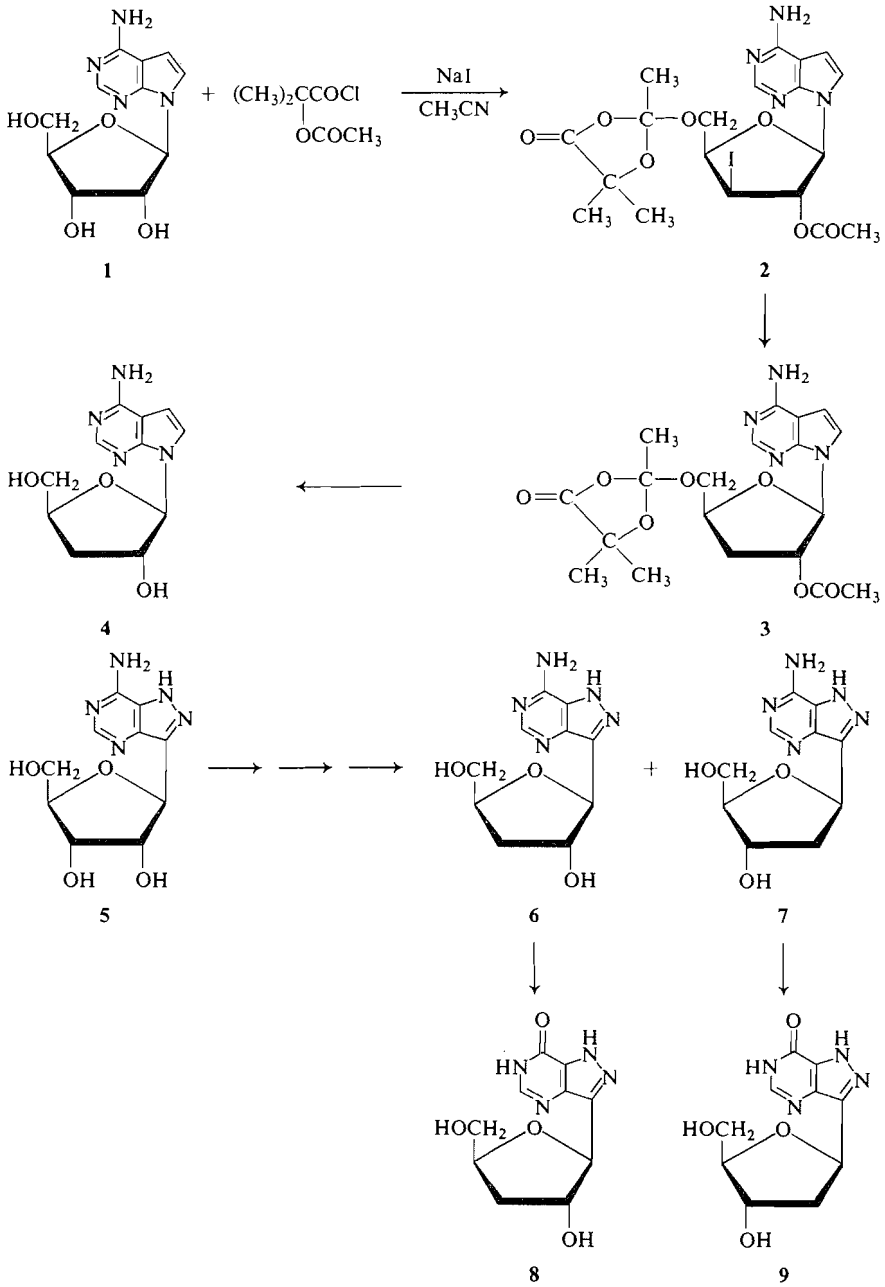

SCHEME 2

the 4′-proton occurred at δ 3.85 for 2′-deoxyformycin (**7**) 4.30 for the 3′-isomer **6** and 3.79 for 2′-deoxyformycin B (**9**) *vs.* δ 4.18 for the 3′-isomer **8**. Again the Δδ shifts of 0.45 p.p.m. for the 4′-protons of the deoxyformycins and 0.39 p.p.m. for the deoxyformycin B isomers correspond to proton shifts observed with *cis–trans* 1′-H to 2′-OH orientations in anomeric nucleoside pairs (18) and suggest a diamagnetic *shielding* effect of a *cis–vicinal* hydroxyl group. This effect has been discussed by Smith and coworkers (19). However, the same authors have referred to this paper (19) to support the *deshielding* effect of a *cis*-hydroxyl group on the $H_{2''}$ resonance of

deoxyuridine in a later article (20). Fraser-Reid and Radatus (21) have demonstrated by specific deuteration that the $H_{2''}$-proton *cis* to the 3'-OH is at lower field in deoxycytidine but anisotropy or conformational effects due to the pyrimidine base could also be involved.

The present study exemplifies a convenient route (2) for the modification of nucleoside antibiotics (ribofuranosides) to the biologically interesting 2'- and 3'-deoxy derivatives with retained stereochemistry. A new procedure (22) for access into deoxy and other modified nucleoside structures employing intact nucleosides and a study of factors affecting substitution reactivity of sugar carbons in different nucleosides will be reported separately.

Experimental

Melting points were determined on a Kofler micro melting point apparatus and are uncorrected. N.m.r. spectra were determined on Varian A-60 and HA-100 instruments with sodium, 5,5-dimethyl-5-silapentanesulfonate, or TMS as reference. U.v. spectra were determined on a Cary 14M spectrometer by dissolving the sample in distilled water and then diluting a 1 ml portion of this quantitative stock solution to 10 ml with 0.1 *N* HCl, freshly prepared 0.001 *N* or 0.1 *N* NaOH, or alcohol. Evaporations were accomplished using a Büchler rotating evaporator under reduced pressure (aspirator or vacuum pump) at 40 °C or lower unless otherwise specified. Hydrogenations were effected using a Parr shaking apparatus at specified hydrogen pressure and room temperature. Optical rotations were determined on a Perkin–Elmer model 141 polarimeter using a 1 ml, 10 cm micro cell. Mass spectra were obtained by the Mass Spectroscopy Laboratory at the University of Alberta on AEI MS-2 and MS-9 spectrometers using a direct probe at 70 eV and 200° or higher temperature. The peak intensity values are not completely reproducible under these conditions and somewhat different relative intensity patterns at higher *m/e* ranges have been observed especially with compound **9** which requires 250°. Tubercidin was purchased from The Upjohn Company, Kalamazoo, Michigan. Type II adenosine deaminase was purchased from Sigma Chemical Company, St. Louis, Missouri.

3'-Deoxytubercidin (4-Amino-7-(3-deoxy-β-D-erythro-pentofuranosyl)pyrrolo[2,3-d]pyrimidine) (4)

To a vigorously stirred solution of 15 g (0.10 mol) of dried sodium iodide in 100 ml of anhydrous acetonitrile (distilled from P_2O_5) was added 5.8 g (0.035 mol) of α-acetoxyisobutyryl chloride (7) (separation of a white solid occurred, presumably NaCl) followed immediately by 2.66 g (0.01 mol) of dried (18 h at 100°/15 mm Hg) tubercidin (**1**). The brown reaction mixture was stirred for 1 h at room temperature while protected from moisture and then poured into a stirred solution made by mixing 250 ml of saturated aqueous $NaHCO_3$ and 150 ml of saturated aqueous $Na_2S_2O_3$. A 100 ml portion of $CHCl_3$ was added and the layers were separated. The aqueous layer was extracted with two 50 ml portions of $CHCl_3$ and the combined organic phase was washed with water, dried over Na_2SO_4, filtered, and evaporated to dryness. A small sample of this white solid foam was purified for analysis by chromatography on a column of acid washed charcoal (Barnebey Cheney, AU-4) using MeOH–$CHCl_3$ (1:9) followed by a column of silica gel (Mallinckrodt CC-7) using Me_2CO–$CHCl_3$ (1:1). The amorphous solid obtained in 80% yield from evaporation of the appropriate middle fractions was completely free of trace impurities observed in the crude sample by t.l.c. Pure **2** had u.v. (MeOH) max 268 (ε 13 400), min 238 nm (ε 3100); (0.1 *N* HCl) max 271 (ε 11 700), min 245 nm (ε 4100); (0.1 *N* NaOH) max 270 (ε 12 200), min 245 nm (ε 5200); i.r. ($CHCl_3$) ν 1796 (lactone, C=O), 1746 cm^{-1} (acetate, C=O); n.m.r. ($CDCl_3$) δ 1.52, 1.59 (s, s; 3,3; $(CH_3)_2$-C(O—)CO—), 1.79 (s, 3, CH_3C(O—)(O—)O—), 2.12 (s, 3, CH_3COO—), 3.86 (m, 3, $H_{5',5'',4'}$), 4.25 (m, 1, $H_{3'}$), 5.28 (br, 2, NH_2), 5.79 (m, 1, $H_{2'}$), 6.24 (m, 2, $H_{1'}$, H_5), 7.49 (m, 1, H_6), 8.28 (s, 1, H_2) mass spectra, calcd. for M^+ ($C_{19}H_{23}IN_4O_7$), 546.0611; found *m/e*, 546.0595.

Anal. Calcd. for $C_{19}H_{23}IN_4O_7$: C, 41.77; H, 4.24; I, 23.23; N, 10.26. Found: C, 41.53; H, 4.21; I, 23.01; N, 10.30.

The bulk of the crude white solid foam (**2**) was dissolved in 75 ml of ethanol and 0.83 g (0.011 mol) of NaOAc in 25 ml of water was added. This solution was hydrogenated for 18 h at 50 p.s.i. in the presence of 1.2 g of 10% Pd/C catalyst. The mixture was filtered using a Celite pad and the filtrate was evaporated to dryness. The resulting product was partitioned between $CHCl_3$ and H_2O and the organic phase was washed with water, dried over Na_2SO_4, filtered, and evaporated to dryness. A small sample of this residue which was obtained in 63% yield was chromatographed on silica gel (Mallinckrodt CC-7) using Me_2CO–$CHCl_3$ (1:1). Evaporation of middle fractions which were homogeneous by t.l.c. gave **3** as a white solid foam, u.v. (MeOH) max 270, min 243 nm; (0.1 *N* HCl) max 272, min 246 nm; (0.1 *N* NaOH) max 271, min 242 nm; i.r. ($CHCl_3$) 1795 (lactone, C=O), 1736 cm^{-1} (acetate, C=O); n.m.r. ($CDCl_3$) δ 1.50 (s, 6, $(CH_3)_2$-C(O—)CO—), 1.77 (s, 3, CH_3C(O—)(O—)O—), 2.11 (s, 3, CH_3COO—), 2.16 (m, 1, $H_{3'}$), 2.56 (m, 1, $H_{3''}$), 3.78 (m, 2, $H_{5',5''}$), 4.50 (m, 1, $H_{4'}$), 5.37 (br, 2, NH_2), 5.55 (m, 1, $H_{2'}$), 6.34 (m, 2, $H_{1'}$,H_5), 7.14 (m, 1, H_6), 8.28 (s, 1, H_2); mass spectra, calcd. for M^+ ($C_{19}H_{24}N_4O_7$), 420.1645; found *m/e*, 420.1658.

The bulk of the sample of crude **3** was dissolved in 100 ml of methanol presaturated with ammonia at −5° and allowed to stand at room temperature for 18 h. The solution was evaporated to dryness and the residue was coevaporated several times with ethanol and then dissolved in 5 ml of MeOH–H_2O (5:95). This solution was applied to a column (2.6 × 60 cm; 300 ml) of Dowex 1-X2 (OH^-) (200–400 mesh) packed in 5% aqueous methanol. The column was eluted using 3000 ml of this solvent, and then with 15% methanol in water, 10 ml fractions were collected. Fractions 7–13 (after changing to 15% MeOH) contained **4** contaminated with a slightly

For personal use only.

slower migrating spot on t.l.c. (EtOAc – *n*-PrOH – H_2O, 4:1:2 upper phase; neutral alumina on glass plates). Continuing fractions 15–150 contained chromatographically pure **4** and were combined and evaporated to dryness. The resulting white foam was crystallized from 100 ml of EtOAc to give 0.95 g (38% overall from **1**) of needles of **4**, m.p. 180–181°; $[\alpha]_D^{27}$ −75.1° (*c*, 1, EtOH); u.v. max (0.1 *N* HCl) 270, 227 nm (ε 11 000, 24 700); (0.001 *N* NaOH) 268 nm (ε 12 300); (MeOH) 269 nm (ε 11 700); n.m.r. (DMSO-d_6) δ 8.04 (s, 1, H_2), 7.28 (d, 1, J_{6-5} = 3.8 Hz, H_6), 6.92 (s, 2, 4-NH_2), 6.52 (d, 1, J_{5-6} = 3.8 Hz, H_5), 5.95 (d, 1, $J_{1'-2'}$ = 2.7 Hz, $H_{1'}$), 5.43 (broad s, 1, 5′-*OH*), 4.98 (broad s, 1, 2′-*OH*), 4.34 (m, 1, $H_{2'}$), 4.20 (m, 1, $H_{4'}$), 3.48 (m, 2, $H_{5',5''}$), 1.98 (broad m, 2, $H_{3',3''}$); mass spectra, calcd. for M^+ ($C_{11}H_{14}N_4O_3$), 250.1066; found *m/e*, 250.1082 (and see discussion).

Anal. Calcd. for $C_{11}H_{14}N_4O_3$: C, 52.79; H, 5.64; N, 22.39. Found: C, 53.01; H, 5.92; N, 22.41.

*3′-Deoxyformycin (7-Amino-3-(3-deoxy-β-D-erythro-pentofuranosyl)pyrazolo[4,3-d]pyrimidine) (**6**) and 2′-Deoxyformycin (7-Amino-3-(2-deoxy-β-D-erythro-pentofuranosyl)pyrazolo[4,3-d]pyrimidine) (**7**)*

To a solution of 30 g (0.20 mol) of dried sodium iodide in 200 ml of dry acetonitrile (distilled from P_2O_5) was added 11.6 g (0.070 mol) of α-acetoxyisobutyryl chloride (**7**) and then 5.34 g (0.020 mol) of dry formycin (dried at 100° under aspirator vacuum for 15 h) was added to the vigorously stirred mixture. The resulting dark-colored mixture was stirred for 1 h at room temperature while protected from moisture and was then poured into a solution made by mixing 500 ml of saturated aqueous $NaHCO_3$ and 300 ml of saturated aqueous $Na_2S_2O_3$. Chloroform (200 ml) was added and the phases separated. The aqueous layer was washed with two 100 ml portions of $CHCl_3$. The combined organic phase was washed with H_2O, dried over Na_2SO_4, and evaporated to dryness. The resulting white foam was dissolved in 100 ml of EtOH and this solution was evaporated to dryness. The residue was dissolved in 115 ml of EtOH and 1.7 g (0.021 mol) of sodium acetate dissolved in 35 ml of H_2O was added. This mixture was hydrogenated at 50 p.s.i. for 18 h in the presence of 2.5 g of 10% Pd/C catalyst. The catalyst was removed by filtration using a Celite pad and the filtrate was evaporated to dryness. The resulting solid was partitioned between 200 ml of $CHCl_3$ and 100 ml of H_2O. The $CHCl_3$ layer was washed with 100 ml of H_2O, dried over Na_2SO_4, and evaporated to dryness. The resulting white solid foam was dissolved in 100 ml of methanol presaturated at −5° with ammonia and this solution was allowed to stand for 15 h at room temperature and was then evaporated to dryness. The residue was dissolved in a minimal volume of EtOAc–MeOH (8:2) and applied to a column (2.4 × 105 cm, 400 g) of neutral alumina packed in the same solvent. The column was washed with 600 ml of EtOAc–MeOH (8:2) and this wash was discarded. The column was then developed with the upper phase of EtOAc – *n*-PrOH – H_2O (4:1:2) and 10 ml fractions were collected. Fractions 85–143 were homogeneous on t.l.c. (alumina, glass plates, upper phase of EtOAc – *n*-PrOH – H_2O (4:1:2)) and migrated more slowly than did small quantities of material in earlier fractions. These fractions were combined and evaporated to dryness to yield 1.7 g (34%) of amorphous solid which was a 3:2 mixture of 3′-deoxyformycin (**6**) and 2′-deoxyformycin (**7**), respectively, as estimated by n.m.r. analysis.

A sample of this solid (0.5 g) was dissolved in 30 ml of MeOH and 50 ml of 1% HCl in dry MeOH was added. The solution was evaporated to dryness and the residue was crystallized from absolute EtOH to give 0.5 g (87% recovery) of 2′- and 3′-deoxyformycin hydrochlorides, m.p. 195–215°.

Anal. Calcd. for $C_{10}H_{13}N_5O_3$·HCl: C, 41.74; H, 4.90; N, 24.34; Cl, 12.32. Found: C, 41.52; H, 4.80; N, 24.08; Cl, 12.20.

A solution of 0.6 g of the above amorphous solid in 4 ml of 0.2 *N* NH_4Cl adjusted to p*H* 9.35 with NH_4OH was applied to a column (3.3 × 134 cm) of Dowex 1-X2 (Cl^-) (200–400 mesh packed in the same NH_4Cl–NH_4OH buffer solution). The column was developed with this buffer solution and migration and separation of the bands corresponding to 3′-deoxyformycin and 2′-deoxyformycin could be observed visually using a 2537 Å u.v. hand lamp. The formycin aglycone has strong absorption at 295 nm and blue fluorescent bands can be seen through the Pyrex column in a dark room. The eluate was also monitored with an automatic recording u.v. cell at 2537 Å.

After a fore-run of 10.33 l, 3′-deoxyformycin (**6**) was eluted in the next 5.15 l of buffer solution. There was then a volume of 750 ml which was u.v. transparent at 296 nm followed by a volume of 4.5 l which contained 2′-deoxyformycin (**7**).

The 5.15 l of fractions containing 3′-deoxyformycin (**6**) were combined and stirred for 15 h with 1.5 g of acid-washed activated charcoal (Barnebey-Cheney, AU-4). The charcoal was collected by filtration and washed well with H_2O. The combined aqueous filtrate and washings were u.v. transparent at 296 nm. The charcoal was placed in a Soxhlet thimble and was continuously extracted with EtOH – 28% NH_4OH (7:3) for several days. The combined extracts were evaporated to dryness and the residue was converted (as described earlier for the mixture) to the hydrochloride salt (recrystallized from EtOH) to give 0.39 g (56% recovery) of 3′-deoxyformycin (**6**) hydrochloride, m.p. 214–216°; $[\alpha]_D^{24}$ −31.4° (*c*, 1, H_2O); u.v. (0.1 *N* HCl) max 296, 233 (ε 10 900, 8400), min 267, 223 nm (ε 3700, 7300); (0.1 *N* NaOH) max 303, 233 (ε 8400, 19 400), min 272, 223 nm (ε 3700, 15 500); n.m.r. (DMSO-d_6) δ 8.52 (s, 1, H_5), 5.06 (d, 1, $J_{1'-2'}$ = 3.6 Hz, $H_{1'}$), 4.44 (m, 1, $H_{2'}$), 4.30 (m, 1, $H_{4'}$), 3.61 (m, 2, $H_{5',5''}$), 1.98 (m, 2, $H_{3',3''}$); mass spectra, calcd. for M^+ ($C_{10}H_{13}N_5O_3$), 251.1018; found *m/e* 251.1018.

Anal. Calcd. for $C_{10}H_{13}N_5O_3$·HCl: C, 41.74; H, 4.90; N, 24.34; Cl, 12.32. Found: C, 41.71; H, 5.09; N, 24.14; Cl, 12.36.

Identical treatment of the 4.5 l of combined fractions containing 2′-deoxyformycin (**7**) with 1 g of activated charcoal followed by the above-described isolation procedure gave 0.17 g (25% recovery) of 2′-deoxyformycin hydrochloride, m.p. 200–202°; $[\alpha]_D^{24}$ 19.1° (*c*, 1, H_2O); u.v. (0.1 *N* HCl) max 295, 233, (ε 10 200, 7700), min 265, 222 nm (ε 3400, 6300), (0.1 *N* NaOH) max 303, 234 (ε 8100, 18 000), min 272, 223 nm (ε 3400, 14 000); n.m.r. (DMSO-d_6) δ 8.50 (s, 1, H_5), 5.43 ("t", 1, $J_{1'-2',2''}$ = 8.1 Hz, $H_{1'}$), 4.28 (m, 1, $H_{3'}$), 3.85 (m, 1, $H_{4'}$), 3.55 (m,

2, $H_{5',5''}$), 2.24 (m, 2, $H_{2',2''}$); mass spectra, calcd. for M^+ ($C_{10}H_{13}N_5O_3$), 251.1018; found *m/e*, 251.1010.

Anal. Calcd. for $C_{10}H_{13}N_5O_3 \cdot HCl$: C, 41.74; H, 4.90; N, 24.34; Cl, 12.32. Found: C, 41.46; H, 5.14; N, 24.29; Cl. 12.10.

The deoxyformycins **6** and **7** could be resolved for analytical observation on t.l.c. employing two or three developing–drying cycles using glass plates coated with silica gel (p*H* 7) and the upper phase of freshly prepared *n*-BuOH – H_2O – concentrated NH_4OH (3:1:0.05). The 2′-deoxy isomer **7** migrated slightly faster in this system.

3′-Deoxyformycin B (3-(3-Deoxy-β-D-erythro-pentofuranosyl)pyrazolo[4,3-d]pyrimidin-7-one) (8)

To a solution of 0.40 g (0.0014 mol) of 3′-deoxyformycin (**6**) hydrochloride in 80 ml of water was added 20 mg of adenosine deaminase and the solution was stirred for 3 days at room temperature. A 5 ml portion of Amberlite IRC-50 resin was added and the mixture was stirred. After 0.5 h a precipitate began to separate. The reaction mixture was filtered using a Celite pad and the pad was then washed with 20% aqueous ammonia. The u.v. spectrum of the ammoniacal filtrate indicated the presence of the formycin B chromophore. The filtrates were combined and evaporated to dryness. The resulting solid was crystallized from 25 ml of water to give 0.26 g (74%) of crystalline **8**. Recrystallization of this material from H_2O proceeded readily to give needles of **8**, m.p. 263–264°; $[\alpha]_D^{24}$ −48.3° (*c*, 0.5, H_2O); u.v. (0.1 *N* HCl) max 277, 220 (ε 7370, 13 800), min 243 nm (ε 4150); (distilled H_2O) max 279, 219 (ε 7380, 14 300), min 238 nm (ε 3630); (0.1 *N* NaOH) max 292, 228 (ε 8140, 15 900), min 250 nm (ε 3400); n.m.r. (DMSO-d_6) δ 7.83 (s, 1, H_5), 4.87 (d, 1, $J_{1'-2'}$ = 3.9 Hz, $H_{1'}$), 4.50 (m, 1, $H_{2'}$), 4.18 (m, 1, $H_{4'}$), 3.44 (m, 2, $H_{5',5''}$), 1.97 (broad m, 2, $H_{3',3''}$); mass spectra, calcd. for M^+ ($C_{10}H_{12}N_4O_4$), 252.0859; found *m/e*, 252.0854.

Anal. Calcd. for $C_{10}H_{12}N_4O_4$: C, 47.62; H, 4.80; N, 22.21. Found: C, 47.69; H, 4.64; N, 22.44.

2′-Deoxyformycin B (3-(2-Deoxy-β-D-erythro-pentofuranosyl)pyrazolo[4,3-d]pyrimidin-7-one) (9)

To a solution of 0.138 g (0.00048 mol) of 2′-deoxyformycin (**7**) hydrochloride in 60 ml of distilled water was added 7 mg of adenosine deaminase and the solution was stirred for 24 h at room temperature.

The solution was evaporated to approximately 3 ml and this was applied to a column (0.5 × 5 cm) of Dowex 50W-X8 (30–80 mesh) (H^+). The column was eluted with water and after 400 ml the concentration of **9** in the eluate was minimal. The combined eluant was neutralized with aqueous sodium bicarbonate and then evaporated. The residue was triturated with 30 ml of absolute ethanol which was filtered and the filtrate evaporated to dryness. The solid (100 mg) was dissolved in 2 ml of water and applied to a column (0.8 × 9 cm, 2 g) of acid-washed activated charcoal (Barnebey-Cheney AU-4). This column was washed with water until the eluate gave no precipitate when treated with nitric acid–silver nitrate. Elution with ethanol–concentrated aqueous ammonia (7:3) (approximately 50 ml) and evaporation of this solution gave 80 mg (76%) of a white solid. This product crystallized slowly from methanol to give needles of **9**, m.p. 229–230°; $[\alpha]_D^{24}$ 9.0° (*c*, 0.97, H_2O); u.v. (0.1 *N* HCl) max 277; 220 (ε 6490, 12 500), min 242 nm (ε 3670); (distilled H_2O) max 278; 218 (ε 6620, 12 800), min 238 nm (ε 2910); (0.1 *N* NaOH) max 292, 228 (ε 7150, 14 000), min 250 nm (ε 2970); n.m.r. (DMSO-d_6) δ 7.80 (s, 1, H_5), 5.27 ("q", 1, $J_{1'-2',2''}$ = 10.1 and 6.1 Hz, $H_{1'}$), 4.25 (m, 1, $H_{3'}$), 3.79 (m, 1, $H_{4'}$), 3.43 (m, 2, $H_{5',5''}$), 2.44 and 1.98 (m and m, 1 and 1, $H_{2'}$ and $H_{2''}$); mass spectra calcd. for M^+ ($C_{10}H_{12}N_4O_4$), 252.0859; found *m/e*, 252.0847.

Anal. Calcd. for $C_{10}H_{12}N_4O_4$: C, 47.62; H, 4.80; N, 22.21. Found: C, 47.53; H, 5.01; N, 22.02.

Received November 27, 1972

The constitution and stereochemistry of five new diterpenoids from *Solidago juncea* Ait., junceic acid (**3***a*), the related epoxide (**6***a*), junceanol W(**4***a*), junceanol X (**4***b*), and junceanol Y (**5***a*), have been assigned on the basis of their chemical and spectroscopic properties. Of key importance in these deductions have been the transformations of **4***b* and **5***a* into the previously described hydrocarbon **19** and of **3***a* into **3***e*. Two known diterpenoids, (−)-hardwickiic acid (**2***a*), which has also been converted into **3***e*, and *ent*-16-kauren-19-oic acid (**1**), are further constituents of *S. juncea*.

La constitution ainsi que la stéréochimie de cinq nouveaux diterpènes issus du *Solidago juncea* Ait., l'acide junceique (**3***a*), l'époxyde parent (**6***a*), le junceanol W(**4***a*), le junceanol X (**4***b*) et le junceanol Y (**5***a*) ont été attribuées en se basant sur les propriétés chimiques et spectroscopiques. Les transformations de **4***b* et **5***a* pour donner l'hydrocarbure **19** décrit antérieurement et de **3***a* en **3***e* ont été de la plus grande importance dans ces déductions. Deux diterpènes connus, l'acide (−) hardwickiique (**2***a*) qui a aussi été transformé en **3***e* et l'acide kauren-16-*ent* oique-19 sont aussi d'autres constituants du *S. juncea*.
[Traduit par le journal]

Can. J. Chem., **51**, 1322 (1973)

Continuing our investigations of the constituents of *Solidago* species we have examined two samples of *S. juncea* Ait. (Early Goldenrod), one collected[3] near New London, Connecticut and the other[4] in Hamilton, Ontario. From ether extracts of the former we have obtained two known diterpenoids, *ent*-16-kauren-19-oic acid (**1**) (2) and (−)-hardwickiic acid (**2***a*) (3), and four new diterpenoids which we have named junceic acid (**3***a*), junceanol W (**4***a*), junceanol X (**4***b*), and junceanol Y (**5***a*). Of these six compounds all but hardwickiic acid were detected in similar extracts of the Hamilton sample, while in this case an additional new diterpenoid, junceic acid epoxide (**6***a*), was isolated. The formulation of these new diterpenoids as shown rests on the evidence which follows.

The ent-Clerodanes

Junceic acid (**3***a*) was isolated as an oil by successive column and preparative t.l.c. over silica gel and its molecular formula established as $C_{20}H_{28}O_3$ by mass spectrometry. The acidic nature of the compound was deduced from its behavior on t.l.c. ("streaking"), the broad absorption band between 3000 and 3400 cm^{-1} in its i.r. spectrum and the strong peak at *m/e* 271 ($M - CO_2H$) in its mass spectrum. The presence of a β-substituted furan moiety in junceic acid, first indicated by its color reaction with Ehrlich's reagent, was readily confirmed by its absorption in the i.r. at 877 cm^{-1} and the three characteristic resonances at τ 2.63, 2.76 (α-furan), and 3.70 (β-furan) in its n.m.r. spectrum. Also clearly evident in the n.m.r. spectra of junceic acid and the derived methyl ester (**3***b*), alcohol (**3***c*), and acetate (**3***d*), m.p. 82–84°, are resonances attributable to an olefinic, a secondary, and a tertiary methyl group, and a vinylic proton. These data were taken to indicate a close structural relationship between junceic and hardwickiic acid and this conclusion was reinforced when the latter (**2***a*) was found to be a minor constituent of *S. juncea*.

Two plausible structures, **3***a* and **7***a*, for junceic acid emerged at this point and that one or other did indeed represent the correct constitution and stereochemistry was shown un-

ambiguously by the conversion of both junceic acid and hardwickiic acid (**2***a*) into the furano-olefin (**3***e*). Methyl junceate (**3***b*) on reduction with lithium aluminum hydride formed the alcohol (**3***c*) which was then converted smoothly into the aldehyde (**3***f*) with the Sarett reagent. Huang–Minlon reduction of this aldehyde under carefully controlled conditions yielded the oily furano-olefin (**3***e*), $[\alpha]_D$ −58°. The transformation of hardwickiic acid (**2***a*) into **3***e* was effected via the acetate (**2***b*). This acetate on hydrogenation in triethylamine–ethanol over palladized charcoal suffered hydrogenolysis of the allylic ester group and produced the furano-olefin (**3***e*), identical in all respects with that synthesized from junceic acid.

The decision that **3***a* rather than **7***a* correctly represented junceic acid was made on the following grounds. First, clerodanes with a furan ring in the side chain often (4) have major fragments at M − 95 in their mass spectra resulting from scission of the C_9—C_{11} bond. However, in the case of junceic acid, the ion of this type is absent and replaced by one at *m/e* 222 (M − 94), which presumably arises by transfer of a hydrogen atom in a process such as that outlined in **8**. Second, in contrast to solidagoic acid A (**9**) (5), junceic acid does not decarboxylate readily. It was, for example, recovered after heating at 290° under nitrogen for 30 min. Such thermal stability would be surprising for a βγ-unsaturated acid as in **7***a*. Finally, certain n.m.r. data indicate the close proximity of the carboxyl and the secondary methyl group. The magnitudes (see Experimental) of the downfield shifts observed in pyridine for the C—CH_3 resonances on going from the methyl ester (**3***b*) to the acid (**3***a*) reveal (6) not only the 1:3 diaxial arrangement of the carboxyl and the tertiary methyl group but also the juxtaposition of the former to the secondary methyl group. In addition, examination of the spectrum of the alcohol (**3***c*) containing progressively increasing concentrations of tris(dipivalomethanato)europium indicates that the tertiary and the secondary methyl group are similar distances (7) from the interacting europium atom (1.2:1 respectively) while the olefinic methyl and vinylic proton are further removed. This evidence accords only with the structure **3***a* for junceic acid. However, with a view to final confirmation of this, efforts were made to establish the steric relationship between the furan ring and the carboxyl group. To this end, the epoxides **6***b*, m.p. 98–101°, and **6***c* were prepared but attempts to convert the former into the acid (**10**) and thence to the lactone (**11**) failed. An examination of the buffered acetolysis of the toluene-*p*-sulfonate (**3***g*) was next undertaken. No acetates were detected in the product mixture which was shown by t.l.c. on silver nitrate–silica gel to consist essentially of one minor and three major components. These were separated by repeated preparative t.l.c. and tentative structures assigned to the major products on the basis of their u.v. and n.m.r. spectra. As anticipated, all three had retained the β-substituted furan ring and the Δ^3-olefinic bond as evidenced by the characteristic signals for the furanic protons and the C-3 olefinic hydrogen and C-4 methyl group. Surprisingly, they also all contain

a secondary methyl group. Further, none of these compounds exhibits absorption in the u.v. arising from conjugation of the newly introduced olefinic bond with either of the unsaturated systems already present. Easily recognized in the n.m.r. spectrum of the compound of intermediate polarity is a new AX_2 system (τ 4.70, 1H, t; 6.89, 2H, d; J = 7 Hz) of the type encountered (8) in anhydromarrubiin (**12**) and attributed to 1 H-11 and 2 H-12. A compound with this functionality would be expected to arise from the toluene-*p*-sulfonate **3***g* rather than from the alternative **7***b* and thus convincingly proves that junceic acid has the constitution and stereochemistry depicted in **3***a*.[5] Bearing in mind its genesis, the furano-diene could be formulated as **13** or **14**. The latter is preferred since double irradiation experiments show that the secondary methyl is coupled (J = 6 Hz) to a proton which resonates as a broad multiplet at τ 7.34, a shift value attributable to an *allylic* proton. The least polar of these solvolysis products also contains the AX_2 system and may be simply the geometric isomer (at C-11) of the compound discussed above. However, in this case, the structures **13** cannot be ruled out since the resonance of the C-8 proton was located by double irradiation at τ 7.67, a value less readily ascribed to an allylic methine. In the third, most polar, furano-diene a new olefinic proton resonates at τ 4.97 (d, J = 6 Hz). Double irradiation experiments showed that this proton and the secondary methyl group are spin–spin coupled to two *different* allylic methines (τ 7.64 and 7.42 respectively) and thus the structure **15** can be assigned to the compound.

The structure of the other new naturally-occurring *ent*-clerodane was readily established as an epoxyjunceic acid (**6***a*). Its n.m.r. spectrum is similar to that of junceic acid except that the resonances of the olefinic proton and methyl group are replaced by signals attributable to a proton (τ 7.18) and methyl group (τ 8.90) attached to an epoxide ring. This structural assignment was confirmed by the preparation of the corresponding ester (**6***d*) from methyl junceate. Treatment of the latter (**3***b*) with *m*-chloroperbenzoic acid in carbon tetrachloride yielded two epoxides the minor of which (**6***d*) was identical with the methyl ester of the acid

[5]Indeed the compound of structure **7***a*, maingayic acid, has been isolated recently (9) from *Callicarpa maingayi*.

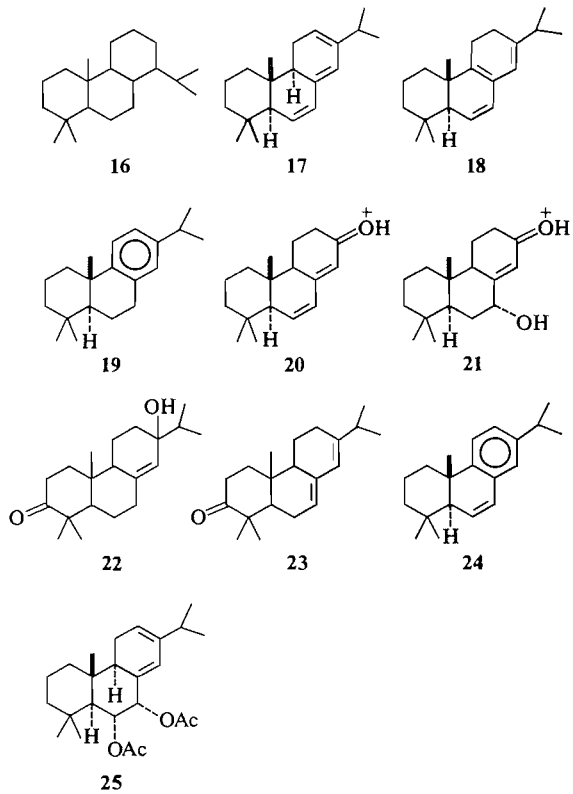
of natural provenance. The C_3—C_4 stereochemistry in these two epoxides can be deduced from the multiplicity of the H-3 resonances. In the major isomer (**6***e*), m.p. 82–86°, H-3 appears as a broadened doublet (J = 3.5 Hz) and in the minor (**6***d*) as a singlet. Examination of models and application of a suitably modified (10) Karplus equation leads to the assignments shown. Indeed a preponderance of **6***e* might be expected from the epoxidation reaction since the β-face appears more open to attack.

The Abietanes

Later fractions from column chromatography of the plant extract over silica gel yielded three additional new diterpenoids, junceanols W (**4***a*), X (**4***b*), and Y (**5***a*). The most polar, junceanol Y, m.p. 136–140°, analyzed for $C_{20}H_{34}O_2$. Inspection of the n.m.r. spectrum of the derived monoacetate (**5***b*) reveals the presence of one isopropyl and three tertiary methyl groups as expected for an abietane (or totarane, **16**) skeleton. Only two resonances are present at low field, one attributable to an olefinic proton (τ 4.17). Thus the molecule contains a trisubstituted double bond and a secondary acetate and these together with a tertiary hydroxyl, which gives rise to a peak at about τ 8.3 in its n.m.r. spectrum (lost on D_2O exchange) and at 3615 cm^{-1} in the i.r., account for all the functionality in a tricyclic system.

Definitive evidence for the skeletal structure and the location of the functional groups was next sought. In an attempt to interrelate the tertiary hydroxyl group and the olefinic bond, the monoacetate (**5***b*) was subjected to a variety of conditions, each aimed at its dehydration. However, of these, only one, treatment with toluene-*p*-sulfonyl chloride in pyridine at 100°, proved successful. Separation of the three major products by preparative t.l.c. on silver nitrate – silica gel afforded a stable (**17**) and an unstable (**18**) triene (λ_{max} 315 and 288 nm respectively) and the known (11) abietatriene (**19**), m.p. 38–43°, $[\theta]_{277}$ −320, $[\theta]_{269}$ −320, $[\theta]_{262}$ −120. The production of this last compound allows the assignment of the abietane skeleton to Y and in addition provides unequivocal proof of the absolute configurations at C-5 and -10 (as in **5***a*).

The following arguments suggest that the functional groups are located as shown in **5***a*. The facile formation of the aromatic hydrocarbon (**19**) *and* the nonaromatic trienes (**17** and



18) from the monoacetate (**5***b*) indicates the probability that two of the functional groups are borne by ring C and the third by ring B. It soon became evident that this indeed is the case. Thus an intense M − 61 peak and an even more intense one for M − 43 in the mass spectrum of Y (**5***a*) were taken as representing the oxonium ions **20** and **21** (or equivalent species) respectively, produced by excision of the isopropyl side chain. This cleavage would be expected (12) for a C-13 tertiary alcohol especially if a $\Delta^{8(14)}$ double bond were also present. This substitution pattern in ring C would also explain the sharpness ($w_{1/2}$ < 3 Hz) of the olefinic proton resonance in Y and its acetate since it would have no vicinal but only long range spin–spin couplings. Confirmation that the olefinic proton and isopropyl group are both in close proximity to the tertiary hydroxyl was obtained by recording the n.m.r. spectrum of the monoacetate (**5***b*) in the presence of tris-(dipivalomethanato)europium. Indeed, the magnitude of the induced shifts (see Experimental) was similar to that obtained for the hydroxyketone (**22**) from *Solidago patula* Muhl. (13) and *S. missouriensis* Nutt. (14). A decision as to

the location and orientation of the acetate group in **5***b* was also forthcoming. As mentioned above, the production of the nonaromatic trienes made it appear likely that this third substituent is attached to ring B. Two distinct pieces of evidence allow its assignment to C-7. First, **5***b* is much more stable than the related **22**, which even on standing in chloroform at 20° slowly formed the diene (**23**). This suggests that C-7 is functionalized in **5***b*. Second, although nuclear magnetic double resonance experiments on the monoacetate (**5***b*) failed[6] to show spin–spin coupling between the two protons responsible for the resonances at low field, they did reveal that the proton assignable to *H*COAc is coupled to two protons of near-identical chemical shift, the value of which indicates that they are probably *not allylic*. Irradiation at τ 8.33 (2 H-6) caused the narrow triplet (J = 2 Hz) at 4.73 to collapse to a sharp singlet. A further experiment located the resonance attributable to H-9, since irradiation at τ 7.96 sharpened the singlet at 4.17 (olefinic proton). The multiplicity of the signal at τ 4.73 (see above) indicates the equatorial nature of the proton involved (H-7) and thus the monoacetate of Y can be assigned the structure and stereochemistry shown in **5***b*. The stereochemistry at C-9 is tentatively assigned on a biogenetic basis, while that at C-13 remains unresolved. The structures of junceanols W (**4***a*) and X (**4***b*) discussed below lend credence to the substitution pattern proposed for Y (**5***a*).

The structural similarity of junceanols W and X, first indicated by the observation that they both gave a characteristic pink color when sulfuric acid was used for spot location after analytical t.l.c., was established by the following chemical and spectroscopic studies. The n.m.r. spectra of the two are markedly similar, each containing resonances attributable to an isopropyl and three tertiary methyl groups, an olefinic proton and two protons of the type *H*—C—O. The signals arising from these two protons appeared to suggest that the two compounds are derived from a single diterpenoid which contains two secondary alcohol groups. In W, one of these groups is esterified, while in X, it is the other. Thus the relevant two protons resonate as a doublet (J = 3.5 Hz) and an ill-resolved quartet (J = 3.5, 12 Hz) at τ 4.63 and 6.07 respectively in W and at τ 5.90 and 4.97 respectively in X. The validity of our conclusions as to the relationship of the two compounds was substantiated in two ways. First, distillation of X *in vacuo* furnished a mixture of **24**, X and W, the last resulting from acyl group migration. Second, X and W on saponification or reduction with lithium aluminum hydride produced the same compound (**4***c*). This product on acetylation formed a diacetate (**4***d*) which still showed stretching absorption in the i.r. attributable to a hydroxyl group at 3618 cm^{-1}. This must be tertiary in nature since the n.m.r. spectrum contains no resonances arising from carbinyl protons. It seemed clear that W and X are related to Y but bear an additional oxygen function at C-6. The vicinal nature of the C-6, -7 substituents was demonstrated by a nuclear magnetic double resonance experiment on X. Irradiation at τ 4.97 (H-6) caused collapse of the doublet at τ 5.90 (H-7) to a sharp singlet. The resonance arising from H-5 was located at τ 8.15 since irradiation at this point reduced the quartet at τ 4.97 to a doublet (J = 3.5 Hz). When the n.m.r. spectrum of the diacetate (**4***d*) was run in the presence of a europium shift reagent, H-5 was clearly seen as a clean doublet (J = 12 Hz). The multiplicity of H-6 convincingly demonstrates the equatorial nature of the functional group at C-6. In the thermal conversion of X (**4***b*) into W (**4***a*), described above, the acyl group, although moving from an equatorial to an axial orientation, escapes a strong steric interaction with the geminal methyl groups at C-4. The assignment of the secondary functional groups to ring B rather than ring C, at C-11 and -12, in W and X can be rationalized by arguments analogous to those applied above to Y. However, in addition, it was noted that dehydration of the diacetate (**4***d*) with toluene-*p*-sulfonyl chloride in pyridine afforded, as the major product, the *homocyclic* diene (**25**), λ_{max} 273 nm. Significantly, in the n.m.r. spectrum of this product, neither resonance from the *H*—C—OAc protons had been shifted to appreciably lower field and presumably therefore has not *become* allylic.

Final confirmation of the structure of X as **4***b*, and consequently of W as **4***a*, was achieved by treating it with hydrochloric acid in chloroform. The resulting styrene (**24**) on catalytic hydrogenation furnished the identical abietatriene (**19**) to that prepared earlier from Y. The abso-

[6]An equatorial proton at C-7 would be expected (15), because of its orientation, to have a minimal coupling to an olefinic proton at C-14.

lute configuration can be assigned with assurance to all centers save C-9 and -13 although the former is tentatively advanced on biogenetic grounds.

Remaining for discussion is the nature of the ester grouping in W and X. An important clue as to its identity was obtained from the n.m.r. spectra of these two compounds which contain three resonances not attributable to the diterpenoid moiety, namely, an olefinic proton at τ 4.31 and two methyl groups attached to an olefinic bond at τ 7.81 and 8.08. This suggested that W and X are senecioates and indeed the corresponding acid was recovered from alkaline hydrolysis of the latter and identified by its n.m.r. and mass spectra.[7]

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage apparatus. Specific rotations refer to solutions in chloroform unless otherwise stated. For analytical and preparative t.l.c., chromatoplates were spread with Kieselgel G (Merck). G.l.c. was carried out using a Varian Aerograph 1200 gas chromatograph and a stainless steel column ($\frac{1}{8}$ in. × 5 ft packed with 3% SE-30) and nitrogen as carrier gas with a flow rate of 25 ml/min. Light petroleum was of b.p. 60–80°. Microanalyses were by Miss F. Cowan, Glasgow. I.r. solution spectra were recorded in carbon tetrachloride on a Beckmann IR12 or IR5A spectrophotometer, u.v. spectra in ethanol unless otherwise stated on a Unicam S.P.800 spectrophotometer, and circular dichroism curves on a Cary 61 spectropolarimeter. P.m.r. spectra were run on a Varian Associates A-60A or HA 100 spectrometer in carbon tetrachloride, unless otherwise stated, using approximately 0.3 *M* solutions and tetramethylsilane as internal standard. Mass spectra were run on a Varian Associates CH7 instrument.

Isolation Procedure, the Root Extract

(*i*) The ground, dried roots (82 g) of *Solidago juncea* (New London sample) were continuously extracted with ether for 8 h in a Soxhlet apparatus. The extract (4.7 g), which showed one intense and one faint spot on analytical t.l.c. when sprayed with the Ehrlich reagent, was submitted to preparative t.l.c. (ether – light petroleum, 1:4) and four fractions were recovered. Fraction I contained non-polar, essentially non-terpenoid (n.m.r. evidence) material and was not investigated further. Fraction II afforded the major furanoid component, junceic acid (**3***a*, 2.2 g) as an oil, contaminated with a small amount of a second component (n.m.r. evidence), later shown to be *ent*-16-kauren-19-oic acid (**1**). Further purification, by preparative t.l.c. followed by distillation *in vacuo* provided junceic acid (**3***a*) as an oil which had $[\alpha]_D$ −59° (*c*, 0.84); ν_{max} 3400–3000 (br), 1743(w), 1696(s), and 877 cm^{-1} (0.006 *M*); 1743(vw), 1723(s) and 1696(m) cm^{-1} in presence of tetrahydrofuran (0.3 *M*); τ 2.63, 2.76, 3.70 (all m, 1H; furan protons), 4.72 (m, 1 H-3 $w_{1/2}$ = 8 Hz), 8.40 (broad s, 3 H-18), 8.83 (d, 3 H-17, J = 6 Hz), and 9.04 (s, 3 H-19); τ (pyridine) 8.60 (d, 3 H-17, J = 6 Hz) and 8.75 (s, 3 H-19); *m/e* 316 (M; $C_{20}H_{28}O_3$). The corresponding methyl ester (**3***b*) prepared by treatment of the acid with diazomethane in ether, was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:30) and distillation at 160°/0.4 mm. It had $[\alpha]_D$ −54° (*c*, 1.57); ν_{max} 1735 and 878 cm^{-1}; τ 4.83 (m, 1 H-3, $w_{1/2}$ = 7 Hz), 6.47 (s, 3H, —OCH_3), 8.45 (broad s, 3 H-18; sharpens on irradiation at τ 4.83), 8.88 (d, 3 H-17, J = 6 Hz; s on irradiation at τ 8.34) and 9.20 (s, 3 H-19); τ (pyridine) 8.76 (d, 3 H-17, J = 6 Hz) and 9.06 (s, 3 H-19); *m/e* 330 (M).

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.32, H, 9.15. Found: C, 76.58; H, 8.93.

Preparative t.l.c. (acetic acid – ether – light petroleum, 1:2:17) of fraction II (160 mg) afforded the minor component, *ent*-16-kauren-19-oic acid (**1**, 12 mg); **1** was more readily separated as its methyl ester from the mixture resulting from treatment of fraction II with diazomethane. The mixture of esters (250 mg) gave by preparative t.l.c. (ethyl acetate – light petroleum, 1:20; silica gel – silver nitrate, 9:1) the oily methyl ester of **1** (28 mg), which had $[\alpha]_D$ −92° (*c*, 1.55) (lit. (2) $[\alpha]_D$ −104°). Alternatively, reduction of the mixture of esters with lithium aluminum hydride allowed easy separation by preparative t.l.c. (1:15, ethyl acetate – chloroform) of *ent*-16-kauren-19-ol, m.p. 141–143°, $[\alpha]_D$ −85° (*c*, 1.4) (lit. (2) m.p. 143–145°, $[\alpha]_D$ −78°).

Fraction III (190 mg), which contained two furanoid compounds, (t.l.c., Ehrlich stain), was treated with diazomethane. Preparative t.l.c. (ethyl acetate – light petroleum, 1:30, run thrice) afforded in addition to methyl junceate (**3***b*, 28 mg) the more polar (−)-methyl hardwickiate (39 mg), $[\alpha]_D$ −89° (*c*, 1.3) (lit. (3) $[\alpha]_D$ −113.5°), identified by conversion with lithium aluminum hydride into hardwickiol (**2***c*) and comparison (t.l.c., n.m.r.) of this product with an authentic sample (**9***b*).

Fraction IV contained polar compounds which were present (t.l.c.) in greater abundance in an extract of the whole plant and are discussed below.

(*ii*) The ground, dried roots (158 g) of *S. juncea* (Hamilton sample) were extracted as above to give an oil (6.3 g). Preparative t.l.c. (acetic acid – ether – light petroleum, 1:2:17) of this oil (1 g) afforded, in addition to junceic acid (**3***a*, 460 mg), epoxyjunceic acid (**6***a*, 18 mg). This compound (**6***a*) was more conveniently separated as its methyl ester. Preparative t.l.c. (ethyl acetate – light petroleum, 1:10, run twice) of the methylated extract (1 g) afforded the oily epoxyester (**6***d*, 47 mg) which distilled at 160°/0.01 mm and had $[\alpha]_D$ −49° (*c*, 2.1); τ 6.43 (s, 3H, —OCH_3), 7.18 (broad s, 1 H-3), 8.85 (d, 3 H-17, J = 6 Hz), 8.89 (s, 3 H-18) and 9.16 (s, 3 H-19); *m/e* 346 (M).

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73. Found: C, 72.61; H, 8.85.

[7]These showed the presence of small amounts of isovaleric acid (less than 10%), thus "compound" X is probably a mixture consisting mainly of **4***a* but in addition a small proportion of the corresponding monoisovalerate (**4***e*). Indeed, a small fraction which was isolated from the original plant extract runs just ahead of **4***a* on t.l.c. and appears on n.m.r., i.r., and mass spectral evidence to consist mainly of **4***e*.

Epoxidation of Methyl Junceate (3b)

Methyl junceate (**3b**, 166 mg) in carbon tetrachloride (10 ml) was treated with *m*-chloroperbenzoic acid (120 mg) in the dark at 20° for 16 h. The reaction mixture was eluted through a short alumina column with carbon tetrachloride, the solvent evaporated, and the crude product submitted to preparative t.l.c. (ethyl acetate – light petroleum, 1:12, run four times). Three compounds were recovered, unreacted **3b** (10 mg), the β-epoxyester (**6e**, 66 mg), and the α-epoxyester (**6d**, 20 mg). The less polar epoxyester (**6e**) after crystallization from light petroleum had m.p. 82–86°; τ 6.44 (s, 3H, —OCH_3), 7.21 (m, 1 H-3, $w_{1/2}$ = 5.5 Hz), 8.87 (s, 3 H-18), 8.88 (d, 3 H-17, J = 6 Hz), and 9.13 (s, 3 H-19).

Anal. Calcd. for $C_{21}H_{30}O_4$; C, 72.80; H, 8.73. Found: C, 73.00; H, 8.78.

The minor, more polar epoxyester (**6d**) had $[\alpha]_D$ −43° (*c*, 1.0) and was identical (t.l.c., n.m.r., and mass spectral fragmentation pattern) to the methyl ester of the naturally occurring epoxyacid (**6a**) (see above).

Attempted Decarboxylation of Junceic Acid (3a)

Junceic acid (20 mg) was heated at 290° under nitrogen in a sublimation tube for 30 min and the material was then distilled at the same temperature and 0.2 mm. T.l.c. (ethyl acetate – light petroleum, 1:30 and ethyl acetate – chloroform, 1:15) and its n.m.r. spectrum showed that the distillate was essentially pure starting material.

Reduction of Methyl Junceate (3b) with Lithium Aluminum Hydride

Methyl junceate (**3b**, 460 mg) was treated with excess lithium aluminum hydride in dry refluxing ether for 20 h. Work-up with saturated aqueous sodium sulfate afforded the crude product (416 mg). Preparative t.l.c. (ethyl acetate – chloroform, 1:15) of this material yielded the oily alcohol (**3c**, 365 mg) which after distillation *in vacuo* had $[\alpha]_D$ −49° (*c*, 1.3); ν_{max} 3650, 3460, and 877 cm^{-1}; τ 2.72, 2.80, 3.78 (all m, 1 H, furan protons), 4.84 (m, 1 H-3, $w_{1/2}$ = 7 Hz), 6.33 (s, 2 H-20), 8.42 (broad s, 3 H-18), 8.97 (s, 3 H-19) and 9.08 (d, 3 H-17, J = 6 Hz); with a 0.36 *M* ratio of Eu(DPM)$_3$ to **3c**, τ −2.2 (m, 2 H-20, $w_{1/2}$ = 9 Hz), 2.35, 2.62, 3.17 (all m, 1H, furan protons), 4.20 (m, 1 H-3, $w_{1/2}$ = 8 Hz), 6.23 (broad s, 3 H-17), 7.15 (s, 3 H-19), 7.87 (narrow m, 3 H-18); *m/e* 302 (M; $C_{20}H_{30}O_2$).

Treatment of **3c** with acetic anhydride – pyridine furnished the corresponding acetate (**3d**), which was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:10) and then crystallization from light petroleum. It had m.p. 82–84°, τ 5.92 (s, 2 H-20), 8.04 (s, 3H, —OCOCH_3), 8.43 (narrow m, 3 H-18), 8.98 (s, 3 H-19), and 9.07 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36. Found: C, 76.79; H, 9.44.

The Aldehyde 3f

Chromium trioxide (295 mg) in pyridine (10 ml) was added to the alcohol (**3c**, 150 mg) in the same solvent (10 ml) and the mixture kept at 20° for 6 h. The solvent was removed by azeotroping with benzene and the reaction product (100 mg) recovered from the residue with ether. Preparative t.l.c. (ethyl acetate – light petroleum, 1:20) of the product afforded the unstable aldehyde (**3f**, 58 mg) as an oil, which had ν_{max} 1715 and 873 cm^{-1}; τ 0.15 (s, 1 H-20), 4.82 (m, 1 H-3), 8.38 (broad s, 3 H-18), 8.92 (d, 3 H-17, J = 6 Hz), and 9.08 (s, 3 H-19); *m/e* 300 (M; $C_{20}H_{28}O_2$).

The Furano-olefin 3e

The aldehyde (**3f**, 58 mg) was heated under nitrogen with 99% hydrazine hydrate (2 ml) in ethylene glycol (2 ml) at 85° for 3 days. Potassium hydroxide pellets (145 mg) were then added and the temperature was raised to 195°, allowing excess hydrazine hydrate to distill out of the mixture. After 8 h at this temperature the mixture was allowed to cool and then diluted with ethyl acetate. This ethyl acetate solution was washed successively with dilute sulfuric acid, saturated aqueous sodium bicarbonate, and brine. Preparative t.l.c. (ethyl acetate – light petroleum, 1:20) of the crude product (66 mg) gave the furano-olefin (**3e**, 37 mg) which had $[\alpha]_D$ −58° (*c*, 1.09); τ 2.73, 2.86, 3.82 (all m, 1H, furan protons), 4.85 (m, 1 H-3), 8.43 (narrow m, 3 H-18), 9.00 (s, 3H, quaternary C—CH_3), 9.14 (d, 3 H-17, J = 6 Hz), and 9.26 (s, 3H, quaternary C—CH_3); with a 0.3 *M* ratio of Eu(DPM)$_3$ to **3e**, practically no change in spectrum except furan protons, now at τ 2.65, 2.77, and 3.78; *m/e* 286 (M; $C_{20}H_{30}O$). **3e** was identical (n.m.r., mass spectrum, t.l.c., g.l.c. and $[\alpha]_D$) to the furano-olefin obtained (**9b**) by hydrogenolysis of hardwickiol acetate (**2b**).

Epoxidation of Acetate 3d

The acetate (**3d**, 68 mg) was reacted with *m*-chloroperbenzoic acid (45 mg) in carbon tetrachloride for 2.5 h in the dark at 20°. The reaction mixture was washed through a short alumina column with ether and the crude product (53 mg) submitted to preparative t.l.c. (ethyl acetate – light petroleum, 1:10, run twice). Three compounds were isolated, the unreacted acetate (**3d**, 6 mg) and the epoxyacetates (**6b**, 32 mg; **6c**, 11 mg). The less polar β-epoxyacetate (**6b**) crystallized from light petroleum and had m.p. 98–101°, τ 5.96 (s, 2 H-20), 7.23 (m, 1 H-3, $w_{1/2}$ = 5 Hz), 8.05 (s, 3H, —OCOCH_3), 8.84 (s, 3 H-18), 8.93 (s, 3 H-19) and 9.10 (broadened d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.23; H, 8.91.

The minor α-epoxyacetate (**6c**), after distillation *in vacuo*, solidified and had m.p. 85–91°; τ 6.00 (d, 1 H-20, J = 11 Hz), 6.07 (d, 1 H-20, J = 11 Hz), 7.21 (s, 1 H-3, $w_{1/2}$ = 3.5 Hz), 8.03 (s, 3H, —OCOCH_3), 8.88 (s, 3 H-18), 8.97 (s, 3 H-19), and 9.10 (broadened d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.17; H, 9.16.

Attempted Formation of the Lactone 11

The less polar epoxyacetate (**6b**, 78 mg) was treated with chromium trioxide (85 mg) in an acetic acid (2 ml) – water (0.2 ml) mixture for 4.5 days. The crude product from work-up, from its t.l.c. behavior (ethyl acetate – light petroleum, 3:2) appeared to be a mixture of acids. Treatment with potassium hydroxide in ethanol (to hydrolyze the acetate) followed by attempted lactonization with toluene-*p*-sulfonic acid in refluxing benzene, or dicyclohexylcarbodiimide in pyridine at 100°, afforded very complex mixtures of mainly polar compounds.

The Tosylate 3g

Toluene-*p*-sulfonyl chloride (470 mg) and alcohol **3c** (290 mg) were dissolved separately in pyridine (3 ml

each) and the resulting solutions cooled to 0° and then mixed. After 26 h at 20° the reaction was worked-up (ice-water – ether). The resulting tosylate (**3***g*, 445 mg) ran as one spot on t.l.c. (ethyl acetate – light petroleum, 1:6) and had τ 2.27, 2.67 (benzenoid protons), 2.74, 2.90, 3.83 (all m, 1H, furan protons), 4.86 (m, 1 H-3), 5.97 (s, 2 H-20), 7.54 (s, 3H, Ar—CH_3), 8.44 (narrow m, 3 H-18), 9.08 (s, 3 H-19) and 9.12 (d, 3 H-17, J = 6 Hz).

Solvolysis of the Tosylate 3g

A solution of the tosylate (**3***g*, 675 mg) in acetic acid (41 ml) containing sodium acetate (1 g) was heated under reflux for 8 h. The solvent was removed by azeotroping with benzene and the residue dissolved in ether–water. The ether fraction was washed with brine, saturated aqueous sodium bicarbonate, and again brine. Evaporation of the solvent gave an oil (455 mg) which by t.l.c. over silica gel impregnated with silver nitrate (10%) (ethyl acetate – light petroleum, 1:60, or benzene – light petroleum, 1:7) was shown to contain one minor and three major components. Samples of each of the three major constituents were obtained by repeated preparative t.l.c. using the above conditions (ethyl acetate – light petroleum mixture). The least polar furano-diene (**13** or **14**, 50 mg) after distillation at 125°/0.06 mm had $[\alpha]_D$ −126° (*c*, 1.57); τ 4.75 (m, 1 H-3 and 1 H-11, $w_{1/2}$ = 12 Hz), 6.89 (d, 2 H-12, J = 7 Hz; s on irradiation at τ 4.76), 8.39 (broadened d, 3 H-18, J = 1.5 Hz), 8.94 (d, 3 H-17, J = 6 Hz; s on irradiation at τ 7.67) and 9.12 (s, 3 H-19); *m/e* 284 (M).

Anal. Calcd. for $C_{20}H_{28}O$: C, 84.45; H, 9.92. Found: C, 84.25; H, 9.83.

The furano-diene of intermediate polarity (**14**, 37 mg) was distilled at 120°/0.04 mm and had $[\alpha]_D$ −106° (*c*, 1.8); τ 4.70 (t, 1 H-11, J = 7 Hz; s on irradiation at τ 6.89), 4.83 (m, 1 H-3, $w_{1/2}$ = 8 Hz), 6.89 (d, 2 H-12, J = 7 Hz; s, on irradiation at τ 4.70), 8.41 (broadened d, 3 H-18, J = 1.5 Hz), 9.02 (s, 3 H-19) and 9.04 (d, 3 H-17, J = 6 Hz; s on irradiation at τ 7.34); *m/e* 284 (M).

Anal. Calcd. for $C_{20}H_{28}O$: C, 84.45; H, 9.92. Found: C, 84.47; H, 10.03.

The most polar furano-diene (**15**, 67 mg) was distilled at 120°/0.03 mm and had $[\alpha]_D$ −84° (*c*, 1.12); τ 4.70 (m, 1 H-3, $w_{1/2}$ = 10 Hz; t, J_{obs} = 6 Hz, on irradiation at τ 8.41), 4.97 (d, 1 H-20, J = 6 Hz; s on irradiation at τ 7.64), 8.41 (narrow m, 3 H-18), 8.92 (d, 3 H-17, J = 7 Hz; s on irradiation at τ 7.42) and 9.17 (s, 3 H-19); *m/e* = 284 (M).

Anal. Calcd. for $C_{20}H_{28}O$: C, 84.45; H, 9.92. Found: C, 84.45; H, 9.74.

Isolation Procedure, the Whole Plant Extract

Ground, dried, whole plant (120 g) of *S. juncea* was extracted with ether for 9 h in a Soxhlet apparatus. The crude extract (5.2 g) was chromatographed over silica gel (200 g) using light petroleum – ethyl acetate solvent mixtures. Early fractions contained junceic acid. Later fractions (10–40% ethyl acetate) were submitted to repeated preparative t.l.c. (ethyl acetate – light petroleum, 2:1) and afforded (in order of increasing polarity), junceanol W (**4***a*, 120 mg), junceanol X (**4***b*, 950 mg) and junceanol Y (**5***a*, 375 mg). Junceanol W (**4***a*) was obtained as an oil which decomposed fairly rapidly at 20° (t.l.c. evidence). It had ν_{max} 1720 cm^{-1}; τ 4.07 (broad s, 1 H-14, $w_{1/2}$ = 3 Hz), 4.63 (d, 1 H-7, J = 3.5 Hz), 6.07 (q, 1 H-6, J = 3.5, 12 Hz), 8.88, 8.96, 9.20 (all s, quaternary C—CH_3's), 8.92 and 9.06 (both d, 3 H-16 and 3 H-17, J = 6 Hz). Junceanol X (**4***b*), also an oil, on distillation *in vacuo* suffered extensive decomposition (see below). It was purified by further preparative t.l.c. (taking only a central "cut" from the band) and had $[\alpha]_D$ −11° (*c*, 1.3); ν_{max} (0.0025 *M*) 3615, 3595 (sh), 3530 (w) cm^{-1}; ν_{max} (0.01 *M*) 1737, 1720, and 1652 cm^{-1}; τ 4.29 (broad s, 1 H-14 and olefinic proton of senecioate), 4.97 (q, 1 H-6, J = 3.5, 12 Hz; d, J = 3.5 Hz on irradiation at τ 8.15), 5.90 (d, 1 H-7, J = 3.5 Hz; s on irradiation at τ 4.97), 7.35 (broad s, —O*H*; disappears on D_2O exchange), 7.80, 8.08 (both broad s, senecioate methyls), 8.97 (s, quaternary C—CH_3), 9.07, 9.12 (both d, 3 H-16 and 3 H-17, J = 6 Hz) and 9.13 (s, 6H, quaternary C—CH_3's). Junceanol Y (**5***a*) crystallized from ether – light petroleum and had m.p. 136–140°; $[\alpha]_D$ −34° (*c*, 2.0); ν_{max} 3600 and 3400 cm^{-1}; τ 4.37 (broad s, 1 H-14, $w_{1/2}$ = 3.5 Hz) 5.7 (broad s, 2 —O*H*; disappears on D_2O exchange), 5.82 (broad s, 1 H-7, $w_{1/2}$ = 4 Hz), 9.10 (m, 12H, —CH_3's) and 9.28 (s, quaternary C—CH_3); *m/e* 263 (M-43) and 245 (M-61).

Anal. Calcd. for $C_{20}H_{34}O_2$: C, 78.43; H, 11.11. Found: C, 78.54; H, 11.37.

Hydrolysis of Junceanol X (4b)

Junceanol X (entire t.l.c. band, see above) (**4***b*, 205 mg) was treated with potassium hydroxide (350 mg) in refluxing ethanol (15 ml) for 4 h and the mixture was then diluted with water and extracted with ether. The ether extract was washed with water (the aqueous layer and aqueous washings being retained, see below) and afforded the crude triol (**4***c*, 126 mg). Purification of this material by preparative t.l.c. (ethyl acetate – light petroleum, 2:1) followed by crystallization from moist ether gave **4***c*, m.p. 90–96°; τ 4.30 (broad s, 1 H-14), 5.95 (d, 1 H-7, J = 3.5 Hz), 6.25 (q, 1 H-6, J = 3.5 ,12 Hz), 6.75 (broad s, 2? —O*H*; lost on D_2O exchange), 8.85, 8.96, 9.25 (all s, quaternary C—CH_3's), 9.06 and 9.11 (both d, 3 H-16 and 3 H-17, J = 6 Hz); *m/e* 304 (M − 18), 280 (M − 42), 279 (M − 43) and 261 (M − 61).

Anal. Calcd. for $C_{20}H_{34}O_3.H_2O$: C, 70.59; H, 10.59. Found: C, 70.32; H, 10.83.

The aqueous fractions from the above reaction were combined, evaporated to near dryness *in vacuo* and acidified with the minimum quantity of dilute sulfuric acid. A large amount of anhydrous sodium sulfate was added and the mixture was then extracted with carbon tetrachloride. The n.m.r. of this solution corresponded to that of a mixture (*ca.* 10:1) of authentic samples of senecioic and isovaleric acids. The above reaction was repeated and the mixture of acids recovered this time in ether. This extract was evaporated carefully to small bulk and submitted to mass spectral analysis which showed *m/e* 100 (senecioic; M) and 60 (isovaleric; M − propene).

Conversions of Junceanol W (4a) into Triol 4c

Junceanol W (**4***a*, 10 mg) was treated with excess lithium aluminum hydride in refluxing dry ether (2 ml) for 1 h. Work-up afforded triol **4***c* (8.5 mg).

Junceanol W (9 mg) was heated in refluxing ethanol with potassium hydroxide (80 mg) for 1 h. The mixture was diluted with ether and then washed with brine. Evaporation of the ether layer gave triol **4***c* (8 mg).

These two samples were identical in n.m.r. and t.l.c. (ethyl acetate – light petroleum, 2:1) behavior to the triol prepared (see above) from junceanol X (**4***b*).

The Acetate 5b

Junceanol Y (**5***a*, 110 mg) was treated with acetic anhydride (0.5 ml) and pyridine (0.5 ml) at 20° for 14 h. The mixture was diluted with ether, washed with saturated aqueous sodium bicarbonate and water, and the solvent evaporated. Preparative t.l.c. (ethyl acetate – light petroleum, 2:1) of the residue afforded the oily acetate **5***b* (95 mg) which was distilled at 135–140°/0.02 mm and had $[\alpha]_D$ −26° (*c*, 1.3); ν_{max} 3615 and 1735 cm^{-1}; τ 4.17 (broad s, 1 H-14, $w_{1/2}$ = 4 Hz; sharpens on irradiation at τ 7.96), 4.73 (t, 1 H-7, J_{obs} = 2 Hz; s on irradiation at τ 8.33), 8.03 (s, 3H, —OCOCH_3), 8.3 (broad s, —O*H*, lost on D_2O exchange), 9.12, 9.17 (both d, 3 H-16 and 3 H-17, *J* = 7 Hz), 9.15 (s, 6H, quaternary C—CH_3's), and 9.24 (s, 3H, quaternary C—CH_3); with a 0.46 *M* ratio of Eu(DPM)$_3$ to **5***b*, τ −2.9 (broad s, —O*H*), 0.03 (broad s, 1 H-7), 0.63 (broad s, 1 H-14), 5.32 (s, 3H, —OCOCH_3), 7.73 (was 9.12), and 7.91 (was 9.07) (both d, 3 H-16 and 3 H-17, *J* = 7 Hz), 8.25, 8.45, and 8.77 (all s, quaternary C—CH_3's).

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.81; H, 10.41. Found: C, 75.59; H, 10.24.

Eu Shifts in Model Compounds

(*i*) Compound **22** (13, 14) had τ 4.53 (broad s, 1 H-14), 8.97 (s, 6H, quaternary C—CH_3's), 9.00 (s, quaternary C—CH_3), 9.08 and 9.13 (both d, 3 H-16 and 3 H-17, *J* = 6 Hz); with a 0.42 *M* ratio of Eu(DPM)$_3$ to **22**, τ 1.53 (broad s, 1 H-14), 6.83, 7.21, 7.47 (all s, quaternary C—CH_3's), 7.15 and 7.25 (both d, 3 H-16 and 3 H-17, *J* = 6 Hz).

(*ii*) Compound **23** (13, 14) had τ 4.27 (broad s, 1 H-14), 4.60 (broad s, 1 H-7), 8.91 (s, quaternary C—CH_3), 8.98 (s, 6H, quaternary C—CH_3's), and 8.98 (d, 3 H-16 and 3 H-17, *J* = 6 Hz); with a 0.21 *M* ratio of Eu(DPM)$_3$ to **23**, τ 4.16 (broad s, 1 H-14), 4.42 (broad s, 1 H-7), 7.92, 8.12, 8.63 (all s, quaternary C—CH_3's), and 8.93 (d, 3 H-16 and 3 H-17, *J* = 6 Hz).

Treatment of Acetate 5b with Toluene-p-sulfonyl Chloride

The acetate (**5***b*, 165 mg) was heated in pyridine (6 ml) with toluene-*p*-sulfonyl chloride (200 mg) at 100° for 10 h. The reaction mixture was poured into ice-water and extracted with ether. The crude product (124 mg) showed three spots on analytical t.l.c. (ethyl acetate – light petroleum, 1:70) on silica gel impregnated with silver nitrate (10%), and separation of the components was achieved by preparative t.l.c. using the same conditions. The least polar component was the known aromatic hydrocarbon (**19**, 39 mg), m.p. 37–43° (lit. (11) 41–43°); λ_{max} (cyclohexane) 269 (ε 850) and 277 nm (ε 900) (lit. (11) (ethanol) 275 nm (ε 800)); τ 2.93 (d, 1 H-11, *J* = 8 Hz), 3.17 (q, 1 H-12, *J* = 8, 1.5 Hz), 3.23 (broad s, 1 H-14), 8.80 (d, 3 H-16 and 3 H-17, *J* = 6 Hz), 8.83 (s, quaternary C—CH_3), and 9.05 (s, 6H, quaternary C—CH_3's); c.d. (ethanol) $[\theta]_{277}$ −320, $[\theta]_{269}$ −320 and $[\theta]_{262}$ −120; g.l.c. retention time 10.9 min at 175°; identical by g.l.c., t.l.c., n.m.r., and c.d. to an authentic sample[8] of **19**. The second component (27 mg) was the oily triene **17** which had λ_{max} 329, 315, and 304 nm; τ 4.13 (m, 1 H-6, 1 H-7, and 1 H-14), 4.38 (broadened t, 1 H-11, J_{obs} = 6 Hz), 8.80, 8.98 (both d, 3 H-16 and 3 H-17, *J* = 6.5 Hz), 8.86 (s, 6H, quaternary C—CH_3's) and 9.15 (s, quaternary C—CH_3); *m/e* 270 (M). The most polar component (21 mg) was the oily triene **18** which underwent very rapid decomposition (t.l.c.) to more polar material. It had λ_{max} 301 (sh), 288 and 276 nm.

[8]We cordially thank Professor E. Wenkert for supplying this sample.

The Diacetate 4d

The triol **4***c* (126 mg) in pyridine (2 ml) was treated with acetic anhydride (2 ml) at 20° for 15 h. Work-up afforded an oil (156 mg) from which the diacetate **4***d* (125 mg) was recovered by preparative t.l.c. (ethyl acetate – light petroleum, 1:2). After crystallization from light petroleum **4***d* had m.p. 114–118°, $[\alpha]_D$ +31° (*c*, 2.7); ν_{max} (0.005 *M*) 3618 (s), 3588 (vw) and 1745 (s) cm^{-1}; τ 4.20 (s, 1 H-14, $w_{1/2}$ = 3 Hz), 4.65 (d, 1 H-7, *J* = 3.5 Hz), 5.02 (q, 1 H-6, *J* = 12, 3.5 Hz), 8.00, 8.09 (both s, 3 H each, 2—OCOCH_3), 9.00 (s, quaternary C—CH_3), 9.06, 9.11 (both d, 3 H-16 and 3 H-17, *J* = 6 Hz) and 9.13 (s, 6H, quaternary C—CH_3's); with a 0.51 *M* ratio of Eu(DPM)$_3$ to **4***d*, τ 0.55 (broad s, 1 H-14), 1.23 (d, 1 H-7, *J* = 3.5 Hz), 3.05 (q, 1 H-6, *J* = 12, 3.5 Hz), 6.73, 7.42 (both s, 3 H each, 2—OCOCH_3), 6.97 (d, 1 H-5, *J* = 12 Hz), 7.28, 7.43 (both d, 3 H-16 and 3 H-17, *J* = 6 Hz), 8.02, 8.35, and 8.48 (all s, quaternary C—CH_3's).

Anal. Calcd. for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42. Found: C, 70.96; H, 9.66.

Treatment of Junceanol X with Hydrochloric Acid

Concentrated hydrochloric acid (0.1 ml) was added to a solution of junceanol X (**4***b*, 75 mg) in chloroform (1 ml). After *ca.* 2 min, the solution was applied to a preparative t.l.c. plate, heated for *ca.* 1 min with a hair dryer, and the plate then developed with light petroleum in the usual fashion. The major non-polar product was the oily styrene (**24**, 23 mg) which after distillation at 125°/0.1 mm had $[\alpha]_D$ −136° (*c*, 1.55); λ_{max} 266 nm (ε 9000); c.d. (ethanol) $[\theta]_{258}$ +7000; τ 3.06 (d, 2H, aromatic protons, *J* = 1 Hz), 3.21 (narrow m, 1H, aromatic proton), 3.55 (q, 1 H-7, *J* = 10, 3 Hz), 4.07 (q, 1 H-6, *J* = 10, 3 Hz), 7.17 (septet, 1 H-15, *J* = 7 Hz), 7.88 (t, 1 H-5, *J* = 3 Hz), 8.77 (d, 3 H-16 and 3 H-17, *J* = 7 Hz), 8.94, 8.98 and 9.02 (all s, quaternary C—CH_3's); *m/e* 268 (M).

Anal. Calcd. for $C_{20}H_{28}$: C, 89.49; H, 10.51. Found: C, 89.27; H, 10.68.

Catalytic Hydrogenation of the Styrene 24

The styrene (**24**, 25 mg) in ethyl acetate was shaken with hydrogen over palladized charcoal (5%, 25 mg) for 2 h. Removal of catalyst and solvent left an oil (24 mg) which was purified by preparative t.l.c. (light petroleum) and gave the aromatic hydrocarbon **19** (18 mg). This material was identical (t.l.c., g.l.c., n.m.r., u.v., and c.d.) to the sample of **19** prepared from junceanol Y (see above).

Treatment of Diacetate 4d with Toluene-p-sulfonyl Chloride

The diacetate **4***d* (80 mg) was heated with toluene-*p*-sulfonyl chloride (95 mg) in refluxing pyridine (3 ml) for 11 h. Work-up afforded an oil (60 mg) which was subjected to preparative t.l.c. (ethyl acetate – light petroleum,

1:5), two major constituents being obtained. The less polar component (28 mg) was identified as the styrene **24** by its n.m.r. and t.l.c. behavior. The more polar component (24 mg) was the oily diene **25** which had λ_{max} 273 nm; τ 4.12 (broad s, 1 H-14), 4.45 (d, 1 H-7, J = 3.5 Hz), 4.68 (broad s, 1 H-12), 4.91 (q, 1 H-6, J = 12, 3.5 Hz), 7.97. 8.07 (both s, 3 H each, 2—OCOCH_3), 8.95 (s, quaternary C—CH_3), 9.02 (s, 6H, quaternary C—CH_3's) and 9.07 (d, 3 H-16 and 3 H-17, J = 6 Hz); with a 0.48 M ratio of Eu(DPM)$_3$ to **25**, τ 2.6 (d, 1 H-7, J = 3.5 Hz), 3.73 (broad s, 1 H-14), 3.78 (q, 1 H-6, J = 12, 3.5 Hz), 4.30 (broad s, 1 H-12), 7.13, 7.57 (both s, 3H each, 2—OCOCH_3), 8.63, 8.73, 8.81 (all s, quaternary C—CH_3's) and 9.03 (d, 3 H-16 and 3 H-17, J = 6 Hz).

Distillation–Pyrolysis of Junceanol X

(*i*) Junceanol X (51 mg) was heated at 200° under N_2 for 5 min and the product distilled at that temperature and 0.2 mm. The distillate on t.l.c. (ethyl acetate – light petroleum, 1:2) showed a non-polar compound, one of R_F *ca.* 0.5 and polar material but no substrate. Preparative t.l.c. using the same solvent mixture furnished the two less polar compounds. The first of these was identified as the styrene **24** (12 mg) by its n.m.r. and t.l.c. behavior while the second was identified as essentially pure junceanol W (**4***a*, 18 mg) on similar evidence.

(*ii*) Junceanol X (50 mg) was heated at 270° under nitrogen for 3 min and the product then distilled out at the same temperature and 0.1 mm. The distillate contained no detectable amounts of junceanols W or X (t.l.c. evidence). Preparative t.l.c. (light petroleum) afforded the styrene **24** (6 mg) which was again identified by its n.m.r. and t.l.c. behavior.

We thank the Science Research Council of the U.K. for a maintenance award (to M.S.H.), the National Research Council of Canada for an operating grant (to R.McC.), and Mr. Jyoti Chatterji for his assistance in the isolation of junceanols W and X.

Received November 27, 1972

Solidagoic acids A and B, two new diterpenoids from *Solidago gigantea* Ait. var. *serotina* (Kuntze) Cronqu., are formulated (absolute configuration tentative) as **1***a* and *b* on the basis of chemical, spectroscopic, and optical evidence.

On propose les formules **1***a* et **1***b* pour les acides solidagoïques A et B, deux nouveaux diterpénoides isolés de *Solidago gigantea* Ait. var. *serotina* (Kuntze) Cronqu. Ces structures pour lesquelles les configurations absolues ne sont pas définitives sont attribuées en se basant sur des preuves chimiques spectroscopiques et optiques. [Traduit par le journal]

Can. J. Chem., **51**, 1332 (1973)

In the course of our studies on the constituents of *Solidago* species, we have obtained (1) from the roots of *S. gigantea* Ait. var. *serotina* (Kuntze) Cronqu.[3] several new diterpenoids. In the present paper we discuss the constitution and stereochemistry of two of them, solidagoic acids A (**1***a*) and B (**1***b*).

The chloroform soluble fraction of an ethyl acetate extract of dried root material was examined by t.l.c. and found to contain a large number of furanoid compounds which were detected by their color reaction with Ehrlich's reagent. Column chromatography of this material over alumina and elution with chloroform – light petroleum furnished nine neutral diterpenoids, which form the subject of the following article. Two acidic compounds, solidagoic acids A and B, were then recovered by elution with ethyl acetate – acetic acid and separated by rechromatography, this time over silica gel.

Solidagoic Acid A

The less polar acid, A, m.p. 169–171°, was isolated in approximately 0.6% yield, based on the weight of dried roots. Analytical and mass spectral data indicated that the compound has the molecular formula $C_{20}H_{28}O_3$. Its i.r. absorption at 875 cm^{-1} taken in conjunction with three narrow multiplets at τ 2.75, 2.94, and 3.82 in its n.m.r. spectrum indicated the presence of a β-substituted furan ring. This probably constitutes part of a furano-ethyl side chain since its mass spectrum has a prominent ion at *m/e* 189 (M – 95; cleavage of C_9—C_{11} bond). The broad absorption band between 3100 and 3600 cm^{-1} in the i.r. confirmed that the remaining oxygen atoms are present in a carboxyl group, as had been deduced from its chromatographic behavior. In the n.m.r. spectrum an olefinic proton and a methyl group attached to a double bond give rise to an unresolved multiplet ($w_{1/2}$ = 11 Hz) at τ 4.45 and a broad singlet at 8.48 respectively, while a three proton singlet at τ 9.02 and a doublet at 9.11 (J = 6 Hz) can be attributed to two additional methyl groups, the former tertiary, the latter secondary. The results presented above indicated the possibility that solidagoic acid A has a clerodane-type skeleton (**2**), one of the tertiary methyl groups in **2** being replaced by a carboxyl group. The n.m.r. spectra of several simple derivatives of the acid added support to this proposal. Thus in the alcohol (**1***c*) and the acetate (**1***d*) the —CH_2O— protons appear as AB quartets (J = 11 Hz) centered at τ 6.47 and

5.96 respectively, while in the related aldehyde (**1***e*) the aldehydic proton resonates as a sharp singlet at τ 0.54. Significantly, none of these protons shows evidence of vicinal spin–spin coupling indicating that these functional groups are indeed attached to a quaternary carbon atom.

Further evidence for a clerodane-type skeleton came from the discovery that the olefinic bond is βγ to the carboxyl group. When acid A (**1***a*) was heated at 270° under N_2 for 20 min, it decarboxylated and furnished the olefin (**3**), which retains a resonance at τ 8.35 attributable to a methyl on a double bond but no resonance from an olefinic proton. Surprisingly, this nor-olefin (**3**) was the only product recovered from treatment of the alcohol (**1***c*) with chloroacetic anhydride in refluxing pyridine. In this case its formation presumably involves a reaction of the retro-Prins type. At this stage acid A could be tentatively assigned either the gross structure **1***a* (no stereochemistry) or the alternative **4**. The latter, which is unlikely on biogenetic grounds, was eliminated from consideration on the basis of the following evidence.

Huang–Minlon reduction of the aldehyde (**1***e*) and of its tetrahydro analog (**5***a*) afforded **1***f* and **5***b* respectively. Oxidation of these and of

the tetrahydro derivative (**5***c*) of methyl solidagoate (**1***g*) with the Sarett reagent slowly produced the enones **6**, **7***a*, and **7***b*, all of which exhibit resonances attributable to a methylene group α to the ketone at about τ 7.5. Significantly, in each case, the multiplets appear to constitute[4] the AB part of an ABX system. Indeed, when the n.m.r. spectrum of the alcohol (**1***c*) was recorded in the presence of tris(dipivalomethanato)europium the resonance of the proton giving rise to the X part in the enones separated out and appeared as a fairly narrow triplet. Therefore this proton (H-10) has probably no further vicinal neighbors. These results, and the observation that catalytic hydrogenation of **7***a* afforded a ketone (**8***a*), the i.r. absorption of which at 1720 cm^{-1} is compatible with its formulation as a cyclohexanone, allows the part structure **9** to be written for acid A with reasonable assurance. Bearing in mind biogenetic considerations and the presence of a β-furanoethyl side chain, a secondary and a tertiary methyl group, this can be expanded to **1***a* (no stereochemistry). The results reported below concerning the stereochemistry of acid A place this assignment of structure beyond reasonable doubt.

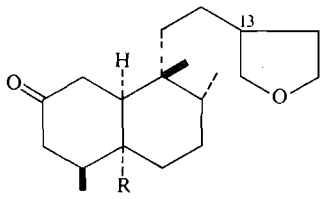
Solidagoic Acid B

The more polar acidic component, solidagoic acid B (**1***b*), m.p. 134–135°, analyzed for $C_{25}H_{34}O_5$, although its mass spectrum shows no peak higher than *m/e* 314, which thus probably corresponds to loss of a five carbon unit. An i.r. absorption band at 1695 cm^{-1} and characteristic (2) resonances at τ 3.96 (1H) and between 7.95 and 8.15 (6H) indicated the presence of an angelate ester. The remainder of the n.m.r. spectrum shows a marked similarity to that of acid A, suggesting a close relationship. Thus two methyl groups, one tertiary, the other secondary, give rise to a singlet at τ 8.97 and a doublet at 9.09 (J = 6 Hz) respectively while a multiplet at 4.02 ($w_{1/2}$ = 10 Hz) may be assigned to an olefinic proton. However, the resonance attributed to the olefinic methyl in acid A has been replaced by a two-proton singlet at τ 5.50, suggesting that in acid B this methyl has suffered oxygenation. The latter compound could then be formulated as **1***b* (no stereochemistry).

Certain nuclear magnetic double resonance and chemical experiments added substance to this conclusion. When the broad singlet at τ 5.50 (—CH_2—OAng) was irradiated the resonance of the olefinic proton at τ 4.02 was converted into a triplet (J_{obs} = 4 Hz). Irradiation at τ 7.93 (allylic protons, 2 H-2) also collapsed the multiplet at τ 4.02, this time to a broad singlet ($w_{1/2}$ = 4 Hz) and in addition sharpened ($w_{1/2}$ = 2.5 Hz) the singlet at τ 5.50. These experiments confirmed that the double bond bears on one end a proton and an allylic methylene and on the other a —CH_2—O— group. Moreover, pyrolysis of the acid at 320° in an evacuated tube afforded, in addition to an oily distillate, crystalline angelic acid (**10***a*), m.p. 45°, which was collected separately in a cold trap. Comparison of this material with an authentic sample of angelic acid was achieved by g.l.c. over 20% free fatty acid phase (FFAP) at 125°, the three isomeric acids, senecioic (**10***b*), tiglic (**10***c*), and angelic, being well separated on this free acid phase. The less volatile material from the above pyrolysis was seen from t.l.c. to consist of two compounds of very similar polarity which were separated only by repeated preparative t.l.c. The less polar component, $C_{20}H_{26}O_3$ (**11**), an oil, which was by far the more abundant, shows a strong absorption in the i.r. at 1778 cm^{-1}, indicative of a γ-lactone. The methylene protons in the lactone ring resonate as a pair of doublets at τ 5.31 and 5.60 (J = 12 Hz), the former being markedly broadened by long range coupling. The very minor component, m.p. 145–147°, on i.r. and mass spectral evidence only, is formulated tentatively as the isomeric lactone **12**. The formation of these lactones can be rationalized by suggesting attack of the carboxyl group at, in the former case the methylene group carrying the ester, in the latter C-3 with a concomitant rearrangement of the olefinic bond into the exocyclic position, each process involving expulsion of angelic acid.

A direct correlation of acids A and B was next sought and accomplished in the following manner. Reduction of the methyl ester of B with lithium aluminum hydride furnished the corresponding diol (**1***h*). Hydrogenation of the derived diacetate (**1***i*) in ethanol–triethylamine over 10% palladized charcoal afforded an acetate identical in all respects to that (**1***d*) previously prepared from A. A minor product from the hydrogenation was the tetrahydro derivative (**5***d*) of **1***d*. These experiments demonstrated that the sole difference in the two acids A and B lies in the nature of the function attached at C-4, in the

[4]This n.m.r. system is more fully discussed below under the heading stereochemistry.



C-13 epimeric mixture

d $R^1 = CH_3$; $R^2 = CHO$

former this is a methyl group, in the latter, an allylic primary angelate ester.

Stereochemistry

The constitutions of acids A and B having been established with some certainty the major problem remaining involved the assignment of stereochemistry at the four asymmetric centers, C-5, -8, -9, and -10. At the outset, attempts were made to correlate **1***a* with hardwickiic acid (**13***a*, 3) in which rings A and B are *trans*-fused. With this intention, the furano-olefin (**1***f*) was prepared from acid A as described above and compared with the analogous compound (**13***b*, 4) from hardwickiic acid. Significant differences were observed in their n.m.r. spectra, for example in the chemical shifts of the resonances of the C-5, -8, and -9 methyl groups (τ 8.83, 9.08, and 8.92 respectively in the former and τ 9.00, 9.14, and 9.26 in the latter). If these two olefins have the same gross structure then they must differ in configuration at one or more centers. Indeed, results gradually accumulated which when taken *in toto* pointed unequivocally to the presence of the relatively rare *cis*-AB ring fusion[5] in acid A (**1***a*).

In this context, the first results which arrested our attention came from studies on the catalytic hydrogenation of **1***a*. Treatment with hydrogen in the presence of platinum oxide produced a mixture of products from which the two major constituents, the tetrahydroacids (**14***a* and *b*), were readily separated. The residue after methylation furnished two compounds (**15***a* and *b*) which had suffered hydrogenolytic cleavage of the furan ring. That these are epimers at C-13 rather than C-15/C-16 structural isomers follows (10) from the presence of an ill-resolved doublet ($w_{1/2}$ = 6 Hz) at τ 6.5 in the n.m.r. spectrum of both. The following aspects of this reaction were initially surprising. First, appreciable quantities of material in which the Δ^3 olefinic

[5]At the time the main bulk of this work was carried out only columbin (5) and its congeners were known to have this type of structure. Since then plathyterpol (6), tinophyllone (7), gutierolide (8), cistodiol, and the related diacid (9) have swollen this list.

16 13*S*

bond had been saturated were absent. Indeed, the methyl ester **14***c* of the less polar tetrahydro acid (**14***a*) and **15***a* only very slowly gave products (**16** and **17**) of hydrogenation of the double bond under the same conditions. The unreactivity of the olefin in this reaction and towards osmium tetroxide, diborane, and *m*-chloroperbenzoic acid (see Experimental) contrasts with the behavior of related compounds (4, 11). The only configurational and conformational assignment for acid A which seemed to explain this situation is the *cis*-fused system **18***a* (or enantiomer) in which one face of the olefinic bond is shielded by the carboxyl group and the other by either the C-9 methyl or C-9 side chain. Second, **14***a* and *b* were very readily separated by chromatography even though they are simply C-13 epimers. This led us to suspect interaction of the tetrahydrofuran moiety with the carboxyl group in the less polar acid and this was confirmed spectroscopically. At high dilution **14***a* shows two strong carbonyl bands in the i.r. at 1729 (intramolecular hydrogen bond) and 1692 (dimer) cm^{-1} while **14***b* has only one band at 1692 and a weak shoulder at 1729 cm^{-1}. It appeared unlikely that a difference of configuration at C-13 could directly affect the conformations of rings A and/or B and lead to a difference in the tendencies of the carboxylic groups in **14***a* and *b* to hydrogen bond to the olefinic bond. Thus the peaks at 1729 cm^{-1} presumably result from hydrogen bonding of the carboxyl to the ethereal oxygen in the side chain. The ν(CO) is considerably lower than that predicted (12, 13) for species with the carboxylic hydroxyl involved in hydrogen bonding intramolecularly to an oxygen atom other than the carboxylic carbonyl. However, the value observed in the present case is very close to that obtained for ν(CO) when the i.r. spectra of **14***a* and *b* are recorded in carbon tetrachloride in the presence of tetrahydrofuran. In both only one band was observed (1724 cm^{-1}) and attributable to free —C(=O)—OH...O (of THF). By reference to molecular models it is apparent that if this interpretation is correct then the tetrahydroacids must have the relative stereochemistry shown in **14***a* (less polar) and *b* (more polar), the assignments at C-13 being tentative. The hydrogen bonding ring size is fairly large, in fact 11-membered. Presumably, substitution effects reduce the number of favorable conformations and facilitate intramolecular hydrogen bonding. The hydroxy esters **15***a* (less polar) and *b* (more polar) also showed evidence of interaction of the C-5 substituent and the functional group in the side chain. Their hydroxyl and carbonyl stretching absorptions provided firm i.r. evidence for the existence of strong intramolecular hydrogen bonds between the hydroxyl and methoxycarbonyl groups. Both have two bands attributable to free and bonded hydroxyl groups (the latter band being much more intense especially for **15***a*), $\Delta\nu_{OH}$ about 100 cm^{-1}, and peaks in the carbonyl region at 1725 and 1712 (less intense) cm^{-1}. This last absorption can be assigned to a conformer in which the hydroxyl is bonded to the ester carbonyl, a situation in which ν(CO) is known to decrease (13). However, to explain the relative intensities of the hydroxyl and carbonyl bands in even approximate terms the presence of a further hydrogen bonded species, —OH...O—C(=O)—, must be proposed. In this ν(CO) should be similar to that of

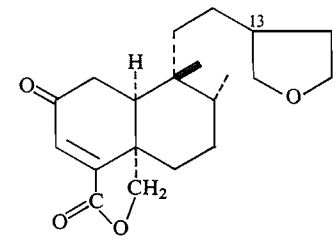
non-bonded conformers (13). The tentative assignment of relative stereochemistry at C-13 to **15***a* and *b* is again based on a study of molecular models. These results appeared to indicate clearly the presence in **1***a* of an A–B *cis*-ring fusion *and* a *cis*-relationship of the carboxyl and furanoethyl side chain.

Further results reinforced these stereochemical conclusions. The acid strength ($pK_{MCS}^* = 8.14$, (14)) of **1***a* corresponds (15) much more closely to that for an angular carboxyl group in a *cis*- rather than a *trans*-fused decalin system. In addition, the relative stereochemistry proposed above would explain the marked difference in reactivity of **14***c* and **16** towards lithium aluminum hydride. Thus in refluxing ether reduction of the former to **14***d* was complete in 4 h while under identical conditions the latter was essentially unchanged. Catalytic hydrogenation of **14***c* in conformation **18***b* would be expected to proceed on the face of the molecule remote from the shielding influence of the C-9 methyl group. The product (**16**) would be expected to flip into the other possible chair–chair conformation (**19**) because of the severe steric interaction between the C-4 and -9 methyl groups. In **18***b* the methoxycarbonyl group is relatively unencumbered and open to attack by lithium aluminum hydride, while in **19** this is not the case.

In the early stages of the investigation it was felt that the n.m.r. spin–spin coupling constants of H-10 to 2 H-1 in derivatives of acid A might serve to distinguish among the various possibilities of mode of A-B ring fusion and ring conformation. With respect to relative stereochemistry three *distinct*[6] possibilities exist, namely, a *trans*-fused decalin (**20**) or a *cis*-fused decalin in either conformation **21** or **22**. In the first two, H-10 is axial to ring A and should show one axial–axial and one axial–equatorial coupling. Recently, as mentioned above, it has been possible in one instance to discern the resonance due to H-10. When spectra of **1***c* were recorded in the presence of gradually increasing concentrations of tris(dipivalomethanato)europium a multiplet separated out downfield from the remaining methylene and methine resonances. In several of these it forms a well-defined, though broadened, triplet presumably because the 2 C-1 protons have become accidentally equivalent. The spacings (5 Hz) observed would then represent an average of the two true coupling constants. Nonetheless, this strongly indicates the stereochemical situation **22***b* for

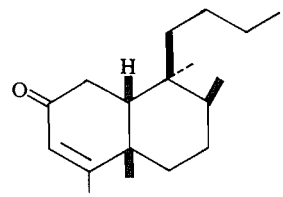
[6]Related conformations with ring A in flattened chair, boat, or twist-boat conformations will be discussed where appropriate.

this compound, in accord with the conclusions reached above. Our original approach to determine the couplings of H-10 involved a study of the resonances arising from the C-1 protons. Readily available for this purpose was the enone **23**, which was formed from diol **1***h* by catalytic hydrogenation of the furan ring and then oxidation (16) with the Sarett reagent. In **23** the C-2 carbonyl effects a downfield shift of the resonances of the two C-1 protons, while the complicating signals of 2 H-12 are shifted upfield by saturation of the furan ring. In deuterobenzene–deuterochloroform (85:15) the C-1 protons are accidentally equivalent and resonate as a clean doublet (splitting 9 Hz) at τ 7.96 while in deuterobenzene alone they form a multiplet with three strong lines at about τ 8. Analysis of this as the AB part of an ABX system gave values for J_{AX} (3.75 Hz) and J_{BX} (14.25 Hz). The magnitude of these coupling constants revealed that the compound has either the *trans*-AB ring fusion or the *cis*-fusion in conformation **21***a*. Other results suggested choice of the latter, conformation **21***a* being preferred to **22***a* in this case probably because the constraint imposed by closure of the lactone ring is less in the former. To investigate the role, if any, of the lactone ring in determining the conformational preference in **23**, the n.m.r. spectra of the enones **6** and **7***a* were recorded for solutions in carbon tetrachloride, benzene, and various mixtures of these. By this means the resonances attributable to 2 H-1 were located for both. In each, the coupling constants of these two protons (A and B) to H-10 (X) were calculated as $J_{AX} = 8.25$ and $J_{BX} = 0.75$ Hz. These results clearly indicated that the compounds should not be formulated as **20***a* or **21***a*. Left for consideration are the ring A *classical* half-boat analogs of **20***a* and **21***a*, which might have coupling constants of this order of magnitude, and **22***a* or related half-boat or twist analogs. Of these, a situation close to **22***a*, but with ring A in a flattened half-boat, is considered to be the favored conformation[7] on the basis of three pieces of evidence. First, of the various possibilities described above this best explains (17) the magnitude of the coupling constants under discussion, the H-1 equatorial/H-10, H-1 axial/H-10 dihedral angles being *ca.* 75 and 45° respectively. Second, in this



C-13 epimeric mixture

23



24

conformation the C-9 methyl group now protrudes over the olefinic bond and should be shielded by it (18). Indeed, in other compounds in this series, this methyl typically produces a resonance at about τ 8.95 but in these enones at about 9.15. Third, the magnitudes of the shifts induced by benzene on the C-4, -5, and -9 methyl groups of **6** and **7***a* accord with the values expected (19) for this conformation. At this stage the relative stereochemistry of acid A at C-5, -9, and -10 could be written with confidence as in **1***a*. Further support for this assignment came from a comparison of the n.m.r. spectrum of **6** with plathyterpenone (**24**) the constitution and relative stereochemistry of which have been rigidly defined (20). In either $CDCl_3$ or C_6D_6 the resonances attributed to 2 H-1, H-3, C-4 CH_3, C-5 CH_3, C-8 CH_3, and C-9 CH_3 are nearly identical in shape and value of chemical shift for both compounds.[8] On this basis the stereochemistry at C-8 is assigned as in **1***a*.

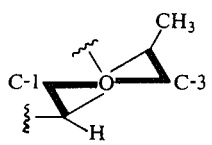
The absolute configuration of acids A and B remains for discussion. Since **6** and **24** appear to have the same relative stereochemistry and conformation of the ring system, a comparison was made of their Cotton effects. Both showed negative Cotton effects for the $n \rightarrow \pi^*$ transition, the former in c.d., the latter (20) in o.r.d., measurements. Thus plathyterpenone and acids

[7]This of course may represent an "average" of several contributing forms.

[8]We are grateful to Professor T. J. King for supplying the n.m.r. spectra and o.r.d. curve of plathyterpenone.

A and B have identical stereochemistry at C-5, -8, -9, and -10. The absolute configuration of plathyterpenone has been assigned (20) as in **24** on the basis of o.r.d. measurements. However, if the conformation deduced above for **6** on the basis of n.m.r. results is indeed preferred, then ring A is in a flattened boat and these compounds on the basis of their Cotton effects should be assigned (21) the *opposite* absolute configuration to that presently accepted for plathyterpenone. Since the deduction of absolute configurations from the Cotton effects of αβ-unsaturated ketones is known (21) to be fraught with difficulties, c.d. measurements were performed on **8***a* and *b*, prepared by catalytic hydrogenation of **7***a* and *b*. The relative stereochemistry at C-4 in **8***a* and *b* would be expected to be that shown, on the basis of their mode of formation and arguments analogous to those applied above to **16**.

Conformational analysis of these compounds appears to suggest that they should adopt conformation **21***b*. On this assumption and on the basis of the octant rule (22) the observed positive c.d. would lead to the assignment of absolute configuration *identical* to that published for plathyterpenone. However, precedent (23) warns that in *cis*-2-decalones related twist-forms although of minor abundance may play a decisive role in the Cotton effect. In the present instance a form of the type **25** might well



25

contribute to the conformational equilibrium and dictate the sign of the c.d., in which case the absolute configuration is *opposite* to that published for plathyterpenone. In a further attempt to resolve the problem, the two norenones **26** and **27** were prepared (16) by oxidation of **1***c* and maingayol (**13***c*, (14)), a compound of known absolute configuration, respectively. It seems probable that in both, C-10 would retain its original stereochemistry. The negative c.d. observed for **27** accords with that expected (24) for a ring B chair/ring A half-chair conformation, with C-9 pseudo-equatorial to the latter ring. The c.d. measured for **26** was opposite in sign and would appear to indicate that this compound and **27** have opposite configurations at C-10, if ring A has the same conformation in both. It appears unlikely that the difference in relative stereochemistry at C-8 could lead to marked changes in the conformation of ring A especially in the absence of a methyl group at C-10 (24). However, conclusions based on the above type of evidence for the absolute configuration of acids A and B, and by extension plathyterpol, can only be regarded as tentative although on balance it would appear that they should be formulated as shown in **1***a* and *b*.

At various stages in these studies, attempts were made to prepare heavy atom derivatives suitable for X-ray crystallographic examination, originally with the purpose of elucidating the relative stereochemistries, but more recently the absolute configuration. So far no suitable compounds have been obtained. Various heavy metal salts of acid A and the iodoacetate and *p*-iodobenzoate of **1***c* all failed to crystallize satisfactorily. Treatment of acid A with bromine in dioxan produced a complex mixture from which the bromofuran (**28***a*), dibromofuran (**28***b*), and butenolide (**29**) were isolated. The former two, although crystalline, again proved unsuitable for X-ray studies, in one case (**28***a*) because of poor crystalline form, in the other (**28***b*), because the data collected were insufficient and of poor quality.

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage apparatus. Specific rotations refer to solutions in ethanol unless otherwise stated. Woelm Grade I alumina, deactivated to the appropriate grade according to Brockmann, was used for chromatography. For analytical and preparative t.l.c., chromatoplates were spread with Kieselgel G (Merck). G.l.c. was carried out with a Varian Aerograph 1200 gas chromatograph using a stainless steel column (1/8 in. × 5 ft packed with 3% SE-30) and nitrogen as carrier gas with a flow rate of 25 ml/min except for angelic, senecioic, and tiglic acids. These were separated on a Pye "Argon" gas chromatograph at 125° with a gas flow rate of 60 ml/min using a glass column (1/8 in. × 4 ft) packed with 20% FFAP. Light petroleum was of b.p. 40–60°. Microanalyses were by Miss F. Cowan, Glasgow. High resolution mass spectra were run on an AEI MS 902 instrument equipped with a PDP 8 computer at the N.T.H., Trondheim by one of us (T.A.). I.r. solution spectra were recorded in carbon tetrachloride on a Unicam SP100 Mark II or Perkin–Elmer 225 or 257 or Beckman IR12 spectrophotometer, u.v. spectra in ethanol on a Unicam S.P. 800 spectrophotometer and circular dichroism curves on a Cary 61 spectropolarimeter. P.m.r. spectra were run on a Perkin–Elmer R-10 or Varian Associates A-60A or HA 100

spectrometer in carbon tetrachloride, unless otherwise stated, using approximately 0.3 *M* solutions and tetramethylsilane as internal standard. Mass spectra were run on a Varian Associates CH7 or A.E.I. MS9 or MS12 instrument.

Isolation of Solidagoic Acids A and B

Finely ground, dried roots of *Solidago gigantea* var. *serotina* (500 g) were extracted for 24 h with ethyl acetate in a Soxhlet apparatus. Evaporation of the solvent afforded the crude extract (27 g) which on t.l.c. showed 11 major components when sprayed with the Ehrlich reagent. The chloroform soluble portion (24 g) of this extract was chromatographed over alumina (Grade III; neutral; 2 kg) using as eluting solvent light petroleum – chloroform mixtures. Non-acidic constituents were isolated from the various fractions (see Part V, ref. 16). After elution with chloroform–methanol (19:1) the acidic components were recovered with ethyl acetate – acetic acid (4:1). These were separated by column chromatography over silica gel. Elution with ether – light petroleum (1:9) afforded solidagoic acid A (**1***a*, 3.1 g) which crystallized as large plates from ethyl acetate – light petroleum and had m.p. 169–171°; $[\alpha]_D$ −58° (*c*, 0.9); ν_{max} 1743 (w) and 1695 (s) cm^{-1} (0.008 *M*); 1741 (vw), 1722 (s), and 1695 (m) cm^{-1} in presence of tetrahydrofuran (0.3 *M*); τ 4.45 (m, 1 H-3, $w_{1/2}$ = 11 Hz), 8.48 (s, 3 H-18), 9.02 (s, 3 H-20) and 9.11 (d, 3 H-17, *J* = 6 Hz); *m/e* 316 (M).

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92. Found: C, 75.75; H, 8.58.

Elution with ether – light petroleum (1:4) afforded solidagoic acid B (**1***b*, 371 mg) which on crystallization from ethyl acetate – light petroleum formed needles, m.p. 134–135°; $[\alpha]_D$ −28° (*c*, 0.7; $CHCl_3$); ν_{max} 3600, 3100, 1720, 1695, 875 cm^{-1}; λ_{max} 221 nm (ε 6000); τ 3.96, 7.95–8.15 (1H and 6H respectively; angelate proton and methyl groups), 4.02 (m, 1 H-3), 5.50 (s, 2 H-18), 8.97 (s, 3 H-20) and 9.09 (d, 3 H-17, *J* = 6 Hz); *m/e* 314 (M − 100).

Anal. Calcd. for $C_{25}H_{34}O_5$: C, 72.43, H, 8.27. Found: C, 72.40, H, 8.55.

Methyl Esters of Acids A and B

The methyl esters were prepared by treatment of the acids in ether with ethereal diazomethane for 5 min. Ester A (**1***g*), an oil, after distillation at 100–105°/0.01 mm had $[\alpha]_D$ −67° (*c*, 1.0); ν_{max} 1728 and 878 cm^{-1}; τ 4.51 (m, 1 H-3, $w_{1/2}$ = 9 Hz), 6.47 (s, 3H, —OCH_3), 8.47 (broad s, 3 H-18), 8.97 (s, 3 H-20) and 9.10 (d, 3 H-17, *J* = 6 Hz).

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15. Found: C, 76.60; H, 9.25.

The oily ester B (**1***j*), purified by preparative t.l.c. (ethyl acetate – light petroleum, 3:17) and then distillation at 110–120°/0.005 mm, had $[\alpha]_D$ −25° (*c*, 0.95; $CHCl_3$); ν_{max} 1728 cm^{-1}; τ 3.97 (m, angelate H), 4.09 (m, 1 H-3), 5.63 (s, 2 H-18), 6.52 (s, 3H, —O*CH*$_3$), 9.05 (s, 3 H-20) and 9.19 (d, 3 H-17, J = 6 Hz); *m/e* 428 (M).

Anal. Calcd. for $C_{26}H_{36}O_5$: C, 72.86; H, 8.47. Found: C, 73.32; H, 8.49.

Reduction of Methyl Ester with Lithium Aluminum Hydride

The methyl ester (**1***g*), (1.58 g) was treated in dry refluxing tetrahydrofuran (50 ml) with excess lithium aluminum hydride for 72 h. Work-up gave the crude alcohol (**1***c*, 1.50 g) which failed to crystallize and was distilled at 115–120°/0.01 mm. The resulting oil had $[\alpha]_D$ −38° (*c*, 1.0); ν_{max} 3630 and 875 cm^{-1}; τ 2.74, 2.82, 3.78 (all m, 1 H each, furan protons), 4.35 (m, 1 H-3), 6.47 (ABq, 2 H-19, J = 11 Hz), 8.33 (broad s, 3 H-18), 8.91 (s, 3 H-20) and 9.10 (d, 3 H-17, J = 6 Hz); with 0.21 *M* ratio of Eu(DPM)$_3$ to **1***c*, τ 1.55 (very broad ABq, 2 H-19, J = 11 Hz), 2.77, 2.90, 3.67 (all m, furan protons), 3.43 (m, 1 H-3), 5.4 (broadened t, 1 H-10, J_{obs} = 5 Hz), 7.32 (broad s, 3 H-18), 8.18 (s, 3 H-20), 8.44 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.57; H, 10.11.

The Acetate **1***d*

The alcohol (**1***c*, 50 mg) in dry pyridine (2 ml) was treated at 20° for 14 h with acetic anhydride (2 ml). The oily acetate obtained on work-up was purified by preparative t.l.c. (benzene) and then distillation *in vacuo*. It had $[\alpha]_D$ −60° (c, 0.8); ν_{max} 1740, 1235, 872 cm^{-1}; τ 4.26 (m, 1 H-3), 5.96 (q, 2 H-19, J = 12 Hz), 8.00 (s, 3 H, —OCO*CH*$_3$), 8.35 (broad s, 3 H-18), 8.91 (s, 3 H-20) and 9.10 (d, 3 H-17, J = 6 Hz); *m/e* 344 (M).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70, H, 9.36. Found: C, 76.99; H, 9.54.

Decarboxylation of Acid A

Solidagoic acid A (**1***a*, 72 mg) was heated at 270° under N_2 for 20 min and the product distilled out at that temperature *in vacuo*. The resulting oil was redistilled at 110–120°/0.005 mm and afforded the furano–olefin **3** (45 mg) which had $[\alpha]_D$ −33° (*c*, 1.0); τ 8.35 (s, 3 H-18), 8.98 (d, 3 H-17, J = 6 Hz), and 9.1 (s, 3H-20); *m/e* 272 (M).

Anal. Calcd. for $C_{19}H_{28}O$: C, 83.77; H, 10.36. Found: C, 83.57; H, 10.19.

When the alcohol (**1***c*, 125 mg) was treated with excess chloroacetic anhydride in refluxing pyridine for 5 days and the mixture resulting from work-up separated by preparative t.l.c. (light petroleum – ethyl acetate, 19:1) this same furano-olefin (**3**, 24 mg) and substrate (43 mg) were obtained.

Oxidation of Alcohol **1***c*

The alcohol (**1***c*, 725 mg) in dry pyridine (10 ml) was treated at 20° for 14 h with chromium trioxide (800 mg). The crude material obtained (782 mg) consisted of three major components, which were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:9). The least polar component, the aldehyde (**1***e*) had $[\alpha]_D$ −161° (*c*, 0.85); ν_{max} 2690, 1722 and 872 cm^{-1}; τ 0.54 (s, 1 H-19), 4.28 (m, 1 H-3), 8.57 (d, 3 H-18, J = 2 Hz), 9.00 (s, 3 H-20) and 9.18 (d, 3 H-17, J = 6 Hz); *m/e* 300 (M).

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39. Found: C, 79.90; H, 9.38.

The compound of intermediate polarity, the nor-enone (**26**, 35 mg) was obtained as an oil and after distillation (160°/0.02 mm) had $[\alpha]_D$ −100° (*c*, 0.7); ν_{max} 1675 and 872 cm^{-1}; λ_{max} (ethanol) 257 nm (ε 13 000); λ_{max} (chloroform) 252 nm (ε 14 500); c.d. (ethanol) $[\theta]_{314}$ +8000 and $[\theta]_{257}$ −37 000; c.d. (chloroform) $[\theta]_{326}$ +7000 and $[\theta]_{250}$ −39 000; τ 8.27 (d, 3 H-18, J = 2 Hz), 8.90 (d, 3 H-17, J = 7 Hz) and 9.06 (s, 3 H-20); *m/e* 286 (M).

Anal. Calcd. for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15. Found: C, 79.58; H, 9.15.

The most polar of the major components was the aldehydo-enone (**7***c*, 25 mg) which was purified further by distillation at 140°/0.03 mm. It had $[\alpha]_D$ −197° (*c*, 0.86); ν_{max} 2700, 1730, 1680 and 873 cm^{-1}; λ_{max} 243 nm (ε 7000); τ 0.43 (s, 1 H-19), 4.09 (s, 1 H-3), 8.29 (s, 3 H-18), 9.04 (s, 3 H-20), and 9.16 (d, 3 H-17, J = 6 Hz); *m/e* 314 (M).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34. Found: C, 76.48; H, 8.40.

*Catalytic Hydrogenation of Methyl Ester A (***1***g)*

Methyl ester A (**1***g*, 380 mg) in absolute ethanol (40 ml) was hydrogenated for 25 min over Adams catalyst (200 mg). Removal of the catalyst and solvent afforded an oil (390 mg) consisting (t.l.c.) of one major and several minor components. Separation of these by preparative t.l.c. (ethyl acetate – light petroleum, 1:3) afforded the oily tetrahydro-methyl ester (**5***c*, mixture of epimers at C-13, 215 mg) which was further purified for analysis by distillation at 130°/0.04 mm. It had ν_{max} 1728 cm^{-1}; τ 4.56 (m, 1 H-3) and 6.33 (s, 3H, —O*CH*$_3$).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.62; H, 10.47.

The Alcohol **5***e*

Reduction of the tetrahydro-methyl ester (**5***c*, 60 mg) with excess lithium aluminum hydride in refluxing ether for 14 h and work-up afforded the oily alcohol (**5***e*, 57 mg) which after distillation at 140°/0.02 mm had $[\alpha]_D$ −16° (*c*, 1.2, $CHCl_3$); τ 4.42 (m, 1 H-3), 6.56 (q, 2 H-19, J = 12 Hz), 8.36 (broad s, 3 H-18), 8.99 (s, 3 H-20) and 9.14 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18. Found: C, 78.52; H, 11.28.

The Aldehyde **5***a*

The above alcohol (**5***e*, 23 mg) in dry pyridine (2 ml) was treated at 20° for 15 h with chromium trioxide (100 mg). Work-up and preparative t.l.c. (ethyl acetate – light petroleum, 1:4) of the product yielded the aldehyde (**5***a*, 17 mg). Distillation *in vacuo* afforded a colorless oil, $[\alpha]_D$ −88° (*c*, 1.2, $CHCl_3$); ν_{max} 1723 cm^{-1}; τ 0.76 (d, 1 H-19, separation 2 Hz) and 4.36 (m, 1 H-3); *m/e* 304 (M).

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59. Found: C, 78.92; H, 11.05.

Huang–Minlon Reduction of Aldehydes **1***e and* **5***a*

Aldehyde **1***e* (50 mg) in ethylene glycol (2 ml) was treated at 95° for 48 h with 100% hydrazine hydrate (3 ml).

Potassium hydroxide (100 mg) was added and the temperature of the mixture allowed to rise to 210° and remain there for 13 h under N_2. After cooling, the solution was acidified and then extracted with ethyl acetate. The product was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:9) and distillation. The resulting furano-olefin (**1***f*, 24 mg) was obtained as an oil and had $[\alpha]_D$ −19° (*c*, 1.0); ν_{max} 872 cm^{-1}; τ 4.67 (m, 1 H-3), 8.36 (broad s, 3 H-18), 8.83 (s, 3 H-19), 8.92 (s, 3 H-20) and 9.08 (d, 3 H-17, J = 6 Hz); *m/e* 286 (M).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 83.82; H, 10.75.

An identical procedure converted **5***a* (125 mg) into the oily tetrahydrofuran (**5***b*, 58 mg) which had τ (deuterochloroform) 4.70 (m, 1 H-3), 8.36 (broad s, 3 H-18), 8.85 (s, 3 H-19), 9.00 (s, 3 H-20), 9.14 (d, 3 H-17, J = 6 Hz).

Mol. Wt. Calcd. for $C_{20}H_{34}O$: 290.2610. Found: (high resolution mass spectrometry): 290.2609.

Oxidation of the Furano-olefin (1f) with the Chromium Trioxide – Pyridine Complex

The furano-olefin (**1***f*, 68 mg) in pyridine (4 ml) was added to chromium trioxide (75 mg) in pyridine (1 ml), and stirred at 20° for 18 days. The resulting mixture was treated with ethanol (1 ml) for 15 min and then diluted with water (20 ml). Extraction with ethyl acetate, followed by preparative t.l.c. (ethyl acetate – light petroleum) afforded, in addition to unreacted **1***f* (26 mg), the enone **6** (17 mg) which was distilled at 175°/0.2 mm. The resulting low melting solid had ν_{max} 1665 cm^{-1}; λ_{max} 247 nm (ε 7500); τ (carbon tetrachloride) 4.21 (broad s, 1 H-3, $w_{1/2}$ = 4 Hz), 7.45 (3 lines, 2 H-1), 8.05 (d, 3 H-18, J = 1 Hz), 8.73 (s, 3 H-19), 8.98 (d, 3 H-17, J = 7 Hz), and 9.10 (s, 3 H-20); τ (benzene) 4.10 (broad s, 1 H-3), 7.45 (d, 2 H-1, J_{obs} = 4.5 Hz), 8.49 (d, 3 H-18, J = 1 Hz), 9.12 (s, 3 H-19), 8.19 (s, 3 H-20) and 9.25 (d, 3 H-17, J = 7 Hz); c.d. (ethanol) $[\theta]_{328}$ −3000 and $[\theta]_{247}$ +2000; c.d. (chloroform) $[\theta]_{335}$ −2300.

Mol. Wt. Calcd. for $C_{20}H_{28}O_2$: 300.2089. Found (high resolution mass spectrometry): 300.2094.

Oxidation of the Ester (5c) with Chromium Trioxide – Acetic Acid

Chromium trioxide (195 mg) was added to the ester (**5***c*, 252 mg) in acetic acid (20 ml) and water (1 ml). After stirring at 20° for 1 h, ethanol (50 ml) was added and then the solvent removed *in vacuo*. The residue was dissolved in ether–brine and the ether layer washed with saturated aqueous bicarbonate and brine. Evaporation of the solvent gave an oil (265 mg). The two major constituents of this complex mixture were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:1). The less polar constituent, the epoxy-ester (**30**, 54 mg) was further purified by preparative t.l.c. (ethyl acetate – chloroform, 1:10) and then distillation *in vacuo*. It had ν_{max} (liquid film) 1720 cm^{-1}; τ 6.37 (s, 3H, $-OCH_3$), 7.06 (m, 1 H-3, $w_{1/2}$ = 4 Hz), 8.97 (s, 3 H-18), 9.21 (s, 3 H-20) and 9.22 (d, 3 H-17, J = 6 Hz).

Mol. Wt. Calcd. for $C_{21}H_{34}O_4$: 350.2457. Found (high resolution mass spectrometry): 350.2456.

The more polar component, the enone-ester (**7***b*, 43 mg) was isolated as an oil and gave one peak on g.l.c. (250°, retention time 6 min). After distillation *in vacuo* it had ν_{max} (liquid film) 1725 and 1670 cm^{-1}; λ_{max} 237 nm; τ 4.24 (broad s, 1 H-3, $w_{1/2}$ = 2.5 Hz), 6.30 (s, 3H, $-OCH_3$), 8.27 (d, 3 H-18, J = 1.5 Hz), 9.11 (s, 3 H-20), and 9.13 (d, 3 H-17, J = 7 Hz).

Mol. Wt. Calcd. for $C_{21}H_{32}O_4$: 348.2301. Found (high resolution mass spectrometry): 348.2303.

Oxidation of the Olefin 5b with Chromium Trioxide – Acetic Acid

Oxidation of the tetrahydrofurano-olefin (**5***b*, 275 mg) with chromium trioxide (275 mg) in acetic acid (20 ml) and water (1 ml) as above afforded an oil (200 mg). Separation of the very complex mixture by preparative t.l.c. (ethyl acetate – light petroleum, 1:3, run thrice) furnished the oily enone (**7***a*, 29 mg) which gave one peak on g.l.c. (230°, retention time 7 min) and after distillation *in vacuo* had ν_{max} 246 nm (ε 8500); τ (carbon tetrachloride) 4.20 (broad s, 1 H-3, $w_{1/2}$ = 3 Hz), 7.46 (3 lines, 2 H-1), 8.06 (d, 3 H-18, J = 1.5 Hz), 8.72 (s, 3 H-19), 9.04 (d, 3 H-17, J = 6.5 Hz) and τ 9.17 (s, 3 H-20); τ (carbon tetrachloride – benzene, 1:1) 7.50 (d, 2 H-1, J_{obs} = 4.5 Hz), 8.34 (d, 3 H-18, J = 1.5 Hz), 8.97 (s, 3 H-19), 9.22 (d, 3 H-17, J = 7 Hz), and 9.24 (s, 3 H-20).

Mol. Wt. Calcd. for $C_{20}H_{32}O_2$: 304.2402. Found (high resolution mass spectrometry): 304.2404.

The Keto-ester 8b

The enone-ester (**7***b*, 63 mg) in 95% ethanol (50 ml) was shaken in a low pressure hydrogenator with hydrogen (33 p.s.i.) over palladized charcoal (5%, 80 mg) for 5 h. Removal of catalyst and solvent left an oil which was submitted to preparative t.l.c. (ethyl acetate – light petroleum, 1:3, run four times). The major, and least polar, component of the mixture was the oily keto-ester (**8***b*, 24 mg) which gave one peak on g.l.c. (250°, retention time 5.3 min) and had ν_{max} 1735 cm^{-1}; τ 6.35 (s, 3H, $-OCH_3$) and 9.20 (broad s, 9H, $3CH_3$); c.d. (ethanol) $[\theta]_{305}$ −45 and $[\theta]_{273}$ +190.

Mol. Wt. Calcd. for $C_{21}H_{34}O_4$: 350.2457. Found (high resolution mass spectrometry): 350.2459.

The Ketone 8a

Hydrogenation of the enone (**7***a*, 43 mg) as described immediately above afforded an oil which showed one major product on t.l.c. Preparative t.l.c. (ethyl acetate – light petroleum, 1:10) afforded the ketone (**8***a*, 22 mg) as an oil, which showed one peak on g.l.c. (230°, retention time 7 min) and had ν_{max} 1720 cm^{-1} (liquid film 1715 cm^{-1}); τ (carbon tetrachloride) 8.78 (s, 3 H-19), 9.03 (d, 3 H-18, J = 7 Hz), 9.10 (s, 3 H-20), and 9.13 (d, 3 H-17, J = 6 Hz); τ (benzene – carbon tetrachloride, 1:1) 8.99 (s, 3 H-19), 9.25 (d, 3 H-18, J = 7 Hz), 9.29 (d, 3 H-17, J = 6 Hz) and 9.30 (s, 3 H-20); c.d. (ethanol) $[\theta]_{283}$ +375.

Mol. Wt. Calcd. for $C_{20}H_{34}O_2$: 306.2559. Found (high resolution mass spectrometry): 306.2557.

Pyrolysis of Acid B (1b)

Acid B (**1***b*, 75 mg) was heated at 300° for 5 min in an evacuated tube. A few crystals of angelic acid, m.p. 45° (sealed tube), collected on a cooled part of the tube. This material was identified by g.l.c. over 20% FFAP at 125°, angelic, senecioic, and tiglic acids being well separated under these conditions, having retention times of 26, 28, and 35 min respectively. The less volatile distillate (49 mg) consisted (t.l.c.) of two products and starting material. The unreacted acid B was removed by filtration through

a short column of neutral alumina and the products were then separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:19). The more abundant lactone (**11**, 20 mg) after distillation *in vacuo* had $[\alpha]_D$ −66° (*c*, 1.4); ν_{max} 1778 and 872 cm^{-1}; τ 4.41 (m, 1 H-3), 5.45 (ABq, 2 H-18, J = 12 Hz), 8.96 (s, 3 H-20), and 9.13 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40, H, 8.34. Found: C, 76.34; H, 8.48.

The more polar lactone (**12**, 6 mg) crystallized from ethyl acetate – light petroleum and had m.p. 145–147°; ν_{max} 1785 cm^{-1}; *m/e* 314 (M).

*The Diol **1h***

Reduction of methyl ester B (**1***j*, 200 mg) in refluxing ether with lithium aluminum hydride gave the diol (**1***h*, 180 mg) which crystallized from ethyl acetate – light petroleum and had m.p. 61–62°; $[\alpha]_D$ −46° (*c*, 0.7); ν_{max} 3620, 3300, and 875 cm^{-1}; τ 4.11 (m, 1 H-3), 8.96 (s, 3 H-20), and 9.11 (d, 3 H-17, J = 6 Hz); *m/e* 318 (M).

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.26; H, 9.30.

*Acetylation of Diol **1h***

The diol (**1***h*, 960 mg) in dry pyridine (20 ml) was treated with acetic anhydride (0.35 ml) at 20° for 2 h. Work-up afforded an oil (975 mg) which was separated into its components by preparative t.l.c. (ethyl acetate – light petroleum, 3:7). The least polar component (320 mg) was the oily diacetate (**1***i*) which after distillation *in vacuo* had $[\alpha]_D$ −44° (*c*, 1.7); ν_{max} 1745, 1238, and 875 cm^{-1}; τ 4.06 (m, 1 H-3), 5.43 (s, 2 H-18), 6.01 (s, 2 H-19), 7.98 (s, 6H, 2 —OCOCH_3), 8.93 (s, 3 H-20) and 9.08 (d, 3 H-17, J = 6 Hz); *m/e* 402 (M).

Anal. Calcd. for $C_{24}H_{34}O_5$: C, 71.61; H, 8.51. Found: C, 71.58; H, 8.72.

The next component, the monoacetate (**1***k*, 175 mg), was also an oil. After distillation at 120°/0.01 mm it had $[\alpha]_D$ −54° (*c*, 0.8); ν_{max} 3460, 1740, 1220, and 872 cm^{-1}; τ 4.08 (m, 1 H-3), 5.53 (q, 2 H-18, J = 12 Hz), 6.49 (q, 2 H-19; J = 12 Hz), 8.00 (s, 3H, —OCOCH_3), 8.94 (s, 3 H-20), and 9.12 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.20; H, 8.82.

The next component, the oily monoacetate **1***l* (170 mg), after distillation at 150°/0.01 mm had ν_{max} 3580, 1745, 1230, and 878 cm^{-1}; τ 4.12 (m, 1 H-3), 5.50 (s, 2 H-18), 6.06 (s, 2 H-19), 8.03 (s, 3H, —OCOCH_3), 8.92 (s, 3 H-20) and 9.16 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.32; H, 8.73.

The final component was unreacted diol (**1***h*, 102 mg).

*Hydrogenolysis of Diacetate **1i***

The diacetate **1***i* (60 mg) was hydrogenated in absolute ethanol (30 ml) containing triethylamine (5 ml) over 10% palladized charcoal for 40 min. Removal of catalyst and solvent afforded an oil which consisted (t.l.c.) essentially of two compounds. These were separated by preparative t.l.c. (benzene). The less polar product was the acetate **1***d* (37 mg), identical (i.r., n.m.r., t.l.c., and $[\alpha]_D$) with the acetate prepared from acid A. The other product, the corresponding tetrahydro-acetate (**5***d*, 14 mg) after distillation at 150°/0.04 mm had $[\alpha]_D$ +28° (*c*, 1.2); ν_{max} 1740 and 1235 cm^{-1}; τ 4.50 (m, 1 H-3), 6.05 (s, 2 H-19), 8.01 (s, 3H, —OCOCH_3), 8.36 (broad s, 3 H-18), 8.97 (s, 3 H-20), and 9.12 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.81; H, 10.41. Found: C, 75.86; H, 10.20.

*Hydrogenation of Acid A (**1a**)*

Acid A (403 mg) in absolute ethanol (20 ml) was shaken with hydrogen over Adams catalyst for 2.5 h. The product (427 mg) was submitted to preparative t.l.c. (chloroform, run thrice) and split into three fractions. The least polar fraction (73 mg) contained the oily tetrahydro-acid **14***a* which distilled at 165–170°/0.02 mm and had ν_{max} 1729 and 1692 cm^{-1} (0.008 *M*); 1724 cm^{-1} in presence of tetrahydrofuran (0.95 *M*); τ 4.58 (m, 1 H-3), 8.47 (broad s, 3 H-18), 9.12 (s, 3 H-20), and 9.20 (broad s, 3 H-17).

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06. Found: C, 74.75; H, 9.88.

The fraction (148 mg) of intermediate polarity contained the tetrahydro-acid **14***b* which after sublimation at 155–165°/0.04 mm had m.p. 156–159°; ν_{max} 1692 and weak shoulder at 1729 cm^{-1} (0.007 *M*); 1724 cm^{-1} in presence of tetrahydrofuran (0.5 *M*); τ 4.58 (m, 1 H-3), 8.47 (broad s, 3 H-18), and 9.12 (broad s, 6H, 2CH_3).

Anal. Calcd for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06. Found: C, 74.89; H, 10.14.

The final fraction (85 mg) ran as two poorly-resolved spots on t.l.c. (methanol–chloroform 1:9). The mixture was treated with diazomethane and the derived esters separated by preparative t.l.c. (chloroform, run twice). The less polar methyl ester (**15***a*, 52 mg) after distillation at 117–122°/0.05 mm was obtained as an oil ν_{max} 3642, 3554, 1725, and 1712 cm^{-1}; τ 4.58 (m, 1 H-3), 6.33 (s, 3H, —OCH_3), 6.55 (m, 2 H-16, $w_{1/2}$ = 6 Hz), 9.12 (s, 3 H-20) and 9.16 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.95; H, 10.78. Found: C, 74.79; H, 10.71.

The more polar methyl ester (**15***b*, 15 mg) also was obtained as an oil and after distillation at 125–130°/0.04 mm it had ν_{max} 3644, 3544, 1725, and 1712 cm^{-1}; τ 4.58 (m, 1 H-3), 6.30 (s, 3H, —OCH_3) 6.55 (m, 2 H-16, $w_{1/2}$ = 6 Hz), and 9.15 (broad s, 6H, 2CH_3).

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.95; H, 10.78. Found: C, 74.81; H, 10.85.

*Methyl Esters **14c** and **e***

The tetrahydro-acids (**14***a* and *b*) were treated with diazomethane and furnished the corresponding methyl esters. The ester (**14***c*) of the less polar acid (**14***a*) was distilled at 107–113°/0.06 mm. The oil obtained had ν_{max} 1728 cm^{-1}; τ 4.56 (m, 1 H-3), 6.33 (s, 3H, —OCH_3), 9.12 (s, 3 H-20), and 9.23 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.60; H, 10.44.

The ester (**14***e*) of the more polar acid (**14***b*) was also obtained as an oil. After distillation at 110–115°/0.02 mm it had ν_{max} 1728 cm^{-1}; τ 4.56 (m, 1 H-3), 6.32 (s, 3H, —OCH_3), 9.12 (s, 3 H-20), and 9.20 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.31; H, 10.27.

A mixture of **14***c* and *e* ran as one spot on t.l.c. in all eluent mixtures examined.

*The Esters **16** and **17***

Ester **14***c* (70 mg) in absolute ethanol (20 ml) was shaken with hydrogen over Adams catalyst (80 mg) for

28 h. Removal of catalyst and solvent left an oil which was subjected to preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run twice). The less polar major constituent was the oily hexahydro-ester **16** (25 mg) which after distillation at 115–120°/0.1 mm had ν_{max} 1722 cm^{-1}; 6.36 (s, 3H, —OCH_3), 9.18 (s, 6H, 2CH_3), and 9.38 (d, 3H, CH_3, J = 6 Hz).

Anal. Calcd. for $C_{21}H_{36}O_3$: C, 74.95; H, 10.78. Found: C, 75.17; H, 10.77.

The more polar constituent was unreacted **14***c* (34 mg).

Hydroxy-ester **15***a* (23 mg) in absolute ethanol (10 ml) was shaken with hydrogen over Adams catalyst (50 ml) for 24 h. The residual oil after removal of catalyst and solvent was separated into its two major constituents by preparative t.l.c. (ethyl acetate – light petroleum, 1:9, run thrice). The less polar constituent, **17** (9 mg), was distilled at 105–112°/0.005 mm and the resulting oil had ν_{max} 3630, 3520, 1722, and 1710 cm^{-1}; τ 6.37 (s, 3H, —OCH_3), 6.50 (m, 2 H-16, $w_{1/2}$ = 6 Hz), 9.18 (s, 6H, 2CH_3), and 9.38 (d, 3H, CH_3, J = 6 Hz).

Anal. Calcd. for $C_{21}H_{38}O_3$: C, 74.51; H, 11.32. Found: C, 74.79; H, 11.26.

The more polar constituent was unreacted **15***a* (7 mg).

Attempted Hydroxylation, Hydroboration, Epoxidation of ***1a***, ***1d***, ***1g***

Acid A (**1***a*), its methyl ester (**1***g*), and the derived acetate (**1***d*) were recovered from treatment with (*a*) osmium tetroxide in ether for 20 h, (*b*) freshly distilled boron trifluoride etherate and lithium aluminum hydride for 2 h and then work-up with sodium hydroxide – hydrogen peroxide, (*c*) *m*-chloroperbenzoic acid in chloroform for 90 min. In each case extended reaction times led to destruction of the furan ring (n.m.r.).

Reduction of Ester ***14c***

The tetrahydro-ester (**14***c*, 113 mg) in dry refluxing ether was treated with excess lithium aluminum hydride for 4.5 h. Work-up gave the alcohol (**14***d*, 88 mg) as an oil which distilled at 120°/0.01 mm and was nearly identical (t.l.c., $[\alpha]_D$ and n.m.r.) with **5***e*.

The hexahydro-ester (**16**, 12 mg) was recovered essentially unchanged (n.m.r., t.l.c.) from attempted reduction with lithium aluminum hydride as above for 4 h.

Hydrogenation of Diol ***1h***

The diol (**1***h*, 325 mg) in absolute ethanol (35 ml) was hydrogenated over Adams catalyst (300 mg) for 2 h. Removal of catalyst and solvent afforded an oil (320 mg) which was seen from t.l.c. to consist of a complex mixture of compounds none of which contained a furan ring (Ehrlich's test). The major component, the tetrahydro-diol (**5***f*, 175 mg) was obtained by preparative t.l.c. (chloroform–methanol, 17:1). Distillation at 180°/0.035 mm gave an oil, $[\alpha]_D$ −47° (*c*, 0.77); ν_{max} 3620 and 3320 cm^{-1}; τ 4.22 (m, 1 H-3), 9.07 (s, 3 H-20), and 9.18 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{34}O_3$: C, 74.49; H, 10.63. Found: C, 74.20; H, 10.80.

The corresponding diacetate (**5***g*) was also obtained as an oil by treatment of the diol with acetic anhydride – pyridine. After distillation at 175°/0.04 mm it had ν_{max} 1745 and 1235 cm^{-1}; τ 4.11 (m, 1 H-3), 5.49 (s, 2 H-18), 6.06 (s, 2 H-19), 8.00 (s, 6H, 2 —OCOCH_3), 8.99 (s, 3 H-20) and 9.10 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42. Found: C, 70.66; H, 9.51.

Oxidation of Tetrahydro-diol ***5f***

The tetrahydro-diol (**5***f*, 102 mg) in dry pyridine (2 ml) was treated with chromium trioxide (500 mg) at 20° for 14 h. The products (98 mg) were separated by preparative t.l.c. (ethyl acetate – light petroleum, 3:17, run four times). Two major components were obtained. The less polar was the lactone **31** (27 mg) which on distillation at 155°/0.015 mm afforded an oil, $[\alpha]_D$ +26° (*c*, 1.1), ν_{max} 1775 cm^{-1}; τ 3.41 (t, 1 H-3, J_{obs} = 3 Hz), 9.11 (s, 3 H-20), and 9.18 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.67; H, 9.47.

The more polar component, the oily enone-lactone **23** (43 mg), was distilled *in vacuo* and had $[\alpha]_D$ −4° (*c*, 0.9); ν_{max} 1783 and 1694 cm^{-1}; τ (carbon tetrachloride) 3.64 (s, 1 H-3), 5.57 (d, 1 H-19, J = 8 Hz), 6.12 (d, 1 H-19, J = 8 Hz), 7.72 (m, 2 H-1), 9.16 (s, 3 H-20), and 9.18 (d, 3 H-17, J = 6 Hz); τ (deuterobenzene–deuterochloroform, 85:15), 3.40 (s, 1 H-3), 5.58 (4 lines, 1 H-19), 6.61 (d, 1 H-19, J = 8 Hz), 7.92 and 8.02 (2 lines, 2 H-1), 9.48 (d, 3 H-17, J = 6 Hz), 9.62 (s, 3 H-20); τ (deuterobenzene) 3.36 (s, 1 H-3), 6.01 (4 lines, 1 H-19), 6.65 (d, 1 H-19, J = 8 Hz), 7.94, 8.02, and 8.05 (3 lines, 2 H-1), 9.50 (d, 3 H-17, J = 6 Hz), and 9.67 (s, 3 H-20); *m/e* 332 (M).

Anal. Calcd. for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49. Found: C, 72.03; H, 8.28.

*Oxidation of Maingayic Alcohol (****13c****)*

The alcohol[9] (**13***c*, 193 mg) in pyridine (10 ml) was added to chromium trioxide (415 mg) in pyridine (8 ml) and kept at 20° with stirring for 5 h. The resulting mixture was treated with methanol (1 ml) for 30 min and then diluted with water (20 ml). Extraction with ethyl acetate, followed by preparative t.l.c. (ethyl acetate – light petroleum, 1:7) afforded three compounds, described below in order of increasing polarity. The known (14) aldehyde (**13***d*, 108 mg) was obtained as an oil. The nor-enone (**27**, 25 mg), also an oil, was distilled *in vacuo* and had ν_{max} 1678 cm^{-1}; λ_{max} (ethanol) 257 nm (ε 13 000); c.d. (ethanol) $[\theta]_{314}$ −12 000 and $[\theta]_{257}$ +37 000; c.d. (chloroform) $[\theta]_{325}$ −9000 and $[\theta]_{250}$ +42 000; τ 8.22 (s, 3 H-18) 9.07 (d, 3 H-17, J = 6 Hz), and 9.33 (s, 3 H-20).

Mol. Wt. Calcd. for $C_{19}H_{26}O_2$: 286.1933. Found (high resolution mass spectrometry): 286.1931.

The aldehydo-enone (**32**, 17 mg), also an oil, was distilled *in vacuo* and had ν_{max} 1715 and 1675 cm^{-1}; λ_{max} 244 nm (ε 9500); τ 0.40 (s, 1 H-19), 3.98 (broad s, 1 H-3, $w_{1/2}$ = 2.5 Hz), 8.29 (d, 3 H-18, J = 1 Hz), 9.13 (d, 3 H-17, J = 6 Hz), and 9.27 (s, 3 H-20).

Mol. Wt. Calcd. for $C_{20}H_{26}O_3$: 314.1882. Found (high resolution mass spectrometry): 314.1880.

*Bromination of Acid A (****1a****)*

Acid A (**1***a*, 355 mg) was treated with bromine (0.15 ml) in dioxan (15 ml) at 0° for 3 h. Work-up afforded an oil which was subjected to preparative t.l.c. (light petroleum – ether, 1:3). By this means ten fractions were

[9]Kindly supplied by Dr. K. Kawazu, Okayama University, Japan.

obtained. The three major components were investigated (from bands 2, 3, and 7, numbered in order of increasing polarity). The least polar component of the three, the dibromide (**28***b*, 35 mg), on crystallization from ethyl acetate – light petroleum had m.p. 170–174° (dec.); τ 3.82 (s, 1 H-14), 4.50 (m, 1 H-3), 8.48 (broad s, 3 H-18), 8.98 (s, 3 H-20), and 9.12 (d, 3 H-17, $J = 6$ Hz); *m/e* 472, 474, 476 (M). The component of intermediate polarity, the monobromide (**28***a*, 14 mg), on crystallization from ethyl acetate – light petroleum had m.p. 173–178° (dec.); τ 2.78 (d, 1 H-15, $J = 2$ Hz), 3.80 (d, 1 H-14, $J = 2$ Hz), 4.47 (m, 1 H-3), 8.46 (broad s, 3 H-18), 8.97 (s, 3 H-20), and 9.14 (d, 3 H-17, $J = 6$ Hz); *m/e* 394, 396 (M). The most polar, the butenolide (**29**, 74 mg), was obtained as an oil and had n.m.r. signals at τ 2.83 (broad s, 1 H-14), 4.55 (m, 1 H-3), 5.25 (broad s, 2 H-15), 9.01 (s, 3 H-20), and 9.15 (d, 3 H-17, $J = 6$ Hz). Treatment with diazomethane afforded the oily methyl ester which was distilled *in vacuo* and had ν_{max} 1767 and 1727 cm^{-1}; τ 2.93 (t, 1 H-14, $J_{ob_s} = 1.5$ Hz), 4.58 (m, 1 H-3), 5.27 (m, 2 H-15), 6.51 (s, 3H, $-OCH_3$), 8.50 (broad s, 3 H-18), 9.02 (s, 3 H-20), and 9.16 (d, 3 H-17, $J = 6$ Hz).

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73. Found: C, 72.70; H, 8.68.

Constituents of *Solidago* Species. Part V.[1] Non-acidic Diterpenoids from *Solidago gigantea* var. *serotina*

M. S. HENDERSON

Department of Chemistry, University of Glasgow, Glasgow, Scotland

AND

R. MCCRINDLE[2] AND D. MCMASTER

Chemistry Department, University of Guelph, Guelph, Ontario

Received November 27, 1972

Eight new furan-containing diterpenoids from *Solidago gigantea* Ait. var. *serotina* (Kuntze) Cronqu., are formulated as **1***c–g*, **2**, **3***a*, and **4***a* on the basis of chemical and spectroscopic evidence and by correlation with solidagoic acid A of previously defined constitution and stereochemistry. The structure (**5***a*) of a ninth related compound is tentatively assigned. The allylic oxidation of some of these new diterpenoids and related compounds with the chromium trioxide – pyridine complex is reported. In the course of this investigation of formal total synthesis of compound Y from *Leonotis leonurus* was achieved.

On propose les formules **1***c–g*, **2**, **3***a* et **4***a* pour huit nouveaux diterpénoïdes contenant du furanne qui ont été isolés de *Soligado gigantea* Ait. var. *serotina* (Kuntze) Cronqu.; ces conclusions sont basées sur des preuves chimiques et spectroscopiques et aussi par corrélation avec l'acid solidagoïque A dont la constitution et la stéréochimie ont été définies précédemment. La structure **5***a* est proposée pour un neuvième composé relié aux précédents. On rapporte aussi les résultats obtenus lors de l'oxydation allylique de quelques-uns de ces diterpénoïdes et composés apparentés par le complexe CrO_3 : pyridine. Au cours de cette étude une synthèse totale formelle du composé Y isolé de Leonotis leonurus a été réussie. [Traduit par le journal]

Can. J. Chem., 51, 1346 (1973)

In the preceding paper (1) we have summarized the evidence which allows the assignment of constitution and relative stereochemistry[3] to solidagoic acids A (**1***a*) and B (**1***b*), constituents of the ethyl acetate soluble extractive of the roots of *Solidago gigantea* Ait. var. *serotina* (Kuntze) Cronqu. The present paper is devoted to nine furan-containing diterpenoids which have been isolated from neutral fractions of the same extract. The complex mixture containing these compounds was separated initially by chromatography over silica gel, final purification of each being achieved by preparative t.l.c. The presence of a β-substituted furan ring in all nine diterpenoids was indicated by their reaction with Ehrlich's reagent and the presence of signals arising from this moiety in their i.r. (ν_{max} near 1500 and 870 cm^{-1}), n.m.r. (near τ 2.65, 2.75, and 3.65; 1H each), and mass (*m/e* 81 and 95) spectra. It thus appeared probable that these compounds and the solidagoic acids have an identical carbon skeleton and indeed it has been possible to interrelate eight of the neutral constituents with the two acids. On this and additional chemical and spectroscopic evidence, firm assignments of constitution and relative stereochemistry can be made for the eight (**1***c–g*, **2**, **3***a*, and **4***a*). A structure (**5***a*) is advanced for the ninth primarily on spectroscopic grounds. The absolute configuration assigned to these compounds rests on their correlation with acid A and is therefore only tentative. The compounds will be discussed in the following order of increasing chromatographic polarity on silica gel (ethyl acetate – light petroleum mixtures as eluant).

Compound I

The least polar constituent was the oily aldehyde **1***c*, $[\alpha]_D$ −164°. Peaks at 2690 and 1722 cm^{-1}, typical of an aldehyde function, are clearly visible in its i.r. spectrum while the —C*H*O proton resonates at τ 0.54 (s). Other resonances which may be readily assigned are those of an olefinic proton (τ 4.28, m) and three methyl groups, one tertiary (τ 9.22, 3H, s), one secondary (τ 9.22, 3H, d, J = 6 Hz), and the

other on an olefinic bond (τ 8.58, 3H, d, J = 2 Hz). These data suggested that this compound is identical with the aldehyde prepared (1) from solidagoic acid A (**1***a*) via the alcohol (**1***e*) and this was verified by direct comparison of the two samples.

Compound II

The next constituent (**2**), m.p. 92–95°, $[\alpha]_D$ +12°, could be readily formulated as a γ-lactone because of the strong carbonyl absorption at 1772 cm^{-1} in the i.r. The presence of a double bond in conjugation with the carbonyl group was deduced from the intensity (ε 18 000) of a u.v. maximum at 210 nm and from the chemical shift value and multiplicity of a resonance attributable to an olefinic proton. This proton resonates as a triplet at τ 3.35, showing only vicinal coupling to the C-2 methylene group and significantly no allylic coupling. This was confirmed by a nuclear double resonance experiment in which irradiation of a broad triplet at τ 7.77 (2 H-2) caused that of the olefinic proton to collapse to a sharp singlet. Double irradiation also located H-8, since with H_2 at τ 8.37 the doublet at τ 9.10 (secondary methyl) collapsed to a singlet. Also assignable in the n.m.r. spectrum are resonances arising from a tertiary methyl group (τ 8.97, 3H, s) and the methylene group in the lactone ring (τ 5.56 and 6.20, both 1H, both d, J = 9 Hz), an *isolated* AB system. Assuming this lactone to have the same skeleton as the aldehyde discussed above, these spectroscopic data indicate the formulation **2**. Confirmation of this conclusion was obtained by its reduction with lithium aluminum hydride to the diol **1***g*. This compound and the derived diacetate (**1***h*) were identical with the corresponding samples prepared (1) from solidagoic acid B (**1***b*). It should be noted that although the lactone described here has the same gross structure as that (**6**) isolated (3) from *Dodonaea* species, they differ in stereochemistry at C-9 and -10.

Compound III

The third component, m.p. 103–105°, $[\alpha]_D$ −49°, was readily assigned the structure **1***d*, the presence of two aldehyde groups being immediately recognized from the n.m.r. singlets at τ −0.17 and 0.89. The chemical shift of the former reflects the allylic nature of the proton involved. Support for our conclusions concerning the structure of this compound came from its i.r. absorption at 1720 (isolated aldehyde) and 1690

cm^{-1} ($\alpha\beta$-unsaturated aldehyde). Reduction of this dialdehyde with lithium aluminum hydride and then acetylation of the resulting diol added final confirmation of the constitution and stereochemistry (as **1***d*), the products again being identical with those prepared from solidagoic acid B.

Compound IV

The next component, an oil, $[\alpha]_D$ $-38°$, shows hydroxyl absorption in the i.r. at 3630 cm^{-1}, while in its n.m.r. spectrum two carbinyl protons form an AB quartet at τ 6.37 and 6.51 (J = 11 Hz). In addition, a proton and methyl group attached to an olefinic bond give rise to signals at τ 4.29 and 8.33 respectively. These data suggested formulation of the compound as **1***e* and direct comparison with a sample of the primary alcohol derived from solidagoic acid A confirmed this.

Compound V

Compound V, $[\alpha]_D$ $-45°$, also failed to crystallize. Its spectral properties appeared to indicate that it is an isomer of compound IV. In the i.r. it lacks carbonyl absorption but a peak at 3620 cm^{-1} reveals the presence of a hydroxyl group. Resonances in its n.m.r. spectrum at τ 9.15 (d, J = 6 Hz), 8.82 (s) and 8.97 (s) can be assigned to a secondary and two tertiary methyl groups, while a multiplet at τ 4.26 (1H) and broad singlet at τ 5.84 (2H) arise from one olefinic and two carbinyl protons respectively. The chemical shift of this last resonance is indicative of the allylic nature of the primary alcohol group. A tentative assignment of structure, **1***f*, can be made on the basis of the above evidence and it gains support from a series of spin–decoupling experiments. Irradiation at τ 7.95 (2 H-2) caused collapse of the multiplet at τ 4.26 (H-3) to a broad singlet and significant sharpening of the singlet at τ 5.84 (2 H-18). In addition, this last signal appeared as a doublet (J = 1.5 Hz) upon irradiation at the olefinic proton (τ 4.26) and conversely with H_2 at τ 5.84 the multiplet at τ 4.26 simplified to a triplet (J_{obs} = 4 Hz). These results suggest the part structure **7***a* which is accommodated in the postulated structure, **1***f*. Our initial attempts to confirm this structural assignment involved preparation of **1***f* from solidagoic acid B (**1***b*) via the diol (**1***g*) and the derived aldehydo-acetate (**1***i*), but conversion of the aldehyde group into a methyl group could not be effected (see below). Correlation of **1***f* with a compound of known constitution was achieved as follows. The derived acetate (**1***j*) when hydrogenated in ethanol–triethylamine over palladized charcoal (1) afforded the furanoolefin (**1***k*) and its tetrahydro- and hexahydroderivatives. The first of these (**1***k*) was identical with the compound prepared previously (1) from solidagoic acid A.

Compound VI

The n.m.r. spectrum of the next component, an oil, $[\alpha]_D$ $-30°$ shows a marked similarity to those of the less polar compounds discussed above. The resonances at τ 4.52 (1 H, m), 9.03 (3H, s), and 9.15 (3H, d, J = 6 Hz) are assignable to an olefinic proton and two methyl groups, the former tertiary, the latter secondary. The n.m.r. spectrum also reveals the presence of a hemiacetal ring. This gives rise to a multiplet at τ 6.65 (—O*H*) which is lost upon exchange with D_2O and two broad singlets, one from —C*H*(OH)O— at τ 4.58, the other from —CH_2O— at τ 5.79. If one considers only structures related to those discussed above for this compound then two possibilities arise, **3***a* and **8**. Certain double resonance experiments demonstrated that the former formulation is preferable. Upon irradiation in turn at τ 4.52 (H-3) and 7.90 (2 H-2) the broad singlet at 5.79 (2 H-18) collapsed to an ill-resolved doublet ($w_{1/2}$ = 5 Hz) and a clean doublet (J = 3 Hz) respectively. These results lead to the part structure **7***b* and then to **3***a*. The coupling of the hydroxyl proton to H-19 was demonstrated by irradiating at τ 6.65 whereupon the resonance at τ 4.58 became a very sharp singlet.

The presence of a cyclic hemiacetal moiety in compound VI was also indicated chemically. Acetylation of this compound furnished **3***b* from which the parent was readily regenerated by chromatography over neutral alumina. Although all attempts to oxidize **3***a* to the corresponding lactone (**9**) (1) failed, correlation with a known compound was achieved by treating it with sodium borohydride. The resulting diol (**1***g*) and the derived diacetate were identical with those prepared previously. Further confirmation of the orientation of the hemiacetal ring was obtained from an examination of the n.m.r. spectrum of the deuterated diacetate, **1***l*, prepared from **3***a* by reduction with lithium aluminum deuteride and acetylation of the product. This spectrum was nearly identical to that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the simple diacetate except that the methylene resonance at *higher field* (τ 6.01) in the latter has been replaced by a signal that integrates for only one proton. An unexpected conversion of the diol (**1***g*) into **3***a* was achieved as follows. In the course of attempts to reduce the aldehyde group in **1***i* to a methyl group, it was treated with hydrazine hydrate in methanol at 20° but none of the desired hydrazone was obtained. However, the only isolable product was identical with the hemiacetal of natural provenance.

Compound VII

Compound VII (**4***a*), $[\alpha]_D$ −47° was isolated as an oil which slowly solidified at −5° but melted at *ca.* 18°. In keeping with its chromatographic polarity it shows evidence of hydroxylic absorption in the i.r. at 3600 and 3400 cm^{-1}. The deduction was made that this group forms part of a hemiacetal ring because of the presence in its n.m.r. spectrum of a singlet at τ 4.49 (H-19) and an AB quartet centered at τ 6.11 (J = 10 Hz, 2 H-18) and since the derived acetate (**4***b*) was readily transformed back to **4***a* by alumina. A structural difference between this compound and those discussed above was clearly evident in its n.m.r. spectrum. Thus, the multiplet at *ca.* τ 4.4 arising from the olefinic proton is absent and replaced by a singlet at τ 6.71, a chemical shift value indicative of a proton attached to an epoxide ring. Treatment of **4***a* with sodium borohydride furnished the diol (**10**) in which the epoxide ring remained intact. It appeared likely that compound VII is the epoxy analog of compound VI, but all attempts to convert the latter into the former with *m*-chloroperbenzoic acid, in various solvents, led either to the recovery of substrate or to non-furanoid products. However, the validity of our structural assignment was demonstrated as follows.

Reduction of **4***a* with lithium aluminum hydride gave the triol **11***a* which was then transformed into the hydroxy-diacetate **11***b*. This compound absorbs in the i.r. at 3590 (hydroxyl) and 1745 (acetate carbonyl) cm^{-1}, while in its n.m.r. spectrum resonances at τ 5.63 (q, J = 13 Hz) and 5.83 (broad s) can be assigned to two functional groups of the type $-CH_2OAc$. The failure of the third hydroxyl group to acetylate and the lack of a resonance attributable to a carbinyl proton in the n.m.r. spectrum of **11***b* was taken to indicate the tertiary nature of the hydroxyl group. Treatment of **11***b* with phosphoryl chloride in pyridine gave mainly one product, the known diacetate **1***h*. These reactions allowed compound VII to be formulated as either **4***a* or **12**. To solve this residual problem the above sequence of reactions (**4***a* → **1***h*) was repeated substituting lithium aluminum deuteride for the corresponding hydride. The mass

spectrum of the resulting hydroxy-diacetate (**13**) revealed the presence of two deuterium atoms as anticipated, while in its n.m.r. spectrum the two-proton singlet at τ 5.83 is still present but the quartet centered at τ 5.63 (in **11***b*) has been replaced by a one-proton singlet at τ 5.35. This reflects the stereospecificity of the reductive opening of the hemiacetal ring. Dehydration as described above yielded the monodeutero-diacetate (**1***l*) prepared previously from compound VI, confirming that both compounds have the hemiacetal ring attached in the same fashion. This second reaction sequence also enables assignments to be made for the resonances between τ 5 and 6 in the n.m.r. spectrum of the hydroxy-diacetate **11***b*. The singlet at τ 5.83 derives from the methylene group of the C-18 acetate function, shifting downfield to τ 5.43 on dehydration since it is now allylic, while the quartet at τ 5.63 from the C-19 methylene shifts upfield to 6.01 and becomes a singlet. The epoxide ring is assigned to α-orientation on the following grounds. First, the narrowness ($w_{1/2}$ = 3 Hz) of the signal arising from the proton attached to the epoxide ring in **4***a* suggests (4) the stereochemical situation **14**. Second, *trans*-diaxial opening (5) of the epoxide in **14** with lithium aluminum hydride would lead to a tertiary alcohol, as is observed. Third, **11***a* has been prepared from **1***g* by a route (see below) which would be expected to introduce the tertiary hydroxyl on the α-face of the molecule.

Compound VIII

The neutral compound penultimate in polarity was the diol (**1***g*), m.p. 60–63°, $[\alpha]_D$ −46°, into which several of the compounds discussed above have been converted. The functional groups in **1***g* were readily inferred from its i.r. and n.m.r. data and those of the derived monoacetates (**1***m* and *n*) and diacetate (**1***h*), while chemical transformations clearly defined the spatial relationship of the two primary hydroxyl groups. In the first of these reactions, the diol was converted into a cyclic ether by treatment with *p*-bromobenzenesulfonyl chloride in pyridine (6). Its formulation as **3***c* followed from its very low polarity on t.l.c. and from spectral evidence. In the i.r. it lacks both carbonyl and hydroxyl absorption while its mass spectrum has the molecular ion at *m/e* 300 ($C_{20}H_{28}O_2$). In its n.m.r. spectrum the ethereal methylene groups resonate as two AB quartets, one centered at τ 5.85 (2 H-18) the other at 6.28 (2 H-19). A second important transformation involved the oxidation of the diol with the Sarett reagent. Under mild conditions (see below) the major product was significantly a γ-lactone (ν_{max} 1772 cm^{-1}), thus providing additional confirmation of the disposition of the two hydroxylic groups. This lactone (**2**) m.p. 89–90°, was in fact shown by direct comparison to be identical to compound II. Unambiguous proof of the structure of the diol **1***g* was obtained by hydrogenation (1) of the derived diacetate in ethanol containing triethylamine over palladized charcoal. The resulting monoacetate (**1***p*) was identical with that prepared from solidagoic acid A (1) of well-defined structure.

Compound IX

The most polar of these neutral furanoid compounds (**5***a*), m.p. 135–137°, $[\alpha]_D$ −18° has no resonances attributable to olefinic protons in its n.m.r. spectrum. However, it does have a multiplet at τ 4.50 which can be assigned to HO—C*H*—O— in a hemiacetal ring. Additional lines which form a complex pattern between τ 5.6 and 6.6 although presumably arising from protons of the type >C*H*—O— were of little diagnostic value. However, the n.m.r. spectrum of the derived hydroxy-diacetate (**5***b*) proved more informative. Thus the methine proton (H-19) of the hemiacetal acetate has shifted downfield and appears as a singlet at τ 3.28 while the ethereal methylene protons (2 H-18) are now clearly visible as an AB quartet centered at τ 5.88. A broadened triplet at τ 5.18 (J = 6 Hz) can be assigned to the methine of a secondary acetate group. The multiplicity and value of the observed coupling constant for this proton indicate that if it is attached to a cyclohexane ring, it is probably axial and vicinally related to two protons. Bearing in mind the above spectral evidence and the structures of the other diterpenoids in this plant the plausible structure (**5***a*) can be advanced for compound IX. In an attempt to relate this compound to one of known structure the hemiacetal **3***a* was treated with osmium tetroxide. However, the resulting triol was not identical with the natural product. The formulation of this new triol as **15** rests on the narrowness of the resonance from H-3 ($w_{1/2}$ = 6 Hz, τ 6.33). Presumably the presence of the hemiacetal ring has induced the decalin system

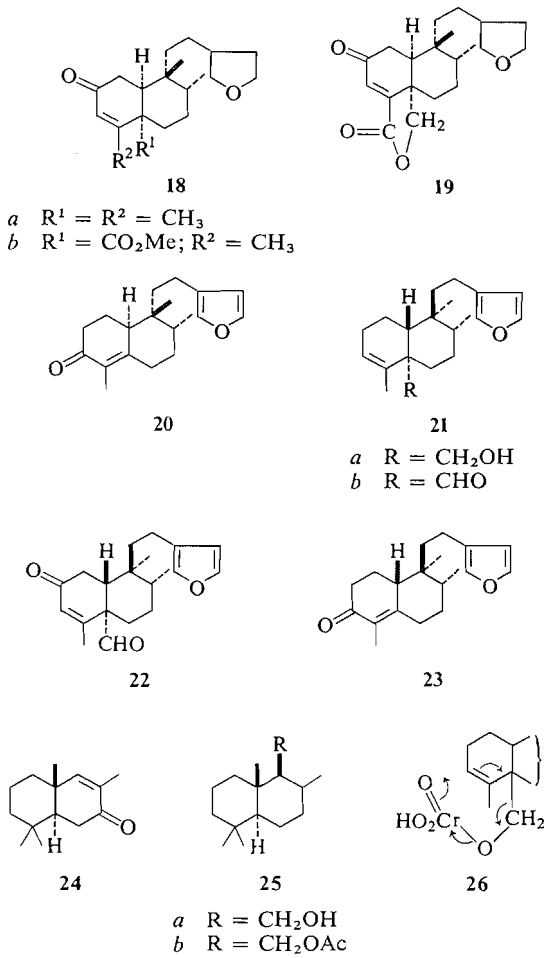
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to adopt the conformation **16** in which, although both faces of the olefinic bond are open to attack, the β would probably be preferred if the C-19 hydroxyl group is α-orientated.

Oxidations with the Chromium Trioxide – Pyridine Complex

Of major importance in our arguments concerning the structure and stereochemistry of solidagoic acids A and B (1), and by extension the related neutral diterpenoids of natural provenance, have been n.m.r. and c.d. studies on the αβ-unsaturated ketones **17***a*, **18***a*, **18***b*, and **19**. A key step in the formation of **17***a* was the introduction of the C-2 ketone using the chromium trioxide – pyridine complex at 20°, conditions which minimize oxidative attack on the furan ring. In the course of our structural studies the reactions of other derivatives of solidagoic acid A and its congeners with this complex were examined and in addition the investigation was extended to related compounds for two reasons. First, compounds containing the enone substitution pattern in **17***a*, but with a *trans*-fused decalin system, were required as models for our n.m.r. work (1). Second, at the time the major portion of the work described in this section was completed[4] (7), only one report of an allylic oxidation with the Sarett reagent existed (9) and the reaction appeared to have enough intrinsic interest to warrant study. It should be noted, that in general, these reactions were carried out using concentrations of chromium trioxide in pyridine of the order of 100 mg/ml.

Oxidation of the methyl ester **1***o* and the acetate **1***p* for 18 days afforded the enones **17***b* and *c* (56 and 50% respectively, based on substrate consumed). The alcohol **1***e* in only 12 h gave (1) the aldehyde **1***c* (67%), the enone-aldehyde **17***d* (3%) and the nor-enone **20** (5%). Maingayol (**21***a*) (10) reacted (1) similarly and furnished **21***b*, **22**, and **23**. The formation of these nor-enones and of **24** from drimenol (**25***a*) (11) might involve a mechanism of the type **26** (arrows) or equivalent intermolecular process. The diacetate **1***h*, as anticipated, was converted into the enone **17***e* (*ca.* 50%) during 17 days. The parent diol (**1***g*) was subjected to oxidation for 14 h under two distinct sets of conditions, namely, with a chromium trioxide – pyridine concentration of first, 250 mg/ml, and second, 2.5 mg/ml. In the former case the major product was the enone-lactone **27** (60%), the minor being the lactone **2** (15%). In the latter oxidation the lactone **2** (74%) was the only isolable product. Our attention was next directed to the two monoacetates **1***m* and *n* (1). The latter with chromium trioxide in pyridine (25 mg/ml) during 14 h smoothly formed the aldehyde **1***q* (74%). The other monoacetate (**1***m*) during 12 h was converted with the complex at a concentration of 2.5 mg chromium trioxide per milliliter of pyridine into the aldehydo-acetate **1***r* (*ca.* 100%)



[4]However, soon thereafter a paper was published (8) concerning the oxidation of 17 olefins with the isolated chromium trioxide – pyridine complex in methylene chloride. In this medium similar results to those reported here were obtained, but the reaction times involved were significantly shorter. Probable mechanisms for the reaction are outlined in this paper (8) and no further discussion is required here.

For personal use only.

and unexpectedly at a concentration of 100 mg/ml into the corresponding epoxide **28** (68%). This epoxide on reduction with lithium aluminum hydride furnished the known triol **11***a*. Formation of an epoxide by chromium(VI) oxidation of an alkene, although a well-known (1, 12, 13) reaction under acidic conditions, is a novel reaction in pyridine solution. The orientation of the epoxide ring in **28** is assigned as α for two reasons. First, in the substrate the β-face of the A ring is probably (1) shielded by the C-9 methyl group. Second, it seems likely that even in pyridine solution, the initial step in the reaction would involve formation of the chromate ester of the primary alcohol at C-5 followed by transfer (13) of an oxygen atom from this ester to the double bond, *i.e.* from the α-side.

As models in our n.m.r. and c.d. studies on the stereochemistry of solidagoic acid A (1), we required compounds of the general type **29** or enantiomer. In view of the results reported above, the diacetate **30***a* from confertifolin (**31**) (14) was treated with chromium trioxide in pyridine (100 mg/ml) for 18 days and afforded, as anticipated, the enone **32***a* (81%). For this compound the relevant coupling constants, H-5/H-6 equatorial and H-5/H-6-axial, were calculated as $J = 3.5$ and 13.5 Hz respectively. When the diol **30***b* was oxidized under similar conditions but for a shorter time (14 h), three products were isolated, the β,β′-disubstituted furan (**33**) (40%), confertifolin (**31**, 22%), and isodrimenin (**34** (14), 25%). The reaction can be envisaged as proceeding through the two possible hydroxyaldehydes to the corresponding hemiacetals and thence by dehydration to the furan or oxidation to the lactones. The oxidation of drimenyl acetate (**25***b*) was examined next. In this case the only product isolated was the enone **32***b* (67%) in which the double bond had migrated into the $\Delta^{8,9}$ position. Earlier workers had reported (15) the isolation of the enone-acid **32***c*, albeit in very low yield, from the products of oxidation of drimenol (**25***a*) with the Sarett reagent. A mechanism which would explain the formation of these isomeric enones has been proposed recently (9). Oxidation of the furanoolefin (**35***a*) (16) gave the expected enone (**35***b*) which showed a negative Cotton effect for the $n \rightarrow \pi^*$ transition.

Oxidation of cholesteryl acetate (**36***a*) for 14 days afforded the 7-keto derivative (**36***b*, 33%). It is noteworthy that in this case the yield

is inferior to that from oxidation by either the chromium trioxide – pyridine complex in methylene chloride (74%) (9) or *t*-butylchromate (60%) (17). Finally, the oxidation of two derivatives of marrubiin (18) was studied. The ester **37***a* during 10 days formed the enone **38***a* (81%) while **37***b* in just less than 1 week gave **38***b* (70%) and over 25 days the corresponding product **39** (12%) which has suffered cleavage of the furan ring. Direct comparison showed that the enone **38***b* is identical to compound Y[5] from *Leonotis*

leonurus (19). Since marrubiin has been synthesized (20), this conversion of marrubiin into compound Y constitutes a formal total synthesis of the latter.

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage apparatus. Specific rotations refer to solutions in ethanol unless otherwise stated. Woelm Grade I alumina, deactivated to the appropriate grade according to Brockmann, was used for chromatography. For analytical and preparative t.l.c., chromatoplates were spread with Kieselgel G (Merck). Light petroleum was of b.p. 40–60°. Microanalyses were by Miss F. Cowan, Glasgow. High resolution mass spectra were run at the N.T.H, Trondheim, by Dr. T. Anthonsen. I.r. solution spectra were recorded in carbon tetrachloride on a Perkin–Elmer 225 or 257 or Beckmann I.R.12 spectrophotometer, u.v. spectra in ethanol on a Unicam S.P.800 spectrophotometer and the circular dichroism curve on a Cary 61 spectropolarimeter. P.m.r. spectra were run on a Perkin–Elmer R-10 or Varian Associates A-60A or HA 100 spectrometer in carbon tetrachloride, unless otherwise stated, using approximately 0.3 *M* solutions and tetramethylsilane as internal standard. Mass spectra were run on a Varian Associates CH 7 or A.E.I. MS9 or MS12 instrument.

Isolation Procedure

The chloroform soluble portion (24 g) of an extract (1) of *Solidago gigantea* var. *serotina* was chromatographed over alumina (Grade III; neutral; 2 kg) using as eluting solvent light petroleum – chloroform mixtures. Compounds were isolated from the various fractions by preparative t.l.c. and then either crystallization or distillation *in vacuo*.

Fraction A (4.3g), eluted with chloroform – light petroleum (1:19) was a complex mixture (t.l.c.) of non-polar compounds which was not investigated further. Fraction B (923 mg) was eluted with chloroform – light petroleum (1:9) and contained compound I, the oily aldehyde **1***c* (471 mg) as the major constituent. It had $[\alpha]_D$ −164° (*c*, 0.9) and was identical (i.r., n.m.r., and t.l.c.) to the aldehyde prepared (1) from solidagoic acid A. Fraction C (1.3 g), eluted with chloroform – light petroleum (1:4), furnished compounds II and III. The first of these, the lactone **2** (311 mg) formed needles from light petroleum and had m.p. 92–95°, $[\alpha]_D$ +12° (*c*, 0.65); ν_{max} 1772 and 874 cm^{-1}; λ_{max} 210 nm (ε 18 000); τ 3.35 (t, 1 H-3, J_{obs} = 3 Hz), 5.56 (d, 1 H-19, *J* = 9 Hz), 6.20 (d, 1 H-19, *J* = 9 Hz), 8.97 (s, 3 H-20) and 9.10 (d, 3 H-17, *J* = 6 Hz); *m/e* 314 (M).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34. Found: C, 76.44; H, 8.41.

Compound III, the dialdehyde **1***d* (472 mg), crystallized from ethyl acetate – light petroleum as needles, m.p. 103–105°, $[\alpha]_D$ −49° (*c*, 0.7); ν_{max} 1720, 1690 and 878 cm^{-1}; τ −0.17 (s, 1 H-18), 0.89 (s, 1 H-19), 3.16 (t, 1 H-3, J_{obs} = 4 Hz), 9.04 (s, 3 H-20) and 9.15 (d, 3 H-17, *J* = 6 Hz) *m/e* 314 (M).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34. Found: C, 76.52; H, 8.43.

Fractions D, E, and F were all eluted with chloroform – light petroleum (1:1). The first of these, fraction D (928 mg), contained two major components. Compound IV, the alcohol **1***e* (38 mg), had $[\alpha]_D$ −38° (*c*, 0.9) and was identical (n.m.r. and t.l.c.) to the alcohol prepared (1) from solidagoic acid A. Compound V, the alcohol **1***f* (671 mg), had $[\alpha]_D$ −45° (*c*, 0.6); ν_{max} 3620, 3400 and 875 cm^{-1}; τ 4.26 (m, 1 H-3; $w_{1/2}$ = 8 Hz), 5.84 (s, 2 H-18), 7.80 (s, —O*H*), 8.82, 8.97 (both s, 3 H-19 and 3 H-20), and 9.15 (d, 3 H-17, *J* = 6 Hz); *m/e* 302 (M).

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00. Found: C, 79.30; H, 9.94.

Fraction E (4.3 g) contained compound VI, the hemiacetal **3***a* (1.7 g), and a sterol (220 mg) which crystallized from ethyl acetate – light petroleum as needles, m.p. 161–163°; ν_{max} 3600 cm^{-1}; *m/e* 412 ($C_{29}H_{48}O$). The hemiacetal had $[\alpha]_D$ −30° (*c*, 1.1; chloroform); ν_{max} 3600, 3390 and 872 cm^{-1}; τ 4.52 (m, 1 H-3, $w_{1/2}$ = 10 Hz), 4.58 (broad s, 1 H-19), 5.79 (broad s, 2 H-18, $w_{1/2}$ = 7 Hz), 6.65 (m, —O*H*), 9.03 (s, 3 H-20) and 9.15 (d, 3 H-17, *J* = 6 Hz); *m/e* = 316 (M).

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92. Found: C, 75.91; H, 9.03.

The derived oily acetate (**3***b*), ν_{max} 1740 and 882 cm^{-1}, τ 3.68 (s, 1 H-19), 4.44 (m, 1 H-3) and 5.72 (m, 2 H-18, $w_{1/2}$ = 12 Hz), on chromatography over alumina (Grade III, neutral) was reconverted into the parent hemiacetal. Fraction F (3.2g) furnished compound VII, the epoxy-hemiacetal **4***a* (1.9g), which solidified on cooling and had m.p. *ca.* 18°; $[\alpha]_D$ −47° (*c*, 0.8); ν_{max} 3600, 3400, and 872 cm^{-1}; τ 4.49 (s, 1 H-19), 6.00 (d, 1 H-18, *J* = 10 Hz), 6.22 (d, 1 H-18, *J* = 10 Hz), 6.71 (s, 1 H-3, $w_{1/2}$ = 3 Hz), 7.03 (m, —O*H*), 9.12 (s, 3 H-20), and 9.19 (d, 3 H-17, *J* = 6 Hz); *m/e* 332 (M).

Anal. Calcd. for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49. Found: C, 72.33; H, 8.64.

Its acetate (**4***b*), τ 3.62 (s, 1 H-19), 6.10 (d, 1 H-18, J = 10 Hz), 6.18 (d, 1 H-18, J = 10 Hz), 6.71 (s, 1 H-3), 8.17 (s, 3H, —OCOCH_3), 9.13 (s, 3 H-20), and 9.20 (d, 3 H-17, J = 6 Hz), was transformed back to the parent hemiacetal on chromatography over alumina.

Fraction G (2.9 g), eluted with chloroform, afforded compound VIII the diol **1***g* (2.6 g), m.p. 60–63°, $[\alpha]_D$ −46° (*c*, 0.9), which was identical to the diol prepared (1) from solidagoic acid B. Fraction H (509 mg) was eluted with methanol–chloroform (1:19) and yielded compound IX, the dihydroxy-hemiacetal **5***a* (284 mg), which on crystallization from ether – light petroleum had m.p. 135–137°; $[\alpha]_D$ −18° (*c*, 0.95); ν_{max} 3425 and 875 cm^{-1}; τ 4.50 (m, 1 H-19, $w_{1/2}$ = 10 Hz), 9.03 (s, 3 H-20) and 9.15 (d, 3 H-17, J = 6 Hz); *m/e* 350 (M).

Anal. Calcd. for $C_{20}H_{30}O_5$: C, 68.54; H, 8.63. Found: C, 68.42; H, 8.89.

The derived diacetate **5***b* had n.m.r. signals at τ 3.28 (s, 1 H-19), 5.18 (t, 1 H-3, J_{obs} = 6 Hz), 5.74 (d, 1 H-18, J = 10 Hz), 6.03 (d, 1 H-18, J = 10 Hz), 7.89, 8.02 (both s, 2—OCOCH_3), 8.98 (s, 3 H-20) and 9.18 (d, 3 H-17, J = 6 Hz).

Reduction of the Lactone **2** *with Lithium Aluminum Hydride*

The lactone **2** (17 mg) was treated with a very large excess of lithium aluminum hydride in refluxing dry ether for 14 h. Work-up afforded an oil (16 mg) which was submitted to preparative t.l.c. (ethyl acetate – light petroleum, 2:3). The major component (11 mg) on crystallization from ethyl acetate – light petroleum had m.p. 57–61°, $[\alpha]_D$ −50° (*c*, 1.1) and was identical (t.l.c. and n.m.r.) to the diol (**1***g*) of natural provenance (see above).

Reduction of the Dialdehyde **1***d* *with Lithium Aluminum Hydride*

The dialdehyde (24 mg) when reduced for 2 h as above gave on work-up and purification the known diol **1***g* (13 mg), m.p. 58–61°, $[\alpha]_D$ −51° (*c*, 1.3).

Conversion of the Alcohol **1***f* *into the Furano-olefin* **1***k*

The alcohol **1***f* (100 mg) in dry pyridine (2 ml) was treated at 20° for 15 h with acetic anhydride (1 ml). The crude product, the acetate **1***j* (98 mg), was purified by preparative t.l.c. (chloroform) and distillation *in vacuo*. It was obtained as an oil $[\alpha]_D$ −34° (*c*, 1.4); ν_{max} 1740, 1230, and 878 cm^{-1}; τ 4.34 (m, 1 H-3), 5.55 (s, 2 H-18), 8.05 (s, 3H, —OCOCH_3), 8.82, 8.93 (both s, 3 H-19 and 3 H-20), and 9.10 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36. Found: C, 76.95; H, 9.34.

Hydrogenation of this acetate (50 mg) in ethanol (25 ml) containing triethylamine (5 ml) over 10% palladized charcoal for 5 min afforded a mixture (t.l.c.) of two products. These were separated by preparative t.l.c. (light petroleum), the less polar being the major component. This compound was the furano-olefin **1***k* (31 mg) which after distillation *in vacuo* had $[\alpha]_D$ −21° (*c*, 1.1) and was identical (i.r., n.m.r., t.l.c.) to the furano-olefin prepared (1) from solidagoic acid A. The minor component was the tetrahydrofuran-olefin on mass spectrometric evidence, *m/e* 290 (M).

In a separate experiment the above acetate (**1***j*, 45 mg) was hydrogenated in ethanol containing triethylamine over palladized charcoal for 40 min. Work-up gave mainly one compound which was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:19) and distillation at 100°/0.05 mm. The resulting oil (28 mg) was the hexahydro derivative of **1***k* and had $[\alpha]_D$ −7° (*c*, 0.7, chloroform); *m/e* 292 (M).

Anal. Calcd. for $C_{20}H_{36}O$: C, 82.12; H, 12.40. Found: C, 81.95; H, 12.23.

Reduction of the Hemiacetal **3***a*

(*i*) The hemiacetal **3***a* (60 mg) in absolute ethanol (5 ml) was treated at 20° for 15 h with a large excess of sodium borohydride. The solution was diluted with water and extracted with ethyl acetate. The product was essentially pure (t.l.c.) diol **1***g* (54 mg) which on crystallization from ethyl acetate – light petroleum had m.p. 60–61°; $[\alpha]_D$ −52° (*c*, 1.2).

(*ii*) The hemiacetal **3***a* (50 mg) was heated with excess lithium aluminum deuteride in refluxing dry ether for 14 h. The deuterodiol (47 mg) obtained after work-up was acetylated with acetic anhydride – pyridine and afforded the corresponding deuterodiacetate (**1***l*, 39 mg). In its n.m.r. spectrum it exhibited resonances at τ 4.06 (m, 1 H-3), 5.43 (s, 2 H-18), 6.01 (s, 1 H-19), 7.98 (s, 6H, 2—OCOCH_3), 8.93 (s, 3 H-20), and 9.08 (d, 3 H-17, J = 6 Hz); *m/e* 403 (M).

Hydroxylation of the Hemiacetal **3***a*

The hemiacetal **3***a* (450 mg) was treated with osmium tetroxide (500 mg) in dry ether for 4 days. The reaction was worked-up with hydrogen sulfide gas, precipitated sulfides being filtered off. The crude product (430 mg) consisted (t.l.c.) of two components which were separated by preparative t.l.c. (chloroform–methanol, 19:1). The less polar (350 mg) was unreacted hemiacetal while the more polar, minor, product (40 mg) was the triol **15**, which could not be induced to crystallize. It had ν_{max} 3500 and 880 cm^{-1}; τ 4.51 (m, 1 H-19), 5.18 (m, 1H, —O*H*; lost on D_2O exchange), 5.56 (s, 1 *H*, —O*H*; lost on D_2O exchange), 6.14 (s, 2 H-18), 6.33 (s, 1 H-3, $w_{1/2}$ = 6 Hz after D_2O exchange), 6.82 (m, 1H, —O*H*; lost on D_2O exchange), 9.01 (s, 3 H-20) and 9.18 (d, 3 H-17, J = 6 Hz); *m/e* 350 (M).

Treatment of Acetoxy-aldehyde **1***i* *with Hydrazine Hydrate*

The acetoxy-aldehyde **1***i* (50 mg) in methanol (5 ml) was treated at 20° for 15 h with hydrazine hydrate (3 ml). Work-up afforded an oil (47 mg) from which the major product (32 mg) was recovered by preparative t.l.c. (chloroform). It had $[\alpha]_D$ −74° (*c*, 1.1) and was identical (n.m.r., i.r., and t.l.c.) with the hemiacetal (**3***a*) of natural provenance.

Attempted Epoxidation of the Hemiacetal **3***a*

Reaction of the hemiacetal **3***a* (15 mg) with *m*-chloroperbenzoic acid (20 mg) in chloroform (5 ml) at 20° for 90 min and work-up by filtration through a short column of neutral alumina afforded essentially pure (t.l.c.) starting material (13 mg). The reaction was repeated this time for 15 h. The products were a complex mixture (t.l.c., Ehrlich, and sulfuric acid staining) of non-furanoid compounds and starting material. Similar results were obtained when carbon tetrachloride or benzene was used as solvent.

For personal use only.

Attempted Oxidation of the Hemiacetal 3a

(*i*) The hemiacetal **3***a* (10 mg) in ether was stirred at 20° for 16 h with activated manganese dioxide. Removal of the reagent and solvent afforded pure (t.l.c.) starting material (8 mg). This experiment was repeated using various grades of manganese dioxide but in all cases the result was similar.

(*ii*) Treatment of the hemiacetal (10 mg) at 20° with excess of the Sarett reagent for 6 h also yielded only starting material (10 mg).

Formation of the Epoxy-diol 10

A large excess of sodium borohydride was added to a solution of the epoxy-hemiacetal **4***a* (50 mg) in ethanol (10 ml) and the mixture allowed to remain at 20° for 15 h. Work-up afforded an oil (47 mg) which contained one major component. This compound, the epoxy-diol **10**, was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:1) and then distillation at 150°/0.04 mm. The resulting oil had $[\alpha]_D$ −6° (*c*, 1.5); ν_{max} 3630, 3380, and 875 cm^{-1}; τ 9.03 (s, 3 H-20) and 9.20 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04. Found: C, 71.89; H, 9.12.

The corresponding acetate had $[\alpha]_D$ −11° (*c*, 0.6); ν_{max} 1745, 1235, and 875 cm^{-1}; τ 5.57 (d, 1 H-18, J = 12 Hz), 5.85 (d, 1 H-19, J = 7 Hz), 5.94 (d, 1 H-19, J = 7 Hz), 6.08 (d, 1 H-18, J = 12 Hz), 6.89 (d, 1 H-3, J = 3 Hz), 7.97, 7.99 (both s, 3H each, 2 —OCOCH_3), 8.97 (s, 3 H-20), and 9.14 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{24}H_{34}O_6$: C, 68.86; H, 8.19. Found: C, 69.04; H, 8.39.

Conversion of the Epoxy-hemiacetal 4a into the Diacetates 1h and l

(*i*) Treatment of the epoxy-hemiacetal **4***a* (50 mg) in refluxing dry tetrahydrofuran with excess lithium aluminum hydride for 15 h gave a product (43 mg) which consisted of two components of similar, high, polarity. These were separated by preparative t.l.c. (ethyl acetate – light petroleum, 3:1). The major, less polar component, the triol **11***a* (21 mg) was an oil which after distillation at 180°/0.1 mm had $[\alpha]_D$ −22° (*c*, 0.75); ν_{max} 3420 and 880 cm^{-1}.

Anal. Calcd. for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59. Found: C, 71.33; H, 9.60.

This triol (50 mg) was acetylated and gave the hydroxy-diacetate **11***b* (46 mg), an oil which was distilled at 75°/0.01 mm and had $[\alpha]_D$ −13° (*c*, 1.0); ν_{max} 3590, 3480, 1745, 1240, and 875 cm^{-1}; τ 5.35 (d, 1 H-19, J = 13 Hz), 5.83 (s, 2 H-18), 5.91 (d, 1 H-19, J = 13 Hz), 8.00, 8.13 (both s 3 H each, 2 —OCOCH_3), 9.07 (s, 3 H-20) and 9.18 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{24}H_{36}O_6$: C, 68.54; H, 8.63. Found: C, 68.74; H, 8.86.

The hydroxy-diacetate **11***b* (15 mg) was heated at 80° with redistilled phosphoryl chloride (0.5 ml) in dry pyridine (3 ml) for 3 h. The reaction mixture was poured onto crushed ice and extracted with ethyl acetate to afford the crude product (17 mg). This consisted (t.l.c.) of two components which were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:4). The major, more polar, component (10 mg) was the oily diacetate which had $[\alpha]_D$ −58° (*c*, 1.0) and was identical (n.m.r., t.l.c.) to that obtained previously by acetylation of the diol **1***g*.

(*ii*) The above sequence of reactions was repeated starting with epoxy-hemiacetal (50 mg) but substituting lithium aluminum deuteride for the hydride. The hydroxy-diacetate **13** had n.m.r. resonances at τ 5.35 (s, 1 H-19) and 5.83 (s, 2 H-18); *m/e* 422 (M). The diacetate **1***l* (17 mg) obtained by dehydration was identical (n.m.r., mass spectroscopy) to that prepared from **3***a*.

Formation of the Ether 3c

The diol **1***g* (50 mg) was heated for 15 h with *p*-bromobenzenesulfonyl chloride (150 mg) in refluxing dry pyridine (5 ml). Work-up afforded an oil (46 mg) from which the major product (32 mg) was obtained by preparative t.l.c. (ethyl acetate – light petroleum, 3:17). This ether **3***c* was distilled at 150°/0.03 mm and had $[\alpha]_D$ −30° (*c*, 0.65), ν_{max} 872 cm^{-1}; τ 4.57 (m, 1 H-3), 5.73 (broad d, 1 H-18, J = 11 Hz), 5.84 (d, 1 H-19, J = 8 Hz), 5.98 (broad d, 1 H-18, J = 11 Hz), 6.73 (d, 1 H-19, J = 8 Hz), 9.01 (s, 3 H-20) and 9.16 (d, 3 H-17, J = 6 Hz); *m/e* 300 (M).

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.95, H, 9.39. Found: C, 79.88; H, 9.52.

Oxidation of Methyl Ester 1o

Oxidation of the ester **1***o* (152 mg) in dry pyridine (2 ml) with chromium trioxide (500 mg) at 20° for 18 days and work-up afforded an oil (172 mg). The two major components of this oil were obtained by preparative t.l.c. (ethyl acetate – light petroleum, 3:7). The less polar component (48 mg) was unreacted ester while the other was the enone-ester **17***b* (63 mg). It was purified further by distillation *in vacuo* and had ν_{max} 1725, 1675, and 882 cm^{-1}; τ 4.23 (s, 1 H-3), 6.50 (s, 3H, —OCH_3), 8.29 (d, 3 H-18, J = 1 Hz), 9.07 (s, 3 H-20) and 9.07 (d, 3 H-17, J = 6 Hz); *m/e* 344 (M).

Anal. Calcd. for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19. Found: C, 73.26; H, 8.35.

Oxidation of Acetate 1p

The acetate **1***p* (40 mg) in dry pyridine (2 ml) was treated at 20° for 17 days with chromium trioxide (100 mg). The oil (38 mg) obtained on work-up was separated by preparative t.l.c. (ethyl acetate – light petroleum, 2:3) to afford unreacted **1***p* (17 mg) as the less polar component. The other component, the enone-acetate **17***c* (12 mg) was obtained as an oil which distilled at 140°/0.04 mm; $[\alpha]_D$ −88° (*c*, 0.08); ν_{max} 1740, 1670, and 872 cm^{-1}; τ 4.07 (s, 1 H-3), 5.84 (d, 1 H-19, J = 12 Hz), 6.18 (d, 1 H-19, J = 12 Hz), 8.00 (s, 3 H, —OCOCH_3), 8.28 (broad s, 3 H-18), 8.97 (d, 3 H-17, J = 6 Hz), and 9.08 (s, 3 H-20).

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44. Found: C, 73.83; H, 8.52.

Oxidation of Diacetate 1h

The crude product (51 mg) obtained from oxidation of the diacetate **1***h* (50 mg) with chromium trioxide (120 mg) for 17 days at 20°, was submitted to preparative t.l.c. (ethyl acetate – light petroleum, 2:3). This furnished two components, starting material (18 mg) and the more polar enone-diacetate **17***e* (16 mg). The latter, an oil, after distillation at 150°/0.03 mm had ν_{max} 1753, 1675, 1220, and 875 cm^{-1}; τ 4.05 (s, 1 H-3), 5.28 (narrow m, 2 H-18), 5.86 (d, 1 H-19, J = 11 Hz), 6.13 (d, 1 H-19, J = 11 Hz), 7.91, 8.02 (both s, 3H each, 2 —OCOCH_3), 8.99 (d, 3 H-17, J = 7 Hz), and 9.12 (s, 3 H-20).

Oxidation of Diol 1g

(*i*) The diol **1***g* (50 mg) in dry pyridine (20 ml) was treated at 20° for 14 h with chromium trioxide (50 mg). The oily product (55 mg) resulting from work-up was purified by preparative t.l.c. (ethyl acetate – light petroleum, 1:19) and afforded as the sole product the lactone **2** (37 mg) which crystallized from ethyl acetate – light petroleum and had m.p. 89–90°, $[\alpha]_D$ +8° (*c*, 1.5). It was identical (m.p., mixed m.p., n.m.r., i.r., t.l.c.) with a sample of the naturally occurring lactone (see above).

(*ii*) The diol **1***g* (75 mg) in dry pyridine (2 ml) was treated at 20° for 14 h with a large excess of chromium trioxide (500 mg). The product consisted of two components (t.l.c.), the less polar of which corresponded to the lactone (**2**) obtained previously. Separation of the two compounds was effected by preparative t.l.c. and afforded **2** (11 mg) as the minor component. The more polar, major product (47 mg) the enone-lactone **27**, crystallized from ethyl acetate – light petroleum and had m.p. 148–149°; $[\alpha]_D$ −9° (*c*, 1.2); ν_{max} 1779, 1690, and 872 cm^{-1}; τ 3.56 (s, 1 H-3), 5.50 (d, 1 H-19, J = 8 Hz), 6.03 (d, 1 H-19, J = 8 Hz), 9.03 (s, 3 H-20), and 9.10 (d, 3 H-17, J = 6 Hz); *m/e* 328 (M).

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.14; H, 7.37. Found: C, 73.11; H, 7.23.

Oxidation of the Monoacetate 1n

The known (1) monoacetate **1***n* (50 mg) was oxidized in dry pyridine (2 ml) with chromium trioxide (50 mg) for 14 h. Work-up gave the crude product (52 mg) which consisted of two compounds (t.l.c.), the more polar being the much more abundant. This component, the acetoxy-aldehyde **1***q* (37 mg) was isolated by preparative t.l.c. (ethyl acetate – light petroleum 1:3). It was an oil which after distillation at 155°/0.025 mm had $[\alpha]_D$ −21° (*c*, 0.88); ν_{max} 2710, 1745, 1695, 1235 and 874 cm^{-1}; τ 0.73 (s, 1H-18), 3.29 (t, 1 H-3, J_{obs} = 4 Hz), 5.51 (d, 1 H-19, J = 12 Hz), 5.77 (d, 1 H-19, J = 12 Hz), 8.14 (s, 3H, —OCOCH_3), 8.97 (s, 3 H-20), and 9.16 (d, 3 H-17, J = 6 Hz); *m/e* 358 (M).

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44. Found: 73.70; H, 8.42.

Oxidation of Monoacetate 1m

(*i*) Oxidation of the known (I) monoacetate **1***m* (45 mg) with chromium trioxide (50 mg) in dry pyridine (20 ml) at 20° for 12 h and work-up afforded an oil (49 mg) which consisted of essentially one compound (t.l.c.). This compound, the acetoxy-aldehyde **1***r* was purified by preparative t.l.c. (chloroform – light petroleum, 4:1) and then distillation at 160°/0.04 mm. The resulting oil had $[\alpha]_D$ −89° (*c*, 0.8); ν_{max} 2690, 1745, 1725, 1230, and 878 cm^{-1}; τ 0.53 (s, 1 H-19), 4.03 (m, 1 H-3), 5.82 (s, 2 H-18), 8.08 (s, 3H, —OCOCH_3), 9.02 (s, 3 H-20), and 9.23 (d, 3 H-17, J = 6 Hz); *m/e* 358 (M).

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71, H, 8.44. Found: C, 73.86; H, 8.47.

(*ii*) When the monoacetate **1***m* (130 mg) was oxidized in dry pyridine (2 ml) at 20° for 12 h with a large excess of chromium trioxide (500 mg) the only product isolable, by preparative t.l.c. (chloroform – light petroleum, 1:9), was the aldehydo-epoxide **28** (90 mg). This was purified further by distillation at 150°/0.015 mm and the resulting oil had $[\alpha]_D$ +3° (*c*, 1.3); ν_{max} 2710, 1755, 1722, 1230, and 878 cm^{-1}; τ 0.05 (s, 1 H-19), 6.09 (d, 1 H-18, J = 12 Hz), 6.40 (d, 1 H-18, J = 12 Hz), 6.97 (s, 1 H-3, $w_{1/2}$ = 4 Hz), 8.04 (s, 3H, —OCOCH_3), 9.13 (s, 3 H-20), and 9.25 (d, 3 H-17, J = 6 Hz); *m/e* 374 (M).

Anal. Calcd. for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08. Found: C, 70.21; H, 7.89.

Reduction of the Aldehydo-epoxide 28

Reduction of the aldehydo-epoxide **28** (60 mg) with excess lithium aluminum hydride in refluxing dry ether for 14 h afforded an oily mixture (t.l.c.) of products (57 mg) the less polar of which was the more abundant. This compound was isolated by preparative t.l.c. (methanol–chloroform, 3:97) and had $[\alpha]_D$ −27° (*c*, 0.91). It was identical (n.m.r., t.l.c.) with the triol **11***a* prepared from the epoxy-hemiacetal **4***a*. Acetylation furnished the hydroxy-diacetate **11***b* (35 mg), $[\alpha]_D$ −16° (*c*, 1.0) which was identical (t.l.c., n.m.r., i.r.) with a sample prepared from **4***a* (see above).

Oxidation of Diol 30b

Diol **30***b* was prepared by reduction of confertifolin[6] (**31**) (14) with lithium aluminum hydride and a sample (150 mg), m.p. 123°, was then treated with chromium trioxide (200 mg) in dry pyridine (2 ml) at 20° for 14 h. Work-up afforded a crude product which consisted (t.l.c.) essentially of three components. These were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:19). The major, and least polar, constituent was the furan **33** (57 mg) which after distillation *in vacuo* had ν_{max} 889 cm^{-1}; τ 2.93 (s, 1 H-11 and 1 H-12), 8.81, 9.08, and 9.10 (all s, 3H each, quaternary C—CH_3's).

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16. Found: C, 82.40; H, 10.12.

The minor components were of similar polarity. The less polar of the two was isodrimenin (**34** (14), 37 mg), m.p. 125–127°, the identity of which was established by comparison (n.m.r., t.l.c., mixed m.p.) with an authentic sample. The more polar was confertifolin (**31** (14), 34 mg), m.p. 150–152°, the identity of which was also established by comparison (n.m.r., t.l.c., mixed m.p.) with an authentic sample.

Oxidation of Diacetate 30a

Acetylation of diol **30***b* (14) furnished the corresponding diacetate (**30***a*) as an oil which after distillation at 100°/0.05 mm had ν_{max} 1743 and 1225 cm^{-1}; τ 5.37, 5.40 (both s, 2 H-11 and 2 H-12), 7.93, 7.97 (both s, 3H each, 2 —OCOCH_3), 8.97, 9.03, and 9.10 (all s, 3H each quaternary C—CH_3's).

Anal. Calcd. for $C_{19}H_{30}O_4$: C, 70.77; H, 9.38. Found: C, 71.05; H, 9.55.

A portion (80 mg) of this diacetate was treated with chromium trioxide (200 mg) in dry pyridine (2 ml) at 20° for 16 days and afforded an oily product which contained two major components. These were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:3). The less polar component was substrate (23 mg) and the more polar the enone-diacetate **32***a* (47 mg) which was purified further by distillation *in vacuo*. The resulting oil had ν_{max} 1750, 1685, and 1230 cm^{-1}; τ 5.16 (s, 2 H-11 and 2

[6]We are grateful to Dr. K. H. Overton for suppling samples of confertifolin, isodrimenin, and drimenol.

H-12), 7.95, 8.00 (both s, 3H each, 2 —OCOCH_3), 8.81, 9.06, and 9.08 (all s, 3H each, quaternary C—CH_3's); *m/e* 336 (M).

Anal. Calcd. for $C_{19}H_{28}O_5$: C, 67.83; H, 8.39. Found: C, 68.26; H, 8.47.

Oxidation of Drimenyl Acetate ***25b***

Drimenyl acetate (**25***b* (15), 70 mg) in dry pyridine (2 ml) was treated at 20° with chromium trioxide (200 mg) for 16 days. The oily product (77 mg) was separated into two components by preparative t.l.c. (ethyl acetate – light petroleum, 3:17). The less polar was starting material (23 mg). The more polar, the enone-acetate **32***b* (33 mg) was obtained as an oil which slowly crystallized at 0° and had m.p. 48–50°; ν_{max} 1745, 1677 and 1228 cm^{-1}; τ 5.27 (d, 1 H-11, J = 13 Hz), 5.29 (d, 1 H-11, J = 13 Hz), 7.97 (s, 3H, —OCOCH_3), 8.24 (s, 3 H-12), 8.91, 9.10, and 9.13 (all s, 3H each, quaternary C—CH_3's).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.34; H, 9.41. Found: C, 73.10; H, 9.40.

Oxidation of the Furano-olefin ***35a***

Treatment of the furano-olefin **35***a* (16, 50 mg) in dry pyridine (4 ml) with chromium trioxide (61 mg) at 20° for 4 weeks afforded an oil (45 mg) on work-up. This oil was separated into two components by preparative t.l.c. (ethyl acetate – light petroleum, 1:4). The less polar was unreacted furano-olefin (**35***a*, 24 mg). The other component was the oily enone **35***b* (16 mg) which was distilled *in vacuo* and had ν_{max} 1665 cm^{-1}; λ_{max} 239 nm (ε 10 500); c.d. in ethanol $[\theta]_{325}$ −4800 and $[\theta]_{241}$ +17 600; c.d. in chloroform $[\theta]_{331}$ −4500; τ 4.37 (q, 1 H-3, J = 1 Hz), 8.13 (d, 3 H-18, J = 1 Hz), 8.87 (s, 3 H-19), 9.12 (d, 3 H-17, J = 6 Hz), and 9.17 (s, 3 H-20).

Mol. Wt. Calcd. for $C_{20}H_{28}O_2$: 300.2089. Found (high resolution mass spectrometry): 300.2094.

Oxidation of Cholesteryl Acetate ***36a***

Cholesteryl acetate (**36***a*, 330 mg) in dry pyridine (10 ml) was treated with chromium trioxide (800 mg) at 20° for 14 days. The product (340 mg) when subjected to preparative t.l.c. (ethyl acetate – light petroleum, 3:17) gave two major fractions. The less polar was starting material (130 mg) and the other, the known (8) enone-acetate **36***b* (68 mg). It crystallized from light petroleum and had m.p. 154° (lit. value 161–163°); ν_{max} 1740 and 1682 cm^{-1}; τ 4.30 (s, 1 H-6) and 5.33 (m, 1 H-3, $w_{1/2}$ = 20 Hz).

Dehydration of Methyl Marrubiate ***40a***

Methyl marrubiate (**40***a*, 421 mg) in dry pyridine was treated at 20° for 7 days with toluene-*p*-sulfonyl chloride according to the method developed (21) by Burn and Rigby for the dehydration of marrubiic acid. Work-up afforded an oil (414 mg) which consisted essentially of only one compound, **37***a*. This was purified by preparative t.l.c. (chloroform) and distillation at 130°/0.02 mm. The resulting oil had ν_{max} 3650, 1772, and 882 cm^{-1}; τ 4.17 (t, 1 H-6, J_{obs} = 3 Hz), 6.37 (s, 3H, —OCH_3), 8.70 (s, 3H, quaternary C—CH_3), 9.00 (d, 3 H-17, J = 6 Hz), and 9.07 (s, 3H, quaternary C—CH_3).

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73. Found: C, 72.61; H, 8.62.

This compound was further characterized by preparation of the corresponding primary alcohol (**37***c*) which was furnished by reduction of **37***b* with lithium aluminum hydride in refluxing ether. It was obtained as an oil, τ 4.38 (broad s, 1 H-6), 6.43 (d, 1 H-19, J = 11 Hz), 6.75 (d, 1 H-19, J = 11 Hz), 8.88, 8.92, (both s, 3H each, quaternary C—CH_3's) and 8.99 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.13; H, 9.27.

The corresponding acetate **37***d*, also an oil, had τ 4.29 (t, 1 H-6, J_{obs} = 3 Hz), 5.86 (d, 1 H-19, J = 11 Hz), 6.15 (d, 1 H-19, J = 11 Hz), 8.90 (s, 6H, quaternary C—CH_3's) and 9.00 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.15; H, 8.92.

Oxidation of the Olefinic-ester ***37a***

Oxidation of the ester **37***a* (750 mg) in dry pyridine (3 ml) with chromium trioxide (500 mg) at 20° for 10 days afforded an oily product (687 mg). This material was chromatographed over neutral alumina (grade III; 60 g). Early fractions containing unreacted **37***a* (320 mg) were eluted with ethyl acetate – light petroleum (1:19). The enone **38***a* (360 mg) was eluted next (ethyl acetate – light petroleum, 3:17) as an oil which had ν_{max} 1730, 1680, and 878 cm^{-1}; λ_{max} 241 nm (ε 12 000); τ 3.82 (sharp s, 1 H-6), 6.38 (s, 3 H, —OCH_3), 8.61 (s, 3 H quaternary C—CH_3) 8.73 (d, 3 H-17, J = 6 Hz), and 8.86 (s, 3H, quaternary C—CH_3). No satisfactory elemental analysis was obtained for this compound and it was characterized by preparation of **38***c*. Reduction of **38***a* with lithium aluminum hydride in refluxing ether gave a mixture (t.l.c.) of two triols (epimeric at C-7). This mixture was oxidized with the Sarett reagent and afforded **38***c*, an oil, which had ν_{max} 1720, 1670 and 882 cm^{-1}; λ_{max} 240 nm (ε 12 500); τ 0.79 (s, 1 H-19), 3.87 (sharp s, 1 H-6), 8.70 (d, 3 H-17, J = 7 Hz), 8.82 and 8.90 (both s, 3H each, quaternary C—CH_3's).

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93. Found: C, 72.65; H, 8.01.

Preparation of the Furano-olefin ***37b***

The known (5) ketone **41** (176 mg) was heated with excess lithium aluminum hydride in refluxing dry ether for 18 h. The product (182 mg) was chromatographed over neutral alumina (Grade III; 25 g), the major component, the axial alcohol **40***b* (88 mg), being eluted with ethyl acetate – light petroleum (1:9). This alcohol failed to crystallize and was purified by distillation at 155°/0.05 mm. It had ν_{max} 3610, 3390, and 865 cm^{-1}; τ 5.70 (m, 1 H-6, $w_{1/2}$ = 7 Hz), 8.75, 8.78, 9.02 (all s, 3H each, quaternary C—CH_3's), and 9.05 (d, 3 H-17, J = 6 Hz).

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.96; H, 10.06. Found: C, 74.73; H, 10.03.

The diol **40***b* (66 mg) in dry pyridine (2 ml) was treated at 20° for 80 min with methane sulfonyl chloride (1 ml). The oil obtained (72 mg) was subjected to preparative t.l.c. (ethyl acetate – light petroleum, 1:19) and afforded the olefin **37***b* (57 mg) which was distilled *in vacuo*. The resulting oil had ν_{max} 3560 and 878 cm^{-1}; τ 4.36 (t, 1 H-6, J_{obs} = 3 Hz), 8.85, 8.88, and 8.90 (all s, 3H each, quaternary C—CH_3's), and 9.00 (d, 3 H-17, J = 6 Hz).

Mol. Wt. Calcd. for $C_{20}H_{30}O_2$: 302.2246. Found (high resolution mass spectrometry): 302.2250.

This olefin (50 mg) in dry pyridine (3 ml) was treated at 20° with chromium trioxide (100 mg) for 25 days. The crude product was submitted to preparative t.l.c. (chloro-

form) which furnished the only isolable product, the enone-lactone **39** (19), (7 mg). This material solidified after distillation *in vacuo* and had m.p. 128–134° and was identical (t.l.c., i.r., u.v., mass spectra) with a sample of **39** supplied by Dr. Rivett. A further sample (16 mg) of the olefin **37***b* was oxidized in dry pyridine (2 ml) with chromium trioxide (35 mg) for 5 days. The product contained (t.l.c.) essentially only two components. These were separated by preparative t.l.c. (ethyl acetate – light petroleum, 1:1). The less polar was starting material (3 mg) and the other, compound Y (**38***b*, (19), 8.5 mg) which crystallized from ethyl acetate – light petroleum. It had m.p. 110–114°, $[\alpha]_D$ −23° (*c*, 0.8), and was identical (mixed m.p. (110–114°), t.l.c., i.r., u.v.) with a sample of **38***b*, m.p. 112–114°, provided by Dr. Rivett.

We thank the Science Research Council of the U.K. for a maintenance award (to M.S.H.) and the National Research Council of Canada for an operating grant (to R.McC.). We are also indebted to Dr. T. Anthonsen, Trondheim, for the high resolution mass spectra and to Mr. E. Nakamura for performing the experiment which effected conversion of **37***b* into **38***b*.

Base-catalyzed Degradations of Carbohydrates. V. The Conversion of 3-Deoxyhex-2-enopyranoses into 2-Furoic Esters

G. O. ASPINALL,[1] R. KHAN, R. R. KING, AND ZOFIA PAWLAK[2]

Department of Chemistry, Trent University, Peterborough, Ontario

Received October 30, 1972

Condensation of 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide and benzyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**2**), followed by removal of protecting groups, affords 2,3,4-tri-*O*-methyl-6-*O*-(β-D-xylopyranosyl)-D-glucopyranose (**5**). Alkaline degradation of the disaccharide **5**, followed by treatment with dilute acid, furnishes 5-β-D-xylopyranosyloxymethyl-2-furaldehyde (**8**), which is converted by oxidation and esterification, followed by acetylation, into methyl 5-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyloxymethyl)-2-furoate (**11**), whose structure has been confirmed by direct synthesis.

La condensation du bromure de tri-*O*-acétyl-2,3,4 α-D-xylopyranosyle et du benzyl tri-*O*-méthyl-2,3,4 β-D-glucopyranoside (**2**), suivie de l'enlèvement des groupes protecteurs, fournit le tri-*O*-méthyl-2,3,4 *O*-(β-D-xylopyranosyl)-6 D-glucopyranose (**5**). La dégradation alcaline du disaccharide **5** suivie d'un traitement acide dilué, conduit au β-D-xylopyranosyloxyméthyl-5 furaldéhyde-2 (**8**) qui est converti après oxydation, estérification et acétylation, en (tri-*O*-acétyl-2,3,4 β-D-xylopyranosyloxyméthyl)-5 furoate-2 de méthyle (**11**) dont la structure a été confirmée par synthèse directe.

3-Deoxyhex-2-enopyranoses, which are formed on alkaline degradation of 2,3-di- and higher *O*-substituted hexopyranoses, may be converted into γ-pyrones (kojic acid derivatives) in a series of reactions in which the initial step involves oxidation with *m*-chloroperbenzoic acid (1, 2). The overall yields in these transformations are not high and of the *O*-substituents originally present only that at O-6 remains in the final product. A much simpler transformation with loss of the same *O*-substituents occurs when 3-deoxyhex-2-enopyranoses are treated with dilute acid, as in the conversion of 3-deoxy-2,4,6-tri-*O*-methyl-D-*erythro*-hex-2-enopyranose into 5-methoxymethyl-2-furaldehyde (3). The disaccharide, 2,3,4-tri-*O*-methyl-6-*O*-(β-D-xylopyranosyl)-D-glucopyranose (**5**), has been synthesized as a model compound for regions of branching in polysaccharides in which alkaline degradation would lead to 3-deoxy-6-*O*-glycosylhex-2-enopyranoses, and the reaction sequence, alkaline degradation, treatment with dilute acid, and appropriate derivatization, has been studied.

The synthesis of the disaccharide **5** from benzyl β-D-glucopyranoside was performed in the following stages: (*i*) tritylation and methylation to give benzyl 2,3,4-tri-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**1**), (*ii*) detritylation, (*iii*) condensation of the derived benzyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**2**) with 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide to give the fully-substituted disaccharide derivative **3**, (*iv*) de-*O*-acetylation to afford the benzyl glycoside **4**, and (*v*) catalytic hydrogenolysis. Treatment of the disaccharide **5** with oxygen-free saturated lime-water furnished 3-deoxy-2,4-di-*O*-methyl-

6-*O*-(β-D-xylopyranosyl)-D-*erythro*-hex-2-enopyranose (**6**) which was characterized by conversion into the crystalline 1-*O*-acetyl-3-deoxy-2,4-di-*O*-methyl-6-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-α-D-*erythro*-hex-enopyranose (**7**).

Reaction of the hex-2-enopyranose **6** with dilute acid at room temperature furnished the crystalline 5-β-D-xylopyranosyloxymethyl-2-furaldehyde (**8**). In order to obtain more stable furan derivatives which could be synthesized independently and which might serve as reference compounds for polysaccharide degradations, 2-furaldehydes were converted into methyl 2-furoates by the procedure of Corey *et al.* (4). Treatment of 5-hydroxymethyl-2-furaldehyde with activated manganese dioxide in methanol in the presence of sodium cyanide and acetic acid afforded methyl 5-hydroxymethyl 5-hydroxymethyl-2-furoate (**9**), and similar reaction of the 2-furaldehyde derivative **8** furnished methyl 5-(β-D-xylopyranosyloxymethyl)-2-furoate (**10**) which was further converted into the triacetate **11**. Methyl 5-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyloxymethyl)-2-furoate (**11**), thus obtained, was identical with a sample prepared by condensation of 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide and methyl 5-hydroxymethyl-2-furoate (**9**). Attempts to de-*O*-acetylate the triacetate **11** with sodium methoxide in methanol were unsuccessful. Since t.l.c. of the reaction products failed to reveal the presence of typical u.v.-absorbing furan derivatives, it is probable that 2-furoic esters, like other furans with strongly electron-withdrawing 2-substituents, *e.g.* 2-nitrofuran (5), undergo ready ring opening in the presence of base. De-*O*-acetylation was satisfactorily achieved with retention of the *O*-glycosyl substituent when methanolic hydrogen chloride was used (6). Base-sensitivity of such furan derivatives probably also accounts for our failure to methylate the sugar residue in **10** using methyl iodide and silver oxide in *N*,*N*-dimethylformamide (7). Repeated treatments of compound **10** with diazomethane – boron trifluoride failed to achieve complete methylation.

Experimental

Unless otherwise stated experimental procedures were as described in Part III (1).

Benzyl 2,3,4-Tri-O-methyl-6-O-trityl-β-D-glucopyranoside (1)

Reaction of benzyl β-D-glucopyranoside (8) (10 g) with chlorotriphenylmethane in pyridine under standard conditions (9) followed by normal work-up and chromatography on silica gel furnished syrupy benzyl 6-*O*-trityl-β-D-glucopyranoside (18 g, 94%). The trityl ether (3.1 g) was methylated with methyl iodide and sodium hydride in *N*,*N*-dimethylformamide (10), and recrystallization of the product from ethanol gave benzyl 2,3,4-tri-*O*-methyl-6-*O*-trityl-β-D-glucopyranoside (**1**) (2.8 g, 83%), m.p. 134–135°, $[\alpha]_D$ −3.2° (*c*, 1.0); n.m.r.: τ 2.40–2.86 (20-proton multiplet, 4 × phenyl), 5.64 (1-proton doublet, $J_{1,2}$ = 7.5 Hz, H-1), 6.38, 6.41, 6.72 (3-proton singlets, 3 × OCH_3).

Anal. Calcd. for $C_{35}H_{38}O_6$: C, 75.83; H, 6.87. Found: C, 75.58; H, 6.81.

Benzyl 2,3,4-Tri-O-methyl-β-D-glucopyranoside (2)

The trityl ether **1** (10 g) in glacial acetic acid (80 ml) was heated to 80°, water was added slowly whilst maintaining complete solution, and the solution was kept at 80° for 1 h and at room temperature overnight. Precipitated tritanol was removed by filtration and washed with cold acetic acid – water (4:1), and the combined filtrate and washings were concentrated during which process further tritanol separated. The syrupy residue was diluted with ethanol and pentane to induce crystallization, and recrystallization from ether–pentane furnished benzyl 2,3,4-tri-*O*-methyl-β-D-glucopyranoside (**2**) (4.8 g, 85%), m.p. 53–54°, $[\alpha]_D$ −46.5° (*c*, 1.0 in CH_2Cl_2); n.m.r.: τ 2.60 (5-proton multiplet, phenyl), 5.64 (1-proton doublet, $J_{1,2}$ = 7.5 Hz, H-1), 6.38, 6.41, 6.49 (3-proton singlets, 3 × OCH_3).

Anal. Calcd. for $C_{16}H_{24}O_6$: C, 61.53; H, 7.68. Found: C, 61.46; H, 7.72.

Benzyl 2,3,4-Tri-O-methyl-6-O-(2,3,4-tri-O-acetyl-β-D-xylopyranosyl)-β-D-glucopyranoside (3)

The benzyl glycoside **2** (4.2 g), silver carbonate (8.3 g), and Drierite (23 g) were stirred in dichloromethane in the dark for 24 h. Iodine (1.4 g) and 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide (4.1 g) were added and the mixture was stirred at room temperature for 48 h. The inorganic residue was removed by filtration, and the filtrate was concentrated to a syrup which crystallized from ether to give benzyl 2,3,4-tri-*O*-methyl-6-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-β-D-glucopyranoside (**3**) (3.5 g, 46%), m.p. 127–129°, $[\alpha]_D$ −75° (*c*, 1.0); n.m.r.: τ 2.64 (5-proton multiplet, phenyl), 6.40 (6-proton singlet, 2 × OCH_3), 6.51 (3-proton singlet, OCH_3), 7.93 (9-proton singlet, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{27}H_{38}O_{13}$: C, 56.80; H, 6.71. Found: C, 56.75; H, 7.17.

Benzyl 2,3,4-Tri-O-methyl-6-O-(β-D-xylopyranosyl)-β-D-glucopyranoside (4)

Methanolic 1.5 *N* barium methoxide (2 ml) was added to the fully-substituted disaccharide **3** (2.39 g) in methanol (100 ml) and the solution was kept at room temperature for 4 h. The solution was deionized by shaking with

Amberlite resins IR-120(H) and IR-45(OH) and the filtrate was concentrated to a syrup which crystallized from ether–pentane to give benzyl 2,3,4-tri-*O*-methyl-6-*O*-(β-D-xylopyranosyl)-β-D-glucopyranoside (**4**) as a monohydrate (1.6 g, 86%), m.p. 67–68°, $[\alpha]_D$ −65.2° (*c*, 1.2).

Anal. Calcd. for $C_{21}H_{32}O_{10}.H_2O$: C, 54.54; H, 6.90; OCH_3, 20.10. Found: C, 54.33; H, 7.07; OCH_3, 20.08.

2,3,4-Tri-O-methyl-6-O-(β-D-glucopyranose) (5)

The benzyl glycoside **4** (0.3 g) in ethanol–water (4:1, 10 ml) was shaken in hydrogen at atmospheric pressure over 5% palladium–charcoal for 18 h. Catalyst was removed by filtration and the filtrate was concentrated to a syrup which crystallized from acetone–pentane to give the disaccharide **5** (0.17 g, 71%), m.p. 142°, $[\alpha]_D$ +7° → +22.7° (equil.) (*c*, 1.0 in water).

Anal. Calcd. for $C_{14}H_{26}O_{10}$: C, 47.46; H, 7.31; OCH_3, 25.54. Found: C, 46.93; H, 7.66; OCH_3, 25.54.

1-O-Acetyl-3-deoxy-2,4-di-O-methyl-6-O-(2,3,4-tri-O-acetyl-β-D-xylopyranosyl)-α-D-erythro-hex-2-enopyranose (7)

The disaccharide **5** (0.2 g) was kept in oxygen-free saturated lime-water (20 ml) at 50° for 30 h. The cooled solution was neutralized with carbon dioxide and concentrated. The residue was extracted with acetone and the filtered solution was concentrated to give syrupy 3-deoxy-2,4-di-*O*-methyl-6-*O*-(β-D-xylopyranosyl)-D-erythro-hex-2-enopyranose (**6**); λ_{max} (H_2O) 198 nm; ν_{max} (film) 1660 cm^{-1} (C=C). Treatment of a sample of the hex-2-enopyranose **6** with acetic anhydride and pyridine in the usual way furnished 1-*O*-acetyl-3-deoxy-2,4-di-*O*-methyl-6-*O*-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl)-α-D-erythro-hex-2-enopyranose (**7**) which, after crystallization from ether–pentane, had m.p. 137–138°, $[\alpha]_D$ −27.5° (*c*, 1.0); *m/e* 490 (M^+) (1), 430 ($M - CH_3CO_2H$) (11), 43 (100); ν_{max} 1745 (acetate C=O), 1660 cm^{-1} (C=C); n.m.r.: τ 3.96 (1-proton singlet, H-1), 6.41, 6.63 (3-proton singlets, 2 × OCH_3), 7.89, 7.93 (3-proton singlets, 4 × $OCOCH_3$).

Anal. Calcd. for $C_{21}H_{30}O_{13}$: C, 51.41, H, 6.17. Found: C, 51.57; H, 6.58.

5-β-D-Xylopyranosyloxymethyl-2-furaldehyde (8)

The hex-2-enopyranose **6** (140 mg) was kept in 0.1 *N* hydrochloric acid (5 ml) at room temperature for 4 days. The solution was neutralized with silver carbonate, filtered, and concentrated to a syrup. The syrup was purified by preparative layer chromatography (ethyl acetate – ethanol, 10:1) to give 5-β-D-xylopyranosyloxymethyl-2-furaldehyde (**8**) (86 mg) as a syrup which crystallized from ethyl acetate and then had m.p. 124–126°, $[\alpha]_D$ −23° (*c*, 1.0); λ_{max} 282 nm (log ε 3.2); ν_{max} 3410 (OH), 1675 (aromatic aldehyde), 1590, 1540 cm^{-1} (heteroaromatic C=C).

Anal. Calcd. for $C_{11}H_{14}O_7$: C, 51.16; H, 5.47. Found: C, 51.29; H, 5.92.

Methyl 5-β-D-Xylopyranosyloxymethyl-2-furoate (10) and Derived Triacetate (11)

Corey oxidation (4) of 5-hydroxymethyl-2-furaldehyde, as a model compound gave methyl 5-hydroxymethyl-2-furoate (11). In a similar manner the 2-furaldehyde derivative **8** (60 mg) in methanol (10 ml) was stirred with sodium cyanide (80 mg), acetic acid (30 mg), and activated manganese dioxide (570 mg) at room temperature for 4 h. The reaction mixture was worked-up as described above and crystallization of the product from ethyl acetate furnished methyl 5-β-D-xylopyranosyloxymethyl-2-furoate (**10**) (42 mg), m.p. 136–138°, $[\alpha]_D$ −21° (*c*, 1.0); ν_{max} 3410 (OH), 1705 (aryl ester C=O), 1596, 1545 cm^{-1} (heteroaromatic C=C).

Anal. Calcd. for $C_{12}H_{16}O_8$: C, 50.00; H, 5.60. Found: C, 49.48; H, 5.63.

The methyl ester **10** (30 mg) in pyridine (3 ml) and acetic anhydride (2 ml) was kept at 0° for 1 h and at room temperature overnight. The reaction mixture was worked-up in the usual way and crystallization of the product from ether – light petroleum afforded methyl 5-(2,3,4-tri-*O*-acetyl-β-D-xylopyranosyloxymethyl)-2-furoate (**11**) (28 mg), m.p. 165–167°, $[\alpha]_D$ −18° (*c*, 1.0); M^+, 414; ν_{max} 1740 (acetate C=O), 1722 (aryl ester C=O), 1590, 1540 cm^{-1}; n.m.r.: τ 2.95 (1-proton doublet, $J_{3',4'}$ = 3.2 Hz, H-3'), 3.65 (1-proton doublet, $J_{3',4'}$ = 3.2 Hz, H-4'), 6.16 (3-proton singlet, OCH_3), 8.96 (9-proton singlet, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{18}H_{22}O_{11}$: C, 52.17; H, 5.35. Found: C, 51.95; H, 5.41.

Synthesis of Methyl 5-(2,3,4-Tri-O-acetyl-β-D-xylopyranosyloxymethyl)-2-furoate (11)

A mixture of the methyl ester **9** (300 mg), 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide (1 g), cadmium carbonate (350 mg), and Drierite (2 g) in toluene (30 ml) was heated with stirring on a steam bath for 2 h. The inorganic residue was removed by filtration, the filtrate was concentrated, and the resulting syrup was purified by preparative layer chromatography (ethyl acetate – light petroleum, 1:1) to give the triacetate **11** (235 mg) which, after crystallization from ether – light petroleum, was identical (m.p. and mixed m.p., t.l.c., and i.r. spectrum) to the previously isolated sample. The triacetate **11** (200 mg) was kept in methanol containing concentrated hydrochloric acid (3 drops) for 2.5 days at room temperature. The solution was neutralized with silver carbonate, filtered, and concentrated to a residue which was crystallized from ethyl acetate to give the methyl ester **10** (96 mg), identical (m.p. and mixed m.p., t.l.c., and i.r. spectrum) to the previously isolated sample. Attempted methylation of the methyl ester **10** with methyl iodide and silver oxide in *N*,*N*-dimethylformamide (7) at room temperature caused extensive degradation of the starting material. Repeated treatments of methyl ester **10** with diazomethane – boron trifluoride in ether furnished a product whose i.r. spectrum (ν_{max} 3430 cm^{-1} (OH)) and mass spectrum (peak of highest mass at *m/e* 316) indicated incomplete methylation.

Substituent Effects on the Acetyl Group Conformation and the Carbonyl Frequency in Acetophenones

P. J. KRUEGER

Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received November 1, 1972

The fundamental carbonyl stretching frequencies for *o*-, *m*-, and *p*-substituted acetophenones in dilute CCl_4 solution are correlated with the electrophilic substituent constant σ^+ by the expression $\nu_{C=O}$ (cm^{-1}) = 11.53 σ^+ + 1691.5 (n = 27, correlation coefficient = 0.988, standard deviation = 1.2 cm^{-1}). The frequencies of carbonyl groups *trans* to an *o*-substituent follow this correlation, assuming $\sigma_o^+ \approx \sigma_p^+$, while those oriented *cis* to the substituent generally do not. Deviations from this correlation are interpreted in terms of dipole–dipole interactions, steric hindrance to planarity, intramolecular hydrogen bonding, and non-additivity of σ^+ values for some combinations of substituents. The carbonyl frequencies for singly *m*- and *p*-substituted acetophenones are also correlated with the polar and resonance components of σ^+ by the expression $\nu_{C=O}$ (cm^{-1}) = 15.66σ_I + 10.99σ_R^+ + 1689.8 (n = 13, correlation coefficient = 0.981, standard deviation = 0.9 cm^{-1}). Thus the sensitivity of the carbonyl frequency to the polar effect is greater than to the resonance effect. In ω-substituted acetophenones no precise correlation with polar substituent constants is observed.

Les fréquences fondamentales d'élongation du carbonyle des acétophénones *o*, *m*, et *p* substituées, en solution diluée dans le CCl_4, ont été reliées à la constante σ^+ du substituant électrophile par l'expression $\nu_{C=O}$ (cm^{-1}) = 11.53σ^+ + 1691.5 (n = 27, coefficient de correlation = 0.988, déviation standard = 1.2 cm^{-1}). Les fréquences des groupes carbonyles en *trans* par rapport à un substituant en *o* satisfont à cette correlation en assumant que $\sigma_o^+ \approx \sigma_p^+$, tandis que ceux qui sont en *cis* par rapport à ce substituant ne la suivent généralement pas. Les déviations par rapport à cette corrélation ont été interprétées en fonction des interactions dipole-dipole, de l'empêchement stérique à la planéarité, de la liaison hydrogène intramoléculaire et de la non additivité des valeurs σ^+ pour certaines combinaisons de substituants. Les fréquences du carbonyle des acétophénones simplement substituées en *m* et *p*, ont été également reliées aux composantes de polarité et de résonance de σ^+ par l'expression $\nu_{C=O}$ (cm^{-1}) = 15.66σ_I + 10.99σ_R + 1689.8 (n = 13, coefficient de correlation = 0.981, déviation standard = 0.9 cm^{-1}). Ainsi, la fréquence du carbonyle est plus sensible à l'effet de polarité qu'à l'effet de résonance. Pour les acétophénones ω substituées, aucune correlation précise n'a été observée avec les constantes de polarité du substituant. [Traduit par le journal]

Introduction

Linear relationships between i.r. "group frequencies" and the Hammett (1, 2) and Taft σ-type substituent constants (3–7) have been demonstrated for a large number of aromatic and aliphatic systems (8–16). For aromatic compounds with substituents in an ortho-position with respect to the group in which the vibration is localized, it has been shown that the Taft ortho-σ substituent constants (3*a*) correlate these i.r. data along with the Hammett σ relationships for *m*- and *p*-substituted members of the series, provided that specific interactions like intramolecular hydrogen bonds and steric effects are absent (7, 13).

The correlation of the carbonyl stretching frequency in *m*- and *p*-substituted acetophenones with Hammett σ values of substituents has been noted previously (10*a*, 14, 15), and Rao and Venkataraghavan (9) have shown that the correlation with σ^+ for a small number of compounds is equally good.

No previous investigation appears to delineate quantitatively the effect of *cis–trans* isomerism of the acetyl group on the transmission of a substituent effect from an ortho-position to the carbonyl bond. Thus a recent correlation of carbonyl stretching frequencies for a large number of compounds of different structural types with a "new" substituent constant uses only average values for acetophenones in which conformational mobility of the acetyl group leads to a doublet carbonyl band (16).

This paper reports additional measurements on a wider range of ring-substituted acetophenones, including compounds with several substituents, and establishes that the linear dependence of $\nu_{C=O}$ on σ^+ (or its additive equivalent for multi-substituted compounds) includes *o*-substituted compounds, for which it

can be used to assign the conformation of the acetyl group.

The σ_I and σ_R substituent parameters (6) were first used by us some time ago to establish the relative sensitivity of i.r. frequencies (and integrated absorption band intensities) to the polar and resonance effect of substituents (13). The result of this approach to ring-substituted acetophenone carbonyl frequencies is also reported here, and compared with the substituent dependence of carbonyl frequencies in ω-substituted acetophenones.

Experimental

All the compounds used were commercial materials which were purified by standard methods until their physical constants were in acceptable agreement with literature values. A spectroscopic grade of CCl_4 shown to be free of water was used as the solvent for the measurements. Spectra were generally recorded in triplicate, using a pair of standard matched 1 mm cells with KBr windows and a purged Beckman IR-7 i.r. spectrophotometer. The frequency scale of the instrument was calibrated, and the accuracy of carbonyl frequency measurements is ± 1 cm^{-1}, except where precluded by large bandwidths or by overlapped carbonyl doublets.

Results and Discussion

The carbonyl frequencies for ring-substituted acetophenones drawn from the literature and supplemented by additional measurements in our own laboratory are given in Table 1, together with the applicable substituent constants. The known high electron accepting ability of the acetyl group makes the electrophilic substituent constant σ^+ the most reasonable choice (11). Although Taft has devised some ortho-σ values (3*a*) the list is not extensive, and as a first

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

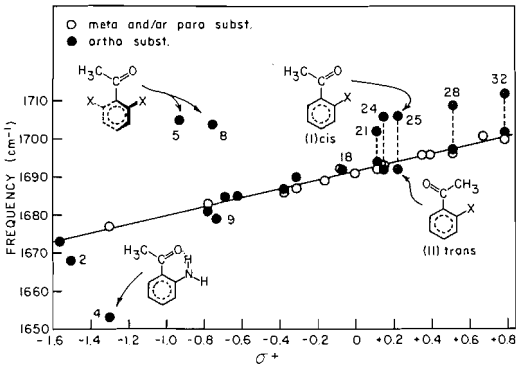

FIG. 1. Dependence of carbonyl frequencies in ring-substituted acetophenones on electrophilic substituent constant σ^+. Numbers refer to compounds listed in Table 1.

approximation it was assumed in this study that $\sigma_o^+ \approx \sigma_p^+$. There is, however, some evidence which indicates that σ values for *o*-substituents are somewhat smaller than those for corresponding *p*-substituents (17). For a full discussion of the "ortho effect" the reader is referred to Charton's recent review (7). For multi-substituted acetophenones additivity of the substituent effects was also assumed (17).

The carbonyl frequencies for compounds **2**, **4**, **5**, **8**, and **9**, and the high frequency components of the doublets observed for compounds **21**, **24**, **25**, **28**, and **32** were found to deviate from the general correlation with σ^+ (Fig. 1) and were removed from the least-squares treatment. The other 27 frequencies are correlated by eq. 1,

$$[1] \qquad \nu_{C=O}\,(cm^{-1}) = 11.53\sigma^+ + 1691.5$$

with a correlation coefficient of 0.988 and a standard deviation of 1.2 cm^{-1}. Frequencies reported for the two components of the carbonyl doublets are undoubtedly not the true band centers because of severe band overlapping, and this may be the cause of some deviations from the straight line. The recent conclusion by Laurence and Wojtkowiak (10*a*) that *m*- and *p*-substituted acetophenones must be treated separately in carbonyl frequency correlations with σ^+ cannot be justified, particularly since eq. 1 includes more compounds and has a higher correlation coefficient.

In **4** intramolecular NH···O hydrogen-bonding is well established (18–20) and $\nu_{C=O}$ is expected to be depressed. In **2** and **9** the additivity of substituent effects is questionable, as the methoxy group in the 5-position may lead to an enhanced electron density at the 2-carbon (with a methoxy substituent) which may be transmitted to the acetyl group. The acetyl group in **5** and **8** is twisted out of planarity with the aromatic ring by the 2,6-methyl groups, thereby increasing the C=O bond order and raising $\nu_{C=O}$ (21).

In ortho-substituted acetophenones where *cis–trans* isomerism can be observed through doublet carbonyl frequencies, Jones *et al.* (15) have previously assigned the high frequency component to the *cis*-conformer (I) (Fig. 1), by analogy with the known increase in $\nu_{C=O}$ in equatorially α-halogenated cyclohexanones where C=O and C—X dipoles are aligned in the same direction. The temperature-dependent equilibrium between I and II was held to depend on the near equivalence of the X···CH_3 repulsive force in I (largely steric) and the X···O repulsive force in II (largely electrostatic).

Figure 1 shows that the carbonyl frequencies for *trans*-isomers in *o*-substituted acetophenones follow the σ^+ correlation as the carbonyl bond is influenced predominantly by the substituent through the aromatic ring.[1] In contrast to *o*-iodo-, *o*-bromo-, and *o*-chloroacetophenone, *o*-fluoroacetophenone (**18**) is thus established to be wholly *trans*. Compounds with an ortho-methoxy group (**1** and **7**) are also in a *trans*-conformation. This correlation is therefore useful in the characterization of conformers in ortho-substituted acetophenones. Relative peak heights and conformer populations support this view, *e.g.* in a comparison of **25** with **28**, both of which have an *o*-Cl substituent, the high frequency *cis* (I) peak of **28** is strongest since the carbonyl dipole has been reduced ($\sigma^+ = 0.513$), whereas in **25** the total electron-withdrawing effect is not as great ($\sigma^+ = +0.228$), the carbonyl dipole is therefore larger, and the low frequency *trans* (II) component dominates (see Fig. 2).

The substituent dependence of $\nu_{C=O}$ can be analyzed further through the use of the σ_I and σ_R^+ substituent parameters (6), where

[1] A direct field effect in the *trans*-form is not ruled out, but it will certainly be small relative to the field effect in the *cis*-form. It should be noted that the term "polar effect" is used to characterize the total influence of an unconjugated remote substituent on the reaction site (here the carbonyl bond). This designation permits the use of the terms inductive and field effect to describe the mechanism of transmission, *i.e.* propagation by the successive polarization of intervening bonds, or by the interaction of bond dipole moments through space according to the classical laws of electrostatics (22).

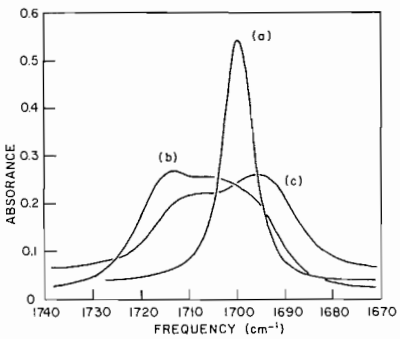

FIG. 2. Carbonyl bands in ring-substituted acetophenones in dilute CCl_4 solution, 1 mm pathlength: (*a*) 3,4-dichloroacetophenone (0.0056 *M*); (*b*) 2,5-dichloroacetophenone (0.0094 *M*); (*c*) 2,4-dichloroacetophenone (0.0080 *M*).

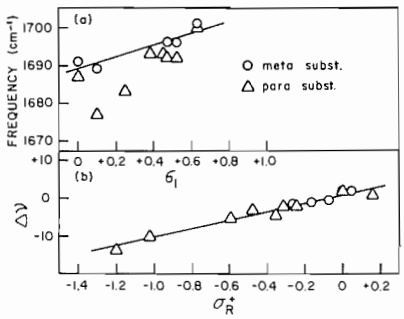

FIG. 3. (*a*) Dependence of carbonyl frequencies on the polar substituent constant σ_I. (*b*) Deviations from linear relationship in (*a*) plotted *vs.* resonance substituent constant σ_R^+. Data from Table 1.

$$[2] \qquad \sigma^+ = \sigma_I + \sigma_R^+$$

for both *m*- and *p*-substituents (23) in an attempt to separate the polar and the resonance effects of substituents. Only compounds with single *m*- or *p*-substituents were selected (**3**, **6**, **14**, **16**, **17**, **19**, **20**, **22**, **23**, **26**, **27**, **30**, and **31**) and $\nu_{C=O}$ plotted against corresponding σ_I values noted in Table 1 (see Fig. 3*a*). After a least-squares fit to the *m*-points, *all* frequency deviations from the straight line were correlated with σ_R^+ (Fig. 3*b*). The 13 carbonyl frequencies, therefore, follow the relationship given by eq. 3

$$[3] \quad \nu_{C=O}\,(cm^{-1}) = 15.66\sigma_I + 10.99\sigma_R^+ + 1689.3$$

with a correlation coefficient of 0.981 and a standard deviation of 0.9 cm^{-1}. The transmission coefficients of σ_I and σ_R^+ indicate that the carbonyl frequency is more susceptible to the polar effect than to the resonance effect in acetophenones. Again, this is a more unified treatment than that reported previously (10*c*).

The effect of ω-substituents on $\nu_{C=O}$ is summarized in Table 2, and the data are presented with respect to σ* of the substituent group (3) in Fig. 4. The frequency behavior of the carbonyl group in aliphatic ketones has been studied extensively, and is generally well understood with respect to *cis–gauche* isomerism and the resulting frequency increase due to field effects in the *cis*-isomer (III) (25). Figure 4 shows that the carbonyl frequencies in both conformations relate to σ* only in terms of broad correlation zones, the carbonyl groups with one (or two) substituents in the *gauche*-position being relative-

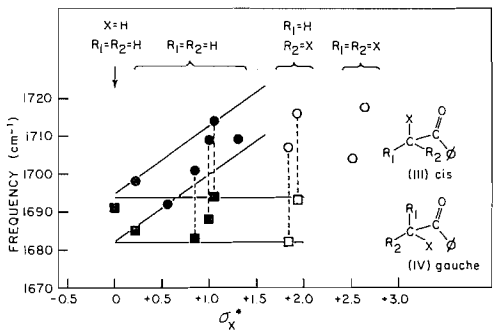

FIG. 4. Carbonyl frequencies in ω-substituted acetophenones *vs.* aliphatic polar substituent constant σ*. Data from Table 2. Closed symbols represent compounds with only a single ω-substituent.

ly insensitive to the substituent effect, whereas carbonyl groups with a polar substituent in the *cis*-orientation show a rise in frequency as σ* increases. The apparent plateau at high σ* values, reflecting the fact that only one substituent can be *cis* to the carbonyl group, emphasizes that the frequency increase in III is due to a direct field effect. Other factors which are hard to assess but which may affect the frequencies in this series are a field effect in IV, and the presence of steric effects leading to conformations not exactly *cis* or *gauche*. The precise correlations in ring-substituted acetophenones clearly relate to the rigidity of that system.

Synthesis of 1,3,4-Dioxazoles from Hydroxamic Acids and Acetylenic Compounds

F. M. F. CHEN AND T. P. FORREST
Chemistry Department, Dalhousie University, Halifax, Nova Scotia
Received October 31, 1972

Hydroxamic acids have been shown to undergo a base-catalyzed reaction with acetylenic compounds containing electron-withdrawing groups, to yield substituted 1,3,4-dioxazoles.

On a démontré que sous l'influence des bases les acides hydroxamiques réagissent avec les composés acétyléniques contenant des groupes électroaffinitaires pour conduire à des dioxazoles-1,3,4 substituées.

The reaction of aryl hydroxamic acids with ethyl ethynyl ether has been reported (1) to yield isocyanates. Although the intermediate in this reaction had not been characterized, it was assumed to be **1**. However, it was later noted that the reaction of hydroxamic acids with methylene ketene diethyl acetal, ethyl orthopropionate, or diethyl ketals yield isolable 1,3,4-dioxazoles, which decompose at elevated temperatures and also yield isocyanates. The possibility (2) that 1,3,4-dioxazoles may be formed by the addition of hydroxamic acids to acetylenic bonds led us to consider using this type of reaction as a method for the synthesis of this heterocyclic ring system. Since nucleophilic reagents are known (3) to add most readily to triple bonds activated by electron-withdrawing groups, the reaction with hydroxamic acids was attempted on acetylenic compounds of this type.

Benzhydroxamic acid and acetohydroxamic acid were found to react with *o*-nitro-phenylacetylene in dimethylsulfoxide with sodium hydride as a catalyst, yielding **2** and **3** respectively. The spectral data of these compounds (see Table 1) leave no doubt as to the structures of the reaction products. An analogous reaction of these two hydroxamic acids with ethyl propiolate yielded the 1,3,4-dioxazoles **4** and **5**.

It was anticipated that the reaction with dimethyl acetylenedicarboxylate might not yield 1,3,4-dioxazoles because this compound has been reported to react with other bidentate nucleophiles by the addition of one nucleophilic atom to the triple bond and substitution of the other at the ester group. The reaction with 1,2-diamines or aminoalcohols has been utilized (4) as a general method for the synthesis of compounds of type **6**. Substituted imidazolidones (**7**) were obtained when guanidines were used as bidentate nucleophiles in the reaction with dimethyl acetylenedicarboxylate (5). However, the reaction with benzo- and acetohydroxamic acids was found to yield the 1,3,4-dioxazoles (**8** and **9**) derived from the addition of both nucleophilic atoms to the same acetylenic carbon.

The yields of the 1,3,4-dioxazoles reported in Table 1 are not necessarily the optimum yields obtainable, since conditions have not been altered to minimize the side reactions. By-products identified are, for example, 1,3-diphenyl urea which is formed in the reactions employing benzohydroxamic acid, and triethyl trimesoate which is formed when ethyl propiolate is used.

Experimental

The following procedure was used in the preparation of all of the 1,3,4-dioxazoles described in Table 1.

The hydroxamic acid (0.003 mol) was dissolved in 3 ml of dry dimethylsulfoxide. A 50% dispersion of sodium hydride and oil (0.0003 mol) was added under nitrogen gas. The acetylenic reactant (0.003 mol) was then added to the mixture in 2 ml of dry dimethyl sulfoxide. After stirring at room temperature for 16 h the mixture was acidified with glacial acetic acid (0.0004 mol). The dimethylsulfoxide was then removed under high vacuum (0.1 mm at 35 °C) and the residue transferred to a silica gel column. The products were eluted with a mixture of chloroform and hexane (1:8). The physical properties and yields of the dioxazoles are given in Table 1.

Heterogeneous Isomerization of Ethylene Oxide to Acetaldehyde

O. O. BERNARDINI[1] AND E. A. CHERNIAK[2]

Department of Chemistry, Carleton University, Ottawa, Canada

Received June 13, 1972

Surface catalyzed isomerization of $(CH_2)_2O$ to CH_3CHO occurs in a small, Pyrex reactor containing 15 or 230 Torr $(CH_2)_2O$ at temperatures in the range 339.2 °C to 461.4 °C. $R_0(CH_3CHO)$, the initial rate of formation of CH_3CHO, depends on the number of successive pyrolyses and on the evacuation time between pyrolyses, which is not true of the initial rates of formation of H_2, CO, CH_4, CH_2CO, and C_2H_6. $R_0(CH_3CHO)$ also depends on the reactor S/V and on pretreatment of the reactor with product gases, particularly H_2. The reproducible and limiting values of $R_0(CH_3CHO)$ are independent of the $(CH_2)_2O$ pressures used. Above 385 °C these initial rates exhibit an Arrhenius temperature dependence while below 385 °C they pass through a maximum.

Analysis of the Langmuir–Hinshelwood, low surface coverage mechanism shows that the $T > 385$ °C isomerization is partially or totally controlled by CH_3CHO desorption and that $-\Delta H_{ads} < (55 \pm 10)$ kcal mol^{-1}, for CH_3CHO on this surface.

$E_a = 57$ kcal mol^{-1} for the homogeneous first order decomposition of $(CH_2)_2O$, in the 15 Torr pyrolysis at temperatures in the range 374.0 to 406.7 °C, and any vibrationally excited CH_3CHO, formed in the gas phase at this pressure (and possibly even at 230 Torr), dissociates into chain initiating radicals.

L'isomérisation catalysée superficiellement du $(CH_2)_2O$ en CH_3CHO se produit dans un petit réacteur en Pyrex contenant 15 ou 230 Torr en $(CH_2)_2O$, pour des températures allant de 339.2 à 461.4 °C. La vitesse initiale de formation du CH_3CHO, $R_0(CH_3CHO)$, dépend du nombre successif de pyrolyses et de la durée d'évacuation entre ces pyrolyses; cette vitesse n'est pas réellement celle de la formation de H_2, CO, CH_4, CH_2CO, et C_2H_6. $R_0(CH_3CHO)$ dépend également du rapport S/V et du prétraitement du réacteur en produit gazeux, en particulier H_2. Les valeurs reproductibles et limitatives sur $R_0(CH_3CHO)$ sont indépendantes des pressions en $(CH_2)_2O$ utilisées. Au dessus de 385 °C, les vitesses initiales varient avec la température selon une fonction d'Arrhénius tandis qu'au dessous de 385 °C, elles passent par un maximum.

L'analyse du recouvrement faible de la surface selon Langmuir et Hinshelwood montre que l'isomérisation pour $T > 385$ °C est partiellement ou totalement contrôlée par la désorption de CH_3CHO et que $-\Delta H_{ads} < (55 \pm 10)$ kcal mol^{-1} pour CH_3CHO sur cette surface.

La décomposition homogène du premier ordre de $(CH_2)_2O$ a un $E_a = 57$ kcal mol^{-1} dans la pyrolyse sous 15 Torr et à des températures de 374.0 à 406.7 °C; le méthanal formé en phase gazeuse et vibrationnellement excité se dissocie alors en radicaux initiateurs de réactions en chaîne pour cette pression et peut être même pour la pression de 230 Torr. [Traduit par le journal]

Can. J. Chem., **51**, 1371 (1973)

The chain mechanism, proposed by Benson (1), for the gas phase pyrolysis of ethylene oxide, is initiated by reactions 1 to 3 which involve highly vibrationally excited (CH_3CHO^*) and normal (CH_3CHO) acetaldehyde molecules (1–3).

$$[1] \quad (CH_2)_2O \rightleftarrows \dot{C}H_2CH_2\dot{O} \longrightarrow CH_3CHO^*$$

$$[2] \quad CH_3CHO^* \longrightarrow \dot{C}H_3 + \dot{C}HO$$

$$[3] \quad CH_3CHO^* + M \longrightarrow CH_3CHO + M$$

Subsequent reactions in this chain mechanism resul in chain catalyzed isomerization of $(CH_2)_2O$ to CH_3CHO and chain decompositions of both $(CH_2)_2O$ and CH_3CHO. While the catalyzed isomerization of propylene oxide to propionaldehyde on seasoned Pyrex surfaces (4) and of $(CH_2)_2O$ to CH_3CHO on supported silver surfaces (5) is established and the catalyzed isomerization of $(CH_2)_2O$ to CH_3CHO on Pyrex surfaces is suspected (6), no evidence for the latter surface catalyzed isomerization is available. This study provides such evidence.

Experimental

The pyrolyses were performed in a cylindrical Pyrex reactor (o.d. = 2.5 cm, $V = 26.3$ cc) with $S/V \sim 1$ cm^{-1}. After washing with chromic acid solution and distilled water the reactor was embedded in a large cylindrical aluminum block which formed the core of a thermistor temperature controlled oven of standard design. The reactor, which was connected through two four-way stopcocks to a Perkin–Elmer 154C gas chromatograph, with thermistor thermal conductivity detector, was

evacuated with a mercury diffusion pump, filled with helium and heated continuously, at temperatures in the range 350 to 500 °C. After withdrawing helium from the reactor, ethylene oxide gas was rapidly introduced, with a Töpler pump, to the desired pressure (either 15 or 230 Torr) and at the end of a pyrolysis period carrier gas was introduced into the reactor to sweep its contents to the chromatograph for analysis. Pyrolyses were performed at temperatures in the range 339.2 ± 0.1 °C to 461 ± 1 °C, as determined by an iron–constantan thermocouple which was fixed to the mid-section of the reactor with aluminum foil.

Ethylene oxide (Matheson) was dried over Linde molecular sieves 5A, treated with dry Ascarite, condensed, and degassed *in vacuo* at −196 °C and vacuum distilled. Acetaldehyde (Eastman) was degassed *in vacuo* at −196 °C and vacuum distilled. Hydrogen, carbon monoxide, methane, and ethane (Matheson) were used without further purification. Ketene, prepared by refluxing the vapor of diketene (Aldrich) over electrically heated tungsten wire, was degassed *in vacuo* at −196 °C and vacuum distilled.

Chromatographic calibration curves for all the above compounds were obtained using standard 2 m, 1/4 in. stainless steel columns, 25 cc min^{-1} carrier gas flow rates and temperatures in the range 23 to 29 °C. Column F (tetraethylene glycol dimethyl ether on diatomaceous earth) was used in the analysis of ethylene oxide and acetaldehyde. A 40 ft, 1/4 in. coiled copper column, filled with 10% (w/w) tetraethylene glycol dimethyl ether on 60–80 mesh Chromasorb W, was used in the analysis of small quantities of acetaldehyde in the presence of excess ethylene oxide. Column I (calcium zeolite) was used for H_2 analysis and column J (silica gel) was used for ethane and ketene analysis, after preconditioning at 125 °C for several hours using a helium carrier gas flow rate of 25 cc min^{-1}. Columns I and J were used in series for the analysis of CO and CH_4. Nitrogen was used as the carrier gas for H_2 analysis and helium was used in the analysis of the remaining gases.

To test the effect of the possible adsorption of each gaseous product on the rates of formation of acetaldehyde the reactor was evacuated overnight and then subjected to 15 min contact with a gaseous product at 230 Torr and the appropriate temperature. The usual pyrolysis run was undertaken after removal of the product gas by evacuation for 1 min.

In some experiments the reactor was filled with Pyrex beads, which had been cleaned in the same manner as the reactor. In these experiments the reactor volume was approximately 21 cc and $S/V \sim 5$ cm^{-1}.

Results and Discussion

In the pyrolysis of 15 Torr $(CH_2)_2O$, in the temperature range 348.4 to 406.7 °C, the major products identified, in addition to CH_3CHO, were CO, CH_4, H_2, C_2H_6, and CH_2CO. Methyl ketene dimer was a minor pyrolysis product.[3]

[3]This product, which was analyzed with column J, had the same retention time as methyl ketene dimer produced by the pyrolysis of methyl ethyl ketone in a conventional ketene generator.

A search was made for formaldehyde and ethylene, in th pyrolys s products, and these compounds were not found.

No special precautions needed to be taken to determine the rates of fo mation of CO, CH_4, H_2, C_2H_6, and CH_2CO. However, to obtain reproducible rates of formation of CH_3CHO, it was found necessary to condition the reactor by repeated reaction and to use short evacuation times between successive runs. This was also true for a series of runs perfo med on 230 Torr $(CH_2)_2O$ in the temperature range 339.2 to 461.4 °C. The dependence of CH_3CHO yields on the number of pyrolysis runs, at two evacuation times, is shown in Fig. 1. The first run was made after a 15 h evacuation and the con tant carrier gas flushing t me was 5 min. Not only is the rate of CH_3CHO production depressed by repeated reaction (Fig. 1) but th reproducible, limiting CH_3CHO yield, $[CH_3CHO]_\infty$, obtained after performing a sufficiently large number of runs, is a function of the time of evacuation (Figs. 1 and 2). Complete reactivation of the reactor was not obtained even after 20 h of

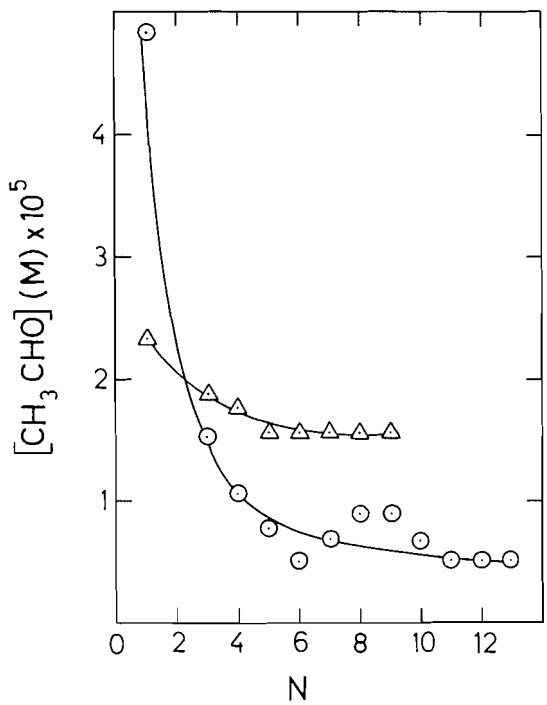

FIG. 1. CH_3CHO yields (mol l^{-1}) as a function of the number (N) of pyrolysis runs in the 40 min pyrolyses of 230 Torr $(CH_2)_2O$ at 374.0 °C. Evacuation times between runs: ○, 1 min; △, 5 min.

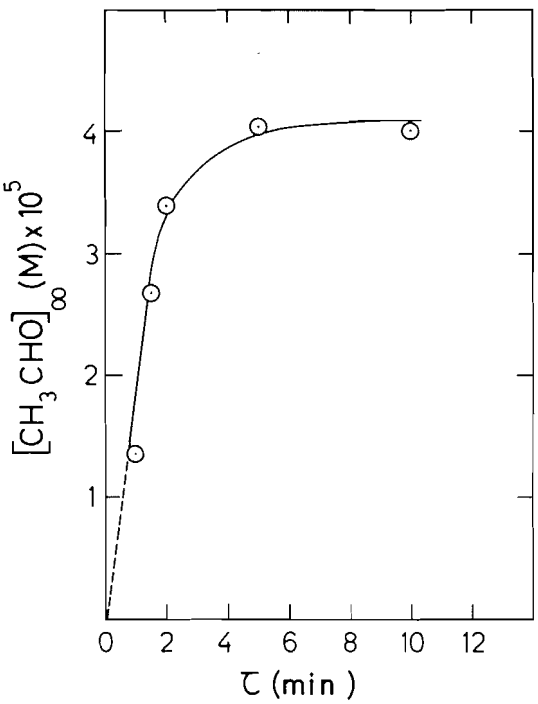

FIG. 2. Reproducible, limiting CH_3CHO yields (mol l^{-1}) as a function of the evacuation time (τ) between 40 min pyrolyses of 230 Torr $(CH_2)_2O$ at 374.0 °C.

evacuation. The CH_3CHO yield, obtained in the first pyrolysis run after 48 h of evacuation, was found to be twice as great as the corresponding yield obtained after 20 h of evacuation. Similar experiments were made at 348.4 and 359.0 °C with analogous results. At 348.4 °C, seven successive runs, separated by 5 min of carrier gas flushing and 1 min of evacuation, reduced the CH_3CHO yield to 1/15th of the yield obtained in the first pyrolysis run.

Initial rates of formation of all major products of the pyrolysis of 15 Torr $(CH_2)O$ in the temperature range 348.4 to 406.7 °C are shown in Table 1. The $R_0(CH_3CHO)$ values represent reproducible, limiting rates obtained after performing a large number of runs with the shortest possible evacuation time (*i.e.* 1 min). Table 1 also shows that in this temperature range good carbon and oxygen atom balances were obtained from the measured initial rates of formation of these products. The oxygen atom balance condition was used to show that the disappearance of $(CH_2)_2O$ (initial pressure = 15 Torr) was first-order at each temperature studied in the range 348.4 to 406.7 °C.[4]

The temperature dependence of ln $R_0(CH_3CHO)$, in the pyrolysis of 230 Torr $(CH_2)_2O$ in the range 339.2 to 461.4 °C and of 15 Torr $(CH_2)_2O$ in the range 348.4 to 406.7 °C, is shown in Fig. 3. This dependence is clearly non-Arrhenius in character in the range 339.2 to 359.0 °C. $R_0(CH_3CHO)$ is also zero order from 348.4 to 406.7 °C, since the reproducible initial rates of formation of CH_3CHO, obtained at initial $(CH_2)_2O$ pressures of 15 and 230 Torr, in this temperature range are the same within the limits of experimental error.

Figure 3 also shows the temperature dependence of ln $R_0(CH_3CHO)$ calculated from the data of Benson (1), Neufeld and Blades (6), and Mueller and Walters (7). The R_0 (CH_3CHO) values of Benson represent initial rates of formation of CH_3CHO in the first order gas phase isomerization of 230 Torr $(CH_2)_2O$ and are given by [4].

[4] $R_0(CH_3CHO) = k_1((CH_2)_2O)_0$ mol min^{-1}

$k_1 = 1.90 \times 10^{16} \exp(-57\,000/RT)$ min^{-1} is the specific rate for the homogeneous formation

[4]Plots of ln $[(CH_2)_2O]$ *vs.* the pyrolysis time t were linear at each temperature studied where $[(CH_2)_2O]_t = [(CH_2)_2O]_0 - [CO]_t - [CH_2CO]_t - [CH_3CHO]_t$ mol l^{-1}.

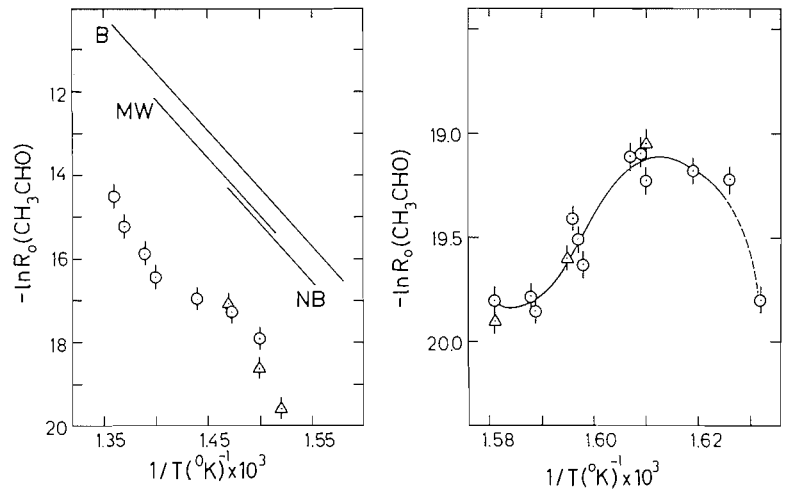

FIG. 3. Temperature dependence of ln $R_0(CH_3CHO)$ in the pyrolysis of 230 Torr ethylene oxide (339.2 to 461.4 °C), ○; and 15 Torr ethylene oxide (348.4 to 406.7 °C, △; B, Benson (1); MW, Mueller and Walters (7); and NB, Neufeld and Blades (6).

of CH_3CHO^* by the overall process [1] and $((CH_2)_2O)_0 = [(CH_2)_2O]_0 \times V/1000 = 0.097/T$ mol. (It is assumed that $k_3(M) \gg k_2$ at a pressure of 230 Torr.) The $R_0(CH_3CHO)$ values of Neufeld and Blades and Meuller and Walters, given by [5] and [6], respectively, represent initial rates of formation of CH_3CHO in the first order gas phase isomerization of 230 Torr $(CH_2)_2O$ in the presence of sufficient propene to provide maximum inhibition.

$$[5]\quad R_0(CH_3CHO) = 9.58 \times 10^{15} \times \exp(-56\,900/RT)((CH_2)_2O)_0 \text{ mol min}^{-1}$$

$$[6]\quad R_0(CH_3CHO) = 1.32 \times 10^{16} \times \exp(-57\,400/RT)((CH_2)_2O)_0 \text{ mol min}^{-1}$$

The $R_0(CH_3CHO)$ values obtained in this study are approximately two orders of magnitude smaller than the $R_0(CH_3CHO)$ values expected for the formation of acetaldehyde in the gas phase, according to Benson, Neufeld and Blades, and Mueller and Walters. Also, the processes responsible for CH_3CHO formation in this study possess an apparent activation energy ($E_A = 55 \pm 10$ kcal mol^{-1}) in the range 384.5 to 461.4 °C.

Not only was the rate of formation of CH_3CHO increased by a factor ~5 when pyrolyses took place in the reactor with $S/V \sim 5$ cm^{-1} but also pretreatment of the reactor (with $S/V \sim 1$ cm^{-1}) with product gases influenced the rate of CH_3CHO production (Table 2). With the possible exception of CH_2CO all product gases inhibit CH_3CHO formation and H_2 is the most powerful inhibitor. One pretreatment with H_2 reduced the CH_3CHO yield to 5-6 μM. For comparison, repeated runs separated by 1 min evacuation and 5 min flushing with carrier gas reduced the CH_3CHO yield from 25 μM in the first run ($N = 1$) to 5–6 μM for $N \geqslant 12$.

TABLE 2. Effect of pretreatment of reactor with product gases on 40 min ($N = 1$) acetaldehyde yields in the pyrolysis of 230 Torr ethylene oxide at 374.0 °C*

Product gas	$[CH_3CHO]$ μM
H_2	5.9
CO	13.5
CH_4	11.3
C_2H_6	21.9
CH_2CO	23.5

*With no pretreatment, $[CH_3CHO] = 25$ μM and $[CH_3CHO]_\infty = 5$–6 μM.

The above observations indicate that in these experiments CH_3CHO is formed by surface catalyzed isomerization of $(CH_2)_2O$. The marked suppression of $R_0(CH_3CHO)$ by preadsorbed H_2 indicates that H_2 and $(CH_2)_2O$ compete for surface active sites; H_2 remains adsorbed while $(CH_2)_2O$ isomerizes to CH_3CHO. If, on evacuation, H_2 does not desorb rapidly enough then repeated runs in the same reactor lead to accumu-

lation of H_2 on adsorption sites. Thus CH_3CHO production is suppressed by repeated reaction (with constant evacuation times between runs), is enhanced by prolonged evacuation at sufficiently high temperatures prior to a given run and occurs from surfaces characterized by high H_2 and other product gas coverage (or low $(CH_2)_2O$ coverage) to provide the reproducible, limiting values of $R_0(CH_3CHO)$ measured in this study. While it is not possible to specify the nature of the surface involved in these experiments it may contain some chromium oxides. That H_2 gas was so effectively adsorbed may be due to the fact that the reactor had received a chromic acid washing (8).

In this study, CH_3CHO may be formed entirely by surface catalyzed isomerization of $(CH_2)_2O$. The Arrhenius plot for the first order decomposition of 15 Torr $(CH_2)_2O$, in the temperature range 348.4 to 406.7 °C is shown in Fig. 4 where the results are again compared with those of Benson (1), Neufeld and Blades (6), and Mueller and Walters (7). In the temperature range 374.0 to 406.7 °C Arrhenius behavior is noted with an activation energy (E_a = 57 kcal mol^{-1}) in good agreement with the activation energies reported by the above workers. In the same temperature range $R_0(-(CH_2)_2O)$ values obtained in this work are approximately twice those predicted by Benson (if $k_3(M) \gg k_2$), approximately four times greater than the "propene inhibited" rates measured by Neufeld and Blades and Mueller and Walters and approximately an order of magnitude greater than the $R_0(CH_3CHO)$ values obtained in this work. At P = 15 Torr it is expected that the condition $k_3(M) \ll k_2$ holds (1), *i.e.* at this pressure homogeneous CH_3CHO formation is not occurring for vibrationally excited CH_3CHO molecules become sources of $\cdot CH_3$ and $\cdot CHO$ radicals and these radicals, directly and indirectly, will be responsible for the larger rates of $(CH_2)_2O$ disappearance obtained. The fact that the reproducible limiting CH_3CHO yield may be zero at $\tau = 0$ (Fig. 2) implies that homogeneous CH_3CHO formation is also not occurring in the 230 Torr $(CH_2)_2O$ pyrolyses at 374.0 °C.

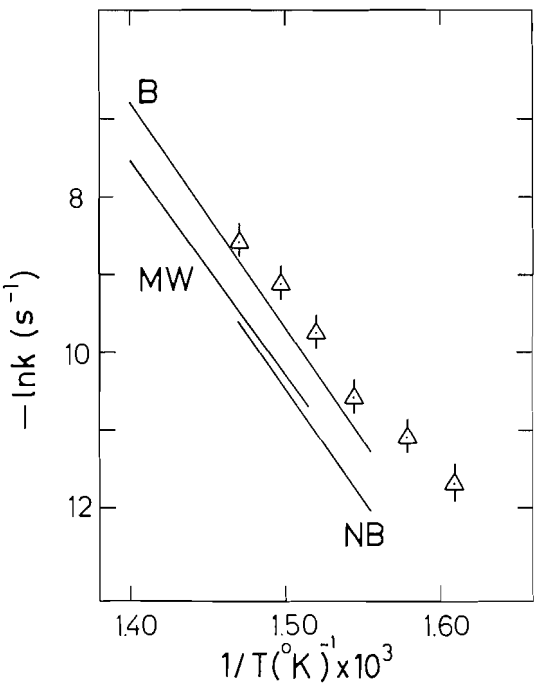

FIG. 4. Temperature dependence of specific rate (k) for first order decomposition of ethylene oxide in the range 348.4 to 406.7 °C. This work, △ (15 Torr ethylene oxide). B, Benson (1); MW, Mueller and Walters (7); and NB, Neufeld and Blades (6).

The Langmuir–Hinshelwood mechanism for the 384.8 to 461.4 °C isomerization is given by reactions 7 to 9, inclusive.[5]

[7] $(CH_2)_2O$ (g) ⇄ $(CH_2)_2O$ (ads)

[8] $(CH_2)_2O$ (ads) ⇄ CH_3CHO (ads)

[9] CH_3CHO (ads) ⇄ CH_3CHO (g)

The adsorption controlled value of $R_0(CH_3CHO)$ is k_7P_0 where P_0 is the initial $(CH_2)_2O$ pressure (11, 12). Adsorption controlled heterogeneous isomerization is not a possibility since $R_0(CH_3CHO)$ has been shown to be independent of P_0 and E_7, the activation energy for the adsorption of $(CH_2)_2O$, is expected to be very much less than $E_A = 55 \pm 10$ kcal mol^{-1}, obtained in this work. The very high and very low $(CH_2)_2O$ coverage, surface reaction controlled values of $R_0(CH_3CHO)$ are k_8 and $K_Ek_8P_0$, respectively, where $K_E = k_7/k_{-7}$, the equilibrium constant for $(CH_2)_2O$ adsorption. If, as assumed above, low $(CH_2)_2O$ coverage exists in this system then surfacereaction controlled heterogeneous isomerization is also not taking place.

[5]Reaction 8 may involve a diradical intermediate. While dioxanes were not searched for in this study large quantities of these products have been found in the pyrolysis of $(CH_2)_2O$ in the presence of magnesia and alumina surfaces (9, 10).

The desorption controlled value of $R_0(CH_3CHO)$ is given by [10].

$$[10] \quad R_0(CH_3CHO) = k_8k_9/(k_8 + k_{-8})$$

For very low $(CH_2)_2O$ coverage, the inequalities, shown in [11], must be satisfied.

$$[11] \quad [1 + (k_8/k_{-8})]^{-1} \ll K_EP_0 \ll 1$$

Now

$$k_8/k_{-8} \simeq \exp(28\,000/RT)$$

since

$$E_{-8} = E_8 - (\Delta H_f^0(CH_3CHO) - \Delta H_f^0((CH_2)_2O))^6 = E_8 + 28 \text{ kcal mol}^{-1}$$

Thus

$$[1 + (k_8/k_{-8})]^{-1} \simeq \exp(-28\,000/RT) \ll 1$$

(at temperatures in the range 384.8 to 461.4 °C) and [11] is very easily satisfied to provide very low $(CH_2)_2O$ coverage. The desorption controlled value of $R_0(CH_3CHO)$, for very low $(CH_2)_2O$ coverage, thus becomes k_9 with $E_9 = E_{-9} - \Delta H_A$ where ΔH_A is the heat of adsorption of CH_3CHO. Desorption-controlled heterogeneous isomerization is thus possible and $-\Delta H_A < (55 \pm 10)$ kcal mol^{-1}. This value is not unreasonable for it is a low CH_3CHO coverage quantity and heats of adsorption values are known to increase with decreasing surface coverage (12).

It is possible for two of the processes [7], [8], and [9] to be slow and rate determining while the third is fast and approaching equilibrium. Of the three possibilities, the one involving slow adsorption and surface reaction steps ([7], [8]) is impossible for k_8/k_{-7} has to be negative in order to provide very low $(CH_2)_2O$ coverage. The adsorption and desorption controlled value of $R_0(CH_3CHO)$ is also given by [10]. For very low $(CH_2)_2O$ coverage, the inequalities shown in [12] must be satisfied. Since

$$k_9/k_{-7} \simeq \exp(\Delta H_A - \Delta H_E)/RT$$

$$[12] \quad (\exp(-28\,000/RT) + k_9/k_{-7}) \ll K_EP_0 \ll 1$$

where ΔH_E is the heat of adsorption of $(CH_2)_2O$. The inequalities shown in [12] can be satisfied only if $\Delta H_A - \Delta H_E$ is negative and a few kcal mol^{-1} in magnitude. For example, if $K_EP_0 = 10^{-3}$ and $(\exp(-28\,000/RT) + k_9/k_{-7}) \simeq 10^{-6}$ then at 384.8 °C, $\Delta H_A = \Delta H_E - 3.4$ kcal mol^{-1}. The surface reaction and desorption controlled value of $R_0(CH_3CHO)$ is given by [13]. For very low surface coverage, the inequalities,

$$[13] \quad R_0(CH_3CHO) = k_8k_9/(k_8 + k_{-8} + k_9)$$

shown in [14] must be satisfied. If $E_9 \sim 55$ kcal mol^{-1} and $E_{-8} \sim 60$ kcal mol^{-1} then $k_9/k_{-8} \simeq \exp(5000/RT)$

$$[14] \quad (1 + k_9/k_{-8})[\exp(28\,000/RT) + k_9/k_{-8}]^{-1} \ll K_EP_0 \ll 1$$

since $k_9/k_{-8} \simeq \exp(E_{-8} - E_9)/RT$. Thus the left term in [14] is again $\simeq \exp(-28\,000/RT) \ll 1$ (at temperatures in the range 384.8 to 461.4 °C) and [14] is again very easily satisfied to provide very low $(CH_2)_2O$ coverage. The surface reaction and desorption controlled value of $R_0(CH_3CHO)$ for very low $(CH_2)_2O$ coverage again becomes k_9.

The above analysis shows that the surface catalyzed isomerization of $(CH_2)_2O$ to CH_3CHO in the temperature range 384.8 to 461.4 °C is partially or totally desorption controlled if the assumption of low $(CH_2)_2O$ coverage is valid. For partial or total desorption controlled heterogeneous isomerization the zero order $R_0(CH_3CHO)$ is predicted to be k_9 from which the upper limit to the low coverage heat of adsorption of CH_3CHO is estimated to be $-(55 \pm 10)$ kcal mol^{-1}.

Acyl Alkyl Diimides. III. Influence of Structure on Decomposition

THOMAS R. LYNCH, FREDERICK N. MACLACHLAN, AND JOHN L. SUSCHITZKY
Chemistry Department and Scarborough College, University of Toronto, West Hill, Ontario

Received October 16, 1972

Eleven compounds of general structure RCON=NC(CN)R_2', where R = C_6H_5, CH_3, $C_6H_5CH_2$ and R_2' = $(CH_3)_2$, $(CH_2)_4$, $(CH_2)_5$, $(CH_2)_6$, have been found to decompose in a first-order manner in dilute toluene solution in the temperature range 60–100°. The *N*-acetyl compounds decompose *ca.* four times faster than the corresponding *N*-benzoyl cases. Variation in R_2' causes changes in rate parallel to those observed by Overberger for the analogous bis-α-cyanoalkyl diimides but of smaller magnitude. The products are those expected from homolytic cleavage, and intermediate *N*-acylketenimines have been trapped by added water in two cases.

Il a été démontré que les onzes composés de structure générale RCON=NC(CN)R_2', où R = C_6H_5, CH_3, $C_6H_5CH_2$ et R_2' = $(CH_3)_2$, $(CH_2)_4$, $(CH_2)_5$, $(CH_2)_6$, se décomposent selon un mode du premier ordre en solution diluée dans le toluène et ceci dans l'intervalle de température suivant 60–100°. Les composés *N*-acétylés se décomposent *ca.* quatre fois plus rapidement que les produits correspondants *N*-benzoylés. Les changements dans R_2' entraînent des variations dans le taux identiques a celles observées par Overberger pour les diimides bis-α-cyanoalcoyle analogues mais avec une amplitude moins prononcée. Les produits sont ceux prévus à partir d'un clivage homolytique et les intermédiaires *N*-acylcetènenimines ont été isolés par addition d'eau dans les deux cas. [Traduit par le journal]

Can. J. Chem., **51**, 1378 (1973)

In previous papers we have reported on the synthesis and spectra of a number of acyl alkyl diimides (1) and on the kinetics of the thermal decomposition of one example (2). Our continuing interest in this heretofore relatively neglected class of diimides has prompted us to undertake a more extensive investigation of their properties. In this paper we report the results of a study in which the effect of alteration of both acyl and alkyl substituents on decomposition rates has been investigated. We have also performed a product study on two cases, and have measured the cage effect exhibited by one example.

$$\underset{\mathbf{1}}{\text{RCONHNHCR}_2'} \xrightarrow{[O]} \underset{\mathbf{2}}{\text{RCON=NCR}_2'}$$

a R = CH_3; R_2' = $(CH_2)_5$
b R = CH_3; R_2' = $(CH_2)_4$
c R = CH_3; R_2' = $(CH_2)_6$
d R = CH_3; R′ = CH_3
e R = $C_6H_5CH_2$; R_2' = $(CH_2)_5$
f R = C_6H_5; R_2' = $(CH_2)_6$
g R = C_6H_5; R_2' = $(CH_2)_4$
h R = C_6H_5; R′ = CH_3
i R = *p*-$MeOC_6H_4$; R_2' = $(CH_2)_5$
j R = *p*-ClC_6H_4; R_2' = $(CH_2)_5$
k R = *p*-MeC_6H_4; R_2' = $(CH_2)_5$

Accordingly, the benzoyl, acetyl, and phenylacetyl α-cyanoalkyl diimides **2***a–k* were obtained by lead tetraacetate oxidation of the *N′*-α-cyanoalkyl acid hydrazides **1***a–k*, the latter being synthesized by a general route previously described (1). An alternate route to these hydrazides was also explored, *viz.*: by transfer of the elements of hydrogen cyanide from acetone cyanohydrin to an acylhydrazone of a ketone. This method gave the desired α-cyanoalkyl acid hydrazides in yields of 25–80%. However, the first-mentioned route generally resulted in higher yields of purer products and was the method of choice.

The kinetic studies were performed in dilute toluene solution by monitoring the disappearance of the n–π* bands at *ca.* 400 nm (due to product absorption, this method was not applicable in the phenylacetyl case, compound **2***e*; disappearance of **2***e* in chlorobenzene was followed by integration of the $C_6H_5CH_2$— methylene signal in its n.m.r. spectrum). The results are collected in Table 1, and except where noted, are derived from two runs at each temperature. High concentration runs in the benzoyl series (compounds **2***h* and *j*) indicate little, if any, induced decomposition; such substrate concentration increases in the acetyl series (compounds **2***a* and *d*) actually led to slight decreases in rate, a phenomenon not normally associated with the onset of induced decomposition, and may be due to changes in the nature of the medium

(now *ca.* 0.4 *M* in diimide). Here it should be noted that diimide **2***e* gave good first-order kinetics over 2–3 half-lives although the concentration was necessarily high (*ca.* 0.5 *M*).

Table 2 gives the calculated rate constants at 80.0° for the unsubstituted diimides studied here, and for *N*-benzoyl *N'*-α-cyanocyclohexyl diimide, **2***l*, reported on previously. It can be seen (column 6) that the *N*-acetyl diimides decompose approximately four times faster than the *N*-benzoyl analogs having the same alkyl group, perhaps suggestive of some degree of *N*-acyl cleavage in the transition state. The very slight rate enhancement of the phenylacetyl case, **2***e*, over its acetyl relative, compound **2***a*, can be taken to indicate that loss of carbon monoxide is not concerted with formation of nitrogen. This contrasts with the case of *t*-butyl phenylperacetate in which formation of carbon dioxide is considered to be simultaneous with cleavage of the perester O—O bond (3). In addition, it can be seen that the effects of *p*-substituents on the rate of decomposition of benzoyl diimides having a common alkyl group (Table 3, compounds **2***i–l*), is small and that there appears to be no significant contribution from a polar transition state such as 3.[1,2]

TABLE 3. Calculated rate constants for the thermal decomposition of $p\text{-}X\text{-}C_6H_4CON{=}NC(CN)(CH_2)_5$ at 80° in toluene

Compound **2**	X	k ($\times 10^5$ s^{-1})	k_{rel}
l	H	0.88	1.00
i	Me	0.88	1.00
j	Cl	0.94	1.07
k	MeO	0.61	0.69

[1]Polar transition states in the formation of benzoyl radicals have previously been invoked (ref. 4 and refs. therein).

[2]It has been suggested from e.s.r. studies (5) that benzoyl radicals are not stabilized by *p*-Cl or *p*-MeO substituents.

3

As inferred previously, the effect of alkyl group variation on rates is quite similar in both the benzoyl and acetyl series (Table 2) and the relative ordering (cyclohexyl < cyclopentyl < isopropyl < cycloheptyl) is the same as that observed by Overberger (refs. 6 and 7, Table 2, column 8) for the corresponding bis-α-cyanoalkyl diimides, and would seem to establish *N*-alkyl bond cleavage. It should be noted that the rate range observed here (10–14) is much less than for the dialkyl compounds (*ca.* 200) of Overberger, and more closely resembles the range of 5 observed for the related *t*-butylcycloalkyl peresters (8, 9). Whether acyl C—N bond cleavage is also occurring is less clear. This bond is expected to be the stronger, being an sp^2–sp^2 bond rather than sp^2–sp^3, and because of conjugation effects. However, the similarity between the activation energies for our compounds and those of Overberger's may support a two bond cleavage, the faster rate of the acetyl compounds reflecting greater acyl C—N bond cleavage, or a more stable acyl radical.

We have also examined the products from the thermal decomposition of compounds **2***d* and *h*. Decomposition of a degassed 0.1 *M* solution of **2***d* in toluene containing added water,[3] at 80° for 8.5 half-lives gave (average of two runs): α-acetylisobutyronitrile (1.3%), tetramethylsuccinonitrile (4%), isobutyramide (7%), *N*-acetylisobutyramide (12%), isobutyronitrile (22%), acetic acid (25%), acetone (14%) and α-methylacrylonitrile (3%), accounting for 67% of the isobutyronitrile radicals but a more disappointing 38% of the acetyl radicals, together with a number of other products which were not identified but which may arise by attack of radicals on the solvent.[4] Decomposition of **2***h* (0.075 *M* in degassed toluene containing water at 90° for 8.5 half-lives) gave (average of two runs): α-benzoylisobutyronitrile (3%), *N*-benzoylisobutyramide (70%),[5] benzaldehyde (2%), tetramethylsuccinonitrile (4%), benzene (2%),[6] and a trace of bibenzyl, accounting for 77% of the benzoyl radicals and 81% of the isobutyronitrile radicals. Neither isobutyronitrile nor α-methylacrylonitrile were detected.

The most notable feature of the product distributions from **2***d* and *h* is the marked preference for combination of the acyl radicals with the isobutyronitrile radicals on nitrogen, rather than on the more sterically hindered carbon, in agreement with the preference previously observed for the recombination of α-cyanoalkyl radicals themselves (12). The *N*-acylketenimines so formed in the cases reported are then presumed to react with water to give the *N*-acylamides observed as the predominant products. Parenthetically, it might be mentioned that *N*-acylketenimines appear to be a hitherto unreported class of ketenimine (13), and, in the absence of water, thermal decomposition of α-cyanoalkyl acyl diimides is a potential route to their isolation.

To return to the products studies, the significant amounts of isobutyronitrile and acetic acid from the diimide **2***d* can most reasonably be explained by nucleophilic attack of water on the carbonyl group of the diimide (14), whilst the isobutyramide probably arises by hydrolysis of *N*-acetylisobutyramide. The acetone formed may arise by reaction of the isobutyronitrile radicals with residual oxygen, although the solutions were considered to be thoroughly degassed.

In contrast to the thermal results, irradiation ($\lambda > 350$ nm) of an 8×10^{-2} *M* solution of **2***h* in toluene containing water, followed by g.l.c. analysis, gave benzaldehyde (6%), tetramethylsuccinonitrile (9%), α-benzoylisobutyronitrile (14%), *N*-benzoylisobutyramide (3%), benzene (1%), and a number of other unidentified products. Isobutyronitrile and α-methylacrylonitrile were not analyzed for. The low yield of *N*-acylamide under these photochemical conditions may be due to the lower solubility of water in toluene at room temperature, or photochemical decomposition of the *N*-acylketenimine when formed, or a combination of these factors.

The cage effect in the decomposition of **2***h*

[3]The rate of decomposition of **2***l* was unaltered on addition of a small amount of water.

[4]No bibenzyl was detected.

[5]In a subsequent set of runs the amounts of α-benzoylisobutyronitrile and *N*-benzoylisobutyramide were determined to be 9 and 58%, respectively.

[6]The decarbonylation of benzoyl radicals generated from dibenzoyl diimide has been observed previously (10) and more recently studied quantitatively in the system:

$$C_6H_5CHO + I_2 \rightarrow C_6H_5ClO + HI \quad (11)$$

in toluene at 90° was measured by the iodine consumption method (15), and found to be 53 ± 3%. Simultaneously, the yield of ketone was measured in the presence of iodine and was observed to fall to 33% of its value in the absence of this scavenger. A similar discrepancy in cage effect determinations by iodine scavenging and product analysis has previously been reported (16).

In conclusion, the work described in this paper establishes that the *N*-benzoyl and *N*-acetyl α-cyanoalkyl diimides examined decompose by first-order kinetics to give radical intermediates. The major mode of recombination leads to *N*-acylketenimines which rapidly react with water present to give *N*-acylamides. *N*-Acetyldiimides decompose more rapidly than the *N*-benzoyl analogs, and variation of the alkyl group affects the rates in a similar, but attenuated, manner to that observed by Overberger, for his bis-α-cyanoalkyldiimides.

Experimental

Instruments used and related information are as reported previously (1, 2). Details of the kinetic method have also been given before (2).

A number of the *N'*-α-cyanoalkyl acid hydrazides and derived diimides have been prepared before; the following are new compounds:

1*b*: yield 50%; m.p. 103–104°; n.m.r.: δ 8.08 (br s, 1H), 4.85 (br s, 1H), 2.02 (s, 3H), 1.55–1.95 p.p.m. (br, 8H).

Anal. Calcd. for $C_8H_{13}N_3O$: C, 57.47; H, 7.84; N, 25.13. Found: C, 57.43; H, 7.82; N, 25.08.

2*b*: yellow oil, yield 92%; λ_{max} (C_6H_{12}) 395 nm (ε 36); n.m.r.: δ 2.30 (s, 3H), 1.8–2.6 p.p.m. (br, 8H).

1*c*: yield 16%; m.p. 94.5°; n.m.r.: δ 8.35 (br s, 1H), 5.02 (br s, 1H), 2.02 (s, 3H), 1.4–2.2 p.p.m. (br, 12H).

Anal. Calcd. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78; N, 21.52. Found: C, 61.74; H, 8.82; N, 21.86.

2*c*: yellow oil, yield 91%; λ_{max} (C_6H_{12}) 397 nm (ε 35); n.m.r.: δ 2.35 (s, 3H), 1.8–2.1 p.p.m. (br, 12H).

1*e*: yield 70%; m.p. 98–99°; n.m.r.: δ 7.20 (br d, J = 5 Hz, 1H), 7.25 (s, 5H), 5.0 (br d, J = 5 Hz, 1H), 3.53 (s, 2H), 0.8–2.0 p.p.m. (br, 10H).

Anal. Calcd. for $C_{15}H_{19}N_3O$: C, 70.01; H, 7.44; N, 16.33. Found: C, 69.69; H, 7.29; N, 16.13.

2*e*: yield 86%; m.p. 43°; n.m.r.: δ 7.27 (s, 5H), 3.93 (s, 2H), 1.90 p.p.m. (br, 10H).

Anal. Calcd. for $C_{15}H_{17}N_3O$: C, 70.56; H, 6.71; N, 16.46. Found: C, 70.52; H, 6.73; N, 16.32.

1*f*: yield 87%; m.p. 123–125°; n.m.r.: δ 7.2–8.17 (m, 6H), 5.2 (d, J = 5 Hz, 1 H), 1.2–2.2 p.p.m. (m, 12H).

Anal. Calcd. for $C_{15}H_{19}N_3O$: C, 70.01; H, 7.44; N, 16.33. Found: C, 70.12; H, 7.19; N, 16.39.

2*f*: yield 80%; m.p. 55.5–57°; λ_{max} (C_6H_{12}) 244 (ε 8600), 290 (sh, ε 1400), 321 (sh, ε 275), 408 nm (ε 50); n.m.r.: δ 7.4–8.0 (m, 5H), 1.46–2.4 p.p.m. (m, 12H).

1*g*: yield 50%; m.p. 124.5–126°, n.m.r.: δ 8.1–8.20 (d, J = 7 Hz, 1H), 7.23–7.90 (m, 5H), 5.24 (d, J = 7 Hz, 1H), 1.57–2.30 p.p.m. (br, 8H).

Anal. Calcd. for $C_{13}H_{15}N_3O$: C, 68.10; H, 6.59; N, 18.33. Found: C, 67.93; H, 6.68; N, 18.39.

2*g*: orange oil, yield 79%; λ_{max} (C_6H_{12}) 244 (ε 8600), 289 (sh, ε 1700), 323 (sh, ε 244), 408 nm (ε 46); n.m.r.: δ 7.47–8.0 (m, 5H), 1.67–2.67 p.p.m. (m, 8H).

1*i*: yield 80%; m.p. 144–146.5°, n.m.r.: δ 8.38 (s, 1H), 7.78 (d, J = 8.5 Hz, 2H), 6.87 (d, J = 8.5 Hz, 2H), 5.33 (br s, 1H), 3.81 (s, 3H), 1.1–2.37 p.p.m. (m, 10H).

Anal. Calcd. for $C_{15}H_{19}N_3O_2$: C, 65.91; H, 7.01; N, 15.37. Found: C, 66.15, H, 7.27; N, 15.26.

2*i*: yield 89%; m.p. 108.5–109°, λ_{max} (CH_3CN) 286 (ε 10 850), 406 nm (sh, ε 56), n.m.r.: δ 7.98 (d, J = 9 Hz, 2H), 7.02 (d, J = 9 Hz, 2H), 3.91 (s, 3H), 1.3–2.37 p.p.m. (m, 10H).

1*k*: yield 65%; m.p. 137–139°, n.m.r.: δ 8.36 (s, 1H), 7.70 (d, J = 8 Hz, 2H), 7.18 (d, J = 8 Hz, 2H), 5.27 (br s, 1H) 2.35 (s, 3H), 0.93–2.27 p.p.m. (m, 10H).

Anal. Calcd. for $C_{15}H_{19}N_3O$: C, 70.01; H, 7.44; N, 16.33. Found: C, 70.16; H, 7.19; N, 16.23.

2*k*: yield 79%; m.p. 80.5–81°; λ_{max} (C_6H_{12}) 255 (ε 10 500), 290 (sh, ε 3000), 321 (sh, ε 510), 409 nm (ε 47); n.m.r.: δ 7.83 (d, J = 8 Hz, 2H), 7.28 (d, J = 8 Hz, 2H), 2.43 (s, 3H), 1.53–2.36 p.p.m. (m, 10H).

1*j*: yield 87%; m.p. 160–162°, i.r. (Nujol): 3290 (w), 3225 (s), 1640 cm^{-1} (s); n.m.r.: not obtainable due to insolubility.

2*j*: yield 86%; m.p. 81.5–82.5, λ_{max} (C_6H_{12}) 259 (ε 13 000), 415 nm (ε 57), n.m.r.: δ 7.80 (d, J = 8 Hz, 2H), 7.50 (d, J = 8 Hz, 2H), 1.0–2.3 p.p.m. (br, 10H).

Anal. Calcd. for $C_{14}H_{14}ClN_3O$: C, 60.98; H, 5.12; N, 15.24. Found: C, 61.00; H, 5.13; N, 15.08.

Reaction of acylhydrazones with acetone cyanohydrin: a mixture of the hydrazone (4 mmol), acetone cyanohydrin (3 ml), methanol (7 ml), and either 10% aqueous sodium carbonate solution (0.5 ml) or triethylamine (0.25 ml) was refluxed overnight. The solvent was removed and the desired hydrazide obtained by crystallization (in some cases colored impurities were removed with charcoal).

A typical oxidation of an α-cyanoalkyl acid hydrazide was as follows: a solution of lead tetraacetate (0.92 g, 2.1 mmol) in dichloromethane (15 ml) was added to a solution of the hydrazide (2.0 mmol) in dichloromethane cooled to −20°. The solution was stirred at −20° for 1 h, then decanted from the insoluble lead salts, washed with ice-cold water (2 × 50 ml), cold saturated aqueous sodium bicarbonate solution (2 × 50 ml), ice-cold water (2 × 50 ml), dried, and the solvent was then removed at *ca.* 10°. The benzoyl and phenylacetyl diimides (with the exception of compounds **2***g* and **2***h*) were solids and were recrystallized from pentane. The remaining diimides were orange or yellow oils and were used as obtained; they were pure by n.m.r. and i.r.

α-Benzoyl isobutyronitrile was obtained by methylation of benzoylacetonitrile (17) with methyl iodide. The crude product (b.p. 73–78°/0.25 mm (lit. (18) b.p. 139°/10 mm)) was purified by preparative g.l.c. (Varian Aerograph Model 700) on a 20 ft × 1/4 in. SE-30 column. The pure material was a colorless liquid, λ_{max} (EtOH) 248 (ε 11 000), 282 nm (sh, ε 1100); ν_{max} 1694 cm^{-1}; n.m.r.: δ 1.71 (s, 6H), 7.4–8.4 p.p.m. (m, 5H).

α-Acetyl isobutyronitrile was prepared by methylation of α-acetylpropionitrile (19) with methyl iodide, b.p.

163–166° (lit. (20) b.p. 162–165°), λ_{max} (EtOH): 233 (ε 195), 281 nm (ε 26); ν_{max} 1725 cm^{-1}; n.m.r.: δ 2.43 (s, 3H), 1.53 p.p.m. (s, 6H). *N*-Benzoylisobutyramide, m.p. 155–156° (lit. (21) m.p. 154°) and *N*-acetylisobutyramide, m.p. 68–70° (lit. (22) m.p. 73–74°) were obtained by treatment of benzamide and acetamide, respectively, with isobutyryl chloride. Tetramethylsuccinonitrile was obtained from azoisobutyronitrile (23).

Product identifications were performed on a Varian Model 1740 Gas Chromatograph using the following 5 ft × 1/8 in. columns: 5% DEGSE on acid-washed 80/100 mesh Chromosorb W; 3% SE-30 on 100/120 mesh VarAport 30; 5% Carbowax 20 M on DMCS-treated 80/100 mesh Chromosorb W, and a 10 ft × 1/8 in. 80/100 mesh Chromosorb 103 column. For quantitative analyses, the detector was calibrated using solutions of known concentration of the products. Peak areas were measured with a planimeter.

For measurement of the cage effect, 2 ml aliquots of toluene, 0.037 *M* in **2***h* and 0.074 *M* in iodine were degassed and sealed in tubes, then heated for 8 h at 90°. The iodine concentration before and after was monitored at 498 nm. The cage effect is then given by [(moles diimide at $t = 0$) − (moles I_2 consumed)]/[moles diimide at $t = 0$]. The results given are the average of three determinations.

Photochemical studies were performed on degassed solutions of **2***h* in Pyrex tubes using a Hanovia #901C1 Xenon lamp, and passing the light through a Corning cso 52 filter.

The authors are grateful to Mr. A. Shum for excellent experimental assistance and to the National Research Council of Canada for financial support.

A Study of Solvent Effects on the ^{13}C Nuclear Magnetic Resonance Spectra of Cholesterol, Pyridine, and Uridine[1]

H. H. MANTSCH[2] AND IAN C. P. SMITH[3]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received November 17, 1972

The ^{13}C n.m.r. chemical shifts for cholesterol in five solvents are reported. All carbon atoms were subject to solvent effects of varying sign and magnitude. The chemical shifts in the solvent pair dioxane–chloroform 1:1 could be predicted on an additivity basis. Pyridine was studied in 24 solvents; the chemical shifts of all carbons were solvent-dependent. Solvent effects at positions β and γ were correlated, while those at position α bore no simple relation to those of the other carbons. A small isotope effect was noted on comparing the data for H_2O and ^2H_2O. Coupling between ^{13}C and ^{14}N was observed in some cases; its magnitude was solvent-dependent. Uridine was studied in four solvents. While all carbons were subject to solvent-induced shifts, evidence for specific solvent interaction at C-4, -5, -1′, and -2′ was obtained. An appreciable contribution to the relaxation of carbonyl C-2 and -4 from dipole–dipole interaction with the hydrogen on N-3 was observed. Solvent effects can result in scrambling and misassignment of ^{13}C resonances if care is not taken with choice of solvent.

Les déplacements chimiques du cholesterol en r.m.n. du ^{13}C ont été rapportés pour cinq solvants. Tous les atomes de carbone sont soumis à des effets de solvant d'amplitude et de signe variables. Les déplacements chimiques dans la paire de solvants dioxane:$CHCl_3$ 1:1 peuvent être prévus par additivité. La pyridine a été étudiée dans 24 solvants, les déplacements chimiques de tous les carbones sont fonction du solvant. Les effets du solvant sur les positions β et γ ont été reliés tandis qu'il n'existe aucune relation simple pour la position α. Un faible effet isotopique a été noté en comparant les données sur H_2O et ^2H_2O. Le couplage entre ^{13}C et ^{14}N a été observé dans certains cas, son amplitude dépend du solvant. L'uridine a été étudiée dans quatre solvants. Alors que tous les carbones subissent des déplacements induits par le solvant, une interaction spécifique du solvant a été mise en évidence pour les C-4, -5, -1′, et -2′. On a noté une contribution notable à la relaxation du carbonyle des C-2 et -4, à partir de l'interaction dipole–dipole avec l'hydrogène sur l'azote 3. Les effets de solvant peuvent masquer et conduire à une mauvaise attribution des pics de résonance du ^{13}C si le solvant n'a pas été choisi avec précaution.

[Traduit par le journal]

Can. J. Chem., **51**, 1384 (1973)

^{13}C n.m.r. spectra are in general much more informative than those of ^1H for structural analyses of complex molecules. Although the ^{13}C chemical shifts are most sensitive to structural changes, solvent effects cannot be minimized and those working with ^{13}C spectra should be aware of such effects. Carbon shieldings are apparently more solvent-sensitive than proton shieldings, yet relatively little is known about the dependence. Solvent effects on ^1H spectra have been studied extensively (1).

A few solute–solvent interactions have been investigated by ^{13}C n.m.r., particularly on carbon atoms bearing functional groups (substituents). Maciel and co-workers examined thoroughly the ^{13}C chemical shifts of carbonyl- and hydroxyl-bearing carbon atoms as a function of solvent (2–7). Solvent effects on the ^{13}C resonances of methyl iodide (8, 9), chloroform and carbon tetrachloride (10), acetonitrile and methyl isocyanide (11), and of monosubstituted benzenes (12, 13) have been reported. In general, a shift towards lower field was observed in more acidic solvents, paralleling the tendency of the solvents to form hydrogen bonds. For the carbonyl carbon this solvent shift could be interpreted reasonably in terms of an increased polarization of the C=X bond by hydrogen bonding. The shifts in aprotic solvents are more difficult to rationalize, but major contributions probably arise from polar and van der Waals interactions. For carbonyl-containing compounds, it has been concluded that the shifts in aprotic solvents reflect the carbonyl π-bond polarity (2, 3, 6).

For obtaining a ^{13}C n.m.r. spectrum, one usually attempts to achieve the highest concentration of compound possible, and therefore

turns to the most favorable solvent. A good example of this is the pioneering work of Reich *et al.* (14) on a wide series of sterols; mixtures of dioxane and chloroform of varying proportions had to be used to maximize solubility. Thus, it is vital at this stage in the development of ^{13}C n.m.r. to demonstrate carefully the types of solvent-induced chemical shift changes one can expect. We have done so for three structurally different compounds, cholesterol, pyridine, and uridine, in a wide variety of solvents.

Experimental

The natural abundance ^{13}C n.m.r. spectra were measured on a VARIAN XL-100-15 spectrometer operating in Fourier transform mode at 25.16 MHz with proton noise decoupling (4 KHz bandwidth). Data were accumulated in a VARIAN 620i computer using 5000 Hz spectral widths and 4096 data points (resolution of 0.1 p.p.m.). Data acquisition and pulse delay times were 0.4 and 0.8 s, respectively (cycle time 1.2 s).

Cholesterol (5-cholesten-3β-ol, Steraloids, Pawling, N.Y. recrystallized from methanol) and uridine (1-β-D-ribofuranosyl-uracil, Raylo Chemicals, Edmonton) were studied as 0.3 *M* solutions in spectrograde solvents; dry spectrograde pyridine was studied at 0.17 mol fraction in each solvent. The samples, in 8 mm o.d. inner Pyrex tubes, were studied in concentric 12 mm n.m.r. tubes containing deuterium oxide for the spectrometer field frequency lock. In this way susceptibility corrections were kept constant and the effects of solvent on internal references were avoided. The susceptibility correction between external TMS (D_2O in outer tube) and TMS in $CDCl_3$ is 1.3 p.p.m. (the internal reference resonates at lower field, higher frequency, than the external reference). Sample temperature was 37 °C (with complete proton decoupling). Increasing positive values of chemical shift indicate increasing frequency (decreasing magnetic field).

Results and Discussion

Cholesterol

The choice of the best solvent becomes particularly important if a large number of ^{13}C resonances are closely situated, as is the case for instance with the 27 carbon atoms in the steroid skeleton. Thus, it is unreliable to compare the absolute values of ^{13}C chemical shifts obtained in different solvents, since a scrambling of resonances is possible. This point is well demonstrated by the ^{13}C n.m.r. data for cholesterol. Cholesterol has the advantage for our purpose of possessing polar, nonpolar, and unsaturated carbon atoms, and a tentative assignment of the resonances has been made (14). For a few closely-situated signals alternative assignments are possible. For cholesterol such an ambiguity arises in the case of resonances separated by less than 0.5 p.p.m., namely C-4 and -13; C-16 and -24; C-10 and -22; C-8, -7, and -2; C-12 and -25; C-15 and -23; and C-27 and -26.

We used for this investigation strictly comparable conditions and the following solvents: benzene, pyridine, *p*-dioxane, chloroform, and carbon tetrachloride. The chemical shifts are shown in Table 1: They are also displayed diagrammatically in Fig. 1 for benzene, *p*-dioxane, and chloroform. The total range of the cholesterol spectrum is 130 p.p.m.

The most solvent-sensitive positions are the hydroxyl-bearing C-3 and the unsaturated C-6, both of which are shifted by about 1 p.p.m. to lower field in $CHCl_3$ and CCl_4 as compared to benzene, pyridine, or *p*-dioxane. The chemical shifts in CCl_4 and $CHCl_3$ are nearly identical, *i.e.* the differences are less than 0.1 p.p.m., always with those in $CHCl_3$ to slightly lower field. This difference is more pronounced, but still in the same direction, for C-6 (0.4 p.p.m.) and -3 (0.7 p.p.m.).

Similarly, benzene and pyridine can be grouped together, the differences of the individual chemical shifts (except for C-6, -5, and -3) are less than 0.2 p.p.m., with shifts in pyridine always to slightly lower field. The corresponding resonances in *p*-dioxane are generally intermediate between those in benzene and pyridine.

The saturated hydrocarbon skeleton is also sensitive to medium effects, although to a lesser extent than C-3 and -6. Most affected are the five CH_3 groups (C-18, -19, -21, -26, and -27). They are shifted by 0.7–0.8 p.p.m. to lower field in CCl_4 and $CHCl_3$ as compared to benzene, pyridine, and dioxane. Less affected are the CH_2 groups which in CCl_4 and $CHCl_3$ are also at lower field by 0.5–0.7 p.p.m., while the CH and the quaternary carbons are shifted by 0.3–0.5 p.p.m. to lower field.

In summary, it is clear that all resonances appear at lower field in CCl_4 or $CHCl_3$ as compared to benzene, pyridine, or *p*-dioxane, with quantitative differences for various groups; even the protected quaternary carbons are sensitive to medium effects. These solvent shifts are roughly additive, provided there is no strong interaction between the solvents. The experimental values obtained for a binary 1:1 mixture of chloroform and *p*-dioxane compare well within experimental error with the calculated mean values from chloroform and *p*-dioxane (Table 1).

*Expressed relative to external tetramethylsilane.
†The ^{13}C resonances of the individual solvent carbons in these solutions are as follows: C_6H_6: 128.7; C_6H_5N: 150.4 (α); 136.1 (γ) and 124.1 (β); $C_4H_8O_4$: 68.0; $CHCl_3$: 78.5; CCl_4: 97.3.

This shows that solvent mixtures could be used conveniently to separate closely-situated signals.

Pyridine

Pyridine provides a good model for heteroaromatic compounds. The natural abundance ^{13}C n.m.r. spectra were obtained for 1:5 mol fraction solutions of pyridine in 25 different solvents which were inert, highly basic, and very acidic. The ^{13}C chemical shifts were measured under strictly comparative conditions for the α (ortho), β (meta), and γ (para) carbon atoms and are shown in Table 2 for all 25 solvents. Because pyridine self-associates weakly through intermolecular hydrogen bonds, we choose pyridine in cyclohexane as a reference. The chemical shifts of pyridine in cyclohexane are given at the bottom of Table 2. Relative to pyridine in cyclohexane all other solvents produce a downfield shift of the resonances of the γ ($\Delta\delta_\gamma$) and β ($\Delta\delta_\beta$) carbon atoms and almost always a high field shift for the α carbon resonances ($\Delta\delta_\alpha$).

Most solvent-sensitive is C-γ with a maximum observed downfield shift ($\Delta\delta_\gamma$) of 14 p.p.m. in hydrobromic acid. A downfield shift is experienced also by C-β, which is less pronounced (maximum $\Delta\delta_\beta$ is 5.8 p.p.m.) and apparently related to $\Delta\delta_\gamma$ for the same solvent. There is a monotonic, although not strictly linear increase of $\Delta\delta_\beta$ with increasing $\Delta\delta_\gamma$ for most solvents and a nearly linear relationship for the seven protonated cations.

The solvent-induced upfield shifts of the α carbons ($\Delta\delta_\alpha$) (maximum −8.7 p.p.m. in trifluoroacetic acid) cannot be simply related to either $\Delta\delta_\beta$ or $\Delta\delta_\gamma$. The downfield shifts of the γ and β carbons appear to be related to charge polarization (inductive) effects dominated by hydrogen bonding to the lone pair nitrogen while the upfield shift of the α carbon is much

more subject to anisotropic magnetic field effects of the solvent as well, making any simple correlation difficult.

To demonstrate this, we could compare chemical shifts in CCl_4 and $CHCl_3$. The γ and β resonances appear in $CHCl_3$ at slightly lower field than in CCl_4 (0.8 and 0.4 p.p.m., respectively); this can be interpreted in terms of the known hydrogen-bonding properties of chloroform. If the effect on the γ and β resonances is only due to hydrogen bonding in a 1:1 complex the α carbon should experience an *upfield* shift of at least 0.5 p.p.m. (*vide infra*, effect of water) while in reality it moves *downfield* by 0.3 p.p.m. from cyclohexane. This suggests that effects other than hydrogen bonding must be considered for the α position.

The values in Table 2 show little correlation with the dipole moments or dielectric constants of the solvent. There is, however, a qualitative relation between the increase of Δδ (relative to the inert solvent cyclohexane) and the ability of the solvent molecules to participate in hydrogen bonding.

It is evident in Table 2 that for each of the α, β, and γ carbon atoms there are two distinct groupings of solvents. For most neutral and basic solvents the medium effects on pyridine are moderate *i.e.* shifts of 2.5 p.p.m. for the more sensitive γ position and about 1.5 p.p.m. for the β and α positions. Much larger shifts occur with acidic solvents which not only form hydrogen bonds to the nitrogen, but protonate the molecule. Although all seven protonating solvents were concentrated acidic solutions, there are individual differences in the magnitude of the corresponding Δδ's, reflecting either a different acidity or effects due to the anions.

Any desired intermediate shift can be obtained by combining two different solvents. Hydration effects, which also can be included here, were investigated by de Jeu on the ^{13}C and ^{17}O resonances of acetone (15) and by Pugmire and Grant on the ^{1}H and ^{13}C chemical shifts in pyridine (16). Increasing the water content from 0 (neat pyridine) to 50 mol % causes the ^{13}C resonances of the γ and β carbons to move downfield by 0.93 and 0.39 p.p.m., respectively, while those of the α carbons move upfield by 0.55 p.p.m. These data correspond to intermediate values between pyridine in cyclohexane and in water at 83 mol %; the shifts in the latter relative to those in the former solvent are 1.67 and 0.91 p.p.m. for the γ and β carbons, respectively, and −0.99 p.p.m. for the α carbon. Hydrogen bonds between water and the nitrogen lone pair electrons have been suggested as the most plausible explanation for the changes in chemical shifts upon dilution in water. The shifts associated with hydration are similar in sign to those of direct protonation, but of smaller magnitude.

It is interesting to notice the slight isotope effect on comparing the data for pyridine in H_2O and D_2O (Table 2). Although the α and β resonances are unaffected, the more sensitive γ resonance moves downfield 0.1 p.p.m. in D_2O. This must be due to the different hydrogen-bonding properties of the two hydrogen isotopes.

Because the resonances for the α and γ carbon atoms in pyridine are only 15.2 p.p.m. apart in cyclohexane solution, and because they vary with protonating power of the solvent ($\Delta\delta_\alpha$ moves upfield by as much as 9 p.p.m. and $\Delta\delta_\gamma$ moves downfield by as much as 14 p.p.m.), at certain solvent compositions there can be a scrambling of the resonances. Besides the differences in intensity in the proton-decoupled spectra, C-α can be distinguished from C-γ by the half band widths of the resonances, the former usually being broader due to coupling to the neighboring nitrogen.

Carbon–Nitrogen Couplings in Pyridine

Variations in $J_{^{13}C,^{1}H}$ due to the nature of the solvent have been observed (17). We report here some preliminary findings on a similar variation of $J_{^{13}C,^{14}N}$ and the relaxation time of the ^{14}N nucleus. Determination of carbon–nitrogen spin–spin couplings is considerably hampered by quadrupole broadening due to ^{14}N. In order to observe ^{13}C–^{14}N couplings, compounds must have nitrogen nuclei with long relaxation times. Such couplings have been observed in tetraalkylammonium ions (18); triplets (1:1:1) were observed in the proton-decoupled spectra of the tetramethyl- (J = 4.15 Hz) and the tetraethylammonium (J = 2.85 Hz) ions. These are in agreement with our data for pyridine in concentrated hydrobromic and hydrochloric acid where corresponding triplets (J = 4–5 Hz) can be observed. If the relaxation time of the nitrogen is shorter, as in most of the other solvents studied, only a broad band is seen for carbons coupled to the nitrogen. Some information is still available from the widths of the ^{13}C resonances. It is interesting to note that in pyridinium salts the magnitude of

TABLE 3. ^{13}C chemical shifts of uridine*

*Measured from 0.3 *M* solutions and expressed in p.p.m. *vs.* external tetramethylsilane.

$J_{^{13}C,^{14}N}$ seems to depend also on the nature of the anion, since the α resonances of pyridine in concentrated H_2SO_4 or concentrated H_3PO_4 have very small half band widths (< 2 Hz) and no coupling with nitrogen can be detected.

Uridine

Uridine is of interest because of its wide diversity of substituents and its biological importance. The ^{13}C chemical shifts of 0.3 *M* uridine in dimethylsulfoxide, pyridine, water, and deuterium oxide are given in Table 3. Some ^{13}C spectra are given in Fig. 2; assignments were made according to earlier studies (19–21).

Comparing the chemical shifts in H_2O and ^2H_2O we find no differences (beyond the limit of experimental accuracy, ±2.5 Hz) for carbons other than those bearing an hydroxyl group. The resonances of C-2′, -3′, and -5′ are shifted upfield by 5 Hz in ^2H_2O relative to H_2O. Thus, a small but detectable isotope effect is manifest.

The spectra of Fig. 2 demonstrate an interesting aspect of the relaxation by carbonyl C-2 and -4. Bearing no hydrogen, they must relax via mechanisms involving spin rotation, chemical shift anisotropy, or dipole–dipole coupling to distant magnetic nuclei. In Fig. 2*a* the resonances of C-2 and -4 are barely distinguishable. Replacement of ^2H_2O by H_2O results in an augmentation of the carbonyl resonances. In dimethylsulfoxide, where the uracil nitrogen at position 3 bears a hydrogen which cannot exchange with the solvent, the carbonyl resonances are much more intense. This demonstrates the importance of dipole–dipole interaction between the carbonyl ^{13}C atoms and the hydrogen on N-3.

On going to the non-aqueous solvents large changes in chemical shift of either sign can occur. Carbonyl C-4 shifts upfield by 2.7 p.p.m. whereas carbonyl C-2 moves upfield by only 0.6 p.p.m. These shifts are indicative of the decreased hydrogen-bonding expected in dimethylsulfoxide and pyridine, but the large differences between the effects on C-2 and -4 are surprising. Special

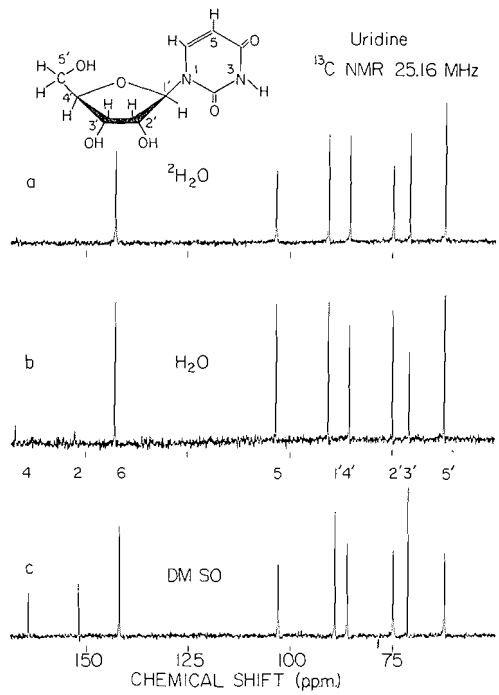

FIG. 2. ^{13}C n.m.r. spectra of 0.3 *M* uridine, pulse angle 90°, data acquisition time 0.4 s, pulse delay 0.8 s, in (*a*) ^2H_2O, p^2H = 7.4, 45 000 accumulations; (*b*) H_2O, p*H* = 7.0, 13 000 accumulations; (*c*) dimethylsulfoxide, 35 000 accumulations.

solvent influences at positions 2 and 4 have already been invoked to explain ^{13}C n.m.r. data (19). Similarly, a dramatic difference in solvent shifts at positions 5 and 6 is apparent. The resonance of C-6 moves −1.9 p.p.m. on going from H_2O (or ^2H_2O) to pyridine, whereas that of C-5 moves only −1.0 p.p.m.; on going to dimethylsulfoxide from H_2O (^2H_2O) the resonance of C-6 moves by −0.7 p.p.m.; and that of C-5 is unchanged. Evidence for specific solvent interactions at C-6 has been obtained earlier from ^1H (22) and ^{13}C (19) n.m.r.

Another surprising effect occurs at C-1′. On going from H_2O (or ^2H_2O) to pyridine a barely

For personal use only.

detectable upfield shift of the C-1′ resonance occurs. On going to dimethylsulfoxide, however, the C-1′ resonance moves −1.4 p.p.m. A specific interaction between dimethylsulfoxide and this region of the molecule must be present! This underlines the importance which must be attached to choice of solvent, particularly for biological molecules where the conformation under physiological conditions is the principal goal.

Pyridine and dimethylsulfoxide have equal effects on the resonance of C-4′, producing a downfield shift of 0.8 p.p.m. relative to H_2O (or ^2H_2O). In sharp contrast the resonance of C-2′, which bears an hydroxyl group, moves only slightly (+0.2 p.p.m.) in dimethylsulfoxide but substantially (+1.1 p.p.m.) in pyridine. This might at first glance be attributed to hydrogen-bonding of the hydroxyl group to pyridine, but the roughly equal influences of dimethylsulfoxide and pyridine (+0.6 and 0.4 p.p.m., respectively) on C-3′ argue against such a simple interpretation. Further rebuttal of this thesis comes from the opposite small shifts in the resonance of C-5′, which also has a contiguous hydroxyl group, noted for pyridine (−0.3 p.p.m.) and dimethylsulfoxide (+0.2 p.p.m.) relative to H_2O.

Thus, it is clear that the interactions between solvents and the various positions in uridine are very different. If assignments of the resonances of related compounds are to be made by reference to the known assignments, care must be taken to obtain spectra in the same solvent.

Conclusion

Solvent effects may be appreciable on all carbon atoms of a molecule, even at relatively protected positions such as the tertiary carbons of steroids. Specific solvent–solute interactions other than hydrogen bonding may be manifest. The solvent-induced shifts can be of such a character as to scramble resonances and thus alter assignments made in other solvents. In some cases coupling between ^{13}C and ^{14}N can be observed, and its magnitude is strongly solvent-dependent. Relaxation times of carbonyl carbons can be appreciably affected by dipole–dipole coupling to hydrogen attached to a neighboring atom.

The Solvent Exchange of $Co(CH_3NH_2)_5OH_2^{3+}$

A. G. SHAVER AND M. PARRIS

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received November 17, 1972

The rate constant for entry of ^{18}O from solvent water into $Co(CH_3NH_2)_5OH_2^{3+}$ ion was found to be 1.1×10^{-4} s^{-1} at 24.9 °C. The equilibrium constant for the formation of $Co(CH_3NH_2)_5Cl^{2+}$ ion was found to be 7.7 M^{-1}. From these data, the competition ratio between chloride ion and water for a hypothetical intermediate $Co(CH_3NH_2)_5$ was calculated as 2.5, unexpectedly high.

La constante de vitesse pour l'introduction de ^{18}O de l'eau utilisée comme solvant dans l'ion $Co(CH_3NH_2)_5OH_2^{3+}$ est de 1.1×10^{-4} s^{-1} à 24.9 °C. La constante d'équilibre pour la formation de l'ion $Co(CH_3NH_2)_5Cl^{2+}$ est de 7.7 M^{-1}. A partir de ces données, il est possible de déduire le taux de compétition entre l'ion chlorure et l'eau pour l'intermédiaire hypothétique $Co(CH_3NH_2)_5$; la valeur trouvée 2.5 est plus haute que prévue. [Traduit par le journal]

Can. J. Chem., **51**, 1392 (1973)

The acid and base hydrolyses of a series of chloropentakis(alkylamine)cobalt(III) complexes have been found (1) to be much accelerated by comparison with the corresponding ammine complex. Since the bulk of the experimental evidence appears to favor an interchange process of the dissociative type for cobalt(III) complexes' substitution reactions (2) this is not unexpected, and it was the possibility that a ligand-selective or dissociative mode of substitution might ultimately be detected in the case of these sterically-hindered complexes which prompted the present investigation.

Experimental

Chloropentakis(methylamine)cobalt(III) Chloride, $[Co(CH_3NH_2)_5Cl]Cl_2$

This was prepared as previously described (3).

Aquated Solution

Excess of an ice-cold solution 2 M in $AgClO_4$, 1 M in $HClO_4$ was added to 3 g chloropentakis(methylamine)-cobalt(III) chloride. The blue-violet slurry was shaken at 5 °C overnight in the dark, when the supernatant liquid became deep red and the AgCl precipitate corresponded to complete aquation. The excess Ag^+ was removed by potentiometric addition of concentrated HCl using Ag/AgCl and calomel/KNO_3 electrodes. The solution was diluted to 25 ml with $HClO_4/H_2O$, and finally was 0.395 M in $Co(CH_3NH_2)_5OH_2^{3+}$, 0.800 M in $HClO_4$. This, solution A, was subdivided into aliquots which were stored, sealed, frozen.

Aquopentakis(methylamine)cobalt(III) Trichloromercurate, $[Co(CH_3NH_2)_5OH_2]3HgCl_3$

To a small amount (1 ml) of the cold aquated solution (A) was added an equal amount of an ice-cold solution 4 M in HCl, 2 M in $HgCl_2$. Within 30 s red needles began to form and after 2 min the precipitation was virtually complete. The red crystals were air-dried for 15 min. Cobalt was analyzed by decomposing the salt in 10% NaOH, adding solid KI, and acidifying with 1 N HCl followed by thiosulfate titration, standardized with KIO_3. Methylamine was determined by steam distillation from a strongly alkaline solution into a standardized aliquot of H_2SO_4. It appeared from the analytical figures that a relatively rapid decomposition was occurring in the solid, evidenced also by the color change from pale red to the bright purple of the chlorocomplex upon standing at room temperature for 2 days. Carbon, hydrogen, and nitrogen analyses were carried out within 1 h of the sample precipitation by the Analytical Chemistry Research Branch of the Department of Agriculture, National Research Council of Canada, Ottawa.

Anal. Calcd. for $[Co(CH_3NH_2)_5OH_2]3HgCl_3$: C, 5.20; H, 2.34; N, 6.04; CH_3NH_2, 13.5; Co, 5.11. Found: C, 5.19; H, 2.5; N, 6.04; CH_3NH_2, 13.7; Co, 5.13.

Analysis of Isotopic Content in the Coordinated Water

In order to determine the conditions required completely to remove occluded water prior to removing ligated water, the freshly-prepared trichloromercurate (0.15 g) was loaded onto a continuously monitored, thermostatted, evacuable quartz spring balance (Worden Laboratories). After 20–30 min the evacuated sample was heated to 50 °C and the gas evolved condensed at 77 °K. The condensate was redistilled onto a clean sodium mirror at 77 °K and the volume of the non-condensible gas evolved upon warming measured with a Toepler pump. Figure 1 shows the weight record throughout these manoeuvres.

Rates of Exchange

The rate of exchange between solvent and aquo complex was determined as follows. Three stock solutions were used: Solution A: the aquated solution (see above), 0.395 M in $Co(CH_3NH_2)_5OH_2^{3+}$, 0.800 M in $HClO_4$, water of normal isotopic composition. Solution B: oxygen enriched water, nominally 5.29% ^{18}O, 0.07% ^{17}O, normalized H content, purchased from Yeda Research and Development Co., Rehovoth, Israel, batch No. 1857. Solution C: 4.0 M HCl, 2.0 M $HgCl_2$, water of normal isotopic composition.

One ml aliquots of solutions A and B were weighed

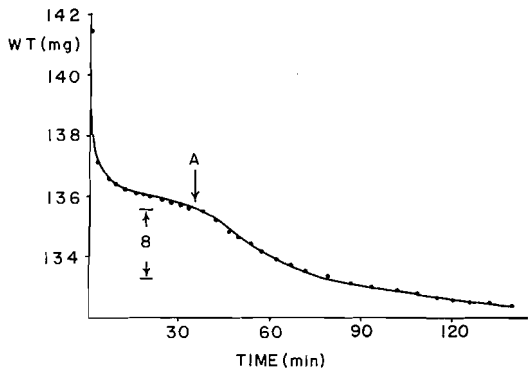

FIG. 1. Quartz spring balance record for $[Co(CH_3NH_2)_5OH_2]3HgCl_3$: *A*, 50 °C water-bath applied to sample compartment; *B*, calculated weight of ligated water.

separately and sealed into ampoules. These were thermostatted (24.9 °C) and at the commencement of exchange crushed together. A small sample (3 drops) of the mixture was taken in order to determine the ^{18}O content of the mixed waters.

To terminate exchange 2.0 ml ice-cold solution C was added and the mixture immediately quenched in ice. The solid was collected after 3 min, washed with a little cold methanol and air-dried for 5–10 min. A portion of the trichloromercurate (30 mg) was dried at room temperature, 3 μ for 30 min. Then the temperature was raised to 50 °C and the water evolved was condensed onto guanidine hydrochloride (B.D.H. 99%, recrystallized from ethanol) contained in a break-seal vial at 77 °K. The vial was sealed off and heated in a furnace at 250 °C for 10 h to convert the water completely to CO_2 (4). The CO_2 was transferred via the break-seal, dried with de-aerated concentrated H_2SO_4, and condensed into a sample bulb at 77 °K. The 3-drop sample of the solvent was similarly treated. The two CO_2 samples were used for mass-spectral analysis, using a Hitachi Perkin–Elmer R.M.U. 6D MS kindly made available by the University of Ottawa. Eight such experiments were performed, with exchange times 0.5, 1, 10, 15, 20, and 30 min.

Equilibrium Constant

The visible spectra of ten solutions, each about 10^{-2} *M* in chloropentakis(methylamine)cobalt(III) chloride, varying HCl ($2 \times 10^{-2} - 2 \times 10^{-1}$ *M*) and constant ionic strength (0.16, adjusted with $NaClO_4$ and $HClO_4$ to p*H* 2), were recorded while being thermostatted (25 °C) for 2–3 days. The absorbances at 363 and 515 mμ were measured using a Gilford 240 spectrophotometer when equilibrium had been attained. The extinction coefficients for the aquospecies were obtained by measuring the absorbance of a solution that had been completely aquated with excess $AgClO_4$ and then filtered.

Results

Figure 1 illustrates the loss of water from the $[Co(CH_3NH_2)_5OH_2]3HgCl_3$ for one typical experiment, where the initial rapid loss of occluded water is accompanied by a continuous slow loss in weight. Under these conditions there is a continuous deposition of $HgCl_2$ upon the walls of the spring balance so that a direct determination of water from the observed weight change is not practicable. For this reason, the indirect determination of water by means of the sodium reaction was undertaken.

TABLE 1. Water determination in $[Co(CH_3NH_2)_5OH_2]3HgCl_3$

	% H_2O	
Expt. No.	Found	Calculated
1	1.6	1.6
2	1.3	1.6
3	1.6	1.6
4	1.4	1.6

Table 1 shows the results obtained for four such water determinations, and it is apparent that the break in the curve of Fig. 1 is caused by complete loss of the ligating water.

In order to determine k, the rate-constant for the exchange reaction,

$$[1]\quad CoL_5{}^{16}OH_2^{3+} + {}^{18}OH_2 \underset{}{\overset{k}{\rightleftharpoons}} CoL_5{}^{18}OH_2^{3+} + {}^{16}OH_2$$

the oxygen isotope effect has been neglected. Considering the complex ions present, the total concentration of aquo species is represented by a and the concentration of aquo species containing the ^{18}O label by x

$$[CoL_5{}^{16}OH_2{}^{3+}] + [CoL_5{}^{18}OH_2{}^{3+}] = a$$

$$[CoL_5{}^{18}OH_2{}^{3+}] = x$$

For the solvent,

$$[{}^{16}OH_2] + [{}^{18}OH_2] = b$$

$$[{}^{18}OH_2] = y$$

The observed rate at which solvent ^{18}O exchanges with ligated ^{16}O is proportional to the fraction of the isotopes in each species

$$\frac{dx}{dt} = k\frac{y}{b}\frac{(a-x)}{a} - k\frac{(b-y)}{b}\frac{x}{a}$$

$$= k\frac{(ay - bx)}{ab}$$

Since

$$y - y_\infty = x_\infty - x$$

TABLE 2. Mass spectrometric ^{18}O assay

Time (min)	$\frac{[\text{mass } 46]}{[\text{mass } 44]}$ (%)	$\frac{[\text{mass } 45]}{[\text{mass } 44]}$ (%)	R_T	R_∞	α (%)	α_∞ (%)
0.5	1.60	1.25	63.3		0.784	
	6.50	1.26		15.6		3.10
1.0	1.79	1.25	56.6		0.876	
	6.53	1.26		15.5		3.12
10.0	3.28	1.20	30.8		1.59	
	5.91	1.25		17.1		2.84
15.0	3.41	1.23	29.7		1.66	
	6.89	1.40		14.7		3.29
20.0	3.56	1.26	28.4		1.73	
	6.56	1.40		15.5		3.12
30.0	4.25	1.25	23.8		2.06	
	6.70	1.31		15.1		3.21

and

$$x_\infty/y_\infty = a/b$$

$$\frac{dx}{dt} = \frac{k(a+b)(x_\infty - x)}{ab}$$

or $$\ln\left(\frac{x_\infty}{x_\infty - x}\right) = k\frac{(a+b)t}{ab}$$

In these exchange experiments $b \simeq 55.5\ M$, $a \simeq 0.2\ M$, that is, $a \ll b$.

$$\therefore \ln\left(\frac{x_\infty}{x_\infty - x}\right) = \frac{kt}{a}$$

Let α be the ^{18}O atom fraction within the aquo species. This was determined from the 44/46 ratio, corrected for the 45/44 ratio

$$R = \frac{[\text{mass } 44]}{[\text{mass } 46]}\left(1 + \frac{[\text{mass } 45]}{[\text{mass } 44]}\right)$$

R values are listed in Table 2.

$$\alpha = \frac{[^{18}OH_2]}{[^{18}OH_2] + [^{16}OH_2]} = \frac{1}{2R+1}$$

Initially, the ^{18}O content in the salt was the normal 0.2%. After complete exchange it is the same as in the solution, *viz.* about 2.5%. $x/a = \alpha$ and in particular $x_\infty/a = \alpha_\infty$

$$\therefore \ln\left(\frac{x_\infty}{x_\infty - x}\right) = -\ln\left(\frac{\alpha_\infty - \alpha}{\alpha_\infty}\right)$$

$$= k_{obs}t$$

where

$$k_{obs} = k/a$$

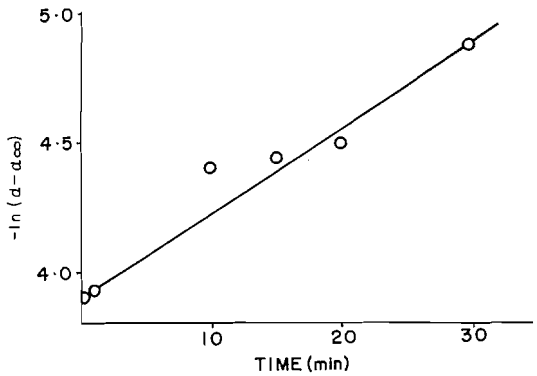

FIG. 2. Exchange of coordinated water for $Co(CH_3NH_2)_5OH_2^{3+}$: $\alpha = {}^{18}O$ atom fraction in $[Co(CH_3NH_2)_5OH_2]3HgCl_3$ precipitate; $\alpha_\infty = {}^{18}O$ atom fraction in solvent.

Figure 2 shows $-\ln(\alpha - \alpha_\infty)$ plotted *vs.* time for 0.20 M solutions, leading to a corrected value of the rate constant $k = 1.1 \times 10^{-4}\ s^{-1}$ at 24.9 °C.

The equilibrium constant for anation

$$[2] \quad CoL_5OH_2^{3+} + Cl^- \overset{K}{\rightleftharpoons} CoL_5Cl^{2+} + OH_2$$

was determined by the Newton–Arcand method (5)

$$K = \frac{1}{[Cl^-]}\frac{\varepsilon - \varepsilon_a}{\varepsilon_c - \varepsilon}$$

where ε = apparent molar extinction coefficient of the complex in the equilibrated solution, and ε_a and ε_c are the extinction coefficients of the aquo and chloro complex respectively. Table 3 contains values of K over a range of $[Cl^-]$. The average K is 7.7 M^{-1}.

*Ionic strength = 0.16, temperature 25 °C.
†Based on $\varepsilon_a = 63.3$, $\varepsilon_c = 47.3$, $K_{calc} = 7.7$ M^{-1}.

Discussion

The values obtained for the solvent exchange and the anation equilibrium constants make it possible to calculate the competition ratio between water and chloride ion for the hypothetical intermediate CoL_5 of reaction 3

$$[3] \qquad CoL_5OH_2^{3+} \underset{k_{+a}}{\overset{k_{-a}}{\rightleftharpoons}} CoL_5 \underset{k_{-c}}{\overset{k_{+c}}{\rightleftharpoons}} CoL_5Cl^{2+}$$

Since

$$\frac{[CoL_5]}{[CoL_5OH_2{}^{3+}]} = \frac{k_{-a}}{k_{+a}}$$

and

$$\frac{[CoL_5Cl^{2+}]}{[CoL_5]} = \frac{k_{+c}}{k_{-c}}[Cl^-]$$

the equilibrium constant for reaction 2

$$K = \frac{k_{-a}}{k_{-c}}\frac{k_{+c}}{k_{+a}}$$

A competition ratio may be defined as

$$c = \frac{k_{+c}}{k_{+a}} = \frac{k_{-c}}{k_{-a}}K$$

Given reaction 3, k_{-c} is the aquation rate constant and equals 3.7×10^{-5} (6, 7), k_{-a} is the oxygen exchange rate constant and equals 1.1×10^{-4}, while K is the anation equilibrium constant and equals 7.7.

The competition ratio c is 2.6, which is a factor of ten larger than those previously measured for similar compounds (8). The values of k_{-c} given in refs. 6 and 7 agree quite closely. It is likely that the k_{-a} obtained presently is an upper limit, for the inclusion of any occluded water in the mass-spectroscopic analysis would produce an apparently faster exchange rate. In any event the ratio k_{-c}/k_{-a} is 0.34 for the methylamine complexes which is almost identical to the ratio 0.31 for the corresponding ammines (9, 10). The high value for c derives mainly from the high value for K. The same constant for the ammine is about 1.25 (8), and it might be expected that K for the methylamine complex should be smaller than this, due to steric crowding. While ion pairing would indeed increase the apparent K, the observed K should now *decrease* with increasing $[Cl^-]$. In fact K, though not particularly reliable, shows a small *increase* with $[Cl^-]$, while ion pairing should be less in the case of the bulkier methylamine complex.

The larger equilibrium constant is consistent with the difficulty of obtaining an aquo salt. It is also consistent with the competition experiments reported in ref. 1. During base hydrolysis of the chlorocomplexes, N_3^- and NCS^- competed more effectively with water for the pentakis(methylamine)cobalt(III) than for the pentaamminecobalt(III) species which may indicate that an intermediate which is longer-lived because of steric interaction is at the same time necessarily more selective in its reactants. The increased steric interaction is also consistent with the rather lower rates of bridged electron transfer between chloropentakis(methylamine)cobalt(III) ion and Fe(II) (11).

The Pyrolysis of Trimethylthallium and Evaluation of $D[(CH_3)_2Tl—CH_3]$

S. J. PRICE,[1] J. P. RICHARD,[2] AND R. C. RUMFELDT
Department of Chemistry, University of Windsor, Windsor 11, Ontario

AND

M. G. JACKO
Bendix Corporation, Detroit, Michigan

Received October 12, 1972

The pyrolysis of trimethylthallium has been studied in a mercury free toluene carrier flow system (452–536 °K, total pressure 6.7–39.3 mm, contact time 0.9–5.1 s, 5.4–90.2% decomposition). In a vessel cleaned with boiling concentrated HNO_3 and coated by decomposing 0.1 g $Tl(CH_3)_3$ no heterogeneous reaction could be detected. The extent of reaction measured by product analysis (CH_4, C_2H_6, $C_6H_5C_2H_5$) assuming three CH_3 per $Tl(CH_3)_3$ undergoing reaction 1

[1] $$Tl(CH_3)_3 \rightarrow Tl(CH_3)_2 + CH_3$$

is in agreement with that determined by analysis for undecomposed alkyl. Least squares analysis of the first order rate constants gives

$$\log k_1(s^{-1}) = 15.10 - (36\,400 \pm 600)/2.3RT$$

Under the conditions used the activation energy should be a good approximation to $D[(CH_3)_2Tl—CH_3]$.

Oxidation of Tl on the surface of Tl_2O causes a marked increase in the rate. Omission of the coating step following cleaning has no effect on the rate based on undecomposed alkyl but initially causes a sharp drop in the yield of products, particularly ethane.

La pyrolyse du triméthylthallium a été étudiée dans un système en continu avec du toluène sans mercure comme gaz vecteur (452–536 °K, pression totale 6.7–39.3 mm, durée de contact 0.9–5.1 s, décomposition de 5.4–90.2%). Dans un réacteur lavé à l'acide nitrique concentré et bouillant puis recouvert par la décomposition de 0.1 g de $Tl(CH_3)_3$, aucune réaction hétérogène n'a pu être détectée. Le cours de la réaction suivi par l'analyse des produits (CH_4, C_2H_6, $C_6H_5C_2H_5$) en supposant trois méthyles par $Tl(CH_3)_3$ dans la réaction 1:

[1] $$Tl(CH_3)_3 \rightarrow Tl(CH_3)_2 + CH_3$$

est en accord avec celle déterminée par l'analyse de l'alkyle intact. L'analyse par la méthode des moindres carrés des constantes de vitesse du premier ordre conduit à:

$$\log k_1(s^{-1}) = 15.10 - (36\,400 \pm 600)/2.3RT$$

Dans les conditions utilisées, l'énergie d'activation pourrait être une bonne approximation pour $D[(CH_3)_2Tl—CH_3]$. L'oxydation superficielle de Tl en Tl_2O provoque un accroissement notable dans la vitesse. Si le réacteur n'a pas été traité après lavage acide, aucun effet ne se manifeste sur la vitesse en alkyle non décomposé mais le rendement initial en produits (en particulier l'éthane) subit une chute notable.

[Traduit par le journal]

Can. J. Chem., 51, 1397 (1973)

Introduction

The only previously reported study of the pyrolysis of trimethylthallium was also carried out in a toluene carrier system (1). The reaction was first order and the rate constants were measured in approximately the high pressure limit. The decomposition was shown to be approximately 80% heterogeneous in an untreated vessel and 14–27% heterogeneous in a vessel pretreated with hot 50% HF. Attempts to reduce the observed heterogeneity below this level were unsuccessful. An estimate of the homogeneous reaction in the pretreated vessel was given as

$$\log_{10} k(s^{-1}) = 10.8 - 27\,400/2.3RT$$

The excessively low A-factor suggests that either the extent of the heterogeneous reaction was underestimated or that the reaction measured was not the simple decomposition of $Tl(CH_3)_3$ to give $Tl(CH_3)_2 + CH_3$.

This study was undertaken with the purpose of isolating the homogeneous release of the first CH_3 group in order to arrive at a reliable value for $D[(CH_3)_2Tl{-}CH_3]$.

Experimental

Materials

(*a*) The trimethylthallium used was purchased from Alfa Inorganics Inc. (Catalog No. 78116). After thorough degassing by bulb-to-bulb distillation *in vacuo*, it was stored under its own vapor pressure in tinted glass storage vessels. Vapor pressure data at 0 and 22.8 °C gave 0.67 and 4.19 mm of Hg and a melting point of 38.4 °C all in excellent agreement with previous results (2).

Trimethylthallium was handled and stored in the dark as it is sensitive to light.

(*b*) Toluene from sulfonic acid (Eastman Organic X325) was used. Gas chromatographic analysis detected traces of higher hydrocarbons (xylenes, ethyl benzene). These were reduced to less than 40 p.p.m. by a fractional distillation in which a large tail fraction was discarded. Prior to use, the toluene was dried by refluxing over sodium metal for 24 h and then degassed by bulb-to-bulb distillation.

Apparatus and Procedure

The toluene carrier system used was similar to that previously employed in studying $In(CH_3)_3$ (3). Toluene vapor is allowed to flow over the $Tl(CH_3)_3$ thus utilizing what may be described as a pick-up system. A weighed sample of the alkyl is distilled into a U-tube equipped with a by-pass through which the toluene vapor flows during the pre-run. After a 5 min flow of toluene part of the toluene flow is diverted through the thermostated U-tube and the run is continued until 5 min after the last visible deposit has disappeared. In the majority of runs some toluene condenses on the $Tl(CH_3)_3$ but the extent to which this occurs has no measurable effect on the observed rate constants. Direct injection of the $Tl(CH_3)_3$ vapor into the toluene stream is precluded by the limited thermal stability of this alkyl (appreciable decomposition above 90 °C (4)).

The apparatus was operated in total darkness except for two shielded 2 W lamps which were used to take manometer readings. The reaction vessel had a volume of 135 cc. The tests for surface effects were carried out in a vessel packed with small quartz tubes. This vessel had a volume of 100 cc and a surface to volume ratio 14 times that of the unpacked vessel. Both vessels were treated with hot fuming nitric acid before use.

The residual acid was baked out under vacuum after the vessels were installed in the system. Preconditioning by decomposition of about 0.1 g $Tl(CH_3)_3$ was then carried out.

The gaseous products were analyzed using a Perkin–Elmer model 154 gas chromatograph equipped with a 1/4 in. × 6 ft silica gel column. The column was maintained at 80 °C and a helium flow rate of 20 cm³ per min was used.

The liquid products which condensed along with the toluene in an acetone – Dry Ice trap were analyzed using a Perkin–Elmer model 800 gas chromatograph equipped with a 150 ft × 0.02 in. i.d. open tubular column coated with poly(propylene glycol). (Isothermal operation at 60 °C, nitrogen carrier flow rate 10 cm³ per min.)

Analysis of the undecomposed alkyl, which also condensed in the acetone – Dry Ice trap, could not be performed by gas chromatography due to decomposition of the alkyl within the injection port. The undecomposed alkyl was determined by volumetric analysis as $Tl(CH_3)_2OH$ (4). The procedure involved treating the products in the acetone – Dry Ice trap with several portions of distilled H_2O and titrating the resulting solution of $Tl(CH_3)_2OH$ with standard 0.1 N H_2SO_4. Loss of toluene and liquid products to the aqueous solution due to their solubilities was negligible. This procedure when carried out with known weights of alkyl always gave a recovery of better than 99%.

Results and Discussion

The results obtained from the pyrolysis of $Tl(CH_3)_3$ in a mercury free toluene carrier system are best discussed in the two separate sections.

(*a*) *Results Obtained when a Preconditioned Reaction Vessel is Used and Air is Excluded both During and Between Runs*

Results obtained under these conditions are given in Tables 1–2 and form the basis of the

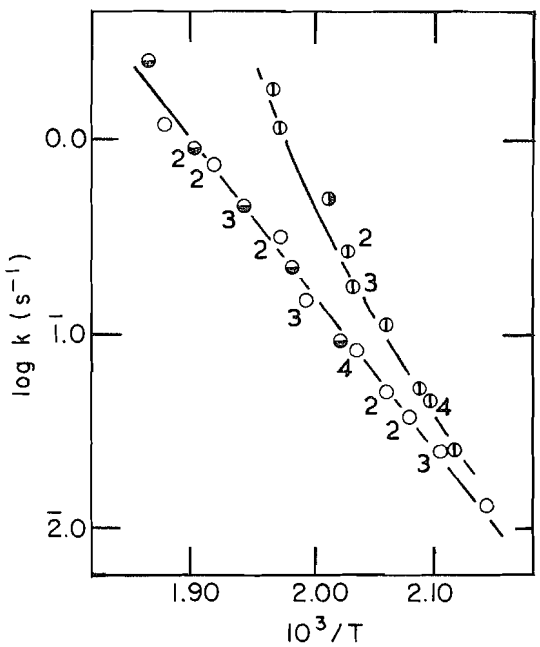

FIG. 1. Arrhenius plots for the pyrolysis of trimethylthallium. Upper curve: Tl_2O on surface. Lower curve: conditioned vessel. Numbers represent the number of runs averaged to obtain the given point. Individual points used to obtain average points for upper curve considerably scattered (see Table 4 obtainable from the Depository of Unpublished Data). Half filled points represent runs in the packed reaction vessel.

lower curve in Fig. 1. They may be discussed in terms of the following mechanism

[1] $Tl(CH_3)_3 \rightarrow Tl(CH_3)_2 + CH_3$

[2] $Tl(CH_3)_2 \rightarrow TlCH_3 + CH_3$

[3] $Tl\,CH_3 \rightarrow Tl + CH_3$

[3a] $2TlCH_3 \rightarrow Tl(CH_3)_2 + Tl$

[4] $CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2$

[5] $2CH_3 + M \rightarrow C_2H_6 + M$

[6] $CH_3 + C_6H_5CH_2 \rightarrow C_6H_5C_2H_5$

[7] $2\,C_6H_5CH_2 \rightarrow$ Dibenzyl

plus the usual reactions leading to trace quantities of xylenes.

Based on the reported Arrhenius parameters for $\dot{H}$ abstraction by CH_3 from related metal alkyls (11) k_8 should be approximately equal to

[8] $CH_3 + Tl(CH_3)_3 \rightarrow CH_4 + (CH_3)_2TlCH_2$

0.23 to 0.55 k_4 at the temperatures used in the present work. With the toluene-to-alkyl ratio used (>35:1) a maximum of 1.5% of the CH_4 may be attributed to reaction 8 and in general no more than 0.5% should be formed this way. This leads to the conclusion that no more than 0.2% of the alkyl reacts via reaction 8 (in most cases probably less than 0.1%). Reaction 8 is therefore of negligible importance with respect to both alkyl removal and methane formation.

Values of k_1 were calculated from the first order equation

$$k = \frac{2.303}{t_c} \log \frac{1}{1 - x}$$

where t_c is the average residence time in the reaction zone. The fraction decomposed, x, may be calculated in two ways. From product analysis

$$x = \frac{\text{moles } (CH_4 + C_6H_5C_2H_5) + 2 \times \text{moles } C_2H_6}{3 \times \text{moles } (Tl(CH_3)_3 \text{ used})}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From alkyl recovery

$$x = \frac{\text{g of alkyl used} - \text{g of alkyl recovered}}{\text{g of alkyl used}}$$

The product distribution in Table 1 and the agreement shown in Table 2 between the percent decompositions calculated from product analysis and from alkyl recovery, indicate that reaction 1 is the rate controlling step in a sequence of reactions that produces three methyl radicals and free thallium. The simple linear nature of the Arrhenius plot of $k_4/k_5^{1/2}$ shown in Fig. 2 is further supporting evidence (3).

After a number of runs the reaction vessel was removed in a helium atmosphere. A bluish-grey deposit was present in the reaction zone. Samples scraped from the walls and subjected to EDTA analysis (5) showed that the deposit was essentially pure thallium (99.7% Tl found).

All contact times used were such that thermal equilibrium and diffusion problems should not be significant (6).

The negligible effect on k_1 of a variation by a factor of 2.5 in concentration in the packed vessel at 515 °K and by a factor of 3.3 in the unpacked vessel at 502 °K indicates that the decomposition is first order. The agreement in Fig. 1 between the experiments in the packed vessel and those in the unpacked vessel shows that no detectable surface reactions are occurring. Least squares analysis of the points used to obtain this plot gives

$$\log_{10} k_1 = 15.10 - (36\,400 \pm 600)/2.3RT$$

From the runs at 491 °K, it is apparent that above approximately 14 mm of Hg total pressure the values of k_1 are close to the high pressure limiting values. The observed activation energy, 36.4 kcal mol^{-1}, should be a reasonable measure of $D[(CH_3)_2Tl{-}CH_3]$.

No studies on the determination of the heat of formation of trimethylthallium have been reported. From trends in the periodic table, a value of 32 ± 3 kcal mol^{-1} may be estimated for the mean metal–carbon bond dissociation energy in trimethylthallium. Using this value and the same arguments used in the study of similar alkyls (7–9), it appears that methylthallium may decompose via reaction 3*a*. However, if the mean bond energy is taken as 29 kcal mol^{-1} (the lower limit of the estimated value), the same arguments lead to the conclusion that methylthallium could decompose via reaction 3. Obviously no significant conclusion can be drawn until the heat of formation of $Tl(CH_3)_3$ becomes available.

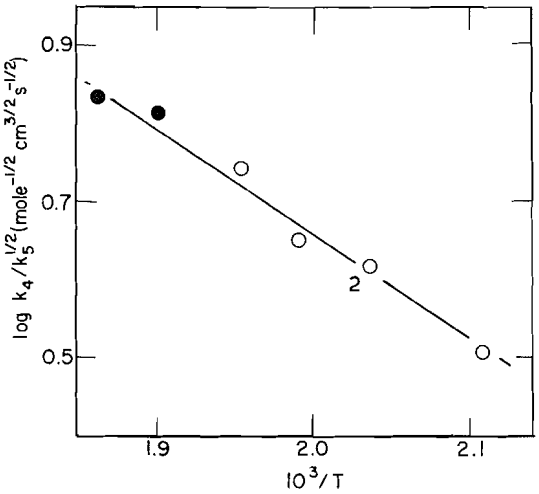

FIG. 2. Arrhenius plot of $k_4/k_5^{1/2}$ for runs at 20–24 mm total pressure. Points shown cover the range 7–90% decomposition. Filled circles: runs in packed reaction vessel.

(b) Results Obtained when Air is Admitted while a Coating of Thallium is Present in the Reaction Zone

The upper curve in Fig. 1 and the results in Table 1 show the behavior observed upon admission of air. It must be emphasized that this catalytic behavior is only observed if thallium metal is present in the reaction zone at the time the air is admitted. The observed effect may be gradually reduced by carrying out further runs while air is carefully excluded. From a practical point of view, however, it is much faster and more economical in terms of alkyl consumption simply to remove the vessel, clean it with boiling concentrated HNO_3, remove the residual acid under vacuum (600 to 700 °K), and precondition by decomposing about 0.1 g of alkyl in the reaction zone. If the preconditioning step is omitted, rate constants based on residual alkyl analysis (k_m) are unaffected. The k_g value is initially very low but increases toward the k_m value over a number of runs. One possible explanation is that a very fast reaction occurs between CH_3 and residual NO on the surface of the reaction zone. This would be consistent with the almost zero yield of C_2H_6 in the first run after cleaning. If such a reaction is occurring the

CH_3NO, whether it exists as such or as the formaldehyde oxime (CH_2:NOH), either remains absorbed on the wall of the reaction zone or reaches the acetone – Dry Ice trap at the outlet of the furnace in a form not detectable by our usual analytical procedures.

As previously mentioned when the reaction vessel is removed in an inert atmosphere following runs in which air has been carefully excluded, a bluish-grey deposit of thallium is found in the reaction zone. Following runs in which catalysis is observed, this deposit is black indicating the probable presence of Tl_2O. The results of solubility tests (10) are in agreement with this.

Finally it is perhaps interesting to note that although the product distribution shown for catalytic runs is not much different from that shown in the homogeneous pyrolysis, comparison of $k_4/k_5^{1/2}$ values shows some enhancement of methane formation in the catalytic system. With the relatively low yields of CH_4 in this work and the extent of scatter in $k_4/k_5^{1/2}$ values it is probably inadvisable to try to draw any formal conclusions. However, it seems possible that over the range of catalytic runs done, some 10–50% of the CH_4 arises from surface reactions with the remainder being formed in the usual way by reaction 4 and associated processes.

This work has been supported by a grant from the National Research Council of Canada.

The Synthesis of Some Analogs of the Hallucinogen 1-(2,5-Dimethoxy-4-methylphenyl)-2-aminopropane (DOM)

RONALD T. COUTTS AND JERRY L. MALICKY

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta

Received October 31, 1972

The synthesis of a series of 4-substituted 1-(2,5-dimethoxyphenyl)-2-aminopropanes, in which the 4-substituent is Br, Cl, I, NO_2, NH_2, and NHAc, is described. These compounds are analogs of 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane (DOM), a known hallucinogen. A synthesis of *N*-(2,5-dimethoxy-4-methylphenethyl)hydroxylamine, the *N*-hydroxy homolog of DOM, is also reported. Brief reference is made to the preliminary pharmacology of these compounds.

La synthèse d'une série de (diméthoxy-2,5 phényl)-1 amino-2 propanes substituées en 4 par Br, Cl, I, NO_2, et NHAc, est décrite. Ces composés sont des analogues de la (diméthoxy-2,5 méthyl-4 phényl)-1 amino-2 propane (DOM), hallucinogène connu. Une synthèse de la *N*-(diméthoxy-2,5 méthyl-4 phénétyl) hydroxylamine, homologue *N*-hydroxyle de la DOM, a été aussi rapportée. Une référence brève a été faite sur la pharmacologie préliminaire de ces composés. [Traduit par le journal]

Structure-activity relationship studies of potential psychotomimetic phenethylamines have shown (1–3) that the most potent psychoactive drugs of this chemical class are ring-methoxylated phenylisopropylamines. The compounds possessing greatest psycho-activity are 1-(2,5-dimethoxy-4-substituted-phenyl)-2-aminopropanes (**1**). Five such compounds (**1***a–e*) have been prepared and pharmacologically evaluated (3–7). Of these, the 4-methyl analog (DOM) (**1***c*) has gained wide publicity as the potent major constituent of the 'street hallucinogen', STP. The related compound, 1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane (**1***e*) has only recently been evaluated and has been found to induce in humans a mescaline-like action more profound than that of an equal amount of DOM (6). Five other bromo-isomers were also evaluated in this study but all were less active than **1***e*. Ho *et al.* (8) described some compounds which retained the 2,4,5-trisubstituted-phenyl moiety of DOM (*i.e.* **2**; R^1, R^2, and R^3 = H or CH_3) and found that psychoactivity (disruption of rat behavior) was also retained.

The studies just described suggest that a 2,5-dimethoxy-4-substituted-phenyl substituent might be important for psychotomimetic activity. For this reason, the preparation of additional compounds of general structure **1** was undertaken.

The synthetic approach most commonly employed to prepare 1-phenyl-2-aminopropanes involves the synthesis of the corresponding phenylnitropropenes which are then reduced by means of lithium aluminum hydride in ether or tetrahydrofuran (*e.g.* 5, 8) (Scheme 1). For the preparation of compounds **1***e–g* by this method, the aldehydes **3***a–c* were required but none of the various synthetic methods attempted proved satisfactory. Formylation of 1-bromo and 1-chloro-2,5-dimethoxybenzene using phosphorus oxychloride and *N*-methylformanilide (5) did produce the aldehydes **3***a* and *b* but yields were very low and purification proved impossible. The synthetic approach summarized in Scheme 1, therefore, could not be used.

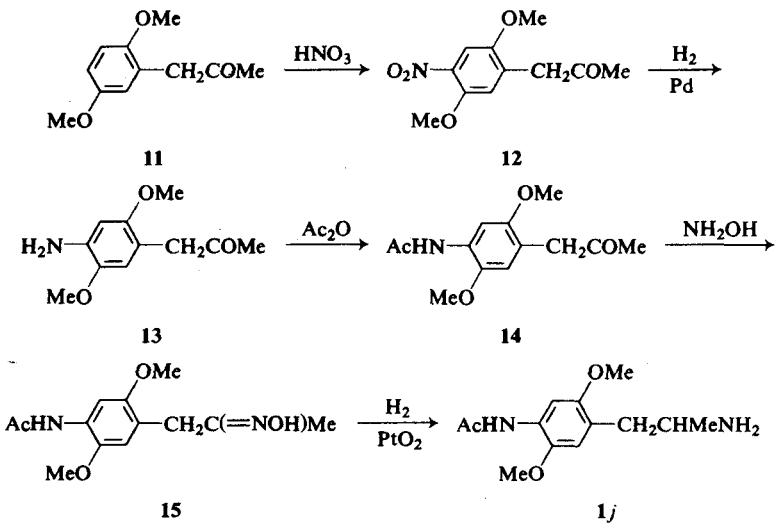
SCHEME 2

The halogenated compounds (**1***e–g*) were prepared successfully from 1-(2,5-dimethoxyphenyl)-2-aminopropane (**4**) which was readily synthesized from 2,5-dimethoxybenzaldehyde using Scheme 1. The reaction sequences employed are summarized in Scheme 2. Acetylation of **4** followed by nitration of the acetate (**5**) gave *N*-acetyl-1-(2,5-dimethoxy-4-nitrophenyl)-2-aminopropane (**6**) in excellent yield. Verification that nitration had occurred at the 4-position was obtained from n.m.r. spectral data. The two aromatic protons came to resonance at δ 6.97 and 7.41 and appeared as singlets, indicative of a para arrangement.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 3

The nitro-compound (**6**) when subjected to catalytic hydrogenation readily incorporated hydrogen and *N*-acetyl-1-(4-amino-2,5-dimethoxyphenyl)-2-aminopropane hydrochloride (**7**) was isolated in good yield. *N*-Acetyl-1-(4-chloro-2,5-dimethoxyphenyl)-2-aminopropane (**8***a*) and the related 4-iodo-compound (**8***b*) were successfully prepared by subjecting the amine (**7**) to the Sandmeyer reaction, whereas the 4-bromo-compound (**9**) was obtained by the action of bromine water on *N*-acetyl-(2,5-dimethoxyphenyl)-2-aminopropane (**5**). The aromatic protons again appeared as singlets in the n.m.r. spectrum of **5**, which confirmed that the bromine atom occupied the 4-position in the ring.

A suitable means of hydrolyzing the amide group of compounds **9**, **8***a*, **8***b*, **6** and **7**, thereby completing the syntheses of **1***e–i* respectively, was sought. In most instances, these aliphatic amides proved resistant to hydrolysis by means of hydrochloric acid, sulfuric acid, or aqueous sodium hydroxide. Various reaction temperatures and times were tried and reagent concentrations were altered, but the amines were usually isolated in low yields, if at all. Eventually, a procedure employing ethylene glycol and sodium hydroxide (9) was used and reasonable yields of the 2-aminopropanes **1***e–h* were recovered.

The hydrolysis of *N*-acetyl-1-(4-amino-2,5-dimethoxyphenyl)-2-aminopropane (**7**) was also successful but the product (**1***i*) could not be purified by crystallization. An alternative procedure, in which 1-(2,5-dimethoxy-4-nitrophenyl)-2-aminopropane (**1***h*) was catalytically reduced, produced the pure amine (**1***i*).

After a preliminary pharmacological screening of compounds **1***e–i*, (see below), it became necessary to prepare and evaluate 1-(4-acetamido-2,5-dimethoxyphenyl)-2-aminopropane (**1***j*). The synthetic route summarized in Scheme 2 cannot be used for this compound in view of the severe hydrolytic conditions necessary to cleave the aliphatic amide group. The most obvious alternative synthetic route involved the preparation of 4-acetamido-2,5-dimethoxyphenylacetone oxime (**15**) which would be expected (10) to reduce catalytically to the desired compound. The series of reactions leading to the synthesis of **1***j* is shown in Scheme 3. The starting material, 2,5-dimethoxyphenylacetone (**11**), together with the related oxime (**11***a*) were the products recovered from a catalytic reduction of 1-(2,5-dimethoxyphenyl)-2-nitropropene-1 (**10**) (see eq. 1).

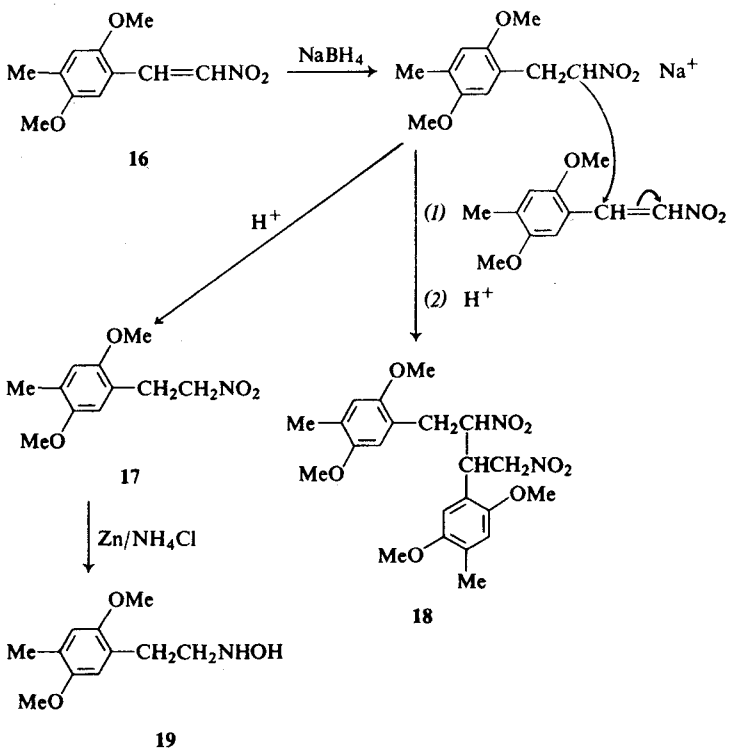
For personal use only.



SCHEME 4

Nitration of 2,5-dimethoxyphenylacetone with nitric acid in glacial acetic acid gave the 4-nitro-derivative (**12**). The position at which nitration occurred was again confirmed by n.m.r. spectral data. Catalytic reduction of **12** followed by acetylation gave the intermediates **13** and **14** respectively in good yields. The preparation of the oxime (**15**) was somewhat difficult. Catalytic hydrogenation of this material yielded the desired amine (**1***j*). Each of the compounds illustrated in Scheme 3 was characterized by its elemental analysis and by i.r. spectral data.

One additional compound related to DOM was required in the present study, *i.e.* the *N*-hydroxy-derivative, *N*-(2,5-dimethoxy-4-methylphenethyl)-hydroxylamine (**19**). The method employed in its synthesis is outlined in Scheme 4. 1-(2,5-Dimethoxy-4-methylphenyl)-2-nitroethene (**16**), the starting material, was obtained from the interaction of 2,5-dimethoxy-4-methylbenzaldehyde and nitromethane (see Scheme 1). Reduction of this styrene with sodium borohydride gave two compounds which were easily separated because of differences in their solubilities in ethanol. The ethanol-soluble product, $C_{11}H_{15}NO_4$, gave i.r. and n.m.r. spectra which established its structure as 1-(2,5-dimethoxy-4-methylphenyl)-2-nitroethane (**17**).

Shechter *et al.* (11) found that the sodium borohydride reduction of nitroalkenes was accompanied by a concurrent reaction of the Michael-type in which the primary reduction product, the nitroalkane salt, added to the initial nitroalkene to yield a 1,3-dinitroalkane. The ethanol-insoluble product from the reduction of the nitrostyrene (**16**), therefore, was suspected to be 2,4-di-(2,5-dimethoxy-4-methylphenyl)-1,3-dinitrobutane (**18**). The elemental analysis of the compound and its i.r. spectrum were consistent with this deduction. The molecular ion in its mass spectrum was located at *m/e* 448 which corresponds to the molecular weight of the dinitroalkane (**18**).

An ethanolic solution of 1-(2,5-dimethoxy-4-methylphenyl)-2-nitroethane (**17**) was heated with zinc and ammonium chloride and yielded the required *N*-(2,5-dimethoxy-4-methylphenethyl)-hydroxylamine (**19**).

Preliminary Pharmacology

The 2-aminopropanes prepared in this study were subjected to a simple preliminary pharmacological screening to provide some guidelines for the synthesis of other compounds and to select compounds for more detailed pharmacological testing. The effects of an oral dose of each compound on male rats (150–500 g) were compared with those caused by an oral dose of DOM (10 mg/kg) which reliably caused hypersalivation, papillary dilation, retraction of scrotum, loss of orientation reflexes, analgesia, hypomotility, and walking with a slinking gait. This crude test revealed that compounds **1***e*, *f*, and *h* (10 mg/kg) were equipotent with DOM but that compound **1***i* was devoid of activity. Compound **1***g* was not evaluated. The inactivity of **1***i* suggested it, or its active metabolite, was not reaching the brain so the acetamide (**1***j*) was prepared and evaluated. It, too, was devoid of activity. The nature of the substituent at C-4 in the phenyl ring undoubtedly has a profound effect on pharmacological activity.

A 60 mg/kg intraperitoneal dose of compound **19** in male rats caused hypersalivation, pupil dilation, loss of orientation reflex, and a reduction in motility, and caused the rat to crouch and walk backwards following a circular path when objects were placed in front of it.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. I.r. spectra were recorded on a Beckman IR-10 spectrophotometer as Nujol mulls and n.m.r. spectra were taken on a Varian A-60D spectrometer. Tetramethylsilane was used as the internal standard. Mass spectra were recorded by Dr. A. M. Hogg and his associates at the Department of Chemistry, University of Alberta, Edmonton, with an A.E.I. MS-9 or MS-12 mass spectrometer at an ionizing potential of 70 eV using the direct probe technique. Elemental analyses were determined at the Department of Chemistry, and at the Faculty of Pharmacy and Pharmaceutical Sciences (by Mr. W. Dylke), University of Alberta, Edmonton.

1-(2,5-Dimethoxyphenyl)-2-nitropropene-1

A solution of 2,5-dimethoxybenzaldehyde (10.0 g), ammonium acetate (4.0 g), and nitroethane (6.8 g) in glacial acetic acid (50 ml) was heated on a boiling water-bath for 3 h, then the solvent was evaporated. The residue which remained was suspended in water and extracted with chloroform. Evaporation of the chloroform left the title compound (11.2 g). Crystallization from ethanol gave m.p. 73–75°; no lit. (12) m.p. reported; i.r. ν_{max} 1300, 1502 (NO_2), 1645 (C=C) cm^{-1}.

Anal. Calcd. for $C_{11}H_{13}NO_4$: C, 59.18; H, 5.87; N, 6.28. Found: C, 58.99; H, 5.88; N, 5.95.

1-(2,5-Dimethoxyphenyl)-2-aminopropane Hydrochloride (4)

A solution of 1-(2,5-dimethoxyphenyl)-2-nitropropene-1 (17.0 g) in dry ether (500 ml) was added slowly to a stirred suspension of lithium aluminum hydride (12.0 g) in the same solvent (150 ml). When the addition was complete, the mixture was refluxed for 20 h, cooled, and the excess lithium aluminum hydride was decomposed by the careful addition of water. The resulting suspension was filtered and the solid which was removed was washed with ether. The combined ether solutions were dried ($MgSO_4$), then saturated with dry hydrogen chloride. This precipitated the title compound (16.3 g), m.p. 114–116° (from ethanol); lit. (13) m.p. 111.5–112.5°; i.r. ν_{max} 1600; 2000–2550 (weak bands) ($\overset{+}{N}$—H) cm^{-1}.

N-Acetyl-1-(2,5-dimethoxyphenyl)-2-aminopropane (5)

Acetic anhydride (40 ml) was added to a solution of 1-(2,5-dimethoxyphenyl)-2-aminopropane hydrochloride (5.0 g) and sodium acetate (25.0 g) in water (300 ml) and the mixture was shaken vigorously until the exothermic reaction ceased. The cooled solution was filtered and gave the title compound (4.2 g), m.p. 104–105.5° when crystallized from ethanol. The i.r. ν_{max} 1635 (C=O); 3100 (NH) cm^{-1}.

Anal. Calcd. for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90. Found: C, 65.75; H, 8.13; N, 5.90.

N-Acetyl-1-(2,5-dimethoxy-4-nitrophenyl)-2-aminopropane (6)

A solution of 70% nitric acid (50 ml) in water (400 ml) was added to a solution of *N*-acetyl-1-(2,5-dimethoxyphenyl)-2-aminopropane (40.0 g) and sodium nitrite (0.5 g) in glacial acetic acid (400 ml). The solution was stirred for 4 h, cooled, then diluted with water (400 ml). The title compound (42.1 g) precipitated and, when crystallized from ethanol, had m.p. 166–168°. The i.r. ν_{max} 1350, 1515 (NO_2); 1640 (C=O); 3310 (NH) cm^{-1}. The n.m.r. ($CDCl_3$) δ 1.16 (d, 3H, J = 7, α-CH_3); 1.88 (s, 3H, $COCH_3$); 2.85 (d, 2H, J = 7, CH_2); 3.85 (s, 3H, OCH_3); 3.90 (s, 3H, OCH_3); 4.0–4.5 (m, 1H, CH); 5.66–5.91 (m, 1H, NH); 6.97 (s, 1H) and 7.41 (s, 1H) (aromatic protons).

Anal. Calcd. for $C_{13}H_{18}N_2O_5$: C, 55.31; H, 6.43; N, 9.92. Found: C, 55.26; H, 6.63; N, 9.92.

N-Acetyl-1-(4-amino-2,5-dimethoxyphenyl)-2-aminopropane Hydrochloride (7)

A solution of *N*-acetyl-1-(2,5-dimethoxy-4-nitrophenyl)-2-aminopropane (39.0 g) in ethanol was hydrogenated over 10% palladium–charcoal (1.0 g) until the theoretical amount of hydrogen was absorbed (3 days). The catalyst was removed and the filtrate evaporated. The residue was suspended in 5% sodium hydroxide solution (100 ml) and extracted with chloroform (3 × 100 ml). The combined chloroform solution was evaporated and the solid which remained was dissolved in dry ether. When dry hydrogen chloride was passed through this solution, the title compound (31.5 g) precipitated. It had m.p. 237–239° when crystallized from ethanol–ether. The i.r. ν_{max} 1635 (C=O); 2450–2600 (weak bands) ($\overset{+}{N}$—H) cm^{-1}.

Anal. Calcd. for $C_{13}H_{21}ClN_2O_3$: C, 54.07; H, 7.33; N, 9.70. Found: C, 54.18; H, 7.40; N, 9.78.

N-Acetyl-1-(4-chloro-2,5-di aminopropane (8a)

A solution of *N*-ace phenyl)-2-aminopropane h chloric acid (15 ml) and w To this stirred solution, s (10 ml) was slowly added w of diazonium salt was ad solution of cuprous chlori (9 ml). The reaction mixt room temperature, then h title compound (2.8 g) pre 152° when crystallized fro (C=O); 3310 (NH) cm^{-1}; J = 7, α-CH_3); 1.85 (s, 3H CH_2), 3.79 (s, 3) and 3. groups); 4.20 (m, 1H, C 6.76 (s, 1H) and 6.90 (s, 1H

1-(4-Bromo-2,5-dimetho Hydrochloride (1e)

(*a*) A suspension of oxyphenyl)-2-aminoprop (60 ml) and water (60 ml) for 18 h during which tim dissolved. Unreacted sta the filtrate evaporated Crystallization from et pound as a colorless so m.p. 198–199°.

N-Acetyl-1-(4-chloro-2,5-dimethoxyphenyl)-2-aminopropane (8a)

A solution of *N*-acetyl-1-(4-amino-2,5-dimethoxyphenyl)-2-aminopropane hydrochloride (5.0 g) in hydrochloric acid (15 ml) and water (30 ml) was cooled to 0°. To this stirred solution, sodium nitrite (1.4 g) in water (10 ml) was slowly added with cooling. This cold solution of diazonium salt was added slowly with shaking to a solution of cuprous chloride (2.5 g) in hydrochloric acid (9 ml). The reaction mixture was allowed to come to room temperature, then heated to 70° and cooled. The title compound (2.8 g) precipitated. It gave a m.p. 150–152° when crystallized from ethanol. The i.r. ν_{max} 1630 (C=O); 3310 (NH) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.11 (d, 3H, $J = 7$, α-CH_3); 1.85 (s, 3H, $COCH_3$); 4.60 (d, 2H, $J = 7$, CH_2), 3.79 (s, 3) and 3.81 (s, 3) (overlapping OCH_3 groups); 4.20 (m, 1H, CH); 5.96 (broad s, 1H, NH); 6.76 (s, 1H) and 6.90 (s, 1H) (aromatic protons).

Anal. Calcd. for $C_{13}H_{18}ClNO_3$: C, 57.46; H, 6.68; N, 5.16. Found: C, 57.35; H, 6.48; N, 5.33.

N-Acetyl-1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (8b)

The diazonium salt of **7** (5.0 g) was prepared as described immediately above and to the cooled (0°) solution was added gradually a solution of potassium iodide (8.0 g) in water (10 ml). The reaction was allowed to warm to room temperature and left until the evolution of nitrogen ceased. The dark brown viscous semi-solid which separated was dissolved in ethanol. On cooling, the title material (1.97 g) separated. It had a m.p. 167–168° when crystallized from ethanol. The i.r. ν_{max} 1645 (C=O); 3310 (NH) cm^{-1}.

Anal. Calcd. for $C_{13}H_{18}INO_3$: C, 42.99; H, 4.99; N, 3.86. Found: C, 43.00; H, 5.01; N, 3.77.

N-Acetyl-1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane (9)

A slight excess of bromine water was added to a solution of *N*-acetyl-1-(2,5-dimethoxyphenyl)-2-aminopropane (3.0 g) in dioxane (30 ml), and the solution was stirred for 6 h. The solvent was removed, leaving the title compound (3.0 g) which was crystallized from ethanol and had a m.p. 153–155°. The i.r. ν_{max} 1630 (C=O); 3310 (NH) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.16 (d, 3, $J = 7$, α-CH_3); 1.90 (s, 3, $COCH_3$); 4.41 (d, 2H, $J = 7$, CH_2); 3.81 (s, 3) and 3.85 (s, 3) (OCH_3 groups); 3.91–4.50 (m, 1H, CH); 5.91 (broad s, 1H, NH); 6.80 (s, 1H) and 7.07 (s, 1H) (aromatic protons.) Mass spectrum: 317 (5) ($C_{13}H_{18}{}^{81}BrNO_3$); 315 (5) ($C_{13}H_{18}{}^{79}BrNO_3$) *m/e* (% relative abundance).

Anal. Calcd. for $C_{13}H_{18}BrNO_3$: C, 49.38; H, 5.74; N, 4.43. Found: C, 49.38; H, 5.85; N, 4.29.

1-(4-Bromo-2,5-dimethoxyphenyl)-2-aminopropane Hydrochloride (1e)

(*a*) A suspension of *N*-acetyl-1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane (2.5 g) in hydrochloric acid (60 ml) and water (60 ml) was heated at reflux temperature for 18 h during which time most of the *N*-acetyl compound dissolved. Unreacted starting material was removed and the filtrate evaporated to give a yellow solid (1.7 g). Crystallization from ethanol–ether gave the title compound as a colorless solid, m.p. 195–196°. Reported (7) m.p. 198–199°.

(*b*) *N*-Acetyl-1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane (1.5 g) was added to a solution of sodium hydroxide (5.0 g) in water (25 ml) and ethylene glycol (50 ml) and the mixture was heated under reflux for 15 h then cooled. The solution was extracted with chloroform and the combined chloroform extracts evaporated. The resulting solid was dissolved in 5% hydrochloric acid (15 ml) and the solution filtered. The title compound (0.85 g) was the product obtained, m.p. 197–198° after crystallization from ethanol–ether. The i.r. ν_{max} 1610, 1980, 2010–2740 ($\overset{+}{N}$—H) cm^{-1}.

Anal. Calcd. for $C_{11}H_{17}BrClNO_2$: C, 42.53; H, 5.52; N, 4.51. Found: C, 42.86; H, 5.72; N, 4.29.

1-(4-Chloro-2,5-dimethoxyphenyl)-2-aminopropane Hydrochloride (1f)

The title compound (0.46 g), m.p. *193–194.5°* (from ethanol–ether) was obtained when *N*-acetyl-1-(4-chloro-2,5-dimethoxyphenyl)-2-aminopropane (1.5 g) was treated as described for the synthesis of **1e**, method *b*. The i.r. ν_{max} 1610, 2010, 2500–2640 ($\overset{+}{N}$—H) cm^{-1}.

For personal use only.

charcoal (0.7 g). After approximately 3 h, the uptake of hydrogen ceased. The mixture was filtered and the solution evaporated, leaving a light yellow oil. A solution of this oil in chloroform (100 ml) was extracted with 5% hydrochloric acid (3 × 50 ml) and the aqueous layer discarded. The oil which remained following evaporation of the chloroform was distilled under reduced pressure and yielded two fractions. The first (2.3 g), b.p. 100° (0.07 mm Hg) was 2,5-dimethoxyphenylacetone (reported (12) b.p. 95° (1.25 mm)). The i.r. ν_{max} 1710 (C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 1.95 (s, 3H, CH_3); 3.45 (s, 2H, CH_2); 4.25 (s, 6, $(OCH_3)_2$); 6.00–6.62 (m, 3, aromatic protons).

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.26. Found: C, 67.87; H, 7.25.

The second fraction (2.4 g), b.p. 150–170° (0.13–0.15 mm), was dissolved in ether and the solution saturated with dry hydrogen chloride. The resulting precipitate (1.2 g) was crystallized from acetone–ether to yield 2,5-dimethoxyphenylacetone oxime hydrochloride, m.p. 94–97°. The i.r. ν_{max} 2560 ($\overset{+}{N}$—H) cm^{-1}; mass spectrum: 209 (55), $C_{11}H_{15}NO_3$; 178 (100), $C_8H_{10}NO_2$ *m/e* (% relative abundance).

Anal. Calcd. for $C_{11}H_{16}ClNO_3$: C, 53.55; H, 6.96; N, 5.68. Found: C, 53.87; H, 6.75; N, 5.98.

*2,5-Dimethoxy-4-nitrophenylacetone (**12**)*

To a solution of 2,5-dimethoxyphenylacetone (4.0 g) and sodium nitrite (0.03 g) in glacial acetic acid (25 ml), stirred and cooled to 5°, was slowly added a solution of 80% nitric acid (6 ml) in water (15 ml). Stirring for 2 h, then dilution with water (100 ml) caused the precipitation of the title compound (3.71 g) which, when crystallized from ethanol, had m.p. 77–79°. The i.r. ν_{max} 1350, 1515 (NO_2); 1730 (C=O) cm^{-1}; n.m.r. ($CDCl_3$) δ 2.23 (s, 3H, CH_3); 3.80 (s, 2H, CH_2); 3.85 (s, 3H) and 3.92 (s, 3H) (OCH_3 groups); 6.98 (s, 1H) and 7.45 (s, 1H) (aromatic protons).

Anal. Calcd. for $C_{11}H_{13}NO_5$: C, 55.23; H, 5.48; N, 5.86. Found: C, 55.00; H, 5.42; N, 5.93.

*4-Amino-2,5-dimethoxyphenylacetone Hydrochloride (**13**)*

A solution of 2,5-dimethoxy-4-nitrophenylacetone (3.5 g) in ethanol (100 ml) and hydrochloric acid (5 ml) was hydrogenated at room temperature and normal pressure under 10% palladium–charcoal (1.0 g) until the theoretical amount of hydrogen was absorbed. The catalyst was removed and the filtrate evaporated *in vacuo* to give a colorless solid (3.1 g). Crystallization from ethanol–ether afforded the title compound, m.p. 195–198°. The i.r. ν_{max} 1711 (C=O); 1980, 2550 ($\overset{+}{N}$—H) cm^{-1}.

Anal. Calcd. for $C_{11}H_{16}ClNO_3$: C, 53.77; H, 6.55; N, 5.70. Found: C, 53.85; H, 6.40; N, 6.03.

*4-Acetamido-2,5-dimethoxyphenylacetone (**14**)*

This compound (2.4 g) was prepared from the amine (**13**, 3.0 g) by the method described for the preparation of compound **5**. The title compound, when crystallized from ethanol, had m.p. 138–140°. The i.r. ν_{max} 1670 (amide C=O); 1710 (ketone C=O); 3390 (NH) cm^{-1}.

Anal. Calcd. for $C_{13}H_{17}NO_4$: C, 62.13; H, 6.82; N, 5.58. Found: C, 61.81; H, 6.67; N, 5.92.

*4-Acetamido-2,5-dimethoxyphenylacetone Oxime (**15**)*

A solution of 4-acetamido-2,5-dimethoxyphenylacetone (2.0 g) and hydroxylamine hydrochloride (2.0 g) in ethanol (30 ml) and pyridine (5 ml) was heated at 75° for 7 h. The solvent was removed *in vacuo* and water (30 ml) was added to the residue. Extraction with chloroform (3 × 30 ml) followed by evaporation of the chloroform gave a pale yellow oil which solidified (1.4 g) on triturating with ether. Crystallization from ethanol yielded the title compound, m.p. 141–144°. The i.r. ν_{max} 1660 (C=O); 3250 broad peak (OH) cm^{-1}.

Anal. Calcd. for $C_{13}H_{18}N_2O_4$: C, 58.63; H, 6.81; N, 10.52. Found: C, 58.63; H, 7.01; N, 10.29.

*1-(4-Acetamido-2,5-dimethoxyphenyl)-2-aminopropane Hydrochloride (**1j**)*

A solution of 4-acetamido-2,5-dimethoxyphenylacetone oxime (1.0 g) in ethanol (50 ml) and hydrochloric acid (1.0 ml) was hydrogenated at room temperature and 50 p.s.i. pressure in the presence of platinum dioxide (0.1 g) for 14 h (arbitrary). Evaporation of the filtrate gave a solid which, when crystallized from ethanol and ether gave the title compound (0.72 g), m.p. 249–250°. The i.r. ν_{max} 1600, 2500–2700 ($\overset{+}{N}$—H); 1660 (C=O); 3250 (NH) cm^{-1}.

Anal. Calcd. for $C_{13}H_{21}ClN_2O_3$: C, 54.07; H, 7.33; N, 9.70. Found: C, 54.35; H, 7.58; N, 9.64.

Sodium Borohydride Reduction of 1-(2,5-dimethoxy-4-methylphenyl)-2-nitroethene

The title compound (8) (15.0 g, m.p. 116°), dissolved in dioxane, was added to a stirred solution of sodium borohydride (5.0 g) in water (25 ml) and dioxane (25 ml) at such a rate that decolorization occurred between additions. The final pale yellow solution was stirred for 1 h, cooled, and diluted with hydrochloric acid until effervescence ceased. The residue which remained after evaporation of the solvent was suspended in water (100 ml) and extracted with chloroform (100 ml). The chloroform extract was evaporated to give a dark brown oil which solidified (10.5 g) when triturated with cold ethanol. Crystallization from ethanol gave an insoluble product (2.8 g) and an ethanol-soluble compound (5.9 g), m.p. 67–70°. The latter was 1-(2,5-dimethoxy-4-methylphenyl)-2-nitroethane (**17**). The i.r. ν_{max} 1370, 1550 (NO_2) cm^{-1}; n.m.r. ($CDCl_3$) δ 2.21 (s, 3H, CH_3); 4.91 (t, 2H, J = 8, CH_2); 4.58 (t, 2H, J = 8, CH_2); 6.63 (s, 1H) and 6.68 (s, 1H) (aromatic protons).

Reactions of Thiyl Radicals. XI. Further Investigations of Thiol–Disulfide Photolyses in the Liquid Phase[1]

DONNA D. CARLSON AND ARTHUR R. KNIGHT

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received October 10, 1972

The photolysis of C_2H_5SH liquid at 2537 Å has been shown to give H_2 and $C_2H_5SSC_2H_5$ at equal rates with a quantum yield of 0.25. The photolysis of ethanethiol – methyl disulfide liquid mixtures leads, via a chain reaction involving propagation by attack of thiyl radicals on the disulfide S—S bond, to the formation with high quantum efficiency of CH_3SH, $C_2H_5SSC_2H_5$ and, as an intermediate that is consumed after long exposures, $CH_3SSC_2H_5$. The net result of the sequence of exchange processes is the essentially irreversible conversion of the methyl disulfide into methanethiol. The same overall reaction occurs thermally at room temperature, but the rate is appreciably less than that of the photochemical process. The quantum yields of formation of the unsymmetrical disulfides arising from the photochemically initiated exchange reaction in equimolar mixtures of CH_3SSCH_3 + n-$C_3H_7SSC_3H_7$ and $C_2H_5SSC_2H_5$ + n-$C_3H_7SSC_3H_7$ have been shown to be 6.9 and 4.4, compared to 355 for CH_3SSCH_3 + $C_2H_5SSC_2H_5$ mixtures. In all three types of system examined in this investigation all thiyl radicals can be accounted for stoichiometrically on the basis of exchange and combination reactions alone, indicating negligible disproportionation of these species in condensed phase.

La photolyse de C_2H_5SH liquide à 2537 Å conduit à H_2 et $C_2H_5SSC_2H_5$ à des vitesses égales, avec un rendement quantique de 0.25. La photolyse de mélanges liquides d'éthane thiol et de disulfure de méthyle conduit (via une réaction en chaîne impliquant une propagation par attaque de radicaux thiyles sur la liaison disulfure) à CH_3SH avec un bon rendement quantique et à $C_2H_5SSC_2H_5$, avec comme intermédiaire $CH_3SSC_2H_5$ qui est consommé au bout d'un certain temps. Le résultat net de la séquence des processus d'échange est la conversion essentiellement irréversible du disulfure de méthyle en méthane thiol. La même réaction globale se produit thermiquement à la température ambiante mais avec une vitesse inférieure à celle du processus photochimique. Les rendements quantiques de formation de disulfures dissymétriques issus de l'échange initié photochimiquement, de mélanges équimoléculaires de CH_3SSCH_3 + n-$C_3H_7SSC_3H_7$ et $C_2H_5SSC_2H_5$ + n-$C_3H_7SSC_3H_7$, ont pour valeurs respectives 6.9 et 4.4 comparées à la valeur 355 pour les mélanges CH_3SSCH_3 + $C_2H_5SSC_2H_5$. Dans les trois types de systèmes examinés au cours de cette étude, tous les radicaux thiyles rendent compte de la stoechiométrie des seules réactions d'échange et de combinaison, indiquant une disproportionation négligeable de ces espèces en phase condensée. Can. J. Chem., **51**, 1410 (1973)

Introduction

In a previous investigation in this laboratory (1) the liquid phase photolysis of disulfide mixtures was examined and it was shown that these systems are characterized by a rapid exchange reaction involving attack by photochemically produced thiyl radicals on the S—S linkage of the disulfide. A number of investigations of the photolysis of thiols (2–4) have demonstrated that the primary process yields thiyl radicals and hydrogen atoms.

We have studied and report on here three aspects of these systems in the liquid phase: the photolysis of neat C_2H_5SH to determine the effective quantum yield of C_2H_5S radical and H-atom formation in condensed phase, the photolysis of ethanethiol – methyl disulfide mixtures in experiments designed to establish the nature and quantum efficiency of the thiyl radical – disulfide exchange reaction and to determine how this process is influenced by the presence of a labile hydrogen, and the photolysis of methyl disulfide – n-propyl disulfide mixtures and ethyl disulfide – n-propyl disulfide mixtures to demonstrate the influence of steric effects on the efficiency of the exchange process.

Experimental

The photolyses were conducted at 25 °C in a grease and mercury free glass and stainless steel vacuum system. The reaction cell was a demountable quartz tube, 4 mm i.d., with axis parallel to that of the Hanovia 687A45 mercury resonance lamp used as the light source for 2537 Å radiation. The cell was suitably masked so that photolysis was confined to the liquid phase. The light source for the photolysis of the disulfide mixtures was a

Hanovia 608A-36 medium pressure lamp with Vycor 7910 filter.

The ethanethiol was expanded, from a liquid reservoir at a fixed temperature, into a known volume in the vacuum system and subsequently frozen out in the reaction cell. In the experiments with thiol–disulfide mixtures the required amount of liquid CH_3SSCH_3 was first admitted to the detached cell with a micro-syringe. Following thorough degassing of the disulfide in the line, the ethanethiol was admitted as before. The photolysate used in these experiments contained a total of 890 μmol of which 8.84% was CH_3SSCH_3. Disulfide mixtures were made up directly from the pure liquids and thoroughly degassed after admission to the reaction cell.

At the conclusion of each reaction with pure ethanethiol H_2 was removed at −196 °C and transferred to a second vacuum system where it was determined in a gas burette. Because of the desirability of carrying out the analyses as rapidly as possible in the thiol-disulfide experiments (see below) hydrogen was not determined in those runs. The fraction condensable at −196 °C was transferred completely to a trap in the vacuum system that also acted as the sampling volume for the thermal conductivity g.c. That fraction, consisting of all unreacted substrate and the products was analyzed on 15% tricresyl phosphate on Gas Chrom Z in ¼ in. stainless steel columns. It was not possible to carry out a complete analysis on a single column. Therefore each experiment was done in duplicate, analyzing for CH_3SH in one analysis using an 18 ft column and for the remainder of the products, that were separated after CH_3SH and C_2H_5SH eluted together, on a 3 ft column. In some preliminary experiments it was found that decomposition of ethanethiol, principally to ethyl disulfide, sometimes occurred when analysis was attempted using copper g.c. columns; the reaction does not occur with stainless steel.

The photolysate from the disulfide mixture experiments was analyzed by flame ionization gas chromatographic determination of two or three syringe extracted aliquots.

The ethanethiol and methyl disulfide used were American Petroleum Institute standard samples with specified minimum purity of 99.95%. The ethyl disulfide and *n*-propyl disulfide (Eastman) were fractionally distilled at atmospheric or reduced pressure before use.

The absorbed light intensity at 2537 Å in the experiments utilizing the Hg-resonance lamp was determined using the photolysis of mixtures of methyl disulfide and ethyl disulfide. The quantum yield of methyl ethyl disulfide formation in this system, 355 ± 15, is independent of time for small percent conversions and does not vary with light intensity over the range $1–25 \times 10^{-2}$ μeinstein min^{-1} (5). A mixture of the two disulfides, 49.8 mol % CH_3SSCH_3, was photolyzed for periods of 5–30 s and an average initial rate of $CH_3SSC_2H_5$ formation determined. Thermal blanks were run simultaneously to allow correction for the small amount of thermal reaction that also yields methyl ethyl disulfide (1, 5). The value of I_a so determined was $9.4 \pm 0.4 \times 10^{-2}$ μeinstein min^{-1}.

Results and Discussion

Ethanethiol

In the first series of experiments pure liquid C_2H_5SH was photolyzed and the yields of the only products that could be detected, H_2 and $C_2H_5SSC_2H_5$, measured as a function of exposure time. The results are shown in Fig. 1 and indicate that the yields are linearly dependent on time in the range investigated. The average rate gives a value of 0.25 for $\Phi(H_2)$ and $\Phi(C_2H_5SSC_2H_5)$. The fact that the quantum yields for these two products are the same, forms part of a growing body of evidence (6) pointing to a very minor role for disproportionation of alkylthiyl radicals in relation to their

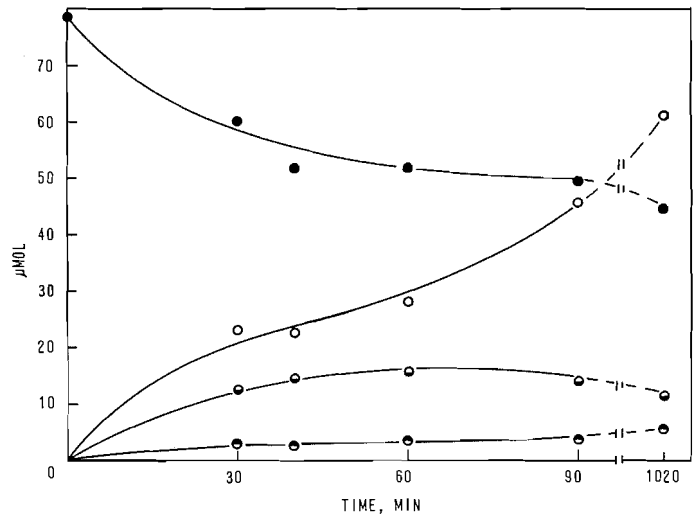

FIG. 2. Yield of CH_3SH, ○, $CH_3SSC_2H_5$, ◒, and $C_2H_5SSC_2H_5$, ◓, and the residual amount of CH_3SSCH_3, ●, as a function of time in the thermal reaction of 78.6 μmol CH_3SSCH_3 with 810 μmol C_2H_5SH at 25 °C.

combination reaction. The observations here are consistent with C_2H_5S radical and H-atom formation in the primary process, followed by abstraction from the substrate giving H_2, and combination of thiyl radicals producing disulfide. It is perhaps suprising, however, that no evidence is found for the C—S bond cleavage that characterizes the gas phase decomposition of thiols (4, 7, 8). This aspect of the system and the fact that the decomposition quantum yield is less than unity indicate the desirability of further investigation of the condensed phase photolysis.

Ethanethiol – Methyl Disulfide Mixtures

When preliminary experiments with C_2H_5SH–CH_3SSCH_3 mixtures were carried out it became apparent that there is some thermally induced thiol–disulfide exchange, leading to the same products anticipated as arising from the photochemical reaction. No reaction can be detected in the thiol or disulfide alone.

Figure 2 shows the total micromoles of products formed and the micromoles of residual disulfide in the thermal reaction. The first 30 min during which no analyses are reported represents the sample "handling-time" in the vacuum line during which the thiol and disulfide are present together at room temperature. As is apparent from the figure the net result of the thermal reaction is the conversion of the disulfide into CH_3SH. The observed yields of products containing the CH_3S group are stoichiometrically consistent within experimental error with the amount of CH_3SSCH_3 consumed. Since 78.8 μmol of disulfide is present initially, $[CH_3S]$, calculated from eq. 1, should remain

$$[1] \quad [CH_3S] = 2\,[CH_3SSCH_3] + [CH_3SH] + [CH_3SSC_2H_5]$$

constant at 157 μmol. The observed concentrations shown in Fig. 2 give $[CH_3S]$ values of 156, 141, 144, 159, and 162 μmol at 30, 40, 60, 90, and 1020 min respectively. The occurrence of the thermal reaction, presumably catalyzed by trace impurities or the container walls, is consistent with the previously reported (1, 5, 9) similar reaction that gives at room temperature in the dark, methyl ethyl disulfide from mixtures of CH_3SSCH_3 and $C_2H_5SSC_2H_5$.

When mixtures of ethanethiol and methyl disulfide are photolyzed there is a very rapid increase in the amount of CH_3SH produced and a concomitant decline in the concentration of CH_3SSCH_3. The yields of CH_3SH, $C_2H_5SSC_2H_5$ and $CH_3SSC_2H_5$ along with the residual amounts of CH_3SSCH_3 are shown as a function of exposure time in Fig. 3. Some fraction of these yields will arise from the thermal reaction, which will occur here principally *after* the exposure, during the 30 min sample processing period. However, since the rate of the thermal reaction initiated by the disulfide will decline as the proportion of CH_3SSCH_3 is reduced, the yields shown in Fig. 2 represent the *maximum* contribution of the thermolysis to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

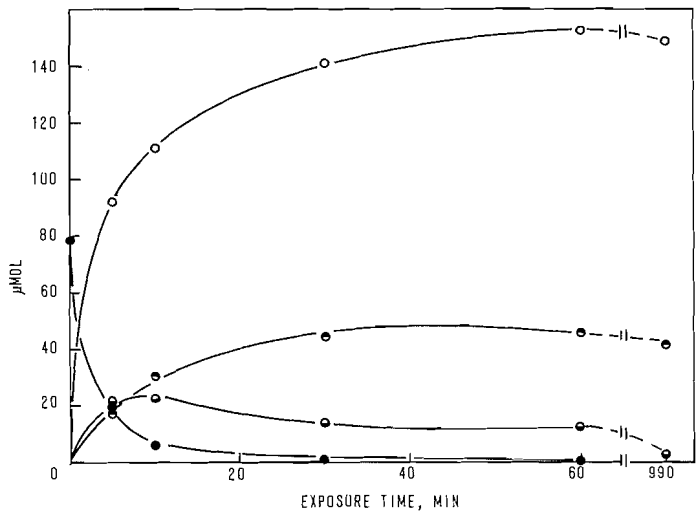

FIG. 3. Yield of CH_3SH, ○, $CH_3SSC_2H_5$, ◒, and $C_2H_5SSC_2H_5$, ◓, and the residual amount of CH_3SSCH_3, ●, as a function of exposure time in the photolysis of 78.6 μmol CH_3SSCH_3 and 810 μmol C_2H_5SH at 2537 Å and 25 °C.

total yields determined in the photolytic experiments. The amounts of the three products formed give a value for $[CH_3S]$ from eq. 1 that is essentially constant and consistent with the initial disulfide concentration. Thus the calculated $[CH_3S]$ values are 151, 147, 159, 165, and 152 μmol for 5, 10, 30, 60, and 990 min exposure time.

In considering the photochemical initiation of the chain processes operative here, the fact that both components of the mixture absorb 2537 Å radiation significantly is important. The absorption coefficient of liquid methyl disulfide at this wavelength is 316 liter mol^{-1} cm^{-1} (5) while that of ethanethiol is 34.2 (10). In the initial mixture, therefore, with 78.6 μmol CH_3SSCH_3 and 810 μmol C_2H_5SH, the ratio of absorbances, $A_{disulfide}/A_{thiol}$, is 0.90. However, after 5 min of exposure the amount of disulfide is reduced to 18.5 μmol and the ratio decreases to 0.22. Therefore, although initially the photolysis of methyl sulfide will be important, absorption and photodecomposition of C_2H_5SH will rapidly become a principal photochemical process. At the same time, however, the two disulfide products, which have absorption coefficients quite close to that of CH_3SSCH_3 (5), will begin to absorb significantly. At the end of 5 min they account together for 26% of the total absorbance in the system. The data in Fig. 3 indicate that their absorption will predominate at longer exposure times.

The observed products and their formation with large quantum efficiencies can be explained on the basis of the mechanism depicted by eqs. 2–11, wherein reactions 4, 5, and 7 are the

[2] $CH_3SSCH_3 + h\nu \rightarrow 2\,CH_3S$

[3] $C_2H_5SH + h\nu \rightarrow C_2H_5S + H$

[4] $C_2H_5S + CH_3SSCH_3 \rightarrow CH_3SSC_2H_5 + CH_3S$

[8] $2\,C_2H_5S \rightarrow C_2H_5SSC_2H_5$

[9] $CH_3S + C_2H_5SSC_2H_5 \rightarrow CH_3SSC_2H_5 + C_2H_5S$

[10] $CH_3SSC_2H_5 + h\nu \rightarrow CH_3S + C_2H_5S$

[11] $C_2H_5SSC_2H_5 + h\nu \rightarrow 2\,C_2H_5S$

exchange processes, involving attack by RS radicals on the S—S disulfide linkage, for which evidence has been given previously (1). As indicated above the secondary photolyses represented by reactions 10 and 11 will become important as the reaction proceeds and the disulfide products accumulate.

The key factor in the interpretation of the results in terms of this mechanism and the relative importance of its component steps is the fundamental difference in the possible reactions of CH_3S and C_2H_5S radicals. Ethylthiyl radicals in this system will have an appreciably longer lifetime since they are regenerated via H-atom

abstraction from the ethanethiol present in "solvent-like" concentrations, or via the exchange reaction with the ethyl disulfide product. The analogous reactions of CH_3S radicals, on the other hand, leads to consumption of that species, in converting CH_3S to methanethiol in the reaction with C_2H_5SH, reaction 6, or to methyl ethyl disulfide in reaction 9. Because of the relative concentrations, reaction 6 would be expected to be considerably more important.

In the initial stages of the photochemical reaction both reactions 2 and 3 are important. The disulfide photolysis leads to the chain production of methanethiol through the sequence of reactions 2, 6, 4, 5, and 6, while the photodecomposition of ethanethiol yields C_2H_5S radicals through reactions 3 and 7, which species then participate in the chain propagation steps 4 and 5. As the concentration of CH_3SSCH_3 is reduced, reaction 5 becomes the more important exchange process and thus the yield of the methyl ethyl disulfide product passes through the observed maximum after *ca.* 10 min. The concentration of $CH_3SSC_2H_5$ is also influenced by the secondary photolysis in reaction 10. Methylthiyl radicals produced in this reaction will be converted to CH_3SH via process 6, but CH_3S species following this sequence are much less important than those involved in the exchange reactions. The contribution of reaction 11 is essentially that of reducing the net effectiveness of reaction 8. Again the net result is the same whether C_2H_5S radicals are formed in reaction 11 or reaction 3.

The initial rates of formation of the three products indicate that a chain reaction is operative in this system. Utilizing measured amounts after 5 min exposure, and subtracting the amount of each product formed in the thermal reaction in 35 min (Fig. 2), the *minimum* initial quantum yields are $\Phi^0(CH_3SH) = 151$, $\Phi^0(C_2H_5SSC_2H_5) = 31$, and $\Phi^0(CH_3SSC_2H_5) = 15$. A smaller net contribution from the thermal conversion would increase these values. The maximum values that would apply if the thermal reaction were neglected are 196, 37, and 46 for CH_3SH, $C_2H_5SSC_2H_5$, and $CH_3SSC_2H_5$ respectively. Because of this uncertainty, the Φ values for the two disulfides have not been corrected for the fact that in the first 5 min of reaction each of these products themselves absorbs on the average *ca.* 10% of the incident radiation.

The large quantum yields are definitive evidence for the important role of the thiyl radical – disulfide exchange processes proposed, and, as well, suggest that disulfide production via the chain terminating step 8 and its analog for CH_3S radicals is minor. The efficiency of the exchange process is also evidenced by the fact that even after relatively short exposure times there is sufficient consumption of the "intermediate" methyl ethyl sulfide that its concentration is increasing at a rate very much less than that of CH_3SH.

In the thermal reaction the initiating step is most likely thiyl radical formation from the thermal decomposition of the disulfide since reactions of thiyl radicals formed in this way are observed in disulfide mixtures but not for thiols. The observed similarity of the time dependence of the concentrations in both the photochemical and thermal systems, although much less pronounced in the latter, also suggests that the same subsequent reactions characterize both processes. The rate of the thermal reaction will decline as $[CH_3SSCH_3]$ is reduced, while the photochemical system should exhibit a constant initiation rate since the latter is governed by the *total* thiol–disulfide concentration.

In summary then the thermally or photochemically induced thiyl radical–disulfide exchange process that is known to occur in disulfide mixtures takes place with high quantum efficiencies in thiol–disulfide systems as well. Because of the lability of the sulfhydryl hydrogen in the thiol, however, the thiyl radicals originating with the disulfide component of the mixture are essentially irreversibly converted to the corresponding thiol when the disulfide is present initially in solute proportions and thus the establishment of a simple photochemical equilibrium characteristic of the disulfide mixture systems does not occur.

Disulfide Mixtures

Three series of equimolar mixtures of (*a*) methyl disulfide + ethyl disulfide, (*b*) methyl disulfide + *n*-propyl disulfide, and (*c*) ethyl disulfide + *n*-propyl disulfide were photolyzed and the initial rate of appearance of the only detectable product, the unsymmetrical disulfide, was determined as well as the total irradiation time required to bring the system to photochemical equilibrium. Using the known values

TABLE 1. Effect of substrate on the thiyl radical – disulfide exchange reaction*

†Reference 5.

for mixture *a*, the relative initial rates, absolute quantum yields, and relative time required to attain equilibrium were calculated for mixtures *b* and *c*. The results are summarized in Table 1.

The dramatic decrease in the efficiency of the thiyl radical – disulfide exchange in moving from the methyl disulfide – ethyl disulfide system to the methyl disulfide – *n*-propyl disulfide mixtures may indicate that facile re-orientation of the thiyl radicals in the liquid cage immediately following their formation is a necessary prerequisite if interaction with surrounding disulfide molecules is to occur to a significant extent. However, the change from methyl disulfide – *n*-propyl disulfide to ethyl disulfide – *n*-propyl disulfide results in a much smaller alteration in the overall rate, suggesting that the principal effect in these systems may be a reduced susceptibility of *n*-propyl disulfide itself to the exchange.

These results suggest that the exchange reaction will not be important in mixtures of higher molecular weight disulfides in the liquid phase, including those disulfides of biological importance. Whether the exchange reaction will occur if the thiyl radicals are produced by the photolysis of a thiol or sulfide component added to the mixture could be determined only by further investigations of a variety of higher molecular weight systems. The absence of detectable thiol yields in these systems indicates that a minor role for disproportionation is apparently a general characteristic of all lower molecular weight alkylthiyl radicals.

The authors gratefully acknowledge the assistance of Miss H. Walker who carried out the experiments with the disulfide mixtures. This research was supported by the Defence Research Board of Canada, grant number 1675-07 and by the National Research Council of Canada.

Some Observations on the Hydrolysis of the Amides of Primary α-Acetylenic Amines

JOHN NICHOLSON GARDNER

Technical Development Department, Hoffmann-La Roche Inc., Nutley, New Jersey 07110

Received October 11, 1972

Some amides of primary α-acetylenic amines were made from the corresponding α-acetylenic alcohols by the Ritter reaction. Depending upon the other substituents on the carbon atom bearing nitrogen and the ethynyl group, hydrolysis resulted in formation of the α-acetylenic amine or in hydration of the triple bond to yield a ketone.

Quelques amides d'amines primaires α-acétiléniques ont été préparées par la réaction Ritter sur les alcools α-acétyléniques correspondants. Dépendant de la nature des autres substituants portés par l'atome de carbone portant l'azote et le groupe éthynyle, l'hydrolyse des amides conduit soit à l'amine α-acétylénique ou à l'hydratation de la triple liaison fournissant la cétone.

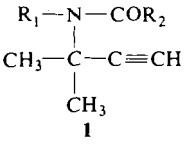
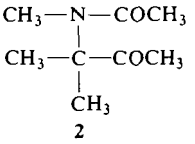
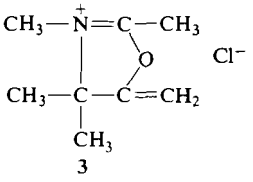
The amide **1** ($R_1 = R_2 = CH_3$) undergoes hydration to **2**, via the oxazolinium salt **3**, upon reaction with aqueous hydrochloric acid (1), but the corresponding formamide derivative **1** ($R_1 = CH_3$, $R_2 = H$) yields, under similar conditions,



1

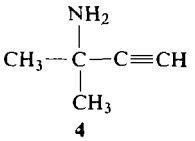


2



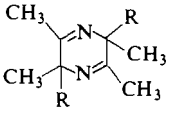
3

the acetylenic amine (1). In contrast the amide **1** ($R_1 = H$, $R_2 = CH_3$) was reported (2) to be insoluble in dilute hydrochloric acid and to yield with the concentrated acid a product in which 3-amino-3-methyl-2-butanone was detected spectroscopically. In the case of **1** ($R_1 = R_2 = H$), almost quantitative hydrolysis to the amine **4** occurs (3) with aqueous mineral acid. Our interest in the efficiency of this last reaction has resulted in observations which extend those already reported.

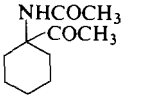


4

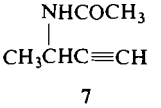
We prepared the amide **1** ($R_1 = H$, $R_2 = CH_3$) by the Ritter reaction of acetonitrile with 3-hydroxy-3-methyl-1-butyne, using a modified version of the published procedure (4). We found that upon hydrolysis with sulfuric or hydrochloric acid in aqueous methanol, followed by basification of the reaction mixture and steam distillation, the dihydropyrazine **5** ($R = CH_3$) was formed in good yield. This product was obtained even when the reaction mixture was



5



6



7

carefully adjusted to p*H* 7 prior to the steam distillation, and thus it may be concluded that alkaline conditions are not necessary for its formation. It clearly results from hydration of **1** ($R_1 = H$, $R_2 = CH_3$) to 3-amino-3-methyl-2-butanone and condensation of two molecules of the latter to yield **5** ($R = CH_3$). The formation of dihydropyrazines from α-amino ketones is well documented (5) and conditions for interconversion of these two classes of compound have been recorded (5), so that this reaction sequence provides a convenient route to compounds of these types. A procedure (which has not been optimized) for obtaining **5** ($R = CH_3$) from 3-hydroxy-3-methyl-1-butyne in 54% yield, without isolation of the intermediate amide **1** ($R_1 = H$, $R_2 = CH_3$), is given in the Experimental. The reaction sequence is thus a viable alternative to the recently reported synthesis (5) of **5** ($R = CH_3$), in 37% yield, by

reaction of methyl isopropyl ketone with aqueous alkaline potassium ferricyanide. The two procedures are not fully equivalent, however, for although 3-hydroxy-3-methyl-1-pentyne was successfully converted to the dihydropyrazine **5** ($R = C_2H_5$) (isolated as the dihydrochloride), with 1-ethynylcyclohexanol as substrate, the product was the amido ketone **6**. It may be that under more rigorous conditions it would be possible to hydrolyze the amide function in **6** and to obtain the corresponding dihydropyrazine which has been prepared (5) by the reaction of cyclohexyl methyl ketone with ferricyanide.

The conditions for hydrolysis of **1** ($R_1 = H$, $R_2 = CH_3$) which led to **5** ($R = CH_3$) also gave a very minor amount of the amine **4**, which was detected by gas chromatography. It was thus of interest to investigate the hydrolysis of the amide **7** to see whether it yielded the corresponding amine or (through hydration of the triple bond, hydrolysis of the amide, condensation, and autoxidation) 2,3,5,6-tetramethylpyrazine. The product obtained from this reaction was 3-amino-1-butyne hydrochloride. Thus, we may conclude that the behavior of the amides of primary α-acetylenic amines on hydrolysis is critically influenced by alterations in the substituents on nitrogen and on the carbon atom α to the triple bond.

Experimental

2,2,3,5,5,6-Hexamethyl-2,5-dihydropyrazine (5, R = CH_3)

Acetonitrile (500 g) was added with stirring to sulfuric acid (98% w/w, 500 g), while cooling to maintain a temperature of 0–5°. When the addition was complete, the mixture was stirred for 15 min at the same temperature and then 3-hydroxy-3-methyl-1-butyne (250 g) was added slowly while continuing to maintain a temperature of 0–5°. Upon completion of the addition, the solution was brought to 10° and stirred for 2.5 h. Ice (2 kg) was added and the resulting mixture was distilled at atmospheric pressure, using a 20-plate Oldershaw[1] column (reflux ratio 4:2) until the vapor temperature reached 97°. The distillation residue was cooled and, while maintaining < 50° by the addition of ice, sodium hydroxide (50% w/w, 750 ml) was introduced. The resultant alkaline solution was subjected to steam distillation. The dihydropyrazine **5** ($R = CH_3$) (219 g, yield[2] 54%) was isolated from the distillate by filtration, m.p. 88–91° (lit. (5) m.p. 88–89°). The assignment of structure was confirmed by the product's i.r., u.v., n.m.r., and mass spectra.

[1]The column was used as it was desired to recover the excess acetonitrile.

[2]Microanalysis indicated that the material was approximately a hexahydrate, and the yield was calculated on this basis.

N-(3-Methylpent-1-yn-3-yl)acetamide

3-Hydroxy-3-methyl-1-pentyne (75 g) was reacted with sulfuric acid (98% w/w, 150 g) and acetonitrile (150 g) as described for the preparation of **5** ($R = CH_3$). After quenching with ice, the reaction mixture was made alkaline with sodium hydroxide solution (20% w/w), saturated with sodium chloride, and extracted with ether (3 × 600 ml). The extracts were washed with water and brine, then dried (sodium sulfate) and evaporated to dryness. The residue was distilled (b.p. 60–75°/2.0 mm) to yield a distillate (27.5 g) which crystallized. Two recrystallizations from hexane-dichloromethane gave pure *N*-(3-methylpent-1-yn-3-yl)acetamide: m.p. 62–65°; i.r. ($CHCl_3$) 3445, 3300, 1680, and 1500 cm^{-1}; n.m.r. ($CDCl_3$) 0.98 (t, 3, $J = 7$ Hz, CH_3CH_2), 1.60 (s, 3, CH_3C), 1.9 (s, 3, CH_3CO), 2.33 (s, 1, ≡CH), and 5.92 p.p.m. (br, 1, NH).

Anal. Calcd. for $C_8H_{13}NO$: C, 69.03; H, 9.41; N, 10.06. Found: C, 69.16; H, 9.50; N, 9.87.

3,6-Diethyl-2,3,5,6-tetramethyl-3,6-dihydropyrazine Dihydrochloride (5, R = C_2H_5)

The aforegoing amide (5.2 g) in methanol (25 ml) and sulfuric acid (12% w/w, 25 ml) was heated under reflux for 3 h. The mixture was then steam-distilled, 200 ml of distillate being collected. The residue was made alkaline with sodium hydroxide solution (20% w/w, 15 ml) and again steam-distilled, 100 ml of distillate being collected. The distillate was brought to pH 2 by addition of hydrochloric acid (37% w/w) and then evaporated to dryness at reduced pressure. The residue was crystallized from ethanol–ether to yield **5** ($R = C_2H_5$) as a dihydrate (1.9 g): m.p. 196–199°; i.r. (KBr) 1705 and 1570 cm^{-1}; n.m.r. ($CDCl_3$) 1.02 (t, 6, $J = 7$ Hz, CH_3CH_2), 1.68 (s, 6, CH_3C), 2.26 (s, 6, CH_3C=), and 8.86 p.p.m. (br, 6, NH and H_2O).

Anal. Calcd. for $C_{12}H_{24}Cl_2N_2 \cdot 2H_2O$: C, 47.53; H, 9.31; N, 9.24; Cl, 23.38. Found: C, 47.50; H, 9.33; N, 9.20; Cl, 23.68.

N-(1-Acetylcyclohexyl)acetamide 6

N-(1-Ethynylcyclohexyl)acetamide (2, 4) (5.2 g) was heated with sulfuric acid exactly as for the preparation of **5** ($R = C_2H_5$), a reaction time of 15 h being used. The reaction mixture was cooled, diluted with its own volume of water, and made alkaline with sodium hydroxide solution (20% w/w, 25 ml). Extraction with ethyl acetate and crystallization from ethyl acetate – hexane gave **6** (1.9 g): m.p. 140–142° (lit. (2) 133–135°); i.r. ($CHCl_3$) 3445, 1715, 1680, and 1500 cm^{-1}; n.m.r. ($CDCl_3$) 2.02 (s, 3, CH_3CO), and 2.12 p.p.m. (s, 3, CH_3CO).

Anal. Calcd. for $C_{10}H_{17}NO_2$: C, 65.54; H, 9.52; N, 7.64. Found: C, 65.81; H, 9.52; N, 7.65.

N-(But-1-yn-3-yl)acetamide (7)

Acetic anhydride (30 ml) was added slowly to sulfuric acid (98% w/w, 50 ml) while the temperature was held at < 40°. The mixture was cooled and, at 15–25°, but-1-yn-3-ol (14.5 g) in acetonitrile (21 g) was added. The reaction vessel was cooled[3] to hold the temperature at 15–25° and after 7 h at this temperature it was poured onto crushed

[3]The reaction is very slowly exothermic and on one occasion the temperature rose to 175° after the reactants had been mixed and the mixture was thought to be quiescent.

ice (200 g) and, using external cooling, made alkaline with sodium hydroxide solution (50% w/w, 125 ml). The product was isolated by extraction with ether and sublimed at 50–80°/2.0 mm. The sublimate (1.53 g) comprised **7**, sufficiently pure for further reactions. Two recrystallizations from dichloromethane–hexane gave pure **7**: m.p. 94–95°; i.r. ($CHCl_3$) 3450, 3310, 1680, and 1510 cm^{-1}; n.m.r. ($CDCl_3$) 1.23 (d, 3, J = 7 Hz, CH_3CH), 2.00 (s, 3, CH_3CO), and 2.26 p.p.m. (d, 1, J = 2.5 Hz, $\equiv CH$).

Anal. Calcd. for C_6H_9NO: C, 64.84; H, 8.16; N, 12.60. Found: C, 64.87; H, 8.05; N, 12.47.

3-Amino-1-butyne Hydrochloride

Compound **7** (1.17 g) was heated under reflux for 4 h in sulfuric acid (12% w/w, 25 ml). The mixture was cooled to 60°, diluted with water (25 ml), and made alkaline with sodium hydroxide solution (20% w/v, 35 ml). This solution was steam-distilled and the distillate (700 ml) adjusted to pH 3 with hydrochloric acid (37% w/w). The water was evaporated and the residue, dissolved in methanol, was treated with charcoal. The methanol solution was evaporated to dryness and the residue sublimed at 135–140°/0.5 mm. The sublimate was recrystallized from methanol – ethyl acetate to give the amine hydrochloride (370 mg); m.p. 162–165°. Three recrystallizations from the same solvents gave analytically pure material: m.p. 166–169°; i.r. (KBr) 3250 cm^{-1}; n.m.r. (D_2O) 2.02 (d, 3, J = 7 Hz, CH_3CH), and 2.45 p.p.m. (d, 1, J = 2 Hz, $\equiv CH$).

Anal. Calcd. for C_4H_8ClN: C, 45.52; H, 7.64; N, 13.27. Found: C, 45.25; H, 7.39; N, 13.44.

Received October 11, 1972

Diisobutylaluminum hydride is shown to be an effective reagent for the reduction of sulfones to sulfides. Yields as high as 70% are obtained in this normally difficult reduction. A technique for the easy isolation from the reaction mixture of volatile sulfides is described.

Il est montré que l'hydrure de di-iso-butylaluminium est un réactif permettant la réduction facile des sulfones en sulfures. Des rendements aussi hauts que 70% ont été obtenus pour cette réduction qui est normalement difficile. On décrit une technique permettant la récupération facile des sulfures volatiles des mélanges réactionnels. [Traduit par le journal]

Can. J. Chem., **51**, 1419 (1973)

We wish to report that diisobutylaluminum hydride (Dibal-H) is an effective and convenient reagent for the reduction of sulfones to sulfides. Over the past 20 years, only one major paper dealing with conversion of sulfones to sulfides (1) has appeared and, indeed, it is widely recognized that this reduction is a difficult operation. This is unfortunate because sulfones are compounds of potential synthetic utility as a result of the ability of the sulfone moiety to stabilize a negative charge on the carbon atom α to sulfur.

In their paper, Bordwell and McKellin (1) describe the reduction of sulfones with lithium aluminum hydride (LAH) using in most cases 3–9 mol of this reagent per mol of sulfone, which is equivalent to 6–18 times the theoretical amount of active hydrogen. Only in cases of sulfones related to benzothiophene and dibenzothiophene were high yields of the corresponding sulfides obtained when using smaller excesses of the reagent. Furthermore, those sulfides which are relatively volatile (*e.g.*, tetramethylene sulfide) were isolated only as their mercuric chloride complexes.

Our results are presented in Table 1. As may be seen, aliphatic, alicyclic, and aromatic sulfones were reduced using between 2.2 and 5.0 mol of Dibal-H per mol of sulfone. The fact that 2.2 mol of Dibal-H effected almost complete reduction of 1 mol of benzyl methyl sulfone strongly suggests that the stoichiometry of the reaction is as indicated in the equation:

$$R_2SO_2 + 2(C_4H_9)_2AlH \rightarrow R_2S + 2(C_4H_9)_2AlOH$$

This equation implies that the sulfide is formed in a free state and does not require water to liberate it from a complex with the aluminum salts. In agreement with this, we have found that volatile sulfides are conveniently made by reduction of sulfones with Dibal-H in mineral oil, the sulfide being distilled directly from the reaction mixture.

The reactivity of the sulfones with Dibal-H follows a similar order to their reactivity with LAH. Thus, in both cases the alicyclic sulfones with five-membered rings are the most easily reduced, and it is noteworthy that the reaction of Dibal-H with tetramethylene sulfone is quite exothermic. The aliphatic sulfones are the most resistant to reduction, while other compounds listed in Table 1 fall between these two extremes.

None of the reductions reported in Table 1 has been optimized, and in three reactions the products were not isolated. The reduction of 2,5-dihydrothiophene sulfone to 2,5-dihydrothiophene is not a simple reaction as several attempts to improve the yield resulted in none of the desired product. It may be that interaction of the Dibal-H with the double bond occurs under all except carefully defined conditions, and it is interesting to note that Bordwell and McKellin obtained only polymeric material when they attempted to carry out this reduction with LAH. Preparation of 2,5-dihydrothiophene in

this way may have some synthetic merit if the reaction can be controlled as the normal preparation, by sodium-in-ammonia reduction of thiophene (2), involves the separation of 2,5- and 2,3-dihydrothiophenes.

In contrast to Dibal-H, sodium diethyl aluminum dihydride (OMH-1), which has recently become commercially available, was ineffective in reducing di-*n*-butyl and tetramethylene sulfones under conditions comparable with those under which Dibal-H brought about reduction.

Experimental

Dibal-H was purchased from the Stauffer Chemical Company as an approximately 20% solution in either toluene or hexane. OMH-1 (25% in toluene) was a gift from the Ethyl Corporation, and the attempted reductions with it were carried out in toluene. All the sulfones were commercial materials and were used as received.

Use of Mineral Oil as the Solvent. Tetramethylene Sulfide

Light mineral oil (500 ml) was added to 500 ml of a 23.5% solution of Dibal-H (0.75 mol) in toluene. The mixture was distilled to a residue temperature of 100° at 0.5 mm and then, while this vacuum and temperature were held, nitrogen was passed through the solution for 2 h to remove the last traces of toluene. The mixture was cooled to 20–25° and tetramethylene sulfide 1,1-dioxide (30 g, 0.25 mol) was added slowly while cooling to hold 20–25°. The mixture was stirred for 1.5 h and then distilled to a residue temperature of 125° at 3 mm. The distillate weighed 11.5 g. The reaction mixture was cooled to ambient temperature and again stirred for 72 h.[1] It was then distilled as before to yield a further 10 g of distillate. The combined distillates were redistilled at atmospheric pressure via a 4 in. × 0.5 in. Goodloe column to yield tetramethylene sulfide (16 g, 0.18 mol; 73%); b.p. 121°.

Use of Toluene as the Solvent. Dibutyl Sulfide

A solution of di-*n*-butyl sulfone (44.5 g, 0.25 mol) in toluene (50 ml) was added to 500 ml of a 23.5% solution of Dibal-H (0.75 mol) in toluene. The mixture was heated under reflux for 72 h and cooled to room temperature, and ethanol (50 ml) was cautiously added, followed by water (200 ml), and concentrated hydrochloric acid (100 ml). The organic layer was separated and washed with water (2 × 50 ml). The solvent was distilled off at atmospheric pressure and the residue was distilled through a Vigreux column to yield the sulfide (18 g); b.p. 69°/11 mm. G.c. evaluation of the residue from fractionation of the recovered solvent detected another 6.8 g of sulfide, giving a total yield of 24.8 g (0.17 mol; 68%).

2,5-Dihydrothiophene

A solution of Dibal-H (0.75 mol) in mineral oil (500 ml) was prepared as in the preparation of tetramethylene sulfide. To this at 20° was added slowly 2,5-dihydrothiophene 1,1-dioxide (30 g, 0.25 mol), the mixture being cooled as required. When the addition was

[1]This time was determined purely on the basis of convenience.

For personal use only.

complete, the reaction mixture was stirred for 1.5 h and then distilled to a residue temperature of 150° at 4 mm. The distillate weighed 10 g. Stirring for another 18 h and distillation gave no additional distillate. The distillate was redistilled at atmospheric pressure through a 4 in. × 0.5 in. Goodloe column to yield 2,5-dihydrothiophene (2.7 g, 0.03 mol; 12%) assaying 92.4% by g.c.; b.p. 122°; n_D^{20} 1.5279; n.m.r. ($CDCl_3$) δ 3.73 (s, 4, CH_2) and 5.83 p.p.m. (s, 2, CH=); Raman (neat liquid) 1630 cm^{-1} (C=C); i.r. ($CHCl_3$) 1638 cm^{-1} (C=C) (lit. (2), b.p. 122.3°; n_D^{20} 1.5306).

Theory of Molecular Size Distribution in Multichain Polymers: Condensation of $R—A_f$ with $R'—B_{f'}$, and $R—A_f$ with $R'—A_{f'}$ [1]

S. G. WHITEWAY, I. B. SMITH, AND C. R. MASSON

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received February 7, 1972[2]

Expressions are derived for the mole fractions of various oligomers formed by condensation of the monomer $R—A_f$ with the monomer $R'—B_{f'}$. It is assumed that A groups can react only with B groups and that intramolecular condensation may be neglected. The results, for cases where comparison is possible, agree with those derived previously for the self-condensation of $R—A_f$. In addition, expressions are derived for the condensation of $R—A_f$ with $R'—A_{f'}$, where A groups react with one another.

Des expressions sont déduites en ce qui a trait aux fractions molaires de plusieurs oligomères formés par condensation du monomère $R—A_f$ avec le monomère $R'—B_{f'}$. On suppose que les groupes A peuvent réagir seulement avec les groupes B et que la condensation intra moléculaire peut être négligée. Les résultats, pour les cas où une comparaison est possible, sont en accord avec ceux obtenus antérieurement pour la condensation sur lui-même du monomère $R—A_f$. De plus, des expressions sont déduites pour la condensation de $R—A_f$ avec $R'—A_{f'}$, où les groupes A réagissent les uns avec les autres.

[Traduit par le journal]

Can. J. Chem., 51, 1422 (1973)

In previous publications (1–3) we derived an expression for the molecular size distribution in multichain polymers formed by self-condensation of the monomer $R—A_f$, where A is a functional group. The method is based on probability considerations, and the result is a particular solution of the Bernoulli binomial probability function. In the above publications the method was discussed from a particular point of view, and the first purpose of this paper is to outline the method briefly in alternative terms. To test this expression experimentally we require polymerizing systems whose characteristics resemble closely those assumed for the model. Some inorganic polymers (silicates) fulfill these conditions and thermodynamic data on these systems agree with the size distribution predicted using our expression (4). However, organic polymers are not well suited for the purpose of investigating quantitatively the self-condensation of $R—A_f$ monomers, and conclusive experiments along these lines have never been performed. The second purpose of this communication is to extend the theoretical treatment to models not treated in the previous work, anticipating that the results can be tested by experiments performed on organic as well as inorganic polymers.

Self Condensation of $R—A_f$

When monomers of type $R—A_f$ condense without intramolecular condensation, molecules of the type shown in Fig. 1 are formed for $f = 3$. If N_0 = number of molecules of monomer RA_f at the beginning of self-condensation, N = total number of molecules after condensation, α = fraction of A groups initially present that have reacted to form AA groups and f = functionality of monomers RA_f, then

$$N = N_0\left(1 - \frac{\alpha f}{2}\right) \qquad [1]$$

It is important to note that N is independent of the distribution of molecular sizes.

The method used to determine the most probable distribution may be described as an

imaginary process of cutting the molecules into fragments and reassembling these by a method which simulates the original random condensation. It is understood, of course, that no attempt is made to reassemble the fragments in their original juxtaposition. Repeated assembly will cause any particular A group, if it could be distinguished from the others, to occur in a different location each time; however, if N_0 is large the same distribution of molecular sizes will result each time. The final step is counting the number of molecules of each size. A virtue of the method is that the numbers of molecules of different types are continually kept in the forefront, so that the calculation of mole fractions is direct. The best way of "cutting" the molecules so that there is no ambiguity about how the parts can be reassembled is to allow the R groups to carry the linkages. Thus molecules of the type shown in Fig. 1 are separated into fragments of the types A—R$\langle$, AA—R$\langle$ and A. Except when $f = 1$, each molecule of size x units (an x-mer) has only one fragment of type A—R$(f-1)$—, $(x-1)$ of type

$$\text{AA—R}(f-1)\text{—}$$

and $(fx - 2x + 1)$ of type A. The entire system of N_0 structural units has $N_0(1 - \alpha f/2)$ fragments of the first type, $N_0\alpha f/2$ of the second and $N_0(f - \alpha f/2 - 1)$ of the third type. (For the situation $f = 1$, of course, not all molecules contain fragments of type A—R$(f-1)$—, so that the above expressions do not apply. This situation is discussed later.)

Reassemblage of these fragments into structures whose size distribution resembles the original requires N molecules. The correct way to achieve this is to let each of the

$$NA\text{—R}(f-1)\text{—}$$

fragments start one molecule.[3] The logic of this step is fundamentally important and deserves elaboration here. Each molecule, in terms of size and configuration, may be regarded as an assembly of fragments arranged relative to one datum fragment. A particular x-mer can then be described on the basis of how all other fragments are arranged relative to the chosen one, which, of course, may be any one of the fragments *known* to be in that x-mer. For example, a 5-mer, $f = 3$, contains 1 A—R$\langle$, 4 AA—R$\langle$, and 6 A fragments. Because all are known to exist in that x-mer, any one of those 11 may be chosen as the datum around which the 42 different 5-mer configurations may be developed. However, if the distribution of x-mers is not stipulated in advance, but rather the process of assembling the molecules is begun and allowed to develop in a random way, the principle of equal reactivity requires that no molecule may have any artificial restriction imposed on its development. For example, no structure may be started by an AA—R$(f-1)$— fragment because the final molecule would have no statistical chance of being a monomer. On the other hand, it is certain that every molecule contains a fragment of the type A—R$(f-1)$—, and therefore it is the datum around which any molecule can be developed. The first step, therefore, is to begin construction of the molecules with a fragment whose probability of occurrence in every molecule is unity. (Other cases will be discussed where this fragment differs from A—R$(f-1)$—, but the basic principle remains the same.)

After N fragments of the type A—R$(f-1)$— have been allotted to starting the N structures, the remaining $N_0\alpha f/2$ fragments of the type AA—R$(f-1)$— and $N_0(f - \alpha f/2 - 1)$ of type A together form a pool from which the uncommitted fragments may be drawn in a random fashion in order to develop the structural patterns. The chance, p_{AA}, of selecting a fragment of the type AA—R$(f-1)$— at random from this pool is $\alpha f/2(f-1)$, while that of selecting a fragment of type A is $1 - p_{AA}$. Structures are developed by filling the reactive sites, consecutively, by AA—R$(f-1)$— or A fragments according as they are withdrawn at random from this pool of uncommitted fragments. The mole fractions of the various x-mers follow directly from this scheme, as has been shown in detail in ref. 1, merely by counting the number of the various species.

Self Condensation of R—A

It should be noted that the above scheme cannot be used directly when $f = 1$ because there

[3]It should be reemphasized that these A—R$(f-1)$— fragments, previously named the "committed" groups (1), do not lead a special existence. If the molecules are cut and reassembled repeatedly each A group of the system occasionally becomes part of one of the N A—R$(f-1)$— fragments.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is no A-containing fragment common to all molecules. (R—A cannot be developed to yield dimer because it is already a stable monomer; R—AA will yield only dimer.) In this case molecules are cut into R—, A, and AA—R. They are reassembled beginning with the N R— fragments, as the probability is unity that every molecule contains at least one R— fragment. All the A and AA—R fragments are in the pool of uncommitted groups, and p_{AA} is $\alpha/2 - \alpha$. The mole fractions of the two possible structures follow directly from this scheme: $N_{monomer} = 2(1 - \alpha)/(2 - \alpha)$; $N_{dimer} = \alpha/(2 - \alpha)$. The correctness of these expressions may, of course, be verified by inspection for this special situation. While this is a trivial case, it is somewhat similar to a more important one which also cannot be treated directly by the method described: this is the condensation of R—A_f and R′—$B_{f'}$ units to yield polymers of which Fig. 2 is an example ($f = 4, f' = 2$).

Condensation of R—A_f with R′—$B_{f'}$

Molecules of the kind shown in Fig. 2 can, in general, be cut into imaginary fragments of the type A—R($f - 1$)—, B—R′($f' - 1$)—, AB—R′($f' - 1$)—, BA—R($f - 1$)—, A and B. However, no single fragment can be associated with every possible molecule: *e.g.* A—R($f - 1$)— cannot be used to start the reassembly of all the molecules as the monomer R′—$B_{f'}$ cannot be constructed; nor can B—R′($f' - 1$)— be used for the corresponding reason.

By an obvious extension of the basic method the way to determine the distribution in these cases is to reassemble the molecules by two schemes starting from two different datum points. Some of the molecules are started with fragments of the type A—R($f - 1$)— while the remainder are started with B—R′($f' - 1$)—. For each of these schemes, as the structures are developed, sites must be filled by either, on one hand, AB—R′($f' - 1$)— or A fragments, or on the other by BA—R($f - 1$)— or B fragments. Thus there must be two separate pools of uncommitted fragments. Some molecules (for example the monomers, as mentioned above) are reassembled by only one of the two schemes. Most molecules will occur in each scheme, and their numbers must be added. It is apparent that the molecular size distribution which will result from operation of such a process is greatly dependent on the relative numbers of molecules started in each scheme. It is important, therefore, that these relative numbers be correctly deduced, in a statistical sense, from α_A and α_B (α_A, α_B = fraction of A or B groups initially present that have reacted, in condensation of RA_f with R′$B_{f'}$), so that no artificial restraint is imposed on the system.

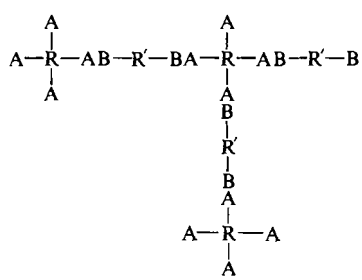

FIG. 2. Polymer formed by condensation of monomer R—A_4 with monomer R′—B_2.

If we define the number of structural units (at the beginning of their condensation) of type R—A_f to be N_A and the number of R′—$B_{f'}$ units to be N_B, and further take $N_B = rN_A$, $f' = qf$, then expressions 2–6 are deduced readily.

$$\alpha_B = \alpha_A/qr \qquad [2]$$

$$\text{Number of molecules} = N = N_A(1 + r - \alpha_A f) \qquad [3]$$

Defining μ_A = fraction of all unreacted groups that are A;

$$\mu_A = \frac{1 - \alpha_A}{1 + qr - 2\alpha_A} \qquad [4]$$

Considering only the stoichiometric range, where α_A and α_B mutually < 1, we have

$$(\alpha_A)_{max} = (1 + r)/f \qquad [5]$$

$$(\alpha_B)_{max} = \left(1 + \frac{1}{r}\right) \Big/ f' \qquad [6]$$

In general we expect X, the fraction of molecules which must be started by fragments of the type A—R($f - 1$)—, to be a function of α_A. The solutions of this function at the lower and upper limits of α_A may be written immediately. When $\alpha_A = 0$, then N_A molecules must be started by fragments of the type A—R($f - 1$)—, and $X = N_A/N = 1/1 + r$. On the other hand if α_A approaches $(\alpha_A)_{max}$ (for conditions where both $(\alpha_A)_{max}$ and $(\alpha_B)_{max} \leqslant 1$) then the system approaches one very large molecule. The fraction of unreacted A groups on this molecule is μ_A, hence at this limit of $\alpha_A = \alpha_{max}$, $X = \mu_A$. As-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

suming that X is a linear function of α_A between these limits, we have

$$[7]\quad X = \frac{1}{1+r} \times \left[1 + f\alpha_A\left(\frac{\alpha_A - r\alpha_A - qr + r}{(1+r)(1+qr-2\alpha_A)}\right)\right]$$

In addition, if Y = the fraction of molecules that must be started by fragments of the type B—R′(f' − 1)—, then

$$[8]\quad Y = 1 - X$$

If the number of molecules started by A—R(f − 1)— and B—R′(f' − 1)— are designated n_A and n_B, then

$$[9]\quad n_A = XN = XN_A(1 + r - \alpha_A f)$$

and

$$[10]\quad n_B = (1 - X)N = YN_A(1 + r - \alpha_A f)$$

All the remaining groups are uncommitted to specific locations in the molecules and must be assigned to these locations at random. All locations, whether in molecules started by fragments of the type

A—R(f − 1)— or B—R′(f' − 1)—,

are of two types: (*1*) those which can be filled only after choosing, in a random fashion, between A and AB—R′(f' − 1)—, and (*2*) those which can be filled after choosing between B and BA—R(f − 1)—. Two pools of fragments must be established, corresponding to these two types of locations. The first pool contains the uncommitted $fN_A(1 - \alpha_A) - n_A$ fragments of type A and $N_B - n_B$ of type AB—R′(f' − 1)—; choosing between these two yields fragments which are chemically correct for filling locations (denoted by ○) of the type ----R○. The second pool contains the uncommitted $f'N_B(1 - \alpha_B) - n_B$ fragments of type B and $N_A - n_A$ of type BA—R(f − 1)—; either may fill locations of the type ----R′○. In the first pool the probability, p_{AB}, of choosing at random a fragment of type AB—R′(f − 1)— is

$$[11]\quad p_{AB} = \frac{N_B - n_B}{N_B - n_B + fN_A(1 - \alpha_A) - n_A} = \frac{r - Y(1 + r - \alpha_A f)}{f - 1}$$

In the second pool the probability, p_{BA}, of choosing a fragment of the type BA—R(f − 1)— is

$$[12]\quad p_{BA} = \frac{N_A - n_A}{N_A - n_A + f'N_B(1 - \alpha_B) - n_B} = \frac{1 - X(1 + r - \alpha_A f)}{r(q f - 1)}$$

The use of these equations may be illustrated for the case where $f = 4$ and $f' = 2$, which yields molecules of the type illustrated in Fig. 2. NX molecules are started, as in Fig. 3, by fragments of type A—R≤ while in Fig. 4 NY molecules are started by B—R′—. (For convenience the R and R′ groups are not shown.) Reactive sites which must be filled by either A or AB—R′— are depicted by circles, while those to be filled

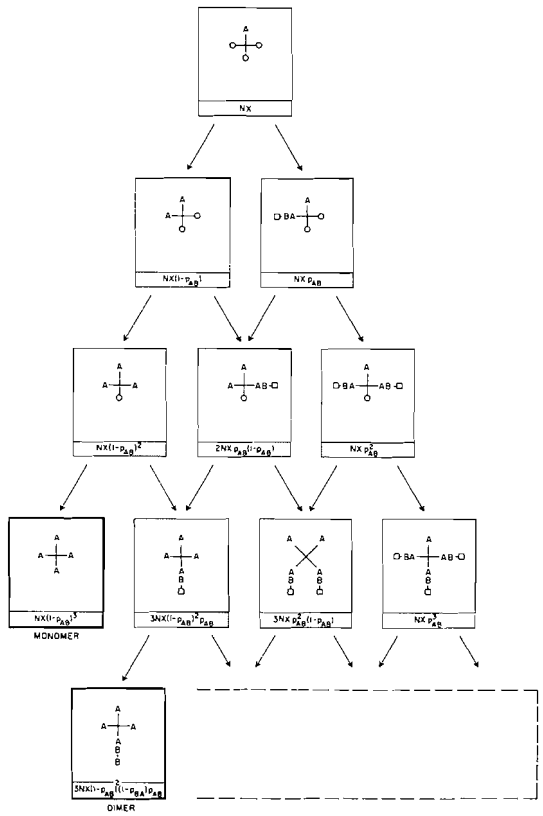

FIG. 3. Derivation of molecular size distribution for polymers started from the fragment A—R≤. Each circle denotes the site of an A or AA—R≤ fragment. Each square denotes the site of a B or BB—R′— fragment. The number in each box is the number of molecules of that structure. For convenience, the R and R′ groups are not shown.

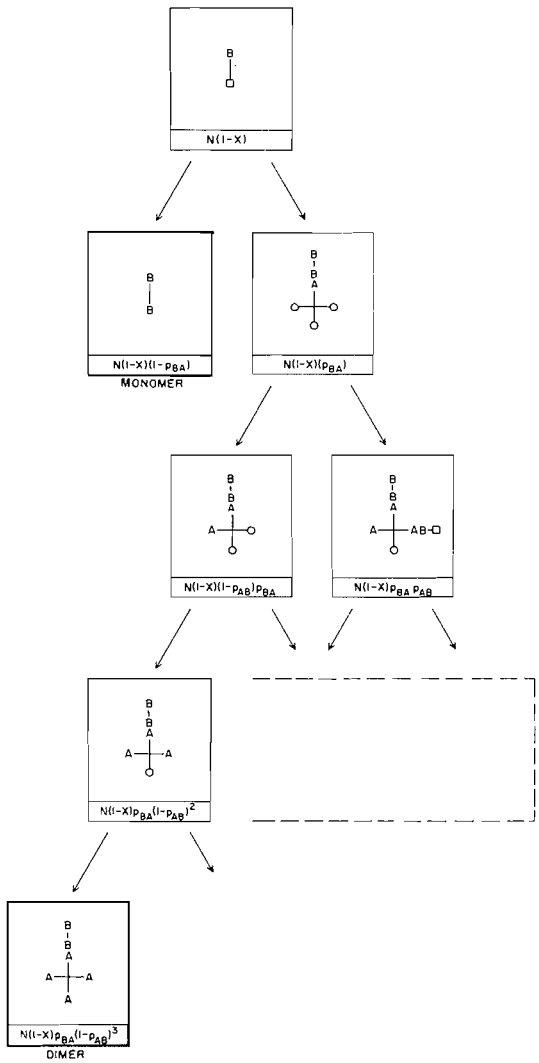

FIG. 4. Derivation of molecular size distribution for polymers started from the fragment B—R′—, with the same symbolism as for Fig. 3.

by either B or BA—R$\lessdot$ are depicted by squares. Sites are filled by removing fragments at random from the appropriate pools; various completed structures, and their number, are shown in the heavily bordered boxes. The mole fractions of these completed structures are obtained from the numbers of molecules in each box, the numbers in Figs. 3 and 4 being added when the same molecule occurs in both. These total numbers are divided by N to obtain the mole fraction. The mole fractions of monomer developed in Figs. 3 and 4, as well as of a few larger molecules,

TABLE 1. Mole fractions of selected oligomers of type $(A_4)_i(B_2)_j$

Molecule	Mole fraction
Monomer A	Xc^3
Monomer B	Yd
Dimer AB	$3Xac^2d + Ybc^3$
Trimer ABB	$3Xa^2cd^2 + 3Yabc^2d$
Trimer AAB	$3Xabc^5$
Tetramer ABBB	$Xa^3d^3 + 3Ya^2bcd^2$
Tetramer AABB	$15Xa^2bc^4d + 3Yab^2c^5$
Pentamer ABBBB	Ya^3bd^3
Pentamer AABBB	$30Xa^3bc^3d^2 + 15Ya^2b^2c^4d$
Pentamer AAABB	$12Xa^2b^2c^7$

are given in Table 1. To simplify, we define $p_{AB} = a$, $p_{BA} = b$, $(1 - p_{AB}) = c$, $(1 - p_{BA}) = d$; a is therefore the probability of selecting an AB—R′(f' − 1)— in a choice between A and AB—R′(f' − 1)—, is the probability of selecting a BA—R(f − 1)— in a choice between B and BA—R(f − 1)—, c is the probability of selecting an A in same choice as for p_{AB}, and d is the probability of selecting a B in same choice as for p_{BA}. Molecules are written as combinations of A and B (*i.e.*, R—A_4 = A, R′—B_2 = B, etc.).

To calculate mole fractions from Table 1, X and Y are calculated from eqs. 7, 8 and a, b, c, d, from eqs. 11 and 12. Figures 5–8 show mole fractions of various species versus α_A for values of r of 1, 1.25, 2, and 3. The values $r = 1$ and $r = 3$ are the limits of the stoichiometric range. At each limit the mole fraction of the appropriate monomer just goes to zero as $\alpha = \alpha_{max}$. For intermediate values of r the mole fraction of each monomer is finite when $\alpha = \alpha_{max}$. The mole fractions of the various polymers are consistent with their relative complexity. For most cases (although this is not universal as for the previous simple case of condensation of R—A_f units (1)) one of the monomers is the most numerous species. Figure 9 is also for the case where $r = 2$, but drawn to a larger scale than Fig. 7 and with the monomers omitted and the trimers, tetramers, and pentamers separated into their main isomers. It is interesting that the theory predicts that at values of α larger than 0.55 the total mole fraction of trimer exceeds that of the dimer.

No attempt is made here to derive a general expression for the mole fraction of an x-mer. In general such an expression would be the combination of two particular solutions of the Bernoulli probability function; Figs. 3 and 4 represent a diagrammatic approach to these solutions.

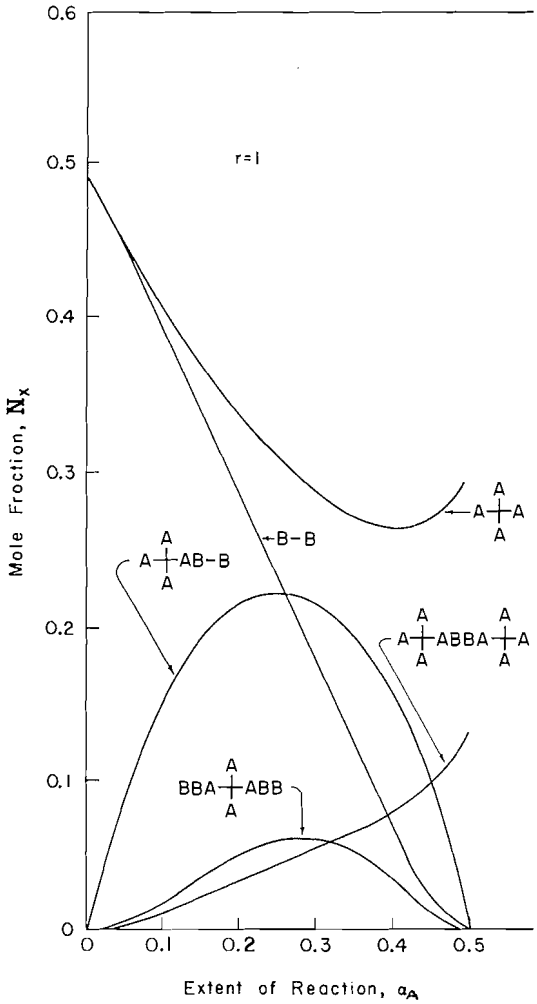

FIG. 5. Mole fractions of various oligomers when r, the ratio of R′—B_2 to R—A_4, is unity.

Distributions for cases where r is outside the stoichiometric range are not given by the above equations, but may be derived readily.

A particularly simple case arises when $r = 1$, $q = 1$, for we begin with equal numbers of equi-functional structural units. When $f = 3$, we have $X = Y = \frac{1}{2}$ and $p_{AB} = p_{BA} = 3\alpha_A/4$. The two schemes for the reassembly of the molecules corresponding to Figs. 3 and 4 are readily constructed, and the mole fractions of the monomers R—A_3 and R′—B_3 each become $\frac{1}{2}(1 - 3\alpha_A/4)^2$. If now we say that the starting units R—A_3 and R′—B_3 are identical we obtain for the mole fraction of monomer $(1 - 3\alpha/4)$, a result identical with that derived directly for the self-condensation of R—A_3. An even more simple case is the one where $f = f' = 2$ and $r = 1$. There $X = Y = \frac{1}{2}$ and $p_{AB} = p_{BA} = \alpha_A$. This equality between α and p occurred before (1) for the condensation of R—A_2.

The expressions given above may be compared with the result of Stockmayer (5) for this system. His p_A, p_B are equivalent to our α_A, α_B and his eq. 2 yields mole fractions when divided by the number of molecules, *e.g.* our eq. 3. For the case considered before, *i.e.*, $f = 4, f' = 2, r = 2$, Stockmayer's expression becomes, in our terminology

$$[13] \quad N_{n,l} = \frac{4[3n]![1 - \alpha_A]^{2+2n}[\alpha_A]^{n+l-1}}{n![3n - l + 1]![l - n + 1]![3 - 4\alpha_A]}$$

where $N_{n,l}$ is the mole fraction of mixed poly-

mer containing nR (tetrafunctional units) and lR (bifunctional units). Figure 10 compares the results of this equation with the present work for the two monomer molecules and the dimer. The main difference is that Stockmayer's equation yields mole fractions which become infinite

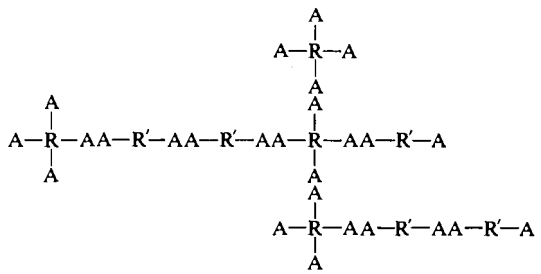

FIG. 11. Polymer formed by condensation of monomer R—A_4 with monomer R′—A_2.

when $\alpha_A = \alpha_{max}$ (0.75 for this system) because the term in the denominator $(3 - 4\alpha_A)$ becomes zero. This is discussed further in the next section.

Condensation of R—A_f with R′—$A_{f'}$

This condensation yields polymers of the type shown in Fig. 11. Expressions derived for this case are important for examining the distributions in silicophosphate and borosilicate glasses.

Molecules of the kind shown in Fig. 11 can, in general, be cut into

$$\text{A—R}(f-1)\text{—},\ \text{A—R}'(f'-1)\text{—},$$

$$\text{AA—R}(f-1)\text{—},\ \text{AA—R}'(f'-1)\text{—},\ \text{and A.}$$

Again no single fragment can be associated with every possible molecule and the molecules must be reassembled by two schemes. We define the number of structural units of type R—A_f to be N_A, the number of type R′—$A_{f'}$ to be M_A, at the beginning of their condensation, and further take $M_A = rN_A, f' = qf$. The following expressions are deduced readily

[14] Number of molecules $= N$

$$= N_A\left[1 + r - \frac{\alpha f}{2}(1 + qr)\right]$$

[15] $$(\alpha_A)_{max} = 2(1 + r)/f(1 + qr)$$

We define X to be the fraction of molecules which must be started by fragments of type A—R$(f-1)$— and Z the remaining fraction which are started by A—R′$(f'-1)$—. As before we determine X as a function of the stoichiometry of the system. When $\alpha_A = 0$ then N_A molecules must be started by these fragments, and $X_{\alpha_A=0} = 1/1 + r$. When α_A approaches $(\alpha_A)_{max}$ the system has condensed to one very large molecule. During this condensation the parts of it composed of R(f)— units exposed $N_A(f-1)$ sites where fragments could be attached while the R′(f')— parts exposed $M_A(f'-1)$ such sites. Therefore the fraction of the A fragments attached to R (and which is also $X_{(\alpha_A=max)}$) is $(f-1)/(f-1+rf'-r)$. Assuming that X is a linear function of α_A between these limits we have

[16] $$X = \frac{1}{1+r} \times \left[1 + \frac{rf^2\alpha(1-q)(1+rq)}{2(1+r)(f-1+rqf-r)}\right]$$

If the number of molecules started by

$$\text{A—R}(f-1)\text{— and A—R}'(f'-1)\text{—}$$

are designated by n_A and m_A, then

[17] $$n_A = XN = XN_A\left[1 + r - \frac{\alpha f}{2}(1 + qr)\right]$$

[18] $$m_A = (1 - X)N = ZN_A \times \left[1 + r - \frac{\alpha f}{2}(1 + qr)\right]$$

None of the remaining fragments has unit probability of being in a specific site relative to the datum site, hence these fragments must be assigned to positions at random. All sites contain AA—R$(f-1)$—, AA—R′$(f'-1)$—, or A, hence the pool of uncommitted fragments must contain all three. In this pool the number of A fragments is the original number minus $n_A + m_A$; expressed as u, this is

[19] $$u = N_A\left[(1-\alpha)(f + f'r) - 1 - r + \frac{\alpha f}{2}(1 + qr)\right]$$

The AA—R$(f-1)$— fragments equal the number of R's remaining after the A—R$(f-1)$— fragments have been committed (eq. 17) and expressing this as v

[20] $$v = N_A - XN$$

Similarly the number of AA—R′$(f'-1)$— fragments in the pool is given by w

[21] $$w = rN_A - ZN$$

Defining the probabilities in the pool of uncommitted fragments as

p_1 = probability of selecting an AA—R$(f-1)$—

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

p_2 = probability of selecting an AA—R′(f' − 1)—

p_3 = probability of selecting an A

we may write

[22] $p_1 = v/u + v + w$

[23] $p_2 = w/u + v + w$

[24] $p_3 = u/u + v + w$

As a specific example it is convenient to take as before $f = 4$, $f' = 2$, $r = 2$, $q = 1/2$. The above expressions become

[25] $N = N_A(3 - 4\alpha)$

[26] $X = (15 + 16\alpha)/45$

[27] $Z = (30 - 16\alpha)/45$

[28] $p_1 = [45 - (3 - 4\alpha)(15 + 16\alpha)]/225$

[29] $p_2 = [90 - (3 - 4\alpha)(30 - 16\alpha)]/225$

[30] $p_3 = (5 - 4\alpha)/5$

Two schemes are started, one by XN A—R< fragments, the other by ZN A—R′— fragments. The schemes are developed as in Figs. 3 and 4 but here there are more structures because each gives rise to three other structures. The mole fractions of a few molecules are shown in Table 2, and in Fig. 12. To simplify, molecules are written as combinations of A_4 and A_2. The chief difference between the distribution of this case and that of condensation of RA_4 with $R'B_2$ is the presence of additional molecules such as A_2A_2, A_4A_4 as well as the effect of these molecules upon the mole fraction of monomers, due to the equilibria involved. Thus dimer A_2A_2 is produced chiefly at the expense of monomer A_2, while the relative decrease in dimer A_4A_2 is reflected by the increase in A_4.

TABLE 2. Mole fractions of selected oligomers of type $(A_4)_i(A_2)_j$

Molecule	Mole fraction
Monomer A_4	p_3^3X
Monomer A_2	p_3Z
Dimer A_4A_2	$3p_3^3p_2X + p_1p_3^3Z$

Trimer $A_2A_4A_2$	$3p_3^3p_2^2X + 2p_1p_3^3p_2Z$
Trimer $A_4A_2A_4$	$3p_3^5p_2p_1X$
Trimer $A_2A_2A_4$	$3p_3^3p_2^2X + 2p_1p_2p_3^3Z$

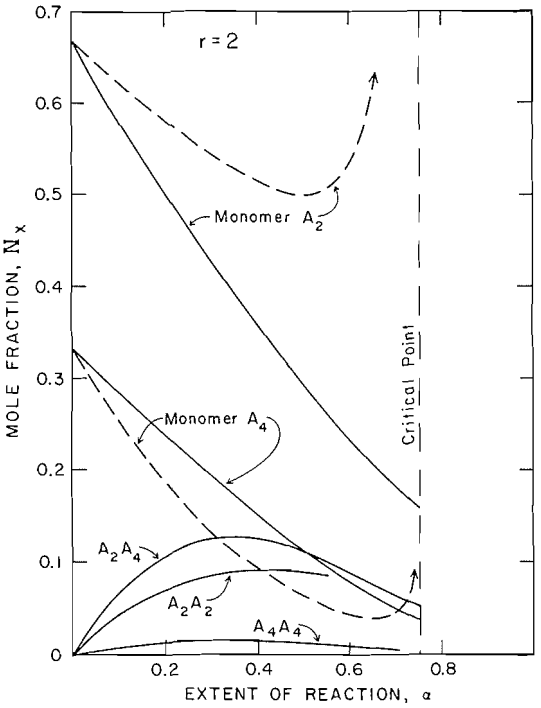

FIG. 12. Mole fractions of various oligomers for $r = 2$ for the condensation of R—A_4 with R′—A_2. Solid lines, this theory. Dashed lines, theory of Flory and Stockmayer.

Stockmayer (6) and Flory (ref. 7, p. 393) give the size distribution for the condensation of R—A_f with R′—A_2. It should be noted that their "p" is equal to our "α", and their ρ is related to our r as follows: $\rho = f/(f + 2r)$. For the example used above their equation becomes:

$$[31]\quad N_{n,l} = \frac{4(l + 3n)!(1 - \alpha)^{2+2n}(\alpha/2)^{n+l-1}}{l!n!(2n + 2)!(3 - 4\alpha)}$$

The results of this expression for the two monomers are shown also in Fig. 12. Again, a major difference between their mole fraction and ours is the behavior as $\alpha \to \alpha_{max}$; our mole fractions remain finite while theirs approach infinity. The reasons for this type of discrepancy, and the errors believed to be inherent in Flory's original derivation, have been discussed before in detail (1, 8) and will not be repeated here.

Further discussion of the molecular size distribution in these systems is given by Gordon and Judd (8) and our reply to their comments (9). The expressions derived in the present work may

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

provide a basis for distinguishing experimentally between the two theories. For example, in the condensation of RA_4 with $R'A_2$ when the initial molar ratio $R'A_2/RA_4$ is 2, the Flory–Stockmayer theory predicts that this ratio will increase during polycondensation to a value of 8 at $\alpha = 0.5$, as shown in Fig. 12, whereas our expressions predict that at this conversion the ratio will be 2.7 and will not exceed 4 at all conversions. In view of the simplifying assumptions in both theories, exact agreement with experiment cannot be expected but the differences may be sufficient to permit an experimental test.

It may be useful to reiterate the underlying principle of our method, as it has been applied to the four cases discussed here. Molecules are "cut" into elementary fragments. Where possible, one type of fragment is chosen so that it is common to every molecule. All molecules then can be reassembled by starting with this type. Because we have no other such definite structural information, the remaining fragments can only be distributed at random among the molecules. (Alternatively two fragments, each common to one class of molecules are produced in the initial imaginary cutting step.) The method ensures a complete accounting of the number of fragments at all stages and guarantees that mole fractions sum to unity over the entire range of α applicable to the model.

A Theoretical Study of the Site of Protonation of Formamide Using Non-empirical LCAO-MO-SCF Calculations

ALAN C. HOPKINSON
Department of Chemistry, York University, Downsview, Ontario
AND
IMRE G. CSIZMADIA
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received November 10, 1972

Molecular orbital calculations are used to show that *O-protonated* formamide is more stable than its *N-protonated* tautomer by 6.2 kcal/mol. The computed proton affinity of formamide (assuming *O-protonation*) is computed to be 254.8 kcal/mol.

On a utilisé des calculs impliquant les orbitales moléculaires pour montrer que la formamide protonée sur l'oxygène est plus stable que son tautomère protoné sur l'azote par 6.2 kcal/mol. L'affinité calculée de la formamide pour un proton (en considérant la protonation sur l'oxygène seulement) est égale à 254.8 kcal/mol. [Traduit par le journal]

The interpretation of physical measurements on protonated amides has led to differing views on the *site* of protonation. Low temperature n.m.r. studies using fluorosulfuric acid as solvent show that the added proton is different from the amino-protons, indicating the amides to be *oxygen-protonated* (1–3). This was reinforced by kinetic studies on the hydrolysis of benzimidates (4). However, in dilute acid the rotational barrier about the C—N bond is reduced below the level of detection and the amino protons exchange with the solvent (5), both suggesting that the amides are *nitrogen-protonated.* The argument for *N-protonation* is further supported by the failure of amide basicities to correlate with the carbonyl stretching frequency (6).

Recently the problem has been re-examined by Liler (3) who suggests that this apparent discrepancy may be explained by amides being *nitrogen-protonated* in dilute aqueous acids but with the *oxygen-protonated* isomer becoming more stable and eventually being predominant as the water activity is decreased. Martin (7), however, using data from proton exchange rates concludes that *oxygen protonation* occurs in all aqueous mineral acid solutions.

The objective of the present work was to use non-empirical molecular orbital calculations to establish which conjugate acid of formamide is the more stable in the gas phase and, using calculated charge densities for the cation, to estimate which will be the more stable in solution. Similar *ab initio* studies have been successful in predicting the relative stabilities of tautomers of CH_3O^+ (8) and $HCOOH_2^+$ (9).

In earlier molecular orbital studies on protonated formamide (10) energy curves were calculated for the approach of the proton to an *unchanged* formamide molecule. We have used a slightly larger basis set and have adopted a different approach, optimizing (*i*) the conformations of the protons on the OH and NH_3 groups and (*ii*) the C—N and C—O bond lengths in both conjugate acids.

The other bond lengths were taken from a previous theoretical study (11); all the bond angles were taken to be trigonal or tetrahedral. The experimental geometry was used for formamide (12). The basis set consisted of 8^S and 3^P-type Gaussian functions on oxygen, nitrogen, and carbon, and 3^S-type functions on hydrogen (13) contracted to 3^S, 1^P, and 1^S, respectively. All the computations were carried out on an IBM-360-65 using a modified version of IBMOL-IV (14).

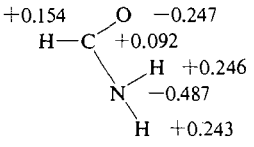
As in previous calculations (15, 16) on formamide, the charge densities show the nitrogen atom to carry the largest negative charge (structure **1**) and, using these as a guide to reactivity, predict *nitrogen protonation.*

The initial calculations on the conjugate acids showed (*i*) the *O-protonated* isomer to be planar

TABLE 1. Computed total energies and energy differences (relative to formamide)

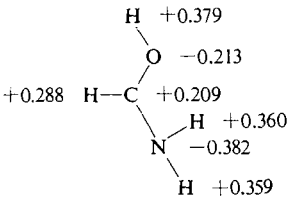
Species	Computed total energy (hartree)	Energy difference (kcal/mol)
Formamide (*a*) experimental geometry	−168.1299	—
(*b*) planar	−168.1296	0.2
O-Protonated formamide	−168.5358	−254.8*
N-Protonated formamide	−168.5259	−248.6*

*These values are proton affinities.

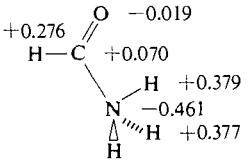


1

with the oxygen proton being *cis* to the hydrogen of the carbon atom (structure **2**) and having a rotational barrier of 12.1 kcal/mol and (*ii*) the rotational barrier about the carbon–nitrogen bond of the *N-protonated* isomer to be 1.3 kcal/mol, with the rotamer in which the in-plane hydrogen is *cis* to the oxygen (structure **3**) being the most stable. This is consistent with other rotational studies in which it has been shown that there is a weak covalent bond between the oxygen of a carbonyl group and an eclipsing hydrogen atom on a neighboring methyl (17) or hydroxy (9) group. The low rotational barrier of the *N-protonated* formamide would result in free rotation about the carbon–nitrogen bond at room temperature, as observed experimentally (5).



2



3

Optimization of the geometry of **2** gave C—N and C—O bond lengths of 1.353 and 1.343 Å, respectively; for **3** optimum values of 1.569, and 1.250 Å were obtained for these bonds. The computed total energies are given in Table 1. The energy difference between the two isomers was found to be 6.2 kcal/mol, with the *O-protonated* formamide being the more stable. In general as the size of the basis set is increased, the energy differences converge on the experimental value (18), and these calculations therefore set an upper value on the energy difference between the isomers.

The molecular orbital calculations are for isolated ions in the gas phase at absolute zero, and it is conceivable that solvation of the ions could still reverse the order of stability in solution. Calculations on the fully solvated tautomers of protonated formamide are computationally too expensive to be attempted by the *ab initio* method. Even addition of only one water molecule, which should result in a stabilization of about 30 kcal/mol (19–23) compared with a total free energy of between 60 and 100 kcal/mol (24) for a small ion, requires too many calculations with a very large number of Gaussian functions to be included in the present work. Also experimental gas phase solvation energies for similar ions are unavailable. However *ab initio* calculations (21–23) on $NH_4^+ \cdot NH_3$ and $H_3O^+ \cdot H_2O$ have shown that the stabilization produced by formation of the monosolvated ion is larger for the hydronium ion. In addition Hogg and Kebarle (25) have shown that NH_4^+ is preferentially solvated in its primary solvation shell by ammonia rather than by water, with $NH_4^+ \cdot 4NH_3$ being more stable than $NH_4^+ \cdot 4H_2O$ by about 5 kcal/mol at 25°C. It therefore seems safe to conclude that addition of at least the first water molecule to the hydroxy group of *O-protonated* formamide will be more exothermic than the same addition to the protonated amino group of the other tautomer. This deduction is in keeping with a previous semi-empirical molecular orbital treatment (11) which showed that one water molecule forms a stable hydrogen bond with *O-protonated* formamide but has no appreciable attractive interaction with the *N-protonated* tautomer.

For personal use only.

The molecular orbital calculations place similar positive charges on the amino protons of both the *O-protonated* and *N-protonated* isomers, and it is therefore reasonable to expect addition of a further two molecules of water to these groups in the monosolvated ions to have similar energies.

Equilibrium results from aqueous acid solutions have shown that weak organic bases which produce hydroxy groups on protonation (*e.g.* ketones, aldehydes, and carboxylic acids) (26, 27) have indicator slopes less than unity, when using the primary aniline acidity function (H_0) (28) as reference. This is interpreted as implying that there is a larger increase in solvation on protonation of the carbonyl group than in the protonation of primary amines (29, 30).

Summarizing the arguments on solvation then (*1*) addition of the initial water molecule to the protonated amides should be more exothermic for the *O-protonated* amide; (*2*) the energies associated with addition of the next two water molecules will probably be very similar for both tautomers, and (*3*) solution results suggest that, contrary to Liler's suggestion (3) the *O-protonated* tautomer will probably have the larger primary solvation shell. (The low ionization slopes for amides have been used to predict that the protonated amides have five water molecules in their primary solvation shells (26, 31, 32).) This reasoning suggests then that solvation will *further stabilize* the *O-protonated* formamide relative to its *N-protonated* tautomer.

Finally, the proton affinity of formamide, assuming *oxygen protonation*, was calculated to be 254.8 kcal/mol. No experimental value is known to the present authors but this estimate is again expected to set an upper limit on the proton affinity (18).

Photochemistry of Ketones in Carbon Tetrachloride Solution

J. O. PAVLIK, P. I. PLOOARD, A. C. SOMERSALL, AND J. E. GUILLET
Department of Chemistry, University of Toronto, Toronto, Ontario

Received September 5, 1972

Acetone, chloroacetone, 4-heptanone, 8-pentadecanone, 12-tricosanone, and dimethyl γ-keto pimellate were photolyzed at 3130 Å in carbon tetrachloride solution. The quantum yields of C_2Cl_6 formed, the decrease in Norrish type I and type II products, the copious yields of HCl and the Stern–Volmer quenching of ketone fluorescence by carbon tetrachloride provide definitive evidence for energy transfer which is rationalized by an exciplex mechanism of low efficiency. The excited $[n,\pi^*]^1$ state of the ketone forms a loose complex with the CCl_4 and radiationless energy transfer leads to dissociation of the CCl_4 in the primary chemical step.

L'acétone, la chloroacétone, la pentadécanone-8, la tricosanone-12 et le γ cétopimellate de diméthyle ont été photolysés à 3130 Å en solution dans le tétrachlorure de carbone. Les rendements quantiques en C_2Cl_6 formé, la décroissance des produits selon le Norrish type I et II, les rendements élevés en HCl et l'extinction de la fluorescence de la cétone selon le mécanisme de Stern–Volmer, par la tétrachlorure de carbone, fournissent une preuve définitive du transfert d'énergie expliqué par un complexe excité de fabile efficacité. L'état excité $[n,\pi^*]^1$ de la cétone forme un complexe labile avec le tétrachlorure de carbone et l'énergie de transfert sans radiation conduit à la dissociation du tétrachlorure de carbone durant l'étape chimique primaire. Introduction

The photochemistry of aliphatic ketones has been intensively investigated both in the vapor phase and in solution (1, 2). Photolysis studies of mixtures of ketones and halogenated compounds have revealed several new and interesting aspects of ketone photochemistry. The importance of the $[n,\pi^*]$ singlet state of ketones in organic photochemistry has only recently become generally appreciated. The sensitization of biacetyl fluorescence (3) and other photophysical processes has now been complemented with the observation of a singlet ketone-sensitized chemical process, the photodecomposition of dichlorobutanes (4–6). Several investigators (7–10) have previously suggested that the photosensitized decomposition of CCl_4 may be an important mechanism in the photolysis of ketones in the presence of CCl_4, but no definitive experiments have been reported to substantiate any general conclusion.

Cvetanović *et al.* (8) observed HCl as a product in the gas phase photolysis of mixtures of acetone and CCl_4 in the region where CCl_4 is transparent and Peterson and Mains (10) obtained a similar result in solution. Mettee (11) monitored phosgene as one of the major products of both continuous and flash photolyses of dilute, oxygenated CCl_4 solutions of acetone, benzophenone, and several α,β-unsaturated ketones. HCl was also detected after the photolyses of degassed acetone and of carvone in CCl_4. In an attempt to confirm that photosensitization could occur, Mettee also found that the emission of acetone at 3130 Å was reduced with increasing CCl_4 pressure but concluded that since quenching could occur by mechanisms other than energy transfer the experiment was not definitive. Gregory and Wijnen (12) found C_2Cl_6 as a minor product on irradiating mixtures of diethyl ketone and CCl_4 in the gas phase as well as other recombination and disproportionation reactions involving $CCl_3\cdot$ radicals.

The present study was initiated to elucidate further the photochemistry of aliphatic ketones in CCl_4 solution.

Experimental

Materials

Acetone, cyclohexane, and carbon tetrachloride were of Fisher spectranalyzed quality. 8-Pentadecanone and 12-tricosanone were prepared by the method of Davis and Schultz (13). The other ketones were purified on a Varian Aerograph preparative gas chromatograph. Dimethyl γ-ketopimelate (DMKP) was synthesized from the crude product furylacrylic acid by the method of Lukes *et al.* (14). The white solid was purified by redistillation at 130°/1 mm and checked by gas chromatography, n.m.r., and u.v. spectra.

Photolysis

The source of u.v. light was a 250 W medium pressure mercury arc lamp (A.E.I., M.E/D box type) fitted with

TABLE 1. Quantum yields of photolysis products of ketones in CCl_4 at 3130 Å (30 °C)

Ketone	$\phi_{C_2Cl_6}$ Air	$\phi_{C_2Cl_6}$ Vacuo	ϕ_{HCl} air	Other products (quantum yield)
Acetone	0.049	0.087	1.5	Chloroacetone (0.068)
4-Heptanone	0.20	0.27	2.4	Not identified
8-Pentadecanone (60 °C)	0.14	—	0.95	1-Chloroheptane (0.018) type I Octanoyl chloride (0.013) type I 1-Hexene (0.034) type II
12-Tricosanone	0.13	0.14	0.88	Not identified
Chloroacetone	0.21	—	Detected	Acetone (0.042)
Dimethyl γ-keto pimelate	0.20	—	—	Methyl propanoate (0.03) type I

an interference filter to isolate 3130 Å light. Samples were irradiated in 1 mm and 10 mm path length quartz cells in a temperature block for C_2Cl_6 measurements. Actinometry was done using both uranyl oxalate and ferrioxalate actinometers. Photolysis products were measured on a Perkin–Elmer Model 800 Gas Chromatograph. Some products of irradiation were identified by comparing retention times on the gas chromatograph, others were collected for mass spectrometric analysis and some remained unidentified.

For measurements of HCl yields a 10 mm cell was fitted with a side arm and bulbs in which liberated gas was collected in distilled water. The water and CCl_4 residues were titrated separately with standardized sodium hydroxide using phenolphthalein as indicator. The total titrant volume was reproducible over several measurements and different radiation times, but in general more titrant was required for the water portion with increasing radiation dose.

Fluorescence Measurements

Fluorescence spectra were obtained in 10 mm quartz cells on a Perkin–Elmer Hitachi MPF-2A Fluorescence Spectrophotometer with a 150 W xenon lamp source. Spectra were ratio recorded to correct for any fluctuation in source intensity and at right angle illumination.

Results

Photolysis

Acetone, chloroacetone, 4-heptanone, 12-tricosanone, and dimethyl γ-keto pimelate (DMKP) were photolyzed in CCl_4 solution at 30° using 3130 Å which was not absorbed by the neat solvent. A more detailed analysis of photolysis products was carried out for 8-pentadecanone under similar conditions, but at 60°. The principal products analyzed by gas chromatography and apparent yields of HCl from titration are summarized in Table 1. The estimated errors are less than 10%. The major products of irradiation of ketones in CCl_4 solution were consistently C_2Cl_6 and HCl. No products were detected after extended irradiation of neat CCl_4. In the case of acetone photolysis, chloroacetone was also a major product. Similarly, in the irradiation of chloroacetone, acetone was a major product. Only one Norrish type I product, acetyl chloride, was observed for acetone and with very low quantum yield ($\sim 10^{-5}$ mol/einstein). However, for the larger representative symmetric ketone, 8-pentadecanone, both Norrish type I and II products were obtained. For the keto diester DMKP the yield of type I product was also significant.

HCl yields were determined by titration and confirmed by precipitation with $AgNO_3$. The quantum yields in air are unusually high, but many irradiations of different ketones gave consistent and reproducible results although neat CCl_4 showed no HCl after extended irradiation. The quantum yield for HCl in the absence of air and moisture was obtained by degassing CCl_4 and 4-heptanone through several freeze–thaw cycles. The CCl_4 was then distilled under high vacuum into the cell containing the frozen ketone and the cell was sealed off for photolysis. After the irradiation, the mixture was cooled in liquid nitrogen, water was added, and the liquid solution titrated. Under these reproducible conditions, the quantum yield of HCl was reduced to 0.56 for 4-heptanone.

Fluorescence Measurements

The broad fluorescence band of aliphatic ketones in solution (λ_{max} 4000 Å) has been characterized recently by O'Sullivan and Testa (15). Similar spectra were obtained in this work for all the symmetric ketones measured in solvent mixtures ranging from neat cyclohexane to neat CCl_4. Stern–Volmer plots of the relative fluorescence intensity values, obtained from area integration of the band spectra, against the CCl_4 concentration show a linear dependence

*Relative to ϕ_F (acetone). The value obtained by O'Sullivan and Testa (ref. 15) of 10^{-3} is assumed as a secondary standard.

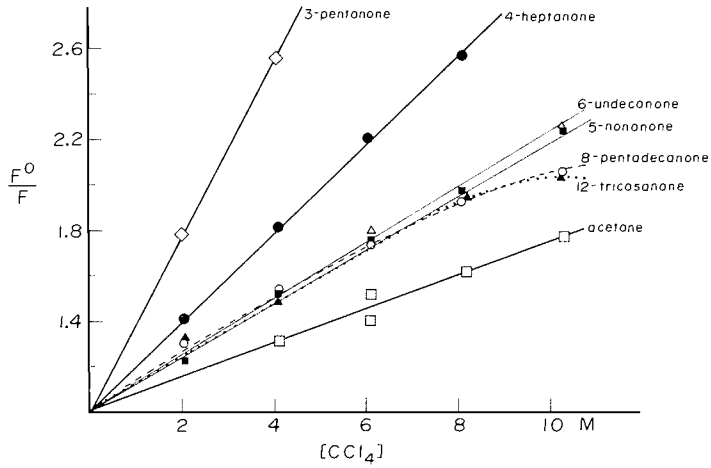

FIG. 1. Stern–Volmer plots for fluorescence quenching of various ketones by CCl_4 at 30 °C in cyclohexane. F^0 is the intensity of fluorescence in absence of quencher, F the intensity in presence of designated concentration of CCl_4.

(Fig. 1). The slopes of these lines give values of $k_q{}^1\tau$ and hence k_q, where ${}^1\tau$ is the singlet lifetime of the ketone and k_q is the rate constant for quenching of the excited ketone singlet by CCl_4. Singlet lifetimes were estimated from the fluorescence quantum yields and integrated absorption spectra following O'Sullivan and Testa (16) and are consistent with values in the literature. Quenching efficiency was estimated from the ratio of the fluorescence quenching constant k_q to the diffusion constant k_{diff} obtained from the equation of Osborne and Porter (17),

$$[1] \qquad k_{diff} = \frac{8RT}{2000\,\eta}$$

where η is the solvent viscosity. The results are summarized in Table 2.

Discussion

The consistent observation of C_2Cl_6 as a photolysis product of ketones in CCl_4 at a wavelength where the solvent is transparent is consistent with radical recombination of $CCl_3^{\cdot}$ formed by sensitized decomposition of CCl_4

$$[2] \qquad CCl_4^* \rightarrow CCl_3^{\cdot} + Cl^{\cdot}$$

The observed increase of the C_2Cl_6 yield in degassed solution probably indicates the removal of $CCl_3^{\cdot}$ radicals by the formation of phosgene in aerated solution. No attempt was made to monitor this latter product. Phosgene, which has been identified in similar work by Mettee (11) in oxygenated solutions would be formed here by the reaction of $CCl_3^{\cdot}$ radicals with oxygen from the dissolved air.

$$[3] \qquad CCl_3^{\cdot} + \tfrac{1}{2}O_2 \rightarrow COCl_2 + Cl^{\cdot}$$

Hartley and Guillet (18) found that for irradiation of 8-pentadecanone at 60° in hydrocarbon solvent, the type II process had a quantum efficiency as high as 0.07 and measured a quantum yield of 0.005 for carbon monoxide. Com-

parison with the results in Table 1 indicates that ϕ_{II} is decreased in CCl_4 compared with hydrocarbon solvents, and $\phi_{C_2Cl_6}$ is too high to be explained by any other ketone decomposition pathway. The type I process of DMKP was shown to give a product quantum yield as high as 0.40 in *p*-dioxane (19) compared to 0.03 in CCl_4. The considerable reduction of the quantum yields of ketone reactions in CCl_4 and the consistent formation of C_2Cl_6 is good evidence for energy transfer from the excited ketone to CCl_4 molecules in solution.

Comparison of the fluorescence quenching efficiencies (Table 2) shows that energy transfer from the excited ketone singlet occurs in only a few encounters in every hundred. However, the linear Stern–Volmer plots for various ketones have slopes ($k_q{}^1\tau$) which follow similar trends to the quantum yields of C_2Cl_6 and HCl, which is consistent with sensitization of CCl_4 decomposition as a result of energy transfer.

It is obvious that the observed kinetics cannot imply that the quenching rate is determined by the number of collisions which takes place by the mutual diffusion of the excited molecule and the quenchers. If diffusion were rate-determining, then at high CCl_4 concentration, the probability of a ketone molecule being surrounded by a quencher molecule would be very high, and instantaneous "static" quenching would have caused the lines to curve upwards sharply. This was not observed in CCl_4 even as a neat solvent for the ketones and therefore some factor other than diffusion must be controlling the quenching rate.

Classical electronic transfer by excitation of the acceptor to an *electronic* level above the ground state on collision, as in the Dexter mechanism (20), cannot be important here because the absorption spectrum of neat CCl_4 shows zero absorbance above 300 nm and the ketone fluorescence showed a cut-off at a minimum above 320 nm. There is therefore a negligible overlap in the emission spectrum of the donor and the absorption spectrum of the acceptor which is demanded by any classical electronic transfer mechanism. However, the excited $[n,\pi^*]^1$ state is estimated to be more than 80 kcal/mol above the ground state for aliphatic ketones (2) and the C—Cl bond strength is only 68 kcal/mol so that exothermic transfer by some other mechanism is energetically feasible.

Quenching of singlet states without classical electronic energy transfer has recently been investigated for the quenching of aromatic compounds by quenchers having no lower-lying singlet states (21). The phenomenon has been visualized by Hammond and his co-workers as involving an interaction between the excited state of the donor and the quencher molecule, forming a loosely bound exciplex or an excited dimer which results in an increase in the rates of non-radiative decay processes. Examples of such a mechanism include the quenching of fluorescence of aromatic molecules by dienes (21), methyl chloroacetate, and chloroacetamide (22), the quenching of ketone singlets at high diene concentration (23) and the sensitization of dichlorobutanes by ketones (4–6). The quenching rate is determined by the efficiency of formation of the exciplex during an encounter and this efficiency is rather low.

The results obtained here for ketone fluorescence quenching by carbon tetrachloride, the measurements of the C_2Cl_6 quantum yields, and the formation of copious amounts of HCl are consistent with the following mechanism, where the ketone molecule is designated as KH:

[4] $KH + h\nu_F$

[5] $KH + \text{heat}$

[6] $KH \xrightarrow{h\nu} {}^1KH^* \rightarrow {}^3KH$

[7] Norrish products

[8] $({}^1KH^*.CCl_4)$

[9] $({}^1KH^*\ CCl_4) \rightarrow KH + Cl^{\cdot} + CCl_3^{\cdot}$

[10] $2CCl_3^{\cdot} \rightarrow C_2Cl_6$

[11] $Cl^{\cdot} + KH \rightarrow K^{\cdot} + HCl$

[12] $K^{\cdot} + CCl_4 \rightarrow (K)Cl + CCl_3^{\cdot}$

[13] $K^{\cdot} + Cl^{\cdot} \rightarrow (K)Cl$

[14] $K^{\cdot} + CCl_3^{\cdot} \rightarrow (K)CCl_3$

In the presence of air and moisture the yield of HCl would increase as other reactions become important:

[15] $CCl_3^{\cdot} + \frac{1}{2}O_2 \rightarrow COCl_2 + Cl^{\cdot}$

[16] $COCl_2 + 2H_2O \rightarrow CO(OH)_2 + 2HCl$

[17] $CO(OH)_2 \rightarrow CO_2 + H_2O$

If the mechanism by which CCl_4 quenches the ketone fluorescence in solution leads to the sensitized decomposition of the CCl_4 as in reactions 8 and 9, and if proton abstraction is very

TABLE 3. Comparison of sensitization data

	$k_q{}^1\tau$	$\phi_{C_2Cl_6}$ (air)	ϕ_{HCl} Air Obsd.	ϕ_{HCl} Air Calcd.	ϕ_{HCl} Vacuo Obsd.	ϕ_{HCl} Vacuo Calcd.
Acetone	0.076	0.05	1.5	1.7		
4-Heptanone	0.20	0.20	2.5	2.7	0.56	0.67
8-Pentadecanone	0.12	0.14	0.95			
12-Tricosanone	0.13	0.13	0.88			

efficient, then in the absence of air and moisture the scheme would predict

$$[18] \qquad \phi_{HCl}(vac) \sim \frac{k_Q[CCl_4]}{k_Q[CCl_4] + \frac{1}{{}^1\tau^0}}$$

Equation 18 predicts for 4-heptanone $\phi_{HCl} \sim 0.67$ which is in good agreement with the measured value 0.6. However in the presence of air and moisture, reactions 15 and 16 also lead to the formation of HCl and would suggest that

$$[19] \qquad \phi_{HCl}(air) \sim 4\phi_{HCl}(vac)$$

Again the results for 4-heptanone and for acetone are quite good (Table 3). The larger ketones do not succumb to such simple treatment as the importance of reactions 13 and 14 and other secondary reactions lead to other products as evidenced by the occurrence of unidentified peaks in the gas chromatograms of these irradiated solutions. Thus transfer to excitation energy from a ketone molecule to CCl_4 leads to exothermic cleavage of a C—Cl bond followed by a complex sequence of free radical reactions, some products of which have been characterized.

The existence of the exciplex as some kind of metastable intermediate is not indispensable to the mechanism since the results are consistent with a single-step transfer process

$$[20] \qquad {}^1K^* + CCl_4 \rightarrow K + Cl^{\cdot} + CCl_3^{\cdot}$$

However it is reasonable to suppose that the exciplex does have a finite lifetime during which electronic–vibrational coupling takes place. The nature of the deactivation pathway for the exciplex is probably dependent on the nature of the donor–acceptor interaction which may be of different types including resonance transfer and more probably charge transfer. An explanation based on the increase in intersystem crossing due to the "heavy atom" effect seems unlikely since it has been shown by Kearns and Case (24) that this effect is very small in the case of n–π* transitions.

Results obtained for chloroacetone photolysis in CCl_4 show that energy transfer also takes place in this case, since C_2Cl_6 is observed as a significant product, but the primary step involved cleavage of the C—Cl bond of the substituted ketone as was shown in the gas phase (25). The C—Cl bond in chloroacetone, unlike the C—H bond in acetone, is weak enough for exothermic cleavage following absorption of 3130 Å radiation.

Conclusions

The evidence from photolysis studies of ketones in carbon tetrachloride at 3130 Å suggests that energy transfer occurs from the $[n,\pi^*]^1$ state of the ketone to CCl_4 leading to photosensitized decomposition of the CCl_4 into Cl atoms and $CCl_3^{\cdot}$ radicals. The major chemical products seem to result from subsequent reactions of these fragments with the substrate. Fluorescence studies are consistent with an exciplex mechanism for the energy transfer process.

Low Temperature Infrared Study of Hydrogen Bonding in Acetone Oxime-d_6

THÉRÈSE DI PAOLO AND CAMILLE SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec
Received November 15, 1972

The infrared spectrum of $(CD_3)_2C{=}N{-}OH$ was measured in solution down to liquid nitrogen temperature. As the temperature is lowered several new "associated bands" appear indicating the presence of species more highly associated than cyclic dimers or trimers.

Le spectre infrarouge de la molécule $(CD_3)_2C{=}N{-}OH$ a été mesuré en solution à des températures différentes jusqu'à celle de l'azote liquide. Plusieurs "bandes associées" nouvelles apparaissent révélant la présence d'espèces plus associées que les dimères et les trimères cycliques.

For personal use only.

Self-association of oximes by hydrogen bonding has been investigated by several authors. Among their works we are mentioning those of Califano and Lüttke (1, 2), Ossart, Sauvaître, and Pineau (3), Hadži and Premru (4), Jackson (5), and Harris and Bush (6). These relate to acetone oxime; for higher oximes we refer to Geiseler and Fruwert (7). All these authors agree that in solution and in the solid state oximes form mainly cyclic dimers and trimers through O—H---N bonds. Cyclic trimers containing O—H---O type bonds were also considered (1). Outside of the free OH band which is near 3610 cm^{-1} in dilute solutions these authors described two associated bands in more concentrated solutions, centered at about 3300 and 3150 cm^{-1}.

We measured the infrared spectrum of acetone oxime in a 1:1 mixture of CCl_3F (Freon-11) and CF_2BrCF_2Br (Freon 114-B-2) (8, 9) (which forms a rigid glass at liquid nitrogen temperature) in order to study the changes in molecular associations over a wide range of temperatures. Since bands affected by hydrogen bond formation appeared in the methyl CH stretching region we studied the deuterated compound $(CD_3)_2C{=}N{-}OH$ instead of the light compound. The isotopic purity of the sample was 99.5%.

Our measurements were made on a Perkin–Elmer model 621 spectrometer. The low temperature techniques used were described earlier (8, 9). $(CD_3)_2C{=}N{-}OH$ was supplied by Merck, Sharp and Dohme of Canada, Ltd.

The spectra obtained at temperatures ranging from 25 to −180 °C are shown in Fig. 1. At room temperature at 0.1 *M* concentration we see the free band, a very broad band centered at 3260 cm^{-1}, a weaker band at about 3100 cm^{-1}, and a band at about 2900 cm^{-1}. (The band at 2675 cm^{-1} is likely to be the first overtone of the free OH bending vibration (2, 6).) As the temperature is lowered the low frequency bands become more intense. At −180 °C we see at least six bands or shoulders located at approximately 3200, 3150, 3075, 3020 sh, 2880, and 2760 cm^{-1}. Although the first overtone of the C=N stretching vibration might be present at about 3300–3250 cm^{-1}, a combination of the C=N stretching and OH bending vibrations may fall into the 3000 cm^{-1} region and may be boosted by Fermi resonance it is plain that we have at least four and possibly more associated species present in the solution. (The OH band falling into the CH_3 stretching region is particularly noteworthy.)

In order to rule out the possibility of the presence of hydrogen bonds involving the bromine atoms of the solvent we measured the spectra in a 1:1 mixture of CCl_3F and fully deuterated methylcyclohexane which also forms a glass at low temperature. The spectra were essentially unchanged.

According to available crystallographic studies (10) the structure of solid acetone oxime consists of sheets of planar trimers having intermolecular O—H---N hydrogen bonds. In the infrared spectrum of the crystal two broad bands are seen in the 3200–3100 cm^{-1} region (2, 6). Thus a comparison with crystal spectra indicates that the bands we have found at lower frequencies must be due to species more highly associated than cyclic dimers and trimers, possibly to hydrogen bonded chainlike structures. Tautom-

A Low-temperature Infrared Study of Self-association in Thiolic Acids

R. BICCA DE ALENCASTRO[1] AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal, Québec

Received November 16, 1972

The i.r. spectra of thioloacetic and thiolobenzoic acids were measured in both the fundamental and first overtone regions of the S—H stretching vibration, in a mixture of CCl_3F and $C_2F_4Br_2$, at temperatures ranging from 20 to −190 °C. S—H---O type bonds are formed at low temperatures or at high concentrations of solute. Two different species can be detected. The first is probably an open dimer and the second a cyclic dimer. The S—H anharmonicity constants are of the order of 50–60 cm^{-1}, for both free and associated species, and have about the same value as in aliphatic or aromatic mercaptans. Carbonyl groups have lower anharmonicities. Their value is about 10 cm^{-1} for both free and associated species.

Les spectres i.r. des acides thioloacétique et thiolobenzoïque ont été mesurés au niveau de la fondamentale et de la première harmonique de la vibration de valence S—H dans un mélange de CCl_3F et $C_2F_4Br_2$ à des températures allant de 20 à −190 °C. Sur l'effet de l'abaissement de la température ou de l'augmentation de la concentration des liaisons du type S—H---O sont formées. Deux espèces différentes sont observées. La première est probablement un dimère ouvert et la deuxième un dimère fermé. Les constantes d'anharmonicité pour les vibrateurs S—H libres et associés sont de l'ordre de 50–60 cm^{-1}, c'est-à-dire du même ordre de grandeur que celles des mercaptans. Les constantes d'anharmonicité pour les carbonyles libres et associés sont plus faibles et sont de l'ordre de 10 cm^{-1}.

Can. J. Chem., 51, 1443 (1973)

Introduction

In previous publications (1, 2) we have studied the self-association in thiols and the association of thiols with organic nitrogen bases. We have been able to detect associated S—H---S type species, in the case of the self-association of thiols and, S—H---N type species, in the presence of the strong bases pyridine and triethylamine. In this paper we deal with the interesting case of the self-association of thiolic acids, where the possibility of S—H---O type hydrogen-bonded species occurs.

Some earlier studies of the association of thiolic acids have been made (3–6). Ginzburg and Loginova (3) studied the self-association of thioloacetic and thiolobenzoic acids, in solution in CCl_4 by i.r. spectrometry, and were able to detect changes in the S—H and C=O stretching vibration regions. They suggested that the predominant associated species is, at room temperature, an open dimer of the S—H---O type. The shape of the associated band suggested, furthermore, that another species was present, probably the cyclic dimer.

In the present work we have studied the self-association of thioloacetic and thiolobenzoic acids over a wide temperature range and have measured both the fundamental and first overtone of the S—H and C=O stretching vibrations. The solvent was a 1:1 mixture of CCl_3F (Freon 11) and $C_2Br_2F_4$ (Freon 114-B2), (FR), which becomes a rigid glass at liquid nitrogen temperature. We hoped to follow the changing pattern of self-association from room to −190 °C temperature and to identify the associated species which appeared.

Experimental

The technique and instruments used were fully described elsewhere (1, 2). CCl_3F (Freon 11) and $C_2Br_2F_4$ (Freon 114-B2) were obtained from E.I. Dupont de Nemours Co., and were distilled and kept over phosphorus pentoxide. Spectrograde quality carbon tetrachloride from Anachemia Chems. Ltd., Montreal, was dried on molecular sieves of the type 4A. The thiolic acids were from Aldrich Chem. Co. Inc., and were i.r. and refraction index controlled. The i.r. spectra of these compounds were practically identical with their previously published spectra. They were handled in inert atmosphere to avoid oxidation or moisture adsorption. The solutions were prepared gravimetrically and the concentrations were corrected for solvent contraction. They were used immediately after preparation.

Results

The results we obtained by concentration and temperature studies are very similar for thioloacetic and thiolobenzoic acids and we shall dis-

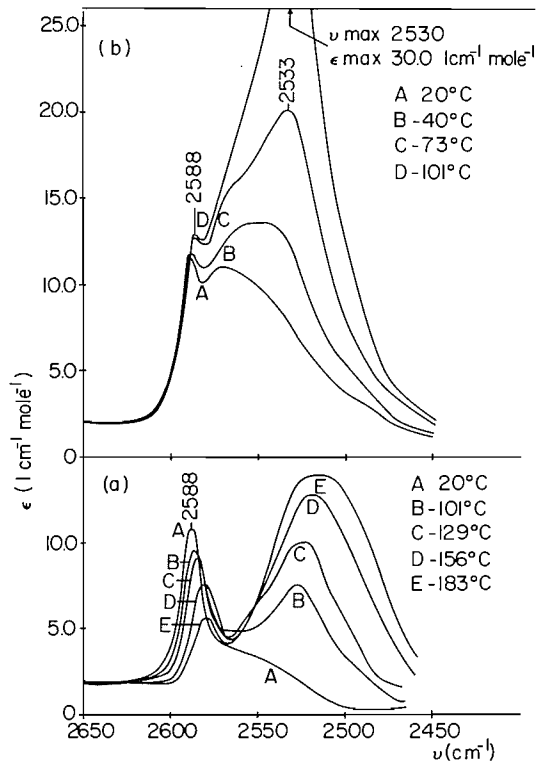

FIG. 1. The i.r. spectra (2450–2650 cm^{-1}) of solutions of thioloacetic acid in FR (*a*) 0.32 *M*; (*b*) 1.55 *M*, at different temperatures.

cuss both cases as a whole (Figs. 1–6). In the case of thiolobenzoic acid our temperature studies were somewhat limited by poor solubility.

(a) The S—H Vibrator

Concentration studies on the S—H stretching region give essentially the same results as those published by Ginzburg and Loginova (3) and, therefore, we shall not reproduce them here. The free band of thioloacetic acid is found to have a half-width of 15 cm^{-1} in a 0.21 *M* solution in CCl_4. Its maximum, located at 2587 cm^{-1}, has an intensity coefficient of about 23.1 cm^{-1} mol^{-1}, which is several times stronger than those we found for the mercaptans (1). In the case of thiolobenzoic acid, the free band has a half-width of 13 cm^{-1} in a 0.31 *M* solution in CCl_4, and its maximum, which is located at 2589 cm^{-1}, has an intensity coefficient of about 28.1 cm^{-1} mol^{-1}. In a solvent less active than CCl_4 (in the present case our solvent FR) the free bands are less intense (about 11.1 cm^{-1} mol^{-1} for both thiolic acids) but have about the same half-widths. The frequency is only slightly changed. These systems seem to behave similarly to the dimethylamine NH stretching band, as described by Wolff and Gamer (7). (For a more elaborate discussion of the effect of "inert" solvents on X—H stretching bands (X = O,N), see ref. 8.)

Upon lowering of the temperature (Figs. 1 and 3), the free band loses intensity and a broad band appears at lower frequencies. In the case of thioloacetic acid, only one large and broad band can be seen in dilute solution (Fig. 1*a*), which has a half-width of 68 cm^{-1}, with maximum near 2515 cm^{-1}, at −183 °C. Temperature studies in a more concentrated solution (Fig. 1*b*) clearly show that this band is actually due to two different species. Naturally, since increasing concentration should favor association, the apparent extinction coefficient of the associated bands is larger in Fig. 1*b* than in Fig. 1*a*, at the same temperature. In dilute solution of thiolobenzoic acid, the lowest temperature we could reach was −129 °C but two bands are also clearly seen (Fig. 3). The frequencies of the associated bands are about the same as for thioloacetic acid.

Concentration and temperature studies on the first overtone of the S—H stretching vibration (Figs. 2 and 4) seem to confirm these observations. Although no new maxima are observable when the concentration of the thiolic acids in CCl_4 is increased, the half-width is greatly increased and the free band loses intensity. In the case of a 0.66 *M* solution of thioloacetic acid in FR, however, two bands are readily seen when temperature is lowered. The case of thiolobenzoic acid in FR is less clear when temperature is lowered, but the associated bands can be seen to appear in the same region. Weaker bands are present near 4915 cm^{-1}, for thioloacetic acid, and 4980 cm^{-1}, for thiolobenzoic acid. Since these bands are found to persist even in very dilute solutions (where the ε_{max} of the free band no longer increases), and the possibility of intramolecular hydrogen bonding is considered unlikely on sterical grounds, these bands are probably combination tones.

(b) The C=O Vibrator

We have studied the C=O stretching region of thioloacetic acid. Thiolobenzoic acid must behave similarly as shown by concentration studies (3).

Figure 5 shows the effect of temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

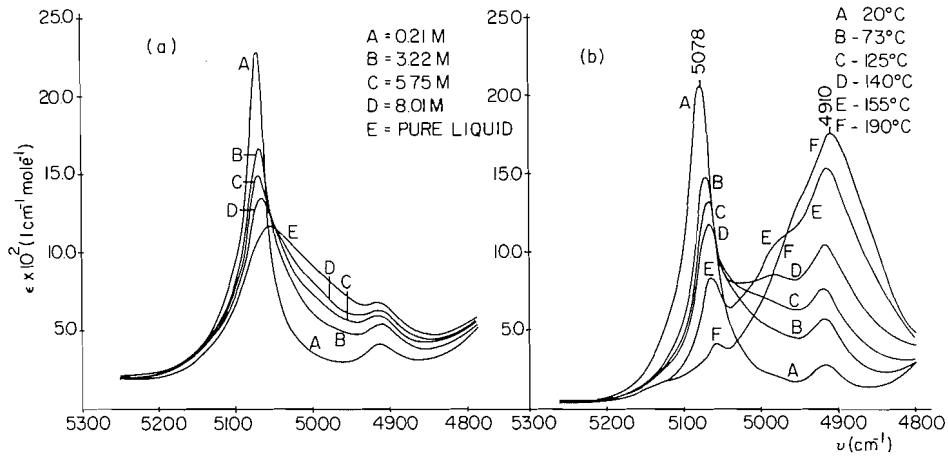

FIG. 2. The i.r. spectra (4800–5300 cm^{-1}) of solutions of thioloacetic acid (*a*) at different concentrations in CCl_4 at 20 °C; (*b*) 0.66 *M* in FR, at different temperatures.

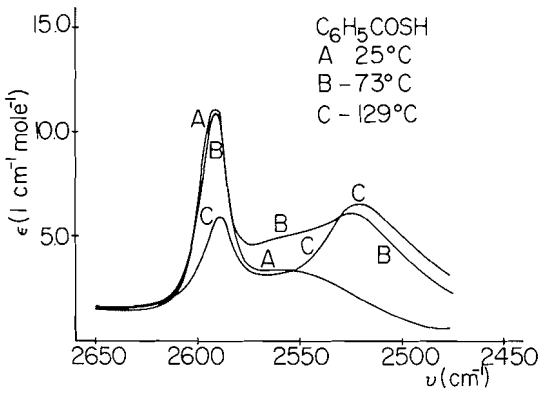

FIG. 3. The i.r. spectra (2450–2650 cm^{-1}) of a 0.59 *M* solution of thiolobenzoic acid in FR at different temperatures.

variation on the frequency of the CO stretching vibration. At room temperature one band is seen in a 0.26 *M* solution of thioloacetic acid in FR, which has its maximum at 1715 cm^{-1}. At −185 °C the band is at 1686 cm^{-1} with a shoulder on the high frequency side. At intermediate temperatures two bands are seen. Concentration studies (3) give, at room temperature, the free carbonyl stretching band at 1710 cm^{-1}, in CCl_4, and the associated carbonyl at 1690 cm^{-1}.

The first overtone of the carbonyl stretching vibration seems to confirm the presence of at least two different carbonyls (Fig. 6), and the maxima shift with temperature in the same way as the fundamental. Concentration studies show no double maxima in CCl_4, but the increase of the half-width and a pronounced asymmetry at the lower frequency side suggests that more than one species are present.

Discussion

Although no spectroscopic evidence is found against the existence of S—H---S hydrogen-bonded species in thiolic acids (these are to be

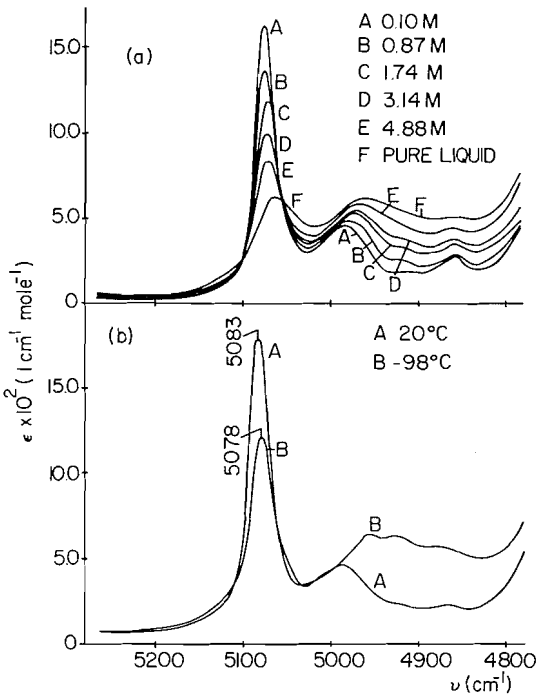

FIG. 4. The i.r. spectra (4800–5300 cm^{-1}) of solutions of thiolobenzoic acid (*a*) at different concentrations in CCl_4, at 20 °C; (*b*) 0.32 *M* in FR, at 20 and −98 °C.

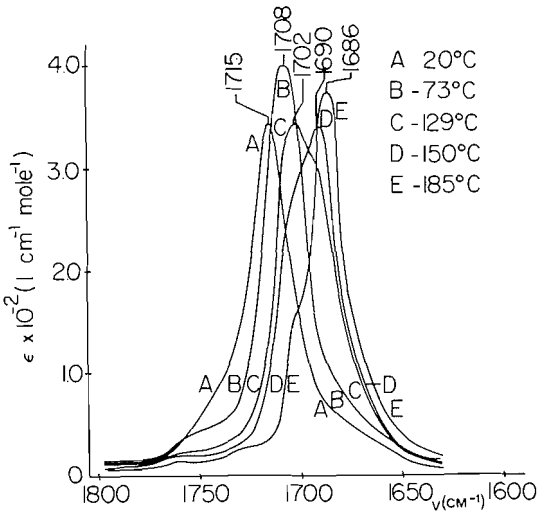

FIG. 5. The i.r. spectra (1600–1800 cm^{-1}) of a 0.26 *M* solution of thioloacetic acid in FR at different temperatures.

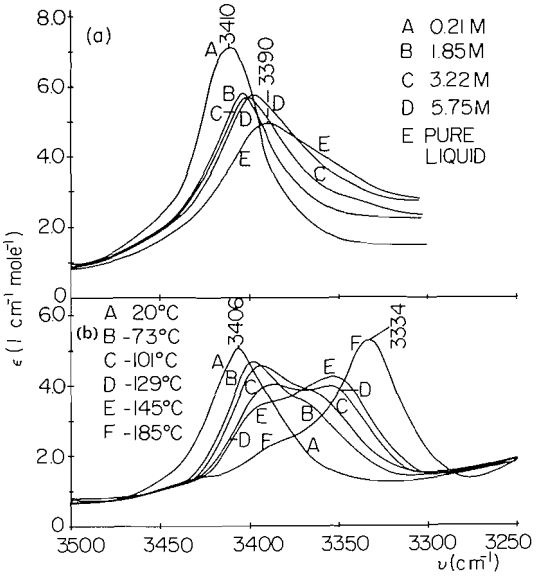

FIG. 6. The i.r. spectra (3250–3500 cm^{-1}) of solutions of thioloacetic acid (*a*) at different concentrations in CCl_4 at 20 °C; (*b*) 0.90 *M* in FR at different temperatures.

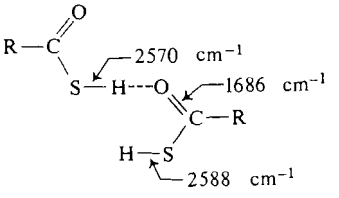
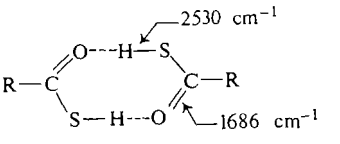
found also in the region 2500–2550 cm^{-1} where we have found the association bands), they should be considered unlikely because the oxygen atom is a better acceptor than the sulfur atom. In fact one can see that the carbonyl stretching frequency undergoes changes paralleling those of the S—H band, both upon increases in concentration of the thiolic acids at the same temperature in solution, or upon decreasing the temperature of a dilute solution. It seems, therefore, that S—H---O type bonds are formed, and that the best analogy for the understanding of self-association in thiolic acids is the carboxylic acids, as pointed out by Ginzburg and Loginova (3). On the other hand, since mercaptans are known to associate less than the corresponding alcohols, we must expect to observe the formation of only a few associated species of the S—H---O type. The possible structures are small chain oligomers and small cyclic structures with probably no more than three molecules in each.

Our evidence (the existence of two associated bands in the S—H stretching region and the virtual absence of free S—H and C=O bands at low temperatures) seems to show that only the cyclic structures remain at the lowest temperature but the possibility of having open structures is likely at intermediate temperatures. Acetic acid is known (9) to form cyclic dimers, both in the gas phase and in dilute solutions. In more concentrated solutions or in the pure liquid, open chain oligomers are found. It seems natural to assign the less displaced associated bands to the open dimer **1** which at lower



1

temperatures changes into a cyclic structure. Earlier data on thioloacetic acid add support for the existence of the cyclic dimer structure **2** (10). A CSH angle of 105° is sufficient to obtain a structure similar to the acetic acid dimer. No distortion in the obtained structure in the gas phase is required supposing a linear hydrogen bonding (compare with a HSH angle of 92° in H_2S (11) and a CSH angle of 96° 30′ in simple mercaptans (12, 13)).



2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The anharmonicity coefficients computed from

$$W_e X_e = \nu_{01} - \nu_{02}/2$$

are of the order of 50–60 cm^{-1}, for both the free and associated S—H groups which is about the same value we found for mercaptans (1). The values for the C=O stretching vibration are of about 10 cm^{-1} and are not very different from those of free or associated carbonyls.

Conclusions

The above results seem to indicate that thiolic acids are associated by S—H---O bonds. Two species are found when temperature is lowered or concentration raised. The first is probably an open dimer and the second a cyclic dimer. The S—H stretching anharmonicity constants are low and are of the order of 50–60 cm^{-1} for both free and associated species and have about the same values as in aliphatic or aromatic mercaptans. Carbonyl groups have lower anharmonicities. Their values are about 10 cm^{-1} for both free and associated species.

We would like to express our thanks to the National Research Council of Canada for financial help. One of us (RBA) would like also to express his gratitude to the National Research Council of Canada and the Conselho Nacional de Pesquisas, Rio de Janeiro, Brazil, for financial support under the Brazil-Canada Program for Scientific Exchange, and to the Instituto de Química da Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, for a special leave of absence.

Synthesis and Rearrangement Control of Substituted Benzobicycloheptane Aziridines

K. WIESNER, PAK-TSUN HO, R. C. JAIN, S. F. LEE, S. OIDA, AND A. PHILIPP

Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received December 1, 1972

A general synthesis of various substituted benzonorbornene derivatives is described. Benzenesulfonyl aziridines of these compounds were prepared and their acetolysis was studied. The influence of various substitution patterns on the direction of the aziridine rearrangement is discussed and it is shown that the rearrangements may be used as a convenient approach to the synthesis of ring B bridged diterpene alkaloids. Considerable general synthetic utility of these techniques is anticipated.

Une synthèse générale de plusieurs dérivés du benzonorbornène substitué est décrite. Les aziridines benzènesulphonyles de ces composés ont été préparés et leurs acétolyses furent étudiées. L'influence de plusieurs patrons de substitution sur la direction du réarrangement de l'aziridine est discutée. On a montré que ces réarrangements peuvent être utilisés pour une approche convenable à la synthèse de l'anneau B des diterpènes alcaloides pontés. Une utilité considérable en synthèse générale de ces techniques est envisagée. [Traduit par le journal]

Can. J. Chem., **51**, 1448 (1973)

In connection with studies aimed at the synthesis of ring B bridged diterpene alkaloids, we wished to develop highly efficient regio and stereospecific routes to tricyclic compounds of the type **i** and **ii**.

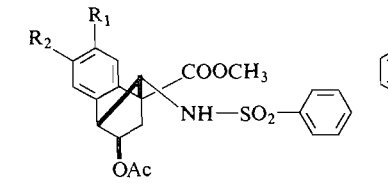
A simple and efficient synthesis of **i** in which the acetolysis of the aziridine **v** was the key step was worked out (1) and the product converted to the songorine intermediate **iii** (2).

The second target of our synthetic work was compound **ii**, which if available could be developed by the same techniques to the chasmanine intermediate **iv**. It turned out, however, that the aziridine **vi** cannot be used to this end since (not surprisingly) it does not yield compound **ii** on acetolysis. This problem has now been fully solved and the synthesis of **iv** is under way. Since the methods which we have developed for the synthesis and rearrangement-control of benzobicycloheptane aziridines are quite novel and of general synthetic interest, we report them in detail in the present paper.

The derivatives which were found to be most suitable for acetolytic rearrangement were benzenesulfonyl aziridines prepared by the action of benzenesulfonyl azide on the corresponding substituted benzobicycloheptenes (3). Consequently, it was first necessary to devise regiospecific methods for the preparation of these last compounds with varying substitution.

The synthesis of the ester **3** was quite simple (3), since no problem with the orientation of a benzene ring substituent existed in this case. Cyclopentadiene carboxylic ester **1**, freshly prepared by distillation of the dimer, was added to the benzyne precursor **2** which had been previously used by Wittig (4). The oily adduct **3** was isolated in a 30% yield by chromatography.[1]

The synthesis of compound **8** had to be performed in an entirely different manner in order to achieve a regiospecific orientation of the methoxyl. The known keto ester **4** (5) was reduced with sodium borohydride to the alcohol **5** and this compound was dehydrated with a



i $R_1 = OCH_3; R_2 = H$
ii $R_1 = H; R_2 = OCH_3$

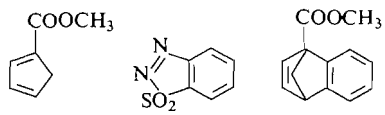
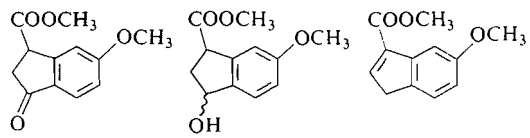
simultaneous double bond shift to the unsaturated ester **6**. Since it was known that indene adds maleic anhydride to yield the anhydride of benzonorbornane dicarboxylic acid (6), it was originally hoped that addition of acetylene or of an acetylene equivalent to **6** would yield directly the desired compound **8**. It turned out however, that while the crystalline adduct with maleic anhydride **7** was formed quantitatively, no other suitable dienophile reacted in an acceptable yield.

After many months of experimentation it was finally discovered that **7** may be bisdecarboxylated to **8** in refluxing diglyme by the action of bistriphenylphosphinenickel dicarbonyl (7) in a yield of 81%. Compound **8** was identical with one of the two products obtained by us previously by the non-regiospecific addition of cyclopentadiene carboxylic ester and methoxy benzyne (8). The entire sequence **4** → **8** was accomplished in a yield of 44% and is consequently quite satisfactory.

The synthesis of compound **16** starting with the ketoester **12** was performed precisely as described above for compound **8**. The ketoester **12** however was not known and it was synthesized as follows. *m*-Methoxyacetophenone



1 **2** **3**



4 **5** **6**

was condensed in methanolic sodium hydroxide with glyoxylic acid, freshly generated by periodate cleavage of tartaric acid. The oily mixture of compounds **9** and **10** which was produced almost quantitatively was directly used in the next step. The mixture was cyclized with aluminum chloride at 185 °C for 90 min. The crystalline phenol **11** was obtained in a yield of 46% based on the starting *m*-methoxyacetophenone. Finally, the phenol **11** was methylated with dimethyl sulfate in the presence of anhydrous potassium carbonate in benzene to yield quantitatively the crystalline methoxyester **12**.

The phenol **11** was also mesylated with mesylchloride in pyridine to the mesyloxyketoester **17** and this compound was transformed by the already described route (via **18**, **19**, and **20**) to compound **21**. The yield in the transformation **19** → **20** was only approximately 50% as compared to the quantitative reaction of the methoxy derivatives **6** and **14**. It would appear that the thermal 1,5 hydride shift which presumably precedes the Diels–Alder addition of maleic anhydride is favored by an electron releasing substituent in the benzene ring.

Finally the compound **24** which contains a methoxy group at the bridgehead was required. It was prepared by a simple adaptation of our general indene approach. The ketoester **12** was stirred with trimethyl orthoformate and a small amount of hydrogen chloride in benzene–methanol to give a quantitative yield of the enolether **22**. The addition of maleic anhydride to **22** yielded the adduct **23** and bisdecarboxylation of

24

this compound gave finally the desired product **24**.

Having described the synthesis of all the desired substituted benzonorbornenes we shall now proceed and discuss the preparation and rearrangements of the corresponding aziridines.

The aziridine **25** (Chart 1) was prepared by treating compound **3** with benzenesulfonyl azide in anhydrous benzene. It was a somewhat unstable oil but gave spectral data (see Experimental) which confirmed its structure and the expected *exo* stereochemistry. In this respect the singlet of the two protons unshielded by the nitrogen (τ 6.65 p.p.m.) in the n.m.r. spectrum was significant. The absence of coupling with the bridgehead proton indicated clearly the *endo* configuration of the protons unshielded by the aziridine.

The acetolysis of the aziridine **25** was performed by heating the compound to 100 °C in glacial acetic acid. Under these conditions the aziridine ring opens with rearrangement and the resulting carbonium ion reacts with acetic acid. This process as portrayed by arrows in formula **25** (Chart 1) leads to the product **26**.

An exactly analogous process initiated by the opening of the second carbon–nitrogen bond yields the product **27**. It was anticipated that the product **26** will greatly predominate, since the formation of compound **27** requires the development of a carbonium ion adjacent to a carbonyl group, a situation known to be energetically very unfavorable.

Thus, we hoped that the ester group shall play a dual role in our projected terpene alkaloid syntheses. It was expected to serve in the annelation of ring A and as a site of a future substituent and at the same time to steer the aziridine rearrangement.

The result of the acetolysis experiment in fact bore out our prediction. The desired acetolysis product **26** predominated over compound **27** in a ratio 94:6. Compound **26** was crystalline and the small amount of **27** remained oily. Spectral data recorded in the Experimental leave no doubt about the assignment of structures to the two compounds. While **26** shows in the n.m.r. spectrum a proton unshielded by acetate (τ 5.33 p.p.m.), compound **27** displays two benzylic bridgehead protons (τ 6.65 p.p.m.) and a methoxy group highly shielded by the benzene ring (τ 7.82 p.p.m.) as a result of the *endo* configuration of the carbomethoxyl.

The songorine intermediate **8** was investigated next. In this case the aziridine formed in benzene by the action of benzenesulfonyl azide proved to be too unstable for isolation and it was acetolyzed at room temperature yielding exclusively the product **28**. The methoxyl located in para position to the migrating carbon–carbon bond greatly accelerates the reaction rate of the rearrangement leading to **28**. At the same time the carbomethoxy group slows down as before the rate of the alternative competing reaction. Thus, complete selectivity and a much faster reaction rate result. Compound **28** was beautifully crystalline and spectral data recorded in the Experimental leave no doubt about its structure. Moreover, the structure of an intermediate derived from **28** on the way to **iii** was corroborated by X-ray crystallography (2).

The unlikely possibility that compound **ii** could be prepared by acetolysis of the benzenesulfonyl aziridine derived from **16** was demolished by a single experiment. The acetolysis proceeded at room temperature and the single amorphous product had clearly the structure **29**. All n.m.r. data obtained for compound **29** were

comparable to those of compound **27** and excluded the desired structure **ii**.

It was thus clear that the great increase in migratory aptitude of the bond para to the methoxyl overpowered the reaction rate decelerating influence of the carbomethoxyl.

Since a compound of the type **ii** was needed as a chasmanine starting material two devices were tried to steer the corresponding aziridine rearrangement.

First the methoxyl of compound **16** was replaced by a mesyloxy group and the substituted benzonorbornene derivative **21** was synthesized by the method which we have described above. Treatment of this product with benzenesulfonyl azide gave the stable crystalline aziridine **30**.

It was anticipated that the behavior of compound **30** on acetolysis will be similar to the unsubstituted aziridine **25**. We assumed that since the electron-releasing properties of a mesyloxy group are approximately equal to those of a hydrogen the aziridine rearrangement will be dominated by the already discussed influence of the carbomethoxyl.

This expectation was born out by experiment. The acetolysis of **30** was slow and had to be performed at 110 °C, but the ratio of the products **31** and **32** was favorable (9:1). However, the overall yield of the acetolysis was a low 52.5% and a few additional steps would be required to convert compound **31** into **ii**. Consequently we have turned to the examination of a still different possibility of rearrangement control.

As described above we have synthesized compound **24** which featured a methoxy group at the bridgehead. Treatment of **24** with benzenesulfonyl azide in a mixture of benzene and acetic acid presumably gave the unstable aziridine **33**. This compound underwent immediate acetolysis, in which the bridgehead methoxyl cooperated with the carbomethoxyl (as indicated by arrows in **33**) to counteract the influence of the aromatic methoxyl. The overall yield of the reaction was 86%. Of this 70% was the ketone **34** which was isolated after being converted into the crystalline ketal **35**. The alcohol **36** and the corresponding acetate **37** formed 30% of the mixture.

Compound **36** was characterized by conversion into the crystalline acetate **37** by acetic anhydride and pyridine.

The ketal **35** is a very advantageous chasmanine starting material and the synthesis is now underway using this supply route. Our methods of synthesis and rearrangement control of various substituted benzonorbornane aziridines are capable of wide synthetic application and consequently are described in the Experimental in considerable detail.

We shall report in the future on synthetic applications of these techniques in several fields unrelated to diterpene alkaloids.

Experimental

Preparation of the Olefin 3

A dimer of methyl cyclopentadiene carboxylate (9) (25 g) was distilled at 90–120 °C (12 mm Hg) and the monomeric ester **1** was collected in a cold flask (−80 °C). The monomer was dissolved in cold anhydrous tetrahydrofuran (200 ml) and added to freshly prepared crystalline 1,2,3-benzothiadiazol-1,1-dioxide (**2**) (4) at −20 °C. When the reaction mixture reached room temperature, evolution of nitrogen and sulfur dioxide occurred and the mixture was left overnight. Evaporation of solvent gave a crude product which was purified by chromatography on silica gel. Elution with benzene yielded 8.3 g (30%) of oily **3**, homogeneous in t.l.c., b.p. 50 °C (0.1 mm Hg).

Preparation of Benzenesulfonyl Aziridine 25

A solution of the olefin **3** (1.03 g) and benzenesulfonyl azide (1.60 g) in anhydrous benzene (2 ml) was stirred at room temperature for 17 h and the mixture was chromatographed on silica gel. Elution with benzene – ethyl acetate (97:3) gave 1.52 g (83%) of the aziridine **25** as an oil, homogeneous in t.l.c.

Acetolysis of the Aziridine 25

A solution of **25** (327 mg) in glacial acetic acid (10 ml) was heated to 100 °C for 2½ h. The mixture was poured into cold aqueous sodium bicarbonate and extracted with chloroform. The chloroform solution was washed with water, dried, and taken to dryness. Analysis of the residue by t.l.c. showed the presence of two products **26** and **27** (ratio, 94:6). The mixture was separated by preparative t.l.c. on silica gel using benzene – ethyl acetate (85:15) to afford 287 mg of **26** (75%) and 16 mg

*Reduction of **4** to **5***

Sodium borohydride (2.3 g) was added in portions over a period of ½ h at room temperature to a stirred solution of the ketone **4** (5) (31.3 g) in tetrahydrofuran (250 ml) and methanol (250 ml). The mixture was stirred at room temperature for 1 h, diluted with water (1 l), and extracted with chloroform three times. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent *in vacuo* gave 30.6 g (97%) of the alcohol **5**. For analysis, **5** was crystallized from benzene–hexane, m.p. 79–80 °C.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.79; H, 6.11.

I.r. (CCl_4): 3480 (OH), 1724 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 6.14 (s, 3H, aromatic methoxyl), 6.20 (s, 3H, —C(=O)—OCH_3), 6.00 (q, 1H, benzylic proton adjacent to —C(=O)—OCH_3), 4.87 (q, 1H, proton adjacent to OH).

*Preparation of the Indene **6***

A solution of the alcohol **5** (30.6 g) in methanol (150 ml) was added dropwise over a period of 1½ h to a refluxing solution of concentrated sulfuric acid (20 ml) in methanol (300 ml) and the mixture was kept at reflux for an additional 2 h. The reaction mixture was cooled, diluted with water (1 l) and extracted with chloroform three times. The extract was washed with a saturated sodium chloride solution and dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was distilled *in vacuo* to give the pure **6** (19.5 g, 67% based on **4**) as an oil homogeneous in t.l.c., b.p. 139 °C (0.3 mm Hg).

Mol. Wt. Calcd. for $C_{12}H_{12}O_3$: 204. Found (*m/e*): 204.

I.r. (CCl_4): 1727 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 2.47 (t, J = 2 Hz, 1H, vinylic proton), 6.05 (s, 3H, aromatic methoxyl), 6.08 (s, 3H, —C(=O)—OCH_3), 6.52 (d, 2H, benzylic protons).

*Preparation of the Adduct **7***

A mixture of compound **6** (19.5 g), maleic anhydride (9.36 g), and a small amount of hydroquinone (10 mg) was heated under nitrogen at 170 °C (oil bath temperature) for 3 h. The adduct **7** was homogeneous in t.l.c. and the yield was quantitative. Material of this purity was used in the subsequent step. An analytical sample was prepared by crystallization from benzene as white crystals, m.p. 147–148 °C.

Anal. Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67. Found: C, 63.45; H, 4.39.

I.r. ($CHCl_3$): 1870, 1790 (anhydride), 1740 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 6.03 (s, 3H, aromatic methoxyl), 6.15 (broad s, 1H, bridgehead proton), 6.18 (s, 3H, —C(=O)—O—CH_3), 7.67 (m, 2H, apex protons).

*Preparation of the Olefin **8***

The Diels–Alder adduct **7** (16.4 g) was dissolved in anhydrous diglyme (300 ml) to which bistriphenylphosphinenickel dicarbonyl (42 g) was added. The mixture was heated under reflux in a dry nitrogen atmosphere for 6 h. The solvent was distilled off under reduced pressure. The residue was dissolved in chloroform and the black precipitate was removed by filtration. After evaporation of the solvent, the product was isolated by chromatography on silica gel. Elution with benzene gave the crystalline olefin **8** (10.2 g, 81%), homogeneous in t.l.c. The analytical sample had m.p. 63–64 °C after recrystallization from hexane.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13. Found: C, 73.05; H, 5.92.

I.r. (CCl_4): 1745 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 3.17 (broad d, 2H, vinylic protons), 6.10 (broad s, 1H, bridgehead benzylic proton), 6.09 (s, 3H, aromatic methoxyl) 6.21 (s, 3H, —C(=O)—OCH_3), 7.45 (broad s, 2H, apex protons).

*Preparation of Rearranged Sulfamido Acetate **28***

A solution of the olefin **8** (38 g) and benzenesulfonyl azide (80 g) in anhydrous benzene (150 ml) was stirred at room temperature for 3 days. Glacial acetic acid (240 ml) was then added to this stirred solution and the reaction mixture was kept at room temperature for 2 days. After this time, benzene and most of the acetic acid was distilled off *in vacuo*. The residue was then dissolved in benzene–hexane and the product **28** crystallized on standing. Recrystallization of the product from benzene–hexane gave 56.5 g (75%) of **28**, m.p. 137 °C.

Anal. Calcd. for $C_{21}H_{23}O_7NS$ (mol. wt. 445): C, 59.13; H, 5.24; N, 3.14. Found (*m/e* 445): C, 59.23; H, 5.26; N, 3.19.

I.r. ($CHCl_3$): 3300 (NH), 1740 (ester and acetate), 1345, 1170 cm^{-1} (sulfonyl); n.m.r. ($CDCl_3$): τ 4.20 (d, J = 9 Hz, 1H, —NH), 5.24 (broad t, 1H, proton adjacent to acetate), 6.17 (d, J = 9 Hz, 1H, apex proton), 6.24 (s,

3H, aromatic methoxyl), 6.34 (s, 3H, —C(=O)—OCH_3), 6.70 (s, 1H, bridgehead benzylic proton), 7.84 (s, 3H, acetate methyl).

*Preparation of the Condensed Products (**9**, **10**)*

A solution of *d*-tartaric acid (20 g) in distilled water (30 ml) was added to a cooled suspension of trisodium periodate (para) (30 g) in concentrated sulfuric acid (3 ml) and distilled water (160 ml), and the mixture was stirred at room temperature for ½ h. *m*-Methoxyacetophenone (20 g), sodium hydroxide (20 g) in distilled water (360 ml), and methanol (300 ml) were added in sequence. The reaction mixture was stirred at room temperature overnight. The solution was poured into ice-water, acidified with dilute hydrochloric acid and extracted with ether (3 × 500 ml). The ethereal extract was washed with water and dried over anhydrous sodium sulfate. The volume of the dried ethereal solution was reduced to 200 ml, and treated with diazomethane. The solvent was removed *in vacuo*, the mixture (30 g) was immediately used in the subsequent step.

Analysis by t.l.c. showed that the mixture consisted of two components, **9** and **10** (ratio, 8:1). A portion (121 mg) was separated by preparative t.l.c. Compound **9** (85 mg) was oily; compound **10** (15 mg) was a waxy solid.

Mol. Wt. Calcd. for $C_{13}H_6O_5$ (saturated ketone **9**): 252. Found (*m/e*): 252.

I.r. ($CHCl_3$): 1750 (ester), 1690 cm^{-1} (ketone); n.m.r. ($CDCl_3$): τ 6.17 (s, 3H, aromatic methoxyl), 6.24 (s, 3H, —C(=O)—OCH_3), 6.54 (s, 3H, methoxyl), 6.64 (d, 2H, methylene protons).

Mol. Wt. Calcd. for $C_{12}H_{12}O_4$ (unsaturated ketone **10**): 220. Found (*m/e*): 220.

I.r. ($CHCl_3$): 1725 (ester), 1675 cm^{-1} (conjugated ketone); n.m.r. ($CDCl_3$): τ 2.14 (d, J = 15 Hz, 1H, vinylic proton), 3.15 (d, J = 15 Hz, 1H, vinylic proton), 6.15 (s, 3H, aromatic methoxyl), 6.19 (s, 3H, —C(=O)—OCH_3); u.v. (EtOH): λ_{max} 235 nm (ε 12 000).

*Preparation of the Phenol **11***

A solution of **9** and **10** (30 g) in a small volume of anhydrous dichloromethane (30 ml) was added dropwise over a period of 5 min to a preheated (at 130 °C) mixture of anhydrous aluminum chloride (300 g) and sodium chloride (45 g). The mixture was shaken mechanically and at the same time the temperature was raised to 185 °C (oil bath temperature) and maintained at this temperature for 1½ h. While the mixture was cooled to 100 °C, water and concentrated hydrochloric acid (200 ml) were added slowly in sequence. The product was extracted with ether and the ethereal solution was dried over anhydrous sodium sulfate and evaporated to dryness. The resulting brown residue (20 g) was dissolved in methanolic hydrogen chloride (300 ml) and heated under reflux for 2 h. After removal of the solvent, the residue was chromatographed on silica gel to give 12 g (46%, based on *m*-methoxylacetophenone) of the crystalline phenol **11**. Recrystallization from acetone–ether gave an analytical sample as white crystals, m.p. 141–142 °C.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.07; H, 4.88. Found: C, 64.20; H, 4.88.

I.r. ($CHCl_3$): 3600, 3500 (OH), 1740, 1710 cm^{-1} (ester and ketone); n.m.r. ($CDCl_3$): τ 5.82 (q, 1H, benzylic proton), 6.20 (s, 3H, —C(=O)—OCH_3), 6.99 (t, 2H, methylene).

*Preparation of the Methyl Ether **12***

A mixture of the phenol **11** (1.03 g), benzene (20 ml), anhydrous potassium carbonate (1.42 g), and dimethyl sulfate (1 ml) was refluxed under nitrogen for 8 h and then stirred at room temperature overnight. The precipitate was filtered and washed with dichloromethane. The filtrate was washed with dilute aqueous hydrochloric acid and water, dried over anhydrous sodium sulfate, and evaporated to give the methyl ether **12** (1.10 g, 100%) homogeneous in t.l.c. Recrystallization of **12** from benzene–hexane gave colorless plates, m.p. 73–74 °C.

Anal. Calcd. for $C_{12}H_{12}O_4$ (mol. wt. 220): C, 65.44; H, 5.49. Found (*m/e* 220): C, 65.46; H, 5.55.

I.r. (CCl_4): 1750, 1725 cm^{-1} (ester, ketone); n.m.r. (CCl_4): τ 5.87 (two d, 1H, benzylic proton), 6.17 (s, 3H, aromatic methoxyl), 6.27 (s, 3H, —C(=O)—OCH_3).

*Reduction of **12** to **13***

The ketone **12** (678 mg) was dissolved in methanol (10 ml) and tetrahydrofuran (5 ml), and sodium borohydride (90 mg) was added at 0 °C. The mixture was stirred for 40 min and the same work-up as described above yielded 680 mg (100%) of the alcohol **13** as white crystals. Recrystallization of **13** from chloroform–ether gave crystals, m.p. 93–94 °C.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.81; H, 6.10.

I.r. ($CHCl_3$): 3612, 3484 (OH), 1740 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 4.10 (q, 1H, benzylic proton), 4.97 (m, 1H, proton unshielded by OH), 6.22 (s, 3H, aromatic methoxyl), 6.27 (s, 3H, —C(=O)—OCH_3).

*Dehydration of **13** to **14***

A solution of **13** (324 mg) in 12% methanolic sulfuric acid (15 ml) was heated under reflux for 2 days. The reaction mixture was worked-up in the same way as described above. Recrystallization of the product from ether gave 120 mg (40%) of **14** as colorless needles, m.p. 96 °C.

Anal. Calcd. for $C_{12}H_{12}O_3$ (mol. wt. 204): C, 70.57; H, 5.92. Found (*m/e* 204): C, 70.52; H, 5.84.

I.r. ($CHCl_3$): 1708 cm^{-1} (unsaturated ester); n.m.r. ($CDCl_3$): τ 2.72 (t, 1H, vinylic proton), 6.12 (s, 3H, aromatic methoxyl), 6.20 (s, 3H, —C(=O)—OCH_3), 6.57 (d, 2H, benzylic protons).

*Preparation of the Diels–Alder Adduct **15***

The indene **14** (230 mg) and maleic anhydride (140 mg) were heated to 168 °C for 13 h in a sealed tube. The adduct **15** was recrystallized from acetone–ether to a m.p. of 154–155 °C. The yield was 270 mg (80%).

Anal. Calcd. for $C_{14}H_{14}O_6$ (mol. wt. 302): C, 63.57; H, 4.67. Found (*m/e* 302): C, 63.35; H, 4.66.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

I.r. ($CHCl_3$): 1844, 1792 (anhydride), 1744 cm^{-1} (ester); n.m.r. (acetone-d_6): τ 6.14 (s, 3H, aromatic methoxyl), 6.21 (broad s, 1H, bridgehead proton), 6.25 (s, 3H, —C(=O)—OCH_3), 7.70 (t, 2H, apex protons).

Preparation of the Olefin ***16***

The crude adduct **15** (370 mg) was dissolved in anhydrous diglyme (6 ml) and bistriphenylphosphinenickel dicarbonyl (1.2 g) was added. The mixture was refluxed under nitrogen for 40 min and it was worked-up as described above. The product was isolated by preparative t.l.c. on silica gel to give 126 mg (48% based on **14**) of oily **16**, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{14}O_3$: 230.0943. Found (*m/e*): 230.0947.

I.r. ($CHCl_3$): 1733 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 3.20 (m, 2H, vinylic protons), 6.11 (broad s, 1H, bridgehead proton), 6.14 (s, 3H, aromatic methoxyl), 6.25 (s, 3H, —C(=O)—OCH_3), 6.57 (d, 2H, apex protons).

Preparation of the Rearranged Product ***29***

A mixture of **16** (91 mg) and an excess of benzenesulfonyl azide (1 ml) in anhydrous benzene (0.5 ml) was stirred at room temperature for 3 days. Glacial acetic acid (1.5 ml) was added, the solution was stirred for an additional day, and the reaction mixture was worked-up as described above. Examination of the residue by t.l.c. in several solvent systems showed one product only. Preparative t.l.c. on silica gel gave 129 mg (74%) of **29** (homogeneous in t.l.c.) as a foam which refused to crystallize in several solvents.

Mol. Wt. Calcd. for $C_{21}H_{23}O_7NS$: 445.1195. Found (*m/e*): 445.1183.

I.r. ($CHCl_3$): 3400 (NH), 1756, 1740 cm^{-1} (acetate and ester); n.m.r. ($CDCl_3$): τ 4.50 (d, J = 8 Hz, 1H, —NH), 6.26 (s, 3H, aromatic methoxyl), 6.36 (broad s, 1H, benzylic proton), 6.40 (d, J = 8 Hz, 1H, apex proton), 6.67 (s, 3H, —C(=O)—OCH_3 shielded by benzene ring), 6.70 (s, 1H, benzylic proton), 7.84 (s, 3H, acetate methyl).

Preparation of the Mesylate ***17***

The phenol **11** (5.3 g) was dissolved in anhydrous pyridine (35 ml) and methane sulfonyl chloride (3 ml) was added at 0 °C. The reaction mixture was stirred for 5 h at that temperature and worked-up in the usual manner. The product **17** was recrystallized from chloroform to a m.p. 141–142 °C. The yield was 6.6 g (90%).

Anal. Calcd. for $C_{12}H_{12}O_6S$: C, 50.69; H, 4.25. Found: C, 50.66; H, 4.30.

I.r. ($CHCl_3$): 1744, 1725 (ester and ketone), 1375, 1144 cm^{-1} (sulfonyl); n.m.r. ($CDCl_3$): τ 5.67 (q, 1H, benzylic proton), 6.20 (s, 3H, —C(=O)—OCH_3), 6.80 (s, 3H, —OSO_2—CH_3).

Reduction of ***17*** *to the Alcohol* ***18***

The ketone **17** (2.0 g) was dissolved in methanol (30 ml) and tetrahydrofuran (15 ml), and sodium borohydride (250 mg) was added at 0 °C. The mixture was stirred for 20 min and the same work-up as described above yielded 2.0 g (quantitative yield) of the alcohol **18** as a colorless oil, homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{12}H_{14}O_6S$: 286. Found (*m/e*): 286.

I.r. (film): 3490 (OH), 1735 (ester), 1365, 1125 cm^{-1} (—OSO_2—); n.m.r. ($CDCl_3$): τ 4.90 (q, 1H, proton adjacent to hydroxyl), 6.09 (q, 1H, benzylic proton), 6.25 (s, 3H, —C(=O)—OCH_3), 6.89 (s, 3H, —OSO_2—CH_3), 7.50 (m, 2H, methylene).

Dehydration of ***18*** *to the Indene* ***19***

A mixture of the alcohol **18** (690 mg) and potassium bisulfate (700 mg) in anhydrous benzene (25 ml) was heated under reflux for 20 min with a water separator. The solid was removed by filtration, the filtrate was diluted with benzene (200 ml), washed, dried over anhydrous magnesium sulfate and evaporated to dryness. The residue was recrystallized from ether to give 445 mg (70%) of pure **19**, m.p. 106–107 °C.

Anal. Calcd. for $C_{12}H_{12}O_5S$: C, 53.72; H, 4.51. Found: C, 53.57; H, 4.55.

I.r. ($CHCl_3$): 1719 cm^{-1} (unsaturated ester); n.m.r. ($CDCl_3$): τ 2.54 (t, 1H, vinylic proton), 6.09 (s, 3H, —C(=O)—OCH_3), 6.45 (d, 2H, benzylic protons), 6.85 (s, 3H, —OSO_2—CH_3).

Preparation of the Diels–Alder Adduct ***20***

The indene carboxylic ester **19** (200 mg) and maleic anhydride (90 mg) were heated to 165 °C for 3 h in a sealed tube. The adduct **20** was homogeneous in t.l.c. and was used in the crude form for further work. For analysis it was purified by recrystallization from acetone to a constant, m.p. 223–224 °C.

Anal. Calcd. for $C_{16}H_{14}O_8S$ (mol. wt. 366): C, 52.45; H, 3.85. Found (*m/e* 366): C, 52.39; H, 3.88.

I.r. ($CHCl_3$): 1844, 1792 (anhydride), 1744 cm^{-1} (ester); n.m.r. (acetone-d_6): τ 6.02 (broad s, 1H, bridgehead proton), 6.07 (s, 3H, —C(=O)—OCH_3), 6.67 (s, 3H, —OSO_2—CH_3), 7.57 (t, 2H, apex protons).

Preparation of the Olefin ***21***

The crude adduct **20** (290 mg) was dissolved in anhydrous diglyme (6 ml) and bistriphenylphosphinenickel dicarbonyl (1.1 g) was added. The reaction mixture was refluxed under nitrogen for 2 h and worked-up as described above. Chromatography of the residue on silica gel gave 62 mg (30%, based on the indene **19**) of the pure olefin **21** as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{14}H_{14}O_5S$: 294.0562. Found (*m/e*): 294.0568.

I.r. ($CHCl_3$): 1737 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 3.17 (m, 2H, vinylic protons), 6.03 (broad s, 1H, bridgehead proton), 6.10 (s, 3H, —C(=O)—OCH_3), 6.90 (s, 3H, —OSO_2—CH_3), 7.42 (d, 2H, apex protons).

Preparation of the Aziridine ***30***

A solution of the olefin **21** (210 mg) and benzenesulfonyl azide (1.5 ml) in benzene (1 ml) was stirred at room

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

temperature for 2 days. The reaction mixture was purified by preparative t.l.c. on silica gel to yield 223 mg (70%) of the pure aziridine **30** as the only crystalline product. Recrystallization from benzene gave an analytical sample, m.p. 155–156 °C.

Anal. Calcd. for $C_{20}H_{19}O_7NS_2$ (mol. wt. 449): C, 53.44; H, 4.26; N, 3.11. Found (*m/e* 449): C, 53.47; H, 4.41; N, 3.20.

I.r. ($CHCl_3$): 1740 (ester), 1370, 1325 (OSO_2), 1160 cm^{-1} (aziridine); n.m.r. ($CDCl_3$): τ 6.35 (s, 3H, —C(=O)—OCH_3), 6.39 (broad s, 1H, bridgehead proton), 6.67 (broad s, 2H, —CH—CH— (N)), 6.87 (s, 3H, —OSO_2—CH_3), 7.67 (d, J = 9 Hz, 1H, one apex protons), 8.20 (d, J = 9 Hz, 1H, one apex protons).

Acetolysis of the Aziridine 30

A solution of **30** (130 mg) and *p*-toluenesulfonic acid (4 mg) in glacial acetic acid (2.5 ml) was heated to 110 °C for 2 h. After removal of the solvent *in vacuo*, chloroform (150 ml) was added to the residue and the solution was washed with water three times, dried, and evaporated to dryness. Analysis of the residue by t.l.c. showed the presence of two acetates **31** and **32** (ratio 9:1). This mixture was separated by preparative t.l.c. on silica gel to give 97 mg (67%) of crystalline **31** and 11 mg (7.5%) of the tertiary acetate **32** as an oil, homogeneous in t.l.c. Recrystallization of **31** from benzene gave an analytical sample, m.p. 196–197 °C.

Anal. Calcd. for $C_{22}H_{23}O_9NS_2$ (acetate **31** mol. wt. 509): C, 51.85; H, 4.55; N, 2.75. Found (*m/e* 509): C, 51.56; H, 4.67; N, 2.66.

I.r. ($CHCl_3$): 3400 (NH), 1750 cm^{-1} (acetate and ester); n.m.r. ($CDCl_3$): τ 4.20 (d, J = 8.5 Hz, 1H, —NH), 5.24 (m, 1H, proton unshielded by acetate), 6.17 (d, J = 8.5 Hz, 1H, apex proton), 6.30 (s, 3H, —C(=O)—OCH_3), 6.59 (s, 1H, benzylic proton), 6.85 (s, 3H, —OSO_2—CH_3), 7.85 (s, 3H, acetate, methyl).

Mol. Wt. Calcd. for $C_{22}H_{23}O_9NS_2$ (tertiary acetate **32**): 509. Found (*m/e*): 509.

I.r. ($CHCl_3$): 3400 (NH), 1755, 1738 cm^{-1} (acetate and ester); n.m.r. ($CDCl_3$): τ 4.40 (d, J = 8 Hz, 1H, —NH), 6.40 (d, J = 8 Hz, 1H, apex proton), 6.62 (broad s, 1H, benzylic proton), 6.89 (s, 1H, benzylic proton), 6.69 (s, 3H, —C(=O)—OCH_3 shielded by benzene ring), 6.91 (s, 3H, —OSO_2—CH_3), 7.80 (s, 3H, acetate).

Preparation of the Enol Ether 22

Methanol (1 ml), trimethyl orthoformate (1.2 ml), and saturated methanolic hydrogen chloride (10 drops) were added in sequence to a solution of the ketoester **12** (1.13 g) in benzene. The mixture was stirred under nitrogen at room temperature for 24 h after which time it was evaporated to dryness *in vacuo*. The residue was heated under reflux for 20 min in 10 ml of xylene. After evaporation of the solvent *in vacuo*, **22** was obtained quantitatively as an oil homogeneous in t.l.c. and it was used immediately for further work.

Mol. Wt. Calcd. for $C_{13}H_{14}O_4$: 234.0892. Found (*m/e*): 234.0887.

I.r. (CCl_4): 1745, 1625 cm^{-1} (ester, enol ether); n.m.r. (CCl_4): τ 4.75 (d, J = 2 Hz, 1H, vinylic proton), 5.82 (d, J = 2 Hz, 1H, benzylic proton), 6.14 (s, 3H, aromatic methoxyl), 6.34 (s, 3H, —OCH_3); u.v. (EtOH): λ_{max} 237 (log ε 4.06), 257 (log ε 3.66), 293 nm (log ε 3.43).

The Diels–Alder Adduct 23

The enol ether **22** (1.19 g) was dissolved in xylene (5 ml) and maleic anhydride (500 mg) was added. The mixture was heated under nitrogen to 170 °C (oil bath temperature) for 12 h. The solvent was evaporated to give a solid (1.68 g), homogeneous in t.l.c. An analytical sample of **23** was obtained by recrystallization from chloroform as colorless plates, m.p. 206–207 °C.

Anal. Calcd. for $C_{17}H_{16}O_7$ (mol. wt. 332): C, 61.44; H, 4.85. Found (*m/e* 332): C, 61.34; H, 4.78.

I.r. ($CHCl_3$): 1870, 1790 (anhydride), 1740 cm^{-1} (ester); n.m.r. ($CDCl_3$): τ 6.07 (s, 3H, aromatic methoxyl), 6.20 (s, 3H, —C(=O)—OCH_3), 6.40 (s, 3H, bridgehead —OCH_3), 7.54 (d, J = 2 Hz, 2H, apex protons).

Preparation of the Olefin 24

The crude Diels–Alder adduct **23** (1.68 g) was dissolved in anhydrous diglyme (30 ml) and bistriphenylphosphinenickel dicarbonyl (3.84 g) was added. The mixture was heated under nitrogen to 200–210 °C for 7 h and worked-up in the usual manner. The residue was chromatographed on silica gel. Elution with benzene gave 765 mg (58%, based on **22**) of **24** as an oil homogeneous in t.l.c.

Mol. Wt. Calcd. for $C_{15}H_{16}O_4$: 260.1049. Found (*m/e*): 260.1041.

I.r. (CCl_4): 1740 cm^{-1} (ester); n.m.r. (CCl_4): τ 3.33 (m, 2H, vinylic protons), 6.18 (s, 3H, aromatic methoxyl), 6.27 (s, 3H, —C(=O)—OCH_3), 6.50 (s, 3H, bridgehead methoxyl), 7.38 (q, J = 6 Hz, 2H, apex protons).

Preparation of Rearranged Products From 24

The olefin **24** (205 mg) was dissolved in anhydrous benzene (2 ml) to which benzenesulfonyl azide (275 mg), *p*-toluenesulfonic acid (10 mg), and glacial acetic acid (0.4 ml) were added. The solution was stirred under nitrogen at room temperature for 7 days. Removal of the solvent *in vacuo* gave a light brown residue which was chromatographed on silica gel. Elution with ether–benzene (1:9) yielded 336 mg of foam. This material appeared to be homogeneous when examined by t.l.c. on silica gel in several solvent systems. However, its n.m.r. spectrum showed that it consisted of three products, **34**, **36**, and **37** which could not be separated.

The mixture was refluxed with *p*-toluenesulfonic acid (42 mg) and ethylene glycol (1 ml) in dry benzene (50 ml) for 18 h with a water separator. After cooling the solution was diluted with methylene chloride, washed with aqueous sodium bicarbonate and water, dried, and taken to dryness. The residue was chromatographed by preparative t.l.c. on silica gel to yield 213 mg of the crystalline

ketal **35** (60%, based on **24**) and 94 mg of the mixture **36** and **37**. After recrystallization from benzene–ether the pure **35** melted at 149–150 °C.

Anal. Calcd. for $C_{22}H_{23}O_7NS$ (ketal **35**, mol. wt. 445): C, 59.32; H, 5.21; N, 3.14. Found (*m/e* 445): C, 59.20; H, 5.20; N, 3.07.

I.r. ($CHCl_3$): 3340 (NH), 1740 (ester), 1350, 1160 cm^{-1} (sulfonyl); n.m.r. ($CDCl_3$): τ 3.70 (d, J = 10 Hz, 1H, —NH), 5.97 (d, J = 10 Hz, 1H, apex proton), 6.13 (m, 4H, dioxolane), 6.23 (s, 3H, aromatic methoxyl), 6.37 (s, 3H, $-\overset{\overset{O}{\|}}{C}-O-CH_3$), 7.21 (broad s, 1H, bridgehead benzylic proton).

The mixture of **36** and **37** was dissolved in pyridine (3 ml) and acetic anhydride (2 ml) was added. The reaction mixture was heated to 45 °C for 3 h, kept at room temperature for 10 h and worked-up in the usual manner. Preparative t.l.c. (silica gel) of the product followed by recrystallization from chloroform–benzene gave 94 mg (26%, based on **24**) of the tertiary acetate **37**, m.p. 217–218 °C.

Anal. Calcd. for $C_{23}H_{25}O_8NS$ (acetate **39**, mol. wt. 475): C, 58.10; H, 5.30; N, 2.95. Found (*m/e* 475): C, 58.08; H, 5.28; N, 2.83.

I.r. ($CHCl_3$): 3390 (NH), 1755, 1745 (acetate and ester), 1340, 1165 cm^{-1} (sulfonyl); n.m.r. ($CDCl_3$): τ 4.25 (d, J = 9 Hz, 1H, —NH), 6.20 (d, J = 9 Hz, 1H, apex proton), 6.21 (s, 3H, aromatic methoxyl), 6.57 (s, 3H, bridgehead $-OCH_3$), 6.67 (s, 3H, $-\overset{\overset{O}{\|}}{C}-OCH_3$, shielded by aromatic ring), 6.80 (broad s, 1H, bridgehead benzylic proton), 7.83 (s, 3H, acetate methyl).

Deketalization of 35 to 34

A solution of the ketal **35** (96 mg) in 70% aqueous acetic acid (4 ml) was heated to 80 °C for 20 h. After cooling dichloromethane (100 ml) was added and the solution was washed with aqueous sodium carbonate, then with water, dried, and evaporated to dryness. The product **34** was recrystallized from benzene–hexane to a m.p. of 180–181 °C. The yield was 85 mg (98%).

Mol. Wt. Calcd. for $C_{20}H_{19}O_6NS$: 401.0933. Found: (*m/e*): 401.0927.

I.r. ($CHCl_3$): 3350 (NH), 1755, 1730 (ketone and ester), 1330, 1160 cm^{-1} (sulfonyl); n.m.r. ($CDCl_3$): τ 4.13 (d, 1H, —N—H), 6.08 (broad s, 2H, apex and bridgehead protons), 6.13 (s, 3H, aromatic methoxyl), 6.22 (s, 3H, $-\overset{\overset{O}{\|}}{C}-OCH_3$), 7.46 (two d, 2H, methylene).

Mass Spectrometry of Some Substituted 2-Benzylidenecyclohexanones and 2,6-bis-Benzylidenecyclohexanones

P. J. SMITH[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

AND

J. R. DIMMOCK AND W. A. TURNER[2]

College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 4, 1972

The mass spectra of a series of some substituted 2-benzylidenecyclohexanones and a series of substituted 2,6-bis-benzylidenecyclohexanones have been determined at 70 eV. The major fragmentation pathways include an intramolecular aromatic substitution reaction leading to the loss of an ortho-substituent with the formation of a stable benzopyrylium ion, loss of carbon monoxide and ethylene from the parent ion and also further ions derived from subsequent cleavages of the cyclohexanone ring. The structural and electronic factors involved in the aromatic substitution reaction were examined by comparing the M − H/M and M − Cl/M ratios determined from the spectra of the various substrates.

Les spectres de masse d'une série de benzylidène-2 cyclohexanones substituées et d'une série de bis-benzylidène-2,6 cyclohexanones ont été enregistrés à 70 eV. Le processus principal de fragmentation comprend une réaction de substitution aromatique intramoléculaire conduisant à la perte d'un substituant en ortho avec la formation d'un ion benzopyrylium stable, à la perte de monoxyde de carbone et d'éthylène à partir de l'ion parent et aussi à d'autres ions provenant de clivages subséquents de l'anneau de la cyclohexanone. Les facteurs structuraux et électroniques impliqués dans la réaction de substitution aromatique ont été examinés à partir des spectres de plusieurs substrats. [Traduit par le journal]

Introduction

A series of α,β-unsaturated ketones have been synthesized, since these alkylating agents (1, 2) are known to possess anticancer activity.[3] The availability of these compounds led us to examine their mass spectral fragmentation patterns which we compared with the electron-induced fragmentation of a series of acyclic analogs, series 3, which was recently reported (3).

In our earlier paper on the mass spectra of a series of substituted styryl ketones (series 3) (3) we showed that an intramolecular aromatic substitution reaction occurred in the molecular ion to give a benzopyrylium ion. This fragmentation pattern was pronounced when the aromatic ring contained an ortho-chlorine atom and was only of minor significance when the ortho position contained solely hydrogen atoms. We postulated that this substitution reaction required a prior isomerization of the *E* substrates to the *Z* configuration. In addition, an α-cleavage product was obtained as well as the McLafferty rearrangement product. The styryl ketones in series 3 are capable of existing in the *s-cis* and *s-trans*

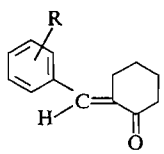
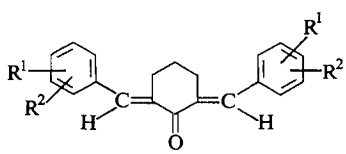
configuration (4) but the exocyclic α,β-unsaturated cycloalkanones (series 1 and 2) have a fixed *s-cis* configuration of the olefinic group with respect to the carbonyl function. However, both *E* and *Z* isomers are possible in series 1 and 2. In the case of some 2-(4-halobenzylidene)cyclohexanones including **4** and also 2,6-bis-(4-halobenzylidene)cyclohexanones, it has been shown from dipole moment measurements that the compounds exist as the *E* isomers (5). Furthermore, Hassner and Mead (6) have shown that condensation of benzaldehyde with 2-methylcyclohexanone and 2,2-diphenylcyclohexanone gave the *E* isomers (ε 16 000 and 17 000, respectively) which were converted to the *Z* isomers (ε 6700 and 7810, respectively) by u.v. irradiation. The molar absorptivities of our compounds (Table 5) were similar to the *E* isomers prepared by Hassner and Mead. Furthermore, 2-benzylidene derivatives of 1-indanones and a substituted 1-tetralone have been shown from n.m.r. spectroscopy to have the *E* configuration (7). The vinylic proton of these derivatives ranged from δ 7.65–7.71 in the *E* isomers and from 6.63–6.89 in the *Z* isomers which were prepared from the *E* isomers by u.v. irradiations. The n.m.r. spectra of the compounds in series 1 and 2 showed a vinylic proton ranging from δ 7.30–7.85. It was assumed, therefore, that in series 1 and 2 the compounds were the *E* isomers, the shape of which is indicated below.



Series 1



Series 2

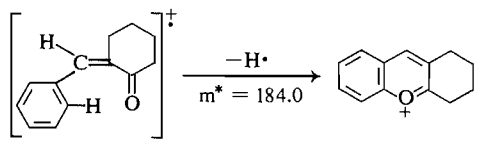
Thus, in series 1 and 2, after the prior isomerization from the *E* arrangement to the *Z* configuration, the carbonyl oxygen atom is in close proximity to the ortho substituent of the aromatic ring. Furthermore, in the cyclohexanone series, α-cleavages to the carbonyl and McLafferty rearrangement processes would be inhibited or suppressed thereby allowing the intramolecular substitution reaction to be a major fragmentation pathway. Finally, it was considered of interest to examine the effect of substituents on the aromatic ring on the formation of various benzopyrylium ions in the light of the relative stabilization of these ions compared with the corresponding parent ion.

Results and Discussion

The mass spectral data for the major ions of the compounds in series 1 and 2 are recorded in Tables 1 and 2.[4] Figures 1–4 are bar graphs of the spectra of **1**, **6**, **2**, and **7**, respectively.

Mass Spectrum of 2-Benzylidenecyclohexanone

Figure 1 indicates the mass spectrum of 2-benzylidenecyclohexanone. This spectrum exhibits an intense M − 1 peak at *m/e* 185(*a*), and M − 1/M = 1. This ion presumably has the benzopyrylium structure and is formed by a loss of a hydrogen atom after *E* to *Z* isomerization has occurred. This reaction is favored since in the *Z* isomer the ortho-hydrogen and carbonyl oxygen are in close proximity and loss of a hydrogen atom is favored. The mass spectrum of the *Z* isomer of **1** is virtually identical to that of **1**. At 15 eV the M − 1/M ratio is 0.36, whereas in the case of the unsubstituted styryl ketone in series 3, there is absence of the M − 1 peak at this ionization voltage. In both compounds further fragmentation at 15 eV is negligible. Thus the geometry of the rigid structure in **1** allows a hydrogen to be abstracted more readily than from the corresponding flexible acyclic analog in series 3.



1 (*Z*) *m/e* 186 (*a*) *m/e* 185

The ion at *m/e* 158 (M − 28) can arise from either of two possible α-cleavages of the parent ion to form structures (*b*) and (*c*) with subsequent loss of carbon monoxide or ethylene to give (*d*), (*e*), and (*f*), m/e 158 (Scheme 1). It is of interest to note that (*E*)-2-furfurylidene-9-methyl-1-decalone also loses carbon monoxide by a similar fragmentation pathway (8). It is expected that (*c*) would be more favored than (*b*) for the α-cleavage product due to resonance stabilization. Consequently, the loss of 28 mass units

[4]A complete listing of the mass spectral peaks for all of the compounds in series 1 and 2 down to 3% intensity (except in the cases where the peak represented the parent or M − 1 ion where intensities of less than 3% were recorded) is available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

*The base peak for compound 8 was at *m/e* 377 and for compound 9 at 412 due to the presence of more than one chlorine atom in the ions. The ions used for discussion will be those with *m/e* values corresponding to the presence of only the ^{35}Cl isotope.

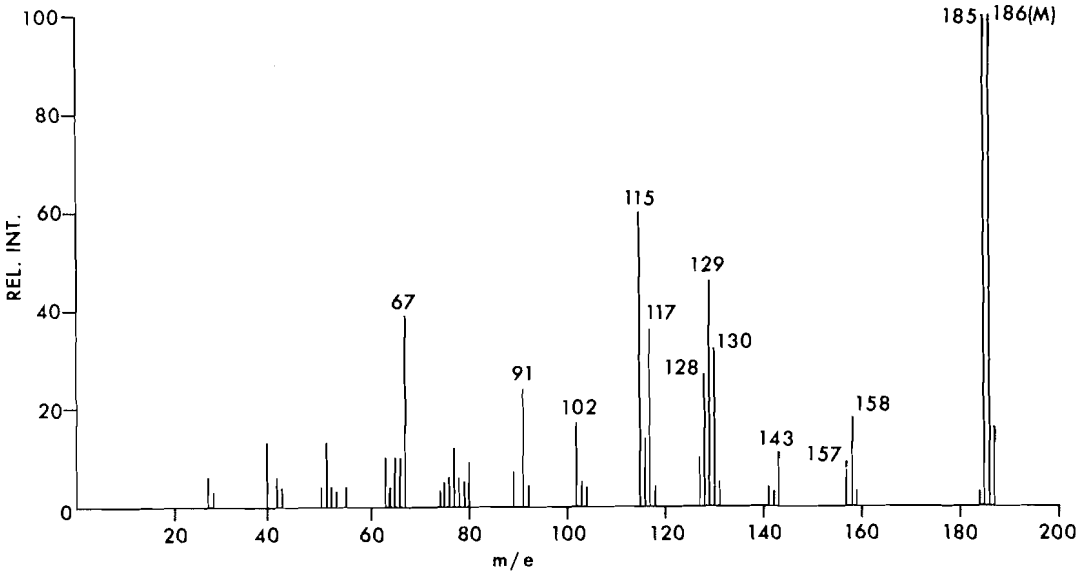

FIG. 1. Mass spectrum (70 eV) of **1**.

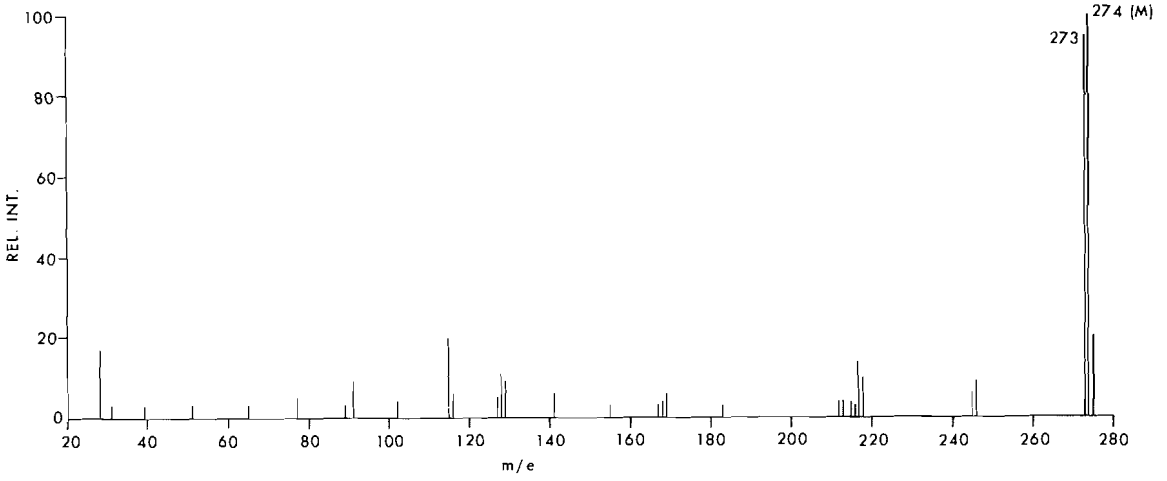

FIG. 2. Mass spectrum (70 eV) of **6**.

from the parent ion would emanate principally from (*c*) to give (*e*) and (*f*). Indeed, when the ion at *m/e* 158 was examined using high resolution mass spectrometry it was found that these ions, $C_{12}H_{14}$ (*e* and possibly *d*) and $C_{11}H_{10}O$ (*f*), were formed in the approximate ratio of 2:1. It should be noted that the usual fragmentation scheme for cyclohexanone (9) to give such ions as $CH_2{=}CH{-}C{\equiv}\overset{+}{O}$ is blocked for structure (*c*). Scheme 2 illustrates possible fragmentation of the ions (*c*), (*e*), and (*f*).

Scheme 3 shows that the precursor of the ion at *m/e* 117 is *m/e* 158 (*e*) as evidenced by a metastable ion at 86.6. Identical processes involving loss of the allyl radical were observed for both the 3-chloro and 4-chloro compounds,

3 and **4**, respectively, as indicated by the appropriate metastable peaks. The ion at *m/e* 117 loses two hydrogen atoms to give *m/e* 115 (m* = 113.0). An indenyl structure (*k*) has been proposed for *m/e* 115 (10) and this ion was observed to lose acetylene (m* = 68.9). The indenyl cation is also confirmed to be formed from *m/e* 130 (*i*) by loss of methyl radical (m* = 101.7).

The origin and structure of the ion at *m/e* 67 is of particular interest since this ion appears in the spectra of all the substituted 2-benzylidenecyclohexanones except **5**. In fact, the most intense ion in the spectrum of the 3-chloro substrate (**3**) is at *m/e* 67. High resolution mass spectrometry has shown this ion to have the elemental composition, $C_5H_7^+$. It is noteworthy that *m/e* 67 does not appear in any of the spectra obtained for the bis-substrates (**6**–**10**) which suggests that the origin of the ion is from the cyclohexanone ring. It has been proposed that *m/e* 67 has the structure of the pentadienyl cation, $CH_2{=}CH{-}CH{=}CH{-}CH_2^+$, and a mechanism has been proposed for its formation from cyclohexene (11). As well, 1-pentyne loses a hydrogen atom to give *m/e* 67, the most intense ion in the spectrum (12).

Mass Spectra of Some Substituted 2-Benzylidenecyclohexanones

The effect of substituents on the intramolecular aromatic substitution reaction was investigated for both the loss of a hydrogen atom and a chlorine atom from the parent ion. The results are shown in Table 3.

The loss of a hydrogen atom from the parent ion to give the M − 1 ion was observed for all the substituted 2-benzylidenecyclohexanones. It is seen from Table 3 that the ratio of M − 1/M varies from 1.0 for the unsubstituted compound (**1**) to 0.3 for the 4-dimethylamino substrate (**5**). A comparison with the styryl ketones in series 3 shows that the M − 1/M ratio is considerably

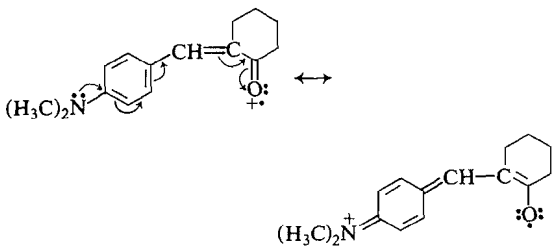
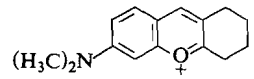
less for series 3 than for the 2-benzylidenecyclohexanones, conforming with the view that facile α-cleavage and McLafferty rearrangement mechanisms compete in series 3 and that loss of a hydrogen atom is less favorable in the acyclic compounds than in series 1.

The correlation of substituents with log Z/Z_0 values, where Z is defined as M − fragment/M and Z_0 refers to the unsubstituted compound has received considerable attention in recent years (13–15). Although a Hammett-like correlation is not expected when the fragment retains the charge at high ionization voltages (70 eV), since further fragmentation can be influenced by the substituent, it is of interest to compare the M − 1/M ratios for the substrates under discussion. A comparison of the ratio for **1** and **5** is the most meaningful since these compounds do not have the competing fragmentation mode of the loss of chlorine from the parent ion and, indeed, **5** has as the major fragmentation process the loss of a hydrogen atom. A reasonable explanation for the decrease in the ratio M − 1/M from 1.0 to 0.3 for compounds **1** and **5**, respectively, is that the parent ion[5] receives considerable stabilization from the electron-donating dimethylamino function in **5**, making attack of the carbonyl oxygen on to the aromatic ring less favored. Alternatively, the presence of



two hetero atoms in **5** allows the possibility of charge localization on either atom which might lead to fewer fragment ions as observed. In fact, the ionization potentials of *N*,*N*-dimethylaniline and cyclohexanone are 7.14 and 9.14 eV, respectively (16), which suggests that the positive charge probably resides mainly on nitrogen. It should be noted that the stabilization of the M − 1 ion is not the prime factor since **A** would be more stable than the corresponding unsubstituted benzopyrylium ion.



A

A comparison of the M − 1/M ratio for the chloro compounds (**2**–**4**) with the unsubstituted compound (**1**) is difficult due to the competing M − Cl reaction. Indeed, this loss of chlorine leads to the base peak in the spectrum of the 2-chloro compound (**2**) where M has only a relative intensity of 3%.

From Table 3 it may be seen that both the 3-chloro and 4-chloro substrates give M − 1/M ratios considerably less than for the unsubstituted compound. This is reasonable for the 4-chloro compound since the chlorine can stabilize the parent ion by the mesomeric effect as discussed for the dimethylamino substrate. The 3-chloro substituent cannot directly conjugate with the carbonyl function and presumably makes the substitution reaction less favorable than for the unsubstituted compound by withdrawing electron density from the benzene ring. It should be noted that the 3-chloro substituent is lost more readily than the 4-chloro from the parent ion in a competing reaction with the formation of the M − 1 species. This would presumably lead to a relatively higher M − 1/M ratio than observed for the former substrate in the absence of the M → M − Cl · reaction.

The parent ion is destabilized for the 3-chloro derivative relative to the 4-chloro substrate as is shown from the data in Table 1 where it is seen that the parent ion for the 3-chloro substrate (**3**) carries 13% of the total ion current whereas the parent ion for the 4-chloro compound (**4**) carries 24% of the total ion current. The base peak for the 3-chloro compound is at *m/e* 67, $C_5H_7^+$, which further suggests that the chlorine in the 3-position on the ring deactivates the parent ion and fragment ions bearing the substituent, which leads to increased intensity of ions derived from the cyclohexanone ring ($C_5H_7^+$). This is borne out by the data for the 4-dimethylamino compound where the parent ion and subsequent fragment ions bearing the dimethylamino group are stabilized by the electron-donating substituent; no ion at *m/e* 67 was observed (Table 1).

The loss of the chlorine from the 2-chloro compound (**2**), as expected, was considerably more favored than loss from either the 3-chloro (**3**) or 4-chloro (**4**) substrates; *i.e.* M − Cl/M =

[5]It is assumed that ease of isomerization of the *E*-substrates to the *Z*-isomers is independent of substituents on the benzene ring.

*Data taken from ref. 3.
†Ratio was calculated using the peaks corresponding to the parent and the fragment ions containing only the ^{35}Cl isotope. The ion corresponding to the loss of a chlorine atom can also arise from the M + 2 peak with loss of ^{37}Cl.

33.3, 0.69, and 0.35, respectively. The loss of the ortho-chlorine from (**2**) is considerably more favored than loss of the ortho-chloro from 1-(2-chlorophenyl)-1-nonen-3-one; M − Cl/M = 33.3 and 3.3, respectively, Table 3. The trend in ratio is the same as observed for the loss of hydrogen from the unsubstituted substrates of series 1 and 3. It is of interest to note that a large M − Cl ion has also been observed in a number of acyclic chlorophenyl ureas, thioureas, and carbamates in the case of the 2-chloro substituted but not in the 3- and 4-substituted compounds (17).

The fragmentation of both the 3-chloro and 4-chloro compounds is considerably more extensive than for the 2-chloro substrate, Table 1. This is presumably due to the ease of formation of the M − Cl ion (*d*) from the 2-chloro substrate via the intramolecular substitution reaction. Compounds **3** and **4** presumably lose a halogen atom by simple carbon–chlorine bond cleavage as does chlorobenzene (18). From the data in Table 3 it is noted that the ease of loss of a chlorine atom from the 3-position is approximately twice as facile as from the 4-position.

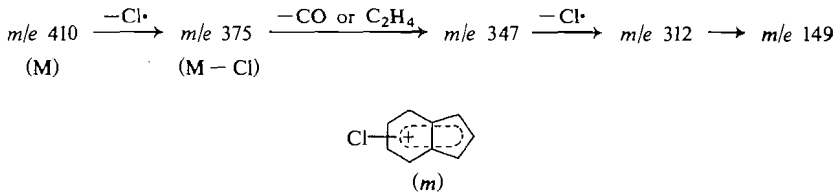
The loss of 28 mass units from the parent ion was noted for compounds **3**, **4**, and **5**, but as expected, the 2-chloro compound did not exhibit such an ion due to the much greater propensity for loss of the ortho-chlorine. It is noteworthy that a metastable ion was observed for the M → M − 28 process only for the 4-dimethylamino substrate (**5**), m* = 176.4 for the transition 229 → 201. In fact, this metastable peak was observed to be broad and have a relatively flat top. These flat top metastable peaks have been attributed to the release of a small amount of kinetic energy during the dissociation process (19). This is consistent with the earlier discussion dealing with substituent effects on the formation of the M − 1 ion for the various substrates since the M—CO ion can be stabilized when a good electron-releasing substituent is in the 4-position, *e.g.* a dimethylamino group.

Mass Spectra of Some Substituted 2,6-bis-Benzylidenecyclohexanones

The spectra of several substituted 2,6-bis-benzylidenecyclohexanones were determined and the major ions with their relative intensities recorded in Table 2. The ratio of M − 1/M and M − Cl/M for these compounds (**6**–**10**) is shown in Table 4 along with ratios obtained in series 3.

It is noted from the data in Table 2 that there is generally considerably less fragmentation at 70 eV for the bis-compounds than in series 1. The only major ions for the bis-unsubstituted compound (**6**) and the 2,6-bis-(4-dimethylaminobenzylidene)cyclohexanone (**10**) are the M and M − 1 ions. The 2,6-bis-(2,6-dichlorobenzylidene)cyclohexanone (**7**) and 2,6-bis-(2,4-dichlorobenzylidene)cyclohexanone (**8**) exhibited essentially only one peak (M − Cl) with the parent ions for both these compounds having a relative intensity of approximately 1.0. The only substrate in the bis-series (Series 2) where significant fragmentation was observed is the 2,6-bis-(3,4-dichlorobenzylidene)cyclohexanone (**9**) and the fragmentation pattern is illustrated in Scheme 4. The formation of the ions down to *m/e* 312 presumably proceeds as described for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 4

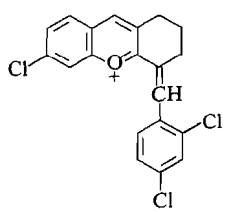
the unsubstituted compound in series 1. It is suggested that the ion at *m/e* 149 has the structure (*m*), an analogous structure to *m/e* 115 (*k*) discussed earlier.

The M − l/M ratios for the bis-substrates are approximately the same as found for the compounds of series 1. The ratios for compounds **7** and **8** are not meaningful since the parent ion has only a relative intensity of 1.0 (Table 2).

The loss of a chlorine atom from the bis-3,4-dichloro compound (**9**) occurs with approximately the same ease as from 2-(3-chlorobenzylidene)cyclohexanone (**3**) since both processes involve cleavage of the meta-chlorine atom from the aromatic ring. The M − Cl/M ratio for the 1-(3,4-dichlorophenyl)-1-nonen-3-one as shown in Table 4 is zero as expected since this substrate can fragment by pathways not available in the cyclohexanone series.

The M − Cl ion is the only appreciable ion found in the spectra of both the bis-2,6-dichloro (**7**) and bis-2,4-dichloro (**8**) compounds. The M − Cl/M ratio in both cases is approximately 100 in comparison with a ratio of 33 observed for the 2-(2-chlorobenzylidene)cyclohexanone (**2**). This difference presumably arises from the increased stability of the fragment ion when it retains an electron-donating ortho- or para-substituent. Isomerization at only one double bond of the bis-compounds is necessary for the intramolecular substitution reaction. The second aromatic ring, where the two chlorines are retained, is able to stabilize the benzopyrylium ion, as shown below.

It is of interest to note that the 2,4-dichloro and 2,6-dichloro substrates from series 3 have a M − Cl/M ratio of 2.5 and 16.7, respectively. In this series, where also a prior *E* to *Z* isomerization is necessary before the intramolecular substitution can occur, the low ratio for the 2,4-dichloro compound compared with the 2,6-dichloro compound could reflect in some measure the relative ease of formation of ions (*n*) and (*o*) of which only (*n*) can lose a chlorine atom from the ortho-position (Scheme 5). In the case of the 2,6-dichloro compounds on isomerization it will always have a chlorine atom at an ortho-position.



M − Cl ion from **8**

Experimental

Mass spectra were determined by Mr. D. Bain with an MS-12 mass spectrometer operating at 70 eV and an ion source temperature of 100°. The samples were introduced via the direct probe technique. M.p. and b.p. are uncorrected. Microanalyses were performed by Mr. O. Douglas of the College of Pharmacy, University of Saskatchewan, Saskatoon.

N.m.r. spectra were run on a Varian T-60 spectrometer, using deuterochloroform as solvent, with tetramethylsilane as the internal standard. U.v. spectra were obtained on a Beckman DU spectrophotometer in 95% ethanol as solvent. G.l.c. was performed on a Pye Series 104 Gas Chromatograph equipped with a flame ionization detector. The glass column (5 ft × 0.25 in. o.d.) was packed with 4% SE-30 adsorbed onto acid washed Chromosorb W (100/200 mesh). The column temperature was 160–180° and the nitrogen flow rate was 50 ml/min.

*General Procedure for the Preparation of Substituted 2-Benzylidenecyclohexanones (Table 5, **1–4**)*

A mixture containing cyclohexanone (2.0 mol), the appropriate aromatic aldehyde (1.0 mol), sodium hydroxide (1.0 mol), and water (1000 ml) was heated under reflux with stirring for 20 h. After cooling to room temperature, the mixture was extracted with chloroform, the organic extracts were washed with water and dried ($MgSO_4$). The chloroform was evaporated *in vacuo* to give a crude product, purified by vacuum distillation followed by repeated recrystallization from methanol.

*(Z)-2-Benzylidenecyclohexanone (**11**)*

A solution of the *E* isomer (**1**) (20 g) in methanol (300 ml) was irradiated with a Hanovia 450 W u.v. lamp through quartz, the solution being cooled by a water jacket. Aliquot samples were taken at 1 h intervals and the course of the reaction was followed by g.l.c. analysis.

After 4 h the *Z–E* ratio was 88:12; unchanged after irradiation for a further 4 h. The solvent was removed under reduced pressure and the residual liquid was distilled, b.p. 122–130°/2 mm, to give a yellow syrup (18.3 g). Crystallization from Skelly F gave pure **11** as colorless crystals (12 g, 60%), m.p. 37–38°; λ_{max} 272 (ε 5575) and 222 mμ (ε 7900); N.m.r.: δ 6.27 (1H, t, J = 2 Hz, C_6H_5—C*H*=).

Anal. Calcd. for $C_{13}H_{14}O$: C, 83.83; H, 7.52. Found: C, 83.90; H, 7.61.

11 reverts to **1** on prolonged heating (120° for 40 h).

*2-(4-Dimethylaminobenzylidene)cyclohexanone (**5**) and 2,6-bis-(4-Dimethylaminobenzylidene)cyclohexanone (**10**)*

The general method used in preparing compounds **1–4** was followed except that after cooling the crude product was removed by filtration and heated under reflux with ethanol. The insoluble material was removed by filtration and **5** deposited from the mother liquor as yellow crystals and purified by repeated recrystallization from ethanol. The residue from filtration was extracted several times with hot alcohol and recrystallization from acetone gave **10** as orange crystals.

*2,6-bis-Benzylidenecyclohexanone (**6**)*

Cyclohexanone (0.05 mol) and benzaldehyde (0.10 mol) were dissolved in ethanol (20 ml) containing aqueous sodium hydroxide solution (3 *N*, 10 ml). The solution was heated for 30 min at 100°. Removal of the ethanol gave a yellow solid which was recrystallized from ethanol to give **6** as bright yellow crystals.

*Preparation of Substituted 2,6-bis-Benzylidenecyclohexanones (Table 6, **7–9**)*

A mixture containing cyclohexanone (0.34 mol), the appropriate aromatic aldehyde (0.085 mol), and aqueous sodium hydroxide solution (1 *N*, 86 ml) was heated at 50° for 12 h. After cooling, the mixture was extracted with chloroform, the organic extracts were washed with water and dried ($MgSO_4$). The chloroform was evaporated *in vacuo* to give a crude product, purified by recrystallization

College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 4, 1972

The mass spectra of several substituted 2-benzylidenecyclohexanone oximes have been determined at 70 eV and at lower ionization voltages. The major fragmentation pathways for the oximes are loss of the ortho substituent from the parent ion as well as loss of hydroxyl radical. The facility of loss of the ortho substituent is compared with a similar process involved in the fragmentation of substituted 2-benzylidenecyclohexanones. In addition, the mass spectrum of the acetate of 2-benzylidenecyclohexanone oxime was determined and showed a M − 1 peak and also a peak corresponding to the parent oxime formed by loss of ketene.

Les spectres de masse de plusieurs oximes substitués de la benzylidène-2 cyclohexanone ont été enregistrés à 70 eV et à des voltages d'ionisation moins élevés. Le processus principal de fragmentation pour les oximes comprend la perte d'un substituant en ortho à partir de l'ion parent ainsi que la perte d'un radical hydroxyle. La facilité impliquée dans la perte du substituant en ortho est comparée à celle d'un processus similaire que l'on retrouve dans la fragmentation des benzylidène-2 cyclohexanones substituées. De plus, le spectre de masse de l'acétate de l'oxime de la benzylidène-2 cyclohexanone a été enregistré et a montré un pic M − 1 et aussi un pic correspondant à l'oxime parent formé par la perte d'un groupe cétène.

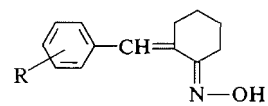
Introduction

In our previous work the mass spectra of a series of nuclear substituted styryl ketones (1) and also some substituted 2-benzylidenecyclohexanones and 2,6-bis-benzylidenecyclohexanones (2) were determined. As well, the structural and electronic factors involved in an intramolecular aromatic substitution reaction with loss of an ortho substituent to give an ion with a benzopyrylium structure were examined and discussed using the measured ratios M − H/M and M − Cl/M.

In order to further investigate this aromatic substitution reaction, it was decided to prepare the oximes of several of the mono-substituted 2-benzylidenecyclohexanones. Since oximes have two hetero atoms the possibility of charge localization on either atom exists which might lead to fewer fragment ions emanating from the cyclohexanone ring, favoring the formation of the substitution product. Furthermore, ring closure with nitrogen in the ring rather than oxygen might be expected to be more favorable since the electron in the C=N bond is more available than in the C=O bond due to the difference in electronegativities of the two hetero atoms.

Results and Discussion

The following compounds (**1**–**4**) were prepared in addition to the acetate of **1** (compound **5**). Figures 1–5 are bar graphs of the spectra of compounds **1**–**5**, respectively.



1 R = H
2 R = 4-N(CH$_3$)$_2$
3 R = 4-Cl
4 R = 2-Cl

The parent 2-benzylidenecyclohexanones have the *E* configuration (2) and it has been shown that 2-benzylidenecyclohexanone oxime exists as a single isomer as revealed by n.m.r. spectroscopy and t.l.c. (3). In view of the large steric effect of the 2-benzylidene groups, it is probable

that the oximes **1**–**4** have the *E* configuration with respect of the oxime hydroxyl groups to the benzylidene groups and in fact the *E* configuration has been assigned as the most probable structure in several 2-substituted cyclohexanone oximes (4).

A striking feature of the spectra of the four oximes is a large peak at M − 1. In fact this peak is approximately three times more intense than the parent ion peak for all the substrates except the 4-dimethylamino derivative (**2**) where it is only one-third as intense as the parent ion. The spectrum of the acetate of the unsubstituted oxime (**5**) shows an appreciable M − 1 peak indicating that the M − 1 peak in the oximes **1**–**4** is not mainly due to loss of the hydrogen atom from the hydroxyl group. In the light of our recent studies on the intramolecular substitution reaction of 2-benzylidenecyclohexanones leading to the formation of the stable benzopyrylium ion (2), it is reasonable to assume that such a mechanism is operative in the case of the oximes with nitrogen-bonding to the aromatic ring. In all cases a metastable peak was observed for this process (see Scheme 1).

The formation of the M − 1 ion in the oxime series appears to be more favorable than for the substituted 2-benzylidenecyclohexanones as the ratio M − 1/M is greater for the former substrates with the exception of the 4-dimethylamino compound (**2**). Indeed, the M − 1 ion represents the base peak in the spectra of compounds **1** and **3**. This high ratio for M − 1/M is surprising since it is expected that the oxime parent ions would be relatively more stable than the ketone parent ions due to the

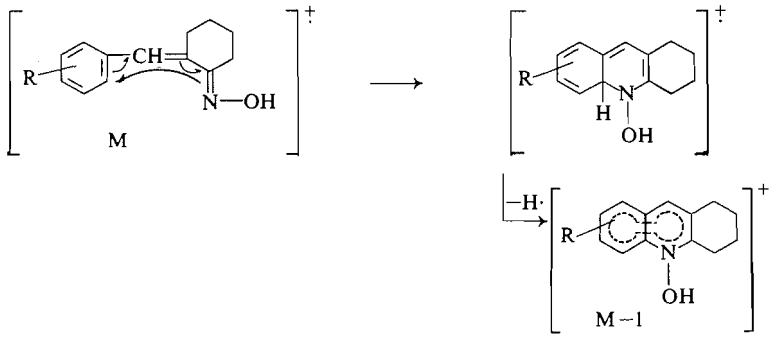
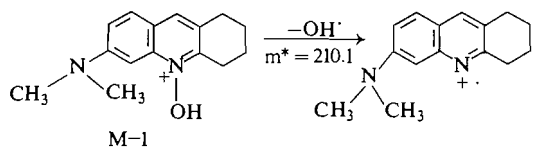


SCHEME 1

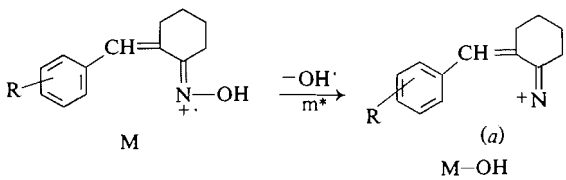
presence of the two hetero atoms and less fragmentation would result (5). However, the formation of the even-electron M – 1 ion could be the driving force for the loss of a hydrogen atom from the parent ion (6). As well, it is expected that ring closure using the electron in the C=N rather than in the C=O bond would be more facile due to the decrease in electronegativity of the hetero atom.

It was noted that the M → M – 1 process was considerably less favorable for the 4-dimethylamino substrate (**2**) than for any of the other oximes. Apparently, for this compound the strongly electron-donating para substituent makes the parent ion sufficiently stable due to greater charge delocalization, so that further fragmentation is retarded. The electron-donating substituent influences markedly the mode and ease of fragmentation as shown by the observation of a fairly intense ion resulting from the loss of a hydroxyl radical from the M – 1 ion. Such a process is very minor or non-existent for the other substrates. Presumably, the electron-donating substituent allows the formation of this odd-electron ion while for the other substrates the loss of hydroxyl radical from the M – 1 ion would lead to a relatively more unstable ion.



The intramolecular aromatic substitution reaction was further investigated as in the substituted 2-benzylidenecyclohexanone series by preparing the corresponding para- and ortho-chloro oximes, **3** and **4**, respectively. In the oxime series as in the ketone series it is noted that the loss of the ortho-chlorine is extremely facile leading to the most intense peak in the spectrum, M – Cl, Fig. 4. This process is confirmed by the appropriate metastable peak. The loss of the para-chlorine from the parent ion of **3**, however, is not observed for the oxime, Fig. 3, in contrast to the corresponding cyclohexanone where such a loss of chlorine was observed (2). This is consistent with a more facile cyclization process for the oxime and consequently the competing process, loss of chlorine, is not observed.

A major fragmentation pathway observed for oximes **1**–**4** is the loss of a hydroxyl radical from the parent ion to form the even-electron M – OH species, ion (*a*), Figs. 1-4. In fact, ion (*a*) is



the most intense ion in the spectrum of the 4-dimethylamino substrate (**2**). Such a process has been observed for aliphatic aldoximes and ketoximes as well as alicyclic ketoximes (6) but is of minor importance due to the competing McLafferty rearrangement observed in the aliphatic series. However benzophenone oxime (5) has the M – OH ion as the base peak which suggests that its formation is made favorable by conjugation.

An interesting feature of the mass spectra of aliphatic ketoximes and aromatic ketoximes (5) is the loss of an oxygen atom from the parent ion which is a very rare process. Loss of an oxygen

atom from the oximes studied in the present investigation was not observed.[3]

Experimental

Mass spectra were determined with an MS-12 mass spectrometer operating at 70 eV and lower ionization voltages with an ion source temperature of 100°. The samples were introduced using the direct probe technique. Melting points are uncorrected. Microanalyses were performed by Mr. O. Douglas of the College of Pharmacy, University of Saskatchewan, Saskatoon, Sask.

General Procedure for the Preparation of Substituted 2-Benzylidenecyclohexanone Oximes (Table 1, 1–4)

A mixture of the appropriate ketone (0.087 mol) in 95% ethanol (250 ml), hydroxylamine hydrochloride (0.105 mol) in water (25 ml), and sodium acetate (0.096 mol) in water (20 ml), was heated at 60° for 1 h with stirring. The mixture was diluted with water and cooled. The crude product was removed by filtration, washed with water, and purified by repeated recrystallization from acetone.

2-Benzylidenecyclohexanone Oxime Acetate (5)

A solution of 2-benzylidenecyclohexanone oxime (3.5 g, 0.0175 mol) in freshly distilled acetic anhydride (15 ml) was heated under reflux for 0.5 h. Crushed ice was added to the cooled solution and 10% aqueous sodium carbonate solution was added to decompose the excess acetic anhydride. The gummy yellow precipitate (2.3 g) was removed by filtration and recrystallized from methanol to give pure **5** as colorless needles (1.0 g, 24%), m.p. 105.5°.

Partial Oxidation of Vicinal Hydroxyl Groups of Methyl 4,6-*O*-Benzylidene-α- and β-D-Glucopyranosides with Dimethyl Sulfoxide and Phosphorus Pentoxide[1]

YÔTARO KONDO AND FUJIKAZU TAKAO
Department of Agricultural Chemistry, Kyoto University, Kyoto, Japan
Received October 5, 1972

Oxidation of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside with dimethyl sulfoxide – phosphorus pentoxide gives the corresponding 3-ketone (**3**), the 2,3-*O*-oxidomethylenebenzylidene acetal (**5**), and the 2,3-*O*-oxidodimethylene acetal (**6**). By a similar treatment of methyl 4,6-*O*-benzylidene-β-D-glucopyranoside only starting material was recovered.

L'oxydation du méthyl-*O*-benzylidène-4,6-α-D-glucopyranoside par le pentoxyde de phosphore-diméthylsulfoxyde conduit à la cétone-3 correspondante (**3**), à l'*O*-oxydométhylène benzylidène-2,3 acétal (**5**) et à l'*O*-oxydodiméthylène-2,3 acétal (**6**). Par un traitement similaire, le méthyl-*O*-benzylidène-4,6-β-D-glucopyranoside a été retrouvé inchangé. [Traduit par le journal]

Can. J. Chem., **51**, 1476 (1973)

Introduction

Oxidation of "isolated" secondary hydroxyl groups of carbohydrates to the corresponding keto sugars, which are important intermediates in the synthesis of amino, branched-chain, and rare sugars (1), has been reported by many authors (2). It has been demonstrated that a dimethyl sulfoxide (DMSO) – acid anhydride (acetic anhydride, phosphorus pentoxide (P_2O_5) mixture is useful for oxidation of "isolated" secondary hydroxyl groups of monosaccharides (3, 4) and also for the partial oxidation of "vicinal" hydroxyl groups of polysaccharides (5, 6). However, little is known about the partial oxidation of "vicinal" diols of monosaccharides by these reagents. For the comparative studies of partial oxidation of mono- and polysaccharides, we selected methyl 4,6-*O*-benzylidene-α- and β-D-glucopyranosides (**1** and **2**) and 6-*O*-tritylamylose[2] (7) as the respective models. This communication describes the partial oxidation of **1** and **2** with DMSO–P_2O_5 and also identification of the products obtained by a side reaction of this oxidation.

Results and Discussion

Treatment of compound **1** with DMSO-P_2O_5 for 3 days at 40 °C gave seven compounds as detected by t.l.c. (silica gel G, benzene–ether, 4:1, v/v). The reaction mixture was extracted with chloroform and the extract was evaporated to afford crystalline material which on recrystallization from hot benzene gave methyl 4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose (**3**). The assigned structure of **3** is based on the p.m.r. and i.r. spectral properties, revealing respectively the signal of H-1 as a one-proton doublet ($J_{1,2}$ = 4.5 Hz) at τ 4.90, which indicates that H-2 remained intact, and characteristic absorptions in the carbonyl region at 1740 cm^{-1} and in the hydroxyl region at 3500 cm^{-1}. Acetylation of **3** with acetic anhydride in pyridine yielded methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose (**4**)[3] of which analytical data were in good agreement with those of an authentic sample prepared via oxidation of methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside. These observations suggest that the C-3 hydroxyl of the vicinal diol of **1** is selectively oxidized with DMSO-P_2O_5. Upon silicic acid column chromatography of the mother liquor, from which compound **3** was previously removed, six compounds were isolated (see Experimental). The i.r. spectra of these compounds did not show any absorption of the carbonyl group.

The structures of compounds **5** and **6** isolated chromatographically were determined by elemental analysis, p.m.r., and mass spectrometry. The p.m.r. spectrum (Fig. 1) of **5** showed the signal of H-1 as a one-proton doublet ($J_{1,2}$ =

[1]Presented in part at the 274th Meeting of the Kansai Division of the Agricultural Chemical Society of Japan, October 1971, Kagawa, Japan.

[2]Oxidation of 6-*O*-tritylamylose with DMSO-P_2O_5 gave results similar to those obtained with DMSO – acetic anhydride oxidation (6). The details will be published elsewhere.

[3]It is of particular interest that the p.m.r. spectrum of **4** showed $^4J_{a,a}$ long-range coupling ($J_{2,4}$ = 1.0 Hz).

3.5 Hz) at τ 5.09, and two singlets at 4.43 and 6.62 corresponding to the 4,6-benzylic proton and the glucosidic methyl proton respectively. Furthermore, new signals appeared as a one-proton singlet at τ 3.97 and as a two-proton quartet (AB system) at 4.76 due to the 2,3-benzylic proton and the methylene portion of the seven-membered 2,3-cyclic acetal, respectively. Compounds **5** and **6** showed a similarity in their p.m.r. spectra, except that the methylene moiety of the 2,3-cyclic acetal of **6** occurred as a four-proton quartet at τ 5.01 which was superimposed upon the signal of H-1 appearing as a one-proton doublet at τ 5.11 ($J_{1,2}$ = 3.6 Hz) (Fig. 2). To provide further structural confirmation for the position of the 2,3-benzylidene group of **5**, the chemical shift of H-1 of compounds **5**, **6**, and methyl 4,6-*O*-benzylidene-2,3-oxidodiethylidene-α-D-glucopyranoside (**7**) which was prepared by the method of Appel *et al.* (8) were compared; the signal of H-1 of **7** appeared at τ 5.17 higher field by 0.06 p.p.m., as compared with that of **6**. Since structures of **6** and **7** are different only in substituted groups (R_1 and R_2), this significant upfield shift of the H-1 signal of **7** may be due to the shielding effect of the methyl moiety of the ethylidene group attached to C-2 in the 2,3-cyclic acetal of **7** provided that the cyclic acetals of **6** and **7** adopt a twist-chair conformation as suggested by Stoddart (9) for methyl 4,6-*O*-ethylidene-2,3-oxidodiethylidene-α-D-glucopyranoside (**9**). If this is the case, a considerable change in the chemical shift of H-1 would be expected for the

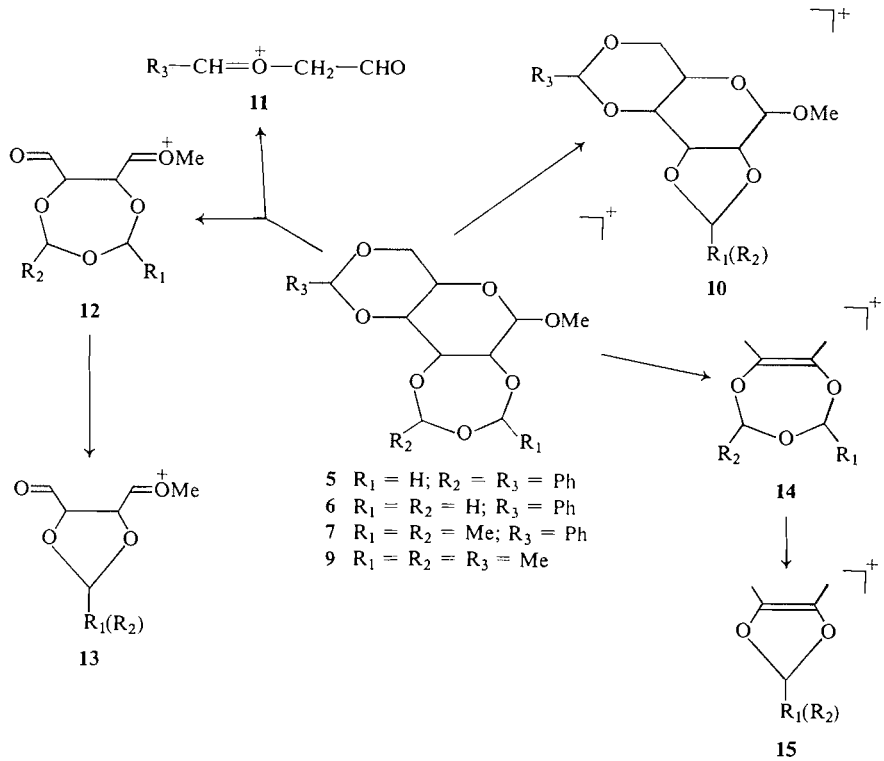

SCHEME 1. Mass spectrometric fragmentation pattern.

acetal analog of **5** with the benzylidene group attached to C-2 rather than to C-3. However, it was found that the H-1 signals of compounds **5** and **6** appeared at nearly the same field at τ 5.09 and 5.11, respectively, suggesting that the benzylidene group of the 2,3-cyclic acetal in compound **5** is attached to the oxygen atom of C-3 as shown in Fig. 1.

The formation of the methyleneoxy linkages of compounds **5** and **6** may be attributed to the reaction of hydroxyl groups of the sugar moiety with formaldehyde derived from DMSO, in view of the fact that treatment of **1** with paraformaldehyde–P_2O_5 in *N*,*N*-dimethylformamide (DMF) for 3 days at 40 °C gave compound **6** as the major product. Furthermore, the 2,3-benzylidene group in compound **5** is presumably derived from benzaldehyde which is liberated by acid degradation of the 4,6-benzylidene group of the starting material.

The low yield of **3** may be explained in terms of a rapid condensation of the diol with formaldehyde, which may occur faster than the formation of the oxidation product, thus giving methyleneoxy acetals as the major product. It is of interest to note that the reaction of **2** with DMSO–P_2O_5 yields neither cyclic acetals nor oxidized products under the same reaction conditions as that described for α-anomer, while treatment of **2** with paraformaldehyde gave methyl 4,6-*O*-benzylidene-2,3-*O*-oxidodimethylene-β-D-glucopyranoside (**8**) as observed with α-anomer.

Finally, the mass spectrometric fragmentation of the 2,3-cyclic acetals of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**5**, **6**, **7**, and **9** (8)) was examined (see Scheme 1 and Table 1). All the mass spectra of the above 2,3-cyclic acetals exhibited the peak of molecular ion and the peak characteristic of the fragment **10** in the higher mass range which is formed by the loss of an aldehyde (R-CHO). Fragments **11** and **12** are formed by an elimination similar to "h-rupture" which is one of the characteristic fragmentations to methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (10). The resulting ion **12** further loses an aldehyde leading to fragment **13**, and the cleavage at C-1 and -3 bonds of the molecular ion produces fragment **14**, which upon loss of an aldehyde gives fragment **15**. It appears that the

fragmentation accompanied by the loss of aldehydes is characteristic of the mass spectrometry of 2,3-cyclic acetals.

Experimental

The t.l.c. was performed on silica gel G (Merck, benzene–ether, 4:1, v/v) and the spots were detected by spraying a solution of 10% sulfuric acid and by heating. Column chromatography was carried out on silicic acid (Mallinkrodt, 100 mesh) by stepwise elution with the solvent systems; benzene–ether, 4:1, 2:1 (v/v), and pure ether. Melting points were determined on a Yanagimoto hot stage microscope and are uncorrected. The optical rotations were measured with a Yanagimoto Model OR-20 direct reading polarimeter and the i.r. spectra were recorded with a Shimazu AR-7 spectrophotometer by the potassium bromide disk method. The p.m.r. spectra were measured on a Varian A-60 spectrometer using tetramethylsilane as an internal reference at the normal operating temperature of the instrument. The mass spectra were taken with a Hitachi RUM-60 at 200 °C and ionizing potential 70 eV.

Reaction of Methyl 4,6-O-Benzylidene-α-D-glucopyranoside with Dimethyl Sulfoxide – Phosphorus Pentoxide

A mixture of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**, 5 g) and P_2O_5 (2.5 g) in dry DMSO (75 ml) was stirred for 3 days at 40 °C. After dilution with chloroform (250 ml) and water (250 ml) followed by neutralization with aqueous 3 *M* K_2CO_3 solution, the reaction mixture was extracted with chloroform (50 ml × 3). The extract was washed with saturated aqueous NaCl solution (50 ml × 5) and dried over Na_2SO_4. After evaporation to dryness *in vacuo*, the crystalline residue obtained was recrystallized from hot benzene to give methyl 4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose (**3**, 0.55 g, 11%) which is slightly soluble in common organic solvents, m.p. 190–192 °C; $[\alpha]_D^{23}$ +113.0° (*c*, 1, pyridine) (lit. (11), m.p. 184–186 °C, $[\alpha]_D^{23}$ +128.4° (*c*, 0.48, acetone)); i.r.: ν_{max} 1740 (C=O), 3500 cm^{-1} (OH); p.m.r. (in DMSO-d_6): τ 4.34 (one-proton singlet, benzylic H), 4.90 (one-proton doublet, H-1, $J_{1,2}$ = 4.5 Hz), 6.67 (three-proton singlet, OMe).

Anal. Calcd. for $C_{14}H_{16}O_6$: C, 60.0; H, 5.9. Found: C, 59.96; H, 6.22.

The mother liquor, from which **3** was previously removed, was applied to a silicic acid column (415 × 40 mm) which is subjected to sequential elution. A mixture of benzene and ether (4:1, v/v) first eluted a trace amount of syrupy compound (0.02 g, R_f 0.85), followed by 2,3-oxidomethylenebenzylidene acetal (**5**) (0.24 g, 3.4%, R_f 0.70) and then 2,3-oxidodimethylene acetal (**6**) (0.45 g, 7.5%, R_f 0.50). The syrupy compound was not further investigated because of its low yield.

Methyl 4,6-*O*-benzylidene-2,3-*O*-oxidomethylenebenzylidene-α-D-glucopyranoside (**5**) had m.p. 127–128 °C and $[\alpha]_D^{23}$ +82.0° (*c*, 1, $CHCl_3$); p.m.r. (in $CDCl_3$): τ 3.97 (one-proton singlet, 2,3-benzylic H), 4.43 (one-proton singlet, 4,6-benzylic H), 4.76 (two-proton quartet, $-CH_2-$, J_{gem} = 7.6 Hz), 5.09 (one-proton doublet, H-1, $J_{1,2}$ = 3.5 Hz), 6.62 (three-proton singlet, OMe).

Anal. Calcd. for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04. Found: C, 65.85; H, 6.28.

Methyl 4,6-*O*-benzylidene-2,3-*O*-oxidodimethylene-α-D-glucopyranoside (**6**) had m.p. 133–134 °C and $[\alpha]_D^{23}$ +89.5° (*c*, 1.8, $CHCl_3$); p.m.r. (in $CDCl_3$): τ 4.36 (one-proton singlet, benzylic H), 5.01 (four-proton quartet, $-CH_2-$, J_{gem} = 7.8 Hz), 5.11 (one-proton doublet, H-1, $J_{1,2}$ = 3.6 Hz), 6.75 (three-proton singlet, OMe).

Anal. Calcd. for $C_{16}H_{20}O_7$: C, 59.25; H, 6.22. Found: C, 59.14; H, 6.36.

Further elution of the above column with a mixture of benzene and ether (2:1, v/v) gave crystals (0.45 g, R_f 0.30) having m.p. 272–275 °C, $[\alpha]_D^{23}$ −89.0° (*c*, 1, pyridine), and M^+ 564[4] and then crystals (0.71 g, R_f 0.15) having m.p. 236–238 °C, $[\alpha]_D^{23}$ +76.0° (*c*, 1, pyridine), and M^+ 576.[5] The complexity of their p.m.r. spectra precluded detailed structural elucidation. However, on the basis of the mass spectral data dimeric structures may be suggested. Starting material **1** (0.71 g, R_f 0.08) was eluted with pure ether and had m.p. 169–170 °C, and $[\alpha]_D^{23}$ +110.0° (*c*, 1, $CHCl_3$).

Anal. Calcd. for $C_{14}H_{18}O_6$: C, 59.56; H, 6.43. Found: C, 59.52; H, 6.24.

Methyl 2-O-Acetyl-4,6-O-benzylidene-α-D-ribo-hexopyranosid-3-ulose (4)

Preparation A

A solution of the 3-keto sugar **3** (0.1 g) in dry pyridine (20 ml) and acetic anhydride (20 ml) was stirred overnight at room temperature. The reaction mixture was poured into ice-water and extracted with chloroform (150 ml). The extract was washed successively with aqueous sulfuric acid, saturated aqueous sodium bicarbonate and water, and dried over Na_2SO_4. The residue from evaporation of the solution was recrystallized from ethanol to give title compound **4** (0.12 g) as fine needles, m.p. 190–193 °C, $[\alpha]_D^{23}$ +69.0° (*c*, 1, $CHCl_3$), that was identical with the product of preparation B.

Preparation B

A solution of methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (**12**) (0.5 g) in dry DMSO (15 ml) and acetic anhydride (5 ml) was stirred for 4 days at room temperature. The solution was diluted with chloroform and water, and then extracted with chloroform. The extract was washed with saturated sodium bicarbonate solution and water, dried over Na_2SO_4, and evaporated. The syrupy residue was co-distilled with ethanol to give a crystalline mass. Recrystallization yielded the 3-ketone **4** (0.29 g, 60%), m.p. 189–190 °C; $[\alpha]_D^{30}$ +65.0° (*c*, 1, $CHCl_3$); i.r.: ν_{max} 1753 (C=O), 1743 cm^{-1} (C=O, ester); p.m.r. (in $CDCl_3$): τ 4.44 (one-proton singlet, benzylic H), 4.62 (one-proton quartet, H-2, $J_{1,2}$ = 4.3, $J_{2,4}$ = 1.0 Hz), 4.81 (one-proton doublet, H-1, $J_{1,2}$ = 4.3 Hz), 6.57 (three-proton singlet, OMe), 7.80 (three-proton singlet, OAc).

Anal. Calcd. for $C_{16}H_{18}O_7$: C, 59.62; H, 5.63. Found: C, 59.56; H, 5.85.

Reaction of Methyl 4,6-O-Benzylidene-α-D-glucopyranoside with Paraformaldehyde in N,N-Dimethylformamide

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**, 0.5 g) was stirred with paraformaldehyde (0.5 g) in DMF (5 ml) containing P_2O_5 (0.25 g) for 3 days at 40 °C. The

[4]The mass spectrum was measured at 320 °C.

[5]The mass spectrum was measured at 350 °C.

reaction mixture was diluted with chloroform (100 ml) and filtered through Celite to remove the excess paraformaldehyde. The solution was extracted with chloroform (50 ml × 3) and the extract was evaporated to a thin syrup. It was then chromatographed on a silicic acid column to yield a colorless syrup which was crystallized from methanol to give methyl 4,6-*O*-benzylidene-2,3-*O*-oxidodimethylene-α-D-glucopyranoside (**6**) as fine needles (0.11 g, 19%), m.p. 133–134 °C, $[\alpha]_D^{30}$ +91.1° (*c*, 0.5, $CHCl_3$).

Reaction of Methyl 4,6-O-Benzylidene-β-D-glucopyranoside with Paraformaldehyde in N,N-Dimethylformamide

Methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (**2**, 2 g) was added to a mixture of paraformaldehyde (2 g) and P_2O_5 (1 g) in dry DMF (40 ml) and stirred for 3 days at 40 °C. It was worked-up as described for α-anomer to give a crystalline residue which was recrystallized from a mixture of chloroform and petroleum ether to afford methyl 4,6-*O*-benzylidene-2,3-*O*-oxidodimethylene-β-D-glucopyranoside (**8**) as fine needles (0.5 g, 20%), m.p. 205–206 °C; $[\alpha]_D^{23}$ −34.4° (*c*, 1, $CHCl_3$); p.m.r. (in $CDCl_3$): τ 4.36 (one-proton singlet, benzylic H), 5.10 (four-proton quartet, $-CH_2-$, J_{gem} = 6.0 Hz), 5.43 (one-proton doublet, H-1, $J_{1,2}$ = 7.8 Hz), 6.75 (three-proton singlet, OMe).

Anal. Calcd. for $C_{16}H_{20}O_7$: C, 59.25; H, 6.22. Found: C, 59.09; H, 6.16.

cis Virtual Coupling

G. M. BANCROFT[1] AND E. T. LIBBEY
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 20, 1972

The proton n.m.r. spectra of the new compounds *cis*-$Fe(NCS)_2(PR_3)$ (R = Me, MeO) consist of two identical triplets assignable to *trans* PR_3 and *cis* PR_3 linkages in the same complex.

On observe que les spectres R.M.N. des composés $Fe(NCS)_2(PR_3)_4$ *cis* (R = Me et OMe) sont formés de deux triplets identiques attribuables aux groupes PR_3 *trans* et PR_3 *cis* d'un même complexe.
[Traduit par le journal]

Can. J. Chem., **51**, 1482 (1973)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The phenomenon of "virtual coupling" has been used extensively in both square planar (1) and octahedral systems (2, 3) to establish the *trans* configuration of ligands in coordination compounds. Using ligands such as $P\phi_2Me$, $P(OMe)_3$, and $P\phi Me_2$, a triplet of apparent $J(PH)$ of about 4–5 Hz was observed, although the width of the central peak often varied markedly. There have been several suggestions in the literature (4, 5) recently that the appearance of a triplet should be interpreted with caution, and at least two recent experimental papers (5, 6) indicate that broadened triplets can be observed for *cis* phosphines or phosphites. Theoretical considerations (7, 8) suggest that a sharp triplet will occur when the ^{31}P–^{31}P coupling is large, and that the central line will broaden and collapse as the ^{31}P–^{31}P coupling decreases. We report here identical "virtual coupling" patterns for both the *trans* PR_3 pair and *cis* PR_3 pair (R = Me, MeO) in two new compounds, *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ and *cis*-$Fe(NCS)_2[P(Me)_3]_4$. Unfortunately, other analogous *cis* compounds containing other halides (or pseudohalides) and simple phosphines or phosphites could not be prepared. Indeed, these are the first two Fe(II) low spin octahedral phosphine or phosphite compounds yet reported which do not contain the powerful ligands H or CO. Thus Booth and Chatt (9) were able to prepare just the tetrahedral ferrous complexes.

Experimental

All reactions were performed under a nitrogen atmosphere using deoxygenated solvents. Trimethyl phosphite was obtained from J. T. Baker Chemical Co. and redistilled prior to use. Trimethyl phosphine was prepared by standard Grignard techniques: phosphorous trichloride was added slowly, with vigorous stirring, to excess MeMgBr in di(*n*-butyl ether) at 0 °C (10). PMe_3 was distilled out in a N_2 stream at ~120 °C and trapped in saturated AgI/KI solution as the $(AgI{\cdot}PMe_3)_n$ complex which was used without further purification.

Preparation of Compounds

cis-Diisothiocyanate Tetrakis(trimethyl Phosphite) Iron(II)

To 1.98 g (1 mmol) of $FeCl_2{\cdot}4H_2O$ and 2.5 g of NH_4NCS (~3 mmol) in 50 cc methanol, 5 cc of $P(OMe)_3$ were added. Crystals of *trans*-$Fe(NCS)_2[P(OMe)_3]_4$ began to form after a few minutes. These were washed with cold methanol and dried under vacuum. Yield 80%.

Anal. Calcd. for *trans*-$Fe(NCS)_2[P(OMe)_3]_4$: C, 25.15; H, 5.38; N, 4.18. Found: C, 25.04; H, 5.76; N, 4.28.

Recrystallization of the *trans* isomer from acetone–ether afforded the *cis* isomer.

Anal. Calcd. for *cis*-$Fe(NCS)_2[P(OMe)_3]_4$: C, 25.15; H, 5.38; N, 4.18. Found: C, 25.53; H, 5.40; N, 3.80.

The *trans* isomer is air stable, but the *cis* isomer is moderately air sensitive.

cis-Diisothiocyanate Tetrakis(trimethyl Phosphine) Iron(II)

0.06 g (0.5 mmol) of anhydrous $FeCl_2$ and 0.12 g (2 mmol) of NH_4NCS were dissolved in 40 cc of absolute ethanol. 2.6 g of $AgI{\cdot}PMe_3$ (~8 mmol of PMe_3) was heated on a wax bath at ~170 °C in a stream of dry nitrogen. At this temperature, the PMe_3 was evolved, and the gases were passed directly into the ethanol solution. After about 15 min ~0.15 g of the desired product slowly formed as a red powder. Attempts at recrystallization resulted in loss of phosphine. The compound is unstable in air and solution. Yield 70%.

Anal. Calcd. for the compound: C, 35.3; H, 7.6; N, 5.9. Found: C, 35.3; H, 7.4; N, 5.9.

Infrared spectra were recorded on a Perkin–Elmer 621 instrument. In the NC stretching region, the *trans*-$P(OMe)_3$ isomer gave a sharp line at 2114 cm^{-1}, while the *cis*-$P(OMe)_3$ isomer gave a broad doublet at 2118 and 2131 cm^{-1}. Similarly, the *cis*-PMe_3 isomer gave a broad line centered at 2100 cm^{-1} with two shoulders at 2120 and 2049 cm^{-1}. The Mössbauer quadrupole splittings confirm

[1]To whom correspondence should be addressed.

For personal use only.

the above structural assignments. Mössbauer spectra, run at 78 °K on an Austin Science Associates Spectrometer showed the expected 2:1 *trans*:*cis* ratio (11) of quadrupole splittings for the $P(OMe)_3$ complexes (*trans* = 0.56 mm s^{-1}; *cis* = 0.30 mm s^{-1}), and the small quadrupole splitting for *cis*-$Fe(NCS)_2[P(Me)_3]_4$ (= 0.31 mm s^{-1}) is also consistent with *cis* geometry. The n.m.r. spectra were recorded on Varian HA 100 and T60 instruments in $CHCl_3$. For the $P(OMe)_3$ compounds, 5% excess phosphite was added. This phosphite slowed down both the rate of isomerism and the rate of ligand exchange which, at ambient temperatures, produced broad unresolved absorptions.

Results and Discussion

The proton n.m.r. spectrum of *trans*-$Fe(NCS)_2[P(OMe)_3]_4$ shows the pentet pattern characteristic of the square planar environment of phosphites (6), $\tau = 6.32$.

The proton n.m.r. spectra of both *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ (Fig. 1) and *cis*-$Fe(NCS)_2[P(Me)_3]_4$ consist of two sharp chemically shifted 1:2:1 triplets which are indistinguishable. For *cis*-$Fe(NCS)_2[P(OMe)_3]_4$, $\tau_1 = 6.25$, $\tau_2 = 6.48$, and $^3J(PH) + {}^5J(PH) = 9.9 \pm 0.2$ Hz. For *cis*-$Fe(NCS)_2[P(Me)_3]_4$, $\tau_1 = 8.50$, $\tau_2 = 8.72$, and $^2J(PH) + {}^4J(PH) = 7.6 \pm 0.4$ Hz.

Selective decoupling experiments on *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ collapsed each triplet independently with no observable change in the other triplet. Although the line widths are a function of both temperature and concentrations, the central lines of each triplet remain of equal width. At 30 °C, all the lines in the *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ spectrum (Fig. 1) have a width of ~0.8 Hz compared to the ligand line width of ~0.5 Hz. All the lines in *cis*-$Fe(NCS)_2[P(Me)_3]_4$ have widths which are somewhat broader (~2 Hz), but all lines in this spectrum are still of very similar width.

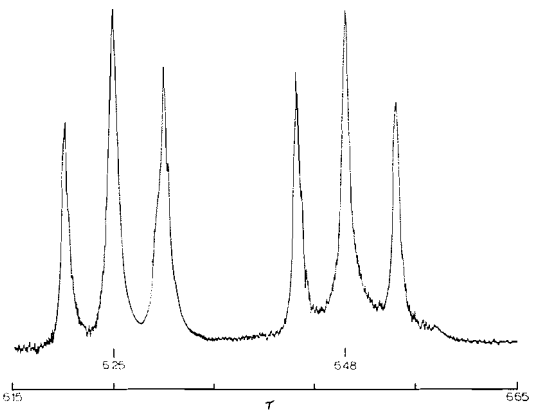

FIG. 1. Proton n.m.r. spectrum of *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ at 30 °C in $CHCl_3$ obtained on a Varian HA 100 instrument. The small peaks due to the *trans*-isomer are not shown.

These spectra represent the first observation of two sharp "virtual coupled" triplets from within one molecule. The only reasonable assignment is: one triplet to the *trans*-PR_3 pair, and the other triplet to the *cis*-PR_3 pair *trans* to the NCS groups. It is apparent then that the ^{31}P–^{31}P coupling between the *trans*-$P(OMe)_3$ pair and the coupling between the *cis*-$P(OMe)_3$ pair are of comparable magnitude, and surprisingly that cross coupling between the two pairs is very small.

The slight asymmetry of the outer lines of the triplets indicates that some protonic cross coupling is occurring (7), but that it is small compared with both the *cis* and *trans* "virtual coupling". Because the low field triplet in the *cis*-$Fe(NCS)_2[P(OMe)_3]_4$ spectrum has a similar chemical shift to *trans*-$P(OMe)_3$ linkages in *trans*-$Fe(NCS)_2[P(OMe)_3]_4$, we assign the low field triplets to the *trans*-PR_3 pairs and the high field triplets to the *cis*-PR_3 pairs.

The simplicity of the "double-triplet" line patterns make a polymeric species highly unlikely; *e.g.* the simple dimer, $[P(OMe)_3]_4Fe(NCS)_2Fe[P(OMe)_3]_4^{2+}$, would have three chemically different phosphites, those *trans* to phosphites, thiocyanate, and isothiocyanate, presumably distinguishable in the n.m.r. spectrum. Similarly, the possibility of two monomeric species is small since the triplets are of equal intensity.

Our results suggest strongly that the appearance of a sharp triplet in the proton n.m.r. need not be characteristic of *trans* phosphines or phosphites (4).

We are grateful to Drs. J. Thompson and I. Pete of the University of Toronto for running the decoupled spectra, Drs. A. G. MacDiarmid and M. L. H. Green for helpful discussions, and the National Research Council of Canada for financial support.

Acid-catalyzed Exchange at 250 °C; a Simple and Quantitative Method for the Replacement of Aromatic Protons by Deuterium[1]

NICK H. WERSTIUK AND TONY KADAI

Department of Chemistry, McMaster University, Hamilton, Ontario

Received January 29, 1973

Treatment of benzene (**1**), biphenyl (**2**) and *o*- and *m*-xylene (**3** and **4**) with 4% v/v concentrated HCl (concentrated DCl) in D_2O at 250 °C results in selective deuteration of the aromatic nucleus with excellent isotopic incorporation and quantitative yield.

Le traitement à 250 °C du benzène (**1**), du biphényle (**2**), de l'*o*- et du *m*-xylène (**3** et **4**) avec une solution à 4% v/v de DCl concentré dans D_2O conduit à une deutération sélective du noyau aromatique avec une incorporation isotopique excellente et un rendement quantitatif.

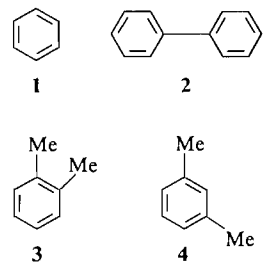
[Traduit par le journal]

Can. J. Chem., **51**, 1485 (1973)

The introduction of one or more deuterium atoms into organic molecules is usually accomplished by one of many possible methods, depending on the nature of the molecule and the extent and stereospecificity of deuteration desired (1). Of the methods available, only metal-catalyzed homogeneous and heterogeneous exchange, base-catalyzed exchange and acid-catalyzed exchange have been used extensively for perdeuteration (1–5). Most, if not all, acid-catalyzed exchange procedures involve highly acidic media (1). Typically, liquid DBr and DCl, D_3PO_4, $DFSO_3$–SbF_5, and 50–80% D_2SO_4 in D_2O may be used to accomplish exchange at moderate temperatures. Many of these systems, however, are unsatisfactory because of cost, complicated apparatus and procedures (2, 3),[2] incomplete or slow exchange (4) and low yields (2–4) (*i.e.* due to sulfonation and decomposition).

In contrast, exchange under the conditions of high temperature and dilute acid has not been explored in any detail (6).

In this communication, we report preliminary results which establish a simple and quantitative one-step procedure for the perdeuteration of the aromatic hydrocarbons. The process utilizes dilute acid and the most inexpensive deuterium source, D_2O. The results are listed in Table 1.



1 **2** **3** **4**

Although aqueous acetic acid is sufficiently acidic to effect slow exchange in dialkyl substituted benzenes (entry 9), benzene and biphenyl require increased acidity (entries 1 and 4). Entries 2, 3, 5, 6, 10, and 11 show that a temperature of at least 250 °C is required to facilitate exchange. Entries 2, 5, 7, and 10 show that *one cycle* results in complete equilibration and maximum exchange as dictated by the deuterium pool. Entries 7 and 8 show that *two cycles only*, using DCl in the final cycle, are required to accomplish at least 98% exchange in 95–100% yield.

In a typical experiment a mixture of *o*-xylene (25 g) and 4% v/v concentrated DCl–D_2O (100 ml) was sealed in each of three glass tubes (10 in. × 2 in. O.D.) after being degassed three times *via* freeze–thaw cycles. The tubes were heated at 250 °C in a 2 l Parr Pressure Apparatus, Model 4914 containing H_2O and *o*-xylene to

[1]Patent pending.

[2]Perdeuteration of benzene in 98% isotopic purity and 72% yield has been accomplished with DCl and $AlCl_3$ at room temperature in 50–60 h using a complicated vacuum apparatus (3).

TABLE 1. Exchange of benzene and its derivatives with dilute hydrochloric acid in D_2O at 250 °C

Entry	Substrate	Conditions* Acid	Temperature (°C)	Time (h)	D/molecule†	% Exchange‡	Position of Deuterium‡	% Recovery
1	**1**	a	250	60	0.0	0	—	—
2	**1**	b	250	48	5.3	88	—	98
3	**1**	b	200	48	1.3	22		98
4	**2**	a	250	48	0.0	0	—	—
5	**2**	b	250	48	9.4	94	—	98
6	**2**	b	200	48	4.0	40		98
7	**3**	c	250	43	3.5	88	ring	99
8§	**3**	c	250	42	3.9	98	3.9 ring 0.1 methyl	100
9	**4**	a	250	48	0.9	24	ring	—
10	**4**	b	250	40	3.8	91	3.6 ring 0.3 methyl	97
11	**4**	b	200	48	3.2	78	3.1 ring‖ 0.2 methyl	97

*a = 10% v/v CH_3COOD–D_2O; b = 4% v/v concentrated HCl–D_2O; c = 4% v/v concentrated DCl–D_2O.
†These values were determined mass spectrometrically.
‡The % exchange is based only on exchange in the aromatic ring as determined by n.m.r. integration analysis. The total deuterium content determined by n.m.r. is slightly greater than that by mass spectrometry.
§The *o*-xylene used was obtained from entry 7.
‖Total equilibration at all the ring positions did not occur. The 5 position contained only 0.3 D.

equalize the internal pressure. After 43 h, the clear, colorless *o*-xylene (74 g) layers were drawn off with the aid of a separatory funnel. The clear D_2O–DCl solution was retained for the first cycle of a subsequent exchange. N.m.r. analysis showed 90% of the aromatic and less than 1% of methyl hydrogens had been exchanged. The *o*-xylene was heated in three tubes in a second cycle with fresh DCl–D_2O solution (75 ml per 25 g) for 42 h. The *o*-xylene (74 g >98% pure by g.l.p.c.) isolated after the second cycle, contained 3.9 deuterium atoms in the aromatic nucleus and 0.1 deuterium atoms in the methyl groups as established by n.m.r. and mass spectrometric analysis.

The dilute acid – high temperature method presents substantial advantages over the other perdeuteration methods (*vide supra*) because of selectivity, simplicity, cost, freedom from steric effects and side reactions, high degree of isotope incorporation, essentially quantitative yields and most importantly its adaptibility to large scale preparations.[3]

At this time, the results are describable on the basis of initial electrophilic attack of D^+ on the aromatic system (7) followed by rearomatization. Interestingly, deprotonation from the methyl group is not competitive with aromatization even at elevated temperatures.

The obvious extensions of these studies to the perdeuteration and/or selective deuteration of substituted aromatics, polynuclear aromatics, bicyclics, and heterocyclics are presently underway.

We thank the National Research Council of Canada for financial support.

[3]Large scale reactions may be carried out directly in a 2 liter Hastelloy B bomb which is inert to HCl.

A Stereochemical and Kinetic Study of the Conversion of Methyl Cyclopropyl Ketones to 4,5-Dihydrofurans[1]

DONALD EDWARD MCGREER AND JAMES WILLIAM MCKINLEY

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received December 5, 1972

The thermal and photochemical conversion of (1R*,2R*,3S*), (1S*,2R*,3S*), and (1S*,2R*,3R*)-1-acetyl-1,2-dimethyl-3-phenylcyclopropane (**1**, **2**, and **3**) to *cis*- and *trans*-2,3,4-trimethyl-5-phenyl-4,5-dihydrofurans has been studied. Concurrent with this reaction is an equilibration of **1**, **2**, and **3**, a thermal ring opening of **1** by a 1,5-hydrogen shift, and a cyclopropane-to-propene type reaction under the photochemical conditions. The dihydrofuran from **1** and **2** by the thermal and photochemical conditions is 97% *trans*- and 3% *cis*- corresponding to predominant retention at the migrating carbon. The dihydrofuran formed from **3** by the thermal and photochemical reaction is 85% *cis*- and 15% *trans*- again corresponding to predominant retention. A kinetic study of the rearrangement of 1-acetyl-1-methyl-2-phenylcyclopropane to 1,2-dimethyl-5-phenyl-4,5-dihydrofuran provides E_a of 48.1 kcal/mol and log A of 14.9 for this first order reaction in the temperature range of 255–288 °C.

It is concluded that the thermal and photochemical reactions occur by a non-concerted process through a common 1,3-diradical intermediate in which bond rotation and ring closure steps are competitive.

La transformation thermique et photochimique du (1R*,2R*,3S*), (1S*,2R*,3S*), et (1S*, 2R*, 3R*) acétyl-1 diméthyl-1,2 phényl-3 cyclopropane (**1**, **2**, et **3**) en *cis* et *trans* triméthyl-2,3,4 phényl-5 dihydro-4,5 furanes, a été étudiée. Entrent en compétion avec cette réaction, une équilibration de **1**, **2**, et **3**, une ouverture thermique de cycle de **1** par transfert-1,5 d'hydrogène et une réaction du type cycloprane–propène dans les conditions photochimiques. Le dihydrofurane issu de **1** et **2** dans les conditions thermique et photochimique est à 97% *trans* et 3% *cis* avec rétention prédominante sur le carbone qui migre. Le dihydrofurane formé à partir de **3** par réaction thermique et photochimique est à 85% *cis* et 15% *trans* avec encore rétention prédominante. Une étude cinétique du réarrangement thermique de l'acétyl-1 méthyl-1 phényl-2 cyclopropane en diméthyl-1,2 phényl-5 dihydro-4,5 furane conduit à un E_a de 48.1 kcal/mol et à un log A de 14.9 pour cette réaction de premier ordre dans l'intervalle de température de 255–288 °C.

Il a été conclu que les réactions thermique et photochimique se produisent selon un processus non concerté, par l'intermédiaire d'un diradical-1,3 dans lequel les étapes de rotation autour de la liaison et de fermeture de cycle sont en compétition. [Traduit par le journal]

Can. J. Chem., **51**, 1487 (1973)

The non-catalyzed conversion of cyclopropyl ketones to dihydrofurans formally resembles the conversion of vinylcyclopropanes to cyclopentenes. This latter reaction has been studied extensively by kinetic and stereochemical means; however, the former reaction has been discussed in only a few notes. The thermally induced reaction was first noted by Wilson and Armitage (1, 2) and a photochemically induced reaction has been reported by Dauben and Shaffer (3). The reverse reaction of dihydrofurans to cyclopropanes has also been observed (1, 4–7). In the present paper we examine in more detail the stereochemistry and kinetics of the thermal and

For personal use only.

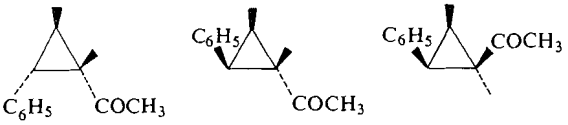
photochemical conversion of a series of methyl cyclopropyl ketones to 4,5-dihydrofurans.

Stereochemistry

From an earlier study (8) we have on hand three stereoisomers of 1-acetyl-1,2-dimethyl-3-phenylcyclopropane (**1**–**3**). The fourth possible isomer (**4**) has not been available. These ketones at 300 °C or on irradiation with 310 nm light (Rayonet Reactor) are converted to a variety of products illustrated in eqs. 1–3 by the reaction of **1**.



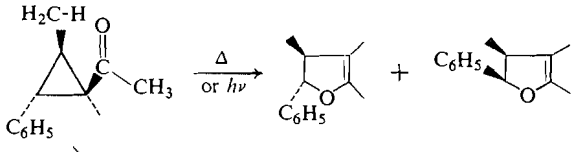
Reaction 1 is the conversion of a cyclopropyl ketone to a dihydrofuran. This reaction is (at least, formally) a 1,3 sigmatropic shift from carbon to oxygen and in this case permits one to evaluate the stereochemistry of the migrating carbon. Reaction 2 is the *cis*:*trans* interconversion of cyclopropane stereoisomers and in this case is expected to occur exclusively through the breaking of the bond between the carbons bearing the phenyl and acetyl groups, since both of these groups would provide major stabilization of the intermediate diradical or transition state. Reaction 3 is a well-known ring opening of a cyclopropyl ketone carrying an alkyl group *cis* to the carbonyl group (9, 10). A further minor reaction encountered in our work results from a hydrogen migration yielding a cyclopropane-to-propene type ring opening.

Typical data that we have collected are presented in Table 1 for the reactions of **1**, **2**, and **3**.

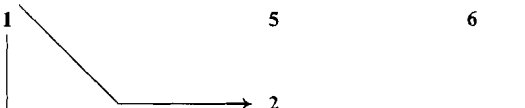
The structures of **1**, **2**, and **3** and the reaction of **1** to form **7** and **8** have been reported earlier (8). A series of dihydrofurans related to **5** and **6** and having a C-4 methyl and a C-5 phenyl have been reported by Scribe and Delepine (11). The stereochemical assignment to them was based on the argument that in the *cis* compounds the C-5 phenyl should shield the C-4 methyl and they reported values of 9.48 for the *cis* C-4 methyl against 8.85 τ for the *trans* C-4 methyl. The major dihydrofuran from **1** and **2** gave a C-4 methyl at 8.88 τ and the major dihydrofuran from **3** (run 9) gave a C-4 methyl at 9.50 τ and thus these compounds can be assigned the *trans*-**5** and *cis*-**6** structures respectively. As additional verification of this assignment we determined the nuclear Overhauser effect (n.O.e.) on the C-5 hydrogen (5.28 τ) in **5** that resulted from irradiation of the C-4 methyl. An enhancement of 23% was observed. The measured distances between these groups in models were 2.8 Å and >3.6 Å for **5** and **6** respectively. Thus the enhancement of 23% is only consistent with structure **5** (12).

The results of Table 1 suggest a reaction scheme such as Scheme 1 involving thermal or photochemical bond-breaking in the cyclopropanes, followed by ring closures to cyclopropane or dihydrofurans competitive with bond rotations at the diradical stage. The only significant amount of bond rotation, however, is in the thermal reaction of **2** or **3**, whereby **2** and **3** are interconverted. This corresponds to the rotation of the terminal carbon of the trimethylene diradical species carrying one substituent (phenyl), in preference to that carrying two substituents. This effect of substituents on bond

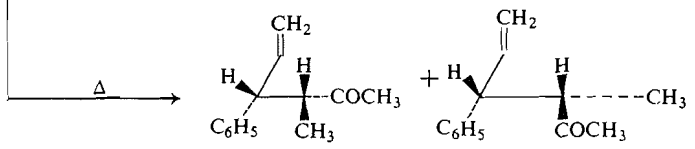
[1]

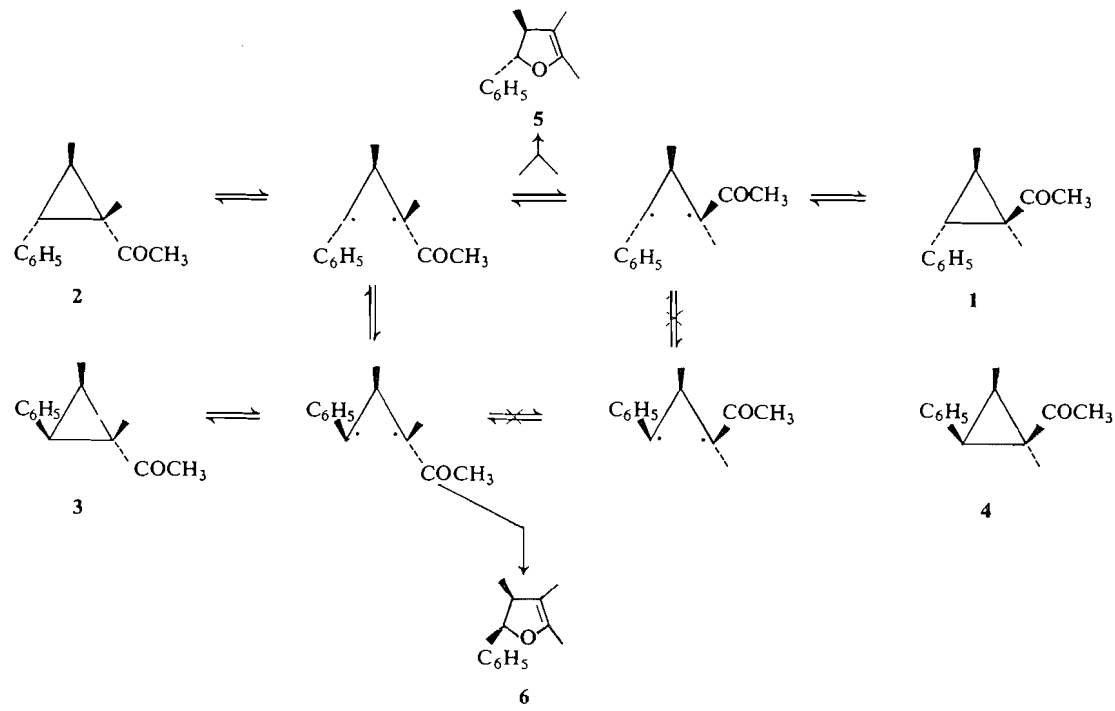


[2]



[3]





SCHEME 1

rotation rates has previously been noted by Berson *et al.* and has been described as a ponderal effect (13).

A secondary consequence of the interconversion of **2** and **3** is the variation, with degree of reaction, of the ratio of **5**:**6**. The stereochemistry of the cyclopropane to dihydrofuran reaction needs to be determined at as early a stage as possible and when this is done it becomes clear that the cyclopropane to dihydrofuran reaction is not stereospecific. Bond rotation again competes with ring closure and it is significant that a greater degree of bond rotation occurs in the system which would lead to the dihydrofuran having the C-4 methyl and C-5 phenyl *cis*. It is particularly interesting that the photochemical and thermal reactions give the *same* stereoselectivity.

All of the above observations suggest that the cyclopropane to dihydrofuran reaction is not a concerted reaction, although there is some stereoselectivity. Similar conclusions have been made concerning the vinylcyclopropane to cyclopentene reaction where similar stereochemical evidence is available (14). Supporting stereochemical evidence also comes from a study on the degenerate rearrangement of vinylcyclopropane which must pass through a diradical intermediate (15).

Of closer interest to our study is the photochemical conversion of *cis*- and *trans*-5-(1-methylpropenyl)-3,4-dimethyl-4,5-dihydrofuran to 2-(1-methylpropenyl)-1,2-dimethylcyclopropane carboxaldehyde (7). Stereoselectivity was observed favoring retention at the migrating carbon and to almost the same degree as our results for the reverse reaction, with the *cis* isomer giving 80% retention and the *trans* 94%. Scribe and Wiemann (7), because of this selectivity, favored a concerted mechanism. The factor swinging our support to the diradical mechanism is the parallel results found for the thermal and photochemical modes of reaction. The possibility, however, of competitive concerted reactions cannot be overlooked (18).

To obtain a further correlation between our reaction and the vinylcyclopropane to cyclopentene reaction we have made a preliminary kinetic study. Unfortunately the reactions of **1**, **2**, and **3** are just too complicated for such a study and

therefore we have looked at the reaction of *cis*- and *trans*-1-acetyl-1-methyl-2-phenylcyclopropane (**9** and **10**).

Kinetics

Addition of phenyl diazomethane to methyl isopropenyl ketone at room temperature gives directly a 1:2 mixture of the isomeric 1-acetyl-1-methyl-2-phenyl cyclopropanes (eq. 4) Pre-

[4] $C_6H_5CHN_2 + CH_2{=}C(CH_3)COCH_3 \rightarrow$

9 **10**

sumably a pyrazoline is formed as an intermediate; however it is not stable at room temperature (16). The cyclopropanes were separated by v.p.c. and identified by their n.m.r. spectra. The major isomer has the acetyl and C-1 methyl at 7.87 and 8.98 τ respectively. The minor isomer has the acetyl methyl and the C-1 methyl at 8.33 and 8.54 τ. Thus based on the shielding effect by the phenyl the major isomer has the C-1 acetyl and the C-2 phenyl groups *trans* as in **10** and the minor isomer has the C-1 acetyl and the C-2 phenyl *cis* as in **9**.

Samples of **9** or **10** when heated in sealed ampoules, such that reaction would take place in the gas phase at 250–290°, led to an initial rapid equilibrium of **9** and **10**, to the value of 15:85 respectively, followed by conversion to 2,3-dimethyl-5-phenyl-4,5-dihydrofuran (**11**). Kinetic runs made use of **9** and **10** close to equilibrium. The dihydrofuran proportion of the total samples rose to a maximum value of about 89%, at which time equilibrium between it and the cyclopropanes **9** and **10** was reached. Clearly there are a number of subtle substituent effects, which determine the position of such an equilibrium under thermal and photochemical conditions, and which as yet are still unclear (1–5, 7). The kinetic data are reported in Table 2 and yield by an Arrhenius plot E_a of 48.1 kcal/mol and log A of 14.9.

These kinetic parameters correlate well with those found for vinylcyclopropanes (17) with some selected values given in Table 3. One might however have anticipated a lower activation energy with both phenyl and acetyl groups capable of stabilizing the transition state. These factors show up in the faster rate of reaction, however, since the rate for **9** and **10** is comparable to vinylcyclopropane at a temperature 60° below that for vinylcyclopropane. Thus the kinetics support the view that the cyclopropyl methyl ketone-to-dihydrofuran rearrangement is of the same mechanistic form as the vinylcyclopropane-to-cyclopentene rearrangement.

Experimental

The preparation and characterization of cyclopropanes **1**–**3** and products **7** and **8** have been reported earlier along with some general procedures used (8).

cis- and trans-2,3,4-Trimethyl-5-phenyl-4,5-dihydrofuran (6 and 5)

Several ampoules of about 920 μl volume containing 12 mg of **1** were degassed and sealed under vacuum and heated at 338° for 10 min. The separate samples were combined and v.p.c. analysis (20% FFAP at 205°) showed a major peak well separated and to lower retention time than **1**, **2** or **3**, or any possible unsaturated ketone product. The peak was collected and high resolution v.p.c. on a Perkin–Elmer 226 instrument using a Carbowax 20 M 0.01 in. i.d. × 150 ft column at 175° showed it to be a 96:4 mixture of two components. For the major component: i.r. 1700 cm^{-1}, n.m.r. τ (60 MHz, CCl_4) 8.47 and 8.22 (singlets showing long-range coupling) for the C-2 and -3 methyls, 8.88 (doublet, J = 7.0 Hz) for the C-4 methyl, 7.33 (multiplet) for the C-4 hydrogen, 5.28 (doublet, J = 8.0 Hz) for the C-5 hydrogen, and 2.78 for the aromatic hydrogens.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.74; H, 8.34.

To a solution of 36 mg of the above sample in 1.0 ml

of CCl_4 was added 2.2 mg of *p*-dioxane (internal standard) and 50 μl of *sym*-tetrachloroethane (internal lock). Using an HA100 spectrometer the C-4 methyl peak was irradiated while the peaks for the C-4 and -5 hydrogens were being observed for nuclear Overhauser enhancements. The average enhancement to the C-4 hydrogen was 30% and that to the C-5 hydrogen 23%. Models of **5** and **6** gave the internuclear distances for the hydrogens of the C-4 methyl and the C-5 hydrogen of 2.8 and 3.6–4.0 Å respectively, corresponding to expected enhancements of 21 and < 6% respectively (12). Coupled with the fact that the C-4 methyl appears at 8.88 τ compared to 9.50 in the minor isomer, we have assigned the *trans*-stereochemistry **5** to the major dihydrofuran isomer from **1**.

Photolysis of a sample of 100 mg of **1** in 100 ml of ether for 24 h using 310 nm radiation (Rayonet Reactor) gave a product which contained a peak (65%) at the same v.p.c. retention time as **5** and when isolated was found to have the same n.m.r. spectrum as **5**, with peaks at τ 8.50 and 8.26, 8.90 (doublet), 7.35 (multiplet), 5.32 (doublet) and 2.80.

Several sealed ampoules of **3** were heated at 338° for 10 min. The products were combined and the dihydrofuran peak isolated by v.p.c. Analytical v.p.c. showed this sample to be a 83:17 mixture of **5** and **6** respectively. The n.m.r. spectrum of this mixture showed peaks for *cis*-2,3,4-trimethyl-5-phenyl-4,5-dihydrofuran (**6**) at τ 4.62 (doublet, J = 9.2 Hz) for the C-5 hydrogen and 9.50 (doublet, J = 7.2 Hz) for the C-4 methyl. The other peaks for **6** were not clearly separated from the peaks of **5**.

Experimental Conditions for the Rearrangement Reactions

Samples of about 2.2 mg were degassed and sealed under vacuum in Pyrex tubes (4.2 × 100 mm for the thermal runs and 4.2 × 50 mm for the photochemical runs). For the thermal runs the tubes were placed in a constant-temperature salt ($NaNO_3$–KNO_3) bath and samples removed at appropriate times for analysis. For the photochemical runs the tubes were placed in a Rayonet Reactor fitted with 310 nm lamps. Product distributions were monitored using a P.E. 226 analytical v.p.c. using a column (0.01 in. i.d. × 150 ft) charged with Carbowax 20 M. Typical results are recorded in Table 1.

Samples of the dihydrofurans **5** and **6** as prepared above in the ratio of 96:4 and 83:17 respectively, were heated over 10 half-lives at 285° with no change in the ratio of **5** to **6**. Similar samples were irradiated with 310 nm light for 15.5 h with again no change in the ratio of **5**:**6** being observed, although trace peaks corresponding to **1** and **2** were observable. Although dihydrofurans often readily polymerize (5, 7), control runs indicated that **5** and **6** did not show this tendency under the reaction conditions. They did, however, rapidly deteriorate on exposure to air either due to polymerization or hydration or both.

cis-[2] *and trans-1-Acetyl-1-methyl-2-phenylcyclopropane (**9** and **10**)*

Addition of 8.4 g (0.1 mol) of methyl isopropenyl ketone to a petroleum ether solution of phenyldiazomethane (prepared from 0.1 mol of benzaldehyde hydrazone and 0.1 mol of yellow mercuric oxide (8)) caused immediate evolution of nitrogen. After 2 h, the red color of the diazo compound had completely disappeared. Rotatory evaporation of the solvent followed by vacuum distillation (90–95° at 0.3 mm Hz) yielded 12.6 g of a slightly yellowed solution. The v.p.c. (20% FFAP, 205°, 60 ml/min) indicated two peaks in a 1:2 ratio with respective retention times of 7.7 and 9.3 min. The two peaks were separated and collected by v.p.c. The first peak was identified by n.m.r. as the *cis*-isomer 9 and the second peak as the *trans*-isomer **10**. For the *cis*-cyclopropyl ketone (**9**): i.r. 1695, 1605, 725, and 697 cm^{-1}; n.m.r. τ (60 MHz, CCl_4) 8.33 and 8.54 (singlets) acetyl and C-1 methyls respectively, 7.75 (triplet, J = 7.7 Hz) C-2 hydrogen, 8.09 (doublet of doublets, J = 4.6 and 7.5 Hz) one C-3 hydrogen, 9.04 (doublet of doublets, J = 8.4 and 4.6 Hz) other C-3 hydrogen, and 2.80 (aromatic).

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.76; H, 8.05. Found: C, 83.03; H, 8.25.

For the *trans*-cyclopropyl ketone (**10**): i.r. 1690, 1605, 778 and 698 cm^{-1}; n.m.r. τ (60 MHz, CCl_4) 7.87 and 8.98 (singlets) acetyl and C-1 methyls respectively, 7.34 (doublet of doublets J = 7.0 and 9.0 Hz) C-2 hydrogen, 8.37 (doublet of doublets, J = 4.2 and 9.0 Hz) one C-3 hydrogen, 8.94 (doublet of doublets, J = 4.2 and 7.0 Hz) other C-3 hydrogen, and 2.84 (aromatic).

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.76; H, 8.05. Found: C, 82.54; H, 8.02.

*2,3-Dimethyl-5-phenyl-4,5-dihydrofuran (**11**)*

Six 50 μl samples of a mixture of ketones **9** and **10** were sealed in ampoules (4.2 × 100 mm) and were heated at 335° for 10 min. The slightly charred samples were bulb-to-bulb vacuum distilled (bath temperature of 85–100° at 0.5 mm Hg). V.p.c. of this combined product (20% FFAP column at 205°) showed five peaks: The first of these peaks was the dihydrofuran **11**; i.r. 1701 cm^{-1}, n.m.r. τ (60 MHz, CCl_4) 2.80 (singlet) phenyl hydrogens, 4.70 (doublet of doublets with J = 8.0 and 10.0 Hz) for the C-5 hydrogen, 6.7–7.8 (multiplet) for the C-4 hydrogens, 8.26 and 8.40 (singlets showing long range coupling) for the C-2 and -3 methyls.

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.78; H, 8.05. Found: C, 82.43; H, 8.25.

The remaining peaks in the vapor chromatogram were identified as **9**, **10**, and two unsaturated ketones 3-methyl-5-phenyl-3- and -4-pentene-2-one which were identified by their n.m.r. These olefins were completely absent in the kinetic runs and became particularly noticeable as byproducts when the reaction vials were too small to allow all of the sample to enter the gas phase.

Kinetics

Samples (3.0–3.5 mg) of **9** and **10** near an equilibrium composition were sealed under vacuum after degassing in Pyrex ampoules (4.2 × 100 mm) and were heated in a constant temperature bath (a 50:50 mixture of sodium nitrate and potassium nitrate) equipped with a stirrer and a thermometer calibrated against an N.B.S. calibrated thermometer. The progress of the reaction was monitored by analyzing samples with an Aerograph Model A-90-P3 v.p.c. (20% FFAP, 205°, 120 ml/min helium) equipped with a thermal conductivity detector. A Honeywell Model Electronic 15 recorder having a disc

[2] *cis* refers to the C-1 acetyl and C-2 phenyl.

chart integrator was used to estimate the ratio of products.

Straight line fits were calculated by the method of least squares using a Hewlett Parkard 9100 Calculator equipped with a 9125A Calculator plotter. The results are presented in Table 2. The percent of dihydrofuran **11** at equilibrium varied from 88.4% at 287.5° to 89.7% at 254.9°.

It is estimated that the main source of error is in controlling the bath temperature to ±0.4 °C leading to estimated error limits in E_a of ±5%.

The authors gratefully appreciate the support received for this work from NRCC and from the Committee on Research of the University of British Columbia.

Rearrangement Studies with ^{14}C. XXXVIII. Isotopic Scrambling in the Synthesis of Labeled 2-Phenylethyl Triflate

C. C. LEE AND D. UNGER

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received November 27, 1972

2-Phenylethyl triflate (**1**-OTf) was synthesized by the reaction of AgOTf with 2-phenylethyl iodide (**1**-I) in cyclohexane as solvent. However, when 1-^{14}C-2-phenylethyl iodide (**1**-I-1-^{14}C) was used as a reactant, the resulting **1**-OTf-^{14}C showed an essentially complete scrambling of the ^{14}C-label over the C-1 and -2 positions. Similar reactions of **1**-I-1-^{14}C with AgOTs and with AgOAc gave **1**-OTs-^{14}C and **1**-OAc-^{14}C with, respectively, about 49 and 11% rearrangement of the label from C-1 and -2.

Le triflate de phényl-2 éthyle (**1**-OTf) a été synthétisé par réaction du AgOTf avec l'iodure de phényl-2 éthyl (**1**-I) dans le cyclohexane comme solvant. Cependant, lorsque l'iodure de ^{14}C-1 phényl-2 éthyl a été utilisé comme réactif, le produit **1**-OTf-^{14}C résultant s'est révélé être un mélange pratiquement complet en ce qui a trait à la distribution du ^{14}C sur les positions C-1 et -2. Des réactions semblables du **1**-I-^{14}C-1 avec du AgOTs et avec du AgOAc ont donné le **1**-OTs-^{14}C et le **1**-OAc-^{14}C avec, respectivement, un réarrangement de la distribution du ^{14}C de C-1 à -2 d'environ 49 et 11%.

Can. J. Chem., **51**, 1494 (1973)

The trifluoromethanesulfonate (triflate) anion is a facile leaving group in solvolytic reactions (1). Studies on the kinetics and deuterium isotope effects for the ethyl and propyl systems, however, have led to the conclusion that solvolyses of such primary alkyl triflates and tosylates are mechanistically similar, the reaction of the triflate being no more limiting than the tosylate (2, 3).

Since a great deal of work has been done on the isotopic scrambling that occurs in the solvolyses of 1-^{14}C-2-phenylethyl tosylate (**1**-OTs-1-^{14}C) (4–7), it would be of interest to have another comparison of the behaviors of triflates and tosylates by an investigation on the analogous solvolyses of 1-^{14}C-2-phenylethyl triflate (**1**-OTf-1-^{14}C). Hence attempts were made to synthesize **1**-OTf-1-^{14}C.

1-OTf was prepared from the reaction of 2-phenylethyl iodide (**1**-I) with silver triflate by the method of Gramstad and Haszeldine (8) as used in the synthesis of ethyl triflate, except that cyclohexane instead of ether was employed as solvent. When the reaction was carried out in ether, the product was highly contaminated by ethyl 2-phenylethyl ether and di-2-phenylethyl ether, apparently derived from *O*-alkylation of ethers by the triflate ester (9). When the synthesis was attempted by reacting **1**-I-1-^{14}C with AgOTf, the product obtained, however, showed an essentially complete scrambling of the ^{14}C-label over the C-1 and -2 positions (Table 1). The method thus failed to give the desired **1**-OTf-1-^{14}C.

Alternative syntheses of triflate esters were considered, but they too failed to give the desired result. Schleyer and coworkers (1) prepared a number of triflates of relatively inert systems by treatment of the alcohol with trifluoromethanesulfonic acid anhydride in the presence of pyridine. This method was not attempted in the present work since **1**-OTf was found to react readily with pyridine to give a solid product, presumably the result of *N*-alkylation, giving rise to the pyridinium salt (9, 10). Hansen (11) has prepared a series of 1,1-dihydroperfluoroalkyl triflates by treating the appropriate alcohol with trifluoromethanesulfonyl fluoride in the presence of triethylamine at −30°. When **1**-OH was treated in an analogous way using commercially purchased trifluoromethanesulfonyl chloride, no **1**-OTf could be obtained. A number of phenols have been converted to the corresponding aryl triflates by reaction with trifluoromethanesulfonic imidazolide at 80–90° (12). When the reaction was tried with **1**-OH, extensive decomposition occurred at 80–90°, while at room temperature or 50°, much of the **1**-OH remained unreacted. Thus **1**-OTf was successfully synthesized only by the treatment of **1**-I with AgOTf, and this reaction led to a complete scrambling of the ^{14}C-label when **1**-I-1-^{14}C was used as a reactant.

The isotopic scrambling in the **1**-OTf-^{14}C

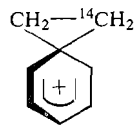
could be most reasonably explained by the intervention of the ethylenebenzenium ion[1] (**2**) formed in the reaction of 1-I-1-^{14}C with Ag^+ ion. Support for this interpretation was obtained



2

from the isotopic scramblings observed when 1-I-1-^{14}C was treated with silver tosylate or silver acetate. As can be seen from Table 1, reaction with AgOTs also gave a product, 1-OTs-^{14}C, with nearly complete scrambling of the label over C-1 and -2, while the 1-OAc-^{14}C from the reaction of 1-I-1-^{14}C with AgOAc showed about 11% rearrangement of the label from C-1 to -2. The lesser amount of scrambling in the 1-OAc-^{14}C could be explained on the basis of concurrent S_N1–S_N2 processes (7). The more nucleophilic acetate ion could take part in a non-scrambling direct displacement and effectively compete with phenyl participation in the formation of **2**, thus giving rise to a net result of 11% rearrangement, much less than the 50% rearrangement expected in a product formed solely via **2**.

Experimental

Reaction of 1-^{14}C-2-Phenylethyl Iodide (1-I-1-^{14}C) with Silver Salts

A solution of 18.6 g (0.08 mol) of 1-I-1-^{14}C, obtained from treatment of 1-OTs-1-^{14}C with NaI in acetone (4), in 50 ml of cyclohexane, was added dropwise to a stirred suspension of 25.7 g (0.10 mol) of AgOTf in 150 ml of cyclohexane. The resulting mixture was stirred at room temperature for 4 h. The AgI was then removed by filtration through Celite and the cyclohexane was distilled off under reduced pressure to give 16.2 g (80%) of residual ^{14}C-2-phenylethyl triflate (1-OTf-^{14}C) as a colorless liquid. (In the second run, the yield of 1-OTf-^{14}C calculated from isotope dilution was 87%). The product so obtained decomposed readily at elevated temperatures, but purification was effected by distillation at 65–70° and 1 Torr using an apparatus with a short condensation column jointed directly to the receiver to minimize any refluxing of the condensate into the distillation flask. The distilled 1-OTf obtained from inactive trials gave the following data.

Anal. Calcd. for $C_9H_9O_3SF_3$: C, 42.52; H, 3.56. Found: C, 42.67; H, 3.51.

N.m.r. (CCl_4) δ 7.2 (m, 5, aromatic H), 4.60 (t, 2, J = 7 Hz, CH_2OTf), 3.08 (t, 2, J = 7 Hz, $PhCH_2$); mass spectrum *m/e* 254 (M^+) and major peaks at *m/e* 105 $(M - OTf)^+$, 104 $(M - HOTf)^+$, 91 ($C_7H_7^+$). The titrimetric rate constant for the acetolysis of 0.5 *M* 1-OTf at 30° was found to be 9.44×10^{-5} s^{-1}. Comparison with data extrapolated from Coke's results (6) indicated that at 30°, the acetolysis of 1-OTf is faster than the acetolysis of 1-OTs by a factor of about $10^{4.9}$.

The reaction of 1-I-1-^{14}C with AgOTs or AgOAc was carried out in a similar way with only minor modifications. In the reaction with AgOTs, the mixture was refluxed for 4 and 10 h in the two runs, giving yields of 1-OTs-^{14}C, based on isotope dilution, of 67 and 90%, respectively. The reaction mixture between 1-I-1-^{14}C and AgOAc was refluxed for 20 h and the yields of 1-OAc-^{14}C, based on isotope dilution, were 94 and 96% for the two runs.

Degradation

1-OTf-^{14}C and 1-OAc-^{14}C were oxidized directly with alkaline $KMnO_4$ to give PhCOOH, while the 1-OTs-^{14}C was converted to 1-I-^{14}C by treatment with NaI in acetone before being oxidized to PhCOOH (4). The ^{14}C activity in the PhCOOH gave the extent of rearrangement of the label from C-1 to -2.

[1]Previously, **2** has been commonly referred to as the ethylenephenonium ion. In accordance with the nomenclature recently suggested by Olah (13), **2** should be named as the ethylenebenzenium ion.

The Static Dielectric Constants of the Liquified Fluoromethanes[1]

PETER TREMAINE AND MAURICE G. ROBINSON
Chemistry Department, University of Alberta, Edmonton, Alberta, T6G 2G2

Received November 9, 1972

The static dielectric constants of CF_4, CHF_3, CH_2F_2, and CH_3F have been measured at temperatures ranging from their melting points to their normal boiling points. The molar polarization of CF_4 agrees with that of the gas phase to within experimental error. The deviation of the dielectric constants of the polar fluoromethanes from the values predicted by the Onsager equation cannot be fully due to their non-spherical shape.

It is postulated that although a significant parallel dipole correlation may be present in each fluoromethane, the polarization resulting from the liquid lattice vibrations, may account for much, or all, of the effect in CH_3F and CH_2F_2.

Les constantes diélectriques statiques de CF_4, CHF_3, CH_2F_2, et CH_3F ont été mesurées à des températures comprises entre leur température de fusion et d'ebullition normales. La polarization molaire de CF_4 est en accord, dans les limites d'erreurs expérimentales, avec celle en phase gazeuse. Les déviations des constantes diélectriques de ces fluorométhanes polaires par rapport aux valeurs prédites par l'équation d'Onsager ne peuvent être attribuées entièrement à leur forme non-sphérique ou à l'anisotropie de leur polarizabilité.

Bien que pour chaque fluorométhane polaire une corrélation significative de dipole parallèle puisse être présente, il est postulé que la polarization résultant des vibrations du réseau liquide puisse expliquer la plus grande partie si ce n'est la totalité de l'effet présent dans CH_3F et CH_2F_2.

Can. J. Chem., **51**, 1497 (1973)

Introduction

Although the dielectric constants of the other halomethane liquids have been studied exhaustively (1), the dielectric properties of the liquid fluoromethanes have not been reported. The dielectric constants of most chloro, bromo, and iodo methanes have been satisfactorily described by a spheroidal modification to the Onsager equation (2), which took account of the molecular shape, but ignored intermolecular association, the anisotropy of the polarizability, and atomic polarization. Since these latter assumptions should be less valid for the fluoromethanes, it is of interest to attempt to account for their static dielectric constants by an Onsager treatment.

The purpose of this work was to determine the dielectric constants of the liquified fluoromethanes, and to treat this data using the spheroidal Onsager equation.

Experimental

Purification of Materials

Matheson reagent grade CF_4 and CHF_3, and reagent grade CH_2F_2 amd CH_3F from the Columbia Organic Chemicals Co. were introduced into a high vacuum system through a 25 × 2 cm column containing sodium hydroxide pellets and then passed through an 80 × 1.5 cm column of high activity silica gel at room temperature. The silica gel was supplied by the Burrell Corporation and was previously activated by heating at 220 °C for several hours under a pumping vacuum of less than 10^{-5} Torr. The gas was then condensed into a trap at −196 °C. After about 25 ml of the solidified gas had been collected, it was distilled into a flask containing sodium hydroxide pellets, allowed to warm up, and held at −90 °C for 1 h (−130 °C for CF_4). It was then distilled into a cell and electrolized at ~1 kV/cm and −90 °C (−130 °C for CF_4) for 1 h. After this purification stage, the sample was distilled into the previously cooled and evacuated capacitance cell.

To avoid contamination of the samples, the vacuum system was thoroughly evacuated overnight, and the silica gel reactivated between runs. CF_4 was introduced into the system first, followed by CHF_3, CH_2F_2, and lastly, CH_3F. This was the order of increasing sample conductance, and should have minimized the accumulation of ionic impurities in the cell. Sample conductances ranged from $< 1 \times 10^{-10}$ mho/cm for CF_4 to 8.2×10^{-8} mho/cm for CH_3F, as measured at 5 kHz and the warmest temperature to which each sample was taken.

Techniques

Capacitance measurements were carried out in a guarded, 3-terminal dielectric cell which had stainless steel plates set 3 mm apart. The cell constant was determined to be 2.4870 ± 0.0080 pF from room temperature measurements on Eastman spectro-grade cyclohexane, Matheson–Coleman and Bell spectro-grade carbon tetrachloride, and carbon disulfide, from freshly opened bottles. The capacitance of the evacuated cell at low

temperatures was used to determine the temperature dependence of the cell constant, assuming that the lead capacitance did not change from its value of 0.020 pF. Capacitance was measured using a General Radio 1615A bridge in conjunction with a GR 1310B oscillator and a Rhode–Schwartz type UBM null detector. The bridge was calibrated against a GR 1404B 100 pF reference standard capacitor.

Temperature control was achieved by surrounding the cell with an insulated box which was cooled by a controlled stream of cold nitrogen gas. Regulation of the gas stream was effected by feedback from an iron–constantan thermocouple which was placed inside a 25 ml bulb of isopentane. A copper–constantan thermocouple, surrounded by indium for good thermal contact, was glued to the outside of the cell to monitor temperature. The thermocouple was calibrated against a Hewlett–Packard 2801A quartz thermometer which had, in turn, been calibrated against an NBS platinum resistance thermometer. The temperature measurements are considered accurate to ± 0.1 °C at -80 °C and ± 0.3 °C at -160 °C.

Runs were carried out on two samples of each compound. After a sample had been distilled into the cell, it was allowed to reach thermal equilibrium. Capacitance readings were then taken at 5, 10, 20, and 50 kHz before changing the temperature. Although some electrode polarization was observed for CH_3F, the 50 kHz value of the dielectric constant was taken to be correct since it agreed with the values at 20 kHz and 10 kHz to within 0.025% and 0.045% respectively in the worst case. The results obtained for each compound are listed in Table 1 and illustrated in Fig. 1.

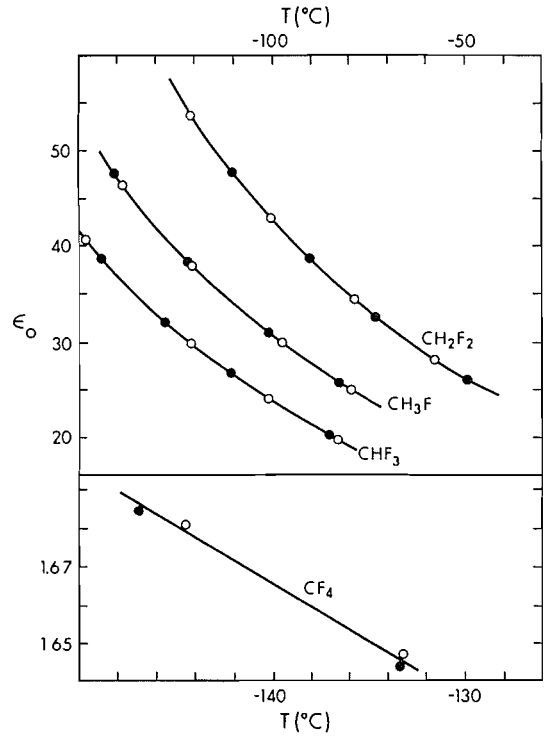

FIG. 1. Static dielectric constants of the liquids CF_4, CHF_3, CH_2F_2, and CH_3F as a function of temperature. Open and closed circles represent measurements on the two samples of each compound.

Results and Discussion

Carbon Tetrafluoride

The listed value of 1.624 g/cm^3 for the density of CF_4 at -131.2 °C (3) allowed the density to be calculated from the dielectric constant at each temperature using the Clausius–Mossotti relationship (4), which should be valid over this small temperature range. It is these calculated values which are listed in Table 1.

From a linear least squares fit of ε *vs.* T, as shown in Fig. 1, $\varepsilon_{CF_4} = 1.644 \pm 0.005$ at -131.2 °C. The error estimate is based on uncertainties in the cell constant and differences in the results of the two runs. The molar polarization, $P = P_a + P_e = [(\varepsilon - 1)/(\varepsilon + 2)](M/d) = 9.58 \pm 0.06$ cm^3, where M is the molecular weight and d is the density in g/cm^3.

This result compares with a value of $P = 9.73$ cm^3 and a maximum error of ± 0.08 cm^3, reported for the gas phase by Tipton *et al.* (5) in the range 20 to 350 °C.

Fluoroform, Difluoromethane, and Methyl Fluoride

The dielectric constants of the polar fluoromethanes are listed in Table 1. The absolute error is estimated to be $\pm 0.8\%$ for all values, with a precision of $\pm 0.3\%$ between the two samples of each compound.

The Onsager equation (6) attempts to describe the behavior of the dielectric constants of liquids by assuming the liquids to be composed of spherical, non-associated, dipolar molecules which possess isotropic polarizabilities. Buckley and Maryott (2) have extended the Onsager equation to include both prolate and oblate spheroidal molecules in which the permanent dipole is aligned along the axis of symmetry.

Their equation takes the form

$$[1]\quad \frac{(\varepsilon_0 - 1)(2\varepsilon_0 + 1)}{9\varepsilon_0}\,\overline{V} = \frac{4}{3}\pi N_0\left[\frac{\alpha k_\alpha}{1 - \frac{\alpha}{v}gk_R} + \frac{\mu_0^2}{3kT\left(1 - \frac{\alpha}{v}gk_R\right)^2}\right]k_c$$

where ε_0 = static dielectric constant, $\overline{V}$ = molar volume, N_0 = Avogadro's number, α = isotropic polarizability, μ_0 = gas phase dipole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

moment, v = the volume of the cavity surrounding each dipole = $\overline{V}/N_0$, $g = (4\pi/3)\ (2\varepsilon_0 - 2)/(2\varepsilon_0 + 1)$. k_α, k_R, and k_c are constants which are calculated (2) from the eccentricity of the molecule, e, where:

$$[2]\quad \begin{cases} e = \sqrt{1 - \left(\frac{b}{a}\right)^2} & \text{for a prolate spheroid} \\ e = \sqrt{1 - \left(\frac{a}{b}\right)^2} & \text{for an oblate spheroid} \end{cases}$$

where a and b are the axes of the spheroid, with a being the dipolar axis.

The calculations of ref. 2 could only be reproduced if, in the prolate case, $k_c = k_R/\beta$ with β defined as in ref. 2, and not $k_c = \beta k_R$ as stated in that reference. For a spherical molecule $k_\alpha = k_c = k_R = 1$ and eq. 1 reduces to the Onsager equation (6). The criterion for a successful fit is to calculate $G = \mu_0^2(\text{calculated})/\mu_0^2$ from eq. 1. If $G = 1$ at many temperatures, then the fit is perfect. Buckley and Maryott found empirically that G values which drifted with temperature often became constant if the cavity volume, v, was fixed at some arbitrary value, rather than being allowed to vary with the density, as in the original Onsager equation.

The values of G listed in Table 1 were calculated from the spheroidal Onsager equation at various levels of sophistication. The data used for all of these calculations is listed in Table 1. The densities of CHF_3 (7), CH_2F_2 (8), and CH_3F (9) were taken from the data of other workers. The densities listed for CF_4, CH_3F, and CHF_3 agree with those of Shinsaka and Freeman (8) to within 0.6%. The gas phase dipole moments were taken to be 1.851 for CH_3F (10), 1.97 for CH_2F_2 (11), and 1.649 for CHF_3 (10). The polarizations, P, were considered interchangeable with the polarizabilities, α, by the Clausius–Mossotti equation (4). The values of the gas phase atomic plus electronic polarizations, $P_a + P_e$, were obtained from ref. 10. Values of the electronic polarizations, P_e, were obtained for CH_3F and CH_2F_2 from the bond polarizabilities (12). The value of P_e for CHF_3 was measured by Bridge and Buckingham (13).

Equation 1 makes no distinction between the polarizability in the direction of the cavity field and that in the direction of the dipolar axis in calculating the reaction field (14, 15). The former may be approximated by the isotropic polarizability of the molecule, while the latter is the anisotropic polarizability along the axis of the dipole moment of the molecule. Both polarizabilities should include the atomic polarization, P_a. In addition, the cavity field polarizability should include the lattice mode polarization, P_{lm}, that is the additional contribution to the atomic polarization caused by the intermolecular lattice vibrations of the liquid state (16). If ε_0 is large, it can be shown (17) that eq. 1 requires the use of the polarization along the dipolar axis unless the cavity field polarization is itself very large. Otherwise a value of P, intermediate between the cavity field and dipolar axis values can be chosen so that eq. 1 still provides a reasonably accurate description of the dielectric data. Buckley and Maryott (2), however, were able to treat many systems successfully using values of P which did not include P_a, P_{lm}, or the anisotropy of the polarization.

Columns 1 and 2 of Table 1 show that the spherical Onsager equation cannot describe these systems well, although the G values were closer to unity when atomic polarization was included. The data for the prolate spheroid, CH_3F, is particularly interesting, since its shape should cause the Onsager value of G to be less than unity (2). The axial ratios, b/a were determined from Fisher–Hirschfelder–Taylor atomic models to be 0.9 for CH_3F, 1.2 for CH_2F_2, and 1.1 for CHF_3. The values of G listed in column 3 of Table 1 were calculated using these axial ratios and the spheroidal modification to Onsager's equation. These results show that the large values of G in columns 1 and 2 cannot be explained by molecular shape alone. In no case was the drift in G improved by assuming a constant arbitrary cavity volume.

By analogy with the treatment of Buckley and Maryott (2), or with the Frohlich–Kirkwood theory (14), these results could be interpreted as indicating a definite tendency for parallel alignment of the molecular dipoles in the liquid. This conclusion must be treated with caution, however, because the treatment has neglected the anisotropy of the molecular polarizability, and the contribution to the polarization from that part of the far infrared absorption which is due to the intermolecular lattice vibrations in the liquid.

The polarization along the dipolar axis of CHF_3 and CH_3F molecules can be crudely estimated by adding the anisotropic P_e (13, 18)

along that axis, to the isotropic values of P_a. The values are shown in Table 1. Column 4 of Table 1 lists G values calculated from them, using the geometric eccentricities. Column 5 lists values of G which were fitted to unity by using rather large values of P. The large discrepancy between the estimated anisotropic polarization and that required to set G near unity must indicate either a very strong contribution from the lattice vibrations of the liquid to the cavity field polarization, or the presence of intermolecular forces which favor parallel alignment of these dipoles and, hence, values of G greater than unity.

The lattice mode polarization undoubtedly arises primarily from rotational oscillations of the molecules about their equilibrium positions (19). The intensity of the resulting absorption band in the far infrared is, very crudely, proportional to μ_0^2/I, where I is the moment of inertia (16, 19). From the Kramers–Kronig relationship (20), the contribution of this band to the polarization will be highly dependent on its position and shape, but a very rough correlation between μ_0^2/I and Δn, the contribution of the band to the low frequency refractive index, would be expected.

Table 2 lists values of μ_0^2/I for several halomethanes as calculated from values of the rotational constants, B_0 and C_0, obtained from microwave spectra (21). Because the far infrared absorption includes a contribution from the orientational polarization (22) it is not possible to calculate the lattice mode contribution from the far infrared spectrum alone. A Kramers–Kronig treatment of the spectrum of CH_3I (19) indicates, however, that the total absorbance from 20 to 70 cm^{-1} would increase the polarization from the "sodium D" value of 19.3 to 24, and so the contribution of the lattice modes might well be significant. From the relative values of μ_0^2/I, the effect of lattice vibrations on cavity field polarization would follow the order $CH_3F > CH_2F_2 > CHF_3$. Hence, although this effect might account for the high values of the molar polarization required to set $G = 1$ for CH_3F, and possibly for CH_2F_2, the high value of G for CHF_3 must indicate at least in part, that the molecular dipoles tend to align parallel, perhaps due to hydrogen bonding (23–26).

If the lattice vibrations do significantly influence the reaction fields of the fluoromethanes, they might also be expected to influence those of the methyl halides. Using Buckley and Maryott's data (2), that is using the "sodium D" values of the polarizations which should be a lower limit, the spheroidal Onsager equation fits CH_3Cl and CH_3Br quite well with $G = 1$, assuming the gas phase geometries. CH_3I, however, requires a polarization which is 22% smaller than this lower limit (Table 3).

These results can be rationalized using arguments similar to those used above, if the tendency for antiparallel dipole alignment increases in the order $CH_3F < CH_3Cl < CH_3Br < CH_3I$ because, as can be seen in Table 2, the

TABLE 3. The discrepancies between the gas phase molar polarizations and those required to fit the methyl halides to the spheroidal Onsager equation using molecular geometries*

Halomethane	P, the gas phase molar polarization (cm^3)	P', the polarization required to fit the Onsager equation (cm^3)	$\frac{P' - P}{P}$
CH_3F	9.00	12.2	+0.36
CH_3Cl	11.7	12.5	+0.05
CH_3Br	14.6	14.6	+0.00
CH_3I	19.3	14.9	−0.22

*P is the gas phase anisotropic polarization of methyl fluoride and the isotropic "sodium D" polarization in all other cases.

contribution of the lattice vibrations is expected to increase in the reverse order. These two effects may roughly cancel each other for CH_3Br and CH_3Cl and thus enable their static dielectric constants to be fitted to the Onsager equation with $G = 1$.

Conclusion

In the absence of an exact knowledge of the dipolar axis and cavity field polarizations, deviations of G from unity do not necessarily imply liquid structure. The static dielectric constants of the fluoromethanes can be rationalized either by assuming significant parallel dipole correlation in all members of the series or, by assuming a significant lattice mode polarization which follows the order $CH_3F > CH_2F_2 > CHF_3$, and that a degree of parallel dipole correlation is present in CHF_3. An increasing tendency for antiparallel alignment of the methyl halides, with increasing size of the halogen, is consistent with both arguments.

The authors wish to thank Dr. J. E. Bertie and Dr. G. R. Freeman for many invaluable discussions and much assistance. The National Research Council of Canada is thanked for the award of a 1967 Science Scholarship to P.T.

The Reaction of O_3 with CCl_2CH_2 [1]

LESLIE A. HULL,[2] I. C. HISATSUNE, AND JULIAN HEICKLEN

Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pa. 16802

Received October 10, 1972

The gas-phase reaction of O_3 with CCl_2CH_2 at 25 °C was studied by monitoring O_3 consumption by ultraviolet absorption and product formation and olefin consumption by infrared absorption. In the absence or presence of excess N_2, and for initial olefin-to-O_3 ratios, $[CCl_2CH_2]_0/[O_3]_0$, in excess of 20 ($[O_3]_0 \sim 1.0$ Torr), the rate law is

$$-d[O_3]/dt = k[CCl_2CH_2][O_3]^2$$

with $k = 2.4 \times 10^6\ M^{-2}\ s^{-1}$. At lower olefin-to-$O_3$ ratios, the rate is initially more rapid than predicted by the above equation, but follows the equation after the reaction has proceeded for some time. In the presence of excess O_2, the rate is markedly reduced, and the rate law becomes

$$-d[O_3]/dt = k'[CCl_2CH_2][O_3]$$

with $k' = 2.2\ M^{-1}\ s^{-1}$.

The products of the reaction are CCl_2O, HCOOH, $CH_2ClCCl(O)$, CO, O_2, HCl, and presumably H_2O. In the absence of O_2, the CCl_2CH_2-to-O_3 consumption ratio approaches 2, but the CCl_2O produced per O_3 consumed is between 0.25 and 0.4. With excess O_2, the latter ratio becomes unity, but the CCl_2CH_2-to-O_3 consumed approaches 5.

The results are interpreted in terms of a chain mechanism with CCl_2O_2 as the chain carrier. The mechanism developed explains the main features of the reaction.

La réaction en phase gazeuse de O_3 sur CCl_2CH_2 à 25 °C a été étudiée en suivant la disparition de O_3 par absorption ultraviolette, formation de produit et disparition de l'oféline par absorption infrarouge. En l'absence ou en présence d'un excès de N_2 et pour des rapports initiaux oléfine sur O_3, $[CCl_2CH_2]_0/[O_3]_0$ de 20 avec ($[O_3]_0 \sim 1.0$ Torr), la loi de vitesse est

$$-d[O_3]/dt = k[CCl_2CH_2][O_3]^2$$

avec $k = 2.4 \times 10^6\ M^{-2}\ s^{-1}$. Pour des rapports oléfine sur O_3 plus faibles, la vitesse initiale est plus rapide que celle qui est prévue par l'équation ci-dessus, mais au bout d'un certain temps la réaction satisfait à cette équation. En présence d'un excès de O_2, la vitesse est réduite de façon appréciable et la loi de vitesse devient

$$-d[O_3]/dt = k'[CCl_2CH_2][O_3]$$

avec $k' = 2.2\ M^{-1}\ s^{-1}$.

Les produits de la réaction sont CCl_2O, HCOOH, $CH_2ClCCl(O)$, CO, O_2, HCl, et vraisemblablement H_2O. En l'absence de O_2, la consommation de CCl_2CH_2/O_3 tend vers deux mais le CCl_2O produit par O_3 consommé, oscille entre 0.25 et 0.4. Avec un excès de O_2, ce dernier rapport vaut un, le CCl_2CH_2 consommé par O_3 tend vers 5.

Les résultats sont interprétés par un mécanisme de réaction en chaîne avec CCl_2O_2 comme initiateur. Le mécanisme évoqué rend compte des principales caractéristiques de la réaction.

Can. J. Chem., **51**, 1504 (1973)

Introduction

The gas-phase reaction of O_3 with olefins has been examined in several laboratories in recent years (1–5). Wei and Cvetanović (3) found that the ratio of olefin-to-ozone consumed was 1.0 in the presence of excess N_2, but between 1.4 and 2.0 in the presence of excess O_2. They attributed the increase to secondary attack of some species on the olefin in the latter case. At temperatures below room temperature (−40 to −95 °C), DeMore (5) found the rate of O_3 consumption to be independent of the absence or presence of excess O_2 in the O_3–C_2H_4 reaction.

The products of the reaction have been examined by Vrbaski and Cvetanović (2). While the detailed mechanism has never been fully explained, the products are consistent with addition of O_3 to the olefin followed by cleavage to a carbonyl compound and a zwitterion. For C_2H_4, the reaction steps would be

$$C_2H_4 + O_3 \rightarrow CH_2—CH_2 \rightarrow CH_2O + CH_2O_2$$

The CH_2O_2 zwitterion has never been trapped in the gas phase and presumably rearranges quickly to excited formic acid (HCOOH) which can either be stabilized or decompose to CO plus H_2O.

In our laboratory, we have initiated studies of the reaction of O_3 with halogenated ethylenes. The halogen atom migrates less readily (if at all) than the hydrogen atom. Thus stabilization of the zwitterion should be enhanced. In fact oxidation of perhaloolefins has been interpreted in terms of stable (to isomerization) zwitterions (6).

In this paper we report our results on the reaction of O_3 with CCl_2CH_2. The reaction of chlorinated olefins with O_3 in the gas phase has not been reported previously. Williamson and Cvetanović (7) have examined the reaction in CCl_4 solution at 25 °C. For CCl_2CH_2, they found that the ratio of olefin-to-ozone consumption was one, that one $COCl_2$ was formed per O_3 consumed, and that the rate of reaction was first order in both olefin and O_3 concentration. An explosive white solid compound was also found after evaporation of the solvent.

Experimental

The kinetic apparatus has been described previously (8). It consists of two 100 cc bulbs connected by a T-stopcock (one that opens simultaneously in three directions) to a stem adaptor which leads either through a stopcock to the vacuum line or through a stopcock to the optical cell. Silicone grease was used in all the stopcocks. Two optical cells were used. One was a 10.0 cm long quartz cell for following O_3 decay at 2537 Å in a Cary 14 spectrometer. The other cell was 10.3 cm long and had NaCl windows to permit monitoring olefin decay at 1620 cm^{-1} and phosgene – acid chloride appearance at 1830 cm^{-1} by infrared spectroscopy. A Perkin–Elmer 112 infrared spectrometer with a CaF_2 prism was used. All experiments were performed at room temperature, about 25 °C.

Before a run, the kinetic apparatus was evacuated for at least an hour by an oil diffusion pump and then conditioned for 10 min with about 5 Torr of O_3 before final evacuation. The O_3 was prepared from a tesla coil discharge through O_2, the excess O_2 being removed at −196 °C. A desired amount of freshly prepared O_3 was then measured into the cell with a Kel-F oil manometer. The half-life of the O_3 in the cell was about 8 h, which was very much longer than the rest of the procedure. The 1,1-dichloroethylene was obtained from the Fisher Scientific Co. and distilled at −98 °C before use. Mixtures of it and the appropriate diluent gas were prepared in the 100 cc bulbs.

The kinetic apparatus then was removed from the vacuum line and transferred to the appropriate spectrometer with the cell in the optical path. The spectrometer was set at a fixed wavelength, and the reaction was initiated by opening the T-stopcock first and then opening and closing the stopcock to the cell. The reaction was followed continuously for 4 or more half-lives and then intermittently for 3 more to get an infinity point. The initial pressures of the olefin and diluent gas in the cell were calculated using the measured ratio of the volumes of the bulbs to the entire kinetic apparatus. These were 0.485 for the infrared cell and 0.75 for the quartz cell. Kinetic runs in which the O_3 was added to the olefin were performed in a similar manner by reversing the roles of the O_3 and olefin.

Runs for product analysis were performed in the infrared cell in the manner described for the kinetic runs, except that the entire region (4000–600 cm^{-1}) was scanned on a Perkin–Elmer 521 grating infrared spectrometer. HCl was identified from its known band sequence (2750–3050 cm^{-1}), but no quantitative estimates could be made. Quantitative analysis for the olefin, CCl_2O, $CH_2ClCCl(O)$, and CO were made from their respective bands at 1620, 850, 720, and 2050–2200 cm^{-1}. In experiments to measure O_2, the diluent gas was a halocarbon (CCl_4, CH_2Cl_2, or CF_3CFCl_2) that was condensable at −196 °C. The residual pressure of gas noncondensable at −196 °C was considered to be CO plus O_2, and the O_2 computed by difference.

Results

Initially kinetic runs were done in which the rate of disappearance of O_3 was monitored by ultraviolet absorption. Experiments were done in both the absence and presence of excess N_2 and both by adding the olefin to the O_3 and *vice versa*. In the absence of N_2 for O_3 pressures >2 Torr, explosions occurred. Therefore all experiments were done with initial O_3 pressures <2 Torr. Typical runs are shown in Fig. 1 for three different initial olefin pressures, $[CCl_2CH_2]_0$. The data are displayed as second order kinetic plots. At $[CCl_2CH_2]_0/[O_3]_0$ ratios >20, the plots are linear to >90% conversion indicating a rate law second-order in $[O_3]$. At lower initial ratios, the O_3 decay is rapid at first and then becomes second order as the run progresses.

The pseudo second order rate coefficients increase proportionately with the olefin pressure, so that the rate law follows the expression

$$-d[O_3]/dt = k[CCl_2CH_2][O_3]^2$$

For several runs the values of k are listed in Table 1. At low values of $[CCl_2CH_2]_0/[O_3]_0$, the rate coefficients were obtained late in the run, when the O_3 decay became second order. In one case the olefin consumption, rather than the O_3

consumption, was monitored by infrared analysis. In this case, the amount of olefin consumed was measured at the end of the run to provide a stoichiometric factor to compute k. In all cases k is approximately the same, there being no discernible trend with $[CCl_2CH_2]$. The average value for k is $(2.4 \pm 0.6) \times 10^6\ M^{-2}\ s^{-1}$.

Next, kinetic runs were done in the presence of excess O_2. The rate of O_3 consumption was markedly reduced for comparable conditions in the presence of N_2. Furthermore the decay law was first order in $[O_3]$ to at least 90% removal at large $[CCl_2CH_2]_0/[O_3]_0$ as shown in Fig. 2. The pseudo first order rate coefficients were approximately proportional to the CH_2CCl_2 pressure, suggesting the rate law

$$-d[O_3]/dt = k'[O_3][CCl_2CH_2]$$

The rate coefficients k' are listed in Table 2. They are independent of the O_2 pressure, for O_2 pressures >43 Torr. However there are two trends. Those coefficients based on olefin consumption or $CCl_2O + CH_2ClCCl(O)$ formation appear somewhat larger than those based on O_3 consumption. Presumably this reflects stoichiometric uncertainties, since it is difficult to explain such a phenomenon otherwise. The second and more meaningful trend is the approximately

factor of 2 drop as the olefin pressure increases from 8.5 to 99 Torr. This suggests that the rate law is slightly less than first order in $[CCl_2CH_2]$. However for simplicity, we shall assume first order kinetics, which leads to an average value of k' of 2.2 ± 0.6 M^{-1} s^{-1}.

As in the absence of O_2, runs in the presence of O_2 at low initial olefin pressures showed an excessive rate initially. As the reaction progressed the rate slowed and became first order in both $[O_3]$ and $[CCl_2CH_2]$.

Finally the products of the reaction were measured. The products were $CH_2ClCCl(O)$, CCl_2O, HCOOH, CO, O_2, and HCl. Presumably H_2O was also produced, but no measurements for it were attempted. (Separate experiments showed that H_2O and CCl_2O are stable in the presence of each other, if the pressure of each is <5 Torr.) Notable for its absence was CH_2O. In all cases $[HCOOH] \lesssim [CCl_2O]$. Quantitative analysis for HCl was too difficult to be reliable and no quantitative results are reported.

In the presence of excess N_2, the olefin-to-ozone consumed was approximately unity at low ratios of $[CCl_2CH_2]_0/[O_3]_0$, but rose towards 2 as the ratio increased to 20. The CCl_2O production to O_3 consumption remained between 0.25 and 0.40 throughout the whole range of $[CCl_2CH_2]_0/[O_3]_0$ ratios.

In the presence of excess O_2, the olefin consumption and CCl_2O formation were about the same as in excess N_2 for low olefin-to-O_3 ratios. However at higher ratios, CCl_2CH_2 consumption approached 5 times the O_3 consumption, and CCl_2O production approached O_3 consumption.

In order to detect the noncondensable products more easily, some runs were done with halocarbon diluents which are condensable at −196 °C. Presumably these diluents act like N_2. In the presence of a relatively small amount of CCl_4 (38 Torr), no HCOOH or $CH_2ClCCl(O)$ was formed, but one O_2 was formed for each O_3 removed. At higher diluent pressures, the O_2 produced to O_3 consumed was about 1/3 at medium $[CCl_2CH_2]_0/[O_3]_0$ ratios, but dropped to 0.09 at an initial ratio of 22. In all cases the CO produced was about 1/4 of the O_3 consumed.

Discussion

It is clear that the gas-phase ozonolysis of CCl_2CH_2 is considerably different than in CCl_4 solution or that for C_2H_4, especially at high olefin to O_3 ratios. At high ratios the rate law is second order in $[O_3]$, the olefin-to-O_3 consumption exceeds unity, and the CCl_2O production is 0.25–0.40 of the O_3 consumption. Furthermore a long chain is involved since the presence of excess O_2 markedly reduces the rate and changes the rate law. Even at low olefin-to-O_3 ratios, differences exist, since CCl_2O production is less than O_3 consumption.

The reaction mechanism must be complex and cannot be elucidated in detail from our studies. However some overall formal mechanistic conclusions can be drawn, even though they must be speculative at this time.

Presumably the initial step is the addition of O_3 across the double bond of the olefin followed by cleavage to form a carbonyl compound and a zwitterion. This can occur in two ways. One possibility is

$$O_3 + CCl_2CH_2 \rightarrow CCl_2O + CH_2O_2$$

The CH_2O_2 zwitterion could then rearrange to HCOOH or decompose to CO + H_2O. If this were the sole reaction, then this reaction should be similar to the ozonolysis of C_2H_4, *i.e.* the rate should be first order in each of the reactants, the olefin-to-O_3 consumption should be unity, the CCl_2O production to O_3 removal should be unity, and the addition of O_2 should have no effect. Of course it is possible that the CH_2O_2 zwitterion could be stabilized long enough to enter into a chain reaction. However in no other

system is such a stabilization known for CH_2O_2, and it is difficult to see why it should occur here.

It seems more likely to us that all or part of the time, the ozonolysis proceeds via the alternate pathway

[1] $O_3 + CCl_2CH_2 \rightarrow CCl_2O_2 + CH_2O$

The CCl_2O_2 zwitterion, which should be stable to isomerization, could then react with either O_3 or CCl_2CH_2

[2] $CCl_2O_2 + O_3 \rightarrow CCl_2O + 2O_2$

[3] $CCl_2O_2 + CCl_2CH_2 \rightarrow A$

where we envision A as a diradical adduct. Actually A could be any fragment that carries the chain to regenerate CCl_2O_2. If A is the adduct it could either add to O_3 or react with it

[4a] $A + O_3 \rightarrow AO_3$

[4b] $\rightarrow CCl_2O_2 + CCl_2O + HCOOH$

Likewise it could undergo similar reactions with O_2

[5a] $A + O_2 \rightarrow AO_2$

[5b] $\rightarrow 2CCl_2O + HCOOH$

or it could decompose via

[6] $A \rightarrow CCl_2O + CH_2ClCCl(O)$

The product $CH_2ClCCl(O)$, which is observed, may be formed through rearrangement of a "hot" epoxide. Presumably it also is formed with excess energy, and if not stabilized by collision can decompose to form HCl and CO among other things. We believe this to be the source of HCl and some of the CO. The absence of $CH_2ClCCl(O)$ at low pressures of diluent gas (*i.e.* at 38 Torr of CCl_4) supports this argument.

No CH_2O was observed under any conditions. This can be attributed to the reaction of CH_2O with O_3 to produce either HCOOH or CO + H_2O

[7] $CH_2O + O_3 \rightarrow O_2 + HCOOH$ (or $CO + H_2O$)

It is known that O_3 reacts readily with aldehydes (9, 10), though the detailed mechanism has not been elucidated. For our purposes reaction 7 should be adequate, though if free radical intermediates are involved, the mechanism will be more complex.

In order to account for the chain nature of the reaction the following reactions (or others mechanistically similar) are needed

[8] $AO_3 + 2CCl_2CH_2 \rightarrow 3CH_2ClCCl(O) + CCl_2O_2$

[9] $AO_2 + CCl_2CH_2 \rightarrow 2CH_2ClCCl(O) + CCl_2O_2$

In the gas phase in the absence of O_2, the mechanism consisting of reactions 1–4 and 6–8 leads to the prediction

$$[10] \quad -d[O_3]/dt = k_1[CCl_2CH_2][O_3] \times \left(2 + \frac{k_2[O_3] + k_3[CCl_2CH_2]}{k_2[O_3] + k_3k_6[CCl_2CH_2]/k_4[O_3]}\right)$$

if $k_6 \ll k_4[O_3]$. Since our results will be shown to be consistent with a value of $k_4/k_6 = 2.1 \times 10^6\ M^{-1}$, the condition is valid over our entire experimental range.

At sufficiently high pressures of CCl_2CH_2 and low pressures of O_3, $k_2[O_3] \ll k_3k_6[CCl_2CH_2]/k_4[O_3]$, and eq. 10 reduces to

$$[11] \quad -d[O_3]/dt = k_1k_4[O_3]^2[CCl_2CH_2]/k_6$$

Thus $k = k_1k_4/k_6 = 2.4 \times 10^6\ M^{-2}\ s^{-1}$.

Under all of our conditions, $k_2[O_3] \ll k_3[CCl_2CH_2]$, but at low CCl_2CH_2 pressures and high O_3 pressures, $k_2[O_3] \gg k_3k_6[CCl_2CH_2]/k_4[O_3]$. Then eq. 11 reduces to

$$[12] \quad -d[O_3]/dt = k_1k_3[CCl_2CH_2]^2/k_2$$

For these conditions, *i.e.* $[O_3] \sim 1.0$ Torr, $[CCl_2CH_2] < 10$ Torr, the rate is higher than predicted by eq. 11 and does not follow the same rate law. At the cross over point $k_2[O_3] = k_3k_6[CCl_2CH_2]/k_4[O_3]$, so that $k_2 \sim 1.9 \times 10^5\ k_3k_6/k_4\ M^{-1}$.

For all conditions of the reaction, the mechanism predicts $d[CCl_2CH_2]/d[O_3] = 1 + 2\ k_{4a}/k_4$ and $-d[CCl_2O]/d[O_3] = k_{4b}/k_4$. The results are consistent with values of $k_{4a}/k_4 = 0.6$ and $k_{4b}/k_4 = 0.4$.

For the kinetic runs in the presence of excess O_2, $k_{5b}[O_2] \gg k_6$, $k_5[O_2] \gg k_4[O_3] + k_6$, and $k_2[O_3] \ll k_{5b}k_3[CCl_2CH_2]/k_5$. Then the mechanism predicts

$$[13] \quad d[CCl_2O]/dt = -d[O_3]/dt = 2k_1[CCl_2CH_2][O_3]$$

Thus $k_1 = k'/2 = 1.1\ M^{-1}\ s^{-1}$. Furthermore $d[CCl_2CH_2]/d[O_3] = 1 + k_{5a}/k_{5b} = 5$, so that $k_{5a}/k_{5b} \sim 4$.

From the values of k_1k_4/k_6 and k_1, the value of k_4/k_6 is computed to be $2.1 \times 10^6\ M^{-1}$. All the rate coefficient ratios obtained in this study are summarized in Table 4.

Finally it is pointed out that if $[CCl_2CH_2]_0/$

TABLE 4. Rate constant ratios

Ratio	Value	Units
k_1k_4/k_6	2.4×10^6	$M^{-2}\ s^{-1}$
k_{4a}/k_4	0.6	None
k_{4b}/k_4	0.4	None
k_2k_4/k_3k_6	$\sim 1.9 \times 10^5$	M^{-1}
k_1	1.1	$M^{-1}\ s^{-1}$
k_{5a}/k_{5b}	4	None
k_4/k_6	2.1×10^6	M^{-1}

$[O_3]_0$ is sufficiently small, as it is in some of the product studies, CCl_2CH_2 will be consumed sufficiently rapidly so that reaction 2 can compete with reaction 3. Then, in the limiting case, $d[CCl_2O]/dt = -d[CCl_2CH_2]/dt = -(1/3)d[O_3]/dt$. Such a limit is being approached in the first entry in the presence of O_2 in Table 3.

A comparison of our results in the absence of excess O_2 to those obtained in CCl_4 solution (7) show marked differences. The gas-phase rate law is second order in $[O_3]$, whereas the liquid phase results are first order in $[O_3]$. A chain mechanism must be involved in the gas phase, since the addition of excess O_2 reduces the rate and gives a second order rate coefficient.

Chemistry of Metal Hydrides. XIV. Insertion Reactions of an Iridium(III) Hydride

H. C. CLARK AND R. K. MITTAL

Department of Chemistry, University of Western Ontario, London, Ontario

Received November 27, 1972

The iridium(III) hydride, $IrHCl_2\{P(C_2H_5)_3\}_3$, gave 1:1 insertion products with perfluoropropene and 3,3,3-trifluoropropyne containing two and three phosphines per iridium respectively. With tetrafluoroethylene, or 1,1-difluoroethylene a simple fluorine – hydridic hydrogen exchange reaction appears to occur. An unusual tricyanovinylic derivative is obtained as a major product of the reaction with tetracyanoethylene, while dimethylacetylene dicarboxylate gave an interesting product containing two acetylene molecules per molecule of hydride. This is formulated as the π-acetylenic complex of the vinylic insertion product. The importance of ligand dissociation in these insertion processes is discussed.

L'hydrure d'iridium(III), $IrHCl_2\{P(C_2H_5)_3\}_3$, a donné avec le perfluoropropène et le trifluoro-3,3,3 propyne un produit d'insertion 1:1 contenant deux et trois groupes phosphines par iridium respectivement. Avec le tétrafluoroéthylène ou avec le difluoro-1,1 éthylène une simple réaction d'échange entre l'hydrogène de l'hydrure et un fluor a semblé se produire. Comme produit majeur de la réaction avec le tétracyanoéthylène, on a obtenu un dérivé tricyanovinylique inhabituel alors que le diméthylacétylène dicarboxylate a donné un produit intéressant contenant deux molécules d'acétylènes par molécules d'hydrure. Ce fait a été formulé comme étant le complexe π-acétylènique du produit d'insertion vinylique. L'importance de la dissociation du coordinat dans ces processus d'insertion est discutée.

Can. J. Chem., 51, 1511 (1973)

Introduction

The insertion of unsaturated compounds into transition metal – hydrogen bonds has been widely studied, particularly for square planar d^8 complexes (1, 2) and for metal carbonyl hydrides (3, 4). The mechanism is thought to involve a π-complex as intermediate followed by insertion into the M—H bond, this being a reversible process in some cases (1). Such a process requires either a vacant coordination site on the transition metal for facile formation of the transition state or alternatively at least one labile ligand, exchange of which can facilitate π-complex formation by the unsaturated reactant. In most studies to date, one or other of these requirements has been met, and it seemed desirable to examine the insertion reactions of a hydride with less favorable characteristics.

Iridium(III) forms a large number of stable hydrido complexes in which the neutral ligands are usually tertiary phosphines, arsines, or stibines. These are essentially octahedral in geometry, and so do not contain a coordination site that can be regarded as "vacant"; moreover, iridium(III) complexes with this d^6 configuration are inert towards substitution reactions, so that facile ligand exchange reactions are unlikely to occur. We have therefore examined the behavior of $IrHCl_2\{P(C_2H_5)_3\}_3$ towards a variety of olefins and acetylenes. Here we report on reactions with some fluorinated olefins and acetylenes, these being employed since their insertion reactions with transition metal hydrides are usually not reversible (4, 5) and the products of insertion frequently have considerable stability. We have also investigated some similar reactions with cyanoolefins and with dimethylacetylene dicarboxylate.

Experimental

Standard high vacuum techniques were used throughout. Infrared spectra were recorded on a Beckman IR-10 spectrometer. ^1H and ^{19}F n.m.r. spectra were recorded on a Varian HA-100 spectrometer; chemical shifts are given in p.p.m. relative to TMS or $CFCl_3$ as internal standard. Microanalyses were carried out by Schwarzkopf Microanalytical Laboratory, New York. All reactions with fluoro-olefins were performed in a stainless steel autoclave, and all others in thick-walled Pyrex glass tubes.

Tetrafluoroethylene was obtained from dibromotetrafluoroethane (6) and trifluoropropyne by the method of Finnegan and Norris (7). Other fluoro-olefins and perfluorobut-2-yne were obtained commercially and used without further purification. All solvents were of spectroscopic grade and were dried by standard methods. Tetracyanoethylene, fumaronitrile, acrylonitrile, and cinnamonitrile were all obtained commercially; liquids were purified by distillation and solids by crystallization before use. The starting material $IrHCl_2\{P(C_2H_5)_3\}_3$, **1**, was prepared by the method of Chatt and Shaw (8).

In the reactions described below, the following procedure was employed to separate and purify reaction products chromatographically. The reaction mixture was eluted through a small column of silica gel using *n*-hexane, or *n*-hexane-benzene mixtures, in which the products described below were soluble. Purification was usually attempted by crystallization from *n*-hexane–benzene mixtures, but in a number of cases complete separation of products from fluorocarbon oligomers was impossible (see Discussion).

Reaction with Tetrafluoroethylene

This reaction was performed several times in different solvents (cyclohexane, pentane, toluene), at different temperatures (60–120°) and for different reaction times (6–60 h), using Pyrex glass reaction tubes or a stainless steel autoclave. Since all reactions gave similar results, a typical procedure is described. Tetrafluoroethylene (0.44 g, 4.4 mmol) with **1** (0.618 g, 1.0 mmol) was heated in toluene (10 ml) at 100° for 10 h. Removal of solvent left a yellow viscous material which was purified chromatographically. The product then gave an infrared spectrum which displayed no Ir—H stretching absorption (2000–2200 cm^{-1}) but did show absorptions assignable to C—F stretching (1000–1300 cm^{-1}). However, on standing for a few hours this viscous material slowly gave a white crystalline solid, insoluble in benzene, which showed no C—F stretching absorption. From the remaining liquid, a yellow crystalline solid was finally obtained after recrystallizations from benzene–*n*-hexane mixtures. The infrared spectrum of this material also indicated the absence of fluorocarbon groups. Analytical results suggested, but did not clearly establish, that these products were isomers of $IrFCl_2\{P(C_2H_5)_3\}_3$.

Reaction with 1,1-Difluoroethylene

1,1-Difluoroethylene (0.26 g, 4.0 mmol) and **1** (0.618 g, 1.0 mmol) were heated in toluene (10 ml) for 10 h at 100° in the autoclave. Removal of solvent gave a viscous yellow oil, purification of which was attempted chromatographically. The infrared spectrum of the resulting yellow oil showed absorption in the C—F stretching region and the Ir—H stretching absorption was no longer present. On standing for a few hours, a white crystalline solid was deposited and this was washed with benzene. Evaporation of the benzene solution followed by recrystallization from a benzene–*n*-hexane mixture gave a yellow solid whose composition was identical with that of the white material which separated first. Both the white and yellow solids were the same as those obtained in the reactions with C_2F_4.

Reaction with Trifluoroethylene

Trifluoroethylene (0.33 g, 4.0 mmol) and **1** (0.62 g, 1.0 mmol) were heated with toluene (10 ml) in the autoclave for 10 h at 100°. Evaporation of the solvent, followed by chromatographic separation and recrystallization from *n*-hexane–benzene gave a yellow crystalline product. Analytical and spectroscopic results (see Discussion) suggested that this was $IrCl_2(C_2F_3H_2)\{P(C_2H_5)_3\}_3$ contaminated with fluorocarbon polymer.

Reaction with Perfluoropropene

Perfluoropropene (0.60 g, 4 mmol) and **1** (0.62 g, 1 mmol) were heated in toluene (10 ml) at 100° for 10 h. Removal of solvent gave a yellow oil, which was purified chromatographically to give, on crystallization from benzene–*n*-hexane, a yellow crystalline product (0.06 g). This showed no absorption in the infrared spectrum associated with the Ir—H group, but did show strong C—F absorption.

Anal. Calcd. for $IrCl_2F_6P_2C_{15}H_{31}$: C, 27.69; H, 4.80; F, 17.61; P, 9.52. Found: C, 27.25; H, 4.72; F, 17.30; P, 9.81. M.p. 100–101.

Reaction with 1,1,1-Trifluoropropyne

The propyne (0.38 g, 4.0 mmol) and **1** (0.62 g, 1.0 mmol) were heated in dichloromethane in a sealed glass tube at 60° for 2 h. A yellow oil was obtained which was purified chromatographically, and then recrystallized from benzene–*n*-hexane. The yellow crystals so obtained (0.125 g) showed infrared absorption bands due to ν(C—F) and ν(C=C) but not to ν(Ir—H).

Anal. Calcd. for $IrCl_2F_3P_3C_{21}H_{47}$: C, 35.39; H, 6.64; F, 8.00; P, 13.03. Found: C, 34.97; H, 6.52; F, 8.11; P, 13.13. M.p. 120–122.

Reaction with Perfluorobut-2-yne

Perfluorobut-2-yne (0.65 g, 4.0 mmol) and **1** (0.62 g, 1.0 mmol) underwent complete reaction in dichloromethane (10 ml) in 2 h at 60°; the solution changed in color from yellow to red. Removal of solvent gave a red oil which was purified chromatographically to give an orange solid (0.06 g). The infrared spectrum showed no absorption due to Ir—H but an intense absorption at 1550 cm^{-1} ν(C=C) and absorption in the 1000–1200 cm^{-1} region ν(C—F).

Reaction with Tetracyanoethylene

Tetracyanoethylene (0.064 g, 0.5 mmol) and **1** (0.309 g, 0.5 mmol) in 10 ml toluene were heated at 60° for about 2 h during which time the mixture turned dark brown. The solution was decanted off and solvent removed by evaporation to give a brown solid which was purified by dissolving it in ethanol and re-precipitating by addition of methylene dichloride.

Anal. Calcd. for $IrCl_2P_2N_3C_{17}H_{30}$: C, 33.08; H, 5.14; N, 6.97; P, 10.30; Cl, 11.80. Found: C, 33.07; H, 5.44; N, 6.55; P, 10.40; Cl, 11.56.

Reaction with Fumaronitrile

The complex **1** (0.309 g, 0.5 mmol) and fumaronitrile (0.039 g, 0.5 mmol) were heated in toluene (10 ml) at 60° for 4 h with stirring. The solution turned deep violet. The solution was decanted off any solid and the solvent evaporated, to leave a brown compound which was then reprecipitated from a dichloromethane – diethyl ether mixture.

Reaction with $CH_3COOC{\equiv}CCOOCH_3$

The complex **1** (0.62 g, 1.0 mmol) and the acetylene (1 mmol) were heated in toluene for 4 h at 100°. After decantation from a small amount of residue, the solvent was evaporated off, and the solid recrystallized from a dichloromethane – diethyl ether mixture.

Anal. Calcd. for $IrCl_2O_8P_2C_{24}H_{43}$: C, 36.70; H, 5.40; P, 7.80; Cl, 9.00. Found: C, 37.03; H, 5.51; P, 7.84; Cl, 8.80.

Results and Discussion

The iridium(III) hydride, $IrHCl_2\{P(C_2H_5)_3\}_3$, **1**, exists in several isomeric forms; the yellow isomer used here has *trans* choride ligands, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydridic hydrogen *trans* to phosphine. It is not surprising, therefore, that many of its reactions with olefins and acetylenes proceed slowly and give low yields of products.

The reaction of **1** with tetrafluoroethylene was examined under a variety of conditions, but in no case was a fluorocarbon product identified. The only new compound, formed in an impure state, appeared to be a fluorodichloride of iridium(III) which apparently exists in white and yellow isomeric forms. The same product was also obtained from the reaction of **1** with 1,1-difluoroethylene. These simple fluorine – hydridic hydrogen exchange reactions, presumably also leading to trifluoroethylene and ethylene from tetrafluoroethylene and 1,1-difluoroethylene, respectively, perhaps involve formation and decomposition of iridium fluoroalkyl derivatives. Similar exchanges have been observed in reactions of fluoro-olefins with organo-tin hydrides (9).

With trifluoroethylene, at 100°, **1** gave a yellow crystalline product which showed no $\nu_{(Ir-H)}$ stretching absorption in the infrared spectrum at 2100–2250 cm^{-1}, but did show strong C—F absorptions in the 950–1300 cm^{-1} region. Together with the analytical data which showed a very high fluorine content, these results suggest that the product is $IrCl_2(C_2F_3H_2)\{P(C_2H_5)_3\}_3$ contaminated possibly with fluorocarbon polymer. Nor did the ^{19}F n.m.r. spectrum provide definitive structural information.

The compound obtained from **1** and perfluoropropene, after reaction at 100°, had a composition corresponding to a bis(phosphine) product incorporating one unit of the olefin, *i.e.* for $IrCl_2(C_3F_6H)\{P(C_2H_5)_3\}_2$. Again the infrared spectrum showed the loss of Ir—H stretching absorption as well as the appearance of strong absorptions at 950–1300 cm^{-1} associated with fluorocarbon groupings. Unfortunately, the ^{19}F n.m.r. spectrum could not be completely resolved because of low solubility problems, but two resonances were observed at 67.5 and 100 p.p.m., each consisting of a 1:2:1 triplet in which each line was split into a doublet. However, the resonance at 100 p.p.m. was very broad and clearly contained additional unresolved couplings. If the molecule was trigonal bipyramidal with axial phosphines, then assuming that the signal from the single fluorine nucleus is too weak to be resolved, these observations still do not distinguish clearly between an $IrCF(CF_3)CF_2H$ and an $IrCF_2CFH(CF_3)$ structure. The resonance at 67.5 p.p.m. showed couplings of 10 Hz (splitting into 1:2:1 triplet) and 3 Hz (each component split to doublet), consistent with couplings of the CF_3 fluorine nuclei to two equivalent phosphorus nuclei and to the α-fluorine nucleus of an $IrCF(CF_3)CF_2H$ group. The 100 p.p.m. resonance might then arise from a terminal $—CF_2H$ group attached to an asymmetric α-carbon atom, so that the two fluorines are inequivalent. A coupling between these two fluorines of 136 Hz and a further coupling F—H of approximately 30 Hz would be consistent with the observed spectrum. However, no other case has been reported for the formation of an $MCF(CF_3)CF_2H$ group from perfluoropropene and a metal hydride, and further spectroscopic data are needed to confirm this.

The reaction of **1** with trifluoropropyne $CF_3C{\equiv}CH$, was much cleaner and gave a product readily identified by analysis as $IrCl_2\{P(C_2H_5)_3\}_3CH{=}CHCF_3$, thus showing the retention of three phosphines per molecule. The infrared spectrum showed the loss of Ir—H due to the disappearance of the 2110 cm^{-1} band; also, a strong sharp band is observed at 1595 cm^{-1} characteristic of $\nu_{(C=C)}$, while intense absorptions at 1100 and 1035 cm^{-1} are characteristic of a single CF_3 group, although shifted some 40 cm^{-1} to frequencies lower than those usually observed (see, for example, ref. 10). The ^{19}F n.m.r. spectrum consists just of a sharp singlet at 62.4 p.p.m., while the proton spectrum in addition to the expected resonances of the phosphine protons shows two signals at lower field, at $\delta = -8.2$ p.p.m. consisting of a sharp doublet with a splitting of 18 Hz, and a more complex signal at $\delta = -6.80$ p.p.m. showing a coupling of 18 Hz with further smaller couplings apparent. These data are consistent with a geometry $Ir—CH{=}CHCF_3$ with the hydrogens *trans* to each other with $J(H—H) = 18$ Hz. The complexity of the absorption at $\delta = -6.80$ p.p.m. must be due to the H—H coupling together with further couplings to two *cis* and one *trans* phosphorus nuclei. The fact that the product appears to have exclusively the *trans* geometry about the C=C bond is probably not significant since ready isomerization of such compounds is known to occur.

With perfluorobut-2-yne, reaction of **1** again gave an impure product which probably contained polymerized fluorocarbon as well as an iridium-containing product.

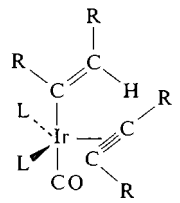
One of the chief reasons for studying reactions of unsaturated fluorocarbons, such as those described above, lies in the enhanced stability of fluorocarbon – transition metal compounds compared with their hydrocarbon analogues. It is also well-known (11 and references therein, 12) that cyano-olefins form more stable complexes with noble metal compounds than do the analogous hydrocarbons, and this presumably also holds for other olefins and acetylenes containing strongly electron-withdrawing substituents. Thus tetracyanoethylene (TCNE) forms 1:1 adducts with *trans*-$PtHCN(PR_3)_2$ (13) and $IrX(CO)(Ph_3E)_2$ where X = halide, etc., and E = P or As (14). Also, 1:1 adducts of the types $IrCl(CO)L_2$ (acetylene) and $RhCl(CO)L_2$ (acetylene) where L = tertiary phosphine, etc., are readily formed (15) by disubstituted acetylenes containing electron-withdrawing substituents. With the five coordinate iridium(I) hydride, $IrH(CO)(Ph_3P)_3$, TCNE, and related compounds such as cinnamonitrile, fumaric acid, dimethyl maleate, etc., give (11) stable complexes of the type $IrH(CO)(Ph_3P)_2$(olefin), in which the olefin has displaced one of the original three phosphine ligands. Moreover, perfluorobut-2-yne and dimethylacetylene dicarboxylate give complexes containing two units of acetylene per iridium formulated as having structure **2**,



2

in which insertion into the Ir—H bond has occurred, with the other acetylene unit π-bonded to the metal.

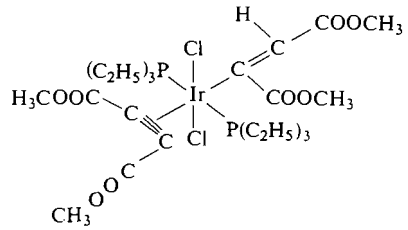
With the iridium(III) complex **1**, reaction with tetracyanoethylene occurs fairly readily at 60°, with loss of one phosphine unit. However the product does not contain an Ir—H bond, since neither $\nu_{(Ir-H)}$ nor the Ir—H bending absorption at 880 cm^{-1} is observed in the infrared spectrum, nor is the hydridic resonance observed at high field in the proton n.m.r. spectrum. A strong peak appears in the infrared spectrum at 2200 cm^{-1} and also a broad strong peak at 1600 cm^{-1}. Bearing in mind the analytical data, the product is therefore formulated as $IrCl_2[C_2(CN)_3][P(C_2H_5)_3]_2$, containing a tricyanovinyl group σ-bonded to iridium. Interestingly, a number of tricyanovinylic derivatives have been reported very recently by other workers (16), although not all of them were prepared from tetracyanoethylene; presumably the mechanism leading to this vinyl product involves elimination of HCN from a 1:1 adduct $IrHCl_2[P(C_2H_5)_3]_2$.TCNE. This is very different from the reductive elimination of HX observed, for example, in the reaction of TCNE with *trans*-$PtHX(PR_3)_2$ leading (13) to the formation of $(PR_3)_2Pt$(TCNE).

Although other cyano-olefins such as cinnamonitrile and acrylonitrile (11) are known to form adducts with $IrH(CO)(Ph_3P)_3$ (and indeed acrylonitrile proceeds further to give the insertion product $Ir(CH_2CH_2CN)(CO)(Ph_3P)_2(NCCH{=}CH_2)$), reactions of **1** with a variety of other cyano-olefins were unsuccessful, in that pure products were not obtained. With fumaronitrile, the product had a composition close to that expected for the 1:1 adduct, although the high carbon, hydrogen, and nitrogen contents suggested that some polymeric material was also present. The infrared spectrum showed no $\nu_{(Ir-H)}$ and no $\delta_{(Ir-H)}$ at 880 cm^{-1}. No absorption attributable to C=C was observed although there was an intense band at 2200 cm^{-1} due to $\nu_{(C\equiv N)}$. The proton n.m.r. spectrum showed no high field resonance due to an hydridic hydrogen. It seems likely that insertion of the nitrile C=C bond into Ir—H has occurred, and again it is noticeable that one phosphine molecule has been lost. Neither acrylonitrile nor cinnamonitrile gave identifiable products other than polymeric material.

However, dimethylacetylene dicarboxylate gave a pure crystalline product containing two units of the acetylene per molecule of hydride. Loss of the hydridic hydrogen was apparent from the fact that the infrared spectrum showed no absorption in the 1800–2500 cm^{-1} region, and also that no high field signal was observed in the proton n.m.r. spectrum. The infrared spectrum showed a strong absorption at 1710 cm^{-1} which we assigned to $\nu_{(C\equiv C)}$, lowered in frequency because of coordination to iridium through the triple bond, as well as a strong band at 1535 cm^{-1} assigned to $\nu_{(C=C)}$. The appearance of a medium intensity band at 340 cm^{-1} assigned to $\nu_{(Ir-Cl)}$ is consistent with two *trans* chlorines, rather than with chlorines *trans* to phosphine or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

some other ligand. These data are all consistent with geometry **3** and this is also supported by the proton n.m.r. spectrum.



3

The phosphine ethyl protons showed a well-resolved quintet at $\delta = -0.62$ p.p.m. consistent with coupling of the $-CH_3$ protons to methylene protons and to two equivalent *trans* phosphorus nuclei, and also a broad, poorly resolved resonance centered at $\delta = -1.65$ p.p.m. presumably associated with the methylene protons. Additionally, three sharp singlets are observed at $\delta = -3.35$, -3.25, and -3.10 p.p.m., these being in the intensity ratio of 1:2:1. The total integrated intensity of these three resonances with respect to the intensities of the phosphine methylene and $-CH_3$ protons was in the ratio 2:2:3. On the basis of structure **3**, we therefore assign the singlet at -3.25 p.p.m. to the methyl protons of the coordinated acetylene, since the CH_3 groups are equivalent, and the two singlets at -3.35 and -3.10 to the protons of the two methyl groups of the substituted vinylic function.

While the above results are, in general, to be expected, they show several interesting features. In every case in which there is evidence for insertion into the Ir—H bond, with the exception of the reactions with trifluoroethylene and 3,3,3-trifluoropropyne, loss of one phosphine molecule is observed. Not only would such a loss be anticipated as the first step of a reaction with an octahedral complex such as **1**, presumably as an equilibrium

$$IrHCl_2[P(C_2H_5)_3]_3 \rightleftharpoons IrHCl_2[P(C_2H_5)_3]_2 + P(C_2H_5)_3$$

but it is also consistent with the behavior reported by Baddley and Frazer (11) for $IrH(CO)[P(C_6H_5)_3]_3$ with cyano-olefins. In those reactions, displacement of the phosphine by olefin occurs to give hydrido olefin complexes (*e.g.* where the olefin is fumaronitrile) and this is then followed by insertion into Ir—H. For this five coordinate Ir(I) hydride such displacement of phosphine is presumably necessary in order that the effective atomic number of iridium-(I) not be exceeded in the transition state; *i.e.* that the 18-electron configuration not be exceeded.

The fact that the products obtained with 3,3,3-trifluoropropyne and trifluoroethylene contain three phosphines per iridium is difficult to account for. A process consisting of loss of one phosphine, coordination of alkene or alkyne to give a hydrido π-complex, followed by insertion to form the alkyl or vinyl derivative appears possible, but there seems no reason to suppose that for these cases only, this should be followed by recombination of the third phosphine with iridium.

Another point of interest concerns the geometry of the product **3** obtained with dimethylacetylene dicarboxylate. This geometry indicates that the phosphine *trans* to the hydride is lost in the first step, presumably because of the large *trans*-influence of hydride. This may then be followed by coordination of the acetylene in that *trans* position, then by insertion in Ir—H with coordination of the second acetylene unit. Interestingly, this type of mechanism is very similar to that observed (17) for insertion of an olefin into Pt—H in the square planar geometry, *i.e.*, the most important step is displacement of the ligand *trans* to the hydride.

Quenching and Trapping of Lyman-α Fluorescence at Large Optical Depths

LEON FRANCIS PHILLIPS

Chemistry Department, University of Canterbury, Christchurch, New Zealand

Received December 18, 1972

Trapping times for 121.6 nm hydrogen resonance radiation in atomic hydrogen gas have been determined by a phase shift method. Rate constants for quenching of H atoms in the $n = 2$ level have been calculated from the measured trapping times together with the slopes of Stern–Volmer plots obtained under steady-state conditions. The results indicated that the trapping times characteristic of fluorescence decay, and of steady-state fluorescence, differed by less than a factor of two. For quenching by O_2, Ar, and He, the values of quenching cross sections obtained (all $\times 10^{-16}$ cm^2) were 30 ± 8, 0.9 ± 0.4, and 0.4 ± 0.2, respectively.

Les temps de piégeage de la radiation de résonance de l'hydrogène à 121.6 nm dans l'hydrogène atomique gazeux, ont été déterminés par la méthode du changement de phase. Les constantes de vitesse d'extinction des atomes H au niveau $n = 2$ ont été calculées à partir des temps de piégeage mesurés et des pentes des courbes de Stern Volmer obtenues à l'état stationnaire. Les résultats indiquent que les temps de captage caractéristiques de la décroissance de fluorescence et de la fluorescence à l'état stationnaire, diffèrent d'un facteur de deux au plus. Dans l'extinction par O_2, Ar, et He, les valeurs obtenues pour des sections droites d'extinction (toutes $\times 10^{-16}$ cm^2) sont respectivement de 30 ± 8, 0.9 ± 0.4 et 0.4 ± 0.2.

Trapping of resonance radiation by gaseous atoms has been the subject of a number of theoretical and experimental investigations (1–5). For the purpose of the present study the most important conclusions to be drawn from this work are that in the presence of trapping the observed decay of the resonance radiation remains exponential (2, 5) and that when trapping is significant the usual Stern–Volmer expression for fluorescence quenching

$$[1] \qquad I_0/I = \tau_0/\tau = 1 + k\tau_0[Q]$$

has to be replaced by

$$[2] \qquad I_0/I = T_0/T = 1 + kT_0[Q]$$

Here I_0 and I are the fluorescent intensity in the absence of quencher, and in the presence of a quencher whose concentration is [Q], respectively, the lifetimes τ_0 and τ are reciprocals of the observed first order rate constant for decay of fluorescence in the absence and in the presence of quencher, and k is the rate constant of the quenching reaction. When trapping occurs the natural lifetime of the excited state, τ_0, must be replaced by a trapping time T_0, and τ must similarly be replaced by T. The ratio of T_0 to τ_0 may be regarded as a particular kind of average of the number of times a primary emitted photon is reabsorbed and re-emitted before it escapes from the front of the fluorescence cell, and depends on the geometry of the system as well as on the density of absorbers in the cell.

Provided the decay of fluorescence with time t follows a single exponential of the form $\exp(-t/T)$, the use of a modulated exciting beam allows the trapping time T to be determined from the phase-shift δ between the exciting radiation and the fluorescence, by means of the formula

$$[3] \qquad \tan \delta = 2\pi fT$$

where f is the modulation frequency (6). Thus it is possible, in principle, to determine both k and T_0 by measuring the phase and amplitude of a modulated fluorescence signal as a function of [Q]. The calculations of Van Volkenburgh and Carrington (4) have shown that for systems of low or intermediate optical depth the decay of fluorescence does not in general correspond to a single exponential except at long decay times. However, their results appear to indicate that the decay approaches more closely to a single exponential at larger optical depths, so that in such circumstances the phase-shift method should still be applicable to the determination of T_0. A more serious complication is that their calculations also lead to a difference between the trapping time characteristic of the lowest fluorescence decay mode, T_0', and the value T_0 characteristic of a steady-state experiment in which I_0/I is measured. For the case of an infinite slab, with

observation of the face of the slab away from the lamp, T_0' is smaller than T_0, so that rate constants k evaluated on the assumption that $T_0' = T_0$ will be too large. For an experimental system in which observations are made at right angles to the incident beam, the relationship between T_0' and T_0 is expected to depend on the geometry of the particular experiment. For experiments reported here it appears that T_0' is greater than T_0, but the difference is less than a factor of two.

A diagram of the apparatus is given in Fig. 1. Apart from the provision for introducing a steady stream of atoms from a microwave discharge, it is the same as that used in several previous studies (7, 8). The modulating signal (10–100 kHz) for the microwave-powered hydrogen–argon lamp was derived from a Hewlett–Packard audio-frequency oscillator. The reference signal for a PAR model HR-8 lock-in amplifier was obtained from an EMI 9603B particle multiplier which observed the direct radiation transmitted by the cell. The reference signal frequency was monitored with a digital frequency meter. Cell windows (diameter 25 mm) were of magnesium fluoride. The 121.6 nm fluorescence emitted at right angles to the exciting beam was isolated with a McPherson model 218 vacuum monochromator, and detected with an EMR 541G photomultiplier. Gas flows were monitored by calibrated ball-type flowmeters; the pressure in the viewing region was measured with a Texas Instruments quartz spiral gauge. The experiments were performed at room temperature (299 ± 2 K). Hydrogen atoms were produced by discharging a mixture of helium or argon with 1–3% of hydrogen at pressures between 1.5 and 5 Torr. Under the fast-flow conditions which existed in these experiments the H_2 could be expected to be more than 50% dissociated in the viewing region. DC measurements of the Lyman-α signal, using a Keithley picoammeter, showed that trapped radiation from the atom-producing discharge entered the monochromator with almost the same intensity as the fluorescence excited by the lamp, despite the presence of a light trap and two right-angle bends between discharge and cell. The modulation system normally prevented this radiation from contributing to the measured fluorescence.

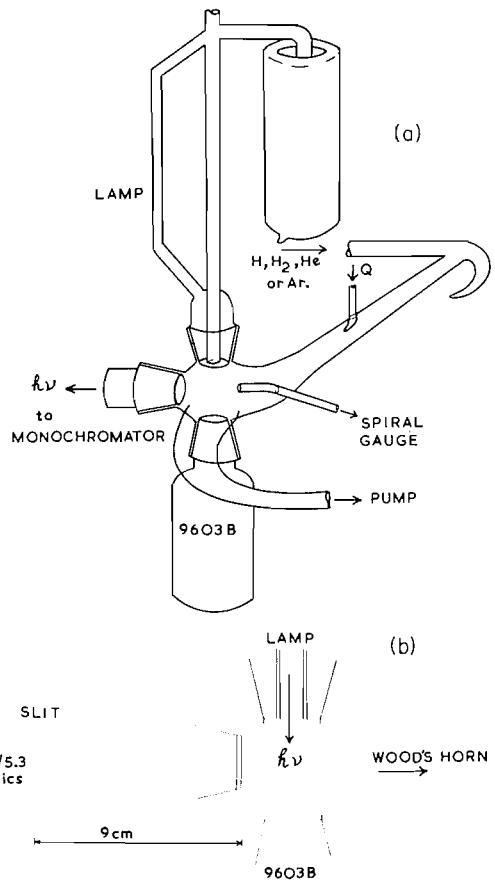

FIG. 1. (*a*) Experimental system. Magnesium fluoride windows are fastened to the glass standard-taper joints with epoxy cement. The taper joints are held together with vacuum wax. (*b*) Geometry of fluorescence cell.

Some representative Stern–Volmer plots for I_0/I, with quenching by O_2, are shown in Fig. 2. These results effectively correspond to steady-state fluorescence, since the measured phase shifts at 75 kHz and 100 kHz were all small (see Fig. 3). Values of the quenching rate constant k can be calculated from the slopes of the lines in Fig. 2 once T_0 is known. To determine T_0' the phase angle φ of the Lyman-α signal was measured, relative to an arbitrary zero phase, as a function of O_2 pressure, and a quantity Δφ was evaluated as the difference between the phase angles observed with and without quencher. If δ_0 is the phase angle corresponding to the trapping time T_0', in terms of eq. 3, then the phase angle corresponding to T' (*i.e.* in the presence of quencher) is given by

$$\delta = \delta_0 - \Delta\varphi \qquad [4]$$

According to eq. 2, and assuming $T_0 \sim T_0'$, we can write

$$\tan \delta_0/\tan (\delta_0 - \Delta\varphi) = 1 + kT_0[Q] \qquad [5]$$

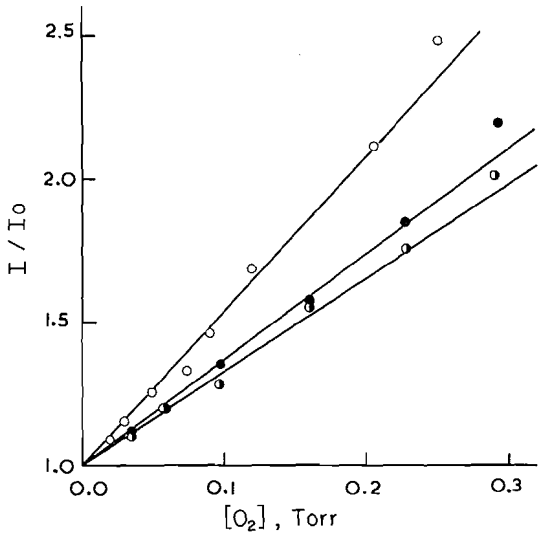

FIG. 2. Stern–Volmer plots for quenching by O_2: ○, He = 1.76 Torr, H_2 + ½H = 0.05 Torr, f = 100 kHz; ●, Ar = 2.22 Torr, H_2 + ½H = 0.06 Torr, f = 75 kHz; ◑, Ar = 3.08 Torr, H_2 + ½H = 0.08 Torr, f = 75 kHz.

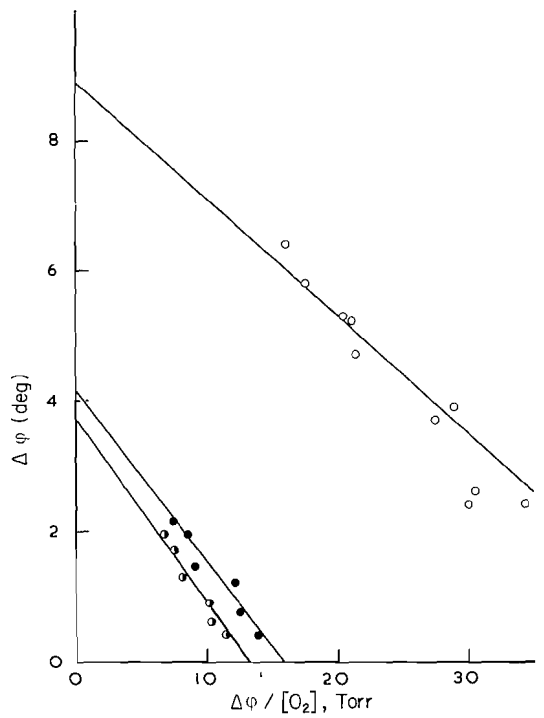

FIG. 3. Test of eq. 6 for experimental data of Fig. 2. ○, 100 kHz, $T_0 = 2.49 \times 10^{-7}$ s; ●, 75 kHz, $T_0 = 1.52 \times 10^{-7}$ s; ◑, 75 kHz, $T_0 = 1.37 \times 10^{-7}$ s.

which for small values of δ_0 reduces to

$$[6] \qquad \delta_0/(\delta_0 - \Delta\varphi) = 1 + kT_0[Q]$$

This can be rearranged to

$$[7] \qquad \Delta\varphi = \delta_0 - \Delta\varphi/(kT_0[Q])$$

Thus a graph of $\Delta\varphi$ *vs.* $\Delta\varphi/[Q]$ should be a straight line of slope $-1/kT_0$. Examples of the use of this result to determine δ_0 are shown in Fig. 3. In each case a line of the required slope (*i.e.* having slope equal to the reciprocal of the slope of the corresponding line in Fig. 2) was drawn to give the best fit with the observed points, and δ_0 was obtained from the intercept at $\Delta\varphi/[O_2] = 0$. Observed trapping times T_0 ranged from 0.8 to 2.5×10^{-7} s (the natural lifetime τ_0 is 1.6×10^{-9} s). At any given pressure the trapping time was longer when the carrier gas was helium than when it was argon. The reasonable fit of the experimental points to the lines of slope $1/kT_0$ in Fig. 3 indicates that T_0 and T_0' are not greatly different from one another. Resulting values of the quenching rate constant k, and corresponding cross-section σ (equal to k divided by $(8RT/\pi\mu)^{\frac{1}{2}}$), are given in Table 1. For argon and helium the

TABLE 1. Rate constants k (cm^3 $molecule^{-1}$ s^{-1}) and cross sections $\sigma(cm^2)$ for quenching of Lyman-α fluorescence

Quencher	$10^{11}k$	$10^{16}\sigma$
O_2	78 ± 20	30 ± 8
Ar	2.3 ± 1.0	0.9 ± 0.4
He	1.2 ± 0.6	0.4 ± 0.2

cross sections were obtained from Stern–Volmer plots for I_0/I (rather than T_0/T) using T_0 values derived from O_2 quenching measurements. The ratio of cross sections for O_2 and Ar is significantly different from the ratio of ~5 obtained previously (10). This demonstrates that the use of relative slopes of Stern–Volmer plots for I_0/I to determine relative quenching cross sections is not a reliable procedure at large optical depths. For all of these quenchers their absorption of Lyman-α radiation could be neglected. Under the conditions of these experiments the 2^2P and 2^2S levels are interconverted very rapidly, so that the rate constants refer to an equilibrium mixture of the two levels. The limits of error shown in Table 1 derive from uncertainties associated with the slopes of Stern–Volmer plots such as those in

Fig. 2, and with the δ_0 values obtained by extrapolation as in Fig. 3. These limits also give an indication of the scatter of the experimental results.

Rate constants for quenching of Lyman-α fluorescence which were previously reported from this laboratory (10) were based on theoretically estimated trapping times, and were found to be anomalously small. Braun and co-workers (11) pointed out that this was due to our having made insufficient allowance for quenching by undissociated H_2, which must have greatly reduced the trapping time from the value T_0. Braun *et al.* measured the quenching of Lyman-α fluorescence in an optically thin system, and used the natural lifetime of the ^2P level to convert the slopes of Stern–Volmer plots into rate constants. The values so obtained were very large; the reported cross sections of 84 and 62 $\times$ 10^{-16} cm^2 for H_2 and N_2, respectively, correspond to rate constant values of 2.5 $\times$ 10^{-9} and 3.6 $\times$ 10^{-9} cm^3 $molecule^{-1}$ s^{-1}, comparable in magnitude with the rates of fast ion–molecule reactions. However, similarly large values have been reported for quenching of the metastable 2^2S level (12–14). In comparison, the present results appear to be low, since O_2 is probably a more efficient quencher than H_2 or N_2 (10). If the Lyman-α emission observed by Braun and coworkers was derived partly from $H(^2S)$, as a result of electrical or other perturbations causing the transition to $H(^2P)$, the effective lifetime could have been significantly longer than τ_0. However, the difference between T_0 and T_0' is clearly the most likely cause of any discrepancy between their work and the present results. More direct observations of the decay time T_0', not dependent on the assumption of a single decay mode, appear to be required.

Fluoroalicyclic Derivatives of Cobalt Carbonyl

WILLIAM. R. CULLEN AND A. J. T. JULL

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received December 28, 1972

The compounds $(C_6H_5)_3P(CO)_3CoC{=}CCl(CF_2)_nCF_2$ (n = 2, 3) are obtained by reacting the metal carbonyl anion with the appropriate 1,2-dichloro olefin. Similar compounds are not isolated following treatment of cobalt carbonyls with $XC{=}CXCF_2CF_2$ (X = Cl or I). The new bridged complex $(CH_3)_2AsC{=}C[As(CH_3)_2](CF_2)_3CF_2Co_2(CO)_6$ is described.

Les composés $(C_6H_5)_3P(CO)_3CoC{=}CCl(CF_2)_nCF_2$ (n = 2, 3) ont été obtenus en faisant réagir l'anion du dérivé métal carbonyle avec la dichloro-1,2 oléfine appropriée. Des composés similaires n'ont toutefois pas été isolés lors du traitement de dérivés cobalt carbonyles avec $XC{=}CXCF_2CF_2$ (X = Cl ou I). Le nouveau complexe ponté $(CH_3)_2AsC{=}C[As(CH_3)_2](CF_2)_3CF_2Co_2(CO)_6$ est décrit.

The ditertiary arsine f_4fars,

$$(CH_3)_2AsC{=}CAs(CH_3)_2CF_2CF_2,$$

has a strong tendency to act as a bridging ligand when treated with metal carbonyls (1) and an example is the complex $f_4farsCo_2(CO)_6$, obtained by reaction with dicobalt octacarbonyl (2). The complex has the structure shown in Fig. 1 (3). When a cyclohexane solution of $f_4farsCo_2(CO)_6$ is warmed, one of the products isolated proved to have the structure shown in Fig. 2 (4) in which two cyclobutane rings have condensed to give the bicyclobutenyl moiety following the cleavage of two As—C bonds. It is possible that the molecule contains two hydrogen atoms, one on each of the two carbonyl bridged cobalt atoms. Cleavage of As—C bonds in complexes of this type is now recognized as not being uncommon (1). However, this is the only instance in which the residual cyclobutene moieties have been found to couple together.

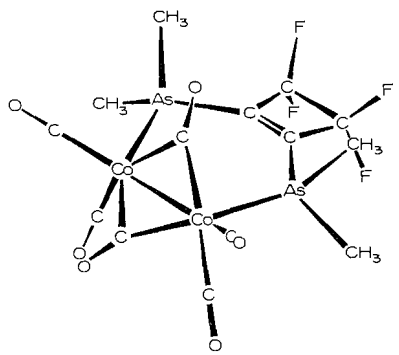

FIG. 1. The structure of $f_4farsCo_2(CO)_6$ (3).

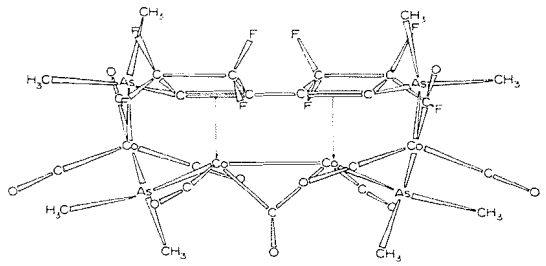

FIG. 2. The structure of $(f_4fars)_2Co_4(CO)_9(2H?)$ (4).

Since metal carbonyls can facilitate the coupling of organic halides with the elimination of metal halides (5) it seemed reasonable to attempt to couple 1,2-dihalotetrafluorocyclobutenes using cobalt carbonyl, since such studies could provide insight into the decomposition of $f_4farsCo_2(CO)_6$.

Park and co-workers (6) have recently synthesized polyhalobicyclobutenyl compounds by coupling reactions using copper bronze.

Experimental

All reactions were carried out under a nitrogen atmosphere. Infrared spectra were recorded on a Perkin–Elmer model 457 spectrophotometer. ^{19}F n.m.r. spectra were obtained using a Varian T-60 instrument, chemical shifts being reported upfield from $CFCl_3$. Mass spectra were recorded on an AEI MS-9 instrument with direct introduction of solid samples. A Mechrolab vapor pressure osmometer was used to obtain solution molecular weights in benzene. Chromatographic separations were carried out using Florisil columns. Microanalyses were performed by P. Borda of this department.

(1) Reaction of Dicobalt Octacarbonyl with 1,2-Dichlorotetrafluorocyclobutene

(a) Cyclohexane Solution

The carbonyl (2.0 g) and the 1,2-dichlorocyclobutene (1.0 g) were refluxed in cyclohexane (50 ml) for 2 h. A black solid precipitated. The solvent was evaporated and chromatography yielded a small amount of unreacted dicobalt octacarbonyl. The black solid was identified as $Co_4(CO)_{12}$ by means of its infrared spectrum.

(b) Tetrahydrofuran Solution

The carbonyl (3.5 g) and the cyclobutene (2.0 g) were refluxed in 50 ml of THF (3 h). Initial reaction between the solvent and the carbonyl was apparent. Removal of the solvent followed by chromatography gave a very small amount of an orange oil whose infrared spectrum showed bands at 2100(w), 2061(m, sh), 2051(s), 2036(s), 2019(w), 1730(vs), 1600(w), 1580(w), 1380(m), 1270(vs), 1120(s), 1080(s), 1031(m), 1011(m) cm^{-1}. A black band, identified as $Co_4(CO)_{12}$, was also eluted from the column.

(2) Reaction of Dicobalt Octacarbonyl with 1,2-Diiodotetrafluorocyclobutene

The di-iodocyclobutene was prepared following the published procedure by treating the dichloro compound with potassium iodide in dimethylformamide (6). In our hands the method gave a low yield (1.2%) of 1-chloro-2-iodotetrafluorocyclobutene and a 14.5% yield of the di-iodo derivative. The infrared and n.m.r. spectra of the latter compound were as published (6). In addition the mass spectrum showed a parent ion at $m/e = 378$ and intense peaks at 251 and 124 due to loss of iodine.

Dicobalt octacarbonyl (1.0 g) and the di-iodide (1.0 g) were refluxed in 50 ml of THF (3 h). Removal of the solvent yielded a dark solid residue. Extraction of this with cyclohexane gave a small amount of a dark red solid whose mass spectrum showed a peak at $m/e = 622$ and peaks due to the loss of 12 carbonyl groups. The infrared spectrum showed ν(CO) bands at 2087(w), 2061(vs), and 2017(m) cm^{-1}.

The remaining reaction product consisted of $Co_4(CO)_{12}$ (soluble in dichloromethane) and cobalt salts (soluble in acetone).

(3) Preparation of 1-Chlorotetrafluorocyclobuten-2-yltriphenylphosphinetricarbonylcobalt

The sodium salt $NaCo(CO)_3P(C_6H_5)_3$ was prepared by stirring a suspension of 1.5 g of the appropriate dimer in 50 ml of THF over 1% sodium amalgam for 24 h. Excess amalgam was removed in the usual way (7) and 1,2-dichlorotetrafluorocyclobutene (1.0 g) was added. After 2 h the solution was filtered and the solvent removed. Extraction of the residue with ether followed by recrystallization of the residue from petroleum ether/diethyl ether gave 0.82 g (39%) of yellow crystals of 1-chlorotetrafluorocyclobuten-2-yltriphenylphosphinetricarbonylcobalt, m.p. 110–112 °C (dec.).

Anal. Calcd. for $C_{25}H_{15}ClCoF_4O_3P$: C, 53.2; H, 2.66; mol. wt., 564. Found: C, 53.1; H, 2.64; mol. wt. (mass spec.) 564.

^{19}F n.m.r. spectrum: multiplets at 112.0 and 116.0 p.p.m. Infrared spectrum ν(CO): 2078(w), 2009(vs), 2005(vs) cm^{-1}.

In a subsequent preparation of the cyclobutenyl derivative in which the anionic solution was centrifuged to remove suspended mercury prior to addition of the olefin, a total yield of 60.2% was obtained.

(4) Preparation of 1-Chlorohexafluorocyclopenten-2-yltriphenylphosphinetricarbonylcobalt

A THF solution of the sodium salt $NaCo(CO)_3P(C_6H_5)_3$ was prepared as described above and 1,2-dichlorohexafluorocyclopentene (1.0 g) was added. After 2 h the solution was filtered and the solvent removed to leave a dark solid residue. Extraction of this solid with hexane gave a light yellow solution which yielded 0.21 g (9.5%) of light yellow crystals of 1-chlorohexafluorocyclopenten-2-yltriphenylphosphinetricarbonylcobalt, m.p. 100° (dec.) (from petroleum ether/diethyl ether).

Anal. Calcd. for $C_{26}H_{15}ClCoF_6O_3P$: C, 50.8; H, 2.44; mol. wt., 614. Found: C, 52.4; H, 2.90; mol. wt. (osmometer). 590 ± 27.

^{19}F n.m.r. spectrum: multiplets at 101.0, 113.0, 130.6 p.p.m. Infrared spectrum: ν(CO), 2074(w), 2013(vs), 1998(vs) cm^{-1}.

A further 0.19 g (8.4%) of the same compound was obtained by extracting the "hexane insoluble" residue with diethyl ether.

(5) Preparation and Decomposition of $(CH_3)_2AsC{=}C[As(CH_3)_2](CF_2)_3CF_2Co_2(CO)_6$ *[$f_8farsCo_2(CO)_6$]*

The ligand (0.55 g) (8) and dicobalt octacarbonyl (0.40 g) were stirred in 35 ml of hexane at 20 ° (3 h). The solvent was removed and chromatography of the remaining reddish solid gave an orange-brown band which eluted with petroleum ether. On concentration and cooling to −78° this solution gave 0.1 g (14%) of orange-brown crystals of $f_8farsCo_2(CO)_6$, m.p. ~90 ° (dec.).

Anal. Calcd. for $C_{16}H_{12}As_2Co_2F_8O_6$: C, 26.7; H, 1.67; mol. wt., 720. Found: C, 26.4; H, 1.59; mol. wt. (mass spec.), 720.

Infrared spectrum ν(CO): 2059(s), 1997(vs), 1817(w), 1802(m) cm^{-1}.

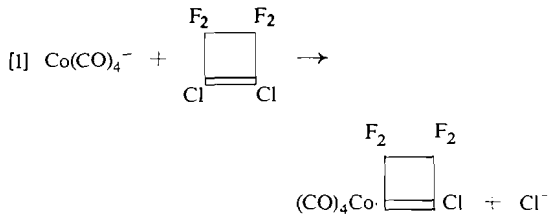
On warming a solution of $f_8farsCo_2(CO)_6$ (0.08 g) in cyclohexane (15 ml) at 58° the solution turned dark. After 45 min the solvent was evaporated to dryness to give a mixture of white and brown solids. The latter was insoluble in acetone and the former was spectroscopically identified as f_8fars.

Results and Discussion

When 1,2-dichlorotetrafluorocyclobutene is warmed with dicobalt octacarbonyl in a nonbasic solvent the only reaction that is evident is the formation of $Co_4(CO)_{12}$ which is the expected product when the dicobalt species is warmed alone (5). In more basic THF solution where carbonylcobaltates are present as well as $Co_4(CO)_{12}$ (9), reaction with the dichloride yields a small amount of an orange oil which contains Co—CO, C=C, and C—F groups although probably not all associated with one compound. Repetition of the reaction failed to increase yields of the fraction significantly. Since the $[Co(CO)_4]^-$ species was probably present in the initial reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mixture (9) it seemed possible that this could have reacted with the cyclobutene, to give a cyclobutenylcobalt compound (1, 10). Although



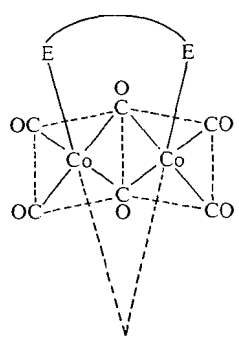
fluoroalicyclic derivatives were known for many elements (1, 11, 12) cobalt complexes had not been isolated so in order to investigate the feasibility of reaction 1 we also studied the reaction of $NaCo(CO)_4$ with 1,2-dichlorotetrafluorocyclobutene, using the deliberately prepared (13) sodium salt. Reaction 1 does not seem to occur, probably because of the low nucleophilicity of the $Co(CO)_4^-$ ion (10, 14). However, when the more nucleophilic triphenylphosphine-containing anion was prepared, reaction proceeded as anticipated, with both 1,2-dichlorotetrafluorocyclobutene and 1,2-dichlorohexafluorocyclopentene (reaction 2).

$$[2]\quad NaCo(CO)_3P(C_6H_5)_3 + ClC{=}CCl(CF_2)_nCF_2 \rightarrow (C_6H_5)_3P(CO)_3CoC{=}CCl(CF_2)_nCF_2 + NaCl \qquad (n = 1, 2)$$

Both new compounds are yellow solids, which is characteristic of simple σ bonded cobalt carbonyl derivatives (15). The cyclopentenyl derivative is not very stable in solution and was not obtained in a pure enough state to give a really satisfactory elemental analysis. However, the carbonyl infrared spectrum of the compound, which is virtually the same as the well characterized cyclobutenyl derivative, and the characteristic ^{19}F n.m.r. spectrum substantiate the formulation (10–12). The mass spectrum of the cyclobutenyl derivative showed a parent ion and peaks due to the progressive loss of three carbonyl groups. The ^{19}F n.m.r. spectrum showed the typical pattern of bands with the expected chemical shifts (10–12). The infrared spectrum is of interest in that it gives a lower limit for the frequencies expected for the product of reaction 1 since triphenylphosphine can be regarded as a poorer π-acceptor than carbon monoxide. A recent relevant example is found in $\pi\text{-}C_5H_5(CO)_2FeC{=}CClCF_2CF_2$ which has ν(CO) at 2056, 2007, and 1997(sh) cm^{-1}. Replacing one carbonyl group by triphenylphosphine lowers the frequencies to 1965(sh), 1961 cm^{-1} (12). Similarly $(CO)_5MnC{=}CF(CF_2)_3CF_2$ has ν(CO) at 2137(w), 2075(vw), 2047(vs), 2020(s) cm^{-1}, the *trans*-triphenylphosphine substituted compound at 2185(w), 2038(w), 1996(s) cm^{-1}, and the *cis*-triphenylphosphine substituted compound at 2088(s), 2015(s), 2010(s), 1970(s) cm^{-1} (16). Thus since the carbonyl infrared frequencies of the orange oil obtained from 1,2-dichlorotetrafluorocyclobutene and cobalt carbonyl in THF solution are only slightly higher than those of the products of reaction 2, 1-chlorotetrafluorocyclobuten-2-yltetracarbonylcobalt (reaction 1) is probably not present.

In an attempt to employ a compound with a better leaving group, 1,2-di-iodotetrafluorocyclobutene was heated with dicobalt octacarbonyl in THF solution. The reaction was difficult to reproduce, but in one attempt a small amount of a dark red solid was isolated whose mass spectrum indicated the formula $CF_2Co_4(CO)_{12}$. Since dicobalt octacarbonyl and tetrafluoroethylene afford the 1:1 "adduct" $(CO)_4CoCF_2CF_2Co(CO)_4$ which on warming decomposes and eventually gives $CF_3CCo_3(CO)_9$ (17, 18), breakdown of the fluorocarbon is not unexpected.

Finally we prepared the complex $f_8farsCo_2(CO)_6$ ($f_8fars = (CH_3)_2AsC{=}CAs(CH_3)_2(CF_2)_3CF_2$) in an attempt to see if the coupling reactions which occur when $f_4farsCo_2(CO)_6$ is warmed, would also occur for this compound. The carbonyl infrared spectrum of the new complex is not like that of the f_4fars derivative. The two bridging carbonyl bands are only 15 cm^{-1} apart, whereas they are 56 cm^{-1} apart in the f_4fars derivative. This is an indication that the structure of $f_8farsCo_2(CO)_6$ is the symmetrically bridged one indicated in **1** (2), where $\widehat{EE}$ represents the ligand,



1

and not the asymmetric bridged one of Fig. 1. The symmetrical bridge seems to be favoured by most fluorocarbon-bridged ligands (2, 19). On warming a cyclohexane solution of $f_8farsCo_2(CO)_6$ to 58° slow decomposition took place with liberation of the free ligand.

Studies on Hydrogen–Oxygen Systems in the Electrical Discharge. VI. Detection by Laser Raman Spectroscopy of O_2 and O_3 Trapped at 80 °K

JOSÉ L. ARNAU AND PAUL A. GIGUÈRE

Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec 10, Québec

Received October 20, 1972

Further study by Raman spectroscopy of the condensed products from electrically dissociated water vapor and other related systems has revealed the presence, not only of ozone in appreciable amounts, but also of molecular oxygen in still greater amounts trapped at 80 °K. The concentration of ozone relative to the hydrogen oxides varied somewhat with experimental conditions, and also locally due to some segregation effect in the glassy condensate. The concentration of trapped oxygen showed still wider fluctuations depending particularly on surface effects in the discharge–flow system. On warming up under vacuum the intensity of the O_2 and O_3 bands began to decrease even before the crystallization temperature was reached (about 150 °K), thereby confirming that the gas evolution at that stage is mainly a desorption process. Therefore, the often quoted ratio of total evolved O_2 to residual H_2O_2 could not be a reliable index of the formation of hydrogen polyoxides, H_2O_3 and H_2O_4, in these systems. A mechanism is proposed for the formation *in situ* of the trapped gases and in particular, for a source of oxygen atoms in dissociated water vapor.

The fundamental vibrations of the ozone molecule, $\nu_1 = 1106$, $\nu_2 = 703$, and $\nu_3 = 1036\ cm^{-1}$, were confirmed by polarization and isotope shift measurements.

Continuant l'étude par spectroscopie Raman à laser des produits de la dissociation électrique de la vapeur d'eau et autres systèmes analogues nous avons mis en évidence des quantités appréciables d'ozone, et encore plus d'oxygène moléculaire piégées à environ 80 °K. Les concentrations d'ozone variaient quelque peu avec les conditions expérimentales, et même d'un point à l'autre à cause des effets de ségrégation dans le solide vitreux. Les concentrations d'oxygène piégées variaient encore plus selon l'état des surfaces dans la décharge. En se réchauffant sous vide le dépôt vitreux accusait une diminution graduelle d'intensité des bandes de l'ozone et de l'oxygène avant même que la cristallisation ne s'amorce (vers 150 °K). On doit en conclure que le dégagement gazeux à ce stade provient surtout de la désorption plutôt que d'une réaction de décomposition. Aussi le rapport moléculaire de l'oxygène total dégagé au peroxyde d'hydrogène résiduel, O_2/H_2O_2, souvent cité comme indice de la formation des polyoxydes H_2O_3 et H_2O_4 dans ces systèmes, ne saurait être valide dans ces conditions. Les molécules piégées doivent être formées à la surface froide par réaction entre atomes et radicaux libres. Un mecanisme est proposé à cette fin qui prévoit également une source d'oxygène atomique à partir de la vapeur d'eau dissociée.

Les vibrations fondamentales de la molécule d'ozone, soit $\nu_1 = 1106$, $\nu_2 = 703$, et $\nu_3 = 1036\ cm^{-1}$ ont été confirmées par les décalages isotopiques et des mesures de polarisation.

Can. J. Chem., **51**, 1525 (1973)

Introduction

In the preceding paper of this series (1) we reported on the Raman spectra of the glassy solid formed by trapping in liquid nitrogen the dissociation products from water or hydrogen peroxide vapor and their deuterated analogs. Besides three or four new bands belonging to the polyoxides H_2O_3 and H_2O_4 we observed a weak band at $1025\ cm^{-1}$, and occasionally, a second still weaker one near $1120\ cm^{-1}$. We assigned them tentatively to the ν_3 and ν_1 modes of trapped ozone molecules. However, this required confirmation because the relative intensities were in the wrong order for such an assignment. Furthermore, ozone formation has significant implications for the mechanism of the low temperature reactions in these complex systems. In particular, the evolution of oxygen from the condensed products on warming has often been related quantitatively to the decomposition of H_2O_4 (2).

Experimental

The combined liquid nitrogen trap and laser Raman cell devised previously (1) was modified as shown in Fig. 1. Mainly the flat condensing surface was replaced by a stainless steel block with a concave mirror surface. This made it possible to vary the angle of incidence of the laser beam, from 10° near the bottom to about 30° at the top. In practice the optimum angle was near 15°. The beam was spread slightly by reflection in the glassy deposit, and then deflected upwards. Thus, only the scattered light was focused on the monochromator slit instead of the whole laser beam as before. This reduced considerably the stray light which caused so much noise with the original cell, and was also responsible, incidentally, for the two "ghost" bands erroneously assigned to ozone. In addi-

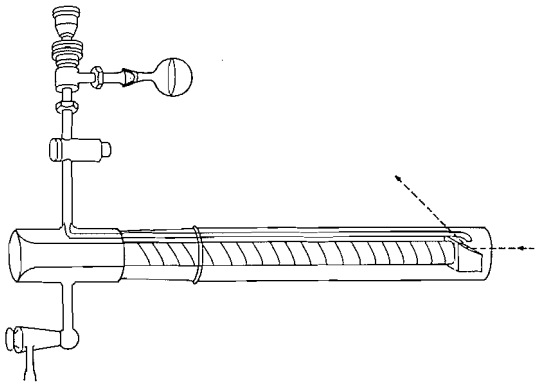

FIG. 1. Modified low-temperature Raman cell (1) for the study of vitreous matrices under laser excitation.

tion, it was now possible to get much closer to the exciting line (about 60 cm^{-1}).

Glass-clear deposits of the right thickness were needed for good quality spectra; that is with low noise level for proper resolution of the bands, and accurate polarization measurements. This required considerable attention and practice. For instance, crystallization invariably resulted from a too rapid deposition rate or the slightest disturbance; such as brief extinction of the electrical discharge, or pressure surge in the system, specks of dust from the coating of the discharge tube, imperfections in the stainless steel surface, etc. Thick deposits tended to develop minute cracks due, no doubt, to temperature gradients and improper heat transfer. To avoid fogging of the glassy deposit, once the reaction was over, it was necessary to prevent condensation of ice in the injector tube and on the coolant well by insulating the latter with tightly wound Teflon tape.

The deposition time was of the order of 4 h with dissociated water or hydrogen peroxide (98%) vapor, and only half as much with mixtures of hydrogen and oxygen gas diluted (3 to 4-fold) in argon. Indeed, with the latter system there was much less tendency of the deposit to crystallize due, probably, to a more exothermic reaction at the cold surface. It was essential to use gases of the highest purity in an absolutely airtight handling system to avoid formation of nitrogen oxides in the discharge. Their presence could easily be detected by the yellow-orange color of the deposit as well as some characteristic Raman bands; particularly in the 1300 and 600 cm^{-1} regions. A few runs were tried with hydrogen alone in the electrical discharge, the other gas being fed through a second injector opening on the other side of the cold surface. In that case, as observed before (3), the attack of the glass surface of the discharge tube was much more pronounced than in presence of oxygen. The whole injector was soon covered with a very fine white powder which greatly impaired the optical quality of the deposit. We intend to investigate this phenomenon further.

With the microwave discharge (4) the Pyrex tube had to be coated with phosphoric acid, as recommended (5), to reduce recombination of hydrogen atoms and secure a better deposit. However, this treatment was unnecessary with a radio-frequency discharge. The latter (6) was of the electrodeless type, some 300 W at 20 MHz, confined in a 100 ml Pyrex bulb. With this the glow of ionized gases extended much further; even down to the cold surface in some instances.

An ionized argon laser (Coherent Radiation, Model 52) was substituted for the helium–neon one used originally. The increased power (600 mW instead of 50 mW) coupled with the greater sensitivity of the photomultiplier cell for the green-blue light (ITT, Model FW-130) resulted in a marked improvement (over 20-fold) in signal-to-noise ratio.

Results

In Fig. 2 we have reproduced the spectrum of the condensed products from ordinary water dissociated in a microwave discharge. The strongest band, as in all cases, is that of H_2O_2 at 880 cm^{-1}. The weak shoulder at about 865 cm^{-1} is now clearly discernible. By means of ^{18}O isotope shift we have confirmed that this band, like the other weak one at 830 cm^{-1}, and the three much stronger ones at 760, 500, and 450 cm^{-1}, all belong to skeleton vibrations of the polyoxide molecules, H_2O_3 and H_2O_4. Detailed description and assignments of these bands based on intensity and polarization data, as well as of the already published infrared bands (7), will be given in a future paper. The broad scattering centered around 1470 cm^{-1} arises from the OOH bending of the various species present in the glassy condensate, as confirmed by the isotope shift on deuteration. Likewise, the much weaker one near 1620–1640 cm^{-1}, which was shifted to 1200 cm^{-1} on deuteration, must belong to the bending mode of H_2O molecules.

The other novel features in our spectra are the three fundamentals of ozone, and, quite unexpectedly, the strong one of molecular oxygen at 1551 cm^{-1}. When this work was done no data were available on the Raman spectra of condensed ozone. Since then Andrews (8) has observed them for the various isotopic species isolated in an argon matrix. The two sets of frequencies agree closely, within reasonable shifts (Table 1). However, our polarization measurements are more accurate due to the absence of scrambling effect in a clear vitreous matrix. A characteristic of these bands of trapped ozone and oxygen was that their intensities (relative, for instance, to that of the H_2O_2 band at 880 cm^{-1}) showed wide variations from one run to another. This was specially true of the oxygen band which varied almost within an order of magnitude. In the case of ozone, part of the intensity fluctuations was traced to segregation effects in the glassy deposit, as confirmed by scanning across

the latter with the laser beam. In contrast the bands of the various hydrogen oxides showed no such intensity variations.

Generally speaking the amounts of trapped ozone and molecular oxygen seemed particularly sensitive to surface conditions in the discharge-flow system. For instance, one of the best yields (Fig. 2) was achieved by dissociating ordinary water vapor with a microwave discharge in a new, uncoated Pyrex tube. In subsequent runs the yield decreased steadily; eventually a coating of phosphoric acid was required. The composition of the dissociated system had little influence on the concentration of trapped ozone and oxygen, except in the case of an excess (3 to 1) of hydrogen over oxygen, which yielded very little trapped gases. The reaction of dissociated (in the r.f. discharge) oxygen with molecular hydrogen yielded only traces of ozone. The other trapped products, including oxygen, were about in the usual ratios, but the absolute quantities were much smaller (longer deposition time) due, obviously, to the low concentration of oxygen atoms reaching the cold surface.

In one experiment the glassy deposit was allowed to warm slowly, in steps of about 10°, and then cooled back to liquid nitrogen temperature for recording the spectrum. On approaching

the maximum workable temperature, near 160 °K, the ozone and oxygen bands decreased noticeably (by roughly 20 to 30% as far as could be ascertained; the increased noise level of the spectra prevented a more accurate estimate). For that reason, and also because the crystallized deposit tended to peal off its support, it was not possible to follow the whole desorption process. The pressure of residual gas in the Raman cell, originally of the order of 10^{-4} Torr, meanwhile rose noticeably. Unfortunately, the experimental arrangement did not allow significant pressure measurements. We intend to develop a different spectroscopic technique for that purpose. Nevertheless, a vague idea of the relative concentrations of the trapped gases may be gained from the over-all intensity of the bands. In the spectra of Fig. 2 the three O—O stretching bands of (*a*) hydrogen peroxide, (*b*) molecular oxygen, and (*c*) ozone (*viz.* ν_1) are approximately in the ratios 60:6:1. As for the hydrogen polyoxides, the H_2O_4 band at 760 cm^{-1} turned out in that particular instance to have about the same intensity as the oxygen fundamental at 1551 cm^{-1}.

Discussion

The outstanding result of this investigation is certainly the confirmation, for the first time, of the trapping of substantial concentrations of molecular oxygen in the products from dissociated water vapor condensed at liquid nitrogen temperature. This had been a much debated question (for a review, *cf.* (2)) ever since the original hypothesis of Willey some forty years ago (11). The suggestion that the oxygen evolved on warming was trapped or occluded in the glassy deposit was opposed vigorously, in particular by the Russian workers, on the basis of various experimental evidence, such as thermal, diffraction, and magnetic measurements. Their results must now be reinterpreted in the light of the present finding. Thermochemical measurements, either by calorimetric (12) or thermographic methods (13) of the first exothermic reaction (beginning around 160 °K) yielded inordinately large, and rather widespread results (61 to 81 kcal/mol) when related to evolved oxygen. Much more reasonable (2.6 kcal/mol) and concordant values were arrived at when the heat effect was related to the amount of residual hydrogen peroxide in the condensate (14, 15). Furthermore, the fair agreement of that quantity with the heat of devitrification of the peroxide glass (16) confirms that a physical transformation is involved at that stage. The decomposition of the hydrogen polyoxides must begin at higher temperature: *viz.* above 200 °K (7).

As for the electron diffraction results (17), they could not provide conclusive evidence in the present case because the diffraction patterns of amorphous solids show only diffuse rings. Therefore, the absence of the characteristic lines of crystalline oxygen and ozone in the glassy deposit does not rule out the occlusion hypothesis. Magnetic susceptibility measurements are better suited to the problem at hand. Here the Russian authors (18) found only a very weak diamagnetism for the condensed product below the crystallization temperature. This seems in direct opposition to the present finding, considering the high paramagnetism of molecular oxygen ($\chi = 106 \times 10^{-6}$ e.m.u.). However, it must be noted that the measurements were made, not on the original condensate, but on the finely ground (under liquid nitrogen) solid. Such a treatment must release most of the trapped gases. In fact the slightly lower diamagnetism observed (-0.1 to -0.2×10^{-6} e.m.u.) compared to that expected for a water – hydrogen peroxide mixture, could be due to a few parts per thousand of residual oxygen.

Another objection often levelled at the occlusion hypothesis was the failure of repeated attempts to trap more than traces of oxygen in a vitreous ice or hydrogen peroxide matrix (19). We have checked this point once again by condensing in our Raman cell the vapor from a sample of concentrated hydrogen peroxide decomposing briskly on a platinum foil. Although the spectrum was of good quality no trace of any scattering by molecular oxygen could be detected under the best conditions: *viz.* with wide slits and high amplifier gain. In an elaborate investigation Ghormley (20) has succeeded in absorbing substantial amounts of oxygen (and also of nitrogen, argon, etc.) in amorphous ice having remarkably high surface area. However, he could absorb much greater amounts of oxygen from dissociated water vapor. Judging from our previous manometric measurements on various systems (3) we believe that the total gas evolved on crystallization could be as large as that from decomposition of the polyoxides.

From all the above it is clear that the trapped gas molecules must be generated *in situ* from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reactions between atoms and molecules at the cold surface. That this is so in the case of ozone has been proved abundantly (2). Now, the formation of ozone in our system requires a source of atomic oxygen. The latter could not very well be a major component of our water vapor discharges because the lifetime of oxygen atoms is too short to survive under such conditions: *viz.* the long travel (some 40 cm) between the active zone of the microwave discharge and the cold mirror. A more plausible source, on kinetics and thermodynamics grounds (21), is the following sequence of fast reactions:

[1] $$H + HO_2 \rightarrow 2OH$$

[2] $$2OH \rightarrow H_2O + O$$

As for molecular oxygen, it is generated in the recombination reactions

[3] $$2HO_2 \rightarrow H_2O_2 + O_2$$

[4] $$HO + HO_2 \rightarrow H_2O + O_2$$

the latter to a lesser extent in view of the low steady state concentration of OH. In addition, these two reactions afford the possibility of trapping the metastable intermediates H_2O_3 and H_2O_4.

Finally, another obvious conclusion from the present study is the ambiguity of the often quoted ratio of total evolved oxygen to residual hydrogen peroxide (22, 23). That this parameter cannot provide a reliable measure of the formation of hydrogen polyoxides H_2O_3 and H_2O_4 in these systems is now evident, since (*a*) a large portion of the evolved oxygen may have been occluded in the glassy deposit, and (*b*) that portion varies considerably with experimental conditions (especially surface) in the discharge–flow systems. In particular, the contention (24) that the system liquid ozone – atomic hydrogen is much superior to the others in that respect now appears unfounded.

This work was supported by research grants from the National Research Council of Canada, and the Defence Research Board of Canada. The authors are grateful to Messrs. F. Bouchard, glassblower, and G. Marier, mechanic, for the intricate construction of the Raman cell.

Determination of the Stoichiometry of the Adducts Formed between some Heterocyclic Bases and Copper(II) Bis(diethyldithiocarbamate) in Various Solvents

J. B. FARMER, F. G. HERRING,[1] AND R. L. TAPPING

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received October 30, 1972

The stoichiometry of the adducts formed between copper(II) bis(diethyldithiocarbamate) and pyridine in benzene, toluene, and chloroform and between 3-picoline, 4-picoline, and 3,4-lutidine in benzene are shown to be 1:1. The method employed is that of Scatchard using electron paramagnetic resonance studies.

On démontre que la stoichiométrie des composés formés par action d'une part du bis(diéthyldithiocarbamate) de cuivre(II) et d'autre part de la pyridine dans le benzène, le toluène et le chloroforme et de la picoline-3, de la picoline-4, et de la lutidine-3,4 dans le benzène est de 1:1. La méthode utilisée est celle de Scatchard faisant appel à des études de résonance paramagnétique électronique.

[Traduit par le journal]

Can. J. Chem., **51**, 1530 (1973)

Introduction

Recent studies (1–3) of fast Lewis acid–base equilibria between copper(II) bis(dialkyldithiocarbamate) and pyridine in benzene assumed, on the basis of chemical arguments (3), that the formation of a 1:2 adduct is unlikely. Extension of the study of reaction between copper(II) bis(diethyldithiocarbamate), $Cu(DDC)_2$, with pyridine in benzene (3) to reaction in other solvents and with different bases (4) rendered the confirmation of 1:1 adduct formation a necessity in view of the unusual "activation energy" observed in the previous study. Two of the previous studies (1, 3) have observed zero or negative "energies of activation" for the forward reaction, *i.e.* adduct formation.

The determination of adduct stoichiometry, together with the equilibrium, or formation, constant has been the subject of some attention in the past (5–9), with many authors putting undue confidence on unreliable data (6–8). The important work of Person (5) emphasized that the most reliable values for the formation constant are obtained when the concentration of the adduct (or complex) is approximately the same as that of the unbound concentration of the most dilute component. Following Person, and invoking the methods of Weber (10), Deranleau (6) presented a simple graphical method of determining the stoichiometry of simple adducts. Deranleau (6) also discussed the range of Lewis base concentration necessary to obtain both a significant graphical analysis of the experimental data and a reliable value of the formation constant. Deranleau's discussion was detailed for both optical absorption and nuclear magnetic resonance (n.m.r.) measurements, and extension to electron paramagnetic resonance (e.p.r.) follows the discussion for n.m.r. as is now shown.

We assume in the first instance that the adduct formed is simply the result of 1:1 binding between metal chelate ($Cu(DDC)_2$) and Lewis base

$$[1] \qquad A + B \rightleftharpoons AB$$

where A represents the metal chelate and B the Lewis base; then the saturation fraction, S, is defined (5) by

$$[2] \qquad S = [AB]/[A_0]$$

where $[A_0] = [AB] + [A]$. The equilibrium expression is, assuming ideality,

$$[3] \quad K = \frac{[AB]}{[A][B]} = \frac{[AB]}{([A]_0 - [AB])([B_0] - [AB])}$$

where $[B_0] = [B] + [AB]$, *i.e.* total concentration of base. The sensitivity of e.p.r. measurements together with the necessity to avoid spin–spin interactions means that the concentration of the metal complex will be typically 10^{-4} M. The base concentrations employed are 10^{-2} to 10 M so that $[B_0] \gg [A_0]$ whence $[B_0] \gg [AB]$

and consequently $K = [AB]/([A_0] - [AB])[B_0]$ to a very good approximation. In addition the fractional populations of A and AB can be written

$$[4] \quad P_A = \frac{1}{1 + K[B_0]} \quad \text{and} \quad P_{AB} = \frac{K[B_0]}{(1 + K[B_0])}$$

In an e.p.r. study of an exchanging two-site system, such as $Cu(DDC)_2$ and pyridines (1–3), the average line position, $\langle\omega\rangle$, can be expressed as the weighted average,

$$[5] \quad \langle\omega\rangle = P_A\omega_A + P_{AB}\omega_{AB}$$

Where ω_A and ω_{AB} are the Larmor frequencies of A and AB, respectively. Following n.m.r. terminology we can define an observed shift δ, such that

$$[6] \quad \delta = \langle\omega\rangle - \omega_A$$

and letting $\delta_0 = \omega_{AB} - \omega_A$ we have

$$[7] \quad \delta = P_{AB}\delta_0 = K[B_0](\delta_0 - \delta)$$

Equation 7 is the basis of the so-called Scatchard (11) plot used by Deranleau (6) in which a linear relationship between $\delta/[B_0]$ *vs.* δ confirms 1:1 adduct formation.

Consider now the conceivable situation that the square planar copper complex forms a 1:2 adduct. The chemical arguments (3) against the formation of 1:2 adducts by square planar copper(II) *bis*(chelate) are very strong but nonetheless the *stepwise* formation of a 1:2 adduct is not impossible. This stepwise formation can be written

$$A + B \rightleftharpoons AB \quad K_1$$
$$AB + B \rightleftharpoons AB_2 \quad K_2$$

and we shall assume that the overall rates of formation and dissociation of the adducts are all in the fast exchange range for the e.p.r. measurements. We emphasize here that if this were not the case *and* two adducts were formed the e.p.r. spectra observed would consist of at least two overlapping spectra, which is not the case (3). The observed average line position in the fast exchange range is (12)

$$[8] \quad \langle\omega\rangle = P_A\omega_A + P_{AB}\omega_{AB} + P_{AB_2}\omega_{AB_2}$$

whence, using detailed balancing,

$$[9] \quad \langle\omega\rangle = \frac{\omega_A + K_1[B_0]\omega_{AB} + K_1K_2[B_0]^2\omega_{AB_2}}{1 + K_1[B_0] + K_1K_2[B_0]^2}$$

and hence

$$[10] \quad \delta = \frac{(\omega_{AB} - \omega_A)K_1[B_0] + (\omega_{AB_2} - \omega_A)K_1K_2[B_0]^2}{1 + K_1[B_0] + K_1K_2[B_0]^2}$$

The behavior of eqs. 7 and 10 will now be discussed.

Discussion

Deranleau pointed out (6) that a graphical presentation of optical absorption, n.m.r., or e.s.r. data is most illuminating when a Scatchard-type (11) plot is used. Such a plot is simply a plot of $\delta/[B_0]$ *vs.* δ over a suitable range of base concentration. Deranleau (6) noted that for meaningful and reliable estimates of K (or K_1 and K_2), the saturation fraction, $S(=\delta/\delta_0)$, must cover the range $0.2 \leq S \leq 0.8$, which in turn means $0.2\delta_0 \leq \delta \leq 0.8\delta_0$. Thus if reliable estimates of ω_A and ω_{AB} can be made then the experiments must be designed so that

$$0.2(\omega_{AB} - \omega_A) \leq (\langle\omega\rangle - \omega_A) \leq 0.8(\omega_{AB} - \omega_A)$$

In many cases (8) the saturation fraction covered by some experimentalists is $0 < S \leq 0.4$ and often $0 < S \leq 0.2$. In the present work on the adducts formed between $Cu(DDC)_2$ with several pyridines in benzene, toluene, and chloroform, S always covers the prescribed range.

An examination of eq. 7 shows that a Scatchard plot will be linear over the entire S range if the 1:1 model is applicable to the exchange system being examined. In order to investigate the effect of two equilibria on a plot of $\delta/[B_0]$ *vs.* δ we chose values of ω_A, ω_{AB}, and ω_{AB_2} that might be expected for CuL_2, CuL_2B, and CuL_2B_2 and then varied K_1 and K_2 to obtain values of δ from eq. 10.

The resultant Scatchard plots are shown in Fig. 1 and correspond to the particular choice $2(\omega_A - \omega_{AB}) = (\omega_A - \omega_{AB_2})$ with the ratio (K_1/K_2) varying from (0.38/0.0) to (0.38/1.0). The curves in Fig. 1 are highly nonlinear except for the special case $K_1 = 4K_2$. That such a situation could obtain was pointed out by Deranleau (6), but it must be emphasized that the linear plot in a two step equilibrium demands that both $K_1 = 4K_2$ *and* $(\omega_A - \omega_{AB_2}) = 2(\omega_A - \omega_{AB})$. These latter conditions are somewhat specialized

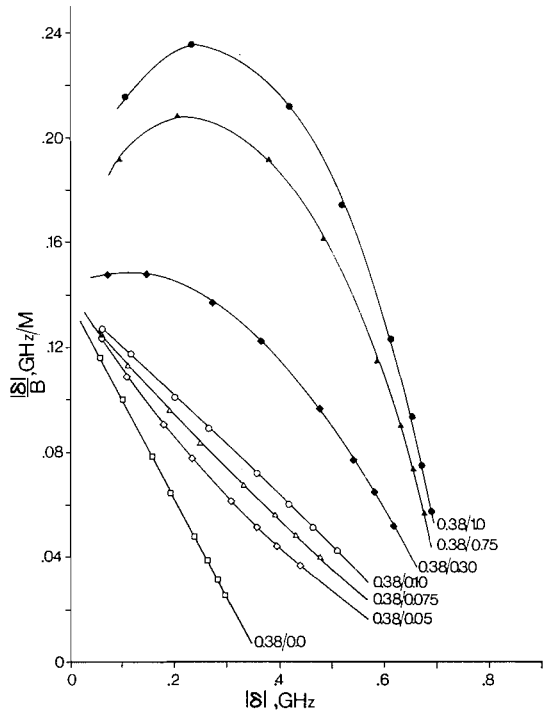

FIG. 1. Scatchard plots for a two equilibrium system. The numbers next to the curves indicate the values of K_1 and K_2 used (K_1/K_2).

and refer to a condition of equivalent and independent binding sites being available. It may be noted that for stepwise complex formation processes, such as that being considered here, the sites represented as AB and AB_2 are neither independent nor equivalent. However should it arise that $K_1 = 4K_2$ and $(\omega_{AB_2} - \omega_A) = 2(\omega_{AB} - \omega_A)$ then, of course, the Scatchard plot will be linear and an ambiguity will exist. In such a circumstance additional data are required to decide between 1:1 stoichiometry or stepwise 1:2 stoichiometry; this point will be discussed later. In passing we note that the special case $(\omega_{AB_2} - \omega_A) = (\omega_{AB} - \omega_A)$ and $K_1 \neq K_2$ will lead to highly non-linear Scatchard plots as might be expected. That this and the previous special case give rise to such slopes can be deduced by making the appropriate substitutions into the equation for the slope

$$-d(\delta/[B_0])/d\delta = \{K_1(\omega_{AB} - \omega_A) - K_2(\omega_{AB_2} - \omega_A) + 2K_1K_2(\omega_{AB} - \omega_A)[B_0] + K_1K_2^2(\omega_{AB_2} - \omega_A)[B_0]^2\}/\{(\omega_{AB} - \omega_A) + 2K_2(\omega_{AB_2} - \omega_A)[B_0] + K_1K_2(\omega_{AB_2} - \omega_{AB})[B_0]^2\}$$

The slope of a Scatchard plot for a 1:1 binding system is equal to $-K$ and the intercept $K\delta$. Thus such plots can be used to determine K and δ_0 provided that the special case outlined above can be ruled out. An alternative procedure, which has been applied previously (3), is to least squares fit eq. 5 in conjunction with eqs. 4 allowing free variation of ω_{AB}, ω_{AB}, and K. This latter method requires that the 1:1 binding model be established and this can be achieved using the Scatchard plot provided that the above ambiguity can be removed (see below).

The Scatchard plot requires a knowledge of ω_A, the Larmor frequency of the free Lewis acid. The procedure that we have adopted to determine this value is to extrapolate the curve of $\langle\omega\rangle$ *vs.* $[B_0]$ to zero base strength. The reason for doing this rather than measuring ω_A in pure solvent is that the curve of $\langle\omega\rangle$ *vs.* $[B_0]$ does not extrapolate smoothly to $[B_0] = 0$; this is illustrated in Fig. 2. We observe that ω_A measured in neat solvent is less than the extrapolated value at zero base concentration. Figure 2 shows that as $[B_0] \leq [A_0]$ the curve of $\langle\omega\rangle$ *vs.* $[B_0]$ turns down toward the value of ω_A measured in pure solvent (benzene was the solvent used in Fig. 2). As is expected the least squares fitting procedure in which $[B_0] > [A_0]$ led to values of ω_A equal to the extrapolated value of ω_A; in addition it was found that the ω_A values obtained from the least squares fitting are independent of solvent to within experimental error. This fact leads us to postulate that the downward turn of $\langle\omega\rangle$ is a manifestation of a change of solvation of the complex on going from the situation when $[B_0] > [A_0]$ to $[B_0] \leq [A_0]$. The ω_A's obtained

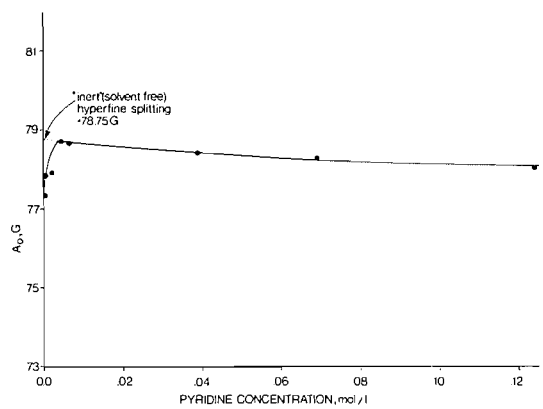

FIG. 2. Variation of the isotropic hyperfine coupling constant of copper(II) bis(diethyldithiocarbamate) with pyridine concentration in benzene.

TABLE 1. Comparison of formation constants obtained from Scatchard plots and least squares analysis of eq. 6

System	Scatchard (mol^{-1})	Least squares (mol^{-1})
$Cu(DDC)_2$ and pyridine in toluene at 280 °K	0.70	0.67
$Cu(DDC)_2$ and pyridine in benzene at 300 °K	0.35	0.38
$Cu(DDC)_2$ and pyridine in chloroform at 320 °K	0.14	0.15
$Cu(DDC)_2$ and 3-picoline in benzene at 310 °K	0.36	0.37
$Cu(DDC)_2$ and 4-picoline in benzene at 310 °K	0.48	0.46
$Cu(DDC)_2$ and 3,4-lutidine in benzene at 310 °K	0.69	0.71

by extrapolation or least squares fitting (3) can in some sense be regarded as solvent-interaction-free parameters and this is borne out experimentally (*e.g.* ω_A is 59.587, 59.578, 59.588 $\times$ 10^9 s^{-1} in benzene, toluene, and chloroform at 300 °K, respectively). We can note here that the formation constants obtained from the Scatchard plots are identical, to within experimental error, to those obtained from the least squares analysis; that this is so is demonstrated by the data in Table 1.

The problem of determining ω_A outlined above does not appear to occur to any appreciable extent in n.m.r. studies. It should also be emphasized that this problem does not invalidate the establishment of stoichiometry since any value of $\langle\omega\rangle$ could be used as an end-point. To illustrate let $\delta' = \langle\omega\rangle - \langle\omega\rangle'$

where $$\langle\omega\rangle' = \omega_A + \alpha$$

then eq. 7 becomes, with $\delta_0' = (\omega_B - \langle\omega\rangle')$

$$\delta' = K[B_0](\delta_0' - \delta')$$

then

$$\delta = K[B_0](\delta_0 - \delta) + \alpha$$

and it is apparent the correction α will not destroy the linearity of the Scatchard plot if the model is 1:1.

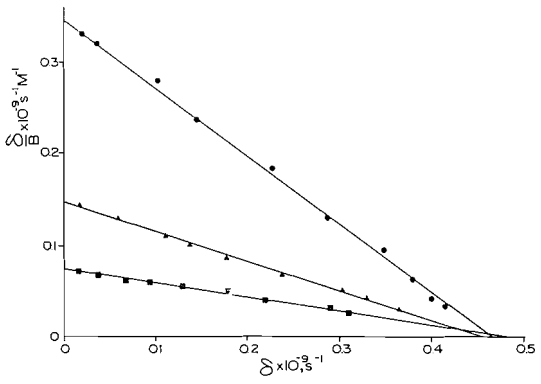

FIG. 3. Scatchard plots for copper(II) bis(diethyldithiocarbamate) and pyridine in benzene (triangles), toluene (circles), and chloroform (squares).

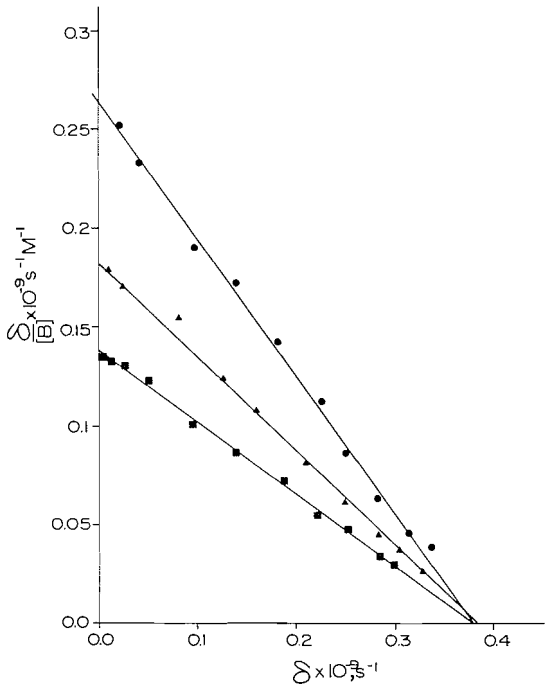

FIG. 4. Scatchard plots for copper(II) bis(diethyldithiocarbamate) and 3,4-lutidine (circles), 4-picoline (squares), and 3-picoline (triangles) in benzene at 310 °K.

The results of carrying out Scatchard plots for the systems $Cu(DDC)_2$ and pyridine in benzene, toluene, and chloroform and $Cu(DDC)_2$ and 3- and 4-picoline, and 3,4-lutidine in benzene are shown in Figs. 3 and 4.

The observed linearity shows that either 1:1 adducts are formed in all cases or that in all cases the special condition that $K_1 = 4K_2$ and $(\omega_{AB_2} - \omega_A) = 2(\omega_{AB} - \omega_A)$ obtains. The latter is very unlikely and can be ruled out on the basis of other e.p.r. evidence.

The rate of chemical exchange is dependent on temperature so that by carrying out experiments

For personal use only.

at suitable low temperatures all sites contributing to the higher temperature fast-exchange-averaged spectrum will be detected. If the particular condition $4K_2 = K_1$ and $(\omega_{AB_2} - \omega_A) = 2(\omega_{AB} - \omega_A)$ occurs then the high sensitivity of the e.p.r. measurements will certainly detect resonances from all three sites, expecially since the line positions should be well separated due to the required conditions on ω_A, ω_{AB}, and ω_{AB_2}. It may be argued that the relative shifts in ω_A, ω_{AB}, and ω_{AB_2} could be so small that only one broad line for each hyperfine component ($I = 3/2$ for both copper isotopes) will be seen; then, of course, the ambiguity will persist. The observation of any separation will obviously rule out this special case. The results of experiments carried out by Corden and Rieger (1), Shklyaev and Anufrienko (2), and in this laboratory (13), however, demonstrate that apparently two sites are resolvable. Thus the special case $(\omega_{AB_2} - \omega_A) = 2(\omega_{AB} - \omega_A)$ can be discounted and so can the situation that $(\omega_{AB_2} - \omega_A) = (\omega_{AB} - \omega_A)$ and all other two step processes since the Scatchard plot would not be linear in such cases (see above). The fact that one of the exchange sites is $Cu(DDC)_2$ is confirmed by the observation that the isotropic hyperfine coupling constant computed from the Larmor frequencies obtained from the least squares analysis is 78.7 ± 0.2 G and that measured from the e.p.r. spectrum of $Cu(DDC)_2$ in the solid state is 81 ± 1.0 G (14).

The above collection of evidence we feel demonstrates convincingly that in all the cases studied here 1:1 adducts are formed exclusively. The "negative activation energy" observed (3) for the forward rate constant cannot, therefore, be due to multiple equilibria of the type considered here.

Experimental

E.p.r. spectra were recorded on a Varian E-4 X-band spectrometer equipped with a Varian V6040 variable temperature accessory. Field and frequency measurements, and temperature calibration, are as detailed previously (3).

Solvents and bases used were spectrograde where possible (Fisher, Eastman–Kodak), and highest available purity otherwise (3,4-lutidine, Eastman–Kodak). N.m.r. and gas chromatographic analysis failed to detect any significant impurities, and all solvents and bases were kept dry after opening. Sample preparation and spectral analysis were as reported earlier (3).
