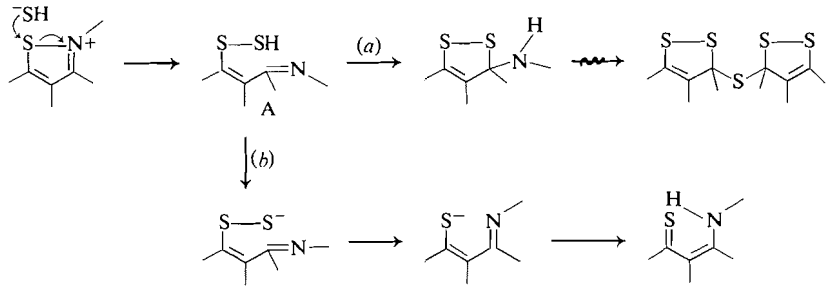
Sykes and Ullah (9) found that attack of hydrogen sulfide on the isothiazolium system in aqueous solution gave bis-1,2-dithiol-3-yl sulfides **6** instead of reduction products. Accordingly, we treated a number of the isothiazolium salts with hydrosulfide ion in ethanol, or hydrogen sulfide in water, and examined the products. Little difference if any was found in the reaction products derived from either method, and the course of the reaction appears to depend mainly on whether the original isothiazolium salt is *N*-aryl or *N*-alkyl substituted. The former give mainly reduction products, β-aminopropenethiones or derivatives **2**, while the latter give reduction, bis-1,2-dithiol-3-yl sulfides **6**, or 1,2-dithiole-3-thione **4** products.

The differences in the products obtained probably arise from changes in the mechanism shown in Scheme 1.

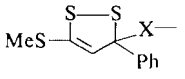
The intermediate disulfide imine A could either



SCHEME 1

add to the imine group (path a), to give an aminodithiole, with eventual formation of a bis-dithiolyl sulfide, or extrude sulfur (path b) to give a β-aminothione derivative. For aliphatic imines A the former would be the preferred route, but where the imine is stabilized by conjugation with an aromatic ring, the latter would be preferred, leading to an acyclic reduction product. Path a is analogous to a step in the formation of 1,2-dithiolium salts from 1,3-diketones with hydrogen disulfide in acidic media (14), while path b is analogous to steps in the known reactions of 1,2-dithiolium salts with bases, particularly with primary aromatic amines (17). In path a, the conversion of the aminodithiole to the sulfide could be accomplished by nucleophilic exchange between the aminodithiole and hydrogen sulfide, as has been suggested (17) for reactions of 1,3-dithioles. Intermediate formation of a 1,2-dithiolium cation (9) may be involved.

With one compound, 2-methyl-5-methylthio-3-phenylisothiazolium perchlorate (**1***h*) the acyclic reduction product **2***d* was obtained. The other product isolated was not a bis-dithiolyl sulfide, but was 5-phenyl-1,2-dithiole-3-thione (**4***b*). While the exact mechanism leading to this is unknown, it is not unreasonable that it could be derived from a compound of the type



X = S or NHMe

formed by cyclization of the intermediate disulfide suggested in Scheme 1. The reactions leading to the formation of **2***d* and **5***b* from isothiazolium salt **1***h* and of **2***g* and **4***b* from **1***f* likely follow a similar scheme.

The isolation of only the thione **4***a* from reaction of the isothiazolium salt **1***k*, instead of a sulfide **6***b*, presents some difficulty. However, the thione does appear to be derived from the sulfide since prolonged treatment of the latter with hydrogen sulfide or sodium hydrosulfide gave thione. The necessary oxidation could be accomplished by unreacted isothiazolium salt, intermediate dithiolium cation as suggested above, or by sulfur arising from decomposition of either of these.

Treatment of two isothiazolium salts **1***e* and **1***b* with sodium benzenethiolate in ethanol gave reduction products **2***b* and **2***d* respectively, and diphenyldisulfide. These results are comparable to other such studies made (9).

Experimental

The i.r. spectra were obtained on a Perkin–Elmer model 337 spectrophotometer in liquid paraffin mulls. The n.m.r. spectra were obtained on a Varian Model 56/60A spectrometer and, unless otherwise stated, in deuterochloroform at 40°, using tetramethylsilane as an internal standard. Mass spectra were obtained on a Finnegan 1015 quadrupole mass spectrometer. T.l.c. was performed using "Camag" silica gel D.S.F.5, and column chromatography on alumina 506-C-1, Brockman activity 1, both supplied by Mondray Ltd. Development of both, unless otherwise stated, was by benzene. Melting points were obtained on a Fisher–Johns melting point apparatus.

*Preparation of 2-Methylisothiazolium Perchlorate (**1***a*)*

Isothiazole (0.85 g, 0.01 mol) and dimethyl sulfate (1 ml) were heated at 100° for 1 h. The mixture was treated with ether and the precipitated oil dissolved in acetic acid, and treated with 70% perchloric acid (0.5 ml). Colorless needles, m.p. 145°, were obtained (61%). A sample of the perchlorate treated with aqueous sodium iodide gave the iodide identical (mixed m.p. and i.r.) with an authentic sample (10).

Reaction of 3-Methylthio-5-phenyl-1,2-dithiolium Iodide with Methylamine

This reaction was performed as described (12) except that the equivalent quantity of 40% ethanolic methylamine solution was used. Work-up gave 5-phenyl-1,2-dithiole-3-thione, methyl β-methylaminodithiocinnamate, and 2-methyl-5-phenylisothiazoline-3-thione as described. When the reaction was performed with a fourfold excess of the

The mass spectrum: M^+ 206, calcd. 206, 173 (M—SH)

*Preparation of 2-Methyl-5-methylthio-3-phenylisothiazolium Perchlorate (**1h**)*

Methyl β-methylaminodithiocinnamate (446 mg, 2 mmol) in ethanol (5 ml) was treated with saturated iodine solution until there was a slight permanent cloudiness. 70% perchloric acid (1 ml) was added, and dilution with ether produced yellow crystals. The product was recrystallized from acetic acid containing perchloric acid as yellow needles, m.p. 184–186 (83%).

Anal. Calcd. for $C_{11}H_{12}NS_2ClO_4$: C, 41.05; H, 3.73; N, 4.35; S, 20.55; Cl, 11.05. Found: C, 41.07; H, 3.86; N, 4.23; S, 20.08; Cl, 10.92.

N.m.r. (dimethylsulfoxide-d_6) τ 7.21 (3H singlet, the S—CH_3 group), 5.99 (3H singlet, the N—CH_3 group), 2.51–2.15 (5H bands, the aromatic protons).

Treatment of 2-Methyl-5-phenylisothiazoline-3-thione with Methylamine

The thione (50 mg) and 40% methylamine solution in ethanol (1 ml) were refluxed together 1 h. The starting material was recovered on work-up.

*Reaction of 3-Methylthio-4,5-diphenyl-1,2-dithiolium Iodide with Methylamine, 2-Methyl-4,5-diphenylisothiazoline-3-thione (**3b**)*

The salt (4.28 g, 0.01 mol) in tetrahydrofuran (70 ml) was treated with 60% methylamine solution in ethanol (6 ml) at room temperature and stirred until homogeneous. The solution was evaporated, and the residue chromatographed in benzene on 5% deactivated alumina. Two bands were obtained. A red band gave 4,5-diphenyl-1,2-dithiole-3-thione (31%), and a strongly adsorbed yellow band was extracted with acetone. Evaporation gave a yellow solid which was recrystallized from ethanol as pale-yellow needles, m.p. 133° (28%).

Anal. Calcd. for $C_{16}H_{13}NS_2$: C, 67.85; H, 4.59; N, 4.94; S, 22.62. Found: C, 67.82; H, 4.45; N, 5.01; S, 22.81.

N.m.r. τ 6.21 (3H singlet, the methyl protons), 2.53–2.87 (10H bands, the aromatic protons).

The mass spectrum: calcd. M^+ 283. Found, 283.

*Preparation of 2-Methyl-5-phenylisothiazolium Perchlorate (**1b**)*

(a) From 2-Methyl-5-phenylisothiazoline-3-thione

Powdered thione (103.5 mg, 0.5 mmol) in acetic acid (4 ml) was treated with 30% hydrogen peroxide (0.15 ml). The solid dissolved almost immediately and the solution became dark yellow. After 1 h, the solution was treated with ether, and the precipitated oil treated with 70% perchloric acid (0.1 ml). The oil solidified and was recrystallized from acetic acid as pale-yellow plates, m.p. 144–145° (80%). Identical mixed m.p. and i.r. with an authentic specimen (11).

(b) From 3-Phenyl-1,2-dithiolium Perchlorate

The perchlorate (1.035 g, 5 mmol) in ethanol (10 ml) was treated with 40% ethanolic methylamine solution (2 ml) and warmed gently with stirring until homogeneous. The red solution was treated with saturated ethanolic iodine solution (2 ml), and 70% perchloric acid (1 ml) added. Dilution with ether and scratching gave a brown precipitate which was recrystallized from acetic acid containing perchloric acid as yellow plates, identical (mixed m.p. and i.r.) with the above (20%).

*Preparation of 2-Methyl-4,5-diphenylisothiazolium Perchlorate (**1d**)*

(a) From 2-Methyl-4,5-diphenylisothiazoline-3-thione

This reaction was performed as for the previous synthesis. Pale-yellow needles, m.p. 99°, were obtained (75%). Identical (mixed m.p. and i.r.) with an authentic specimen (8).

(b) From 3,4-Diphenyl-1,2-dithiolium Perchlorate

This reaction was carried out as described for the previous compound, except that recrystallization was effected from acetone containing perchloric acid. Pale-yellow needles of the salt were obtained (25%), identical (mixed m.p. and i.r.) to an authentic specimen.

*Preparation of 5-Methylthio-2,4-diphenylisothiazolium Perchlorate (**1g**)*

2,4-Diphenylisothiazoline-5-thione (8) (0.566 g, 2 mmol) in *n*-butyl acetate (10 ml) was treated with methyl iodide (2 ml) and allowed to stand. An oily precipitate which was deposited initially crystallized on further standing. The mixture was diluted with ether, filtered, and the salt converted to the perchlorate in acetic acid containing perchloric acid. Recrystallization from acetic acid gave pale-yellow prisms, m.p. 158°, identical (mixed m.p. and i.r.) with an authentic specimen (8).

Reaction of Isothiazolium Salts with Sodium Benzoylacetate: General Method

The isothiazolium salts (~1 mmol) were added to a suspension in ethanol of sodium benzoylacetate (~1.5 mmol) (prepared by addition of benzoylacetic acid (18) to a molar solution of sodium ethoxide in ethanol). The mixture was stirred and gently warmed until homogeneous. The mixture was diluted with water and the ether extract dried. Evaporation gave either crystalline material directly or oils which were purified by t.l.c. prior to crystallization. Products were recrystallized from ethanol or ethanol–benzene, 1:1, mixture. Reactions and products are summarized in Table 1.

Treatment of salt **1*f*** with sodium benzoylacetate gave an oily product which on examination by t.l.c. gave the thiophene **5*e***. The first band on elution gave 30 mg of an orange oil, whose n.m.r. had a broad band at −4.5 τ, typical of β-aminoenethiones (9, 22). This was not analyzed, but an iodine oxidation in the presence of perchloric acid gave back salt **1*f***, confirming its structure as **2*g***.

TABLE 2. Reactions of isothiazolium salts with sodium hydrosulfide (method a) or hydrogen sulfide (method b)

†This could not be isolated sufficiently pure for analysis, and was converted by treatment with perchloric acid into 3,4-diphenyl-1,2-dithiolium perchlorate (11), similarly to known methods (17).
‡Identified by conversion (I_2, $HClO_4$) to 1*f*.
§Reference 11.
‖Reference 8.

Reactions of Isothiazolium Salts with Hydrogen Sulfide or Sodium Hydrogen Sulfide

(a) The isothiazolium salts (~1 mmol) in ethanol (10 ml) were treated with equivalent quantities of ethanolic molar sodium hydrosulfide solution, and stirred until homogeneous. The solutions were diluted with water and ether-extracted.

(b) The salts (~1 mmol) in water suspension were treated with hydrogen sulfide and boiled 10 min. The mixtures were cooled and ether-extracted.

The ether extracts from *a* or *b* were dried, evaporated, and examined by t.l.c. The results are summarized in Table 2. There was little to choose between the two methods, and yields and products by each were comparable when performed on identical compounds.

*Reaction of 2,3,5-Triphenylisothiazolium Perchlorate (**1e**) with Sodium Benzenethiolate*

The isothiazolium salt (613.5 mg, 1 mmol) in ethanol (20 ml) was treated with the equivalent quantity of sodium benzenethiolate in ethanol (1 ml), and stirred until homogeneous. The dark-red solution was diluted with water and extracted with ether. Chromatography afforded 1-anilino-1,3-diphenylprop-1-ene-3-thione (81%) identical (mixed m.p. and i.r.) with an authentic sample (17). Diphenyl disulfide (89 mg) was also isolated from the reaction mixture.

*Reaction of 2-Methyl-5-methylthio-3-phenylisothiazolium Perchlorate (**1h**) with Sodium Benzenethiolate*

The reaction, performed as above, gave methyl β-methylaminodithiocinnamate (59%), identical with an authentic specimen (12).

Reaction of Bis-4-phenyl-1,2-dithiol-3-yl Sulfide with Hydrogen Sulfide

The sulfide (0.2 g) (23) in water (10 ml) was boiled and a stream of hydrogen sulfide passed through. After 10 min the mixture was cooled and ether-extracted. The extract on examination by t.l.c. gave unreacted material, and 4-phenyl-1,2-dithiole-3-thione **4***a* (30%). Boiling of the sulfide with sodium hydrogen sulfide gave similar results.

The authors are very grateful to the National Research Council of Canada for financial support of this research. We also wish to thank Mr. M. Arneson for the preparation of mass spectra and Mr. R. Dickenson for the preparation of n.m.r. spectra.

The Geometrical Dependence of Experimental and Theoretical Nuclear Spin–Spin Coupling Constants in the $^{15}NH_2$ Fragment

RODERICK E. WASYLISHEN[1]

National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Maryland 20014

AND

T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received April 6, 1973

Approximate molecular orbital theory at the INDO level of approximation has been used to examine $^1J(^{15}N,H)$ and $^2J(HNH)$ in ammonia as a function of the HNH angle. The couplings are very sensitive to the value of the HNH angle in the range from 110 to 120°. The computed trends are compared with those observed in other compounds containing the $^{15}NH_2$ fragment. The signs and magnitudes of $^1J(^{15}N,H)$ and $^2J(HNH)$ have been measured for 2-aminoacetophenone at temperatures where the amino protons are nonequivalent. The observed and calculated results suggest that the amino group lies in the plane of the benzene ring. In aniline the magnitude of $^2J(HNH)$ lies between 1 and 2 Hz and on the basis of the trends in the calculated and experimental values the sign can be confidently taken as negative.

La théorie approchée de l'orbitale moléculaire au niveau d'approximation INDO a été utilisée pour examiner $^1J(^{15}N,H)$ et $^2J(HNH)$ dans l'ammoniac en fonction de l'angle HNH. Les couplages sont très sensibles à la valeur de l'angle HNH dans l'intervalle 110–120°. Les tendances calculées ont été comparées à celles observées pour d'autres composés contenant le fragment $^{15}NH_2$. Les signes et amplitudes de $^1J(^{15}NH)$ et $^2J(HNH)$ ont été mesurés pour l'amino-2 acétophénone aux températures où les protons de l'amine ne sont pas équivalents. Les résultats observés et calculés suggèrent que le groupe amino est dans le plan du cycle benzènique. Dans l'aniline l'amplitude de $^2J(HNH)$ vaut 1 à 2 Hz et sur la base des valeurs calculées et expérimentales prévues, le signe peut être pris négatif en toute confiance.

Introduction

Experimental data on one-bond $^{15}N,H$ spin–spin coupling constants, $^1J(^{15}N,H)$, in the $^{15}NH_2$ fragment (1–3) vary from −61.2 Hz in ammonia (4) to −92.6 Hz in $(C_6H_5)_2C{=}\overset{+}{N}H_2$ (5). The variations have been interpreted on the basis that $^1J(^{15}N,H)$ is linearly related to the % 2s character of the N—H bonding orbitals. By taking $\overset{+}{N}H_4$ as an sp^3 hybridized system and $(C_6H_5)_2C{=}\overset{+}{N}H_2$ as an sp^2 hybridized system, Binsch and co-workers (5) deduced the empirical relationship

$$[1]\quad \%\ 2s\ \text{character} = 0.43\ ^1J(^{15}N{-}H) - 6$$

Recently Axenrod *et al.* (6) used this relationship to interpret $^1J(^{15}N,H)$ values observed in a large number of substituted anilines. $^1J(^{15}N,H)$ values varied from −74.8 Hz (4-$N(Me)_2$ in $CDCl_3$) to −92.6 Hz (2,4-$(NO_2)_2$ in DMSO). On the basis of eq. 1 the authors suggested that the nitrogen hybridization state changes from essentially sp^3 in the presence of strongly electron-donating substituents such as 4-$N(Me)_2$, to sp^2 in the presence of strongly electron-withdrawing substituents.

Similar conclusions had earlier been reached by Randall and co-workers (6*b*, 6*c*). *Ab initio* molecular orbital (MO) calculations indicate that para substitution by π electron acceptors flattens the nitrogen pyramid and that π electron donors have the opposite effect (6*d*).

Equation 1 and similar relationships (7–12), including those which relate $^1J(^{13}C,H)$ to "carbon 2s character", can be rationalized either by localized MO theory (11) or by valence bond theory (12). McConnell's (13) MO formulation gives

$$[2]\quad J_{XH} = (4/3)^2 h\beta^2\gamma_X\gamma_H(\Delta E)^{-1}s_X^2(0)s_H^2(0)P^2_{s_Xs_H}$$

In this expression β is the Bohr magneton, $s_X^2(0)$ is the 2s orbital density at the nucleus,

[1]NRCC Postdoctorate Fellow, 1972–73.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

X (where X = ^{13}C or ^{15}N), $s_H^2(0)$ is the orbital density at the proton, ΔE is a mean "excitation energy", and $P_{s_X s_H}$ is the s_X,s_H element of the bond-order matrix.

If the factor $s_X^2(0)\ s_H^2(0)\ (\Delta E)^{-1}$ does not vary from one molecule to another then ^1J(X,H) is linearly related to $P^2_{s_X s_H}$, assuming that the Fermi contact mechanism dominates. The use of simple relationships between $^1J(^{13}C,H)$ and carbon hybridization or "% 2s character" has been criticized (10, 11, 14–16).[2] In some cases variations in $^1J(^{13}C,H)$ have been accounted for in terms of changes in effective nuclear charge, $s_c^2(0)$ (16).

The more general MO theory of Pople and Santry (17) does not make the average energy approximation, but there are other problems (18). Valence bond methods share some of the problems encountered by the MO methods (19).

Recently Pople and co-workers (18, 20, 21) have developed a finite perturbation technique which allows the calculation of coupling constants without making some of the approximations inherent in the earlier MO methods. The application of this technique using unrestricted INDO MO wave functions in an approximate SCF framework has been described (22–24). Briefly, the Fermi contact contribution to nuclear spin–spin coupling between two nuclei, A and B, is given by the equation

$$[3]\quad J_{AB} = h/2\pi[(8\pi/3)\beta]^2\gamma_A\gamma_B s_A^2(0)s_B^2(0) \times [(\partial/\partial h_B)\rho^{spin}_{s_A s_A}(h_B)]_{h_B=0}$$

The parameter h_B is the perturbation due to the nuclear moment μ_B and has the form, $h_B = 8/3\pi\beta\mu_B s_B^2(0)$. The valence s-orbital densities at the nucleus, s_A^2 (0) and $s_B^2(0)$, are assumed to be invariant from molecule to molecule, depending only on the nature of atoms A and B. All other terms in eq. 3 have their usual meaning.

Using this technique, Maciel *et al.* (22) have shown that calculated $^1J(^{13}C,H)$ values are closely related to *calculated* $P^2_{C(2s),H(s)}$ values in the absence of $-I^-$ substituents ($-CF_3$, $-C(O)X$, $-NO_2$, $-CN$, etc.).

In this paper we use this approach to examine the relationship between $^1J(^{15}N,H)$ in the NH_2 fragment and parameters such as bond order and nitrogen pyramidalization. Calculated results are reported for ammonia, formamide, aniline, and 2-aminoacetophenone. The possible application of $^2J(HNH)$ values to the determination of the geometry of the amino group is also discussed. The results of low-temperature proton n.m.r. studies on 2-aminoacetophenone-^{15}N are reported.

[2]Similar criticisms would also apply to the interpretation of $^1J(^{15}N,H)$ values.

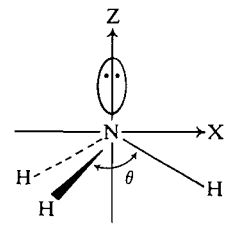
Results and Discussion

Computational Results

All coupling constants were calculated using eq. 3 with the same parameterization as used previously by Pople *et al.* (18, 21, 22). The convergence criterion used here was previously described (24).

Ammonia

Spin–spin coupling constants in ammonia were calculated as a function of θ, the HNH



1

angle. The N—H bond length was taken as 1.0136 Å (25) in all calculations, and θ was varied from 90 to 120° in steps of 2°. Calculated values of $^1J(^{15}N,H)$, $^2J(HNH)$, $P^2_{N(s),H(s)}$, and the nitrogen and hydrogen charge densities (q) are given in Table 1. In Figs. 1 and 2, $^1J(^{15}N,H)$ and $^2J(HNH)$ are plotted against θ. Notice that as θ increases $^1J(^{15}N,H)$ increases in magnitude and $^2J(HNH)$ becomes more positive. In Fig. 3, $^1J(^{15}N,H)$ is plotted against $P^2_{N(s)H(s)}$.

In order to assess the importance of variations in the effective nuclear charges on calculated $^1J(^{15}N,H)$ values, a procedure analogous to that used by Maciel *et al.* (22) was applied. The correction factor for ^{15}N—H coupling constants is given by

$$[4]\quad \frac{s_H^2(0)s_N^2(0)}{[s_H^2(0)s_N^2(0)]_0} = \frac{(1.0 - 0.30q_H)^3(3.90 - 0.35q_N)^3}{(3.90)^3}$$

where the denominator $[s_H^2(0)s_N^2(0)]_0$ corresponds to the nonpolar neutral case. q_H and q_N refer to the net electron charge densities on hydrogen and nitrogen respectively. On going

*The authors of ref. 2 report on page 154 that Pople, McIver, and Ostlund calculate −42.7 Hz for a pyramidal situation and −99.4 Hz for a hypothetical planar form.

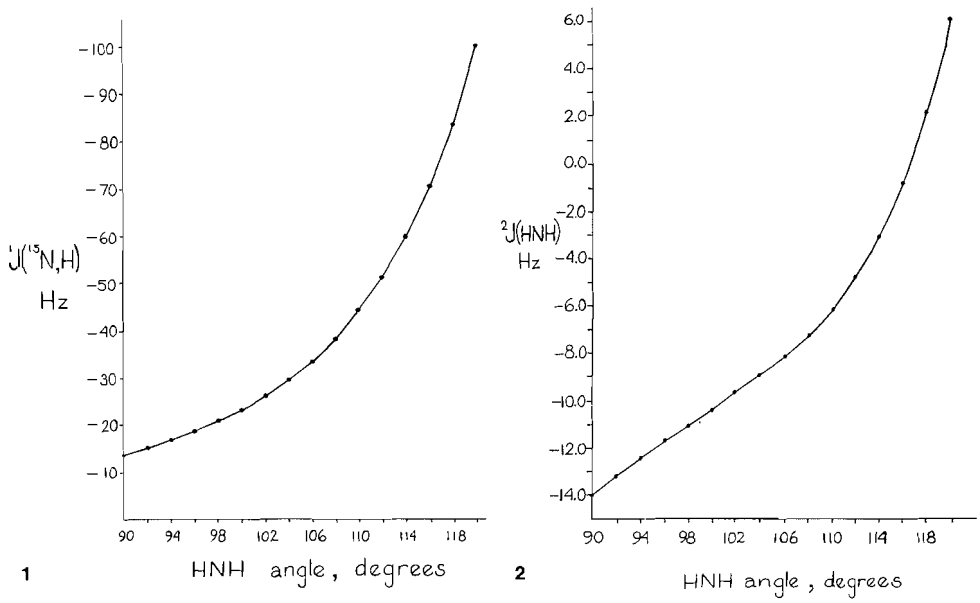

FIG. 1. A plot of the calculated $^1J(^{15}N,H)$ values in Hz *vs.* the HNH bond angle for ammonia.
FIG. 2. A plot of the calculated $^2J(HNH)$ values in Hz *vs.* the HNH angle in ammonia.

from θ = 90 to 120°, the correction factor given by eq. 4 changed from 0.9917 to 0.9877. Thus the adjusted $^1J(^{15}N,H)$ values varied by less than 1 Hz from those given in Table 1.

Calculated $^2J(HNH)$ values were also adjusted in order to account for variations in $s_H^2(0)s_N^2(0)$. Using eq. 2 in ref. 22 the correction factor varied from 0.8722 for θ = 90° to 0.8248 for θ = 120°, thus giving rise to significant adjustments in $^2J(H,H)$. For θ = 90, 100, 110, and 120°, $^2J(HNH)_{adj}$ = −12.21 Hz, −9.01 Hz, −5.22 Hz, and 5.06 Hz, respectively. The calculations

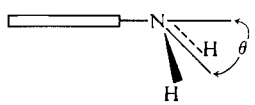
yield a steep dependence of both $^2J(HNH)$ and $^1J(^{15}N,H)$ on the HNH angle in the range from 110 to 120° and suggest the measurement of both coupling constants in attempts to determine the geometry of the NH_2 fragment in molecules in solution.

Other Molecules

Approximate MO calculations of $^1J(^{15}N,H)$ and $^2J(HNH)$ at the INDO level of approximation for aniline and 2-aminoacetophenone have been presented (9). For aniline the geometry of the amino group was taken from the microwave results of Lister and Tyler (26), which give the angle θ between the extension of the C—N bond and the bisector of the HNH angle as 37.7°.



2

Another calculation on aniline assumed complete planarity of the molecule with C—N and N—H bond lengths equal to those given (26) for the nonplanar molecule. Standard geometries were used in a planar (apart from the methyl protons) model of 2-aminoacetophenone. INDO calculations of $^2J(HNH)$ in the ammonium ion and formamide were also carried out. For the ammonium ion the N—H bond length was taken as 1.03 Å. Two calculations were made for formamide, one using Pople's standard geometries (a planar geometry), the other using a slightly nonplanar geometry derived from microwave studies. The results of these calculations are presented in Table 2 together with available experimental data. Notice that for the compounds in Table 2, $^2J(HNH)_{calcd}$ is slightly more positive than $^2J(HNH)_{obs}$. Similar problems are encountered in the case of calculated $^2J(HCH)$ values (18, 22, 23).

Of particular interest are the calculated $^1J(^{15}N,H)$ values for formamide. The use of atomic coordinates obtained from a microwave study (27) results in $|^1J(^{15}N,H_A)| > |^1J(^{15}N,H_M)|$, in agreement with experiment. However, for standard geometries, but using 1.40 Å for the C—N bond length, the calculated absolute value of $^1J(^{15}N,H_M)$ is greater than that of $^1J(^{15}N,H_A)$. It should be pointed out that the microwave results (27) indicate that the N—H_M bond is slightly longer than the N—H_A bond. Also, using the microwave data, INDO gives $P_{N(2s),H(1s)_A} = 0.5333$ while $P_{N(2s),H(1s)_M} = 0.5186$. When one assumes equal N—H bond lengths, INDO calculates $P_{N(2s),H(1s)_A} < P_{N(2s),H(1s)_M}$.

The agreement between calculated and observed $^2J(HNH)$ values in Table 2 is tolerably good for those molecules in which the HNH angle is expected to be considerably larger than 109.5°.

Experimental Results and Discussion

General Problems in Measuring $^2J(HNH)$

While experimental values of $^1J(^{15}N,H)$ are fairly readily available, values for $^2J(HNH)$ are scarce. Reasons for this scarcity are: 1, amino protons are usually chemically equivalent due to rapid rotation (on the n.m.r. time scale) about the X—N bond in the X—NH_2 fragment; exceptions are formamide and some of its derivatives; 2, ^{14}N(99.635% natural abundance) causes substantial broadening of the amino proton resonance; 3, amino protons are often undergoing rapid intermolecular exchange on the n.m.r. time scale (9).

Deuterium substitution yields $^2J(H,D)$ but $g_H = 6.55g_D$ and the accurate deduction of small $^2J(H,H)$ values becomes difficult. Also, since deuterium has a quadrupole moment, the rate of deuterium spin–lattice relaxation must be small in order to observe a well-resolved triplet in the proton spectrum. This should not be a problem if the amino group is free to rotate (*i.e.*, has a short correlation time, see ref. 29). Tritium ($I = \frac{1}{2}$, $g_T/g_H = 1.067$) substitution would be the most sensible method of eliminating

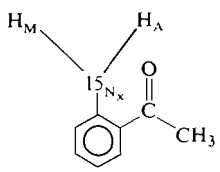
problem 1 if it were not for its radioactivity. Some applications have been reported (30, 31). The second problem can of course be overcome by using ^{15}N enriched compounds ($I = \frac{1}{2}$). The third problem can be removed by drying samples with basic alumina (8, 9, 32) and NaOH (8, 9) or Na–K metal alloys (33).

2-Aminoacetophenone-^{15}N, (3)

At low temperatures (~ −70 °C) rotation about the C—N bond in **3** is slow on the n.m.r. time scale (34) and one observes an AMX type of



3

spectrum for the $^{15}NH_2$ moiety. For a 15 mol % sample of **3** in diethylether at approximately −90 °C, ν_A = 8.31 p.p.m. and ν_M = 6.21 p.p.m. from internal TMS, J_{AM} = 4.9 ± 0.2 Hz, J_{AX} = −90.8 ± 0.2 Hz, and J_{MX} = −89.5 ± 0.2 Hz. The sign of $^2J(H_A,H_M)$ relative to $^1J(^{15}N,H_A)$ and $^1J(^{15}N,H_A)$ was determined by standard heteronuclear tickling experiments (35). Irradiation of the highest frequency nitrogen transitions (10, 133, 937.1 Hz) perturbed the highest frequency peaks of the H_A and H_M doublets. The doublets referred to here are those due to the coupling $^2J(H_A,H_M)$. Irradiation of the lowest frequency nitrogen transitions (10, 133, 755.2 Hz) perturbed the lowest frequency peaks of the H_A and H_M doublets. These results indicate a positive ratio of the reduced couplings, $^1K(N,H)/^2K(H_A,H_M)$. Because $^1J(^{15}N,H)$ is negative, $^2J(H_A,H_M)$ is positive.

It is of interest to compare the chemical shifts of the amino protons in **3** at 20 °C with those observed at −90 °C. At 20 °C the amino protons resonate at approximately 6.75 p.p.m. to low field of TMS. This is 0.51 p.p.m. upfield from the average shift [(6.21 + 8.31)/2 = 7.26 p.p.m.] observed at −90 °C. Assuming that the chemical shift of the amino proton, H_M, is approximately temperature independent, then the chemical shift of H_A at 20 °C must be [6.75 + (6.75 − 6.21)] = 7.29 p.p.m. Thus proton H_A experiences a low-field shift of approximately 1.01

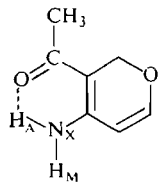
p.p.m./110 °C or 0.009 p.p.m./°C. Calculations by Muller and Reiter (36) predict a temperature dependence of the chemical shift of 0.002 to 0.008 p.p.m./°C for hydroxyl protons involved in hydrogen bonding to oxygen. These calculations have been experimentally confirmed by Schaefer and Kotowycz (37) and by Gramstad and Becker (38).[3] In **3** part of the apparent observed temperature dependence of the $N-H_A$ proton shift may arise from hydrogen bonding to ether by the $N-H_M$ proton and/or from changes in the conformation of the methyl–keto group and/or the amino group with temperature. Notice that at room temperature $^1J(^{15}N,H) = -89.0 \pm 0.5$ Hz, while at low temperature $^1J(^{15}N,H)_{av} = -90.1 \pm 0.4$ Hz.

[3]Gramstad and Becker (38) have observed values between 0.01 and 0.018 p.p.m./°C.

Our experimental results for **3** are similar to the ones recently observed for **4** by Negrebetskii, Bogdanov, and Kessenikh (39). For a solution of **4** in dimethylsulfoxide, $\nu_A - \nu_M = 1.56$ p.p.m., $^1J(^{15}N,H_A) = -91.0$ Hz, $^1J(^{15}N,H_M) = -92.3$ Hz, and $^2J(H_A,H_M) = +5.0$ Hz. It is



4

interesting that we observe $|^1J(^{15}N,H_A)| > |^1J(^{15}N,H_M)|$ in **3**, however, in qualitative agreement with theory. Solvent effects are probably responsible for this apparent discrepancy, the

dimethylsulfoxide molecule being a strong proton acceptor in hydrogen bonding (47).

Other examples where rotation of the amino group is slow and $^2J(HNH)$ values have been measured are formamide (7, 40), acetamide (41), thioacetamide (42), 4-chloro-2-nitroaniline (1), and 1-methylcytosine (43). The results are summarized in Table 3. The sign of $^2J(HNH)$ in formamide is positive. On the basis of the calculations described above for ammonia, aniline, and 2-aminoacetophenone, the relatively large and negative $^1J(^{15}N,H)$ values observed for the compounds in Table 3 indicate positive $^2J(HNH)$ values for these molecules.

Aniline and 2-Chloroaniline

By using deuterium substitution we had shown at 100 MHz that $^2J(HNH) \leq |1\text{ Hz}|$ in 2-chloroaniline (8) and ± 2 Hz in aniline (9). These results were confirmed by the 220 MHz proton spectra of the $^{15}NH_2$ and ^{15}NHD fragments of these compounds. Considering this result and the observed $^1J(^{15}N,H)$ values for aniline (−78.88 Hz, 17 mol % in benzene-d_6), and for 2-chloroaniline (−82.3 Hz, 10 mol % in benzene-d_6), it is reasonable to suggest $^2J(HNH)$ as negative in aniline.

$^2J(HXH)$ in Other Systems

It has been reported that $^2J(HPH)$ becomes more positive as the H—P—H bond angle increases (44). For example in PH_3 (H—P—H bond angle 93.9°), $^2J(HPH) = -13.3$ while in $^+PH_4$ (H—P—H bond angle 109.47°), $^2J(HPH) \leq |1.3|$ (44). Two-bond H—C—H fragments show a similar trend (45). In methane $^2J(HCH) = -12.5$ Hz, while in ethylene $^2J(HCH) = +2.4$ Hz.

Other Factors Affecting $^1J(^{15}N,H)$ and $^2J(HNH)$

Intrinsic Substituent Effects—Although changes in geometry probably account for most of the observed variations in these couplings, intrinsic substituent effects may be present. For example, in *p*-substituted toluenes where changes in the methyl group geometry are probably small, $^1J(^{13}C,H)$ varies from 127.2 Hz in *p*-nitrotoluene to 125.4 Hz in *p*-*t*-butyltoluene (46). The total variation of 1.4% is much less than that of 13.3% in $^1J(^{15}N,H)$ for the analogous anilines (6). On this basis intrinsic substituent effects could probably account for as much as 10% of the observed variation in $^1J(^{15}N,H)$ in a closely related set of molecules such as ring-substituted anilines.

Turning to $^2J(HNH)$, the calculated values for *planar* aniline and *o*-aminoacetophenone (Table 2) differ by less than 10%; while the experimental values differ widely, clearly reflecting the predominant effect on $^2J(HNH)$of the different geometry of the amino group in the two molecules. In 4-chloro-2-nitroaniline (Table 3) $^2J(HNH)$ is 2.8 Hz (assumed positive), rather less than the +5.2 Hz observed for *o*-aminoacetophenone. Rather than interpreting this as an intrinsic substituent effect, we prefer to assume that the amino group in the nitro compound is not completely planar. Indeed, i.r. data (47) on *o*-nitroaniline and *o*-acetophenone indicate substantially stronger hydrogen bonding in the latter compound (an HNH angle difference of 12° being implied).

Solvent Effects—$^1J(^{15}N,H)$ increases in magnitude in anilines as the polarity of the solvent rises (32) in a manner similar to $^1J(^{13}C,H)$ in chloroform (48), and is probably explained by the perturbations caused by intermolecular electric fields (49, 50). In fact, Axenrod and Wieder (51) propose the use of solvent effects on $^1J(^{15}N,H)$ in measuring the relative strengths of intramolecular hydrogen bonds in ortho-substituted anilines.

Similarly, in *o*-aminoacetophenone the internal electric field arising from the lone pair electrons of the carbonyl group could account for the larger magnitude of $^1J(^{15}N,H_A)$ for the intramolecularly hydrogen bonded proton than of $^1J(^{15}N,H_M)$ (Table 2). The opposite order of the magnitudes of these couplings (39) in **4** must then be caused by the strong intermolecular hydrogen bond to the dimethylsulfoxide solvent molecule.

In both **3** and **4** the intramolecular hydrogen bond involves the carbonyl group, but in **4** the solvent is the very polar dimethyl sulfoxide. Yet $^2J(HNH)$ has the same magnitude in **3** and **4**, suggesting a relatively small solvent effect on this coupling constant. But $^2J(HCH)$ is sensitive to solvent polarity (50) and due care should therefore be exercised when comparing $^2J(HNH)$ in different solvents.

Conclusions

In a series of closely related molecules, *e.g.*, substituted anilines, it is probably safe to use

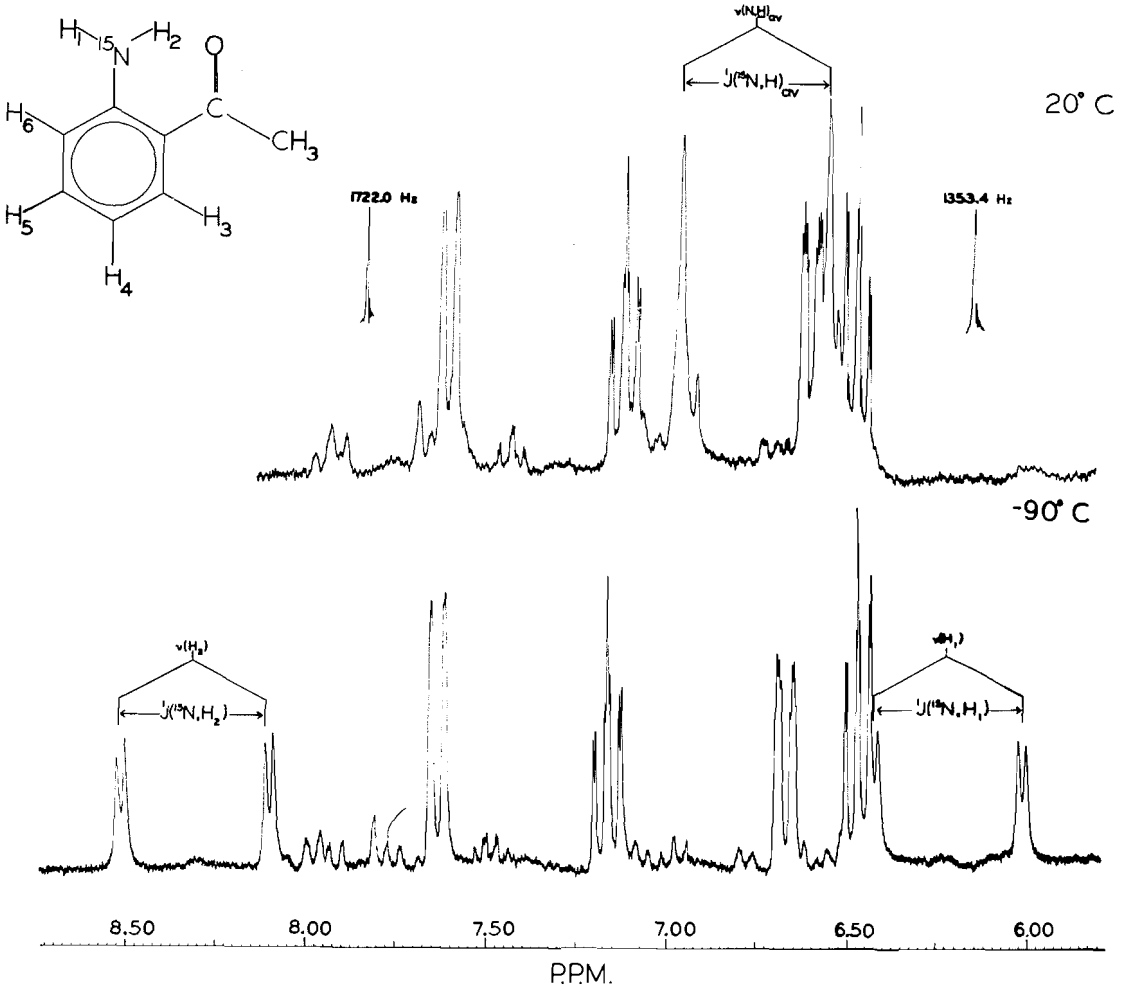

FIG. 4. The p.m.r. spectrum at 220 MHz of 2-aminoacetophenone-^{15}N as a 15 mol % solution in ether, the shift scale being relative to internal tetramethylsilane. At −90 °C the amino proton spectrum displays the 5.2 Hz coupling constant between these protons. The ring proton spectrum has been fully analyzed in ref. 9. The many small peaks arise from impurities introduced during the synthesis of the compound from aniline-^{15}N (9), enriched to 95 at. % in ^{15}N.

observed values of $^1J(^{15}N,H)$ and $^2J(HNH)$ in estimating the planarity of the $—NH_2$ fragment. Because of possible substituent and solvent effects the estimates of nitrogen planarity are at best semiquantitative, *i.e.* the calculation of HNH angles to the nearest 1° on the basis of observed $^1J(^{15}N,H)$ and $^2J(HNH)$ values is not recommended.

Ideally, all measurements should be carried out in a solvent which does not compete with substituents for hydrogen bonding to the N—H protons. In addition, the temperature of measurement should be low enough so that the amino group does not rapidly rotate about the C—N bond on the n.m.r. time scale.

The observed values of $^2J(HNH) = +4.9 \pm 0.2$ Hz and $^1J(^{15}N,H) = -90.8 \pm 0.2, -89.5 \pm 0.2$ Hz in 2-aminoacetophenone, together with previous estimates (9) of $^6J_p(NH,H) < |0.06|$ Hz, indicate that the amino group in 2-aminoacetophenone is very nearly coplanar with the aromatic ring.

On the basis of a comparison of experimental measurements with present calculations we predict that $^2J(HNH)$ is probably small and negative (−1.5 Hz) in aniline, while in 2-chloro-

aniline the coupling is probably very close to zero. The use of tritium substitution for the deduction of $^2J(HNH)$ values is suggested.

Experimental

The synthesis of 2-aminoacetophenone-^{15}N has been described (9). The diethylether solution, approximately 15 mol %, was degassed by the freeze–pump–thaw technique. Figure 4 displays the p.m.r. spectrum at 220 MHz at 20 °C and at −90 °C. The preparation of aniline-^{15}N and 2-chloroaniline -^{15}N samples containing the ^{15}NHD group has been given (9). Coupling constant measurements were made with either Varian HA-100 or Varian HR-220 spectrometers by methods similar to those described in detail before (9). The double resonance experiments were carried out on the HA-100 spectrometer. Computations were carried out using an IBM 360/65 computer.

We thank Dr. Ludger Ernst for preparing the sample of 2-aminoacetophenone-^{15}N, Dr. Herman J. C. Yeh for his assistance in measuring the sign of ^2J(H,H) in 2-aminoacetophenone, and Dr. Edwin Becker for several helpful comments concerning this manuscript. We are grateful to the National Research Council for financial assistance.

Quantum Organic Photochemistry. IV. The Photoisomerization of Diimide and Azoalkanes[1]

N. Colin Baird and Jerrald R. Swenson

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ontario

Received April 10, 1973

Potential energy surfaces for the isomerization of diimide and azomethane in the ground, $^1(n,\pi^*)$, $^3(n,\pi^*)$, and $^3(\pi,\pi^*)$ states have been calculated by *ab initio* molecular orbital methods. Two mechanisms are considered in detail, the first involving in-plane motion of the substituent group and the second involving twisting about the N—N bond. The first mechanism is preferred for the ground and $^3(\pi,\pi^*)$ states, whereas the second mechanism is preferred for the (n,π^*) states. A significant barrier to rotation is predicted for the $^3(\pi,\pi^*)$ state. The vibrationally-relaxed (twisted) lowest triplet of diimide is predicted to lie 36 kcal mol^{-1} above the ground state.

Les surfaces d'énergie potentielle pour l'isomération de la diimide et de l'azométhane, dans les états fondamentaux $^1(n,\pi^*)$,^{3} (n,π^*) et $^3(\pi,\pi^*)$, ont été déterminées par les méthodes des orbitales moléculaires *ab initio*. Deux mécanismes ont été considérés en détail, le premier impliquant un mouvement dans le plan du substituant et le second, une torsion autour de la liaison N—N. On a préféré le premier mécanisme pour les états fondamentaux et $^3(\pi,\pi^*)$ tandis que le second mécanisme répond mieux aux états (n,π^*). Une barrière de rotation notable a été prévue pour l'état $^3(\pi,\pi^*)$. Le triplet de relaxation vibrationnelle (torsion) la plus basse est de 36 kcal mol^{-1} au-dessus de l'état fondamental selon nos prévisions.

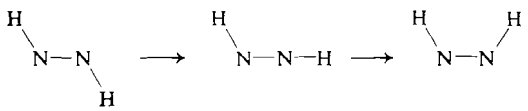
Can. J. Chem., **51**, 3097 (1973)

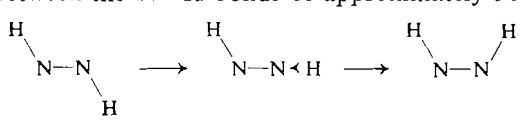
Introduction

cis–trans Isomerization is frequently observed in photochemical studies of azoalkanes. Using diimide, HNNH, as a model system for such compounds, one can imagine two simple mechanisms by which the isomerization can occur. In mechanism **I**, the affected hydrogen atom moves in the plane defined by the remaining atoms throughout the reaction; the transition state presumably occurs when the hydrogen atom lies approximately on the N—N axis. In



I

mechanism **II** the affected hydrogen atom rotates about the N—N bond such that the transition state corresponds to a conformation with equal HNN angles and a dihedral angle between the N—H bonds of approximately 90°.



II

(A third possible mechanism, which involves a linear HNNH conformation in the transition state, can be eliminated from consideration on the basis of our own and previous (2, 3) *ab initio* calculations.)

Since a C_2 axis is preserved throughout mechanism **II**, orbital symmetry considerations (4) can be applied to predict the existence or absence of symmetry-imposed barriers in the isomerization. The important molecular orbitals to be considered are the N—N π and π^* orbitals and the lone pair orbitals on each nitrogen atom. The lone pairs will interact to yield a symmetric combination n_+, and an antisymmetric combination n_-. Since the through space interaction of the lone pairs in azo compounds is considerable, the two resulting MOs are well separated in energy; the n_+ combination lies above n_- for the *trans* isomer whereas n_- lies above n_+ for the *cis* (5) (see Fig. 1). Although the position of the π-bonding MO relative to n_+ and n_- is not intuitively obvious, both our calculations for HNNH and azomethane and the analysis of the photoelectron spectrum of *trans*-azomethane (6) place the π MO *between* the two "nonbonding" lone pair MO's. The completed orbital correlation diagram with the MOs labelled according to their behavior under C_2 is shown in Fig. 1.

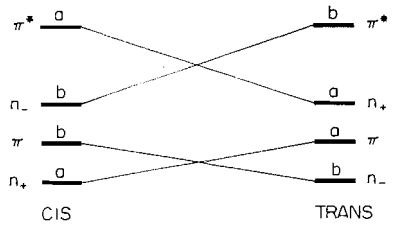

FIG. 1. Orbital correlation diagram for diimide.

Since the electron configuration $(n_-)^2(\pi)^2(n_+)^2$ for the *trans* ground state correlates with a doubly excited configuration of the *cis* isomer, rotation about the double bond is symmetry-forbidden in the ground state. In contrast, isomerization via twisting is an allowed reaction in the lowest (n,π^*) singlet and triplet states, since the configuration $(n_-)^2(\pi)^2(n_+)^1(\pi^*)^1$ of the *trans* isomer correlates with the $(n_+)^2(\pi)^2(n_-)^1(\pi^*)^1$ configuration of the *cis* isomer. Finally, the electron configuration for (π,π^*) states of the *trans* isomer, namely $(n_-)^2(\pi)^1(n_+)^2(\pi^*)^1$ correlates with the *doubly excited* configuration $(n_+)^1(\pi)^2(n_-)^1(\pi^*)^2$ of the *cis* isomer. Thus isomerization by twisting is a symmetry-forbidden process in the (π,π^*) states of diimide, in complete contrast to the situation in ethylene for which there should not only be no barrier to rotation, but in which the conformation with the methylene groups twisted 90° should represent a minimum in the (π,π^*) energy surfaces (7).

To test the predictions made above, and to determine the relative energetic and geometric demands for isomerization by mechanisms **I** and **II**, we have carried out *ab initio* molecular orbital calculations for the ground, $^1(n,\pi^*)$, $^3(n,\pi^*)$, and $^3(\pi,\pi^*)$ states of diimide and, to a lesser extent, of azomethane.

Method of Calculation

The wavefunctions have been determined by the closed shell SCF-LCAO-MO method of Roothaan (8). A minimal basis set of Slater type orbitals (STO's) was used to expand the molecular orbitals. Each s and p type STO was simulated by a linear combination of three Gaussian type orbitals using the STO-3G expansions of Pople and co-workers (9). Unless otherwise indicated, the energies of the excited states were evaluated from the ground state wavefunction with no configuration interaction (CI). Standard molecular exponents (9) were employed throughout except for the nitrogen $2p_\sigma$ STO exponent which was assumed to be 2.20 by analogy with optimized exponents for N_2 (10).

Results and Discussion

Ground-state Geometries and Isomerization Surfaces for Diimide and Azomethane

The potential energy surface for HNNH was explored with respect to the N—N distance, the H—N—N bond angle, and the dihedral angle between the two N—H bonds. (For simplicity, all N—H bond lengths were taken as 1.01 Å and the two H—N—N angles were assumed to be equal.) The absolute minimum in the surface occurs at the *trans* conformation (*i.e.* dihedral angle of 180°) with an H—N—N angle of 109° and a N—N bond length of 1.21 Å. The calculated geometry agrees very well with that deduced from an analysis of the i.r. spectrum of *trans* diimide, R_{N-N} = 1.238 Å, angle H—N—N = 109° (11). In parallel with our observations regarding the C—C distance in ethylene,[2] the agreement between the calculated and observed N—N distance is improved further if configuration interaction between the ground electronic configuration and the $(\pi)^0(\pi^*)^2$ configuration is included (R_{N-N} = 1.25 Å with CI).

Although the N—N bond length in *trans* diimide is close to that expected by analogy with the isoelectronic hydrocarbons (since the central bond distance increases by ~0.13 Å in going from a triple to a double bond in both cases), the H—N—N angle of 109° is much smaller than the H—C—C angle of 121° observed for ethylene. Our calculations predict, however, that the H—N—N angle opens appreciably to 115° at the second minimum in the potential surface which corresponds to an exactly planar *cis* conformation (R_{N-N} = 1.21 Å). The *cis* isomer is predicted to be less stable than the *trans* by 5 kcal mol^{-1}, in reasonable agreement with other calculations (2, 12). An even larger increase in bond angle in going from the *trans* to the *cis* geometry is predicted by a limited search of the potential surface for CH_3NNCH_3; using assumed values of 1.09 and 1.47 Å for the C—H and C—N bond distances, respectively, the optimum C—N—N angle for *trans* azomethane is predicted to be 113° (in excellent agreement with the experimental value (13) of 112°), whereas that for the *cis* conformation is predicted to be 122°. Presumably, relief of steric interactions between the alkyl groups in *cis* azo compounds provides the driving force for the greater *cis–trans* angle increase. Indeed, an

empirical correlation between the R—N—N bond angle and the predicted $^1(n,\pi^*)$ excitation energy of *cis* azo compounds suggests that the C—N—N angle in *cis*-azo-2-methyl-2-propane is approximately 131° (14). Unfortunately, there is no structural information available for any *cis* azoalkane with which to test this prediction of large C—N—N angles.

In order to evaluate activation energies for isomerization in the ground state of diimide, optimum geometries were obtained for the "idealized" transition states of mechanisms **I** and **II** (*i.e.* angle $N_A—N_B—H = 180°$ for **I**, dihedral angle = 90° for **II**). In agreement with the intuitive expectation that mechanism **I** requires only rehybridization at N_B but does not significantly affect either the N—N or the N_A—H bond, the optimum $H—N_A—N_B$ angle of 110° and the optimum N—N distance of 1.21 Å predicted for the type **I** transition state are very similar to those for the *trans* conformation. A plot of energy *vs.* $N_A—N_B—H$ angle yields a value of 182° (*i.e.* a quasi *trans* conformation) rather than 180° for the transition state, the point for 182° lying only 0.1 kcal mol^{-1} higher than for the idealized geometry.

The optimized geometry for the idealized transition state of mechanism **II** occurs for an H—N—N angle of 124° and an N—N distance of 1.24 Å; although the N—N bond distance is slightly longer than for the planar ground state, the increase is much less than in ethylene for reasons which will be discussed later. Using the "idealized" bond angle and bond length quoted above, the energy maximum in the potential energy curve for twisting (see curve *a* of Fig. 2) is found to occur at a dihedral angle between the N—H bonds of 98°; the energy at this angle is 9 kcal mol^{-1} more positive than at 90°. Since a level crossing occurs for the ground state in going from *trans* to *cis*, configuration interaction between the ground configuration and the $(n)^0(\pi^*)^2$ and $(\pi)^0(\pi^*)^2$ doubly excited configurations has been included in the determination of the potential energy curve for the ground state illustrated in Fig. 2.

The activation energy for isomerization via mechanism **I** is predicted to be significantly smaller than by mechanism **II** for both diimide and azomethane. The calculated activation energy for the *trans* to *cis* isomerization of diimide is 60 kcal mol^{-1} for mechanism **I** and 84 kcal mol^{-1} for mechanism **II**. These values are in reasonable agreement with the 50 and

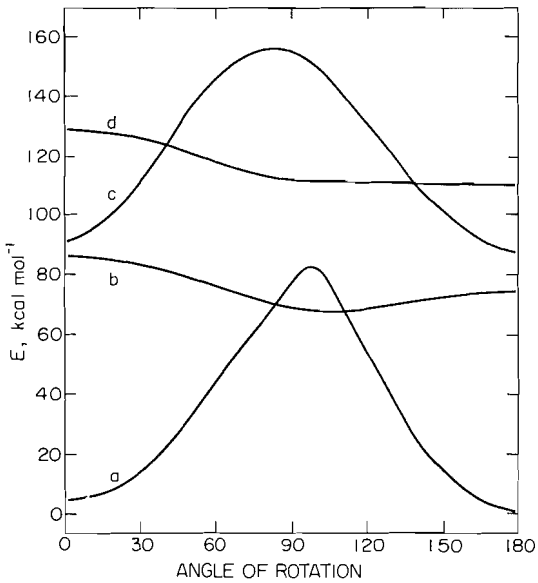

FIG. 2. Calculated potential energy curves for rotation about the N—N bond in diimide: (*a*) the ground state; (*b*) the $^3(n,\pi^*)$ state; (*c*) the $^3(\pi,\pi^*)$ state; (*d*) the $^1(n,\pi^*)$ state. The zero of the energy scale is the *trans* ground state.

84 kcal mol^{-1} values computed by Lehn and Munsch (3), especially considering their use of an idealized transition state for mechanism **II**. Dimethyl substitution is predicted to lower barriers to ~58 and ~78 kcal mol^{-1} for mechanisms **I** and **II**, respectively, according to prototype calculations on azomethane (using N—N distances appropriate to diimide). Unfortunately, there exist no experimental data for either diimide or azoalkanes with which to compare these predictions, since simple azoalkanes appear to decompose rather than isomerize thermally.[3] Our calculated activation energy of 60 kcal mol^{-1} for isomerization of diimide is consistent with this result, since the experimental activation energy for azomethane decomposition is only 50.2 kcal mol^{-1} (16).

Excited State Geometries, Energies, and Isomerization Pathways

The optimum H—N—N angles and N—N distances calculated for the lowest $^1(n,\pi^*)$, $^3(n,\pi^*)$, and $^3(\pi,\pi^*)$ states of diimide are listed in Table I for the *cis*, *trans*, idealized bent, and

[3]Difluorodiimide is known to isomerize thermally with an activation energy of 33.2 kcal mol^{-1} (15). However, since fluorine as a substituent may well act differently than hydrogen or methyl, it is difficult to compare our predictions with this result.

TABLE 1. Calculated geometries for diimide[a]

State	*trans*		*cis*		Bent		Twisted	
	R_{N-N}	Angle H—N—N	R_{N-N}	Angle H—N—N	R_{N-N}	Angle H—N—N	R_{N-N}	Angle H—N—N
Ground	1.21 (1.25)	109	1.21	115	1.21	110	1.24 (1.26)	124
$^1(n,\pi^*)$	1.26	121	1.22	133	1.24	116	1.22	127
$^3(n,\pi^*)$	1.26	120	1.22	132	1.24	118	1.26	117
$^3(\pi,\pi^*)$	1.42	105	1.42	114	1.38	108	1.36	128

[a]Bond distances in Å; bond angles in degrees. Values in parentheses refer to calculations which include Cl (see text).

idealized twisted conformations. The effect of (n,π^*) excitation upon the N—N bond distance in the planar geometries is rather small compared to the C—O bond elongation found for the (n,π^*) states of formaldehyde (17). The difference is due to the fact that whereas the highest occupied molecular orbital (HOMO) in formaldehyde is essentially C—O nonbonding, the HOMO in both *cis* and *trans* diimide is N—N *antibonding*. Thus, removal of an electron from the n_- MO of *cis* diimide increases the N—N overlap population by 0.21, an amount which almost compensates for the decrease of 0.29 due to single occupancy of the π^* MO. A greater increase in N—N distance is predicted for the *trans* conformation, since the HOMO of the ground state is less antibonding (−0.11) than for the *cis* conformation.[4] The large increase in the N—N distance predicted for the $^3(\pi,\pi^*)$ excitation is not unexpected, since the π bond is destroyed in the process.

Potential energy curves obtained from closed-shell calculations for isomerization by twisting (mechanism **II**) in these three excited states are shown in Fig. 2. In all cases the shape of the curves agrees qualitatively with that expected from the orbital symmetry arguments above and with that obtained by Kearns (18) from Huckel-like calculations. For the $^3(n,\pi^*)$ state the calculations predict no barrier to isomerization by twisting; indeed the minimum for this lowest triplet state occurs at a dihedral angle of 103°, at which point the energy is 7 kcal mol^{-1} lower than for the *trans* conformation according to calculations which employ ground state eigenvectors. Recalculation of this curve using the Roothaan open-shell method (19) leads to an even deeper minimum (of 14 kcal mol^{-1}) at 97° relative to the *trans* conformation; this value is very similar to the energy gain of 16 kcal mol^{-1} predicted for twisting ethylene by 90° in its $^3(\pi,\pi^*)$ state.[5] Note that the triplet curve crosses that for the singlet ground state for dihedral angles in this region. The existence of this crossing provides a rationalization for the failure to observe phosphorescence in simple azoalkanes (20). As the excited triplet molecule relaxes from the planar to the optimum twisted conformation, its energy approaches and eventually crosses that for the ground state. Such a situation should be particularly favorable for a T_1–S_0 radiationless transition.

In contrast to the behavior in the ground state, isomerization by the "allowed" twisting process (mechanism **II**) is much preferred energetically to mechanism **I** for both the $^3(n,\pi^*)$ and $^1(n,\pi^*)$ states of diimide. The energies required to reach the type **I** transition state are 25 and 23 kcal mol^{-1}, respectively, compared to the zero to reach the twisted conformation in both the triplet and singlet (n,π^*) states. Note, however, that *trans* to *cis* isomerization by mechanism **II** in the $^1(n,\pi^*)$ state should require a significant activation energy if the *trans* conformer is vibrationally relaxed, since the *cis* conformer is predicted to be significantly less stable than the *trans* in the $^1(n,\pi^*)$ state (see curve *d* of Fig. 2). As noted by Kearns (18) this effect should be accentuated in azo compounds due to additional destabilization of the *cis* conformation by steric effects.

The prediction that twisting in the $^3(\pi,\pi^*)$ state is a forbidden process is indeed substan-

[4]Ionization of the least tightly bound electron should result in a *decrease* in the central bond distance for diimide and azo compounds (particularly the *cis* conformations), an effect which is rare in polyatomic molecules.

[5]The value for ethylene is obtained using the same open-shell procedure.

tiated by the *ab initio* calculations; the *trans* to *cis* barrier is predicted to be 71 kcal mol^{-1} by mechanism **II** compared to 65 kcal mol^{-1} for mechanism **I**. Although no configuration interaction is included in the calculation of these values, it is most unlikely that the barriers would be altered substantially by CI since there exists no other low-lying triplet which is strongly coupled to the π,π^* triplet.

In summary, *ab initio* calculations confirm the orbital symmetry prediction that isomerization by twisting about a N=N bond is forbidden in the ground and $^3(\pi,\pi^*)$ states; in both cases isomerization via in-plane motion requires a lesser amount of activation energy. The orbital symmetry prediction that twisting is an allowed process in (n,π^*) states is also confirmed by the calculations; for such states isomerization via the in-plane motion requires a substantial amount of activation energy.

Finally, we have made an attempt to estimate the triplet energy of diimide. Since the calculation of a triplet energy involves comparing the energies of two different states, care must be taken to allow for the unequal correlation energies of the different states. The procedure followed here is the CI(PCMO) method developed by Buenker and Peyerimhoff (21). The ground state energy is that obtained after a limited configuration interaction with the two lowest doubly excited configurations, using eigenvectors appropriate to the ground state. The energy for the 90° twisted $^3(n,\pi^*)$ state is that obtained after configuration interaction with the three other configurations of the same symmetry obtained by single and double excitations among the four MO's shown in Fig. 1 and using an open-shell wavefunction for the $^3(n,\pi^*)$ state.[6] The O—O band S_0–T_1 transition energy deduced in this manner for *trans* diimide is 36 kcal mol^{-1}, a value which lies between those for the isoelectronic species O_2 and C_2H_4, but at an energy somewhat greater than the 14–18 kcal mol^{-1} range estimated by Kosower (22).

[6]The total energies for the planar ground state and twisted triplet are −108.6199 and −108.5627 a.u., respectively, which correspond to improvements of 0.0521 and 0.0316 a.u., respectively, due to the inclusion of CI.

Evidence is presented in support of the stereostructures **4** and **5** for cimicine and cimicidine, respectively. Alkaloids **4** and **5**, as well as the lactonic bases aspidophytine (**23**) and haplophytine (**1**), are converted by alkaline hydrogen peroxide to the corresponding 10-oxo derivatives.

On présente des preuves qui justifient l'attribution des stéréostructures **4** et **5** à la cimicine et à la cimicidine, respectivement. Les alcaloïdes **4** et **5**, de même que les bases lactoniques aspidophytine (**23**) et haplophytine (**1**), sont transformés par l'action de péroxyde d'hydrogène alcalin en dérivés oxo-10.

Haplophyton cimicidum (Apocynaceae) has been shown to contain a number of alkaloids of the aspidospermine type. Among these are the novel binuclear indole base haplophytine (**1**) (1–5), the carbinolamine-ether bases haplocine (**2**) and haplocidine (**3**) (6), and the carbinolamine-lactone bases cimicine (7) and cimicidine (1, 2, 7).[1] In this paper, evidence is presented in support of the stereostructures **4** and **5** for cimicine and cimicidine, respectively, and some additional chemistry of these alkaloids is discussed.

Cimicine, m.p. 229–231°, $[\alpha]_D$ +113° ($CHCl_3$), has the molecular formula $C_{22}H_{26}N_2O_4$. Its p.m.r. spectrum shows a number of points of similarity to that of its companion alkaloid haplocine (**2**) (6). Thus, neither base shows a peak attributable to either a methoxyl or an *N*-methyl group. Cimicine shows a strongly hydrogen-bonded hydroxyl at δ 10.70, analogous to that (δ 10.80) shown by haplocine. Furthermore, a three-proton triplet at δ 1.32 coupled to a two-proton quartet at δ 2.64 (J = 8 Hz) strongly suggested the presence in cimicine of an *N*-propionyl function similar to that found in haplocine. Both bases give a complex three-proton signal in the aromatic region. The u.v. spectra of cimicine and haplocine (Table 1) are very similar, both in neutral and in basic solution, suggesting the presence of the same chromophoric system in both compounds.

[a]The c.m.r. spectra were recorded in deuteriochloroform at 25.16 MHz with a Varian XL-100-15 instrument operating in the pulsed Fourier transform mode.
[b]See structures 4 and 5 for the numbering system.
[c]Chemical shift values (δ) are reported in p.p.m. downfield from tetramethylsilane as internal standard. The multiplicities of the signals, determined by comparison of random noise-decoupled spectra with off-resonance partially decoupled spectra, represent coupling between the carbon atom and the protons that are directly bonded to it.
[d]*Cf.* second and third footnotes.
[e]Superimposed signals.

N-acyldihydroindole chromophore, at 6.15, 6.24, and 6.37 μ; the corresponding spectrum of cimicine shows the same three bands at identical positions, as well as a split carbonyl band at 5.63 and 5.71 μ. In chloroform solution, the latter band appears at 5.65 (sh) and 5.72 μ.

The spectral relationships between haplocine and cimicine, combined with a consideration of their molecular formulas, suggested that cimicine is an oxo derivative of haplocine. The position of the shorter-wavelength carbonyl band of cimicine and the fact that cimicine, but not haplocine, is soluble in dilute aqueous alkali, led to the γ-lactone formulation **4** for cimicine. Direct confirmation of this structure was obtained by chromic oxide – pyridine oxidation of (+)-haplocine, which gave (+)-cimicine, albeit in low yield.

The stereostructure **2** has been established for haplocine by direct chemical correlation with the alkaloids limaspermine, palosine, and aspidospermine (8). The conversion of (+)-haplocine to (+)-cimicine thus establishes the stereostructure **4** for natural cimicine.

The c.m.r. spectrum of cimicine (Table 2) is in good accord with this structural assignment. Low-field singlets at δ 172.2 and 175.4 can be assigned to the *N*-propionyl and lactone carbonyl carbon atoms, respectively,[2] and six signals in

[2]The individual assignment of the carbonyl carbon signals are based on comparison with the spectrum of 10-oxocimicine (*vide infra*).

the δ 115–150 region are assignable to the aromatic carbon atoms. A singlet at δ 106.1 can be assigned to C-19, the sp^3-carbon atom of the carbinolamine lactone function; a similar signal is present in the spectrum of haplophytine. Two signals in the δ 50–100 region at δ 67.0 and 58.5 are assignable on the basis of their chemical shifts and multiplicities to C-2 and -12, respectively. The remaining signals can be assigned on a like basis as shown in Table 2.[3]

The molecular formula $C_{23}H_{28}N_2O_5$, proposed earlier for cimicidine (1), has now been confirmed by mass spectrometry (m.s.). The i.r. spectrum of cimicidine in KBr shows carbonyl bands at 5.65, 5.70, and 6.15 μ corresponding to those of cimicine; in chloroform solution, the short-wavelength doublet appears at 5.64 and 5.72 μ. The p.m.r. spectrum of cimicidine resembles that of cimicine in that it shows the absence of an *N*-methyl signal, and the presence of signals attributable to a hydrogen-bonded hydroxyl (at δ 10.75) and an *N*-propionyl group (a three-proton triplet at δ 1.32 (J = 8 Hz) and a two-proton quartet at δ 2.64 (J = 8 Hz). In contrast to the p.m.r. spectrum of cimicine, however, that of cimicidine shows a methoxyl signal at δ 3.87. The δ 3.87 peak represents four protons, the fourth proton corresponding to the C-2 hydrogen, whose signal is discernible at δ 3.98 in the spectrum of cimicine. Finally, the p.m.r. spectrum of cimicidine shows only two aromatic proton signals in the form of an AB quartet at δ 6.73 and δ 7.02 (J = 8 Hz). All of the above data are in accord with the assignment of either a 14- or a 16-methoxycimicine structure to cimicidine. The latter structure, **5**, is strongly favored because of the frequent occurrence of 16-oxygenated aspidospermine-type alkaloids, *e.g.*, aspidocarpine (9), aspidolimidine (10), aspidoalbine (11), and pyrifolidine (12), and the absence of reports of the occurrence in nature of 14-oxygenated alkaloids of this type. Also, the appreciable chemical shift between the aromatic proton signals is in better accord with the 16-methoxycimicine formulation. The above data, together with the dextrorotatory nature of both cimicine and cimicidine, lead to the stereostructure **5** for cimicidine.

As expected, the c.m.r. spectrum of cimicidine closely resembles that of cimicine (Table 2), except for the presence of a quartet at δ 56.2, arising from the methoxyl carbon, and changes in the aromatic carbon region associated with the introduction of the methoxyl substituent.

In the course of the original investigation of cimicidine, catalytic hydrogenation of the alkaloid was reported to give a dihydrocimicidine (2). We have confirmed this observation, and we formulate dihydrocimicidine as the zwitterionic structure **7**. The carboxylate anion of **7** gives rise to an i.r. band at 6.13 μ. As expected, the hydrochloride (**10**) of **7** contains an unionized carboxyl group, which gives rise to a band at 5.83 μ that shifts to shorter wavelength (5.78 μ) on conversion to the methyl ester **11**. The closely related cimicine is reduced either catalytically or by sodium borohydride to the analogous dihydro derivative **6**. Dihydrocimicine (**6**), its hydrochloride (**8**), and its methyl ester (**9**) show carbonyl bands at the same positions as those of the corresponding cimicidine derivatives. The hydrogenolysis of the carbinolamine lactone system of cimicine and cimicidine is analogous to the reduction of carbinolamine ethers, *e.g.*, the reductive cleavage of haplocine (**2**) to limaspermine (6, 8); the assignment of configuration at C-19 is based on this analogy.

Snyder *et al.* have reported that both haplophytine and cimicidine react with alkaline hydrogen peroxide to give transformation products containing an additional oxygen and two fewer hydrogen atoms (2). We now propose that these compounds are 10-oxohaplophytine (**12**) and 10-oxocimicidine (**13**), respectively.

In view of the relative abundance of cimicine as compared to cimicidine, the alkaline hydrogen peroxide oxidation of cimicine was chosen by us for detailed study. A solution of cimicine (**4**) in dilute aqueous base reacted slowly with hydrogen peroxide to give a precipitate of a new, neutral compound, 10-oxocimicine (**14**). In accord with this formulation, **14** showed carbonyl absorptions at 5.56 μ (γ-lactone), 5.82 μ (γ-lactam), and 6.14 μ (*N*-propionyl group). The γ-lactam carbonyl band of the closely related *O*-methyl-N_a-acetyl-10-oxoaspidoalbine (**17**) appears at 5.88 μ (11). Proof that the phenolic hydroxyl of cimicine is intact in the hydrogen peroxide oxidation product was obtained by converting the latter into its *O*-methyl derivative (**15**) and into its *O*-acetyl derivative (**16**).

The p.m.r. spectrum of **14** resembles that of cimicine, but shows a two-proton multiplet in

[3]There are ambiguities in the assignment of some close-lying signals.

the δ 3.8–4.3 region in contrast to the one-proton multiplet at δ 4.0 in the latter spectrum attributed to the proton at C-2. The additional signal in the spectrum of **14** is assigned to one of the C-8 protons, which lies in the plane of the carbonyl group at C-10.[4] The c.m.r. spectrum of **14** (Table 2) resembles that of cimicine, except for the replacement of the C-10 methylene carbon triplet at δ 48.1 by a lactam carbonyl carbon singlet at δ 172.5. There are also significant upfield shifts of the signals assignable to C-12, -19, -21; these shifts can be accounted for in terms of the interpretation given below of the effect engendered by introduction of the 10-oxo group on the i.r. spectrum of cimicine.

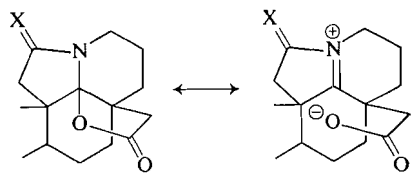
17

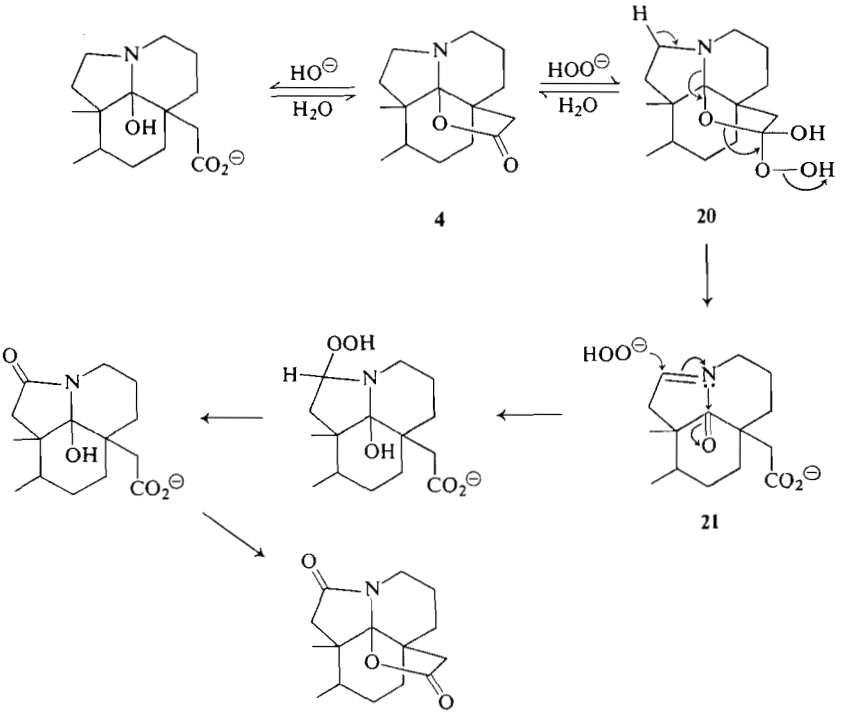
Brief comment may be made concerning the relative positions of the γ-lactone carbonyl bands of cimicine and 10-oxocimicine. The lactone band of 10-oxocimicine (**14**) appears at 5.56 μ, or at somewhat shorter wavelength than the usual γ-lactone range (5.62–5.68 μ) (13). The corresponding lactone carbonyl band of cimicine by contrast appears at the abnormally long wavelength value of 5.72 μ, despite the fact that the inductive effect of the adjacent carbinolamine nitrogen might be expected to *shorten* the lactone carbonyl wavelength. We suggest, therefore, that the position of the cimicine lactone carbonyl reflects a contribution from the open-chain dipolar canonical form **18**, as shown below. Resonance of this type would be expected to be inhibited in the case of 10-oxocimicine, since the positive nitrogen of the dipolar form (**19**) would be adjacent to a carbonyl carbon.



18 X = H_2
19 X = O

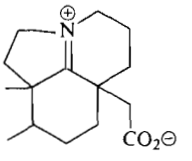
A plausible mechanism for the conversion of

cimicine (**4**) to 10-oxocimicine (**14**) is outlined below:

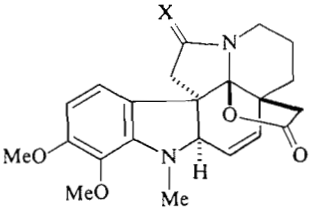


The initial steps involve addition of hydroperoxide anion to the lactone carbonyl giving **20** and fragmentation of the pyrrolizidine system. Addition of hydroperoxide anion to the resulting imine **21** can take place with transannular attack on the ketonic carbonyl. Elimination of water from the α-hydroperoxy amine and lactonization complete the reaction sequence.

Two features of this mechanism require comment. First, the selective elimination of the proton from C-10 in intermediate **20**, rather than from C-8, is in accord with the fact that Dreiding models show that only the former elimination process can take place via a coplanar transition state. Second, the initial hydroperoxide attack is pictured as taking place on the lactone system in an alkaline solution, a medium in which no free lactone might be expected to survive. The presence of a small amount of cimicine in equilibrium with the ring-opened carboxylate form in aqueous base can be proven experimentally, however, by the slow extraction of cimicine by organic solvent from an aqueous alkaline solution. Precedent exists for the closure of a γ-lactone ring in an aqueous basic medium (14).[5]



22



25 X = H_2
26 X = O

The hydrogen peroxide oxidation product of haplophytine (**1**) may be assigned the structure 10-oxohaplophytine (**12**) on the assumption that, as in the case of cimicine, oxidation takes place in the neighborhood of the carbinolamine lac-

[5]The imine **21** might also arise by attack of hydroperoxide anion on a small amount of the immonium ion **22** in equilibrium with **4**, followed by fragmentation.

tone system. In confirmation of this assignment, oxohaplophytine gives a methyl ether (**23**) and an acetyl derivative (**24**), showing that the phenolic function of haplophytine has survived the oxidation. Furthermore, acid cleavage of oxohaplophytine does not yield aspidophytine (**25**) (4, 5) as does haplophytine, but rather a compound assigned the structure 10-oxoaspidophytine (**26**). As expected, alkaline peroxide oxidation of aspidophytine also afforded 10-oxoaspidophytine, the spectral properties of which showed it to be closely analogous to 10-oxocimicine (**14**).

Experimental

Cimicine (4) and Cimicidine (5)

The alkaloid mixture (1) (100 g) from *Haplophyton cimicidum* was stirred twice with distilled water (1500 ml) for 6 h at room temperature, and the mixture was filtered (5). The combined aqueous filtrates were extracted with chloroform (5 × 200 ml), and the extract was dried and evaporated to give a semi-crystalline residue (60–70 g). This was dissolved in absolute ethanol (2 l), and the material that crystallized was recrystallized five times from absolute ethanol to give cimicine (**4**; *ca.* 10 g), m.p. 229–231°; $[\alpha]_D$ +113° ($CHCl_3$); λ_{max} (KBr) 5.63, 5.71, 6.15 μ; λ_{max} (EtOH) (ε) 221 (31 700), 257 (8630), 295 (4600) nm; λ_{max} (EtOH–NaOH) (ε) 235 (23 000), 260 (infl., 5750), 311 (5180) nm; δ 1.32 (t, J = 8 Hz, 3 H), 2.64 (q, J = 8 Hz), 3.98 (m, 1 H), 6.8–7.2 (m, 3 H), 10.70 (s, 1 H); *m/e* 382, 338.

Anal. Calcd. for $C_{22}H_{26}N_2O_4$: C, 69.09; H, 6.85; N, 7.33. Found: C, 69.30; H, 6.58; N, 7.45.

The mother liquor from the first crop of cimicine was concentrated to two-thirds volume; on standing the solution deposited a mixture of cimicine and cimicidine (7:3, as estimated by p.m.r. spectroscopy). This was fractionally crystallized from acetone followed by final crystallization from ethanol to give cimicidine (**5**; *ca.* 1.0 g), m.p. 266–268° dec. (lit. (1) m.p. 268–270° dec.); λ_{max} (Nujol) 5.65 (sh), 5.70, 6.15 μ; λ_{max} (EtOH) (ε) 228 (23 900), 262 (7300), 293 (infl., 1500) nm; λ_{max} (EtOH–NaOH) (ε) 234 (21 900), 308 (4900) nm; δ ($CDCl_3$) 1.32 (t, J = 8 Hz, 3 H), 2.64 (q, J = 8 Hz), 3.87 (s, 3 H), 3.8–4.2 (m, 1 H), 6.73 (d, J = 8 Hz, 1 H), 7.02 (d, J = 8 Hz, 1 H), 10.75 (s, 1 H); *m/e* 412, 368.

Anal. Calcd. for $C_{23}H_{28}N_2O_5$: C, 66.97; H, 6.84; N, 6.79. Found: C, 66.61 H, 6.84; N, 6.87.

Oxidation of Haplocine to Cimicine

To a solution of haplocine (65 mg) in dichloromethane (10 ml) was added a solution of Collins' reagent (15) (700 mg) in dichloromethane. A red-brown solid precipitated at once. After 10 min the mixture was treated with ammonia, and the organic layer was separated after filtration through a Celite pad. The residue (42 mg) from evaporation of the organic layer was treated with aqueous 10% sodium hydroxide and the mixture was shaken with ether to remove non-lactonic material; the aqueous layer was made just acid, then basified with ammonia, and extracted with dichloromethane. The residue (28 mg) was subjected to t.l.c. on basic silica with development with chloroform – 10% methanol. Extraction of the band with the same R_f as that of cimicine yielded 6 mg of cimicine, m.p. 228–230° (identified by spectral comparison); $[\alpha]_D$ +82° ($CHCl_3$).

Reduction of Cimicine: Formation of Dihydrocimicine (6)

Cimicine (564 mg) in absolute ethanol (30 ml) was hydrogenated over prereduced platinum oxide (50 mg) at room temperature and atmospheric pressure. After 40 min 1.1 mol. equiv. of hydrogen had been taken up, and a fluffy solid had separated from solution. The solid was filtered and dissolved in methanol. The solution was filtered to remove the catalyst and concentrated to give dihydrocimicine (**6**). Two recrystallizations from methanol yielded the pure compound (140 mg), m.p. 266–270° dec.; λ_{max} (Nujol) 3.8 (br), 6.13 μ.

Anal Calcd. for $C_{22}H_{28}N_2O_4$: C, 68.72; H, 7.34; N, 7.29. Found: C, 68.31; H, 7.59; N, 7.64.

The *hydrochloride* was obtained as a glass; λ_{max} (Nujol) 3.8 (br), 5.82, 6.15 μ. The *methyl ester*, prepared by treatment of the hydrochloride with ethereal diazomethane, had m.p. 193–197°; λ_{max} ($CHCl_3$) 5.78, 6.14 μ; *m/e* 398, 168.

Dihydrocimicine was also obtained by reduction of cimicine (100 mg) in methanol (10 ml) with sodium borohydride (100 mg) for 10 h at room temperature. Addition of water (10 ml) and acetic acid (2 drops), extraction with chloroform (3 × 25 ml), and evaporation of the extract gave a semi-crystalline residue. Crystallization from methanol gave dihydrocimicine as a microcrystalline solid, m.p. 265–267° dec., identical with the hydrogenation product from cimicine.

Hydrogenation of Cimicidine: Formation of Dihydrocimicidine (7)

Cimicidine was hydrogenated by the method of Snyder *et al.* (2) to give the dihydrate of dihydrocimicidine, m.p. 265–267° dec. (lit. (2) m.p. 262–264° dec.); λ_{max} (Nujol) 3.0 (br), 3.7 (br), 6.13, 6.30 μ. The *hydrochloride*, m.p. *ca.* 255° dec. (lit. (2) m.p. 245–260° dec.), had λ_{max} (Nujol) 3.9 (br), 5.83, 6.13 μ. The *methyl ester* was obtained as an amorphous solid; λ_{max} ($CHCl_3$) 5.78, 6.14 μ; *m/e* 428, 168.

Oxidation of Cimicine with Alkaline Hydrogen Peroxide: Formation of 10-Oxocimicine (14)

Cimicine (1.00 g) was dissolved in aqueous 1% sodium hydroxide (50 ml) and treated with 30% hydrogen peroxide (20 ml). The mixture was stirred at 0° for 1 h and at room temperature for a further 2 h. The solid that separated was filtered, and a further 20 ml of 30% hydrogen peroxide was added to the filtrate. The mixture was stirred for 5 h at room temperature, and the additional solid that separated was filtered and combined with the first crop (total: 520 mg). The crude product was crystallized from ethanol to give 10-oxocimicine (480 mg) as needles, m.p. 297–299°, λ_{max} (Nujol) 5.56, 5.82, 6.14 μ; λ_{max} (EtOH) (ε) 220 (20 500), 256 (5900), 294 (1800) nm; λ_{max} (EtOH–NaOH) (ε) 234 (19 400), 259 (infl., 5100), 315 (4700) nm; δ ($CDCl_3$) 1.23 (t, J = 8 Hz, 3 H), 3.8–4.3 (m, 2 H), 6.8–7.2 (m, 3 H), 10.55 (s, 1 H); *m/e* (relative abundance) 396 (50), 340 (100).

*O-Acetyl-10-oxocimicine (**16**)*

Acetylation of 10-oxocimicine with acetic anhydride and pyridine for 6 h at room temperature followed by crystallization of the product from ethanol gave the *O*-acetyl derivative, m.p. 257–260°; λ_{max} (Nujol) 5.56 (sh), 5.64, 5.80, 5.97 μ; δ ($CDCl_3$) 1.17 (t, J = 8 Hz, 3 H), 2.25 (s, 3 H), 3.9–4.3 (m, 2 H), 7.0–7.6 (m, 3 H); *m/e* 438.

*Oxidation of Haplophytine with Alkaline Hydrogen Peroxide: Formation of 10-Oxohaplophytine (**12**)*

Haplophytine (1.00 g was dissolved in aqueous 1% sodium hydroxide (50 ml) and treated with 30% hydrogen peroxide (50 ml). The temperature of the solution was maintained at 15° throughout the course of the reaction. The solid that separated was filtered after 1, 2, 4, 7, and 24 h and air dried (total: 410 mg). The crude product was recrystallized from ethanol to give 10-oxohaplophytine, m.p. 220–222° and 268° dec. (lit. (16) m.p. 216–219° and 250–260° dec.); λ_{max} ($CHCl_3$) 5.62, 5.72, 5.88, and 6.05 μ; λ_{max} (EtOH) (ε) 220 (51 200), 268 (15 500), 307 (4000) nm; δ ($CDCl_3$) 2.43 (s, 3 H), 2.98 (s, 3 H), 3.17 (s, 3 H); 3.65 (s, 3 H), 4.02 (d of d, J = 10, 2 Hz, 1 H), 5.60 (d, J = 11 Hz, 1 H), 5.97 (d of d, J = 11, 2 Hz, 1 H), 6.27 (d of d, J = 8, 2 Hz, 1 H), 6.9–7.2 (m, 3 H), 8.94 (s, 1 H)[6] (together with peaks arising from ethanol of solvation); *m/e* (relative abundance) 666.2659 (13; M^+ = 666.2690), 638.2802 (100; M − CO = 638.2741).

Anal. Calcd. for $C_{37}H_{38}N_4O_8.2C_2H_5OH$: C, 64.91; H, 6.60; N, 7.39. Found: C, 65.02; H, 6.37; N, 7.61.

A sample, m.p. 222–224° and 255° dec., crystallized from benzene also tenaciously retained solvent.

Anal. Calcd. for $C_{37}H_{38}N_4O_8.0.75\ C_6H_6$: C, 68.72; H, 5.91; N, 7.73. Found: C, 68.73; H, 5.99; N, 7.43.

*O-Methyl-10-oxohaplophytine (**23**)*

10-Oxohaplophytine in benzene–methanol was methylated with excess of ethereal diazomethane for 7 days with additions of fresh ethereal diazomethane after 2, 4, and 5 days. The crude product obtained after removal of the solvents was crystallized from ethanol to give the *O*-methyl derivative, m.p. 252–255° dec.; λ_{max} ($CHCl_3$) 5.61, 5.73 (sh), 5.85 μ; δ ($CDCl_3$) 2.47 (s, 3 H), 3.08 (s, 3 H), 3.18 (s, 3 H), 3.65 (s, 3 H), 3.75 (m, 1 H), 3.95 (s, 3 H), 4.15 (m, 1 H), 5.68 (d of d, J = 11, 1 Hz, 1 H), 6.02 (d of d, J = 11, 2 Hz, 1 H), 6.28 (d of d, J = 7, 2 Hz, 1 H), 6.8–7.3 (m, 3 H); *m/e* 680.

Anal. Calcd. for $C_{38}H_{40}N_4O_8.1.5\ H_2O$: C, 64.48; H, 6.12; N, 7.92. Found: C, 64.56; H, 6.06; N, 8.02.

*O-Acetyl-10-oxohaplophytine (**24**)*

10-Oxohaplophytine was acetylated with acetic anhydride and pyridine at reflux for 40 min. The crude product obtained after dilution with water, adjustment of the p*H* to 8 with aqueous 10% sodium bicarbonate, and extraction with dichloromethane was crystallized from aqueous ethanol to give the *O*-acetyl derivative, m.p. 287–289° dec.; λ_{max} ($CHCl_3$) 5.64, 5.72, 5.85 μ; λ_{max} (EtOH) (ε) 219 (54 000), 263 (13 900), 304 (3800) nm; δ 2.27 (s, 3 H), 2.47 (s, 3 H), 2.98 (s, 3 H), 3.14 (s, 3 H), 3.60 (s, 3 H), 3.7 (m, 1 H), 4.0 (br d, J = 12 Hz, 1 H), 5.60 (br d, J = 11 Hz, 1 H), 5.95 (d of d, J = 11, 2 Hz, 1 H), 6.55 (m, 1 H), 7.0–7.3 (m, 3 H).

Anal. Calcd. for $C_{39}H_{40}N_4O_9$: C, 66.10; H, 5.65; N, 7.91. Found: C, 65.79; H, 5.76; N, 7.87.

*Acid Cleavage of 10-Oxohaplophytine: Formation of 10-Oxoaspidophytine (**26**)*

A solution of 10-oxohaplophytine (320 mg) in 6 *N* hydrochloric acid (10 ml) was heated on the steam bath for 1 h under nitrogen. The solution was then cooled and basified with ammonia. The precipitated solid was extracted into chloroform. The extract was dried and evaporated to give a dark residue (89 mg), which was dissolved in ether; the solution was filtered to remove some dark insoluble solid and evaporated. The residue (69 mg) was crystallized from ether–hexane to give 55 mg of unchanged 10-oxohaplophytine, m.p. 220°. The pale-yellow solid (14 mg) from the mother-liquor of crystallization was chromatographed on alumina (Neutral, Grade II) in chloroform solution to yield 9 mg of 10-oxoaspidophytine in the 4 × 10 ml fraction, m.p. 236–237° after one crystallization from ethanol, *m/e* 396. This was identified as **26** by i.r., p.m.r., and t.l.c. comparison.

*Oxidation of Aspidophytine with Alkaline Hydrogen Peroxide: Formation of 10-Oxoaspidophytine (**26**)*

Aspidophytine (200 mg) was dissolved in ice-cold aqueous 2% sodium hydroxide (10 ml) and 30% hydrogen peroxide (10 ml) was added with stirring at 0°. After 2 h 6 *N* hydrochloric acid was added to bring the solution to p*H* 6, and the latter was rapidly extracted with dichloromethane (2 × 15 ml). The extract was dried and evaporated, and the residue was sublimed at 200° (0.05 mm) to give colorless needles (55 mg), m.p. 242–243°; λ_{max} ($CHCl_3$) 5.65, 5.63, 5.85 μ; λ_{max} (EtOH) (ε) 222 (28 700), 259 (4800), 306 (1550) nm; δ ($CDCl_3$) 3.17 (s, 3 H), 3.68 (m, 1 H), 3.77 (s, 3 H), 3.80 (s, 3 H), 4.03 (br d, J = 12 Hz, 1 H), 5.57 (d of d, J = 10, ~1 Hz, 1 H), 6.01 (d of d, J = 10, 2.5 Hz, 1 H), 6.25 (d, J = 8.5 Hz, 1 H), 7.03 (d, J = 8.5 Hz, 1 H); *m/e* 396.

Anal. Calcd. for $C_{22}H_{24}N_2O_5$: C, 66.65; H, 6.10; N, 7.07. Found: C, 66.98; H, 6.52; N, 7.20.

This work was supported in part by grants from the National Institutes of Health (HE-12961) and the National Research Council of Canada.

[6]In this and subsequent p.m.r. spectra the methyl proton signals are frequently superimposed on multiplet signals of other protons and the relative areas assigned to them represent approximate estimates.

Reactions of Ozonides. XI. A ^{14}C Tracer Study of the Ozonolysis of Ethylidenecyclohexane in Cyclohexanone

DUNDAPPA R. KERUR AND DENNIS G. M. DIAPER
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario

Received March 19, 1973

Using ^{14}C labelling of cyclohexanone or ethylidenecyclohexane, examination of the products of ozonolysis of the alkene in the presence of the ketone reveal 6-hexanolide to be initially formed in $< 1\%$ yield. Cyclohexanone peroxides are the major products from ethylidenecyclohexane ozonized in cyclohexanone. Carbonyl-modified alkene ozonolysis is therefore suggested to be explicable by the Criegee mechanism, and it is unnecessary to invoke Baeyer–Villiger interactions. Ozonide formation is not totally suppressed by cyclohexanone.

L'utilisation du marquage au ^{14}C de la cyclohexanone ou de l'éthylidènecyclohexane pour examiner les produits d'ozonolyse de l'alcène en présence d'une cétone, montre que la formation initiale d'hexanolide-6 est $< 1\%$ de rendement. Les peroxydes de la cyclohexanone sont les produits majeurs de l'éthylidènecyclohexane et l'ozone dans la cyclohexanone. L'ozonolyse de l'alcène modifié par un carbonyle peut donc être expliquée par le mécanisme de Criegee sans qu'il sont nécessaire d'invoquer les interactions de Baeyer–Villiger. La formation d'ozonide n'est pas totalement supprimée par la cyclohexanone.

Introduction

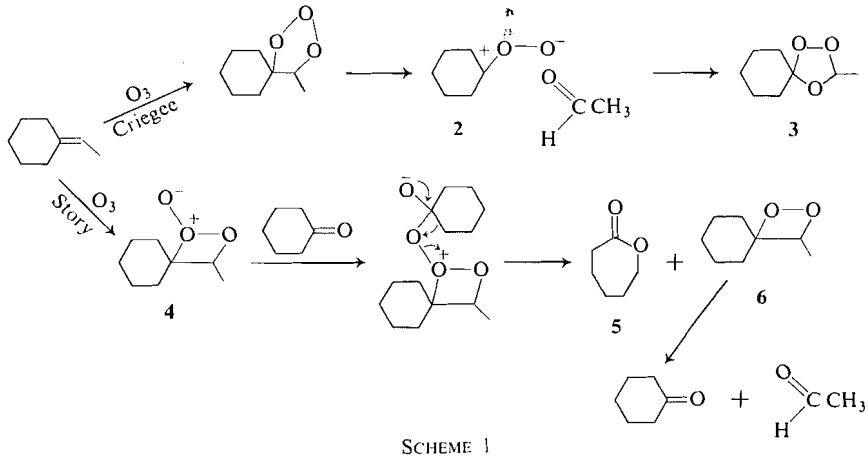
Story and co-workers (1, 2, 3) have recently studied the ozonolysis of certain alkenes in the presence of carbonyl compounds and find that surprisingly the yield of ozonide is very small, although previous theories of ozonolysis mechanisms require the same carbonyl compound to be a precursor in ozonide formation. In *n*-pentane, for example, ozonolysis of ethylidenecyclohexane (**1**) gives good yields of the expected ozonide **3**; however, in the presence of excess of cyclohexanone, the reaction produced "no" ozonide, but only cyclohexanone, acetaldehyde, and 6-hexanolide (**5**) were found. These authors accordingly proposed a mechanism involving reduction of the initially produced Staudinger molozonide (**4**) by cyclohexanone to give an intermediate dioxetane (**6**), the cyclohexanone producing, in a Baeyer–Villiger type of reaction, 6-hexanolide. Subsequent decomposition of the dioxetane would then produce cyclohexanone and acetaldehyde (Scheme 1). Since the ozonolysis solution, after solvent removal, was reported to be viscous, it seemed desirable to consider polymeric reactions as alternative explanations. If, for example, alternating cyclohexane ring units in a polymer chain were derived from cyclohexanone and the zwitterion from ethylidenecyclohexane with subsequent random decomposition to 6-hexanolide, valuable information on the course of the reaction mechanisms could be obtained from specific activities using one or the other starting material labelled with ^{14}C. Other possible explanations of 6-hexanolide formation, such as zwitterion–carbonyl reactions of an unusual type, as well as the side-products of ozonolysis, could also be studied in a labelling experiment. Accordingly we examined the ozonolysis of ethylidenecyclohexane labelled with ^{14}C in the ring using unlabelled cyclohexanone as solvent; also we studied the ozonolysis of unlabelled ethylidenecyclohexane using labelled cyclohexanone as a solvent. These experiments made possible the examination of the reaction products by the isotopic dilution technique in a reliable quantitative fashion.

Experimental

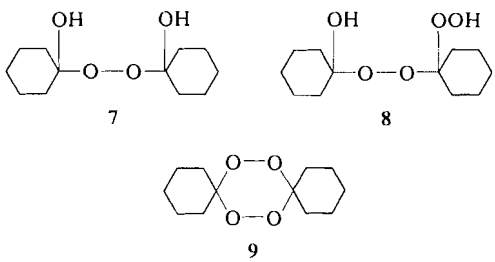
Materials and Reference Compounds

6-Hexanolide, b.p. 118–120°/15 mm (lit. 118–119°/15 mm (4)) was prepared in 77% yield by the Baeyer–Villiger reaction of peroxytrifluoroacetic acid with cyclohexanone (cf. 5). Its n.m.r. spectrum (Varian A-60-A; all spectra measured undiluted or in CCl_4 with tetramethylsilane internal standard) had peaks at δ 4.13–4.26 ($COOCH_2$), 2.51–2.68 (CH_2COO), and 1.78–1.80 p.p.m. (ring CH_2). Attempts to convert it to 6-hydroxyhexanoic acid by saponification using NaOH gave a syrup which polymerized readily to $HO((CH_2)_5CO)_nH$, m.p. 52–54° (6). The lactone was readily converted to 6-hydroxyhexanoic acid hydrazide, m.p. 112–113°, in 82% yield (6).

"Cyclohexanone peroxides" (**7**, **8**, and **9**) were obtained by known procedures (7). 1,1′-Dihydroxycyclohexyl



SCHEME 1



peroxide (**7**), m.p. 71–73°, was prepared in 67% yield by the action of 30% hydrogen peroxide on cyclohexanone in the molar ratio of 1:2. 1-Hydroxy-1′-hydroperoxydicyclohexyl peroxide (**8**), m.p. 76–77°, was obtained in 75.2% yield by reaction of 30% hydrogen peroxide on **7** in the presence of dilute HCl. Its n.m.r. spectrum showed peaks at δ 1.78 and 1.58 p.p.m. and structureless absorption between 2.56–2.83 and 2.21–2.47 p.p.m. **8** reacted vigorously with 85% hydrazine hydrate, but **9** did not. Dicyclohexyl diperoxide (**9**), m.p. 130–131°, was prepared in 3.7% yield by the action of 30% hydrogen peroxide on cyclohexanone (1:1) in the presence of perchloric acid. Its n.m.r. spectrum had a strong peak at 1.55 p.p.m. and broad peaks at 2.60–2.77 and 1.78–1.93 p.p.m. **8** slowly changed into **9** on standing; accordingly purification to constant specific activity in the labelling experiments was not tried.

Ethylidenecyclohexane ozonide (**3**) was prepared in 87% yield by ozonation of the alkene in *n*-pentane at −30°. This reaction also gave **9** in 9.7% yield. An undiluted sample of the ozonide had an n.m.r. spectrum with a well-defined quartet at 5.28 (J = 5 Hz, CH), a broad peak at 1.65 (ring CH_2), and a doublet at 1.32 p.p.m. (J = 5 Hz, CH_3).

Cyclohexanol-^{14}C was obtained in 96% yield by hydrogenation of phenol containing some ring-labelled phenol (Amersham-Searle Corp., Arlington Heights, Ill., 32 mCi/mmol) over Raney nickel at 1200 p.s.i. and 175–200°. Dichromate oxidation in acid gave cyclohexanone-^{14}C in 50% yield, b.p. 154–158° (lit. 155° (8)), 2,4-dinitrophenylhydrazone, m.p. 161–162° (lit. 162° (8)). The i.r. and n.m.r. spectra of the labelled and unlabelled samples were identical. Specific activity of the labelled ketone was 538.3 ± 2.4 c.p.m./mg. Samples were spread on planchets and counted using a Nuclear Chicago end-window counter. Corrections were made for self-absorption. The statistical error is recorded.

Ring-labelled ethylidenecyclohexane was obtained from the ketone by a Wittig synthesis as follows: triphenylethylphosphonium bromide, m.p. 206–208° (lit. 205–207° (9)), was prepared in 67% yield, based on triphenylphosphine, by boiling the latter with an excess of ethyl bromide in dry benzene. Phenyllithium reacted with the bromide and labelled cyclohexanone to give ethylidenecyclohexane-^{14}C, b.p. 134–138° (lit. 135–136° (10)), 597.4 ± 8.9 c.p.m./mg, having n.m.r. and i.r. spectra identical with those of an authentic sample (Aldrich).

Ozonation of Unlabelled Ethylidenecyclohexane in Unlabelled Cyclohexanone

An ozone–oxygen stream was passed into a solution of 1.40 g of the alkene in 50 ml of cyclohexanone at −15°. Removal of excess cyclohexanone with the aid of a high vacuum pump and a cold trap at −78° gave 1.75 g of a colorless viscous residue (dioxetanes are frequently yellow). This residue liberated iodine immediately and copiously from a solution of potassium iodide in acetic acid. A broad band, attributed to OH, was observed in the i.r. spectrum at 2.9–3.0 μ and there was a strong carbonyl peak at 5.9 μ. The n.m.r. spectrum showed peaks at δ 2.21–2.31, 1.75–1.78, and 1.63 p.p.m. Minor unstructured absorption was also noted at δ 5.0–5.3, 4.1–4.3, and 2.7–3.1 p.p.m. When 85% hydrazine hydrate was added, effervescence and evolution of heat occurred, but on boiling with ethanol and subsequent evaporation no 6-hydroxyhexanoic acid hydrazide crystals were formed.

Analysis of the syrupy residue by t.l.c. on Eastman "Chromagram" sheets gave inadequate separation in most single or mixed solvents. Almost complete resolution into four components was obtained in butyl acetate; their R_f values were respectively 0.90, 0.70, 0.44, and 0.25. Authentic **9**, **8**, and **3** had R_f values respectively of 0.96, 0.74, and 0.49. **7** was absent. The other spot, attributed to peroxy polymers, showed considerable "tailing".

Spray reagents used for t.l.c. spot visualization were 3% KI in 5% aqueous acetic acid and concentrated H_2SO_4.

Ozonation of Ethylidenecyclohexane in Labelled Cyclohexanone

The above experiment was repeated except that 241.8 mg of cyclohexanone-^{14}C (totalling 1.3×10^5 c.p.m.) was added as well as 50 g of unlabelled cyclohexanone. The residue after solvent removal had 4.03 ± 0.1 c.p.m./mg and therefore contained only about 0.5% of the added tracer. The recovered cyclohexanone had specific activity 2.7–3.0 ± 0.2 c.p.m./mg (at least 98% recovery based on the weight of recovered ketone).

T.l.c. failed to isolate the 6-hexanolide present in this residue, therefore a dilution analysis as the hydrazide was attempted as follows. To the residue was added 0.5 g of authentic 6-hexanolide. After adding 5 ml of 85% hydrazine hydrate and 25 ml of 95% ethanol, the reaction mixture was boiled for 1 h. Evaporation gave the semi-solid hydrazide, which was recrystallized twice from ethyl acetate, m.p. 113–115°. No radioactivity could be detected in the recovered 6-hydroxyhexanoic acid hydrazide.

Ozonation of Labelled Ethylidenecyclohexane in Unlabelled Cyclohexanone

The alkene (704.6 mg, specific activity 114.4 ± 1.7 c.p.m./mg) in 25 ml of cyclohexanone was treated with ozone as above. The residue after solvent removal (889.1 mg, 57.5 ± 0.5 c.p.m./mg, radiochemical yield in this experiment 63.4%) was divided into several portions. The recovered cyclohexanone was divided into several portions. The recovered cyclohexanone registered 0.3–1.2 ± 0.3 c.p.m./mg.

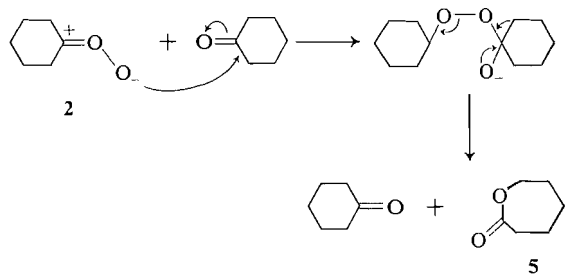
To 259.5 mg of the residue, 255.5 mg of authentic 6-hexanolide, 3 ml of 85% hydrazine hydrate, and 10 ml of 95% ethanol were added. After boiling for 1 h, the reaction product was recovered and recrystallized as before, giving 312.3 mg of 6-hydroxyhexanoic acid hydrazide, m.p. 114–116°, specific activity 1.5 ± 0.3 c.p.m./mg. After four successive recrystallizations of a portion, radioactivity became undetectable. Another portion after seven recrystallizations had a constant residual activity of 0.6 ± 0.1 c.p.m./mg. This experiment, together with the preceding experiment, shows a yield of not more than 0.25% of 6-hexanolide in the residue as determined by radioactive assay.

To 33.1 mg of the residue in 1 ml of ether, 51.6 mg of authentic purified ozonide was added and the components of the mixture were separated by t.l.c. Ozonide recovered by ether extraction of the silica gel (9.6 mg) had a specific activity of 1.2 ± 0.5 c.p.m./mg. Authentic cyclohexanone peroxides **3**, **8**, and **9** were chromatographed with the sample for comparison. **9** was visualized by sulfuric acid spray; it liberates iodine from acid KI only slowly. **9** separated as crystals from the ozonation residue on long standing at room temperature. Although **8** was not obtained crystalline from the ozonation residue, its presence was detected by t.l.c. and its concentration, from intensity of t.l.c. spots, appeared similar to that of **9**; **3** was present in smaller quantity and polymeric peroxides were also detected. Some cyclohexanone was also present in the residue (i.r.).

Discussion

The major products of ethylidenecyclohexane ozonolysis in cyclohexanone are "cyclohexanone peroxides" **8** and **9**. The latter crystallizes well, and may in fact be more conveniently prepared by carbonyl-modified ozonolysis of this and other alkylidenecyclohexanes (11) than by published procedures. The former does not crystallize so well. Both are known to decompose under a variety of conditions, including thermolysis in the presence or absence of acids, to 6-hexanolide and related products (12–14). Isolation of 6-hexanolide by gas chromatography of a mixture containing cyclohexanone peroxides is unreliable evidence of its initial presence.

Isotopic dilution analysis enables an accurate upper limit to be set for the concentration of the substance analyzed. 6-Hexanolide was below detection limits (<0.04%) in the labelled cyclohexanone experiment and <0.25% in the experiment using labelled alkene in unlabelled cyclohexanone. Story's proposed mechanism (Scheme 1) (1, 2, 3) would require labelled 6-hexanolide from the former but not the latter experiment. The isotopic dilution study rules out significant formation of 6-hexanolide by Scheme 1 and also by other routes such as Scheme 2 which are in agreement with the Criegee mechanism. Formation of small quantity of 6-hexanolide from the ethylidenecyclohexane moiety argues its origin from zwitterion **2**, possibly through dimeric forms **8** and **9**.



SCHEME 2

Ozonide (**3**) formation was not suppressed completely by the cyclohexanone but the yield was diminished from 86.6% in pentane to 2.9% in cyclohexanone as solvent. In the competition between ozonide formation and other reactions a difference of a few kilocalories in activation energies would account for this difference in yield; such an energy difference may be explained

by solvent polarity effects. Kopecky *et al.* (15) incline to this view, which they support by demonstrating the absence of dioxetane **6** when ethylidenecyclohexane is ozonized in pinacolone. In cyclohexanone **5** and **6** should be produced in equimolecular proportions according to Scheme 1.

Formation of labelled cyclohexanone from ethylidenecyclohexane is explicable in a number of ways. Direct formation by the Criegee mechanism and bimolecular loss of O_2 from the zwitterion (16, 17) or zwitterion – carbonyl redox reaction (18) are all plausible. Formation of labelled cyclohexanone by Scheme 1 would require production of an equimolecular quantity of 6-hexanolide **5**; this was not observed. Cyclohexanone itself is only slowly attacked by ozone, giving adipic acid (19).

We wish to thank Professor S. N. Naldrett for the use of a Nuclear-Chicago counter. Financial support from Defence Research Board of Canada under Grant 9530-17 is gratefully acknowledged.

Thermodynamic Properties of Zinc Chloride in Alkali Chloride Melts by Electromotive Force Measurements

RON J. ROBERTSON[1] AND ALFRED S. KUCHARSKI
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario

Received January 5, 1973

Electromotive force measurements on the $ZnCl_2$–ACl systems where A = K, Rb, and Cs were made using cells of the type

$$Zn_{(l)}|ZnCl_2\text{–}ACl_{(l)}|\text{graphite, } Cl_{2(g,\ 1\ atm)}$$

in the temperature range 450° to 800 °C. The partial molar free energies, enthalpies, and excess entropies have been determined from the temperature dependence of the emf results. These thermodynamic properties exhibit increasing negative departure from ideality as the basicity of the alkali metal salt increases. The results are interpreted in terms of an acid–base reaction and are discussed in relation to current models.

On a évalué la force électromotrice des système $ZnCl_2$–ACl où A = K, Rb et Cs en utilisant des piles du type

$$Zn_{(l)}|ZnCl_2\text{–}ACl_{(l)}|\text{graphite, } Cl_{2(g,\ 1\ atm)}$$

pour des températures de 450 à 800 °C. Les énergies libres molaires partielles, les enthalpies ainsi que les entropies en excès ont été déterminées à partir de la dépendance des résultats fem par rapport à la température. Pour ces propriétés thermodynamiques, on a trouvé un écart négatif par rapport au cas idéal qui va en augmentant à mesure que la basicité du sel métallique alcalin augmente. Les résultats sont interprétés en fonction d'une réaction acide–base et sont comparés aux modèles classiques.

[Traduit par le journal]

Can. J. Chem., 51, 3114 (1973)

Introduction

Acid–base reactions at high temperatures are important in many metallurgical processes. For example, in the smelting and the converting of copper–nickel sulfide ores, iron is eliminated as an iron oxide by reacting it with silica to form a fluid slag. In this type of reaction, silica acts as an acid by accepting oxygen from other basic oxides to break down the three dimensional network structure of liquid silica. In this manner, highly viscous slags can be made more fluid by the addition of basic oxides. The basicity of a particular metallic oxide can be simply related (1) to the coulombic force of attraction that a metal cation exerts on an oxygen anion.

The theoretical interpretation of this phenomena has been hampered by the lack of accurate thermodynamic data. In particular there is a lack of data reported for the enthalpy and entropy of mixing for metallic oxide – silica molten systems. The inherent difficulties encountered at the very high temperatures required to study these molten oxide systems accounts for this fact. However, the free energies (2–4) and the enthalpy of mixing (5) for the PbO–SiO_2 have been reported in the literature excluding the silica-rich compositions.

A plot of the interaction parameter, $\Delta H/(X_{PbO})(X_{SiO_2})$ *vs.* X_{SiO_2} by the latter authors for the PbO–SiO_2 system exhibits a minimum in the composition range $X_{SiO_2} = 1/3$. Also, the partial excess entropy of mixing of SiO_2 calculated from the combination of the electrochemical free energies and calorimetric enthalpies of mixing indicate a similar discontinuity at approximately $X_{SiO_2} = 1/3$. The formation of the orthosilicate via the reaction

$$[1] \qquad 2PbO + SiO_2 \rightarrow Pb_2SiO_4$$

is postulated to account for this unusual behavior. The binary phase diagrams for other MO–SiO_2 systems (6) exhibit immiscibility gaps; however, with increasing basicity of the metal oxide, MO, the gap diminishes and even disappears as in the alkali metal oxide – SiO_2 binary systems. Thus heats of mixing for such partially miscible systems should be positive in the region of the miscibility gap. Heats of mixing for systems of this type have not been reported

in the literature in spite of their technical and theoretical importance.

To understand the acid–base behavior of molten oxide systems, molten fluoride systems have been considered by Holm and Kleppa (7) to be "weak oxide" analogs. The ionic radius of the fluoride ion ($r_{F^-} = 1.36$ Å) is approximately equal to the ionic radius of oxygen ($r_{O^{2-}} = 1.40$ Å). Both BeF_2 and SiO_2 are highly viscous and poor conductors in the liquid state and thus reflect the polymeric nature of their liquid state.

The enthalpies of mixing for the BeF_2–LiF and BeF_2–KF systems reported by these authors indicate that the BeF_2–LiF system exhibits both negative and positive deviations. But this immiscibility tendency is not reflected in the BeF_2–KF system since the enthalpy of mixing for this system is totally negative with a maximum occurring approximately at the composition $X_{BeF_2} = 1/3$. If the ionic radii for the alkali metal ions are considered, the immiscibility tendencies in the BeF_2–LiF system and the lack of it in the BeF_2–KF system can be understood. The small lithium ion ($r = 0.60$ Å) makes LiF a poor base since it is able to form strong electrostatic bonds with the surrounding F^- ions and approaches the Be^{2+}—F^- bond strength. In contrast, the larger potassium ion ($r = 1.33$ Å) is able to donate F^- ions to the acidic Be^{2+} ion to form the tetrahedral complex, BeF_4^{2-} in the basic composition range. The partial entropy of mixing for BeF_2 was computed from the free energies of mixing determined from both phase diagrams and emf measurements. The results indicate large negative deviations in the LiF rich range.

The analogy between the BeF_2–LiF and SiO_2–alkaline earth oxide systems has been suggested by Cantor *et al.* (8) in their viscosity and density measurements in the BeF_2–LiF system. The calculated activation energy for viscous flow decreases with LiF concentrations similar to the analogous SiO_2 – alkaline earth oxide systems.

The enthalpies of mixing of metallic chloride – alkali chloride measured by Kleppa and coworkers (9–12) also exhibit this type of acid–base behavior in varying degrees. A discrete complex anion model has been developed by Pelton (13) to establish a semi-quantitative basicity scale for MY_2–AY halide systems where M is a divalent metal cation and A is an alkali metal cation.

The similarities of the liquid structures for $ZnCl_2$ and SiO_2 have been proposed by Angell and Wong (14) and indicate that a $ZnCl_2$-based analog could be used to elucidate the behavior of the baulky oxide systems. Spectroscopic investigation (15, 16) of zinc chloride – alkali chloride systems indicate that these systems exhibit extreme acid–base behavior. This behavior is quite similar to the oxide systems in that the polymeric species are broken down by the ligands from the donating base. In addition, viscosity (17), density (18), and electrical conductivity (19) support this view. However, the enthalpies and entropies of mixing of these binary systems has not been determined (20).

From the temperature dependence of the free energy it has been demonstrated for the $MnCl_2$–ACl systems (A = Li, Na, K, Cs) (21) that enthalpies and entropies can be accurately determined. The acidic solution properties of $ZnCl_2$ can be investigated in the reaction

$$[2] \qquad Zn_{(l)} + Cl_{2(g,\ 1\ atm)} \rightarrow ZnCl_{2(l,\ soln)}$$

by means of an electrolytic cell of the type

$$Zn_{(l)}|ZnCl_2\text{–}ACl_{(l)}|\text{graphite},\ Cl_{2(g,\ 1\ atm)}$$

This type of cell has been used by Takahashi (22) to determine the thermodynamic properties of $ZnCl_2$ in a solvent consisting of a LiCl–KCl eutectic. The activity of $ZnCl_2$ is low in the alkali chloride-rich concentrations reflecting the tendency of the acidic character of Zn^{2+} cation to coordinate four Cl^- anions to form the tetrahedral complex, $ZnCl_4^{2-}$. This result is substantiated by Flengas and Ingraham (23) in the e.m.f. measurements of dilute solutions of $ZnCl_2$ in a solvent of equimolar NaCl–KCl. In addition Markov and Chernov (24) have calculated the liquidi in the alkali chloride-rich concentrations for the $ZnCl_2$–RbCl and $ZnCl_2$–CsCl phase diagrams by postulating the formation of the tetrahedral complex. The thermodynamic properties of $ZnCl_2$–ACl (A = Li, Na, K, Rb, Cs, Ba) have been reviewed by Dijkhuis *et al.* (20), however; the free energies of mixing for the $ZnCl_2$–KCl, $ZnCl_2$–RbCl, and $ZnCl_2$–CsCl systems were measured by Markov and Volkov (25, 26) using a non-equilibrium technique. It was not possible to determine accurately the enthalpies and entropies of mixing for these systems. Thus, the aim of the present investigation is to determine electrochemically the free energies of mixing and thereby be able to cal-

culate the enthalpies and entropies of mixing to elucidate the thermodynamic properties of acid–base reactions at high temperatures.

Experimental

Anhydrous zinc chloride and alkali chloride were prepared by heating slowly reagent grade material under vacuum to 200 °C and 400 °C respectively for a period of several hours. To insure final dehydration, the zinc chloride salt was fused under a stream of anhydrous hydrogen chloride gas. This gas was bubbled through the melt for approximately 20 min followed by flushing with argon gas to remove the dissolved hydrogen chloride gas. In a similar manner, the alkali chlorides were dehydrated in the solid state using anhydrous hydrogen chloride gas or chlorine. After the salts were cooled under an argon atmosphere, the zinc chloride or alkali chloride salts were transferred to a dry box and stored in sealed containers.

The design of the electrochemical cell used in this series of measurements is given in Fig. 1. This cell differs slightly from the one that was employed previously (21). To minimize the volatility of $ZnCl_2$, each half cell had a diameter of approximately 10 mm. This small cross-sectional area limited the loss of $ZnCl_2$ through volatilization and the area was further reduced by insertion of the graphite electrodes. The effectiveness of this design was verified by the facts that very little $ZnCl_2$ was observed on the colder walls of the cell even in the pure $ZnCl_2$ and $ZnCl_2$-rich compositions and that the cell potentials could be reproduced in a heating and cooling cycle. The latter would not be feasible if there was an excessive $ZnCl_2$ loss.

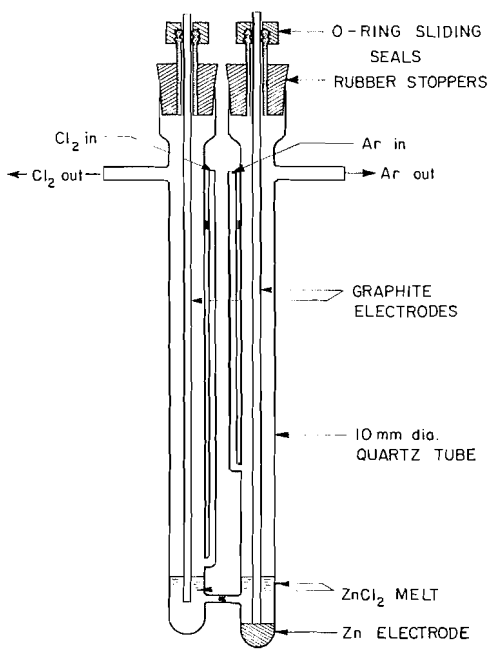

FIG. 1. EMF formation cell.

The zinc metal half-cell compartment was extended to accommodate a liquid zinc electrode. The zinc metal used in this work had a purity of 99.9%.

The graphite electrodes were treated in the usual manner (20) by heating to 1000 °C under vacuum and then passing chlorine gas over the electrodes. No attack or swelling of the graphite was observed as reported previously for the $CdCl_2$–NaCl (27) and the $MnCl_2$–ACl (A = Li, Na, K, and Cs) systems (21).

A period of approximately 1 day was required for chlorine saturation in pure $ZnCl_2$ and $ZnCl_2$-rich concentrations especially at low temperatures. However, once the melts were saturated with chlorine, the cell potentials were stable and reproducible. Only a short time was necessary to saturate the alkali chloride-rich concentrations. The reversibility of the cell potentials was verified by polarization tests in which a current from an external source was passed through the cell. The cell potential always returned to the former unpolarized value within a minute upon removal of the external polarizing source.

In order to correct for the lowering of the chlorine pressure in the chlorine half-cell by the $ZnCl_2$ vapor at high temperatures, the vapor pressure was measured by a transportation method. Chlorine gas was passed over a boat of the molten salt and the volume of chlorine gas was determined by a displacement method. This correction is appreciable in the pure $ZnCl_2$ and $ZnCl_2$-rich concentrations.

Results

As indicated, the vapor pressure of the $ZnCl_2$ becomes appreciable in the pure state or in the $ZnCl_2$-rich compositions. The vapor pressure of pure $ZnCl_2$ was measured at 569 °C and found to be 54 mm Hg. This result agrees to within 4 mm Hg of the measurements made by Bloom *et al.* (28) and George *et al.* (29). Thus the emf data for the pure $ZnCl_2$ were corrected for the vapor pressure of $ZnCl_2$ using the equation determined by Bloom and is given in Table 1.

The vapor pressure of $ZnCl_2$ for several $ZnCl_2$-rich compositions is also given in Table 1. The vapor pressure in the $ZnCl_2$–RbCl and the $ZnCl_2$–CsCl systems is expected to be much

lower than the $ZnCl_2$–KCl system following the trends reported for the $MnCl_2$–ACl (A = K, Rb, and Cs) systems (21). Therefore, no correction was applied to the compositions greater than $X_{ACl} = 0.48$ where A = Rb, Cs. The maximum correction applied to the solutions was only approximately 3 mV and 10 mV in pure $ZnCl_2$ in the temperature range studied. The corrected E^0 emf values for two separate experimental runs were fitted by least square analysis to give the linear equation

$$E^0 = 1927.5 - 0.45472T$$

The standard deviation for the fit was found to be 1.7 mV.

In Table 2, the standard potential is compared at various temperatures with those calculated from the available standard free energy data. Also, the standard potentials are compared with the new values obtained when the lower heat of fusion (2450 cal) measured by Cubicciotti *et al.* (30) is combined with the tabulated thermochemical data of Wicks and Block (36).

The solution properties were measured using the cell shown in Fig. 1 representing reaction 2. The partial free energy of mixing for $ZnCl_2$, $\Delta\bar{G}_{ZnCl_2}$, is given as

$$[3] \qquad \Delta\bar{G}_{ZnCl_2} = -ZF(E - E^0)$$

The partial molar free energies are related to partial enthalpies and entropies of mixing by the equation

$$[4] \qquad \Delta\bar{G}_{ZnCl_2} = \Delta\bar{H}_{ZnCl_2} - T\Delta\bar{S}_{ZnCl_2}$$

If the enthalpy and entropy of mixing are taken to be temperature independent the quantity $(E - E^0)$ can be expressed as a linear function of temperature over a narrow temperature range. Thus, the partial enthalpies and entropies of mixing for $ZnCl_2$ were obtained from the intercepts and the slope of the linear functions $(E - E^0)$ plotted *vs.* temperature. The plots of $(E - E^0)$ *vs.* temperature for the three binary systems are given in Figs. 2, 3, and 4. It is seen that the data are well represented by the least square lines shown. The maximum deviation in all three binary systems is 2 mV and the largest deviation of an individual experimental point is approximately 4 mV. The equations are given in Table 3 along with the standard and maximum deviations for each line. The partial molar excess free energies of mixing of $ZnCl_2$, $\Delta\bar{G}^{XS}_{ZnCl_2}$ at 600 °C are also listed in Table 3 along with the partial molar enthalpies and excess entropies of mixing for $ZnCl_2$. These two properties are temperature independent as shown by the linearity of the plots. The partial molar heats of mixing for KCl, RbCl, and CsCl were calculated using the Gibbs–Duhem equation. These calculations are shown in Figs. 5, 6, and 7. Also, the partial molar heats of mixing for $ZnCl_2$ and the integral heats for each binary system are given in the figures.

TABLE 2. Comparison of the thermochemical and electrochemical standard potential (mV) for the formation of $ZnCl_2$

Parameter	Value at (°C) 450	500	550	600	Reference

For personal use only.

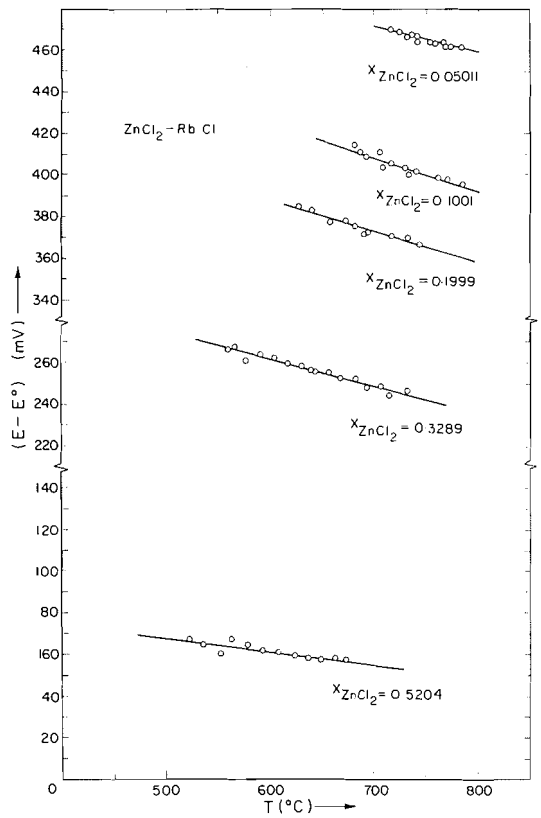

FIG. 3. Plots of $E - E^0$ *vs.* temperature for the $ZnCl_2$–RbCl system.

The integral heats of mixing were calculated from the well known expression

$$[5] \quad \Delta H_M = X_{ACl}\Delta\bar{H}_{ACl} + X_{ZnCl_2}\Delta\bar{H}_{ZnCl_2}$$

By using the standard deviations given in Table 3, the uncertainty in calculating integral heat of mixing is estimated to lie in the range of 150 to 350 cal per g-mol. This uncertainty limit is not significant in these systems with a large exothermic heat of mixing.

The partial excess free energy of mixing of $ZnCl_2$ at 600 °C for the three systems is plotted in Fig. 8. The dashed lines indicate that the partial excess free energies of $ZnCl_2$ have been extrapolated below the liquidus temperature. Also, the results of Markov and Volkov (25) have been plotted as solid circles for the $ZnCl_2$–KCl and the $ZnCl_2$–RbCl systems. These results were obtained using a nonequilibrium technique. The values of $\Delta\bar{G}^{XS}_{ZnCl_2}$ at infinite dilution are seen to be approximately −20, −23, and −25 kcal/mol for the KCl, RbCl, and CsCl systems. This increasing negative departure from ideality parallels the increasing basicity of the alkali chloride from KCl through to CsCl.

Discussion

In previous publications (21, 31) a model has been tested to account for the enthalpies of mixing for reactive charge asymmetrical systems of the type MCl_2–ACl where M represents a transition metal divalent cation and A an alkali metal cation. In this model the enthalpy of mixing is divided into two effects; the heat of mixing arising from the reaction to form the tetrahedral complex according to the reaction

$$[6] \quad 2ACl + ZnCl_2 \rightarrow A_2ZnCl_4$$

and the mixing of the products with remaining reactants to form a solution. Hence, the enthalpy of mixing is given as

$$[7] \quad \Delta H_M = \Delta H_R + \Delta H_m$$

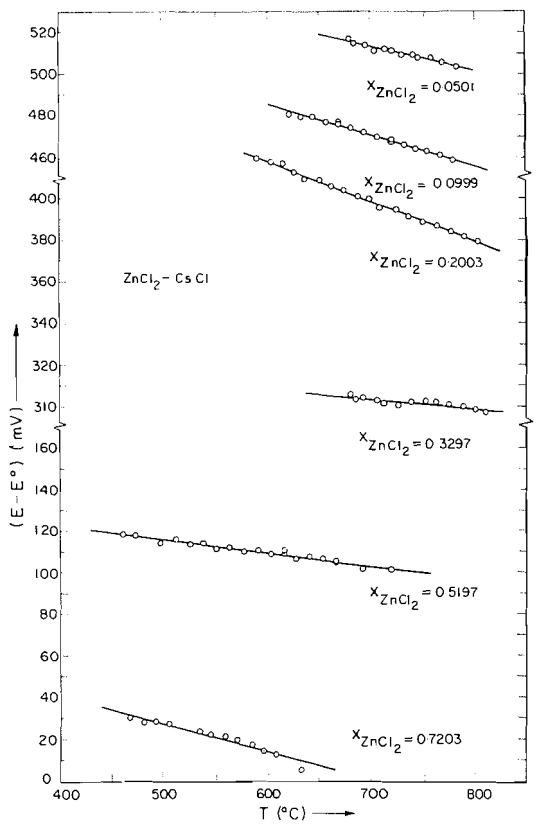

FIG. 4. Plots of $E - E^0$ *vs.* temperature for the $ZnCl_2$–CsCl system.

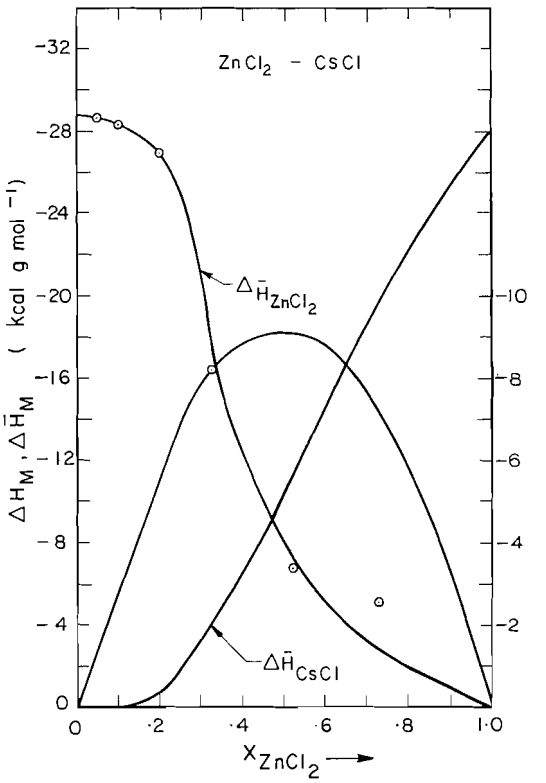

FIG. 7. Partial and integral enthalpies of mixing in the $ZnCl_2$–CsCl system.

major contributor to the enthalpy of mixing and is proportional to the amount of complex formed. The "reaction heat" is calculated in the composition range $X_{ZnCl_2} > 1/3$ as

$$\Delta H_R = 0.5 X_{ACl} b_R \quad [8]$$

and in the range $X_{ZnCl_2} < 1/3$ as

$$\Delta H_R = X_{ZnCl_2} b_R \quad [9]$$

The parameter, b_R can be simply determined at the composition $X_{ZnCl_2} = 1/3$ since the "mixing" contribution vanishes and thus the total heat of mixing becomes

$$\Delta H_M = b_R/3 \quad [10]$$

The values for b_R that were determined for the systems $ZnCl_2$–KCl, $ZnCl_2$–RbCl, and $ZnCl_2$–CsCl are listed in Table 4 along with the Pauling ionic radius and "polarizing power" of the alkali cation. It is evident that as the polarizing power of the alkali metal cation decreases the "reaction part" of the enthalpy becomes more pronounced, reflecting the increasing basicity of the alkali metal salt.

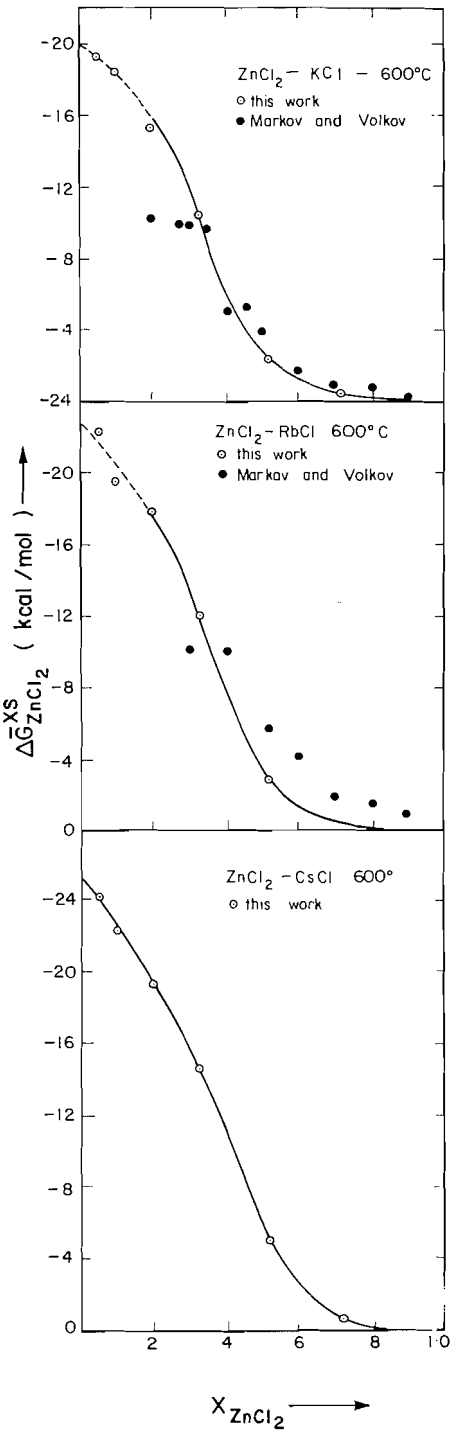

FIG. 8. Partial excess free energy of mixing of $ZnCl_2$ at 600 °C for the systems $ZnCl_2$–KCl, $ZnCl_2$–RbCl, and $ZnCl_2$–CsCl. The solid circles represent the results Markov and Volkov for the $ZnCl_2$–KCl and the $ZnCl_2$–RbCl systems.

For personal use only.

TABLE 4. Enthalpy and entropy parameter for the $ZnCl_2$–ACl system

Parameter	Value KCl	RbCl	CsCl	Unit
b_R	−21.0	−22.8	−24.6	kcal/mol
ε	−9	−9	−10	kcal/K mol
r_{A+}	1.33	1.48	1.69	Å
$1/(r_{A+} + 1.80)^2$	0.102	0.093	0.082	$(Å)^{-2}$

This tendency also becomes more apparent when the model is applied to the entropies of mixing. The entropy of mixing is determined by considering a vibrational and a configurational contribution. The partial entropy of mixing for $ZnCl_2$ is calculated from the model as

$$[11]\quad \Delta\bar{S}_{ZnCl_2} = -R \ln \frac{4(2X_{ZnCl_2} - X_{ACl})^3}{(1 + X_{ZnCl_2})(4X_{ZnCl_2} - X_{ACl})^2}$$

in the composition range $X_{ZnCl_2} > 1/3$ and in the composition range $X_{ZnCl_2} < 1/3$

$$[12]\quad \Delta\bar{S}_{ZnCl_2} = \varepsilon - R \ln \frac{X_{ZnCl_2}(X_{ACl} - X_{ZnCl_2})}{(X_{ACl} - 2X_{ZnCl_2})^2}$$

The vibration contribution, ε, is associated with reaction 6 and can be calculated from eq. 12 and the experimental results. The corresponding average values that were determined are shown in Table 4. However, eq. 11 indicates that there is no vibrational contribution from the formation of the tetrahedral complex since the addition of $ZnCl_2$ to compositions in this range would not result in the formation of more tetrahedral complexes of the type $ZnCl_4^{2-}$. In addition, the partial entropy of mixing given by eq. 11 is positive in this composition range and thus the partial excess entropy of $ZnCl_2$ should not have a negative value in this range. This prediction of the model for the entropy is not substantiated by the large negative partial excess entropies for $ZnCl_2$ in the acidic range reported in Table 3. For acidic compositions ($X_{ZnCl_2} > 1/3$) it would appear that other complexes become possible to satisfy Zn^{2+} cation desire for a tetrahedral chloride environment through sharing arrangements.

In the treatment by Pelton (13) only two parameters are used in the model to account for the acid–base behavior of MY_2–AY halide systems. One of the parameters (b_1) used in the model reflects the inherent appetite of M^{2+} ion to form the tetrahedral complex ion. For example, the values of b_1 parameter found for BeF_2, $CoCl_2$, and $MnCl_2$ systems are −50, −22, and 0.0 kcal per mol indicating the decreasing acidity of the M^{2+} ion. The average value of −27 kcal per mol for the b_1 parameter that was estimated from the present enthalpy results indicate that $ZnCl_2$ is highly associated in the pure state. Hence, the application of the discrete complex anion model in the highly acidic composition becomes doubtful as with the previous model. It would appear that polymeric models developed by Masson *et al.* (32) and Baes (33) would be more applicable in the acidic regions. However, these polymeric models would have to be modified to include vibrational entropy effects.

The Effects of Potassium Fluoride and Potassium Iodide on the Expansivity of Water

NOEL M. BURNS

Canada Centre for Inland Waters, Department of the Environment, Burlington, Ontario

Received October 18, 1972

An examination of the specific volumes of KF and KI solutions over the concentration range 0.1 to 2.0 *m* and over the temperature range 0° to 95° has led to the conclusion that the partial molal expansivity of the salts is due almost entirely to changes in the electrostrictive processes in water with temperature and are not due to changes in the structural effects of the salts on the bulk water with changing temperature. However, structural effects are considered to be of significant magnitude below 70°.

Un examen des volumes spécifiques des solutions de KF et KI dans l'intervalle de concentration de 0.1 à 2.0 *m* et de température de 0° à 95°, a permis de conclure que l'expansion partielle molaire des sels est presqu'entièrement due aux changements dans les processus électrostrictifs de l'eau avec la température et non aux changements des effets structuraux des sels sur la masse d'eau. On considère cependant qu'au dessous de 70° des effets de structure peuvent avoir une amplitude significative.

Introduction

In a recent discussion (1) of ion–water interactions, the partial molal volume of an ion at infinite dilution, $\bar{V}^0_{ion}$ has been attributed to the following components:

$$[1] \quad \bar{V}^0_{ion} = \bar{V}^0_{cryst} + \bar{V}^0_{elect} + \bar{V}^0_{disord} + \bar{V}^0_{caged}$$

where $\bar{V}^0_{cryst}$ is the crystal partial molal volume, $\bar{V}^0_{elect}$ is the electrostriction partial molal volume, $\bar{V}^0_{disord}$ is the disordered or void-space molal volume, and $\bar{V}^0_{caged}$ is the caged or structural partial molal volume.

The crystal volume of the ion $\bar{V}^0_{cryst}$ is usually considered to be temperature independent (2, 3) so that eq. 1 can be simplified by differentiating with respect to temperature, giving

$$[2] \quad \bar{E}^0_{ion} = \bar{E}^0_{elect} + \bar{E}^0_{disord} + \bar{E}^0_{caged}$$

where $\bar{E}^0_{ion}$ represents the partial molal expansivity of the ion and the other symbols represent the appropriate partial molal expansivity contributions. If a study is made of the partial molal expansivities over a range of temperatures, it is possible to learn about the magnitude of the different effects, since $\bar{E}^0_{elect}$ would have a large effect at high temperatures and $\bar{E}^0_{caged}$ would have a more obvious effect at low temperatures. The partial molal expansivity of a salt would represent the sum of the effects of the positive and negative ions.

In order that the relative magnitudes of the above mentioned quantities could be estimated, an investigation of the expansivities of potassium fluoride and potassium iodide solutions over an extended concentration range and temperature range was carried out.

Experimental

Eleven solutions each of KI and of KF were made up having molal concentrations: 0.1 *m*; 0.2 *m*, and thereafter with increments of 0.2 *m* up to 2.0 *m*. Shawinigan analytical grade KI was dried for 2 days at 180° and then used to make up the iodide solutions with distilled, deionized water. It was found that prolonged heating of KF caused the production of some insoluble material; thus, Allied Chemical analytical grade, anhydrous KF was placed in a vacuum desiccator for 2 weeks and the fluoride solutions were made up from this salt.

Specific gravities were measured using 25 ml Fisher density bottles, filled with deaerated solution, and then placed in a thermostated water bath controlled to ±0.005°. When the bottles had equilibrated, they were removed from the bath and dried. After equilibration to room temperature, the bottles were weighed to within 0.0001 g. The procedure was then repeated at a higher temperature. This was done at 5° intervals from 0° to 95°. The volumes of the density bottles were determined at each temperature by carrying out the same experimental procedure with pure water as was done with the solutions and using the values given in the literature (4) for the specific volume of water.

Results

The values reported for the specific volumes, V (V = volume of 1 g of solution), of the solutions at the different temperatures are the average of three experimentally determined values. The

average deviation from the mean for each density determination was 4×10^{-5} g ml^{-1} for 0.1 to 1.0 m solutions of both salts and 7×10^{-5} g ml^{-1} for 1.2 to 2.0 m solutions. These errors are sufficiently large to throw doubt on the fifth decimal figure in the values reported below and lead to an uncertainty of about ±2.5% of the volume difference observed due to a 5° temperature change in a solution; and a ±0.5% uncertainty in the specific volume change associated with an increase of 0.2 m in KF concentration. The twenty values for the specific volume of each solution were fitted to a polynomial of the form,

$$[3] \qquad V = \sum_{i=0}^{4} a_i t^i$$

where a_i are adjustable coefficients (i refers to the different terms in the expression) and t is the temperature in degrees Celsius. The coefficients of eq. 3 for each of the KI solutions are shown in Table 1 and those for the KF solutions are given in Table 2. The average difference between the observed value of V and those calculated by means of eq. 3 for the same conditions of temperature and concentration, was $\pm 5 \times 10^{-5}$ ml g^{-1}.

Table 3 shows a comparison of expansivities of 0.1 m KI at different temperatures determined from the volume measurements of Millero and Drost-Hansen (5) who used a magnetic float densitometer, with the results obtained in this study by using density bottles.

The partial molal volumes obtained for each solution at the different temperatures were fitted to a polynomial expression of the form

$$[4] \qquad \bar{V} = \sum_{i=0}^{3} a_i t^i$$

TABLE 3. Comparison of expansivities of 0.1 *m* KI

Temperature	Calculated*	This work
20	2.17×10^{-4} deg^{-1}	2.20×10^{-4} deg^{-1}
25	2.66	2.69
30	3.10	3.14
35	3.52	3.54
40	3.92	3.91

*From values listed in ref. 5.

These expressions were then differentiated with respect to temperature so that values were obtained for the partial molal expansivities of all the solutions at the different temperatures. The results of these calculations are shown in Fig. 1. The values obtained by the above calculations for the partial molal expansivity of KI at 25° are: infinite dilution, 0.121 ml mol^{-1} deg^{-1}; 0.1005 *m*, 0.117 ml mol^{-1} deg^{-1}. These values compare with the value obtained by Noyes (6) for KI at 25° at infinite dilution of 0.127 ml mol^{-1} deg^{-1} and the value obtained by Millero and Drost-Hansen (5) for 0.10153 *m* KI at 25° of 0.092 ml mol^{-1} deg^{-1}. Millero (1) has calculated the partial molal expansivity of KF solutions at infinite dilution between 25° and 40° and the values calculated from his expression are 0.06 ml mol^{-1} deg^{-1} at 25° and 0.0 ml mol^{-1} deg^{-1} at 40° which compare with values calculated in this work of 0.07 ml mol^{-1} deg^{-1} at 25° and 0.03 ml mol^{-1} deg^{-1} at 40 °C.

Expansivities of the individual solutions were obtained from the expression

$$[5] \qquad E = \frac{1}{V}\frac{dV}{dt}$$

where the values for dV/dt were obtained by differentiating eq. 3 with respect to temperature. The use of expansivities enables a comparison to be made of the behavior of solutions having different densities. The expansivity data were smoothed by being fitted to an equation of the form

$$[6] \qquad E = \sum_{i=0}^{3} B_i m_i$$

at each temperature, where B_i are adjustable coefficients and m is molality. The values for E calculated by means of eq. 6 varied from the unsmoothed values by 0.5% on average.

Figures 2 *a*, *b*, *c*, *d*, and 3 *a*, *b*, *c*, *d*, show plots of the expansivities, E *vs.* temperature for water and for the KF and KI solutions. The trends are

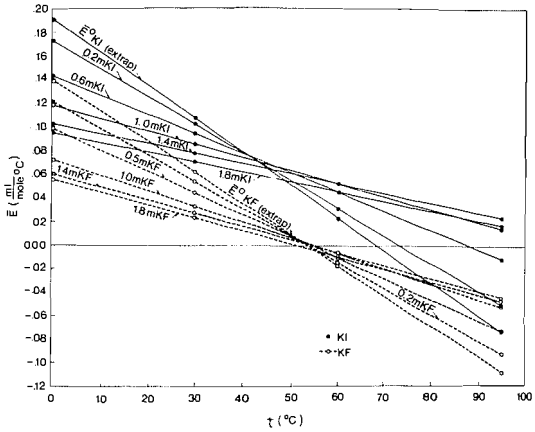

FIG. 1. Partial molal expansivities of KI and KF solutions *vs.* temperature. The calculated uncertainty for E for the KF solutions is ±0.01 ml mol^{-1} and for the KF solutions is ±0.02 ml mol^{-1}.

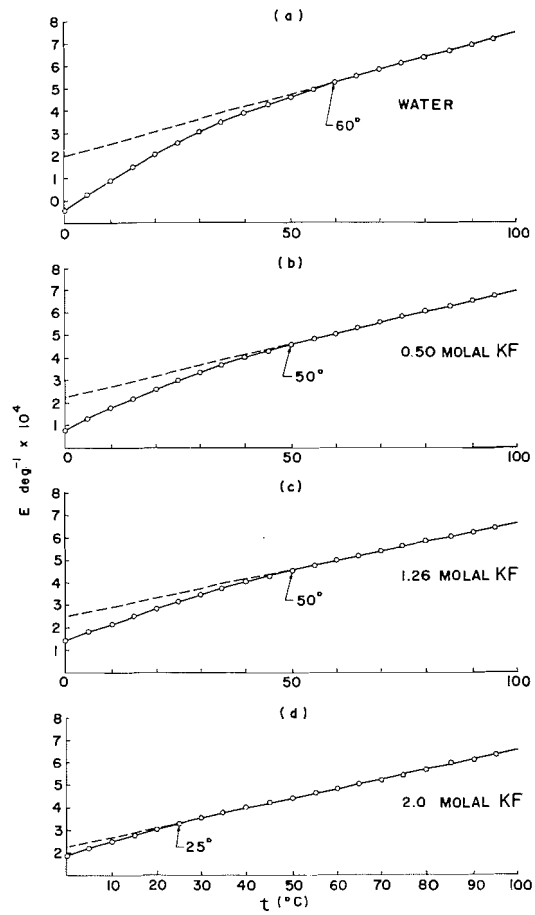

FIG. 2. Expansivities of pure water and KF solutions between 0° and 95°.

gradual and only part of the calculated data is shown.

Discussion

Part I

As an ion is introduced into water, the segment of water which is affected by the ion changes from having normal water structure to being subject to incorporation as water of hydration or structure modification outside of the hydrated ion or void space effects as the hydrated ion is fitted into the surrounding fluid. Because of these processes, the partial molal expansivity gives information relative to change in the expansivity of the water which has been effected by the introduction of the ion into the solvent.

The predominant feature of the data (Fig. 1) is that the partial molal expansivities of KF and KI solutions are concentration independent at about 53° and 50°, respectively. This means that in this temperature range there is an effect of the salt on the expansivity of water which either disappears or is constant for all concentrations, whereas at other temperatures this effect is significant and variable. It is of interest to examine the various terms of eq. 2 to find which effect causes the observed predominant feature.

The quantity, $\bar{V}^0_{disord}$, is the volume taken up when the hydrated ion does not fit exactly into the surrounding fluid and a commonly used expression for evaluating this quantity is given by Millero (1),

$$[7] \qquad \bar{V}^0_{disord} = Ar^2$$

where A is a proportionality constant having the values 4.09 (6) and 4.03 (2). Also, Millero (7) has estimated the value of $\bar{V}^0_{disord}$ over the temperature range 0° to 200° for an ion having a diameter of 1.0 Å and found $\bar{V}^0_{disord}$ increased slightly with temperature. Consequently, $\bar{E}^0_{disord}$ would probably be small and fairly constant over a wide temperature range and would increase with increasing ion size with no major change in $\bar{E}^0_{disord}$ at 50°.

The term, $\bar{V}^0_{caged}$ refers to the effect of the hydrated ion on the bulk liquid. Simple monovalent ions are considered (8) to decrease structure in the adjacent bulk liquid and this would cause $\bar{V}^0_{caged}$ to have a negative value. Since the amount of structure in the bulk liquid decreases with increasing temperature, $\bar{V}^0_{caged}$ would become less negative with increasing temperature. This reasoning would lead to the conclusion that a structure breaking solute would cause the value for $\bar{E}^0_{caged}$ to be positive but there is no reason to believe that there would be any major change in the value of $\bar{E}^0_{caged}$ about 50°.

Hepler (9) has developed an expression for $\bar{V}^0_{elect}$ of an ion

$$[8] \qquad \bar{V}^0_{elect} = -\int_r^\infty \int_p^0 \beta dP 4\pi r^2 dr$$

where r = Goldschmidt crystal radius of the ion (10), β = isothermal compressibility of the solvent, P = internal pressure due to the charge on the ion = KZ^2/r^4 where Z is the charge on the ion. Taking P and r to be independent of temperature, differentiation of eq. 8 leads to

$$[9] \qquad \bar{E}^0_{elect} = -\frac{\partial \beta}{\partial t_{p,r}} \int_r^\infty \int_p^0 dP 4\pi r^2 dr$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The isothermal compressibility of water has a significant temperature dependence (Fig. 5) so $\bar{E}^0_{elect}$ could be expected to be temperature sensitive; being positive below 47° since in this temperature range $d\beta/dt$ is negative; being equal to zero at 47° since at this temperature $d\beta/dt = 0$ (11), and being negative above 47° where $d\beta/dt$ is positive. The magnitude of the term $\bar{E}_{elect}$ depends on the temperature of the water which is taken from its normal state in the bulk liquid into the compressed state of water of hydration since it is dependent on the value of $\partial\beta/\partial t$ of water, although in its final state the water of hydration would be dissimilar from that in normal water. However, the temperature of minimum isothermal compressibility of water as calculated from the data of Kell and Whalley (12) does not appear to be significantly affected by moderate pressure changes ($\beta_{min} = 44.17$ bar^{-1} at 47° at 1 bar; $\beta_{min} = 28.56$ bar^{-1} at 57° at 2000 bar). The argument outlined above would suggest that $\bar{E}_{elect} \approx 0.0$ at about 50° for most hydrated ions.

It would seem that the pattern of observed values for $\bar{E}_{(KF)}$ follow the pattern which would be predicted for $\bar{E}_{(elect)}(KF)$ on the basis of eq. 9. This fact, together with eqs. 10, 11, and 12 which are proposed below, would make it possible to explain the observed values for $\bar{E}_{(KF)}$.

$$[10]\quad \bar{E}_{elect}(KF) \gg \bar{E}_{disord}(KF) + \bar{E}_{caged}(KF)$$

$$[11]\quad \bar{E}_{disord}(KF) + \bar{E}_{caged}(KF) \approx 0.0 \text{ ml mol}^{-1} \text{ deg}^{-1}$$

$$[12]\quad \frac{\partial E_{elect}}{\partial t}(KF) \gg \frac{\partial}{\partial t}(\bar{E}_{disord}(KF) + \bar{E}_{caged}(KF))$$

It is to be expected that eq. 10 would hold because the fluoride ion is small causing $\bar{V}_{elect}(F^-)$ to be large and $\bar{V}_{disord}(F^-)$ to be small.

The observation that the plots of $\bar{E}$ *vs.* temperature for different concentrations of KI have a common value of 0.6 ± 0.1 ml mol^{-1} deg^{-1} at about 53° can be similarly explained by proposing that the processes which are described by eqs. 13 and 14 operate simultaneously with the electrostrictive effects of KI in water.

$$[13]\quad (\bar{E}_{disord}(KI) + \bar{E}_{caged}(KI)) \approx 0.6 \pm 0.1 \text{ ml mol}^{-1} \text{ deg}^{-1}$$

and

$$[14]\quad \frac{\partial \bar{E}_{elect}}{\partial t}(KI) \gg \frac{\partial}{\partial t}(\bar{E}_{disord}(KI) + \bar{E}_{caged}(KI))$$

The value given in eq. 13 is probably due to $\bar{V}_{disord}(I^-)$ being large in this case as is demonstrated by eq. 7 because (I^-) is a relatively large ion.

Figure 1 shows that the value dE/dt decreases with increasing concentrations for both KF and KI to 1.4 *m* and thereafter appears to remain constant. This is to be expected since the amount of free water for the salt to interact with diminishes with each addition of salt due to ion hydration. An alternative explanation is that at concentrations greater than 1.4 *m*, the ionic spheres of influence begin to overlap as suggested by Gurney (13) causing dE/dm to be small. Thus the generalized statement can be made that in the case of KF solutions the electrostrictive effects of the ions on the water predominate over the structure modifying and the void space effects but in the case of KI solutions the electrostrictive effects are of the same order of magnitude as the other two effects.

In the foregoing discussion the assumption has been made that the ionic radius, *r*, is temperature independent. This assumption is probably not entirely correct but if the temperature dependence of *r* is small, the arguments above will remain valid.

Part II

It would seem from the discussion above that the volume effects of salts on the structure in liquid water outside of the hydrated ion are very small or non-existent. The question then arises as to whether there are significant volume effects of structure in water and whether salts affect this structure in an observable manner, *i.e.*, is $\bar{V}_{caged}$ of significant magnitude. In this regard, data from the literature on specific volume, isothermal compressibility, excess acoustic absorbance of water, the specific volume of heavy water, and the expansivities of KF and KI solutions have been examined.

Figure 4 shows a plot of the data published by Kell (11) for the thermal expansivity, $E = (1/V)(dV/dt)$, of water against temperature. The thermal expansivities are estimated to be accurate to 2×10^{-6} deg^{-1} near 100 °C and it is possible to draw a straight line from 70° to 100° within the limits of this error.

Kell (14) has also published an equation for

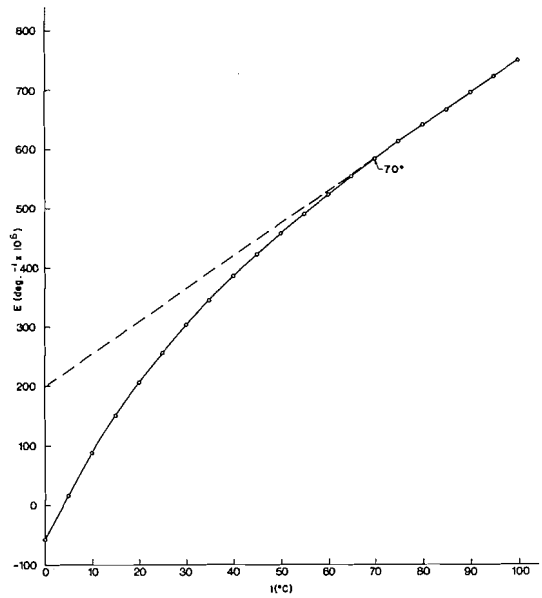

FIG. 4. Expansivity of water between 0° and 100°.

the calculation of the isothermal compressibility of water from 0° to 110° with a standard error of 0.002×10^{-6} bar^{-1}. This expression was differentiated with respect to temperature, t, and Fig. 5 shows a plot of $d\beta/dt$ *vs.* t. Again, there appears to be a straight-line section between 70° and 100°.

In addition, the excess acoustic absorbance data as reported by Hall were plotted. The values for 90° and 100° were calculated by extrapolation of Hall's expression (15). Hall's theory has been seriously questioned (16, 17) but the expression may be regarded as correct from the empirical standpoint and as such is useful for the extrapolation of data (17). The plot of the excess acoustic absorbance of water *vs.* temperature, Fig. 6, shows a straight-line section between 60°–70° and 100° with a large increase in absorption as the temperature drops below 60°–70°.

There is no special significance to the straight-line sections discussed above except in that they are curves of significantly reduced curvature when compared to the more obvious curves at the lower temperatures. In reality, what has been demonstrated is that the pattern of change with temperature is significantly different below 70° to that above 70° in the three properties discussed here.

The patterns observed in the data above can be explained in terms of either the mixture model of liquid water (18–23) or the continuum model (24–26). If the mixture model is considered, then it is necessary to postulate the existence of a bulky species of water which increases in concentration in liquid water as the temperature is lowered below 70°. This type of species has frequently been discussed in the literature (18–20, 23). If the continuum model is considered, then it is necessary to postulate that there is a significant increase in the number of molecules in the

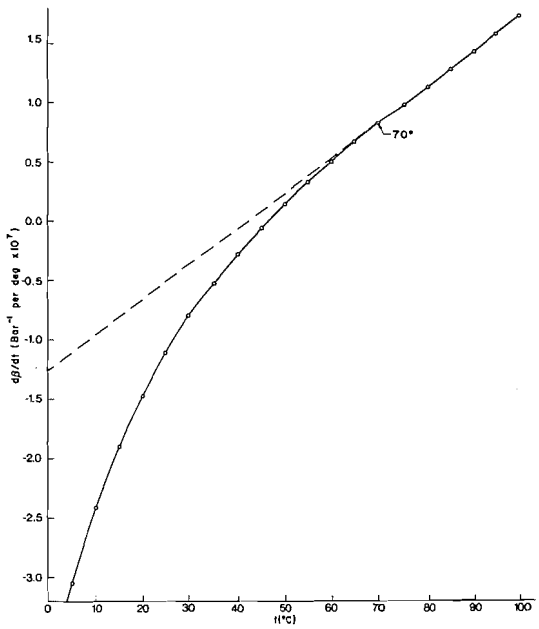

FIG. 5. The variation of isothermal compressibility of water with temperature between 0° and 100°.

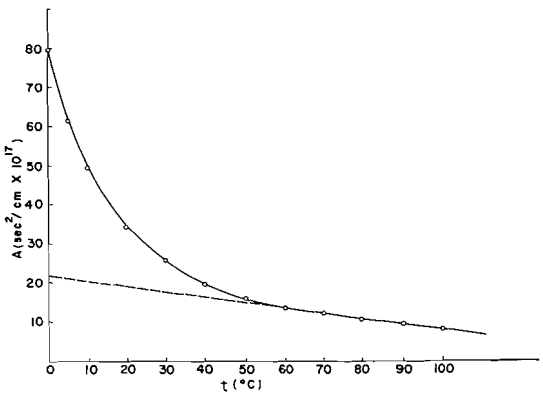

FIG. 6. Variation of excess acoustic absorbance of water between 0° and 100°.

higher volume states as the temperature is lowered below 70°.

The lowered value of the observed expansivity of water below 70° (Fig. 4) E_{obs} can be explained by the disappearance of water in a bulky state with increasing temperature.

In general terms, the experimental compressibility of a liquid, β_{obs} can be expressed by,

$$[15] \qquad \beta_{obs} = \beta_\infty + \beta_r$$

$$[16] \qquad \frac{d\beta_{obs}}{dt} = \frac{d\beta_\infty}{dt} + \frac{d\beta_r}{dt}$$

where β_∞ is the instantaneous compressibility and is a measure only of the decrease in the average distance between molecules with pressure and is independent of molecular rearrangement. β_∞ increases with increasing temperature as the average distance between molecules increases due to expansion; that is, $d\beta_\infty/dt$ is positive. β_r is the relaxational compressibility due to volume decrease as a bulky arrangement transforms into a denser arrangement with increased pressure, in accord with the Le Chatelier principle. In the case of water, β_r would decrease with increasing temperature as a result of the decreasing concentration of bulky species, that is $d\beta_r/dt$ is negative. Thus, it can be seen from eq. 16 that $d\beta_{obs}/dt$ is lowered by the presence of a bulky compressible species below 70°.

The excess acoustical absorbance of ultrasound is the sound energy absorbed due to bulk viscosity, *i.e.*, the energy absorbed by friction as a structure collapses under the compression of a sound wave and reforms again. Figure 6 shows a high absorbance at low temperatures which decreases markedly as the temperature increases to 60°–70° and thereafter decreases linearly with temperature. The marked increase in excess acoustic absorbance below 70° can be attributed to the presence of some molecules in an arrangement which is significantly more bulky than the molecular arrangements which exist above that temperature and that these bulky structures absorb energy as they collapse and reform under the pressures and rarefactions of a sound wave.

The data presented above would appear to support the postulate that there are a number of water molecules present in water in a bulky-structured arrangement and that the number of such molecules increases significantly as the temperature decreases below 70°.

Both KF and KI are what would be termed "structure-breakers" with KI being the strongest "structure-breaker". Thus, if the effect of these two salts on water structure is observable, they should affect the three structure-sensitive properties discussed above. The data shown in Figs. 2 and 3 demonstrate that the curvature below 70° in the *E vs.* temperature plot of water is definitely diminished by the addition of KF and KI to the water. However, it would appear that even at 2.0 *m*, there is structure present in water at the lower temperatures. There does not seem to be any significant difference in the structure-removing ability of the different salts. It would then seem that the effect of monovalent ions on structure in water outside of the hydrated ion is not large but is nevertheless significant.

The data of Kell and Whalley (12) provide the opportunity of checking whether the removal of bulky structure by increased pressure causes a decrease in the curvature in the $d\beta/dt$ *vs.* t plot below 70°. The plot of $d\beta/dt$ *vs.* t (Fig. 5) is very similar to the dV/dt *vs.* t (Fig. 4) and the curvature below 70° in the $d\beta/dt$ *vs.* t plot has been attributed to the presence of bulky structure in water at these temperatures. Since increased pressure should decrease the amount of bulky structure in water, increased pressure should diminish the curvature in the $d\beta/dt$ *vs.* t plot if the postulate is correct that the presence of bulky structure in water lowers the value of $d\beta/dt$ and dV/dt below 70°. In Fig. 7 the change in the specific volume V with temperature and pressure is studied and it is quite obvious that the feature attributed to the presence of bulky structure in water is diminished by increased external pressure in a similar manner to the changes produced on *E vs.* t by additions of halide salts to water.

As a final check on the above reasoning, it was considered that an increase in the amount of bulky structure present in water should cause a decrease in the expansivity at the lower temperatures. D_2O is considered to be more structured than H_2O (27–29); for example, the temperature of maximum density of D_2O, $t_{max}(D_2O) = 11.18°$ whereas for water $t_{max}(H_2O) = 3.98°$. A comparative plot of the expansivities of H_2O and D_2O is shown in Fig. 8. It is not possible to state in terms of the data available (11) whether there is in reality a straight-line segment above 80°. Nevertheless, it can be seen that D_2O has a lower expansivity than H_2O below 70° in accord with the suggested hypothesis.

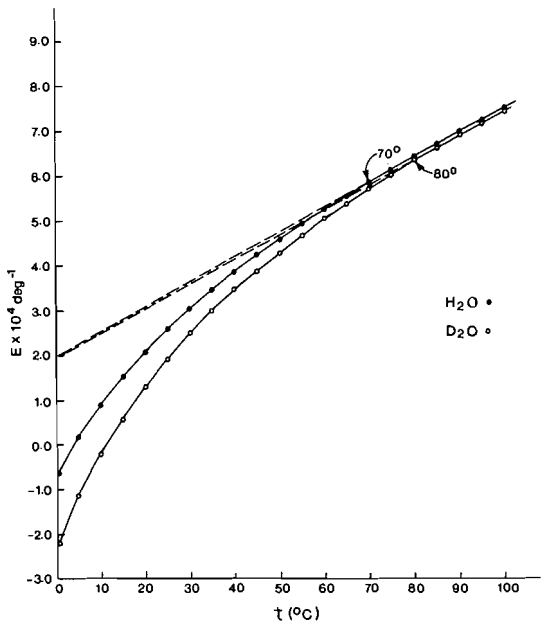

FIG. 8. A comparison of the expansivities of H_2O and D_2O at different temperatures.

Conclusions

Data on the partial molal expansivity of KF and KI solutions have been presented which can be explained simply by assuming that the temperature of minimum isothermal compressibility of water which has undergone electrostriction is similar to that of normal water at atmospheric pressure. It would appear that the effect of temperature on $\overline{V}_{elect}$ is much greater than on $\overline{V}_{disord}$ or $\overline{V}_{caged}$.

Literature data on the expansivity, compressibility, and excess acoustical absorbance of sound in pure water have been examined along with data on the expansivity of heavy water. This data led to the formulation of the hypothesis that water structured in a bulky arrangement exists in pure water at temperatures below 70°. An examination of the data on the expansivity of KF and KI solutions showed that the proposed bulky structure in water is significantly removed by the addition of the halide salts to pure water.

The author is grateful to the University of Alberta and the Province of Alberta for financial assistance while measurements were carried out at the Department of Chemistry, University of Alberta, Edmonton, and also to H. B. Dunford, J. E. Desnoyers, and W. A. Adams for helpful discussions.

Received March 16, 1973

Aqueous solutions of penicillamine (RSH) and penicillamine disulfide (RSSR) have been pulse irradiated at several pH's and the ensuing reactions studied. The rate constant for the reaction of solvated electrons with penicillamine disulfide decreases from $7.3 \times 10^9\ M^{-1}\ s^{-1}$ at pH 7 to $0.8 \times 10^9\ M^{-1}\ s^{-1}$ at pH 10. The first-order rate constant for the decomposition of the resulting radical anion, $RSSR^-$, increases from $1.77 \times 10^6\ s^{-1}$ at pH 7 to $6.5 \times 10^6\ s^{-1}$ at pH 10. Both of these pH effects are attributed to deprotonation of the two amino groups of the disulfide which have microscopic pK values of 7.9 and 8.5. The equilibrium constant for the reaction

[2] $$RS\cdot + RS^- \rightleftharpoons RSSR^-$$

is $(2.31 \pm 0.2) \times 10^2\ M^{-1}$ at pH 8 but increases to $3.04 \times 10^2\ M^{-1}$ at pH 7 and decreases to $0.96 \times 10^2\ M^{-1}$ at pH 9. Measured from the kinetics of the build-up of $RSSR^-$, $k_{-2} = 1.83 \times 10^6\ s^{-1}$ at pH 8.

Decay of $RSSR^-$ in the presence of RSH follows second-order kinetics at high dose rates and first-order kinetics at low dose rates. At high dose rates two second-order reactions

$$RS\cdot + RS\cdot \rightarrow RSSR$$

$$RS\cdot + RSSR^- \rightarrow RSSR + RS^-$$

appear to be involved with rate constants of $1.7 \times 10^9\ M^{-1}\ s^{-1}$ and $6.4 \times 10^9\ M^{-1}\ s^{-1}$ respectively at pH 8. At low dose rates the decay appears to be due to a pseudo first-order reaction between $RSSR^-$ and H_2O, $k \sim 2 \times 10^3\ s^{-1}$, with valine (RH) and penicillamine trisulfide (RSSSR) as principal products. These products are obtained in similar yields by gamma radiolysis of penicillamine solutions. At pH 5, the thiyl radical decays by second-order kinetics, $2k = (2.85 \pm 0.15) \times 10^9\ M^{-1}\ s^{-1}$.

Studies of solutions containing penicillamine and methanol showed that penicillamine repairs methanol radicals very efficiently by hydrogen transfer, $k = (1.1 \pm 0.1) \times 10^8\ M^{-1}\ s^{-1}$. The implications of the results for chemical radioprotection are discussed.

Des solutions aqueuses de penicillamine (RSH) et du disulfide de penicillamine (RSSR) ont été soumises à des irradiations pulsées à plusieurs pH et on a étudié les réactions suivantes. La constante de la vitesse de la réaction entre l'électron solvaté et le disulfide de penicillamine a diminué de $7.3 \times 10^9\ M^{-1}\ s^{-1}$ à pH 7.0 jusqu'à $0.8 \times 10^9\ M^{-1}\ s^{-1}$ à pH 10.0. La constante de vitesse de premier ordre pour la décomposition du produit radical ($RSSR^-$) augmente de $1.77 \times 10^6\ s^{-1}$ à pH 7 jusqu'à $6.5 \times 10^6\ s^{-1}$ à pH 10. On attribue ces deux effets de pH à la déprotonation des deux groupes amino du disulfide qui ont des pK microscopiques de 7.9 et 8.5. La constante d'équilibre de la réaction

[2] $$RS\cdot + RS^- \rightleftharpoons RSSR^-$$

est $(2.31 \pm 0.2) \times 10^2\ M^{-1}$ à pH 8.0 mais augmente jusqu'à $3.04 \times 10^2\ M^{-1}$ à pH 7.0 et diminue jusqu'à $0.96 \times 10^2\ M^{-1}$ à pH 9.0. La cinétique obtenue par la mesure de la formation de $RSSR^-$ à pH 8.0 fournit une constante de vitesse de $k_{-2} = 1.83 \times 10^6\ s^{-1}$.

En présence de RSH, la décomposition suit une cinétique du deuxième ordre à fortes intensités d'exposition et du premier ordre à faibles intensités d'exposition. Dans le cas des fortes intensités d'exposition il semble que deux réactions du deuxième ordre soient à considérer

$$RS\cdot + RS\cdot \rightarrow RSSR$$

$$RS\cdot + RSSR^- \rightarrow RSSR + RS^-$$

[1]Issued as DREO Report No. 683 and NRCC No. 13318.

dont les constantes de vitesse respectives sont $1.7 \times 10^9\ M^{-1}\ s^{-1}$ et $6.4 \times 10^9\ M^{-1}\ s^{-1}$ à pH 8.0. Aux faibles intensités il semble que la décomposition soit dûe à une réaction entre $RSSR^-$ et H_2O, $k \sim 2 \times 10^3\ s^{-1}$, dont les produits de réaction sont la valine (RH) et le trisulfide de penicillamine (RSSR). Ces mêmes produits sont obtenus avec des rendements semblables par irradiation des solutions de penicillamine à l'aide des rayons gammas. A pH 5.0, le radical RS· se décompose selon une cinétique du deuxième ordre, $2k = (2.85 \pm 0.15) \times 10^9\ M^{-1}\ s^{-1}$.

Par étude des solutions contenant de la penicillamine et du méthanol, on a montré que la penicillamine peut reconstituer efficacement les radicaux du méthanol par transfert de l'hydrogène avec une vitesse de réaction, $k = (1.1 \pm 0.1) \times 10^8\ M^{-1}\ s^{-1}$. Les résultats obtenus sont discutés au point de vue de la protection chimique contre les rayonnements.

Introduction

The effect of ionizing radiation on aqueous solutions of thiols and disulfides has been studied extensively and in recent years the pulse radiolysis technique has been applied to this problem. A major reason for the interest in these compounds is that many thiols and some of the corresponding disulfides protect mammals from the damaging effects of ionizing radiation (1). Although cysteamine (2-mercaptoethylamine), cysteine, and many closely related compounds are protective *in vivo*, penicillamine (β,β-dimethylcysteine) has no protective property (2). This lack of protective ability bears no obvious relationship to the reaction rates of penicillamine with free radicals from water as it reacts rapidly with both hydrated electrons (3) and hydroxyl radicals (4). However, it was observed earlier that the radiation chemistry of penicillamine disulfide differs considerably from that of disulfides of radioprotective thiols (see ref. 5 and references therein) but the difference was difficult to relate to radioprotective efficiency. Thus it is important to study the initial reactions and the free radicals involved in the radiolysis of penicillamine. A detailed knowledge of the differences between penicillamine and radioprotective thiols may provide an insight into the chemical processes involved in radioprotection.

Pulse radiolysis of aqueous solutions of cysteamine was studied by Adams *et al.* (6) and they concluded that the thiyl radical (RS·) produced initially combines with the sulfhydryl anion to give a radical anion ($RSSR^-$) in an equilibrium process

$$[1] \qquad OH\cdot + RSH \rightarrow H_2O + RS\cdot$$

$$[2] \qquad RS\cdot + RS^- \rightleftharpoons RSSR^-$$

The same transient is produced when a solvated electron reacts with a disulfide:

$$[3] \qquad RSSR + e_{aq}^- \rightarrow RSSR^-$$

Analogous radical anions have been reported for such compounds as hydrogen sulfide (7), cysteine (8), glutathione (9, 10), several alkyl mercaptans (11), selenourea (12), and enzymes containing disulfide bonds (13).

As reported previously (14), we have identified both the thiyl radical and the radical anion of penicillamine and we now describe further details including the kinetics of the formation and decay of these radicals and related product analysis.

Experimental

Penicillamine was purchased from Calbiochem and the disulfide was obtained from Wateree Chemical Co., Lugoff, S.C. Solutions, prepared in cleaned glassware with triply distilled water, were buffered with 8 mM phosphate and the final pH was adjusted by using NaOH or H_2SO_4 when necessary. The solutions were deaerated by bubbling with N_2O or argon as required. *t*-Butanol (Fisher Certified) was added as a hydroxyl radical scavenger in some cases.

For steady-state radiolysis a ^{60}Co "Gammacell 220" (Atomic Energy of Canada Ltd.) with a dose rate of 130 rad/s was employed.

In the pulse experiments the radiation source was the National Research Council linac. Pulse widths between 10 ns and 1 μs were used, and the dose per pulse was varied between 70 rad and 6 krad. Solutions were contained in a single-pass cell 2 cm long. Spectral measurements were made with a split light-beam system which included a Xe arc lamp, Bausch and Lomb high intensity monochromators, suitable filters to reduce scattered light, and either Phillips XP1003 photomultipliers or EG & G YAG-100 Si photodiodes as detectors. A Pyrex filter was always placed between the lamp and sample in measurements above 320 nm to prevent photolysis. For some kinetic measurements, in which the analyzing light was not split, a tungsten lamp replaced the Xe arc and an interference filter centered at 450 nm with a bandpass of 50 nm was used instead of the monochromator. Small variations in dose from pulse to pulse were monitored by a secondary emission chamber behind the cell, and dosimetry was done with $5 \times 10^{-3}\ M$ KSCN solutions saturated with N_2O, for which $G\varepsilon_{500}(CNS)_2^- = 4.2 \times 10^4\ M^{-1}\ cm^{-1}$ (100 eV)$^{-1}$ (15).

Samples for product analysis were acidified and run as soon as possible on a Technicon amino acid analyzer, with care being taken to exclude air (16).

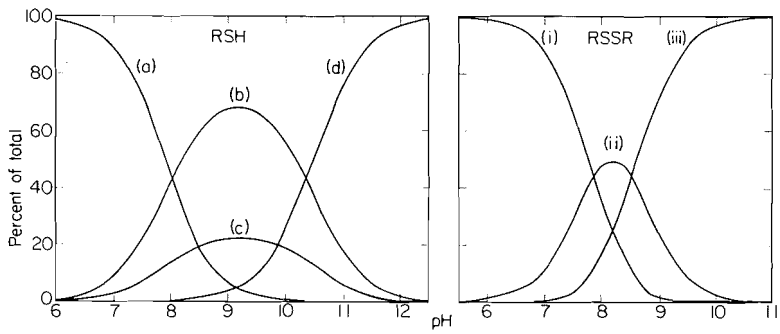

FIG. 1. Percentages calculated for the different ionic forms of penicillamine (Scheme 1) and penicillamine disulfide (Scheme 2).

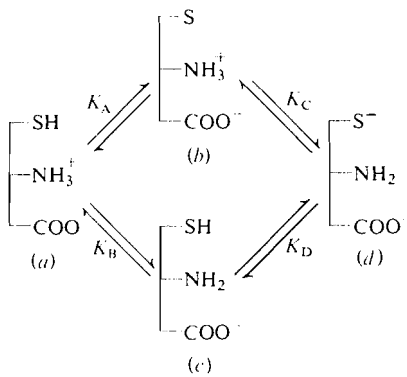
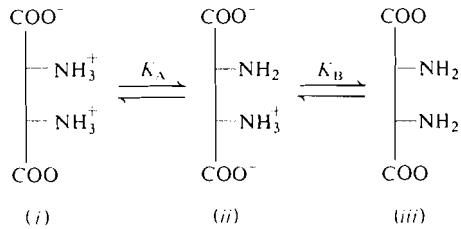
Results and Discussion

Titration of Penicillamine and Penicillamine Disulfide

The carboxyl, amino, and sulfhydryl groups of penicillamine are deprotonated as the pH is increased. Between pH 5 and 10, the range used in this work, the carboxyl group is completely deprotonated. The deprotonation of the amino and sulfhydryl groups may be represented schematically (Scheme 1). Titration of *a* with alkali leads to a mixture of *b* and *c*. The ratio of *b* to *c* was determined as 3:1 for penicillamine from measurements of the absorption due to the deprotonated sulfhydryl at the λ_{max} of 230 nm; this method has been described by Benesch and Benesch (17). This ratio was combined with literature (18) values of the dissociation constants, $pK_1 = 1.8$, $pK_2 = 7.9$, and $pK_3 = 10.5$, to obtain the micro-ionization constants: $pK_A = 8.02$, $pK_B = 8.50$, $pK_C = 10.33$, and $pK_D = 9.90$. The percentages of the different forms were calculated as a function of pH and are illustrated in Fig. 1.



SCHEME 1



SCHEME 2

Deprotonation in penicillamine disulfide, represented in Scheme 2, is simpler since the two amino groups are indistinguishable due to the symmetry of the molecule. Nevertheless, as in the case of cystine (19), removal of one proton makes the second one more difficult to remove. The experimental pK values for the amino groups were determined by titration of the disulfide with alkali to be $pK_3 = 7.6$ and $pK_4 = 8.8$. Then by following the procedure described for cystine (19), the microscopic pK values were found to be $pK_A = 7.9$ and $pK_B = 8.5$ and the dissociation curves shown in Fig. 1 were calculated.

e_{aq}^- + *Penicillamine Disulfide*

Argon saturated solutions of RSSR were irradiated for the purpose of determining the extinction coefficient for $RSSR^-$ at 450 nm (λ_{max}) as a function of pH. The solutions also contained *t*-butanol at 100 times the concentration of RSSR in order to remove OH radicals. The rate of reaction 3 was measured as a function of pH by observing the decay of the electron at 700 nm. As seen in Table 1, the observed k_3 decreases considerably as the pH is increased, and this decrease is probably associated with the change in the net charge on penicillamine disulfide from 0 at pH 7 to −2 at pH 10.

The ionic strength of the solutions was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

TABLE 1. Rate constants for reaction of e_{aq}^- with penicillamine disulfide

	$k_3 \times 10^{-9}$ (M^{-1} s^{-1})	
p*H*	Obs.	Corr.
6.0	7.3	7.3
7.0	7.3	7.3
8.0	4.5	3.7
9.0	2.3	1.6
10.0	1.4	0.8

negligible because of the 8 m*M* phosphate buffer and the disulfide itself. This should have no effect at p*H* 6 but should increase the rate of reaction at the higher p*H* values. The rate constants corrected to zero ionic strength were obtained from the equation (20)

$$\log (k_{corr}/k_{obs}) = 1.02\, Z\, \mu^{1/2}/(1 + a\mu^{1/2})$$

where μ is the ionic strength of the solution, $a = R/3$ where R is the sum of the radii of the two reactants, taken as 6.5 Å and Z is the charge on the disulfide. The corrected k's are also given in Table 1.

The rate of a diffusion-controlled reaction between two solute molecules, at least one of which is uncharged, is given by the Smoluchowski equation (20)

$$k = \frac{4\pi DRN_0}{10^3}\, M^{-1}\, s^{-1}$$

where D is the sum of the diffusion coefficients of the two species, R is the sum of their radii, and N_0 is Avogadro's number. This equation may be applied to the reaction of e_{aq}^- with the disulfide at p*H* 7. At p*H* 10 where the charge on the disulfide is -2, the Debye equation should be used (20):

$$k = \frac{-4\pi DZ_AZ_Br_0N_0}{10^3[1 - \exp(Z_AZ_Br_0/R)]}\, M^{-1}\, s^{-1}$$

where Z_A is the charge on species A, $r_0 = e^2/\varepsilon kT$ where e is the charge on the electron and ε is the dielectric constant. The radius of the electron is about 2.5 Å (21) and we estimate the effective radius of the disulfide at 4 Å so that R is taken as 6.5 Å. The diffusion coefficient of the electron is 4.7×10^{-5} cm^2 s^{-1} (22), that of the disulfide is probably about 0.7×10^{-5} cm^2 s^{-1}, so that we assume D is 5.4×10^{-5} cm^2 s^{-1}. The calculated rate constants, in M^{-1} s^{-1}, at p*H* 7 and 10 for diffusion-controlled reaction, are 2.7×10^{10} and 0.7×10^{10}, respectively, as compared to our corrected experimental values of 0.7×10^{10} and 0.08×10^{10}. Thus the values calculated for a diffusion-controlled reaction are somewhat greater than the corrected values in Table 1. It should be noted that the rate constant calculated at p*H* 10 is quite sensitive to the choice of R. Also the assumption that the net charge on the molecule should be used in the Debye equation may not be valid. We conclude that although the decrease in rate constants in going from p*H* 7 to 10 is qualitatively in accord with the effect of the change in charge on diffusion-controlled reactions, other effects would seem to be involved as well. Hoffman and Hayon found values for k_3 of 1.2×10^{10} M^{-1} s^{-1} and 0.35×10^{10} M^{-1} s^{-1} at p*H* 7.0 and 12.4, respectively (23). They concluded from their measurements of the rates of reaction of e_{aq}^- with several disulfides over a range of p*H* that the effect of net charge on the rate constant is relatively small.

Rate of Decomposition of RSSR⁻

The decay of $RSSR^-$ in the absence of RSH was followed at its λ_{max} of 450 nm at p*H* 6–10, and the results are shown in Fig. 2 and Table 2. Electron decay was greater than 90% by the time of the first point for each of the curves of Fig. 2. At p*H* 6 (not shown in Fig. 2) and 7 the decay obeys good first-order kinetics over the three half-lives, and comparison with Fig. 1 shows that the decay is due to splitting of the radical anion of species *i* of Scheme 2. It is likely that the p*K* values of the amino groups of the radical anion are higher than those of the disulfide due to the additional negative charge. However, protonation should not influence the observed decay since the decay is very fast in all cases. For example, if protonation is rapid with a rate constant about 10^{10} M^{-1} s^{-1}, then the first-order rate constant at p*H* 8 is 10^2 s^{-1} which is too slow to compete with the decay ($k_{-2} = 1.75 \times 10^6$ s^{-1}). At p*H* 10 the decay is much faster, again obeys good first-order kinetics, and is the dissociation of the radical anion of species *iii* of Scheme 2 which has a net charge of -3. Presumably the decay is faster because of the repulsion of the negative charges on both halves of the anion. At p*H* 8 the decay is fast initially but after about 50% decay obeys first-order kinetics with a rate constant approximately equal to that at p*H* 6 and 7. The decay curve at

†Initial fast decay, see Fig. 2.

p*H* 8 suggests that the anion of species *ii* of Scheme 2 dissociates at about the same rate as the anion of species *i*; the faster rate initially is due to the faster dissociation of a small amount of anion of species *iii*. At p*H* 9 the decay curve shows a fast initial rate, due to the dissociation of the anion of species *iii*, followed by a slower rate which is approximately the same as the rate at p*H* 7 and due to the dissociation of the anion of species *ii*.

The effect of concentration of disulfide was studied only at p*H* 8, and as seen in Table 2 the rate decreases as the concentration is increased. This is similar to the observation of Shafferman that the rate constant for the decay of the electron adduct of glutathione decreases with glutathione concentration (10). Possibly it is simply a salt effect, that is, repulsion between negative charges on the two halves of the anion is decreased at higher ionic strength.

Spectra of $RSSR^-$ and RS

As reported previously (14), the absorption spectrum of $RSSR^-$, produced by reaction 3, was measured at p*H* 6. The spectrum has now been measured at p*H* 7 and 8 and found to be identical within experimental error. At p*H* 9 it was difficult to measure precisely due to the rapid initial decay of the absorption as discussed above, but λ_{max} was found to be still at 450 nm. As described previously (14) the thiyl radical, produced at p*H* 5 by reaction 1, has $\lambda_{max} = 330$ nm and $\varepsilon_{330} = 1.22 \times 10^3\ M^{-1}\ cm^{-1}$. The spectra of RS· and $RSSR^-$ are redrawn in Fig. 3 to illustrate that of the RS· more clearly. No correction was necessary for the absorption of the parent compounds. Only the disulfide absorbs above 300 nm. Its extinction coefficient is 1.3% of that of the radical anion at 300 nm and less at higher wavelengths.

Extinction Coefficients of $RSSR^-$

Extinction coefficients of $RSSR^-$ at 450 nm were obtained from dosimetry and by extrapolating decay curves such as those in Fig. 2 back to the time of formation of half the maximum [$RSSR^-$]. In all cases this time was about 20 ns after the start of the 10 ns wide pulses used in these experi-

ments. The values found at different pH values are shown in Table 2. Because the initial portions of the decay plots at pH 8 and 9 are far from being straight lines, the extrapolations and therefore estimates of the extinction coefficient are rather uncertain at these pH values. From the data of Table 2 we conclude that ε_{450} for $RSSR^-$ is 7.5×10^3, with little pH dependence between 6 and 10.

Determination of K_2

The equilibrium constant for reaction 2 is defined as

$$K_2 = [RSSR^-]_{eq}/[RS\cdot]_{eq}[RS^-]$$

where $[RSSR^-]_{eq}$ and $[RS\cdot]_{eq}$ are the concentrations of RS· and $RSSR^-$ under equilibrium conditions. K_2 was determined by irradiating N_2O saturated solutions of penicillamine at pH 7, 8, and 9, and following the transient absorption at 450 nm. We calculated $[RS\cdot]_{eq}$ from the stoichiometric relationship $[RS\cdot]_{eq} = [RS\cdot]_0 - [RSSR^-]_{eq}$, where $[RS\cdot]_0$ is the total production of RS·.

$[RS\cdot]_0$ results from the production of RS· in several ways. The major source of RS· is reaction 1 and $G(OH) = 5.95$ in N_2O saturated solutions (15). It has been reported that 31% of hydrogen atoms react with penicillamine to give H_2 and RS·, and the remainder give H_2S and R· (24). The R· radicals might eventually give RS· by the reaction

$$R\cdot + RSH \rightarrow RH + RS\cdot$$

However, the rate constant for this reaction is only $1.1 \times 10^8\ M^{-1}\ s^{-1}$ when R· is $\cdot CH_2OH$ (see below). This reaction could not yield any RS· radicals until after the maximum absorption is reached, at least at the lower concentrations of penicillamine. Since $G(H) = 0.6$, the G of RS· from reactions of hydrogen atoms is 0.2. This is added to $G(OH)$ to give $G(RS\cdot)_0 = 6.15$. Another factor is important only at high concentrations of RSH where some of the e_{aq}^- is captured by RSH rather than by N_2O to give OH, and by analogy to the reaction between e_{aq}^- and cysteine (25), this reaction does not give RS·. The rate of e_{aq}^- + penicillamine has been measured as 5.1×10^9 at pH 6.5 (3). It was assumed that this reaction applies only to reaction with RSH, and that reaction with RS^- is very much slower by analogy with the effect of deprotonation on the rate of e_{aq}^- + RSSR. By using this rate constant and the known rate constant for e_{aq}^- + N_2O it was calculated that $G(OH)$ in N_2O saturated 10 mM penicillamine solution at pH 8.0 is 94% of its value in very dilute solutions.

$[RSSR^-]$ extrapolated to mid pulse was taken as a first approximation to $[RSSR^-]_{eq}$. The extrapolated value was never more than 9% greater than $[RSSR^-]$ at the maximum. However, the absorption at 450 nm is due to both $RSSR^-$ and RS· (see Fig. 3). A first approximation to $[RS\cdot]_{eq}$ was made by assuming that the absorbance at 450 nm represented only $RSSR^-$ and subtracting the value of $[RSSR^-]_{eq}$, obtained by extrapolation, from $[RS\cdot]_0$. A first approximation of the absorbance at 450 nm by $[RS\cdot]_{eq}$ could then be made. Repetition of this mathematical procedure converged to the results that absorbance at 450 nm due to RS· was 16 and 1.6% of that due to $RSSR^-$ for 0.5 and 5 mM solutions, respectively, at pH 8, and 27 and 11% for 1 and 2.5 mM solutions, respectively, at pH 7. Values of K_2 calculated from $[RS\cdot]_{eq}$, $[RS\cdot]_0$, and $[RSSR^-]_{eq}$ determined as described above are shown in Table 3.

It is seen that at pH 8 K_2 remains constant over a 20-fold range in concentration; the fraction of RS· radicals combined with RS^- in the complex at equilibrium varies from 5 to 44% over this concentration range. It is also seen that as the pH increases, K_2 decreases. This is quite reasonable since as the pH increases, the rate of decomposition of $RSSR^-$ increases as seen above. In general because of the difference in dissociation constants of the NH_3^+ groups in penicillamine and penicillamine disulfide, and the differences between the effect of charge of both species on k_2 and the charge on RSSR on k_3, the average charge on $RSSR^-$ might be different depending on whether it is formed by reaction 2 or 3. How-

FIG. 5. Second-order plots of the decay of $RSSR^-$ in penicillamine solutions irradiated with high doses: ○, 1 mM RSH, pH 8.0, left hand scale; ●, 10 mM RSH, pH 8.0, right hand scale.

ever, at pH 7 both amino groups on $RSSR^-$ are protonated regardless of how it is formed, and we can combine the equilibrium constant with the value of k_{-2} given in Table 2 to calculate $k_2 = 5.3 \times 10^8\ M^{-1}\ s^{-1}$.

Our equilibrium constant K_2 for penicillamine of $2.3 \times 10^2\ M^{-1}$ at pH 8 may be compared to that of $6 \times 10^3\ M^{-1}$ found for cysteamine ($NH_2CH_2CH_2SH$) at pH 8.5 by Adams *et al.* (6), and that of $9.5 \times 10^3\ M^{-1}$ found for cysteine at pH 8.2 by Barton and Packer (26). Comparison with K found in the cysteine system is particularly interesting since the only difference is substitution of the two hydrogens on the α-carbon in cysteine by methyl groups in penicillamine. The much smaller K for penicillamine could be due to steric hindrance by the methyls, and/or extra stability of RS· due to the electron-donating properties of the methyl groups.

Growth of $RSSR^-$ in N_2O Saturated Penicillamine Solutions

Under our experimental conditions the production of RS· by reaction 1 in N_2O saturated solutions of penicillamine is much faster than the formation of $RSSR^-$ by reaction 2. For example, the formation of $RSSR^-$, as evidenced by its absorption at 450 nm, is shown in inset of Fig. 4 for a 2.5 mM solution of penicillamine at pH 8.0. The $t_{1/2}$ for formation of $RSSR^-$ is about 0.3 μs. On the other hand, Armstrong measured k_1 as $4.7 \times 10^9\ M^{-1}\ s^{-1}$ at pH 1 (4), so that $t_{1/2}$ for the formation of RS· should be only 0.06 μs at 2.5 mM if k_1 is independent of pH. Adams and co-workers found k_1 was independent of pH for cysteamine (6) and we measured $k_1 = 4.3 \times 10^9\ M^{-1}\ s^{-1}$ for penicillamine at pH 11 by competition experiments using carbonate ions. It can also be seen from the inset to Fig. 4 that the decay of $RSSR^-$ is negligible during its formation. Under such conditions the formation of $RSSR^-$ should be described by the first-order kinetics expression

$$\ln \frac{[RSSR^-]_{max}}{[RSSR^-]_{max} - [RSSR^-]} = k_{-2}(1 + K_2[RS^-])t$$

where $[RSSR^-]_{max}$ and $[RSSR^-]$ are the maxi-

mum concentration of $RSSR^-$ and its concentration at time t respectively. Hence a plot of $-\ln [O.D._{max} - O.D.]$ *vs.* time should give a straight line from the slope of which k_{-2} may be calculated. Figure 4 shows such a plot for the 2.5 m*M* solution at p*H* 8.0 illustrated in the inset and Table 3 contains the values of k_{-2} calculated from such plots. The average value of k_{-2} at p*H* 8.0 is 1.8×10^6 s^{-1}. The predominant formation reaction at p*H* 8.0 should be the radical of species *a* of Scheme 1 reacting with species *b* to give the radical anion identical to that produced from the disulfide at p*H* 6 and 7. From Table 2 it is seen that the value of k_{-2} at these p*H* values is about 1.7×10^6 s^{-1}. Thus we obtain good agreement for the value of k_{-2} by two quite different methods.

Decay Kinetics of $RSSR^-$ in RSH Solutions

With high-dose pulses, $RSSR^-$ decayed by second-order kinetics, especially at the lower concentrations of penicillamine. This is illustrated in Fig. 5, where it is seen that second-order kinetics are obeyed to at least 85% decay in a 1 m*M* penicillamine solution at p*H* 8.0. These decay reactions are expected to be the same as those found previously in cysteamine and cysteine solutions (6, 27).

[4] $$RS\cdot + RS\cdot \rightarrow RSSR$$

[5] $$RS\cdot + RSSR^- \rightarrow RSSR + RS^-$$

We have already seen that the rate of build-up of absorption due to $RSSR^-$ is much faster than its decay, so that $RS\cdot$ and $RSSR^-$ are in equilibrium during decay of $RSSR^-$. Hence the following expression for decay of $RSSR^-$:

$$-\frac{d}{dt}[RSSR^-] = k_{obs}[RSSR^-]^2$$

$$k_{obs} = \frac{1}{K_2[RS^-] + 1}\left(\frac{2k_4}{K_2[RS^-]} + k_5\right)$$

The values for k_{obs} determined from second-order plots at concentrations from 0.5 to 10 m*M* at p*H* 8.0 are listed in Table 4. The values at 0.5 and 5 m*M* were used to solve for k_4 and k_5 by simultaneous equations. It was calculated that $2k_4 = 1.73 \times 10^9$ M^{-1} s^{-1} and $k_5 = 6.4 \times 10^9$ M^{-1} s^{-1}. These values of k_4 and k_5 were then used to calculate the values of k to be expected at the other concentrations, and it is seen in Table 4 that these are in good agreement with the experimental k_{obs} values. This agreement

TABLE 4. Second-order rate constants for decay of $RSSR^-$

p*H*	[RSH] (*mM*)	$k \times 10^{-10}$ (M^{-1} s^{-1}) Obs.	Calcd.

7.0	1	10.0	—
	2.5	3.5	—

constitutes good evidence that no other decay reactions are important at high initial concentrations of $RSSR^-$; more specifically the reaction

$$2\ RSSR^- \rightarrow \text{Products}$$

does not seem to be important. These rate constants indicate that for p*H* 8.0 solutions at 0.5 m*M* the rate of reaction 4 is 5.7 times that of reaction 5, whereas at 10 m*M* it is only 0.28 times that of reaction 5.

Our second-order rate constants are rather similar to those reported for aqueous solutions of cysteamine; for the reaction corresponding to reaction 4, $2k = 1 \times 10^9$ M^{-1} s^{-1} and for the reaction corresponding to 5, $k = 5 \times 10^9$ M^{-1} s^{-1} in the cysteamine system (27).

At p*H* 7.0 reaction 5 is not very important at the two concentrations at which the decay rate was measured. If it is assumed that $k_5 = 6.4 \times 10^9$ M^{-1} s^{-1} at p*H* 7.0 also, then $2k_4$ is calculated to be 2.4×10^9 M^{-1} s^{-1} at 1 m*M* and 2.0×10^9 M^{-1} s^{-1} at 2.5 m*M*. We previously reported that $2k_4 = 2.6 \times 10^9$ M^{-1} s^{-1} (14); this measurement was made at p*H* 5 by observing the decay of absorption due to the $RS\cdot$ radical directly. By the same technique we have now redetermined k_4 more accurately and find $2k_4 = (2.85 \pm 0.15) \times 10^9$ M^{-1} s^{-1} over a range of penicillamine concentration from 0.5 to 5 m*M*. We attribute the slight increase in $2k_4$ with decrease in p*H* to protonation of the amino group so that at p*H* 5 all $RS\cdot$ radicals have a net charge of 0.

At lower concentrations of $RSSR^-$ and higher initial concentrations of penicillamine, the decay of $RSSR^-$ was found to deviate from second-order kinetics and approach first-order behavior. Figure 5 shows that a 10 m*M* p*H* 8.0 solution deviates more from second-order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

kinetics than a 1 mM pH 8.0 solution irradiated with a pulse of the same dose. When pulses of smaller dose were used to irradiate 10 mM solutions, they showed deviations at smaller percent decay. Thus $RSSR^-$ appears to decay by a reaction in addition to reactions -2, 4, and 5 discussed above. We propose that this additional reaction is a pseudo first-order reaction of the type,

[6] $$RSSR^- + H_2O \rightarrow RSS\cdot + RH + OH^-$$

Obviously this reaction is favored at low $[RSSR^-]$ as compared to reactions 4 and 5, and it is also favored at high concentrations of penicillamine where k_{obs} is smaller. However, we were not able to work at a low enough $[RSSR^-]$ such that reaction 6 is the only mode of decay, because of the necessity of having enough absorption to follow $RSSR^-$ with reasonable precision. Under conditions such that reactions 2, -2, 4, 5, and 6 are important, the total rate expression for decay of $[RSSR^-]$ is

$$-\frac{d}{dt}[RSSR^-] = k_{obs}[RSSR^-]^2 + k_6[RSSR^-]$$

This expression is readily integrated to give

$$\ln \frac{[RSSR^-]_0\ (k_6 + k_{obs}[RSSR^-])}{[RSSR^-]\ (k_6 + k_{obs}[RSSR^-]_0)} = kt$$

where $[RSSR^-]_0$ is the initial $[RSSR^-]$. From this expression k_6 was determined by obtaining the best computer fit to data obtained in experiments with small $[RSSR^-]_0$. The values used for k_{obs} were the experimental values of Table 4, obtained at much higher $[RSSR^-]_0$. In Fig. 6 we compare the experimental points and computed curve for the best value of k_6 of $(2.3 \pm 0.2) \times 10^3\ s^{-1}$ for a 10 mM pH 8.0 solution of penicillamine, and the agreement is quite good. In this case the kinetics are very close to first order; $[RSSR^-]_0$ for the experiment of Fig. 6 is only 1.8% of that of the 10 mM experiment of Fig. 5.

We find values of k_6 of $(1.7 \pm 0.2) \times 10^3\ s^{-1}$ and $(1.5 \pm 0.1) \times 10^3\ s^{-1}$ for 5 and 2.5 mM solutions, respectively, at pH 8.0, and $k_6 = (2.8 \pm 0.5) \times 10^3\ s^{-1}$ for a 2.5 mM solution at pH 7.0. We favor the interpretation of these data that the pseudo first-order rate constant is independent of pH and concentration of penicillamine, but the data are not extensive enough to eliminate the possibility that the following reactions are also important:

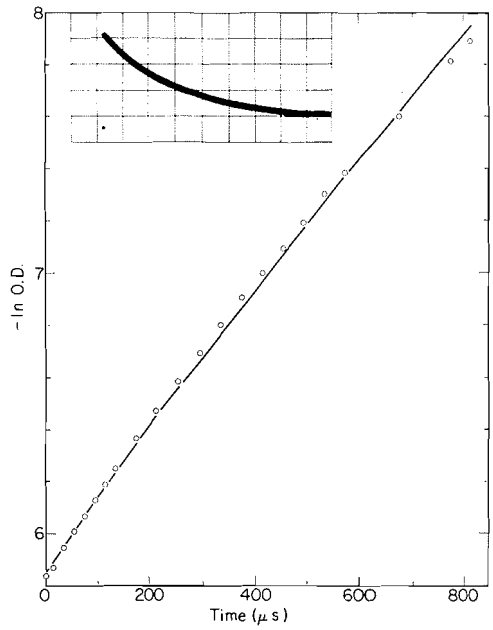

FIG. 6. First-order plot of the decay of $RSSR^-$ in penicillamine solution, 10 mM, pH 8.0. ○, Experimental points; solid line computed from first- and second-order rate constants. Inset: oscilloscope trace; sweep speed 100 μs per division; absorption at maximum, 0.67%.

[7] $$RSSR^- + RSH \rightarrow \text{Products}$$

[8] $$RSSR^- + H^+ \rightarrow \text{Products}$$

However, Hoffman and Hayon (23) have measured the second-order rate constant of [8] as $(3.3 \pm 1.0) \times 10^9\ M^{-1}\ s^{-1}$, which is a pseudo first-order rate constant of $33 \pm 10\ s^{-1}$ at pH 8.0. Therefore reaction 8 does not seem to be important under our conditions.

Product Yields

Table 5 presents the yields of the main products found in the radiolysis of solutions of

*D. A. Armstrong and G. C. Goyal have independently obtained penicillamine trisulfide by γ-radiolysis of penicillamine in aqueous solution (personal communication).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

penicillamine under a variety of conditions. The G values were reproducible with a maximum deviation of ± 0.2 except for the disulfide where the results were less reproducible (± 0.4). We confine our attention first to 10 mM pH 8.0 solutions. Each solution was analyzed after an absorbed dose of about 20 krad. In the pulse experiments a sequence of high or low dose-rate pulses was used. In the high dose-rate pulse experiments the dose per pulse was about 5 krad, comparable to that used in the experiments of Fig. 5. Under these conditions reactions 4 and 5 are most important in the decay of $RSSR^-$, and therefore penicillamine disulfide should be the most important product. Table 5 shows that this expectation is borne out. In the low-dose experiments the dose per pulse was about 34 rad, less than that used in the experiment of Fig. 6. By our kinetic scheme, reaction 6 should be the only important decay reaction of $RSSR^-$ for both γ and low dose-rate pulse irradiation at pH 8. Table 5 shows that under these conditions the yields of penicillamine trisulfide (RSSSR) and valine (RH) are somewhat higher than those of the disulfide. We suggest that these products result from the reactions

[6] $RSSR^- + H_2O \rightarrow RSS\cdot + RH + OH^-$

[9] $RSS\cdot + RS\cdot \rightarrow RSSSR$

One expects, along with reaction 9, the reactions

[4] $RS\cdot + RS\cdot \rightarrow RSSR$

[10] $RSS\cdot + RSS\cdot \rightarrow RSSSSR$

We looked carefully for product tetrasulfide and found only a trace, but discovered that it reacts with penicillamine, possibly in a disproportionation reaction

[11] $RSSSSR + RSH \rightarrow RSSSR + RSSH$

The rate of this reaction is such that any tetrasulfide produced by irradiation would have mostly disappeared in the interval of about an hour between the times of irradiation and product analysis.

Thus product yields provide evidence for the formation of RSS· in reaction 6, although this reaction may not be general for disulfide radical anions. Hoffman and Hayon (23) have observed the RS· radical as a product of reaction 8 for the radical anions of several disulfides, and also as a product of the reaction of hydrogen atoms with the disulfides. Both reactions are presumed to involve the short-lived radical RSSHR as intermediate. However, they did not observe the RS· radical as a product of the reaction of H atoms with penicillamine disulfide. Reaction 6 might be expected to involve the same intermediate and it appears to dissociate by breaking a C—S rather than an S—S bond. The C—S bond of penicillamine may be weaker because the carbon is tertiary. The same reason accounts for the difference between cysteine and penicillamine in the competition

$$RSH + H \rightarrow H_2 + RS\cdot$$

$$RSH + H \rightarrow H_2S + R\cdot$$

In cysteine (α carbon is primary) the reaction to give H_2 is favored by 3.5:1 (28), whereas with penicillamine the reaction to give H_2S is favored by 2.5:1 (24). Similarly in the photosensitized decomposition of disulfides, C—S cleavage is an important process for t-butyl disulfide, but not important for cyclohexyl and hexyl disulfides (29).

Trisulfide must be produced by one or more reactions other than 6 and 9 in order to explain the formation of trisulfide at pH 5 where no $RSSR^-$ is formed.

Repair of Free Radicals by Hydrogen Transfer

Adams *et al.* (30) found that the hydrogen transfer reaction

[12] $R'\cdot + RSH \rightarrow R'H + RS\cdot$

could be followed by measuring the rate of formation of the radical anion by reaction 2 at a suitable pH. We investigated this by using 2.5 and 5 mM penicillamine solutions containing 0.5 or 1 M methanol. The results were analogous to those of Adams *et al.*; at the low dose used (70 rad/pulse) the maximum absorption observed at 450 nm in the presence of methanol was equal to the maximum absorption in the absence of methanol. The build-up of the absorption was slower in solutions containing methanol and followed good first-order kinetics. From the kinetic plot $k_{12} = (1.1 \pm 0.1) \times 10^8\ M^{-1}\ s^{-1}$ was calculated. This rate constant is a little faster than that reported for cysteamine (30), $6.8 \times 10^7\ M^{-1}\ s^{-1}$. Thus the lack of radioprotective properties in penicillamine cannot be related to the hydrogen transfer reaction.

Implications for Radioprotection

It is clear that penicillamine differs signifi-

cantly in its radiation chemistry from other sulfhydryl compounds which have been studied. However, it requires some extrapolation to relate the unusual behavior to the absence of radioprotective properties. As reported above, penicillamine transfers hydrogen efficiently to repair other radicals so this reaction does not explain the difference. It is possible that radical anions are less harmful than thiyl radicals in biological systems and the low K_2 discussed above indicates fewer RS· radicals of penicillamine will combine with ionized thiols to form $RSSR^-$ complexes. However, at physiological p*H* (about 7) the concentration of RS^- will be very low and hence a large fraction of RS· radicals of, for example, cysteamine, will also remain uncomplexed.

The ready formation of trisulfide may be important as it indicates a relatively weak carbon-sulfur bond in penicillamine. It appears that trisulfides are formed by more than one pathway. Trisulfides were also obtained in high yield by radiolysis of penicillamine disulfide and cysteine – penicillamine disulfide (16). If RS· radicals of penicillamine react with protein disulfide bridges with resultant formation of trisulfides, irreversible damage may be done. This may occur by a simple sulfur exchange reaction

$$RS\cdot + R'SSR' \rightarrow R\cdot + R'SSSR'$$

or by a sequence of reactions. Trisulfide formation in proteins will change the tertiary structure and, in many cases, would be harmful. Thus, although penicillamine scavenges free radicals efficiently and repairs alkyl radicals rapidly, the thiyl radicals formed may not be harmless.

We are grateful to Mr. G. G. Teather and Mrs. D. E. Hanafi for excellent technical assistance, and to Dr. K. Lokan for assistance with computer programming.

Hexamethylazoxybenzene. Structure, Basicity, and Rearrangement[1]

ROBIN A. COX[2] AND ERWIN BUNCEL
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 14, 1973

2,2′,4,4′,6,6′-Hexamethylazoxybenzene (**1**) has been prepared and characterized. The u.v. spectrum is indicative of large distortion from coplanarity. **1** is only slightly more basic than azoxybenzene despite expectations due to electronic effect of the methyl substituents. Two factors are considered responsible for this: steric inhibition of resonance in the unprotonated species and steric hindrance to hydration in the conjugate acid.

Rearrangement of **1** in moderately concentrated sulfuric acid gives rise to the alcohol 4-hydroxymethyl-2,2′,4′,6,6′-pentamethylazobenzene (**6**). A Bamberger type phenolic product which would result from methyl migration is not observed. Possible reaction mechanisms are given.

L'hexaméthyl-2,2′,4,4′,6,6′-azoxybenzène (**1**) a été préparé et caractérisé. Le spectre u.v. indique une forte distorsion par rapport au plan. **1** n'est que légèrement plus basique que l'azoxybenzène malgré l'effet électronique attendu des substituants méthyles. Deux facteurs ont été considérés comme responsables de cet état: l'inhibition stérique à la résonance dans l'espèce non protonée et l'empêchement stérique à l'hydratation dans l'acide conjugué.

Le réarrangement de **1** dans l'acide sulfurique de concentration moyenne conduit à l'alcool hydroxyméthyl-4 pentaméthyl-2,2′,4′,6,6′ azobenzène (**6**). Un produit phénolique de type Bamberger résultant de la migration de méthyle n'a pas été observé. Des mécanismes possibles pour la réaction ont été donnés.

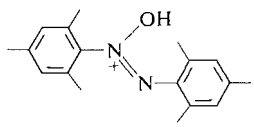
Can. J. Chem., **51**, 3143 (1973)

As part of a continuing study on structure and reactivity of azoxy compounds (1, 2), we have prepared for the first time the symmetrically polysubstituted derivative 2,2′,4,4′,6,6′-hexamethylazoxybenzene, **1**. We report in this paper on the spectral characteristics of **1**, on its basicity as defined by eq. 1, and on its rearrangement.

[1]  + H^+ ⇌

1



2

Spectral Characterization

The compound **1**, prepared by oxidation of the hexamethylazobenzene, has the u.v.-visible spectral characteristics given in Table 1. The assignments of the bands are similar to previous designations (3–5). The E_1 band is an electronic transition of the benzene rings, the E_2 band probably involves the azoxy function and one of the benzene rings, while the K band represents a $\pi \rightarrow \pi^*$ transition involving the entire conjugated system. For purposes of comparison Table 1 also contains the K-band data for azoxybenzene, and for some dialkyl derivatives.

It is seen that the K band in **1** is shifted to shorter wavelength, relative to azoxybenzene, and the extinction coefficient is considerably smaller. This effect is also observed with the 2,2′-dialkyl azoxybenzenes, though to a lesser extent, but it is reversed with the 4,4′-dialkyl azoxybenzenes. The bathochromic shift in the K band for the 4,4′-azoxybenzenes has been attributed in the past to operation of the inductive effect (6) and the hyperconjugative effect (3). On the other hand, the hypsochromic shift and the diminution in absorption intensity of the K band which is observed with the 2,2′-dialkyl azoxybenzenes has been generally attributed to steric hindrance to coplanarity, since steric inhibition of resonance would raise the energy level of the excited state relative to the ground state, and to reduced overlap between the π and π^* orbitals.

The distortion from coplanarity (deformation

TABLE 1. Spectral characteristics of substituted azoxybenzenes

Azoxybenzenes[a]	λ (nm)	ε	Band	Δλ	Δε	θ(°)
2,2′,4,4′,6,6′-Hexamethyl	214(s)	18 300	E_1			
	240(s)	7 500	E_2			
	307	3 800	K	−16	−10 700	67
4,4′-Dimethyl	330	18 100	K	+7	+3 600	—
2,2′-Dimethyl	312	11 100	K	−11	−3 400	38
4,4′-Diethyl	334	20 700	K	+11	+6 200	—
2,2′-Diethyl	309	9 300	K	−14	−5 200	48
Unsubstituted	323	14 500	K	0	0	—

[a]Data for 2,2′,4,4′,6,6′-hexamethylazoxybenzene are from the present work and refer to methanol solvent. The rest of the data are taken from the literature (3, 6).

angle, θ) may be calculated from the diminution in the molar extinction of the K band, according to the relationship[3] (7), $\cos^2\theta = \varepsilon/\varepsilon_0$. In this equation ε is the molar extinction coefficient for the ortho-substituted derivative while ε_0 is the value for the para-substituted analog; this assumes that the electronic effect of the substituent(s) is independent of the position of substitution (ortho or para) and that in the absence of steric effects the extinction coefficients for the two isomers should be the same. Application of this relationship to the dimethyl- and diethylazoxybenzenes leads to deformation angles of 38 and 48°, respectively (3, 6).

The choice of a reference model in the present study provides a difficulty. If one assumes, as has been done previously (6), that the contribution of each alkyl group is additive, then the theoretical decrease in intensity would be given by $+3600 \times 3 = +10\,800$, so that in the absence of steric effects the extinction coefficient for **1** should be $14\,500 + 10\,800 = 25\,300$. Hence θ is calculated from the relationship $\cos^2\theta = 3800/25\,300$ which yields θ = 67°. Though the absolute value is somewhat in doubt, it is clear that **1** has the largest distortion so far observed in the azoxybenzene series. It may be noted that X-ray structure data give an angle of twist of 22.6° for 4,4′-dimethoxyazoxybenzene (9) so that the calculated deformation angles shown in Table 1 should all be augmented correspondingly.

Basicity

The pK_a of **1** was determined by the spectrophotometric method employed previously (10).

[3]The alternative relationship $\cos\theta = \varepsilon/\varepsilon_0$ has also been proposed (8) and leads to somewhat larger values of the deformation angle θ. For consistency with previous work (3, 6) we use the relationship given in the body of the text.

TABLE 2. Spectral data for pK_a measurements

[a]Contains 5% dioxane.
[b]Data from ref. 11.
[c]Absorbance at 378 nm.
[d]Absorbance at 306 nm.
[e]Ionization ratio, $I = (A - A_B/A_{BH^+} - A)$, calculated at 378 nm, using $A_B = 0.145$ and $A_{BH^+} = 0.916$ (see text).

The acidic medium used was aqueous sulfuric acid containing 5% dioxane, the organic co-solvent being required in order to enhance solubility of the substrate. An H_0 scale applicable to this medium is available (11).

Protonation of **1** is characterized by appearance of an absorption maximum in the 387 nm region due to species **2**. Measurements over a range of acid concentrations give a typical sigmoid curve when A_{387} is plotted against H_0 (data of Table 2). One thus obtains a pK_a of −5.02 corresponding to the H_0 value at the inflection point.[4] Absorbances at 307 nm corresponding to the unprotonated species did not show a consistent decrease with increased acidity, possibly due to a selective medium effect since isosbestic point behavior was not observed. The Davis–Geissman (12) procedure was therefore not deemed applicable. However,

[4]The measured pK_a refers to the H_0 value at 50% protonation rather than to the thermodynamic dissociation constant.

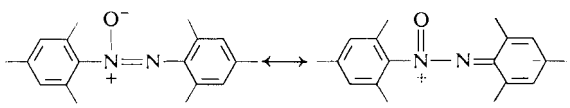
the smooth sigmoid curve of A_{387} *vs.* H_0 yielded values of ε_B and ε_{BH^+} which were then used to calculate ionization ratios over the acidity region examined. The log I *vs.* H_0 plot is linear with a slope of 1.51. A pK_a value of -5.02 is obtained from this plot corresponding to log $I = 0$, in good agreement with the value derived from the A_{387} *vs.* H_0 plot. The "Hammett slope" of 1.51 is considerably higher than the value 1.0 recorded for azoxybenzene and 0.9–1.0 for the naphthyl azoxy series (10), though it is well within the range of slope values compiled by Bunnett and Olsen for a variety of organic bases (13). Apparently **1** is a poor Hammett base, which could be due to the abnormal amount of twist in this molecule. The different acidity response of **1** compared to azoxybenzene, as reflected in the dependence of log I on H_0, is thus not too surprising.

It is of interest to discuss the basicity of **1** in terms of structural and electronic effects and to compare the pK_a value with that of the parent azoxybenzene. For that purpose the measured pK_a of **1** may be reduced to the value applicable to aqueous medium by means of an appropriate correction factor (11), which then yields pK_a (aq) $= -4.85$. It follows that **1** is a stronger base than azoxybenzene, pK_a (aq) $= -5.15$, but only moderately so. Qualitatively, one can account for the increased basicity of **1** by examining the possibility of delocalization of charge due to contribution by canonical structures such as the following:



1a *1b*

The electron-releasing effect of methyl will result in diminished importance of structures such as **1***b*. The consequent increased charge density on the azoxy oxygen relative to that of azoxybenzene should lead to **1** being more basic than azoxybenzene, which is as observed. A more complete treatment should also consider inductive and steric effects.

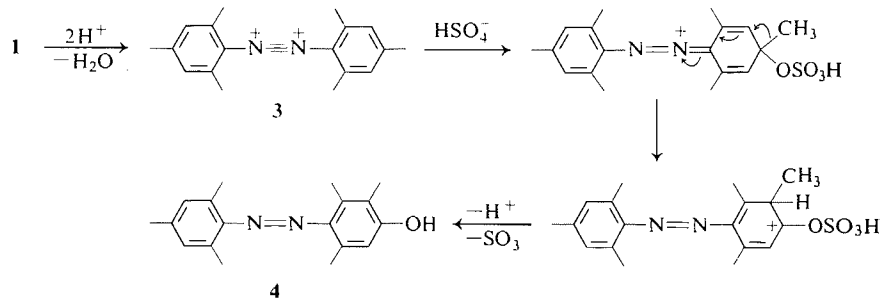
However, quantitatively, the increased basicity of **1** over that of azoxybenzene is far less than might have been anticipated. The data of Hahn and Jaffé (14) on the pK_a of substituted azoxybenzenes show that 4,4′-dimethylazoxybenzene has increased basicity by almost 1 pK unit over that of azoxybenzene. If one assumes the effect of the methyl substituents to be additive then the calculated pK_a of **1** would be around -2.

It is probable that the variance between the anticipated and the actual pK_a value of **1** is due, in part, to steric inhibition of resonance. Thus to the extent that the methyl groups cause distortion from planarity in the molecule, the hyperconjugative capability of these methyls will become diminished. The second factor to be considered is steric hindrance to hydration (15). Since the protonated form of the base will be more hydrated by solvent molecules than the neutral form, the presence of the ortho methyl groups in **1** will interfere with solvation of the protonated azoxy function and hence destabilize the protonated form. This factor will also result in decreased basicity relative to the situation in azoxybenzene. Corroboration of the role of this factor in the present system is indicated by a negative ϕ value (-0.55) when the data are plotted according to the procedure of Bunnett and Olsen (13), which is indicative of less than optimum hydration of the BH^+ species. The hydration factor may well weigh the most heavily in reducing the basicity of **1** (cf. ref. 16).

Acid Catalyzed Rearrangement

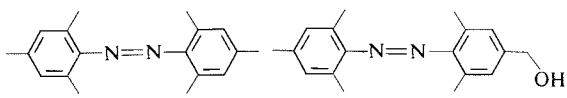
Investigation of the Wallach rearrangement of **1** in acidic media promised to be of particular interest since a "normal" type rearrangement (2), whereby hydroxyl enters a vacant ortho or para position, is precluded in this system. It appeared possible, however, that an alternative pathway would prevail, with a methyl group migrating from a para to a meta position, as indicated in Scheme 1. This pathway is based on a presumed analogy with the Bamberger rearrangement of substituted phenyl hydroxylamines in acid media where methyl migration follows nucleophilic attack thus leading to a rearranged phenolic product (17, 18). The proposal of initial formation of the dication **3** is by analogy with our previous hypothesis of the intervention of such a metastable intermediate in the reaction of azoxybenzene (19, 20).

If the overall process shown in Scheme 1 were in fact to occur this would constitute the first example of alkyl migration in the Wallach rearrangement. On the other hand it was tempting to conceive of the possibility that, in the absence of group migration, **3** would be stabilized in these media and thus become spectrally observable or otherwise lead to some product characteristic of that species.



SCHEME 1

Examination of **1** in strong sulfuric acid solutions (75–95% H_2SO_4) shows rather quickly that some kind of reaction does occur, since the spectrum characteristic of the protonated reactant disappears with time and is replaced by a new absorption which is stable in these reaction media (21). However, it was apparent that the reaction product was not phenolic since the spectrum of the base-quenched reaction mixture was qualitatively quite similar to the spectrum of the neutral or slightly acidic solution of the reaction product. This contrasts with the situation for azoxybenzene where the azophenolate ion was found to have its principal absorption displaced to longer wavelengths compared to the azophenol (19). To remove any possible doubt that **4** could have been formed from **1**, the authentic **4** was examined spectrally and found to have different characteristics in acidic and basic media. Similarly, 2,2′,4,4′,6,6′-hexamethylazobenzene, **5**, which could conceivably have been formed from **1** by reduction (by analogy with the reported (22) reduction of hexabromoazoxybenzene in strong acid) was found to have different spectral properties than the reaction product.



5 **6**

Since the reaction product did not appear to be a known compound, its isolation and physical characterization was deemed necessary. Product isolation was effected by treatment of a 6×10^{-4} *M* solution in 85.6% H_2SO_4 at 44.4° for 1 h (a concurrent spectral examination showed reaction to be complete) and work-up. A red crystalline solid was obtained whose u.v.-visible spectral characteristics corresponded to those of the species produced in the reaction as followed spectrophotometrically. The complete u.v. spectral data for the product as well as the reference compounds **1**, **4**, and **5** are given in Table 3, in neutral, acidic, and basic media. Some spectra in acid medium are shown in Fig. 1.

Elemental analysis of the reaction product showed it to be an isomer of the reactant. The i.r. spectrum showed pronounced absorption due to OH, pointing to an alcoholic material, since it is known not to be a phenol. In the n.m.r. spectrum, a 2-proton signal at 4.52 p.p.m. was indicative of the $ArCH_2OH$ grouping, in accord with structure **6**, and the rest of the n.m.r. spectrum was in complete agreement with that assignment. The presence of two distinct 2-proton peaks in the aromatic region shows that the CH_2OH function could not be present in an

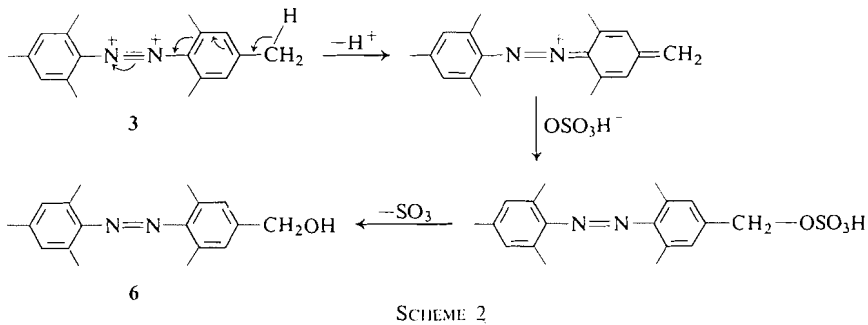

SCHEME 2

ortho position since in that case three aromatic signals should have been present in the ratio 2:1:1. Acetylation of the product resulted in loss of the O—H absorption and the appearance of a C=O peak in the i.r., while the n.m.r. spectrum showed the presence of a CH_3CO signal as well as a shift of the $ArCH_2O$ signal down-field by 0.4 p.p.m. from that of the reactant. The mass spectra of the reaction product and of the acetyl derivative were fully characteristic of the structural assignment given, *viz.* **6** for the reaction product and **6**-acetate for the derivative.

The unusual course of rearrangement of the substrate **1** could arise as a result of the reaction pathway indicated in Scheme 2, starting from the dicationic intermediate **3** which would be formed as previously (20). It should be pointed out that other pathways leading to product **6** are possible, for instance by direct nucleophilic attack by H_2O or HSO_4^- on a proton of the para methyl group of the conjugate acid **2**. However, the recent demonstration by Olah *et al.* that a dicationic species is formed from azoxybenzene in superacid (23) tends to lend support to the dicationic intermediate postulated in Scheme 2. Finally, we wish to draw attention to the synthetic potential of this reaction since nucleophilic substitution on methyls attached to aromatic rings is quite uncommon (24, 25).

Experimental

2,2′,4,4′,6,6′-Hexamethylazoxybenzene (1)

This compound was prepared by the peracid oxidation of 2,2′,4,4′,6,6′-hexamethylazobenzene (26). The azobenzene (6.66 g, 0.025 mol) was dissolved in chloroform (50 ml) in a 100 ml flask fitted with a reflux condenser and drying tube. *m*-Chloroperbenzoic acid (5.33 g, 0.026 mol, 85% Aldrich technical grade) was then added, and the solution refluxed on a steam-bath until it was a clear lemon-yellow color (4 h). The solution was cooled, washed with bicarbonate and water, and dried over calcium chloride. Rotary evaporation of the chloroform gave the product as a yellow oil which slowly crystallized into an amorphous yellow solid. Two recrystallizations

4-Hydroxy-2,2′3,4′,6,6′-hexamethylazobenzene (4)

This substance was prepared by a standard diazo-coupling procedure (27), from 2,4,6-trimethylaniline and 2,3,5-trimethylphenol. Recrystallization from 60–80 petroleum ether gave the product as small red needles, m.p. 117–118°.

Anal. Calcd. for $C_{18}H_{22}N_2O$: C, 76.56; H, 7.85; N, 9.92. Found: C, 76.16; H, 7.68; N, 9.73.

U.v. spectrum, see Table 3; n.m.r. δ 2.16 (s, ~3, 3-CH_3); 2.28 (s, ~3, 4′-CH_3); 2.33 (s, ~6, 2′- and 6′-CH_3); 2.36 (s, ~6, 2- and 6-CH_3); 4.80 (broad, 1, OH); 6.26 (s, 1, 5-H); 6.78 (s, 2, 3′- and 5′-H).

4-Hydroxymethyl-2,2′,4′,6,6′-pentamethylazobenzene (6): Reaction Product Isolation

Hexamethylazoxybenzene (103.5 mg) was dissolved in 85.6% sulfuric acid (600 ml) in a 1 l flask which was heated in an oil-bath at 44.4° while stirring. A small portion of this solution was continuously scanned in the SP 800 spectrophotometer, using a 1 mm cell in a thermostatted cell block. When the scanned sample indicated that reaction was complete (1 h, 10 half-lives) the main reaction solution was cooled in ice. A portion of the reaction solution was quenched in 1 *M* NaOH in EtOH–H_2O (20:80) for spectral examination. The acidic reaction solution was then carefully diluted to 1200 ml with cold water and cooled again. The diluted acid solution was added slowly with continuous stirring and cooling to a solution of 750 g NaOH in 2 l water in a 20 l flask. Additional water had to be added to keep the Na_2SO_4 in solution and the final volume was about 10 l. This solution, which was cloudy with precipitated product, was extracted with small portions of ether until the aqueous layer was quite clear. The combined ether extracts were washed with water and dried over calcium chloride. Rotary evaporation of the ether left a red solid; the yield at this stage was 94.7 mg, or 91.5% of starting material. Purification was achieved by chromatography over neutral alumina, eluting with ether, and recrystallization from CCl_4. A mat of very fine red needles was obtained, m.p. 94–95°.

Anal. Calcd. for $C_{18}H_{22}N_2O$: C, 76.56; H, 7.85; N, 9.92. Found: C, 76.56; H, 7.85; N, 10.01.

U.v. spectrum, see Table 3; n.m.r. δ 2.32 (s, ~3, 4′-CH_3); 2.39 (s, ~12, 2-, 2′-, 6-, and 6′-CH_3); ~3.4 (broad, 1, OH); 4.52 (s, 2, Ar-CH_2-O); 6.83 (s, 2, 3′- and 5′-H); 6.98 (s, 2, 3- and 5-H). I.r. (cm^{-1}) 3445 (broad, bonded OH); 3618 (sharp, free OH). Mass spectrum, *m/e* (relative intensity) 282 (48), molecular ion; 135 (59), $C_6H_2(CH_3)_2CH_2OH^{\cdot+}$; 119 (100), $C_6H_2(CH_3)_3^{\cdot+}$; otherwise characteristic of an azo-compound (28).

4-Acetoxymethyl-2,2′,4′,6,6′-pentamethylazobenzene

The reaction product **6** was acetylated by refluxing it overnight in acetic acid – acetic anhydride (50:50). Rotary evaporation gave a red solid which was purified by column chromatography over acid-washed alumina, eluting with benzene – 60–80 petroleum ether (50:50), and recrystallization from ethanol. The product was a red crystalline solid, m.p. 65–66°.

Anal. Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.05; H, 7.46; N, 8.63. Found: C, 74.27; H, 7.58; N, 8.63.

U.v. (CH_3OH) λ 239 nm (ε 8700); 317 (12 400); 458 (1040). N.m.r. δ 2.01 (s, 3, CH_3—C═O); 2.27 (s, 3, 4′-CH_3); 2.40 (s, 12, 2-, 2′-, 6-, and 6′-CH_3); 4.94 (s, 2, Ar-CH_2-O); 6.82 (s, 2, 3′- and 5′-H); 7.00 (s, 2, 3- and 5-H). I.r. (cm^{-1}) 1730 (C═O). Mass spectrum, *m/e* (relative intensity) 324 (52), molecular ion; 177 (19), $C_6H_2(CH_3)_2CH_2OCOCH_3^{\cdot+}$; 119 (100), $C_6H_2(CH_3)_3^{\cdot+}$; 220 (23); otherwise typical of an azo-compound (28).

Spectral Measurements

The u.v.-visible spectral measurements were performed by the method previously described (10). The n.m.r. spectra were taken on a Varian T60 instrument, in CCl_4 solution, and the data are quoted as p.p.m. relative to TMS internal standard. The i.r. spectra were obtained in $CHCl_3$ solution using a Unicam SP 1000 spectrophotometer.

Synthetic Approaches to a Novel Carbohydrate Conjugated Diene: 4,6-*O*-Benzylidene-1,2,3-trideoxy-3-*C*-methylene-D-*erythro*-hex-1-enopyranose[1]

STEVE Y-K. TAM, DAVID E. ILEY,[2] NEVILLE L. HOLDER,[3] DAVID R. HICKS, AND BERT FRASER-REID
Chemistry Department, University of Waterloo, Waterloo, Ontario

Received January 16, 1973

Four routes to the title compound **1** are outlined, three of which (i), (ii), and (iv) are simple one-step processes from readily available carbohydrate precursors. In the third route (iii) the α-keto benzoate **6***a* is methylenated and the benzoate group replaced by methanesulfonate. The product (**6***d*) rearranges upon iodinolysis giving the primary allylic iodide (**2***b*) which undergoes 1,4-elimination with methyl lithium to give the title compound (**1**). All reaction intermediates are readily crystallizable and with the exception of (**6***b*) obtainable in > 80% yield.

Quatre voies de synthèse menant au composé **1** sont décrites; trois (i), (ii) et (iii) sont des processus simples n'impliquant qu'une réaction à partir de sucres précurseurs facilement disponibles. Dans la troisième voie (iii) l'α-cétobenzoate **6***a* est méthylé et le groupe benzoate remplacé par un méthanesulfonate. Le produit **6***d* se réarrange par iodolyse pour donner l'iodure allylique primaire (**2***d*) qui subit une élimination-1,4 en présence de méthyl-lithium pour fournir le composé 1. Tous les intermédiaires de ces réactions sont facilement cristallisables et à l'exception de **6***b* sont obtenus avec des rendements > 80%. [Traduit par le journal]

Can. J. Chem., **51**, 3150 (1973)

Alkoxyhalogenation of the novel diene **1** proceeds in a highly stereoselective manner to give α-D-hex-2-enopyranosides of type **2**, in which the aglycon may be a simple alcohol residue (1) or another monosaccharide (2). These structures (**2**) are remarkably equipped for diverse structural manipulation and are therefore of value for the preparation of highly modified mono- and disaccharides. However, prosecution of these interests requires better avenues to **1** than presently exist (3). Accordingly we now report four additional routes, three (i, ii, and iv) being one-step processes from known materials, and the fourth a more elaborate process in which the intermediates are synthetically interesting in their own right.

(i) The most direct route conceivable is Wittig methylenation (4) of the known enone **3** (5). However, in practice the reaction proceeded in less than 10% yield owing, undoubtedly, to **3** being a vinylogous lactone.[4]

(ii) The methyl olefin **4** may be prepared from **2***a* by LAH reduction (1) or from the 3-*C*-methyl

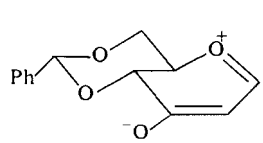
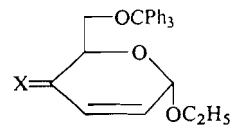
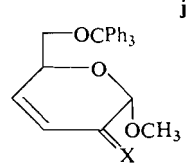
[4]The positive charge required at carbon-3 for methylenation of enone **3** to occur (4) is dissipated to the ring oxygen as in **g**. Accordingly other arrangements of the



g

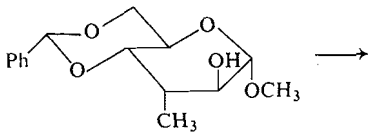


h X = 0
j X = CH_2

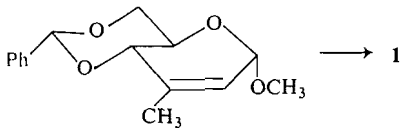


i X = 0
k X = CH_2

chromophore in **h** (6) and **i** (7) in which the lactol oxygen is δ-located, undergo methylenation to **j** and **k**, respectively, in greater than 60% yield (8).



5



4

alcohol, **5** (9). Brief (0.25 h) pyrolysis of the xanthate ester of **5** in biphenyl gives **4** but prolonged (0.5 h) pyrolysis of **5** gives diene **1** in about 25% yield (10).

1 Z = CH_2
3 Z = O

(iii) The keto benzoate **6***a* (11) reacted with methylene phosphorane (4) to give a plethora of products; however, with the Cainelli reagent (12) at room temperature, the desired substance **6***b* (m.p. 152–154°), was obtained along with some readily separated debenzoylated material **6***c*[5] (m.p. 192.5–194°. Anal. Calcd.: C, 64.74; H, 6.52. Found: C, 64.87; H, 6.66). Complete debenzoylation of the reaction mixture and methanesulfonylation afforded **6***d* (m.p. 174–174.5°. Anal. Calcd.: C, 53.95; H, 5.61; S, 9.00. Found: C, 53.51; H, 5.86; S, 9.27). When **6***d* was treated with a 15-fold excess of lithium iodide in refluxing diethyl ether for 1 h it was converted to the allyl iodide **2***b*, so recognized because of the similarity of its n.m.r. spectrum to that of **2***a* (1). 1,4-Elimination of methyl hypoiodite from **2***b* was effected in 2 h by use of a 5 *M* excess of methyl lithium in refluxing ether, whereupon diene **1** was the sole product, isolable in >85% yield. The conversion of **6***a* → **1** can be executed without isolation of intermediates in an overall yield of ~40%.

(iv) The fourth route arises from the gratifying discovery that the tosyl ketone **6***e* (13) when treated in benzene–ether with an excess of the Cainelli reagent (12) for 3 h at room temperature,[5] gave **1** directly. The yield after silica column chromatography using 1:4 ethyl acetate – petroleum ether (35–60) mixture was usually ~50%.

The reaction in route iv undoubtedly passes through stages akin to those in iii, iodinolysis being effected by iodide ion produced *in situ*. The superiority of the tosylate as a leaving group precludes the need for the vast excess of iodide and refluxing temperatures required to convert **6***d* to **2***b*. In iv the Grignard reagent is evidently sufficiently basic to cause 1,4-elimination of $IOCH_3$.

We are indebted to the National Research Council and Bristol Laboratories for financial support. In addition

[5]Magnesium turnings (445 mg) previously washed successively with dilute HCl, water, absolute ethanol, and anhydrous ether, and then thoroughly dried in an oven, are added to pre-distilled mercury (150 g) and stirred at room temperature for 2 h in a nitrogen atmosphere. The amalgam is then covered with 1:1 benzene–ether (16 ml) and cooled to −10°. Methylene iodide (1.75 g) dissolved in 1:1 benzene–ether (30 ml) is added during 20 min and stirring continued for 5 min. At this point the supernatant liquid should be translucent and devoid of colour. Ketone **6***a* (1.0 g) dissolved in 1:1 benzene–ether (160 ml) is added as rapidly as possible and stirred at room temperature for 5 h. (A nitrogen atmosphere must be rigorously maintained in the reaction vessel throughout these operations). After quenching with ammonium chloride solution, the mixture is poured into a separatory funnel and the mercury is drawn off. The organic layer is then isolated and worked up in the usual way.

The Master Equation for the Dissociation of a Dilute Diatomic Gas. X. How Rotation Causes Low Arrhenius Temperature Coefficients

HUW O. PRITCHARD

Chemistry Department, University of Manchester Institute of Science and Technology, Manchester 1, England[1] *and Centre for Research in Experimental Space Science, York University, Downsview, Ontario*[2]

Received June 4, 1973

It is shown that previously calculated nonequilibrium rate constants for the dissociation of H_2 and D_2 appear to approach a rotationally averaged equilibrium expression at low temperature. This equilibrium form of the rate expression *itself* has an Arrhenius temperature coefficient for dissociation which is significantly less than the dissociation energy, and the corresponding recombination rate constant has a negative temperature coefficient. The reasons for this are explained.

On a montré que les constantes de vitesse de non équilibre pour la dissociation de H_2 et D_2 précédemment calculées semblaient tendre vers une expression d'équilibre de rotation moyennée à basse température. Cette forme d'équilibre pour l'expression de vitesse en elle-même possède un coefficient de température d'Arrhénius pour la dissociation qui est inférieur de façon notable à l'énergie de dissociation et la constante de vitesse de recombinaison correspondante possède un coefficient de température négatif; une explication a été donnée. [Traduit par le jurnal]

Can. J. Chem., **51**, 3152 (1973)

In an earlier paper in this series (1) we calculated approximate theoretical rate constants for the dissociation of H_2 and D_2 by the third body He over the temperature range 700–5000 °K. Pursuing our previous assertion (2) that low Arrhenius temperature coefficients in diatomic dissociations reflect increasing departures from a Boltzmann distribution among bound states with increasing temperature, we examine here the possibility that at low temperatures, the rate constants may tend to some equilibrium form of the rate expression; for reasons already explained (1), 700 °K is the lowest temperature at which nonequilibrium calculations are feasible with existing computing facilities.

One may formulate a rotationally averaged form of the standard collision-theory rate constant for dissociation as

$$[1] \qquad \tilde{k}_d = \frac{Z(T)}{\mathrm{pf}_{\mathrm{total}}} \sum_J \mathrm{pf}(J) e^{-D(J)/kT}$$

where $Z(T)$ is a collision number (assumed at the

TABLE 1. Comparison of nonequilibrium and rotationally averaged equilibrium rate constants for dissociation of H_2 and D_2; k_d = nonequilibrium rate constant, $\tilde{k}_d$ = equilibrium rate constant, both in units of cm^3 $molecule^{-1}$ s^{-1}

	H_2			D_2		
T	$\tilde{k}_d$	k_d	$\tilde{k}_d/k_d$	$\tilde{k}_d$	k_d	$\tilde{k}_d/k_d$
5000	5.54×10^{-13}	3.5×10^{-14}	16	3.09×10^{-13}	4.5×10^{-14}	6.9
4000	4.68×10^{-14}	—	—	2.57×10^{-14}	—	—
3000	6.81×10^{-16}	(6.8×10^{-17})	(10)	3.60×10^{-16}	—	—
2000	1.28×10^{-19}	1.9×10^{-20}	6.8	5.91×10^{-20}	2.1×10^{-20}	2.9
1500	2.07×10^{-23}	4.2×10^{-24}	4.9	8.89×10^{-24}	4.0×10^{-24}	2.2
1000	5.72×10^{-31}	1.7×10^{-31}	3.4	1.88×10^{-31}	$\sim1.1\times10^{-31}$	1.7
700	1.11×10^{-40}	4.3×10^{-41}	2.6	2.49×10^{-41}	$\sim1.7\times10^{-41}$	1.5
500	1.28×10^{-53}	—	—	1.71×10^{-54}	—	—
300	8.75×10^{-84}	—	—	3.51×10^{-85}	—	—

moment to be independent of J for consistency with the earlier work), $pf(J)$ and pf_{total} are rotation–vibration partition functions as before (1), and $D(J)$ is the effective dissociation energy of the J'th rotational state; this expression can be cast in other useful equivalent forms, *e.g.*

$$[2] \quad \tilde{k}_d = \frac{Z(T)}{pf_{total}} \sum_J (2J+1) e^{-[D_0 + U_{max}(J)]/kT}$$

or

$$[3] \quad \tilde{k}_d = Z(T) e^{-D_0/kT} \sum_J \frac{(2J+1) e^{-U_{max}(J)/kT}}{pf_{total}}$$

Using the same collision numbers as were used previously (1), Table 1 compares the calculated nonequilibrium rate constants (Table 12 of ref. 1) for H_2 and D_2 with the rotationally averaged equilibrium rate constants. The summation in [2] was taken over all J (both odd and even) and $U_{max}(J)$ was taken to be *either* the maximum rotational barrier height, as tabulated by LeRoy (3), *or* the topmost quasi-bound level if the resonance width was greater than 1 cm^{-1}, again as tabulated by LeRoy; we have already discussed in detail the justification for cutting off the top of the rotational barrier for those quasi-bound rotation–vibration states having short lifetimes (1). As expected, the equilibrium rate constant always exceeds the nonequilibrium rate constant, but by a factor which decreases rapidly with decreasing temperature: the data are compared graphically in Fig. 1 and, although the nonequilibrium results for D_2 are much less extensive, it seems entirely reasonable to continue both curves towards an intercept at $T = 0$ where the equilibrium and nonequilibrium rate constants would coincide. Furthermore, the disparity between the equilibrium and nonequilibrium rates is less for D_2 than for H_2, consistent with the fact that D_2 has more rotation–vibration levels than does H_2, and therefore more pathways in the network (1); unlike the nonequilibrium rates, however, the equilibrium dissociation rate for D_2 is always less than it is for H_2.

TABLE 2. Equilibrium and nonequilibrium Arrhenius temperature coefficients ($\tilde{E}$ and E respectively) for dissociation, in kcal mol^{-1}; values of E taken from ref. 1

	H_2		D_2	
T	$\tilde{E}$	E	$\tilde{E}$	E
4000–5000	98.2	92	98.9	(94)
3000–4000	100.9	94	101.7	(96)
2000–3000	102.8	97	103.9	(99)
1500–2000	103.6	100	104.9	102
1000–1500	103.7	101.5	105.3	103.5
700–1000	103.7	102.5	105.4	104.5
2000–5000	101.5	96	102.5	97

NOTE: $D_0^{H_2}$ = 103.3 kcal mol^{-1}; $D_0^{D_2}$ = 105.1 kcal mol^{-1}.

Table 2 shows the Arrhenius temperature coefficients of the equilibrium and nonequilibrium rates: it will be seen that, although the effect is not as marked as in the nonequilibrium case, even the equilibrium Arrhenius temperature coefficients fall progressively below the respective dissociation energies at high temperatures. The reason for this is simple. Rotation has always been discounted in the past as a cause of low Arrhenius temperature coefficients because it was assumed that the dissociation paths for molecules with high J quantum numbers must be high-energy paths, and are therefore discriminated against (2, 4, 5). However, if we *insist* that the

molecules are rotationally equilibrated, then the higher the temperature, the more molecules are forced to take these high-energy paths. In effect, the critical energy for dissociation is temperature dependent, and rises slowly with temperature: simple differentiation of the expression $k =$ const. exp $[-D(T)/kT]$ with respect to temperature shows that dk/dT is *less* than it would be for constant D if $dD(T)/dT$ is positive, and therefore the Arrhenius temperature coefficient will also be less than expected.

Inspection of either expression 2 or 3 reveals that at very low temperatures the equilibrium rate constant for dissociation will tend to the standard collision theory result of $Z(T)$ exp $[-D_0/kT]$, whence it follows that the rate constant for recombination (*i.e.*, $\tilde{k}_d/K$) will also tend to a very simple form. The rotationally averaged equilibrium rate constants for recombination, calculated using the equilibrium constants (1) and the corresponding dissociation rate constants, are shown in Table 3. It will be noticed, rather surprisingly, that they decrease monotonically throughout the whole range 300–5000 °K (despite the fact that $Z(T)$ increases with temperature).[3]

It is often the case that it is possible to rationalize the occurrence of unexpected Arrhenius temperature coefficients from the point of view of one of the two processes, *i.e.*, *either* dissociation *or* recombination, but quite difficult to visualize the complementary effect on the reverse process: a complete understanding of such effects requires that we can visualize *both* processes *equally* satisfactorily. We have accounted for the dissociation case very simply by saying that as the temperature rises, the assumption of rotational equilibration forces more and more molecules to dissociate via high-energy paths, and therefore the rate of dissociation does not rise as rapidly as it otherwise would. Likewise in recombination, an increase in the approach velocity of a pair of atoms means that, except for a head-on collision, the encounter has more angular momentum. Hence, as the temperature rises and gas-kinetic velocities increase, more and more encounters possess high angular momenta, and are therefore forced to take recombination paths which have higher and higher centrifugal barriers: in other words, more and more pairs of atoms face higher and higher activation energy barriers, at the expense of those low-J encounters which face no barrier, and the total rate of recombination actually falls.

It had been tentatively concluded, both by us (1) and by Dove and Jones (7), that rotational

TABLE 3. Rotationally averaged equilibrium recombination rate constants in cm^6 molecule^{-2} s^{-1}

T	H_2	D_2

300	2.05×10^{-32}	1.13×10^{-32}

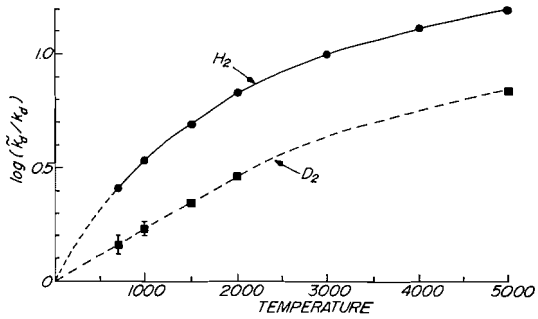

FIG. 1. Comparison of nonequilibrium and rotationally averaged equilibrium rate constants for dissociation of H_2 and D_2; k_d = nonequilibrium rate constant, $\tilde{k}_d$ = equilibrium rate constant.

[3]Again, the rotationally averaged equilibrium recombination rate for D_2 is always less than that for H_2, by a factor of about 0.57–0.58 at most temperatures. The figure 0.57_7 is $0.8165\times(\frac{1}{2})^{3/2}\times2$ where 0.8165 is the ratio of the two collision numbers used (1) and the other two factors arise in the ratio of the standard statistical mechanical expressions for the two equilibrium constants (6): the term $(\frac{1}{2})^{3/2}$ comes from translational partition function terms, and the factor of 2 comes from rotational partition function terms. Thus as $T\rightarrow0$ and the rotational partition function no longer has its classical form, the ratio of the rotationally averaged equilibrium recombination rates for D_2 and H_2 will be

$$(\tfrac{1}{2})^{3/2}\,(pf_{rot}^{D2}/pf_{rot}^{H2})\,(Z_{M,D_2}/Z_{M,H_2})$$

In the absence of nuclear spin effects the rotational partition function ratio would eventually drop out, but for H_2 and D_2 this will not happen; on top of this, nonequilibrium (network) effects will introduce approximately another factor of between 1 and 2 (cf. Fig. 1).

effects *may* have something to do with the observation of low Arrhenius temperature coefficients in diatomic dissociation reactions, because of the fact that theoretically computed temperature coefficients were much more in line with experimental observation if rotational disequilibrium was explicitly considered in the model calculations. It seems clear from the present examination that, in fact, an equilibrium model including rotational effects can account (at least in the energy-transfer dominated regime) for negative temperature coefficients in diatomic recombination, or for "low" temperature coefficients of the dissociation rate: however, it is also clear from Fig. 1 that nonequilibrium effects must be superimposed and that although these nonequilibrium effects decrease in importance with decreasing temperature, they are likely to be present even down to the lowest temperatures where recombination has yet been studied (8).

The author would like to thank the National Research Council of Canada and the Nuffield Foundation for travel assistance, and the University of Manchester Regional Computer Centre for the use of its facilities.

Diterpenoid Metabolites of *Cyathus helenae*. Cyathin B_3 and Cyathin C_3

WILLIAM A. AYER AND LESLIE L. CARSTENS

Chemistry Department, University of Alberta, Edmonton, Alberta T6G 2E1

Received April 9, 1973

Cyathin B_3, a metabolite of *Cyathus helenae* is shown to possess structure **3***a*. Cyathin C_3 is 1,2-dehydrocyathin B_3 (**4***a*). Cyathin B_3 has been correlated with cyathin A_3 (**1**) and cyathin C_3 with allocyathin B_3 (**2**).

On a montré que la cyathine B_3, métabolite du *Cyathus helenae* possède la structure **3***a*. La cyathine C_3 correspond au déhydro-1,2 cyathine B_3 (**4***a*). Une corrélation entre la cyathine B_3 et la cyathine A_3 (**1**), la cyathine C_3 avec l'allocyathine B_3 (**2**), a été rapportée.

[Traduit par le journal]

Can. J. Chem., 51, 3157 (1973)

The bird's nest fungus *Cyathus helenae* Brodie (Gasteromycetes) when grown on liquid culture produces a mixture of substances showing antibiotic activity (1). Our initial report on the separation of the components describes six components of the mixture, including 2,4,5-trihydroxybenzaldehyde and five C_{20} compounds (1). Recently (2) we have shown that one of these C_{20} compounds, cyathin A_3, possesses the novel diterpenoid structure **1**, and that an additional component of the mixture, allocyathin B_3, possesses structure **2**. The stereochemistry shown in **1** and **2**, including the absolute configuration, has been established by X-ray crystallography (3). We now wish to report the structure of cyathin B_3 (1) and that of a newly detected component of the cyathin mixture, cyathin C_3.[1]

Crude cyathin B_3 was isolated by column chromatography (silicic acid) of an ethyl acetate extract of the culture broth of *Cyathus helenae* grown on a defined (1) medium, and crystallized from ether–pentane (m.p. 131–133°). The mass spectrum shows an apparent molecular ion at *m/e* 316 ($C_{20}H_{28}O_3$, h.r.m.s.).[2] However, the appearance of a strong peak at *m/e* 314 in the mass spectrum and the complexity and nature of the n.m.r. spectrum (see Experimental) suggested that the crystalline material is a mixture of cyathin B_3 and a dehydro analog (cyathin C_3). T.l.c. over silica gel and over alumina and with several solvent systems showed a single spot, but t.l.c. over silica gel impregnated with 10% silver nitrate revealed two overlapping spots at higher R_f values along with apparent decomposition products near the origin (no decomposition was observed in the absence of silver nitrate). Preparative t.l.c. (silica gel – $AgNO_3$) afforded only partial separation and was accompanied by extensive loss of material. Since the n.m.r. and i.r. spectra indicated that the material was a mixture of unsaturated aldehydes

[1]The C_{20} compounds are named in the following way (1): compounds containing 30 hydrogens are placed in the A series of cyathins; those with 28 hydrogens in the B series; those with 26 hydrogens in the C series. The subscript after the letter denotes the number of oxygens. Isomers of the first isolated cyathins are designated allocyathins, *e.g.*, cyathin B_3 is $C_{20}H_{28}O_3$ and isomeric with allocyathin B_3.

[2]Because of the small quantities of pure material available, all molecular formulas have been established by high resolution mass spectrometry (h.r.m.s.). Eventual correlation with compounds of established molecular formula validates the deductions made in this manner.

(n.m.r. signals at δ 9.91 and 9.61, i.r. bands at 2810, 2710, 1692 cm^{-1}), it seemed possible that the two components of the mixture were the aldehydes **3***a* (cyathin B_3) and **4***a* (cyathin C_3), C-15 dehydro analogs of cyathin A_3 (**1**) and allocyathin B_3 (**2**), respectively. The correctness of this supposition is supported by the experiments described below.

Cyathin A_3 (**1**) and allocyathin B_3 (**2**) are readily transformed into the internal methyl ketals **5** and **6**, respectively, by treatment with methanolic HCl (2). Similar treatment of the cyathin B_3 – cyathin C_3 mixture gave a mixture of cyathin B_3 methyl ketal (**7***a*) and cyathin C_3 methyl ketal (**8***a*) which was separable, without extensive decomposition, by p.t.l.c. on silica gel – 10% silver nitrate. As expected (4) the more highly unsaturated ketal **8** displayed the lower R_f value.

Cyathin B_3 methyl ketal (**7***a*) absorbs at 233 nm (ε 5300) in the u.v. (α,β-unsaturated aldehyde (5)) and shows characteristic α,β-unsaturated aldehyde absorption in the i.r. The n.m.r. spectrum displays an aldehydic proton at δ 9.88, a one-proton signal at δ 7.00 (β-proton of α,β-unsaturated carbonyl system), a multiplet at δ 4.97 (C-11 proton), a methoxyl signal at δ 3.26, as well as the appropriate *C*-methyl signals. The mass spectrum shows the appropriate parent peak at *m/e* 330 and no $M^+ - 2$ peak.

The spectroscopic properties of cyathin C_3 methyl ketal (**8***a*) are similar to those of **7** except for those attributable to the cyclopentadiene moiety. Thus, the u.v. spectrum shows a shoulder (257 nm) due to the cyclopentadiene chromophore (2, 6) superimposed on the unsaturated aldehyde chromophore (236 nm). This absorption band is clearly resolved in the circular dichroism (c.d.) spectrum. The olefinic protons at C-1 and -2 in **8***a* appear as an AB quartet (J = 5.5 Hz) centered at δ 6.15 in the n.m.r. Characteristic olefinic C—H stretching bands appear at 3050 cm^{-1} in the i.r.

Acetylation of the cyathin B_3 – cyathin C_3 mixture with acetic anhydride – pyridine led to the formation of at least three products (t.l.c.), separable by p.t.l.c. Besides *O*-acetylcyathin B_3 (**3***b*) and *O*-acetylcyathin C_3 (**4***b*), a compound of higher R_f value showing u.v. absorption at 325 nm (β 10 600) and 260 nm (ε 6200) was obtained. This latter compound showed an apparent molecular ion at *m/e* 298 ($C_{20}H_{26}O_2$) and is assigned structure **9** (anhydrocyathin B_3).

In order to prove rigorously the structure assigned to cyathin B_3, a direct correlation with cyathin A_3 (**1**), the structure and absolute stereo-

chemistry of which is known with certainty (2, 3), was established. Reduction of cyathin B_3 methyl ketal (**7**) with sodium borohydride in ethanol gave cyathin A_3 methyl ketal (**5**) identical in all respects (t.l.c. behavior, m.s., i.r., n.m.r., optical rotation, c.d. spectrum) with an authentic sample. Similarly, reduction of cyathin C_3 methyl ketal (**8**) gave allocyathin B_3 methyl ketal (**6**). Thus cyathin B_3 has the structure and stereochemistry depicted in **3***a*, and cyathin C_3 is **4***a*.[3]

The mass spectra of cyathin A_3 methyl ketal (**5**) and allocyathin B_3 (**6**) are both completely dominated by an intense peak at *m/e* 141, presumed to have structure **10** (2). It is noteworthy that the mass spectra of ketals **7** and **8** *do not* show an appreciable peak at *m/e* 139 for the corresponding ion **11**. It appears that the electron-withdrawing formyl group markedly destabilizes an ion of this type.

Experimental

Mass spectra including high resolution mass spectra were recorded on an A.E.I. model MS-9 mass spectrometer, i.r. spectra on a Perkin-Elmer model 421 dual grating spectrometer or on a Unicam SP 1000 dual grating spectrometer, u.v. spectra on a Cary model 14M spectrophotometer, and c.d. spectra on a Jasco model 5 spectropolarimeter. N.m.r. spectra were measured on a Varian HA-100 spectrometer, tetramethylsilane being used as an internal standard. In the description of n.m.r. spectra s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet. Silica gel thin-layer chromatograms were carried out using 0.5 mm layers of Silica Gel G (E. Merck, Darmstadt) containing *ca.* 1% Electronic Phosphor (General Electric, Cleveland); materials were detected by viewing under u.v. light or by spraying with 30% sulfuric acid and charring. Argentated silica gel plates were prepared by slurrying 45 g Silica Gel G with 100 ml of an aqueous solution containing 5 g silver nitrate; the adsorbent layers were activated at 120° for 2 h, protected from light as much as possible, and used within 24 h. For preparative separations, layers of 0.5–0.7 mm were employed. Unless otherwise specified the solvent system used to develop chromatograms was benzene–acetone – acetic acid (75:25:1). All solvents were distilled before use.

Isolation of Cyathin B_3 – Cyathin C_3 Mixture

Total ethyl acetate soluble metabolites of *Cyathus helenae* (1) (2.7 g) were chromatographed in a quartz column (50 mm diameter) over silicic acid (220 g, Mallinckrodt 100 mesh) containing Electronic Phosphor (1 g) using chloroform (0.75% ethanol) as eluent. The progress of the separation was monitored with a short wavelength u.v. lamp. The thirteenth 125 ml fraction (0.33 g) was crystallized from ether–pentane and gave colorless needles (0.13 g), m.p. 131–133°, which proved to be a mixture of cyathin B_3 and cyathin C_3 showing the following properties: mass spectrum (70 eV) *m/e* (relative intensity) 316 (23), 314 (11), 301 (22), 299 (5), 273 (11), 255 (12), 204 (23), 203 (23), 201 (21), 189 (58), 187 (21), 175 (14), 173 (10), 161 (28), 159 (17), 119 (37), 105 (39), 91 (46), 55 (57),

[3]The similarity between the u.v. spectra of the ketalized and unketalized forms of cyathin B_3 and cyathin C_3 and the fact that their i.r. spectra in solution show only one carbonyl band suggests that these compounds, like cyathin A_3 and allocyathin B_3, exist substantially in the hemiketal forms **7***b* and **8***b*, at least in the solvents used for the spectral measurements.

41 (100); exact mass measurement, 316.2037 (calcd. for $C_{20}H_{28}O_3$, 316.2038); i.r. (CCl_4) 3585, 3350 (br) 3050 (w), 2810, 2710, 1692 (v.s.), 1625 cm^{-1} (w); u.v. (dioxane) 233 nm (ε 6800); n.m.r. ($CDCl_3$) δ 9.91 (s), 9.61 (s), 7.01 (s), 6.6–6.2 (complex), 5.01 (m), methyl region complex.

Attempted Separation of Cyathin B_3 – Cyathin C_3 Mixture

The crystalline material described above (100 mg) was applied to four 10 × 20 cm plates coated with silica gel – 10% $AgNO_3$ and these were developed with Skellysolve B – acetone (3:2). Two overlapping bands were detected by u.v. These were removed in 3 fractions, and the top and bottom fractions rechromatographed on silica gel. In this way it was possible to obtain cyathin B_3 (47 mg), m.p. 130–132°, only slightly contaminated with cyathin C_3 (as judged by n.m.r. and m.s.) Cyathin B_3 showed the following properties: mass spectrum (70 eV) *m/e* (relative intensity) 316 (68), 301 (57), 273 (28), 255 (27), 204 (42), 203 (39), 189 (100), 175 (28), 161 (42), 105 (41), 91 (45), 55 (54), 41 (84); n.m.r. ($CDCl_3$) δ 9.91 (1H, s), 7.06 (1H, s), 5.08 (1H, m), 1.08 (3H, s), 1.03 (6H, d, J = 6.5 Hz), 0.94 (3H, s).

Preparation and Separation of Cyathin B_3, Cyathin C_3 Methyl Ketals (7a and 8a)

The mixture of cyathin B_3 and cyathin C_3 (77 mg) was dissolved in anhydrous methanol (2 ml) and a saturated solution of hydrogen chloride in methanol (1.5 ml) was added at room temperature. After 48 h, t.l.c. indicated complete reaction and the solvent was removed at the pump. Preparative t.l.c. over silica gel – 10% $AgNO_3$ (solvent system, Skellysolve B – acetone (3:1), R_f values 0.58 (*7a*) and 0.51 (**8***a*)) was used to separate the two components, neither of which could be induced to crystallize.

Cyathin B_3 methyl ketal shows the following properties: $[\alpha]_D^{24}$ −105° (*c* 0.1, isooctane); mass spectrum (70 eV) *m/e* (relative intensity) 330 (24), 315 (14), 301 (20), 299 (23), 255 (21), 227 (23), 204 (21), 199 (21), 189 (100), 175 (31), 161 (33), 133 (35), 119 (47), 105 (63), 91 (65), 55 (67), 41 (86); exact mass measurement 330.2184 (calcd. for $C_{21}H_{30}O_3$, 330.2195); i.r. (CCl_4) 2850, 2720, 1692 (s), 1625 cm^{-1}; u.v. (isooctane) 233 nm (ε 5300); n.m.r. (CCL_4) δ 9.88 (s, H-15), 7.00 (s, *H*-13), 4.97 (br s, *H*-11), 3.26 (s, methoxyl), 2.93 (septet, *H*-18, J = 7 Hz), 2.3–1.1 (complex), 0.98 (d, J = 7 Hz, one isopropyl methyl), 0.94 (s, 3H, *H*-16 or -17), 0.90 (s, 3H, *H*-17 or -16), 0.89 (d, J = 7 Hz, one isopropyl methyl); c.d. (*c* 0.1 in isooctane) $\Delta\varepsilon_{346}$ − 0.97, $\Delta\varepsilon_{235}$ − 2.78.

Cyathin C_3 methyl ketal shows the following properties: $[\alpha]_D^{24}$ − 89° (*c* 0.043, isooctane); mass spectrum (70 eV) *m/e* (relative intensity) 328 (39), 313 (13), 299 (25), 295 (21), 253 (25), 225 (20), 202 (27), 187 (100), 173 (28), 159 (23), 145 (32), 133 (20), 119 (24), 105 (22), 101 (45), 91 (25), 75 (77), 55 (16), 41 (29); exact mass measurement 328.2042 (calcd. for $C_{21}H_{28}O_3$, 328.2039); i.r. (CCl_4) 3050, 2850, 2810, 2720, 1693 (s), 1625 cm^{-1}; u.v. (isooctane) 236 nm (ε 7400), 257 (sh) nm (ε 4300); n.m.r. (CCl_4) δ 9.92 (s, *H*-15), 7.03 (s, *H*-13), 6.20 and 6.10 (AB quartet, *H*-1 and -2, J = 5.5 Hz), 5.05 (m, *H*-11), 3.29 (s, methoxyl), 2.95 (septet, *H*-18, J = 7 Hz), 2.5–2.1 (complex, 2H), 1.8–1.1 (complex), 1.09 and 1.03 (two nonequivalent isopropyl methyls, *J*'s 7 Hz), 0.88 (s, 3H, *H*-16 or -17), 0.77 (s, 3H, *H*-17 or -16): c.d. (*c* 0.043 in isooctane) $\Delta\varepsilon_{356}$ −1.23, $\Delta\varepsilon_{258}$ −4.31, $\Delta\varepsilon_{235}$ −9.23.

Acetylation of Cyathin B_3 – Cyathin C_3 Mixture

Cyathin B_3 – cyathin C_3 mixture (20 mg) was acetylated for 8 h at 40° in methylene chloride (1 ml) containing pyridine (0.16 ml) and acetic anhydride (0.08 ml). The crude product (21 mg) showed three spots on t.l.c. and was separated into its components by p.t.l.c. on silica gel (solvent system, Skellysolve B – acetone (3:1), double development). The least polar compound (5 mg), assigned structure **9**, showed an apparent molecular ion at *m/e* 298 in the mass spectrum (base peak at *m/e* 283) corresponding to $C_{20}H_{26}O_2$. The u.v. spectrum of this material had $\lambda_{max}^{(dioxane)}$ 260 mm (ε 6300) and 325 nm (ε 10 600) and the i.r. spectrum (CCl_4) showed aldehyde C—H stretch at 2810 and 2710 cm^{-1}, carbonyl absorption at 1710 and 1680 cm^{-1}, and C=C stretch at 1615 and 1580 cm^{-1}, and active methylene at 1421 cm^{-1}.

The compound of intermediate R_f value (7 mg) showed properties consistent with those expected for *O*-acetylcyathin B_3 (**3***b*): mass spectrum (70 eV) *m/e* 358, 343,316, 298, 283; i.r. (CCl_4) 2810, 2710, 1745, 1710, 1680 cm^{-1}.

The compound of lowest R_f value was obtained in very small quantity (2 mg). The mass spectrum (M^+ 356) and i.r. (1750, 1705, 1690 cm^{-1}) suggest that it is *O*-acetylcyathin C_3 (**4***b*).

Sodium Borohydride Reduction of Cyathin B_3 Methyl Ketal

Cyathin B_3 methyl ketal (*7a*, 14 mg) was dissolved in 95% ethanol (0.5 ml) and 0.5 ml of a solution of sodium borohydride in ethanol (1 mg/ml) was added. After 15 min, t.l.c. indicated complete reduction. The solvent was removed, water added, and the solution extracted with carbon tetrachloride. Purification by p.t.l.c. on silica gel G provided cyathin A_3 methyl ketal (**5**, 4 mg) as a gum, identical in t.l.c. behavior, mass spectrum, i.r. spectrum, and optical rotation ($[\alpha_D^{24}$ −158° (isooctane), authentic cyathin A_3 methyl ketal shows $[\alpha]_D^{25}$ − 154° (7)) with an authentic sample (2).

Sodium Borohydride Reduction of Cyathin C_3 Methyl Ketal

Cyathin C_3 methyl ketal (**8***a*, 22 mg) was reduced as described above for **7***a*. Isolation and purification afforded allocyathin B_3 methyl ketal (14 mg), identical (t.l.c., m.s., i.r., u.v. (λ_{max} 255 nm), c.d. ($\Delta\varepsilon_{253}$ −3.46)) with an authentic sample (2).

We wish to thank the National Research Council of Canada for financial support, Dr. H. Taube for valuable advice and assistance, and J. Ball for technical assistance.

Nucleic Acid Related Compounds. 8. Direct Conversion of 2′-Deoxyinosine to 6-Chloropurine 2′-Deoxyriboside and Selected 6-Substituted Deoxynucleosides and Their Evaluation As Substrates of Adenosine Deaminase[1,2]

MORRIS J. ROBINS AND GERALD L. BASOM

Department of Chemistry, The University of Alberta, Edmonton, Alberta T6G 2G2

Received April 9, 1973

Trifluoroacetylation of 2′-deoxyinosine (**2**), obtained by enzymatic deamination of 2′-deoxyadenosine (**1**), gave the 3′,5′-bis-*O*-trifluoroacetate (**3**). Reaction of the electronegatively substituted deoxynucleoside, **3**, with DMF – thionyl chloride complex in refluxing methylene chloride gave a high yield of 6-chloropurine 2′-deoxyriboside (**4**) after deblocking.

Displacement of chloride of **4** by hydrosulfide to give 6-mercaptopurine 2′-deoxyriboside (**5**) followed by sulfur alkylation with *p*-nitrobenzyl bromide gave 6-*S*-(*p*-nitrobenzyl) thiopurine 2′-deoxyriboside (**6**) which was alternatively prepared by displacement of chloride from **4** by *p*-nitrobenzyl mercaptide, generated *in situ* from the isothiouronium salt. Methyl mercaptide reaction with **4** gave 6-methylthiopurine 2′-deoxyriboside (**7**). Treatment of **4** with trimethylamine gave the corresponding quaternary ammonium chloride (**8**) which was allowed to react with potassium fluoride to give 6-fluoropurine 2′-deoxyriboside (**9**). Respective amine displacements on **4** gave 6-benzylaminopurine 2′-deoxyriboside (**10**), and 6-hydroxylaminopurine 2′-deoxyriboside (**11**). Reaction of **4** with liquid ammonia completed the first reported transformation of 2′-deoxyinosine (**2**) to 2′-deoxyadenosine (**1**).

Biological rationale for the synthesis of these 2′-deoxynucleosides and their evaluation as substrates of adenosine deaminase are discussed. Major mass spectral fragmentations are tabulated.

La trifluoroacétylation du déoxy-2′ inosine (**2**), obtenu par désamination enzymatique du déoxy-2′ adénosine (**1**), conduit au bis-*O*-trifluoroacétate-3′,5′ (**3**). La réaction du déoxy nucléoside substitué par un groupe électronégatif **3**, avec le complexe DMF – chlorure de thionyle dans le chlorure de méthylène à reflux conduit au chloro-6 purine déoxy-2′ riboside (**4**) après déblocage.

Le déplacement du chlorure dans **4** par l'hydrogénosulfure pour donner le mercapto-6 purine déoxy-2′ riboside (**5**), suivi d'une S-alkylation par le bromure de *p*-nitrobenzyle conduit au *S*-(*p*-nitrobenzyl)-6 thiopurine déoxy-2′ riboside (**6**) qui peut être préparé d'une autre façon par déplacement du chlorure dans **4** par le *p*-nitrobenzylsulfure engendré *in situ* à partir de sel d'isothiouronium. La réaction du méthylsulfure sur **4** conduit au méthyl-6 thiopurine déoxy-2′ riboside (**7**). Le traitement de **4** par la triméthylamine conduit au chlorure d'ammonium quaternaire correspondant (**8**) qui, mis en présence de fluorure de potassium, conduit au fluoro-6 purine déoxy-2′ riboside (**9**). Les déplacements respectifs sur l'amine dans **4** conduisent au benzylamino-6 purine déoxy-2′ riboside (**10**) et à l'hydroxylamino-6 purine déoxy-2′ riboside (**11**). La réaction de **4** sur l'ammoniac liquide complète la transformation déoxy-2′ inosine (**2**) en déoxy-2′ adénosine (**1**), rapporté pour la première fois.

La justification biologique pour la synthèse de ces déoxy-2′ nucléosides et leur évaluation comme substrats pour l'adénosine déaminase ont été discutées. Un tableau sur les fragments majeurs en spectrométrie de masse a été rapporté. [Traduit par le journal]

Can. J. Chem., **51**, 3161 (1973)

We wish to report the conversion of 2′-deoxyinosine (**2**) into 6-chloro-9-(2-deoxy-β-D-*erythro*-pentofuranosyl)purine (**4**) as the first such successful functionalization of a purine 2′-deoxynucleoside.

A large number of 6-substituted purines and their nucleosides have been prepared and biologically evaluated (for reviews see ref. 1). Some nucleoside derivatives of this type show significant activity and are useful in cancer chemotherapy and other biochemical applications (2).

The syntheses of 6-substituted purine ribosides have been effected by several routes including coupling of suitable purine and sugar derivatives (3–5) but most conveniently by the direct chlorination of a tri-*O*-acylated inosine (6–8). Due to the acid and heat lability of purine 2′-deoxynucleosides, however, analogous attempts with di-*O*-

acylated 2′-deoxyinosine have failed. The useful synthetic intermediate 6-chloro-9-(2-deoxy-β-D-*erythro*-pentofuranosyl)purine (6-chloropurine deoxyriboside) (**4**) has been prepared previously by base–sugar coupling using the chloromercuri procedure (9) or the fusion method (10). Each of these routes gives **4** in only about 6% yield.

We had observed some time ago (11) that 3′-*O*-*p*-toluenesulfonyl-2′-deoxyadenosine survived intact during hot 80% acetic acid removal of a trityl function. Several groups have recently concluded that nucleosides are acid hydrolyzed by an A-1 mechanism resulting in dissociation of protonated base from positively charged glycosyl ion (12). Thus, substitution of strongly electronegative groups on the sugar moiety would be expected to destabilize glycosyl carbonium ion formation and thus retard sugar–base cleavage.

Reaction of 2′-deoxyinosine (**2**) with trifluoroacetic anhydride gave amorphous 3′,5′-di-*O*-acylate (**3**) (see Scheme 1) as evaluated by t.l.c. and spectroscopic methods. Treatment of this unisolated intermediate (**3**) with thionyl chloride – DMF (7, 8) in refluxing methylene chloride with constant nitrogen purging, followed by methanol treatment and chromatography gave **4** in greater than 80% overall yield from **2** with only about 8% cleavage to hypoxanthine. As observed by others using various conditions (A.D. Broom, private communication and J. Žemlička, private communication), attempted analogous reaction of 3′,5′-di-*O*-acetyl-2′-deoxyinosine resulted in quantitative cleavage of the glycosidic bond.

Paterson and co-workers have found that certain 6-*p*-nitrobenzylthiopurine-9-β-D-ribofuranosides inhibit mediated nucleoside transport across cell membranes (13, and other papers from that laboratory). The 2′-deoxy analog (**6**) was prepared by two routes. Reaction of *p*-nitrobenzyl bromide with thiourea followed by addition of **4** and potassium hydroxide (*in situ* generation of benzyl mercaptide from the isothiouronium salt) gave **6** contaminated with an unidentified product which was removed by chromatography. Alternatively, treatment of **4** with hydrosulfide produced 6-mercaptopurine deoxyriboside (**5**) (9, 14) in 86% yield, and sulfur alkylation of **5** with benzyl bromide gave pure **6** in 87% yield.

Since 6-methylthiopurine riboside has been shown to be active against tumor cell lines resistant toward 6-mercaptopurine riboside and to be phosphorylated by and resistant to different enzymes (15, 16), its 2′-deoxy analog is of interest. When **4** was treated with methyl mercaptide, 6-methylthio-9-(2-deoxy-β-D-*erythro*-pentofuranosyl)purine (**7**) was obtained in 90% yield. The enzymic preparation of **5** and its methylation to **7** are recorded in abstract form (14) with a comparable m.p. for characterization.

Kiburis and Lister (17) succeeded in synthesizing the elusive (18) 6-fluoropurines and their nucleosides employing fluoride displacement on 6-purinyl-trimethylammonium salts. They prepared 6-fluoropurine riboside in some 30% yield by this procedure (17). Reaction of **4** proceeded quantitatively with trimethylamine to give the quaternary salt **8** which was treated with potassium fluoride to provide **9** in 66% yield.

The 2′-deoxynucleoside (**10**) of the potent plant cytokinin (19) 6-benzylaminopurine was prepared in 93% yield by stirring **4** with benzylamine. The properties of **10** are identical to those of a sample prepared by alkylation–rearrangement of 2′-deoxyadenosine (**1**) with benzyl bromide (20).

Treatment of **4** with hydroxylamine gave 6-hydroxylamino-9-(2-deoxy-β-D-*erythro*-pentofuranosyl)purine (**11**) whose 9-riboside analog has been reported to be a potent anti-leukemic agent (21).

Finally, reaction of **4** with liquid ammonia proceeded cleanly to give a 96% yield of 2′-deoxyadenosine (**1**). Alcoholic ammonia (9) was not as satisfactory and alkoxy attack may lead to additional products (22). Adenosine deaminase (adenosine aminohydrolase) cleanly and quantitatively converts 2′-deoxyadenosine (**1**) to 2′-deoxyinosine (**2**). However, this enzymatic reaction is apparently irreversible (23). The present chemical sequence of trifluoracetylation of **2** to give **3**, chlorination to give **4**, and ammonolysis to **1** represents the first recorded reversal of the overall enzymatic process (*i.e.* conversion of 2′-deoxyinosine to 2′-deoxyadenosine).

The mass spectra of these compounds (see Table 1) are for the most part readily interpreted following the fragmentation scheme of McCloskey and co-workers (24). This is summarized in Scheme 2, path 1. However, there are several interesting exceptions.

The mass spectral base peak occurs at *m/e* 81 (relative intensity 100%) for 6-mercaptopurine deoxyriboside (**5**). There is also a significant

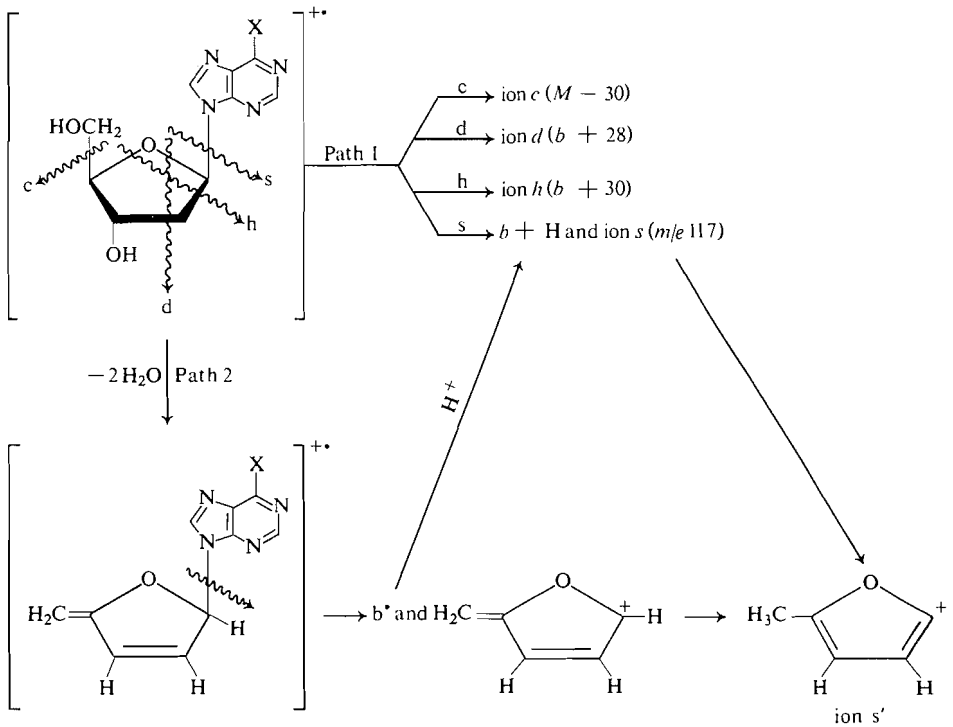
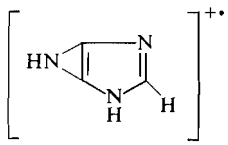
[a]Nomenclature is for ions formed *after* loss of CH_3Cl from **8**.
[b]Nomenclature is for ions formed *after* loss of O.



SCHEME 2

peak at *m/e* 232 corresponding to $M - 36$. The *m/e* 81 peak is compatible with a methylfuran ion (ion *s'*) which may arise as shown in Scheme 2. However, an ion of *m/e* 81 has been reported in the fragmentation of several purines (25, 26) to which the following structure was assigned:



High resolution peak matching for the peak observed in the mass spectrum of **5** gave the value *m/e* 81.0341 as an apparent singlet. The calculated value for ion *s'* (C_5H_5O) is 81.0340 whereas that for $C_3H_3N_3$ is 81.0327. Thus, while ion *s'* is favored, the theoretical masses for the two possible ions are too close to allow conclusive assignment. Therefore, a mass spectrum of 6-thioinosine (probe temperature 200°) was obtained for comparison. The peak at *m/e* 81 was observed at a relative intensity of only 6% (*m/e* 152 (*b* + H), relative intensity 100%), which indicates that the peak at *m/e* 81 in the deoxynucleoside **5** arises primarily from the sugar moiety. Although a significant *m/e* 81 peak has not been reported for free 2'-deoxynucleosides previously, this peak was found to be significant for 3',5'-bistrifluoracetates (27). Thus structural features in 2'-deoxynucleosides may alter the relative importance of paths 1 and 2 which will affect the intensities of ions *c*, *d*, *h*, etc.

Path 2 apparently contributes strongly in the fragmentation of **11**. A further complication occurs by initial extrusion of the hydroxylamino oxygen atom. This loss of oxygen was found to occur also in the spectrum of the riboside analog.[3] The mass spectra of **11** varied markedly with changes in probe temperature.

The spectrum of the 6-fluoro compound **9** is interesting in that the relative intensities of the fragment ions differ significantly from those of the other compounds studied. The most intense peak is due to ion *s*, normally a relatively weak peak. Ions *d* and *b* + 2H are more than twice as abundant as the *b* + H ion which normally gives the most intense peak. An

[3] N^6-Hydroxyadenosine (6-*N*-hydroxylaminopurine riboside) prepared by the procedure of Giner-Sorolla *et al.* (21).

TABLE 2[a]. Enzyme substrate activity

Compound	$K_m(\times 10^5)$	$V_{max}(\%)$	Substrate activity[b]
1	2.4	100	+
4	16.7	15	+
5	—	—	−
6	—	—	−[c]
7	—	—	+[d]
9	22	100	+
10	—	—	−
11	6.3	44	+

[a]K_m and V_{max} values were obtained from plots of $1/C_0$ *vs.* $1/V_0$. V_0 values were determined by measuring the decrease in absorption between substrate and product (**2**) at 265 nm (**1**, $\Delta\varepsilon = 7500$; **11**, $\Delta\varepsilon = 7000$) or the corresponding increase in absorption at 250 nm **4**, $\Delta\varepsilon = 6000$; **9**, $\Delta\varepsilon = 6000$) for the 5–65 s period following addition of substrate to enzyme. The changes in absorption were recorded on a Cary 15 spectrophotometer using a moving chart to verify the linear $\Delta A/\Delta t$ relationship. V_0 values were determined for at least five initial substrate concentrations from $1\text{–}10 \times 10^{-5}$ *M*. Enzyme solutions were freshly prepared for each substrate and maintained at 0° in 0.05 *M* tris-HCl buffer (p*H* 8 at 0°) and varied from $1\text{–}10 \times 10^{-4}$ mg/0.1 ml. Each determination was initiated by the rapid addition of 1.4 ml of substrate solution in 0.05 *M* KH_2PO_4 buffer (p*H* 7 at 25°) to 0.1 ml of enzyme solution.

[b]Substrate activity was evaluated by treating 5×10^{-4} *M* substrate in 0.05 *M* KH_2PO_4 buffer (p*H* 7 at 25°) with 100 times the normal amount of enzyme. After 30 h, an aliquot was diluted tenfold and the u.v. spectrum compared to control solutions.

[c]Tested in DMSO–buffer (1:1).

[d]Relative rate compared to 1 *ca.* 0.00005.

unusually abundant $M + H$ peak is also present, with approximately the same intensity as the M peak. Decomposition of the $M + H$ ion to form ion *s* due to the enhanced ease of glycosidic bond cleavage (12) offers a possible explanation for the observed anomalous fragment ion intensities.

Adenosine Deaminase Substrate Activity

A number of 6-substituted-purine ribosides have been found to be substrates of adenosine aminohydrolase; chloro, iodo, methylamino, etc., functions are hydrolyzed to yield inosine (28). Deoxyadenosine (**1**) is also a well-known substrate which is deaminated with efficiency comparable to that of adenosine (29).

The deoxynucleosides prepared in this study were subjected to the enzyme, and kinetic parameters were determined for those which were hydrolyzed with reasonable velocity (see Table 2).

The present facile preparation of **4** makes the synthesis of any 6-substituted-purine-9-(2-deoxy-β-D-*erythro*-pentofuranoside), obtainable by nucleophilic displacement, readily available. Analogous studies on 2′-deoxyguanosine are in progress in this laboratory.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. N.m.r. spectra were recorded on a Varian 56/60 spectrometer with TMS or DSS as reference for proton spectra. U.v. spectra were recorded on Cary 14 or 15 spectrometers. Optical rotations were determined on a Perkin-Elmer model 141 polarimeter using a 10 cm, 1 ml micro cell. Mass spectra were determined by the mass spectrometry laboratory of this department on AEI MS-2 and MS-9 instruments at 70 eV. Sample introduction was via direct probe at temperatures specified. Micro analyses were obtained by the microanalytical laboratory of this department and by Schwarzkopf Microanylitical Laboratory, Woodside, N.Y. Evaporations were effected using a Büchler rotating evaporator under aspirator or mechanical oil pump vacuum at 40° or less.

Types I and II adenosine deaminase were purchased from Sigma Chemical Company.

Enzymatic Preparation of 2′-Deoxyinosine (2)

To a suspension of 20 g (0.08 mol) of **1** in 1.1 l of 0.02*M* KH_2PO_4 aqueous buffer (p*H* 7) was added 0.1 g of Type II adenosine deaminase and the mixture was stirred for 20 h at room temperature. The resulting clear solution was evaporated (40°) to about 800 ml and the suspension produced was filtered. The filtrate was similarly concentrated to 200 ml and again filtered. Ethanol (200 ml) was added to the filtrate and this mixture was concentrated to 20 ml and filtered. The combined filter cakes were dissolved in 1 l of hot 80% ethanol, filtered, and the filtrate cooled at 5° for 18 h. Crystalline **2** (16.4 g, 82%) was collected by filtration. This product had m.p. 216–217° (a commercial sample had m.p. 216–218°) and was of adequate purity to use in the following reaction. Further material of lower purity could be obtained from the above filtrates. Mixed m.p., t.l.c., u.v., n.m.r., and mass spectral comparison verified the identity of this material and a commercial sample of 2′-deoxyinosine.

6-Chloro-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine [6-Chloropurine 2′-Deoxyriboside] (4)

A suspension of 10.1 g (0.04 mol) of anhydrous **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(dried at 75°/0.5 mm Hg for 15 h) in 200 ml of anhydrous CH_2Cl_2 in a dried 5 l three-necked flask protected by drying tubes was flushed well with dry nitrogen and cooled in an ice bath. Trifluoroacetic anhydride (90 g (0.43 mol) freshly distilled from P_2O_5) was added and the mixture stirred for 2 h while the temperature was allowed to rise to 15°. An aspirator with a drying tube in the line was attached and the cooling bath was removed. The mixture was stirred *in vacuo* at room temperature until a white solid foam remained and then a mechanical oil pump (1 mm Hg) was attached for 20 min. This product (**3**) migrated with $R_F \sim 0.42$ (t.l.c. Eastman silica gel No. 6060; $ClCH_2CH_2Cl$–acetone 10:7; **2**, $R_F \sim 0.03$). The ^1H n.m.r. spectrum of **3** in DMSO-d_6 had peaks at δ 2.6–3.3 (m, 2, $H_{2',2''}$), 4.65 (m, 3, $H_{4'}$, $H_{5',5''}$), 5.80 (m, 1, $H_{3'}$), 6.40 ("t", $J_{H_1'-H_2',2''} = 7.0$ Hz, 1, $H_{1'}$), 8.00 and 8.30 (s and s, 1 and 1, H_2 and H_8). These positions correspond to downfield Δδ shifts of approximately 0.1, 0.6, 1.4, 0.8, and 1.0 p.p.m. for the 1′, 2′-2″, 3′, 4′, and 5′-5″ protons, respectively, compared to the resonance positions for 2′-deoxyinosine (**2**) in the same solvent. There was essentially no change in the heterocyclic 2 and 8 proton peak positions of **3** compared to **2** which confirmed that no reaction of the highly electronegative trifluoroacetyl groups with the hypoxanthine moiety of **3** had occurred. The ^{19}F n.m.r. spectrum of **3** had a doublet at δ 74.5 and a singlet at 75.8 (DMSO-d_6, $CFCl_3$ internal) of equal intensity, corresponding to the two trifluoroacetyl groups. The mass spectrum of **3** corresponded to published values (27). The flask was fitted with a dropping funnel, an efficient condenser, and a gas purging tube, and 1 l of dry CH_2Cl_2 was added. A solution of 32 ml (53 g, 0.45 mol) of freshly distilled $SOCl_2$ and 16 ml of DMF (distilled from P_2O_5 and stored over Linde 5A molecular sieves) in 400 ml of dry CH_2Cl_2 was added dropwise over a 2 h period while the reaction was maintained at gentle reflux in an oil bath at 55° and a steady stream of dry nitrogen was bubbled through the stirred solution. The reaction was allowed to proceed an additional 5 h under these conditions and the mixture was cooled. Filtration gave 0.38 g (0.003 mol, 7.5%) of hypoxanthine. The filtrate was slowly poured into an ice-cold solution of 60 g (0.71 mol) of $NaHCO_3$ in 1 l of H_2O with vigorous stirring. Stirring was continued for 15 min, the phases were separated, the aqueous layer was extracted with two 250 ml portions of CH_2Cl_2, and the combined organic phase was dried over Na_2SO_4. Drying agent was removed by filtration, washed with dry CH_2Cl_2, and the combined filtrate was evaporated. The resulting thin syrup was dissolved in 10 ml of cold MeOH and this solution was applied to a column (2.5 × 40 cm, 150 g) of neutral alumina packed in MeOH. The column was developed with MeOH. The first 50 ml contained no product and was discarded. The following 400 ml of eluate was combined and evaporated to give a white solid foam which was crystallized from EtOAc–MeOH (6:1) to give 8.77 g (81%) of **4**, m.p. 139–143°; $[\alpha]_D^{22}$ −12.7° (*c* 1, MeOH) u.v. max (H_2O) 264 nm (ε 10 400); n.m.r.[4] (D_2O) δ 6.64 (t, 1, $J_{H_1'-H_2',H_2''} =$ 6.7 Hz, H_1'), 8.76 and 8.84 (s and s, 1 and 1, H_2 and H_8); lit. m.p. 142–145°, $[\alpha]_D^{26}$ −11.0 ± 0.5° (MeOH) (9); m.p. 144–145°, $[\alpha]_D^{25}$ −10.8° (*c* 1.04, MeOH) (10).

Anal. Calcd. for $C_{10}H_{11}ClN_4O_3$: C, 44.37; H, 4.09; Cl, 13.10; N, 20.70. Found: C, 44.44; H, 3.83; Cl, 13.05; N, 20.50.

9-(2-Deoxy-β-D-erythro-pentofuranosyl)purine-6-thione [6-Mercaptopurine 2′-deoxyribofuranoside] (5)

Hydrogen sulfide was slowly bubbled for 1 h through an ice-cold solution prepared by adding 0.12 g (0.005 mol) of sodium to 15 ml of anhydrous MeOH. A solution of 0.54 g (0.002 mol) of **4** in 15 ml of MeOH was then added, the ice-bath removed, and the solution stirred at room temperature while maintaining slow introduction of H_2S. Crystallization of product from the reaction solution began after about 1 h. After 4 h, H_2S introduction was terminated and the flask was stoppered and allowed to stand for 18 h. The resulting product was collected by filtration and recrystallized from 40 ml of MeOH–H_2O (3:2) to give 0.46 g (86%) of **5**, m.p. 184–186°; $[\alpha]_D^{22}$ −22.5° (*c* 1, 0.1 *N* NaOH), −14.0° (*c* 1, 1.0 *N* NaOH); u.v. max (0.1 *N* HCl) 324; 224 nm (ε 20 900; 9700) (0.1 *N* NaOH) 311; 231 nm (ε 20 700; 14 500); n.m.r.[4] (DMSO-d_6) δ 6.32 (t, 1, $J_{H_1'-H_2',H_2''} = 7.0$ Hz, $H_{1'}$), 8.20 and 8.50 (s and s, 1 and 1, H_2 and H_8); lit. m.p. 180–185° (9), 193–197° (9), 180–181° (14); $[\alpha]_D^{26}$ −23.5 ± 1° (1 *M* NaOH) (9), $[\alpha]_D^{22}$ −13.6° (1.0 *N* NaOH) (14).

Anal. Calcd. for $C_{10}H_{12}N_4O_3S$: C, 44.78; H, 4.51; N, 20.89; S, 11.93. Found: C, 44.55; H, 4.43; N, 20.95; S, 12.21.

6-S-(p-Nitrobenzyl)thio-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine (6)

Method A

A solution of 0.86 g (0.004 mol) of *p*-nitrobenzyl bromide and 0.30 g (0.004 mol) of thiourea in 20 ml of absolute EtOH was stirred at room temperature for 1 h. A solution of 1.08 g (0.004 mol) of **4** in 30 ml of absolute EtOH was then added and the combined reaction was purged well with dry nitrogen. A solution of 0.45 g (0.008 mol) of KOH in 20 ml of absolute EtOH was added dropwise over a period of 30 min while stirring and slow nitrogen purging was continued. The resulting mixture was then refluxed for 3 h on a steam-bath and allowed to stand under nitrogen at room temperature for 15 h. H_2O (150 ml) was added and the mixture was filtered. The filter cake was washed with two 25 ml portions of H_2O and then recrystallized from 500 ml of MeOH–H_2O (4:1) to give 1.1 g of white crystals. This material was composed of 6 plus a minor impurity migrating about 20% faster on t.l.c. (upper phase of EtOAc–*n*-PrOH–H_2O 4:1:2, silica gel). It was dissolved in 200 ml of hot 1,2-dimethoxyethane (glyme) and 10 g of silica gel was added. This mixture was evaporated to dryness and the resulting impregnated powder was added to the top of a column (1.5 × 60 cm, 60 g) of dry-packed silica gel. The column was developed with 5% MeOH in $CHCl_3$ and 20 ml fractions were collected. T.l.c. homogeneous fractions were combined and evaporated to give a white solid which was crystallized from 400 ml of MeOH–H_2O (7:1) to afford 0.81 g (50%) of **6**, m.p. 174–176°; $[\alpha]_D^{22}$ −19.5° (*c* 1, DMF); u.v. max (MeOH) 284 nm (ε 31 300), Sh 290 nm (ε 30 400); n.m.r.[4] (DMSO-d_6) δ 4.83 (s, 2, —SCH_2—), 6.52 (t, 1, $J_{H_1'-H_2',H_2''} =$ 7.0 Hz, H_1'), 7.6–8.4 (A_2B_2 m, 4, *phenyl H's*) 8.76 and 8.80 (s and s, 1 and 1, H_2 and H_8).

[4]The sugar moiety of all these 2′-deoxynucleosides gives rise to a similar n.m.r. pattern: δ ~2.1–3.1 (br m, 2, $H_{2'},H_{2''}$), ~3.7 (m, 2, $H_{5'},H_{5''}$), ~4.0 (m, 1, $H_{4'}$), ~4.5 (m, 1, $H_{3'}$). For actual n.m.r. spectra see ref. 10.

Anal. Calcd. for $C_{17}H_{17}N_5O_5S$: C, 50.62; H, 4.25; N, 17.36; S, 7.95. Found: C, 50.76; H, 4.24; N, 17.14; S, 8.25.

Method B

To a stirred suspension of 0.28 g (0.002 mol) of anhydrous potassium carbonate and 0.27 g (0.001 mol) of **5** in 10 ml of DMF (distilled from P_2O_5 and stored over Linde 5A molecular sieves) was added a solution of 0.22 g (0.001 mol) of *p*-nitrobenzyl bromide in 5 ml of dry glyme dropwise over a period of 5 min. The resulting mixture was stirred for 2 h at room temperature and filtered. The pink filtrate was evaporated to a thin syrup which was coevaporated with two 10 ml portions of xylene. The resulting white solid was crystallized from MeOH to give 0.35 g (87%) of **6**, m.p. 173–176°. A 1:1 mixture with product from method A had m.p. 174–176° and spectral properties and t.l.c. behavior of the samples were identical.

6-Methylthio-9-(2-deoxy-β-D-erythro-pentofuranosyl)-purine (7)

To an ice-cold solution prepared by adding 1 ml (0.86 g, 0.018 mol) of methanethiol to a solution of 0.14 g (0.006 mol) of sodium metal in 20 ml of absolute EtOH was added a solution of 0.54 g (0.002 mol) of **4** in 15 ml of absolute EtOH. The resulting mixture was stirred for 90 min (the ice-bath was removed after 30 min) and then filtered. The filtrate was evaporated to 20 ml and 20 ml of EtOAc was added. This mixture was evaporated to 10 ml and 30 ml of EtOAc was added. The mixture was briefly cooled at −15° and filtered. The filtrate was evaporated and the resulting solid was crystallized from MeOH–EtOAc (1:1) to afford 0.51 g (90%) of **7**, m.p. 157–158° (lit. (14) m.p. 155–156°); $[\alpha]_D^{22}$ −16.3° (*c* 1, H_2O); u.v. max (H_2O) 282 nm (ε 22 400), Sh 290 nm (ε 20 700); n.m.r.[4] (D_2O) δ 2.50 (s, 3, $-SCH_3$), 6.40 (t, 1, $J_{H_1'-H_2',H_2''}$ = 6.7 Hz, H_1'), 8.25 and 8.40 (s and s, 1 and 1, H_2 and H_8).

Anal. Calcd. for $C_{11}H_{14}N_4O_3S$: C, 46.81; H, 5.00; N, 19.85; S, 11.34. Found: C, 46.62; H, 5.07; N, 20.08; S, 11.05.

9-(2-Deoxy-β-D-erythro-pentofuranosyl)purin-6-yltrimethylammonium Chloride (8)

To a solution of 1.0 g (0.0037 mol) of **4** in 250 ml of dry 1,2-dimethoxyethane (glyme) was added 10 ml (6.1 g, 0.10 mol) of trimethylamine and the mixture was stirred at room temperature for 30 min while protected from moisture by a drying tube. The white solid product was collected by filtration and the filter cake immediately washed with 40 ml of anhydrous ethyl ether and transferred to a vacuum desiccator. The dried salt, **8**, 1.14 g (93%), had m.p. 154–155°; u.v. max (MeOH) 266 nm (ε 9000); n.m.r.[4] (DMSO-d_6) δ 3.90 (s, 9, $-N(CH_3)_3$), 6.58 (t, 1, $J_{H_1'-H_2',H_2''}$ = 6.5 Hz, H_1'), 9.06 and 9.13 (s and s, 1 and 1, H_2 and H_8).

Anal. Calcd. for $C_{13}H_{20}ClN_5O_3$: C, 47.34; H, 6.11; Cl, 10.75; N, 21.24. Found: C, 47.13; H, 6.07; Cl, 10.87; N, 20.81.

6-Fluoro-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine (9)

To a stirred suspension of 1.75 g (0.03 mol) of KF (dried at 170° for 15 h) in 20 ml of dry DMF maintained at 40° in an oil bath was added 1.0 g (0.003 mol) of **8**. The reaction was allowed to proceed for 40 min, cooled, and filtered. The filtrate was added to 6 g of neutral silica gel and the slurry was evaporated (25°, mechanical oil pump). The resulting impregnated powder was added to the top of a column (1.5 × 40 cm, 30 g) of dry-packed neutral silica gel. The column was developed with EtOAc and after a 20 ml forerun, the following 900 ml of eluate was combined and evaporated to 50 ml. This was allowed to stand at −15° for 20 h and 0.51 g (66%) of crystalline **9** was collected by filtration. This product, **9**, had m.p. 148–150°; $[\alpha]_D^{22}$ −20.5° (*c* 1, H_2O); u.v. max (H_2O) 249 nm (ε 7000); n.m.r.[4] (DMSO-d_6) δ 6.53 (t, 1, $J_{H_1'-H_2',H_2''}$ = 6.7 Hz, H_1'), 8.70 and 8.87 (s and s, 1 and 1, H_2 and H_8); ^{19}F n.m.r. (DMSO-d_6, $CFCl_3$ internal reference) δ 72.5 (s, 1, 6-*F*).

Anal. Calcd. for $C_{10}H_{11}FN_4O_3$: C, 47.24; H, 4.36; F, 7.47; N, 22.04 Found: C, 47.30; H, 4.44; F, 7.67; N, 21.82.

6-N-Benzylamino-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine [N⁶-Benzyl-2′-deoxyadenosine] (10)

To 3 ml of benzylamine was added 0.27 g (0.001 mol) of **4** and the mixture was stirred for 1 h at room temperature. Et_2O (20 ml) was added and the resulting mixture was filtered. The solid was discarded and the filtrate was evaporated. The residue was treated with 20 ml of Et_2O, filtered, and the filtrate was evaporated. A mechanical oil pump was attached and most of the remaining benzylamine was evaporated *in vacuo*. The resulting thin syrup was triturated with Et_2O while cooling in ice to give crystalline **10**, m.p. 167–174°, in quantitative yield. This material was recrystallized from MeOH to afford 0.32 g (93%) of **10**, m.p. 174–176°; $[\alpha]_D^{22}$ −20.4° (*c* 1, MeOH); u.v. max (MeOH) 269 nm (ε 22 600); n.m.r.[4] (DMSO-d_6) δ 4.75 (br d, 2, NH—CH_2—Ph), 6.36 (t, 1, $J_{H_1'-H_2',H_2''}$ = 7.0 Hz, H_1'), 7.1–7.4 (m, 5, *Ph*), 8.20 and 8.34 (s and s, 1 and 1, H_2 and H_8). This product was identical to **10** prepared by an alternative procedure (20).

Anal. Calcd. for $C_{17}H_{19}N_5O_3$: C, 59.81; H, 5.61; N, 20.52. Found: C, 59.56; H, 5.58; N, 20.37.

6-N-Hydroxylamino-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine [6-Hydroxylaminopurine 2′-Deoxyriboside] (11)

To a hot solution of 1.51 g (0.027 mol) of KOH in 60 ml of absolute EtOH was added a hot solution of 1.67 g (0.024 mol) of hydroxylamine hydrochloride in 75 ml of absolute EtOH. This was allowed to cool, finally in an ice-bath, and was filtered. To the clear filtrate was added 0.65 g (0.0024 mol) of **4** and the resulting solution was refluxed for 3 h by heating in an oil bath at 100°. The reflux condenser was removed and the solution concentrated to about 50 ml. A solution of 0.15 g (0.0027 mol) of KOH in 15 ml of absolute EtOH was added and the volume was again reduced to about 50 ml by open distillation. The mixture was cooled, filtered, and the filtrate evaporated to a white gum. This material was dissolved in 30 ml of hot absolute EtOH, the solution was treated with 100 ml of hot EtOAc, and allowed to stand for 5 days at −15°. Crystalline **11** (0.40 g) was collected by filtration and another 0.16 g of product was obtained from the mother liquor by concentration and cooling. Total yield of **11**, 0.56 g (87%), m.p. 139–140°, softening at 110–115° and 130–135°; $[\alpha]_D^{22}$ −21.8° (*c* 1, MeOH);

u.v. max (MeOH) 266 nm (ε 12 500); n.m.r.[4] (DMSO-d_6) δ 6.29 (t, 1, $J_{H_1'-H_2',H_2''}$ = 7.0 Hz, H_1'), 7.88 and 8.18 (s and s, 1 and 1, H_2 and H_8), 8.2–10.4 (br s, 2, 6-*NHOH*).

Anal. Calcd. for $C_{10}H_{13}N_5O_4$: C, 44.94; H, 4.90; N, 26.21. Found: C, 45.08; H, 5.19; N, 25.57.

6-Amino-9-(2-deoxy-β-D-erythro-pentofuranosyl)purine [2′-Deoxyadenosine] (1)

A solution of 0.27 g (0.001 mol) of **4** in about 2 ml of liquid ammonia was sealed in a stainless steel pressure reactor and allowed to stand for 20 h at room temperature. The ammonia was allowed to evaporate and a solution of 0.04 g (0.001 mol) of NaOH in 20 ml of H_2O was added. T.l.c. showed only one product with migration identical to naturally occurring 2′-deoxyadenosine. The solution was evaporated, 20 ml of absolute EtOH was added, and the resulting mixture was filtered. The filtrate was evaporated and this process was repeated using 10 ml of warm absolute EtOH to remove NaCl. Recrystallization of the resulting solid from EtOH gave 0.24 g (96%) of **1**, m.p. 189–190°; $[\alpha]_D^{22}$ −24.5° (*c* 1, H_2O); u.v. max (H_2O) 259 nm (ε 14 000). These constants and other physical data compare well with those of naturally occurring 2′-deoxyadenosine.

Anal. Calcd. for $C_{10}H_{13}N_5O_3$: C, 47.80; H, 5.21; N, 27.87. Found: C, 47.58; H, 5.32; N, 27.96.

Nuclear Magnetic Resonance Experiments on Acetals. 43. Reversal of Previous Conformational Assignment in 5-Fluoromethylated-5′-Me-1,3-dioxanes

M. ANTEUNIS AND F. BORREMANS

State University of Gent, Department of Organic Chemistry, Laboratory for NMR Spectroscopy, Krijgslaan, 271 (S.4B) Gent; Belgium B-9000

Received September 13, 1972[1]

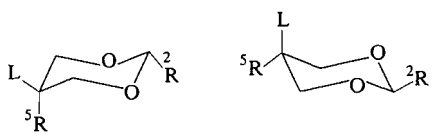
Additional n.m.r. investigations on 5-fluoromethylated-5′-Me-1,3-dioxanes have made it necessary for us to reverse the spectral assignments which were forwarded recently (1) in this journal. Thus, the 5-CF_2H group prefers the *axial* position to the extent of *ca.* 900 cal/mol, whereas the 5-CFH_2 group displays a similar preference for the axial position to the extent of *ca.* 200 cal/mol. An explanation for these unexpected results is advanced. Final structural assignments have been made possible by homo- and heteronuclear double resonance experiments and by ASIS-studies. The observed relative shifts for 5-CF_nH_{3-n} and 5-CH_3 signals are shown to be normal (*e.g.* δ(5e) < δ(5a)). Also, the previously reported ^4J(F,H) long range couplings follow a classical M-path.

Une étude r.m.n. (assistée d'irridiations multiples) sur les CHF_2-5 CH_3-5′ CH_3-2 dioxannes-1,3 dans C_6D_6 a démontré que l'assignation de configurations proposée récemment pour ces dérivés est erronnée. Il en découle qu'en faite les groupements CF_nH_{3-n}-5 (n = 1,2) préfèrent vis à vis de CH_3-5 la position axiale (*ca.* 900 cal/mol pour CF_2H-5 et *ca.* 200 cal/mol pour CFH_2-5). Ceci est inattendu en vue des moments dipolaires macroscopiques. Une explication est avancée. Comme pour tout autre dioxanne on trouve que δ(5e) < δ(5a).

Can. J. Chem., 51, 3170 (1973)

We wish to focus attention upon the pitfall we encountered with respect to the conformational aspects of 5-CF_nH_{3-n}-1,3-dioxanes,[2] published recently (1) in this journal.

We attributed the n.m.r. spectrum shown in Fig. 1 (ref. 1) to a,e-5-difluoromethyl-5′-Me-2-Me-1,3-dioxane, and we assigned the n.m.r. spectrum shown in Fig. 2 (ref. 1) to the corresponding e,a-isomer. Consequently, the conformational equilibrium **1***b* ⇌ **2***b* was believed to favor the conformer with the equatorial CF_2H group. The same situation was also accepted for the case of 5-fluoromethyl-1,3-dioxane (**1***a* ⇌ **2***a*). These conclusions seemed logical considering the group dipole moments in the system. Moreover, they were strengthened by the observation of a small equilibrium shift when switching from CS_2 to $CHFCl_2$ as solvent.



1 **2**

a L = CFH_2; ^{5}R = Me; ^{2}R = H
b L = CF_2H; ^{5}R = Me; ^{2}R = H

We had at that time tacitly accepted (see tables and figures in ref. 1) that the chemical shift (δ) values in these 5,5′-geminally disubstituted derivatives would fall in the order δ(Me-5e) > δ(Me-5a), δ(CF_2H-5e) > δ(CF_2H-5a), and δ(CFH_2-5e) > δ(CFH_2-5a). This situation would then be of opposite trend to that observed in mono-alkyl- and 5,5′-*gem*-dialkyl substituted dioxanes (3). Although we noted this discrepancy, quantitative treatment was precluded by the highly polar, nonspherical nature of the CH_2X or CHX_2 groups, each of which might present nonidentical rotameric distributions in the 5-axial *vs.* 5-equatorial positions, respectively.

We have now obtained convincing evidence that our original structure attributions are incorrect. Thus, the n.m.r. spectrum shown in Fig. 2 (ref. 1), corresponds to *r*-2,*trans*-5-dimethyl-*cis*-5′-CF_2H-1,3-dioxane (**3**), the most stable isomer with lowest GC retention time, while the n.m.r. spectrum displayed in Fig. 1 (1) belongs to *r*-2,*cis*-5-dimethyl-*trans*-5′-CF_2H-1,3-dioxane (**4**). This conclusion follows from the following new evidence.

Table 1. ^{1}H n.m.r. shifts (in p.p.m.) in C_6D_6 of compounds **3** and **4**

	H-2	H-4,6e	H-4,6a	Me-5	Me-2	CHF_2
3	4.25	3.8	2.9	0.4	1.22	6.38
4	4.18	3.48	3.35	1.19	1.25	4.73

TABLE 2. ASIS for 2-Me-5-Me-5′-CHF_2-1,3-dioxanes in p.p.m.

$\Delta\delta^{CS_2}_{C_6C_6}$	5-CH_3	2-CH_3	H-4,6a	H-4,6e	H-2	CHF_2
3	0.30	0.01	0.38	0.05	0.25	−0.25
4	0.05	−0.02	0.25	0.12	0.25	0.58

(*a*) Double and triple irradiations in C_6D_6 solutions clearly demonstrate the existence of a nonzero $^4J(CHF_2, H\text{-}4,6a)$ for **3** (3.7 Hz), whereas the corresponding long range $^4J(F,H)$ is *not* observed in **4**. The magnitude of this observed long range coupling requires that the CHF_2 substituent occupy the axial position in 3. Additionally, in C_6D_6 solution the signals due to H-4,6 and due to Me-2 and Me-5 in **4** are found to be well differentiated (Table 1), and one can observe a long range coupling ^4J(Me-5, H-4,6a) in **4** (~0.7 Hz) but *not* in **3**. This corresponds to the classical planar zig-zag patterns (M-mode) observed earlier (4) in these derivatives. The occurrence of this long range coupling in **4** requires that the Me-5 group be axial in this compound. These observations alone unequivocally permit our assigning the n.m.r. spectra of compounds **3** and **4**.[3]

(*b*) ASIS values for **3** and **4** are gathered in Table 2. ASIS data obtained by Anderson (5) on 5,5′-diMe-2-alkyl-1,3-dioxanes reveal the 5-equatorial position to be particularly shielded (0.3 to 0.4 p.p.m. with respect to the 5-axial position), while H-4,6 axial is shielded 0.1 to 0.15 p.p.m. more than is H-4,6 equatorial. Thus, the ASIS (Table 2) on 5-Me and 5-CHF_2, (+0.3 and +0.58 p.p.m. for an equatorial position in **3** and **4** respectively) and the pronounced positive ASIS values for H-4,6 axial, also conform to the assignments of H-4,6 as pointed out under (*a*), and are strongly indicative and consistent with the newly proposed assignments of structures **3** and **4**.

(*c*) The axial 5-Me in **4** and the axial 5-CF_2H signals in **3** appear at lower field relative to the corresponding equatorial signals in **3** and **4** respectively, in agreement with what is observed in all other 5,5′-disubstituted-1,3-dioxanes (3).

Heteronuclear ^{19}F–^1H decoupling on both **3** and **4** discloses a more pronounced long range interaction 5-CF_2H/5-CH_3 in **4** (~1 Hz) than in **3** (<0.5 Hz). This may be the result of a preferred orientation in the latter compound for the CF_2H group, as depicted in structure **3**, which excludes a classical M-path.[4] The rotamers pointing the C—F bond over the ring seemingly are disfavored, presumably for electrostatic and steric reasons.

Consequently, as a result of the new reversed assignment, the estimations for the conformational preferences of CF_2H and CFH_2 groups (as deduced from naïve additive contributions for geminal substitution) now become ΔG_{200} (CFH_2) ≃ +200 cal/mol (in $CHFCl_2$) $\Delta G_{300}(CF_2H)$ ≃ +980 cal/mol (in CS_2), and $\Delta G_{300}(CF_2H)$ ≃ +800 cal/mol (in $CHFCl_2$), respectively. These results clearly illustrate the unexpected behavior of CH_2X groups, in general, *for which the axial position is preferred.* This situation is paralleled by the behavior of the 5-Me-5′-CH_2OH-1,3-dioxane (7 and references therein). Typically, the 5-CH_2OMe group has almost no conformational preference, as $\Delta G°$(CH_2OMe-5) was found to be close to zero

[3]Similar proof by multiple irradiation n.m.r. experiments could not be obtained in CS_2 for the CF_2H derivative **2***h* in ref. 1 (now structure **4**), since the 5-Me and 2-Me signals overlap and the 4,6 protons are isochronous. This has been, in fact, the origin of our entanglement.

[4]It should be pointed out that the conformation pictured in **3** might in principle also show a long range 5-CF_2H/5-CH_3 interaction, to be compared with the syn-axial $^4J(F,H)$ interactions observed in some but not all fluorinated hexopyranosyl fluorides (6). Obviously, ^4J couplings obtained in these derivatives "indicate that some caution may be necessary before such syn–axial couplings are used for configurational assignments" (6).

(8). Our present results disclose an unexpected behavior for which no satisfactory explanation has been offered previously.[5] We believe that the phenomenon may find its origin in the fact that the electronegative substituent causes an increase in % s character of the carbon atom in the CH_2X and CHX_2 moieties, with the result that successive polarization of the hydrogen atoms in the C—H bonds involved confers a high degree of positive character upon them. The hydrogen atom which is situated above the dioxane ring then experiences an attractive force from (the axial p orbitals of) the ring oxygen atoms. Thus, a microscopic, highly localized dipole–dipole interaction, and *not* an overall molecular dipole, must be considered to understand the conformational behavior of multi-site polar molecules.[6] It is interesting to observe, however, that hetero atoms directly bonded on C-5 in 1,3-dioxanes do follow the general trend expected from separated dipole–vector considerations (with the possible exception of F-5 (12) and OH-5 (13), for which in the latter hydrogen bonding effects might be anticipated (13)). Work on the conformational behavior of other 5-Me-5′-CH_2X-1,3-dioxanes (X = Cl, Br, I) is in progress, and preliminary results of ^1H n.m.r. measurements at $T < T_c$ do indicate a similar axial preference for the CH_2X group. We plan to report the results of these shortly.

The Ministry of Scientific Programmation is thanked for the funds allowing the acquisition of a 300 MHz machine. The National Fonds voor Wetenschappelijk Onderzoek (N.F.W.O.) has provided valuable financial support of the research program.

[5]Recently Eliel *et al.* (private communication, September 15 1972; see ref. 9) have found axial preferences for positively charged 5-substituents (*e.g.* $MeS^+—O^-$ and $MeSO_2$). This was considered to result from an electrostatic attraction involving the syn-axial O-p lobes and S^+.

[6]Very recently, after the first draft of our paper was submitted for publication, Abraham and Rossetti (10) found that the anomalous stabilization of the diaxial form of *trans*-1,4-dichlorocyclohexane may be explained in terms of syn–axial H:Cl interactions as the result of the enhanced acidities of the H atoms involved. Such inductive polarization, caused by the presence of the second halogen atom, was found by CNDO/2 calculation to even be important for the geminal H atom. Thus, our picture of attractive forces existing between an axial CF_nH_{3-n} and the oxygen p-lobes may indeed substantially favor this conformer relative to the equatorial form. Furthermore, such attractions would be impossible in the related 4-fluoromethylated-6-Me-1,3-dioxanes, where indeed it was found (11) that the behavior of such systems more or less follows the predictions made on the basis of simple dipole–dipole explanations.

Thermal Isomerization of α,β-Epoxyketones

PRABHAKER G. KHAZANIE AND EDWARD LEE-RUFF
Department of Chemistry, York University, Downsview 463, *Ontario*

Received March 8, 1973

Pyrolysis of α,β-epoxyketones at 260° resulted in the formation of β-diketones derived from a 1,2 shift of a β hydrogen or alkyl substituent to the α carbon. Hydrogen migrates in preference to methyl in the case of 2-ethylidenecyclopentanone and 2-ethylidenecyclohexanone oxides. Thermal conversion of 2-cyclopentylidenecyclopentanone oxide to the spiro β-diketone **4** was quantitative.

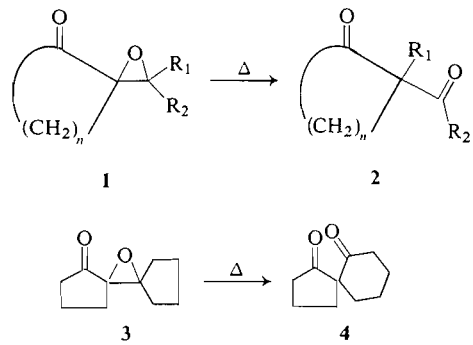
La pyrolyse d'α,β-époxycétones à 260° a conduit à la formation de β-dicétones via la migration 1,2 d'un hydrogène β ou d'un substituant alcoyle vers le carbone α. Dans le cas des oxydes d'éthylidène-2 cyclopentanone et d'éthylidène-2 cyclohexanone, le groupe hydrogène migre de préférence au groupe méthyle. La conversion thermique de l'oxyde de cyclopentylidène-2 cyclopentanone en β-dicétone spiro **4** a été quantitative. [Traduit par le journal]

Can. J. Chem., **51**, 3173 (1973)

Photochemical transformations of α,β-epoxyketones are known to give β-diketones in low yields (1–3). Johnson and co-workers (2) have shown that irradiation of ether solutions of α or β pulegone oxides resulted in their interconversion and also in the formation of stereoisomeric 2-acetyl-2,5-dimethylcyclohexanones. A similar mixture was obtained on pyrolysis of either the α- or β-pulegone oxide. It was suspected that the formation of the photoproducts was the result of decomposition of vibrationally excited α,β-pulegone oxide. In order to establish the generality of such thermal transformations of α,β-epoxyketones we undertook a study of the thermal chemistry of various spiro α,β-epoxyketones. Furthermore, since it was reported (1) that 2-cyclopentylidenecyclopentanone oxide upon irradiation resulted in the formation of spiro[4·5]decane-1,6-dione in 25% yield, it was of interest to us to see if the thermolysis of 2-cycloalkylidenecycloalkanone oxides would undergo similar transformations to give spiro β-diketones. These could serve as important synthetic intermediates in the synthesis of natural products possessing the spirobicyclic ring system.

Results and Discussion

The syntheses of epoxyketones **1***b–d* and **3** were accomplished by direct treatment of the corresponding 2-alkylidenecycloalkanones with either *m*-chloroperbenzoic acid or hydrogen peroxide. Attempted synthesis of **1***a* by treatment of 2-ethylidenecyclopentanone with hydrogen peroxide or *m*-chloroperbenzoic acid was unsuccessful, with only trace amounts of the



a $R_1 = H$, $R_2 = CH_3$, $n = 3$
b $R_1 = R_2 = CH_3$, $n = 3$
c $R_1 = H$, $R_2 = CH_3$, $n = 4$
d $R_1 = R_2 = CH3$, $n = 4$

SCHEME 1

epoxide detectable. The synthesis of epoxide **1***a* was accomplished by epoxidation of the 2-ethylidenecyclopentanol and subsequent oxidation of the epoxy-alcohol with chromium trioxide in acetic acid. The structures of **1***a–d* and **3** (Scheme 1) were established from spectral data and comparison with data reported in literature. The stereochemistry of **1***a* and **1***c* could not be ascertained; however, the n.m.r. spectra of these indicated the presence of one stereoisomer.

Samples (50–250 mg) of pure epoxyketone were pyrolyzed in sealed pyrex tubes at 260° for 65–80 min. The reactants were degassed by six freeze–thaw cycles and evacuated to 10^{-3} mm pressure. The products were analyzed and collected by v.p.c. In all cases only the major product was identified (Table 1). The structures of

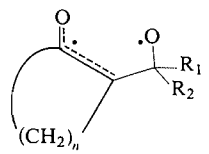
1*c*	80	79	3
1*d*	80	59	8
3	65	100	0

pyrolysis products **2***a–d* and **4** were established from their spectral data as well as independent synthesis by known routes. The major products in all cases are the result of an alkyl or hydrogen shift from the β to α carbon with initial bond fission occurring between the α-carbon–oxygen bond. Such a process would give rise to a stable delocalized diradical of the type



The preferred migration of hydrogen to methyl in the case of epoxyketones **1***a* and *c* is analogous to the reported greater migratory aptitude of hydrogen compared to an alkyl group in carbonium ion rearrangements (4). The quantitative thermal conversion of epoxyketone **3** to **4** suggests that its reported photochemical conversion in low yields proceeds by vibrationally excited levels of the electronic ground state of the epoxyketone. The high yield in the thermal conversion of **3** to **4** suggests that spiro β-diketones of similar type can be obtained by pyrolysis of the appropriate 2-cycloalkylidenecycloalkanone oxides. We are currently investigating the generality of such transformations as a synthetic route in the preparation of spirobicyclic β-diketones.

Experimental

Melting points and boiling points were uncorrected. The i.r. spectra were recorded with a Unicam SP 1000 instrument. The n.m.r. spectra were measured with a Varian A-60 and a Varian HA-100 instrument. Samples were dissolved in CCl_4 and $CDCl_3$ solvents using tetramethylsilane as the internal standard. V.p.c. was performed on a Varian Aerograph Series 1700 instrument using the following columns: (*a*) 3% SE-30 on Varaport 30 (0.25 in., 5 ft 4 in.); (*b*) 10% FFAP on chromosorb P (0.25 in., 6 ft); (*c*) 6% SE-30 + 4% QF 1 on chromosorb W AW, DMCS treated (0.25 in., 6 ft). Microanalyses were performed by Gygli Microanalytical laboratory, Toronto, Ontario.

Pyrolysis of Epoxides (General Procedure)

The pyrolysis of epoxides was carried out in a steel oven at 260°. The temperature gauge of the oven was calibrated using a thermocouple. Samples were placed in pyrex tubes, 1 cm diameter, 1 mm thick glass, and 6–7 cm long. The samples were degassed by five or six freeze–pump–thaw cycles at 10^{-3} mm pressure, sealed, wrapped in an aluminum foil, and heated for varying lengths of time. The samples were then cooled, opened, and the pyrolytic mixtures were analyzed by v.p.c., i.r., and n.m.r. spectroscopy.

Lithium Aluminum Hydride Reduction of 2-Ethylidenecyclopentanone

2-Ethylidenecyclopentanone (5) (11 g, 0.1 mol) dissolved in absolute ether (50 ml) was added dropwise with stirring to a slurry of lithium aluminum hydride (1.6 g, 0.04 mol) in ether (50 ml) at room temperature. Upon completion of addition, the reaction mixture was refluxed at 40° for an additional hour. Excess hydride was then decomposed by addition of moistened ether, and 10% Na–K-tartarate. The organic layer was separated, filtered, washed with brine, and dried over anhydrous sodium sulfate. Removal of ether gave alcohol, 2-ethylidenecyclopentanol (10.3 g, 92%). The alcohol was obtained pure by distillation, b.p. 74°/15 mm: i.r. 3420 cm^{-1} (OH stretch); n.m.r. δ 5.3–5.82 (1H, m) 4.75 (1H, disappeared with D_2O), 4.28 (1H), 1.45–2.5 (9H, m).

2-Ethylidenecyclopentanol Oxide

To an ice-cold solution of 72% *m*-Cl-perbenzoic acid (16.4 g) in chloroform (175 ml) was added 8.5 g of 2-ethylidenecyclopentanol in 20 ml chloroform. The reaction mixture was kept at 0° for 2 h and then at room temperature for 6 h. It was then washed with 10% sodium sulfate, 5% sodium carbonate, and brine, and dried over anhydrous sodium sulfate. Removal of chloroform under reduced pressure gave a thick liquid which upon distillation afforded pure epoxy alcohol (6.3 g): i.r. 3475 cm^{-1} (OH stretch), 862, 910, 1100, 1250 cm^{-1}; n.m.r. δ 3.55–3.9 (1H, m), 2.8–3.2 (1H, q), 2.25 (OH, disappeared with D_2O), 1.45–2.05 (6H, m), 1.23 (3H, d, J = 5 Hz).

2-Ethylidenecyclopentanone Oxide (1a)

Chrominum trioxide (1.1 g) was dissolved in 15 ml glacial acetic acid and frozen in an ice bath. To this was added 1.1 g of above epoxy alcohol in 5 ml acetic acid. The mixture was allowed to thaw. After complete thawing the reaction mixture was stirred for 5 min. The solution gave a greenish color and the temperature increased. The flask was again cooled in an ice bath for 2 min, allowed to thaw, and stirred for an additional 20 min. The mixture was transferred to a 250 ml Erlenmeyer flask and 150 ml of diethyl ether was added. A precipitate formed and was filtered off. The filtrate was neutralized with saturated sodium bicarbonate solution, washed with brine, and dried over anhydrous sodium sulfate. Removal of ether under reduced pressure gave a crude mixture (0.5 g),

which was purified by v.p.c. (6% SE-30 + 4% QF 1 column at 100 °C; rate of He flow, 46 cc/min: i.r. (CCl_4) 1752 cm^{-1} (C=O stretch), 880, 1060, 1255, 1290, 1420 cm^{-1}; n.m.r. δ 3–3.3 (1H, q), 1.28 (3H, d, J = 5Hz), 1.95–2.38 (6H, m); M^+: *m/e* 126.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.68; H, 7.93. Found: C, 66.50; H, 8.01.

2-Isopropylidenecyclopentanone Oxide (1b)

To an ice-cold solution of 10.68 g of 72% *m*-Cl-perbenzoic acid in 125 ml chloroform was added 6.2 g (0.05 mol) 2-isopropylidenecyclopentanone (6) in 20 ml chloroform. The reaction mixture was stirred between 0–5° for 8 h. The reaction mixture was then washed with 10% sodium sulfite, 5% sodium carbonate, brine, and dried over anhydrous magnesium sulfate. Removal of solvent under reduced pressure gave a mixture of two products (5.3 g). The mixture was distilled over a short path at 0.03 mm pressure to give 2.05 g of epoxide (30%): i.r. 1746 cm^{-1} (C=O stretch), 820, 930, 1030, 1250 cm^{-1}; n.m.r. δ 1.34 (6H, d, J = 2Hz), 1.85–2.4 (6H, m); u.v. max (EtOH) 209 mm (ε 2280); M^+: *m/e* 140.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.57; H, 8.57. Found: C, 68.49; H, 8.85.

2-Ethylidenecyclohexanone Oxide (1c)

A mixture of 2-ethylidenecyclohexanone (7) (7.44 g, 0.06 mol), methanol (60 ml), and 30% hydrogen peroxide (17.22 ml, 0.18 mol), in a 200 ml three-necked flask equipped with a stirrer, a dropping funnel, and a thermometer was cooled to 15–20°. A solution of 6 *N* sodium hydroxide (5.1 ml, 0.03 mol) was added dropwise with stirring over a period of 20 min. Stirring was continued for 4 h with the temperature being maintained at 25°. The reaction mixture was then poured into 150 ml brine and extracted with two 200-ml portions of ether. After the combined ether extracts were washed and dried, the solvent was removed under reduced pressure and the residual liquid analyzed by v.p.c. The crude product (7 g) which consisted principally of only one compound was distilled, b.p. 75°/0.5 mm, to give 4.5 g (58%) of pure **1***c*: i.r. 1720 cm^{-1} (C=O stretch), 790, 890, 990, 1275, 1410, 1450, cm^{-1}; n.m.r. δ 2.85–3.28 (1H, q), 1.25 (3H, d, J = 5Hz), 1.7–2.6 (8H, m); u.v. max (EtOH) 207 nm; (ε 600); M^+ *m/e* 140.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.57; H, 8.57. Found: C, 68.66; H, 8.54.

2-Isopropylidenecyclohexanone Oxide (1d)

(*A*). Using the method described for the preparation of 2-ethylidenecyclohexanone oxide, from 6.9 g (0.05 mol) of 2-isopropylidenecyclohexanone (8), 14.5 ml hydrogen peroxide (30%) and 4.1 ml of 6 *N* aqueous sodium hydroxide in 35 ml methanol was obtained 6.5 g crude product. The crude product was distilled over a short path at 0.03 mm to give 5.34 g of **1***d*: i.r. 1720 cm^{-1} (C=O stretch), 790, 890, 1120, 1235, 1275 cm^{-1}; n.m.r. δ 1.55–2.6 (8H, m), 1.12 (3H, s) 1.36 (3H, s); M^+: *m/e* 154.

(*B*) Using the procedure described for the preparation of 2-isopropylidenecyclopentanone oxide, from 2.76 g (0.02 mol) of 2-isopropylidenecyclohexanone and 4 g of 72% *m*-Cl-perbenzoic acid in 40 ml chloroform was obtained 1.9 g of **1***d*.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.13; H, 9.09. Found: C, 70.08; H, 9.30.

2-Cyclopentylidenecyclopentanone Oxide (3)

Using the method described for the preparation of 2-isopropylidenecyclopentanone oxide, from 6 g of 2-cyclopentylidenecyclopentanone (9) and 8.96 g of 72% *m*-Cl-perbenzoic acid in 120 ml chloroform was obtained 5.8 g of a crude mixture. This was chromatographed on 100 g silica gel, activity III–IV (50 × 3 cm) with 8:2 benzene – diethyl ether. The epoxide was then crystallized from *n*-hexane (39%), m.p. 39–40° (lit. (1) m.p. 38–40°): i.r. 1743, 1160, 960 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.6–1.4 (m); u.v. max (EtOH) 305 nm.

Pyrolysis of 2-Ethylidenecyclopentanone Oxide (1a)

The epoxide **1***a* (55 mg) was pyrolyzed at 260° and 10^{-3} mm pressure for 75 min. The pyrolyzed sample gave six peaks on v.p.c. (3% SE-30, 100°, He flow 44 cc/min). The major component **2***a* was collected by freezing the vapors in a U-shaped glass tube dipped in ice – salt water mixture. The structure of β-diketone was deduced from analytical and spectroscopic data as well as independent synthesis[1] (10): i.r. 1240, 1615, 1660, 1710, and 1740 cm^{-1}; n.m.r. (CCl_4) δ 1.85–2.65 (10H, m, containing sharp singlets at 1.92 and 2.23).

Pyrolysis of 2-Isopropylidenecyclopentanone Oxide (1b)

A sample of 150 mg of **1***b* was pyrolyzed as above for 80 min. The pyrolyzed sample gave eight peaks on v.p.c. (column *c*, 100°, gas flow 46 cc/min). The major compound was identified to be the diketone **2***b* by spectral data and independent synthesis (11): i.r. 1705, 1743 cm^{-1}; n.m.r. δ 1.3 (3H, 5), 1.5–2.75 (9H, m, with a sharp singlet at 2.12).

Pyrolysis of 2-Ethylidenecyclohexanone Oxide (1c)

The above procedure was followed. The pyrolyzed sample when analyzed on column a at 90° (He flow rate 42 cc/min) showed nine peaks. The major component (79%) was identified as β-diketone **2***c* by independent synthesis (11), and spectroscopic data: i.r. 1612, 1710 cm^{-1}; n.m.r. δ 1.6–2.5 (12H, m, with sharp singlet at 2.06).

Pyrolysis of 2-Isopropylidenecyclohexanone Oxide (1d)

The procedure used for the pyrolysis of **1***b* was followed. The major product (59%) was identified as β-diketone **2***d* by independent synthesis (11) and spectroscopic data: 1700 cm^{-1} (C=O stretch, broad); n.m.r. δ 1.17 (3H, s), 1.98 (3H, s), and 1.4–2.7 (8H, m).

Pyrolysis of 2-Cyclopentylidenecyclopentanone Oxide (3)

A sample of 250 mg of **3** was heated to 260° at 10^{-3} mm pressure for 65 min. V.p.c. analysis of the pyrolyzed sample showed a 100% yield of spiro β-diketone (4). The spectra of this β-diketone were identical to those of the compound obtained by photolysis (1) of 2-cyclopentylidenecyclopentanone oxide (3): u.v. max (EtOH) 287 nm; i.r. 1732, 1698 cm^{-1}; n.m.r. ($CDCl_3$) δ 2.9–1.1 (m).

The authors wish to acknowledge the support of the National Research Council of Canada by a grant in aid of this research.

Nuclear Magnetic Resonance Study of Hydrogen Bonding in 1,1,1-Trifluoro-2-hydroxy-4-alkanones

EBERHARD KIEHLMANN, B. C. MENON, AND NORA MCGILLIVRAY
Department of Chemistry, Simon Fraser University Burnaby 2, British Columbia

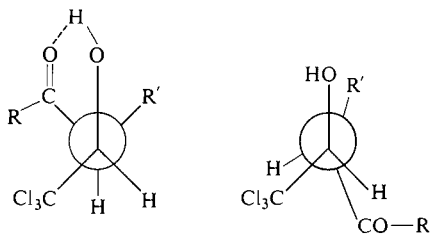
Received April 24, 1973

Addition of fluoral at the α-carbon of 3-pentanone, cyclohexanone, 4-methyl-2-pentanone, and acetone gives 1,1,1-trifluoro-2-hydroxy-3-methyl-4-hexanone (**1***a* and *b*, diastereomers), 2-(1-hydroxy-2,2,2-trifluoroethyl)cyclohexanone (**2***a* and *b*, diastereomers), 1,1,1-trifluoro-2-hydroxy-6-methyl-4-heptanone (**3**), and 1,1,1-trifluoro-2-hydroxy-4-pentanone (**4**), respectively. Hydrogen-bonding studies, based on proton and fluorine n.m.r. measurements, show strong intramolecular >C=O···H—O bonding with relatively weak intermolecular interactions in **1***a* and **2***a*, and intermolecular F···H—O bonding in **1***b*, **2***b*, **3**, and **4**.

L'addition de fluoral sur le carbone α de la pentanone-3, cyclohexanone,méthyl-4 pentanone-2 et acétone conduit au trifluoro-1,1,1 hydroxy-2 méthyl-3 hexanone-4 (**1***a* et **1***b*, diastéréoisomères), (hydroxy-1 trifluoroéthyl-2,2,2)-2 cyclohexanone (**2***a* et **2***b*, diastéréoisomères), trifluoro-1,1,1 hydroxy-2 méthyl-4 heptanone-2 (**3**) et trifluoro-1,1,1 hydroxy-2 pentanone (**4**) respectivement. Les études sur les liaisons hydrogène, effectuées par résonance magnétique nucléaire du proton et du fluor, montrent une liaison intramoléculaire >C=O···H—O forte et des interactions intermoléculaires relativement faibles pour **1***a* et **2***a*; et une liaison intermoléculaire F···H—O pour **1***b*, **2***b*, **3** et **4**. [Traduit par le journal]

Can. J. Chem., **51**, 3177 (1973)

In an earlier paper (1), we have characterized several diastereomeric pairs of 1,1,1-trichloro-2-hydroxy-4-alkanones, including 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (Cl analogs of **1***a* and *b*) and 2-(1-hydroxy-2,2,2-trichloroethyl)-cyclohexanone (Cl analogs of **2***a* and *b*), and made configurational assignments on the basis of p.m.r. and i.r. spectral studies of hydrogen-bonding interactions and dihedral —CHOH—CHR— bond angles. The low-melting isomer of each pair was found to exhibit strong intramolecular hydrogen bonding, attributable mainly to >C=O···H—O rather than Cl···H—O interaction, and was assigned the *threo* structure while the high-melting isomer was assigned the *erythro* structure (Fig. 1).



threo (low m.p.) *erythro* (high m.p.)

FIG. 1. Structure assignments for RCO—CHR'—CHOH—CCl_3.

If, instead of chloroketols (Fig. 1), the corresponding fluoroketols are used for the spectroscopic studies, the presence of F···H—O hydrogen bonds should be discernible from their F-19 n.m.r. spectra and hence should settle the question whether halogen or the carbonyl oxygen is the preferred proton acceptor site in intramolecularly hydrogen-bonded 1,1,1-trihalo-2-hydroxy-4-alkanones. With this goal in mind, we have synthesized a series of fluoroketols and recorded their proton and fluorine n.m.r. spectra as a function of their concentrations in chloroform-*d* at room temperature.

Results and Discussion

Reaction of Fluoral with Ketones

The fluoroketols were prepared by crossed aldol condensation of fluoral with the respective aliphatic ketones in glacial acetic acid – sodium acetate medium using a modification of the procedure described previously (2) for chloral–ketone condensations (eq. 1). Cyclohexanone and 3-pentanone gave two diastereomeric products, respectively, while only one ketol was obtained from the reaction of acetone with fluoral. In the case of 4-methyl-2-pentanone, only the ketol (**3**) resulting from fluoral addition

at the α-methyl carbon could be isolated from the product mixture although the F-19 n.m.r. spectrum of the crude product showed the presence of traces of the isomeric methylene condensation product, 1,1,1-trifluoro-2-hydroxy-3-isopropyl-4-pentanone. In contrast, no 1,1,1-trichloro-2-hydroxy-3-isopropyl-4-pentanone was detected in the reaction mixture formed from chloral and 4-methyl-2-pentanone (2). Thus, addition at the methylene carbon is sterically inhibited by the bulky isopropyl substituent but, with the relatively small fluoral molecule as electrophile, this steric hindrance is less pronounced than with chloral.

Anhydrous fluoral (b.p. −19°) was obtained by treatment of commercial fluoral hydrate with concentrated sulfuric acid and phosphorus pentoxide (3) and trapping at −78°. The gas was then bubbled into a mixture of ketone, acetic acid, and sodium acetate at the desired reaction temperature (70–100°) using a slow stream of nitrogen to prevent oxidation. Although anhydrous fluoral appears to interact strongly with the solvent (acetic acid) and react fairly rapidly with the ketone, evaporation losses during its preparation and low fluoral hydrate reagent purity are believed to be the main reasons for the low product yields. Diastereomeric fluoroketols were separated and purified by adsorption chromatography on silicic acid and elution with chloroform.

Hydrogen Bonding Studies by Nuclear Magnetic Resonance

Proton magnetic resonance measurements on alcohols and amines have shown that hydrogen bond formation is accompanied by a displacement of the chemical shift of the protons involved toward lower magnetic field strength (4, 5). When the OH group of a molecule forms a hydrogen bond to a donor atom X, the electronic structure and hence the magnetic susceptibility of that OH bond are altered leading to a change in the magnetic shielding. Thus it is the generation of a strong electric field in the vicinity of the OH bond which causes the observed downfield shift (6).

Trifluoromethylcarbinols which are structurally closely related to the fluoroketols under discussion have been studied spectroscopically to establish conformational preferences as a function of hydrogen bonding interactions. Cannon and Stace (7) have reported a "free" OH stretching band for trifluoroethanol in carbon tetrachloride solution (3617 cm^{-1}) which persisted even in the pure liquid state (3628 cm^{-1}). They have interpreted this observation as evidence for the absence of intramolecular F···HO bonding. Oki and Iwamura (8) found an OH band for trifluoroethanol in 0.003 *M* carbon tetrachloride solution which was asymmetric on the high-frequency side and explained it in terms of an unresolved doublet due to *trans* ⇆ *gauche* isomerism and restricted rotation about the carbon–oxygen single bond (eq. 2). They

[2] 
gauche *trans*

concluded from a mathematical resolution of the doublet that trifluoroethanol exists predominantly in the intramolecularly hydrogen-bonded *gauche* form. A temperature-dependent *trans* ⇆ *gauche* equilibrium (eq. 2), with a relatively small population in the *trans* form, was also observed by Krueger and Mettee (9).

Because of their structural similarity to the fluoroketols (**1***a* and *b*, **2***a* and *b*, **3**, and **4**) under investigation, we have included 1,1,1-trifluoro-2-propanol (**5**) and 2,2,2-trifluoroethanol (**6**) as part of our hydrogen-bonding studies. The chemical shift data are summarized in Table 1. The upfield shift of the hydroxyl proton on dilution observed for all eight compounds is typical for the behavior of intermolecularly hydrogen-bonded aggregates of solute molecules being broken up into monomeric species. The dilution shifts measured for the fluoroketols **1***b*, **2***b*, **3**, and **4** are similar to those for the trifluoromethylcarbinols **5** and **6**, with relatively steep slopes at lower concentrations, suggesting similar hydrogen-bonding interactions for all six compounds. Since the monomeric species of **5** have already been shown to exist predominantly in the intramolecularly hydrogen-bonded *gauche* form (7–9), it is reasonable to assume that the hydroxyl protons of the monomeric species of **1***b*, **2***b*, **3**, and **4** are also hydrogen-bonded to fluorine (Fig. 2).

The i.r. spectra of **1***b*, **2***b*, **3**, and **4**, taken in carbon tetrachloride solution at as low a concentration as 0.005 *M*, show a broad peak at 3520 cm^{-1} with a small shoulder at 3600 cm^{-1}

pointing to a preponderance of hydrogen-bonded OH groups in the monomeric species. Finally, the downfield dilution shift observed in the fluorine n.m.r. spectra (Table 1) shows clearly that the halogen atoms are involved in intermolecular hydrogen-bond formation to the hydroxyl groups of these compounds. The larger proton dilution shifts reported earlier for the chlorine analogs of **1***b* and **2***b* may be taken as evidence for the larger chlorine atom being a somewhat better hydrogen bond acceptor site than fluorine.

In sharp contrast to the behavior of **1***b*, **2***b*, **3**, and **4**, dilution results in a very small upfield shift in the absorption position for the hydroxylic protons of the *threo*-fluoroketols **1***a* and **2***a*. Huggins, Pimentel, and Shoolery (10) have interpreted this flattening of the dilution shift curve as being due to the intrusion of intramolecularly hydrogen-bonded species even at relatively high concentrations. Since the position of the hydroxylic proton relative to the fluorine atoms has not been changed in going from one diastereomer (**1***b* or **2***b*) to the other (**1***a* or **2***a*) and the shape of the dilution shift curves now is drastically different from that observed for the carbonyl-free trifluoromethylcarbinols **5** and **6**, we must conclude that in **1***a* and **2***a* intramolecular hydrogen bonding occurs to the carbonyl group rather than to the halogen atom. This conclusion is further supported by the following experimental observations: (*a*) the F-19 n.m.r. spectra of **1***a* and **2***a* show negligible dilution shifts (Table 1) pointing to the non-involvement of fluorine in hydrogen-bond formation, and (*b*) the i.r. spectra of **1***a* and **2***a* at high dilution exhibit a broad absorption peak at 3520 cm^{-1} with a weak shoulder at 3600 cm^{-1} indicating the presence of hydrogen-bonded hydroxyl groups.

[1]The H—C—C—H dihedral angles for the *erythro* (140°) and *threo* (60°) forms of the fluoroketols have been assumed to be similar to the values reported for the corresponding chlorine analogs.

A comparison of hydroxyl proton chemical shifts ($\delta_{OH}°$) at infinite dilution, obtained by extrapolation of the data listed in Table 1, is informative and shows that **1***a* and **2***a* absorb at approximately the same magnetic field strength (250 Hz downfield from TMS); the same relationship applies to the pairs **1***b* and **2***b* (185 Hz), and **3** and **4** (210 Hz), respectively. Thus, the structure of the alkyl groups R and R′ has a negligible effect on $\delta_{OH}°$ while the nature of specific intramolecular hydrogen-bonding interactions causes considerable chemical shift differences. The higher $\delta_{OH}°$ values for **1***a* and **2***a* relative to **1***b* and **2***b*, respectively, indicate that the hydroxyl proton is deshielded more by hydrogen bonding to carbonyl oxygen than by hydrogen bonding to fluorine. It is also noteworthy that the F-19 absorption of **1***b*, **2***b*, **3**, **4**, **5**, and **6** is shifted *downfield* on dilution while the H-1 absorption is shifted *upfield*. These opposite trends are to be expected since hydrogen-bonding interactions cause a decrease in the symmetry of the fluorine p-orbital which overlaps with the hydroxyl proton 1s-orbital, and the resulting increase in the fluorine paramagnetic screening term shifts the CF_3 resonance peak to lower magnetic field (11, 12). The $\delta_{OH}°$ values for the chlorine analogs of **1***b*, **2***b*, and **3** are approximately 190, 190, and 200 Hz, respectively (extrapolation of data reported in ref. 1), *i.e.*, substitution of fluorine by chlorine has only a small effect on the OH proton chemical shift. This is in agreement with $\delta_{OH}°$ values reported in the literature (3) for trichloro- and trifluoroethanol and has been attributed to similar bond polarities for trichloro- and trifluoromethyl groups.

In conclusion, a strongly concentration-dependent equilibrium between monomeric and intermolecularly hydrogen-bonded species prevails in fluoroketols **1***b*, **2***b*, **3**, and **4** while **1***a* and **2***a* form strong intramolecular hydrogen bonds even at low concentrations.

Experimental

Melting points are uncorrected. I.r. spectra were run in CCl_4 solution on a Perkin–Elmer 457 or Beckman IR-12 spectrometer, u.v. spectra in 95% ethanol on a Unicam SP-200 instrument. N.m.r. spectra were recorded in $CDCl_3$ on a Varian A56/60 spectrometer, using TMS as internal standard for proton spectra (60 MHz) and $CFCl_3$ as external standard for F-19 spectra (56.4 MHz). Analytical-scale separations of diastereomeric 1,1,1-trifluoro-2-hydroxy-4-alkanones and other v.p.c. analyses were performed on a Varian Aerograph Model 1200-1 HY-FI III gas chromatograph using a 5 ft × 1/8 in. column packed with 5% SE-52 or 1% OV-17 on Aeropak 30 (column temperature 50–85°) and nitrogen as carrier gas (30 ml/min). Trifluoroethanol (Aldrich) and 1,1,1-trifluoro-2-propanol (Aldrich) were purified by fractional distillation.

Preparation of Anhydrous Fluoral

Using a modification of the procedure described in the literature (3), 53 g (0.45 mol) of fluoral hydrate (practical, Columbia Organic Chemicals) was added dropwise (2 h) to a stirred, preheated (90–95°) mixture of 83 ml concentrated sulfuric acid and 22 g of phosphorus pentoxide, and the fluoral (b.p. −19°) was swept with nitrogen into a cold trap (−78°). After completion of the addition, heating and stirring was continued for another hour. The anhydrous product (27 g = 61% yield) was used for the aldol condensations (see below) without further purification. The formation of small amounts of an unidentified, white polymeric material in the glass tubing leading to the trap was noticed in all experiments.

Reaction of Fluoral with 3-Pentanone

A mixture of 56.5 g (0.66 mol) of freshly distilled 3-pentanone, 39.6 g (0.66 mol) of glacial acetic acid, and 1.55 g (0.019 mol) of anhydrous sodium acetate was placed in a 500-ml three-necked flask fitted with condenser, thermometer, and gas inlet tube. Using a slow stream of nitrogen, anhydrous fluoral gas, prepared from 0.45 mol of commercial fluoral hydrate (see before), was evaporated slowly from a condensing trap by removing the cooling bath and bubbled into the magnetically stirred reaction mixture over a 1-h period. The temperature rose to 34° and some unreacted fluoral was collected in a second trap (−78°) connected to the condenser. The mixture was then heated in an oil bath at 84° for 17½ h, allowed to cool, filtered (NaOAc), and distilled (aspirator) to leave a yellow liquid residue which, on fractional high-vacuum distillation, gave 8.3 g (10% yield) of a mixture of *erythro-* and *threo*-1,1,1-trifluoro-2-hydroxy-3-methyl-4-hexanone (**1***a* and *b*). The diastereomers were separated by column chromatography on silicic acid (Mallinckrodt, Analytical Reagent, 100 mesh).

1*a*: b.p. 55–58°/1.0 mm; n.m.r. ($CDCl_3$) τ 8.95 (t, 3H, CH_3CH_2), 8.75 (d, 3H, CH_3CH), 7.43 (q, 2H, CH_3CH_2), 7.00 (m, 1H, CH_3CH), and 5.97 (broad peak, 1H, CHOH); i.r. (0.1 *M* CCl_4) 3450 cm^{-1} (OH; shoulders at 3530 and 3600) and 1710 (CO; shoulder at 1720).

1*b*: b.p. 60–63°/1.0 mm; n.m.r. ($CDCl_3$) τ 8.95 (t, 3H, CH_3CH_2), 8.73 (d, 3H, CH_3CH), 7.42 (q, 2H, CH_3CH_2), 7.02 (m, 1H, CH_3CH), and 5.58 (broad m, 1H, CHOH); i.r. (0.05 *M* in CCl_4) 3520 cm^{-1} (OH; shoulder at 3600) and 1715 (CO; shoulder at 1720); u.v. (EtOH) λ_{max} 216 nm (ε 80) and 273 nm (ε 35).

Reaction of Fluoral with Cyclohexanone

Anhydrous fluoral prepared from 0.45 mol of fluoral hydrate was bubbled into a mixture of 84.3 g (0.86 mol) of cyclohexanone, 51.6 g (0.86 mol) of acetic acid, and 2.03 g (0.025 mol) of sodium acetate as described before and the reagents were heated at 95° for 17 h. The normal work-up procedure yielded 63.7 g of crude product from which 30.3 g (35% yield) of a mixture (ratio 3:7 by v.p.c.) of the two fluoroketols **2***a* and *b* was obtained by frac-

tional distillation under high vacuum (68–76°/0.05 mm). The diastereomers were separated by adsorption chromatography (see before).

2*a*: b.p. 68–70°/0.05 mm; n.m.r. ($CDCl_3$) τ 7.0–8.5 (broad multiplet, 9H), and 5.90 (broad multiplet, 1H, C*H*OH); i.r. 3462 cm^{-1} (OH; shoulders at 3550 and 3620; 0.005 *M* in CCl_4) and 1705 (CO; 0.1 *M* in CCl_4); u.v. (EtOH) λ_{max} 223 nm (ε 88) and 280 nm (ε 38).

2*b*: m.p. 35–37°, b.p. 74–76°/0.05 nm; n.m.r. ($CDCl_3$) τ 7.0–8.5 (broad multiplet, 9H) and 5.28 (sharp quartet of doublets, 1H, C*H*OH); i.r. 3628 cm^{-1} (OH; 0.005 *M* in CCl_4) and 1710 (CO; 0.1 *M* in CCl_4); u.v. (EtOH) λ_{max} 204 nm (ε 35) and 281 nm (ε 31).

*Preparation of 1,1,1-Trifluoro-2-hydroxy-6-methyl-4-heptanone (**3**)*

Anhydrous fluoral prepared from 0.425 mol of fluoral hydrate was bubbled into a mixture of 70.0 g (0.70 mol) of 4-methyl-2-pentanone, 32.0 g (0.53 mol) of acetic acid, and 6.0 g (0.073 mol) of sodium acetate as described before and the reagents were heated at 110° for 3 h. Work-up and fractional distillation gave 12.0 g (14% yield) of **3**, m.p. 13–15°, b.p. 77–80°/1.25 mm, which was further purified by column chromatography. The fluorine n.m.r. spectrum revealed the presence of small amounts of the two diastereomeric 1,1,1-trifluoro-2-hydroxy-3-isopropyl-4-pentanones (doublets at 4368 and 4386 Hz upfield from $CFCl_3$). Characterization of **3**: n.m.r. ($CDCl_3$) τ 9.07 (d, 6H, $(CH_3)_2C$), 7.65 (m, 3H, $CHCH_2CO$), 7.22 (m, 2 diastereotopic protons, CH_2CHOH) and 5.48 (m, 1H, C*H*OH); i.r. (0.1 *M* in CCl_4) 3520 cm^{-1} (OH; broad, with shoulder at 3620) and 1715 (CO); u.v. (EtOH) λ_{max} 212 nm (ε 400) and 269 nm (ε 180).

*Preparation of 1,1,1-Trifluoro-2-hydroxy-4-pentanone (**4**)*

Fluoral was generated from 0.43 mol of fluoral hydrate (see before) and admitted into a mixture of 49.9 g (0.86 mol) of acetone, 51.6 g (0.86 mol) of acetic acid, and 2.03 g (0.025 mol) of sodium acetate over a 45 min period. The reagents were heated at 70° (oil bath temperature) for 72 h. after which time most of the solvent and unreacted ketone were removed at aspirator vacuum (oil bath below 60°). The remaining yellow-green liquid was taken up in methylene dichloride, washed with aqueous $NaHCO_3$ solution and water, dried ($MgSO_4$), and distilled (after CH_2Cl_2 evaporation) to give 18 g (27% yield) of 1,1,1-trifluoro-2-hydroxy-4-pentanone (**4**), b.p. 45–50°/0.7 nm. Removal of the last traces of acetic acid by extraction and distillation proved to be difficult in this case due to the high volatility (sublimation) of this compound. A pure product sample was obtained by adsorption chromatography (see before). Characterization of **4**: n.m.r. ($CDCl_3$) τ 7.75 (s, 3H, CH_3CO), 7.17 (m, 2 diastereotopic protons, CH_2) and 5.48 (m, 1H, C*H*OH); i.r. (0.1 *M* in CCl_4) 3520 cm^{-1} (OH; broad, with shoulder at 3620) and 1725 (CO).

The authors wish to thank the National Research Council of Canada for the financial support of this work and Messrs. M. Pudek and D. Sabourin for technical assistance.

Kinetic Study of the Epimerization of 1,1,1-Trichloro-2-hydroxy-3-methyl-4-hexanone

EBERHARD KIEHLMANN, FRED MASARO, AND FREDERICK J. SLAWSON
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received April 13, 1973

The acetate-catalyzed epimerization of 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone has been studied in glacial acetic acid as solvent at five different temperatures. The reaction follows pseudo first-order, reversible kinetics and is associated with an activation energy of 24.0 ± 0.4 kcal/mol. Rate and product studies have shown that epimerization occurs by an enolization–ketonization pathway rather than dehydration–rehydration or retroaldol–aldolization. The ratio of diastereomeric ketols formed by condensation of 2-pentanone and 2-heptanone with chloral does not change as a function of time while the stereochemistry of the chloral addition to cyclohexanone is kinetically controlled during the initial reaction period.

L'épimérisation catalysée par l'entité acétate de la trichloro-1,1,1 hydroxy-2 méthyl-3 hexanone-4 a été étudiée à cinq différentes températures en utilisant comme solvant l'acide acétique glacial. La réaction se définit comme étant une réaction de pseudo premier ordre àcaractère réversible et possédant une énergie d'activation de 24.0 ± 0.4 kcal/mol. Des études de la vitesse ainsi que des produits obtenus ont montré que l'épimérisation se produit à la suite d'un processus d'énolisation–cétonisation plutôt qu'à la suite d'une déshydratation–réhydratation ou d'une rétroaldolisation–aldolisation. Le rapport des cétols diastéréoisomériques formés par condensation de la pentanone-2 avec l'heptanone-2 en présence de chloral ne change pas en fonction du temps alors que la stéréochimie de l'addition du chloral sur le clyclohexanone est controlée cinétiquement durant la période initiale de la réaction.

Can. J. Chem., 51, 3182 (1973)

The crossed aldol condensation of an aldehyde with a symmetrical aliphatic ketone of the general structure RCH_2COCH_2R leads to the creation of two asymmetric centers in the β-hydroxycarbonyl product of the addition step. Thus, if the reaction can be stopped at the ketol stage, the product mixture will consist of two diastereomers each composed of a *dl*-pair of enantiomers (eq. 1). Under conditions permitting equilibration (epimerization) of the two diastereomers, the product ratio is said to be thermodynamically controlled and the product of greater thermodynamic stability will predominate. On the other hand, if equilibration does not occur or if the rate of epimerization is much slower than the rate of the preceding condensation reaction, the observed ratio of diastereomers is said to be kinetically controlled, *i.e.*, it reflects the relative rates of their formation and therefore permits conclusions to be drawn about the preferred transition state geometry in the aldol addition step.

As a continuation of our interest in the regio- and stereochemistry of the crossed aldol condensation of trihaloacetaldehydes with aliphatic ketones (1, 2), we have now carried out a kinetic study of the epimerization of 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (**1**) in glacial acetic acid – acetate medium in order to elucidate its mechanism. Three pathways may be postulated for this reaction which has been observed (1) for several diastereomeric 1,1,1-trichloro-2-hydroxy-4-alkanones (eq. 2): dissociation of **1** into chloral and diethyl ketone followed by re-con-

[2] 
densation to form the ketol with opposite configuration at one of the two asymmetric carbons (retro-aldol reaction, route a), elimination of water followed by rehydration (route b), or an enolization–ketonization sequence (route c). It was hoped that a comparison of the epimerization rate with previously measured rate constants for hydrogen–deuterium exchange and aldol condensation under similar reaction conditions (2) would not only permit determination of the epimerization pathway but also, indirectly, conclusions about the rate-determining step in the formation of **1** from chloral and diethyl ketone.

The two diastereomers of **1** were selected as model compounds because they give well-separated peaks on the gas chromatogram, the preparative reaction does not yield any other, structurally isomeric ketols (as would be the case for the condensation of chloral with unsymmetrical dialkyl ketones), and the preparative separation of the high-melting component (**1***b*) from the diastereomeric product mixture can be readily accomplished by fractional distillation and crystallization. Also, the relative configurations of the *threo* (**1***a*) and *erythro* (**1***b*) isomer are known from previous spectroscopic studies (3).

Experimental

Reagents

Pure anhydrous chloral (b.p. 97°) was obtained by distillation of commercially available material (Chloral, Practical, Stabilized, MCB) from phosphorus pentoxide. Commercial diethyl ketone (b.p. 102°) was purified by fractional distillation while glacial acetic acid (Baker and Adamson, U.S.P.) and sodium acetate (Baker and Adamson, anhydrous reagent) were used without further purification in the preparative experiments. For the kinetic studies, 'Baker Analyzed' reagent-grade acetic acid was used and the anhydrous sodium acetate was purified by heating at 160° for 2 h and storing in a desiccator.

*Preparation of erythro-1,1,1-Trichloro-2-hydroxy-3-methyl-4-hexanone (**1***b*)*

In a 1-l flask, fitted with Friedrich condenser and $CaCl_2$ drying tube, were placed 86 g (1 mol) of diethyl ketone, 119 g (0.81 mol) of anhydrous chloral, 16.7 g (0.20 mol) of anhydrous sodium acetate, and 96.6 g (1.61 mol) of glacial acetic acid. After heating the mixture at 100–105° for 52 h, solvent and unreacted starting materials were removed by vacuum distillation (25–30°/0.9 mm). Ether (500 ml) and water (200 ml) were added to the residue, the ether layer was separated, washed (H_2O and aqueous $NaHCO_3$), and dried ($MgSO_4$), and the solvent was evaporated. High-vacuum distillation of the remaining oily product mixture gave six fractions (b.p. 89–115°/0.05–0.26 mm) the last of which (16.3 g, b.p. 105–115°/0.05–0.09 mm) contained more than 80% (by v.p.c.) of the desired diastereomer and solidified on cooling. Filtration and two recrystallizations from cyclohexane gave pure **1***b*, m.p. 58–58.5° (lit. (4) 58.5°).

Epimerization Rate Measurements

Into a long-neck, pear-shaped 10-ml flask were placed 6.00 g (0.10 mol) of reagent-grade acetic acid and 0.30 g (0.00365 mol) of anhydrous sodium acetate; the sodium acetate was allowed to dissolve and 1.50 g (0.00643 mol) of **1***b* was added to the cooled solution. The flask was fitted with a reflux condenser (using a Teflon sleeve), drying tube, and mercury valve and lowered into a thermostatted oil bath (paraffin oil, Saybolt viscosity 335/350) which had been equilibrated overnight at the desired temperature (±0.03°). Timing was started 1 min after immersion and 25-μl samples were withdrawn at various time intervals using a specially adapted micropipette. The fraction of **1***b* remaining at time *t* was determined by injection of each sample, dissolved in chloroform (0.2 ml), into a gas chromatograph (Varian Aerograph Model 1200-1 HY-FI III with 1% OV-17 on 80/100 Chromosorb G column at 117°) and by several planimetric integrations of the peak areas for the two epimers. The v.p.c. peak area ratios were shown to correspond to concentration ratios by repeated injections of samples of known concentrations (standard deviation $\sigma = \pm 0.015$ for 10 injections of $[\mathbf{1}b]/([\mathbf{1}a] + [\mathbf{1}b]) = 0.536$). Heating of the reaction mixture (>90°) for prolonged time periods (>5 days) resulted in the formation of small quantities of a white crystalline substance which was identified as sodium chloride.

Aldol Condensation Product Ratios as Function of Time

To obtain an approximate measure of the variation of the product ratio as a function of time when cyclohexa-

[3] 
none, 2-pentanone, and 2-heptanone react with chloral under typical aldol condensation conditions, mixtures of sodium acetate, dimethoxyethane (DME), chloral, and the respective ketone (molar ratio 1:8:4:5) were heated at 100 ± 2° for 48 h and kinetically assayed (by v.p.c.) at various time intervals. For 2-pentanone and 2-heptanone, the ketol product ratio was found to remain essentially constant (based on eight assays) at A:B:C = 22:18:60 and 23:21:56 (average relative deviation ± 15%), respectively, where A and B represent the two diastereomeric methylene condensation products and C is the ketol resulting from condensation at the α-CH_3 carbon. The same constancy was observed for the reaction of diethyl ketone with chloral in acetic acid (**1***a*:**1***b* = 50:50) while the composition of the ketol mixture formed from cyclohexanone and chloral in DME changed drastically from 63:37 (after ½ h) to 50:50 (1 h), 37:63 (2 h), and 23:77 (8 h), remaining constant thereafter.

Results and Discussion

The epimerization mechanism was first investigated by several types of product studies under conditions similar to those of the kinetic experiments. Heating a mixture of the two diastereomeric 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanones (**1***a* and *b*) at 100° for 20 h, using glacial acetic acid as solvent and sodium acetate as catalyst, gave no diethyl ketone detectable by v.p.c. of the reaction mixture on a Reoplex-400 column at 60°. Also, admixture of acetone did not result in the formation of 1,1,1-trichloro-2-hydroxy-4-pentanone as would be expected if chloral was formed as intermediate. These findings are in agreement with the previously reported observation that the condensation products of chloral with *unsymmetrical* ketones do not undergo structural isomerization under the preparative reaction conditions (1) and rule out the retroaldol reaction pathway (eq. 2, route a) for the epimerization. Independent preparation of an authentic sample of 1,1,1-trichloro-3-methyl-2-hexen-4-one (5), determination of its v.p.c. retention time (5% SE-52 column at 120°), and injection of a sample of the reaction product obtained by heating **1***b* at 100° for 96 h demonstrated that the epimerization reaction was not accompanied by dehydration[1] (eq. 2, route b) thus leading us to the conclusion that the epimerization of **1***b* proceeds via the enolization pathway (eq. 3). Furthermore, the ratios of the diastereomeric ketols formed from chloral and various acyclic aliphatic ketones were found to remain constant over the entire reaction period indicating that the epimerization rate is much faster than the rate of chloral–ketone addition, *i.e.*, the stereochemistry of the aldol condensation under these conditions is thermodynamically controlled while the regiochemistry (1) is kinetically controlled. The stereochemistry of the aldol addition of cyclohexanone to chloral, on the other hand, is subject to kinetic control as evidenced by the observed change in the diastereomeric product composition from 63:37 to 23:77 over the initial 8-h period. In this case, the enol double bond is locked into *cis* configuration due to its confinement in a six-membered ring leading to a preferred transition state geometry for the reaction with chloral. Stiles and co-workers (6) have reported similar results for the condensation of *p*-nitrobenzaldehyde with cyclohexanone. It is noteworthy that both 3-(*p*-nitrophenyl)-1,2-diphenyl-3-hy-

[1]The remote possibility that reversible elimination occurs to an undetectable extent has been ruled out by treating the solution of a typical 1,1,1-trichloro-2-alken-4-one in acetic acid with an equimolar amount of water and testing (by v.p.c.) for the presence of the expected hydration product. After 72 h at 80°, no 1,1,1-trichloro-2-hydroxy-4-pentanone was formed from 1,1,1-trichloro-2-penten-4-one under these conditions. We are grateful to one of the referees for suggesting this experiment.

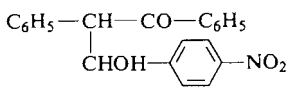
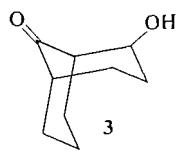
droxy-1-propanone (**2**) in basic medium (aqueous dioxane) and 2-hydroxybicyclo[3.3.1]-nonan-9-one (**3**) in basic (KOH – acetone-d_6) and acidic medium (aqueous HCl) have been found to epimerize by the reverse aldolization readdition mechanism as evidenced by the lack of deuterium incorporation required for the alternative dehydration–rehydration and enolization pathways (7, 8).



2



3

Our rate studies have confirmed the enolization route (eq. 3) for the epimerization of **1***b*. The reaction follows pseudo first-order, reversible kinetics and is associated with an equilibrium constant of approximately one. If B, B_0 and B_e represent the concentrations of **1***b* at time t, time zero, and at equilibrium, respectively, k_f and k_r the rate constants for the forward and reverse reaction, and K_{eq} the equilibrium constant for the reaction, then the expressions summarized in eqs. 4–6 permit calculation of the individual rate constants (Table 1).

[4] $$\mathbf{1}b \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \mathbf{1}a$$

[5] $$\ln \frac{B_0 - B_e}{B - B_e} = (k_f + k_r) \cdot t$$

[6] $$K_{eq} = \frac{B_0 - B_e}{B_e} = \frac{k_f}{k_r}$$

Experimental values were fitted to eq. 5 by means of a linear, least-squares computer program giving the ($k_f + k_r$) values listed in Table 1. The equilibrium constants were calculated from several concentration measurements after at least 322 h at the respective temperatures (eq. 6). Approximate rate constants for the forward reaction were also determined graphically by measuring the initial slope of a plot of ln B_0/B *vs.* time giving values of 3.06, 4.97, 7.68, 13.53, and 22.74 ($k_f \times 10^3$ h^{-1}) at 70, 75, 80, 85, and 90°, respectively. In this approach, the reverse reaction (**1***a* → **1***b*) is neglected during the initial period which has the predictable effect of retarding the forward rate thus leading to smaller k_f values than obtained from eqs. 5 and 6. The data of Table 1 were found to agree well with those of two other runs and the activation energy was calculated to be 24.0 kcal/mol (Fig. 1) with an estimated root-mean-square error of ±0.4 kcal/mol.

A comparison of these kinetic results with those reported for the hydrogen–deuterium

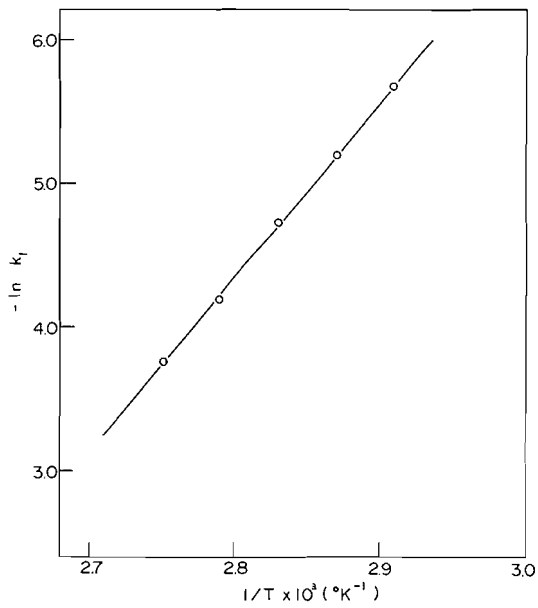


FIG. 1. Effect of temperature on epimerization rate.

exchange and the crossed aldol reaction of chloral at the methylene carbon of 2-heptanone and butanone under similar reaction conditions (2) confirms our earlier conclusions based on product studies, namely that the epimerization rate is of the same order of magnitude as the enolization rate of structurally similar ketones but much faster than the rate of the aldol addition step. This is to be expected on the basis of a common enolization–ketonization mechanism for both isotope exchange and epimerization and agrees with the observation by Rappe and Sachs (9) that the rates of acid-catalyzed deuteration of butanone and 3-methyl-2-butanone are approximately equal, *i.e.*, very little affected by additional branching at the α-carbon. The ratio of the diastereomeric ketols formed from diethyl ketone and chloral in glacial acetic acid with sodium acetate as catalyst is, therefore, thermodynamically controlled so that it is impossible to draw conclusions about the transition state geometry of the aldol addition on the basis of rate and/or product studies with this and other acyclic, aliphatic ketones. Saturated cyclic ketones, however, appear to be suitable model compounds for an investigation of the stereochemistry of the aldol condensation (10, 11) since they permit a systematic study of diastereomer ratios and configurations before equilibration has occurred. We are presently pursuing research along these lines.

The authors wish to thank Miss N. McGillivray for technical assistance and the National Research Council of Canada for the financial support of these investigations.

Further Studies in the Reactions of Triethylaluminum with Bis-(diphenylphosphino) amines

DONALD F. CLEMENS, ROBERT B. SMITH, JR., AND JOHN G. DICKINSON
The Chemistry Department, East Carolina University, Greenville, North Carolina 27834

Received January 8, 1973

Triethylaluminum reacts with bis(diphenylphosphino)-*n*-propylamine and bis(diphenylphosphino)-*n*-butylamine to form the 1:1 adducts in which the aluminum atom is pentacoordinate. Triethylaluminum does not react with other bis(diphenylphosphino)amines in which the third substituent on the nitrogen atom is α-methylbenzyl, benzyl, or 1,1-dimethylamine. The formation of adducts from straight-chain hydrocarbons and the total lack of reactivity for the Lewis bases containing bulky groups leads to the postulation that steric hindrance prevents the free pair of electrons on the phosphorus atoms from being available to the triethylaluminum.

Le triéthylaluminium réagit sur la bis(diphénylphosphino)-*n*-propylamine et la bis(diphénylphosphino)-*n*-butylamine pour former des adduits 1:1 dans lesquels l'atome d'aluminium est pentacoordiné. Le triéthylaluminium ne réagit pas sur les autres bis(diphénylphosphino) amines dans lesquelles le troisième substituant sur l'azote est l'α-méthylbenzyle, benzyle ou diméthyl-1,1 amine. La formation d'adduits à partir des chaînes droites hydrocarbonées et le manque total de réactivité pour les bases de Lewis contenant des groupes volumineux conduisent à postuler que l'encombrement stérique empêche la disponibilité des paires d'électrons libres du phosphore au triéthylaluminium.

It has been shown that triethylaluminum reacts with hydrazines (1), biphosphines (2), and aminophosphines (2) to form adducts in which the aluminum atom is pentacoordinate by virtue of being symmetrically located with respect to two adjacent electron donor atoms. A recent study of the reactions of triethylaluminum with hydrazinophosphorus compounds (3), such as $P[(CH_3)NN(CH_3)]_3P$, indicated that, although reaction did occur, the aluminum atom was tetracoordinate, not pentacoordinate as in the above cases. In the course of extending this work it was decided to examine the reactions of triethylaluminum with a variety of bis(diphenylphosphino)amines similar to some of the P—N—P compounds reported previously (2). The purpose of this study was to determine whether the third substituent on the nitrogen atom may, through steric hindrance, prevent the formation of the Lewis acid–base adduct or allow compounds to be formed in which only one of the phosphorus atoms interacts with the aluminum. Reactions were attempted with molecules such as $RN[P(C_6H_5)_2]_2$ in which the R groups were *n*-propyl, *n*-butyl, α-methylbenzyl, benzyl, and 1,1-dimethylamine. Pentacoordinate aluminum complexes were formed only in the reactions where R represented a straight chain hydrocarbon. The other compounds failed to react indicating no tendency to form a complex involving the bonding of only one of the phosphorus atoms to triethylaluminum.

Experimental

Materials

Solvents used in these experiments were distilled and stored over calcium hydride. Diphenylchlorophosphine, obtained as a gift from Stauffer Chemical Co., was vacuum distilled under nitrogen at 113° (0.14 mm). Triethylaluminum, obtained as a gift from Texas Alkyls, was distilled under nitrogen at 48° (0.045 mm). 1,1-Bis-(diphenylphosphino)-2,2-dimethylhydrazine was prepared by the method of Nielsen and Sisler (4). The bis(diphenylphosphino)amines were synthesized by the reaction of diphenylchlorophosphine with the appropriate amine according to standard procedures (5–7).

General Methods

All manipulations were done either in an inert atmosphere chamber filled with dry nitrogen or in a typical high-vacuum line. I.r. spectra were obtained from KBr pellets using a Beckman IR-12 spectrophotometer. The proton n.m.r. spectra were recorded using a Perkin–Elmer Model R-20 spectrometer operated at 60 MHz. The shift values were obtained using TMS as an internal reference. ^{31}P n.m.r. spectra were obtained by Charles Moreland, University of North Carolina at Raleigh, at 40.5 MHz using P_4O_6 as an internal reference on a Varian HA-100 spectrometer. Elemental analyses were done by Galbraith Laboratories, Inc., Knoxville, Tenn.

The Interaction of Bis(diphenylphosphino)-n-propylamine with Triethylaluminum

$$2\ C_3H_7N[P(C_6H_5)_2]_2 + Al_2(C_2H_5)_6 \rightarrow 2\ C_3H_7N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$$

A 0.545 g (0.0048 mol) sample of triethylaluminum was dissolved in a mixture of 3 ml of benzene and 3 ml of hexane in a 200 ml, two-necked reaction flask containing a Teflon-coated magnetic stirring bar. Bis-(diphenylphosphino)-*n*-propylamine (2.00 g, 0.0047 mol) was placed in a tipping tube and attached to the reaction flask. A vacuum stopcock was fitted into the other neck of the reaction flask and the entire apparatus was attached to the vacuum line. After degassing the reactants, a small portion of the bis(diphenylphosphino)-*n*-propylamine was added to the reaction flask which was cooled with a Dry Ice – acetone bath. The mixture was then stirred as it was allowed to warm to room temperature. After coming to room temperature, the mixture was again chilled and the addition process repeated. This procedure was continued until all of the solid had been added. The reaction was allowed to proceed for 2 h at room temperature after which the solvent was removed leaving a white crystalline reaction product. The reaction flask was then transferred, still under vacuum, to the inert atmosphere chamber where the crude product was washed with six small portions of hexane and recrystallized from hot hexane. The crystals were dried by passing nitrogen through the solid on a glass frit, m.p. 106–108°.

Anal. Calcd. for $C_3H_7N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$: C, 73.17; H, 7.83; N, 2.59; P, 11.43; Al, 4.98. Found: C, 72.90; H, 7.72; N, 2.50; P, 11.29; Al, 5.04.

The i.r. spectrum contained peaks at 3000 (m), 2900 (m), 1963 (w), 1820 (w), 1670 (vw, b), 1590 (m), 1470 (s), 1375 (w, b), 1325 (sh, w), 1305 (m), 1270 (w, b), 1215 (w), 1180 (m), 1165 (m), 1125 (m), 1090 (s), 1060 (s), 1020 (m), 995 (w), 925 (sh, m), 912 (s), 885 (vw), 850 (sh, w), 838 (sh, w), 825 (s, b), 740 (s, b), 692 (s, b).

The ^1H spectrum obtained using $CDCl_3$ as a solvent consists of a peak at τ 2.57 assigned to phenyl protons, and a multiplet at τ 6.80 (average) assigned to the NCH_2 group, a broad multiplet at about τ 8.9 (average) assigned to the CH_3CH_2 methylene group, a triplet at τ 9.00 (J = 8.0 Hz) assigned to the methyl protons of the ethyl group bonded to aluminum, a triplet at τ 9.62 (J = 6.0 Hz) assigned to the CH_3 signal in the *n*-propyl group, and a quartet at τ 9.99 (J = 8.0 Hz) assigned to the methylene protons adjacent to the aluminum atom.

The ^{31}P n.m.r. spectrum obtained from a benzene solution consists of a single peak at +51 p.p.m. from P_4O_6 or −62 p.p.m. from H_3PO_4.

Increasing the ratio of triethylaluminum to aminophosphine in subsequent reactions had no effect on the composition of the product.

The Interaction of Bis(diphenylphosphino)-n-butylamine with Triethylaluminum

$$2\ C_4H_9N[P(C_6H_5)_2]_2 + Al_2(C_2H_5)_6 \rightarrow 2\ C_4H_9N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$$

By the same procedure described previously 2.00 g (0.00453 mol) of bis(diphenylphosphino)-*n*-butylamine was allowed to react with 0.516 g (0.0452 mol) of triethylaluminum to give a quantitative yield of a white crystalline solid which had a melting point range of 91–93° after recrystallization from hot hexane.

The i.r. spectrum contained peaks at 3000 (m), 2850 (s), 1970 (w), 1900 (w), 1825 (vw), 1775 (vw), 1670 (w), 1600 (m), 1590 (sh, w), 1475 (s), 1455 (m), 1435 (s), 1410 (w), 1465 (w), 1300 (m), 1260 (w), 1230 (m), 1200 (sh, w), 1175 (m), 1155 (m), 1125 (vw), 1115 (sh, vw), 1080 (s, b), 1065 (s, b), 1050 (sh, w), 1025 (w), 975 (s, vb), 925 (w), 885 (sh, w), 855 (s), 795 (sh, m), 775 (s), 750 (sh, s), 740 (vs, b), 695 (vs, b).

The ^1H n.m.r. spectrum obtained using $CDCl_3$ as a solvent consists of a peak τ 2.60 assigned to phenyl protons, a multiplet at τ 6.77 (average) assigned to the NCH_2 group, a triplet at τ 9.02 (J = 8.0 Hz) assigned to the methyl protons of the ethyl group bonded to aluminum, a very broad multiplet at τ 9.1 (average) assigned to the methyl and methylene protons of the butyl group, and a quartet at τ 9.97 (J = 8.0 Hz) assigned to the protons of the methylene group bonded to aluminum. (The $AlCH_2CH_3$ triplet rises well above the broad signal at τ 9.1 and can be reasonably accurately assigned; however, the CH_3 signal of the *n*-butyl group, which is at about τ 9.5 cannot be accurately assigned because it merges into the broad τ 9.09 peak.) This spectrum is consistent with the 1:1 adduct that has been shown to form in other cases such as the *n*-propyl compound described above.

The ^{31}P n.m.r. spectrum obtained from a benzene solution consists of a single peak at +51 p.p.m. from P_4O_6 or −62 p.p.m. from H_3PO_4.

The reaction was repeated with increased concentrations of triethylaluminum but in each case the 1:1 reaction product was isolated.

The following compounds were mixed with triethylaluminum but no reaction was observed regardless of stoichiometry or temperature: 1,1-bis(diphenylphosphino)-2,2-dimethylhydrazine, $(CH_3)_2NN[P(C_6H_5)_2]_2$; bis(diphenylphosphino)-α-methylbenzylamine, $(C_6H_5)CH(CH_3)N[P(C_6H_5)_2]_2$; and bis(diphenylphosphino)-benzylamine, $C_6H_5CH_2N[P(C_6H_5)_2]_2$.

Discussion

The reactions of triethylaluminum with bis-(diphenylphosphino)-*n*-propylamine and with bis(diphenylphosphino)-*n*-butylamine to produce the new compounds $C_3H_7N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$ and $C_4H_9N[P(C_6H_5)_2]_2 \cdot Al(C_2H_5)_3$ are in accord with published data and the products are the expected results of these reactions. These two new compounds have structures in which the aluminum atom is symmetrically located with respect to the two phosphorus atoms and thus can be considered to be pentacoordinated.

The ^{31}P n.m.r. spectra indicate that the two phosphorus atoms have the same environment since a single sharp peak is observed in both compounds. These results obviate the possibility of only one phosphorus atom being bonded to aluminum. The possibility of the aluminum being bonded to nitrogen can be discounted by the fact that the NCH_2 signals in the ^1H n.m.r. spectra fall at the same location in the parent phosphorus compounds as they do in the aluminum complexes. A change in the electron density on the

For personal use only.

nitrogen atom would be expected if there was an Al—N bond and this would cause an upfield shift in the NCH_2 protons.

The i.r. spectra of these compounds have many absorption bands which may be readily assigned from i.r. data in the literature. Among the more readily identified bands are those in the 3120 to 2860 cm^{-1} region which are characteristic of the phenyl C—H, the methyl C—H, and the methylene C—H stretching vibrations. Three weak absorptions attributed to monosubstituted benzene are found between 1975 and 1820 cm^{-1}. A strong sharp band at 1440 to 1430 cm^{-1} is assigned to the *P*-phenyl vibration (8). The P—N bands are known to vary and have generally been assigned the 1000–800 cm^{-1} (5, 9, 10) and 773–743 cm^{-1} regions (8). Phenyl peaks characteristic of monosubstituted benzene are also found at 760–720 and at 700–690 cm^{-1}.

Steric hindrance problems due to the bulk of the group bonded to the bridging nitrogen atom were first encountered during the attempted synthesis of bis(diphenylphosphino)-*t*-butylamine, $(CH_3)_3CN[P(C_6H_5)_2]_2$. In this case the only compound that could be obtained was diphenylphosphino-*t*-butylamine, $(CH_3)_3CNHP(C_6H_5)_2$. Hirschfelder models of these compounds indicated that the bulk of the *t*-butyl group would not permit synthesis of the bis(diphenylphosphino)-*t*-butylamine.

Models of the bis(diphenylphosphino)amines containing -1,1-dimethylamine, α-methylbenzyl, or benzyl groups on the bridging nitrogen atom were compared to models of the bases that formed stable adducts $(CH_3(CH_2)_2N[P(C_6H_5)_2]_2$ and $CH_3(CH_2)_3N[P(C_6H_5)_2]_2)$. These comparisons indicated that the bulky groups bonded to the bridging nitrogen atom in the unreactive bases do cause the phenyl rings to be rotated in such a manner as to cover or shield the phosphorus atoms. The only orientation of the phenyl rings that exposed the phosphorus atoms sufficiently for attack would be unlikely because the rings had face-to-face orientations. These face-to-face orientations would result in considerable repulsions brought about by the interpenetrations of π electron clouds.

The results of this study indicate that the steric nature of the group bonded to the bridging nitrogen atom in bis(diphenylphosphino)amines is the determining factor that governs whether adduct formation will take place. It is interesting to note that there appears to be no tendency for the aluminum atom to react with just one of the phosphorus atoms. If the aluminum can get into position to form a bond with phosphorus it bonds with both phosphorus atoms.

The Hemicelluloses of Western Red Cedar (*Thuja plicata* (Donn))

GUY G. S. DUTTON AND NORMAN A. FUNNELL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received December 27, 1972[1]

The hemicelluloses of *Thuja plicata* (Donn) of the family Cupressaceae have been examined as part of a chemotaxonomic study. Little difference has been found from other Coniferales except that the xylan contains a percentage of L-arabinose lower than for many Pinaceae. Although 2- and 3-*O*-methylxylitol acetates are not separable by g.l.c. the composition of such a mixture may be determined by circular dichroism (c.d.) or by proton magnetic resonance (p.m.r.) spectroscopy.

Une étude chemotaxonomique a été faite sur les hémicelluloses de *Thuja plicata* (Donn) de la famille des Cupressacées. Une différence minime a été constatée comparativement à d'autres Conifères, à part que le xylane renferme un pourcentage d'arabinose inférieur à celui normalement trouvé chez des Pinacées. Bien que les acétates de méthylxylitol-2 et 3 ne soient pas séparés par la c.p.g., la composition d'un tel mélange peut être dosée par le dichroisme circulaire (d.c.) ou par la spectroscopie de résonance magnétique nucléaire (r.m.n.).

Can. J. Chem., **51**, 3190 (1973)

Trees may be classified as angiosperms (hardwoods) or gymnosperms (softwoods) and the hemicelluloses of these two groups are different in that the former consist mainly of the xylan type whereas the latter contain substantial quantities of mannose rich polysaccharides in addition to xylans. The literature pertaining to wood hemicelluloses has been reviewed extensively by Timell (1). The gymnosperm group, however, contains at least 6 main families which comprise 50 genera and about 600 species (2, 3). Of these families that of the Pinaceae (Abietaceae) contains the genera more commonly encountered commercially *e.g.* Pinus and Picea, and reference to the review by Timell (1) shows that it is almost exclusively members of this family whose hemicelluloses have been examined in detail. In continuation of previous work on the hemicelluloses of west coast trees we now report a study on *Thuja plicata* (Donn), a member of the family Cupressaceae and will, in due course, discuss the non-cellulosic polysaccharides of *Sequoia sempervirens* of the family Taxodiaceae. It is hoped that these structural studies may be useful in establishing a chemotaxonomic classification amongst the order Coniferales since it is considered (2) that the family Cupressaceae is more highly evolved than the Pinaceae. Certain aspects of the hemicelluloses of western red cedar have been examined previously (4) but no complete study has been made of these polysaccharides.

Western red cedar sawdust was solvent extracted, delignified (5), and extracted sequentially with potassium and sodium hydroxides (6) to give a mixture of xylan and galactoglucomannan (GGM) and a substantially pure glucomannan (GM). Each fraction was delignified at room temperature with buffered sodium chlorite (7) and precipitation with barium hydroxide was used to separate the xylan and GGM and to purify the GM (6, 8). The yields, on an ash-free basis, of xylan, GGM, and GM were 4.0, 1.5, and 6.4% of the wood. An attempt was made to separate the xylan and GGM on a column of DEAE-cellulose in the carbonate form (9) with several different eluents but no resolution was obtained except for a small quantity of degraded cellulose. The use of an ion-exchange column (10, 11) was similarly unproductive.

The arabino-4-*O*-methylglucuronoxylan had an equivalent weight of 775 and a molecular weight (12) of about 17 000, corresponding to a d.p. of 110, $[\alpha]_D$ $-36°$ (*c* 1.5, water), and the neutral sugars comprised 91% xylose and 5% arabinose with the balance being hexoses. The relatively high proportion of uronic acid was confirmed by analysis of the carboxyl reduced polymer (13) which gave the ratio of xylose:4-*O*-methylglucose as 4.5:1. An equivalent weight of 775 corresponds to approximately 27% uronic acid. The acidic component was characterized by the isolation of the crystalline aldotriouronic acid (14) 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-β-D-xylopyranosyl-D-xylose after partial hydrolysis.

Fractionation of the fully methylated (15, 16) xylan gave a main fraction having 38.6% methoxyl and which, on hydrolysis, gave the components shown in Table 1. These figures suggest a chain length of 20 while the data (Table 1) on the reduced methylated xylan indicate a value of about 15. This xylan must therefore have a small degree of chain branching in addition to the single unit pendant groups. This was substantiated by periodate oxidation of the xylan when a significant amount of ethylene glycol was obtained in addition to glycerol and xylose.

The separation of the methylated sugars shown in Table 1 is conveniently made by g.l.c. using alditol acetates but since the 2- and 3-*O*-methylxylitol acetates are inseparable it has been necessary to use some other system to resolve this pair of compounds. We have drawn attention (17) to the fact that 3-*O*-methylxylitol is achiral and the percentage in a mixture with the 2-isomer may be determined by measurement of the $\Delta\varepsilon$ value of the c.d. spectrum of the mixture of alditol acetates. Alternatively, the chemical shift in p.m.r. spectroscopy of the *O*-methyl group is different for the two alditols: 2-methylxylitol tetraacetate, τ 6.55; 3-isomer, τ 6.40. Thus integration of the signals permits a quantitative analysis. In this manner the monomethylxylitol tetraacetate fraction isolated by g.l.c. was shown by both c.d. and p.m.r. to contain the 2- and 3-methyl derivatives in the ratio of 1:2.

Purified galactoglucomannan (GGM_5) had $[\alpha]_D$ −3.8° (*c* 1, water), mol. wt. 9000 (d.p. 55), and a hexose content of 90%. The mannose:glucose:galactose ratio was 8:2:1 and from the methylated polysaccharide the sugars shown in Table 2 were obtained. The small proportion of tetramethyl sugars indicates the essential linearity of this polysaccharide, a result confirmed by periodate oxidation which yielded mainly glycerol and erythritol.

The glucomannan had $[\alpha]_D$ −38° (*c* 0.4, 2 *N* sodium hydroxide) and on hydrolysis the ratio of mannose:glucose:galactose was approximately 4:1:0.1. The components shown in Table 2 were obtained from the methylated polysaccharide. The results confirm the small amount of D-galactose in the GM and show that

For personal use only.

little branching is possible, a conclusion substantiated by the fact that periodate degradation gave almost exclusively erythritol. The poor solubility of the GM in methyl sulfoxide, and hence the failure of the initial Hakomori methylation, is almost certainly due to incomplete removal of barium ions (6).

The advantages of separating certain methylated sugars as their acetates has been discussed elsewhere (18) but it may be noted that this technique, when employed here, permits the demonstration that the chains of GGM are terminated preferentially by D-mannose units whereas the chains of GM are primarily terminated with D-glucose residues. In the analysis of each of the methylated polysaccharides the amount of di- (or mono-) methyl sugars always greatly exceeded that required by the amount of tetra- (or tri-) methyl sugars isolated. It has been shown (19) that undermethylation by only 0.5% will result in 3.9% higher dimethylhexose content in the hydrolyzate but also, and perhaps less obviously, that hydrolysis under different conditions of the same methylated polysaccharide gives widely different ratios of tetra- to dimethyl (tri- to mono-) sugars (20). The advent of g.l.c. has facilitated the determination of minor components in a mixture but has also thrown into sharp focus the dangers of attempting to distinguish between n and $n + 1$ branch points.

When the data of Table 2 are used to deduce the ratio of the three hexoses present in each of the GM and GGM and these values are compared to those obtained from the original polysaccharides it will be noted that fair agreement is obtained in the case of the GM but that there is a significant difference in the case of the GGM. It has been pointed out elsewhere (20) that the conventional solvent extraction of a methylated polysaccharide may give fractions in which the sugar ratio differs greatly. This suggests that these fractions which, for convenience, are called xylans, GGM's, and GM's are, in fact, mixtures of related polysaccharides.

It has been shown (21), in the case of bacterial polysaccharides, that p.m.r. spectroscopy is most useful in determining the relative number of α and β linkages in such materials. The accepted (1) structures for galactoglucomannans have the glucose and mannose joined by β-D-linkages with the galactose linked in an α-configuration. Similarly, in xylans the xylose units have β-D-linkages with the arabinose and 4-*O*-methylglucuronic acid joined by α-glycosidic bonds. It should therefore be possible to distinguish the relative number of such linkages as in the case of the bacterial polysaccharides. However, when this p.m.r. technique was applied to such hemicelluloses no discrete peaks were obtained in the spectral region associated with anomeric protons. In like manner, gel filtration of hemicelluloses does not give sharp peaks but diffuse bands. All of the present evidence, and particularly that obtained from p.m.r. spectroscopy, suggests that these hemicelluloses are indeed mixtures of related polysaccharides. It seems likely that in the area of hemicellulose chemistry no one has yet studied a pure polysaccharide in the true sense of the word.

In so far as one is entitled to draw conclusions from the above results it would seem that the general nature of the hemicelluloses of western red cedar is similar to that of other conifers. The amount of xylan appears to be relatively high and that of GM to be on the low side but the figures cited (1) for other genera are sufficiently varied that generalization is difficult. In the xylan the percentage of uronic acid is on the high side while that of arabinose is definitely lower than for many of the Pinaceae (1) and these observations may prove to be characteristic of the Cupressaceae.

Experimental

General Methods

Melting points were taken between glass slides on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer model 141 polarimeter at 23 ± 1°. Gas–liquid partition chromatography was carried out using an F & M 720 instrument equipped with a thermal conductivity detector. Peak areas were determined with an Infotronics CRS-100 electronic integrator. The following column and operating conditions were used: 8 ft × 1/4 in. 3% ECNSS-M on 60–70 mesh Chromosorb W (non-acid washed) with a helium flow rate of 75 ml/min. For alditol acetates the program was 170° for 10 min, then to 220° at 2°/min; for aldose acetates 150 to 210° at 2°/min; for periodate oxidation products 130 to 180° at 2°/min. All sugar analyses were by g.l.c. of alditol acetates. Paper chromatographic separations were carried out on Whatman No. 1 paper using the following solvent systems: *A*, ethyl acetate – pyridine – water (8:2:2) for 24 h; *B*, butanone–water azeotrope for 5–8 h; *C*, butanol–ethanol–water (4:1:5) for 24 h; *D*, ethyl acetate – acetic acid – formic acid – water (18:3:1:4) for 24 h. Separations were visualized using silver nitrate in acetone for non-reducing compounds (22) and *p*-anisidine hydrochloride spray for reducing sugars (23); R_G indicates with respect to 2,3,4,6-tetra-*O*-methyl-D-glucose. All evaporations were carried

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

out under reduced pressure below 40°. I.r. spectra were run in carbon tetrachloride solution at a concentration of about 10%. All hydrolyses were done with trifluoroacetic acid (2 *M*) at 100° for 4 h unless otherwise noted (24). Samples for mass spectral analysis were collected in capillary tubes from the gas chromatograph (25). Demethylations were carried out using boron trichloride (26). Solutions of dimethylsulfinyl anion used for methylations (15, 16) were assayed as described for the methylation of the glucomannan.

Molecular Weight Determinations

Molecular weight determinations were carried out using gel permeation chromatography (12). A polyethylene column (1.15 × 86 cm) of Bio-Gel P-300 (Bio-Rad Laboratories), treated with dichlorodimethylsilane and equipped with a suction pump, was used. Sodium chloride (*M*) was used as eluant. Carbohydrate material was assayed by the phenol – sulfuric acid method (27). Both xylan and galactoglucomannan samples gave broad maxima, indicating a wide distribution in molecular weights. The figures quoted are weight averaged molecular weights but these values should only be considered approximate since the column was calibrated with a series of dextrans (12) which have different exclusion volumes to hemicelluloses.

Circular Dichroism Measurements

Circular dichroism (c.d.) measurements were carried out using a JASCO J-20 instrument as described elsewhere (17) by observing the acetoxy chromophore of alditol acetates. By this means, it was shown that all mannose and glucose residues are of the D series, while all arabinose residues are of the L series. Galactose and xylose were also shown to be of the D series, since their partially methylated derivatives gave c.d. curves corresponding to authentic 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-galactitol and 1,3,4,5-tetra-*O*-acetyl-2-*O*-methyl-D-xylitol, respectively.

Isolation of Western Red Cedar Holocellulose

Samples of western red cedar were ground to sawdust in a Wiley mill and extracted batchwise (750 g) with methanol (2 l) in a Soxhlet extractor for 12 h. Extracted sawdust (225 g, moisture 5%) was delignified by treatment with sodium chlorite and acetic acid (5); 2-octanol was used to suppress foaming. After air drying the yield of holocellulose was 154 g (72%, residual Klason lignin 3%).

Extraction of Western Red Cedar Holocellulose with Alkali

Holocellulose (140 g) was extracted with potassium hydroxide (24%, 1500 ml) under nitrogen (28). The mixture was shaken for 6 h and allowed to stand overnight. Filtration and washing, followed by precipitation into ethanol (6 l) containing an excess of glacial acetic acid (1 l) and drying by solvent exchange (ethanol – acetone – petroleum ether), yielded the potassium hydroxide extract (19.7 g, 10.2% of wood, ash 12.5%). G.l.c. gave xylose 75%, mannose 12.8%, arabinose 5.4%, galactose 3.8%, and glucose 3.0%.

The solids remaining after potassium hydroxide extraction were similarly extracted with sodium hydroxide (17.5%) containing boric acid (4%) (1500 ml) (29). After precipitation into ethanol – acetic acid and drying by solvent exchange, the hemicellulose was obtained (14.1 g, 7.3% of wood, ash 8.6%). G.l.c. gave mannose 71.5%, glucose 19%, xylose 4.1%, galactose 2.8%, and arabinose 2.6%.

Fractionation of the Potassium Hydroxide Extract

The potassium hydroxide extract (18.1 g) was suspended (7) in sodium chlorite (100 g/l, 150 ml) buffered with sodium acetate (5 g) and glacial acetic acid (10 ml). After stirring for 22 h the solution was centrifuged to remove a small amount of insoluble material, precipitated into 4 volumes of ethanol acidified with glacial acetic acid, recovered, and dried by solvent exchange (16.3 g). The material was then dissolved in water (150 ml), potassium hydroxide (20%, 150 ml) was added, and barium hydroxide (5%, 1100 ml) was added over 2 h with vigorous stirring. The precipitate was recovered by centrifugation, dissolved in acetic acid (50%, 50 ml), and reprecipitated into ethanol (200 ml). After drying by solvent exchange, polysaccharide GGM_1 was obtained (4.4 g, ash 44.2%). The supernatant remaining after barium hydroxide addition was concentrated to 500 ml, then precipitated into ethanol (2 l) containing an excess of glacial acetic acid (200 ml). After drying, polysaccharide X_1 was obtained (11.2 g, ash 29.2%).

Purification of Arabinoglucuronoxylan

A portion of X_1 (10.1 g) was suspended in water (200 ml), then sodium hydroxide (17.5%) and boric acid (4%) (200 ml) were added. A small amount of insoluble material was removed by centrifugation. Barium hydroxide (5%, 800 ml) was then added dropwise with stirring. The precipitate formed was recovered by centrifugation to yield X_2 (0.40 g). Paper chromatography in solvent *A* of this fraction showed the presence of substantial amounts of hexose and the fraction was not further examined. The supernatant was poured into 3 volumes of ethanol, the precipitate was recovered by centrifugation, dissolved in ice-cold acetic acid (50%, 50 ml), then reprecipitated into 2 volumes of ethanol, and recovered by centrifugation to yield X_3 (7.85 g, $[\alpha]_D$ −36° (*c* 1.5, water), ash 0.4%, equiv. wt. 775 by titration, mol. wt. 17 000). Paper chromatography of X_3 hydrolyzate indicated a high pentose to hexose ratio. G.l.c. gave xylose 91%, arabinose 5.1%, mannose 1.7%, glucose 1.2%, and galactose 1%.

Methylation of Arabinoglucuronoxylan

A sample of X_3 (1.50 g) after dialysis overnight, deionization, freeze drying, and drying *in vacuo* for 24 h at 40°, was methylated in dry dimethyl sulfoxide (30 ml) with methylsulfinyl anion (1.5 *M*, 30 ml) and methyl iodide (6.5 ml). After 1½ h reaction time the solution was poured into water and the precipitate formed was removed by spatula, dissolved in chloroform (50 ml), extracted three times with water (25 ml), then evaporated to dryness (1.1 g). Fractionation with petroleum ether (30–60°) and chloroform (v/v) gave: fraction 1 (90:10), 56 mg; fraction 2 (80:20), 316 mg; fraction 3 (75:25), 600 mg, $[\alpha]_D$ −22.2° (*c* 1, chloroform), OMe 38.6%, no i.r. absorption at 3400 cm^{-1}.

Characterization of Component Sugars

Paper chromatography of the hydrolyzate of fraction 3 in solvents *B* and *C* showed five components which were tentatively identified by comparison with standards.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

More positive identification and quantitative determination were achieved by g.l.c. of the alditol acetates (30), including co-chromatography with standards, and by mass spectrometry (31, 32).

Component **1** (15 min) was identified as 2,3,5-tri-*O*-methyl-L-arabinose (0.03 mol) and component **2** (20 min) as 2,3,4-tri-*O*-methyl-D-xylose (0.12). The principal constituent was component **3** (31 min) characterized as 2,3-di-*O*-methyl-D-xylose (1.0). The mass spectrum of components **4***a* and *b* (43 min, 0.15 mol) was consistent with that to be expected from a mixture of the alditol acetates of 2- and 3-monomethylpentitols. Collection (25) of this fraction from the g.l.c. and solution of 7 mg in 0.4 ml of 99.8% D_2O gave a p.m.r. spectrum (60 MHz) showing $-OCH_3$ signals at τ 6.40 (3-*O*-methylxylitol) and τ 6.55 (2-*O*-methylxylitol) in the approximate proportion of 2:1. The c.d. spectrum of pure 2-*O*-methyl-D-xylitol tetraacetate gives $\Delta\varepsilon_{212}^{MeCN}$ +0.37 whereas the 3-methyl derivatives has $\Delta\varepsilon = 0$. A solution of components **4***a* and *b* (1.1 mg) in acetonitrile (0.12 ml) had $\Delta\varepsilon_{212}^{MeCN}$ +0.13 hence the mixture contains 35% of 2-*O*-methyl-D-xylitol tetraacetate.

Periodate Oxidation of Arabinoglucuronoxylan

X_3 (157.3 mg) was reacted with sodium metaperiodate (0.0488 *M*, 50 ml) at 5° in the dark. The periodate uptake was initially rapid becoming essentially constant (1.10 mol/sugar unit) after 1 week. Iodate and excess periodate were destroyed by the addition of ethylene glycol (0.5 ml); the solution was dialyzed overnight, then reduced with sodium borohydride (130 mg). After neutralization with glacial acetic acid, hydrolysis with trifluoroacetic acid (2 *N*, 10 ml, 6 h) at room temperature, and distillation four times with methanol, paper chromatography in solvents *A* and *D* showed the presence of a large amount of xylose. After a further reduction with sodium borohydride (20 mg), g.l.c. of the alditol acetates showed the presence of three major components, which cochromatographed with the peracetates of ethylene glycol, glycerol, and xylitol, together with a small peak due to an unidentified component.

Isolation and Identification of the Aldotriouronic Acid

A sample of X_3 (0.5 g) was hydrolyzed for 1 h by refluxing in trifluoroacetic acid (2 *N*). After centrifugation, evaporation, and passage through columns of Amberlite IR 120 (H^+) resin and Duolite A-4 (OH^-) resin, the acidic fraction was eluted with 10% formic acid. Paper chromatography (solvent *D*) showed the presence of five spots with R_{xylose} 1.17, 0.87, 0.60, 0.48, and 0.24. The fraction with R_{xylose} 0.48 corresponded to that of the genuine aldotriouronic acid *O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-(1 → 2)-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylopyranose. Preparative paper chromatography in solvent *D* was used to isolate the acid (60 mg). The crystalline material had m.p. 175–177° (14) and $[\alpha]_D$ +50° (*c* 0.60, water). P.m.r. data (D_2O) of sodium salt: singlet τ 6.55 (OMe); 1 proton broad singlet τ 4.74 (H-1 of 4-*O*-methyl-α-D-glucopyranosyluronic acid); 1.5 proton doublets τ 5.43 and 5.40 (J = 7 and 8 Hz) (H-1 of non-reducing xylose and H-1 (β) of reducing xylose); 0.5 proton doublet τ 4.85 (J = 3 Hz) (H-1 (α) of reducing xylose).

Reduction of the Xylan

A portion of the xylan (200 mg) was reduced by the method of Dutton and Kabir (13). After freeze drying (yield 131 mg), the material showed no i.r. absorption in the carbonyl region. Paper chromatographic analysis (solvent *A*) of the hydrolyzate showed the presence of 4-*O*-methyl-D-glucose. G.l.c. examination of the hydrolyzate as alditol acetates on a column of 5% butanediol succinate (13) gave a pentose to 4-*O*-methyl-glucose ratio of 4.5–5:1.

The reduced xylan was methylated (16, 17) and on hydrolysis gave the components shown in Table 1.

Purification of Galactoglucomannan

Western red cedar GGM (18 g) was suspended in water (150 ml), potassium hydroxide (20%, 150 ml) added, and the mixture stirred for 0.5 h. The insoluble material was removed by centrifugation, dissolved in acetic acid (50%, 10 ml), precipitated into ethanol (50 ml), and dried by solvent exchange to yield GGM_4 (1.28 g). This fraction, as indicated by g.l.c., was enriched in pentoses and was not examined further. To the material soluble in potassium hydroxide, barium hydroxide (5%, 1 l) was added dropwise with stirring. The precipitate formed was centrifuged, redissolved in acetic acid (50%, 50 ml), precipitated into ethanol (200 ml), and dried by solvent exchange to yield GGM_2 (3.70 g). G.l.c. of the alditol acetates of this fraction showed a hexose to pentose ratio of 7:1. To the barium hydroxide supernatant, ethanol was added to give a flocculent precipitate (8) which was recovered by centrifugation and dried by solvent exchange to yield GGM_3 (3.78 g, $[\alpha]_D$ −15.8° (*c* 1.5, water). This fraction was shown by g.l.c. to have a pentose to hexose ratio of 3.5:1 and was not further examined.

GGM_2 (3.5 g) was suspended in water (125 ml), potassium hydroxide (20%, 125 ml) was added, and barium hydroxide (5%, 500 ml) was added dropwise with stirring. The precipitate was recovered by centrifugation to yield GGM_5 (2.50 g, $[\alpha]_D$ −3.8° (*c* 1, water), ash 0.75%, mol. wt. 8850). Further addition of ethanol yielded a flocculent precipitate GGM_6 (1.05 g), which was shown by paper chromatography in solvent *A* to be enriched in pentoses with respect to GGM_5. This fraction was not further examined.

Paper chromatography of GGM_5 hydrolyzate indicated a high hexose to pentose ratio. G.l.c. gave mannose 66%, glucose 16%, xylose 8.4%, galactose 8.0%, and arabinose 1.6%.

Methylation of Galactoglucomannan

A sample of GGM_5 (0.4 g) after deionization, freeze drying, and drying *in vacuo* at 50° for 24 h, was methylated in dry dimethyl sulfoxide (10 ml) with methylsulfinyl anion (1.5 *M*, 10 ml) and methyl iodide (5 ml). After 6 h reaction time, the solution was poured into water, dialyzed for 36 h against running tap water, and freeze dried (yield 380 mg). Fractionation, as for the methylated xylan gave a product (fraction 3, 80:20, 125 mg) having $[\alpha]_D$ −4.3° (*c* 1, chloroform) and showing no i.r. absorption at 3400 cm^{-1}.

Characterization of Component Sugars

Paper chromatography of the hydrolyzate of fraction 3 in solvents *B* and *C* showed the presence of six major components, the molar ratios of which are given in Table 2. Component **1** was resolved into **1***a* and *b* in the ratio 1:2 by chromatography of the aldose acetates (18) at 170°. All components co-chromatographed with authentic alditol acetate samples and had mass spectra

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

consistent with the assigned structures. In addition **3** and **4** were demethylated (26) and acetylated to give (g.l.c.) D-mannitol hexaacetate, m.p. 115–117° and D-glucitol hexaacetate, m.p. 95–97°. Other minor components, investigated only by mass spectrometry, were tentatively identified as two 2,6-di-*O*-methylhexitols and a 2,3,4-tri- and 2,3-di-*O*-methylpentitol, presumably from contaminating xylan.

Periodate Oxidation of Galactoglucomannan

Western red cedar GGM_5 (148.9 mg) was reacted with sodium metaperiodate (0.0488 *M*, 50 ml) at 5° in the dark. The periodate uptake was initially very rapid, becoming constant (1.28 mol/sugar unit) after 1 week. Iodate and excess periodate were destroyed by the addition of ethylene glycol (0.5 ml), the solution was dialyzed overnight, then reduced with sodium borohydride (150 mg). After neutralization with glacial acetic acid, deionization, hydrolysis with trifluoroacetic acid (2 *M*, 10 ml, 6 h) at room temperature, and distillation four times with methanol, paper chromatography in solvents *A* and *D* showed the presence of erythritol and glycerol. G.l.c. of the alditol acetates showed two major peaks, the faster co-chromatographing with glycerol triacetate (18 min), the slower with erythritol tetraacetate (36 min), m.p. 85°.

Purification of Glucomannan

Crude sodium hydroxide extract (9.0 g) was suspended in sodium chloride (100 g/l, 75 ml) buffered with sodium acetate (2.5 g) in glacial acetic acid (5 ml). After stirring for 18 h, the mixture was poured into ethanol (500 ml), washed three times with water (20 ml), then partially dried by solvent exchange. While still moist the solid was redissolved in sodium hydroxide (10%) and boric acid (4%) (250 ml) and a small amount of insoluble material was removed by centrifugation. Barium hydroxide (5%, 300 ml) was added dropwise with vigorous stirring. The precipitate was collected by centrifugation, washed twice with sodium hydroxide (5%, 20 ml), redissolved in ice-cold acetic acid (50%, 150 ml), precipitated into ethanol (500 ml), and recovered. Repetition of this procedure yielded GM_2 (5.80 g, $[\alpha]_D$ −38° (*c* 0.4, 2 *N* sodium hydroxide), ash 2.2%) (4). G.l.c. gave: mannose 77%, glucose 18.5%, galactose 1.6%, xylose 2.9%, and a trace of arabinose.

Methylation of Glucomannan

Purified GM_2 (1.5 g), after dialysis overnight, freeze drying, passage through a 200 mesh screen, and drying *in vacuo* at 55° for 17 h, was dispersed in dry dimethyl sulfoxide (50 ml) under dry nitrogen. Sodium hydride (57% oil dispersion, 3 g) was washed free of oil with dry petroleum ether (30–60°), then reacted with dry dimethyl sulfoxide (30 ml) for 4 h at 50–60°. Titration of this reagent with sulfuric acid (0.5 *M*) showed a strength of 2.6 *M*; however, titration with formanilide using triphenylmethane as indicator gave a strength of only 1.2 *M*. The methylsulfinyl ion (25 ml) was then added at room temperature to the polysaccharide suspension. Little gel formation occurred; the reaction mixture was stirred overnight under nitrogen. Methyl iodide (4 ml) was added over 10 min at 10°, the reaction allowed to proceed for 3 h, then poured into water, dialyzed for 48 h, and recovered by freeze drying. The material was insoluble in chloroform and thus a Haworth methylation was carried out using sodium hydroxide (30%, 125 ml) and methyl sulfate (60 ml) with addition of sodium hydroxide (5 g) and methyl sulfate (5 ml) hourly for 7 h. After stirring overnight at 0°, the mixture was neutralized with sulfuric acid (*M*), dialyzed, and the polysaccharide (1.4 g) recovered by freeze drying. A second Hakomori methylation was then carried out to yield fully methylated polysaccharide (1.1 g).

Fractionation with petroleum ether (30–60°) and chloroform (v/v) gave: fraction 1 (90:10), 0.128 g, $[\alpha]_D$ −17.5° (*c* 1, chloroform); fraction 2 (80:20), 0.657 g, $[\alpha]_D$ −23.8°, OMe 44.6%; fraction 3 (75:25), 0.344 g, $[\alpha]_D$ −23.1°, OMe 43.0%. Fractions 2 and 3 did not show any i.r. absorption at 3400 cm^{-1}.

Characterization of Component Sugars

Paper chromatography in solvents *B* and *C* of the hydrolyzate of fraction 2 showed the presence of six major components, the molar ratios of which, as determined by g.l.c. of the alditol acetates, are given in Table 2.

Component **1** (30 min) was readily shown to be a mixture of the derivatives of 2,3,4,6-tetra-*O*-methyl-D-glucose (**1***a*) and 2,3,4,6-tetra-*O*-methyl-D-mannose (**1***b*) in the ratio of 8.1:1 by chromatography of the aldose acetates (18) isothermally at 170°.

All components, as their alditol acetates, co-chromatographed with authentic samples and gave mass spectra consistent with their assigned structure. In addition **3** and **4** were demethylated (26) and acetylated to give (g.l.c.) D-mannitol hexaacetate, m.p. 119–121° and D-glucitol hexaacetate, m.p. 95–96°, respectively. Several very minor components were also detected as noted for the methylated GGM.

Periodate Oxidation of Glucomannan

Purified GM_2 (149.2 mg) was reacted with sodium metaperiodate (0.0483 *M*, 100 ml) at 5° in the dark. The periodate uptake was initially very rapid, becoming constant (0.81 mol/sugar unit) after 1 week. Iodate and excess periodate were destroyed with ethylene glycol (0.5 ml), the solution was dialyzed overnight, and reduced with sodium borohydride (150 mg). After neutralization with glacial acetic acid, hydrolysis with trifluoroacetic acid (2 *M*, 20 ml, 7 h) at room temperature, distillation four times with methanol, and deionization, paper chromatography in solvents *A* and *B* showed the presence of erythritol and faint spots corresponding to mannitol and glycerol.

Periodate oxidation products (50 mg) were acetylated with acetic anhydride (1 ml) and sodium acetate (10 mg) for 1 h at 100°. G.l.c. gave two major peaks which co-chromatographed with glycerol triacetate (12 min) and erythritol tetraacetate (27 min), m.p. 85°.

The authors thank the National Research Council of Canada for financial support and for the award of a scholarship to N.A.F. We appreciate the assistance of Mr. G. M. Barton in obtaining the wood and preparing the sawdust.

Gas–Liquid Chromatography – Mass Spectrometry of Permethylated Aldosyl Aldonates

JOHN N. C. WHYTE

Fisheries Research Board of Canada, 6640 N.W. Marine Drive, Vancouver 8, British Columbia

Received April 30, 1973

Oxidation of neutral disaccharides yielded aldosyl aldonic acids which were methylated and separated by g.l.c. and subjected to mass spectrometry. The electron-impact fragmentation patterns afforded by these derivatives discriminated between (1 → 3), (1 → 4), and (1 → 6) linked residues and differed from that postulated for (1 → 2) intermolecular bonds. Primary scission of the aldonate moieties provided for the ionized hexosyl containing fragments which formed the high mass diagnostic peaks in these spectra. The mass spectra exhibited by the oxidized products could be correlated to those obtained from reduced, permethylated pseudoaldobiouronic acids.

L'oxydation de disaccharides neutres a conduit aux acides aldosyl aldoniques qui furent méthylés et séparés par c.g.l. pour ensuite être analysés par spectrométrie de masse. Les pics de fragmentation obtenus à l'aide de l'impact électronique de ces dérivés ont permis de choisir entre les résidus liés de manière (1 → 3), (1 → 4) et (1 → 6) et sont différents de ceux appartenant aux liens intermoléculaires (1 → 2). La première cassure des unités aldonates explique la présence de fragments renfermant des unités hexosyles ionisées qui forment la région des pics d'identification de ces spectres. Les spectres de masse obtenus des produits oxydés peuvent être reliés à ceux obtenus à partir des formes réduites des acides pseudoaldobiouroniques perméthylés. [Traduit par le journal]

Introduction

In the determination of the structural features of oligosaccharides by mass spectrometry a variety of derivatives have been employed. The spectral analyses of the derived peracetates (1), *N*-arylamine peracetates (2), *N*-phenylosotriazole peracetates (3), and 1-phenylflavazole peracetates (4) have been used to assess the molecular weight, the sequence of monosaccharide units, and in some cases the position of the glycosidic linkages in the parent oligomers. Similarly the derived pertrimethylsilyl ethers (5, 6) and corresponding alditol pertrimethylsilylates (7) of oligosaccharides have provided fragmentation patterns which, when coupled with analyses of peak intensity ratios, established most of the glycosidic linkages in the molecules (8). In contrast to the above derivatives which provided spectra with diagnostic peaks of low intensity and high mass, the permethylated derivatives offered fragmentation patterns of much lower mass units, thus facilitating the use of lower resolution instruments. The mass spectra of permethylated disaccharides have discriminated between (1 → 2), (1 → 4), and (1 → 6) linked residues (9). To distinguish between (1 → 3) and (1 → 4) linked moieties the corresponding permethylated alditols were investigated (10) employing sodium borodeuteride for the reduction stage, since without deuterium labelling the derivatives were too symmetrical for the electron-impact fragmentation pattern to be meaningful. In our studies (11), however, we have found that the relatively low abundance of the few diagnostic peaks in these spectra, together with the incomplete shift to one higher mass unit of those ions incorporating deuterium, do not allow for unequivocal assignment of the (1 → 3) and (1 → 4) glycosidic linkages in disaccharides.

This study on the mass spectrometry of permethylated aldosyl aldonates, where oxidation of the neutral disaccharides afforded nonsymmetrical structures, was an attempt to obviate the identical fragmentation patterns associated with those previously cited derivatives. In addition, the results of this study could also be correlated to the mass fragmentation patterns provided by the permethylated derivatives of reduced pseudoaldobiouronic acids.

Experimental

Commercial samples of maltose, cellobiose, lactose, isomaltose, and melibiose were used. Laminaribiose was obtained from the partial hydrolysate of laminaran (12) by separation on a charcoal column (13) and sodium

*Reference standard.

2-*O*-α-D-mannopyranosyl-D-glycerate was isolated from the red seaweed *Rhodomela larix* (14).

G.l.p.c. was carried out using a Hewlett-Packard 5750 gas chromatograph with hydrogen flame detectors and fitted with columns (180 × 0.45 cm) packed with (*a*) 10% SE30 (w/w) on DMCS treated Chromosorb W (60–80 mesh), (*b*) 1.5% XE60, 1.5% EGS (w/w) on DMCS treated Chromosorb W (60–80 mesh), (*c*) 3% QF1 (w/w) on Gas Chrom Q, and (*d*) 1% OV-17 (w/w) on Gas Chrom Q. Development was made with nitrogen at a flow rate of 60 ml/min at the column temperature specified and retention times are quoted relative to permethylated maltitol. The mass spectrometer, Nuclide 12-90G, was operated at a source temperature of 240° and an ionization potential of 70 eV.

To the disaccharide (20 mg) in water (20 ml, 0°) containing barium carbonate (100 mg) was added bromine (0.1 ml) and the mixture shaken, then stored 24 h in the dark at room temperature. Excess bromine was removed by aeration and the mixture reduced to half volume by evaporation in a round bottom flask on a rotary evaporator. Neutral red indicator was added to the mixture at 0° followed by the dropwise addition of aqueous barium hydroxide at 0° to maintain an orange coloration (p*H* 8.0) for a period of 2.5 h. Carbon dioxide was then passed into the mixture to p*H* 7.0 and the barium salts dried by evaporation with the last traces of water being removed on a high vacuum pump. Dry distilled methyl sulfoxide (10 ml) was introduced into the nitrogen-flushed flask through a rubber septum (15) followed by a solution of methylsulfinyl carbanion in methyl sulfoxide (2 *M*, 10 ml) and the mixture ultrasonicated for 1 h. The resultant mixture after a further 1 h was solidified by cooling and methyl iodide (5 ml) added to complete the methylation. The reaction solution was poured into cold dilute aqueous acetic acid to minimize possible high alkalinity and the resultant mixture extracted with chloroform. The combined extracts were water washed, dried over anhydrous magnesium sulfate, and evaporated to yield the permethylated aldosyl aldonate which was dissolved in distilled ethyl acetate prior to injection on the g.l.c. using column *b*. Occasionally, in addition to the major component peak, some minor peaks were evident in the g.l.c. of these preparations.

Samples for spectroscopic analysis were collected at the exit port of the gas chromatograph by condensation in glass capillary tubes which were then inserted directly into the mass spectrometer.

Results and Discussion

Oxidation of the disaccharides with buffered bromine water yielded the barium salts of the aldonic acids together with the corresponding lactones. The latter were converted into the aldonic acid salts by mild treatment with dilute barium hydroxide and after thorough desiccation the combined oxidation mixture was methylated with the Hakomori procedure (16) to furnish the methyl esters and methyl ethers of the derived aldosyl aldonates.

The relative retention times on g.l.c. for these derivatives, together with the corresponding permethylated aldosyl alditols, are presented in Table 1. The aldonate derivatives had retention times significantly greater than the respective alditols, yet only the column with 3% QF1 as the stationary phase proved effective in separating discretely these two groups of derivatives. Thus, this would be the most versatile column for the separation and mass spectrometric study of pseudoaldobiouronic acid components present in the reduced, permethylated, partial hydrolysate of an acidic polysaccharide. The best separation within the group of alditols and

aldonates was provided by the mixed stationary phase 1.5% XE60 and 1.5% EGS and would be the obvious choice when dealing specifically with either of these groups of derivatives; the aldonate derivatives separated on this column provided the mass spectra presented in Table 2.

The electron-impact fragmentation pattern of a permethylated aldosyl aldonate can be considered to originate from the molecular ion (odd-electron ion radical) formed by abstraction of an electron from the oxygen atom in the pyranose ring or from an oxygen atom in one of the methoxyl groups of the acyclic moiety, then principally by subsequent homolytic fission of the adjacent bonds or by rearrangements involving conjugated electronic shifts in the pyranose ring to furnish even-electron carbonium ions.

The spectra of these aldosyl aldonate derivatives were devoid of molecular ions but had common ion fragments originating from scission at the glycosidic linkages. The ion of mass 219 for the hexose unit also provided, by subsequent elimination of one or two molecules of methanol, for the ions at *m/e* 187 (m* = 159.7) and 155. Further elimination and rearrangement mechanisms for this hexose moiety as outlined by Kochetkov and Chizhov (17) provided for the common ions at *m/e* 71, 73, 88 (base peak of all spectra), 101, and 111. The corresponding ion fragment at *m/e* 249 for the ionized aldonate moiety provided for the ions at *m/e* 217 and 185 by progressive loss of methanol.

Most of the high mass ions arose from the primary cleavage of the bonds in the aldonate

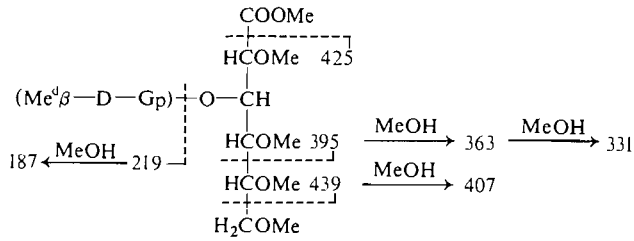
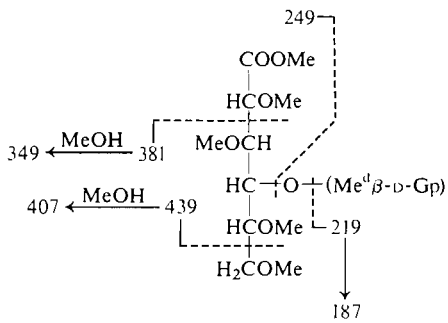


SCHEME 1

residues. As illustrated in Scheme 1, scission of the (1 → 3) linked permethylated laminaribionate allowed for the ions of mass 439[$M^{\ddagger}$ – $^{\bullet}CH_2OMe$], 425[$M^{\ddagger}$ – $^{\bullet}COOMe$], and 395[$M^{\ddagger}$ – $^{\bullet}CH(OMe).CH_2OMe$] which also provided, by progressive loss of the methanol molecules, for the ions at mass 407, 363, and 331.

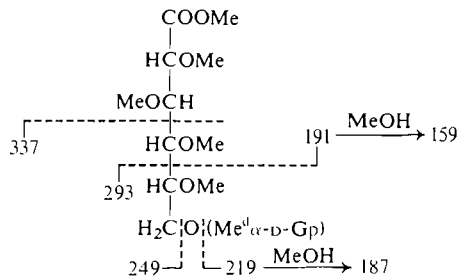
By similar bond cleavage in the acyclic moiety of the (1 → 4) linked permethylated cellobionate derivative, the diagnostic ions at *m/e* 381[$M^{\ddagger}$ – $^{\bullet}CH(OMe).COOMe$] and 349[$M^{\ddagger}$ – $^{\bullet}CH(OMe).COOMe$-MeOH] were formed from cleavage of the C_2—C_3 bond, as illustrated in Scheme 2. The ions at mass 439 and 407 which



SCHEME 2

are common to the spectra of (1 → 4) and (1 → 3) linked molecules were totally absent in the spectrum of the (1 → 6) linked derivatives and of the major diagnostic ions of mass 337 and 293, 191 and 159(191 – MeOH) were formed respectively by scission of the C_3—C_4 and C_4—C_5 bonds of the acyclic moiety of permethylated isomaltonate as shown in Scheme 3.

Common to all these spectra were the ions at *m/e* 351, 319, and 309 which were associated with rearrangement processes involving the hexose residue. Proof for the formation of these ions was presented by considering the simplified spectrum afforded by permethylated 2-*O*-α-D-mannopyranosyl-D-glyceric acid, Fig. 1. As out-



SCHEME 3

lined in Fig. 1, the sequence of conjugated electronic shifts gave rise to the ions of mass 177 and 251 which corresponded in the aldosyl hexonic acid series to the ions at 309 and 383 respectively, the latter ion by elimination of methanol providing the observable ion fragments in the spectra at *m/e* 351 and 319. Evidence that the ion at mass 309 originated from the fragment at *m/e* 383 was demonstrated by the presence of the metastable peak at *m/e* 249.3. The intense metastable peak at *m/e* 200.7 corresponded to the transition of the fragment of mass 309 affording by heterolytic bond cleavage,

MeO—CH=O—aldonate, the aldonate carbonium ion at *m/e* 249. This fragmentation pattern was corroborated by studying the mass spectra of permethylated aldosyl alditols where the metastable peak at *m/e* 187.2 confirmed the transition of the corresponding ion at *m/e* 295,

MeO—CH=O—alditol to the ionized alditol moiety at *m/e* 235.

It is evident from the fragmentation pattern of these derivatives that the hexosyl glycosidic linkage prevents cleavage of the adjacent carbon bonds in the aldonate residue and that this effect is negated progressively through the β and γ bond positions especially when the carbon atoms forming these bonds bear the electron donating methyl groups (18). It has been observed from

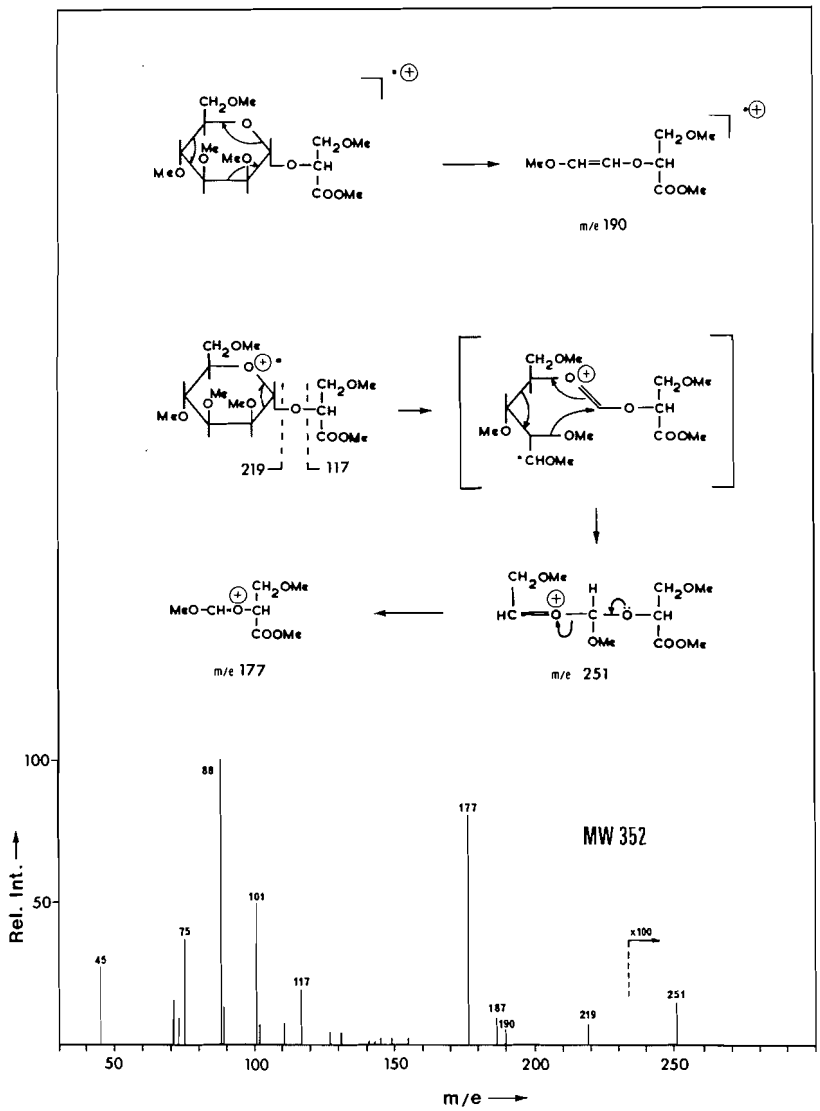

FIG. 1. Mass spectrum (70 eV) and mode of fragmentation of permethylated 2-*O*-α-D-mannopyranosyl-D-glyceric acid.

the fragmentation of permethylated aldonic acids (19) that the bonds adjacent to the ester group are more stable to electron impact than those adjacent to methoxyl groups. Thus it can be postulated that the mass spectra of (1 → 2) linked permethylated aldosyl hexonic acids would exhibit intense peaks at *m/e* 351 and 133 formed by the cleavage of the susceptible C_3—C_4 aldonate bond and minor peaks at *m/e* 395, 363(395 – MeOH), and 331(363 – MeOH) due to the cleavage of the extremely susceptible C_4—C_5 bond. Consequently it can be concluded that the mass spectra of (1 → 2), (1 → 3), (1 → 4), and (1 → 6) linked residues in permethylated aldosyl aldonates exhibit ions at *m/e* (395, 363, 331, and 133), (439, 425, 407, 395, 363, and 331), (439, 407, 381, and 349), and (337, 293, 191, and 159) respectively, which offer when collated diagnostic analyses of these derivatives.

These results indicated the utility of the oxidized permethylated derivatives of neutral disaccharides as eminently suitable derivatives for the mass spectrometric determination of the

position of the intermolecular bonds. As the mass spectra of stereoisomeric sugars are practically indistinguishable, the above results might be correlated to the linkage analyses by mass spectrometry of reduced permethylated pseudoaldobiouronic acids. Thus it is reasonable to assume that the (1 → 4) and (1 → 3) linked pseudoaldobiouronic acid derivatives would exhibit spectra identical to those provided by the (1 → 3) and (1 → 4) linked neutral disaccharide derivatives respectively.

The author is indebted to Mr. J. Love for mass spectral determinations.

Fluorine N.M.R. Spectra of Sulfur, Phosphorus, and Silicon Fluorides: Hydrolysis and Intra- and Intermolecular Mechanisms of Fluorine Exchange

JAMES ANDREW GIBSON, DAVID GEORGE IBBOTT, AND ALEXANDER F. JANZEN

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, R3T 2N2

Received February 15, 1973

The fluorine n.m.r. spectra of SF_4, $[(CH_3)_2CH]_2NSF_3$, $PF_5{:}O(C_2H_5)_2$, SiF_5^-, $SiF_5{:}NH_3^-$, and $SiF_5{:}HN(C_2H_5)_2^-$ have been recorded after treatment of glassware and reagents with $[(CH_3)_3Si]_2NH$ to remove H_2O and HF impurities. A mechanism of intramolecular and intermolecular fluorine exchange, involving Lewis acid – Lewis base interaction and rapid equilibration of five and six coordinate geometries, is proposed.

Les spectres r.m.n. du fluor pour le SF_4, $[(CH_3)_2CH]_2NSF_3$, $PF_5{:}O(C_2H_5)_2$, SiF_5^-, $SiF_5{:}NH_3^-$ et $SiF_5{:}HN(C_2H_5)_2^-$ ont éte enregistrés, après avoir traité la verrerie ainsi que les réactifs avec du $[(CH_3)_3Si]_2NH$ afin d'éliminer les impuretés attribuables à l'H_2O et au HF. On propose un mécanisme se rattachant à l'échange intramoléculaire et intermoléculaire du fluor, qui impliquerait une interaction acide de Lewis – base de Lewis ainsi qu'une équilibration rapide des géométries à cinq et six coordinats. [Traduit par le journal]

Can. J. Chem., **51**, 3203 (1973)

The stereochemistry and "rigidity" of trigonal bipyramidal molecules has received much attention in recent years and the rapid exchange of axial and equatorial fluorines in phosphorus, sulfur, and silicon fluorides has been explained by various mechanisms, in particular, Berry pseudorotation (1–3), as well as turnstile rotation (4), bimolecular exchange (5–7), collision activated exchange (8), solvent assisted exchange (9), impurity catalyzed exchange (*vide infra*) and others (10).

We have re-emphasized the role of trace amounts of water or hydrogen fluoride in exchange phenomena and demonstrated that the rate of fluorine exchange in $(CH_3)_3SiF$, $(CH_3)_2NSF_3$, and $(C_2H_5)_2NSF_3$ may be reduced by adding silicon–nitrogen compounds such as $(CH_3)_3SiNR_2$ or $[(CH_3)_3Si]_2NH$ which may reduce the concentration of H_2O and HF by chemical reaction (11–13). Additional evidence of the effect of these impurities on the n.m.r. spectra of sulfur, phosphorus, and silicon fluorides is now presented. The results are consistent with Lewis acid – Lewis base interactions and rapid equilibration of five and six coordinate geometries. The proposed mechanism distinguishes between inter- and intramolecular exchange of fluorine atoms.

Results and Discussion

Sulfur Fluorides

The fluorine n.m.r. spectrum of SF_4 has been reported previously by Cotton, George, and Waugh (14), Muetterties and Phillips (7), and Bacon, Gillespie, and Quail (15). The spectra were resolved at different temperatures, suggesting that impurities might be the cause of this discrepancy. The sensitivity of the n.m.r. spectrum of SF_4 to trace catalysts and the possibility of impurity catalyzed exchange was pointed out by Muetterties and Phillips (16). If these impurities are H_2O and HF, then treatment of SF_4 sample with silicon–nitrogen compounds should reduce the concentration of these impurities and further raise the temperature at which resolution is possible.

Silicon–nitrogen compounds react with SF_4, however, if a 2:1 molar ratio of SF_4 and $[(CH_3)_3Si]_2NH$ was used, about 30–40% unreacted SF_4 remained for n.m.r. studies. The volatile components of this reaction, consisting of unreacted SF_4, $(CH_3)_3SiF$, and SOF_2, along with solvent $CFCl_3$, were not separated since this led to loss of resolution, but were condensed into an n.m.r. tube which was sealed and kept at $-196°$ until required for n.m.r. studies. This method was repeated on at least four occasions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

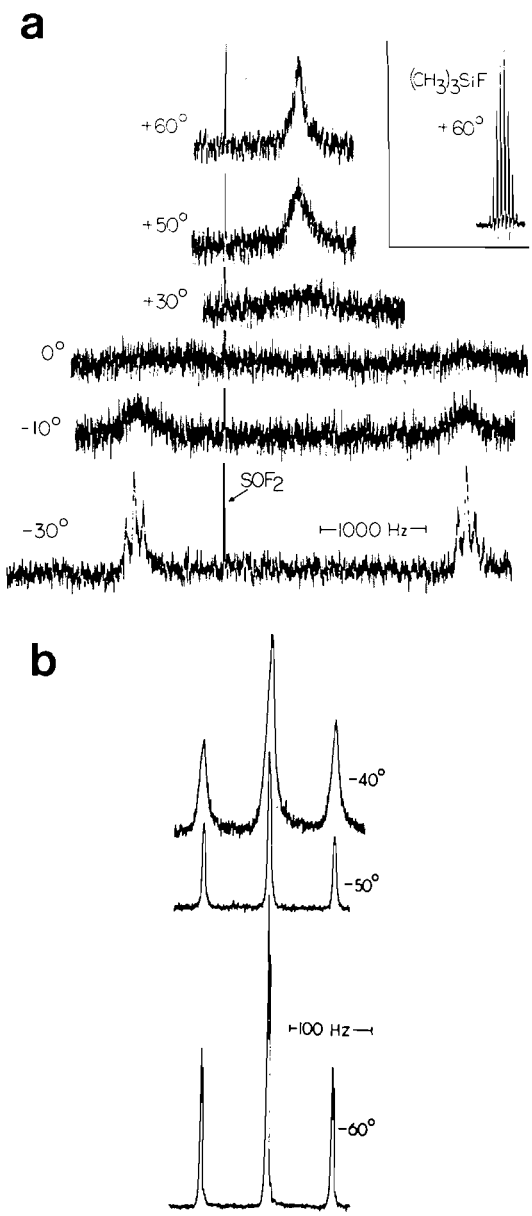

FIG. 1(*a*). Temperature dependent fluorine n.m.r. spectrum of SF_4 in $CFCl_3$ solvent. Sample contained SOF_2 (sharp singlet) and $(CH_3)_3SiF$ (dectet at upper right of figure). (*b*) Low temperature n.m.r. spectrum of SF_4 showing only high field multiplet of symmetrical spectrum, on expanded scale.

and in each case the temperature dependent spectra shown in Fig. 1*a* and 1*b* could be reproduced. Other techniques were unsuccessful. For example, repeating the above procedure with $(CH_3)_3SiN(C_2H_5)_2$ instead of $[(CH_3)_3Si]_2NH$, or treating glassware with $[(CH_3)_3Si]_2NH$ but omitting direct addition to SF_4, gave only poorly resolved spectra.

Once the sample is heated to $+60°$, then resolution is lost on re-cooling. Thus the triplets seen at $-30°$ in Fig. 1*a* do not re-appear until $-60°$, and the resolution seen at $-60°$ in Fig. 1*b* cannot be attained again. On the other hand, if SF_4 is treated with $[(CH_3)_3Si]_2NH$ and gaseous products stored in sealed n.m.r. tube, then after one month at room temperature the spectra of Fig. 1*a* and 1*b* may be reproduced. These results suggest strongly that only *in situ* reaction of $[(CH_3)_3Si]_2NH$ with trace amounts of H_2O and HF is sufficient to remove these contaminants, while transferring SF_4 in vacuum line or heating sample re-introduces contaminants.

The spectra of Fig. 1*a* and *b* may be compared with spectra published previously. The spectrum seen at $-60°$ (Fig. 1*b*) was observed by Gillespie and co-workers at $-90°$ and explained on the basis of an A_2B_2 system. The triplets seen at $-30°$ (Fig. 1*a*) were previously seen at $-60°$ (15), $-85°$ (7), and $-94°$ (14). The half-height width at $+60°$ is about 90 Hz, the same as reported by Muetterties and Phillips at $+23°$ (7). The half-height width increases slightly on raising the temperature to $+70°$, presumably due to more rapid introduction of contaminants. The coupling constants at $-60°$ are identical to those reported by Gillespie and co-workers at $-101°$, while the chemical shift is 3125 Hz, compared to 2935 ± 10 Hz for the neat sample (15).

An activation energy may be estimated from Fig. 1. By inspection, the temperature at which the axial and equatorial fluorines merge into a single peak occurs at about $+15 \pm 5°$, and the collapse of the triplets at about $-18 \pm 5°$. Calculation of τ at the two temperatures (17) gives $\tau = \sqrt{2}/2\pi(3125)$ and $\sqrt{2}/2\pi(78)$ and plot of $-\ln 1/\tau$ *vs.* $1/T$ gives $E_a = 16.3 \pm 5$ kcal/mol. This value for the activation energy may be compared with previous estimates of 4 ± 1 kcal/mol (14) and 4.5 ± 0.8 kcal/mol (17).[1] That a higher activation energy is observed after treatment of SF_4 sample with $[(CH_3)_3Si]_2NH$ supports our assumption that the concentration of H_2O and HF has been reduced and therefore the low energy impurity catalyzed pathway of fluorine exchange is no longer available. The value of E_a

[1]The results of Bacon, Gillespie, and Quail (15) imply an activation energy greater than 4 kcal/mol.

may represent only a lower limit to the uncatalyzed exchange process, since we cannot claim that all impurities have been removed, furthermore, the removal of H_2O and HF probably involves equilibrium processes for which the equilibrium constants have not been determined.

The mechanism of the uncatalyzed exchange reaction was not investigated, however, the n.m.r. spectra of Fig. 1*a* and 1*b* appear to rule out fluorine exchange of SF_4 with either SOF_2 or $(CH_3)_3SiF$ up to at least $+60°$ since, during the entire temperature run, the SOF_2 remained as a sharp singlet and $(CH_3)_3SiF$ as a well resolved dectet (J_{FH} = 7.5 Hz).

Previously, we reported the n.m.r. spectra of *N,N*-dialkylaminosulfur trifluorides, R_2NSF_3 where R = CH_3 and C_2H_5 (11). The analogous *N,N*-diisopropylamino derivative was prepared by eq. 1 and the n.m.r. spectrum recorded at

[1] $(CH_3)_3SiN[CH(CH_3)_2]_2 + SF_4 \rightarrow [(CH_3)_2CH]_2NSF_3 + (CH_3)_3SiF$

$-68°$, as shown in Fig. 2. A doublet, $J_{F^aSF^e}$ = 53 Hz, at -61.9 p.p.m. is assigned to the axial fluorines and the triplet, $J_{F^eSF^a}$ = 53 Hz, at -18.3 p.p.m. is assigned to the equatorial fluorine. Each component of the triplet appears to have triplet fine structure, with $J_{F^eSNCH} \sim 4$ Hz. Because of the similarity of chemical shifts and coupling constants to those of the *N,N*-dimethyl- and *N,N*-diethyl-analogs, the synthesis of $[(CH_3)_2CH]_2NSF_3$ was carried out only once and no attempt was made to improve the resolution of Fig. 2.

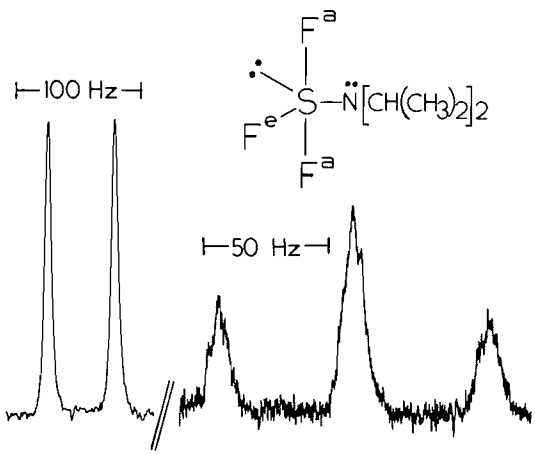

FIG. 2. Fluorine n.m.r. spectrum of $[(CH_3)_2CH]_2NSF_3$ at $-68°$.

Phosphorus and Silicon Fluorides

Since ^{31}P and ^{29}Si (natural abundance 4.67%) have spin 1/2, n.m.r. may distinguish between intermolecular and intramolecular fluorine exchange. Intermolecular exchange involves bond breaking and loss of P—F or Si—F coupling, whereas intramolecular exchange retains bonding and coupling. In the case of sulfur fluorides it is difficult to establish whether exchange is inter- or intramolecular since sulfur lacks a convenient spin.

An n.m.r. study of the diethylamine catalyzed hydrolysis of trimethylfluorosilane established that fluorine exchange occurs via an intermolecular mechanism with loss of ^{29}Si—F coupling

[2] $(CH_3)_3SiF + H_2O \rightleftarrows (CH_3)_3SiOH + HF$

(12). On the basis of the kinetics and rate expression, it appeared that one or two H_2O molecules may coordinate to $(CH_3)_3SiF$ in the transition state, prior to Si—F bond breaking. Therefore, depending on the symmetry of the molecule, a rapid pre-equilibrium involving water coordinated to the central atom may result in an observable intramolecular averaging of fluorine environments. If intramolecular exchange involving H_2O is too rapid on the n.m.r. time scale, perhaps other Lewis bases such as amines or ethers may slow down intramolecular exchange.

Phosphorus pentafluoride is known to form 1:1 complexes with a variety of Lewis bases such as ethers, sulfoxides, amines, amides, and esters (18–20). The structure of the PF_5:base complex was shown to be octahedral on the basis of the doublet–quintuplet fine structure observed in the ^{19}F n.m.r. In the case of $PF_5:O(C_2H_5)_2$, only a pair of doublets, but not the pair of quintuplets, was resolved at $-78°$, while on warming the pair of doublets merged into single peaks. Loss of fine structure, but retention of P—F coupling, as required for intramolecular fluorine exchange, was attributed to the rapid equilibrium (18).

[3] $PF_5 + \text{base} \rightleftarrows PF_5\text{:base}$

A re-investigation of the ^{19}F n.m.r. spectrum of $PF_5:O(C_2H_5)_2$ in excess diethyl ether (molar ratio 1:4) showed some improvement in resolution. As seen in Fig. 3, the pair of quintuplets assigned to F^a may be observed at $-65°$. On warming to $-40°$, the quintuplets become two broad peaks while at $-20°$ only a broadened doublet (P—F coupling) remains. The coupling constants at $-65°$ are J_{F^aP} = 745 Hz, J_{F^bP} = 790

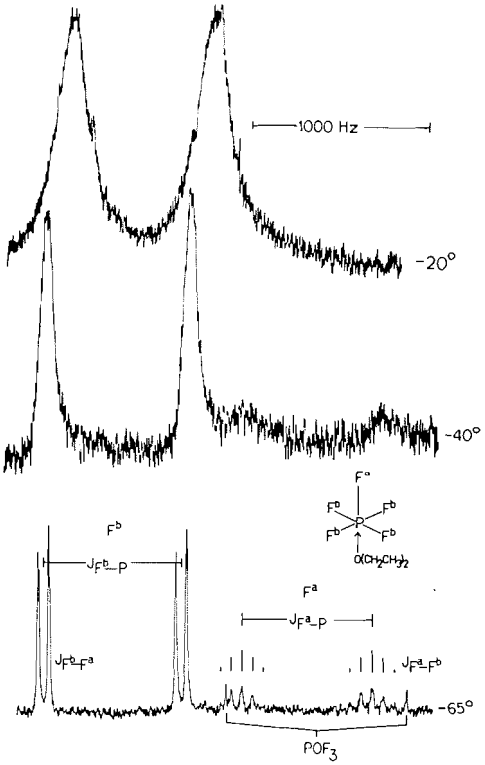

FIG. 3. Temperature dependent fluorine n.m.r. spectrum of PF_5:$O(C_2H_5)_2$ adduct. Sample contained some POF_3.

Hz, and $J_{F^aF^b}$ = 62 Hz, and the chemical shifts of F^b and F^a are +66.3 and +86.0 p.p.m., respectively. At −20° the averaged chemical shift is +69.6 p.p.m. and the averaged coupling constant J_{FP} = 820 Hz, The averaged values of the chemical shift and coupling constant at −20° are between the values of the weighted averages at −65° and free PF_5,[2] as required if the equilibrium of eq. 3 shifts to the left with increasing temperature.

An activation energy may be estimated from Fig. 3 (and other spectra not shown). The temperature at which axial and basal fluorines merge into a doublet occurs at about −30 ± 5°, and the loss of axial to basal fluorine coupling occurs at about −55 ± 5°, hence $\tau = \sqrt{2}/2\pi(1111)$ and $\sqrt{2}/2\pi(62)$ and E_a = 12.2 ± 5 kcal/mol.

In addition to the intramolecular fluorine exchange process of eq. 3, the spectrum shown in Fig. 3 provides evidence for an intermolecular process, in which P—F bond breaking occurs. This is demonstrated by the significant line broadening above −20°, which is most likely due to more rapid hydrolysis or decomposition of the PF_5 – diethyl ether solution at higher temperatures. Consistent with this view, it was found that line broadening is a function of time, for example, the half-height width increased from 55 to 150 Hz over a period of 85 min at +38°. This result would argue against self-ionization or bimolecular exchange as the mechanism of intermolecular fluorine exchange in these PF_5 – diethyl ether solutions.

The fluorine n.m.r. spectra of pentafluorosilicates have been reported by Klanberg and Muetterties (22) who found that SiF_5^-, $RSiF_4^-$, and $R_2SiF_3^-$ showed spectroscopic equivalence of fluorine atoms at room temperature, while $(C_6H_5)_2SiF_3^-$ showed axial and equatorial fluorines at lower temperature. It was suggested that the dominant exchange process for the equilibration of fluorine atom environments in SiF_5^- probably is intramolecular Berry pseudorotation; in addition the loss of F—^{29}Si coupling above −60° suggested an intermolecular mechanism, due either to a dissociative or associative (fluorine bridging) process. At the same time, Klanberg and Muetterties noted the influence of impurities on the n.m.r. spectra and, interestingly, proposed the existence of $CH_3SiF_4(H_2O)^-$.

Conclusive evidence that intermolecular fluorine exchange in SiF_5^- is due to hydrolysis is presented in Fig. 4. Figure 4*a* shows the fluorine n.m.r. spectrum of re-crystallized $(n\text{-}C_3H_7)_4N^+SiF_5^-$ in CH_2Cl_2 solvent at +38°. Since no F—^{29}Si coupling is observed, SiF_5^- must be undergoing rapid intermolecular fluorine exchange. Figure 4*b* shows the n.m.r. spectrum of the same sample after addition of $[(CH_3)_3Si]_2$-

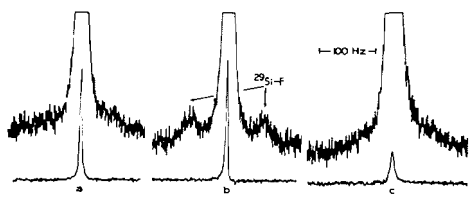

FIG. 4. Fluorine n.m.r. spectra at +38° of $(n\text{-}C_3H_7)_4N^+SiF_5^-$ in CH_2Cl_2 solution (*a*) untreated; (*b*) after addition of $[(CH_3)_3Si]_2NH$ (0.0062 g); (*c*) after addition of H_2O (0.001 g). The high amplitude spectra were obtained with fast sweep (4 Hz/s), high Rf power and high bandwidth (4 Hz) and without spinning of sample. Chemical shift of centre singlet peak is +136.7 p.p.m.

[2]The chemical shift of PF_5 is reported as +75.87 p.p.m. and J_{FP} = 916 Hz (7, 21).

NH. Now F—^{29}Si coupling (140 Hz) is clearly evident, hence intermolecular exchange has been slowed down. Introduction of H_2O results once more in loss of F—^{29}Si coupling, as seen in Fig. 4*c*. These results are entirely consistent with hydrolysis as the mechanism of intermolecular fluorine exchange.

[4] $$SiF_5^- + H_2O \rightleftarrows SiF_4OH^- + HF$$

While the evidence based on F—^{29}Si coupling shows that intermolecular exchange may be slowed down, the fact that all five fluorine atoms give a single peak at $+38°$ (and also at $-90°$) is proof that a lower energy intramolecular mechanism of exchange is still equilibrating axial and equatorial fluorines. If intramolecular exchange is due to Lewis acid – Lewis base interactions, then a variable temperature n.m.r. study of SiF_5^- and a suitable base might provide experimental evidence on this point.

Adducts of SiF_5^- are known. The enthalpies of dissociation of ammonia and amine adducts of tetraalkylammonium pentafluorosilicates have been determined by Wharf and Onyszchuk (23). Clark and co-workers concluded from infrared studies that a variety of Lewis bases form adducts SiF_5:base$^-$, where base is $(C_2H_5)_2NH$, $(C_2H_5)_3N$, $(n\text{-}C_3H_7)_3N$, C_5H_5N, and $(C_2H_5)_3P$ (24).

Ammonia was added to a solution of $(n\text{-}C_3H_7)_4N^+SiF_5^-$ in CH_2Cl_2 which was treated with $[(CH_3)_3Si]_2NH$. The molar ratio of NH_3 to SiF_5^- was 14:1.0. As seen in Fig. 5, the variable temperature n.m.r. spectrum shows a sharp single peak at $+123.6$ p.p.m. at $+24°$ which broadens on cooling and eventually splits into two components, a low field peak at $+118.6$ p.p.m. assigned to the four basal fluorines, F^b, and a peak at $+136.6$ p.p.m. assigned to the apical fluorine, F^a. The spectrum is reversible on warming the sample and the results are consistent with rapid equilibrium:

[5] $$SiF_5^- + NH_3 \rightleftarrows SiF_5{:}NH_3^-$$

This behavior is very similar to that of the PF_5 and $(C_2H_5)_2O$ system.

The equilibrium of reaction 5 involves intramolecular fluorine exchange and requires retention of F—^{29}Si coupling. This coupling could be observed at $+24°$ ($J_{F^{29}Si} = 120 \pm 5$ Hz), as well as at $-83°$ ($J_{F^a{}^{29}Si} = 120 \pm 10$ Hz and $J_{F^b{}^{29}Si} = 125 \pm 5$ Hz). Coupling between axial and basal fluorines is small, probably $J_{F^aF^b} \sim 3$ Hz. Klanberg and Muetterties found previously

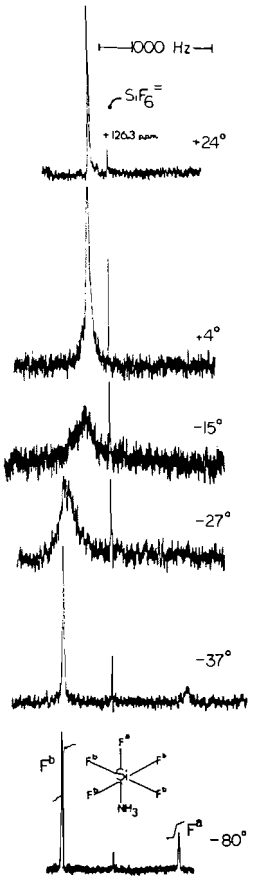

FIG. 5. Temperature dependent fluorine n.m.r. spectrum of $(n\text{-}C_3H_7)_4N^+SiF_5^-$ (0.11 g) and NH_3 (0.09 g) in CH_2Cl_2 solution (0.5 ml).

that coupling between axial and equatorial fluorines in $(C_6H_5)_2SiF_3^-$ is probably <5 Hz (22).

The temperature at which axial and basal fluorines merge into a single averaged peak is estimated, by inspection of Fig. 5, as $-20 \pm 5°$. Unfortunately, the temperature at which F^a—F^b coupling is lost could not be estimated because of the small coupling constant. In an attempt to observe coupling to nitrogen, the complex $SiF_5{:}^{15}NH_3^-$ was prepared, but the FSi—^{15}N coupling at low temperature was also small (<15 Hz) and partly obscured by FSi—^{15}NH coupling, hence an activation energy could not be calculated for the exchange process of reaction 5.

The behavior of the diethylamine adduct of SiF_5^- was studied and found to be similar to that of the ammonia adduct. The variable temperature n.m.r. spectrum of a solution containing 5.8:1.0 molar ratio of $(C_2H_5)_2NH$ to SiF_5^- is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

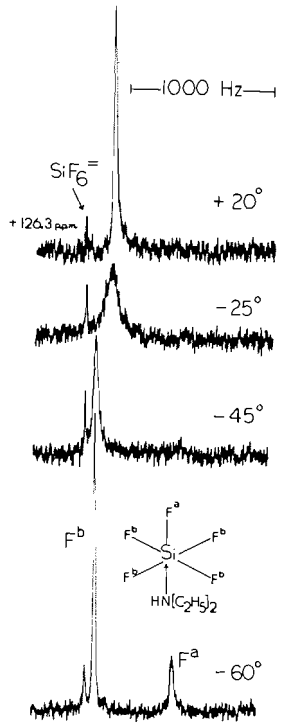

FIG. 6. Temperature dependent fluorine n.m.r. spectrum of $(n\text{-}C_3H_7)_4N^+SiF_5^-$ (0.077 g) and $(C_2H_5)_2NH$ (0.11 g) in CH_2Cl_2 solution (0.5 ml).

shown in Fig. 6. At +20° a single peak is observed at +129.8 p.p.m. which broadens and, on further cooling to −60°, splits into two components, a low field peak at +127.5 p.p.m. assigned to the basal fluorines and an upfield peak at +136.9 p.p.m. assigned to the apical fluorine. By inspection of Fig. 6, the temperature at which axial and basal fluorines merge is estimated as $-35 \pm 5°$.

Comparison of the chemical shifts of ammonia and diethylamine adducts at low temperature shows that the apical fluorines are in nearly identical positions, however, the basal fluorines vary, going from +118.6 p.p.m. for the ammonia adduct to +127.5 p.p.m. for the diethylamine adduct. In both cases, the chemical shift at room temperature is the weighted average of the low temperature spectrum, therefore the equilibrium involving SiF_5^- and base must be essentially to

[6] $$SiF_5^- + \text{base} \rightleftarrows SiF_5\text{:base}^-$$

the right, consistent with the large excess of base used, and changes in the position of equilibrium are not detected by changes in chemical shift.

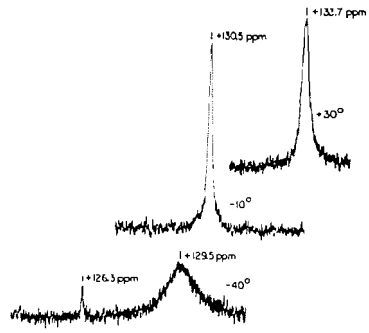

FIG. 7. Temperature dependent fluorine n.m.r. spectrum of $(n\text{-}C_3H_7)_4N^+SiF_5^-$ (0.11 g) and $(C_2H_5)_2NH$ (0.083 g) in CH_2Cl_2 solution (0.5 ml). Spectrum below −40° is identical to that of Fig. 6.

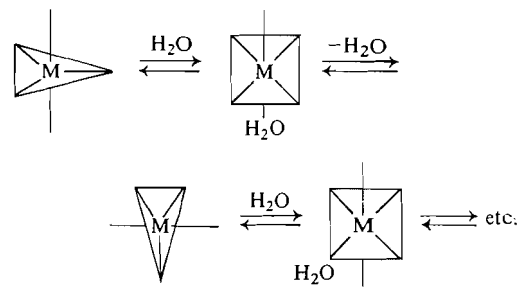
Such changes may be detected by reducing the molar ratio of $(C_2H_5)_2NH$ to SiF_5^- to 3.1:1.0. As seen in Fig. 7, the chemical shift varies from +133.7 p.p.m. at +30° to +129.5 p.p.m. at −40°. Below −40° the spectrum is identical to the low temperature region of Fig. 6. The equilibrium of reaction 6 therefore shifts to the left with increasing temperature, consistent with the behavior observed for the PF_5 and diethyl ether system.

Mechanism of Fluorine Exchange

A mechanism of fluorine exchange which describes the effect of trace amounts of H_2O and HF and distinguishes clearly between intermolecular and intramolecular fluorine exchange is summarized in reactions 7 and 8.

[7] $$R_xM\text{—}F + H_2O \rightleftarrows R_xM\text{—}OH + HF$$

[8]



Reaction 7 illustrates an equilibrium leading to intermolecular fluorine exchange with loss of coupling as the bond between fluorine and the central atom is broken.

Reaction 8 illustrates intramolecular exchange. Lewis bases such as H_2O, NH_3, $(C_2H_5)_2NH$, or $(C_2H_5)_2O$ may interact with Lewis acids such as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

PF_5, SiF_5^- etc., resulting in rapid interconversion between five and six coordinate geometries. The positions of the fluorine atoms are therefore averaged, but coupling of fluorine to the central atom is retained.

In the case of hydrolysis of reactive fluorides. Reaction 8 may be viewed as the first step of the reaction; a rapid pre-equilibrium involving coordination of water to the central atom, followed by elimination of HF, as in reaction 7.

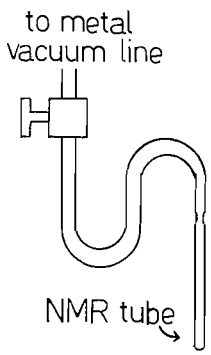
Experimental

General procedures have been described previously (11, 12). SF_4 (Matheson Co.), PF_5 (PCR, Gainesville), and $[(CH_3)_3Si]_2NH$ (Alfa) were purified by trap-to-trap distillation and stored in a metal vacuum system. Ammonia-^{15}N (99% isotopic purity) was purchased from Stohler Isotope Chemicals, Montreal. $(n\text{-}C_3H_7)_4NSiF_5$ was prepared and purified by the method of Clark and co-workers and characterized by its m.p. and i.r. spectrum (24). Diisopropylamine (6.0 g, 60 mmol) was dried over sodium and condensed onto $(CH_3)_3SiCl$ (2.5 g, 250 mmol); reaction occurred on warming to room temperature to give $(CH_3)_3SiN[CH(CH_3)_2]_2$, which was purified by distillation at $50°/10^{-3}$ cm and identified by ^1H n.m.r.: septet(H), $J = 6.7$ Hz at -2.9 p.p.m.; doublet(CH_3), $J = 6.7$ Hz at -0.7 p.p.m.; and singlet($(CH_3)_3Si$) at $+0.2$ p.p.m. Chemical shifts are relative to external tetramethylsilane.

N.m.r. spectra were recorded on a Varian A-56/60A spectrometer equipped with variable temperature probe, using 56.4 and 60 MHz for fluorine and proton, respectively. Temperatures were calibrated with the aid of a variable temperature *vs.* chemical shift chart (25). Fluorine chemical shifts are relative to internal $CFCl_3$.

Sulfur Tetrafluoride

The Pyrex U-tube, shown below, was treated with $[(CH_3)_3Si]_2NH$ by gently refluxing for several hours, then evacuated at 10^{-4} mm and flamed out. $[(CH_3)_3Si]_2NH$ (0.19 g, 1.2 mmol) and SF_4 (0.26 g, 2.4 mmol) were condensed into the U-tube at $-196°$. A vigorous



reaction occurred on warming to 25°. Only the volatile components of the reaction mixture, consisting of about 30–40% unreacted SF_4 as well as $(CH_3)_3SiF$ and SOF_2, identified by n.m.r. and mass spectral investigation, were condensed into the n.m.r. tube, along with solvent $CFCl_3$ (0.5 ml) and the n.m.r. tube sealed and kept at $-196°$ until required for n.m.r. study. Gaseous products were not separated since this led to loss of resolution. At the completion of the n.m.r. studies the n.m.r. tube was opened and SF_4 separated by trap-to-trap distillation and identified by i.r. and mass spectrometry.

N,N-Diisopropylaminosulfur Trifluoride

SF_4 (0.26 g, 2.4 mmol) was condensed onto $(CH_3)_3SiN[CH(CH_3)_2]_2$ (0.42 g, 2.4 mmol) in a U-tube at $-196°$ and allowed to react on warming to 25°, according to the procedure described previously for the analogous *N,N*-dimethyl- and *N,N*-diethyl- derivatives (11). The product, $[(CH_3)_2CH]_2NSF_3$, as well as $(CH_3)_3SiF$ and some SOF_2, were condensed into the n.m.r. tube along with solvent $CFCl_3$ (0.5 ml) and the spectrum recorded at $-68°$. $[(CH_3)_2CH]_2NSF_3$ was identified on the basis of the similarity of its ^{19}F n.m.r. spectrum to that of the *N,N*-dimethyl- and *N,N*-diethyl- analogs.

Phosphorus Pentafluoride – Diethyl Ether Complex

The $PF_5{:}O(C_2H_5)_2$ complex was prepared by condensing PF_5 (0.15 g, 1.3 mmol) and $(C_2H_5)_2O$ (0.43 g, 5.8 mmol) into a silylated (with $[(CH_3)_3Si]_2NH$) and flamed out n.m.r. tube, which was sealed and kept at $-196°$ until required for n.m.r. studies. The variable temperature n.m.r. spectrum of the complex is shown in Fig. 3. Attempts to slow down the rate of exchange in uncomplexed PF_5 have, so far, been unsuccessful.

Pentafluorosilicate Ammonia and Diethylamine Adducts

Solutions of $(n\text{-}C_3H_7)_4NSiF_5$ were made up by weighing out suitable amounts into dry n.m.r. tubes and adding CH_2Cl_2 as solvent through silicone septum cap. A small amount of $[(CH_3)_3Si]_2NH$ was added through cap to assist in "drying" solution. The ^{19}F n.m.r. spectrum at $+38°$ gave a sharp singlet at $+136.7$ p.p.m., with $J_{F^{29}Si} = 140 \pm 5$ Hz (lit. $+136.0$ p.p.m. and $J_{F^{29}Si} = 148 \pm 2$ Hz at $-66°$ (22). Ammonia and diethylamine were condensed onto these solutions and the n.m.r. tube sealed. The ^{19}F n.m.r. spectra of the adducts are shown in Figs. 5, 6, and 7.

The Photochemically Produced Ketyl of Perfluorobenzophenone: Electron Spin Resonance Studies of Solvent Effects[1]

FREDERICK PETER SARGENT AND MARSHALL GRANT BAILEY

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba, R0E 1L0

Received April 5, 1973

The ketyl radical is formed when solutions of perfluorobenzophenone are photolyzed with u.v. light. The radical was identified by electron spin resonance (e.s.r.) studies of the effects of solvent, temperature, chemical exchange, and deuteration on the spectra. Solvent mixtures of cyclohexane and ethanol gave spectra which were very sensitive to the mole fraction of alcohol in the range 0–1%. An equilibrium constant for solvent molecule exchange has been deduced.

Le radical cétyle est produit lorsque des solutions de perfluorobenzophénone sont photolysées avec de la lumière ultraviolette. Le radical a pu être identifié grâce à la résonance de spin électronique impliquant des effets de solvant, de température, d'échange chimique et de deutération. Des mélanges de solvant, cyclohexane-éthanol, ont conduit à des spectres où l'on a dénoté une très grande sensibilité vis-à-vis la fraction molaire d'alcool dans l'intervalle allant de 0–1%. De même, on a déduit une constante d'équilibre pour l'échange solvant–molécule. [Traduit par le journal]

Can. J. Chem., 51, 3211 (1973)

Introduction

In an earlier publication we reported the e.s.r. spectrum observed during the photolysis of perfluorobenzophenone, $(C_6F_6)_2CO$, in 2-propanol (1). This was assigned to the perfluorobenzophenone ketyl $(C_6F_6)_2\dot{C}OH$. Our studies have now been extended to other solvents to show that the observed spectra are indeed due to the ketyl, and not to radicals derived from the addition of solvent radicals to the keto group or the aromatic rings of perfluorobenzophenone (PFB). It will be shown that the spectra are very similar in all the solvents, and the identity of the radical is established as the ketyl.

Experimental

E.s.r. spectra were recorded with a Varian V4500 spectrometer. Aqueous alkaline solutions of Fremy's salt were used for magnetic field sweep calibrations, taking $a_N = 13.0$ G.

Solutions of perfluorobenzophenone (PFB) in various solvents were photolyzed *in situ* with a 100 W compact mercury arc lamp. The samples were held in 4 mm o.d. quartz tubes or in flat cells, depending on the dielectric properties of the solvent. All chemical reagents were used as received, with the exception of cyclohexane, which was dried with sodium wire.

Theoretical e.s.r. spectra were computer-simulated, and plotted with appropriate scaling, to permit direct comparison with the experimental charts. When the line positions and intensities agreed, it was assumed that the interpretation was correct.

[1]AECL No. 4561.

Molecular orbital calculations of the coupling constants and spin densities were of the McLachlan type (2), using the heteroatom method (3).

Results and Discussion

Spectra in Alcohols and Other Solvents

Photolysis of PFB in methanol, ethanol, and 2-propanol gave different spectra, but only because of differences in the value of one hyperfine splitting (h.f.s.). The spectrum in 2-propanol was poorly resolved at room temperature, but was much improved at +80 °C; a typical spectrum at +80 °C is shown in Fig. 1*a*. The more obvious features were interpreted visually, but it was necessary to use computer simulation of the spectrum to arrive at a complete interpretation. The simulated 2-propanol spectrum of Fig. 1*b* was computed by assuming that the unpaired electron interacts as follows:

(*i*) A Lorentzian line shape with peak to peak line width of 0.25 G.

(*ii*) Two equivalent nuclei of spin $\frac{1}{2}$ and h.f.s. of 8.23 G.

(*iii*) Four equivalent nuclei of spin $\frac{1}{2}$ and h.f.s. of 4.66 G.

(*iv*) Four equivalent nuclei of spin $\frac{1}{2}$ and h.f.s. of 1.77 G.

(*v*) One nucleus of spin $\frac{1}{2}$ and h.f.s. of 2.42 G.

The agreement between the experimental and the simulated spectra of Fig. 1*a* and *b* is good, and was shown to be almost perfect for expanded

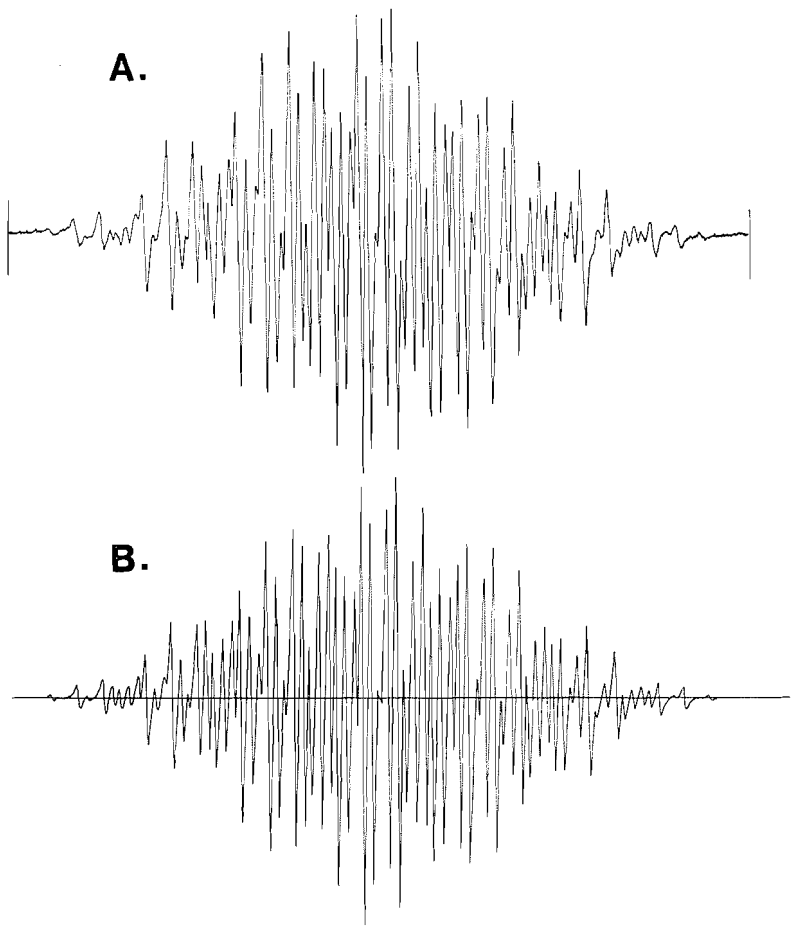

FIG. 1. (*a*) E.s.r. spectrum observed during the photolysis of perfluorobenzophenone in 2-propanol at 80 °C. Sweep width 50 G. (*b*) Simulated spectrum using values of Table 1.

charts recorded at slower magnetic-field sweep speeds. We have identified the radical as the ketyl of PFB, $(C_6F_6)_2\dot{C}OH$, for reasons explained in the next section. The h.f.s. are assigned to the positions in the radical listed in Table 1, on the basis of symmetry and simple molecular orbital calculations. The h.f.s. of 2.42 G is due to the ketyl hydroxyl proton, and the others to fluorine nuclei. No line width variations were observed in the ketyl spectra in contrast to those of partly fluorinated nitrobenzene anions (4, 5) and the cations of perfluorinated hydrocarbons (6).

The spectra in methanol and ethanol, although different in appearance, have similar h.f.s. to those in 2-propanol. The main difference is in the magnitude of the hydroxyl proton coupling, a_{OH}^{H}.

Photolysis of PFB in the other solvents of Table 1, with the exception of cyclohexane, gave very similar spectra, which were all assigned to the ketyl radical.

Identity and Mechanism of Formation of the Observed Radicals

The motive for this study was to substantiate our previous assignment (1) of the e.s.r. spectra to the PFB ketyl. There is always the possibility of an adduct radicals being formed from the addition of a solvent radical to the PFB. The similarity of the spectra, apart from the magnitude of a_{OH}^{H}, in methanol, ethanol, and 2-pro-

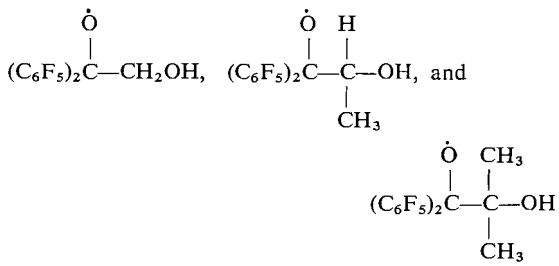
panol, discounts this possibility. The adduct radicals would be



respectively. These would be expected to give vastly different spectra, as would also radicals derived from addition to the aromatic rings. Therefore we are confident that the species observed during the photolysis of PFB in all the solvents of Table 1 is the ketyl. In addition, the magnitudes of a_{OH}^{H} for the hydroxyl proton h.f.s. are in approximate agreement with values for the unfluorinated benzophenone ketyl (7).

The mechanism for the formation of the ketyl radical is probably similar to that generally accepted for benzophenone itself, *i.e.* reactions 1–3, where superscript *S and *T refer to electronically excited singlet and triplet states respectively. In the case of alcohols, R· may further reduce PFB to the ketyl.[2]

[1] $$(C_6F_5)_2CO \rightarrow (C_6F_5)_2CO^{*S}$$

[2] $$(C_6F_5)_2CO^{*S} \rightarrow (C_6F_5)_2CO^{*T}$$

[3] $$(C_6F_5)_2CO^{*T} + RH \rightarrow (C_6F_5)_2\dot{C}OH + R\cdot$$

[2]See reference 18.

To provide evidence for the existence of triplet PFB, we performed photosensitization experiments in the glassy state at 77 °K similar to those reported by Farmer *et al.* (8) for benzophenone. Solutions of PFB and naphthalene in a mixed solvent consisting of two volumes of absolute ethanol and one volume of diethyl ether were frozen in liquid nitrogen to give clear glasses. When the samples were photolyzed *in situ* at 77 °C with light of wavelength greater than 340 nm (Corning Filter 4-76/9780) the ($\Delta M = 2$) half-field e.s.r. absorption of naphthalene triplet was easily detected. No triplet naphthalene e.s.r. absorption was found when PFB was not present. We interpret these observations in the same way as those for benzophenone (8, 9). The exciting light is only absorbed by the PFB, therefore it must generate the triplet of naphthalene indirectly by energy transfer from the PFB triplet. We assume that the triplet state of PFB is also formed in the photolysis of liquid solutions. Recent flash photolysis experiments support this conclusion (10).

In our experiments we observed that, after prolonged photolysis of the solutions, some ketyl remained when the u.v. light had been extinguished. This suggests that a thermal equilibrium exists, between PFB, the ketyl radical, and the products. This point should be borne in mind if the system is adopted as an actinometer, as has been proposed (11).

The presence of a hydroxyl proton in the radical was further substantiated by studies of temperature and exchange effects.

Temperature Effects

The hydroxyl proton h.f.s. of the ketyl radical was shown to increase with increasing temperature, and was similar to that reported for the unfluorinated ketyl (7) and other OH containing radicals.

Proton Exchange Effects

The assignment of the 2.42 G h.f.s. in 2-propanol to a hydroxyl proton was also confirmed by the observation of acid-catalyzed exchange effects on the spectrum. Samples containing 0.1 *M* PFB with varying amounts of hydrochloric acid were examined during photolysis at 80 °C. Care was taken to maintain a constant proportion of water in these, since its presence decreases the value of a_{OH}^{H}. We found that a_{OH}^{H} decreased with increasing concentration of acid and the line width increased. We attribute these changes to the exchange reaction 4.

[4] $$(C_6F_5)_2COH + H^+ \leftrightarrows (C_6F_5)_2COH_2^+$$

This decreases the lifetime of the spin states of the hydroxyl proton and therefore broadens the e.s.r. lines. Such effects are well known (12, 13), and the theory has been given elsewhere (14, 15).

Therefore the proton h.f.s. observed for spectra in all the solvents of Table 1 is due to hydroxyl proton. This is further substantiated by the results in deuterated solvents.

Deuterated Solvents

Reactions 1–3 show that the ketyl radical of PFB is formed during photolysis by abstraction of a hydrogen atom from a solvent molecule. Therefore, in a deuterated solvent a deuterium atom will be abstracted and the ketyl radical $(C_6F_5)_2\dot{C}OD$ formed. The spectrum in perdeuterated 2-propanol should only differ from that in the protiated solvent in that the hydroxyl doublet of 2.42 G should be replaced by a triplet of about 0.37 G.[3] The spectrum taken at 80 °C gave a_{OD}^{D} equal to 0.33 G. The line width of 0.18 G was the smallest found in these studies.

Spectra in Cyclohexane–Ethanol Mixtures

The spectrum observed during the photolysis of PFB in cyclohexane did not give a hydroxyl proton h.f.s. This could mean that a different radical was formed, or that a_{OH}^{H} for the ketyl in cyclohexane is zero. The latter seemed the most likely, and it implies that in mixtures of cyclohexane and ethanol a_{OH}^{H} should increase with increasing alcohol content. Photolysis of such solutions gave the expected variation, as shown in Table 2 and Fig. 2. The rapidly changing portion of the curve of Fig. 2 was not very reproducible for different stock solutions. This was shown to be due to small variations in the water content of the alcohol used.

The variation of a_{OH}^{H} with alcohol content follows a smooth curve which can be extrapolated to zero for pure cyclohexane. Therefore we conclude that the radical observed in cyclohexane is the same as in the other solvents, namely the ketyl.

This variation may be analyzed to yield a solvent exchange equilibrium constant. The theory (16, 17) assumes that relatively stable one-to-one complexes are formed between the radical and the solvents S_A and S_B. In the mixed solvent the equilibrium 5 exists

[5] $$RS_A + S_B \rightleftarrows RS_B + S_A$$

and the rate of solvent exchange is so rapid that the spectra of RS_A and RS_B are time-averaged to give only one spectrum. The relationship

between the observed h.f.s., a_{OH}^{H}, the equilibrium constant K, and the ratio of the solvent concentration α is given in eq. 6.

$$[6] \qquad a_{OH}^{H} = 2.16K\alpha/(K\alpha + 1)$$

where 2.16 is the OH coupling constant (h.f.s.) in pure ethanol. Analysis of our data leads to K values in the range 200–300. The curve for K equal to 250 is shown in Fig. 2. This very simple model implies that in a 0.5 volume % solution of ethanol in cyclohexane the PFB ketyl will be half solvated by ethanol. Such specific solvation is quite common for anion radicals such as those of nitro compounds, but is comparatively rare for neutral radicals.

The Variation of the Hyperfine Splittings

Temperature Effects

We interpret the variation of a_{OH}^{H} with temperature in much the same way that Wilson did for the unfluorinated ketyl (7). This h.f.s. arises from two effects, one direct and the other indirect. If the $>\dot{C}OH$ group is planar, then a_{OH}^{H} only arises from spin density on the oxygen atom. This is the indirect effect, since it involves spin polarization of the OH bond to give spin density at the hydrogen nucleus. If the OH group is rotated out of the plane the hydrogen 1s orbital can overlap with the carbonyl carbon 2p orbital leading to spin density at the hydrogen nucleus. This is the direct effect. The total interaction is expressed in eq. 7 where Q_I and

$$[7] \qquad a_{OH}^{H} = Q_I\rho_O + Q_D\rho_C$$

Q_D are constants and ρ_O and ρ_C are the spin densities at the oxygen and carbonyl carbon atoms respectively. To account for the increase of a_{OH}^{H} with increasing temperature and its zero value in cyclohexane, we assume Q_I and Q_D to be of opposite sign and Q_D to be positive. Increasing the temperature increases the proportion of those torsional isomers which permit direct overlap, so a_{OH}^{H} increases.

Solvent Effects

The data presented in Tables 1 and 2 show that as the hydroxylic-proton coupling increases that of the aromatic ring fluorine decreases. These differences are most marked between cyclohexane and the alcohols. The cyclohexane–ethanol mixtures of Table 2 show a smooth change from one solvent to the other. We assign these changes to differences in the solvent–ketyl radical interactions, and note that increasing the solvent polarity increases the value of a_{OH}^{H} at the expense of the aromatic-ring fluorine couplings.

The temperature variation of the OH proton coupling shows that a_{OH}^{H} has a positive sign, and that the direct overlap of the hydrogen 1s orbital with the adjacent carbon 2p orbital is the dominant interaction. In the case of cyclohexane a_{OH}^{H} is zero, and we conclude that the direct overlap is equal and opposite to the contribution from spin polarization of the OH bond due to spin density resident on the oxygen. Therefore the increase in a_{OH}^{H} when the solvent is changed from cyclohexane to an alcohol is due to an increase in the proportion of the OH coupling arising from direct overlap. Since this change in solvent also decreases the fluorine couplings, we conclude that spin density has shifted from the aromatic rings to the $>\dot{C}OH$ group.

Simple molecular orbital calculations of the effect of solvent on the e.s.r. spectra of radical anions have been described by Gendell *et al.* (16) and successfully applied to the benzophenone ketyl by Wilson (7). We have extended these to the PFB ketyl, and find that the theory accounts for the general direction of the effects. For example, increasing the polarity of the solvent from cyclohexane to ethanol is accounted for by merely increasing the electronegativity of the carbonyl oxygen atom. This has the effect of decreasing the spin density on the aromatic rings and on the oxygen, but increasing it on the carbonyl carbon. It leads to a decrease in the fluorine h.f.s. and an increase in a_{OH}^{H} from direct overlap. Hence the theory is in agreement

with the experimental observations summarized in Tables 1 and 2

Conclusions

The radical observed during the photolysis of solutions of perfluorobenzophenone has been shown to be the ketyl $(C_6F_5)_2\dot{C}OH$ This assignment has been substantiated by deuteration, proton exchange, and effects of temperature and solvent, together with simple molecular orbital calculations.

Na^+ and K^+ Binding by Fulvic Acid[1]

DONALD S. GAMBLE
Soil Research Institute, Canada Agriculture, Ottawa, Canada K1A 0C6

Received May 8, 1973

The electrostatic binding of Na^+ and K^+ by fulvic acid in aqueous solution has been measured with cation electrodes at 25.00 °C ± 0.05. The binding equilibria were followed during the course of acid–base titrations, and have revealed distinct binding regions in the titration curves. In one of these regions Na^+ is more strongly bound than is K^+. The standard free energies of binding were 11.7×10^3 to 20.5×10^3 J/mol ± 2% for Na^+, and 11.5×10^3 to 17.8×10^3 J/mol ± 1%, for K^+.

La combinaison électrostatique de Na^+ et de K^+ par l'acide fulvique en solution aqueuse a été mesurée à l'aide d'électrodes sensibles aux cations à 25.00 C ± 0.05. Les états d'équilibre lors de la combinaison ont été évalués lors de titrations acide–base et ont mis en relief différentes régions de combinaison existant dans les courbes de titrations. Dans une de ces régions, le Na^+ est lié plus fortement que le K^+. Les énergies libres standards de liaison sont comprises dans l'intervalle allant de 11.7×10^3 jusqu'à 20.5×10^3 J/mol ± 2% pour le Na^+ et dans l'intervalle allant de 11.5×10^3 jusqu'à 17.8×10^3 J/mol ± 1% pour le K^+. [Traduit par le journal]

Can. J. Chem., 51, 3217 (1973)

Introduction

The literature gives various indications of the electrostatic binding of cations by humic polyelectrolytes. Among these are the electrical conductance measurements of Mukherjee and Lahiri in 1958 (1). Posner observed that alkali chlorides make humic acid more strongly acidic, and has used acid–base titrations to measure these changes in the acid dissociation equilibrium (2, 3).

More recently, KCl was found not only to have this same effect on fulvic acid, but also to displace the first titration equivalence point to a higher value (4, 5). Reporting fulvic acid – metal ion complexing stabilities in 1970, Schnitzer and Hansen demonstrated that generally log K was a decreasing linear function of KCl concentration in the ionic strength range 0.0 to 0.15 (6).

The only direct measurements of alkali ion binding by humic materials were those previously reported in 1953 by Marshall and Patnaik (7, 8). They found stronger binding for Na^+ than for K^+. The purpose of the present work is to check this unexpected result and obtain detailed chemical information by making direct potentiometric measurements with metal ion electrodes.

[1]Presented in part at the 56th Canadian Chemical Conference of the Chemical Institute of Canada, Montreal, Quebec June 4–6, 1973. Contribution No. 460.

Theory

It is assumed that the alkali metal ions are electrostatically held in the neighborhood of ionized functional groups, and that conceptually they can be assigned to these functional groups. Any prior assumptions as to which functional groups or fulvic acid fractions bind the metal ions would be difficult to justify. Such assumptions are, however, unnecessary. Instead, the binding equilibrium is defined in terms of all of the ionized functional groups, according to eq. 1.

$$T^- + M^+ \overset{\bar{K}_5}{\rightleftharpoons} (T^-M^+) \qquad \bar{K}_5 = m_{TM}/(m_T m_M) \qquad [1]$$

$\bar{K}_5$ is found to be a weighted average function, in just the same way as has been described previously for the H^+ dissociation and Cu^{2+} complexing equilibrium quotients of fulvic acid (9, 4, 5, 10). Equation 2 gives the result for the present case.

$$\bar{K}_5 = \frac{1}{\chi_T} \int_0^{\chi_T} K_5(\chi_T) d\chi_T \qquad \chi_T = m_T/C_T \qquad [2]$$

m_T and χ_T are the molality and mole fraction, respectively, of acid functional groups free from both H^+ and metal ions. C_T is the molality of functional groups titrated up to the second

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

acid–base equivalence point. K_5 is defined by eq. 3 for the infinitesimal increment of functional groups $\delta c_T = \delta m_T + \delta m_{TM}$.

$$[3] \quad K_5 = \frac{\delta m_{TM}}{m_M \delta m_T} = \left(\frac{\gamma_M \gamma_T}{\gamma_{TM}}\right) \kappa_5{}^0 \exp\left(-\Delta G_5{}^e/RT\right)$$

Assuming that no covalent bonding exists for alkali ion binding, then $\kappa_5{}^0 \equiv 1$. $K_5 = K_5(\chi_T)$ may be calculated from experimental data by differentiating along the path described by a titration, according to eq. 4.

$$[4] \quad K_5 = \mathrm{d}(\chi_T \bar{K}_5)/\mathrm{d}\chi_T$$

If the functional groups in a particular region of the titration curve, χ_T' to χ_T'', do not bind metal ions, then this will be reflected in the $\bar{K}_5$ curve. The calculation with eq. 4 will accordingly give $K_5 = 0$ for $\chi_T' \leqslant \chi_T \leqslant \chi_T''$. This formulation of the problem is therefore perfectly general.

Rigorous numerical values for the activity coefficients in eq. 3 are unavailable. Experimental results are therefore presented as values of $\Delta G_5{}^b$, which is defined by eq. 5.

$$[5] \quad \Delta G_5{}^b \equiv \Delta G_5{}^e - 2.303\, RT \log \frac{\gamma_M \gamma_T}{\gamma_{TM}}$$

Experimental

Chemicals

The fulvic acid used was the Batch FA1, which has been previously described (4). H_2O redistilled under N_2 and 0.1 *N* standard bases were also used. The other chemicals were all of Reagent Grade quality.

Equipment

Orion Na^+ Specific Ion combination electrode Model No. 96-11, and Metrohm combination glass/AgCl micro electrodes, p*H* range 0 to 11, temperature range 10 to 100 °C were used with a Beckman Research Model p*H* meter. The Na^+ electrode cable was covered with a grounded shield before use.

Corning Monovalent Cation electrode and a Fisher calomel reference electrode were used with a Fisher Accumet Model 520 digital p*H*/ion meter. A 5.000 ml calibrated microburett, ±0.005 ml was also used.

Thermostats and calibrated thermometers were used to maintain the temperature at 25.00 °C ± 0.05.

Cation Molality Standards

The H^+ standards were prepared essentially as previously described (4), with NaOH or KOH being used as appropriate.

Each Na^+ standard curve was constructed with 12 to 15 standard solutions prepared gravimetrically to cover the NaCl concentration range 2. × 10^{-3} *m* to 12. × 10^{-3} *m*. The molality *vs.* Volts data points were fitted to polynomials by the method of least squares.

K^+ standards were prepared gravimetrically in sets of 8 or 9 to cover the KCl concentration range 3. × 10^{-3} *m* to 11. × 10^{-3} *m*. Because biases among these sets of standards were not observable outside the extent of scatter within a set, all of the data from these standards were fitted by least squares to a single standard curve.

Experimental Methods

Four independent experiments, from which CO_2 was excluded, were carried out at 25.00 °C ± 0.05. Each experiment consisted of at least six independent but identical titrations. Each titration used 100. g of sample solution having 0.1 g of fulvic acid dissolved in H_2O. There were generally about 70 data points per titration. For each experiment an average titration curve was calculated by least squares fitting. Random scatter and random biases were thus averaged out. The first two experiments were done by NaOH titration, with free Na^+ molality being measured in one and free H^+ molality being measured in the other. A pair of K^+ binding experiments was done in the same way. The last of these four experiments was previously published work (4). The potentiometric measurements were conducted essentially as previously described (4).

Results

Data from the four experiments are given in Fig. 1 and Tables 1 and 2. The Na^+ curve of Fig. 1 and the H^+ molalities of Table 1 represent the average titration curves of Experiments 1 and 2, respectively. Likewise the K^+ curve of Fig. 1 and the H^+ molalities of Table 2 represent the average titration curves of Experiments 3 and 4. The significant points are:

(*a*) For both cations, binding evidently begins at 4. mequiv./g and then increases steeply.

(*b*) Na^+ shows stronger binding than does K^+ up to about 11.0 mequiv./g. This is in qualitative accord with the results reported by Marshall and Patnaik (7).

(*c*) The Na^+ binding curve of Fig. 1 goes through a maximum of 2.880 × 10^{-3} *m* at 8.6 mequiv./g, after which some of the bound Na^+ is released.

(*d*) The K^+ binding curve of Fig. 1 has a drastic change of slope at just about 8.0 mequiv./g, and then apparently approaches as a limit the same value of 2.880 × 10^{-3} *m* attained by the Na^+ binding maximum.

The K_5 curves of Fig. 2 reveal very distinct ion binding regions in the NaOH and KOH titrations. Each curve has a peak standing on a 1.5 mequiv./g base, and a plateau also 1.5 mequiv./g wide. These regions are, however, interchanged in the two titration curves. Except

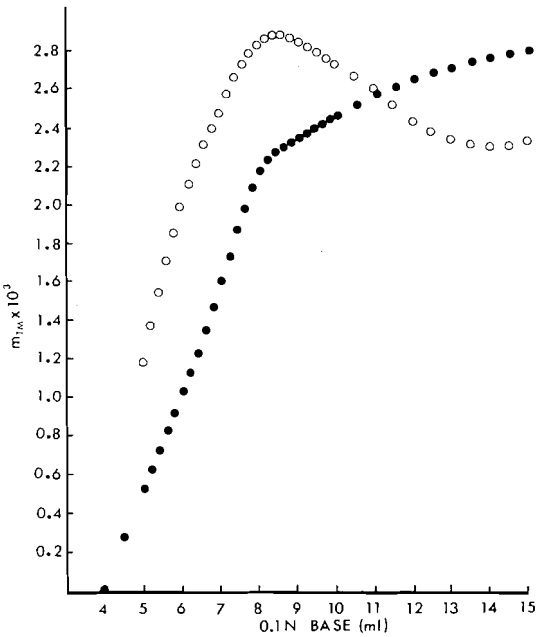

FIG. 1. Alkali metal ion bound during the acid–base titration of fulvic acid at 25.00 °C ± 0.05: ○, Na^+, standard error ±0.66% to ±1.7%; ●, K^+, standard error ±1.2% to ±1.8%.

in the plateau regions, the Na^+ binding is clearly seen to be somewhat stronger here than is the K^+ binding.

An examination of Tables 1 and 2 shows that in the 5.000 ml to 6.000 ml region, the NaOH titration curve has H^+ concentrations greater than those of the KOH titration curve, by a factor of more than 10^3. This difference is in exactly the same region as the Na^+ peak and K^+ plateau of Fig. 2. The corresponding effect for the K^+ binding peak is shown in Fig. 3. Δm_H is the change in H^+ molality resulting from the replacement of Na^+ with K^+. Although the H^+ displacement effect of Fig. 3 is almost obscured by experimental error, Δm_H changes sign in just the right region. In addition, the Δm_H peak occurs at 7.4 mequiv./g. This is the exact location of the K^+ binding peak in Fig. 2. The K_5 peaks of Fig. 2 thus have corroboration from independent experiments.

Numerical values for the free energy function of eq. 5 are listed in Table 3. Assuming that $(\gamma_{T\,Na}/\gamma_T) \approx 1$, and using the data of Robinson and Stokes (11) for 0.01 *m* NaCl, one obtains for the corresponding standard free energies,

$$[6] \qquad \Delta G_5^{e} \approx \Delta G_5^{b} + 0.3 \times 10^3 \text{ J/mol}$$

TABLE 1. Na^+ binding by fulvic acid at 25.00 °C ± 0.05 calculated for 0.10020 g fulvic acid in 100.0000 g of solution

14.000	2.31×10^{-12}	51.3	0.660
14.500	2.14×10^{-12}	49.9	0.658
15.000	$2.02\times10^{-12}\pm1.7\%$	$49.1\pm6.0\%$	0.654

The magnitudes of these values in Table 3 are very similar to those reported in the literature for theoretical and experimental work on polyelectrolytes (12–15).

Experimental Errors

The errors in the H^+ measurements have been discussed previously (4, 5). In the same way, potentiometric measurements were the chief source of error in the determination of Na^+ and K^+ concentrations. The errors in the answers were estimated from the standard deviations of the least squares fit computer printouts, and from the errors in the published equivalence point values (4).

Error estimates are not available for the published work of Marshall and Patnaik (7).

Discussion

The very distinct binding and nonbinding regions of the titration curves seen in Fig. 1 suggest the possibility that the fulvic acid has discrete binding and nonbinding fractions. Figure 2 in turn indicates that the binding region has two distinct parts. Although the peaks and plateaus are interchanged in the two curves of Fig. 2, the peak in each curve may nonetheless represent the same fulvic acid fraction or set of functional groups. One cannot assume that the

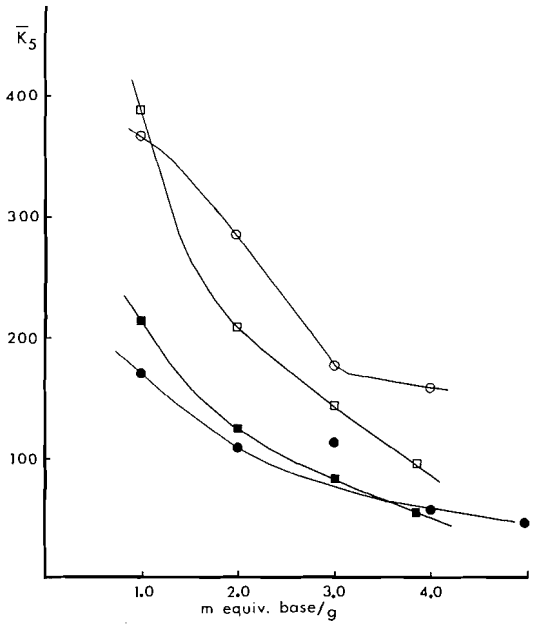

FIG. 4. Alkali ion binding equilibria for Wisconsin peat fractions; from Marshall and Patnaik (7). $\bar{K}_5$ calculated assuming from their titrations $\approx$ 5.0 mequiv./g of acidic functional groups, and $\alpha_T \approx$ (mequiv. of base)/5.0/g. Hymatomelanic acid: ⊙, Na^+; ●, K^+. Humic acid: ⊡, Na^+; ■, K^+.

acidic functional groups will be ionized in the same order during titration with the two standard bases.

The two humic fractions extracted from a Wisconsin peat by Marshall and Patnaik differed in both the geographical source and the preparation method from the fulvic acid used here. Despite this, the curves in Fig. 4 are quite comparable to the present results. This raises the question, therefore, of whether the binding preference for Na^+ over K^+ is common or widespread.

Structural causes are suspected for this binding preference, especially since it is so closely identified with a particular region of the titration curve. Structure is known to affect the binding of alkali ions by such neutral molecules as the crown ethers and certain antibiotics (16–19). The metal ions are held within rings or cages lined with oxygen atoms.

In aqueous systems such complexing usually requires removal of some or all of the cation's solvating water molecules. The usual preference for K^+ over Na^+ resulting from this is reversed for special cases in which the enclosure is too small for the K^+. The standard free energies for such complexes are evidently characteristic of ion–dipole interactions (17).

The fulvic acid – alkali metal ion "complexes" probably differ from the above complexes in two ways. Firstly, the standard free energies of Table 3 are more characteristic of ion–polyion interactions. Secondly, there is evidence (9) to suggest that fulvic acid has an open structure consisting of a two or three dimensional array of poorly condensed aromatic rings. These are highly substituted with functional groups and side chains. Such a structure is unlikely to possess the rigidity or uniformity of size required to selectively bind Na^+ rather than K^+. The experimental results may, however, be explained by postulating that fulvic acid in aqueous solution possesses cages lined by solvated carboxylate groups. If the incoming cation is able to share solvating water molecules with the carboxylate groups, then the smaller bare-ion diameter of Na^+ could be favored over that of K^+.

Mr. D. A. Hindle carried out the large number of careful measurements and assisted with the calculations. The author is indebted to Professor J. A. Marinsky of the Department of Chemistry, State University of New York at Buffalo, for valuable discussions.

Some New Iron Carbonyl Cluster Complexes of Di(tertiary arsines)

L. S. CHIA, W. R. CULLEN, J. R. SAMS, AND J. E. H. WARD
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received April 5, 1973

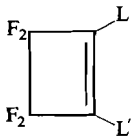
New polynuclear iron carbonyl complexes having the stoichiometry $LFe_3(CO)_{10}$ have been obtained from the reactions of $Fe_3(CO)_{12}$ with the di(tertiary arsine) ligands $(CH_3)_2AsC(X)(Y)CF_2As(CH_3)_2$ (X = Y = H; X = H, Y = F; X = F, Y = CF_3). The structures of the new cluster complexes have been investigated using i.r., n.m.r., and Mössbauer spectroscopies. Mössbauer data are also reported for $LFe_3(CO)_{10}$ and $LFe_3(CO)_9$ derivatives of the mixed ligand $(CH_3)_2AsC{=}CP(C_6H_5)_2CF_2CF_2$.

De nouveaux complexes polynucléaires fer-carbonyle ayant la stoechiométrie $LFe_3(CO)_{10}$ ont été obtenus à partir de réactions du $Fe_3(CO)_{12}$ avec des coordinats di(arsine tertiaire) $(CH_3)_2AsC(X)(Y)CF_2As(CH_3)_2$ (X = Y = H; X = H, Y = F; X = F, Y = CF_3). Les structures des nouveaux complexes d'agrégat ont été étudiées à l'aide des spectroscopies infra-rouge, r.m.n. et Mössbauer. Les résultats tirés de la spectroscopie Mössbauer sont aussi présentés pour les dérivés $LFe_3(CO)_{10}$ et $LF_3(CO)_9$ du coordinat mélangé $(CH_3)_2AsC{=}CP(C_6H_5)_2CF_2CF_2$. [Traduit par le journal]

Can. J. Chem., 51, 3223 (1973)

Introduction

The fluorocarbon-bridged di(tertiary arsine) $f_4$fars (**1***a*) forms the interesting complex $f_4farsFe_3(CO)_{10}$ (**2***a*)(1, 2) in which the ligand has replaced one terminal carbonyl group from each of the equivalent iron atoms (B and C) of $Fe_3(CO)_{12}$. However, no such $Fe_3(CO)_{10}$ derivative is formed by the related di(tertiary phosphine) $f_4$fos (**1***b*), nor by the hydrocarbon-

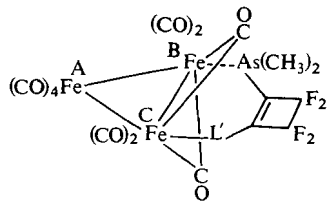


1

a L = $(CH_3)_2As$ = L′, $f_4$fars
b L = $(C_6H_5)_2P$ = L′, $f_4$fos
c L = $(CH_3)_2As$, L′ = $(C_6H_5)_2P$, f_4AsP

bridged ligands diphos and diars (diphos = 1,2-bis(diphenylphosphino)ethane and diars = 1,2-bis(dimethylarsino)benzene) (3). On the other hand the reaction of the mixed ligand f_4AsP (**1***c*) with $Fe_3(CO)_{12}$ does result in the formation of an $Fe_3(CO)_{10}$ complex (4), believed to have structure **2***b*.

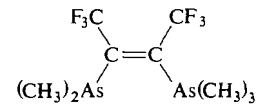
It appears that the bite of the ligand is probably more important than electronic factors in determining its ability to form an (L—L′)-$Fe_3(CO)_{10}$ derivative. Thus the ligand **3**, which is electronically similar to $f_4$fars but should have a smaller As...As separation because of the



2

a L′ = $(CH_3)_2As$
b L′ = $(C_6H_5)_2P$

acyclic bridging group, does not form an $Fe_3(CO)_{10}$ complex (5). The importance of



3

ligand bite is also evident in the tendency of these and related ligands to act as chelating groups (4–9).

In view of the difference in properties between **1***a* and **3** it was of interest to examine the reactions of the related di(tertiary arsines) **4** with $Fe_3(CO)_{12}$. The longer C—C distances compared to **3** and free rotation about the C—C bond, should provide a slightly bigger bite for the ligands **4**, and hence favor the formation of $Fe_3(CO)_{10}$ complexes. We find in all three cases that (L—L′)$Fe_3(CO)_{10}$ derivatives are in fact obtained but spectroscopic evidence indicates they do not all have structures analogous to **2**.

4

a X = H = Y
b X = H, Y = F
c X = F, Y = CF_3

A preliminary report on these compounds has appeared (5).

We also report here ^{57}Fe Mössbauer data for $f_4AsPFe_3(CO)_{10}$ (4) and a complex of formula $f_4AsPFe_3(CO)_9$ in which the ligand has undergone rearrangement and the $Fe_3(CO)_{12}$ skeleton is no longer present (4, 10).

Experimental

The Mössbauer spectrometer and attendant experimental details have been described previously (8). I.r. spectra were recorded on a Perkin–Elmer 457 instrument, mass spectra on an AEI MS-9 spectrometer, and ^{1}H n.m.r. spectra (C_6H_6 solution) on a Varian HA-100 spectrometer. Chemical shifts are given in p.p.m. downfield from external TMS. The ligands **4** were prepared as reported elsewhere (11–13).

Preparation of [(CH$_3$)$_2$AsCF(CF$_3$)CF$_2$As(CH$_3$)$_2$]-Fe$_3$(CO)$_{10}$

A mixture of triiron dodecacarbonyl (1.25 g, 2.48 mmol) and 1,2-bis(dimethylarsino)hexafluoropropane (0.75 g, 2.08 mmol) was refluxed in 30 ml of 40–60° petroleum ether under a nitrogen atmosphere for 13 h. The solvent was removed under reduced pressure and the resulting products were chromatographed on Florisil while eluting with petroleum ether – diethyl ether mixtures. The $Fe_3(CO)_{10}$ complex eluted as a dark red band, second last off the column (0.063 g, 4%). Other products obtained were $[(CH_3)_2AsCF(CF_3)CF_2As(CH_3)_2]Fe(CO)_3$ identified only by i.r. spectroscopy and the previously known $[(CH_3)_2AsFe(CO)_3]_2$ (14).

The $Fe_3(CO)_{10}$ derivatives of **4***a* and *b* were prepared in a manner identical to the above, yields of 27 and 38%, respectively, being obtained. In the former case other products identified were (L—L′)$Fe(CO)_4$ (42%) and (L—L′)$Fe_2(CO)_8$ (10%), although neither was characterized further.

Results and Discussion

Analytical and spectroscopic data for the new cluster complexes are given in Tables 1 and 2. The mass spectra of the three new $Fe_3(CO)_{10}$ derivatives formed by the ligands **4** all show a parent ion followed by the loss of 10 carbonyl groups. The remainder of the cracking patterns are of little help in determining the structures and will not be considered further here.

The spectroscopic properties of $[(CH_3)_2AsCHFCF_2As(CH_3)_2]Fe_3(CO)_{10}$ (**5**) are very similar to those of **2***a* (1), although due to the ligand asymmetry the ^{1}H n.m.r. spectrum of **5** is more complicated, showing three methyl proton singlets of relative areas 1:2:1. There are only four terminal carbonyl bands in the i.r. spectrum of **5**, indicating a fairly symmet-

rical structure. The ^{57}Fe Mössbauer spectra of **2***a* and **5** are virtually identical, the only significant differences being that the outer lines in the latter are slightly broadened and show a somewhat greater splitting (Table 2). Both these effects may arise from the small asymmetry of the ligand structure, which could make the two dimethylarsino groups slightly different in σ-donor and π-acceptor properties resulting in a very slight inequivalence of Fe^B and Fe^C. However, the spectroscopic evidence leaves little doubt that in **5** the ligand is bonded to the $Fe_3(CO)_{10}$ moiety in an identical way to **2***a*.

On the other hand the Mössbauer spectrum of $[(CH_3)_2AsCF(CF_3)CF_2As(CH_3)_2]Fe_3(CO)_{10}$ (**6**) derived from ligand **4***c* is very different in appearance, consisting of four lines of approximate relative areas 1:2:1:2. For a compound containing three iron atoms and giving rise to a four-line Mössbauer spectrum with the relative areas of two lines being twice those of the other two, there are six possible combinations of lines. For each of these combinations there are 3! permutations of the iron atoms making a total of 36 possible ways of assigning the spectral lines. In trying to rule out as many of these assignments as we can, we shall rely on data we have collected for more than 40 iron carbonyl derivatives of related di(tertiary arsines and phosphines) in which the iron atoms are formally in the zero oxidation state (1, 4, 6, 8, 15). Although the quadrupole splittings in such complexes can vary widely depending on details of the stereochemistry about the iron atom, isomer shift values have invariably been found to lie within the range $+0.16 \leqslant \delta \leqslant +0.51$ mm s^{-1}. It therefore seems best to base conclusions on isomer shift data where possible, and to eliminate those assignments for which δ values fall well outside the above range.

The possible line combinations in the Mössbauer spectrum of **6** and the values of isomer shifts and quadrupole splittings derived therefrom are shown in Scheme 1. Combinations i–iv can be ruled out at once, since in every case at least two of the three isomer shift values are unreasonable, one being negative and the other at either +0.80 or +1.07 mm s^{-1}. Neither of the remaining combinations can be discarded solely on the basis of the magnitudes of the δ values, although the +0.09 mm s^{-1} value from combination v seems suspect. Therefore we shall examine both these combinations in terms of the possible structures for **6** shown in Fig. 1. In struc-

SCHEME 1. Possible line combinations and corresponding parameters in the Mössbauer spectrum of $[(CH_3)_2AsCF(CF_3)CF_2As(CH_3)_2]Fe_3(CO)_{10}$.

tures **I** and **II** the ligand is acting as a bridging group, having replaced one carbonyl group from each of two different iron atoms, while in structures **III** and **IV** the ligand is chelating.

Since combination v requires degeneracy of two of the iron atoms, the only possible structures consistent with this combination are **I** and **III**. For the former we would clearly expect the Mössbauer parameters for **6** to be very nearly the same as those for **2***a* and **5**, which they are not. In particular it would be very difficult to explain the large changes in both δ and ΔE_Q for Fe^A (lines a), since for this structure these parameters should be little altered. Moreover, the δ values for the two equivalent iron atoms are greater than anticipated, since our experience has been that replacement of one carbonyl group by an arsine or phosphine ligand raises the isomer shift of that iron atom by about 0.04–0.08 mm s^{-1}. The chelate structure **III** is similarly subject to objections regarding the isomer shift values, in that δ_A should increase rather than decrease compared to $Fe_3(CO)_{12}$, while $\delta_B(=\delta_C)$ should be approximately unchanged. We therefore consider that both these structures, and hence combination v, can be eliminated as highly unlikely on the basis of the Mössbauer data.

Only structures **II** and **IV**, each with three inequivalent iron atoms, are consistent with the sole remaining combination vi. For the bridged structure **II** we would expect both δ_A and δ_C to increase slightly compared to their values in $Fe_3(CO)_{12}$, while δ_B should be nearly constant. From the data in Table 2 we must associate the value $\delta_b = 0.36$ mm s^{-1} with Fe^B, neither of the other δ values being at all reasonable for this iron atom. This immediately leads to the difficulty that δ_a is slightly lower than δ_A in $Fe_3(CO)_{12}$ while δ_c has increased markedly, both effects being contrary to expectations. For structure **IV**, we would expect the δ values for Fe^A and Fe^B to be essentially unchanged from their values in $Fe_3(CO)_{12}$ while δ_c is expected to increase by about 0.08–0.16 mm s^{-1}. If we assign the isomer shifts of 0.24, 0.36, and 0.51 mm s^{-1}

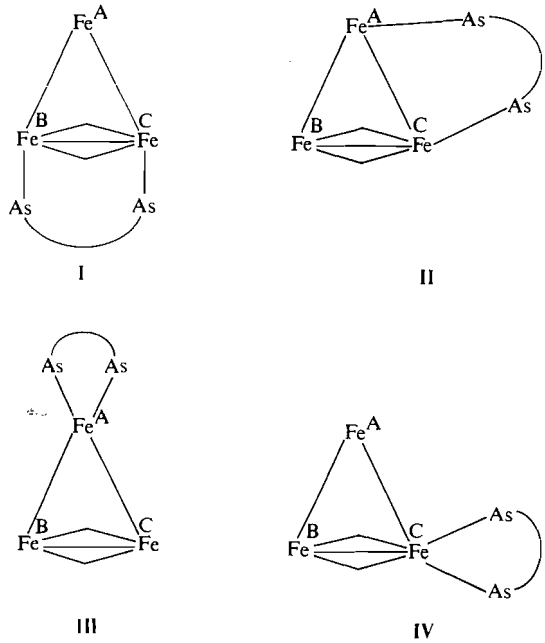

FIG. 1. Possible structures for $(As–As)Fe_3(CO)_{10}$ complexes. To avoid complicating the figure all terminal CO groups have been omitted and the ligand is symbolized simply as As As. Bridging carbonyl groups between iron atoms B and C (equivalent in the parent $Fe_3(CO)_{12}$) are denoted by "bent" bonds.

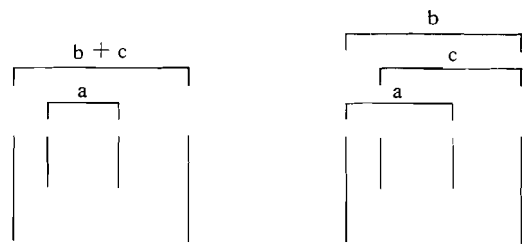
to iron atoms A, B, and C, respectively, all the δ values are in good agreement with our predictions. The only point about the Mössbauer parameters which seems slightly unusual for structure **IV** is the increase in ΔE_Q for Fe^B, which one might have expected to be unaffected by chelation of the ligand at Fe^C. However, this could presumably be caused by the bulkiness of the ligand or solid state packing effects, and the assignment of structure **IV** to compound **6** seems most consistent with the available data.

The Mössbauer spectrum of $[(CH_3)_2AsCH_2CF_2As(CH_3)_2]Fe_3(CO)_{10}$ (**7**) consists of lines at −0.15, −0.01, +0.55, and +1.05 mm s^{-1} with relative areas of approximately 2:1:1:2. While the line positions are quite similar to those of **6**, the area ratios are like those of ***2a***. Again there are six possible combinations of lines, and again four of these can be ruled out on the grounds that they all lead to unreasonable isomer shift values for at least two of the iron atoms. The remaining possibilities vii and viii are shown in Scheme 2 together with the parameters derived from these combinations. By arguments entirely



Line	δ	ΔE_Q
a	0.28	0.56
b	0.45	1.21
c	0.45	1.21

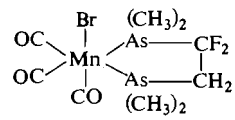
Line	δ	ΔE_Q
a	0.20	0.71
b	0.45	1.21
c	0.52	1.06

SCHEME 2. Line combinations in the Mössbauer spectrum of $[(CH_3)_2AsCH_2CF_2As(CH_3)_2]Fe_3(CO)_{10}$ having acceptable isomer shift values.

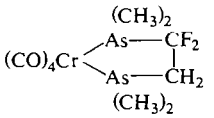
analogous to those employed above it can be shown that only structures **II** and **IV** of Fig. 1 are compatible with vii while only **I** and **III** are consistent with viii.

First consider combination vii. In going from $Fe_3(CO)_{12}$ to structure **II** one would expect the δ values for Fe^A and Fe^C to each increase by about 0.04–0.08 mm s^{-1}, with δ for Fe^B remaining nearly constant. However, there is no way of permuting the three isomer shifts and three iron atoms so as to satisfy these requirements and we conclude that **II** is not the correct structure. Although structure **IV** is less objectionable on the basis of Mössbauer data and was tentatively suggested as a possible structure for this complex (5), there are certain difficulties associated with the δ values since two of the three should be essentially the same as in $Fe_3(CO)_{12}$.

The n.m.r. spectrum of **7** provides additional evidence. With this particular ligand (***4a***) structure **IV** should lead to inequivalence of all four methyl groups, but only two equal-area singlets due to the methyl protons are observed. By comparison we note that the compound



which has approximately the same symmetry as **IV** shows methyl proton resonances (C_6H_6 solution) at τ = 8.530, 8.660, 8.806, and 8.959 p.p.m. (13). On the other hand, the more symmetrical



shows only two methyl proton singlets at τ 9.42 and 9.52 p.p.m. (C_6H_6 solution) (13). Thus the n.m.r. data for **7** would seem to favor the symmetrical structures **I** or **III**.

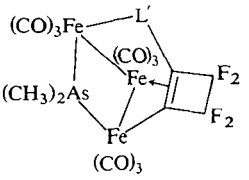
For combination viii of the Mössbauer lines, structure **III** seems highly unlikely in view of the δ values, since replacement of two CO groups on Fe^A should give a substantial increase in δ_A while having little or no effect on δ_B and δ_C. It therefore appears that **7** has structure **I**, analogous to **2***a* and **5**, but different from **6**.

It is possible that the bulky CF_3 group restricts rotation about the C—C bond in the ligand to such an extent that only the chelate complex **IV** is possible for ligand **4***c*. In the other two ligands **4***a* and *b*, which have smaller groups (H, F) attached to the bridging carbon atoms, the rotational barrier could be small enough to allow the bite of the ligand to become sufficient to complex as in **I**.

Complex **2***b*, the $Fe_3(CO)_{10}$ derivative of the mixed ligand f_4AsP(**1***c*) (4), has spectroscopic properties which are quite similar to those of $f_4$fars complex **2***a*. The highest peak in the mass spectrum of **2***b* corresponds to $f_4AsPFe_3(CO)_{10}$ and there is a stepwise loss of 10 carbonyl groups. The ^1H n.m.r. spectrum indicates that both the $(CH_3)_2As$ and $(C_6H_5)_2P$ groups are coordinated (4, 6). The ^{19}F n.m.r. spectrum, which is very similar to that of f_4AsP, suggests that both arsenic and phosphorus are bonded to the triiron fragment in such a way that the original symmetry of the ligand is preserved. The i.r. spectrum shows the presence of both terminal and bridging carbonyl groups.

These data are all consistent with the proposed (4) structure **2***b*, but rather surprisingly the Mössbauer spectrum of this complex is more like that of the parent $Fe_3(CO)_{12}$ than that of **2***a* (see Table 2). The most significant difference between the spectra of $Fe_3(CO)_{12}$ and $f_4AsPFe_3(CO)_{10}$ is a small increase in the splitting of the central doublet in the latter. However, the outer pair of lines is substantially and unsymmetrically broadened, an effect which could easily result from the slight inequivalence of Fe^B and Fe^C in the bridged structure **2***b*, but is difficult to rationalize for the only other structure compatible with the i.r. and n.m.r. data, *i.e.*, a chelated structure analogous to **III**. The general chemical behavior of f_4AsP towards the iron carbonyls $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$ (4) also suggests that a chelate $Fe_3(CO)_{10}$ species is unlikely. Whereas $f_4AsPFe(CO)_4$ in which the ligand is monodentate is produced in all the reactions of f_4AsP with the iron carbonyls so far investigated and is indeed the most characteristic product, $f_4AsPFe(CO)_3$ can only be obtained in low yield under forcing conditions. The apparent ease with which f_4AsP substitutes just one carbonyl group from an iron carbonyl moiety is illustrated by the isolation and characterization of such derivatives as $f_4AsPFe_2(CO)_8$ in which the ligand is bridging two $Fe(CO)_4$ fragments, $(f_4AsP)_2Fe(CO)_3$ in which both ligands are monodentate and P-bonded, and $(f_4AsP)_2Fe_2(CO)_4$ in which one ligand is terdentate and the second is bridging the two iron atoms (4).

The similarity in chemical properties of $f_4farsFe_3(CO)_{10}$ and $f_4AsPFe_3(CO)_{10}$ also suggests they have similar structures. Both compounds are readily converted to $(L—L')Fe_3(CO)_9$ derivatives when refluxed in cyclohexane for $\sim$1 h(1, 4), and both $Fe_3(CO)_9$ products have been shown by X-ray diffraction studies to have structure **8** (10, 16). Thus the conversion to the



8

a L′ = $(CH_3)_2As$, $f_4farsFe_3(CO)_9$
b L′ = $(C_6H_5)_2P$, $f_4AsPFe_3(CO)_9$

$Fe(CO)_9$ complexes results in ligand fragmentation and involves breaking a bond between arsenic and the fluorocarbon bridging group, with the formation of Fe—As and Fe—C σ-bonds.

Whereas the Mössbauer spectrum of **8***a* can be fitted by five independent Lorentzian lines of approximate relative areas 1:1:1:1:2 consistent with the presence of three inequivalent iron atoms (1), we are able to resolve only four independent lines in the case of **8***b* with areas in the approximate ratios 1:2:1:2. In overall appearance, however, the two spectra are very

similar, with the second line in the spectrum of the f_4AsP derivative corresponding to a superposition of lines two and three in the spectrum of the f_4fars complex. Detailed arguments have been given (1) concerning the assignment of the Mössbauer spectral lines for $f_4farsFe_3(CO)_9$. On the same basis the assignments for $f_4AsPFe_3(CO)_9$ given in Table 2 have been obtained. It should be noted that in both compounds corresponding iron atoms have almost identical isomer shifts as expected. Differences in corresponding ΔE_Q values are not large ($\sim$0.1 mm s^{-1}) and presumably reflect primarily slight differences in bond angles at the various iron atoms.

We thank the National Research Council of Canada for financial support and Mrs. A. Sallos for technical assistance.

Terpenes and Terpenoids. IV.[1] Some Esters and Amides of Thujic Acid

V. HACH[2] AND ELIZABETH C. MCDONALD
MacMillan Bloedel Research Limited, Vancouver 12, British Columbia

Received October 16, 1972[3]

Representatively substituted esters (**3***c–h*) and amides (**4***a–l*) of thujic acid (**3***a*) were prepared using the acid chloride as intermediate and were screened for their insect repellent and attractant potential. *N,N*-Diethyl thujamide (**4***d*) was found to be a highly active repellent of the yellow fever mosquito (*Aedes aegypti*) as well as of other insect species.

Des amides (**4***a–l*) ainsi que des esters (**3***c–h*) dérivés de l'acide thujique **3***a* et substitués de manière caractéristique ont été préparés en utilisant comme intermédiaire le chlorure d'acide. Ces composés furent par la suite étudiés en fonction de leur potentiel répulsif ou attracteur vis-à-vis des insectes. La *N,N*-diéthyl thujamide (**4***d*) s'est révélée être un produit à caractère répulsif très efficace contre les moustiques responsables de la fièvre jaune (*Aedes aegypti*) aussi bien que contre les autres espèces d'insectes.

The wood of western red cedar (*Thuja plicata Donn*) is renowned for its resistance to bacterial and mycotic decay and for its ability to withstand insect attack both in timber stands and sawmill products (1, 3). The antibacterial and antimycotic properties of this wood have been studied in detail and are generally attributed to the low molecular weight extractives (1–3), particularly the three thujaplicins (**1***a–c*). On the other hand investigations of these extractives for possible insect control agents have been few and consequently our present interest is concentrated in this area.

The major cedar wood extractives are the thujaplicins (**1***a–c*), plicatic acid (**2**), thujic acid (**3***a*), and its methyl ester (**3***b*). β-Thujaplicin (**1***b*) was tested by Becker (4) against larvae of *Hylotrupes bajulus* (Crambycidae)[4] and was found to be a highly active insecticide. Experiments (2) with larvae of *Reticulothermes flavipes* showed a very low degree of termicidal activity in either β- or γ-thujaplicin (**1***b* and *c*) and in plicatic acid (**2**). The methyl ester of thujic acid (**3***b*) showed toxicity to larvae of the black carpet beetle, the furniture carpet beetle, and the case-making moth. Unfortunately, detailed quantitative results of these experiments have not been published (1). Recently Arndt (2) examined the so called "neutral fraction" of the wood extract

detail two classes of derivatives of thujic acid (**3***a*). The series of esters **3***c–h* was an obvious choice. The second series, substituted amides of thujic acid (**4***a–l*), was conceived on the basis of analogy with *N,N*-diethyl-*m*-toluamide (**5**). This amide, developed in 1954 by systematic testing of various synthetic compounds (5, 6), is an extremely potent repellent commonly used against various species of insects. Surprisingly, Jones and Jacobson (7) recently discovered that amide **5** also is a key component of the female sex attractant of the pink bollworm moth and thus a natural compound.[5] Further pertinent support for the projected exploration of the amide function came from recent work on insect juvenile hormone and juvabione analogs (9). This had shown that replacement of an ester group by an alkylamido function leads to profound enhancement of several types of insect controlling activity in both series of compounds.

We isolated thujic acid (**3***a*) from the viscous oil obtained by steam distillation of western red cedar wood (12, 15). This oil contained as main components the above mentioned extractives **1***a–c*, **3***a*, and methyl thujate (**3***b*). The acid was extracted by a solution of $NaHCO_3$, precipitated by acidification, and purified by crystallization. The acid chloride used as intermediate for the preparation of both the esters and the amides was obtained in excellent yield by the dimethylformamide catalyzed reaction (10) of thujic acid with $SOCl_2$ at room temperature. However, it was not possible to purify the crude liquid acid chloride by distillation due to ensuing decomposition of the product. Thus, the crude acid chloride was used directly.[6] It is known that under acidic

[5]It is important to note that there is a high degree of structural specificity associated with this amide in regard to its repellent and sex attractant activity. None of the isomers derived from *o*- or *p*-toluic acid showed any appreciable degree of activity. Consequently, the activity of amide **5** will perhaps be, apart from other necessary conditions, closely associated with the distance between the ring-positioned CH_3 group and the nitrogen of the amide group. Inspection of Dreiding models revealed that in diethyl-*m*-toluamide (**5**) and in contemplated amide structures (*e.g.* in **4***d* = **6**), the distance between the ring-positioned methyl group and the N of the amide group could be almost identical, averaging about 5 Å. Thujic acid was assumed to be in the well established (8) trough-like conformation. In both cases the amide nitrogen was projected into the center of a circle circumscribed by this atom in a freely rotating carboxamido group. However, we do not make any claims as to the conclusiveness of this assumption and accept it merely as a working hypothesis.

[6]Hurd and Edwards (13) prepared this chloride by a pyridine catalyzed reaction between the acid and $SOCl_2$. However, as in our case, they were unable to purify the crude chloride. Action of $SOCl_2$ without a catalyst led to a product which after hydrolysis gave a mixture of acids, presumably cumic and thujic. Apparently, the elevated temperature necessary for the acid chloride formation without catalyst was sufficient to bring about isomerization of thujic to cumic acid by action of HCl evolved in the reaction mixture.

conditions thujic acid easily rearranges into cumic acid (11, 12), eq. 1.

[1] 
We assured ourselves that under the present reaction conditions the thujic acid chloride formed did not contain any cumoyl chloride.[7]

The desired esters were prepared by reacting a slight excess of the crude thujic acid chloride with the appropriate alcohol in pyridine solution at 50° for 6 h. The crude esters were purified by distillation indicating that up to 150° the cycloheptatriene ring is thermally stable. The esters are summarized in Table 1. Three modifications of the common reaction between acid chloride and amine were used[8] to prepare amides **4***a–l* summarized in Table 2.

Methyl thujate (**3***b*) accompanying the free acid in the steam distillate of cedar wood appeared to be a potential starting material for the preparation of these amides. Indeed, it was possible to obtain several of them by reaction of **3***b* with aliphatic amines at elevated temperature. Unfortunately, the yields were low and products obtained contained considerable amounts of by-products. Most probably the α,β-unsaturated ester grouping of methyl thujate (**3***b*) was sufficiently reactive and a Michael-type addition took place parallel with the expected amide formation; eq. 2 exemplifies this point for the reaction with diethylamine. Although analytical and spectral properties of these products were in accord with this formulation we did not pursue this line to conclusive evidence.

[2] 
Only the unsubstituted amide and anilide of thujic acid and the ethyl and *p*-bromphenacyl esters were prepared previously (8, 13). None of these compounds has been reported to possess any type of biological activity.

[7]See Experimental.

[8]See Experimental for details.

We presented details of methods applied in evaluating the insect-controlling potential of our compounds, as well as discussion regarding structure–activity relationships in a separate paper (14). Therefore here we confine ourselves to outlining the most pertinent results in Table 3. In summary, the diethylamide of thujic acid (**4***d*) has been shown to be an extremely potent repellent of several insect species. Of particular interest is its activity against the blood-sucking yellow fever transmitter, *Aedes aegypti*. In contrast, thujic acid esters showed only traces of activity against species represented in Table 3. This again emphasizes the potential of the alkylamido group as a modifying substructure for various types of insect-controlling compounds of natural origin, as has already been exemplified in the case of juvenile hormone and juvabione analogs (9).

Finally, we may note that representative compounds of both series were screened[9] against several leaf eating insects. However, as yet, no distinct ovicidal, attractant or repellent activity has been observed. This testing program is continuing.

Experimental

General

Alcohols and amines used in the preparation of the respective esters and amides were of commercial origin, mostly reagent grade, and were used without further purification. G.l.c. analyses[10] were carried out using a 5 ft × 1/8 in. column packed with 5% OV-17 on 100–120 mesh GasChrom Q with a gas flow rate of 25 ml N_2/min and an appropriate temperature in the 100–250° range depending on the mol. wt. and type of compound tested. I.r. spectra of all compounds prepared were taken on a Perkin-Elmer 521 instrument and were in agreement with the expected structures. Melting points determined on a Kofler hot stage microscope and boiling points were not corrected. Elemental analyses were made by Galbraith Laboratories, Knoxville, Tennessee.

Isolation of Thujic Acid 3a

One hundred and twenty grams of a dark tarry oil obtained by steam distillation of cedar wood[11] was stirred with 500 ml of cyclohexane for 2 h at 25° until most of the oil dissolved. The solution was filtered to remove a small amount of undissolved material and the

[9]We appreciate the co-operation of Dr. I. Weatherston, Insect Pathology Research Institute, Sault St. Marie, Ontario.

[10]The analyses were kindly provided by Dr. W. G. Howells and Mr. K. L. McDonald and their staff. Their assistance in this regard is gratefully acknowledged.

[11]Our thanks are due to Mr. R. J. Rocchini and his staff for providing us with the steam distilled material.

For personal use only.

filtrate was stirred with 900 ml of a saturated $NaHCO_3$ solution until gas evolution ceased. The two phases were separated and another 200 ml of the $NaHCO_3$ solution was added to the cyclohexane layer and stirred for 1 h. Upon separation the aqueous phases were combined and carefully acidified with 10% HCl. The resulting yellow precipitate was filtered off and dried *in vacuo*. The thujic acid thus obtained was about 80% pure by g.l.c. The crude acid was effectively purified by recrystallization from 80% acetic acid and was then better than 95% pure by g.l.c., m.p. 86–89°, lit. (12, 13, 15) m.p. 88–89°. For the purpose of further identification the acid was converted by the method described below into its methyl ester, m.p. 35°, lit. (12, 16) 34–35°. The n.m.r. spectrum (60 MHz) of this methyl ester was identical with those published in the literature (15, 17).

Thujic Acid Chloride

Thujic acid (16.4 g, 0.1 mol) was slowly (1 h) added to a mixture of 17.8 g (0.15 mol) thionyl chloride and 0.73 g (0.01 mol) dimethylformamide. The mixture was left for 2 h at 25° and subsequently the excess of $SOCl_2$ was evaporated *in vacuo* at 40°. The crude chloride, a straw-colored oil, was used in subsequent esterifications and amidations directly.

The chloride (1 g) was stirred (1 h, 25°) with 20 ml of a 10% $NaHCO_3$ solution. Then the mixture was acidified with concentrated HCl and extracted with 1,2-dichloroethane; the extract was evaporated and the residue was tested for the presence of cumic acid by g.l.c. and i.r. None was detected.

Esters of Thujic Acid (3c–h)

The respective alcohol (0.08 mol) was dissolved in 20 ml of pyridine and 0.1 mol of the above acid chloride was added with stirring. The reaction mixture was kept at 60° for 6 h, left overnight at 25°, and then poured into water. The ester was extracted with ethyl ether and the extract was washed consecutively with water, 5% HCl, 10% $NaHCO_3$, and water. The dried ether solution was evaporated and the crude ester was purified by fractional distillation. All distilled esters showed only one peak on g.l.c. analysis with impurities estimated at less than 1%. Yields obtained were mostly better than 75% and no effort was made to optimize them. Using a similar procedure, the isopropyl ester of cumic acid was prepared and used as standard in a search (g.l.c.) for any traces of it in isopropyl thujate. Thus an additional proof was obtained that the thujic – cumic acid rearrangement did not take place during the acid chloride formation.

Amides of Thujic Acid (4a–l)

Method A. N,N-Di-n-butyl Thujamide (4f)

A benzene solution of di-*n*-butylamine (20%, 0.3 mol) was placed in an ice–water bath and 0.1 mol thujic acid chloride was added with stirring over 30 min so that the temperature did not exceed 40°. The mixture was stirred for 2 h and then left overnight. Water (150 ml) was added and the benzene layer which formed was separated. The aqueous phase was extracted with benzene, the original benzene phase and extracts were then combined, washed consecutively with H_2O, 10% HCl, 10% aqueous

$NaHCO_3$, and H_2O, and evaporated. The crude amide was purified by fractional distillation. See Table 2.

Method B. N,N-Diethyl Thujamide (4d)

An aqueous solution (20%) of diethylamine (0.3 mol) was stirred in an ice–water bath and 0.1 mol acid chloride was added over 30 min so that the temperature did not exceed 25°. Stirring was continued for 2 h and the mixture was then left overnight. The amide was extracted with benzene. Subsequent treatment of the extract and isolation procedure were similar to those in method A.

Method C. N-p-Chlorophenyl Thujamide (4j)

p-Chloroaniline (2.1 g, 0.016 mol) was dissolved in 15 ml pyridine and 3 g (0.016 mol) of thujic acid chloride was added over 10 min at 10°. After 2 h at 25° the mixture was quenched with ice and the subsequent work-up was similar to that of methods A and B.

This work was supported, in part, by a grant from the National Research Council of Canada, Industrial Research Assistance Program (IRAP). The skillful experimental collaboration of Mrs. E. C. Fryberg is appreciated.

Hot-Tube Reactions of Dehydroabietic Acid with Ketene-Producing Reagents. Pyrolysis of the Acid Chloride and Symmetrical and Mixed Anhydride Derivatives of Dehydroabietic Acid

RAY F. SEVERSON AND WALTER H. SCHULLER
Naval Stores Laboratory,[1] *Olustee, Florida 32072*

Received March 26, 1973

Dehydroabietic acid (**1***a*) was reacted with diketene, acetic acid, acetic anhydride, isopropenyl acetate, acetyl chloride, and acetone on Vycor rod at 450 °C in a hot tube. Dehydroabietic anhydride (**1***b*) and acetyl dehydroabietate (**1***c*) were pyrolyzed at 450 °C and dehydroabietyl chloride (**1***d*) was pyrolyzed over a temperature range of 290–500 °C. The major olefin products resulting from decarboxylation of the various derivatives were 19-norabieta-4,8,11,13-tetraene (**2**), 19-norabieta-4(18),8,11,13-tetraene (**3**), 19-norabieta-3,8,11,13-tetraene (**4**), and *cis*-1,10a-dimethyl-7-isopropyl-1,2,3,9,10,10a-hexahydrophenanthrene (**5**). High conversions to these compounds were obtained. In the presence of the ketene-producing reagents the olefins were oxidized to yield substantial amounts of retene (**6**), compounds **2** and **5** being the most readily dehydrogenated. The acid isomerization of **2**, **3**, **4**, and **5** was studied using *p*-toluenesulfonic acid in toluene at 110 °C.

On a fait réagir l'acide déhydroabiétique (**1***a*) avec le dicétène, l'acide acétique, l'anhydridre acétique, l'acétate d'isopropényle, le chlorure d'acétyle et l'acétone sur une tige Vycor à 450 °C dans un tube chaud. L'anhydride déhydroabiétique (**1***b*), le déhydroabiétate d'acétyle (**1***c*) ont été pyrolysés à 450 °C et le chlorure de déhydroabiétyle (**1***d*) dans l'intervalle de température 290–500 °C. Les produits oléfiniques majeurs qui résultent de la décarboxylation des divers dérivés sont le norabiéta-19 tétraène-4,8,11,13 (**2**), le norabiéta-19 tétraène-4(18),8,11,13 (**3**) le norabiéta-19 tétraène-3,8,11,13 (**4**) et le *cis*-diméthyl-1,10a isopropyl-7 hexahydro-1,2,3,9,10,10a phénanthrène (**5**). Les conversions en ces composés sont élevées. En présence de réactifs producteurs de cétène, les oléfines ont été oxydées en des quantités substantielles de rétène (**6**), les composés **2** et **5** étant deshydrogénés le plus rapidement. L'isomérisation acide de **2**, **3**, **4** et **5** a été étudiée en utilisant l'acide *p*-toluène sulfonique dans le toluène à 110 °C.

Can. J. Chem., 51, 3236 (1973)

Introduction

Our previously described work has illustrated that under certain conditions (400–500 °C) hot-tube pyrolysis of certain resin acids, in particular dehydroabietic acid (**1***a*), yields isolable A-ring olefins (19-norabieta-4,8,11,13-tetraene (**2**), 19-norabieta-4(18),8,11,13-tetraene (**3**), and 19-norabieta-3,8,11,13-tetraene (**4**)) (1, 2). Those conditions, however, which minimized further decomposition of the initial decarboxylation products, resulted in only about a 7% conversion of the acids to olefins.

It seemed feasible that the pyrolysis of some of the more thermally labile carboxylate derivatives of **1***a*, such as anhydrides and acid halides (3), would result in a much improved route to the A-ring olefins. Because of the increased reactivity of these derivatives it was considered possible to substantially decrease secondary decomposition products, while still maintaining desirable conversion levels, by reducing the reaction temperatures. The increased bulk of the derivatives made it seem probable that the carbonyl moiety would be eliminated more selectively and the yield of the vinylidine compound **3** would be improved. Recent interest in a facile transformation of **1***a* to **3**, to be used as a possible precursor in steroid synthesis (4), makes an increase in the relative amount of **3** in the olefin product highly desirable.

Since ketene can be produced from a variety of reagents under hot-tube conditions (3, 5), **1***a* might be reacted with these materials in the pyrolysis tube to form mixed anhydrides which then would decompose to yield the desired olefins, thus eliminating a prior synthetic step.

In this paper, work designed to verify these assumptions will be reported. The acid isomerization of the olefins obtained also was studied.

Experimental

Dehydroabietic Anhydride (1b)

This previously reported compound (6) was prepared by heating, under nitrogen, 5 g of **1***a* and 75 ml acetic

[1]One of the laboratories of the Southern Region, Florida/Antilles Area, Agricultural Research Service, U.S. Department of Agriculture.

anhydride and allowing the acetic acid which formed to distill out at a rate which maintained the pot temperature at 140 °C. Heating was stopped when the pot temperature reached 200 °C. The residue was dissolved in 20 ml of anhydrous acetone and the solid which formed upon cooling was collected and dried to yield 4.7 g, m.p. 137–40 °C (lit. (6) 142 °C). Recrystallization from hot heptane yielded 3.2 g of product, m.p. 140.5–142 °C; i.r. (KBr): ν_{max} 1810 and 1740 cm^{-1} (C=O, $Ab_{1740}/Ab_{1810} = 0.89$, $Ab_{2920(CH)}/Ab_{1805(CO)} \simeq 1.0$).

Acetyl Dehydroabietate (1c)

Ketene (prepared in a ketene generator from acetone (5)) was bubbled through a cold solution of 5 g of **1***a* in acetone until all the acid was consumed. The solvent was removed to yield an oil which solidified upon standing. The product was recrystallized from hot heptane to yield 3.2 g; m.p. 68–70 °C; i.r. (KBr): ν_{max} 1800 and 1735 cm^{-1} (C=O), $Ab_{1735}/Ab_{1805} = 0.9$, $Ab_{2920(CH)}/Ab_{1805(CO)} \simeq 0.5$); u.v. (heptane): λ_{max} 275.5 (ε 600) and 267.0 nm (ε 580); $[\alpha]_D^{25}$ +57.2° (*c*, 2.0 EtOH, no change in 2 h), +56.6° (*c*, 2.0 heptane).

Anal. Calcd. for $C_{22}H_{30}O_2$: C, 77.15; H, 8.82; O, 14.02. Found: C, 76.93; H, 8.93; O, 13.79.

Dehydroabietyl Chloride (1d)

This compound was prepared as described by Jeger and Durst (7). The previously uncharacterized crude product was distilled at 140 °C and 0.1 mm Hg in a molecular still to yield a colorless sirup with a neutralization equivalent of 319.7 (theory 318.9); i.r. (neat): ν_{max} 1800 cm^{-1} (C=O); u.v.: λ_{max} (isooctane) 275 (ε 735) and 267 nm (ε 740); $[\alpha]_D^{25}$ +125° (*c*, 3.2 isooctane).

Anal. Calcd. for $C_{20}H_{27}ClO$: C, 75.35; H, 8.56; Cl, 11.12. Found: C, 75.37; H, 8.60; Cl, 10.90.

Pyrolysis

The pyrolysis apparatus used has been described (2). Typically, 4 g of **1***a* in 20 ml of acetic acid was added dropwise into the Vycor rod pyrolysis column over a 60-min period (N_2 flow 20 ml/min). When addition was complete, the pyrolyzate was removed quantitatively with acetone and stripped on a rotoevaporator at 40 °C under water jet vacuum. Similar runs were made with acetic anhydride, isopropenyl acetate, acetyl chloride, and acetone. In the diketene experiment, a solution of 4 g of **1***a* and 4 ml of diketene in 16 ml of acetone was used. Compounds **1***b*, *c*, and *d* were pyrolyzed as 10% solutions in benzene (2 g in 20 ml). The pyrolyzates from the acid chloride runs were trapped over aqueous Na_2CO_3. The solvent was removed under reduced pressure on a rotoevaporator. Ether was added to the residue and the p*H* of the aqueous layer was adjusted to about 7 with dilute HCl. The ether extracts were washed with water until neutral, dried over Na_2SO_4, filtered, and the solvent was removed to yield oils. All pyrolyzates were protected from the atmosphere until they were analyzed for product composition.

Determination of Percent Yield

A weighed portion of each pyrolyzate was treated with an ethyl ether – diazomethane solution, a known amount of hexacosane (internal standard) was added, and the resulting solution was analyzed by g.l.c. using a 15 ft × 3/16 in. 10%-Dexsil 300 GC column (80/100 mesh NAW Chromosorb W, 100 ml/min He and temperature program 220–280 °C at 2 °C/min). The peak area for each component was corrected for differences in response, before percent yield data was calculated. All unidentified products were assumed to have the same response as the olefins. Response factors were determined from a solution containing known amounts by weight of the olefins, retene (1-methyl-7-isopropylphenanthrene (**6**)), **1***e*, and hexacosane.

Identification of Products

The products identified were collected from the Dexsil 300 column at 250 °C and rechromatographed and collected. Compounds **2**, **3**, **4**, **6**, and methyl dehydroabietate (**1***e*) were identified by g.l.c. retention data and i.r. and u.v. spectra (1).[2]

cis-1,10a-Dimethyl-7-isopropyl-1,2,3,9,10,10a-hexahydrophenanthrene (5)[3] was collected as a colorless oil which solidified upon standing, m.p. 34–35 °C; i.r. (neat): 1650 (R_1R_2C=CHR) (8), 1616 and 1500 (C=C, Ar), 884 (isolated ArH), 825 (two adjacent ArH), and 805 cm^{-1} (R_1R_2C=CHR) (8); n.m.r. (CCl_4): δ 0.84 (s, 3, C_{10a}—Me), 0.96 (d, 3, J = 6.0 Hz, C_1—Me), 1.21 (d, 6, J = 6.8 Hz, isopropylmethyls), 6.01 (t, 1, $J \simeq 3$ Hz, C_4—H), 6.79 (s, 1, C_8—H), 6.85 (d, 1, J = 7.5 Hz, C_6—H) and 7.29 p.p.m. (d, 1, J = 7.5 Hz, C_5—H); λ_{max} (95% EtOH) 296 (ε 1500), 287 (ε 1900), and 255 (ε 16 300) nm; $[\alpha]_D^{25}$ −93.4° (*c*, 1.3 95% EtOH). Mass spectrum *m/e* (relative intensity) 254.2049 ($C_{19}H_{26}$ requires 254.2034) (100), 239 (43.6), 212 (6.4), and 213 (18.3).

Anal. Calcd. for $C_{19}H_{26}$: C, 89.70; H, 10.30. Found: C, 89.40; H, 10.29.

Olefin Acid Isomerization

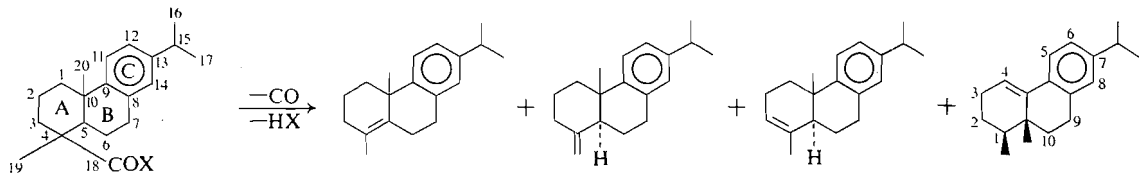
A stock acid solution containing 0.58 mg/ml of *p*-toluenesulfonic acid (*p*-TSA) in toluene was prepared (water of hydration was removed by azeotropic distillation). Several glass Carius tubes were placed on Dry-Ice and charged with 1-ml portions of the stock *p*-TSA solution and 1 ml of an anhydrous toluene solution containing 1.24 mg/ml of the A-ring olefin mixture consisting of 42% of **2**, 21% of **3**, and 37% of **4**. The tubes were flushed with argon, sealed under vacuum, and placed in an oil-bath at 110 °C. The tubes were removed at intervals, placed on Dry-Ice, opened, hexacosane internal standard added, and the *p*-TSA removed by washing with Na_2CO_3. The samples were analyzed by g.l.c.

The initial isomerization of **5** was run under identical conditions. After 48 h reaction time, the remaining tubes were opened and an additional 0.5 ml of a solution containing 1.33 mg/ml of *p*-TSA was added. The tubes were

---

[2]The n.m.r. data for compounds **2** and **3** given in ref. 1 were reported incorrectly. The C_{10}—Me resonance for **2** was at δ 1.33 instead of 1.24 and the C_4—Me at 1.66 instead of 1.33. The value for the C_4—Me for compound **3** was at 1.72 instead of 1.27. We thank Professor J. W. Huffman, Clemson University, for bringing these errors to our attention.

[3]The abietane nomenclature cannot be used for olefin **5** since it no longer has the β-C_4—methyl. In all discussions centered around **5**, the numbering system used for phenanthrene derivatives, as shown in structure **5** in Scheme 1, will be used. The term "A-ring olefins" will only be used in discussing those compounds with the normal abietane stereochemistry (β-C_4—Me), *i.e.* compounds **2**, **3** and **4**.



1 2 3 4 5

a X = OH
b X = dehydroabietate
c X = $OCOCH_3$
d X = Cl
e X = OCH_3

SCHEME 1

resealed and replaced in the oil-bath at 110 °C. The samples were analyzed at intervals as given above. Mass balances (from g.l.c. internal standard) were excellent (97–103%) at all intervals monitored.

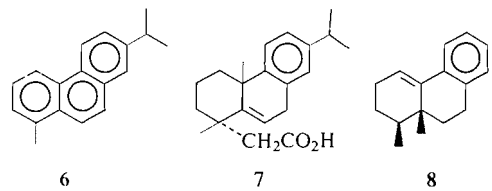
Results and Discussion

Solutions of **1***a* in ketene-producing reagents, *i.e.* diketene–acetone, acetic acid, acetic anhydride, isopropenyl acetate, acetyl chloride, and acetone, were reacted in a hot tube under nitrogen at 450 °C on Vycor rod. Compounds **1***b* and *c* were pyrolyzed in benzene solutions under the same conditions. The compositions of the pyrolyzates obtained are shown in Table 1.

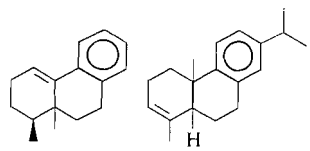
In order to study the effect of temperature on the pyrolyzate composition, the acid chloride **1***d* was pyrolyzed at 290 °C over Na_2CO_3 in the g.l.c. injection port and at 350–500 °C in the hot tube. Product analysis of these runs is given in Table 2.

Compounds **2**, **3**, **4**, **6**, and **1***a* were identified by comparison of their g.l.c. retention data and i.r. and u.v. spectra with the authentic compounds. The mass spectrum of **5** showed that it was isomeric with **2**, **3**, and **4** (molecular ion, *m/e* 254). Unlike the other olefins, the u.v. spectrum of **5** showed strong absorption at 255 nm (ε 16 300), indicating the presence of an aromatic conjugated double bond (9). Since Δ^5-dehydrohomodehydroabietic acid (**7**) has the normal **1***a* u.v. maxima (λ_{max} 267 and 275.5 nm (10)), the only compounds consistent with the spectral data are the *cis*- or *trans*-1,10a-dimethyl-7-isopropyl-1,2,3,9,10,10a-hexahydrophenanthrene. Comparison of the methyl and vinyl n.m.r. resonances of **5** with the n.m.r. data of the known *cis*- and *trans*-deisopropyl analogs **8** and **9** (11) clearly showed that **5** is the *cis*-dimethyl compound.

Inspection of Table 1 shows that, as anticipated, **1***a* did react directly with the reagents or with ketene produced by thermal decomposition of the various reagents in the hot tube to form a mixed anhydride which then decomposed to yield olefins. The fact that **1***c* gave essentially the same spectrum of products substantiates this conclusion. In contrast to the mixed anhydride pyrolyzates, only a trace of **6** was found when the symmetrical anhydride **1***b* was pyrolyzed.



6 7 8



9 16

Also, a much higher relative yield of the new olefin, **5**, was found. This observation indicates that ketene or radicals formed during ketene formation are behaving as dehydrogenation agents and are oxidizing the olefins to **6**, compounds **2** and **5** being most readily dehydrogenated. The percent recovery data show that decomposition of **1***b* is essentially complete under these conditions. Amounts of g.l.c. volatile material were considerably lower in some of the other runs, probably due to the reaction of **1***a* with ketene in the pyrolyzate-trapping system. (The i.r. spectrum of the crude pyrolyzate from

SCHEME 2

all the acid chloride decomposed to yield hydrocarbon products. A theoretical recovery of g.l.c. volatile products was obtained over the 350–450 °C range. The extremely low conversion to **6** at 450 °C and below substantiates our previous rationalization for the high yields of this material observed in the presence of ketene. As with the resin acids (1), a large decrease in recovered material and increase in multi lower molecular weight unidentified hydrocarbons were observed at 500 °C. These lower molecular weight materials and **6** appear to be formed predominantly by secondary decompositions of **2** and **5**. Both of these olefins have the structural requirements to readily undergo the thermal retro Diels–Alder reaction (12) resulting in the loss of ethylene from **2** (1) and propylene from **5** as shown in Scheme 2. This is substantiated by the fact that compounds **8** and **9** undergo a retro Diels–Alder reaction to lose propylene in the mass spectrometer (11). The loss of the isopropyl group to yield an ion at *m/e* 213 somewhat complicates this observation of the retro Diels–Alder reaction in the mass spectrum of **5**. However, after correction for higher isotopes resulting from isopropyl fragmentation, one-half of the intensity of the ion at *m/e* 212 can be attributed to retro Diels–Alder fragmentation. The formation of **10** at higher temperatures readily explains the formation of the various 2-methylnaphthalenes and substituted acenaphthenes (**11**) formed during the pyrolysis of **1***e* at 600–800 °C (2).[4]

In contrast to the other olefins, **5** was produced from **1***d* in decreasing relative amounts with increasing reaction temperature. The recovery rate at 450 °C and below clearly indicates that the retro Diels–Alder reaction does not occur to any appreciable extent at these temperatures. A possible explanation for the decreasing yield of **5** could be gas-phase acid isomerization of the primary decomposition olefin products. It has been reported that the normal A-ring olefins

[4]Although not previously identified, the neutral fraction of the 450 °C pyrolyzate from **1***a* contained 2.5% of **5** (1).

[a]Data obtained using *p*-TSA in toluene at 110 °C.
[b]Assignments were made by g.l.c. retention and u.v. data.

(**2**, **3**, and **4**) are readily isomerized by *p*-TSA in refluxing toluene to yield an olefin mixture containing predominantly **4** and a new compound, 19-nor-5-β-abieta-3,8,11,14-tetraene (**16**), in which the latter predominates (13). Since no effort was made to carry this reaction to completion, the isomerization was repeated.

An olefin mixture consisting of 42% of **2**, 21% of **3**, and 37% of **4** was heated at 110 °C with *p*-TSA in toluene under an inert atmosphere. The course of the isomerization was monitored by g.l.c. at various intervals (Table 3). After 160 h a steady-state composition of 52% of **1***b*, 43% of **2**, 2% of **4**, and 1% of **3** was obtained.[5] The normal A-ring olefins reached an equilibrium condition in 40 h consisting of 93% of **2**, 5% of **4**, and 2% of **3**. A very slow conversion to **5** also had occurred, with 2% of the mixture being **5** after 300 h. Pure **5** was treated under the same conditions and no change was observed after heating for 90 h. The fact that **5** is stable to acid is consistent with its proposed structure,

[5]The plot of percent composition *vs.* time (Fig. 1) for the acid isomerization of the 19-norabieta-tetraenes (**2**, **3**, and **4**) using *p*-TSA in toluene at 110 °C is available at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

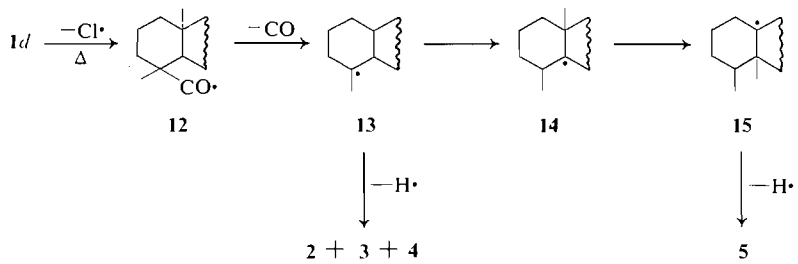

SCHEME 3

since the phenyl-conjugated double bond system should result in the most stable system.

From the isomerization data it should be safe to conclude that little if any acid-catalyzed rearrangement of the initially formed **5** had occurred in the hot tube. The absence of **16** and the constant A-ring olefin ratios below 450 °C on the **1***d* pyrolyzate indicate that acid induced rearrangement does not readily take place during pyrolysis. The constant relative A-ring olefin ratios in the pyrolyzates of **1***d* below 450 °C also indicate that thermally induced isomerization is not important at the lower temperatures. If thermal double bond rearrangements were occurring, a relative increase would be expected in the yield of **2** and **5** with increasing pyrolysis temperatures.

A possible rationale for the decreasing yield of **5** with increasing temperature may be the mechanism by which the various products are formed. From other pyrolysis work on acid halides (14), the first step in the decomposition of **1***d* may be assumed to be the loss of a chlorine radical, followed by decarbonylation to yield intermediate **13**, as shown in Scheme 3. The lower temperatures favor rearrangement to the most stable radical (**15**) and therefore the formation of **5**. As the temperature increases, the concentration of radicals increases, making hydrogen abstraction more probable. Thus, radical stability becomes less important and an increased yield of **2**, **3**, and **4** results.

The authors wish to thank Dr. Bernard A. Parkin, Jr. and Mr. Gordon S. Fisher of the Naval Stores Laboratory for many helpful discussions; Miss Lynn Griffin, Dept. of Chem., Florida State University, for the mass spectral analysis; and Mr. Richard Rosanski, Dept. of Chem., Florida State University, for obtaining the n.m.r. data.

The gas phase equilibria

$(n,n-1)$ $\quad NH_4^+(NH_3)_n = NH_4^+(NH_3)_{n-1} + NH_3$

$(w,w-1)$ $\quad NH_4^+(H_2O)_w = NH_4^+(H_2O)_{w-1} + H_2O$

and those leading to mixed clusters like

$$NH_4^+(NH_3)_{n-1}(H_2O)_w + NH_3 = NH_4^+(NH_3)_n(H_2O)_w$$

were measured with a pulsed electron beam high pressure ion source mass spectrometer. The ion source contained pure ammonia or mixtures of ammonia and water vapor at pressures in the Torr range. Determination of the temperature dependence of the equilibrium constants led to the evaluation of ΔG^0, ΔH^0, and ΔS^0 values for the equilibria from $n = 1$ to 4 and $w = 1$ to 5. The ΔG^0 values for the $NH_4^+(NH_3)_n$ equilibria were in good agreement with previous determinations from this laboratory. Fair agreement was observed for the ΔH^0 and ΔS^0 values. Comparison with the corresponding results for $NH_4^+(H_2O)_w$ showed that the $\Delta H_{n,n-1}$ and $\Delta G^0_{n,n-1}$ were larger than $\Delta H_{w,w-1}$ and $\Delta G^0_{w,w-1}$. The difference was largest for the first step (1,0) and decreased progressively until a reversal with water values becoming larger occurred at the (5,4) step. The stronger hydrogen bonds of NH_3 to NH_4^+ for low ligand numbers is explained by the greater basicity of NH_3. As the ionic charge becomes dispersed and more distant stronger interactions are obtained with water which gives stronger H bonds in the absence of positive ionic charge. Breaks in the $\Delta H_{n,n-1}$ values indicate existence of a relatively stable $NH_4^+(NH_3)_4$ symmetric ion. A much smaller and less distinct break is observed with pure water ligands.

The mixed ammonia–water clusters show similar effects. The addition of a NH_3 molecule to a pure water ligand complex gives the strongest interaction. The addition of H_2O to a pure ammonia cluster gives the weakest interaction. The above effect is strongest at lowest ligand numbers. The difference decreases gradually and becomes reversed for more than four ligands.

Les équilibres en phase gazeuse

$(n,n-1)$ $\quad NH_4^+(NH_3)_n = NH_4^+(NH_3)_{n-1} + NH_3$

$(w,w-1)$ $\quad NH_4^+(H_2O)_w = NH_4^+(H_2O)_{w-1} + H_2O$

et ceux qui conduisant aux mélanges d'association du type

$$NH_4^+(NH_3)_{n-1}(H_2O)_w + NH_3 = NH_4^+(NH_3)_n(H_2O)_w$$

ont été étudiés par la mesure du rayon électronique pulsé à haute pression dans une source d'ion d'un spectromètre de masse. La source ionique contient de l'ammoniac pur ou des mélanges d'ammoniac–vapeur d'eau à des pressions de l'ordre du Torr. L'étude de l'influence de la température sur les constantes d'équilibre conduit aux valeurs ΔG^0, ΔH^0 et ΔS^0 des équilibres pour $n = 1$ à 4 et $w = 1$ à 5. Les valeurs de ΔG^0 obtenues pour les équilibres de $NH_4^+(NH_3)_n$ sont en bon accord avec les déterminations antérieures faites au laboratoire. Les valeurs de ΔH^0 et ΔS^0 concordent également. La comparaison avec les résultats correspondant pour $NH_4^+(H_2O)$ montre que $\Delta H_{n,n-1}$ et $\Delta G^0_{n,n-1}$ sont supérieurs à $\Delta H_{w,w-1}$ et $\Delta G^0_{w,w-1}$. La différence est la plus forte dans la première étape (1,0) et décroît progressivement jusqu'à une situation inversée c'est à dire des valeurs supérieures pour l'eau dans l'étape (5,4). Les liaisons hydrogènes plus fortes entre NH_3 et NH_4^+ pour des nombres de ligands faibles s'expliquent par une plus forte basicité de NH_3. A mesure que la charge ionique se disperse et que les interactions lointaines deviennent plus fortes avec l'eau, celle-ci donne des liaisons H plus fortes en l'absence de charge positive ionique. La coupure dans les valeurs $\Delta H_{n,n-1}$ indique l'existence d'un ion relativement stable $NH_4^+(NH_3)_4$ symétrique. Avec les ligands eau pure, cette coupure est plus faible et moins distincte. Les associations mixtes ammoniac-eau donnent des effets similaires. L'addition d'une molécule d'ammoniac au ligand eau pure complexée conduit à l'interaction la plus forte. L'addition d'eau à l'ammoniac associé donne l'interaction la plus faible. L'effet ci-dessus est le plus prononcé lorsque les nombres de ligands sont les plus bas. La différence décroît graduellement pour devenir inversée pour plus de quatre ligands.

Introduction

Some of the earliest measurements of gas phase clustering equilibria done in this laboratory dealt with the ammonium ion.

$$(n,n-1) \quad NH_4^+(NH_3)_n = NH_4^+(NH_3)_{n-1} + NH_3$$

Studies of the equilibria $(n,n-1)$ at different temperatures led to values (1) for $\Delta H_{n,n-1}$ and $\Delta S_{n,n-1}$ for $n = 1$ to $n = 5$. The ΔH values obtained were 27 kcal/mol for the (1,0) step followed by a much decreased 17 kcal for the second step (2,1) then slower decreases for the (3,2) and (4,3) steps and again a somewhat larger decrease to the (5,4) step. These results were interpreted (1*a*) as an indication of a particularly stable $NH_3H^+NH_3$ with a symmetrically shared proton followed by the "normal" ammonium ion clusters $NH_4^+(NH_3)_n$ from $n = 3$ to $n = 4$ and then a change over to an "outer shell" position for the fifth ligand molecule. The existence of a symmetric four ammonia species $NH_4^+(NH_3)_4$ was supported by the findings of an earlier study (2) in which the mixed clusters $NH_4^+(NH_3)_n(H_2O)_w$ had been observed. These experiments were done with mixtures of water and ammonia vapor at a single temperature. The relative abundances of the clusters showed that when $n + w$ was less than four (*i.e.* inner shell) ammonia was taken into the cluster in preference to water. For clusters where $n + w$ was bigger than four the data could be interpreted by assuming preference of NH_3 in the inner shell of four molecules and preference for water in the outer shell (2).

The present work is intended as an improvement and extension of the earlier findings. More complete measurements were made this time, including the study of the ammonium ion solvated by water molecules alone, *i.e.* the species $NH_4^+(H_2O)_w$. Furthermore the mixed cluster stabilities were studied as a function of temperature so that enthalpy changes and entropy changes for the NH_3, H_2O exchange and addition to given mixed clusters could be obtained. We believe that these new results give a more accurate and consistent picture of ammonia ion solvation by ammonia and water molecules and the importance of hydrogen bonding. Furthermore, these results also connect to recent gas phase studies of the proton held alkyl amine dimers (3) and to the hydrogen bonded species obtained in protonated water, methanol, and dimethyl ether (4).

Experimental

The measurements were done with a pulsed electron beam high pressure mass spectrometer which was described earlier (5). Some specific details in procedures relating to the systems treated are shown below.

(a) The $NH_4^+(NH_3)_n$ Equilibria

These measurements were made with pure NH_3 at pressures between 2–7 Torr and temperatures between 25–450 °C. The ammonium clusters were the only ions observed. Pulsing of the electron beam allowed detection of the time dependent intensities of the ions extending over a few ms. The observed relative concentrations became constant in less than 100 μs after the electron pulse indicating rapid achievement of clustering equilibrium. A rapid establishment of the equilibrium for the conditions used is expected since the rate constants for the clustering reactions should be similar to those measured for the $H^+(H_2O)_n$ system (5).

(b) The $NH_4^+(H_2O)_w$ Equilibria

To observe the $NH_4^+(H_2O)_w$ equilibria one must use a very large H_2O:NH_3 pressure ratio. In such a system primary ionization leads to H_2O^+ and OH^+ ions which are rapidly converted to H_3O^+ and higher water clusters. The NH_4^+ and $NH_4^+(H_2O)_w$ ions are produced by bimolecular reactions of H_3O^+ and $H^+(H_2O)_n$ with NH_3. The rate constants for these reactions should be in the $k = 10^{-9}$ cm^3 molecule^{-1} s^{-1} range. The half life for formation of NH_4^+ should thus be in the $t_{1/2} = 0.7\ (10^{-9}n)^{-1}$ range where n represents the number of NH_3 molecules per cm^3. At a pressure of NH_3 equal to 10 mTorr, $n \approx 10^{14}$ and $t_{1/2} \approx 10^{-5}$ s. Thus only 10 mTorr NH_3 are sufficient for a rapid conversion to ammonium ion clusters. Typically 2–7 Torr of water vapor containing 1–10 mTorr of NH_3 were used in the experiments. No H_3O^+ or $H^+(H_2O)_n$ clusters were observed under these conditions. The equilibrium concentrations of the proton hydrates are expected to be very small since the proton affinities of NH_3 and H_2O differ by some 40 kcal.

(c) The Mixed Cluster Equilibria $NH_4^+(NH_3)_n(H_2O)_w$

The mixed clusters were observed with water vapor at pressures 2–8 Torr containing a few percent of ammonia vapor. These small concentrations of ammonia were found generally sufficient to produce all mixed clusters. This is possible since NH_3 is strongly preferred in the inner shell. The water pressure was determined directly by the ion source manometer reading. The partial pressure of ammonia was determined by observing the ions $NH_4^+(NH_3)_n$ and $NH_4^+(NH_3)_{n-1}$ and using the $K_{n-1,n}$ determined in the experiments with pure ammonia

$$(n,n-1) \quad NH_4^+(NH_3)_n = NH_4^+(NH_3)_{n-1} + NH_3$$

In the mixed solvent system the number of positive ions coexistent at equilibrium was often very large, some 12 mixed clusters being present in some experiments. It was found difficult to record the time dependent ion intensities of all these ions in a given experiment. The time required for this was very long (2–3 h) and it was difficult to maintain constant reaction conditions over such a period. To overcome this problem a gated single channel scaler was used instead of the multichannel analyzer. The master pulse generator, triggering the electron pulse, activated a

second pulse generator which kept the gate of the scaler closed for the first 100 μs after the electron pulse. In this manner all ions with reaction times greater than 100 μs were collected together. The achieved increase in signal intensity allowed direct, slow, mass scanning of the cluster ion intensities. Spot checks with the multiscaler were made. No differences in the equilibrium constants determined by the two methods were found which was to be expected since equilibria should have become established in less than 100 μs.

In all runs, described in parts *a*, *b*, and *c* above, a slow gas flow through the flow type ion source (3) was maintained. The flow rate through the ion source corresponded to some 70 cm^3/s which leads to a gas residence time of 50 ms in the ionization region.

Results

The $NH_4^+(NH_3)_n$ results are summarized in Table 1. Figure 1 gives an illustration of the temperature and pressure range used for the (0,1) equilibrium. The equilibrium constant is seen to be independent of the ammonia pressure used. Similar results were obtained for the pressure dependence of the other equilibrium constants. Figure 2 gives the van't Hoff plots from which $\Delta H_{n,n-1}$ and $\Delta S_{n,n-1}$ for the pure ammonia system were determined. Included in the table are the results from the earlier determination (1*a*). The ΔG^0 values are seen to be very close to those of the earlier determination. The new ΔH values and consequently also the ΔS values are somewhat lower. The reason for the differences is not too well understood. The earlier determination (1*a*) was done with a proton beam high pressure ion source at significantly lower pressures and no time dependence measurement. The earlier temperature measurement in the high temperature range was also suspected to be somewhat inaccurate, since somewhat similar differences were observed between recent (5) and

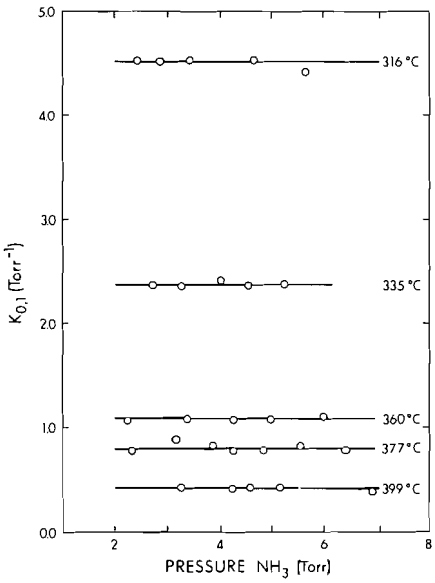

FIG. 1. Dependence of equilibrium constant $K_{0,1}$ for reaction $NH_4^+ + NH_3 = NH_4^+NH_3$ on pressure of NH_3 at different reaction temperatures. Standard state 1 Torr.

older determinations of the $H^+(H_2O)_n$ equilibria. Table 1 also includes some recent ΔG^0 determinations by Fehsenfeld and Ferguson (6) based on measurements with the flowing afterglow (7) method. The afterglow results were obtained by measurement of the forward and reverse rates of the reactions with O_2 and CO_2 as buffer gases. Since the measurements were done at a single temperature only $K = k_f/k_r$ and ΔG^0_{296} were obtained by Fehsenfeld and Ferguson. The agreement with the present results for $\Delta G^0_{4,3}$ and $\Delta G^0_{3,2}$ is seen to within 0.3 and 0.4 kcal. A difference of 0.7 kcal or larger

exists for the $\Delta G^0{}_{2,1}$ value. Probably, the Fehsenfeld–Ferguson determination is more accurate since it deals with a ΔG^0 determination at the quoted temperature, while the present $\Delta G^0{}_{298}$ is based on equilibria measurements obtained at considerably higher temperature. On the whole the agreement between the ΔG^0 values is quite good considering the difference of experimental technique and the experimental difficulties.

The results for the $NH_4{}^+(H_2O)_w$ clusters are also given in Table 1. The van't Hoff plots of the equilibrium constants from which the data were derived are shown in Fig. 2. The van't Hoff plots for the mixed cluster equilibria are given in Figs. 3, 4, and 5 and the resulting thermodynamic values in Tables 2 and 3. In order to shorten the designations an abbreviated notation was used. A clustering reaction like

$$NH_4{}^+(NH_3)_2(H_2O)_1 + H_2O = NH_4{}^+(NH_3)_2(H_2O)_2$$

was replaced by n_2w_1,n_2w_2, and an exchange reaction like

$$NH_4{}^+(NH_3)_3(H_2O)_1 + H_2O = NH_4{}^+(NH_3)_2(H_2O)_2 + NH_3$$

was replaced by n_3w_1,n_2w_2, etc.

As evident from the van't Hoff plots in Figs. 3, 4, and 5, in general the mixed cluster determinations were carried out over a fairly narrow temperature range. The ΔH and ΔS values are therefore of correspondingly reduced accuracy.

The exchange reaction data in Table 3 were derived from the clustering reaction data in Table 2, since ΔG for a reaction like (n_3w_1,n_2w_2) is equal to ΔG^0 for (n_2w_1,n_2w_2) minus ΔG^0 for (n_2w_1,n_3w_1). The ΔG^0 values for several exchange reactions observed in the early work (2) from this laboratory on mixed ammonia–water clusters are also given in Table 3. These values

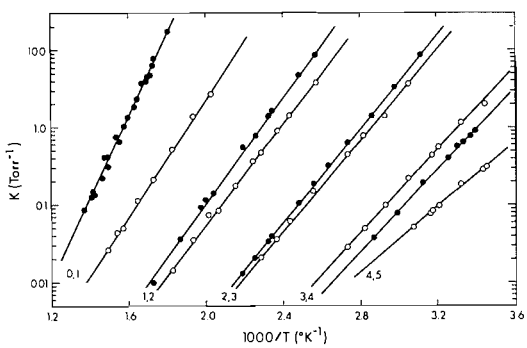

FIG. 2. Van't Hoff plots for reactions $NH_4{}^+(NH_3)_{n-1} + NH_3 = NH_4{}^+(NH_3)_n$, ●; and $NH_4{}^+(H_2O)_{n-1} + H_2O = NH_4{}^+(H_2O)_n$, ○. Results show very clearly the much greater stability of $NH_3H^+NH_3$ over $NH_4{}^+OH_2$. However, the interaction with water becomes progressively less unfavorable and at the (3,4) equilibrium the water cluster has become more stable. Standard state 1 Torr.

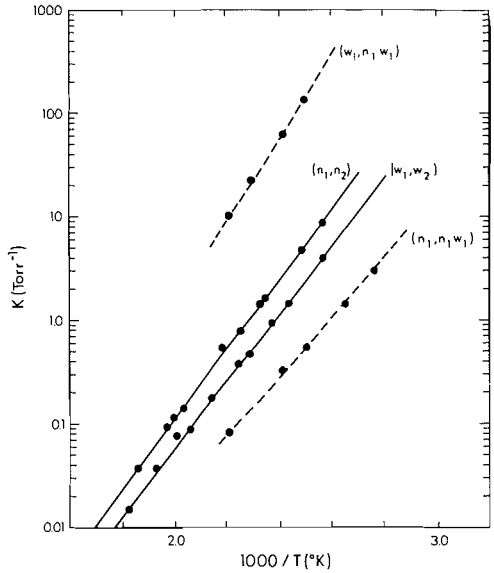

FIG. 3. Van't Hoff plots for equilibria: $NH_4{}^+ + H_2O = NH_4{}^+NH_3H_2O$ (n_1,n_1w_1); $NH_4{}^+H_2O + H_2O = NH_4{}^+(H_2O)_2$ (w_1,w_2); $NH_4{}^+NH_3 + NH_3 = NH_4{}^+(NH_3)_2$ (n_1,n_2); and $NH_4{}^+H_2O + NH_3 = NH_4{}^+NH_3H_2O$ (w_1,n_1w_1). Standard state 1 Torr.

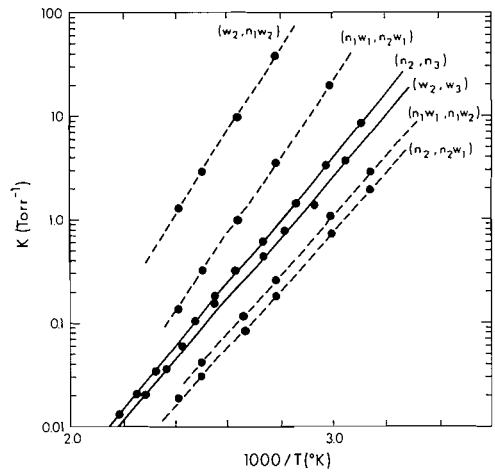

FIG. 4. Van't Hoff plots for mixed ammonia–water clusters equilibria involving the addition of one ligand (H_2O or NH_3) to a cluster containing two ligands. For notation see Fig. 3 and text. Strongest interaction is obtained by adding NH_3 to a pure water ligand cluster, weakest by adding H_2O to a pure ammonia cluster. Standard state 1 Torr.

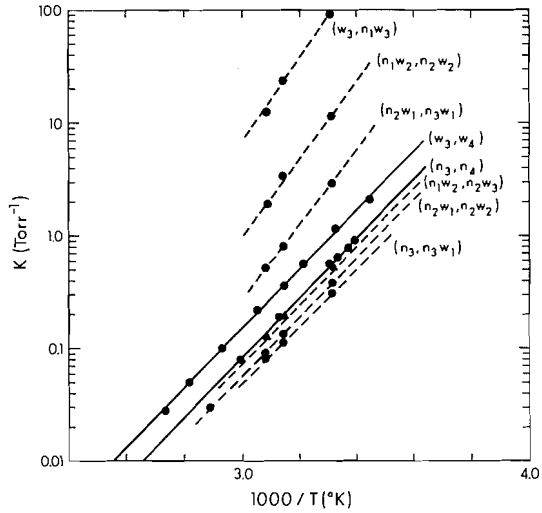

FIG. 5. Van't Hoff plots for mixed ammonia–water cluster equilibria involving the addition of one ligand (H_2O or NH_3) to a cluster containing three ligands. For notation see Fig. 3 or text. Strongest interaction is obtained when adding one NH_3 to a pure water ligand cluster, weakest interaction on adding H_2O to a pure water ligand cluster. Notable are also the much bigger intervals (ΔG decreases) between the upper plots, *i.e.* addition of NH_3 compared with the lower plots, *i.e.* addition of H_2O. Standard state 1 Torr.

were obtained from the intensities given in Table 2 of ref. 2. ΔG^0 values measured by Fehsenfeld and Ferguson (6) for the exchange reactions are also included in Table 3. On the whole there is fair to good agreement between these three sets of ΔG^0 values.

Discussion

The new data support the conclusions from the earlier work which were outlined in the introduction. The availability of the new $NH_4^+(H_2O)_w$ and extensive mixed cluster data permit some new insights. Figure 6 shows the enthalpy changes $\Delta H_{n,n-1}$ of Table 1 plotted *vs.* n. The enthalpy changes for the formation of $NH_4^+(NH_3)_n$ species are seen to be generally larger than those for $NH_4^+(H_2O)_w$. The difference is largest for the $\Delta H_{1,0}$ step and decreases progressively. In the earlier work this effect was explained on basis of the higher polarizability of ammonia. An alternate description used in more recent, related work (3, 8) is to consider the hydrogen bond, formed between NH_4^+ and the incoming NH_3 or HOH as a partial acid base reaction where NH_4^+ is the acid and NH_3 or HOH the base. From this viewpoint the stronger gas phase base (3) NH_3 should lead to the stronger hydrogen bond, *i.e.* larger $\Delta H_{1,0}$ and $\Delta G_{1,0}$ values. The partial proton transfer, *i.e.* partial acid–base reaction concept, was shown to be valid for Cl^-–HR complexes (8) and the alkyl amine proton held dimers (3).

Recently Peyerimhoff and co-workers (10) have published a theoretical study of the $[H_3N—H—NH_3]^+$ species based on *ab initio* s.c.f. calculations. The binding energy for dissociation to $NH_4^+ + NH_3$ calculated by these authors is 36 kcal, which is considerably higher than the present experimental value of ~25 kcal for $\Delta H_{1,0}$. Allowing for a couple of kcal correction for the zero point energy one still must conclude that the difference is considerable beyond the experimental error of the present determination and that the theoretical value is probably incorrect. More interesting are the theoretical results on the geometry of the complex and the charge distribution. Peyerimhoff and co-workers

n_3w_1,n_2w_2	1.2		3.3	6.5
n_2w_2,n_1w_3	1.9		3.5	5.4
n_1w_3,w_4	2.8		5.1	7.8

[a]Values calculated from data of Table 2. For explanation of notation used in designation of reactions see Table 2 or text.
[b]Private communication (6), after present experimental work was completed.
[c]Reference 2.
[d]These values show reversed change from that expected. This is probably due to experimental error. $\Delta H(n_2,n_1w_1)$ is expected to be smaller than $\Delta H(n_1w_1,w_2)$.

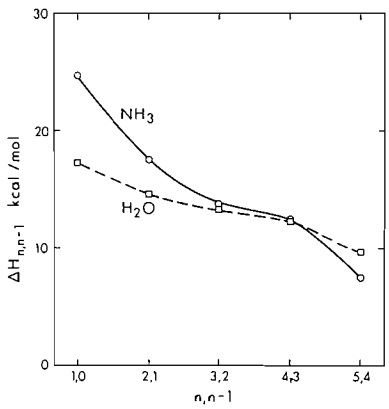

FIG. 6. Plot of $\Delta H_{n,n-1}$ for reactions: $NH_4^+(NH_3)_n = NH_4^+(NH_3)_{n-1} + NH_3$ and $NH_4^+(H_2O)_n = NH_4^+(H_2O)_{n-1} + H_2O$ *vs.* $n,n-1$. Gradual change to more favorable interactions with water is indicated for n larger than 4.

(10) find that the lowest energy configuration is not symmetric but that the proton is closer to one of the N atoms. The barrier for proton transfer was found to be ~3.5 kcal for a fixed N—N distance but became only ~2 kcal when the N—N distance was allowed to adjust (decrease) to give minimum energy while the proton was transferred. This low energy barrier indicates very nearly free exchange of the proton at room temperature. The authors also found significant electron density decrease in the N—H bonds on formation of the dimer showing that considerable positive charge dispersal occurs in that species. It is interesting to note that theoretical (11) and experimental (12) findings for the isoelectronics species $[H_2OHOH_2]_2^+$ predict a symmetric equilibrium position of the proton between the two O atoms. However, the potential minimum for motion of the proton along the line of O centers is very broad (11) which shows that the ammonia and water proton dimers are not totally devoid of similarity.

The present results (Table 1 and Fig. 6) show that with increasing number of ligands the NH_4^+ interactions with water molecules become progressively closer in magnitude to those with ammonia. A crossover occurs with the $\Delta H_{5,4}$ value for water becoming larger than that for ammonia (see Fig. 6). It is interesting to note that the ΔG values cross over even earlier, *i.e.* $\Delta G^0_{4,3}$ for water is larger than that for ammonia. This gradual change and reversal is also seen very directly in the van't Hoff plots of Fig. 2. One may understand these results by considering that the positive charge becomes progressively dispersed and less important to the bonding with increase of the number of ligand molecules. Therefore, gradually, the greater hydrogen bonding ability of HOH (in the absence of an ionic charge) becomes more and more important.

The mixed clusters show the operation of similar principles. The data in Table 2 show that for a total of up to four ligands the addition of an ammonia molecule is always favored over the addition of a water molecule. The effect is larger the smaller the total number of ligands and the smaller the number of NH_3 molecules initially present in the cluster. Again this effect is most directly observed in the van't Hoff plots of Figs. 3, 4, and 5. The straight lines corresponding to the different equilibria are spread out like a fan. The center of the fan falls between the two lines for the pure ammonia or pure water clusters. The top line, *i.e.* the most favorable interaction, is always that for the addition of NH_3 to a pure water cluster while the bottom line is that for the addition of a water molecule to a pure ammonia cluster.

The same trends are expressed in the exchange or switching reactions shown in Table 3. For example the exchange reaction

$NH_4^+(H_2O)_4 + NH_3 = NH_4^+(NH_3)_1(H_2O)_3 + H_2O$

is strongly exothermic while the reaction

$NH_4^+(NH_3)_3H_2O + NH_3 = NH_4^+(NH_4)_4 + H_2O$

is almost thermoneutral. The entropy changes for the exchange reactions (Table 3) are generally small as is to be expected for reactions of this type. The data show that ΔS becomes more positive the more unfavorable the exchange. For example the exchange n_3,n_2w_1 has a ΔH of 1.4 kcal and a ΔS of 1.1 e.u. The less favorable exchange n_1w_2,w_3 in which the last ammonia molecule is lost has a larger ΔH of 4.8 kcal and a larger ΔS of 5.2 e.u. Such a relationship between ΔH and ΔS is often observed. It should be noted that on grounds of probability only, the first reaction should have the larger ΔS since the number of ammonia molecules that can be replaced is larger.

The treatment of the data in the earlier work (2) on mixed ammonia and water clusters utilized a factor γ for the preferential intake of ammonia over water molecules in a cluster. γ was obtained by a statistical fit of the relative intensities of mixed clusters with a fixed total number of ligands. The data indicated that γ does not change much with the number of ammonia molecules present in the cluster. It is evident from the present work and the present treatment of the data that this is not so. We realize now that the early set of experimental results was not sufficiently extensive to show that the preference factor approach was not useful and that it leads to a somewhat misleading averaging of the changing preference for ammonia in a cluster with a fixed total number of ligands.

Unfortunately the present results do not include measurements with a low temperature source which would have permitted good measurements for the equilibria involving more than five molecules. Such a source was constructed and is in use (4) but has not yet been applied to the ammonium ion. The available data in Table 1 show that there is a break in the ΔH values between $\Delta H_{4,3}$ and $\Delta H_{5,4}$ for the pure ammonia clusters but a considerably smaller break for the NH_4^+–water system. A small but still distinct break occurs between the $\Delta G^0_{4,3}$ and $\Delta G^0_{5,4}$ values for pure ammonia, while there is no noticeable break for the NH_4^+–water system. This difference of behavior between ammonia and water should be caused by factors similar to those outlined in the discussion of the one to four molecule results. Since ammonia is a stronger base than water, it hydrogen bonds more strongly when H atoms with appreciable positive charge are available. The dispersal of positive charge increases from $NH_4^+NH_3$ to $NH_4^+(NH_3)_4$ and the strength of the H bonding decreases. In $NH_4^+(NH_3)_4NH_3$ an additional bonding decrease occurs since no more "ammonium" hydrogens are available. The decrease is smaller than one might have expected since charge was dispersed all along during the growth of the cluster. HOH, on the other hand, is a strong hydrogen bonding species even in the absence of ionic charge and can be expected to show an even less distinct transition from "inner" to "outer" shell. This result is in line with observations in the $H_3O^+(H_2O)_w$ system (13) where only a very indistinct break between $\Delta H_{3,2}$ and $\Delta H_{4,3}$ was observed. Similarly no distinct breaks were observed in the hydration of the alkali and halide ions (14). Very large and distinct breaks can be observed in the gas phase with systems in which hydrogen bonding is restricted by the presence of other substituents. For example recent work (4) has shown that the ΔH and ΔG^0 for the dissociation of the proton held dimethyl ether dimer $(CH_3)_2OH^+O(CH_3)_2$ are large and comparable to those for $H_2OH^+OH_2$ species. However, the stability of the $(CH_3OCH_3)_3H^+$ species is found to be very much lower than that of the corresponding proton trihydrate.

The authors wish to acknowledge the support of the National Research Council of Canada.

Infrared Absorption Band Shape Studies: Fundamental OH Stretching Vibration of Benzyl Alcohol Conformers in Dilute Carbon Tetrachloride Solution[1, 2]

P. J. KRUEGER AND B. F. HAWKINS
Department of Chemistry, University of Calgary, Calgary, Alberta T2N 1N4

Received April 24, 1973

The fundamental OH stretching doublet in the i.r. spectra of a series of monomeric *p*-X-benzyl alcohols (X = OCH_3, CH_3, H, Cl, NO_2) observed in dilute CCl_4 solution over the temperature range −5 to +40 °C is resolved into two components corresponding to different molecular conformers, using digital computing techniques and a Cauchy–Gauss sum band model. The temperature and substituent dependence of frequencies, band shape indices, and band widths are discussed in terms of intramolecular (electronic displacements and OH···π hydrogen bonds) and intermolecular (OH···Cl_4C and π–σ electron donor–acceptor) interactions. The OH band shapes, which range from 60–98% Cauchy character, reflect variations in the intermolecular interactions which impede molecular re-orientation, and can be correlated with the electronic nature of X and the molecular conformation. The formation of an intramolecular OH···π hydrogen bond results in significantly slower rotational relaxation of the alcohol molecule. The enthalpy differences between the two conformers are found to be 1.52 ± 0.13, 1.57 ± 0.15, 1.53 ± 0.08, 1.06 ± 0.13, and 1.15 ± 0.11 kcal/mol for the compounds in the order stated above.

Le doublet de la vibration fondamentale d'élongation du OH dans les spectres i.r. d'une série d'alcools *p*-X-benzyliques monomères (X = OCH_3, CH_3, H, Cl, NO_2) observé en solution diluée dans CCl_4, dans l'intervalle de température −5 à +40 °C, a été résolu en deux composantes correspondant aux différentes conformations moléculaires par les techniques de calcul digital et sur un modèle de sommation de bande selon Cauchy–Gauss. Les variations des fréquences en fonction de la température, substituant, indices de forme et largeurs de bande, ont été discutées par rapport aux interactions intramoléculaires (déplacement électronique et liaisons hydrogène OH···π) et intermoléculaires (OH···Cl_4C et π–σ donneur–accepteur d'électron). Les formes des bandes OH qui ont un caractère de Cauchy de 60 à 98%, reflètent les variations des interactions intermoléculaires qui gênent la réorientation moléculaire et peuvent être en corrélation avec la nature électronique de X et la conformation moléculaire. La formation d'une liaison hydrogène intramoléculaire OH···π a pour résultat une relaxation rotationnelle nettement plus lente pour la molécule alcool. Les différences d'enthalpie entre les deux conformères sont de 1.52 ± 0.13, 1.57 ± 0.15, 1.53 ± 0.08, 1.06 ± 0.13 et 1.15 ± 0.11 kcal/mol pour les composés dans l'ordre cité ci-dessus.

Introduction

Mathematical Models

The quantitative measurement of band shapes in condensed phase i.r. absorption spectra and their physical interpretation have remained rather elusive objectives until recently. The statistical approach to such measurements has recently been reviewed by Young and Jones (1), while Gordon (2) and Shimizu (3) independently developed a detailed kinetic picture using the time correlation function. The two methods are clearly related (1), and this paper attempts to show how, using one particular model, the analog spectrophotometer record with which the chemist is familiar can be correlated with solute/solvent perturbations at the molecular level, and on the picosecond time scale.

A comprehensive review of the experimental and theoretical factors influencing the measurement of profiles and intensities of i.r. absorption bands for materials in condensed states is available (4). The shape of an isolated vibrational absorption band arising in a molecule which rotates in an undamped fashion in a solvent medium may be expressed by a Gaussian function

$$[1] \quad A(\nu)_g = ab_g^{-2} \exp\{-(\nu - \nu_0)^2 \times \ln 2b_g^{-2}\}$$

and the corresponding band shape where strong

[1]Taken in part from the M.Sc. Thesis of B. F. Hawkins.
[2]Presented at the 24th Conference on Analytical Chemistry and Applied Spectroscopy, Cleveland, Ohio, March 5–9, 1973.

For personal use only.

solute/solvent perturbations exist may be given by a Cauchy function

$$[2] \qquad A(\nu)_c = a\{b_c^2 + (\nu - \nu_0)^2\}^{-1}$$

where ν_0 is the position of the band center, $2b$ is the width of the band at one-half the maximal intensity, and a/b^2 is the peak height. For a computer-oriented least squares analysis the variables can be generalized as X_1, X_2, X_3,..., etc. (1) and eqs. 1 and 2 can then be written as

$$[3] \qquad A(\nu)_g = X_5 \exp\{-X_4^2(\nu - X_2)^2\}$$

and

$$[4] \qquad A(\nu)_c = X_1\{1 + X_3^2(\nu - X_2)^2\}^{-1}$$

respectively. Here X_1 and X_5 are the Cauchy and Gauss peak heights (a/b^2), respectively, X_2 is the position of the band center, $X_3 = 1/b_c$, and $X_4^2 = \ln 2/b_g^2$.

While several functions can be used to describe absorption bands which have shapes that are intermediate between those of the limiting pure Cauchy and pure Gaussian types,[3] the sum function

$$[5] \qquad A(\nu)_s = X_1\{1 + X_3^2(\nu - X_2)^2\}^{-1} + X_5 \exp\{-X_4^2(\nu - X_2)^2\}$$

was employed as a model in these studies (1). Pitha and Jones have shown (5) that the sum function is much better than the product function in describing the absorption band profile. For an overlapping band system composed of M bands, and where an adjustable absorption baseline parameter is allowed for, a total of $(3M + 1)$ parameters require minimization when using a Cauchy function to represent the absorption profile, and $(5M + 1)$ parameters when using the sum function for each component. It has been shown (6) that the sum function with the restraint that $(X_4/X_3) = 0.8$ is successful in fitting simulated absorption profiles convoluted with a triangular slit function. This mathematical convenience was adhered to in this investigation; it means that the half-band width of the Cauchy part of the sum function is held nearly equal to the half-band width of the Gaussian part.[4]

Band areas can be determined by simple integration once observed profiles have been fitted mathematically, and for the Cauchy curve

$$[6] \quad \text{Area} = \int_{-\infty}^{+\infty} A(\nu)_c = (X_1/X_3)\tan^{-1}\{X_3(\nu - X_2)\}\Big|_{-\infty}^{+\infty} = \pi(X_1/X_3)$$

for the Gaussian curve

$$[7] \quad \text{Area} = \int_{-\infty}^{+\infty} A(\nu)_g = (\pi)^{1/2}(X_5/X_4)$$

and for the sum function

$$[8] \quad \text{Area} = [6] + [7] = \pi(X_1/X_3) + (\pi)^{1/2}(X_5/X_4)$$

For bands fitted with the sum function, the amount of Cauchy character, expressed as a fraction, can be determined from the ratio

$$[9] \quad \text{Band shape index} = \text{Area [6]}/\text{Area [8]}$$

A schematic representation of this band shape model is found in Fig. 1.

Computer programs using the method of damped least squares to fit spectra with Cauchy, and Cauchy–Gauss sum and product functions are available (7) and will not be discussed further here. The convergence between the observed and calculated band envelope may be evaluated through the minimization function

$$[10] \qquad \phi = \sum_{i=1}^{M} [(I_i)_{obs} - (I_i)_{calcd}]^2$$

where the I's are transmittance values and M is

[3]These include the Voigt profile and the Cauchy–Gauss product function (4).

[4]Actually $(X_4/X_3) = (\ln 2)^{1/2} = 0.83$ for the two half-band widths to be exactly equal. While a shallow minimum in the maximal error in the curve fitting process has been noted previously for synthetic singlet bands when $(X_4/X_3) = 0.8$ (5), this could not be duplicated in our study of overlapped doublets. Fraser and Suzuki (6) claim that the improvement in fit when this ratio is held at 0.8 is marginal, and that equal half-band widths for the two components of the hybrid sum function are preferred. Our computer resolution studies on *p*-methoxybenzyl alcohol OH bands, where the greatest differences in half-band widths and shape indices are observed for the two conformers, show that for (X_4/X_3) values chosen in the range 0.6–1.0 the conclusions drawn subsequently in this paper are not affected significantly.

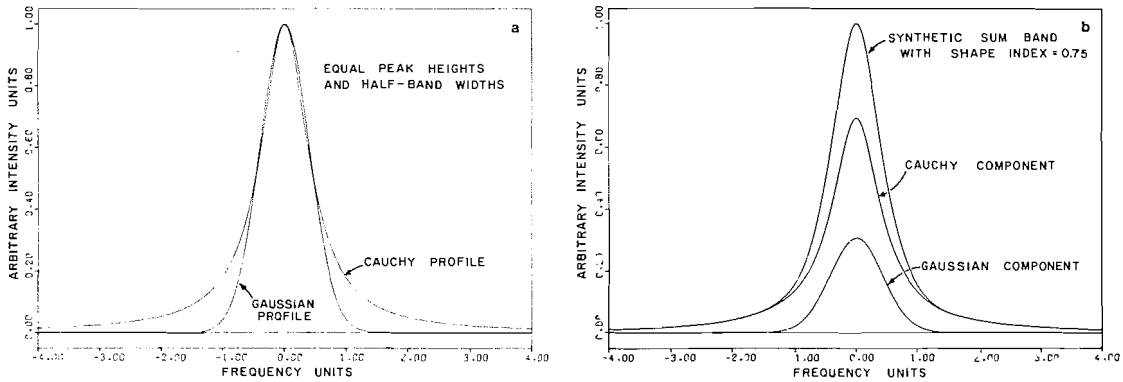

FIG. 1. Schematic representation of i.r. absorption band shape model. (*a*) Limiting Gaussian and Cauchy profiles, normalized to the same peak height and half-band width. (*b*) Synthetic sum band with shape index 0.75, showing Cauchy and Gaussian components ($X_4/X_3 = 0.8$).

the number of ordinate measurements. Two other criteria used to determine the significance of the final solution are the maximum transmittance difference between the observed and the calculated envelope (ΔT_{max}), and the standard error

$$[11] \qquad S = [\phi/(M - N)]^{1/2}$$

where N is the number of band indices X_1, X_2, X_3,..., X_N which are varied to obtain a minimum value of ϕ.

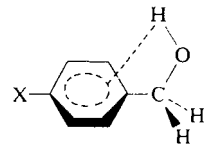
Benzyl Alcohol Conformers

The doublet absorption in the 3600 cm^{-1} region of benzyl alcohol was first noted by Fox and Martin (8), who assigned the high frequency component to a conformer in which the OH was well removed from the phenyl group and the low frequency component to a conformer with an intramolecular OH···π bond. While Flynn *et al.* (9) and Pitha and Horak (10) ascribed the doublet to rotational isomerism about the C—O bond, as observed in aliphatic alcohols, the intramolecular hydrogen bond was confirmed by Oki and Iwamura (11) who noted that the relative intensity of the low frequency band increased with respect to the intensity of the high frequency band when electron donating substituents were attached to the phenyl ring.[5]

[5]While Oki and Iwamura (11) concluded that the substituent dependence of the relative intensities of the doublet implies an intramolecular OH···π hydrogen bond involving the π-electrons on C_1, their band resolution procedure assumed a Cauchy band shape for all components. In the light of band shape variations observed in the present study, this conclusion should be treated with caution.

The essential features of the conformational equilibrium in benzyl alcohols can be expressed by

[12] 
(I) "free" OH



(II) intramolecular OH···π bonded OH

where, in dilute solution in a solvent like CCl_4 the "free" OH group in **I** is interacting with the solvent, and no specific orientation of the OH is implied in **II**, other than that it be engaged in an OH···π hydrogen bond. For purposes of band resolution in this investigation, it was assumed that the observed envelope consisted of two symmetrical overlapped component bands of unknown shape ranging somewhere between the pure Cauchy and pure Gaussian forms.

The equilibrium constant (K) can be obtained as a function of temperature by measuring the relative areas (A) of the absorption bands corresponding to each conformer, and, provided that the ratio of intrinsic molar absorbances for the two bands is temperature independent, the enthalpy difference (ΔH) between the two conformers, under the measurement conditions, follows directly from the integrated form of the

Van't Hoff equation. Experimentally, this is the slope of the log (A_I/A_{II}) *vs.* $1/T$ plot. The entropy difference (ΔS) between the two conformers can only be obtained if the ratio of the intrinsic molar absorptivities for the two bands is equal to unity (or some other known value).

The benzyl alcohol OH bands are strongly overlapped, and thus typical of many i.r. absorption spectra in which separate band areas cannot readily be determined directly. Graphical and other analog procedures to resolve the component bands have been applied with varying degrees of success, but normally some assumption has to be made about the basic band shape(s), and this may strongly bias the "solution".[6]

This investigation was designed to see if computer resolution of the OH bands in benzyl alcohol spectra could give some information about band shapes, within the limits imposed by the Cauchy–Gauss sum function model, and whether the shape indices could be interpreted in terms of molecular dynamics and the general chemical behavior of the system. Since the band resolution process employed cannot guarantee a unique solution in view of the large number of variables minimized, particularly for Cauchy–Gauss hybrid functions, interpretations of the model are largely based on general trends with changes in temperature and in the ring substituent, which emerge from the collective evaluation of a large number of independent spectra and computing runs.

Experimental

Apparatus

Spectra were recorded on a Perkin–Elmer Model 621 double beam grating spectrophotometer, and both the frequencies and transmittance readings were simultaneously encoded digitally on eight track paper tape using a Perkin–Elmer DDR-1 digital data recorder. A constant encoding interval of 0.5 cm^{-1} was used, leading to some 800 pairs of data points over the range 3830 to 3430 cm^{-1}. Contact points on the transmittance encoder were at intervals of 0.001 transmittance units, and the encoder was calibrated with a set of standard rotating sector disks with transmittance values of 0.710, 0.501, 0.251, 0.126, and 0.063 supplied by Research and Industrial Instruments Co. The scanning rate was 7 cm^{-1}/min and the spectral slit width was 5 cm^{-1}. The experimental procedure was essentially the same as that described by Jones (12).

Alcohol solutions ($\sim 3.0 \times 10^{-3}$ *M*) were made up volumetrically in Fisher "spectral quality" CCl_4 which had been doubly dried over Linde 4A molecular sieves. Matched 2.0 cm "Infrasil" quartz cells were used, with pure solvent in the reference beam. The quartz cells were both enclosed in brass holders through which methanol was circulated, in parallel, using a Lauda TK-30D Ultra Kryomat capable of maintaining a cell temperature stability of ± 0.1 °C over the temperature range employed (-5 to $+45$ °C). The temperature of the solution in the sample cell was monitored continuously with an Atkins calibrated thermistor probe inserted into the solution through a Teflon stopper in the filling port. The absolute accuracy of the temperatures measured is ± 0.2 °C. Spectra were recorded only after temperature stability had been achieved. The sample compartment and the spectrophotometer itself were purged with dry air.

Data Collection

Transmittance values encoded at 10 cm^{-1} intervals with the rotating sectors (5000–7000 r.p.m.) were the basis of the transmittance scale, and a parabolic function was used to obtain true transmittance values by interpolation. Transmittance values at frequencies other than those where sector values had been encoded were also obtained by interpolation. An encoded background spectrum (solvent *vs.* solvent) was subtracted from the sample spectrum to eliminate any baseline irregularities.

The frequency scale of the spectrophotometer was calibrated using water vapor as a standard (13), and the reported frequencies are considered to be accurate to ± 0.5 cm^{-1}. Calibration spectra indicated that deviations of the frequency drive from linearity were insignificant in the range in question.

Data Analysis

All calculations were performed on an IBM 360/50 computer initially, and later on a CDC 6400 computer using the Fortran IV programs developed by Jones *et al.* (7).

Initial values of X_1, X_2, and X_3 were estimated from the analog version of the spectra, and the digital spectrum (doublet OH peak) resolved into two optimized pure Cauchy components. For the Cauchy–Gauss hybrid (sum function) band fitting process, the optimized indices of the Cauchy fit were used as input values. The Gaussian contribution (X_5) was restricted to zero or positive values, and (X_4/X_3) was held at 0.8.

After each iteration the calculated band envelope (undistorted) was convoluted with a symmetrical triangular spectrophotometer slit function before comparison with the experimentally observed envelope. Synthesized curves were computed at 0.5 cm^{-1} intervals and transmittance values rounded to the nearest 0.001. Iteration was continued until there was little change in the minimization function (ϕ) over several cycles. Computation was also set to end if the maximal transmittance difference became less than 0.001 or the standard error became less than 0.002.

The spectra were typically recorded at noise levels of 0.005 to 0.010 transmittance units. From eq. 11, since $N \ll M$, it follows that a "fit" of the calculated band envelope would have been achieved when $\phi \leq S^2M$. Thus, for noise levels of 0.005 to 0.010 transmittance units ϕ should be equal to or less than 2.0×10^{-2} or 8.0×10^{-2}, respectively.

[6]Spectrophotometer slit distortion must also be taken into consideration.

Materials

The benzyl alcohols used were commercial materials. Spectral grade benzyl alcohol and anisyl alcohol were dried over anhydrous $CaSO_4$ and $MgSO_4$ and then distilled through a spinning band column. *p*-Chloro-, *p*-nitro-, and *p*-methylbenzyl alcohol were recrystallized from water and dried over P_2O_5 in a vacuum desiccator. The samples used had physical constants in acceptable agreement with literature values.

Results and Discussion

Test of Band Resolution Procedures

Jones *et al.* (14) have shown that the method of pseudodeconvolution to correct for spectral slit distortion leads to incomplete recovery of half-band widths and areas for bands with true peak absorbances of less than 0.2. For bands of Cauchy profile, the errors involved approached 5% for half-band widths and 10% for areas even at $s/\Delta\nu_{1/2}$ ratios near 0.1. The alternative method of accounting for spectral slit distortion used here, that of convoluting the synthesized curve with a slit function before fitting it to the experimentally observed envelope after each iteration in the least squares minimization process, has only been tested on a synthetic doublet composed of two bands of the same peak height, half-band width, and shape (15). It was felt desirable to determine the ability of this method to recover true band parameters under conditions more analogous to the system under investigation. Two tests were applied.

Test spectra simulating two overlapped Cauchy profiles with wide variations in peak height and half-band width, and with the approximate spacing of the doublet in the benzyl alcohols, were generated and convoluted with a symmetrical triangular slit function of 5.0 cm^{-1} half-width. For a fixed Cauchy band shape the recovery of true peak heights and band-widths was extremely efficient, with errors of less than 0.1%. For *p*-nitrobenzyl alcohol spectra of the same solution obtained at slit widths of 5.0, 3.5, and 2.2 cm^{-1}, Cauchy–Gauss sum band fitting led to variations of the order of 2–5% in recovered "true" peak heights, half-band widths, band areas, and shape indices. For duplicate spectra on the same solution at the same slit-width, the recovered band indices showed variations up to 2.5%. The recovered frequencies of the band centers lay well within 0.5 cm^{-1} for this series.

Resolved Spectra

A comparative view of the spectra is found in Fig. 2*a*. Figure 2*b–f* shows Calcomp plots of the experimentally observed OH doublets for the five benzyl alcohols, as regenerated from the digital data, as well as the corresponding fitted synthetic spectra based on convoluted Cauchy–Gauss sum bands, and the error curves showing the deviation between the experimental spectra and the calculated spectra.[7] For the 75 spectra reported here (60 000 data points) the "goodness of fit" criteria used had the following mean values: minimization function (ϕ) = 0.0162 (transmittance units)^2; standard error (S) = 0.0043 transmittance units; maximum deviation (ΔT_{max}) = 0.0142 transmittance units. Figure 2*g* shows the typical temperature dependence observed in the experimental spectra.

Table 1 summarizes and compares all the relevant data for the resolved OH band components at 25 °C.

Without exception, the resolution of the doublet into two pure Cauchy components led to a poorer fit; for all 75 spectra mean values of ϕ = 0.0337 (transmittance units)^2, S = 0.0063 transmittance units, and ΔT_{max} = 0.0235 transmittance units were obtained. Furthermore, the statistical validity of the Cauchy fit decreased with decreasing temperature, a result of the temperature dependence of the shape index, which is discussed later.

[7]As noted by one of the referees, the presence of ^{13}C, and the possibility of hot bands and weak overtones may contribute to the inability to fit i.r. spectra precisely to an equation like [5].

FIG. 2. (*a*) Comparative view of *p*-X-benzyl alcohol spectra in dilute CCl_4 solution, with absorbance expressed per mol of alcohol. Spectra for *p*-CH_3 and *p*-H compounds omitted since they are qualitatively similar to the *p*-OCH_3 spectrum. See Table 2 for intensity data. (*b*)–(*f*) Curve A: experimentally observed OH bands for benzyl alcohols in dilute CCl_4 solution, as regenerated from normalized digital data with a Calcomp plotter. Concentrations ~3 × 10^{-3} *M*. Temperatures ~28 °C. Path length = 2.0 cm. Peak transmittance values indicated. Curves B: resolved OH band components, using Cauchy–Gauss sum profiles, and calculated doublet (all displaced with respect to curve A for display purposes). Components convoluted with a triangular slit function of 5 cm^{-1} half-width to match spectrophotometer distortion of curve A. Curve C: deviations between experimental and convoluted calculated spectra. Transmittance scale expanded relative to curve A. Frequencies

The OH frequencies reported in Table 1 for both conformers are based on the frequency *vs.* temperature plots in Fig. 3 which smooth out small irregularities which arise in the curve fitting process. Figure 3 approximates the temperature dependence of the frequencies as being linear, although in some cases a tendency toward regular curvature is apparent. Frequency increases for the "free" OH range from 0.04–0.08 cm^{-1}/°C, while those for the intramolecularly hydrogen bonded OH range from 0.06–0.10 cm^{-1}/°C (Table 1). For each compound the intramolecularly hydrogen bonded OH is more temperature sensitive than the free OH, which may be related to the greater (induced) polarity of the former ($O^{\delta-}$—$H^{\delta+}$···π). Solvent dependent shifts of inter- and intramolecular hydrogen bonded XH frequencies have been noted previously (17).

The polarity of the OH bond and the OH frequency in **I** increase only slightly as the electron withdrawing character of the ring substituent increases,[8] due to the insulating methylene group. The frequency displacement on intramolecular hydrogen bond formation ranges from 16.6 cm^{-1} in *p*-methylbenzyl alcohol to 19.6 cm^{-1} in *p*-nitrobenzyl alcohol.

Intensities

The integrated molar absorption for the OH doublet increases by 65% from *p*-methoxy- to *p*-nitrobenzyl alcohol, and parallels the Hammett σ values of the *p*-substituent, while the corresponding ratio of band intensities A_{II}/A_{I} drops from 1.48 to 0.60 (Table 2). Absolute A_{I} and A_{II} values cannot be determined since the absolute population of the two conformers is not known. The ratio A_{II}/A_{I} only gives this if the intrinsic molar absorptions of **I** and **II** are identical; that is unlikely to be the case here. Since the high frequency OH component moves from being the minor component of the doublet in *p*-methoxybenzyl alcohol to the major component in *p*-nitrobenzyl alcohol (Fig. 2*a*), the overall intensity increase of the doublet referred to above can be related to increasing polarity of the OH bond.

For bands established to be of near-Cauchy shape, *e.g.* the high frequency band of *p*-methoxybenzyl alcohol, the band areas reported by Oki and Iwamura (11) are within

[8]On intermolecular OH···O hydrogen bond formation to tetrahydrofuran as a common base in dilute CCl_4 solutions, the OH frequency displacement increases with increasing Hammett σ values of the *p*-substituent (18).

5% of our values, but for those now shown to have a hybrid shape, the inflexible Cauchy model used by them without an iterative curve-fitting procedure leads to differences in excess of 55%, *e.g.* in the low frequency band of *p*-methoxybenzyl alcohol.

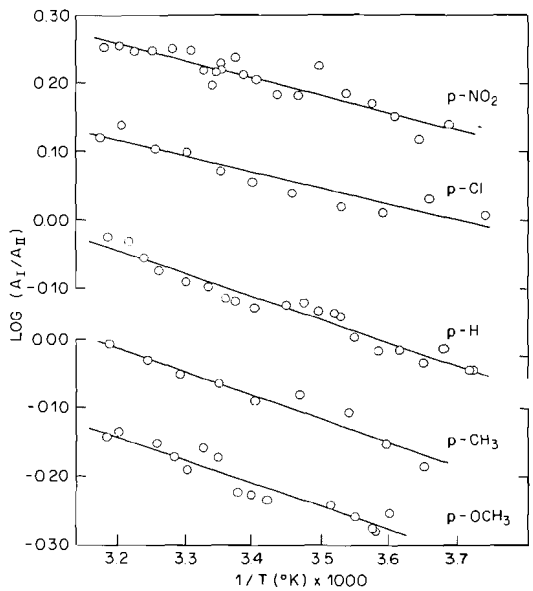

FIG. 4. Temperature dependence of the logarithm of the OH band area ratios for the conformational equilibrium in *p*-X-benzyl alcohols in dilute CCl_4 solution.

Thermodynamics

From the least squares treatment of the log (A_I/A_{II}) *vs.* $1/T$ plots in Fig. 4, the enthalpy difference between conformers **I** and **II** may be established, assuming that the intrinsic molar absorbance ratio for these two conformers is temperature independent over this temperature range. These thermodynamic quantities are summarized in Table 1, together with their deviations, and their substituent dependence is illustrated in Fig. 5. The low frequency band clearly belongs to the thermodynamically more stable conformer. Conformer **I** is stabilized by interactions of the OH with the solvent (favored

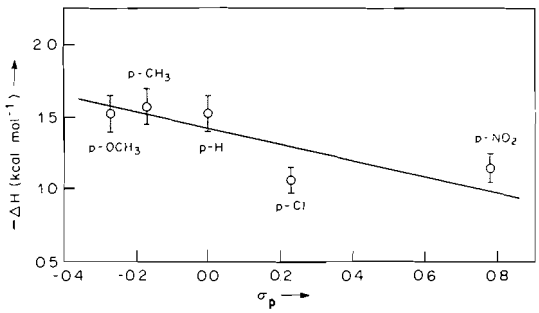

FIG. 5. Dependence of $-\Delta H$ for intramolecular OH···π hydrogen bond formation in *p*-X-benzyl alcohols in dilute CCl_4 solution, on the Hammett substituent constant of X.

as σ increases) and by π-electron/solvent interactions (favored as σ decreases). The stability of conformer **II** is related to the strength of the OH···π interaction, and this depends on the OH acidity (hydrogen bond favored as σ increases) and, more importantly, the basicity of the aromatic ring (hydrogen bond favored as σ decreases). Furthermore, some π-electron/solvent interactions will also exist in **II**.

The enthalpy differences found are similar to those reported for other intramolecular OH···π bonds (20). For benzyl alcohol itself in dilute CCl_4 solution, $-\Delta H$ for the conformational equilibrium was reported to be 2.34 kcal/mol (21), based on graphical resolution of the OH doublet, and using spectra uncorrected for slit distortion. This is substantially higher than our present value of 1.53 ± 0.08 kcal/mol.

The intercepts of the lines in Fig. 4 are not significantly different, suggesting similar entropy differences between conformers **I** and **II** for these compounds. No evaluation of ΔS was attempted since the intrinsic molar absorptions for the OH bands in the two conformers are not known.

Band Shape Index

The computed shape indices for both conformers are plotted as a function of temperature in Figs. 6 and 7. Least squares lines were fitted to the points. The "free" OH bands of *p*-methoxy and *p*-methyl benzyl alcohol are almost pure Cauchy in character, and their shape is temperature independent, since the slight slope shown for these compounds in Fig. 6 is not deemed to be significant in view of the lack of precision in the determination of this parameter. For the remaining compounds the "free" OH

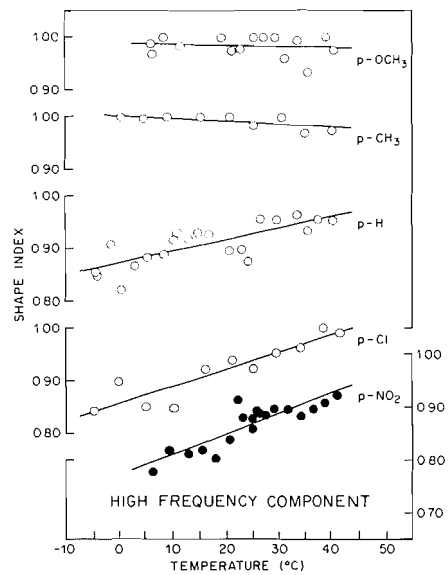

FIG. 6. "Free" OH band shape index dependence on temperature for benzyl alcohols in dilute CCl_4 solution. Pure Cauchy band = 1.00; pure Gaussian band = 0.00.

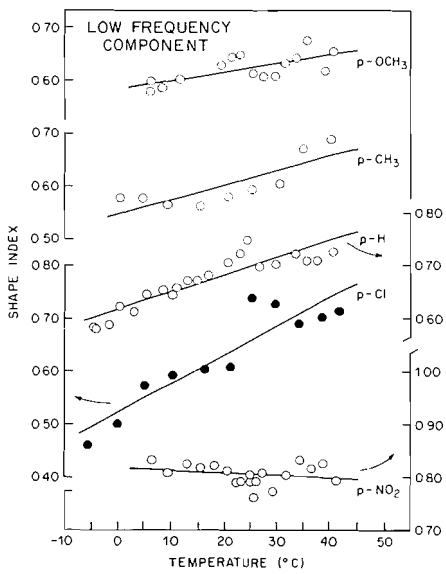

FIG. 7. Intramolecularly hydrogen bonded OH band shape index dependence on temperature for benzyl alcohols in dilute CCl_4 solution.

band is more Gaussian, and the Gaussian character increases as the temperature decreases.

For a given *p*-substituent the intramolecularly hydrogen bonded OH band is always much more Gaussian than the corresponding "free" OH band. Further, the intramolecularly hydrogen

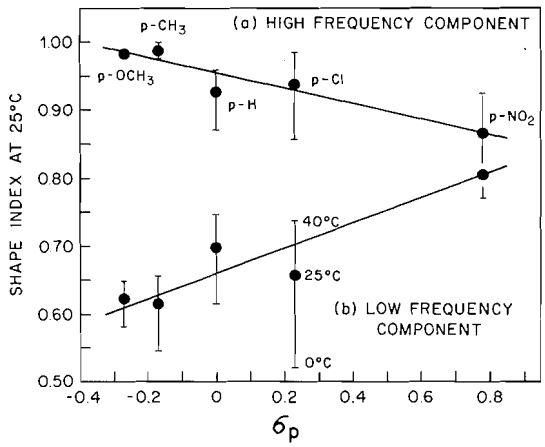

FIG. 8. Dependence of OH band shape index in *p*-X-benzyl alcohols on the Hammett substituent constant of X. Circles refer to values at 25 °C; ranges indicate spread of values between 0 and +40 °C. (*a*) "Free" OH band, (*b*) intramolecularly OH···π bonded band.

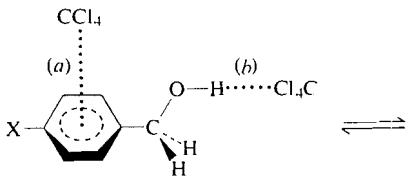
bonded OH band again becomes more Gaussian as the temperature is lowered, except in *p*-nitrobenzyl alcohol, where its shape is temperature independent (Fig. 7).

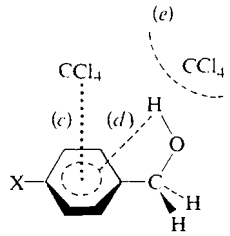
Figure 8 shows that the shape indices for both components are linearly related to the electron donating or withdrawing ability of the ring substituent, as measured by the Hammett substituent constant, but that the two conformers have an *opposite* dependence, leading to a situation in which anisyl alcohol has an almost pure Cauchy "free" OH band and an intramolecularly hydrogen bonded OH band which is approximately 40% Gaussian, whereas in *p*-nitrobenzyl alcohol the corresponding bands are about 10 and 20% Gaussian, respectively (figures cited at 25 °C; see also Table 1). The points in Fig. 8 are based on values at 25 °C derived from the least squares lines in Figs. 6 and 7, in order to minimize the reliance on any individual spectrum.

These band shape measurements can be rationalized in terms of two basic types of solute–solvent interactions which impede molecular re-orientation in these solutions, an OH···Cl_4C hydrogen bond and a π–σ electron donor–acceptor (charge transfer) type of interaction between the aromatic π-electrons and CCl_4. Both are well known. Alcohol OH frequencies in CCl_4 are displaced to lower values from their position in hexane, and such shifts correspond to specific intermolecular interactions, with general dielectric effects playing a secondary role (22). Charge transfer complexes between aromatic π-electrons and CCl_4 are also well documented (23). The following solid compounds have been identified in freezing point diagrams (24): CCl_4·benzene; $(CCl_4)_2$·benzene; CCl_4·toluene; CCl_4·1,2,4-trimethylbenzene; $(CCl_4)_2$·anisole. These same authors found no solid complexes of CCl_4 with *o*-xylene, *m*-xylene, chlorobenzene, bromobenzene, or nitrobenzene (24, 25). The heats of dissociation of the 1:1 complexes of CCl_4 with benzene and *p*-xylene are 3.5 and 6.3 kcal/mol, respectively (24). Other workers have reported the equilibrium constants for complex formation between CCl_4 and benzene, mesitylene, and hexamethylbenzene, based on ultraviolet measurements in *n*-hexane at 25 °C, to be 0.009 ± 0.004, 0.113 ± 0.044, and 0.64 ± 0.12 l mol^{-1} (26, 27). Other evidence for such π–σ interactions between aromatic compounds and CCl_4 comes from enthalpies of mixing (28), far i.r. spectra (29), and submillimeter dielectric absorption of mixtures (30), among many other measurements.

These concepts can now be applied as follows, with a substituent dependence of interactions (*a*)–(*e*) as discussed below in terms of the order of X = *p*-OCH_3, *p*-CH_3, *p*-H, *p*-Cl, and *p*-NO_2:



(I)



(II)

(1) A pure Gaussian profile implies unhindered molecular rotation; increasing Cauchy character corresponds to increasing intermolecular interactions which impede molecular re-orientation.

(2) Interaction (*a*) decreases as the π-electron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

density falls, and (*b*) increases slightly as the OH polarity increases, but (*a*) dominates in conformer **I**. The molecular re-orientation of **I** is thus most hindered when X = *p*-OCH_3 (near Cauchy band shape), and somewhat less hindered when X = *p*-NO_2 (decreased Cauchy band character).

(3) For a given X, interaction (*c*) < interaction (*a*) because the aromatic π-electrons in **II** are at least to some degree tied up in an intramolecular OH···π hydrogen bond. This accounts for the fact that for a given X, conformer **II** is always freer to rotate (more Gaussian band shape) than conformer **I**.

(4) In conformer **II** the intramolecular OH···π hydrogen bond (*d*) strength decreases as the π-electron density falls. Whereas hydrogen bond strength in general is controlled by both the acidity of the proton donor and the acceptor power of the base, the latter appears to be the dominant factor here, masking the small intrinsic increase in OH polarity due to X. Geometric restrictions prohibiting proper access of the hydroxyl proton to the π-electrons may play an important role here.

(5) The reduction in intramolecular OH···π interaction in **II** as the π-electron density falls leaves the residual π-electrons more available for π–σ donor–acceptor interaction with CCl_4. Interaction (*c*) thus increases with X in the order given, because this is the order of increasing *availability* of π-electrons as far as the solvent is concerned. Of all the species studied, conformer **II** of *p*-methoxybenzyl alcohol is least perturbed by the solvent since its OH group and π-electrons are largely tied up internally (most Gaussian band), whereas *p*-nitrobenzyl alcohol (**II**) experiences more rotational damping, leading to a greater Cauchy band character (almost equivalent to that of **I** for this compound, as the OH···π interaction is weak).

(6) Interaction (*e*) in **II** plays a minor role, with an undetermined substituent dependence. While the intrinsic polarity of the OH bond would increase with X in the order given, the OH···π interaction decreases in this order, with an accompanying decrease in the OH polarity induced by hydrogen bond formation. The substituent dependence of the net OH polarity can, therefore, not be predicted. Furthermore, it appears reasonable to suggest considerable shielding of the hydroxyl proton in **II**, reducing OH···Cl_4C interaction, particularly when (*d*) is strong.

(7) In general, increasing Gaussian character as temperature decreases implies a longer period of unperturbed rotation of the solute molecule before solvent molecules interfere kinetically. In conformer **I**, when X = *p*-OCH_3 or *p*-CH_3 the ring electron density is large enough to provide for sufficient interaction with CCl_4 over the entire temperature range investigated to lead to an almost pure Cauchy and temperature independent band shape, *i.e.* these are near limiting cases. For *p*-nitrobenzyl alcohol, conformer **I** shows the normal temperature dependence which may reflect the polar OH group and OH···Cl_4C interaction, but in conformer **II** the combination of π-electron withdrawal by the substituent plus the intramolecular OH···π bond appear to leave this species less sensitive to changes in the interaction with CCl_4 over this temperature range.

Band Widths

Half-band widths for both component OH bands are shown to increase with increasing temperature, in general, in Fig. 9. Values extracted for 25 °C from the least squares lines in this figure are found in Table 1. Band widths are normally very sensitive to slight band shape changes, and to the degree of misfit in the curve fitting process. Hence the apparent decrease in the width of the intramolecularly OH···π bonded band in *p*-chlorobenzyl alcohol with increasing temperature may be anomalous; the data may only warrant an interpretation that this band width is relatively temperature independent.

The temperature dependence of the OH band width in conformer **II** is smaller than that of the OH band width in conformer **I**, with the exception of *p*-nitrobenzyl alcohol, where not only the absolute values of the half-band widths but also their temperature dependencies are nearly identical. The fact that the band shapes and the half-widths for both conformers of *p*-nitrobenzyl alcohol are nearly identical supports the view that π–σ electron–donor acceptor interaction with the solvent is the dominant factor hindering molecular re-orientation.

While half-band widths have been related directly to mean re-orientation times and their temperature dependence to mean reorientational potential barriers (31), such approximations rest on an assumed Cauchy band shape, which does not apply to most of the bands studied here. On the other hand, our observations are qualitatively consistent with the relative magnitudes of

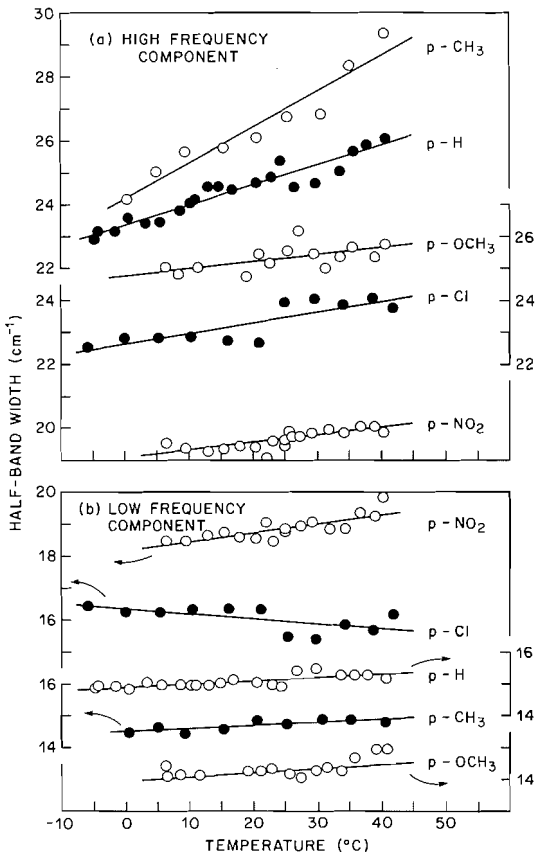

FIG. 9. Temperature dependence of half-band widths of OH bands in benzyl alcohols in dilute CCl_4 solution. (*a*) "Free" OH band, (*b*) intramolecularly OH···π bonded band.

the rotational diffusion constant (β), which, for the Cauchy–Gauss sum function, is defined by the half-band width of the Cauchy component; this corresponds to the slope of the linear portion of the logarithmic time correlation plot (1) after rotational diffusion is the principal factor, and can be obtained from

$$[13] \qquad \beta = 2\pi c b_c = 2\pi c / X_3$$

For a given ring substituent, β for conformer **I** is expected to be greater than for conformer **II**, since the latter interacts less with neighboring solvent molecules. By the same token β (and b_c, or the band width of the sum band in this model) is expected to be less temperature dependent in **II** than in **I**, as observed.

The general relationship between half-band widths at 25 °C with σ (Fig. 10) is similar to that observed for the band shape index (Fig. 8). These figures also summarize the temperature dependence of these two parameters, indicating that (*a*) for the high frequency component, the temperature dependence of the shape index increases with σ, while the corresponding temperature dependence of the half-band width decreases with σ (the only exception being the *p*-OCH_3 compound), and (*b*) for the low frequency component, the temperature dependence of the shape index also increases with σ, but here the temperature independent exception is the *p*-NO_2 compound, while the corresponding temperature dependence of the half-band widths is relatively small and increases slightly with σ (the exception being the *p*-OCH_3 compound).

The symmetry of molecular vibrations and the direction of the transition moment relative to the axis about which molecular orientation takes place have also been shown to affect the temperature dependence of i.r. band widths in liquids (31–33). For liquid toluene, molecular re-orientation about an axis perpendicular to the phenyl ring is indicated (33). In conformer **I** of the benzyl alcohols the OH bond is approximately perpendicular to the sixfold axis of the phenyl ring, while in conformer **II** it is at an angle of about 51° to this axis. Assuming the OH transition moments to lie parallel to the OH bonds, and π–σ electron donor–acceptor interaction as being the dominant solvent perturbation, then a higher temperature dependence would be expected for conformer **I** than for **II**, as observed.

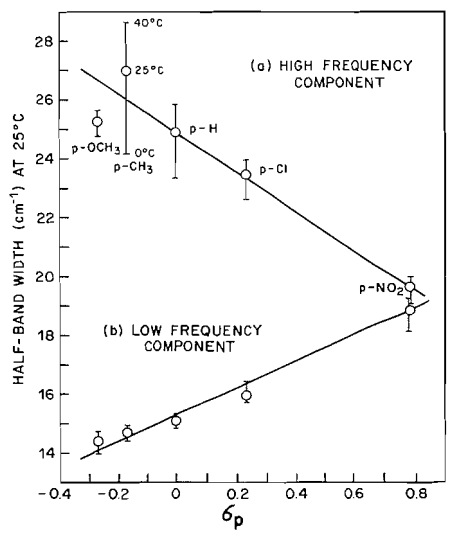

FIG. 10. Dependence of OH half-band widths in *p*-X-benzyl alcohols on the Hammett substituent constant of X. Circles refer to values at 25 °C; ranges indicate spread of values between 0 and +40 °C. (*a*) "Free" OH band, (*b*) intramolecularly OH···π bonded band.

Concluding Remarks

The general assumption that i.r. absorption bands in liquids and solutions have a Cauchy profile is unwarranted in the absence of a rigorous assessment of the experimentally observed contour (corrected for slit width effects). The Cauchy–Gauss sum function appears to be an adequate and convenient model for the quantitative evaluation of the shapes of symmetrical bands. Band shape and band width changes may be induced by conformational changes in the molecule as well as by intramolecular electronic effects. Band shapes may thus eventually provide information about the nature of molecular conformations. Furthermore, the temperature dependence of band shapes and band widths can act as probes of solute/solvent interaction, particularly rotational re-orientation. Further details of the mechanisms involved should become apparent as other carefully selected chemical systems are investigated; in particular the extent to which band shapes and widths independently reflect different facets of molecular dynamics in the condensed state requires further experimental study.

α-Pyrones. II.[1] The Synthesis of α-Pyrones From α,β-Unsaturated Aldehydes. Part II[1,2]

CH. R. ENGEL, A. F. DE KRASSNY, A. BÉLANGER,[3] AND G. DIONNE[4]

Department of Chemistry, Laval University, Quebec, Quebec G1K 7P4

Received April 17, 1973

It is shown that the reaction of acrolein with bromomalonate in the presence of an alkali alkoxide, leading to a 2-formylcyclopropane-1,1-dicarboxylate, may be applied to the steroid series; thus, a 20-methylene 21-aldehyde gives in excellent yield the corresponding cyclopropane derivative. The possibility of converting such systems to α-pyrones was investigated in the case of the acrolein adduct, diethyl 2-formylcyclopropane-1,1-dicarboxylate. While its cyclopropane ring could not be isomerized to an olefin with aluminum chloride or by reactions catalyzed by transition metals and while photolysis led to a dihydrofuran derivative, pyrolysis in high vacuum at 550–575° afforded directly an α-pyrone, ethyl coumalate. Evidence is put forward for the intermediacy of 3-ethoxycarbonyl-α-pyrone in this reaction.

La réaction de l'acroléine avec un bromomalonate en présence d'un alcoolate alcalin, qui conduit à un formyl-2 cyclopropanedicarboxylate-1,1, peut être appliquée à la série stéroïde, un 21-aldéhyde 20-méthylénique donnant en excellent rendement le dérivé cyclopropanique correspondant. Nous avons étudié la possibilité de convertir de tels systèmes en α-pyrones dans le cas du formyl-2 cyclopropanedicarboxylate-1,1 de diéthyle, dérivé de l'acroléine. Tandis que son cycle à trois chaînons ne put être isomérisé en oléfine avec le chlorure d'aluminium ou par des réactions catalysées par des métaux de transition et tandis que sa photolyse conduisit à un dérivé dihydrofurannique, sa pyrolyse, à 550–575° et sous haut vide, donna directement une α-pyrone, le coumalate d'éthyle. Nous suggérons l'α-pyrone 3-éthoxycarbonylée comme intermédiaire dans cette réaction.

Can. J. Chem., **51**, 3263 (1973)

In 1969 our laboratory reported one of the first syntheses of bufadienolides, a class of steroids comprising highly active cardiotonics, which are characterized by an α-pyrone ring whose position 5 is linked to the 17β-position of the steroid nucleus. The salient feature of our synthesis (1, cf. also 2) (compare Scheme 1, pathway *a*) consisted in a Michael addition of diethyl malonate to a 20-methylene 21-aldehyde, the hydrolysis product of the resulting adduct being subsequently subjected to enol-lactonization with concomitant decarboxylation, and the still required double bond, in conjugation with the carbonyl function of the lactone, being then introduced by a variety of methods. This pathway to bufadienolides (and generally to α-pyrones) suffers only from the relatively low yield of the dehydrogenation step which, in our experiments, did not exceed 35% of *pure* product; Pettit *et al.* (3) report yields of 43–60% of *crude* product when the dehydrogenation is carried out with sulfur.

The attempt to "prefigure" the desired double bond in the form of a suitable substituent of the malonate employed (cf. Scheme 1, pathway *b*) is obviously problematic. The olefin-forming elimination from the addition product, involving a leaving group (X in adduct **iii** of Scheme 1) which is α and not β to the ester groups, could hardly be expected to compete successfully with a 1,3-elimination resulting in a cyclopropane; indeed, the hydrogens β to the ester functions show no particular mobility, in contradistinction to the hydrogen α to the aldehyde group. Not surprisingly therefore, Warner and Moe obtained (cf. 4 also 5, 6), by the reaction of acrolein with diethyl bromomalonate not, as they first surmised (7), diethyl 3-formyl-1-propene-1,1-dicarboxylate (cf. **vi** in Scheme 1), but the 2-formylcyclopropane-1,1-dicarboxylate (cf. **v** in Scheme 1). In spite of this, the potential for an α-pyrone synthesis of the addition of a substituted

[1]Paper XXX in our series on Steroids and Related Products (1) has to be considered the first communication of the present series.

[2]The main results of this paper were the subject of a communication presented before the 55th Annual Conference and Exhibition of the Chemical Institute of Canada, Quebec, June 1972.

[3]Some of the results reported here are contained in the B.Sc. thesis of A. Bélanger, presented to the Department of Chemistry, Laval University, April 1970.

[4]Abbreviated from part of the doctoral thesis of G. Dionne, to be presented to the School of Graduate Studies of Laval University.

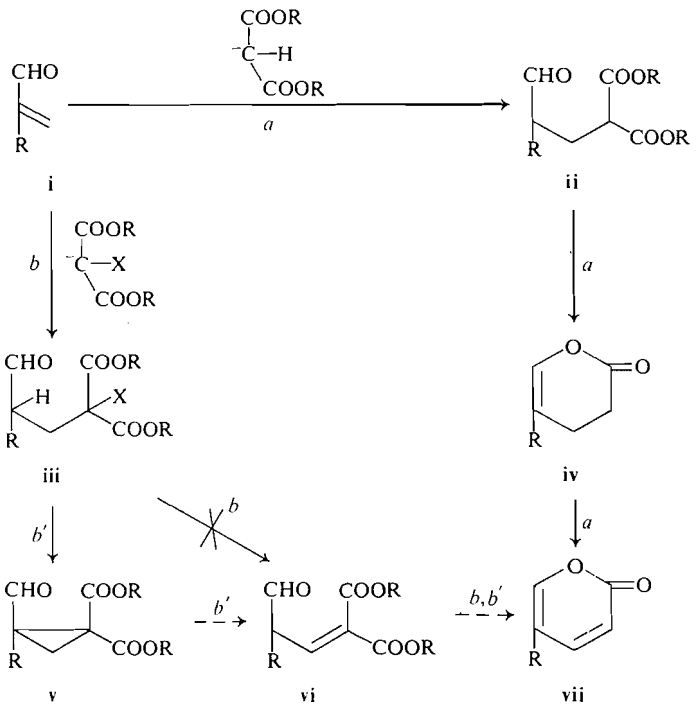
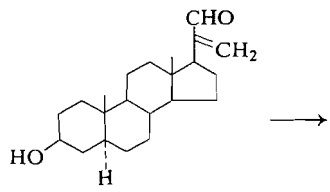


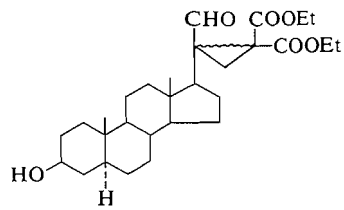
SCHEME 1

malonate such as bromomalonate to an α,β-unsaturated aldehyde still seemed worth exploring since the resulting cyclopropane derivatives (cf. **v**) are valence isomers of 4-formyl 2-butenoic esters (cf. **vi**), the immediate precursors of α-pyrones. If an isomerization of cyclopropanes of type **v** to olefins of type **vi** could be effected, an attractive modification of our first α-pyrone synthesis would be realized.

We at first attempted to apply Warner and Moe's synthesis of cyclopropane derivatives of type **v** (Scheme 1) to steroids, in particular to the 20-methylene 21-aldehyde **1** (1) from which our original bufadienolide synthesis had originated. Treatment of aldehyde **1** with an excess of diethyl bromomalonate in the presence of tertiary sodium butoxide in tertiary butanol afforded in 74% yield the desired cyclopropane derivative **2**. This product gave a marked reaction with tetranitromethane, showed an u.v. absorption maximum (in cyclohexane) at 205 nm (log ε 3.5), attributable to a carbonyl-conjugated cyclopropane, and exhibits in the i.r. (in KBr), apart from the peaks characteristic of the aldehyde, ester, and hydroxyl functions, a band at 1020 cm^{-1} which we assign to the cyclopropyl moiety. In the n.m.r. one proton of the cyclopropyl–methylene group appears as a doublet at 2.20 δ with a coupling constant of 5 Hz. The structure was confirmed by elemental analysis.



1



2

Since, in preliminary experiments, we were unable to isomerize the cyclopropane ring of the aldehydo ester **2** and even encountered difficulties in hydrolyzing its ester functions, we decided to investigate the valence isomerization

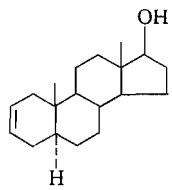
of such systems in the series originally studied by Warner and Moe. Using the American authors' procedure (7), we realized a 64% yield of diethyl 2-formylcyclopropane-1,1-dicarboxylate (**3**). We record in the Experimental its spectroscopic data since the product has not yet been fully characterized in this respect (cf. 4–7). Attention is drawn to the u.v. absorption maximum at 207 nm (log ε 3.3) and to the fact that the n.m.r. signals closely parallel those of cyclopropane-1,1,2-tricarboxylic acid (8): the protons of the cyclopropyl–methylene group form with the cyclopropyl proton of the formyl-substituted carbon atom 2 an ABX system, the C_2-proton being, of course, also coupled with the aldehydic proton.[5]

In view of the great ease of the reductive opening of the cyclopropane ring of the 2,4-dinitrophenylhydrazone of compound **3** with a 5% palladium-on-charcoal catalyst at room temperature and 1.8 atm (7), the inertness of the system to isomerization to an olefinic derivative is noteworthy. Treatment with aluminum chloride, even at temperatures exceeding those reported in the literature (cf. 10) gave no results. Neither were reactions catalyzed by transition metals successful. When the cyclopropane derivative was heated in benzene with bis(triphenylphosphine)iridium carbonyl chloride to 130°, following the procedure of Volger *et al.* (11) or when it was treated with *trans*-dichlorobis(tri-*n*-butylphosphine)nickel(II) (12)[6] and diisobutylaluminum chloride according to the method of Miller and Pinke (13), the starting material was recovered unchanged.[7]

Numerous examples of photolytic valence isomerizations to olefins of cyclopropanes conjugated with carbonyl functions (cf. 15–18) or with phenyl or nitro groups (19, 20) have been reported. We therefore irradiated the cyclopropane derivative **3** in benzene solution using a Pyrex filter, according to the method of Beugelmans (18). Instead of obtaining an aliphatic olefin we isolated the dihydrofuran **5**. Its structure was evident from its elemental composition and from its spectral characteristics. In the i.r. the aldehyde band had disappeared, the ester bands were visible at 1750 and 1275 cm^{-1} (in KBr), and the 4,5-double bond at 3122 and 1630 cm^{-1}, the latter band having the intensity characteristic of a vinyl ether; the maximum at 1065 cm^{-1} corroborated this structural feature. The n.m.r. spectrum confirmed the absence of the aldehyde group and of the cyclopropane ring and the presence of the ester groups; the two olefinic protons together with the methylene protons of carbon atom 3 form an AMX_2-system comprising a multiplet centered at 6.33 δ corresponding to one proton ($H_A = H_5$), a multiplet centered at 4.95 δ also corresponding to one proton ($H_M = H_4$), and finally a multiplet corresponding to two protons centered at 3.18 δ ($2H_X = 2H_3$). The chemical shifts agree well with those reported in the literature for dihydrofuran (21*a*), if one takes into consideration that the deshielding by the neighboring ester groups should result in a downfield shift of the 3-protons (which amounts to 0.65 p.p.m.). The coupling constants (cf. Experimental) correspond well to the expected values (21*b*).

A plausible mechanism for the formation of the dihydrofuran derivative **5** is formally represented in Scheme 2. The participation of the aldehyde carbonyl group in the ring opening is substantiated by the fact that no photolytic ring opening occurs in the case of the ethylenedioxy

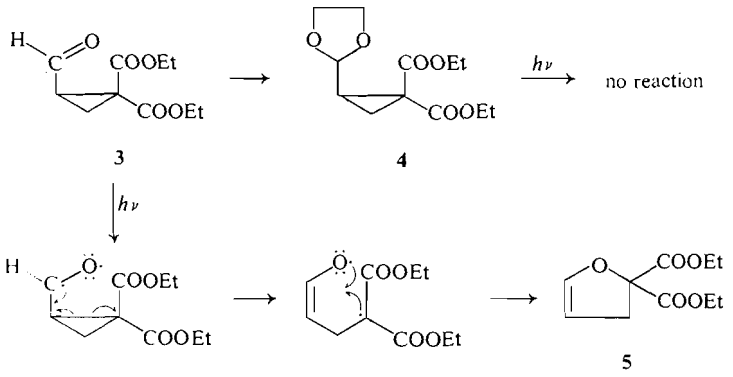
[5]The formation of the three-membered ring by a Perkin cyclization seems perfectly plausible and far more probable than by a reaction involving a carbene, formed by the action of the alcoholate on the bromomalonate. Indeed, while the carbanion formed by proton abstraction from a haloform is only stabilized by inductive effects and converts readily to a carbene, the anion formed from bromomalonate is also significantly stabilized by conjugative effects. We were able to establish the non-intermediacy of a carbene by subjecting a steroid with an unhindered isolated double bond, 5α-androst-2-en-17β-ol (**I**) (9) to the action of excess bromomalonate and sodium *t*-butoxide in *t*-butanol. Even after prolonged reaction periods and at elevated temperatures, the starting material was recovered in almost quantitative yield.



I

[6]We sincerely thank Professor Ray G. Miller for very kindly providing us with the description of the preparation of this reagent.

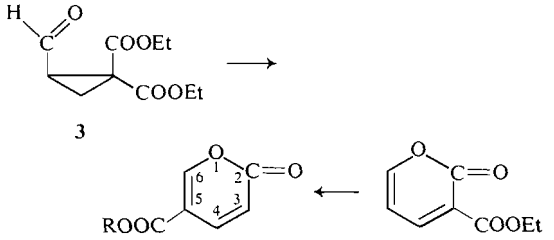
[7]The fact that certain cyclopropane systems cannot be opened by transition metal-catalyzed reactions is, however, not novel; it was discussed in the quoted paper by Volger *et al.* (11) and was recently again demonstrated by Gassman *et al.* (14).



SCHEME 2

derivative **4**. We refer for the preparation of ketal **4** to the Experimental.

We finally succeeded in opening the cyclopropane ring of the diethoxycarbonyl aldehyde **3** by pyrolysis under nitrogen at 0.1 mm Hg at 550–575°. The remarkable feature of this reaction resides in the fact that it is accompanied by cyclization to an α-pyrone and by an apparent 1,3-migration of the remaining ethoxycarbonyl substituent (cf. below), pure ethyl coumalate (**6***a*) being isolated in 20% yield. At 500°, a temperature sufficient for the opening of most cyclopropanes (for instance, for the transformation of cyclopropyl ketones into cyclopentenones (22)), no reaction occurred.



The structure of the coumalic ester was proved by elemental analysis and by its spectral characteristics. In the u.v. it showed maxima at 245 and 288 nm ($\log \varepsilon_{245}$ 3.83, $\log \varepsilon_{288}$ 3.45), in the i.r. (in KBr) maxima at 1760, 1650, and 1565 cm^{-1}, typical of the α-pyrone ring, and at 1730 and 1300 cm^{-1}, attributable to the ester group. These data agree well with those reported in the literature (23). The n.m.r. spectrum revealed, apart from the signals of the ethyl ester, the 3-, 4-, and 6-protons as three distinct multiplets representing an AMX system. The signal of the 6-proton (H_X), centered at 8.35 δ, shows small coupling constants with the vinylic protons 4 (H_A) and 3 (H_M) ($J_{4,6}$ = 3 Hz, $J_{3,6}$ = 1 Hz), whereas the coupling constant of the 3- and 4-protons (the signals of which are centered respectively at 6.28 and 7.8 δ) amounts to 10 Hz. The identity of the compound was confirmed by its hydrolysis with aqueous sulfuric acid to coumalic acid **6**, an authentic sample of which was prepared according to the method of Wiley and Smith (24, cf. also 25) from malic acid. Conversely, authentic coumalic acid was transformed according to the method of Pechmann (25) into its ethyl ester **6***a* which was found identical to the product arising from the pyrolysis of the cyclopropyl aldehyde **3**.[8]

It seems logical to assume that 3-ethoxycarbonyl-α-pyrone (**7**) is an intermediate in the formation of ethyl coumalate (**6***a*) from the formyl cyclopropane dicarboxylate **3**. While no plausible mechanism for the direct formation of the 5-substituted α-pyrone **6***a* can be advanced, the transformation of the cyclopropane derivative **3** to 3-ethoxycarbonyl-α-pyrone (**7**) can be rationalized readily (cf. Scheme 3);[9] furthermore, Pirkle *et al.* (27) have shown that apparent methyl and bromine 5 → 3 migrations occur upon pyrolytic decarboxylation of 5-methyl and 5-bromo 6-carb-

[8]We recall that coumalic acid may be decarboxylated in excellent yield (cf. 25, 26).

[9]In Scheme 3 the conversion of diethyl 2-formylcyclopropane-1,1-dicarboxylate (**3**) to 3-ethoxycarbonyl-α-pyrone (**7**) is *formally* represented as involving a concerted transformation of the cyclopropane system to an α-pyrone derivative. Naturally, one can also consider that the valence isomerization of the cyclopropane into an olefin precedes the formation of the heterocycle (cf. Scheme 1). Furthermore, while the symbolism employed in Scheme 3 implies ionic reactions, one has to consider that under pyrolytic conditions the reaction may well involve free radicals.

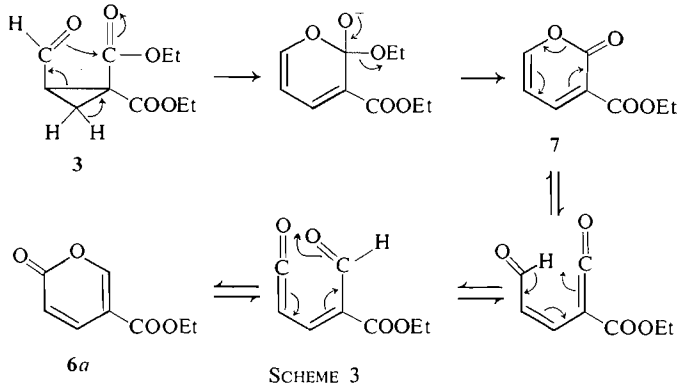

SCHEME 3

oxy-α-pyrones. The American authors explain these apparent migrations by the assumption of a ring opening to a ketene,[10] followed by a 1,5-sigmatropic hydrogen shift and ring closure to an isomeric α-pyrone. Since these transformations have to be regarded as reversible (cf. 27), the formation at high temperatures of ethyl coumalate (**6***a*) from 3-ethoxycarbonyl-α-pyrone (**7**) may be explained as summarily depicted in Scheme 3. In the case of 3- and 5-ethoxycarbonyl-α-pyrones, in contradistinction to the case of 3- and 5-methyl-α-pyrones, the equilibrium is displaced towards the 5-substituted product.

In order to substantiate the intermediacy of 3-ethoxycarbonyl-α-pyrone (**7**) in the formation of ethyl coumalate (**6***a*) from the formylcyclopropane dicarboxylate **3**, we synthesized 3-ethoxycarbonyl-α-pyrone (**7**) from 1,1,3,3-tetraethoxypropane and diethyl malonate (cf. 29) and subjected it to pyrolysis under the conditions used for the preparation of ethyl coumalate (**6***a*) from the cyclopropane derivative **3**. This resulted in a high yield of ethyl coumalate (**6***a*).

Further studies are required and are in progress in our laboratory in order to determine whether or not the two-step synthesis of ethyl coumalate from acrolein can be applied to the synthesis of other α-pyrones.

Experimental[11]

Ethyl 3β-Hydroxy-21-oxo-23-ethoxycarbonyl-20,23-cyclo-5α,20ξ-cholanate (2)

Sodium (80 mg) was dissolved in *t*-butanol (40 ml). To an aliquot of 10 ml of this solution, 790 mg of diethyl bromomalonate was added in a nitrogen atmosphere and, subsequently, 960 mg of 3β-hydroxy-20-methylene-5α-pregnan-21-al (**1**) (1), dissolved in 30 ml of *t*-butanol. A white precipitate formed and the mixture became acidic. The remainder of the sodium *t*-butoxide solution was added slowly and the mixture was stirred for 1 day. Another 15 ml of a sodium *t*-butoxide solution (prepared from 30 mg of sodium) was added, followed by 0.1 ml of diethyl bromomalonate, and the mixture was heated to 30–35° for 3 h. According to thin-layer analysis, the reaction was complete and the mixture was poured into ice water, the precipitate was extracted with dichloromethane, the organic solution was washed with water, and was dried over sodium sulfate. Evaporation of the solvent gave 1.469 g of a product which was chromatographed on 150 g of silica gel. Elutions with benzene – ethyl acetate (90:10) gave 1.029 (74% yield) of the formyl dicarboxylate **2**, m.p. 158–165°. A sample was recrystallized three times from dichloromethane–hexane and sublimed twice in high vacuum at 150–168° for analysis. Fine needles, m.p. 180–180.5°; $[\alpha]_D^{25}$ −36.6° (*c*, 1.000 in $CHCl_3$); λ_{max} (cyclohexane) 205 nm (log ε 3.47); ν_{max} (KBr) 3450 (OH), 2750 (aldehyde), 1740 and 1720 (ester groups), 1712 (aldehyde), 1240 (esters), 1082 and 1050 (hydroxyl), 1020 cm^{-1} (cyclopropyl); δ ($CDCl_3$)[12] 0.69 (s) (18-CH_3), 0.81 (s) (19-CH_3), 1.22 (t, J = 7 Hz), and 1.29 (t, J = 7 Hz) (ester-CH_3), 1.57 (s) (OH, exchanged with D_2O), 2.20 (1 H, d, J = 5 Hz) (1 H of cyclopropyl-CH_2), 3.68 (1 H, m) (3α-H), 4.10 (q, J = 7 Hz), and 4.22 (q, J = 7 Hz) (CH_2 of esters), 9.95 (1 H, s) (aldehyde).

[10]For the photolytic formation of ketenes from α-pyrones cf. ref. 28.

[11]The melting points were taken in evacuated capillaries and the temperatures were corrected. For elution column chromatography, neutral aluminum oxide Woelm, activity III, and Davison's silica gel no. 923 were employed. Dry-column chromatography was performed with Woelm dry-column chromatography silica gel, activity III; t.l.c. with Merck-Darmstadt silica gel. The i.r. spectra were recorded on Beckman IR-4 and IR-12 spectrophotometers and the u.v. spectra on a Beckman DK-1A instrument. The n.m.r. spectra were taken on a Varian A-60 spectrometer, tetramethylsilane serving as internal standard, if not otherwise stated. The microanalyses were performed by Dr. F. Pascher, Bonn, Germany, and Ayerst Laboratories, Montreal (Director of the Analytical Division: Dr. G. Schilling), to whom we express our sincere appreciation.

[12]Recorded on a Varian HA-100 spectrometer by Prof. G. Just, McGill University, Montreal, to whom we express our sincere appreciation.

Diethyl 2-Formylcyclopropane-1,1-dicarboxylate (3)

According to the procedure of Warner and Moe (7), 23 g of acrolein and 95.2 g of diethyl bromomalonate were transformed into 54.2 g (64.1% yield) of purified diethyl 2-formylcyclopropane-1,1-dicarboxylate (3), b.p. 79.5–82°/0.25–0.3 mm Hg; the crude product (70.675 g, 84%) had been purified by fractional vacuum distillation using a Vigreux column. The analytical sample was prepared by two further vacuum distillations; b.p. 78–80°/0.08 mm Hg (lit. (4): 88–90°/0.01 mm Hg); n^{25} 1.4490 (lit. (4), n^{25} 1.4509); λ_{max} (cyclohexane) 207 nm (log ε 3.29); ν_{max} (film) 3120 (cyclopropyl-CH_2), 2720 (aldehyde), 1747 and 1732 (esters), 1720 (aldehyde), 1270 and 1205 (esters), 1025 cm^{-1} (cyclopropyl); δ (CCl_4) 1.3 (t, J = 7 Hz) (ester-CH_3), 1.50–2.10 (m) (cyclopropyl-CH_2), 2.45–2.82 (m) (cyclopropyl-CH), 4.12 (q, J = 7 Hz) (ester-CH_2), 9.25 (d, J = 5 Hz) (aldehyde).

Diethyl 2-Ethylenedioxymethylcyclopropane-1,1-dicarboxylate (4)

From a solution of 1.5 g of diethyl 2-formylcyclopropane-1,1-dicarboxylate (3) in 230 ml of absolute benzene, 40 ml of solvent was removed by distillation and 20 ml of freshly distilled ethylene glycol and 93 mg of *p*-toluenesulfonic acid were added. The mixture was refluxed for 10 h and then poured into an iced saturated sodium bicarbonate solution. The product was extracted with ether, the organic solution was washed with a 2 *N* sodium carbonate solution and with water, and was dried over sodium sulfate. Evaporation of the solvent gave 1.6 g (89% yield) of ketal **4**. The product was purified by fractional vacuum distillation, giving 1.32 g (73.5%) of pure material; b.p. 100–103°/0.04 mm Hg. For analysis the product was redistilled *in vacuo*; b.p. 102°/0.04 mm Hg; n^{25} 1.4565; ν_{max} (film) 3120 (cyclopropyl), 1740 and 1270 (esters), 1140 cm^{-1} (ketal); δ (CCl_4) 1.25 (t, J = 7 Hz) (ester-CH_3), 3.88 (m) (ketal-CH_2), 4.18 (q, J = 7 Hz) (ester-CH_2), 4.7 (d, J = 5 Hz) (H on ethylenedioxy-substituted C).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 7.03. Found: C, 55.45; H, 7.02.

Unsuccessful Attempts at Valence Isomerization of Diethyl 2-Formylcyclopropane-1,1-dicarboxylate (3)

(a) With Aluminum Chloride

For 90 min, 1 g of the formyl cyclopropane dicarboxylate **3** was treated with 1.6 g of aluminum chloride at 100–110°. The usual work-up gave 852 mg of a yellow oil, the u.v., i.r., n.m.r., and thin-layer analyses of which clearly indicated that it consisted of slightly decomposed starting material. There was no evidence for the formation of an olefinic derivative. When the reaction was carried out at 150° for a period of 3 h, a far less pure product was obtained which again showed the characteristics of the starting material but which also indicated the formation of other (in part hydroxylated) products which were not further investigated and which did not contain appreciable amounts of olefins.

(b) With Bis(triphenylphosphine)iridium Carbonyl Chloride

A solution of 1 g of the formyl cyclopropane dicarboxylate **3** in 25 ml of absolute benzene was heated with 78 mg of bis(triphenylphosphine)iridium carbonyl chloride to 130° for 18 h. The solution was filtered, washed with water, dried and taken to dryness to give 888 mg of a brownish oil, identified as impure starting material. The same result was obtained when the reaction was carried out at 160° for 24 h.

(c) With trans-Dichlorobis(tri-n-butylphosphine)-nickel(II) and Diisobutylaluminum Chloride

A solution of 1 g of the formyl cyclopropane dicarboxylate **3** in 20 ml of absolute toluene was treated with 210 mg of diisobutylaluminum chloride and 87 mg of *trans*-dichlorobis(tri-*n*-butylphosphine)nickel(II) for 3 h. Ice was added and the product was extracted with ether. The ethereal solution was washed with water and dried over sodium sulfate, and the solvent was evaporated. The remaining yellow oil was identified as the starting material. The reaction was repeated at reflux temperature for 5 h with the same result.

Photolysis of Diethyl 2-Formylcyclopropane-1,1-dicarboxylate (3)

A solution of 4.429 g of the formyl cyclopropane dicarboxylate **3** in 500 ml of absolute benzene was irradiated under nitrogen with an immersed 450 W Hanovia mercury lamp, using a Pyrex filter and a quartz vessel, cooled by a cold-water jacket. After 30 h the reaction was interrupted and the solvent was removed under reduced pressure. A portion of 3.4 g of the residue (4.435 g of a brownish oil) was subjected to dry-column chromatography (31) on 1 kg of silica gel, using petroleum ether – ether (2:1) as solvent system. Thus 2.039 g (60% yield) of pure diethyl *2,3-dihydrofurane-2,2-dicarboxylate* (**5**) was obtained. Vacuum distillation gave the analytical sample; b.p. 79–80°/0.1 mm Hg; n^{25} 1.4452; λ_{max} (cyclohexane) 203 nm (log ε 3.2), λ_{max} (EtOH) 203 nm (log ε 3.45); ν_{max} (film) 3122 (double bond), 1750 (esters), 1635 (strong band of enolic double bond), 1270 cm^{-1} (esters); δ (CCl_4) 1.32 (6 H, t, J = 7 Hz) (ester-CH_3), 4.30 (4 H, q, J = 7 Hz) (ester-CH_2), 3.18 (2 H, d of d, $J_{3,4}$ = 2.5 Hz, $J_{3,5}$ = 2.0 Hz) (H_2 of C-3 = 2 H_X of AMX_2 system), 4.95 (1 H, d of t, $J_{4,3}$ = 2.5 Hz, $J_{4,5}$ = 2.5 Hz) (H_4 = H_M of AMX_2 system), 6.32 (1 H, d of t, $J_{5,3}$ = 2.0 Hz, $J_{5,4}$ = 2.5 Hz) (H_5 = H_A of AMX_2 system).

Anal. Calcd. for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59. Found: C, 55.57; H, 6.68.

Photolysis of Diethyl 2-Ethylenedioxymethylcyclopropane-1,1-dicarboxylate (4)

A quantity of 1.6 g of the ketal derivative **4** of the aldehydo ester **3** was irradiated as described for the photolysis of the free aldehyde **3**. The work-up gave 1.6 g (quantitative crude yield) of a yellow oil, the i.r. and n.m.r. spectra of which revealed that it only contained the starting material, the cyclopropane derivative **4**. A portion of this product (1.5 g) was dissolved in 300 ml of absolute benzene and was again irradiated, this time without a Pyrex filter and for 17 h. Evaporation of the solvent gave 1.5 g (quantitative crude yield) of a yellowish oil which was again identified by i.r., n.m.r., and thin-layer analyses as unchanged starting material **4**.

Ethyl Coumalate (6a)

(a) By Pyrolysis of Diethyl 2-Formylcyclopropane-1,1-dicarboxylate (3)

A quantity of 9 g of diethyl 2-formylcyclopropane-1,1-dicarboxylate (**3**) was slowly distilled, in the course of 10 h, under nitrogen at 0.1 mm Hg, and the vapors were passed through a Vycor tube, filled with crushed Vycor glass, preheated to 550–575°. The distillate was collected in a Dry-Ice trap, the dark-brown product (3.728 g) was diluted with ether, the solution was washed with a saturated sodium bicarbonate solution and with water and was dried over sodium sulfate. Evaporation of the solvent gave 3.126 g of a brown oil. A portion of 2 g of this product was purified by dry-column chromatography on 600 g of silica gel, using petroleum ether – ether (1 : 1) as solvent system. Thus, 903 mg (corresponding to an overall yield of 20.2%) of ethyl coumalate (ethyl 2-pyrone-5-carboxylate) (**6a**) was obtained. For analysis, the product was redistilled under vacuum; b.p. 82–83°/0.1 mm Hg; m.p. 35–35.5° (lit. (25): 36°); n^{25} 1.4782; λ_{max} (EtOH) 245 (log ε 3.8) and 288 nm (log ε 3.4); ν_{max} (film) 3100 (double bond), 1760 (lactone), 1730 (ester), 1665 and 1650 (double bonds), 1300 cm^{-1} (ester); δ (CCl_4) 1.38 (3 H, t, J = 7 Hz) (ester-CH_3), 4.35 (2 H, t, J = 7 Hz) (ester-CH_2), 6.28 (1 H, d of d, $J_{3,4}$ = 10 Hz, $J_{3,6}$ = 1 Hz) (H_3 = H_A of AMX system), 7.80 (1 H, d of d, $J_{4,3}$ = 10 Hz, $J_{4,6}$ = 3 Hz) (H_4 = H_M of AMX system), 8.35 (1 H, d of d, $J_{6,4}$ = 3 Hz, $J_{6,3}$ = 1 Hz) (H_6 = H_X of AMX system).

Anal. Calcd. for $C_8H_8O_4$: C, 57.14; H, 4.80. Found: C, 56.69; H, 4.84.

(b) From Coumalic Acid (6)

A solution of 10.2 g of coumalic acid (**6**), prepared as described below (cf. 24), in 150 ml of absolute ethanol was refluxed for 1.5 h with 60 ml of concentrated sulfuric acid. The cooled solution was poured onto 100 g of ice and the product was extracted with ether. The organic solution was washed with a saturated sodium bicarbonate solution and with water and was dried over sodium sulfate. Evaporation of the solvent gave 11.9 g of a brown oil which was purified by fractional vacuum distillation. The product (b.p. 72–74°/0.04 mm Hg, m.p. 34–35°) was found identical to a sample prepared as described under (*a*), by the comparison of the u.v., i.r., and n.m.r. spectra.

(c) By Pyrolysis of Ethyl α-Pyrone-3-carboxylate (7)

Pyrolysis of 10.2 g of ethyl α-pyrone-3-carboxylate (7) (cf. below), under the conditions described under (*a*), led to 7.8 g (76.5%) of a dark-brown oil, the u.v., i.r., and n.m.r. spectra of which established its identity with ethyl coumalate (**6a**). Vacuum distillation gave 7.05 g (69%) of pure ethyl coumalate (**6a**), b.p. 79–81°/0.08 mm Hg, the spectra of which were superimposable on those of the products described under (*a*) and (*b*).

Coumalic Acid (6)

(a) From Ethyl Coumalate (6a), Obtained by Pyrolysis of the Cyclopropane Derivative 3

To a solution of 3.36 g of ethyl coumalate (**6a**), prepared from the formyl cyclopropane dicarboxylate **3**, in 40 ml of 95.5% sulfuric acid, 25 cc of water was added slowly. The solution was left for 20 h at room temperature and was then precipitated on 150 g of ice. The product was extracted with ether–chloroform (3 : 1), the organic solution was washed with water and was then extracted with a saturated sodium bicarbonate solution. The alkaline, aqueous extract was acidified to the Congo-blue reaction with concentrated hydrochloric acid and the product was extracted with ether–chloroform (3 : 1). The organic layer was washed with water and dried over sodium sulfate. Removal of the solvent gave 2.41 g (81%) of a light-brown solid, m.p. 190–195°. The product was dissolved in 20 ml of hot methanol and this solution was treated with 250 mg of Norit-A. The hot mixture was filtered and the volume of the filtrate was reduced to approximately 15 ml and cooled in an ice bath. The precipitate was filtered, washed with cold methanol and dried. Thus 1.505 g (50.5% yield) of light yellow crystals, m.p. 208–210°, were obtained. Recrystallization from methanol raised the melting point to 210–212°. A sample was sublimed twice in high vacuum between 120 and 130° for analysis. Almost colorless powder, m.p. 214.5–215° (lit. (24) 209–210°); λ_{max} (EtOH) 243 (log ε 3.7) and 288 nm (log ε 3.5); ν_{max} (KBr) 3200–2500 (acid), 1720 (lactone), 1680 (acid), 1630 and 1550 (double bonds), 1405 and 1230 cm^{-1} (acid); δ (CF_3COOH) 6.78 (1 H, d of d, $J_{3,4}$ = 10 Hz, $J_{3,6}$ = 1 Hz) (H_3 = H_A of AMX system), 8.25 (1 H, d of d, $J_{4,3}$ = 10 Hz, $J_{4,6}$ = 3 Hz) (H_4 = H_M of AMX system), 8.70 (1 H, d of d, $J_{6,4}$ = 3 Hz, $J_{6,3}$ = 1 Hz) (H_6 = H_X of AMX system).

Anal. Calcd. for $C_6H_4O_4$: C, 51.44; H, 2.88. Found: C, 51.42; H, 2.97.

(b) From Malic Acid

A quantity of 50 g of malic acid was transformed, as described by Wiley and Smith (24), into 21.2 g (80.5% yield) of crude coumalic acid (**6**), m.p. 196–203°. The product was purified in hot methanol with Norit-A and recrystallized twice from methanol to give 16.4 g (62.5% yield) of pure coumalic acid (**6**), m.p. 208–211°, which was found identical with the one prepared as described under (*a*), by the comparison of the u.v., i.r., and n.m.r. spectra, and by the determination of a mixture melting point.

Ethyl 2-Pyrone-3-carboxylate (7)

A quantity of 55 g of 1,1,3,3-tetraethoxypropane was transformed, according to the procedure of Windholz *et al.* (29), with 40 g of diethyl malonate, 100 ml of acetic anhydride, and catalytic amounts of zinc chloride, to 58.4 g of *diethyl 3-ethoxyallylidenemalonate*; b.p. 114°/0.08 mm Hg (lit. (29): b.p. 128°/0.2 mm Hg); ν_{max} (CH_3OH) 300 nm (log ε 4.32) (lit. (29): 300 nm (log ε 4.39)); ν_{max} (film) 1720 (esters), 1630 (double bond), 1245 cm^{-1} (esters); δ (CCl_4) 1.28 (3 H, t, J = 7 Hz) (enol ether-CH_3), 1.32 (6 H, t, J = 7 Hz) (ester-CH_3), 4.22

(2 H, q, J = 7 Hz) (enol ether-CH_2), 4.26 (4 H, q, J = 7 Hz) (ester-CH_2), 6.20 (1 H, t, J = 12 Hz) (olefinic proton), 7.18 (1 H, d, J = 12 Hz) (olefinic proton), 7.38 (1 H, d, J = 12 Hz) (olefinic proton).

As described by Windholz *et al.* (29), a quantity of 12.6 g of diethyl 3-ethoxyallylidenemalonate was heated in 140 ml of 99% formic acid for 1 h to give 6.1 g (72.7% yield) of *ethyl 2-pyrone-3-carboxylate* (**7**); b.p. 95–97°/0.08 mm Hg (lit. (29): b.p. 122–123°/0.2 mm Hg), λ_{max} (CH_3OH) 308 nm (log ε 3.72) (lit. (29): 309 nm (log ε 3.87)); ν_{max} (film) 3110 (double bonds), 1760 (lactone), 1745 (ester), 1630 and 1555 (double bonds), 1270 cm^{-1} (ester); δ (CCl_4) 1.37 (3 H, t, J = 7 Hz) (ester-CH_3), 4.4 (2 H, q, J = 7 Hz) (ester-CH_2), 6.62 (1 H, d of d, $J_{5,4}$ = 7 Hz, $J_{5,6}$ = 5 Hz) (H_5 = H_A of AMX system), 7.95 (1 H, d of d, $J_{6,5}$ = 5 Hz, $J_{6,4}$ = 2.5 Hz) (H_6 = H_M of AMX system), 8.35 (1 H, d of d, $J_{4,5}$ = 7 Hz, $J_{4,6}$ = 2.5 Hz) (H_4 = H_X of AMX system).

Treatment of 5α-Androst-2-en-17β-ol (I) with Diethyl Bromomalonate

To 10 ml of a solution prepared from 140 mg of sodium and 100 ml of *t*-butanol, 1.2 ml of diethyl bromomalonate was added and, subsequently, 1 g of 5α-androst-2-en-17β-ol (I) (9), dissolved in 50 ml of *t*-butanol. The rest of the sodium *t*-butoxide solution was added and the mixture was kept for 3 h at room temperature and subsequently at 90° for 5 h. No reaction was observed by thin-layer analysis. The product was poured into ice water and the precipitate was extracted with dichloromethane. The organic solution was washed with water and dried over sodium sulfate. Evaporation of the solvent gave 991 mg of the starting material. The result was analogous when the diethyl bromomalonate was added to a solution containing the steroid and sodium *t*-butoxide. Variations of the reaction conditions did not alter the results.

Sincere thanks are extended to Mrs. J. Capitaine for her assistance in some of the experiments and to Professor G. Just, McGill University, for kindly subjecting one of our products to an n.m.r. analysis at 100 MHz. We gratefully acknowledge the technical cooperation of the late Mr. D. Capitaine and of Mrs. G. Pelletier. Our appreciation is expressed to the National Research Council of Canada, the Ministère de l'Education du Gouvernement du Québec, to Ayerst Laboratories, Montreal, Quebec, and to the Schering Corporation, Bloomfield, New Jersey, for financial assistance. One of us (G. D.) sincerely thanks the National Research Council of Canada for the award of a scholarship.

Selective Benzoylation of Methyl 6-Deoxy-α- and β-D-glucopyranosides

YÔTARO KONDO, KIYOSHI MIYAHARA, AND NAOKI KASHIMURA
Department of Agricultural Chemistry, Kyoto University, Kyoto, Japan

Received February 28, 1973

Selective dimolar benzoylation of methyl 6-deoxy-α- and β-D-glucopyranosides yielded the 2,3-di-*O*-benzoate of the respective glucopyranoside as the major product in 61 and 29% yields. The orders of the reactivity of the secondary hydroxyl groups in α- and β-anomers were different, *i.e.*, the order was 2-OH > 3-OH > 4-OH for the former and 3-OH > 2-OH > 4-OH for the latter.

La benzoylation bimolaire sélective des méthyls déoxy-6 α- et β-D-glucopyranosides a conduit au dérivé di-*O*-benzoate-2,3 des glucopyranosides comme produit majeur avec des rendements de 61 et de 29% respectivement. L'ordre de réactivité des groupes hydroxyles secondaires dans les anomères α et β s'est révélé être différent, *i.e.*, l'ordre était dans le premier cas OH-2 > OH-3 > OH-4 et dans le second cas OH-3 > OH-2 > OH-4. [Traduit par le journal]

Can. J. Chem., 51, 3272 (1973)

Introduction

Selective benzoylation of hexopyranosides (1–9) is of theoretical interest in relation to the relative reactivity of primary and secondary hydroxyl groups and provides a facile route for the preparation of important synthetic intermediates (3, 6–8). There are few comparative studies on selective benzoylation of α- and β-hexopyranosides. This communication describes the selective benzoylation of methyl 6-deoxy-α- and β-D-glucopyranosides and factors determining the reactivity of the hydroxyl groups are discussed.

Results and Discussion

Treatment of methyl 6-deoxy-α-D-glucopyranoside (**1**) with 2 mol. equiv. of benzoyl chloride in pyridine at −40 °C gave the syrupy 2,3-di-*O*-benzoate **4** as the major product in 61% yield after column chromatography on silicic acid. Its structure was established by tosylation,[1] giving methyl 2,3-di-*O*-benzoyl-6-deoxy-4-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (**5**), previously described by Jary and Capek (10). The sulfonate **5** undergoes bimolecular displacement with sodium azide in *N*,*N*-dimethylformamide to yield methyl 4-azido-2,3-di-*O*-benzoyl-4,6-dideoxy-α-D-galactopyranoside, which exhibited absorption of the azido group at 2110 cm^{-1} in the i.r. spectrum.

The chromatographic fractionation further afforded a syrupy dibenzoate **2** on the basis that tosylation of the dibenzoate gave methyl 2,4-di-*O*-benzoyl-6-deoxy-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (**3**), which was readily distinguishable from the known 2- and 4-*O*-*p*-tolylsulfonyl isomers by comparison of their physical properties.

Assignment of the position of *p*-tolylsulfonyl group in **3** and **5** was further confirmed by p.m.r. spectroscopy. The signals of H-3 of **3** and H-4 of **5** appeared respectively 0.69 and 0.64 p.p.m. to higher field than those of the corresponding hydrogens of tribenzoate **6** (Table 1). The *p*-tolylsulfonyl groups of **3** and **5** are therefore attached to C-3 and C-4 respectively. Because of the powerful deshielding effect of benzoyloxy group, the signal of ring proton attached to the same carbon atom as the ester group occurs to low field of the other protons with exception of the anomeric proton (4, 11).

By similar treatment of methyl 6-deoxy-β-D-glucopyranoside (**7**) with 2 mol. equiv. of benzoyl chloride, methyl 2,3-di-*O*-benzoyl-6-deoxy-β-D-glucopyranoside (**9**) was obtained as the major product in 29% yield after column chromatography. The structure of the dibenzoate

[1] Migration of the benzoyl ester group is unlikely to occur under tosylating conditions (4, 5).

*The values in the parentheses of compounds **3** and **5**, and those of **10**, **11** and **8**, indicate the increments of the chemical shifts relative to those of **6** and **12**, respectively; s = singlet; d = doublet; t = triplet; q = quartet; o = octet.

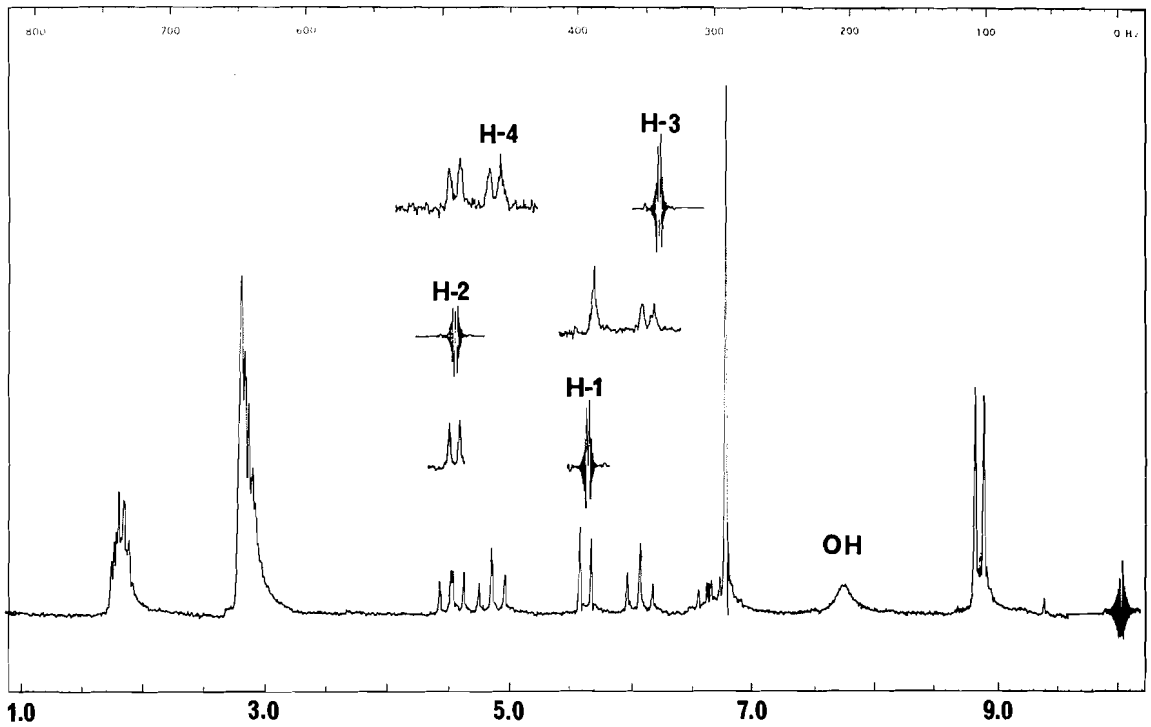

FIG. 1. The 90 MHz p.m.r. spectrum of 2,4-di-*O*-benzoate **8** in C_6D_6 (τ).

was established by tosylation, giving methyl 2,3-di-*O*-benzoyl-4-*O*-*p*-tolylsulfonyl-β-D-glucopyranoside (**10**) of which physical constants were in good agreement with those of an authentic sample reported by Kaufmann (12).

Two dibenzoates were further isolated in 1 and 4% yields which were shown to be the 2,4- and 3,4-di-*O*-benzoates (**8** and **11**) by p.m.r. spectroscopy. The spectrum of **8** shown in Fig. 1 exhibited at the lowest field (τ 4.52) a quartet (J = 8.0 and 9.8 Hz) characteristic of H-2 of the β-anomer, and in the p.m.r. spectra of tribenzoates **6** and **12** their H-3 signals appeared at the lowest field. Accordingly, the high field triplet at τ 6.07 (J = 9.8 Hz) must correspond to H-3 attached to the same carbon atom as free hydroxyl rather than benzoyl group. The H-4 signal appeared as a triplet at τ 4.86 (J = 9.8 Hz) and the H-1 signal as a doublet at τ 5.62 (J = 8.0 Hz). In the dibenzoate **11** (Fig. 2), the H-3 signal occurred as a triplet at the lowest field (τ 4.17, J = 9.5 Hz) and therefore the triplet at high field (τ 4.67) must be attributed to H-4. The H-2 signal appeared as a quartet characteristic of the β-anomer (J = 7.7 and 9.5 Hz) at 1.09 p.p.m. higher field (τ 6.21) compared with that of **12**, indicating that C-2 is unsubstituted. The H-1 signal was observed as a doublet at τ 5.74 (J = 7.7 Hz). These assignments were in good agreement with the decoupling experiments (Figs. 1 and 2).

In dibenzoylation of methyl 6-deoxy-α-D-glucopyranoside (**1**), the preponderance of the 2,3-di-*O*-benzoate (61%) over the 2,4-di-*O*-benzoate (17%) shows that the relative reactivity (judged by the yield of reaction products) of the secondary hydroxyl groups in **1** is in the order, 2-OH > 3-OH > 4-OH, which is consistent with that obtained by Williams and Richardson (4) for methyl α-D-glucopyranoside. This result suggests that the substituted groups at C-5, methyl and hydroxymethyl (or benzoyloxymethyl) groups, do not affect the order of reactivity in benzoylation. On the other hand, the yield of dibenzoates in dibenzoylation of methyl 6-deoxy-β-D-glucopyranoside (**7**) was in the order of the 2,3- (29%), 3,4- (4%), and 2,4-di-*O*-benzoates (1%). Therefore, the order of reactivity of the secondary hydroxyl groups in **7** is 3-OH > 2-OH > 4-OH.

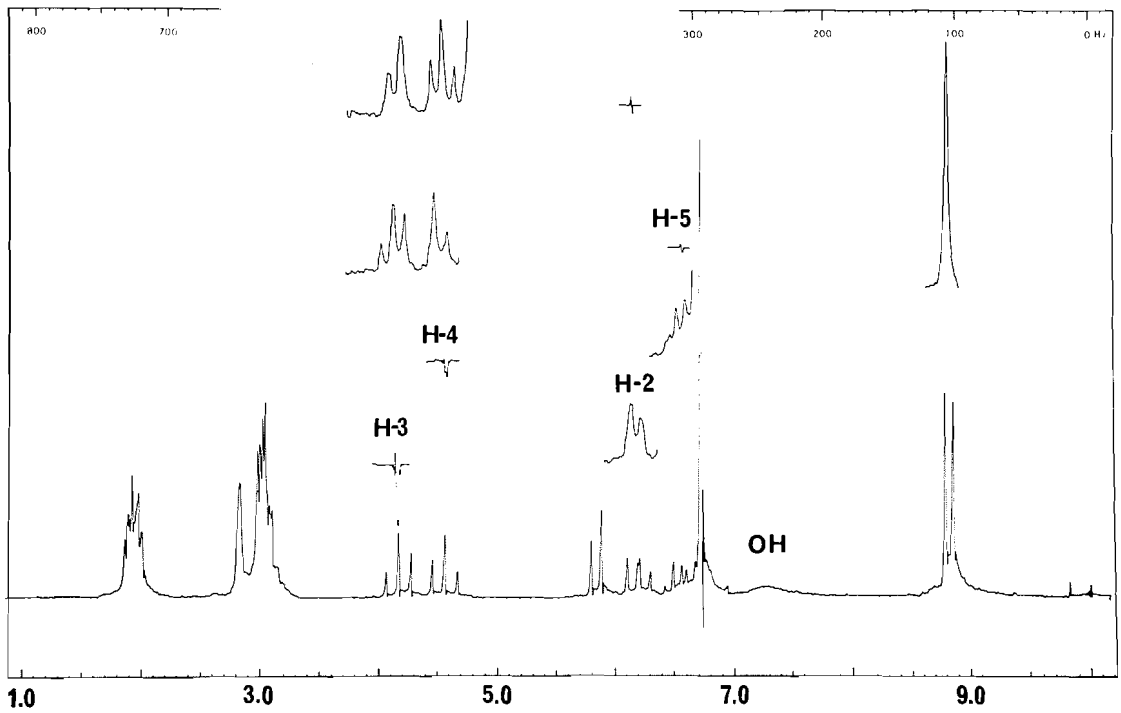

FIG. 2. The 90 MHz p.m.r. spectrum of 3,4-di-*O*-benzoate **11** in C_6D_6 (τ).

The higher total yield of the reaction products of the α-anomer (77.7%) compared with that of the β-anomer (57.1%) indicates that the former is more rapidly benzoylated than the latter. In the β-anomer the 3-OH group is more reactive than the 2-OH group while the reverse is true for the α-anomer. The high reactivity of the 2-OH group in the α-anomer may be due to intramolecular hydrogen bonding between the 2-OH group and the axial C-1 methoxyl group (8, 9, 13, 14), and the lower reactivity of the 2-OH group in the β-anomer may be attributed to lack of hydrogen bond formation (13, 15, 16). It is of interest to note that the 4-OH group in methyl 6-deoxy-α- and β-D-glucopyranosides is the least reactive towards benzoylation while it is more reactive than the other secondary hydroxyl groups in selective disulfonylation of methyl β-D-glucopyranoside (17).

Experimental

Melting points were determined with a Yanagimoto micro hot-stage apparatus and are uncorrected. Optical rotations were measured with a Yanagimoto OR-20 polarimeter. T.l.c. was carried out on silica gel G (Merck) with benzene–ether (4:1, v/v) as mobile phase and column chromatography was performed using silicic acid (Mallinkrodt, 100 mesh). The i.r. spectra were recorded with a Hitachi EPI-G3 and the p.m.r. spectra with a Hitachi–Perkin–Elmer 90 MHz instrument using benzene-d_6 solution with tetramethylsilane as an internal standard. Benzoyl chloride used was purified by distillation from its benzene solution.

Selective Dimolar Benzoylation of Methyl 6-Deoxy-α-D-glucopyranoside (1)

Benzoyl chloride (0.61 ml, 2.1 equiv.) was added dropwise over a period of 15 min to a stirred solution of compound **1** (18) (0.0025 mol, 445 mg) in anhydrous pyridine (17.8 ml) at −40 °C. The bath temperature was kept below −20 °C for 3 h, at 0 °C for 24 h, and then stirred at room temperature for 2 days and extracted with chloroform. The extract was washed with dilute sulfuric acid, saturated sodium bicarbonate, and water, and dried over Na_2SO_4. The crude syrupy product after evaporation of the solution was shown to contain two major and one minor components by t.l.c. Fractionation of the mixture on a silicic acid column (300 g) using benzene–ethyl acetate mixture yielded two syrupy fractions, 2,4-di-*O*-benzoate **2** (160 mg, 16.6%) and 2,3-di-*O*-benzoate **4** (590 mg, 61.1%), that could not be crystallized. The minor component appears to be tri-*O*-benzoate **6** from the result of t.l.c.

Methyl 2,3-Di-O-benzoyl-6-deoxy-4-O-p-tolylsulfonyl-α-D-glucopyranoside (5)

The dibenzoate **4** (240 mg) in pyridine (2.5 ml) was treated with toluene-*p*-sulfonyl chloride (600 mg) for 5 days at room temperature with stirring. The mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was extracted and purified as described above to give the crystalline product. Recrystallization from ethanol gave the title compound (260 mg, 77.4%), m.p. 141–142 °C, $[\alpha]_D^{24}$ +95.8° (*c* 0.5, $CHCl_3$), lit. (10) m.p. 140–142 °C, $[\alpha]_D^{24}$ +98.6° (*c* 0.55, $CHCl_3$).

The sulfonate **5** (100 mg) in *N*,*N*-dimethylformamide (3 ml) was further heated with sodium azide (100 mg) for 3 days at 65 °C with stirring to yield a syrupy methyl 4-azido-2,3-di-*O*-benzoyl-4,6-dideoxy-α-D-galactopyranoside which could not be crystallized. The i.r. spectrum showed the absorption of the azido group (ν_{max} film 2110 cm^{-1}) but the sulfonyl group was absent. The product was not further investigated.

Methyl 2,4-Di-O-benzoyl-6-deoxy-3-O-p-tolylsulfonyl-α-D-glucopyranoside (3)

The dibenzoate **2** (160 mg) in pyridine (1.7 ml) was treated with toluene-*p*-sulfonyl chloride (400 mg) for 4 days to give the sulfonate **3** (115 mg, 51.4%), m.p. 140–141 °C, $[\alpha]_D^{24}$ +69.0° (*c* 0.5, $CHCl_3$), cf. methyl 3,4-di-*O*-benzoyl-6-deoxy-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (19), m.p. 120–122.5 °C, $[\alpha]_D^{21}$ +15.78° (*c* 0.5, $CHCl_3$).

Anal. Calcd. for $C_{28}H_{28}O_9S$: C, 62.21; H, 5.23; S, 5.93. Found: C, 61.96; H, 5.04; S, 5.95.

Selective Dimolar Benzoylation of Methyl 6-Deoxy-β-D-glucopyranoside (7)

Methyl 6-deoxy-β-D-glucopyranoside (18) (7, 0.005 mol, 890 mg) in pyridine (35.6 ml) was treated with benzoyl chloride (1.22 ml, 2.1 equiv.) as described for the α-anomer. T.l.c. examination of the crude product indicated the presence of several components. Chromatographic separation of the components on a silicic acid column gave five fractions. The first eluted syrupy compound was identified as the tri-*O*-benzoate **12** (50 mg, 2.1%) by comparison of the R_f value with that of an authentic sample. The syrupy 2,4-di-*O*-benzoate **8** (20 mg, 1.1%) was crystallized from ether, m.p. 160–161 °C, $[\alpha]_D^{30}$ −24.6° (*c* 0.3, $CHCl_3$).

Anal. Calcd. for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74. Found: C, 65.11; H, 5.67.

The 2,3-di-*O*-benzoate **9** was obtained as a syrup (550 mg, 28.5%), and the 3,4-di-*O*-benzoate **11** (80 mg, 4.1%) was crystallized from ether, m.p. 164–165 °C, $[\alpha]_D^{30}$ −82.4° (*c* 0.5, $CHCl_3$).

Anal. Calcd. for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74. Found: C, 64.89; H, 5.74.

The syrupy monobenzoates (300 mg, 21.3%) were shown to be composed of three components by t.l.c.

Methyl 2,3-Di-O-benzoyl-6-deoxy-4-O-p-tolylsulfonyl-β-D-glucopyranoside (10)

Treatment of the dibenzoate **9** (240 mg) in pyridine (2.5 ml) with toluene-*p*-sulfonyl chloride (600 mg) for 6 days gave the sulfonate **10** (224 mg, 66.7%), m.p. 158–159 °C, $[\alpha]_D^{24.5}$ +20.0° (*c* 0.2, MeOH), lit. (13) m.p. 162 °C, $[\alpha]_D^{19}$ +19.9 ± 2° (*c* 0.99, MeOH).

Methyl 2,3,4-Tri-O-benzoyl-6-deoxy-β-D-glucopyranoside (12)

A solution of **7** (100 mg) in pyridine (3.5 ml) was stirred with benzoyl chloride (0.5 ml) for 4 days at room temperature. It was worked-up in the usual manner to give a syrup which was crystallized from ethanol (190 mg, 69.0%), m.p. 251–252 °C, $[\alpha]_D^{17}$ −42.9° (*c* 0.28, pyridine).

Anal. Calcd. for $C_{28}H_{26}O_8$: C, 68.6; H, 5.35. Found: C, 68.55; H, 5.37.

Carbon-13 Resonance Spectroscopic Studies on the Formation of Borate and Diphenylborinate Complexes of Polyhydroxy Compounds[1]

PHILIP A. J. GORIN AND MYTOSK MAZUREK

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received February 22, 1973

On complexing with sodium tetraborate the ^{13}C magnetic resonance (c.m.r.) spectra of certain sugars contain considerably broadened signals. Replacement of the reagent with sodium diphenylborinate resulted in spectra with sharp singlets corresponding to the diphenylborinate complex, indicating that ^{13}C–^{11}B coupling likely does not occur. Most of the broadening is due rather to either the presence of more than one conformer of the borate complex or the rapid interconversion of the compound with borate complexes of types II and III. In one group of experiments the complexing of diphenylborinate with several low molecular weight sugars and polysaccharides was followed through c.m.r. spectroscopy. In another, complexing was observed with pyranosides having 1,3-hydroxyl groups with orientations that were almost diaxial. In the equilibrium reactions the approximate extent of complexing was estimated and with compounds that can form more than one complex, such as glycerol, the number and structures of the complexes were determined.

Par complexation avec le tétraborate de sodium les spectres de résonance magnétique du ^{13}C de certains sucres comportent un élargissement des signaux considérable. Le remplacement de ce réactif par le diphénylborinate de sodium a pour résultat spectral des singulets fins correspondant au complexe avec le diphénylborinate, montrant que le couplage ^{13}C-^{11}B n'existe probablement pas. La majeure partie de cet élargissement est due plutôt soit à la présence de plus d'un conformère du complexe borate ou à l'interconversion rapide du composé dans les complexes borates de type II et III. Dans une série d'expériences, la complexation du diphénylborinate avec plusieurs sucres de bas poids moléculaire et polysaccharides a été suivie par r.m.n. du ^{13}C. Dans d'autres, cette complexation a été observée avec des pyranosides comportant des groupes hydroxyle-1,3 dont les orientations sont presque diaxiales. Dans les réactions d'équilibration, le pourcentage approximatif de complexation a été évalué; avec des composés pouvant former plus d'un complexe, tel le glycérol, le nombre et les structures des complexes ont été déterminés. [Traduit par le journal]

Can. J. Chem., 51, 3277 (1973)

Introduction

It was shown in a previous publication (1) that following addition of sodium tetraborate to solutions of carbohydrates in D_2O the formation of borate complexes could be followed by changes in the carbon-13 magnetic resonance (c.m.r.) spectra of the parent compounds. Two types of spectral effects were observed. In one type the signals remain sharp and changes in chemical shift take place and in the other the resonances of the signals remain the same, but broadening of signals of ^{13}C nuclei in the vicinity of the complex occurs[2] (Fig. 3 in ref. 1). Three possible explanations for the latter phenomenon were considered, two of which involve conformational factors. One is that the ring containing the boron atom interconverts rapidly between two or more conformations thus giving an average c.m.r. spectrum. It is more likely that the borate complexes of type II and one or two stereoisomeric type III complexes (Fig. 1) are in equilibrium with the sugar but their interconversion is so fast that they cannot be detected individually by c.m.r. spectroscopy. No change in resonance of the ^{13}C signals was observed since presumably the conformations of the carbon skeletons of sugar and its type II or III complexes were not appreciably different and the carbons were not deshielded to any extent in the borate forms. The other possible explanation is that the signals of ^{13}C nuclei are coupled to ^{11}B nuclei of spin $\frac{3}{2}$ and that quadrupole type broadening occurs.

The latter is now shown to be likely incorrect, however, by the following experiment. In the previous study addition of borax to a D_2O solution of methyl 2,3-di-*O*-methyl-α-D-mannopy-

[1]NRCC No. 13302.

[2]These signals are very stunted and have a line width of 40 Hz. This compares with 5–7 Hz for the other signals. All of the latter were also broadened (to 8–12 Hz) in accord with the finding that a general slight line broadening occurs on addition of sodium diphenylborinate or borate to sugar solutions.

*Percentage of unchanged compound was estimated by comparison of this signal with that of the MeOH standard.
†S–DPB = ratio of sugar to diphenylborinate and S–B = molar ratio of sugar to sodium tetraborate.

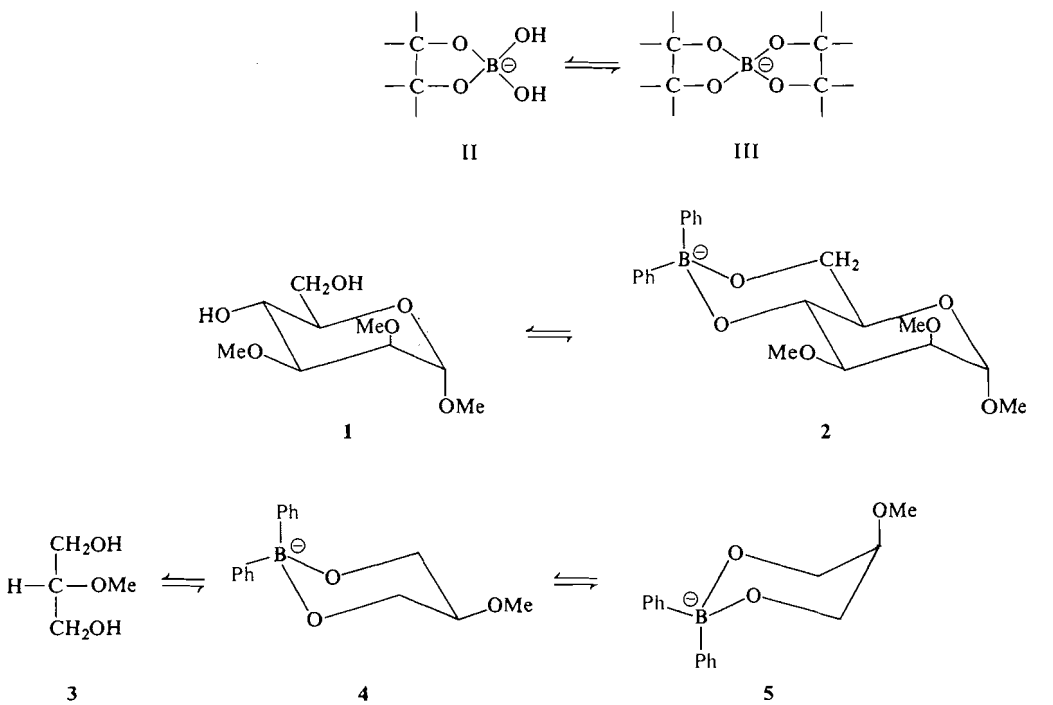

FIG. 1. Equilibria of polyhydroxy compounds with borates and diphenylborinates.

ranoside (Fig. 1; **1**) resulted in marked broadening of the C-4, -5, and -6 signals of the c.m.r. spectrum (Fig. 3 in ref. 1). However, when borax was replaced with 3 mol equiv. of sodium diphenylborinate six new signals appeared (Fig. 3, compare spectra A and B) which corresponded to C-1 to -6 of the diphenylborinate complex (Fig. 1; **2**). No ^{13}C–^{11}B splitting was observed in the ^{13}C signals of carbons in the sugar ring or the aromatic rings of the complex. Their line widths were comparable with those of unreacted sugar.

Two other compounds, *myo*-inositol and 1,4,5,6-tetra-*O*-methyl-*myo*-inositol both gave c.m.r. spectra which contained broadened signals following addition of sodium tetraborate (1). They also complexed with diphenylborinate as indicated by the appearance of new c.m.r. signals (Table 1). This finding is in accord with that of Garegg and Lindström (2) who showed that the p.m.r. spectrum of *epi*-inositol was modified on addition of sodium diphenylborinate. The cyclitol contains several *cis*-1,2-diol groups capable of complexing in addition to 1,3-diaxial hydroxyls which may also possibly react (see later discussion). However, *cis*-cyclohexane-1,2-diol does not form a diphenylborinate complex in appreciable amount since the c.m.r. spectrum remains unchanged on addition of the reagent. The glycol group evidently lacks the inductive effect of adjacent hydroxyls which would favor complex formation. Such an explanation was used by Angyal and McHugh (3) when it was found that on paper electrophoresis in aqueous borax *cis*-cyclohexane-1,2-diol is less mobile than a structurally related compound having an additional *trans*-hydroxyl adjacent to the glycol group.

The degree of complexing of polyhydroxy compounds with diphenylborinate in deuterium oxide cannot be estimated directly on the basis of the signal size of carbons in the complex because of the possibly different nuclear Overhauser effect and the difference of relaxation times of the various nuclei. However, the proportion of uncomplexed material can be estimated by comparing the size of a suitable signal with that of the methyl resonance of methanol (δ_C 49.5), which is used as an internal standard during graded addition of sodium diphenylborinate. Since there are insufficient data points to completely define any given signal the accuracy of the measurements is not great and

the percentages quoted for uncomplexed material should be regarded as accurate to only ±10%. The chemical shifts of certain polyhydroxy compounds, those of the diphenylborinate compounds, and the percentage of complex formed on addition of 1 and 3 mol equiv. of sodium diphenylborinate are recorded in Table 1.

Many of the diphenylborinate complexes known to be formed on the basis of c.m.r. spectroscopy were previously found to give borate complexes (ref. 1 and references contained therein) and should have structures analogous to the type II (Fig. 1) complex. Compounds containing only two hydroxyl groups with suitable stereochemistry complex on these positions and hexopyranosides should give rise to a 4,6-complex (4). C.m.r. spectral evidence was obtained for complexing of the OH-2 and OH-4 hydroxyl groups of methyl 3,6-anhydro-α-D-glucopyranoside (**6**, Fig. 2) with sodium diphenylborinate since five new c.m.r. signals were obtained (Table 1). With 1 and 3 mol equiv. of reagent 30% and 70% of the complex was formed, respectively. The pyranoid ring of **6** should be in the 1C conformation or a close approximation to it by analogy with 3,6-anhydro-α,α-trehalose hexaacetate (5) and 3,6:3′,6′-dianhydro-α,α-trehalose tetraacetate (6), which had their bicyclic portions assigned this conformation on the basis of p.m.r. spectral evidence. Furthermore, the H-1 signal of **6** had J = 3 Hz, which is very close to the splitting of the H-1 signals of the bicyclic portions of the above derivatives. Examination of Büchi molecular models of **6** show that the restriction of a 3,6-anhydro group distorts the 1C conformation so that the *syn*-axial oxygen atoms on C-2 and -4 are closer than in an unstrained 1C-pyranoid ring.

FIG. 2. Compounds connected with the reaction of borate with 1,3-*syn*-hydroxyl groups.

The β-anomer of methyl 3,6-anhydro-D-glucopyranoside reacts to a greater extent with sodium diphenylborinate (Table 1). In this case p.m.r. spectral examination showed that, in contrast to the α-anomer, the H-1 signals of the free sugar had different chemical shifts. Quantitation showed that 55% and 90% of the complex was formed on addition of 1 and 3 mol equiv. of reagent, respectively. The coupling constants of H-1 of the anhydride and its complex were both 0 Hz, indicating that the dihedral angles of H-1 and -2 of each compound are similar and that the conformation of the anhydride is close to that of its complex, which can only exist in a slightly distorted 1C form. Moreover, the other possibility, that a conformation of the anhydride is a skew-boat form is precluded since the dihedral angle of H-1 and -2 would approach 180°. This would give rise to a large H-1 coupling constant since values of 8–11 Hz are obtained when two vicinal hydrogen atoms on a six-membered ring are *trans* (7). As noted above β-anomer complexes to a higher extent than the α-anomer. This is probably due to non-bonded interactions in the latter between one of the phenyl groups on the borinate ring (in a chair form) and the equatorial OCH_3-1 group.

In a related anhydride, 1,6-anhydro-β-D-glucopyranose (**7**, Fig. 2), c.m.r. spectral examination showed that it does not form a diphenylborinate complex. This is perhaps not surprising since X-ray crystal-structure analysis showed that the *syn*-axial oxygen atoms on C-2 and -4 are separated by 3.30 Å whereas in an unstrained pyranoid system they would be ~2.5 Å apart (8). Although Garegg and Lindström (2) suggested that this type of complexing is possible in *epi*-inositol, which is unstrained and contains 1,3-diaxial hydroxyl groups, the p.m.r. spectrum of the mixed diphenylborinates could not be completely rationalized. It would be of interest to investigate compounds such as this, which can only form complexes between the 1,3-diaxial

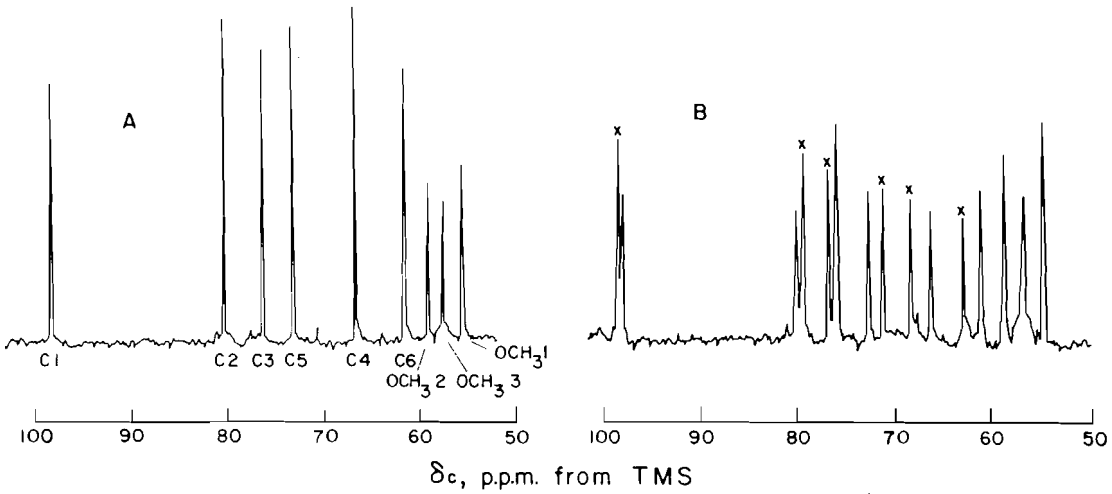

FIG. 3. C.m.r. spectra of methyl 2,3-di-*O*-methyl α-D-mannopyranoside (A) and the equilibrium mixture formed on addition of 3 mol equiv. of sodium diphenylborinate (B) (the new signals of the complex are marked with a cross).

hydroxyl groups. Related compounds, as represented by the 2,4-benzeneboronate of methyl α-D-xylopyranoside (9) and *N*-(*p*-bromophenyl)-α-D-ribopyranosylamine (10), have been prepared, but under kinetically controlled conditions.

The experiments with the anhydrides were parallelled using sodium tetraborate as reagent. C.m.r. spectroscopy showed that whereas the α- and β-anomers[3] of methyl 3,6-anhydro-D-glucopyranoside complex readily, 1,6-anhydro-β-D-glucopyranose does not. On addition of 0.25 mol equiv. of sodium tetraborate (0.5 mol equiv. of "available borate") to methyl 3,6-anhydro-α-D-glucopyranose in D_2O the c.m.r. spectrum showed that approximately 50% of the sugar did not react whereas when the amount of reagent was increased to 0.5 mol equiv. unchanged sugar could not be detected (Table 1). This is suggestive of formation of a type II complex (Fig. 1) in which the ratio of sugar to boron is 1:1. This contrasts with the reaction of tetraborate with methyl 3,6-anhydro-β-D-glucopyranoside since the sugar reacted completely after addition of 0.25 mol equiv. of reagent (Table 1) thus indicating formation of a type III spirane complex (Fig. 1). The c.m.r. spectrum was not altered on addition of a further 0.25 mol equiv. of sodium tetraborate. The difference between the type of borate complex formed suggests that the distance between the *syn*-O-2 and -4 atoms in the α-anomer differs from that of the β-anomer, and that the conformations of the 1C rings are therefore somewhat different.

In a previous publication (*1*) it was shown by c.m.r. spectroscopy that 2,4-di-*O*-methyl-D-mannose reacts in D_2O with sodium tetraborate to form a borate and a tridentate structure involving O-1, -3, and -6 (**8**, Fig. 2) was proposed. In order to show whether O-6 had a role in complex formation the action of sodium tetraborate and diphenylborinate on 2,4-di-*O*-methyl-α,β-L-rhamnose was determined. Participation was demonstrated since c.m.r. and p.m.r. spectroscopy showed that no reaction occurred with OH-1 and -3 alone in the $1C_\beta$ form (**9**, Fig. 2).

Certain polyhydroxy compounds have a stereochemistry suitable for formation of more than one diphenylborinate complex and c.m.r. spectroscopy can be used for analysis of the mixtures. For example, the c.m.r. spectrum of glycerol in D_2O (Fig. 4, spectrum C) is modified on addition of 3 mol equiv. of sodium diphenylborinate to spectrum F (Fig. 3), which can be rationalized in terms of complexes with five- and six-membered rings. The more prominent features of spectrum F are a broad complex signal centered on δ_C 65.4 and a sharp signal at δ_C 74.2, the latter being assigned to C-2 since it was absent from the c.m.r. spectrum of a solution of DL-glycerol-2-*d* containing diphenylborinate in D_2O. The signal was shown to arise from C-2 of a glycerol 1,2-diphenylborinate anion by consideration of the spectra obtained from 1-*O*-

[3]Electrophoretic mobility of the borate complex of the β-anomer was noted by Theander (34).

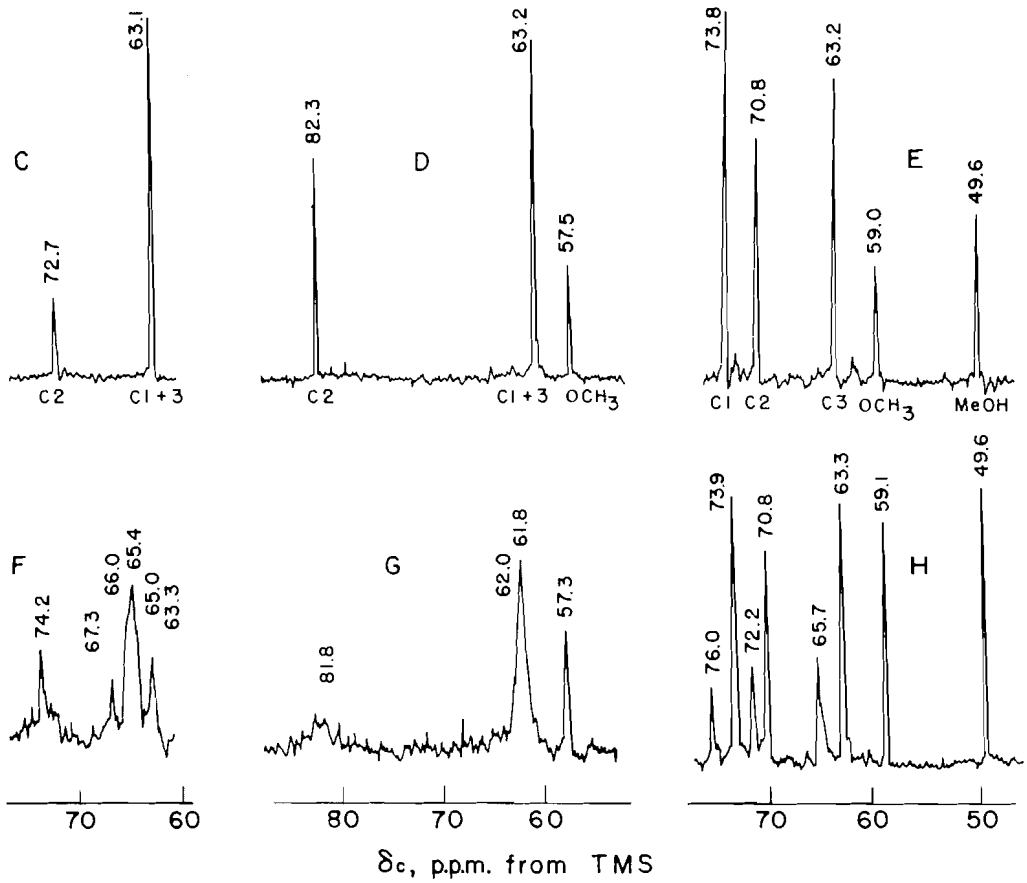

FIG. 4. C.m.r. spectra of glycerol (C) (with 3 mol/mol of sodium diphenylborinate (F)), 2-*O*-methylglycerol (D) (with 1 mol/mol of sodium diphenylborinate (G)), and 1-*O*-methyl-D-glycerol (E) (with 1 mol/mol of sodium diphenylborinate).

methyl-D-glycerol. The spectrum of the polyol contains c.m.r. signals (Fig. 4, spectrum E) which can be assigned as δ_C 73.8 (C-1), δ_C 70.8 (C-2), δ_C 63.2 (C-3), δ_C 59.0 (OCH_3) by taking into account the downfield shift of a CHOH group of a compound when it is converted to a $CHOCH_3$ group (11). Following addition of 1 mol equiv. of sodium diphenylborinate the signals of C-1, -3, and -2 apparently undergo downfield displacements of 2.1, 2.4, and 1.4 p.p.m., respectively (Fig. 4, spectrum H), the last value being close to that of 1.5 p.p.m.observed for the downfield shift of the C-2 signal of glycerol on complexing (Fig. 4; compare spectra C and F). The remaining broad signal centered at δ_C 65.4 (Fig. 4, spectrum F) of the glycerol–diphenylborinate system can be assigned to a 1,3-complex by comparison with the c.m.r. spectrum of the 1,3-diphenylborinate complex of 2-*O*-methylglycerol in D_2O. When an equivalent proportion of reagent was added the C-1 + C-3 signal in spectrum D (Fig. 4) was broadened and shifted downfield by about 1.6 p.p.m. and the C-2 signal was broadened to a line width of 2.8 p.p.m. (Fig. 4, spectrum G). This likely is due to a time averaging effect caused by rapid interconversion of conformers **4** and **5** (Fig. 1). The c.m.r. spectra D and G show that in the 2-*O*-methylglycerol system the equilibrium greatly favors the phenylborinate complex, whereas in the 1-*O*-methylglycerol system the complex is the minor component. This suggests that the diphenylborinate complexes of glycerol are mainly in the six-membered ring form.

Although 1,2-*O*-isopropylidene-α-D-glucofuranose should be able to form two diphenylborinate complexes, it was found that on addition of excess sodium diphenylborinate the c.m.r. spectrum contained only nine signals, which corresponded to formation of only one complex. The

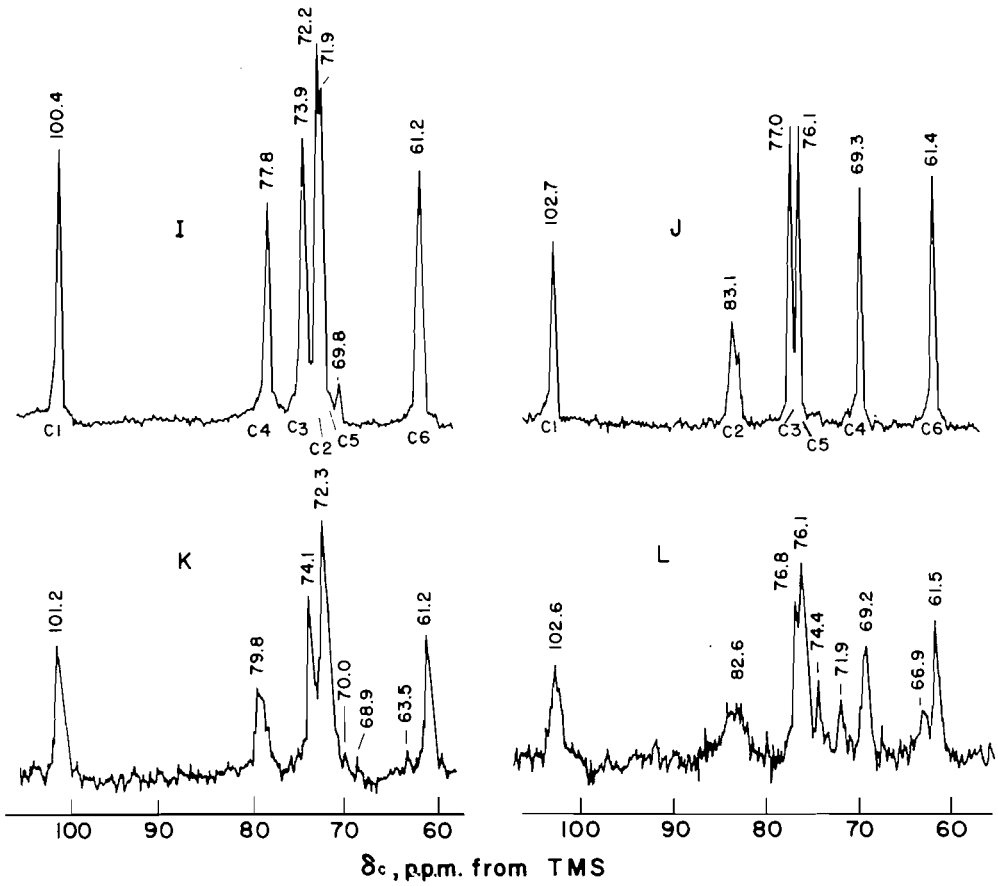

FIG. 5. C.m.r. spectra of soluble potato starch (I) (with 1 mol/mol of sodium diphenylborinate (K)) and a (1→2)-linked β-D-glucopyranan (J) (with mol equiv. of sodium diphenylborinate (L)). The minor signal in *I* is absent in the spectrum of amylose.

equilibrium was on the side of the complex since the new signals greatly predominated in the spectrum following addition of 1 mol equiv. of reagent. In order to determine whether a 5,6- or 3,5-complex was formed the degree of complexing of model compounds was determined following addition of 1 mol equiv. of reagent. Unfortunately 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose on one hand and the 6-*O*-methyl and 6-*O*-isopropyl derivatives of 1,2-*O*-isopropylidene-α-D-glucofuranose on the other, complexed to approximately the same degree and an assignment could not be made (Table 1).

C.m.r. spectroscopy of the borate complexes of polysaccharides is impractical by virtue of the general line broadening phenomenon described above and elsewhere (1) and the ability of borate to form intermolecular complexes which are highly viscous in solution. As sodium diphenylborinate should not give rise to either of these effects a number of polysaccharides of known chemical structure were tested.

The spectral properties of potato starch, which contains mainly (1→4)-linked α-D-glucopyranose units and only relatively few non-reducing end-units that can complex with diphenylborinate, were compared with those of a (1→2)-linked β-D-glucopyranan from *Arthrobacter radiobacter* (12), in which each unit has the potential to complex at the 4 and 6 hydroxyls. After 1 mol equiv. of the reagent was added to potato starch in D_2O, all the signals in the c.m.r. spectrum were broadened, likely due to the presence of sodium ion, and two new very small signals at δ_C 68.9 and δ_C 63.5 appeared. Since two new signals with similar chemical shift appeared when diphenylborinate was added to methyl α-D-glucopyranoside it would appear that they form on a non-reducing end-unit carbon (Table 1; Fig. 5; spectra I and K). On addition of sodium di-

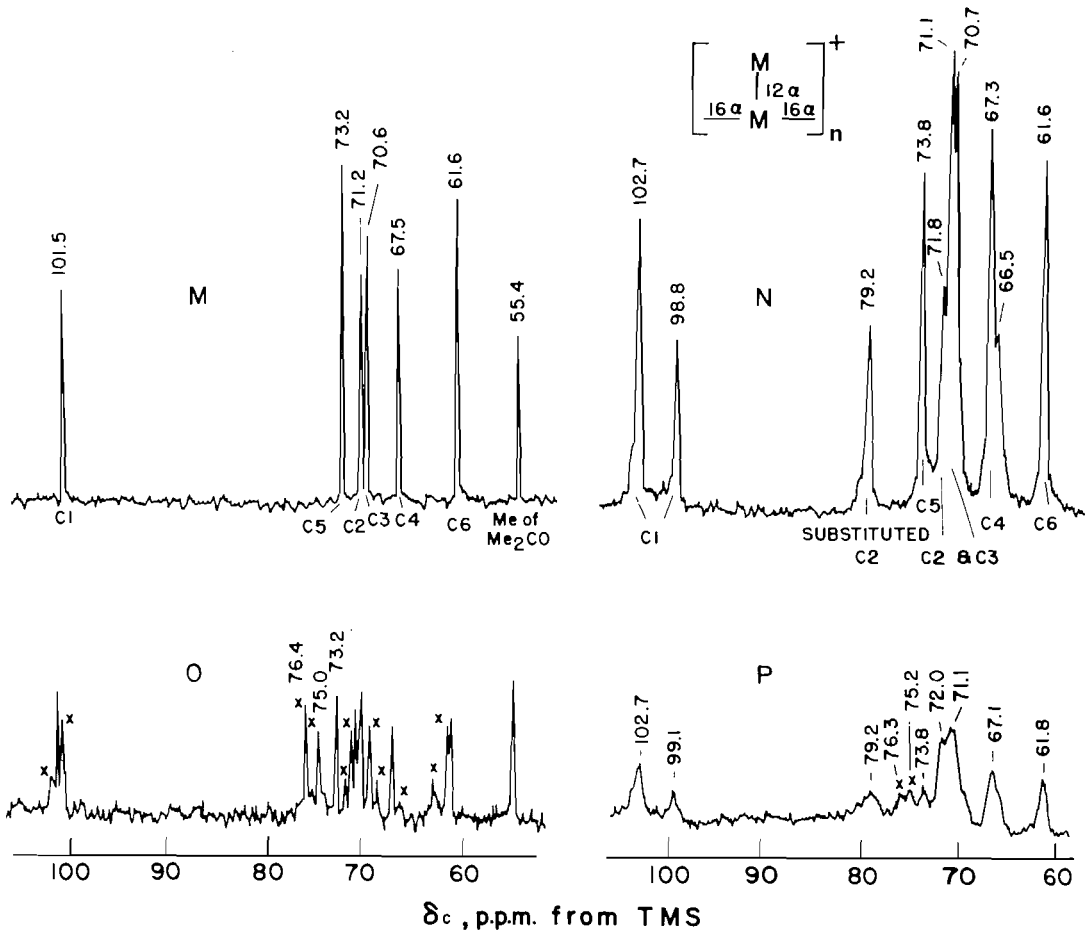

FIG. 6. C.m.r. spectra of methyl-α-D-mannopyranoside (M) and mannan from *E. fibuliger* (N) and those obtained on addition of 1 mol equiv. of sodium diphenylborinate (O and P, respectively) (+structure of mannan; ×signals of complexes).

phenylborinate to a D_2O solution of the (1→2)-linked β-D-glucopyranan the c.m.r. spectrum became less well-resolved and several new signals were formed. In this case two new signals at δ_C 66.9 and δ_C 71.9 appeared, which compares with signals at δ_C 63.1 and δ_C 71.6 in the c.m.r. spectrum of the diphenylborinate of methyl β-D-glucopyranoside. The signal of the glucan diphenylborinate at δ_C 82.6 is much broader than the others.[4] It should arise from C-2 because of its proximity to C-2 in the glucan, which was assigned by its downfield displacement (13) from the C-2 region of β-D-glucose (11). Apparently its resonance is more sensitive to whether the substituted unit contains a diphenylborinate group and whether the glucosyl group at C-2 is diphenylborinated or not.

Interpretation of the c.m.r. spectra of the diphenylborinate derivatives of more complex polysaccharides is more difficult since they contain a larger number of relatively broad signals. However, certain c.m.r. spectra could be partly rationalized. For example, the mannan from *Endomycopsis fibuliger* consists of a (1→6)-linked α-D-mannopyranose main chain with each unit substituted in the 2-position predominantly with single α-D-mannopyranose units (14; see insert in spectrum N, Fig. 6). After addition of 1 mol equiv. of diphenylborinate the c.m.r.

[4]The line widths of the signals of the polysaccharides were broad (20 Hz) compared with those of monosaccharides (5–7 Hz). Even those of starch, which was not complexed to any degree, broadened to about 30 Hz on addition of sodium diphenylborinate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

spectrum developed two new signals at δ_C 76.3 and δ_C 75.2. These could arise from C-2 and -3 of a non-reducing end-unit substituted in the 2- and 3-positions by diphenylborinate, since on complexing the c.m.r. spectrum of methyl α-D-mannopyranoside contained new signals at δ_C 76.4 and δ_C 75.0. When a similar approach was used on the mannans from *Saccharomyces rouxii* (15, 16) and *Saccharomyces cerevisiae* (17), which contain longer side-chains and therefore a lower proportion of non-reducing end-units, comparable new signals of a relatively smaller magnitude were detected. These mannans have (1→6)-linked α-D-mannopyranose main chains with the units substituted in the 2-positions. The mannan from *S. rouxii* contains mainly *O*-α-D-mannopyranosyl-(1→2)-*O*-α-D-mannopyranosyl side-chains and the one from *S. cerevisiae* contains a high proportion of *O*-α-D-mannopyranosyl-(1→3)-*O*-α-D-mannopyranosyl-(1→2)-*O*-α-D-mannopyranosyl side-chains.

Experimental

Carbon-13 Magnetic Resonance Spectroscopy

C.m.r. spectra were obtained using a Varian XL-100-15 n.m.r. spectrometer with Fourier transform on approximately 1 mmol of carbohydrate in deuterium oxide (2 ml) at 27° contained in a n.m.r. tube (12 mm diameter) incorporating a Teflon plug which prevented vortex formation on spinning. Under these conditions approximately 5000 transients were used. The spectra incorporated 4096 data points when a sweep width of 5000 Hz (198.4 p.p.m.) was used. Quantitative estimation of complexing was carried out by comparison of the size of a given signal with that of the methyl resonance of methanol, used as internal standard. The sweep width was then 2500 Hz (94.2 p.p.m.) and the number of transients correspondingly greater. In the former runs the acquisition time was 0.4 s, the pulse width 50 μs, and the maximum decoupling power (10 W) was used, and was centered on 500 Hz downfield from the ^1H resonance of TMS, corresponding to the approximate center of the p.m.r. spectra. The hetero-noise bandwidth was 2000 Hz.

Chemical shifts are in p.p.m., the term δ_C describing the downfield difference of the signal resonance and that of external TMS contained in a coaxial capillary. Under these conditions the methyl signal of methanol is at δ_C 49.5.

Diphenylborinic acid was prepared by the method of Coates and Livingstone (18) from the ethanolamine complex of diphenylboric acid (supplied by Aldrich Chemical Company) and converted to its sodium salt by the procedure of Garegg and Lindström (2). Starting from the complex (5 g) an aqueous solution (20 ml) of the acid was prepared and adjusted to p*H* 10 with aqueous sodium hydroxide. The solution was evaporated, weighed, and then made up to 20 ml in deuterium oxide. In each experiment involving c.m.r. spectroscopy of sugars and their diphenylborinates 1 mmol of polyhydroxy compound was dissolved in deuterium oxide (2 ml) and immediately after preparation of the spectrum 1 mol equiv. of sodium diphenylborinate in deuterium oxide (1.1 ml) was added, the spectra determined, and then a third spectrum was obtained following addition of a further 2 mol equiv. of reagent in deuterium oxide (2.2 ml). The percentage of complexing was estimated by comparing the size of unchanged material with the CH_3 resonance of methanol.

The compounds tested for diphenylborinate complex formation are as follows: 1,2:5,6-di-*O*-isopropylidene-D-mannitol (19), methyl 4,6-di-*O*-methyl-α-D-mannopyranoside (20), methyl 2,3-di-*O*-methyl-α-D-mannopyranoside (21), 1,4,5,6-tetra-*O*-methyl-*myo*-inositol (22), 1,2:3,4-di-*O*-isopropylidene-L-*chiro*-inositol (23), 1,2-*O*-isopropylidene-α-D-glucofuranose (24), 6-*O*-isopropyl-1,2-*O*-isopropylidene-α-D-glucofuranose (25), 1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (26), 2-*O*-methylglycerol (27), methyl 3,6-anhydro-α-D-glucopyranoside (28), *S. cerevisiae* mannan (17), *S. rouxii* mannan (15, 16), *E. fibuliger* mannan (14), *A. radiobacter* glucan (12), glycerol (Nichols Chemical Co.), methyl α-D-glucopyranoside (Calbiochem), methyl α-D-mannopyranoside (Sigma Chemical Co.), soluble potato starch (Fischer Scientific Co.), *cis*-cyclohexane-1,2-diol (K. and K. Laboratories Inc.), ethylene glycol (Fischer Scientific Co.), and *myo*-inositol (H. M. Chemical Co.).

1-*O*-Methyl-D-glycerol was prepared by methylation of 1,2-*O*-isopropylidene-L-glycerol (29) with silver oxide – methyl iodide followed by hydrolysis of the product with 80% acetic acid at 100°.

Glycerol-2-*d* was obtained by the reduction of dihydroxyacetone with sodium borodeuteride in deuterium oxide.

1,2-*O*-isopropylidene-6-*O*-methyl-α-D-glucofuranose was obtained by methylation of 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-glucofuranose (30) with silver oxide – methyl iodide followed by removal of the *O*-benzylidene group with 80% acetic acid at 35° for 18 h.

Proton Magnetic Resonance Spectroscopy

The p.m.r. spectra of compounds were obtained using an XL-100-15 Varian n.m.r. spectrometer on a continuous wave mode on the same D_2O solutions as used above. The temperature was 27° and chemical shifts are expressed in δ (p.p.m.) based on the CH_3 resonance of tetramethylsilane contained in a coaxial capillary.

The p.m.r. (and c.m.r.) spectra of 1,6-anhydro-β-D-glucopyranose (31) and 2,4-di-*O*-methyl-L-rhamnose (32) were not changed on addition of sodium tetraborate in one series of experiments and sodium diphenylborinate in another. The percentage of complex formed on addition of sodium diphenylborinate to methyl 3,6-anhydro-β-D-glucopyranoside (33) was measured by comparison of the size of the H-1 signal of the sugar at δ 5.30 (J = 0 Hz) with that of H-1 of the complex at δ 5.37 (J = 0 Hz). The H-1 signal of methyl 3,6-anhydro-α-D-glucopyranoside was at δ 5.47 (J = 3 Hz) and was indistinguishable from that of its diphenylborinate.

The Synthesis of (±)-Cordrastine. A New Route to the Phthalideisoquinoline System

V. SMULA, N. E. CUNDASAWMY, H. L. HOLLAND, AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received April 27, 1973

The phthalideisoquinoline system has been synthesized from substituted 2-phenyl-1,3-indandiones as starting materials. The key step in the synthesis is the rearrangement of the spirobenzylisoquinoline ring system to the phthalideisoquinoline system. The diastereomeric cordrastines, I and II, have been synthesized by this method and their relative configurations have been established by comparison of their p.m.r. spectra with those of phthalideisoquinoline alkaloids of known configuration.

Le système phtalideisoquinoléine a été synthétisé à partir des phényl-2 indanediones-1,3 substituées comme composés de départ. L'étape clé dans la synthèse correspond au réarrangement du système cyclique spirobenzylisoquinoléine en système phtalidéisoquinoléine. Les cordrastines diastéréoisomères I et II ont été synthétisées par cette méthode et leurs configurations relatives établies par comparaison des spectres r.m.n. avec ceux d'alcaloides phtalideisoquinoléine de configuration connue.
[Traduit par le journal]

Can. J. Chem., **51**, 3287 (1973)

The alkaloid cordrastine, a member of the phthalideisoquinoline group, was isolated by Manske in 1936 from *Corydalis aurea* Willd (1, 2). It was originally assigned its structure on the basis of an exceptionally good correspondence of the analytical figures with the formula $C_{18}H_{13}NO_2(OCH_3)_4$ and similarities in chemical behavior between it and the known phthalideisoquinoline alkaloid, hydrastine. A synthesis of cordrastine, reported in 1950 by Haworth and Pinder (3), yielded two racemic modifications of the alkaloid, designated cordrastine I and cordrastine II. Their synthetic route, outlined in Scheme 1, involved the cyclization of a substituted phenylethylamide of a phthalidecarboxylic acid followed by reduction of the intermediate dehydrophthalideisoquinoline (Scheme 1). This method was also used to synthesize hydrastine.

Earlier syntheses of phthalideisoquinoline alkaloids, such as that of narcotine (4, 5), hydrastine (6), bicuculline (7), and adlumine (7) have all involved the condensation of a substituted 7-nitrophthalide with a 1-hydroxytetrahydroisoquinoline as shown in Scheme 2. In the absence of the activating nitro group, condensations between hemiaminals of the type shown and a dialkoxyphthalide gave only poor yields of phthalideisoquinolines (4). This synthetic method suffers both from the lack of readily available starting materials and from the formation of side products arising from coupling

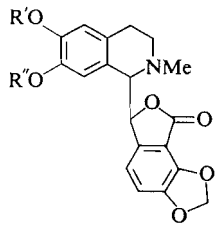
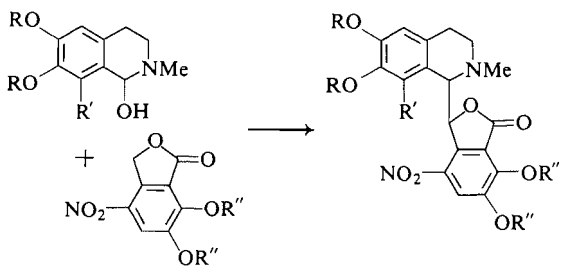
Hydrastine, R = H



Bicuculline, R′ + R″ = CH_2
Adlumine R′ = R″ = OMe

of the two benzene rings in the steps required for the removal of the nitro group. The synthetic route of Haworth and Pinder mentioned above, although it is potentially one of general applicability, has not been extended beyond the preparation of cordrastine and hydrastine. We report here a new approach to the phthalideisoquinoline system, exemplified by a synthesis of the diastereomers, cordrastine I and cordrastine II, which is outlined in Scheme 3.

The key step in our synthesis, the rearrangement of a spirobenzylisoquinoline to a phthalideisoquinoline, is shown in Scheme 4. In a previous publication (8), the preparation of 2-acetyl-6,7-dimethoxy-1,2-dihydroisoquinoline-1-spiro-2′-(1′,3′-indandione) (**10**) as an intermediate in a model synthesis of (±)-ochrobirine was described.



SCHEME 2

It has been found that the spirobenzylisoquinoline **10**, if treated under vigorous conditions with 6 *M* HCl in aqueous ethanol, rearranges to the phthalideisoquinoline **11** in high yield.

The i.r. spectrum of **10** shows absorption in the carbonyl region at 1715 and 1750 cm^{-1} typical of 1,3-indandiones reported in this and a previous paper (8); it also shows amide absorption at 1642 cm^{-1}. In the i.r. spectrum of **11** the absorptions attributed to the indandione system and the amide have disappeared but a new absorption at 1772 cm^{-1} typical of a γ-lactone is present. The aromatic region of the p.m.r. spectra of **10** and **11** is complex but the p.m.r. spectra reported for **5**, **6**, and **7** below are easily interpreted and are in accord with rearrangement of the spirobenzyl- to the phthalideisoquinoline system.

To evaluate the usefulness of this approach in the synthesis of the phthalideisoquinoline alkaloids, the spirobenzylisoquinoline **5**, in which both benzene rings carry two methoxyl substituents, was prepared by a method directly analogous to that used for the preparation of **10** (8). The reactions leading to spirobenzylisoquinolines such as **5** and **10** have been discussed fully (8) and the synthesis of **5** through the sequence **1** → **2** → **3** → **4** → **5** outlined in Scheme 3 presents no novel features.

Treatment of **5** with 6 *M* HCl in aqueous ethanol at the reflux temperature led, as expected, to the phthalideisoquinolines **6** and **7**. This reaction is thought to proceed by the mechanism outlined in Scheme 5, in which the ammonium salt formed by hydrolysis of the acetamide suffers attack by water at one of the carbonyl groups. Ring opening of the indanedione system then gives an intermediate which, in the presence of acid, cyclizes to the phthalideisoquinoline system. Attack occurs either at C-1′ or -3′ leading to an approximately equimolar mixture of two phthalideisoquinolines, one with the methoxy groups at C-4′ and -5′ (**6**) and the other with the methoxy substituents at C-6′ and -7′ (**7**). For the sake of clarity only the steps leading to the desired product **6** have been shown in Scheme 5. The driving force for this rearrangement is apparently the formation of the aromatic system. It is noteworthy that analogous tetrahydroisoquinolines (8) do not rearrange under similar reaction conditions.

The spectral properties of **6** and **7** agree with the structure assigned and are very different

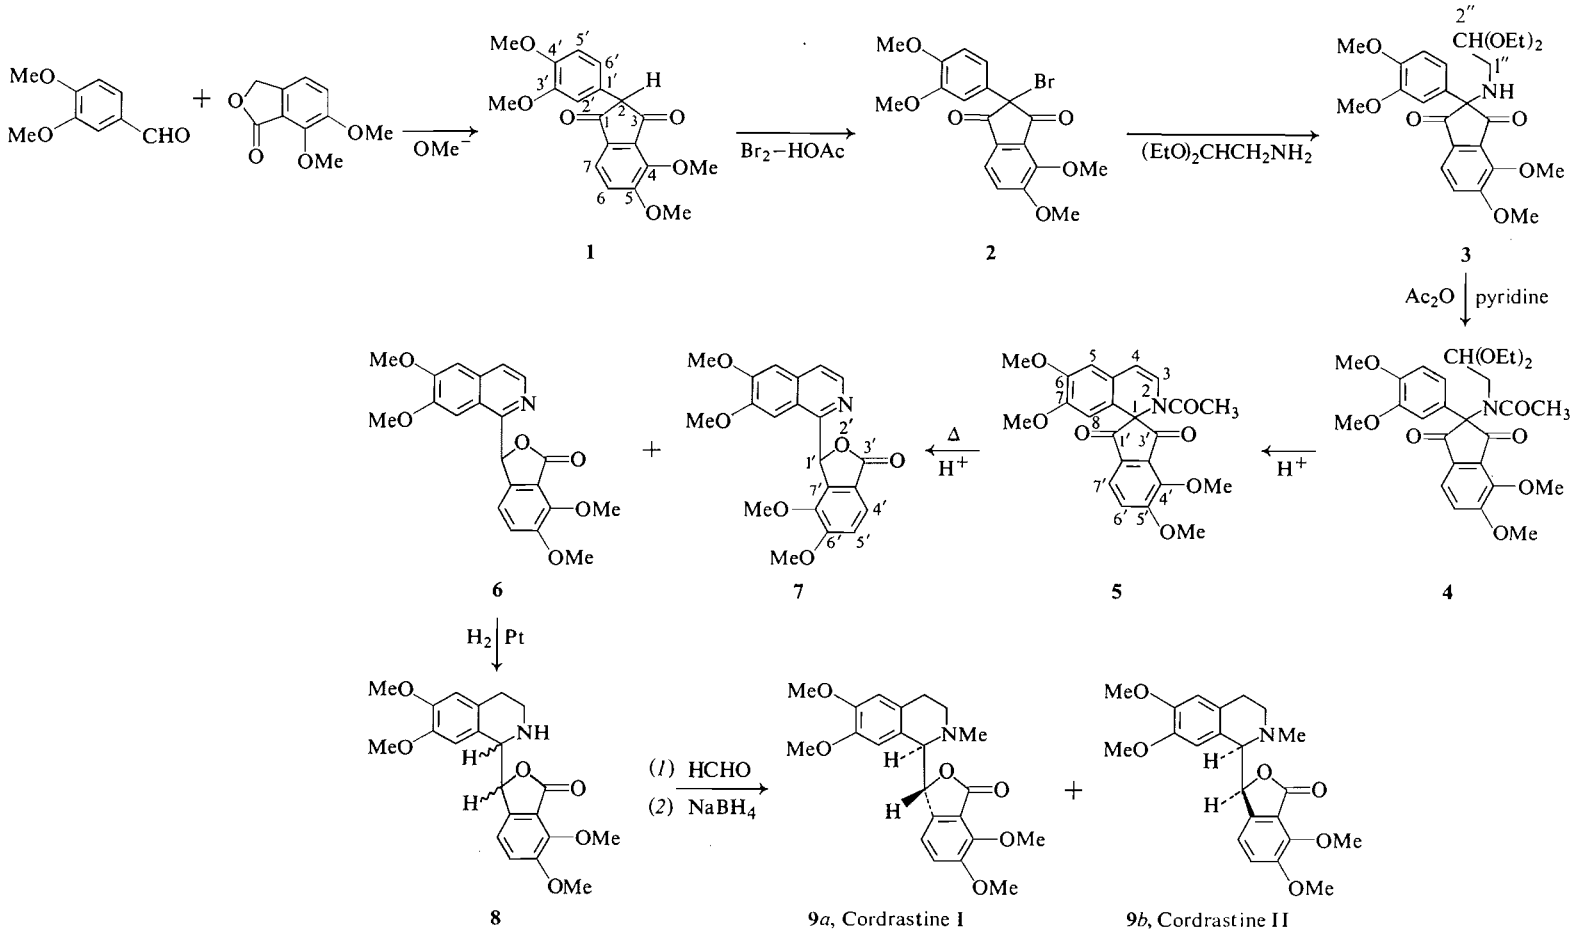
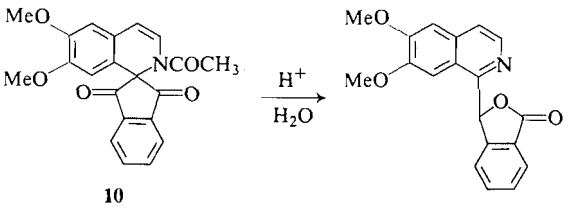


SCHEME 3



10 11

SCHEME 4

from those of **5**. Compound **5** has carbonyl absorption at 1710 and 1745 cm^{-1} typical of 1,3-indandione, and amide absorption at 1640 cm^{-1}. These absorptions are absent in **6** and **7** and are replaced by a single absorption in the carbonyl region at 1760 cm^{-1} in each compound. The p.m.r. spectra also agree with the structural assignment. Thus in **5** the protons of the double bond at the 3,4 position of the dihydroisoquinoline appear as an AB quartet at δ 5.65 and 6.86 whereas the same protons appear in **6** as an AB quartet at δ 7.48 and 8.33 and in **7** at δ 7.48 and 8.30. The downfield shift exhibited by this pair of protons would be expected in the transformation of the dihydroisoquinoline system of **5** to the aromatic isoquinoline system in **6** and **7**. On the other hand the AB system found for the C-6′ and -7′ protons at δ 7.45 and 7.85 in **5** has moved upfield as expected, in **6** to δ 7.02 and 7.20.

The phthalideisoquinolines **6** and **7** may be distinguished readily by their p.m.r. spectra. Thus **6** shows an AB quartet assignable to the C-6′ and -7′ protons at δ 7.02 and 7.20, whereas **7**, in which the proton at C-4′ is adjacent to the carbonyl group of the phthalide moiety, shows signals due to the C-4′ and -5′ protons as an AB quartet at δ 7.10 and 7.71. One half of the AB quartet of **7** (that due to the proton at C-4′) appears at considerably lower field than does the corresponding signal in **6** because of deshielding by the adjacent carbonyl.

Having obtained the phthalideisoquinoline **6**, it was subjected to mild hydrogenation over Adam's catalyst to yield a diastereomeric mixture of two phthalidetetrahydroisoquinolines (**8**) which was difficult to separate. Accordingly the mixture was treated directly with formaldehyde and sodium borohydride (8) to give, in good yield, a mixture of two products readily separable by preparative layer chromatography. These compounds had melting points similar to those reported for cordrastine I and II (3).

The p.m.r. spectra of the cordrastines are in accord with the structure proposed for natural cordrastine (2). Cordrastine I has absorptions at δ 4.01 (J = 3.4 Hz) and at δ 5.33 (J = 3.4 Hz) assigned to the protons at C-1 and -1′, respectively. These assignments are made by analogy with other phthalideisoquinoline alkaloids (9) and follow also from the decoupling experiments

TABLE 1. Aromatic signals of the phthalide ring of the cordrastines, adlumine, and hydrastine

	δ value			
Proton	Cordrastine I	Adlumine (9)	Cordrastine II	Hydrastine (9)
C-6′	6.90	6.87	7.06	7.09
C-7′	7.23	7.19	6.54	6.50

reported below. Irradiation at δ 4.01 collapses the doublet at δ 5.33 to a singlet and also sharpens the aromatic singlet at δ 6.62 ($w_{\frac{1}{2}}$ = 2.0 Hz before irradiation and $w_{\frac{1}{2}}$ = 1.4 Hz during irradiation) which may now be assigned to the proton at C-8. The second aromatic singlet was virtually unaffected. Irradiation at δ 5.33 collapses the doublet at δ 4.01 and also affects the low field half of the AB quartet arising from the ortho aromatic protons at C-6′ and -7′ at δ 6.90 and 7.23, respectively. Thus the signal at δ 7.23 sharpened during irradiation from $w_{\frac{1}{2}}$ = 2.0 Hz to $w_{\frac{1}{2}}$ = 1.0 Hz. Similar observations have been made in related systems (9). Assignment of the resonance at δ 6.29 to the C-5 proton was confirmed by another double irradiation experiment in which the signal at δ 6.29 sharpened from $w_{\frac{1}{2}}$ = 2.0 Hz to $w_{\frac{1}{2}}$ = 1.4 Hz when the sample was irradiated at δ 2.52, presumably at a C-4 proton.

A similar series of double irradiation experiments confirms the assignment of the p.m.r. spectrum of cordrastine II. Thus irradiation at the C-1 proton resonance at δ 4.00 collapses the C-1′ proton doublet at δ 5.54 and sharpens the signal of the C-8 proton at δ 6.19 from $w_{\frac{1}{2}}$ = 2.8 Hz to $w_{\frac{1}{2}}$ = 1.9 Hz. Irradiation of the C-1′ proton resonance at δ 5.54 collapses the C-1 proton doublet at δ 4.00 and sharpens that half of the AB quartet at δ 6.54, assigned to the C-7′ proton, from $w_{\frac{1}{2}}$ = 2.8 Hz to $w_{\frac{1}{2}}$ = 1.8 Hz. In addition, irradiation at δ 2.70 causes a sharpening of the C-5 proton resonance at δ 6.54 from $w_{\frac{1}{2}}$ = 2.0 Hz to $w_{\frac{1}{2}}$ = 1.5 Hz.

P.m.r. studies (9, 10), along with other studies using physical methods such as o.r.d. (11) have been used to establish the relative and absolute configuration at C-1 and -1′ of many of the phthalideisoquinoline alkaloids. Thus hydrastine and adlumine differ in the relative configuration at C-1 and -1′ (11) and this difference is reflected characteristically in the phthalide aromatic region of their p.m.r. spectra (9). The relevant proton absorptions, together with those of cordrastine I and cordrastine II, are listed in Table 1.

The p.m.r. data strongly suggest that cordrastine I has the same relative configuration at C-1 and -1′ as does adlumine, and is therefore represented by structure *9a* in Scheme 3. Cordrastine II ought to have the relative configuration *9b*, corresponding to that of hydrastine, and indeed a close correlation is observed between the phthalide aromatic region of the p.m.r. spectra of cordrastine II and hydrastine. The assignment of the relative configuration at C-1 and -1′ of cordrastines I and II is therefore in accord with the results of Teitel and coworkers (12).

Haworth and Pinder were unsuccessful in their attempts to achieve a resolution of cordrastine I or cordrastine II and no attempt has been made to resolve the cordrastines produced in this synthesis. The synthesis, however, does provide a new route to the phthalideisoquinoline system which requires only readily available starting materials and which should prove to be of general applicability.

Experimental

Apparatus, Methods, and Materials

Melting points were determined on a Kofler block and are uncorrected. I.r. spectra were recorded on a Beckman IR5 or a Perkin–Elmer 337 spectrophotometer in chloroform solution unless otherwise stated. The p.m.r. spectra were obtained at 100 MHz on a Varian HA100 instrument or at 60 MHz on a Varian A60, using deuteriochloform as solvent and tetramethylsilane as internal standard. Chemical shifts are reported in p.p.m. (δ) from TMS, the symbols s (singlet), d (doublet), t (triplet), q (quartet), and m (multiplet) being used in reporting the spectra. Mass spectra were routinely run on all samples using a C.E.C. 21-110B double-focusing instrument. High resolution mass spectrometry was performed by the described methods (13). Column chromatography was carried out on basic alumina (Fisher) and t.l.c. employed Merck silica gel, F-254.

The microanalyses were performed by Gygli Microanalytical Laboratory, Toronto, Ontario.

*1-(1′-Phthalide)-6,7-dimethoxyisoquinoline (**11**)*

A solution of 2-acetyl-6,7-dimethoxy-1,2-dihydro-

isoquinoline-1-spiro-2′-(1′,3′-indandione) (**10**) (8) (0.182 g, 0.0005 mol) in ethanol (12 ml, absolute) and hydrochloric acid (12 ml, 12 *M*) was heated under reflux for 12 h. The mixture was taken to dryness, water added, the solution basified with ammonia and extracted with chloroform.

The extract was washed, dried, and evaporated to give a residue which on crystallization from ether gave a sample (0.133 g, 83%) melting at 175–177°.

Anal. Calcd. for $C_{19}H_{15}NO_4$: C, 71.03; H, 4.67; N, 4.36. Found: C, 70.84; H, 4.58; N, 4.44.

I.r.: ν_{max} 1772 cm^{-1}; p.m.r.: 3.77 (3H, s, $—OCH_3$), 4.03 (3H, s, $—OCH_3$), 7.07 (1H, s, benzylic H), 7.32–8.27 (8H, m, aromatic H's).

2-(3′,4′-Dimethoxyphenyl)-4,5-dimethoxy-1,3-indandione (1)

A mixture of meconin (45 g, 0.23 mol), 3,4-dimethoxybenzaldehyde (38.6 g, 0.23 mol), and ethyl propionate (112 ml) was dissolved in a solution of sodium methoxide (37.7 g, 0.7 mol) in methanol (140 ml), and the resulting solution was heated to reflux under a nitrogen atmosphere. After 10 min the solution solidified to give a red solid which was dissolved in 1 l of water and extracted with ether. The aqueous phase was then acidified with concentrated hydrochloric acid to p*H* 2 and cooled in ice. The white solid that separated was filtered, washed with ice-water and dried at 50° to yield the crude product **1** in almost quantitative yield. Recrystallization from chloroform–methanol afforded an analytically pure sample melting at 187–189° (lit. 190–191° (14)).

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.65; H, 5.29. Found: C, 66.63; H, 5.53.

I.r.: ν_{max} 1710, 1745 cm^{-1}; p.m.r.: 3.88 (s, 6H, 2—OCH_3), 4.03 (s, 3H, $—OCH_3$), 4.13 (s, 3H, $—OCH_3$), 4.20 (s, 1H, benzylic H), 6.81 (broad s, 3H, aromatic H's), 7.44 and 7.84 (2H, ABq, J = 9.0 Hz, C-6 and C-7 H's).

2-Bromo-2-(3′,4′-dimethoxyphenyl)-4,5-dimethoxy-1,3-indandione (2)

The indandione **1** (14.9 g, 0.044 mol) was suspended in acetic acid (150 ml) and the stirred suspension treated with a solution of bromine (7 g, 0.044 mol) in acetic acid (200 ml) at room temperature under a nitrogen atmosphere. After the addition was complete (10–15 min) the solution was stirred for a further 5 min and then the solvent was removed under reduced pressure without heating above 30 °C. The green oily residue so obtained (19.4 g) was homogeneous by t.l.c. (2% methanol–chloroform, R_f 0.6) and was used directly in the next stage. Compound **2** decomposed on storage and when attempts were made to purify it.

2-(2″,2″-Diethoxyethylamino)-2-(3′,4′-dimethoxyphenyl)-4,5-dimethoxy-1,3-indandione (3)

Compound **2** prepared as above (19.4 g) was dissolved in dry ether (500 ml) and the solution stirred under nitrogen at room temperature during the addition of aminoacetaldehyde diethyl acetal (13.2 ml, 0.1 mol). Stirring was continued at room temperature for a further 40 h and then water (500 ml) was added to the solution and the mixture was transferred to a separatory funnel. The aqueous layer was discarded and the ethereal layer washed twice with further 500-ml portions of water, dried over sodium sulfate, and evaporated to yield 19.9 g of solid material. Crystallization from ether–ligroin (b.p. 110–115°) then afforded **3** (15.1 g, 72% from **1**), melting at 95–97°. Anal. Calcd. for $C_{25}H_{31}NO_8$: mol. wt. 473.2049; C, 63.40; H, 6.60; N, 2.96. Found: mol. wt. 473.2060; C, 63.40; H, 7.06; N, 2.96.

I.r.: ν_{max} 1710, 1745 cm^{-1}; p.m.r.: 1.19 (6H, t, J = 6.5 Hz, $—CH_2CH_3$), 2.33 (1H, broad s, N—H), 2.73 (2H, d, J = 6.0 Hz, $N—CH_2—$), 3.30–3.80 (4H, m, $—CH_2CH_3$), 3.84 (3H, s, $—OCH_3$), 3.90 (3H, s, $—OCH_3$), 4.01 (3H, s, $—OCH_3$), 4.22 (3H, s, $—OCH_3$), 4.65 (1H, t, J = 6.0 Hz, $—CH_2—CH(OEt)_2$), 6.74 (1H, ABd, J = 9.0 Hz, C-5′ H), 6.88 (1H, ABXq, J = 9.0, 2.1 Hz, C-6′ H), 7.18 (1H, d, J = 2.1 Hz, C-2′ H), 7.36 and 7.76 (2H, ABq, J = 8.2 Hz, C-6 and C-7 H's).

N-Acetyl-2-(2″,2″-diethoxyethylamino)-2-(3′,4′-dimethoxyphenyl)-4,5-dimethoxy-1,3-indandione (4)

A solution of the amine **3** (15.0 g, 0.032 mol) in pyridine (40 ml) and acetic anhydride (70 ml) was stirred at room temperature for 40 h. The solvent was then removed under reduced pressure and the residue dissolved in benzene and applied to a column of basic alumina. Elution from benzene to chloroform in 5% steps afforded **4** as a pale green oil (14.9 g 74%) which crystallized in contact with petroleum ether (b.p. 80–100°). Recrystallization from the same solvent gave a pale yellow product, m.p. 67–68°.

Anal. Calcd. for $C_{27}H_{33}NO_9$: C, 62.90; H, 6.45. Found: C, 63.13; H, 6.50.

I.r.: 1645 cm^{-1} (amide carbonyl), 1710, 1745 cm^{-1}; p.m.r.: 1.10 (6H, t, J = 6.5 Hz, $—OCH_2CH_3$), 2.25 (3H, s, $—NCOCH_3$), 3.20–3.70 (6H, m, methylene H's), 3.77 (3H, s, $—OCH_3$), 3.82 (3H, s, $—OCH_3$), 3.83 (3H, s, $—OCH_3$), 4.05 (3H, s, $—OCH_3$), 4.48 (1H, t, J = 6.0 Hz, $—CH_2CH(OEt)_2$), 6.81 (1H, ABd, J = 8.0 Hz, C-5′ H), 7.13 (1H, ABXq, J = 8.0, 2.1 Hz, C-6′ H), 7.17 (1H, d, J = 2.1 Hz, C-2′ H), 7.22 and 7.64 (2H, ABq, J = 8.0 Hz, C-6 and C-7 H's).

2-Acetyl-6,7-dimethoxy-1,2-dihydroisoquinoline-1-spiro-2′-(4′,5′-dimethoxy-1′,3′-indandione) (5)

A solution of the amide **4** (14 g, 0.026 mol) in ethanol (100 ml, absolute) and hydrochloric acid (100 ml, 12 *M*) was stirred at room temperature for 20 h. The mixture was then poured onto ice (300 g) and the resulting solution basified with ammonia and extracted with chloroform. The chloroform extract was dried and evaporated to give a residue (13.2 g) that was chromatographed on basic alumina. A 5% stepwise elution from benzene to chloroform yielded **5** (7.9 g) which was recrystallized from ethanol to give a sample (7.4 g, 67%) melting at 210–211°.

Anal. Calcd. for $C_{23}H_{21}NO_7$: C, 65.24; H, 5.00; N, 3.31. Found: C, 65.53; H, 5.22; N, 3.35.

I.r.: ν_{max} 1640 cm^{-1} (amide), 1710, 1745 cm^{-1}; p.m.r.: 2.21 (3H, s, $N—COCH_3$), 3.40 (3H, s, $—OCH_3$), 3.77 (3H, s, $—OCH_3$), 3.95 (3H, s, $—OCH_3$), 4.01 (3H, s, $—OCH_3$), 5.65 and 6.86 (2H, ABq, J = 8.0 Hz, C-3 and C-4 H's), 6.13 (1H, s, C-8 H), 6.68 (1H, s, C-5 H), 7.45 and 7.85 (2H, Abq, J = 8 Hz, C-6′ and C-7′ H's).

1-[1′-(4′,5′-Dimethoxyphthalide)]-6,7-dimethoxyisoquinoline (6) and 1-[1′-(6′,7′-Dimethoxyphthalide)]-6,7-dimethoxyisoquinoline (7)

A solution of the amide **5** (2.60 g, 0.006 mol) in ethanol (80 ml, absolute) and hydrochloric acid (80 ml, 12 *M*), was heated under reflux for 2 h. After cooling the solution it was diluted with water (50 ml) and extracted with dichloromethane. The aqueous portion was then basified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with ammonia and reextracted with dichloromethane and the basic extract dried and evaporated to give a residue (1.7 g) which on crystallization from ethanol gave the phthalideisoquinoline **6**. Recrystallization of crude **6** from dichloromethane – petroleum ether (60–80°) gave a sample (0.9 g, 40%) melting at 179–181° with decomposition.

Anal. Calcd. for $C_{21}H_{19}NO_6$: C, 66.13; H, 5.02; N, 3.67. Found: C, 66.08; H, 4.84; N, 3.71.

I.r.: ν_{max} 1760 cm^{-1}; p.m.r.: 3.89 (3H, s, —OCH_3), 3.92 (3H, s, —OCH_3), 3.99 (3H, s, —OCH_3), 4.14 (3H, s, —OCH_3), 6.93 (1H, s, aromatic or methine H), 7.02 and 7.20 (2H, ABq, J = 8.0 Hz, C-6′ and C-7′ H's) 7.16 (1H, s, aromatic or methine H), 7.30 (1H, s, aromatic or methine H), 7.48 and 8.33 (2H, ABq, J = 6.0 Hz, C-4 and C-3 H's).

Evaporation of the ethanolic mother liquor after the removal of **6** gave a residue (0.74 g) from which the phthalideisoquinoline 7 was isolated by crystallization from aqueous methanol. Recrystallization from the same solvent gave a sample of 7 (0.6 g, 27%) melting at 198–200° with decomposition.

Anal. Calcd. for $C_{21}H_{19}NO_6$; C, 66.13; H, 5.02; N, 3.67. Found: C, 66.17; H, 5.15; N, 3.81.

I.r.: ν_{max} 1760 cm^{-1}; p.m.r.: 3.35 (3H, s, —OCH_3), 3.92 (3H, s, —OCH_3), 3.94 (3H, s, —OCH_3), 4.00 (3H, s, —OCH_3), 7.10 and 7.71 (2H, ABq, J = 7.5 Hz, C-4′ and C-5′ H's), 7.08 (1H, s, aromatic or methine H), 7.13 (1H, s, aromatic or methine H), 7.38 (1H, s, aromatic or methine H), 7.48 and 8.30 (2H, ABq, J = 6.0 Hz, C-4 and C-3 H's).

The phthalideisoquinolines **6** and **7** were separable by t.l.c. Elution with ethyl acetate showed **6** at R_f 0.42 and **7** at R_f 0.35.

*1-[1′-(4′,5′-Dimethoxyphthalide)]-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (**8**)*

A solution of the amine **6** (0.38 g, 0.001 mol) in ethanol (25 ml, absolute) and 70% perchloric acid (0.25 ml) was hydrogenated over a platinum oxide catalyst (0.1 g) at 50 p.s.i. pressure and room temperature for 3 h. After the catalyst had been removed by filtration, evaporation of the solvent yielded a solid residue which was dissolved in dilute ammonia. This solution was extracted with dichloromethane and the extract dried over sodium sulfate and evaporated to give an oil (0.29 g) which upon examination by t.l.c. was found to consist of two components (R_f 0.5 and 0.37, with 10% methanolic chloroform). This oil was used in the next stage without further purification.

*1-[1′-(4′5′-Dimethoxyphthalide)]-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (Cordrastine, **9**)*

The amine **8** (0.2 g, 0.00052 mol), without purification, was dissolved in 37% aqueous formalin (2 ml) and the solution heated under reflux for 2 h. After this time, the solution was evaporated *in vacuo* and the resulting solid dissolved in methanol (10 ml) and the solution then cooled in an ice bath. An excess of sodium borohydride (*ca.* 0.04 g) was added cautiously to this solution, with rapid stirring, and after the addition was complete the stirring was continued for a further 15 min. The solution was then poured into water and the aqueous mixture extracted with dichloromethane. The extract was dried over sodium sulfate and evaporated to give a residue which was applied to a 2 mm preparative layer plate (Merck Silica Gel F-254). Elution with 5% methanolic chloroform afforded two major components corresponding to cordrastine I (0.096 g, 46%) and cordrastine II (0.089 g, 43%) at R_f's 0.6 and 0.3 respectively. Cordrastine I was purified by crystallization from methanol, m.p. 156–157° (lit. 155–156° (3)).

Anal. Calcd. for $C_{22}H_{25}NO_6$; C, 66.14; H, 6.31; N, 3.50. Found: C, 66.21; H, 6.50; N, 3.53.

I.r.: ν_{max} 1760 cm^{-1}; p.m.r.: 2.61 (3H, s, N—CH_3), 2.0–3.2 (4H, m, C-3 and C-4 H's), 3.67 (3H, s, —OCH_3), 3.76 (6H, s, 2—OCH_3's), 3.84 (3H, s, —OCH_3), 4.01 (1H, d, J = 3.4 Hz, C-1 H), 5.53 (1H, d, J = 3.4 Hz, C-1′ H), 6.29 (1H, s, C-5 H), 6.62 (1H, s, C-8 H), 6.90 and 7.24 (2H, ABq, J = 8.5 Hz, C-6′ and C-7′ H's, respectively).

Cordrastine II was converted into the picrate salt which was recrystallized from methanol–acetone, m.p. 208° (dec.) (lit. m.p. 202°, dec. (3)).

Anal. Calcd. for $C_{28}H_{28}N_4O_{13}$; C, 53.50; H, 4.49; N, 8.91. Found: C, 53.42; H, 4.61; N, 8.76.

Decomposition of the picrate on an alumina column by elution with methanol gave the free base, m.p. 117–118° (lit. m.p. 118–119° (3)). I.r.: ν_{max} 1755 cm^{-1}; p.m.r.: 2.54 (3H, s, N—CH_3), 2.40–3.20 (4H, m, C-3 and C-4 H's), 3.60 (3H, s, —OCH_3), 3.80 (3H, s, —OCH_3), 3.83 (3H, s, —OCH_3), 3.96 (3H, s, —OCH_3), 4.00 (1H, d, J = 3.5 Hz, C-1 H), 5.54 (1H, d, J = 3.5 Hz, C-1′ H), 6.19 (1H, s, C-8 H), 6.54 (1H, s, C-5 H), 6.54 and 7.06 (2H, ABq, J = 8.0 Hz, C-7′ and C-6′ H's respectively).

Received December 18, 1972[1]

The sterol fraction from *Scenedesmus obliquus*, grown in heavy water, has been shown by combined g.l.c. – mass spectrometry to contain $\Delta^{7,22}$-ergostadiene-3β-ol, Δ^{7}-ergostenol, chondrillasterol, and Δ^{7}-chondrillastenol. The same algae, grown in light water, contain these four sterols and, in addition, ergosterol and corbisterol.

La fraction des stérols obtenus de *Scenedesmus obliquus*, une álgue croissant dans l'eau lourde, a été analysée par la combinaison c.p.v. et spectrométrie de masse. Il est montrée que les stérols isolés sont le $\Delta^{7,22}$-ergostadiene-3β-ol, le Δ^{7}-ergostenol, le chondrillasterol et le Δ^{7}-chondrillastenol. La même algue croissant dans l'eau ordinaire contient aussi l'ergostérol et le corbistérol en plus des quatres autres stérols déjà mentionnés.

Can. J. Chem., **51**, 3294 (1973)

Introduction

The identification of the components in a mixture from a biological source is a recurring challenge to the natural products chemist. Among the recently developed methods for the characterization of compounds on the microgram scale, probably none surpasses combined gas–liquid chromatography (g.l.c.)–mass spectrometry (m.s.) in success for the analysis of multicomponent samples. The steroid field has been a particularly active area for the application of this method (1).

We now wish to report on the use of combined g.l.c.–m.s. in the identification of the sterols found in the algae *Scenedesmus obliquus* grown in both light and heavy water.

Experimental

Isolation of the Sterol Fraction

Scenedesmus obliquus algae were grown following the methods of Williams *et al.* (2) in heavy water having a deuterium content greater than 99%. The harvested cells (5 g) were placed in a 500-ml flask and saponified by refluxing for 2 h in 250 ml 2 *M* potassium hydroxide (1:1 aqueous ethanol). The resulting solution was cooled and extracted twice with an equal volume of petroleum ether (b.p. 30–60 °C). The aqueous layer containing the fatty acids was set aside. The organic layer containing the unsaponifiables was dried over sodium sulfate after two washings with water and was concentrated to a syrup at reduced pressure. The residue (410 mg) was then dissolved in 20 ml acetone–ethanol (1:1) and 500 mg of digitonin added as a 0.5% solution in the same solvent mixture. The solution was left at room temperature overnight.

The resulting digitonide was collected by filtration, washed first with a 1:1 mixture of ether–acetone and then with ether. The solid was taken up in 10 ml dimethylsulfoxide, heated on a steam bath for 10 min, cooled, and extracted four times with hexane. A white solid (42 mg) was obtained when the hexane solution was evaporated to dryness.

The light cells (5 g) obtained from *Scenedesmus obliquus* that grew in ordinary water yielded by a similar treatment 65 mg of the light sterol fraction.

G.l.c.–m.s.

Combined g.l.c.–m.s. was carried out with an LKB Model 9000 instrument. A 7 ft × 3 mm i.d. glass column was employed. It was packed with 1% SE-30 on 80–100 mesh acid-washed and silanized Gas-Chrom P. The column was operated isothermally at 250 °C with the helium carrier gas flow set at 30 ml/min. Spectrometer conditions: source temperature, 270 °C; electron energy, 70 eV; accelerating potential, 3.5 kV; trap current, 60 μA.

Trimethylsilylation was effected by dissolving the sample (~100 μg) in 100 μl bis(trimethylsilyl)acetamide (BSA) and allowing the mixture to stand at room temperature for 2 h.

Results and Discussion

The chromatograms resulting from the isothermal analysis of the light and deuterated

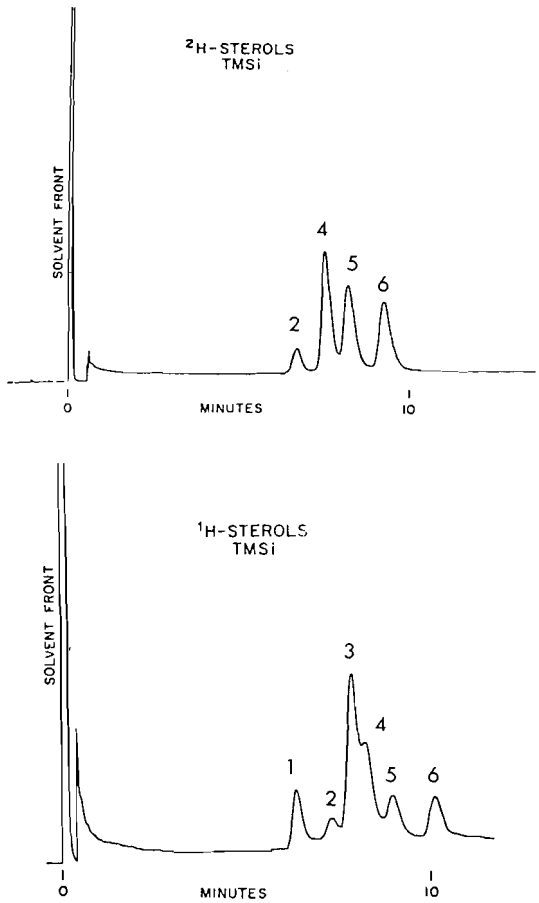

FIG. 1. Elution pattern of heavy sterols (upper chromatogram) and light sterols (lower chromatogram) as their TMSi derivatives.

sterol fractions are presented in Fig. 1. Changes in relative retention times are often observed with related hydroxy steroids which differ in the stereochemistry or position of the hydroxyl group following TMSi derivative formation. No change in relative retention time relationships was observed following trimethylsilylation of the sterol fraction, suggesting that the sterols possess similarly situated hydroxyl groups and differ in positions remote from the hydroxyl function.

It is clear from the mass spectra presented in Fig. 2 that the deuterium content of the sterols is less than that of heavy water in which the algae were grown (99%). A measure of the level of label in these sterols was obtained by comparing the weight average molecular weight (3) taken from these spectra together with that of unlabelled sterol and that calculated for 100% ^{2}H sterol, the isotope correction being made only for carbon-13. The results of this calculation are close to 96% ^{2}H and this method provides a rough but convenient measure of the extent of labelling. The more precise computation, described by Wendt and McCloskey (4), yielded values that are lower by a few percent and are reported in Table 1.

The reason for such a low deuterium content is obscure at present as the water used in growing the *Scenedesmus obliquus* was never less than 99% ^{2}H. A possible source of this apparent dilution may be the residual amount of light isotope in the cells, an amount which can be slow to disappear completely as the rate of multiplication of cells in heavy water is 2.5–3.5 times slower than the rate in ordinary water. Another source of hydrogen contamination could be an isotope effect which would tend to concentrate the lighter isotope in the cells, resulting in deuterium content somewhat lower than expected.

The mass spectra of the TMSi sterols were also obtained and the molecular ion values for these derivatives and the free sterols are reported in Table 2. The difference between the TMSi deriva-

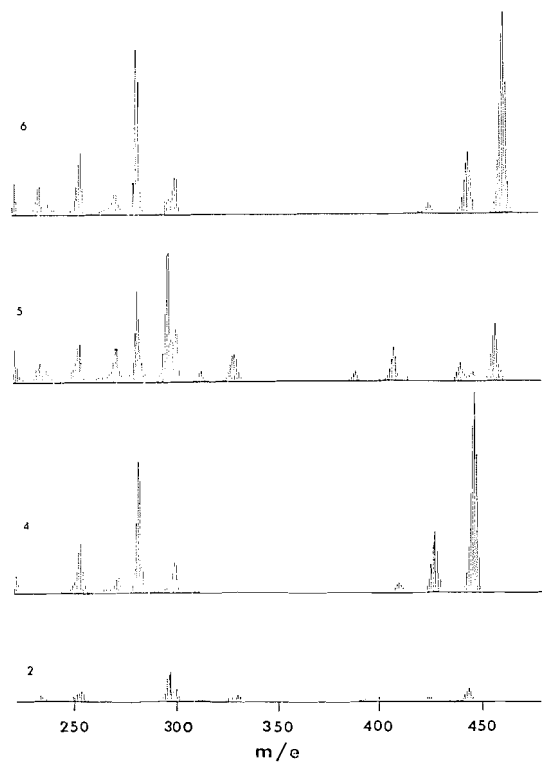

FIG. 2. Normalized mass spectra of ^{2}H-sterols.

TABLE 1. Elution time for the light and heavy TMSi sterols

Sterol	Isotope content	Retention time* Heavy	Light	Isotope effect
2	94.6	6.7	7.4	1.10
4	93.9	7.5	8.2	1.09
5	94.4	8.2	9.0	1.10
6	95.2	9.3	10.1	1.09

*Retention times are reported in minutes away from the solvent front. Isothermal —250 °C.

TABLE 2. Molecular ions and empirical formulae for deuterosterols and TMSi ethers

Sterol	Free sterols *m/e*	Empirical formula	TMSi ethers *m/e*	Empirical formula
2	443	$C_{28}D_{45}OH$	515	$C_{28}D_{45}OTMSi$
4	447	$C_{28}D_{47}OH$	519	$C_{28}D_{47}OTMSi$
5	459	$C_{29}D_{47}OH$	531	$C_{29}D_{47}OTMSi$
6	463	$C_{29}D_{49}OH$	535	$C_{29}D_{49}OTMSi$

tive and the free sterol is 72 a.m.u. in each case, the hydroxyl group being —OH rather than —O^{2}H. This is not unexpected as the isolation of the sterols is carried out in light water and ethanol. On the basis of the resulting empirical formulae, the mixture contains two C_{28} sterols (mono- and diene) and two C_{29} sterols (also mono- and diene).

Examination of the fragmentation patterns of the deuterated derivatives demonstrates the position of the double bonds. It is known from the work of Knights (5) and Brooks *et al.* (1, 6) that TMSi derivatives of Δ^5-3β-ol sterols are easily recognized in mass spectrometry by the presence of an intense (often base) peak at *m/e* 129 which corresponds to the ion $Me_3SiO^+=\!\!/\!\!-\!\!-$. There is no analogous signal at *m/e* 133 in the mass spectra of the deuterated TMSi sterols. All four spectra of Fig. 2, however, contain ions centered at *m/e* 301 and 282, which can be attributed to fragmentation typical of a Δ^7-containing 3β-ol sterol. The ions M − (side chain) and M − (side chain + HDO) are explained by a mechanism proposed by Brooks (1).

According to Knights (5) the presence of a 22:23 double bond results in intense peaks arising from loss of the side chain with the additional extrusion of two hydrogen atoms in addition to the ions M − (side chain). In Fig. 2, spectra of **2** and **5** exhibit distributions centered at 301 and also 297 a.m.u., strongly suggesting that the corresponding sterols possess a 22:23 double bond. This deuterium transfer from the nucleus does not occur with a saturated side chain, and spectra of **4** and **6** do not exhibit it. A process of this type has been postulated by Wyllie and Djerassi (7) to explain the fragment centered at 297 a.m.u., whereas the fragment around 301 is a simple side chain elimination.

Δ^7-Ergostenol (**4**), chondrillasterol (**5**), and Δ^7-chondrillastenol (**6**) have been identified in the sterol fraction from *Scenedesmus obliquus* grown in light water (8). The molecular formulae of the three sterols correspond to those of deuterated sterols **4**, **5**, and **6**, respectively (Fig. 1). Chondrillasterol would be expected to exhibit a shorter retention time with SE-30 than Δ^7-chondrillastenol, as stigmasterol ($\Delta^{22,23}$ double bond) is eluted prior to β-sitosterol (saturated side chain) (9). A possible structure for sterol **2** is $\Delta^{7,22}$-ergostadiene-3β-ol, which possesses the appropriate molecular formula, M − (side chain + D_2) fragmentation, and is eluted faster than the C_{28}-monoene. As the two C_{29} sterols differ by a $\Delta^{22,23}$ double bond, an analogous difference between the C_{28} sterols would not be surprising.

The sterol fraction from *Scenedesmus obliquus* grown in light water was also analyzed by combined g.l.c.–m.s. The chromatogram resulting from the analysis of this fraction as the TMSi ethers is presented in Fig. 1.

The mixture of light sterols appears to be composed of six compounds. Components **2**, **4**, **5**, and **6** in the light sterol fraction were found, on the basis of combined g.l.c.–m.s. data, to correspond respectively to the four components of the heavy sterol fraction. The relative amounts of the sterols were estimated from the TMSi ether peak areas and are contained in Table 3.

The molecular ion *m/e* 396 found for component **1** from light water suggested that it was a C_{28} sterol with three double bonds. Comparison of the mass spectra for this compound and its TMSi ether with those of ergosterol (free and TMSi ether) demonstrated conclusively the equivalence of these two compounds.

Sterol **3** was found to exhibit a molecular ion of *m/e* 410, indicating it to be a C_{29} sterol with three double bonds. The low mass (up to *m/e* 250) portion of the spectrum for sterol **3** is virtually identical to that of ergosterol. At higher

masses the fragmentation pattern is also very similar to that of ergosterol, but with the signals increased by 14 a.m.u. *e.g.* *m/e* 395 and 381 (M − 15), *m/e* 392 and 378 (M − 18), *m/e* 377 and 363 (M − (15 + 18)), *m/e* 351 and 337 (M − 59); this last fragment is held by Brooks *et al.* (1, 6) to be characteristic of the ergosterol nucleus, requiring that the additional methyl group in sterol **3** be placed on the side chain.

A likely candidate for sterol **3** is thus corbisterol (10), both on the basis of its fragmentation pattern and also by analogy with the C_{28} series where the three sterols are well characterized.

The retention times for the light and perdeuterated sterols are presented in Table 1. It can be readily observed that the heavy sterols are eluted faster than the analogous light sterols. This isotope effect has been reported in a large number of cases (4, 11–13) and has been discussed by Saha and Sweeley (14). It is of greater magnitude and more easily detected when the molecules under study contain a large number of hydrogen atoms.

As both the light and heavy sterol fractions were obtained from the same type of algae, the absence of two sterols in the deuterium oxide derived sample is somewhat surprising. Several possibilities can account for this absence. This difference may be attributable to the occurrence of a mutation during the growth of the organism in heavy water. It has been shown in yeast (*Saccharomyces cerevisiae*) (15) that ergosterol is produced by successive dehydrogenation with insertion of the 5:6 double bond as the final step. A second explanation for the difference in composition may be the result of an isotope effect upon this key step. The most reasonable explanation, however, is that growth of the algae in deuterium oxide is conducive to the selection of

recessive cell types not capable of producing the third double bond.

Conclusion

The sterol fraction from *Scenedesmus obliquus* grown in heavy water has been shown by combined g.l.c.–m.s. to contain $\Delta^{7,22}$-ergostadiene-3β-ol, Δ^{7}-ergostenol, chondrillasterol, and Δ^{7}-chondrillastenol. The same algae grown in light water contain these four sterols and, in addition, ergosterol and corbisterol.

Metabolites from a *Scytalidium* Species

JOHN A. FINDLAY AND DAVID KWAN

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received April 11, 1973

The structure **1**, 3,6,8-trihydroxytetralone, proposed (1) earlier for scytalone is corroborated by synthesis of an aromatization product 1,3,8-trimethoxynaphthalene. A new minor metabolite of the same *Scytalidium* species is shown to be 4,8-dihydroxytetralone (**6**).

La structure **1**, trihydroxy-3,6,8 tétralone, qui a été proposée auparavant (1) pour la scytalone est corroborée par la synthèse d'un produit d'aromatisation soit le triméthoxy-1,3,8 naphtalène. On démontre qu'un nouveau métabolite mineur de la même espèce *Scytalidium* est la dihydroxy-4,8 tétralone, **6**. [Traduit par le journal]

Can. J. Chem., 51, 3299 (1973)

Recently we proposed (1) the structure **1**, 3,6,8-trihydroxytetralone, for a new metabolite isolated from culture filtrates which had supported growth of a species of *Scytalidium*. The juxtaposition of the oxygen substituents in **1** was deduced, in part, from its transformation into tri-oxygen substituted naphthalene derivatives whose substitution patterns were determined to be 1,3,8 by analysis of n.m.r. data. One of these derivatives, namely the triacetate **2***a* (m.p. 120–123°), has been reported by Stetter and Heidel (2) to have a melting point of 111°.[1] These authors prepared their material by acetylation of the product of dehydrogenation of 1,3,8-decalintrione. This discrepancy in physical characteristic prompted us to seek synthetic corroboration of our conclusions about the oxygen substitution pattern. Accordingly we have now transformed scytalone into 1,3,8-trimethoxynaphthalene in 76% yield by treatment with dimethylsulfate and potassium carbonate in anhydrous acetone and confirmed the structure of this aromatization product by independent synthesis.

Treatment of 3-bromopropionic acid with triphenylphosphine in boiling benzene provided the corresponding triphenylphosphonium salt from which the ylid **3** was generated and condensed with commercially available 3,5-dimethoxybenzaldehyde (**4**) to furnish 4-(3′,5′-dimethoxyphenyl)-3-butenoic acid (**5**) in 60% yield. Attempts to cyclize **5** to 8-hydroxy-1,3-dimethoxynaphthalene (**2***c*) under a variety of conditions gave poor yields and it was tentatively concluded that product **5** must be largely the *trans* isomer. Since in the n.m.r. spectrum of **5** the signals for the olefinic protons are superimposed on those arising from the aromatic protons it was not possible to make any firm conclusions about *cis–trans* isomer ratios. Conversion of the cyclization product **2***c* to 1,3,8-trimethoxynaphthalene was accomplished using the same reagents employed for the trimethylation of scytalone. The product **2***b* proved to be identical in all respects with the scytalone aromatization product.

It should be noted that attempts to bring

[1]A sample (m.p. 111°) supplied later by Dr. H. Stetter proved to be non-identical with our material and appeared to be 6,8-diacetoxytetralone from spectral data.

about a substantial degree of isomerization or possible migration of the double bond in **5** by treatment with strong base were ineffective.

From the same culture filtrates which afforded scytalone we have now isolated a minor metabolite whose structure **6**, 4,8-dihydroxytetralone, was tentatively assigned on the basis of spectroscopic data and confirmed by synthesis of its racemate from juglone. The mass spectrum of this new metabolite shows a molecular ion *m/e* 178 ($C_{10}H_{10}O_3$) and a base peak at *m/e* 160 ($M^+ - H_2O$). As in the case of scytalone the presence of an orthohydroxyphenone system is indicated by the u.v. spectrum chromophore (3) and supported by i.r. data. The n.m.r. spectrum ($CDCl_3$) shows a one-proton singlet at δ 12.4 p.p.m. typical of a bonded hydroxyl proton of such orthohydroxyphenone systems (1) while the presence of a 1,2,3-trisubstituted aromatic ring is apparent from the three single proton signals centered at δ 6.9, 7.0, and 7.5 p.p.m. whose mutual couplings (*vide infra*) can only be interpreted in terms of an aromatic AMX system (4). A one-proton triplet at δ 5.9 (J = 5 Hz) is assigned to the C-4 hydrogen of **6** while a pair of two-proton multiplets centered at δ 2.2 and 2.7 p.p.m. are accounted for by the C-3 and -2 methylenes, respectively. The remaining hydroxyl proton gives rise to a broad signal centered at δ 1.9 p.p.m. Thus the features of the n.m.r. spectrum are adequately explained in terms of structure **6**.

To confirm this conclusion racemic 4,8-dihydroxytetralone was prepared by reduction of β-hydrojuglone obtained from juglone (5). The n.m.r., u.v., and solution ($CHCl_3$) i.r. spectra are identical with those recorded from the new metabolite. Minor differences in the solid state (KBr) i.r. spectra and melting point characteristics indicate that the material from the natural source occurs in optically active form. Insufficient material was available to make optical rotation measurements.

In contrast to syctalidin (6) neither scytalone nor 4,8-dihydroxytetralone proved to have significant antifungal activity against selected test organisms.

Experimental

The i.r. spectra were recorded on a Perkin-Elmer model 237B instrument. Mass spectra were obtained with an Hitachi Perkin-Elmer RMU-6D spectrometer. The u.v. spectra were determined on a Perkin-Elmer model 467 spectrophotometer. N.m.r. spectra were recorded with a Varian T-60 instrument employing tetramethylsilane as internal standard. A Kofler hot stage apparatus was employed to determine melting points which are uncorrected.

Methylation of Scytalone (1)

A mixture of scytalone (**1**) (27 mg), dimethylsulfate (0.5 ml), and anhydrous potassium carbonate (0.96 g) in dry acetone (8 ml) was refluxed for 36 h. Evaporation of acetone, dilution with water, and extraction with chloroform afforded a brown oil which was purified by preparative t.l.c. to furnish a yellowish crystalline product (20 mg, 76%): m.p. 74–76°; ν_{max} (KBr) 2930, 2830, 1620, 1580, 1450, 1410, 1385, 1350, 1290, 1250, 1215, 1200, 1155, 1125, 1100, 1040, 995, 940, 960, 845, 795, 745, 725 cm^{-1}; δ ($CDCl_3$) 3.9 (3H, s), 3.95 (6H, s), 6.4–6.8 (4H, complex multiplet), 7.2–7.4 (1H, m); λ_{max} (95% C_2H_5OH) 235, 285, 296, 320, 335 (log ε 4.69, 3.73, 3.73, 3.4, 3.6) nm; *m/e* 218 (M^+, $C_{13}H_{14}O_3$, 100%), 203 ($M - CH_3$), 189, 175, 160, 145, 130, 115.

3-Triphenylphosphonium Propanoic Acid Bromide

A mixture of triphenylphosphine (28.8 g), 3-bromopropanoic acid (15.3 g), and dry benzene (50 ml) was refluxed for 18 h. The benzene layer was decanted and the yellow oily residue was triturated with acetone affording 3-triphenylphosphonium propanoic acid bromide (33.1 g, 80%) as white crystals: m.p. 196–197°; ν_{max} ($CHCl_3$) 3100 (broad), 2940, 1740, 1590, 1480, 1440, 1385, 1320, 1110, 1000 cm^{-1}; δ ($CDCl_3$) 2.96 (2H, m), 3.8 (2H, m), 7.8 (15 H, bd) p.p.m.

4-(3′,5′-Dimethoxyphenyl)-3-butenoic Acid (5)

A mixture of 3,5-dimethoxybenzaldehyde (8.3 g) and 3-triphenylphosphonium propanoic acid bromide (20.8 g) in dimethylsulfoxide and tetrahydrofuran (50 ml each) was dropped slowly into a flask containing sodium hydride (2.4 g) at 0° under nitrogen. The mixture was stirred overnight at room temperature and then water was added and the solution washed three times with ether. The aqueous layer was acidified with dilute hydrochloric acid and extracted with three portions of ether. After washing with water and drying ($MgSO_4$) the ether was evaporated yielding a brown viscous oil (11.9 g) which was chromatographed on a silica gel column. From ether eluates the white solid (6.7 g, 60%) was recovered and recrystallized from benzene–*n*-hexane yielding compound **5**: m.p. 56–64°; ν_{max} ($CHCl_3$) 3060 (broad), 2940, 2820, 1720, 1590, 1460, 1280, 1150 cm^{-1}; δ ($CDCl_3$) 3.25 (2H, d, J = 5 Hz), 3.75 (6H, s), 6.5 (5H, m) and 11.4 (1H, s) p.p.m.; λ_{max} (95% C_2H_5OH) 227, 260, 298 (log ε 4.58, 4.35, 3.78) nm; M (mass spectrometry) 222.

6,8-Dimethoxy-1-naphthol (2c)

A mixture of 4-(3′,5′-dimethoxyphenyl)-3-butenoic acid (**5**) (0.44 g) and polyphosphoric acid (22 g) was stirred at 90–100° for 4 h. The resulting black viscous liquid was dissolved in ice cold water and extracted with chloroform. Evaporation of the chloroform layer afforded a brown paste (0.38 g) which was subjected to preparative t.l.c. White crystalline solid **5** (0.028 g, 7%) m.p. 57–63° was thus recovered: ν_{max} (KBr) 3360 (broad), 2920, 1610, 1590, 1450, 1430, 1405, 1370, 1320, 1240, 1195, 1160, 1125, 1070, 1060, 1025, 980, 935, 830, 815, 750, 710 cm^{-1}; δ ($CDCl_3$) 3.9 (3H, s), 4.0 (3H, s), 6.45 (1H, d, J = 2 Hz),

6.6–6.8 (2H, m), 7.2–7.5 (2H, m), 9.1 (1H, s) p.p.m.; λ_{max} (95% C_2H_5OH) 232, 288, 300, 323, 337.5 (log ε 4.38, 3.55, 3.55, 3.36, 3.38); *m/e* 204 ($C_{12}H_{12}O_3^+$, 100%), 189 ($M^+ - CH_3$), 175, 161.

1,3,8-Trimethoxynaphthalene (2b) from 6,8-Dimethoxy-1-naphthol (2c)

A mixture of 6,8-dimethoxy-1-naphthol (**2***c*) (30 mg), dimethylsulfate (0.5 ml), and anhydrous potassium carbonate (0.96 g) in dry acetone (8 ml) was refluxed for 16 h. Evaporation of acetone, dilution with water, and chloroform extraction afforded a brown oil (0.45 mg) which was purified by preparative t.l.c. giving crystalline 1,3,8-trimethoxynaphthalene (**2***b*) (28 mg, 92%), m.p. 74–76° identical in spectroscopic characteristics with material obtained from scytalone (**1**) and giving no melting point depression on admixture.

Isolation of 4,8-Dihydroxytetralone from Scytalidium FY Strain Culture Medium

The crude chloroform extract (0.55 g) from the culture filtrate medium which had supported growth of *Scytalidium* FY strain (2) was chromatographed on a silica gel column. The ether–benzene (1.4) eluates were combined, evaporated, and rechromatographed on a preparative t.l.c. silica gel plate developed with acetone–benzene 1:4. The metabolite (R_f 0.46) showed green phosphorescence under long u.v. light and was recovered as a yellowish white solid (12 mg) and recrystallized from *n*-hexane to furnish crystals: m.p. 70–72°; ν_{max} ($CHCl_3$) 3600, 2925, 1640, 1580, 1450, 1365, 1335, 1260, 1100, 985, 930, 890 cm^{-1}; ν_{max} (KBr) 3320, 2920, 2850, 1630, 1615, 1570, 1450, 1405, 1365, 1336, 1325, 1308, 1260, 1216, 1200, 1160, 1100, 1075, 1065, 1046, 1030, 973, 890, 845, 820, 806, 770, 746, 703, 615 cm^{-1}; λ_{max} (95% C_2H_5OH) 220, 260, 332 (log ε 4.1, 3.8, 3.5); λ_{max} (95% C_2H_5OH + OH^-) 223, 230, 263, 372 (log ε 4.2, 4.1, 3.7, 3.7); *m/e* 178 (M^+, $C_{10}H_{10}O_3$), 160 ($M - H_2O$), 150 (100%, $M - C_2H_4$); δ ($CDCl_3$) 1.9 (1H, broad, exchanges with D_2O), 2.2 (2H, m), 2.75 (2H, m), 5.9 (1H, t, J = 5 Hz), 6.9 (1H, dd, J = 8 Hz, J = 1 Hz), 7.0 (1H, bd, J = 8 Hz), 7.5 (1H, t, J = 8 Hz), 12.4 (1H, s, exchanges with D_2O) p.p.m.

Reduction of β-Hydrojuglone to 4,8-Dihydroxytetralone

A solution of β-hydrojuglone (5) (0.55 g) in dry tetrahydrofuran (10 ml) was dropped slowly into a flask containing lithium aluminum hydride (38 mg) in dry tetrahydrofuran (10 ml) immersed in a Dry Ice – acetone bath. The mixture was stirred for 7 h at −40°. Water was added and the aqueous suspension treated with dilute hydrochloric acid and extracted with ether until the aqueous layer remained clear. The green ethereal extract was washed with water, dried ($MgSO_4$), and evaporated. Purification of the crude product by preparative t.l.c. gave yellowish white crystalline **6** (0.25 g, 38%): m.p. 99–100°; ν_{max} (KBr) 3270, 2980, 2870, 1630, 1610, 1570, 1450, 1410, 1360, 1345, 1330, 1310, 1290, 1250, 1215, 1200, 1160, 1095, 1075, 1045, 1030, 982, 925, 895, 845, 815, 780, 746, 705, 610 cm^{-1}. Other spectral data are identical with those of material isolated from the natural source (*vide supra*).

The authors are grateful to Dr. G. M. Strunz, M. A. Stillwell, and M. Kakushima, Canadian Forestry Service, Fredericton, New Brunswick for providing material for this study. This work was supported in part by a grant from the National Research Council of Canada. The authors thank Dr. H. Stetter, Institut für Organische Chemie, Aachen, Germany for providing a sample for comparison purposes.

Singlet and Triplet States of Aminonitrenes: An *Ab Initio* Molecular Orbital Study[1]

N. C. BAIRD AND R. F. BARR[2]

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ontario

Received April 13, 1973

Ab initio STO-3G molecular orbital calculations are reported for the lowest singlet and the lowest triplet state of the aminonitrenes H_2NN, $CH_3(H)NN$, F(H)NN, and HCO(H)NN. The optimum geometry calculated for the H_2NN triplet is nonplanar (C_s symmetry), with N—N and N—H bond distances of 1.436 and 1.034 Å, and HNN and HNH angles both of 107.5°. The optimum singlet is predicted to be planar (C_{2v} symmetry), with N—N and N—H distances of 1.276 and 1.041 Å respectively, and an HNN angle of 124°. An analysis of the calculated geometries and electron density distributions indicates that the "idealized" representations **3** and **5** are adequate to explain the bonding in the triplet and singlet respectively. The effects of methyl, fluoro, and carbonyl substitution upon the singlet–triplet splitting and upon the charge distribution are discussed. The optimum-geometry triplet is predicted to be slightly more stable than the optimum-geometry singlet in all cases.

On présente les calculs d'orbitales moléculaires, *ab initio* STO-3G, pour l'état singulet de plus basse énergie et pour l'état triplet de plus basse énergie des aminonitrènes H_2NN, $CH_3(H)NN$, F(H)NN et HCO(H)NN. La géométrie optimum calculée pour le triplet du H_2NN est non planaire (symétrie C_s), avec des longueurs de liaison N—N et N—H égales à 1.436 et 1.034 Å et avec des angles HNN et HNH égaux tous les deux à 107.5°. On prédit que la géométrie optimum du singulet est planaire (symétrie C_{2v}) avec des longueurs de liaison N—N et N—H égales à 1.276 et 1.041 Å et avec un angle HNN égal à 124°. Une analyse des géométries calculées ainsi que des ditributions de densité électronique a montré que les représentations "idéalisées" **3** et **5** sont suffisantes pour expliquer les liaisons dans l'état triplet et dans l'état singulet respectivement. On discute des effets de la substitution par les groupes méthyle, fluoro et carbonyle sur la séparation singulet–triplet et sur la distribution des charges. On prédit que, dans tous les cas, la géométrie optimum de l'état triplet sera légèrement plus stable que la géométrie optimum de l'état singulet. [Traduit par le journal]

Introduction

The chemistry of aminonitrenes (1,1-diazenes) has received some attention recently (1), due to the synthetic utility of these species in the preparation of aziridines. A considerable amount of information concerning the reactivity of the "nitrene nitrogen" has been collected by Rees and co-workers (2, see also ref. 3) via experiments using phthalimido nitrene **1** and related compounds. In particular, these compounds are found to add stereospecifically to olefins, and this addition occurs exclusively in a 1,2-manner even at low olefin concentrations.

Yields of the aziridine **2** are found to increase if olefins substituted by electron-withdrawing groups are employed. These observations have led to the conclusion that the reacting species is a singlet, and that this singlet corresponds to the ground state of aminonitrenes. In contrast, the

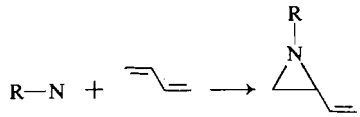
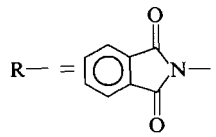
[2]Holder of NRCC Studentships, 1970–74.



1 2



ground state of most other types of nitrenes (which, unlike aminonitrene, do not possess a substituent which can stabilize the singlet state by donation of a lone pair of π electrons) is known to be a triplet (1).

Unfortunately there exists, at present, very little information from either physical measurements or accurate quantum-mechanical calculations concerning the relative stabilities, geometries, and bonding of the low-lying states of either the (unknown) parent compound H_2NN or its derivatives. Although semiempirical calculations by the CNDO/2, (4 *cf.* ref. 1) and INDO (5) methods for H_2NN have been reported recently, their reliability in this context is questionable, especially since the singlet–triplet splitting predicted (5) of more than 1 a.u. (*i.e.* >630 kcal mol^{-1}) is obviously much too large. For these reasons, we have undertaken *ab initio* calculations for H_2NN and some of its simple derivatives in order to obtain a better estimate of the relative energies of the singlet and triplet states, to find the effect of substituents on this splitting, and to determine the optimum geometry for the parent molecule.

Method of Calculation

The wave functions and energies reported herein are the result of nonempirical ("*ab initio*") calculations using the SCF–LCAO–MO theories of Roothaan (6). For the triplet states, open shell theory was employed to determine the best single-configuration energy and wave function, while for the closed shell singlet, the best single-configuration wave function was impoved by including configuration interaction with the doubly excited state corresponding to a $(\pi)^2 \rightarrow (\pi^*)^2$ excitation.

A minimal basis set of Slater-type orbitals was employed to expand the molecular orbitals; the STO exponents used were the standard molecular values suggested by Pople and co-workers (7). All integrals over STO's were expanded in terms of integrals over Gaussian-type orbitals using the STO-3G technique of Pople and co-workers (7); integrals over GTO's were evaluated using subroutines from the IBMOL package.[3] All calculations were executed on the CDC Cyber 73 computer at the University of Western Ontario.

All orbital and electron densities and overlap populations were computed from single-determinant wave functions using the Mulliken population analysis scheme.

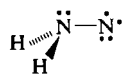
Results and Discussion

The Lowest Triplet State

Simultaneous optimization of the geometric variables for the lowest triplet state of H_2NN yields a *nonplanar*, almost tetrahedral, structure of C_s symmetry with a relatively long nitrogen–nitrogen bond:

$$R_{NN} = 1.43_6 \text{ Å} \qquad HNN = 107.5°$$
$$R_{NH} = 1.03_4 \text{ Å} \qquad HNH = 107.5°$$

The total energy of -108.5889 a.u. for this pyramidal shape is 7.6 kcal mol^{-1} more negative than for the optimum planar triplet (in which the N—N distance contracts to 1.40 Å); this inversion barrier should probably be regarded as an upper limit, given that Pople and co-workers have found that the NH_3 barrier is greatly overestimated using an STO-3G basis set (8). Both the quasi-tetrahedral shape and the Mulliken population analysis for triplet aminonitrene are consistent with the valence-bond representation



3

3. In particular, the unpaired spin is almost completely localized (96%) on the nitrene nitrogen atom, and the symmetry-allowed delocalization of the amino lone pair into the quasi-π $2p_z$ orbital of the nitrene nitrogen occurs only to the extent of 0.06*e*. Similarly, the population of 1.01*e* (Table 1) for the nitrene N $2p_y$ orbital is very close to the idealized value expected from **3**. Thus the nitrogen–nitrogen linkage in the triplet is almost exactly that of a single σ bond.

[3]The IBMOL program used was the modification by W. A. Saunders (Catholic University of America) of the original version by E. Clementi and D. R. Davis.

TABLE 1. Gross orbital populations for singlet and triplet H_2NN

Atom	Orbital[a]	Population (in *e*) Singlet	Triplet
N_{amino}	1s	1.995	1.996
	2s	1.441	1.591
	$2p_x$	1.639	1.629
	$2p_y$	1.114	1.068
	$2p_z$	1.092	1.066
	Total atomic	7.281	7.350
$N_{nitrene}$	1s	1.998	1.999
	2s	1.833	1.894
	$2p_x$	0.361	1.061
	$2p_y$	1.927	1.010
	$2p_z$	0.985	1.034
	Total atomic	7.104	6.998
H	1s	0.808	0.826

[a]The origin of the coordinate system was chosen at the amino nitrogen with the *z* axis coincident with the N—N bond, the *y* axis lying in the plane of the H_2N unit, and the *x* axis mutually perpendicular to *y* and *z*. The optimum molecular geometry for the state in question is used in both cases.

The Lowest Singlet State

The "idealized" distribution of the nonbonding and π electrons among atomic orbitals of planar aminonitrene is illustrated in Scheme 1. Since the triplet **4** correlates with the $^3(n,\pi^*)$ state of the isoelectronic molecule formaldehyde, and since the splitting between singlet and triplet (n,π^*) states in H_2CO is rather small (9), one might anticipate that the singlet state **5** in H_2NN would not lie far above the triplet. The *ab initio* calculations predict, however, that the splitting between **4** and **5** is rather large—approximately 46 and 48 kcal mol^{-1} for planar and pyramidal geometries, respectively, compared to ~13 kcal mol^{-1} calculated for H_2CO.[4] The difference between H_2NN and H_2CO is due to the fact that the "odd" π electron in H_2NN is localized heavily on the "nitrene nitrogen", and thus the nπ* exchange integral and the singlet–triplet splitting is rather substantial, whereas the corresponding odd π electron density in H_2CO is localized largely on the carbon atom, thus yielding a much smaller nπ* exchange integral and singlet–triplet split.

Thus, although the triplet **4** is predicted to correspond to the ground state of aminonitrene (*vide infra*), the most stable singlet is the closed-shell species **6** rather than the open-shell configuration **5**. Simultaneous optimization of all geometrical variables for the closed-shell configuration **6** yields a planar C_{2v} structure with a nitrogen–nitrogen bond length similar to the double-bond value of 1.25 Å predicted for diimide (10):

$$R_{NN} = 1.27_6 \text{ Å} \qquad HNN = 124°$$
$$R_{NH} = 1.04_1 \text{ Å}$$

These values are in good agreement with those in an earlier *ab initio* calculation for planar singlet H_2NN by Allen and co-workers (1.282 Å, 1.003 Å, 122° respectively) (11) and with the semiempirical CNDO/2 (4) and INDO (5) calculations. Both the short NN distance and the requirement for a planar geometry are indicative of a relatively strong coordinate π bond between the nitrogens, even though the transfer of charge from the amino lone pair to the vacant $2p_\pi$ orbital of the nitrene nitrogen amounts to only 0.36*e*. As discussed elsewhere (12), the existence of a strong coordinate π bond does *not* require near-equal sharing of the electron pair; thus, the 0.36*e* transfer here yields a π overlap population which is 73% of the maximum "covalent" value (*i.e.* the value which would be achieved if the electron pair was shared equally). The π bonding in singlet H_2NN is sufficient that the π bonding MO (predicted ionization potential 12.3 eV) is *not* the highest-occupied orbital but rather it is the second highest; the HOMO (predicted

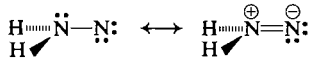
ionization potential 7.6 eV) corresponds to an in-plane orbital of *b* symmetry which is almost completely localized on the nitrene nitrogen. The energetic stability of this "nitrene lone pair orbital" is significantly lower than that in ammonia (predicted ionization potential 9.7 eV for NH_3).[4]

Overall, the polarity of the nitrogen–nitrogen multiple linkage agrees qualitatively with that anticipated from resonance between the two important valence-bond structures **7***a* and **7***b* for the singlet, since the transfer of π electron density from the amino to the nitrene nitrogen exceeds the back transfer of σ electron density in the opposite direction.



7a *7b*

The *overall* charge distribution (Fig. 1) is in *apparent* disagreement with this resonance since the amino nitrogen is more negatively charged than is the nitrene nitrogen; however the high electron density at the amino N is due primarily to the polarity of the N—H bonds.

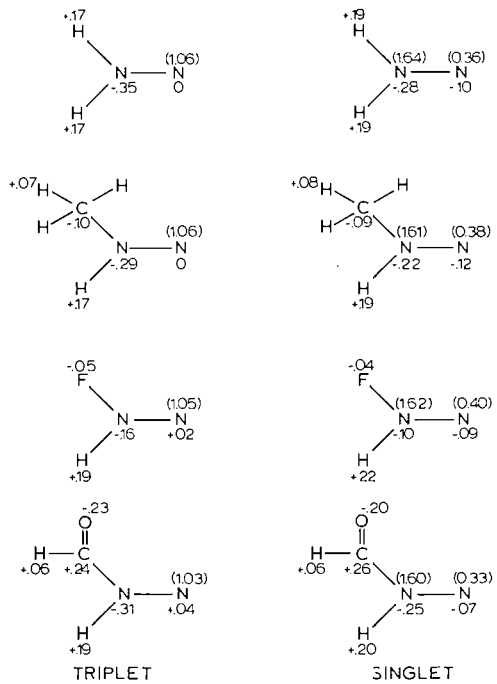


FIG. 1. Gross atom net charges (signed quantities) and selected gross π orbital populations (in parentheses) for the lowest triplet and singlet states of aminonitrenes. All quantities are in electron units.

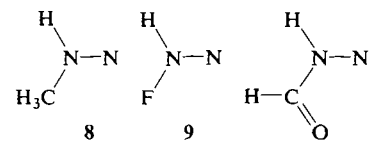
Finally, it should be noted that the total energy of −108.5470 a.u. calculated for singlet aminonitrene corresponds to a structure which is some 36.4 kcal mol^{-1} *less* stable than for the isomeric *trans*-diimide (calculated using 2 × 2 CI with the same doubly excited configurations in both cases). In contrast, the lowest *triplet* state of H_2NN is predicted to be 46.2 kcal mol^{-1} more stable than is the lowest (twisted) triplet of diimide (10).

Aminonitrene Derivatives

Ab initio calculations for the monomethyl (**8**), monofluoro (**9**), and monocarbonyl (**10**) derivatives of aminonitrene were carried out for both singlet and triplet states. In all cases, nitrogen–nitrogen bond lengths and amino nitrogen bond angles which are optimum for H_2NN were assumed in the derivatives. All remaining distances and angles in **10** were assumed equal to the experimental values established for formamide (13).



8 **9** **10**

The N—C and N—F distances of 1.47 and 1.37 Å respectively assumed in **8** and **9** were taken by analogy with $(CH_3)_3N$ and N_2F_4 (14); C—H distances of 1.089 Å and exactly tetrahedral HCH angles were assumed for the methyl group.

Gross atomic partial charges and selected gross π orbital populations for these derivatives are compared to those for the parent aminonitrene in Fig. 1. Note that the overall effect of each substituent considered, including methyl, is to withdraw electron density from the HNN framework relative to the values for singlet and triplet H_2NN.

The net charge of the nitrene nitrogen is approximately −0.1*e* in the parent aminonitrene singlet and in all the singlet derivatives considered. Although this amounts to less than half the negative charge predicted by semiempirical calculations, the conclusion by the authors of the latter calculations (4, 5) that the nitrene nitrogen should be nucleophilic is not altered. For both the methyl and carbonyl derivatives, the changes due to substitution in the net charges on the

TABLE 2. Calculated energies for aminonitrene triplets relative to the singlet at its optimum geometry

Geometry used for triplet	Relative energy (kcal mol^{-1})			
	H_2NN	$CH_3(H)NN$	F(H)NN	HCO(H)NN[a]
Optimum triplet geometry	−26.3	−25.7	−24.3	−28.6
Optimum singlet geometry	−5.3	−6.0	+3.3	−16.9

[a]The C=O and N=N bonds in HCO(H)NN are assumed to be *cis* with respect to each other.

nitrene nitrogen are almost entirely due to changes in the $2p_\pi$ orbital population (given in parentheses in the diagrams of Fig. 1), whereas both the σ and π orbital populations of the amino nitrogen are altered. The fluorine atom in **9** donates 0.02*e* to the NN π electron system, whereas the carbonyl group in **10** withdraws 0.07*e*; both effects agree qualitatively with intuitive expectations for such substituents. Note, however, that the sum of the π electron density associated with the two nitrogen atoms remains close to 2.0*e* in all cases.

The changes in the atomic charges due to substitution in the aminonitrene triplets closely parallel those established for the singlets. The total electron density at the amino nitrogen is about 0.07*e greater*, and that for the nitrene nitrogen is about 0.11*e less* in the triplet compared to the singlet in all cases. Note that the nitrene nitrogen is predicted to be electrically neutral in the parent compound.

Singlet–Triplet Splitting and the Ground State of Aminonitrenes

The calculated singlet–triplet splittings for each aminonitrene are listed in Table 2; all values are relative to the singlet in its optimum geometry. The calculated energy splittings are interesting in several respects. First, the singlet–triplet separation is quite low and is nowhere near the >600 kcal mol^{-1} estimate for H_2NN from INDO calculations (5). Second, the triplet at its optimum molecular geometry is predicted to be more stable than the optimum singlet, again in contrast to the semiempirical calculations. Note, however, that the separation is almost zero at the optimum singlet geometry. Third, the singlet–triplet splitting is relatively unaffected (within ±3 kcal mol^{-1} when optimum geometries are compared) by substitution.

Although we believe the present *ab initio* calculations on H_2NN to yield much more realistic energy separations than can be obtained from semiempirical calculations, previous experience with calculations of the S_0–T_1 splitting in CH_2 (15, 16) suggests that the values listed in Table 2 are somewhat too negative. In particular, the methylene triplet is predicted to be ~29 kcal mol^{-1} more stable than the singlet by STO-3G calculations using 2 × 2 CI for the singlet, whereas calculations using a much larger basis set and a much greater degree of configuration interaction lowers this value to ~12 kcal mol^{-1} (16), which agrees well with the most recent experimental determinations (17). Because CH_2 is isoelectronic with the parent nitrene NH, the "error" in the present calculations is probably in the same direction and of the same magnitude as for CH_2. One would anticipate that more refined calculations would predict that the optimum triplets for aminonitrenes are ~10 kcal mol^{-1} more stable than the optimum singlets, and that in most cases the singlet lies below the triplet *at the optimum singlet geometry*. Thus the observed chemical reactions of aminonitrenes, all of which have been interpreted as arising from a singlet ground state, may be explicable in terms of a singlet state which undergoes intersystem crossing very slowly to the ground state triplet; *i.e.* the initially formed aminonitrene becomes "trapped" in the singlet well. Obviously, more refined calculations are indicated to settle this important question.

The Effect of Refractive Index of the Medium on the Position of the Camera Lens in Schlieren Optics

L. Ivan Epstein and Percival Nixon

Department of Biophysics, Medical College of Virginia, Health Sciences Division, Virginia Commonwealth University, Richmond, Virginia 23219

AND

Alfred J. Richard

Department of Chemistry and Pharmaceutical Chemistry, Medical College of Virginia, Health Sciences Division, Virginia Commonwealth University, Richmond, Virginia 23219

Received April 9, 1973

A linear relation has been established between the plane of focus for schlieren optics in the ultracentrifuge cell along the optic axis, and the refractive index of the liquid contained in the cell. Such a relation shows that there occurs a defocussing effect when a large change in refractive index is generated in the liquid column during centrifugation of multi-component systems.

Une relation linéaire est établie entre le niveau focale pour les optiques schlieren dans la cellule de l'ultracentrifugeuse le long de l'axe optique, et de l'indice de réfraction du liquide contenue dans la cellule. Une telle relation montre qu'il existe un effet sur les optiques si l'indice de réfraction change beaucoup durant la centrifugation des liquides avec de plusieurs composants.

Can. J. Chem., **51**, 3309 (1973)

Introduction

The need has become apparent for focussing of the camera lens of schlieren and interferometric optical systems of the analytical ultracentrifuge on different levels of the centrifuge cell along the optic axis (1–6). For macromolecular solutions, the 1/2 plane, the 2/3 plane, even the 5/6 plane have been recommended, depending upon experimental conditions. Richards *et al.* (1) mentioned the need for refocussing every time a solvent of different refractive index was used. The method for focussing on any chosen plane in the cell was given clearly and in great detail. The authors showed a linear relation between the position of the camera lens of their ultracentrifuge and the position in the rotor of the ruled disk upon which the lens was focussed. The position of the ruled disk was varied by spacers placed beneath it in the rotor. This paper suggests a simple relation for choosing the plane of focus when the centrifuge cell is filled with pure liquids, rather than with solutions.

Measurements of the isothermal compressibilities of organic liquids by ultracentrifugation in the Beckman Model E ultracentrifuge have thus far been done with the camera lens of the schlieren optical system presumably focussed at the mid plane of the cell (7–9). When the calculations of Richards *et al.* (1) were applied to centrifuge cells filled with organic liquids, it was found that the camera lenses had, in fact, been focussed on various planes within the cell, depending upon the refractive indexes of the liquids studied. It would appear, however, that all compressibility experiments should be performed with the camera lens focussed on a level of the cell along the optic axis such that the emerging ray would be recorded on the photograph at its entrance coordinate along the centrifugal axis. The optic and centrifugal axes are at 90° to each other.

Experimental

As an aid in focussing the camera lens on any level in the cell, a simple device was fabricated to hold the ruled quartz disk in the rotor. The new disk holder had the same exterior dimensions as a centrifuge cell housing, but with an interior thread (40/in) which allowed a threaded, o-shaped, cap to be driven down the entire length of the holder. A 2 mm wide slot was cut in the side of the holder, leaving 3 mm of metal at each end for strength. The disk was placed upon the cap, its position accurately measured through the slot, on a microcomparator, and the unit then placed in the rotor for the focussing procedure. A tool of this nature should be of some usefulness if refocussing were at least necessary for every change of drive in the ultracentrifuge (1).

Results

The level of choice for focussing in the cell filled with pure liquids was determined by the method of Wiener (10) which states that if the velocity of light (v) is a linearly decreasing function of distance (r) from the center of rotation, then the path of the light ray in the cell would be an arc of a circle whose center is located on r at that point where $v = 0$. Therefore, since $v = c/n$

$$[1] \qquad dv/dr = \text{constant} = \frac{d(c/n)}{dr} = -(c/n^2)(dn/dr)$$

where c is the speed of light in a vacuum and n is the refractive index of the medium. After integration of

$$[2] \qquad \int_{v_m}^{v=0} dv = (\text{constant}) \int_{r_m}^{r_{v=0}} dr$$

and substitution for the constant and for v_m, it follows that

$$[3] \qquad r_{v=0} = r_m + \frac{n_m}{(dn/dr)_m}$$

where the subscript m refers to the entrance plane of the light into the cell. Next, as illustrated in Fig. 1, the arc of a circle of radius $(r_{v=0} - r_m)$ was drawn across the thickness of the cell with center at the point $r_{v=0}$. The cell thickness was 1.2 cm. A chord equal to twice the cell thickness would give

$$[4] \quad \text{chord} = (2)(1.2) = 2(r_{v=0} - r_m)\sin a$$

where by geometry it can be shown that a is the angle of incidence of the light ray at the side of energence of the cell. Snell's law gave the exit angle a',

$$[5] \qquad \sin a'/\sin a = n/n'$$

where $n' = 1$ (refractive index in the vacuum chamber) and n was the refractive index of the medium, assumed equal to the refractive index at the entrance plane of the light.

Reference to Fig. 1 shows that (1.2) (tan $a/2$) gave the depth (dr) below the entrance plane, at which the light ray emerged from the cell. Similarly, (1.2) (tan a') gave the height (dr') above the exit depth at which the back extrapolation of the exit ray struck the back of the cell. The point where the back extrapolated line crossed the entrance plane of the light determined

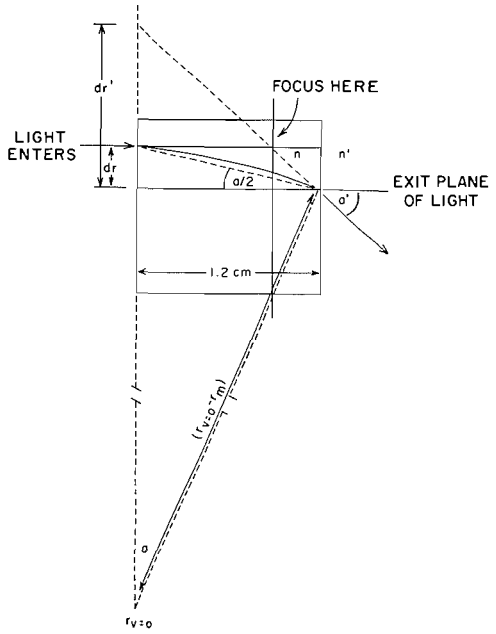

FIG. 1. Curved path (solid line) followed by light passing through a centrifuge cell. The values of dr and of dr' are greatly exaggerated for the purpose of illustration. The camera lens should be focussed on that plane in the cell where the back extrapolated line crosses the entrance plane of the light.

the plane (along the optic axis) upon which the camera lens was focussed. It was then possible to determine the exact position of the camera and cylinder lenses as described by Richards *et al.* (1). In Fig. 2, the back extrapolated lines are shown for benzene at two speeds of the centrifuge, two temperatures at each speed, and at two values of r_m. For the meniscus (r_m was arbitrarily set at 6.0 cm) the refractive index and density data for benzene at 20 °C and 1 atm were available (11, 13), but $(dn/dr)_m$ was calculated from the equation of Dayantis (7, 8).

$$[6] \qquad dn/dr = \frac{\beta(n^2 + 2)(n^2 - 1)\rho w^2 r}{6n}$$

where β was the isothermal compressibility of the medium in bars^{-1}; w was the angular velocity; ρ was the density of the medium. For benzene, the compressibility data of Holder and Whalley (12) was used. When an entrance plane for the light was chosen somewhere below the meniscus, for instance, at 7.0 cm, the pressure dependence of the refractive index, of the density, of the refractive index gradient, and of the isothermal

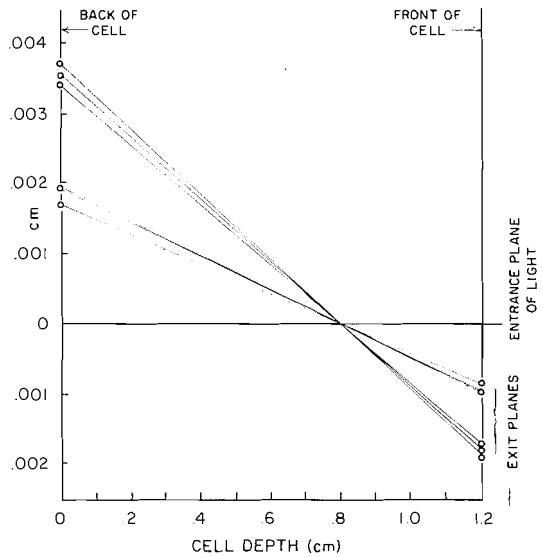

FIG. 2. Back extrapolated lines for benzene. Beginning with the upper line on the left the conditions are: 33 450 r.p.m., 20 °C, entrance plane 7.0 cm; 33 450 r.p.m., 25 °C, entrance plane 6.0 cm; 33 450 r.p.m., 20 °C, entrance plane 6.0 cm; 23 150 r.p.m., 25 °C, entrance plane 7.0 cm; 23 150 r.p.m., 25 °C, entrance plane 6.0 cm; 23 150 r.p.m., 20 °C, entrance plane 6.0 cm. All lines cross the entrance plane of light at 0.8 cm, or the 2/3 level of the cell.

compressibility of benzene had to be considered (8) before introduction of these terms into the equation of Dayantis. In the region up to about 200 bars, normally encountered in the centrifuge (15) plots of the data of Waxler *et al.* (13) showed that for benzene at several temperatures and wavelengths, $dn/dp \cong 5 \times 10^{-5}$ refractive index units per bar; from which the refractive index of benzene could be approximated at the pressures found in the centrifuge cell. Specific volumes were also given by Waxler *et al.* for benzene at several pressures and temperatures. The pressure dependency of the isothermal compressibility of benzene was given by Holder and Whalley (12) at several temperatures, and was extrapolated to 20 °C. The six lines of Fig. 2 cross the entrance plane at a common point, 0.8 cm from the back of the cell. Similar graphs were obtained for water (14) and for carbon tetrachloride (12). Again each of these compounds had a single crossing point, whose position, however, was determined by the refractive index of the compound at 1 atm, 20 °C, and 5461 Å.

Figure 3 shows the plane of focus for 6 liquids measured from the back of the 1.2 cm centrifuge cell, for 20 °C and utilizing the refractive index at the green line of mercury, 5461 Å. Least squares analysis gave the relation

$$[7] \qquad y(\text{cm}) = 0.243\, n_{5461}{}^{20^\circ} + 0.436 \qquad r = 0.997$$

The regression coefficient (r) measures the fit of experimental points to the equation. A value of 1.00 for r would indicate a perfect fit. With the refractive index at 25°, similar analysis would result in the expression

$$[8] \qquad y(\text{cm}) = 0.2726\, n_{5461}{}^{25^\circ} + 0.3914 \qquad r = 0.999$$

It should be noted that eqs. 7 and 8 apply only for cells of 1.2 cm thickness. The focal plane in a 3.0 cm cell is readily obtained for any liquid by the ratio

$$[9] \qquad y_{3.0\text{ cm}} = (y_{1.2\text{ cm}})\,(3.0/1.2)$$

Similar relations may be written to calculate the focal plane in cells of any thickness.

Discussion

In this laboratory (9), with the camera lens presumably focussed on the middle of a cell with sapphire windows, isothermal compressibilities were obtained at 1 atm and 20 °C from meniscus readings of dn/dr on schlieren patterns at 23 150

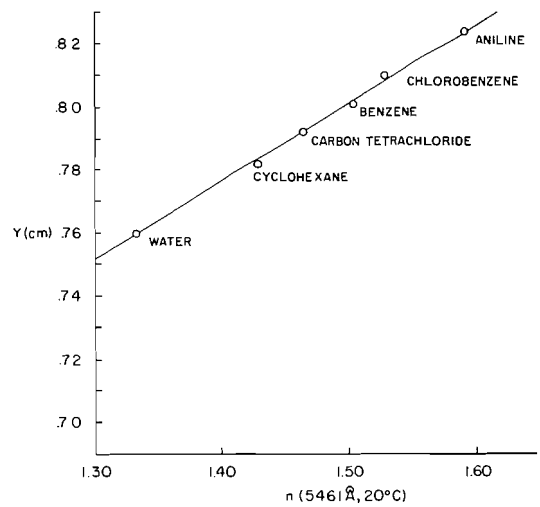

FIG. 3. Focal plane distance (cm) from the back of the cell, plotted against the refractive index of the liquid contained in the cell. Refractive index measured at 20 °C and 5451 Å.

r.p.m. for seven liquids, in good agreement with published values obtained by different methods (12). When an attempt was made to study the pressure dependence of isothermal compressibilities, by taking schlieren pictures at several rotor speeds, and measuring dn/dr along the liquid column (8) it was observed that the meniscus values of compressibility for all the liquids studied dropped 4 to 5% as the rotor speed increased up to 39 000 r.p.m. Since it was assumed that the pressure at the meniscus remained at 1 atm regardless of rotor speed, the compressibilities should have stayed constant. This effect was presumably due to the errors described by Wiener (10) at high values of dn/dr. In fact, it was completely eliminated by correct focussing for each liquid according to eq. 7. Fortunately, as shown in Fig. 2, the plane of focus did not vary with rotor speed, temperature, or position along the centrifugal axis for pure liquids. It should be stressed, however, that such is not necessarily the case when multicomponent systems are centrifuged (1, 6). A fundamental assumption in this work is that the refractive index gradient be essentially constant from the top to the bottom of the cell. It is not possible to justify this assumption in solutions where the solute sediments appreciably, except perhaps in the plateau region, as was done by Dayantis (7, 16). With low molecular weight solutes, however, sedimentation may be negligible at rotor speeds that give measurable values of dn/dr, and thus the focal plane in the cell would be determined by the refractive index of the mixture at 1 atm.

Pyrolyses and Mass Spectra of 2-Benzoxazolinone, 2-Benzimidazolinone, and 2-Benzothiazolinone

MICHAEL L. THOMSON AND DON C. DEJONGH[1]

Department of Chemistry, University of Montreal, P.O. Box 6128, Montreal 101, Quebec

Received March 22, 1973

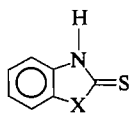
The electron-impact and chemical-ionization mass spectra of 2-benzoxazolinone (**5**), 2-benzimidazolinone (**6**), and 2-benzothiazolinone (**7**) have been compared with their pyrolysis products and parallels have been found. In each case, loss of CO occurs from M^+, followed by loss of CO for **5** and by HCN for **6** and **7**. At 950° in a stream of N_2, **5** gave 17% of C_5H_5N isomers, related to the loss of 2CO, along with 5.6% of quinoline. Compound **6** gave 14% of $C_6H_4N_2$ isomers, related to the loss of CO. At 950°, **7** gave 2-thiophenecarbonitrile (1.1%), cyanonaphthalenes (4.5%), aniline (3%), cyanobenzene (2.5%), naphthalene (1.5%), and phenylisocyanate (2.5%). From **5**–**7** 20–70% of the starting material was recovered or accounted for by isolation and identification of products in each case. G.c./m.s. was used to study pyrolysis mixtures.

On rapporte les spectres de masse de la benzoxazolinone-2 (**5**), de la benzimidazolinone-2 (**6**) et de la benzothiazolinone-2 (**7**), tels qu'obtenus par impact électronique et par ionisation chimique en utilisant l'isobutane. On compare ces spectres avec les produits de pyrolyse des composés **5**–**7**. Dans chaque cas, l'ion moléculaire élimine une molécule de CO. Pour les composés **6** et **7**, ce processus est suivi d'une élimination de HCN, alors que pour le composé **5**, il est suivi de la perte d'une deuxième molécule de CO. La pyrolyse du composé **5** à 950° dans un courant d'azote conduit à la formation de quinoline (5.6%) et d'isomères répondant à la formule C_5H_5N, ces derniers à la suite de l'élimination de deux molécules de CO. Parallèlement, le composé **6** donne des isomères répondant à la formule C_5H_5N, ces derniers à la suite de l'élimination de deux molécules de CO. Parallèlement, le composé **6** donne des isomères répondant à la formule $C_6H_4N_2$ par élimination d'une molécule de CO et d'une molécule de H_2. Les produits de la pyrolyse du composé **7** à 950° sont le thiophènecarbonitrile-2 (1.1%), les cyanonaphthalènes (4.5%), l'aniline (3%), le cyanobenzène (2.5%), le naphthalène (1.5%) et l'isocyanate de phényle (2.5%). Les produits formés ainsi que les produits originaux récupérés représentent de 20 à 70% des produits de départ. La combinaison de la chromatographie en phase gazeuse avec la spectrométrie de masse était employée pour étudier les mélanges obtenus des pyrolyses.

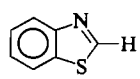
Can. J. Chem., **51**, 3313 (1973)

Introduction

We have compared the electron-impact (e.i.) and chemical-ionization (c.i.) mass spectra of 2-benzothiazolinethione (**1**), 2-benzimidazolinethione (**2**), and 2-benzoxazolinethione (**3**) with their pyrolysis products, and parallels have been found (1). The loss of S from the molecular ions



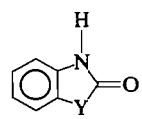
1 X = S
2 X = NH
3 X = O



4

is the lowest energy fragmentation observed at low voltages. Also, the loss of S is the only fragmentation observed from their (M + H) ions in the chemical-ionization mass spectra. The loss of S is also observed upon pyrolysis. For example, 2-benzothiazolinethione (**1**) gives a 23% yield of benzothiazole (**4**) and a 13% yield of cyanobenzene at 800°. The formation of **4** can be accounted for by the loss of S from **1**; cyanobenzene forms by loss of S_2 from the 2-thione and by loss of S from **4**. This one-step loss of S_2 is also observed in the mass spectrum of **1**.

This study has now been extended to 2-benzoxazolinone (**5**), 2-benzimidazolinone (**6**), and 2-benzothiazolinone (**7**). U.v. and i.r. spectra indicate that **5** exists predominantly in the lactam form (2), so we will use this structure in the schemes even though we don't know the structure of the molecular ions. Likewise, i.r. spectra and dipole moments provide evidence for the presence of the keto structure of **6**, (3) and



5 Y = O
6 Y = NH
7 Y = S

measured ^{14}N chemical shifts have shown that **7** exists exclusively in the thiazolinone form (4).

In each case, the 2-ones **5**–**7** have been pyrolyzed several times at a variety of temperatures. Their mass spectra have been obtained under conditions of electron impact (e.i.) at 70 and lower eV. Exact-mass measurements have been made in order to determine the elemental compositions of the ions. Also, the chemical ionization (c.i.) mass spectra have been obtained for comparison with the e.i. spectra and with the products of pyrolysis.

Millard and Temple have briefly described the e.i. mass spectrum of 2-benzothiazolinone (**7**) (5), and the e.i. mass spectrum of 2-benzoxazolinone (**5**) has been reported but not discussed (6). The 70 eV e.i. mass spectrum of 2-benzimidazolinone (**6**) is given in Fig. 1. Even though the mass spectrum of **6** has not been published, the e.i. mass spectra of 11 substituted 2-benzimidazolinones have been studied (7).

Our samples were pyrolyzed by sublimation into a stream of N_2 which passed through a hollow quartz tube surrounded by a 12 in. furnace (1,8). In general, a N_2 flow rate of 0.25 l/min and a system pressure of 2.5 Torr were used. Pyrolysis products have been identified by isolation and characterization. Combined gas chromatography – mass spectrometry (g.c.–m.s.) was also used.

Experimental

Melting points were determined by the open capillary method using a Mel-Temp apparatus and were corrected.

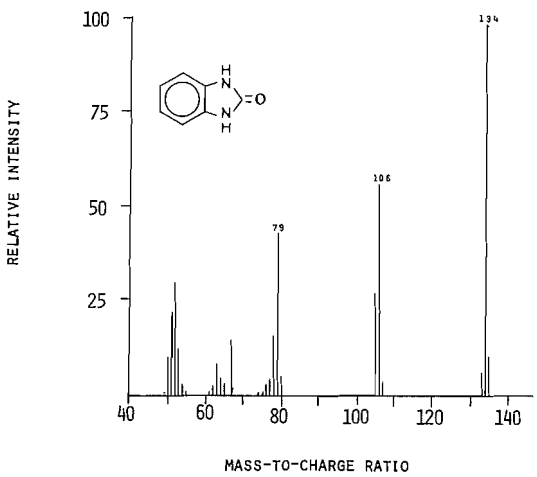

FIG. 1. The e.i. mass spectrum (70 eV) of 2-benzimidazolinone.

I.r. spectra were recorded with a Beckman IR8 and a Perkin-Elmer Infracord. N.m.r. spectra were taken on a Varian T-60 spectrometer using 1% TMS as an internal standard. U.v. spectra (1 cm path) were determined on a Bausch and Lomb Spectronic 505. Low resolution mass spectra were obtained from a Hitachi RMU-6D mass spectrometer. Electron voltage readings were taken directly from the dial since more precise values were not needed. Combined g.c.–m.s. data were determined with a LKB 9000 instrument.

Exact-mass data were obtained from an AEI MS 902 mass spectrometer linked to a PDP 8 computer. All experimental values agreed with the calculated values within ± 0.0015 mass units. The c.i. mass spectra were taken from a Dupont 21/491 mass spectrometer at a source temperature of 250° and a probe temperature of 80°, using isobutane.

The g.l.p.c. work was carried out using a Hewlett-Packard 5752B Research Chromatograph with a thermal conductivity detector. Columns were prepared with 0.25 in. copper tubing and 60/80 mesh Chromosorb W as a solid support, unless otherwise stated. A total of 13 columns was used; during the initial stages of analysis of the pyrolysis mixtures most of the columns were tried. However, only the column that gave the best separations is reported for each analysis. Comparison of the areas under the peaks of the pyrolysis products with the areas under the peaks of solutions of known concentrations of the same compound was used to determine yields.

Chemicals

2-Benzoxazolinone (**5**) was purchased from Eastman Organic Chemicals, m.p. 138–139° (lit. (9) m.p., 137–138°). 2-Benzimidazolinone (**6**) was obtained from Aldrich Chemical Co., m.p. 316–317° (lit. (10) m.p., 313–316°). Their purities were also checked by g.l.p.c., t.l.c., and mass spectrometry. 2-Cyanoaniline, 2-cyanopyridine, 3-cyanopyridine, and 4-cyanopyridine were also purchased from Aldrich. 1- and 2-cyanonaphthalene were purchased from Eastman.

2-Benzothiazolinone (7)

2-Benzothiazolinone (**7**) was prepared from 2-benzothiazolinethione (**1**) by the procedure of Efros and Davidenkov (11). Yield 6.5 g (36%), m.p. 136–137° (lit. (11) m.p. 136°), i.r. ($HCCl_3$) 3350 and 1675 cm^{-1}.

Anal. Calcd. for C_7H_5NOS: C, 55.63; H, 3.31. Found: C, 55.77; H, 3.40.

cis,cis-2,4-Hexadienedinitrile

A mixture of *o*-phenylenediamine (2.4 g, Aldrich), lead tetraacetate (27.9 g), and 130 ml of ether was stirred under N_2 for 3 h. The solution turned dark brown, was filtered and washed with aqueous $NaHCO_3$ until neutral, and then washed with water. The ether layer was dried ($MgSO_4$) and evaporated under vacuum. The brown residue was sublimed at 66°, 0.5 Torr, giving a white solid, m.p. 124–126° (lit. (12) m.p. 128–129°). G.l.p.c. traces and u.v. spectra showed no trace of the diamine.

Pyrolysis Apparatus and Procedure

The pyrolysis apparatus and procedure have been described previously (1). The sample in a stream of nitrogen passes through a quartz tube heated by an electric furnace 12 in. long. The flow rate is 0.25 l/min at 2.5 Torr. A series of traps is placed between the quartz

[a]Compounds **8**–**10** are isomeric; product **8** is pyridine; **9** and **10** are *cis* and *trans* isomers of 2,4-pentadienenitrile; **11** is quinoline; **12** is cyanobenzene; **13** is aniline; and **14** is phenol.
[b]It was assumed that one molecule of **5** is needed to produce one molecule of all products except **11**, in which case two molecules of **5** are needed.

tube and the pump. A solution is made of the material in the traps. G.l.p.c. and t.l.c. are used to separate the compounds in this solution.

Pyrolysis of 2-Benzoxazolinone (5)

The temperatures used in the pyrolyses of 2-benzoxazolinone (**5**) and the results are summarized in Table 1. A N_2 flow rate of 0.25 l/min was used. The initial pressure of the system was 0.8–1.2 Torr; it increased to a maximum of 6.0 Torr as **5** was sublimed into the N_2 stream and returned to its original value when all starting material had passed through. The products were collected in three traps, each cooled with liquid nitrogen. These traps were eluted with CH_3OH, acetone, and $CHCl_3$, and the combined washings were analyzed by g.l.p.c. The best separation of lower molecular weight components was achieved with a 12 ft 10% Carbowax 20M column held at 100° for 10 min, then programmed to 230° at 8°/min, and then held at 230° for 10 min. The other components were studied with a 6 ft 3% OV-225 CHROM HP 80/100 mesh column held at 100° for 2 min, then programmed to 250° at 8°/min, and then held at 250° for 4 min.

The mass spectra of products **8**–**10** show molecular-ion peaks at *m/e* 79 and a loss of HCN, giving *m/e* 52. Product **8** was identified as pyridine by comparison of its u.v. spectrum and g.l.p.c. retention time with those of a commercial sample. Products **9** and **10** were identified as the *cis* and *trans* isomers of 2,4-pentadienenitrile on the basis of their mass, n.m.r., i.r., and u.v. spectra. For example, absorption at 2220 cm^{-1} is characteristic of the cyano group; also, absorptions at 1570 and 665 cm^{-1} are characteristic of the *cis* form whereas 1592 and 950 cm^{-1} are characteristic of the *trans* form (13). It is interesting to note that approximately equal amounts of the two isomers were formed via equilibration at 575° of the *cis* form to the *cis,trans* mixture (14). We also obtain nearly equal amounts of each isomer.

Product **11** was shown to be quinoline on the basis of its u.v. spectrum and retention time, compared to those of a commercial sample. Likewise, product **12** was found to be cyanobenzene; **13** was found to be aniline; and **14** was found to be phenol by comparison of their retention times and spectra with those of commercial samples.

Pyrolysis of 2-Benzimidazolinone (6)

The temperatures used in the pyrolyses of 2-benzimidazolinone (**6**) and the results are given in Table 2. A flow of N_2 of 0.23 l/min and a system pressure of 1–3 Torr were used. The air-cooled trap and the two liquid nitrogen-cooled traps were eluted with EtOH, MeOH, acetone, and CH_2Cl_2. The solutions were combined and concentrated.

Mass spectra of the products were obtained from a LKB 9000 g.c.–m.s. combination using a 6 ft 3% OV-210 CHROM HP 80/100 mesh column programmed between 100 and 200° at 4°/min. The products were collected from a 6 ft 10% QF-1 CHROM HP 80/100 mesh column programmed in the same manner. Since starting material (**6**) does not elute from either column, it was recovered from a 6 ft 3% OV-1 CHROM HP 80/100 mesh column programmed between 100 and 250° at 15°/min and then held at 250° for 5 min.

Products **15**–**20** are isomeric; their mass spectra contain molecular ions at *m/e* 104 and intense fragment peaks at *m/e* 77. Compounds **15**–**17** are the isomeric cyanopyridines and **18**–**20** are the isomeric 2,4-hexadienedinitriles. 2-Cyanopyridine (**15**) and its 3-cyano (**16**) and 4-cyano (**17**) isomers and 2-aminocyanobenzene (**21**) were identified by g.l.p.c. retention times compared with those of commercial samples, g.l.p.c. peak enhancement, and comparison of their mass, i.r., and u.v. spectra with those of the known materials. The product *cis,cis*-2,4-hexadienedinitrile (**18**) was identified by retention time, peak enhancement, and mass and u.v. spectra, compared with the sample prepared as described above. Aniline (**13**) and cyanobenzene (**12**) were likewise characterized by comparison.

The three hexadienedinitriles gave identical mass spectra and very similar u.v. spectra with maxima at 261 nm. All three have been reported to have maxima near 260 nm (15). The *cis,cis* isomer (**18**) was identified on the g.l.p.c. trace by comparison and peak enhancement. For the two remaining isomeric hexadienedinitriles,

[a]Compound **25** is 2-thiophenecarbonitrile; **23** and **24** are 1- and 2-cyanonaphthalene; **12** is cyanobenzene; **13** is aniline; **22** is naphthalene; and **26** is methyl carbanilate.

the one which eluted first was assigned the *cis,trans* structure (**19**) and the other one, the *trans,trans* structure (**20**). Our experience with the isomeric 2,4-pentadienenitriles (**9** and **10**) showed that the *cis* isomer (**9**) eluted before the *trans* isomer (**10**).

Pyrolysis of 2-Benzothiazolinone (7)

The temperatures used in the pyrolyses of 2-benzothiazolinone (**7**) and the results obtained are given in Table 3. A N_2 flow rate of 0.25 l/min was used, and the system pressure varied between 1.5 and 3.0 Torr during the pyrolyses. The traps were eluted with methanol, acetone, and CH_2Cl_2; the solutions were combined, concentrated, and analyzed. The 6 ft 3% OV-210 CHROM HP 80/100 mesh column was held at 100° for 4 min, and then programmed to 200° at 4°/min. After reaching 200°, the oven was held there for 10 min.

Cyanobenzene (**12**), aniline (**13**), naphthalene (**22**), 1- and 2-cyanonaphthalene (**23** and **24**), and starting material (**7**) were identified by comparison of their retention times and u.v. and mass spectra with those of commercial samples, and by g.l.p.c. peak enhancement.

Product **25** was identified as 2-thiophenecarbonitrile on the basis of its mass (M+, *m/e* 109), i.r. (2250 cm^{-1}), and u.v. (λ_{max} in CH_2Cl_2, 241.5 nm) spectra. The u.v. spectrum of 2-thiophenecarbonitrile has been observed at λ_{max} 242 nm (16) whereas the 3-isomer absorbs at λ_{max} 236 nm (17).

Another product (**26**) was identified as methyl carbanilate by comparison of its u.v., i.r., and mass spectra with those of a sample prepared by addition of phenylisocyanate to methanol.

Discussion

2-Benzoxazolinone (5)

The 70 eV e.i. mass spectrum of 2-benzoxazolinone (**5**) is summarized in Scheme 1. Intense metastable peaks are found for losses of CO_2 and 2CO from the molecular ions. The loss of CO from the molecular ions, followed by CO, is also observed in the metastable peaks, al-

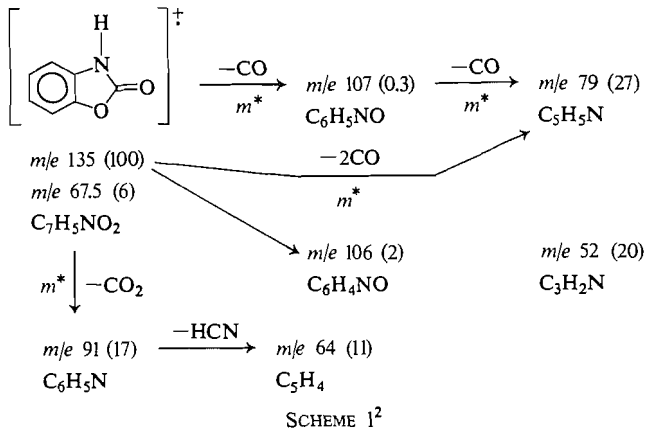
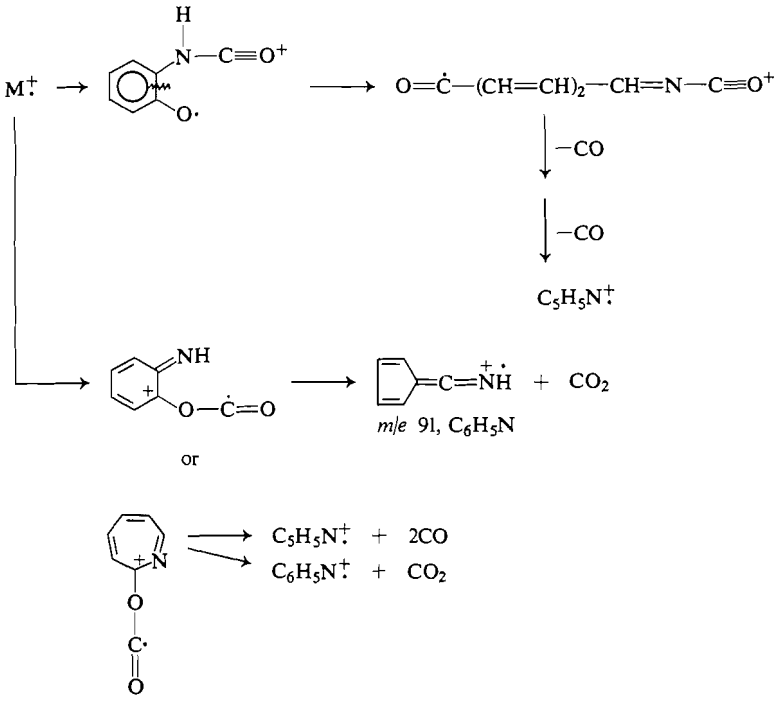


SCHEME 1[2]



SCHEME 2

though the metastable peak for the loss of 2CO is much more intense. The width and shape of the small metastable peak for the loss of CO indicates that internal energy is being released as translational energy of the fragments. For a discussion of the significance of the shapes of metastable peaks see ref. 18. At 15 eV, *m/e* 91 and 79 are approximately equally abundant, ~2%. The (M + H) ion is present in the c.i. mass spectrum but there are no appreciable fragment ions present.

One can attempt to rationalize these data as shown in Scheme 2, as well as with other speculative ion structures. The loss of 2CO from the open-chain ion would require the two molecules to be lost from opposite ends of the chain. Previously, examples have been cited where a loss of two molecules from different parts of an ion

[2]The elemental compositions are the result of the exact-mass measurements; the values in parentheses are relative intensities; *m** denotes a metastable peak found in the mass spectrum.

[I]

5 8, 3.5% 10, 6.3% 9, 7.0%

+ 11, 5.6%

gives rise to a metastable peak for the combined loss (Scheme 1, ref. 19). In comparison, the low energy fragmentations of the molecular ions of 2-benzoxazolinethione (**3**) are losses of S and COS (1). The only fragmentation in the c.i. spectrum of **3** is loss of S from the (M + H) ions (1).

The major products in the pyrolyses of **5** are three C_5H_5N isomers. When 1.9 g of **5** was pyrolyzed at 950° with a N_2 flow rate of 0.23 l/min and an initial system pressure of 0.8 Torr, 2.9% of **5** was recovered and 16.8% of C_5H_5N (**8–10**) was isolated, as shown in eq. 1.

Other products isolated were quinoline (**11**, 5.6%), cyanobenzene (2.8%), phenol (1.6%), and aniline (0.7%), for a total of 30.4% of the starting material accounted for. The formula of quinoline, C_9H_7N, corresponds to the dimerization of C_5H_5N, followed by loss of HCN and H_2.

Aniline could form by loss of CO_2 from **5** followed by abstraction of 2H· and phenol by loss of HNCO followed by addition of 2H·. However, aniline, phenol, and/or cyanobenzene, which are common pyrolysis products from this type of heterocyclic compound (1), could form by a degradation–recombination mechanism.

If, indeed, **8–11** arise from C_5H_5N via initial loss of 2CO from the molecule, they, along with the 2.9% of recovered **5**, account for 25.2 of the 30.4% of products isolated. Thus the major fragmentations observed in the mass spectrum of **5** can be used to rationalize the products formed upon pyrolysis.

2-Benzimidazolinone (6)

The 70 eV e.i. mass spectrum of 2-benzimidazolinone (**6**) is given in Fig. 1. In the c.i. spectrum of **6**, the (M + H) ion at *m/e* 135 is present, but there are no abundant fragment ions. The major fragmentation pathway of **6** is the consecutive losses of CO and 2HCN, as summarized in Scheme 3. At 15 eV, the peaks which remain are *m/e* 134 (100), 106(5), and 105(3). The metastable peak for the loss of CO is broad and concave (18).

The structures given in eq. 2 can account for the major fragmentation path. In comparison, oxidation of 2-iminobenzotriazole (**27**) with lead tetraacetate gives 2,4-hexadienedinitrile in good yield (eq. 3) (20). The intermediate in brackets in eq. 3 could not be trapped with acetylene dicarboxylate. Also, the decomposition of aromatic *o*-diazides at 160–170° to 2,4-hexadienedinitriles via the same intermediate seems to be a general reaction (21).

At 1000°, we recovered 10.2% of the starting material (**6**), and we isolated 13.9% of $C_6H_4N_2$ isomers, as shown in eq. 4. In addition, 2.0% of 2-aminocyanobenzene, 2.1% of cyanobenzene, and 1.5% of aniline were isolated. Thus, in all, 29.7% of the starting material has been accounted for. The percentages of the isomeric

cyanopyridines were 3.9% of the 2-isomer (**15**), 4.6% of the 3-isomer (**16**), and 1.8% of the 4-isomer (**17**). The 2,4-hexadienedinitriles were present as the *cis,cis* isomer (**18**, 1%), the *cis,trans* isomer (**19**, 1.8%) and the *trans,trans* isomer (**20**, 0.8%).

We have pyrolyzed benzimidazole (**28**) at 1000° and isolated 2-aminocyanobenzene (**21**), eq. 5 (1). It is possible that **6**, in a high energy path, loses H_2O or HO· to give an intermediate,

[5]  $\xrightarrow{1000°}$ 
28 **21**

similar to the intermediate from **28**, which leads to formation of **21**. The pyrolysis of **21** at 1000° gave aniline (1). Thus the formation of **21** and of aniline in the pyrolysis of **6** may be related.

Once again, the resemblance of the fragmentation in the e.i. mass spectrum to its pyrolytic paths is striking.

2-Benzothiazolinone (7)

In the c.i. mass spectrum of 2-benzothiazolinone (**7**), the (M + H) peak is present and there are no abundant fragment ions. In contrast, the peak for loss of S in the c.i. spectrum of the isomeric 2-benzoxazolinethione (**3**) is 6% of the intensity of the (M + H) peak (1).

In the 70 eV e.i. spectrum of **7** there is one major fragmentation path (eq. 6). As was the

[6]  $\xrightarrow[m^*]{-CO}$

m/e 151(100)
m/e 75.5(7)
C_7H_5NOS

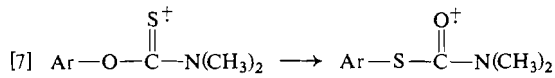
m/e 123(40) $\xrightarrow[m^*]{HCN}$ *m/e* 96(41)

C_6H_5NS C_5H_4S

case with the molecular ions of **5** and **6**, the metastable peak for the loss of CO is broad and concave, indicating a release of internal energy. The peaks at *m/e* 123 and 96 persist as the electron voltage is lowered, with *m/e* 96 disappearing before *m/e* 123.

In the 70 eV e.i. mass spectrum of **3**, the major fragmentations are losses of S and COS (1). However, there are small peaks at *m/e* 123(4%) for loss of CO and at *m/e* 96(7%) for loss of CO followed by HCN. Thus, it is possible that some of the molecular ions of **3** rearrange to the molecular ions of **7** before fragmenting. There are no substantial peaks at (M − S) or (M −

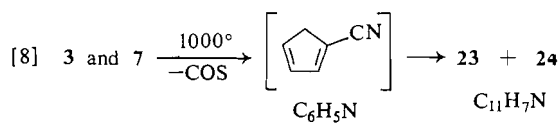
COS) in the mass spectrum of **7**. Dimethylthioncarbamates have been found to rearrange to dimethylthiolcarbamates upon heating and also upon electron impact (eq. 7) (22).



[7] $Ar-O-\overset{S^+}{\overset{\|}{C}}-N(CH_3)_2 \longrightarrow Ar-S-\overset{O^+}{\overset{\|}{C}}-N(CH_3)_2$

No products were isolated from the pyrolyses of **7** which could be directly related to the fragmentations in its mass spectrum. This is probably due to the fact that the sulfur atom is retained and gives products such as cyclopentadienethione (C_5H_4S) which polymerize. At 950°, 8.7% of starting material was recovered and 14.4% of products was isolated and identified.

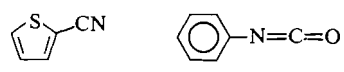
The major products are 1-cyanonaphthalene (**23**, 2.4%), 2-cyanonaphthalene (**24**, 1.8%), naphthalene (1.3%), aniline (2.7%), and cyanobenzene (2.6%). One can speculate that naphthalene and the cyanonaphthalenes are formed by the loss of COS and/or CO and S from **3** and **7**, perhaps through the intermediacy of cyanocyclopentadiene (eq. 8). For example, dimerization



[8] **3** and **7** $\xrightarrow[-COS]{1000°}$ [C_6H_5N] $\longrightarrow$ **23** + **24** ($C_{11}H_7N$)

of C_6H_5N gives $C_{12}H_{10}N_2$ which can yield $C_{11}H_7N$ (**23** and **24**) by losses of HCN and H_2, and naphthalene ($C_{10}H_8$), by loss of 2HCN. We considered a similar possibility for the formation of quinoline from the pyrolysis of **5**. Naphthalene (6.7%), **23** (12.3%), and **24** (14.9%) have also been obtained from the pyrolysis of **3**, in addition to benzoxazole (**4**, O in place of S, 1.3%), and 2-cyanophenol (37.7%) (1). The possible intermediacy of cyanocyclopentadiene is being investigated.

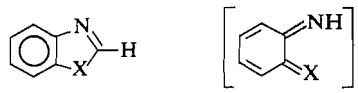
Two other products were isolated in small yields at 950°, 2-thiophenecarbonitrile (**25**, 1.1%) and phenylisocyanate (**29**), isolated as its methyl carbanilate derivative (2.5%). Compound **29** can be formed from **7** by the loss of S and is trapped



25 **29**

by methanol when the traps which are cooled by liquid N_2 are washed out after the pyrolysis is terminated. The origin of the small amount of **25** is more obscure.

The overall yields obtained from the pyrolysis of the 2-ones **5**–**7** are substantially lower than the yields obtained from the corresponding 2-thiones **1**–**3** (1). The 2-thiones expel an atom of S, leaving a stable aromatic azole **30**. On the other hand, the 2-ones expel CO, leaving an



30 X = S, NH, O **31** X = O, NH, S

ortho-quinoid intermediate (**31**), or a rearranged isomer which is unstable and polymerizes or degrades further.

Nevertheless, the C_5H_5N isomers (17% yield) and the quinoline (5.6% yield) obtained from the pyrolysis of **5** can be associated with the loss of CO from **31** (X = O). The loss of 2CO is also the major fragmentation in the mass spectrum of **5**. Similarly, the formation of the $C_6H_4N_2$ isomers (14% yield) from the pyrolysis of **6** can be associated with the loss of H_2 from **31** (X = NH) and with the loss of CO from **6**, followed by H·, observed in the mass spectrum.

If compound **7** indeed forms **31** (X = S) upon pyrolysis, the loss of HCN would give C_5H_4S, cyclopentadienethione, which would not be expected to be stable and would polymerize. Loss of CS from **31** would give C_5H_5N which could react with S and lose H_2 to give thiophenecarbonitrile (**25**). On the other hand, loss of S from **31** (X = S) would give C_6H_5N which could lead to **23** and **24**. The loss of CO followed by HCN is the major fragmentation observed in the mass spectrum of **7**, whereas the loss of S from the (M − CO) ions is minor. It seems that the formation of **23** and **24** in the pyrolyses of **3** and **7** are likely related. In summary, the relationship between the pyrolysis and mass spectrum of **7** is ambiguous possibly because of the instability of sulfur containing products.

In conclusion, it has been possible to interpret the mass spectra and pyrolyses of **1**–**7** in terms of the extrusion of small species such as HCN, CO, and S, demonstrating another series of compounds which show similarity between the two processes. Upon pyrolysis, it is possible that major products do not survive to be isolated. If a large percentage of the starting material is not accounted for, this factor must be considered when the comparison is made between mass spectra and pyrolysis. If most of the starting material can be accounted for, on the other hand,

it is evident that a major pyrolytic path has not been obscured.

Etude cinétique du système Cu(II)–adénine

G. Boivin et M. Zador

Département de Chimie, Université de Montréal, c.p. 6128, Montréal 101, Québec

Reçu le 16 mars 1973

La cinétique de la formation et de la dissociation de divers complexes Cu(II)–adénine a été étudiée par les méthodes de la relaxation thermique et du "flux stoppé".

Entre p*H* 3.5 et 5 la formation de Cu(II)·aH est très rapide; celle de Cu(II)·$(aH)_2$ a été étudiée et les constantes de vitesse ont été déterminées. A pH < 3 les formes protonées ont une contribution importante à la vitesse de réaction. En milieu basique deux complexes différents ont été étudiés; la réaction d'échange avec l'EDTA se fait par deux voies parallèles.

Le mécanisme des diverses réactions est discuté et comparé au système Cu(II)–adénosine.

The kinetics of formation and dissociation of Cu(II)–adenine complexes have been studied by stopped flow and relaxation methods.

Between pH 3.5 and 5 the formation of Cu(II)·aH is too fast to be measured; formation of Cu(II)·$(aH)_2$ has been studied and rate parameters have been determined. At pH < 3 protonated species make an important contribution to measured reaction rates. In basic media two different complexes have been investigated. The exchange reaction with EDTA proceeds by two parallel reaction paths.

The mechanism of these reactions is discussed and compared with that proposed for the Cu(II)–adenosine system.

Can. J. Chem., 51, 3322 (1973)

L'adénine est une des quatre bases constituantes de l'ARN et de l'ADN; on la retrouve aussi dans certains coenzymes comme l'ATP et le NAD. Les métaux de transition bivalents forment des complexes avec l'adénine. Le Cu(II) en particulier forme des complexes très stables qui ont fait l'objet de nombreux travaux tant au point de vue de leur nature qu'au point de vue de leur stabilité en solution aqueuse (1–12). Ces études ont montré l'existence de plusieurs complexes dont la nature dépend de l'acidité du milieu réactionnel. En effet, en milieu acide, les complexes Cu(II)·aH et Cu(II)·$(aH)_2$ (aH = adénine) prédominent, tandis qu'en milieu basique, les espèces Cu(II)·$(OH^-)_n$·(a^-) et Cu(II)·$(OH^-)_m$·$(a^-)_2$ ont été mises en évidence (5).

Nous nous proposons dans ce travail d'étudier la cinétique de formation et de dissociation des divers complexes du Cu(II) avec l'adénine en solution aqueuse.

Partie expérimentale

Les réactifs

L'adénine est un produit de Aldrich Chemical Co. Le perchlorate cuivrique a été obtenu en dissolvant l'oxyde cuivrique dans l'acide perchlorique. La solution stock a été dosée par iodométrie et par absorption atomique. L'EDTA est un produit Fisher Scientific Co. Le pyrophosphate et le tripolyphosphate de sodium sont de Alfa Inorganics. Les solutions d'adénine ont été fraîchement préparées avant chaque série d'expériences. La force ionique des solutions a été maintenue constante à l'aide du perchlorate de sodium. Le pH des solutions est ajusté en utilisant de l'acide perchlorique ou de l'hydroxyde de sodium.

Appareillage

La cinétique des réactions a été étudiée par les méthodes de la relaxation thermique et du "flux stoppé", dont les principes sont décrits dans la littérature (13).

L'appareil de relaxation provient de Messenlagen Studiengesselschaft m.b.H., Göttingen, Allemagne. L'appareil du "flux stoppé" est constitué d'un système à mélange rapide Durrum–Gibson et d'un monochromateur Jarrel–Ash 0.25 m. Dans chaque cas, les variations de densité optique ou de transmission des solutions sont enregistrées sur un oscillographe cathodique et le signal obtenu est photographié. Les spectres visibles ont été obtenus sur un spectrophotomètre Cary–14. Les cellules réactionnelles sont thermostatées et, dans le cas de la relaxation, la température est mesurée avant chaque expérience à l'intérieur de la cellule, à l'aide d'un thermocouple cuivre–constantan.

Méthodes cinétiques

La cinétique de relaxation du système Cu(II)·adénine, en milieu acide, peut être suivie par la diminution de l'absorption sur une des extrémités de la bande d'absorption du complexe Cu(II)·$(aH)_2$ à 570 nm ou du cuivre vers 715 nm. La cinétique de formation et de dissociation du complexe Cu(II)·$(aH)_2$, en milieu acide, peut également être étudiée par "flux stoppé" aux mêmes longueurs d'onde. La dissociation des complexes, en milieu basique, est étudiée par la méthode du "flux stoppé". Les solutions à mélanger sont ajustées au même pH. On suit la cinétique de disparition des complexes aux longueurs d'onde appropriées.

Les solutions ont été dégazées pour empêcher la forma-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion de bulles. Les solutions à mélanger ont la même force ionique pour éviter des phénomènes provoqués par une chaleur de mélange. Dans chaque cas, des vérifications ont été faites pour s'assurer qu'un des réactifs seul ne présentait pas de relaxation.

Résultats et discussion

(1) Etude cinétique du système Cu(II)·adénine entre pH 3.5 et pH 5

L'étude spectrophotométrique du système a été effectuée en vue de déterminer les conditions expérimentales optimales pour l'étude cinétique.

L'examen des spectres d'absorption dans le visible permet de mettre en évidence deux complexes. L'addition du Cu(II) à l'adénine est accompagnée d'abord d'une augmentation d'absorption de la bande de l'adénine à $\lambda < 400$ nm et de l'apparition d'une nouvelle bande à $\lambda =$ 570 nm. Simultanément, un épaulement de la bande de l'adénine se manifeste de $\lambda \simeq 350$ à 450 nm. L'augmentation de la concentration en Cu(II) entraîne originalement l'augmentation de ces deux bandes; elles passent ensuite par un maximum, ce qui est suivi d'une diminution d'intensité. Les bandes finissent par s'atténuer et disparaître à très haute concentration en Cu(II). Il ne demeure finalement que la bande à $\lambda < 400$ nm, dont l'intensité n'est plus modifiée significativement par une augmentation de la concentration en Cu(II).

Il est raisonnable d'admettre que dans ce dernier cas, l'augmentation d'absorption de la bande de l'adénine correspond à la formation complexe Cu(II)·aH, d'après l'éq. 2, qui serait favorisé en excès de cuivre.

$$[1]\quad aH_2^+ \rightleftharpoons aH + H^+ \qquad K_a = [aH][H^+]/[aH_2^+]$$

$$[2]\quad Cu(II) + aH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu(II)\cdot aH \qquad K_1 = \frac{[Cu(II)\cdot aH]}{[Cu(II)][aH]}$$

L'existence du complexe Cu(II)·aH a déjà fait l'objet d'une étude spectrophotométrique et sa constante d'équilibre de formation fut déterminée ($K_1 = 500\ M^{-1}$ à 25 °C) (5).

La bande à $\lambda \simeq 570$ nm et l'épaulement de $\lambda \simeq 350$ nm à 450 nm dénotent la formation du complexe Cu(II)·$(aH)_2$, d'après l'éq. 3.

$$[3]\quad Cu(II)\cdot aH + aH \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Cu(II)\cdot(aH)_2,$$

$$K_2 = \frac{[Cu(II)\cdot(aH)_2]}{[\overline{Cu(II)\cdot aH}][\overline{aH}]}$$

Le complexe Cu(II)·$(aH)_2$ serait prépondérant à grande concentration en adénine.

En étudiant la relaxation de ce système dans diverses conditions expérimentales, c'est-à-dire à plusieurs concentrations en réactifs, à des pH, des températures et des longueurs d'onde différents, on observe une seule relaxation, avec des temps de l'ordre de 1–100 ms, attribuée à la formation du complexe Cu(II)·$(aH)_2$.

Les résultats ont été interprétés en admettant que la relaxation est due à la réaction [3] et que la réaction [2] est très rapide. Le temps de relaxation τ est donné par l'éq. 4.

$$[4]\quad \tau^{-1} = k_2([\overline{Cu(II)\cdot aH}] + [\overline{aH}]) + k_{-2}$$

où les concentrations sont celles à l'équilibre.

Les concentrations à l'équilibre ont d'abord été calculées en utilisant les valeurs de K_a et de K_1 de la littérature. On détermine ensuite les paramètres k_2 et k_{-2} ainsi que K_2. On effectue alors un nouveau calcul en tenant compte de cette dernière valeur. Ainsi, par approximations successives, on arrive au meilleur accord entre résultats expérimentaux et calculés. Ces calculs ont été effectués par ordinateur. L'ensemble des résultats est présenté dans le tableau 1. L'éq. 4 a pu être vérifiée et les valeurs de k_2 et de k_{-2} ainsi que les énergies d'activation ont été déterminées et les valeurs correspondantes sont groupées au tableau 2. On remarque que la valeur de K_2 obtenue est supérieure à celle de K_1, ce qui est contraire à ce que l'on observe généralement. Il est hasardeux de tirer une conclusion de cette observation étant donné que les deux constantes ont été obtenues par des méthodes très différentes.

Nous avons pu également étudier ce système par la méthode du "flux stoppé". En effectuant

TABLEAU 1. Temps de relaxation du système Cu(II)·adénine à pH = 4.5*

17	3.3 ± 0.3	6 ± 2	5.6 ± 2

*E_2 = 5 ± 1.5 kcal/mol, E_{-2} = 25 ± 3 kcal/mol.

le mélange, on constate initialement une variation brusque de densité optique (à λ = 340 nm) avec une constante de temps plus petite que 1 ms qui est probablement due à la formation du complexe Cu(II)·aH. Ce phénomène est suivi d'une réaction plus lente due à la formation du complexe Cu(II)·$(aH)_2$, d'après l'équation de vitesse de deux réactions opposées d'ordre un. Les valeurs de k_2 et k_{-2} ainsi déterminées sont identiques à celles du tableau 2 obtenues par relaxation.

Il est intéressant de constater que les constantes de vitesse de formation du complexe Cu(II)·$(aH)_2$ sont d'un facteur de plus de dix plus grandes que celles pour le complexe Cu(II)·adénosine (14). Dans ce dernier cas une des sites de coordination (N_9) est altérée dû à la présence du groupe ribose; ceci cause également une diminution de basicité. Il est à noter également que la vitesse de formation de Cu(II)·aH est nettement plus grande que celle du complexe 1:2, contrairement à ce que l'on a constaté, *e.g.* dans le cas de l'éthylènediamine (15) où l'introduction de la deuxième molécule se fait avec une vitesse deux fois plus lente que celle de la première molécule. Cet effet a déjà été noté dans le cas de certains complexes avec les acides aminés (16).

Il faut souligner aussi que la valeur de la constante k_2 est de plusieurs ordres de grandeur inférieure à celle observée par exemple pour l'éthylènediamine (15). Bien que l'on pourrait parler ici d'effet stérique ou de basicité moindre du ligand, les résultats sont difficilement compatibles avec un mécanisme impliquant comme étape lente le départ d'une molécule d'eau de coordination du Cu(II). Le mécanisme intime de formation de complexes du Cu(II) reste donc relativement peu compris.

L'influence du pH sur la vitesse de réaction a été étudiée à concentration d'adénine constante, et prise en excès par rapport au Cu(II). Les résultats ont montré une augmentation de τ avec une diminution du pH entre pH 4.9 et 3.5. Toutefois, l'influence du pH peut être interprétée en tenant compte de l'éq. 1 impliquant une diminution de [aH] avec l'augmentation de l'acidité. En introduisant les concentrations à l'équilibre dans l'équation de vitesse 4, on obtient des valeurs convenables pour les constantes de vitesse k_2 et k_{-2}.

(2) Influence de l'acidité sur la cinétique de relaxation à pH < 3

Le mécanisme simple représenté par les éq. 1 à 3 ne laisse prévoir qu'une influence indirecte de l'acidité sur la vitesse de réaction, tel que confirmé par les résultats à pH ⩾ 3.5. A pH < 3 par contre, quand le cuivre est pris en excès par rapport à l'adénine, l'augmentation de l'acidité entraîne l'augmentation de la vitesse de réaction.

Les temps de relaxation en fonction de l'acidité du milieu dans différentes conditions figurent dans le tableau 3. D'après ces résultats, l'inverse du temps de relaxation augmente linéairement avec la concentration en acide à l'équilibre (fig. 1). Pour expliquer cette catalyse acide, il faut ajouter deux étapes supplémentaires au mécanisme correspondant aux éq. 1–3.

[5] $$Cu(II)\cdot(aH)_2 + H^+ \rightleftharpoons Cu(II)\cdot(aH)_2H^+, \qquad K_3 = \frac{[Cu(II)\cdot(aH)_2H^+]}{[Cu(II)\cdot(aH)_2][H^+]}$$

[6] $$Cu(II)\cdot aH + aH_2^+ \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} Cu(II)\cdot(aH)_2H^+$$

Les réactions 3 et 6 se feraient parallèlement et les réactions 1, 2 et 5 seraient à l'équilibre.

L'éq. 5 implique la protonation rapide de l'adénine à un site différent du site de coordination du métal, et l'éq. 6 la formation et la dissociation de ce complexe. La vitesse totale est donnée par la contribution des éq. 3 et 6. L'éq. 7

[7] $$d[Cu(II)\cdot aH]/dt = -k_2[Cu(II)\cdot aH][aH] + k_{-2}[Cu(II)\cdot(aH)_2] - k_4[Cu(II)\cdot aH][aH_2^+] + k_{-4}[Cu(II)\cdot(aH)_2H^+]$$

peut être résolue linéairement. Bien qu'il soit possible d'obtenir une solution exacte, elle contient trop de termes pour être vérifiée quantitativement. Il faut accomplir une série d'approximations en éliminant les termes très petits pour ce cas particulier, en tenant compte: (*i*) de la valeur calculée des concentrations à l'équilibre, (*ii*) des constantes d'équilibres et (*iii*) en admettant que $k_2 > k_4$, $k_{-2} < k_{-4}$ et $K_3 < K_n^{-1}$. On obtient alors l'éq. 8.

TABLEAU 3. Influence de l'acidité sur les temps de relaxation du système Cu(II)·adénine en excès de Cu(II)*

T = 21 °C		T = 30 °C		T = 31 °C	
$[H^+] \times 10^3$ (M)	τ (ms)	$[H^+] \times 10^3$ (M)	τ (ms)	$[H^+] \times 10^3$ (M)	τ (ms)
1.4	50	1.8	21	1.4	20
2.6	40	3.4	18	2.0	18
4.6	30	7.1	11	3.0	15
8.0	22	10.0	8	4.2	13
13.0	17	13.0	7	6.5	10
15.0	16	—	—	9.2	8
18.0	14	18.0	5.5	16.0	5.5

*[Cu(II)] = 0.144 M, [aH] = 5.0×10^{-3} M, force ionique = 0.5 M, λ = 340 nm.

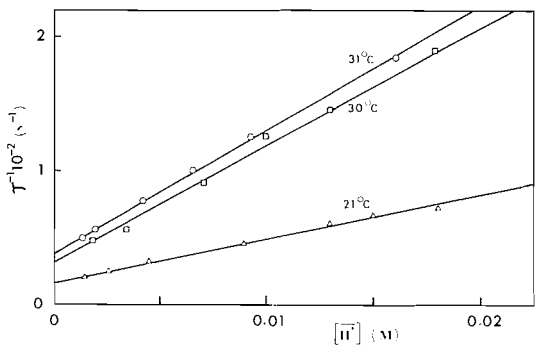

FIG. 1. Influence de l'acidité sur les temps de relaxation. [Cu(II)] = 0.144 M, [adénine] = 5.0×10^{-3} M, force ionique = 0.5 M, λ = 340 nm.

$$[8]\quad \tau^{-1} = k_{-2} + k_4([\overline{Cu(II)\cdot aH}] + [\overline{aH_2}^+]) + 2k_2K_3K_a[\overline{Cu(II)\cdot aH}] + (k_{-4} + 2k_4[\overline{Cu(II)\cdot aH}])\,K_3[\overline{H^+}] + 2k_2K_a[\overline{Cu(II)\cdot aH}]/[\overline{H^+}].$$

La comparaison de cette dernière équation avec les résultats expérimentaux permet de dégager les conclusions suivantes: (*i*) La droite expérimentale de la fig. 1 implique que le terme $2k_2K_a[\overline{Cu(II)\cdot aH}]/[\overline{H^+}]$ est négligeable, ce qui est confirmé à partir des résultats obtenus en excès d'adénine. (*ii*) L'ordonnée à l'origine, correspondant aux termes qui ne contiennent pas $[H^+]$, est égale à k_{-2} compte tenu de l'erreur expérimentale, ce qui implique que la contribution des autres termes ne dépasse pas 10% (voir tableau 4). (*iii*) A des acidités s'approchant de 0.01 M, la contribution des éqs. 5 et 6 est prépondérante et la catalyse acide observée est due à la dissociation rapide de $Cu(II)(aH)_2H^+$.

La pente de la droite obtenue ne permet pas de connaitre les valeurs exactes de k_4, k_{-4} et de K_3.

TABLEAU 4. Paramètres des droites de la Fig. 1.

T (°C)	Ordonnée à l'origine (s^{-1})	Pente $\times 10^{-3}$ ($M^{-1}\,s^{-1}$)	k_{-2}* (s^{-1})
21	17	3.2	19
30	32	8.7	36
31	38	9.5	40

*Valeurs tirées du tableau 2 pour la température de l'expérience.

On peut estimer à 21 °C, la limite inférieure de $k_{-4} \sim 10^2\ s^{-1}$, pour une limite supérieure de $K_3 \sim 10^2\ M^{-1}$; la limite supérieure de k_4 compatible avec les résultats est d'environ $10^3\ M^{-1}\ s^{-1}$. Ceci est fait en tenant compte en première approximation, uniquement des équilibres 1–3 pour calculer les concentrations à l'équilibre, ce qui est raisonnable étant donné que $K_3 \ll K_a^{-1}$.

La concentration en Cu(II) en *excès* n'a pas d'influence sur les temps de relaxation à acidité constante. Entre 0.072 et 0.43 M les temps de relaxation restent constants. Ceci est en accord avec le mécanisme proposé, puisque dans la solution exacte de l'éq. 8 les termes contenant le Cu(II) sont négligeables. Il faut souligner que l'influence de la concentration en Cu(II) serait tout autre si la réaction enregistrée était la formation de Cu(II)·aH; alors on devrait obtenir une variation linéaire de τ^{-1} en fonction de la concentration en Cu(II).

La mécanisme proposé n'est pas le seul à être compatible avec les résultats expérimentaux. Dans divers cas étudiés, impliquant des ligands protonés (15, 17), on admet plutôt une déprotonation du ligand, tel l'éthylènediamine, avant la formation du complexe, due au fait que les

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sites de protonation et de complexation sont les mêmes (15). Dans le cas de l'adénine ceci n'est pas le cas, étant donné que le site de protonation est l'azote N_1, tandis que la complexation avec le Cu(II) se fait en positions N_3 et N_9 et l'existence du complexe protoné tel $Cu(II)\cdot(aH)_2H^+$ est possible. Toutefois, un mécanisme semblable à celui proposé pour l'éthylènediamine (15) ne peut pas être exclu, ni un transfert de proton lent conduisant à une catalyse acide générale qui fut mise en évidence dans les réactions d'échange de ligand de complexes Cu(II)·peptides (18).

(3) Dissociation du complexe $Cu(II)\cdot(aH)_2$ par le pyrophosphate et le tripolyphosphate

Il est connu que les ions pyrophosphates et tripolyphosphates forment divers complexes avec le Cu(II). Ces anions complexent très fortement le cuivre en milieu faiblement acide (19); en présence de polyphosphate, les complexes entre le Cu(II) et l'adénine se trouvent donc complètement dissociés.

La dissociation du complexe $Cu(II)\cdot(aH)_2$ a été étudiée en mélangeant une solution contenant le Cu(II) et l'adénine à l'équilibre avec une solution de polyphosphate en grand excès par rapport au complexe $Cu(II)\cdot(aH)_2$ à acidité constante (l'excès de polyphosphate servant de tampon). Une seule courbe de dissociation est observée avec une cinétique d'ordre un. Les constantes de vitesse expérimentales sont données au tableau 5. La fig. 2 montre que la constante varie linéairement avec la concentration en polyphosphate (ph). Ceci indique que la réaction s'effectue par deux voies parallèles: (*i*) l'une, indépendante du

TABLEAU 5. Variation de la constante expérimentale de dissociation du complexe $Cu(II)\cdot(aH)_2$ en fonction de la concentration en polyphosphate*

	Pyrophosphate		Tripolyphosphate	
	$pH = 4.5$	$pH = 3.5$	$pH = 4.0$	$pH = 3.5$
$[ph] \times 10^3$ (M)	k_{exp} (s^{-1})	k_{exp} (s^{-1})	k_{exp} (s^{-1})	k_{exp} (s^{-1})
50	62.7	46.0	76.0	53.0
30			53.0	43.0
25	43.0	36.0		
20			43.0	34.4
10			31.4	26.6
0.5	23.0	23.0		
0.3	21.6	19.2	21.6	19.7
0.15	19.2	19.2		

*$k_{-2} = 19.5\ s^{-1}$, $k_{-2} = 18\ s^{-1}$, force ionique = 0.5 M, $\lambda = 570$ nm, $[Cu(II)] = 2.13 \times 10^{-3}$ M, $[aH] = 5 \times 10^{-3}$ M, $T = 25$ °C.

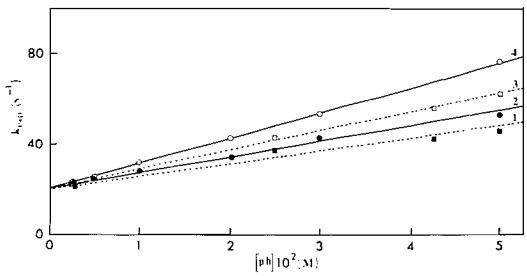

FIG. 2. Variation de la constante de vitesse de dissociation de $Cu(II)\cdot(aH)_2$ avec la concentration en polyphosphate. (1) pyrophosphate, $pH = 3.5$; (2) tripolyphosphate, $pH = 3.5$; (3) pyrophosphate, $pH = 4.5$; (4) tripolyphosphate, $pH = 4.0$. $T = 25$ °C; $[Cu(II)] = 2.13 \times 10^{-3}$ M; [adénine] $= 5.0 \times 10^{-3}$ M; force ionique = 0.5 M; $\lambda = 570$ nm.

polyphosphate, correspond au déplacement des éqs. 2 et 3 vers la gauche, avec la réaction 3 comme étape lente, suivi de la réaction rapide du Cu(II) avec le polyphosphate et (*ii*) l'autre, qui est d'ordre un en polyphosphate, serait la réaction d'échange d'après l'éq. 9.

$$[9] \qquad Cu(II)\cdot(aH)_2 + ph \xrightarrow{k_5} Cu(II)\cdot ph + 2aH$$

La constante expérimentale correspondant à ce mécanisme est donnée par l'éq. 10.

$$[10] \qquad k\ exp = k_{-2} + k_5\,[ph]$$

La pente des droites de la fig. 2 donne k_5, qui, comme attendu, varie avec le pH du milieu. Bien que le mécanisme de cette réaction nécessiterait une étude plus approfondie, l'on peut déjà conclure que k_5 augmente avec la basicité du ligand entrant. En effet, l'augmentation du pH favorisant les espèces les moins protonées, donc les plus basiques, entraîne l'augmentation de k_5. Ceci permet aussi de suggérer qu'une catalyse acide générale est à exclure dans ce cas.

Le fait que toutes les droites ont la même ordonnée à l'origine, soit environ $20\ s^{-1}$ correspondant à k_{-2}, montre que l'éq. 10 est bien vérifiée.

(4) Etude du système Cu(II)·adénine en milieu basique

L'existence de complexes du Cu(II) avec l'adénine ayant perdu un proton a été mise en évidence par des mesures potentiométriques (2, 3). On a pu montrer par une étude potentiométrique la formation de deux types de complexes, ayant des constantes de stabilité assez

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

élevées, soit: $Cu(II)(OH)_n\cdot(a^-)(\log K_1 = 6.99)$ et $Cu(II)(OH)_m\cdot(a^-)_2(\log K_2 = 6.3)$ (5).

L'étude spectrophotométrique de ce système montre que ces deux complexes peuvent être différenciés et que leur importance varie avec les conditions expérimentales. A pH = 8.8 avec un rapport [aH]/[Cu(II)] = 4, on a le complexe $Cu(II)(OH)_m\cdot(a^-)_2$, de couleur violette, qui absorbe à λ_{max} = 570 nm. Une augmentation du pH jusqu'à pH = 11.5 entraîne le déplacement de la bande vers les plus grandes longueurs d'onde (λ_{max} = 630 nm), correspondant à la formation de $Cu(II)\cdot(OH)^-_n\cdot(a^-)$, de couleur bleu qui est le seul complexe observé pour un rapport Cu(II)/aH = 1. Les deux complexes semblent contenir un nombre d'ions hydroxyles différent ($n > m$) ce qui explique le changement observé avec l'augmentation du pH. Comme ce comportement n'est pas prévu d'après les résultats de Reinert et Weiss (5), il est clair qu'une étude plus approfondie de ce système est encore nécessaire.

L'étude cinétique a révélé que la formation des complexes était trop rapide pour être étudiée par "flux stoppé"; la très grande stabilité des complexes rend la méthode de relaxation inutilisable. Les constantes de vitesse de dissociation ont, néanmoins, pu être déterminées en étudiant la réaction d'échange avec l'EDTA.

Pour simplifier l'étude, on a choisi tout d'abord des conditions expérimentales où $Cu(II)\cdot(OH^-)_n\cdot(a^-)$ prédomine. En mélangeant une solution du complexe avec une solution d'EDTA au même pH, on observe une seule réaction dont la vitesse expérimentale d'ordre un varie linéairement avec la concentration en EDTA et un mécanisme par deux voies parallèles est en accord avec les résultats:

$$[11]\quad Cu(II)\cdot(OH^-)_n(a^-) \xrightarrow{k_6} Cu(II)\cdot(OH^-)_n + a^-$$

$$[12]\quad Cu(II)\cdot(OH^-)_n + EDTA \xrightarrow{\text{rapide}} Cu(II)\cdot EDTA$$

$$[13]\quad Cu(II)\cdot(OH^-)_n(a^-) + EDTA \xrightarrow{k_7} Cu(II)\cdot EDTA + a^-$$

Les éqs. 11 et 12 correspondent à la dissociation du complexe suivie de la formation rapide de Cu(II)·EDTA. L'éq. 13 correspond à la réaction d'échange dont le mécanisme détaillé reste encore à élucider. La constante de vitesse expérimentale est donnée par:

$$[14]\quad k_{exp} = k_6 + k_7\,[EDTA]$$

Par voie graphique, on obtient à 25 °C: k_6 = 0.05 s^{-1} et k_7 = 7.5 $M^{-1}\,s^{-1}$. On peut aussi estimer la constante de vitesse de formation du complexe, en utilisant la valeur de la constante d'équilibre, à environ $5 \times 10^5\ M^{-1}\,s^{-1}$.

TABLEAU 6. Variation de la constante expérimentale de dissociation en fonction de la concentration en EDTA pour les complexes $Cu(II)(OH^-)_n\cdot(a^-)$ et $Cu(II)(OH^-)_m\cdot(a^-)_2$*

[EDTA] (M)	k_{exp} (a) (s^{-1})	k_{exp} (b) (s^{-1})	k_{exp} (c) (s^{-1})
0.085	0.64	0.63	173
0.075	0.58	0.53	173
0.050	0.40	0.38	173
0.0375	0.34	0.29	173
0.025	0.23	0.20	153
0.010	0.11	0.12	115

*k_{-6} = 0.05 s^{-1}, pour le complexe $Cu(II)(OH^-)_n\cdot(a^-)$ [Cu(II)] = 3.6×10^{-3} M, force ionique = 0.5 M, T = 25 °C; (a) pH = 11.0, [aH] = 0.02 M, λ = 290 nm; (b) réaction lente, pH = 9.0, [aH] = 0.01 M, λ = 570 nm; (c) réaction rapide, pH = 9.0, [aH] = 0.01 M, λ = 570 nm.

Quand on étudie la réaction à pH = 9 où $Cu(II)\cdot(OH^-)_m(a^-)_2$ prédomine, deux réactions sont observées. La réaction la plus rapide ($\tau_{\frac{1}{2}} \sim 4$ ms) est attribuée à la dissociation de $Cu(II)\cdot(OH^-)_m(a^-)_2$; dans le domaine de concentration accessible expérimentalement, la constante de vitesse de cette réaction semble être indépendante de la concentration en EDTA, bien qu'à faible concentration on observe une diminution (voir tableau 6), ce qui indiquerait qu'il s'agit de la dissociation de $Cu(II)\cdot(OH^-)_m(a^-)_2$. Malheureusement, le signal faible ne permet pas une étude quantitative plus poussée.

La réaction lente correspond à celle étudiée à pH = 11 et les constantes de vitesse correspondent à celle obtenue a ce pH.

Il est à noter que ces réactions sont de type différent de celles observées dans le cas du système Cu(II)·adénosine en milieu basique; dans ce dernier cas la coordination s'effectue au moyen des groupes hydroxyles du ribose. Ceci se reflète dans la valeur des constantes de vitesse de dissociation de complexes et les constantes de vitesse d'échange avec l'EDTA (14).

Conclusion

L'adénine et le Cu(II) forment en solution divers complexes, suivant le domaine de leur concentration et le pH de la solution, qui ont été étudiés au point de vue cinétique.

En milieu acide, les constantes de vitesse de formation et de dissociation du complex Cu(II)·

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$(aH)_2$ ont pu être mesurées; la formation de ce complexe se fait d'un facteur de dix plus rapidement que celle de Cu(II)·adénosine, mais nettement plus lentement que celle de Cu(II)·aH.

A pH < 3 les formes protonées jouent un rôle prépondérant; le temps de relaxation diminue avec la diminution du pH, ce qui est attribué à la décomposition rapide du complexe protoné $Cu(II)\cdot(aH)_2H^+$.

Les complexes existant en milieu basique ont pu être étudiés grâce à leurs réactions d'échange avec l'EDTA. A pH 11 la dissociation du complexe $Cu(II)\cdot(OH^-)_n(a^-)$ se fait parallèlement à la réaction d'échange. Ceci est analogue aux réactions des complexes Cu(II)–adénosine avec l'EDTA en milieu basique (14).

A pH 9 deux réactions successives ont pu être mises en évidence; la premiére, la plus rapide, correspond à la dissociation de $Cu(II)\cdot(OH^-)_m(a^-)_2$ et la deuxième est la réaction observée à pH 11.

Bien que nos résultats aient été obtenus en milieu acide ou basique à cause de limitations expérimentales, ils permettent néanmoins d'élucider la complexité de la cinétique de l'interaction Cu(II)–adénine aux pH physiologiques où plusieurs de ces complexes coexistent.

Les auteurs remercient le Ministère de l'Education du Québec pour l'octroi qui a rendu possible la réalisation de ce travail et le Conseil national de recherches du Canada pour la bourse d'entretien accordée (G.B.).

4-Chlorothiane 1-Oxide Conformations: a Large 1,4-Dipolar Effect

GORDON WOOD, C. C. BARKER[1], AND ANNE KLIGERMAN
Department of Chemistry, University of Windsor, Windsor 11, Ontario

Received May 24, 1973

Conformational ratios of *cis*- and *trans*-4-chlorothiane 1-oxide were obtained through low temperature n.m.r. studies. The former compound exists predominantly in the S—O axial form (74:26) and the latter almost exclusively in the S—O axial form (at least 96:4). The *cis* compound approximates additive behavior; the large discrepancy in the *trans* compound is consistent with a 1,4-dipolar interaction.

Les rapports conformationnels des oxydes des chloro-4-thiane-1 *cis* et *trans* ont été obtenus par études r.m.n. à basse température. Le premier composé existe principalement (74:26) dans la forme avec le groupe S—O axial alors que le deuxième existe presqu'exclusivement (au moins 96:4) avec le S—O axial. Les caractéristiques du produit *cis* sont approximativement celles que l'on peut évaluer sur la base de propriétés additives; le fait que cette propriété soit loin d'être vérifiée avec l'isomère *trans* indiquerait qu'une forte interaction dépolarisée 1,4 est présente.

[Traduit par le journal]

Can. J. Chem., 51, 3329 (1973)

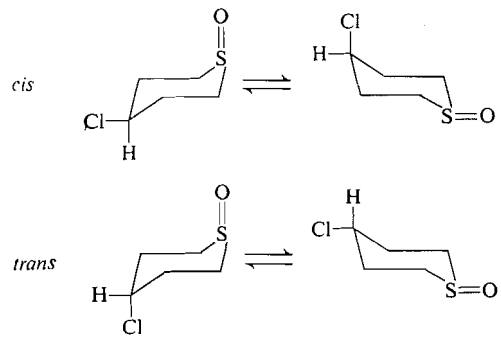
Introduction

In the past five years numerous conformational studies on six-membered ring compounds have suggested that 1,4-interactions of polar substituents are important (1–3). The 4-chlorothiane 1-oxides are particularly interesting in this connection because of the unusual preference of the S=O group for the axial position.

The only attempt to assign conformations to these compounds to date (4) was based on i.r. studies which required an assumption about the relative extinction coefficients of axial and equatorial C—Cl bonds. The approximate result for the *cis* compound obtained in this work (1:1 ratio) was not in strict agreement with additivity of ΔG° values (additivity is expected since electrostatic interactions are equal in both chair conformations). The result for the *trans* compound deviated significantly from additivity in a direction consistent with a 1,4 electrostatic effect. (The estimate of 8:1 in favor of the diaxial form implies a 1.2 kcal/mol preference, whereas additivity would predict −0.2 kcal/mol.)

We undertook to determine the conformational ratios for these compounds through the more direct low temperature n.m.r. procedure by measurement of integrated intensities of the methine proton at C-4 (below coalescence).

[1]Taken in part from the M.Sc. Thesis of C. C. Barker, University of Windsor, October, 1971.



Results and Discussion

The isomeric 4-chlorothiane 1-oxides were prepared by oxidation of the corresponding sulfides and separated by fractional crystallization and sublimation.

A solution (10% in CD_2Cl_2) of *cis*-4-chlorothiane 1-oxide had a methine signal at $\delta = 4.1$ which showed coalescence between −50 and −55° and clean separation of two peaks below −70°. Several scans of the spectrum at −75° and integration yielded a ratio of 26:74 for the methine signals. The former was downfield by 28 Hz and had a $w_{1/2}$ of 8.5 Hz and was therefore assigned to equatorial hydrogen. The larger signal had $w_{1/2}$ of 21.3 Hz centered at 241 Hz and was assigned to axial hydrogen. The weighted average of the half-widths of the two signals at low temperature is 18 Hz, which agrees reasonably well with 15 Hz found at room temperature.

The discrepancy could be caused in part by an entropy factor, although reduced resolution (0.6 Hz) at the lower temperature may also be a factor.

A solution (3% in CD_2Cl_2) of the *trans* compound showed a methine proton signal with $w_{1/2} = 10$ Hz at $\delta = 4.5$ which underwent no observable change on cooling to $-84°$. The methine signal was predominantly equatorial ($w_{1/2} = 9$ Hz at $-65°$). Since the limit of detection was estimated at 4% (see Experimental), we conclude that the *trans* isomer is at least 96% in the diaxial form. The low temperature experiment on this compound was repeated in CD_2Cl_2–$ClCD_2CD_2Cl$ solution. No change in the signal with temperature was noted but interference from solvent absorption could perhaps have obscured a small signal. The fact that the $w_{1/2}$ observed at $-65°$ is less than at room temperature suggests that a small amount of axial proton may be present at room temperature, so that the estimate of 96% equatorial proton should be fairly close to the true value.

Comparison of these results with the previous work (4) shows some disagreement and, in particular, the new results are more consistent with additivity of conformational free energies for the *cis* compound. Using the "best value" (5) for chlorine and for S=O, the value determined for thiane oxide (6), additivity would give $\Delta G° = +0.4\,(Cl) - (-0.2)\,(S{=}O) = 0.6$ kcal/mol. (The sign convention emphasizes that S=O prefers the axial position.) This rough calculation agrees reasonably well with the present experimental result of 0.4 kcal/mol favoring the S=O axial, Cl equatorial form.

The n.m.r. result for the *trans* compound corresponds to a minimum value of 1.3 kcal/mol of preference for the diaxial form at $-65°$. Additivity would give a 0.2 kcal/mol preference for the diequatorial form and the discrepancy is thus 1.5 kcal/mol. We attribute this discrepancy to a 1,4-dipolar effect; to our knowledge this is the largest deviation from additivity of this kind yet observed. Some perspective on the magnitude of this effect may be gained by comparison with related systems.

It should be pointed out that while the i.r. method suffers from the lack of verifiable extinction coefficients, our low temperature work was done in different solvents and part of the disagreement with the earlier work may result from this fact.

Rationalization of 1,4-dipolar effects by resort to calculation has not been very productive so far (3*a*). The result presented here is particularly difficult to understand in terms of simple electrostatic interactions, because the positive charge on the ring atom (sulfur) is partial, whereas in the piperidinium system it is approximately unity. It is possible that the partial negative charge on oxygen increases the diaxial preference. The related cyclic sulfone was synthesized for comparison, but gave no evidence for the presence of a form with equatorial chlorine (methine $w_{1/2} = 7.5$ Hz, unchanged except for some loss of resolution between $+30$ and $-120°$).[2]

Experimental

All melting points were determined on a Fisher–Johns melting point block and are uncorrected. G.l.c. was conducted on an F. and M. Model 720 instrument using a 6 ft × 1/2 in. silicone gum rubber column (GE XE-60). The i.r. spectra were recorded on a Beckman Model IR-12 spectrometer. Ambient n.m.r. spectra were recorded on a JEOLCO JNM-C60S spectrometer in CD_2Cl_2 solution. Low temperature n.m.r. spectra were taken on a JNM-C60HL spectrometer with a JRA-1 accumulator using solutions in CD_2Cl_2. Saturation was shown to have a negligible effect on the area ratio for the *cis* compound by increasing the r.f. level.

3-Carbomethoxy-4-oxothiacyclohexane

Cyclization of dimethyl 3,3-thiodipropionate (Aldrich) followed the procedure of Onesta and Castelfranchi (7).

4-Chlorothiopyrane

The three-step procedure of Adlerova and Protiva (8) was used to convert the cyclization product to 4-chlorothiopyrane.

4-Chlorothiane-1-oxide

The oxide (mixed isomers) was prepared by periodate oxidation (9) of 4-chlorothiopyrane. Overall yield for the five steps was 15%.

Separation of cis- and trans-4-Chlorothiane 1-Oxide

A crude sample of the mixed isomers (2.2 g) was recrystallized from CCl_4. The needle-like crystals (0.8 g), after repeated crystallization, yielded a pure (98% by g.l.c.) sample of *cis*-4-chlorothiane 1-oxide, m.p. 119–123° (lit. 120–121° (4)). The n.m.r. spectrum had a single methine proton band at 4.1 p.p.m. (246 Hz, previously reported (4) 251 Hz). The i.r. spectrum showed sulfoxide (S=O) absorption at 1000–1100 cm^{-1} and C—Cl stretching at 760 cm^{-1} (KBr) and in CS_2, 729, 756 cm^{-1} (lit. 719, 748 (4)).

Anal. Calcd. for C_5H_9ClOS: C, 39.3; H, 5.9; Cl, 23.2. Found: C, 39.8; H, 6.2; Cl, 22.9.

The residue from initial CCl_4 crystallization was alternately sublimed and the sublimate crystallized from

CCl_4 to remove the last trace of *cis* isomer. Finally, the residue was crystallized from petroleum ether to a purity of 98% (g.l.c.). The n.m.r. spectrum showed a single methine band at 4.5 p.p.m. (270 Hz, previously reported (4) at 271 Hz). The i.r. spectrum had sulfoxide (S=O) absorption at 1000–1100 cm^{-1} and C—Cl stretching bands (CS_2 solution) at 765 and 719 cm^{-1} (lit. 747, 714 cm^{-1} (4)).

Anal. Calcd. for C_5H_9ClOS: C, 39.3; H, 5.9; Cl, 23.2. Found: C, 39.6; H, 6.1; Cl, 23.1.

Estimation of Detection Limit in trans-1-Chlorothiane 1-Oxide

Two attempts were made to estimate the concentration of minor conformer (equatorial Cl, equatorial S=O) present in the *trans* compound. Accumulation of 36 scans of the low temperature spectrum showed no sign of an additional signal in the appropriate region. Finally, addition of small amounts of the *cis* isomer to the 3% CD_2Cl_2 solution of the *trans* compound demonstrated that at a *trans*:*cis* ratio of 98:2, the minor signal was not detected, but at 96:4 it was.

We wish to acknowledge the technical assistance of Mr. D. Hill and Dr. M. H. Miskow in obtaining n.m.r. spectra, and of Mr. Brian Adlam for the 4-chlorothiane 1,1-dioxide experiment.

The financial assistance of the National Research Council of Canada is gratefully acknowledged.

Binary Dinitrogen Complexes of Rhodium, $Rh(N_2)_n$ (where n = 1–4), in Low Temperature Matrices

GEOFFREY A. OZIN AND ANTHONY VANDER VOET

Lash Miller Chemical Laboratories and Erindale College, University of Toronto, Toronto, Ontario M5S 1A1

Received March 19, 1973

The products of the cocondensation reactions of Rh atoms with N_2 and N_2/Ar mixtures at 10 °K are investigated by matrix isolation infrared spectroscopy and are shown to be binary dinitrogen complexes of the form $Rh(N_2)_n$. Examination of the reaction products in pure $^{14}N_2$, $^{15}N_2$, $^{14}N_2/^{15}N_2$, and in dilute $Ar/^{14}N_2$, $Ar/^{14}N_2/^{15}N_2$, and $Ar/^{14}N_2/^{14}N^{15}N/^{15}N_2$ matrices establish the values of n to be 1-4. Isotopic frequencies are computed for the NN stretching modes of the individual dinitrogen complexes on the basis of the Cotton–Kraihanzel (C.K.) force field approximation and are found to be in close agreement with observed values. Trends in the best fit C.K. force constants for $Rh(N_2)_n$ (n = 1-4) and the thermodynamic stabilities of the individual complexes as indicated by the function ΔH_c^n, a measure of the enthalpy of decomposition, are discussed. Comparisons are made between $Ni(N_2)_n$ and $Rh(N_2)_n$ (where n = 1–4). The structure of $Rh(N_2)_4$ in solid nitrogen is shown to be that of a distorted tetrahedron. Calculations show that a site symmetry of D_{2d} for $Rh(N_2)_4$ satisfactorily accounts for all of the spectral lines observed for the complex in nitrogen. In solid argon, $Rh(N_2)_4$ appears to have an approximately regular tetrahedral structure. The relationship between RhN_2 and N_2 chemisorbed on Rh metal is discussed and compared with the analogous Ni–, Pd–, and Pt–nitrogen systems.

Les produits de réactions de cocondensation des atomes Rh sur N_2 et sur des mélanges N_2/Ar à 10 °K, ont été étudiés par spectroscopie infrarouge sur des matrices isolées. Les produits formés sont des complexes binaires diazotés du type $Rh(N_2)_n$. L'examen des produits de réaction dans des matrices pures de $^{14}N_2$, $^{15}N_2$, $^{14}N_2/^{15}N_2$ et diluées de $Ar/^{14}N_2$, $Ar/^{14}N_2/^{15}N_2$ et $Ar/^{14}N_2/^{14}N^{15}N/^{15}N_2$, permet d'établir les valeurs de n de 1 à 4. Les fréquences isotopiques ont été calculées pour les vibrations d'élongation NN dans les complexes diazotés individuels sur la base de l'approximation du champ de force de Cotton–Kraihanzel (C.K.); un accord proche des valeurs observées a été trouvé. Les tendances dans les meilleures constantes de force C.K. pour $Rh(N_2)_n$ (n = 1 à 4) et les stabilités thermodynamiques des complexes individuels indiquées par ΔH_c^n (qui mesure l'enthalpie de décomposition) ont été discutées. Des comparaisons entre $Ni(N_2)_4$ et $Rh(N_2)_4$ ont été faites (où n = 1 à 4). La structure de $Rh(N_2)_4$ dans l'azote solide est celle d'un tétraèdre distordu. Les calculs montrent qu'un site de symétrie D_{2d} pour $Rh(N_2)_4$ tient compte de façon satisfaisante de toutes les raies spectrales observées pour ce complexe dans l'azote. Dans l'argon solide, $Rh(N_2)_4$ apparaît sous forme de tétraèdre approximativement régulier. La relation entre RhN_2 et N_2 chimisorbé sur Rh métal a été discutée et comparée avec les systèmes analogues Ni–, Pd–, Pt– azote. [Traduit par le journal]

Introduction

Because of their relationship to biological nitrogen fixation problems and transition metal carbonyl complexes, inorganic compounds containing molecular dinitrogen as a ligand have been of considerable interest to both synthetic and structural chemists. Many of the transition metals have been shown to form stable complexes (1, 2) with one or two dinitrogen groups coordinated to the metal atom.

Recently, matrix isolation vibrational spectroscopy of metal atom vapors cocondensed with molecular nitrogen have shown the existence of binary transition metal dinitrogen compounds $M(N_2)_n$, with as many as four dinitrogen molecules coordinated to a single metal atom (3, 4). One of the obvious benefits of the study of these matrix isolated species (as well as the analogous $M(CO)_n$ (5, 6) and $M(O_2)_m$ (7) complexes) is the ability to study the effect of increased coordination on the strengths of the ligand and metal–ligand bonds, without the necessity of including other stabilizing ligands. This, in conjunction with the ability to prepare mixed ligand species such as $Ni(CO)_n(N_2)_{4-n}$ (8) and $Ni(O_2)(N_2)_m$ (9) (n = 1–3, m = 1, 2) also enables direct comparison of the sigma and pi bonding characteristics of different ligands when bonded to the same metal atom and competing for the same bonding electrons.

In the majority of these binary dinitrogen complexes the molecular ligand was shown by

$^{14}N^{15}N$ isotopic substitution to be bonded in an "end-on" fashion, and in the unmixed species to have molecular structures analogous to the metal carbonyls, for example, tetrahedral $Ni(N_2)_4$ and $Ni(CO)_4$ (3), trigonal planar $Pd(N_2)_3$ and $Pd(CO)_3$ (3, 6), linear symmetrical $Pd(N_2)_2$ and $Pd(CO)_2$ (3, 6), etc.

An exception to this mode of bonding was observed in the products of the cocondensation of cobalt atoms and dilute N_2/Ar matrices where the $Co(N_2)$ species was shown to have the N_2 ligand bonded in a dihapto or side-on manner (10). Moreover, the products of co-condensing Co atoms with pure nitrogen gave rise to a (as yet unassigned (11)) four line spectrum in the NN stretching region, belonging to a single species, an unusual result when compared to the Ni, Pd, and Pt systems. The investigation of the rhodium/dinitrogen system is therefore an important next step in the understanding and identification of the cobalt dinitrogen compounds and indeed of all members of the group. Accordingly, cocondensation reactions of rhodium atoms with pure nitrogen and nitrogen–argon mixtures were undertaken. The results are reported in the following sections.

Experimental

Monatomic Rh vapor was generated by directly heating a thin (0.005 in.) ribbon filament of Rh with AC. The rhodium (99.99%) was supplied by McKay Inc., New York. Research grade $^{14}N_2$ (99.99%) and Ar (99.99%) were supplied by Matheson. Isotopically enriched $^{15}N_2$ (99.5%) was supplied by Prochem.

The furnace used for the evaporation of the metals has been described previously (12). The rate of metal atom depositions was continuously monitored using a quartz crystal microbalance (13). In the infrared experiments matrices were deposited on a cryotip cooled to 10 °K by means of an Air Products Displex closed cycle helium refrigerator. Spectra were recorded on a Beckmann IR 12 spectrophotometer.

Results and Discussion

Rhodium Monodinitrogen, $Rh(N_2)$

Cocondensation of rhodium atoms with very dilute nitrogen–argon mixtures ($^{14}N_2$:Ar < 1:250) at 10 °K gave rise to an intense infrared absorption band at 2154 cm^{-1}. When slightly higher concentration matrices were used, for example, $^{14}N_2$:Ar = 1:250 to 1:100 (see Fig. 1*A*), the most intense absorption band was still at 2154 cm^{-1} but was accompanied by a very weak shoulder at 2159 cm^{-1} (shown below to be a matrix splitting of the 2154 cm^{-1} band) and another weak band at 2188 cm^{-1} which under high resolution was also a closely spaced doublet, 2189/2186.5 cm^{-1} (Fig. 1*A*), also attributed to a matrix splitting. Warm-up experiments performed on these dilute $^{14}N_2$/Ar matrices indicated the gradual disappearance of the band at 2154 cm^{-1}, the increase in intensity of the 2188 cm^{-1} band, and the appearance of a new band at 2195 cm^{-1} and a stronger doublet at 2179.5/2175 cm^{-1}. The spectrum obtained after warm-up of the $^{14}N_2$:Ar = 1:100 matrix to 30–35 °K is shown in Fig. 1*B*, where it is seen that the 2159/2154 cm^{-1} doublet has almost completely disappeared and the bands at 2195, 2188, and 2179.5/2175 cm^{-1} predominate. These four main lines grew and decayed at different rates during warm-up experiments and appeared with markedly different relative intensities in experiments in which the $^{14}N_2$:Ar ratio was varied. This behavior suggested the formation of at least *four* different dinitrogen species from the Rh/N_2 matrix cocondensation reaction. *A priori* the complex of lowest coordination number could be associated with the main absorption band at 2154 cm^{-1} observed in very dilute mixtures. The stoichiometry of this species was defined by examining the products

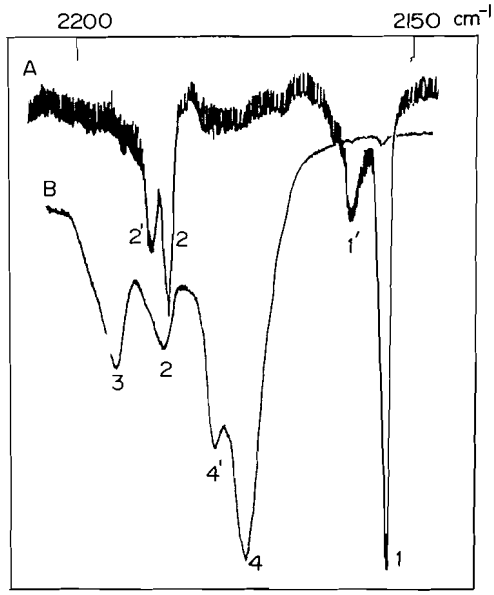

FIG. 1. The matrix infrared spectrum of the products of the cocondensation reaction of Rh atoms with $^{14}N_2$:Ar = 1:100 (*A*) after deposition at 10 °K and (*B*) after warm-up to 30–35 °K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

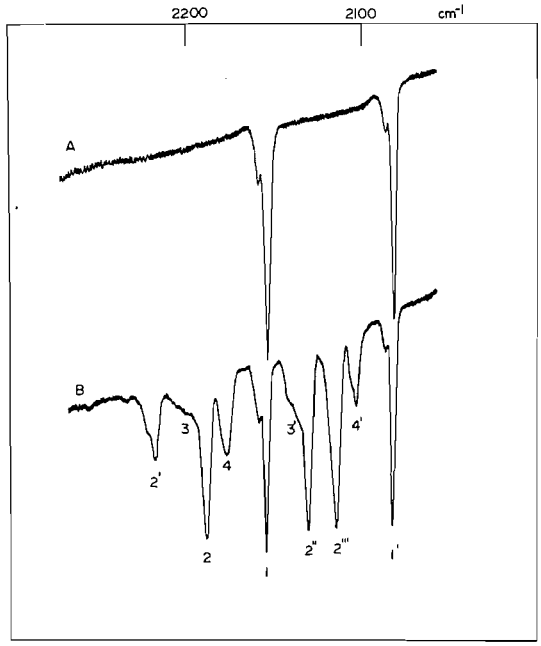

FIG. 2. The matrix infrared spectrum of the products of the cocondensation reaction of Rh atoms with $^{14}N_2$:$^{15}N_2$:Ar ≅ 1:1:500 (*A*) after deposition at 10 °K and (*B*) after warm-up to 20–25 °K.

of the cocondensation reaction of Rh atoms with $^{14}N_2$:$^{15}N_2$:Ar ≅ 1:1:500 at 10 °K. The spectrum, given in Fig. 2*A*, shows that the 2159/2154 cm^{-1} absorption has a *single* nitrogen-15 counterpart absorption at 2088/2083 cm^{-1}. This doublet isotope pattern is characteristic of a monodinitrogen species where the lines at 2159/2154 and 2088/2083 cm^{-1} are assigned to Rh$^{14}N_2$ and Rh$^{15}N_2$, respectively. Cocondensation of Rh atoms with a statistically scrambled isotopic mixture $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$:Ar = 1:2:1:2000 resulted in a spectrum containing *four* lines of almost *equal* intensity (Fig. 3) at 2154.1, 2119.7, 2118.0, and 2082.5 cm^{-1}. The equality of the band intensities, the similar band widths at half height (≃1.0 cm^{-1}), and the 1.7 cm^{-1} separation observed for the central Rh($^{14}N^{15}N$)/Rh($^{15}N^{14}N$) doublet prove unequivocally that the dinitrogen ligand in Rh(N_2) is bonded in an "end-on" fashion to the rhodium atom.

Rhodium Tetradinitrogen, Rh(N_2)$_4$

When Rh atoms were cocondensed with a 1:10 mixture of $^{14}N_2$ in Ar at 10 °K the matrix infrared spectrum shown in Fig. 4*A* was obtained. Intense absorptions were observed at 2196, 2188, 2177.5, and 2154.5 cm^{-1} with very weak bands at approximately 2232 and 2136 cm^{-1}. Upon warm-up in the range 10–40 °K the *four* main bands grew and decayed in intensity at different rates (see Fig. 4(*B–D*)) yielding finally a strong line at 2177.5 cm^{-1} with a weaker line at 2196 and a shoulder at 2187 cm^{-1}. Prolonged warm-ups at 35–40 °K gave a final spectrum showing the bands at 2196 cm^{-1} and 2177.5 cm^{-1}. The very weak lines observed at about 2232 and 2136 cm^{-1} on deposition grew in intensity on warm-up to 40 °K and were assigned to aggregate species (see later). The results of more dilute $^{14}N_2$/Ar experiments (1/100 and 1/250, see, for example, Fig. 1) initially showed absorptions at 2159/2154 cm^{-1} (RhN_2) and at 2188 cm^{-1}. However, the warm-up characteristics of these matrices paralleled the behavior of the $^{14}N_2$/Ar = 1/10 experiments. A *prima facie* interpretation suggests, therefore, that all four Rh/N_2 species were formed in the concentrated N_2/Ar matrices when initially deposited at 10 °K and that the band at 2177.5 cm^{-1} (2179.5/2175 cm^{-1} in more dilute matrices) probably corresponds to the highest coordinated species.

Rh atoms were cocondensed with pure $^{14}N_2$ at 10 °K and yielded the infrared spectrum shown

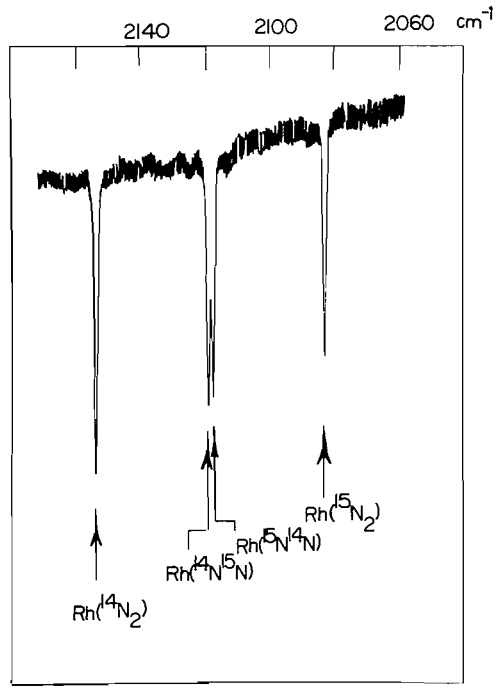

FIG. 3. The matrix infrared spectrum of the products of the cocondensation reaction of Rh atoms with $^{14}N_2$:$^{14}N^{15}N$:$^{15}N_2$:Ar ≅ 1:2:1:2000 at 10 °K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

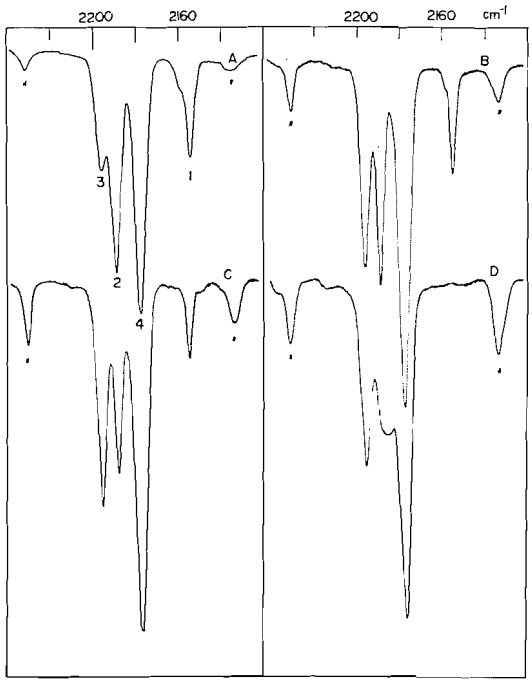

FIG. 4. The matrix infrared spectrum of the products of the cocondensation reaction of Rh atoms and $^{14}N_2$:Ar = 1:10 (*A*) after deposition at 10 °K, (*B–D*) after successive warm-up experiments at 20, 30, and 35–40 °K, respectively. The asterisks indicate aggregate species (see text).

in Fig. 5*A*. The spectrum showed a very intense absorption at 2179 cm^{-1}, an absorption of medium intensity at 2203 cm^{-1}, and two extremely weak absorptions at about 2238 and 2218 cm^{-1}. The relative intensities of the two bands at 2179 and 2203 cm^{-1} were essentially invariant to changes in the rate of deposition of Rh atoms. In addition it was observed that in matrix warm-ups to 35–40 °K the intensities of the main lines at 2203/2179 cm^{-1} gradually *decreased* retaining approximately equal relative intensities (Fig. 5*B*). The very weak lines originally at 2238 and 2218 cm^{-1} grew in intensity during warm-up to yield lines at 2242/2238 and 2218/2215 cm^{-1} (Fig. 5*B*) as well as another very weak line at about 2113 cm^{-1} and are assigned to rhodium–nitrogen aggregate species (see later for details). The frequencies observed after the cocondensation of Rh atoms with $^{14}N_2$:$^{15}N_2$ = 1:1 are listed in Table 1. These and the intensity pattern are reminiscent of the results obtained in the analogous $Ni(^{14}N_2)_n$-$(^{15}N_2)_{4-n}$ system (where n = 0–4) in solid N_2 (3).

Since the principal band at 2179 cm^{-1} appears to correspond to the 2177.5 cm^{-1} line in N_2/Ar matrices,[1] and since one must conclude that the 2203 cm^{-1} line derives from the same species as the 2179 cm^{-1} line, both bands can be assigned to $Rh(N_2)_4$. The two lines must arise therefore from the *partial* or complete removal of the degeneracy of either the T_2 (tetrahedral) or E_u (square planar) NN stretching mode in the lattice of α-$^{14}N_2$ (the low temperature phase of solid N_2 (14)).

An attempt to obtain isotopic frequencies of $Rh(N_2)_4$ and to avoid the distortion problem by deposition of Rh atoms with a $^{14}N_2/^{15}N_2$/Ar = 1/1/20 mixture and warming the matrix to 35–40 °K was considered. However, since after warm-up of $^{14}N_2$/Ar = 1/10 matrices over a prolonged period of time the 2196 cm^{-1} band persists with medium intensity, it was felt that the intermediate responsible for this line would be present as well in the isotopic experiment with bands of intensity sufficient to obscure some of the isotopic components of $Rh(^{14}N_2)_n$-

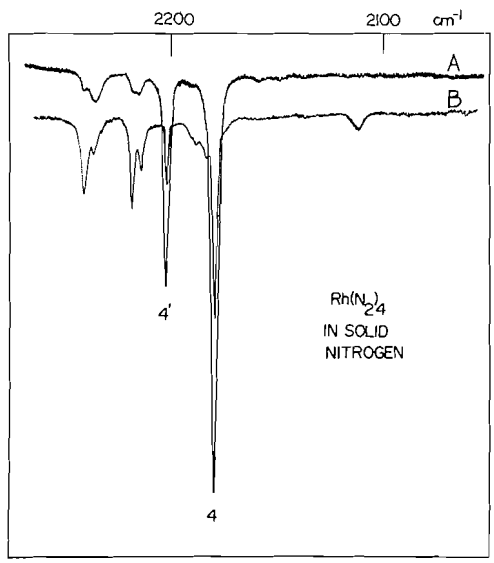

FIG. 5. The matrix infrared spectrum of the products of the cocondensation reaction of Rh atoms with pure $^{14}N_2$ (*A*) after deposition at 10 °K and (*B–C*) after warm-up to 25 and 35 °K, respectively.

[1]The much smaller doublet splitting for the T_2 or E_u mode of $Rh(N_2)_4$ in dilute N_2/Ar (1/250, 1/100) matrices observed at 2179.5/2175 cm^{-1} may also reflect a "slight" lattice perturbation of the regular symmetry but is a very much less serious effect than is observed in solid α-N_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$(^{15}N_2)_{4-n}$ (n = 0–4) and complicate the assignments. Thus this isotopic experiment was not thought to be worthwhile.

In order to clarify the structure of $Rh(N_2)_4$ in solid nitrogen and consequently in N_2/Ar matrices, one first assumes the perturbation to be caused by the coordinated dinitrogen molecules attempting to adopt, as much as possible, orientations similar to those they would have had in the pure unsubstituted nitrogen lattice. As in the $Ni(N_2)_4$ system (3), the rhodium atom would probably choose to reside in the more spacious substitutional site of the f.c.c. lattice of α-N_2. If the preferred interaction of the rhodium were with four tetrahedrally disposed nearest neighbor N_2 molecules, then the "distortion" of the end-on bonded N_2 molecules would be toward the substitutional site symmetry of N_2 in the unsubstituted lattice, *i.e.* C_2. Whether in actual fact the lattice affects the N—Rh—N skeletal angles or causes deviation of the Rh—N≡N angle away from linearity (which seems more likely), as shown below, cannot be determined. If the preferred interaction with four N_2 molecules in $Rh(N_2)_4$ were square planar (D_{4h}), the α-nitrogen lattice would favor the site symmetry C_{2h} with the C_2 axis in the square plane.

Therefore the 2203/2179 cm^{-1} doublet may arise from (*i*) a regular tetrahedral molecule whose symmetry is very *slightly* distorted towards D_{2d}, (*ii*) the same as (*i*) but with a considerable angular distortion towards D_{2d} ("squashed" tetrahedral molecule), or (*iii*) a regular square planar D_{4h} molecule whose symmetry is reduced to C_{2h} in the nitrogen lattice. A resumé of the splittings expected for the two possible $Rh(N_2)_4$ symmetries and the respective intensity relationships expected are compared with the observed data below.

	T_d	D_{2d}	ν_{NN}	I_E/I_{B_2} Calculated	I_E/I_{B_2} Observed
(*i*)	T_2	B_2	2203	$\tan^2(\theta/2) \cong 2(\theta = 109°28')$	3.59–3.89
		E	2179		
(*ii*)	T_2	B_2	2203	$\tan^2(\theta/2)$*	3.59–3.89
		E	2179		

	D_{4h}	C_{2h}	ν_{NN}	I_{B_u}/I_{A_u} Calculated	I_{B_u}/I_{A_u} Observed
(*iii*)	E_u	A_u	2203	1	3.59–3.89
		B_u	2179		

*Best fit for calculated value $\theta = 124°21' \rightarrow 126°21'$.

The results clearly indicate that the lattice distortion is to a D_{2d} configuration with an "effective" N_2—Rh—N_2 angle of $126°14' \rightarrow 124°21'$. The two intensity ratios and postulated angles given are compatible with the observed spectra on deposition at 10 °K and after diffusion controlled warm-up to 35 °K, respectively.

Frequency and C.K. Force Constant Calculations for $Rh(N_2)_4$ in Solid N_2

On the basis of the D_{2d} symmetry model, the C.K. force constants (15) were calculated by applying a least squares analysis of the observed isotopic frequencies for the six molecules $Rh(^{14}N_2)_n(^{15}N_2)_{4-n}$ (n = 0–4) shown below ($k_{NN,NN}$ is associated with θ and $k'_{NN,NN}$ with β).

The calculated and observed frequencies are compared in Table 1. (Included in the table are the best fit C.K. k_{NN} and $k_{NN,NN}$ force constants.) The agreement is within 3 cm^{-1} for all observed lines and provides convincing support for our vibrational assignment of these lines to $Rh(N_2)_4$ having distorted tetrahedral D_{2d} symmetry in solid α-N_2.

Rhodium Bisdinitrogen, $Rh(N_2)_2$, and Rhodium Trisdinitrogen, $Rh(N_2)_3$

The species giving rise to the two major bands at 2196 and 2188 cm^{-1}, observed on deposition of concentrated $^{14}N_2$/Ar = 1/10 matrices and during warm-up of dilute $^{14}N_2$/Ar matrices, have not as yet been characterized. A *prima*

facie assignment of these two lines, in light of the foregoing discussions, is to a bis- and trisdinitrogen dinitrogen complex.

$Rh(N_2)_2$

The 2188 cm^{-1} absorber was the *first* to appear on warm-up of very dilute N_2/Ar matrices initially showing only $Rh(N_2)$, and often accompanied $Rh(N_2)$ in more concentrated matrices, upon cocondensation at 10 °K. Warm-up studies indicated that as the 2188 cm^{-1} line intensity began to decrease, that of the band at 2179.5/2175 cm^{-1} assigned to $Rh(N_2)_4$ increased. At 35–40 °K the band assigned to $Rh(N_2)$ at 2159/2154 cm^{-1} had disappeared and a new band at 2196 cm^{-1} appeared. It is significant that in very dilute matrices this 2196 cm^{-1} line *only* appeared at the end of the warm-up experiments, whereas the $Rh(N_2)_4$ species (2179.5/2175 cm^{-1}) was already present. Only in more concentrated matrices ($^{14}N_2$/Ar = 1:10) did the 2196 cm^{-1} line appear with any appreciable intensity (see Fig. 4 and section on warm-up characteristics and stabilities).

When Rh atoms were cocondensed with an isotopic mixture $^{14}N_2$:$^{15}N_2$:Ar = 1:1:500 at 10 °K and warmed up to 20–25 °K, the isotopic counterparts of the band at 2188 cm^{-1} were observed. The spectrum is shown in Fig. 2*B* and in addition to the lines at 2159/2154 and 2088/2083 cm^{-1} assignable to $Rh(^{14}N_2)$ and $Rh(^{15}N_2)$, a *doublet of doublets* isotope pattern is observed at 2218, 2188 and 2130, 2115 cm^{-1}. Further warm-up studies of this matrix showed that these four bands behaved in a similar manner and could be assigned to the four expected NN stretching modes of the mixed isotopic bisdinitrogen molecules, $Rh(^{14}N_2)_n(^{15}N_2)_{2-n}$ (where n = 0–2). The observation of only one line at 2188 cm^{-1} in $^{14}N_2$/Ar matrices[2] assignable to a bisdinitrogen species, suggests that the $Rh(N_2)_2$ molecule is probably linear, with $D_{\infty h}$ symmetry (analogous to other transition metal binary carbonyl and dinitrogen compounds, observed thus far, *e.g.* $Ni(N_2)_2$, $Ni(CO)_2$, $Pd(CO)_2$, $Pd(N_2)_2$) (3, 5, 6). The C.K. force constants for $Rh(N_2)_2$ were calculated for a linear $D_{\infty h}$ molecule in the manner outlined for $Rh(N_2)_4$. Table 2 shows the results of the frequency calculation and lists the best fit C.K. k_{NN} and $k_{NN,NN}$ force constants. The agreement between the observed and calculated frequencies is within 1.7 cm^{-1} for all observed lines, indicating the assignment of these bands to a linear bisdinitrogen molecule to be compatible with the observed data.

$Rh(N_2)_3$

The characterization of a trisdinitrogen complex of rhodium proved to be difficult in part, because it was only when concentrated $^{14}N_2$/Ar matrices were used that the remaining unassigned band at 2196 cm^{-1} was observed with any appreciable intensity. Unfortunately, at these concentrations, mixed $^{14}N_2/^{15}N_2$/Ar experiments are complicated by the presence of the isotopic components of the bis- and tetradinitrogen molecules. Careful examination of

[2]The small splitting of this line (2.5 cm^{-1}) is ascribed to a matrix site splitting.

2120.4	2118	$Rh(^{15}N_2)_3$

*Assuming trigonal planar structure.
†Best fit NN C.K. force constants were $k_{NN} = 20.168$ and $k_{NN,NN} = 0.302$ mdyn/Å. Least squares analyses were performed with the assignment of the 2145 cm^{-1} band to both $Rh(^{14}N_2)_2(^{15}N_2)$ and $Rh(^{14}N_2)(^{15}N_2)_2$, the latter giving the best fit.
‡These two lines are expected to have low intensities compared to the corresponding isotopic line at 2145 cm^{-1}.
§Probably obscured by aggregate lines in this region (see text).
‖Expected to be overlapped by the stretching modes of $Rh(^{14}N_2)(^{15}N_2)$ at 2219.2 and 2130.0 cm^{-1} (see Table 3).

the spectra resulting from Rh atoms cocondensed with $^{14}N_2:^{15}N_2:Ar = 1:1:500$ at 10 °K and warm-up at 40 °K, resulted in the identification of two isotopic lines in the nitrogen-15 region at 2145 cm^{-1} and 2118 cm^{-1} which were not observed in any of the other runs and which are *not* assignable to $Rh(N_2)$, $Rh(N_2)_2$, or $Rh(N_2)_4$. These are associated with the expected $^{15}N_2$ modes of two of the isotopic trisdinitrogen molecules $Rh(^{14}N_2)_2(^{15}N_2)$, $Rh(^{14}N_2)(^{15}N_2)_2$, and $Rh(^{15}N_2)_3$, respectively. As the infrared absorption at 2196 cm^{-1} is the only major band which can be associated with $Rh(^{14}N_2)_3$ in $^{14}N_2$/Ar matrices, it is not unreasonable to assume a trigonal planar D_{3h} structure for the trisdinitrogen rhodium complex (similar to the known tris-complexes $Ni(CO)_3$, $Ni(N_2)_3$, $Pd(CO)_3$, $Pd(N_2)_3$, $Pt(CO)_3$, and $Pt(N_2)_3$) (3–6). The best fit C.K. force constants k_{NN} and $k_{NN,NN}$, were determined for planar $Rh(N_2)_3$, using the observed isotopic lines at 2196, 2145, and 2118 cm^{-1}. The calculated frequencies are listed in Table 3 and are in reasonably close agreement for the three observed lines and lend some support to the assignment.

The Observation of Low Frequency Skeletal Modes in $Rh(N_2)_n$ and the Nature of the Rh—N Band

The detection of low frequency modes for matrix isolated binary dinitrogen and carbonyl complexes has proven difficult on a number of previous occasions generally because of (*i*) the low matrix concentrations required for efficient isolation, (*ii*) the low absorptivities associated with these vibrations and the corresponding low intensities of the bands, and (*iii*) the occurrence of those modes below the low frequency limit of the infrared spectrometer.

In the case of $Rh(^{14}N_2)$ in pure $^{14}N_2$, only when the NN stretching mode at 2179.5 cm^{-1} was arranged to be fully absorbing was it possible to observe very weak broad infrared absorptions at 392–412, 532, and 543 cm^{-1} and a weak line at 345 cm^{-1}.

The mode in $Rh(^{14}N_2)_4$ at 345 cm^{-1} showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

a band width at half height of about 6.4 cm^{-1}. This mode in the $Rh(^{14}N_2)_n(^{15}N_2)_{4-n}$ spectrum was observed at about 343 cm^{-1} but with a corresponding band width of 11.0 cm^{-1} and could represent an envelope of all the νRh—N stretching modes of the isotopic molecules n = 0–4.[3] Molecular $Rh(^{14}N_2)_4$ has four infrared active vibrations of T_2 symmetry: νNN, stretching; δRh—N—N, bending; νRh—N, stretching; δNRhN, bending.

By analogy with $Ni(^{12}C^{16}O)_4$ which shows the δC—Ni—C mode at 80 cm^{-1}, it is unlikely that the δNRhN bending mode would be observed for $Rh(^{14}N_2)_4$, as the range of the spectrometer was 4000–200 cm^{-1}. The NN stretching mode (T_2) of $Rh(^{14}N_2)_4$ has been assigned, therefore it remains to identify the low frequency mode at 345 cm^{-1} as either the νRhN stretching or δRh—N—N deformational mode. In $Ni(^{12}C^{16}O)_4$ the corresponding νNiC and δNi—C—O vibrations lie at 423.1 and 458.9 cm^{-1}, where it is noteworthy that the νNiC stretching mode is by far the most intense. It thus seems reasonable to deduce that the band observed at 345 cm^{-1} for $Rh(^{14}N_2)_4$ is the T_2 νRhN metal–ligand stretching mode.[4] For the purpose of comparison we have listed below the observed metal–ligand infrared active stretching modes for a selection of binary dinitrogen and carbonyl complexes of Ni, Pd, and Pt.

Compound	νMN (cm^{-1})	k_{MN} (mdyn/Å)	Symmetry type	Reference
$Ni(N_2)_4$	283	0.81	T_2	3
$Rh(N_2)_4$	345	1.44	T_2*	This study
$Ni(CO)_4$	422	1.80	T_2	17
$Pd(CO)_4$	256	0.82	T_2	16
$Pt(CO)_4$	304	1.28	T_2	16
$Pd(N_2)_2$	340	1.25†	Σ_u^+	16

*Assumed to be approximately tetrahedral for the purpose of this discussion.
†Obtained using the approximation that $Pd(N_2)_2$ is PdX_2(X = 28 a.m.u.) and $\lambda = k_{PdN}(\mu_X + 2\mu_{Pd})$.

Clearly there is insufficient data for $Rh(^{14}N_2)_4$ to permit a complete vibrational analysis. However, it is interesting that a full analysis of $Ni(^{12}C^{16}O)_4$ (23) yielded potential energy distributions which indicated that there was very little coupling between the νNiC stretching and δNi—C—O deformational modes. Therefore, a reasonable estimate of the Rh—N bond stretching force constants may be obtained using a simple analysis, in which $Rh(^{14}N_2)_4$ is considered to be RhX_4, where X is treated as a point mass of 28 a.u. and $\lambda = k_{M-C}(\mu_X + \frac{4}{3}\mu_M)$ where μ_X and μ_M are the reciprocal masses of X and M respectively, k_{MC} is the M—C bond stretching force constant, and $\lambda = 0.58915\ (\nu/1000)^2$ where ν is the metal–ligand stretching frequency. The values obtained for various M—N and M—C bond stretching force constants using this approximation are shown in the above table. It is reassuring to note that the full analysis for $Ni(^{12}C^{16}O)_4$ based on all vibrations (23) yields a k_{NiC} of 1.98 mdyn/Å to be compared with 1.80 mdyn/Å obtained from the simple analysis.

[3]Low frequency modes associated with the molecules $Rh(N_2)_n$ (where n = 1–3) were too weak to observe.

Rhodium Dinitrogen Aggregate Species

When Rh atoms were cocondensed with pure N_2 matrices, in addition to the strong lines assigned to $Rh(N_2)_4$, very weak lines were observed at about 2238 and 2218 cm^{-1} (Fig. 5*A*) which grew in intensity upon warm-up to 35 °K to yield lines at 2242/2238, 2218/2215 with a new weak line at about 2213 cm^{-1}. By decreasing the rate of Rh atom deposition these weak lines became vanishingly small compared to the lines of $Rh(N_2)_4$. Warm-up of these nitrogen matrices containing low concentrations of Rh atoms caused the very weak lines at 2242, 2218, and 2113 cm^{-1} to grow in intensity (the 2113 cm^{-1} being now more intense than the other two bands) while the $Rh(N_2)_4$ lines gradually disappeared. These observations together with the close proximity of these weak high frequency lines to the frequency reported for N_2 chemisorbed on Rh metal (18) indicate that aggregate species $Rh_x(N_2)_y$ are probably being formed in the Rh/N_2 experiments. Weak lines at similar frequencies are also formed in

[4]This assignment must be regarded as tentative. However, this does not in any way change the conclusions reached in the remainder of the paper.

$N_2/Ar = 1:10$ experiments and upon warm-up of more dilute N_2/Ar matrices. Intuitively one might relate the presence of terminal NN stretching modes of the aggregate formed with high rates of Rh atom deposition (at 2238, 2215 cm^{-1}), the absence of bridging (low frequency) NN stretching modes of the aggregate, and the analogy with the Co—Co bonded form of $Co_2(CO)_8$ to the formation of $Rh_2(N_2)_8$ containing a Rh—Rh bond. However, when low rates of Rh atom deposition are employed and the matrices warmed, both terminal and bridge NN stretching modes appear for the aggregate species (2242, 2218 cm^{-1} (terminal) and 2113 cm^{-1} (bridge)).

One can speculate as to the formation of an aggregate (which by analogy with $Co_2(CO)_8$ will be referred to as $Rh_2(N_2)_8$) by one or both of the following reaction schemes.

(*i*) Reaction of diatomic rhodium (Rh_2) (formed in the matrix on cocondensation at 10 °K, using high rates of Rh atom deposition) with N_2,

$$Rh_2 + 8N_2 \rightarrow Rh_2(N_2)_8 \quad \text{(A)}$$

(*ii*) Dimerization of $Rh(N_2)_4$ during matrix warm-up experiments,

$$2Rh(N_2)_4 \rightarrow Rh_2(N_2)_8 \quad \text{(B)}$$

where

$$A = (N_2)_4Rh—Rh(N_2)_4$$

$$B = (N_2)_3Rh\begin{matrix}\diagup N_2 \diagdown \\ \diagdown N_2 \diagup\end{matrix}Rh(N_2)_3$$

These two reaction schemes are compatible with the spectral changes and lend support to the idea of two forms of $Rh_2(N_2)_8$ analogous to $Co_2(CO)_8$.

It is interesting to note that although these discussions regarding the formation and presence of $Rh_2(N_2)_8$ must be regarded as purely speculative, the formation of both isomers of $Co_2(CO)_8$ (16) has been observed in a series of analogous Co/CO matrix infrared experiments. In these, $Co(CO)_4$ was synthesized and $Co_2(CO)_8$ was observed after warm-up experiments of the tetracarbonyl as well as directly after depositions at 10 °K employing high metal atom deposition rates.

Warm-Up Characteristics and Stabilities of the Binary Dinitrogen Complexes of Rhodium

From our experiences with the binary carbonyl and dinitrogen complexes of Ni, Pd, and Pt, it has proven possible to relate qualitatively the difference between the force constant of the free ligand and the respective C.K. force constant in a series of closely related compounds to their relative thermodynamic stabilities (3, 4).

The assumption that was made was that ΔH_{ML}, the average metal–ligand bond energy, is given by

$$\Delta H_{ML} \propto k^L - k^L{}_{C.K.}$$

where k^L and $k^L{}_{C.K.}$ are the free ligand and C.K. bond stretching force constants respectively, and that ΔH_c, the enthalpy of decomposition of the compound to the metal and free ligand, is given by

$$\Delta H_c \propto n\Delta H_{ML}$$

where n is the coordination number of the complex.

The results for Ni and Pd paralleled their warm-up behavior and confirmed that the most stable complexes were those with the highest stoichiometries, that is $Ni(N_2)_4$ and $Pd(N_2)_3$.

The values of ΔH_c for $Ni(N_2)_n$, and $Rh(N_2)_n$ are shown below.

	ΔH_c	
n	Ni	Rh
4	11.00	9.76
3	9.66	6.78
2	7.68	4.50
1	4.63	3.28

The order for Rh is that expected from the warm-up behavior of $Rh(N_2)_n$ ($n = 1$–4) but also seems to indicate the considerably *greater* stability of $Rh(N_2)_4$ as compared to $Rh(N_2)_3$ or $Rh(N_2)_2$. It will be recalled that warm-up of dilute matrices yielded bands assigned to $Rh(N_2)_4$ before any bands due to $Rh(N_2)_3$ appeared. One can appreciate these relative stabilities more easily by reference to the graphical plot of $\Delta H_c{}^n$ *vs.* n (Fig. 6), where $\Delta H_c{}^n$ is the enthalpy of decomposition of $M(N_2)_n$. Particularly noteworthy is the large difference between $\Delta H_c{}^4$ and $\Delta H_c{}^3$ for $Rh(N_2)_4/Rh(N_2)_3$ as compared to the much smaller difference between $Ni(N_2)_4/Ni(N_2)_3$.

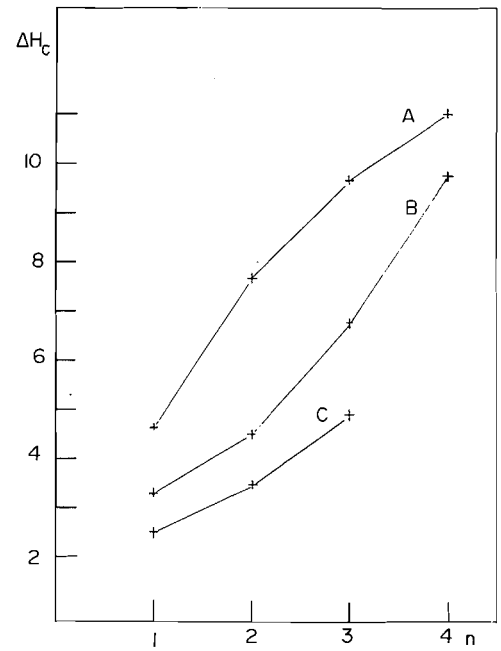

FIG. 6. Graphical plot of ΔH_c^n *vs.* n for (*A*) $Ni(N_2)_n$, (*B*) $Rh(N_2)_n$, and (*C*) $Pd(N_2)_n$ (see text for notation).

Relationship between RhN_2 and N_2 Chemisorbed on Rh

We have recently reported data for MN_2 (where M = Ni, Pd, and Pt) and have compared it with N_2 chemisorbed onto M (3, 4). It was found that the extent of metal–ligand bond weakening was approximately the same for the three metals when going from MN_2 to the chemisorbed ligand which suggested that the forces which bind molecules to surfaces upon chemisorption might be similar in many ways to those operating in more conventional metal–ligand coordination complexes (19).

Data for chemisorbed N_2 on Rh metal indicates the NN stretching frequency to lie at 2236 cm^{-1} (18) (note that lines at about this frequency appeared at the final warm-up stages of the matrices at 40 °K and were considered to belong to higher aggregate species). As with Ni, Pd, and Pt dinitrogen systems, the NN stretching frequency for chemisorbed N_2 lies above that of the respective monodinitrogen compound, indicative of a lower M—N_2 bond strength. As discussed previously (3, 4) this may arise from the fact that a surface metal atom releases some of its electrons into the conduction band of the metal. This formally raises the oxidation state of the metal, thereby decreasing the extent of back bonding below that which takes place when a single metal atom is bonded to a nitrogen molecule. It is interesting to note that the ratio $(\Delta\nu_{RhN_2}/\Delta\nu_{Rh.ChemiN_2}) = 1.9$ compared to 1.9, 1.7, and 1.6 for the Ni, Pd, and Pt nitrogen systems respectively, indicating that the extent of bond weakening in dinitrogen is approximately the same for the four metals when going from MN_2 to chemisorbed N_2.

Summary of Structure and Bonding in Binary Dinitrogen Complexes of Rhodium

Matrix cocondensation reactions of rhodium with N_2 and dilute N_2/Ar mixtures have resulted in the identification of the dinitrogen species $Rh(N_2)_n$ (where n = 1–4). Assignments are made for the $Rh(N_2)_n$ complexes on the basis of variable concentration experiments, isotopic substitutions, and diffusion warm-up experiments. Cotton–Kraihanzel force constants were obtained for all molecules using least squares analysis of the isotopic frequencies (Table 4). $Rh(N_2)_4$ in solid α-nitrogen appears to have a squashed tetrahedral structure (D_{2d}) but an approximately regular tetrahedral configuration (T_d) in solid argon.

The bonding of the dinitrogen molecule(s) in $Rh(N_2)_n$ appear in many respects to be similar to the coordinated dinitrogen molecule in the few stable rhodium dinitrogen complexes that have been prepared (see Table 5) as well as coordinated dinitrogen in $Ni(N_2)_n$ and $Pd(N_2)_m$. The structures of $Rh(N_2)_n$ appear to be similar to those found for the corresponding binary carbonyl and dinitrogen complexes of Ni and Pd although we cannot eliminate totally the possibility of $Rh(N_2)_2$ being non-linear and $Rh(N_2)_3$ being non-planar with this data alone.

In conclusion one should perhaps comment on the fact that the electronic configuration of ground state atomic rhodium is $5s^14d^8$ and the

TABLE 4. Cotton–Kraihanzel k_{NN} and $k_{NN.NN}$ force constants* for $Rh(N_2)_n$ (where n = 1–4)

*Raman spectrum.

configuration of Rh(0) in $Rh(N_2)_4$ is expected to be d^9 and a Jahn–Teller distortion from regular tetrahedral symmetry is predicted. Under circumstances where lattice sites effects are minimal (*i.e.* in dilute N_2/Ar matrices) only a very small splitting (4.5 cm^{-1}) of the T_2 NN stretching mode was observed. Whether this splitting is indicative of a matrix site effect or a genuine Jahn–Teller distortion cannot be decided upon with the available data. Whatever the cause of the perturbation of $Rh(N_2)_4$ in argon may be, it is clearly very small.

We wish to thank Mr. Ted Huber and Mr. Peter Kündig for helpful discussion and technical assistance, Dr. Martin Moskovits for his assistance with the frequency and intensity calculations of $Rh(N_2)_4$, and the National Research Council of Canada, the Research Corporation, and Erindale College for financial assistance.

The Infrared and Raman Spectra and Vibrational Assignment of *t*-Butyl Bromide-h_9 and -d_9

JOHN E. BERTIE AND SHAM SUNDER
Department of Chemistry, The University of Alberta, Edmonton, Alberta

Received January 11, 1973

The infrared spectra between 4000 and 10 cm^{-1} of *t*-butyl bromide-h_9 and -d_9 in the gas and liquid states, and the Raman spectra between 3500 and 10 cm^{-1} of the liquids under parallel and perpendicular polarizations, have been recorded and assigned. The compatibility of the assignments for the light and heavy molecules has been checked by normal coordinate calculations, in which 14 valence force constants have reproduced 40 fundamental frequencies with an average error of 1.5%. The calculated thermodynamic properties of both molecules are presented for temperatures between 50 and 500 °K.

Les spectres infra-rouges dans la région de 4000 à 10 cm^{-1} des bromures de *t*-butyle-h_9 et -d_9 à l'état gazeux et liquide ainsi que les spectres Raman dans la région de 3500 à 10 cm^{-1} des liquides à l'aide de lumière polarisée parallèlement et perpendiculairement, ont été enregistrés et interprétés. La concordance des attributions pour les molécules légères et lourdes a été vérifiée à l'aide de calculs en coordonnées normales lesquels ont permis de relier 40 fréquences fondamentales à 14 constantes de force valentielle avec une erreur moyenne de 1.5%. De même on présente les propriétés thermodynamiques calculées des deux molécules pour des températures allant de 50 à 500 °K. [Traduit par le journal]

Can. J. Chem., 51, 3344 (1973)

Introduction

As part of a study of the infrared and Raman spectra of *t*-butyl bromide in its three solid phases, we have recorded the infrared spectrum of the gas and liquid between 4000 and about 10 cm^{-1}, and the Raman spectrum of the liquid to 3500 cm^{-1} away from the exciting line, for both C_4H_9Br and C_4D_9Br at room temperature. With this data we have assigned the intramolecular modes of these molecules, and have checked the consistency of the assignments for the h_9 and d_9 molecules by a normal coordinate calculation.

The vibrational spectrum of C_4H_9Br has been discussed many times in the literature (1–15). However, no paper exists which reports the entire infrared spectrum of the liquid, aside from simply citing the fundamental frequencies, and neither the infrared nor the Raman spectrum of the vapor has been published. The most complete published infrared spectrum of the liquid covers the region from 3500 to 450 cm^{-1} (5) and suffers only from the rather low resolution available in 1950. Other workers (13–15) have extended the range to below 100 cm^{-1}, and Zeil and co-workers (10, 11) have recorded the infrared spectrum of the liquid and gas between 600 and 4000 cm^{-1} but only report a partial spectrum of the liquid and a list of fundamental frequencies drawn from both spectra. The only Raman polarization data for the liquid was published (3) in 1940, and only a partial Raman spectrum has been published (11) since.

With the exception of the methyl torsional modes, which have only recently been assigned (14, 15), the assignment of the spectrum of C_4H_9Br below 800 cm^{-1} has not been seriously challenged since Sheppard (5) assigned it using his own infrared data and Wagner's (3) Raman data. Various assignments for the remainder of the bands have been based on the same data (5, 6, 9, 12), and Huttner and Zeil (11) used their own data and assigned the fundamentals with the aid of a normal coordinate calculation.

The only report of the spectrum of C_4D_9Br is that of Zeil and co-workers (10) who published the infrared spectrum of the liquid between 950 and 1350 cm^{-1} and listed and assigned the fundamental frequencies above 700 cm^{-1}. Their assignment suffers from a misunderstanding over the probable frequencies of the CD_3 stretching and CD_3 deformation modes. The error in the assignment of the deformation modes was subsequently recognized (11), but the spectrum of C_4D_9Br was not reassigned.

Experimental

The *t*-butyl bromide-h_9 was Matheson, Coleman and Bell's research grade. To remove isobutene and hydrogen bromide impurities it was washed with 10% aqueous sodium bicarbonate followed by water. After drying over

anhydrous calcium chloride it was fractionated on a Teflon, spinning-band column and collected at 73.0 ± 0.5 °C.

t-Butyl bromide-d_9 was prepared from *t*-butyl alcohol-d_9, purchased from Merck, Sharp, and Dohme of Canada, by reaction with DBr in heavy water. It was purified as described above, collecting the fraction distilling at 72.5 ± 1 °C. Mass spectrometric analysis indicated about 7% of C_4D_8HBr and less than 1% $C_4D_7H_2Br$ in the product. No other impurities were detected.

The mid-infrared spectra were recorded on a Beckman I.R. 12 spectrophotometer calibrated, to ± 0.5 cm^{-1} below 2000 cm^{-1} and ± 1 cm^{-1} above 2000 cm^{-1}, using standard gases (16) and the Beckman fiducial marker accessory. The resolution was better than 1 cm^{-1} above 650 cm^{-1} and better than 2 cm^{-1} below 650 cm^{-1}. Individual gas-phase bands were studied at 0.5 cm^{-1} resolution.

Far-infrared spectra, up to about 380 cm^{-1}, were recorded using a Beckman-RIIC interferometer at a resolution of 1 cm^{-1}. The details of this instrument have been described elsewhere (17).

Raman spectra were recorded at 1 or 1.5 cm^{-1} resolution, using a Carson's lab 10SP Ar^+, Kr^+ laser, a SPEX 1401 monochromator, an ITT FW-130 photomultiplier cooled to −30 °C and photon-counting electronics. To excite the spectra, the 6471 and 5682 Å lines were used at a power of about 50 mW at the sample, after filtering to remove emission lines. Calibration to ± 1 cm^{-1} was achieved using the 459 cm^{-1} band of carbon tetrachloride (18), the spectrum of indene (19), and the manufacturer's statement of scale linearity to within ± 1 cm^{-1}; no evidence which contradicted this statement was found in this work. Ninety-degree excitation was used, the polarizations were selected by a polaroid analyzer, and a polarization scrambler was used in front of the entrance slit.

The Raman samples were held in melting-point capillary tubes. The infrared samples were contained in standard 10 cm path gas cells, or standard liquid cells, fitted with cesium iodide or polyethylene windows. The liquid cells were fitted with spacers 0.2 mm or less thick, but the film thicknesses are not known with certainty.

Results

The infrared spectra of *t*-butyl bromide-h_9 in the gas and liquid states at room temperature are shown in Figs. 1 and 2. The Raman spectrum of liquid *t*-butyl bromide-h_9 at room temperature is shown in Fig. 3 along with that of *t*-butyl bromide-d_9; no features were detected in the region omitted from Fig. 3. Figure 4 shows the more intense bands in the infrared spectrum of *t*-butyl bromide-h_9 on a scale which shows the band contours clearly. The frequencies of the features observed are listed in Table 1 to an accuracy of ± 1 cm^{-1}.

The infrared spectra of *t*-butyl bromide-d_9 are shown in Fig. 5 for the gas and liquid phases at room temperature. The intense bands in the spectrum of the gas are shown in Fig. 6 and the frequencies of the features observed in the infrared and Raman (Fig. 3) spectra are listed in Table 2 to an accuracy of ± 1 cm^{-1}.

For both compounds the frequencies of corresponding features in the infrared and Raman spectra of the liquid coincided within the combined errors of measurement. All of the weaker features in the spectra presented have been confirmed from spectra in which they are more intense, except for certain bands in the Raman spectrum of C_4D_9Br. A significant fluorescence problem was encountered with C_4D_9Br and its Raman lines appear to be weaker than those of C_4H_9Br. Both of these factors contributed to the following uncertainties in the Raman data for C_4D_9Br: the existence, frequency, and polarization of the features at 207 and 904 cm^{-1}; the details of the perpendicular spectrum between 2050 and 2200 cm^{-1}; whether the bands at 2221 cm^{-1}, 2238 cm^{-1}, and between 1150 and 1300 cm^{-1} are depolarized or partly polarized.

Discussion

The molecule was assumed to have C_{3v} symmetry with the unique hydrogen atom on each methyl group *anti* to the bromine. The detailed molecular structure is not known and the following parameters were used: $r_{C-H} = 1.093$ Å (assumed all equal); $r_{C-C} = 1.54$ Å; $r_{C-Br} = 1.96$ Å; all angles tetrahedral (20). The moments of inertia calculated from these parameters are: for C_4H_9Br, $I_a = 183 \times 10^{-40}$, $I_b = 416 \times 10^{-40}$; for C_4D_9Br, $I_a = 241 \times 10^{-40}$, $I_b = 488 \times 10^{-40}$; where the units are g cm^2, and bromine-79 is the assumed isotope. In the simplest approximation for gas-phase band contours, one expects (21, 22) an A_1 transition to yield a parallel band with well-defined PQR structure and a degenerate, *E*, transition to yield a perpendicular band which is a smooth peak showing no fine structure under our resolution. In fact, very few of the bands in the spectra of the gases could be classified with certainty in this way (Figs. 4 and 6), presumably due to complicating factors such as Coriolis interaction, hot bands, and the change in rotational constants with vibrational state. In most cases, therefore, the bands were assigned to parallel or perpendicular transitions on the basis of the Raman polarization data. The only assignments that are totally, or heavily, based on the shapes of the bands in the spectrum of the gas are those of ν_3 of C_4H_9Br (Fig. 4 and Table 1) and ν_1, ν_{13}, and ν_{15} of C_4D_9Br (Fig. 6 and Table 2).

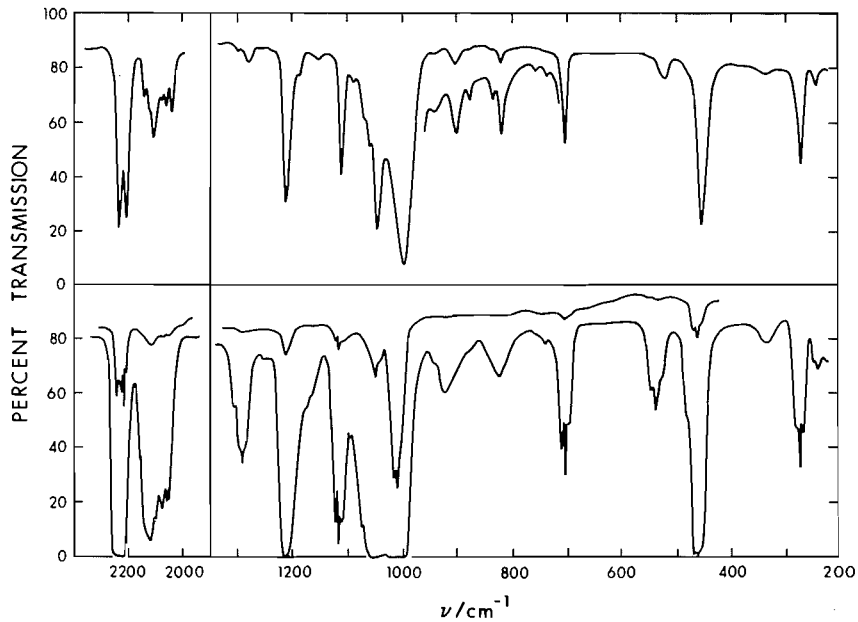

FIG. 5. The infrared spectra of *t*-butyl bromide-d_9 in the gas (lower box) and liquid (upper box) phases at room temperature. The gas pressures were 50 and 5 Torr and the pathlength was 10 cm. The liquid pathlength was nominally 0.1 mm but is uncertain. The resolution was 1 cm^{-1} above, and about 2 cm^{-1} below, 650 cm^{-1}.

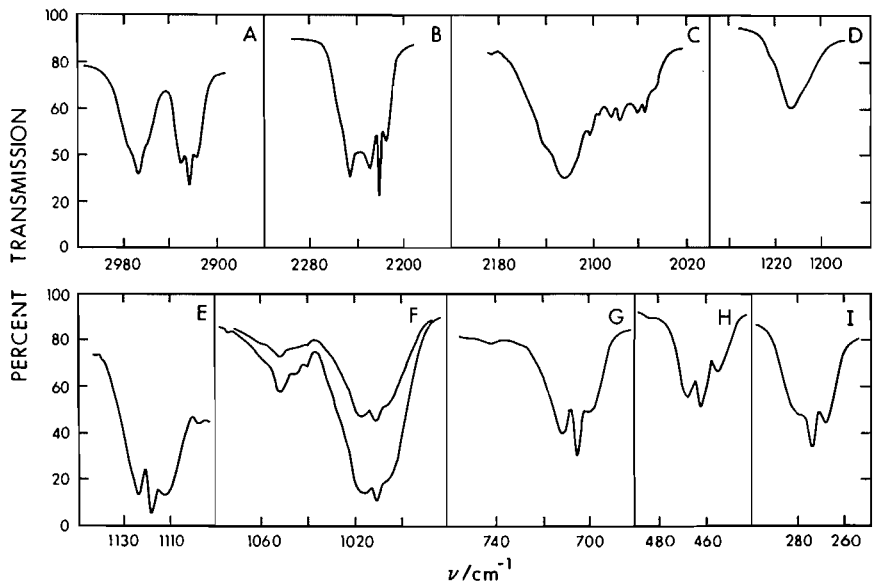

FIG. 6. The intense bands in the infrared spectrum of gaseous *t*-butyl bromide-d_9. The resolution was 0.5 cm^{-1}. The bands in box A are due to *t*-butyl bromide-d_8.

[a]For C-12 and Br-79. The frequencies calculated for Br-81 are within 0.2 cm^{-1} of these.
[b]Frequencies for the liquid state. All others are for the gas.
[c]These frequencies were given half-weight during the refinement.

The $8A_1 + 12E$ active fundamentals were assigned (Tables 1 and 2), using the approximate symmetry coordinate descriptions of the modes, to the more intense transitions of the correct symmetry in the frequency ranges which are known to be appropriate from the spectra of other molecules. Only two points require further comment. The degenerate methyl torsion of C_4H_9Br is assigned (Table 1) to a feature at 285 cm^{-1}, instead of at 272 cm^{-1} (15), to place it closer to its frequencies in *t*-butyl fluoride, 298 cm^{-1} (9), and *t*-butyl chloride, 290 cm^{-1} (23). The stretching and deformation modes of the methyl groups are assigned in terms of the symmetric (s.) and asymmetric (as.) displacements within the individual methyl groups, even though these have only C_s local (site) symmetry. For the stretching modes this can be shown to be useful by making use of the bands at 2925 and 2971 cm^{-1} in the infrared spectrum of gaseous C_4D_9Br which are assigned to the C_4D_8HBr impurity. Similar bands have been observed in other systems (23, 24). From the moments of inertia of C_4D_8HBr, calculated from the parameters presented above, one expects (22) that the band due to the stretching vibration of a C—H bond *anti* to the CBr bond closely resembles a parallel band, and can be assigned at 2925 cm^{-1}, while that of a C—H bond *gauche* to the C—Br bond resembles a perpendicular band and can be assigned at 2971 cm^{-1}. The force constants derived from these frequencies can be

For personal use only.

used, without an interaction constant, to calculate the frequencies and eigenvectors of the C_s methyl group. These approximate those of a C_{3v} methyl group although, of course, the two higher frequencies differ by about 20 cm^{-1} in the C_s model and are degenerate in the C_{3v} model. Therefore one can expect that, in *t*-butyl bromide, the $A_1 + A_2 + 2E$ asymmetric CH_3 stretching modes occur approximately 50 cm^{-1} (about 100 cm^{-1} for CD_3) to high frequency of the $A_1 + E$ symmetric CH_3 stretching modes.

The assignment for C_4H_9Br presented in Table 1 agrees with that of Huttner and Zeil (11) except for the CH_3 stretching and deformation modes, for which the present data differs significantly from 'heirs. The only assignments which we regard as very uncertain are those of ν_{14} and ν_{15}. No obvious alternative assignment exists for ν_{14}, but ν_{15} could be assigned to the broad maximum at 2910 cm^{-1} in the spectrum of the gas. The assignment for C_4D_9Br is presented in Table 2. The evidence for the assignment of ν_4, ν_{14}, ν_{15}, ν_{18}, ν_{19}, and ν_{24} is less convincing than that for the remaining modes, but no alternatives are clear except that ν_{15} could be assigned at 2149 cm^{-1} in the liquid.

The frequencies of the fundamental vibrations of both molecules are presented in Table 3, along with the results of a normal coordinate calculation which was done to check the compatibility of the assignments for the two molecules and to obtain more detailed descriptions of the vibrational modes. The calculations used Wilson's GF method (25) through the programs GMAT (26) and FPERT (27), and are reported in detail elsewhere (28). One set of initial values of the diagonal valence force constants was taken from *t*-butyl chloride (23) and a different set was taken from a previous study of *t*-butyl bromide (11). These two quite different sets of force constants converged to the same values, when refined to fit the frequencies of C_4H_9Br with the methyl torsional force constant set to zero. The methyl torsional force constant and selected interaction constants were then added to the diagonal force constants so obtained, and the force field was refined to fit the frequencies of both molecules. The calculated frequencies and assignments (based on the eigenvectors and the potential energy distribution) are shown in Table 3 and the force constants are listed in Table 4. The 40 frequencies were fitted by the 14 force constants with an average error of 8 cm^{-1} or 1.2%. One feature of this calculation is that the potential energy of ν_7 and ν_8 contained large (25–50%) contributions from the CBr, CCBr interaction constant (28). The force field of Huttner and Zeil (11) also yields this feature, which could only be avoided by constraining many of the force constants about the central carbon atom during the refinement. The frequencies so obtained (28) are not quite so close to the observed ones as are those presented here, but the calculated assignments are essentially the same.

TABLE 4. Valence force constants for *t*-butyl bromide[a]

Co-ordinate	Value
C—Br	2.560[b]
C—C	4.0546
C—H[c]	4.8097
C—C—Br	0.8800
H—C—H[c]	0.5336
C—C—H[c]	0.6823
C—C—C	1.1390
CH_3 torsion	0.0148[b]
C—Br C—C	0.7396
C—C C—C′	0.5284
C—H C—H′[c]	0.0946
C—Br C—C—Br	0.4753
C—C—H C—C—H′[c]	−0.0347
C—C C—C—H[c]	0.2196

[a]The units are mdyn Å^{-1}, mdyn, and mdyn Å for bond stretching, stretch–bend interaction, and angle deformation constants, respectively.
[b]During refinement these constants were constrained to the values shown, which were selected from many trials.
[c]All of the force constants of this type were assumed to be equivalent.

The calculated assignments (Table 3) confirmed the empirical assignments (Tables 1 and 2) except that ν_3 of C_4D_9Br was calculated to be the symmetric CD_3 deformation, with some admixture of CD_3 rock and C—C stretch, rather than the asymmetric deformation which was calculated to be ν_4 and to contribute somewhat to ν_5. The calculations also showed (Table 3) that several other modes must be described in terms of more than one symmetry coordinate. The full potential energy distribution and eigenvectors, as well as the **U**, **G**, and **F** matrices used in these calculations, are given in ref. 28.

Table 5 presents the thermodynamic functions of *t*-butyl bromide-h_9 and -d_9 (in parentheses). These were calculated from the observed fre-

Preparation of 2-Methoxytetrahydropyran-3-one from Halogenated Dihydro- and Tetrahydropyran Precursors

J. E. ROFF[1] AND R. K. BROWN

The Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 4, 1972[2]

The reaction of 5-halo-3,4-dihydro-2*H*-pyran with halogen and sodium methoxide gives in good yield the corresponding 3,3-dihalo-2-methoxytetrahydropyran. The latter, upon treatment with aqueous sodium hydroxide or sodium methoxide in methanol failed to provide 2-methoxytetrahydropyran-3-one but instead gave the 3-halo-2-methoxy-5,6-dihydro-2*H*-pyran. The ketone, 2-methoxytetrahydropyran-3-one was obtained by the treatment of 5-chloro-3,4-dihydro-2*H*-pyran with *m*-chloroperoxybenzoic acid followed by the addition of sodium methoxide.

Attempts to prepare the 3,3-dibromo-2-methoxytetrahydropyran by the reaction of 3-bromo-2-methoxytetrahydropyran with bromine were unsuccessful, but gave the ring cleavage product, methyl 2,5-dibromopentanoate.

La réaction d'un halo-5 dihydro-3,4-2*H*-pyrane sur un halogène et du méthoxyde de sodium conduit au dihalo-3,3 méthoxy-2 tétrahydropyrane avec un bon rendement. Ce dernier, après traitement avec de la soude aqueuse ou du méthoxyde de sodium dans le méthanol, conduit au halo-3 méthoxy-2 dihydro-5,6-2*H*-pyrane au lieu du méthoxy-2 tétrahydropyranone-3. La cétone méthoxy-2 tétrahydropyranone-3 a été obtenue par traitement du chloro-5 dihydro-3,4-2*H* pyrane à l'acide *m*-chloroperoxybenzoique suivi d'une addition de méthoxyde de sodium. Des tentatives de préparation du dibromo-3,3 méthoxy-2 tétrahydropyrane par réaction du bromo-3 méthoxy-2 tétrahydropyrane sur le brome ont échoué et ont conduit au dibromo-2,5 pentanoate de méthyle, produit de rupture de cycle.

[Traduit par le journal]

Can. J. Chem., **51**, 3354 (1973)

As part of a program exploring avenues leading to the total synthesis of monosaccharides, the preparation of 2-methoxytetrahydropyran-3-one from halogenated dihydro- and tetrahydropyran precursors was undertaken, since the ketone might be a useful intermediate for some monosaccharide syntheses. This note describes the results obtained.

The reaction of 5-chloro-3,4-dihydro-2*H*-pyran (**1**, X = Cl (1)) or its bromo analog, (**1**, X = Br (2)) with chlorine in the presence of methyl alcohol and sodium methoxide gave 3,3 - dichloro - 2 - methoxytetrahydropyran, (**2**, X = Y = Cl) and 3-bromo-3-chloro-2-methoxytetrahydropyran, (**2**, X = Cl, Y = Br) respectively, in very good yield (Scheme 1). Similarly, **2**, X = Y = Br, was obtained by bromination of **1**, X = Br. Attempts to prepare **2**, X = Y = Br, by direct bromination of the acetal 3-bromo-2-methoxytetrahydropyran failed, but instead provided the acyclic compound methyl 2,5-dibromopentanoate.

Base catalyzed hydrolysis of **2**, X = Y = Cl or Br, or X = Cl, Y = Br, failed to produce the desired ketone **4** but instead gave **3** in 2% yield along with 90% of unchanged **2** when X = Y = Cl in **2**, in 74% yield when X = Y = Br in **2**, and in 95% yield when X = Cl, Y = Br in **2**. Similarly, the reaction of **2**, X = Cl, Y = Br, with sodium methoxide in methanol gave **3**, X = Cl, in excellent yield while **3**, Y = Br, was obtained in 62% yield by the same reaction with **2**, X = Y = Br. In contrast, the methanolic sodium methoxide reaction with **2**, X = Y = Cl, proved to be much more difficult, as with the hydrolysis reaction above, and provided **3**, Y = Cl, in 5% yield along with 90% of unchanged **2**, X = Y = Cl.

The ketone **4** was made available by the reaction of **1**, X = Cl, with *m*-chloroperoxybenzoic acid in methylene chloride followed by addition of sodium methoxide (as shown in Scheme 2). There was obtained a mixture of six compounds (as shown by g.l.c.) in which **4** predominated in the relative proportion of 70% accompanied by unchanged **1**, X = Cl (8%), 3-chloro-2-methoxytetrahydropyran (10%), 3,3-dichloro-2-methoxytetrahydropyran (~1%), and two unidentified substances (each about 5%). Identifi-

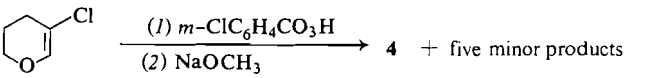

SCHEME 2

cation was made by both isolation of small samples by g.l.c. and by comparison of g.l.c. retention times with those of known compounds. It was possible to isolate **4** by fractional distillation from the mixture but decomposition and polymerization reduced the isolated yield to 20–25%.

Experimental

All melting points and boiling points are uncorrected. The elemental analyses were performed by Mrs. D. Mahlow of this Department. The p.m.r. spectra were obtained by Mr. R. N. Swindlehurst using a Varian Associates A60 spectrometer and by Mr. Glen Bigam using a Varian Associates HR100 spectrometer in this Department. Tetramethylsilane was used as reference. G.l.c. analyses were made with an F and M model 700 chromatograph using a column, 1/8 in. × 12 ft, containing 20% butanediol succinate on Gas-Chrom P (60–80 mesh) with a helium flow-rate of 40 ml/min. The i.r. spectra were obtained with Perkin-Elmer instruments, models 21 and 421. Solvents were removed by rotary evaporator under reduced pressure unless otherwise stated.

Halogenation of 3,4-Dihydro-2H-pyrans

By use of the reported procedure (5) for the bromination of 2-methoxymethyl-3,4-dihydro-2*H*-pyran, the following compounds were obtained.

3,3-Dichloro-2-methoxytetrahydropyran

This was obtained from the addition of 0.5 mol of chlorine in 300 ml of carbon tetrachloride to 0.5 mol of 5-chloro-3,4-dihydro-2*H*-pyran (1) in 1 l of methanol containing 0.5 mol of sodium methoxide. Yield 83%; b.p. 54° at 1.6 mm; n_D^{25} 1.4752 (lit. (3) b.p. 40–42° at 2 mm).

3-Bromo-3-chloro-2-methoxytetrahydropyran

This was obtained from the addition of 0.5 mol of bromine in carbon tetrachloride to 0.5 mol of 5-chloro-3,4-dihydro-2*H*-pyran (1) in methanol (1 l) containing sodium methoxide (0.5 mol). Yield 78%; b.p. 56° at 0.9 mm; n_D^{25} 1.5027.

Anal. Calcd. for $C_6H_{10}BrClO_2$: C, 31.39; H, 4.39; halogen determined as chloride, 30.90. Found: C, 31.29; H, 4.14; halogen (as chloride) 30.88.

Both the p.m.r. and i.r. spectra agreed with the structure proposed.

In addition there was obtained an 8% yield of *cis-trans*-3-chloro-2-methoxytetrahydropyran, b.p. 60° at 8 mm, n_D^{23} 1.4583 (lit. (1) b.p. 74° at 18 mm, n_D^{12} 1.4646).

3,3-Dibromo-2-methoxytetrahydropyran

The addition of bromine to 5-bromo-3,4-dihydro-2*H*-pyran (2) in methanolic sodium methoxide as described above gave 3,3-dibromo-2-methoxytetrahydropyran in 91% yield: b.p. 63° at 0.6 mm; n_D^{25} 1.5305.

Anal. Calcd. for $C_6H_{10}Br_2O$: C, 26.29; H, 3.68; Br, 58.33. Found: C, 26.47; H, 3.91; Br, 58.49.

Both the p.m.r. and i.r. spectra agreed with the structure proposed.

3-Chloro-2-methoxy-5,6-dihydro-2H-pyran

(a) From 3-bromo-3-chloro-2-methoxytetrahydropyran

The dehydrohalogenation procedure reported for the preparation of *trans*-2-methoxy-6-methoxymethyl-5,6-dihydro-2*H*-pyran (5) was followed. From 22.9 g (0.1 mol) of the bromo-chloro compound there was obtained, by distillation under reduced pressure, 14.1 g (95%) of 3-chloro-2-methoxy-5,6-dihydro-2*H*-pyran; b.p. 64° at 12 mm; n_D^{25} 1.4706.

Anal. Calcd. for $C_6H_9ClO_2$: C, 48.49; H, 6.10; Cl, 23.85. Found: C, 48.39; H, 6.09; Cl, 23.80.

The p.m.r. spectrum obtained in $CDCl_3$ agreed with the structure and showed a quartet centered at 6.05 p.p.m. (1H) J ~3 and 6 Hz; a singlet at 4.68, $w_{1/2}$ ~2.5 Hz; a multiplet at 4.20–3.65 (2H); a singlet at 3.42 (3H); a multiplet at 2.80–1.50 (2H). The i.r. spectrum (neat) showed weak absorption at 1660 cm^{-1} (C=C).

The reaction of 3-bromo-3-chloro-2-methoxytetrahydropyran with aqueous sodium hydroxide gave a 93% yield of 3-chloro-2-methoxy-5,6-dihydro-2*H*-pyran.

(b) From 3,3-dichloro-2-methoxytetrahydropyran

The reaction of 18.5 g (0.1 mol) of 3,3-dichloro-2-methoxytetrahydropyran with 0.2 mol of sodium methoxide in methanol, following the procedure used in (*a*) above gave 0.7 g (5%) of 3-chloro-2-methoxy-5,6-dihydro-2*H*-pyran and 16.6 g (90%) of unchanged 3,3-dichloro-2-methoxytetrahydropyran.

A similar reaction, using aqueous sodium hydroxide gave a 2% yield of the olefin and 90% recovered unchanged dichloro compound.

3-Bromo-2-methoxy-5,6-dihydro-2H-pyran

Following the above procedure to prepare 3-chloro-2-methoxy-5,6-dihydro-2*H*-pyran, 27.4 g (0.1 mol) of 3,3-dibromo-2-methoxytetrahydropyran heated with methanol and sodium methoxide, gave 4.4 g (16%) of unchanged dibromo compound and 12.0 g (62%) of 3-bromo-2-methoxy-5,6-dihydro-2*H*-pyran: b.p. 52° at 2.2 mm; n_D^{25} 1.4970 (lit. (4) b.p. 92–94° at 14 mm; n_D^{27} 1.4960).

The p.m.r. spectrum in $CDCl_3$ agreed with the structure and showed a quartet at 6.28 p.p.m., J ~2.5 and 5.5 Hz (1H); a singlet at 4.75, $w_{1/2}$ ~2.5 Hz (1H); a multiplet at 4.10–3.65 (2H); a singlet at 3.42 (3H); a multiplet at 2.90–1.65 (2H). The i.r. spectrum (film) showed a weak band at 1648 cm^{-1} (C=C).

When heated with aqueous sodium hydroxide at 65° for 18 h, 3,3-dibromo-2-methoxytetrahydropyran gave 3-bromo-2-methoxy-5,6-dihydro-2*H*-pyran in 74% yield. Higher temperatures resulted in lower yields.

3-Bromo-2-methoxytetrahydropyran

The reaction of 3,4-dihydro-2*H*-pyran with bromine and methanol was carried out by the procedure reported for the preparation of 3-bromo-2-methoxy-6-methoxymethyltetrahydropyran (5).

From 84 g (1 mol) of the dihydropyran there was obtained 165 g (85%) of 3-bromo-2-methoxytetrahydropyran which from previous experience with the bromomethoxylation of similar compounds (5) is considered to be nearly completely the *trans* isomer. B.p. 87° at 12 mm (lit. (6) b.p. 88–89° at 18 mm).

Methyl 2,5-Dibromopentanoate

To a well-stirred mixture of 3-bromo-2-methoxytetrahydropyran (9.75 g, 0.1 mol) and 15.9 g of anhydrous sodium carbonate in 150 ml of carbon tetrachloride, kept at 35°, was added dropwise a solution of bromine (16.0 g, 0.1 mol) in 50 ml of carbon tetrachloride. The mixture was then stirred overnight and allowed to reach room temperature. The solids were then removed and the solution was shaken several times with saturated aqueous sodium bicarbonate. The organic solution was dried (Na_2SO_4), freed from solvent and the residue was distilled under reduced pressure yielding 9.6 g (35%) of methyl 2,5-dibromopentanoate: b.p. 63° at 0.6 mm; $n_D^{26.5}$ 1.5090 (lit. (7) b.p. 93–95° at 1.5 mm; n_D^{25} (1.5099).

2-Methoxytetrahydropyran-3-one

To a stirred solution of 35.5 g (0.3 mol) of 5-chloro-3,4-dihydro-2*H*-pyran in 250 ml of dichloromethane kept between 0 and 10°, was added slowly a solution of 64.8 g (0.3 mol) of 80% *m*-chloroperoxybenzoic acid in dichloromethane. The mixture was then stirred overnight and allowed to reach room temperature. The precipitated *m*-chlorobenzoic acid was removed and to the residual solution, kept cool with an ice bath, was added 32.4 g (0.6 mol) of sodium methoxide. The mixture was then stirred overnight (room temperature), following which the solids were separated and the solvent removed under reduced pressure. The residual oil (24 g, ~60%) was found by g.l.c. to consist of 2-methoxytetrahydropyran-3-one (70%), unchanged 5-chloro-3,4-dihydro-2*H*-pyran (8%), 3-chloro-2-methoxytetrahydropyran (9%), 3,3-dichloro-2-methoxytetrahydropyran (1–2%), and two unidentified substances (each about 5%).

The crude mixture, when subjected to fractional distillation under reduced pressure, decomposed with polymerization and provided only a relatively small amount (20–25%) of pure 2-methoxytetrahydropyran-3-one: b.p. 44° at 2 mm; $n_D^{26.5}$ 1.4611.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.74. Found: C, 54.60; H, 7.72.

The p.m.r. spectrum in $CDCl_3$ agreed with the structure proposed, showing a singlet at 4.54 mm (1H); broad multiplet, 4.4–3.7 (2H); singlet, 3.49 (3H); broad multiplet, 2.9–2.0 (4H). The i.r. spectrum (film) showed strong absorption at 1730 cm (C=O) and at 1100 cm^{-1} (C—O—C).

The Synthesis of Some Alkyl Hex-3-enopyranosiduloses[1,2]

N. L. HOLDER[3] AND B. FRASER-REID
Chemistry Department, University of Waterloo, Waterloo, Ontario

Received February 13, 1973

Routes to methyl 3,4-dideoxy-α-D-*glycero*-hex-3-enopyranosidulose **1***a* have been developed which use cheap readily-available chemicals, which are operable on a large scale and which have readily crystallizable materials as key intermediates (Scheme 4). Extensive use is made of reductive elimination of vicinal sulfonyloxy groups which is shown to operate equally well whether these groups on the pyranoside ring are in *cis* or *trans* relationship. Contrary to other reported cases, it is found that the carbon-2 allylic hydroxyl goup is oxidized with manganese dioxide whether it is in pseudoaxial or equatorial orientation.

Différentes méthodes utilisant des produits chimiques peu coûteux et facilement disponibles, pouvant facilement être rentables à grande échelle et impliquant des produits intermédiaires facilement cristallisables, on été développées afin d'obtenir le méthyl didéoxy-3,4 α-D-*glycéro* hexèno-3 pyranosidulose **1***a* (schéma **4**). Dans ces méthodes, on a très souvent utilisé la réaction d'élimination réductive des groupes sulfonyloxy vicinaux qui fonctionne bien, indépendamment de la relation *cis* ou *trans* pouvant exister entre ces groupes sur l'anneau pyranosyde. Contrairement à ce qui a déjà été rapporté dans d'autres cas, on a trouvé que le groupe hydroxyle allylique sur le carbone-2 est oxydé à l'aide du bioxyde de manganèse sans tenir compte de son orientation pseudoaxiale ou équatoriale.

[Traduit par le journal]

Can. J. Chem., **51**, 3357 (1973)

Introduction

Carbohydrate molecules possessing ketonic (1) and/or olefinic (2) unsaturation are currently the preferred precursors for the synthesis of branched-chain, amino, and rare sugars as may be evinced by a number of recent reviews (3). In recent years, major advances have been made in the study of molecules possessing both types of unsaturation in conjugation (4), these molecules being of interest in view of the array of synthetic techniques available to them (5). We wish to report the synthesis of some alkyl 3,4-dideoxy-hex-3-enopyranosiduloses from readily available starting materials by way of simple laboratory processes.

At the inception of this project, there existed confirmatory evidence for the structures and conformations of some methyl 3,4-dideoxy-α- and β-D-*glycero*-hex-3-enopyranosiduloses **1** (6, 7). These compounds were obtained as syrups in low yields by acid-catalyzed elimination from enolic precursors **2** having the appropriate anomeric configurations (6), or by way of their anomeric fluorides **3** (7). However, there existed no synthetic methods by which these seemingly

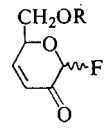
2



3

valuable precursors could be obtained in large quantities from readily available and cheap starting materials. Because of their synthetic utility and the success in this laboratory in synthesizing some alkyl 2,3-dideoxy-α-D-*glycero*-hex-2-enopyranosid-4-uloses (4*g*, *h*) we addressed ourselves to the synthesis of **1***a*.

Results and Discussion

One conceivable route to **1***a* has as its final step the selective oxidation of the corresponding allylic alcohol. This was of additional interest in view of the recently observed failure of certain allylic alcohols to respond to manganese dioxide oxidation (4*c* and *i*). Hence we were prompted to investigate this effect on the C-2 epimeric allylic alcohols **4***a* and **5***a* whose syntheses there-

SCHEME 1

fore became our initial objective (Schemes 1 and 2).

One synthetic approach to **4***a* is summarized in Scheme 1. Obtainment of starting material **6***a* was greatly simplified by treating methyl α-D-glycopyranoside with α,α-dimethoxytoluene according to the method described by Evans (8). The selective benzoylation of **6***a* → **6***b* developed by Carey and Hodgson (9) paved the way to the key intermediate, the dibenzoate **7***a*, via debenzylidination of **6***b* and then selective benzoylation of the derived monobenzoate **7***b*. This three step route to **7***a* was better in overall yield and easier in execution than direct dibenzoylation of methyl α-D-glucopyranoside reported earlier (10). Compound **7***a* was di-*O*-methanesulfonylated and reductive elimination (11) of the resulting 3,4-dimesylate (**7***c*) gave a mixture of **4***b* and *c*. The configurational relationship of **4***b* and **4***c* follows from the fact that the mixture upon benzoylation gave only **4***c* and upon deesterification gave only **4***a* as a mobile oil. The compound **4***a* was characterized as its di-*O*-*p*-nitrobenzoate **4***d* and its 6-*O*-trityl ether **4***e*; the n.m.r. parameters of **4***a* and its benzoate esters are recorded in Table 1.

It is now clear that an ester adjacent to a vicinal dimesylate grouping is usually lost during reductive elimination (11*a*). However the deesterification is not complete and there is no change in configuration.

For reasons of completeness, we desired to determine whether *cis*-di-*O*-methanesulfonyl groups in a pyranoside molecule as in **10***a* would

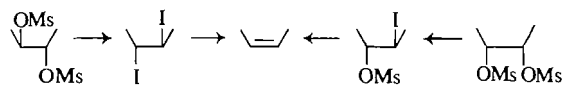
SCHEME 2

also undergo ready reductive elimination. Although this reaction had been applied successfully to *cis*- and *trans*-sulfonyl esters of cyclohexanes (12), iodide displacement of the *cis*-groups may be influenced by steric effects of other groups present on the pyranoside ring. The pathway to **10***a*, as outlined in Scheme 2, requires **9***a*, the reported synthesis of which is bedevilled by the production of variable quantities of the unwanted isomer **9***b*, and the dibenzoate **9***c* (13). In an alternative approach to **9***a*, based upon ample precedent (14), the oxirane **8** obtained from **6***c* was treated with sodium benzoate in DMF, a highly nucleophilic medium (15), in the hope that the *trans*-diaxial product **9***a* would be favored. However, the ratio of **9***a* to the 3-*O*-benzoyl glucopyranoside **6***e*, arising from diequatorial scission of **8** was discouragingly small. All modifications of the above method failed to give the desired compound in acceptable yields (16).

In view of the ready availability of **9***d* (17), the selective benzoylation method of Carey and Hodgson (9) was applied. In the event, **9***a* was obtained in only 50% yield; however, it was the only benzoylated product formed (18). Catalytic hydrogenolysis of **9***a* afforded **10***b* but attempted C-6 selective benzoylation of this latter compound resulted in a complex mixture. Accordingly, a solution of **10***b* and trityl chloride in anhydrous pyridine was allowed to stand at room temperature (19, 20) until the reaction was complete (t.l.c.), whereupon excess methanesulfonyl chloride was added to esterify the secondary hydroxyl groups leading to **10***a*.

Elimination of the methanesulfonyl groups from **10***a* with concomitant introduction of 3,4-unsaturation was readily achieved under the usual experimental conditions (11*a*). Here too, as in earlier examples, the reductive elimination was accompanied by some debenzoylation at carbon-2. The mixture **5***b* and **5***c* was debenzoylated to give the alcohol **5***b* as a crystalline material.

The successful reductive eliminations of **7***c* and **10***a* indicate that this process may be applied to carbohydrate molecules bearing either *cis*- or *trans*-dimethanesulfonate groups. The presence or the orientation of acid or base labile groups does not effect the outcome of the reaction. Therefore, the reaction pathway opined by one of us in 1969 (11*a*) and reproduced here probably holds.



The spacing (J_{12} = ~1 Hz) in **5***b* and **10***a* indicates that the carbon-2 retained its configuration during the reductive elimination **10***a* → **5***b* + **5***c*. In the light of earlier results **7***c* → **4***b* + **4***c* (*vide supra*) and the results

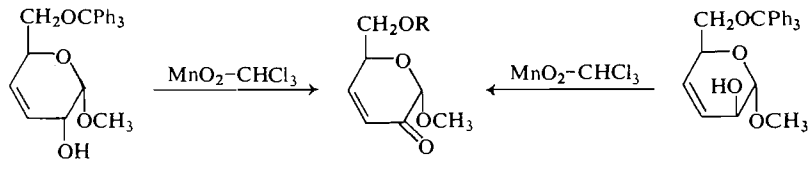

SCHEME 3

recorded earlier by Fraser-Reid and Boctor (11*a*) this process may now be regarded as normal. In **4***a* H-3 and H-4 give overlapping signals ~4τ and show very little fine structure. This is to be expected since the dihedral angles between H-2 and H-3 on the one hand, and H-4 and H-5 on the other, are approximately 90° in each case, which according to the observations of Garbish (21) correlates with very small coupling constants.

It is commonly observed that a sulfonate situated at C-2 of a pyranoside ring is loathe to displacement by a charged nucleophile (22, 23). However in the light of the success of Ferrier and co-workers (24) in displacing a C-4 allylic sulfonyloxy group, we undertook to treat the mesylate **4***f* with sodium benzoate in refluxing DMF. The experiment was successful yielding a single substance which upon debenzoylation gave **5***b*. This salutary result (*a*) strongly supports the hypothesis that the enhanced reactivity of the secondary allylic esters at C-2 is attributable to resonance stabilization of the transition state (25) and (*b*) shows unequivocally that there was no inversion of stereochemistry at C-2 during debenzoylation which accompanied the reductive eliminations in Schemes 1 and 2.

The final stage in the synthesis of the methyl 3,4-dideoxy-α-D-hex-3-enopyranosiduloses **1**, is the selective oxidation of the allylic alcohol at C-2. In the preliminary experiments it was found that the diol **4***a* was oxidized by manganese dioxide to a crystalline hydroxy-ketone **1***a* without affecting the primary alcohol (*Cf.* 4*g*). However on a preparative scale, **1***a* was obtained as a brown syrup and consequently the 6-*O*-trityl ether **4***e* was oxidized to a crystalline enone **1***g* (Scheme 3) in 94% yield; n.m.r. parameters are tabulated (Table 1). Similarly, the pseudoaxial alcohol **5***b* was oxidized to the same ketone **1***g* in comparable yields and purity. Therefore, contrary to the observations that the pseudoaxial allylic alcohols at C-4 (4*c*) and at C-3[4] (4*i*) are not oxidized with manganese dioxide, both epimeric C-2 allylic alcohols **4***e* and **5***b* are oxidized to the hex-3-enopyranosidulose. It is instructive to note that oxidation of **4***e* could also be achieved with chromium trioxide in pyridine (4*i*); however the yield of the enone **11** was only 64%. Removal of the protective group of **1***g* with hydrogen chloride in chloroform (26) was readily accomplished, whereby **1***a* was isolated in about 83% yield in crystalline form.

The elegance of the synthetic route summarized in Scheme 1 is vitiated by the necessity for chromatographic separations and the isolation of several non-crystalline intermediates. In view of this and in light of the knowledge gained from Schemes 2 and 3 the most economical route to **1***a* is outlined in Scheme 4. This path originates with the previously described monobenzoate **6***b* and the key intermediates **7***e* and **4***e* were isolated as crystalline derivatives in high yields. The overall yield of **1***a* from **6***b* is about 50%.

The hydroxy-ketone **1***a* could be esterified to give the benzoate **1***d*, *p*-nitrobenzoate **1***e*, and acetate **1***f*. Methyl 6-*O*-benzoyl-3,4-dideoxy-α-D-hex-3-enopyranosidulose **1***d* was also obtained by manganese dioxide oxidation of the monobenzoate **4***b*. The benzoate esters **1***d* and **1***e* are crystalline compounds and gave satisfactory analytical and spectroscopic data. On the other hand, the acetate **1***f* is non-crystalline and its structure was based on its n.m.r. and i.r. spectra. Some 60 MHz n.m.r. data for these esters are given in Table 1. The physical data are in complete agreement with the parameters recorded by

[4]By contrast the C-3 equatorial alcohol in 1,2-dideoxy-4,6-*O*-isopropylidine-D-*arabino*-hex-1-enopyranose was oxidized by activated manganese dioxide (16).

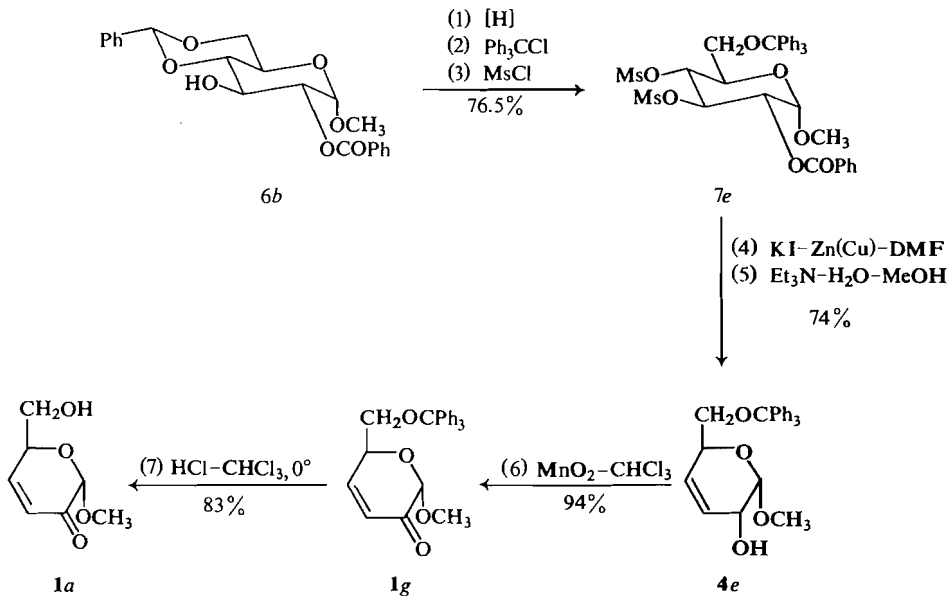

SCHEME 4

Anet (6) for the 6-*O*-methyl derivative and by Bock and Pedersen (7) for the 6-*O*-benzoyl and 6-*O*-acetyl compounds.

Experimental

Melting points were determined on a Fisher-Johns heating stage and are uncorrected. Elemental analyses were performed by Chemalytics Inc., Tempe, Arizona 85281. The n.m.r. spectra ($CDCl_3$, TMS) were determined on a Varian T-60 spectrometer, the *J* values quoted in the table being the spacings measured directly from the spectra. I.r. spectra were determined on a Beckman model I.R. 10 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent). U.v. spectra were obtained from a Beckman DBG Grating Spectrophotometer and a Cary Recording Spectrophotometer model 14 (methanol as solvent). Mass spectra were measured with a CEC model 21-110B double focusing instrument at an i.p. of 70 eV. Optical rotations were determined on a Carl Zeiss model LEP nür 370740 Lichtelektusches Praizision-polarimeter at 23 °C.

T.l.c. was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The chromatograms were first viewed under u.v. light and then sprayed with concentrated sulfuric acid. For column chromatography E. Merck Silica Gel (0.063–0.20 mm 70–230 mesh, A.S.T.M.) was used.

The procedures for reductive elimination (11) and manganese dioxide oxidation (4*g*) were as described previously.

Methyl 4,6-O-Benzylidene-α-D-glucopyranoside **6***a*

The following modification of Evans' recently reported synthesis (8) is recommended.

Methyl-α-D-glucopyranoside (97 g, 0.5 mol), 76 ml of α,α-dimethoxytoluene, and 10.0 g of *p*-toluenesulfonic acid in 400 ml of dry DMF were refluxed on a steam bath under water-aspirator vacuum for 1 h. The solvent was removed from the reaction mixture and the final traces of DMF evaporated under high vacuum. The white crystalline residue was heated with saturated sodium bicarbonate until the product was finely dispersed. The mixture was cooled to room temperature and the product filtered off and washed thoroughly with water and then petroleum ether (30–60°) or hexane until free of benzaldehyde. The product was dried at normal pressure and then under high vacuum at ~70 °C for about 12–18 h. Yield: 127 g (90%); m.p. 162–164° (*cf.* lit. (17) value 163–164°).

Methyl 2-O-Benzoyl-α-D-glucopyranoside 7b

Compound **6***b* (9) was debenzylidinated by atmospheric hydrogenolysis in methanol containing a few drops of H_2SO_4, platinum oxide being the catalyst. The title compound **7***b* was obtained in 95% yield after crystallization from chloroform; m.p. 181–182°; $[\alpha]_D^{23}$ +152.3 (*c*, 1 in ethanol).

Anal. Calcd. for $C_{14}H_{18}O_7$: C, 56.37; H, 6.08. Found: C, 55.69; H, 6.25.

Methyl 2,6-Di-O-benzoyl-α-D-glucopyranoside **7***a*

Method (a)

Methylene chloride (100 ml) was cooled to −78 °C and a solution of **7***b* (6.0 g, 20.13 mmol) in pyridine (50 ml) added. Benzoyl chloride (2.7 ml, 23.4 mmol) was added dropwise over a period of 0.5 h. The solution was maintained at this temperature for a further 0.5 h and then placed in a refrigerator (*ca.* 8 °C) for an additional 48 h. The reaction mixture was poured into an ice–water mixture (about 700 ml), the solution acidified with dilute hydrochloric acid, and the product extracted with methylene chloride (4 × 100 ml). After washing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with saturated sodium bicarbonate, water, and drying with sodium sulfate, the methylene chloride was removed leaving a residue which crystallized from benzene – petroleum ether (60–80 °C), affording 5.0 g (61% yield) of **7***a*; m.p. 138–140° (*cf.* lit. (10*b*) value 141–142°).

Method (b)

This is a modified version of the method reported by Lieser and Schweizer (10*b*). A solution of methyl-α-D-glucopyranoside (200 g, 1.03 mol) in methylene chloride (1.0 l) and pyridine (2.0 l) was cooled to ~ −30 °C. Benzoyl chloride (258 ml, 2.234 mol) was added over a period of 3 h and the benzoylation conducted as described above. The desired product, **7***a* 242.5 g was obtained in 59% yield.

Methyl 2,6-Di-O-benzoyl-3,4-di-O-methanesulfonyl-α-D-glucopyranoside **7***c*

The di-*O*-benzoyl glucopyranoside **7***a* (10.0 g, 24.8 mmol) was dissolved in pyridine (66 ml) and the solution cooled to −10 °C with an ice–salt bath. Methanesulfonyl chloride (10 ml, 128.5 mmol) was added slowly over a period of 2.5 h. Work-up procedure (as for **7***a* above) gave an amorphous solid, **7***c*, 13.0 g (93% yield); $[\alpha]_D^{23}$ +125.22 (*c*, 6.0 in $CHCl_3$); i.r. ν_{max} 1730 (benzoate ester), 1180, 1453 (CH_3—SO_2—) cm^{-1}. A satisfactory elemental analysis could not be obtained for this compound. In the mass spectrum the molecular ion was very weak; however for M − C_6H_5COOH($C_{16}H_{20}O_{10}S_2$) calculated mass 436.050, observed 436.047.

When the preparation was operated on a 20 times larger scale, the product failed to crystallize although from the t.l.c. it was homogeneous and had the proper R_f value. It could be used in the reductive elimination step directly.

Methyl 2-O-Benzoyl-3,4-di-O-methanesulfonyl-6-O-trityl-α-D-glucopyranoside **7***e*

The 2-*O*-benzoate **7***b* (9.0 g, 0.03 mol) was treated with trityl chloride (15.0 g, 0.054 mol) in 50 ml dry pyridine at room temperature for 48 h. T.l.c. indicated the absence of **7***b* and a substance presumed to be **7***d*. Without isolation, more pyridine (50 ml) was added, the solution cooled to −10 °C, and 50 ml methanesulfonyl chloride added. Work-up as for **7***a* above gave a gummy residue which crystallized readily from ether–methanol and yielded 14.0 g (76.5%) of **7***e*; m.p. 169–170°; $[\alpha]_D^{23}$ +103.57 (*c*, 5 in $CHCl_3$). I.r. ν_{max} 1730 (aromatic ester); 1365, 1180 (CH_3—SO_2—); 1605 (aromatic) cm^{-1}.

Anal. Calcd. for $C_{35}H_{36}S_2O_{11}$: C, 60.33; H, 5.21; S, 9.20. Found: C, 60.12; H, 5.19; S, 9.30.

Reductive Elimination of Methyl 2,6-Di-O-benzoyl-3,4-di-O-methanesulfonyl-α-D-glycopyranoside **7***c*. *Methyl 3,4-dideoxy-α-D-erythro-hex-3-enopyranoside* **4***a*, *its 6-O-benzoyl (***4***b) and 2,6-Di-O-benzoyl (***4***c) Derivatives*

To a solution of **7***c* (250 g, 0.436 mol) in 1.7 l of dry DMF was added sodium iodide (312.5 g, 2.180 mol) and zinc–copper couple (134 g, 2.180 mol). The rapidly-stirred solution was refluxed for 3 h, this time having been determined previously in a small-scale experiment. Isolation as previously described (11*a*) afforded an oily residue (90 g) which showed two spots on t.l.c. with R_f values 0.6 and 0.27 ($CHCl_3$–EtOAc, 1:1). A portion (7 g) of the mixture was chromatographed on a silica column. Elution with chloroform – ethyl acetate (1:1) gave a gum (4.0 g) which was homogeneous on t.l.c. (R_f 0.6). The n.m.r. parameters (Table 1) provide strong evidence for the dibenzoate **4***c*.

Further elution of the column afforded 2.5 g of material which was also chromatographically pure (R_f 0.27). The chemical shifts and coupling constants of the protons compiled in Table 1 are consistent with the proposed structure **4***b*. Independent proof of structure was provided by oxidation to the known ketone **1***d* (*vide infra*).

A 2% solution of **4***b* and **4***c* (separately or as a mixture) in methanol–water–triethylamine mixture (5:2:1) was kept at room temperature for 18 h. The solvent was evaporated leaving a mobile oil which was washed twice with petroleum ether (30–60°). T.l.c. showed the diol **4***a*, R_f 0.1 in ethyl acetate. A mixture of **4***b* and **4***c* (90 g) yielded 35 g of **4***a* (~35%) from **7***a*. The diol was characterized as its di-*O*-*p*-nitrobenzoate **4***d*; m.p. 152–153; $[\alpha]_D^{23}$ −57.7 (*c*, 5.0 in $CHCl_3$).

Anal. Calcd. for $C_{21}H_{18}N_2O_{10}$: C, 55.03; H, 3.96; N, 6.11. Found: C, 55.13; H, 3.99; N, 6.15.

N.m.r. parameters for **4***a*, *b*, *c*, and *d* are given in Table 1.

Methyl 3,4-Dideoxy-6-O-trityl-α-D-erythro-hex-3-enopyranoside **4***e*

Method (a)

A solution of syrupy **4***a* (6.0 g) and chlorotriphenylmethane (12.0 g) in dry pyridine (30 ml) was kept at room temperature for 72 h. The reaction mixture was poured into ice–water and the solid was triturated with saturated sodium bicarbonate, washed with water, and dried. The product was chromatographed on a silica column. Elution with 2 l of methylene chloride removed triphenyl carbinol (6.2 g). Further elution with 2 l chloroform – ethyl acetate (9:1) gave 8.0 g of **4***e* which crystallized from diethyl ether – ethanol.

Method (b)

The tritylated dimesylate prepared above **7***e* (2.32 g) was subjected to reductive elimination as described for **7***c*. After 3 h t.l.c. indicated a mixture presumed to be **4***e* and **4***g*. Debenzoylation was effected with the methanol–water–triethylamine system (*cf.* **4***a*) for 36 h. Purification by column chromatography gave **4***e* which crystallized from methanol (1.0 g, 74% from **7***e*).

Compound **4***e* had m.p. 122–123°; $[\alpha]_D^{23}$ −11.34 (*c*, 6.05 in $CHCl_3$); i.r. ν_{max} 3490 (hydroxyl) and 1595 (aromatic) cm^{-1}. Its n.m.r. spectrum, summarized in Table 1, is in agreement with the structure **4***e* assigned.

Anal. Calcd. for $C_{26}H_{26}O_4$: C, 77.59; H, 6.51. Found: C, 77.75; H, 6.46.

Methyl-2-O-benzoyl-4,6-O-benzylidene-α-D-glucopyranoside **9***a*

Methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (**8**) (17) (1.0 g, 3.78 mol) and sodium benzoate (4.0 g) in *N*,*N*-dimethylformamide (100 ml) was refluxed for 12 h. The solution was diluted with water and extracted with ether. Drying and evaporation of the organic phase yielded a product which was chromatographed on a silica column using chloroform – ethyl acetate (1:3) for elution. The fractions collected yielded methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside **6***e* (~20%) (27), starting epoxide **8** (~20%), and monobenzoate **9***a* (~45%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Monobenzoate **9***a* crystallized from methanol as long needles; m.p. 139–140° (lit. (13) m.p. 138–139°); $[\alpha]_D^{23}$ +9.75 (*c*, 5.5 in $CHCl_3$).

Anal. Calcd. for $C_{21}H_{22}O_7$: C, 65.28; H, 5.74. Found: C, 65.25; H, 5.72.

Methyl 2-O-Benzoyl-3,4-di-O-methanesulfonyl-6-O-trityl-α-D-altropyranoside **10***a*

A solution of **9***a* (2.9 g, 8.925 mmol) in methanol (200 ml) was hydrogenolyzed as described above for **6***b*. The product **10***b* (2.0 g) was treated with trityl chloride (3.5 g) in anhydrous pyridine (15 ml) for 12 h when t.l.c. indicated that the reaction was complete. A further 14 ml of pyridine was added, the mixture cooled to ~ 10 °C, and treated with methanesulfonyl chloride (10 ml). The usual work-up afforded an oil which crystallized readily from ether to give 3.16 g (58.5%) of **10***a*; m.p. 194 °C (dec.); $[\alpha]_D^{23}$ −13.88 (*c*, 6.0 in $CHCl_3$); i.r. ν_{max} 1745 (ester), 1425, and 1188 (CH_3—SO_2—) cm^{-1}.

Anal. Calcd. for $C_{35}H_{36}S_2O_{11}$: C, 60.33; H, 5.21; S, 9.20. Found: C, 60.22; H, 5.08; S, 8.90.

Methyl 3,4-Dideoxy-6-O-trityl-α-D-threo-hex-3-enopyranoside **5***b*

Method (a)

The tritylated altroside **10***a* (232 mg, 0.333 mmol) was dissolved in 3 ml of dry dimethylformamide and to this solution was added sodium iodide (249.6 mg, 1.6665 mmol) and zinc–copper couple (108.9 mg, 1.6665 mmol) and the mixture refluxed for 6 h after which time t.l.c. indicated the presence of two new compounds. The reaction products were isolated in the usual way and the n.m.r. spectrum of the residue (129 mg) showed a composition of 60% benzoate **5***c* and 40% alcohol **5***b*. Debenzoylation was completed by treating the product mixture with methanol–water–triethylamine (5:1:1) for 13 h. The resulting **5***b* crystallized from methanol; m.p. 152–153°; $[\alpha]_D^{23}$ +37.98 (*c*, 5.0 in $CHCl_3$); i.r. ν_{max} 3490 (hydroxyl) and 1595 (aromatic) cm^{-1}. The n.m.r. parameters are tabulated in Table 1.

Anal. Calcd. for $C_{26}H_{26}O_4$: C, 77.59; H, 6.51. Found: C, 77.69; H, 6.58.

Method (b)

Compound **4***e* (5.0 g, 12.4 mmol) was converted to the methenesulfonate in the usual way (*vide supra*). Crystallization from ethyl acetate – ethanol gave **4***f*, 5.0 g (83.75%); m.p. 69–70°; $[\alpha]_D^{23}$ −28.48 (*c*, 5.0 in $CHCl_3$); i.r. ν_{max} 1350, 1170, 850, 890 (CH_3SO_2—) cm^{-1}; n.m.r. τ 6.95 (s, 3, —SO_2—CH_3), 6.77 (d, 2, $J_{5,6'} = J_{5,6'} =$ 5.0 Hz, H-6, H-6′), 6.5 (s, 3, —OCH_3), 5.5–5.9 (m, 1, H-5), 4.9 (d, 1, $J_{1,2} = 4$ Hz, H-1), 4.75 (m, 1, H-2), 3.9–4.4 (AB quartet, 2, $J_{3,4} = 10$ Hz, H-3, H-4), 2.3–2.9 (m, aromatic protons).

Anal. Calcd. for $C_{27}H_{28}SO_6$: C, 67.49; H, 5.87; S, 6.66. Found: C, 67.30; H, 5.83; S, 6.57.

A mixture of **4***f* (4.0 g, 8.3 mmol) and sodium benzoate (20.0 g) in 300 ml of dry DMF was refluxed for 24 h. The product, isolated in the usual way, showed a single spot on a t.l.c. plate. However the product was placed on a silica column and eluted with chloroform. This afforded a light straw-colored foam, 3.5 g (83.5%) whose n.m.r. spectrum was consistent with the *threo* benzoate **5***c*.

Debenzoylation as in method *a* afforded 1.9 g (82.6%) of the title compound **5***b*.

Methyl 3,4-Dideoxy-6-O-trityl-α-D-glycero-hex-3-enopyranosidulose **1***g*

Method (a)

The tritylate **4***e* (7.0 g, 17.4 mmol) in chloroform (3.5 l) was stirred with activated manganese dioxide (84.0 g) for 48 h. The solids were filtered and the filtrate evaporated to give compound **1***g* (6.5 g, 94% yield) which readily crystallized from diethyl ether – ethanol (or ethanol) as long needles; m.p. 127.5–128°; $[\alpha]_D^{23}$ −15.86 (*c*, 5.75 in chloroform); u.v. λ_{max} 228.2 nm (ε 20 100); i.r. ν_{max} 1706, 1613 (α,β-unsaturated ketone) cm^{-1}. The n.m.r. parameters are given in Table 1.

Anal. Calcd. for $C_{26}H_{24}O_4$: C, 77.98; H, 6.04. Found: C, 78.14; H, 5.87.

Method (b)

Compound **5***b* (300 mg; 0.746 mmol) was oxidized with manganese dioxide as in method *a* for 40 h. Ketone **1***g* was isolated in 93.8% yield.

Method (c)

The oxidant was prepared (*cf.* 4*i*) by adding 15.0 g of CrO_3 to pyridine (500 ml) which was previously cooled to ~ −5 °C. The mixture was then allowed to come to room temperature and compound **4***e* (8.8 g, 21.88 mmol) dissolved in 30 ml of pyridine was added and the mixture stirred at room temperature. A chromatogram, in chloroform – ethyl acetate (3:1), taken after 12 h showed that the reaction had gone to completion. Ether (~800 ml) was then added and the mixture filtered. The filtrate was evaporated to a low volume, methylene chloride (200 ml) was added followed by 400 ml of ether, and the mixture filtered. The filtrate was treated twice again in a similar manner. Evaporation of solvent left a residue which crystallized from ethanol to give 6.0 g (67.8%) of **11**.

Methyl 3,4-Dideoxy-α-D-glycero-hex-3-enopyranosidulose **1***a*

Method (a)

Methyl 3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside **4***a* (oil, 1.32 g) was oxidized with manganese dioxide as described above for compound **4***e*. After 24 h the residue (870 mg) showed two spots on t.l.c. in ethyl acetate. The mixture (870 mg) was separated on a silica gel column and eluted with ethyl acetate (250 ml). The first fraction yielded **1***a* which crystallized as long needles from diethyl ether – petroleum ether (30–60°) and yielded 600 mg; m.p. 60.5–61°; $[\alpha]_D^{23}$ +54.65 (*c*, 5.0 in $CHCl_3$); u.v. λ_{max} 225.2 nm (ε 9521); i.r. ν_{max} 3571 (hydroxyl), 1700, 1653 (α,β-unsaturated ketone) cm^{-1}. The n.m.r. parameters are shown in Table 1.

Anal. Calcd. for $C_7H_{10}O_4$: C, 53.16; H, 6.37. Found: C, 53.12; H, 5.88.

Further elution of the column with ethyl acetate (100 ml) afforded unchanged starting material **4***a* (150 mg).

Method (b)

Chloroform was cooled down to about −5 °C and hydrogen chloride gas bubbled through for 5 s. The ice-cold HCl–chloroform solution (10 ml) was then added to the compound **1***g* (1.0 g, 2.5 mmol) dissolved in 5 ml of cold chloroform and the resulting solution kept at 0 °C with an ice bath. After 0.5 h, t.l.c. indicated that the reaction had gone to completion. The acid was neutralized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

after 1 h with solid sodium carbonate and after filtration, the solvent evaporated by blowing a stream of nitrogen over the solution. The solid residue was chromatographed on a silica gel column. Elution with 1000 ml of chloroform gave triphenylcarbinol and further elution with chloroform – ethyl acetate (9:1) afforded 350 mg (85%) of **1***a*.

Methyl 6-O-Benzoyl-3,4-dideoxy-α-D-glycero-hex-3-enopyranosidulose **1***d*

Method (a)

The 6-*O*-benzoate **4***b* was oxidized with manganese dioxide in the usual way to the keto-benzoate **1***d* (90%); m.p. 87–88° (lit. (7) 85.5–86°).

Method (b)

Alternatively, ketone **1***a* (0.474 g; 3.0 mmol) was dissolved in methylene chloride (6 ml) and cooled to −30 °C with Dry-Ice – acetone before adding dry pyridine (3 ml). Benzoyl chloride (0.61 ml, 5.0 mmol) was added dropwise during 0.5 h and the mixture maintained for an additional 0.5 h at −30 °C. The usual work-up gave a gum which crystallized from ethanol giving 0.600 g (76.3% yield) of the benzoate **1***d*.

Methyl 3,4-Dideoxy-6-O-p-nitrobenzoyl-α-D-glycero-hex-3-enopyranosidulose **1***e*

p-Nitrobenzoylation of ketol **1***a* in the usual way (28) gave the title compound **1***e*; m.p. 138.5–139°; $[\alpha]_D^{23}$ −47.64 (*c*, 5.0 in $CHCl_3$). N.m.r. parameters are in Table 1.

Anal. Calcd. for $C_{14}H_{13}NO_7$: C, 54.73; H, 4.26; N, 4.56. Found: C, 54.71; H, 4.24; N, 4.55.

Methyl 6-O-Acetyl-3,4-dideoxy-α-D-glycero-hex-3-enopyranosidulose **1***f*

Ketol **1***a* (0.237 g, 1.5 mmol) was dissolved in dry pyridine and the solution cooled in an ice–salt bath. Acetic anhydride (3 ml) was added slowly to the cold solution which was well stirred during the addition. The reaction flask was placed in the refrigerator and left overnight. Methanol was added to the solution in order to destroy the excess acetic anhydride after which the solution was evaporated under reduced pressure at about 40 °C. Toluene was evaporated from the residue a number of times to remove the last traces of pyridine. The residue (homogeneous on t.l.c.) had a red color and was filtered on a short silica column using ethyl acetate – chloroform (1:3) as solvent. The residue **1***f* 0.273 g (90% yield) was an oil and its n.m.r. parameters are given in Table 1.

We are grateful to the National Research Council of Canada and Bristol Laboratories for financial support.

Free Radical Substitution Reactions of Sulfur Monochloride. A Limited Synthesis of Mercaptans[1]

DENNIS D. TANNER AND BRIAN G. BROWNLEE
The Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 8, 1973

The photolysis of sulfur monochloride with a series of saturated aliphatic hydrocarbons yielded alkyl chlorides, di- and polysulfides, hydrogen chloride, and elemental sulfur. The free radical substitution reactions leading to the production of alkyl chloride and the di- and polysulfides were shown to proceed via a chlorine atom abstraction reaction. The major products, the di- and polysulfides could be transformed quantitatively, by lithium aluminum hydride reduction into their corresponding mercaptans. The reaction describes a simple free radical route to the synthesis of a variety of alkyl mercaptans.

La photolyse du monochlorure de soufre avec une série d'hydrocarbures aliphatiques saturés conduit aux chlorures d'alkyles, di- et polysulfures, acide chlorhydrique et au soufre élémentaire. On a montré que les réactions de substitution par radicaux libres conduisant à la formation de chlorure d'alkyde etaux di- et polysulfures procèdent par une réaction d'abstraction d'un atome de chlore. Les produits majeurs, les di- et polysulfures peuvent être transformés quantitativement par réduction à l'hydrure de lithium et aluminium en leurs mercaptans correspondants. La réaction constitue une voie d'accès simple par radicaux libres à une variètè d'alkylmercaptans.

Can. J. Chem., 51, 3366 (1973)

Introduction

Although sulfur monochloride is a widely used substance for a large variety of industrial processes little has been published on the free radical reactions of this reagent (1). The photo-induced reaction of sulfur monochloride with a number of hydrocarbon substrates has been carried out in a continuous flow reactor in order to obtain as the desired substitution products, alkylthiosulfenyl chlorides (2). The products were characterized by converting them to their derivative thiocyanates, and dimethylamino disulfides.

$$RSSCl + 2KCN \rightarrow RSCN + KSCN + KCl$$

$$RSSCl + 2HN(CH_3)_2 \rightarrow RSSN(CH_3)_2 + H_2N(CH_3)_2Cl$$

The main side reaction reported was the formation of elemental sulfur. Alkyl chlorides were obtained, but were not quantitated.

Müller and Schmidt (2) suggested that the initial step in the reaction was the photo-initiated homolysis of the S—Cl bond, eq. 1.

$$[1] \qquad S_2Cl_2 \xrightarrow{h\nu} Cl\cdot + \cdot S_2Cl$$

Hydrogen abstraction was suggested to be by chlorine atoms, eq. 2.

$$[2] \qquad RH + Cl\cdot \rightarrow R\cdot + HCl$$

Two possibilities were proposed for the formation of the alkyl thiosulfenyl chlorides, eqs. 3 and 4.

$$[3] \qquad R\cdot + S_2Cl_2 \rightarrow RS_2Cl + Cl\cdot$$

$$[4] \qquad R\cdot + \cdot S_2Cl \rightarrow RS_2Cl$$

Alkyl chlorides were suggested as arising from coupling reactions, eq. 5.

$$[5] \qquad R\cdot + Cl\cdot \rightarrow RCl$$

In order to explore the synthetic utility of sulfur monochloride as a reagent to form carbon sulfur bonds free radically, the photolysis was investigated in a static system and the reactions were carried out until all of the active halogen was consumed.

Results and Discussion

The photolysis of sulfur monochloride with a selected series of saturated hydrocarbons each yielded a similar mixture of products. The composition of these mixtures can best be illustrated by the major products (>1%) obtained from the reaction of cyclohexane (Table 1). It was determined that, under the reaction conditions, for each mol of sulfur monochloride that was used approximately 1 mol (±10%) of cyclohexane was consumed.

The mechanism of the reaction is apparently complex and could not be written as a chain reaction since, although it was photo-initiated,

it could not be induced by benzoyl peroxide (80°) or AIBN (40°) and comparable photochemical reactions were not retarded by molecular oxygen or nitric oxide. The lack of an appreciable chain length for the photo-induced reaction is undoubtedly due to the presence of molecular sulfur, an effective radical scavenger (3), which is formed during the reaction.

In the reactions of the hydrocarbons studied, the hydrocarbon material that was consumed during the reaction appeared as (>90%) monosubstituted alkyl chlorides or di- and polysulfides. An analysis of the products from the reaction of butane and isobutane is given in Table 2. The primary:secondary:tertiary selectivities per hydrogen of sulfur monochloride with butane and isobutane could be calculated from the product yields given in Table 2 by comparing the ratios of the primary chlorides plus sulfides with those of the secondary and tertiary isomers. The values obtained, 1:3.1:4.6, are quite comparable to those reported for molecular chlorine with these substrates, 1:3.5:4.8 (vapor phase, 40°) (4).

The substitution pattern for the sulfur containing compounds was determined by n.m.r. spectral analysis. The validity of this analysis was confirmed by carrying out a lithium aluminum hydride reduction of the reaction mixture, quantitatively transforming the di- and polysulfides into mercaptans, and comparing the g.l.p.c. analysis of the mercaptans obtained with those of the di- and polysulfides analyzed by n.m.r.

The selectivities obtained for the reactions of sulfur monochloride with the two isomeric butanes suggested that the hydrogen abstracting species in the reaction was the chlorine atom. This suggestion was further substantiated by determining the relative rates of reaction of sulfur monochloride with a number of substrates and comparing these rates with those previously obtained for the reactions of molecular chlorine (see Table 3).

If one assumes that the di- and polysulfides, which are the major products of the substitution reaction, are formed by alkyl radical displacement on sulfur and that the alkyl chlorides are

$$R\cdot + Y-(S)_n-R \rightarrow R-(S)_n-R + Y\cdot \qquad \begin{matrix} n \geq 2 \\ Y = Cl, RS, SCl \end{matrix}$$

formed by displacement on a terminal chlorine, then the partition of the products between chlorides and sulfides would be subject to steric interactions. From these assumptions the generalization follows that the primary alkyl radicals would most likely favor displacement on sulfur while tertiary radicals would give lower values of the ratio of sulfides to chlorides (S ratios). Values of these ratios calculated from the distribution of products found in the reaction of the appropriate substrates are listed in Table 4 for a number of radicals, and can be of use in predicting the product distribution of sulfides and chlorides produced in the reaction.

The synthetic limitations of the reagent are that it gives the distribution of products determined by the nonselective chlorine atoms and that it gives a mixture, although easily separable after reduction, of mercaptans and chlorides.

A number of model substrates were subjected to the photochemical reactions of sulfur monochloride and reduced to their mixtures of alkyl chloride and mercaptans. The yields of mercaptans, although not outstanding (see Table 5), provide a simple free radical route to alkyl mercaptans, and may possibly be useful in the synthesis of otherwise difficultly obtainable compounds.

Experimental

Materials

Sulfur monochloride was supplied by Hooker Electrochemical Co. (highest purity grade) and was purified by the Method of Brauer (6). It was distilled from elemental sulfur (4% by weight) at atmospheric pressure, b.p. 126° (680 mm), lit. (6) b.p. 138°. A further distillation from elemental sulfur (2% by weight) under reduced pressure gave pure material, b.p. 71° (70 mm).

Anal. Calcd. for S_2Cl_2: Cl, 52.51. Found: Cl, 52.39, 52.45.

The u.v. spectrum (C_6H_{12}) showed maxima at 201 (log ε 3.71) and 265 mμ (log ε 3.83). Literature values (2, 7) are 265 and 266 mμ (log ε 3.80). The absorbance went to zero above 510 mμ for a concentrated solution

(1.1×10^{-2} *M*). For 1% of contaminating sulfur dichloride the absorbance would have been 0.01 at 520 mμ (7). This absence of absorption above 510 mμ, the excellent agreement of the extinction coefficient at 265 mμ with the literature value (7), and the elemental analysis were taken as proof of the absence of sulfur dichloride in the purified sulfur monochloride. After purification the sulfur monochloride was stored at room temperature protected from light and atmospheric moisture.

Cyclohexane was Phillips Petroleum Co. pure grade material. Cyclopentane was Matheson, Coleman and Bell practical grade material. It was purified by treating with concentrated sulfuric acid, followed by dilute potassium permanganate solution. After drying and distillation it had b.p. 46.5° (700 mm) and was > 99.5% pure by g.l.p.c. analysis. Butane, isobutane, and neopentane were Phillips Petroleum Co. research grade gases. Toluene was purified by distilling from phosphorus pentoxide and had b.p. 107.5° (700 mm). 2,3-Dimethylbutane was Phillips Petroleum Co. research grade. Adamantane was *puriss* grade material supplied by Aldrich Chemical Co. Freon 112 (1,1-difluoro-1,2,2,2-tetrachloroethane) had b.p. 89.5–90.0° (700 mm); Freon 113 (1,1,2-trichloro-1,2,2-trifluoroethane) had b.p. 45.5° (704 mm). The carbon tetrachloride solvent used in reactions of sulfur monochloride with hydrocarbons was Fisher Scientific Spectranalyzed Reagent and it was distilled before use.

Reactions of Sulfur Monochloride with Hydrocarbon Substrates

A carbon tetrachloride solution of sulfur monochloride (0.3 *M*) and the desired hydrocarbon (3 *M*) were placed in Pyrex ampoules, degassed, and sealed under vacuum. After equilibration in a Pyrex water bath at 40.0 ± 0.1°, the ampoules were irradiated with two 200 W tungsten lamps. Irradiation times were 20–80 h depending on the size of sample and initial concentration of reactants. The reactions could be followed visually. After several h, the original pale yellow color of the sulfur monochloride had deepened. As the reactions progressed this yellow color faded until, at complete reaction, the reaction mixtures were nearly colorless. Reaction mixtures were tested at this point with moist potassium iodide – starch paper and found to be free from active chlorine.

Preparative reactions were carried out either in large sealed ampoules for the reactions of the more volatile hydrocarbon substrates or in a three-necked flask equipped with a magnetic stirrer and reflux condenser. The condenser outlet was connected to a gas bubbler filled with KEL-F oil so that a positive pressure was maintained in the reaction vessel. After flushing the system with nitrogen irradiation was begun, at ambient temperatures, with two 200 W incandescent lamps. In these reactions the heat from the lamps caused the temperature to rise to approximately 50–60°.

Reaction of Cyclohexane with Sulfur Monochloride

When reaction ampoules were opened the sharp smell of hydrogen chloride was apparent. When the escaping gas was bubbled through water, the aqueous portion acidified, and silver nitrate solution added, a precipitate of silver chloride was observed. Hydrogen chloride yields were determined by breaking ampoules under water and titrating the hydrogen chloride with standard 0.1 *M* sodium hydroxide solution using phenolphthalein as the indicator. The amount of hydrogen chloride per mol of S_2Cl_2 was found to vary from 1.39–1.46 for reactions 0.094–0.300 *M* in S_2Cl_2 and 2.8 *M* in cyclohexane.

The absence of hydrogen sulfide was confirmed by a negative test with lead acetate and acetic acid.

Elemental sulfur could conveniently be isolated from the reaction mixtures by column chromatography. Four reaction mixtures (20 ml each) from sulfur monochloride (0.111 *M*, 0.009 mol) and cyclohexane (2.8 *M*, 0.22 mol) were combined and the solvent was removed by distillation. Treatment of the residue with Skellysolve B left 0.097 g of undissolved elemental sulfur. Chromatography of the soluble portion on silica gel (70 g) gave a further 0.104 g of elemental sulfur eluted with Skellysolve B. The total yield of sulfur (0.201 g) represented 35% of the sulfur originally present as sulfur monochloride. A duplicate experiment yielded 30% of elemental sulfur. The sulfur isolated was identical to elemental sulfur in melting point (116–118°), mixture melting point, R_f upon analysis by t.l.c. on silica gel, and color test with pyridine – sodium hydroxide reagent (8).

Cyclohexyl chloride was determined by analyzing reaction mixtures by g.l.p.c. (5 ft × ¼ in., 20% SE-30 at 100°) after addition of chlorobenzene as the external standard. Fractional distillation of a reaction mixture yielded pure cyclohexyl chloride, whose identity and purity was established by a comparison of its identical g.l.p.c. retention time, i.r. spectrum, and refraction index (n_D^{20} 1.464; lit. (9) n_D^{20} 1.462) with those of an authentic sample.

Dicyclohexyl disulfide was estimated for one reaction mixture (sulfur monochloride 0.31 *M*, cyclohexane 3 *M* in carbon tetrachloride) by g.l.p.c. (5 ft × ¼ in., 20% SE-30 column programmed from 115–200°) after addition of naphthalene as the external standard. A yield of 0.084 mol of dicyclohexyl disulfide/mol of sulfur monochloride was determined. Its identity was established by the comparison of its g.l.p.c. retention time, its t.l.c. R_f (silica gel), and mass and i.r. spectra, with those of an authentic sample.

The dicyclohexyl polysulfides were analyzed by n.m.r. or by reduction with lithium aluminum hydride to cyclohexyl mercaptan.

Nuclear Magnetic Resonance Analysis of the Polysulfides

A 10-ml portion of a reaction mixture (sulfur monochloride 0.306 *M*, cyclohexane 3.0 *M* in carbon tetrachloride) was evaporated and benzyl chloride (0.062 g, 0.49 mmol) was added to the residue. From the n.m.r. spectrum (benzene) the ratio of the methylene protons of the standard (τ 5.9) to the α-protons of the dicyclohexyl polysulfides (τ 6.7–7.7) was 1:1.9. From this, a yield of 0.30 mol of dicyclohexyl polysulfides (including the disulfide) per mol of sulfur monochloride was calculated. Resonances for the α-proton of residual cyclohexyl chloride and the ring protons were observed at τ 6.1–6.5 and τ 7.7–9.4. The analysis was calibrated by using known mixtures of di- and tetrasulfides made from authentic materials.

Lithium Aluminum Hydride Reduction of the Polysulfide

The residue obtained after the distillation of the volatile materials (cyclohexane, carbon tetrachloride, and cyclohexyl chloride) from the reaction mixture was dissolved in THF and added dropwise to a stirred solution of lithium aluminum hydride in THF (0°). The reaction mixture was stirred at room temperature for 0.5 h and then heated under reflux for 3 h. Excess hydride was decomposed by dropwise addition of water to the cooled solution (0°). Toluene was added as the standard. After addition of concentrated hydrochloric acid (2 ml) and stirring for 10–15 min the reaction mixture was analyzed for cyclohexyl mercaptan by g.l.p.c. (10 ft × ¼ in., 10% SE-30 column programmed from 40–150°). The yield of cyclohexyl mercaptan was 0.608 ± 0.020 mol per mol of sulfur monochloride for the two reactions analyzed. The method of analysis was found to be quantitative by carrying it out on known mixtures of di- and tetrasulfides. The mercaptan was further characterized by converting it to cyclohexyl 2,4-dinitrophenyl disulfide, m.p. 114.5–115.5 and comparing its m.p., mixture m.p., and i.r. with those of authentic materials.

Competitive Reactions

For the competition experiments, 2-ml portions of a solution of cyclohexane (2.8 *M*, 5.6 mmol), the second hydrocarbon (2.7–2.9 *M*, 5.4–5.8 mmol) and Freon 112 (3 *M*) were placed in ampoules containing sulfur monochloride (0.42 g, 3.1 mmol). The ampoules were degassed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and sealed under vacuum. The original solution, without sulfur monochloride, was analyzed by g.l.p.c., using a 10 ft × ¼ in., 10% SE-30 on 60/80 Chromosorb W AW column, to give the initial peak area ratio of Freon 112 to cyclohexane and to the second hydrocarbon. The ampoules containing sulfur monochloride were irradiated at 40° for 60–85 h. The reaction mixtures were then analyzed by g.l.p.c. to give the final peak area ratios. Relative reactivities ($k_{RH}/k_{C_6H_{12}}$) were calculated in the usual manner (10). The results of these calculations are listed in Table 3.

Reaction of Sulfur Monochloride with n-Butane and Isobutane

The desired amount of hydrocarbon (5 ml, 50 mmol) was transferred into an ampoule cooled in Dry Ice. An aliquot (10.0 ml) of a standard solution of sulfur monochloride (0.3 *M*, 3.0 mmol) and Freon 112 (0.2 *M*, 2.0 mmol) in carbon tetrachloride was then pipetted into the ampoule. The ampoule was degassed, sealed under vacuum and irradiated at 40° for 80–100 h.

The reactions with *n*-butane when analyzed by g.l.p.c. (20 ft × ⅛ in., 5% SF-96 on Chromosorb W AW-DMCS column) gave (four reactions) 0.08 ± 0.01 mol per mol S_2Cl_2 of 1-chlorobutane and 0.20 ± 0.01 mol per mol S_2Cl_2 of 2-chlorobutane. The reactions with isobutane when analyzed by g.l.p.c. (SF-96 column) gave for four reactions 0.18 ± 0.01 mol per mol of S_2Cl_2 of *tert*-butyl chloride. The chlorides were quantitated using standard calibration curves determined for Freon 112 and the authentic materials.

The polysulfides produced in the reaction were collected, after the removal of solvent and alkyl chlorides, by distillation, and were analyzed directly by n.m.r. spectroscopy, and also by analysis of the mercaptans formed upon lithium aluminum hydride reduction of the mixture of polysulfide.

To the mixture of mercaptans isolated after reduction was added an external standard (Freon 113). The mixture was analyzed by g.l.p.c. (20 ft × ⅛ in., SF-96 column). *n*-Butane yielded 0.23 mol per mol of S_2Cl_2 of 1-butyl mercaptan and 0.45 mol per mol of S_2Cl_2 of. 2-butyl mercaptan. Isobutane yielded 0.45 ± 0.01 mol per mol of S_2Cl_2 of isobutyl mercaptan and 0.18 ± 0.01 mol per mol of S_2Cl_2 of *tert*-butyl mercaptan.

The mercaptans were identified and characterized by their n.m.r. spectra and the spectra of their 2,4-dinitrophenyl disulfide derivatives. The n.m.r. analysis of the polysulfides of *n*-butane was carried out by adding a known amount of anisole as a standard to the polysulfide residue and the n.m.r. spectrum of the mixture was obtained using carbon tetrachloride as the solvent. In preparing the samples undissolved elemental sulfur was removed by filtration. The spectrum was assigned by comparison with di-*n*-butyl and di-*sec*-butyl disulfides as model compounds by peak enhancement. Terminal methyl groups appeared as overlapping signals at τ 8.8–9.3, the doublet for the —S—CH—CH_3 methyl group was at τ 8.63, methylene protons were from τ 8.0–8.8, and the α-protons were unresolved from τ 6.8–7.6 in good agreement with literature values (11) for the chemical shifts of the α-protons of di-*n*-butyl and di-*sec*-butyl and di-, tri-, and tetrasulfides. The isomer distribution, determined from the integrated spectra, agreed within the experimental limits determined by the analysis of the mercaptan mixtures.

The analysis of the n.m.r. spectra of the polysulfides of isobutane was carried out by assigning the absorption peaks, using di-*tert*-butyl disulfide, di-*tert*-butyl tetrasulfide, and di-isobutyl disulfide as model compounds. Singlets for *tert*-butyl protons were present at τ 8.71 (disulfide) and τ 8.62 (polysulfides). The *gem*-dimethyl doublet was at τ 9.0, a multiplet for the tertiary hydrogens was at τ 7.4–8.2 and a multiplet for the α-protons was at τ 7.05–7.35 for the isobutyl groups. The chemical shifts of the α-protons and the *tert*-butyl singlets were in agreement with literature values (11, 12). The isomer ratios were determined by comparing the integrated area for the *gem*-dimethyl doublet to that for the *tert*-butyl singlets. The total yield of butyl groups was determined by comparing their nine proton signals to the eight proton signals of an added standard, anisole. The results agreed within the experimental limits given by the reduction method.

Reaction of Sulfur Monochloride with Cyclopentane

In the vessel described for preparative reactions cyclopentane and sulfur monochloride were reacted to 75% completion in 5 days (iodometric titration). The deep amber reaction mixture was stirred with excess potassium iodide in 10% aqueous acetic acid. The aqueous portion was separated and the organic layer was washed with aqueous sodium thiosulfate solution, water, and then dried over anhydrous sodium sulfate. The reaction mixture was analyzed as was that for cyclohexane and yielded after reduction 0.42 ± 0.03 mol per mol S_2Cl_2 of cyclopentyl mercaptan and 0.24 mol per mol S_2Cl_2 of cyclopentyl chloride.

Reaction of Sulfur Monochloride with Neopentane

Neopentane (6 ml) and a carbon tetrachloride solution (10 ml) of sulfur monochloride (0.29 *M*, 2.9 mmol) were placed into five large ampoules. One of these ampoules contained Freon 112 (0.133 g, 0.65 mmol) as the internal standard. The ampoules were degassed, sealed, and irradiated at 40° for 3 days after which time the reaction mixtures were nearly colorless.

The reaction mixture containing Freon 112 was analyzed by g.l.p.c. (25 ft × ¼ in., 10% UCON POLAR or Firebrick column) in order to estimate the yield of neopentyl chloride. Using calibration data for Freon 112 *vs.* isobutyl chloride, a yield of 36% (0.11 g, 1.05 mmol) of neopentyl chloride was estimated.

The solvent was removed from all five reaction mixtures and the combined polysulfides were reduced with lithium aluminum hydride (1.0 g, 0.026 mol) in ether (75 ml, heated under reflux for 24 h). After decomposition of excess hydride the ether solution was poured into ice–water (100 ml) containing hydrochloric acid (10 ml). The layers were separated, the aqueous portion was extracted with ether (50 ml), and the combined ether extracts were washed with water (50 ml) and saturated sodium chloride solution (50 ml) and dried over anhydrous sodium sulfate. The ether was removed by distillation through a short Vigreux column. Distillation of the residue gave 0.70 g (46%) of neopentyl mercaptan: b.p. 95–100° (688 mm);

For personal use only.

n_D^{20} 1.4689; i.r. (CS_2) 2950, 2920, 2905, 2855, 1380, and 1355 cm^{-1}; n.m.r. (CCl_4) τ 7.63 (d, 2, J = 9 Hz, —S—CH_2—), τ 8.88 (t, 1, J = 9 Hz, S—H), and τ 9.03 (s, 9, *tert*-butyl).

The 2,4-dinitrobenzenesulfenyl derivative was prepared from the mercaptan (0.19 g, 1.8 mmol) and 2,4-dinitrobenzenesulfenyl chloride (0.445 g, 1.9 mmol) by the usual method (13). After crystallization of the crude product from methanol, 0.35 g (69%) of neopentyl 2,4-dinitrophenyl disulfide, m.p. 85–88° was obtained. Two further crystallizations from methanol gave an analytically pure sample, m.p. 91–92°.

Anal. Calcd. for $C_{11}H_{14}N_2O_4S_2$: C, 43.69; H, 4.67; N, 9.27. Found: C, 43.46; H, 4.81; N, 9.28.

Reaction of Sulfur Monochloride with Adamantane

The reaction was carried out in a three-necked flask. Adamantane (20 g, 0.147 mol) was reacted for 4 days with sulfur monochloride (2.00 g, 0.0148 mol) in carbon tetrachloride (100 ml). The solvent was removed from the reaction mixture and the residue was subjected to column chromatography using an alumina column packed in Skellysolve B. Elution with Skellysolve B gave 15.3 g of recovered adamantane and 2.05 g of a misture of elemental sulfur and chloroadamantane. The sulfur was isolated by dissolving the chlorides in acetone. The soluble portion (1.61 g) was shown to possess an n.m.r. spectrum ($CDCl_3$) consistent with a 60:40 mixture of 1-chloroadamantane and 2-chloroadamantane by comparison with published spectral data for these two compounds (14, 15). The yields of 1-chloroadamantane and 2-chloroadamantane calculated were therefore 38% (5.6 mmol) and 26% (3.8 mmol) respectively based on sulfur monochloride. The isomers could be separated by preparative g.l.p.c. 1-Chloroadamantane had m.p. 168–169°, lit. (16) m.p. 168.5–169.5°. The n.m.r. spectrum ($CDCl_3$) of the material was identical to that reported in the literature (14). 2-Chloroadamantane had m.p. 196–197°, lit. (17) m.p. 196°. The n.m.r. spectrum of this material was identical to that reported in the literature (15).

Lithium Aluminum Hydride Reduction of the Polysulfides of 1-Adamantyl Mercaptan and 2-Adamantyl Mercaptan

A portion (1.32 g) of the polysulfides previously obtained by column chromatography was reduced with lithium aluminum hydride (1.0 g, 0.026 mol) in THF (50 ml, heated under reflux for 3 h). After decomposition of excess hydride, the reaction mixture was poured into ice–water (300 ml) containing sulfuric acid (10 ml). After extraction with chloroform (2 × 150 ml) the combined extracts were washed with water (2 × 150 ml) and dried over anhydrous sodium sulfate. Removal of the solvent gave 1.04 g of a pale yellow semisolid. This material was subjected to column chromatography on a column of 30 g of alumina packed in Skellysolve B. Elution with Skellysolve B gave 0.585 g of material consisting of two components by g.l.p.c. analysis (5 ft × ¼ in., SE-30 column). The isomer of shorter retention time was the 1-isomer (30%) and the isomer of longer retention time was the 2-isomer (70%). Using the yield of isolated material and the isomer ratio from g.l.p.c. analysis the yield of 1-adamantyl mercaptan was 9% (1.3 mmol) and the yield of 2-adamantyl mercaptan was 21% (3.1 mmol) based on sulfur monochloride and corrected for the reduction of all of the polysulfide residue.

Pure samples of the two mercaptans were isolated by preparative g.l.p.c. 1-Adamantyl mercaptan had m.p. 95–97°, lit. (18) m.p. 100–102°; i.r. (CCl_4) 2910, 2850, 1450, and 2565 cm^{-1} (S—H, weak); n.m.r. (CCl_4) τ 8.06 (s, 9, β and γ hydrogens), τ 8.29 (s, 6, δ hydrogens), and τ 8.57 (s, 1, S—H); mass spectrum *m/e* (relative intensity) 168 (14), 136 (12), 135 (100), 93 (15), 79 (17).

Mol. Wt. Calcd. for $C_{10}H_{16}S$: 168.0973. Found (exact mass): 168.0970.

2-Adamantyl mercaptan had m.p. 146–148°; i.r. (CCl_4) 2910, 2850, 1465, 1455, and 2580 cm^{-1} (S—H, very weak); n.m.r. (CCl_4) τ 6.65 (d broad, 1, J = 7 Hz, —S—C—H), τ 7.77 and 8.48 (q broad, 4, J_{gem} = 13 Hz, A_2B_2 quartet) τ 8.15 (s, broad, 10) and τ 8.54 (d, 1, J = 7 Hz, S—H); mass spectrum *m/e* (relative intensity) 168 (33), 136 (15), 135 (100), 93 (20), 91 (11), 81 (10), 79 (21).

Mol. Wt. Calcd. for $C_{10}H_{16}S$: 168.0973. Found (exact mass). 168.0974.

1-Adamantyl 2,4-dinitrophenyl Disulfide and 2-Adamantyl 2,4-dinitrophenyl Disulfide

1-Adamantyl mercaptan (0.011 g, 0.06 mmol) was reacted with 2,4-dinitrobenzenesulfenyl chloride (0.015 g, 0.06 mmol) in the usual manner. After crystallization of the product from methanol 0.013 g (59%) of 1-adamantyl 2,4-dinitrophenyl disulfide was obtained as yellow needles, m.p. 159–160°.

Anal. Calcd. for $C_{16}H_{18}N_2O_4S_2$: C, 52.44; H, 4.95; N, 7.65. Found: C, 52.23; H, 4.94; N, 8.10.

2-Adamantyl mercaptan (0.025 g, 0.15 mmol) was reacted with 2,4-dinitrobenzenesulfenyl chloride (0.038 g, 0.16 mmol). The crude product was crystallized from ethyl acetate – cyclohexane. After a further crystallization from methanol 0.018 g (33%) of analytically pure 2-adamantyl 2,4-dinitrophenyl disulfide, m.p. 144–145° was obtained.

Anal. Calcd. for $C_{16}H_{18}N_2O_4S_2$: C, 52.44; H, 4.95; N, 7.65. Found: C, 52.78; H, 5.26; N, 7.33.

On the Thermodynamically Controlled Epimerization of Deoxynitroinositol Monomethyl Ethers[1]

JAN KOVÁŘ AND HANS H. BAER
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5

Received June 8, 1973

1-Deoxy-4-*O*-methyl-1-nitro-*scyllo*-inositol (**1**), its *myo*-1 epimer (**2**), 3-deoxy-6-*O*-methyl-3-nitro-*epi*-inositol (**3**), and its *muco*-3 epimer (**4**) in the presence of excess base give nitronates (**1′** from **1**, **2′** from **2**, and **3′** from **3** and **4**) which are mutually interconverted by epimerization. The equilibrium constants were determined, revealing the order of thermodynamic stabilities of the nitronates to be **3′** > **2′** > **1′**. In the presence of a catalytic amount of base, the nitro inositols epimerize also, and the order of stability of the free nitro compounds is **1** > **2** ≫ **4** > **3**. The connection between these epimerization equilibria and the pK_a values of the compounds is discussed. The results are explained in terms of conformational analysis, whereby the importance of the $A^{(1,3)}$ strain is reasserted and good agreement with calculated conformational energy data is obtained.

Le déoxy-1-*O*-méthyl-4 nitro-1 *scyllo* inositol (**1**), son épimère *myo*-1 (**2**), le déoxy-3-*O*-méthyl-6 nitro-3 *épi*-inositol (**3**) et son épimère *muco*-3 (**4**), en présence d'un excès de base conduisent aux nitronates (**1′** à partir de **1**, **2′** à partir de **2**, et **3′** à partir de **3** et **4**) qui s'interconvertissent mutuellement par épimérisation. Les constantes d'équilibre ont été déterminées et indiquent l'ordre de stabilité thermodynamique suivant pour les nitronates **3′** > **2′** > **1′**. En présence de quantité catalytique de base, les inositols nitro s'épimérisent également et l'ordre de stabilité des composés nitro libres est **1** > **2** ≫ **4** > **3**. La relation entre les équilibres d'épimérisation et les valeurs des pK_a des composés a été discutée. Les résultats ont été interprétés par l'analyse conformationnelle et l'importance de la tension $A^{(1,3)}$ a été confirmée; un bon accord avec les données d'énergie conformationnelle calculée a été obtenu.
[Traduit par le journal]

Can. J. Chem., **51**, 3373 (1973)

In recent articles we have described the synthesis (2) of the four stereoisomeric deoxynitroinositol monomethyl ethers (**1–4**) having the *scyllo*, *myo*-1, *epi*-3, and *muco*-3 configurations, and have discussed the formation of these products by cyclization of 6-deoxy-6-nitro-D-glucose and -L-idose from the viewpoint of kinetic control (3). We now report on the results of base-catalyzed epimerizations that lead to equilibria of **1–4**, and discuss the factors by which these are governed.

Results

It is seen in n.m.r. spectra that addition of excess sodium deuteroxide to solutions of the nitro inositols in D_2O leads to rapid conversion of the compounds into their nitronates. This is also revealed in u.v. spectra by the generation of strong nitronate absorption peaks at 250–253 nm. The nitronates **1′** and **2′** (derived from **1** and **2**, respectively) and **3′** (derived from **3** and **4**) then undergo epimerization so that, within 24 h at ambient temperature, mixtures of **1′**, **2′**, and **3′** showing nearly identical n.m.r. spectra are produced from each of the four individual nitro compounds. The percentage compositions given in Table 1 were obtained by integration of the methoxyl signals. Mainly because of overlap of ring proton signals with the methoxyl signal of **3′**, and to a lesser extent of **2′** (Table 2), these data cannot claim great accuracy. Nevertheless, the mean ratio of approximately 1:3:7 for **1′**, **2′**, and **3′** at equilibrium, as derived from Table 1, is in fair agreement with results obtained by another, more accurate mode of analysis, namely v.p.c. For such analysis the nitroinositols **1–4** were allowed to epimerize in the presence of excess barium hydroxide at room temperature and the equilibrated mixtures were acidified, deionized, and subjected to v.p.c. after trimethylsilylation in the manner detailed earlier (3). The results show excellent agreement in the equilibrium compositions arrived at from **1**, **2**, and **3** while the values obtained starting with **4** deviated slightly (Table 3). Excluding the latter set of values, the mean ratio of nitronates **1′**:**2′**:**3′** at equilibrium was found to be 1:4.5:9.1; with inclusion of the set, it was 1:4.6:9.7.

§Could not be measured.

When any one of the nitroinositols was allowed to epimerize, not in strongly alkaline medium but at p*H* 7 in the presence of only a catalytic amount of barium hydroxide, an equilibrium of the free nitro compounds (**1** ⇌ **2** ⇌ **3** ⇌ **4**) was established. Under these conditions, the equilibrations of both **1** and **2** required 3 days[2] and led to identical mixtures containing **1**, **2**, and **3** + **4** in the % ratio **74**:**23**:**3** (Table 4). Compounds **3** and **4** cannot be distinguished by the v.p.c. method (3); however, it was possible to estimate from n.m.r. spectra that they exist at equilibrium in a ratio of about 2:3. The ratio of **1**:**2**:**3**:**4** can therefore be expressed as 74:23:1.2:1.8. It was found that equilibrium between **3** and **4** (as distinct from the final equilibrium between all four isomers) was reached in 2.5 h departing from **4** and in about 2 days departing from **3**.

†Unidentified product, possibly 6-deoxy-3-*O*-methyl-6-nitro-L-idose arising by ring-opening of **1** (2).

mixture of nitroinositols was quantitatively recovered. This mixture consisted to at least 80% of the *epi*-3 isomer **3** and 18–19% of the *myo*-1 isomer **2**, but no **4** was regenerated as far as could be detected by n.m.r. spectroscopy. Formation of **3** was thus revealed to be very strongly favored kinetically over formation of **4** from their common nitronate.

Discussion

From the nitronate equilibrium **1′** ⇌ **2′** ⇌ **3′**, the free energy differences of epimeric pairs were calculated (Table 5). The order of nitronate stability is seen to be **3′** > **2′** > **1′**. This result is in full accord with expectations considering the calculated conformational stabilities of these molecules. Using the parameters for nonbonded substituent interactions previously employed in similar systems (4–6) and, in particular, taking for the $A^{(1,3)}$ interaction (7) between the nitronate grouping and an adjacent equatorial hydroxyl group a value (5, 6) of 2.0 kcal/mol, one arrives at conformational enthalpies ΔH for each of the two chair conformations of each nitronate (Table 6). On the basis of these values, the conformational free energies ΔG of compounds **1′**, **2′**, and **3′** were calculated and it follows from the data that the calculated free energy differences between **1′** and **2′**, **1′** and **3′**, and **2′** and **3′** are 0.80, 1.30, and 0.50 kcal/mol, respectively. These differences show good agreement with those found experimentally (see Table 5), which lends support to the premise on which the calculations were based, namely, the existence and magnitude of the $A^{(1,3)}$ effect.

TABLE 5. Free energy differences of nitronates as calculated from equilibrium constants

Epimer pair	$\Delta G°$ (kcal/mol) based on n.m.r.	v.p.c.
1′/2′	0.7	0.90
1′/3′	1.2	1.34
2′/3′	0.5	0.44

For the nitronates **1′** and **2′**, the preponderance of the conformer with an equatorial methoxyl group was borne out by the ring proton coupling constants. In the spectrum of **3′** the corresponding signals, which should have afforded proof of conformation, unfortunately were not resolved. However, in view of the large energy difference which conformational theory allocates to the two chair forms of **3′**, there can be no doubt that the one having an equatorial methoxyl group is vastly preferred.

From the composition ratio 74:23:1.2:1.8 of the free nitro compounds **1**–**4** at equilibrium, the free energy differences (in kcal/mol) of epimeric pairs were derived as 2.43 (for **1** and **3**), 1.74 (for **2** and **3**), and 0.24 (for **4** and **3**). Let us now compare these values with conformational free energy data derived for the compounds from the calculation of their nonbonded substituent interactions. Inspection of the conformational formulas in Table 7 shows that in **1**, **2**, and **3** the conformer having an axial nitro group is encumbered by a *syn*-triaxial interaction between that group and two hydroxyl groups. A numerical value for the energy of this type of arrangement is not available. However, one can safely assume that it is at least as large as (and probably larger than) the interaction energy of three *syn*-axial hydroxyl or methoxyl groups. A rough estimate then leads readily to the conclusion that these conformers are highly disfavored so that one need consider only the alternate, equatorial nitro conformations. In the *muco*-3 isomer **4**, the same problem does not arise since, in the axial nitro conformer, the nitro group does not interact with hydroxyls but with two hydrogen atoms instead, and for the latter interaction a value of 1.05 kcal/mol may be used (8). Another unknown parameter is the *gauche* interaction between an equatorial nitro group and a vicinal hydroxyl. However, we are here concerned only with energy *differences* between given conformations which mostly contain two such nitro–hydroxyl *gauche* arrangements each, and the

†Range resulting from use of an estimated range of 0.3–0.4 kcal/mol for B.

numerical value (B) of the unknown factor will therefore cancel in these cases. An exception occurs in the assessment of the conformational equilibrium in **4**. The n.m.r. spectrum of **4** suggests that the equatorial-nitro conformer predominates (although the extent of this predominance may be small), and one is therefore led to conclude that the B-value does not exceed, and could possibly be less than, a *gauche* hydroxyl–hydroxyl interaction of 0.35 kcal/mol. Table 7 lists conformational energies calculated in this manner. The free energy differences (kcal/mol) are 2.40 (between **1** and **3**), 1.50 (between **2** and **3**), and 0.1–0.2 (between **4** and **3**). Comparison of these values with the aforementioned experimental values shows good agreement.

Further, it is interesting to correlate with each other the epimeric equilibria of the free nitro compounds and those of their nitronates. Since the base-catalyzed equilibrium of the free nitro compounds must proceed through anion formation, the acidity constants should determine these correlations. Thus, it follows from Scheme 1, in which HA and HB represent a pair of epimeric nitro compounds and A^- and B^- their respective anions, that the ratio of equilibrium constants for the epimerizations equals the ratio of acidity constants (eq. 1).[3]

$$\begin{array}{ccc} HA & \overset{K_1}{\rightleftharpoons} & H^+ + A^- \\ {\scriptstyle K_{HA/HB}}\Big\uparrow\Big\downarrow & & \Big\uparrow\Big\downarrow{\scriptstyle K_{A^-/B^-}} \\ HB & \overset{K_2}{\rightleftharpoons} & H^+ + B^- \end{array}$$

SCHEME 1

$$[1] \qquad K_{A^-/B^-}/K_{HA/HB} = K_1/K_2$$

We have measured the pK_a values of **1–4** by half-titration and found 10.7 and 9.9 for **1** and **2**, respectively. For **3** and **4** in equilibrium with **3′**, a pH value of 8.75 at half-titration was determined. It follows from Scheme 2 that "K", the apparent acidity constant of this system, is given by eq. 2.[4]

$$HC_1 \underset{K_4}{\overset{K_3}{\rightleftharpoons}} H^+ + C^- \rightleftharpoons HC_2$$

(where HC_1 = **3**, HC_2 = **4**, and C^- = **3′**)

SCHEME 2

$$[2] \qquad \text{"}K\text{"} = K_3K_4/(K_3 + K_4)$$

Furthermore, it is seen[4] that

$$[3] \qquad K_3/K_4 = HC_2/HC_1$$

Since we have found the equilibrium ratio of **3** and **4** to be 2:3, the pK_a values of **3** and **4** may be calculated from eqs. 2 and 3 to be 8.35 and 8.52, respectively. Table 8 allows a comparison of the experimentally determined ratios of epimerization constants with those of the acidity constants, both expressed as differences of their logarithms.[5] Reasonable agreement with the equality of ratios anticipated from eq. 1 is observed.

Experimental

The preparation (2) of compounds **1–4** and the analytical procedures (3) have been described previously. N.m.r. spectra were recorded on a Varian T60 instrument. The pH measurements were made using a glass electrode and a Philips pH-meter.

Epimerizations

The epimerization reactions were carried out essentially like the cyclizations of nitro hexoses earlier described in detail (3), with the following modifications.

All the reactions that were monitored by v.p.c. were performed at room temperature (25–27°). The epimeriza-

[3]Equation 1 is derived as follows.

$K_1 = [H^+][A^-]/[HA]$ and $K_2 = [H^+][B^-]/[HB]$

Further,

$K_{A^-/B^-} = [A^-]/[B^-]$ and $K_{HA/HB} = [HA]/[HB]$

Consequently,

$$K_1/K_2 = \frac{[H^+][A^-]/[HA]}{[H^+][B^-]/[HB]} = \frac{[A^-]}{[B^-]} \times \frac{[HB]}{[HA]} = K_{A^-/B^-} \times \frac{1}{K_{HA/HB}}$$

[4]Equation 2 is derived as follows.

$K_3 = [H^+][C^-]/[HC_1]$ and $K_4 = [H^+][C^-]/[HC_2]$

Since at half-titration,

$[HC_1] + [HC_2] = [C^-]$ and "K" $\equiv [H^+]$,

it follows

$$K_4 = \frac{[H^+][C^-]}{[C^-] - [HC_1]}$$

and further, from

$$[HC_1] = \frac{[H^+][C^-]}{K_3}, \quad K_4 = \frac{[H^+][C^-]}{[C^-] - [H^+][C^-]/K_3} = \frac{[H^+]}{1 - [H^+]/K_3}$$

which can be rearranged to $[H^+] \equiv \text{"}K\text{"} = \frac{K_3K_4}{K_3 + K_4}$.

[5]In terms of free energies $\Delta\Delta G^\circ = 2.3\ RT\Delta \log K = 2.3\ RT\Delta pK_a$[kcal/mol].

tions at about pH 7 were done at 0.25 M in inositol and 0.025 N in barium hydroxide. The epimerizations in strongly alkaline medium (Table 3) were carried out in the presence of a larger excess of base than previously (3). Thus, the nitroinositol (2–3 mg) was dissolved in 2.0 ml of 0.053 N $Ba(OH)_2$ and the solution was allowed to stand in a closed vial protected from atmospheric carbon dioxide.

The reactions monitored by n.m.r. spectroscopy were performed at the temperature of the probe (35°). For example, 18.0 mg of the nitroinositol was dissolved in deuterium oxide (0.32 ml) and rendered alkaline by the addition of 0.08 ml of 1.22 N NaOD solution (1.2 mol equiv.). A solution of **3′** obtained in this way from **4** was acidified, after 40 min, by pouring it into 0.1 N acetic acid (2 ml). The solution was then passed consecutively through layers of Dowex-1 × 2 (acetate form; 0.3 ml) and Rexyn 101 (H^+; 0.6 ml) which were washed with water. Evaporation followed by two coevaporations with added ethanol, and drying of the residue *in vacuo*, gave a material (20 mg) that, according to v.p.c. analysis, consisted of **3** or **4** (80%), **2** (19%), and **1** (trace). According to n.m.r. analysis, the main product must have been **3** since the readily distinguishable OCH_3 signal of **4** was not observed so that only a very small proportion of **4** could have been present. Crystallization from ethanol gave 6 mg of **3** as colorless, lustrous crystals, m.p. 160–162°.

Conformational Study of *N*-Methyl-5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]-azocine by Nuclear Magnetic Resonance Spectroscopy[1]

ROGER N. RENAUD AND ROBERT B. LAYTON[2]
National Research Council of Canada, Ottawa, Canada

AND

ROBERT R. FRASER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 10, 1973

A study of the n.m.r. spectra of *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]azocine, its deuterated derivative, and its conjugate acid in deuteriochloroform and in trifluoracetic acid at 27 and at −62° has shown that the molecule prefers the rigid "crown" conformation. From the equilibrium constant for the equilibrium flexible ⇄ crown at 27 and at −62°, ΔH and ΔS values of -3.2 ± 0.5 kcal/mol and -7 ± 3 e.u. respectively were determined, indicating the preference for the crown conformer. A barrier to interconversion of the flexible to crown form at −62° was determined to be 15.3 ± 0.3 kcal/mol.

These parameters provide the first experimental data pertinent to the conformational properties of the 1,4-cyclooctadiene system.

Une étude des spectres de résonance magnétique nucléaire du *N*-méthyl dihydro-5,6-7*H*,12*H* dibenz-[*c*,*f*] azocine, de son dérivé deutérié et de son acide conjugué dans le deutériochloroforme et dans l'acide trifluoroacétique, à 27 et −60°, montre que la molécule adopte préférentiellement la conformation rigide en couronne. A partir de la constante de l'équilibre forme flexible ⇄ couronne à 27 et −62°, les valeurs de ΔH et ΔS de -3.2 ± 0.5 kcal/mol et -7 ± 3 u.e. ont été déterminées, respectivement, indiquant une préférence pour le conformère couronne. Une barrière d'interconversion de la forme flexible à la forme couronne a été déterminée à −62° et vaut 15.3 ± 0.3 kcal/mol. Ces paramètres fournissent les premières données expérimentales pertinentes sur les propriétés conformationnelles du système cyclooctadiène-1,4.

Introduction

In the last decade, eight-membered ring compounds have been the object of extensive investigation, including molecular orbital calculations (3), dipole moment studies (4), X-ray crystallography (5–7), and n.m.r. spectroscopy (8–11). By far, n.m.r. has proved to be the most powerful tool in the conformational determination of cyclic molecules in solution (10, 12, 13). Among the eight-membered rings, the cyclooctanes and cyclooctatetraenes are the two classes on which the majority of conformational analyses have been conducted (10, 14). The conformations of the cyclooctenes (6, 10, 15), cyclooctadienes (16), and cyclooctatrienes (17), on the other hand, have been less extensively investigated.

Of the three cyclooctadiene isomers only the 1,5-diene has been the object of experimental study (18). The cycloocta-1,4-diene has, however, been recently discussed from the point of view of possible conformations. Dunitz and Waser (16) have proposed that this compound should exist as flexible **1** and crown **2** isomers. Experimental efforts to examine this claim by n.m.r. would undoubtedly be hampered by the spectral complexity of such multi-spin systems. Spectral simplification, though, can be achieved by a number of current techniques such as substitution of one or more protons on the ring by deuterium (9), fluorine (11), heteroatoms (19, 20), and/or aromatic rings (14).

We have undertaken an n.m.r. study of the conformational properties of an hetero analogue of cycloocta-1,4-diene, namely *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]azocine (**3**) (21, 22), with a view to determining its most favorable ground state. The presence of the aromatic rings and nitrogen in the molecule provides a simple n.m.r. spectrum[3] from which its conformational properties ought to be determinable.

$\phi = 0°$ $\phi = 90°$

5 6

The parent compound **3** has been prepared by Pala and co-workers (22) utilizing an intermediate previously prepared by Bergmann and Pelchowicz (23), 2,2′-bis(bromomethyl)-diphenylmethane. It was our belief that their yield of this compound (22% after eight steps) could be improved by the choice of a better synthon (38) for its generation. Consequently, we utilized the readily available dibenzsuberone **4** (Scheme 1) as starting material and, after a sequence of five steps, obtained the desired intermediate in a yield of 53%. Treatment of 2,2′-bis(bromomethyl)-diphenylmethane with methylamine gave **3** in 57% yield.

Experimental

All melting points are uncorrected. All i.r. spectra were recorded on a Perkin–Elmer 237 Grating Spectrometer. Only the characteristic bands are reported (cm^{-1}). Routine n.m.r. spectra were measured using a Varian A-60 spectrometer. Precise studies on the title compound were carried out using a Varian HA-100 spectrometer. All coupling constants were determined with an accuracy of ± 0.1 Hz. The n.m.r. spectra were measured in deuteriochloroform unless otherwise specified and the chemical shifts are reported on the scale.

For the kinetic measurements at $-62\,°C$ intergrals were taken every 150 s and the rate constant obtained by a least squares analysis of the data. The standard deviation (1.5×10^{-5}) in the rate constant and the possible error in measurement of the probe temperature (2°) lead to an uncertainty in ΔG^{+} of 0.3 kcal/mol. The above relatively accurate integral measurements are possible as we are monitoring the intensity of a sharp singlet as a function of time. Thus, systematic errors are minimized and only random errors produce scatter in the data.

Benzophenone-2,2′-dicarboxylic Acid

An acetone solution of dibenzsuberone (5 g) was oxidized with potassium permanganate (14 g) in the presence of sodium bicarbonate, according to the method of Smith and Rouault (24). Work-up and recrystallization from ethanol afforded 4.7 g (72%) of product: m.p. 213.5–2.4° (lit. (25) 212°); i.r. (Nujol) 3300–2200, 1700, 1670; n.m.r. (DMSO-d_6) 7.15–8.40 (8H, multiplet, aromatic), 10.15 (2H, broad singlet, OH).

Diphenylmethane-2,2′-dicarboxylic Acid

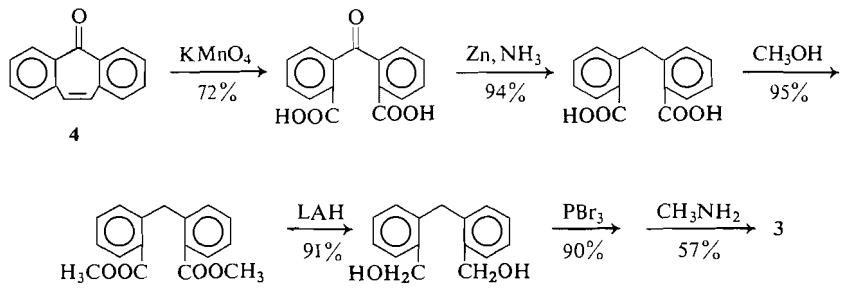
Benzophenone-2,2′-dicarboxylic acid (6.0 g) in ammonia was treated with zinc dust (19.0 g) over 20 h in a manner similar to that described by Bergmann and Pelchowicz (23). The yield of the diacid, m.p. 259–261° (lit. (23) 254.5°) was 5.4 g (94%): i.r. (Nujol) 3300–2200, 1720; n.m.r. (DMSO-d_6) 7.00–8.20 (10H, multiplet, aromatic and OH; elimination of 2H by exchange with D_2O), 4.88 (2H, singlet, methylene).

Dimethyl-diphenylmethane-2,2′-dicarboxylate

Diphenylmethane-2,2′-dicarboxylic acid (4.6 g) was esterified with methanol (240 ml) in presence of concentrated sulfuric acid (1 ml) under reflux for 36 h. Then, the product was freed from excess methanol and collected in ether. The ethereal solution was washed with a cold solution of sodium bicarbonate, dried over $MgSO_4$, filtered and the solvent removed to give 4.8 g (95%) of an oily residue which solidified on standing: m.p. 42–44° (lit. (23) 44°); i.r. ($CHCl_3$) 1725; n.m.r. (DMSO-d_6) 7.00–8.10 (8H, multiplet, aromatic), 4.82 (2H, singlet, methylene), 3.79 (6H, singlet, methyl).

2,2′-Bis(hydroxymethyl)-diphenylmethane

Dimethyl-diphenylmethane-2,2′-dicarboxylate (4.8 g)



SCHEME 1

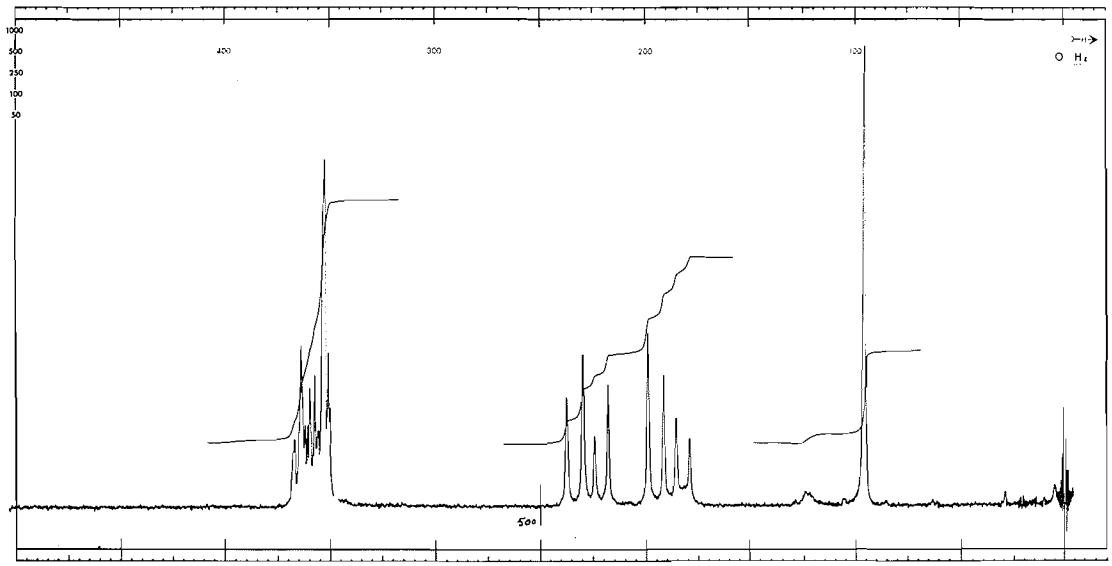


FIG. 1. The ^1H n.m.r. spectrum of *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz[*c*,*f*]azocine (**3**) in deuteriochloroform.

was reduced to 2,2′-bis(hydroxymethyl)-diphenylmethane as described in the literature (23) in 91% yield: m.p. 162–162.5° (lit. (23) 158–158.5°); i.r. (Nujol) 3350–2800; n.m.r. (DMSO-d_6) 6.8–7.8 (8H, multiplet, aromatic), 4.56 (4H, singlet, methylene), 4.10 (2H, singlet, methylene), 3.42 (2H, broad singlet, hydroxyl).

2,2′-Bis(bromomethyl)-diphenylmethane

2,2′-Bis(hydroxymethyl)-diphenylmethane (1.5 g) was reacted with phosphorous tribromide according to Bergmann and Pelchowicz (23). The pale yellow crystalline product was recrystallized from benzene to afford 2.1 g (90%) of solid melting at 92° (lit. (23) 93–94°): n.m.r. 7.0–7.7 (8H, multiplet, aromatic), 4.54 (4H, singlet, methylene), 4.37 (2H, singlet, methylene).

N-Methyl-5,6-dihydro-7H,12H-dibenz[c,f]azocine

2,2′-Bis(bromomethyl)-diphenylmethane (1.5 g was reacted with methylamine according to the procedure of Casadio *et al.* (22). There was obtained after sublimation of the crude product, 1.0 g (57%) of *N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz-[*c*,*f*]azocine: m.p. 92° (lit. (22) 93°); n.m.r. 6.98–7.40 (8H, multiplet, aromatic), 4.26 (4H, quartet, methylene adjacent to N), 4.00 (2H, quartet, methylene), 1.90 (3H, singlet, methyl).

5,5,7,7-Tetradeuterio-N-methyl-5,6-dihydro-7H,12H-dibenz[c,f]azocine

Using a procedure analogous to that quoted above, dimethyl-diphenylmethane-2,2′-dicarboxylate was reduced with lithium aluminum deuteride. The tetradeuterated product of that reaction was converted in an identical manner to that described above into 5,5,7,7-tetradeuterio-*N*-methyl-5,6-dihydro-7*H*,12*H*-dibenz-[*c*,*f*]azocine. The isotopic purity was estimated by n.m.r. spectroscopy to be better than 95%.

Results and Discussion

A. Nuclear Magnetic Resonance Spectral Parameters

The n.m.r. spectrum of **3** in deuteriochloroform exhibits two well-defined AB quartets in a ratio of 2:1 (Fig. 1). These quartets, centered at δ 4.30 (J = 14.9 Hz)[4] and δ 4.09 (J = 12.7 Hz), correspond to the protons on C-5 and C-7, and on C-12 respectively. The *N*-methyl region of the spectrum shows that more than one isomer is present. At room temperature a sharp singlet at δ 1.94 represents the major isomer (91.7% of methyl absorption) and a small broad peak at δ 2.44 represents the minor isomer (8.3% of methyl absorption). Absorptions due to the methylene protons of the minor isomer were too weak to be observed.

When trifluoroacetic acid (TFA) is added gradually to the sample in deuteriochloroform, the low field protons of the quartet, centered at δ 4.30, shift slowly downfield and finally appear at δ 5.26 (J = 14.0 Hz) in pure TFA. This shift to low field is typical of protons α to nitrogen because of a decreasing shielding of the adjacent protons by the positively charged nitrogen in the

[4]All the geminal coupling constants discussed herein are assumed to be negative as has been found for the benzylic methylene protons of 2,3-diphenylpropionic acid (27).

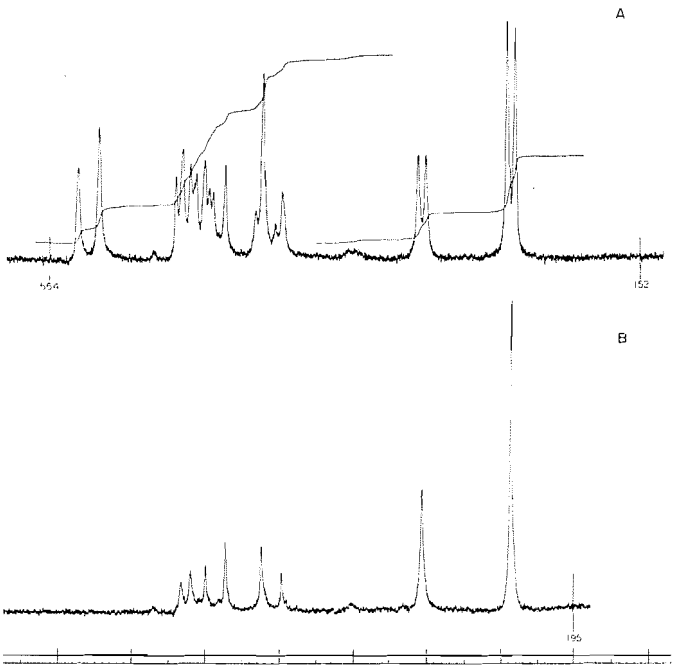

FIG. 2. The ^1H n.m.r. spectrum of (A) **3**-H^+ in TFA and (B) **3**-H^+ (5,5,7,7-d_4) in TFA-d_1.

conjugate acid **3**-H^+ (26). Of particular significance is the fact that in pure TFA this signal is still a doublet, *i.e.* $J_{H-\overset{+}{N}-C-H}$ must be less than 1 Hz since all the other protons α to nitrogen show vicinal (H—$\overset{+}{N}$—C—H) splittings that indicate the exchange of the $\overset{+}{N}$—H proton with solvent is slow on the n.m.r. time scale. We have previously established the presence of a Karplus relationship between the magnitude of vicinal H—H coupling for the H—N—C—H fragment of amines in TFA (28) and the dihedral angle between the vicinal protons. The lack of vicinal coupling in the low field absorption of **3** in TFA shows, therefore, that the angle between the proton on nitrogen and these protons on the α carbons is ≈90°.

Examination of Dreiding models shows that the geometry of the flexible conformer permits both of the H—$\overset{+}{N}$—C—H bond angles[5] to vary between 0 and 120°. Thus, for the flexible form, one must expect, on the average, a coupling of some magnitude between the proton on nitrogen and both of the adjacent methylene protons. In the rigid crown conformer, however, the H—$\overset{+}{N}$—C—H bond angles are fixed at 90 and 30° for the non-equivalent protons. As a result, the absence of observable H—$\overset{+}{N}$—C—H splitting indicates a 90° dihedral angle and is consistent only with assignment of the crown conformation[6] to the major isomer.

The relative intensities of the two methyl peaks are also affected by the presence of acid. The addition of TFA to the sample in deuteriochloroform causes a downfield shift of both *N*-methyl groups (26). Concomitantly, the smaller peak increases in intensity as the concentration of TFA increases until, in pure TFA, it accounts for 28% of the total methyl absorption and appears at δ 2.98. The other *N*-methyl peak has

[5]In general, the Dreiding models are too rigid and estimated bond angles are only accurate to within 5°. Bond angles reported in this paper are to be considered within this range.

[6]An X-ray crystallographic examination of the azocine **3** (37) has since shown that the preferred conformer in the crystal state is also the crown form.

shifted to δ 2.39. Both peaks are doublets and display the characteristic $H-\overset{+}{N}-C-H$ coupling of 5.3 Hz (26).[7]

The remainder of the methylene proton absorption of the two isomers of **3** in TFA is not sufficiently resolved to allow individual assignments to be made (Fig. 2A). However, the assignment of the methylene bridge protons of the two isomers is made possible by the examination of the deuterated derivative of **3** in which the hydrogens at C-5 and C-7 have been replaced by deuterium.

The spectrum of **3**-H^+ (5,5,7,7-d_4) in TFA-d_1 shows a quartet for the major isomer centered at δ 4.08 (J = 13.5 Hz) and a second isomer centered at δ 4.60 (J = 19.0 Hz) (Fig. 2B). The magnitudes of these two geminal coupling constants allow assignment of crown and flexible conformations to the major and minor isomers respectively. It is recognized that a benzene ring on a methylene group causes a negative shift on the geminal proton–proton coupling constant and that this shift varies with conformation. Empirical (29, 30) and theoretical (31, 32) evidence support this correlation and estimate the effect to be at least 4 Hz in the most favorable conformation **5** and zero in the conformation **6**, achieved by a rotation of 90° about the phenyl—CH_2 bond. A Dreiding model of the crown form of **3** shows φ to be very close to 90° for both benzene rings, leading to the expectation that they should have a negligible influence on ^2J. On the other hand, a model of the flexible form allows one of the two methylene groups to be oriented at φ = 30° and the other at φ = 90° in either of two equivalent "twist-boat" types of conformation. Thus, an appreciable negative shift of the geminal coupling constant ought to be caused by the hyperconjugative effect of the benzene rings in the flexible conformation. The observed value ^2J of −13.5 Hz for the major isomer represents a normal value for a diphenylmethane-type methylene group possessing φ = 90° for both benzenes to CH_2 bonds (33). The 5.6 Hz more negative value of ^2J in the minor isomer is only consistent with a flexible conformation for this isomer.

B. Temperature Dependence of Equilibrium Constant

From integration of the peaks for the N-CH_3 groups of the two isomers at room temperature and −62°, the equilibrium constants K_{eq} (minor ⇄ major) were found to be 11.0 and 124 respectively. From such a temperature dependence, ΔS_{eq} is calculated to be -7 ± 3 e.u. and $\Delta H_{eq} = -3.2 \pm 0.5$ kcal/mol.[8] The much greater entropy for the minor isomer is corroborative evidence that it possesses a flexible conformation. A comparable difference in entropy between the "crown" and "boat-chair" forms of tetroxocane has been found by Anet and Degen (20).

C. Barrier to Inversion

While it should be possible to determine the barrier to interconversion of the crown and flexible forms by DNMR (34), the strongly biased equilibrium makes line-shape measurements difficult and relatively less accurate. Since the two N-CH_3 peaks were observed to coalesce at about 40°, thus indicating a barrier of the order of 15 kcal/mol, we have undertaken a direct measurement of this interconversion by a "temperature-jump" experiment. A deuteriochloroform solution of **3** was plunged into liquid nitrogen. The sample after 5 min was warmed quickly to −62° and placed in the proble of the HA-100 spectrometer which was also held at −62°. Integration showed the proportion of isomers to be 96.5 and 3.5. The rate of relaxation to the equilibrium position of 99.2 to 0.8 at −62°, determined by repeated integrations, was found to be $6 \pm 1.2 \times 10^{-4}$ s^{-1}. This corresponds to a free energy of activation of 15.3 ± 0.3 kcal/mol for conversion of the flexible to crown forms.

In conclusion, we have established the presence

[7]A point to be noted here is that protonation of a crown–flexible conformer mixture could give rise to four different conjugate acids and thus four sets of methyl doublets. However, only two doublets are observed, indicating the presence of only two isomeric conjugate acids. The other two isomers (having the opposite but undetermined configuration at nitrogen) are presumably too unstable to populate the mixture in measurable quantity. Interconversion of all isomers occurs readily via the following equilibria: $\text{crown}_1 \rightleftarrows \text{flexible}_1 \rightleftarrows \text{flexible}_2 \rightleftarrows \text{crown}_2$ (the subscripts indicating the configuration at nitrogen).

[8]The rather large uncertainty in ΔS results from the limits of accuracy in integration which we estimate to be ±0.5% for the measurement of well-resolved sharp singlets. There can be no doubt that there is a large entropy difference between conformers for, if ΔS were zero, the concentration of flexible form at −62 °C ought to have been 3.2%.

of two conformations of the azocine **3** whose n.m.r. and thermodynamic properties allow assignment of a "crown" conformation to the energetically favored isomer and a "flexible" conformation to the less abundant isomer. Both the thermodynamic and kinetic parameters for this conformational equilibrium have been determined. It is tempting to propose the data for **3** as providing reasonable estimates of the conformational equilibrium in *cis*-1,4-cyclooctadiene. Indeed, substitution of aromatic rings in the place of double bonds does not appear to alter conformations significantly (18) nor alter the barrier to interconversion appreciably (35) unless the rings are adjacent to one another (14). Similarly, replacement of a CH_2 group by a nitrogen atom causes little change in bond length and resultant geometry (36). We can, therefore, propose that the conformational properties exhibited by **3** constitute a reasonable estimate of the analogous properties of 1,4-cyclooctadiene.

Finally, the predominant isomer, the crown conformation of **3**, possesses some unique geometric features that should prove helpful in the study of other phenomena, in particular the study of substituent effects on geminal coupling constants (30) since the projected angle ϕ is 90°.

Further work related to azocines having different alkyl groups on nitrogen is in progress. Hopefully, such studies will provide information on steric effects in these eight-membered rings.

Arrhenius *A* Factors of Unimolecular Decomposition of Alcohols Formed by Insertion of $O(^1D_2)$ Atoms into the CH Bonds of Paraffins[1]

K. J. MINTZ[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R9

Received December 21, 1972

The Arrhenius *A* factors of unimolecular decomposition of alcohols have been calculated approximately by a simple formula from the experimental rate constants of decomposition of "chemically activated" alcohols (formed by insertion of $O(^1D_2)$ atoms into the CH bonds of paraffins) and the structural and thermochemical properties of the alcohols. The more exact R.R.K.M. method of calculation is shown to be in reasonable agreement with the simpler method for CH_3OH decomposition. The resultant large positive entropies of activation are consistent only with involvement of "loose" activated complexes in the unimolecular decomposition of alcohols.

Les facteurs Arrhénius *A* pour la décomposition monomoléculaire des alcools ont été calculés approximativement à l'aide d'une simple formule tirée des constantes de vitesses pour la décomposition d'alcools chimiquement activés (formés par insertion d'atomes $O(^1D_2)$ à l'intérieur des liens CH des paraffines) ainsi que des propriétés structurales et thermochimiques des alcools. La méthode de calcul R.R.K.M., plus exacte, est en accord avec la méthode plus simple utilisée, comme il est démontré dans le cas de la décomposition du CH_3OH. Les entropies élevées et positives d'activation résultantes sont en accord seulement avec la présence de complexes activés "instables" lors de la décomposition monomoléculaire des alcools. [Traduit par le journal]

Can. J. Chem., **51**, 3386 (1973)

Introduction

In recent studies in this laboratory (1–4), it has been shown that $O(^1D_2)$ atoms insert into the CH bonds of hydrocarbons to form alcohols. The alcohol molecules formed are, however, vibrationally excited ("hot", "chemically activated") and decompose if not stabilized by collisions with other molecules. The experimental values of the rate constants (k_a) of their unimolecular decomposition show qualitatively the expected dependence on the exothermicity of the insertion reaction, the number of degrees of freedom, and the bond dissociation energy of the weakest bond in the molecule. Furthermore, approximate calculations based on Kassel's classical expression (5) for k_a indicate (3, 4) that the Arrhenius pre-exponential factors (A) of decomposition are likely to be high (considerably in excess of the "normal" values of about 10^{13} s^{-1}), *i.e.*, that these reactions have large positive entropies of activation ($\Delta S^{\neq}$). The latter are a common feature of unimolecular decomposition of polyatomic molecules into two free radicals (6) and are in principle explainable by the R.R.K.M. quantum mechanical theory of unimolecular reactions by postulating formation of "loose" activated complexes (7).

For the unimolecular decomposition of the hot alcohols formed by insertion of $O(^1D_2)$ atoms into the CH bonds of hydrocarbons, no meaningful R.R.K.M. calculations could be carried out since experimental values of the Arrhenius *A* factors are not available. Conversely, *a priori* R.R.K.M. calculations of the *A* factors require arbitrary assumptions about the structure of the activated complexes. This latter procedure has been the usual method (8) for the interpretation of experimental data from both chemical and thermal activation studies. An example particularly relevant to the present work is the recent study of Growcock, Hase, and Simons (9) on the unimolecular decomposition of chemically activated alkanes formed by insertion of singlet methylene into CH bonds of alkanes. For the reactions of $O(^1D_2)$ with some paraffins, the *A* factors were calculated (3, 4) from Kassel's expression, but, as will be mentioned later, this required the use of an adjustable ("empirical") parameter and the values obtained are only very approximate. The above conclusions regarding the activation entropies and structure of the

activated complexes for these reactions remained therefore doubtful. In fact, it remained uncertain whether these reactions do involve "chemically activated" alcohol molecules in the ground electronic state and conform to the general pattern. In the present note, we show that approximate values of A (and hence of $\Delta S^{\ddagger}$) can be easily calculated directly from the experimental k_a values using only knowledge of the properties of the reactant molecules (and not of the activated complexes).

Forst (10) has recently derived the following expression for the specific probability of unimolecular decomposition in thermal systems at an energy E:

$$k(E) = AN(E - E_\infty)/N(E) \quad E > E_\infty \qquad [1]$$
$$= 0 \quad E < E_\infty$$

where E_∞ is the high pressure activation energy for reaction and $N(E)$ is the density of states of the reactant molecule at energy E. Equation 1 assumes implicitly that A and E_∞ are temperature independent quantities. In chemical activation studies, the reactant can frequently be regarded as being monoenergetic because of the large exothermicity of the activating reaction relative to the thermal energy distribution at room temperature. Under such conditions, $k(E)$ can be set equal to k_a and [1] can be used directly to obtain the Arrhenius A factor.[3]

Procedure

The following basic assumptions of the R.R.K.M. theory are used throughout this work: there is fast energy flow among the vibrations but none between the vibrations and external rotations, *viz.*, all of the vibrational modes are treated as "active" and the external rotations as "adiabatic". The torsions are treated as free internal rotations. The "strong collision" assumption is made; the experimental justification for these reactions has been given (2).

If the classical density of states is used, [1] reduces to eq. 2, which is of a form somewhat similar to Kassel's expression (5)

$$k(E) = A((E - E_\infty)/E)^{v-1+r/2} \qquad [2]$$

[3]The theoretical rate constant, $k(E)$, in [1] should be increased by the appropriate factor to account for centrifugal effects (11, 12). However, in this work, the experimental value, *viz.* k_a, is used; hence, it is not necessary to make this correction.

where v is the number of vibrations excluding the torsional modes and r is the number of internal rotations. In the application of Kassel's theory, the exponent in [2] is $(s - 1)$, where s represents the total number of vibrations, and it is usually regarded as a fitting parameter. Also, E_∞ is replaced by E_0, the "critical" energy.

In this work the densities of states are calculated by a semi-classical method due to Whitten and Rabinovitch (12) as modified by Forst (13). At the fairly high energies involved, this approximation is quite acceptable. The effects of anharmonicity (13) should not be important for the size of molecules involved in the present study and are not considered. The formula for the rate constant is

$$k(E) = A\left(\frac{E - E_\infty + a'E_z}{E + aE_z}\right)^{v-1+r/2} \qquad [3]$$

where E_z is the zero-point energy of the molecule and a' and a are functions of E, E_z, and the vibrational frequencies, having values between zero and unity (13).

Since the reactions of $O(^1D_2)$ with paraffins

$$RH + O(^1D_2) \rightarrow ROH^* \qquad [4]$$

occur at approximately each collision, their activation energies must be very close to zero (14). The average values of the energy, E, of the alcohols formed (ROH*) are therefore given by

$$E = -\Delta H_{f_0}^0(ROH) + \Delta H_{f_0}^0(RH) + \Delta H_{f_0}^0(O(^1D_2)) + E_{th} \qquad [5]$$

where E_{th} is the average thermal energy of the reactants. It should be noted that the translational energy of ROH* is unavailable for decomposing the molecule since translation–vibration energy transfer can occur only during a collision, in which case the molecule becomes de-excited (from the "strong collision" assumption). Similarly, the external rotations have been assumed to be adiabatic. Assuming that the translations and external rotations are both classically excited, a value of $3RT$ should be subtracted from the value of E calculated by [5]. This correction is included in the values of E used here which were calculated from thermochemical data (15, 16) and are shown in Table 1. However, it must be noted that this correction is only very approximate because of the improbability that the reaction of $O(^1D_2)$ with paraffins yields vibrationally excited alcohols with transla-

tions and rotations in a Boltzmann distribution. Although, fortunately, this problem does not create any significant uncertainty in this study, in chemical activation studies in which E is much smaller, this effect may be important.

Calculation of E_z and a requires knowledge of all the vibrational frequencies. Methanol is the only alcohol for which a complete vibrational analysis has been done (17). The frequencies of the other alcohols in Table 1 were estimated by analogy with CH_3OH and alkanes or cycloalkanes of similar structure (17, 18). The values of E_z are listed in Table 1 together with their estimated uncertainties.

The Arrhenius activation energy, E_∞, for the forward step of the unimolecular process

$$\text{Reactant} \rightleftharpoons (^*) \rightleftharpoons \text{Products}$$

can be related (6), using transition state theory, to the enthalpy of the reaction, $\Delta H_T{}^0$, *viz*,

$$E_\infty = \Delta H_T{}^*(\text{f}) + RT$$

or

$$[6] \quad E_\infty = \Delta H_T{}^0 + \Delta H_0{}^*(r) + T\langle \Delta C_V{}^* \rangle(\text{r}) + (1 - \Delta n)RT$$

where (f) and (r) refer to the forward and reverse steps, respectively. $\langle \Delta C_V{}^* \rangle(\text{r})$ is the average heat capacity change in the formation of the activated complex from the products.

In the particular case of a bond scission reaction, $\Delta H_0{}^*(\text{r})$, *i.e.* $\Delta H_0{}^*$ for recombination of two free radicals, is usually assumed to be zero and the same assumption will be made in the present work. Also in this case $\Delta n = 1$ so that:

$$[7] \quad E_\infty = \Delta H_T{}^0 + T\langle \Delta C_V{}^* \rangle(\text{r})$$

For recombination of two free radicals, $\langle \Delta C_V{}^* \rangle(\text{r})$ is at most a relatively small quantity (6). By taking extremes of "loose" and "tight" activated complexes, it can be shown that $|\Delta C_V{}^*(\text{r})| < \frac{3}{2}R$. Benson and O'Neal (6) have pointed out that the usual assumption of zero activation energy of radical recombination at all temperatures implies that $\langle \Delta C_V{}^* \rangle(\text{r}) = 0$, in which case $E_\infty = \Delta H_T{}^0$. For the present case, the error due to neglecting $\langle \Delta C_V{}^* \rangle(\text{r})$ in eq. 7 is considerably less than that due to uncertainty in $\Delta H_T{}^0$ (*i.e.*, the room temperature bond dissociation enthalpies of the critical bonds in the alcohols).

The $\Delta H_T{}^0$ values were calculated from the heats of formation (at 298 °K) of the two radical fragments (15, 19), *viz.* (in kcal/mol) CH_3, 34.8 ± .3; OH, 9.4 ± .2; C_2H_5, 25.7 ± 1; *i*-C_3H_7, 17.6 ± 1; *t*-C_4H_9, 6.8 ± 1; CH_2OH, −8 ± 3; CH_3CHOH, −18 ± 3; $(CH_3)_2COH$, −29 ± 3. The last value was obtained by assuming for the $(CH_3)_2C(OH)$—H bond dissociation energy 88–89 kcal/mol, from the extrapolation of the $CH_2(OH)$—H and $CH_3CH(OH)$—H bond dissociation energies of 92 and 90 kcal/mol (19), respectively. The resultant C—C bond dissociation energies shown in Table 1 appear to be internally consistent.

Obviously, since $\Delta H_T{}^0$ is a (weak) function of T, the value of A calculated by [1] will depend to some extent on the temperature chosen. For CH_3OH decomposition, $\Delta H_T{}^0$ (kcal/mol) is 90.35 at 0 °K, 92.30 at 298, 94.03 at 1000, and 92.84 at 2000 °K, with an uncertainty of 0.7 at 0° and 298° and probably larger uncertainties at higher temperatures. The corresponding values are not available for the other reactions, though

similar variation with temperature would be expected.

Results and Discussion

The calculated values of A, obtained by matching eq. 3 to the experimental rate constants, are shown in Table 1 together with their corresponding entropies of activation for a temperature of 1000 °K, which were calculated from the expression:

$$[8] \qquad A = (ekT/h) \exp (\Delta S^{\ddagger}/R)$$

The reason for choosing this particular temperature will be evident from the discussion further below. The uncertainties in E_z and E cause about 10–20% uncertainty in the values of A; this is of the same magnitude as the likely uncertainty in the experimental rate constant, k_a. On the other hand, the uncertainty in ΔH_T^0 causes A to be uncertain to about a factor of two. Although most bond-dissociation energies cannot be estimated much more precisely than 3 kcal/mol, the relative values in a given series should be somewhat more accurate; therefore, the relative A factors have smaller uncertainties. The value for CH_3OH appears to be subject to considerably less uncertainty. The uncertainty regarding $\langle \Delta C_V^{\ddagger} \rangle$(r) discussed above introduces at most an uncertainty of ± 0.6 kcal/mol in the values of E_∞ and therefore errors in A of not more than 15%.

In principle, the distribution of the energy of the activated species should be taken into account, as has been done by Rabinovitch and Setser (8). Fortunately, the calculated A is very nearly a linear function of E over the rather narrow range of energies in this distribution; hence considering the system as monoenergetic with an average E does not create any significant increase in uncertainty in these calculations. Moreover, as discussed above, there is some question about the appropriate distribution to be used in the general equations of Rabinovitch and Setser. In any case, the uncertainty in A due to this problem is certainly much smaller than that due to uncertainty in the bond-dissociation energy.

The large positive $\Delta S^{\ddagger}$ values in Table 1 have been derived directly from the experimental rate constants of unimolecular decomposition of the chemically activated alcohols without assuming structures for the activated complexes. In principle they could be used to determine the structure of the activated complex. Unfortunately, as is shown below, the calculation of $\Delta S^{\ddagger}$ from an Arrhenius A factor is not very useful for distinguishing details of activated complexes. However, in general terms, it has been shown (7) that large positive $\Delta S^{\ddagger}$ in unimolecular decompositions requires the postulate of loose activated complexes. In fact, the A factors in Table 1 are quite similar in magnitude, for example, to the A factors observed experimentally in thermal dissociation of alkanes (6) (10^{16}–10^{17} s^{-1}) which are generally rationalized by postulating formation of "loose" activated complexes.

The methanol decomposition has an A factor about half of the other acyclic alcohol decompositions. This can be attributed to a different type of bond being broken. The cyclopentanol decomposition has an A factor which is very much smaller than that of the other alcohols. This difference, no doubt, is caused by the former case involving a ring opening which does not allow complete separation of the fragments. In this connection, it is interesting to note that Michaud and Cvetanović (4), by assuming that the entropy of the activated complex could be approximated by that of n-pentanol, had estimated $\Delta S^{\ddagger} = 12$ cal/deg mol, which is somewhat higher than the value in Table 1. The decomposition of t-C_4H_9OH has a reaction path degeneracy of 3; hence its A factor for a single reaction path is 1.7×10^{16} s^{-1}, in close agreement with those for the other acyclic compounds.[4]

It is of interest to compare the A factors calculated by the method proposed in this paper with those calculated by the usual application of R.R.K.M. theory. This calculation was done only for the CH_3OH decomposition, the only case for which sufficiently accurate data are available. According to the R.R.K.M. theory (7)

$$[9] \qquad k(E) = \frac{1}{h} \frac{Q^{\ddagger}}{Q} \frac{G^{\ddagger}(E - E_0)}{N(E)}$$

where $Q^{\ddagger}/Q$ is the ratio of the product of the adiabatic partition functions in the activated complex to that in the molecule; $G^{\ddagger}(E - E_0)$ is

[4]Similarly the decomposition of i-C_3H_7OH has a reaction path degeneracy of 2. Unfortunately, k_a for i-C_3H_7OH as well as n-C_3H_7OH could not be determined very accurately (1). However, if the relative k_a values for these decompositions are assumed to be more reliable, then the A factor for i-C_3H_7OH is about 40% greater than that for n-C_3H_7OH.

the sum of states of the active degrees of freedom in the activated complex up to energy $E - E_0$. E_0, the critical energy, was assumed to be equal to ΔH_0^0, *i.e.*, it was assumed that there is no energy barrier for the reverse reaction.

The structure of the activated complex was assumed to be identical to that of the molecule except that the C—O distance was increased to 2 Å (models I and I*a*), 3 Å (model II), or 5 Å (model III). Since the activated complex is "loose", it should resemble the products more than the reactants. Hence, in model I*a* the vibrational frequencies of CH_3 and OH are used rather than those of CH_3OH. The method used for determining the frequencies of the activated complex is the same as used by other workers (9): the frequencies of the normal modes in CH_3OH that change into translations or rotations in the products are reduced by a constant factor (while holding all other frequencies constant) until the theoretical rate constant calculated by [9] becomes equal to the experimental value. This procedure is obviously rather arbitrary.[5] The resultant frequencies are shown in Table 2 and the values of $\Delta S^{\ddagger}$ calculated by standard statistical-thermodynamic methods, assuming the ideal-gas, rigid-rotator, simple-harmonic oscillator approximation, are listed in Table 3.[6] As can be seen from Table 3, $\Delta S^{\ddagger}$ is most sensitive to the structure of the activated complex at low temperatures. At 1000 °K, the R.R.K.M. calculations predict values of A (using eq. 8) similar to that calculated by eq. 1.

It is of some interest to test the validity of the assumption of constant A factors implicit in eq. 1. The theoretical thermal rate constant calculated by the standard transition state theory expression

$$[10] \qquad k_{\text{theor}} = \frac{kT}{h} e^{\Delta S_T^{\ddagger}/R} e^{-\Delta H_T^{\ddagger}/RT}$$

was plotted in Arrhenius form for model I*a* as shown in Fig. 1. This plot shows that the Arrhenius equation should provide an excellent empirical approximation over the temperature range of interest (298 °K and above). A least-squares determination of the slope and intercept using the points marked on the graph yields Arrhenius parameters: $E_\infty = 93.5 \pm 0.2$ kcal/mol; $A = 5 \pm 1 \times 10^{15}$ s^{-1}. On the other hand, using [8] to calculate A from $\Delta S^{\ddagger}$ (as is usually done) apparently predicts that A should change rather rapidly with temperature. This apparent anomaly is due to the compensating effect of the temperature variation of A and E_∞ when plotted in the Arrhenius form. (If the plot in Fig. 1 is broken into a series of Arrhenius plots for small temperature intervals, a series of A and E_∞ values varying slightly with temperature may be obtained.)

TABLE 2. Frequencies and C—O bond lengths (r_{C-O}) used in the R.R.K.M. calculations for CH_3OH decomposition

		Value			
		Transition state model

have been calculated from the Arrhenius equation using the A and E_∞ values (7.8×10^{15} s^{-1} and 92.3 kcal/mol, respectively) obtained in our calculations based on eq. 1. The R.R.K.M. values have been calculated from eq. 10 using the activation parameters obtained in our calculations for the four transition state models. Evidently, the two approaches predict very similar values of k_f. (Even better agreement is obtained if in the calculation of the eq. 1 values the actual values of ΔH_T^0 at the three temperatures are used for E_∞ instead of the uniform value of 92.3 kcal/mol. However, in view of the simplifying assumptions implicit in the present treatment and the uncertainties in the data, this correction would be difficult to justify and has not been incorporated into the k_f values in Table 3.)

It is evident that eq. 1 can be used to obtain the "empirical" values of the Arrhenius parameters and thus to predict the experimental values of the decomposition rate constants from a single $k(E)$ value and the structural properties of the reactant. However, information on the transition state and on the finer details of energy dependence of $k(E)$ requires a more exact theoretical treatment. For example, the ratio $k(E)_{\text{R.R.K.M}}/k(E)_{\text{eq. 1}}$ for methanol varies for our transition state model I from 0.88 to 1.09 as E is increased from 120 to 150 kcal/mol.

A useful check on the present method of determining A would be to calculate rate constants of the reverse radical combinations from our A-factors and compare them with experimental values. (This procedure has been used by Simons and co-workers (9), who found, in fact, that their A factors for the unimolecular decomposition of alkanes, determined from chemical activation rate constants through R.R.K.M. theory, could not be correlated with the known rate constants for the reverse alkyl radical combinations.) Since reasonably accurate entropies of the reaction and the rates of the reverse reaction are known only for the methanol reaction, only one comparison can be made. For this reaction, $CH_3 + OH \rightarrow CH_3OH$, Fenimore (20) obtained a rate constant of $4 \pm 2 \times 10^{12}$ cm^3 mol^{-1} s^{-1}, independent of temperature between 1970 and 2190 °K. The predicted rate constant (k_r) for the radical combination reaction is given by

$$[11] \qquad k_r = k_f \, e^{\Delta H_T^\circ/RT} \, e^{-\Delta S_T^\circ/R}(RT)$$

The k_r values obtained, based on the k_f derived from eq. 1 and from the R.R.K.M. calculations, are shown in Table 3. They are in good mutual agreement at 2000 °K but appear to be significantly higher than the experimental value. It is of interest to note that the R.R.K.M. calculations predict a significant variation of the free

radical combination rate constant with temperature, which, when plotted in Arrhenius form, yields an activation energy of about 1.5 kcal/mol for model I*a*. On the other hand, the calculations based on eq. 1, which implicitly assumes temperature independent Arrhenius parameters for k_f, predict that k_r should be virtually independent of temperature.

Simons and co-workers (9) carried out an extensive study of the decomposition of chemically activated alkanes produced by methylene insertion into paraffinic CH bonds. They found that the rate constants of the reverse (radical combination) reactions, predicted by R.R.K.M. theory in the same manner as was used here, were substantially lower than the experimental values at 298 °K. They suggested that there exists a dilemma of theoretical importance. It is clear from our calculations (see Table 3) that the "dilemma" is that the absolute rate theory calculations with loose transition states predict a marked increase of the rate constant with temperature, so that it is smaller than experimental at low temperatures and larger at high temperatures. Most experimental evidence (in particular, on methyl radical combination) indicates that the rate constant changes only slightly with temperature and, if anything, decreases with increasing temperature. Hase (21) has recently proposed that adoption of a negative critical energy (of -2.0 kcal/mol) for CH_3 radical recombination will eliminate the discrepancy between the forward and reverse rates for ethane decomposition. However, his model predicts that the CH_3 recombination rate constant should change from 2.4×10^{13} at 400 °K to 1.2×10^{14} cm^3 mol^{-1} s^{-1} at 298 °K. The predicted large change appears to be inconsistent with the experimental evidence so that the dilemma does not seem to be resolved.

The results of the present calculation show that the trends in the experimental values of the rate constants of unimolecular decomposition of the hot alcohols formed by insertion of $O(^1D_2)$ atoms into the CH bonds of different alkanes are consistent with the postulate that the decomposition into free radicals involves highly vibrationally excited ("chemically activated") alcohol molecules in their ground electronic state and that it proceeds through "loose" activated complexes, as anticipated. In this connection, it is necessary to point out that in thermal systems the primary step in the unimolecular decomposition of *t*-butanol has been shown (22, 23) to be

[12] $$t\text{-}C_4H_9OH \rightarrow i\text{-}C_4H_8 + H_2O$$

which clearly involves a four-center activated complex. This may appear to contradict the assumption in the present work that the unimolecular decompositions of alcohols in chemical activation systems involve bond scissions, *e.g.*

[13] $$t\text{-}C_4H_9OH \rightarrow CH_3 + (CH_3)_2\dot{C}OH$$

However, the products observed in the chemical activation studies and behavior in the presence of free radical scavenger (O_2) are compatible only with bond scissions leading to formation of free radicals. This apparent anomaly can be easily resolved by comparing the Arrhenius parameters of reactions 12 and 13.

For *chemically* activated *t*-butanol formed by insertion of $O(^1D_2)$ into the tertiary CH bond of isobutane (*i.e.* for $E = 154$ kcal/mol, as listed in Table 1), and with Tsang's (23) $A_{12}(2.5 \times 10^{13}$ s$^{-1})$ and $E_{\infty 12}$ (61.6 kcal/mol), eq. 3 gives $k_{12}(E) = 1.8 \times 10^8$ s^{-1}. This is much smaller than the experimental value of 3.8×10^9 s^{-1}. Therefore, even if reaction 12 were occurring, it would amount to less than about 4% of total reaction and would be difficult to observe, in agreement with the experiment.

On the other hand, for *thermally* activated *t*-butanol, say at 1000 °K, fission into free radicals (reaction 13) should be relatively small. For thermal activation, the ratio of the integrated rate constants, k_a, is

[14] $$\frac{k_a(13)}{k_a(12)} = \frac{\int_{E_{0(13)}}^{\infty} k_{13}(E)N(E)\exp(-E/RT)\,dE}{\int_{E_{0(12)}}^{\infty} k_{12}(E)N(E)\exp(-E/RT)\,dE}$$

For simplicity, all $k(E)N(E)$ values in eq. 14 were calculated from eq. 3, although the latter is strictly valid only at larger E, and the respective E_0 values were equated to E_∞. The computed ratios of $k_a(13)/(k_a(12) + k_a(13))$ are 0.003 at 700 °K, 0.16 at 1000 °K, 0.62 at 1300 °K, and 0.95 at 2000 °K. Although these computations are approximate and are based on a particular choice of Arrhenius parameters for reactions 12 and 13, an appreciable contribution from the

bond fission reaction 13 may be expected at temperatures in excess of about 1000 °K. In fact, Tsang, who worked in the range 1050–1300 °K, did observe some "side products" (*i.e.* products other than isobutene) at 1300 °K, though he suggested that they might be due to decomposition of *i*-butene. It is evident that thermal and chemical activation do not necessarily follow the same mechanism; chemical activation makes it possible to study a reaction which would be difficult or impossible to study thermally.

Recombination of Iodine Atoms by Flash Photolysis over a Wide Temperature Range. V. I_2 in CF_4, SF_6, CO_2, Ne, Kr[1]

HEN WON CHANG AND GEORGE BURNS

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario M5S 1A1

Received April 30, 1973

Recombination rate constants for iodine atoms in CF_4, SF_6, CO_2, Ne, and Kr were studied by flash photolysis. The results can be summarized as follows:

$$\log k_r^{CF_4} = 10.247 - 2.627 \log (T/300) \text{ (between 300 and 810 °K)}$$
$$\log k_r^{SF_6} = 10.315 - 2.590 \log (T/300) \text{ (between 300 and 810 °K)}$$
$$\log k_r^{CO_2} = 10.224 - 3.274 \log (T/300) + 1.867 \log^2 (T/300) \text{ (between 300 and 980 °K)}$$
$$\log k_r^{Ne} = 9.190 - 1.898 \log (T/300) + 1.294 \log^2 (T/300) \text{ (between 300 and 960 °K)}$$
$$\log k_r^{Kr} = 9.572 - 2.654 \log (T/300) + 1.850 \log^2 (T/300) \text{ (between 300 and 1000 °K)}$$

These rate constants are compared with those available in the literature, and analyzed, qualitatively, in terms of current theories of recombination reactions.

Les constantes de vitesse pour la recombinaison des atomes d'iode dans le CF_4, SF_6, CO_2, Ne et Kr ont été évaluées à l'aide de la photolyse (éclair). Les résultats peuvent être résumés ainsi:

$$\log k_r^{CF_4} = 10.247 - 2.627 \log (T/300) \text{ (entre 300 et 810 °K)}$$
$$\log k_r^{SF_6} = 10.315 - 2.590 \log (T/300) \text{ (entre 300 et 810 °K)}$$
$$\log k_r^{CO_2} = 10.224 - 3.274 \log (T/300) + 1.867 \log^2 (T/300) \text{ (entre 300 et 980 °K)}$$
$$\log k_r^{Ne} = 9.190 - 1.898 \log (T/300) + 1.294 \log^2 (T/300) \text{ (entre 300 et 960 °K)}$$
$$\log k_r^{Kr} = 9.572 - 2.654 \log (T/300) + 1.850 \log^2 (T/300) \text{ (entre 300 et 1000 °K)}$$

Ces constantes de vitesse ont été comparées avec celles existant dans la littérature et ont été analysées, qualitativement, en fonction des théories modernes des réactions de recombinaison.

Recently, it became possible to measure the recombination rates of iodine (1–4) and bromine (5–6) atoms by flash photolysis over a wide temperature range. When these data were interpreted in terms of classical trajectory calculations (7–11), it was determined that two mechanisms are responsible for the recombination: the energy transfer (e.t.) mechanism

$$[1] \qquad X + X \rightleftarrows X_2^*$$

$$[2] \qquad X_2^* + M \rightarrow X_2 + M$$

and the radical molecule complex mechanism (r.m.c.)

$$[3] \qquad X + M \rightleftarrows XM$$

$$[4] \qquad XM + X \rightarrow X_2 + M,$$

where X is Br or I atom, X_2^* is an unstable orbiting pair produced via two body collision, XM is a weakly bound dimer, and M is the third body.

The trajectory calculations suggest that, if the third body is inert and light, the e.t. mechanism predominates. On the other hand, if the molecule M is either large or heavy, or is chemically active, it would be the r.m.c. mechanism that would determine the overall rate of the reaction. In most cases studied so far (7–11), both mechanisms contributed to the reaction. However, the interpretation of the experimental results would have been simpler if only one of these mechanisms would have been predominant.

In the present work, recombination of iodine in CF_4, SF_6, CO_2, Ne, and Kr is studied over a wide temperature range. Since Ne is inert and is a relatively light third body, it is probable that the recombination would proceed via the e.t. mechanism. On the other hand, one can deduce qualitatively from earlier work (7–11) that the recombination in CF_4, SF_6, and CO_2 would most likely proceed via the r.m.c.

mechanism. Recombination of I atoms in Kr is of special interest, because the interaction between I and Kr is presently being investigated by the cross molecular beam technique (12). It will be possible to employ data obtained (12) in order to calculate the recombination rate constant using a minimum number of assumptions. We were also interested in CO_2 as a third body because we wanted to compare the recombination rate to the rate of dissociation of I_2 in CO_2, which is available in the literature (13*a*). All these measurements were done in hope that interactions between iodine and the third body used could be described by a sufficiently reasonable and simple potential energy surface, so that meaningful comparison between experiments and trajectory calculations would be possible.

The apparatus used in this work, and the data analysis, were previously described (1, 2). B.D.H. reagent iodine was used and the diluent gases were obtained from the Matheson Company with the following specification: CF_4, 99.7% pure; SF_6, 99.8% pure; CO_2, 99.8% pure; Ne, 99.995% pure; Kr, 99.995% pure.

The experimental results are shown in Figs. 1 and 2. Here k_r^M is defined via the expression $d[I_2]/dt = k_r[I]^2[M]$ and is given in $l^2\ mol^{-2}\ s^{-1}$. The rate constants were fitted to the following relationship as a function of temperature.

$$\log k_r^{CF_4} = 10.247 - 2.627 \log (T/300) \quad \text{(between 300 and 810 °K)}$$

$$\log k_r^{SF_6} = 10.315 - 2.590 \log (T/300) \quad \text{(between 300 and 810 °K)}$$

$$\log k_r^{CO_2} = 10.224 - 3.274 \log (T/300) + 1.867 \log^2 (T/300) \quad \text{(between 300 and 980 °K)}$$

$$\log k_r^{Ne} = 9.190 - 1.898 \log (T/300) + 1.294 \log^2 (T/300) \quad \text{(between 300 and 960 °K)}$$

$$\log k_r^{Kr} = 9.572 - 2.654 \log (T/300) + 1.850 \log^2 (T/300) \quad \text{(between 300 and 1000 °K)}$$

CF_4, SF_6, and CO_2 are more efficient third bodies than any of the inert gases (1, 2). It appears that for these three gases the r.m.c. mechanism may be even more important than in the case of xenon (10). A similar result was obtained in the study of bromine atom recombination in the presence of an excess of CF_4 and SF_6 (5). Recombination of either iodine or bromine atoms proceeds at the same rate in CF_4; the same is true for SF_6. However, earlier measurements (13*b*) of $k_r^{SF_6}$ for Br are about 2.5 times smaller than $k_r^{SF_6}$ for Br reported more recently (5). We are unable to account for this discrepancy, especially because k_r^{He}, k_r^{Ar},

$k_r^{N_2}$, and k_r^{Ne} for Br, reported in ref. (13*b*) agree very well with those obtained previously in our laboratory (6). The recombination rate constant of iodine atoms in CO_2, obtained in this work at 300 °K, is considerably smaller than that obtained by Rabinowitch and Wood (14), but agrees well with that measured by Russell and Simons (15), and by Porter and Smith (16) (Table 1). Russell and Simons reported one ratio of rate constants, $k_r^{CO_2}(400\ °K)/k_r^{CO_2}(293\ °K) = 0.4$ which agrees well with that obtained in the present work. Britton and co-workers (13*a*) calculated $k_r^{CO_2}$ at 1120 °K from the dissociation rate constant obtained in shock wave experiments and the equilibrium rate constant. As can be seen from Fig. 1 and Table 1, their $k_r^{CO_2}$ value is in good agreement with $k_r^{CO_2}$ (1120 °K) obtained by extrapolation of our data. There has been a great deal of controversy in the literature regarding the validity of the rate quotient law ($k_{forward}/k_{reverse} = K_{eq}$) as applied to recombination–dissociation (18,19). There is a large body of experimental data (20–25) which suggest that the law may not be valid for these particular reactions. Unfortunately, these data were obtained in shock wave experiments, which, in general, may be susceptible to large, and sometimes unpredictable, errors. On the other hand, theoretical investigations (26–35) strongly suggest that the rate quotient law should be valid under the experimental conditions (20–25). Present work supports theoretical conclusions (26–35), as far as $2I + CO_2 \rightarrow I_2 + CO_2$ reaction is concerned.

Christie and co-workers (36) and Bunker and Davidson (17) measured k_r^{Ne} and k_r^{Kr} at 293 °K, and their values all agree well with our values (Table 2). The rate constant of iodine recombination in the presence of inert gases increases as the atomic number of the inert gas increases, as shown in Fig. 2 except at highest temperatures, where k_r^{Ar}, k_r^{Kr}, and k_r^{Xe} are nearly equal to each other. This trend was also found in the recombination of bromine atoms (6).

A Quantitative Investigation of the Ozonolysis Reaction. XVIII. A Kinetic Study of the Ozone Attack on Phenylethylenes

H. HENRY, M. ZADOR, AND S. FLISZÁR
Département de Chimie, Université de Montréal, Montréal, Québec

Received April 18, 1973

Absolute reaction rates for the ozonolysis of phenylethylenes in the liquid phase indicate: (*i*) a Hammett dependence, with $\rho \simeq -1$, for the ring-substituted *trans* stilbenes, (*ii*) a solvent effect, whereby the ozone attack is promoted by polar solvents, and (*iii*) no temperature effect between 15 and 35 °C, thus indicating $\Delta H^{\neq} \simeq 0$.

L'étude des constantes de vitesse pour l'ozonolyse de phényléthylènes en solution montre: (*i*) une relation de Hammett pour les stilbènes *trans* substitués dans le noyau, avec $\rho \simeq -1$, (*ii*) un effet de solvant, l'attaque de l'ozone étant promue en milieu polaire et (*iii*) l'absence d'un effet de température entre 15 et 35 °C, conduisant à $\Delta H^{\neq} \simeq 0$.

Can. J. Chem., **51**, 3398 (1973)

Early kinetic measurements of the reaction between ozone and organic compounds were made on benzene and derivatives thereof, *e.g.* the halogen- and alkyl-substituted benzenes (1–5). On the basis of these results, as well as from the observation that catalysts (such as aluminum chloride and boron trifluoride) which promote attack by electrophiles enhance the rate of reaction between ozone and the benzene derivatives (2, 3), it was concluded that the ozone attack on unsaturated organic compounds is electrophilic in nature. This is not at variance with the evidence that the ozone–olefin reaction is usually a 1,3-dipolar cycloaddition (6).

The rate constants for the reaction of ozone with substituted benzenes are relatively small, ranging (at 25 °C in CCl_4) from 0.028 to 245 $l\ mol^{-1}\ s^{-1}$ for benzene and hexamethylbenzene respectively (5). Hence, conventional techniques for "slow" reactions are adequate for these studies. This, however, is no longer the case for the study of the ozone reaction with ethylenic carbon–carbon double bonds, both in the gas and in the liquid phase. Fast reaction techniques are required in order to measure the rate constants which are of the order of $10^4 - 10^5\ l\ mol^{-1}\ s^{-1}$ (7–9).

The investigations by Cvetanović and coworkers using stopped-flow techniques (8, 9), have confirmed the electrophilic nature of the ozone attack on ethylenic carbon–carbon double bonds in a variety of cases. Ozone, due to its dipolar character, exhibits both an electrophilic and a nucleophilic tendency in the cycloaddition to give the 1,2,3-trioxolane (primary ozonide) (9–11). The observed trends in reactivity cannot be explained simply in terms of an electrophilic attack. It is now recognized that predictions on the ordering of rate constants according to the substituents on the ethylenic carbon atoms may well be in error if they are based *only* on the acceptance of an electrophilic tendency of the ozone attack. In fact, present results indicate that in some cases, *e.g.* the phenylethylenes (12, 13), the initial electrophilic attack proceeds rapidly via an irreversible 1,3-dipolar cycloaddition to give the final product, the primary ozonide. A different pathway, however, implying the reversible formation of a π or σ complex is also considered likely (9, 10, 12, 13).

These two aspects have been investigated recently in a systematic study of series of closely related compounds, such as alkyl-substituted ethylenes (13) and substituted phenylethylenes (12), in order to gain a better knowledge of the substituent effects governing the rate constants. Competitive kinetic techniques were used; these have the advantage over absolute rate measurements of being easier from the experimental point of view and, hence, less susceptible to possible errors.[1]

[1]Previous kinetic results (14) concerning the ozonolysis of ring-substituted styrenes are in error. Slowly decomposing products (probably open-chain benzaldehyde peroxides (15)) arising from the cleavage of the primary ozonides have interfered with the u.v. measurements of the ozone concentrations. By coincidence, the erroneous results also agreed in their comparison with relative reaction rates, as determined from the consumption of olefin in competitive experiments.

The interest in kinetic data is twofold. Firstly, in the ozonolysis of molecules containing several carbon–carbon double bonds relatively little is known about the preferential site of ozone attack. A better knowledge of kinetic data and of both electronic and steric factors of the substituents may prove helpful in discussing the preferential sites of ozone attack. Secondly, such knowledge proves helpful in elucidating the modes of attack from a mechanistic point of view.

The object of the present paper is a study of the specific reaction rates for the ozonolysis in liquid phase of selected phenylethylenes, covering electronic, solvent, and temperature effects. These ethylenes present the advantage that their reactions with ozone as far as final reaction products resulting from the cleavage of the primary ozonides are concerned have already been studied in some detail (15). The ozonolysis of these ethylenes in inert and in participating (ROH) solvents has been shown to be in complete agreement with Criegee's mechanism (16). In particular, the 1:1 olefin–ozone stoichiometry is clearly established and no reaction path other than that described by Criegee's mechanism has ever been observed for these compounds (15).

Experimental

The ring-substituted stilbenes were prepared by Dr. M. Granger, using standard methods; the other olefins are commercial products. Their purity was verified by g.l.c. Spectrograde solvents were used. The solvents were treated to prevent the rapid decomposition of ozone by impurities. A stream of ozonized oxygen was bubbled through the solvent at a rate of about 15 mmol of O_3 per h at room temperature for 45 min. The solution was then flushed with a stream of dry nitrogen for 2–3 h until the emergent N_2 gas contained no ozone. The pretreated solvents were used for preparing the olefin solutions. Ozone was delivered to the pretreated solvents at a flow rate of 15 mmol/h to give the ozone solutions. These are stable for several hours when CCl_4 and CH_2Cl_2 are used as solvents. In $CHCl_3$ the stability is somewhat reduced. In CH_3CN, however, special care must be taken to prepare the solutions immediately before use as the decomposition of the O_3 solution becomes quite noticeable within a few minutes. This decomposition is, however, of no kinetic importance because these reactions take place in about 100 ms.

A Durrum–Gibson stopped-flow apparatus with a Kel-F mixing chamber was used, together with a Jarrel–Ash 0.25 meter monochromator. The reaction was followed by means of a Tektronix 535A oscilloscope and photographs were taken of the signals.

The kinetics were followed by the measurement of the decrease in olefin absorbance (D) with time. The wave length was chosen in such a manner that no absorption from the ozone or from the reaction products could interfere. This was controlled by experiments indicating no residual absorbance at the particular wave length used, after a complete reaction of the olefin with excess amounts of ozone.

The rate constants were calculated from eq. 1,

$$[1]\quad \log([Ol]/[O_3]) - \log([Ol]_0/[O_3]_0) = ([Ol]_0 - [O_3]_0)kt/2.3$$

representing the ozone–olefin reaction assuming first order kinetics with respect to each reactant. Assuming the validity of the Beer–Lambert law, it follows, that

$$[2]\quad \log[D_t/(D_t - D_\infty)] - \log[D_0/(D_0 - D_\infty)] = D_\infty[Ol]_0 kt/2.3\ D_0$$

where D_0 is the absorbance at $t = 0$, and D_t the corresponding value at $t = t$. The absorption D_∞ at $t = \infty$ is a measure of the unreacted olefin and, hence, $D_0 - D_\infty$ a measure of the olefin consumed at $t = \infty$. All the kinetic runs were made using an excess of olefin with respect to ozone. Hence, the olefin consumed at $t = \infty$ is also equal to the initial amount of ozone. Consequently, the latter quantity need not be determined separately and, indeed, does not appear as such in eq. 2. Therefore, no error is introduced by the uncertainty of the initial ozone concentration and, thus, by any instability of the ozone solutions used for the experiments. In addition, it must be remembered that on the time scale of the kinetic runs the decomposition of the ozone solution is negligible.

The results of a typical run for the ozonolysis of *trans*-stilbene in CCl_4 at 25 °C are given in Table 1. As indicated by the kinetic plot (Fig. 1) obtained from these results, eq. 2 is obeyed satisfactorily, thus supporting the assumptions made in its derivation.

Results and Discussion

Most of the hitherto reported kinetic measurements have been based on ozone consumption relative to time (8, 9, 17), as determined by u.v. spectroscopy. In the present work the measurements are based on the rate of consumption of olefin. As indicated below for the case of styrene, a cross-checking of values obtained by these alternative methods confirms their adequacy.

Previous reports indicate a certain possibility of a dependence of measured rate constants on the concentrations of the reactants, when the concentrations were changed over several orders of magnitude (8). The results for *trans*-stilbene in CCl_4 at 25° reported in Table 2 indicate, however, a satisfactory constancy of the rate constants over a reasonable range of concentrations. The value $k = 3.8 \pm 0.2 \times 10^5\ M^{-1}\ s^{-1}$ thus obtained for *trans*-stilbene at 25° from the measurement of the rate of olefin consumption

TABLE 1. Ozonolysis of *trans*-stilbene in CCl_4 solution, at 25°

Reaction time (ms)	[Ol] × 10^5 (M)[a]	[O_3] × 10^5 (M)[b]	k × 10^{-5} (M^{-1} s^{-1})

[Ol]$_0$ × 10^5 (M)	[O_3]$_0$ × 10^5 (M)	k × 10^{-5} (M^{-1} s^{-1})
2.5	0.8	3.90 ± 0.2
5.0	2.4	3.81
7.5	5.0	3.76
10.0	9.0	3.92

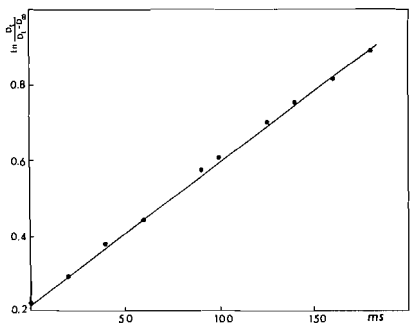

FIG. 1. A verification of eq. 2: ln $[D_t/(D_t - D_\infty)]$ *vs.* time, in ms.

can be used for a comparison with results previously reported (8) obtained from measurements of ozone consumption with time. From this k value for *trans*-stilbene and from the relative rate constant k(*trans*-stilbene)/k(styrene) = 3.48 ± 0.07 (12), the calculated rate constant for styrene is 1.09 × 10^5 M^{-1} s^{-1}. This value compares favorably with the value 1.03 × 10^5 M^{-1} s^{-1} reported by Cvetanović and co-worker (9), which is based on the determination of k for 1-hexene (from the measurement of ozone consumption) and on k(styrene)/k(1-hexene).

The effect of ring substitution was examined in the case of the stilbenes at 25°. The results are reported in Table 3, together with a comparison of the relative rate constants with respect to *trans*-stilbene obtained from (*i*) the present direct measurements of k and (*ii*) from relative rate constants determined with respect to styrene (12). The over-all agreement appears to be reasonable, within experimental limits.

The Hammett plot (Fig. 2) obtained from the present k values appears to be satisfactory. The negative slope ($\rho \simeq -1.0$) compares favorably with that determined from competitive measurements ($\rho = -0.9$). This result is thus in line with previous results (12) which had been interpreted in terms of an electrophilic attack of ozone on the ethylenic carbon–carbon double bond, proceeding by an "irreversible" 1,3-dipolar cycloaddition to give the primary ozonide.[2]

The effect of solvent on k was examined for *trans*- and *cis*-stilbene and for triphenylethylene at 25° (Table 4). The results consistently indicate

[2]In the present work, we have no experimental indication for any appreciable formation of π or σ complex intermediates which have been discussed in other cases (9, 13, 18, 19). The addition of ozone to olefin proceeds without an initial abrupt change in the optical density which would be expected to occur if a complex with different u.v. absorption were rapidly formed.

CH_2Cl_2	91 ± 2		
CH_3CN	140 ± 9	4.77 ± 0.1	5.86 ± 0.2

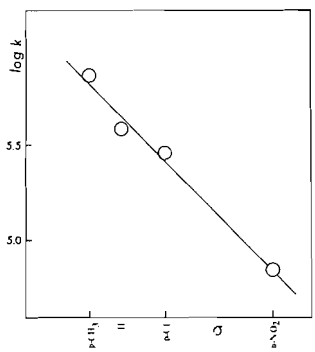

FIG. 2. Hammett plot of log *k* for the ring-substituted *trans* stilbenes, in CCl_4 solution at 25°, *vs.* the substituent constants σ.

that the rate constant increases as the dielectric constant of the solvent is increased. This can be regarded as an indication that the transition state is more polar than the reactants in their ground states.

The effect of α-substitution on 1,3-dipolar cycloadditions is described by Huisgen as "dramatic" (6). This effect can be recognized from the comparison of the results obtained with α-substituted stilbenes at 25° in CCl_4 (Table 5). With respect to *trans*-stilbene, both phenyl and methyl substitutions in the α position result in a significant decrease in the rate constant. A similar though less pronounced substitution effect is observed for α-methylstyrene relative to styrene, indicated by *k*(α-methylstyrene)/*k*(styrene) = 0.86. A better insight into

TABLE 5. Rate constants for the ozonolysis of α-substituted *trans* stilbenes and of *cis*-stilbene, in CCl_4 at 25°

Olefin	$k \times 10^{-4}$ (M^{-1} s^{-1})
trans-Stilbene	38 ± 2
α-Methyl-*trans*-stilbene	10 ± 1
Triphenylethylene	1.69 ± 0.10
cis-Stilbene	1.77 ± 0.10

the effect of methyl substitution on the kinetics is obtained from the consideration that, in principle, replacement of an ethylenic H by CH_3 results in an increase of the rate constant. From competitive kinetic studies (12) it follows that *k*(β-methylstyrene)/*k*(styrene) = 5.1 ± 0.15. In the case of the triphenylethylene, the significant decrease in the rate constant with respect to *trans*-stilbene can be attributed *in part* to a steric effect by which the geminal phenyl groups are no longer in the plane of the remainder of the molecule. The resulting decrease in polarizability of the ethylenic carbon–carbon double bond could be invoked to explain the decrease in the rate constant. This result would be in line with previous assumptions (6), *i.e.* that any increase of the polarizability of the ethylenic C—C double bond should enhance its dipolarophilic nature, and conversely. However, it must also be considered that the steric hindrance to ozone attack contributed by the geminal substituents may be largely

TABLE 6. Effect of temperature on the rate of ozonolysis of selected phenylethylenes, in CCl_4 solution

Olefin	$k \times 10^{-4}$ (M^{-1} s^{-1}) 15°	25°	35°
trans-Stilbene	37.5	38.2	38.6
cis-Stilbene	1.61	1.77	1.88
Triphenylethylene	1.64	1.69	1.66

responsible for the observed decrease in rate constants.

The effect of temperature on the rate constants has been studied for the ozonolysis of *cis*- and *trans*-stilbene and of triphenylethylene. The results clearly indicate that the rate constants are practically invariant with temperature in the range from 15 to 35 °C. This indicates that the activation energy for this reaction is close to 0. The present results agree with those reported for the ozonolysis of 1-dodecene in the temperature range −40 to 12.5 °C (20).

The activation entropies deduced from the present results for *cis*- and *trans*-stilbene, and triphenylethylene (in CCl_4 solution) are −39, −33, and −39 entropy units respectively. These values are similar to those observed in other cycloadditions (6). The present case is particular in that the activation entropy term represents the major, if not the only, contribution to the activation free energy. Thus, any reduction of the rate constant can be attributed, at least to a major extent, to the fact that a cycloaddition demands a concerted action with well-defined geometric requirements, resulting in very negative $\Delta S^{\ddagger}$ values.

Activation energies close or equal to 0 have been found in the ozonolysis of ethylene (21) and 1-hexene (21) in the gas phase, and of 1-hexene (17) and 1-dodecene (20) in the liquid phase. Contrasting with this situation for the ozone–olefin reaction, the decomposition of the primary ozonides hereby formed exhibits a non-zero activation energy in the limited number of cases which are known, *i.e.*, 1-hexene ($\simeq$7 kcal/mol) (22) and *trans*-3-hexene ($\simeq$8 kcal/mol) (23). These observations suggest that at sufficiently high temperatures and low reactant concentrations the ozone–olefin reaction is the rate determining step, whereas at sufficiently low temperatures the product formation is controlled largely by the decomposition of the primary ozonide.

Arylsulfanes—Synthesis and Nuclear Magnetic Resonance Spectra

H. J. LANGER[1] AND J. B. HYNE
Alberta Sulphur Research Ltd., University of Calgary, Calgary, Alberta

Received February 15, 1973

The synthesis of a series of variously substituted arylsulfanes of the general formula $RC_6H_4S_xH$ is described. The proton n.m.r. spectra of the members of the series are reported and discussed in terms of intramolecular electronic effects, conformational factors, and hydrogen bonding.

On décrit la synthèse d'une série d'arylsulfanes de formule générale $RC_6H_4S_xH$. Les spectres r.m.n. de ces composés sont décrits et discutés en termes d'effets électroniques intramoléculaires, de facteurs conformationnels et de ponts hydrogène. [Traduit par le journal]

Can. J. Chem., 51, 3403 (1973)

Introduction

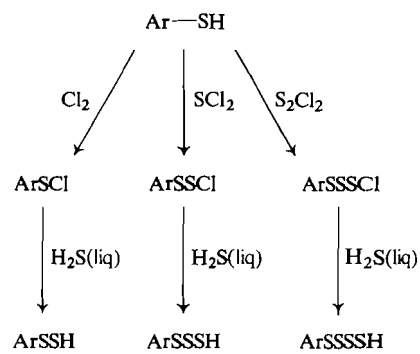
The preparation, isolation, and characterization of asymmetrical sulfanes having the general formula ArS_xH has presented a considerable synthetic challenge to many workers. Disproportionation, rearrangement, and the general instability of longer sulfur chains under the preparative reaction conditions have been the major problem areas. Fehér's work (1) on the preparation and isolation of the hydrogen polysulfides or sulfanes (HS_xH) is a classic illustration of such rearrangement and disproportionation. Tsurugi and co-workers (2) have refined the original method of Böhme and Zinner (3) for the preparation of aryldisulfanes using acylchlorosulfanes followed by alcoholysis, thus building up the sulfane chain one atom at a time. In this work an extension of Fehér's original technique using dichloromonosulfane (SCl_2) or dichlorodisulfane (S_2Cl_2) followed by "thiohydrolysis" with liquid hydrogen sulfide has permitted the synthesis of the higher members of the homologous series of substituted arylsulfanes by adding sulfur atoms in steps of two or three at each stage (see Scheme 1).

N.m.r. has been shown to be a useful analytical tool for simultaneously identifying and quantitatively estimating the individual sulfane members in complicated mixtures (4). In a mixture of sulfanes the exchange rate of protons between individual —SH species takes place sufficiently slowly that the n.m.r. spectrum is characterized by separate distinct signals for the sulfhydryl protons. By using the ratios of the respective peak areas a quantitative analysis of the mixture is possible. This analytical method was used successfully to study the formation of sulfanes in the sulfur–H_2S system, and in the kinetic study of the thiol–sulfur reaction (5).

[1]Present address: Ashland Oil, Inc., Columbus, Ohio.

Synthesis

The general procedure for arylsulfane chain lengthening commencing with the appropriate thiol is summarized in Scheme 1. It is important to note that because of the extreme difficulty of separation and purification of higher members of the sulfane series the n.m.r. shift values reported for some tri-, tetra-, and higher homologues are taken from mixtures of the sulfanes. These cases where actual isolation was not performed are clearly identified in the data compilations.



SCHEME 1

Reaction of arylchlorosulfanes (ArS_xCl) with mercaptans rather than H_2S to yield disubstituted sulfanes ($R_1S_xR_2$) has been previously reported (6).

Arylchloromonosulfane, the precursor of the

respective sulfane was synthesized by treatment of an aromatic thiol with chlorine, *i.e.*

$$Ar—SH + Cl_2 \rightarrow Ar—SCl + HCl$$

The arylchlorodisulfane was prepared in good yield and with satisfactory purity by careful, slow addition of the thiol in CS_2 solution to a very large excess of SCl_2 at -70 °C.

$$Ar—SH + SCl_2 \rightarrow Ar—SSCl + HCl$$

The solvent and excess of SCl_2 must be distilled off *in vacuo* at low temperature. Under similar conditions the reaction of excess S_2Cl_2 with ArSH yields ArS_3Cl.

Under rigorous exclusion of moisture an excess of liquid H_2S reacted with the arylchlorosulfanes at -70 °C to yield the corresponding monosubstituted sulfanes according to

$$Ar—S_xCl + H_2S \rightarrow Ar—S_{x+1}H + HCl$$

The reaction proceeds smoothly and it is unnecessary to isolate the intermediate ArS_xCl. The products were obtained in nearly quantitative yields and were yellow viscous liquids at room temperature, soluble in CS_2 and characterized by a less unpleasant odor than the corresponding thiols. They are relatively stable and may be stored for some weeks when kept near 0 °C and under anhydrous conditions. The products were analyzed by iodometric titration and n.m.r. The results are summarized in Table 1.

The absence of sulfur analysis data as a criterion in Table 1 deserves comment. Sulfur analyses, while certainly informative, suffer from the difficulty that with a homologous series such as the sulfanes, a mixture of disproportionated members of the series, *e.g.* penta- and trisulfane can give a sulfur analysis which would correspond to a pure tetrasulfane. Therefore, *in situ* identification by n.m.r., which reflects the specific molecular integrity of the species, was preferred in combination with iodometric titration of the terminal —SH function. Table 1 also shows the percentages of other sulfanes present in the various samples as obtained from n.m.r. analysis.

Following the synthesis of the sulfanes ArS_xH, a number of experiments were carried out mainly in order to support the structure assignments which were initially based on spectroscopic data, by conversion of these compounds into known sulfane derivatives.

Aryldisulfane was oxidized with iodine;

$$2\ ArS_2H + I_2 \rightarrow ArS_4Ar + 2\ HI$$

or was converted to the trisulfane by treatment with ArSCl.

$$ArS_2H + ArSCl \rightarrow ArS_3Ar + HCl$$

Reaction of aryltrisulfane with arylchloromonosulfane yielded diaryltetrasulfane;

$$ArS_3H + ArSCl \rightarrow ArS_4Ar + HCl$$

the end products were characterized (m.p. and mixed m.p.) by comparison with an authentic sample prepared by an independent synthesis.

Several variables must be considered when planning the synthesis of a particular sulfane. These variables are (1) the molar ratio of the thiol to chlorosulfane or of the arylchlorosulfane to hydrogen sulfide, (2) the reaction temperature, and (3) the reaction time, *i.e.* controlled rate of

addition of reactant. In general, increasing the number of sulfur atoms in the sulfane requires more careful control of these conditions for optimum results.

An interesting observation was made in attempts to catalyze the synthesis of arylsulfanes (ArS_xH) by means of HCl. The reaction was performed both with liquid H_2S saturated with HCl before addition of the arylchlorosulfanes and without addition of HCl. No difference could be observed. This is interesting since Muller and Hyne found (7) in the preparation of HS_3H and HS_4H that satisfactory results were obtained only with H_2S saturated with HCl.

Higher Homologues by Disproportionation and Decomposition

On prolonged standing at room temperature and during distillation, sulfanes were found to decompose into diarylpolysulfanes, thiol, hydrogen sulfide, and sulfur. Attention was focussed in this work on the unsubstituted parent phenylsulfanes. The principal end products of the decomposition of phenyldisulfane, for instance, were sulfur, diphenyldisulfane and tetrasulfane, benzenethiol, and hydrogen sulfide;

$$3ArSSH \rightarrow ArS_xAr + ArSH + H_2S + S$$

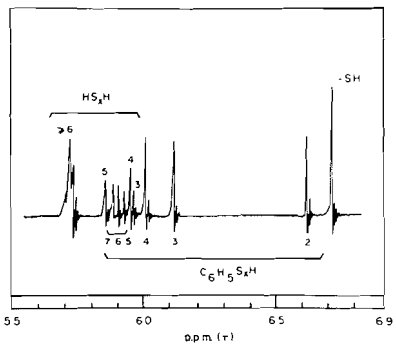

FIG. 1. Expanded n.m.r. spectrum of polysulfane region with assignments. Numbers indicate value of x.

By examining the reaction mixture by n.m.r. during and after distillation it was found that the sulfanes do not decompose directly into the final products Ar—S_xAr, Ar—SH, H_2S, and S but do so through the formation of a number of higher sulfanes of both the ArS_xH and HS_xH type. A typical spectrum of such a polysulfanes mixture showing the presence of the ArS_xH, HS_xH, and parent thiol is shown in Fig. 1. The n.m.r. chemical shifts for the phenylsulfanes are listed in Table 2. In the spectrum the —SH resonance signals are clearly assignable as

indicated by the superscript numbers indicating the length of the sulfur chain. The n.m.r. signals resulting from HS_xH species in the spectrum were assigned according to Hyne *et al.* (5). Inspection of Fig. 1 shows that arylsulfanes up to a sulfur chain length of seven may be identified by clearly separated signals. With increasing sulfur chain length chemical shifts of the sulfhydryl protons are shifted downfield. Assignments were made accordingly and confirmed by adding samples of known sulfane composition to the reaction mixture and observing an increase in the area of the appropriate signals.

The reactions involved in the decomposition of arylsulfanes are evidently complex as evidenced by the production of a large number of intermediates and end products. There is a considerable body of results on the thermal decomposition of sulfanes (8–11) and, for the most part, the evidence indicates that a radical mechanism predominates. Analogies between arylsulfane disproportionation and previous studies on the thermal decomposition of HS_xH (11) suggest a primary homolytic dissociation of the S—S bond into free radicals.

$$ArSSH \rightarrow ArS\cdot + \cdot SH$$

Hydrogen abstraction reactions between primary radical products and the parent sulfane must follow the dissociation step above.

$$ArSSH + ArS\cdot \rightarrow ArSH + ArSS\cdot$$

$$ArSSH + HS\cdot \rightarrow H_2S + ArSS\cdot$$

Subsequent reactions may involve radical–radical recombination of the type

$$ArSS\cdot + HS\cdot \rightarrow ArS_3H$$

$$ArSS\cdot + ArSS\cdot \rightarrow ArS_4Ar$$

$$ArS\cdot + ArS\cdot \rightarrow ArS_2Ar$$

Thermal decomposition of the higher sulfanes ArS_3H and ArS_4H would then proceed by a similar initial homolysis;

$$ArS_3H \rightarrow ArS. + .S_2H$$
$$ArS_3H \rightarrow ArS_2. + .SH$$

$$ArS_4H \rightarrow ArS. + .S_3H$$
$$ArS_4H \rightarrow ArS_2. + .S_2H$$
$$ArS_4H \rightarrow ArS_3. + .SH$$

The primary radicals again abstract hydrogen from the parent sulfane which is present in relatively large excess. The occurrence of higher sulfanes of the type ArS_xH and HS_xH with $x \geqslant 6$ indicates that further disproportionation reactions take place and result in chain propagation and chain termination by similar radical–radical recombinations.

While this investigation represents only a cursory examination of the decomposition of arylsulfanes ArS_xH, the results indicate that the decomposition is a complex reaction involving disproportionation into polysulfanes HS_xH and higher and lower members of the series ArS_xH.

Nuclear Magnetic Resonance Spectra

The availability of a range of variously substituted arylsulfanes of the general formula $RC_6H_4S_xH$ has permitted the determination of the proton n.m.r. behavior of the series of compounds and hence the examination of intramolecular electronic transmission effects. Variation of the R substituent through CH_3, H, Cl, and NO_2 provides both electron donating and withdrawing influences on the aromatic ring. Values of x, the sulfur chain length, from 1 to 4 permit examination of the influence of this factor on the transmission of electronic effects from the aromatic ring to the terminal sulfane proton. The pertinent n.m.r. data are reported in Table 2. Marcus and Miller (12) and Tsurugi and co-workers (2) have reported n.m.r. data on substituted thiols ($x = 1$) and disulfanes ($x = 2$) and have commented on the need to extrapolate to zero concentration because of the possibility of intermolecular hydrogen bonding effects. In the substituted arylsulfanes examined in this work the dependence of S—H proton shift on concentration was found to be small in all but the nitro case. All determinations were therefore made at the same dilution (1.0 *M* in CS_2). While these values may differ slightly from infinite dilution values (C_6H_5SSH 6.62 τ, this work; 6.61 τ, ref. 2) the values for the series are internally consistent. Van Wazer and Grant (13) have reported the dependence of methyl proton n.m.r. shift on sulfur chain length for the series of dimethylsulfanes, $CH_3S_xCH_3$. Schmidbaur *et al.* (4) and Muller and Hyne (14) have provided corresponding data for the simple sulfane series, HS_xH. All of these results show a downfield

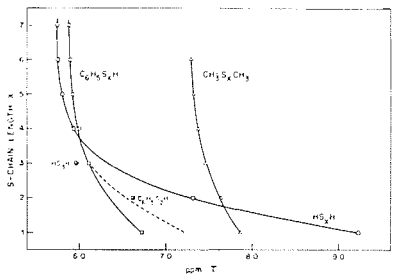

FIG. 2. Dependence of the sulfane proton signal positions on the sulfur chain length. ○ HS_xH: TMS internal reference in CS_2 solution (concentration: 1.0 mol^{-1}); values from reference 14. □ $C_6H_5S_xH$: TMS internal reference in CS_2 solution (concentration: 1.0 mol^{-1}). △ $CH_3S_xCH_3$: TMS internal reference in $(CH_3)_2S$ solution; Values from ref. 13.

shift or deshielding effect on the terminal protons as the sulfane chain length is increased. As illustrated in Fig. 2 the arylsulfanes are no exception to this rule. There is a clear indication, however, that the aryldisulfane is somewhat anomalous as has been noted for the trisulfane in the HS_xH series.

This anomalous behavior in the disulfanes is clearly established by the data for the variously substituted sulfanes plotted in Fig. 3. The *p*-CH_3 and *p*-Cl series both show precisely similar deviations from the smooth curve behavior as is noted for the unsubstituted parent phenylsulfane. Tsurugi and co-workers (2) in their examination of the effect of varying ring substitution on SH proton shift for the RC_6H_4-SSH series concluded that the S—S bond in the disulfane does not transmit conjugation and

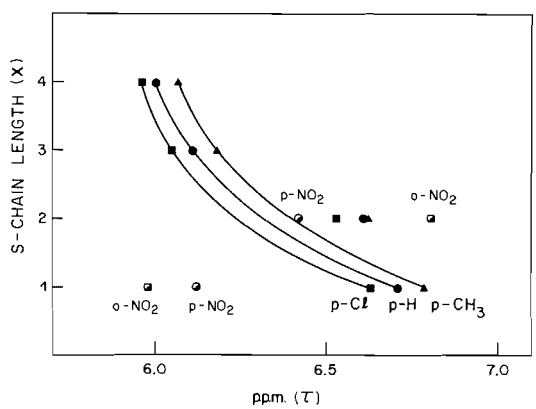

FIG. 3. Sulfhydryl proton signal position of substituted arylsulfanes as a function of sulfur chain length.

permits only very little inductive effect transmission. This might be considered as an explanation for the anomalous behavior of the disulfanes illustrated in Fig. 2 if the phenomenon persisted at higher sulfur chain lengths. Clearly, however, this is not so and it is therefore difficult to accept that by simply extending the sulfur chain the transmission effect is restored.

Downfield shifts from expected values as observed in the case of H_2S_3 are generally attributed to decreased proton shielding resulting from intra- or intermolecular hydrogen bonding. Schmidbaur *et al.* (4) first suggested this explanation for the anomalous n.m.r. signal in H_2S_3 and self association in both thiols and sulfanes has been subsequently demonstrated by i.r. and Raman spectroscopy (31, 32). In the case of phenyldisulfane and the corresponding *p*-methyl and *p*-chloro species, however, the observed anomalous shift of the terminal S—H proton is *upfield* implying increased rather than decreased proton shielding relative to that experienced by other members of the homologous sulfane series. The fact that a change from electron donating to electron withdrawing ring substituents does not significantly affect the anomalous n.m.r. response suggests that the source of the anomaly in the disulfane is not likely inductive or electromeric. While there is a very noticeable concentration effect on n.m.r. shifts in the nitrophenylsulfanes as discussed below the signal position for the other phenylsulfanes is not markedly concentration dependant. This argues against the source of the anomaly being intermolecular association between the —SH proton of one sulfane and the shielding (diamagnetic) basal plane of the aromatic ring of a second phenylsulfane molecule. One possible rationalization of the anomalous shift observation is that the —SH proton in the phenyldisulfane is, by virtue of the C—S—SH bond angle, constrained to move on or close to the "zero effect" surface between the paramagnetic (deshielding) and diamagnetic (shielding) regions associated with the aromatic ring (see Fig. 4). Compared with thiophenol, therefore, the —SH proton in the disulfane would be subject to much less deshielding. In the higher sulfanes the increasing number of rotamer conformations and distance of the terminal SH from the ring will markedly reduce any anomalous shift influence. In a sense, the

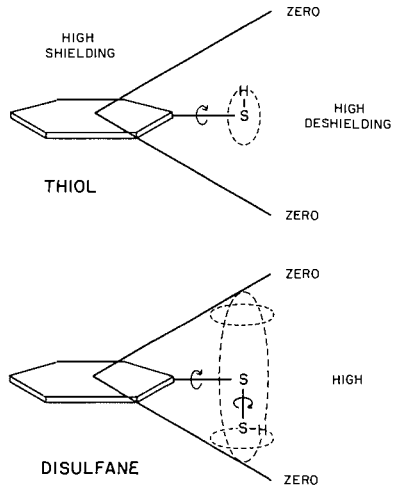

FIG. 4. Anisotropy effects.

apparently anomalous n.m.r. response for the phenyldisulfane is really more a manifestation of "anomalous" deshielding in the parent thiol. The dotted line shown in Fig. 2 represents a graphical interpretation of this suggestion.

In a very recent paper Tsurugi (33) reports the n.m.r. shifts for various benzyl, benzhydryl, and triphenylmethyl sulfanes. The anomalous shift associated with the disulfane is not observed as might be expected due to the insertion of the $-CH_2-$ or $-CH-$ group between the sulfur chain and the ring. The markedly different behavior of the triphenylmethyl sulfane shifts as a function of sulfur chain length is, however, suggested by Tsurugi to be the result of anisotropic factors associated with restricted rotation of the aromatic rings.

The n.m.r. behavior of both the *p*-NO_2 and *o*-NO_2 thiols and sulfanes indicates that these members of the series are significantly different from the other substituted arylsulfanes. The SH proton shift in the *p*-NO_2 case is markedly concentration dependant. The difference between the 1 *M* value and infinite dilution values is 8–10 Hz (0.15 τ). There seems little doubt that intermolecular hydrogen bonding is responsible for this concentration dependence. Confirmation of this conclusion is found in the lack of corresponding proton shift dependence in the *o*-NO_2 case where intramolecular hydrogen bonding would be expected. The added complication of hydrogen bonding, whether intra- or intermolecular, makes it unwise to speculate at this time regarding the relative position of the nitroarylsulfanes in Fig. 3. The anomalous upfield position of the disulfanes relative to the smooth curve prediction noted in the parent, chloro, and methyl substituted series is nonetheless more pronounced in the nitro substituted cases. More extensive examination of the relative roles of hydrogen bonding and conformation effects would be necessary to permit precise analysis of the observed nitro compound shifts but it is unlikely that the upfield shift observed on extending the sulfur chain from one to two atoms is simply an artifact of concentration.

Experimental

Thiols not commercially available were prepared by the standard literature methods indicated below. Each compound was recrystallized or distilled *in vacuo* using a spinning band column just prior to use. All melting points (m.p.) were determined on a Kofler hot stage and are corrected. Boiling points (b.p.) designated by * are converted to pressure used in this work. Some of the thiols were observed to undergo rapid oxidation in the presence of air, particularly in solution. Precautions were therefore taken to minimize contact of the reagent with air.

The work with sulfanes and chlorosulfanes requires special care and cleanliness. All glass apparatus with which these materials come in contact must be thoroughly cleaned with hot chromic acid, carefully dried, and stored in a dust-free atmosphere. All reactions must be protected from moisture and pure starting materials must be used since the intermediates and end products were not purified by distillation due to their very considerable tendency to disproportionate.

Sources of Materials and Reagents

Chlorine (Matheson of Canada Ltd.), was dried and used without further purification. Dichloromonosulfane (sulfenylchloride) (SCl_2) (Hooker Electro Chemical Co.), was stabilized with PCl_3 and redistilled at atmospheric pressure just prior to use. The middle fraction, b.p. 59–60 °C, was employed. Dichlorodisulfane (S_2Cl_2) (Hooker Electro Chemical Co.), was redistilled just prior to use, b.p. 29°C/12 mm. Hydrogen sulfide (Matheson of Canada Ltd.), from a steel cylinder was passed through columns containing $CaCl_2$ and a tube containing P_2O_5, and finally into a container placed in a Dry Ice – acetone bath, where it was condensed and liquefied. The liquefied H_2S was then re-evaporated from this trap into the reaction flask passing through P_2O_5 drying tubes. Carbon disulfide (Fisher Scientific Spectro Grade) was used without further purification. Benzenethiol (Matheson Coleman and Bell) was redistilled before use, b.p. 51–52 °C/12 mm (lit. b.p. 51 °C/12 mm (15)). *p*-Methylbenzenethiol (Aldrich), was recrystallized from ethanol, m.p. 44 °C (lit. m.p. 44 °C (16)). *p*-Chlorobenzenethiol (Matheson Coleman and Bell) was recrystallized from ethanol, m.p. 53–54 °C (lit. m.p. 53–54 °C (17)). *o*-Nitrobenzenethiol was prepared by reduction of the disulfane with glucose and sodium hydroxide following essentially the procedure of Claasz (18). Yield 60% m.p. 57–58° (lit. m.p. 57–58 °C (18)). *p*-Nitrobenzenethiol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

For personal use only.

was prepared in the same manner as the *o*-isomer. Yield 63%, m.p. 77–78 °C (lit. m.p. 77 °C (19)). 2,2′-Dinitrodiphenyldisulfane was prepared by a procedure based on that of R. Möhlau *et al.* (20) from *o*-chloronitrobenzene and sodium disulfide in refluxing ethanol. Yield 64%, m.p. 195 °C (from CH_3CO_2H) (lit. m.p. 195 °C (20)). 4,4′-Dinitro-diphenyldisulfane was prepared from *p*-chloronitrobenzene and sodium disulfide in refluxing ethanol as described by Zinke and Lenhardt (21). Yield 75%, m.p. 181 °C (lit. m.p. 181 °C (21)). Diphenyldisulfane. Benzenethiol in aqueous NH_3 was oxidized with air following the procedure of Steinkopf and Müller (22). Yield 76%, m.p. 61–61.5 °C (lit. m.p. 61.5 °C (22)). Diphenyltrisulfane: the compound was prepared by the method of Chakravarti (23) and recrystallized from ether. Yield 36%, m.p. 28–30 °C (lit. m.p. 30 °C (24)). Diphenyltetrasulfane: following essentially the procedure of Lecher and Holzschneider (25) benzenethiol in dry ether was treated with the calculated amount of S_2Cl_2 to yield the tetrasulfide in 87% yield as crude product. Recrystallization from ether gave pure product, m.p. 33–34 °C (lit. m.p. 34–35 °C (25)). 4,4′-Dimethyl-diphenyltrisulfane was prepared by the same procedure used for diphenyltrisulfane. Recrystallization from acetic acid gave pure product, m.p. 81 °C (lit. m.p. 81–82 °C (16)). 4,4-Dimethyl-diphenyltetrasulfane in the crude form was prepared in the above way (25) in 90% yield and was recrystallized from ethanol, m.p. 75 °C (lit. m.p. 75 °C (26)).

Arylchlorosulfanes

Arylchloromonosulfanes (ArSCl)

The aromatic chloromonosulfanes were synthesized by means of two essentially similar methods involving the interaction of elemental chlorine with the thiols or diaryldisulfanes. The halogenation was conducted at relatively low temperatures under anhydrous conditions in solvents such as CS_2 and CCl_4.

Phenylchloromonosulfane—This was prepared by a slight modification of the method of Lecher and Holzschneider (27). A solution of 5 g freshly distilled thiophenol in 50 ml dry CS_2 was added dropwise under stirring into 150 ml dry CS_2 kept at −5 °C through which a slow current of chlorine dried with sulfuric acid was passed. After evaporating the solvent the product was obtained by fractionating *in vacuo*. Yield 90%, b.p. 78–80 °C/12 mm (lit. b.p. 78–80 °C/12 mm (27)).*

p-Methylphenylchloromonosulfane—This was prepared from *p*-methyl-thiophenol and chlorine at −10 °C as described under the preparation of phenylchloromonosulfane. Yield 80%, b.p. 63–66 °C/1 mm (lit. b.p. 64–66 °C/1 mm (28)).

p-Chlorophenylchloromonosulfane—This compound was prepared from *p*-chlorothiophenol and chlorine as described under the preparation of phenylchloromonosulfane. Yield 82%, b.p. 50–51 °C/0.03 mm (lit. b.p. 50 °C/0.03 mm (29)).

p-Nitrophenylchloromonosulfane—This was prepared from the disulfide and chlorine in CCl_4 at 50–60 °C following the procedure of Zinke and Lenhardt (21). Yield 83%, m.p. 52 °C (lit. m.p. 52 °C (21)).

o-Nitrophenylchloromonosulfane—This was prepared in the same manner as the *p*-isomer above. Yield 70%, m.p. 75 °C (lit. m.p. 75 °C (30)).

Arylchlorodi- and Arylchlorotrisulfanes (ArS_2Cl, ArS_3Cl)

Except for slight variations, each compound was prepared in the same way by reacting an excess of the chloromono- or chlorodisulfane with the corresponding thiol, followed by evaporation of the solvent and of the excess reactant.

General Procedure—A 300 ml, three-necked round-bottomed flask was fitted with a low-temperature thermometer, magnetic stirrer, addition funnel, and condenser. Freshly distilled SCl_2 or S_2Cl_2 was placed in the flask and cooled to −70 °C. Under conditions of careful exclusion of moisture the thiol, dissolved in CS_2, was added dropwise to the chlorosulfane as slowly as was practicable. It was generally found that the more slowly the thiol was added to the chlorosulfane the better the yield. Stirring was continued for 30 min and the mixture then allowed to warm to room temperature. The excess of SCl_2 (or S_2Cl_2) and the solvent were removed by evaporation at reduced pressure and the last traces in high vacuum. The molar ratio of the thiol to chlorosulfane was between 1:20 and 1:30.

Arylchlorodi- and arylchlorotrisulfanes thus prepared were used immediately without further purification.

Arylsulfanes ($Ar—S_xH$)

General Procedure

The reaction was carried out in a 300 ml, two-necked round-bottomed flask, provided with a low-temperature thermometer, addition funnel, Dry Ice condenser, and a magnetic stirrer.

Hydrogen sulfide gas was purified and dried as described above and distilled into the reaction flask, passing through $CaCl_2$ and P_2O_5 tubes. The reaction flask was cooled with a Dry Ice – acetone bath and the gas thus liquefied. The arylchlorosulfane, dissolved in CS_2 was carefully added drop by drop over a period of time under vigorous stirring to the liquefied H_2S, the temperature being maintained at −70 °C. After stirring at −70 °C for 1 h, the excess H_2S was slowly evaporated. The last traces were removed under reduced pressure. The desired product was generally a clear yellow oily liquid. The products were analyzed by n.m.r. and by iodometric titration.

Phenyldisulfane—Following the above method 2.88 g (0.02 mol) of phenylchloromonosulfane and 140 g (4 mol) hydrogen sulfide yielded 2.78 g (95%) product. This was oxidized by iodine and gave diphenyltetrasulfane, m.p. 33–34 °C, mixed m.p. with an authentic sample 33–34 °C. The n.m.r. spectrum showed one sulfhydryl proton at 6.62 τ (—SH) and five aromatic protons at 2.68 τ (center of the multiplet). The product contained also 8% contamination of $C_6H_5S_3H$ as determined by n.m.r. Iodometric titration Calcd. for 0.2482 g substance: 17.45 ml 0.1 *N* I_2. Found: 16.96 ml.

p-Methylphenyldisulfane—In the above way there was obtained 3.10 g (98%) of disulfane from 3.17 g (0.02 mol) of *p*-methylchloromonosulfane and 140 g (4 mol) hydrogen sulfide. The product was oxidized by iodine and gave 4,4′-dimethyldiphenyltetrasulfane, m.p. 75 °C, mixed m.p. with an authentic sample 75 °C. The n.m.r. spectrum showed three methyl protons at 7.70 τ, one sulfhydryl proton at 6.61 τ (—SH), and four aromatic protons at 2.83 τ (center of the multiplet). N.m.r. indi-

cated that the product contained 12% p-$CH_3C_6H_4S_3H$. Iodometric titration Calcd. for 0.2362 g substance: 15.12 ml 0.1 N I_2. Found: 14.75 ml.

p-Chlorophenyldisulfane—From 3.58 g (0.02 mol) *p*-chlorophenylchlorosulfane and 140 g (4 mol) hydrogen sulfide, 3.46 g (98%) of product was obtained. The n.m.r. spectrum showed one sulfhydryl proton at 6.53 τ (—SH) and four aromatic protons at 2.84 τ (center of the multiplet). Iodometric titration Calcd. for 0.2031 g substance: 11.49 ml 0.1 N I_2. Found: 11.40 ml.

p-Nitrophenyldisulfane—From 3.80 g (0.02 mol) *p*-nitrophenylchlorosulfane and 140 g (4 mol) hydrogen sulfide, 3.50 g (94%) of product was obtained. The n.m.r. spectrum showed one sulfhydryl proton at 6.42 τ (—SH) and four aromatic protons at 2.04 τ (center of the multiplet). N.m.r. indicated that the product was greater than 99% disulfane. Iodometric titration Calcd. for 0.2851 g substance: 15.23 ml 0.1 N I_2. Found: 15.11 ml.

o-Nitrophenyldisulfane—From 2.0 g (0.01 mol) *p*-nitrophenylchlorosulfane was 70 g (2 mol) hydrogen sulfide, 1.56 g (79%) of product was obtained. The n.m.r. spectrum showed one sulfhydryl proton (—SH) at 6.81 τ and four aromatic protons at 2.25 τ (center of the multiplet). N.m.r. indicated that the product was greater than 99% disulfane. Iodometric titration Calcd. for 0.3064 g substance: 16.36 ml 0.1 N I_2. Found: 16.49 ml.

Phenyltrisulfane—From 1.8 g (0.01 mol) phenylchlorodisulfane and 105 g (3 mol) hydrogen sulfide, 1.60 g (90%) of product was obtained. This was allowed to react with phenylchloromonosulfane and gave diphenyltetrasulfane, m.p. 33–34 °C, mixed m.p. with an authentic sample 33–34 °C. The n.m.r. spectrum showed sulfhydryl proton resonance at 6.11 τ (—SH) and aromatic protons at 2.74 τ (center of the multiplet). N.m.r. indicated that the product was 82.2% phenyltrisulfane and 17.8% phenyldisulfane. Iodometric titration Calcd. for 0.2671 g: 15.34 ml 0.1 N I_2. Found: 15.98 ml.

p-Methylphenyltrisulfane—From 2.30 g (0.012 mol) *p*-methylchlorodisulfane and 110 g (3.4 mol) hydrogen sulfide, 2.18 g (96%) of product was obtained. This was allowed to react with *p*-methylchloromonosulfane and gave 4,4′dimethyl-diphenyltetrasulfane, m.p. 75 °C, mixed m.p. with an authentic sample 75 °C. The n.m.r. spectrum showed sulfhydryl proton resonance at 6.18 τ (—SH) and aromatic protons at 2.82 τ (center of the multiplet). N.m.r. indicated that the product was 84.1% *p*-methyltrisulfane and 15.9% *p*-methyldisulfane. Iodometric titration Calcd. for 0.2605 g substance: 13.84 ml 0.1 N I_2. Found: 14.32 ml.

Phenyltetrasulfane—Freshly prepared phenylchlorotrisulfane 2 g (0.01 mol) and 70 g (2 mol) hydrogen sulfide yielded 1.5 g (73%) of product. The n.m.r. spectrum showed sulfhydryl proton resonance at 6.02 τ ($—S_4H$), at 6.11 τ ($—S_3H$), and aromatic protons at 2.62 τ (center of the multiplet). The material contained 60% phenyltetrasulfane and 40% phenyltrisulfane as analyzed by n.m.r. Iodometric titration Calcd. for 0.2541 g substance: 12.31 ml 0.1 N I_2. Found: 9.41 ml.

p-Methylphenyltetrasulfane—From 4.2 g (0.02 mol) *p*-methylphenylchlorotrisulfane and 70 g (2 mol) hydrogen sulfide, 3.2 g (80%) of product was obtained. N.m.r. indicated that the material contined 59% *p*-methylphenyltetrasulfane, sulfhydryl proton resonance at 6.07 τ ($—S_4H$), and 41% *p*-methylphenyltrisulfane, sulfhydryl proton resonance at 6.18 τ (S_3H). The aromatic protons are observed at 2.89 τ (center of the multiplet). Iodometric titration Calcd. for 0.1963 g substance: 8.91 ml 0.1 N I_2. Found 9.41 ml.

Chemical Analysis

For the determination of the arylsulfanes the iodometric method of Böhme and Zinner (3) was employed.

Procedure

The sample 0.10–0.20 g was weighed in a small weighing pipette and dissolved in 20 ml carbon disulfide. An excess of a standard solution of iodine was added and the mixture immediately shaken. Since the titration of the iodine with thiosulfate requires a long time, a back-titration method was adopted, an excess of thiosulfate being first added and the excess then determined by means of a 0.1 N I_2 solution to the starch end point.

Nuclear Magnetic Resonance Analysis

A Varian A-60 high-resolution n.m.r. spectrometer was used to analyze the reaction products. The n.m.r. spectra were determined at 35 °C (probe temperature) using TMS as internal standard. Chemical shifts are given on the τ scale in p.p.m. relative to TMS (τ = 10.00). The chemical shifts for the sulfhydryl and the phenyl protons taken at the center of the multiplet structure are presented in Table 2. Relative areas determined by cutting out tracings of the spectra or counting squares yielded a quantitative measure of relative concentrations of aromatic and sulfhydryl protons of the various sulfanes.

Phosphates d'énols-X. Détermination des isomères géométriques diversement substitués par résonance magnétique nucléaire

EMILE M. GAYDOU

Institut Universitaire de Technologie de Marseille-Nord, Rue des Géraniums, 13337 Marseille Cedex 3, France

Reçu le 28 mars

La configuration des phosphates énoliques *E* et *Z*, substitués sur le premier atome de carbone de la double liaison, a été déterminée dans 27 cas, en utilisant les constantes de couplage $^4J_{POC=C-H}$ et les constantes d'écran selon la méthode de Tobey-Pascual. Les facteurs qui influencent les constantes de couplage $^4J_{POC=C-H}$ et $^5J_{POC=C-CH_3}$ sont discutés.

The *E* and *Z* configuration of enol phosphates substituted on the first carbon of the double bond are determined, in 27 cases, using $^4J_{POC=C-H}$ coupling constants and the Tobey-Pascual substituent shielding constants method. The factors influencing $^4J_{POC=C-H}$ and $^5J_{POC=C-CH_3}$ coupling constants are discussed.

Can. J. Chem., **51**, 3412 (1973)

Introduction

L'étude en r.m.n. de phosphates d'énols substitués sur le carbone 1 a fait l'objet de quelques travaux (1–4). L'absence d'une constante de couplage $^3J_{HH}$ *cis* ou *trans* sur la double liaison de l'enchaînement énolique rendait difficile l'identification des isomères *E* et *Z* résultant de la réaction de Perkow (30) (schéma 1).

Par ailleurs, la valeur absolue de la constante de couplage $^4J_{PH}$ variable suivant la nature de R′, rend l'interprétation des résultats assez délicate. Certains auteurs comme Cohn *et al.* (4) et Stubbe et Kenyon (3) ont utilisé les constantes de couplage $^{13}C^1H$ pour résoudre leurs problèmes. Borowitz *et al.* (2) se heurtent à certaines difficultés en utilisant la méthode de Tobey (5) et Pascual *et al.* (6) pour identifier les isomères *E* et *Z*. Nous avons étudié par r.m.n. du ^1H et du ^{31}P une série de phosphates d'énols substitués sur le carbone 1 (tableau 1). La discussion des constantes de couplages $^4J_{PH}$ nous permettra d'avoir une idée des conformations possibles dans cette série de phosphates. Bothner-By et Trautwein (11) ont montré que la constante de couplage $^3J_{POCH}$ dépend de l'angle dièdre formé par les quatre atomes P, O, C, H. Cette dépendance est similaire à la relation bien connue de Karplus (12). Dans le cas de notre série, nous ne pouvons tenir compte que de la constante $^4J_{POCCH}$.

Avec les hétérocycles contenant un atome de phosphore (10, 13–15, 45), il apparait que la constante $^4J_{POCCH}$ peut prendre des valeurs comprises entre 0 et 6 Hz. Avec les composés en libre rotation, ces constantes sont généralement inférieures à 1 Hz (18 à 22). Dans le cas des phosphates d'énols les constantes $^4J_{POCCH}$ peuvent être de trois types:

(*a*) $^4J_{P-O-\underset{\underset{C}{\diagup\diagdown}}{C}=C-H}$ on notera $^4J_{POCCH\ I}$

(*b*) $^4J_{P-O-\underset{|}{C}=\underset{|}{C}-H}$ on notera $^4J_{POCCH\ II}$ cisoïde

(*c*) $^4J_{P-O-\underset{|}{C}=\underset{|}{C}-H}$ on notera $^4J_{POCCH\ II}$ transoïde

La constante $^4J_{POCCH\ I}$ de type isopropylidénique (7, 17) dépend de deux contributions dues aux électrons π et σ. Peu d'études ont été effectuées dans ce sens à l'exclusion de celles de Stiles *et al.* (1). Les constantes de couplage $^4J_{POCCH\ II}$, de type allylique, peuvent prendre des valeurs positives ou négatives suivant l'importance des contributions π et σ comme nous l'avons montré précédemment (51) et par voie de

conséquence, la valeur absolue de ces constantes pourra varier de manière considérable.

Résultats

Les résultats sont presentés en fonction de la nature des substituants sur le carbone 1.

Phosphates d'énols comportant un groupement méthyle sur le carbone 1

Isopropenylphosphates

Nous sommes en présence d'un système du type A_3KLX dans lequel le phosphore (X) intervient comme perturbation du premier ordre. Ce système a été résolu à l'aide d'une version modifiée (9) du programme LAOCOON III (23). L'attribution des différents types de protons peut se faire assez aisément. En effet, le proton en position cisoïde par rapport au groupement phosphate est nettement déblindé car il forme une liaison hydrogène partielle, intramoléculaire, que l'on peut mettre en évidence en élevant la température (fig. 1). Le proton en position transoïde a

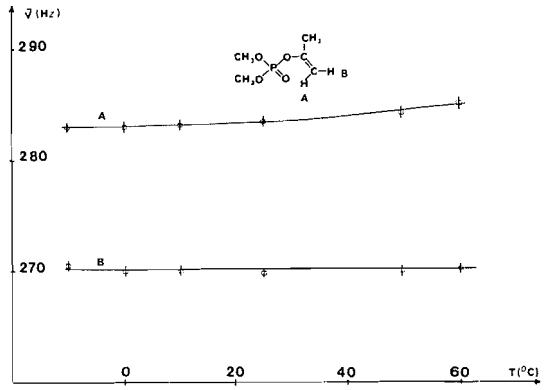

FIG. 1. Influence de la température sur le déplacement chimique des protons vinyliques du composé **1**.

tendance à s'associer pour former des liaisons intermoléculaires que l'on peut atténuer en diminuant la concentration (fig. 2).

L'ensemble des valeurs obtenues est rassemblé dans le tableau 2. On peut remarquer que la

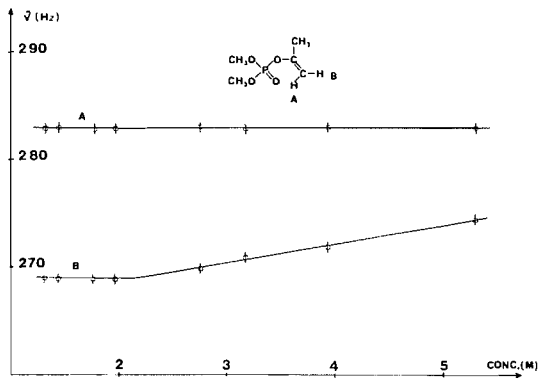

FIG. 2. Influence de la concentration sur le déplacement chimique des protons vinyliques du composé **1**.

constante de couplage allylique cisoïde $^4J_{H_1H_2}$ est systématiquement très supérieure à la constante de couplage allylique transoïde $^4J_{H_1H_3}$. Ce phénomène a d'ailleurs déjà été observé dans le cas du propène (24) des halogéno-2 propènes (25, 26), du phényl-2 propène (27), du méthyl-3 butenyne (28), de l'acrylonitrile (31), etc. Par analogie avec l'étude de Barfield et Chakrabarti (7), on peut penser que ces constantes de couplages sont négatives. En ce qui concerne les constantes $^4J_{POCCH\ I}$ et $^4J_{POCCH\ II}$ cisoïde et transoïde, la nature du groupement R (tableau 2) n'influe pas beaucoup sur les valeurs de ces constantes de couplages. Il est à noter que la présence du groupement méthyle sur le carbone 1a, par contre, une très grosse influence sur la valeur absolue de $^4J_{POCCH\ II}$ cisoïde et transoïde puisque dans le cas du vinylphosphate diméthylique, on a (51)

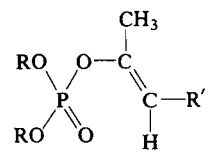
$$^4J_{POCCH\ II}\ \text{cisoïde} = 1.14 \pm 0.1\ \text{Hz}$$

$$^4J_{POCCH\ II}\ \text{transoïde} = 2.85 \pm 0.1\ \text{Hz}$$

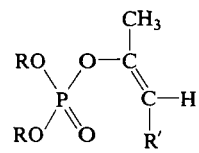
Il n'a pas été possible d'obtenir une variation de la constante de couplage $^4J_{POCCH}$ mesurable dans le cas du composé **1** lorsque l'on fait varier la température de -40 à $+150$ °C dans l'hexachlorobutadiène.

Phosphates d'énols comportant un groupement méthyle sur le carbone 1 et un autre groupement sur le carbone 2

Il est possible d'envisager dans ces conditions deux isomères géométriques *E* et *Z* (29). La



E



Z

réaction de Perkow (2, 30) n'étant pas absolument stéréospécifique, il était assez difficile d'identifier l'isomère *E* ou *Z*, sans faire une analyse approfondie du spectre r.m.n.

Nous avons rassemblé dans le tableau 3 quelques exemples de phosphates énoliques de ce type, où nous avons fait varier le groupement R′. Les paramètres relatifs au composé **8** sont ceux fournis par Stiles et coll. (1). On peut remarquer que la constante $^4J_{HH}$ allylique cisoïde

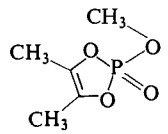
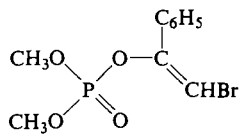
est sensiblement égale à $^4J_{HH}$ allylique transoïde, pour R′ ≠ H, dans la plupart des cas. Ce phénomène est analogue à celui observé dans le cas de l'isobutène (26), du méthylvinyléther (32), de l'isoprène (33), etc. Le proton vinylique dans le cas du vinylphosphate *E* est systématiquement plus déblindé que dans le cas du vinylphosphate *Z* correspondant. La constante de couplage $^4J_{POCCH\ I}$ est variable et comprise entre 0 et 1.6 Hz. Nous avons déjà signalé (53), dans le cas du diméthyl-4,5 oxo-2 méthoxy-2 dioxaphosphole-1,3,2 (**28**), que la constante $^4J_{POCCH\ I} \sim 0$. La constante $^4J_{POCCH\ II}$ transoïde est faible et toujours inférieure à 1 Hz. La constante $^4J_{POCCH\ II}$ cisoïde est toujours supérieure à $^4J_{POCCH\ II}$ transoïde et sa valeur oscille entre 1.8 et 2.6 Hz.



28

Phosphates d'énols comportant un groupement phényle sur le carbone 1

Borowitz *et al.* (2) ont essayé, sans succès, par différentes méthodes, d'obtenir un dérivé phénylé sur le carbone 1 suivant une réaction stéréospécifique. Lorsque l'on est en présence des deux isomères *E* et *Z*, ce sont les spectres les plus difficiles à interpréter car les constantes de couplage sont élevées dans les deux cas. Par exemple avec le bromo-2 phényl-1 vinylphosphate diméthylique (**15**) (tableau 4), la constante



15

de couplage $^4J_{POCCH\ II}$ vaut 1.9 et 2.8 Hz suivant l'isomère considéré.

Il paraît délicat de faire un choix dans ces conditions, compte tenu des résultats précédemment obtenus en ce qui concerne les phosphates d'énols non substitués sur le carbone 1 (9, 51) et substitués par un groupement méthyle. Par contre, dans tous les cas précédemment cités, le proton en position cisoïde par rapport au groupement phosphate, est nettement plus déblindé que le proton en position *trans*. Si l'on se base sur ce phénomène, il est possible de distinguer les deux isomères **15***E* et *Z* et l'on peut faire l'attribution suivante:

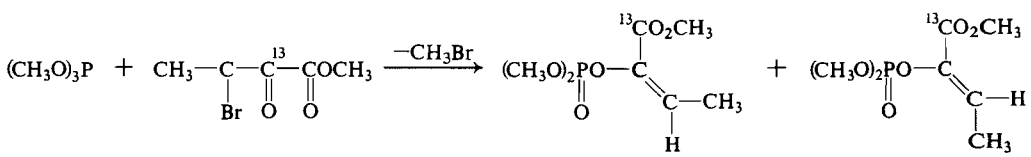
$^4J_{POCCH\ II}$ cisoïde = 2.8 Hz

$^4J_{POCCH\ II}$ transoïde = 1.9 Hz

Cette hypothèse est confirmée par les travaux de Stubbe (3). Cet auteur résout le problème de l'identification des composés *E* et *Z* en utilisant les constantes $^{13}C^1H$. En effet, l'action du triméthylphosphite sur l'oxo-2 bromo-3 butanoate (^{13}C-1) de méthyle conduit au mélange des phosphates d'énols **19***E* et *Z* correspondant (schéma 2).

On sait, par ailleurs, que $^3J_{^{13}CCCH}$ *cis* est inférieure à $^3J_{^{13}CCCH}$ *trans* (34). Il est donc possible, dans ces conditions, de discerner sans ambiguité les isomères *E* et *Z* (tableau 5). La variation des constantes de couplage $^4J_{POCCH\ II}$ du composé **19** est du même ordre de grandeur que celle du composé **15**. D'autre part, les travaux de Marecek et Griffith (46) confirment notre hypothèse en ce qui concerne le blindage des protons β vinyliques. En effet, ils arrivent à obtenir sélectivement le diéthyl phosphate énolique **17***Z* ou **17***E* suivant le schéma 3. Le composé **17***Z* pouvait conduire, par ailleurs, au phosphate énolique **29**. Il est à remarquer que, dans le composé **29**, la valeur obtenue par Marecek et Griffith (46) en ce qui concerne la constante de couplage $^4J_{POCCH\ II}$ transoïde est plus faible. Ceci s'explique très bien par le fait que la contribution due aux électrons π est peu importante compte tenu de la géométrie de cette molécule.

Nous avons rassemblé dans le tableau 4, les principaux résultats relatifs aux phosphates



19*E* **19***Z*

énoliques comportant un groupement phényle sur le carbone 1. Dans le cas des composés **10** et **11** (R′ = H), il est possible, par élévation de température, de simplifier le système vinylique et d'obtenir un doublet (fig. 3). Dans le cas du composé **12**, le doublet est obtenu à température ambiante. La description et l'étude sommaire en r.m.n. du ^1H effectuée par Tidwell *et al.* (44) montrent que ce phénomène est également observé dans le cas d'une série de α-arylvinylphosphates diéthyliques para et métasubstitués. Une étude approfondie de ce phénomène fera l'objet d'un mémoire ultérieur.

Phosphates d'énols diversement substitués

Nous avons rassemblé dans le tableau 6 quelques résultats relatifs à des phosphates d'énols diversement substitués. La substitution du groupement méthyle par un groupement éthyle ne perturbe que très peu le système (composé **20**). Par contre, si l'on place un groupement bromométhyle sur le carbone 1, on peut constater un phénomène analogue à celui observé dans le cas des dérivés α-phénylés **10**, **11** et **12**, c'est à dire que les deux protons vinyliques ont sensiblement le même déplacement chimique, et la figure de couplage se simplifie par élévation de

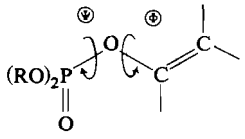
température. Le même phénomène est observé avec les dérivés diéthylique et di *n*-butylique. Dans le cas des dérivés cyclaniques **21**, **22**, **23** et **24** on peut constater un fort déblindage du proton vinylique et une constante $^4J_{POCCH\ II}$ cisoïde de l'ordre de 2 Hz.

Discussion des résultats

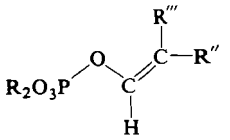
Il est possible, compte tenu des résultats décrits, d'effectuer une analyse conformationnelle de ces phosphates d'énols. Dans cette étude il faut envisager la rotation autour de la liaison P—O et autour de la liaison O—C (51).



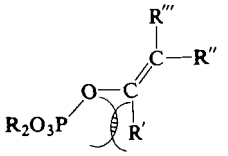
Les deux groupements méthoxy fixés sur l'atome de phosphore sont toujours équivalents dans le domaine de température considéré (−40 à +150 °C). On ne tiendra pas compte, comme nous l'avons fait précédemment (51), de la rotation autour de la liaison P—O.

Nous avons montré, en ce qui concerne l'enchaînement énolique, qu'il est possible d'envisager quatre formes stables pour les phosphates d'énols: deux formes planes où l'angle dièdre ϕ formé par l'intersection des plans P—O—C= et O—C=C prend la valeur 0 ou 180°; deux formes *gauches* où cet angle dièdre peut prendre les valeurs ϕ ou $-\phi$ (fig. 4).

Dans le cas des phosphates d'énols non substitués sur le carbone 1, nous avons montré (51) que la forme la plus stable était celle où l'angle dièdre $\phi = 180°$.



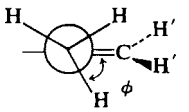
Il paraît logique de supposer que la présence d'un groupement volumineux sur le carbone 1 va augmenter considérablement l'énergie totale de la molécule dans cette conformation, par suite d'une gêne stérique importante entre le groupement R′ et le groupement phosphate.



Cas des composés substitués par un méthyle sur le carbone 1

Avec les isopropénylphosphates, on conçoit facilement que la gêne stérique sera du même ordre de grandeur pour $\phi = 0°$ (forme B), et $\phi = 180°$ (forme A) (Fig. 4). Il paraît logique d'envisager comme forme stable une forme *gauche*. La contribution due aux électrons π: $^4J_{PH}{}^{\pi}$ sera donc prépondérante (7, 35–40). Dans le cas d'un fragment isopropénique $CH_3—C=CH_2'$, cette contribution est (7, 35–40)

$$^4J_{HH'}{}^{\pi} = A \sin^2\phi + B \text{ avec (40) } B \sim 0,\ A \sim -3.36$$



où ϕ est l'angle dièdre représenté ci-dessus. Dans notre cas la constante de couplage $^4J_{P-O-C=C-H\ II}$ sera de la forme

$$\langle {}^4J_{PH}\rangle = x\,{}^4J_{PH}(180°) + y\,{}^4J_{PH}(0°) + 2[1 - (x + y)]{}^4J_{PH}(\phi)$$

x et y étant les populations des formes A et B (fig. 4).

Avec les phosphates isopropéniques, x et y seront très petites compte tenu de la gêne stérique. Par ailleurs, on sait que la contribution due aux électrons σ dans le cas du propane est

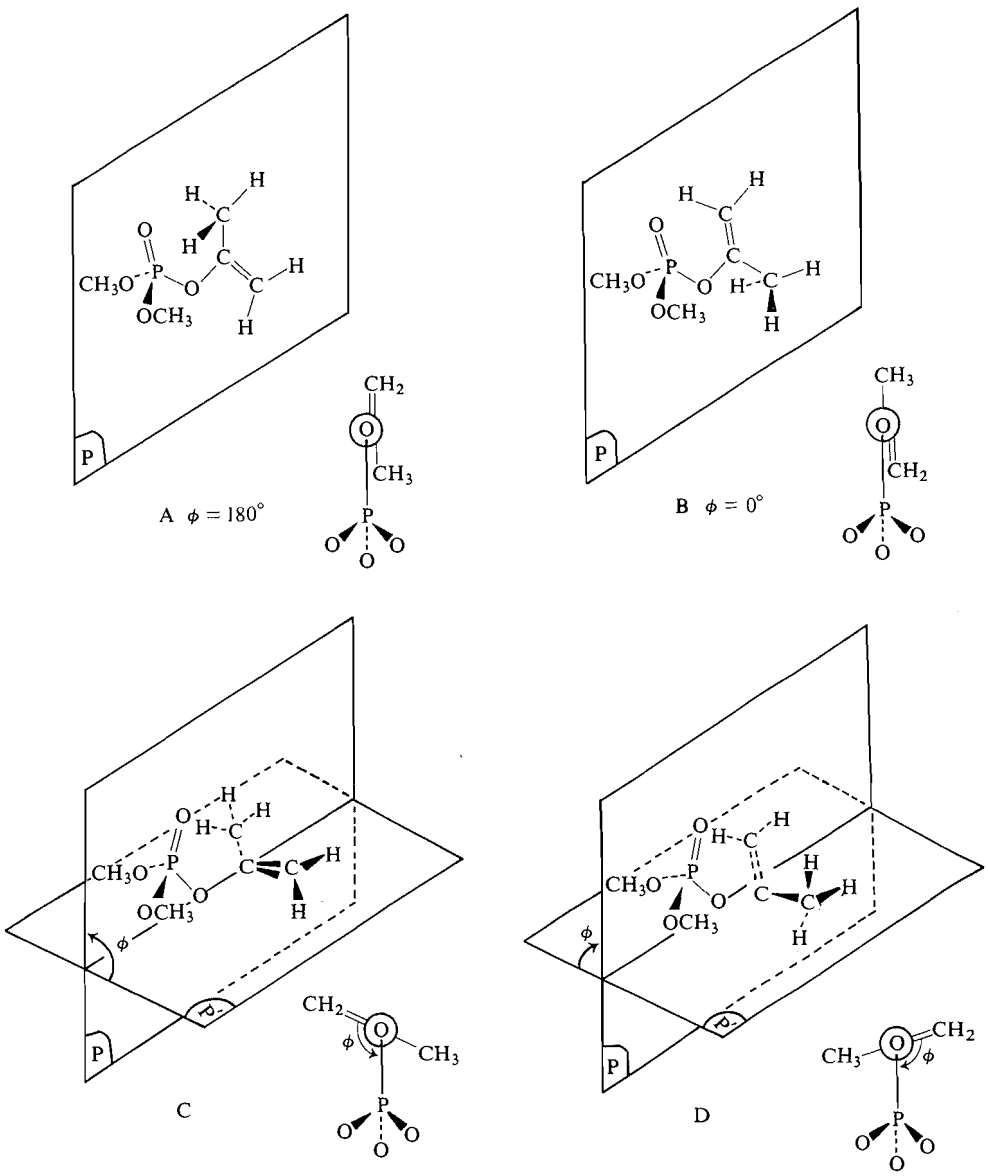

FIG. 4. Conformations stable du méthyl-1 vinylphosphate diméthylique.

positive et telle que (7, 40–43)

$$\langle {}^4J_{HH'}{}^{\sigma}(\text{transoïde})\rangle > \langle {}^4J_{HH'}{}^{\sigma}(\text{cisoïde})\rangle$$

Nous avons montré que le même phénomène se produit dans le cas des phosphates d'énols (51). Dans ces conditions on comprend très bien que pour le composé **1** nous ayons (tableau 7)

$$|{}^4J_{POCCH\ II}\ \text{cisoïde}| > |{}^4J_{POCCH\ II}\ \text{transoïde}|$$

En effet, si la contribution ${}^4J^{\sigma}$ transoïde qui est positive annule la contribution ${}^4J^{\pi}$ transoïde qui est négative, la constante ${}^4J_{POCCH\ II}$ transoïde sera très faible en valeur absolue. La contribution ${}^4J^{\sigma}$ cisoïde étant plus faible que la contribution ${}^4J^{\sigma}$ transoïde, la constante de couplage ${}^4J_{POCCH\ II}$ cisoïde sera supérieure en valeur absolue à la constante de couplage ${}^4J_{POCCH\ II}$ transoïde, les contributions ${}^4J^{\pi}$ transoïde et ${}^4J^{\pi}$ cisoïde étant sensiblement égales (16). En conséquence, on peut penser que ${}^4J_{POCCH\ II}$ cisoïde est négative.

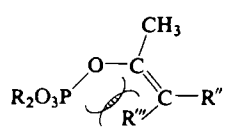
TABLEAU 8. Influence de la température sur $^4J_{POCCH\ II}$ cisoïde de **9***E**

Température (°C)	$\lvert^4J_{POCCH\ II}\rvert$† cisoïde
25	2.40
53	2.30
98.5	2.10

*Solvant, hexachlorobutadiene.
†En Hz.

Il n'est pas possible pour l'instant (compte tenu de nos résultats expérimentaux) d'émettre une hypothèse en ce qui concerne le signe de $^4J_{POCCH\ II}$ transoïde dans le cas de **1**. Si l'on augmente la température, on devrait augmenter la population des formes planes *x* et *y* et par voie de conséquence $^4J_{POCCH\ II}$ cisoïde, devrait diminuer en valeur absolue. C'est effectivement ce que l'on observe dans le cas du composé **9***E* comme le montre le tableau 8.

Dans le cas des composés **5***Z*, **6***Z*, **7***Z*, **8***Z* et **9***Z*, $\lvert^4J_{POCCH\ II}\rvert$ transoïde est comprise entre 0.5 et 0.9 Hz. Nous avons vu (51) que la forme B (fig. 4) ne peut exister compte tenu de la gêne stérique provoquée par le substituant placé en position cisoïde par rapport au groupement phosphate. Si la population de la forme plane B est nulle, on constate une augmentation des



$\phi = 0°$

formes *gauches* et de la forme plane A. Compte tenu du fait que pour les composés **5***Z* à **9***Z*, $\lvert^4J_{POCCH\ II}\rvert$ transoïde est supérieure à celle du composé **1**, cette constante de couplage devrait être négative pour ces cinq composés.

Cas des composés substitués par un groupement autre qu'un méthyle sur le carbone 1

La valeur fortement élevée de $^4J_{POCCH\ II}$ cisoïde autorise l'hypothèse que la forme plane A (ϕ = 180°) ne peut exister dans le cas de cette série substituée par un phényle sur le carbone 1, ou dans la série substituée par un groupement carboxylique sur le carbone 1. Seules les formes planes B (ϕ = 0°) et *gauches* sont susceptibles d'exister dans le cas des composés **10**, **11**, **12**, **13***E*, **14***E*, **15***E*, **16***E*, **17**, **18***E* et **19***E*. La constante $^4J_{POCCH\ II}$ cisoïde doit être négative, par analogie avec les dérivés comportant un méthyle sur le carbone 1. Si l'on augmente la température, la proportion de la forme plane B va augmenter, donc, si la forme *gauche* est la plus stable $^4J_{POCCH\ II}$ cisoïde doit diminuer, c'est ce que l'on observe dans le cas du composé **15***E* comme le montre le tableau 9. Par ailleurs, dans le cas des composés **13***Z*, **14***Z*, **15***Z*, **16***Z*, **18***Z* et **19***Z*, seule la forme *gauche* est susceptible d'exister, ce qui explique, d'une part que $^4J_{POCCH\ II}$ transoïde, dans le cas de **15***Z*, ne varie pas avec la température (tableau 9) et d'autre part une valeur absolue de $^4J_{POCCH\ II}$ transoïde supérieure à celle des dérivés méthylés sur le carbone 1. Dans ces conditions, cette constante de couplage doit être négative car on aura essentiellement une contribution de type π.

Le cas des dérivés diversement substitués et notamment des dérivés cycliques, peut être inclus dans le cadre des dérivés du type méthyl-1 vinylphosphates *E* substitués sur le carbone 2. On peut remarquer, en effet, que $^4J_{POCCH\ II}$ cisoïde est toujours de l'ordre de 2 Hz.

Le déplacement chimique du ^{31}P est d'une manière générale plus positif que pour les dérivés non substitués sur le carbone 1 (51). Ce phénomène pourrait également être en faveur de

TABLEAU 9. Influence de la température sur $^4J_{POCCH\ II}$ de **15** (dans l'hexachlorobutadiène)

Composé	$\|J\|$ (Hz)	Température (°C) 25	53	98.5
15*E*	$^4J_{POCCH\ II}$ cisoïde	2.80	2.70	2.50
15*Z*	$^4J_{POCCH\ II}$ transoïde	1.90	1.85	1.90

la forme *gauche* en tant que forme prépondérante. On peut penser que, dans ces conditions, l'atome de phosphore se trouve dans le cône d'anisotropie de la double liaison et aura tendance à être plus blindé.

Calcul des déplacements chimiques des protons vinyliques

Nous avons montré qu'il est possible de déterminer le déplacement chimique des protons vinyliques (51*c*) en utilisant la méthode de Tobey (5) et Pascual *et al.* (6). Dans le cas de groupements volumineux, comme les groupements OCH_3 et CO_2CH_3, Tobey (5) montre que σ peut varier de plus de 0.5 p.p.m. Nous avons donc déterminé de nouvelles valeurs de σ *cis* et σ *trans* pour les phosphates d'énols substitués sur le carbone 1, puisque comme le montre la variation des constantes de couplages $^4J_{POCCH\ II}$, il y a une gêne stérique importante entre le substituant sur le carbone 1 et le groupement phosphate. Nous avons choisi pour le calcul de ces constantes σ, 13 phosphates d'énols diversement substitués (**1**, **5**, **6**, **8–10**, **13–17**, **19** et **22**) et l'on trouve

$$\sigma\ cis = -0.08 \text{ p.p.m.}$$
$$\sigma\ trans = +0.36 \text{ p.p.m.}$$

Ces valeurs diffèrent sensiblement de celles déterminées à partir de phosphates d'énols non substitués sur le carbone 1 puisque nous avions trouvé (51*c*)

$$\sigma\ cis = +0.28 \text{ p.p.m.}$$
$$\sigma\ trans = +0.68 \text{ p.p.m.}$$

Les déplacements chimiques calculés à l'aide de ces valeurs sont rassemblés dans le tableau 10. On peut constater une parfaite analogie entre les valeurs calculées et observées, sauf dans le cas de quelques dérivés substitués par un méthyle sur le carbone 1 et dans le cas des composés cyclaniques. Nous avons rassemblé dans le tableau 11 les valeurs observées et calculées en utilisant les contributions aux constantes d'écrans correspondant aux phosphates d'énols substitués ou non sur le carbone 1. Cette méthode nous permet donc, non seulement de déterminer sans ambiguité l'isomère géométrique considéré, mais d'avoir aussi une idée sur la possibilité d'existence de cette molécule suivant une conformation plane. En effet, dans le cas des phosphates non substitués sur le carbone 1, la conformation

SCHÉMA 4

la plus stable est une forme plane. Dans le cas de groupements très volumineux, ces formes planes ne peuvent exister.

Avec les composés **1–5**, **21–27** où les conformations planes peuvent exister, les déplacements chimiques des protons vinyliques observés sont différents de ceux calculés en utilisant les contributions aux constantes d'écrans σ *cis* et σ *trans*. D'une manière générale on peut écrire que l'on a dans tous les cas

$$-0.08 \leqslant \sigma\, cis \leqslant +0.28$$
$$+0.36 \leqslant \sigma\, trans \leqslant +0.68$$

Constantes de couplage $^5J_{POCCCH}$

Lorsque la double liaison de l'enchaînement énolique est totalement substituée, les considérations précédentes ne nous permettent pas de distinguer les différents stéréoisomères susceptibles d'exister. C'est le cas du bromo-2 phényl-1 propenyl phosphate diéthylique (**30**) obtenu par Borowitz *et al.* par action du triéthylphosphite sur la dibromopropiophénone (49) (schéma 4). Il est possible d'identifier les composés **30***Z* et **30***E* en considérant la constante $^5J_{P-O-C=C-C-H}$. Il s'agit d'une constante de type homoallylique qui est relativement importante si la double liaison est fortement substituée. En effet, dans ces conditions, les formes *gauches* seront préférentielles et la valeur absolue de $^5J_{PH}$ sera relativement importante puisque la contribution due aux électrons π, dépend de $\sin^2 \phi$ (7). Par ailleurs, dans le cas des dérivés du butène-2, il a été montré que $^5J_{HH}$ (*trans*) est supérieure à $^5J_{HH}$ (*cis*) d'environ 0.3 Hz (16–50). Nous observons un phénomène analogue dans le cas

TABLEAU 13.

Composé	Formes supposées	Formes stables	$^4J_{POCCH\ II(Hz)}$ cisoïde	$^4J_{POCCH\ II(Hz)}$ transoïde
	A, B, C, D	C, D	−1.8 à −2.6	—
	A, C, D	C, D	—	0 à −0.9
 $R' = C_6H_5CO_2R$	B, C, D	C, D	−2.6 à −2.8	—
 $R' = C_6H_5CO_2R$	C, D	C, D	—	−1.0 à −2.5

de nos dérivés, comme le montre le tableau 12. Le tableau 12 montre bien que le composé **30***Z* est celui où la constante $^5J_{PH} = 3.2$ Hz, ce qui nous permet de dire, compte tenu des résultats obtenus par Borowitz *et al.* (49), que l'action de la dibromopropiophénone conduit à 60% du composé **30***Z* et 40% du couposé **30***E*.

Conclusion

L'analyse r.m.n. des phosphates d'énols *E* et *Z* substitués sur le carbone 1, nous a permis d'identifier ces composés sans ambiguité. Le proton vinylique en position cisoïde sur le carbone 2 est toujours plus déblindé que le proton transoïde sauf dans le cas de **19** et **20**. Une association intramoléculaire se produit et il est possible de la diminuer par élévation de température. Dans le cas où le groupement fixé sur le carbone 1 est un groupement carboxylique, c'est le proton transoïde par rapport au groupement phosphate qui est le plus déblindé (composés **18** et **19**). Les résultats que nous proposons sont en bon accord avec les calculs effectués suivant la méthode de Tobey (5) et Pascual *et al.* (6).

Nous avons pu justifier d'une part, les variations des constantes de couplages $^4J_{POCCH\ II}$ cisoïde et transoïde et d'autre part, déterminer ainsi les conformations susceptibles d'exister et leur stabilité relative par rotation autour de la liaison O—C de l'enchaînement énolique. L'ensemble de ces résultats est résumé dans le tableau 13.

La constante $^5J_{POC=CCH_3}$ est comprise entre 2 et 3.2 Hz suivant la nature des substituants sur la double liaison, mais dans tous les cas envisagés cette constante est supérieure en valeur absolue lorsque le méthyle est en *trans* par rapport au groupement phosphate.

NOTE AJOUTÉE À LA CORRECTION DES ÉPREUVES: L'utilisation de $Eu(DPM)_3$ a permis à Borowitz

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

et al. (54) d'étudier les configurations des phosphates énoliques substitués sur le carbone 1. Les résultats qu'il obtient sont en excellent accord avec les nôtres.

Partie expérimentale

La synthèse des produits a été décrite précédemment (52, 53).

Enregistrement des spectres

Les spectres du ^1H ont été enregistrés sur un appareil Varian A 60 ou HA 100, en solution (30% en poids) dans du tétrachlorure de carbone avec du TMS comme référence interne. Les spectres à température variable l'ont été sur un appareil Varian A 60 dans de l'hexachlorobutadiène; quant aux spectres du ^{31}P ils ont été enregistrés sur un appareil HA 100 Varian équipé d'une sonde pour le phosphore à 40.5 MHz.

Calcul des spectres

Les calculs des spectres ont été effectués à l'aide du programme LAOCOON III. Ce programme permet d'optimiser la valeur des glissements chimiques et des constantes de couplage en minimisant l'écart observé entre les raies expérimentales du spectre et les transitions calculées par la méthode des moindres carrés. Ce programme a été adapté sur IBM 360/44, sa capacité a été étendue aux systèmes de sept spins et il lui a été adjoint un programme de tracé de courbes utilisant les fonctions de Lorentz, sur Plotter IBM 1627. A chaque paramètre magnétique optimisé est associée une erreur statistique évaluée sur un intervalle de confiance à 95%.

Nous tenons à exprimer notre reconnaissance à J. R. Llinas pour l'intérêt qu'il a manifesté au cours de ce travail ainsi qu'à Mlle Berger et M. Archavlis pour le grand nombre de spectres qu'ils ont enregistré.

Photoionisation en milieu rigide. Evolution de la fonction de distribution des électrons piégés autour des cations

JACQUES BULLOT, DOMINIQUE CECCALDI, ET ODILE GALLAIS

Laboratoire de Physico-Chimie des Rayonnements, Associé au CNRS, Université de Paris-Sud, centre d'Orsay, 91 Orsay, France

Reçu le 22 mars 1973

Nous proposons un modèle cinétique permettant de décrire la luminescence de recombinaison isotherme (ITL) en milieu rigide. Nous supposons que les cavités piégeantes pré-existent dans le verre et que le champ coulombien du cation crée une distribution continue des profondeurs de piège. La décroissance ITL est une somme infinie de décroissance du 1er ordre résultant de la recombinaison des électrons corrélés. A l'aide de ce modèle, on peut retrouver les décroissances expérimentales avec une précision de $\pm 3\%$. Les solutions numériques sont testées à l'aide d'une fonction de distribution gaussienne pour les électrons piégées (paramètres r_{max} Å et largeur b Å); les paramètres des pièges à électrons sont gardés égaux à $L = 1.70$ Å (demi-largeur) et $\theta\ (r \rightarrow \infty) \simeq 10^3$ s (durée de vie à l'infini). Le modèle est utilisé pour étudier l'évolution de la fonction de distribution des électrons piégés en fonction de plusieurs paramètres expérimentaux. (1) Pendant la relaxation configurationnelle du verre. r_{max} passe de 32.0 à 40.0 Å et b de 6.2 à 9 Å après 24 h de relaxation. Tout au long de l'évolution le nombre d'électrons piégés décroît régulièrement. (2) En fonction de la durée d'irradiation u.v. t_{irrad}. Le maximum de la fonction de distribution s'éloigne du cation quand t_{irrad} augmente. (3) En fonction de l'intensité J de la lumière u.v. Le nombre d'électrons piégés au temps $t = 0$ (arrêt de l'irradiation u.v.) est proportionnel à l'intégrale S de la fonction de distribution à $t = 0$. Quand J varie le modèle indique que S varie comme J^2, c'est-à-dire que l'ionisation est biphotonique—un résultat bien connu. Nous considérons ce résultat comme un test positif de la cohérence interne du modèle.

A kinetic model for describing isothermal recombination luminescence (ITL) of trapped electrons in a rigid medium is proposed. Assuming that cavities in the glass are pre-existing, a continuous trap-depth distribution is generated from the long-range Coulomb field of the cation. ITL decay kinetics simply is the superposition of an infinite sum of first order decays of correlated electrons. This model is able to fit experimental decays within $\pm 3\%$. Numerical solutions are tested by introducing a Gaussian trapped electron distribution function (parameters: r_{max} Å and width b Å) and keeping the formerly found trap parameters: half-width $L = 1.70$ Å and lifetime at infinity $\theta(r \rightarrow \infty) \simeq 10^3$ s. This model is used for studying how the trapped electron distribution function is shifted when experimental conditions are altered. (1) During the glass isothermal relaxation. The initial values $r_{max} = 32.0$ Å, $b = 6.2$ Å found just after cooling are shifted to $r_{max} = 40.0$ Å and $b = 9.0$ Å, 24 h after cooling. The model indicates that the total number of trapped electrons is steadily decreasing as long as the relaxation is proceeding. (2) As a function of the u.v. irradiation period. The trapped electron distribution function is pushed away from the cationic center when t_{irrad} is increasing. Near the saturation plateau the distribution function is no longer shifted; only the total number of trapped electrons is increased. (3) As a function of u.v. light intensity. By integrating as a function of r the trapped electron distribution function at time $t = 0$ when u.v. light is turned off, the resulting area, which is proportional to the total number of trapped electrons, is shown to be proportional to the square of the light intensity. In others words with this model the well-known one-electron two-photon ionization law is recovered. This is to be considered as a test of the model self-consistency.

Can. J. Chem., 51, 3428 (1973)

I. Introduction

Dans un article récent (1), nous avons proposé une interprétation de la cinétique de décroissance de la luminescence isotherme (ou ITL) observée à 77 °K après la photoionisation d'une solution rigide de TMPD[1] dans le 3-MP.[2] Ce modèle nous a permis de retrouver par le calcul la cinétique de décroissance expérimentale et d'étudier sommairement l'influence de la relaxation de la matrice rigide sur celle-ci.

Dans le présent article, nous présentons une étude plus détaillée de l'influence de la relaxation de configuration du verre sur l'évolution de la fonction de distribution des électrons autour des cations, c'est-à-dire en fonction du temps écoulé depuis la trempe du verre. Nous utilisons aussi ce modèle pour étudier comment se déplace la fonction de distribution des électrons

[1]TMPD = *N,N,N-N*-tétraméthylparaphénylènediamine.

[2]3-MP = 3-méthylpentane.

piégés quand on fait varier la durée d'irradiation en lumière ultra-violette et l'intensité de celle-ci.

Rappelons tout d'abord que l'irradiation à 77 °K d'une solution rigide de TMPD dans le 3-MP à 313 nm, c'est-à-dire dans la première bande d'absorption du soluté, conduit à l'ionisation de cette molécule par l'absorption consécutive de deux photons (2). Une partie des électrons éjectés dans la matrice rigide est retenue dans des puits de potentiel, ou "pièges", caractéristiques de la matrice considérée. Après la fin de l'irradiation ultra-violette, ces électrons se recombinent avec les cations $TMPD^+$ pour donner une molécule neutre excitée, qui se désexcite partiellement par émission de fluorescence et de phosphorescence (voir par exemple réf. 2). Cette émission (ITL) peut être observée avec une bonne précision à 77 °K pendant un temps très long, de l'ordre de l'heure. Sa cinétique est complexe. Elle dépend des paramètres physiques qui caractérisent les pièges à électron et de la répartition des électrons autour des cations.

Selon nous, les paramètres physiques permettant de décrire les pièges, c'est-à-dire la dimension du piège et sa profondeur, sont caractéristiques d'un solvant donné et restent les mêmes d'un échantillon à l'autre (d'une trempe à l'autre). Par contre, la répartition des électrons piégés autour des cations va varier avec les conditions expérimentales: conditions de préparation du verre (histoire thermique, trempe), évolution isotherme du verre (relaxation de configuration), conditions d'irradiation en lumière ultra-violette (durée de l'irradiation, intensité de la lumière excitatrice, longueur d'onde utilisée, etc.). En abordant ces différents aspects à l'aide du modèle proposé, nous avons pour but à la fois de tester la validité du modèle en retrouvant certains résultats connus et de cerner des paramètres physiques encore mal connus comme ceux qui caractérisent les pièges à électron dans le 3-MP.

II. Modèle cinétique

Le modèle repose sur 5 hypothèses fondamentales.

(1) Il y a dans la matrice rigide un grand nombre de types de cavités $i = 1, 2, \ldots p$, susceptibles de piéger les électrons, auxquelles correspondent des énergies d'activation E_i.

(2) L'éjection de l'électron hors de son piège est activée thermiquement dans le 3-MP. Ceci semble bien démontré (3). Au contraire, dans le cas du méthylcyclohexane, on est tenté de faire l'hypothèse d'un dépiégeage par effet tunnel (4). Cependant, l'un d'entre nous (1*b*) a montré que le modèle thermique pouvait être appliqué dans le cas du méthylcyclohexane à 77 °K.[3]

(3) Nous ne considérons que les électrons piégés qui sont corrélés avec leurs cations-parents, c'est-à-dire ceux qui se recombinent suivant une réaction du premier ordre. Des expériences d'électrophotoluminescence (5) ont montré que ces électrons sont localisés à une distance $r \lesssim 45$–50 Å du cation $TMPD^+$.

(4) Chaque électron corrélé est soumis au champ coulombien du cation-parent. Ce champ à longue portée a pour résultat d'abaisser la barrière de potentiel opposée à l'éjection de l'électron d'une quantité variable en fonction de r et donc de créer une distribution continue des profondeurs de piège, c'est-à-dire une distribution continue des durées de vie des électrons piégés.

(5) Lors de la recombinaison électron–cation, nous négligeons le repiégeage. En effet, on sait que l'électron libre se recombine en un temps $\lesssim 10^{-9}$ s (6).

Dans ces conditions, l'intensité de la luminescence de recombinaison, à un instant t après la fin de l'irradiation, résulte de la superposition de p sommes infinies (il y a p types de pièges) de décroissances du premier ordre, dont les durées de vie ont une distribution continue.

Tel quel le problème reste très complexe. Mais un raisonnement simple va nous montrer que pour un temps d'observation relativement court devant la durée totale de l'émission, on n'observe qu'un seul type de piège et qu'on peut négliger la contribution des pièges profonds (ou très éloignés du cation). En effet, considérons un électron piégé dans l'état lié. Soit L_i une longueur de l'ordre de grandeur de la demi-largeur du piège de type i. Le champ coulombien du cation abaisse la barrière de potentiel opposée au dépiégeage de l'électron d'une quantité $e^2 L_i/\varepsilon r^2$, où ε est la constante diélectrique statique du 3-MP ($\varepsilon \simeq 2$) et e la charge de l'électron. La constante de vitesse de dépiégeage thermique s'écrit

[3]Rappelons que la température de transition vitreuse est $T_g \approx 77$ °K pour le 3-MP, alors que $T_g \approx 90$ °K pour le méthylcyclohexane.

[1] $k_i(r) = 1/\theta_i(r) = \nu_i \exp\left[-\frac{1}{kT}(E_i - e^2L_i/\varepsilon r^2)\right]$

où ν_i est un facteur de fréquence ($\sim 10^{13}$ s^{-1}) et $\theta_i(r)$ la durée de vie de l'électron dans un piège de type i, à la distance r.

Or, la profondeur de piège $E_i \simeq 0.2$ eV (1*b*) est très grande devant le terme de perturbation $e^2L_i/\varepsilon r^2$. En effet, si on prend $L = 1.70$ Å (1) et $\varepsilon \simeq 2$, ce terme varie de 43×10^{-3} eV à 6×10^{-3} eV quand r passe de 15 Å à 40 Å. Comme par ailleurs à 77 °K, $kT = 6 \times 10^{-3}$ eV, on voit que le rapport $E_i/kT \simeq 0.2/6 \times 10^{-3}$ eV, et donc $k_i(r) = 1/\theta_i(r) \simeq \nu_i \exp -(E_i/kT)$ varient très rapidement avec E_i. Ainsi une faible augmentation de E_i entraîne une très forte augmentation de la durée de vie $\theta_i(r)$ de l'électron piégé. Ceci nous permet de supposer qu'au début de la décroissance de l'ITL, les électrons qui se recombinent sont issus en majorité d'un seul type de piège de profondeur E, la contribution des autres pièges restant négligeable. Ainsi le modèle décrit précédemment (1) avec $i = 1$ reste applicable au début de la décroissance, même si le verre contient plusieurs types de cavités piégeantes. C'est sur cette base que nous allons décrire les résultats expérimentaux et en donner l'interprétation cinétique.

Rappelons que l'intensité de l'ITL à un temps t après la fin de l'irradiation en lumière ultraviolette s'écrit

[2] $I_{ITL}(t) = K \int_0^\infty \frac{D(r, t = 0)}{\theta(r)} \exp[-t/\theta(r)]\, dr$

$D(r,t)$ est la fonction de distribution des électrons au temps t autour des cations, et $\theta(r)$ correspond à l'équation 1 avec $i = 1$ (pour plus de détails voir réf. 1).

L'équation 2 se prête à un calcul numérique à condition qu'on connaisse la longueur L et $\theta(r \to \infty) = \nu \exp(\beta E)$, c'est-à-dire la durée de vie de l'électron piégé dans une cavité de profondeur E située à une très grande distance du cation ($r \gg 50$ Å). De plus, il faut connaître la distribution $D(r,t = 0)$ des électrons à la fin de l'irradiation.

En ce qui concerne L et $\theta(r \to \infty)$, nous considérons que ces paramètres caractérisent le solvant et qu'ils ne doivent pas varier (ou très peu) d'une trempe à l'autre. C'est pourquoi nous leur imposerons dans ce travail les valeurs trouvées avec un échantillon différent (1):

$$L = 1.70 \text{ Å et } \theta(r \to \infty) = 10^3 \text{ s}$$

En ce qui concerne $D(r,t) = 0$, nous ne disposons malheureusement d'aucun renseignement précis sur la distribution réelle des électrons autour des cations. C'est pourquoi nous maintenons une fonction de distribution gaussienne comme dans le travail de la réf. 1:

[3] $D(r,t = 0) = C \exp[-\{(r - r_{max})/b\}^2]$

Nous sommes conscients de l'approximation que représente une telle distribution et pensons qu'en réalité il faudrait choisir une fonction de distribution asymétrique.

III. Partie expérimentale

L'échantillon utilisé est une solution $\sim 10^{-3}$ *M* de TMPD dans le 3-MP. La TMPD est purifiée par sublimation sous vide et le 3-MP par ébullition à reflux sur un mélange de tamis moléculaires ($\frac{1}{3}$ 5A + $\frac{1}{3}$ 10X + $\frac{1}{3}$ 13X) suivie d'une distillation. Dans ces conditions le solvant émet une luminescence parasite environ 10^3 fois plus faible que la luminescence de recombinaison.

L'irradiation en lumière ultra-violette est faite au moyen de la raie 313 nm d'une lampe à vapeur de mercure Osram HBO 200 W/2, isolée à l'aide d'un filtre Jena UG-11. La luminescence émise passe au travers d'un filtre MTO A 365 b, de telle sorte qu'on élimine la phosphorescence et qu'on enregistre seulement la fluorescence de la TMPD. L'échantillon est trempé brutalement à 77 °K au temps $\tau = 0$. On observe ensuite l'évolution de la cinétique de l'ITL en fonction du temps τ qui s'est écoulé entre le moment de la trempe et la fin de l'irradiation. Pour cela on irradie pendant 30 s la solution, enregistre l'ITL pendant environ 30 min et blanchit l'échantillon avec de la lumière visible. Ce cycle est répété un grand nombre de fois jusqu'à ce qu'aucune modification de la cinétique ITL en fonction de τ ne soit plus décelable avec notre dispositif expérimental.

Dans ce qui suit, le temps τ écoulé depuis la trempe de l'échantillon est mesuré en heures et le temps t écoulé depuis la fin d'une irradiation particulière est mesuré en secondes. Nous désignerons par $I^{\tau}_{ITL}(t)$, l'intensité de la luminescence isotherme enregistrée τ h après la trempe de l'échantillon et t s après la fin de l'irradiation à 313 nm. Quand la relaxation de l'échantillon a atteint un palier, nous étudions l'influence de la durée d'irradiation t_{Irrad}, à 313 nm, à flux constant. L'étude en fonction de l'intensité de la lumière excitatrice a été faite dans les mêmes conditions, mais sur un échantillon ayant relaxé pendant 24 h. Les calculs sont effectués à l'aide d'un ordinateur IBM 360.

IV. Relaxation de la matrice de 3-MP

Nous avons suivi l'évolution de la cinétique ITL pendant un temps $\tau \simeq 80$ h. Un palier est atteint à $\tau \simeq 23$ h comme le montre la fig. 1 sur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

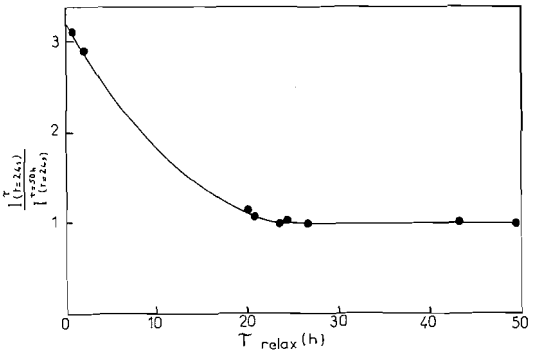

FIG. 1. Variation du rapport $I^{\tau}(t = 24\text{ s})/I^{\tau=50\text{h}}(t = 24\text{ s})$ en fonction du temps écoulé depuis la trempe du verre.

laquelle nous portons le rapport $I^{\tau}_{ITL}(t = 24\text{ s})/I^{\tau\infty}_{ITL}(t = 24\text{ s})$. Quatre cinétiques expérimentales ont été exploitées numériquement pour $\tau = 0.42$ h; 2 h; 20 h et 80 h. Dans chaque cas, un jeu de paramètres r_{max} et b nous permet de retrouver à partir de l'éq. 2 les cinétiques expérimentales avec une bonne précision. La fig. 2 montre que l'accord entre la valeur théorique et la valeur expérimentale est de l'ordre de $\pm 3\%$, pour $t \lesssim 900$ s. Ceci donne une idée de l'erreur introduite par les approximations du modèle cinétique. Pour les temps $t \gtrsim 900$ s, la théorie prévoit une décroissance plus rapide que ne l'indique l'expérience. Ce résultat est compatible avec la remarque du paragraphe II. En effet, il est vraisemblable que pour les temps $t \gtrsim 900$ s, nous observons aussi la recombinaison d'électrons issus de pièges plus profonds que ceux que nous observions pour $t \lesssim 900$ s. Donc l'intensité observée expérimentalement doit être plus grande que l'intensité théorique qui, elle, ne tient compte que des électrons de durées de vie $\theta(r \to \infty) \simeq 10^3$ s.

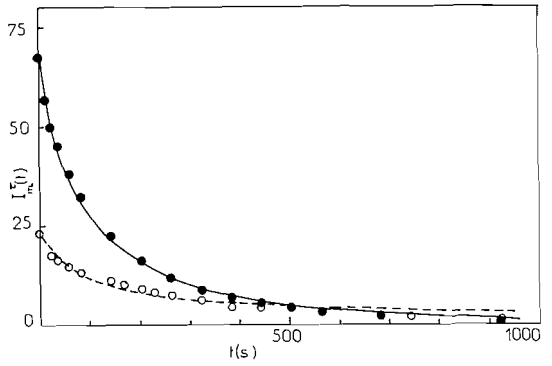

FIG. 2. Cinétique de recombinaison ITL pour des temps de relaxation; $\tau = 0.42$ h (—trait plein) et $\tau = 80$ h (--): ●, points calculés avec $r_{max} = 32$ Å et $b = 6.2$ Å; ○, points calculés avec $r_{max} = 40$ Å et $b = 9$ Å.

Dans le tableau 1, nous avons rassemblé les valeurs choisies pour r_{max} et b qui donnent le meilleur accord avec l'expérience. A titre de comparaison, nous avons consigné les valeurs obtenues dans le travail précédent (1). Celles-ci sont en bon accord avec les notres. Ces résultats peuvent être interprétés à partir de la théorie du volume libre (voir par exemple réf. 7) dans les verres. Selon Kovacs (7*c*) l'évolution isotherme des verres à laquelle correspond une diminution du volume macroscopique[4] est due à la relaxation configurationnelle du milieu amorphe. Le réarrangement moléculaire entraîne la disparition d'un certain nombre de cavités. Dans ces conditions si, comme nous le supposons, les cavités pré-existantes dans le verre sont capables de piéger les électrons, quand τ augmente, les électrons éjectés doivent parcourir en moyenne un trajet de plus en plus long avant d'être piégés. D'où le déplacement de r_{max} et l'élargissement de la fonction de distribution.

Si notre interprétation est correcte, le nombre de cavités disponibles diminuant quand τ augmente, le nombre d'électrons piégés après une irradiation de durée constante (30 s) doit décroître. C'est ce que nous avons vérifié en intégrant la fonction de distribution des électrons piégés à $t = 0$ (éq. 3), soit $S = \int_0^{\infty} D(r,t = 0)dr$.

L'aire S est proportionnelle au nombre d'électrons piégés à un temps τ donné. Les résultats sont consignés dans le tableau 1. S varie d'environ 40% entre $\tau = 0.42$ h et $\tau = 20$ h.

Enfin, nous avons calculé l'évolution de $D(r,t)$ en fonction de t. La fig. 3 montre à $\tau = 0.42$ h l'évolution de $D(r,t)$ entre $t = 36$ s et $t = 600$ s. Le maximum de $D(r,t)$ s'est déplacé d'environ 1.6 Å.

V. Evolution de la fonction de distribution $D(r,t = 0)$ avec la durée d'irradiation en lumière ultra-violette

On sait que, quand on irradie à flux constant une solution rigide de TMPD/3-MP, on observe tout d'abord une augmentation linéaire de l'intensité d'ITL en fonction de la durée

[4]Le verre de glucose, par exemple, trempé à partir de $T = 40$ °C, à 19.8 °C après 100 h de relaxation subitune contraction $(v_{initial} - v_{\infty})/v_{\infty} \simeq 3.6 \times 10^{-3}$ (ref. 7*c*).

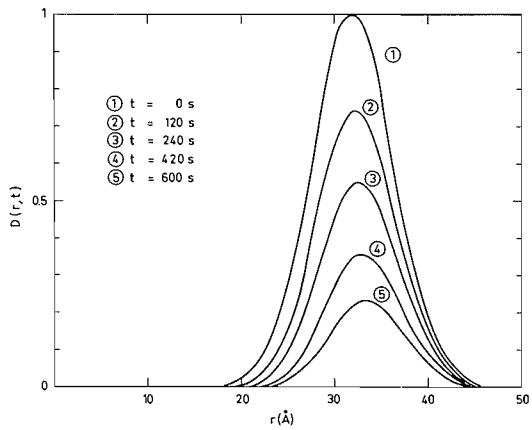

FIG. 3. Evolution de la fonction de distribution des électrons autour du cation, $D(r,t)$ au cours d'une cinétique de décroissance ITL, pour τ_{relax} = 0.42 h. t est le temps écoulé depuis la fin de l'irradiation.

d'irradiation t_{irrad} puis une lente évolution vers un palier.

Parallèlement, la cinétique de décroissance de l'ITL varie rapidement au début et tend vers une cinétique d'équilibre (voir réf. 5, fig. 2). Il est alors intéressant de savoir comment évolue la fonction de distribution des électrons autour des cations quand t_{irrad} augmente. Nous avons donc calculé r_{max}, b et l'aire S pour plusieurs durées d'irradiation. Les observations expérimentales sont faites sur l'échantillon complètement relaxé ($\tau > 80$ h), de telle sorte que nous éliminons toutes les variations de cinétique ITL dues à la relaxation.

Les variations de r_{max}, b et S sont indiquées sur les figs. 4 et 5. r_{max} passe de 35 ± 0.2 Å pour t_{irrad} = 5 s à 40 ± 0.2 Å pour $t_{irrad} \simeq 30$ s; b de 7 ± 0.2 Å à 9 ± 0.2 Å pour les mêmes durées. Pour $t > 30$ s, r_{max} et b restent égaux à 40 et 9 Å. Il est intéressant de noter que pour $t > 30$ s l'aire S continue à augmenter lentement alors que r_{max} et b restent constants. Il est probable qu'on atteint là une des limites du modèle qui s'avère incapable de déterminer avec précision de faibles variations de la fonction de distribution.

La fig. 5 montre que pour $t_{irrad} \lesssim 20$ s, le nombre d'électrons piégés est proportionnel à la durée d'irradiation, un résultat connu qui nous permet de tester la cohérence du modèle.

A la lumière de ces résultats, on voit qu'il y a une expansion de la fonction de distribution autour des cations pendant l'irradiation, mais

que, même au voisinage de la saturation, la majorité des électrons restent localisés dans une sphère de rayon ~ 60 Å. De plus, nous pouvons déduire que pendant l'irradiation un certain nombre d'électrons piégés absorbent la lumière excitatrice $\lambda = 313$ nm, et vont se piéger à une plus grande distance du cation. La probabilité d'absorption de cette longueur d'onde est certainement très faible mais non nulle. L'électron dépiégé pourrait alors être promu dans les états excités localisés situés au-dessus de la bande de conduction étudiés par Funabashi et Maruyama (8).

VI. Variation de la fonction de distribution $D(r,t = 0)$ avec l'intensité de la lumière excitatrice

On sait que l'ionisation du système TMPD/3-MP à 77 °K est un mécanisme biphotonique, c'est-à-dire que le nombre d'électrons piégés dans la matrice est proportionnel au carré de l'intensité J de la lumière excitatrice ($\lambda = 313$ nm). Afin de tester la cohérence interne du modèle nous avons voulu vérifier que le nombre d'électrons piégés à $t = 0$ $N \propto S = \int_0^\infty D(r,t = 0)\, dr$ varie comme J^2. Pour cela, nous avons utilisé un échantillon ayant relaxé pendant 15 h et l'irradions avec des intensités J variables, au moyen de filtres appropriés (l'échantillon est donc différent de celui utilisé auparavant paragraphes IV et V). Pour chaque intensité J, nous déterminons r_{max} et b et calculons l'aire S de la fonction de distribution des électrons à $t = 0$. La fig. 6 montre la variation

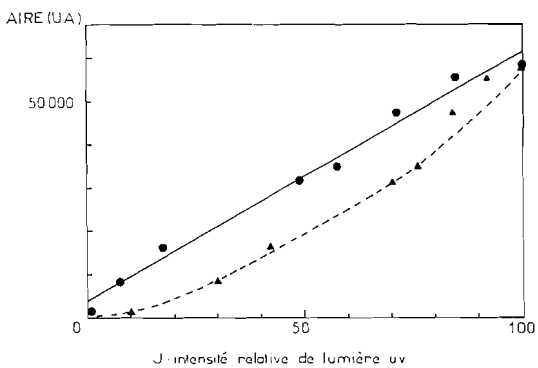

FIG. 6. Vérification à l'aide du modèle que la photoionisation est un phénomène biphotonique. Le nombre d'électrons piégés $N \propto S = \int_0^\infty D(r,t = 0)dr$ est porté en fonction du carré de l'intensité J^2 de la lumière excitatrice (●) et de J (▲). La meilleure droite a pour équation $S = 5.74J^2 + 3886$.

de S en fonction de J^2 et en fonction de J. Il est évident que seuls les points $S = f(J^2)$ s'alignent sur une droite. La meilleure droite qui a été calculée par la méthode des moindres carrés a pour équation: $S = 5.74J^2 + 3886$. Elle passe très près de l'origine (la droite théorique passe évidemment par ce point). Par ailleurs, nous avons porté log S en fonction de log J et obtenu une droite de pente ~ 1.76 au lieu de 2.

TABLEAU 2.*

I (%)	r_{max} (Å)†	b (Å)†	S (u.a.)
100	40.5	9.0	57 800
92.4	40.5	9.0	55 000
84.2	39.0	8.5	47 760
75.8	38.5	8.5	34 860
70	37.5	8.5	31 680
42	36.5	7.5	16 500
27.75	36.5	7.5	8 600
10.9	36	7.5	1 500

*L'échantillon utilisé ici est différent de celui des expériences décrites dans les paragraphes IV et V.
†Comme ci-dessus $L = 1.70$ Å et θ ($r \to \infty$) 10^3 s.

Deux remarques importantes sont à noter.

(1) Les paramètres r_{max} et b varient avec l'intensité de la lumière excitatrice (tableau 2), à condition que le temps d'irradiation soit choisi sur la *partie linéaire* de la courbe de saturation (fig. 6, courbe 1) c'est-à-dire pour $t_{irrad} \lesssim 20$ s.

(2) Si au contraire $t_{irrad} \gtrsim 20$ s, la variation de r_{max} et b est moins rapide et même pour $t = 60$ s, ces paramètres restent constants quelle que soit l'intensité J utilisée.

Parallèlement, et ceci est à souligner, les points $S = f(J^2)$ ne sont plus alignés avec l'origine pour $t_{irrad} \gtrsim 20$ s, c'est-à-dire que sur cette partie de la courbe de saturation, bien que l'ionisation demeure essentiellement biphotonique, des processus de recombinaison et de repiégeage pendant l'irradiation ultra-violette interviennent pour diminuer le rendement de l'ionisation. C'est une conclusion parallèle à celle que nous avons tirée dans le paragraphe V et qui corrobore les études d'électrophotoluminescence. En effet, celles-ci avaient montré qu'on ne pouvait déduire une cinétique perturbée de la cinétique non perturbée que si le temps d'irradiation était choisi sur la partie linéaire de la courbe de saturation (réf. 5, paragraphe IV.C). L'interprétation donnée dans ce travail était qu'au fur et à mesure qu'on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

s'approche de la saturation, les recombinaisons bimoléculaires des électrons avec les cations voisins (et non pas avec les cations-parents) deviennent importantes. Dans la mesure où le présent modèle ne permet de calculer une cinétique expérimentale que s'il y a corrélation entre l'électron et le cation (la cinétique est une somme infinie de décroissances exponentielles), cette conclusion doit être modifiée. Tous les électrons resteraient corrélés et le mauvais accord entre cinétique EPL théorique et EPL expérimentale serait dû aux recombinaisons (corrélées) et au repiégeage des électrons pendant l'irradiation ultra-violette. Quoi qu'il en soit, la fig. 6 montre que le modèle est capable de démontrer que l'ionisation est un processus bi-photonique, et nous considérons ceci comme un test positif pour le modèle.

VII. Conclusion

Le modèle cinétique que nous proposons nous permet:

(1) de décrire la cinétique de décroissance de l'ITL avec une précision $\pm 3\%$, pour des temps d'observation $t \lesssim 900$ s. Au delà de ce temps la cinétique théorique s'écarte de la cinétique expérimentale. Nous interprétons cette différence comme la conséquence de l'existence de plusieurs types de pièges E_i, le modèle ne traitant que le cas simple où il n'existe qu'un piège de profondeur E.

(2) Le piège E est caractérisé par une longueur $L \simeq 1.70$ Å qui est de l'ordre de grandeur de la demi-largeur du piège. L est à rapprocher du paramètre de couplage $d \simeq 1.6$ Å, découvert lors d'études d'électrophotoluminescence (5). L'électron localisé dans un piège E situé à une distance r Å très grande par rapport à 50–60 Å a une durée de vie $\theta(r \to \infty) \sim 10^3$ s. La valeur exacte de E reste indécise puisque dans l'équation $\theta(r \to \infty) = \nu \exp(\beta E) \sim 10^3$ s, le facteur de fréquence ν est inconnu.

(3) La fonction de distribution des électrons autour des cations varie en fonction de nombreux paramètres. Si r_{max} et b caractérisent la fonction de distribution gaussienne que nous avons testée dans ce travail, nous constatons que ces paramètres varient: (*a*) d'une trempe à l'autre; (*b*) pour un même échantillon, avec le temps écoulé depuis la trempe du verre; (*c*) avec la durée d'irradiation en lumière ultra-violette; (*d*) avec l'intensité de la lumière excitatrice à condition que t_{irrad} soit sur la partie linéaire de la courbe de saturation. Bien que la fonction de distribution des électrons piégés que nous avons choisie soit une approximation, il est vraisemblable que les mêmes variations seraient décelées avec une fonction de distribution plus proche de la réalité.

(4) Le fait que le nombre d'électrons piégés diminue quand le temps écoulé depuis la trempe du verre augmente, corrobore la théorie du volume libre qui prévoit qu'au cours de la relaxation isotherme d'un verre certaines cavités disparaissent à la suite de modifications configurationnelles. Les pièges à l'électron seraient ainsi préexistants dans les verres non polaires du type 3-MP. Au contraire, dans les solvants polaires, l'électron libre peut polariser les molécules de solvant voisines et créer ainsi son propre piège.

(5) Enfin, nous constatons que tous les électrons piégés (dépiégeables au cours de l'ITL pour $t < 900$ s) se trouvent situés dans une sphère de rayon $r \sim 50$–60 Å, dont le centre est le cation. Là encore, nous sommes d'accord avec un résultat obtenus par l'étude de l'électrophotoluminescence du même système.

Ces résultats sont encourageants. Toutefois, la description que permet ce modèle simple reste limitée, car il ne tient compte que d'une partie des électrons présents dans le 3-MP après irradiation. Il reste donc à écrire un modèle plus élaboré dans lequel on considère p types de pièges.

Mean Lifetime of an Embryo in the Homogeneous Nucleation from Solution of the Tetracyanoplatinates(II) of Barium, Calcium, and Magnesium

O. A. BEMPAH AND O. E. HILEMAN, JR.[1]

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 18, 1972[2]

The mean lifetime of an embryo in the homogeneous nucleation from aqueous solution of the tetracyanoplatinates(II) of barium, calcium, and magnesium has been studied using the droplet technique. Supersaturation in the droplets was generated by selective extraction of the solvent into the surrounding silicone oil. Crystallization in the droplets was followed by photomicrography using plane polarized light.

The data were analyzed using both the classical model and the mean lifetime model of Carlier and Frisch. The experimental results are consistent with the predicted relationship between the logarithm of the nucleation rate or the logarithm of the mean lifetime of an embryo and the inverse of the square of the logarithm of the supersaturation ratio at high supersaturation ratios. The calculated values of the interfacial energy, using both models, are in close enough agreement to justify the assumptions made in the analysis.

La durée de vie moyenne d'un germe lors du processus de nucléation homogène à partir d'une solution aqueuse des tétracyanoplatinates(II) de baryum, de calcium et de magnésium a été étudiée à l'aide de la technique impliquant des gouttelettes de solution. La supersaturation dans les gouttelettes a été obtenue par extraction sélective du solvant dans l'huile de silicone environnante. La cristallisation dans les gouttelettes a été suivie à l'aide de la photomicrographie en utilisant de la lumière polarisée selon un plan.

Les données furent par la suite analysées selon le modèle classique et le modèle impliquant la durée de vie moyenne de Carlier et Frisch. Les résultats expérimentaux sont en accord avec la relation anticipée qui existe entre le logarithme de la vitesse de nucléation ou le logarithme de la durée de vie moyenne d'un germe et l'inverse du carré du logarithme du rapport de supersaturation pour des rapports élevés de supersaturation. Les valeurs calculées de l'énergie interfaciale, en utilisant les deux modèles, sont suffisamment proches pour justifier les hypothèses faites durant l'analyse.

[Traduit par le journal]

Can. J. Chem., **51**, 3435 (1973)

Introduction

The time lapse between the creation of the supersaturated or super-cooled state and the detection of a new phase by some device is known as the induction time or "time lag" (1–3). It is expressed by the equation

$$[1] \qquad t_p = t_i + t_n + t_g$$

where t_i = the time required to attain the steady state embryo distribution; t_n = the time required for nucleation; and t_g = the time required for growth of the nucleus to detectable dimensions.

Attempts at a theoretical evaluation of the induction time "t_p" have been made by several authors, especially Zeldovitch (4), Turnbull (5), and Kantrowitz (6). But for purposes of homogeneous nucleation, none of the factors on the right side of eq. 1 have been evaluated independently until quite recently. Frisch and Carlier (7) have considered the whole question of induction time and found the expression for the mean lifetime of the critical sized embryo to be

$$[2] \quad L_1 = (\pi)^{1/2} \frac{kT\eta^{1/2}d}{\sigma^{1/2}M^{1/2}SC_{A_0}} \times \exp\left[\frac{-(4\pi)^{1/3}(3Md)^{2/3}\sigma}{\eta^{2/3}kT} + \ln S + \frac{16\pi\sigma^3M^2}{3\eta^2d^2(kT)^3 \ln^2 S}\right]$$

where η = Avogadro's number; σ = surface tension in erg/cm^2; d = density in g/cc; M = the g-mol. wt. of solute; S = supersaturation ratio; k = Boltzman's constant; T = the absolute temperature; and C_{A_0} = equilibrium solubility of the solute at the temperature of the experiment.

L_1 may be equated with t_n in eq. 1, since the nucleation time is the time required for a critical-

[1]Author to whom all correspondence should be directed.

[2]Revision received June 13, 1973.

sized embryo to acquire the extra molecule or ion to become a nucleus.

Experimental data on induction time is scarce and as far as can be ascertained, there are no published data on the mean lifetime of an embryo. It was therefore decided that the droplet technique would be used to study this aspect of nucleation from solution.

One major problem associated with the use of the droplet technique in nucleation studies is the creation of sufficient supersaturation within each droplet to ensure crystallization. The reduction of solubility by gradually cooling the droplets limits the usefulness of the method to the study of highly soluble substances because of the narrow temperature range available, *e.g.*, 100 to 0 °C. The technique of generating one of the reaction partners in solution also limits the number of substances which can be studied. The droplet contraction technique is more versatile in that a very high supersaturation can be generated in each of a population of droplets by the selective diffusion of the solvent (water) into the surrounding medium. The latter was the obvious method of choice for our studies on the tetracyanoplatinates.

Experimental

A droplet contraction experiment consists of two parts: (*a*) the dispersion of a saturated aqueous solution of the compound of interest in a suitable silicone oil, and (*b*) photomicrographic recording of the size changes and the crystallization events occurring in the droplet population.

Apparatus

The dispersions were prepared with the aid of a Virtis microhomogenizer (Fisher Scientific Company) and a 7 ml flask which was obtained as an accessory.

The selection of a suitable number of drops within the desired size range was accomplished by centrifugation (International Clinical Centrifuge, Central Scientific Company, Chicago, Illinois). The apparatus was adapted to enable the rotation of Nessler cups.

The Nessler cups (diameter 3.2 cm, height 2.5 cm) were made from Nessler tubes (Fisher Scientific Company). The inside bottom of the thoroughly clean and dry cup was coated with a thin layer of clear silicone fluid (viscosity 60 000 cP). The cup was placed upside down in an oven at 160 °C for about 3 days to drain off excess fluid. On cooling, the inside wall of the cup was wiped clean of fluid. Precautions were taken to exclude dust particles from the cup both immediately before and after its preparation.

The disperisons were examined with a M15 polarizing microscope (Vickers Instruments Inc., Scarborough, Ontario).

Photographs of selected fields of view were taken with an Autowind 35 mm camera and J35 Exposure Unit (Vickers Instruments Inc.). The film used was Ansochrome Color Slide Film – 500 ASA (GAF (Canada) Ltd., Mississauga, Ontario). The photographs were studied with the aid of a Leitz slide projector.

Preparation of the Salts and Their Saturated Solutions

Magnesium Tetracyanoplatinate

A saturated solution of barium tetracyanoplatinate(II) (Alfa Inorganics, Inc., Beverly, Mass.) was prepared by dissolving about 4 g of the salt in 50 ml of deionized water. The solution was warmed to about 60 °C, allowed to cool to room temperature, and then filtered. A saturated magnesium sulfate solution was added to the filtrate. The thick white precipitate of barium sulfate was separated from the solution by centrifugation and then filtration. The filtrate was evaporated until a large amount of precipitate formed. The crude magnesium tetracyanoplatinate was collected and recrystallized twice. The saturated solutions used in the nucleation studies were prepared by dissolving the purified salt in deionized water.

Calcium Tetracyanoplatinate

The preparation of the calcium tetracyanoplatinate was similar in procedure to that used for the magnesium salt except that calcium chromate solution was used to precipitate the barium from solution.

Barium Tetracyanoplatinate

The saturated solutions of the barium salt were prepared from the recrystallized commercial stock.

Procedure

About two drops (0.05 ml) of a freshly filtered saturated solution of the appropriate salt was placed in the microhomogenizer flask containing about 5 ml light mineral oil (viscosity 20 cP). The flask was placed in position on the microhomogenizer stand. The stirrer was lowered to within a few millimeters from the bottom of the flask and the homogenizer turned on for 5 s at a preselected speed of 4000 r.p.m. The resulting dispersion was quickly transferred into a centrifuge tube containing about 5 ml of heavy mineral oil (viscosity 180 cP). The centrifuge tube and contents were rotated for 60 s. By means of a dropping pipette, some of the heavy oil containing droplets of various sizes but no air bubbles was withdrawn and put into the Nessler cup. The Nessler cup was then rotated in the centrifuge for about 90 s. Part of the contents of the cup was decanted off, leaving a layer of droplets anchored in silicone fluid. The side of the cup was wiped clean. Silicone oil (viscosity 100 cP) was added and the whole rotated in the centrifuge for about 5 s. The mineral oil – silicone oil mixture was decanted off and fresh silicone oil (100 cP) added. This operation was usually repeated two or three times, the aim being the exchange of silicone oil for the mineral oil present. Finally a layer of about 2 mm of silicone oil was left on top of the droplet layer. The cup was then placed on the microscope stage, examined, and suitable fields of view selected for observation.

Photographs of these fields were taken at regular intervals varying from 2–4 min depending on the compound.

The photographs were developed and the slides, numbered in sequence, were projected on a calibrated screen. The diameter of each droplet (except the ones of

very small initial diameters, *ca.* 10 μ) was measured on each slide. Also the number of droplets and the time a crystal was first detected in each of them were noted.

Results

Qualitative Observations

One major requirement of the droplet technique experimental system is that the formation of each nucleus must induce the formation of one crystal in one droplet. This implies that the growth rate of the crystallite formed must be fast compared with the nucleation rate so that multiple nucleation in each droplet is avoided. This requirement was met in all the salts described in this study. In the very small droplets with a final diameter range between 8 and 10 μ, the individual droplets solidified completely and suddenly. With the larger droplets (final diameter range of 20 to 30 μ), however, the crystal(s) formed could usually be detected long before the whole droplet soldified completely. Throughout the experiments the contents of a droplet were assumed to have nucleated at the first detection of a crystal.

In the course of observing the droplets under the microscope, each droplet in the population disappeared completely and uniformly and then reappeared before nucleation occurred. This complete and uniform disappearance of the droplets irrespective of size indicates that there is no significant concentration gradient from the center of the droplet to the solution/oil interface. Also, when nucleation occurred, the position of the crystals in the droplets appeared to be random; that is crystals appeared at the edge of some droplets, and in others at the center. (Of course, there was no way to determine the position of crystals which appeared at the solution/oil interface nearest to, or farthest from, the microscope objective; they might appear to lie in the center of the droplet.)

The effect of the dispersion medium (silicone oil and silicone grease) was also studied. Table 1 shows the combinations used and the data found for the calcium salt. The $t_{1/2}$ was taken as the time (in laboratory coordinates) when 50% of the droplets under observation had crystals in them. The data shows that the dispersion medium did not affect the nucleation process. Similar results were found for the other salts.

It has been suspected that in droplet experiments where many droplets in close proximity are observed at the same time, dendrites shoot from crystallized droplets and catalyze the nucleation of neighboring droplets. This "neighborhood effect" if present will generate a nucleation "front"; that is, the photomicrographs will show a field of droplets in which droplets with crystals in them would appear first at one side of the field and progress to the other. This effect was observed in the preliminary studies on ammonium tetracyanoplatinate. Because of this the salt was rejected from any further study. In the case of the remaining compounds studied, the absence of local extraneous effects on particular droplets was indicated by the fact that the spatial distribution in which crystals appeared in the droplets was found to be entirely random.

TABLE 1. Effect of reaction medium on droplet nucleation (for calcium salt)

Silicone oil	Silicone grease	$t_{1/2}$ (min)*
100 cP (used as purchased)	1 000 000 cP	43
100 cP	60 000 cP	56
100 cP (vacuum dried)	1 000 000 cP	56
	60 000 cP	47
200 cP (used as purchased)	1 000 000 cP	61
200 cP (used as purchased)	60 000 cP	45

*Mean $\bar{t}_{1/2}$ = 51.3 min (s.d. = 7.6).

The size range studied for all the compounds was 10 through 60 μ final diameter. It was found that droplets which did not contain a crystal included those of all diameters. Therefore, the probability of a crystal not appearing in a droplet did not depend on its size.

Statistical consistency of the data was also considered, since data from four or five sets of experiments, conducted over a period of time, were necessary to enable a significant number of droplets to be obtained for analysis. The $t_{63\%}$ test showed that the reproducibility of the separate experiments was satiafactory because it was nearly the same for a particular salt. Consequently all the droplets for a particular salt were analyzed together irrespective of the time separating different experimental runs.

Further examination of the photomicrographs revealed that the diameter of each droplet decreased sharply and rapidly at the beginning of the experiment but the decrease tailed off until eventually the diameter remained nearly constant for a time before a crystal appeared in the droplet. It was observed that for some droplets, this near constancy of the diameter

was not attained before nucleation occurred, but these were few in number. The time taken by each droplet to reach this near constant diameter range was found to depend on the initial diameter and on its position in relation to other droplets in the field of view. It must be borne in mind that droplets with different initial diameters could, and did have, the same final diameter. Similarly, droplets of the same initial diameter did not necessarily attain the same final diameter.

Calculation of the Supersaturation Ratio for Each Droplet

The problem is to find the concentration of any component in a droplet located in a medium in which the solvent is transferring from the droplet to the surrounding medium. Physical transfer is assumed, that is, there is no chemical reaction at the droplet/bulk phase interface, and mass transfer corresponds to transfer from a spherical droplet into a stagnant medium. The assumptions in the analysis are:

(1) The concentration of the transferring component in the bulk phase remains constant during the time interval (*i.e.*, small amounts of the transferring phase are actually transferred).

(2) The concentration at the droplet/bulk phase interface corresponds to equilibrium conditions.

(3) The droplet has a uniform concentration.

(4) The equilibrium concentration of the transferring component is independent of the concentration of the nontransferring component in the droplet (this is expected to be realistic for low concentrations).

Using kinetic considerations it has been shown (8) that at the end of time "t" in laboratory coordinates, from the moment when the dispersion was prepared for observation, the concentration of the solute, C_A, is given by

$$[3] \qquad C_A = (C_{A_0} D_0^3)/(D_0^2 - k_2 t)^{3/2}$$

where D_0 = the initial diameter; k_2 = a constant term (8); and $(D_0^2 - k_2 t)^{3/2}$ = the final volume of the droplet.

The supersaturation ratio, C_A/C_{A_0}, then, is given by eq. 4.

$$[4] \qquad S = C_A/C_{A_0} = D_0^3/(D_0^2 - k_2 t)^{3/2}$$

Determination of the Mean Life of an Aggregate of Embryos

The picture that emerges for the rate of change of droplet diameter with time is as illustrated in Fig. 1. Only curves of two droplets which have the same initial diameter are used for clarity of explanation, even though all the droplets used in this study were similarly analyzed. In the figure, $X = 0$ is zero time in laboratory coordinates, and represents the time when the first photomicrograph was taken. $X = t_{B_0}$ and t_{A_0} is the time in laboratory coordinates at which each droplet diameter was just distinguishable from its final diameter. For most droplets the points "M" and "N" represent about 105% of the final diameter, but for droplets of small final diameter (less than 10 μ) they represent about 110% of the final diameter. $X = t_{B_F}$ and $X = t_{A_F}$ are the times in laboratory coordinates when a crystal was detected in droplets B and A respectively. The difference in time between these two identifiable events is given by eqs. 5 and 6.

$$[5] \qquad L_B = t_{B_F} - t_{B_0}$$

$$[6] \qquad L_A = t_{A_F} - t_{A_0}$$

This time interval was determined for each droplet in the population.

For generality, L_A, L_B, etc. were replaced by L_n, where L_n represents the time interval for the nth droplet. Experimentally, L_n varies from zero to infinity. $L_n = 0$ represents those droplets in which crystals appeared before reaching near

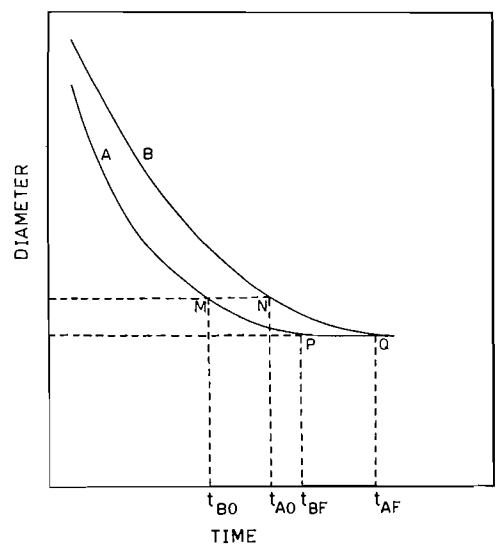

FIG. 1. Schematic diagram of rate of change of droplet diameter *vs.* time.

constancy in diameter, while $L_n = \infty$ represents droplets in which crystals did not appear at all during the duration of the experiment. Observation was normally stopped when more than 98% of the droplets had crystals in them.

The interval, L_n, was identified with the lifetime of an embryo in each droplet. Since nucleation is a probabilistic phenomenon, individual values of L_n are meaningful only when they are viewed as one of an aggregate. To obtain the mean of an aggregate, all the droplets were first grouped according to final diameter ranges at constant supersaturation and the *probability of nucleation vs. time* was plotted on a probability paper. It was found that the time for 63% of the droplets to nucleate, in any size range, was independent of the volume.

The droplets were then grouped according to supersaturation ratios independent of size, and a histogram of the number of droplets nucleating with time was made. The histograms are shown in Figs. 2, 3, and 4. The median time, L_m, for the population of droplets at a particular supersaturation was read from the histogram. This

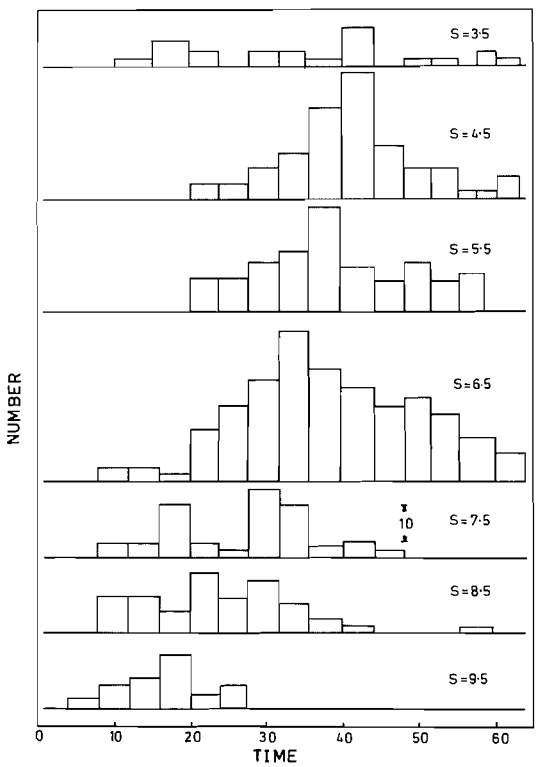

FIG. 2. Histogram of number of droplets nucleating with time for barium tetracyanoplatinate.

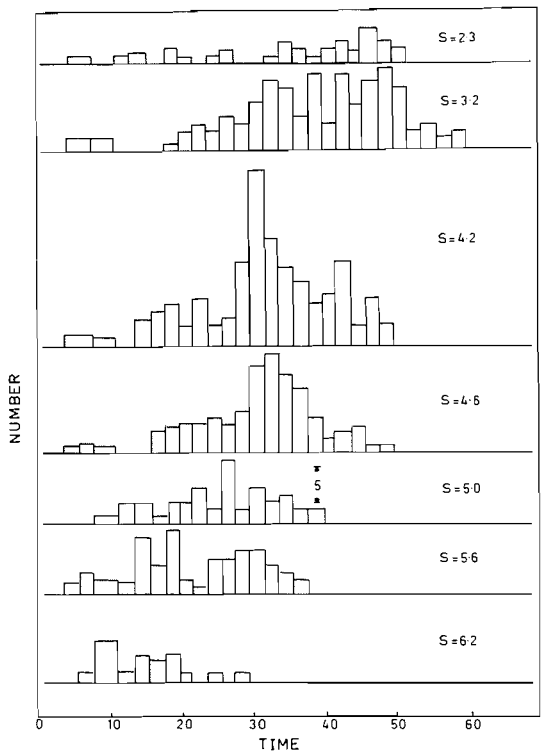

FIG. 3. Histogram of number of droplets nucleating with time for calcium tetracyanoplatinate.

was identified with the L_m of an embryo at any given supersaturation. Rewriting eq. 2 in logarithmic form and writing L_m for L_1 gives eq. 2*a*,

$$[2a] \quad \ln L_m = \ln B - E + (16\pi\sigma^3 v^2)/3(kT)^3 \ln^2 S$$

where B and also E, if σ is assumed constant, are constants and v = the molecular volume in the forming phase.

A plot of $\ln L_m$ *vs.* $(\ln S)^{-2}$ was made for each salt studied (see Fig. 5). The results of the calculation of σ from the slope of each plot are shown in Table 2.

TABLE 2. Summary of parameters obtained using both the classical model and the mean lifetime model of analysis

Compound	σ(erg cm^{-2}) (*a*)*	(*b*)†	n^* (*a*)	r^* (Å) (*a*)	log *A* (*a*)
Barium salt	11.00	9.60	47	13.2	8.70

Magnesium salt	8.10	6.90	74	14.3	6.80

*(*a*) Calculated using the classical model.
†(*b*) Calculated using the mean lifetime model.

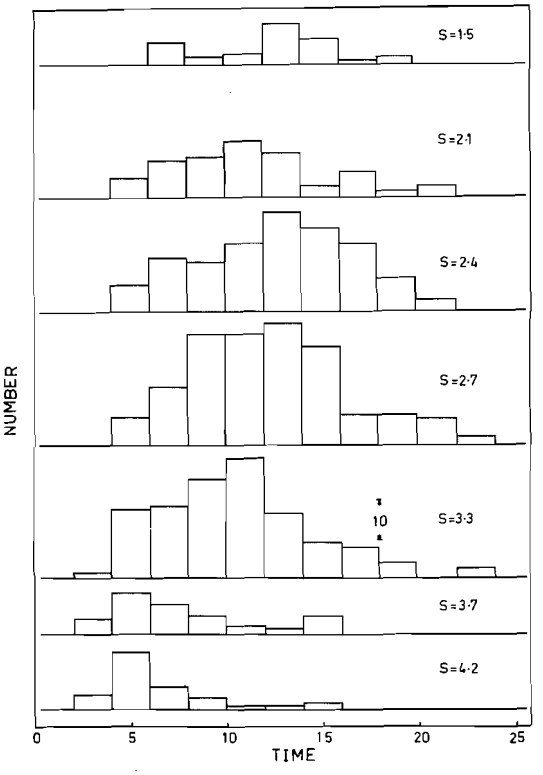

FIG. 4. Histogram of number of droplets nucleating with time for magnesium tetracyanoplatinate.

Calculation of Experimental Rate of Nucleation

The method used here is analogous to that used in reducing experimental observations on freezing water drops to nucleation rates. In such experiments it can be shown (9, 10) that if only N of the original N_0 droplets, each having the same volume V, remain unfrozen after a time interval Δt, then the nucleation rate can be calculated as

$$[7] \qquad J = \frac{1}{V} \cdot \frac{1}{1 - P} \cdot \frac{\Delta P}{\Delta t}$$

where J = the rate of nucleation per second per unit volume (ml) and P = the probability of nucleation.

By means of the histogram of number nucleated *vs.* time for each supersaturation ratio, it was possible to obtain the number N of the total N_0 nucleating at any time. From these data, plots of the probability of nucleation as a function of time were constructed (see Fig. 6). Then the rates of nucleation were calculated with the aid of eq. 7.

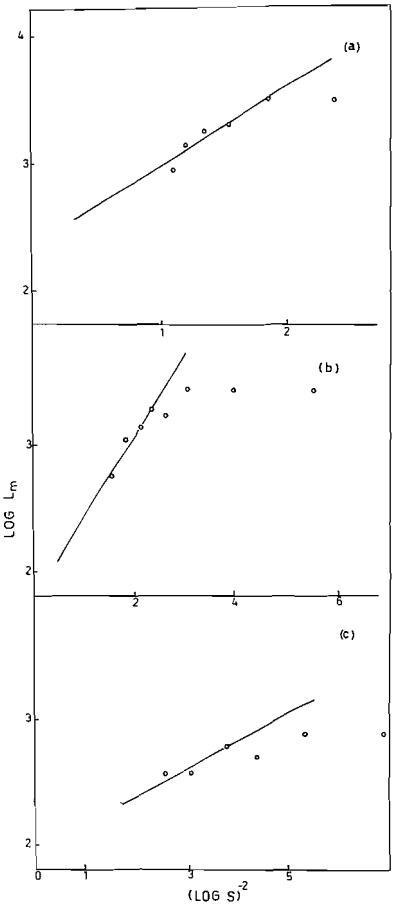

FIG. 5. Logarithm of mean embryo life time *vs.* $(\log S)^{-2}$ for the three salts: (*a*) barium tetracyanoplatinate; (*b*) calcium tetracyanoplatinate; and (*c*) magnesium tetracyanoplatinate.

The J values obtained were plotted against the corresponding supersaturation ratios, as $\log J$ *vs.* $(\log S)^{-2}$, for each of the compounds (see Fig. 7). The values of $\log A$ and σ obtained as intercepts and calculated from the slopes respectively are shown in Table 2.

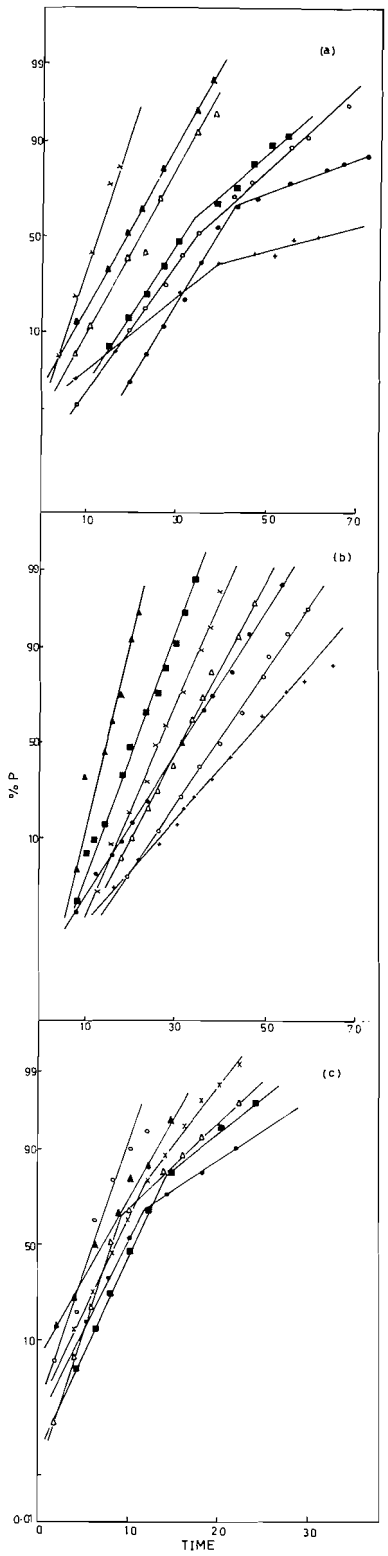
Other parameters (n^*,r^*) derivable from the classical model were calculated using the values of σ obtained and eqs. 8 and 9.

$$[8] \qquad n^* = 32\pi\sigma^3 v^2/3(kT \ln S^*)^3$$

$$[9] \qquad r^* = 2\sigma v/kT \ln S^*$$

where n^* = number of monomers in the critical nucleus; r^* = radius of the critical nucleus; and S^* = value of S when $J = 1$.

The results of the calculations are shown in Table 2.



Discussion

In this section, a discussion of the general aspects of the experimental and derived results obtained using both the classical model of analysis and the mean lifetime of embryo model is given.

Close examination of the data shown in Figs. 2–7 reveals that there are two different processes controlling the formation of crystals in the droplet population. This conclusion results from the following collateral observations. Firstly, the value of L_m initially increases to some maximum value then decreases (see Figs. 2–4) as the supersaturation increases. Secondly, the probability *vs.* time plots (Fig. 6) show, at low supersaturation values, two separate droplet populations whose relative frequency distribution curves share a common area. In addition, the first of the two processes tends to overwhelm the second as the supersaturation in the droplet population increases. And thirdly, the anticipated linear relationships expected for the *log* L_m or *log* J *vs.* $(log\ S)^{-2}$ plots were found only for data observed at high supersaturation values. We feel that these observations clearly show that both heterogeneous and homogeneous nucleation processes are taking place in the droplet population.

The values of the rate of nucleation calculated using eq. 7 are limited in accuracy by three major factors. Firstly, the droplet volumes used in this work are not all equivalent as is presumed by the equation; the error involved, however, by using a mean volume is not considerable, especially since the total numbers of the very small and very large droplets in any group of data are less then 10% of the total number of droplets. Since we are dealing with an aggregate of large numbers, this slight deviation is tolerable. Secondly, the probabilistic nature of crystal formation in droplets, which is the basis of eq. 7, must also be considered. The probability of a droplet

nucleating is determined experimentally by the number of nucleation events (N) occurring in a sample of size (N_0). To make the observed ratio represent reality, a large number of droplets have to be examined. In this work at least 900 droplets were examined for each set of data, thus making it feasible to use the equation for our analysis. Finally, the assumed constant supersaturation over the duration of the "time lag" interval is not strictly realizable. In view of the expected exponential dependence of the nucleation rate on supersaturation ratios, this could lead to a serious error in the calculated rate. The error here may be minimized because an average of a large number of droplets has been used and, in addition, the supersaturation is nearly constant after $S = S^*$.

The experimental values obtained for the pre-exponential or kinetic factor for the barium, calcium and magnesium salts are well below the much debated theoretical value of $10^{25\pm5}$. This is as should be expected. The blocking tendency of ionic charge and water of solvation is not accounted for in the theoretical calculations. These factors will impede and subsequently slow down the rate of addition of monomers to embryos. A slow rate of addition will lower the kinetic factor. In solution it may be necessary to overcome (at least partially) the solvation of the monomers before nucleation can take place. Thus it would be expected that both the energy barrier to desolvation and the large entropy changes coupled with the blocking tendency of escaping solvent molecules will lower the kinetic factor. Also, in highly supersaturated solutions, the viscosity is high, resulting in an increase in the energy barrier to active transport. And finally, the possibility of embryos being charged in ionic solution must be considered. In such a situation the presence of an electrical double layer around the embryo will have a blocking tendency, resulting in a lowered kinetic value. The values obtained in this work are similar, at least in order of magnitude, to values reported in the literature (see Table 7 of ref. 8).

The values of the interfacial energy reported for all the salts were calculated in two different ways. One value was obtained from the mean lifetime model and the other from the classical model. The degree of similarity between these sets of values gives much confidence to the order of magnitude one should expect.

A Correlation between Critical Volumes and Work Function Data for Electrons in Liquid Hydrocarbons

H. T. DAVIS[1] AND L. D. SCHMIDT[2]

Departments of Chemistry and Chemical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Received April 2, 1973

Electron-molecule hard-core radii determined with the aid of Springett, Jortner, and Cohen's quasi-free electron theory from electron work function data are shown to correlate with the critical volumes of several hydrocarbons. The radii are approximately equal to the van der Waals radii determined from the critical volumes.

On a montré que les rayons de l'ensemble rigide électron–molécule, déterminés par la théorie de l'électron quasilibre selon Springett, Jortner et Cohen à partir des données fonction travail de l'électron, sont en corrélation avec les volumes critiques de plusieurs hydrocarbures. Les rayons sont pratiquement égaux à ceux de van der Waals déterminés à partir des volumes critiques.

In this article we present a correlation between the critical volumes and the electron–molecule hard-core radii determined from electron work functions in hydrocarbon liquids. The hard-core radii are determined from a theory developed by Springett, Jortner, and Cohen (1) (SJC) for the ground state energy V_0 of quasi-free (conduction) electrons in inert gas liquids. These investigators combine the Wigner–Seitz boundary conditions on an average lattice representation of a liquid with a pseudopotential model in which the electron potential is the sum of the mean-field potential and a hard-core potential representing the repulsive Hartree–Fock pseudopotential. Their final result for the ground state energy of the quasi-free electron is

$$V_0 = T_0 + U_p \quad [1]$$

with

$$U_p = \frac{-3\alpha e^2}{2r_s^4}\left[\frac{8}{7} + \left(1 + \frac{8}{3}\pi\alpha n\right)^{-1}\right] \quad [2]$$

and

$$T_0 = \hbar^2 k_0^2/2m \quad [3]$$

where r_s and k_0 are determined by the relations

$$\tfrac{4}{3}\pi r_s^3 n = 1 \quad [4]$$

and

$$\tan k_0(r_s - a) = k_0 r_s \quad [5]$$

[1]Department of Chemistry and Chemical Engineering.
[2]Department of Chemical Engineering.

α denotes the molecular polarizability, n the number density of the fluid, and a the electron–molecule hard-core cutoff length. Work function measurements provide experimental values of V_0.

According to the SJC theory the ground state energy is the sum of the mean polarization energy U_p and the zero point kinetic energy T_0. The latter is determined essentially by the free volume available to the electron in a Wigner–Seitz cell. If there were no hard-core region, *i.e.* if $a = 0$, then, according to eqs. 5 and 3, k_0 and T_0 would be zero. On the other hand, when $a \neq 0$, the electron in the Wigner–Seitz cell can only move in a concentric sphere of thickness $r_s - a$. This restriction of the motion of the electron gives rise to a finite zero point kinetic energy T_0.

The theoretical values of V_0 compare favorably with the measured work functions of electrons photoinjected into the inert gas liquids (1). In estimating scattering lengths for electrons in hydrocarbons Fueki, Feng, and Kevan (2) and the authors (3) have suggested that the theory is also valid for hydrocarbons if α and a are taken to mean the average (isotropic) molecular polarizability and the average electron–molecule hard-core cutoff. We believe the correlations offered in the present communication represent further evidence that the SJC theory applies to hydrocarbons.

Since both arise from the repulsion between overlapping electron distributions, it seems reasonable to expect the low energy electron–molecule hard-core radius to be proportional to

TABLE 1. Correlation of work function determined electron–molecule hard-core radii, a, with the critical volumes, V_c. The work function data were taken at room temperature (~300 °K) and at the saturated vapor pressure of the fluid being studied

Compound	Observed work functions, V_0(eV)	"Observed" radii a (Å)	$a/V_c^{1/3}$ (Å/(cm^3/mol)$^{1/3}$)

[b]Reference 5.
[c]Reference 6.

the average molecule-molecule hard-core radius. If these two hard-core radii are proportional to one another, dimensional analysis leads one to expect the ratio of a to the cube root of the critical volume to be the same for nonpolar hydrocarbon fluids. The observed ratios $a/V_c^{1/3}$ are given in Table 1. The ratios are fairly close to the mean value of 0.305 Å/(cm^3/mol)$^{1/3}$. For comparison, we can estimate the molecule–molecule hard-core radius from van der Waals' model, according to which $V_c = 3b_0 = 12[\frac{4}{3}\pi\ a_{vdW}{}^3]$. Thus, we find $a_{vdw}/V_c^{1/3} = 0.271$, a result only about 8% lower than the mean value of $a/V_c^{1/3}$.

We believe the correlation reported here is interesting in itself and lends support to the Springett–Jortner–Cohen model of the work functions of electrons in nonpolar fluids. An important implication of their model is that the work function depends on molecular structure primarily through the packing geometry of the fluid, or, in other words, through the free volume available to the electron as measured by $r_s - a$.

We are grateful to the National Science Foundation and the Petroleum Research Fund for financial support of this work.

Spectrométrie de masse des cyclohexanones *gem*-diphénylées. I. Localisation de la charge positive

CLAUDE J. FORTIN, M. FOREST, C. VAZIRI, D. GRAVEL ET YVES ROUSSEAU
Département de chimie, Université de Montréal, C.P. 6128, Montréal, Québec

Reçu le 5 avril

A l'aide de molécules contenant à la fois des groupements *gem*-diphényle et carbonyle, on évalue l'importance relative de ceux-ci en tant que site porteur de charge régissant la fragmentation. L'influence de chaque fonction est reconnue en étudiant des molécules où cette fonction est isolée. Les résultats obtenus démontrent que le carbonyle ne joue pas un rôle important en tant qu'agent directeur de la décomposition des cyclohexanones *gem*-diphénylées par impact électronique. De plus, on trouve que les potentiels d'ionisation des molécules contenant les deux groupes fonctionnels sont très rapprochés de ceux des molécules correspondantes ne contenant que le groupement *gem*-diphénylé.

Using *gem*-diphenyl cyclohexanones as models, the relative importance of *gem*-diphenyl *vs.* carbonyl functions as possible site of localized charge initiating and directing fragmentation has been determined. The influence of each function is recognized by studying molecules where this group has been isolated. The results show that the carbonyl does not play an important role in the *gem*-diphenyl cyclohexanones decomposition under electron impact. Furthermore the ionization potentials of the molecules containing both functions are very close to those of the corresponding molecules comprising the *gem*-diphenyl function exclusively.

Introduction

Depuis quelques années, un effort considérable a été fait (1–13) dans le but de clarifier le concept de la localisation de la charge positive (ou du centre électrodéficient) dans les processus impliquant la décomposition de molécules par impact électronique. Une des conditions préalables à ces études est liée à la structure des molécules choisies. D'une part, on exige la présence de deux sites favorisés de localisation de charge, sans interférence possible d'autres sites qui gêneraient l'interprétation des résultats. D'autre part, la séparation de ces deux sites doit être assez grande de façon à pouvoir assigner à chacun d'eux son rôle spécifique lors de la fragmentation. Il est évident que la présence de sites adjacents rend difficile le partage des rôles respectifs et que l'on ne saurait alors conclure aux effets de l'un sans parler de l'influence possible des autres fonctions. Il nous a semblé désirable d'étudier les importances relatives des groupes diphényle et carbonyle en tant que sites initiateurs de l'ionisation et de la dégradation en ions fragments. La synthèse des produits étudiés est rapportée ci-dessous et résumée dans le schéma 1.

Partie expérimentale

Les spectres de masse à basse résolution ont été enregistrés à l'aide d'un spectromètre Hitachi RMU-6D par injection directe, la température de la chambre d'ionisation étant 250 °C. Les spectres à haute résolution ont été pris avec un spectromètre AEI MS-902 à double focalisation; la méthode de recouvrement des pics est utilisée pour la mesure précise des masses. L'énergie des électrons ionisants est de 70 eV.

Les spectres r.m.n. ont été déterminés au moyen des appareils JEOL C-60H et 4 H-100 avec référence au tétraméthylsilane; le solvant utilisé est le chloroforme deutérié dans tous les cas. Les spectres i.r. ont été obtenus à l'aide d'un spectrophotomètre Beckman IR-8; les produits sont en solution dans le chloroforme. La chromatographie en phase gazeuse préparative est effectuée sur un chromatographe Varian A90-P3. Les points de fusion sont non corrigés et ont été obtenus avec un appareil Buchi. Les analyses élémentaires ont été confiées à Midwest Microlab Co. Indianapolis.

Diphényl-4,4 cyclohexène-2 one-1 (1)

La méthode utilisée est celle décrite antérieurement par Zimmerman (14): p.f. 92–93° (lit. (14) 88–91.5°).

Diphényl-4,4 cyclohexanone (2)

L'hydrogénation (15) de **1** (6.8 g, 0.0274 mol) en milieu acide acétique glacial (50 ml) contenant 1.09 g de palladium-sur-charbon 10%, fournit après extraction 5.65 g (82%) de diphényl-4,4 cyclohexanone (**2**): p.f. 140–142° (lit. (15) 143–144°); i.r. 1715 cm^{-1} (C=O).

Méthyl-1 diphényl-4,4 cyclohexanol (3)

La méthode utilisée s'inspire des indications rapportées par Houlihan (16). A une suspension de magnésium (1.94 g, 0.08 atome-g) dans 50 ml d'éther anhydre maintenue sous atmosphère d'azote, une solution d'iodure de méthyle (12.5 g, 0.088 mol), dans 20 ml d'éther, est ajoutée goutte à goutte. La solution obtenue est portée à reflux pendant 1 h puis refroidie dans un bain de glace–

For personal use only.

méthanol. Une solution composée de **2** (10 g, 0.04 mol), dans un mélange de 50 ml de tétrahydrofurane et 25 ml d'éther, est mise en contact avec le réactif de Grignard tout en maintenant la température entre 0 et 5 °C. La température est ensuite ramenée à 25 °C pendant 1 h puis le mélange porté à reflux durant deux heures et enfin refroidi à 5°. Une solution aqueuse et saturée de chlorure d'ammonium est introduite jusqu'à séparation de deux phases. Après extraction à l'éther, lavage, séchage, évaporation du solvant, cristallisation dans le mélange éther – *n*-hexane, la réaction fournit 8.8 g (83%) de **3**: p.f. 110–111°.

Anal. calc. pour $C_{19}H_{22}O$: C, 85.67; H, 8.32. Trouvé: C, 85.51; H, 8.17. Spectre de masse $[M]^+$ à *m/e* 266; i.r. 3620 cm^{-1} (OH libre); r.m.n.: δ 1.1 (s, 3H), 1.97 (s, 1H).

Méthyl-1 diphényl-4,4 cyclohexène (4)

En suivant les indications de Vanderwahl (17), le méthyl-1 diphényl-4,4 cyclohexanol (82.2 g, 0.309 mol) est distillé à 170° sous 0.06 Torr en présence de 50 g de sulfate acide de potassium finement pulvérisé. Après cristallisation (éther–*n*-hexane) 65 g (85%) de **4** sont obtenus: p.f. 49.5–50.5°.

Anal. calc. pour $C_{19}H_{20}$: C, 91.88; H, 8.07. Trouvé: C, 91.47; H, 8.07.

Spectre de masse $[M]^+$ à *m/e* 248; r.m.n. δ 2.34 (t, J = 6 Hz, 2H), 7.2 (s, 10H).

Méthyl-2 diphényl-5,5 cyclohexanone (5)

Une solution de **4** (2.5 g, 0.1 mol) dans 20 ml de diglyme, est additionnée à une solution de borohydrure de sodium (1.77 g, 0.0465 mol) dans 60 ml de diglyme purifié selon la méthode de Brown (18). La température étant maintenue à 25°, 30 ml de diglyme, contenant 4 ml d'éthérate de trifluorure de bore fraîchement distillés, sont introduits goutte à goutte. Après 2 h de contact, 10 ml d'eau sont ajoutés. Le diglyme est alors distillé à 35° sous pression réduite. La pâte collante obtenue est délayée dans 60 ml d'éther anhydre.

Un mélange sulfochromique composé de 22 g de bichromate de sodium, 16.5 ml d'acide sulfurique concentré et complété à 90 ml par de l'eau distillée, est additionné goutte à goutte. Après un reflux de 2 h, la phase aqueuse est décantée et extraite à l'éther selon la méthode usuelle; 24.2 g de produit brut sont obtenus, la purification par chromatographie sur colonne de gel de silice permet d'isoler un produit cristallin: p.f. 72°.

Anal. calc. pour $C_{19}H_{20}O$: C, 86.82; H, 7.63; Trouvé: C, 86.25; H, 7.54.

Spectre de masse $[M]^+$ à *m/e* 264; i.r. 1710 cm^{-1} (C=O); r.m.n. δ 1.00 (d, J = 6 Hz, 3H).

Méthyl-4a oxo-7 diphényl-2,2 octahydro-1,2,3,4,4a,5,6,7 naphtalène (7)

Un mélange de **5** (10.56 g, 0.04 mol), 10 ml d'éthanol et de 10 ml d'une solution obtenue par dissolution de 0.378 g de sodium dans 20 ml d'éthanol absolu est refroidi à −5°. A l'aide d'une seringue, 6.88 ml (0.088 mol) de méthylvinylcétone sont ajoutés lentement. La solution résultante est versée dans une solution aqueuse et glacée de NaCl surmontée d'une phase éthérée. Après extraction et purification sur une colonne de gel de silice, 10.35 g (77%) de méthyl-2(oxo-3 butyl)-2 diphényl-5,5 cyclohexanone (**6**) sont recueillis sous forme d'huile.

Une solution de 45 ml d'hydroxyde de potassium à 5% dans l'eau est ajoutée, sous atmosphère d'azote, à une solution de dicétone **6** (9.131 g, 0.274 mol) dans 15 ml de méthanol. Le mélange réactionnel est porté à reflux et son évolution suivie par c.p.g.; au bout de 4 h la réaction est totale. Après extraction, lavage, séchage et évaporation du solvant, 6.47 g (75%) de **7** sont recueillis: p.f. 101–102°.

Anal. calc. pour $C_{23}H_{24}O$: C, 87.30, H, 7.64. Trouvé: C, 87.47; H, 7.81.

Spectre de masse $[M]^+$ à *m/e* 316; i.r. 1670 cm^{-1} (C=O conjugué); r.m.n. δ 1.3 (s, 3H), 5.95 (s, 1H), 7.22 (s, 10H).

Diphényl-1,1 cyclohexane (8)

La réduction de Wolf–Kishner modifiée par Huang et Minlon (19) effectuée sur la diphényl-4,4 cyclohexanone (**2**) conduit à **8**: p.f. 44–45° (lit. (20) 43–44°). Spectre de masse $[M]^+$ à *m/e* 236.1547, $[M]^+$ calculé pour $C_{18}H_{20}$: 236.1565.

Méthyl-4 diphényl-1,1 cyclohexane (9)

L'hydrogénation catalytique (palladium-sur-charbon, 10%) de **4** (0.3 g, 0.0012 mol) en milieu acide acétique glacial fournit le composé **9**. R.m.n. δ 0.83 (d, J = 5 Hz, 3H); spectre de masse $[M]^+$ à *m/e* 250.1626, $[M]^+$ calculé pour $C_{19}H_{22}$: 250.1676.

Diphényl-3,3 cyclohexène (10)

Le traitement de la cétone **1** (3.0 g, 0.012 mol) par la tosylhydrazine (2.0 g, 0.01 mol) conduit à la tosylhydrazone de la diphényl-4,4 cyclohexène-2 one-1 avec un rendement quantitatif: p.f. 191–193°. La réduction de cette tosylhydrazone (0.9 g, 0.0021 mol) est effectuée en milieu tétrahydrofurane par $LiAlH_4$ (1.2 g, 0.031 mol). Un reflux de 17 h est maintenu; après extraction selon la méthode habituelle, une purification par chromatographie en phase gazeuse préparative (colonne silicone S.E. 30, température 170°) permet l'obtention de l'alcène **10**. R.m.n. δ 1.4 à 2.76 (m, 6H), 5.9 (m, 2H), 7.23 (m, 10H); spectre de masse $[M]^+$ à *m/e* 234.1414, $[M]^+$ calculé pour $C_{18}H_{18}$: 234.1408.

Méthyl-4a diphényl-2,2 octahydro-1,2,3,4,4a,5,6,7 naphtalène (11)

La cétone 7 (0.3 g, 0.0095 mol) est transformée en tosylhydrazone comme précédemment: p.f. 201–202°. La réduction de cette dernière. par $LiAlH_4$ en milieu tétrahydrofurane conduit, après purification par c.p.g. préparative (colonne silicone Q.F.1, température 195°) à l'alcène **11**. Spectre de masse $[M]^+$ à *m/e* 302.2024, $[M]^+$ calculé pour $C_{23}H_{26}$: 302.2034.

Diphényl-2,2 cyclohexanone (13)

Les étapes choisies pour synthétiser la diphényl-2,2 cyclohexanone (**13**) sont celles proposées dans la littérature par Burger et Bennet (21), exception faite pour la dernière.

La cyclopentanone est mise en réaction avec le cyanure de sodium en présence de bisulfite de sodium. Le produit brut est porté à reflux dans l'acide chlorhydrique concentré. Il fournit l'hydroxy-acide correspondant (p.f. 103–104°) qui est estérifié au cours d'un reflux dans le méthanol, en présence d'acide sulfurique. L'addition de 2 mol de bromure de phénylmagnésium sur l'hydroxy ester, ainsi préparé, conduit directement au (diphényl-hydroxy) méthyl-1 cyclopentanol (**12**): p.f. 125–126° (lit. (22) 125°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

La transposition pinacolique sur le glycol **12** peut être effectuée selon la méthode déjà décrite (23) ou selon la méthode suivante. Une solution de **12** (50 g, 0.187 mol) dans 200 ml d'acide acétique glacial porté à quelques degrés au dessous du point d'ébullition et une solution d'iode (0.3 g) dans 150 ml d'acide acétique glacial chauffé à la même température sont rassemblées rapidement. Le mélange est immédiatement porté à ébullition pendant 5 min puis versé sur 50 g de glace contenant 2 g de thiosulfate de sodium. Le précipité formé est filtré, lavé à l'eau glacée et dissous dans le benzène; la solution résultante est lavée au bicarbonate de sodium, à l'eau, séchée et le solvant chassé. Le résidu est repris dans le méthanol et décoloré par le charbon actif. Après évaporation du solvant et recristallisation dans le méthanol, la réaction fournit 39 g (84%) de diphényl-2,2 cyclohexanone sous forme de paillettes: p.f. 94–95° (lit. (21) 98.5–99°; lit. (24) 99–100°; recristallisation dans l'éthanol dans les deux cas). Une recristallisation dans le *n*-hexane fournit des cristaux en forme de prisme: p.f. 100–101°. Ces deux formes allotropiques de **13** peuvent être converties l'une dans l'autre par changement de solvant de cristallisation, leurs caractéristiques sont parfaitement identiques. Spectre de masse $[M]^+$ à *m/e* 250; i.r. 1710 cm^{-1} (C=O); r.m.n. δ 1.84 (m, 4H), 2.50 (m, 4H), 6.90 et 7.35 (m, 10H).

*n-Butylthiométhylène-2 diphényl-6,6 cyclohexanone (**14**) et Méthyl-2 diphényl-6,6 cyclohexanone (**15**)*

Les tentatives de monoalcoylation directes de la diphényl-2,2 cyclohexanone (**13**) par l'iodure de méthyle en présence d'une base forte (25) (amidure de sodium, *tert*-butylate de potassium) ont conduit invariablement à la diméthyl-2,2 diphényl-6,6 cyclohexanone (**16**). Ainsi le procédé plus long consistant en la réduction du dérivé *n*-butylthiométhylène par le nickel de Raney (26) est mis à profit pour la synthèse de la cétone **15**. Une solution de formiate d'éthyle (30 g, 0.405 mol) fraîchement distillée, dans 40 ml de benzène est additionnée à une suspension de méthylate de sodium (12 g, 0.222 mol) dans 20 ml de benzène anhydre gardé sous atmosphère d'azote à 0° (27). Après refroidissement à −10°, une solution de **13** (20 g, 0.08 mol) dans 40 ml de benzène, est ajoutée goutte à goutte et le milieu réactionnel laissé au repos pendant 16 h, à température ambiante. La masse compacte obtenue est délayée dans 400 ml d'eau glacée puis extraite à l'éther. La phase aqueuse, traitée par l'acide chlorhydrique concentré jusqu'à p*H* neutre, laisse déposer un précipité blanc qui est repris à l'éther; cette fraction éthérée fournit 21.08 g (94.8%) d'hydroxyméthylène-2 diphényl-6,6 cyclohexanone après traitement habituel et recristallisation dans le méthanol: p.f. 88–89°; l'analyse élémentaire et les résultats des méthodes spectroscopiques sont satisfaisants.

Le thioéther énolique **14** est préparé (26) par réaction du *n*-butanethiol fraîchement distillé (12 ml, 0.11 mol) sur de l'hydroxyméthylène-2 diphényl-6,6 cyclohexanone (16 g, 0.0575 mol), en présence de 0.1 g d'acide *p*-toluène sulfonique dans du benzène anhydre (200 ml). L'eau formée est distillée azéotropiquement avec un appareil Dean Stark. Après 1½ h de contact, la réaction est complète (contrôle par chromatographie sur couche mince). Une extraction habituelle suivie d'une distillation du résidu sous 0.2 Torr et d'une cristallisation du distillat dans le mélange éther–méthanol donne 19.13 g (95.2%) de **14**: p.f. 62–63°; spectre de masse $[M]^+$ à *m/e* 350; i.r. 1660 cm^{-1} (C=O conjugué), 1550 cm^{-1} (C=C portant le soufre); r.m.n. δ 7.84 (t, J = 2 Hz, 1H), 7.25 (s, 10H).

Le thioéther **14** (35 g, 0.1 mol) est désulfurisé (26) par introduction dans une suspension préalablement saturée d'hydrogène, composée de 175 ml de nickel de Raney (28) et de 600 ml d'éthanol absolu. Le mélange maintenu vigoureusement agité, est porté à reflux. L'évolution de la réaction est suivie par spectroscopie i.r. Après 1½ h de contact, deux bandes: 1715 cm^{-1} (cétone attendue) et 1665 cm^{-1} sont présentes; cette dernière est due à la méthyl-2 diphényl-6,6 cyclohexène-2 one-1, r.m.n. δ 6.55 (t, J = 4 Hz, 1H) provenant d'une hydrogénolyse de la liaison carbone-soufre et d'une isomérisation subséquente. Le catalyseur est filtré et le mélange brut remis en réaction avec une nouvelle quantité de nickel de Raney saturé d'hydrogène (68 ml). Après 1 h de réaction, dans les conditions citées plus haut, la réduction s'avère complète (disparition de la bande à 1665 cm^{-1}). La séparation du catalyseur et l'évaporation de l'éthanol laissent 17.4 g (66%) de méthyl-2 diphényl-6,6 cyclohexanone (**15**): p.f. 85–86°, (lit. (24) 85–86°).

Anal. calc. pour $C_{19}H_{20}O$: C, 86.32; H, 7.63. Trouvé: C, 86.57; H, 7.85.

Spectre de masse $[M]^+$ à *m/e* 264; i.r. 1710 cm^{-1} (C=O); r.m.n. δ 1.07 (d, 3H).

*Diméthyl-2,2 diphényl-6,6 cyclohexanone (**16**)*

A une solution de *tert*-butylate de potassium (0.08 mol) dans 15 ml de benzène anhydre gardé sous atmosphère d'azote, une solution de **13** (5 g, 0.02 mol) dans 15 ml de benzène anhydre est ajoutée goutte à goutte. Après refroidissement à −10°, un excès d'iodure de méthyle (5.8 g, 0.04 mol) est additionné. Le mélange est porté à reflux pendant 2 h, le solvant distillé et 60 ml d'eau sont ajoutés au résidu blanc obtenu. L'extraction habituelle, suivie d'une distillation sous 0.3 Torr fournit 4.46 g (84.1%) d'un liquide incolore cristallisant dans l'éthanol: p.f. 76–77°.

Anal. calc. pour $C_{20}H_{22}O$: C, 86.29; H, 7.97. Trouvé: C, 86.36; H, 8.05.

Spectre de masse $[M]^+$ à *m/e* 278; i.r. 1710 cm^{-1} (C=O); r.m.n. δ 0.97 (s, 6H), 2.5 (t, J = 6 Hz, 2H).

*Méthyl-2 (chloro-3 butényl-2)-2 diphényl-6,6 cyclohexanone (**17**)*

La méthode utilisée est une modification de celle décrite dans la littérature (29, 30). A une solution de *tert*-butylate de potassium (0.15 mol) dans 150 ml de benzène fraîchement distillé, une solution de cétone **15** (26.4 g, 0.10 mol) dans 50 ml de benzène anhydre est ajouté sous atmosphère d'azote, à 0°. Le mélange réactionnel est ramené à 25° puis porté à reflux pendant 1 h. Après un nouveau refroidissement sur un bain de glace, une solution de dichloro-1,3 butène-2 (24 g, 0.19 mol) dans 100 ml de benzène, est additionnée rapidement. Le mélange est porté à reflux 6 h, laissé à 25° pendant 14 h puis traité à 0 °C par un mélange 1:1 d'acide chlorhydrique concentré – eau. Après extraction à l'éther, le résidu (31.8 g) est analysé par chromatographie sur couche mince et deux produits sont révélés dont un est la cétone de départ (**15**). La séparation est effectuée par chromatographie sur une colonne de gel de silice (benzène) sur une petite quantité de produit. La cétone chlorée (**17**) cristallise dans le *n*-hexane: p.f. 73–74°.

For personal use only.

Anal. calc. pour $C_{23}H_{25}OCl$: C, 78.28; H, 7.14; Cl, 10.05. Trouvé: C, 78.32; H, 7.26; Cl, 10.30.

Spectre de masse $[M]^+$ à *m/e* 352; i.r. 1700 cm^{-1} (C=O), 1665 cm^{-1} (C=C); r.m.n. δ 0.94 (s, 3H), 5.4 (t, J = 7 Hz, 1H), 6.86–7.44 (m, 10H).

*Méthyl-2 (oxo-3 butyl)-2 diphényl-6,6 cyclohexanone (**18**)*

Un courant d'azote est mis à barbotter dans une solution de **17** (1 g, 0.0028 mol) dans 3 ml de dichlorométhane à −20°. Un mélange à 0° d'acide sulfurique concentré et d'eau dans le rapport 9:1 (7 ml) est ajouté rapidement. Le bain de glace–méthanol est maintenu pendant 2 h au cours desquelles l'azote entraîne le gaz chlorhydrique formé, ainsi que le dichlorométhane. La température est ramenée à 25°, le mélange réactionnel précipité sur 20 g de glace et extrait à l'éther. Après lavage, séchage et évaporation, le résidu laisse cristalliser 0.78 g (82%) de dicétone **18** après dilution dans quelques gouttes d'éther: p.f. 96–97°.

Anal. calc. pour $C_{23}H_{26}O_2$: C, 82.60; H, 7.84. Trouvé: C, 82.53; H, 7.90.

Spectre de masse $[M]^+$ à *m/e* 334; i.r. 1705 cm^{-1} (C=O), 1715 cm^{-1} (C=O); r.m.n. δ 0.97 (s, 3H), 2.02 (s, 3H), 7.00 et 7.50 (m, 10H).

*(Méthyl-1 oxo-2 diphényl-3,3 cyclohexyl)-3 propanal (**19**)*

Selon les indications de Hajos et collaborateurs (31), une suspension de 0.4 g d'hydrure de sodium (dispersion dans l'huile à 51%) dans 12 ml de DMSO fraîchement distillé est portée à 60° pendant 1 h. Le tout étant gardé sous atmosphère d'azote, la température est ramenée à 25° et une solution de méthyl-2 diphényl-6,6 cyclohexanone (**15**) (1.1 g, 0.004 mol) dans 12 ml de DMSO est ajoutée goutte à goutte. Après 1½ h de contact à 50° une solution de chloro-3 diéthoxy-1,1 propane (1.3 g, 0.077 mol) dans 6 ml de DMSO est additionnée au mélange. Après extraction, 1.67 g de résidu sont obtenus, contenant outre la cétone de départ (**15**), un nouveau composé; 50 ml de dichlorométhane y sont additionnés. La solution obtenue est hydrolysée (32) par 50 ml d'acide chlorhydrique 2 *N*, agitée pendant 1 h à 25°, portée à reflux pendant 20 min, ce qui provoque la disparition complète du nouveau produit au profit d'un composé plus polaire. Après extraction habituelle, 0.64 g de produit brut est recueilli. Une chromatographie sur colonne de gel de silice (*n*-hexane–éther, 5.3) fournit 0.38 g ce cétone de départ et 0.21 g (16%) de cétoaldéhyde (**19**) cristallisant après dilution dans le *n*-hexane: p.f. 85–86°; spectre de masse $[M]^+$ à *m/e* 320; i.r. 1720 cm^{-1} (C=O), 1695 cm^{-1} (C=O); r.m.n. δ 0.95 (s, 3H), 6.86 et 7.4 (m, 10H), 9.55 (m, 1H).

*Tétradeutério-2,2,5,5 cyclopentanone (**20**)*

Le chauffage sous reflux de la cyclopentanone provoquant une autocondensation, la deutériation est effectuée à température ordinaire (33, 34). La cyclopentanone (20 g, 0.238 mol), 100 ml d'eau lourde et 10 g de carbonate de potassium sont agités vigoureusement (secoueuse) pendant 5 jours. Le taux d'incorporation de deutérium contrôlé par r.m.n. s'avère être supérieur à 90%. L'eau est enlevée avec une seringue et une deuxième deutériation accomplie par addition de 75 ml d'eau lourde et 7.5 g de carbonate de potassium. Une agitation de 6 jours suivie d'une extraction à l'éther et une distillation sous vide donnent 11 g (52%) de **20**. Le spectre r.m.n. (100 Mc, avec découplage de deutérium) révèle un singulet fin centré à 1.975 p.p.m.

*Dideutério-3,3 diphényl-2,2 cyclohexanone (**21**)*

Cette cétone est obtenue à partir de **20** en suivant les méthodes détaillées précédemment (cyclopentanone → **13**) sauf pour l'étape de la transposition pinacolique ou la méthode utilisée est celle de Zaugg (10): p.f. 94–95° (recristallisation dans méthanol); la spectrométrie de masse révèle la composition isotopique suivante: d_3, 5%; d_2, 86%; d_1, 9%; $[M]^+$ à *m/e* 252.1490, $[M]^+$ calculé pour $C_{18}H_{16}O_1D_2$: 252.1482; r.m.n. δ 1.88 (m, 4H), 2.50 (m, 2H), 22 (m, 10H).

*Dideutério-2,2 diphényl cyclohexane (**22**)*

La réduction de Wolf–Kishner (7) effectuée sur la dideutério-3,3 diphényl-2,2 cyclohexanone (**21**) conduit après purification par chromatographie préparative en phase gazeuse (colonne silicone S.E. 30, température 200°), à l'hydrocarbure **22**: p.f. 44–45°; la spectrométrie de masse donne la composition isotopique suivante: d_2, 89%; d_1, 11%; $[M]^+$ à *m/e* 238.1679, $[M]^+$ calculé pour $C_{18}H_{18}O_2$: 238.1690; r.m.n. δ 1.50 (s, élargi 6H), 2.22 (m, 2H), 7.20 (m, 10H).

*Tétradeutério-2,2,6,6 diphényl-4,4 cyclohexanone (**23**)*

Trois deutériations successives de la diphényl-4,4 cyclohexanone (**2**) par de l'eau lourde en milieu basique (carbonate de potassium) contenant des traces de dioxane, fournissent la cétone tétradeutériée (**23**). Spectre de masse: d_4, 95%; r.m.n. δ 2.66 (s, élargi par le couplage $J_{H\text{-}D}$, 4H), 7.30 (s, 10H).

Résultats et discussion

Parmi ceux qui répondent aux critères énoncés, on compte les composés **2**, **3** et **5**. Les produits **7**, **8**, **9** et **11** sont inclus pour fins de comparaison. On doit pouvoir examiner séparément les influences respectives des groupes diphényle et carbonyle en tant que site porteur de charge en favorisant une décomposition amorcée par une des fonctions en l'absence de l'autre. Chaque cyclohexanone *gem*-diphénylée (CGDP) peut ainsi être considérée par rapport à deux analogues, diphénylé (AD) et carbonylé (AC). La première étape de l'étude comporte une mesure des potentiels d'ionisation qui ont été déterminés par la méthode semi-logarithmique (35) en utilisant le xénon comme gaz étalon. Les mesures de potential d'ionisation qui sont rapportées au tableau 1 indiquent que le groupe carbonyle régit l'ionisation pour les analogues carbonylés et que le groupe diphényle joue le même rôle dans le cas des analogues diphénylés. Lorsque les deux fonctions sont en présence, les résultats montrent le rôle prépondérant de la fonction diphényle lors de l'ionisation. On peut ainsi conclure qu'au voisinage de l'énergie minimum requise pour ioniser la molécule, un des électrons est éjecté de la partie de la molécule contenant les deux groupements phényles. Bien qu'il s'agisse d'une extrapolation, il est permis de sup-

poser qu'à 70 eV, la fonction diphényle sera celle qui régira la fragmentation (36). On peut vérifier cette assertion en comparant les principaux ions dans les spectres de masse des analogues carbonylés et diphénylés avec ceux issus de la dégradation des produits *gem*-diphénylés carbonylés. Dans chacun des cas, les modes de fragmentation caractéristiques des principaux ions sont établis et comparés. Pour ce faire, on enregistre les spectres à haute résolution et confirme chacune des transitions importantes par la mise en évidence des ions métastables appropriés. De plus, dans les cas critiques, on a marqué certaines positions en remplaçant l'atome d'hydrogène par un deutérium.

Les ions importants provenant de la décomposition des dérivés diphénylés sont rapportés au tableau 2. Il en ressort clairement que tous ces produits donnent effectivement les mêmes ions. De plus, leurs abondances relatives sont comparables. Ceci est compatible avec une fragmentation initiée et dirigée par le groupement diphényle puisque le schéma de fragmentation de ces molécules est indépendant de l'énergie des électrons entre 20 et 70 eV (les ions formés sont les mêmes; seuls leurs % I.R. varient). Les transitions métastables données au tableau 3 indiquent

m/e 193	$\xrightarrow[*]{}$	*m/e* 115 $(C_9H_7)^+$	+		(78)

la provenance des principaux ions. Le processus primaire donne naissance à deux ions, *m/e* 193 et 180, dont la décomposition produit les autres ions observés. Pour confirmer ces mécanismes de formation ionique, le produit **22** a été synthétisé et ses principaux ions fragments sont énumérés au tableau 4. Les ions à *m/e* 193 et 180 peuvent être expliqués par deux processus bien connus en spectrométrie de masse (37). D'une part le clivage benzylique de la liaison C_1—C_2 suivi d'un transfert spécifique de l'atome d'hydrogène en C-6 avec la perte de C-2, -3 et -4. Ceci conduit à la formation de l'ion à *m/e* 193 dont la charge positive est délocalisée et stabilisée par les deux noyaux phényles. Le produit étant symétrique, il existe une probabilité égale de rupture de la liaison C_1—C_6, accompagnée du transfert de l'un des deutérium en C-2 par un mécanisme identique.

La présence d'un ion à *m/e* 194 dans ce dernier cas confirme le transfert spécifique de l'hydrogène en α du carbone benzylique. Le rapport des intensités relatives *m/e* 193:194 est de 1.3:1.0 (schéma 2).

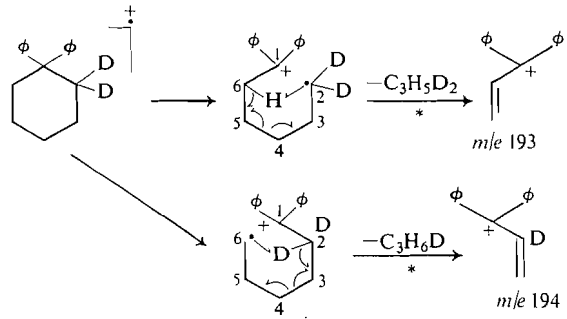

SCHÉMA 2

TABLEAU 4. Intensités relatives des ions principaux du AD et CGDP deutériés (%)

	Composé	
		m/e	**22**	**23**
M^+	238 (100.0)	254 (45.8)
193	194 (77.4)	
	193 (98.5)	195 (100.0)
180	182 (10.2)	180 (53.3)
	180 (31.0)*	
179	181 (20.7)	179 (18.7)
	179 (23.4)*	
178	178 (23.8)	178 (13.8)
167	167 (51.0)	167 (3.2)
165	165 (33.3)	165 (24.1)
152	152 (9.5)	152 (3.9)
115	116 (25.8)	117 (19.8)
	115 (47.6)	116 (11.7)
91	93 (9.4)	93 (6.1)
	92 (20.5)	92 (6.7)
	91 (42.8)	91 (5.8)

*Ces pourcentages comprennent les contributions des *m/e* 178 et 179

Ce mécanisme est d'ailleurs analogue à celui proposé pour la formation de l'ion à *m/e* 171 à partir du phényl-10 décaline-*trans* (37). D'autre part, le clivage de la liaison C_1—C_2 (C_1—C_6) peut être concerté avec celui de la liaison C_5—C_6 (C_2—C_3) pour former l'ion à *m/e* 180 (182) (schéma 3).

Le rapport des intensités relatives *m/e* 182:180 est de 1:3. Toutefois il faut noter que l'ion à *m/e* 180 est dû en partie à l'équivalent des ions à *m/e* 178 et 179 contenant respectivement deux et un atome de deutérium. En effet, les ions à *m/e* 193 et 180 sont responsables de la formation des ions à *m/e* 179 et 178 (schéma 4).

SCHÉMA 3

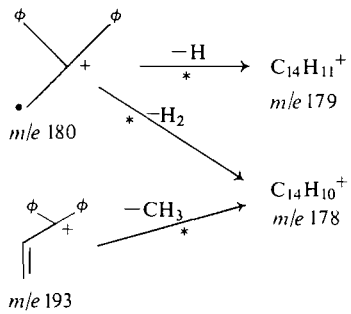

SCHÉMA 4

Une perte de méthyle à partir de l'ion à *m/e* 193, suggérée par un ion métastable à $m^* = 164.20$, mène aussi à la formation du *m/e* 178. Toutefois à cause de la position adjacente de ces deux ions, il n'est pas possible de faire ressortir clairement les résultats obtenus à l'aide de l'analogue deutérié.

La présence d'un métastable à 151.25 confirme la formation du *m/e* 165 à partir de *m/e* 180 par perte de méthyle (schéma 5).

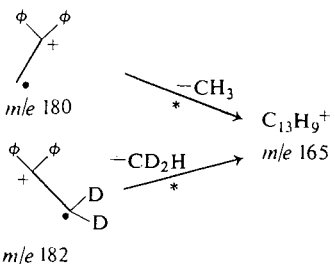

SCHÉMA 5

La perte de CD_2H à partir de l'ion à *m/e* 182 révèle également l'absence de brouillage (scrambling) dans l'ion précurseur précédant la formation de cet ion.

L'observation d'un ion métastable à 68.26 suggère l'ion *m/e* 193 comme précurseur du fragment à *m/e* 115 par perte de benzène (schéma 6).

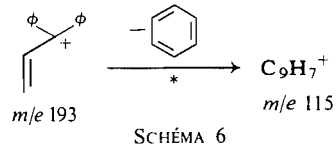

SCHÉMA 6

La deutériation nous indique que l'ion *m/e* 194 mène soit à *m/e* 116, soit *m/e* 115 dans les rapports 1.0:1.0.

L'examen des mécanismes de formation des principaux ions des AC où le carbonyle est le site porteur de charge, est susceptible de nous révéler quels types de fragmentation cette fonction pourrait engendrer dans les produits *gem*-diphénylés carbonylés. Les spectres des composés cyclohexanone, méthyl-2 cyclohexanone, méthyl-1 cyclohexanol et leurs analogues deutériés, étant rapportés dans la littérature (38–40), ne sont pas discutés dans la présente publication.

*Par d'ion moléculaire.

Il en est ainsi du méthyl-4a oxo-7 octahydro-1,2,3,4,4a,5,6,7 naphtalène dont les mécanismes de dégradation sont connus, puisqu'il constitue en fait les anneaux A et B d'un squelette stéroide (2).

Le tableau 5 rapporte les intensités relatives des principaux ions fragments pour les composés contenant un groupe diphényle et un groupe carbonyle. On peut constater l'identité de ces ions avec ceux obtenus pour les analogues diphénylés. Ceci confirme que le carbonyle n'est pas le site initiateur de la fragmentation dans ces cas: sa présence n'entraine la formation d'aucun ion important autre que ceux qui se retrouvent dans les analogues diphénylés. L'oxygène est donc expulsé dans chaque cas en tant que constituant du fragment neutre. De plus, les spectres enregistrés à haute résolution, la mesure des ions métastables ainsi que les résultats obtenus pour le produit **23** deutérié (tableau 4) confirment la similitude des mécanismes de formation des ions principaux pour les composés *gem*-diphényles carbonylés et les analogues diphénylés. L'ion à *m/e* 193 se retrouve à *m/e* 195 tel que prévu. Ceci démontre la spécificité de l'abstraction de l'atome d'hydrogène en C-3 et nous amène à suggérer l'absence de brouillage dans l'ion moléculaire. On note aussi qu'il ne peut y avoir de brouillage précédant la formation de l'ion à *m/e* 180 puisque la masse de cet ion demeure inchangée dans le produit deutérié. Des ions métastables à $m^* = 178.0$ et 176.0 indiquent la provenance des *m/e* 179 et 178 à partir de l'ion *m/e* 180. L'ion à *m/e* 178 est aussi formé à partir de *m/e* 193 (195) ainsi que le démontre la présence d'un métastable à 164.2. L'élimination d'un groupe méthyle de l'ion à *m/e* 180 ($m^* = 151.25$) mène à la formation du fragment *m/e* 165. Enfin, l'ion 193 (195) donne aussi naissance à *m/e* 117 et 116 par perte de benzène-d_0 et benzène-d_1 dans les proportions 1.6:1.0 et révèle effectivement la formation de l'ion *m/e* 115 à partir du *m/e* 193. Des transitions métastables à $m^* = 70.20$ et 69.00 le confirment également.

Le tableau comparatif 6 souligne la similitude des mécanismes de formation des ions primaires des AC, CGDP et AD. En considérant ce tableau, on peut attribuer la formation du *m/e* 195 ($C_{15}H_{15}^+$, 21.1%) dans le cas du produit *gem*-diphénylé hydroxylé, au fait que l'oxygène soit dans ce cas particulier le porteur de charge positive. S'il en est ainsi, cet ion constitue alors une exception ce qui n'est pas surprenant, puisque le potentiel d'ionisation de ce produit, par sa valeur plus élevée, indique une influence plus grande du groupement hydroxyle.

D'une façon générale, il ressort de cette étude que les mécanismes menant à la formation des ions 193 et 180 dans le processus primaire des AD, expliquent aussi une grande partie des ions fragments principaux des AC. Mais, lorsque l'on reporte ces mêmes mécanismes de formation sur les CGDP, en assignant à tour de rôle aux deux groupements en présence la fonction de porteur de charge, il en découle qu'aucun ion important n'est engendré lorsque l'oxygène est le site de

localisation de charge (sauf peut-être le cas du *m/e* 195 du composé hydroxylé). De même, l'application aux CGDP des mécanismes menant à la formation d'autres ions importants des AC (38–40) ne donne lieu à la formation d'aucun ion majeur ce qui confirme la conclusion énoncée précédemment.

Effets de la position adjacente des groupements fonctionnels et de la substitution sur le site de localisation de la charge positive

Bien que les produits suivants ne se soumettent pas aux caractéristiques édictées initialement, il est intéressant de voir, à la lumière des résultats obtenus jusqu'ici, si leurs comportements sont affectés soit par la présence du groupement carbonyle en α du carbone benzylique soit par une plus grande substitution, ou si au contraire les conclusions de l'étude précédente s'appliquent intégralement. Leurs potentiels d'ionisation, rapportés au tableau 7, nous indiquent qu'il devrait y avoir peu de changement dans les conclusions générales, puisque l'ionisation, là aussi, est régie entièrement par le groupement diphényle. On remarque, en effet, l'identité des potentiels d'ionisation entre les AD, CGDP et $CGDP_\alpha$. Par ailleurs, le tableau 8 rapportant les % I.R. des ions principaux des $CGDP_\alpha$ suggère une absence complète d'influence du (C=O) ou du substituant. On note effectivement que tous les ions fragments principaux, sauf celui à *m/e* 206, sont exactement les mêmes que dans le cas des AD et CGDP.

L'ion *m/e* 206, qui se retrouve dans la dégradation de six des sept produits, constitue en fait la seule différence par rapport aux AD et CGDP. Dans chacun de ces cas, un ion métastable nous indique qu'il est formé à partir de M^+ et le spectre à haute résolution montre qu'il s'agit de $C_{16}H_{14}^+$. Puisque cet ion ne se retrouve pas dans les spectres des AD et CGDP, on peut en conclure, d'une part, que sa formation dépend de la présence du groupement carbonyle et, d'autre part, que la position adjacente de la fonction cétonique par rapport au carbone benzylique favorise sa formation. Il est aussi intéressant de noter que sa présence peut être expliquée de la même façon que celle de l'ion *m/e* 156 dans le spectre de la phényl-10 décalone-2-*trans* (37) par le transfert de deux atomes d'hydrogène de la partie hydrocarbure et ceci avant la décomposition, tel qu'indiqué au schéma 7.

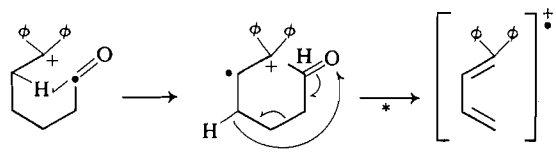

SCHÉMA 7

Conclusions

Il ressort de cette étude que le groupement *gem*-diphényle, dont le potentiel d'ionisation est inférieur à celui du groupe carbonyle, est le principal agent initiateur et directeur de la frag-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mentation des molécules étudiées. Ceci est confirmé par des mécanismes de dégradation similaires des produits avec et sans fonction carbonyle. L'extrapolation généralement faite que la partie d'une molécule complexe ayant le plus bas potentiel d'ionisation régit la fragmentation principale, semble donc être valide dans le cas présent. Même si les résultats indiquent une fixation de la charge positive sur une partie définie de la molécule, nous ne croyons pas que ceci constitue un argument décisif en faveur de sa localisation lorsque les électrons sont accélérés à un potentiel de 70 V. Suite à une ionisation qui peut se produire n'importe où sur la molécule, il est tout aussi possible de conclure, dans le même sens que Vetter *et al.* (11), à une distribution de charge sur les fonctions carbonyle et diphényle maximisée sur ce dernier groupement. Par ailleurs, la fraction de charge sur le groupe carbonyle ne serait pas suffisante pour induire une redistribution électronique et causer la rupture de liaisons. En effet, le fait de ne pas observer de fragmentation due au carbonyle ne constitue pas en soi une preuve de l'absence de densité de charge positive à cet endroit. Il est évident que ce concept doit être étudié plus à fond.

Spectrométrie de masse des cyclohexanones *gem*-diphénylées. II. Chaleurs de formation et structures possibles des principaux ions fragmentaires

CLAUDE J. FORTIN ET YVES ROUSSEAU

Département de Chimie, Université de Montréal, C.P. 6128, Montréal, Québec

Reçu le 19 avril

L'aspect énergétique des processus menant à la formation des principaux ions fragmentaires de cyclohexanones *gem*-diphénylées et de leurs analogues diphénylés est étudié. Plusieurs des ions obtenus de la dégradation de ces produits par impact électronique se retrouvent également dans la décomposition d'un grand nombre de produits aromatiques et font ainsi l'objet de comparaisons. Certaines structures sont proposées pour représenter les ions discutés tandis que certaines autres sont éliminées, en se basant sur leurs chaleurs de formation ioniques.

The energetics of the processes leading to the formation of the major ions of *gem*-diphenyl cyclohexanones and analogues were studied. Many of the ions coming from the electron impact induced decomposition of these products appear in quite a large number of aromatic compounds which can thus be used for comparisons. We are proposing structures to represent these ions while some are eliminated on the basis of their ionic heats of formation.

Can. J. Chem., **51**, 3457 (1973)

Introduction

Un certain nombre de travaux concernant l'étude des structures ioniques communes à partir de différents précurseurs aromatiques ont été rapportés. Ceux-ci se rapportent au benzène (1), à un certain nombre d'alkylbenzène (2), aux isomères du naphtalène et de l'azulène (3), ainsi qu'à un certain nombre de composés diphénylés (4). On propose, dans beaucoup de ces études, la présence d'une structure ionique commune pour expliquer le comportement similaire de certains produits sous impact électronique. Un bon nombre des ions provenant de la dégradation des cyclohexanones *gem*-diphénylées (CGDP) soumises à l'impact électronique se retrouvent aussi lors de la fragmentation de produits tels que le fluorène, le stilbène, le dihydro-9,10 phénanthrène, le phénanthrène, le méthyl-9 fluorène et plusieurs autres. Nous croyons que l'étude de l'aspect énergétique des différents processus de formation des ions peut nous amener à une meilleure compréhension des étapes par lesquelles les ions aromatiques se décomposent. La présente étude a pour but d'une part, d'établir si les ions de même rapport masse/charge provenant des 17 produits *gem*-diphénylés étudiés peuvent être assimilés à une même structure, ou si le fait de varier le substituant peut engendrer la formation de différentes structures ioniques. D'autre part, en se référant à la littérature, il est également possible d'effectuer des corrélations de structures et de tenter d'assigner aux ions fragmentaires principaux une structure probable. A ces fins, les potentiels d'ionisation de tous les produits (5), de même que les potentiels d'apparition de leurs ions fragmentaires principaux, ont été déterminés et les chaleurs de formation des différents ions ont été calculées et comparées. La méthode d'impact électronique étant employée, les conclusions apportées à la possibilité de structures ioniques communes doivent être interprétées sur une base qualitative puisque les ions formés par une telle méthode peuvent

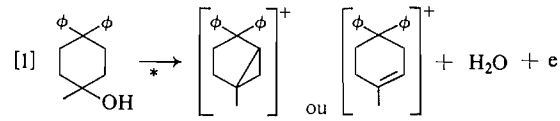
posséder des excès d'énergie interne ou cinétique. Par contre, les conclusions sur le rejet de certaines structures pour représenter les ions discutés sont probablement indépendantes de tels facteurs.

Partie expérimentale

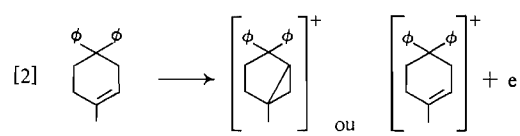
Les potentiels d'apparition sont obtenus à l'aide d'un appareil Hitachi RMU-6D. Le voltage des électrons ionisants est ainsi contrôlé par un potentiomètre, permettant des accroissements successifs de 0.1 V. Les intensités ioniques sont obtenues à l'aide d'un voltmètre digital Weston modèle 240. Le xénon est utilisé comme gaz étalon et la pression xénon–produit est suffisamment basse pour éviter les effets de pression sur le profil de la courbe d'efficacité d'ionisation. La méthode semi-logarithmique (6) a été jugée satisfaisante pour tous les potentiels déterminés. Les valeurs des potentiels d'apparition rapportées sont des moyennes de plusieurs déterminations. La reproductibilité des valeurs de potentiels d'apparition des ions fragments est habituellement de 0.05 à 0.1 eV mais l'incertitude est portée à 0.4 eV. La synthèse des produits utilisés (tableau 1) a été décrite précédemment (5). Les composés de référence méthyl-9 fluorène et dihydro-9,10 phénanthrène ont été obtenus de K et K Laboratories et le fluorène de J. T. Baker Chemical Co.

Résultats et discussion

Il est bien établi maintenant que, sous impact électronique, les alcools engendrent la formation des alcènes correspondants par perte d'une molécule d'eau. Les produits **10** et **17** peuvent donc être utilisés afin de comparer les chaleurs de formation de l'ion $(C_{19}H_{20})^+$ formé par les deux processus suivants:



[1] **10** → (*a*) ou (*b*) + H_2O + e



[2] **17** → ou + e

Il semble que dans les cyclohexanols, la perte de H_2O soit attribuable à des éliminations

TABLEAU 2. Potentiels d'apparition et chaleurs de formation de l'ion *m/e* 248 pour les composés **10** et **17**

Composé	P.A. eV	P.A. kcal/mol	I.R. (%)	ΔH_f(M) (kcal/mol)	$\Delta H_f(248)^+$ (kcal/mol)
10	9.2	214	37.5	−28	240
17	8.7	202	6.0	+41	243

1,4 et 1,3 (7–13). Le premier cas étant géométriquement empêché ici, la formation du *m/e* 248 procéderait alors par perte de l'hydrogène tertiaire (*a*) plutôt que secondaire (*b*). De toute façon, le but proposé n'est pas de déterminer la structure de l'alcène correspondant mais bien de démontrer l'identité ou non de ces structures. Les réactions 1 et 2 nous mènent aux équations suivantes:

$$\Delta H_f{}^1(248)^+ = \text{P.A.}_{248}{}^+ - \Delta H_f(H_2O) + \Delta H_f(\mathbf{10}) - E_1$$

$$\Delta H_f{}^2(248)^+ = \text{P.I.}_{248}{}^+ + \Delta H_f(\mathbf{17}) - E_2$$

Les chaleurs de formation des molécules à l'état fondamental sont calculées théoriquement à l'aide de la méthode de Cox (14, 15) basée sur la contribution de chaque liaison ou groupe de liaisons au ΔH_f. Les termes E_1 et E_2 représentent l'excès d'énergie cinétique libéré durant la formation des ions (16, 17); E_1 est évalué à 0.15 eV à partir de la largeur de l'ion métastable tandis que E_2 peut être négligé (17). Le tableau 2 rapporte les valeurs calculées et mesurées qui mènent au calcul des $\Delta H_f(248)^+$. L'erreur expérimentale sur la détermination des potentiels d'apparition limite la précision des résultats à ± 10 kcal/mol ce qui est suffisant pour conclure à l'identité de structure quelle qu'elle soit, entre ces deux ions, et à vérifier la validité de la méthode employée. Toujours dans cette même optique, il est possible d'étudier l'aspect énergétique de chaque ion important dans les spectres des cyclohexanones *gem*-diphénylées. Les mécanismes de formation de chacun de ces ions sont détaillés à la référence (5).

L'ion à m/e 206

Cet ion est un des plus intenses dans les spectres de six des sept produits (**1**–**5** et **7**) ayant la fonction carbonyle adjacente au carbone benzylique et est absent dans ceux des autres composés. Il semble que ce soit l'influence de cette position adjacente et la présence d'oxygène qui sont responsables de sa formation (5). Dans chaque cas, un ion métastable indique sa provenance à partir de $[M]^{+\cdot}$ et le spectre à haute résolution montre qu'il s'agit de $C_{16}H_{14}{}^+$. Les potentiels d'apparition, présentés au tableau 3 indiquent que la formation de cet ion est favorisée énergétiquement puisque les valeurs sont de quelques dixièmes d'eV seulement au-dessus des potentiels d'ionisation. Les données obtenues pour les chaleurs de formation de cet ion ne permettent pas de conclure à une structure commune quelque soit son précurseur. Toutefois, ces résultats ne sont pas incompatibles avec une telle conclusion, surtout si l'on tient compte du fait qu'il peut être formé avec un excès d'énergie dans certains cas. La valeur du $\Delta H_f(206)^+$ à l'état fondamental se rapproche sans doute plus de celle de **7**.

L'ion à m/e 193

Cet ion est un des plus intenses dans les spectres de 14 des 17 produits. Le fragment expulsé étant radicalaire, la méthode de Franklin (18) est utilisée pour le calcul du ΔH_f(F). Cette méthode assigne au ΔH_f les contributions des différents groupes d'atomes dans une molécule. Une transition métastable indique sa provenance à partir de $[M]^{+\cdot}$ et le spectre à haute résolution montre qu'il s'agit de $C_{15}H_{13}{}^+$. Les données thermodynamiques relatives à cet ion, sont rapportées au tableau 4. Il indique, là aussi, que l'ion à *m/e* 193 est formé avec un excès d'énergie; on peut alors énoncer que le ΔH_f de l'ion $C_{15}H_{13}{}^+$ non-excité se rapproche certainement de la valeur la plus faible soit 231 kcal/mol.

L'ion à m/e 180

Cet ion est important pour la plupart des produits CGDP et AD (analogue diphénylé). Les diverses transitions $M^{+\cdot} \rightarrow 180 + N$ donnent dans chaque cas des ions métastables faibles mais en forme de plateau indiquant que l'ion est formé avec un excès d'énergie cinétique. Celle-ci a été évaluée à 2 kcal/mol. La mesure précise des masses révèle que cet ion est $C_{14}H_{12}{}^+$. Dans chacun des cas, le fragment expulsé peut être sous forme cyclique (dans ce cas, l'énergie

reliée à la tension apportée par la cyclisation est incluse) ou sous forme de l'alcène à chaîne ouverte correspondant. Les valeurs rapportées au tableau 5 supposent la forme cyclique, mais dans tous les cas, le ΔH_f de la forme alcène correspondante ne diffère pas de plus de ± 3 kcal/mol de celles rapportées ici. Les résultats indiquent là aussi que la réaction de formation de cet ion se produit avec un excès d'énergie. Dans ce cas, la valeur du ΔH_f(**1**) qui est de 233 kcal/mol, se rapproche probablement le plus de celle de l'ion $C_{14}H_{12}^+$ non-excité. Ces mesures ne sont pas incompatibles avec une identité de structure pour cet ion quelle que soit la substitution du produit précurseur bien qu'elles ne le démontrent pas explicitement.

Un certain nombre de structures ont été proposées pour l'ion à *m/e* 180 à partir de différents précurseurs (19–22); il est souhaitable de savoir si l'une ou l'autre structure peut s'apparenter à celle provenant de la dégradation des CGDP et AD sous impact électronique. Il a été suggéré (19–21) que cet ion puisse être représenté par l'ion radical méthyl-9 fluorène (MF) en se basant sur une étude effectuée à partir de produits deutériés et enrichis en carbone 13. L'énergie requise pour la formation de cet ion à partir du méthyl-9 fluorène révèle effectivement la possibilité d'un tel cas pour l'ion *m/e* 180 de nos produits. Le potentiel d'ionisation de ce produit, n'étant pas rapporté dans la littérature, a été déterminé et se situe à 8.2 eV.

17	9.8	227	100.0	+25	241

NOTE: les ΔH_f(M) sont rapportées au tableau 4. Les valeurs du ΔH_f(11) et ΔH_f(17) sont respectivement de 50 et +40 Kcal/mol.

La chaleur de formation de cette molécule à l'état fondamental, par la méthode de Cox, est de 41 kcal/mol. Ces deux valeurs nous conduisent à un $\Delta H_f{}^{MF}(180)^+$ de 231 kcal/mol ce qui tend à renforcer l'hypothèse d'une structure méthyl-9 fluorène pour l'ion à *m/e* 180 des CGDP et AD. En effet, la comparaison de cette valeur avec celle postulée pour l'ion $C_{14}H_{12}{}^+$ non-excité indique que ces deux ions peuvent être considérés comme isoénergétiques. La possibilité d'autres structures ne doit toutefois pas être exclue ce qui nous incite à effectuer une étude similaire en postulant cette fois l'ion stilbène comme intermédiaire. Bien que sa formation à partir des CGDP et AD exige une migration de phényle, celle-ci ne doit pas être considérée comme un obstacle puisque cet ion assure une stabilisation de la charge positive due à sa conjugaison. D'ailleurs, cette migration de phényle (à partir de carbones adjacents pour former un ion *gem*-diphénylé) est importante pour la formation du *m/e* 165 dans les v-triazoles (23). Les paramètres énergétiques nécessaires ont ainsi été déterminés et mènent aux valeurs suivantes: P.I.(stilbène) = 8.7 eV; ΔH_f(stilbène = 56 kcal/mol (à l'aide de la méthode de Cox). Cette dernière valeur peut d'ailleurs être évaluée expérimentalement de la façon suivante: la chaleur de combustion du stilbène est de −1.765 kcal/mol (24) ce qui nous conduit à un ΔH_{solide} de +39 kcal/mol. La comparaison du $\Delta H_{sublimation}$ de produits aromatiques analogues nous indique que l'ordre de grandeur du $\Delta H_{sublimation}$ (stilbène) $\simeq$ 15–25 kcal/mol. La combinaison des ΔH_{solide} et $\Delta H_{sublimation}$ donne une valeur de ΔH_{gaz}(stilbène), expérimentale comprise entre 54 et 64 kcal/mol ce qui confirme la valeur calculée à l'aide de la méthode de Cox. De ces valeurs, on déduit un ΔH_f de l'ion stilbène compris entre 256–266 kcal/mol. Le tableau 4 nous indique que cette structure ne devrait pas représenter l'ion à *m/e* 180 puisque les énergies calculées pour sa formation, à partir des différents précurseurs, sont plus faibles dans tous les cas que l'énergie minimum requise pour la formation de l'ion stilbène. Enfin, la structure du dihydro-9,10 phénanthrène (DHP) a été proposée (25) également pour représenter l'ion à *m/e* 180. Aucune donnée énergétique n'est rapportée dans la littérature pour cet ion. La méthode de Cox nous mène à une valeur de 37 kcal/mol pour son ΔH de formation à l'état fondamental et son potentiel d'ionisation a été déterminé et se situe à 8.6 eV. A l'aide de ces deux valeurs, sa chaleur de formation ionique est alors calculée comme étant 236 kcal/mol. Cette valeur est très rapprochée de celle du méthyl-9 fluorène et cette proximité nous empêche de discerner entre l'une ou l'autre structure probable pour cet ion même si dans le tableau quelques valeurs du $\Delta H_f{}^{CGDP,AD}(180)^+$ sont inférieures à celle du $\Delta H_f{}^{DHP}(180)^+$. Puisque les deux structures de référence sont isoénergétiques, il est alors possible que l'ion à

11	10.4	239	14.8	254
14	9.3	215	20.8	230
15	9.6	221	27.7	236
16	10.2	237	51.9	252

m/e 180 dans les CGDP et AD se retrouve sous ces deux formes, la différence d'énergie requise étant fournie par l'excès d'énergie avec lequel l'ion est formé. De cette façon, un équilibre pourrait être établi entre ces deux structures et de là, chacune serait susceptible de se dégrader ultérieurement selon des chemins caractéristiques et différents.

L'ion à m/e 178

La perte de H_2 ou 2H à partir de l'ion à *m/e* 180 conduit à sa formation (haute résolution $C_{14}H_{10}^+$) et ceci est démontré par la présence d'un ion métastable à 176.0. Dans la littérature (26), cet ion est fréquemment associé à la structure du phénanthrène bien qu'une structure du type diphénylacétylène ne soit pas exclue même si cette dernière demande une migration de phényle dans le cas des CGDP et AD. L'énergie de ce processus de formation a été examinée dans chacun des cas et les résultats sont rassemblés au tableau 6. Ceux-ci indiquent une possibilité de structure commune pour cet ion dans le même sens que nous l'avons discuté précédemment. La production de cet ion s'accompagne également d'un excès d'énergie et il est probable que le $\Delta H_f(C_{14}H_{10})^+$ non-excité se rapproche de 230–236 kcal/mol. Ces valeurs supposent notamment la perte de H_2 à partir du *m/e* 180, la perte de 2H conduisant à des valeurs beaucoup trop faibles pour être retenues. Natalis et Franklin (4) rapportent un $\Delta H_f(178)^+$ de 235 kcal/mol pour le phénanthrène. Cette valeur est compatible avec celle rapportée pour le $\Delta H_f^{CGDP,AD}(C_{14}H_{10})^+$ non-excité et supporte l'hypothèse d'une structure phénanthrène pour cet ion. Les mêmes auteurs rapportent également la chaleur de formation ionique du *m/e* 178 à partir du diphénylacétylène comme étant 303 kcal/mol. Cette structure peut alors être éliminée comme possibilité indiquant par là que la migration de phényle nécessaire à sa formation n'est pas favorisée dans les CGDP et AD. Par ailleurs si l'hypothèse des deux structures isoénergétiques pour l'ion *m/e* 180 est valable, l'ion phénanthrène pourrait bien alors provenir de la perte de H_2 à partir de l'intermédiaire dihydro-9,10 phénanthrène.

L'ion à m/e 165

L'ion à *m/e* 165 dans les spectres de méthyl-9 fluorène, diphénylméthane, bromodiphénylméthane, stilbène et dihydro-9,10 phénanthrène correspond au cation fluorényle (27, 28). Cet ion est également présent dans les spectres de 16 des 17 CGDP et AD et est formé par perte d'un radical méthyle à partir de l'ion *m/e* 180 (m^* = 151.25; haute résolution $C_{13}H_9^+$). Les données thermodynamiques pour sa formation sont présentées au tableau 7. On note que la formation de cet ion est plus énergétique que dans le cas des ions discutés précédemment. Une structure commune pour l'ion $C_{13}H_9^+$ peut être supposée pour tous les produits bien qu'elle ne soit pas démontrée rigoureusement. Cet ion est aussi formé avec un excès d'énergie. Par conséquent, le $\Delta H_f^{CGDP,AD}(C_{13}H_9)^+$ non-excité se rapproche probablement de la valeur

TABLEAU 7. Données thermodynamiques pour l'ion *m/e* 165

minimale qui est de 286 kcal/mol. Afin de vérifier l'hypothèse que l'ion *m/e* 165 puisse être représenté par un cation fluorényle, les potentiels d'apparition du *m/e* 165 des produits fluorène (F) et méthyl-9 fluorène (MF) ont été déterminés comme étant respectivement 12.5 et 11.9 eV. Ces valeurs, combinées avec leurs ΔH de formation à l'état fondamental, nous conduisent aux $\Delta H_f{}^{F}(165)^+ = 282$ kcal/mol et $\Delta H_f{}^{MF}(165)^+ = 284$ kcal/mol. On voit donc, par la comparaison avec la valeur du $\Delta H_f{}^{CGDP,AD}(C_{13}H_9)^+$ non-excité, qu'il est énergétiquement possible d'assigner à l'ion *m/e* 165 une structure fluorényle. Poursuivant l'hypothèse des deux structures isoénergétiques pour représenter le *m/e* 180, le cation fluorényle proviendrait alors de l'intermédiaire méthyl-9 fluorène par perte d'un radical méthyle.

L'ion à m/e 115

La perte de benzène à partir du *m/e* 193 donne naissance à l'ion *m/e* 115, telle que suggérée par la présence d'un ion métastable à 68.26 et le spectre à haute résolution indique qu'il s'agit de $C_9H_7{}^+$. Comme l'ion *m/e* 165, cet ion est formé par un processus requérant plus d'énergie que ceux des autres ions discutés jusqu'ici. Les résultats des calculs thermodynamiques (tableau 8) suggèrent également l'hypothèse de la probabilité d'une structure commune pour cet ion. Natalis et Franklin (4) rapportent la formation de cet ion à partir du biphényl par perte de C_3H_3 et évaluent sa chaleur de formation ionique à 321 kcal/mol. Ces auteurs ne proposent aucune structure pour cet ion fragmentaire mais, les résultats rapportés indiquent qu'elle ne devrait pas s'identifier à celle de l'ion à *m/e* 115 provenant des CGDP et AD. Cet ion est également très intense dans le spectre de l'indène (IN). Pour cette raison, son $\Delta H_f{}^{IN}(115)^+$ a aussi été déterminé. La chaleur de formation de cette molécule à l'état fondamental est de 43 kcal/mol (29) et le potentiel d'apparition de l'ion *m/e* 115 a été mesuré comme étant 12.4 eV ce qui nous conduit à un $\Delta H_f{}^{IN}(115)^+$ de 277 kcal/mol. Bien que la possibilité de la formation d'autres structures ne soit pas exclue, l'ion à *m/e* 115 provenant des CGDP et AD pourrait bien avoir la structure de l'ion indène formé avec un excès d'énergie. Celle-ci est d'ailleurs une des structures proposées pour la formation de l'ion *m/e* 115 à partir de l'ion *m/e* 171 de la phényl-10 décaline-*trans* (30).

TABLEAU 8. Données thermodynamiques pour l'ion *m/e* 115

Composé	P.A. eV	P.A. kcal/mol	I.R. (%)	$\Delta H_f(115)^+$ (kcal/mol)

16	13.5	312	78.5	299

Conclusion

Les chemins de dégradation des CGDP et AD en ions principaux sont résumés au schéma 1. Les structures rapportées sont celles qui sont corroborées par la mesure des énergies de formation. Le tableau 9 rassemble les structures proposées et rejetées, pour chaque ion traité. Il a été démontré que l'ion à *m/e* 206 est formé à partir du $M^{+\bullet}$ et qu'une structure commune est probable indépendamment de la substitution de l'ion précurseur. Cette conclusion s'applique également à l'ion *m/e* 193. Dans le cas de ces deux ions, et de tous les autres discutés ici, on ne rejette toutefois pas l'idée qu'ils puissent être formés dans des états excités. L'ion à *m/e* 180 est aussi formé avec un excès d'énergie ce qui rend possible un équilibre entre la structure dihydro-9,10 phénanthrène et méthyl-9 fluorène, les chaleurs de formation ioniques de ces deux intermédiaires étant très rapprochées. Chacune de ces deux entités serait alors susceptible de se dégrader selon des chemins différents. Ainsi la perte de H_2 à partir de cet ion pour mener à la formation du *m/e* 178, est compatible avec la forme dihydro-9,10 phénanthrène du *m/e* 180. Il est en effet probable que la structure du *m/e* 178 soit du type phénanthrène tel que montré par les données thermodynamiques. Ces résultats démontrent en outre que cet ion n'est pas assez énergétique pour s'apparenter à une structure diphénylacétylène qui requiert 303 kcal/mol et demande par surcroît une migration de

TABLEAU 9. Synthèse des structures proposées et rejetées en se basant sur les calculs énergétiques

Ions	Structures	Chaleur de formation (kcal/mol) Calculée	Chaleur de formation (kcal/mol) Valeur minimale mesurée

phényle sur le carbone adjacent. Le cation fluorényle, qui est proposé comme intermédiaire dans la dégradation de plusieurs composés aromatiques, identifie l'ion à *m/e* 165 dans les CGDP et AD et provient de la perte d'un radical méthyle à partir de la structure méthyl-9 fluorène de l'ion à *m/e* 180. Enfin, le fragment à *m/e* 115, provenant de l'ion à *m/e* 193, n'a pas la même structure que celui provenant de la fragmentation du biphényle mais correspond possiblement à l'ion indényle formé avec un excès d'énergie.

Effect of Solvents on the Quantum Efficiency of Rubrene Electrogenerated Chemiluminescence

A. PIGHIN
Bell-Northern Research, Ottawa, Canada K1Y 4H7

Received May 3, 1973

A simple and precise method for measuring the efficiency of electrogenerated chemiluminescence (e.g.c.l.) in terms of photons/(Faradaic electron)(Φ_{coul}) is described and applied to rubrene e.g.c.l. A symmetrical square wave potential having a frequency of 20–1000 Hz was employed to produce the e.g.c.l. The electrogenerated ion radicals were shown to be completely stable at these frequencies; consequently, Φ_{coul} was determined in the absence of side reactions. Change of solvent from *N,N*-dimethylformamide (DMF) to equivolume benzene–DMF resulted in an increase in Φ_{coul} from 0.67 to 1.21% at 20 Hz. Φ_{coul} decreased with increasing frequency. Varying the electrolyte (tetra-*n*-butylammonium perchlorate, TBAP) concentration did not affect Φ_{coul}.

Une méthode simple et précise pour mesurer l'efficacité de la chimiluminescence électroengendrée (c.l.e.e.) en termes de photons par électron faradaique (Φ_{coul}) a été décrite et appliquée au rubrène c.l.e.e. Un potentiel d'onde à symétrie carrée ayant une fréquence de 20–1000 Hz a été utilisée pour produire la c.l.e.e. On a montré que les ions radicaux électroengendrés étaient complètement stables à ces fréquences, par conséquent, Φ_{coul} a été déterminé en l'absence de réactions parasites. Le passage de la *N,N*-diméthylformamide (DMF) au mélange équivolume benzène-DMF a pour résultat d'accroître Φ_{coul} de 0.67 à 1.21% à 20 Hz. Φ_{coul} décroît lorsque la fréquence croît. La variation dans la concentration en électrolyte (perchlorate de tétra-*n*-butylammonium, PTBA) n'affecte pas Φ_{coul}.

Can. J. Chem., 51, 3467 (1973)

Introduction

The efficiency of electrogenerated chemiluminescence (e.g.c.l.),[1] in this article expressed in photons/(Faradaic electron) and represented by Φ_{coul}, can be a useful parameter in elucidating the e.g.c.l. mechanism. Bard *et al.* (1) have recently reviewed the reported e.g.c.l. efficiencies and discussed the difficulties in these measurements. Rubrene is a popular electrochemiluminescent compound and its reported e.g.c.l. efficiencies range from a low of 0.1% (1) which has been corrected for lost electrogenerated species to a high of 8.7% (2) without any corrections. Bezman and Faulkner (3) obtained intermediate values and recorded greater efficiencies in benzonitrile than in *N,N*-dimethylformamide (DMF). Other e.g.c.l. systems have shown either a solvent composition or electrolyte concentration dependence of their efficiencies (1). In this article, we present evidence of a large solvent effect, a frequency dependence, and no electrolyte concentration effect on the quantum efficiency of stable rubrene e.g.c.l.

[1]Electrogenerated chemiluminescence is abbreviated as ECL in the existing literature. To avoid confusion with Emitter-Coupled Logic we employ e.g.c.l.

Experimental

The rubrene was purchased from the Aldrich Chemical Co. and recrystallized repeatedly from xylene–methanol and then dried by vacuum heating. Tetra-*n*-butylammonium perchlorate (TBAP), polarographic grade from MC&B, was recrystallized repeatedly from ethanol and dried by vacuum heating. The two solvents, Fisher D-133 DMF and Fisher B-414 benzene, were dried with molecular sieves and outgassed. The solutions were prepared and used inside a nitrogen-filled dry box.

The apparatus used to measure Φ_{coul} is illustrated in Fig. 1. The electrolysis cell was formed from a TS 10/30 Pyrex ground glass joint while the electrodes were two parallel 0.020 in. diameter platinum wires rigidly fixed about 1 mm apart by beads of soft glass. A symmetrical square wave potential was employed to electrolyze the solution in the cell. Two identical pulses of light per cycle from each electrode were observed and the overall intensity remained constant for at least several hours of continuous electrolysis. The driving potential was restricted to those values which produced stable e.g.c.l. The bottom of the electrolysis cell rested inside an open box whose walls and floor were made of five 1 cm^2 solar cells connected in parallel. The level of the solution inside the electrolysis cell was kept below the top of the solar cell box. The solar cells were operated in the current mode and their output measured with a picoammeter. The solar cell box was calibrated using a red light-emitting diode of known efficiency (traceable to the National Research Council of Canada). The correction factor was 1.7, *i.e.* (measured current × 1.7) = corrected current. The electrical current through the electrolysis cell was converted

and amplified by a factor of 1000 to a voltage, rectified with a fast linear rectifier, and then measured with an integrating digital voltmeter. This signal processing of the electrical current yields the rectified average value of the current. Specifically, 1 V d.c. was equivalent to 1 mA average rectified a.c. The Φ_{coul} experiments were performed at 23 ± 1 °C.

Electrochemical measurements were performed with a Princeton Applied Research Model 170 Electrochemistry System and a three electrode cell. A silver wire immersed in the test solution was used as the reference electrode; it was contained inside a compartment whose Luggin tip extended to within 2 mm of the platinum bead working electrode. The counter electrode consisted of a large platinum wire helix around the working electrode and Luggin tip. *iR* compensation was employed in the recordings.

Results and Discussion

The two solvents employed in this investigation were DMF and equivolume benzene–DMF and were selected for their physical properties (Table 1). The solution viscosities are only slightly different but the dielectric constant of DMF is much greater than that of benzene. It was therefore expected that the bulk dielectric constant of the mixed solvent solution would be significantly less than that of the DMF solution. The viscosities were measured with an Ostwald viscometer that was calibrated with water and the diffusion coefficients of the 1 m*M* rubrene in 0.100 *M* TBAP solutions were determined from chronoamperograms of the reductions at a shielded platinum disk electrode of known area. Note that the products of (viscosity) (diffusion coefficient) are essentially the same in obeyance of the Stokes–Einstein equation (6).

Table 2 contains the potential differences between the half-wave oxidation and reduction potentials of rubrene in both solutions at selected temperatures. These data were derived from cyclic voltammograms of the oxidation and reduction at a scan rate of 100 mV/s with *iR* compensation. The peak potentials were measured from the cyclic voltammogram, $1.109RT/nF$ (7) V were subtracted from their absolute values to obtain the half-wave potentials, and then the

half-wave reduction potential was subtracted from the half-wave oxidation potential. Nemec's (8) equation for calculating *iR* losses for spherical microelectrodes was used to estimate our *iR* losses in the absence of *iR* compensation. The peak currents were about 20 μA in both solutions at 25 °C, the radius of our electrode was about 0.5 mm, and the Luggin tip was positioned about 2 mm from the electrode's surface. The specific conductances of the 0.100 *M* TBAP solutions were measured and were 0.0039 $ohm^{-1}\ cm^{-1}$ for DMF and 0.0023 $ohm^{-1}\ cm^{-1}$ for equivolume benzene–DMF at 25 °C. When all these values are inserted into Nemec's eq. 2, and multiplied by 2 since the *iR* losses occur during both the oxidation and reduction, and are therefore additive, the *iR* losses are calculated to be about 12 mV for the DMF solution and 20 mV for the mixed solvent solution. Assuming that the *iR* compensation is 80% effective, we see that the residual, uncompensated *iR* is only a few mV in both cases. The temperature coefficient of the conductance is negative and greater in magnitude than the positive temperature coefficient of the peak current. Consequently, the amount of residual, uncompensated *iR* tends to decrease with increasing temperature.

From the temperature coefficient of the potential difference between the half-wave oxidation and reduction potentials (Table 2), the standard entropy of the homogeneous electron transfer reaction in each solution was calculated using the following equation in which the symbols have their usual significance:

$$[1] \qquad \Delta S^0 = \frac{nF\Delta(E_{\frac{1}{2},ox} - E_{\frac{1}{2},red})}{\Delta T}$$

The temperature coefficient was assumed to be constant and the slope was calculated using linear regression analysis. The results of these calculations are listed in Table 3 along with other relevant thermodynamic and spectroscopic data of rubrene in both solvents. It should be noted that because the amount of residual, uncompensated *iR* decreases with increasing temperature then the above entropies are slightly *smaller* than the true values.

The change in enthalpies in Table 3 are for the homogeneous electron transfer reaction between the monoanion and monocation radicals of rubrene and were calculated from the equation

$$[2] \qquad -\Delta H_T = nF(E_{\frac{1}{2},ox} - E_{\frac{1}{2},red})_T - T\Delta S^0$$

The energy of the lowest excited singlet ($E_{^1S^*}$) was determined from the crossover point between the absorption and fluorescence spectra of rubrene in each conducting solution. The relative fluorescence efficiencies were obtained by comparing the intensities of the fluorescences of 10^{-5} m*M* rubrene in each conducting solvent. The fluorescences were excited with 4500 Å radiation. Neither solvent absorbs at this wavelength so that the fluorescence intensities did not have to be corrected for differences in absorption but only for the ratio of the squares of the refraction indices of their solutions (9).

An important conclusion can be made from the data in Table 3. The change in enthalpy of the homogeneous electron transfer reaction in both solutions is clearly less than the energy of the emitting species, $E_{^1S^*}$. Residual, uncompensated *iR* in the electrochemical measurements used to calculate the $-\Delta H$'s have made the calculated values of $-\Delta H$ slightly larger (more negative) than the true values. Rubrene e.g.c.l. is therefore "energy deficient" and must proceed in both solutions via the "triplet route" (10). This mechanism is summarized in Table 4. In this scheme, each homogeneous electron transfer reaction produces an average of 3/4 triplets. This fraction is given by spin statistics assuming that the solvent does not preferentially enhance either the formation of triplets or singlets (11). This seems probable considering rubrene is a simple aromatic hydrocarbon (12). Triplet-triplet annihilation can then produce either triplets, singlets, or

${}^1R^* \rightarrow R + h\nu$	Radiative decay of excited singlet

quintets. If we make the usual assumption that the formation of quintets is energy-forbidden, then spin statistics predict an average yield of 1/4 singlets per triplet-triplet annihilation. The singlets immediately radiate to their ground state with the emission of light. The excited triplets produced by the triplet–triplet annihilation reaction engage in further triplet–triplet encounters, thereby increasing the singlet yield per triplet–triplet annihilation from 1/4 to 2/5. Thus, two electrons (one homogeneous electron transfer reaction) ultimately results in the emission of an average of 3/20 photons. However, about 8 (3) to 17% (2), say 12.5%, of the ion radicals are neutralized by the reversal of the polarity of the electrode potential. The maximum theoretical efficiency of an energy deficient e.g.c.l. system, such as rubrene e.g.c.l., using square wave stimulation is 6.6% photons/electron.

Figure 2 illustrates a typical current–voltage curve of the electrolysis cell. Prior to the appearance of e.g.c.l., the current increases linearly with applied voltage and at constant voltage this current was nearly directly proportional to the frequency. Since these characteristics are peculiar to capacitive currents, then this current must be the current that is needed to polarize the electrode–solution interphase. The abrupt rise in current at about 2.3 V (peak) coincides with the detection of e.g.c.l. Assuming that the Faradaic processes do not alter the double layer capacity and that the double layer capacity remains constant in the potential region for e.g.c.l., then by extrapolating the capacitive current into the region for e.g.c.l. and subtracting it from the total at that potential, the Faradaic current at that voltage is obtained. A plot of the corrected photon current *vs.* the Faradaic current is then made and Φ_{coul} calculated from the slope of this plot. Linear regression analysis was used to obtain the slopes. Figure 3 illustrates one of these plots. The photon current measured with the picoammeter is twice that emitted at one electrode.

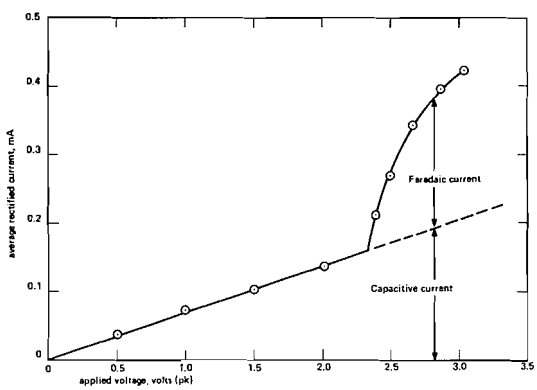

FIG. 2. Typical electrical characteristics of the electrolysis cell. The 1.01 m*M* rubrene in 0.100 *M* TBAP – equivolume benzene–DMF was electrolyzed with 100 Hz square wave potential.

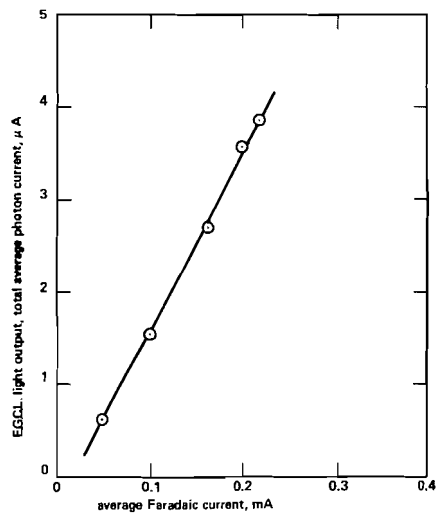

FIG. 3. Typical variation in photon current with Faradaic current. The 1.01 m*M* rubrene in 0.100 *M* TBAP – equivolume benzene–DMF was electrolyzed with 100 Hz square wave potential.

Therefore, the Φ_{coul} calculated from this plot must be divided by 2 to obtain the value of Φ_{coul} at each electrode.

The results of our Φ_{coul} measurements are given in Fig. 4. These results, when corrected for the fraction of ion radicals lost by the reversal of the electrode potential (8–17%), are at most 20% of the maximum theoretical value previously calculated.

A frequency dependence of Φ_{coul} is seen in all cases, in contradiction to theory (2). If a quencher were present in the bulk of the solution, the fractional probability of quenching will decrease with increasing frequency because the triplet concentration would increase within a steadily more compact reaction zone. It has been suggested (1) that the triplet state may be quenched by the parent ion radicals and by the electrode. The effectiveness of the former mode is frequency independent because the ratio ion radicals: triplets remains constant with changing frequency whereas the effectiveness of the latter mode increases with increasing frequency because the reaction layer becomes more compact at the electrode. Our frequency dependence of I_{coul} is consistent with quenching of the triplets by the electrode.

Reducing the electrolyte concentration from 0.100 to 0.020 *M* TBAP in DMF did not affect the efficiency of the rubrene e.g.c.l. which is in contrast to the increase reported by Bard *et al.* (1) in the e.g.c.l. efficiency of 9,10-dimethylanthracene-tri-*p*-tolylammonium perchlorate with decreasing electrolyte concentration in TBAP–tetrahydrofuran. In this latter case, ion pairing was suggested as a cause. In our case, TBAP is less dissociated in equivolume benzene–DMF than in DMF (based on conductivity measurements) but the absence of an electrolyte effect on the Φ_{coul} of rubrene in TBAP–DMF renders the degree of electrolyte dissociation unimportant.

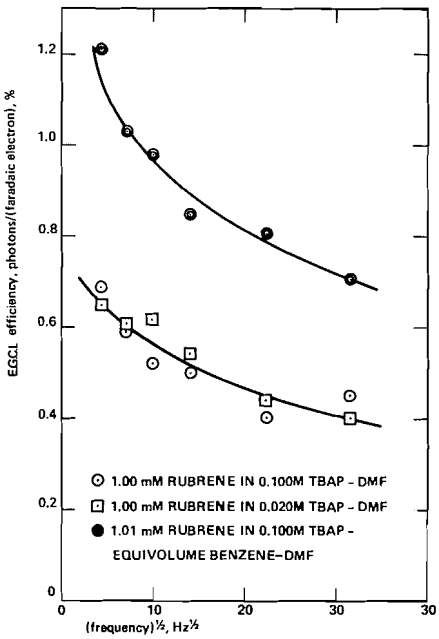

FIG. 4. Variation in Φ_{coul} of rubrene in selected solutions with frequency of driving potential.

Addition of one part of benzene to DMF increased the Φ_{coul} of rubrene from 0.67 to 1.21% at 20 Hz for the same concentration of fluorescor (1 m*M*) and electrolyte (0.100 *M*). The luminescences obtained were spectrally identical and the fluorescence efficiencies are the same in both solutions (Table 3). We established earlier that the e.g.c.l. proceeds in both solutions via the "triplet route".

The greater potential differences between the oxidation and reduction potentials of rubrene in the mixed solvent solution (Table 2) indicates that the rubrene is more strongly solvated in the mixed solvent solution than in the DMF solution. We obtained e.s.r. spectra of the electrogenerated monoanion radicals in both solutions and the spectra were identical: the difference in solvation of the monoanions was either apparently not sufficient to cause a shift in the e.s.r. spectrum or the monoanions were similarly solvated (by DMF) in both solutions. Because of the heteropolar nature of the mixed solvent, *i.e.* one aromatic and one polar component, it is likely that the benzene fraction will preferentially solvate the neutral rubrene, including excited forms, while the DMF fraction will preferentially solvate the ion radicals. If the triplets were quenched by the parent ion radicals and/or electrode, their greater solvation in the mixed solvent system could shield them from the quenching agents thereby accounting for the greater Φ_{coul} in the mixed solvent solution. The common element between our solvent effect on Φ_{coul} and those reported by Bezman and Faulkner (3) and Bard *et al.* (1) is that we all obtained higher efficiencies in the less polar, or more aromatic, solvent.

This work was supported in part by the National Research Council of Canada through its Industrial

Research Assistance Program. The assistance of R. M. van Dyk in the design of the electronic circuitry and of D. P. Malanka in performing the experiments, and the helpful criticism of Dr. M. A. Kabayama are gratefully acknowledged.

γ-Deuterium Isotope Effects on Solvolysis of 7-Halonorbornyl Brosylates-6-*d*[1]

NICK H. WERSTIUK, GEORGE TIMMINS, AND FRANK P. CAPPELLI
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 27, 1973

The γ-deuterium isotope effects for the solvolysis of *anti*- and *syn*-7-chloro-, *anti*- and *syn*-7-bromo-*exo*-2-norbornyl brosylates-6-*endo*-*d* and *syn*-7-chloro-*exo*-2-norbornyl brosylate-5,6-*exo*,*exo*-d_2 in 80:20 EtOH–H_2O, 0.04 *M* NaOAc at 65° are 1.11 ± 0.01, 1.11 ± 0.01, 1.13 ± 0.01, 1.05 ± 0.01, and 1.11 ± 0.01, respectively. The results indicate that the γ-isotope effect observed in the solvolysis of *exo*-norbornyl brosylate likely is not derived via neighboring group (non-vertical) participation of the C_1—C_6 bond.

La solvolyse des brosylates *exo*-2 des chloro-7 *anti* et *syn* et des bromo-7 *anti* et *syn* deutéro-6 *endo* norbornyle ainsi que du brosylate *exo* du chloro-7 *syn* dideutéro-5,6 *exo*,*exo* norbornyle a été effectuée à 65°C, dans un mélange contenant 0.04 *M* de NaOAc dans 80:20 de EtOH–H_2O; les effects isotopiques γ du deutérium ont été évalués respectivement à 1.11 ± 0.01, 1.11 ± 0.01, 1.13 ± 0.01, 1.05 ± 0.01 et 1.11 ± 0.01. Ces résultats indiquent que l'effet isotopique observé dans la solvolyse des brosylates *exo* de norbornyle ne proviennent pas de participation non verticale des liens C_1—C_6.

Can. J. Chem., **51**, 3473 (1973)

α-, β-, and γ-deuterium isotope effects have been used extensively to probe the nature of cations generated solvolytically especially in cyclic systems (1–10). We have undertaken solvolysis studies to determine (*a*) the effect of substituents at C-1 and C-7 in the [2.2.1] system on the magnitude of the γ-effect to establish more accurately the origin of the isotope effect (10), (*b*) the stereochemistry of the 1,3-elimination which yields tricyclic product, and (*c*) whether or not the 6-*endo*-C—H bond participates directly in solvolysis especially in "locked"[2] systems (11–14).

In this communication we report (Table 1) the γ-deuterium isotope effects for the solvolysis of the *anti*- and *syn*-7-chloro- (16–19) and bromonorbornyl brosylates in 80:20 EtOH–H_2O containing 0.04 *M* NaOAc.

Surprisingly, the solvolytic γ-isotope effects for the 7-halonorbornyl brosylates are essentially identical and in fact somewhat larger than those observed for *exo*-norbornyl brosylate (3,4). Since 7-halogen certainly retards charge development at C-1 (18) as indicated by the reduced solvolytic reactivity of the halo system, the

1*a* **5**	1.11±0.01

*Mean of four to five runs; the standard deviation of the slope was taken as the error in the slope. For example the data from the computer of one of the runs for 1*a* and *b* were: slope for 1*a* 9.435 × 10^{-3} min^{-1}, standard deviation 3.157 × 10^{-5}; slope for 1*b* 8.525 × 10^{-3}, standard deviation 2.670 × 10^{-5}.

†The 6-*endo*-*d* substrates required for our study were prepared from the halohydrins obtained from the haloacetates prepared by the acid catalyzed (H^+, HOAc; D^+, DOAc) opening of the halonortricyclanes (20). The dideuteriochlorohydrin required for the preparation of 5 was obtained from the addition of HOCl to norbornene-5,6-*endo*,*endo*-d_2 (21). The solvolytic isotope effects were obtained by simultaneously observing the solvolysis of the protiated and deuterated substrates spectrophotometrically (22) in 80:20 EtOH–H_2O, 0.04 *M* in NaOAc at 60–65.00 ± 0.02°.

[2]A locked [2.2.1] system is one in which non-vertical involvement (15) (a 1,2 Wagner–Meerwein shift) is prohibited by the introduction of the charge destabilizers at C-7 or C-1. For example, a COOMe or C≡N group (11, 13) at C-1 would be a more effective lock than halogen at C-7.

degree of norbornonium ion-type (**6**) stabilization in the transition state (neighboring group or non-vertical participation) in the two systems is certainly not the same. Our results therefore cast doubt on the premise that norbornonium ion (**6**) formation is the source of the solvolytic γ-isotope effects observed for the *exo*-2-norbornyl brosylates-6-*d* (3,4).

Direct involvement of the 6-*endo*-C—H(D) bond in the ionization step could account for the isotope effects observed for **1**, **2**, **3**, and **4**. The result for **5** is also accountable on this basis if

spatial reorganization of the 6-*exo*-C—H(D) bond is the source of the *exo*-isotope effect. That is, the *exo*-deuterium isotope effect is "α-like", and originates from conversion of a sp^3 C—H bond to a cyclopropyl-like C—H bond (**7** or **10**). Alternatively the solvolytic isotope effect could result from the 1,3-elimination (23) which occurs only *after* ion-pair formation is complete.[3] That the "α-like" effect is important at least in the 1,3-elimination step is supported by the data listed in Table 2. The degree of 1,3-elimination, within experimental error, being the same from **1***b* and **5**, although cleavage of the *endo*-C—H(D) bond is preferred, establishes that the exo "α-like" isotope effect and the isotope effect for cleavage of the *endo*-C—H(D) bond are of comparable magnitude.

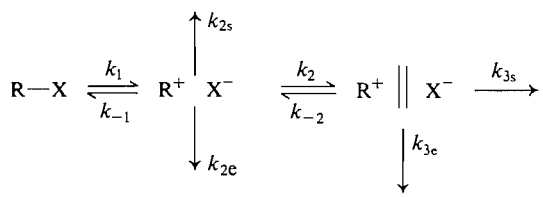
A possibility also is that both **7** and **8** contribute to the stabilization of the norbornyl cation so that the 6-*exo*- and 6-*endo*-C—H(D) bonds undergo essentially identical force constant changes during ionization of the brosylate with however no direct involvement of the C_1—C_6 bond. The question then arises as to whether or not the composite of **7** and **8** is the halogen substituted analog (**9**, X = Cl or Br) of H-nortricyclonium ion (**9**, X = H) described by Olah (24).

The endo stereochemical preference (Table 2) established in this study provides additional support for our thesis that loss of a proton occurs via edge-protonated nortricyclane rather than the norbornonium ion and is consistent with previous observations (14) and explains the results obtained by Collins and Benjamin (12) on the solvolysis of deuterated 3-hydroxy-3-phenyl- and 7-hydroxy-7-phenyl-*exo*-2-norbornyl tosylates.

That the γ-effect for the *syn*-7-bromo-brosylate differs from the *anti*-isomer and the chloro systems is of interest. The decreased γ-effect may be due to partial bromonium-3 (Br-3) participation (bonding to C-1) or Br-4 involvement (25,26) in the ion-pair scheme thereby influencing internal return (27,28). A possibility also, as indicated by models, is that the steric interaction of the *syn*-7-bromine and the *exo*-2-brosylate distorts the [2.2.1] system and alters the favorable alignment of the *endo*-C—H(D) bond and developing p orbital.

Financial support by the National Research Council of Canada is gratefully acknowledged.

[3]Steady state treatment of an ion-pair scheme (Scheme 1) which includes the elimination rate constants establishes that the observed γ-isotope effect is a composite of the ionization isotope effect (IIE) and the terms *R* and *S* as described in eq. 1.



SCHEME 1

$$[1]\quad \left(\frac{k_H}{k_D}\right)_{obs} = \left(\frac{k_{1H}}{k_{1D}}\right)\left(\frac{1+Y_D}{1+Y_H}\right) \times \left(\frac{\frac{k_{2sH}+k_{2eH}}{k_{2H}} + \left(\frac{k_{3eH}}{k_{3sH}}+1\right)\left(\frac{1}{1+Z_H}\right)}{\frac{k_{2sD}+k_{2eD}}{k_{2D}} + \left(\frac{k_{3eD}}{k_{3sD}}+1\right)\left(\frac{1}{1+Z_D}\right)}\right)$$

$$\left(\frac{k_H}{k_D}\right)_{obs} = (IIE)(R)(S)$$

where

$$Y = \frac{k_{-1}+k_{2e}+k_{2s}}{k_2} \quad \text{and} \quad Z = \frac{k_{-2}+k_{3c}}{k_{3s}}$$

That the isotope effects for elimination from ion pairs can control k_H/k_D can be seen from consideration (*S* term) of eq. 1.

The Crystal and Molecular Structure of *trans*-(Methyl)(but-2-yne)-bis(dimethylphenylphosphine)platinum(II) Hexafluorophosphate $[(CH_3)(H_3CC{\equiv}CCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$

BRIAN W. DAVIES AND NICHOLAS C. PAYNE

Department of Chemistry, University of Western Ontario, London, Ontario, N6A 3K7

Received March 6, 1973

The crystal and molecular structure of *trans*-(methyl)(but-2-yne)bis(dimethylphenylphosphine)-platinum(II) hexafluorophosphate, $[(CH_3)(H_3CC{\equiv}CCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$, has been determined from three dimensional X-ray diffraction data recorded by diffractometric methods. The structure has been refined by full-matrix least-squares methods on F using 1060 unique data to a conventional agreement factor $R = 0.036$. The crystals are orthorhombic, space group $Pnma(D_{2h}^{16})$, with $a = 15.447(5)$, $b = 15.344(4)$, $c = 11.005(3)$ Å, and $Z = 4$. The coordination about the platinum atom is approximately square planar, if the acetylene is considered to be a unidentate ligand. There is crystallographic mirror symmetry imposed on the ions, such that the platinum atom, the methyl carbon atom, and the four carbon atoms of the acetylene ligand all lie on the mirror plane. The acetylene C≡C bond is approximately perpendicular (86.5(1.5)°) to the coordination plane of the platinum atom. The mean platinum–carbon(acetylene) bond length is 2.278(5) Å, and the mean angular departure from linearity of the ligand is 12(4)°. There is a small (156 cm^{-1}) reduction of ν_{str} (C≡C) for the but-2-yne ligand upon coordination, and the acetylenic carbon–carbon bond length, 1.22(3) Å, is not significantly different from the value of 1.21(2) Å observed in the free ligand.

La structure cristalline et moléculaire de l'hexafluorophosphate de platine(II) *trans*-(méthyl)(butyne-2)-bis(diméthylphénylphosphine), $[(CH_3)(H_3CC{\equiv}CCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$ a été élucidée par l'étude des figures de diffraction en trois dimensions des rayons-X enregistrées à l'aide de diverses méthodes de diffractométrie. La structure a été raffinée par la méthode des moindres carrés appliquée sur F à partir de 1060 données et ce, jusqu'à un facteur d'agrément $R = 0.036$. Les cristaux sont du type orthorhombique appartenant au groupe $Pnma(D_{2h}^{16})$; les dimensions de la maille sont $a = 15.447(5)$, $b = 15.344(4)$, $c = 11.005(3)$ Å et $Z = 4$. La coordination autour de l'atome de platine correspond approximativement à une structure plane carrée si l'on considère que le groupe acétylène est un monocoordinat. L'atome de platine, l'atome de carbone du méthyle et les quatre atomes de carbone du coordinat acétylène se situent sur le plan de coordination de l'atome de platine. La longueur moyenne du lien platine–carbone (acétylène) est de 2.278(5) Å et l'écart moyen angulaire par rapport à la linéarité est de 12(4)°. Lors de la coordination, l'on note une légère diminution (156 cm^{-1}) pour le ν_{str} (C≡C) du coordinat butyne-2 alors que la longueur de la liaison carbone–carbone (acétylène), 1.22(3) Å, n'est pas différente, d'une manière significative, de la valeur, 1.21(2), observée dans le coordinat libre.

Introduction

Although acetylene complexes of transition metals have been known for many years, there is still considerable interest (1–4) in such complexes, particularly in view of the enhanced reactivity of the coordinated acetylene. To date there have been few structural studies on acetylene complexes. A preliminary communication of the structure of the trigonal Pt(0) complex, bis-(triphenylphosphine)platinum(diphenylacetylene)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

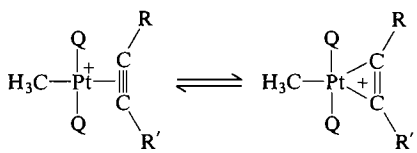
appeared in 1967 (5). A square planar platinum (II) complex, *trans*-dichloro(di-*t*-butylacetylene) (*p*-toluidine) platinum(II), was structurally characterized in 1970 (6). Dickson and Ibers recently described a trigonal Ni(0) complex, bis(*t*-butylisocyanide)(diphenylacetylene)Ni(0) (7). We recently reported a trigonal bipyramidal Pt(II) complex, *trans*-chloromethyl bis(trimethylarsine) platinum(II) hexafluorobut-2-yne, which was postulated as an intermediate in the conversion of an acetylene to a vinyl derivative (8). A second five coordinate acetylene complex of Ir(I) has been described by Kirchner and Ibers (9).

The title compound, **1**, was prepared initially by Chisholm and Clark (10) by the reaction

$$\textit{trans}\text{-}PtClCH_3Q_2 + R{-}C{\equiv}C{-}R' + AgPF_6 \xrightarrow{\text{solvent}} \textit{trans}\text{-}[PtCH_3(R{-}C{\equiv}C{-}R')Q_2]PF_6 + AgCl$$

1

where Q is $P(CH_3)_2C_6H_5$ or $As(CH_3)_3$. The products obtained from the above reaction are dependent on the nature of the acetylene, the ligands Q, the solvent and the reaction conditions. Thus, dialkyl and diaryl acetylenes in methanol generally formed the complexes (**1**), which could be isolated in crystalline form. Monoalkyl acetylenes under similar conditions underwent further reaction to give cationic alkoxycarbene complexes. Disubstituted acetylenes containing electron withdrawing groups produced vinyl complexes. These observations were rationalized by Chisholm and Clark by assuming that formation of the acetylene complex occurred initially, and it was postulated that these acetylene complexes were intermediates that could be regarded as being "metal-stabilized carbonium ions" (11).



We undertook this structural study of the complex (**1**) both to determine whether the enhanced reactivity of the acetylene was characterized by any particular structural aspects, and also as part of our continuing investigations of acetylene complexes. In addition, it was hoped that further information could be obtained regarding the crystallographic *trans*-influence of the methyl group in these and related complexes.

Experimental

Crystals of *trans*-$[(CH_3)(H_3C{\equiv}CCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$ were supplied by M. H. Chisholm. A preliminary photographic examination of reciprocal lattice layers (0–2)*kl*, *h*(0–2)*l*, and *hk*(0–2) showed the crystals to be orthorhombic, with Laue symmetry *mmm*. Systematic absences of $0kl$ for $k + l \neq 2n$, and of $hk0$ for $h \neq 2n$ are consistent with the centric space group, *Pnma*, (D_{2h}^{16} No. 62), or the acentric space group, $Pna2_1$, (C_{2v}^{9} No. 33), in a non-standard setting (12).

The unit cell dimensions, and their estimated standard deviations at 22 °C were determined from a least-squares refinement of the angular settings of 14 reflections centered on a four circle, computer controlled Picker diffractometer. The density of the crystals was measured by flotation in a mixture of carbon tetrachloride and ethylene dibromide. The value observed, 1.75(2) g cm^{-3}, is in excellent agreement with the calculated value of 1.748 g cm^{-3}, assuming four formula units in the unit cell. There are no crystallographic symmetry constraints imposed on the ion in the acentric space group, $Pna2_1$, but in the centric space group, *Pnma*, each ion must have an internal mirror plane.

Crystal data

$PtP_3F_6C_{21}H_{31}$ f.w. = 685.6

Orthorhombic, $a = 15.447(5)$, $b = 15.344(4)$, $c = 11.005(3)$ Å, $V = 2608$ Å^3, (22 °C, MoKα_1, $\lambda = 0.70926$ Å).

The crystal chosen for data collection was a thin, colorless, diamond shaped plate of approximate dimensions 0.20 × 0.18 × 0.08 mm. An optical examination identified faces of the forms {100} and {011}. The crystal dimensions were determined with a microscope fitted with a micrometer eyepiece in preparation for an absorption correction. The linear absorption coefficient for MoKα radiation is 53.8 cm^{-1} (values for μ/ρ were obtained from the tabulation of Cromer and Liberman (13)). Intensity data were collected using MoKα radiation. The crystal was mounted with b^* offset by approximately 5° from the diffractometer ϕ axis (14). Prior to data collection a number of ω-scans of intense, low angle reflections were performed, using a narrow source and a wide-open counter. A mean width at half height of 0.08° was considered suitable (15). The θ–2θ scan technique was employed, with a scan range of 1°, corrected for dispersion, at a rate of 1/2 deg per min. The incident X-ray beam was filtered through a niobium filter of thickness 0.08 mm situated at the end of the collimator. The diffracted beam was collected after passage through an aperture of dimensions 4 mm × 4 mm situated 32 cm from the crystal. Background counts were made with a stationary crystal, and a stationary counter for 20 s at the limits of each scan. A take-off angle of 1.4° was employed for the source, under which conditions an intensity of 83% of the maximum attainable for a selected reflection was observed. During the collection of data six intense axial reflections (200, $\bar{2}00$, 020, $0\bar{2}0$, 002, $00\bar{2}$) were monitored every 100 reflections. All six standard reflections showed a small linear decay in intensity (approximately 3%) for which no correction was made. All reflections in the range $0 < 2\theta < 45°$ were collected in the octant $hk\bar{l}$, and all reflections in this 2θ range with $-2 \leqslant l < 0$ in the octant hkl were also collected as a test of instrumental and crystal stability. In all the intensities of 2364 reflections were recorded.

Corrections were applied for background, Lorentz, and polarization factors[1]. Standard deviations were assigned to each observation $(\sigma(I))^2 = \text{COUNT} + \frac{1}{4}(t_c/t_b)^2(b_1 + b_2) + (cI)^2$ where the total count is given by COUNT, measured in a time t_c. b_1 and b_2 are the background counts, each measured in a time t_b. The constant c was chosen as 0.04, and $I = \text{COUNT} - \frac{1}{2}(t_c/t_b)(b_1 + b_2)$. Those reflections with a corrected intensity value greater than three times the estimated standard deviation were considered to be observed. In all there were 1275 such reflections, of which 1060 were unique.

Structure Solution and Refinement

Prior to data collection it had been noticed that the cell dimensions were similar, and the systematic absences identical, to those of an analogous methylmethoxy carbene complex, *trans*-$[(CH_3)(CH_3C(OCH_3))Pt(P(CH_3)_2C_6H_5)_2]PF_6$, the structure of which had previously been determined in this laboratory (16). A comparison of the films of nine reciprocal lattice layers suggested that the two compounds are almost isostructural.

Accordingly, positional parameters for the platinum atom, one phosphorus atom (of the phosphine ligand) and the phosphorus atom of the anion were taken from the carbene study, and the solution attempted in the centric space group assigned to the carbene complex, *Pnma*. Two cycles of full matrix least-squares refinement of F, minimizing the function $\sum w(|F_o| - |F_c|)^2$ led to agreement factors $R_1 = 0.224$ and $R_2 = 0.300$. $|F_o|$ and $|F_c|$ are the observed and calculated structure amplitudes, the weight assigned an observation is defined as $w = 4F_o^2/\sigma^2(F_o^2)$ and $R_1 = \sum(||F_o| - |F_c||)/\sum|F_o|$ and $R_2 = (\sum w(|F_o| - |F_c|)^2/\sum wF_o^2)^{1/2}$. Atomic scattering factors for Pt, P, F, and C were taken from Cromer and Waber's tabulation (17); those for H from Stewart *et al.* (18). The values of $\Delta f'$ and $\Delta f''$ of Cromer and Liberman (13) were included in the calculated structure factors. These agreement factors, and the observed geometry at this stage were considered to justify the model and the choice of space group. A difference Fourier synthesis located the remaining 28 non-hydrogen atoms in the structure. A comparison of the positional parameters obtained with those of the analogous carbene complex showed that the two complexes are, in fact, isomorphous, and almost isostructural. Two further cycles of refinement using only unique *hkl* reflections with all atoms refined with anisotropic thermal parameters (with the exception of the phenyl ring carbon atoms which were refined as a rigid group with D_{6h} symmetry and a carbon–carbon bond length of 1.392 Å (19)) resulted in agreement factors $R_1 = 0.043$ and $R_2 = 0.051$ for 112 variables and 1060 observations. Absorption correction trials showed that the transmission factors varied by as much as 25%. A numerical absorption correction utilizing a 4 × 12 × 8 grid was used (20). The maximum value of the transmission coefficient was 0.697 and the minimum value was 0.519. Two further cycles with all atoms allowed to vibrate anisotropically, and removing the rigid group constraints for the phenyl ring carbon atoms led to agreement factors $R_1 = 0.038$ and $R_2 = 0.043$. Hydrogen atom contributions for the phenyl hydrogen atoms were included in the calculated structure factors at this stage. Idealized positions were assumed with a C—H bond length of 1.05 Å, and a temperature factor of 4.0 Å^2 assigned to each hydrogen atom. A difference Fourier plane was calculated for each of the methyl carbon atoms of the dimethylphenyl phosphine ligand, assuming tetrahedral geometry at each atom (C—H = 1.09 Å, H—C—H = 109° 27′). Positive rings of electron density were seen in each case. The hydrogen atoms for these two methyl groups were best described as spinning rotors and contributions to the calculated structure factors were accordingly calculated (21). No contributions were calculated for the hydrogen atoms of the methyl ligand and of the but-2-yne ligand which lie on the mirror plane. Two further cycles of refinement under these conditions (154 variables and 1060 unique reflections) led to agreement factors $R_1 = 0.036$ and $R_2 = 0.041$.

An examination of the thermal ellipsoids of the acetylene carbon atoms at the conclusion of refinement caused some concern. In particular, C(2) and C(4) showed pronounced anisotropic vibrations. To ascertain whether these vibrations would affect the final geometry of the acetylene ligand, the refinement was also converged with the acetylenic carbon atoms, C(2) and C(3), constrained to vibrate isotropically. No significant change in geometry was observed, the acety-

[1]Computing was performed on the PDP-10 and the CDC Cyber 73/14 at the University of Western Ontario. Fourier syntheses were computed with a version of Zalkin's FORDAP. Statistical studies of intensity distributions were calculated with a version of Dewar's FAME. Least-squares refinements employed WOCLS, a local modification of Ibers' NUCLS, and illustrations were drawn using Johnson's ORTEP. Errors in derived quantities were computed with ORFFE, written by Busing, Martin, and Levy.

lenic bond length being 1.22(3) Å and the isotropic thermal parameters being 4.3(4) Å^2 and 4.5(5) Å^2 respectively. However, C(4) still showed pronounced anisotropic vibrations. Constraint of the thermal motion of all four acetylenic carbon atoms to be isotropic resulted in an acetylenic bond length of 1.18(3) Å. Of these three models, we prefer that with isotropic thermal parameters for C(2) and C(3), and anisotropic thermal parameters for C(1) and C(4). At convergence, $R_1 = 0.036$ and $R_2 = 0.040$ for 148 variables and 1060 observations. In the final cycle of this refinement, no parameter shift exceeded 0.25 of its estimated standard deviation. The error on an observation of unit weight is 1.14 electrons.

In order to confirm our choice of the centric space group to be correct, the structure was also refined in the acentric group $Pn2_1a$, equipoints (x,y,z), $(\bar{x},\frac{1}{2}+y,\bar{z})$, $(\frac{1}{2}-x,\frac{1}{2}+y,\frac{1}{2}+z)$ and $(\frac{1}{2}+x,y,\frac{1}{2}-z)$. Two cycles of refinement with the carbon atoms assigned isotropic thermal parameters (93 variables, 1275 observations) led to agreement factors $R_1 = 0.050$ and $R_2 = 0.059$. The resulting platinum–phosphorus distances were 2.20 and 2.39 Å, and this model was deemed chemically unfeasible. There also existed the possibility that the chirality of the model was incorrect if the acentric space group is assumed, and two cycles with the *hkl* reflections refined as $h\bar{k}l$ led to agreement factors $R_1 = 0.052$ and $R_2 = 0.061$. Although the platinum–phosphorus distances, 2.27 and 2.31 Å, were comparable, and chemically reasonable, the phosphorus–carbon distances of the phosphine ligands varied from 1.84 to 2.05 Å. Again this model was considered chemically unfeasible. A statistical study of the distribution of the intensities of the absorption corrected data suggested that the centric space group, *Pnma*, best fitted the observed distribution, and the final results presented therefore correspond to the refinement in *Pnma*.

No evidence for extinction was observed. A statistical examination of the structure amplitudes (in terms of F, $\lambda^{-1}\sin\theta$, indices, and diffractometer setting angles (2θ, χ, and Φ)) showed no abnormal trends. We do not feel there is anything systematically at fault with the data; as evidence for this the 358 reflections which were collected in both the *hkl* and $hk\bar{l}$ octants were averaged, and the agreement factor for averaging was 3.3%. In a final difference Fourier synthesis the largest peak of electron density, 0.70(15) e Å^{-3}, at (0.14, 0.26, 0.02) is in the vicinity of the methyl carbon, C(5). In Table 1 a listing of $|F_o|$ and $|F_c|$ is given in electrons together with the weight assigned to each reflection.[2] The final non-group atom positional and thermal parameters are listed in Table 2. In Table 3 the root-mean-square amplitudes of vibration of all the atoms in the asymmetric unit are given.

Description of the Structure

The structure is ionic, with the closest cation–anion interaction being 3.38 Å between F(4) and C(4). A selection of bond distances and bond angles is given in Table 4, together with estimated standard deviations.

The inner coordination sphere of the platinum atom is approximately square planar, if the acetylene is considered to be a unidentate ligand. Figure 1 shows a view of the inner coordination sphere, and some selected bond distances. The atom numbering scheme and an overall view of the cation are shown in Fig. 2.

The four carbon atoms of the acetylene, the platinum atom and the methyl carbon atoms, C(5), all lie on a mirror plane. The phosphine phosphorus atoms, P(1) and P′(1), are related to one another by reflection in this mirror plane.

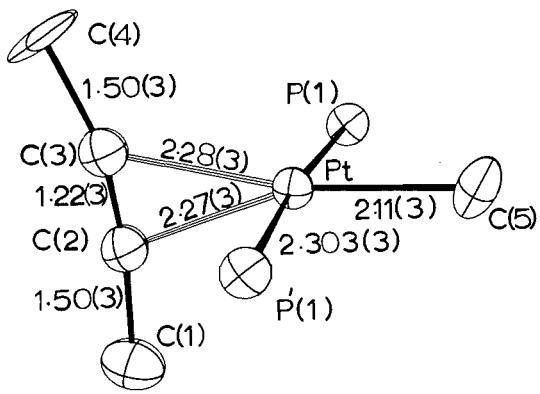

FIG. 1. Inner coordination sphere of the cation. Atoms are plotted as 30% probability thermal ellipsoids.

There is a slight deviation from an ideal square planar geometry, as the P(1)—Pt—P′(1) angle is 174.7(2)° and the P(1)—Pt—C(5) angle is 87.5(1)°. The Pt—C(2) and Pt—C(3) distances are equivalent although the acetylenic carbons C(2) and C(3) are 0.75(3) Å and 0.47(3) Å respectively above and below the plane containing P(1), Pt, and C(5). A weighted least squares plane was calculated through the atoms Pt, P(1), C(5), C(2), and C(3) and the results are shown in Table 5.

TABLE 5. Weighted least squares plane*

Atom	Deviation (Å)
Pt	−0.0019(8)
P(1)	−0.001(4)
C(5)	−0.02(2)
C(2)	0.72(2)
C(3)	−0.49(2)

*Equation of plane: $4.183x + 0.261y - 10.6z = 0.666$.

TABLE 6. Comparative details of square planar Pt(II) acetylene complexes

Compound	Mean Pt—C distance (Å)	Mean bend back angle (°)	C≡C bond length	Angle acetylenic bond makes with coordination plane	Reference
trans-$[Cl_2Pt(p\text{-}H_3CC_6H_5NH_2)((t\text{-}C_4H_9)C{\equiv}C(t\text{-}C_4H_9))]$	2.16(2)	16(2)	1.24(2)	85.2	6
trans-$[(CH_3)(H_3CC{\equiv}CCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$	2.278(5)	12(4)	1.22(3)	86.5(1.5)	This work
$CH_3C{\equiv}CCH_3$		0	1.21(2)		30

The platinum–phosphorus distance of 2.303(3) Å is smaller than the sum of the covalent radii, 2.42 A, (22) but comparable to the values of 2.283(3) Å found in *trans*-$[(CH_3)(CH_3C(OCH_3))Pt(P(CH_3)_2C_6H_5)_2]PF_6$ (16), 2.295(4) Å found in *trans*-$[(CH_3)((CH_3)_2NCCH_3)Pt(P(CH_3)_2C_6H_5)_2]PF_6$ (23) and 2.305(3) Å observed in *trans*-$(CH_3)IPt(P(C_6H_5)_3)_2\cdot SO_2$ (24). Other Pt(II)–phosphorus distances determined to date vary considerably, ranging from 2.230(9) Å in $[Cl_4Pt(P(C_3H_7)_3)_2]$ (25) to 2.365(8) Å in $[(CF_3)((CH_3)_4C_4)Pt(P(CH_3)_2C_6H_5)_2]SbF_6$ (26).

The platinum – methyl carbon distance of 2.11(2) Å lies in the range expected for a normal covalent Pt—C σ bond, the sum of the covalent radii being 2.09 Å (22). Thus it appears that the crystallographic *trans*-influence of the but-2-yne ligand is small. It would appear that the lengthening of the Pt—N bond trans to the *t*-butyl acetylene in *trans*-$[Cl_2Pt(p\text{-}H_3C{-}C_6H_4NH_2)((t\text{-}C_4H_9)C{\equiv}C(t\text{-}C_4H_9))]$ may be due to other reasons (6). (The observed Pt—N bond length of 2.10(1) Å, while longer than the radius sum, 2.02 Å, is barely significantly different from the value of 2.05(1) Å observed in *trans*-$[Pt(NH_3)_2Cl_2]$ (27), with $\Delta = 3.5\,\sigma$.) However, the mean platinum – acetylene carbon distance of 2.28(2) Å is longer than any previously reported. In *trans*-$[Cl_2Pt(p\text{-}H_3C{-}C_6H_4NH_2)((t\text{-}C_4H_9)C{\equiv}C(t\text{-}C_4H_9))]$ the mean platinum – acetylene carbon distance is 2.16(2) Å. The difference, 0.12(2) Å, may be attributed to the *trans*-influence of the methyl ligand.

The phosphorus–carbon distances in the dimethylphenylphosphine ligand are 1.81(1), 1.79(1), and 1.81(1) Å. Comparable values of 1.79(1), 1.80(1), and 1.80(1) Å are found in *trans*-$[(CH_3)(CH_3C(OCH_3))Pt(P(CH_3)_2C_6H_5)_2]PF_6$ (16). The mean angle subtended by the carbon atoms at the phosphorus atom is 105(1)°, significantly different from the value (109° 27′) expected for pure sp^3 hybridization.

The mean carbon–carbon bond length in the phenyl ring of the phosphine ligand is 1.380(4) Å, not significantly different from the value of 1.392 Å for free benzene (28). The mean ring angle of the phenyl ring is 120(1)°.

The geometry of the hexafluorophosphate anion is approximately octahedral. The mean P—F distance is 1.55(1) Å. This is shorter than the value observed in $NaPF_6$, 1.58 Å (29), but a difference Fourier synthesis revealed no evidence of disorder in the anion, or residual electron density.

The most interesting feature of the structure, however, is the geometry of the coordinated acetylene. The acetylene adopts the *cis*-bent configuration, the two bend back angles being 16(2) and 8(2)°. These two values are not significantly different from the mean, 12(4)°. The acetylenic carbon–carbon bond length of 1.22(3) is not significantly different from the value observed in the free ligand, 1.21(2) Å. The acetylenic triple bond makes an angle of 86.5(1.5)° with the coordination plane of the platinum atom. A comparable value of 85.2° was observed in *trans*-$[Cl_2Pt(p\text{-}H_3CC_6H_4NH_2)((t\text{-}C_4H_9)C{\equiv}C(t\text{-}C_4H_9))]$. The acetylene – methyl carbon distances of 1.50(3), (C(1)—C(2)), and 1.50(3), (C(3)—C(4)) are not significantly different from the value observed in the free ligand, 1.47(2) Å (30). Table 6 shows some of the values of bond distances and bond angles obtained in this study and in the one previously determined acetylene complex of this type, *trans*-$[Cl_2Pt(p\text{-}H_3CC_6H_4NH_2)((t\text{-}C_4H_9)C{\equiv}C(t\text{-}C_4H_9))]$.

Discussion

Molecular orbital theory best describes the bonding between transition metals and olefins or

acetylenes. Maitlis and co-workers (4) proposed a scheme which satisfactorily describes platinum–acetylene bonding in both the trigonal Pt(0) acetylene complexes and the square planar Pt(II) acetylene complexes. In this scheme there are two components to the bonding, *viz.* (*i*) overlap of the acetylene π clouds with empty metal d or dp hybrid orbitals of the appropriate symmetry and energy to form a σ type bond and (*ii*) concomitant donation of electron density from the metal to the vacant π^* orbitals of the acetylene.

The trigonal Pt(0) complexes, which in valence bond theory are considered to contain metallocyclopropene rings, *i.e.* $M\begin{smallmatrix}C\\ \|\\ C\end{smallmatrix}$, in this scheme represent one extreme in a continuum of bond types. The back donation from metal → acetylene is considerable, as evidenced by the large perturbation of the acetylene in these complexes.

The square planar Pt(II) complexes, in which the acetylene perturbation is less, have the σ component as the major contributor to the metal–acetylene bond, and back donation to the acetylene π^* orbitals is less.

The concept of a continuum of bond types can be extended to the trigonal bipyramidal Pt(II) acetylene complexes, which have recently received much attention (31–34). Both the σ and π contributions are important in these complexes.

Blizzard and Santry (35) showed using CNDO calculations that the removal of density from the π_u acetylene orbitals to vacant metal orbitals did not, *per se*, result in a change in the geometry of the coordinated acetylene. However, when it is accompanied by the addition of density to the acetylene π^* orbitals it strongly enhanced the metal–acetylene bonding.

The bonding in **1** corresponds to situation D in the Maitlis scheme (4): in this case the energy of the metal valence shell orbitals is lower than that of the acetylene π orbitals. Thus the bonding orbital has mostly metal character and the antibonding orbital has mostly acetylene character. The large energy difference between the metal orbitals and the acetylene π^* orbitals means that the degree of back bonding is small.

The *trans*-influence of the methyl ligand, as evidenced by the observed bond lengths, has been shown to be large, while that of the but-2-yne ligand is small. This is consistent with the observations that ν_{str} (Pt—CH_3) is approximately 550 cm^{-1}, and the coupling constant J(Pt—CH) for the platinum – methyl carbon bond is 76 Hz (10). Further studies on the structures of platinum–acetylene complexes are in progress.

Note added in proof

Recently in this journal Beauchamp *et al.* (36) reported the structure of $K[Cl_3Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)]$. The C≡C bond length is 1.18(3) Å, and the bend back angles are 21(2)° and 19(2)°, consistent with a weakly perturbed acetylene.

The Photochemistry of 2-Cyano-1,4-dihydro-1,4-ethenoanthracene

CHRISTOPHER OWEN BENDER AND HELEN DIANA BURGESS[1]
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received May 14, 1973

The direct photolysis of 2-cyano-1,4-dihydro-1,4-ethenoanthracene (**5**) yields 8-cyanocycloocta[*b*]-naphthalene (**8**, $\Phi = 0.02$) and 1- and 6-cyanonaphtho[2,3-*c*]tricyclo-[3.3.0.$0^{2,8}$]octa-3,6-diene (**6**, $\Phi = 0.30$ and **7**, $\Phi = 0.04$). The benzophenone sensitized irradiation of **5** yields **6** ($\Phi = 0.40$) and **7** ($\Phi = 0.04$) only. Deuterium labeling studies reveal that **8** derives from an initial $2\pi + 2\pi$ cycloaddition reaction which proceeds with bonding between the vinyl and vinylcyano bridges.

La photolyse directe du cyano-2 dihydro-1,6 étheno-1,4 anthracène (**5**) conduit au cyano-8 cycloocta-[*b*]naphtalène (**8**, $\Phi = 0.02$) et au cyano-1 et -6 naphto [2,3-*c*] tricyclo [3,3,0,$0^{2,8}$] octadiène-3,6 (**6**, $\Phi = 0.30$ et **7**, $\Phi = 0.04$). L'irradiation sensibilisée par la benzophénone de **5** conduit à **6** ($\Phi = 0.40$) et **7** ($\Phi = 0.04$) seuls. Les études de marquage au deutérium montrent que **8** dérive d'une réaction initiale de cycloaddition $2\pi + 2\pi$ qui procède par liaison entre les ponts vinyle et vinylcyano.

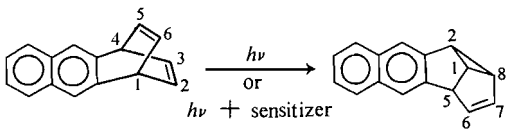
Can. J. Chem., **51**, 3486 (1973)

Introduction

Previously we reported that 2,3-naphthobarrelenes seemed to exhibit photoreactivities that were curiously different to those of other mono-fused aromatic barrelenes (1). Principally, 2,3-naphthobarrelenes (*e.g.* **1**) had not been observed to photoisomerize to cyclooctatetraene product (2). Instead, only semibullvalenes (*e.g.* **2**), derived from di-π-methane rearrangement of the triplet excited state species, were found (see Scheme 1).



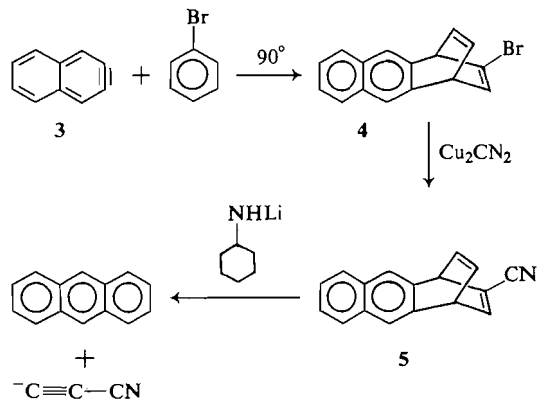
1 **2**

SCHEME 1

In order to examine this behavior further, we have undertaken a study of substituent effects on the photochemistry of the 2,3-naphthobarrelene system. Herein we report our results with 2-cyano-1,4-dihydro-1,4-ethenoanthracene (**5**), the first member thus far to give directly a cyclooctatetraene product, and equally significantly, the first aromatic barrelene to yield a cyclooctatetraene by way of a $2\pi + 2\pi$ cycloaddition mechanism which does not involve initial bridging to the aromatic nucleus.

Results

Although 2-cyanobarrelene (**5**) could be prepared directly by the 1,4-addition of 2,3-naphthyne (**3**) to benzonitrile, the material obtained in this way was difficult to purify. Suitably pure **5** (m.p. 178–180°, $\nu_{CN} = 2220\ cm^{-1}$) could be more conveniently synthesized by cuprous cyanide treatment of 2-bromobarrelene (**4**), isolated from the addition of 2,3-naphthyne (**3**) to bromobenzene (Scheme 2). The structure of **5** follows



3 **4** **5**

SCHEME 2

from its n.m.r. spectrum which shows a 2H multiplet centered at τ 4.92 (bridgeheads), a 2H multiplet centered at τ 3.12 (ethylene bridge), and a complex 7H absorption region between τ 2.18 and 2.74 (aromatics and vinylcyano proton). Degradative evidence supporting the structure was obtained when anthracene was found to be the main isolable product (41%) from treatment of **5** with lithium cyclohexylamide. The formation of anthracene is rationalized as deriving from initial loss of the acidic vinylcyano

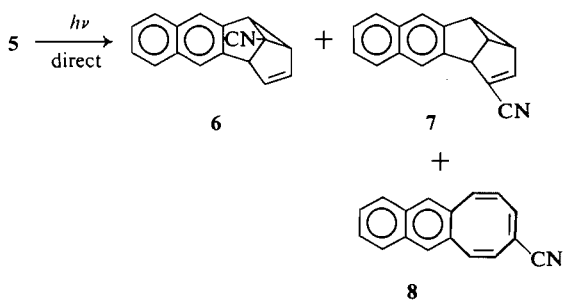
proton of **5**, followed by retro Diels–Alder expulsion of the stabilized cyanoacetylide anion.

The direct irradiation of cyanobarrelene (**5**) led cleanly to the formation of a trace amount of anthracene and three photoproducts isomeric with the starting material (see Scheme 3): 1- and



SCHEME 3

6-cyanonaphtho[2,3-*c*]tricyclo[3.3.0.0^{2,8}]octa-3,6-diene (**6** and **7**), and 8-cyanocycloocta[*b*]naphthalene (**8**, CN-COT). The photoproducts were isolated by careful column chromatography on Silicar CC-7. The structures of the semibullvalenes **6** and **7** were deduced from the n.m.r. data (see Experimental), which were characteristic of 2,3-naphthosemibullvalene derivatives (1, 2). In the case of CN-COT (**8**), the proposed structure was assigned on the basis of comparison of its n.m.r. spectral parameters with those of 2,3-naphtho-COT (**9**) (3), 6-methoxy-2,3-naphtho-COT (**10**) (1), and 1,2-naphtho-COT (**11**)[2] (Table 1), and is supported by spin-decoupling experiments: irradiation of H-7 collapsed H-6 to a singlet; irradiation of H-10 collapsed both H-9 and H-11 to singlets; and irradiation of H-9 collapsed H-10 to a doublet ($J_{10,11} = 11.5$ Hz). The deshielding effect of the cyano group on the adjacent coplanar vinyl proton amounts to ~τ 0.9 in both the cyclooctatetraene **8** (H-9) and semibullvalene **7** (H-7), and compares well with the substituent constant of 0.8 for the *cis* proton of acrylonitrile (4). The extent of the deshielding in barrelene **5** could not be ascertained because H-3 was buried in the aromatic region.

To rule out the possibility that cyclooctatetraene **8** is a secondary photoproduct deriving from the further photolysis of **6** or **7**, the individual semibullvalenes were irradiated directly and were found to be essentially unreactive ($\Phi_{dis} < 10^{-4}$). We note, however, that even if **6** or **7** did undergo the well-known phototransformation to COT product via cleavage of the semibullvalene C_2—C_8 and C_1—C_5 bonds (5), this process would, in the first instance, lead to β-cyano COT. This compound was not observed. The direct and sensitized irradiations of CN-COT (**8**) were also examined. Whereas no reaction was detectable upon direct irradiation, the sensitized photolysis of CN-COT (**8**) with benzophenone as sensitizer, did lead to the slow disappearance ($\Phi_{dis} = 0.1$) of starting material, but no identifiable product was obtained.

In contrast to the direct irradiation of barrelene **5**, sensitization with benzophenone led cleanly to the semibullvalenes **6** and **7** only; the

formation of CN-COT (**8**) was not detected at any conversion level. Thus, it appears that the CN-COT (**8**) formed during the direct irradiation of barrelene **5** derives from the singlet excited state and represents the first example of a $2\pi + 2\pi$ photocycloaddition in the 2,3-naphthobarrelene series.

Quantum yield studies (ferrioxalate actinometry (6)) were carried out with cyanobarrelene **5** to determine the relative efficiencies of the direct and sensitized irradiations and to provide information on the excited state species involved in the transformations; these data are summarized in Table 2.

Mechanistic Considerations

Inspection of the possible modes of $2\pi + 2\pi$ cycloadditions of barrelene **5** shows that CN-COT (**8**) can result from either of two pathways (see Scheme 4): one involving initial vinyl–vinylcyano interaction (pathway *i*), and the other initial naphtho–vinyl interaction (pathway *ii*). Bonding between the naphtho ring and the vinylcyano bridge need not be considered, since this would lead to the unobserved α-CN-COT. To distinguish between the pathways *i* and *ii* the deuterated barrelene **12** was synthesized. This was accomplished by the addition of 2,3-naphthyne to *p*-deuterobromobenzene, followed by treatment of the deuterobromobarrelene product with cuprous cyanide. Labeled material with 94% d_1 content at C-5 was obtained (n.m.r. analysis).

Direct irradiation of deuterobarrelene **12** led to the formation of cyclooctatetraene **15**, containing exclusive β-labeling; the olefinic region of the n.m.r. spectrum of the deuterated COT product showed a doublet centered at τ 3.05 (H-6, J = 11.5 Hz), a broad singlet at τ 3.07 (H-11), a singlet at τ 3.35 (H-9), and a doublet at τ 3.98 (H-7, J = 11.5 Hz). Thus the $2\pi + 2\pi$ cycloaddition proceeds with initial vinyl–vinylcyano bonding.

N.m.r. examination of the labeled semibullvalene product from either direct or sensitized irradiations of barrelene **12** showed the deuterium to be located at C-7 in **6** and C-8 in **7** (*i.e.* **21** and **23**, Scheme 5). However, this label distribution does not permit a unique pathway for the di-π-methane rearrangement to be delineated since although there is only one route that can account for the labeling pattern found in **23** (see Scheme 5, route *i*), there are two which could lead to labeled **21** (route *i* and route *ii*). Thus semibullvalene **21** might arise solely from route *i* or from some combination of routes *i* and *ii*. A means of determining the importance of route *ii* was obtained by examining the fate of the mixture of barrelenes **26**, which was composed of approximately equal amounts of two singly labeled isomers, one incorporating deuterium at C-4 and the other deuterium at C-6 (see Scheme 6). The barrelene mixture **26** was synthesized in essentially the same way as the deuterated barrelene **12** but starting with *m*-deuterobromobenzene; (within experimental error no deuterium isotope effects were discernible in the naphthyne addition stage or in subsequent photoisomerizations).

N.m.r. examination of the 1-cyanosemibullvalene material isolated from either the direct or the benzophenone sensitized irradiations of deuterobarrelene mixture **26** showed the labels to appear exclusively at C-2 and C-6, *i.e.* the semibullvalene mixture **28** was the 1-CN-semibullvalene product. Route *i* is therefore solely utilized in the cyanobarrelene di-π-methane rearrangement.

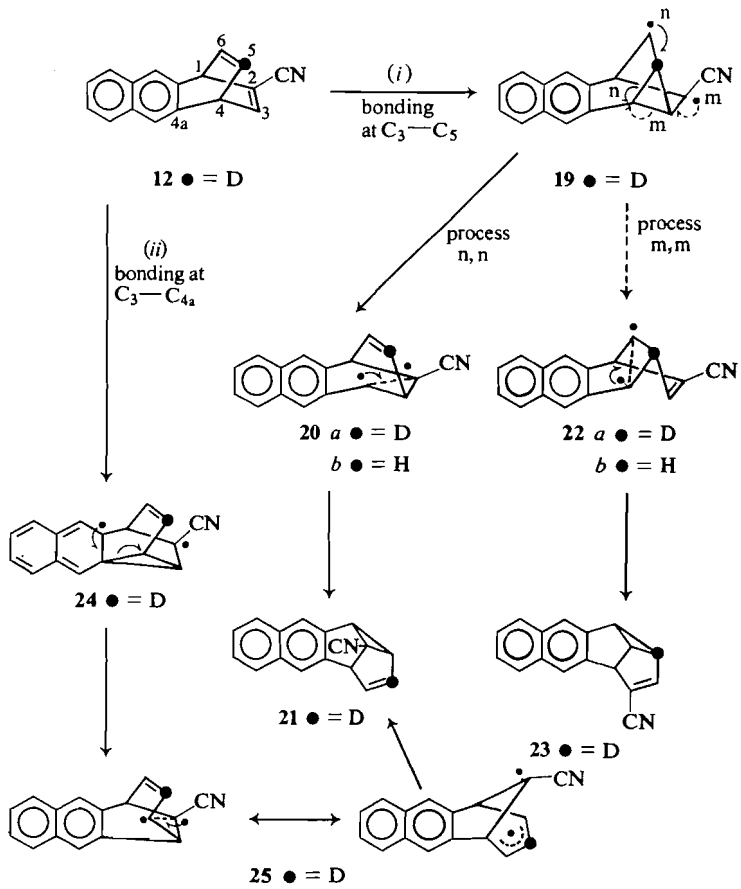
Discussion

The formation of the semibullvalenes **6** and **7** in the same ratios (~1:8, within experimental error) and, when the deuterated barrelenes **12** and **26** were used, with the same label locations from direct and sensitized irradiations, suggests that the same triplet excited state species is involved in both excitation processes. The quantum yield data (Table 2) showing the sensitized formation of **6** and **7** to be the slightly more efficient process are also consistent with this view. Thus, although COT product has been obtained from a 2,3-naphthobarrelene, the effect of the cyano group is modest, possibly contributing to a lowering of the transition-state energy of the singlet reaction; the main fate of the barrelene excited singlet state is still a remarkably efficient intersystem crossing to the triplet. The subsequent triplet di-π-methane rearrangement then proceeds by bonding between C-3 and C-5 of the vinylcyano and vinyl bridges. The preference for the formation of **6** over **7** is attributed to the greater stabilization of the radical centers in species **20***b* (naphtho and cyano stabilization) than in **22***b* (naphtho stabilization only).

With respect to the barrelene cycloaddition, the observation that the reaction proceeds without involving bonding to the aromatic nucleus is unique and conflicts with the earlier view that bonding with the aromatic moiety is expected on the basis that this part of the molecule is of lowest singlet excitation energy and therefore concentrated with energy (1, 5). Thus, minimization of energy along the reaction coordinate controls the reaction, not the initial excitation process.

In order to rationalize the vinyl–vinyl bonding preference over the naphtho–vinyl alternatives, it is noted that Zimmerman and his coworkers have developed an excellent method for predicting the favored bridging mode for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 5

di-π-methane rearrangement of excited triplet state aromatic barrelenes (2, 5, 7). Extension of this method to the excited singlet reaction involves considering the initial stages of each possible cycloaddition to be a perturbation of the 2π–2π system into cyclic overlap, wherein a cyclobutadiene-like transition state is approximated prior to formal bonding. The most probable bridging mode is then assigned as that which approximates the cyclobutadiene species of lowest singlet excitation energy. Because of the paucity of information concerning cyclobutadienes, we can presently compare only the u.v. spectra of butadiene itself with that of 1,2-dibromo-3,8-diphenylnaphtho[*b*]cyclobutadiene. Masamune *et al.* (8) have attributed a broad peak at λ_{max} 300–305 nm (ε ~ 100) tailing to 400 nm, to cyclobutadiene, while Cava and Mitchell (9) report that the longest absorption band of 1,2-dibromo-3,8-diphenylnaphtho[*b*]cyclobutadiene (a yellow–orange colored compound) occurs at 270 nm (ε 10 000, shoulder). In the absence of fluorescence spectra for these and model cyano derivatives it is clearly impossible to assign an order for the singlet energies with any certainty but we are nevertheless encouraged that the available evidence indicates that our requirement for a lower singlet energy for cyanocyclobutadiene than for naphtho[*b*]cyclobutadiene or for 1-cyanonaphtho[*b*]cyclobutadiene is not improbable. If this rationale is correct, then it follows that both benzocyclobutadiene and naphtho[*a*]-cyclobutadiene should have singlet excited state energies below that of cyclobutadiene, since aromatic–vinyl bonding is observed for the 2π + 2π cycloaddition in the cases of benzobarrelene (5) and 1,2-naphthobarrelene (2).

Finally, the rearrangement of the proposed cycloaddition intermediate **13***b* to give CN-COT (**8**) but apparently not β-CN-COT (**16***b*), is at-

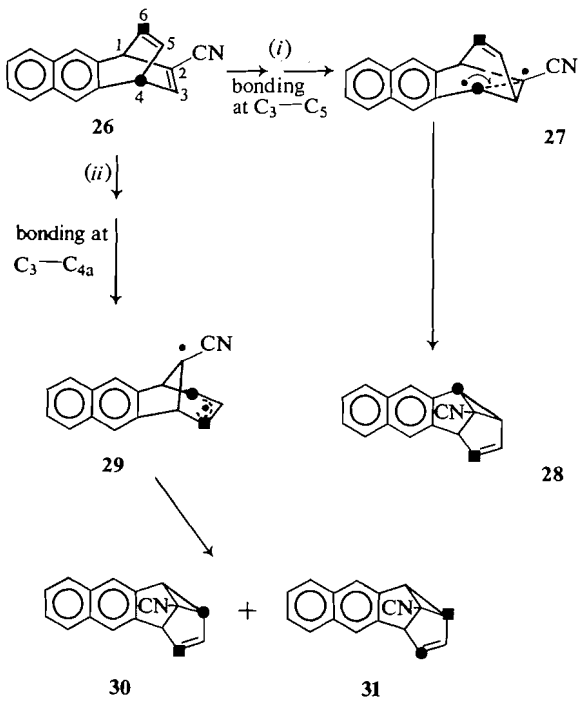

SCHEME 6. Individual structures represent an approximately 50:50 mixture of two component compounds, each singly labeled with deuterium at the positions designated by ● and ■.

tributed to the preferred initial rupture of the C_1—C_2 bond as a consequence of the favorable stabilization afforded the radical centers in the species **14***b* by the cyano and naphtho groups (see Scheme 4).

Experimental

The n.m.r. spectra were run on Varian A-60 and HA-100 instruments with TMS as internal standard. The i.r. spectra were recorded on a Perkin-Elmer Model 337 spectrophotometer, the u.v. spectra on a Cary 15 spectrophotometer, and the mass spectra on an MS 9 (A.E.I.). All m.p. are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, Tennessee. Benzene solvent for photolyses was shaken three times with acidic potassium permanganate solution, scrubbed with 20% fuming sulfuric acid, washed with 10% aqueous sodium hydroxide, dried ($MgSO_4$), and distilled from calcium hydride. Benzophenone sensitizer was recrystallized twice from ethanol, m.p. 47–49°.

2-Bromo-1,4-dihydro-1,4-ethenoanthracene (4)

A mixture of 6.0 g of 3-diazoniumnaphthalene-2-carboxylate (2) and 1 l of bromobenzene (distilled from calcium hydride) was heated with stirring at 90° for 4 h in a dry nitrogen atmosphere. The mixture was concentrated *in vacuo* and the residue column chromatographed on silicic acid. Elution with cyclohexane gave crude **4** from early fractions and crystallization from ethanol gave 419 mg (5%) m.p. 160–162°: u.v.$_{max}$(hexane) 236 (49 000), 255 sh (9500), 265 (9800), 274 (8300), 284 (4300), 298 (710), 311 (430), 321 (190), and 325 nm (310); n.m.r. (100 MHz, CCl_4) τ 2.40–2.82 (m, 6H, aromatic), 3.28 (m, 3H, vinyl), and 5.28 (m, 2H, bridgehead).

Anal. Calcd. for $C_{16}H_{11}Br$: C, 67.87; H, 3.91; Br, 28.22. Found: C, 67.91; H, 3.91; Br, 27.95.

2-Cyano-1,4-dihydro-1,4-ethenoanthracene (5)

A solution of 288.8 mg (1.02 mmol) of **4** and 231.1 mg (1.29 mmol) of cuprous cyanide in 5 ml of dry DMF was stirred under reflux for 4 h. The mixture was cooled, diluted with 200 ml of benzene, extracted with 5% aqueous HCl (2 × 50 ml), then with 5% aqueous NaOH (2 × 50 ml), and finally with water (50 ml). The benzene solution was dried ($MgSO_4$), concentrated *in vacuo*, and the residue column chromatographed on silicic acid. Elution with 0.5% ether–cyclohexane and crystallization of crude **5** from ethanol gave 183.8 mg (79%) of colorless material, m.p. 178–180°: i.r. (KBr) 2220 cm^{-1}, C≡N; u.v.$_{max}$ (hexane) 232 (55 000), 237 (62 000), 254 (7400), 264 (8100), 273 (7900), 283 (5100), 297 sh (320), 311 (250), 319 (140), and 323 nm (80); n.m.r. (60 MHz, $CDCl_3$) 2.18–2.74 (m, 7H, aromatic and H-3), 3.12 (m, 2H, H-5 and H-6), and 4.92 (m, 2H, bridgeheads).

Anal. Calcd. for $C_{17}H_{11}N$: C, 89.05; H, 4.85; N, 6.10. Found: C, 89.31; H, 4.86; N, 5.83.

Action of Lithium Cyclohexylamide on Cyanobarrelene 5

A solution of 244.8 mg (1.08 mmol) of **5**, 40 ml of cyclohexylamine (CaH_2 dried and distilled), and 4 ml (8.0 mmol) of 2 *M* butyllithium in hexane was stirred at 83° for 45 h in a nitrogen atmosphere. The mixture was cooled, quenched with 50 ml of water, diluted with 250 ml of benzene, and extracted with 10% HCl (2 × 200 ml) and then with water. The benzene solution was dried ($MgSO_4$), concentrated *in vacuo*, and the residue chromatographed on silicic acid with cyclohexane as solvent. Colorless material, 77.6 mg (41%), was obtained, m.p. 200–205°, which was raised to 216–218° by crystallization from ethanol, and was shown by t.l.c., i.r. and mixed m.p. to be identical to anthracene.

Photolysis Apparatus

The same apparatus was used for both preparative runs and quantum yield studies. The apparatus consisted of a "merry-go-round" fitted with a 450 W Hanovia medium-pressure mercury arc and surrounded by a water-cooled quartz immersion well and filter solutions. For direct irradiations, 313 nm light was isolated by a two compartment filter consisting of a 1.5 cm path length of a solution of 28 g of cobaltous sulfate heptahydrate per 100 ml of water, and a 0.6 cm path length of a solution of 0.252 g of potassium carbonate; transmittance was 300–332 nm with a maximum at 313 nm (13%). For benzophenone sensitized irradiations, 343 nm light was isolated by a one compartment filter consisting of a 2.0 cm path length of a solution of 450 g of cobaltous chloride hexahydrate, 60 g of stannous chloride dihydrate, and 150 g of nickel chloride hexahydrate per1.2 l of 20% aqueous HCl; transmittance was 319–382 nm with a maximum at 343 nm (5%). Prior to irradiations, solutions of samples in 35 ml of benzene, contained in 25 × 150 mm Pyrex irradiation tubes, were deoxygenated by nitrogen flushing. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tubes were sealed under a positive pressure of nitrogen, which was maintained throughout the course of photolyses.

Direct Irradiation of Cyanobarrelene **5**

A solution of 260.5 mg (1.14 mmol) of **5** in 35 ml of benzene was photolyzed for 8 h with 313 nm light. The solvent was removed *in vacuo* and the residue was chromatographed on silicic acid and eluted with 0.5% ether–cyclohexane. The first band contained a trace amount of anthracene; (accumulated material from several runs was shown to be identical with an authentic sample). Band two contained 11.0 mg (4%) of **8**, a colorless solid, m.p. 176–178° (from ethanol): i.r. (KBr) 2200 cm^{-1}, C≡N; u.v.$_{max}$ (hexane) 227 (50 500), 247 sh (18 700), 285 (16 000), 292 sh (14 500), 305 sh (6900), and 343 nm sh (1050); n.m.r., see Table 1; Mass spectrum (70 eV, direct inlet) showed molecular ion at *m/e* 229.0899 (93%), $C_{17}H_{11}N$ requires 229.0891.

Band three contained a mixture of **5**, **6**, and **7**. Crystallization of the mixture from ethanol (twice) gave 121.7 mg (45%) of colorless **6**, m.p. 205–207°: i.r. (KBr) 2230 cm^{-1}, C≡N; u.v.$_{max}$ (cyclohexane) 239 (70 000), 267 sh (4600), 275 (5800), 289 (6000), 299 (3800), 314 (610) 317 sh (350), 322 (290), and 327 nm (610); n.m.r. ($CDCl_3$) the aliphatic–olefinic region comprises an ABMXY spin system, τ 2.07–2.76 (m, 6H, aromatic), 4.34 (*A*BM q, 1H, H-6, J_{56} = 2.5 Hz, J_{67} = 5.0 Hz), 4.79 (A*B*X q, 1H, H-7, J_{67} = 5.0 Hz, J_{78} = 3.0 Hz), 5.64 (A*M* d, 1H, H-5, J_{56} = 2.5 Hz), 6.30 (X*Y* d, 1H, H-2, J_{28} = 7.0 Hz), and 6.69 (B*X*Y q, 1H, H-8, J_{28} = 7.0 Hz, J_{78} = 3.0 Hz).

Anal. Found: C, 89.30; H, 4.79.

The mother liquors from the ethanol crystallization of band three were concentrated *in vacuo* to give 119.9 mg of an oil, which upon analysis by n.m.r. was found to contain 26% of **5**, 49% of **6**, and 25% of **7**. The oil was divided into six portions which were rechromatographed separately on a 2 × 200 cm silicic acid column and eluted with 0.5% ether–hexane; 50 ml fractions were collected. In a typical run, fractions 76–88 contained a mixture of **5**, **6**, and **7**; fractions 89–95 contained pure 7. Crystallization of the (ethanol) fractions of **7** from all runs gave 12.1 mg (5%) of colorless material, m.p. 183–185°: i.r. (KBr) 2225 cm^{-1}, C≡N; u.v.$_{max}$ (cyclohexane) 233 (77 600), 262 sh (10 000), 286 (6600), 297 sh (5400), 307 sh (2800), 315 (1750), 322 (980), and 329 nm (1790); n.m.r. (60 MHz, $CDCl_3$) the aliphatic–olefinic region comprises an AMXYZ spin system, τ 2.03–2.81 (m, 6H, aromatic), 3.96 (*A*Z d, 1H, H-7, J_{78} = 3 Hz), 5.79 (*M*X d, 1H, H-5, J_{15} = 6.5 Hz), 6.48 (*X*YZ d of d, 1H, H-1, J_{15} = J_{12} = J_{18} = 6.5 Hz), 6.73 (X*Y*Z t, 1H, H-2, J_{12} = J_{28} = 6.5 Hz), and 7.31 (XY*Z* d of t, 1H, H-8, J_{18} = J_{28} = 6.5 Hz, and J_{78} = 3 Hz). Mass spectrum (70 eV, direct inlet) showed molecular ion at *m/e* 229.0899 (95%).

Sensitized Irradiation of Cyanobarrelene **5**

A solution of 208.1 mg (0.91 mmol) of **5** and 1.0025 g (5.51 mmol) of benzophenone in 35 ml of benzene was photolyzed with 343 nm light for 1.5 h. The solvent was removed *in vacuo* and the residue was chromatographed on silicic acid with 0.5% ether–cyclohexane as eluting agent. The first band contained 931.1 mg of benzophenone, m.p. 47–49°. Band two contained a mixture of **6** and **7**. Recrystallization of the mixture twice from ethanol gave 152.1 mg (73%) of colorless **6**, m.p. 205–207°. Concentration of the mother liquors *in vacuo* gave 54.0 mg of an oil, which upon analysis by n.m.r. was found to contain 69% of **6** and 31% of 7. The oil was divided into three equal portions and each was chromatographed separately on a 2 × 200 cm silicic acid column which was eluted with 0.5% ether–hexane. Compound 7, 8.2 mg (4%), m.p. 182–185°, was obtained from the last fraction of the main band as described in the isolation of **7** from the direct irradiation of **5** (*vide supra*).

Quantum Yield Irradiations

Quantum yield runs were carried out on solutions of samples (*ca.* 0.50 mmol) and benzophenone (*ca.* 2.75 mmol, if any) in 35 ml of benzene solvent, and the lamp output was measured by potassium ferrioxalate actinometry (6). Photolysates were concentrated *in vacuo*, a known amount of *p*-xylene was added as internal standard, and the product composition was determined by n.m.r. analysis; the peak areas were calibrated against authentic mixtures of similar constitution. Quantum yields for the direct and sensitized photolyses of **5** are shown in Table 2.

5-Deuterocyanobarrelene (***12***)

A solution of 140 g (0.59 mol) of *p*-dibromobenzene in 450 ml of ether was added to a stirred mixture of 24.3 g (1.00 g atom) of magnesium turnings, a crystal of iodine, and 50 ml of ether, at a rate that maintained reflux. After all the magnesium had reacted, the cooled solution was treated with 100 ml of 5% DCl in D_2O. The ether layer was separated, dried ($MgSO_4$), concentrated *in vacuo*, and the residue distilled. The fraction of b.p. 151–155° (691 mm), 42 g (45%), was collected.

A mixture of 1.0 g of 3-diazoniumnaphthalene-2-carboxylate and 230 ml of the *p*-deuterated bromobenzene was heated with stirring at 90° for 4 h in a dry nitrogen atmosphere. The mixture was distilled and the distillate was recycled through the decomposition reaction a total of 5 times, in each case using a 1 g portion of the naphthyne precursor. The distillate residues were collected together and after column chromatography, as described for **4** (*vide supra*), 140.0 mg (1.7%) of colorless 4-d_1 was obtained, m.p. 160–162°.

A solution of 125 mg (0.44 mmol) of **4**-d_1 and 93.2 mg (0.52 mmol) of cuprous cyanide in 7 ml of dry DMF was refluxed for 6 h. The reaction was worked-up in the same way as for **5**, to give 59.7 mg (59%) of colorless **12**, m.p. 178–180°: n.m.r. (60 MHz, $CDCl_3$) τ 2.17–2.63 (m, 7.11 ± 0.14 H, aromatic and H-3), 3.08 (d, 1.06 ± 0.02 H, H-6, J_{16} = 5.5 Hz), and 4.92 (m, 2.00 H, bridgeheads), *i.e.*, 94 ± 2% deuteration at C-5 (based on comparison of bridgehead (assumed 0%-d_1) and H-6 proton integrations).

Direct Photolysis of 5-Deuterocyanobarrelene (***12***)

A solution of 187.7 mg (0.82 mmol) of **12** in 35 ml of benzene was photolyzed for 7.2 h with 313 nm light. The products were isolated as described for the direct irradiation of **5** (*vide supra*). Band two contained 5.2 mg (3%) of **15**, m.p. 175–177°: n.m.r. (100 MHz, $CDCl_3$) τ 2.16–2.63 (m, 6.02 ± 0.10 H, aromatic), 3.05 and 3.07 (d, s, 2.00 ± 0.07 H, H-6 and H-11, J_{67} = 11.5 Hz), 3.35 (s, 1.0 H, H-9), and 3.98 (d, 1.08 ± 0.04 H, H-7 and H-10). Hydrogen distribution required for pathway *i* (Scheme 4):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

aromatic, 6.0 H; H-6 and H-11, 2.00 H; H-9, 1.00 H; H-7 and H-10, 1.06 ± 0.02 H.

Recrystallization of band three from ethanol twice gave 107.7 mg (57%) of **21**, m.p. 205–207°: n.m.r. (60 MHz, $CDCl_3$) τ 2.08–2.70 (m, 6.04 ± 0.09 H, aromatic), 4.33 (d, 0.94 ± 0.07 H, H-6, J_{56} = 2.5 Hz), 4.60–5.00 (no discernible signal, 0.07 ± 0.01 H, residual H-7), 5.63 (d, 1.00 H, H-5, J_{56} = 2.5 Hz), 6.32 (d, 1.02 ± 0.07 H, H-2, J_{28} = 7.0 Hz), and 6.73 (d, 1.08 ± 0.09 H, H-8, J_{28} = 7.0 Hz). Hydrogen distribution required for routes *i* or *ii* (Scheme 5): aromatic, 6.00 H; H-6, 1.00 H; H-7, 0.06 ± 0.02 H; H-5, 1.00 H; H-2, 1.00 H; H-8, 1.00 H.

Concentration of the ethanol mother liquors and chromatography of the residue (*vide supra*) gave 5 mg (3%) of **23**, m.p. 181–183°: n.m.r. (100 MHz, $CDCl_3$) τ 2.10–2.77 (m, 6.07 ± 0.11 H, aromatic), 3.96 (s, 0.96 ± 0.08 H, H-7), 5.79 (d, 100 H, H-5, J_{15} = 6.5 Hz), 6.47 (t, 1.02 ± 0.07 H, H-1, J_{12} = J_{15} = 6.5 Hz), 6.75 (d, 1.06 ± 0.08 H, H-2, J_{12} = 6.5 Hz), and 7.00–7.50 (no discernible signal, 0.10 ± 0.05 H, residual H-8). Hydrogen distribution required for route *i* (Scheme 5): aromatic, 6.0 H; H-7, 1.00 H; H-5, 1.00 H; H-1, 1.00 H; H-2, 1.00 H; H-8, 0.06 ± 0.02 H.

*Sensitized Irradiation of 5-Deuterocyanobarrelene (**12**)*

A solution of 172.3 mg (0.75 mmol) of **12** and 771.1 mg (4.23 mmol) of benzophenone in 35 ml of benzene was photolyzed with 343 nm light for 1.2 h. The products were isolated as described for the sensitized irradiation of **5** (*vide supra*). Recrystallization of the contents of band two from ethanol twice gave 111.3 mg (65%) of **21**, m.p. 205–207°: n.m.r. (60 MHz, $CDCl_3$) τ 2.08–2.70 (m, 6.08 ± 0.08 H, aromatic), 4.33 (d, 0.99 ± 0.07 H, H-6, J_{56} = 2.5 Hz), 4.60–5.00 (no discernible signal, 0.05 ± 0.03 H, residual H-7), 5.63 (d, 1.00 H, H-5, J_{56} = 2.5 Hz), 6.32 (d, 1.05 ± 0.09 H, H-2, J_{28} = 7.0 Hz), and 6.73 (d, 1.01 ± 0.12 H, H-8, J_{28} = 7.0 Hz).

Concentration of the ethanol mother liquors and chromatography of the residue (*vide supra*) gave 5 mg (3%) of **23**, m.p. 180–183°: n.m.r. (100 MHz, $CDCl_3$) τ 2.10–2.77 (m, 6.11 ± 0.10 H, aromatic), 3.96 (s, 1.01 ± 0.08 H, H-7), 5.79 (d, 1.00 H, H-5, J_{15} = 6.5 Hz), 6.47 (t, 0.99 ± 0.06 H, H-1, J_{12} = J_{15} = 6.5 Hz), 6.75 (d, 1.09 ± 0.09 H, H-2, J_{12} = 6.5 Hz), and 7.00–7.50 (no discernible signal, 0.06 ± 0.04 H, residual H-8).

*4- and 6-Deuterocyanobarrelene Mixture **26***

Mixture **26**, m.p. 178–180°, was obtained in 1% overall yield (based on naphthyne precursor) using essentially the same method as that used to prepare **12** (*vide supra*), except that *p*-dibromobenzene was replaced by *m*-dibromobenzene in the naphthyne addition stage: n.m.r. (60 MHz, $CDCl_3$) τ 2.13–2.76 (m, 7.00 H, aromatic and H-3), 3.08 (m, 1.53 ± 0.04 H, H-5 and residual H-6), and 4.87 (m, 154 ± 0.03 H, H-1 and residual H-4), *i.e.*, 93 ± 7% d_1 content (assuming 0% d_1 content in aromatics and H-3), distributed at C-4 (46 ± 3%) and C-6 (47 ± 4%).

*Direct Photolysis of 4- and 6-Deuterobarrelene Mixture **26***

A solution of 48.1 mg (0.21 mmol) of **26** in 35 ml of benzene was photolyzed for 3 h with 313 nm light. Chromatography and recrystallization of band three from ethanol (*vide supra*) gave 16.3 mg (34%) of the deuterated 1-cyanosemibullvalene material **28**, m.p. 205–207°: n.m.r. (100 MHz, $CDCl_3$) τ 2.13–2.69 (m, 5.99 ± 0.03 H, aromatic), 4.33 (*A*BM q, 0.53 ± 0.02 H, H-6, J_{56} = 2.5 Hz, J_{67} = 5.0 Hz), 4.78 (m, 1.01 ± 0.01 H, H-7), 5.63 (br s, 1.00 H, H-5), 6.31 (d, 0.55 ± 0.02 H, H-2, J_{28} = 7.0 Hz), and 6.73 (m, 1.00 ± 0.02 H, H-8). Hydrogen distribution required for route *i* (Scheme 6): aromatic, 6.00 H; H-6, 0.53 ± 0.04 H; H-7, 1.00 H; H-5, 1.00 H; H-2, 0.54 ± 0.03 H; H-8, 1.00 H.

*Sensitized Photolysis of 4- and 6-Deuterobarrelene Mixture **26***

A solution of 81.6 mg (0.35 mmol) of **26** and 418.5 mg (2.30 mmol) of benzophenone in 35 ml of benzene was irradiated for 0.5 h with 343 nm light. The deuterated 1-cyanosemibullvalene material (**28**), 26.0 mg (32%), m.p. 205–207°, was isolated from the photolysate via chromatography and ethanol recrystallization (*vide supra*): n.m.r. 100 MHz, $CDCl_3$) τ 2.13–2.69 (m, 6.02 ± 0.04 H, aromatic), 4.33 (*A*BM q, 0.52 ± 0.03 H, H-6, J_{56} = 2.5 Hz, J_{67} = 5.0 Hz), 4.78 (m, 0.99 ± 0.02 H, H-7), 5.63 (br s, 1.00 H, H-5), 6.31 (d, 0.56 ± 0.02 H, H-2, J_{28} = 7.0 Hz), and 6.73 (m, 0.99 ± 0.03 H, H-8).

The authors thank the Spectroscopic Services Laboratory of the University of Alberta for the 100-MHz n.m.r. (Dr. T. Nakashima) and mass spectra (Dr. A. Hogg), and gratefully acknowledge the financial support of the National Research Council of Canada, and the University of Lethbridge Research Committee.

Aggregation of *p*-Nitrophenyl Alkanoates in Aqueous Solution. Limitations on Their Use as Substrates in Enzyme Model Studies

J. PETER GUTHRIE

Department of Chemistry, University of Western Ontario, London, Ontario

Received April 18, 1973

p-Nitrophenyl alkanoates are aggregated at extremely low concentrations in aqueous solution. Second-order rate constants for imidazole or hydroxide catalyzed hydrolysis are independent of ester concentration up to a critical concentration of ester, and then decrease with increasing ester concentration. The critical concentrations at 25 °C are: *p*-nitrophenyl hexanoate, 1×10^{-4} *M*; octanoate, 9.6×10^{-6} *M*; decanoate, 1.2×10^{-6} *M*. For the dodecanoate ester, the critical concentration was estimated as *ca.* 10^{-7} *M*. Addition of 10% methanol causes only a modest increase in the critical concentration. The critical concentration probably represents the solubility limit of the ester. The rate constants for the hydrolysis of the longer chain esters evaluated here are significantly larger than those in the literature, suggesting that the earlier work was done using conditions where the esters were aggregated.

Les alcanoates de *p*-nitrophényle donnent lieu à des agrégations en solution aqueuse à des concentrations extrèmement faibles. Les constantes de vitesse du deuxième ordre de l'hydrolyse, catalysée par l'imidazole ou l'hydroxyde, sont indépendantes de la concentration en ester jusqu'à une valeur critique puis décroissent lorsque la concentration en ester croît. Les concentrations critiques à 25 °C sont: pour l'hexanoate de *p*-nitrophényle 1×10^{-4} *M*; octanoate 9.6×10^{-6} *M*, décanoate 1.2×10^{-6} *M*. Pour l'ester dodécanoique la concentration critique a été estimée à *ca.* 10^{-7} *M*. L'addition de 10% de méthanol provoque seulement un accroissement modeste de la concentration critique. Celle-ci représente probablement la solubilité limite de l'ester. Les constantes de vitesse de l'hydrolyse des esters des chaînes plus longues calculées ici sont nettement plus grandes que celles de la littérature laissant penser que les travaux précédents aient été effectués dans des conditions où les esters s'agrégeaient.

Various recent studies (1–4) of enzyme models have used *p*-nitrophenyl alkanoates as substrates in the hope that hydrophobic binding of the alkyl group of the ester to the enzyme model compound would lead to an increased effective concentration of the reactive groups, manifesting itself as a rate enhancement. These substrates appeared attractive because of the ease with which hydrolysis can be followed, their simplicity of structure, and their commercial availability. However, it has not been recognized sufficiently that these compounds have *very* low solubility in water and that a major fraction of a long chain *p*-nitrophenyl alkanoate can be aggregated without observable turbidity. The studies reported in this paper characterize the aqueous solution behavior of the hexanoate, octanoate, and decanoate esters. A preliminary account of this work has been published (5).

Results and Discussion

In Table 1[1] and Fig. 1 are shown the results obtained for the imidazole catalyzed hydrolysis of *p*-nitrophenyl acetate, hexanoate, octanoate, and decanoate at 0.1 *M* ionic strength. For the decanoate ester it is difficult to obtain an accurate value for the limiting rate constant for monomeric ester because of the very small absorbance change at the low concentrations involved. For rates where the small absorbance change is a major source of error, error bounds are shown.

In Table 2[1] and Fig. 2 are shown the results for similar studies of the hydroxide catalyzed hydrolysis. Most of these experiments were done at constant buffer concentration, since the feature of interest was the dependence of the rate constant on the concentration of ester, rather than in the rate constants themselves. After this dependence had been established, sets of experiments at differing buffer concentrations permitted extrapolation to zero buffer, and evaluation of the true rate constant for the hydroxide ion reaction of the monomeric ester.

Buffer catalysis causes increases in the observed rate constants (at 0.03 *M* total carbonate buffer) of 20–25% except for the acetate

[1]Tables 1 and 2 are available, at a nominal charge, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2.

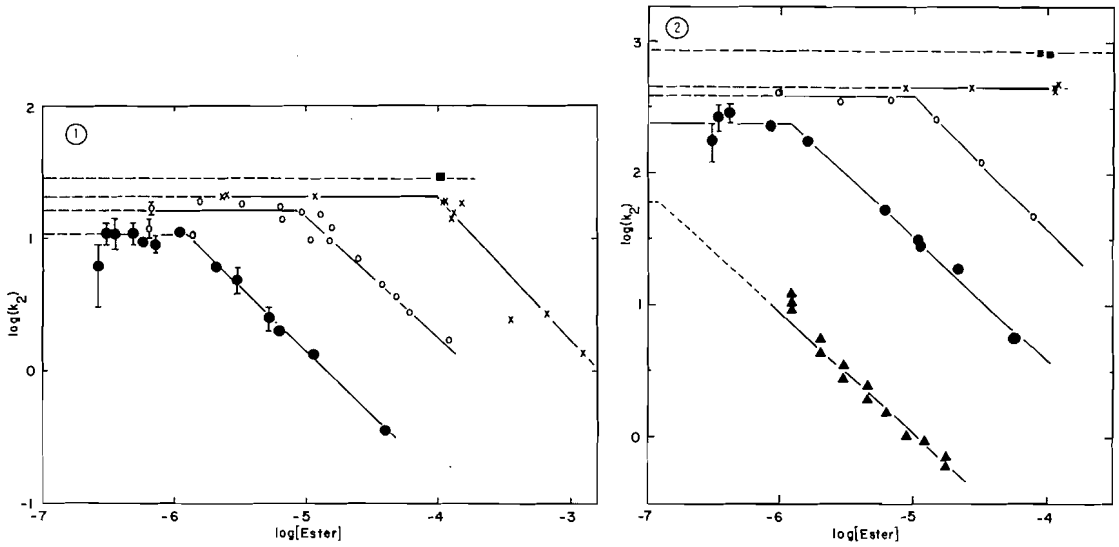

FIG. 1. Reactions of *p*-nitrophenyl acetate (■), hexanoate (X), octanoate (○), and decanoate (●) with imidazole. Dependence of the logarithm of the second-order rate constant on the logarithm of the ester concentration. Critical concentrations are: hexanoate, 1×10^{-4} *M*; octanoate, 9.6×10^{-6} *M*; and decanoate, 1.3×10^{-6} *M*.

FIG. 2. Reactions of *p*-nitrophenyl acetate (■), hexanoate (X), octanoate (○), decanoate (●), and dodecanoate (▲) (data for dodecanoate from ref. 6) with hydroxide ion. Dependence of the logarithms of the second-order rate constant on the logarithm of the ester concentration. Critical concentrations are: octanoate, 1.0×10^{-5} *M*; decanoate, 1.2×10^{-6} *M*; and dodecanoate (estimated, see text), 1.2×10^{-7} *M*.

ester, where the increase is 40%. The rate constants for *p*-nitrophenyl dodecanoate shown on Fig. 2 are from a study by Menger and Portnoy (6) and were measured in 0.1 *N* sodium hydroxide solution. These data show the trend anticipated on the basis of this work and extrapolation (*vide infra*) suggests that the dodecanoate ester will only be monomeric in aqueous solution at concentrations at or below 10^{-7} *M*.

In Fig. 3 are shown plots of log k_2 *vs.* number of carbon atoms in the alkanoate for the reactions of imidazole and hydroxide ion with the monomeric esters. Within experimental error these plots appear linear. This progressive decline in the rate constant seems somewhat surprising since there can be no electrostatic effect on increasing the length of the chain from 6 to 10 carbons and there would be no steric effect if the alkyl chain were in an extended conformation. Bruice and co-workers (7), however, have pointed out that long alkyl chains are expected (8) to be coiled up in aqueous solution and so could have a larger steric bulk. In addition it seems reasonable that for the longer chain esters the alkyl chain could come into contact with the aryl portion of the ester. Examination of space filling models suggests that this is feasible. A molecule coiled back on itself in this manner should have an effective "solvent" near the ester linkage which is much less polar than the bulk solvent and so less favorable to nucleophilic attack on the ester.

Figure 4 shows a plot of the logarithms of the "critical concentrations" for the esters studied here *vs.* $\Sigma\pi$, the Hansch hydrophobicity parameter (9). These points fall on a straight line and furthermore lie close to the empirical line relating *solubility* to $\Sigma\pi$ (10). Extrapolation of the observed correlation permits estimation of the critical concentration for *p*-nitrophenyl dodecanoate; the value so obtained is 1.2×10^{-7} *M* and this value was used in constructing Fig. 2. This concentration falls below the limits imposed by most spectrophotometers, even with 10 cm cells. Thus in aqueous or predominantly aqueous solutions, *p*-nitrophenyl dodecanoate cannot be employed as a monomeric substrate.

The behavior of *p*-nitrophenyl octanoate was studied in 10% methanol – 90% water, since it has been suggested (4) that 10% methanol will abolish aggregation of *p*-nitrophenyl alkanoates. The results (Table 1[1] and Fig. 2 of ref. 5) clearly

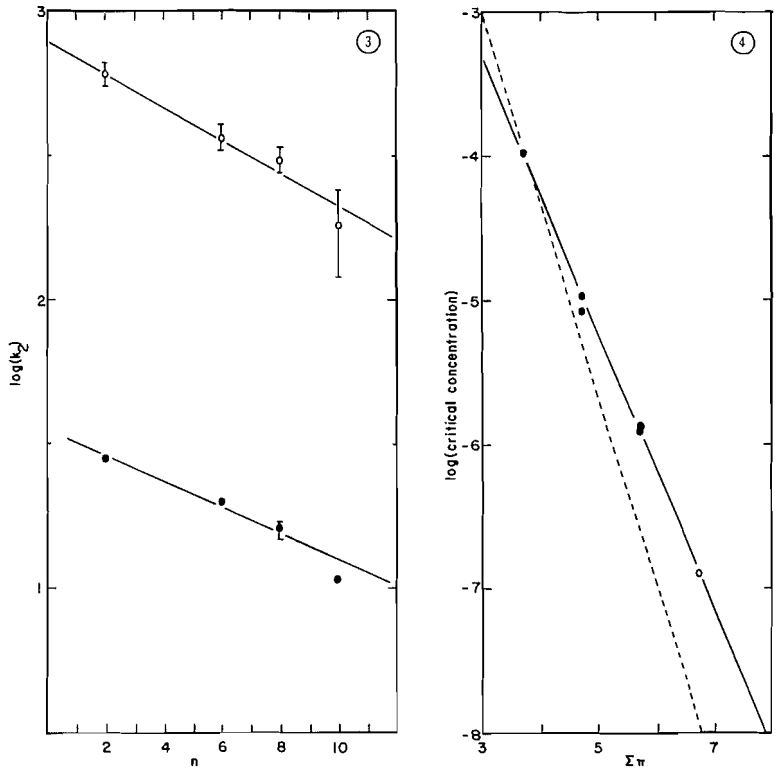

FIG. 3. Relation between rate constants and number of carbons in the alkanoate (n) for reactions of p-nitrophenyl alkanoates with hydroxide (○) and imidazole (●).

FIG. 4. Relation between critical concentration and the Hansch Σπ value. Experimental points (●); point estimated for p-nitrophenyl dodecanoate (○). Σπ values were calculated from values in ref. 9, using log P = 1.49 for C_6H_5OAc, $\pi = 0.24$ for $—NO_2$ (using the value from $O_2N—C_6H_4—OCH_2COOH$, since this is the most nearly analogous compound from the set Hansch has studied), and $\pi = 0.50$ for $—CH_2$. The solid line was drawn through the experimental points; the dashed line was calculated from the empirical equation relating solubility and Σπ (set 11 of ref. 10).

show that although 10% methanol does increase the critical concentration (to 1.6×10^{-5} M) the effect is small and does not alter the qualitative pattern.

Initially it was believed that micelle formation was responsible for the kinetic behavior reported above. However, the low hydrophilicity of the p-nitrophenyl ester moiety is not in accord with this concept, since a stable micelle requires a molecule with both a hydrophobic and a hydrophilic end (11). The nitro group of a p-nitrophenyl ester is probably hydrophobic, judging by the most closely analogous π values which are available (9). The ester group is mildly hydrophilic, but is between the hydrophobic alkyl and aryl groups so that it is not likely that it could be exposed to water while the hydrophobic groups were removed from water. All the behavior of these alkanoates is consistent with the critical concentration being the solubility limit. In particular, the close correspondence between the observed critical concentrations and the solubilities predicted by the empirical correlation of Hansch *et al.* (10) very strongly supports this view. This interpretation is reinforced by phenomena observed when the critical concentration for p-nitrophenyl hexanoate was evaluated. At concentrations above the critical concentration, the solutions were not only turbid but showed visible though minute droplets several minutes after reaction was initiated. Obviously no great significance can be attached to rate constants measured under such disreputable conditions; nevertheless the initial rate constants so obtained gave qualitatively the same behavior when log k_2 was plotted as a function of log [ester] as was shown by the larger esters at lower concentrations. It should be

[e]Ref. 3, 0.99% (v/v) acetone; relative rate constants for reaction with *N*-ethyl imidazole; k_2 for the acetate was 24 M^{-1} min^{-1}.
[f]Ref. 4, p*H* 6.80 phosphate buffer, μ = 0.088, with 1.75% acetonitrile, 10.55% methanol. Rate constants for reaction with $(Me_2CHCH_2)_2NCH_2CON(Me)OH$, relative to that for the acetate, 0.693 M^{-1} min^{-1}.
[g]Ref. 12, 1.6% (v/v) acetonitrile; k_2 for the acetate was 620 M^{-1} min^{-1}.
[h]Estimated value; see text.

noted that *p*-nitrophenyl octanoate showed visible turbidity at concentrations well above the critical concentration but not at concentrations just above this limit. *p*-Nitrophenyl decanoate showed no observable turbidity for a wider concentration range above its critical concentration. Thus clear solutions may still have most of the solute present in aggregates if the solute is a large hydrophobic compound.

In Table 3 the results of this investigation are summarized and compared with other work. It is noteworthy that the relative rates for *p*-nitrophenyl octanoate and decanoate reported here are larger than those reported previously. This implies that in the earlier work the conditions were such that these esters were aggregated. Included in Table 3 is an estimated rate constant for *p*-nitrophenyl dodecanoate, obtained using the critical concentration estimated from Fig. 4. Our value for k_{OH^-} for *p*-nitrophenyl octanoate does not agree with that of Marshall and Akgün (12), who were working at concentrations low enough that the ester should have been monomeric; we do not know the reason for this discrepancy.

Jones and Gordon (13, 14) independently developed an analogous kinetic method for determining whether a compound is aggregated and have also found that with very low total concentrations (*ca.* 1×10^{-6} *M*) there can be extensive aggregation without detectable turbidity (13).

In conclusion, the results reported above show that with water as solvent, long chain *p*-nitrophenyl alkanoates are monomeric only at very low concentration. By implication *any* neutral long chain compound will be aggregated at very low concentrations and it is necessary to perform stringent control experiments before any such compounds can be used in studies where 1:1 substrate–catalyst complexes are desired. Furthermore, although we find a decrease in the rate of reaction of the esters with increasing chain length, this decrease is much less than has been reported in various investigations where these compounds have been used as substrates for enzyme models. Accordingly it seems necessary to consider carefully the question of whether 1:1 complexes were being studied in these earlier investigations or whether the phenomenon involved was one of catalyst molecule interacting with a droplet of substrate.

The kinetic method for determining solubility should be of considerable generality and for favorable cases will permit determination of the solubility of *extremely* insoluble compounds where more traditional methods would be very difficult to employ.

Experimental

p-Nitrophenyl alkanoates (Sigma Chemical Co.) were used without further purification and stored in a freezer over desiccant. Purity was checked by measuring initial and final color yield at 400 nm in reaction with *p*H 10 buffer. Imidazole was recrystallized three times (acetone–hexane) and dried *in vacuo* before use. Inorganic reagents were reagent grade. Glass distilled water was used to make up solutions. Acetonitrile (Eastman Spectro grade) was passed through a column of grade 1 acid alumina to remove nucleophilic contaminants.

Kinetics were measured using a Gilford model 240 spectrophotometer; temperature was regulated (25.0 ± 0.1 °C) with a Braun Thermomix 11 circulator. For dilute solution 10 cm cells were used with a Gilford Model 2470 sample chamber. Stock solutions of esters were prepared in acetonitrile. Reaction was initiated by adding a suitable portion of ester solution (Hamilton Syringe) to thermally equilibrated buffer, containing acetonitrile if needed to maintain constant final acetonitrile concentration. Mixing was accomplished by repeated inversion of the cell. Points were taken at suitable intervals, normally quite frequently for the first half-life, then at least four per half-life for the next 3 or 4 half-lives of reaction. Infinity points were taken after 10 half-lives. For runs at concentrations below the critical concentration, first-order plots were used to evaluate pseudo first-order rate constants. For runs at higher concentration initial rates were used, since marked deviations from first-order behavior were observed. At concentrations well above the critical concentration, first-order plots often showed an initial rather rapid reaction slowing down after a few minutes, then a long nearly linear period extending for 1 or more half-lives, and then an increase in apparent rate of reaction. This is interpreted in terms of an initial metastable state where the aggregation is not completely established, then a period of hydrolysis at a rate dependent on the degree of aggregation, and finally, as the concentration of ester decreased, an increase in the rate of reaction as the aggregate is dispersed. When plots of this type were observed the rate constant was calculated leaving out data from the first 4 min of reaction and using only data from the linear region before the final rate increase occurred. Best lines were fitted by inspection; for runs where the total optical density change was small, error limits were estimated taking the error in absorbance as 0.002, so that the error in $A_\infty - A_0$ is 0.004. These limits were taken account of in drawing the best line and were used to estimate limits of error on the rate constant by drawing the extreme lines which would fit the data. p*H* values were measured at the end of the run (Radiometer p*H* Meter 25SE with a GK301C combined electrode). Second-order rate constants for imidazole reactions were calculated by dividing the observed pseuso first-order rate constant by the total concentration of imidazole. Hydroxide ion activity was calculated from the p*H* measurements and used to calculate the apparent second-order rate constants for the hydroxide ion reactions. For these reactions carbonate buffer was present so that the pseudo first-order rate constant will include a small contribution from buffer catalysis. For each ester a buffer dilution series was done at an ester concentration lower than the critical concentration so that the true hydroxide ion rate constant for monomeric ester could be evaluated.

Reaction of an Aryl Thiocyanate with *p*-Nitrothiophenoxide Ion and with Thioacetate Ion; Consequences of Nucleophilic Displacement at Sulfur

MARGARET M. KAYSER AND MARTIN S. GIBSON
Department of Chemistry, Brock University, St. Catharines, Ontario

Received June 1, 1973

Reaction of *p*-acetamidophenyl thiocyanate (Ar_1SCN) with *p*-nitrothiophenol (Ar_2SH) in presence of triethylamine gives the diaryl disulfides Ar_1SSAr_1, Ar_1SSAr_2, and Ar_2SSAr_2. Reaction of Ar_1SCN with potassium thioacetate gives Ar_1SCOMe and Ar_1SSAr_1. The role of cyanide and arylmercaptide ions in equilibration of disulfides is indicated.

La réaction du thiocyanate de *p*-acétamidophényle (Ar_1SCN) avec le *p*-nitrothiophénol (Ar_2SH) en présence de triéthylamine donne les disulfures diarylés Ar_1SSAr_1, Ar_1SSAr_2 et Ar_2SSAr_2. La réaction du Ar_1SCN avec le thioacétate de potassium donne le Ar_1SCOMe et le Ar_1SSAr_1. Le rôle des ions cyanures et arylthiolates en équilibre avec les disulfures est indiqué. [Traduit par le journal]

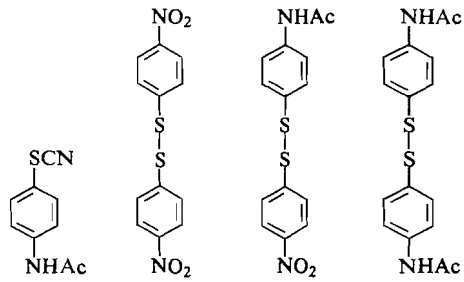
In connection with other work in the 4*H*-1,3,4-benzothiadiazine series (1), we noted that the reactivity of aromatic thiocyanato groups towards sulfur nucleophiles such as thioacetate ion and *p*-nitrothiophenoxide ion was sufficient to vitiate the synthetic work then in hand.[1] We have accordingly examined the corresponding reactions of *p*-acetamidophenyl thiocyanate (**1**) as models for the processes involved.

p-Acetamidophenyl thiocyanate (Ar_1SCN) was treated under nitrogen with *p*-nitrothiophenol (Ar_2SH) in the presence of triethylamine. Some gas evolution was noted (by inference hydrogen cyanide) and a precipitate began to form. This precipitate readily yielded 4,4-dinitrodiphenyl disulfide (**2**),[1] identical with a sample prepared by aerial oxidation of *p*-nitrothiophenol in alkaline solution, raising the question of a similar oxidative origin of **2** from the reaction under investigation. However, this seemed most unlikely in view of the consistency of yields of **2** produced under rigorously anaerobic conditions. Careful examination of the reaction mixture indicated the presence of two other products which were separated with difficulty and identified as the diaryl disulfides **3** and **4** by mass spectrometry and in the case of **4** by correlation with one of the products from the reaction of **1** with thioacetate ion (*vide infra*).

[1]P. D. Callaghan, A. J. Elliott, and M. S. Gibson, unpublished results.



1 **2** **3** **4**

Ar_1 = *p*-$CH_3CONHC_6H_4$; Ar_2 = *p*-$NO_2C_6H_4$

These results may be rationalized in terms of known general reactions (2, 3). *p*-Nitrothiophenoxide ion (Ar_2S^-) displaces cyanide ion from **1** giving the unsymmetrical disulfide **3**. Under alkaline conditions, disulfide **3** may revert by reaction with cyanide ion to starting materials or alternatively proceed to *p*-nitrophenyl thiocyanate (Ar_2SCN) and *p*-acetamidothiophenoxide ion (Ar_1S^-).

[1] $Ar_2S^- + Ar_1S{-}C{\equiv}N \rightleftharpoons Ar_2S{-}SAr_1 + \bar{C}N \rightleftharpoons Ar_2SCN + Ar_1S^-$

The ingredients are now present for the establishment of further equilibria, involving formation of the symmetrical diaryl disulfides **2** and **4** (eqs. 2–5).

[2] $Ar_1S^- + Ar_1SCN \rightleftharpoons Ar_1SSAr_1 + \bar{C}N$

[3] $Ar_2S^- + Ar_2SCN \rightleftharpoons Ar_2SSAr_2 + \bar{C}N$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

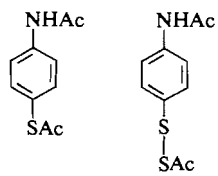
[4] $Ar_1S^- + Ar_2SSAr_2 \rightleftharpoons Ar_1SSAr_2 + Ar_2S^-$

[5] $Ar_1S^- + Ar_1SSAr_2 \rightleftharpoons Ar_1SSAr_1 + Ar_2S^-$

The sparing solubility of **2** under the reaction conditions constrains these equilibria such that almost all of the *p*-nitrothiophenol employed is recovered as the symmetrical disulfide **2**. It may be noted that, although nucleophilic displacement at sulfur is clearly implicated in these mechanisms, there is another possible contributing mechanism to the overall equilibrium indicated in [1], namely [6]; process 6 alone, however, is insufficient to provide the observed products.

[6] $Ar_1S{-}C{\equiv}N \quad Ar_1S \quad Ar_1S^- \rightleftharpoons C{=}N^- \rightleftharpoons$; $Ar_2S^- \quad Ar_2S \quad Ar_2{-}S{-}C{\equiv}N$

The reaction of *p*-acetamidophenyl thiocyanate (**1**) with potassium thioacetate in boiling acetonitrile was examined next. This gave *N*,*S*-diacetyl-*p*-aminothiophenol (**5**), with the disulfide **4** as minor product.



5 **6**

These observations may be accommodated by considerations similar to those above. Nucleophilic displacement of cyanide ion, possibly reversible, by thioacetate ion from **1** would give *p*-acetamidophenyl acetyl disulfide (**6**). Subsequent reaction of **6** with cyanide ion would regenerate the starting materials or, alternatively, lead to acetyl thiocyanate and *p*-acetamidothiophenoxide ion. *p*-Acetamidothiophenoxide ion (Ar_1S^-) may now displace cyanide ion from **1** to give **4** (eq. 2) or thiocyanate ion from the intermediate acetyl thiocyanate to give **5**.

[7] $CH_3COS^- + Ar_1S{-}C{\equiv}N \rightleftharpoons CH_3COS{-}SAr_1 + \bar{C}N$

$\rightleftharpoons CH_3COSCN + Ar_1S^-$

[8] $Ar_1S^- + CH_3COSCN \rightleftharpoons Ar_1SCOCH_3 + \bar{S}CN$

As in the reaction of **1** with *p*-nitrothiophenoxide ion, there is another possible contributing mechanism parallel to that formulated in eq. 6, namely [9].

[9] $Ar_1S{-}C{\equiv}N \quad Ar_1S \quad Ar_1S^- \rightleftharpoons C{=}N^- \rightleftharpoons$; $AcS^- \quad AcS \quad AcS{-}C{\equiv}N$

The possibility that **5** might arise by direct nucleophilic displacement of thiocyanate ion by thioacetate ion is considered unlikely since the *p*-acetamido substituent would contribute little to stabilization of the negative charge on the transition state for such a process.

Experimental

General Methods

General procedures follow those described previously (1). The experiments involving **1** are representative of a number of experiments conducted under slightly differing conditions, but with essentially similar results.

Mass spectra were determined with an AEI-MS30 double-beam double-focusing mass spectrometer.

p-Acetamidophenyl Thiocyanate (1)

Aniline was treated with bromine and potassium thiocyanate to give *p*-aminophenyl thiocyanate (4), which was then acetylated (acetic anhydride – sodium acetate) to give **1**. After crystallization from aqueous methanol, **1** had m.p. 186–187° (lit. (5) m.p. 189°).

Reaction of 1 with p-Nitrothiophenoxide Ion

Compound **1** (1.8 g), *p*-nitrothiophenol (1.4 g), and triethylamine (1 ml) were stirred in ethanol (30 ml) for 2 h. The reaction mixture was flushed continually with nitrogen; some gas evolution was noted (by inference HCN). The yellow solid was collected and combined with further solid material obtained by diluting the filtrate with water. The dried solid (2.7 g) had m.p. 150–155°. The mass spectrum showed peaks at *m/e* 308(M^+, **2**), 320(M^+, **3**) and 332(M^+, **4**). T.l.c. (silica gel) revealed one spot assignable to **2** and a second (elongated) spot assignable to **3** and **4**.

The crude reaction product was chromatographed on Florisil using benzene followed by benzene–ether mixtures as eluants. First eluted was compound **2** (1.3 g) which, after crystallization from ethanol, had m.p. 178–179° (mixed m.p. 178–179°); mass spectrum *m/e* 308(M^+), 292, 278, 276, 262, 232, 215, 171, 155 ($NO_2C_6H_4SH$), 154, 139, 125, and 124.

Later eluates contained residual traces of **2** together with poorly separated mixtures of **3** and **4**. These fractions were combined and evaporated and the resulting material was chromatographed again on Florisil. A small amount of **2** was followed by **3** admixed with **4** and in turn by **4**.

The fractions rich in **3** were combined and evaporated. Three crystallizations from ethanol gave almost pure **3**, m.p. 140°; mass spectrum *m/e* 320(M^+), 303, 290, 288, 278, 267, 246, 236, 192, 167 ($AcNHC_6H_4SH$), 166, 155 ($NO_2C_6H_4SH$), 150, 149, 139, 125, and 124.

The fractions rich in **4** were similarly treated and after three crystallizations from ethanol gave **4**, m.p. 182–183° (lit. (6) for the α-form, m.p. 183°); mass spectrum *m/e* 332(M^+), 300, 290, 198, 167 ($AcNHC_6H_4SH$), 166, 156, 150, 149, 125, and 124.

*Reaction of **1** with Thioacetate Ion*

A mixture of **1** (2.5 g) and potassium thioacetate (1.5 g) in acetonitrile (80 ml) was boiled under reflux for 4 h and then poured into ice-cold water (350 ml) and kept overnight at 0°. The precipitated solid was collected, washed with water, and dried. The dried solid (1.8 g) had m.p. 130–135°. The mass spectrum showed peaks at *m/e* 209(M^+, **5**), 241(M^+, **6**), and 332(M^+, **4**); the peak at *m/e* 241 provides support for the involvement of **6**, although **6** was not isolated in the subsequent procedure.

Crystallization from aqueous ethanol gave a crystalline fraction (A) containing **5** and a small amount of starting material **1** (t.l.c.); concentration of the mother liquor gave a second fraction (B) containing **5** and **4** (t.l.c.). Fraction A, after two crystallizations from aqueous ethanol, gave **5** (1.1 g), m.p. 143–144° (lit. (7) m.p. 143–144°); mass spectrum *m/e* 209(M^+), 167, and 125; n.m.r. ($CDCl_3$), methyl proton signals of equal intensity at δ 2.42 (s) and 2.12 (s).

Fraction B, after two crystallizations from ethanol, gave a few mg of **4**, m.p. and mixed m.p. (with above sample) 182–183°. The mass spectrum was identical with that of the above sample.

We thank the National Research Council of Canada for financial support.

Some Reactions of 3β-Mesyloxycholestane-5α,6β-diol and Cholest-2-ene-5α,6β-diol Acetates

P. TSUI AND G. JUST

Department of Chemistry, McGill University, Montreal, Quebec

Received June 22, 1971[1]

Reaction of 3β-mesyloxycholestane-5α,6β-diol 6-monoacetate (**1***e*) with potassium *t*-butoxide gave the 3α,5α-oxycholestan-6β-ol (**4***a*), which rearranged further to 5β,6β-epoxycholestan-3α-ol (**5**). Treatment of **1***c* with triethylamine gave cholest-2-ene-5α,6β-diol diacetate (**7***a*), whereas heating diacetate **1***c* in pyridine–dimethylformamide gave cholestan-3α,5α,6β-triol 3,6-diacetate (**2***a*). Cholest-2-ene-5α,6β-diol diacetate (**7***a*) reacted with *m*-chloroperbenzoic acid to give the α-epoxide **10**. Reaction of **7***a* with aqueous *N*-bromosuccinimide gave 2β-bromo-3α-hydroxy-5α,6β-diacetoxycholestane (**8**). Both epoxide **10** and bromohydrin **8** rearranged in acidic media to the tetrahydrofuran **11**.

La réaction de l'acétate-6 de mésyl-3β cholestane-5α diol-6β (**1***e*) avec le *t*-butylate de potassium, donne l'oxy-5α,3α cholestanol-6β (**4***a*) qui se réarrange ultérieurement en époxy-5β,6β cholestanol-3α (**5**). Le traitement de (**1***c*) avec la triéthylamine, conduit au diacétate de cholestène-2,5α diol-6β (**7***a*), tandis que le chauffage du diacétate (**1***c*) dans un mélange pyridine–diméthylformamide conduit au diacétate-6,3 de cholestanetriol-3α,5α,6β (**2***a*). Le diacétate de cholestène-2,5α diol-6β (**7***a*) réagit avec l'acide *m*-chloroperbenzoique pour donner l'époxyde-α (**10**). La réaction de (**7***a*) avec une solution aqueuse de *N*-bromosuccinimide donne le bromo-2β hydroxy-3α,5α diacétonycholestane-6β (**8**). L'époxyde (**10**) et la bromhydrine (**8**) se réarrangent tous deux en milieu acide en tétrahydrofuranne (**11**).

Can. J. Chem., **51**, 3502 (1973)

In connection with some other work, we required a substantial amount of 2β-hydroxy-3α-bromo-5α,6β-diacetoxycholestane. An obvious precursor for such a compound is the readily available cholestane-3β,5α,6β-triol, which can be obtained by oxidation of cholesterol with hydrogen peroxide in formic acid, followed by hydrolysis (1). Acetylation gave the known triacetate **1***a* (2), which was transformed to the mesylate **1***c* via triol diacetate **1***b* (3). This mesylate was heated under reflux in dimethylformamide containing pyridine in order to form the olefin **7***a*. The product obtained, however, was a cholestanetriol diacetate to which we assigned structure **2***a* (Scheme 1). Partial hydrolysis of this diacetate gave triol monoacetate **2***b*. Chromic acid oxidation of both triol monoacetates **2***b* and **1***d* (4) gave the ketone **3**. Since the stereochemistry at position 3 of alcohol **1***d* is known, the stereochemistry of the hydroxy function of **2***b* must be as depicted.

The new compound **2***a* is most likely formed by participation of the 5α-acetate group during the solvolytic reaction. The intermediate acetoxonium ion is then hydrolyzed to give exclusively the 3α-acetate **2***a*.

Since the 5α-acetoxy group seemed to interfere in the desired elimination reaction, we next prepared the 5α-hydroxy-3β-mesylate **1***e*. The compound could be readily obtained by partial hydrolysis of the known cholestan-3β,5α,6β-triol 3,6-diacetate **1***f* (4). Mesylation of the monoacetate **1***d* gave the desired mesylate **1***e* in good yield. Treatment of **1***e* with pyridine in dimethylformamide gave a low yield of the desired olefin **7**. Treatment of **1***e* with potassium *t*-butoxide in *t*-butanol gave two isomeric ethers **4***a* and **5**. Ether **4***a* was an intermediate in the formation of **5**, since it could be converted to **5** by submitting it to the reaction conditions.

Oxetane **4***a* (ν 3420 cm^{-1}, *m/e* 402) exhibited peaks in the n.m.r. at 4.6 p.p.m. (3β-H) and 4.0 p.p.m. (6α-H, $w_{1/2}$ 6 Hz) the latter signal being shifted to 5.17 p.p.m. upon acetylation. The two protons at C-4 appeared as a four-line system centered at 2.65 p.p.m. in both oxetane **4***a* and its acetate **4***b*. Treatment of **4***b* with methanesulfonic acid in ether regenerated the mesylate **1***e*, thereby confirming the structure of oxetane **4***a*.

Epoxide **5** had an i.r. and mass spectrum very similar to that of its 3-epimer **5***a*, which was obtained by treatment of triacetate **1***a* with potassium hydroxide in ethanol (5). Both **5** and **5***a* gave **6** upon Sarett oxidation (6).

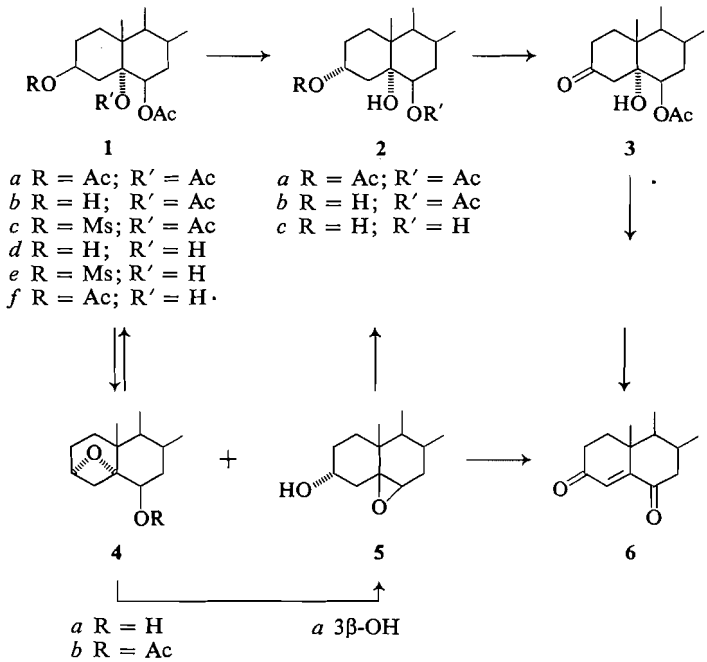

SCHEME 1

The n.m.r. spectra of both **5** and **5***a* were identical except for the position of the 3-hydrogen, which appeared in **5** as a signal at 4.25 p.p.m. ($w_{1/2}$ 10 Hz) and in **5***a* at 3.7 p.p.m. ($w_{1/2} \sim$ 18–20 Hz). This indicated that the hydroxy group in **5** is axial, and its 3-epimer **5***a* equatorial. There is no doubt that the 3-hydroxy group in **5** is α, since treatment of **5** with acid gave the known triol **2***c* (1). Equally, there is no doubt about the stereochemistry of the 3β-hydroxy group in **5***a*, since it was derived from cholesterol by a simple sequence. The 5β,6β-epoxide in **5** and **5***a* must therefore impose on ring B of the steroid molecule a boat-like conformation.

The elimination of methanesulfonic acid was finally achieved upon heating mesylate **1***e* with triethylamine to give **7** (17) in approximately 70% yield. Monoacetate **7** could be converted to diacetate **7***a* by heating **7** with acetyl chloride and *N*,*N*-dimethylaniline (7).

The desired 3α-bromocholestan-2β,5α,6β-triol-5,6-diacetate can in principle be obtained by epoxidation of olefin **7***a*, followed by treatment of the epoxide with hydrobromic acid, if the preferential side of the electrophilic attack is β, or by the action of hypobromous acid on olefin **7***a*, if the preferential side of attack is α (8). At the outset, it was difficult to assess whether the steric hindrance due to the 5α-acetate group would alter the well-known rule of preferential α-side attack in electrophilic reactions on steroids.

Treatment of olefin **7***a* with 1 equiv. of *N*-bromosuccinimide in aqueous dioxane (9) gave bromohydrin **8** as a major product (Scheme 2). The position of the hydroxy group in **8** was established by oxidation of **8** to **9**, which was then dehydrobrominated with lithium carbonate in dimethylformamide (10) to dienone **12**.

The formation of the *trans*-diequatorial bromohydrin bearing the hydroxy group at C-3 could be excluded because of the strong deshielding of the C-19 methyl group in bromohydrin **8**. It therefore seemed that attack of olefin **7***a* by the bromonium ion took place preferentially from the β-side, presumably because of the steric hindrance due to the 5α-acetoxy group.

Since the bromonium ion seemed to have attacked the double bond preferentially from the β-side of the molecule, it was anticipated that epoxidation would lead to the formation of 2β,3β-epoxycholestane-5α,6β-diol diacetate **13**, which could then be converted to the desired bromohydrin by means of hydrobromic acid.

Treatment of olefin **7***a* with *m*-chloroperbenzoic acid gave in good yield the α-epoxide **10**.

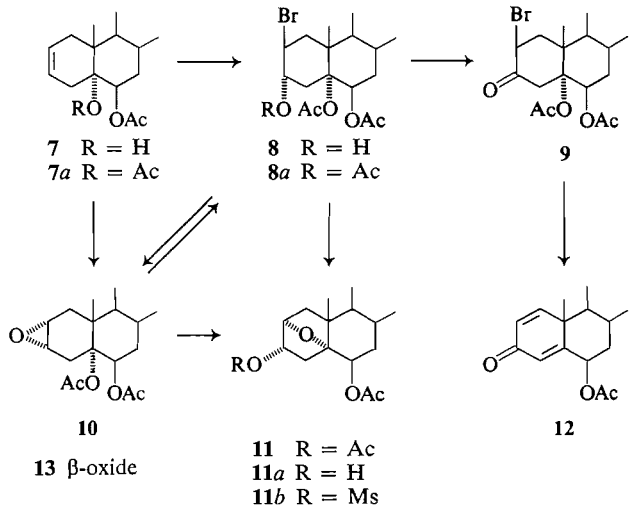

SCHEME 2

The stereochemistry of the epoxide **10** was deduced from the chemical shift of the C-19 methyl group, which remained at the same position as in the starting material. Furthermore, it was identical to the epoxide obtained by base treatment of bromohydrin **8** (11). The reason for a reversal of the preferential side of attack by bromonium ion and by peracid are not clear.

Treatment of the α-epoxide **10** with hydrogen bromide gave, in addition to the expected bromohydrin **8**, a new diacetoxy oxide, to which we assigned structure **11**. The same compound **11** was obtained by treating bromohydrin **8** with *p*-toluenesulfonic acid. The formation of this type of furan has been described recently by H. Tanida and co-workers (12) and by T. Komeno and co-workers (13, 14).[2]

The assignment of structure **11** is supported by its n.m.r. spectrum and decoupling experiments. A peak at 5.32 p.p.m. was assigned to the 6α-H, a double doublet at 4.7 p.p.m. (1H, $J = 7, J = 3$ Hz) to the 3β-H, a doublet at 4.35 p.p.m. (1H, $J = 7$ Hz) to the 2β-H, a four-lines pattern centered at 2.6 p.p.m. (2H, $J = 13$, $J = 7$ Hz) to the methylene protons at C-4, and a sharp signal at 2.0 p.p.m. (6H) was assigned to the acetates at C-3 and -6. The presence of an ABX system was further verified by spin decoupling analysis[3] of the splitting pattern produced by the protons giving rise to signals at 4.7, 4.35, and 2.6 p.p.m.

The formation of **11** may best be rationalized in terms of migration of acetate from 5α to 3α followed by a displacement of the 2β-bromide by the 5α-alcohol. The driving force in this reaction is quite clearly a relief of steric strain between the C-19 methyl group and the β-bromide (14).

The compound **11** was characterized by hydrolysis to the monoacetate **11***a*, ν 3400 and 1760 cm^{-1} and its mesylate **11***b*, ν 1750, 1640, and 1350 cm^{-1}; M^+ 538.

Experimental

All melting points are uncorrected. I.r. spectra were recorded on a Perkin–Elmer 257 grating i.r. spectrophotometer using potassium bromide pellets, unless otherwise stated. Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer using deuterochloroform as solvent and tetramethylsilane as an internal standard. Chemical shifts are reported in p.p.m. Mass spectra were taken on a AEI MS902 spectrometer operating at 75 eV. All t.l.c. was carried out on silica gel HF 254 plates. Analyses were performed by Beller Laboratories, 34 Gottingen, Theaterstrasse 23, Germany.

3β-Mesyloxy-5α,6β-diacetoxycholestane (1c)

Cholestane-3β,5α,6β-triol 5,6-diacetate (**1***b*) (200 mg) in pyridine (3 ml) was cooled to 0°. Mesyl chloride (0.5 ml) was added and the mixture was stirred at 0° for 3 h and poured into ice-water. The precipitate was crystallized from methanol, m.p. 75–78°; ν_{max} 1740, 1380, 1350, 1320, and 1230 cm^{-1}; δ 4.8 (3α-H) and 6.0 p.p.m. (6α-H).

Anal. Calcd. for $C_{32}H_{54}O_7S$: C, 65.95; H, 9.34; S, 5.49. Found: C, 65.82; H, 9.21; S, 5.38.

3β-Mesyloxy-5α-hydroxy-6β-acetoxycholestane (1e)

1*d* (200 mg) in pyridine (3 ml) was cooled to −5°.

[2]We wish to thank the referee for drawing our attention to these papers.

[3]The spin decoupling analysis was performed by Mr. R. Simoneau, the Pulp and Paper Research Institute, McGill University, Montreal, Que.

Methanesulfonyl chloride (1 ml) was added and the mixture was stirred at 0° for 5 h. The mixture was poured into ice-water and the precipitate collected was crystallized from chloroform–ether, m.p. 162–166°. Recrystallization from methanol raised the m.p. to 167–168°; ν 3440, 1715, 1370, 1355, and 1330 cm^{-1}.

Anal. Calcd. for $C_{30}H_{52}O_6S$: C, 66.73; H, 9.69; S, 5.92. Found: C, 66.70; H, 9.86; S, 5.99.

Cholestane-3α,5α,6β-triol 3,6-Diacetate (2a)

1*c* (120 mg) was warmed in *N,N*-dimethylformamide (3 ml) and pyridine (1 ml) for 16 h at 102°. The mixture was poured into ice-water and extracted with chloroform (5 × 35 ml). The chloroform solution was washed with 5% hydrochloric acid. The organic layer was dried and evaporated to give a yellow gum. Preparative t.l.c. (ether–hexane 3:1) permitted the isolation of a major band, R_f 0.5, which was extracted with ether. The oil (72 mg) obtained was crystallized from ether–hexane, m.p. 86–88° (lit. (15) 86°); ν_{max} 1730 and 3450 cm^{-1}; δ 4.75 (3α-H), 5.3 (6α-H), and 2.15 p.p.m. (two acetates).

Anal. Calcd. for $C_{31}H_{52}O_5$: C, 73.76; H, 10.38. Found: C, 73.63; H, 10.31.

Partial Hydrolysis of Cholestane-3α,5α,6β-triol 3,6-Diacetate (2a)

A mixture of **2***a* (300 mg), sodium bicarbonate (330 mg), and methanol (30 ml) was stirred at room temperature and the reaction was monitored by t.l.c. After approximately 6 h, the mixture was extracted with ether (5 × 40 ml). The ethereal layer was washed with water (3 × 50 ml) and dried with anhydrous sodium sulfate. Evaporation of solvent gave **2***b* as crystals, m.p. 175–180°; ν_{max} 3480, 3420, and 1720 cm^{-1}, δ 3.8 (3β-H) and 5.3 p.p.m. (6α-H). Recrystallization from methanol twice gave needles, m.p. 181–182°.

Anal. Calcd. for $C_{29}H_{52}O_5.H_2O$: C, 72.45; H, 10.90. Found: C, 72.30; H, 10.37.

Partial Hydrolysis of Cholestane-3β,5α,6β-triol 3,6-Diacetate (1f)

This partial hydrolysis was carried out as described for **2***a*. Two crystallizations from methanol gave needles of **1***d*, m.p. 144–145° (lit. (4) 146°).

Oxidation of Cholestane-3α,5α,6β-triol 6-Acetate (2b) and of 1d

Triol acetate **2***b* (72 mg) was submitted to a Sarett oxidation (6). Crystallization of the reaction product from methanol gave **3**, m.p. 161° (lit. (4) 157–158°). This product was identical to the product of oxidation of **1***d* (mixed m.p., t.l.c., and comparison of i.r. spectra).

Reaction of 3β-Mesyloxy-5α-hydroxy-6β-acetoxycholestane (1e) with Potassium t-Butoxide

1*e* (500 mg) was heated under reflux for 4 h in a nitrogen atmosphere in 50 ml of *t*-butanol containing 300 mg of potassium. The reaction mixture was poured into ice-water. Neutralization with dilute hydrochloric acid and extraction with ether gave an oil (410 mg). Preparative t.l.c. (petroleum ether – ether 1:1) permitted the isolation of two bands.

(*a*) From the band with lowest R_f was obtained 100 mg of **5**, m.p. 120–126°. Recrystallization from methanol gave plates, m.p. 144–146°; ν_{max} 3420, 3320, 1350, and 1240 cm^{-1}; δ 4.2 (1H broad, 3β-H) and 3.1 p.p.m. (1H, J = 3 Hz, 6α-H). The mass spectrum showed a molecular ion at *m/e* 402.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.41; H, 11.38.

(*b*) The band with R_f 0.4 gave 210 mg of **4***a*, m.p. 119–123°. Recrystallization from methanol gave 170 mg of **4***a*, m.p. 121–122°; ν_{max} 3450 cm^{-1}; δ 4.05 (1H, triplet 6α-H) and 4.7 p.p.m. (1H, multiplet C_3—H). Mass spectrum provided confirmation of the expected molecular weight of 402.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.51; H, 11.32.

3α,5α-Oxycholestan-6β-ol Acetate (4b)

Acetylation of **4***a* (65 mg) in the usual manner gave 82 mg of the acetoxy oxetane **4***b* as an oil. Attempt to crystallize **4***b* failed; ν_{max} 1746 and 1242 cm^{-1}; δ 4.6 (1H, broad C_3—H), 5.15 (1H, multiplet 6α-H), 2.5–2.9 (4H, 2 multiplets), and 2.1 p.p.m. (3H, CH_3CO). The mass spectrum confirmed the expected molecular weight of 444.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.32; H, 10.88. Found: C, 78.12; H, 10.79.

Acid Treatment of 5β,6β-Epoxycholestan-3α-ol (5)

To 35 mg of epoxide **5** in 5 ml of chloroform was added 2 drops of 71% perchloric acid. The mixture was refluxed for 10 min. Anhydrous magnesium sulfate was added and the organic layer was then evaporated to dryness to give a solid. The solid residue was dissolved in 1 ml of pyridine and 0.5 ml of acetic anhydride was added. The mixture was left overnight at room temperature. Removal of solvents *in vacuo* gave crystals of **2***a*, m.p. 85–86°. It was identical with **2***a* obtained from **1***c* (mixed m.p. and comparison of t.l.c. behavior and i.r. spectra).

Reaction of 3α,5α-Oxycholestan-6β-ol Acetate (4b) with Methanesulfonic Acid

To oxetane **4***b* (22 mg) in 5 ml of ether was added 3 drops of methanesulfonic acid and the reaction mixture was stirred at 25° for 4 h. Exactly 4 ml of 10% sodium bicarbonate solution was added to the stirring mixture. The organic layer was separated, dried with 1 g of anhydrous magnesium sulfate, and evaporated giving 19 mg of solid **1***e* which was crystallized from ether, m.p. 169–170°. It was identical with **1***e*, obtained from **1***d* (mixed m.p., comparison of i.r. spectra and t.l.c. mobility).

Reaction of 3α,5α-Oxycholestan-6β-ol Acetate (4b) with Base

A mixture of oxetane **4***b* (22 mg), potassium *t*-butoxide (22 mg), and dry tetrahydrofuran (5 ml) was refluxed for 24 h under a nitrogen atmosphere. The mixture was evaporated to dryness under reduced pressure and the semi-solid was stirred at room temperature with 10 ml of ether. The solid residue was filtered and the filtrate was evaporated to dryness. The gum obtained was shown to contain two compounds, which were identified as hydroxy oxetane **4***a* and epoxide **5** by comparing R_f values and i.r. spectra.

Sarett Oxidation of 5β,6β-Epoxycholestan-3α-ol (5) and of 5β,6β-Epoxycholestan-3β-ol (5a)

A solution of 64 mg of **5** in 1.2 ml of pyridine was mixed with 120 mg of chromium trioxide in 1.2 ml of pyridine and allowed to stand at room temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

overnight. The mixture was poured into ice-water and extracted with three portions of benzene–ether 1:1. The extract was passed through celite to break the emulsion. This was dried and evaporated under high vacuum to give a gum. Crystallization from hexane gave leaflets of **6**, m.p. 120–124°; λ_{max} (EtOH) 254 mμ (lit. (4) m.p. 125°, λ_{max} 253 mμ). This product was identical with the product obtained from **3** (t.l.c., mixed m.p.).

Oxidation of the 3β-epimer of **5**, using the same procedure, gave the same dione **6**.

Cholest-4-en-3,6-dione (6)

To **3** (15 mg) dissolved in 3 ml of absolute ethanol, was added 22 mg of solid potassium hydroxide and the mixture was refluxed for 2 h. Evaporation to near dryness and ether extraction gave 11 mg of a solid. The solid was dissolved in 3 ml of acetone, the mixture was cooled to 5° and 1 ml of Jones' reagent (16) was added dropwise. The reaction mixture was allowed to stir at 5° for 1.5 h. Isopropanol (5 ml) was added and the mixture was extracted with ether to give 7 mg of a pale yellow gum. Attempts to crystallize from hexane failed. T.l.c. mobility, i.r. and u.v. spectra of the product proved its identity as **6**.

5α-Hydroxy-6β-acetoxycholest-2-ene (7)

3β-Mesyloxy-5α-hydroxy-6β-acetoxycholestane (**1***e*) (40 g) was refluxed under nitrogen for 38 h with 120 ml of triethylamine. Excess solvent was evaporated completely under reduced pressure. This gave a gum which was chromatographed on alumina (1 kg, activity III). Elution with 1000 ml of petroleum ether gave an impure oil fraction (2.8 g) which was not further characterized. Elution with petroleum ether – benzene 8:1 and 7:1 gave 7 (26.2 g) as an oil, ν_{max} 3500, 3030, 1740, 1660, and 1240 cm^{-1}; δ 5.6 (vinyl protons, 2H), 4.8 (1H, multiplet 6α-H), and 2.0 p.p.m. (CH_3CO, 3H); *m/e* 444, 402, 384, 366.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.32; H, 10.88. Found: C, 78.12; H, 10.81.

5α,6β-Diacetoxycholest-2-ene (7a)

A mixture of 7 (2.3 g), dry chloroform (50 ml), dimethylaniline (20 ml), and acetyl chloride (12 ml) was heated under reflux in a nitrogen atmosphere for 30 h. This was diluted with 500 ml of chloroform and the mixture was washed with 5–10% cold hydrochloric acid solution (5 × 250), with water and dried with anhydrous magnesium sulfate. Evaporation of the organic solvent gave a light blue gum (3.4 g). This was chromatographed on alumina (200 g, activity III). Petroleum ether (400 ml) eluted 1.1 g of dimethylaniline. Elution with petroleum ether – benzene 8:1 (2.4 l) gave 1.4 g of diacetate **7***a* (17) as a solid. Recrystallization from hexane gave needles, m.p. 136–137°; ν_{max} 3030, 1725, 1625, 1250, 1230, and 1210 cm^{-1}; δ 5.95 (multiplet 6α-H), 5.6 (unsymmetric triplet 2 vinyl H), and 2.1 and 2 p.p.m. (2 acetates). The mass spectrum confirmed the expected molecular weight of 486.

Anal. Calcd. for $C_{31}H_{50}O_4$: C, 76.50; H, 10.36. Found: C, 76.55; H, 10.29.

2β-Bromo-3α-hydroxy-5α,6β-diacetoxycholestane (8)

To a mixture of the olefin **7***a* (100 mg) in 2.5 ml of dioxane was added a solution of 60 mg of *N*-bromosuccinimide in 1 ml of water and 1 ml of 5% perchloric acid. The mixture was stirred at room temperature for 2.5 h. Water was added and the product was isolated by filtration. The filtrate was washed with cold water and dried; 112 mg of a fine powder, m.p. 126–129° was obtained. T.l.c. of this compound indicated one spot (chloroform–methanol 95:5 and hexane–ether 1:1). Recrystallization from acetone gave 36 mg of **8** as cubes, m.p. 132–134°; ν_{max} 3480, 1745, 1712, 1245, and 1045; δ 6 (6α-H), 4.43 (multiplet, 2α-H, 3β-H), and 2.1 and 2.2 p.p.m. (singlets, 2 acetates). A second crop of 40 mg of **8**, m.p. 128–131° was further obtained. Evaporation of the solvent from the mother liquor gave 26 mg of a gum. Attempts to recrystallize failed.

Anal. Calcd. for $C_{31}H_{51}O_5Br$: C, 63.80; H, 8.74; Br, 13.70. Found: C, 63.84; H, 8.88; Br, 13.78.

Acetylation of **8** with pyridine – acetic anhydride gave acetate **8** m.p. 173–177°; ν_{max} 2980, 2880, 1750, 1740, 1730, 1265, 1250, 1230, and 1040 cm^{-1}; δ 6 (6α-H), 5.5 (multiplet 3β-H), 4.5 (multiplet 2α-H), and 2.1 p.p.m. (3 acetate peaks).

Anal. Calcd. for $C_{33}H_{53}O_6Br$: Br, 12.81. Found: Br, 12.72.

6β-Acetoxycholesta-1,4-dien-3-one (12)

Bromohydrin **8** (78 mg) in 5 ml of acetic acid was allowed to stand at 25° for 1 day with a mixture of 42 mg of chromic oxide in 2 ml of acetic acid. Excess of chromic acid was destroyed by addition of methanol and the solution was diluted with cold water. Extraction with ether and evaporation gave bromoketone **9** as an oil. Crude **9** was heated at 110° with *N,N*-dimethylformamide (2 ml), lithium carbonate (45 mg), and lithium bromide (17 mg) in a nitrogen atmosphere for 30 h. The reaction mixture was acidified with 5% hydrochloric acid and extracted with chloroform, and the organic solution washed with 5% hydrochloric acid and with water. Evaporation under reduced pressure gave 55 mg of an oil. Preparative t.l.c. (hexane–ether 2:1) permitted the isolation of 45 mg of **12** as a colorless oil, λ_{max} (MeOH) 247 mμ (ε 9800); ν_{max} ($CHCl_3$) 2940, 2860, 1735, 1665, 1620, and 1200 cm^{-1}; δ 7.2 and 6.35 (AB quartet, 1-H, 2-H), 6.42 (singlet, 4-H), 5.6 (multiplet, 6α-H), and 2.18 p.p.m. (6-acetate); *m/e* 440.

Anal. Calcd. for $C_{29}H_{44}O_3$: C, 79.04; H, 10.07. Found: C, 78.69; H, 10.01.

2α,3α-Epoxy-5α,6β-diacetoxycholestane (10)

Olefin **7***a* (300 mg) in 5 ml methylene chloride was stirred at room temperature for 5 h with 200 mg of 85% *m*-chloroperbenzoic acid in 5 ml methylene chloride. After addition of 10% aqueous sodium sulfite solution, the organic layer was washed with 5% aqueous sodium bicarbonate solution and water, and dried. Evaporation gave 340 mg of an oil which solidified upon standing. Recrystallization from methanol gave 195 mg of epoxydiacetate **10**, m.p. 191–193°. Preparative t.l.c. permitted the isolation of 37 mg of **10**, m.p. 188–191° and 12 mg of a solid which was not further characterized. ν_{max} 1740, 1725, 1370, 1250, 1220, 1040, and 1025 cm^{-1}; δ 5.75 (multiplet 6α-H), 3.25 (singlet, 2H), 2.1 and 2 (2 singlets, 2 acetates), and 1.1 p.p.m. (singlet 19-CH_3); *m/e* 502.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03. Found: C, 73.80; H, 10.24.

Reaction of 2α,3α-epoxy-5α,6β-diacetoxycholestane (10) with Hydrobromic Acid

Epoxide **10**, m.p. 192–194° (242 mg) in 10 ml of dioxane was stirred with approximately 0.3 ml of 48% hydro-

bromic acid and 0.12 ml of water for 2.5 h at room temperature. The mixture was poured into water and the precipitate (270 mg) was purified by preparative t.l.c. (ethyl acetate – cyclohexane 1:4) (*1*). The band at R_f 0.4 gave 134 mg of bromohydrin **8**, m.p. 139°, which was identical to **8** obtained from the *N*-bromosuccinimide reaction of *7a* (t.l.c., i.r., mixed m.p.) (*2*). The band at R_f 0.55 gave 130 mg of furan **11** which was crystallized from methanol, m.p. 142–145°; ν_{max} 2940, 2860, 1730, 1240, 1210, and 1030 cm^{-1}; δ 5.32 (6α-H), 4.7 (double doublets, collapses upon irradiation at 2.6 p.p.m., 3β-H), 4.38 (doublet, 2β-H), 2.6 (2 doublets, collapse upon irradiation at 4.7 p.p.m., 4α and 4β-H), and 2.0 p.p.m. (3,6-diacetates, 6H); *m/e* 502.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03. Found: C, 73.80; H, 9.68.

Reaction of 2β-Bromo-3α-hydroxy-5α,6β-diacetoxycholestane (8) with p-Toluenesulfonic Acid

A mixture of bromohydrin **8** (130 mg) in 8 ml of methylene chloride and a few crystals of *p*-toluenesulfonic acid in 0.25 ml of tetrahydropyran was allowed to stand overnight. The solvent was removed *in vacuo* and the resulting oil reacetylated with acetic anhydride and pyridine. Evaporation and extraction with methylene chloride gave an oil which solidified after some time. The t.l.c. mobility, n.m.r. and i.r. spectra of this oil were identical to those of **11** obtained from epoxide **10**.

Partial Hydrolysis of 2α,5α-Oxy-3α,6β-diacetoxycholestane (11)

3,6-Diacetate **11** (23 mg) was stirred at −4° for 0.5 h with 3 ml of 5% ethanolic potassium hydroxide. Ether extraction gave 18 mg of an oil **11***a*, ν (NaCl) 3400 cm^{-1} (—OH), 1760 cm^{-1} (—OAc); δ 5.4 (m, 1H, 6α-H), 4.38 (d, 1H, J = 6 Hz, 2β-H), 3.9 (m, 1H, 3β-H), and 2.05 p.p.m. (s, 3H, acetate); M^+ 460.

Anal. Calcd. for $C_{29}H_{50}O_5$: C, 72.76; H, 10.53. Found: C, 72.52; H, 10.32.

3α-Mesyloxy-2α,5α-oxy-6β-acetoxycholestane (11b)

Hydroxy-furan **11***a* (45 mg) was stirred at 2° for 4.5 h with a few drops of mesyl chloride in pyridine (3 ml). Work-up as usual gave 62 mg of mesylate **11***b*. Attempts on recrystallization failed. ν 1740 (—OAc), 1370, 1320, and 1260 cm^{-1} (—SO_2—); δ 5.4 (m, 1H, 6α-H), 4.8 (d, 1H, J = 6 Hz, 2β-H), 4.6 (m, 1H, 3β-H), 3.1 (s, 3H, CH_3SO_2—), and 2.1 p.p.m. (s, 3H, CH_3CO—); *m/e* 538, 478, 442, 400, and 382.

Anal. Calcd. for $C_{30}H_{50}O_6S$: C, 66.88; H, 9.36; S, 5.94. Found: C, 66.72; H, 9.40; S, 5.92.

The authors would like to thank Mr. P. Currie for taking the mass spectra, Mr. V. Yu for taking the n.m.r. spectra, and the National Research Council of Canada for financial support.

Received March 27, 1973

The irradiation of 9-phenylacridine in methanol, ethanol, or ether leads to the formation of the 9-phenylacridinyl radical. In methanol-d_4, the radical formed is the singly deuterated analog. The structure of these radicals, which exhibit a hyperfine structure in their e.s.r. spectra measured at 233 °K, is supported by simulation of the spectra using calculated spin densities. The agreement between the experimental and theoretical second moment values of the deuterated radical indicates that the parameters previously chosen for the calculation of the theoretical second moments of pyridinyl-type radicals derived from six-membered ring azaaromatics are suitable and that the second moment method can be used in studies of radicals of this type. We conclude that acridine irradiated in methanol-d_4 leads to the formation of the singly deuterated acridinyl radical.

L'irradiation de la phényl-9 acridine dans le méthanol, l'éthanol ou l'éther, a conduit à la formation du radical phényl-9 acridinyle. Dans le méthanol-d_4, le radical formé est l'analogue comportant un seul deutérium. La structure de ces radicaux, dont les spectres r.p.e. montrent une structure hyperfine lorsqu'enregistrés à 233 °K, est en accord avec la reconstitution des spectres à partir des densités de spin calculées. L'accord entre les valeurs expérimentales et théoriques des seconds moments pour les radicaux deutériés montre que les paramètres choisis antérieurement pour le calcul des seconds moments théoriques des radicaux du type pyridinyle obtenus de cycles azaaromatiques à six membres sont cohérents et que la méthode des seconds moments peut être utilisée pour l'étude des radicaux de ce type. On conclut alors que l'acridine irradiée dans le méthanol-d_4 conduit à la formation du radical acridinyle comportant un seul deutérium. [Traduit par le journal]

Can. J. Chem., 51, 3508 (1973)

The second moment method (2) was employed in the characterization of radicals formed by u.v. irradiation of six-membered ring azaaromatics in protic solvents in several of our previous studies. The radicals formed from pyridine (3), quinoline (4), isoquinoline (4), quinoxaline (5), pyrazine (5), pyrimidine (6), phthalazine (7), and cinnoline (7) are stable only in glassy matrices and give no hyperfine splitting in their e.s.r. spectra. On the other hand, the irradiation of 9-phenylacridine in ether, methanol, methanol-d_4, or ethanol leads to radicals stable at room temperature, with hyperfine splittings in the spectra. We have simulated the spectra of these radicals and have found that there is good agreement between the experimental second moment of the radical formed by u.v. irradiation of 9-phenylacridine in methanol-d_4 and its theoretical value calculated from the equation used previously for unstable radicals, with the same parameters (3–7).

The main goal of this paper is to show that, if cautiously used, the second moment method can be an efficient tool in studies of radicals derived from six-membered ring azaaromatic compounds. Zanker and Erhardt (8) have already studied the e.s.r. spectra formed by u.v. irradiation of 9-phenylacridine and of 9-phenylacridane

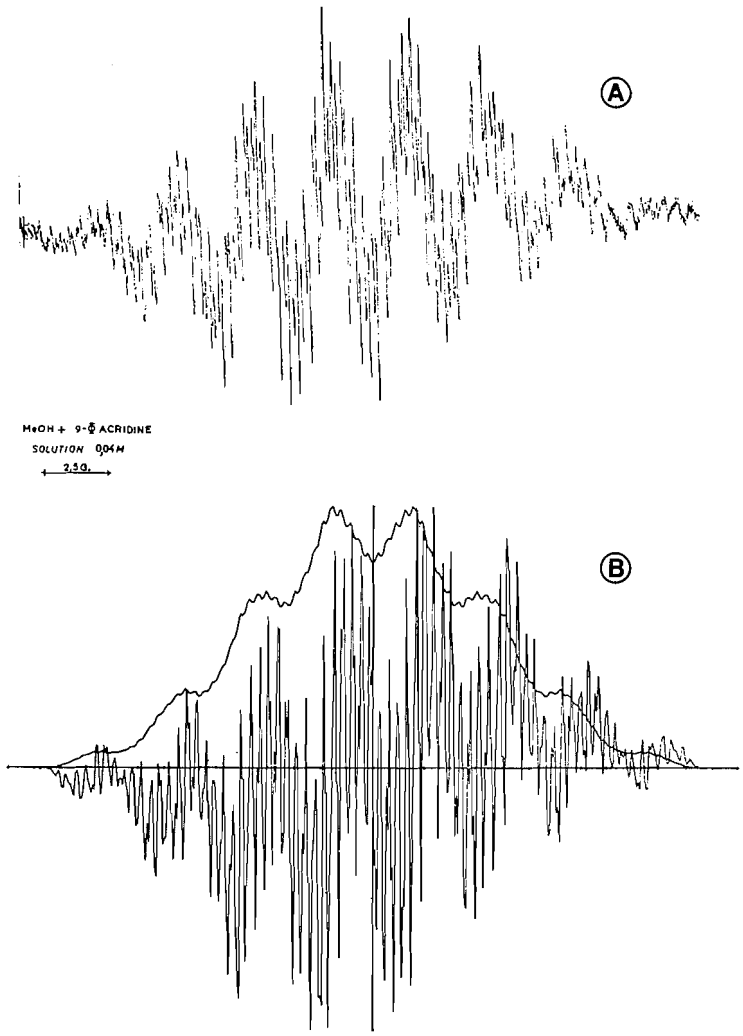

FIG. 1. Experimental (A) and simulated e.s.r. spectra (B) of 9-phenylacridinyl radical II.

in ethanol at 173 °K, but they did not prove the structure of the radicals formed.

The structure which we suggest for the radical derived from 9-phenylacridine is in complete agreement with the structures known from the many previous photochemical studies of the acridine system (for a review on acridine photochemistry, see ref. 9). The π-radicals in the case of 9-phenylacridine are I and II. All these radicals contain sp^2 hybridized N and C-9 atoms.

Results

U.v. irradiation of 9-phenylacridine in 0.2 *M* solution at 233 °K in methanol, ethanol, or ether gives rise to an e.s.r. spectrum containing eight bands with a total width of 23.45 G. When the solvent is methanol-d_4 the spectrum (for the same concentration of 9-phenylacridine) has only seven bands. Its total width is 20.90 G.

If the temperature is lowered following the irradiation, the hyperfine structure disappears rapidly. When the sample becomes glassy, only one band is observed. The width of the band is larger when the solvent is methanol than when it is methanol-d_4. Otherwise, both spectra are identical.

When 9-phenylacridine is irradiated at a lower concentration, the spectrum has a much more complex hyperfine structure which is a function of the concentration and of the temperature. Figures 1*a* and 2*a* show the e.s.r. spectra obtained by irradiation of 0.04 *M* solutions of

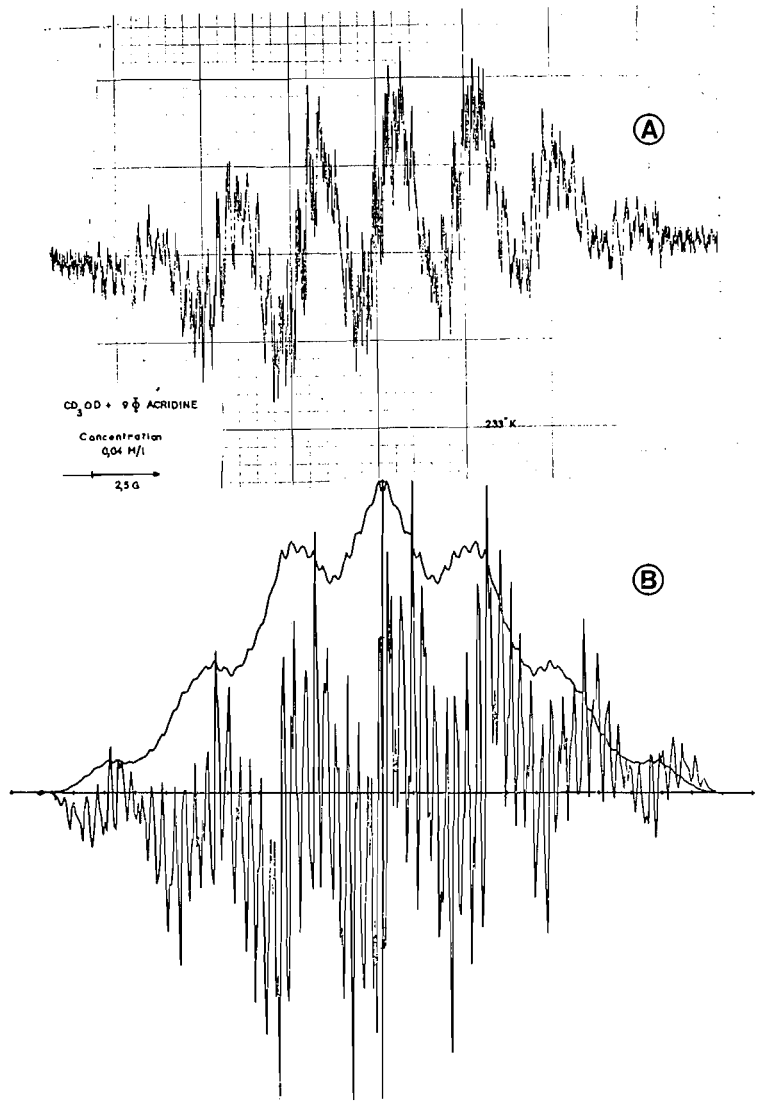

FIG. 2. Experimental (A) and simulated e.s.r. spectra (B) of 9-phenyl-10-deuteroacridinyl radical IV.

9-phenylacridine in methanol and in methanol-d_4, respectively, at 233 °K.

The spectra obtained by irradiation of a 0.2 *M* solution of acridine in methanol or ether are very similar and are observed only at a temperature lower than 173 °K. The signal consists of a broad band with a very poorly resolved hyperfine structure which is different when methanol-d_4 is used as the solvent instead of methanol. It is larger in methanol than in methanol-d_4.

Structure of the Radical Formed by U.V. Irradiation

From our earlier e.s.r. results (3–7) and from the knowledge of acridine photochemistry (9), the observed signals can be identified as those of the π-radicals I and II in the case of 9-phenylacridine and of III and IV in the case of acridine. The C-9 and N atoms in these radicals are sp^2 hybridized. The identification is supported by simulation of the spectra having hyperfine structure and by comparison of the experimental and theoretical second moments. In both cases, calculated spin densities of the radicals were used.

Calculation of Spin Densities

The spin densities were calculated using the McLachlan method (10) as was done in our pre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

vious studies (4, 5). The parameters were taken in the usual form, *i.e.*

$$\alpha_N = \alpha_C + h\beta_{C-C}$$

(where α_N is the Coulomb integral of the nitrogen, α_C is the Coulomb integral of an electron in the $2p_z$ atomic orbital of carbon and β_{C-C} is the resonance integral of a C—C bond in benzene)

and $$\beta_{C-N} = k\beta_{C-C}$$

β_{C-N} being the resonance integral of the C—N bond.

The numerical values of the coefficients h and k used in our study were: $h = 0.9$, $k = 1$, and $\lambda = 1.2$ where λ is the parameter of the interatomic exchange integral. Its value is that already used by Lunazzi *et al.* in the case of the quinoline and isoquinoline anion radicals (11).

In the case of 9-phenylacridine, the value of the resonance integral between C-9 and C-15 is certainly different from β_0, being a function of the interatomic distance between C-9 and C-15 and of the angle θ between the planes of the phenyl substituent and of the acridine ring. According to Dewar (12), $\beta = \beta_0 \cos\theta$. Wheeler and coworkers (13) have found that the angle of the plane of the phenyl substituent and of the anthracene ring is 68° for the 9,10-diphenylanthracene anion radical and 61° for the corresponding cation radical. They assumed all the interatomic distances between adjacent carbons as equal. In our calculations we have chosen $\beta = 0.3\,\beta_0$ which corresponds to $\theta \simeq 70°$.

Table 1 shows the calculated spin densities for 9-phenylacridinyl radicals, I and II, whereas Table 2 gives the calculated spin densities for acridinyl radicals III and IV.

Simulation of the Spectra with Hyperfine Structure

Spectra obtained from 9-phenylacridine in the liquid phase have been simulated. A series of theoretical coupling constants were calculated from spin densities by varying the Q parameter until the simulated spectra matched the experimental spectrum. The values at which this occurs are: $Q_{C-H} = 25.0$ G; $Q_N = 28.3$ G; $Q_{N-H} = 31.8$ G. These optimized values of Q_N and Q_{CH} are nearly equal to those which were used for the calculation of the theoretical second moment of quinoline (4), isoquinoline (4), and quinoxaline (5) ($Q_N = 28.0$ and $Q_{CH} = 24.5$ G). The value chosen for Q_{N-H} is also very similar to the value (32.0) used by Malrieu and Pullman for a sp^2 hybridized nitrogen (14). Variation of width of the Lorentzian bands can be used to simulate the influence of temperature and of concentration upon the shape of the spectra of the radicals. Figures 1*b* and 2*b* contain the simulated spectra of radicals I and III for a 0.04 *M* solution and a temperature 233 °K. The band width in this case is 0.25 G. The coupling constant of deuterium has been neglected in the simulation of radical II. There is good agreement between the experimental and theoretical total width of the spectrum of radical I: 23.45 and 24.31 G, respectively. The experimental total width of the spectrum of radical II is 20.90 G, the theoretical one 20.75 G. Assuming that $a_{N-D} = 0.15\,a_{N-H}$, we deduce experimentally $a_{N-H} = 3.64$ G. The theoretical value is $a_{N-H} = 3.56$ G.

The agreement between the theoretical and experimental results supports the postulated structure of radicals I and II and indicates that the parameters used in our previous calculations

Second Moments of the Spectra with no Hyperfine Structure

To test the validity of the second moment method, which experimental factors obliged us to use in earlier studies (4, 5), and the values of the parameters used in the calculations of the theoretical second moment, we have determined the experimental and theoretical second moment of the spectra obtained by irradiation of 9-phenylacridine and acridine in a glassy matrix at 113 °K. The experimental second moments have been calculated as about $g = 2.0023$ for solutions in methanol, methanol-d_4, and ether. The results are summarized in Table 3. Note that similar values are obtained for all hydrogenated solvents. When the solvent is methanol-d_4, the second moment is smaller than in methanol, because the N–D coupling constant is lower than the N–H constant although this difference is rather small.

We have calculated the theoretical second moments of radicals II and IV, using the same equations as previously (4, 5). They are deduced from Vincow and Johnson's work (2): the second moment M_2 of radical II is

$$M_2 = M_{2H} + M_{2g} + \frac{\sigma^2}{4} + M_{2N} + M_{2ND}$$

$M_{2H} = \sum_i n_i 174\, \rho_i^2$ contribution of the aromatic hydrogen

$M_{2N} = 914\, \rho_N^2$ contribution of the nitrogen

$M_{2ND} \simeq 0$

For the sum of $M_{2g} + (\sigma^2/4)$, M_{2g} being the contribution of the anisotropy of g and σ the width of the "monocristalline band", we took 10 G^2 as we did previously.

The theoretical value of the second moment calculated from the previous equations is 31 G^2 for radical II, 65 G^2 for radical IV. They agree with the experimental values: 38 and 66 G^2, respectively. Using the second moment method on spectra with unresolved hyperfine structure we conclude that II is the radical formed by u.v. irradiation of 9-phenylacridine in methanol-d_4 and IV is the radical formed under the same conditions from acridine.

Conclusions

The results obtained by simulation of spectra and by calculation of the second moment of the spectra confirm our hypothesis concerning the structure of the radicals formed by u.v. irradiation of 9-phenylacridine in protic solvents.

Radicals I and II are the first to be described of the pyridinyl type, obtained by u.v. irradiation of azaaromatic compounds in a neutral protic solvent, which are stable at room temperature and have a hyperfine structure.

In previous work (3–7) we were unable to obtain radicals in phase other than the glassy one. The spectra so formed had no hyperfine structure and so we were forced to use the second moment method to characterize them and thus were obliged to choose many parameters empirically. The validity of the conclusions made from those calculations was not, therefore, certain.

In this study, we were able to identify a radical with a hyperfine structure and to prove its structure unambiguously by simulation of its spectra. This demonstrates that the parameters chosen for the calculations of the theoretical second moments of the radicals previously studied are reasonable and that the conclusions we made are correct. Thus we are now able to use the second moment method to characterize the structure of pyridinyl type radicals derived from six-membered ring azaaromatic compounds even if their spectra have no hyperfine structure. We conclude from the second moment results that the radical formed by u.v. irradiation of acridine in methanol-d_4 is IV and must be III in methanol and ether.

Experimental

Products and Solvents

9-Phenylacridine was synthetized by Dr. L. Ivan according to the method of Bernthsen (15). The reaction product was washed with methanol, recrystallized four times from methanol, and dried. Fluka acridine was used without further purification.

Methanol used was Merck methanol for analysis; 100% ethanol and ether were commercial products redistilled four times. Ether was dried over sodium.

Methanol-d_4 was obtained from "Spectrometrie. spin et technique". Its purity was greater than 99%.

Samples and Irradiation

The experimental technique was the same as reported previously (4).

We thank Dr. L. Ivan for the synthesis of a 9-phenylacridine sample.

Diffusion of Light Hydrocarbons in 5A Zeolite

D. M. RUTHVEN, R. I. DERRAH, AND K. F. LOUGHLIN
Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick

Received March 29, 1973

Experimental diffusivity data are presented for the diffusion of ethane, ethylene, propane, propylene, cyclopropane, *n*-butane, 1-butene, *cis*-2-butene, and *trans*-2-butene in Linde 5A zeolite. It is shown that the concentration dependence of the diffusivity may be accounted for by considering the non-linearity of the equilibrium isotherms. Activation energies for diffusion, derived from the temperature dependence of the limiting diffusivity at zero sorbate concentration, show a clear correlation with the critical diameters of the sorbate molecules. The data are interpreted in terms of the transition state theory of diffusion and it is shown that, for the simpler molecules, this theory gives a quantitatively correct prediction of the pre-exponential factor governing the temperature dependence of the zeolitic diffusivity.

Les données expérimentales de diffusion à travers la zéolite Linde 5A ont été présentées pour l'éthane éthylène, propane, propylène, cyclopropane, *n*-butane, butène-1, *cis* butène-2 et *trans* butène-2. Il a été possible de tenir compte de la dépendance entre la diffusion et la concentration en considérant des équilibres isothermes non linéaires. Les énergies d'activation de diffusion, dérivées à partir de la fonction diffusion limite-température pour une concentration nulle de sorbat, montrent une corrélation claire avec les diamètres critiques des molécules de sorbat. Les données ont été interprétées par rapport à la théorie de l'état de transition de diffusion et on a montré que pour des molécules simples, cette théorie conduit à une bonne prévision quantitative du facteur préexponentiel gouvernant la diffusion zéolitique en fonction de la température. [Traduit par le journal]

Can. J. Chem., **51**, 3514 (1973)

The kinetics of sorption of hydrocarbons in molecular sieve zeolites have been widely studied but there are, as yet, few systems for which the dependence of the zeolitic diffusivity on sorbate concentration, temperature and molecular geometry has been clearly established (1). To obtain such information requires experimental data over a wide range of conditions since, with currently available experimental techniques, the inherent errors can easily conceal the real physical effects. In this laboratory we have used a gravimetric method to measure the diffusivities of several light hydrocarbons in Linde 5A zeolite and the data from these studies (2–4) are analyzed and interpreted in this paper. The diffusivities for each sorbate show regular trends with concentration and temperature and the effect of molecular size is clearly evident. For the simpler molecules, diffusivities predicted theoretically from transition state theory show good agreement with the experimental data.

Experimental

In most of the experiments a Cahn vacuum microbalance system was used to follow the change in weight of a sample of zeolite crystals when subjected to a small differential step change in sorbate pressure. The sorption of *cis*-butene, which is rather slow, was studied in a similar manner using a quartz spring balance in place of the electrobalance (4). Details of the experimental technique and the method by which diffusivities are calculated from the transient sorption curves have been given previously (5, 6). Prior to the experimental measurements the zeolite samples were dehydrated at 375–400 °C, 2×10^{-6} Torr for two days but for regeneration between successive runs a shorter period was sufficient.

Results and Discussion

Concentration Dependence of Diffusivity

Diffusivities calculated from adsorption and desorption curves showed no significant difference provided that the concentration steps over which the sorption curves were measured were sufficiently small. Typical data illustrating the variation of diffusivity with sorbate concentration are shown in Figs. 1 and 2. The data for the other sorbates and at other temperatures showed similar trends and some further curves for the saturated hydrocarbons have been presented elsewhere (6–8).

Within the accuracy of the experimental data the pronounced increase in diffusivity with sorbate concentration may be quantitatively accounted for by considering the non-linearity of the relationship between sorbate activity and concentration, as defined by the equilibrium isotherm. Assuming the driving force for transport within the zeolite lattice to be the gradient

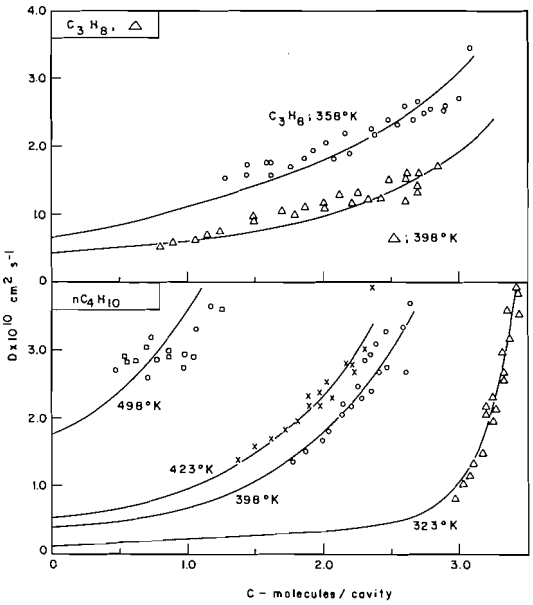

FIG. 1. Variation of zeolitic diffusivity with sorbate concentration (experimental points; theoretical curves from eq. 1).

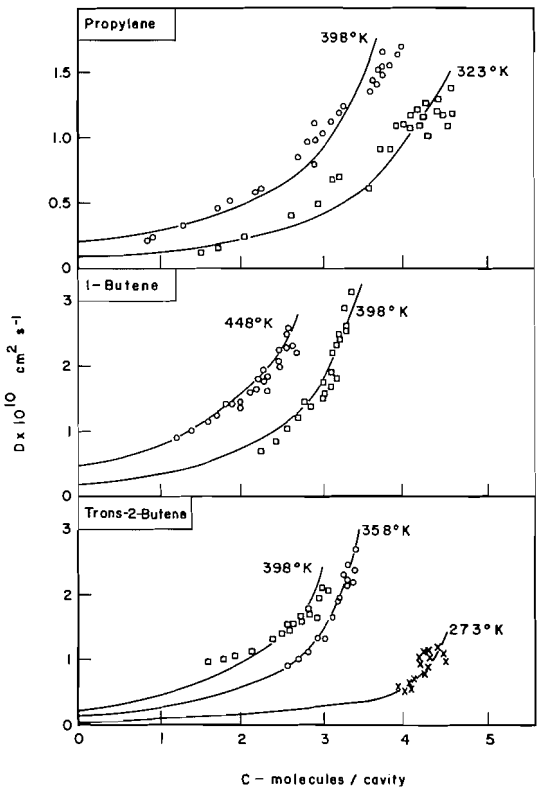

FIG. 2. Variation of zeolitic diffusivity with sorbate concentration (experimental points, theoretical curves from eq. 1).

of chemical potential (1, 7) one may define an intrinsic mobility (B) which is related to the diffusivity by the expression:

$$[1] \quad D = RTB\left(\frac{\partial \ln p}{\partial \ln c}\right)_T = D_0\left(\frac{\partial \ln p}{\partial \ln c}\right)_T$$

where the derivative $(\partial \ln p/\partial \ln c)_T$ represents the gradient of the equilibrium isotherm at temperature T, plotted in logarithmic coordinates.

The equilibrium data obtained from the end points of the sorption curves were fitted, over the range of the experimental measurements, by a polynomial expression from which the derivative $(\partial \ln p/\partial \ln c)_T$ could be readily calculated. This procedure avoids the errors inherent in the use of a model isotherm but the polynomial expression cannot be extrapolated outside the range of the experimental data.

Values of B calculated from the diffusivity data according to eq. 1 showed no significant variation with concentration, suggesting that the concentration dependence of the diffusivity arises entirely from the activity correction term $(\partial \ln p/\partial \ln c)_T$ and that the intrinsic mobility is essentially independent of concentration. The value of $D_0 = RTB$ is thus equal to the limiting diffusivity at low concentrations within the Henry's Law region. Values of D_0, calculated from the average values of the mobility at each temperature, are summarized in Table 1.[1]

In order to obtain theoretical diffusivity–concentration curves over a wider range of concentrations than that covered by the experimental measurements, values of the derivative $(\partial \ln p/\partial \ln c)_T$ were calculated from the best fitting theoretical isotherms (eq. 4 of ref. 9). This theoretical isotherm has been shown to provide a good fit of the experimental equilibrium data for light hydrocarbons in 5A zeolite (9, 10) over the region of low and intermediate sorbate concentrations and it has the correct asymptotic behavior since it reduces, in the low concentration limit, to Henry's Law. Theoretical diffusivity–concentration curves calculated in this way, using the values of D_0 given in Table 1, are

cis-2-butene	3.28	—	—	151	9.2

*The values of K_0 and q_0 for the methane are slightly different from those given by Ruthven and Loughlin (9) as a result of the inclusion of additional experimental data (18).

shown in Figs. 1 and 2. The theoretical curves fit the experimental data well, indicating that eq. 1 provides an adequate interpretation of the concentration dependence of the diffusivity. Similar behavior has been recently reported for the diffusion of light paraffins in H-chabazite (11).

The constancy of the mobility should however be regarded as a property of these particular systems rather than as a general property. In all these systems the free diameter of the zeolite window is of the same order as the critical diameter of the sorbate molecules so that the zeolite lattice offers a considerable resistance to diffusion. For the diffusion of small molecules in large port zeolites a concentration dependent mobility is to be expected and has been observed in this laboratory for the diffusion of noble gases in 5A zeolite.

Activation Energies for Diffusion

The temperature dependence of the limiting diffusivity D_0 is illustrated in Fig. 3. Limiting diffusivities for ethane were also measured at several temperatures by an independent technique involving analysis of the breakthrough curves for a molecular sieve column (12). The values so obtained agree well with the gravimetric data, thus providing valuable confirmation of the experimental technique. Apparent activation energies (E) and pre-exponential factors (D_*), defined by the relation $D_0 = D_* e^{-E/RT}$, were calculated from the experimental data by the method of least squares. The theoretical lines are shown in Fig. 3 and the values of the parameters D_* and E are listed in Table 2.

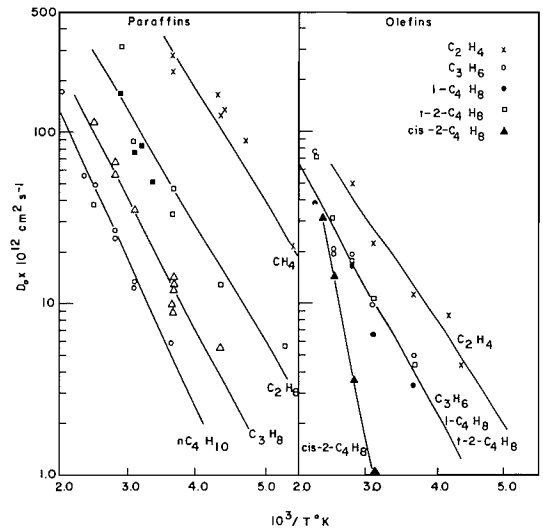

FIG. 3. Temperature dependence of limiting diffusivity for sorption in 5A zeolite (diffusivity data for C_2H_6 calculated from the column studies of Garg (12) are indicated by filled squares).

The increase in activation energy with molecular diameter is illustrated in Fig. 4, which shows the diffusional activation energy plotted against σ'. This dimension, which may be calculated from available bond lengths and angles (13), is defined as the diameter of the smallest cylinder which can be drawn around the molecule, in its most favorable conformation, through the centers of the extreme hydrogen atoms. The values of σ' for the various sorbates are given in Table 2. To obtain the critical diameters of the molecules the effective van der Waals

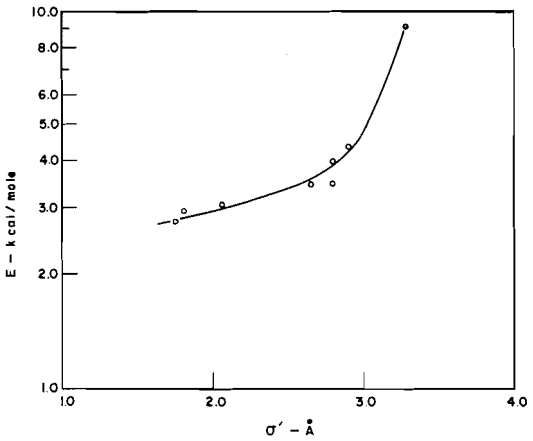

FIG. 4. Variation of diffusional activation energy with critical diameter σ'.

diameter of a hydrogen atom (≃2.3 Å) must be added to σ' (14).

Propylene, 1-butene and *trans*-2-butene all have the same critical diameter and it may be seen that the diffusivities and activation energies for these species are very similar. The critical diameter of *cis*-2-butene is considerably larger, leading to a substantially greater energy of activation. These data provide strong evidence that the activation energy for zeolitic diffusion is determined by the critical diameter of the molecule and that other factors such as molecular weight, chain length or type of bond are of only minor significance.

Correlations of activation energy with molecular diameter have been reported by Barrer and co-workers (15–17) for several gases in natural zeolites. In previous studies of the diffusion of hydrocarbons in type A zeolites, however, the dependence of diffusivity on sorbate concentration has generally not been considered. Such effects may easily conceal the clear correlation which emerges from the present study.

Transition State Theory of Diffusion

A hydrocarbon molecule occluded within a cavity of a type A zeolite crystal is in a region of low potential energy and has considerable freedom of movement within the particular cavity. The diffusion process involves the passage of occluded molecules through the windows between adjacent cavities. In passing through the window the freedom of movement of the sorbate molecule is severely constrained and, depending on the critical diameter, there may also be an appreciable energy barrier due to repulsion forces. The molecule in passage through the window may therefore be identified as the transition state and the following theoretical expression for the limiting diffusivity may be de ved from absolute rate theory (18):

$$[2] \qquad D_0 = \left(\frac{\delta^2}{6h}\right) \frac{1}{K_0} \frac{f_z^*}{f_g'} \exp\left[-(u' + q_0)/kT\right]$$

whence:

$$[3] \qquad D_* = \left(\frac{\delta^2}{6h}\right) \frac{1}{K_0} \frac{f_z^*}{f_g'}$$

$$\frac{E}{R} = \frac{u' + q_0}{k}$$

In these expressions δ is the lattice parameter (12.3×10^{-8} cm for type A zeolites), h and k are respectively Planck's and Boltzmann's constants, u' is the difference in potential energy between a molecule in the window and the same species in the gas phase, q_0 is the limiting heat of sorption at zero sorbate concentration, and K_0 is related to the Henry constant K by the expression $K = K_0 \exp(q_0/kT)$. f_z^* is the partition function for a molecule in the window, for all degrees of freedom except that corresponding to translation through the window, while f_g' represents the partition function per unit volume for a sorbate molecule in the gas phase.

The value of K_0 may be obtained from experimental equilibrium data so that, if the ratio f_z^*/f_g' can be estimated, eq. 3 will give an *a priori* prediction of D_*. The degrees of freedom of the transition state may be represented as a two dimensional oscillation of the center of gravity of the molecule in the plane of the window together with a rotational and/or rocking motion. For molecules with critical diameters equal to or greater than the nominal aperture of the window (~4.2 Å), the vibrational freedom of the center of gravity will be small as a result of repulsion forces, and the principal contribution to the partition function of the transition state will arise from rotation or rocking vibrations. We therefore consider the two limiting cases represented by a freely rotating transition state, having the same rotational freedom as the gaseous molecule at the same temperature, and a transition state having neither rotational nor rocking freedom. Assuming that the internal vibrational degrees of freedom are the same for the transition state as for the gaseous molecule

TABLE 3. Comparison of experimental and theoretically predicted values of D_* for diffusion in 5A zeolite*

Sorbate	Values of $D_* \times 10^8$ cm^2 s^{-1} Experimental value	Theoretical value for non-rotating transition state	Theoretical value for freely rotating transition state	f_{rot}	Experimental value of f^+ from eq. 6
C_2H_6	1.28	1.01	332	329	1
C_2H_4	0.2	0.24	133	560	1
C_3H_8	0.82	0.014	90	6 500	58
C_3H_6	0.25	0.0077	96	12 500	32
△	1.06	0.015	25	1 700	72
nC_4H_{10}	0.73	0.0021	57	27 000	350
1-C_4H_8	0.18	0.062	1660	27 000	3
trans-2-C_4H_8	0.26	0.028	750	27 000	9

*Theoretical values are calculated for 273 °K. Values of f_{rot} are calculated from data given by Herzberg (23) and Sutton (13). Moments of inertia for the C_4 species are not available, and the value of f_{rot} is based on an approximate estimate.

we have

Free rotation

$$[4] \qquad \frac{f_z^*}{f_g'} = \frac{1}{f_{trans}'}$$

No rotation or rocking

$$[5] \qquad \frac{f_z^*}{f_g'} = \frac{1}{f_{trans}' f_{rot}}$$

where $f_{trans}' = (2\pi mkT/h^2)^{3/2}e$ is the translational partition function per unit volume and $f_{rot} = (8\pi^2 IkT/h^2)^{3/2}(\sqrt{\pi}/s)$ is the rotational partition function for a gaseous molecule of mass m, moment of inertia I, and symmetry number s.

Values of D_* calculated from eqs. 3 and 4 or 5 are compared with the experimental values in Table 3. For the smaller molecules (C_2H_4 and C_2H_6) the assumption of a non-rotating, non-rocking transition state gives a good approximation to the experimental values of D_*. The contribution of rocking vibrations or restricted rotational freedom may be expected to increase with the length of the molecule and the experimental values of D_* for the larger molecules are seen to lie, as expected, between the two theoretical limits.

Also shown in Table 3 are the values of f^+, the partition functions for the transition state calculated directly from the experimental values of D_* according to the relationship:

$$[6] \qquad f^+ = \frac{6hD_*K_0}{\delta^2} f_{trans}' f_{rot}$$

The experimental values of f^+, for all species, are much smaller than the corresponding rotational partition functions suggesting severe inhibition of rotational freedom in the transition state. The rotation of the smaller molecules CH_4 (18), C_2H_6, and C_2H_4 appears to be completely inhibited ($f^+ \simeq 1$) while the numerical values of f^+ for the C_3 and C_4 species are consistent with a weak rocking vibration. However, in view of the inherent uncertainties in the numerical values more detailed analysis is probably not justified.

Comparison of Diffusivities for 4A and 5A Zeolites

The heats of adsorption and the Henry constants for the sorption of light paraffins in the 4A and 5A zeolites have been found to be essentially the same (9) and one may expect that the values of f_z^* will also be similar. Transition state theory (eq. 2) therefore predicts that the values of D_* for the diffusion of a given molecule in the 4A and 5A zeolites should be essentially the same and that the observed difference in diffusivity should be attributable to a difference in the diffusional

TABLE 4. Comparison of experimental diffusivity data for sorption of paraffins in 4A and 5A zeolite

activation energy which can arise from a difference in the value of u'. This conclusion is supported by the experimental diffusivity data which are summarized in Table 4. It may be seen that the activation energies for diffusion in 4A zeolite are 4–5 kcal greater than for the 5A form and that the values of D_* for methane, propane, and butane are all quite similar. The data for the diffusion of ethane in 4A zeolite however show poor agreement between the results of different studies so no very valid comparison can be made.

Conclusion

For the systems considered in the present paper the variation of zeolitic diffusivity with sorbate concentration may be satisfactorily explained by considering the non-linearity of the relationship between activity and concentration as defined by the equilibrium isotherm. The temperature dependence of the limiting diffusivity at zero concentration may be described by an Arrhenius type of relationship and the activation energies for diffusion show a clear correlation with the critical diameters of the sorbate molecules. Transition state theory provides a satisfactory interpretation of the experimental data and, for the simpler molecules, the theory gives a correct quantitative prediction of the pre-exponential factor D_*.

A Kinetic and Surface Study of the Water-Gas Shift Reaction on Manganese(II) Oxide

BORDAN WALTER KRUPAY AND ROBERT ANDERSON ROSS
Department of Chemistry, Lakehead University, Thunder Bay "P", Ontario

Received April 5, 1973

The kinetics of the water-gas shift reaction on a manganese(II) oxide catalyst possessing surface nonstoichiometry has been studied from 300 to 400 °C at atmospheric pressure. The experimental rate expression obtained was $r = k(p_{CO})^{0.75}$ in the carbon monoxide partial pressure range 20 to 80 Torr and $r = k(p_{CO})^{0.5}$ from 100 to 240 Torr. The rate of reaction has been related to the Langmuirian-type adsorption of carbon monoxide and a redox mechanism involving surface oxygen species is proposed. When the reaction rate was determined in increasing 10 °C intervals from 300 °C, two activation energies were observed; 16 ± 0.5 kcal mol^{-1} from 350 to 400 °C and 11 ± 0.5 kcal mol^{-1} from 300 to 340 °C. The temperature at which the change occurs corresponds closely to the Curie temperature of the oxide. The possible use of manganese(II) oxide as a catalyst or catalyst component in a commercial shift process is critically appraised.

La cinétique de la réaction de déplacement eau-gaz sur un catalyseur oxyde de manganèse(II) ayant une surface non stoechiométrique a été étudiée de 300 à 400 °C à la pression atmosphérique. L'expression de vitesse expérimentale obtenue était $r = k(p_{CO})^{0.75}$ dans l'intervalle de pression partielle en monoxyde de carbone de 20 à 80 Torr et $r = k(p_{CO})^{0.5}$ de 100 à 240 Torr. La vitesse de réaction a été reliée à l'adsorption du type Langmuir du monoxyde de carbone et un mécanisme rédox faisant intervenir une espèce oxygène à la surface a été proposé. Lorsque la vitesse de réaction a été déterminée en augmentant la température par des écarts de 10 °C à partir de 300 °C, deux énergies d'activation ont été observées; 16 ± 0.5 kcal mol^{-1} de 350 à 400 °C et 11 ± 0.5 kcal mol^{-1} de 300 à 340 °C. La température à laquelle le changement se produit correspond étroitement à la température de Curie de l'oxyde.

L'utilisation possible de l'oxyde de manganèse(II) comme catalyseur ou constituant d'un catalyseur dans le processus de déplacement a été évaluée de façon critique. [Traduit par le journal]

Can. J. Chem., 51, 3520 (1973)

Introduction

It is well known that the rate of the water-gas shift reaction is a controlling parameter in many established industrial and technological catalytic processes (1). In recent years, new impetus has been given to studies of the reaction over solid catalysts by its importance in hydrocarbon fuel cell operations (2) and in the suppression or removal of gaseous pollutants from the exhausts of internal combustion engines (3).

Although many catalytic studies of the water-gas shift reaction have been reported, these are mainly directed towards the various technological aspects of the reaction and are generally focused on iron oxide-based catalysts (4). In a recent paper (5) the mechanism of the shift reaction on iron(III) oxide was re-examined using an isotope tracer technique and two possible reaction mechanisms were proposed; both of which involve the reaction between adsorbed carbon monoxide and either oxygen or hydroxyl species. Elsewhere, conclusions obtained from rate studies on chromium oxide (6) have been extended to explain the results of catalysis on copper chromite.

No detailed work has been reported on manganese oxides as catalysts for this reaction but their use as a catalyst stabilizer and promoter has received attention for a commercial shift catalyst containing zinc, copper, and chromium components (7). Hence, a kinetic study of the water-gas shift on manganese(II) oxide containing excess lattice oxygen, has been initiated. The general catalytic properties of this oxide are not yet well-defined and were only recently examined specifically in the heterogeneous decompositions of isopropanol (8, 9) and nitrous oxide (10).

Experimental

Apparatus and Procedure

The all-glass flow system and quartz reactor were described previously (11, 12). High-purity helium was used as the carrier gas at atmospheric pressure in the flow system and in the Beckman GC-5 gas chromatograph. Carbon monoxide, water, and carbon dioxide were analyzed by a thermal conductivity bridge at 110 °C using stainless-steel columns, 72 × 0.125 in., o.d., packed with "Poropak Q".

Surface areas were determined by low-temperature krypton adsorption (B.E.T.; -196 °C; $\sigma = 21.5$ Å^2).

To establish the experimental conditions for which the reaction rate was not influenced by external or internal diffusion, the influence of space velocity, catalyst mass, and particle size was studied in the usual manner (11). As a result of these preliminary experiments, kinetic measurements were conducted at a total flow rate of 350 ml min^{-1} (N.T.P.) which was equivalent to space velocities from 7.48 to 8.78 (cc gas) (cc. catalyst)$^{-1}$ s^{-1} between 300 and 400 °C.

All reaction rate measurements were made after the steady catalyst activity level was attained and the experimental rates were determined from the rates of carbon dioxide production. The validity of this procedure was established by obtaining a quantitative mass balance for all components at both 320 and 380 °C.

Materials

Manganese(II) oxide. A bulk quantity of α-manganese(III) oxide was prepared as described (9). A calculated amount of this oxide sample was placed in the reactor such that, after reduction, it would yield one gram of manganese(II) oxide. All catalyst samples were pretreated for 5 h at 380°C in the standard water-gas mixture consisting of a 350 ml min^{-1} (N.T.P.) stream of helium containing 40 Torr carbon monoxide and 16 Torr water vapor.

The methods used for the chemical and structural analyses of the catalyst have been described (8, 9).

Carbon monoxide (C.P.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), hydrogen (ultra-high purity; 99.999%), and helium (high purity; 99.995%) were supplied by Matheson of Canada Ltd. and the water in the gas-saturators was de-ionized and boiled prior to use.

Electron transmission micrographs were recorded with a Philips EM 300G electron microscope at 100 kV. Specimens were crushed in an agate mortar and suspended in *n*-butanol. Drops of the suspension were placed on the carbon-support film on 200 mesh copper grids, and the alcohol subsequently removed by evaporation at 10^{-5} Torr.

Results

The Nature of the Catalyst

Analysis of the catalysts after reduction indicated a bulk stoichiometry of $MnO_{1.0}$ but as reported earlier (8) the samples contained enough excess oxygen to retain the black color associated with manganese(III) oxide (13). The colors of the catalyst samples varied slightly with the temperature and time of exposure to the water-gas mixture; catalysts used at 300 °C were darker than those used for periods longer than 24 h at 380 °C. The X-ray powder diffraction patterns of all used catalyst samples showed characteristic lines of manganese(II) oxide only and this together with the chemical analyses of several samples, verified the catalyst composition. Prior to analysis, the pyrophoric catalysts were cooled to room temperature in helium at 100 ml min^{-1} (N.T.P.) before removal from the catalyst reactor in order to prevent spontaneous oxidation.

Rate measurements were recorded after allowing the catalyst to equilibrate in the standard water-gas mixture for 300 min. Constant activity was observed after 100 min exposure time.

Stoichiometric manganese(II) oxide, which was prepared by reducing α-Mn_2O_3 with a surface area 16.5 $\pm$ 0.5 m^2 g^{-1} for 12 h in 600 ml min^{-1} (N.T.P.) of hydrogen at 600 °C (14), yielded catalysts with a surface area 14.5 m^2 g^{-1} and the 12% loss in surface area could not explain the very low activity; less than 1% of that prepared by reduction in the standard water-gas mixture. The stability of the latter catalysts, after continuous exposure to the water-gas mixture for 24 h, showed a decrease of activity per m^2 of less than 10% at 380 °C and a much smaller decrease at 320 °C. Both surface areas and electron transmission micrographs of the catalysts, determined after various periods of exposure, indicated that oxide sintering was an important factor in this loss of activity.

Electron transmission micrographs of the catalyst immediately after the standard pretreatment showed the presence of small crystallites, approximately 700 Å diameter, which were fused into highly irregular macro-structures averaging 0.06 mm in diameter. The irregularity of the fused crystallites diminished with prolonged reaction times at the higher temperatures. Dark-field electron transmission micrographs of sintered samples indicated that large assemblies of crystallites were fused mainly into preferred crystal orientations in contrast to the random distribution expected in the absence of sintering.

Figure 1 shows (*A*) the electron transmission micrograph typical of a freshly prepared catalyst sample; (*B*) the transmission micrograph of a sample exposed at 380 °C for 24 h to the standard water-gas mixture (microscope magnification × 26 000; total magnification × 120 000) and (*C*) the dark-field micrograph of (*B*) (microscope magnification × 26 000; total magnification × 55 000).

These observations were substantiated by surface area measurements which were reproducible on any given sample to within $\pm$0.5 m^2 g^{-1}. Thus, the surface area of a freshly-prepared catalyst sample, 16.5 m^2 g^{-1}, decreased to 16.0 m^2 g^{-1} after 6 h exposure to the standard water-

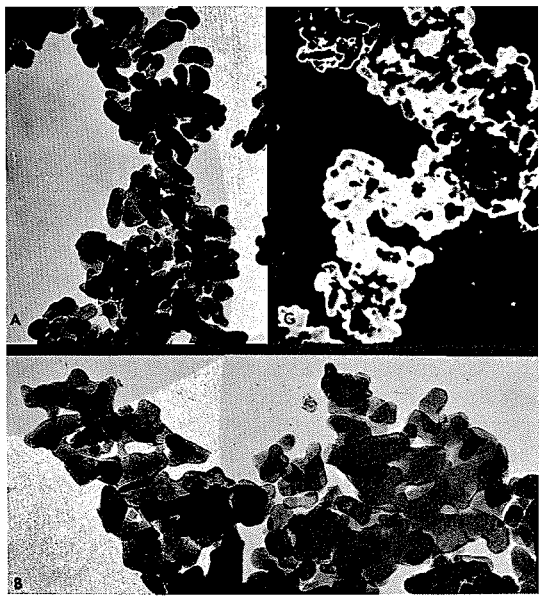

FIG. 1. Electron micrograph (*A*) of a freshly prepared catalyst sample; (*B*), a sample exposed at 380 °C for 24 h to the standard water–gas mixture showing crystallite sintering, (both microscope magnifications × 26 000 and total magnifications × 120 000); and (*C*) the dark-field micrograph of (*B*) (microscope magnification × 26 000 and total magnification × 55 000).

gas mixture at 380 °C, whereas exposures at 320 °C for 7 h did not yield any measurable change in the surface area. After exposure of the catalyst for 48 h at 380 °C the surface area was 14.5 m^2 g^{-1}.

The Relationship between Exposure Time and the Reaction Orders

Reaction orders with respect to carbon monoxide, hydrogen, carbon dioxide, and water vapor were determined at 320 and 380 °C on catalyst samples which had been exposed to the standard water-gas mixture for a maximum of 12 h. Further, reaction orders were re-determined on catalysts which had been exposed to the same mixture for more than 48 h at both these temperatures and no change was observed in the order results.

The Effects of Variations of the Partial Pressures of Carbon Monoxide, Water Vapor, Hydrogen, and Carbon Dioxide on the Reaction Rate

Rate orders were determined at 320 and 380 °C. For carbon dioxide and hydrogen rate-order determinations, the partial pressures of carbon monoxide and water vapor were kept constant at 40 and 16 Torr, respectively. The reaction-rate data are summarized in Table I and the logarithmic plots for the determination of the reaction orders are shown in Fig. 2. Thus, separate variation of the partial pressures of hydrogen from 5.4 to 65.1 Torr, and carbon dioxide from 10.9 to 87.0 Torr showed an overall zero order dependence of the rate of reaction on the partial pressures of both components at each temperature. Similarly, variation of the water vapor pressure from 4 to 56 Torr, while maintaining the carbon monoxide partial pressure at 40 Torr, did not influence the rate of reaction.

The effect of varying the carbon monoxide partial pressure, while maintaining the partial pressure of water vapor at 16 Torr at both temperatures, indicated a reproducible order of 0.75 with respect to carbon monoxide partial pressure in the range 20 to 80 Torr. At 320 °C, this order changed to 0.5 in the partial pressure range 100 to 240 Torr, Fig. 2.

TABLE 1. The effect of variations of the partial pressures of carbon monoxide, water, hydrogen, and carbon dioxide on the rate of the water–gas shift reaction

Component	Partial pressure (Torr)	Rate of reaction × 10^8 (mol m^{-2} s^{-1}) 380 °C	320 °C
Carbon monoxide (p_{H_2O} = 16 Torr)	20	4.84	2.19
	30	—	2.79
	40	8.51	3.39
	60	11.48	4.73
	80	14.79	5.28
	100	18.41	6.76
	120	—	7.50

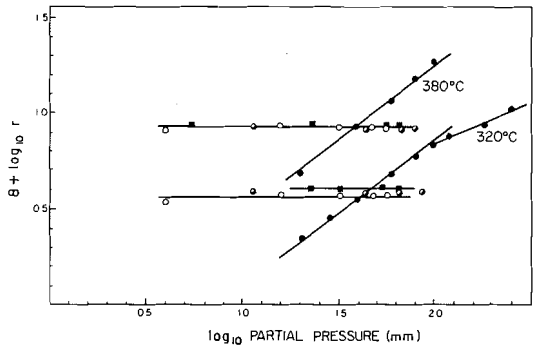

FIG. 2. The effects of variations in the partial pressures of carbon monoxide (●), water vapor (○), carbon dioxide (◑), and hydrogen (■) on the reaction rates at 320 and 380 °C. (for experimental details, see text).

Thus, the rate of reaction r(mol m^{-2} s^{-1}), can be represented as:

[1] $$r = k(p_{CO})^{0.75} \quad (20 \leqslant p_{CO} \leqslant 80 \text{ Torr})$$

and

[2] $$r = k(p_{CO})^{0.5} \quad (100 \leqslant p_{CO} \leqslant 240 \text{ Torr})$$

The Isolated Effects of Components of the Water-Gas Mixture on the Catalyst Surface

A stabilized catalyst sample was exposed to 50 Torr of carbon dioxide in a total gas flow rate of 350 ml min^{-1} (N.T.P.). At 380 °C this resulted in a 98% conversion to carbon monoxide after 7 min exposure. This conversion decreased to zero after 45 min, curve *B*, Fig. 3. When 40 Torr of carbon monoxide was immediately introduced in a separate experiment, an initial 53% conversion to carbon dioxide was measured 6 min later which decreased to zero after 35 min, curve *A*, Fig. 3. Subsequent treatment with 16 Torr of water vapor for 30 min followed by 40 Torr of carbon dioxide did not yield any carbon monoxide. Then, the introduction of the standard water-gas mixture immediately showed a 44% increase in the rate of reaction which returned to the steady level after 30 min; inset Fig. 3, curve *C*.

These results imply that the manganese(II) oxide surface is subject to a reversible redox process with either water vapor or carbon dioxide acting as oxidizing agents and carbon monoxide as a reducing agent for the oxidized surface.

If this enhanced initial activity was associated with the presence of excess surface oxygen, then, an initially lower rate of reaction might be expected to occur on a surface reduced with carbon monoxide. Hence, the stabilized catalyst was

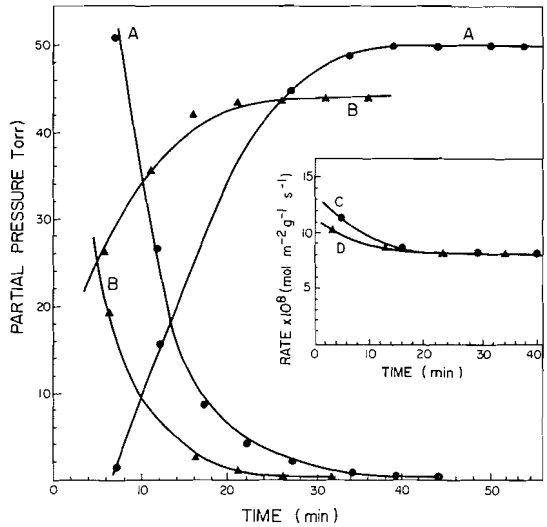

FIG. 3. The isolated effects of carbon monoxide (*A*) and carbon dioxide (*B*) at 380 °C. Inset: the rate of conversion after carbon dioxide (*C*) and carbon monoxide (*D*) treatments.

treated first with 40 Torr of carbon monoxide for 30 min followed immediately by the standard water-gas mixture. Contrary to the expected decrease in reaction rate, a 38% increase was recorded that returned to the original rate of reaction after 20 min; inset Fig. 3, curve *D*.

The Effect of Temperature on the Reaction Rate

The rate of reaction was determined from 300 to 400 °C at progessive 10 °C intervals. After the standard pretreatment, the temperature was lowered to 300 °C and the catalyst left for 9 h in contact with the standard water-gas mixture before determining the rate.

Rate constants were calculated by integration of the rate eq. 1 as a function of concentration rather than partial pressure and the values obtained used in an Arrhenius plot to establish the apparent activation energy, Fig. 4. The plot, curve *A*, shows two distinct regions with activation energies of 16 ± 0.5 kcal mol^{-1} from 350 to 400 °C and 11 ± 0.5 kcal mol^{-1} from 300 to 340 °C. The pre-exponential factors were 1.8×10^9 and 3.7×10^7 molecules$^{0.25}$ $l^{-0.25}$ m^{-2} s^{-1}, respectively. This change in the value of the apparent activation energy was easily reproducible on fresh catalyst samples. When the rates were measured at decreasing 10 °C intervals from 400 to 300 °C using either fresh samples or those previously exhibiting a change in activation energy,

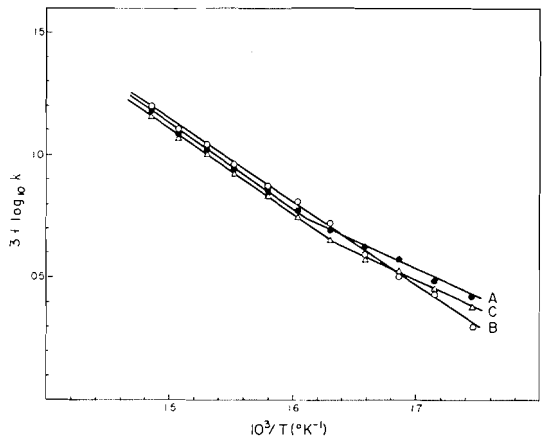

FIG. 4. Arrhenius plots of the reaction rates of the water-gas shift reaction on manganese(II) oxide from 300 to 400 °C. Curves *A* and *C* determined for step-wise temperature increments from 300 to 400 °C; curve *B*, determined from 400 to 300 °C.

a reproducible linear relationship was observed over the entire temperature range with an apparent activation energy of 16 ± 0.5 kcal mol^{-1}, and a pre-exponential factor 1.2 × 10^9 $molecules^{0.25}$ $l^{-0.25}$ m^{-2} s^{-1}, Fig. 4, curve *B*. It is worth noting that the observed change in value of the activation energy corresponds with the Curie temperature of manganese(II) oxide, 337 °C (15).

In order to substantiate these results, the water vapor partial pressure was increased from 16 to 40 Torr while the carbon monoxide partial pressure was maintained at 40 Torr, and the catalyst temperature was again increased in a stepwise fashion. The Arrhenius plot, Fig. 4, curve *C*, showed two distinct regions with activation energies of 16 ± 0.5 kcal mol^{-1} from 350 to 400 °C and 11 ± 0.5 kcal mol^{-1} from 300 to 340 °C with corresponding pre-exponential factors of 1.4 × 10^9 and 2.2 × 10^9 $molecules^{0.25}$ $l^{-0.25}$ m^{-2} s^{-1}, respectively. An activation energy of 18 kcal mol^{-1} has been reported (16) for this catalyst assuming first order kinetics.

Discussion

Previously, the mechanism of the water-gas shift reaction on an iron(III) oxide catalyst promoted with chromium oxide (17) has been interpreted as proceeding via a two-step alternating oxidation–reduction scheme while a concerted redox mechanism has been proposed from results on iron–chromium oxides (18) and copper chromite (19) catalysts. The possibility that rate control is exercised within the surface interactions that take place between adsorbed carbon monoxide and water has been considered to occur on iron(III) oxide based catalysts (4) while an alternative mechanism involving the formation of surface formate species on zinc(II) oxide (20) and magnesium(II) oxide (20, 21) has also been suggested. However, studies of the decomposition of formic acid on manganese(II) oxide (22) have indicated that the formation of formate intermediates is not involved in the water-gas shift reaction on this catalyst from 300 to 400 °C.

Various assumptions were made, in the usual way, with respect to the rate-determining step in the shift reaction and the most satisfactory model was obtained by assuming that rate control was associated with the surface reactions. Thus, if the rate of reaction, r, is determined by the surface coverage, θ, of both carbon monoxide and water absorbed on sites specific to each species, then:

$$[3] \qquad r = k\theta_{CO}\theta_{H_2O}$$

and if θ_{CO} and θ_{H_2O} obey the simple Langmuir relationship, eq. 3 becomes:

$$[4] \qquad r = \frac{k b_{CO} p_{CO} b_{H_2O} p_{H_2O}}{(1 + b_{CO}p_{CO})(1 + b_{H_2O}p_{H_2O})}$$

which is commonly known to describe the Langmuir–Hinshelwood mechanism.

Since it is reasonable to assume from the effect of water-vapor partial pressure on the reaction rate that the amount of water vapor adsorbed is fixed, for example if the water adsorption sites are saturated, then the term $(b_{H_2O}p_{H_2O})$ could be considered constant, so that eq. 3 can be reduced to:

$$[4a] \qquad r = \frac{b_{CO}p_{CO}}{\alpha(1 + b_{CO}p_{CO})}$$

or

$$[5] \qquad \frac{1}{r} = \beta\frac{1}{p_{CO}} + \alpha$$

where $\alpha = (1 + b_{H_2O}p_{H_2O})/(kb_{H_2O}p_{H_2O})$ and $\beta = \alpha/b_{CO}$.

The Langmuir-type plots of $(1/r)$ *vs.* $(1/p_{CO})$ are shown in Fig. 5. Linear plots were obtained over the entire partial pressure range studied from 20 to 240 Torr at 320 °C and 20 to 100 Torr at 380 °C.

The observation that the water-gas conversion can be maintained at the lowest water vapor

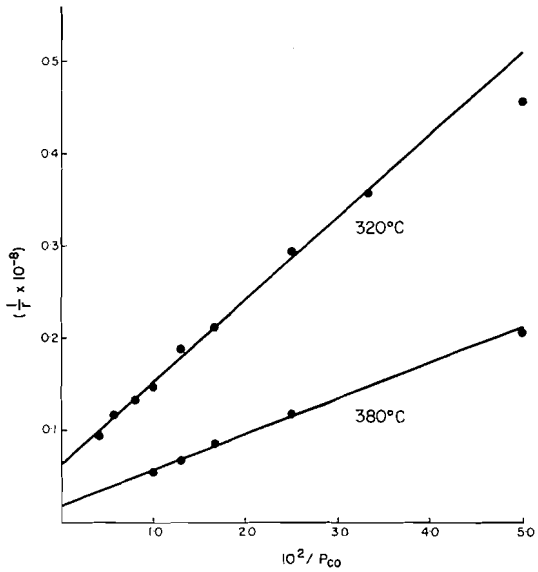

FIG. 5. Langmuir-type plots for the water-gas shift reaction on manganese(II) oxide at 320 and 380 °C.

partial pressure appears to justify the assumption that the amount of adsorbed water vapor is constant. Rapid saturation of adsorption sites specific to water or slow desorption would be expected to result in the observed zero-order correspondence in the experimental rate expression (1).

The derived rate equation (4*a*) also predicts a decrease in the rate of reaction when $\alpha(1 + b_{CO}p_{CO}) > b_{CO}p_{CO}$. This is in agreement with the experimental change detected in the carbon monoxide reaction order from 0.75 in the partial pressure region 20 to 100 Torr, to 0.5 between 120 and 240 Torr. Thus, the 38% increase in the rate of conversion observed after the carbon monoxide pretreatment, curve *D*, Fig. 3, may be associated with an increase in the surface coverage of carbon monoxide as a result of the pretreatment.

A useful indication of the nature of the reaction mechanism can be obtained from the results of the experiments shown in Fig. 3. Thus the surface of the catalyst is susceptible to a reversible oxidation–reduction process since either carbon dioxide or water vapor can act separately as oxidizing agents, as shown, for example, by the 44% increase in the rate of conversion of the water-gas mixture immediately after the pretreatments with water vapor and carbon dioxide. Further, the green manganese oxide with a surface area 14.5 $m^2\ g^{-1}$, prepared by reduction of α-Mn_2O_3 in hydrogen at 600 °C, gave less than 1% of the rate of conversion obtained with the catalyst prepared by reduction in the standard water-gas mixture and a surface area of 16.0 $m^2\ g^{-1}$. Clearly the conversion rate process is sensitive to the stoichiometry of the catalyst studied.

On the basis of the present findings, the mechanism of the surface reaction may be summarized:

$$[6] \qquad CO_{(ads)} + [O] \rightarrow CO_{2(g)} + [\ ]$$

$$[7] \qquad [\ ] + H_2O \rightarrow H_{2(g)} + [O]$$

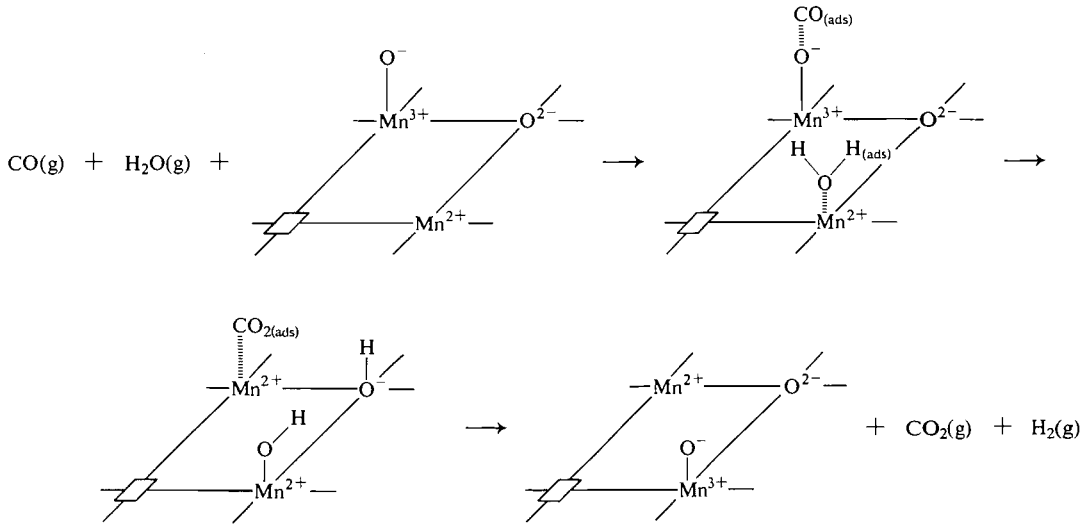
where [O] and [ ] represent an oxygen atom or ion and an oxide vacancy on the surface of the catalyst, respectively. The rate-determining step is then the reaction between adsorbed carbon monoxide and some surface oxygen species (6).

Studies of the simultaneous dehydrogenation and dehydration of 2–propanol on manganese(II) oxide (9) have shown that the water vapor partial pressure has virtually no effect on the dehydrogenation process but that the dehydration process is inhibited which implies that specific dehydrogenation and dehydration sites exist on the surface of this catalyst. The observed zero order rate dependence on the water vapor partial pressure in the shift reaction suggests that reaction 7 may occur on the dehydrogenation sites since this reaction can be regarded as dehydrogenation. Also the decomposition of N_2O on manganese oxides (10) of variable metal oxidation states has been explained by a redox-type mechanism which is facilitated by the presence of Mn^{III} sites and it was proposed that oxidation reactions should be assisted by conditions that tend to preserve the 3+ oxidation state of the metal. Such a proposal is also consistent with the present results, and the following surface scheme may be suggested here for steady-state catalysis.

The amount of excess surface oxygen would be maintained at a constant level during the course of the conversion. An essentially similar scheme has been proposed to account for catalysis on copper chromite (19).

The results of oxygen-exchange reactions on manganese(IV) oxide indicate that non-uniform oxygen species are present on the oxide surface (23). And while other relevant studies (24) have shown that surface Mn(III)—O bonds are weaker than those formed between manganese(II)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



and oxygen, there is also clear evidence that at least two forms of chemisorbed oxygen are present on manganese(II) oxide (10). Hence it is proposed that the change in the value of the apparent activation energy at 340 to 350 °C may be associated with a switch from one type of active surface oxygen species in the reaction to another during the course of the temperature rise. The exact nature of these species is still uncertain (10) but the close correspondence between the temperature at which the apparent activation energy changes and the Curie transition from ferromagnetic to paramagnetic properties of the oxide at 337 °C may be significant. The constant value of the apparent activation energy found from curve *B*, Fig. 4 is believed to be a consequence of the removal or destruction of low-temperature active oxygen sites due to oxide sintering at the higher temperatures before and during the stepwise decrease in temperature from 400 °C. The possibility of characterizing these surface species presents an interesting problem for further study.

It may be concluded that the use of manganese(II) oxide as a major component in commercial shift catalysts would be most favored at temperatures around 300 °C. The major long-term deterioration in the catalytic activity of the oxide would be associated with solid sintering and the loss of excess surface oxygen. It has been observed previously that the conversion efficiency of commercial iron oxide (4) and mixed iron/chromium oxide (25) catalysts is known to fall off as a result of sintering.

Solubility Products of Aluminum Hydroxide in Various Ionic Solutions

DAVID T. Y. CHEN

Department of Chemistry, New Asia College, The Chinese University of Hong Kong, Shatin, Hong Kong

Received January 2, 1973

Solubility products of $Al(OH)_3$ were determined in various solutions of NH_4^+, Li^+, Na^+, K^+, and Ca^{2+} ions. Increasing amounts of these hydroxides were added to the respective chloride solutions containing aluminum chloride. The solutions were aged for 3 months. Activities of the OH^- ions were calculated from the p*H* values of the solutions. The total Al concentrations remaining in solutions were determined by Hsu's modified aluminon method. The Al^{3+} ion concentrations were computed using the hydrolysis equilibria of Aveston. The ion product, $a_{Al^{3+}}(a_{OH^-})^3$, was found to vary linearly with the [OH]/[Al] ratio. The solubility product of $Al(OH)_3$ was obtained by extrapolating this ratio to 3. The pK_{sp} values thus obtained were 30.55, 33.15, 30.75, 30.36, and 31.00 in NH_4^+, Li^+, Na^+, K^+, and Ca^{2+} systems respectively. The anomalously low solubility product of $Al(OH)_3$ in the Li^+ system was attributed to the specific "lithium effect".

Les produits de solubilité de $Al(OH)_3$ ont été déterminés dans diverses solutions d'ions NH_4^+, Li^+, Na^+, K^+ et Ca^{2+}. Des quantités croissantes d'hydroxydes ont été ajoutées aux solutions respectives de chlorure contenant du chlorure d'aluminium. Les solutions dataient de 3 mois. Les activités des ions OH^- ont été calculées à partir des valeurs du p*H* des solutions. Les concentrations totales en Al restant en solution ont été déterminées par la méthode modifiée de l'aluminon selon Hsu. Les concentrations en ions Al^{3+} ont été calculées d'après les équilibres d'hydrolyse d'Aveston. Le produit ionique $a_{Al^{3+}}(a_{OH^-})^3$ varie linéairement avec le rapport (OH)/(Al). Le produit de solubilité de $Al(OH)_3$ a été obtenu par extrapolation de ce rapport à 3. Les valeurs pK_{sp} ainsi obtenues ont été de 30.55, 33.15, 30.75, 30.76 et 31.00 pour les systèmes NH_4^+, Li^+, Na^+, K^+ et Ca^{2+} respectivement. Le produit de solubilité anormalement bas de $Al(OH)_3$ dans le système Li^+ a été attribué à l'effet spécifique de lithium.

[Traduit par le journal]

Can. J. Chem., **51**, 3528 (1973)

Introduction

In work described in a previous paper (1) it was found that the thermodynamic solubility product of $Al(OH)_3$ was different when different cations, NH_4^+, Li^+, K^+, were present as counter ions. In that work, bentonite was also present in the system. It might be suspected that the observed difference in the solubility product could be attributed to the presence of clay; $Al(OH)_3$ might form some sort of complex or double salts with different types of clay. It is therefore desirable to investigate the solubility product in the absence of clay and this has been done in the present work.

The solubility product of $Al(OH)_3$ has been investigated by many authors, with considerable discrepancies between the results. Gayer *et al.* (2), for example, obtained a pK_{sp} value of 32.96, Korenman *et al.* (3) one of 29.92. Using a polarographic method, Kovalenko and Nestorovich (4) deduced a pK_{sp} value of 30.32 at 22 °C. Frink and Peech (5) obtained an experimental pK_{sp} value of 33.5, and calculated a pK_{sp} value of 33.8 from thermodynamic data. Recently Turner and Brydon (6) observed that the solubility product of $Al(OH)_3$ in a clay system depends on the amount of $Al(OH)_3$ precipitated; when this amount is large, the pK_{sp} value is 33.0, while when this amount is small, the pK_{sp} value is greater than 33.0. Singh (7) obtained a pK_{sp} value of 33.6 ± 0.1 in the presence of clay. In a later paper (8), the same author reported that the pK_{sp} value of $Al(OH)_3$ in the absence of clay depends on the aluminum ion concentration; the value is 32.1, 32.7, and 33.0 when the latter is 10^{-4}, 10^{-3}, and 10^{-2} *M* respectively.

Experimental

The solubility product of $Al(OH)_3$ in K^+ system was determined by mixing $AlCl_3$ with an equivalent amount of KOH. A solution of 10.0 ml of 0.25 *M* $AlCl_3$ and a solution of 20.0 ml of 1.00 *M* KCl were mixed in a 250 ml Erlenmeyer flask. Then 83.3 ml of 0.090 *M* KOH solution was added slowly with constant shaking, and the mixture was diluted to 200 ml with redistilled water. p*H* measurements were carried out from time to time, using a Metrohm Herisau E388 compensator which can be accurately read to three figures. In the final measurement of p*H*, temperature of the solution was adjusted to 25 °C. After 3 months of aging, the solution was filtered through Whatman No. 42 filter paper and aliquots were taken for analysis. The solubility products of $Al(OH)_3$ in other sys-

tems were determined in the following way. A solution of 10.0 ml of 0.25 *M* $AlCl_3$ and 20.0 ml of 1.00 *M* of different alkali chloride solutions were mixed in separate 250 ml Erlenmeyer flasks. Different amounts of approximately 0.1 *M* alkali hydroxide solutions were added to each flask to produce different degrees of turbidity. The mixtures were all diluted to a final volume of 200 ml with redistilled water. The supernatant liquids remained cloudy even after $3\frac{1}{2}$ months of aging. Clear solutions could not be obtained by filtration or high speed centrifugation (10 000 r.p.m. for 1 h). The colloidal suspensions were dialyzed with 0.01 *M* sodium acetate and acetic acid buffer of the same p*H* as that of the sample. Cellulose dialyzing sacs made by the Arthur H. Thomas Company were used, the colloidal suspensions and buffer solutions being shaken overnight to attain equilibrium. In both cases, aluminum contents were determined using Hsu's improved aluminon method (9).

Theoretical

The activities of the OH^- ions were calculated from the p*H* values of the solutions. The activities of the Al^{3+} ions were calculated from their concentrations and their activity coefficients. There are many equations available for computing the activity coefficient of an ionic species; they yield different values. The Debye–Hückel limiting law gives very low values. The Debye–Hückel equation gives slightly higher values than the Davies equation (10). The extended Debye–Hückel equation with the salting out term yields the highest values. The author believes that the large discrepancies among the solubility product data of a certain substance reported by different workers are, at least in part, due to their ways of calculating the activity coefficient. Grunwald and Fong (11) found that the extended Debye–Hückel equation was unsatisfactory and claimed that the value of *a* in the Debye–Hückel equation should be taken as 6 Å. Although different pK_{sp} values were obtained by employing different equations for activity coefficients, the general trend was the same. In the present treatment, the Debye–Hückel equation is used. With $z = 3$, the activity for Al^{3+} ion is

$$[1] \qquad \log \gamma_{Al^{3+}} = \frac{-4.58\sqrt{\mu}}{1 + 1.97\sqrt{\mu}}$$

In computing the ionic strength, the total Al concentration found experimentally was considered as Al^{3+}.

Aluminum exists as several species in aqueous solution. The hydrolysis of Al^{3+} ion has been studied by many workers; different conclusions were obtained. Thus, Brosset and co-workers (12) suggested that aluminum probably exists as a polynuclear complex $Al_6(OH)_{15}^{3+}$ in neutral and weakly acid solutions. Aveston (13) suggested the existence of polynuclear species $Al_2(OH)_2^{4+}$ and $Al_{13}(OH)_{32}^{7+}$. Grunwald and Fong (11) suggested that only the dimer $Al_2(OH)_4(H_2O)_8^{4+}$ was present in solution of an aluminum salt and the existence of this dimer was confirmed by Akitt, Greenwood, and Lester (14) using ^{27}Al n.m.r. technique. The reason that other polynuclear complexes were not found by these authors is certainly due to the high acidity of their system (p$H = 3$). In the present case, the p*H* of the solutions was as high as 5 and even up to 8; therefore the equilibria suggested by Aveston (13) was adopted to calculate the activity of Al^{3+} ion present in the solution. According to Aveston, Al^{3+} ion hydrolyzes in aqueous solution with the existence of the following equilibria:

$$[2] \qquad 2Al^{3+} + 2H_2O \rightleftharpoons Al_2(OH)_2^{4+} + 2H^+$$

$$[3] \quad K_1 = \frac{[Al_2(OH)_2^{4+}]\gamma_{Al_2(OH)_2^{4+}}(a_{H^+})^2}{[Al^{3+}]^2(\gamma_{Al^{3+}})^2} = 10^{-7.07}$$

and

$$[4] \qquad 13Al^{3+} + 32H_2O \rightleftharpoons Al_{13}(OH)_{32}^{7+} + 32H^+$$

$$[5] \quad K_2 = \frac{[Al_{13}(OH)_{32}^{7+}]\gamma_{Al_{13}(OH)_{32}^{7+}}(a_{H^+})^{32}}{[Al^{3+}]^{13}(\gamma_{Al^{3+}})^{13}} = 10^{-104.5}$$

where *a* denotes activities, the square brackets denote concentrations, and γ denotes activity coefficients. From [3] we obtain

$$[6] \quad [Al_2(OH)_2^{4+}] = \frac{10^{-7.07}(\gamma_{Al^{3+}})^2}{\gamma_{Al_2(OH)_2^{4+}}(a_{H^+})^2}[Al^{3+}]^2$$

From [5], we have

$$[7] \quad [Al_{13}(OH)_{32}^{7+}] = \frac{10^{-104.5}(\gamma_{Al^{3+}})^{13}}{\gamma_{Al_{13}(OH)_{32}^{7+}}(a_{H^+})^{32}}[Al^{3+}]^{13}$$

To evaluate the ratio of activity coefficients of two species, the Debye–Hückel's limiting law was simply employed, *i.e.*

$$[8] \qquad \log \gamma_i = -0.509\, z_i^2 \sqrt{u}$$

The following relationships are thus obtained:

$$[9] \qquad \frac{\log \gamma_{Al_2(OH)_2^{4+}}}{\log \gamma_{Al^{3+}}} = 1.78$$

$$[10] \qquad \frac{\log \gamma_{Al_{13}(OH)_{32}^{7+}}}{\log \gamma_{Al^{3+}}} = 5.44$$

or

$$[11] \qquad \gamma_{Al_2(OH)_2^{4+}} = \gamma_{Al^{3+}}^{1.78}$$

$$[12] \qquad \gamma_{Al_{13}(OH)_{32}^{7+}} = \gamma_{Al^{3+}}^{5.44}$$

On the assumption that all other complex species are present to a negligible extent, the following relationship holds,

$$[13] \quad 13[Al_{13}(OH)_{32}^{7+}] + 2[Al_2(OH)_2^{4+}] + [Al^{3+}] = [Al_t]$$

where $[Al_t]$ is the experimentally determined concentration of all the Al species in solution. Substituting eq. 6, 7, 11, and 12 into eq. 13, simplifying, and replacing $\gamma_{Al^{3+}}$ simply by γ, we obtain

$$[14] \quad \frac{13 \times 10^{-104.5}\gamma^{7.56}}{(a_{H^+})^{32}}[Al^{3+}]^{13} + \frac{2 \times 10^{-7.07}\gamma^{0.22}}{(a_{H^+})^2}[Al^{3+}]^2 + [Al^{3+}] - [Al_t] = 0$$

The concentration of the Al^{3+} ion was obtained from a computer solution of the above equation.

Results and Discussion

When alkali hydroxides were added slowly to aluminum salt solutions, the pH increased rapidly at first, then slowly. At the end of titration it again increased rapidly. Figure 1 shows typical titration curves of $AlCl_3$ in different systems. It is interesting to note that the pH of the solution in the NH_4^+ system was the highest when equal amounts of corresponding hydroxides were added to different systems. When all the Al^{3+} ions were precipitated, the pH of the solution in this system was the lowest.

The solubility products of $Al(OH)_3$ in different systems were first determined by the same method as that used in the K^+ system. Equivalent amounts of different alkali hydroxides were added separately to $AlCl_3$ solutions containing the corresponding alkali chlorides. The solutions were cloudy at first, but after standing overnight, white gelatinous precipitates were formed, the supernatant solutions remaining clear. The precipitates in the Na^+ and K^+ systems looked whiter and denser, while those in the Li^+ and NH_4^+ systems looked somewhat translucent.

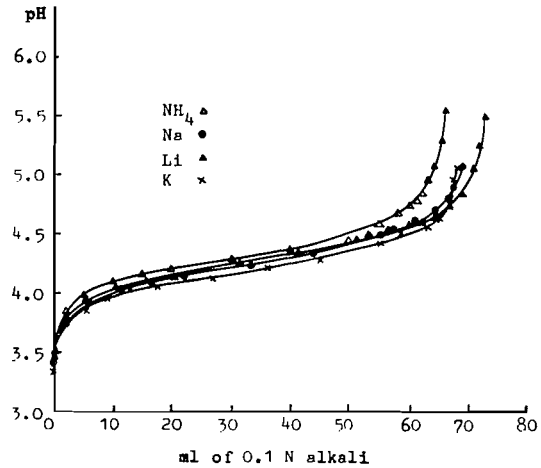

FIG. 1. Titration curves of $AlCl_3$ with hydroxides in different systems.

After aging for 3 months, the pH values of the solutions remained practically constant. The pK_{sp} values were then determined. The results are shown in Table 1. It is seen that only the solubility product of $Al(OH)_3$ in the K^+ system can be determined in this way; the solubilities of $Al(OH)_3$ in the other systems were too small to give determinable amounts of aluminum ions. Slightly different methods were then used to determine the solubility products of $Al(OH)_3$ in other systems, as described in the Experimental section. The results are shown in Tables 2 to 6. If the calculated pK_{sp} values in each system were plotted against the [OH]/[Al] ratio, straight lines were obtained, as shown in Fig. 2.

The solubility product of a crystalline precipitate should be independent of the reagent added, or the amount of precipitate formed.

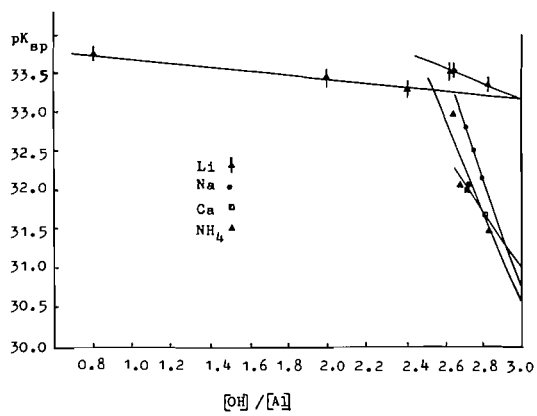

FIG. 2. Variation of pK_{sp} with [OH]/[Al].

This is because crystalline precipitates have definite compositions. $Al(OH)_3$ is amorphous; its composition may not be definite. In systems where the [OH]/[Al] ratio is less than 3, there are surplus Al^{3+} ions in the solution. The $Al(OH)_3$ precipitate formed will definitely adsorb some Al^{3+} ions on its surface. Amorphous solids have very large surface area. Since they have no definite structure, there is really no difference between the precipitated Al^{3+} ions and the adsorbed Al^{3+} ions. Surface adsorption is almost a linear function of the concentration of the adsorbable substance when the latter is low. Therefore, we can expect that the composition of the aluminum hydroxide formed, *i.e.* the ratio of [OH]/[Al] in the precipitate, would be a linear function of the added [OH]/[Al] ratio. Since our results show that the pK_{sp} values are linear to the added [OH]/[Al] ratio, it must mean that the pK_{sp} value is also a linear function of the com-

pK_{sp}	32.00	31.68	32.06

position of the precipitate. If the pK_{sp} values were extrapolated to the added [OH]/[Al] ratio of 3, the value obtained should represent the true pK_{sp} of $Al(OH)_3$. The values thus obtained for the NH^{4+}, Na^+, Ca^{2+}, and Li^+ systems are 30.55, 30.75, 31.00, and 33.15 respectively. For the pK_{sp} values in the Li^+ system two lines with different slopes are shown. Experiments 7, 8, and 9 give a line of steeper slope while experiments 10, 11, and 12 give a line of smaller slope. The reason for this is that the latter experiments were aged for a shorter time, only for about 1 month. Nevertheless, the two lines extrapolate to a common intercept with the [OH]/[Al] = 3 line. This is to be expected, because the common intercept represents the true pK_{sp} of $Al(OH)_3$ in that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

system. Since the composition of the precipitate changes during aging, so will the pK_{sp} value. Therefore the slope of the pK_{sp} *vs.* [OH]/[Al] ratio line is not the same when the aging time is different.

It can therefore be concluded that the solubility of $Al(OH)_3$ in the presence of the Li^+ ion is significantly lower than its solubility in the presence of other metal ions. There is another proof for this fact. When hydroxides were slowly added to the $AlCl_3$ solutions in different systems, the p*H* values increased and the solutions became cloudy. On standing, the cloudiness disappeared and the p*H* of the solutions fell. The behavior was somewhat different in the Li^+ system. The solution may reach a higher p*H* value than in other systems, but with less cloudiness by the addition of a large amount of LiOH. After the solution had been left overnight, considerable precipitate was formed. Much smaller amounts of LiOH than other hydroxides were needed to form small amounts of precipitate. In one experiment (No. 10), the ratio of [OH]/[Al] was only 0.8. On rapid addition of LiOH, the solution showed slight coludiness at first, then cleared up after an hour; however cloudiness returned after standing overnight, small amounts of precipitate being formed on further standing. In the K^+ system, when the ratio of [OH]/[Al] was 0.9, the solution showed slight cloudiness at the end of addition of KOH. Cloudiness disappeared on standing and the solution remained clear afterwards.

It was first thought that $Al(OH)_3$ might form some sort of double or complex salt with LiCl or LiOH. But the precipitate, after it had been freed from chloride by dialysis, was found to contain negligible amounts of Li (0.15%) by atomic absorption analysis. The larger pK_{sp} value of $Al(OH)_3$ in the Li^+ system must, therefore, be attributed to the influence of the Li^+ ions present in the solution. Krishnamurti (15) considered the solubility product of a substance from a dynamic point of view. The rate of dissolution of a precipitate is governed by the coulombic force between the ions in the crystal and the ion–solvent interaction. The rate of recombination of ions to form a crystal is governed by the coulombic force between the ions and their ionic atmosphere as well as the ion–solvent interaction. The last term is less important, because it operates in both directions. The difference in solubility of an ionic substance in aqueous solutions of different compositions is, therefore, due to the coulombic force between its ions and their ionic atmospheres. In the present work the differences among ionic atmospheres in various systems are the cations. The charge density of the bare Ca^{2+} ion is approximately the same as that of the bare Li^+ ion and is greater than those of the other metal ions being investigated, yet the solubility product of $Al(OH)_3$ in the Ca^{2+} system does not differ much from those in other alkali metal systems, but differs markedly from that in the Li^+ system. This rules out the size effect. The abnormal effect of the Li^+ ion as compared to the effect of other metal ions on the solubility product of $Al(OH)_3$ must, therefore, be attributed to a specific effect of the Li^+ ions in solution. This specific "lithium effect" was also observed on the distribution coefficients in their anion exchange separation of the rare earths by Chen and Liao (16).

The author is grateful to Professor J. H. Wang of Yale University for his atomic absorption analysis, and to Mr. L. Li of the computing center of the Chinese University of Hong Kong for solving the higher power equations. He is indebted to professor K. J. Laidler of the University of Ottawa for correcting the manuscript and valuable suggestions.

On The "Low" *A*-Factors of Alkyl Radical Isomerization

K. J. MINTZ[1] AND D. J. LE ROY

Department of Chemistry, Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario M5S 1A1

Received April 5, 1973

Recent chemical activation studies of isomerizations of alkyl and alkenyl radicals involving 5, 6, and 7 member ring complexes are shown to be consistent with earlier thermal studies and support the conclusion that the *A*-factors of these reactions are "low", *i.e.* substantially less than 10^{11} s^{-1}. A possible explanation, consistent with transition state theory, is given in terms of configurational entropy.

Des études récentes d'activation chimique des réactions d'isomérisation de radicaux alkyles et alkényles impliquant des complexes de cycles à 5, 6 et 7 chaînons sont en accord avec des études thermiques antérieures et corroborent la conclusion selon laquelle les facteurs -*A* de ces réactions sont "bas", c'est-à-dire beaucoup moindre que 10^{11} s^{-1}. Une explication possible, en accord avec la théorie des états de transition, est donnée en termes d'entropie configurationnelle. [Traduit par le journal]

Can. J. Chem., **51**, 3534 (1973)

Introduction

Although isomerization of alkyl radicals (by H-shift) had been postulated for some time (1), quantitative kinetic data have been obtained only fairly recently. The first study, by Endrenyi and Le Roy (2) on the isomerization of *n*-pentyl radicals in a thermal system, yielded $k = 1.4 \times 10^7 \exp(-10.8 \times 10^3/RT)$. Somewhat later, Watkins and Ostreko (3), in a similar study on the isomerization of *n*-hexyl radicals, obtained $k = 2.1 \times 10^7 \exp(-8.3 \times 10^3/RT)$. These *A*-factors are difficult to rationalize on the basis of the usual formulation of the transition-state theory since, if reasonable values of entropies of internal rotation are assumed, the predicted *A*-factors are about 10^3 larger. In fact, this discrepancy has led other authors (4) to reject the experimental results. Recently several studies on the isomerization of chemically activated alkyl radicals have been made (5–8) in which the authors have interpreted their results (through the use of activated complex theory) to be consistent only with "normal" *A*-factors, in disagreement with the thermal studies.

The purpose of this paper is to use a recently developed method (9) to obtain approximate *A*-factors directly from experimental data obtained from chemical activation studies, a method which does not require assuming a structure for the activated complex, and to show that they are reasonably consistent with the results of the thermal studies.

[1]Present address: Chemistry Division, National Research Council of Canada, Ottawa, Canada K1A 0R6.

Procedure

Forst (10) has recently derived the following equation for the theoretical rate constant at an energy *E* for a unimolecular reaction, assuming that *A* and E_∞ are temperature independent:

$$[1] \qquad k(E) = A\,N(E - E_\infty)/N(E)$$

where E_∞ is the Arrhenius activation energy for reaction and $N(E)$ is the density of states of the reactant molecule at the energy *E*. Since in many chemical activation studies the energy distribution can be regarded as being monoenergetic, $k(E)$ may be equated to the experimental rate constant, k_a. Hence, eq. 1 allows the calculation of the Arrhenius *A*-factor directly from k_a using only knowledge of the reactant molecule. This method has recently been applied to the decompositions of excited alcohols (9); the results obtained are consistent with decomposition of alkanes in thermal systems.

The densities of states were calculated by a method due to Rabinovitch and Whitten (11) as modified by Forst (12). Knowledge of the vibrational frequencies of the radicals was required. Since they are unknown, they were assumed to be the same as for the corresponding alkanes but with a C—H stretch and two C—H bends eliminated. The frequencies for the *n*-alkanes are available (13); those of the branched alkanes were estimated by analogy with other compounds. It should be stressed that very little uncertainty in *A* is caused by the uncertainty in the frequencies.

The average energies of the activated radicals were calculated by the method previously given (9); the differences between these (shown in Table 1) and those given by the original authors are small and have no significant effect on the results.

Unfortunately, it is impossible to estimate E_∞ with sufficient accuracy to calculate *A* accurately. Almost certainly, E_∞ will not be smaller than the activation energy for intermolecular abstractions (about 8.3 kcal/mol). Therefore, the *A*-factors were calculated for three different values of E_∞, 10, 15, and 20 kcal/mol, covering the range of probable values.

The values of k_a in Table 1 are the experimental values reported by the authors cited. According to Hardwidge *et al.* (7), and Larson *et al.* (8), their values are probably accurate to within a factor of two; the others should be rather more accurate.

Discussion

n-Pentyl Radical Isomerization

Watkins and Lawson (5) suggested that chemically activated radicals were involved in the work of Endrenyi and Le Roy (2) and concluded that, since k_a does not have as strong a temperature dependence as $k_{thermal}$, and because both chemical activation and thermal activation contribute to the "apparent" unimolecular rate constant, the observed rate constant would have a smaller temperature dependence than if the reaction were completely thermal. This situation could account for both the "low" A-factor and low activation energy reported by Endrenyi and Le Roy. However, in later experiments (14), Endrenyi and Le Roy added 506 Torr of CO_2 and found no change in the isomerization rate constant of n-pentyl radicals, from which they concluded that there was no evidence for chemical activation in their work. Furthermore, in the study by Watkins and Ostreko (3) on the isomerization of n-hexyl radicals in which a "low" A-factor was also found, addition of excess Xe and also C_3F_8 was found not to change the rate of isomerization and they concluded that "the radicals undergoing isomerization are in thermal equilibrium with the bath".

Very recently, Watkins (15) has suggested that the "low" A-factor in the work of Endrenyi and Le Roy is due to the neglect of the effect of the thermal decomposition of the isomerized radicals. By doing a mass balance on the propene and attributing the "excess" to this decomposition, the Arrhenius parameters were calculated to be: $\log A = 11.7$, $E_\infty = 21$ kcal/mol. However, propene is produced by a large number of reactions in this system; conclusions based on it can be misleading. A careful re-examination of Endrenyi and Le Roy's data shows that the reactions of n- and sec-pentyl radicals with ethylene, acetone, and acetonyl radicals are not negligible as originally assumed. We have therefore made a new analysis of their data; the resultant Arrhenius parameters are: $\log A = 8.5 \pm 0.4$, $E_\infty = 13.0 \pm 0.8$ kcal/mol. (The error limits are standard deviations from the least squares plot.) Although these values are somewhat higher than those originally reported (2), they indicate that no serious error was made in the original analysis and that the A-factor for isomerization determined from the thermal experiments is definitely "low".

Watkins (16) has also studied the isomerization of n-pentyl radicals by a photochemical method and obtained $\log A = 8.3$ and $E_\infty = 15$ kcal/mol. However, these results were considered to be unreliable, supposedly because of experimental complications. The values obtained are remarkably close to the recalculated values of Endrenyi and Le Roy.

In order to interpret their experimental results, Watkins and Lawson postulated a model for the activated complex. From this, they calculated a theoretical rate constant using the R.R.K.M. expression. The latter expression requires knowledge of E_0; since this was not known, they chose a value of E_0 (18–19 kcal/mol) that made the theoretical rate constant equal to the experimental. Obviously, this procedure can not test the chosen model. A value of E_0 of 18–19 kcal/mol implies that the value of E_∞ will be about 19–20 kcal/mol,[2] from which we calculate that A will be about 2×10^{10} s^{-1}, still somewhat less than "normal". On the other hand, if the value of E_∞ is taken to be equal to the activation energy determined by Endrenyi and Le Roy (as revised here), the chemical activation study yields an A-factor of 1.4×10^9 s^{-1}, which is within the error limit of the revised value of Endrenyi and Le Roy.

It should be noted that choosing a model for the complex and assigning frequencies is equivalent to assigning a standard entropy to the model complex and hence, in terms of conventional transition state theory is equivalent to *assigning* an A-factor to the thermal reaction. The value of A corresponding to the model of Watkins and Lawson, calculated from the expression $A = (ekT/h) \exp(\Delta S^*/R)$, is approximately 1×10^{11} s^{-1}.

In a system which involves only chemical activation, a plot of the isomerization:stabilization ratio *vs.* pressure^{-1} should yield a straight line going through the origin. However, Watkins and Lawson found that the intercept of this plot was definitely positive. It is not unreasonable to assume that this was due to the presence of

[2] $E_\infty = E_0 + T\langle\Delta C_v^*\rangle + RT$ (17). Reasonable values of $|T\langle\Delta C_v^*\rangle|$ for the formation of a ring complex are < 1 kcal/mol.

thermal isomerization. An approximate steady-state analysis of their system at the high-pressure limit at 57 °C yields a thermal isomerization rate constant of about 0.2 s^{-1}. This is in good agreement with the extrapolated value of the revised rate constants of Endrenyi and Le Roy, *viz.* 0.3 s^{-1}.

In view of the above discussion, it seems clear that the thermal experiments of Endrenyi and Le Roy and the chemical activation experiments of Watkins and Lawson are mutually consistent. Hence, the experimental evidence seems to favor a "low" A-factor for the isomerization of n-pentyl radicals.

Isomerization of 3-Methyl-1-buten-1-yl Radicals

Applying R.R.K.M. theory to their model[3] of the activated complex, Watkins and O'Deen (6) found that the best agreement with experiment occurred for $E_0 = 17.1$ kcal/mol, slightly smaller than they calculated for the isomerization of n-pentyl radicals. Regardless of the model, one would not expect a large difference in E_0 between these two reactions, both of which involve a five-member ring in the activated complex. Table 1 shows clearly that if E_∞ is about the same, then the A-factor should be about 100 times that for the n-pentyl reaction. Furthermore, if A for the isomerization of 3-methyl-1-buten-1-yl were assumed to be "normal" (10^{11} s^{-1}), then E_∞ would be about 14 kcal/mol which is very close to the recalculated value of the activation energy of n-pentyl isomerization. Hence, this study of the chemically activated isomerization of 3-methyl-1-buten-1-yl gives even more support for the "low" A-factor of n-pentyl radical isomerization.

Other Alkyl Radical Isomerizations

It would seem most likely that all alkyl isomerizations which involve an H atom transfer and a five-member ring in the activated complex have about the same activation energy (within 1–2 kcal/mol). However, it is evident from Table 1 that any choice of a common value of E_∞ leads to the conclusion that the A-factors will range over nearly two orders of magnitude. Furthermore, a reasonable choice of E_∞, *viz.* 15 kcal/mol, yields "low" values of A.

Isomerization involving 6-member rings in the activated complex are generally assumed to have little strain energy, and would therefore be expected to have values of E_∞ similar to that of intermolecular hydrogen abstractions, *viz.* about 8.3 kcal/mol. Again, one can see from Table 1 that whilst there is a large range of values of A, almost all appear to be "low".

Only one isomerization has been studied which involves a 7-member ring in the activated complex (2-nonyl radical). The calculated A-factor for this reaction, which should involve a strain free complex, is significantly smaller than that of the isomerization of the same species via a 6-member ring in the activated complex.

Larson and co-workers (7, 8) have interpreted their results by assuming a certain model of the activated complex (which yields A factors of approximately 10^{11} s^{-1}) and finding the value of E_0 that makes the theoretical (R.R.K.M.) value of k_a equal to the experimental value. This procedure is the same as was used by Watkins and Lawson (5). It seems to us that, at the present time, there is not sufficient experimental evidence to attribute all differences in k_a values solely to differences in E_0, rather than to differences in both A and E_∞.

Estimation of E_∞

Several authors (5–7) have estimated activation energies for these isomerizations by using the value for intermolecular hydrogen abstractions as the base value and then adding in contributions from strain energy estimated by analogy with cyclic carbon compounds. Although this procedure is valid qualitatively and allows one to show, for example, that the activation energy for isomerization of n-pentyl is greater than that of n-hexyl radicals, it is not valid to apply the method quantitatively for the following reasons, derived from the knowledge of the potential-energy surfaces for intermolecular hydrogen atom transfer:

(*1*) The col of the minimum energy path is located at rather larger distances than the equilibrium bond distances.

(*2*) Since a linear reaction path is strongly favored, the use of a symmetric ring for the transition state may not be justified.

(*3*) Tunneling may play an important role in reducing the apparent activation energy.

(*4*) The activation energy of the intramolecular hydrogen abstractions may be slightly higher than that of the intermolecular due to strain caused by eclipsing of H atoms in the activated complex.

[3]This model yields an A-factor of about 1×10^{11} s^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Unfortunately, the experimental data on activation energies of these isomerizations are not yet of sufficient accuracy to allow meaningful comparisons to be made with theory.

Interpretation of the "Low" A-Factors

One possible approach toward an explanation for these effects is contained in the observation of Hardwidge *et al.* (7) that "An H atom transfer occurring internally in a long-chain molecule can be thought of as a 'bimolecular' process between two ends of the molecule with the relative 'translation' being supplied by the excited bending modes". It is evident that one can classify unimolecular reactions of long-chain molecules into two types: (*a*) those involving adjacent centers, and (*b*) those involving non-adjacent centers. Those in the second category could be thought of as involving intramolecular collisions, and possibly requiring a special theoretical treatment.

From the point of view of reaction dynamics, unimolecular reactions of type (*b*) are subject to an additional condition before reaction can take place, namely a unique configuration of the chain. Thus, if a long-chain radical were capable of undergoing reactions of both types, each with the same energy requirement, one would expect the reaction of type (*b*) to be slower.

From the thermodynamic point of view of transition state theory, this difference in rates should be accountable in terms of the differences in entropy of formation of the corresponding complexes, provided that entropies are calculated correctly. In evaluating the molar entropy in the standard state of, say, *n*-pentyl radicals no cognizance is normally taken of the configurational entropy. If this reactant exists in n equally probable different configurations its configurational entropy would be equal to $R \ln n$.

For any chemical reaction in which the "product" also has a configurational entropy of $R \ln n$, for example the formation of a complex for a reaction of type (*a*), the configurational entropy will cancel out (or approximately so) in evaluating the entropy of formation of the complex. In this case, there would be no reason to include the configurational entropy in the evaluation of $\Delta S^{\ddagger}$, for the same reason that one need not include the contribution of nuclear spin in calculating ΔS^0 for chemical reactions. However, if the reaction consists in the formation of a complex for a reaction of type (*b*), the configurational entropy of the reagent will not cancel out completely. The standard entropy of the complex will then be less than that of the reagent, not only by an amount corresponding to the loss of internal rotational degrees of freedom, but also by an amount equal to the loss in configurational entropy. The former is, of course, evaluated in terms of the corresponding partition functions. The latter can only be evaluated by a separate detailed examination of the configurations available to the reagent and the complex.

In summary, it is suggested that in applying transition state theory to unimolecular reactions of type (*b*) the value of $\Delta S^{\ddagger}$ should include the difference in configurational entropy of the reagent and complex.

Maleic Anhydride – Triethylamine Complex

MAHMOOD F. MAYAHI AND M. F. EL-BERMANI
Chemistry Department, College of Science, Adhamia, Baghdad, Iraq

Received March 26, 1973

Reaction of triethylamine with maleic anhydride (MA) forms first a yellow solution, which immediately turns into a dark brown product with a large increase in temperature. The addition product is a 1:1 open chain inner salt  . The spectral properties of this salt are reported.

La réaction de la triéthylamine avec l'anhydride maléique (MA) donne au départ une solution jaune qui devient immédiatement brun foncé avec une augmentation notable de la température. Le produit provient d'une addition 1:1 et correspond à un sel interne en chaîne ouverte  . Les propriétés spectrales de ce sel sont rapportées.

Introduction

Maleic anhydride enters into many non-photochemical and photochemical reactions both of which may proceed through charge-transfer complexes (1). In this paper we report the reaction of maleic anhydride (MA) with triethylamine (TEA). The MA molecule is planar (2), and it is an acceptor with an electron affinity of 0.11 eV (ref. 1, p. 387), and a dipole moment of 3.95 D (3), while TEA is a strong organic base, with a pK_a of 10.5 (4). Thus the MA–TEA system promises to be an interesting one, in that it shows a two stage reaction, the formation of the expected charge-transfer complex, and the collapse of this complex into a stable product.

Experimental

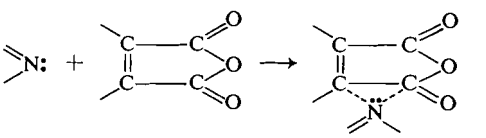
Maleic anhydride was supplied by British Drug Houses, Poole, England. It was purified by two recrystallizations from chloroform, the solvent being removed under partial vacuum at room temperature. TEA was distilled before use.

The u.v. and visible spectra were recorded on a Unicam SP800, using 1 mm and 10 mm quartz cells. The i.r. spectra were recorded on a Hilger and Watt H 800 NaCl prism spectrophotometer using KBr windows. The n.m.r. spectra were recorded on a Varian 60A at a probe temperature of 37 °C.

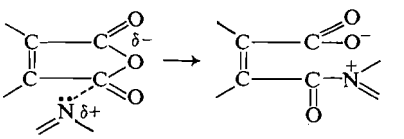
The reaction of MA and TEA was done in a 250 ml calorimeter. MA (8.671 g) was added to 10.913 g of TEA (a slight excess of the 1:1 ratio). The temperature was read every 30 s. From a plot of temperature *vs.* time (not shown) it was found that the temperature increased 10° in the first 5 min and increased 50° in the next 4 min, The mixture finally became a dark brown solid after 9 min. Qualitatively MA was added to TEA in a beaker, giving a clear yellow solution which quickly turned into dark brown paste, with evolution of heat. The product was dried in a vacuum desiccator.

Results and Discussion

The formation of the charge-transfer complex, and the collapse of this complex into a dark brown product can be written as follows:



π-complex, yellow



σ-complex dark brown product

The nature of the product was established by u.v., n.m.r., and i.r. studies. Table 1 shows the u.v. and visible spectra of the product. The band in the 210 nm range has a high ε_{max} ($\sim 10^4$), which is of the same order as that of pure MA, indicating the presence of the C=C bond in the product. The bands found in the visible region indicate the presence of the extended conjugated system.

TABLE 1. Ultraviolet and visible spectra of the MA–TEA complex in different solvents*

Solvent	λ_{max} (ε_{max}) (nm)		Pure MA
n-Heptane	206	490, 526	
Ethanol	212 (1.14×10^4)		203 (0.83×10^4)
Methanol	210	350, 407, 510, 540	
Ether	210		
Dioxane	220 (3.75×10^4)		206 (0.77×10^4)
Water	212 (3.4×10^4)	350, 403, 510, 540	210 (2.84×10^4)
TEA	—	490, 537	

*In ethanol, ether, and dioxane, only the u.v. spectra are given because the complex is very slightly soluble in these solvents and no bands in the visible region were observed. The *n*-heptane solution was gently warmed, then cooled before taking the spectrum.

The n.m.r. spectra of the product was obtained in D_2O. The presence of the  bond is indicated by the band at 6.43δ, compared to that of MA at 6.52δ. The band for the CH_3 group, a triplet, is at 1.026δ in pure TEA, while it is at 1.22δ in the product, a shift of 0.20δ to lower field. The band for the CH_2 group, a quartet, is at 2.56δ in pure TEA, while it is at 3.14δ in the product, a shift of 0.58δ to lower field. The down field shift of both of these bands is due to the electron withdrawing effect of the positive nitrogen $-\overset{+}{N}\equiv$ present in the product.

The i.r. spectrum of a thin film of the product shows bands at 1730 cm^{-1} (a shoulder) and in the 1716 cm^{-1} region, which may be due to the group  . The loss of resonance in this amide group shifts the $\nu_{C=O}$ from 1680–1650 cm^{-1} in the simple amide to higher wavenumbers. These bands are at lower frequency than that of MA (1853 cm^{-1} and 1784 cm^{-1} in this study) because of loss of ring strain. There is a strong band at 1580 cm^{-1} which may be due to  δ–(5). However, the absence of a band in the region 1200–1300 cm^{-1} indicates the disappearance of the C—O bond present in pure MA (ν_{C-O} 1268, 1068 (2), and at 1264 cm^{-1} in this study) thus indicating the opening of the MA ring by TEA in the product.

The participation of π- and σ-complexes in chemical reactions is well known (1). The π-complex involves the interaction between the pair of electrons in TEA and the π-orbitals of both of the C=C and C=O bonds, since the addition of succinic anhydride, with a dipole moment of 3.83 D (3), to TEA does not form a yellow color nor any product.

Theoretical Considerations and Equilibrium Conditions in Analytical Potentiometry. Computer Facilitated Mathematical Analysis of Equilibria in a Multicomponent System

BIHUDHENDRA SARKAR[1] AND THEO P. A. KRUCK

Division of Biochemistry, The Research Institute, The Hospital for Sick Children, Toronto, and Department of Biochemistry, University of Toronto, Toronto, Ontario M5G 1X8

Received June 14, 1972[2]

A method entitled "analytical potentiometry" is described which permits the accurate determination of the stability constants and of the distribution of simultaneously existing complex species in multicomponent systems. A series of computer programs are introduced to facilitate the otherwise tedious mathematical analysis of data. Besides simple binary systems, this method is capable of dealing with mixed ligand coordination complexes and can be adapted to polynuclear systems. For many metal ions, there are no electrodes permitting the accurate determination of those ions over a wide enough concentration range. This method eliminates the need for metal ion specific electrodes. The concentration of free metal ions is determined indirectly by the use of a weak base and the glass electrode. These features bear great significance in resolving complex systems containing multiple species simultaneously which cannot be solved by the commonly known classical methods.

On décrit une méthode appelée "potentiométrie analytique" qui permet une évaluation précise des constantes de stabilité et de distribution de plusieurs espèces de complexes existant simultanément dans des systèmes à plusieurs composantes. On présente aussi une série de programmes de calcul afin de faciliter l'analyse mathématique des résultats qui, autrement, serait laborieuse. En plus des systèmes binaires simples, cette méthode permet d'analyser des mélanges de complexes de coordination et peut être adoptée afin d'étudier des systèmes polynucléaires. Pour plusieurs ions métalliques, il n'existe pas d'électrode permettant une détermination précise de ces ions dans un intervalle de concentration suffisamment large. Cette méthode élimine donc la nécessité de posséder des électrodes spécifiques de ces ions métalliques. La concentration des ions de métal libre est en effet déterminée indirectement en utilisant une base faible et une électrode de verre. Ces qualités sont donc d'une grande utilité lors de l'étude de systèmes complexes contenant plusieurs espèces simultanément qui, autrement, ne pourraient être étudiés par les méthodes classiques que nous connaissons. [Traduit par le journal]

Can. J. Chem., 51, 3541 (1973)

Introduction

The importance of metal ions in biological systems led many bio-inorganic chemists to investigate equilibria between metal ions and biological ligands in aqueous solution. A variety of techniques have been developed to study simple and complex systems (1, 2). Only in recent years, with the introduction of high speed and large memory computers, has it been feasible to study multiple equilibria in solution. The most accurate probes available for measuring concentrations of various ions are ion specific electrodes, especially the glass electrode used to measure p*H*. With proper care, four to five digit accuracy of the e.m.f. can now be obtained between p*H* 2 and 12. Using the glass electrode, Bjerrum (3) demonstrated its usefulness in examining the stepwise equilibrium constants of reactions between metal and ligands, where the ligand was the conjugate base of a weak acid. If proton liberation is involved in the equilibrium reaction, potentiometry will be the method of choice for the study of the stability of the products formed. Using the law of mass action, equilibrium conditions can be analytically defined, which could then describe the whole system.

Several authors (4–13) have elaborated on this subject to follow the fate of an individual constituent in a complex reaction mixture. The purpose of the present study is to determine the stability constants and the quantitative distribution of all reaction products existing simultaneously in the system, and to propose a reasonably noncomplicated technique to study simple or complex equilibria. To facilitate the large amount

of calculations necessary, we have developed a series of computer programs[3] which can be used individually or serially. The method described has been successfully employed for the study of a number of metal complexes with amino acids and peptides (14–23)[4].

Theoretical Considerations

Derivation of Working Formula from Basic Thermodynamic Concepts (Gibbs–Duhem Equation)

(A) Consider a closed system in equilibrium where any number of reagents A, B, C, D,...react with each other in reversible manner to give the products $A_iB_jC_kD_l$... where, i, j, k, l, ... can be any positive integral number defining the stoichiometric amount of reagents A,B,C, or D integrated into the product molecule $A_iB_jC_kD_l$. For one selected case eq. 1 will describe the system.

$$[1] \qquad iA + jB + kC + lD \leftrightarrows A_iB_jC_kD_l$$

It should be noted that more than one reaction of the type described can occur simultaneously in the system yielding a different product $A_iB_jC_kD_l$.

The Gibbs–Duhem equation describes the relationship between the chemical potential of the reacting species in a closed system. In its differential form the equation reads as shown in eq. 2:

$$[2] \qquad a\mathrm{d}\mu_A + b\mathrm{d}\mu_B + \ldots h\mathrm{d}\mu_H + \ldots z\mathrm{d}\mu_Z + V\mathrm{d}P - S\mathrm{d}T = 0$$

Terms concerning the chemical potential of the solvent are also contained in this statement. Under conditions of constant temperature and pressure eq. 2 reduces to eq. 3:

$$[3] \qquad a\mathrm{d}\mu_A + b\mathrm{d}\mu_B + c\mathrm{d}\mu_C + \ldots h\mathrm{d}\mu_H + \ldots + z\mathrm{d}\mu_Z = 0$$

where $a, b, \ldots, h, z$ are the number of moles of components A, B, ..., H, ..., Z. This holds true for any number of reactants and products in the closed system. It should be noted that this relationship does not contain any assumptions of ideality but states the general condition for equilibrium at constant temperature and pressure. Furthermore, no assumptions have to be made whether the reagents are liquids or solids or whether they are in any other physical form.

For our purposes eq. 3 is not immediately adaptable to experimental design. Utilizing the rule for differentiation of products

$$[4] \qquad \mathrm{d}(uv) = v\mathrm{d}u + u\mathrm{d}v$$

we get

$$[5] \qquad \mathrm{d}(a\mu_A + b\mu_B + \ldots + h\mu_H + \ldots + z\mu_Z) = (a\mathrm{d}\mu_A + b\mathrm{d}\mu_B + \ldots + h\mathrm{d}\mu_H + \ldots + z\mathrm{d}\mu_Z) + (\mu_A\mathrm{d}a + \mu_B\mathrm{d}b + \ldots + \mu_H\mathrm{d}h + \ldots + \mu_Z\mathrm{d}z)$$

Since, at equilibrium, the concentration of all species in the reaction mixture are constant, therefore, $\mathrm{d}a = 0, \mathrm{d}b = 0, \ldots, \mathrm{d}h = 0$. Hence, eq. 5 reduces to eq. 6.

$$[6] \qquad \mathrm{d}(a\mu_A + b\mu_B + \ldots + h\mu_H + \ldots + z\mu_Z) - (a\mathrm{d}\mu_A + b\mathrm{d}\mu_B + \ldots + h\mathrm{d}\mu_H + \ldots + z\mathrm{d}\mu_Z) = 0$$

The chemical potential of a reagent can be expressed as

$$[7] \qquad \mu_A = \mu_A^0 + RT\ln\alpha = \mu_A^0 + RT\ln[\mathrm{A}]$$

where α is the activity of the reagent and under suitable conditions can be approximated by [A], the concentration of A. Also

$$[8] \qquad \mathrm{d}\mu_A = 2.3RT\,\mathrm{d}\log[\mathrm{A}]$$

[3]Computer programs: PLOT, GUESS, and LEASK were written in Fortran IV. The programs have been deposited as document number NAPS-01563 with the ASIS National Auxiliary Publication Service, c/o CCM Information Corp., 866 Third Avenue, New York, N.Y. 10022. Substituting eq. 8 into eq. 6 and dividing by $2.3RT$ we get

[9] $$\mathrm{d}(a \log [\mathrm{A}] + b \log [\mathrm{B}] + \ldots + h \log [\mathrm{H}] + \ldots + z \log [\mathrm{Z}]) = (a \,\mathrm{d} \log [\mathrm{A}] + b \,\mathrm{d} \log [\mathrm{B}] + \ldots + h \,\mathrm{d} \log [\mathrm{H}] + \ldots + z \,\mathrm{d} \log [\mathrm{Z}])$$

Rearrangement yields eq. 10.

[10] $$(h \,\mathrm{d} \log [\mathrm{H}] + a \,\mathrm{d} \log [\mathrm{A}] + b \,\mathrm{d} \log [\mathrm{B}] + \ldots + z \,\mathrm{d} \log [\mathrm{Z}]) = \mathrm{d}(a \log [\mathrm{A}] + b \log [\mathrm{B}] + \ldots + h \log [\mathrm{H}] + \ldots + z \log [\mathrm{Z}])$$

Integration of eq. 10 yields

[11] $$\int_{\log H_0}^{\log H_1} h \,\mathrm{d} \log [\mathrm{H}] = \int_{\log H_0}^{\log H_1} (\mathrm{d}\, a \log [\mathrm{A}] + \mathrm{d}\, b \log [\mathrm{B}] + \ldots + \mathrm{d}\, m \log [\mathrm{M}] + \ldots + \mathrm{d}\, z \log [\mathrm{Z}]) = [a \log [\mathrm{A}] + b \log [\mathrm{B}] + \ldots + m \log [\mathrm{M}] + \ldots + z \log [\mathrm{Z}]]_{\log H_0}^{\log H_1}$$

Introducing $-\log [\mathrm{H}] = \mathrm{p}H$, $-\log [\mathrm{A}] = \mathrm{p}A$, etc., eq. 11 reads

[12] $$-\int_{\mathrm{p}H_0}^{\mathrm{p}H_1} h \mathrm{d}\mathrm{p}H = -[a\mathrm{p}A + b\mathrm{p}B + \ldots + m\mathrm{p}M + \ldots + z\mathrm{p}Z]_{\mathrm{p}H_0}^{\mathrm{p}H_1}$$

This implies that pA, pB, pM, etc. are a function of pH. Then it can be shown that

[13] $$\int_{\mathrm{p}H_0}^{\mathrm{p}H_1} h \mathrm{d}\mathrm{p}H = a\mathrm{p}\frac{A_i}{A_0} + b\mathrm{p}\frac{B_i}{B_0} + \ldots + m\mathrm{p}\frac{M_i}{M_0} + \ldots + z\mathrm{p}\frac{Z_i}{Z_0}$$

where A_0, B_0, ..., M_0, ..., Z_0 and A_i, B_i, ..., M_i, ..., Z_i are the molar amounts of A, B, ..., M, ..., Z at the beginning and at the end of the event. Now, if we arrange our conditions such that only the concentration of one reactant is varied at any one time, say a change (δm) in the metal concentration takes place, then in order to keep the other terms constant only the addition or removal of extra protons, 'h', to the system will maintain the equilibrium conditions which includes the amount of free protons (pH).

Under these constraints eq. 13 reduces to eq. 14.

[14] $$\delta \int_{\mathrm{p}H_0}^{\mathrm{p}H_1} h \mathrm{d}\mathrm{p}H = \delta\left(m\mathrm{p}\frac{M_i}{M_0}\right)$$

Rearrangement of eq. 14 gives

[15] $$\frac{\delta}{\delta m} \int_{\mathrm{p}H_0}^{\mathrm{p}H_1} h \mathrm{d}\mathrm{p}H = \mathrm{p}M_i - \mathrm{p}M_0$$

or

[16] $$\mathrm{p}M_i = \mathrm{p}M_0 + \int_{\mathrm{p}H_0}^{\mathrm{p}H_1} \frac{\delta h}{\delta m} \mathrm{d}\mathrm{p}H$$

In eq. 16 the term ($\delta h/\delta m$) represents the amount of base δC_{OH} needed to maintain the pH of the system when an amount, δC_{M}, of metal is added to the system. δC_{OH} is representative of (or equal to) the proton liberation δH_1^+ from the ligand or solvent molecules. Therefore, we can rewrite eq. 16 to give

[17] $$\mathrm{p}M_i = \mathrm{p}M_0 + \int_{\mathrm{p}H_0}^{\mathrm{p}H_1} \left(\frac{\delta H_1^+}{\delta C_{\mathrm{M}}}\right)_{A,B,\ldots,P,V,T} \mathrm{d}\mathrm{p}H$$

where H_1^+ is the moles of protons being titrated per liter of solution. Similarly, we can hold constant everything in the system except ligand A, which is varied, and arrive at a similar expression

[18] $$\mathrm{p}A_i = \mathrm{p}A_0 + \int_{\mathrm{p}H_0}^{\mathrm{p}H_1} \left(\frac{\delta H_1^+}{\delta C_{\mathrm{A}}}\right)_{M,B,\ldots,P,V,T} \mathrm{d}\mathrm{p}H$$

Furthermore, our theoretical conditions permit us to derive similar expressions for every component taking part in any one reaction leading to the multispecies equilibrium including binary, ternary, quaternary, polynuclear systems, etc. An expression similar to eq. 18 has been derived in a different manner for a binary (one metal and one ligand) system by Österberg (7) and Sillén (8).

Their derivations again were based on earlier work by Hedström (4).[5]

Equilibrium Conditions

Consider a reaction mixture which contains, under standard conditions, C_A moles of ligand anion A, C_M moles of metal ion M, and C_H moles of hydrogen ion H, then the mass law will describe the equilibrium situation of the reaction

$$[19] \qquad pM + rA + qH \leftrightarrows M_pH_qA_r$$

and the equilibrium constant for the reaction 19 can be expressed as

$$[20] \qquad \beta_{pqr} = \frac{[M_pH_qA_r]}{m^p h^q a^r}$$

where m, h, a, are the concentrations of free metal ion, hydrogen ion and ligand anions. Then, if four values are known the fifth one may be calculated.

$$[21] \qquad [M_pH_qA_r] = \beta_{pqr} m^p h^q a^r$$

where β_{pqr} is the stoichiometric stability constant of the complex species $M_pH_qA_r$. This holds true for each of the multiple equilibria existing simultaneously in a complex reaction mixture. Since we are dealing with a closed system, all of the reactants can be accounted for in the following manner:

$$[22] \qquad C_M = m + \sum p(\beta_{pqr} m^p h^q a^r)$$

$$[23] \qquad C_H = h + \sum q(\beta_{pqr} m^p h^q a^r)$$

$$[24] \qquad C_A = a + \sum r(\beta_{pqr} m^p h^q a^r)$$

The system can be expanded to the treatment of ternary or quaternary systems by the simple addition of appropriate terms B and C, etc.

Experimental Considerations

In order for the mathematical expressions to hold, we require that the volume and molar concentration of the reactants to remain constant. Also the ionic strength should be kept constant in order to permit the use of molalities instead of activities for the subsequent calculations. At the extremes of the pH scale, the measured pH value does not reflect accurately the hydrogen ion activity. Proper corrections will have to be made in those regions. Experience has shown that in the range between pH 2–11 hydrogen ion concentration can be used to represent the hydrogen ion activity. The proton liberation H_1^+ is only a function of the titrant and is independent of hydrogen ion activity.

Since hydrogen ion activities enter into β value calculations the errors will be propagated accordingly. Hence, the β values of complex species, having maximum concentration in the extreme regions of pH, will also carry the largest bias.

For the evaluation of eq. 18 the integration constant pA_0 has to be obtained first. If the initial conditions can be selected such that no complexation involving proton liberation occurs then pA_0 can be calculated from C_A and the appropriate pK_a of the ligand. In the case of an amino acid–Cu(II) system we would select a starting pH below 2 where little or no complexation takes place. In this case, most of the amino acid molecules will be fully protonated. The concentration of fully protonated amino acid A^+ can be calculated using the Henderson–Hasselbach equation. This calculated concentration will represent the initial condition of the system, hence, the $pA_0{}^+$ is fixed. Calculation of the β values, however, requires values of pA, the completely deprotonated ligand. The conversion of pA^+ to pA is accomplished utilizing the acid dissociation constants for the J-basic ligand

$$[25] \qquad pA_x = pA_x{}^+ + \sum_1^J pK_{a_j} - JpH_x$$

This conversion is performed after eq. 18 has been evaluated. A further illustration of this can be found in the papers following (20, 22).

Evaluation of Stability Constants

Each of the above expressions (eqs. 22–24) represents a system of simultaneous equations of the general form

$$[26] \qquad a_{i,1}x_1 + \ldots a_{i,n}x_n - d_i = 0$$

where $x_1, \ldots, x_n$ may represent a series of unknown stability constants and the elements $a_{i,1} \ldots a_{i,n}$ may represent the corresponding values of $m^p h^q a^r$, *i.e.*

[5]The authors acknowledge the extensive and helpful discussions they have had with Professor W. A. E. McBryde concerning the derivations of equations to describe the equilibria governing complex formation. Unfortunately complete agreement could not be reached and Professor McBryde therefore offers an alternative treatment for the binary system only, which appears in the present issue of the journal immediately following this series of four papers.

[27] $$a_{i,1} = (m^p h^q a^r)_{i,1}$$

This same situation can be more briefly described in vector notation.

[28] $$A_{ij} \cdot \boldsymbol{x} = \boldsymbol{d}$$

where A_{ij} describes the coefficient matrix with elements a_{ij}, $\boldsymbol{x}$ being a vector which produces the desired result $\boldsymbol{d}$ when $\mathbf{A}_{ij}$ is post-multiplied by $\boldsymbol{x}$. In our case $\mathbf{A}_{ij}$ and $\boldsymbol{d}$ can be calculated from the experimental data, and $\boldsymbol{x}$ becomes the solution vector containing the values $(x_1 \ldots x_n)$ which represent the $\beta_1, \ldots, \beta_n$ values or stability constants.

There are a variety of ways in which equations of this type can be solved. Since observed data have inherent experimental errors associated with them, purely analytical solutions are not very useful. Hence, we decided on solutions which can be obtained by an iterative least squares refinement procedure. The computer program LEASK[3] was designed to find solutions for the unknowns of m sets of equations in n unknowns provided $m \geqslant n$. The operation of this program will be described further on. In order to solve for stability constants, we first must obtain the values for m, a, and h from the experimental data.

Computer Calculations

The programs are described in the order of their use.

Evaluation of Eq. 18 by Program PLOT[3]

All the parameters except pA_0 which are necessary to solve eq. 18 can be calculated from the experimental data which are represented by the titration curves. A value for pA_0 can be calculated from the total concentration of component A. For the ease of processing, the continuous titration curves are converted into digitized tabular form by the operator, preferably, but not essentially, using equal intervals on the pH scale. These data are put on paper tape or cards, which then constitute the input to the program PLOT together with dimension statements and other experimental constants, *i.e.* pK_{a_1}, pK_{a_2}, pK_{a_3} for a tribasic ligand.

Step A: Calculation of the Differential Expressions $\delta H_1^+/\delta C_A$

(1) The input data are read from titration curves such as are represented in Fig. 1. These titration curves, A_1 to A_5, are obtained by titrating metal ligand mixtures of varying composition as prescribed by the particular experimental conditions. These data constitute a three dimensional array (x, y, z) where x stands for the amount of titrant (base) used, y represents the pH, and z stands for the amount of ligand or metal in the system. This array is stored as (x, y) pairs for a series of constant z values. The program first rearranges this array to produce a new array where the (x, z) pairs are stored for a series of constant y values yielding numerical functions $x = f(z)$ at constant y, as shown in Fig. 2.

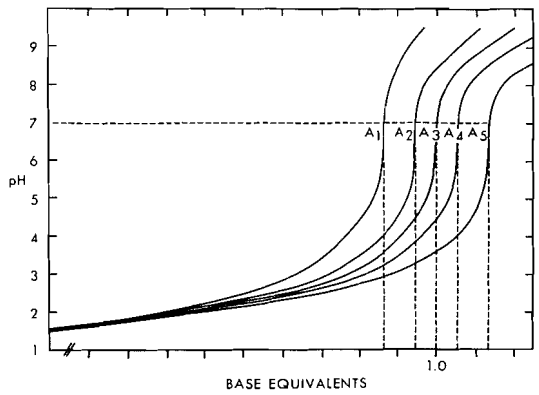

FIG. 1. Typical titration curves for a bidentate amino acid in the presence of Cu(II) with different Cu(II):ligand ratios. Curves A_1 to A_5 represent increasing concentrations of ligand with metal concentration kept constant.

(2) The differential $\delta H_1^+/\delta C_A$ which corresponds to $\delta x/\delta z$ in Fig. 2 at constant pH (constant y) is obtained as the slope of the function $H_1^+ = f(A)$.

(3) Next, the program performs an analytical curve fit to the data $x = f(z)$ using a standard subroutine POLFIT. The series of functions obtained are stored with respect to pH.

(4) A slightly modified version of POLFIT (POLFIT*) is called, and by numerical differentiation, finds the slope of the functions $x = f(z)$ at the midpoint A_i for each pH.

(5) The values found for the slopes $\delta H_1^+/\delta C_A$ are now printed out in tabular form with their respective pH_i values. Fig. 3 graphs an example of this new numerical function

[29] $$\delta H_1^+/\delta C_A = f(\mathrm{p}H)$$

Step B: Evaluation of the integral expression eq. 18

(1) The program again calls the subroutine POLFIT which is now used to fit a curve through the points $(\delta H_1^+/\delta C_A)_i$, pH_i yielding an equation in polynomial form. The integration is accom-

For personal use only.

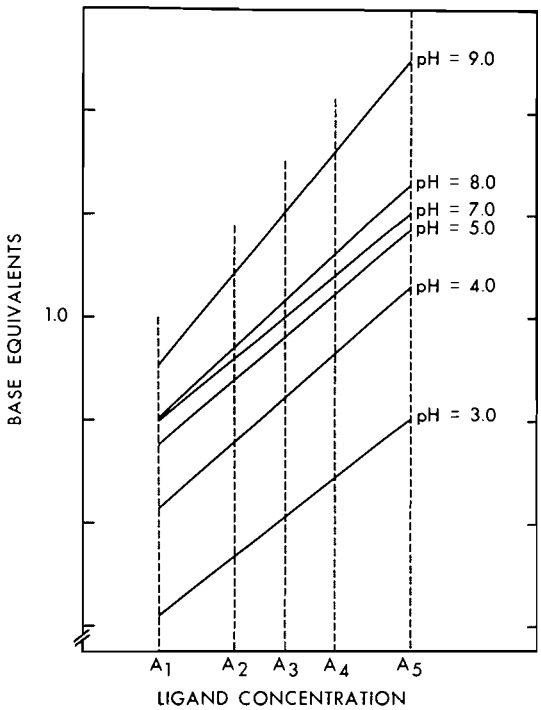

FIG. 2. Base equivalents are graphed as a function of ligand concentration at constant pH values. Solid lines represent the data for the respective pH values and dotted lines represent the ligand concentrations A_1 to A_5.

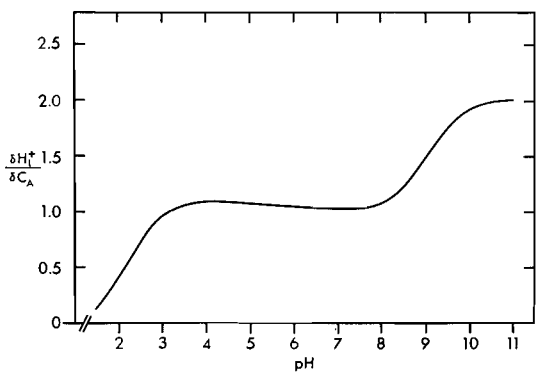

FIG. 3. Proton liberation ($\delta H_1^+/\delta C_A$) is graphed as a function of pH.

plished by appropriate conversion of the terms and subsequent insertion of the limits necessary to evaluate the definite integral.

(2) This transposition is performed by the program and the integral is then evaluated for each upper limit pH_i and added to pA_0 as required by eq. 18. This operation evaluates pA as a function of pH (Fig. 4).

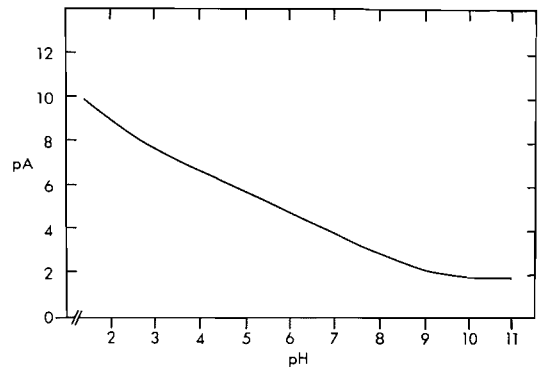

FIG. 4. Unbound ligand concentration (pA) is graphed as a function of pH.

(3) The numerical values of pA_i are printed out in tabular form, which constitutes the final output of the program PLOT. This output is stored under a coded file-name for further usage by subsequent programs.

This same method is followed for any of the constituents whose concentration in the reaction mixture has to be estimated. It should be noted that up to this point pA and pM are obtained as functions of pH only without the need of assuming anything about complexity of the system.

Calculation of the Coefficient Matrix A_{ij} by Program GUESS[3]

(1) The program GUESS reads in the tabular results of $pA = f(pH)$ and $pM = f(pH)$ which were computed by the program PLOT.

(2) For each triplet pA, pM, pH, antilogs are found and then all likely combinations of $m^p h^q a^r$ are performed to give the elements a_{ij} for the matrix $\mathbf{A}_{ij}$ by letting p, q, and r take on values which are likely to represent real complexes.

Assumptions and limitations have to be taken at this point in order to keep the matrix small enough to fit into the computer memory available. It has been found that an upper limit of ten unknowns, representing simultaneously existing complex species, was quite satisfactory. Fewer unknowns of course greatly speed up the processing of the data.

(3) The coefficient matrix $\mathbf{A}_{ij}$ provides the input for the following program LEASK.

Determination of Stability Constants by Program LEASK[3]

The problem at hand is to solve a set of simultaneous equations with n unknowns. Standard techniques of matrix inversion are not usable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

since they operate analytically (no error provisions). They can also produce negative values for the unknowns which, in the case of stability constants, is nonsense. Therefore, we decided to employ an iterative least squares method in our program LEASK which attempts to minimize the error sum $R = \sum_i (d_{i,\text{exptl}} - d_{i,\text{calcd}})^2$ where $d = f(x_1,x_2,...,x_n;a_1,a_2,...,a_n)$ as shown in eq. 26.

Step A

(1) The coefficient matrix $\mathbf{A}_{ij}$ is read into the active part of the computer from an internal file. At the same time, the $\boldsymbol{d}_{\text{exptl}}$, which consists of all the experimental d_i values, is read in and aligned for further processing.

(2) An initial estimate of the elements of the $\boldsymbol{x}$ vector is read in, plus several commands which the program will refer to as it goes through with its execution.

Step B

Minimization of dR/dX. Numerically this is achieved by

(1) Multiplying $\mathbf{A}_{ij}$ with $\boldsymbol{x}$ estimates to give the column vector $\boldsymbol{d}_{\text{calcd}}$. The difference between this and $\boldsymbol{d}_{\text{exptl}}$ is found element by element

$$[30] \qquad (d_{i,\text{exptl}} - d_{i,\text{calcd}}) = F_i$$

and these F_i are squared and summed to give $R = \sum_i F_i^2$ which is stored.

(2) Now the $\boldsymbol{x}$ is operated on element by element, *i.e.*, x_1 is set to $x_1 + x_1 \cdot k$. The computation $\mathbf{A}_{ij} \cdot \boldsymbol{x}' = \boldsymbol{d}'_{\text{calcd}}$ is again executed and the new $\boldsymbol{d}'_{i,\text{calcd}}$ are used to find new $(F''_i)^2$ which sum up to give a new R'. If the test for this trial shows $R > R'$, then this new vector is stored and used as a new first approximation for the next try. If the initial try was bad, as to give $R < R'$, then k will be altered including change of sign until a better minimum is found. If no minimization can be located after a preset number of trials, x_1 is retained and the operation moves on to x_2 and repeats itself.

(3) After $\boldsymbol{x}$ has been scanned completely and a new R' has been found which is smaller than R_i, this new x' will be stored together with R'.

(4) The program loops back to No. 2 above, sets x'_1 equal to $x'_1 + x'_1 \cdot k$, and goes through the logic and arithmetic again to give R''.

(5) If $R'' < R'$, then $\boldsymbol{x}$ will be stored and another iteration will be initiated. However, if $R'' > R'$, then $\boldsymbol{x}$ will be accepted as the solution vector corresponding to the minimum deviation of the calculated from the experimental results and will be printed out in tabular form.

(6) Additional criteria of acceptable convergence are built into the program. Only a predetermined number of oscillations about a constant value for R are allowed. Also, the number of iterations are limited. By the choice of k values the program keeps all x_i's positive or drives them towards the lower limit of computational accuracy. Another criterion of acceptance is provided if all the d_{calcd} come to within a preset percentage of d_{exptl}.

(7) After the minimum $\boldsymbol{x}_{\min}$ is found, the matrix $\mathbf{A}_{ij}$ is multiplied element by element with $\boldsymbol{x}$. These products are printed out in tabular form, they represent the species distribution of all the complexes found in the system analyzed.

Recalling, $[M_pH_qA_r] = \beta_{pqr}a_{ij}$, then each column will represent the concentration of the species at pH_i values and the associated x_j will represent the stability constant for that species.

Discussion

All the classical methods for evaluating stability constants (1) necessitate prior knowledge or assumptions of the species composition before meaningful computations can be performed. The logic contained in the present mathematical treatment of the data and computations for obtaining unbound metal and ligands are rigorous and do not require any assumptions as to the species present in the system. Utilizing eq. 21 and assuming $\log \beta_{pqr} = x$, then inserting values for a, m, and h for different pH values, a pH profile for all the theoretical species $M_pH_qA_r$ can be constructed. If x is set equal to $\log m^p h^q a^r$ then all species will show a maximum concentration of 1.0 (provided $p = 1$) if expressed in terms of bound metal. On the basis of this preliminary species distribution one can judge which species are likely to exist and where on the pH scale they have maximum concentration. If two species show identical shapes, *i.e.* if they overlap all along their pH profile the matrix $\mathbf{A}_{ij}$ cannot be solved because two columns are identical. Then one of the two species must be eliminated before proceeding to program LEASK. If we have proposed a species that does not exist, the program will eliminate it. If we fall short, then the residual error will be large and the species distribution will indicate on the pH scale where it is missing.

The operator will simply come up with a suitable combination of $a_{ij} = f(pH)$ to fill the void.[6]

The batch oriented LETAGROP programs (9) are very versatile in this area of investigation. It requires a large memory computer and the operational expenses are rather high. Whereas our programs are specialized and are aimed at economical operation by using high speed remote terminal time-sharing systems. Even though input data are somewhat different, the output data (β values) are of equivalent precision.

The analytical system proposed here has several features which are desirable and should prove advantageous. Our method in addition to the stability constant values will yield other intermediate data, such as proton liberation data as a function of p*H* and also as a function of metal or ligand concentration. This information is very useful as an aid in structural interpretation (21). Also, while operating these programs in conversational mode, the operator has a constant check on the progress of the computations, which is useful in spotting erroneous input data which would influence the magnitude of the β values and cause large error sum squares. Thus, execution of the program can be terminated prematurely with resulting economy in computer usage. Since this is only possible when operating in conversational mode we have therefore adjusted our programs to run on time-sharing systems accepting FORTRAN IV language.

This work was supported by grants from the John A. Hartford Foundation of New York and the Medical Research Council of Canada.

[6]Our proposed method was verified by Professor W. A. E. McBryde. The well known Cu(II)–glycine system was chosen for the purpose of verification of our method. Using published protonation constants and complex stability constants calculations were performed to produce synthetic data sets equivalent to real titration data (p*H* *vs.* strong base). Also values for p*M* and p*A* for the various p*H* values were calculated. This was done for a variety of C_A and C_M. These synthetic titration data in turn were processed by the Sarkar and Kruck method to produce values for p*A*, p*M*, and the complex stability constants β_{11} and β_{12} for the metal ligand interaction. The values found showed excellent agreement throughout the full range of titration data.

Equilibria of the Simultaneously Existing Multiple Species in the Copper(II)–L-Histidine System

THEO P. A. KRUCK AND BIBUDHENDRA SARKAR[1]

Division of Biochemistry, The Research Institute, The Hospital for Sick Children, Toronto, and Department of Biochemistry, University of Toronto, Toronto, Ontario M5G 1X8

Received June 14, 1972[2]

The complete species distribution and the stability constants of the complex species in the Cu(II)–L-histidine system have been worked out for the p*H* range 2–11. The method of "analytical potentiometry" has been applied successfully to this system having excess ligand with respect to Cu(II) ion. The equilibria of three systems of Cu(II) (M) and L-histidine (H_3A) in molar ratios of 1:2, 1:4, and 1:8 were investigated by this technique in 0.15 *M* NaCl at 25°. The following species were detected in this system: MHA, MA, MH_2A_2, MHA_2, MA_2, $MH_{-1}A_2$, $MH_{-1}A$, and $M_2H_{-2}A_2$. Statistical analysis on the numerical results has been performed and is given as standard deviation together with the individual values for the stability constants.

La distribution complète des espèces et les constantes de stabilité des espèces complexes dans le système Cu(II)–L-histidine ont été étudiés dans le domaine de p*H* de 2 à 11. La méthode de "potentiométrie analytique" a été appliquée avec succès à ce système qui possède un excès de ligand par rapport à l'ion Cu(II). Les équilibres des trois systèmes Cu(II) (M) et L-histidine (H_3A) dans les rapports molaires 1:2, 1:4, et 1:8 ont été étudiés par cette technique dans NaCl 0.1 *M* à 25°. Les espèces suivantes ont été détectées pour ce système: MHA, MA, MH_2A_2, MHA_2, MA_2, $MH_{-1}A_2$, $MH_{-1}A$ et $M_2H_{-2}A_2$. L'analyse statistique du résultat numérique a été faite et donnée comme dérivation standard de même que les valeurs individuelles des constantes de stabilité. [Traduit par le journal]

Can. J. Chem., 51, 3549 (1973)

Introduction

The Cu(II)–L-histidine system has been of interest to many workers in the field of metal complexation because of the many different geometric arrangements that are possible when attempting to coordinate one or two tridentate ligands to Cu(II) ion. The stability constants for Cu(II)–L-histidine complexes of the type MA and MA_2 have been reported by several authors (1). Leberman and Rabin (2) considered the coordination of a water molecule to the 1:1 L-histidine:Cu(II) complex and the subsequent dissociation of a proton from the hydrated complex. However they only reported the stability constants for the species MA and MA_2. Perrin and Sharma (3) later expanded the system to include MHA, MHA_2, MH_2A_2, and all other previously reported species. In addition, they also worked out stability constants for hydroxylated complexes $MH_{-1}A$ and $M_2H_{-2}A_2$. Freeman and Martin (4) had worked out the most exhaustive list of stability constants for this system while studying a mixed complexation reaction involving L-histidine. But, so far, the complete species distribution of all the complexes existing in solution in the p*H* range 2 to 11 has not been worked out in detail.

Our interest in the Cu(II)–L-histidine system dates back to the isolation of the Cu(II)–L-histidine complex from normal human blood serum (5) and the demonstration of the existence of the mixed complex L-histidine – Cu(II) – L-threonine and other mixed complexes (6). Previous work involving Cu(II)–L-histidine complexes (7–10) demonstrated the need for an extensive analysis of the Cu(II)–L-histidine system. This, as well as the need to test our newly proposed analytical technique (11), prompted us to examine the Cu(II)–L-histidine system precisely over as large a p*H* range as possible. The low p*H* and high p*H* cutoff was determined by the need to introduce assumptions beyond these limits relating to the accurate determination of p*H* and activity coefficients.

Experimental Section

Materials

All reagents used were of analytical grade. L-Histidine free base ($[\alpha]_D^{20}$ + 39.9° ± 0.5°) was obtained from Nutritional Biochemicals. The amino acid was tested for its purity by chromatography. It was dried and stored over anhydrous calcium chloride at room temperature

under vacuum. The water was first distilled and then deionized by passing it through a commercial ion exchange column ILICO WAY-X research model which had been extensively rinsed with distilled water before use. Prepurified nitrogen was used to maintain a nitrogen atmosphere throughout the titration. The base used for the titration was carbonate free 5.010 *N* NaOH standardized against weighed amounts of dried potassium hydrogen phthalate. It was stored in a dry, CO_2-free atmosphere. A solution of 1.0 *N* HCl was prepared by dilution of constant boiling high purity 6 *N* HCl and subsequently standardized against 5.010 *N* NaOH. The stock solutions of L-histidine, anhydrous $CuCl_2$, and NaCl were prepared from vacuum dried materials. The L-histidine and the $CuCl_2$ solutions were checked titrimetrically.

Titration Apparatus

The potentiometric titrations were performed by a Radiometer automatic titrator. The assembly consisted of the expanded scale p*H* meter pHM26, automatic titrator TTT11B, automatic recorder SBRII, automatic syringe, and the 50 ml thermostated titration assembly set to 25 ± 0.05°.

Electrodes and Calibrations

In order to perform repetitive titrations starting from p*H* 1 through to p*H* 11, it was necessary to select a suitable electrode pair. Both the glass electrode and calomel reference electrode had to be carefully scrutinized. A salt bridge furnished with a porous sintered glass plug was used in conjunction with a radiometer reference electrode K401. The flow rate of the saturated KCl solution was in the order of 50 µl/h. A radiometer glass electrode of the G2222 series was found to be linear over the range of p*H* 1.00 to 11.00 using standard buffer solutions of ±0.02 p*H* unit accuracy. The standard buffer solutions were of p*H* 1.00, 2.00, 3.00, 4.00, 7.00, 9.00, and 11.00. This electrode permitted a maximum of three consecutive titrations before extensive low p*H* incubation became necessary to have stable linear p*H* response. A radiometer glass electrode of the series G202B was found to permit up to five consecutive titrations before instability due to increased impedance set in. Regeneration of this electrode could be obtained by immersing it in 1 *N* HCl for 1 h or else by incubating it overnight in p*H* 7.00 buffer. To calibrate the p*H* scale of the apparatus in terms of hydrogen ion concentration, several solutions of known concentrations of HCl in 0.15 *M* NaCl were titrated before and after every experiment. The solutions were prepared from calibrated standard HCl by exact dilution.

Method

The equilibria of the Cu(II)–L-histidine system can be expressed by the general equation[3]

$$[1] \qquad pM^{2+} + qH^{+} + rA^{-} \leftrightarrows M_pH_qA_r^{(2p+q-r)}$$

The overall equilibrium constant for this system can be defined as

$$[2] \qquad \beta_{pqr} = \frac{[M_pH_qA_r]}{m^p h^q a^r}$$

[3]See preceeding article for definitions of symbols.

Certain experimental conditions must be met in order for the theoretically derived functions (11)[4] to hold. We have presented functions as in eqs. 3 and 4

$$[3] \quad p(H_3A) = p(H_3A)_0 + \int_{pH_0}^{pH_1} \frac{\delta H_1^{+}}{\delta C_A} dpH \Bigg|_{C_M,P,V,T,\mu=\text{constant}}$$

$$[4] \quad pm = pm_0 + \int_{pH_0}^{pH_1} \frac{\delta H_1^{+}}{\delta C_M} dpH \Bigg|_{C_A,P,V,T,\mu=\text{constant}}$$

which permit the calculation of unbound ligand *a* or the unbound metal *m* as a function of p*H* in the presence of other reactants, provided the concentrations of those reactants do not vary. Also, pressure, temperature, and volume must be kept constant. Nitrogen provides an inert atmosphere of constant pressure. A thermostated reaction vessel $T \pm 0.1$ °C is sufficient to provide constant temperature. Constant volume is more difficult to achieve and can only be approximated. It is done by using large volumes of reaction mixtures and keeping the added titrant volume small. The inevitable change of volume, although small, must be taken into account when calculating the hydrogen ion concentration *h* from p*H* values. Furthermore, the activity coefficients of all the reactants must be controlled for eq. 2 to hold. Using a background electrolyte in excess of the concentration of the reacting species permits one to use concentration terms instead of activities of the reactants. In order to relate this system to physiological conditions, 0.15 *M* NaCl was chosen as background electrolyte being fully aware that Cl^- is a ligand for Cu(II) competing to a low degree with L-histidine and OH^- for this metal ion. All titrations were done in duplicate and if they did not agree

within 2 μl on the base scale and 0.05 pH units on the pH scale, then a third titration was performed. Possible zero errors in base delivery were accounted for by comparing inflection points on the titration curves.

"Analytical potentiometry" (11) was used to resolve the Cu(II)–L-histidine system and produce stability constants for all the species detected. Using integrating and differentiating techniques (eqs. 3 and 4) it is possible to deduce from families of titration curves, the free metal m and ligand a concentrations in the system after the initial values m_0 and $[H_3A]_0$ have been determined. At a starting pH of about pH 2 one can calculate the concentration of the fully protonated ligand H_3A species from the known acid dissociation constant pK_a, of the ligand utilizing eq. 5

$$[5] \quad [H_3A] = \frac{C_A}{1 + \text{antilog}\,(pH - pK_a)}$$

At low pH in this system $m_0 = C_M$. Also, during any titration equilibrium must be maintained. None of the total concentrations of reactants excepting h (pH) must change in order for eqs. 3 and 4 to be true. The required change δC_M or δC_A for the mathematical treatment of data was produced by performing different titrations containing systematically varied concentrations of $CuCl_2$ and L-histidine as part of the reaction mixtures. It should be noted that if the pH is low enough that $m_0 = C_M$ then all the titration curves will show a common starting pH as can be seen in Fig. 1. The same is true for the protonated ligand. The method for evaluating the functions given in eqs. 3 and 4 will be discussed later. The resulting data $m = f(pH)$ and $a = f([H_3A]) = f(pH)$ now can be used to evaluate the stability constants of complex species represented by eq. 2.

Data: C_A, a, C_H *and* h; *System*: A, H

Although good values for the acid dissociation of L-histidine are available from the literature (4) we preferred to check the pK_a values for L-histidine in our system. L-Histidine solutions were titrated in the presence of 0.15 M NaCl with standard acid or base. The values found were in good agreement with literature values (4). Our own values were used in subsequent calculations.

Data: C_M, m, C_A, a, C_H *and* h; *System*: M, A

Potentiometric titrations were carried out on a series of solutions (50 ml volume) of a 0.15 M NaCl, 0.1 N HCl, containing combinations of L-histidine (10, 20, 40, and 80 mM) and $CuCl_2$ (0, 5, 10, 20, 30, and 40 mM).[5]

Calculation of Results

The families of titration curves obtained are presented in Figs. 1 and 2. The data obtained from sets 1–3 were used to obtain the proton liberation $\delta H_1^+/\delta C_M$ at constant pH due to the

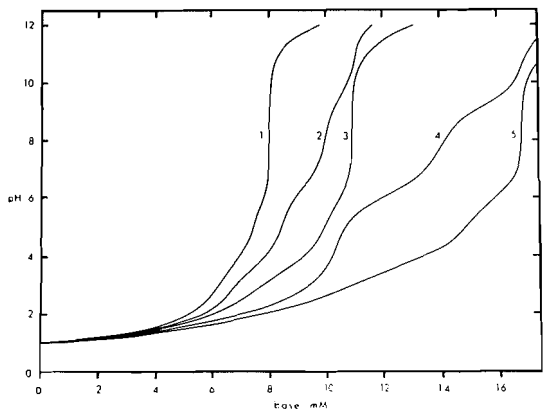

FIG. 2. Titration curves for the system Cu(II)–L-histidine (ligand variations). Curve 1, $C_A = 20 \times 10^{-3}\ M$, $C_M = 10 \times 10^{-3}\ M$; curve 2, $C_A = 40 \times 10^{-3}\ M$, $C_M = 10 \times 10^{-3}\ M$; curve 3, $C_A = 40 \times 10^{-3}\ M$, $C_M = 20 \times 10^{-3}\ M$; curve 4, $C_A = 80 \times 10^{-3}\ M$, $C_M = 10 \times 10^{-3}\ M$; curve 5, $C_A = 80 \times 10^{-3}\ M$, $C_M = 40 \times 10^{-3}\ M$.

[5]The solution of Cu(II)–L-histidine was prepared freshly for each experiment. The maximum time elapsed between the preparation of the Cu(II)–L-histidine solution and the completion of the experiment, was 30 min. This procedure was followed routinely since Cu(II)–L-histidine in aqueous solution is not stable according to the spectral features of the system taken at different time intervals. These spectral features seem to arise from the relatively slow, time-dependent formation of other compounds of undetermined nature. Thus, the experiments with Cu(II)–L-histidine must be completed within a time limit during which formation of no other compounds is assured (17). The titration curves coincided initially at low pH.

For personal use only.

variation of Cu(II) concentration. The data from sets 4 and 5 were processed, yielding the proton displacement $\delta H_1^+/\delta C_A$ at constant pH due to variations of the ligand concentration. The data $\delta H_1^+/\delta C_M$ were further processed according to eq. 4 to obtain pm as a function of pH. Similarly, the data $\delta H_1^+/\delta C_A$ were treated mathematically according to eq. 3 to give p(H_3A) as a function of pH. It should be noted here that

$$[6] \quad pa = p(H_3A) + pK_1 + pK_2 + pK_3 - 3pH$$

A series of computer programs[6] was written for the treatment of these data. The original titration curves were digitized and subsequently the program PLOT was used to normalize and rearrange the raw data. The same program performed operations of curve fitting and differentiation yielding the numerical value of the slopes $\delta H_1^+/\delta C_M$ *vs.* pH in the case of metal variation. Another curve fit was executed on the function $\delta H_1^+/\delta C_M$ and a cumulative integration was performed according to eq. 4 where pH_i was chosen to progress in intervals of 0.5 units starting from pH_0. The resulting output pm *vs.* pH was printed in tabular form. The same program PLOT was employed to evaluate the data for the ligand variation in order to get pa as a function of pH.

The stoichiometric stability constant is expressed in eq. 2. The bound M is represented by the summation of all complex species present.

$$[7] \quad (C_M - m) = \sum p[M_pH_qA_r] = \sum p(\beta_{pqr} m^p h^q a^r)$$

Replacing β_{pqr} and $M^pH^qA^r$ by β_j and C_j respectively eq. 7 becomes

$$[8] \quad (C_M - m) = \sum p\beta_j C_j$$

Equation 8 is of the form

$$[9] \quad y = C_1\beta_1 + C_2\beta_2 + C_n\beta_n$$

Using pH, pm, and pa as input, the program GUESS was employed to calculate the coefficients $(C_1 \ldots C_n)$ and the corresponding y vector. This matrix was solved by the third program LEASK, which is an iterative least squares refinement technique, requiring approximate values for $(\beta_1 \ldots \beta_n)$ to obtain refined values for the stability constants. Repeating this process for the different experimental data from sets 1–5 we obtained the species distributions in 1:2, 1:4, and 1:8 Cu(II)/L-histidine systems in

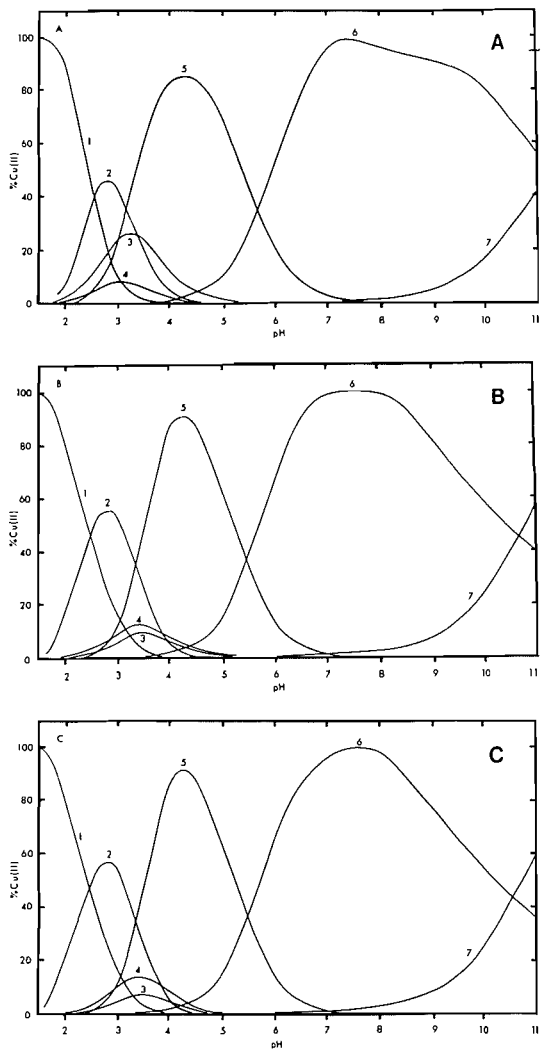

FIG. 3. Species distribution in Cu(II)-L-histidine system as a function of pH. *A*, *B*, and *C* represent the metal to ligand ratios of 1:2, 1:4, and 1:8, respectively. Curve 1, unbound Cu(II); curve 2, MHA; curve 3, MA; curve 4, MH_2A_2; curve 5, MHA_2; curve 6, MA_2; curve 7, $MH_{-1}A_2$.

[6]Three computer programs: PLOT, GUESS, and LEASK were written in Fortran IV. The programs have been deposited as Document No. NAPS-01563 with the ASIS National Auxiliary Publication Service, c/o CCM Information Corp., 866 Third Avenue, New York, N.Y. 10022. A copy may be secured by citing the document number and by remitting $1.00 for microfiche or $3.00 for photocopies. Advance payment is required. Make cheques or money orders payable to: ASIS-NAPS.

p*H* range 2–11 (Fig. 3 *A–C*).[7] The respective stability constants of the species are tabulated in Table 1.

All calculations were performed on a General Electric model 440 computer.

Discussion

In the present study the following species were detected and their stability constants have been evaluated: MHA, MA, MHA_2, MH_2A_2, MA_2, $MH_{-1}A$, $M_2H_{-2}A_2$, and $MH_{-1}A_2$. The β values computed are in close agreement with values obtained by other authors (Table 1), excepting the ones obtained for the hydroxylated complex $MH_{-1}A$ and its dimer $M_2H_{-2}A_2$. Our values reported for these complexes tend to come to closer agreement with those reported by Freeman and Martin (4). It should be noted, however, that a slight deviation in these figures may arise from the difficulty of calculating the very small amounts of these complexes being formed when excess ligand is available. Also inspection of the standard deviations reveals very large values casting doubt on the accuracy of the stability constant values presented for these complexes.

In addition, we found that a new species $MH_{-1}A_2$ appears at high p*H* in appreciable amounts reading about 20% of the total bound copper at p*H* 10 and exceeding that amount at higher p*H* values (Fig. 3*A–C*). Comparing the species distributions, apart from the absolute profiles for the individual species, one can see that the relative amounts of MA and MH_2A_2 are varying in accordance with the metal-to-ligand ratio. As the ratio decreases more of the 1:1 complex MA is being formed at the cost of MH_2A_2 while the other complexes MHA and MHA_2 existing in the same p*H* range seem relatively unaffected. This situation would be expected to change drastically once the ratio of Cu(II) to L-histidine is reduced below 1:2. Then the 1:1 complexes predominate as shown by Perrin (12). We are, however, not interested in examining a system which is forced towards favoring certain complexes but rather we wanted to show the influence or lack of it upon the species distribution in the presence of excess ligand. In the range around the physiological p*H* it seems that varying concentrations of excess L-histidine do not change the amount of MA_2 present in the system.

Our method for evaluation of stability constants by program LEASK (11) is sensitive to experimental errors occurring at the extreme values of the p*H* scale. This can be accounted

[7]Although we observed a slow breakdown of L-histidine in the Cu(II)–L-histidine systems at high p*H* which expressed itself in a color change from deep blue to black in the course of several hours, the process did not materially affect our study since the solutions used for potentiometry never spent more than 10 min (usually less) at high p*H* values. At p*H* values beyond 11 the breakdown was noticeable and the data were discarded.

for by including weighting factors in the simultaneous equation at very low or at very high p*H* values. As an alternative, one can run the titration curves beyond these values, *e.g.* p*H* 1 to 12 and subsequently incorporate only the data between p*H* 2 and p*H* 11 in the calculation of the stability constants. In this manner weighting and biasing the data becomes unnecessary. In these calculations we have taken the latter course, and the resulting values for the stability constants support the applicability of our analytical method. However, if the extreme p*H* regions are of interest weighting factors could be included.

Species distributions are simple enough to be calculated from the experimental data. However, this has never been worked out previously for Cu(II)–L-histidine system covering wide enough p*H* range and in the presence of excess ligand. The knowledge of species distribution is necessary when analyzing structures of complex species in solution in a multispecies system. The delineation of the complete species distribution in this system has helped greatly in the elucidation of structures of the species in the Cu(II)–L-histidine system as well as in the studies of mixed complex equilibria involving L-histidine in the following two papers (13, 14).[8]

This work was supported by grants from the John A. Hartford Foundation of New York and the Medical Research Council of Canada.

Ternary Coordination Complexes Between Copper(II) and Amino Acids, and an Appraisal of the Enhancement of Ternary Complex Stability

THEO P. A. KRUCK AND BIBUDHENDRA SARKAR[1]

Division of Biochemistry, The Research Institute, The Hospital for Sick Children, Toronto and Department of Biochemistry, University of Toronto, Toronto, Ontario M5G 1X8

Received June 14, 1972[2]

The equilibria involved in the ternary systems Cu(II)–A–B′ and Cu(II)–A–B″ (A = L-histidine, B′ = L-serine, B″ = L-glutamine) have been investigated by potentiometry in aqueous solution (0.15 *M* NaCl, 25°). In the ternary system Cu(II)–A–B′, three mixed complexes (MHAB′, MAB′, and $MH_{-1}AB'$) were detected in addition to the binary complex species (MHA, MA, MH_2A_2, MHA_2, MA_2, $MH_{-1}A_2$, MB′, MB'_2). The results observed in the Cu(II)–A–B″ system were quite similar to the system Cu(II)–A–B′ except that it did not show the presence of the species $MH_{-1}AB''$. The stability constants were refined with a general least squares treatment. In the case of an equimolecular mixture of the constituents, a maximum of about 75% of Cu(II) is present as MAB′ at p*H* 5.5–9 and about 60% of Cu(II) as MAB″ at p*H* 5–10 when the concentration of each constituent is set equal to 10^{-2} *M*. A theoretical analysis and derivations of the expected stability constants of the complexes are presented on the basis of successive formation constants of the individual complexes carrying identical ligands. In each case an enhancement of the stability was observed with the ternary coordination complexes. Attempts have been made to explain the enhanced stability of the ternary coordination complexes.

Les équilibres impliqués dans les systèmes ternaires Cu(II)–A–B′ et Cu(II)–A–B″ (A = L-histidine, B′ = L-sérine, B″ = L-glutamine) ont étudiés par potentiométrie en solution aqueuse (0.15 *M* NaCl, 25°). Dans le système ternaire Cu(II)–A–B′, trois complexes en mélange (MHAB′, MAB′ et $MH_{-1}AB'$) ont été détectés en plus des espèces du complexe binaire (MHA, MA, MH_2A_2, MHA_2, MA_2, $MH_{-1}A_2$, MB′, MB'_2). Les résultats observés pour le système Cu(II)–A–B″ sont très semblables au système Cu(II)–A–B′ à part l'absence des espèces $MH_{-1}AB''$. Les constantes de stabilité ont été raffinées par la méthode générale des moindres carrés. Dans le cas du mélange équimoléculaire de constituants, un maximum d'environ 75% de Cu(II) est présent comme MAB′ à p*H* 5.5–9 et 60% environ de Cu(II) en tant que MAB″ à p*H* 5–10 lorsque la concentration de chaque constituant est de 10^{-2} *M*. Une analyse théorique et les dérivés des constantes de stabilité attendues pour les complexes ont été présentées en se basant sur les constantes de formation successives des complexes individuels portant des ligands identiques. Dans tous les cas, un accroissement de stabilité a été observé pour les complexes ternaires de coordination qu'on a essayé d'expliquer.

Introduction

Ternary coordination complexes are known to play important roles in many biological processes. Many enzymes are known to be activated by metal ions through the formation of enzyme – metal – substrate bridge structures (1). Metal coordination bonds have been suggested to participate in the interaction of polypeptide subunits of multichain enzymes providing the conformational stability of these enzyme molecules (2–5). Ternary coordination also appears to be functional in the mobilization and exchange of trace metals (6–8). It is known that in Cu(II)–amino acid complexes, the Cu(II) ion, with its preferred square planar geometry, binds a maximum of two amino acids. This provides the possibility for mixed Cu(II)–amino acid coordination to occur which has been demonstrated under physiological conditions (9), as well as *in vitro* systems (10–13). As part of a continuing investigation of the biologically important ternary coordination complexes of amino acids, peptides, proteins, and enzymes (6–16), we have made a detailed investigation of the multiple equilibria in two ternary systems: L-histidine–Cu(II)–L-serine and L-histidine–Cu(II)–L-glutamine in 0.15 *M* NaCl at 25°. We also present, in this paper, a theoretical analysis and the derivations of the expected stability constants of the complexes based on the successive formation constants of the individual complexes carrying

identical ligands. In each case we observed an enhancement of the stability with the ternary coordination complexes.

Experimental Procedure

Materials

All reagents used were of analytical grade. L-Histidine free base ($[\alpha]_D^{20} = 39.9° \pm 0.5°$), L-serine ($[\alpha]_D^{20} = 14.3° \pm 0.2°$), and L-glutamine ($[\alpha]_D^{20} = 31.5° \pm 0.3°$) were obtained from Nutritional Biochemicals, Cleveland, Ohio. The amino acids were tested for purity by chromatography. They were oven-dried at 110° for 1 h and then stored over anhydrous calcium chloride at room temperature under vacuum. Distilled water was deionized by passing it over commercial ion exchange resin (ILICO-WAY-X research model). All titrations were performed under nitrogen atmosphere. Carbonate free base (5.010 *N*) was used, which was standardized against oven-dried potassium hydrogen phthalate. The 1.0 *N* HCl was standardized against the 5.010 *N* base. Stock solutions of the amino acids and $CuCl_2$ were prepared gravimetrically and then standardized titrimetrically.

Titration Apparatus, Electrodes, and Calibrations

The experimental conditions were as mentioned in the previous papers (17, 18) of this series.

Data: *M*, *m*, *A*, *a*, *B'*, *b'*, *B''*, *b''*, *and h*

Potentiometric titrations were carried out on a series of solutions (50 ml total volume) 0.15 *M* in NaCl, and sufficient HCl to bring the starting p*H* close to 1.0.[3] The solutions contained various combinations of concentrations in copper(II) chloride, L-histidine, L-serine, or L-glutamine as outlined under Results section. All titration curves coincided initially at low p*H*. Before each titration the Nernst slope of the glass electrode was checked against standard buffer solutions. The necessary adjustments were performed on the apparatus to ensure linear response throughout the p*H* range 1.0–12.0. The accuracy achieved with repetitive titrations was 0.002 p*H* units and 0.002 ml of base. The duration for the titration of each sample usually was less than 20 min.

Calculation of Results

Computational Methods

Based on the thermodynamic expression for the chemical potential, the following integral expression, eq. 1, can be derived (17)

$$[1] \quad pm = pm_0 + \int_{pH_0}^{pH_1} \frac{\delta H_1^+}{\delta C_M} dpH \Big|_{C_A,\ldots,P,V,T}$$

This permits us to follow the fate of component M which participates in the chemical reaction in the presence of other reactants, provided that the total concentration of these and *P*, *V*, and *T* are kept constant throughout the reaction. The only variation is done on the component M and the resulting proton liberation is observed where m_0 denotes the concentration of the unreacted component M at pH_0.

Calculations were performed to establish the unbound amounts of each reactant taking part in the equilibrium reaction as a function of p*H*. Then the general equilibrium expression, eq. 2

$$[2] \quad \beta_{pqrs} = \frac{[M_pH_qA_rB_s]}{m^p h^q a^r b^s}$$

for the calculation of the stability constants was employed to obtain relationships eqs. 3–5 between the amount of complex formed and the unbound reagents.

$$[3] \quad (C_M - m) = \sum p\,[\beta_{pqrs}\, m^p h^q a^r b^s]$$

$$[4] \quad (C_A - a) = \sum r\,[\beta_{pqrs}\, m^p h^q a^r b^s]$$

$$[5] \quad (C_B - b) = \sum s\,[\beta_{pqrs}\, m^p h^q a^r b^s]$$

Each of these equations could be used to establish the desired relationships. Since we have determined independently *m*, *h*, *a*, and *b*, we can substitute in eq. 3 and get an equation with the stability constants being the only unknowns, its general form being

$$[6] \quad y = C_1\beta_1 + C_2\beta_2 \ldots\ldots C_n\beta_n$$

The *m*, *h*, *a*, and *b* data being functions of p*H* (or *h*) permit us to set up a system of simultaneous equations as in eq. 6 which then can be solved for the stability constants. The evaluation is accomplished by an iterative least squares method which accepts a crude first approximation of the stability constants to be evaluated.

The binary system for the individual amino acid – Cu(II) complexes are worked out separately and the resulting stability constants obtained are used in the calculations of the ternary system amino acid (*A*) – Cu(II) – amino acid (*B*). The excess bound metal not involved in the formation of the homogeneous complexes is assumed to be present in the ternary complexes as bound Cu(II) ion. These ternary complexes and their stability constant β_{pqrs} are evaluated and the total system is refined together to yield a least squares fit with minimized deviations be-

[3]The decision to use 0.15 *M* NaCl was based on the necessity to apply the present results directly to biological systems.

tween the observed and calculated values of bound reactants.

The vast amount of calculations involved in this analysis were performed on a General Electric 440 computer system. All programs were written in Fortran IV and are deposited with the National Auxiliary Publications Service.[4] Three programs, PLOT, GUESS, and LEASK were employed in this analysis.

Results

Proton – Amino Acid Systems

The H_2B systems were studied by titrating solutions containing H_2B ($C_{B'} = C_{HCl} = 20 \times 10^{-3}$ and $C_{B'} = C_{HCl} = 40 \times 10^{-3}$ *M*; $C_{B''} = C_{HCl} = 20 \times 10^{-3}$ *M* and $C_{B''} = C_{HCl} = 40 \times 10^{-3}$ *M*) in 0.15 *M* NaCl with standard 5.010 *N* NaOH. The results of several titrations were averaged and the resulting values for the dissociation constants with estimated standard deviations are listed in Table 1.

Binary Cu(II) – Amino Acid Systems

Solutions containing various combinations of M and B′ or B″ concentrations in the presence of 0.15 *M* NaCl were titrated through the p*H* range 1.5 – 11.0. The concentrations used to obtain the data are as follows:

System M:B′

The families of titration curves obtained from these solutions were processed as described and the resulting species distributions were plotted in Figs. 1 and 2, covering the pH range 2–11. The stability constants of the species were calculated and are listed in Table 1. Dimers and polynuclear complexes were looked for but not found in these systems within the mathematical accuracy employed in our calculations. The Cu(II)–L-histidine system is reported separately (18).

Discussion

Binary Cu(II) – Amino Acid Complexes

In the Cu(II)–L-serine system investigated by Sharma (19), only two species, MB′ and MB'_2 were reported, having stability constants log $\beta_{101} = 7.56$ and log $\beta_{102} = 14.01$. The system was not examined in a wide enough pH range, and consequently, the formation of the additional species $MH_{-1}B'_2$ and $MH_{-2}B'_2$, which are reported in this paper, were not observed. Our results of the Cu(II)–L-serine system are consistent with those of the Cu(II)–L-threonine system reported earlier by Freeman and Martin (20) as well as by ourselves (15).

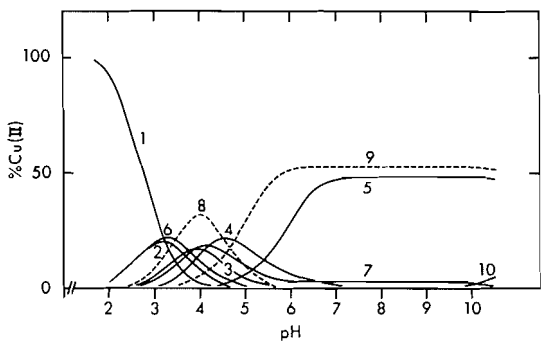

FIG. 4. Variation of complex species concentration with pH in the ternary system L-histidine–Cu(II)–L-glutamine in 0.15 M NaCl at 25°. $C_M = 1 \times 10^{-2} M$, $C_A = C_B = 2 \times 10^{-2} M$. Solid lines: curve 1, M; curve 2, MHA; curve 3, MA; curve 4, MHA_2; curve 5, MA_2; curve 6, MB′; curve 7, MB'_2; curve 10, $MH_{-1}A_2$. Broken lines: curve 8, MHAB′; curve 9, MAB′.

Titration results alone are not good enough to draw any conclusions regarding the structure of a species. However, some pertinent observations must be made. Both pK_1(carboxyl) = 2.21 and pK_2(amino) = 8.95 fell within our titration range. The pK_3(hydroxyl) was not obtained since it was outside the pH range covered in our study. The involvement of the carboxyl and amino groups in both MB′ and MB'_2 is necessary in order to obtain proton balance regarding the titration data. When exceeding pH 8, there is a clear demonstration of extra hydrogen ions being liberated and species such as $MH_{-1}B'_2$ and $MH_{-2}B'_2$ being formed. We do not know at the present time the source of the protons. They can originate from the hydrolysis of water in the formation of these complexes. An alternate source could be the hydroxyl group involvement of L-serine in the above complexes.

In a recent publication, Hallman, Perrin, and Watt (21) reported the β values for the species in the Cu(II)–L-glutamine system at 37° and I = 0.15 M KNO_3 but did not include the species distribution. Since their experimental conditions are markedly different from ours, it is not easy to compare our stability data with those obtained by these authors.

An interesting difference becomes evident if one compares the species distribution of the Cu(II)–L-glutamine system to that of the Cu(II)–L-serine system. The Cu(II)–L-serine system shows the presence of complex species $MH_{-1}B'_2$ and $MH_{-2}B'_2$ while in the Cu(II)–L-glutamine system these species are absent. One way to explain this observation may be that in the Cu(II)–L-serine system the species $MH_{-1}B'_2$ and $MH_{-2}B'_2$ represent hydroxylated complexes where OH^- would originate from H_2O taking up the additional coordination sites. Whereas, in Cu(II)–L-glutamine, the coordination positions are filled and consequently no hydroxyl species were formed. The only likely group is provided by the amide group of glutamine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which, upon coordination to the central Cu(II) atom, in addition to carboxyl and amino involvement, would then effectively eliminate the hydroxyl group binding. However, until further physicochemical results are obtained on this system, no definitive conclusion can be made on this subject.

Ternary Cu(II) – Amino Acid Complexes

In the L-histidine–Cu(II)–L-serine system, three mixed ligand complexes, MHAB′, MAB′, and $MH_{-1}AB'$ were detected in addition to the binary complexes, MHA, MA, MHA_2, MA_2, $MH_{-1}A_2$, MB′, and MB'_2. Some species which do exist in the binary systems: Cu(II)–L-histidine and Cu(II)–L-serine, have not been detected in appreciable amounts in the ternary system. There was about 35% of Cu(II) present in the protonated mixed ligand complex MHAB′ at p*H* 5. With increasing p*H* the mixed complex MAB′ was formed and accounted for about 75% of Cu(II) in the p*H* range 5.5–9. A closely related mixed ligand complex L-histidine–Cu(II)–L-threonine reported by us earlier (9, 12) showed its unique structure with L-histidine being tridentate involving *N*-amino and *N*-imidazole coordination in a square plane around the Cu(II) ion with the carboxyl oxygen in a very distorted axial position. The amino and carboxyl groups of L-threonine occupied the other positions in the square plane of the Cu(II) coordination square. There was no involvement of the hydroxyl group of L-threonine in Cu(II) coordination. The same results may be expected for MAB′. At p*H* > 9.5 significant amounts of a mixed complex species $MH_{-1}AB'$ was formed. This species may well be an hydroxo complex. However, definite proof of an hydroxyl ion involvement is lacking. The protons could originate either from a water molecule being coordinated or else by dissociation of a proton from the hydroxyl group of serine upon coordination of the alcohol oxygen to the central Cu(II) ion. The same arguments, as raised with the species $MH_{-1}B'_2$ in the binary system, can be applied to this ternary system.

The results observed in the L-histidine–Cu(II)–L-glutamine system were quite similar to the system M:A:B′ discussed earlier, except that there were no species such as $MH_{-1}AB''$. Again, at low p*H* (p*H* < 4) we found that binary Cu(II) complexes predominated and, on raising the p*H* the mixed complexes MHAB″ and MAB″ appeared sequentially with 60% Cu(II) in the form of MAB″ in the p*H* range 5–10. The absence of the species $MH_{-1}AB''$ can be interpreted using arguments similar to those employed in the Cu(II)–L-glutamine system.

An Appraisal of the Enhancement of the Stability Constants of the Ternary Complexes

It was observed in the ternary complex system that the stability constants of the ternary complexes invariably had higher values than those which would be predicted on theoretical grounds based on observations on the isolated binary systems. From successive formation constants of the 1:1 and 1:2 Cu(II):ligand complexes, one could predict on theoretical basis, the stability constant of the mixed complex if one assumes that the addition of the second amino acid is not influenced by the nature of the first amino acid attached to the Cu(II) ion.

For complex MA_2 we have:

$$[7] \qquad M + A \overset{K_1}{\rightleftarrows} MA$$

$$[8] \qquad MA + A \overset{K_2}{\rightleftarrows} MA_2$$

For complex MB_2 we have:

$$[9] \qquad M + B \overset{K'_1}{\rightleftarrows} MB$$

$$[10] \qquad MB + B \overset{K'_2}{\rightleftarrows} MB_2$$

The mixed complex can be arrived at (*i*) by addition of B to MA or, (*ii*) by addition of A to MB to give MAB. Then, if we assume eq. 7 as first step in the "pathway" then, the stability constant of the mixed complex should be arrived at by following "pathway" (*i*).

$$[11] \qquad \beta_{mix(i)} = K_1 K'_2$$

or

$$[12] \qquad \log \beta_{mix(i)} = \log K_1 + \log K'_2$$

where

$$[13] \qquad \log K'_2 = \log \beta'_2 - \log \beta'_1$$

Therefore,

$$[14] \qquad \log \beta_{mix(i)} = \log \beta_1 + \log \beta'_2 - \log \beta'_1$$

If we assume eq. 9 as first step in the "pathway" (*ii*) then we obtain

$$[15] \qquad \log \beta_{mix(ii)} = \log \beta'_1 + \log \beta_2 - \log \beta_1$$

TABLE 2. log stability constants (log β_{pqrs}) of complex species $M_pH_qA_rB_s$; observed and calculated values and their differences ($\Delta \log \beta_{pqrs} = \log \beta_{pqrs(obsvd)} - \log \beta_{pqrs(calcd)}$)

						Calculated values			
p	q	r	s'	s''	Observed values	Pathway (*i*)	$\Delta \log \beta_{pqrs}$	Pathway (*ii*)	$\Delta \log \beta_{pqrs}$
L-*Histidine* – *Cu(II)* – L-*Serine*									
1	0	1	1		17.54	16.67	0.87	16.37	1.17
1	1	1	1		21.70	20.75	0.95	20.73	0.97
L-*Histidine* – *Cu(II)* – L-*Glutamine*									
1	0	1		1	17.62	16.95	0.67	16.12	1.50
1	1	1		1	21.65	21.03	0.62	20.40	1.25

Now, we would expect the log β value of the mixed complex to be somewhere between log $\beta_{mix(i)}$ and log $\beta_{mix(ii)}$. Depending on which "pathway" predominates, one has to incorporate statistical weights (w_i, $i = 1, 2$) which will yield equations of the following type

$$[16] \quad w_1 \log \beta_{mix(i)} = w_1 \log \beta_1 + w_1 \log \beta'_2 - w_1 \log \beta'_1$$

and

$$[17] \quad w_2 \log \beta_{mix(ii)} = w_2 \log \beta'_1 + w_2 \log \beta_2 - w_2 \log \beta_1$$

Then, averaging of these weighted equations should give the expected value as the weighted mean

$$[18] \quad \log \bar{\beta}_{mix(calcd)} = \frac{1}{w_1 + w_2} (w_1 \log \beta_{mix(i)} + w_2 \log \beta_{mix(ii)})$$

or

$$[19] \quad \log \bar{\beta}_{mix(calcd)} = \frac{1}{w_1 + w_2} (w_1 \log \beta_1 + w_1 \log \beta'_2 - w_1 \log \beta'_1 + w_2 \log \beta'_1 + w_2 \log \beta_2 - w_2 \log \beta_1)$$

The weights are generally unknown. If we assume $w_1 = 1$, $w_2 = 0$, Then

$$[20] \quad \log \bar{\beta}_{mix(i)} = \log \beta_1 + \log \beta'_2 - \log \beta'_1$$

And if we assume $w_1 = 0$, $w_2 = 1$, then

$$[21] \quad \log \bar{\beta}_{mix(ii)} = \log \beta'_1 + \log \beta_2 - \log \beta_1$$

For the protonated, hydroxyl, and polynuclear complexes, the arguments and derivations are analogous.

The observed stability constants and the calculated stability constants following either of the "pathways" (*i*) or (*ii*) are presented in Table 2. In these two mixed complex systems we have observed larger values for the mixed complexes than predicted on theoretical grounds. This enhancement phenomenon in the case of heterogeneous ligands represents a striking departure from the theoretical expectations. Explanations at this stage lack precise supporting proof and tend to be highly speculative. In the case of MAB complexes, one can offer the reasonable explanation that the pathway through MA as a first step is preferred, yielding log $\beta_{1011} = 16.67$ which is still 0.87 log units below the observed value for the mixed complex MAB. This is supported by the fact that the stability of MA (log $\beta_{101} = 10.2$) is by two decades higher than the stability constants of MB′ or MB″ (log $\beta_{101} = 8.01$ and $= 7.76$, respectively).

Since even the largest calculated β value, by "pathway" (*i*), is smaller than the observed β value, we must consider other stabilizing influences in the complex molecule. Having two different amino acids linked to the same central Cu(II) ion evidently means additional contribution to the stability of the ternary complex molecule. The electronic structure of the Cu(II) ion must be such that the influences of one ligand can be transmitted through the coordinating bonds to the other remote ligand molecule. This stability enhancement cannot be attributed to the observed pentacoordination of Cu(II) in L-histidine–Cu(II)–L-threonine (12) where L-histidine and L-threonine participate in tridentate and bidentate coordination, respectively. The reasoning that the pentacoordination of Cu(II) would be more stable than either square planar or hexadentate coordination can be ruled out on the evidence that a mixed complex of glycine–Cu(II)–DL-alanine (22) showed a stability constant of log $\beta_{1011} = 15.60$ as compared to a

For personal use only.

calculated value of 15.18. The only explanation can be found in the effects of asymmetry around the central Cu(II) ion. This asymmetry may express itself thermodynamically in the entropy term of the system causing the sizably increased value of the overall stability constant.

Structure of the Species in the Copper (II)–L-Histidine System

THEO P. A. KRUCK AND BIBUDHENDRA SARKAR[1]

Division of Biochemistry, The Research Institute, The Hospital for Sick Children, Toronto, and Department of Biochemistry, University of Toronto, Toronto, Ontario M5G 1X8

Received June 14, 1972[2]

The presence of simultaneously existing multiple species were taken into account in interpreting the structures of the complex species in the Cu(II)–L-histidine system. A refined proton displacement technique was utilized for structure elucidation of the species in solution. The absorbance and the molar extinction of the individual species were computed from the total absorbance and the species distribution over the p*H* range studied. The i.r. spectra of L-histidine and Cu(II)–L-histidine in D_2O were obtained as a function of p*D*. They were interpreted in view of the species detected in a given p*H* range. The results of the species distribution as a function of p*H*, proton displacement, visible spectra of the individual species, and infrared data, were all combined to make structural interpretations. The following modes of metal coordination were proposed for the major species in the Cu(II)–L-histidine system: MHA, *O*(carboxyl) and *N*(imidazole); MH_2A_2, *O*(carboxyl) and *N*(amino) in both L-histidines; MA, *O*(carboxyl), *N*(imidazole), and *N*(amino); MHA_2 *O*(carboxyl), *N*(imidazole), and *N*(amino) in one L-histidine and *O*(carboxyl) and *N*(amino) in the other; MA_2, *O*(carboxyl). *N*(imidazole), and *N*(amino) in both L-histidines, or *O*(carboxyl), *N*(imidazole), and *N*(amino) in one L-histidine and *N*(amino) and *N*(imidazole) in the other or an equilibrium mixture of both structures.

Lors de l'interprétation des structures des complexes appartenant au système Cu(II)–L-histidine, il a été nécessaire d'envisager la présence de plusieurs espèces pouvant exister simultanément. Une technique raffinée impliquant le déplacement des protons a été utilisée afin d'élucider les structures des espèces en solution. L'absorption ainsi que le coefficient d'extinction molaire de chacune des espèces ont été calculés à partir de l'absorption totale et de la distribution des espèces pour l'intervalle de pHétudié. Les spectres i.r. de la L-histidine et du complexe Cu(II)–L-histidine ont été obtenus dans le D_2O en fonction du p*D*. Ceux-ci furent interprétés en fonction des espèces détectées dans un intervalle de p*H* défini. Les résultats obtenus de la distribution des espèces en fonction du pH, du déplacement des protons, des spectres visibles de chacune des espèces ainsi que des études en i.r., ont été combinés afin d'interpréter les structures. Les différentes méthodes de coordination au métal furent présentées afin d'expliquer les espèces majeures dans le système Cu(II)–L-histidine: MHA, *O*(carbonyle) et *N*(imidazole); MH_2A_2, *O*(carbonyle) et *N*(amino) dans les deux L-histidines; MA, *O*(carbonyle), *N*(imidazole) et *N*(amino); MHA_2, *O*(carbonyle), *N*(imidazole) et *N*(amino) pour un groupe L-histidine et *O*(carbonyle) et *N*(amino) pour l'autre; MA_2, *O*(carbonyle), *N*(imidazole) et *N*(amino) dans les deux L-histidines ou *O*(carbonyle), *N*(imidazole) et *N*(amino) pour un groupe L-histidine et *N*(amino), *N*(imidazole) pour l'autre ou un mélange à l'équilibre des deux structures. [Traduit par le journal]

Can. J. Chem., 51, 3563 (1973)

Introduction

Several proposals have been made for the structures of a number of Cu(II)–L-histidine complexes, based on various physical and chemical studies. Unfortunately, due to the lack of a detailed knowledge of the species distribution throughout the p*H* range of interest, the quantitative implications of multiple species existing simultaneously at the p*H* in question were overlooked in almost all of these investigations. It cannot be overemphasized that the lack of knowledge pertaining to the system concerned can lead to serious errors in making structural interpretation. The physiological implications (1–5) of the Cu(II)–L-histidine complexes make it essential to investigate precisely the structures of the complex species in solution. The species, their stability constants, and their quantitative distribution over a wide p*H* range reported in the preceeding paper (6),[3] provided a suitable platform to study the structure of individual species in solution by physical and chemical means. The combined results of the visible and i.r. spectra, as well as those obtained from the proton displacement studies, were utilized to propose the structures in solution of all the major species in the Cu(II)–L-histidine system.

Experimental Section

Materials

L-Histidine free base ($[\alpha]_D^{20}$ + 39.9° ± 0.5°) was obtained from Nutritional Biochemicals. The purity was tested by chromatography. It was dried at 110° for 24 h and then stored over anhydrous calcium chloride at room temperature under vacuum. The water was first distilled and then deionized by passing it through a commercial ion exchange column (ILICO-WAY-X research model). The base used for p*H* adjustments was carbonate free 5.010 *N* NaOH. The stock solutions of L-histidine and $CuCl_2$ were prepared from vacuum dried materials and subsequently checked titrimetrically. All other reagents were of analytical grade. The deuterated products D_2O, DCl, and NaOD (99% isotopically pure) were obtained from Merck, Sharp and Dohme, Montreal, Canada.

Proton Displacement

Potentiometric titrations were carried out on a series of solutions: 50 ml 0.15 *M* in NaCl, 0.1 *N* in HCl, containing combinations of L-histidine (40 m*M*) and $CuCl_2$ (0, 3, 5, 7, 10, and 20 m*M*). All titration curves coincided initially at low p*H*. Before each titration the calibrations of electrodes and chart recorder were checked. The precision of repetitive titrations was 0.001 p*H* units and 0.002 ml of base. It was necessary to obtain titration curves of samples containing constant amounts of ligand while varying the metal component from sample to sample. A computer program PLOT[4] was used to treat the data. First, the titration curves were digitized and formated for input to this program. Then, a table of $\delta H_1^+/\delta C_M$ was printed out.[5] These results formed the basis for comparison to the theoretical values as done in the proton displacement analysis using the program SELECT.[4]

Spectrophotometric Measurements

A Cary 15 recording spectrophotometer was used to obtain the absorption spectra in the visible region from wavelength 800 to 300 nm. The Cu(II)–L-histidine solutions were measured against L-histidine solutions of the same p*H*, as reference. All experimental conditions regarding the samples measured, were the same as those for the potentiometric titrations. Samples were scanned at a series of p*H* values ranging from p*H* 1.00–11.00 at 25°.

A Beckman IR-20 double beam infrared spectrophotometer was used to obtain the percent transmission spectra in the range 2000 to 800 cm^{-1}. The samples were made up in D_2O taking care to exclude any H_2O contamination. Infrared spectra of 1:2 Cu(II)–L-histidine (0.2 *M*) were obtained using Irtran-2 cells having a lightpath of 0.05 mm. The spectra were obtained at varying p*D* values starting from p*D* 0.8–10.2 at 25°.[6] An even distribution of the sample and exclusion of minute gas bubbles were insured.

Results

Structural Interpretation of Species by Proton Displacement

Information about the specific group involvement in metal–ligand interaction can be obtained if the group in question shows a buffering region in the p*H* range studied or, if the group is fully protonated at that p*H*. In the Cu(II)–L-histidine case, advantage was taken of the well separated buffering regions of carboxyl, imidazole, and amino groups for the above purpose. The proton displacement data shown in Fig. 1 are unbiased.

TABLE 1. Scheme for proton displacement calculations

Coordination pattern*	Number of potential groups involved in coordination†			
	MHA_2		MA_2	
	NH_2	N_{im}	NH_2	N_{im}
A	1	1	2	1
B	2	1	2	0
C	2	0	2	2

*There are several other possible combinations but no reasonable fit could be obtained.
†The numerals indicate the number of protons which will be released upon metal coordination with the particular group listed.

[4]Programs PLOT, SELECT, and LEASK were written in Fortran IV language. The programs have been deposited as Document No. NAPS-01563 with ASIS National Auxiliary Publication Service, c/o CCM Information Corp., 866 Third Avenue, New York, N.Y. 10022. A copy may be secured by citing the document number and by remitting $1.00 for microfiche or $3.00 for photocopies. Advance payment is required. Make cheques or money orders payable to: ASIS-NAPS.

[5]Since in this system it was found that $\delta H_1^+/\delta C_M$ was a linear function of p*H* we can consider $\delta H_1^+/\delta C_M = \Delta C_{OH}/\Delta C_M$.

[6]Differences between p*H* and p*D* values are considered within the tolerances required for meaningful interpretation of the results where p*D* = meter reading + 0.4 (7).

TABLE 2. Differences between the calculated and observed proton displacement data for structure analyses

			$(H_l{}^+_{calcd} - H_l{}^+_{obs})$

9	C	C	−0.64	−0.12	−0.13	−0.02	−0.02

They were obtained without any assumptions concerning probable complex species in solution. In other words, no assumptions had to be made as to the origin of these protons. The total proton liberation, however, must equal the contribution of each species yielding protons when the metal–ligand bonds are formed. In making theoretical calculations of proton displacement at a given p*H*, it is necessary not only to consider all the species in the system, but, also to take into account all possible modes of binding in the metal–ligand complex. The necessary computations were performed with the program SELECT.[4]

The scheme in Table 1 shows the permutations for the possible modes of coordination in the main species MHA_2 and MA_2 existing simultaneously in the p*H* range 5–7. Contributions to the proton displacement data by the small amounts of MA, MH_2A_2, and $MH_{-1}A_2$ in the p*H* range studied were considered to be negligible and therefore were omitted from the calculations. Besides the species considerations, a correction was also made for the lowering of the pK_a of potential groups of the multidentate ligand when previous coordination had occurred through another group. In the p*H* region 5–7, the following transition takes place (6)

[1] $$MHA_2{}^+ \leftrightarrows MA_2 + H^+$$

An estimate of the actual pK_a of the protonated group in MHA_2 can be obtained from the following equations:

[2] $$M + H^+ + 2A \overset{\beta_{112}}{\rightleftharpoons} MHA_2{}^+$$

[3] $$M + 2A \overset{\beta_{102}}{\rightleftharpoons} MA_2$$

Subtracting eq. 3 from eq. 2 yields the desired pK_a of this group

[4] $$pK_a = \log \beta_{112} - \log \beta_{102} = 24.01 - 18.46 = 5.55$$

Utilizing the pK_a values of the potential coordinating groups, sets of theoretical values of proton displacement were obtained on the basis of the various structural assumptions made for multiple species existing simultaneously at a given p*H*. Based upon the goodness of fit between the experimental value of the proton displacement and the theoretical value for an assumed structure, we concluded the possible mode of binding in a given complex species.

The best fit between calculated and observed proton displacement data was obtained in structural combination number (*6*) in Table 2. This combination was consistent with 2 amino, 1 imidazole in MHA_2; 2 amino and 2 imidazole in MA_2. No conclusion can be drawn about the carboxyl involvement from these data since they were obtained in p*H* 5–7, where the carboxyl proton is already titrated.

A previous attempt (8) to employ a similar analysis was not satisfactory because of a lack of knowledge of the species distribution; only average values were obtained. This technique, combined with other supporting methods, should prove very useful in the study of metal–ligand interaction. The resolving power of such an analysis depends largely on the precision of the initial measurements. The chief error in potentiometry arises mainly from the electrodes being used. The only other major source of error arises out of faulty assumptions regarding the system: if a complex species that is present in

solution has a potential influence on the analysis and is being ignored, then erroneous results and interpretations are the consequence.

Visible Spectra of the Species

Spectra of solutions containing 1:4 molar ratio of Cu(II) and L-histidine were recorded in the wavelength region 300–800 nm at various pH values. Since a species distribution in 1:4 Cu(II)–L-histidine system had been obtained (ref. 6, Fig. 3*B*) from the potentiometric measurements, we were able to separate the total absorbance into absorptions of the individual species. The only assumptions necessary are, the Beer–Lambert's law is obeyed and, that the total absorbance A_λ is due to the linear summation of the component absorptions. Therefore, for every pH_i value

$$[5] \qquad A_{\lambda,[pH_i]} = \sum_1^n \varepsilon_{\lambda,pqr} C_{pqr}$$

where C_{pqr} is the concentration of the pqrth species and $\varepsilon_{\lambda,pqr}$ is its molar extinction at that wavelength for a 1 cm lightpath. We employed our LEASK[4] program to obtain the absorbance and molar extinction of the species at a given wavelength. The ε_{pqr} values thus obtained were plotted as a function of wavelength λ in Fig. 2.

Results of Infrared Measurements

Infrared spectra for the 1:2 Cu(II)–L-histidine system in D_2O were obtained in the pD range 0.8–10.2. The scans showing the characteristic bands of the antisymmetric carboxyl stretching frequency of L-histidine are presented in Fig. 3. The peaks marked *a* represent the absorption bands due to the antisymmetric stretching of the protonated carboxyl groups ($\nu = 1735$ cm^{-1}), the peaks marked *b* are due to vibrations of the same carboxyl group which has been deprotonated ($\nu = 1622$ cm^{-1}). The pD dependence of these two peaks identifies them as being due to the protonated and deprotonated forms of the carboxyl group. Plotting optical densities of the absorption bands versus pD results in a $pK_{COOH} = 1.8$ at the 50% dissociation point which is in close agreement with our potentiometric results (6).

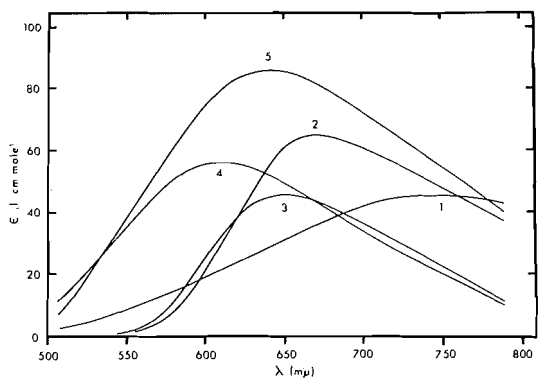

FIG. 2. Computed spectra of the species in the Cu(II)–L-histidine system. Curve 1, MHA; curve 2, MA; curve 3, MHA_2; curve 4, MH_2A_2; curve 5, MA_2.

In Fig. 4, i.r. spectra are shown representing paired systems, where, at selected pD values, the metal-free system is compared to the Cu(II)-containing system. A quantitative presentation of the shifts of the antisymmetric carboxyl stretching frequency is given in Fig. 5, where curve *A* refers to observations on the L-histidine system and curve *B* refers to data obtained from the Cu(II)–L-histidine system. Considering the frequency shift during titration of L-histidine (curve *A*) it is noted that up to pD ~5 the frequency remains constant; however, as the protonated imidazole group releases its proton, this band shifts towards lower frequency. At the end of the imidazole buffering region, we again achieve constant frequency ($\nu = 1612$ cm^{-1}) which persists up to pD ~8.0 with almost constant amplitude. As the pD is raised further, the amplitude decreases rapidly with no further shift in frequency. However, a new band ($\nu = 1578$ cm^{-1}) appears at pD ~8.0, and reaches a maximum amplitude at pD ~10.2 (Fig. 4). This drastic shift in the antisymmetric carboxyl stretching frequency can be attributed to the deprotonation of the carboxyl group plus the inductive effects arising from the deprotonation of both the imidazolium and ammonium groups in L-histidine. Infrared studies of EDTA titration showed similar influence of the deprotonation of the ammonium group in the antisymmetric carboxyl stretching frequency (9).

In Fig. 5, curve *B*, the results of the $\Delta\nu$ *vs.* pD are presented for the 1:2 Cu(II)–L-histidine system, where we selected 1622 cm^{-1} as reference ν. The notable feature of this curve is the stepwise increase in $\Delta\nu$ going from low to high pD. The first inflection occurs at pD ~5.0 where $\Delta\nu = 30$ cm^{-1}. These results are best explained in conjunction with the results obtained by potentiometric analysis. It is shown (ref. 6, Fig. 3*A*) that for the 1:2 Cu(II)–L-histidine system, the species MHA is the major component below

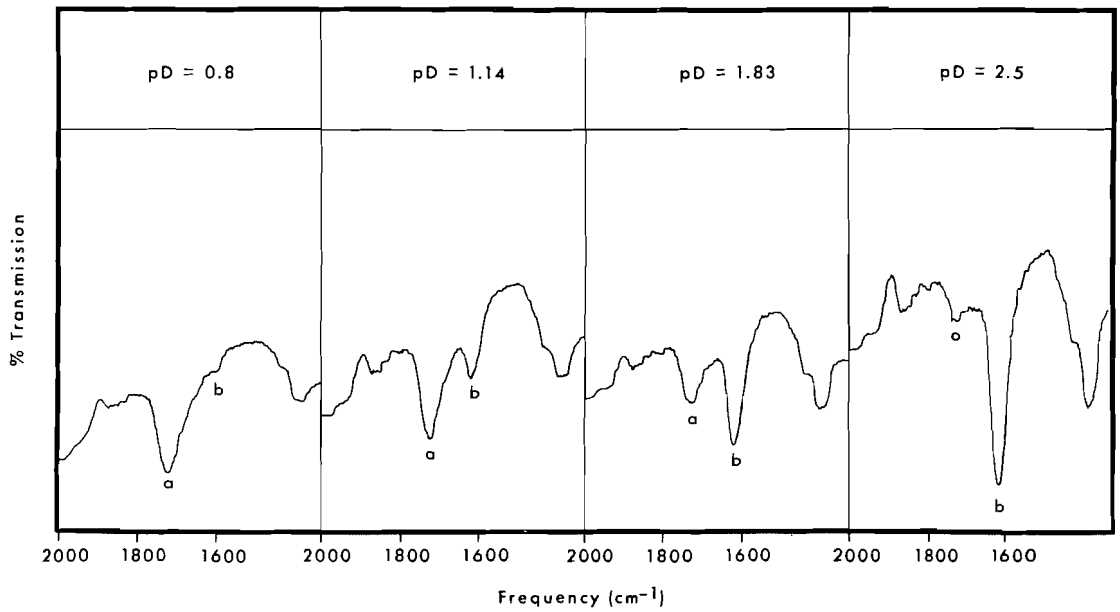

FIG. 3. Infrared spectra showing the antisymmetric carboxyl stretching frequency bands. Peak *a*, protonated carboxyl group; peak *b*, deprotonated carboxyl group.

p*H* 2.5. From infrared observations, we find that at and below p*D* ~2.5 the amplitude of the vibration of the protonated carboxyl group at $\nu = 1735\ cm^{-1}$ decreases upon addition of Cu(II) while the amplitude of the deprotonated carboxyl group increases proportionally to Cu(II) complexation. At the same time a $\Delta\nu$ is observed for the deprotonated carboxyl group due to metal complexation. An example is shown in Fig. 4 (p*D* 2.5). The proton displacement from the carboxyl group due to Cu(II) addition, signifies Cu(II)–carboxyl coordination. As the p*D* is increased, we observe a shift of this absorption band ($\nu = 1612\ cm^{-1}$) towards lower frequency. This tendency continues up to p*D* ~3.0, where a shoulder is formed with an inflection occurring at $\Delta\nu = 11\ cm^{-1}$. The initial part of curve *B* resembles the characteristics of curve *A*. A parallelism can be drawn in curve *B* where a similar shift ($\Delta\nu = 11\ cm^{-1}$) is apparent well below the pK_a of the imidazole group. The p*D* region, where the first plateau in $\Delta\nu$ is reached in curve *B*, coincides with the corresponding p*H* scale where the maximum amount of MHA is formed (ref. 6, Fig. 3*A*). Hence, it is concluded that in MHA, the imidazole group is also coordinated to Cu(II) in conjunction with the carboxyl group. The next species to appear are MA and MH_2A_2. There is a corresponding sharp increase in $\Delta\nu$ indicating carboxyl participation. Complete characterizations of these species are presented in the discussion section in combination with other experimental evidence. Carlson and Brown (10) investigated the 1:1 Cu(II)–L-histidine system and proposed a monodentate complex involving Cu(II)–carboxyl coordination for p*D* < 3.0; but, in their interpretation they appear not to have taken into account that multiple complex species may be present in their system at the p*D* values at which their experimental data were gathered.

The 1:2 Cu(II)–L-histidine complexes rapidly increased in abundance above p*H* 3.0. The species MHA_2 reaches a maximum at p*H* 4.2. Similarly, starting at p*D* 3 (Fig. 5, curve *B*), a sharp increase is seen in the $\Delta\nu$, reaching a plateau ($\Delta\nu = 30\ cm^{-1}$) at p*D* = 5.0 and remaining constant up to p*D* = 10.2. Evidence in support of carboxyl involvement at higher p*D* values is provided by the fact that in the absence of Cu(II) at p*D* 10.2 (Fig. 4) we observe a band at $\nu = 1578\ cm^{-1}$ ($\Delta\nu = 44\ cm^{-1}$) which is due to the deprotonated carboxyl group. However, in the presence of Cu(II) we observe a $\Delta\nu = 30\ cm^{-1}$. Since we do not get comparable shifts in $\Delta\nu$ in the metal-free system, we can ascribe this effect to the carboxyl–Cu(II) interaction of the histidine anion. No observable change

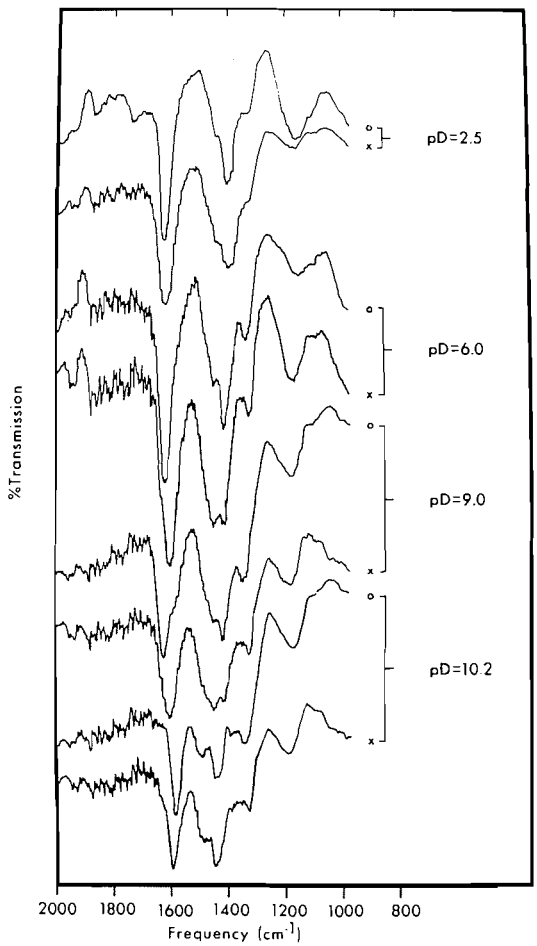

FIG. 4. Infrared spectra of L-histidine and 1:2 Cu(II)–L-histidine in D_2O at different pD values: O, L-histidine; ×, Cu(II)–L-histidine.

occurs in $\Delta\nu$ going from pD 5.0–10.2, where the transition of MHA_2 to MA_2 takes place. The maintaining of the carboxyl binding of both L-histidines in the species MHA_2 and MA_2 is probable since, if one of the carboxyl groups were to leave the coordination sphere of Cu(II), then we would expect a significant absorption peak at $\nu = 1578\ cm^{-1}$. This is not the case. Only one single peak at $\nu = 1592\ cm^{-1}$ is observed.

Discussion

A complete analysis of the equilibria is essential to study the structure of the species in solution in a multispecies system. In the present investigation, the species and their distributions

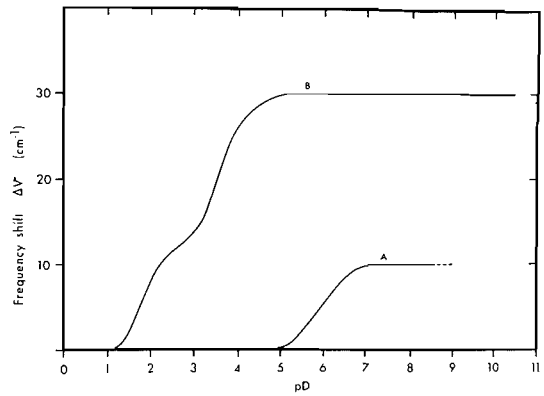

FIG. 5. Shift of the antisymmetric carboxyl stretching frequency ($\Delta\nu$) towards lower frequency from reference $\nu = 1620\ cm^{-1}$. Curve *A*, L-histidine; curve *B*, 1:2 Cu(II)–L-histidine.

over a wide pH range were taken into account to study the structure of individual species in solution by physical and chemical means.[7]

We shall discuss the structure of the species in the 1:2 Cu(II)–L-histidine system as they appear with increasing pH. At pH 2.00, the predominant species is MHA having a structure as shown in Fig. 6*A*, on the basis of the following results. On addition of Cu(II) to L-histidine, an increase in the absorption maximum and a simultaneous shift in the antisymmetric carboxyl stretching frequency of the deprotonated carboxyl group was observed at pD = 2.5 and below (Fig. 5). This observation, in conjunction with potentiometric results, was interpreted as an indication for carboxyl involvement in the species MHA. The imidazole nitrogen binding is also evident from the i.r. results. The location of the λ_{max} of 750 nm of this species (Fig. 2) can be assigned to a carboxyl oxygen and an imidazole nitrogen involvement. Although it has been reported that the introduction of nitrogen in the ligand field surrounding the Cu(II) nucleus causes a shift to a lower wavelength (11), recent

[7]The chemical and physical probes for structural interpretations are not sensitive enough to study the minute amounts of $MH_{-1}A$ and $M_2H_{-2}A_2$. The species $MH_{-1}A_2$ is a high pH species and any structural assignment of this species must be followed with caution, since enough physicochemical data could not be obtained because of the instability of the Cu(II)–L-histidine system in the high pH region. For these reasons, no structures are proposed for the species $MH_{-1}A$, $M_2H_{-2}A_2$, and $MH_{-1}A_2$.

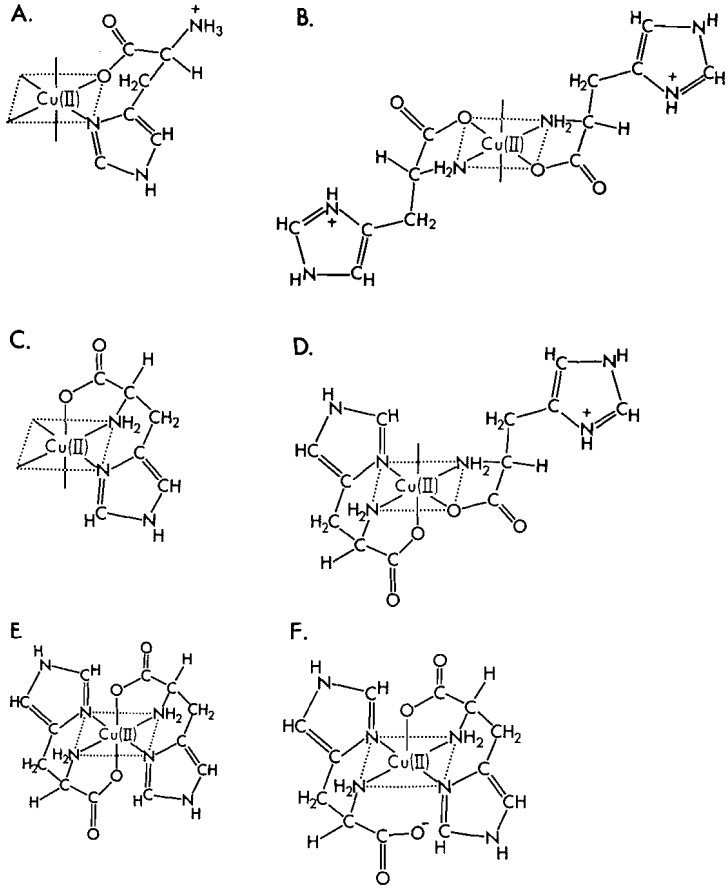

FIG. 6. Proposed structures of the species in the Cu(II)–L-histidine system. *A*, MHA; *B*, MH_2A_2; *C*, MA; *D*, MHA_2; *E* and *F*, MA_2. The diagrams are not to be taken to represent absolute steric configurations.

studies show that all nitrogens do not behave in the same manner. Ligand-field effects of *N*(imidazole) and *O*(carboxyl) appear to be similar (19).

On raising the p*H* the next species to appear are MH_2A_2 and MA which show maximum concentration at almost the same p*H* value (ref. 6, Fig. 3). The infrared data again suggest carboxyl involvement (Fig. 5). The crystal structure of MH_2A_2, which crystallized from a solution of p*H* 3.7 as the dinitrate dihydrate, has been solved (12). In this species two L-histidine molecules coordinate to a central Cu(II) atom, each through the amino nitrogen and carboxyl oxygen as shown in Fig. 6*B*. The observed λ_{max} of 650 nm would indicate carboxyl and amino involvement, hence the structural identity of the species MH_2A_2 in solution and in crystalline state could be demonstrated. The continued shift in carboxyl stretching, as well as deprotonation of 3 hydrogens from the L-histidine molecule in the formation of MA, strongly favor its structure as shown in Fig. 6*C* involving carboxyl, amino, and imidazole groups. The involvement of an amino nitrogen in conjunction with carboxyl and imidazole groups in MA is also consistent with the λ_{max} of 670 nm.

In the p*H* region 4.5–7.5 the major species are MHA_2 and MA_2. The species MHA_2 reaches its maximum concentration at about p*H* 4.5. The i.r. observations suggest carboxyl involvement; the antisymmetric carboxyl stretching frequency reaching a maximum shift of about 30 cm^{-1}. Involvement of the amino nitrogens is also sug-

gested by the shift of the λ_{max} towards lower wavelength (λ_{max} = 610 nm). The proton displacement results clearly indicate the involvement of 2 amino and 1 imidazole groups in MHA_2 (Table 2). The complex MHA_2 can be considered a mixed complex similar to the previously reported L-histidine–Cu(II)–L-threonine complex (1). Considering the overall stability constants of these complexes (13), we find a striking similarity in the stepwise addition of the second amino acid. To elaborate this point, the following reactions 6 to 9 are considered:

[6] L-thr + Cu(II) $\overset{\beta_{101}}{\rightleftharpoons}$ Cu(II)–L-thr $\quad \beta_{101} = 8.01$

[7] L-Hhis + Cu(II) $\overset{\beta_{111}}{\rightleftharpoons}$ Cu(II)–L-Hhis $\quad \beta_{111} = 14.18$

[8] Cu(II)–L-thr + L-his $\overset{\beta_{1011}}{\rightleftharpoons}$ L-thr – Cu(II) – L-his $\quad \beta_{1011} = 17.55$

[9] Cu(II)–L-his + L-Hhis $\overset{\beta_{112}}{\rightleftharpoons}$ L-his – Cu(II) – L-Hhis $\quad \beta_{112} = 24.17$

It can be seen that the difference between the overall stability constants of the mixed complexes $\beta_{112} - \beta_{1011} = 6.6$ is close to the difference $\beta_{111} - \beta_{101} = 6.2$ between the first formation constants of the Cu(II)–L-histidine and Cu(II)–L-threonine complexes. It suggests almost equal strength of binding of the second ligand. This thermodynamic evidence points towards a similarity between the structure of MHA_2 and that of L-histidine – Cu(II) – L-threonine (14), where one ligand is tridentate and the second is in bidentate configuration. Thus, for MHA_2 a structure involving 1 imidazole, 2 carboxyl, and 2 amino groups is suggested (Fig. 6*D*).

The greatest controversy had been centered around the structure of MA_2. The investigations by three groups (15–17) using similar experimental techniques resulted in different proposals for the structure of MA_2. The n.m.r. investigation by Sigel and McCormick (18), did not settle the question of all the coordinating groups in MA_2 either. The common shortcomings seem to be a lack of knowledge of the precise concentration of the complex species in their respective systems. Corroborating evidence obtained by a different experimental approach was not presented in order to verify their structural proposals for MA_2. The proton displacement studies definitely indicated quantitative involvement of 2 imidazole and 2 amino groups in MA_2 (Table 2). Since Cu(II) coordination to imidazole nitrogen and carboxyl oxygen appears to show similar ligand field effects (19), the absorption maxima (640 nm) of MA_2 can best be explained by the involvement of amino nitrogens in conjunction with carboxyl and imidazole groups. The involvement of one or two carboxyl groups in MA_2 is evident from the observed frequency shift from 1622 to 1592 cm^{-1} in the region where MA_2 exists almost exclusively. If the carboxyl group was not coordinated, then MA_2 should have shown a major peak at 1578 cm^{-1} for free carboxylate anion. On the contrary, a constant shift of 30 cm^{-1} was observed from p*H* 5–7 (Fig. 5), implicating Cu(II) coordination to the carboxyl oxygen. Thus, in addition to 2 imidazole and 2 amino groups in MA_2, the involvement of at least one, if not both, carboxyl groups, is apparent. This is consistent with our previous suggestion (14) for the structure of MA_2, interpreted on the basis of the crystal structure of the L-histidinato-L-threoninato-aquocopper(II) hydrate. Consequently, MA_2 may either have a structure as shown in Fig. 6*E* or such as shown in Fig. 6*F*. It is also possible that both structures are present in an equilibrium mixture.

On An Extension of the Use of p*H*-Titrations for Determination of Free Metal and Free Ligand Concentrations During Metal Complex Formation

W. A. E. McBryde

Department of Chemistry, University of Waterloo, Waterloo, Ontario N2L 3G1

Received May 30, 1973

A method introduced by R. Osterberg for the measurement of free ligand concentration during the formation of metal complexes has recently been extended by Sarkar and Kruck to include measurement of free metal concentration. The method is based on suitable manipulation of the data from sets of p*H* titrations. This paper gives a new theoretical treatment of the method and its extension, and shows how the functions developed are related to other parameters of complex formation. A special advantage of Osterberg's method as extended is its capability of being applied when protonated or deprotonated complexes form.

La méthode introduite par R. Osterberg pour mesurer la concentration en ligand libre pendant la formation de complexes métalliques a été récemment développée par Sarkar et Kruck pour inclure la mesure de concentration en métal libre. La méthode est basée sur une manipulation convenable des données à partir des tableaux de titration p*H*. Cette communication décrit un nouveau traitement théorique de la méthode et son extension qui montre comment les fonctions développées sont reliées à d'autres paramètres de formation de complexes. Un avantage spécial de la méthode d'Osterberg ainsi étendue est d'être applicable aux formations de complexes protonés et déprotonés.

[Traduit par le journal]

Can. J. Chem., **51**, 3572 (1973)

Introduction

Sarkar and Kruck (1) have recently revived a procedure introduced by Osterberg (2) for the determination of free ligand concentration during the controlled formation of metal–ligand complexes with a view to establishing the stability constants of the latter. These authors have extended Osterberg's procedure to the determination of the free metal concentration, and have improved the practice of the method by introduction of computer-based numerical procedures.

As Beck has pointed out (3), Osterberg's procedure, which is based on a set of p*H* titrations, has the advantage over the earlier Calvin–Bjerrum titrations in that it can be applied even when protonated or deprotonated species are formed. With the addition developed by Sarkar and Kruck it becomes possible to determine in a solution during a p*H*-titration the simultaneous concentrations of free metal ion, free ligand, and free hydrogen ion. The method comprises a powerful tool to analyze complex formation and to assign stability constants, and deserves wider recognition.

It may be inferred from a lack of published applications that the method is either not well known or not well understood. As the writer had the opportunity to examine a pre-publication copy of the papers by Sarkar and Kruck, the occasion was taken to develop the following alternative to Osterberg's derivation of the key relationships. This method of derivation is thought to be based on more chemical and less mathematical intuition than the original, and reveals the relationships among the functions derived and applied in terms of other familiar quantities.

Titration of a Weak Acid in the Absence of Metal Ion

We consider a series of titrations of a weak v-basic acid, each differing in C_L where C_L is the total concentration of ligand in all forms. These titrations may be depicted by a set of titration curves in the form C_H $(= vC_L - C_{OH}$, with suitable allowance being made for any added mineral acid) *vs.* p*H* (C_H = concentration of total ionizable hydrogen free or bound; C_{OH} = concentration of added strong base, adjusted for dilution; pX = $-\log$ [X], thus in this context p*H* refers not to the conventional quantity but to p[H]).

We draw isohydric lines (constant p*H*) at intervals of p*H*, cutting these curves. The points of intersection are displayed as plots of C_H *vs.* C_L, and these comprise a series of straight lines,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

one for each isohydric pH. The slopes of these give $(\partial C_H/\partial C_L)_H$ for each value of pH. Since the plots of C_H *vs.* C_L are straight lines, the value of $(\partial C_H/\partial C_L)_H$ is independent of C_L. Let us inquire into the nature of this function.

We note the relationships

$$[1] \quad F = 1 + \beta_1^0[H] + \beta_2^0[H]^2 + \beta_3^0[H]^3 + \ldots$$

$$[2] \quad G = \beta_1^0[H] + 2\beta_2^0[H]^2 + 3\beta_3^0[H]^3 + \ldots$$

$$[3] \quad = dF/d \ln [H]$$

$$[4] \quad C_H = [H] - [OH] + G[L]$$

In the above, β_j^0 refers to the cumulative proton association constant for the acid species H_jL ($\beta_j^0 = [H_jL]/[H]^j[L]$).

$$[5] \quad C_L = F[L]$$
$$(\partial C_H/\partial[L])_H = G$$
$$(\partial C_L/\partial[L])_H = F$$

$$[6] \quad (\partial C_H/\partial C_L)_H = G/F = \bar{n}_H$$

where $\bar{n}_H$ is the degree of protonation of ligand L. For a particular titration, *i.e.*, fixed C_L

$$dpL = d \log F$$
$$d \log F/d \log [H] = \bar{n}_H$$
$$dpL = \bar{n}_H \, d \log [H] = -\bar{n}_H \, dpH$$

$$[7] \quad pL - pL_0 = \int_{pH}^{pH_0} \bar{n}_H \, dpH \Big|_{C_L}$$

Equation 7 specifies the relationship between two values of pL and the corresponding values of pH, and indicates that the difference in these values of pL may be expressed by and indeed determined by an integral. From purely experimental quantities, the integrand $\bar{n}_H$ may be taken as values of $(\partial C_H/\partial C_L)_H$, and the integral found as an area under a plot of the latter *vs.* pH. Such a procedure is practically unnecessary since the relationship between pL and pH is already implied by [5]. In this case $(\partial pL/\partial pH)_{C_L} = -\bar{n}_H$, which is independent of the particular value of C_L taken.

Titration of the Same Acid in the Presence of Metal Ion

We next consider a similar series of titrations of the same weak acid, but in the presence of a fixed concentration of metal C_M (C_M = concentration of metal in all forms in solution). The metal is one that reacts with L to form a series of complexes ML, ML_2 ...., which in this case is restricted to mononuclear complexes, not protonated or deprotonated.

In this case, although [4] still applies, [5] must be changed to

$$[8] \quad C_L = F[L] + \bar{n}_L C_M$$

where $\bar{n}_L$ is the degree of metal complex formation (Bjerrum). Then

$$(\partial C_H/\partial[L])_H = G$$
$$(\partial C_L/\partial[L])_H = F + C_M(\partial \bar{n}_L/\partial[L])_H$$

Hence

$$[9] \quad (\partial C_H/\partial C_L)_H = G(F + C_M(\partial \bar{n}_L/\partial[L])_H)^{-1}$$
$$= \bar{n}_H(1 + C_M F^{-1}(\partial \bar{n}_L/\partial[L])_H)^{-1}$$

We may also write

$$(\partial C_L/\partial \ln [L])_H = F[L] + C_M(\partial \bar{n}_L/\partial[L])_H[L]$$
$$(\partial C_L/\partial \ln [H])_L = G[L]$$

Since C_M is held constant C_L is a function of [H] and [L] only. The total differential dC_L may be written

$$dC_L = (\partial C_L/\partial \ln [H])_L \, d \ln [H] + (\partial C_L/\partial \ln [L])_H \, d \ln [L]$$

If we impose the further requirement that C_L is constant, $dC_L = 0$

$$[10] \quad \left(\frac{\partial \ln [L]}{\partial \ln [H]}\right)_{C_L} = \frac{-G}{F + C_M(\partial \bar{n}_L/\partial[L])_H} = -\left(\frac{\partial C_H}{\partial C_L}\right)_H$$

This is the Osterberg relationship, which may also be written

$$[11] \quad pL - pL_0 = \int_{pH}^{pH_0} \left(\frac{\partial C_H}{\partial C_L}\right)_H dpH \Big|_{C_L}$$

This is the same relationship as before, except that $(\partial C_H/\partial C_L)_H$ is no longer $\bar{n}_H$. Two features of the foregoing merit further comment and explanation. Equations 6 and 9 are identical when $C_M = 0$. Equation 9 describes the Osterberg relationship in terms of other parameters of the system of complexes.

To demonstrate the validity of these relationships we have calculated sets of titration data

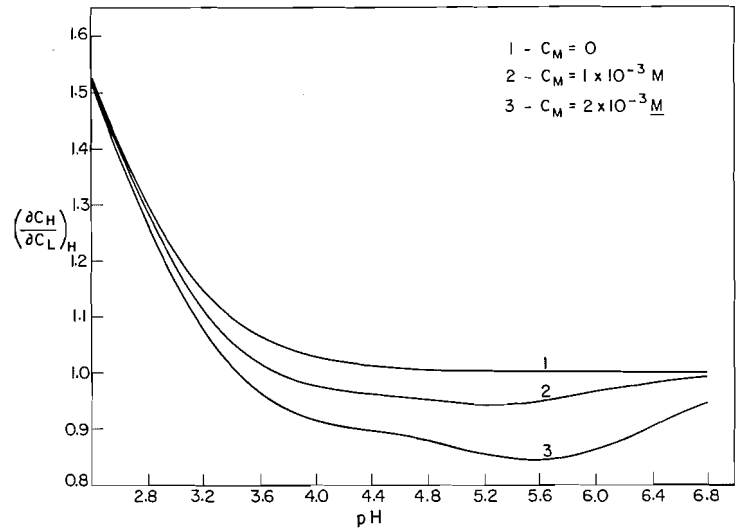

FIG. 1. Values of $(\partial C_H/\partial C_L)_H$ as a function of pH for solutions of glycine with and without copper(II) added. $C_L = 4 \times 10^{-3}$ M.

(pH, C_H) for two model systems, *viz.* copper(II)–glycine and nickel(II)–ethylenediamine, basing these calculations on published values of the appropriate equilibrium constants and selected values of C_M and C_L. We have determined $(\partial C_H/\partial C_L)_H$ in the manner previously described, for a number of pH values, and then also evaluated the function on the right-hand side of eq. 9. The values agreed to within about 1% throughout the full range of the titration data.

Figure 1 shows the calculated values of $(\partial C_H/\partial C_L)_H$ for solutions of glycine with and without copper(II) added. When metal is present the values are smaller than the corresponding values of $\bar{n}_H$ in accord with [9]. In the case of curve 2, Fig. 1, the value of the ordinate is approaching that of curve 1, which is to be expected since at pH 7 in this case $\bar{n}_L \to 2$ and $(\partial \bar{n}_L/\partial[L])_H \to 0$. Also in agreement with [9] curve 3 lies below curve 2 throughout the range shown. At still higher pH when $\bar{n}_H < 1$, all the curves will coincide.

In the absence of metal ion the plots of C_H *vs.* C_L for each chosen [H] take the form of straight lines with slope $\bar{n}_H$. In the account of Osterberg's work with copper(II) complexes of *O*-phosphorylethanolamine (2) these plots again appear as straight lines. From that paper an uncritical reader might infer that values of $(\partial C_H/\partial C_L)_H$ were independent of C_L. However, in evaluating this quantity with the aid of [9] it is apparent that values of $(\partial \bar{n}_L/\partial[L])_H$ are dependent on the value of [L] corresponding to the pH selected. And eq. 8 shows that at a particular pH, [L] depends on C_L.

The point may be illustrated in another way. Equation 11 can be used to evaluate pL once a value of pL_0 has been fixed. It is assumed that the system permits the latter to be done at a pH sufficiently low that $\bar{n}_L \to 0$, in which case $[L]_0 = C_L/[F]_0$. But [11] shows that if $(\partial C_H/\partial C_L)_H$ were independent of C_L, [L] at a particular [H] would always be directly proportional to C_L. Such a proportionality can only be approximated, as [8] shows, if $\bar{n}_L C_M$ is small compared to C_L. Hence plots of C_H *vs.* C_L will only be linear if $C_L \gg C_M$ or if $\bar{n}_L$ remains small. The latter condition will not be suitable if it is desired to study complexes of ligand number greater than unity. Figure 2 shows the curvature in plots of $(\partial C_H/\partial C_L)_H$ for the system nickel(II)–ethylenediamine. The slopes to these curved lines still conform to [9].

Analogous Relationship for Free Metal Concentration

We next consider a series of similar titrations, each differing in C_M but with fixed C_L. The quantity C_H is again plotted against pH to give titration curves, one for each value of C_M. Isohydric lines are again drawn, cutting the titration curves at fixed pH values. The points

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

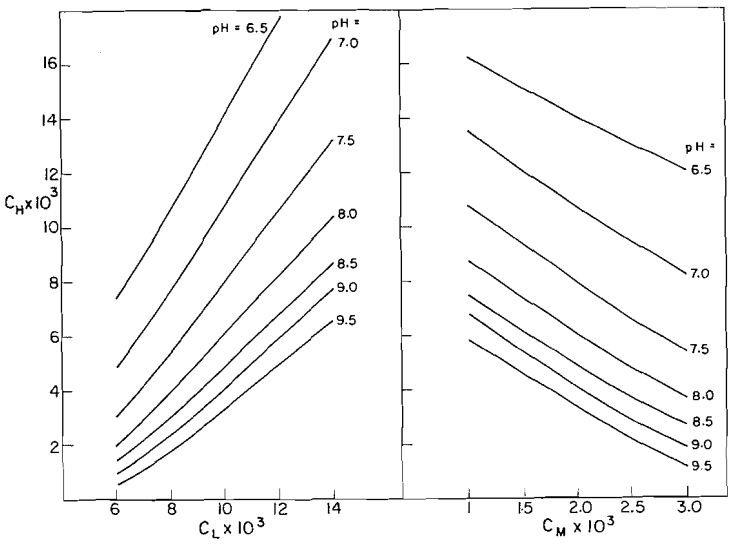

FIG. 2. Typical plots of C_H *vs.* C_L or C_M for the system nickel(II)–ethylenediamine.

of intersection are plotted as C_H *vs.* C_M, one line for each isohydric p*H*. Slopes of these lines are taken at a suitable value of C_M. These slopes comprise a function $(\partial C_H/\partial C_M)_H$ which we proceed to examine.

Equation 4 still applies, and [8] can be rearranged to give

$$C_M = (C_L - F[L])/\bar{n}_L$$

Then

$$(\partial C_H/\partial[L])_H = G$$

$$(\partial C_M/\partial[L])_H = \{-\bar{n}_L F - (C_L - F[L])(\partial\bar{n}_L/\partial[L])_H\}\bar{n}_L^{-2}$$

Whence

$$(\partial C_H/\partial C_M)_H = \frac{-\bar{n}_L^2 G}{\bar{n}_L F + (C_L - F[L])(\partial\bar{n}_L/\partial[L])_H}$$

$$= \frac{-\bar{n}_L G}{F + C_M(\partial\bar{n}_L/\partial[L])_H}$$

$$[12] \qquad = \frac{-\bar{n}_L\bar{n}_H}{1 + C_M F^{-1}(\partial\bar{n}_L/\partial[L])_H}$$

$$[12a] \qquad = -\bar{n}_L\left(\frac{\partial C_H}{\partial C_L}\right)_H$$

This derivation shows that this function can be evaluated for any particular values of C_L and [H]. The function $(\partial C_H/\partial C_L)_H$ will be known for any particular values of C_M and C_L (see above). Again values of the slopes of the plots of C_H *vs.* C_M for a selected value of C_M compared favorably with calculated values of this function for the model systems examined. Figure 3 shows the variation and interrelationship of the quantities $\bar{n}_H$, $\bar{n}_L$, and $(\partial C_H/\partial C_M)_H$ when plotted against p*H* for a solution in the system nickel(II)–ethylenediamine.

The usefulness of this function is shown in the following derivation

$$[13] \quad C_M = [M](1 + \beta_1[L] + \beta_2[L]^2 + \ldots)$$

$$(\partial C_M/\partial \ln [M])_L = C_M$$

$$(\partial C_M/\partial \ln [L])_M = [M](\beta_1[L] + 2\beta_2[L]^2 + \ldots) = \bar{n}_L C_M$$

$$[14] \quad dC_M = C_M\, d\ln [M] + \bar{n}_L\, C_M\, d\ln [L]$$

$$[15] \quad (\partial \ln [M]/\partial \ln [L])_{C_M} = -\bar{n}_L$$

At constant C_M and C_L

$$[16] \quad dpM = -\bar{n}_L\, dpL = \bar{n}_L\left(\frac{\partial C_H}{\partial C_L}\right)_H dpH$$

$$[17] \quad pM - pM_0 = \int_{pH_0}^{pH} \bar{n}_L\left(\frac{\partial C_H}{\partial C_L}\right)_H dpH = \int_{pH}^{pH_0}\left(\frac{\partial C_H}{\partial C_M}\right)_H dpH$$

The foregoing derivation of eqs. 11 and 17 is based on a system of metal complexes which is neither protonated nor deprotonated. However, it is quite simple to reach essentially the same conclusion when allowance is made for addi-

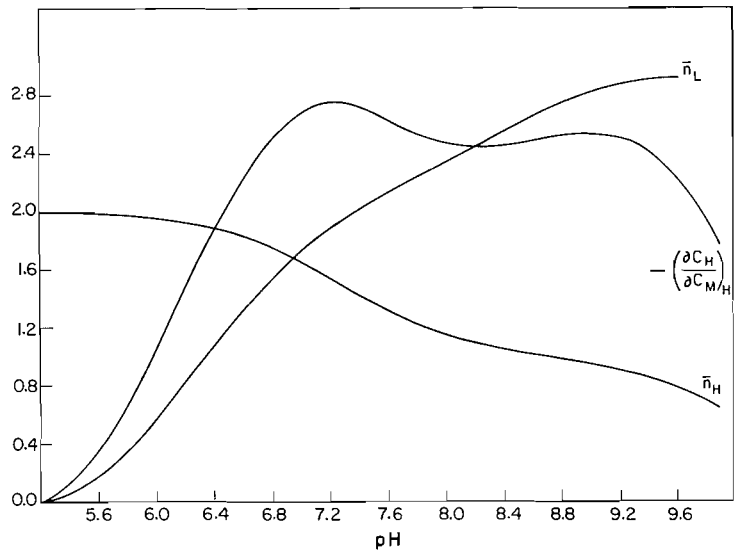

FIG. 3. Function $(\partial C_H/\partial C_M)_H$ and its relationship to $\bar{n}_H$ and $\bar{n}_L$ for the system nickel(II)–ethylenediamine.

tional complexes of this type. The only difference is that eq. 9 defining $(\partial C_H/\partial C_L)_H$ must include in the numerator a term $F^{-1}\sum_{qr}\beta_{qr}[M][H]^q[L]^{r-1}$ (where q may be a positive or negative integer) which arises from the additional complexes. It is also possible to show that these relationships still apply in the presence of a second ligand which forms mixed complexes with the metal and first ligand.

Osterberg (2) showed that $(\partial C_L/\partial \ln [H])_L = (\partial C_H/\partial \ln [L])_H$, and then a transformation previously introduced by Hedström (4) was employed to show that $(\partial \ln [L]/\partial \ln [H])_{C_L} = -(\partial C_H/\partial C_L)_H$ (*cf.* [10]). By entirely similar reasoning Osterberg's equations can be used to show that $(\partial C_M/\partial \ln [H])_M = (\partial C_H/\partial \ln [M])_H$, from which, by Hedström's transformation, one gets $(\partial \ln [M]/\partial \ln [H])_{C_M} = -(\partial C_H/\partial C_M)_H$ (*cf.* [16]). The use in this way of Hedström's transformation, which was derived strictly for a two-component system where no "competitive complex formation with any third reagent C is assumed", at first appeared to the writer as questionable. However, it is evident from [8] and [13] that once values of C_M and C_L are fixed the values of [M], [L], and [H] become interdependent. Thus for any particular value of [H], the values of [M] and [L] become invariant. Hence in evaluating the quantities $(\partial C_H/\partial C_L)_H$ or $(\partial C_H/\partial C_M)_H$ we need not be concerned with the respective variations of the third constituent [M] or [L].

Etude par Spectroscopie Infrarouge de la Solvatation Préférentielle du Cation Li^+ [1]

ANDRÉ REGIS ET JACQUES CORSET

Laboratoire de Spectrochimie Moléculaire, Université de Paris VI, 75230, Paris Cedex 05 et Laboratoire de Chimie Physique, C.N.R.S., 2, rue Henri Dunant, 94320 Thiais, France

Reçu le 20 février 1973

L'analyse des spectres de vibration de mélanges ternaires $LiClO_4$–S_1–S_2 révèle la solvatation préférentielle du cation Li^+ par l'ammoniac et les amines méthylées (S_2) dans l'acétonitrile ou le tétrahydrofuranne (S_1) et par l'acétonitrile (S_2) dans le nitrométhane (S_1). L'apparition de bandes larges dans la région des vibrations "ion-cage" est liée à la formation de différents édifices $[Li(S_1)_{n-i}(S_2)_i]^+$ dont l'évolution, en fonction du rapport $\rho = [S_2]/[LiClO_4]$, explique les déplacements de fréquence; l'énergie d'interaction ion Li^+ – molécule de solvant diminue quand le nombre de molécules S_2 de la première couche de solvatation augmente. Elle est par contre peu sensible à la constante diélectrique du milieu environnant. La variation de la composition moyenne de cette première couche de solvatation est déterminée par les mesures d'intensités des bandes d'absorption des molécules S_2 non liées au cation; dans les cas favorables ($S_2 = ND_3$, CH_3CN), le nombre de solvatation de cet ion par le solvant pur peut être estimé. Il est montré en outre que le pouvoir solvatant des bases examinées décroit dans l'ordre $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N > CH_3CN > CH_3NO_2$, en faisant intervenir à la fois les interactions donneur–accepteur et ion–dipole.

The analysis of the infrared spectra of ternary mixtures $LiClO_4$–S_1–S_2 shows a preferential solvation of the Li^+ ion by ammonia and methylamines (S_2) in acetonitrile or tetrahydrofuran (S_1) and by acetonitrile (S_2) in nitromethane (S_1). The appearance of wide bands in the "ion-cage" vibration region is related to the formation of different species $[Li(S_1)_{n-i}(S_2)_i]^+$. The variation of their relative concentration when $\rho = [S_2]/[LiClO_4]$ increases explains the frequency shift of the bands. The interaction energy Li^+ ion – solvent molecule decreases when the number of S_2 molecules in the first solvation shell increases and does not seem to depend on the dielectric constant of the surrounding medium. The mean composition of the first solvation shell is obtained from intensity measurements of absorption bands of the S_2 molecules not bonded to the ions; in favorable cases ($S_2 = ND_3$, CH_3CN) the solvation number of the Li^+ ion in the pure solvent could be estimated. The solvating power of the different bases used is shown to decrease in the order $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N > CH_3CN > CH_3NO_2$ and involves both donor–acceptor and ion–dipole interactions.

Can. J. Chem., **51**, 3577 (1973)

Introduction

La solvatation des anions X^- par l'acétonitrile (1, 2) et par différents solvants "donneurs de proton" (3–8) a pu être étudiée par spectrométrie de vibration, en milieu ternaire, dans le cas des halogénures de tétraalkylammonium dissous dans un diluant inerte, mais seule la solvatation du cation Na^+ par le tétrahydrofuranne a été analysée à l'aide du tétrabutylaluminate de sodium dans le cyclohexane (9, 10).

Pour des raisons de solubilité, l'étude des sels minéraux nécessite l'emploi de diluants plus actifs, tels que l'acétonitrile ou le nitrométhane (11–15), dont les molécules entrent en compétition avec celles du ligande dans la première couche de solvatation de l'ion. Ces mélanges ternaires comprenant deux solvants S_1 et S_2, S_2 étant plus actifs que S_1, donnent lieu à des équilibres successifs tels que

$$[M(S_1)_{n+1-i}(S_2)_{i-1}]^{z+} + S_2 \overset{K_i}{\rightleftharpoons} [M(S_1)_{n-i}(S_2)_i]^{z+} + S_1$$

n étant le nombre de solvatation de cation M^{z+} dans S_1 pur; $i \geqslant 1$. La composition de la couche de solvatation peut être différente de celle du reste de la solution s'il y a solvatation préférentielle (16, 17).

Notre étude porte sur le cation Li^+. Nous examinerons les vibrations "ion-cage" (2, 18–22) et les vibrations internes des molécules en fonction du rapport $\rho = [S_2]_{total}/[SEL]_{total}$ les mélanges de solvants étant soit l'ammoniac ou les

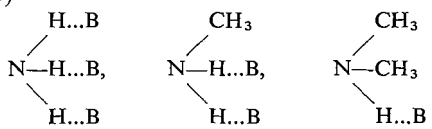
amines méthylées dans l'acétonitrile, soit l'acétonitrile dans le nitrométhane.

Résultats expérimentaux[2]

Mélanges perchlorate de lithium – ammoniac, amine-acétonitrile

Les fréquences des vibrations internes des molécules d'ammoniac et d'amines, en solution dans l'acétonitrile pur ou additionné de sel, sont rassemblées dans les tableaux 1–4.

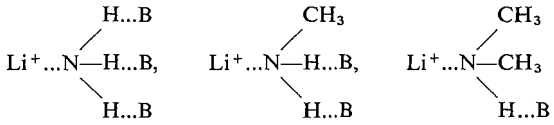
En solution diluée dans une base organique B telle que l'acétonitrile, l'ammoniac et les amines primaires et secondaires forment des complexes (5, 23)



Par suite, leurs vibrations ν(NH) subissent un abaissement de fréquence notable par rapport à celles observées en gaz, sauf pour la diméthylamine;[3] ces vibrations restent fixes en fréquence (figs. 1, 2, 9), leur intensité est proportionnelle aux concentrations (figs. 10 et 11). De même (*cf.* mêmes figures), les bandes d'absorption des vibrations de déformation restent fixes et proportionnelles aux concentrations. Nous admettrons donc que la nature des complexes ne varie pas de façon appréciable dans le domaine étudié ($C \leqslant 2\ M$).

Dans le cas de la triméthylamine, pour les bandes observées (fig. 12, tableau 4) l'intensité varie encore linéairement avec la concentration. L'imprécision des mesures due à la faible solubilité de cette amine explique sans doute la plus grande dispersion des points (fig. 11) (*cf.* cond. expérimentales).

En milieu ternaire, l'addition de faibles quantités ($\rho \sim 1$) d'ammoniac ou d'amine à une solution 0.2 *M* en $LiClO_4$ dans l'acétonitrile, provoque dans la région des vibrations internes de ces molécules l'apparition de bandes d'absorption relativement intense (figs. 1, 2 et 9) que nous attribuons aux molécules engagées dans les complexes.



L'interaction par le doublet libre de l'azote (5, 26) perturbe surtout les vibrations de déformation $\nu_2(ND_3)$, $\nu_9(CH_3NH_2)$ et $\nu_{11}(CH_3)_2NH$ (tableaux 1–3); les différences $\Delta\nu = \nu_{ternaire} - \nu_{binaire}$ sont maximales pour les faibles valeurs de ρ; ce sont celles qui ont été relevées dans les tableaux. Les figs. 1, 2, et 9 montrent qu'en outre réapparaissent les absorptions dues aux molécules liées uniquement à l'acétonitrile; elles sont cependant d'intensité moins forte (figs. 1-(2) et 1-(3)), ce qui indique l'existence d'un équilibre entre molécules liées et non liées aux ions Li^+. Pour les vibrations d'élongation ν(NH), cet équilibre ne s'observe nettement que pour la diméthylamine où bandes libres et associées sont suffisamment distinctes (fig. 2). Pour les vibrations de valence de l'ammoniac $\nu(ND)_3$ (fig. 1), il n'apparait qu'un glissement de fréquence avec un élargissement des bandes vers les hautes fréquences quand ρ augmente.

Pour la triméthylamine (fig. 12), les perturbations des bandes observées sont faibles et analogues à celles observées dans les complexes iode–amine (27).

Dans la région des vibrations "ion-cage" (figs. 1, 13, 14, 15) la bande de vibration $\nu(Li^+...N{\equiv}C{-}CH_3)$, relevée à 405 cm^{-1} dans le binaire $LiClO_4$–CH_3CN (1, 2) diminue rapidement d'intensité dès les premières additions d'ammoniac ou d'amine; simultanément apparait, à plus haute fréquence, une bande large dont le maximum se déplace et se stabilise à 545 cm^{-1} pour NH_3 (fig. 13) et 475 cm^{-1} pour ND_3 (fig. 1). La fig. 3 permet de comparer les massifs des vibrations "ion–ligande", des ammoniacates $^7LiNO_3$–$4NH_3$ et $^7LiNO_3$–$4ND_3$ (28) et les bandes observées en solution dans l'acétonitrile pour un rapport ρ = 4: ces dernières correspondent à l'enveloppe des massifs situés vers 450 (ND_3) et 520 cm^{-1} (NH_3) -limités sur la figure par un trait pointillé et attribués aux vibrations de translation cation–ammoniac (28). On peut donc conclure qu'en solution, au moins pour les valeurs élevées de ρ, les bandes sont dues essentiellement aux mouvements de translation des

[3]L'absence anormale de variation de fréquence de cette vibration s'explique peut-être par la variation d'anharmonicité de la liaison N—H, provoquée par la formation de liaison hydrogène (24); à l'état gazeux on a: $\omega_e = 3568\ cm^{-1}$; $\omega_e x_e = 93\ cm^{-1}$ (25).

molécules d'ammoniac par rapport à l'ion Li^+ dans sa première couche de solvatation.

Pour la monométhylamine, on observe le même phénomène et la bande se stabilise vers 514 cm^{-1} (fig. 14) à une fréquence voisine de celle de l'ammoniac NH_3; cette bande correspond aux mouvements de translation des ions Li^+ par rapport aux molécules d'amine, puisqu'aucune vibration interne n'est attendue dans cette région, la vibration de torsion[4] du groupement NH_2 ayant été située à l'état gazeux à 264 cm^{-1} (29).

Pour les deux autres amines (fig. 15), l'observation est rendue plus difficile par l'apparition de bandes dues probablement à un couplage des vibrations $\nu(Li^+...amine)$ et $\delta(CNC)_{amine}$ pour les molécules d'amines situées dans la première couche de solvatation, couplage déjà observé (2) pour les vibrations $\nu(Li^+...N{\equiv}C{-}CH_3)$ et δ(CCN) de l'acétonitrile; pour la triméthyl-

[4]Cette vibration, élevée en fréquence par complexation de l'amine avec le solvant, est sans doute responsable de l'absorption large dont le maximum est situé vers 350 cm^{-1}.

amine, on sait en effet que les déformations $\delta(NC_3)$ montent en fréquence par complexation avec l'iode (27) ou le bromure de magnésium (30) (tableau 4); d'autre part, on prévoit que les vibrations $\nu(Li^+...amine)$ correspondent à une bande plus basse en fréquence que celles observées pour l'ammoniac et la monométhylamine. Toutes ces observations dénotent une solvatation préférentielle du cation Li^+ par l'ammoniac ou les amines par rapport à l'acétonitrile, ce qui est en accord avec la diminution d'intensité de la vibration $\nu(CN)_{ass}$ à 2278 cm^{-1} du binaire $LiClO_4$–CH_3CN (1, 2) par addition de ND_3 (fig. 1).

Mélange perchlorate de lithium – acétonitrile – nitrométhane

Les absorptions des vibrations ν(CN) et δ(CCN) de l'acétonitrile (2) en solution dans le nitrométhane apparaissent à 2254 cm^{-1} (fig. 16) et 380 cm^{-1} (fig. 4), la première, très intense, variant proportionnellement avec la concentration. La présence de sel provoque la diminution de leur intensité et fait apparaitre deux autres absorptions, l'une à 2278 cm^{-1}, correspondant aux vibrations des molécules d'acétonitrile liées aux cations, l'autre à 401 cm^{-1} (fig. 4), due à la vibration $\nu(Li^+...N{\equiv}C{-}CH_3)$ couplée avec la déformation de l'angle CCN (2). Il y a superposition avec l'absorption large centrée à 368 cm^{-1}, attribuée aux mouvements de translation relatifs des ions Li^+ et des molécules de nitrométhane de la première couche de solvatation (31). Quand ρ augmente, la bande à 401 cm^{-1} ne varie pratiquement pas en fréquence.

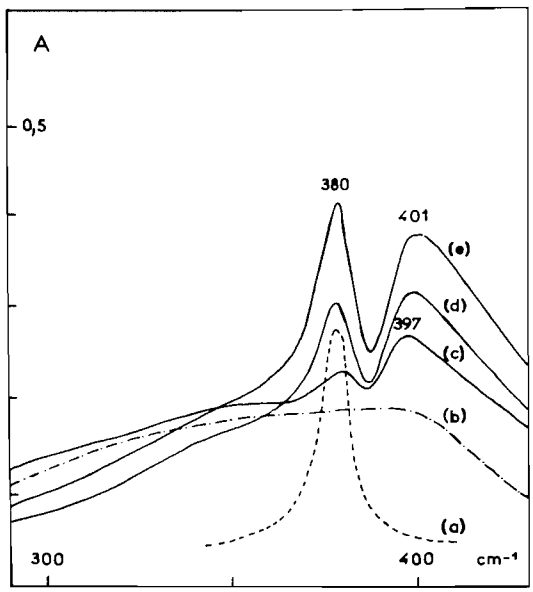

FIG. 4. Spectres dans la région des vibrations ion-cage des mélanges CH_3CN–CH_3NO_2 (---), $LiClO_4$–CH_3NO_2 (-·-) et $LiClO_4$–CH_3CN–CH_3NO_2 (—). (a) $[CH_3CN]$ = 2 *M*, (b) à (e) $[LiClO_4]$ = 0.1 *M*, $[CH_3CN]$ = (b) 0, (c) 0.37, (d) 1.5, (e) 2 *M*. *l* = 200 μ polyéthylène. Toutes les courbes sont obtenues par soustraction de l'absorption du nitrométhane.

Discussion

Déplacement de fréquence—vibration "ion-cage"

La variation de fréquence de la bande due aux vibrations ion-cage en fonction de ρ est représentée sur la fig. 5 pour quelques mélanges ternaires $LiClO_4$–NH_3–CH_3CN, $LiClO_4$–ND_3–CH_3CN et $LiClO_4$–NH_3–THF. Pour les solutions d'ammoniac dans l'acétonitrile, le maximum de la bande se déplace d'abord rapidement, puis se stabilise à 545 cm^{-1} avec NH_3 et à 475 cm^{-1} avec ND_3. Le point d'intersection des deux segments de droite autour desquels se groupent les points figuratifs expérimentaux a une abscisse voisine de ρ = 4; le déplacement progressif de la bande peut s'expliquer par l'existence de différentes espèces $[Li(CH_3CN)_{n-i}(NH_3)_i]^+$ en équilibre dans la solution; à chacun de ces édifices correspond une absorption due aux vibrations ion-cage dont la fréquence est d'autant plus basse que le nombre de molécules

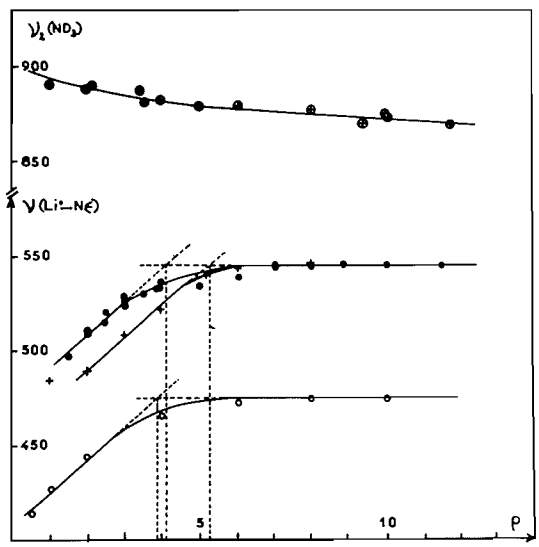

FIG. 5. Déplacement des bandes $\nu_2(ND_3)$, $\nu(Li^+...NH_3)$ et $\nu(Li^+...ND_3)$ en fonction de ρ dans les mélanges ternaires. (●) $LiClO_4$–NH_3–CH_3CN, (+) $LiClO_4$–NH_3–THF, (○ et ●) $LiClO_4$–ND_3–CH_3CN.

d'acétonitrile, plus lourdes et moins basiques que celles de l'ammoniac, est plus grand. L'absorption large et disymétrique observée serait l'enveloppe de ces différentes bandes. Son déplacement en fréquence serait relié à la variation d'intensité relative des différentes absorptions qui la composent.

Pour le mélange $LiClO_4$–NH_3–THF, c'est à la même fréquence que se stabilise la bande pour des valeurs ρ élevées, mais les deux segments de droite se coupent pour une valeur de ρ voisine de cinq. Le tétrahydrofuranne, plus basique que l'acétonitrile, forme des liaisons "hydrogène" plus fortes avec l'ammoniac et solvate mieux l'ion Li^+; par suite, la compétition des interactions ammoniac–solvant et ammoniac–cation se traduirait par des constantes successives de formation K_1, $K_2 ... K_i$, différentes dans le tétrahydrofuranne et dans l'acétonitrile; cet exemple montre que le nombre déterminé par cette méthode $\nu = f(\rho)$ peut n'être pas significatif de la composition de la première couche de solvatation de l'ion.[5]

Néanmoins, la fréquence limite 545 cm^{-1} étant la même avec le tétrahydrofuranne et l'acétonitrile, on peut penser que pour les valeurs élevées de ρ, la bande observée correspond aux édifices $[Li(NH_3)_4]_{S_1}^+$ où S_1 représente l'acétonitrile ou le tétrahydrofuranne. On constate que la fréquence de vibration ion-cage d'un tel édifice dépend peu de la constante diélectrique du milieu environnant (7.4 pour THF et 36.2 pour CH_3CN); il est d'ailleurs peu probable qu'une constante diélectrique macroscopique ait une signification au niveau du calcul des interactions cation–solvant.

Dans le cas des mélanges $LiClO_4$–CH_3NH_2–CH_3CN, les fréquences des vibrations ion-cage sont relevées sur le graphique de la fig. 6; il n'est plus possible de discerner deux segments de droite. Ce fait est prévisible: on attend des écarts de fréquence plus faibles entre les différents solvates formés et d'autre part, les constantes d'équilibre sont probablement différentes. Il semble donc qu'en plus des restrictions apportées plus haut pour les di- et triméthylamines, ces déplacements de fréquence $\nu = f(\rho)$ ne soient exploitables que si les vibrations ion-cage correspondant aux deux solvants S_I et S_2 sont suffisamment espacées en fréquences.

[5]Wuepper et Popov (12) ont utilisé cette méthode pour des mélanges $LiClO_4$–1-méthyl-2-pyrrolidone-dioxanne.

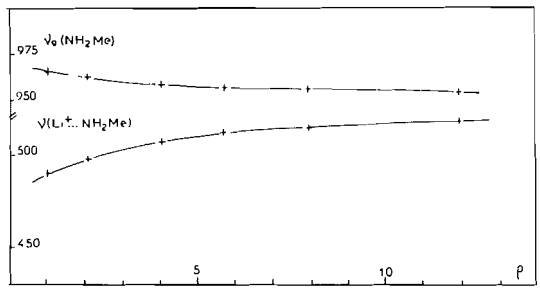

FIG. 6. Déplacement des bandes $\nu_9(NH_2Me)$ et $\nu(Li^+...NH_2Me)$ en fonction de ρ dans les mélanges ternaires $LiClO_4$–NH_2Me–CH_3CN.

Vibrations internes des molécules solvatantes

Pour les vibrations fortement perturbées lors de l'association avec le cation Li^+, telles que les bandes $\nu_2(ND_3)$ et $\nu_9(CH_3NH_2)$ la fréquence de la bande associée varie avec ρ (figs. 5 et 6). En effet si l'on remplace des molécules d'acétonitrile de la première couche de solvatation de l'ion par des molécules d'ammoniac ou d'amines ayant une charge disponible sur l'atome d'azote plus élevée que les molécules d'acétonitrile, l'interaction est maximum pour la première molécule d'ammoniac ou d'amine, et décroit ensuite au fur et à mesure de la substitution des autres molécules d'acétonitrile. Cette interprétation est tout à fait cohérente avec les variations d'enthalpie (32) $\Delta H_{(n-1),n}$ mesurées par spectrométrie de masse pour différents ions à l'état gazeux pour les réactions

$$M^+(S)_{n-1} + S \rightleftharpoons M^+(S)_n$$

n représentant le nombre de molécules de solvant liées au cation.

Quand n augmente, les valeurs de $\Delta H_{(n-1),n}$ diminuent d'autant plus que le cation est moins gros. On sait en effet que la perturbation de la vibration de déformation ν_2 de l'ammoniac lié aux différents cations alcalins ou alcalino-terreux est plus marquée si le cation est petit et chargé (26).

Les perturbations de fréquence des vibrations de valence ν(NH) sont moins importantes (tableaux 1–3): elles augmentent dans l'ordre: ammoniac, monométhylamine, diméthylamine; les écarts moyens étant respectivement de 10, 24 et 37 cm^{-1}. Cette sensibilité accrue des vibrateurs NH à l'interaction avec la paire libre de l'atome d'azote peut être reliée à l'accroissement du pouvoir donneur de proton caractérisé par la valeur des constantes de force de liaison

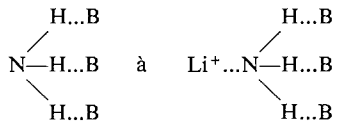
For personal use only.

K(N—H) mesurées à l'état gazeux (6.4 (33), 6.29 et 5.9 (34) pour l'ammoniac, la monométhylamine et la diméthylamine). Dans le cas de l'ammoniac, la perturbation de fréquence des vibrations de valence, quand on passe du complexe



augmente lorsque le tétrahydrofuranne remplace l'acétonitrile (tableau 1). Ce fait s'explique par un effet coopératif déjà signalé à propos de l'ammoniac (26) et de l'eau (13).

Variation d'intensité

Nombre de solvatation

Différentes méthodes de calcul permettent de relier les grandeurs mesurées expérimentalement à la concentration de chaque édifice formé et aux constantes d'équilibre K_i (35, 36). Celle de Bjerrum introduit le nombre moyen $\bar{n}$ caractérisant la composition moyenne de la première couche de solvatation

$$\bar{n} = \frac{\sum [M(S_1)_{n-i}(S_2)_i]^{z+} \times i}{\sum [M(S_1)_{n-i+1}(S_2)_{i-1}]^{z+}} = \frac{[S_2]_{liée} - [S_2]_{libre}}{[Sel]_{total}}$$

Les diminutions d'intensité des bandes correspondant aux vibrations internes des molécules S_2 en interaction avec les molécules S_1 lors de l'addition de sel à un mélange S_2–S_1 permettent de calculer ce nombre moyen. Pour éviter les corrections dues au recouvrement des bandes rendues difficiles par le déplacement en fréquence des bandes associées, nous avons utilisé les vibrations les plus perturbées par le cation. Cependant le peu de précision ne permet pas d'atteindre des valeurs significatives pour les constantes K_i (35–39). C'est pourquoi nous avons préféré suivre l'évolution de $\bar{n}$ en fonction de ρ (figs. 7 et 8). Cette évolution est nette pour les mélanges NH_3–CH_3CN et CH_3CN–CH_3NO_2 bien qu'il ne soit pas possible d'attribuer un sens aux détails des courbes tracées (figs. 7 et 8); cependant, ces courbes tendent vers la valeur 4; valeur généralement attendue pour le nombre de solvatation de l'ion Li^+ dans l'ammoniac liquide (28, 40) ou dans l'acétonitrile pur (2). Ces courbes ne dépendent pas de la concentration en sel, ce qui indique que le perchlorate de lithium est totalement dissocié en ions solvatés dans ces solvants de constante diélectrique relativement élevée ($D_{CH_3CN} = 38$, $D_{CH_3NO_2} = 35.9$), ce qui n'est pas le cas pour les mélanges cyclohexane–tétrahydrofuranne (9, 10).

Pour la diméthylamine, les valeurs de $\bar{n}$ calculées à partir de la vibration ν_1 à 3349 cm^{-1} sont inférieures à celles obtenues à partir de la bande ν_{11} à 792 cm^{-1} pour laquelle nous n'avons pas tenu compte du recouvrement avec sa bande associée (fig. 2). Pour la triméthylamine la vibration r (CH_3) à 1185 cm^{-1}, la plus perturbée est beaucoup moins sensible à la complexation par le cation; il en découle une incertitude sur $\bar{n}$ d'autant plus grande que la courbe d'étalonnage est moins précise (voir conditions expérimentales).

A notre connaissance, deux essais de détermination de n par spectroscopie de vibration ont été effectués avant les nôtres. Wuepper et Popov ont étudié des mélanges $LiClO_4$–CH_3COCH_3–CH_3NO_2 et utilisé la variation d'intensité de la

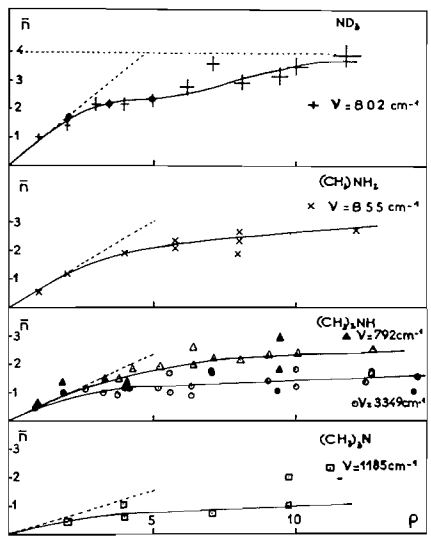


FIG. 7. Nombre de solvatation moyen $\bar{n}$ en fonction de ρ = [Amine]/[$LiClO_4$] en solution dans l'acétonitrile. Les fréquences des bandes utilisées pour les mesures sont indiquées sur les courbes. Les croix, ronds, triangles et carrés clairs indiquent que les mesures ont été effectuées à [$LiClO_4$] = 0.2 M. Les ronds ou triangles foncés indiquent que les mesures ont été effectuées à concentration constante en ammoniac ou amine: [ND_3] = 0.97 M, [CH_3NH_2] = 1.3 M. Pour l'ammoniac ND_3, les dimensions des croix indiquent la précision des points. Une courbe moyenne a été tracée à titre indicatif pour chacun des composés.

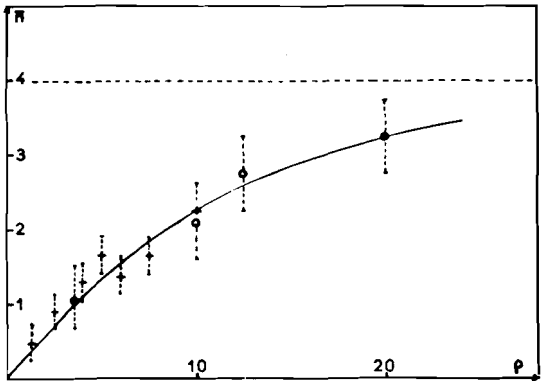

FIG. 8. Nombres moyens de solvatation $\bar{n}$ en fonction de $\rho = [CH_3CN]/[LiClO_4]$ en solution dans le nitrométhane. (+) $[LiClO_4] = 0.2\ M$, (○) $[LiClO_4] = 0.1\ M$. La précision des points est indiquée par un trait pointillé.

bande ion-cage à 425 cm^{-1} (14). Ils ont cru pouvoir mettre en évidence l'apparition de nouvelles espèces. Si l'on trace la courbe "absorption de la bande à 425 cm^{-1}" en fonction de la concentration en sel, la concentration de l'acétone demeurant constante, on observe en effet pour $\rho = 4$ une variation de pente. Mais cette bande étant complexe et englobant l'absorption large due à la solvatation des ions Li^+ par le nitrométhane (31) aucune indication précise ne peut être espérée. Rouvière et coll. (15), pour des mélanges ternaires $LiClO_4$–C_5H_5N–CH_3NO_2, ont utilisé des bandes de vibration interne de la pyridine libre et associée au sel. Le coefficient d'extinction et la fréquence au maximum de la bande associée peuvent varier avec la nature des divers ions complexes formés $[Li(CH_3NO_2)_{n-i}(C_5H_5N)_i]^+$. En outre, dans l'hypothèse où ils seraient les mêmes, la courbe A_{ass} ou $A_{lib} = f(C_{sel})$ renseignerait seulement sur la variation du nombre moyen de solvatation $\bar{n}$, qui ne peut être interprétée de façon simple.

Comparaison du pouvoir solvatant des amines

Malgré l'imprécision des mesures, les courbes de la fig. 7 permettent de comparer valablement les pentes à l'origine. Celles-ci sont respectivement de 0.8; 0.6; 0.45 et 0.30 pour ND_3, CH_3NH_2, $(CH_3)_2NH$, et $(CH_3)_3N$. On constate d'ailleurs que pour une même valeur de ρ les nombres $\bar{n}$ varient dans le même ordre. Ces différences traduisent une décroissance du pouvoir solvatant quand on passe de l'ammoniac aux mono-, di- et triméthylamines.

La comparaison du seul pouvoir donneur d'électron de ces bases, caractérisé soit par leur p*K* (41), soit par l'abaissement de fréquence Δν(OH) du phénol dans les complexes formés avec ces bases, soit par les variations d'enthalpie $\Delta H_{A\ldots D}$ de réaction avec un accepteur d'électrons tel que I_2 ou $B(CH_3)_3$ ou par leur potentiel d'ionisation (*cf.* tableau 3, réf. 42), soit par leur nombre donneur de Guttman (43), ne permet pas d'expliquer un tel comportement. La comparaison de leur moment dipolaire, qui varie de 1.46 à 0.67 D (44) quand on passe de l'ammoniac à la triméthylamine semble par contre indiquer une importante contribution de l'interaction ion-dipole à l'énergie libre de solvatation.

Conditions expérimentales

Produits utilisés—origine et purification

Le perchlorate de lithium $^7LiClO_4$ est un produit K & K Laboratories (anhydre à 99%) que nous avons soumis à un chauffage lent sous vide avant utilisation.

L'acétonitrile (Spectro Prolabo), le tétrahydrofuranne (99% Carlo Erba) et le nitrométhane (Spectro Eastman Kodak) ont été séchés sur tamis moléculaire 4 Å; le nitrométhane contient des traces d'éthylnitrile que nous avons caractérisé par la bande ν(C≡N) à 2252 cm^{-1} (45) et par l'étude du spectre de masse de fragmentation à 70 eV; les points d'ébullition très voisins CH_3NO_2 (101 °C) et CH_3CH_2CN (97.1 °C) n'ont pas permis une purification par distillation. Nous avons vérifié cependant que la concentration de cette impureté était toujours inférieure à 0.05 *M*.

L'ammoniac (Air Liquide) a été purifié par séchage sur sodium puis distillé. L'ammoniac à taux de deutérium supérieur à 98% a été préparé par décomposition du nitrure de magnésium par l'eau lourde (46) puis séché sur sodium.

Les amines CH_3NH_2 et $(CH_3)_2NH$ ont été préparées à partir de leur chlorhydrate, la triméthylamine est un produit Matheson débarassé de traces de monométhylamine par passage sur tamis moléculaire; elles ont toutes été séchées sur sodium et distillées. Leur pureté a été contrôlée par spectroscopie infrarouge.

Préparation des solutions d'ammoniac ou d'amines dans les solvants purs ou contenant un sel. Calcul des concentrations

Pour préparer ces solutions, nous avons piégé à la température de l'azote liquide, une masse connue de gaz dans un volume *V* (5 ou 10 cm^3) de solvant pur ou contenant un sel, préalablement gelé sous vide à cette même température. L'ensemble contenu dans un ballon de 100 cm^3 est progressivement réchauffé jusqu'à la température ambiante, en agitant fortement pour obtenir une dissolution aussi complète que possible du gaz; ce ballon est ouvert en boîte sèche au moment du remplissage des cellules.

Ce mode de préparation doit faire intervenir, dans le calcul des concentrations, l'augmentation de volume Δ*v* du mélange provoquée par la dissolution d'une masse *m* de gaz; ce volume Δ*v* n'étant pas négligeable surtout aux fortes concentrations, celles-ci ont toutes été corrigées en calculant Δ*v* à partir de la densité (*d*) des amines liquides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$\Delta v = \frac{m}{d},\ C_{\text{amine}} = \frac{m/M}{V + m/d} \times 1000\,(M),$$

$$C_{\text{sel}} = \frac{C_0 V}{V + m/d}\,(M)$$

C_0 étant la concentration de la solution de sel avant piégeage du gaz. Au cours d'une série d'expériences réalisées à partir d'une même solution binaire de concentration C_0, la concentration est dite "constante".

La régularité des droites d'étalonnage absorbance = f (concentration) pour les solutions de NH_3, ND_3, CH_3NH_2, et $(CH_3)_2NH$ dans l'acétonitrile prouve que la dissolution des quantités piégées est complète. Cette grande solubilité est due à la formation de liaison hydrogène entre ces molécules et le solvant. Par contre, la plus grande dispersion des points de la droite d'étalonnage obtenue avec la triméthylamine peut provenir d'une dissolution incomplète.

La teneur en eau de tous les solvants et des solutions binaires ou ternaires a été contrôlée par une mesure d'absorption dans la région des vibrations de valence $\nu(OH)_{H_2O}$ sous une épaisseur de 615 μ. Dans le cas de l'utilisation de l'ammoniac ND_3, il a été vérifié de plus, à partir de la vibration ν (NH) des molécules ND_2H, que la quantité de ces molécules qui auraient pu se former en présence de traces d'eau (H_2O) est négligeable. On peut cependant noter (fig. 1) que dans les mélanges ternaires, il s'est formé une faible quantité de ND_2H décelable à partir de la vibration $\nu_4'(ND_2H)$ à 1249 cm^{-1}.

La présence de telles impuretés (H_2O, ND_2H, CH_3CH_2CN) peut conduire à une surestimation de la valeur de $\bar{n}$; en effet, si l'on admet que l'impureté se solvate comme le ligande (ND_2H pour NH_3, CH_3CH_2CN pour CH_3CN) on peut montrer que la valeur mesurée $\bar{n}_{exp}$ est reliée à la valeur réelle n_r par la relation approchée

$$\bar{n}_{\text{exp}} \simeq \bar{n}_r\left(1 + \frac{x}{2C_0}\right)$$

où x est la concentration en impureté et C_0 la concentration en sel.

Enregistrement des spectres

Les spectres sont obtenus avec des cellules à liquide d'épaisseur fixe munies de fenêtres en bromure de potassium (région au dessus de 350 cm^{-1}), en fluorure de calcium (au dessus de 1000 cm^{-1}) et en polyéthylène pour l'étude des solutions dans le nitrométhane, entre 250 et 500 cm^{-1}. Ils ont été enregistrés sur un spectromètre Beckman IR 12, à la température ambiante. La précision des fréquences est de ±1 cm^{-1} pour les bandes fines. Les fréquences estimées pour les épaules sont indiquées entre parenthèses sur les tableaux.

Nous remercions Mademoiselle M. L. Josien, Professeur à l'Université de Paris VI, de l'intérêt qu'elle a porté à ce travail et pour ses conseils lors de la rédaction de ce manuscrit.

The Specific Activity of Silica Supported Platinum for the Catalysis of Hydrogen–Methane Deuterium Exchange[1,2]

NORMAN HENRY SAGERT AND RITA MARY LOUISE POUTEAU

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba R0E 1L0

Received March 15, 1973

Rate data are reported as a function of temperature for the exchange of D_2 with CH_4 over a number of platinum–silica catalysts. Two different methods of preparing catalysts, impregnation and ion exchange, were used to get two series of metal particle sizes. Within each series, the particle size was increased by sintering batches in air at temperatures to 800 °C. These methods produced platinum particles ranging from 0.9 to 10 nm diameter. The metal surface areas were measured by hydrogen chemisorption and, where possible, by X-ray diffraction and electron microscopy.

The specific rate coefficients or rate coefficients per unit surface area of platinum varied by a factor of up to 40 within each series and reached a maximum for sintering temperatures of about 500 °C. The maximum specific rate coefficients for CH_4 conversion at 200 °C, and total pressure of 60 kN m^{-2}, were 1.3 and 1.9 × 10^{-6} mol CH_4 m^{-2} s^{-1} for the ion-exchanged and impregnated catalysts respectively. Activation energies were in the range 60 to 100 kJ mol^{-1}. Since a relatively small change in specific rate coefficient was noted between the two series as compared to the changes within each series, no large effect of particle size on the specific rate coefficient was demonstrated. The different specific rate coefficients within the series are ascribed to other effects of sintering, particularly the formation of the lower energy Pt(111) surface. Some evidence was noted for a particle size effect in the distribution of products, with more multiple exchange being observed for the smallest particles.

Les données de vitesse en fonction de la température pour l'échange de D_2 avec CH_4 sur un certain nombre de catalyseurs platine–silice ont été rapportées. Deux méthodes différentes de préparation des catalyseurs (par imprégnation et par échange ionique) ont été utilisées pour obtenir deux types de tailles pour les particules métalliques. Dans chaque type, les dimensions des particules ont été accrues par une opération de frittage dans l'air à des températures allant jusqu'à 800 °C. Ces méthodes conduisent à l'obtention des particules de platine de 0.9 à 10 nm de diamètre. Les aires des surfaces métalliques ont été mesurées par chimisorption de l'hydrogène et par diffraction des rayons X et microscopie électronique quand c'était possible.

Les coefficients de vitesse spécifique ou coefficients de vitesse par unité de surface de platine, varient d'un facteur de 40 à l'intérieur de chaque série et atteignent un maximum pour des températures de frittage d'environ 500 °C. Les coefficients de vitesse spécifique maximale pour la conversion de CH_4 à 200 °C et sous une pression totale de 60 kN m^{-2} ont été de 1.3 et 1.9 × 10^{-6} mol CH_4 m^{-2} s^{-1} pour les catalyseurs obtenus par échange ionique et imprégnation respectivement. Les énergies d'activation varient de 60 à 100 kJ mol^{-1}. Bien qu'un changement relativement faible dans le coefficient de vitesse spécifique ait été noté entre les deux séries comparé aux changements à l'intérieur de chaque série. il n'a pas été possible de démontrer d'effet notable des dimensions des particules sur le coefficient de vitesse spécifique. Les différences dans les coefficients de vitesse spécifique à l'intérieur des séries ont été imputées aux autres effets du frittage, en particulier la formation de surface de Pt(111) de plus basse énergie. Un effet de la taille des particules sur la distribution des produits a été mis en évidence, un échange plus fréquent étant observé pour les particules les plus petites. [Traduit par le journal]

Can. J. Chem., **51**, 3588 (1973)

Introduction

Following a previous study (1) in which we found the specific rate (rate per unit surface area) of the H_2–HDO exchange reaction over silica supported platinum to be essentially independent of particle size, we have examined the D_2–CH_4 exchange over a similar series of supported platinum catalysts. For this geometrically simple exchange reaction, one would not expect any geometric effects on the specific rate in the sense described by Bond (2), Anderson and coworkers (3–5), and Boudart *et al.* (6). However, an electronic effect may exist since, as the size of the particles decreases, the electronic properties of these particles must change from those of bulk metal to those of single atoms (7, 8). Such an

electronic effect might be more likely with a reaction having a large activation energy than for the H_2–HDO exchange which only has an activation energy of around 40 kJ mol^{-1} (1).

We have examined the D_2–CH_4 exchange over catalysts produced by two common methods for catalyst preparation, impregnation with H_2PtCl_6, and exchange with $Pt(NH_3)_4(OH)_2$, followed by different degrees of sintering to see if activity was more readily correlated with the actual size of the platinum particle, or with the sintering temperature (9).

The mechanism of the methane–deuterium exchange is reasonably well established from the studies of Kemball (10–12) on metal films. Recently Cece and Gonzales (13) noted changes in apparent activation energies for methane–deuterium exchange over supported nickel as a function of particle size.

Experimental

Materials

Reagents

C.P. Grade deuterium (99.5%) was purified by diffusion through a hot palladium–silver thimble. The methane was Research Grade (99.99%). It was admitted to the system through a stainless steel regulator, and was degassed by the freeze–pump–thaw technique at solid nitrogen temperature. Then it was distilled into the storage reservoir, and the final portion was rejected. Standards for the deuterated methanes were obtained commercially.

Catalysts

The preparation of the silica supported catalysts has been described previously (1). For this work, platinum on silica catalysts were prepared by H_2PtCl_6 impregnation and by $Pt(NH_3)_4(OH)_2$ ion exchange. Portions of these catalysts were sintered for 5 h in air at various temperatures to promote crystallite growth. Most catalysts contained 5% (w/w) platinum.

Kinetic Studies

Exchange rates were measured in the Pyrex and Teflon recirculation reactor shown in Fig. 1. The total volume was 8.55×10^{-4} m^3, with about 75% of this volume in the two bulbs and the pump. The pump was a double-acting Teflon-in-glass magnetically actuated pump similar to that described by Chambers *et al.* (14) except that an electronic switching circuit was used. It could circulate up to 7×10^{-5} m^3 s^{-1}, but was usually run at about half speed. The sampling system was arranged so that 10^{-6} m^3 samples could be taken and expanded into pre-evacuated tubes. These sampling tubes contained a small quantity of P_2O_5, added as a precaution against moisture, since the sample tubes were only pumped out during the time between analyses.

Usually about 3×10^{-3} kg of the platinum on silica catalyst were weighed into the reactor and the system evacuated. The catalyst temperature was raised to 150 °C and evacuation continued until about 7×10^{-4} N m^{-2} was obtained. Then trap T was immersed in liquid nitrogen and about 40 kN m^{-2} of D_2 was circulated around the system while the temperature was raised to 300 °C. After 2 h the system was pumped out, and the trap warmed to remove the water which had desorbed from the catalyst. This was a standard pre-treatment.

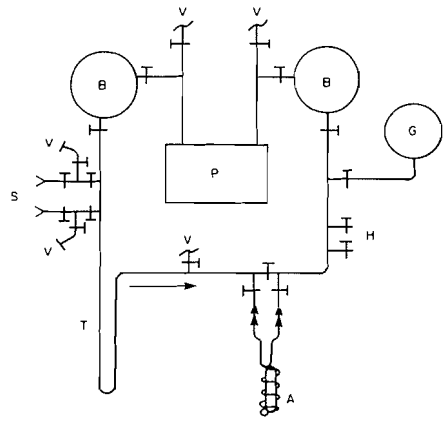

FIG. 1. Schematic diagram of the recirculating system: A, the reactor; B, 2.10×10^{-4} m^3 bulbs; G, pressure gauge; H, to gas purification; P, pump; S, sampling points; T, trap; V, to vacuum.

Before every run the catalyst was reduced at 300 °C for 2 h in 40 kN m^{-2} D_2 and was then evacuated while cooling to the reaction temperature. The catalyst was isolated and D_2 and CH_4 were measured into calibrated portions of the circulating system. Generally a total pressure of 60 kN m^{-2} was used with $D_2/CH_4 = 2$. The circulating system was isolated and gas was circulated for 20 min in order to mix thoroughly. Then, at time zero, the gas flow was diverted through the catalyst and samples were taken at convenient intervals. Analyses were performed on a Consolidated 21-130 mass spectrometer, with H_2, HD, D_2, and isotopic methanes being determined. Spectra were processed by a Varian Data Processing Computer 620i which calculated the gas composition from stored corrected cracking patterns of the standards. The cracking patterns of the standards were additive to within experimental error (±0.1%) showing that there was no exchange among the methanes themselves in the mass spectrometer. Also no exchange was noted between D_2 and CH_4 in the mass spectrometer to within our experimental error (±0.1%), so that deuterium transfer between the "hydrogen" and methane does not occur to a significant extent in our instrument.

Surface Areas and Particle Size Measurements

Surface areas were measured by hydrogen chemisorption at 27 °C and, for most of the impregnated catalysts, by X-ray diffraction and by electron microscopy as previously described (1). For the ion-exchanged catalysts, the particles were too small to be measured by our X-ray diffraction and electron microscopy techniques.

Results

Rate coefficients for the exchange reactions were calculated from the rates of formation of the deuterated methanes using the first order equations given by Kemball (15). If a deuterium concentration parameter, ϕ, is defined such that

$$[1] \qquad \phi \equiv \sum_i [CH_{4-i}D_i]i$$

with concentrations in mol %, then

$$[2] \qquad \frac{d\phi}{dt} = k_\phi\left(1 - \frac{\phi}{\phi_\infty}\right)$$

if isotope effects are neglected. Here k_ϕ is a rate coefficient equivalent to the number of deuterium atoms entering 100 molecules of methane in unit time, and ϕ_∞ is ϕ at infinite time. On integrating

$$[3] \quad -\log_{10}(\phi_\infty - \phi) = \frac{k_\phi t}{2.303\phi_\infty} - \log_{10}(\phi_\infty - \phi_0)$$

A second similar equation represents the conversion of CH_4:

$$[4] \quad -\log_{10}(X - X_\infty) = \frac{k_x t}{2.303(100 - X_\infty)} - \log_{10}(100 - X_\infty)$$

where X is the percent of CH_4. The ratio M, defined as k_ϕ/k_x, gives the initial average number of hydrogen atoms replaced by deuterium atoms in each methane molecule.

A plot of the results of a typical run according to eqs. 3 and 4 is given in Fig. 2. The equations

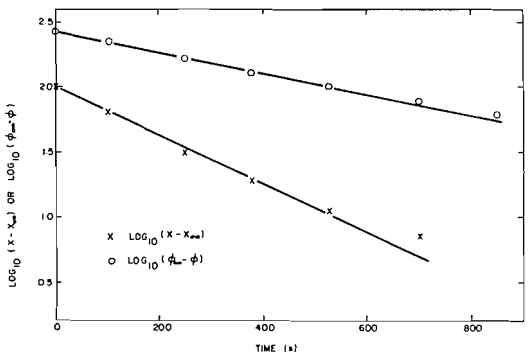

FIG. 2. Logarithmic plots of the conversion of CH_4, and uptake of deuterium as a function of time. Impregnated catalyst sintered at 500 °C. Catalyst temperature 215 °C, CH_4/D_2 = 1/3.6.

fit the data in the initial stages of the reaction, so that k_ϕ,k_x, and M can be determined. Deviations appear at higher conversions. The course of the reaction could be predicted over a longer period using equations developed by Mikovsky and Wei (16). However in this work the simple equations above were adequate.

Values of X_∞ and ϕ_∞ were obtained experimentally at high temperatures, and at lower temperatures ϕ_∞ was calculated from the hydrogen–methane deuterium separation factors given by Varshavskii and Vaisberg (17). Calculated values agreed satisfactorily with experimental values where comparison was possible. X_∞ was calculated using equations described by Apse and Missen (18) which were solved numerically. Calculated X_∞ values also agreed with the experimental values where comparison was possible. Actually, provided the slopes to eqs. 3 and 4 used to evaluate k_x and k_ϕ were taken at short times, the corrections to values of ϕ_∞ and X_∞ used were not critical. Thus between 140 °C and 300 °C the calculated values of ϕ_∞ fell from 230 to 217 compared to the statistical value at infinite temperature of 200. The experimental values were within ± 5 of the calculated values. Similarly between 140 °C and 300 °C the calculated values of X_∞ rose from 2.3 to 4.7 compared to 6.2 at infinite temperature. Experimental values were within ± 0.5.

Reaction parameters should not be affected by pore diffusion. The highest conceivable rate for methane conversion compatible with the speed of the recirculating pump was about $0.2\%\ s^{-1}$. This rate, together with appropriate values of surface area, porosity, and tortuosity factors of the gel (18), led to an estimated value $\Phi_s = 0.1$ for the pore diffusion parameter at the maximum rate (19). This corresponds to an efficiency factor of essentially 1.0 for a thermoneutral reaction with an activation energy of about 80 kJ mol^{-1}.

Typical hydrogen chemisorption isotherms are shown in Fig. 3 for catalysts prepared from H_2PtCl_6 and sintered at various temperatures. The linear portions of these isotherms were extrapolated to low pressure, and the intercepts on the zero pressure axis were taken as the volumes of chemisorbed hydrogen. Surface areas were calculated from these volumes by assuming that the adsorption site for a hydrogen atom covers 8.9×10^{-20} m^2. Particle sizes were then calculated from a knowledge of the surface area

TABLE 1. Particle diameters for H_2PtCl_6 impregnated catalysts

Sintering temperature (°C)	Particle diameter (nm)			
	Hydrogen adsorption (sphere model)	Electron microscopy		X-ray
		$\Sigma n_i d_i^3/\Sigma n_i d_i^2$	$\Sigma n_i d_i^4/\Sigma n_i d_i^3$	
None	2.75	—	—	5.5
300	2.88	3.62	4.08	4.8
400	2.92	4.35	4.90	5.46
500	3.95	5.46	6.26	5.64
600	8.58	7.58	8.82	7.42
700	9.78	7.89	8.95	8.6
800	9.40	9.57	10.94	9.0

and the platinum concentration, assuming the particles to be spherical in shape. Table 1 gives the particle sizes so calculated for the impregnated catalysts, and compares these with sizes obtained from electron microscopic examination, and from X-ray diffraction data using the Debeye–Scherrer line broadening technique. The hydrogen chemisorption gives a surface averaged size, $\Sigma_i n_i d_i^3/\Sigma_i n_i d_i^2$, and the X-ray diffraction gives a volume averaged size, $\Sigma_i n_i d_i^4/\Sigma_i n_i d_i^3$, where n_i and d_i are the number and size of the i'th sized particle. Agreement between these methods is not as good as with the 1% catalysts examined previously (1), although it is still satisfactory. The difference between the two averages is relatively small, indicating a reasonably narrow distribution of particle sizes.

The data in Table 1 imply that the particles are stable in air at temperatures up to 400 °C. At higher temperatures some particles grow by diffusion while the smallest particles disappear. It would appear that at about 700 °C, all the smaller particles have disappeared and a quasi-equilibrium is set up where no particles grow in size at the expense of others. A similar phenomenon was noted by Stolyarenko and Vasev (20) for platinum blacks sintered in air.

From a knowledge of the number of moles of methane and the surface areas of the catalysts, specific rate coefficients (k_x^1 or k_ϕ^1) can be calculated in mol CH_4 (or mol D) m^{-2} s^{-1}. Figure 4 shows k_x^1 data obtained from the impregnated catalysts plotted as a function of temperature in

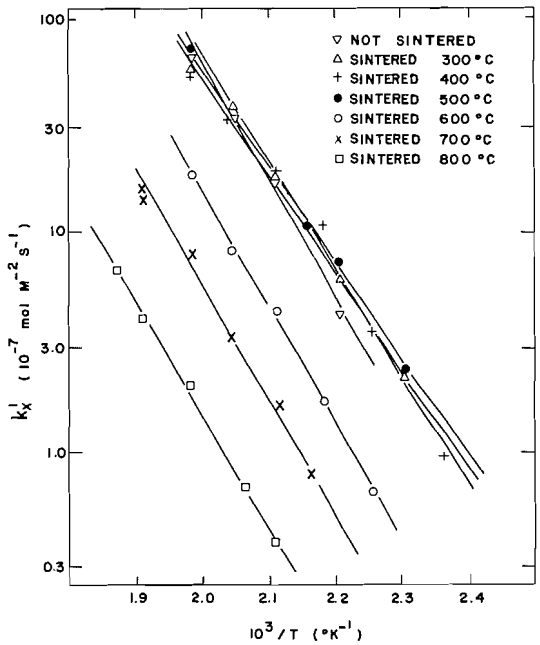

FIG. 4. Specific rates for CH_4 conversion over impregnated catalysts sintered at indicated temperatures. Rates are plotted in the Arrhenius form.

the Arrhenius form. The activation energies E_x are reasonably constant at 91 ± 12 kJ mol^{-1}. For the same series of catalysts the activation energies for deuterium appearance, E_ϕ, are 102 ± 16 kJ mol^{-1}. In every case E_ϕ was greater than E_x, implying that multiple exchange has a higher activation energy than single exchange. The value of M was 1.24 ± 0.04, and there was no observable trend with sintering temperature. Similarly, for catalysts prepared by ion exchange E_x was in the range 72 ± 10 kJ mol^{-1} and E_ϕ was 84 ± 12 kJ mol^{-1}. M was significantly higher for this series of catalysts at 1.70 ± 0.15. Thus, interestingly enough, multiple exchange seems to be more important on the smaller particles of the ion exchanged catalyst (Table 1).

Attempts were made to vary the platinum particle size by varying the concentration of platinum in the H_2PtCl_6 impregnating solution. Ideally this technique should give catalysts with the same number of platinum particles, but of varying size (21). In our case, going to a 0.5% platinum on silica catalyst gave a catalyst with a metal surface area of 530 m^2 kg^{-1}, almost exactly 10% that from a 5% catalyst. Hence the particle diameter, 2.6 nm, was almost identical to the 2.8 nm of the 5% catalyst. The rate coefficients were very low, but k_x^1 was about 1×10^{-6} mol CH_4 m^2 s^{-1} at 200 °C. Attempts to make catalysts with greater than 10% platinum gave catalysts with extremely broad size distributions. Since we did not get significantly smaller particles at lower concentrations, and could not make good catalysts with more than 10% platinum, no further effort was devoted to varying particle size by this method. Attempts were made to prepare catalysts by impregnation with $Pt(NH_3)_2(NO_2)_2$ (1). We could not successfully prepare 5% platinum catalysts by this method as electron microscopy indicated that the catalyst produced, even after a multiple evaporation technique, was a mixture of spongy platinum and silica, and was not a true supported catalyst.

To see if carbonaceous poisons were affecting the rate, the exchange was studied at 200 °C over the unsintered ion exchanged catalyst and at 230 °C over the impregnated catalyst sintered at 800 °C, after treating with dry air at 300 °C for 1 h followed by re-reducing. In neither case was the rate changed by more than 10%.

The variation in rate coefficients with varying hydrogen pressure was studied briefly at 215 °C using the H_2PtCl_6 catalyst sintered at 500 °C. The order was 0.7 ± 0.2 in methane and -0.7 ± 0.2 in deuterium.

The specific rate coefficients for CH_4 conversion at 200 °C (k_x^1) are plotted in Fig. 5 as a function of the particle size in a double logarithmic form. Results of McKee and Norton (22) and of Kemball (11) using platinum black and films are included for comparison. The data of McKee and Norton were extrapolated to 200 °C using their kinetic parameters. It is seen that in both our catalyst series the maximum specific rate coefficients are obtained with sintering temperatures of 500 °C. The variations in specific rate coefficients within each series are very much greater than are the variations between each series or between the specific rate coefficients on the much larger platinum black particles. Thus no significant variation in specific rate coefficient with particle size could be demonstrated. The sintering process, however, appears to lead to very large decreases in specific rate coefficients. In fact, the temperature at which the catalyst was sintered seems to be a better indicator of its specific rate coefficient than does the particle size.

Discussion

There is both theoretical and experimental evidence that electronic properties undergo

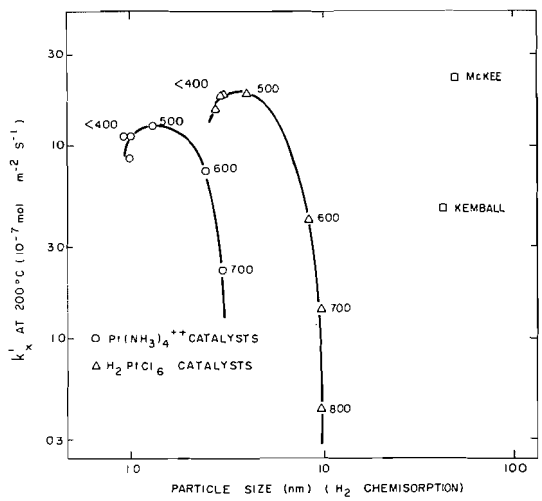

FIG. 5. Specific rates for CH_4 conversion at 200 °C as a function of particle size. Data by Kemball on platinum films (ref. 11) and by McKee and Norton on powders (ref. 22) are included.
