The Transformations of Dimeric Tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-hexopyranosyl Chlorides in Dimethylformamide[1]

R. U. LEMIEUX, T. L. NAGABHUSHAN,[2] AND K. JAMES[3]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

The dimeric nitrosyl chloride adducts of tri-*O*-acetyl-1,5-anhydro-2-deoxy-D-*arabino*-hex-1- and D-*lyxo*-hex-1- enitols (glycals) dissociate in dimethylformamide to the monomeric forms which rapidly isomerize to the corresponding tri-*O*-acetyl-2-oximino-α-D-hexopyranosyl chlorides. Evidence is provided for the dehydrochlorination of these latter compounds to highly reactive tri-*O*-acetyl-1,5-anhydro-2-deoxy-2-nitroso-D-hex-1-enitols.

Les adduits entre le chlorure de nitrosyle dimère et les tri-*O*-acétyl anhydro-1,5 déoxy-2 D-*arabino* et D-*lyxo*-hexenitols-1 (glycals) se dissocient dans le diméthylformamide en formes monomères qui s'isomèrisent rapidement en chlorures de tri-*O*-acétyl oximino-2-α-D, hexopyranosyles. La déhydrochloration de ces derniers composés en tri-*O*-acétyl-anhydro-1,5 deoxy-2-nitroso-D-hexenitols-1 hautement réactifs a été mise en évidence. [Traduit par le journal]

Can. J. Chem., **51**, 1 (1973)

Previous communications (1–3) have shown that nitrosyl chloride adds readily to the acetylated 1,5-anhydro-2-deoxy-D-hex-1-enitols of the *arabino*- and *lyxo*-configurations and 1,5-anhydro-2-deoxy-D-*threo*-pent-1-enitol (acetylated glycals) to give acetylated 2-deoxy-2-nitroso-α-D-glycopyranosyl chlorides of the *gluco*-, *galacto*-, and *xylo*-configurations, respectively. The compounds crystallize as the dimers (1). Tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer (**1**) was shown to react with alcohols in dimethylformamide to form alkyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosides in high yield and with a high degree of stereoselectivity for the *Z*- (4) and α-D-configurations (5–7). Furthermore, it was shown that the oximinoglycosides of the *arabino*-configuration can be reduced to 2-amino-2-deoxy-α-D-gluco and 2-amino-2-deoxy-α-D-mannopyranosides (8). Also, deoximation of the acetylated 2-oximino-α-D-*arabino*-hexopyranosides followed by reduction with sodium borohydride was shown to provide α-D-glucopyranosides in good yield (6, 7, 9). Further accounts of these reactions are presented in the accompanying publications (10–14). The purpose of this communication is to report a study of the chemical properties of the dimeric nitrosyl chloride adducts of the triacetates of D-glucal (**1**) and D-galactal (**5**) as reflected by dissolution in anhydrous dimethylformamide (DMF) (see Scheme 1).

Freshly prepared solutions (0.05 *M*) of either dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) or dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-galactopyranosyl chloride (**5**) in DMF are virtually colorless but mutarota-

TABLE 1. First order velocity constants* for the formation of tri-*O*-acetyl-2-oximino-α-D-hexopyranosyl chlorides from dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glycopyranosyl chlorides

Configuration	Initial concentration of the dimer (*M*)	Method†	$k \times 10^3$ min^{-1}
arabino (**1**)	0.05	Polarimetric	11.8
arabino (**1**)	0.4	Polarimetric	11.6
arabino (**1**)	0.4	N.m.r.	12.0
2-Deuterio-	0.4	Polarimetric	11.4
arabino (**1**)	0.4	N.m.r.	12.6
lyxo (**5**)	0.05	Polarimetric	7.2
lyxo (**5**)	0.4	Polarimetric	7.8
lyxo (**5**)	0.4	N.m.r.	9.6

*At 25° in anhydrous dimethylformamide.
†The experimental error was estimated to be about ±2% for the polarimetric rates and about ±5% for those determined using n.m.r. by following the change in the relative intensities of the signals for the anomeric protons of **1** and **3**.

tion occurs: for **1**, $[\alpha]_D^{25}$ + 172° → +248° (8 h); for **5**, $[\alpha]_D^{25}$ + 137° → +238° (9.5 h). At this concentration, the final rotations are highly stable with little change being observed over a period of 3 days. Log plots of the changes in rotation indicated first order processes; $t_{1/2}$ = 59 min for **1** and $t_{1/2}$ = 96 min for **5** (see Table 1). It was desired to study the course of the reaction using n.m.r. and for this purpose (see below) 0.4 *M* solutions in DMF were used. At this higher concentration, the same maximum specific rotations were reached but these decayed with extended periods of time (greater than 8 h for **1** and 10 h for **5**). This change is attributed to slow decomposition of the product. By taking the observed α_{max} as equal to α_∞, velocity constants were calculated and found to be in good agreement with those determined for the mutarotation for 0.05 *M* solutions (Table 1).

In order to establish the cause of the mutarotation, the changes in n.m.r. spectra accompanying the mutarotation for 0.4 *M* solutions were determined. The spectra for the freshly prepared solutions and the solutions at maximum rotation using DMF-d_7 as solvent are presented in Fig. 1. At all intermediate reaction times, the spectra

*Broad peak.
†Sharp singlet.

were those of the starting material superimposed on that of the product. Examination of the signals and their integration clearly required the formation in each case of only one observable product. No intermediates were detected.[4] The rates of the reactions were calculated from the n.m.r. data and the first order velocity constants were found to be in close agreement (see Table 1) with those determined polarimetrically.

The products **3** and **6** proved to be highly labile and neither was obtained in crystalline form. Nevertheless, preparations of greater than 90% purity could be obtained by removal of the DMF in high vacuum. The n.m.r. parameters are compared for solutions in DMF-d_7 and $CDCl_3$ in Table 2 where it is seen (as in Fig. 1) that the products are assigned the tri-*O*-acetyl-2-oximino-α-D-*arabino*- (**3**) and tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranosyl chloride (**6**) structures. These assignments are required by the singlets for the anomeric hydrogens and the presence in each

[4]In early experiments, there was an appearance of a singlet at τ 4.11 during the mutarotation of **1** which disappeared with prolonged reaction time. This phenomenon was traced to the presence of small amounts of water leading to 3,4,6-tri-*O*-acetyl-2-oximino-D-glucose which subsequently was consumed by condensation with the excess glycosyl chloride.

case of signals for oxime hydroxyl groups (see Table 2). The positions of the anomeric signals at lower field than those of the starting material, the high dextrorotations, and theoretical considerations (5) leave no doubt that the anomeric configurations are α-D in both cases. The rearrangement of dimeric nitrosyl chloride adducts of alkenes to α-chlorooximes is well known (15).

Since the monitoring of the reactions by n.m.r. did not reveal intermediate compounds, it was apparent that the rate-determining step for the overall reactions in both cases was the dissociation of the dimeric starting material. This was confirmed for the *gluco*-compound **1** by a kinetic investigation of the 2-deuterio derivative. The compound was prepared in the normal manner starting from 2-deuterio-D-glucose pentaacetate which in turn was prepared from isopropyl 2-deuterio-α-D-glucopyranoside (6). Two distinctly different routes (16, 17) can be envisaged for the conversion of **1** to **3**. One route would involve a prototropic shift involving H-2 of the monomeric nitrosochloride **2** to yield **3**. The other route would involve dehydrochlorination of **2** to the nitrosoglycal **4** which subsequently undergoes 1,4-addition of the hydrogen chloride to form **3**. Both of these reaction routes are expected to display primary kinetic isotope effects since in both cases cleavage of the C_2—H_2 bond occurs in the rate-controlling stage. Since the 2-deuterated **1** underwent conversion to **3** at about the same rate, within experimental error, as did **1** (see Table 1), it is further apparent that dissociation of **1** to **2** is indeed the rate-controlling step. Thus, the slower transformation of the *lyxo*-dimer (**5**) appears related to an inherently greater stability of this dimer rather than shielding of H-2 by the axial acetoxy group at C-4 affecting the rate of the isomerization of the monomeric form.

The formation of α-oximinoglycoside on reacting **1** with an alcohol in DMF is considered to proceed by way of the nitrosoglycal **4** (10). Glycoside formation also takes place starting from the oximinochloride **3** (10) and **4** is a plausible intermediate in this reaction as well. Indeed, the possibility existed that, starting with **1** in the presence of an alcohol, the formation of oximinochloride **3** is effectively the first stage of the reaction and that oximinoglycoside formation then follows. An accompanying paper (10) establishes this to be essentially the route of reaction.

The postulation of the nitrosoglycal **4** as an intermediate in oximinoglycoside formation was previously based on the appearance of a faintly blue coloration for concentrated solutions of **1** in methylene chloride buttressed by theoretical considerations (5). We now wish to report direct observation of this intermediate.

It is known that solutions of cyclic α,β-unsaturated monomeric nitroso compounds are blue and show absorption maxima in the neighborhood of 700 mμ (15). A 0.2 *M* solution of **1** in chloroform was faintly blue and showed a weak absorption maximum at 680 mμ with a shoulder at 620 mμ. On addition of triethylamine, the blue coloration became intense and the intensity of the peak at 680 mμ was greatly enhanced. Oximinochloride (**3**) formation is a very slow process with chloroform as solvent in spite of nitrosoglycal formation being evident. Thus, both 0.2 and 0.425 *M* solutions in $CDCl_3$ showed essentially no change in their n.m.r. spectra over 4 days at 25°. It is reasonable to assign the shoulder at 620 mμ to monomer **2**. Although the dimer **1** does not absorb in the visible, it shows an absorption maximum at 300 mμ (ε 10 000) which is characteristic of dimeric α-chloronitroso structures (16). It is apparent then that, in chloroform, **1** reversibly dissociates to **2** which dehydrochlorinates to **4** and that the latter process is reversed by highly preferential 1,2-addition of the hydrogen chloride. This may also be the case with DMF as solvent but the relative rates of the various reactions do not allow investigation of this matter. It is likely that in chloroform, as in DMF, the oximinochloride **3** is the stable reaction product but its rate of formation is extremely slow. Lemieux *et al.* (5) demonstrated the preparation of oximinoglycosides by reaction of **1** with an alcohol in refluxing methylene chloride. Under these conditions, the hydrogen chloride is continuously removed from the reaction mixture by volatilization. Thus, reaction of **4** with the alcohol is promoted.

Both freshly prepared 0.4 *M* solutions of **1** and solutions of **3** in DMF are colorless. However, addition of triethylamine to either solution rapidly leads to a deep blue coloration which disappears in a few minutes. The maximum coloration was greater starting from the oximinochloride **3** and this is in line with the requirement that the dimer **1** must first dissociate before dehydrochlorination to nitrosoglycal **4** can occur. When a 0.4 *M* solution of **1** was treated with 0.5 equiv of triethylamine, the deep blue solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

rapidly filtered free of precipitated triethylamine hydrochloride, and the n.m.r. spectrum was determined within 2 min, the intensity of the signal for anomeric hydrogen of **1** was decreased to half its original intensity and there appeared a sharp singlet at τ 0.3. This signal decayed rapidly at about the same rate as the blue coloration as judged by visual inspection. Further addition of triethylamine deepened the blue coloration, and completely eliminated the doublet at τ 3.61 but slightly increased the intensity of the signal at τ 0.3 before it vanished completely with the disappearance of the blue color. The latter signal is assigned to H-1 of tri-*O*-acetyl-2-nitroso-D-glucal (**4**). The nitroso group is expected (5) to strongly deshield H-1 especially in the *syn*-configuration. The signal for H-1 of tri-*O*-acetyl-2-nitro-D-glucal is at τ 1.67 (2).

The discoloration of the blue color of solutions of 1-nitrosocyclohexene has been attributed to polymerization (15). Addition of 1 equiv of triethylamine to a freshly prepared 0.022 *M* solution of **1** in DMF led to a deep blue solution with an absorption maximum at 645 mμ. The decrease in the intensity of the absorption with time was followed. A clear yellow solution resulted after 7 h. At higher (0.5 *M*) initial concentrations of **1**, the blue coloration disappeared more rapidly. The product is an amorphous solid with the composition and average molecular weight (osmometric) corresponding to about a tetramer of **4**.

The reaction properties of **5** were not examined in as much detail as those of **1** but cursory tests indicated very similar properties.

In conclusion, the present results indicate that the dimeric nitrosyl chloride adducts of acetylated glycals have very similar properties to those described by Pritzkow and coworkers (15, 16) for α-chloronitrosoalkanes. Because of activation by the ring oxygen in the development of positive charge at the anomeric center, the glycosyl chlorides are much more reactive. Further details on the reaction properties of these compounds in the presence of alcohols are presented in an accompanying paper (10).

Experimental

Absorption spectra were obtained with a Cary Recording Spectrophotometer Model 14 M using a 1 cm cell. N.m.r. spectra were recorded at 60 MHz on a Varian A 56–60 instrument at 25 ± 0.5° using tetramethylsilane as the external standard. Optical rotations were determined in a Perkin–Elmer Model 141 automatic recording polarimeter at 25 ± 0.5°.

Tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer (**1**) and its *galacto*-isomer **5** were prepared as previously described (2, 7), recrystallized twice from chloroform – *n*-hexane, and dried *in vacuo* over phosphorus pentoxide and stored at 4°. Before each experiment, the compounds were redried and the purity of the materials checked by t.l.c. (ethyl acetate – *n*-hexane (1:1)) and m.p.

Reagent grade dimethylformamide and dimethylformamide-d_7 (Merck, Sharp and Dohme of Canada Ltd., Montreal) were distilled from phosphorus pentoxide.

2-Deuterio-β-D-glucopyranose pentaacetate (Raylo Chemicals Ltd., Edmonton, Alberta) was converted to 2-deuterio-D-glucal triacetate using standard procedure (18). The structure of the compound was confirmed by n.m.r. in deuteriochloroform at 100 MHz using tetramethylsilane as the internal standard (τ 3.54, H-1, $J_{1,3}$ = 1.5 Hz (deuterium decoupled at 15.351 MHz); 4.66, H-3, $J_{3,4}$ = 6.0 Hz; 4.80, H-4, $J_{4,5}$ = 7 Hz). The dimeric nitrosyl chloride adduct of 2-deuterio-D-glucal triacetate was prepared as previously described for the non-deuterated analog (2, 7).

We wish to thank the National Research Council of Canada for support of this work through a grant-in-aid of research (A-172) to R.U.L., and Mr. W. Merlo and Miss P. Nayar for technical assistance. Thanks are also expressed to R.N. Swindlehurst, J. Hoyle, and Mrs. D. Formanski for measurements of n.m.r. spectra.

The Reaction of Dimeric Tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-hexopyranosyl Chlorides with Alcohols[1]

R. U. LEMIEUX, Y. ITO,[2] K. JAMES,[3] AND T. L. NAGABHUSHAN[4]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

The kinetics of the reactions of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) with simple aliphatic alcohols (4 mol equiv) in dimethylformamide to form alkyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosides (**5**) were investigated by n.m.r. and optical rotation. It is concluded that the conversion of **1** to **5** proceeds basically by way of three successively formed intermediates, namely, the monomeric form (**2**) of **1**, the tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl chloride (**3**), and the tri-*O*-acetyl-1,5-anhydro-2-deoxy-2-nitroso-D-*arabino*-hex-1-enitol (**4**). Direct evidence was obtained only for the intermediacy of **3** and the transient existence at low concentration of an uncharacterized intermediate which may be the β-anomer of **5**. The intermediate **4** could form directly from **2** and thereby provide a mechanism for the formation of **5** which by-passes **3**. However, the kinetic investigations showed this route to be of very minor, if any, importance. In all cases, the rate of the disappearance of **1** was virtually the same and within experimental error the same as for the isomerization of **1** to **3** in the absence of the alcohol for which the rate-controlling stage is dissociation of **1** to **2**. Methanol reacts with **4** only about 5 times faster than does *t*-butanol.

The utility of the reaction for the preparation of oximinoglycosidic structures related to disaccharides is illustrated by glycosidations of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose, 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose both by **1** and by the dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-galactopyranosyl chloride (**6**) and of 2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranose by **1**. The reaction of **6** with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose provided an 8.7% yield of the β-oximinoglycoside along with an 80% yield of the α-anomer.

Les cinétiques de réaction entre le chlorure de tri-*O*-acétyl déoxy-2 nitroso-2-α-D-glucopyranosyle dimère (**1**) et les alcools aliphatiques simples (4 mol equiv) dans le diméthylformamide pour conduire aux alkyles tri-*O*-acétyl oximino-2-α-D-*arabino*-hexopyranosides (**5**) ont été étudiées par r.m.n. et rotation optique. On a conclu que la conversion de **1** à **5** procède surtout par la formation successive de trois intermédiaires à savoir, la forme monomère (**2**) de **1**, le chlorure de tri-*O*-acétyl oximino-2-α-D-*arabino*-hexopyranosyle (**3**) et le tri-*O*-acétyl anhydro-1,5 deoxy-2 nitroso-2-D-*arabino*-hexenitol (**4**). Une preuve directe a été obtenue seulement pour l'intermédiaire **3** de même que l'existence transitoire, à faible concentration, d'un intermédiaire non caractérisé qui pourrait être l'anomère β de **5**. L'intermédiaire **4** peut se former directement à partir de **2** et de ce fait, fournit un mécanisme pour la formation de **5** sans passer par **3**. Les études cinétiques montrent que cette voi est cependant d'importance mineure. Dans tous les cas, la vitesse de disparition de **1** reste virtuellement la même; de même que pour l'isomèrisation de **1** en **3**, dans les limites de l'erreur expérimentale, en l'absence d'alcool pour laquelle l'étape déterminante est la dissociation de **1** en **2**. Le méthanol réagit avec **4** environ 5 fois plus vite que le *t*-butanol.

L'utilité de cette réaction dans la préparation de structures oximinoglycosidiques apparentées aux disaccharides est illustrée par les glycosidations du di-*O*-isopropylidène-1,2,3,4-α-D-galactopyranose, du di-*O*-isopropylidène-1,2,5,6-α-D-glucofuranose par **1** et par le chlorure de tri-*O*-acétyl-deoxy-2 nitroso-2-α-D-galactopyranosyle (**6**) et du di-*O*-isopropylidène-2,3,5,6-α-D-mannofuranose par **1**. La réaction de **6** avec le di-*O*-isopropylidène-1,2,3,4-α-D-galactopyranose conduit à 8.7% de β-oximinoglycoside et 80% d'anomère α. [Traduit par le journal]

Can. J. Chem., **51**, 7 (1973)

The reaction of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) with simple alcohols in dimethylformamide (DMF) was reported to yield tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosides in high yield (1). The synthetic usefulness of this reaction was reported in previous (2–6) and accompanying communications (7–11) where it is shown that the α-oximinoglycosides are excellent precursors of α-glucopyranosides and α-glucopyranosaminides. In view of this, we have examined in some detail the reaction of **1** with simple alcohols and ex-

tended it to the preparation of tri-*O*-acetyl-2-oximino-α-D-*arabino*- (and α-D-*lyxo*-) hexopyranosyl derivatives of suitably protected monosaccharides (see Scheme 1).

When the course of the reaction of either tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer (**1**) or its *galacto*-isomer **6** with an alcohol in DMF is followed polarimetrically, an initial upward mutarotation of the solution occurs which is soon followed by a downward change. Typical mutarotation curves obtained for reactions of **1** with 4 mol equiv (2 mol equiv per mol of monomeric form) of alcohols in dry DMF at 25° are shown in Fig. 1. It was established in the previous paper (12) of this series that compounds **1** and **6** isomerize in dimethylformamide to the more dextrorotatory oximinochlorides **3** and **7**, respectively. Therefore, the initial increases in rotation observed for the reactions of **1** and **6** with alcohols in DMF were expected to be related to the appearance of compounds **3** and **7**, respectively, as reaction intermediates. Indeed, when the reactions were followed by p.m.r. using DMF-d_7 as solvent, compounds **3** and **7** were clearly apparent as the main reaction intermediates.

The formation of the oximinoglycosides (**5**) is not expected to occur with direct involvement of the oximinochloride precursor. The reactions of α-chlorooximes appear generally to proceed first by dehydrochlorination to highly reactive nitrosoalkene intermediates which subsequently undergo nucleophilic attack to form the α-substituted oximes (13). The formation of tri-*O*-acetyl-1,5-anhydro-2-deoxy-2-nitroso-D-*arabino*-hex-1-enitol (**4**) from the oximinochloride (**3**) was demonstrated (12) by the addition of triethylamine in order to render the rate of its formation more

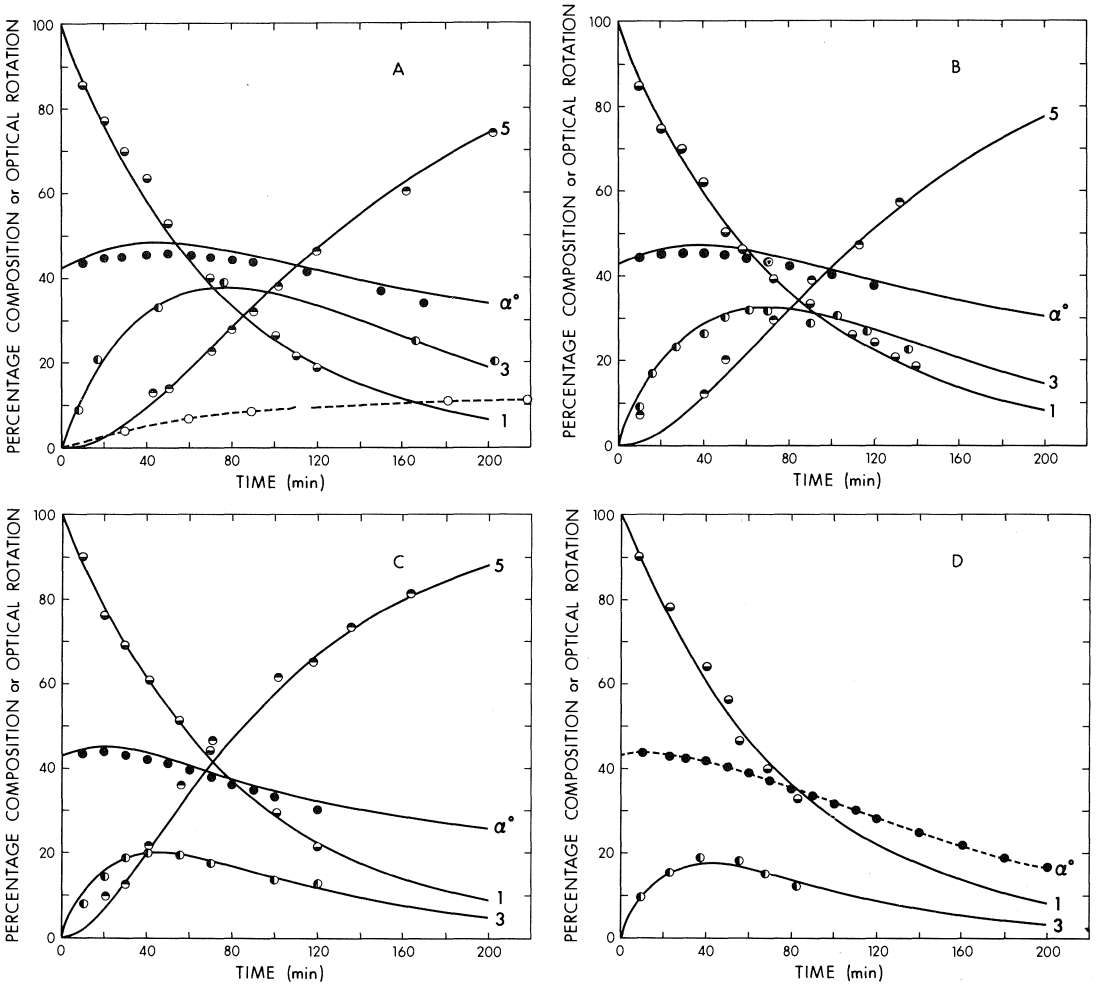

FIG. 1. Experimental values for the concentrations of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**), ◒; tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl chloride (**3**), ◐; and alkyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**5**), ◓; plus an apparent glycocidic intermediate. The approximate concentration of the intermediate is represented by the dotted line, ○, in part A. All measurements involved reaction of 0.4 *M* **1** with the hydroxy compound (1.6 *M*) in DMF at 25°. The alcohol was *t*-butanol in A, isopropanol in B, and methanol in C. Part D is for the reaction using deuterium oxide. These values were estimated by n.m.r. The solid lines are the result of calculations assuming that only **3** and **5** were formed. The points represented by ● are the observed rotations of the reaction mixtures. The solid α° lines in A, B, and C are the observed rotations expected with only **3** and **5** as products of the reaction. The dotted α° line in D represents the observed rotations.

rapid than its rate of disappearance through polymer formation.

For the above-stated reasons, the course of events on mixing the dimer **1** with an alcohol (ROH) in DMF is considered to first involve reversible dissociation of **1** to a very low near steady-state concentration of the monomer **2**. The formation of the oximinochloride **3** could occur by loss of hydrogen chloride (**2** → **4**) followed by addition of hydrogen chloride (**4** → **3**). However, the direct conversion of **2** to **3** by simple prototropic shift may be considered the predominant route since, as will be seen below, no evidence was obtained for the formation of **5** without the intervening formation of **3**. The oximinochloride (**3**) is expected to be particularly prone to dehydrochlorination (15) to the intermediate **4** and this reversible reaction is expected to be promoted by the weakly basic polar solvent DMF. That the acidity of the oximino group pro-

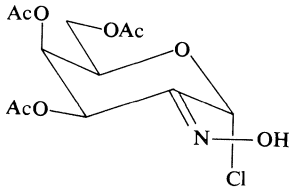
6



7

vides a facile mechanism for the dehydrochlorination is supported by the observation that the *O*-acetyl derivative of **3** (2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl chloride) did not react with isopropanol in DMF. However, neither the rate of the formation of **3** from **1** nor the formation of **5** from **3** is appreciably affected by the presence of hydrogen chloride. This was evident from the observation that the presence of hydrogen chloride (0.4 *M*) at the beginning of the reactions had no effect on the mutarotation observed and reported in Fig. 1. Furthermore, in the case of the reaction with methanol, the reaction in the presence of the added hydrogen chloride was followed by n.m.r. The values for k_1 and k_2 estimated were, within experimental error, the same as those reported in Table 1.

Hydrogen chloride is expected to depress the concentration of **4** but to catalyze the reaction of **4** with ROH to form oximinoglycosides. In the absence of alcohol or hydrogen chloride **4** can polymerize (12). When the reaction of **1** with isopropanol in DMF was kept weakly basic throughout the course of reaction by the presence initially of an equimolar amount of *sym*-collidine, the initial rise in optical rotation was not observed and the yield of α-oximinoglycoside was low (about 50%). Thus, we do not recommend basic reaction conditions for the preparation of α-oximinoglycosides (16). As will be seen below, the possibility exists that α-oximinoglycoside formation may involve to some extent anomerization of initially formed β-oximinoglycoside.

A study was made of oximinoglycoside formation from the oximinochloride (**3**). In view of the uncertainty in the purity of the starting material, the results can only be considered semi-quantitative. A 0.4 *M* solution of **1** in DMF was first allowed to isomerize to **3** and then 2 equiv of either methanol or *t*-butanol were added. Reaction began immediately to form eventually the corresponding alkyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**5**) in greater than 85% yield. Since these alkyl groups provide singlet n.m.r. signals and the chemical shifts of the glycosidic alkyl groups were to lower field than those of the alcoholic alkyl groups, it was possible to estimate the rates of glycoside formation by measuring, after various reaction times, the intensities of these signals relative to the group of signals arising from the acetoxy groups. Analysis showed the rates of appearance of oximinoglycoside (**5**) to be first-order as were the changes in optical rotation during the course of the reactions. The velocity constant thus determined for methanol was 0.025 min^{-1} by n.m.r. and 0.028 min^{-1} by polarimetry. For *t*-butanol, the velocity constant was estimated to be 0.012 min^{-1} by n.m.r. and 0.018 min^{-1} by polarimetry. These first-order changes together with the observation that an electrophilic reaction with methanol is only about twice as fast as for *t*-butanol indicated that the overall rate of reaction was controlled by the rate of the conversion of **3** to the nitrosoglycal **4**. Since the solutions remained colorless and **4** is a deeply blue-colored compound (12), the concentration of **4** must remain extremely small throughout the course of reaction. When the product formed from a 0.4 *M* solution of **1** in DMF containing 1 mol equiv of both methanol and *t*-butanol was analyzed by n.m.r., the ratio of the methyl to *t*-butyl oximinoglycosides was near 5 after 10 h and this ratio remained constant within experimental error up to 48 h. Thus, the nitrosoglycal **4** shows little discrimination between the two alcohols as may be expected for a highly reactive species. The *t*-butyl oximinoglycoside was dissolved in DMF at 25° which was 0.8 *M* both in methanol and in hydrogen chloride to afford a 0.8 *M* concentration of the oxime. There was no change in the n.m.r. spectrum of the solution after 5 h and no appearance of the

§Calculated values by curve fitting (see Fig. 1) assuming two consecutive first-order processes $\mathbf{1} \xrightarrow{k_1} \mathbf{3} \xrightarrow{k_2} \mathbf{5}$. The found values are from the polarimetric rates starting with **3**. The values in parentheses were determined by following the reaction by n.m.r. These constants must be considered as very approximate.

methyl glycoside after 2 days at 25°. However, some decomposition (about 10%) of the *t*-butyl glycoside had occurred. Thus, the formation of the α-oximinoglycosides (**5**) is essentially irreversible under these reaction conditions. For these reasons, as will be seen below, an effort was made to rationalize the reactions of **1** with methanol, isopropanol, and *t*-butanol on the basis of two irreversible consecutive first-order reactions, namely,

$$\mathbf{1} \xrightarrow{k_1} \mathbf{3} \xrightarrow{k_2} \mathbf{5}$$

The reactions of **1** with deuterium oxide, methanol, isopropanol, and *t*-butanol were followed both polarimetrically and by n.m.r. under the conditions described in Table 1. The data accumulated are plotted in Fig. 1. The n.m.r. measurements were complicated by the movement of a wide band attributed to signal from exchangeable hydrogen across the τ 3–4 region (where the signals for the anomeric hydrogens of **1**, **3**, and **5** occur) as reaction proceeded. As a result, it was not possible to estimate the relative concentrations of **1** and **3** to an acceptable degree of accuracy at some of the reaction times. The extent of glycoside formation was best assessed when methanol and *t*-butanol were the reagents since in these experiments it was possible to measure the intensity of the signal arising from the alkyl group of the glycoside relative to that arising from the three acetyl groups. In both cases, two signals for the glycosidic alkyl group were present shortly after the beginning of the reaction. The less intense signal reached a maximum somewhat later than did the oximinochloride intermediate (**3**) and was not present at the end of the reaction (about one day). When reaction mixtures containing the two signals were worked-up by solvent removal, the product showed only one signal. Thus, isomerization of this labile intermediate to the *Z*-α-oximinoglycoside (**5**) (14) appears to occur during the work-up. This phenomenon could not be traced to oxime hydrochloride formation. It could conceivably arise through transient formation of either *Z*- or *E*-β-oximinoglycoside (17) or *E*-α-oximinoglycoside in their acetylated forms.

The intermediate was also observed when **3** was the starting material and its formation appears to be promoted by dilution of the mixture. Thus, when *t*-butanol (4 mol equiv) was reacted with **1** at initial concentrations of **1** of 0.4, 0.2, and 0.1 *M*, the reaction mixtures after 26 h, as measured by n.m.r., contained ~0, 11, and 19% of the reactive intermediate. After 48 h, the 0.2 *M* solution was free of the signal for the intermediate and that for the 0.1 *M* solution was reduced to 12%.

The extent of the formation of this intermediate could only be estimated quantitatively for *t*-butyl glycoside formation and only very approximately since the two singlets were partially overlapped. These data are plotted in Fig. 1A where it is seen that the maximum accumulation was about 11% under the conditions described.

The structure of this intermediate is under investigation. That it may be the β-anomer of **5** is possible since direct evidence for the formation of β-oximinoglycoside in low yield was obtained by the isolation of 6-*O*-(tri-*O*-acetyl-2-oximino-β-D-*lyxo*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (**10**) in 8.7% yield. It is believed that the β-anomer of compound **8** was also formed but this product was not characterized as such. Thus, it may prove that to a degree

β-oximinoglycoside formation precedes formation of the α-anomer but is anomerized by way of **4**.

In an attempt to gain insight on the nature of the unknown intermediate, an examination was made of whether or not the polarimetric and n.m.r. rates were compatible by assuming only the presence of compounds **1**, **3**, and **5** during the course of reaction. As seen in Fig. 1 and Table 1 treatment of the data as resulting from two consecutive first-order reactions allowed fairly good fits of theoretical curves.[5] As seen from Table 1, this was accomplished with $k_1 = 0.0126$ min^{-1} for deuterium oxide, methanol, and isopropanol. The determination of k_1 in the absence of alcohol was previously reported (12). The slightly higher value, $k_1 = 0.0136$ min^{-1} was required for an equally good fit for the data using *t*-butanol. Using these calculated values and the observed rotations of **1** (42.5°), **3** (67.0°), and of the appropriate glycoside, methyl (12.2°), isopropyl (22.3°), and *t*-butyl (24.5°), measured in 0.8 *M* hydrogen chloride in DMF at 25°, the expected polarimetric curves were calculated and shown in Fig. 1. Considering the rather large experimental uncertainties involved, the fit is considered to be remarkably good in all instances and it must be concluded that the overall process is largely **1** → **3** → **5**. It is noteworthy, however, that for the three alcohols the measured upward change in rotation was slightly less than that expected by calculation. This result would be in line with the formation of a labile intermediate of lower optical rotation than the *Z*-α-oximinoglycoside (**5**) such as would be the case for its *Z*-β-anomer.

The main objective of this investigation was to establish practical means for the synthesis of α-linked oligosaccharide structures. In order to assess the method for this purpose, the reactions of the dimeric nitrosochlorides **1** and **6** with the well known di-*O*-isopropylidene derivatives of D-galactopyranose, D-glucofuranose, and D-mannofuranose were examined. Thus, experience was gained with the glycosidation of a primary hydroxyl group, a hindered secondary hydroxyl group, and an hemiacetal hydroxyl group. In each case, the desired α-oximinoglycoside was obtained in crystalline condition in good to excellent yield (see **8**, **9**, **11**, **12**, and **13**). The compositions and n.m.r. spectra (see Table 2) were in agreement with the assigned structures and the anomeric configurations of the oximinoglycosyl units were firmly established by conversion of compounds **8**, **9**, **11**, and **12** to α-glycosides (10). A consideration of the n.m.r. data presented in Table 2 leaves no doubt on this matter and the data also infer like configurations for the oximino groups since much greater changes in chemical shifts for the hydrogens of the oximinoglycosyl units, especially H-1′ and -3′, would be expected should any of the oximes not be in the *Z*-configuration (14).

To date, all our syntheses of oximinoglycosides using the nitrosyl chloride adducts **1** and **6** have led to the α-anomer as the major glycosidic product of reaction. However, evidence for the formation of the β-anomer was obtained for both the reactions of **1** and **6** with the primary hydroxyl group of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. In the case of the crude product from the reaction of **1**, thin layer chromatographic examination showed the presence of a minor component with an R_f value very close to that of the major product (**8**) which gave a positive ferric chloride – ferricyanide reaction for oxime. This product could not be isolated in pure condition for characterization but its behavior was very similar to a minor product isolated in 8.7% yield in crystalline condition from the reaction of **6** with the diisopropylidene galactose. In an experiment prior to our achieving crystalline **8**, a crude preparation of **8** was reduced with lithium aluminum hydride and the *N*-2,4-dinitrophenyl derivative of the products were chromatographed on a silicic acid column. A chromatographic fraction containing a minor component was acetylated and the two products separated by preparative t.l.c. The composition and n.m.r. spectrum of one of the components were consistent with those expected for 6-*O*-[tri-*O*-acetyl-2-deoxy-(2,4-dinitroanilino)-β-D-mannopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose.

Reaction of **6** with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose provided the above-mentioned minor product and the major product (**9**) isolated in 80% yield. The minor product appeared to be the β-D-*lyxo*-isomer (**10**) of compound **9** since their compositions and n.m.r. spectra required the compounds to be isomers. The possibility that compound **10** was the *anti*-form of the major product did not appear compatible with the chemical shift of the anomeric

[5]The authors are indebted to Dr. R. E. D. McClung of this Department for his generous offer to provide the analog computer simulations shown in Fig. 1, which enabled us to obtain the calculated values listed in Table 1.

hydrogen of the oximinoglycosyl unit since the signal was only 0.28 τ values to higher field than that of the major product. A shift of near 0.9 τ-value would be expected (14). Furthermore, the chemical shift of H-3′ was near that for the isomer (**9**). The compound (**10**) was deoximated and the product reduced with sodium borohydride to provide a single product which on acid hydrolysis liberated only D-talose and D-galactose (7). The specific rotation of the intermediate 1,2;3,4-di-*O*-isopropylidene-6-*O*-(β-D-talopyranosyl)-α-D-galactopyranose, was $-24.6°$ as compared to $+10°$ for 1,2,3,4-di-*O*-isopropylidene-6-*O*-(α-D-talopyranosyl)-α-D-galactopyranose (10). Thus, the β-

configuration was required. The 100 MHz n.m.r. spectra of the latter two compounds in deuterium oxide were virtually superimposable and could readily be taken as identical. However, the compounds were clearly different since they were readily separated by t.l.c.

Condensation of **1** with 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose afforded crystalline 3-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (**11**) in 59% yield. Similarly, the *lyxo*-isomer **12** was obtained in crystalline form from **6** in 53% yield. The n.m.r. spectra (Table 2) indicated that the oximinoglycosyl portion of compounds **11** and **12** possessed the α-configuration and this conclusion was confirmed by conversion to α-D-glycopyranosides (9).

The α-configuration of the oximinoglycosyl unit of 1-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranose was indicated by the n.m.r. spectrum (Table 2) and confirmed by the n.m.r. spectrum of the 1-*O*-(α-D-glucopyranosyl)-2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranose (18). The α-configuration is assigned to the mannofuranosyl portion of these compounds since in both cases the anomeric proton of this structural unit was a sharp singlet as found for the starting material, 2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranose and expected only for vicinal hydrogens in *trans*-relationship on a furanose ring. Thin layer chromatograms of the crude reaction product showed the presence of a second major component. The structure of this compound was not established but presumably is the β-D-*manno*-isomer of **13** which formed as the result of anomerization of the starting material during the course of the reaction.

Experimental

Optical rotations were measured in a 1 dm tube with a Perkin–Elmer model 141 polarimeter. Mutarotations were recorded automatically at 25 ± 0.5°. N.m.r. spectra were taken on a Varian A60 spectrometer.

The column chromatograms employed silicic acid (CC7, 100–200 mesh, Mallinckrodt Chemical Works, St. Louis, Mo.) using 10 g per gram of reaction product with ether – Skellysolve B (3:2) as the developing solvent unless otherwise stated. T.l.c. on silica gel G (E. Merck A.G., Darmstadt) was performed using 20 cm^2 plates with ether – Skellysolve B (4:1) as the developing solvent. The spots were visualized by spraying the plates with a solution of chlorosulfonic acid (10% v/v) in glacial acetic acid and then heating in an oven at 120°.

Dimethylformamide (DMF) was dried over barium oxide and then distilled from phosphorus pentoxide and stored under strictly anhydrous conditions. All solvent removals were carried out *in vacuo* (water aspirator or oil pump).

1,2;5,6-Di-*O*-isopropylidene-α-D-glucofuranose and 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose were purchased from Raylo Chemicals Ltd., Edmonton, Alberta.

Kinetic Studies

Solutions (3.2 *M*) of deuterium oxide, methanol, isopropanol, and *t*-butanol in dry DMF were prepared. At 0 time, a 5 ml aliquot of the solution (16 mmol) was added at 25° to 4 mmol (2.70 g) of the dimeric compound **1**. The solution was rapidly made up to 10 ml using dry DMF while maintaining the temperature at 25°. A sample was transferred to an n.m.r. tube for examination at 60 MHz at 25 ± 1°. The changes in composition with time were estimated by comparing integrations of the signals for anomeric hydrogen at τ 3.16 (singlet for compound **3**), 3.64 (doublet for compound **1**), and 8.1–8.3 (the acetyl group signals used as internal reference). After about 1 h reaction time, a broad band of exchangeable hydrogens moved downfield across the τ 3–4 region and interfered with the integration of the signals for the anomeric hydrogens. This phenomenon appears related to the liberation of signal for the oxime hydroxyl at low field since it was not observed in reactions starting with the oximino chloride **3**. The signals at τ 6.83 were used to estimate the total amount of glycoside with R = CH_3 and those at τ 9.02 to estimate the total amount of glycoside with R = $C(CH_3)_3$. The relative intensities of the signals after a given reaction time could be reproduced well within 5%. The glycoside contents using methanol and *t*-butanol were estimated from the relative intensities of the alkyl group and acetyl group signals. Both the glycosidic methyl and *t*-butyl groups appeared as two signals, τ 6.83 and 6.84 for methyl and 9.01 and 9.04 for *t*-butyl. The lower field signal is that due to oximinoglycoside **5**. The higher field signal must be assigned to uncharacterized intermediate. In both cases, the amount of this product was about the same as of the glycoside **5** in the very early (less than 5 min) stage of the reaction. Because of the small shift difference, the relative amounts could not be estimated in the case of methanol. For *t*-butanol, the amount of the intermediate could be roughly estimated (see Fig. 1A).

In the case of isopropanol, the amount of glycoside formation was estimated by comparing the intensities of the signals for the anomeric protons of **1** and **3** to the intensity of the signals for acetyl groups and attributing the loss of signal for these anomeric hydrogens to glycoside formation.

The polarimetric rates were determined on a sample of the solution used for the n.m.r. study. The observed rotation of the dimer **1** (0.4 *M*) in DMF was estimated to be 42.5° by extrapolation to 0 time and that of the oximinochloride **3** (0.8 *M*) to be 67.0°, the maximum rotation achieved in the transformation of the 0.4 *M* solution of **1** to **3**. The observed rotations of the oximinoglycosides were 12.2 (R = CH_3), 22.3 (R = $CH(CH_3)_2$) and 24.5° (R = $C(CH_3)_3$) as 0.8 *M* solutions in DMF. The rotations were not appreciably changed by the presence of hydrogen chloride (0.8 *M*).

The n.m.r. spectrum of the above solution using *t*-butanol showed no signal for the by-product after 26 h. However, when the initial concentrations of the reactants were decreased to one-half, the yield of the by-product after 26 h was 11%. At one-half this concentration, the yield of by-product was 19%. The solutions were evaporated to dryness *in vacuo* at about 40° (water bath). The n.m.r. spectra of the residue in DMF were measured. The product prepared from the 0.2 *M* solution of **1** now showed no evidence of the by-product. That from the 0.1 *M* solution of **1** still contained about 14% of the uncharacterized compound. The products were purified by chromatography on silicic acid. The yields of pure crystalline oximinoglycoside (**5**, R = *t*-butyl) were, within experimental error, the same at 66%. The actual yields were estimated to be about 90% from the n.m.r. spectra of the solutions prior to the chromatograms.

In order to estimate the rate of reaction of the oximino chloride **3** with methanol and *t*-butanol, a 0.59 *M* solution of **1** in DMF was prepared and its transformation to **3** followed both by polarimetry and n.m.r. When the reaction appeared complete, 6.77 ml of the solution was brought to 25° and 2.5 ml of a 6.4 *M* solution of the alcohol in DMF was added. The resulting solution was then rapidly made up to 10 ml by the addition of DMF and kept at 25°. A portion of the solution was used to follow the change in optical rotation with time and another portion to follow the change in its n.m.r. spectrum.

2-Acetoximino-tri-O-acetyl-α-D-arabino-hexopyranosyl Chloride

A solution of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (10.13 g, 15 mmol) in acetyl chloride (70 ml) was cooled to 5°. Triethylamine (3.03 g, 30 mmol) was then added, dropwise, with stirring. The reaction mixture was allowed to reach room temperature after which time the thick slurry was shaken at room temperature for 18 h. T.l.c. (ethyl acetate – Skellysolve B (2:1)) showed the presence of no starting material but a single spot for the product. Anhydrous ether (100 ml) was then added and the mixture stirred for 15 min. The precipitated triethylamine hydrochloride was removed by filtration and the filtrate was evaporated to an oil (10.54 g, 92%). The n.m.r. spectrum of the product in deuteriochloroform at 60 MHz showed a singlet at τ 2.95 (H-1), a doublet at 3.95 (H-2, $J_{2,3}$ = 10.0 Hz), a triplet at 5.40 (H-3, $J_{3,4}$ = 9.50 Hz). The acetyl signals appeared at τ 7.78, 7.85, and 7.90 in the ratio of 1:1:2. The spectrum required the compound to be greater than 95% pure.

The optical rotation, $[\alpha]_D^{25}$ +184°, of a 0.8 *M* solution of a freshly prepared sample of 2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl chloride in DMF containing 2 equiv of isopropanol at 25° was unchanged over a period of 12 h. T.l.c. examination of the solution (ethyl acetate – *n*-hexane (1:1)) showed a single spot with the same R_f value as that of the starting material which could be separated from isopropyl 2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranoside (1).

*6-O-(Tri-O-acetyl-2-oximino-α-D-arabino-hexopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (**8**)*

The product obtained from the reaction of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (8.0 g) with dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) (3) (13.0 g) in DMF (210 ml) for 36 h at room temperature was isolated and purified by column chromatography on silicic acid. Crystallization of the main fraction from ethyl acetate – Skellysolve B provided the pure material (11.5 g, 67%) m.p. 137–138°, $[\alpha]_D^{27}$ +9.2° (*c*, 1.8 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.33; H, 6.28; N, 2.49. Found: C, 51.13; H, 6.26; N, 2.40.

Evidence for the formation of the β-oxime as a minor product in the reaction of **1** with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was obtained in an experiment involving the lithium aluminum hydride reduction of an oxime preparation, $[\alpha]_D^{25}$ −1.05°, obtained in 73% yield by chromatographic purification of the crude reaction product on a silicic acid column using ethylene chloride – ethyl acetate (2:1) as the eluent. This product was reduced in ether following the procedure described in an accompanying paper (8). The 2,4-dinitrophenyl derivative (19) of the crude ninhydrin-positive product (obtained in 55% yield) (8) was chromatographed on a silicic acid column using chloroform – benzyl alcohol – acetic acid (24:10:1). Two main fractions were isolated. The faster moving material was characterized as 6-*O*-[2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (8). The slower moving component proved to be the *manno*-isomer. A fraction was collected between the two bands but close to the glucosaminide fraction which was acetylated with acetic anhydride in pyridine. The product, 100 mg, was subjected to t.l.c. on silica gel using benzene–methanol (20:1). Two components were detected. The faster moving material was isolated (51 mg) and established to be 6-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-α-D-glucopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose, $[\alpha]_D^{30}$ −29° (*c*, 0.4 in chloroform) (8). The slower moving component (28 mg) had $[\alpha]_D^{25}$ −128° (*c*, 0.4 in chloroform). The 100 MHz spectrum in deuteriochloroform required a high degree of purity and established the compound to be 6-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-β-D-mannopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. The expected signals for the acetyl and *C*-methyl groups were present. The chemical shifts and approximate coupling constants for the hydrogens on the pyranose ring of amino-sugar residue were established and confirmed by appropriate spin-decoupling experiments. The chemical shifts for H-1′, -2′, -3′, -4′, and -5′ were τ 5.06, 5.39, 4.82, 4.65, and 6.25, respectively. The approximate coupling constants observed were $J_{1',2'}$ = 1.25, $J_{2',3'}$ = 4.0, $J_{3',4'}$ = 9.0, and $J_{4',5'}$ = 9.5 Hz. The magnitude of $J_{2',3'}$ requires the *manno*-configuration. The doublet signal for the amide hydrogen was at τ 0.97 with a spacing of 9.0 Hz. For both the α-*manno*- and α-*gluco*-isomers, the chemical shift of H-5′ was to lower field, τ 5.92, as is expected in view of the deshielding effect of the axial O-1′ on the *syn*-axial H-5′ (20).

6-O-(2-Acetoximino-tri-O-acetyl-α-D-arabino-hexopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

Acetylation of the oxime **8** with acetic anhydride in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pyridine yielded an oil, $[\alpha]_D^{23}$ +0.65° (*c*, 2.6 in chloroform).

Anal. Calcd. for $C_{26}H_{37}NO_{15}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.59; H, 6.08; N, 2.48.

*6-O-(Tri-O-acetyl-2-oximino-α-D-lyxo-hexopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose (**9**) and the β-Anomer (**10**)*

A solution of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-galactopyranosyl chloride (**6**) (13.0 g) (21) and 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (8.0 g) in DMF (210 ml) was kept at room temperature for 36 h. The resulting pale yellow solution was concentrated at a bath temperature of less than 50° to an oil which was dissolved in ether (500 ml). The ethereal solution was washed four times with water (300 ml). Evaporation of the ether left an oil which crystallized spontaneously on the addition of ethanol. Recrystallization from ethyl acetate – Skellysolve B gave the α-anomer (13.8 g, 80%); m.p. 171–172°; $[\alpha]_D^{23}$ +14° (*c*, 3.0 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.33; H, 6.28; N, 2.49. Found: C, 51.08; H, 6.05; N, 2.38.

Evaporation of the alcoholic mother liquors left an oil which crystallized on the addition of ether. Recrystallization from ethanol yielded the β-anomer (**10**) (0.3 g, 1.7%); m.p. 90–92°; $[\alpha]_D^{23}$ −94° (*c*, 2.6 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.33; H, 6.28; N, 2.49. Found: C, 51.13; H, 6.46; N, 2.59.

In a larger scale experiment this compound was obtained in 8.7% yield.

A solution of the oxime (**10**) (1.5 g) in acetonitrile (5 ml), hydrochloric acid (4 ml of 1 *N*) and acetaldehyde (1.5 ml) was kept at room temperature for 4 h. The product was isolated and reduced with sodium borohydride (10). Complete deacetylation of the product with triethylamine (0.5 ml) in aqueous methanol for 12 h at 0° yielded, on work-up, an oil which only showed one component on t.l.c. analysis using the upper phase of an ethyl acetate – dioxane–water (2:2:1) system as the developing solvent. Chromatography on Dowex 1-X2 (200–400 mesh OH^- form) gave an amorphous powder, $[\alpha]_D^{21}$ − 24.6° (*c*, 2 in DMF). Hydrolysis with dilute hydrochloric acid produced only talose and galactose. The compound was clearly different from 6-*O*-(α-D-talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose on the basis of t.l.c. comparisons. This evidence together with the n.m.r. data indicated that the compound was 6-*O*-(β-D-talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose.

6-O-(2-Acetoximino-tri-O-acetyl-α-D-lyxo-hexopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

A solution of 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (6.0 g) (**9**) in pyridine (18.0 ml) was cooled to 0° and acetic anhydride (3.0 ml) added. This solution was kept at 0° for 12 h and then concentrated to an oil which was dissolved in dichloromethane. The resulting solution was washed sequentially with water, dilute hydrochloric acid, water, saturated aqueous sodium bicarbonate solution, water and then evaporated to afford an oil (6.4 g); $[\alpha]_D^{23}$ +6.1° (*c*, 3.8 in chloroform).

Anal. Calcd. for $C_{26}H_{37}NO_{15}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.52; H, 6.00; N, 2.49.

*3-O-(Tri-O-acetyl-2-oximino-α-D-arabino-hexopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose (**11**)*

The product from the reaction of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (8.0 g) and dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) (13.0 g) (3) in DMF (210 ml) at room temperature for 36 h was chromatographed on silicic acid. The main component crystallized from ethyl acetate – Skellysolve B (10.2 g, 59%), m.p. 160–161°, $[\alpha]_D^{27}$ +66° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.33; H, 6.28; N, 2.49. Found: C, 51.14; H, 6.03; N, 2.31.

3-O-(2-Acetoximino-tri-O-acetyl-α-D-arabino-hexopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

The appropriate oxime **11** (4.0 g) was acetylated with acetic anhydride in pyridine and the product isolated as an oil. Crystallization from ether – Skellysolve B yielded the title compound (3.7 g, 86.6%), m.p. 102–104°, $[\alpha]_D^{23}$ +46° (*c*, 4 in chloroform).

Anal. Calcd. for $C_{26}H_{37}NO_{15}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.21; H, 6.20; N, 2.65.

*3-O-(Tri-O-acetyl-2-oximino-α-D-lyxo-hexopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose (**12**)*

A solution of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (8.0 g) and dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-galactopyranosyl chloride (**6**) (13.0 g) in DMF (210 ml) was kept at ambient temperature for 36 h. The product was isolated as an oil (22.0 g). Column chromatography on silicic acid yielded an oil which crystallized in 53% yield from ethyl acetate – Skellysolve B, m.p. 149–150°, $[\alpha]_D^{23}$ +62° (*c*, 1 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.01; H, 6.12; N, 2.26.

*3-O-(2-Acetoximino-tri-O-acetyl-α-D-lyxo-hexopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose (**17**)*

The oxime precursor (**12**) (4.09 g) was acetylated and the product was isolated as an oil which crystallized from ethyl acetate – Skellysolve B, (4.39 g), m.p. 134–135°, $[\alpha]_D^{23}$ +44.2° (*c*, 3.8 in chloroform).

Anal. Calcd. for $C_{26}H_{37}NO_{15}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.30; H, 5.99; N, 2.68.

*(Tri-O-acetyl-2-oximino-α-D-arabino-hexopyranosyl)-2,3;5,6-di-O-isopropylidene-α-D-mannofuranoside (**13**)*

The crude product isolated from the reaction of 2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranose (8.0 g) with dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) (13.0 g) in DMF (210 ml) was purified by column chromatography on silicic acid. The appropriate column fractions were combined and crystallized from ethanol, (7.0 g, 41%), m.p. 86–87°, $[\alpha]_D^{32}$ +87.9° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{24}H_{35}NO_{14}$: C, 51.33; H, 6.28; N, 2.49. Found: C, 51.06; H, 6.21; N, 2.44.

(2-Acetoximino-tri-O-acetyl-α-D-arabino-hexopyranosyl)-2,3;5,6-di-O-isopropylidene-α-mannofuranoside (23)

(Tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-2,3;5,6-di-*O*-isopropylidene-α-D-mannofuranoside **(13)** (6.2 g) was acetylated to provide an oil (6.5 g), $[\alpha]_D^{23}$ +99° (*c*, 3.3 in chloroform).

Anal. Calcd. for $C_{26}H_{37}NO_{15}$: C, 51.74; H, 6.18; N, 2.32. Found: C, 51.71; H, 6.22; N, 2.57.

The research was supported by a grant (A-172) to R.U.L. from the National Research Council of Canada. Technical assistance was provided by the spectroscopy and microanalytical service laboratories of this Department and by Miss P. Nayar and W. Merlo.

Isopropyl Tri-*O*-acetyl-α-D-hexopyranosulosides. The Configurations of the Parent Oximes[1]

R. U. LEMIEUX, R. A. EARL,[2] K. JAMES,[3] AND T. L. NAGABHUSHAN[4]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

A variety of methods are described for the deoximation of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**1**) to isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside (**3**). Using acetaldehyde in acetonitrile and hydrochloric acid, both **3** and its *lyxo*-isomer (**4**), from the corresponding oxime (**2**), were obtained in crystalline form. Comparisons of the chemical shifts of the anomeric hydrogens of the ulosides with those of the corresponding oximes require the oximes to possess the C-1/OH *syn*- or *Z*-configuration.

Diverses méthodes de déoximation de l'isopropyl tri-*O*-acétyl-oximino-2-α-D-*arabino*-hexopyranoside (**1**) en isopropyl tri-*O*-acétyl-α-D-*arabino*-hexopyranosuloside (**3**) sont décrites. En utilisant l'acétaldéhyde dans l'acétonitrile et l'acide chlorhydrique, **3** et son isomère *lyxo* (**4**) sont tous deux obtenus sous forme cristalline à partir de l'oxime correspondante **2**. Les comparaisons des déplacements chimiques des hydrogènes anomères des ulosides avec ceux d'oximes correspondantes impliquent une configuration C-1/OH *syn* ou *Z* pour les oximes. [Traduit par le journal]

Can. J. Chem. **51**, 19 (1973)

The reduction of tri-*O*-acetyl-α-D-hexopyranosulosides, which are obtained by deoximation of the readily prepared tri-*O*-acetyl-2-oximino-α-D-hexopyranosides (1, 2) promises to become a generally useful method for the preparation of a number of α-D-hexopyranosides (3–5). We wish to provide a proof of the configuration of the oximes obtained as intermediates and to describe methods for their deoximation to the ulosides.

The classical deoximation procedure utilizes a transoximation reaction in which a ketoxime or an aldoxime is treated with an excess of a hydroxylamine acceptor in the form of an aldehyde or ketone in the presence of a mineral acid. Hershberg (6) has recommended aqueous pyruvic acid buffered with sodium acetate as the reagent. DePuy and Ponder (7) have reported that excess levulinic acid in the presence of mineral acid is a highly satisfactory reagent and, in some cases, superior to pyruvic acid. Levulinic acid was used in our initial experiments (3) but, because of the problems associated with the separation of this compound from the product, a variety of other carbonyl compounds were examined including acetone, acetylacetone, pentane-2,4-dione, hexane-2,5-dione, benzaldehyde, and acetaldehyde.[5] Deoximation occurred in all cases and for obvious reasons of convenience attention was concentrated on the two simple aldehydes. Although complete deoximation could be effected with either compound, the reaction with acetaldehyde was much more rapid and has become our method of choice when the strongly acidic conditions are allowed. By using 1.3 equiv of acetaldehyde in acetonitrile containing 1 equiv of hydrochloric acid, the reaction is complete within 3 h at room temperature. Thus, the oxime **1** was converted to the uloside **3** isolated in the hydrated form in near quantitative yield. Dehydration and recrystallization provided **3** in 77% yield. The experience in converting **2** to **4** was similar. Since compounds **3** and **4** are the first examples of crystalline acetylated ulosides, their n.m.r. spectra are reproduced in Fig. 1. It is seen that the spectra are in complete accord with the structures assigned.

Recently, Timms and Wildsmith (8) reported a mild deoximation procedure involving reduction of oximes with trivalent titanium followed by hydrolysis of the resulting imine. Accordingly,

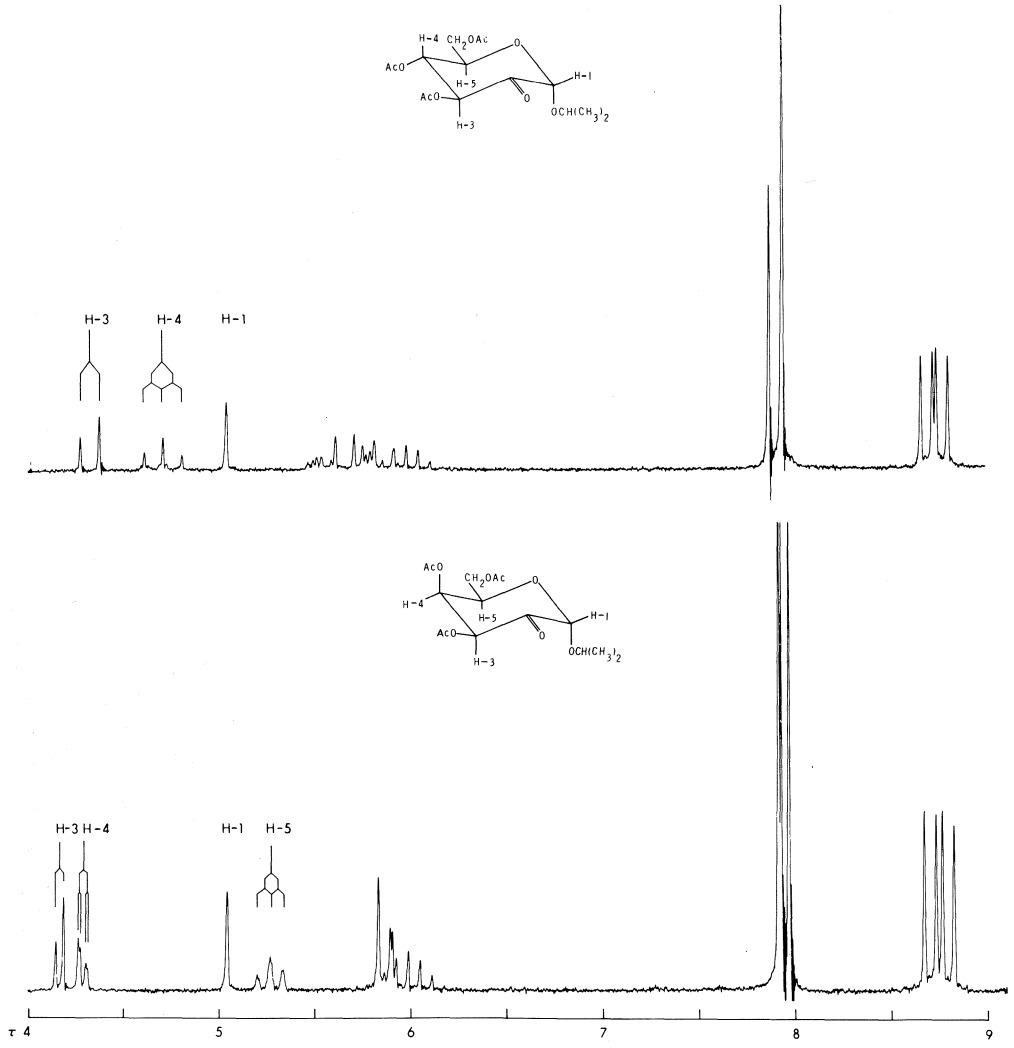

FIG. 1. The 100 MHz spectra of isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside (**3**) ($J_{3,4} = J_{4,5} = 10$ Hz) and isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranosuloside (**4**) ($J_{3,4} = 5.5$, $J_{4,5} = 1.5$ Hz) in deuteriochloroform.

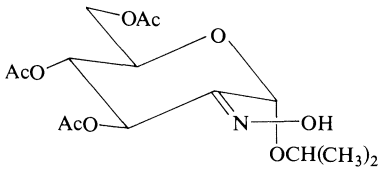
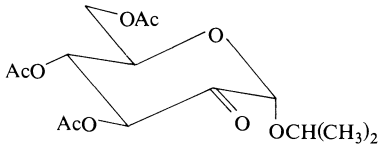
the oximinoglycoside **1** was treated with 6 equiv of 20% aqueous titanium trichloride solution in dioxane containing ammonium acetate. Crude uloside (**3**) was isolated in the same yield (90%) as using acetaldehyde and the purity was similar (t.l.c. and n.m.r.).

Deoximation of **1** by nitrous acid under the conditions reported by Wolfrom (9) for deoximation of acetylated *aldehydo*-sugar oximes was also examined. Although the crude uloside product (**3**) was of a high degree of purity, the yield was only 55%. This low yield was probably mainly related to problems of isolation from the aqueous acetic acid.

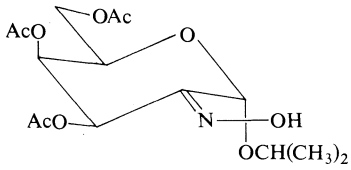
Reduction of the crude uloside preparations mentioned above using sodium borohydride in aqueous dioxane followed by deacetylation and purification by passing down a resin column in the hydroxide form (10) gave pure isopropyl α-D-glucopyranoside in 78, 75, and 71% yields using the acetaldehyde, titanium trichloride, and nitrous acid methods, respectively. It was found that isopropyl α-D-glucopyranoside could be recovered from the resin column in only 90% yield.



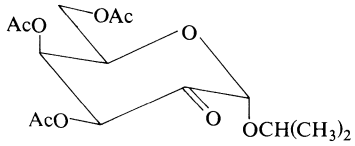
1



3



2



4

Thus, the actual yields of the glucoside from the reductions of the crude ulosides were 87, 84, and 79%, respectively. Using either the levulinic acid or acetaldehyde methods for deoximation and subsequent reduction of the crude uloside followed by acetylation, isopropyl tetra-*O*-acetyl-α-D-glucopyranoside was obtained in approximately 80% yield. Although chromatography on the basic resin appears wasteful in product, the quality of the separations achieved, especially for complex structures (11), strongly commends the method. The essentially neutral conditions present in deoximations using titanium trichloride have proven useful for preparing complex ulosides which possess highly acid-labile *O*-isopropylidene groups (5).

The oximinoglycosides **1** and **2** are shown in the C-1/OH *syn*-form which corresponds to the *Z*-form using the recently proposed nomenclature (12). This configuration was previously surmised (1) on theoretical grounds because of the stereoselectivity of the reaction and the fact that only one of the two possible forms was detected in the crude reaction products. Recent studies (13) of the conformational properties of 2-substituted cyclohexanone oximes have provided results in accordance with the predictions made. It was intended to obtain evidence by X-ray crystallography but a publication by Trager and Huitric (14) provided the basis for a simple n.m.r. proof of structure. It was pointed out that, when both the isomeric *syn*- and *anti*-forms of a six-membered cyclic oxime are available, the deshielding of an equatorially oriented vicinal hydrogen by the opposing oxime hydroxyl allows an assignment of configuration. This deshielding effect has been observed in other laboratories (13, 15, 16) and is similar to the deshielding of an axial hydrogen by a *syn*-axial oxygen atom (17). Thus, for example, Trager and Huitric found the equatorial hydrogens at the 2- and 6-positions of 4-*t*-butylcyclohexanone oxime to be chemically shifted by 0.91 τ-values. It occurred to us that, when only one form of an oxime is available, a decision could be reached by comparing the chemical shift of a vicinal equatorial hydrogen in the parent ketone with its shift in the oxime derivative. Thus, in the case of 4-*t*-butylcyclohexanone and its oxime, one of the vicinal hydrogens in the oxime produces its signal only 0.28 τ-values to lower field than H-2 (or H-6) of the ketone whereas the other is 1.19 τ-values to lower field. It seemed desirable to test this hypothesis by the comparison of a number of suitable model compounds.

Reaction of a mixture of the *cis*- and *trans*-4-*t*-butylcyclohexene oxides with benzyl alcohol in the presence of boron trifluoride occurred predominantly by axial attack to produce a mixture of the compounds **5** and **6** which were readily separated by fractional crystallization. Hydrogenolysis of both compounds gave the known *trans*-2-hydroxy-*cis*-4-*t*-butylcyclohexanol (18). The position of the benzyl group was established by first replacing the hydroxyl group of **6** by chlorine using phosphorus trichloride, then removing the benzyl group by hydrogenolysis and oxidizing the product to chloroketone. Finally, hydrogenolysis of the chloroketone produced 3-*t*-butylcyclohexanone.

O-Methylation of **5** followed by hydrogenolysis of the benzyl group produced *cis*-4-*t*-butyl-*trans*-

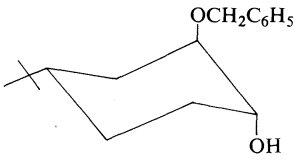
5



6

2-methoxycyclohexanol which was oxidized to the ketone **7**. Oxidation of **5** to *cis*-2-benzyloxy-5-*t*-butylcyclohexanone and reduction with sodium borohydride provided *cis*-2-benzyloxy-*cis*-5-*t*-butylcyclohexanol which was *O*-methylated. Removal of the benzyl group by hydrogenolysis followed by oxidation provided the ketone **10**. Oxidation of **7** provided both the isomeric oximes **8** and **9** but only the *E*-oxime **9** was obtained pure. Only the oxime **11** was detected in the product from **10**.

The chemical shifts for H-2 and -6 in equatorial orientations are presented as τ-values for compounds **7** to **11** alongside the symbols for these hydrogens in the formulas. The chemical shift shown for H-2 of the *Z*-oxime **8** was obtained from the n.m.r. spectrum of the crude reaction product. Consideration of these chemical shifts shows H-2 of **8** to be deshielded by 1.4 τ-values from the value for the parent ketone **7**. On the other hand, relatively little effect was observed on the chemical shift of H-6. It is seen that the reverse was found for the isomeric oxime **9**. In this case, it is H-6 that was strongly deshielded (about 0.9 τ-values) on oximation. The chemical shift of H-2 was decreased by only 0.3 τ-values. In contrast to the oximation of **7**, the ketone **10** provided only one detectable oxime, the expected (1, 13) *Z*-oxime **11**. The configuration of this oxime was evident from the fact that the oximation had a strong deshielding effect (0.9 τ-value) on the chemical shift of the equatorial H-6. It is seen that there was little effect on the chemical shift of the axial H-2.

In view of the above data, it can be concluded that the oximinoglycosides **1** and **2** possess the C-1/OH *syn*(*Z*)-configuration. This follows since the chemical shift of the equatorial anomeric hydrogen of **1** is 1.14 τ-values to lower field than that of the parent uloside **3** and that of the oximinoglycoside **2** is 1.34 τ-values to lower field than that of the parent uloside **4**. Furthermore, treatment of the uloside **3** with hydroxylamine under buffered conditions provided **1** in high yield. As previously pointed out (1), the steric requirements for C-1/OH *syn*-oxime formation is likely an important component of the driving force responsible for the high stereoselectivity of α-oximinoglycoside formation.

It may be noted that a number of other 2-substituted 4-*t*-butylcyclohexanones and their oximes were prepared (19) and all provided n.m.r. spectra in accord with expectations based on the above findings.

Experimental

Deoximation Reactions

Except for the reaction using titanium trichloride, the course of the reaction was followed by t.l.c. on silica gel G with ether – Skellysolve B (3:2) as the developing solvent and the product isolated after the presence of the oxime could not be detected. In all cases, the n.m.r. spectrum of the crude product required a high degree (> 90%) of purity.

(a) Using Levulinic Acid

The oxime (**1**) (1) (1.08 g) was dissolved in acetic acid (2 ml), levulinic acid (1.74 g) and 1 *N* hydrochloric acid (3 ml) were added. The solution was maintained at room temperature. The reaction was complete after 3 h. The solution was diluted with methylene chloride and the organic layer washed free of acid with water and then sodium bicarbonate solution. The solution was dried and evaporated to an oil (0.94 g, 90%).

(b) Using Acetaldehyde

A solution of **1** (2.00 g) in acetonitrile (6 ml) and 1 *N* hydrochloric acid (4.8 ml) containing acetaldehyde (0.4 ml) was kept at room temperature for 3 h after which time the reaction was complete. The resulting solution was diluted with ethyl acetate (15 ml) and the aqueous layer was extracted with a further portion of ethyl acetate (15 ml). The combined ethyl acetate extracts were washed once with water (10 ml), dried, and evaporated to yield a clear oil (1.80 g, 94%).

(c) Using Titanium Trichloride

Ammonium acetate (4.0 g) was added to a stirred solution of (**1**) (2.0 g) in dioxane (20 ml). Nitrogen was bubbled through the solution to maintain a nitrogen atmosphere and a 20% aqueous solution of titanium trichloride (10 g) was added dropwise. After 3 h, further portions of dioxane (20 ml), ammonium acetate (4.0 g), and titanium trichloride (10 g) were added. The suspension was stirred for a further 2 h prior to extraction with methylene chloride (160 ml). The methylene chloride

For personal use only.

layer was successively washed with water, sodium bicarbonate solution, water, and dried. Solvent removal left a clear oil (1.8 g, 94%).

(d) Using Nitrous Acid

The oxime **1** (2.00 g) was dissolved in glacial acetic acid (38 ml) and a solution of sodium nitrite (7.7 g) in water (15 ml) was added dropwise over 10 min. After 2 h, this addition of sodium nitrite solution was repeated and the stirring continued for a further 1 h. Deoximation was then complete (t.l.c.) and methylene chloride (150 ml) was added. The organic layer was washed successively with water, sodium bicarbonate solution, water, and dried. Solvent removal left a clear oil (1.10 g, 57%).

The above described crude preparations of the uloside **3** were examined as follows.

(i) Conversion to Isopropyl Tetra-O-acetyl-α-D-glucopyranoside

The crude uloside (**3**) was dissolved in a 1:1 mixture of dioxane and water (5 ml/g) and an ice-cold solution of sodium borohydride in the same solvent (1 g/4 ml) was added dropwise to the stirred solution kept below 5°. After standing in an ice-water bath for 0.5 h, the solution was left at room temperature for 2 h. The excess borohydride was decomposed with acetone and the solution deionized with Amberlite MB3. The residue obtained on solvent removal was acetylated with acetic anhydride in pyridine in the usual manner. The crude uloside (**3**) obtained by using levulinic acid provided an 80% overall yield of pure isopropyl tetra-*O*-acetyl-α-D-glucopyranoside (3). The acetaldehyde procedure gave an 81% overall yield.

(ii) Conversion to Isopropyl α-D-Glucopyranoside

The sodium borohydride reduction was performed as described above and the deionized solution was added to a Dowex 1-X2 (200–400 mesh, OH^- form) column (30 in. × 1 in.) and eluted with water. The overall yields using the acetaldehyde, titanium trichloride, and nitrous acid procedures were 73, 70, and 40%, respectively. The yields from crude uloside were 78, 75, and 71%, respectively.

Pure isopropyl α-D-glucopyranoside (1.24 g) was added to the basic resin column and recovered in 90% yield.

Isopropyl Tri-O-acetyl-α-D-arabino-hexopyranosuloside (3)

A solution of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**1**) (20 g) in acetonitrile (60 ml) and 1 *N* hydrochloric acid (48 ml) containing acetaldehyde (4 ml) was stored at room temperature for 3 h. The resulting solution was diluted with ethyl acetate (150 ml), and the aqueous layer was extracted with a further portion of ethyl acetate (50 ml). The combined ethyl acetate extracts were washed once with water (100 ml) and evaporated to yield a clear oil (16 g, essentially pure as shown by t.l.c.). The oil was dehydrated by azeotropic distillation using 200 ml of benzene for 4 h. Solvent removal left an oil which crystallized on storage. Recrystallization from ether – Skellysolve B provided a slightly sticky precipitate (14.8 g, 77%). The analytical sample, m.p. 88.5–89.5°, $[\alpha]_D^{28}$ +40.5° (*c*, 1.3 in chloroform), was obtained by recrystallization from ether at −25°. The n.m.r. spectrum is shown in Fig. 1.

Anal. Calcd. for $C_{15}H_{21}O_9$: C, 52.17; H, 6.13. Found: C, 52.24; H, 6.30.

Isopropyl Tri-O-acetyl-α-D-lyxo-hexopyranosuloside (4)

A solution of isopropyl tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranoside (**2**) (8.5 g) in acetonitrile (25 ml) and 1 *N* hydrochloric acid (20 ml) containing acetaldehyde (1.75 ml) was kept at room temperature for 3 h. The product was isolated and dehydrated as described above to afford an oil (7.5 g) (highly pure by n.m.r. and t.l.c.) which crystallized from ether to yield the pure ketone (3.0 g), m.p. 97.5–98.5°, $[\alpha]_D^{28}$ +89.5° (*c*, 0.79 in chloroform).

Anal. Calcd. for $C_{15}H_{21}O_9$: C, 52.17; H, 6.13. Found: C, 51.94; H, 6.15.

Oximation Reactions

The p*H* of a solution of sodium acetate (1 g) and hydroxylamine hydrochloride (0.5 g) in water (5 ml) was adjusted to 4.5 using glacial acetic acid. Isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside (**3**) (0.40 g) was then added and the solution was kept at room temperature for 1 h. Dichloromethane (10 ml) was added and the organic layer was washed sequentially with water, saturated aqueous sodium bicarbonate solution, and water. Evaporation left an oil (0.40 g) which crystallized from isopropanol. The product (0.35 g, 84%) was indistinguishable from an authentic sample of **1** (1).

Starting with isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranosuloside (**4**) and using the above procedure, the oxime **2** was isolated in 80% yield. The syrupy compound was identical with an authentic sample of **2** (1).

trans-2-Benzyloxy-trans-5-t-butylcyclohexanol and trans-2-Benzyloxy-cis-4-t-butylcyclohexanol

The procedure of Jones and coworkers (20) was used to prepare a mixture of the *cis*- and *trans*-4-*t*-butylcyclohexene oxides except that methylene chloride was used as the solvent with a 30% excess of peracetic acid. The yield of the mixture was 83%.

The mixture (210 g, 1.4 mol) was added dropwise during 40 min to a cold stirred solution of boron trifluoride etherate (3.5 ml) in freshly distilled benzyl alcohol (800 ml, 7.7 mol). The temperature was maintained in the range 7–13°. After the addition was complete, the somewhat viscous mixture was stirred for a further 10 min at room temperature, and then 6 *N* aqueous ammonia (15 ml) and 1 l of ether were added. The solution was washed with water (100 ml), saturated sodium chloride solution (30 ml), and concentrated. The residue was fractionally distilled to a product (319.2 g, 90%), b.p. 128–139°/0.08–0.12 mm, which crystallized. Analysis by g.c. on a 5 ft × 0.25 in. column of 15% ethylene glycol succinate on non-acid washed Chromosorb W (30–60 mesh) at 205° gave two overlapping peaks with retention times of 27.0 and 28.6 min, respectively, in the ratio of 3:2.

The crystalline material was separated into its components by fractional crystallization from Skellysolve B. The more abundant and faster moving (g.c.) isomer crystallized out first. Two recrystallizations yielded pure *trans*-2-benzyloxy-*cis*-4-*t*-butylcyclohexanol, m.p. 61–64°. The n.m.r. spectrum showed 1H multiplets at τ 6.16 (half-band width 7.5 Hz) and 6.44 (half-band width 7.5 Hz) that are assigned to the hydrogens geminal to the benzyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

oxy and hydroxy groups. The small half-band widths require that both of these hydrogens be equatorial.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99. Found: C, 77.63; H, 9.71.

The isomeric *trans*-2-benzyloxy-*trans*-5-*t*-butylcyclohexanol crystallized, on concentrating the mother liquor, in the form of a voluminous precipitate. Five recrystallizations were required to achieve purity, m.p. 79.5–81.7°. The n.m.r. spectrum showed 1H multiplets at τ 6.01 (half-band width 10 Hz) snd 6.6 (half-band width 8 Hz) that are attributed to equatorial hydrogens geminal to the benzyloxy and hydroxy groups.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99. Found: C, 78.01; H, 9.79.

A suspension of *trans*-2-benzyloxy-*cis*-4-*t*-butylcyclohexanol (300 mg, 1.15 mmol) (**6**), 5% palladium-on-carbon (100 mg), and concentrated hydrochloric acid (0.1 ml, 1.2 mmol) in 90% ethanol (10 ml) was hydrogenated for 18 h. The reaction mixture was filtered through Celite, and the filtrate concentrated to a solid material (197 mg, 100%) which was crystallized twice from acetone – Skellysolve B. The white platelets (150 mg) melted at 143.5–146° (lit. (17), m.p. 141–142°).

De-*O*-benzylation of *trans*-2-benzyloxy-*trans*-5-*t*-butylcyclohexanol (**5**) as described above produced a product, m.p. 144–146°, identical to the product obtained from **6**.

Proof of the Structure of trans-2-Benzyloxy-cis-4-t-butylcyclohexanol (6)

(a) trans-2-Benzyloxy-cis-4-t-butylcyclohexyl Chloride

Trans-2-benzyloxy-*cis*-4-*t*-butylcyclohexanol (**6**) was chlorinated using the procedure of Bridgewater and Shoppee (21). A solution of **6** (4 g, 15.3 mmol) in dry Skellysolve B (10 ml) was added, dropwise during 25 min, to a cold (0°) stirred suspension of phosphorus pentachloride (7 g, 33.6 mmol) and anhydrous calcium carbonate (5 g) in Skellysolve B (30 ml). After addition, the mixture was stirred for 1.6 h at room temperature and then washed with ice-water. The organic layer was separated and the aqueous layer extracted twice with Skellysolve B (2 × 10 ml). The extracts were combined and washed with saturated aqueous sodium bicarbonate solution and then concentrated. Distillation of the residue yielded a colorless chlorine-containing oil (3.57 g, 86%), b.p. 105–106°/0.05 mm. The n.m.r. spectrum showed narrow 1H multiplets at τ 6.03 and 6.5 attributed to the hydrogens geminal to the benzyloxy and chloro groups. The half-band width (7 Hz) of these signals indicated that both of these hydrogens were equatorial.

Anal. Calcd. for $C_{17}H_{25}ClO$: C, 72.70; H, 8.97. Found: C, 72.63; H, 8.87.

(b) trans-5-t-Butyl-trans-2-chlorocyclohexanol

A suspension of *trans*-2-benzyloxy-*cis*-4-*t*-butylcyclohexyl chloride (3.02 g, 10.6 mmol), anhydrous sodium acetate (1.64 g, 20 mmol), and 5% palladium-on-carbon (300 mg) in glacial acetic acid (15 ml) was hydrogenated for 18 h. The reaction mixture was filtered through Celite and then partitioned between water (100 ml) and methylene chloride (3 × 20 ml). The methylene chloride extracts were combined, washed with water, and concentrated to a crystalline residue. Recrystallization from Skellysolve B gave 1.67 g (80%) of material, m.p. 76–78.5°. A sample was recrystallized twice from Skellysolve B to give colorless crystals, m.p. 78.5–80° (lit. (22), m.p. 74–76°). The 60 MHz n.m.r. spectrum in carbon tetrachloride was in agreement with the published data (22) and the compound contained chlorine.

Anal. Calcd. for $C_{10}H_{18}ClO$: C, 63.31; H, 9.56. Found: C, 63.19; H, 10.09.

(c) cis-5-t-Butyl-2-chlorocyclohexanone

A solution of *trans*-5-*t*-butyl-*trans*-2-chlorocyclohexanol (1.0 g, 5.2 mmol) in acetone (5.9 ml) was cooled to 0° and chromic acid (2 ml of a 3 *M* aqueous solution) was added dropwise with stirring. After 10 min, the reaction mixture was partitioned between cold water (10 ml) and Skellysolve B (10 ml). The organic layer was washed twice with water followed by saturated sodium bicarbonate solution and then concentrated to a clear oil (0.99 g). The i.r. spectrum showed a sharp carbonyl absorption at 1725 cm^{-1}, but no absorption for hydroxyl group. This compound was used without further characterization.

(d) 3-t-Butylcyclohexanone

A suspension of the α-chloroketone obtained above (0.99 g, 5.2 mmol), anhydrous sodium acetate (0.434 g, 5.3 mmol), and 5% palladium-on-carbon (0.25 g) in anhydrous methanol (10 ml) was stirred under an atmosphere of hydrogen until it absorbed 80 ml and the solids were then removed by filtration through Celite. The filtrate was concentrated to 3 ml, diluted with methylene chloride (10 ml), and washed once with saturated sodium bicarbonate solution and then evaporated to an oil. Short path distillation of the residue yielded ketonic material (0.51 g, 64%) (carbonyl absorption at 1718 cm^{-1}). The 2,4-dinitrophenyl hydrazone derivative melted at 164–166° (lit. (23), m.p. 161–162.5°), the semicarbazone at 207–208° (dec.) (lit. (24), m.p. 205–206°).

trans-4-t-Butyl-2-methoxycyclohexanone (7)

Trans-2-benzyloxy-*trans*-5-*t*-butylcyclohexanol (**5**) was methylated using the procedure of Eades and coworkers (25). A near quantitative yield of a clear oil (b.p. 80–85°/0.05 mm) was obtained.

Anal. Calcd. for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21. Found: C, 78.50; H, 10.28.

The oil, 9.11 g, was dissolved in 250 ml of 95% ethanol containing 2 ml of concentrated hydrochloric acid and the stirred solution subjected to 1 atm of hydrogen in the presence of 0.6 g of 5% palladium-on-charcoal for 17 h. The usual work-up provided 5.75 g (88%) of an oil (b.p. 55–63°/0.06 mm). The n.m.r. spectrum agreed with that expected for *cis*-4-*t*-butyl-*trans*-2-methoxycyclohexanol and provided a phenylurethane derivative, m.p. 152–153°.

Oxidation of 5.0 g of the above alcohol under the conditions described above for the oxidation of *trans*-5-*t*-butyl-*trans*-2-chlorocyclohexanol provided 4.73 g (96%) of liquid, b.p. 90–100°/15–20 mm.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.49; H, 11.16.

The i.r. spectrum showed a sharp carbonyl absorption at 1726 cm^{-1}. The n.m.r. spectrum showed the expected signals for the methoxy and *t*-butyl groups at τ 6.75 and 9.15, respectively. The 1H multiplet, half-band width 7 Hz, at τ 6.53 was assigned to the equatorial H-2. A multiplet centered at about τ 7.7 was assigned to the equatorial H-6.

trans-4-t-Butyl-2-methoxycyclohexanone oxime (E-) (9)

Standard oximation procedure provided a near

quantitative yield of crude oxime as gummy solid. Sublimation at 50°/0.02 mm gave a crystalline solid which had the large melting point range, 64–81°, after recrystallization from methanol water. The n.m.r. spectrum and composition were consistent with that expected for a mixture of the *syn-* (*Z-*) (**8**) and *anti-* (*E-*) (**9**) oximes. Narrow multiplets (half-band widths of 7 Hz) were present at τ 5.10 and 6.18 which were assigned to the equatorial H-2 atoms of **8** and **9**, respectively. Resublimation and recrystallization provided a 55% overall yield of a solid, m.p. 66–73° which appeared (n.m.r.) to be about 85% pure **9**. A broad near 1H multiplet centered at about τ 6.8 which was superimposed on the methoxy group signal was assigned to the equatorial H-6 of **9**.

Anal. Calcd. for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03. Found: C, 66.41; H, 10.82; N, 7.31.

*cis-4-t-Butyl-2-methoxycyclohexanone (**10**)*

Oxidation of *trans*-2-benzyloxy-*trans*-5-*t*-butylcyclohexanol (**6**) with chromic acid as described above gave *cis*-2-benzyloxy-5-*t*-butylcyclohexanone (b.p. 85–90°/0.07 mm) in near quantitative yield. Reduction of this ketone with sodium borohydride in aqueous tetrahydrofuran under the usual conditions provided an oil which appeared to be about a 1:5 mixture of isomers. The major component crystallized on cooling and after three recrystallizations from Skellysolve B there resulted *cis*-2-benzyloxy-*cis*-5-*t*-butylcyclohexanol of high purity, m.p. 55.5–58°.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99. Found: C, 78.08; H, 9.96.

The n.m.r. spectrum was in complete accord with the assigned structure and configuration.

Methylation of the above alcohol using methyl iodide and sodium hydride in tetrahydrofuran (25) gave a near quantitative yield of a liquid, b.p. 65–70°/0.02 mm, which was hydrogenated under the conditions described above for the preparation of the isomeric *cis*-4-*t*-butyl-*trans*-2-methoxycyclohexanol. The overall yield was near quantitative of a liquid with a sweet odor, b.p. 60°/0.06 mm. The n.m.r. spectrum showed signals for a methoxy group (τ 6.63), an hydroxy group (τ 7.64) and a *t*-butyl group (τ 9.17) as expected for *cis*-4-*t*-butyl-*cis*-2-methoxycyclohexanol.

Anal. Calcd. for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90. Found: C, 70.73; H, 11.61.

Chromic acid oxidation (26) provided the title compound (**10**).

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.64; H, 10.99.

The i.r. spectrum possessed the expected sharp carbonyl absorption at 1726 cm^{-1} and t.l.c. showed the ketone to be free of the parent alcohol. The n.m.r. spectrum was in complete accord with the expected structure. The half-band width of 20 Hz observed for the signal of H-2 at τ 6.22 is in accord with the assigned configuration.

*cis-4-t-Butyl-2-methoxycyclohexanone oxime (E-) (**11**)*

The crystalline oxime was readily obtained and appeared pure after two recrystallizations from methanol–water and a sublimation at 80°/0.04 mm. The yield was 66% of material melting at 166–168°.

Anal. Calcd. for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03. Found: C, 66.47; H, 10.48; N, 7.29.

The n.m.r. spectrum was in support of the assigned structure. The 1H quartet at τ 6.28 had spacings, 5 and 9 Hz in accord with an axial H-2. A narrow (half-band width 7 Hz) multiplet at τ 6.84 was assigned to the equatorial H-6.

The financial support of the National Research Council of Canada through a grant-in-aid of research (A-172) to R.U.L. is gratefully acknowledged. The microanalyses and n.m.r. spectra were carried out by the analytical and spectral services laboratories of this department.

Reduction of α-D-Hexopyranosulosides[1]

R. U. LEMIEUX, K. JAMES,[2] AND T. L. NAGABHUSHAN[3]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 2, 1972

Reduction of isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside with sodium borohydride or diborane leads almost exclusively to the *gluco*-configuration. Catalytic reductions, on the other hand, provide an epimeric mixture with the *manno*-configuration predominating in ratios of about 2:1. The reduction of isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranosuloside with either sodium borohydride or diborane is less stereoselective than in the case of the *arabino*-isomer and leads to compounds of the *galacto*- and *talo*-configurations in the ratio of 3:2. The latter is formed highly stereoselectively when the lyxosuloside derivative is hydrogenated catalytically.

2-*O*-(α-D-Mannopyranosyl)-glycerol and the *gluco*-isomer are synthesized.

La réduction de l'isopropyl tri-*O*-acétyl-α-D-*arabino*-hexopyranosuloside par le borohydrure de sodium ou le diborane conduit presqu'exclusivement à la configuration *gluco*. Les réductions catalytiques donnent d'autre part, un mélange d'épimères avec la configuration *manno* prédominante dans des rapports de 2:1 environ. La réduction de l'isopropyl tri-*O*-acétyl-α-D-*lyxo*-hexopyranosuloside soit avec le borohydrure de sodium soit avec le diborane est moins stéréosélective que dans le cas de l'isomère *arabino* et conduit aux composés de configuration *galacto* et *talo* dans le rapport 3:2. Ce dernier est formé de façon hautement stéréosélective lorsque le dérivé lyxosuloside est hydrogéné catalytiquement.

Le *O*-(α-D-mannopyranosyl)-2 glycérol et l'isomère *gluco* ont été synthétisés.

In a previous publication (1), we reported the facile deoximations of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside and its *lyxo*-isomer to the corresponding keto-sugars **1** and **2**, respectively, which were characterized as crystalline compounds. Reductions of these ulosides to glycosides under a variety of conditions have now been examined. The promise of this approach for the synthesis of α-glucopyranosides was reported in a preliminary communication (2) where it was shown that the reduction of crude isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside (**1**) by sodium borohydride followed by *O*-acetylation led to isopropyl tetra-*O*-acetyl-α-D-glucopyranoside in an overall yield of 80% from the oxime precursor.

The purpose of this paper is to report details of this work and to extend the method to preparations of α-D-mannopyranosides, α-D-galactopyranosides, and α-D-talopyranosides.

As previously reported (2, 3), reduction of **1** with sodium borohydride gave isopropyl α-D-glucopyranoside, isolated as the tetraacetate, in high yield (see Table 1). The *manno*-isomer was formed only in about 4% yield. Reduction of **1** with diborane in tetrahydrofuran was equally stereoselective but, in practice, the use of sodium borohydride is more convenient. The high stereoselectivity for the *gluco*-configuration has permitted convenient syntheses of a number of α-linked disaccharides (4) and kanamycin analogs (5).

The synthesis of α-D-mannopyranosides (6) is of considerable interest in view of the widespread natural occurrence of the α-D-mannopyranosyl units. In addition to their presence in a variety of mannans such as yeast mannan (7, 8) and ivory nut mannan (9), and the red algae *furcellario fastigiata* (10), the α-D-mannopyranosyl groups are found in a number of glycolipids (11) and teichoic acids of bacterial cell walls (12). Recently another naturally occurring antibiotic was shown to contain an α-D-mannopyranosyl unit (13), namely, 2-amino-2-deoxy-α-D-glucopyranosyl α-D-mannopyranoside (14), an epimer of the antibiotic trehalosamine.

Acid-catalyzed alcoholysis of D-mannose provides α-D-mannopyranosides but is virtually limited to simple alcohols that can be used as

solvents (15). Since the tetra-*O*-acyl-D-mannopyranosyl halides are only available in the α-configuration and the C_2-acyloxy group is well disposed for participation in the replacement of the *trans*-axial-1-halogen atoms, the so-called acylhalogenomannoses are highly prone to orthoester formation (6, 16). However, the presence of non-participating *O*-substituents at the 2-position has provided a useful synthesis of β-D-mannopyranosides (17). Efforts in this laboratory (18) to obtain α-D-mannopyranosides from the corresponding 1,2-orthoacetyl derivatives have not succeeded under conditions which were partially successful with 1,2-orthoacetyl derivatives of D-glucopyranose (19). However, a recent publication by Franks and Montgomery (20) reports acid-catalyzed rearrangement of tri-*O*-benzyl-β-D-mannopyranose 1,2-(alkyl orthoacetates) to the α-D-mannopyranoside derivatives in yields ranging between 74–79%. Yet another method for the synthesis of α-D-mannopyranosides was demonstrated by Ferrier and Prasad (21). These authors synthesized, although in low overall yield, 6-*O*-α-D-mannopyranosyl-α-D-galactose by reaction of 1,2:3,4-di-*O*-isopropylidene-α-D-galactose with tri-*O*-acetyl-2-deoxy-1,5-anhydro-D-*arabino*-hex-1-enitol (tri-*O*-acetyl-D-glucal) in the presence of boron trifluoride dietherate followed by *cis*-hydroxylation of the resulting 2,3-unsaturated glycoside with aqueous permanganate and then removal of the protecting groups.

It was anticipated that catalytic hydrogenation of **1** may tend to favor formation of the axial alcohol. As seen in Table 1, this was the case for reductions using palladium, ruthenium, and rhodium catalysts. Although the synthesis of an α-D-mannopyranoside by this procedure will require the separation of the epimers, it can provide a useful approach. This is illustrated by the preparation of 2-*O*-(α-D-mannopyranosyl) glycerol (**3**), a compound previously prepared by Charlson and coworkers (7) by degradation of 2-*O*-(α-D-mannopyranosyl)-D-mannose.

The 2-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*O*-benzoyl glycerol was obtained in 71% yield. Deoximation followed by hydrogenation over palladium-on-carbon gave a product which was deacylated. The n.m.r. spectrum showed two glycosidic components in the ratio 1.7:1 with doublet signals for anomeric hydrogens τ 4.83 (spacing 1.75 Hz) and 4.77 (spacing 3.75 Hz), respectively. The product was chromatographed on a Dowex 1-X2 column in the hydroxide form (22) to provide a 42% yield of the major product which liberated mannose and glycerol on acid hydrolysis. The product from

6

periodate oxidation of this component liberated glycerol on acid hydrolysis and the compound is therefore assigned the structure 2-*O*-(α-D-mannopyranosyl)-glycerol (**3**). The specific rotation, 75°, was substantially higher than that, 51°, previously reported (7) for this compound. The hydrolysis and periodate oxidation – hydrolysis data for the other glycosidic component which was obtained in 20% yield allowed assignment of the structure to be 2-*O*-(α-D-glucopyranosyl)-glycerol (**4**). The specific rotation, 122°, was in good agreement with that, 121°, previously reported (7).

The products of the hydrogenation of **1** were isolated as their 3,4,6-tri-*O*-acetyl derivatives by column chromatography. The n.m.r. spectra required high purity and the free hydroxyl is expected to be at the 2-position for both compounds in view of the mode of preparation. The glucose derivative possessed the same n.m.r. spectrum as an authentic sample prepared by treating tri-*O*-acetyl-α-D-glucopyranose 1,2-(ethyl orthoacetate) with isopropanol in methylene chloride containing toluenesulfonic acid (19).

α-D-Galactopyranosyl units are found as building blocks of the capsular substances of pneumococci (23) and the blood group B substances (24). For these reasons, a practical synthesis of α-D-galactopyranosides is becoming of increasing importance and the reduction of α-D-*lyxo*-hexopyranosulosides was examined in this regard.

The reduction of an α-*lyxo*-hexosuloside either with sodium borohydride or diborane proved much less stereoselective than the similar reductions of the *arabino*-isomer. For example, starting from **2**, a mixture of the galacto- (**5**) and talopyranoside (**6**) in about 3:2 ratio, respectively, was obtained (see Table 1). Undoubtedly, this result is related to a hindrance by the axial 4-substituent in **2** to axial attack by the hydride to provide equatorial C_2-hydroxyl. Nevertheless, when combined with the powerful means for separation available by chromatography, especially on resin columns (22, 25), the method is considered to provide a synthetic route to α-D-galactopyranosides of high utility.

Although α-talosides are not widely distributed in nature, the α-D-talopyranosyl group is linked to the *N*-methyldeoxystreptamine residue in the antibiotic hygromycin B_2 (26). In view of this, an α-taloside synthesis by way of reduction of tri-*O*-acetyl-α-D-*lyxo*-hexopyranosulosides could be of synthetic importance. As seen in Table 1, catalytic hydrogenation of isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranosuloside can increase the ratio of *talo*- (**6**) to *galacto*- (**5**) isomer to as high as 4:1.

The above described hexosides were characterized by hydrolysis to the hexoses and by n.m.r. Table 2 reports n.m.r. parameters for the four isopropyl tetra-*O*-acetyl-α-D-hexopyranosides. The assignments of the signals for compounds **5** and **6** were made possible by reduction of **2** with sodium borodeuteride to produce the 2-deuterio derivatives.

Experimental

Melting points were determined in capillary tubes and are uncorrected. Optical rotations were measured in a 1 dm tube with a Perkin–Elmer Model 141 polarimeter. N.m.r. spectra were taken on Varian HA100 spectrometer. Chemical shifts are given in τ-values and refer to spectra measured either in deuteriochloroform using tetramethylsilane (TMS) as the internal standard or in deuterium

oxide using the same reference compound as the external standard.

G.c. was carried out with an F and M Model 500 gas chromatograph using a 6 ft column packed with LP 45 (ethylene glycol adipate 1.5%) on acid washed chromosorb W, 60–80 mesh at 175° (27). Although the actual yields of the glycosides prepared under the various conditions reported in Table 1 were not determined, separations of synthetic mixtures of pure samples established the reliability of the ratios measured. The starting materials (**1** and **2**) survived the g.c. and were not present in the chromatograms of the products of hydrogenation. In all cases, t.l.c. examination of the acetylated reduced products gave no indication of components other than the acetylated glycosides.

Column chromatography was performed on silicic acid, CC7, 100–200 mesh (Mallinckrodt Chemical Works, St. Louis, Mo.), using 10 g per gram of compound and t.l.c. on Silica Gel G (E. Merck A.G., Darmstadt) using 20 cm^2 plates. The spots were visualized by spraying the plates with a solution of chlorosulfonic acid (10%, v/v) in glacial acetic acid and then heating in an oven at 120°. The descending paper chromatograms on Whatman No. 1 paper were developed with *n*-butanol – pyridine–water – acetic acid (6:4:3:1), and visualized by spraying with alkaline silver nitrate. The R_f values for glucose, mannose, galactose, and talose were 0.4, 0.48, 0.35, and 0.58, respectively.

Solutions were dried over magnesium sulfate and all solvent removals were carried out *in vacuo* using a rotary evaporator.

The hydrogenation catalysts were purchased from Engelhardt Industries, Newark, New Jersey. Diborane in THF was bought from Alfa Inorganics, Beverly, Massachusetts.

*Reduction of Isopropyl Tri-O-acetyl-α-D-arabino-hexopyranosuloside(**1**)*

(a) By Sodium Borohydride

A solution of **1** (1) (0.5 g) in dioxane (8 ml) and water (1 ml) was cooled to 0° and sodium borohydride (50 mg) was then added in small portions, while maintaining the temperature at 0°. The resulting solution, after being stirred for 30 min at 0° and then for 3 h at room temperature, was cooled to 0° and neutralized with glacial acetic acid. Evaporation of the solution yielded a white solid which was acetylated with acetic anhydride in pyridine (10 ml of a 1:1 mixture) at 0°. Isolation of the product by standard procedures yielded an oil which crystallized on storage. G.c. analysis of the crude acetylated mixture is reported in Table 1. Recrystallization from 95% ethanol afforded pure isopropyl tetra-*O*-acetyl-α-D-glucopyranoside, m.p. 86–87°, $[\alpha]_D^{24}$ +145° (*c*, 1.6 in chloroform) in 85% yield (lit. (28), m.p. 86–88° (corr.), $[\alpha]_D$ +145° (*c*, 2 in chloroform)). The n.m.r. spectrum of the crystalline compound (Table 2) was identical with that of an authentic sample and the melting point of an admixture of the two was not depressed.

(b) By Diborane

A solution of **1** (3.4 g) was dissolved in tetrahydrofuran (15 ml) and cooled to 0°. Diborane (40 ml of a molar solution in tetrahydrofuran) was then added at such a rate as to maintain the temperature at 0°. On completion of the addition, the temperature of the solution was allowed to rise to room temperature and the mixture was then set aside for 24 h. The solution was again cooled to 0° and excess methanol was added with caution. The solution was concentrated to dryness, dissolved in methanol, and re-evaporated in order to remove methyl borate. This procedure was repeated three more times. The residual oil was dried and acetylated with acetic anhydride in pyridine (20 ml of a 1:1 mixture) at 0°. Isolation of the product by normal procedures afforded a pale yellow oil which was crystallized from ether – Skellysolve B. G.c. analysis of the crude product is reported in Table 1. Recrystallization from 95% ethanol gave pure isopropyl tetra-*O*-acetyl-α-D-glucopyranoside, m.p. 86–87° and $[\alpha]_D^{24}$ +144° (*c*, 1.65 in chloroform), in 85% yield.

(c) By Catalytic Hydrogenation

A solution of **1** (2.0 g) in 95% ethanol (40 ml) was hydrogenated in the presence of 5% by weight of catalyst (Table 1) at 60 p.s.i. and room temperature for 24 h. The catalyst was removed by filtration through a Celite bed and the filtrate concentrated to a mobile oil (1.77 g). T.l.c. examination of the oil using ether – Skellysolve B (3:2) as the developing solvent showed the presence of two components, the one with lower mobility being the major component.

A 50-mg portion of the above oil was acetylated with pyridine and acetic anhydride (1 ml of 1:1 mixture). The crude product isolated in the usual manner was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

examined by t.l.c. and analyzed by g.c. The results are presented in Table 1.

The remaining portion of the oil (1.72 g) was chromatographed on silicic acid using ether – Skellysolve B (3:2) as the developing solvent on a column of 2.5 cm diameter and the eluate was monitored by t.l.c. using the same solvent system. The two compounds were isolated as syrups by removal of the solvents. The faster moving compound, $[\alpha]_D^{28}$ +142° (*c*, 1.86 in chloroform) had an n.m.r. spectrum identical to an authentic sample of isopropyl 3,4,6-tri-*O*-acetyl-α-D-glucopyranoside (19) and was converted by acetylation to crystalline isopropyl tetra-*O*-acetyl-α-D-glucopyranoside characterized as mentioned above.

The slower moving compound, $[\alpha]_D^{28}$ +83° (*c*, 1.23 in chloroform) possessed an n.m.r. spectrum consistent with that expected for isopropyl 3,4,6-tri-*O*-acetyl-α-D-mannopyranoside.

Anal. Calcd. for $C_{15}H_{24}O_9$: C, 51.72; H, 6.90. Found: C, 52.23; H, 7.12.

The above crude reduction product was deacetylated and chromatographed on ion-exchange resin (Dowex 1-X2 200–400 mesh) in the hydroxide form to yield isopropyl α-D-mannopyranoside (0.6 g, 47%) which crystallized from isopropanol to yield material m.p. 113–114°, $[\alpha]_D^{21}$ +83° (*c*, 1.02 in water).

Anal. Calcd. for $C_{10}H_{18}O_6$: C, 48.65; H, 8.11. Found: C, 48.38; H, 8.15.

Hydrolysis by aqueous acid liberated mannose as determined by paper chromatography. The n.m.r. spectrum in D_2O showed a doublet for the anomeric hydrogen at τ 4.88 with a spacing of 1.6 Hz. The spectrum of the tetra-*O*-acetyl derivative is reported in Table 2.

Isopropyl Tetra-O-acetyl-α-D-galacto- and α-D-talopyranosides

Isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranosuloside (**2**) (1) (2.0 g) was reduced with sodium borohydride and the reduction product acetylated with acetic anhydride in pyridine by the procedure described above. The fully acetylated material was subjected to column chromatography using ether – Skellysolve B (4:6) as the developing solvent. The first major fraction was crystallized from methanol and then recrystallized from 95% ethanol to afford pure isopropyl tetra-*O*-acetyl-α-D-galactopyranoside (1.2 g, 51%), m.p. 109–110°, $[\alpha]_D^{27}$ +152.5° (*c*, 0.74 in chloroform). The n.m.r. spectrum is reported in Table 2.

Anal. Calcd. for $C_{17}H_{26}O_{10}$: C, 52.30; H, 6.71. Found: C, 52.26; H, 6.62.

A sample of the above compound (0.05 g) was deacetylated as mentioned above and the n.m.r. spectrum of the product in D_2O showed the anomeric hydrogen at τ 4.8 as a doublet with a spacing of 2.5 Hz.

The second major fraction from the chromatogram crystallized from methanol. Recrystallization from aqueous ethanol gave a pure compound (0.6 g, 26%), m.p. 67–68°, $[\alpha]_D^{27}$ +73° (*c*, 0.57 in chloroform) characterized as isopropyl tetra-*O*-acetyl-α-D-talopyranoside. The n.m.r. spectrum (see Table 2) was fully in accord with this structure.

Anal. Calcd. for $C_{17}H_{26}O_{11}$: C, 52.40; H, 6.45. Found: C, 52.47; H, 6.44.

The preparation was repeated under similar conditions except that sodium borodeuteride was used as reducing agent. The n.m.r. spectra in $CDCl_3$ of these acetylated 2-deuterio-α-D-galacto- and 2-deuterio-α-D-talopyranosides showed that signals at τ 4.94 and 5.02, respectively, had disappeared when compared to spectra of the natural compounds and are assigned to H-2 for these compounds.

The chemical shifts of H-1 (singlet), -3 (doublet), and -4 (quartet) for isopropyl tetra-*O*-acetyl 2-deuterio-α-D-galactopyranoside were at τ 4.78, 4.67, and 4.55, respectively. In the case of the corresponding taloside, the deuteration gave rise to a narrow multiplet with an intensity for two hydrogens at τ 4.73 and sharp singlet for one hydrogen at τ 5.06. The latter signal is assigned to the anomeric hydrogen because of the close correspondence of its chemical shift with that for this signal for isopropyl tetra-*O*-acetyl-α-D-mannopyranoside, namely τ 5.13. The multiplet to lower field was assigned to H-3 and -4.

A sample of isopropyl tetra-*O*-acetyl-α-D-talopyranoside (0.1 g) was deacetylated as mentioned above and the n.m.r. spectrum of the product in D_2O showed the anomeric hydrogen at τ 4.73 with a spacing of 1.2 Hz.

1,3-Di-O-benzoylglycerol

A solution of glycerol (10.0 g) in pyridine (100 ml) was cooled to 0° and benzoyl chloride (34.5 g) was added dropwise with stirring. The resulting solution was kept at ambient temperature for 12 h and then poured into an ice-water mixture. After standing for 12 h the aqueous layer was decanted and the residual semi-crystalline material dissolved in ether. The ether layer was washed sequentially with water, dilute hydrochloric acid, and water and then concentrated to a mobile oil (31.0 g). Column chromatography of this oil using benzene as the developing solvent yielded the tri-*O*-benzoyl glycerol (0.5 g) which was crystallized from ether – Skellysolve B, m.p. 71–72°. The n.m.r. in $CDCl_3$ was that expected with the multiplet signal for H-2 at τ 4.2 and the doublet for the two methylene groups centered at τ 5.3. Subsequent elution of the column with dichloromethane afforded 1,3-di-*O*-benzoyl glycerol (20 g, 61%) which was crystallized from ether – Skellysolve B, m.p. 50–51°.

Anal. Calcd. for $C_{17}H_{16}O_5$: C, 67.99; H, 5.37. Found: C, 68.05; H, 5.20.

The n.m.r. spectrum in $CDCl_3$ showed a doublet for the hydroxyl hydrogen at τ 6.5 (spacing 4 Hz). The five other hydrogens of the glycerol residue appeared as a band in the region τ 5.35–5.7. The doublet for the O*H* and lack of signal for H-2 to lower field require the assigned structure.

2-O-(Tri-O-acetyl-2-oximino-α-D-arabino-hexopyranosyl)-1,3-di-O-benzoylglycerol

A solution of 1,3-di-*O*-benzoylglucerol (2.75 g) and dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glycopyranosyl chloride (4.5 g) in dry dimethylformamide (20 ml) was kept at ambient temperature for 72 h. The resulting highly colored solution was concentrated and the residual oil dissolved in dichloromethane and the solution washed with water (3 × 100 ml) and then concentrated to yield an oil (6.3 g). Column chromatography of this material using ether – Skellysolve B (3:2) as the developing solvent afforded the title compound as an oil (3.75 g, 71%), $[\alpha]_D^{23}$ +42° (*c*, 3.4 in chloroform).

Anal. Calcd. for $C_{29}H_{31}NO_{13}$: C, 57.90; H, 5.19; N, 2.33. Found C, 57.90; H, 5.16; N, 2.30.

*2-O-(α-D-Gluco- and Mannopyranosyl)-glycerol (**3** and **4**)*

A solution of 2-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*O*-benzoylglycerol (5.0 g) in acetonitrile (12 ml) and dilute hydrochloric acid (10 ml) containing acetaldehyde (2 ml) was kept at ambient temperature for 3 h. This solution was diluted with ethyl acetate (150 ml) and the aqueous layer extracted with a further portion of ethyl acetate (50 ml). The combined ethyl acetate extracts were washed once with water and evaporated to a thick oil (4.0 g). Column chromatography of this oil using ether – Skellysolve B (3:2) as the developing solvent afforded 2-*O*-(tri-*O*-acetyl-α-D-*arabino*-hexopyranosulosyl)-1,3-di-*O*-benzoylglycerol (3.6 g). This material (3.0 g) was dissolved in 95% ethanol and hydrogenated using Pd/C (5%) for 24 h at 60 p.s.i. The catalyst was removed by filtration and the solution evaporated to an oil which was deacylated with sodium methoxide in methanol for 3 h. The solution was neutralized with ion-exchange resin (Dowex 50W-X8 H^+ form) and evaporated to an oil. This oil was partitioned between dichloromethane and water. Evaporation of the aqueous layer yielded an oil (1.3 g) which was chromatographed on ion-exchange resin (Dowex 1X2, 200–400 mesh, OH^- form) to yield 2-*O*-(α-D-mannopyranosyl)-glycerol (**3**) (0.54 g, 42%), $[\alpha]_D^{21}$ +75° (*c*, 0.56 in water), (lit. (7), $[\alpha]_D$ +51° (water)) followed by 2-*O*-(α-D-glucopyranosyl)-glycerol (**4**) (0.26 g, 20%), $[\alpha]_D^{21}$ +122° (*c*, 0.92 in water), (lit. (7), $[\alpha]_D$ +121° (water)).

*Periodate Oxidation of 2-O-(α-D-Glucopyranosyl) and 2-O-(α-D-Mannopyranosyl)-glycerol (**4** and **3**)*

To a solution of 0.054 mmol each of **4**, **3**, and isopropyl α-D-glucopyranoside in 0.5 ml water was added sodium metaperiodate (0.04 g) and the mixture was set aside in the dark for 18 h. Excess periodate was destroyed by the addition of sodium bisulfite (0.021 g) and to the resulting solution was added 2 *N* hydrochloric acid (1 ml). The mixture was heated for 1 h at 100° and then concentrated down before spotting on a t.l.c. plate. Simultaneously, a solution of glycerol (3.75 mg) in 2 *N* hydrochloric acid (1 ml) was heated for 1 h at 100°, concentrated down to a low volume, and chromatographed for comparison on the same plate using the upper phase of ether acetate – dioxane–water (2:2:1) as the solvent. The spots were visualized by heating this with sulfuric acid. Only **3** and **4** showed the presence of glycerol (R_f 0.14) thus confirming the assigned structures.

The financial support of the National Research Council of Canada through a grant-in-aid of research (A-172) to R.U.L. is gratefully acknowledged. The microanalyses and n.m.r. spectra were carried out by the analytical and spectral services laboratories of this department.

Reduction of Isopropyl Tri-*O*-acetyl-2-oximino-α-D-hexopyranosides[1]

R. U. LEMIEUX, K. JAMES,[2] T. L. NAGABHUSHAN,[3] AND Y. ITO[4]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

Hydrogenation of 2-oximino-α-D-*arabino*-hexopyranosides in the presence of palladium and hydrazine provided high stereoselectivity for the formation of 2-amino-2-deoxy-α-D-glucopyranosides including disaccharide structures. Similar yields of *gluco*-isomer were normally obtained on reduction by borane of 2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosides in tetrahydrofuran. However, reduction of 2-*O*-(2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl)-1,3-dibenzoylglycerol provided a ratio of about 3:2 of the *gluco*- to *manno*-isomers. Reductions with lithium aluminum hydride were not appreciably stereoselective. Treatment of isopropyl 2-oximino-α-D-*arabino*-hexopyranoside with hydrazine in the presence of palladium catalyst gave isopropyl 2-deoxy-α-D-*arabino*-hexopyranoside in a novel room-temperature Wolff–Kishner type reaction.

Reduction of isopropyl tri-*O*-acetyl 2-oximino-α-D-*lyxo*-hexopyranoside both with borane and lithium aluminum hydride proceeded with slight stereoselectivity for the *galacto*-isomer.

L'hydrogénation des oximino-2-α-D-*arabino*-hexopyranosides en présence de palladium et d'hydrazine conduit à la formation d'amino-2 déoxy-2-α-D-glucopyranosides incluant des structures disaccharides, avec une haute stéréoselectivité. Des rendements similaires en isomère *gluco* ont été normalement obtenus par réduction avec le diborane d'acétoximino-2- tri-*O*-acétyl-α-D-*arabino*-hexopyranosides dans le tétrahydrofurane. La réduction de l'*O*-(acétoximino-2 tri-*O*-acétyl-α-D-*arabino*-hexopyranosyl)-2 dibenzoyl-1,3 glycérol conduit cependant aux isomères *gluco* et *manno* dans un rapport d'environ 3:2. Les réductions par l'hydrure de lithium et d'aluminium ne sont pas stéréosélectives de façon appréciable. Le traitement de l'isopropyl oximino-2-α-D-*arabino*-hexopyranoside par l'hydrazine en présence de palladium fournit le déoxy-2-α-D-*arabino*-hexopyranoside selon un nouveau type de Wolff-Kishner à température ambiante.

La réduction de l'isopropyl tri-*O*-acétyl oximino-2-α-D-*lyxo*-hexopyranoside par le borane et l'hydrure de lithium et d'aluminium se fait avec une stéréosélectivité faible en faveur de l'isomère *galacto*.

Several methods based on Koenigs–Knorr type reactions have provided synthetic approaches to 2-amino-2-deoxy-α-D-glucopyranosides. These include reactions using the *N*-4-methoxybenzylidene (1, 2), *N*-2,4-dinitrophenyl (3–5), and *N*-diphenyl phosphoryl (6) derivatives of 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-α-D-glucopyranosyl bromide. The reactions are not highly selective for the synthesis of the α-linkage and the yields are generally low. Nevertheless, for example, using tri-*O*-acetyl-2-(2,4-dinitroanilino)-2-deoxy-α-D-glucopyranosyl bromide as reagent, it was possible to achieve isolable yields of paromamine (7) and an isomer (8). Trehalosamine was synthesized using tri-*O*-acetyl-2-amino-2-deoxy-*N*-(4′-methoxybenzylidene)-α-D-glucopyranosyl bromide (9). 2-Amino-2-deoxy-α-glycopyranosyl residues are not only found in numerous antibiotics (10) but are also widely distributed in nature in bacterial cell walls (11), mucopolysaccharides (12) such as heparin and glycoproteins and the blood group substances (13). The ease of preparation and the attractive yields obtained for tri-*O*-acetyl-2-oximino-α-D-*arabino*-(**1**) and *lyxo*-hexopyranosides (**2**) (14) prompted the investigation of the reduction of these oximes to amines. In principle, stereoselective reductions would allow these compounds to serve as precursors to 2-amino-2-deoxy-α-D-glucopyranosides (**3**), 2-amino-2-deoxy-α-D-mannopyranosides (**4**),

2-amino-2-deoxy-α-D-galactopyranosides (**5**), and 2-amino-2-deoxy-α-D-talopyranosides (**6**).

The purpose of this publication is to report that conditions were established for the reduction of **1** with a high degree of stereoselectivity to the *gluco*-product **3** and with moderate stereoselectivity to the *manno*- (**4**) and *talo*- (**6**) products. Stereoselective reduction to the *galacto*-configuration (**5**) was not accomplished, the best yields being 60%. An accompanying paper (15) describes the utilization of these reactions for the preparation of six 2-acetamido-2-deoxy-α-D-hexopyranosyl derivatives of hexoses.

The stereochemical result of catalytic hydrogenation of alkyl 2-oximino-α-D-*arabino*-hexopyranosides and methyl 6-*O*-(2-oximino-α-D-*arabino*-hexopyranosyl)-β-D-glucoypranoside over palladium-on-carbon in the presence of hydrochloric acid was discussed in a previous publication (16). The fraction of the *gluco*-isomer formed in each case varied substantially with the nature of the aglycon group; *viz.*, methyl 71%; ethyl or *n*-propyl 62%, isopropyl 80%, and methyl 6-*C*-β-D-glucopyranosidyl 50%. Attempts to hydrogenate the oximes in neutral, weakly acidic or weakly basic media using a variety of catalysts and pressures led to generally slow reactions without marked stereoselectivity. In view of the high yields of aminodeoxyalditols obtained on hydrogenation of sugars in the presence of hydrazine (17), the hydrogenation of the oxime (**7**) in the presence of hydrazine was examined (see Scheme 1). It was anticipated that exchange from oxime (**7**) to hydrazone (**9**) would occur and that the hydrazone would reduce efficiently to amine. Although Paulsen and Stoye (18, 19) have recently reported a number of carbohydrate hydrazones which displayed little tendency for azine formation, experiments aimed at preparing pure hydrazone (**9**) did not succeed. However, the formation of **9** was demonstrated by the addition of hydrazine to the uloside **10** followed by hydrogenation of the mixture. Isopropyl 2-amino-2-deoxy-α-D-glucopyranoside was isolated as its tetraacetyl derivative in 30% yield. When the oxime **7** was used as starting material, the compound was reclaimed unchanged on hydrogenation in the absence of the hydrazine; however, in the presence of hydrazine, the aminoglucoside **11** was formed in nearly quantitative yield. Formation of the hydrazone from the oxime was also indicated by the discovery of a novel Wolff–Kishner type reaction to form deoxyglucoside to be discussed below. The transformation of the oxime to

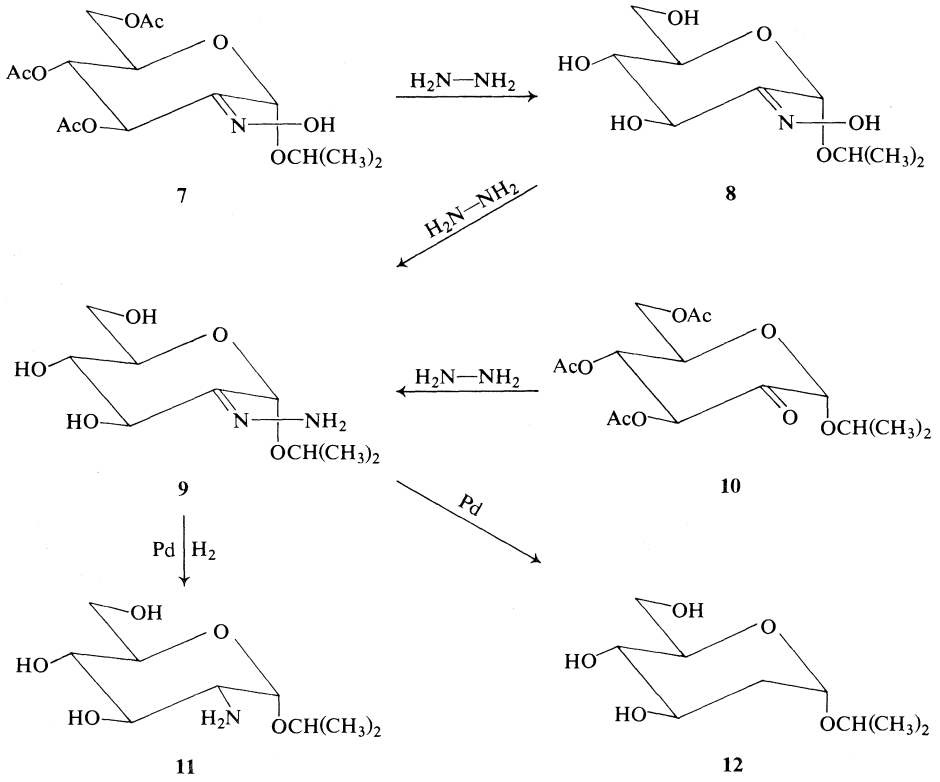
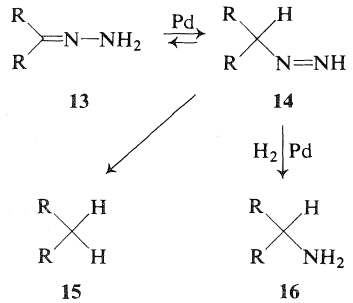


SCHEME 1

hydrazone appears either to be slow or the equilibrium to strongly favor the oxime. The first stage of the reaction involves de-*O*-acetylation. Thus after treating compound **7** in 90% aqueous ethanol with a tenfold molar excess of hydrazine for 2 h at room temperature, acetyl hydrazine and an acetyl-group free product (**8**) were formed. The latter substance gave a positive ferric chloride – ferricyanide test for oxime and, on acetylation, provided isopropyl 2-acetoximo-tri-*O*-acetyl-α-D-*arabino*-hexopyranoside (**17**) in a highly pure form.



SCHEME 2

The reductive aminations of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**7**), 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose, and 3-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose in 90% aqueous ethanol by hydrogenation catalyzed by palladium-on-carbon in the presence of hydrazine were found to provide the *gluco*-configuration (equatorial amine) in excellent yield (better than 90%). However, the reaction was found to be erratic and the high yields not always reproducible. A study of this matter led to the discovery that reaction occurred on stirring the mixture of the oxime **7**, hydrazine, and palladium catalyst in 90% aqueous ethanol at room temperature in the *absence* of hydrogen to provide isopropyl 2-deoxy-α-D-*arabino*-hexopyranoside (**12**). When the palladium catalyst was not included, no trace of the latter compound could be detected in the product. Thus, it is apparent that palladium can catalyze the isomerization of a hydrazone (**13**) to the diimide structure (**14**) which readily decomposes,

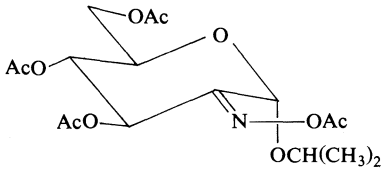
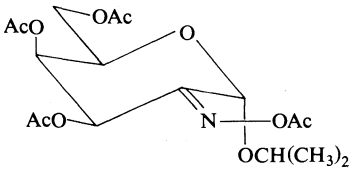
under the influence of the base to hydrocarbon (**15**) following the usually accepted mechanism for Wolff–Kishner reduction on treating a hydrazone with base (20) (see Scheme 2). The generality of this reduction has not been examined but could provide a route to the synthesis of 2-deoxyglycosides (21) under reaction conditions which are much milder than those normally required for Wolff–Kishner reduction (19). Clearly, the existence of this mode of reaction implies hydrazone formation from the oxime. Apparently, when the catalyst is saturated with hydrogen, hydrogenation to amine (**16**) takes precedence over decomposition of the diimide intermediate. The formation of the diimide intermediate as a reversible reaction can be expected to be subject to thermodynamic control. Thus, hydrogenation of the diimide group in the equatorial orientation would explain the high stereoselectivity found for this reaction.

Attempts to apply the hydrogenation–hydrazine procedure to isopropyl tri-*O*-acetyl-α-D-*lyxo*-hexopyranoside failed to yield a characterizable product. It is possible that, because of the axial C_4-substituent, the intermediate uloside is too prone to β-elimination. This matter will receive further examination.



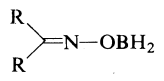
17



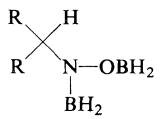
18

The reductions of oxime acetates and oxime tosylates (22) as well as oxime ethers (23) by borane in tetrahydrofuran, wherein the reagent is the complex between the borane (Lewis acid) and the tetrahydrofuran, are reported to provide the amine. Thus, it was of interest to examine the reductions of the *O*-acetyl derivatives of **7** and its *lyxo*-isomer, namely compounds **17** and **18**. Indeed, the yields of amine were excellent. In the case of compound **17**, the yield of the equatorial amine **3** (R = isopropyl) was over 90% by g.c. analysis (see Table 1). Isopropyl 2-amino-2-deoxy-α-D-glucopyranoside was isolated as its crystalline hydrochloride directly from the crude product in 73% yield. The tetraacetyl derivative was formed in 80% yield from the crude product. The reduction of **18** however showed little stereoselectivity. These results are reminiscent of the stereochemical results obtained on reducing the ulosides prepared from these oximes both by sodium borohydride in aqueous dioxane and by borane in tetrahydrofuran (24). Thus, the reactions appear to proceed by axially directed nucleophilic attack by the borane complex at C-2 and the presence of an axial substituent at C-4, as is present in the acetoxime **18**, renders this approach less favorable than was found for the reduction of **17**. Application of this reduction to more complex acetoximes of the *lyxo* configuration was found (15) to be even less favorable for the formation of the equatorial amine.

It was to be expected (23) that borane reduction of the oximinoglycosides would provide the 2-amino-2-deoxy-*N*-hydroxy glycosides. However, this appeared not to be the case, the only products isolated being glycosaminides (see below).



19



20

It is not possible to predict with certainty the mode of the initial attack of an oxime by borane. However, the ease with which borane reduces carboxylic acids suggests that the first stage involves attack of the hydroxyl group of the oxime to form a product of type **19**. Thus, the nucleophilic attack at the unsaturated carbon would be on **19** to form **20** and this product was proposed by Feuer and coworkers (23) as the precursor of the hydroxylamines they obtained on hydrolysis. However, they envisaged attack of the nitrogen by the borane in the first stage of the hydroboration of the double bond. As mentioned above, nucleophilic attack at the carbon center would seem more in accord with our present results. Although Feuer and coworkers generally obtained good to excellent yields of hydroxylamines especially when the product was subjected to

acid hydrolysis, it is noteworthy that basic hydrolysis caused a dismutation of the hydroxylamine to form amine and oxime in the case of an α-aryl aldoxime and an aryl ketoxime. The possibility therefore exists that the amines obtained on borane reduction of our oximes are artifacts of the mode of the decomposition of the reaction mixture and isolation (treatment in methanol with a strongly basic ion exchange resin). However, the yield of amine obtained on borane reduction of the oximes **1** and **2** with R = isopropyl were 48 and 78%, respectively. These yields are too high for production of amine by dismutation of the hydroxylamine only. Evidently, neighboring groups can influence the extent of the borane reduction of an oxime. Many possibilities exist including anchimeric assistance to further reduction of the nitrogen by neighboring borohydride complexes and increased ease of elimination of a species such as $HOBH_2$ from an intermediate such as **20** to an imine structure which is subsequently reduced to hydroborated amine.

Lithium aluminum hydride is well known to reduce oximes to amines (25). Reduction of the oximinoglycoside **1** with this reagent was examined with ether, tetrahydrofuran, and ethylene glycol dimethyl ether as the solvents. The axial amine was formed to a greater extent in most cases but never surpassed in stereoselectivity the 1:1.5 ratio for *gluco*- to *manno*-isomers obtained on reducing **1** (R = isopropyl). A 2.2:1 ratio for *galacto*- to *talo*-isomers was obtained on reducing **2** (R = isopropyl) using tetrahydrofuran as solvent. This ratio was 1.5:1 when ether was the solvent. The lithium aluminum hydride reductions of 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose and 3-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose gave (14) in each case about 1:1 mixtures of the *gluco*- to *manno*-isomers. In contrast, the hydrogenation of these compounds in the presence of hydrazine gave the glucosaminide products in near quantitative yields. The reductions of these oximinodisaccharides by borane are reserved for a separate publication (15).

The reduction of 2-(2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl)-1,3-di-*O*-benzoylglycerol with borane in tetrahydrofuran provided, after chromatographic separation, a 36% yield of 3-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-glycerol, a compound previously synthesized by Hardy (2) in an effort to characterize a degradation product of the intracellular teichoic acid of *Staphylococcus aureus*. A 21% yield of 2-*O*-(2-amino-2-deoxy-α-D-mannopyranosyl)-glycerol was also obtained. This high *manno* to *gluco* ratio (about 3:2) for a borane reduction indicates that the stereochemical route of reduction can be influenced by groups neighboring to the oximino group. The catalytic hydrogenation of 2-(2-oximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl)-1,3-di-*O*-benzoylglycerol in the presence of hydrazine was examined. However, in the one attempt made, a complex product was obtained which was not further characterized. Thus, the scope of this mode of reduction may also be limited. The product will be further investigated.

Experimental

The measurements of optical rotations, n.m.r. spectra, and the techniques of chromatography are the same as those presented in related work (26). The g.c. analyses reported in Table 1 were made using a 6 ft (1/4 in. o.d.) column packed with LP45 (ethylene glycol adipate, 1.5%) (Wilkens Instrument and Research, Inc.) on acid-washed Chromosorb W, 60–80 mesh (Johns–Manville Products Corp.) at 175°. The chromatograms were made with the peracetylated derivatives. These conditions failed to separate isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-galactopyranoside from its *talo*-isomer. The ratios of these isomers in the various products (see Table 1) were estimated from the weights in the fractions from the chromatographic separation of the de-*O*-acetylated mixture on a Dowex 1-X2 (200–400 mesh, hydroxide form) ion-exchange resin and using water as the developing solvent (27).

Methods for Reduction

(a) Hydrogenation in the Presence of Hydrazine

The oxime (5 mmol) was dissolved in 90% aqueous ethanol (25 ml) containing 85% aqueous hydrazine (2.0 g). The solution was kept at room temperature for 2 h prior to hydrogenation at 60 p.s.i. over 5% palladium-on-carbon (3.0 g) for 24 h. Catalyst removal and concentration in the usual manner left a residue which was further processed as described under the preparation of the following compounds.

(b) Reduction with Diborane

A solution of the oxime or the acetoxime (10 mmol) in tetrahydrofuran (20 ml) was cooled to −5° under an atmosphere of nitrogen. A 1 *M* solution of borane (50 ml) in tetrahydrofuran was added with stirring at a rate that maintained the temperature at −5°. After the addition was complete, the solution was allowed to warm to room temperature and left for 24 h in the case of an oxime but only 3 h for an acetoxime. Methanol was then added to destroy the excess borane. Solvent removal left a foam which was dissolved in methanol for treatment with ion-exchange resin (Dowex 1-X8, hydroxide form). Removal of the solvent by evaporation *in vacuo* left a solid which was processed as described below when this procedure was used.

(c) Reduction with Lithium Aluminum Hydride

The oxime (4 mmol) was dissolved in the solvent specified (25 ml). Solid lithium aluminum hydride (0.95 g, 28 mmol) was then added in portions and the resulting mixture was stirred under reflux in a nitrogen atmosphere for about 3 h. The excess hydride was then destroyed by the careful addition of ethyl acetate. The addition of a 50% aqueous methanol (100 ml) caused a precipitation. The precipitate was collected and thoroughly washed with water. The filtrates were combined and the p*H* adjusted to 4.5 with hydrochloric acid. Solvent removal *in vacuo* left a residue which was further processed as described below.

Derivatives of Isopropyl 2-Amino-2-deoxy-α-D-glucopyranoside

The reduction products of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (**7**) (28) were further processed as follows.

The product from the catalytic hydrogenation of **7** in the presence of hydrazine was stirred with tetrahydrofuran (15 ml) for 1 h. The solids were gathered by filtration and dissolved in methanol. The resulting solution was acidified with hydrogen chloride in ether and on evaporation a spontaneous crystallization of material occurred. Recrystallization from ethyl alcohol – ethyl acetate mixture provided a 55% yield of isopropyl 2-amino-2-deoxy-α-D-glucopyranoside as the hydrochloride salt, m.p. 202° (dec.) identical to an authentic sample (16).

Peracetylation of a sample of the crude product followed by g.c. analysis showed an 11.5:1 ratio of the *gluco*- to *manno*-isomers (see Table 1).

The product from the reduction of the oxime **7** with diborane was acetylated with acetic anhydride in pyridine in the usual manner. G.c. analysis of the product showed a 7:3 ratio of the *gluco*- to *manno*-isomers (see Table 1). Chromatography on a silicic acid column using ether – Skellysolve B (4:1) gave a major fraction which was crystallized from ethyl acetate – Skellysolve B. The product was isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-glucopyranoside (48% yield), m.p. 149–150°, $[\alpha]_D^{28}$ 94° (*c*, 1.4 in chloroform) identified by comparison with product obtained in acetylation of isopropyl 2-amino-2-deoxy-α-D-glucopyranoside hydrochloride.

The product from the reduction with diborane of the *O*-acetyl derivative of **7** (the acetoxime **17**) on g.c. analysis showed a 19:1 ratio for the *gluco*- and *manno*-isomers (see Table 1). When the deionized methanolic solution was acidified with hydrogen chloride in ether and the resulting solution was concentrated, isopropyl 2-amino-2-deoxy-α-D-glucopyranoside crystallized as its hydrochloride salt. The yield was 73%, m.p. 202° (dec.), after recrystallization from ethanol – ethyl acetate.

The crude product from the lithium aluminum hydride reduction of **7** in tetrahydrofuran was acetylated with pyridine (15 ml) and acetic anhydride (6 ml) and work-up in the usual manner afforded a sirupy product (90%). G.c. analysis of the oil indicated a 1:1.5 ratio of the *gluco*- and *manno*-isomers. Hydrolysis of a sample by treatment with 4 *N* hydrochloric acid at 100° for 1 h liberated two ninhydrin-positive sugars with migrations on paper electrophoresis (29) corresponding to mannosamine and glucosamine. On standing for 3 days at room temperature, the crude syrupy product deposited crystals which were isolated by trituration with ether (28% yield) and identified by m.p. and 60 MHz n.m.r. to be isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-glucopyranoside (described above).

Derivatives of Isopropyl 2-Amino-2-deoxy-α-D-galactopyranoside and its talo-Isomer

Attempts to hydrogenate isopropyl tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranoside (28) in the presence of hydrazine failed to yield a characterizable product.

The product from the reduction of the oxime with diborane was estimated by chromatography on the ion-exchange resin to comprise a ratio of about 3:2 of the *galacto*- and *talo*-isomers (see Table 1) and was not examined further.

The product from the reduction with diborane of the *O*-acetyl derivative of the oxime (the acetoxime **18**) was *N*-acetylated and found by the ion-exchange chromatography to comprise a mixture of the *galacto*- and *talo*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

isomers in a ratio of about 1:1. The crude reduction product was dissolved in ethanol and the solution was acidified with hydrogen chloride in ether. On concentration, a syrup was obtained which crystallized from ethanol – ethyl acetate. The yield was 18% of isopropyl 2-amino-2-deoxy-α-D-galactopyranoside as the hydrochloride salt, m.p. 160–164°, $[\alpha]_D^{23}$ + 138° (*c*, 1.5 in water).

Anal. Calcd. for $C_9H_{20}NO_5Cl$: C, 41.94; H, 7.82; N, 5.44; Cl, 13.76. Found: C, 41.94; H, 7.55; N, 5.51; Cl, 13.84.

The n.m.r. spectrum of this salt in deuterium oxide was in agreement with the structure assigned.

The salt was acetylated with acetic anhydride in pyridine in the usual manner to provide crystalline isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-galactopyranoside which was recrystallized from ether – Skellysolve B. The yield was 93%, m.p. 139–140°, $[\alpha]_D^{23}$ + 110° (*c*, 1.35 in chloroform).

Anal. Calcd. for $C_{17}H_{27}NO_9$: C, 52.43; H, 6.99; N, 3.60. Found: C, 52.48; H, 7.23; N, 3.78.

The hydrochloride salt was reacted with 1-fluoro-2,4-dinitrobenzene in aqueous bicarbonate–acetone solution and the product acetylated with acetic anhydride and pyridine to provide a yellow solid which was recrystallized from ethanol to yield isopropyl tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)-α-D-galactopyranoside, m.p. 172–173°, $[\alpha]_D^{23}$ −21.5° (*c*, 1 in chloroform).

Anal. Calcd. for $C_{21}H_{27}N_3O_{12}$: C, 49.12; H, 5.30; N, 8.18. Found: C, 48.91; H, 4.98; N, 7.94.

A product obtained by the diborane reduction of the acetoxime (**18**) (2.30 g) was dissolved in 50% aqueous methanol (10 ml) and acetic anhydride (4 ml) was added. The syrup obtained on solvent removal was added to a 40 in. × 3/4 in. column of Dowex 1-X2 (200–400 mesh, hydroxide form) and the column was eluted with water at a flow rate of 1 ml/min. The elution was followed by t.l.c. on silica gel using the upper phase of an ethyl acetate – dioxane–water (2:2:1) system as developing phase. Combination of the appropriate fractions provided solutions of two major components.

Evaporation of the solution of the faster moving compound readily provided crystalline isopropyl 2-acetamido-2-deoxy-α-D-galactopyranoside in 41% yield. Recrystallization from ethyl acetate gave a pure product, m.p. 191–192°, $[\alpha]_D^{23}$ +192° (*c*, 0.8 in dimethylformamide).

Anal. Calcd. for $C_{11}H_{21}NO_6$: C, 50.18; H, 8.04; N, 5.32. Found: C, 49.97; H, 7.83; N, 5.17.

The slower moving product was obtained as an oil, $[\alpha]_D^{21}$ +49° (*c*, 1.7 in dimethylformamide), 37% yield. and assigned the structure isopropyl 2-acetamido-2-deoxy-α-D-talopyranoside on the basis of its composition and n.m.r. spectrum.

Anal. Calcd. for $C_{11}H_{21}NO_6$: C, 50.18; H, 8.04; N, 5.32. Found: C, 49.88; H, 7.98; N, 5.38.

Reduction of the oxime with lithium aluminum hydride in tetrahydrofuran and acetylation of the crude product as before gave a syrupy product in near quantitative yield. Trituration with ether gave crystalline isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-galactopyranoside identical to the product obtained from the diborane reduction of the acetyl derivative of **2** in an overall yield of 40%.

A sample of the crude acetylated reduction product (0.1 g) was *O*-deacetylated with triethylamine (0.5 ml) in 50% aqueous methanol (5 ml) and after removal of the solvents, the residue was freeze-dried from deuterium oxide. Examination of the residue by n.m.r. at 60 MHz showed the presence of a doublet at τ 5.0 (H-1, *galacto*-isomer, $J_{1,2}$ = 3.5 Hz) and a singlet at 5.06 (H-1, *talo*-isomer) in the ratio of about 2.2:1. Furthermore, when the crude *O*-deacetylated product was chromatographed on the basic column as described above, two main fractions were obtained. Hydrolysis of the first fraction that was eluted from the column with 4 *N* hydrochloric acid for 1.5 h liberated galactosamine as indicated by paper electrophoresis (29). The other fraction liberated talosamine. The 60 MHz n.m.r. spectra of the compounds were indistinguishable from those obtained for isopropyl 2-acetamido-2-deoxy-α-D-galactopyranoside and the *talo*-isomer prepared by reduction of **2** with diborane. Judging from the weights of the fractions, the isomers were formed in the ratio of 2.2:1 (*galacto*:*talo*). This ratio was 1.5:1 when ether was used as the solvent for the reduction.

2-O-(2-Amino-2-deoxy-α-D-gluco- and manno-pyranosyl)-glycerol Hydrochlorides

2-*O*-(Tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*O*-benzoylglycerol (5.0 g) (24) was acetylated with acetic anhydride (4.0 ml) in pyridine (20 ml) for 2 h at 0°. The 2-acetoximino derivative was isolated as an oil (5.0 g) and reduced with 1 *M* borane in tetrahydrofuran (50 ml). The crude reduction product was isolated as a foam using the procedure described above. Ion-exchange chromatography of this material on Dowex 1-X2 (200–400 mesh, hydroxide form) yielded first 2-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-glycerol, characterized as its hydrochloride salt (0.85 g, 36%), $[\alpha]_D^{23}$ + 113° (*c*, 1.3 in water) which in our hands resisted crystallization. Hardy (2) reported a crystalline preparation, m.p. 160–162°, $[\alpha]_D$ +117° (water). The n.m.r. spectrum in deuterium oxide showed a one-hydrogen doublet at τ 4.65 with a spacing of 4.0 Hz which was assigned to the anomeric hydrogen.

Further elution of the column produced a product which was converted to the hydrochloride salt (0.40, 21%), $[\alpha]_D^{23}$ −17.6° (*c*, 1.07 in water). The compound liberated mannosamine on acid hydrolysis and produced a doublet signal assigned to anomeric proton at τ 4.90 with spacing of 1.6 Hz.

Anal. Calcd. for $C_9H_{20}NO_7Cl$: C, 37.31; H, 6.96; N, 4.84; Cl, 12.24. Found: C, 37.18; H, 6.86; N, 4.83; Cl, 12.32.

Derivatives of 6-O-(2-Amino-2-deoxy-α-D-glucopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose and 6-O-(2-Amino-2-deoxy-α-D-mannopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

Catalytic hydrogenation of 6-*O*-(3,4,6-tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (**21**) (14) in the presence of hydrazine gave a product which was acetylated using acetic anhydride in pyridine. The n.m.r. spectrum at 100 MHz of the crude product required that 6-*O*-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was formed in near quantitative yield. The compound crystallized from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ethyl acetate – *n*-hexane in 56% yield, m.p. 125–127°, $[\alpha]_D^{25}$ +25° (*c*, 1 in chloroform).

Anal. Calcd. for $C_{26}H_{39}NO_{14}$: C, 52.96; H, 6.67; N, 2.38. Found: C, 52.89; H, 6.44; N, 2.03.

The n.m.r. spectrum was in accord with the assigned structure.

The product from the reduction of **21** with lithium aluminum hydride in tetrahydrofuran gave an n.m.r. spectrum consistent with a 1:1.2 mixture of the *gluco*- and *manno*-isomers, respectively. This ratio was near 1:1 when ethylene glycol dimethyl ether was used as solvent. With ether as solvent, the ratio was 1:1.5.

The product from the reduction in ether was made to react with 1-fluoro-2,4-dinitrobenzene in aqueous sodium bicarbonate – acetone solution in the usual manner. The crude yield of the *N*-dinitrophenyl derivatives was near quantitative. A sample (373 mg) of the mixture was subjected to preparative t.l.c. on silica gel using benzene–pyridine (4:1) as developing phase. Elution of the slower moving yellow band provided a solid sample which, on hydrolysis at 100° in 3 *N* hydrochloric acid for 1 h, liberated a yellow substance with the same R_f value by t.l.c. on silica gel using *n*-butanol – ethanol–water (3:1:1), as an authentic sample of 2-deoxy-2-(2′,4′-dinitrophenylamino)-glucose. The remainder was treated with acetic anhydride and pyridine. The crude acetylated product appeared homogeneous on t.l.c. (benzene–methanol, 20:1) and provided an n.m.r. spectrum at 100 MHz compatible with a high degree of chemical homogeneity. Recrystallization from ethyl acetate – *n*-hexane gave fine needles (107 mg), m.p. 200–202°, $[\alpha]_D^{23}$ −29° (*c*, 0.44 in chloroform).

Anal. Calcd. for $C_{30}H_{39}N_3O_{17}$: C, 50.49; H, 5.51; N, 5.89. Found: C, 50.47; H, 5.29; N, 5.83.

The 100 MHz n.m.r. spectrum of the above compound in deuteriochloroform showed a doublet at τ 5.00 with a spacing of 4.0 Hz which was assigned to H-1 of the amino-sugar residue. On this basis, together with the fact that the spectrum in all other respects was in accord with that expected, the compound was assigned the structure 6-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanalino)-α-D-glucopyranosyl]-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose.

The product isolated from the faster moving yellow band in the above-mentioned preparative thin layer chromatogram was acetylated and the crude product (152 mg) recrystallized from benzene and *n*-hexane. The material, $[\alpha]_D^{30}$ −86° (*c*, 0.42 in chloroform), sintered at 92° and melted in the range 149–151°. The 100 MHz n.m.r. spectrum in deuteriochloroform showed a one-hydrogen doublet at τ 5.03 with a spacing of 1.5 Hz. In view of this observation and the fact that the n.m.r. spectrum in all other regards was consistent with the expected structure, the compound was assigned as 6-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-mannopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose.

Anal. Calcd. for $C_{30}H_{39}N_3O_{17}$: C, 50.49; H, 5.51; N, 5.89. Found: C, 50.52; H, 5.28; N, 5.85.

Derivatives of 3-O-(2-Amino-2-deoxy-α-D-glucopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose and 3-O-(2-Amino-2-deoxy-α-D-mannopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

Catalytic hydrogenation of 3-*O*-(3,4,6-tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (**22**) (14) in the presence of hydrazine provided a product which was reacted with 1-fluoro-2,4-dinitrobenzene prior to acetylation with acetic anhydride and pyridine. The yield of crude crystalline material was 88%. Recrystallization from ethyl acetate and *n*-hexane gave a product, m.p. 211–212°, $[\alpha]_D$ +12° (*c*, 0.5 in chloroform).

Anal. Calcd. for $C_{30}H_{39}N_3O_{17}$: C, 50.49; H, 5.51; N, 5.89. Found: C, 50.31; H, 5.33; N, 5.84.

The n.m.r. spectrum at 100 MHz in deuteriochloroform allowed assignment of the structure 3-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanalino)-α-D-glucopyranosyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose. A one-hydrogen doublet at τ 5.32 with a spacing of 4.5 Hz was assigned to H-1 of the glucosamine residue.

Reduction of the oxime **22** with lithium aluminum hydride in ethylene glycol dimethyl ether provided a ninhydrin-positive product which was converted to the *N*-2,4-dinitrophenyl derivative. The product showed two yellow major components on t.l.c. with benzene–pyridine (4:1) as solvent. Preparative t.l.c. under the same conditions gave two products which were acetylated with acetic anhydride and pyridine.

The material originating from the slower moving band crystallized readily and was identical in every respect to the product described above and obtained by way of hydrogenation.

The material from the slower moving band also crystallized readily. The relative amounts of the two crude products were 1.2:1 from the slower and faster moving zones, respectively. Recrystallization from ethyl acetate and *n*-hexane mixture gave a product, $[\alpha]_D^{25}$ −76° (*c*, 0.4 in chloroform) which melted in the range 93–105°. However, the n.m.r. spectrum at 100 MHz in deuteriochloroform allowed the conclusion that the product was highly pure and to be 3-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanalino)-α-D-mannopyranosyl]-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose. The one-hydrogen doublet at τ 5.15 with a spacing of 2.0 Hz and assigned to H-1′ is consistent with the α-configuration.

*Isopropyl 2-Deoxy-α-D-arabino-hexopyranoside (**12**)*

A solution of isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (5.0 g) (7) in 90% aqueous ethanol (75 ml) containing 85% hydrazine hydrate (10 g) was kept at ambient temperature for 2 h. Palladium-on-carbon (5 g of 5% containing approximately 60% water) was then added and the suspension was stirred for 72 h open to the atmosphere (vigorous initial evolution of a gas occurred). The catalyst was removed and the filtrate was concentrated *in vacuo* to an oil (4.0 g) which was chromatographed on an ion-exchange resin (Dowex 1-X2 (200–400 mesh) hydroxide form). The major fraction (1.4 g, 51%) was a chromatographically pure oil which crystallized on storage. Recrystallization from ethyl acetate gave material, m.p. 103–104°, $[\alpha]_D^{21}$ +128° (*c*, 1.4 in water).

Anal. Calcd. for $C_9H_{18}O_5$: C, 52.41; H, 8.80. Found: C, 52.62; H, 8.82.

The n.m.r. spectrum was that expected (30) for 2-deoxy-α-D-glucopyranosides. The chemical shifts for H-1, -2_{ax}, -2_{eq}, and the two methyl groups were τ 4.39, 7.66, 8.03, 8.51, and 8.57, respectively. The spacings required coupling constants of about $J_{1,2_{eq}} = 1.5$, $J_{1,2_{ax}} = 3.5$, $J_{2_{eq},2_{ax}} = 13$, $J_{2_{eq},3} = 5.5$, $J_{2_{ax},3} = 11.5$ Hz.

Acetylation provided isopropyl tri-*O*-acetyl-2-deoxy-

α-D-*arabino*-hexopyranoside, m.p. 73–74°, $[\alpha]_D^{23}$ +127° (*c*, 1.0 in chloroform) in near quantitative yield.

Anal. Calcd. for $C_{15}H_{24}O_8$: C, 54.21; H, 7.28. Found: C, 54.04; H, 7.16.

The n.m.r. spectrum was in complete accord with assigned structure: $J_{1,2_{eq}} = \sim 1.5$, $J_{1,2_{ax}} = \sim 3.5$, $J_{2_{eq},3} = 5.5$, $J_{2_{ax},3} = 11.0$, and $J_{3,4} = J_{4,5} = 9.5$ Hz (as derived by measuring the spacings).

When the above experiment was repeated except that the palladium catalyst was omitted, t.l.c. examination of the crude reaction product showed no evidence for isopropyl 2-deoxy-α-D-*arabino*-hexopyranoside. The t.l.c. was made on silica gel using the upper phase of an ethyl acetate – dioxane–water (2:2:1) system and developed with 10% chlorosulfonic acid in glacial acetic acid, a reagent which provided an intense black spot on heating at 120° and which detects trace amounts of 2-deoxyglycosides.

Crude isopropyl tri-*O*-acetyl-α-D-*arabino*-hexopyranosuloside obtained from the oxime precursor (5 g) (24) was treated as described above. The product from the ion-exchange chromatogram was an oil (1.4 g) which resisted crystallization. The material was acetylated with acetic anhydride in pyridine and the product was chromatographed on a silicic acid column using ether – Skellysolve B (2:3) as developing solvent. The product obtained was identical with the above-mentioned isopropyl tri-*O*-acetyl-2-deoxy-α-D-*arabino*-hexopyranoside.

When the crude uloside obtained from isopropyl tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranoside (7) (5 g) was treated under the hydrogenation conditions in the presence of hydrazine, a product was obtained which was acetylated as above. Column chromatography on silicic acid using ethyl acetate – Skellysolve B (3:2) resulted in the isolation of 1.6 g (30% yield) of isopropyl 2-acetamido-tri-*O*-acetyl-2-deoxy-α-D-glucopyranoside.

The financial support of the National Research Council of Canada through a grant-in-aid of research (A-172) to R.U.L. is gratefully acknowledged. The microanalyses and n.m.r. spectra were determined by the analytical and spectral services of this Department.

Chemical Syntheses of α-Linked Disaccharides[1]

R. U. LEMIEUX, K. JAMES,[2] AND T. L. NAGABHUSHAN[3]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 2, 1972

Chemical syntheses of six α-linked disaccharides are described, namely, 6-*O*-(α-D-glucopyranosyl)-D-galactose (**1**), 6-*O*-(α-D-galactopyranosyl)-D-galactose (**2**), 6-*O*-(α-D-talopyranosyl)-D-galactose (**3**), 3-*O*-(α-D-glucopyranosyl)-D-glucose (nigerose) (**4**), 3-*O*-(α-D-galactopyranosyl)-D-glucose (**5**), and 3-*O*-(α-D-talopyranosyl)-D-glucose (**6**).

Les synthèses chimiques de six disaccharides branchés en α sont décrites, à savoir le *O*-[α-D-glucopyranosyl]-6-D-galactose [**1**], le *O*-[α-D-galactopyranosyl]-6-D-galactose (**2**), le *O*-[α-D-talopyranosyl]-6-D-galactose (**3**), le *O*-[α-D-glucopyranosyl]-3-D-glucose (nigérose) (**4**), le *O*-[α-D-galactopyranosyl]-3-D-glucose (**5**), et le *O*-[α-D-talopyranosyl]-3-D-glucose (**6**).

This paper presents syntheses of the six α-linked disaccharides (**1** to **6**) from previously reported (1) oximino-disaccharide structures; namely, the tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl and tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranosyl derivatives of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose and of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose. The latter compounds were deoximated (2) and the resulting ketonic substances were reduced with sodium borohydride (3) without prior purification. In the preparation of compounds **4**, **5**, and **6**, the use of acetaldehyde in acetonitrile–hydrochloric acid reagent (2) for deoximation caused substantial loss of the acid labile 5,6-*O*-isopropylidene protecting group. However, in the preparation of compounds **1**, **2**, and **3**, deoximation under similar conditions caused only small losses of the *O*-isopropylidene groups. Treatment of the crude ketones in these cases with 2,2-dimethoxypropane and *p*-toluenesulfonic acid monohydrate re-introduced these groups in near quantitative yields. This was not the case in the preparation of compounds **4**, **5**, and **6**. Therefore, for the synthesis of these compounds deoximation under neutral conditions with titanium trichloride (3, 4) was used. Reduction followed by *O*-acetylation enabled compounds **1** to **4** to be isolated as the *O*-(tetra-*O*-acetyl-α-D-hexopyranosyl)-di-*O*-isopropylidene-D-hexoses.

In view of the high degree of stereoselectivity observed in the reductions to α-D-glucopyranosides (3), the preparations of compounds **1** and **4** proceeded with little difficulty in 54 and 67% yields, respectively. Although both the intermediate 6-*O*-(α-D-glucopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose and its tetraacetate failed to crystallize, both 3-*O*-(α-D-glucopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose and its tetraacetate were obtained in crystalline condition.

As previously reported (3), the reduction of a tri-*O*-acetyl-α-D-*lyxo*-hexosuloside with sodium borohydride leads to a mixture of galactosides and talosides. 6-*O*-(Tetra-*O*-acetyl-α-D-galactopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was obtained crystalline in 51% yield and was readily separated from 6-*O*-(tetra-*O*-acetyl-α-D-talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (30% yield as a syrup) by column chromatography on silicic acid. Column chromatography on a resin in the hydroxide form (5) was used to separate 3-*O*-(α-D-galactopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose from the *talo*-isomer. Both compounds were obtained crystalline.

The disaccharides (**1** to **6**) were prepared from the di-*O*-isopropylidene derivatives by hydrolysis of the isopropylidene groups using aqueous trifluoroacetic acid (6) followed by chromatographic purification using an ion-exchange resin in the potassium salt from (7). Although none of the disaccharides was obtained crystalline, all provided the expected hexoses (or hexose) on acid

hydrolysis and possessed n.m.r. spectra in accordance with the assigned structures. The chemical shifts and spacings for the signals of the anomeric hydrogens for mutarotated solutions in deuterium oxide are reported in Table 1. The R_f values relative to maltose on Whatman No. 1 paper using *n*-butanol – pyridine–water – acetic acid (6:4:3:1) are also reported in Table 1.

The above-described results offer a solution to the long-standing problem of carbohydrate chemistry, namely, the controlled synthesis of α-linked oligosaccharide structures in good yield. The key to the method is the high stereoselectivity for 2-oximino-α-glycoside formation (1). Whether or not the preferential formation of the α-linkage will remain essentially independent of the structural features of the alcohol remains to be thoroughly tested. To date, 2-oximino-β-glycoside formation has only been definitely observed in one instance (1) (about 9% yield).

The first preparation of an α-D-glucopyranosyl disaccharide was by anomerization of gentiobiose to isomaltose by Lindberg in 1949 (8). Goldstein and Whelan (9) applied this method to convert synthetic 6-*O*-(β-D-glucopyranosyl)-D-galactose to the α-anomer, compound **1** of the present research, which appears (10) to be liberated on partial hydrolysis of polysaccharides from *Salmonella senftenberg* and *S. typhimurium*.

The first syntheses of α-D-glucopyranosyl disaccharides were those of maltose and sucrose employing tri-*O*-acetyl-1,2-anhydro-α-D-glucopyranose as reagent (11, 12). Haq and Whelan (13) synthesized nigerose, compound **4** of this paper, by a chemically related route. The modification of the Koenigs–Knorr reaction involving the use of mercuric cyanide as condensing agent, introduced by Zemplén and Gerecs (14) and used by Matsuda (15) for the synthesis of α-D-glucopyranosides, failed (9) to provide **1** but did provide nigerose (15, 16). The chemical nature of this approach to the synthesis of α-D-glucopyranosides remains obscure (17) but it has provided syntheses of a number of complex α-D-glucopyranosides in low yield (18–20). Nigerose is liberated on partial hydrolysis of nigeran, a polysaccharide isolated from *Aspergillus niger* (21) and may be a minor structural unit of amylopectin (22). Lemieux, James, and Hendriks (23) have synthesized 3-*O*-(tetra-*O*-benzyl-α-D-glucopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose in 42% yield by their so-called halide-ion

TABLE 1. Characterizations of the disaccharides

Compound	Temperature (°C)	Chemical shifts of the anomeric hydrogens, τ-values (spacings, Hz)* Non-reducing unit	Reducing unit	Paper chromatographic mobilities (cm)†
α-D-Glc*p*-(1 → 4)-D-Glc (maltose)	15	4.37 (3.50)	4.56 (3.50), 5.13 (8.00)	6.7
α-D-Glc*p*-(1 → 6)-D-Gal (**1**)	22	4.83 (3.37)	4.52 (2.87), 5.18 (7.25)	2.7
α-D-Gal*p*-(1 → 6)-D-Gal (**2**)	15	4.82 (2.50)	4.53 (3.00), 5.25 (7.50)	1.9
α-D-Tal*p*-(1 → 6)-D-Gal (**3**)	15	4.79 (0)	4.54 (3.00), 5.22 (7.25)	5.5
α-D-Glc*p*-(1 → 3)-D-Glc (**4**) (nigerose)	15	4.42 (3.50)	4.55 (3.50), 5.12 (8.00)	7.5
α-D-Gal*p*-(1 → 3)-D-Glc (**5**)	33	4.46 (2.50)	4.60 (3.50), 5.16 (8.00)	9.0
α-D-Tal*p*-(1 → 3)-D-Glc (**6**)	15	4.43 (0)	4.56 (3.50), 5.12 (8.00)	9.6

*The n.m.r. spectra were measured at 100 MHz in deuterium oxide (c = 12.5%). In all cases the β to α anomeric ratio of the reducing sugar unit was near 1.5.
†Whatman No. 1 paper using butanol – pyridine–water – acetic acid (6:4:3:1) for 36 h.

catalyzed synthesis of α-glucopyranosides. The yield of 6-*O*-(tetra-*O*-benzyl-α-D-glucopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was 65%. The key step in these syntheses was the reaction of tetra-*O*-benzyl-α-D-glucopyranosyl bromide with the di-*O*-isopropylidene-hexose in methylene chloride and in the presence of tetraethylammonium bromide and ethyldiisopropylamine. This promising alternative approach to the synthesis of α-D-hexopyranosides is under further investigation and details will be published in the near future. Recent publications (24, 25) from other laboratories report related research. 6-*O*-(α-D-Galactopyranosyl)-D-galactose (**2**) has been obtained both by acid reversion (26) and by enzymic polymerization (27) of D-galactose. The present report appears to be the first controlled synthesis of this compound. 3-*O*-(α-D-Galactopyranosyl)-D-glucose (**4**) has not been previously characterized. It is noteworthy that Rebers and Heidelberger (28) have provided evidence that this disaccharide is a building unit of the specific polysaccharide of type VI pneumococcus. The talosides **3** and **6** were isolated as by-products; these are not known to have direct biological significance.

Experimental

Descending paper chromatography was performed on Whatman No. 1 paper using *n*-butanol – pyridine–water – acetic acid (6:4:3:1) as the developing solvent and the components visualized by spraying with alkaline silver nitrate (30). The thin layer chromatograms were developed on silica gel G (E. Merck A.G., Darmstadt) using 20 cm² plates and in the solvent specified. The adsorption chromatograms were conducted on silicic acid, CC7, 100–200 mesh (Mallinckrodt Chemical Works, St. Louis, Mo.) using a 3:2 mixture of ether and Skellysolve B. The chromatograms on ion exchange resin in the hydroxide form were performed using Dowex 1-X2 (200–400 mesh) supplied by Sigma Chemicals Co., St. Louis, Mo. and eluted with water. The chromatograms on resin in the potassium form were developed with water and used ion exchange resin CGC 241 (200–400 mesh) supplied in the sodium form by J. T. Baker Chemical Co., Phillipsburg, N.J. The eluants for the column chromatograms were collected in 10 ml fractions. The presence of material in a given fraction was established and the nature and purity of the material assessed by either t.l.c. or paper chromatography prior to pooling. All deionizations employed Amberlite MB-3 (20–50 mesh) supplied by Mallinckrodt.

All the products described were examined by 100 MHz n.m.r. and the spectra obtained were in accord with the structures assigned. The chemical shifts and spacings observed for the disaccharides are reported in Table 1. The disaccharides were further characterized by hydrolysis using 1 *N* hydrochloric acid at 100° for 1 h followed by comparison of the hydrolysis products by paper chromatography with authentic samples of the hexoses.

*6-O-(α-D-Glucopyranosyl)-D-galactose (**1**)*

A solution of 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (4.40 g) (1) in acetonitrile (13.5 ml), 1 *N* hydrochloric acid (11.5 ml), and acetaldehyde (4.0 ml) was kept at room temperature for 4 h. The solution was then diluted with ethyl acetate (50 ml) and the organic layer was washed once with water (20 ml). Concentration of this solution afforded a syrup which was dissolved in 2,2-dimethoxypropane (25 ml) containing *p*-toluenesulfonic acid monohydrate (25 mg). The resulting solution was left for 12 h st 5°, diluted with ethyl acetate, and subsequently washed with saturated aqueous sodium bicarbonate solution. Evaporation left an oil which was dissolved in dioxane (25 ml) and water (20 ml). The solution was cooled to 0° with stirring and sodium borohydride (0.30 g) was added in small aliquot portions. On completion of the addition, the solution was maintained at ambient temperature for 3 h. Excess sodium borohydride was then destroyed by the addition of acetone and the resulting solution concentrated to a semi-crystalline mass which was extracted with ethyl acetate to remove inorganic material. Evaporation left an oily residue which was de-

For personal use only.

acetylated by treatment with triethylamine (5 ml) in 50% aqueous methanol (20 ml) for 12 h at 4°. Solvent removal left a residue (3.42 g) which was dissolved in 90% aqueous trifluoroacetic acid (34 ml). The solution was kept at about 25° for 15 min and then concentrated *in vacuo* (below 40°) to a syrup which turned to an amorphous powder (2.9 g) on trituration with ether. Paper chromatography indicated that the major portion of this material was a reducing disaccharide. Purification was achieved by chromatographing 1.0 g portions, at a flow rate of 1 ml/min, on a 48 in. × 1.5 in. ion-exchange column in the potassium form. The appropriate fractions were combined and concentrated to yield the title compound (1.45 g, 54%); $[\alpha]_D^{22}$ +127° (*c*, 0.69 in water) (lit. (29) $[\alpha]_D$ +125 → 138° (water)).

A number of the intermediates were characterized as follows.

(a) 6-O-(Tetra-O-acetyl-α-D-glucopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

The above described crude product from the sodium borohydride reduction (0.50 g) was acetylated with acetic anhydride (4 ml) in pyridine (5 ml). After isolation of the product by normal procedures followed by column chromatography on silicic acid using ether – Skellysolve B (6:4) as the developing solvent, the title compound was obtained as an oil (0.35 g), $[\alpha]_D^{25}$ +47° (*c*, 3.3 in chloroform).

Anal. Calcd. for $C_{26}H_{38}O_{15}$: C, 52.87; H, 6.49. Found: C, 52.91; H, 6.44.

(b) 6-O-(α-D-Glucopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

The above described compound (0.50 g) was deacetylated with triethylamine (2 ml) in 50% aqueous methanol (10 ml) at 4°. Evaporation of the solution left the title compound as an oil (0.34 g), $[\alpha]_D^{25}$ +29.2° (*c*, 0.92 in chloroform).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 51.01; H, 7.00.

6-O-(Tetra-O-acetyl-α-D-galactopyranosyl)- and 6-O-(Tetra-O-acetyl-α-D-talopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

A solution of 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (6.50 g) (1) in acetonitrile (20 ml), 1 *N* hydrochloric acid (16.2 ml), and acetaldehyde (6 ml) was kept at room temperature for 4 h. The ketone obtained from the reaction was isolated, treated with 2,2-dimethoxypropane (25 ml), and then reduced with sodium borohydride as described above. The material obtained from the borohydride reduction was acetylated with acetic anhydride (15 ml) in pyridine (20 ml) for 48 h at room temperature and the product isolated as an oil (6.5 g) by normal procedures. Analysis of this material by t.l.c. using ether – Skellysolve B (4:1) as the developing solvent indicated the presence of two main components. Column chromatography on silicic acid yielded 6-*O*-(tetra-*O*-acetyl-α-D-galactopyranosyl)-1,2;3,4 di-*O*-isopropylidene α-D-galactopyranose (3.5 g, 51%) which crystallized from ethyl acetate – Skellysolve B, m.p. 87–89°, $[\alpha]_D^{23}$ +54.5° (*c*, 2 in chloroform).

Anal. Calcd. for $C_{26}H_{38}O_{15}$: C, 52.87; H, 6.49. Found: C, 52.57; H, 6.46.

Further elution provided a second major fraction, 6-*O*-(tetra-*O*-acetyl-α-D-talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (2.0 g; 30%) as an oil, $[\alpha]_D^{23}$ +13° (*c*, 1.3 in chloroform).

Anal. Calcd. for $C_{26}H_{38}O_{15}$: C, 52.88; H, 6.49. Found: C, 53.08; H, 6.15.

6-O-(α-D-Galactopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

6-*O*-(Tetra-*O*-acetyl-α-D-galactopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (2.0 g) was deacetylated with triethylamine (4 ml) in 50% aqueous methanol (20 ml) for 12 h at 4°. Evaporation of the solution afforded an oil, $[\alpha]_D^{23}$ +55.4° (*c*, 1.7 in DMF).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 50.98; H, 7.27.

6-*O*-(α-D-Talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was obtained as a syrup from its tetra-*O*-acetyl derivative by deacetylation as described above, $[\alpha]_D^{23}$ +10° (*c*, 0.5 in DMF).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 51.15; H, 7.22.

6-O-(α-D-Galactopyranosyl)-D-galactose (2)

A solution of 6-*O*-(α-D-galactopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (1.40 g) in 90% aqueous trifluoroacetic acid (14 ml) was kept at room temperature for 15 min and then concentrated *in vacuo* to an oil. Trituration of this material with ether gave an amorphous powder which was purified by chromatography as described above in the preparation of **1**. The product (0.75 g, 66.1%), was an amorphous powder, $[\alpha]_D^{22}$ +149° (*c*, 0.36 in water) (lit. (26) $[\alpha]_D$ +149° (water)).

6-O-(α-D-Talopyranosyl)-D-galactose (3)

The compound was prepared from 6-*O*-(α-D-talopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (0.50 g) and the product purified by the procedures described above for the preparation and purification of **2** to give an amorphous powder (0.30 g, 74%), $[\alpha]_D^{22}$ +101° (*c*, 0.64 in water).

3-O-(Tetra-O-acetyl-α-D-glucopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

A solution of 3-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (3.25 g) in dioxane was reduced with titanium trichloride and the product (3.10 g) isolated as an oil by the procedures to be described below for the deoximation of the *lyxo*-isomer. Without further purification the material was reduced with sodium borohydride (0.15 g) in 60% aqueous dioxane (25 ml). After 3 h this solution was de-ionized with the mixed-bed resin and then concentrated to yield an oil which was subsequently acetylated with acetic anhydride in pyridine. Isolation of the peracetylated material by normal procedures followed by crystallization from ethyl acetate – Skellysolve B yielded the title compound (2.5 g, 73%), m.p. 139–140°, $[\alpha]_D^{21}$ +75.3° (*c*, 1.48 in chloroform).

Anal. Calcd. for $C_{26}H_{37}O_{15}$: C, 52.97; H, 6.33. Found: C, 52.80; H, 6.50.

3-O-(α-D-Glucopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

3-*O*-(Tetra-*O*-acetyl-α-D-glucopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.70 g) was deacetyl-

ated with triethylamine (1.0 ml) in 50% aqueous methanol (10 ml) for 12 h at 0°. The solution was then concentrated and the residual oil chromatographed on ion-exchange resin in the hydroxide form using a 36 in. × 3/4 in. column to give the title compound (0.50 g, 79%) which crystallized from ethyl acetate – Skellysolve B, m.p. 174–175°, $[\alpha]_D^{22}$ +74.6° (*c*, 1.02 in DMF).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 51.47; H, 6.83.

3-O-(α-D-Glucopyranosyl)-D-glucose (4)

3-*O*-(α-D-Glucopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.70 g) was hydrolyzed with 90% aqueous trifluoroacetic acid and the product purified by the general procedure described above to yield an amorphous material (0.38 g, 67%), $[\alpha]_D^{20}$ +136° (*c*, 0.45 in water) (lit. (29), $[\alpha]_D$ 125 → 138° (water)).

3-O-α-D-Galactopyranosyl- and 3-O-α-D-Talopyranosyl Derivatives of 1,2;5,6-Di-O-isopropylidene-α-D-glucofuranose

A 20% aqueous solution of titanium trichloride (30.0 g) was added dropwise with stirring under an atmosphere of nitrogen to a solution of 3-*O*-(tri-*O*-acetyl-2-oximino-α-D-*lyxo*-hexopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (6.50 g) and ammonium acetate (12.0 g) in dioxane (60 ml). Stirring was continued for 3 h after the addition was complete, following which ammonium acetate (12.0 g) and dioxane (60 ml) were added and then titanium trichloride (30.0 g) added dropwise. The resulting suspension was stirred for a further 2 h and then extracted with dichloromethane (500 ml). The organic extract was washed first with saturated aqueous sodium bicarbonate solution and then water. Evaporation yielded an oil which partially crystallized on storage. Recrystallization from ethyl acetate – Skellysolve B afforded material (2.10 g) which is considered to be the hydrated ketone (n.m.r. spectrum). An oil (3.80 g) was isolated from the mother liquor.

The crystalline material (1.90 g) was reduced with sodium borohydride (0.20 g) in 60% aqueous dioxane (15 ml) for 3 h and the resulting solution was then deionized with the mixed-bed resin. Subsequent evaporation of the solution left an oil which was deacetylated with triethylamine (2 ml) in 60% aqueous methanol for 12 h at 4°. Concentration of this solution gave an oil (1.66 g) which was shown, by t.l.c. using the upper phase of an ethyl acetate – dioxane – water (2:2:1) system as the developing solvent, to be a two component mixture. Ion-exchange chromatography of this material on a 36 in. × 3/4 in. column of resin in hydroxide form yielded 3-*O*-(α-D-galactopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.48 g) which crystallized from ethyl acetate – Skellysolve B, m.p. 154–156°, $[\alpha]_D^{23}$ +94.4° (*c*, 0.89 in DMF).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 51.23; H, 7.00.

Further elution with water afforded 3-*O*-(α-D-talopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.57 g) which crystallized from ethyl acetate – Skellysolve B, m.p. 144–145°, $[\alpha]_D^{23}$ +51.4° (*c*, 1.1 in DMF).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.18; H, 7.16. Found: C, 51.00; H, 7.17.

Similar treatment of the above-described oil (3.80 g) yielded 3-*O*-(α-D-talopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.82 g), and 3-*O*-(α-D-galactopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.66 g). The compounds were identical to the products described above and obtained from the hydrated uloside intermediate.

3-O-(α-D-Galactopyranosyl)-D-glucose (5)

A solution of 3-*O*-(α-D-galactopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (0.70 g) in 90% aqueous trifluoroacetic acid (7.0 ml) was kept at room temperature for 15 min and then concentrated *in vacuo*. Trituration of the residue with ether yielded an amorphous powder which was chromatographed on a 48 in. × 1.5 in. column of ion-exchange resin in the potassium form to yield a pure disaccharide as an amorphous solid (0.40 g, 71%), $[\alpha]_D^{22}$ +159° (*c*, 1.06 in water).

3-O-(α-D-Talopyranosyl)-D-glucose (6)

3-*O*-(α-D-*Talopyranosyl*)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (1.1 g) was hydrolyzed with 90% trifluoroacetic acid (11.0 ml) and the product purified as described above to yield an amorphous powder (0.65 g, 73%), $[\alpha]_D^{22}$ +115° (*c*, 0.65 in water).

The financial support of the National Research Council of Canada through a grant-in-aid of research (A-172) to R.U.L. is gratefully acknowledged. The microanalyses and n.m.r. spectra were carried out by the analytical and spectral services laboratories of this department.

Chemical Synthesis of α-Linked 2′-Amino-2′-deoxydisaccharides

R. U. LEMIEUX, K. JAMES,[1] AND T. L. NAGABHUSHAN[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

The reduction by borane in tetrahydrofuran of the 2-acetoximino-tri-*O*-acetyl-α-D-*arabino*-hexopyranosyl derivatives of 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose and 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1** and **4**, respectively) proceeds with a high degree of stereoselectivity for the α-D-*gluco*-configuration and affords a convenient route to 2-amino-2-deoxy-α-D-glucopyranosides. The reduction of the corresponding 2-acetoximino-tri-*O*-acetyl-α-D-*lyxo*-hexopyranosyl derivatives (**7** and **12**) proceeds with slight stereoselectivity favoring the α-D-*talo*-configuration. Chromatographic separation was required to provide the *N*-acetyl derivatives of 2-amino-2-deoxy-α-D-galactopyranosides and 2-amino-2-deoxy-α-D-talopyranosides.

La réduction par le borane dans le tétrahydrofurane des dérivés de l'acétoximino-2-tri-*O*-acétyl-α-D-*arabino*-hexopyranosyle du di-*O*-isopropylidène-1,2;3,4-α-D-galactopyranose et di-*O*-isopropylidène-1,2;5,6-α-D-glucofuranose (**1** et **4**, respectivement) se fait avec un haut degré de stéréosélectivité en faveur de la configuration α-D-*gluco* et fournit une voie d'accès commode aux amino-2 déoxy-2-α-D-glucopyranosides. La réduction des dérivés acétoximino-2-tri-*O*-acétyl-α-D-*lyxo*-hexopyranosyles correspondants (**7** et **12**) se fait avec une stéréosélectivité faible en faveur de la configuration α-D-*talo*. La séparation chromatographique a été nécessaire pour obtenir les dérivés *N*-acétylés des amino-2-déoxy-2-α-D-galactopyranosides et des amino-2-déoxy-2-α-D-talopyranosides. [Traduit par le journal]

Can. J. Chem., **51**, 48 (1973)

Umezawa has recently offered the opinion that "the preparation of α-glycopyranosides in high yields still remains the most important problem of carbohydrate chemistry" (1). This challenge also applies to the related problem of the synthesis of α-linked 2-amino-2-deoxyglycopyranosides (2, 3). In this paper, we report by way of the preparation of six 2-acetamido-2-deoxy-α-D-glycopyranosyl-D-hexopyranoses (compounds **3**, **6**, **10**, **11**, **15**, and **16**) a synthetic approach which offers a solution to this problem. The *N*-acetyl compounds were prepared primarily for reasons of convenience; the method provides ready access to the free aminoglycosides. 2-Amino-2-deoxy-α-D-glucopyranosides are obtained in high yield but 2-amino-2-deoxy-α-D-galactopyranosides are only available as the minor component of a mixture with the *talo*-isomer.

A previous publication (4) described the preparation of the acetoximes **1**, **4**, **7**, and **12**. In another paper (3), methods were developed for the reduction of these compounds and the parent oximes to 2-amino-2-deoxyglycopyranosides mainly through a study of model 2-oximinoglycopyranosides. The reduction of the above-mentioned acetoximes with borane in tetrahydrofuran and characterization of the products leading to the disaccharide structures **3**, **6**, **10**, **11**, **15**, and **16** was reserved for this paper.

The reduction of the 2-acetoximino-α-D-*arabino*-hexopyranosides **1** and **4** provided the 2-amino-2-deoxy-α-D-glucopyranosides **2** and **5** in near quantitative yield. These latter products were characterized as the *N*-acetyl derivatives which, on hydrolysis to remove the isopropylidene groups, provided the disaccharide structures **3** and **6**.

In contrast to the high degree of stereoselectivity achieved in the reductions of compounds **1** and **4** by borane, the reductions of the 2-acetoximino-α-D-*lyxo*-hexopyranosides **7** and **12** gave mixtures of the epimeric *galacto*- and *talo*- products. This result appears related to hindrance by the C_4-substituent to axial approach to the reacting center (3, 5). The ratio of compounds **8** (*galacto*) and **9** (*talo*) isolated by chromatography of their *N*-acetyl derivatives was 1:2. This ratio was 3:4 for compounds **13** (*galacto*) and **14** (*talo*). The *N*-acetyl derivatives of compounds **8**, **9**, **13**, and **14** were isolated in pure crystalline condition. The characterizations were by n.m.r. and hydrol-

ysis to the component monosaccharides. Hydrolytic removal of the isopropylidene groups in 90% aqueous trifluoroacetic acid provided the disaccharide structures **10**, **11**, **15**, and **16** (see Table 1).

In summary, this research has led to a synthetic method which promises to offer means for the synthesis in good overall yield of 2-amino-2-deoxy-α-glucopyranosides with complex aglycons as are found in many important antibiotics (6, 7). The research was to an important degree motivated by the occurrence of a 2-acetamido-2-deoxy-α-D-galactopyranosyl residue in the antigenic determinant of blood group substance A (8). Although the method has allowed the synthesis of 3-*O*-(2-acetamido-2-deoxy-α-D-galactopyranosyl)-D-galactose (9), the yield of the *galacto*-configuration in the borane reduction was low as

experienced in the preparations of compounds **8** and **13**. The challenge then remains to establish means for the stereoselective reduction of 2-oximino-α-D-*lyxo*-hexopyranosides to 2-amino-2-deoxy-α-D-galactopyranosides. This matter is under investigation.

Experimental

The experimental procedures were the same as those previously reported (3, 10). The elution chromatograms on microcrystalline cellulose (Avicel, FMC Corporation, Newark, Delaware) (11) employed 100 g per gram of crude mixture using *n*-butanol – pyridine – water – acetic acid (6:4:3:1) as the developing phase. The conditions for the ion-exchange and thin layer chromatograms were reported in an accompanying paper (10).

The 100 MHz spectra were measured for all the products reported herein. In each case, the spectrum required high purity and was in complete accord with that expected for the assigned structure

Reductions with Diborane

The acetoxime, compound **1**, **4**, **7**, or **12** (10 mmol) was dissolved in 45 ml of tetrahydrofuran (THF) and the solution was cooled to −5° under an atmosphere of nitrogen. A molar solution of borane in THF (45 ml) was then added at such a rate as to maintain the temperature near −5°. The resulting solution was left at room temperature for 3 h. Methanol (100 ml) was then added dropwise and the solution evaporated to a solid residue. The residue was taken up in methanol (150 ml) and the solution stirred briefly with ion-exchange resin (Dowex 1-X8 in the hydroxide form) (50 ml). Removal of the resin and evaporation provided a solid foam which was further processed as described below depending on the compound reduced.

Hydrolysis of the Isopropylidene Groups

The compound (approximately 10 mmol) was dissolved in 50 ml of 90% trifluoroacetic acid and the solution kept at room temperature for 15 min (12). The solution was then evaporated, *in vacuo* below 40°, to an oil which, on trituration with ether, provided an amorphous powder.

Acetylations

Direct *N*-acetylations were performed by dissolving the amine (10 mmol) in 50% aqueous methanol (20 ml) and adding acetic anhydride (10 ml). After 2 h at room temperature, the solution was evaporated to dryness *in vacuo*.

Peracetylations were carried out by dissolving the compound (10 mmol) in acetic anhydride – pyridine (1:2) and maintaining the solution at 4° for 12 h. The product was isolated by first removing the solvents *in vacuo*, adding water, and isolating the product by extraction with chloroform in the usual manner.

De-*O*-acetylations were performed by dissolving the compound (10 mmol) in 50% aqueous methanol (50 ml) and adding 2 ml of triethylamine. The solution was kept refrigerated for 12 h and then evaporated to yield the crude product.

N-2,4-Dinitrophenylation

The amine, about 1 mmol, was dissolved in water (10 ml) containing sodium bicarbonate (0.21 g). A solution of 1-fluoro-2,4-dinitrobenzene (0.25 g) in acetone (5 ml) was then added. After stirring for 24 h, the solution was taken to dryness and the residue acetylated.

Hydrolyses

Hydrolysis of the 2′-acetamido-2′-deoxydisaccharides was effected by heating a solution in 4 *N* hydrochloric acid at 100° for 1 h. The amino-sugar liberated was identified by paper electrophoresis (13).

The aglycon-sugars were best identified by paper chromatography (10) after hydrolyzing the disaccharide in 1 *N* hydrochloric acid at 100° for 1 h.

6-O-(2-Acetamido-tri-O-acetyl-2-deoxy-α-D-glucopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

The crude product (**2**) obtained by reduction of **1** was acetylated to yield material which appeared to be homogeneous on t.l.c. examination. Crystallization from ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yielded the title compound (77%), m.p. 128–129°, $[\alpha]_D^{28}$ +23° (*c*, 1.7 in chloroform).

Anal. Calcd. for $C_{26}H_{39}NO_{14}$: C, 52.96; H, 6.67; N, 2.38. Found: C, 53.13; H, 6.74; N, 2.23.

6-O-(2-Acetamido-2-deoxy-α-D-glucopyranosyl)-D-galactopyranose (3)

The above compound was de-*O*-acetylated in quantitative yield to a single product (t.l.c.) which was not further characterized. Hydrolysis of the isopropylidene groups gave a powder which was taken up in methanol and reprecipitated by adding ether. The yield was 62% of a white powder, $[\alpha]_D^{23}$ +126° (*c*, 0.65 in water). The n.m.r. spectrum and paper chromatographic behavior were consistent with the assigned structure in a high degree of purity (see Table 1).

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 44.04; H, 6.83; N, 3.92.

6-O-[Tri-O-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl]-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

A sample of the crude reduction product of **1** was converted to the *N*-2,4-dinitrophenyl derivative and then acetylated. The product crystallized readily and was recrystallized from ethanol, m.p. 201–202° (sintering 185–190°), $[\alpha]_D^{28}$ −28° (*c*, 1.2 in chloroform).

Anal. Calcd. for $C_{30}H_{39}N_3O_{17}$: C, 50.49; H, 5.51; N, 5.89. Found: C, 50.20; H, 5.30; N, 5.93.

3-O-(2-Acetamido-tri-O-acetyl-2-deoxy-α-D-glucopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

The product (impure **5**) from the reduction of **4** was acetylated. The product crystallized readily and was recrystallized from ethyl acetate – Skellysolve B in 75% yield, m.p. 168–170°, $[\alpha]_D^{23}$ +32° (*c*, 1.2 in chloroform).

Anal. Calcd. for $C_{26}H_{39}NO_{14}$: C, 52.96; H, 6.67; N, 2.38. Found: C, 52.51; H, 6.72; N, 2.48.

3-O-(2-Acetamido-2-deoxy-α-D-glucopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

De-*O*-acetylation of the above compound gave a crystalline product which was recrystallized from ethanol (90% yield), m.p. 228–229°, $[\alpha]_D^{23}$ +80° (*c*, 1.8 in DMF).

Anal. Calcd. for $C_{20}H_{33}NO_{11}$: C, 51.82; H, 7.19; N, 3.02. Found: C, 52.10; H, 7.23; N, 3.24.

3-O-[Tri-O-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl]-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

This compound was prepared from crude **5**. After recrystallization from ethanol, the product melted at 216–218°, $[\alpha]_D^{28}$ +15° (*c*, 1.7 in chloroform).

Anal. Calcd. for $C_{30}H_{39}N_3O_{17}$: C, 50.49; H, 5.51; N, 5.89. Found: C, 50.31; H, 5.57; N, 5.86.

3-O-(2-Acetamido-2-deoxy-α-D-glucopyranosyl)-D-glucopyranose (6)

The above-described 3-*O*-(2-acetamido-2-deoxy-α-D-glucopyranosyl)-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose was hydrolyzed to remove the isopropylidene groups to provide an amorphous material. The product crystallized from ethanol in 45% yield, m.p. 212–215°, $[\alpha]_D^{21}$ +182.2 → 157.8° (*c*, 0.92 in water).

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 44.18; H, 6.44; N, 3.51.

6-O-(2-Acetamido-2-deoxy-α-D-galactopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose and 6-O-(2-Acetamido-2-deoxy-α-D-talopyranosyl)-1,2;3,4-di-O-isopropylidene-α-D-galactopyranose

N-Acetylation of the reduction product (crude mixture of **8** and **9**) of compound **7** gave an amorphous powder which was chromatographed on ion-exchange resin (Dowex 1, 200–400 mesh, hydroxide form) to yield first, 6-*O*-(2-acetamido-2-deoxy-α-D-galactopyranosyl)-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (1.39 g; 29%) which crystallized from ethyl acetate – Skellysolve B, m.p. 151–153°, $[\alpha]_D^{23}$ +69° (*c*, 1 in DMF).

Anal. Calcd. for $C_{20}H_{33}NO_{11}$: C, 51.82; H, 7.19; N, 3.02. Found: C, 51.43; H, 7.12; N, 3.24.

The *talo*-isomer followed (2.79 g, 59%) which crystallized from water, m.p. 119–121°, $[\alpha]_D^{23}$ −9.7° (*c*, 1.5 in DMF).

Anal. Calcd. for $C_{20}H_{33}NO_{11}$: C, 51.82; H, 7.19; N, 3.02. Found: C, 51.52; H, 7.38; N, 2.89.

6-O-(2-Acetamido-2-deoxy-α-D-galactopyranosyl)-D-galactose (10) and 6-O-(2-Acetamido-2-deoxy-α-D-talopyranosyl)-D-galactose (11)

The crude product from the reduction of the acetoxime **7** was *N*-acetylated, the *O*-isopropylidene groups removed, and the product chromatographed on a column of microcrystalline cellulose. The first fraction was compound **11** (*talo*-isomer) isolated in 48% yield, $[\alpha]_D^{21}$ +65° (*c*, 3.2 in water). This compound liberated talosamine and galactose on acid hydrolysis and was identical to the product formed on hydrolysis of the above-described di-*O*-isopropylidene derivative.

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 43.62; H, 6.55; N, 3.57.

Further elution afforded 6-*O*-(2-acetamido-2-deoxy-α-D-galactopyranosyl)-D-galactose (**10**) in 25% yield, $[\alpha]_D^{25}$ +137° (*c*, 0.6 in water); (lit. (14), $[\alpha]_D$ +142° (water)).

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 43.77; H, 6.58; N, 4.14.

This compound was also obtained on removal of the isopropylidene groups of the above described *N*-acetyl derivative of **8**.

3-O-(2-Acetamido-2-deoxy-α-D-galactopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose and 3-O-(2-Acetamido-2-deoxy-α-D-talopyranosyl)-1,2;5,6-di-O-isopropylidene-α-D-glucofuranose

N-Acetylation of the reduction product (crude mixture of **13** and **14**) of compound **12** gave an amorphous powder which was chromatographed on ion-exchange resin (Dowex 1, 200–400 mesh in the hydroxide form). The first fraction, 35% yield, crystallized spontaneously and was recrystallized from ethyl acetate, m.p. 223–224°, $[\alpha]_D^{23}$ +95° (*c*, 0.6 in DMF).

Anal. Calcd. for $C_{20}H_{33}NO_{11}$: C, 51.82; H, 7.19; N, 3.02. Found: C, 51.63; H, 7.36; N, 3.15.

The corresponding *talo*-isomer was then obtained from the chromatogram as an oil in 47% yield which crystallized from ethyl acetate – Skellysolve B, m.p. 163–165°, $[\alpha]_D^{23}$ +27.3° (*c*, 0.52 in DMF).

Anal. Calcd. for $C_{20}H_{33}NO_{11}$: C, 51.83; H, 7.13; N, 3.02. Found: C, 51.79; H, 6.95; N, 3.30.

3-O-(2-Acetamido-2-deoxy-α-D-galactopyranosyl)-D-glucose (15)

Hydrolysis of the above-described *N*-acetyl derivative of **13** provided a product which crystallized from ethanol, m.p. 212–215°, $[\alpha]_D^{21}$ +177→ 187° (*c*, 0.9 in water) (see Table 1).

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 44.18; H, 6.44; N, 3.63.

3-O-(Acetamido-2-deoxy-α-D-talopyranosyl)-D-glucose (16)

Hydrolysis of the above-described *N*-acetyl derivative of **14** provided a product which crystallized from ethanol, m.p. 190–195°, $[\alpha]_D^{23}$ +82 → 70° (*c*, 0.5 in water) (see Table 1).

Anal. Calcd. for $C_{14}H_{25}NO_{11}$: C, 43.86; H, 6.57; N, 3.65. Found: C, 43.65; H, 6.83; N, 3.43.

The Synthesis of Kanamycin Analogs I. α-D-Glucopyranosyl Derivatives of Deoxystreptamine[1]

R. U. LEMIEUX, T. L. NAGABHUSHAN,[2] K. J. CLEMETSON,[3] AND L. C. N. TUCKER[4]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 2, 1972

The procedure developed in this laboratory for the synthesis of α-D-glucopyranosides based on the reaction of dimeric tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride with alcohols was employed to synthesize the three α-D-glucopyranosyl deoxystreptamines and 4,6-di-*O*-α-D-glucopyranosyl deoxystreptamine. Effects of p*H* change on the n.m.r. spectra of kanamycins A and B and of the above synthetic compounds are interpreted in terms of a conformational change.

Le procédé développé au laboratoire pour la synthèse des α-D-glucopyranosides à partir de la réaction entre le chlorure de tri-*O*-acétyl-déoxy-2 nitroso-2-α-D-glucopyranosyle dimère et les alcools, a été utilisé pour obtenir les trois α-D-glucopyranosyl déoxystreptamines et le di-*O*-α-D-glucopyranosyl-4,6-déoxystreptamine. Les effets du p*H* sur les spectres r.m.n. des kanamycines A et B des composés synthétiques ci dessus sont interprétés par rapport au changement conformationnel.

[Traduit par le journal]

Can. J. Chem., **51**, 53 (1973)

The widespread distribution of α-glycosidic bonds in naturally occurring antibiotics (1) has strongly motivated an interest in improved methodology for the stereoselecive synthesis of α-glycosides in high yield. Such developments are of interest not only for the possible total synthesis of therapeutically useful antibiotics, but also, by making available synthetic analogs, for improving our knowledge of structure-activity relationships.

The so-called aminocyclitol group of antibiotics (1) provide a most interesting subject for synthetic investigations in view of the large and ever increasing number of the members of this family which have deoxystreptamine (1,3-diamino-1,2,3-trideoxy-*myo*-inositol) as a building unit. The deoxystreptamine antibiotics include the kanamycins A, B, and C, the neomycins A, B, and C, the paromomycins I and II, the gentamycins, hygromycin B_2, the nebramycins (see ref. 1 for a review of the foregoing antibiotics), butyrosins (2), destomycin A (3), and sisomycin (4). In many of these antibiotics at least one of the glycosidic bonds to the deoxystreptamine residue involves an α-D-*gluco*-linkage with or without an amino group at the 2-position. Thus, in order to effectively synthesize such structures, the stereoselective synthesis of α-D-glucopyranosides in good yield is a basic requirement. For this reason, research was initiated in this laboratory several years ago toward the development of improved methodology to cope with this classical problem of carbohydrate chemistry. As a result, a method was established (5–8) based on the nitrosyl chloride adduct of D-glucal triacetate (tri-*O*-acetyl-1,5-anhydro-2-deoxy-D-*arabino* hex-1-enitol) (9, 10) as the glycosylating reagent. A main purpose of the present research was to test the effectiveness of this approach for the synthesis of α-D-glucopyranosides of deoxystreptamine. It has already been demonstrated (11) that the method can be used for the preparation of simple glycosides of 6-amino-6-deoxy-D-glucose, a building unit of kanamycin. A second purpose of the research was to obtain model compounds for the study of the chemical shifts which occur for the two anomeric hydrogens of kanamycin A, since such studies may provide information on the conformation of kanamycin A in aqueous solution.

A number of total syntheses of aminocyclitol antibiotics have appeared since the advent of this research program. All these syntheses were

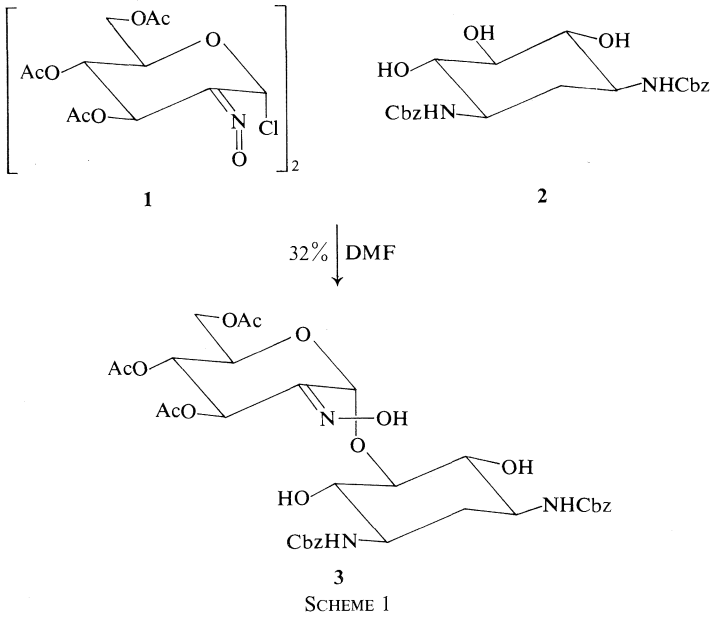

SCHEME 1

modelled on more classical approaches to the synthesis of α-D-glycosidic linkages and include the syntheses of kanamycin A (12, 13), kanamycin B (14), kanamycin C (15), paromamine (16), and neomycin A (neamine) (17). The nitrosyl chloride adduct of a glycal structure was employed in an ingenious preparation of the cyclitol antibiotic kasugamycin by Umezawa and coworkers (18). This antibiotic possesses a 2,3,4,6-tetradeoxy-α-D-*arabino*-hexopyranosyl building unit. Our approach to the synthesis of α-D-glucopyranosides of deoxystreptamine proceeds by way of 2-oximino-α-D-*arabino*-hexopyranosides. These intermediates can also be reduced to 2-amino-2-deoxy-α-D-glucopyranosyl derivatives of deoxystreptamine, the structural units of which are found in the aminocyclitol antibiotics, for example, kanamycin C, paromomycin, and streptomycin.

Syntheses of Mono-O-α-D-glucopyranosyl Derivatives of Deoxystreptamine

The 1,3-di-*N*-benzyloxycarbonyl derivative of deoxystreptamine (**2**) has been reported (19) to be a suitable derivative of deoxystreptamine for the synthesis of a variety of its *O*-glycosides. The good solubility of **2** in dimethylformamide and the ease of removal of the protecting groups by catalytic hydrogenation appeared in our hands also to be superior to other possible derivatives. Since Umezawa and Ito (19) reported a good yield of the di-*O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine by reaction of **2** (without further blocking) with tetra-*O*-acetyl-α-D-glucopyranosyl bromide in the presence of mercuric cyanide, it was thought that it should be possible to prepare kanamycin A analogs similarly. However, when **2** was reacted with an equivalent amount of the nitrosyl chloride adduct **1** (10), the main product formed (32% yield) was characterized as 5-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**3**) (see Scheme 1). The crude glycosidic products were obtained in 83% yield (calculated as pure **3**) and 11% of **2** was reclaimed. The crude material was separated into three fractions by column chromatography. Comparison of these materials with samples of 4,6-di-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**17**, to be described below) and the mixture of the diastereoisomeric 4- and 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**11** and **12**, also to be described below) were made by t.l.c. The substance which moved fastest was different to the latter three compounds. The second fraction from the column chromatogram had the same R_f value as the dioximinoglycoside **17** and the third had the same R_f value

as the above-mentioned mixture of monooximinoglycosides, **11** and **12**, the components of which could not be separated. These latter two fractions were not further characterized.

The first substance to appear in the eluate of the above chromatogram was found to be the 5-*O*-monooximinoglycosyl derivative (**3**) of 1,3-di-*N*-benzyloxycarbonyldeoxystreptamine as follows. The substance was deoximated and then reduced with borohydride. Acetylation provided a crystalline product **4** (see Scheme 2). The protecting groups of **4** were removed to give a basic, dextrorotatory material **5** which was purified by chromatography on Dowex-1-X2 in the hydroxide form in 88% yield from **4**, corresponding to an overall yield of 23% from **2**. The pure but amorphous compound was obtained in the crystalline form after rechromatographing until its optical rotation was constant (two chromatographs). The overall yield of the crystalline material **5**, m.p. 191–192° with decomposition beginning at 180°, $[\alpha]_D^{25}$ +107.5°, was 14% from 1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**2**). The n.m.r. spectrum showed a doublet at τ 4.70 with a spacing of 3.0 Hz, the approximate position and structure of which is characteristic of the signal for the anomeric hydrogen of α-D-glucopyranosides. Both paper electrophoresis and paper chromatography indicated the compound to be homogeneous. Furthermore, acid hydrolysis cleaved it to only D-glucose and deoxystreptamine as identified by paper chromatography. The position of attachment of the α-D-glucopyranosyl group was established to be the 5-position of the deoxystreptamine residue by periodate oxidation of the 1,3-di-*N*-acetyl derivative **6**. As expected from this structure, the deoxystreptamine residue survived the oxidation. This was not the case, as will be seen below, for the isomers **15** and **16** which have the α-D-glucopyranosyl group at the 6- and the 4-position, respectively, of the 1,3-di-*N*-acetyldeoxystreptamine. On the basis of these results it is concluded that the rate of reaction of **1** with **2** occurs substantially more rapidly at the 5-position of **2** than at either positions **4** or **6**, a remarkable finding in view of the opposite situation in the case of β-D-glucopyranoside formation (19).

In order to synthesize 4-*O*-α-D-glucopyranosyldeoxystreptamine (**14**) and the diastereoisomer **13** which has the glucose residue at the 6-position, it was necessary to block the 5-position of **2**. A suitable derivative appeared to be the racemic mixture of 4,5- and 5,6-*O*-isopropylidene-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**7** and **8**) described by Nakajima and coworkers (20). Condensation of **1** with this compound in dimethylformamide at room temperature for 5 days afforded a mixture of products from which the desired diastereoisomeric mixture of 4-*O*- and 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-*O*-isopropylidene-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine was isolated in 53% yield (from compound **2**) by column chromatography (see Scheme 3). This mixture, $[\alpha]_D^{24}$ +30°, gave an n.m.r. spectrum, τ 8.60 (isopropylidene group), 7.96 (*O*-acetyl groups), 3.86 (H-1, singlet), 4.92 and 2.71 (benzyloxy groups), which was in agreement with the expected structures. Some cleavage of the acid-labile *trans*-*O*-isopropylidene groups occurred during the condensation.

Deoximation of the mixture in the presence of hydrochloric acid led to simultaneous hydrolysis of the isopropylidene groups (see Scheme 4). Reduction of the crude ketone with sodium borohydride followed by *O*-acetylation afforded hexa-*O*-acetyl-α-D-glucopyranosyl-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine as a mixture of isomers. After removal of the *O*- and *N*-protecting groups, the two main components, which showed signals for anomeric hydrogens in the n.m.r. spectrum at τ 4.92 and 4.72 were separated by chromatography on a Dowex-1-X2 (hydroxide form) column. The compounds (**13** and **14**) were indistinguishable by both paper electrophoresis and chromatography. However, the substance which was eluted from the column first possessed an n.m.r. spectrum showing a single anomeric signal at τ 4.91 with a spacing of 3.5 Hz. On rechromatographing the product four times, until its rotation was constant, the compound crystallized, m.p. 264–265° with decomposition beginning at 240°, $[\alpha]_D^{25}$ +86.5°, $[\alpha]_{436}^{24}$ +170° (water), $\Delta[M]_{TACu}$ −720° (21, 22). In a subsequent preparation of this compound, it could be isolated directly from the crude mixture in the crystalline form by seeding.

The other compound had an n.m.r. spectrum showing the H-1 signal at τ 4.71 with a spacing of 3.5 Hz. Although this product was obtained in a very high state of purity by chromatographing several times until its rotation was constant, the product has failed to crystallize. The amorphous white solid had $[\alpha]_D^{25}$ +98°, $[\alpha]_{436}^{24}$ +159.5° water and $\Delta[M]_{TACu}$ +746° (21, 22).

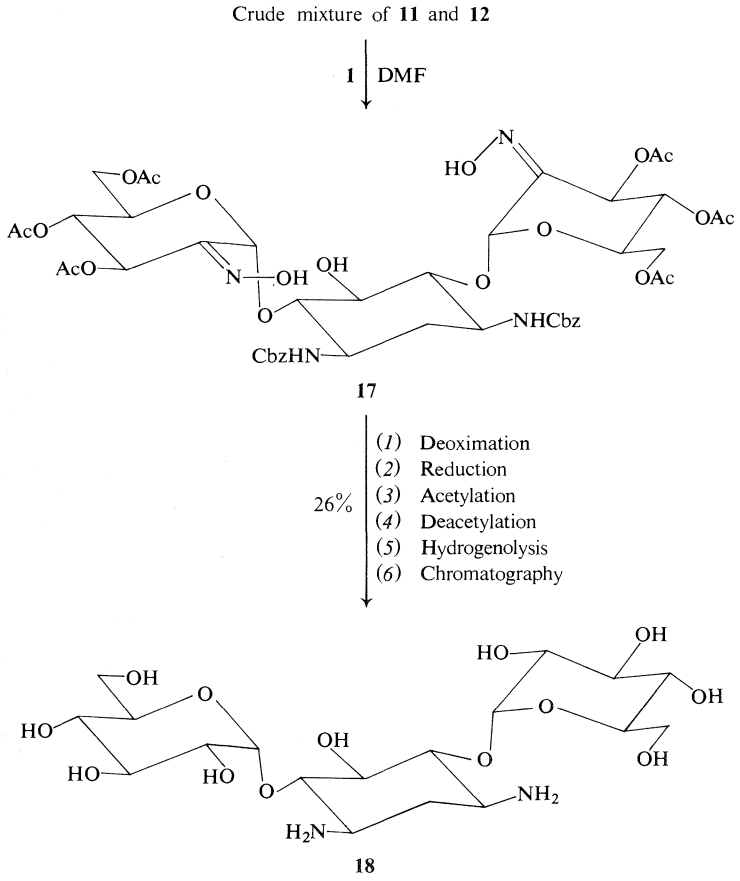
From n.m.r. and optical rotary data it was evident that the compounds **13** and **14** were α-D-glucopyranosyl derivatives of deoxystreptamine. The positions of linkages to deoxystreptamine were established to be O-6 and O-4, respectively, since periodate oxidation of both **13** and **14** and their respective *N*-acetyl derivatives **15** and **16** destroyed the deoxystreptamine molecule completely as ascertained by acid hydrolysis of the oxidized products followed by their analysis by paper electrophoresis. The observed positive $\Delta[M]_{TACu}$ for compound **14** required (21, 22) it to be the 4-isomer. Similarly, the negative $\Delta[M]_{TACu}$ shown by **13** indicates that it is the 6-isomer.

During the preparation of this manuscript Nishimura *et al.* (23) reported the preparation of **13** and **14** from 1,3-diethoxycarbonyldeoxystreptamine by a modified Koenigs–Knorr reaction. It is noteworthy that while the overall yield of **13** and **14** by their procedure is 6.3 and 0.5%, respectively, the yields by the method described in this paper are 17 and 9%. The $\Delta[M]_{TACu}$ values of $-720°$ for compound **13** and $+746°$ for **14** found in this laboratory are in close agreement with those, $-730°$ and $+735°$, reported for the same compounds by the above authors.

Synthesis of 4,6-Di-O-α-D-glucopyranosyl-deoxystreptamine (18)

For the synthesis of a kanamycin A analog, 4,6-di-*O*-α-D-glucopyranosyl-deoxystreptamine (**18**), it was felt that condensation of the diastereoisomeric mixture of 4- and 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**11** and **12**) with the nitrosyl chloride adduct **1** should give mainly 4,6-di-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**17**) (see Scheme 5). This reasoning was based on the fact that attempted condensation of **3** with excess **1** did not yield an appreciable amount of either the 4,5- or the 5,6-diglycoside. Thus, the introduction of a glycosidic linkage strongly hinders further glycosidation at a neighboring position. Further evidence in this regard was by our observation (24) that reaction of a mixture of 4- and 6-*O*-acetyl-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (prepared from **7** and **8** by *O*-acetylation followed by removal of the *O*-isopropylidene group) with a large excess of **1** gave only very low yields of the 4,5- and 5,6-dioximinoglycoside. Similar results were obtained by Nakajima and coworkers (12) in the condensation of 4-*O*-(6-acetamido-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine with 3-acetamido-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride. Whereas the 4,6-derivative was formed in 41% yield at 30°, the 4,5-isomer was formed in only 5% yield. Indeed, when the mixture of compounds **9** and **10** was hydrolyzed to remove the isopropylidene groups and the product (mixture of **11** and **12**) was condensed with a slight excess of **1**, 4,6-di-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**17**) was formed in good yield. Deoximation of this product followed by borohydride reduction and removal of the protecting groups as before gave pure 4,6-di-*O*-α-D-glucopyranosyldeoxystreptamine (**18**) after column chromatography on Dowex 1-X2 hydroxide form ion-exchange resin in an overall yield of 26% from 1,3-di-*N*-benzyloxycarbonyl deoxystreptamine (**2**). The white solid thus obtained was homogeneous when examined by paper chromatography and paper electrophoresis. The structure of the compound was established as follows. Acid hydrolysis gave only D-glucose and deoxystreptamine as identified by paper chromatography. The n.m.r. spectrum showed two anomeric signals at τ 4.64 and 4.83 each with a spacing of 3.5 Hz indicating the α-*gluco*-configuration. This conclusion was substantiated by the close agreement between the specific rotation of the compound, $+130°$ in water and that of kanamycin A free base, $+130.5°$ in water. The rotation of the corresponding β,β-anomeric structure is reported to be $-4.69°$ (19).

The points of attachment of the glucose residues in **18** were established by demonstrating that, whereas both deoxystreptamine and 5-*O*-α-D-glucopyranosyldeoxystreptamine (**5**) underwent oxidation by periodic acid with destruction of the aminocyclitol ring, the deoxystreptamine residue of both kanamycin A and compound **18** survived the oxidation in high yield. This data together with the n.m.r. data to be presented later on can leave no doubt that **18** indeed has the structure expected from the mode of synthesis. For unknown reasons, the deoxystreptamine residue did not survive oxidation when kanamy-



SCHEME 5

cin A and the analog **18** were oxidized at higher p*H* using sodium metaperiodate.

The Conformations of α-D-*Glucopyranosyl Derivatives of Deoxystreptamine and Kanamycin A in Solution*

The absolute configuration of kanamycin A was first established by chemical means (25–27) and the conclusions substantiated recently by X-ray crystallography (28). It is noteworthy that although the numbering of the positions in kanamycin A has consistently been made following the proposal by Hichens and Rinehart, Jr. (25), the basis for this proposal has not, to our knowledge, been presented. However, examination of the configurations of the 4- and 6-positions in terms of the Cahn–Ingold–Prelog sequence rule shows these centres to possess the R- and S-configurations, respectively. Thus, following the convention of giving R preference over S, the currently used numbering of the carbon atoms of deoxystreptamine is in accord with this procedure. In order to specify positions in the hexose residues, the carbons of the residue at the 4-position of the deoxystreptamine are assigned primed numbers, for example, 6′-amino-6′-deoxy-α-D-glucopyranosyl, and those at the 6-position are assigned double primed numbers, for example, 3′′-amino-3′′-deoxy-α-D-glucopyranosyl. These conventions for nomenclature are those used in the following discussions.

The n.m.r. spectrum of kanamycin A free base is shown in Fig. 1 and the spacings of the signals for H′ and H′′ clearly establish the α-linkage for both the amino-sugar units. The substantial chemical shift difference of τ 0.29 (see also Table 1) for these two anomeric hydrogens must arise from their different environments in the aqueous (D_2O) solution. These differences would presumably arise, in part, from differences in the

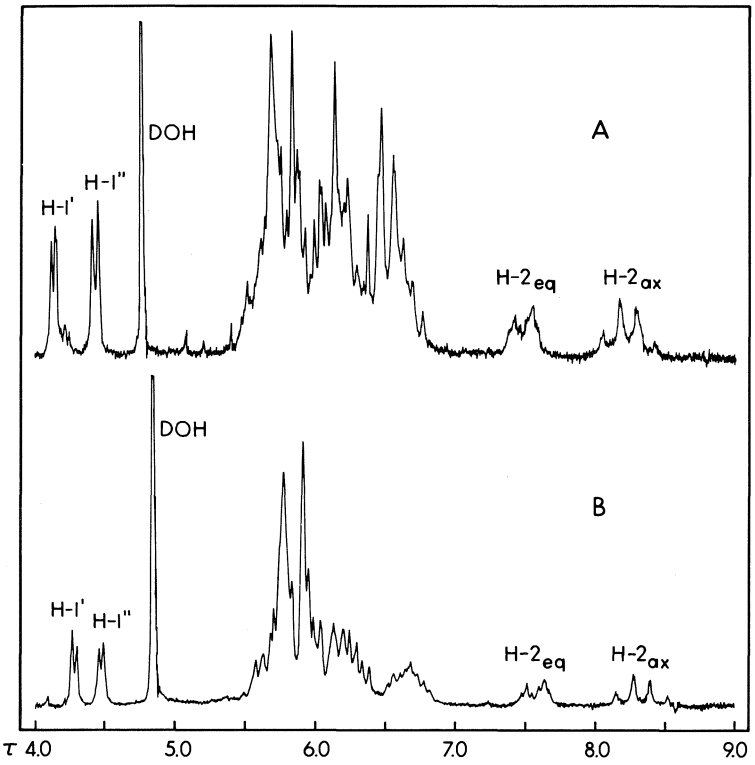

FIG. 1. The 100 MHz n.m.r. spectra in deuterium oxide of kanamycin A (spectrum A) and the synthetic 4,6-di-*O*-α-D-glucopyranosyl-deoxystreptamine (spectrum B) using pure tetramethylsilane as external reference.

structures of the amino-sugar units. However, the influence of the deoxystreptamine portion on the immediate environment of the two anomeric hydrogens could be expected to be different and perhaps dominating. It was of interest, therefore, to examine the n.m.r. spectral properties of 4,6-di-*O*-(α-D-glucopyranosyl)-deoxystreptamine (**18**) to assess these possibilities. The spectrum of this kanamycin analog (Fig. 1) shows that, as for kanamycin A, a substantial chemical shift difference exists between the two anomeric protons. Therefore, it is concluded that the main influence on the relative shielding of these two hydrogens arises from the deoxystreptamine unit.

The chemical shift difference, 0.29 p.p.m., for the anomeric protons of kanamycin A free base is larger than that, 0.19 p.p.m., for the diglucoside **18**. However, the chemical shift difference is increased for both compounds on converting the free base to salts either with acetic acid or hydrochloric acid. These differences are 0.43 and 0.41 p.p.m., respectively, for kanamycin A and 0.26 and 0.31 p.p.m., respectively, for **18**. It is to be noted, however, that this change arises in each case largely by a downfield shift of one of the protons. The signal for anomeric proton at the higher field which has a chemical shift virtually independent of p*H* is assigned to hexose residue at position 6 for two reasons. First of all, as seen in Table 1, the signal for the anomeric proton of 6-*O*-α-D-glucopyranosyl deoxystreptamine (**13**) is 0.16 p.p.m. to higher field than its 4-isomer (**14**) and its chemical shift is essentially p*H* independent. On the other hand, as expected from the behavior of kanamycin A and **18**, the signal for the anomeric proton (H-1′) of 4-*O*-α-D-glucopyranosyl deoxystreptamine moved to lower field for the salt forms. Secondly, it is known that the 2′,6′-diamino-2′,6′-dideoxy-α-D-glucopyranosyl group of kanamycin B is at the 4-position. It would be expected that conversion of kanamycin B to a salt form would lead to strong deshielding of H-1′ since salt formation is at the adjacent 2-position and, if the above assignment is correct, the chemical shift for H-1″ would be little affected. Indeed, as seen in Table 1, on conversion

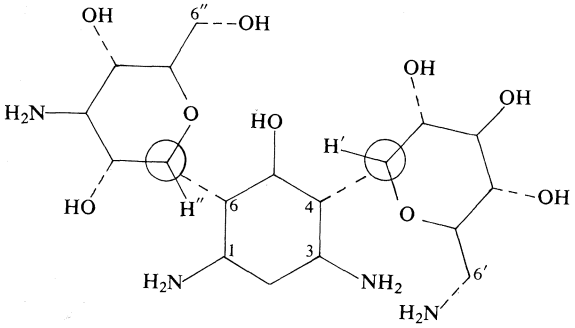
TABLE 1. Chemical shifts* (τ-values) for the anomeric hydrogens of kanamycin A and related compounds in D_2O

	Free base		Acetate salt		Hydrochloride salt		*N*-Acetyl derivative	
	H-1′	H-1″	H-1′	H-1″	H-1′	H-1″	H-1′	H-1″
Kanamycin A	4.67	4.96	4.47	4.90	4.41	4.82	4.67	4.90
Kanamycin B	4.70	4.97	4.12	4.90	4.02	4.85	—	—
4,6-Di-*O*-α-D-Glucopyranosyl-deoxystreptamine (**18**)	4.64	4.83	4.52	4.78	4.49	4.80	4.66	4.92
4-*O*-α-D-Glucopyranosyl-deoxystreptamine (**14**)	4.76	—	4.63	—	4.52	—	4.68	—
6-*O*-α-D-Glucopyranosyl-deoxystreptamine (**13**)	4.92	—	4.96	—	4.94	—	4.94	—
5-*O*-α-D-Glucopyranosyl-deoxystreptamine (**5**)	4.70	—	4.63	—	4.63	—	4.69	—
6-*O*-3″-Amino-3″-deoxy-α-D-glucopyranosyl-deoxystreptamine	—	—	4.88	—	—	—	4.90	—

*Measured at 60 MHz with 5% tetramethylsilane in chloroform as external reference.

of kanamycin B to either salt, the higher field signal has very nearly the same chemical shift as the corresponding signal in the salts of kanamycin A but the lower field signal is substantially to lower field than in the corresponding salts of kanamycin A. These assignments are in agreement with those made by Nakajima and coworkers (12, 29) on the basis of the chemical shifts of *N*-acetyl derivatives of kanamycin A and related structures. The n.m.r. data for the *N*-acetyl derivatives listed in Table 1 further confirm these assignments. It is therefore concluded that it is the anomeric hydrogen (H-1′) of the 6′-amino-6′-deoxy-α-D-glucopyranosyl residue which has a chemical shift highly sensitive to protonation of the amino groups of the deoxystreptamine residue.

Both because of the *exo*-anomeric effect and ordinary steric considerations (30), it is to be expected that both C-4 and -6 will project between the anomeric hydrogen and ring oxygen of the adjacent glucosyl residue as depicted in formula **19**. The torsional angle defined with the anomeric hydrogen may be very small, for example, only about 10° for the 1 → 4′ α-D-glucosidic linkage of crystalline methyl β-maltoside (31). Indeed, the X-ray crystallographic structures of kanamycin A both as the monosulfate and the monoselenate salts in the monohydrate forms conform to this prediction. Therefore, it seems necessary to conclude that in kanamycin A, H-1′ will project toward O-5 and H-1″ will project toward N-1. This conclusion is supported by the fact that H-1′ of 5-*O*-α-D-glucopyranosyl deoxystreptamine (**5**) must project toward an oxygen atom of the deoxystreptamine residue and, indeed, its chemical shift is near those of H-1′ of both kanamycin A and **18** and the shift is not highly sensitive to change in p*H*.



19

It may have been expected that H-1″ would be the anomeric hydrogen of either kanamycin A or **18** with a chemical shift sensitive to protonation rather than H-1′ which is relatively remote from amino groups. Since the reverse is the case, it seems likely that protonation of N-3 brings about a change in the chemical shift of H-1′ through a change in conformation about the glycosidic bond system for the 6′-amino-6′-deoxy-α-D-glucopyranosyl group which exposes H-1′ more to the applied magnetic field. A possible explanation is that protonation of N-3 leads to hydrogen bonding of N-3 with the ring

oxygen O-5′. These considerations are likely of importance since kanamycin A must be extensively protonated under physiological conditions. That the presence of the amino groups and their relative distributions in space is of critical importance to the antibiotic activities of kanamycin A is evidenced by the fact that the diglucoside **18** is virtually devoid of antibiotic activity.

In conclusion, we contend that the above-described syntheses of α-D-glucopyranosidic linkages in kanamycin-like structures exhibit substantial advantage over the relatively sterically uncontrolled methods based in Koenigs–Knorr type reactions and augur well for the ability of the synthetic organic chemist to provide complex glycosidic structures of interest to medicinal chemistry. It is planned to examine the reductions of the oximinoglycosidic structures **3**, **9**, **10**, and **17** to provide the corresponding 2-amino-2-deoxy-α-D-glucopyranosides.

Experimental

Methods

Melting points were determined on a heating stage and are uncorrected. Optical rotations were measured with a Perkin–Elmer Model 141 polarimeter. N.m.r. spectra were taken with Varian A60 and Varian HA100 spectrometers.

Paper electrophoresis was carried out using a Gilson Medical Electronics Model D high voltage electrophorator at 2 kV, 200 mA with pyridine – acetic acid – water, 10:1:89 (p*H* 6.0) buffer on Whatman No. 3MM paper. T.l.c. was carried out on Silica Gel G (E. Merck A. G., Darmstadt) using 25% sulfuric acid as the visualizer. Paper chromatography was carried out on Whatman No. 1 paper, using *n*-butanol – pyridine – water – acetic acid, 6:4:3:1 or *n*-propanol – pyridine – water – acetic acid, 15:10:12:3 as developer. Amino-sugars were detected using ninhydrin spray reagent (32) and other reducing sugars by silver nitrate – sodium hydroxide spray reagents (33). *N*-Acetyl derivatives of deoxystreptamine were detected by periodate–permanganate spray reagent (34).

Unless otherwise stated, dry column chromatography (35) was carried out using Silica Gel PF254 (E. Merck A.G., Darmstadt). Wet column chromatography was carried out using SilicAr CC-7, 100–200 mesh (Mallinckrodt Chemical Works, St. Louis, Mo.). All ion-exchange chromatograms were carried out with Dowex 1-X2 (OH^- form), 200–400 mesh resin using water as eluant (36).

Hydrogenations were carried out at 60 p.s.i. using 5% palladium-on-charcoal (Engelhardt Industries, Newark, New Jersey) as catalyst.

Solutions were dried over anhydrous sodium sulfate and all solvent removals were carried out *in vacuo* using rotary evaporator. Dimethylformamide was removed at 45° using the vacuum from an oil pump.

Determination of Points of Glucosidic Attachment to Deoxystreptamine

(1) By Chemical Degradation

(a) Control Experiments

(i) Determination of time required by periodic acid to oxidize deoxystreptamine

The time required for periodic acid to oxidize deoxystreptamine completely was determined as follows: A 1 mg sample of deoxystreptamine was dissolved in 1 ml water along with 10 mg periodic acid. The solution was set aside in the dark. Aliquots of 0.3 ml were withdrawn after 24, 48, and 72 h, respectively and treated with 0.03 ml ethylene glycol to destroy excess periodic acid. After 2 h, concentrated hydrochloric acid was added to the solution to make it approximately 4 *N* and heated on a steam bath for 1 h. The hydrolyzate thus obtained was analyzed both by paper electrophoresis and paper chromatography as described above. The intensity of the spot was compared with that of deoxystreptamine which had been similarly treated in a simultaneous experiment except for periodic acid which was omitted. Deoxystreptamine was still detected in samples which had been treated with periodic acid for 24 and 48 h, but was completely absent in the sample treated for 72 h. Hence in all the cases where periodic acid oxidations were performed, the samples were oxidized for 72 h.

(ii) Periodic acid oxidation of kanamycin A

A 1 mg sample of kanamycin A was dissolved in 1 ml water together with 10 mg periodic acid.The solution was left in the dark at room temperature for 72 h. Excess periodic acid was destroyed by addition of 0.1 ml ethylene glycol. After 2 h concentrated hydrochloric acid was added to the solution to make it approximately 4 *N* and the mixture was heated on a steam bath for 1 h. The resulting hydrolyzate was analyzed by paper chromatography and paper electrophoresis as described above. The hydrolyzate showed the presence of deoxystreptamine but no 6-amino-6-deoxy-D-glucose or 3-amino-3-deoxy-D-glucose indicating that both the amino-sugar residues were oxidized by periodic acid. In order to further confirm that the amino-sugars were not oxidized after hydrolytic cleavage of the glycosidic bonds, a concurrent experiment was carried out in which a solution of 10 mg periodic acid in 1 ml was set aside 72 h in the dark and then treated with 0.1 ml ethylene glycol for 2 h. Kanamycin A (1 mg) was now introduced followed by concentrated hydrochloric acid as above. The mixture was heated on a steam bath for 1 h and the hydrolyzate analyzed as above. Kanamycin A was also hydrolyzed similarly with 4 *N* hydrochloric acid and comparison of the two hydrolyzates clearly showed the presence of both the amino-sugars in the former thus confirming that the method could be used to determine the position of glycosidic attachment to deoxystreptamine unambiguously.

(b) Determination of the Position of Attachment in α-D-Glucopyranosyl Derivatives of Deoxystreptamine

A 1 mg sample of the glycoside, the position of attachment to deoxystreptamine of which was to be determined and its *N*-acetyl derivative were oxidized by periodic acid, hydrolyzed, and analyzed in the manner similar to that described above for kanamycin A. Authentic samples were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

used to identify spots on paper chromatograms and paper electrophoretograms. Kanamycin A, deoxystreptamine, their *N*-acetyl derivatives, and glucose were used as controls for the periodic acid oxidations. Positive tests for the presence of deoxystreptamine in the hydrolyzates were obtained for kanamycin A, tetra-*N*-acetyl kanamycin A, the monoglucoside **5**, the diglucosyl compound **18**, and its di-*N*-acetyl derivative **20**. Deoxystreptamine was not however found in the hydrolyzates from the monoglucosides **13**–**16**. A positive test for 3-amino-3-deoxy-D-glucose was obtained for tetra-*N*-acetylkanamycin A but not for kanamycin A. 6-Amino-6-deoxy-D-glucose was not present in these hydrolyzates. Glucose was not detected in the hydrolyzates from compounds **5**, **6**, **13**, **14**, **15**, **16**, **18**, and **20**.

(2) By Optical Rotation

The tetramine copper(II) sulfate, $Cu(NH_3)_4SO_4 \cdot H_2O$-(TACu) was prepared according to the method of Horn and Taylor (37) and the $\Delta[M]_{TACu}$ values determined as described by Umezawa *et al.* (21). The weighed sample of the compound (~0.02 mmol) was dissolved in 2 ml of 3.95% w/v TACu solution and the rotation measured at 436 mμ. An aqueous solution of the same compound was prepared at the same time and its rotation at 436 mμ also measured. The $\Delta[M]_{TACu}$ value was then obtained from the expression

$$\Delta[M]_{TACu} = ([\alpha]_{436}TACu - [\alpha]_{436}\,water) \times mol \cdot wt/100$$

as suggested by Umezawa *et al.* (21).

Nuclear Magnetic Resonance Spectra of Derivatives of Deoxystreptamine and Kanamycin A

The n.m.r. spectra were measured at 60 MHz at a concentration of 20% in carbon dioxide free deuterium oxide with the instrument operating at 33 ± 1°. The samples were prepared by freeze drying three times from solution of deuterium oxide. Chemical shifts are given in τ values and refer to spectra measured with 5% tetramethylsilane in chloroform as the external standard. The spectra of kanamycin A and **18** shown in Fig. 1 were obtained at 100 MHz at 33°.

*5-O-α-D-Glucopyranosyl-deoxystreptamine (**5**)*

1,3-Di-*N*-benzyloxycarbonyldeoxystreptamine (**2**) (19) (1 g, 2.32 mmol) and tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer (**1**) (10) (0.9 g, 1.33 mmol, 0.34 mequiv excess) were dissolved in 20 ml of dry dimethylformamide. The solution was left in the dark at room temperature until the t.l.c. (acetone – *n*-hexane 1:1) indicated completion of reaction (120 h). The solution was then concentrated to a thin syrup which was dissolved in chloroform for washing with water. In the course of the two water washes a precipitate appeared which was collected by filtration and identified (i.r) as the starting material **2**. The amount recovered was 110 mg (11%). The clarified chloroform solution was dried and concentrated to a light yellow solution (~10 ml) which was poured with stirring into 500 ml of *n*-hexane. The solid precipitate was collected by filtration, washed with *n*-hexane, and dried. The yield was 1.4 g (83%). Inspection by t.l.c. as above showed the substance to contain one major component (R_f 0.53), two minor components (R_f 0.46 and 0.29), a trace amount of **2**, and traces of very minor components.

A dry column of silica gel (22 cm × 4 cm in diameter) was prepared and the product was added to the top of the column as a solution in 10 ml of 1:1 mixture of acetone – *n*-hexane. The column was eluted with a mixture of acetone – *n*-hexane 3:7. Ten-milliliter fractions of the eluate were collected and examined for purity by t.l.c. Three main fractions were separated and only those portions were pooled which appeared homogeneous by t.l.c. In this manner, products A (535 mg), B (124 mg), and C (212 mg) were obtained. A total of 220 mg of interzone material was also isolated. Product B is considered to be a mixture of di-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-derivatives of **2** since its R_f value was in close correspondence with that observed on the same t.l.c. for authentic sample of this compound (see below). Furthermore, the relative intensities of the signals for acetyl (τ, 7.9–8.1) and phenyl group (τ, 2.68) protons in the n.m.r. spectrum were consistent with this structural assignment. Fractions A and C both appeared to be monoglycosyl derivatives of **2** as judged from the relative intensities of the signals for acetyl (τ 7.95, 8.01, and 8.05) and phenyl group (τ, 2.68) protons in their n.m.r. spectra.

Fraction A, $[\alpha]_D^{24}$ +65.5° (*c* 2 in chloroform), was an amorphous white solid (32% yield).

Anal. Calcd. for $C_{34}H_{41}O_{15}N_3$: C, 55.81; H, 5.65; N, 5.74. Found: C, 55.82; H, 5.60; N, 5.89.

Fraction C possessed the same R_f value on t.l.c. as the mixture of the 4- and 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino* hexopyranosyl)-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**13** and **14**).

Fraction A, assigned structure **3** (0.535 g), was dissolved in a mixture of acetonitrile (4 ml) and 1 *N* hydrochloric acid (1 ml) and acetaldehyde (4 ml) was added. After stirring for 3 h, the acetaldehyde was removed by partial evaporation and the mixture partitioned between ethyl acetate and water. The water layer was extracted with ethyl acetate and the combined ethyl acetate fractions were washed with saturated aqueous sodium bicarbonate solution. The extract was dried and concentrated to a yellow syrup. The syrup was dissolved in dichloromethane (5 ml) and added with stirring to 200 ml *n*-hexane. The precipitate was isolated, washed with *n*-hexane and dried. Yield 0.473 g, 88%. $[\alpha]_D^{24}$ +67° (*c*, 2 in $CHCl_3$). N.m.r. τ, 8.08, 8.11 (3 *O*-acetyl groups), 5.05 (2 CH_2 groups of the benzyloxy group).

Anal. Calcd. for $C_{34}H_{40}N_2O_{15} \cdot (H_2O)$: C, 55.58; H, 5.76; N, 3.81. Found: C, 55.48; H, 5.55; N, 3.55.

The above product (0.473 g) was dissolved in 10 ml of dioxane and 5 ml of water. The solution was cooled to 0° and sodium borohydride (200 mg) dissolved in 7.5 ml of dioxane–water (2:1) was added dropwise with stirring. The mixture was stirred at 0° for 0.5 h and then at room temperature for 1.5 h. The solution was then acidified with acetic acid and taken to dryness. The boric acid was was removed as methyl borate by co-distillation with methanol three times. The residue was acetylated overnight using 10 ml of pyridine and 2 ml of acetic anhydride at room temperature. The product, 0.513 g (94% yield from the above ketone) was isolated in the usual manner and 5-*O*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-4,6-di-*O*-acetyl-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**4**) was obtained in the form of a white fibrous crystalline solid (from benzene – *n*-hexane), m.p. 111–112°, $[\alpha]_D$

+66.5° (*c*, 2 in $CHCl_3$). The n.m.r. spectrum at 60 MHz showed the following features; six acetyl singlets at τ 8.13, 8.08, 8.02, 7.98, 7.93, 7.86; two phenyl groups at 2.70, and two methylene protons of the benzyloxycarbonyl group at 4.91.

Anal. Calcd. for $C_{40}H_{48}N_2O_{18}$: C, 56.87; H, 5.73; N, 3.32. Found: C, 56.71; H, 5.78; N, 3.15.

The above compound (0.513 g) was dissolved in a mixture of methanol (15 ml) and water (3 ml) and triethylamine (1.5 ml) was added. The resulting solution was left overnight at room temperature prior to solvent removal. The syrupy residue was dissolved in a mixture of dioxane (5 ml), water (2.5 ml), and acetic acid (0.3 ml) and hydrogenated for 8 h in the presence of 100 mg of catalyst. The solids were removed by filtration through a bed of Celite and the filtrate was concentrated to a pale brown syrup. The syrup was taken up in 5 ml of water for transfer to the ion-exchange resin column, 100 cm × 1.5 cm in diameter. Examination of fractions for purity by paper electrophoresis led to the pooling of fractions which, on freeze drying, provided 170 mg of a white amorphous powder. This corresponds to an overall yield of 23% from **2**. The n.m r spectrum at 100 MHz showed the following features: τ 4.76 (H-1, doublet, $J_{1,2}$ = 3.5 Hz); 7.8–9.1 (methylene protons of deoxystreptamine).

Anal. Calcd. for $C_{12}H_{24}O_8N_2$: C, 44.44; H, 7.46; N, 8.64. Found: C, 44.14; H, 7.47; N, 8.22.

A sample of the above compound (0.125 g) was rechromatographed as above on a 2.5 cm × 100 cm column until its rotation was constant (required twice rechromatographing). The product was crystallized from aqueous ethanol to give 0.077 g (14% overall yield from **2**), m.p. 191–192° with decomposition beginning at 180°, $[\alpha]_D^{24}$ +107.5° (*c*, 2 in water).

Anal. Calcd. for $C_{12}H_{24}O_8N_2$: C, 44.44; H, 7.46; N, 8.64. Found: C, 44.28; H, 7.39; N, 8.52.

5-O-α-D-Glucopyranosyl-1,3-di-N-acetyldeoxystreptamine (6)

Acetic anhydride (0.08 g) was added to a solution of **5** (0.108 g) in water (0.7 ml) and methanol (0.3 ml). The clear solution was set aside 1 h after which time 1 ml of Amberlite IRA 400 (OH^- form) was added and the mixture stirred for additional 1 h. The resin was removed and the solution concentrated to dryness. The residual solid was dried, dissolved in hot anhydrous methanol, and after cooling to room temperature precipitated with ether. The white precipitate was isolated by filtration, washed with ether and dried. The yield of **6**, $[\alpha]_D^{25}$ +65.5° (*c*, 0.3 in water) was 89%. The n.m.r. spectrum of the compound showed the anomeric signal at τ 4.69 with a spacing of 3.5 Hz and the *N*-acetyl protons appeared at τ 7.99 as a sharp singlet.

Anal. Calcd. for $C_{16}H_{28}N_2O_{10}$: C, 47.05; H, 6.91; N, 6.86. Found: C, 46.80; H, 6.86; N, 6.56.

6-O-α-D-Glucopyranosyl-deoxystreptamine (13) and 4-O-α-D-Glucopyranosyl-deoxystreptamine (14)

A mixture of 4,5- and 5,6-di-*O*-isopropylidene-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**7** and **8**) (20) (19.75 g, 42 mmol) and tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) (15.8 g, 46.5 mmol) was dissolved in dimethylformamide (200 ml) and left for 120 h in the dark at room temperature. The solution was concentrated to ~50 ml and diluted with 150 ml of dichloromethane. Some precipitate separated which was collected by filtration (0.5 g yield) and shown by i.r. spectroscopy to be 1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**2**). The clear filtrate was washed with water three times, then with saturated sodium chloride solution, dried, and concentrated to a brown foam. Yield 34.0 g (still contained some dimethylformamide).

Examination by t.l.c. (acetone – *n*-hexane, 1:1) showed one major fast-moving component R_f 0.73 and three minor components R_f 0.53, 0.46, and 0.29. The above mixture was transferred to the top of a silica gel column (120 cm × 4 cm) as a saturated solution in acetone – *n*-hexane 3:7 and eluted with the same solvent system. Twenty-milliliter fractions were collected and examined by t.l.c. Those containing pure, faster moving component were pooled and concentrated to give a brownish sticky foam which resisted crystallization. The yield of **9** and **10** was 17.2 g (53%), $[\alpha]_D^{24}$ +30° (*c*, 2 in $CHCl_3$). The n.m.r. spectrum of the material showed the isopropylidene signals at τ 8.59 (6-protons), the *O*-acetyl signals at 7.98 (9-protons), the methylene signals of the benzyloxycarbonyl group at 4.89 (4-protons), and the phenyl signal at 2.64 (10-protons).

Anal. Calcd. for $C_{37}H_{45}N_3O_{15}$: C, 57.58; H, 5.88; N, 5.45. Found: C, 57.16; H, 5.80; N, 5.28.

The crude material (10 g, 13 mmol) was dissolved in acetonitrile (100 ml) and 1 *N* hydrochloric acid (10 ml) and acetaldehyde (20 ml) were added. After stirring for 5 h, the acetaldehyde was removed by partial evaporation and the mixture partitioned between ethyl acetate (100 ml) and water (100 ml). The water was extracted with ethyl acetate (50 ml) and the combined ethyl acetate fractions were washed with sodium bicarbonate solution, dried, and concentrated to 9.5 g of residue. N.m.r. data: τ 8.02, 7.98, and 7.92 (three *O*-acetyl groups); 4.93 (four-methylene protons of the benzyloxycarbonyl group), 2.62 (ten aromatic hydrogens).

Anal. Calcd. for $C_{34}H_{40}N_2O_{15} \cdot H_2O$: C, 55.58; H, 5.76; N, 3.81. Found: C, 55.51; H, 5.45; N, 3.99.

The above material (9.0 g) was dissolved in dioxane (140 ml) and water (70 ml). The solution was cooled to 0° and sodium borohydride (2.5 g) dissolved in 30 ml of dioxane–water (2:1) was added dropwise with stirring. The mixture was stirred at 0° for 0.5 h and then at room temperature for 2.5 h. The solution was then acidified with acetic acid and taken to dryness. The boric acid was removed as methyl borate by codistillation with methanol three times. The residue was acetylated overnight using 30 ml of pyridine and 5 ml of acetic anhydride. The product, 5.63 g (51% from **9** and **10**), was isolated in the usual manner.

The above material (4.5 g, 5.34 mmol) was dissolved in 300 ml of ethanol–water (2:1) and triethylamine (5 ml) added. The mixture was left overnight at room temperature. The solution was concentrated and the residue dissolved in 100 ml of dioxane–water (2:1). Acetic acid (5 ml) and catalyst (1.0 g) were added to the solution and the mixture hydrogenated for 24 h. The solids were removed by filtration through a bed of Celite and the filtrate concentrated to a pale brown syrup (5.1 g). The syrup was taken up in 20 ml of water and transferred to the ion-exchange resin column (100 cm × 2.5 cm) for chromatography. Ten-milliliter fractions were collected and examined by paper electrophoresis. Two major

For personal use only.

products, with identical mobilities on paper electrophoresis, but moving at different rates on the ion-exchange resin were obtained from the pooled fractions. Fraction I (32% yield from **9** and **10**), $[\alpha]_D^{24}$ +70.1° (*c*, 2.2 in water) showed an n.m.r. spectrum which had the anomeric signal at τ 4.92 with a spacing of 3.5 Hz. A sample of this fraction (0.6 g) was rechromatographed as above until its rotation was constant (required four chromatographs) and crystallized from aqueous methanol to give 0.1 g of pure **13**, m.p. 264–265° (with decomposition beginning at 240°), $[\alpha]_D^{24}$ +83.5° (*c*, 2.2 in water), $[\alpha]_{436}^{24}$ +170° (*c*, 0.3 in water), $[\alpha]_{436}^{24}$ −52.4° (*c*, 0.26 in TACu), $\Delta[M]_{TACu}$ −721° (lit. (23); m.p. 231–232° (dec.), $[\alpha]_D^{15}$ +102° (*c*, 1 in water), $[\alpha]_{436}^{15}$ +186° (*c*, 0.1 in water), $[\alpha]_{436}^{15}$ −40° (*c*, 0.1 in TACu), $\Delta[M]_{TACu}$ −730°). In a subsequent experiment it was found that crystalline **13** could be directly obtained from fraction I by seeding in an overall yield of 21% from **2**. The n.m.r. spectrum of crystalline **13** in deuterium oxide showed the anomeric signal at τ 4.92.

Anal. Calcd. for $C_{12}H_{24}O_8N_2$: C, 44.44; H, 7.46; N, 8.64. Found: C, 44.12; H, 7.19; N, 8.53.

Fraction II (17% yield from **9** and **10**), $[\alpha]_D^{24}$ +92.5° (*c*, 2.2 in water) showed an n.m.r. spectrum which had the anomeric signal at τ 4.72 with a spacing of 3.5 Hz. This fraction was rechromatographed twice as above (until its rotation was constant) to obtain pure **14** in an overall yield of 11% from **2**. The product had $[\alpha]_D^{24}$ +95° (*c*, 2 in water), $[\alpha]_{436}^{24}$ +159.5° (*c*, 0.42 in water), $[\alpha]_{436}^{24}$ +390° (*c*, 0.26 in TACu), $\Delta[M]_{TACu}$ +747° (lit. (23); $[\alpha]_D^{15}$ +127° (*c*, 0.15 in water), $[\alpha]_{436}^{15}$ +238° (*c*, 0.15 in water), $[\alpha]_{436}^{15}$ +465° (*c*, 0.15 TACu), $\Delta[M]_{TACu}$ +735°). The n.m.r. spectrum of pure **14** showed the anomeric signal at τ 4.76 with a spacing of 3.5 Hz.

Anal. Calcd. for $C_{12}H_{28}N_2O_8$: C, 44.44; H, 7.41; N, 8.64. Found: C, 44.64; H, 7.33; N, 8.29.

*6-O-α-D-Glucopyranosyl-1,3-di-N-acetyldeoxystreptamine (**15**)*

This compound was prepared from **13** (0.2 g) in a manner similar to that described above for the preparation of **6** from **5**. The yield of **15**, $[\alpha]_D^{25}$ +61.5° (*c*, 0.5 in water) was 85%. The n.m.r spectrum of the compound showed the anomeric hydrogen at τ 4.94 as a doublet with a spacing of 3.5 Hz.

Anal. Calcd. for $C_{16}H_{28}N_2O_{10}$: C, 47.05; H, 6.91; N, 6.86. Found: C, 46.74; H, 6.71; N, 7.11.

*4-O-α-D-Glucopyranosyl-1,3-di-N-acetyldeoxystreptamine (**16**)*

This compound was prepared from **14** (0.2 g) in a manner similar to that described above for the preparation of **6** from **5**. The yield of **16**, $[\alpha]_D^{25}$ +73.4° (*c*, 0.7 in water), was 85%. The n.m.r. spectra of the compound in deuterium oxide showed the anomeric proton at τ 4.68 as a doublet with a spacing of 3.5 Hz. The *N*-acetyl protons gave a signal at τ 8.01.

Anal. Calcd. for $C_{16}H_{28}N_2O_{10}$: C, 47.05; H, 6.91; N, 6.86. Found: C, 47.15; H, 6.95; N, 6.66.

*4,6-Di-O-(α-D-glucopyranosyl)-deoxystreptamine (**18**)*

The above described mixture of the 4- and 6-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl)-*O*-isopropylidene-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine (**9** and **10**) (3.9 g, 8.3 mmol) was dissolved in 80% acetic acid (30 ml) and set aside 18 h. The solution was concentrated and partitioned between methylene chloride (200 ml) and water (100 ml). The methylene chloride layer was dried, concentrated to ~50 ml, and poured into *n*-hexane (500 ml) with stirring. The precipitate was collected by filtration, washed with *n*-hexane, and dried. The crude product (3.5 g) (mixture of **11** and **12**) was dissolved with tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer ((**1**) (10), 1.78 g, 2.65 mmol (0.50 mequiv excess)) in 50 ml of dry dimethylformamide. The solution was left at room temperature in the dark for 96 h. After this reaction time, t.l.c. using acetone–*n*-hexane 1:1 indicated completion of reaction as noted by the disappearance of **1**. The solution was concentrated to 20 ml, the residue was dissolved in 200 ml of chloroform, and the solution washed three times with water. After drying, the solution was concentrated to about 50 ml and poured with stirring into 500 ml of *n*-hexane. The precipitate was collected, washed with *n*-hexane, and dried to give 5.10 g of a light yellow powder, $[\alpha]_D^{24}$ +30.7° (*c*, 2 in chloroform). The n.m.r. spectrum showed bands for acetyl groups (τ 8.00) and benzyloxycarbonyl groups (τ 2.67 and 4.92) about the relative intensities expected for di-*O*-(tri-*O*-acetyl-2-oximino-α-D-*arabino*-hexopyranosyl-deoxystreptamine (**17**).

The above crude product, 5.10 g, was dissolved in a mixture of acetic acid (60 ml), levulinic acid (4.5 ml), and 1 *N* hydrochloric acid (4.1 ml) and the solution was left at room temperature overnight. The solution was diluted with methylene chloride (50 ml) and washed with water and then with saturated aqueous sodium bicarbonate until neutral. After drying, the solvent was removed to leave 3.8 g of syrupy material which was not characterized. The syrup was dissolved in dioxane (40 ml) and water (10 ml). A solution of sodium borohydride (0.6 g) in dioxane (10 ml) and water (5 ml) was then added dropwise in the range 0–5°. The solution was then left at room temperature for 1.5 h before adding acetic acid to destroy the excess borohydride. The solution was then concentrated to a syrupy residue which was taken up in methanol and the methanol removed by distillation to remove the boric acid as trimethyl borate. The residual solvent was removed and the product acetylated with pyridine (40 ml) and acetic anhydride (7 ml). Work-up in the usual manner afforded a syrup which was dissolved in 50 ml methylene chloride and the solution poured with stirring into 1 l of *n*-hexane. The resulting precipitate was collected, washed with *n*-hexane, and dried to give 3.7 g of a light brown powder. Integration of the n.m.r. spectrum indicated the presence of about 4.5 acetyl groups per benzyloxycarbonyl group as required for a di-*O*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-5-*O*-acetyl-1,3-di-*N*-benzyloxycarbonyldeoxystreptamine.

The above material (500 mg) was dissolved in methanol (20 ml), water (5 ml) and triethylamine (2.5 ml) and the solution left overnight at room temperature. Solvent removal left 342 mg of a solid which was dissolved in dioxane (4 ml), water (2.5 ml), and acetic acid (0.3 ml). This solution was hydrogenated for 8 h in the presence of 100 mg of catalyst. Catalyst removal followed by solvent removal left 233 mg of a brown syrup which was applied in aqueous solution to the top of a 100 cm × 1.5 cm ion-exchange resin column and chromatographed. Examination of the fractions (10 ml) containing nin-

hydrin-positive material by electrophoresis allowed the pooling of fractions containing only material of the same mobility (R_f 0.54 as compared to deoxystreptamine and 0.66 as compared to kanamycin A). Removal of most of the water followed by freeze-drying left 155 mg (26% overall from **9** and **10**) of a white solid, $[\alpha]_D^{24}$ +130° (*c*, 2 in water).

The n.m.r. spectrum (Fig. 1) at 100 MHz showed the following features: τ 4.64, H-1′ (doublet, $J_{1',2'}$ = 3.5 Hz); 4.83, H-1″ (doublet $J_{1'',2''}$ = 3.5 Hz); 7.9–9.1 (methylene protons of deoxystreptamine).

Anal. Calcd. for $C_{18}H_{34}N_2O_{13}$: C, 44.44; H, 7.05; N, 5.76. Found: C, 44.14; H, 7.22; N, 5.42.

*4,6-Di-O-(α-D-glucopyranosyl)-1,3-di-N-acetyldeoxystreptamine (**20**)*

The free base **18** (0.2 g) was *N*-acetylated following the procedure described for the preparation of **6**. The product was isolated in near quantitative yield. The n.m.r. spectrum of the compound in deuterium oxide showed two doublets at τ 4.66 and 4.92 for the two anomeric signals each with a spacing of 3.5 Hz. The *N*-acetyl protons appeared at τ 8.04.

Anal. Calcd. for $C_{22}H_{38}N_2O_{15}$: C, 46.31; H, 6.71; N, 4.91. Found: C, 46.11; H, 6.49; N, 4.77.

Kinetics of Reactions of Hexa(dimethylsulfoxide)nickel(II) Ion with Dithiocarbamate Ligands

R. R. SCHARFE, V. S. SASTRI, C. L. CHAKRABARTI,[1] AND C. H. LANGFORD

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 1, 1972

The kinetics of complex formation $Ni(DMSO)_6^{2+}$ with dithiocarbamate ligands at 25 °C in DMSO is reported. The reactions display the apparent "anomaly" in the direction of slow reaction reported earlier for some other complex formation reactions of $Ni(DMSO)_6^{2+}$ in DMSO.

Les cinétiques de formation du complexe $Ni(DMSO)_6^{2+}$ avec les ligands dithiocarbamates, à 25 °C, dans le DMSO sont rapportées. Les réactions manifestent une "anomalie" apparente dans le sens d'une réaction lente précédemment rapportée pour quelques autres réactions de formation de complexe de $Ni(DMSO)_6^{2+}$ dans le DMSO. This paper concerns complex formation kinetics in the reaction of $Ni(DMSO)_6^{2+}$ (1–5) (DMSO = dimethylsulfoxide) with several dithiocarbamate ions (DTC). Commonly, such kinetics have been interpreted via the Eigen mechanism (3) shown in reaction 1.

$$Ni(DMSO)_6^{2+} + L^- \overset{K_E}{\rightleftharpoons} Ni(DMSO)_6^{2+}, L^- \quad [1]$$

$$Ni(DMSO)_6^{2+}, L^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni(DMSO)_4L^+ + 2DMSO$$

In most cases, including that of the present study, observed complex formation kinetics are second order (1) and the mechanism of reaction 1 has been tested as follows. The experimental rate constant for complex formation is assumed to be equal to the equilibrium constant for outer sphere complex formation (first step of reaction 1) multiplied by the first order rate constant for entry into the inner sphere. If we define k_f as the *experimental* rate constant for complex formation, $k_f = K_E k_1$. k_1 is determined as k_f/K_E after theoretical calculation of K_E from an electrostatic model (6, 7). This procedure involves an approximate theoretical calculation but a superior approach to mechanistic analysis is not generally available.

The experimental methods here are essentially those described in ref. 1. Kinetics were obtained from stopped flow measurements. The sodium dithiocarbamate salts are characterized in ref. 8. Reactions were followed at 390 nm where $Ni(DTC)^+$ complexes absorb strongly with confirmation from some runs at 340, 350, and 365 nm. Figure 1 shows the spectrum of the diethyldithiocarbamate complex of Ni(II) in DMSO at a concentration of $2.5 \times 10^{-5} M$. In all experiments, Ni(II) was in excess to ensure that the observed kinetics were pseudo first order and that only mono complexes, $Ni(DTC)^+$, would be formed.

In these circumstances (1), a plot of the pseudo first order rate constants (evaluated as the average of at least triplicate determinations) against the concentration of the excess reagent, Ni^{2+}, should give a straight line with a slope equal to k_f and an intercept equal to the rate constant for dissociation of the $Ni(DTC)^+$ complex in s^{-1}. The success of this treatment is illustrated in Fig. 2 for the case of the di-isopropyldithiocarbamate

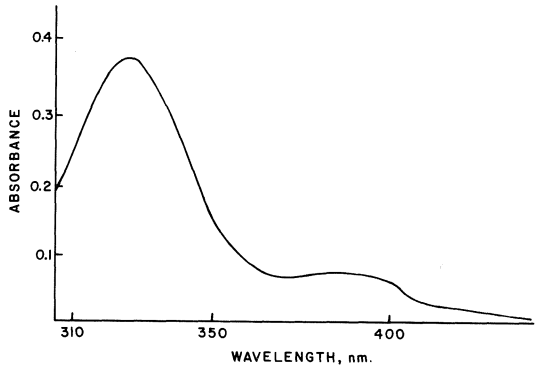

FIG. 1. Spectrum of $2.5 \times 10^{-5} M$ $NiEt_2DTC^+$ in DMSO; concentration of DTC was $2.5 \times 10^{-5} M$; concentration of Ni^{2+} was $50 \times 10^{-5} M$ (1 cm cell).

[1]To whom correspondence should be addressed.

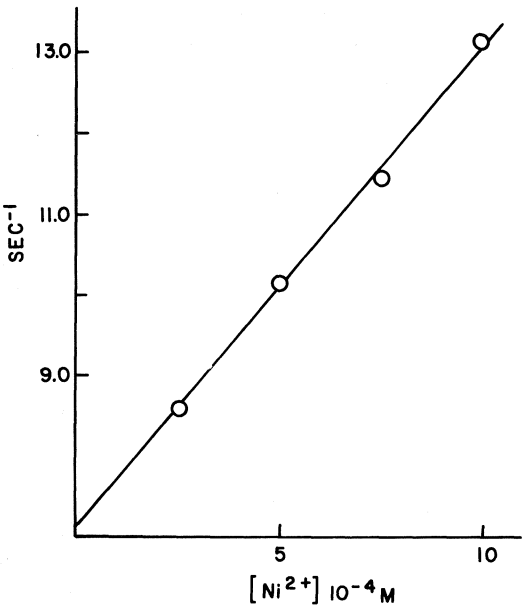

FIG. 2. Apparent rate constant for formation of Ni(*i*-pr$_2$DTC)$^+$ in DMSO at 25 °C as a function of concentration of Ni^{2+}; the initial concentration of DTC was 2.50×10^{-5} *M*; the initial concentration of Ni^{2+} was from 10 to 40 times that of DTC.

reaction. A summary of results for various dithiocarbamates appears in Table 1.

The interpretation of k_f values in Table 1 according to the mechanism in reaction 1 requires the theoretical evaluation of K_E, an "ion pairing" constant, so that k_1 may be calculated. This evaluation is carried out using the Fuoss–Eigen equation (1, 6, 7) based on an electrostatic model. There is one crucial adjustable parameter, the distance of closest approach between the two ions of the outer sphere complex. In Table 2, values of k_1 are collected and computed from Fuoss–Eigen K_E values for both a lower (5 Å) and upper (7 Å) value for the distance of closest approach.

TABLE 1. Rates of formation in DMSO: slope and intercept of plot of apparent rate as a function of Ni^{2+} concentration at 25 °C; Ni^{2+} from $2–10 \times 10^{-4}$ *M*; DTC = 2.5×10^{-5} *M*

Ligand*	Slope ($l\ mol^{-1}\ s^{-1}$) (k_f)	Intercept (s^{-1})
Me_2DTC	1.5×10^4	19
Et_2DTC	1.6×10^4	11
n-pr$_2$DTC	2.7×10^4	7.9
i-pr$_2$DTC	0.59×10^4	7.1
Pyrr DTC	2.4×10^4	11
PipDTC	2.0×10^4	10
HexaDTC	2.5×10^4	9.0

*Me = CH_3—, Et = CH_3CH_2—, *n*-pr and *i*-pr = normal and isopropyl, pyrr = pyrrolidine, pip = piperidine, and hexa = hexamethylene. These abbreviations will be repeated in the next table.

We now come to the significance of the results. The k_1 values in Table 2 range from 10 to 50 times smaller than the rate of solvent exchange of $Ni(DMSO)_6^{2+}$ in DMSO, which recent studies evaluate between 4 and $9 \times 10^3\ s^{-1}$ (9). The usual "dissociative interchange" (3) interpretation of the mechanism of eq. 1 does not *easily* accommodate this difference. That mechanism requires that complex formation rates should fall below solvent exchange rates by *only* a statistical factor for the number of outer sphere sites (1, 3). This has been estimated to be a matter of a factor of 5–10. We are inclined, therefore, to conclude that complex formation reactions of $Ni(DMSO)_6^{2+}$ with dithiocarbamate ions are "anomalously" slow. This conclusion has been reached by Bennetto and Caldin (4) with respect to

TABLE 2. Values of k_1 with K_E calculated for 5 Å and 7 Å distance of closest approach

Ligand	$k_E K_1$ ($l\ mol^{-1}\ s^{-1}$)	k_1 (s^{-1}) K_E = 5 Å	k_1 (s^{-1}) K_E = 7 Å	p*k**
Me_2DTC	1.5×10^4	3×10^2	5×10^2	3.22
Et_2DTC	1.6×10^4	3×10^2	5×10^2	3.38
n-pr$_2$DTC	2.7×10^4	5×10^2	9×10^2	3.47
i-pr$_2$DTC	0.6×10^4	1×10^4	2×10^2	4.3
PyrrDTC	2.4×10^4	5×10^2	8×10^2	3.30
PipDTC	2.0×10^4	4×10^2	7×10^2	3.21
HexaDTC	2.5×10^4	5×10^2	9×10^2	3.29

*This column records the logarithm of the acidity constant of the DTC as reported in ref. 8.

reactions with bipyridine, and by Langford and Tsiang (1) with respect to reactions with murexide and thiocyanate ions. (Recently, Hoffman and co-worker (5) have challenged the conclusion for SCN^-.) The "anomaly" may reflect a new mechanism or failure of the simplistic Fuoss–Eigen equation. This cannot be decided by kinetic studies alone (10).

Refinement of the Crystal Structure of Synthetic Chervetite, $Pb_2V_2O_7$

ROBERT D. SHANNON[1] AND CRISPIN CALVO

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received July 20, 1972

The structure of synthetic chervetite has been refined by full matrix least-squares to a $\omega_R = 0.029$ using 1105 reflections. Unit cell dimensions are $a = 13.3689(7)$, $b = 7.1607(4)$, $c = 7.1027(4)$ Å, $\beta = 105935(5)°$, and the space group is $P2_1/a$. The structure, originally solved by Kawahara, is a dichromate-type structure with a $V_2O_7^{4-}$ group eclipsed to within $11 \pm 5°$. The Pb^{2+} ions are irregularly coordinated to 8 or 9 oxygens with distances from 2.40 to 3.20 Å. The distortion of the Pb–O distances is considerably greater than the corresponding distortions of the Sr–O distances in the similar β-$Sr_2V_2O_7$ structure and is related to the tendency of Pb^{2+} to form directional covalent bonds. The V–O distances range from 1.665 to 1.720 Å for terminal oxygens and are 1.812 and 1.821 Å for the bridging oxygens. The V–O distances are consistent with the strengths of the Pb—O bonds.

Nous avons raffiné la structure de la chervétite synthétique par moindres carrés de matrice pleine, au moyen de 1105 réflexions, jusqu'à une valeur finale de $\omega_R = 0.029$. Les dimensions de la maille sont $a = 13.3689(7)$, $b = 7.1607(4)$, $c = 7.1027(4)$ Å, $\beta = 105.935(5)$, et le groupe spatial est $P2_1/a$. La structure résolue pour la première fois par Kawahara, est du type dichromate avec un groupe $V_2O_7^{4-}$ éclipsé de $11 \pm 5°$. Les ions Pb^{2+} sont coordonnés de façon irrégulière à 8 ou 9 oxygènes, à des distances de 2.40 à 3.20 Å. La distorsion des distances Pb–O est considérablement plus grande que celle qu'on remarque pour les liaisons Sr—O, dans la structure semblable présentée par le β-$Sr_2V_2O_7$ et tend de façon semblable à Pb^{2+}, à former des liens covalents directionnels. Les distances V–O varient de 1.665 à 1.720 Å, pour les oxygènes terminaux et vont de 1.812 et 1.821 Å pour les oxygènes de ponts. Les distances V–O sont compatibles avec la force des liaisons Pb—O.

[Traduit par le journal]

Can. J. Chem., **51**, 70 (1973)

Introduction

The structure of natural chervetite was solved by Kawahara (1). The structure contains pyrovanadate groups in the eclipsed configuration which is typical of dichromates and some diphosphates (2). We were interested in comparing the average V—O distances in this compound with average distances in other vanadates containing more electropositive cations because there was some indication of a correlation between average electronegativity of cations and bond distances (Noll (3), Brown and Gibbs (4), and Shannon (5)).

Kawahara's results were obtained from a mineral specimen using visually estimated Weissenberg data. In this paper we report the results of a refinement of the crystal structure of synthetic $Pb_2V_2O_7$ using counter data collected on a four circle diffractometer.

Experiments

Stoichiometric quantities of reagent grade PbO and V_2O_5 were melted together in a Pt crucible at 760 °C. Crystals were grown on the end of a Pt wire dipped into the melt. The resultant light tan boule was not a single crystal; however, mono-crystalline fragments approximately 1 mm in size were obtained upon fracturing the boule. These fragments were ground into spheres. X-Ray powder diffraction patterns were taken using a Hägg–Guinier camera and a KCl internal standard according to a procedure described earlier (6). The cell dimensions obtained from a least-squares refinement with KCl as an internal standard of these data are: $a = 13.3689(7)$, $b = 7.1607(4)$, $c = 7.1027(4)$ Å, and $\beta = 105.935(5)°$ at 20 °C with these errors indicating the precision indicated by the refinement. Other crystal data are: Space group = $P2_1/a$, formula weight = 628.30, $V = 653.8$ Å^3, $D_x = 6.381$ g/cc, $Z = 4$, and $\mu = 535.2$ cm^{-1}.

A sphere of radius 0.138 mm ($\mu_r = 7.39$) was chosen for data collection. The average and maximum deviation from the mean radius was about 2 and 5%, respectively. Intensity data were collected on a Syntex automatic diffractometer using MoKα radiation, 4° take-off angle, a graphite monochromator ($2\theta = 12°$) and a scintillation detector. Reflections were scanned at variable rates from 2.0 to 24.0°/min, depending on the peak count, through an angle of 2° plus the α_1–α_2 separation. Background counts were made at the extreme of each scan for times equal to the peak count. A total of 2300 reflections were measured out to $2\theta = 50.0°$. After averaging of equivalent reflections, there were 1105 reflections of which 863 were considered to be observed. Intensities with less than 3 times the standard deviation of the background were considered to be unobserved. The intensities were corrected for Lorentz and polarization factors and absorp-

*Standard deviations are given in parentheses.
†Calculated from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where $T = \exp -(\beta_{11}h^2 + \ldots + 2\beta_{12}hk + \ldots)$ is the temperature factor appearing in the structure factor equation and b_i's are the reciprocal lattice vectors.

tion using the X-ray 67 Program System for X-ray Crystallography written by J. M. Stewart, University of Maryland, and adapted to the CDC 6400 computer by H. D. Grundy. Secondary extinction coefficients were calculated for each reflection according to Zachariasen (7).

The initial parameters used for refinement were those of Kawahara (1). Several cycles of refinement using the full-matrix least squares program CUDLS (8) reduced

$$\omega R = \left\{\frac{\sum \omega||F_o| - |F_c|^2}{\sum \omega|F_o|^2}\right\}^{1/2} \text{ to } 0.053$$

using isotropic temperature factors and weights

$$\omega = \left\{86.86 - 1.095|F_o| + 0.00368|F_o|^2 + 4072\left|\frac{\sigma(F_o)}{|F_o|}\right|^2\right\}^{-1}$$

This weighting scheme was chosen to make the variation in $\omega||F_o| - |F_c||^2$ independent of the variation in F_o. Further refinement using anisotropic temperature factors for Pb and V and varying the secondary extinction parameters according to the method of Larson (9), with $\beta(2\theta)$ ranging from 18.7 to 2.1, lowered ω_R to 0.029, and R to 0.040. The standard deviation, S, of an observation of unit weight was 1.03. Several cycles of refinement using anisotropic temperature factors for the oxygen atoms had no effect on ω_R and the temperature factors for O(1) and O(3) become non-positive definite. Scattering factors for Pb^0, V^0, and O^0 were taken from Cromer and Waber (10) and anomalous dispersion corrections were taken from Cromer (11). The final positional and thermal parameters for the model using anisotropic Pb and V and isotropic O temperature factors are listed in Table 1 and observed and calculated structure factors are listed in Table 2.[2] Table 3 lists the pertinent bond distances and angles.

Results and Discussion

The basic structure of $Pb_2V_2O_7$ as reported by Kawahara (1) is correct. However, Kawahara noted that the distance between V(1) and the terminal oxygen O(3) was unreasonably long (1.88 Å) and the Pb(2)—O(7) distance was too short (2.24 Å). The refinement reported here using 3-dimensional data has produced significant shifts in the oxygen parameters and thus results in changes in the detailed geometry of the $V_2O_7^{4-}$ ion.

Figures 1 and 2 show a perspective view looking down the *b* axis showing only the Pb—O bonds and V—O bonds, respectively. All the

cations lie in layers approximately parallel to $(10\bar{1})$. Pb(1) is surrounded by 8 oxygen atoms at distances of 2.40 to 2.96 Å with a mean value of 2.67 Å and Pb(2) is surrounded by 9 oxygens at distances of 2.40 to 3.20 Å with a mean value of 2.76(1) Å. Each Pb(1) polyhedron shares O(1) and O(5) with Pb(2) in its layer and is linked to two other Pb(2) polyhedra in the adjacent layer by O(2) and O(7) and by O(3) and O(6). Adjacent Pb(1) atoms in the layer share O(2) atoms whereas Pb(1) atoms in different layers share O(5).

There is a weak link between adjacent Pb(2) atoms in the layer via O(3) at 3.12 Å and O(6) at 3.20 Å.

A comparison of the cation environments in β-$Sr_2V_2O_7$ (12) and $Pb_2V_2O_7$ reflects the formation of four strong Pb—O and four weaker bonds about both Pb(1) and Pb(2). In β-$Sr_2V_2O_7$, Sr(1) and Sr(9) which are bonded to pyrovanadate bridging oxygens and thus correspond to Pb(2) in $Pb_2V_2O_7$, have 8 or 9 oxygen neighbors at distances of 2.53–3.04 Å, respectively. Thus Sr(1) and Sr(4) have a smaller range of distances than Pb(2). Furthermore, in spite of the fact that the ionic radius (13) of Sr^{2+} (1.25 Å) is smaller than that of Pb^{2+} (1.29 Å), Sr(1) and Sr(4) have larger minimum contact distances. This tendency to form directional bonds is of course most pronounced in PbO (14, 15) where Pb^{2+} is at the apex of a square pyramid with oxygen atoms at the corners of the base. A comparison of the four smallest Pb—O bond distances and the pertinent O—Pb—O angles in PbO and $Pb_2V_2O_7$ in Table 4 shows that some degree of Pb—O covalent bonding is probably present in $Pb_2V_2O_7$. In both compounds the shorter Pb—O bond lengths all lie on one side of the ion. Pb(2), however, shows an additional short interaction to O(6) which has distorted the angles somewhat.

The pyrovanadate ion has an approximately eclipsed configuration typical of the alkali dichromate structures (2). The average angle of twist from the V1–V2 axis is 11 ± 5°. The geometry of the $V_2O_7^{4-}$ ion is almost identical to the pyrovanadate ion in β-$Sr_2V_2O_7$. Figure 3 shows a comparison of the pyrovanadate ion in $Pb_2V_2O_7$ with the two corresponding groups in β-$Sr_2V_2O_7$. Table 5 compares the observed V—O distances with those calculated according to Baur's scheme (16) assuming a CN of 8 for Pb(1), Sr(1), and Sr(3) and 9 for Pb(2), Sr(2), and Sr(4) but using $d(V—O) = 1.721 + 0.1602(\Delta p_0)$ (17, 18). The agreement is not satisfactory and, as in the case of $Cu_3V_2O_8$ (19) is a consequence of the distorted nature of the M—O polyhedron. Figure 3*A* shows that longer V—O distances are associated with more and shorter M—O bonds (M = Sr or Pb) and conversely shorter V—O distances are associated with fewer and long M—O bonds. For example d(V(1)–O(2)) > d(V(1)–O(3)) because the sum of the Pb—O(2) distances is less than the sum of the Pb—O(3) distances. These principles have been systematized by Brown and Shannon (20) for the

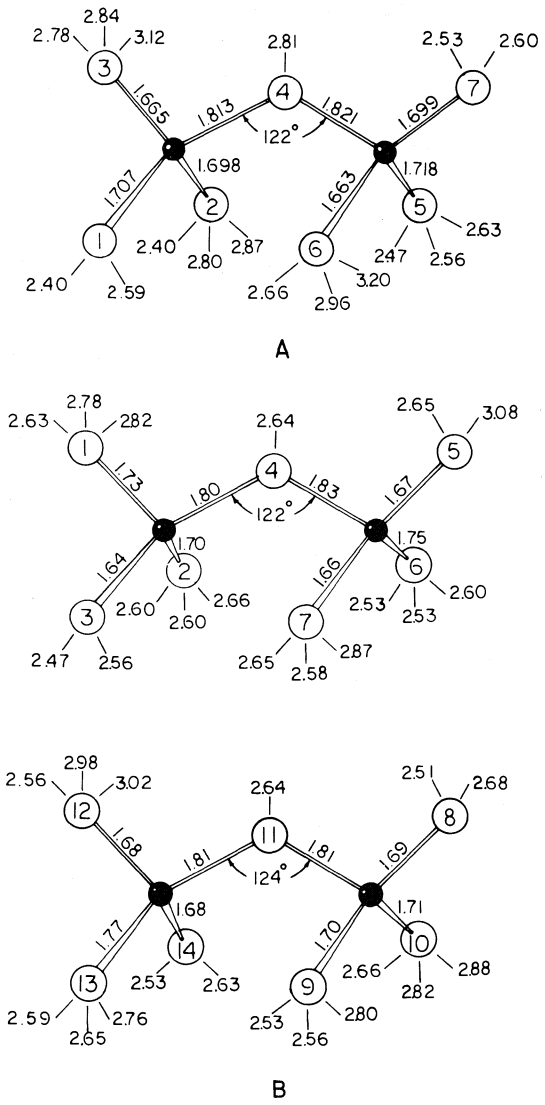

FIG. 3. The pyrovanadate ions in (*A*) $Pb_2V_2O_7$ and (*B*) β-$Sr_2V_2O_7$, showing V—O bonds and distances of neighboring Pb or Sr ions from the oxygen ions.

first three rows of the periodic table. Although a Sr—O bond strength – bond length curve is not available and the e.s.d.'s on the V—O bonds in β-$Sr_2V_2O_7$ are quite large (0.03 Å), it is possible using just qualitative bond strength considerations mentioned above for $Pb_2V_2O_7$ to make some estimates of the validity of the distances assuming the Sr—O distances are not in error by more than 0.03 Å. Most of V—O bonds are consistent with the number and distances of Sr neighbors but several deviate; thus, the following relationships should hold:

V(1)—O(1) < V(1)—O(2)
V(1)—O(1) < V(2)—O(9)
V(1)—O(2) > V(2)—O(10)
V(1)—O(2) > V(2)—O(13)
$\Big\}$ $d_{pred} = 1.70$[3]

V(1)—O(3) > V(1)—O(5)
V(1)—O(3) > V(2)—O(8)
V(1)—O(3) > V(2)—O(14)
$\Big\}$ $d_{pred} = 1.66$[3]

V(1)—O(6) > V(2)—O(13) $d_{pred} = 1.70$[3]

Several of these deviations are as large as 0.04–0.07 Å. It should be noted that all of these pairs according to Baur's predictions based on average coordination number of Sr should be equal. A more accurate structure refinement of β-$Sr_2V_2O_7$ will be necessary to resolve these inconsistencies.

The mean V—O distances within the two tetrahedra are 1.721 and 1.726 Å and agree well with the grand mean value of 1.721 ± 0.012 Å determined from 22 accurately refined vanadate structures (18). The effective ionic radius of V^{5+} in $Pb_2V_2O_7$, obtained by subtracting the appropriate oxygen radius (5) (0.351) is intermediate between that in $Cu_3V_2O_8$ (0.365) (19) or $Cu_5V_2O_{10}$ (0.364) (21) and Li_3VO_4 (0.337) (18), $Na_3VO_4 \cdot 12H_2O$ (0.321) (22), Ca_2VO_4Cl (0.327) (23), and $Ca_3V_2O_8$ (0.335) (24). This behavior, discussed in more detail in refs. 5 and 18, is associated with the bond strength (as determined by electronegativity or electrostatic bond strength criteria) of the M—O bonds where M = Cu^{2+}, Pb^{2+}, Li^+, Na^+, or Ca^{2+}. Stronger bonds such as Cu^{2+}—O and Pb^{2+} result in longer average V^{5+}—O bonds than weaker bonds such as Li^+—O, Na^+—O, or Ca^{2+}—O.

[3] $d_{pred} = 1.721 + 0.1602(\Delta p_0)$.

We would like to thank Mrs. S. Leung for preparing the crystals of $Pb_2V_2O_7$, R. Faggiani for assistance with intensity measurements, and Dr. J. F. Whitney and Mrs. C. F. Foris of the Central Research Laboratory, E. I. duPont de Nemours and Co. for the Guinier photographs. This research was supported by the National Research Council of Canada.

Rearrangements in the Diterpenoid Series. I. The Solvolysis of Methyl 15β-tosyloxy-13-isopropyl-17-noratis-13-en-18-oate

WILLIAM A. AYER AND PANDURANG D. DESHPANDE[1]

Chemistry Department, University of Alberta, Edmonton, Alberta

Received July 5, 1972

The synthesis of methyl 15β-hydroxy-13-isopropyl-17-noratis-13-en-18-oate (**14***b*) is described. Compound **14***b* was prepared from the ketone **12***b*, in turn derived from the Diels–Alder adduct formed between levopimaric acid (**7**) and α-acetoxyacrylonitrile. Solvolysis of the tosylate of **14***b* proceeds predominantly with rearrangement and elimination to give methyl 16-isopropylidene-7,17-secoacon-8(15)-en-18-oate (**16***a*). This rearrangement serves as a model for the proposed biosynthetic transformation of atisine-type alkaloids into alkaloids of the aconitine series. The degradation of **16***a* into the unsaturated ketone **19**, which contains the 19 carbons of the aconane skeleton, is described. The Diels–Alder addition of methyl vinyl ketone to levopimaric acid is reported and the adduct is shown to possess structure **8**.

La synthèse du β-hydroxy-15 isopropyl-13 nor-17 atisène-13 oate-18 de méthyle (**14***b*) est décrite. Le composé **14***b* a été préparé à partir de la cétone **12***b*, qui dérive à son tour de l'adduit entre l'acide levopimarique (**7**) et l'α-acétoxyacrylonitrile, selon une réaction de Diels–Alder. La solvolyse du tosylate de **14***b* procède de façon prédominante par réarrangement et élimination pour conduire à l'isopropylidène-16 secoacon-7,17 ène-8(15) oate-18 de méthyle (**16***a*). Ce réarrangement sert de modèle pour la transformation biosynthétique proposée pour les alcaloides de type atisine en alcaloides de la série aconitine. La dégradation de **16***a* en cétone insaturée **19**, qui contient les 19 carbones du squelette aconane, est donnée. L'addition, selon Diels–Alder, de la méthylvinylcétone sur l'acide lévopimarique est rapportée; l'adduit résultant possède la structure **8**. [Traduit par le journal]

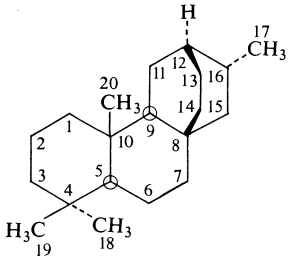
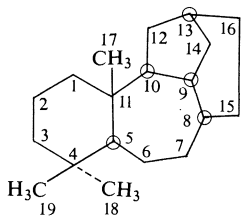
In 1956 the simple relationship between the atisane (**1**)[2] and the 7,17-secoaconane (**2**) skeleton was noted (1, 2). At that time it was pointed out



1



2

that rearrangement (Scheme 1) (1) of an atisine-type intermediate **3**, coupled with demethylation (loss of C-17, atisane numbering), would lead to an intermediate **4** which on closure of the C_7—C_{17} (aconane numbering) bond would furnish the lycoctonine–aconitine skeleton **5**. Since it appeared that compounds of the type **6***a*, where X is a suitable leaving group, would be readily available by Diels–Alder addition of the appropriate dienophile (3) to levopimaric acid (**7**, R = H), we decided to investigate the solvolytic reactions of compounds of type **6***a* as a model for the atisine–aconitine skeletal rearrangement. Attempts to execute this rearrangement on derivatives of atisine itself have met with limited success. Pelletier and Ichihara (4) observed only migration of the C-13,14 bridge on solvolysis of appropriate derivatives, whereas Johnston and Overton (5) observed both this migration (solvolytic conditions) and the desired rearrangement (pyrolytic conditions). This paper describes the preparation and rearrangement of the tosylate **6***b*. A later paper will describe the preparation and deamination of the amine **6***c*.

The simplest route to compounds of type **6***a* with an oxygen function at C-15 appeared to be the Diels–Alder addition of vinyl acetate to levopimaric acid. We were, however, unable to effect this addition. Addition of methyl vinyl ketone to levopimaric acid proceeded smoothly in refluxing benzene to give the keto acid **8**

[1]Taken in part from the Ph.D. thesis of P. D. Deshpande, University of Alberta, Edmonton, Alberta, 1967.

[2]Nomenclature is based on "The Common and Systematic Nomenclature of Cyclic Diterpenes", third revision with addenda and corrigenda, February 1969, available from Dr. J. W. Rowe, U.S. Forest Products Laboratory, Madison, Wisconsin 43705.

c R = CH_3; X = NH_2

(R = H), isolated as its cyclohexylamine salt in 70% yield. Decomposition of the salt with dilute phosphoric acid gave the crystalline acid **8** (R = H) which on treatment with diazomethane gave the keto ester **8** (R = CH_3). The i.r. and n.m.r. spectra of the acid and its ester are consistent with the assigned structure. In particular, the chemical shift of the C-10 methyl group (τ 9.38) indicates (6) that addition has occurred from the α-face and the unusually high chemical shift of the acetyl methyl (τ 8.07) is indicative of its *endo* orientation, in which the methyl protons are shielded by the C_{13}—C_{14} double bond. By analogy with the reaction of other monosubstituted dienophiles with levopimaric acid (3) it was expected that addition would occur in such a way as to give the 15-acetyl compound **8** rather than the 16-acetyl compound. In order to confirm the position and orientation of the acetyl group the adduct was treated with sodium hypobromite. After the crude product of this reaction was esterified with diazomethane and subjected to chromatography over alumina the isopropylidene lactone **9** of known constitution (3, 7, 8) was obtained in 11% yield, establishing that the acetyl group is located at C-15 and supporting the *endo* assignment of configuration.

Alkyl methyl ketones when subjected to Baeyer–Villiger oxidation usually afford alkyl acetates of retained configuration (9). Ordinarily a carbon–carbon double bond is more reactive than a ketone towards peracids. In this case approach

to the double bond is hindered (10) and it was hoped that a selective reaction could be induced at the ketonic carbonyl of the ester **8** (R = CH_3). However, treatment of ester **8** (R = CH_3) with either *m*-chloroperbenzoic acid in benzene or monoperphthalic acid in ether gave the epoxide **10**. None of the desired Baeyer–Villiger product could be detected. The i.r. spectrum of **10** showed ketonic carbonyl absorption at 1700 cm^{-1} and the n.m.r. spectrum showed a one-proton singlet at τ 6.90 attributable to the proton on C-14, as well as a three-proton singlet at τ 7.98 due to the acetyl methyl. The remaining features on the n.m.r. spectrum were similar to those reported (10, 11) for the epoxide of methyl maleopimarate. The epoxide **10** was obtained as an amorphous solid which could not be isolated in pure form. The material crystallized after contact with chloroform, but the properties of the crystalline material were markedly different from those of the crude epoxide **10**. The crystalline material proved to be a compound $C_{25}H_{38}O_4$, isomeric with the epoxide **10**, to which we tentatively assign the ketal structure **11**. The i.r. spectrum of the crystalline material shows a single band in the carbonyl region at 1720 cm^{-1} attributable to the carbomethoxyl group. In the n.m.r. spectrum of **11** there is no signal in the τ 7.8–8.1 region due to an acetyl group but there is a signal (3H) at τ 8.50 due to the methyl attached to the ketal carbon.[3] The signal which appears at τ 6.90 in the spectrum of **10** is replaced by a singlet at τ 5.73 in the spectrum of **11**, a shift which is as expected for the change from an oxirane proton to an α-proton of a tetrahydrofuran system (12).

The epoxide oxygen in **10** is ideally situated for acid-catalyzed ketal formation with the carbonyl group (Scheme 2), a reaction for which there are numerous precedents (13). Examination of models indicates that the non-bonded interaction between the C-13 isopropyl and the C-10 methyl is, at least in part, relieved in the transformation of **10** into **11**. This may help to explain the facility with which this reaction occurs and the fact that the ketal **11** is recovered unchanged from attempted acid hydrolysis.

The desired alcohol **6***a* (X = OH) was obtained

[3]The methyl attached to the acetal carbon of acetaldehyde diethyl acetal appears at τ 8.68 (23).

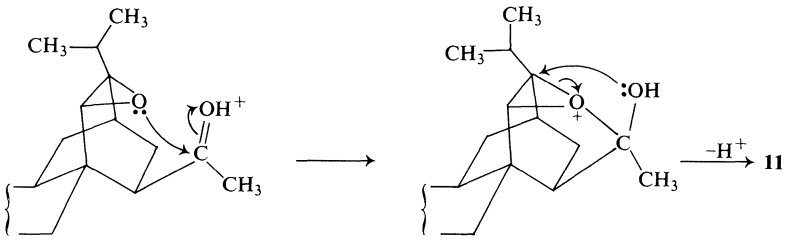

SCHEME 2

in the following manner. Addition of α-acetoxyacrylonitrile to levopimaric acid (**7**, R = H) was effected in refluxing toluene. The reaction mixture was extracted with dilute alkali. The crude acidic product thus obtained did not show nitrile absorption in the i.r., but did show intense absorption in the carbonyl region as well as a band at 1410 cm^{-1} (scissoring vibration of an active methylene) suggestive of a ketone. It was inferred that the Diels–Alder reaction had taken place and that the acetoxycyano compound(s) thus formed had been hydrolyzed to the ketone(s) **12***a* and/or **13** during the work-up. Isolation of the ketoacid **12***a*, obtained in 35% yield, was facilitated by the use of Girard's T reagent. Further quantities of **12***a* were obtained by alkaline hydrolysis of the neutral portion of the addition product which apparently contained the mixed anhydride of the desired acid and acetic acid. The i.r., n.m.r., and mass spectra of the acid **12***a* and its methyl ester **12***b* were consistent (see Experimental) with the assigned structure. In particular, the signal for the C-10 methyl group appeared at high field (τ 9.25) indicating α-addition (see above), and the base peak in the mass spectrum of the methyl ester **12***b* appeared at $M^+ - 42$ (loss of ketene via retro-Diels–Alder). These spectra however did not serve to distinguish **12***a* from **13**. This distinction may be made on the basis of optical rotatory dispersion measurements (14). A strongly positive Cotton effect is predicted (14) for **12***a* and a strongly negative Cotton effect is predicted for **13**. The ketoacid shows a strongly positive Cotton effect ($a = +523$) indicating that it has structure **12***a*.

The ketoacid **12***a* was reduced with sodium borohydride in dimethoxyethane. The crude product was esterified with diazomethane and then acetylated to give a mixture of acetoxyesters **14***a* and **15***a*. The n.m.r. spectrum of the mixture shows signals at τ 8.08 and 7.94 (ratio about 3:4) attributable to the C-15 acetoxyl groups. Since it seemed reasonable to assign the signal at τ 8.08 to the *endo* acetoxy compound **14***a* (acetoxyl methyl shielded by the C_{13}—C_{14} double bond) it appeared that the desired alcohol **14***b* was the minor product of the borohydride reduction. Reduction with lithium–ammonia–methanol, which should favor the production of the thermodynamically more stable alcohol, gave the same two alcohols in a ratio of about 4:3, this time the *endo* alcohol **14***b* predominating. Attempts to separate the mixture of alcohols **14***b* and **15***b* met with limited success, however, the corresponding acetyl derivatives **14***a* and **15***a* were readily separable by chromatography over alumina. The *exo* acetoxy compound **15***a* was eluted first. The n.m.r. spectrum showed the acetoxyl methyl signal at τ 7.94 and a doublet ($J = 9$ and 3 Hz) at τ 5.84 for the proton geminal to the acetoxyl group. In the *endo* compound **14***a* this latter signal appeared as a doublet ($J = 8$ and 3 Hz) at τ 5.44, in keeping with the observation (15) that the *endo* proton in a bicyclo[2.2.2]octene system appears at higher field than the corresponding *exo* proton. Hydrolysis (methanolic KOH) of the acetoxy compounds **14***a* and **15***a* gave the alcohols **14***b* and **15***b*, respectively. In support of the assigned structures, alcohol **14***b* shows an intramolecularly hydrogen-bonded (OH to π) hydroxyl absorption in the i.r. (16) whereas **15***b* shows only free hydroxyl absorption.

It has been shown (17) that solvolysis of *endo*-bicyclo[2.2.2]oct-5-en-2-yl *p*-toluenesulfonate gives mainly rearranged bicyclo[3.2.1]octene derivatives. In order to study the solvolysis in this case, the alcohol **14***b*, a readily purified, crystalline solid was transformed to the tosylate **14***c* by treatment with *p*-toluenesulfonyl chloride in pyridine. Tosylate **14***c* was obtained as an amorphous solid which could not be induced to crystallize. The spectroscopic properties (see Experimental) of the product were, however, in complete accord with structure **14***c*. In an attempt

to purify the tosylate the crude product was subjected to chromatography over silica gel. As soon as the colorless benzene solution of the tosylate was transferred to the column the top portion of the adsorbent became deep purple. Elution of the column with benzene gave the diene **16***a* in 70% yield. Further elution gave the alcohol **14***b* in 15–20% yield.

The structure of diene **16***a* is assigned on the following basis. The i.r. spectrum does not show absorption attributable to a tosyloxy group, but does show ester carbonyl (1720 cm^{-1}) and conjugated olefin (1635, 1620) absorption. The conjugated diene system gives rise to an absorption maximum in the u.v. at 258 nm (ε 18 000). The n.m.r. spectrum reveals the presence of only two methyl groups attached to saturated carbon. The signal at τ 9.13 is assigned to the C-11 methyl and that at τ 8.78 to the C-4 methyl. The methyl groups of the isopropylidene group appear at τ 8.28 and 8.34. The olefinic proton gives rise to a singlet at τ 4.15. The ester group at C-4 proved difficult to saponify, however hydrolysis was achieved using potassium *t*-butoxide – dimethylsulfoxide (18) to give the acid **16***b*. The acid, like the ester, was unstable in air and attempted recrystallization led to decomposition.

Catalytic hydrogenation of the ester **16***a* over Adams' catalyst gave the tetrahydro compound **17***a* (stereochemistry at C-8 and -16 assigned on the assumption that the catalyst would approach from the less hindered side). Treatment of **17***a* with potassium *t*-butoxide-dimethylsulfoxide gave the stable, crystalline acid **17***b*. The n.m.r. spectrum shows no olefinic absorption and the methyls of the isopropyl group gave rise to a pair of doublets centered at τ 9.11 and 9.14. When the hydrogenation of **16***a* was carried out for a short time in the presence of palladium–charcoal the dihydro derivative **18** was obtained. The n.m.r. spectrum clearly shows that the double bond of the isopropylidene group has been hydrogenated, since an isopropyl methyl doublet (6H, $J \simeq 6$ Hz) is apparent at τ 9.15 and an olefinic proton signal is evident as a broadened singlet at τ 4.93.

Since it appeared that the tetrasubstituted double bond was more reactive (accessible) than the trisubstituted double bond we decided for two reasons to attempt a selective cleavage of this double bond. Firstly, the spectral properties of the α,β-unsaturated ketone **19** would serve to further confirm the structure of the diene and secondly, the ketone **19** contains the 19 carbon atoms of the aconane skeleton and might

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

possibly serve as a useful synthetic intermediate in the construction of compounds related to the aconite alkaloids. Accordingly, the diene **16***a* was treated with a limited amount of ozone in methylene chloride (19) at $-70°$. Chromatography of the neutral portion of the product over silica gel gave the ketone **19** in about 10% yield. The presence of the conjugated keto grouping was indicated by i.r. absorption at 1670 and 1630 cm^{-1} and by u.v. absorption at 243 nm (ε 11 000). The n.m.r. spectrum of **19** shows the presence of only two C-methyl groups (singlets at τ 9.18 (C-10 methyl) and 8.77 (C-4 methyl)). The olefinic proton gives rise to a singlet at τ 4.38. Ketone **19** has also been obtained by the action of nitrous acid on the amine **6***c* (7).

To determine whether the rearrangement of tosylate **14***c* to diene **16***a* is specifically brought about on the surface of silica gel, or whether it is of more general nature, the crude tosylate was subjected to solvolysis in hot acetic acid containing sodium acetate. The product consisted mainly of diene **16***a* and *endo* acetate **14***a* as judged from the n.m.r. spectrum. Chromatography of the solvolysis product over alumina furnished the diene **16***a* in *ca.* 40% yield and **14***a* in *ca.* 12% yield. The n.m.r. spectra of intermediate fractions indicated the presence of minor amounts of at least two other acetates, but these were not isolated in pure form. It thus appears that a carbonium ion, most economically represented as **20**, is formed during the solvolysis and that this reacts further either by elimination of a proton to give the rearranged diene **16***a* (path *a*) or by attack of solvent at C-15 to give the *endo* acetate **14***a* (path *b*) (see Scheme 3).

Attempts to prepare the tosylate of the alcohol **15***b* have so far been unsuccessful. Treatment of **15***b* with *p*-toluenesulfonyl chloride in pyridine results in the formation of a mixture of products free of both hydroxyl and tosyloxyl absorption in the i.r. The products of this reaction have not as yet been identified. It is apparent, however, that the diene **16***a* is not formed, at least to any great extent in this reaction.

The ease with which the desired rearrangement (*i.e.*, **14***c* → **16***a*) occurs in this case contrasts with that observed (4, 5) in the case of derivatives of atisine itself. It appears, not unexpectedly (20), that the presence of the C_{13}—C_{14} unsaturation greatly facilitates the rearrangement. Attempts to hydrogenate the hindered olefinic linkage in **14***b*, and thereafter to compare the reactivity of the saturated with the unsaturated compound, were unsuccessful.

Experimental Section[4]

*Preparation of 15β-Acetyl-13-isopropyl-17-noratis-13-en-18-oic Acid (**8**, R = H)*

A solution of levopimaric acid (12 g) (21), methyl vinyl ketone (20 ml), and hydroquinone (0.2 g) in benzene (50 ml) was heated on the steam bath for 8 h. Excess methyl vinyl ketone and solvent were removed under reduced pressure, the residue dissolved in benzene (100 ml), washed with water, dried ($MgSO_4$), and concentrated to a white foam (14 g). This was dissolved in cold acetone (100 ml), cyclohexylamine (6 ml) added, and the resulting precipitate filtered and washed with cold acetone to give the cyclohexylamine salt of **8** (R = H) (13 g). The salt was suspended in ether (200 ml) and shaken with 10% phosphoric acid (50 ml). The ether layer was washed with water, dried ($MgSO_4$), and concentrated to a colorless foam (10.5 g) which was crystallized from acetonitrile to give the acid **8** (R = H) (8 g): m.p. 135–136°; i.r. ($CHCl_3$) 3200–2400 (carboxyl OH), 1700 cm^{-1} (C=O of acid and ketone); n.m.r. τ 9.38 (s, 3, C-10 methyl), 8.95 (d, 6, J = 6.5 Hz, isopropyl methyls), 8.86 (s, 3, C-4 methyl), 8.07 (s, 3, acetyl methyl), 4.58 (s, 1, H-14), −0.75 (s, 1, COOH).

Anal. Calcd. for $C_{24}H_{36}O$ (mol. wt. 372.2665): C, 77.38; H, 9.74. Found (372.2669 (h.r.m.s.)): C, 77.30, 77.09; H, 9.75, 9.84.

Treatment of the acid with ethereal diazomethane gave the oily methyl ester **8** (R = CH_3), which was purified by evaporative distillation: i.r. 1730 (ester), 1700 cm^{-1} (ketone); n.m.r. τ 9.40 (s, 3, C-10 methyl), 8.95 (d, 6,

[4]Melting points were determined on a hot-stage and are uncorrected. Unless otherwise stated i.r. spectra were determined in carbon tetrachloride, u.v. spectra in 95% ethanol, and n.m.r. spectra in deuteriochloroform with tetramethylsilane as internal standard. Mass spectra were determined on an A.E.I. MS-2H or A.E.I. MS-9 mass spectrometer. High resolution measurements (h.r.m.s.) were performed on the latter instrument. Alumina, unless otherwise specified, means basic alumina of activity II–III (Brockmann scale). Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°. Microanalyses were performed by G. Gygli, Toronto, Ontario, and D. Mahlow of this Department.

For personal use only.

J = 6.5 Hz), 8.87 (s, 3, C-4 methyl), 8.08 (s, 3, acetyl methyl), 6.36 (s, 3, methoxyl), 4.55 (s, 1, H-14); mass spectrum (70 eV) *m/e* (relative intensity) 386 (3), 316 (39), 301 (38), 43 (100).

Treatment of **8** *(R = H) with Sodium Hypobromite*

The adduct **8** (R = H) (157 mg) was added in small portions to an ice-cold stirred solution of bromine (0.36 g) and sodium hydroxide (1.86 g) in water (8 ml). The solution was kept at room temperature overnight then excess bromine destroyed with sodium sulfite. The solution was acidified (concentrated HCl) and extracted with chloroform to give an amorphous material (0.16 g) which was treated with ethereal diazomethane. A portion (0.14 g) of the product was chromatographed over neutral alumina (7 g, activity II). Elution with benzene (90 ml) gave 58 mg of unidentified material. Further elution with benzene (90 ml) gave the lactone **9** (15 mg), m.p. 191–192° (lit. (8) m.p. 196–197°), identical with a sample prepared by methylation of the corresponding acid (3). Elution with benzene–ether gave further crystalline material which has not been identified.

Peracid Oxidation of Ester **8** *(R = CH_3)*

(a) With m-Chloroperbenzoic Acid

A solution of the ketoester **8** (R = CH_3) (105 mg) and *m*-chloroperbenzoic acid (69 mg) in benzene (15 ml) was kept at room temperature for 12 days (t.l.c. at this point indicated complete disappearance of starting material). The reaction mixture was diluted with ether and washed with dilute sodium sulfite and then dilute sodium bicarbonate, dried ($MgSO_4$), and concentrated to an amorphous solid (95 mg), believed on the basis of the following spectroscopic data to consist mainly of the expoxide **10**: i.r. 1735 (ester), 1700 cm^{-1} (ketone); n.m.r. τ 9.28 (d, 3, J = 7 Hz, nonequivalent methyl of isopropyl), 9.19 (s, 3, C-10 methyl), 8.94 (d, 3, J = 7 Hz, nonequivalent methyl of isopropyl), 8.85 (s, 3, C-4 methyl), 7.98 (s, 3, acetyl methyl), 6.9 (br.s, 1, H-14), 6.37 (s, 3, methoxyl). The solution used to measure the n.m.r. spectrum was concentrated to a glassy solid which slowly solidified. Trituration with Skellysolve B left the ketal **11**, m.p. 149–150°: i.r. ($CHCl_3$) 1720 cm^{-1} (ester); n.m.r. τ 9.06 (d, 6, J = 7 Hz, isopropyl methyls), 9.04 (s, 3, C-10 methyl), 8.84 (s, 3, C-4 methyl), 8.50 (s, 3, ketal methyl), 6.37 (s, 3, methoxyl), 5.90 (br. s, 1, H-14); mass spectrum (70 eV *m/e* (relative intensity) 402 (69), 387 (20), 359 (61), 343 (59), 342 (54), 331 (45), 317 (76), 316 (69), 43 (100).

Mol. Wt. Calcd. for $C_{25}H_{38}O_4$: 402.2770. Found: 402.2767.

Ketal **11** in aqueous acetone was heated under reflux for 6 h in the presence of *p*-toluenesulfonic acid. Work-up in the usual manner gave unchanged ketal **11** as indicated by i.r. spectroscopy.

(b) With Monoperphthalic Acid

A solution of ketoester **8** (R = CH_3) (0.41 g) in ether (10 ml) was added to an ice-cold solution of monoperphthalic acid (0.8 g) in ether (20 ml) and the resulting solution kept at 0–5° for 3 weeks. The solution was then washed with dilute sodium sulfite, dilute sodium bicarbonate, dried ($MgSO_4$), and concentrated. The product thus obtained possessed spectral properties (i.r. and n.m.r.) identical with those displayed by the product obtained when *m*-chloroperbenzoic acid was used.

*Preparation of 13-Isopropyl-15-oxo-17-noratis-13-en-18-oic Acid (***12***a)*

A solution of levopimaric acid (2.5 g), α-acetoxyacrylonitrile (5 g, (22)), and hydroquinone (0.14 g) in toluene was heated under reflux for 8 h, then kept overnight at room temperature. Ether (100 ml) was added and the solution washed several times with water to remove hydroquinone. The organic layer was then extracted with aqueous sodium hydroxide (5%, 3 × 50 ml), washed with water, dried ($MgSO_4$), and concentrated to give neutral material (0.44 g), which showed i.r. absorption at 1800 and 1750 cm^{-1}.

The alkaline extract was acidified with concentrated HCl and extracted with ether to give 2.68 g of acidic material. This was combined with a further 1.1 g from another experiment and crystallized from acetonitrile to give keto acid **12***a* (1.25 g), m.p. 195–196°: i.r. ($CHCl_3$) 3200–2400, 1700–1715 (carbonyl of carboxyl and ketone), 1410 cm^{-1} (active methylene); n.m.r. τ 9.25 (s, 3, C-10 methyl), 8.97 (d, 6, J = 6.5 Hz, isopropyl methyls), 8.83 (s, 3, C-4 methyl), 4.72 (s, 1, H-14), −1.3 (s, 1, COO*H*); r.d. in methanol (*c*, 0.038): $[\alpha]_{500}$ +210, $[\alpha]_{400}$ +525, $[\alpha]_{319}$ +7350 (peak), $[\alpha]_{279}$ −7900° (trough).

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.38. Found: C, 76.58; H, 8.92.

Further keto acid **12***a* was obtained in the following manner. The acetonitrile mother liquors from several preparations were combined and concentrated. A solution of the noncrystalline residue (4.7 g) and Girard T reagent (2.35 g) in ethanol (45 ml) containing acetic acid (5 ml) was heated on the steam bath for 2 h. The cooled solution was then added to a mixture of ether (225 ml) and water (225 ml) containing sodium chloride (10 ml of saturated solution). The aqueous layer was separated, concentrated HCl (11 ml) added, and the solution heated on the steam bath for 45 min. The cooled solution was extracted with ether to give a colorless foam (1.68 g), which on crystallization from acetonitrile gave ketoacid **12***a* (1.1 g). The neutral material (0.44 g) obtained from the Diels–Alder reaction was heated under reflux with 10% methanolic sodium hydroxide (30 ml) for 3 h. Work-up in the usual way gave a colorless foam (0.35 g) which on crystallization from acetonitrile gave ketoacid **12***a* (0.2 g), m.p. 192–194°.

Esterification of **12***a* with ethereal diazomethane gave the methyl ester **12***b*, m.p. 83–84° (from Skellysolve B): i.r. ($CHCl_3$) 1720 (ester and ketone), 1415 cm^{-1} (active methylene); mass spectrum (70 eV) *m/e* (relative intensity) 358 (25), 316 (100), 299 (28), 239 (25), 146 (55), 134 (30), 133 (33), 121 (40), 105 (27), 101 (30).

Mol. Wt. Calcd. for $C_{23}H_{34}O_3$: 358.2508. Found (h.r.m.s.): 358.2511.

Reduction of Ketoacid **12***a*

(a) With Sodium Borohydride

Sodium borohydride (55 mg) was added to a solution of ketoacid **12***a* (110 mg) in dimethoxyethane (20 ml) and the resulting solution was stirred at room temperature for 5 h, then more sodium borohydride (55 mg) was added, and stirring continued overnight. The solution was concentrated, diluted with water, and acidified with phosphoric acid. Extraction with ether gave an amorphous solid (105 mg) which consisted mainly of two components as determined by t.l.c. The mixture was esterified (diazomethane) and acetylated (acetic anhy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dride – pyridine). The ratio of *endo*-acetate **14***a* to *exo*-acetate **15***a*, as determined from the relative intensities of the signals at τ 8.08 and 7.94 in the n.m.r. was 3:4. The separation and characterization of the components is described below.

(b) With Lithium–Ammonia–Methanol

A solution of ketoacid **12***a* (1.0 g) in ether (25 ml) was added to liquid ammonia (100 ml) containing methanol (15 ml). Lithium (1.5 g) was added in small portions, with stirring, over 70 min. More methanol (5 ml) was then added and the stirring continued for 40 min, then ammonium chloride (15 g) was added and the ammonia was allowed to evaporate. The residue was diluted with water, acidified with phosphoric acid, and extracted with chloroform. The crude product (1.0 g) was esterified and acetylated as in section *a*. N.m.r. analysis indicated that **14***a* and **15***a* were present in a ratio of 4:3.

*Isolation of **14**a and **15**a*

The mixture of acetates **14***a* and **15***a* obtained above (1.1 g) was chromatographed over alumina (55 g). Elution with Skellysolve B (400 ml) gave unidentified material (25 mg). Elution with Skellysolve B – benzene (1.2 l of 1:1) gave the oily *exo*-acetate **15***a* (0.36 g) which was purified by evaporative distillation (125°/0.05 mm): i.r. ($CHCl_3$) 1720 (ester carbonyls), 1650 (w, C=C); n.m.r. τ 9.37 (s, 3, C-10 methyl), 9.02 (d, 6, J = 6 Hz, isopropyl methyls), 8.86 (s, 3H, C-4 methyl), 7.94 (s, 3, $OCOCH_3$), 6.36 (s, 3, methoxyl), 5.84 (q, 1, J = 9 and 3 Hz, H-15), 4.72 (s, 1, $w_{1/2}$ = 4 Hz, H-14). Continued elution with Skellysolve B – benzene (200 ml of 1:1) and benzene (100 ml) gave a mixture of **14***a* and **15***a* (24 mg). Elution with benzene (1.3 l) gave the oily *endo*-acetate **14***a* (0.475 g), characterized as the alcohol **14***b* (see below). The acetate **14***a* showed the following properties: i.r. ($CHCl_3$) 1720 (ester carbonyls), 1640 cm^{-1} (v.w., C=C); n.m.r. τ 9.37 (s, 3, C-10 methyl), 8.93 (d, J = 7 Hz, isopropyl methyls), 8.86 (s, 3, C-4 methyl), 8.08 (s, 3, $OCOCH_3$), 6.38 (s, 3, methoxyl), 5.44 (q, 1, J = 8 and 3 Hz, H-15), 4.72 (s, 1, $w_{1/2}$ = 3.5 Hz, H-14).

*Methyl 15β-Hydroxy-13-isopropyl-17-noratis-13-en-18-oate (**14**b)*

The acetate **14***a* (0.30 g) was heated on the steam bath with 10% potassium hydroxide in methanol (30 ml) for 3 h. The solution was concentrated on a rotary evaporator and the residue diluted with water and acidified with concentrated HCl. Extraction with chloroform gave the crude *endo*-alcohol **14***b* (0.25 g). Since the i.r. spectrum indicated the presence of some C-4 acid, the crude product was treated with ethereal diazomethane. Crystallization from Skellysolve B gave pure **14***b*, m.p. 92–93°: i.r. ($CHCl_3$) 3570 (concentration independent, intramolecular hydrogen-bonded OH), 1720 (ester), 1635 cm^{-1} (C=C); n.m.r. τ 9.38 (s, 3, C-10 methyl), 8.97 (d, J = 6.5 Hz, isopropyl methyls), 8.86 (s, 3, C-4 methyl), 6.64 (q, 1, J = 8 and 3 Hz, H-15), 6.38 (s, 3, methoxyl), 4.75 (s, 1, H-14).

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.62; H, 10.00. Found: C, 76.77; H, 9.91.

*Methyl 16-Isopropylidene-7,17-secoacon-8(15)-en-18-oate (**16**a)*

A solution of alcohol **14***b* (234 mg) and *p*-toluenesulfonyl chloride (185 mg) in pyridine (2 ml) was kept at room temperature for 3.5 days. Water (50 ml) and ether (100 ml) were added and then the ether layer was separated and washed successively with dilute sulfuric acid, water, saturated sodium bicarbonate, and water. The dried ($MgSO_4$) ether solution was concentrated to a pale green amorphous solid (0.32 g). The crude tosylate **14***c* showed the following properties: i.r. ($CHCl_3$) 1720 (ester), 1645 (C=C), 1600 (aromatic), 1350 and 1175 (tosyloxy), 910 and 890 cm^{-1}; n.m.r. τ 9.42 (s, 3, C-10 methyl), 9.02 (d, 6, J = 7 Hz, isopropyl methyls), 8.88 (s, 3, C-4 methyl), 7.60 (s, 3, aromatic methyl), 6.38 (s, 3, methoxyl), 5.66 (d of d, 1, J's 8 and 2.5 Hz, H-14), 4.78 (s, 1, H-15), 2.73 (d, 1, J = 8 Hz, aromatic) and 2.33 (d, 1, J = 8 Hz, aromatic).

A benzene solution of tosylate **14***c* (0.24 g) was adsorbed on a column of silica gel (6 g, BDH, 60–120 mesh for chromatography). The top portion of the column immediately turned deep purple on introduction of the solution. After 2 h the column was eluted with benzene (200 ml) to give the oily diene **16***a* (0.11 g), purified by evaporative distillation (130°/0.05 mm): i.r. ($CHCl_3$) 1720 (ester), 1635 and 1620 (conjugated olefin); u.v. (95% EtOH) 258 nm (ε 18 000); n.m.r. τ 9.13 (s, 3, C-11 methyl), 8.78 (s, 3, C-4 methyl), 8.34 and 8.28 (three-proton singlets, olefinic methyls), 6.36 (s, methoxyl), 4.15 (s, 1, $w_{1/2}$ = 3 Hz, H-15); mass spectrum (70 eV) *m/e* (relative intensity) 342 (46), 327 (17), 107 (100).

The diene was somewhat unstable in air and was analyzed by h.r.m.s.

Mol. Wt. Calcd. for $C_{23}H_{34}O_2$: 342.2559. Found (h.r.m.s.): 342.2564.

Elution of the silica gel column with ether (150 ml) gave the alcohol **14***b* (36 mg).

The diene **16***a* was also prepared by solvolysis of the tosylate **14***c* in acetic acid as follows: a solution of the tosylate **14***c* (166 mg) in glacial acetic acid (15 ml) containing sodium acetate (123 mg) was heated under reflux for 5 h. The cooled solution was diluted with ether (100 ml) and the resulting solution was washed successively with water, 10% sodium carbonate, and water. The dried ($MgSO_4$) ether solution was concentrated and the residue (125 mg) was subjected to chromatography over alumina (6.25 g). Elution with Skellysolve B (180 ml) and Skellysolve B – benzene (270 ml of 9:1) gave diene **16***a* (47 mg). Elution with Skellysolve B – benzene (300 ml) and benzene (90 ml) gave unidentified material (14 mg). Further elution with benzene (135 ml) gave the *endo*-acetate **14***a* (16 mg), identical in i.r. spectrum and t.l.c. behavior with an authentic sample. Further elution with ether, chloroform, and chloroform–methanol (9:1) gave intractable material (25 mg).

*Hydrolysis of **16**a*

The diene **16***a* (0.11 g) was added to a solution of potassium *t*-butoxide (0.4 g) in anhydrous dimethyl sulfoxide (6 ml) and the resulting solution was heated on the steam bath for 1 1/2 h, then diluted with water (60 ml), acidified (concentrated HCl), and extracted with ether. The ethereal extract was washed with water, dried ($MgSO_4$), and concentrated. The residue (0.10 g) crystallized from acetonitrile to give round clusters (0.06 g) of the acid **16***b*: i.r. ($CHCl_3$) 3200–2400 (carboxyl OH), 1725 sh (monomeric carboxyl), 1685 (dimeric carboxyl), 1630 and 1620 cm^{-1} (conjugated olefin); n.m.r. τ 9.12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(s, 3, C-11 methyl), 8.77 (s, 3, C-4 methyl), 8.32 and 8.28 (three-proton singlets, isopropylidene methyls), 4.11 (s, 1, H-15); mass spectrum (70 eV) *m/e* (relative intensity) 328 (26), 313 (11), 107 (100), 106 (66), 91 (20).

Attempted recrystallization of **16***b* from acetonitrile resulted in the formation of an intractable dark material.

Catalytic Hydrogenation of Diene **16***a*

(a) Over Platinum

The diene **16***a* (57 mg) was dissolved in ethanol (20 ml) and the solution hydrogenated over Adams' catalyst (26 mg) at room temperature and atmospheric pressure for 3.5 h. Removal of the catalyst and solvent left the oily ester **17***a* (57 mg), purified by evaporative distillation (125°/0.05 mm); i.r. ($CHCl_3$) 1715 cm^{-1}; n.m.r. τ 9.13 (br.d, 6, $J \simeq 6$ Hz, isopropyl methyls), 8.92 (s, 3, C-11 methyl), 8.79 (s, 3, C-4 methyl), 6.38 (s, 3, methoxyl); mass spectrum (70 eV) *m/e* (relative intensity) 346 (66), 303 (21), 218 (86), 217 (93), 121 (59), 107 (53), 95 (79), 93 (58), 91 (48), 81 (85), 55 (100).

Hydrolysis of the ester using potassium *t*-butoxide – dimethylsulfoxide as above gave the acid **17***b*, m.p. 128–132° (from acetonitrile): i.r. ($CHCl_3$) 3200–2400 (carboxyl OH), 1730 sh (monomeric carboxyl), 1690 cm^{-1} (dimeric carboxyl); n.m.r. τ 9.14 and 9.11 (two three-proton doublets, non-equivalent methyls of isopropyl), 8.88 (s, 3, C-11 methyl), 8.76 (s, 3, C-4 methyl), −0.4 (broad, 1, COO*H*).

Mol. Wt. Calcd. for $C_{22}H_{36}O_2$: 332.2715. Found (h.r.m.s.): 332.2718.

(b) Over Palladium–Charcoal

Diene **16***a* (70 mg) in ethanol (20 ml) was hydrogenated over 5% palladium-on-charcoal at room temperature and atmospheric pressure. After an uptake of hydrogen (5 ml) during the first 20 min no further absorption was noticeable and the hydrogenation was discontinued. Removal of the catalyst and solvent gave the dihydro compound **18** as a glass: i.r. ($CHCl_3$) 1715 (ester), 1655 (C=C); n.m.r. τ 9.15 (d, 6, $J = 6$ Hz, isopropyl methyls), 9.02 (s, 3, C-11 methyl), 8.80 (s, 3, C-4 methyl), 6.36 (s, 3, methoxyl), 4.93 (s, 1, H-15); mass spectrum (70 eV) *m/e* (relative intensity) 344 (21), 329 (26), 301 (39), 121 (52), 91 (100).

*Methyl 13-Oxo-7,17-secoacon-8(15)-en-13-on-18-oate (**19**)*

A solution of diene **16***a* (48 mg) in methylene chloride was cooled to −70° and a saturated solution of ozone in methylene chloride (6 ml (19)) at −70° was added. The blue color of the ozone solution soon disappeared. After 0.5 h at −70° the solution was allowed to warm to room temperature, the solvent removed at the pump, and the residue treated with water (10 ml) and 30% hydrogen peroxide (0.8 ml) on the steam bath for 0.5 h. The reaction mixture was extracted with chloroform. The chloroform solution was washed with 5% sodium carbonate, water, and concentrated to give neutral material (37 mg), which was chromatographed over silica gel (4 g). Elution with benzene (160 ml) gave unidentified material (8 mg). Elution with benzene–ether (60 ml of 32:1 and 100 ml of 9:1) gave material (15 mg) rich in ketone **19** as judged by i.r. In another experiment conducted in the same manner 62 mg of diene **16***a* gave 17 mg of material rich in ketone **19**. The ketone-rich fractions were combined (32 mg) and chromatographed over alumina (2.5 g). Fractions eluted with benzene (120 ml) and benzene–ether (100 ml of 19:1) gave crystalline ketone **19** (14 mg), m.p. 132–133° (from Skellysolve B): i.r. 1720 (ester), 1670 (ketone), 1625 (conjugated C=C); n.m.r. τ 9.18 (s, 3, C-11 methyl), 8.77 (s, 3, C-4 methyl), 6.33 (s, 3, methoxyl), 4.38 (s, 1, H-15); u.v. (EtOH) 243 nm (ε 11 000); mass spectrum (70 eV) *m/e* (relative intensity) 316 (100), 301 (12), 257 (43), 181 (15), 136 (85), 121 (78), 91 (34).

A recrystallized sample which showed a single spot on t.l.c. (alumina and silica gel) was used for analysis.

Mol. Wt. Calcd. for $C_{20}H_{28}O_3$: 316.2040. Found: 316.2044.

*Methyl 15α-Hydroxy-13-isopropyl-17-noratis-13-en-18-oate (**15***b*)*

The *exo*-acetate **15***a* (0.65 g) was hydrolyzed on the steam bath with 10% potassium hydroxide in methanol. Work-up in the usual manner gave the alcohol **15***b* (0.58 g) which after crystallization from Skellysolve B melted at 116–119°: i.r. ($CHCl_3$) 3610 (OH), 1720 (ester), 1640 (C=C): mass spectrum (70 eV) *m/e* (relative intensity) 360 (3), 316 (100), 187 (27), 146 (57), 134 (27), 133 (27), 123 (20), 121 (41), 105 (20), 101 (25).

Anal. Calcd. for $C_{23}H_{36}O_3$ (mol. wt. 360.2665): C, 76.62; H, 10.06. Found (360.2667 (h.r.m.s.)): C, 77.48; H, 9.92.

Crystal Structure of 1-Cyanotetracyclo[3.3.1.1^{3,7}.0^{3,7}]decane

CYRIL S. GIBBONS AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 29, 1972

Crystals of 1-cyanotetracyclo[3.3.1.1^{3,7}.0^{3,7}]decane, $C_{11}H_{13}N$, are monoclinic, a = 6.442(2), b = 11.739(2), c = 11.965(4) Å, β = 98.14(9)°, Z = 4, space group $P2_1/c$. The structure was determined with CuKα scintillation counter data by direct methods, and refined by full-matrix least-squares techniques to R 0.048 for 690 observed reflexions. C(3) and C(7) have all four bonds directed to one side of the atoms, and the central bond distance is 1.643 Å. Other bond lengths and angles are normal.

Le composé cyano-1 tétracyclo[3.3.1.1^{3,7}.0^{3,7}]décane, $C_{11}H_{13}N$, cristallise dans le système monoclinique aux caractéristiques suivantes: a = 6.442(2) Å, b = 11.739(2) Å, c = 11.965(4) Å, β = 98.14 (9)°, Z = 4, groupe d'espace $P2_1/c$. La structure a été déterminée à partir des mesures de diffraction, obtenues par comptage de scintillations (radiation Kα du cuivre), et a été affinée par la méthode de moindres carrés (matrice complète) jusqu'à un facteur de reliabilité R = 0.048 pour 690 réflexions. Toutes les quatre liaisons des carbones C(3) et C(7) se dirigent vers un côté de l'atome, et la longueur de la liaison central est 1.643 Å. Les autres longueurs de liaison et les angles sont normaux.

Introduction

The preparation of a 1,3-dehydro derivative of adamantane has been reported (1), with the suggestion that the bridgehead atoms have all four bonds extended from one side of the atoms, as in tricyclo [3.2.1.0^{1,5}]octane (2). A single crystal X-ray analysis of a cyano-derivative of 1,3-dehydro-adamantane has now been carried out to provide details of the unusual geometry at the "inverted" bridgehead carbon atoms.

Experimental

Crystals of 1-cyanotetracyclo[3.3.1.1^{3,7}.0^{3,7}]decane are colorless prisms elongated along a. The unit cell parameters and space group were determined from precession photographs and diffractometer data, the unit cell parameters being refined by a least-squares procedure applied to the $\sin^2\theta$ values of 20 reflexions measured on the diffractometer with CuKα radiation. Crystal data are:

$C_{11}H_{13}N$ f.w. = 159.32

Monoclinic, a = 6.442(2), b = 11.739(2), c = 11.965(4) Å, β = 98.14(9)°, V = 895.8 Å^3, Z = 4, ρ_c = 1.18, $F(000)$ = 344 (20 °C; CuKα, λ = 1.5418 Å, μ = 5.3 cm^{-1}). Space group $P2_1/c$ from systematic absences. The density was not measured due to the extreme reactivity of the compound.

The intensities of all reflexions with 2θ(CuKα) ≤ 100° (minimum interplanar spacing, 1.01 Å) were measured on a Datex automated General Electric XRD 6 spectrogoniometer with a scintillation counter, approximately monochromatic CuKα radiation (Ni-filter and pulse-height analyzer), and a θ–2θ scan of 4° min^{-1} in 2θ. Background counts were made at the beginning and end of each scan. As the crystals were observed to decompose quickly in the X-ray beam, a new crystal was selected for the data collection from a freshly sublimed sample, and sealed inside a glass capillary. A check reflexion was measured periodically, showing the steady decomposition of the crystal, and the scale was adjusted accordingly.

The crystal used for data collection was a prism with dimensions 0.6 × 0.25 × 0.25 mm, and was mounted with a^* parallel to the φ axis of the goniostat. No absorption correction was made. Lorentz and polarization factors were applied and the structure amplitudes derived. Of the 919 reflexions, 690 (75%) had intensities greater than 3σ(I) above background, where $\sigma^2(I) = S + B + (0.05S)^2$, where S = scan count and B = background count. The remaining 229 reflexions were classified as unobserved.

Structure Analysis

The structure was solved by a direct sign-determining procedure (3), which uses a reiterative application of Sayre relationships (4). The carbon and nitrogen positions were determined from an E-map, and a structure factor calculation carried out with scattering factors from ref. 5, and isotropic temperature factors B = 4.0 Å^2, gave R = 0.30. After two cycles of full-matrix least-squares refinement with $\sqrt{w} = |F_o|/6.0$ when $|F_o| < 6.0$, $\sqrt{w} = 6.0/|F_o|$ when $|F_o| \geq 6.0$, $\sqrt{w}$(unobs) = 0.25, R was 0.16, and a difference electron-density map revealed the positions of the hydrogen atoms. These were included in the refinement with scattering factors from ref. 6, and isotropic B = 4.0 Å^2, and after two cycles of refinement R was 0.11. The carbon and nitrogen atoms were then assigned anisotropic thermal parameters and after several cycles of refinement, the final R value was 0.048. The 002, 020, 110, and 11$\bar{2}$ reflexions were given zero weight in the final cycles because of suspected extinction errors. The maximum parameter shift in the final cycle was 0.11σ, and a final difference map showed maximum fluctuations of ±0.16 e Å^{-3}.

Final positional and thermal parameters are listed in

Discussion

The crystal analysis has shown the present compound to be related to adamantane by the formation of the bond C(3)—C(7) with corresponding loss of hydrogen (in the adamantane numbering system, this corresponds to 1,3-dehydrogenation), and has given details of the geometry of the tetracyclic ring system and the "inverted" bridgehead carbon atoms.

2,4,10	0.3855	0.0101	−0.9227	−6.1062	−0.047	+1.342
6,8,10	0.8936	0.4249	−0.1445	2.1610	−1.330	+0.109

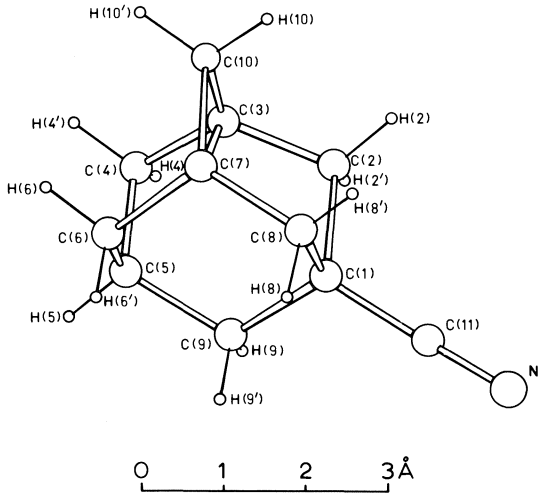

FIG. 1. Molecular diagram showing the numbering system used.

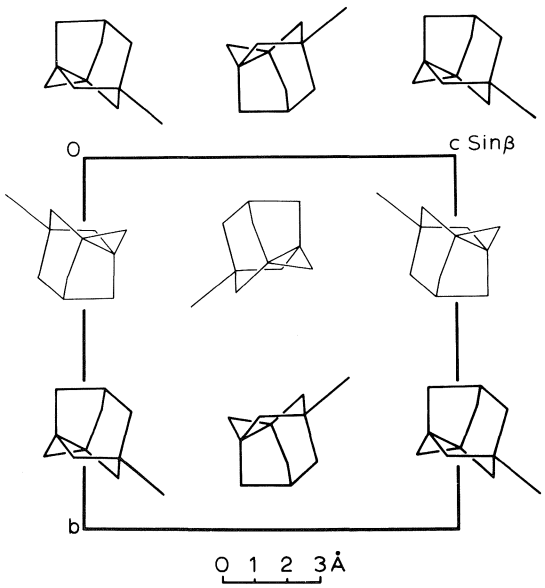

FIG. 2. Packing of the molecules in the unit cell (heavy lines indicate molecules in the top part of the cell).

Planes calculated through atoms C(2), C(4), C(10), and C(6), C(8), C(10) are given in detail in Table 3, and the bridgehead atoms C(3) and C(7) lie on the opposite sides of these planes from the rest of the molecule. Thus, these atoms are "inverted", in the sense that all four bonds are directed to one side of the atoms. It has been shown theoretically for tricyclo[1.1.1.$0^{1,3}$]pentane (7) that the energy minimum is obtained for a central bond length of 1.60 Å, and a side bond of 1.53 Å. The central bond length determined for the present compound agrees well with this at 1.643 Å, but the side bonds (1.476–1.517 Å) appear to be somewhat shorter than the theoretical value, or the observed value for cyclopropane (8, 9), although these differences are small, and the comparison may not be valid. The side bonds correspond closely with the value expected for C(sp^2)—C(sp^3) bonds, 1.515 Å, giving some support for the assumption of sp^2 hybridization at the bridgehead, with pσ overlap for the central bond.

Apart from the "inverted" carbon atom geometry, the bond lengths and angles are normal (9) with a mean C—C distance of 1.532, and a C≡N distance of 1.139 Å. The average C–H distance is 0.96 Å.

Intermolecular contacts correspond to van der Waals interactions, the shortest C...N and C...C distances being 3.72 and 3.87 Å, respectively.

We thank Dr. R. E. Pincock for crystals and discussion, the University of British Columbia Computing Centre for assistance, and the National Research Council of Canada for financial support.

Halogenoammine Complexes of Osmium(III)

A. D. Allen and J. R. Stevens

Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received July 13, 1972

The complexes $[Os(NH_3)_5X]X_2$, *cis*-$[Os(NH_3)_4X_2]X$, and *trans*-$[Os(NH_3)_4X_2]X$ (X = Cl, Br, I) have been prepared and their infrared spectra measured between 4000–150 cm^{-1}. Assignments have been made for the observed absorption bands. The electronic spectra of the complexes were measured and compared with those of the analogous ruthenium(III) species.

Nous avons préparé les complexes $[Os(NH_3)_5X]X_2$, *cis*-$[Os(NH_3)_4X_2]X$, et le *trans*-$[Os(NH_3)_4X_2]X$ (où X = Cl, Br, I) et mesuré leurs spectres infrarouge entre 4000–150 cm^{-1}. Nous avons assigné les bandes d'absorption observées. Les spectres électroniques de complexes ont été mesurés et comparés à ceux de complexes analogues du ruthénium(III). [Traduit par le journal]

Introduction

Little work has been done previously on the ammine complexes of trivalent osmium. This neglect has probably stemmed from the poor synthetic routes so far developed. The first complex of this type prepared was $K_2[OsCl_5(NH_3)]$ (1) although for many years this was thought to be $K_2[OsCl_5(NH_2)]$ (2). Dwyer and Hogarth (3) isolated $[Os(NH_3)_5Br]Br_2 \cdot H_2O$ and $[Os(NH_3)_5Cl]Cl_2 \cdot \frac{1}{2}H_2O$ from the reaction of $(NH_4)_2[OsBr_6]$ and $(NH_4)_2[OsCl_6]$, respectively, with ammonia under pressure. Later they identified $[Os(NH_3)_6]^{3+}$ as a more soluble product from the same reaction (4). This reaction was investigated in more detail by Watt and Vaska (5), who determined that for the bromo complex the two major products were $[Br(NH_3)_4OsNOs(NH_3)_4Br]Br_3$ and $[Os(NH_3)_6][OsBr_6]$. These authors, and Belova and Syrkin (6), who were working about the same time, both reported that the reactions were extremely sensitive to the conditions under which they were performed.

The only reported spectroscopic studies of osmium(III) ammines are infrared measurements of $[Os(NH_3)_6]Br_3$ (7) and $[Os(NH_3)_6][OsBr_6]$ (8). In contrast trivalent ruthenium ammine complexes have been studied in some detail (8–10). This report describes a convenient synthetic route to the complexes $[Os(NH_3)_5X]X_2$, *cis*-$[Os(NH_3)_4X_2]X$, and *trans*-$[Os(NH_3)_4X_2]X$ (X = Cl, Br, I) and their characterization by infrared and electronic spectroscopy.

Experimental

The infrared spectra were recorded on a Perkin–Elmer 180 Spectrophotometer as Nujol mulls between KBr plates or polyethylene sheets. The electronic spectra were recorded on either a Bausch and Lomb 505 Spectrophotometer or a Unicam SP 800A Ultraviolet Spectrophotometer in 1 cm quartz cells using distilled water. Microanalyses were performed by A. B. Gygli, Toronto, Ontario and halides were determined by potentiometric titration at 0° with silver nitrate. $[Os(NH_3)_5(N_2)]Cl_2$ was prepared in the usual manner (11) and *cis*-$[Os(NH_3)_4(N_2)_2]Br_2$ by the published procedure (12). All other chemicals were reagent grade and used without further purification.

Preparation of the Complexes

Iodopentaammineosmium (III) Iodide, $[Os(NH_3)_5I]I_2$

Nitrogenpentaammineosmium(II) chloride (1 g) was slurried with 50 ml of water and 10 ml of concentrated hydriodic acid. Excess iodine (0.5 g) was added and the mixture refluxed vigorously for 4 h. The excess iodine was expelled from the solution by strong heating and the solution was then cooled to ice temperature. The orange product was collected, washed with 95% ethanol and diethyl ether and air-dried. It was recrystallized from very dilute hot hydriodic acid as orange crystals. Yield 1.5 g (90%). Microanalyses for this and other complexes reported in this work are listed in Table 1.

Chloropentaammineosmium(III) Chloride, $[Os(NH_3)_5Cl]Cl_2$

Iodopentaammineosmium(III) iodide (0.5 g) was dissolved in hot dilute hydrochloric acid (50 ml) and the chloride concentration made as large as possible without precipitating any of the complex, by the addition of concentrated hydrochloric acid. The solution was refluxed for 48 h until it became almost colorless. On cooling and adding more concentrated hydrochloric acid, a lemon-yellow precipitate came down. The product was collected, washed with 95% ethanol and diethyl ether, and air-dried. Yield 0.2 g (70%).

The alternative direct preparation via atmospheric oxidation of $[Os(NH_3)_5(N_2)]Cl_2$ in hydrochloric acid is less satisfactory because a second species believed to be $[OsO_2(NH_3)_4]Cl_2$ is also formed.

Bromopentaammineosmium(III) Bromide, $[Os(NH_3)_5Br]Br_2$

Iodopentaammineosmium(III) iodide (0.5 g) was dissolved in hot dilute hydrobromic acid (75 ml) and the

bromide concentration increased, without causing precipitation, by the addition of concentrated hydrobromic acid. The solution was then refluxed for 24 h or until the 407 nm absorption, characteristic of $[Os(NH_3)_5I]^{2+}$, had disappeared. On cooling and adding concentrated hydrobromic acid, a bright yellow powder was obtained. This was recrystallized from hot dilute hydrobromic acid. Yield 0.3 g (75%).

cis-Dichlorotetraammineosmium(III) Chloride Hydrate, cis-[Os(NH$_3$)$_4$Cl$_2$]Cl·H$_2$O

cis-Bisnitrogentetraammineosmium(II) bromide (0.25 g) was slurried with 20 ml of 3 *M* hydrochloric acid in a flask. The mixture was heated at 60° for 15 h and then refluxed for 5 h. The resulting yellow solution was filtered to remove a little yellow precipitate and 5 ml of concentrated hydrochloric acid and 25 ml of 95% ethanol were added to the filtrate. Upon standing at −20° for 24 h a flocculent yellow precipitate was obtained. This was collected, washed with 95% ethanol and diethyl ether then dried at 65% under vacuum in the presence of P_4O_{10}.

cis-Dibromotetraammineosmium(III) Bromide Tetroethanolate, cis-[Os(NH$_3$)$_4$Br$_2$]Br·¼C$_2$H$_5$OH

cis-Bisnitrogentetraammineosmium(II) bromide (0.2 g) was mixed with 5 ml of concentrated hydrobromic acid and 15 ml of water. The resulting off-white slurry was heated gently for 10 h or until all of the starting material had reacted and the solution had become clear and yellow. After cooling to ice temperature, 5 ml of concentrated hydrobromic acid and 20 ml of 95% ethanol were added and the solution cooled to −20°. A flocculent orange precipitate was obtained. This was collected, washed with 95% ethanol and diethyl ether, then dried for 24 h at 78° under vacuum in the presence of P_4O_{10}. Yield 0.15 g (72%).

cis-Diiodotetraammineosmium(III) Iodide, cis-[Os(NH$_3$)$_4$I$_2$]I

cis-Bisnitrogentetraammineosmium(II) bromide (0.12 g) was slurried with 40 ml of 1:4 hydriodic acid. The mixture was refluxed gently for 15 h during which time a clear orange-red solution formed. A flocculent orange-red precipitate was obtained by adding 5 ml of concentrated hydriodic acid and 25 ml of 95% ethanol and then cooling the solution to −20°. The product was recrystallized from hot dilute hydriodic acid as long, very deep red, leaflets. Yield 0.14 g (85%).

trans-Dichlorotetraammineosmium(III) Chloride Hydrate, trans-[Os(NH$_3$)$_4$Cl$_2$]Cl·H$_2$O

cis-Dibromotetraammineosmium(III) bromide (0.15 g) was dissolved in 10 ml of water and 10 ml of concentrated hydrochloric acid added. The solution was refluxed under nitrogen for 3 days during which time it became a lighter shade of yellow. On cooling and adding 5 ml of concentrated hydrochloric acid a bright yellow precipitate was obtained. This was collected, washed with 95% ethanol and diethyl ether, then dried at 78° under vacuum for 24 h. Yield 0.06 g (55%).

trans-Dibromotetraammineosmium(III) Bromide, trans-[Os(NH$_3$)$_4$Br$_2$]Br

The procedure was identical to that used for *trans*-$[Os(NH_3)_4Cl_2]Cl$ except hydrobromic acid replaced hydrochloric acid. Yield 0.08 g (53%).

trans-Diiodotetraammineosmium(III) Iodide, trans-[Os(NH$_3$)$_4$I$_2$]I

trans-Dichlorotetraammineosmium(III) chloride hydrate (0.1 g) was added to 20 ml of 1:4 hydriodic acid and the solution was refluxed under nitrogen for 24 h. After cooling to 0° to ensure complete precipitation, the product was collected and washed with 95% ethanol and diethyl ether. It was recrystallized from very dilute hot hydriodic acid as dark red shiny needles. Yield 0.08 g (50%).

Results and Discussion

As was reported previously (13), iodine oxidation of $[Os(NH_3)_5(N_2)]^{2+}$ results in a convenient, rapid synthesis of $[Os(NH_3)_5I]^{2+}$. Chatt *et al.* (14) noted the presence of a species having an infrared absorption at 2130 cm^{-1} in the unstable mixture produced by I_2 oxidation of $[Os(NH_3)_5(N_2)](BPh_4)_2$ in ethanol. This is probably the unstable $[Os(NH_3)_5(N_2)]^{3+}$ ion detected by Elson *et al.* (15) and suggests that in the preparation of $[Os(NH_3)_5I]^{2+}$, the first step is an oxidation and this is followed by a substitution.

$$[1]\quad 2[Os(NH_3)_5(N_2)]^{2+} + I_2 \rightarrow 2[Os(NH_3)_5(N_2)]^{3+} + 2I^- \rightarrow 2[Os(NH_3)_5I]^{2+} + 2N_2$$

Atmospheric oxygen was also found to be a suitable oxidizing agent, but the simultaneous formation of $[OsO_2(NH_3)_4]^{2+}$ reduced the yield, and made this method less desirable. Interconversion of the halides by refluxing in the appropriate hydrohalic acid was slow but efficient. An intermediate aqua complex was not detected.

The yellow color of $[Os(NH_3)_5Cl]Cl_2$ and $[Os(NH_3)_5Br]Br_2$ is not in accord with the data of Dwyer and Hogarth (3), Watt and Vaska (5), or Sutton (16). This may be accounted for by different crystal sizes but our compounds were yellow even in powdered form. Neither osmium nor total bromine analysis will distinguish $[Os(NH_3)_5Br]Br_2 \cdot H_2O$ from $[Os(NH_3)_6]Br_3$ or $[Os(NH_3)_5(H_2O)]Br_3$. The low nitrogen analyses reported in refs. 3 and 5 eliminate $[Os(NH_3)_6]Br_3$ from consideration but the lighter color reported for the monohydrate suggests, by analogy with the corresponding ruthenium(III) complexes, that the water is coordinated. Sutton (16) found $[Os(NH_3)_5I]I_2$ to be chocolate brown in color but the cation gave light orange solutions in water as does our orange compound. He found the light brown bromo complex to be a 2:1 electrolyte in methanol and reported that the bromide ligand was very labile in aqueous solution. Dwyer and Hogarth had earlier remarked on the lability of the coordinated chloride in $[Os(NH_3)_5Cl]^{2+}$. By contrast we find that all three halogens are tightly bound to the metal and are very inert to substitution. In fact the ionic halides may be titrated with silver nitrate at 0° without interference from the coordinated halide.

The *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ ion provided a convenient starting material for the preparation of the previously unreported *cis*-$[Os(NH_3)_4X_2]X$ complexes (X = Cl, Br, I). The diiodo complex can be prepared at refluxing temperatures in good yield. The dichloro and dibromo complexes must be prepared at lower temperatures and the formation of side products reduces the yields. If the bisnitrogen complex is treated with hydrohalic acid under nitrogen or argon in the absence of I_2, a disproportionation occurs. The stoichiometry is inferred from the observed products.

$$[2]\quad 3\ cis\text{-}[Os(NH_3)_4(N_2)_2]^{2+} + 4HX \rightarrow 2\ cis\text{-}[Os(NH_3)_4X_2]^{+} + Os + 4NH_4^{+}$$

When *cis*-$[Os(NH_3)_4X_2]^{+}$ (X = Cl, Br) is refluxed in hydrobromic acid under nitrogen for several days, isomerization occurs and *trans*-$[Os(NH_3)_4Br_2]^{+}$ is formed. With hydrochloric acid a similar isomerization occurs to produce *trans*-$[Os(NH_3)_4Cl_2]^{+}$

$$[3]\quad cis\text{-}[Os(NH_3)_4X_2]^{+} + 2HBr \xrightarrow[3\ days]{reflux} trans\text{-}[Os(NH_3)_4Br_2]^{+} + 2HX\ (X = Cl, Br)$$

but with hydriodic acid only substitution occurs.

$$[4]\quad cis\text{-}[Os(NH_3)_4X_2]^{+} + 2HI \xrightarrow[3\ days]{reflux} cis\text{-}[Os(NH_3)_4I_2]^{+} + 2HX\ (X = Cl, Br, I)$$

The *trans*-$[Os(NH_3)_4I_2]^{+}$ ion could be prepared by starting with a *trans* isomer.

$$[5]\quad trans\text{-}[Os(NH_3)_4X_2]^{+} + 2HI \xrightarrow[24\ hr]{reflux} trans\text{-}[Os(NH_3)_4I_2]^{+} + 2HX\ (X = Cl, Br)$$

The principal side product formed during the preparation of *cis*-$[Os(NH_3)_4Cl_2]Cl$ was identified by electronic spectroscopy as *trans*-$[Os(NH_3)_4Cl_2]Cl$. Great care must be exercised during the preparation of *cis*-$[Os(NH_3)_4Cl_2]Cl$ and to a lesser extent, *cis*-$[Os(NH_3)_4Br_2]Br$, not to overheat the solutions or isomerization will occur. The tendency for the stereochemical change, *cis* → *trans*, to occur, decreases markedly in the order Cl > Br > I. No evidence of isomerization of either iodo species was obtained after several days at refluxing temperatures.

The infrared spectral data for the complexes is listed in Table 2. The ammine vibrations were assigned in the usual manner by comparison with other ammine complexes (17).

The far infrared region, 520–160 cm^{-1}, contains the skeletal modes of the complex ions. The bands between 446 and 504 cm^{-1} are assigned to the osmium–nitrogen stretching vibrations (18). For the pentaammine series (C_{4v} symmetry) there are four infrared-active metal–ligand stretching modes ($3A_1 + E$). One A_1 mode is the osmium–halogen stretching mode which leaves three $\nu(Os—NH_3)$ modes. All three are observed in the spectra of the chloro and bromo complexes and two are visible in the spectrum of the iodo complex, (see Fig. 1). The E mode is split in all three complexes and appears as a well-defined doublet. The osmium–halogen stretching vibrations are easily identified since they exhibit the greatest variation on changing the halogen. The osmium–nitrogen deformation modes occur as strong bands about 240 cm^{-1}.

For the *trans*-tetraammine series (D_{4h} symmetry), there are only two infrared-active metal–ligand stretching modes ($A_{2u} + E_u$). The A_{2u} mode is the asymmetric osmium–halogen stretching vibration and the E_u mode is the similar vibration of the osmium–nitrogen bonds. The latter is readily assigned to the 458 cm^{-1} band in the iodo species, the 461 cm^{-1} band is the bromo species, and to the doublet at 455 and 447 cm^{-1} in the chloro species (see Fig. 2). The osmium–halogen stretching modes are assigned to the bands at 180, 222, and 317 cm^{-1} in the iodo, bromo, and chloro salts, respectively.

For the C_{2v} symmetry *cis*-tetraammine complexes, there are six infrared-active stretching fundamentals ($3A_1 + 2B_1 + B_2$). These represent symmetric and asymmetric motions of the three pairs of similar ligands. (The ammonia ligands are differentiated by the nature of the ligand in the *trans* position). Unfortunately only three of the ν(Os—NH_3) frequencies are observed (Fig. 3) and only in the spectrum of the iodo complex are the two osmium–halogen frequencies resolved. However, the ν(Os—Cl) and ν(Os—Br) absorptions are broader in the *cis*-tetraammines than in the pentaammines.

As can be seen in Table 3 the electronic spectra of the complexes $[M(NH_3)_{6-a}X_a]^{(3-a)+}$ (M = Ru, Os; X = Cl, Br, I; a = 1, 2) are characterized by one or two moderately intense absorptions with one or two weaker absorptions at higher energy. More specifically it can be noted that the pentaammines exhibit one intense band, the *cis*-tetraammines two bands, and the *trans*-tetraammines one, but it is considerably more intense than in the other complexes. Jørgensen has classified these bands as $\pi \rightarrow \gamma_5$ or ligand $\pi \rightarrow$ metal $d\pi$ charge transfer bands (19).

The relevant energy levels are depicted schematically in Fig. 4. The observed charge-transfer transitions from the ligand π-orbitals to the metal d-orbitals are indicated. The occurrence of the transition at approximately the same energy for both pentaammine and *trans*-tetraammine complexes suggests that there is very little π interaction between the halide $p\pi$ orbitals and the metal $d\pi$ orbitals. That this is not the case is shown by the significant splitting observed in the *cis*-tetraammine complexes. The origin of this splitting is shown (Fig. 4) to be a result of two types of ligand π-orbitals. There is no metal π-orbital of b_1 symmetry and the $3b_1$ ligand

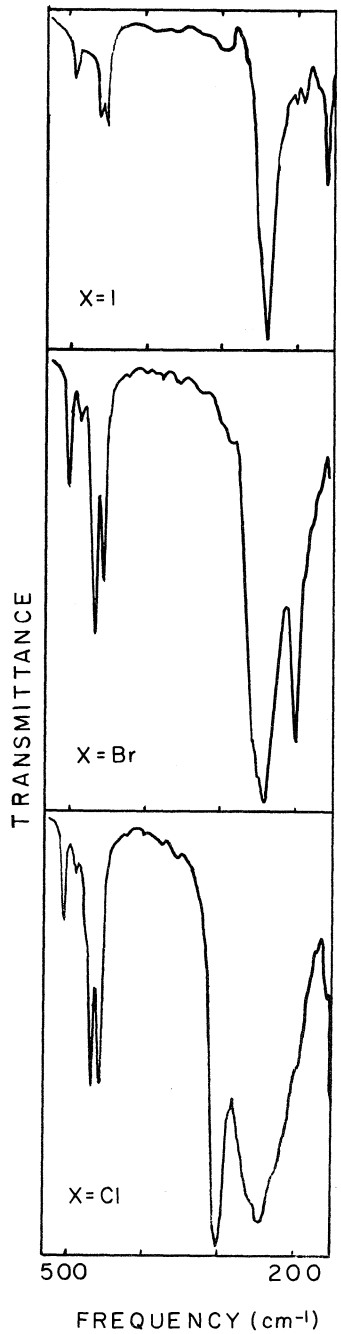

FIG. 1. Far infrared spectra (520–150 cm^{-1}) of $[Os(NH_3)_5X]X_2$ complex salts (X = I, Br, Cl).

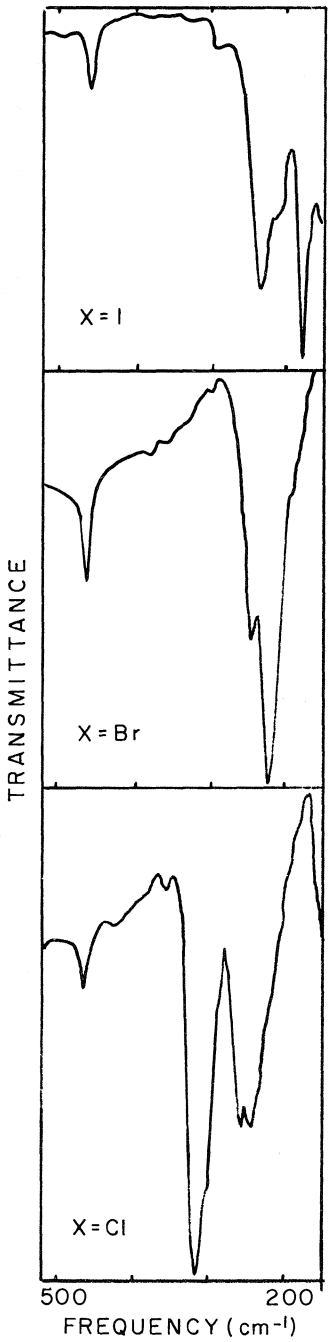

FIG. 2. Far infrared spectra (520–150 cm^{-1}) of *trans*-$[Os(NH_3)_4X_2]X$ complex salts (X = I, Br, Cl). The chloride salt contains water of crystallization.

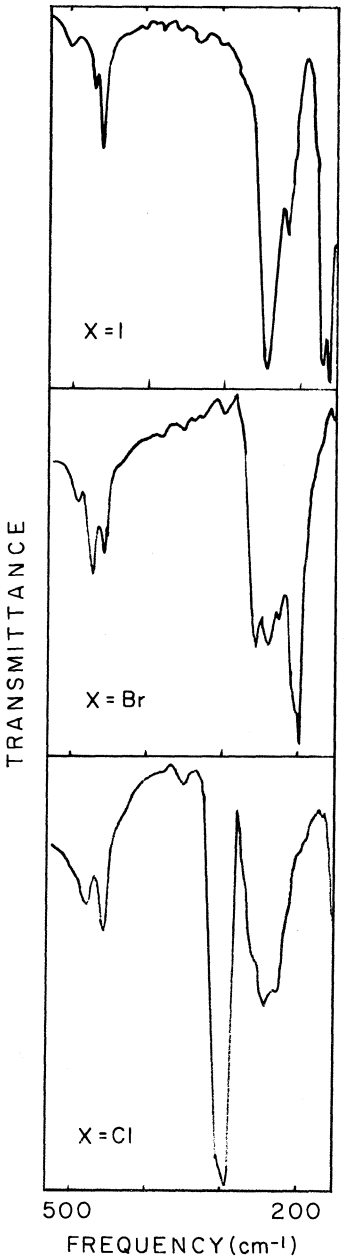

FIG. 3. Far infrared spectra (520–150 cm^{-1}) of *cis*-$[Os(NH_3)_4X_2]X$ complex salts (X = I, Br, Cl). The bromide salt contains ethanol of crystallization.

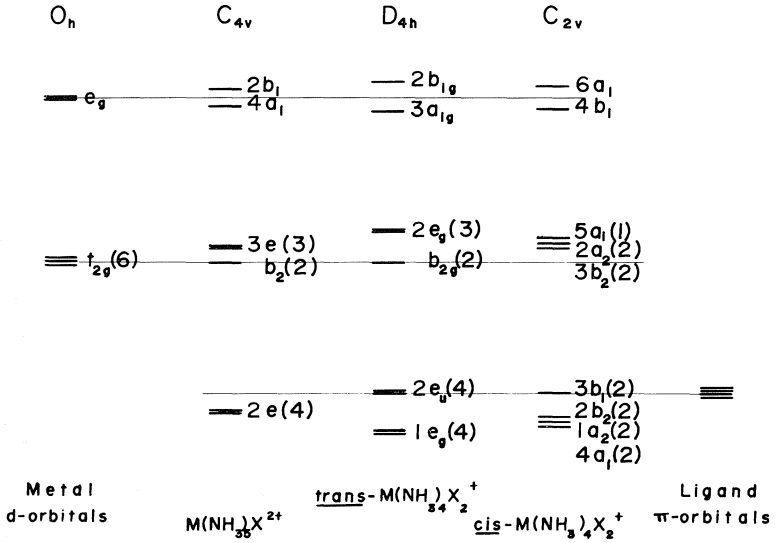

FIG. 4. Schematic energy level diagram (not to scale) of metal d-orbitals and ligand π-orbitals for ruthenium(III) and osmium(III) halogenoammine complexes.

π-orbital remains non-bonding. The other three ligand π-orbitals all interact to some degree with the metal orbital of the appropriate symmetry resulting in a stabilization of the ligand π-orbitals and a destabilization of the metal dπ-orbitals. Thus the similarity of the band positions of the pentaammines and *trans*-tetraammines results from the destabilization of the $3e_g$ level in the D_{4h} complexes being about equal to the stabilization of the $2e$ plus the destabilization of the $3e$ levels in the C_{4v} complexes.

The weaker bands observed at higher energy than the ligand-to-metal charge-transfer bands are undoubtedly ligand field transitions. No assignments are possible because there are a large number of excited states for low-spin d^5 systems and yet no more than two transitions are ever observed. Furthermore there is also the possibility that one or more ligand field bands occur at lower energy and are thus obscured by the charge-transfer bands.

The similarity of the spectra of the analogous complexes of ruthenium and osmium is readily apparent. The charge transfer bands of the osmium complexes lie at higher energy than those of their ruthenium counterparts. It is thus more difficult to reduce trivalent osmium than trivalent ruthenium. In the *cis*-tetraammines the splitting of the charge-transfer bands is relatively independent of the metal atom but slightly dependent on the halide.

Urea – Boron Trihalide Adducts. II. Enhancement of Barriers to Rotation in *sym*- and *unsym*-Dialkylureas on BF_3 Complexation

J. S. HARTMAN[1] AND G. J. SCHROBILGEN[2]

Department of Chemistry, Brock University, St. Catharines, Ontario

Received May 4, 1972

N.m.r. evidence is presented for restricted rotation and oxygen donation in dialkylurea – boron trihalide adducts. Conformer populations in *sym*-dimethylurea.BF_3 are not the same as in the previously reported *sym*-dialkylurea–$SbCl_5$ adducts.

Une preuve par r.m.n. est présentée pour la rotation restreinte et pour la complexation sur l'oxygène dans les complexes dialkylurée–trihalogénure de bore. Les populations des conformations des complexes *sym*-diméthylurée–BF_3 ne sont pas les mêmes que pour le *sym*-dialkylurée–$SbCl_5$ précédemment rapportées. [Traduit par le journal]

Introduction

Both nitrogen and oxygen are potential donor sites in ureas. From a number of different lines of evidence we have proposed that oxygen is the donor site in the 1:1 adduct of tetramethylurea (TMU) and boron trifluoride (1). We now report n.m.r. studies of the BF_3 adducts of *sym*- and *unsym*-dialkylureas ($(RNH)_2CO$ and $R_2NC(O)NH_2$, respectively, R = Me and Et) which show that hindered rotation about the central C—N bonds occurs in these adducts. By analogy with amide adducts (2), this supports oxygen donation. In the course of this work reports have appeared of restricted rotation in *sym*-dialkylureas complexed to antimony pentachloride (3) and in alkylthioureas complexed to cobalt(II) and zinc(II) (4).

Experimental

Materials were handled under anhydrous conditions on a vacuum line or in a dry box. Boron trifluoride and methylene chloride were purified as described previously (1). The dialkylureas (Aldrich) were dried overnight as fine powders under high vacuum before use. Nitromethane was dried overnight over magnesium sulfate. Deuterated *sym*-dimethylurea was prepared by dissolving *sym*-dimethylurea in deuterium oxide and evaporating to dryness. This procedure was repeated four times, giving a 99% *N*-deuterated product. The final product was twice recrystallized from anhydrous diethyl ether, powdered, and dried overnight under high vacuum.

Solutions of the BF_3 adducts were prepared by standard high-vacuum techniques. Methylene chloride – nitromethane mixed solvent (50:50, v/v) was used when solubility in methylene chloride alone was insufficient. Known amounts of BF_3 were condensed from a calibrated volume directly into 5 mm tubes containing degassed solutions of the ureas. Proton and ^{19}F spectra were referenced by condensing in small quantities of tetramethylsilane and trichlorofluoromethane. The samples were sealed off with the contents still at liquid nitrogen temperature, then warmed to room temperature.

The n.m.r. instrumentation has been described (1).

Results

60 MHz ^1H spectra of uncomplexed *sym*- and *unsym*-dimethylureas (DMU's) in methylene chloride solution showed only one methyl environment at temperatures down to $-80°$, rather than separate signals corresponding to methyls *cis* and *trans* to the carbonyl group as are observed in amides (2). The NH and NH_2 peaks were broad and not easily visible due to ^{14}N quadrupole relaxation, but the methyl protons couple to the NH proton in the *sym* compound to give a methyl doublet ($J_{H-C-N-H}$ = 5.0 Hz (3)). This doublet collapsed on addition of a trace of HF or BF_3 to the solution. Complexation with BF_3 shifted the methyl resonances to low field (Table 1). At room temperature a single methyl peak was observed for the BF_3 adduct of *unsym*-DMU; the methyl resonance of the *sym* adduct was split into a doublet ($J_{H-C-N-H}$ = 5.0 Hz) by coupling to the NH proton. When excess urea was present, separate methyl resonances were observed for the free urea and the 1:1 BF_3 adduct. The methyl doublet of uncomplexed *sym*-DMU was collapsed to a singlet when adduct was present, but the doublet survived in the adduct.

[2]Present address: Department of Chemistry, McMaster University, Hamilton, Ontario.

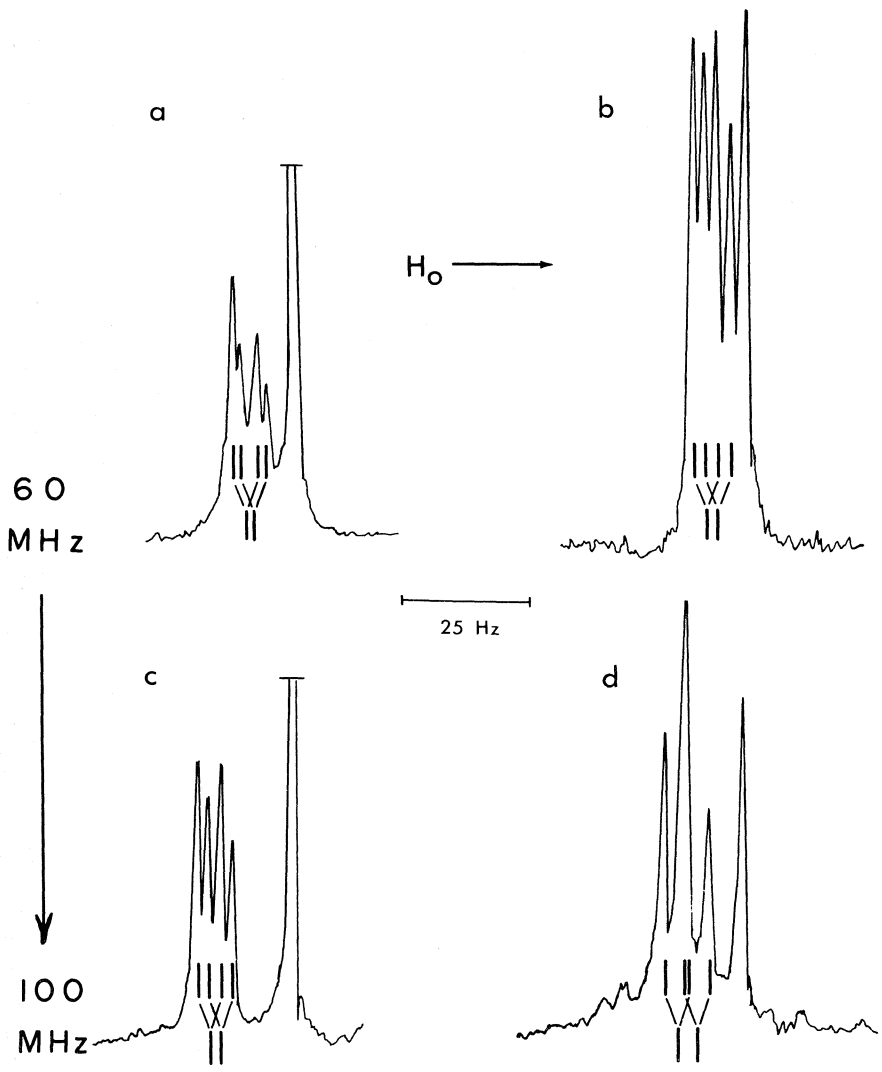

FIG. 1. The $-20°$ ^1H spectra of *sym*-DMU/BF_3 systems for $[BF_3]/[sym\text{-DMU}] = 0.50$ (*a*, *c*) and 0.75 (*b*, *d*) at 60 MHz (*a*, *b*) and 100 MHz (*c*, *d*). Splittings due to J_{HCNH} are shown schematically. The increase in magnetic field strength causes the small methyl chemical shift difference to become comparable to J_{HCNH}.

Cooling caused splitting of the adduct methyl resonances to give two singlets for *unsym*-DMU.BF_3, two doublets ($J_{H-C-N-H} = 5.0$ Hz) for *sym*-DMU.BF_3, and two sets of triplets for each of the DEU adducts. Coalescence temperatures are given in Table 1; $-20°$ 60 MHz and 100 MHz ^1H spectra of solutions of *sym*-DMU and BF_3, with *sym*-DMU present in excess, are shown in Fig. 1. Only the methyl peaks are shown. The high-field singlet arises from uncomplexed *sym*-DMU. The change in magnetic field strength shows that the four adduct peaks are made up of two 1:1 spin–spin doublets of unequal intensity (low field : high field = 61:39). The origin of the splittings was confirmed by studies of the BF_3 adduct of the *N*-deuterated compound, $(MeND)_2CO$, which gave two broadened *singlets* of unequal intensity at low temperatures since the much smaller splittings due to H—C—N—D coupling were not resolved. Peak separations at $-20°$ were somewhat dependent on sample composition, probably as a result of varying degrees of intermolecular association of adduct and free urea.

The BF_3 adducts of the *sym*- and *unsym*-diethylureas (DEU's) gave more complex spectra

because of spin–spin coupling within the ethyl groups. As in the DMU adducts, cooling caused a doubling of the adduct signals due to "freezing out" of the exchange process. The adduct CH_2 signals were complex, but the two overlapping methyl triplets of each of the adducts were easily observed at −20°. In both the *sym*- and *unsym*-DEU adducts the two triplets were of near-equal intensity (low field:high field ratio: *sym*-DEU, 0.47:0.53; *unsym*-DEU, 0.52:0.48; estimated experimental error, ±0.05).

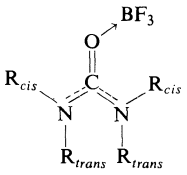
^{19}F chemical shifts of the four dialkylurea adducts are very similar and very close to the value for the tetramethylurea adduct (Table 1). As with TMU.BF_3 (1), at low temperatures the ^{19}F peak is split by a ^{10}B–^{11}B isotope shift.

As in the TMU–BF_3 system (1), traces of the protonated ureas were present as their BF_4^- salts. Thus in the absence of an excess of the urea the ^{1}H spectra of *sym*-DMU.BF_3 solutions contained a small additional peak in the adduct methyl region (2.89 δ), which is assigned to the methyl resonance of *sym*-DMU.H^+. Since this peak was removed by coalescence with the higher-field free-urea peak when free *sym*-DMU was present, relative areas of the adduct peaks could be obtained without interference. The coalescence pattern of the adduct peaks is apparently little affected by the presence of the impurity peak.

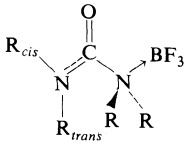
Discussion

Donor Site

Our data are consistent with oxygen donation (**1**) but not with nitrogen donation (**2**). In the *sym*-dialkylureas nitrogen donation would give two *equally* populated alkyl environments: (*a*) the



1



2

alkyl bonded to the donor nitrogen and (*b*) the alkyl far removed from the donor nitrogen. Interconversion of the two alkyl environments would require breaking of the donor–acceptor bond from one nitrogen and formation of an equivalent bond with the second nitrogen, which is unlikely; *inter*molecular exchange of BF_3 is slow and hence the donor–acceptor bonds are not easily broken. Thus both the unequal populations of the alkyl environments and the ease of interconversion of the two environments exclude nitrogen donation in *sym*-DMU.BF_3.

In the *sym*-dialkylureas the distribution of alkyl groups between positions *cis* and *trans* to the carbonyl should be dependent on steric effects, as in *N*-alkylamides (2). Thus the alkyl environments *cis* and *trans* to the carbonyl are likely to be unequally populated if oxygen is the donor. Formation of an adduct by oxygen donation should enhance the multiple bond character in the central C—N bonds, as in amides (5), and hence should decrease the rate of rotation about the central C—N bonds. In addition the relative populations of the *cis* and *trans* alkyl positions should change. By both of these criteria oxygen donation accounts for the spectra of the *sym*-dialkylurea adducts, if the two alkyl environments detectable by n.m.r. are indeed alkyl groups *cis*

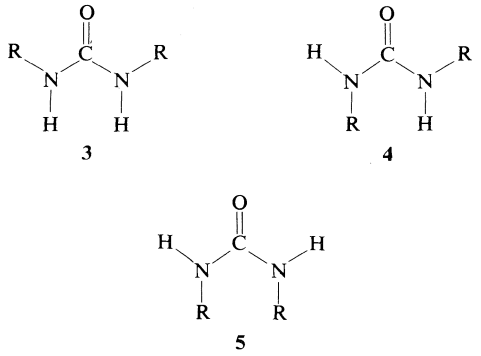
and *trans* to the carbonyl. Although recent n.m.r. studies have shown restricted rotation in ureas (3, 6, 7) and thio- and selenoureas (4, 7, 8), the separate peaks coalesce at much lower temperatures in the free ureas than in their adducts.

In the *unsym*-dialkylurea adducts two equally populated alkyl environments would result from donation by either oxygen or the NH_2 nitrogen. Donation from either of these sites would leave an amide-like $C(O)NR_2$ fragment in which the central C—N bond would still have some double-bond character. However, oxygen donation would enhance the π-bonding in the central C—N bonds and hence the barrier to rotation, while donation from the NH_2 nitrogen would be unlikely to have much effect on the π-bonding or barrier to rotation in the C—NMe_2 bond. The observation of distinct alkyl environments in the BF_3 adducts but not in the free bases thus strongly supports oxygen donation.

Evidence from both the *sym*- and *unsym*-dialkylurea adducts supports oxygen donation. The similar coalescence temperatures for the *sym* and *unsym* adducts confirm that coordination to BF_3 has similar effects on both series and thus that the coordination site is the same in both series. The similarity of the ^{19}F chemical shifts of the dialkylurea adducts to that of the tetramethylurea adduct (Table 1) is further evidence that the coordination site is the same in all of these adducts. Further evidence for oxygen donation has recently been provided by a study of ^{15}N–^{1}H couplings in the BF_3 and $SbCl_5$ adducts of ^{15}N-labelled *sym*-DMU (9). Thus our previous conclusions (1), based on indirect evidence, are confirmed.

Conformer Populations and Interconversion

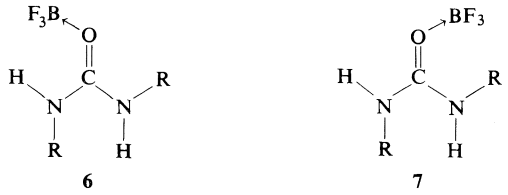
Only one conformation, with the methyl environments *cis* and *trans* to the carbonyl equally populated, is possible in the *unsym*-dialkylureas. Unless chemical shift degeneracy occurs, the observation of a single methyl resonance in *unsym*-DMU shows that rotation about the central C—N bond of the NMe_2 group occurs rapidly. Chemical shift degeneracy seems unlikely since addition of aromatic solvents, which cause very different solvent-induced shifts for *cis* and *trans* methyls in amides (10), does not split the single low-temperature peak. *Sym*-dialkylureas have three possible conformations, **3**–**5**. Calculations on *sym*-DMU indicate that **3** is much more stable than **5** (11), and an infrared study



3 **4** **5**

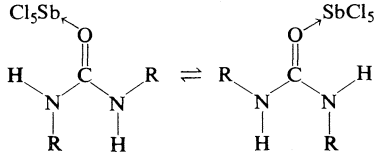
has been interpreted as indicating that *sym*-DMU takes up conformation **3** exclusively in chloroform solution (11). If this is the case all methyl groups are in the same environment and rapid rotation need not be invoked to explain the single methyl peak. However, *sym*-DMU has been reported to give two ^{1}H methyl resonances of unequal intensity at temperatures below −120° in methanol solution (7), showing that two different environments are populated and that interconversion of conformers is rapid on the n.m.r. time scale above −120°. These studies can be reconciled if conformer populations are dependent on solvent. It seems clear that interconversion of conformers occurs in both *sym*- and *unsym*-dialkylureas and is rapid on the n.m.r. time scale at ordinary temperatures.

Formation of the BF_3 adduct by oxygen donation would give a single conformation from each of **3** and **5**, but two possible conformations,



6 **7**

6 and **7**, from **4**. In their study of the $SbCl_5$ adducts of *sym*-dialkylureas Stilbs and co-workers (3) concluded that only the $SbCl_5$ analog of **6** was present and that the collapse of n.m.r. peaks was due to a concerted exchange of all three of the substituents of the central carbon:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Evidence supporting this was obtained from studies of *sym*-dialkylurea–$SbCl_5$ adducts in which the two alkyl groups were different (3). Conformation **6** requires equal populations of alkyl groups *cis* and *trans* to the carbonyl. Since we have found that the two alkyl environments of *sym*-DMU.BF_3 are *unequally* populated, conformation **6** cannot be the only one present in this adduct.

The two methyl peaks of unequal intensities which are observed at low temperatures in the ^1H spectra of *sym*-DMU (7) and its BF_3 adduct probably arise from methyls *cis* and *trans* to the carbonyl group, as in *N*-alkylamides (2). Since only two peaks are observed, it seems that the two NHMe groups in the molecule are quasi-independent in their chemical shift behavior, *i.e.*, the conformation of the second NHMe group in the molecule has little effect on the chemical shift of the first NHMe group. Likewise the possible *cis–trans* orientation of the BF_3 fragment about the carbonyl group does not give rise to additional peaks at $-20°$; *cis–trans* isomerism of BF_3 about a carbonyl group has been detected by n.m.r. only below $-120°$ (12). The large anisotropy effect of the carbonyl group (2) apparently outweighs other effects in determining chemical shift differences.

In dialkylamides the *N*-alkyl absorptions at higher and lower field most frequently arise from the alkyl groups *cis* and *trans* to the carbonyl, respectively (2, 13). A similar assignment best accounts for the changes in relative peak areas of *sym*-DMU on complexation. Thus conformation **3** is favored in free *sym*-DMU (7), as expected (11), but in the BF_3 adduct the methyl groups tend to be forced into positions *trans* to the carbonyl by repulsion from BF_3. As in the $SbCl_5$ adducts, **6** is a likely major conformer. However, by the above assignment 61% rather than 50% of the methyls of *sym*-DMU.BF_3 are in positions *trans* to the carbonyl, implying an appreciable population of the BF_3 adduct of **5**, in spite of the methyl–methyl repulsion involved. With the greater ethyl–ethyl repulsions in *sym*-DEU.BF_3 this conformation apparently becomes negligible, and the pattern becomes consistent with that reported for the *sym*-dialkylurea–$SbCl_5$ adducts (3). We do not feel, however, that a concerted conformational exchange process (3) is the only one which can account for this pattern; small amounts of other conformations might still be present, acting as intermediates in the interconversion of the major conformers.

In an earlier study (1) it was not possible to observe separate methyl resonances for methyls *cis* and *trans* to the carbonyl group in the tetramethylurea.BF_3 adduct. This was attributed to the destabilization of the planar $C_2NC(O)NC_2$ skeleton due to steric hindrance (14). In the dialkylurea–BF_3 adducts steric hindrance is much less important.

We thank the National Research Council of Canada for financial assistance, Dr. P. Bickart and Dr. J. M. Miller for helpful discussions, and Mr. M. J. Bula for assistance with the experimental work.

Phosphonic Acid Analogs of Carbohydrate Metabolites. IV. Synthesis of DL-Glyceraldehyde-3-phosphonic Acid[1]

ERICH BAER AND RANGA ROBINSON

Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario

Received July 19, 1972

A chemical synthesis of DL-glyceraldehyde-3-phosphonic acid, the phosphonic acid analog of DL-glyceraldehyde-3-phosphoric acid, is reported. It was obtained from dimer DL-glyceraldehyde by two procedures differing solely in their protective groups via the following intermediates. *Procedure 1*: 2,5-diiodomethyl-3,6-dimethoxy-1,4-dioxane → 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dimethoxy-1,4-dioxane → 2,5-bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane → DL-glyceraldehyde-3-phosphonic acid. *Procedure 2*: 2,5-bis(*p*-toluenesulfonyloxymethyl)-3,6-dibenzoxy-1,4-dioxane → 2,5-diiodomethyl-3,6-dibenzoxy-1,4-dioxane → 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dibenzoxy-1,4-dioxane → 2,5-bis(methylphosphonic acid)-3,6-dibenzoxy-1,4-dioxane → DL-glyceraldehyde-3-phosphonic acid.

La synthèse chimique de l'acide DL-glycéraldehyde phosphonique-3, analogue de l'acide DL-glyceraldehyde phosphorique-3, est décrite. Cet acide a été obtenu à partir du dimère du DL-glyceraldéhyde selon deux voies différant seulement par les groupes protecteurs engagés, via les intermédaires suivants. *Voie 1*: diiodométhyl-2,5 diméthoxy-3,6 dioxane-1,4 → acide bis(méthylphosphonique)-2,5 diméthoxy-3,6 dioxane-1,4 → acide DL-glycéraldéhyde phosphonique-3. *Voie 2*: bis[*p*-toluenesulfonyloxyméthyl]-2,5 dibenzoxy-3,6 dioxane-1,4 → diiodométhyl-2,5 dibenzoxy-3,6 dioxane-1,4 → diethylester de l'acide bis-(méthylphosphonique)-2,5 dibenzoxy-3,6 dioxane-1,4 → acide bis(méthylphosphonique)-2,5 dibenzoxy-3,6 dioxane-1,4 → acide DL-glycéraldéhyde phosphonique-3. [Traduit par le journal]

Can. J. Chem., **51**, 104 (1973)

In 1929, Mendel (1) made the discovery that DL-glyceraldehyde inhibits *in vitro* the glycolysis of *Jensen* sarcoma.[2] The inhibitory effect according to Needham and Lehman (2) is caused by the L-isomer. One year earlier, Meyerhof *et al.* (3) had shown that the enzyme aldolase condenses dihydroxyacetone-phosphate with D- and L-glyceraldehyde yielding D-fructose-1-phosphate and L-sorbose-1-phosphate, respectively. The latter, according to Lardy *et al.* (4), inhibits hexokinase, thus providing a possible explanation for the inhibition of glycolysis by L-glyceraldehyde. Attempts by Schoeller[3] to effect a cure of cancer by intravenous injections of aqueous solutions of glyceraldehyde were unsuccessful. The aldehyde apparently was metabolized before reaching the tumor. More recently, however, Warburg *et al.* (5) reported that they had succeeded in curing Ehrlich's mouse-ascite tumor with both D- and L-glyceraldehyde by injecting sub-toxic doses of these compounds into the abdominal cavity. No spontaneous recurrences were observed. Neither ingestion nor subcutaneous or intravenous application of glyceraldehyde had any retarding effect on the growth of the ascite tumors. Thus, the feasibility of effecting a cancer cure by destroying the tumor cells through inhibition of their glycolytic process with a compound closely related to a carbohydrate metabolite has been demonstrated, at least for one specific type of tumor. Other types calling for subcutaneous or intravenous application of the cytostatica to reach the tumor site obviously require that they be less prone than glyceraldehyde to inactivation by body fluids. It occurred to us that phosphonic acid analogs of carbohydrate metabolites, in particular of glyceraldehyde-3-phosphoric acid (**A**) may possess the cytostatic activity of glyceraldehyde combined with greater biological stability. Hence the synthesis of glyceraldehyde-3-phosphonic acid (**B**) was undertaken. It is the third in a series of phosphonic acid analogs of carbohydrate metabolites that have been synthesized in

[1]Synonyms: DL-lactic acid aldehyde-3-phosphonic acid, DL-2-hydroxy-3-phosphonopropionaldehyde, DL-1-al-2-hydroxypropyl-3-phosphonic acid.

[2]The initial experiments were carried out with DL-glyceraldehyde provided by one of the present authors (E.B.).

this laboratory. The others are L-α-glycerophosphonic acid (6) and 2,3-diphosphono-DL-glyceric acid (7).

Methods

Glyceraldehyde can exist in both a monomer and dimer form (formulae **C** and **D**, respectively). Derivatives of both forms are known. Thus far, however, only DL-glyceraldehyde has been obtained in crystalline form. D- and L-glyceraldehyde, both highly viscous glasses, when mixed in equimolecular proportions, readily form crystalline DL-glyceraldehyde (8). The dimer glyceraldehyde (formula **D**) can be regarded as a derivative of 1,4-dioxane. It is formed by the intermolecular condensation of the carbonyl groups of 2 mol of monomer glyceraldehyde (**C**) with their secondary hydroxyl groups (reaction **C** → **D**). As long as the hydroxyls of the two hemiacetal groups thus formed are unsubstituted, the reaction is reversible in water (reaction **D** → **C**). On replacing the hydrogen atoms of the hemiacetal-hydroxyl groups by methyl or benzyl radicals, the dioxane structure of dimer glyceraldehyde is stabilized. The use of dimer glyceraldehyde has the advantage that its derivatives are solids and that the carbonyl and secondary hydroxyl functions, in form of the hemiacetal, can be blocked by one protective group. The use of the methyl radical as protective group offers the advantage that it can be removed by a simple chemical operation, *i.e.* acid hydrolysis. This requires, however, that the hydrolysis product is acid-stable. Since we expected DL-glyceraldehyde-3-phosphonic acid to be an acid-stable compound, because of its C—P bond, we attempted its synthesis by using first the methyl radical as protective group. The procedure is outlined by pathway 1 of Scheme 1. Compound **6**, 2,5-bis(*p*-toluenesulfonyloxymethyl)-3,6-dimethoxy-1,4-dioxane, prepared by known methods, was treated with sodium iodide and the reaction product, 2,5-diiodomethyl-3,6-dimethoxy-1,4-dioxane (**7**), was condensed with triethyl phosphite yielding 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dimethoxy-1,4-dioxane (**8**). Hydrolysis of the ester groups of **8** with chlorotrimethylsilane followed by hydrolysis of the methyl cycloacetal groups with 2 *N* hydrochloric acid at 80° for 20 h yielded 2,5-bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane (**9**), and DL-glyceraldehyde-3-phosphonic acid (**10**), respectively. The latter, on treatment in the *cold* with a solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid, gave immediately an orange colored precipitate consisting of a mixture of the dinitrophenylhydrazone and dinitrophenylosazone of glyceraldehyde-3-phosphonic acid. Since glyceraldehyde-3-phosphoric acid under the same conditions yields exclusively the dinitrophenylhydrazone (9), we entertained some doubts as to the homogeneity of compound **10** obtained by acid hydrolysis. To determine whether the facile formation in the cold of the dinitrophenylosazone is a typical reaction of glyceraldehyde-3-phosphonic acid caused by a rapid oxidation of its secondary hydroxyl group by hydrazine, or due to the presence of an oxidation product of glyceraldehyde-3-phosphonic acid formed during hydrolysis of its cyclomethyl acetal, we repeated the synthesis of glyceraldehyde-3-phosphonic acid using benzyl as protective group (pathway 2). It has the advantage that it can be removed under mild conditions in a reducing atmosphere.

Experimental

Materials

DL-Glyceraldehyde was washed several times with anhydrous acetone and dried *in vacuo* at 56°, m.p. 138°. Commercial triethyl phosphite was purified by fractional distillation, and the fraction boiling from 156–157° at 756 mm Hg was used. The palladium black catalyst was prepared by the reduction of palladium chloride with formic acid as described by Tausz and Putnoky (10), except that the catalyst, after washing thoroughly with water, was suspended several times in fresh portions of

2,5-Bis(acetoxymethyl)-3,6-bis(acetoxymethyl)-1,4-dioxane (**2**)(11,12), 2,5-bis(acetoxymethyl)-3,6-dibromo-1,4-dioxane (**3**) (13), 2,5-bis(acetoxymethyl)-3,6-dimethoxy-1,4-dioxane (**4**) (13), 2,5-bis(hydroxymethyl)-3,6-dimethoxy-1,4-dioxane (**5**) (13), and 2,5-bis(*p*-toluenesulfonyloxymethyl)-3,6-dimethoxy-1,4-dioxane (**6**) (14) were prepared as described in the literature.

2,5-Diiodomethyl-3,6-dimethoxy-1,4-dioxane (7)

A mixture of 5.16 g (10.0 mmol) of 2,5-bis(*p*-toluenesulfonyloxymethyl)-3,6-dimethoxy-1,4-dioxane (**6**) and 8.9 g (60 mmol) of anhydrous sodium iodide in 60 ml of dry methyl ethyl ketone was refluxed for 8 h (bath temperature 100°). The mixture was filtered with suction, the sodium *p*-toluenesulfonate was washed thoroughly with methyl ethyl ketone, and the combined filtrates were evaporated to dryness under reduced pressure (10–12 mm Hg) at a bath temperature of 30–35°. The residue was taken up in 30 ml of water and 100 ml of ether, the layers were separated, and the ether layer was washed successively with three 25 ml portions of 0.1 *N* sodium thiosulfate, three 10 ml portions of water, and finally was dried with anhydrous sodium sulfate. Removal of the ether by distillation under reduced pressure and drying the residue at 56° (boiling acetone) for 4 h at a pressure of 0.05 mm Hg gave 3.63 g (84.9% of theoretical yield) of 2,5-diiodomethyl-3,6-dimethoxy-1,4-dioxane, m.p. 138–139°. The compound was obtained in centimeter-long prisms by recrystallization from 80 ml of low-boiling petroleum ether, m.p. 138–139°, R_f 0.53 on silica gel H (solvent mixture: petroleum ether (b.p. 30–60°) and ether, 85:15, v/v). At room temperature, the compound is soluble in ether, sparingly soluble in petroleum ether (b.p. 30–60°) and insoluble in water, 99% ethanol or methanol.

Anal. Calcd. for $C_8H_{14}O_4I_2$ (mol. wt. 428): C, 22.45; H, 3.30; I, 59.30. Found: C, 22.43; H, 3.35; I, 59.60.

2,5-Bis(methylphosphonic acid diethyl ester)-3,6-dimethoxy-1,4-dioxane (8)

Into a two-necked 250 ml round flask equipped with a Liebig condenser and a gas-inlet tube were placed 8.56 g (20.0 mmol) of 2,5-diiodomethyl-3,6-dimethoxy-1,4-dioxane (**7**) and 83 g (0.5 mol) of triethyl phosphite, and the mixture was kept for 44 h at 140–145° (oil bath temperature). To facilitate the removal of ethyl iodide, a slow stream of nitrogen was passed through the apparatus and the temperature of the condenser was kept at 55° (±5°). The excess of triethyl phosphite was removed by distillation under reduced pressure (10–12 mm Hg) at a bath temperature ranging from 60–70°, and the residue was kept at room temperature for 4 h at a pressure of 0.01 mm Hg. The remaining viscous material was triturated with 60 ml of petroleum ether, and the mixture was set aside for crystallization. On standing overnight at room temperature, a crystalline material formed which was filtered off with suction, washed on the filter with 10 ml of petroleum ether, and dried for 4 h at 56° over phosphorus pentoxide at a pressure of 0.01 mm Hg. The 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dimethoxy-1,4-dioxane weighed 8.08 g (90.1 % of theoretical yield), m.p. 62-63°. The melting point remained unchanged

on recrystallization of the substance from 250 ml of a boiling mixture of ether – petroleum ether (4:1, v/v); R_f 0.36 on silica gel G (chloroform–methanol, 95:5, v/v).

Anal. Calcd. for $C_{16}H_{34}O_{10}P_2$ (mol. wt. 448.4): C, 42.85; H, 7.64; P, 13.82. Found: C, 42.90; H, 7.59; P, 13.61.

*2,5-Bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane (**9**)*

(a) Hydrolysis

A mixture of 2.24 g (5.0 mmol) of 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dimethoxy-1,4-dioxane (**8**) and 90 ml of chlorotrimethylsilane, in a pressure bottle, was kept at a temperature of 70–75° for 3 days. The excess of chlorotrimethylsilane was distilled off under reduced pressure at a bath temperature of 30–32°, the residue was dissolved in 100 ml of water, and the water-insoluble material was removed by extraction with three 45 ml portions of chloroform. The aqueous solution was kept for 3 days at a temperature of 45°, freed by filtration of any solid material which may have formed (*; see also Direct Procedure below) and concentrated under reduced pressure to a volume of about 30 ml.

(b) Dicyclohexylammonium salt

To the aqueous solution was added dropwise cyclohexylamine until it was slightly alkaline, approximately 2.6 ml of the base were required, and the solution was further concentrated under reduced pressure to a volume of about 10 ml. To the concentrate were added 20 ml of 99% ethanol and the mixture was kept overnight at −6°. The crystalline material was filtered off with suction, washed on the filter with 10 ml of anhydrous ether, and was dried for 4 h at 100° over phosphorus pentoxide at a pressure of 0.01 mm Hg. The dicyclohexylammonium salt weighed 2.36 g (88.4% of theoretical yield).

Anal. Calcd. for $[C_8H_{18}O_{10}P_2][C_6H_{13}N]_2$ (mol. wt. 534.5): C, 44.94; H, 8.30; N, 5.24; P, 11.59. Found[4]: C, 44.38; H, 8.17; N, 5.32; P, 12.10 and C, 44.50; H, 8.07; N, 5.70; P, 11.21.

(c) Removal of cyclohexylamine

A solution of 2.67 g (5.0 mmol) of the dicyclohexylammonium salt of compound **9** in 60 ml of distilled water was stirred for 1 h with 45 ml of Amberlite® IR-120 (H^+ form). The Amberlite was filtered off, washed with water, and the combined filtrates were evaporated to dryness under reduced pressure (10–12 mm Hg) at a bath temperature of 30–35°. The solid material remaining was dried at 80° over phosphorus pentoxide at 0.01 mm Hg for 3 h. The 2,5-bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane weighed 1.49 g (88.8% of theoretical yield), m.p. 149–150° (slight sintering at 146°).

Anal. Calcd. for $C_8H_{18}O_{10}P_2$ (mol. wt. 336.2): C, 28.58; H, 5.39; P, 18.43. Found: C, 28.11; H, 5.46; P, 18.47.

*2,5-Bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane (**9**) (Direct Procedure)*

The hydrolysis of 2.24 g (5.0 mmol) of **8** with chlorotrimethylsilane was carried out as described above (section *a*) following the procedure to the asterisk. The aqueous solution was evaporated to dryness under reduced pressure at a bath temperature of 30–35°, and the remaining hygroscopic material was triturated with 50 ml of anhydrous ether. The ether was distilled off under reduced pressure and the addition of ether and its removal by distillation was repeated twice more. After a final addition of 50 ml of ether, the mixture was kept for 2 days at −6°. The solid material was filtered off, washed with a small volume of ether, and dried for 3 h at 80° over phosphorus pentoxide at a pressure of 0.01 mm Hg. The 2,5-bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane weighed 1.43 g (85.2% of theoretical yield), m.p. 149–150°.

Anal. Calcd. for $C_8H_{18}O_{10}P_2$ (mol. wt. 336.2): P, 18.43. Found: P, 18.28.

*DL-Glyceraldehyde-3-phosphonic Acid (**10**, **11**).*

A solution of 0.370 g (1.10 mmol) of 2,5-bis(methylphosphonic acid)-3,6-dimethoxy-1,4-dioxane in 30 ml of 2.5 *N* hydrochloric acid in a 100 ml two-necked round flask, equipped with a condenser and gas-inlet tube, was kept at 80° for 24 h, while passing a slow stream of nitrogen through the apparatus. The solution was evaporated under reduced pressure (8–10 mm Hg) at a bath temperature of 30–32°. The residue was dissolved in 3 ml of distilled water, and the water was removed by distillation under reduced pressure as described above. This operation was repeated once more. To ensure a complete removal of hydrochloric acid and water, the material was kept for 7 days in a desiccator over sodium hydroxide powder and calcium chloride at a pressure of 0.01 mm Hg, renewing occasionally both reagents. The glyceraldehyde-3-phosphonic acid, a glass-like mass, weighed 0.317 g (93.9% of theoretical yield).

Anal. Calcd. for $C_3H_7O_5P$ (mol. wt. 154.1): C, 23.39; H, 4.58; P, 20.11. Found: C, 22 96; H, 5.03; P, 20.00.

DL-Glyceraldehyde-3-phosphonic Acid 2,4-Dinitrophenylosazone

To 10 ml of an aqueous solution containing 60 mg of glyceraldehyde-3-phosphonic acid were added 20 ml of 2 *N* hydrochloric acid and 310 mg of 2,4-dinitrophenyl hydrazine, and the mixture was boiled under reflux for 1 h. The dark orange–red osazone was collected by centrifugation, washed with two 6 ml portions of 2 *N* hydrochloric acid, and was dried at room temperature over sodium hydroxide powder and phosphorus pentoxide for 5 h at a pressure of 0.05 mm Hg. The glyceraldehyde-3-phosphonic acid dinitrophenylosazone weighed 188.0 mg (94.3% of theoretical yield).

Anal. Calcd. for $C_{15}H_{13}O_{11}N_8P$ (mol. wt. 512.3): N, 21.87; P, 6.04. Found: N, 22.02; P, 5.98.

Calcium DL-Glyceraldehyde-3-phosphonate

To an ice-cold solution of 154.1 mg (1.0 mmol) of DL-glyceraldehyde-3-phosphonic acid and 264 mg (1.5 mmol) of calcium acetate (1 mol of water) in 2.8 ml of water were added dropwise 3.5 ml of 95% ethanol over a period of 30 min, and the mixture was kept in ice for a further 30 min. The precipitate was collected by centrifugation, washed with two 2 ml portions of a mixture of ethanol and water (4:6, v/v), and was dried for 4 days over calcium chloride and Drierite® at a pressure of 0.01 mm Hg. The calcium salt, weighing 150.7 mg (87.2% of theoretical yield), contained 1 atom of calcium per 2 mol of glyceraldehyde-3-phosphonic acid.

Anal. Calcd. for $[C_3H_6O_5P]_2Ca$ (mol. wt. 346.2): C, 20.81; H, 3.49; P, 17.89; Ca, 11.57. Found: C, 20.67; H, 3.59; P, 17.67; Ca, 11.72.

Stability of the C—P Bond of Glyceraldehyde-3-phosphonic Acid Towards Alkali and Acid

Alkali

To a solution containing 7.52 mg of glyceraldehyde-3-phosphonic acid in 1.0 ml of water were added 5.0 ml of 0.1 *N* sodium hydroxide, and the solution was kept at room temperature (23°) for 1 h. At the end of this period, the contents of inorganic phosphorus in the solution (*a*), and in a blank (*b*) consisting of 5.0 ml of 0.1 *N* sodium hydroxide, were determined colorimetrically by the method of King.

Calcd.: Inorg. P, 1.512 mg (for 100% of liberation of organic P). Found: Inorg. P, 0.006 mg; (*a*) = 0.003 mg, (*b*) = 0.003 mg or 0.2% P.

Acid

A solution of 7.52 mg of glyceraldehyde-3-phosphonic acid in 10.0 ml of 0.1 *N* hydrochloric acid was boiled under reflux for 1 h, and the inorganic phosphorus in an aliquot of 5.0 ml was determined as above.

Calcd.: Inorg. P, 0.756 mg (for 100% liberation of org. P). Found: Inorg. P, 0.022 mg or 2.9% of theory.

Pathway 2

2,5-Bis(acetoxymethyl)-3,6-dibenzoxy-1,4-dioxane (**12**) (15) and 2,5-bis(hydroxymethyl)-3,6-dibenzoxy-1,4-dioxane (**13**) (15) were prepared as described in the literature.

*2,5-Bis(p-toluenesulfonyloxymethyl)-3,6-dibenzoxy-1,4-dioxane (**14**)*

To a solution of 7.21 g (20.0 mmol) of 2,5-bis(hydroxymethyl)-3,6-dibenzoxy-1,4-dioxane (**13**) in a mixture of 8.0 ml (0.1 mol) of anhydrous pyridine and 80 ml of ethanol-free chloroform were added 7.62 g (40 mmol) of *p*-toluenesulfonyl chloride, and the mixture was kept under anhydrous conditions at a temperature of 38–40° for 2 days. At the end of this period, a small amount of ice and 55 ml of 0.1 *N* sulfuric acid were added, and the chloroform solution and the aqueous suspension of the toluenesulfonate were separated. The aqueous suspension was filtered with suction, and the material on the filter was washed with water until the filtrate was neutral. The chloroform solution, after washing several times with water, was dried with anhydrous sodium sulfate and the solvent was removed by distillation under reduced pressure at a bath temperature of 25–30°. The combined solids were triturated three times with 150 ml of water and dried at room temperature over calcium chloride at a pressure of 0.01 mm Hg for 20 h. The already fairly pure toluenesulfonate (m.p. 165–166°) weighed 12.38 g (92.5% of theoretical yield). Dissolving the substance with warming in 360 ml of chloroform, keeping the solution overnight at 6° and drying the precipitate for 4 h over phosphorus pentoxide at 56° (boiling acetone) and a pressure of 0.01 mm Hg, gave 10.06 g (75.2% of theory) of pure 2,5-bis(*p*-toluenesulfonyloxymethyl)-3,6-dibenzoxy-1,4-dioxane, m.p. 169–170° (dec.). T.l.c. on silica gel H with a solvent mixture of ether and low-boiling petroleum ether (80:20, v/v) gave one spot with an R_f value of 0.79. At room temperature, the compound is moderately soluble in chloroform, and sparingly soluble in ether, acetone, methanol, and ethanol (99%).

Anal. Calcd. for $C_{34}H_{36}O_{10}S_2$ (mol. wt. 668.8): C, 61.06; H, 5.42; S, 9.59. Found: C, 61.38; H, 5.11; S, 9.50.

*2,5-Diiodomethyl-3,6-dibenzoxy-1,4-dioxane (**15**)*

To 80 ml of dry methyl ethyl ketone were added 7.70 g (11.5 mmol) of 2,5-bis(*p*-toluenesulfonylhydroxymethyl)-3,6-dibenzoxy-1,4-dioxane (**14**) and 10.4 g (69.4 mmol, three-fold excess) of anhydrous sodium iodide, and the mixture was refluxed under anhydrous conditions for 20 h (temperature of oil bath 90–95°). The reaction mixture then was cooled to room temperature, filtered with suction, and the solid material was washed on the filter with 100 ml of methyl ethyl ketone. The combined filtrates were evaporated to dryness under reduced pressure (8–12 mm Hg), and the solid residue together with the earlier precipitate were suspended with stirring in 200 ml of water. The mixture was filtered with suction, and the material was washed on the filter with 50 ml of 0.1 *N* sodium thiosulfate followed by 200 ml of water. On drying at room temperature over calcium chloride at a pressure of 0.01 mm Hg, the already fairly pure iodo-compound weighed 6.39 g (95.8% of theory), m.p. 127–129°. It was further purified by dissolving it in 500 ml of a warm mixture of ether and low boiling petroleum ether (4:1, v/v), filtering the warm solution if necessary, and keeping the filtrate overnight at room temperature. The 2,5-diiodomethyl-3,6-dibenzoxy-1,4-dioxane, which separated in the form of centimeter-long narrow prisms, was dried as described above. The pure iodo-compound weighed 5.44 g (81.4% of theory), m.p. 129–130°. T.l.c. on silica gel H with a solvent mixture of petroleum ether (30–60°) and ether (85:15, v/v) gave a single spot with an R_f value of 0.57. At room temperature, the iodo-compound is readily soluble in acetone, ether, and chloroform, sparingly soluble or insoluble in dry methanol and ethanol.

Anal. Calcd. for $C_{20}H_{22}O_4I_2$ (mol. wt. 580.2): C, 41.40; H, 3.82; I, 43.75. Found: C, 41.70; H, 3.77; I, 43.92.

*2,5-Bis(methylphosphonic acid diethyl ester)-3,6-dibenzoxy-1,4-dioxane (**16**)*

Into a two-necked 250 ml round-bottomed flask equipped with a Liebig condenser and a gas-inlet tube were placed 4.79 g (8.26 mmol) of 2,5-diiodomethyl-3,6-dibenzoxy-1,4-dioxane (**15**) and 50 g (0.3 mol) of triethyl phosphite, and the mixture was kept at 140–145° (oil bath) for 48 h. To facilitate the removal of ethyl iodide a slow stream of nitrogen was passed through the apparatus and the condenser water was kept at 55° (±5°). At the end of this period, the excess of triethyl phosphite was distilled off under reduced pressure (10 mm Hg) at a bath temperature of 75–80°. To remove the last traces of triethyl phosphite, the highly viscous, pale yellow residue was kept for 4 h at 45–50° and a pressure of 0.01 mm Hg. The remaining material, which solidified on triturating with 25 ml of low boiling petroleum ether, was filtered off with suction, washed with 10 ml of petroleum ether, and was dried for 4 h at room temperature over calcium chloride at a pressure of 0.01 mm Hg. The material, weighing 4.62 g (93.1% of theory), and melting from 70–72°, on crystallization from 100 ml of a mixture of ether and low-boiling petroleum ether (9:1, v/v), and drying as described above, gave 4.60 g (92.7% of theory) of pure 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dibenzoxy-1,4-dioxane, m.p. 74–74.5°. The melting point remained unchanged on further crystallization. T.l.c. on silica Gel H with chloroform and methanol (95:5, v/v) gave a single spot with an R_f value of 0.46. The com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

pound is readily soluble in methanol, ethanol, acetone, chloroform, ethyl acetate, and ether, and in warm petroleum ether (b.p. 30–60°).

Anal. Calcd. for $C_{28}H_{42}O_{10}P_2$ (mol. wt. 600.6): C, 55.99; H, 7.05; P, 10.31. Found: C, 55.70; H, 7.24; P, 10.49.

*2,5-Bis(methylphosphonic acid)-3,6-dibenzoxy-1,4-dioxane (**17**)*

A mixture of 600 mg (1.0 mmol) of 2,5-bis(methylphosphonic acid diethyl ester)-3,6-dibenzoxy-1,4-dioxane and 35 ml of trimethylchlorosilane was kept in a pressure vessel for 3 days at a temperature of 70–75° At the end of this period, the excess of chlorotrimethylsilane was distilled off under reduced pressure at a bath temperature of 30–32°. The residue was dissolved in 200 ml of distilled water and the solution was kept for 4 days at a temperature of 40–42°. The aqueous solution, after extracting with two 25 ml portions of chloroform, was evaporated to dryness under reduced pressure at a bath temperature of 30–32°. The material remaining was dissolved in 15 ml of ethanol (95%), and the solvent was distilled off under reduced pressure. The operation was repeated once more with 15 ml of ethanol. The residue was triturated with 10 ml of dry ether, and the ether was removed by distillation. The crude product after drying weighed 433.4 mg (88.3% of theory). For further purification, it was dissolved with warming in 45 ml of ethanol (95%), the solution was decolorized with a small amount of charcoal (Norit A, acid-washed) and filtered while still warm. The filtrate was kept overnight at −6°. The precipitate was filtered off with suction and was dried for 4 h over phosphorus pentoxide at 80° (boiling benzene) and a pressure of 0.01 mm Hg. The 2,5-bis(methylphosphonic acid)-3,6-dibenzoxy-1,4-dioxane weighing 330 mg was obtained in a yield of 67.5% of theory, m.p. 160–161°. At room temperature (22°), the compound is readily soluble in methanol and ethanol, sparingly soluble in water, and insoluble in acetone, ethyl acetate, ether, petroleum ether, chloroform, or benzene.

Anal. Calcd. for $C_{20}H_{26}O_{10}P_2$ (mol. wt. 488.4): C, 49.18; H, 5.37; P, 12.69. Found: C, 48.79; H, 5.71; P, 12.75.

*DL-Glyceraldehyde-3-phosphonic Acid (**10**, **11**)*

2,5-Bis(methylphosphonic acid)-3,6-dibenzoxy-1,4-dioxane (**17**) (652 mg), 400 mg of palladium black, and 100 ml of glacial acetic acid were placed in an all-glass reduction vessel of 500 ml capacity, and the mixture was shaken vigorously in an atmosphere of pure hydrogen at an initial pressure of 40 cm of water until the absorption of hydrogen ceased. After replacing the hydrogen by nitrogen, the catalyst was removed by filtration, and washed with three 20 ml portions of acetic acid. The combined filtrates were cleared by centrifugation, and the acetic acid was distilled off under reduced pressure (8–10 mm Hg) at a bath temperature of 30–32°. The residue was dissolved in 10 ml of distilled water, the solution, if necessary, was freed of insoluble material and the water was removed by distillation under reduced pressure and a bath temperature of 35°. This operation was repeated once more in 10 ml of water. The remaining, colorless and highly viscous material was freed of last traces of water and acetic acid by keeping it for 3 days over calcium chloride and sodium hydroxide (powder) at a pressure of 0.02 mm Hg, occasionally changing the drying agents. The DL-glyceraldehyde-3-phosphonic acid, a glass-like material, weighed 394 mg (95.8% of theoretical yield).

Anal. Calcd. for $C_3H_7O_5P$ (mol. wt. 154.1): C, 23.39; H, 4.58; P, 20.11. Found: C, 23.86; H, 5.09; P, 19.94.

Glyceraldehyde-3-phosphonic Acid 2,4-Dinitrophenylosazone

Treating a solution of 37.6 mg of glyceraldehyde-3-phosphonic acid in 5 ml of water with 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid, as described above, gave 115.8 mg (92.6% of theory) of glyceraldehyde-3-phosphonic acid 2,4-dinitrophenylosazone.

Anal. Calcd. for $C_{15}H_{13}O_{11}N_8P$ (mol. wt. 512.3): P, 6.04. Found: P, 6.11.

Calcium DL-Glyceraldehyde-3-phosphonate

The calcium salt was prepared as described above and was obtained in a yield of 89.9% of theory.

Anal. Calcd. for $[C_3H_6O_5P]_2Ca$ (mol. wt. 346.2): C, 20.81; H, 3.49; P, 17.89. Found: C, 20.57; H, 3.89; P, 17.79.

Discussion

Having obtained DL-glyceraldehyde-3-phosphonic acid (GLA-3-PnA) by catalytic reduction of its benzyl cycloacetal (pathway 2), it was found that at 0° it also readily forms a mixture of 2,4-dinitrophenylhydrazone and 2,4-dinitrophenylosazone of GLA-3-PnA. It thus behaves towards 2,4-dinitrophenylhydrazine hydrochloride in the same manner as GLA-3-PnA prepared by acid hydrolysis of its methyl cycloacetal (Pathway 1). The formation of the dinitrophenylosazone of GLA-3-PnA at 0°, hence is not caused by an oxidation product of GLA-3-PnA, formed during acid hydrolysis of the methyl cycloacetal, but is a result of the oxidation of the secondary hydroxyl-group of GLA-3-PnA by dinitrophenylhydrazine. The fact that GLA-3-PnA, in contrast to glyceraldehyde-3-phosphoric acid (GLA-3-PA) does not yield a pure dinitrophenylhydrazone at 0°, is an indication that its secondary hydroxyl-group is more readily oxidized than that of GLA-3-PA. The triose-phosphonate, because of its chemically highly stable C—P bond differs from GLA-3-PA also in several other respects. Unlike GLA-3-PA, it neither forms methylglyoxal or lactic acid on treatment with acid or alkali, respectively, nor does it lose its phosphonic acid on forming a dinitrophenylhydrazone or dinitrophenylosazone. GLA-3-PnA and GLA-3-PA thus are readily distinguishable from each other by chemical means. The triose-phosphonate further differs from GLA-3-PA in that under identical experimental conditions it yields a calcium salt which contains only 1 atom of calcium per 2 mol of GLA-3-PnA.

Termolecular Recombination Rate Constant and Triple Collision Cross-section[1]

W. H. Wong and G. Burns

Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received June 1, 1972

The concept of triple collisions cross-section in termolecular recombination reaction was investigated. The hard-sphere model was tested against experimental data, and it was found to predict, in disagreement with experiments, a positive temperature dependence for the recombination rate constants. Average cross-sections were obtained from experimental rate data. Two empirical functions widely used for summarizing experimental rate data were inverted through an inverse Laplace transform to give the triple collision cross-section.

Nous avons étudié le phénomène de surface de triple collision dans les réactions de recombinaison termoléculaire. Le modèle de la sphère rigide a été vérifié à partir des données expérimentales; nous constatons qu'il prédit, contrairement à ce qui découle de l'expérience, une dépendance positive de la température sur les constantes de vitesse de recombinaison. Les surfaces moyennes sont tirées des données expérimentales de vitesse. Deux fonctions empiriques largement utilisées dans l'expression des résultats de vitesse expérimentale, ont été interverties au moyen d'une transformée inverse de Laplace, pour obtenir la surface de triple collision. Introduction

Recent advances in experimental techniques in studying gas phase reaction are beginning to yield data that are more fundamental than the overall rate coefficient. These data, in conjunction with the modern collision theory, will eventually reveal the microscopic properties of the species involved. In collision theory, the basic quantity is the S-matrix, the modulus square of its elements is a measure of the probability of state transformation. The formal expression relating this quantity to the phenonomenological rate coefficient has been obtained by Smith (1). Even though this S-matrix embodies all the dynamical properties of a microscopic process, it is not the physical quantity that is directly observed in experiments. Rather, it is the cross-section which is a ratio of the flux into a specific final channel to the incident flux that is directly observable.

The concept of collision cross-section has been most fruitfully pursued in the study of elementary bimolecular reaction. From the experimental side, various beam experiments directly determine this quantity (see, for example, ref. 2). The theoretical calculations of reaction cross-section by quantum scattering theory (see, for example, ref. 3), by classical mechanics (4), and by some form of statistical theory (5, 6) have been one of the focal points in modern kinetics. The connection between this bimolecular cross-section and the rate coefficient is very well known (7, 8), and the possibility of extracting the former from the rate data has also been studied by several authors (9, 10). Also with the aid of the concept of reaction cross-section, the validity of the conventional formulation of the activated complex theory is being tested (11), and the modern version of this theory is being developed (12). From all these theoretical and experimental efforts, the general features of different categories of bimolecular reaction cross-section have emerged.

The situation in termolecular recombination reaction is much less favorable. In fact, the concept of triple collision cross-section and its relation to the recombination rate coefficient was only recently introduced by Smith (1, 13, 14). Furthermore, the triple collision cross-section suffers from the disadvantage of being less amenable to elementary physical interpretation. In a binary collision, the dimension of the reaction cross-section is length squared per molecule (cm^2/molecule), and it could be interpreted physically as an effective target area of the species undergoing the specified transformation. In triple collision, however, there are a total of six co-ordinates in the

center-of-mass system. After singling out one as progress variable with respect to reaction, there are still five orthogonal co-ordinates that describe the "cross-section" in this 6-dimensional hyperspace. But the fact that the dimension of a triple collision cross-section is $cm^5/molecule^2$ should not obscure the significance of this quantity which, like its counterpart in bimolecular collision, is a measure of the ratio of the flux into the product channel to that from the incident channel. Presently, we further explored Smith's formulation (1, 13–15) which established the formal relationship between the termolecular rate coefficient and the triple collision cross-section. First, recombination rate constants were constructed from the triple collision reactive cross-section obtained from a 3-body hard-sphere model which was suggested by Smith (15) as a standard reference. The trends emerged from this model were discussed in light of experimental observations. Then the experimental rate data obtained over a fairly wide temperature range were converted to approximate triple collision cross-sections and their main features noted. Finally, attempts were made to extract the cross-section function from recombination rate constants.

Triple Collision Cross-section and Atomic Recombination Rate Constant

Completely analogous to bimolecular collision, the reactive cross-section in a triple collision σ_3 can be defined as

$$[1]\quad Z = N_A N_B N_C \int\int\int v_3 \sigma_3(v_3) f_A(\boldsymbol{v}_A) \times f_B(\boldsymbol{v}_B) f_C(\boldsymbol{v}_C) d^3\boldsymbol{v}_A d^3\boldsymbol{v}_B d^3\boldsymbol{v}_C$$

in which Z is the number of reactive triple collision per unit time per unit volume, N_i is the number density of the ith species with a normalized velocity distribution $f_i(\boldsymbol{v}_i)$, and v_3 is the velocity of approach in the 3-body center-of-mass system. (Throughout this paper, the subscript 3 emphasizes the quantity pertinent to a triple collision.) Confining to collisions that lead to recombination, one can write the rate coefficient of the process as

$$[2]\quad k_r(T) = \int\int\int v_3 \sigma_3(v_3) f_A(\boldsymbol{v}_A) f_B(\boldsymbol{v}_B) \times f_C(\boldsymbol{v}_C) d^3\boldsymbol{v}_A d^3\boldsymbol{v}_B d^3\boldsymbol{v}_C$$

In a Boltzmann ensemble, Smith (1, 14, 15) was able to reduce the above expression to

$$[3]\quad k_r(T) = (2\mu_3)^{-1/2}(kT)^{-3} \times \int_0^\infty \exp\left(\frac{-E_3}{kT}\right)\sigma_3(E_3){E_3}^{5/2} dE_3$$

in which k is the Boltzmann constant, μ_3 is the reduced mass in the 3-body system that diagonalizes the kinetic energy and is given by

$$[4]\quad \mu_3 = \frac{\prod m_i}{\left(\sum_i m_i\right)^{1/2}} \qquad i = A, B, C$$

where m_i is the mass of species i. The kinetic energy E_3 in the 3-body system is then

$$[5]\quad E_3 = \frac{1}{2}\mu_3 {v_3}^2$$

It follows from eq. 3 that the recombination rate coefficient is proportional to the Laplace transform of ${E_3}^{5/2}\sigma_3(E_3)$. Similar to the treatment in bimolecular collision, one could in principle extract the cross-section through an inverse Laplace transform

$$[6]\quad \sigma_3(E_3) = (2\mu_3)^{1/2}{E_3}^{-5/2} \times \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} \beta^{-3} k_r(\beta) e^{\beta E_3} d\beta$$

where

$$\beta = 1/kT$$

If $k_r(T)$ and hence $k_r(\beta)$ is formulated by some form of statistical theory, the inversion can either be obtained in closed form or can be evaluated approximately by the method of steepest descent. Similar procedure was employed by Eu, Morokuma, and Karplus (11) and by Lin and Eyring (9) in testing the bimolecular activated complex theory by extracting the 2-body cross-section from the rate coefficient expressed as a ratio of partition functions. Similar principles were used in the work of Marcus and co-worker (6, 12) who developed the statistical–dynamical model of bimolecular reaction cross-section within the framework of the microcannonical activated complex theory. If the $k_r(T)$ is known experimentally over a sufficiently wide temperature range and if it is fitted into a functional form in terms of T, similar procedure could also be applied in the present case. But if the $k_r(T)$ is known only within a limited range of temperature, a more drastic approximation has to be introduced. In the latter case, eq. 3 can be rewritten as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[7] $$k_r(T) = \langle v_3 \rangle \langle \sigma_3 \rangle$$

where

[8] $$\langle v_3 \rangle = (2\mu_3)^{-1/2}(kT)^{-3} \times \int_0^\infty E_3^{5/2} \exp \frac{-E_3}{kT}\, dE_3 = \frac{15\pi}{8}\left(\frac{kT}{2\pi\mu_3}\right)^{1/2}$$

and

[9] $$\langle \sigma_3 \rangle = \frac{\int_0^\infty E_3^{5/2}\sigma_3(E_3) \exp\left(\frac{-E_3}{kT}\right) dE_3}{\int_0^\infty E_3^{5/2} \exp\left(\frac{-E_3}{kT}\right) dE_3}$$

Thus the quantities $\langle v_3 \rangle$ and $\langle \sigma_3 \rangle$ are just velocity and cross-section averaged over the entire ensemble at a specified temperature. The dimension of σ_3 is cm^5 molecule^{-2} in eq. 7, since $k_r(T)$ is in units of cm^6 molecule^{-2} s^{-1}. As discussed by Smith (15), the average velocity of approach in a 3-body system as given by eq. 8 is different from the corresponding quantity in bimolecular collision at the same temperature ($\langle v_2 \rangle = (8kT/\pi\mu_2)^{1/2}$). The resulting energy of approach in these two modes of collision will also be different. In fact the ratio E_3/E_2 is about 2.17. It is interesting to note that if $\sigma_3(E_3)$ in eq. 3 is independent of energy, one could rigorously write

[10] $$k_r(T) = \langle v_3 \rangle \sigma_3^0$$

It is the parallelism between this expression and its counterpart in bimolecular collision that led Smith (15) to suggest a 3-body hard-sphere model for triple collision as a standard for comparison. In this model the radius of the hard-sphere is determined by the geometric mean of impact distance between each pair of colliding species. If the collision radius of the species i is r_i, the normalized distance between each pair of colliding particles is (13, 15)

[11] $$R_{AB} = (r_A + r_B) \times \left[\frac{m_A m_B (m_A + m_B + m_C)}{m_C (m_A + m_B)^2}\right]^{1/4}$$

The hard-sphere radius is then given by the symmetric formula

[12] $$R_0 = (R_{AB}R_{BC}R_{CA})^{1/3}$$

and the cross-section in this 6-dimensional hypersphere is

[13] $$\sigma_3^0 = \frac{8\pi^2}{15} R_0^5$$

When the above expression is substituted into eq. 10, the "hard-sphere" recombination constant is obtained.

Calculation and Discussion

(A) Recombination Rate Constant from a 3-Body Hard-Sphere Model

The rate constants for the recombination of iodine and of bromine in inert gas (Xe, Ar, He) were calculated from the 3-body hard-sphere model as depicted by eqs. 8–11. The main difficulty encountered here was the choice of relevant collision radius of each species in a triple collision. It is not at all clear whether the covalent atomic radius or the van der Waals' radius is appropriate for this purpose. Furthermore, the triple collision cross-section (and hence the rate constant) is even more sensitive to the collision radii of the species involved than its counterpart in a binary collision, because in a triple collision the cross-section is proportional to the fifth power of the radius while in a binary collision it is proportional to the square of the radius. However, our chief objective in this work is to map out the main features of this model; we employed the covalent radii which were summarized in Table 1.

The calculated recombination rate constants for bromine and for iodine as well as the corresponding experimental data (16) are presented in Figs. 1 and 2, respectively. From these plots, it is obvious that the hard-sphere model not only fails to predict the magnitude of the observed rate data, but it also reveals the reverse trend with respect to temperature variation. The discrepancy between the absolute values of the calculated data and the experimental data is not the most damaging since it may just reflect the inappro-

priate choice of collision radius of each species. However, the fact that the recombination rate constant predicted by this model increases with increasing temperature while the reverse trend was observed experimentally does indicate that the difficulty of this model is fundamental.

The result that the hard-sphere rate constant increases with temperature is not at all surprising since eqs. 8 and 10 clearly show that the rate constant should increase monotonically with temperature ($\sim T^{1/2}$), provided that the cross-section is independent of energy.

(B) Approximate Triple Collision Cross-section from Recombination Rate Data

The average triple collision cross-sections in the recombination of bromine and of iodine in inert gas (Xe, Ar, He) were calculated from the experimental data of Burns and co-workers (16). These experimental data cover a fairly wide temperature range (298 to 1300 °K), which permits us to obtain the average cross-section within a range of energy. The recombination dynamics in these systems has also been studied by classical trajectory calculations (17).

The computation of the average cross-section is based on eqs. 7 to 9. The average energy of the system at a specified temperature is defined as (eqs. 4, 5, and 8).

$$\langle E_3 \rangle = \tfrac{1}{2}\mu_3 \langle v_3 \rangle^2 \approx 2.67kT$$

The plots of $\langle \sigma_3 \rangle$ against $\langle E_3 \rangle$ for the recombination of bromine and of iodine are shown in Figs. 3 and 4, respectively. One novel feature of these plots is that unlike the familiar bimolecular (neutral–neutral) reaction cross-section which usually shows a threshold energy below which the reaction cross-section is negligible, the cross-section in a triple (reactive) collision has no such threshold. This is reasonable since in termolecular recombination, there is no energy barrier for the system to surmount. However, the exceedingly steep rise of the cross-section at low energy, particularly in systems with heavy inert gas (Xe, Ar) as third body, certainly reflects the dominance of the mechanism involving bound intermediates (for example, IXe and BrXe complexes held together by van der Waals' attraction). Once the mechanism involving bound intermediates becomes predominant, the rate-controlling elementary process is essentially a binary encounter, and the formulation entirely based on triple collisions will not be appropriate.

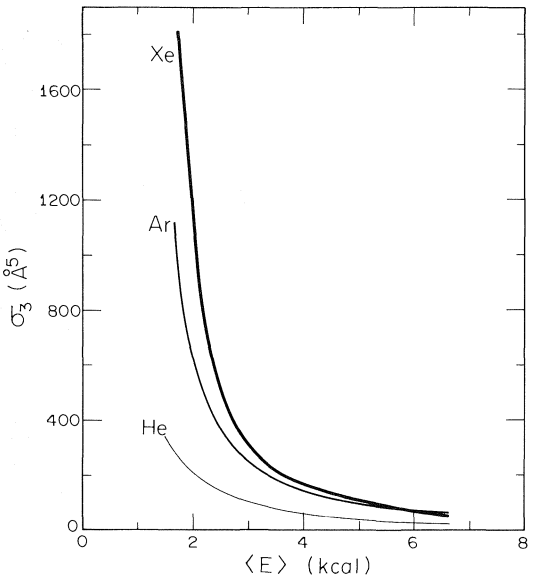

FIG. 3. Average triple collision cross-section (σ_3) extracted from the rate data of bromine recombination.

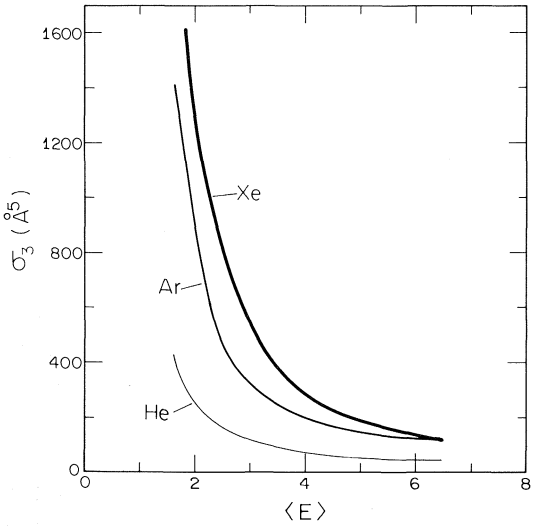

FIG. 4. Average triple collision cross-section (σ_3) extracted from the rate data of iodine recombination.

Trajectory studies performed on these systems (17) did reveal that at low temperature and with heavy inert gas, the mechanism involving bound intermediates was indeed predominant.

Another interesting feature revealed in these calculations is that the cross-section decreases asymptotically within our studied energy range, which is in contrast to the asymptotic increase in the post-threshold region of the corresponding quantity in bimolecular (neutral–neutral) reaction. It is certain though that the triple collision cross-section, just like its counterpart in binary collision (4), should ultimately taper off simply because of the inadequate interaction time at very high energy.

(C) Extraction of Triple Collision Cross-section from Rate Coefficients Expressed as a Function of Temperature

In this section, we attempt to extract the triple collision cross-section from two simple functions which are widely used to summarize observed recombination rate constants which decrease with increasing temperature.

(1) The empirical function is a polynomial of inverse power of T, namely,

$$k_r(T) = \sum_n \frac{A_n'}{T^n}$$

where A_n' is the coefficient of the nth term and n is a positive integer including zero. When k_r is expressed as a function of β ($\beta = 1/kT$), it takes the form

$$k_r(\beta) = \sum_n A_n \beta^n$$

in which

$$A_n = A_n' k^n$$

Then eq. 6 can be rewritten as

$$[14] \quad \sigma_3(E_3) = (2\mu_3)^{1/2} E_3^{-5/2} \times \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \left(\sum_n A_n \beta^{n-3} \right) e^{\beta E_3} d\beta$$

Quite often only a few terms of the polynomial are needed to fit the data. For example, if only three terms are used (*i.e.* $n = 0, 1, 2$), the solution to eq. 14. is simply

$$[15] \quad \sigma_3(E_3) = (2\mu_3)^{1/2} E_3^{-5/2} \times \left[\sum_{n=0}^{2} \frac{A_n}{(2-n)!} E_3^{2-n} \right]$$

It may be pointed out that the polynomial of inverse power of T, presently employed, can only predict the features of the cross-section within a relatively narrow range of energy because the contour integral involved in the inverse Laplace transformation truncates the series.

(2) The empirical relationship is a logarithmic function (16) such as

$$[16] \quad \ln k_r(T) = A + B(\ln aT) + C(\ln aT)^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in which A, B, C, and a are constants. When expressed in terms of β, the above expression assumes the form

$$[17] \quad \ln k_r(\beta) = A + B(\ln D\beta^{-1}) + C(\ln D\beta^{-1})^2$$

in which the constant D is related to a in eq. 16 by

$$D = a/k$$

Equation 6 can then be written as

$$[18] \quad \sigma_3(E_3) = (2\mu_3)^{1/2}E_3^{-5/2} \times \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} \exp[F(\beta)]d\beta$$

where

$$[19] \quad F(\beta) = \ln k_r(\beta) - 3\ln\beta + \beta F_3 = A + B\ln(D\beta^{-1}) + C\ln^2(D\beta^{-1}) - 3\ln\beta + \beta E_3$$

We employed the method of steepest descent to evaluate the above integral (18). The saddle point (β*) can be located by setting

$$\partial F(\beta)/\partial\beta = 0$$

which gives

$$E_3 = \frac{3}{\beta^*} - \frac{\partial \ln k_r(\beta^*)}{\partial\beta^*}$$

The exponent $F(\beta)$ of the integrand in eq. 18 was then expanded in the vicinity of β* in the imaginary direction ($\beta = \beta_1 + i\beta_2$) of the complex β plane to give

$$[20] \quad F(\beta) = \sum_{n=0}^{\infty}(n!)^{-1}\left.\frac{\partial^n F(\beta)}{\partial\beta^n}\right|_{\beta^*}(i\beta_2)^n = F(\beta^*) + \sum_{n=2}^{\infty}(n!)^{-1}\left.\frac{\partial^n F(\beta)}{\partial\beta^n}\right|_{\beta^*}(i\beta_2)^n$$

In this expression, the first partial derivative vanishes because the expansion is around the saddle point. With this expansion we can rewrite eq. 18 as

$$[21] \quad \sigma_3(E_3) = (2\mu_3)^{1/2}E_3^{-5/2}\left\{F(\beta^*) + \frac{1}{2\pi}\int_{-\infty}^{+\infty}\exp\left[\sum_{n=2}^{\infty}(n!)^{-1}\left.\frac{\partial^n F(\beta)}{\partial\beta^n}\right|_{\beta^*}\beta_2{}^n(-1)^{n-1}\right]d\beta_2\right\}$$

in which we have chosen the path of integration as a straight line passing through the saddle point and running parallel to the imaginary axis. In the first-order approximation, we have

$$[22] \quad \sigma_3(E_3) = (2\mu_3)^{1/2}E_3^{-5/2}\left\{F(\beta^*) + \frac{1}{2\pi}\int_{-\infty}^{+\infty}\exp\left[-\frac{1}{2}\left.\frac{\partial^2 F(\beta)}{\partial\beta^2}\right|_{\beta^*}\beta_2{}^2\right]d\beta_2\right\}$$
$$= (2\mu_3)^{1/2}E_3^{-5/2}\left\{F(\beta^*) + \left[2\pi\left.\frac{\partial^2 F(\beta)}{\partial\beta^2}\right|_{\beta^*}\right]^{-1/2}\right\}$$

where $F(\beta)$ is given by eq. 19 and

$$[23] \quad \frac{\partial^2 F(\beta)}{\partial\beta^2} = \frac{3}{\beta^2} + \frac{k_r(\beta)}{\beta}\left[\left(B + 2C\ln\frac{D}{\beta}\right)^2 + B + 2C\left(1 + \ln\frac{D}{\beta}\right)\right]$$

Finally, by combining eqs. 18, 22, and 23, one obtains

$$[24a] \quad \sigma_3(E_3) = (2\mu)^{1/2}E_3^{-5/2}\left[\ln\frac{k_r(\beta^*)}{\beta^{*3}} + E_3\beta^* + \frac{\beta^*}{(2\pi)^{1/2}}H\right]$$

in which

$$[24b] \quad H = 3 + k_r(\beta^*)\left[\left(B + 2C\ln\frac{D}{\beta^*}\right)^2 + B + 2C\left(1 + \ln\frac{D}{\beta^*}\right)\right]^{-1/2}$$

As remarked in previous section, this inversion procedure would be particularly useful if the rate constant could be formulated theoretically. However, care should be taken in selecting a realistic theoretical model. For example, the activated complex theory cannot be meaningfully applied to termolecular atomic recombination reactions. This is because it is difficult to make an unambiguous choice of a meaningful structure for the activated complex. Eyring, Sun, and Gershinowitz (19) have applied the activated complex theory to such reactions; their work is now commonly quoted (20). As can be seen from ref. 20, eq. 15, $k_r \approx T^{-3/2}$ if the H factor is independent (20) of T, and if vibrations of the complex are neglected. However, if vibrations are included, as has been suggested previously (20, 21), then $k_r \approx T^{3/2}$. Recently, it was shown unambiguously (17*b*, 22, 23) that vibrations are strongly coupled to rotations in the "activated complex", and for this reason, use of the activated complex theory would predict $k_r \approx T^{3/2}$, in obvious disagreement with experiment.

Summary

The qualitative features of (reactive) triple collision cross-section relevant to atomic recombination reaction have been investigated. It was found that the recombination rate constant predicted by the hard-sphere model failed to yield the temperature characteristics of the experimental data. This failure led us to conclude that the hard-sphere model, despite its simplicity, had little to offer in explaining recombination reaction.

The approximate triple cross-sections relevant to the recombination of bromine and of iodine in inert gas were deduced from the experimental rate data. These cross-sections decrease asymptotically with increasing energy within the temperature range used, a feature which is in marked contrast to that of the corresponding quantity in bimolecular (neutral–neutral) reaction. An inversion procedure employing the method of steepest descent to obtain the cross-section from recombination rate constants, expressed as simple functions of temperature, was also investigated.

Raman and Infrared Studies of Hexa-, Tetra-, and Dihydrates of Crystalline Magnesium Nitrate[1]

TIEN-CHUNG GODFREY CHANG AND DONALD E. IRISH[2]

Chemistry Department, University of Waterloo, Waterloo, Ontario

Received June 30, 1972

Raman and infrared spectra of $Mg(NO_3)_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 6D_2O$ and partially dehydrated products have been obtained and assigned. As the water content is reduced a different set of lines appears and maximizes at the composition $Mg(NO_3)_2 \cdot 4H_2O$. On further dehydration a third set of lines characteristic of $Mg(NO_3)_2 \cdot 2H_2O$ appears. The existence of the metastable tetrahydrate had not been confirmed since it was reported in 1932. The spectra suggest that four equatorial sites aroung Mg^{2+} in the tetrahydrate are occupied by four water molecules and two axial sites by nitrate ions, oriented in monodentate fashion. The spectra suggest that in the dihydrate approximately octahedral coordination is maintained by having two nitrate ions oriented in bidentate fashion and two water molecules *trans* to each other on the remaining sites.

Nous avons obtenu et assigné les spectres Raman et infrarouge de $Mg(NO_3)_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 6D_2O$ et de leurs dérivés partiellement déshydratés. Si la teneur en eau diminue, un ensemble différent de bandes apparait et devient maxium à la conjonction $Mg(NO_3)_2 \cdot 4H_2O$. Si la molécule est déshydratée un peu plus un troisième groupe de bandes, caractéristiques de $Mg(NO_3)_2 \cdot 2H_2O$ apparait. L'existence du composé tétrahydraté métastable n'a pas été confirmée depuis sa découverte en 1932. Les spectres suggèrent que les quatre sites équatoriaux, autour de Mg^{2+}, dans le tétrahydrate, sont occupés par quatre molécules d'eau et les deux sites axiaux par des ions nitrates, orientés de façon monodentée. On tire aussi des spectres que dans le dihydrate, une coordination approximativement octaédrique est maintenue au moyen de deux ions nitrates orientés de façon bidentée, et de deux molécules d'eau, *trans* une par rapport à l'autre sur les sites restants. [Traduit par le journal]

Can. J. Chem., **51**, 118 (1973)

Introduction

The commonly accepted compositions of hydrated magnesium nitrate crystals are: $Mg(NO_3)_2 \cdot 9H_2O$ (*ca.* 30 °C), $Mg(NO_3)_2 \cdot 6H_2O$, and $Mg(NO_3)_2 \cdot 2H_2O$. Sieverts and Petzold (1) reported the existence of a metastable tetrahydrate which has a small field of existence between 50 and 58 °C in the vicinity of an apparent eutectic point which occurs at a composition of 4 moles water per mole salt. Ewing *et al.* (2) were not able to confirm the existence of this hydrate. In this study we report confirmation of the tetrahydrate and report its Raman and infrared spectra. The spectra of the hexa- and dihydrates are also reported. Spectra of the hexahydrate have been, in part, interpreted in terms of the space group determined in X-ray studies by Braibanti *et al.* (3). For the tetra- and dihydrates inferences, based on the spectral changes, are made concerning the coordination sphere around Mg^{2+}.

Experimental

$Mg(NO_3)_2 \cdot 6H_2O$ was obtained by twice recrystallizing the magnesium nitrate provided by Fisher Scientific Co. $Mg(NO_3)_2 \cdot 6D_2O$ was prepared as follows. Partially dehydrated magnesium nitrate was dissolved in excess D_2O. The solution was placed under vacuum at 30 °C till dried. The resulting solid substance was partially dehydrated, and again dissolved in excess D_2O. This solution was concentrated until crystals were obtained. The water content was determined by Karl–Fisher titration, which yielded results consistent with the formula. Infrared and Raman spectra indicated that only a trace of H_2O was present in the product. Samples of $Mg(NO_3)_2 \cdot nH_2O$ ($n < 6$) were obtained from the hexahydrate by placing the solid under vacuum at 30–40 °C. The partially dehydrated solids were melted to insure homogeneity and then cooled. The water contents of the resulting polycrystalline powders were determined by Karl–Fisher titrations.

Raman spectra of the powders, contained in sealed Pyrex glass tubes of 3 mm i.d., were obtained with a modified Cary 81 Raman spectrometer. Either the 488.0 or the 514.5 nm line of a Coherent Radiation Model 54 argon-ion laser was directed onto the tube, and the Raman radiation was focused by a cylindrical lens directly onto the slits of the monochromator. The laser beam, sample, lens, and slits were arranged in the same horizontal plane and thus the conventional foreoptics of the Cary 81 were not used. Infrared spectra were recorded

using the multiple internal reflectance (MIR) technique (4). A sample was placed against a KRS-5 prism with face angle of either 45° or 60°. The Wilks Model 9 MIR accessory was used in conjunction with a Beckman IR-9 spectrophotometer. Debye–Scherrer X-ray diffraction photographs of the powders were taken with a powder camera (PW 1020) with a diameter of 114.83 mm. A Philips PW 1010 X-ray generator equipped with a fine focus X-ray diffraction tube with copper target (Cu-Kα, 1.541 Å) was used.

Results

Raman spectra of the powders $Mg(NO_3)_2 \cdot nH_2O$ ($n < 6$) can be understood as the superposition of spectra of three different polycrystalline hydrates *viz.* $\cdot 6H_2O$, $\cdot 4H_2O$, and $\cdot 2H_2O$. Consider first the symmetric stretching spectral region of NO_3^-. The hexahydrates (either $\cdot 6H_2O$ or $\cdot 6D_2O$) generate a single line at 1060 cm^{-1}. Samples with a smaller average water content exhibit two new lines at 1050 and 1070 cm^{-1} (Fig. 1). On reduction of the water:magnesium nitrate ratio the 1050 cm^{-1} line grows at the expense of the 1060 cm^{-1} line and attains maximum intensity when n is 4 (Fig. 2). The 1070 cm^{-1} line grows at the expense of the 1050 cm^{-1} line and is the only line present when n is 2. The three nondegenerate modes of vibration are therefore assigned to the three different hydrates. The complementary infrared spectra (Fig. 3) support this interpretation.

Analogous changes are observed in other spectral regions. The 1100–1700 cm^{-1} region is illustrated in Figs. 4 and 5, the low frequency region in Fig. 6 and the 3000–3800 cm^{-1} region (the H_2O stretching region) in Fig. 7. Data, sorted according to crystal type, are presented in Table 1.

The X-ray powder photographs clearly showed that the three crystal types have different structures. The lines are narrow and well defined; the possibility of the samples being glasses after melting is ruled out. Data for the $\cdot 6H_2O$ and $\cdot 6D_2O$ are identical. The data are on file with the National Science Library.[3]

Discussion

$Mg(NO_3)_2 \cdot 6H_2O$ and $Mg(NO_3)_2 \cdot 6D_2O$

Braibanti *et al.* (3) reported that $Mg(NO_3)_2 \cdot 6H_2O$ crystals are monoclinic, space group $P2_1/c$ (C_{2h}^5, No. 14), with 2 molecules per unit cell. The $Mg(H_2O)_6^{2+}$ is a distorted octahedron with the Mg—OH_2 distances 2.053, 2.061, and 2.063 Å; the unique H_2O—Mg—OH_2 angles are 91.3, 90.7, and 90.4°. The nitrate ion is also distorted. The N—O bond lengths are 1.20, 1.25, and 1.26 Å and the four atoms are not exactly coplanar. The similarity of the powder patterns indicates that $Mg(NO_3)_2 \cdot 6D_2O$ and $Mg(NO_3)_2 \cdot 6H_2O$ are isomorphic.

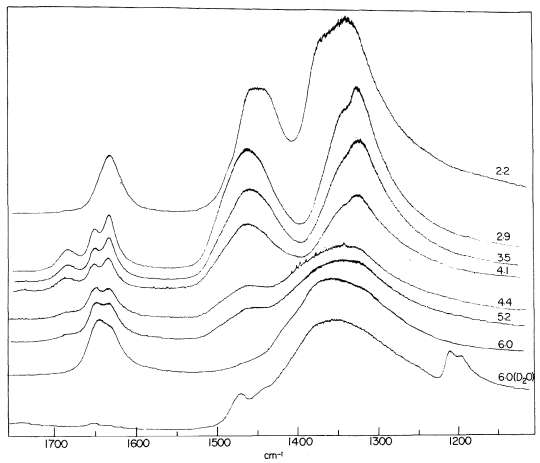

FIG. 5. MIR spectra of $Mg(NO_3)_2 \cdot nH_2O$ and $Mg(NO_3)_2 \cdot 6D_2O$ crystals in the 1100–1700 cm^{-1} region.

The four nitrate ions occupy C_1 sites in the Bravais cell and the correlation field effects may be interpreted in terms of the factor group C_{2h}. The correlation from the symmetry of the undistorted ion, D_{3h}, is as follows:

	D_{3h}	C_1	C_{2h}
ν_1	A_1'(R)		A_g(R)
ν_2	A_2''(i.r.)	A(i.r.,R)	B_g(R)
ν_3, ν_4	E'(i.r.,R)		A_u(i.r.)
			B_u(i.r.)

Since there are two E' modes, if correlation field splitting is detectable there will be twelve Raman active and twelve noncoincident infrared active modes in the spectrum. Under the conditions of the experiment (room temperature powders) these were not all observed. It is noteworthy that the correlation field effects are more pronounced for $Mg(NO_3)_2 \cdot 6D_2O$ than for $Mg(NO_3)_2 \cdot 6H_2O$; especially note the ν_4 region. (*cf.* with $Zn(NO_3)_2 \cdot 6D_2O$ (5).) The assignments are presented in Table 2. The consequences of the perturbation of the nitrate ion by its environment are not large. Low intensities of the infrared component at

1059 cm^{-1} and the Raman component at 824 or 826 cm^{-1} and the lack of observable site splitting of $\nu_4(E')$ in the case of the $Mg(NO_3)_2 \cdot 6H_2O$ may be attributed to the reduction of polarizing power of Mg^{2+} cation by the coordinated water molecules. Distortions of the nitrate ion of the magnitude indicated by Braibanti *et al.* (3) might be expected to generate more pronounced changes in the vibration spectrum; the structural parameters they report have a relatively large uncertainty ($R = 0.156$). Thus the spectral data probably provide a more accurate indication of the symmetry.

A complete analysis of the rotatory and translatory motions would account for 99 optical modes. The data do not warrant such a detailed interpretation. We will consider the vibrations which can clearly be assigned to the $Mg(H_2O)_6^{2+}$ unit. The remaining vibrations which occur in the low frequency region are lattice modes, reported for completeness but unassigned.

The X-ray data suggest a distorted octahedral arrangement of water molecules about Mg^{2+}. If O_h symmetry is adopted and the hydrogen atoms are ignored the unit would generate three low frequency Raman lines.

$$\Gamma_{VIB} = A_{1g}(R) + E_g(R) + F_{2g}(R) + 2F_{1u}(\text{i.r.}) + F_{2u}(\text{inactive})$$

Lines at 362, 312, and 222 cm^{-1} can be assigned to the A_{1g}, E_g, and F_{2g} modes, respectively. These assignments are consistent with the interpretation for solutions (6, 7). They show appropriate shifts to 344, 300, and 208 cm^{-1} when H_2O is replaced by D_2O (6). However, the calculations of Ananthanarayanan (8) suggest different assignments for the $Mg(H_2O)_6^{2+}$ complex. The 362 cm^{-1} band is still assigned to an A_{1g} mode but the broad, relatively intense 222 cm^{-1} line would be

attributed to both the E_g and F_{2g} components in his scheme and the 312 cm^{-1} line must then be a lattice mode despite the shift on deuteration. The unit occupies a C_i site in the crystal and thus a lifting of the degeneracy of the E_g and F_{2g} modes could occur; however, no manifestation of site or coupling effects was apparent.

Two additional Raman lines are expected if

the symmetry is lowered to D_{4h}:

$$\Gamma_{VIB} = 2A_{1g}(R) + B_{1g}(R) + B_{2g}(R) + E_g(R) + 2A_{2u}(i.r.) + B_{2u}(\text{inactive}) + 3E_u(i.r.)$$

Although the lines are broad and may envelope components, the number of observed lines does not provide strong support for a large distortion. The presence of at least two different Mg—OH_2 distances is revealed by the spectra of the deformation (1600 cm^{-1}) and stretching regions (3400 cm^{-1}), however. The distances 2.061 and 2.063 Å and the angles 90.4° and 90.7° are virtually equivalent and thus the X-ray data also suggest two significantly different types of water in the crystal. Consistent with this, the deformation mode is a doublet (1632 and 1647 cm^{-1}). The stretching region is a multiplet which can be understood in terms of different O—H vibrations from the two types of water molecules and additional splitting arising from coupling, probably enhanced by hydrogen bonding. Manifestations of coupling are generally most apparent in the antisymmetric stretching region.

$Mg(NO_3)_2 \cdot 4H_2O$

The nitrate bands attributed to $Mg(NO_3)_2 \cdot 4H_2O$ are listed in Table 1. The lifting of the degeneracy of the $\nu_4(E')$ mode is apparent. The high frequency component is at 748 cm^{-1} (Raman) and 750 cm^{-1} (i.r.), which suggests direct contact between NO_3^- and the Mg^{2+} cation (9). There is evidence that a coordination number of six is retained in the tetrahydrate with four water molecules and two NO_3^- ions in the first coordination sphere. The $\nu_1(A_1')$ and $\nu_2(A_2'')$ modes appear as single bands: $\nu_1(A_1')$: 1050 cm^{-1} (R), 1045 cm^{-1} (i.r.); and $\nu_2(A_2'')$: *ca.* 820 cm^{-1} (R), 814 cm^{-1} (i.r.). The lack of infrared–Raman coincidence is obvious for all the spectral bands, and strongly suggests a center

of symmetry. Thus we infer that the two nitrate ions coordinated to Mg^{2+} are equivalent and *trans* to each other as in Fig. 8. The Raman spectrum shows that in the $\nu_3(E')$ region, the low frequency component, 1352 cm^{-1}, is much more intense than the high frequency component, 1453 cm^{-1}, and an intensity reversal is observed in the infrared spectrum. It is a general rule that, in this region, a polarized Raman band of *A* symmetry has a higher intensity than a depolarized Raman band of *B* symmetry and an intensity reversal occurs in the infrared spectrum. Therefore, it is very likely that the 1352 cm^{-1} band is polarized and the 1453 cm^{-1} band depolarized as observed for very concentrated solutions of $Mg(NO_3)_2$ (10). The implication is that the NO_3^- ions are coordinated to the Mg^{2+} ions in a monodentate fashion (11–13).

The number of low frequency bands is almost double that of $Mg(NO_3)_2 \cdot 6H_2O$ crystal (Table 1, Fig. 6). The complicated situation prevents reliable assignments for all bands. Hester and Krishnan (14, 15) observed no Raman bands in the 200–400 cm^{-1} region of the $Mg(NO_3)_2$–MNO_3 (M = alkali metal) melts. By comparison with the $Mg(NO_3)_2 \cdot 6H_2O$ spectrum, the 350, 300, and 200 cm^{-1} bands can be assigned to Mg^{2+}—OH_2 vibrations. Their frequencies are lower than their counterparts in the $Mg(NO_3)_2 \cdot 6H_2O$ crystal, which probably is due to the weakening of the Mg^{2+}—OH_2 bonds by the introduction of the NO_3^- ions to the first coordination sphere around Mg^{2+} ion and to the change in symmetry.

The infrared spectrum (Fig. 5) shows that there are three bands, 1632, 1650, and 1683 cm^{-1}, for the water bending mode. Of these the 1683 cm^{-1} band has the largest linewidth, which probably implies that there are two bands under the enveloping curve. This leads us to suspect that the four Mg^{2+}—OH_2 bonds are of different lengths. The four pronounced features in the 3400 cm^{-1} region can also be interpreted in this manner. The breadths of the lines suggest extensive hydrogen bonding.

$Mg(NO_3)_2 \cdot 2H_2O$

The $\nu_1(A_1')$ and $\nu_2(A_2'')$ modes are single bands in the Raman or infrared spectra: $\nu_1(A_1')$: 1071 (R), 1070 (i.r.); $\nu_2(A_2'')$: 818 (R), 815 (i.r.). These facts indicate that the nitrate ions are equivalent in the dihydrate crystals. The lifting of degeneracy of the two E' modes of nitrate ions is apparent. In the $\nu_4(E')$ region there are two bands at 733 and 749 cm^{-1} in the Raman spectrum, but four bands, 727, 733, 750, and 755 cm^{-1} in the infrared spectrum. Four bands are found in the $\nu_3(E')$ region in both Raman and infrared spectra. The further splitting of the E' mode from two to four components can be ascribed to correlation field splitting, but it is not interpretable without knowledge of the space group. The Raman spectrum in the $\nu_3(E')$ region shows two distinct features. First, the high frequency band at 1466 cm^{-1} is much more intense than the low frequency band at 1330 cm^{-1}; the opposite intensity ratio was observed for the tetrahydrate. Secondly, the separation between the 1466 and 1330 cm^{-1} bands is 136 cm^{-1}, which is larger than the corresponding separation for the tetrahydrate. These observations suggest that the nitrate ions are oriented in bidentate fashion around magnesium ions (10–13) as shown in Fig. 8. The symmetric model is preferred to one in which nitrate ions are adjacent. It provides for greater negative charge separation and probably more efficient packing. Although the i.r. and Raman lines are virtually noncoincident, implying a centre of symmetry, the evidence is not decisive and proof must await an X-ray structure determination.

The 340 and 226 cm^{-1} bands are assigned to Mg—OH_2 vibrations. The lowering of the frequency of the 340 cm^{-1} band (*cf.* 362 cm^{-1} for hexahydrate, and 350 cm^{-1} for tetrahydrate) is probably due to the influence of the neighboring negatively charged nitrate ions.

Only one infrared band, 1632 cm^{-1} can be attributed to the water bending mode. This band is broad compared with those in other hydrates (Fig. 5). These data suggest that the two Mg—OH_2 bonds are equivalent, or very similar. This is consistent with the proposed model shown in Fig. 8. The Raman and infrared spectra in the 3400 cm^{-1} region are much simpler than those of tetra- and hexahydrates. Hydrogen bonding is much less extensive; the water molecules can be almost considered as isolated discrete units in the inorganic matrix, oriented by the cations. The very low Raman intensity of the 3550 cm^{-1} ν_3 asymmetric stretching frequency is noteworthy.

The Crystal Structure of the Platinum Acetylenic Complex, $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$

A. L. Beauchamp, Fernande D. Rochon,[1] and T. Theophanides

Département de Chimie, Université de Montréal, Montréal, Québec

Received July 7, 1972

The complex salt $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$ forms monoclinic crystals, a = 10.841(5), b = 9.796(4), c = 17.414(6) Å, β = 100.44(2)°, Z = 4, space group $P2_1/c$. Positional and anisotropic thermal parameters were refined to R = 0.069 and R_w = 0.064 by using 1662 independent reflections.

The coordination around platinum is planar, and the triple bond of the acetylenic ligand is approximately perpendicular to the coordination plane. The triple bond is 1.18(3) Å and the C≡C—C angles (≃160°) show a deformation of the ligand in a direction away from the platinum atom with the two hydroxyl groups in *cis* configuration, above and below the plane of the $PtCl_3$ group. The *cis* Pt—Cl bonds are of normal length, but the *trans* Pt—Cl bond seems to be shorter. The K^+ ion is surrounded by four chlorine atoms and two oxygen atoms at relatively short distances. The oxygen–potassium attraction seems to be the predominant direct interaction of the —OH groups with the rest of the crystal.

Le sel complexe $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$ cristallise dans le système monoclinique, a = 10.841(5), b = 9.796(4), c = 17.414(6) Å, β = 100.44(2)°, Z = 4, groupe spatial $P2_1/c$. Les coordonnées et les facteurs thermiques anisotropes ont été affinés au moyen de 1662 réflexions indépendantes jusqu'à R = 0.069 et R_w = 0.064.

Une coordination plane est observée autour du platine et la triple liaison du ligand acétylénique est à peu près perpendiculaire au plan de coordination. La longueur de la triple liaison est de 1.18(3) Å et les angles C≡C—C (≃160°) indiquent que le ligand subit une déformation dans le sens opposé à celui du platine. Les groupes hydroxyles, situés de part et d'autre du plan de coordination, adoptent une configuration *cis*. Les liaison Pt—Cl *cis* sont de longueur normale, mais la liaison Pt—Cl *trans* paraît plus courte. L'ion K^+ est entouré de quatre atomes de chlore et de deux atomes d'oxygène à des distances relativement courtes. Les attractions oxygène–potassium semblent le principal mode d'interaction directe des groupes —OH avec le reste du cristal.

Can. J. Chem., **51**, 126 (1973)

Introduction

Platinum(II) forms compounds of the types $K[Pt(ac)Cl_3]$ and *trans*-$[Pt(ac)Cl_2(amine)]$ with several acetylenic ligands (ac). X-Ray diffraction work on the neutral complex *trans*-$[PtCl_2(Bu^tC{\equiv}CBu^t)(p\text{-toluidine})]$ showed that the triple bond is nearly perpendicular to the coordination plane with the acetylenic carbon atoms above and below the plane (1). The structure is similar to that of Zeise's salt as determined by Owston and co-workers (2). It is generally admitted that the $K[Pt(ac)Cl_3]$ compounds involve the same type of bonding as the olefinic analogs.

A variety of $K[Pt(ac)Cl_3]$ complexes with acetylenic ligands were investigated by Chatt and co-workers (3–5). It was noticed that particularly stable compounds are obtained with α,α′-dihydroxy acetylenic derivatives. The hydroxyl groups were assumed to be involved in the stabilization of the compounds (4–7). It was felt that any important interaction of the hydroxyl groups would force them into a preferred orientation. The crystal structure of the complex salt $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$ was therefore studied in order to locate the hydroxyl groups. A ligand without methyl groups on the tertiary carbon atoms was selected to facilitate the unambiguous identification of the hydroxyl groups in the structure.

Crystal Data

$KPtCl_3C_{12}H_{22}O_2$ *f.w.* = 542.86

Monoclinic, $P2_1/c$, a = 10.841(5), b = 9.796(4), c = 17.414(6) Å, β = 100.44°(2), V = 1818.7Å^3, Z = 4, ρ_c = 1.982, ρ_o = 1.98 (flotation), $\lambda CuK\bar{\alpha}$ = 1.5418 Å, $\lambda CuK\beta$ = 1.3922 Å.

Experimental

The compound was prepared as previously described (7) and recrystallized from an acetone–ether mixture. A yellow plate with dimensions 0.025 × 0.24 × 0.06 mm was found suitable for X-ray work. The $P2_1/c$ space group

was established from a set of Weissenberg and precession photographs.

The intensity data were collected on a manually operated Picker FACS-1 diffractometer, using Ni-filtered CuKα radiation. Prior to data collection, all axial reflections with appreciable intensity were centered in the counter aperture through a search with the angles of the instrument. The refined cell constants so obtained were used to calculate the settings for data collection. Towards the end of the work, a fully automatic FACS-1 system became available and the cell constants were redetermined from 12 automatically centered Kβ peaks. The parameters obtained by the latter method are reported here and do not differ appreciably from those originally determined.

The integrated intensities of 2021 independent reflections (hkl, $hk\bar{l}$) within a sphere of $2\theta \leqslant 105°$ were measured by the $\theta/2\theta$ scan technique. Each peak was scanned at a rate of 1° (2θ)/min over a range of 2° (2θ). Stationary background counts of 20 s were taken at each limit of the scan. Periodic check of the standard reflections 006 and 1 10 0 did not indicate any significant variation. Reflections (359) with net intensities less than 3 times the total count σ were rejected. An absorption correction based on the equations of the crystal faces was applied to the 1662 observed reflections, which were finally corrected for the polarization and Lorentz effects.

The platinum atom was located from the Patterson map. The positions of all other atoms except hydrogens were obtained by structure factor and Fourier map calculations. The parameters were refined by the conventional full-matrix least-squares method. The form factors used were those of Cromer and Waber and the anomalous dispersion contribution $\Delta f'$ and $\Delta f''$ for Pt, K, and Cl were included in the calculations (8). At the latest stages of the refinement, each reflection was assigned an individual weight based on the equations: $\sigma = \sigma_a(1 + b(F_o - c))^{\frac{1}{2}}$ if $F_o > c$, $\sigma = \sigma_a$ if $c > F_o > d$ and $\sigma = \sigma_a(1 + f(F_o - d))^{\frac{1}{2}}$ if $d > F_o$, where $b = 0.15$, $c = 95$, $d = 45$, $f = 0.02$, and σ_a = total count standard deviation. These constants were adjusted to obtain a uniform distribution of the average weighted residual as a function of F_o and sin θ/λ. The hydrogen atoms of the methylene groups were fixed at the calculated positions, while those of the methyl and hydroxyl groups were neglected. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all atoms except hydrogens yielded a residual $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ of 0.069 and a weighted residual $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{\frac{1}{2}}$ of 0.064. The final difference Fourier map using all observed reflections showed no significant peak, except for one peak of ±0.9 e/Å^3 at less than 1 Å from the platinum atom.[2] The refined parameters are given in Table 1.

The calculations were performed with a CDC 6600 computer. The following programs were used: F.R. Ahmed, NRC-1 (diffractometer settings); F.R. Ahmed and C.P. Huber, NRC-2 (data reduction); F.R. Ahmed and P. Singh, NRC-3 (absorption correction); C.T. Prewitt, SFLS5 (full matrix least-squares); A. Zalkin, FORDAP (Patterson and Fourier maps); C.K. Johnson, ORTEP (drawings); M.E. Pippy and F.R. Ahmed, NRC-12 (bond distances and angles); J.S. Wood, MGEOM (molecular geometry); R.E. Elder, PUBTAB (structure factor table).

Description of the Structure and Discussion

The structure of the $[Pt(ac)Cl_3]^-$ complex ion is shown in Fig. 1 and the list of bond lengths and

[2]The structure factor table is available at a nominal charge from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada, KIA 0S2.

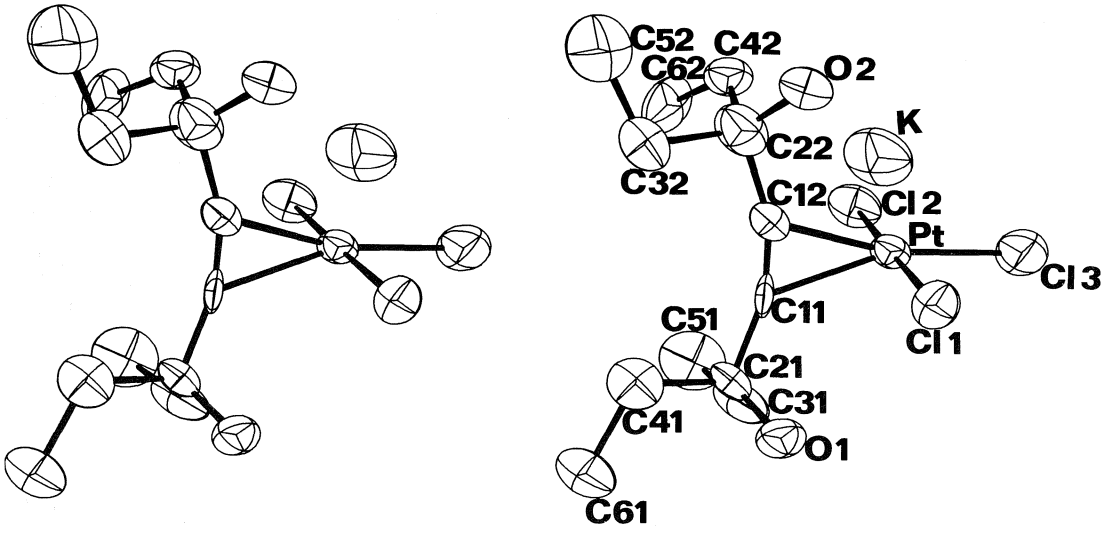

FIG. 1. Structure of $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$

angles is given in Table 2. Three chlorine atoms and the mid-point X of the C(11)—C(12) triple bond achieve the square planar coordination expected for Pt(II) complexes. The weighted best plane was calculated through the platinum and chlorine atoms. The deviations from this plane are: Pt, 0.001; Cl(1), −0.008; Cl(2), −0.007; and Cl(3), 0.007 Å. The mid-point X of the triple bond is ~ 0.1 Å above the plane. The Cl—Pt—Cl angles are all close to the ideal values of 90° or 180°. The triple bond is nearly perpendicular (∠Pt—X—C(11), 93.8°) to the line joining the mid-point X to the platinum atom, and it is also rotated by ~3° around that line.

In Zeise's salt, the geometry of the ethylene molecule is modified upon complexation: the C=C double bond seems to be longer (1.37(3) and 1.354(15) Å) and the hydrogens are not in the plane of the double bond (2, 9). In the present case, the C(11)—C(12) bond length (1.18(3) Å) is not significantly different from a normal triple bond (1.202(5) Å) (10). However, the C(21)—C(11)—C(12)—C(22) segment of the coordinated ligand is not linear. The C(21) and C(22) atoms are displaced, producing a *cis* deformation in the direction opposite to the platinum atom, the C—C≡C angles averaging 160°. A similar non-linearity of the coordinated acetylenic ligand has been reported for the neutral complex $[PtCl_2(Bu^tC{\equiv}CBu^t)(p\text{-toluidine})]$ (1). The ligand conformation in both of these compounds is closely related. In the neutral compound, the main chain of six carbon atoms is roughly C-shaped and occupies a crystallographic mirror plane which also contains the platinum atom and the *trans* nitrogen atom. In the present case, the chain has two more carbon atoms and it is also C-shaped. Eight of the twelve carbon atoms, the platinum atom, and the *trans* chlorine atom are nearly in the same plane. Both hydroxyl groups are found on the same side of the planar chain, the two remaining ethyl groups being on the opposite side. Consequently, the complex ion approximates a C_s point group symmetry with a mirror plane through the coordination plane.

Platinum forms two equal *cis* bonds with Cl(1), 2.334 Å, and Cl(2), 2.339 Å, but the Pt—Cl(3) bond *trans* to the acetylenic ligand appears significantly shorter (2.287 Å). At the moment, there is no definite agreement as to how and by what amount a bond distance should be perturbed when the *trans* position is occupied by a ligand with a high *trans* influence. The crystallographic data on olefinic complexes generally failed to show any significant systematic lengthening or contraction of the *trans* bond (2, 9, 11). To our knowledge, this is the first crystal structure work on a $[Pt(ac)Cl_3]^-$ salt. Even if the difference between the *trans* and the *cis* Pt—Cl bonds corresponds to 4 times the sum of their respective e.s.d.'s, we feel that shorter *trans* Pt—Cl bonds should first be observed with other similar compounds before an interpretation is attempted. We may reasonably believe that in the crystal, the

trans effect might be partially obscured or even reversed by other factors related either to the crystal itself (packing around the cation for example) or to the technique and interpretation of the data (absorption correction, weighting scheme).

Various intramolecular interactions involving the hydroxyl groups have been proposed to explain the stability of the platinum complexes with acetylenic glycols. A direct interaction of the Pt atom with either the oxygen or the hydrogen of the hydroxyl group was first suggested, but subsequently abandoned by Chatt *et al.* (4, 5). If there were such interaction, the —OH groups would be carried inside the molecule, above and below the platinum atom, by a rotation of the tertiary groups around the single bonds. In the present compound, the ligand shows a different conformation. The *cis* conformation of the tertiary carbons towards the outside of the molecule results in large Pt—O distances of 3.54 and 3.45 Å, and unfavorable C—O—Pt angles of 67.4 and 68.2°, which would make the above proposed interactions rather unlikely. Intramolecular hydrogen bonding to one or both of the *cis* chlorine atoms was suggested (4). The oxygen–chlorine contacts given in Table 2 do not suggest strong hydrogen bonding in the crystal. The O(1)—Cl(1) distance (3.26 Å) is just within the range 2.9–3.3 Å suggested for hydrogen bonds of this type (12). A hydrogen atom on the O(1) . . . Cl(1) line would define a C—O—H angle of 104°. This could imply a weak intramolecular hydrogen bonding. The intermolecular oxygen–chlorine contact between O(2) and Cl(1) is 3.37 Å and the angle C—O—H would be 107°. The oxygen–oxygen contacts are all well outside the hydrogen bonding range of 2.4–2.9 Å (12) and the angles are also unfavorable (Table 2). Consequently, although some weak hydrogen bonds might contribute to the stabilization of the compound, it is doubtful that their influence is predominant.

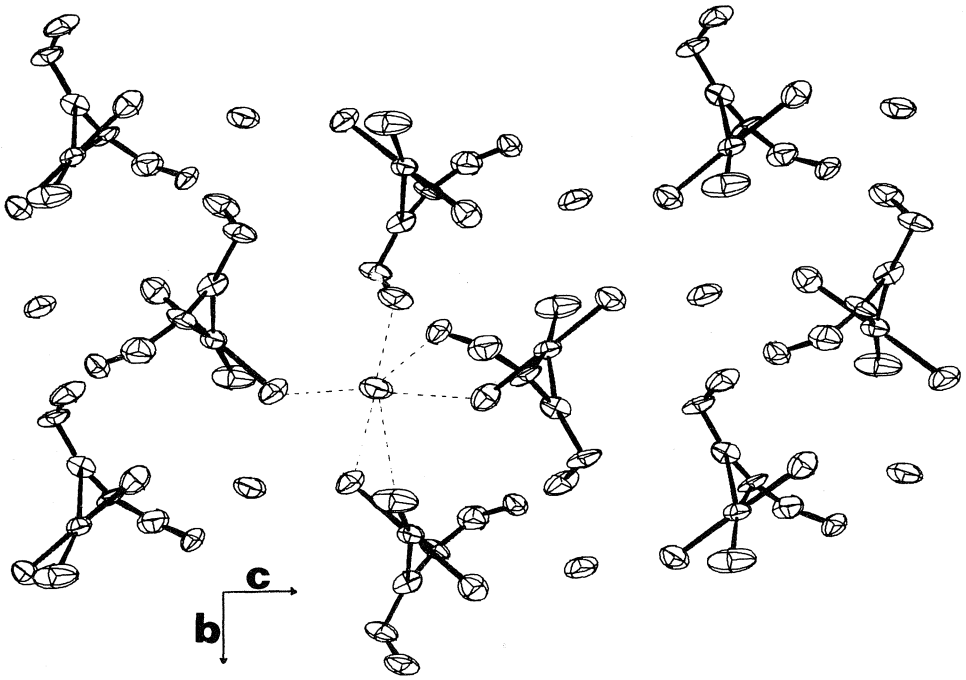

FIG. 2. Packing in the crystal of $K[Pt((C_2H_5)_2C(OH)C{\equiv}CC(OH)(C_2H_5)_2)Cl_3]$ (the ethyl groups have been removed for simplicity reasons).

The infrared spectra of the solid complex (15) show that the OH stretching frequency is lowered from 3610 cm^{-1} (CCl_4) in the free ligand to 3505 and 3475 cm^{-1} in the complex salt (KBr). The slight splitting of the band into two components may be explained by the presence of two hydroxyl groups in different crystallographic environments. Although the lowering of the frequency is usually interpreted in terms of hydrogen bonding, it may also be due to other factors, such as the ligand perturbation by the metal and the potassium–oxygen attraction in the crystal.

For a solid compound, the packing energy may be an important stabilizing factor and its contribution should not be overlooked in the case of the complex salts, where the cation might have a determining influence. Chatt *et al.* (4) mentioned that the Na $[Pt(ac)Cl_3]$ salts are usually less stable than the corresponding K salts, whereas salts with $[NH(C_2H_5)_3]^+$ were isolated while the corresponding K salts could not be isolated (13). In the present case, the K^+ ion is surrounded by four chlorine atoms at 3.07, 3.14, 3.20, and 3.29 Å and two oxygen atoms at 2.79 and 2.66 Å, defining a distorted trigonal prismatic geometry (Fig. 2). The interesting point is that both hydroxyl groups are part of the close environment of the K^+ ion with short K—O contacts similar to those found in carboxylates (2.6–3.0 Å) (14). In a $K[Pt(ac)Cl_3]$ complex with an acetylenic hydrocarbon, the replacement of the —OH groups by methyl groups, for example, would leave only three chlorine atoms per complex ion to fulfill the packing requirements around the cation, not more than two of which could effectively be found near a given cation. This would presumably result in a certain crowding of the complex ions around the cations. Consequently, the chances that the structure of the free complex ion is preserved in the crystals would certainly be better when 5 electronegative atoms or groups are available (glycol complexes) than when only 3 chlorine atoms (hydrocarbon complexes) can fulfill the packing requirements around the cation. It seems therefore that the oxygen–potassium attraction is the predominant direct interaction of the —OH groups with the rest of the crystal. Chatt *et al.* (4) have shown that the stability of the platinum complexes with $R_1—C{\equiv}C—R_2$ hydrocarbons increases with the increasing positive indictive effect of the R_1 and R_2 groups. The above K—O attraction might explain the

stabilization of the platinum glycol salt, in spite of the negative inductive effect of the two —OH groups.

Grateful acknowledgment is made to the National Research Council of Canada for financial support and to Johnson Matthey and Mallory Ltd. for the loan of platinum metal.

The Mass Spectra of Imidoyl Halides and Bromoiminium Bromides

J. GAL,[1] B. A. PHILLIPS,[2] AND R. SMITH

Chemistry Department, West Virginia University, Morgantown, West Virginia 26506

Received July 4, 1972

The mass spectra of imidoyl halides **1–6** and bromoiminium bromides **7–9** have been studied and their fragmentation pattern discussed. Loss of halogen atom from the molecular ion of imidoyl halides to form a *N*-alkylnitrilium ion is a major process. When the *N*-alkyl group is larger than methyl the fragmentation of *N*-alkylnitrilium ions with hydrogen rearrangement to give the $[PhC{\equiv}NH]^+$ ion becomes important. Thermolysis of bromoiminium bromides in the inlet system of the mass spectrometer produces imidoyl bromides via dealkylation (or dehydrobromination) and α,α-dibromobenzylamines via addition of bromide to the C=N bond.

Nous avons étudié le spectre de masse des halogénures d'imidoyl **1–6** et des bromures de bromoiminium **7–9** et étudié leur patron de fragmentation. La perte d'un atome d'halogène de l'ion moléculaire des halogénures d'imidoyl pour former un ion *N*-alkylnitrilium constitue un processus important. Lorsque le groupe *N*-alkyl est plus gros que le méthyle, la fragmentation des ions *N*-alkylnitrilium avec un réarrangement d'hydrogène pour donner l'ion $[PhC{\equiv}NH]^+$, devient importante. La thermolyse des bromures de bromoiminium dans le système d'entrée du spectromètre de masse produit des bromures d'imidoyl via la déalkylation (ou la déhydrobrominature) et des α,α-dibromobenzylamines via l'addition de bromure au lien C=N. [Traduit par le journal]

Imidoyl chlorides (**I**, X = Cl) and chloroiminium chlorides (**II**, X = Cl) have been known for over half a century (1, 2). These compounds provide useful intermediates for the synthesis of numerous nitrogen-containing derivatives, and also play an important role in mechanistic organic chemistry. For example, chloroiminium chlorides and/or imidoyl chlorides have been shown to be intermediates in such classical name reactions as the Vilsmeier–Haack aldehyde synthesis, the von Braun amide degradation, and the Beckmann rearrangement. Recently there has been a marked awakening of interest in these compounds, especially in 1,3-dipolar addition reactions, and in imidoyl fluorides (I, X = F), which had escaped study in earlier years. These and other aspects of the chemistry of imidoyl halides and haloiminium halides have been the subject of several extensive reviews (3). However, no mass-spectral fragmentation study of these compounds has been published.

In connection with our investigation (4, 5) of the mechanism of the von Braun amide degradation a number of imidoyl halides (**1–6**) and bromoiminium bromides (**7–9**) were prepared and their low-resolution mass spectra determined.

Results and Discussion

The results are given in Figs. 1–5 and in Table 1. It was found that imidoyl chlorides **1** and **3** show a weak molecular ion, whereas the imidoyl bromides (**2**, **4**, **6**) and imidoyl chloride **5** show no molecular ion. However, several ions containing the imidoyl chloride functionality were detected in the spectrum of *N*-*n*-butylbenzimidoyl chloride (**5**, Fig. 1). As shown in Scheme 1, β-fission of the *N*-alkyl group leads to the ion at *m*/*e* 152, while γ-fission gives an ion of *m*/*e* 166. The latter ion is probably in the cyclic aziridinium form indicated

in Scheme 1. Similar *N*-alkylideneaziridinium ions are frequently encountered in the spectra of *N*-alkylaziridines (6).

An important process in the fragmentation of all of the imidoyl halides studied is the loss of a halogen atom to give the stable *N*-alkylnitrilium ion (eq. 1). This process is analogous to the loss

[1] 
of halogen from the molecular ion of benzoyl halides (7) to give the corresponding stable acylium ion. The nitrilium ion (*a*) at *m*/*e* 118 (Scheme 2) is the base peak in the spectra of *N*-methylbenzimidoyl halides **1** and **2** (Table 1 and Fig. 2). The ion of *m*/*e* 103 (*b*) most likely arises by loss of the elements of methyl halide from the parent ion. This process is reminiscent of the electron-impact-induced loss of H_2O and H_2S from the imide form of benzamide and thiobenzamide, respectively (8). The alternative formation of (*b*), loss of a methyl radical from the even electron ion (*a*), is unfavored. The benzonitrile ion (*b*) then loses HCN to give $[C_6H_4]^{+\cdot}$ (*m*/*e* 76) and also, to a lesser extent, $H_2CH^{\cdot}$ to give $[C_6H_3]^+$ (*m*/*e* 75). The latter two ions are also observed in the mass spectrum of benzonitrile (9). The nitrilium ion (*a*) may lose either CH_3CN to give the phenyl ion (*m*/*e* 77) or HCN to give the $[C_7H_7]^+$ (most likely tropylium) ion at *m*/*e* 91.

The spectra of imidoyl halides having an *N*-

alkyl group larger than methyl (**3–6**) show the nitrilium ion $[PhC{\equiv}NH]^+$ (*c*) at *m/e* 104 as the base peak. This ion arises from the *N*-alkylnitrilium ion via rearrangement of a hydrogen from the *N*-alkyl group, as shown in eq. 2. Metastables found for this transition are listed in Table 2. This

[2] 
rearrangement has previously been observed in the spectra of *N*-alkyl azomethines (10), amines (11), and ethers (12). Fisher and Djerassi have suggested (10) that the migrating hydrogen may originate from the α, β, γ, or δ carbon atom. The low intensity of (*c*) in the spectra of the *N*-methylbenzimidoyl halides **1** (3%) and **2** (2%) indicate that when the α-carbon is primary, hydrogen rearrangement, as would be expected (13), is not an important process. The $[PhC{\equiv}NH]^+$ ion (*c*) then generates the $[C_6H_5]^+$ ion at *m/e* 77 via loss of HCN as indicated by the appropriate metastable in the spectra of **3**–**6** (found: 57.0; calcd.: 57.0).

The nitrilium ion (*d*) at *m/e* 252 in the spectrum of *N*-5-bromopentylbenzimidoyl bromide (**6**) loses benzonitrile to give the bromine-containing ion at *m/e* 149 (eq. 3). The latter then yields the ion at *m/e* 69.

Heating non-volatile salts in the inlet of a mass spectrometer first leads to the formation of neutral species which are then vaporized (14). Upon

[3] 
heating to 80° in the inlet system *N*-*n*-butylbenzimidoyl bromide hydrobromide (**7**, Table 1) liberates hydrogen bromide. The spectrum of the free base shows, as expected, no molecular ion. Loss of bromine atom gives the nitrilium ion at *m/e* 160, which then fragments with hydrogen rearrangement (eq. 2, Table 2). Interestingly, fragmentations analogous to the processes shown in Scheme 1 for the corresponding imidoyl chloride **5** are not seen in the spectrum of **7**. This is probably due to the greater ease of loss of a bromine atom from the molecular ion.

The thermal decomposition of *N*,*N*-dimethyl-α-bromobenziminium bromide (**8**, Fig. 4) in the mass spectrometer occurs in two ways. Nucleophilic dealkylation, commonly observed in the mass spectra of ammonium salts (14), leads to methyl bromide (*m/e* 94) and *N*-methylbenzimidoyl bromide (**2**, Scheme 3). In fact, this reaction has been shown to proceed by isolation of **2** in 75% yield from refluxing **8** in dibromomethane (5). Comparing Figs. 2 and 4 it can be seen that **2** formed thermally from **8** at 140° generates ions similar to those found in the spectrum of independently synthesized **2**. At this inlet temperature partial decomposition of **2** to benzonitrile and methyl bromide occurs. In the case of imidoyl chlorides this thermal decomposition is well known from the von Braun amide degradation (15) (eq. 4). Such formation of benzonitrile explains the greater relative intensity of the ions at *m/e* 103 (74%) and *m/e* 76 (29%) in the spectrum

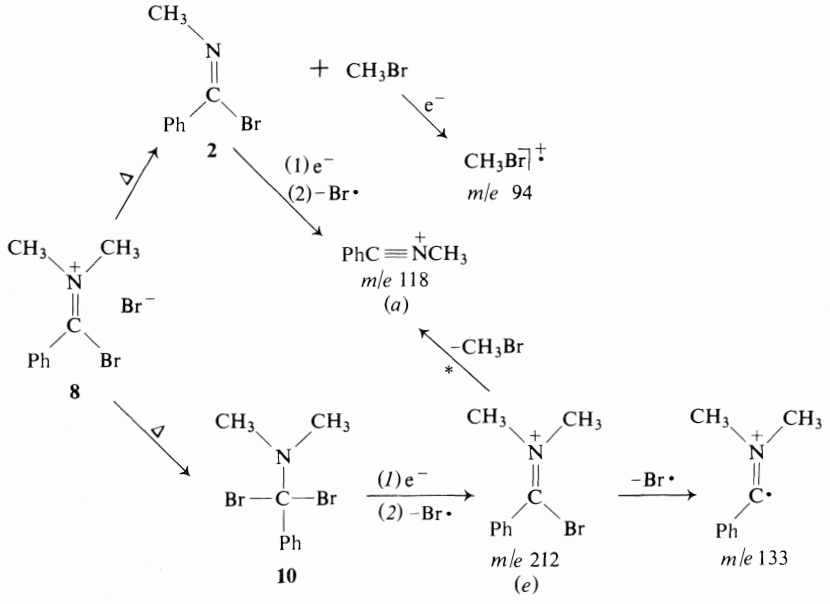
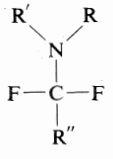


SCHEME 3

[4] 
of **8** (Fig. 4) as compared to 19 and 9%, respectively, in the spectrum of **2** (Fig. 2).

The second thermal neutralization process for **8** is formation of *N*-α,α-dibromobenzyldimethyl amine (**10**) via attack of bromide ion on the sp^2 carbon bonded to nitrogen. Evidence suggesting the existence of *gem*-dihalides such as **10** has been offered in the literature. Namanworth (16) found that chloroformiminium chloride (**11**) is in equilibrium with its *gem*-dichloro isomer (**12**) in chloroform or thionyl chloride solution (eq. 5). Furthermore, the facile exchange of covalent halide in haloiminium salts of type **II** has been suggested (17) to proceed via a *gem*-dihalo intermediate. It is also well established (18) that fluoroiminium fluorides, which are stable, distillable liquids, exist entirely in the covalent *gem*-difluoro form **13**. Volatilization of **10** is followed by ionization, and loss of a bromine atom to give (*e*) at *m/e* 212 (Scheme 3). This ion then loses methyl bromide in a one step process, as indicated by the appropriate metastable (found: 65.5 broad; calcd.: 65.0 and 65.7), to contribute to the intensity of the nitrilium ion (*a*). The ion at *m/e* 133 probably arises via loss of bromine atom from (*e*).

[5] 



In a manner analogous to **8** the thermolysis of *N*,*N*-pentamethylene-α-bromobenziminium bromide (**9**) gives *N*-5-bromopentylbenzimidoyl bromide (**6**) as shown in Scheme 4. With an inlet temperature of 300° the imidoyl bromide **6** undergoes partial von Braun degradation to benzonitrile and 1,5-dibromopentane (*m/e* 228). These von Braun products account for the greater relative intensity of the ions at *m/e* 148, 103, 76, 69, and 41 in Fig. 5, as compared to Fig. 3. The thermal formation of *N*-α,α-dibromobenzylpiperidine (**14**) followed by ionization and loss of a bromine atom from the molecular ion would give an ion (*f*) indistinguishable from the *N*-5-bromopentylnitrilium ion (*d*) at *m/e* 252. However, based

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

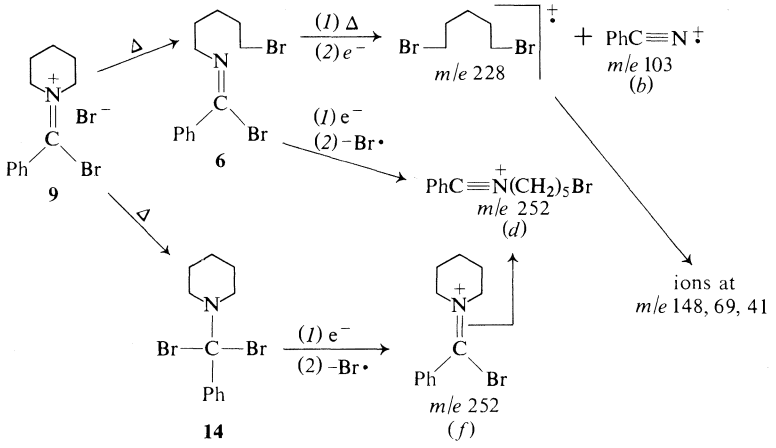

SCHEME 4

on analogy to the fragmentation of **8** (Scheme 3), the process **9** → **14** → (*f*) → (*d*) most likely contributes to the intensity of the *m/e* 252 peak.

Experimental

The mass spectra were obtained on a Nuclide 12-90-G instrument, operated at 70 eV ionizing energy. The imidoyl halides were introduced by the direct insertion technique at a source temperature of 60°. A heated direct-inlet system was used for the iminium salts, with source temperatures as indicated in the text.

Imidoyl chlorides **1**, **3**, and **5** were prepared as described in the literature (19). The synthesis of imidoyl bromides and bromoiminium bromides are described (4, 5) or are to be described (20) in other papers in this series.

Theoretical Evidence for a Stable form of Cyclic Ozone, and its Chemical Consequences

JAMES S. WRIGHT

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 30, 1972

The total energy of the symmetrical, bent O_3 molecule is studied as a function of internuclear angle and internuclear distance. The method used is an *ab initio* molecular orbital calculation with a minimum basis set of Slater-type orbitals, plus limited configuration interaction. Best single configuration energies show the existence of *two* stable minima: a cyclic (60°) structure and a bent (115°) structure. The cyclic structure is preferred by 48 kcal/mol, contrary to experiment (116° 48′). Configuration interaction results with two low lying orbitals show the cyclic form still preferred by 6 kcal/mol. A transition state for the bent-cyclic pathway lies 26 kcal/mol (or less) above the bent form. Based on these results, a possible low energy path via the cyclic form is proposed for the thermal decomposition of ozone. It is also proposed that cyclic ozone may have been observed in the pulse radiolysis of oxygen.

L'énergie totale de la molécule O_3, symétrique et recourbée, a été étudiée en fonction de l'angle et de la distance internucléaires. La méthode utiliséé est celle du calcul *ab initio* des orbitales moléculaires avec unsystème minimal d'orbitales de base de type Slater plus une interaction limitée de configuration. Les meilleures énergies pour une configuration simple montrent l'existence de deux minima stables = une structure cyclique (60°) et une structure recourbée (115°). La structure cyclique est plus favorisée de 48 kcal/mol, contrairement à l'expérience (116° 48′). Les résultats de l'interaction de configuration avec deux orbitales basses montrent encore une préférence pour la forme cyclique de 6 kcal/mol. Un état de transition par le chemin réactionnel "cyclique-courbé" se situe à 26 kcal/mol (ou moins) au dessus de la forme courbe. Ces résultats montrent l'existence d'une voie réactionnelle possible de basse énergie, via la forme cyclique, pour la décomposition thermique de l'ozone. L'ozone cyclique a pu être observé lors de la radiolyse pulsée de l'oxygène, comme cela à été proposé. [Traduit par le journal]

Introduction

The structure determination of the ozone molecule has an interesting history, with much discussion revolving around the interpretation of the gas-phase infrared spectrum. A review by Mulliken (1) in 1942 strongly supported the analysis of the i.r. spectrum by Hettner *et al.* (2), stating that ozone has an acute-angled structure (an isosceles triangle), with the unique internuclear angle $\theta = 39°$.

In 1943 an electron diffraction result (3) showed a symmetrical bent structure with $\theta = 127°$.

Herzberg (4) in 1945 criticized the acute-angled model and vibrational assignment of Hettner *et al.* (2) as leading to an abnormally high force constant between the two closer O-atoms; however, he also pointed to difficulties if the ozone spectrum were assigned to a symmetrical, bent obtuse-angled structure. The spectral difficulties were apparently resolved when Wilson and Badger (5) discovered a previously hidden vibrational peak at 1110 cm^{-1} and assigned the three fundamental frequencies as arising from a symmetrical bent structure, with $\nu_1 = 1110\ cm^{-1}$ (symmetric stretch), $\nu_2 = 705\ cm^{-1}$ (symmetric bend), and $\nu_3 = 1043\ cm^{-1}$ (antisymmetric stretch). Precise microwave studies by Trambarulo *et al.* (6), Kaplan *et al.* (7), and Hughes (8), who assumed the frequencies of Badger and Wilson (5), gave a bent structure with $R = 1.278 \pm 0.002$ Å, $\theta = 116° 45′ \pm 30′$. This was confirmed by an analysis of the far-i.r. spectrum by Danti and Lord (9), and is considered to be the definitive result for the ozone structure. An *ab initio* molecular orbital calculation by Peyerimhoff and Buenker (ref. 10, hereafter referred to as P–B) gave $\theta = 118.5°$, in good agreement with the previous experimental result. Thus theory and experiment agree that ozone possesses a symmetrical, bent structure.

However, the chemistry of ozone is quite puzzling when one assumes this structure. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

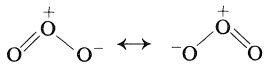
can be seen by considering the bond energies for ozone and molecular oxygen, and by the activation energies for $O_3 \rightarrow O_2 + O$ and the reverse reaction. The *mean thermochemical bond energy* of ozone can be derived from the following thermocycle (11):

$$\begin{aligned} O_2(g) + \tfrac{1}{2}O_2(g) &\rightarrow O_3(g) & \Delta H_f^0 &= 34 \text{ kcal/mol} \\ 2O &\rightarrow O_2(g) & \Delta H^0 &= -118 \text{ kcal/mol} \\ O &\rightarrow \tfrac{1}{2}O_2(g) & \Delta H^0 &= -59 \text{ kcal/mol} \\ O + O + O &\rightarrow O_3(g) & \Delta H^0 &= -143 \text{ kcal/mol} \end{aligned}$$

Since the bent ozone structure has two bonds, the mean thermochemical bond energy is 71.5 kcal/mol per bond. However, the *bond dissociation energy* of ozone is quite different

$$O_3 \rightarrow O_2 + O \quad \Delta H^0 = -34 + 59 = +25 \text{ kcal/mol}$$

The bond dissociation energy of 25 kcal/mol, defined as the energy necessary to break the first bond, is far less than the mean thermochemical value of 71.5 kcal/mol. Writing resonance structures for ozone as



suggests that the bond is intermediate between single and double. Using Pauling's figures (11) of 33 kcal/mol for O—O and 96 kcal/mol for O=O (based on the energy of the $^1\Delta_g$ state) leads to an approximate bond energy of 65 kcal/mol; this is reasonably consistent with the mean thermochemical bond energy but gives no clue as to why the bond dissociation energy should be so low.

The kinetics of the gas phase thermal decomposition of ozone were studied by Benson and Axworthy (12) at temperatures near 100 °C. Assuming the mechanism

$$M + O_3 \underset{k_2}{\overset{k_3}{\rightleftharpoons}} M + O_2 + O$$

$$O_3 + O \xrightarrow{k_3} 2O_2 \quad M = O_3, O_2, N_2, \text{etc.}$$

they obtained

$$k_1 = 4.61 \times 10^{12} \exp(-24\,000/RT) \text{ l/mol s}$$

$$k_2 = 6.00 \times 10^{7} \exp(+600/RT) \text{ l}^2/\text{mol}^2 \text{ s}$$

$$k_3 = 2.96 \times 10^{10} (-6\,000/RT) \text{ l/mol s}$$

The activation energy is thus 24 kcal/mol for the ozone decomposition and negative (0.6 kcal/mol) for its formation. The bond dissociation energy and the activation energy are essentially identical.

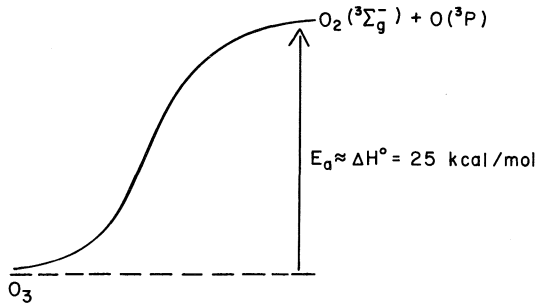


FIG. 1. Thermal activation barrier for $O_3 \rightarrow O_2 (^3\Sigma_g^-) + O (^3P)$.

These energy relationships are diagrammed in Fig. 1.

The activation barrier is seen to be simply the thermochemical energy difference between O_3 and $O_2 + O$. Now the remarkable thing about this barrier is that it is so small; much below the bond energy for bent ozone. This fact would be more understandable if ozone had an acute-angled structure such as

with one relatively intact O_2 molecule and a more distant oxygen atom, weakly held by two equivalent bonds. Indeed, this was pointed out by Herzberg (4) in 1945. Another structure which would be possible is the asymmetric bent structure

with one short and one long bond. Although both the acute-angled and asymmetric structures could be used to explain the infrared spectrum (4), they were excluded on the basis of the electron diffraction result (3) (symmetrical, bent, $\theta = 127°$, $R = 1.26$ Å) and microwave studies (6–8) (symmetrical, bent, $\theta = 116° 45'$, $R = 1.278$). The very low dissociation energy of ozone is therefore difficult to understand.

Another interesting aspect of ozone chemistry which is not well understood is the formation of an ozone "precursor" in the pulse radiolysis of oxygen at atmospheric pressure. According to Riley and Cahill (13), a transient species identified by previous workers (14) as vibrationally excited ozone is incorrect, and they find an ozone precursor with an ultraviolet spectrum distinct from ozone itself. The identity of this precursor was not established, but it was thought to be a distinct chemical species.

It is now proposed that the low bond dissociation energy, and possibly the ozone precursor, can be explained in terms of a new structure: *cyclic ozone.*

A structure in which the oxygen atoms form an equilateral triangle has been discussed by Pauling (ref. 11, p. 87) as a possible ozone geometry; he discards this structure as being unfavored in bond energy (33 kcal/mol per single bond = 99 kcal/mol total) relative to the observed value of 143 kcal/mol. However the calculations of Pererimhoff and Buenker (10) showed a secondary minimum near $\theta = 70°$ (primary minimum at 118.5°) of almost the same energy as the favored bent configuration, the difference between the two minima being about 10 kcal/mol.[1] Because the calculations of P–B focused on the energy variation as a function of internuclear angle θ, and assumed a fixed bond distance of 2.50 a.u. (1.323 Å), it was not clear whether this distance would favor the cyclic or bent structure. Therefore this study was undertaken to examine the variation of energy as a function of internuclear angle and internuclear distance, assuming a symmetric (C_{2v}) structure. As will be shown, closed-shell single configuration minima were found at two angles: 60° (the cyclic structure) and 115° (the experimental structure). The fact that the cyclic structure is energetically *preferred* in these calculations is a startling result, and suggests that the thermal decomposition may proceed through the following path

$$O_3(115°) \xrightarrow{\text{(slow)}} O_3(60°) \xrightarrow{\text{(fast)}} O_2 + O$$

Method

The Roothaan self-consistent field equations (15) are solved using a minimum basis set of Slater-type orbitals. The *ab initio* molecular orbital program used was written by Stevens, and has been described elsewhere (16).[2] All calculations use Clementi's (17) "best atom" exponents for the basis orbitals: $1s_0 = 7.658$, $2s_0 = 2.2458$, $2p_0 = 2.2266$. A check on the program was made by recalculating the minimum basis set result for ozone of Petrongolo *et al.* (18); the two calculations gave identical results. For a given choice of θ, the O—O—O angle, three values of R_{O-O} were used so that an optimum bond distance is established at each angle θ. C_{2v} symmetry was assumed throughout, with the same coordinate axes and symmetry orbitals as used by P–B.

TABLE 1. MO notation and orbital occupancy (C_{2v}) for various closed-shell configurations

Configuration wavefunction	P–B notation	Orbital occupancy (filled)			
		a_1	a_2	b_1	b_2
ψ_1	$\{2b_1^2\}$	6	1	1	4
ψ_2	$\{6a_1^2\}$	5	1	2	4
ψ_3	$\{4b_2^2\}$	6	1	2	3
ψ_4	$\{1a_2^2\}$	6	0	2	4
ψ_5		7	0	2	3

Semilocalized Orbitals and Electron Configuration

To discuss the various possible electronic configurations, the notation of P–B is adopted. Table 1 shows the relevant closed shell electronic configurations. The first column gives a wave function designation by which the configuration may be identified, the second column shows the symbol of P–B used for this wave function, and succeeding columns show the orbital occupancy of each symmetry type in C_{2v} symmetry. The configuration ψ_5 was thought to be important by Mulliken (1) for the acute-angled ozone; this is included along with the configurations $\psi_1 - \psi_4$ studied by P–B.

As shown in Fig. 4 (*a*) of P–B, as θ is closed from 180° to 60° there is a change of ground state configuration from ψ_1 to ψ_3 which occurs near 90°. In this region there is an orbital crossing between the $4b_2$ and $2b_1$ molecular orbitals. Put more simply, two electrons from the π-bond in bent ozone (2 σ-, 1 π-bond) are transferred to a σ-bond in cyclic ozone (3 σ-bonds). The orbitals which are involved here and in the discussion to follow may conveniently be referred to in terms of semi-localized symmetry orbitals.[3] Assuming cyclic ozone to be sp^3 hybridized and bent (~120°) ozone to be sp^2 hybridized (20), the orbitals are shown and classified according to their C_{2v} symmetry type in Figs. 2 and 3. The

[1]Estimated from Fig. 4, P–B.

[2]All calculations on ozone assumed C_{2v} symmetry. Since the program uses molecular symmetry to reduce integral evaluation times, a typical calculation required 5 min of IBM 360/65 CPU time.

[3]See ref. 19 for a similar treatment for cyclobutane.

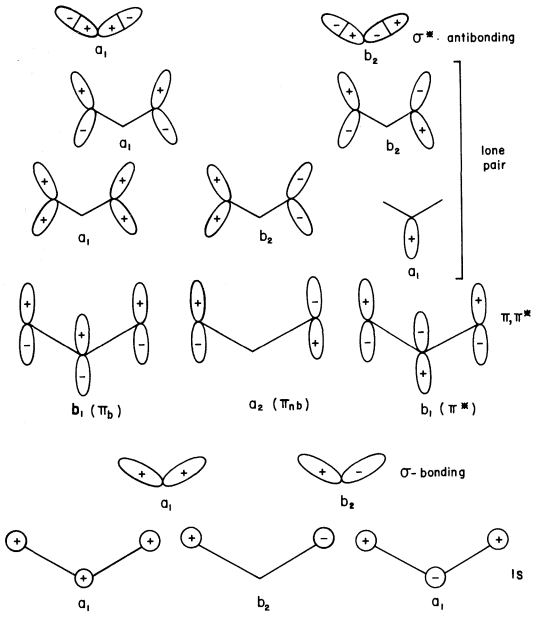

FIG. 2. Semilocalized orbitals for bent (120°) ozone (sp^2, p-hybridization is assumed, with σ, lone pair, and σ* orbitals in the molecular plane, and π, π* orbitals perpendicular to it).

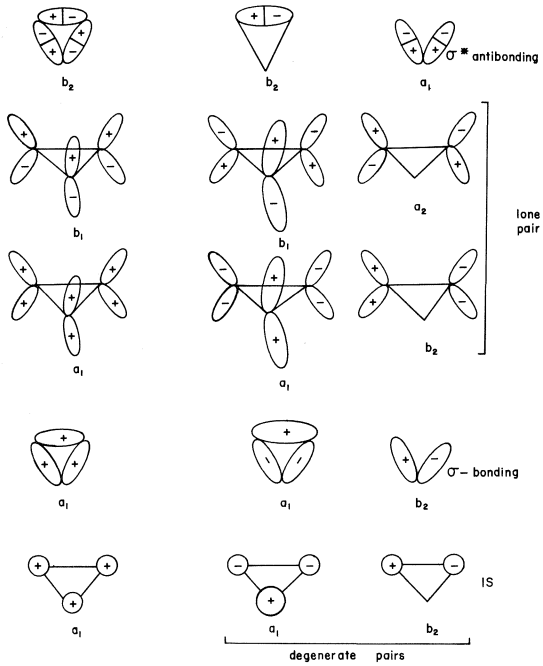

FIG. 3. Semilocalized orbitals for cyclic (60°) ozone (sp^3-hybridization assumed).

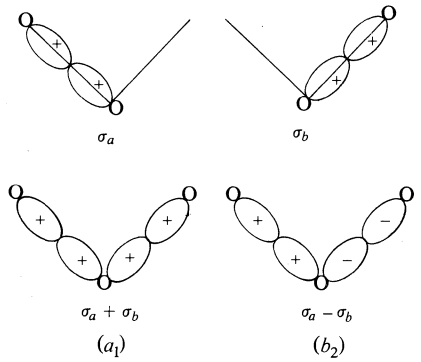
orbitals are also identified at the right by their common names. (A less familiar notation is introduced in Fig. 2, where the π-nonbonding orbitals are distinguished by the subscripts nb, π_{nb}.) In Fig. 2, all orbitals except the π π* lie in the plane of the molecule. The σ-bonding orbitals, for example, are formed by the bonding overlap of sp^2 hybrids:



The lone pair symmetry orbitals (Fig. 2) are derived as symmetric (a_1) and antisymmetric (b_2) combinations of the lone pair sp^2-hybridized basis orbitals. In Fig. 3 the lone-pair orbitals lie outside the plane of the ring, with the other orbitals (1s, σ, σ*) lying in plane. At 60° the C_{2v} group becomes D_{3h}, and the orbitals which actually represent degenerate pairs are grouped together.

The electronic configurations of the bent and cyclic forms can now be guessed by inspection of the semilocalized orbitals. Ozone has 24 electrons, so in the bent structure (Fig. 2) all orbitals will be doubly occupied except the π* and σ*, which are empty. The configuration is therefore $(6a_1)^2(1a_2)^2(1b_1)^2(4b_2)^2$. The $1a_2$ orbital (π_{nb}) is expected to be the highest occupied, and $2b_1$ orbital (π*) the lowest vacant orbital. In cyclic ozone the three antibonding σ* orbitals will be vacant, and the others filled. The configuration of cyclic ozone is thus $(6a_1)^2(1a_2)^2(2b_1)^2(3b_2)^2$ which is different from that of bent ozone. Nodal properties indicate that the $1a_2$ lone pair (or its degenerate equivalent $2b_1$) should be the highest occupied, and the unique b_2 σ* the lowest vacant orbital. We shall see that these results are borne out by the MO calculations.

Results and Discussion

Table 2 shows the variation in the total energy as a function of θ and R. In this table, ψ denotes the electronic configuration referred to in Table 1,

TABLE 2. Energy variation as a function of internuclear angle (optimum R)

*At θ = 40° only a single data point was taken, where R = 3.1 a.u.

R_0 is the optimum distance and E_0 the optimum energy for this (single) configuration. E represents the energy obtained on doing a 3 × 3 configuration interaction calculation based on ψ and its virtual orbitals, and R is the distance which optimizes the CI energy (the CI treatment will be discussed following the analysis of single-configuration energies and molecular orbitals). Except for one calculation at 40° which includes ψ_5, data are given only for configurations ψ_1 and ψ_3 (for configurations ψ_2 and ψ_4 refer to P–B), since these are relevant to a study of the ground state of ozone.

The results in Table 2 are shown graphically in Fig. 4. The dashed lines show the single configuration energies ψ_1 and ψ_3 as a function of θ with R optimized. There is a clear minimum for ψ_1 at θ = 115°, R = 2.444 a.u. (1.291 Å), E_0 = −233.4793 a.u. This is in good agreement with the experimental result (8) of θ = 116° 45′, R = 1.278 Å. However, a much deeper minimum occurs for ψ_3 at θ = 60°, R = 2.677 a.u. (1.417 Å), E_0 = −223.5568 a.u. The cyclic configuration is seen to be a true equilateral triangle (θ = 60°) and its energy is below that of the bent (115°) structure by a remarkable 48 kcal/mole! When one considers that *ab initio* minimum basis set calculations are quite reliable for predictions of molecular geometry (22), this result is indeed surprising. It suggests, on the one hand, that minimum basis set calculations even for comparisons among closed shell molecules can be unreliable by an amount of the order of 2 eV. On the other hand, it also suggests that cyclic ozone should exist as a stable secondary minimum.

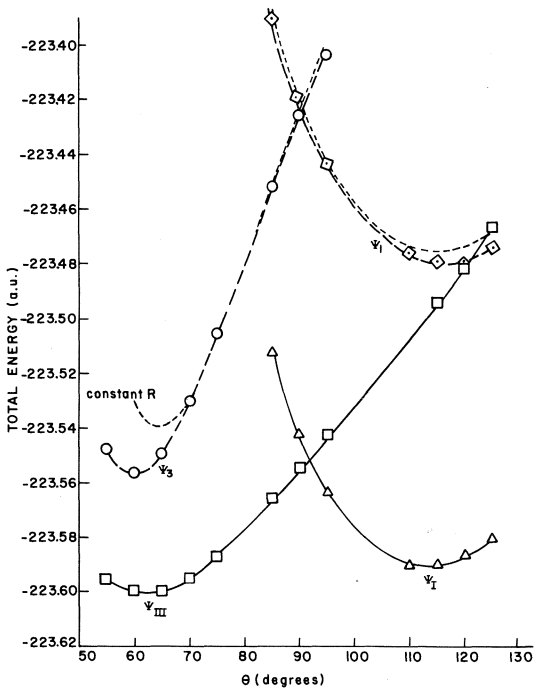

FIG. 4. Variation of the total SCF energy as a function of θ, with R optimized at each angle.

†Considerable mixing occurs between chemical types of symmetry a_1 and b_2.

The importance of including bond distance R as a variable in the calculations is seen by inspection of Table 2, where the optimized R_0's vary from 2.760 a.u. (1.461 Å) for ψ_3 at 55° to 2.432 a.u. (1.287 Å) for ψ_1 at $\theta = 125°$. Since P–B used only a single distance of $R = 2.50$ a.u. for their calculations, the minimum basis set result at $R = 2.50$ a.u. has been included in Fig. 4 (dotted line) for comparison with the result at optimum R (dashed line). Although the fixed-R calculation correctly predicts a minimum at $\theta = 115°$, it incorrectly shifts the energy minimum for the cyclic configuration to $\theta = 65°$. This is because the ring has not been allowed to expand as it closes.

A single data point at $\theta = 40°$, $R = 3.1$ a.u. was calculated to test the prediction of Mulliken (1) that an acute-angled ozone of these approximate dimensions would have electron configuration ψ_5. As shown in Table 2, however, ψ_5 lies far above ψ_3 in energy so calculations using ψ_5 and acute-angled geometries ($\theta < 55°$) were not pursued.

The molecular orbital energies and orbital types for configurations ψ_1 and ψ_3 near their respective minima are listed in Table 3. For ψ_1 the smallest energy gap occurs for the $1a_2$–$2b_1$ (π-π^*) transition, followed by $6a_1$–$2b_1$ and $4b_2$–$2b_1$. The low lying excited states so formed will be of B_2, B_1, and A_2 symmetry, the latter resulting from a forbidden transition. The π–π^* transition is allowed and should be relatively intense. For ψ_3 low lying transitions will be from the degenerate pair ($1a_2$,$2b_1$) to the vacant orbital $4b_2$. These will not give rise to intense absorption. However, the transitions from the pair ($6a_1$,$3b_2$) to $4b_2$ are strongly allowed. It is possible that the u.v. spectrum of the "ozone precursor" is due to this transition, the distinctive u.v. transition being due to the cyclic rather than the bent form of ozone.

The difference in energy between cyclic and bent structures is considerably ameliorated by the introduction of configuration interaction. Figure 4 shows the CI state energies (solid line) for states formed from ψ_1 (labelled ψ_I) and ψ_3 (labelled ψ_{III}) by introducing a 3 × 3 CI in the following way. The virtual orbitals chosen for the CI calculation were those which interact strongly with the ground state. For the double excitation $(\phi_i)^2 \rightarrow (\phi_j)^2$, where two electrons are promoted from occupied molecular orbital ϕ_i to vacant molecular orbital ϕ_j, the interaction was considered important if the energy gap $(E_j - E_i)$ was small and the exchange integral K_{ij} was large. This led to the following CI scheme:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

TABLE 4. Calculated values of θ, R, and E

Structure	θ (deg.)	R (a.u.)	E (kcal/mol)
Cyclic	62.5	2.690	0
Transition state	92	~2.60	31
Bent	112.5	2.487	6

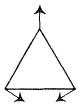
That is, in the bent configuration there is a strong π_{nb}–π^* interaction as well as the π_b–π^* interaction and the CI is very important. Interaction is weaker, but still significant in the cyclic system, where the double excitation now promotes electrons from lone pair (non-bonding) oxygen orbitals to an antibonding σ* orbital. The bent structure is strongly stabilized by an amount 0.1117 a.u. (70.0 kcal/mol) and its energy minimum is slightly shifted (θ = 112.5°, R = 2.487 a.u.). The cyclic structure is stabilized by an amount 0.0437 a.u. (27.4 kcal/mol) with its energy minimum also slightly shifted (θ = 62.5°, R = 2.690 a.u.). The cyclic configuration is now favored by 223.6005 − 223.5910 = 0.0095 a.u. or 6.0 kcal/mol. Since the bent structure has more low-lying orbitals available to it than the cyclic (see discussion to follow, or Fig. 4 or P–B), further introduction of CI should favor the bent structure relative to the cyclic. The correlation correction thus introduced would then be expected to lead to agreement with the experimental results,[4] with the bent structure becoming the most stable.

An indication of the activation energy for the bent-cyclic interconversion is seen by following the variation of ψ_I and ψ_{III} in Fig. 4. The states ψ_I and ψ_{III} have the same energy E = −223.551 a.u. at θ = 92°. Since ψ_1 and ψ_3 are both closed-shell configurations they are both totally symmetric and thus the CI calculation based on ψ_1 and ψ_3 should show an avoided crossing. This is not taken into account in the limited CI actually performed, which shows a genuine crossing of ψ_I and ψ_{III}. The two configurations ψ_1 and ψ_3 differ in the occupancy of the orbitals $2b_1$ and $4b_2$, so if the CI had included the $2b_1$–$4b_2$ excitation the crossing of ψ_I and ψ_{III} should become avoided. However, the difference in spatial properties of the $2b_1$ (a π* type) and $4b_2$ (a σ* type) orbitals leads to a very small exchange integral between the two (about 0.01 a.u., compared to K_{ij} = 0.20 a.u. for $1a_2 \rightarrow 2b_1$) so that the actual crossing point shown for ψ_I and ψ_{III} should be near to, and slightly above, the energy of the true avoided crossing. The crossing point of ψ_I and ψ_{III} thus gives an estimate of the energy of the transition state for the bent-cyclic interconversion. Ignoring zero-point energy differences, the results derived from these calculations, where relative energies are indicated, are listed in Table 4. These results indicate that the cyclic and bent forms of ozone are of comparable stability, with a transition state for interconversion between the two lying 25–30 kcal/mol above.

Since this is close to the observed energy for the thermal decomposition of ozone, it suggests the possible reaction scheme

$$O_3(\text{bent}) \xrightarrow{\text{slow}} O_3(\text{cyclic}) \xrightarrow{\text{fast}} O_2 + O$$

The cyclic ozone should decompose more easily than the bent ozone because it contains three single bonds. A normal mode leading to O_2 + O would then be the degenerate bending vibration[5]



The exploration of this decomposition pathway would be quite interesting. A complete potential surface for the $O_3 \rightarrow O_2$ + O reaction should therefore include the region around the cyclic

[4]The program used is capable of dealing with extended basis sets of Slater-type orbitals. A double-ξ calculation would be interesting as an approximation to the H–F limit for cyclic and bent ozone. This was seriously considered but eventually rejected as too expensive. See, however, an important paper which appeared when this manuscript was completed, which deals with this question also (21).

[5]It has been pointed out (21) that if ozone were an equilateral triangle (D_{3h}) it would decompose into the excited state products $O(^1D) + O_2(^2\Delta_g)$. However, if ozone has C_{2v} symmetry (θ ≠ 60°) the decomposition to $O(^3P) + O_2(^3\Sigma_g^-)$ is allowed. Since it is not certain whether the cyclic molecule has θ = 60°, the correlation with products is uncertain. Also, if ozone has symmetry D_{3h} the degenerate bending vibration is i.r.-active but the ring breathing vibration is not (4). If cyclic ozone were indeed of comparable stability to bent ozone, the bending peak should be present in the ozone i.r. spectrum.

Pressure Dependence of Product Yields in the Direct Photolysis of Methanol Vapor at 1849 Å

O. Sonia Herasymowych[1] and Arthur R. Knight

Departments of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 6, 1972

Hydrogen and methane yields from the 1849 Å photolysis of methanol vapor in an all-quartz system have been investigated as a function of exposure time and pressure of CH_3OH and added CO_2.

Product yields are decreased by the inert addend, and by the substrate itself at high pressures, in contrast to the collision-induced quantum yield enhancement reported to be occurring in this system.

La quantité libérée d'hydrogène et de méthane, lors de la photolyse du méthanol gaseux à 1849 Å dans un système en quartz, a été étudiée en fonction du temps d'exposition et de la pression du méthanol et de CO_2 ajouté.

Les rendements en produits sont diminués par l'addition du composé inerte et par le substrat lui-même à des pressions élevées au contraire de l'augmentation du rendement quantique, induite par des collisions, qui est rapporté se presenter dans ce système. [Traduit par le journal]

Can. J. Chem., **51**, 147 (1973)

It has been reported (1–3) that in the photolysis of methanol vapor in a Pyrex system at 1849 Å a quantum yield enhancement, ascribed to collision-induced predissociation, results from increasing substrate pressure or inert addend pressure. A recent investigation (4) of the photolysis of 2-propanol vapor at 1800–2000 Å carried out in this laboratory, however, indicated that product yields decrease with increasing addend pressure, suggesting a fundamental difference in the two systems. Because the methanol system represents the only reported case of collision-induced predissociation in a polyatomic system, and the possibility that the investigation of CH_3OH may be complicated by the formation of trimethyl borate when methanol vapor is in contact with boron containing glass (5), we have reinvestigated the direct photolysis of methanol vapor at 1849 Å in an all quartz, mercury free system.

Fisher reagent methanol was distilled from sodium into a quartz storage vessel and photolyzed at 25 °C in a 20 cm × 4.5 cm o.d. Supracil cell using a Hanovia LO 735A-7 low pressure Hg resonance lamp. Products non-condensable at −196 °C, H_2, and CH_4, were removed through a liquid nitrogen trap to an auxiliary system where they were measured in a gas burette and subsequently analyzed by g.c. Over the range 5–60 min, the yields of hydrogen and methane were found to vary linearly with exposure time.

Figure 1 shows the observed dependence of $R(H_2)$ and $R(CH_4)$ on methanol pressure. Both rates behave in the same manner, increasing up to

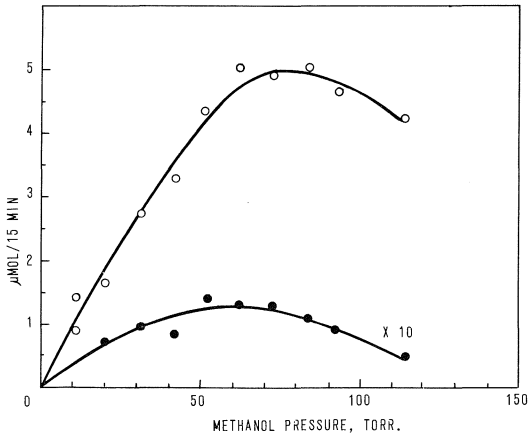

FIG. 1. Rate of formation of hydrogen, ○, and methane, ●, (× 10) in the 1849 Å photolysis of methanol vapor at 25 °C, as a function of CH_3OH pressure, for an exposure time of 15 min.

[1]Present address, Department of Chemistry, University of Alberta, Edmonton, Alberta.

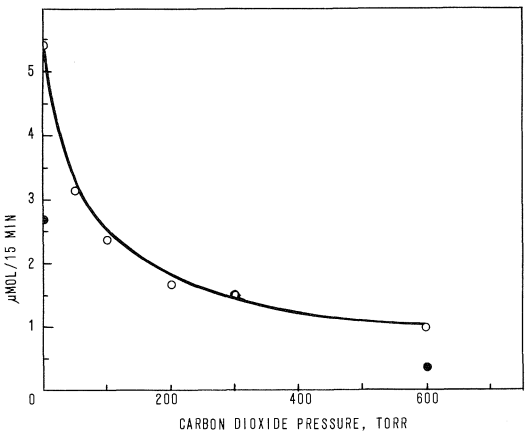

FIG. 2. Rate of formation of hydrogen in the 1849 Å photolysis of methanol vapor at 25 °C and a pressure of 84 Torr, ○, and 31 Torr, ●, as a function of pressure of added carbon dioxide.

$P(CH_3OH) \simeq 60$–70 Torr and thereafter showing a decrease. The proportion of hydrogen and methane formed is consistent with the observations of Porter and Noyes (6) who suggested that *ca.* 5% of the primary process results in the formation of CH_3 radicals. Both Hagege *et al.* (3) and Porter and Noyes (6) have reported that $R(H_2)$ increases continuously up to about 100 Torr methanol. In the latter investigation, however, such an increase is to be expected since a monochromatic light source was not employed. The increase in yields in the low pressure region observed in the present investigation can be ascribed, at least in part, to increased absorption in the reaction cell. A Beer's law calculation indicates that at 1849 Å absorption should be complete at $P(CH_3OH) = 10$ Torr, but unless a perfectly collimated and focused light beam were employed higher pressures might be required.[2]

[2]For example, only 87% absorption was found at 1849 Å at $P(CH_3OH) = 12$ Torr in the cell using a Zeiss PMQ II spectrophotometer with the photolysis lamp as light source. Such measurements determine the absorption through only a small fraction of the total cross section of the light beam.

Wall recombination of hydrogen atoms may also be important since Hagege *et al.* (3) report a dependence of yields on cell geometry.

The rate of hydrogen formation was determined in a series of experiments carried out with up to 600 Torr of CO_2 at methanol pressures of 84 and 31 Torr. The results are given in Fig. 2 and show a very definite decline as the pressure of addend is increased at both substrate pressures. Carbon dioxide was chosen for investigation since this inert addend was reported (2, 3) to be the most efficient in promoting the observed increase in hydrogen quantum yields.

On the basis of the results reported here it would appear that the methanol photolysis at 1849 Å proceeds, at least in part, via an excited state of sufficient longevity to be susceptible to collisional deactivation by either an inert addend or by the substrate itself. The deactivational process is manifested by observed decreases in $R(H_2)$ when the addend is present and at high pressures of the substrate.

Thus when the methanol system is investigated under conditions where the formation of trimethyl borate is not possible, its behavior closely parallels that of 2-propanol and no evidence is obtained for collision induced predissociation.

Charge Scavenging by Benzene in γ-Irradiated Liquid Cyclohexane

MICHAEL G. KENNEDY AND JOHN A. STONE
Chemistry Department, Queen's University, Kingston, Ontario

Received September 20, 1972

The effect of benzene on the yield of propane formed by H_2 transfer to cyclopropane in γ-irradiated liquid cyclohexane has been used to determine the efficiency of cation scavenging by benzene. The reduction of the hydrogen yield from cyclohexane by the addition of low concentrations of benzene may be accounted for by a combination of cation and H atom scavenging. G(benzene in polymer) found in previous studies correlates well with G(H atoms scavenged).

L'effet du benzène sur le rendement en propane, découlant du transfert d'hydrogène sur le cyclopropane dans le cyclohexane liquide γ-irradié, a été utilisé pour déterminer l'efficacité du piègeage du cation par le benzène. La baisse du rendement en hydrogène à partir du cyclohexane par addition de faibles concentrations en benzène, peut être attribuée à la combinaison du cation et de l'atome d'hydrogène piégé. Le G(pour le benzène dans le polymère) tiré des études antérieures est en bonne corrélation avec le G(pour les atomes d'hydrogène piégés). [Traduit par le journal]

The non-linear relationship between the reduction of the hydrogen yield from irradiated liquid cyclohexane and the concentration of added benzene was one of the earliest phenomena studied in radiation chemistry (1, 2). Many mechanistic explanations have been advanced including "excitation" transfer, H atom scavenging, charge transfer, and combinations of all three. (A discussion of published results and suggested mechanisms is given in ref. 3.) Recent pulse radiolysis studies have suggested that benzene is a positive ion scavenger in cyclohexane (4) and that it is also a somewhat inefficient H atom scavenger (5). We have confirmed the positive ion scavenging and have investigated its contribution to the overall decrease in hydrogen yield by measuring the effect of benzene on the propane formed by H_2 transfer to cyclopropane from the cyclohexane molecular ion (6).

[1] $\text{cyclo-}C_6H_{12}^+ + \text{cyclo-}C_3H_6 \rightarrow \text{cyclo-}C_6H_{10}^+ + C_3H_8$

Propane yields in the presence and absence of 0.09 M benzene are shown in Fig. 1. The experimental points have been fitted by the expression developed by Warman, Asmus, and Schuler (6). In the absence of benzene

$$G(\text{propane}) = 0.63\left[G_{fi} + \frac{G_{gi}\sqrt{\alpha_1[\Delta]}}{1+\sqrt{\alpha_1[\Delta]}}\right]$$

while in the presence of benzene

$$G(\text{propane}) = 0.63\left[G_{fi} + \frac{G_{gi}\sqrt{\alpha_1[\Delta]+\alpha_2[B]}}{1+\sqrt{\alpha_1[\Delta]+\alpha_2[B]}}\right]\left[\frac{\alpha_1[\Delta]}{\alpha_1[\Delta]+\alpha_2[B]}\right]$$

Where Δ and B are cyclopropane and benzene, respectively, G_{fi} is the yield of free ions = 0.15 (7), G_{gi} is the yield of geminate ions = 3.8 (6), and α_1 and α_2 are constants which are measures of the relative rates of electron-geminate ion combination and positive charge scavenging by cyclopropane and benzene, respectively. The correction factor 0.63 is used since only 63% of the ion scavenging by cyclopropane occurs via reaction 1 to yield propane (8). The curves are drawn with $\alpha_1 = 0.40\ M^{-1}$ and $\alpha_2 = 1.20\ M^{-1}$. Benzene is therefore three times as efficient a cation scavenger as is cyclopropane and is also slightly more efficient than ND_3 ($\alpha = 0.85\ M^{-1}$ (9)). The above interpretation assumes that the low concentration of benzene does not significantly change the spatial distribution of the electrons at thermalization and that propane is formed solely by the H_2 transfer reaction (reaction 1).

The extent of ion scavenging by benzene in irradiated solutions of benzene in cyclohexane may now be calculated from

$$G(\text{ions scavenged}) = 0.15 + \frac{3.8\sqrt{\alpha_2[B]}}{1+\sqrt{\alpha_2[B]}}$$

TABLE 1. Calculated and experimental reductions in $G(H_2)$ for dilute solutions of benzene in cyclohexane

Benzene (M)	G(ions scavenged)	$G(H\cdot)$	$G(H\cdot$ scavenged)	$\Delta G(H_2)$ Calcd.	$\Delta G(H_2)$ Expt.
1.00×10^{-3}	0.27	1.40	0.005	0.28	0.19
5.00×10^{-3}	0.41	1.37	0.025	0.43	0.33
1.00×10^{-2}	0.51	1.35	0.049	0.56	0.47
5.00×10^{-2}	0.87	1.26	0.20	1.07	1.07
1.00×10^{-1}	1.10	1.21	0.33	1.43	1.42
2.00×10^{-1}	1.26	1.18	0.51	1.87	1.87
3.00×10^{-1}	1.53	1.12	0.60	2.13	2.23

The value of this function is shown in column 2 of Table 1. Since a negligible amount of hydrogen arises from benzene at this concentration (10) G(ions scavenged) may be equated to the reduction in hydrogen yield due to ion scavenging. The measured reduction exceeds this at benzene concentrations greater than 1.00×10^{-2} M (Table 1, column 6). $G(H) = 1.46$ in cyclohexane, 61% of this having ionic precursors (11). Positive ion scavenging will reduce the yield of H atoms and this reduced yield is calculated and presented in column 3. $k_{H+C_6H_6}/k_{H+cyclo-C_6H_{12}} = 35$ (5) is used to determine the number of H atoms scavenged by benzene (column 4). The total calculated reduction in $G(H_2)$ (columns 2 plus 4) appears in column 5.

The agreement between columns 5 and 6 is far greater than is warranted by the experimental uncertainty of at least ± 0.10 in the measured values of $G(H_2)$ and the stated uncertainty in the ratio of rate constants ($\pm 40\%$). Within the limitations imposed by these uncertainties the results show that the reduction in hydrogen yields by benzene *over the concentration range studied* may be completely ascribed to a combination of positive ion and H atom scavenging.

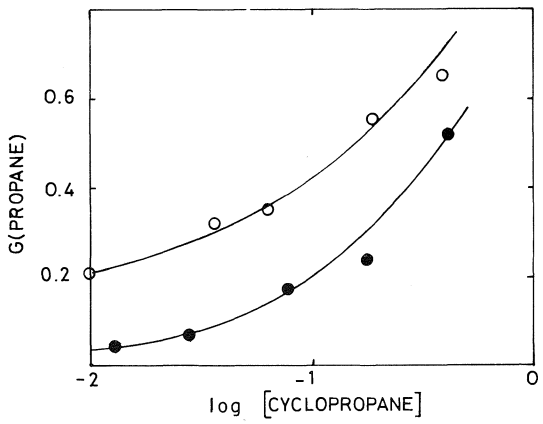

FIG. 1. Propane yields from cyclopropane in cyclohexane in the absence ○ and presence ● of benzene. The curves are calculated as described in the text.

TABLE 2. Propane yield from cyclo-C_6H_{12}/cyclopropane (1.6×10^{-2} M)/carbon tetrachloride (0.26 M) solutions

Benzene (M)	G(Propane)
0	0.78
0.001	0.57
0.012	0.50
0.059	0.33
0.093	0.29
0.10	0.26
0.23	0.14

As a final check on the cation scavenging ability of benzene, propane yields were measured for solutions 1.6×10^{-1} M in cyclopropane and 0.26 M in CCl_4. The presence of the latter will extend the lifetime of the charge separated state leading to an increased propane yield and will eliminate the possibility of electron scavenging by benzene. The results in Table 2 confirm the occurrence of cation scavenging by benzene.

In the cyclohexane/benzene system G(benzene) is approximately 0.3 at 0.1 M benzene (10). The only benzene containing products found are phenylcyclohexane in very low yield ($G \sim 0.1$) (10) and a benzene containing polymer (12). At 1.0, 2.0, and 3.0×10^{-1} M benzene $G(-$benzene in polymer$) = 0.31$, 0.47, and 0.63, respectively (12), which are to be compared with G(H atoms scavenged) of 0.33, 0.51, and 0.60. This comparison strongly suggests that polymer formation is initiated by H atom addition to benzene and that charge transfer does not lead to the disappear-

For personal use only.

ance of benzene. Thomas and Mani (4) suggest that neutralization of the benzene cation leads to a diradical which can either decay to the ground state of benzene or give products. The above correlation favors the former mechanism.

Experimental

Conventional radiation chemical techniques were used for sample preparation and radiolysis (10). The samples containing propane were irradiated in Pyrex tubes with gas space no greater than 10% of the liquid volume. The propane yield was determined by gas solid chromatography using an F1 alumina column at 75 °C and the cyclopropane present as an internal standard. The dose rate in the ^{60}Co γ-source was 5.6×10^{17} eV ml^{-1} min^{-1} in cyclohexane and total doses of 1.1×10^{19} eV ml^{-1} were employed.

A Synthetic Route to Dihydrojasmone; Sulfuric Acid as Dethioacetalization Agent

TSE-LOK HO,[1] HONOR C. HO, AND C. M. WONG

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received August 11, 1972

Dihydrojasmone has been synthesized in three steps from the dithiane **2**. Hydrolysis of vinylic chloride and a dithioacetal group was achieved simultaneously using sulfuric acid. The scope of this dethioacetalization procedure has been explored.

La dihydrojasmone a été synthétisée en trois étapes à partir du dithiane **2**. Utilisant de l'acide sulfurique, l'hydrolyse du chlorure vinylique se fait simultanément avec celle du groupe acétal. Les possibilités de ce procédé de déthioacétalisation ont été explorées.

[Traduit par le journal]

Can. J. Chem., **51**, 153 (1973)

Organic chemists have long been fascinated with *cis*-jasmone (**1***a*) and dihydrojasmone (**1***b*)(1), the odoriferous constituents of the *Jasminum* family, and these molecules are still popular synthetic goals even though the pioneering work of Treff and Werner (2) was nearly forty years ago.[2]

These cyclopentenone derivatives, though of simple stuctures, continue to inspire the design of synthetic methods. Whenever there is a discovery of new synthon related to γ-diketones or cyclopentenones, chemists can hardly resist the temptation of applying it to the synthesis of these natural molecules. In particular, regiospecific hydration of γ-ketoacetylenes (3), Barton's nitrite photolysis of functionalizing a γ-position (4), pyrolytic rearrangement of cyclopropyl ketoesters (5), fragmentation of acylcyclopropanol derivatives (6), cleavage of cyclobutan-1,2-diols (secured in three steps from photocyclization of pentan-2,3-dione) (7), ynamine addition (8), decarbonylative ring contraction (9) of a cyclohexan-1,3-dione, internal Friedel–Crafts acylation of γ-lactones (10) with polyphosphoric acid, and numerous ancillary methods such as titanium-(III)-promoted generation of carbonyl from a

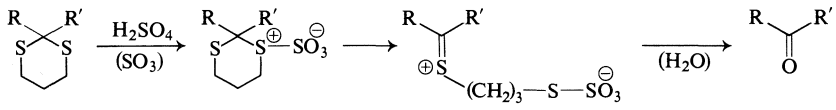
[1]To whom inquiries may be addressed.

[2]Clarification of the side-chain stereochemistry (*cis* double bond) of *cis*-jasmone was first reported by Crombie and Harper (25).



SCHEME 1

nitro group (11), Lindlar hydrogenation (5, 9, 11, 12), ceric ammonium nitrate dethioacetalization (1*a*), and Corey's methyl ketone synthesis (13) using dimsyl sodium, have been either developed specially or further extended in their utility, for this purpose.

We have for some time entertained the idea of synthesizing dihydrojasmone *via* a convenient route outlined as **2**→**3**→**4**→**1***b*. The dithiane **2** (14) is readily available from acid-catalyzed condensation between *n*-heptanal and 1,3-propanedithiol. Its metallation with *n*-butyllithium followed by alkylation with 1,3-dichlorobut-2-ene should present no unforeseen problems, as this type of reaction is now well-documented (15). And since cyclization of **4** → **1***b* is already known (1*a*), the only uncertainty remaining in the whole sequence would be the step **3**→**4**.

At the outset of our research utilizing this dithiane approach, we recognized the requisite of incorporating at C-2 a four-carbon segment with the proviso of subsequently transforming the γ-atom into a carbonyl group. Of the several precursors of this fragment which may be envisaged, 4-bromobut-1-yne, 1-bromobutan-3-one acetal, and thioacetal derivatives suffer, in one way or another, from the drawbacks of instability, low reactivity, and difficult availability, while 1,3-dichlorobut-2-ene does not have any of the above disadvantages.

As the hydrolysis of vinylic chloride is generally done by admixture with concentrated sulfuric acid (Wichterle reaction) (16), we were concerned about the survival of the dithioacetal group in **3** under such drastic conditions. However, it was imagined also, to the advantage of our synthetic strategy, that regeneration of the ketone from the dithiane protecting group could be accomplished during the same treatment. The rationale behind this conjecture lies in the fact that concentrated sulfuric acid is also a very strong oxidizing agent, capable of inducing a reaction such as that proposed in Scheme 1.

The feasibility of this novel procedure for dethioacetalization has been scrutinized, the results of which gratifyingly bear out our expectations. We were, in fact, greatly surprised and encouraged by the excellent yields (Table 1) obtained from this reaction, in comparison with those from known methods (15, 17, 18) and our other experiences with ceric ammonium nitrate (19), thallic trifluoroacetate (20), and methyl fluorosulfonate (21) mediated hydrolysis.

TABLE 1. Dethioacetalization with concentrated sulfuric acid

	Aldehyde or ketone	Yield % of parent compound	B.p. (m.p.) (°C)
1,3-Dithiolanes	Acetophenone	92	199–202
	Benzophenone	98	(237–239)†
	Benzil*	93	(92–94)
	Benzaldehyde	70	178–180
1,3-Dithianes	Phenylacetone	91	214–217
	Cycloheptanone	95	177–181

*Mono(dithiolane) of benzil.
†2,4-Dinitriphenylhydrazone.

In the synthesis of dihydrojasmone, the diketone **4** was obtained directly from **3** in 32% yield after standing in sulfuric acid for 20 min with subsequent quenching by ice-water. Optimization of this reaction has not been attempted, and the low yield must have been caused in part by inefficient dispersion of the sulfuric acid solution during the quenching process. Careful investigation by Marshall and Schaeffer (16) on this facet of the Wichterle reaction has led to yields of approximately 50%.

With the obtention of **4**, the synthesis of dihydrojasmone is formally completed. Recently there appeared a pertinent report (22) of *cis*-jasmone and dihydrojasmone syntheses via successive alkylation of the ethano-bisdithiane **5** (23) with methyl iodide and pentyl or pentenyl bromide.

Experimental

I.r. spectra were determined on a Perkin–Elmer 710 spectrophotometer. N.m.r. spectra were obtained on a Varian A56/60A spectrometer with TMS as internal standard. Analytical t.l.c. was performed using Eastman silica-coated sheets. Elemental analysis was done by

2-(n-Hexyl)-1,3-dithiane

A solution of *n*-heptanal (12.3 g, 0.11 mol) and 1,3-propanedithiol (12 ml) in chloroform (250 ml) was stirred for 1 h at room temperature. After addition of boron trifluoride etherate (5 ml) in one portion, the mixture was stored in the refrigerator for 16 h, washed with dilute alkali, dried over magnesium sulfate, and concentrated in a rotary evaporator. The residual oil was distilled to provide dithiane **1** (17.4 g, 87%), b.p. 122–126° (1.5 Torr); i.r. (CH_2Cl_2) 900 cm^{-1}; n.m.r. (CCl_4) τ 6.06 (1H, t, J = 6 Hz), 7.0–7.4 (4H, m), 9.11 (3H, t, J = 5 Hz).

Alkylation of Dithiane 2

A solution of *n*-butyllithium (2.3 *M* in hexane, Alfa Chemical Co., 4.8 ml, 11.0 mmol) was injected dropwise via a syringe into a stirred solution of dithiane **2** (2.0 g, *ca.* 10 mmol) in anhydrous tetrahydrofuran (15 ml) cooled to −35° under nitrogen. The mixture was kept at −35 to −25° for 3.5 h, and 1,3-dichlorobut-2-ene (1.30 g, 10.4 mmol) was then introduced slowly. The colorless solution turned orange, brown, then green and finally faded to light yellow during the addition. After 2 h at −20°, it was allowed to warm up gradually to room temperature overnight, poured into water, and extracted twice with ether. The combined ether extracts were dried ($MgSO_4$), and concentrated in a rotary evaporator. The residue was distilled to give the dithiane **3** (2.40 g, 82%), b.p. 150–152° (1.5 Torr); i.r. (CH_2Cl_2) 1660 cm^{-1}; n.m.r. (CCl_4) τ 4.47 (1H, txq, J = 6.5, J' = 1.5 Hz), 7.0–7.4 (6H, m), 7.88 (3H, m), 9.10 (3H, t, J = 5 Hz).

Anal. Calcd. for $C_{14}H_{25}ClS_2$: C, 57.34; H, 8.60. Found: C, 57.26; H, 8.65.

Undecan-2,5-dione

Admixture of dithiane **3** (190 mg, 0.65 mmol) with concentrated sulfuric acid (1 ml) at room temperature resulted in a thick, red solution. After standing for 20 min, it was added to a stirred mixture of ice and water. The turbid mixture was extracted with ether, and the extracts were dried ($MgSO_4$) and evaporated to yield an oil which was not resolvable on t.l.c. Therefore it was treated with Girard reagent T (200 mg) in methanol (5 ml, containing 0.2 ml glacial acetic acid) under reflux for 2 h. Standard work-up (24) afforded undecan-2,5-dione (38 mg, 32%), identical with (i.r., n.m.r., t.l.c.) an authentic sample (1*a*).

General Procedure for Hydrolysis of Dithioacetals

The dithioacetal (1 mmol) was homogenized with ice cold concentrated sulfuric acid (1 ml) and allowed to stand at room temperature for 10 min. The solution was then added to a vigorously stirred ice-water mixture and extracted with benzene. Solvent was removed from the dried extracts and the residue was processed by evaporative distillation, recrystallization from an appropriate solvent, or derivatized into the 2,4-dinitrophenylhydrazone. Identification of the product was performed by comparison (i.r., n.m.r.) with authentic specimen.

This work was supported in part by the National Research Council of Canada.

Mass Spectra of Some Sulfinate Esters and Sulfones

W. H. BAARSCHERS AND B. W. KRUPAY

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received June 14, 1972

The mass spectra of some alkyl arenesulfinates were found to be distinctly different from the spectra of the isomeric aryl alkanesulfinates. Both classes of compounds in turn could easily be distinguished mass spectroscopically from the sulfones with which they are isomeric. The preparation of a new aryl alkanesulfinate, $CH_3S(O)OC_6H_4CH_3$, is described.

Il a été trouvé que les spectres de masse de quelques arènesulfinates d'alkyle sont distinctivement différents des alcanes sulfinates d'aryle isomères. Chaque classe de composé peut par ailleurs être facilement distingué par spectrométrie de masse des sulfones isomères. La préparation d'un nouvel alcane sulfinate d'aryle, $CH_3S(O)OC_6H_4CH_3$ est décrite. [Traduit par le journal]

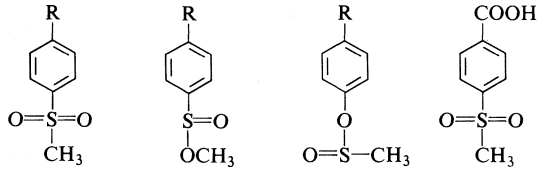
Introduction

The mass spectra of diaryl sulfones (1) and alkyl aryl sulfones (2) have been interpreted partly in terms of a rearrangement in which an aryl group migrates from sulfur to oxygen. In some cases there is evidence for the migration of alkyl groups (3). These migrations lead to the formation of sulfinate esters as intermediates in the fragmentation process. However, the mass spectra of sulfinate esters have, to our knowledge, not been reported in the literature before. The characterization of some novel diarylsulfones, recently prepared in this laboratory, led to the question as to whether, in view of these arrangements, mass spectrometry could be used to distinguish between these sulfones and the isomeric sulfinate esters.

Therefore, a number of suitable model compounds were studied. The spectra of the aryl methyl sulfones **1** and **4** were compared with those of the corresponding *alkyl* arenesulfinates **2** and **5** and of the *aryl* alkanesulfinates **3** and **6**.



1 R = H **2** R = H **3** R = H **7**
4 R = CH_3 **5** R = CH_3 **6** R = CH_3

The preparation of *p*-tolyl methanesulfinate has not been reported in the literature before.

In view of the rearrangements of diarylsulfones to aryl arenesulfinates under electron impact, it was also of interest to study the mass spectra of aryl arenesulfinate esters. However, attempts to prepare *p*-tolyl benzenesulfinate were unsuccessful.

Since the spectra of the sulfones **1** and **4** seemed to indicate that hydrogen migration from the methyl group to oxygen is subject to a substituent effect, the spectrum of the methyl aryl sulfone **7** was used to gain information on the influence of an electron withdrawing substituent on this hydrogen migration.

Experimental

Apparatus

Mass spectra were recorded with a Hitachi–Perkin–Elmer model RMU-7 double focussing mass spectrometer. Unless otherwise stated samples were introduced through an all glass liquid inlet, and subjected to an ionizing potential of approximately 70 eV. The n.m.r. measurements were made with a Varian model A60-A spectrometer for deuteriochloroform or carbon tetrachloride solutions with tetramethylsilane as an internal reference at τ 10.00. The i.r. spectra were recorded with a Beckman IR 12 spectrophotometer.

Sulfones

Methyl *p*-tolyl sulfone (**4**) and 4-(methylsulfonyl)-benzoic acid (**7**) were commercial specimens supplied by Aldrich Chemical Co. Inc., and were used directly. The latter, **7**, was introduced into the mass spectrometer via the direct inlet. Methyl phenyl sulfone (**1**) was prepared by Friedel–Craft sulfonylation of benzene according to the method of Truce and Vriesen (4). The product of this reaction had m.p. 84–85° (lit. 84–85° (4)).

Anal. Calcd. for $C_7H_8O_2S$: C, 53.83; H, 5.16. Found: C, 53.61; H, 5.11.

Deuterium Exchange Reactions

The sulfones (50–100 mg samples) were added to a solution of sodium (10–20 mg) in deuteriomethanol (MeOD, 10 ml) in dry nitrogen. The mixtures were kept

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at room temperature overnight, neutralized with a solution of PCl_5 in D_2O, and extracted with ether. The purity of the deuterated products was confirmed by t.l.c.

Methanesulfinyl Chloride

The acid chloride was prepared from dimethyl disulfide according to Douglas and Poole (5). The product, obtained as a clear yellow oil, gave rise to a single peak in its n.m.r. spectrum at τ 6.62 and was characterized as its anilide **9**, which had m.p. 86–87°, (lit. (6) 86–88°).

Anal. Calcd. for C_7H_9NOS: C, 54.16; H, 5.85; N, 9.02. Found: C, 54.22; H, 5.98; N, 9.08.

Phenyl Methanesulfinate[1]

Phenol (2.65 g) was added to methanesulfinyl chloride (2.40 g) at room temperature in nitrogen. Stirring of the mixture initiated the evolution of hydrogen chloride and the development of an orange color. The reaction vessel was connected to a flash evaporator and kept at 0–5° for 2 h. The resulting light yellow oil (4.57 g) was dissolved in methylene chloride and *p*-toluidine (0.25 g) was added. After 5 min the mixture was filtered and the precipitate washed with methylene chloride (3 × 5 ml). This procedure was repeated with 0.1 g of *p*-toluidine. The combined methylene dichloride solutions were washed with cold water (10 ml), 2 *N* aqueous hydrochloric acid (12 ml), and again with water (3 × 10 ml). Removal of the solvent from the dried organic layer yielded a yellow oil (2.3 g) which was immediately[2] chromatographed on silica gel (60 g). Elution with petroleum ether–ether (3:1) gave phenyl methanesulfinate (**3**) as a colorless oil, which had ν_{max} (SO) 1148 cm^{-1}. The n.m.r. spectrum (CCl_4) contained the S—CH_3 signal at τ 7.24 and the aromatic proton signals at τ 2.50–3.00.

Mass Spec. Calcd. for $C_7H_8O_2S$: M^+, 156.021. Found: M^+, 156.025.

Many chromatography fractions were contaminated with varying amounts of phenol, evident from OH absorption at ν_{max} 3400 cm^{-1}. It was therefore difficult to establish the yield of pure phenyl methanesulfinate (see comments on yield of *p*-tolyl methanesulfinate below).

p-Tolyl Methanesulfinate

p-Cresol (6.91 g) was added to methanesulfinyl chloride (5.28 g) and the mixture was treated as above. The crude product (7.48 g) which was a deep red oil, on chromatography yielded *p*-tolyl methanesulfinate (**6**) as a pale yellow oil. A fraction which did not show any impurities in its n.m.r. spectrum (in CCl_4, τ 7.67 (3H, aromatic CH_3), 7.28 (3H, S—CH_3), and 2.96 (4H)) had ν_{max} (SO) 1120 cm^{-1}. A weak i.r. absorption at ν_{max} 3400 cm^{-1} indicated the possible presence of a small amount of *p*-cresol.

Mass Spec. Calcd. for $C_8H_{10}O_2S$: M^+, 170.040. Found: M^+, 170.043.

The n.m.r. spectrum of the crude product contains the methyl signal of *p*-cresol at τ 7.82. Thus, in this case, the relative intensities of the two aromatic methyl group signals allowed a calculation of the yield of *p*-tolyl methanesulfinate which was found to be 60%.

Attempted Preparation of p-Tolyl Benzenesulfinate

Benzenesulfinyl chloride was prepared by chlorination of thiophenol according to Douglas (8). Its identity was confirmed by its reaction with methanol to give methyl benzenesulfinate (**2**) which was identical in all respects with an authentic specimen.[3] However, several attempts to prepare *p*-tolyl benzenesulfinate by reaction of this acid chloride with *p*-cresol were unsuccessful.

Results and Discussion

Methyl phenyl sulfone (**1**) has been studied before and our results agree with those of Bowie *et al.* (2). The major fragmentation paths (Scheme 1) are reproduced here for comparison.[4] The spectrum[4] of methyl benzenesulfinate (**2**)[3] contains the molecular ion at *m/e* 156 and the loss of the methoxy group leads to the base peak at *m/e* 125 (ion **a** in Scheme 1). Further loss of SO then leads to **b** at *m/e* 77. A corresponding direct cleavage pattern of the sulfone **1** involves loss of the methyl group to give **c**, resulting in a peak at *m/e* 141. Further loss of SO_2 then leads to the ion **b**, to which the base peak of this spectrum at *m/e* 77 may be assigned (Table 1).

Although these direct fragmentations are sufficiently different to be considered characteristic, some fragments arising from rearrangements are even more distinctive. Whereas the sulfone **1** rearranges to the sulfinate ester ion **d** which has been suggested (2) to lead directly to the ionized phenol (**e**, *m/e* 94), the sulfinate ester **2** apparently undergoes a rearrangement similar to that observed for sulfoxides (9) which leads to the thiapyrrylium ion **f** at *m/e* 97.

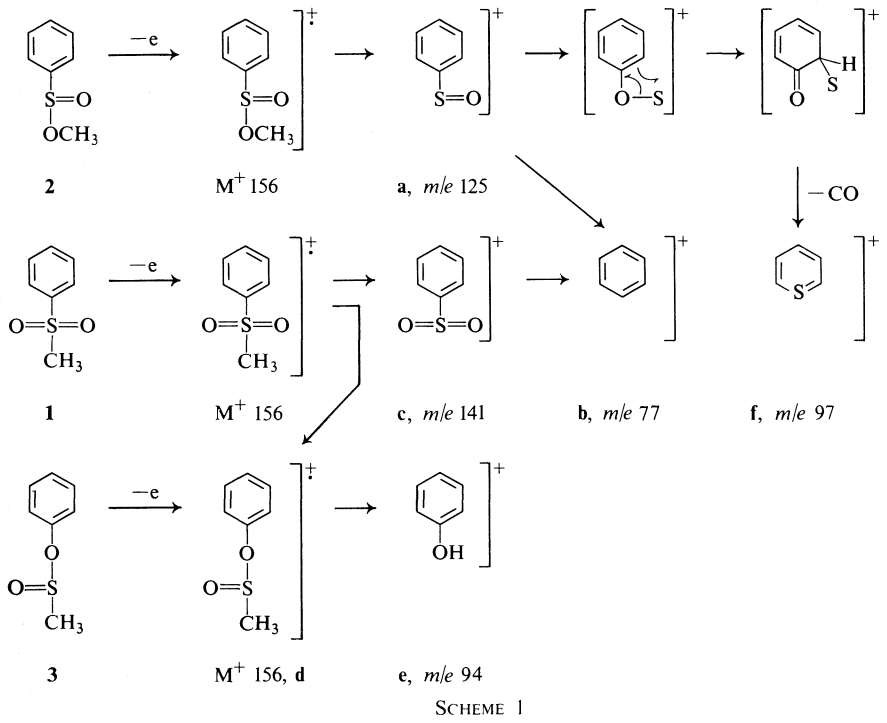
Phenyl methanesulfinate (**3**) only gives a molecular ion when the ionizing voltage is decreased to approximately 14 eV. The rather simple spectrum[4] obtained in this way indicates that the only significant fragmentation for this ester involves S—O cleavage and hydrogen transfer leading again to the ionized phenol **e** at *m/e* 94 (Scheme 1). It was

[1]This compound was first reported by Engberts and Zuidema. The authors gratefully acknowledge the cooperation of Professor Engberts in supplying the experimental details used in his preparation of this ester (7).

[2]When this product was kept under refrigeration for 5 days, it became dark yellow and was no longer soluble in most organic solvents indicating extensive decomposition.

[3]The authors wish to express their appreciation to Dr. I. B. Douglas, Department of Chemistry, University of Maine, for a gift of samples of methyl benzenesulfinate (**2**) and methyl *p*-toluenesulfinate (**5**).

[4]The mass spectra of the compounds described herein have been lodged in the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada K1A 0S2. Table 1 summarizes the major peaks in these spectra.



SCHEME 1

TABLE 1. *m/e* of major peaks (relative intensity, %)

No.	Compound	M^+	M^+-CH_3	M^+-OCH_3	Ar	Other
1	$Ar—SO_2—CH_3$	156(28%)	141(27%)	—	77(100%)	(**e**),94(31%)*
2	$Ar—SO—OCH_3$	156(84%)	141(15%)	125(100%)	77(84%)	(**f**),97(26%)
3	$ArO—SO—CH_3$	156(15%)	—	—	—	(**e**),94(100%)
4	$Ar—SO_2—CH_3$	170(33%)	155(36%)	139(2%)	91(100%)	(**l**),107(27%)
5	$Ar—SO—OCH_3$	170(49%)	155(3%)	139(100%)	91(39%)	(**m**),111(6%)
6	$ArO—SO—CH_3$	170(31%)	—	—	—	(**l**),107(100%)
7	$HOOC—Ar—SO_2—CH_3$	200(37%)	185(36%)	—	—	(**p**),138(88%); (**q**)121(100%); (**r**)93(10%)

*Letters in parentheses refer to ions as indicated in Schemes 1, 2, and 3.

found that repeated chromatography of this ester leads to increasing decomposition without yielding a completely phenol-free product. Since the presence of even small amounts of phenol affects the intensity of the base peak, the relative intensities in table 1 for compound (**3**) are not representative of a pure specimen. However, that at least part of the ion current at *m/e* 94 is due to this fragmentation follows from the observation of a metastable peak at *m/e* 56.6.

A consideration of the toluene homologues **4**, **5**, and **6** leads to an overall picture summarized in Scheme 2 consistent with the above results. Thus, methyl *p*-tolyl sulfone (**4**) not only decomposes with the consecutive loss of CH_3 (**i**, *m/e* 155) and SO_2 (**h**, *m/e* 91) but also loses CH_3SO in a one-step process to give *m/e* 107 ($C_7H_7O^+$).[4] This latter signal which does not shift after deuteration of the methyl group, may be assigned the structure **l** arising from the rearranged molecular ion **k**. The observation that in this case no hydrogen migration from the methyl group takes place is further discussed below.

The loss of CH_3SO from the ion **k** to give **l**, (*m/e* 107) is the major fragmentation observed in the spectrum of *p*-tolyl methanesulfinate **6**.[4] Slight

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

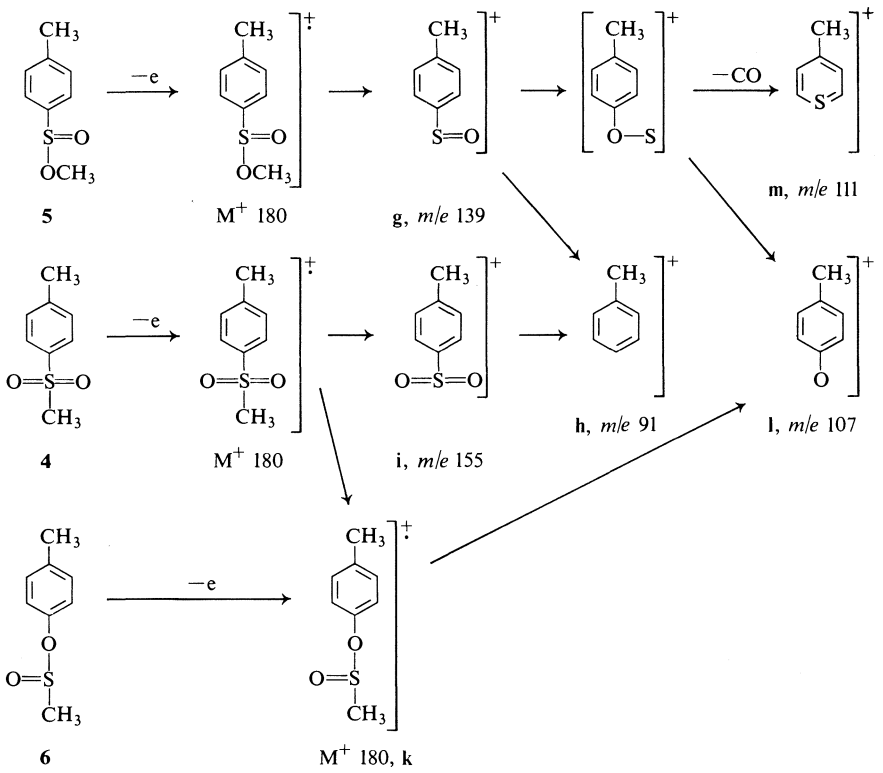


SCHEME 2

contamination of this sample with free *p*-cresol, which is responsible for the ion current at *m/e* 108, in this case does not affect the base peak of the spectrum.

Also, methyl *p*-toluenesulfinate **5**[4] undergoes cleavages similar to the corresponding phenylsulfinate. Thus it is suggested that the base peak at *m/e* 139 represents the ion **g**, which is formed by loss of the methoxy group. Subsequent loss of SO then leads to **h** which gives rise to the peak at *m/e* 91. The rearrangement of **g** to give the methyl thiapyrrylium ion **m** at *m/e* 111 is less pronounced in this case, but is nevertheless evident from the presence of a metastable peak at *m/e* 88.4.

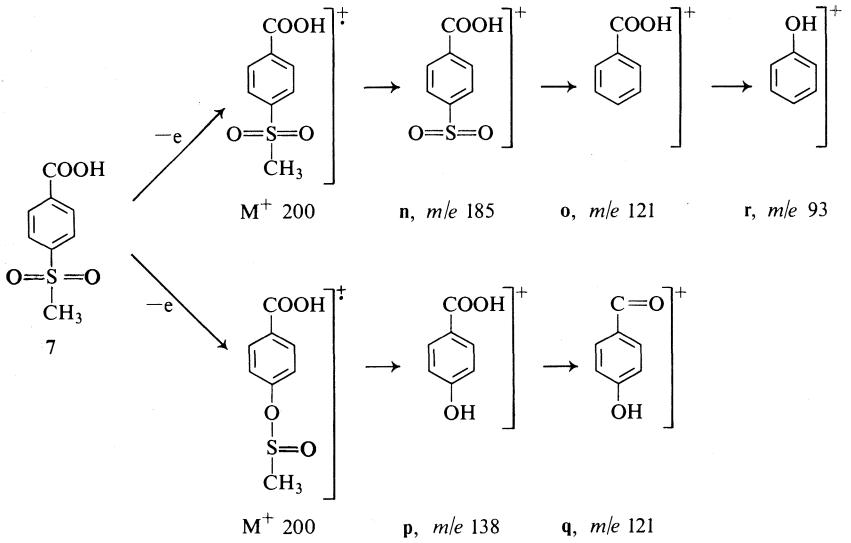
In order to compare in a similar fashion the mass spectra of diaryl sulfones with those of the isomeric aryl arenesulfinates, attempts were made to synthesize *p*-tolyl benzenesulfinate from benzenesulfinyl chloride and *p*-cresol. These attempts, however, were wholly unsuccessful. Examination of the various reaction mixtures suggested that this ester, if at all formed, rapidly decomposed. Sulfinate esters of this kind have, to our knowledge, not been reported in the literature before.

The results discussed so far show that, quite apart from differences in chemical behavior, mass spectrometry is sufficiently characteristic to distinguish alkyl aryl sulfones from the stable sulfinate esters with which they are isomeric.

An anomaly was noted concerning the migration of hydrogen from the methyl group, which in the case of methyl phenyl sulfone (**1**) leads to the formation of ionized phenol (**e**, Scheme 1). Such a hydrogen transfer is distinctly absent from the spectrum of methyl *p*-tolyl sulfone (**4**) which contains **l** at *m/e* 107 rather than ionized *p*-cresol at *m/e* 108. Assuming that the electron donating methyl group inhibits this hydrogen transfer in the latter case, it is of interest to study the effect of an electron withdrawing substituent, particularly since it was found (3) that the *p*-nitro group in 2-chloro-ethyl *p*-nitrophenyl sulfone (**8**) appears to prevent migration of the aryl group to oxygen.

The spectrum[4] of 4-(methylsulfonyl)-benzoic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

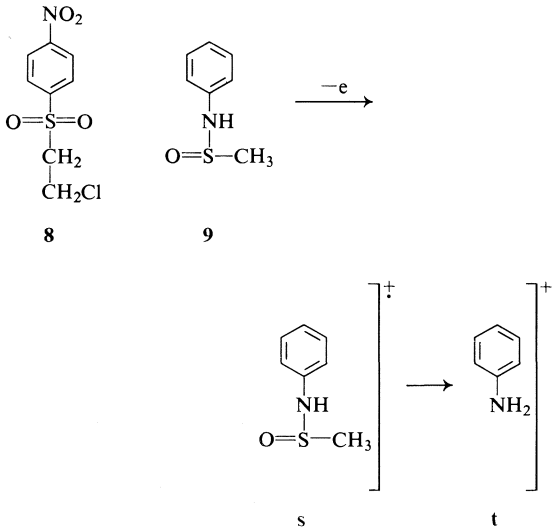


SCHEME 3

acid (**7**) contains a strong peak at *m/e* 138. This peak, which shifts to *m/e* 139 after deuteration of the methyl group may be attributed to the ion (**p**, Scheme 3) as derived from the rearranged molecular ion. Thus the carboxyl group, while preserving the low electron density on the aromatic ring required for hydrogen migration, is not a strong enough electron withdrawing group to prevent the migration of the aryl group to oxygen.

The base peak of this spectrum, which is found at *m/e* 121, originates from two different fragmentation processes, as indicated by the observation of metastable peaks. Firstly, the ion **n** at *m/e* 185 loses SO_2 (*m** 79.2) to give **o** at *m/e* 121, and secondly, the ion **p**, after loss of 17 mass units (*m** − 106.2) also leads to a fragment at *m/e* 121, for which structure **q** is proposed. That the first process (*i.e.* **n** → **o**) makes the largest contribution to the base peak follows from the observation that in the spectrum of the deuterated sulfone, the base peak is still found at *m/e* 121, while only a weak signal (~15%) is observed at *m/e* 122 (*i.e.* monodeuterated **q**). Also, although both **o** and **q** may lead to ionized phenol **r** at *m/e* 93, no peak is observed at *m/e* 94 after deuteration.

Finally, it is of interest to note that the migration of hydrogen from the methyl group is not restricted to sulfones and aryl alkanesulfinates. Methanesulfinanilide (**9**) obtained from the characterization of methanesulfinyl chloride gave a mass spectrum in which the base peak is found



at *m/e* 93, and it is reasonable to suggest that this peak represents the ion **t**, formed according to the sequence **9** → **s** → **t**.

Conformations of Bridged Diphenyls. IV. Diphenyl Ether Conformations and Proton Chemical Shifts

J. J. BERGMAN,[1] E. A. H. GRIFFITH, B. E. ROBERTSON, AND W. D. CHANDLER[2]

Division of Natural Sciences and Mathematics, University of Saskatchewan, Regina, Saskatchewan S4S 0A2

Received June 2, 1972

The conformationally dependent chemical shifts for the ring protons of some diphenyl ethers can be explained approximately by the ring-current model for benzene magnetic anisotropy. Although the model underestimates the shielding in the region above the plane of the ring it is the best of the models investigated for this purpose.

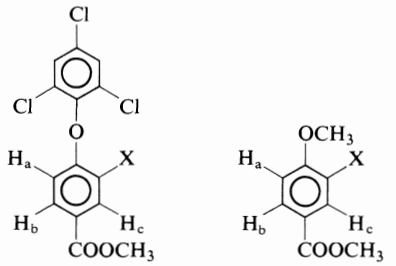
Les déplacements chimiques, en fonction de la conformation des protons du cycle de quelques diphénylethers peuvent être expliqués de façon approximative par le modèle du courant de cycle pour l'anisotropie magnétique du benzène. Bien que ce modèle sous estime le blindage de la région au dessus du plan de cycle, c'est le meilleur étudié jusqu'ici dans ce but. [Traduit par le journal]

Can. J. Chem., **51**, 162 (1973)

Introduction

Using a series of triply ortho-substituted diphenyl ethers, **1**, and the corresponding anisoles, **2**, we have shown previously how a double-difference p.m.r. analysis could be applied to obtain information about diphenyl ether conformations in solution (1). From the derived equations, that part of the chemical shift arising in relative "other-ring" shielding $\delta_{\omega}{}^{j} - \delta_{\omega H}{}^{j}$ was estimated to be -0.396, -0.140, and 0.135 p.p.m. for j = a, b, and c respectively. $\delta_{\omega}{}^{j}$ and $\delta_{\omega H}{}^{j}$ represent the contribution to the chemical shift of the jth ring proton from the conformation-dependent "other-ring" shielding in the diphenyl ethers with X ≠ H and X = H.[3]

At the same time it was shown that it is possible to calculate the "other-ring" shielding expected at each proton for a particular conformation defined by the three angular parameters θ, ϕ, and ψ where θ is the COC bond angle, ϕ the rotation of the X-substituted ring from the COC plane, and



1 **2**

X=NO_2, NH_2, I, Cl, H, OCH_3, CN

ψ the rotation of the trichlorophenyl ring from a plane perpendicular to the COC plane (Fig. 1). These calculations made use of the ring-current model of magnetic anisotropy elaborated by Johnson and Bovey (2). A comparison of the experimental shieldings and those calculated for a number of conformations suggested that θ must have a value near 120° while the ethers librate about an equilibrium H-inside conformation (Fig. 1) by angles up to 20° (ϕ = 0 ± 20°, ψ = 0 ± 20°).

There are three areas in which the previous work could be questioned: (*i*) as a result of the

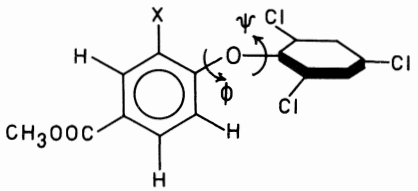


FIG. 1. H-Inside conformation of ethers in series **1**.

[2]Author to whom correspondence should be addressed.

[3]For all of the diphenyl ethers, rotation of the trichlorophenyl ring through 180° produces an identical, mirror-image conformer. In addition, when X = H in series **1** there must be two identical, average conformations, generated by rotation of the X-substituted ring through 180°, to account for the p.m.r. equivalence of the two ortho-protons and the equivalence of the two meta-protons. The resulting AA′BB′ spectral pattern is dependent on the temperature and the nature of the substituents on the other ring (1, 3).

several assumptions and simplifications inherent in the double-difference method, the experimental "other-ring" shielding values could be somewhat in error; (*ii*) in using the ring-current model of magnetic anisotropy for these ethers certain structural parameters had to be assumed; (*iii*) the ring-current model itself is a simplified, classical model.

In this paper new p.m.r. results will be presented that strengthen the case made previously for the double-difference method. In addition, "other-ring" shielding, calculated for structures suggested by recent X-ray diffraction data, will be shown to indicate that, while the ring-current model is better than others, it is not entirely adequate.

Results and Discussion

Experimental Values of "Other-ring" Shielding Chemical Shifts

Additional evidence in support of the double-difference method of obtaining "other-ring" shielding values comes from a comparison of p.m.r. spectra of similarly-substituted compounds in the series **3** and **4**, isomeric with **1** and **2**.

It is reasonable to expect the conformation of the two series, **1** and **3** to be basically the same since the same 2,4-disubstitution pattern occurs in both, and H_a is observed to be shielded by about the same amount, relative to the anisole, for corresponding ethers in both series (Tables 1 and 2).

Series **3** has an advantage over **1** in that the variable substituent X is not ortho to the ether oxygen and should not affect the conformation

by direct steric interference. As a result, the assumption that the conformation is substituent independent is even more valid in this case. However, the double-difference method cannot be applied since **3***e*, the ether having X = H, must have the same conformation as the other six. Nonetheless, if the method of chemical shift dissection has merit (1), for j = b and c,

$$[1]\quad \delta_{DX}{}^{b} - \delta_{AX}{}^{b} = (\delta_{D}{}^{b} - \delta_{A}{}^{b}) + I_{X}{}^{b}(I_{D}{}^{b} - I_{A}{}^{b}) + \delta_{\omega}{}^{b}$$

$$[2]\quad \delta_{DX}{}^{c} - \delta_{AX}{}^{c} = (\delta_{D}{}^{c} - \delta_{A}{}^{c}) + I_{X}{}^{c}(I_{D}{}^{c} - I_{A}{}^{c}) + \delta_{\omega}{}^{c}$$

$\delta_{DX}{}^{j}$ and $\delta_{AX}{}^{j}$ are the chemical shifts of the jth proton in the diphenyl ether and corresponding anisole respectively. $\delta_{D}{}^{j}$ and $\delta_{A}{}^{j}$ are the contributions to the chemical shift from the molecule exclusive of the substituent X. The $I_{Z}{}^{j}$ parameters are interaction contributions and $\delta_{\omega}{}^{j}$ is the "other-ring" shielding.

Since for **3** and **4** both H_b and H_c are meta to the ether oxygen and ortho to the substituent X, $\delta_{D}{}^{b} - \delta_{A}{}^{b} \simeq \delta_{D}{}^{c} - \delta_{A}{}^{c}$, $I_{X}{}^{c} = I_{X}{}^{c}$ and $I_{D}{}^{b} - I_{A}{}^{b} \simeq I_{D}{}^{c} - I_{A}{}^{c}$. The difference between [1] and [2] should then be a constant independent of the substituent X.

$$[3]\quad (\delta_{DX}{}^{b} - \delta_{AX}{}^{b}) - (\delta_{DX}{}^{c} - \delta_{AX}{}^{c}) = \delta_{\omega}{}^{b} - \delta_{\omega}{}^{c}$$

Table 3 shows that the experimental data for these series support this conclusion reasonably well; the average value of $(\delta_{DX}{}^{b} - \delta_{AX}{}^{b}) - (\delta_{DX}{}^{c} - \delta_{AX}{}^{c})$ is −0.270 p.p.m. with the deviations of all but X = OCH_3 falling within the estimated experimental error. There is probably a larger steric interaction between OCH_3 and the ring protons than occurs with other substituents and the single interaction parameters $I_{Z}{}^{j}$ cannot accommodate steric and electronic effects of any size simultaneously.

TABLE 3. Values of $(\delta_{DX}{}^{b} - \delta_{AX}{}^{b}) - (\delta_{DX}{}^{c} - \delta_{AX}{}^{c})$ for series **3** and **4**

X	$(\delta_{DX}{}^{b} - \delta_{AX}{}^{b}) - (\delta_{DX}{}^{c} - \delta_{AX}{}^{c})$ (p.p.m.)
NO_2	−0.282
NH_2	−0.276
I	−0.276
Cl	−0.270
H	−0.276
OCH_3	−0.248
CN	−0.264

In addition to being substituent independent, the values in Table 3 are exactly what would be expected if the diphenyl ethers of series **1** and **3** *did* adopt the same conformation. From the previous work for series **1** $\delta_{\omega}{}^{b} - \delta_{\omega H}{}^{b} = -0.140$ and $\delta_{\omega}{}^{c} - \delta_{\omega H}{}^{c} = 0.135$ p.p.m. Since, as noted in footnote 3, $\delta_{\omega H}{}^{b} = \delta_{\omega H}{}^{c}$

$$[4]\quad (\delta_{\omega}{}^{b} - \delta_{\omega H}{}^{b}) - (\delta_{\omega}{}^{c} - \delta_{\omega H}{}^{c}) = \delta_{\omega}{}^{b} - \delta_{\omega}{}^{c} = -0.275 \text{ p.p.m.}$$

One would conclude then that the double-difference technique does have considerable justification in spite of what appear to be overly-simple assumptions, and that the conformationally-dependent, "other-ring" shielding, $\delta_{\omega}{}^{j} - \delta_{\omega H}{}^{j}$, can be taken with confidence to be −0.40, −0.14, and 0.14 p.p.m. for j = a, b, and c respectively in series **1**.[4,5]

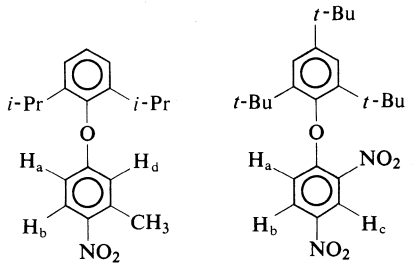
It should be noted that the experimental values provided by the double-difference analysis are actually sums of *two terms* and do not represent a single $\delta_{\omega}{}^{j}$ (1). Montaudo *et al.* (4, 5), using a single-difference method (diphenyl ether and corresponding anisole), estimated the shielding $\delta_{\omega}{}^{a}$ for H_a in some 2,4-disubstituted ethers to be between −0.30 and −0.57 p.p.m. However, the single difference includes terms other than $\delta_{\omega}{}^{j}$ unless they happen to be vanishingly small (1). The wide range of values quoted by Montaudo for ethers of similar structure suggests that allowance has to be made for substituent effects in some way and the double-difference approach does that.

Calculations of "Other-ring" Shielding Based on Conformations in the Solid State

Until recently there have been no reliable studies made of the bond lengths and angles in diphenyl ethers. The previous paper on the double-difference technique (1) used a value of 1.28 Å for the C—O bond length as proposed by Toussaint (6) although this seemed rather low. Since then, in parts I, II, and III of this series

[4]It has been pointed out previously that the fact that $\delta_{\omega}{}^{b} - \delta_{\omega H}{}^{b}$ and $\delta_{\omega}{}^{c} - \delta_{\omega H}{}^{c}$ have the same value, within experimental error, can be taken as a justification for the double-difference technique; based on the assumptions used they should be identical except for sign.

[5]The terms $\delta_{\omega}{}^{j} - \delta_{\omega H}{}^{j}$ have validity as experimental "other-ring" shielding values only for series **1** although the values would presumably be the same for series **3** and other similarly-substituted ethers if they could be obtained for the latter by the double-difference method.



5 6

(7–9), we have reported the crystal structures of ethers **5**, **6**, and ***3a***, and several other authors have published similar structures (10–12).

Our X-ray diffraction studies, besides giving accurate bond lengths and ring angles, have shown that in the solid state (*i*) the conformations are close to the average H-inside conformation predicted from solution p.m.r. work (Table 4), (*ii*) the COC bond angle, θ, is very nearly 120° as predicted, and (*iii*) the ring which is close to being in the COC plane (the ring whose rotation is described by ϕ and the ring to which H_a, H_b, and H_c belong) is deformed somewhat so that H_a and H_b are positioned differently relative to the other ring than would be predicted on the basis of a perfectly hexagonal ring. Figure 2 is a representation of this distortion for the ether **5**.

Using the structural parameters[6] obtained by X-ray diffraction it was possible to calculate the cylindrical coordinates, ρ and *z*, for each ring proton relative to the center of the other ring.[7] With these coordinates and the equations developed by Johnson and Bovey (2) the "other-ring" shielding, δ_ω^j, has been calculated for each proton and is given in Table 5. Since none of the three ethers studied has four ring protons, an imaginary proton had to be placed at C-2′ for ***3a*** and **6**, and at C-3′ for **5**. The proton was placed so that the carbon–proton distance was equal to the average of all similar distances in the molecule. The shielding for this proton was calculated as well and appears in Table 5.

TABLE 4. Angular parameters defining the conformation in the solid state

Compound	ϕ(°)	ψ(°)	θ(°)
3a	8.8*	14.0	119.3
	4.6	0.3	117.9

	2.1	10.5	120.0
6	3.2	2.5	116.8

*There are two different molecules in the unit cell. Differences have been discussed previously (7, 9).

Since for the ether with X = H in series **1**

$$[5] \qquad \delta_{\omega H}{}^a = (\delta_\omega{}^a + \delta_\omega{}^d)/2$$

$$[6] \qquad \delta_{\omega H}{}^b = (\delta_\omega{}^b + \delta_\omega{}^c)/2$$

where H_d is the other ortho-hydrogen, then the calculated values for the "other-ring" shielding will be given by

$$[7] \qquad \delta_\omega{}^a - \delta_{\omega H}{}^a = (\delta_\omega{}^a - \delta_\omega{}^d)/2$$

and

$$[8] \qquad \delta_\omega{}^b - \delta_{\omega H}{}^b = (\delta_\omega{}^b - \delta_\omega{}^c)/2$$

These values, which are to be compared with the experimental ones determined by means of the double-difference technique, have been derived from the data of Table 5 and are shown in Table 6 (see footnote 5).

These data indicate that $\delta_\omega{}^a$ is higher than Montaudo had estimated from his single-difference analysis (4, 5). At the same time $(\delta_\omega{}^a - \delta_\omega{}^d)/2$ for ***3a*** is 7 and 48% higher than our experimental value of −0.40 p.p.m., depending on which of the two different molecules in the crystal is chosen for comparison. The difference could be attributed to the fact that the values in Tables 5 and 6 are calculated using crystal conformations that do not allow for librations in ϕ and ψ which would lower the experimental "other-ring" shielding values obtained for molecules in solution. However, librations would also lower the values of $(\delta_\omega{}^b - \delta_\omega{}^c)/2$ which are already considerably lower than the experimental −0.14 p.p.m. There is an inconsistency in this result in that the predicted value of $(\delta_\omega{}^a - \delta_\omega{}^d)/2$ seems quite reasonable while the predicted value for $(\delta_\omega{}^b - \delta_\omega{}^c)/2$

[6]The scattering factor used for the hydrogen atoms in the X-ray studies was that given by Stewart *et al.* (20) for a bonded hydrogen atom which is part of a hydrogen molecule. These authors have compared the C—H bond lengths obtained using this scattering factor with bond lengths determined by other techniques and have concluded that those obtained by X-ray diffraction, using their factor, are short by 0.07 Å. For this reason, the position of the proton associated with each of H_a, H_b, and H_c has been assumed to be 0.07 Å further from the carbon atom than the center of electron density as determined by X-ray analysis.

[7]The phrase *center of the ring* is somewhat ambiguous since none of the rings has a perfectly hexagonal shape. The center was taken as the point of intersection of two diagonals.

appears to be too low for the fixed crystal conformation and would be even lower for a more mobile system.

There are two possible explanations for the discrepancy between the experimental $\delta_\omega{}^j - \delta_{\omega H}{}^j$ and the calculated values of Table 6 for ether *3a*: (*i*) the nitro-substituted ring, although nearly in the COC plane, is deformed within that plane as in Fig. 2 and it is possible that the deformation does not occur to the same extent in solution; (*ii*) the ring-current model may not give a completely adequate three-dimensional representation of the associated magnetic field.

If the first explanation were correct, the change in deformation on going from solid to dilute solution would have to have a relatively greater effect on H_b and H_c than on H_a and H_d. Such is not the case. The $\delta_\omega{}^j$ values for *3a* were recalculated using the same angular parameters and average bond lengths found in the solid but having all ring angles of 120°. These new values are given in Table 7. On going from the deformed to perfectly hexagonal ring $(\delta_\omega{}^a - \delta_\omega{}^d)/2$ increases by about 28% for both molecules, while $(\delta_\omega{}^b - \delta_\omega{}^c)/2$ increases by only 15%.

Moreover, there are indications that the crystal and solution conformations are qualitatively the same. Tables 5 and 6 indicate the larger shielding calculated for **6** than for *3a* at both H_a and H_b. The differences in $\delta_\omega{}^a$ and $\delta_\omega{}^b$ between **6** and one

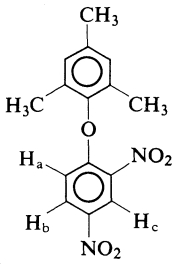
molecule of **3***a* are 0.350 and 0.069 p.p.m. respectively. A similar observation is made for a solution p.m.r. comparison of **6** and the corresponding mesityl ether **7**. H_a is more shielded in the tri-*t*-butyl ether by 0.317 p.p.m. and H_b is more shielded by 0.050 p.p.m. Because the two diphenyl ethers are so similar in structure this difference must be a function of conformation



7

exclusively, making it remarkably close to the calculated difference noted above. In solution, librations in ϕ and ψ would be expected to be somewhat less with the bulky *t*-butyl groups substituted in the ortho positions. The average shielding at H_a and H_b would be greater as the conformation more nearly approaches the H-inside conformation ($\phi = \psi = 0$). The X-ray data of Table 3 indicate that the angles ϕ and ψ are smaller in **6** than in the others for the solid state so that one would conclude that the solution conformations are qualitatively the same as the crystal conformations, and that changes in ring deformations from one phase to the other are not responsible for discrepancies between experimental and calculated values of the "other-ring" shielding.

It would appear that the simple, ring-current theory, although giving an approximate three-dimensional representation of the magnetic field, is not entirely adequate. If, as Haigh and Mallion (21) suggest, it underestimates the shielding of protons above the plane of the ring, it is a greater failure for those protons, like H_b, further away from the ring than H_a.

The fault may arise in three areas: (*i*) no account is taken of the effect of substituents such as the three chlorines in **1** and **3**; (*ii*) the use of two separated π-currents is questionable, and (*iii*) the trichloro-substituted ring has been shown to be deformed slightly in the crystal so that calculations based on loops of cylindrical symmetry may be quite in error (9). However, other models fare even worse in predicting the magnetic field in the region of interest. For example, if one uses the model proposed recently by Haigh and Mallion (21) the calculated "other-ring" shielding values for **3***a*, **5**, and **6** are only 40% of those shown in Tables 5, 6, and 7 for *all* the ring protons. Not only are these values far too small to be taken seriously in comparison with the experimental values, the model has made no improvement in the relative, three-dimensional shielding picture. The double torroidal-shell model of Farnum and Wilcox (22) is no better because it *increases all* δ_ω^j by 13%.

Although the ring-current model of benzene ring, magnetic anisotropy has some inadequacies it is the best one for explaining the results presented for diphenyl ethers.

Experimental

The p.m.r. experimental procedure including concentrations, spectral analysis and estimation of errors has been given previously (1).

Melting points were determined on a Kofler, micro hot-stage apparatus and are reported uncorrected.

The preparation and properties of the following have been described previously (3, 13, 14): 2-(2′-carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene (**3***a*); 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene (**5**); 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*t*-butylbenzene (**6**); 2-(2′,4′-dinitrophenoxy)-1,3,5-trimethylbenzene (**7**). Methyl 2-methoxybenzoate (**4***e*) was purchased from Eastman and was used without further purification.

2-(2′-Carbomethoxy-4′-aminophenoxy)-1,3,5-trichlorobenzene (3b)

2-(2′-Carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene (2.8 g) was dissolved in 95% ethanol (300 ml) and about 2 g of W-2 Raney nickel added. The hot solution was hydrogenated for 3 h at a pressure of 45 lb/in.^{2} using a Parr shaker apparatus. Sufficient acetone was added to dissolve the precipitate before the catalyst was removed by filtration. The colorless filtrate was evaporated to yield 2.47 g (94%) of white crystals, m.p. 106–108°. Further recrystallizations from 95% ethanol gave the analytical sample, m.p. 107–108.5°.

Anal. Calcd. for $C_{14}H_{10}NO_3Cl_3$: C, 48.51; H, 2.91; N, 4.04; Cl, 30.69. Found: C, 48.43, 48.44; H, 2.78, 2.71; N, 4.35, 4.16; Cl, 30.36, 30.28.

2-(2′-Carbomethoxy-4′-iodophenoxy)-1,3,5-trichlorobenzene (3c)

2-(2′-Carbomethoxy-4′-aminophenoxy)-1,3,5-trichlorobenzene (12.0 g) was dissolved in a mixture of concentrated sulfuric acid (125 ml) and glacial acetic acid (125 ml). A solution of sodium nitrite (3.2 g) in a mixture of sulfuric acid (61 ml) and glacial acetic acid (61 ml) was prepared and added slowly, over a period of 2.5 h, to the solution of the amine kept at 5°. After stirring for an additional 1 h, the mixture was poured into a beaker containing water (600 ml), chloroform (250 ml), potassium iodide (39 g), iodine (39 g), and urea (12 g). The contents of the beaker were stirred for 15 h after which the organic layer was separated and washed with a saturated aqueous solution of sodium bisulfite. Evaporation of the chloroform gave a red oil which recrystallized from ethanol–water as brownish crystals (12.6 g). An additional recrystallization from ethanol–water gave 10.1 g (64%) of yellow crystals, m.p. 109–110°, a portion of which was sublimed to give the analytical sample, m.p. 110.5–111.5°.

Anal. Calcd. for $C_{14}H_8Cl_3IO_3$: C, 36.77; H, 1.76; Cl, 23.25; I, 27.74. Found: C, 36.75; H, 1.72; Cl, 23.11; I, 25.82.

2-(2′-Carbomethoxy-4′-chlorophenoxy)-1,3,5-trichlorobenzene (3d)

2-(2′-Carbomethoxy-4′-iodophenoxy)-1,3,5-trichlorobenzene (5 g) was dissolved in dimethylformamide (40 ml) and cuprous chloride (5.1 g) was added. The mixture was heated with stirring at 140° for 18 h and then poured into a beaker containing 6 *N* hydrochloric acid (200 ml) and ferric chloride (10 g). After cooling a brown gum formed which was crystallized from methanol as brown crystals (3.5 g). Since the p.m.r. spectrum of this material showed evidence of the presence of considerable starting material the product was subjected to the same reaction conditions again. This time 2.3 g (58%) of brown crystals were obtained, m.p. 105–110°. Sublimation did not improve the melting point and the p.m.r. spectrum showed the presence of about 5% of the starting iodo compound. The impurity could not be reduced by recrystallization or sublimation so the product was used as it was for p.m.r. analysis.

2-(2′-Carbomethoxyphenoxy)-1,3,5-trichlorobenzene (3e)

Diazotization of 2-(2′-carbomethoxy-4′-aminophenoxy)-1,3,5-trichlorobenzene (4.9 g) was carried out as described in the synthesis of 2-(2′-carbomethoxy-4′-iodophenoxy)-1,3,5-trichlorobenzene. The cold diazonium salt solution was poured into a beaker containing crushed ice (500 g), and 50% hypophosphorous acid (100 ml) with stirring. After being left for 18 h, chloroform (150 ml) was added and the mixture stirred for 15 min. The organic layer was separated and the chloroform evaporated to give 4.2 g (90%) of an orange solid. After two recrystallizations from 95% ethanol and one from ligroin the resulting yellow crystals were sublimed to yield a white product, m.p. 70–71°.

Anal. Calcd. $C_{14}H_9Cl_3O_3$: C, 50.71; H, 2.74; Cl, 32.08. Found: C, 50.50; H, 2.68; Cl, 31.70.

2-(2′-Carbomethoxy-4′-methoxyphenoxy)-1,3,5-trichlorobenzene (3f)

2-(2′-Carbomethoxy-4′-aminophenoxy)-1,3,5-trichlorobenzene (4.9 g) was dissolved in 70% aqueous sulfuric acid (30 ml) and the solution cooled to 5°. A solution of sodium nitrite (1.15 g) in concentrated sulfuric acid (20 ml) was prepared, cooled to 5°, and added to the amine solution over a period of 2 min. The resulting purple solution was allowed to stand at 5° for 45 min and then was added rapidly to boiling 55% aqueous, sulfuric acid (55 ml). After boiling for 15 min and cooling a grey precipitate formed which was collected (4.3 g), m.p. 203–227°. The solid was dissolved in dilute, sodium bicarbonate solution, filtered and the filtrate acidified with dilute HCl to give 3.9 g (79%) of tan crystals, m.p. 221–228°.

All of this crude 2-(2′-carboxy-4′-hydroxyphenoxy)-1,3,5-trichlorobenzene was added to ethereal diazomethane and the ether was evaporated in a fume hood. Of the resulting 3.6 g of white crystals 1.9 g was dissolved in 15% aqueous sodium hydroxide (15 ml) and dimethyl sulfate (20 ml) was added in small portions with stirring and the alternate addition of enough base to maintain a basic solution. Finally, dimethyl sulfate (10 ml) and sodium hydroxide (10 g) were added and the solution was refluxed overnight. Acidification with HCl and filtration of the precipitate produced 1.6 g of 2-(2′-carboxy-4′-methoxyphenoxy)-1,3,5-trichlorobenzene, m.p. 173–177°. The crude acid was treated with ethereal diazomethane and the ether evaporated to give a brown oil (1.5 g). One recrystallization from methanol and a sublimation yielded the analytical sample as white prisms, m.p. 93–93.5°.

Anal. Calcd. for $C_{15}H_{11}Cl_3O_4$: C, 49.82; H, 3.07; Cl, 29.41. Found: C, 50.00; H, 2.95; Cl, 29.25.

2-(2′-Carbomethoxy-4′-cyanophenoxy)-1,3,5-trichlorobenzene (3g)

2-(2′-Carbomethoxy-4′-iodophenoxy)-1,3,5-trichlorobenzene (6 g) was dissolved in dimethylformamide (60 ml) and cuprous cyanide (1.95 g) was added. The dark mixture was refluxed gently for 4 h with stirring and then poured into a beaker containing ferric chloride (15 g) and 6 *N* hydrochloric acid (200 ml). A dark oil formed but solidified on cooling. The aqueous solution was filtered and the filtrate extracted with chloroform (150 ml). The extract was combined with the solid and the chloroform was evaporated. The residue was crystallized from 95% ethanol as tan crystals (4.3 g, 93%), m.p. 151–153°. Two additional recrystallizations from 95% ethanol gave the analytical sample, m.p. 152–153°.

Anal. Calcd. for $C_{15}H_8Cl_3NO_3$: C, 50.52; H, 2.26; N, 3.93; Cl, 29.83. Found: C, 50.23; H, 2.24; N, 3.83; Cl, 29.50.

Methyl 2-Methoxy-5-nitrobenzoate (4a)

2-Methoxybenzoic acid (40 g) was nitrated according to the method of Simonsen and Rau (15). The desired 2-methoxy-5-nitrobenzoic acid was separated from its 3-nitro isomer according to the scheme of Hirwe and Patel (16) and was obtained in pure form after recrystallization from water (18.7 g, 36%) m.p. 161–164°. Esterification followed the general procedure of Clinton and Laskowski (17). Evaporation of the dichloroethane gave a white residue which was recrystallized from 95% ethanol to yield 16.2 g, m.p. 100–101°. The literature m.p. is 99–100° (17).

Methyl 2-Methoxy-5-aminobenzoate (4b)

Methyl 2-methoxy-5-nitrobenzoate (25 g) was dis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solved in hot, 95% ethanol (300 ml) and about 2 g of W-2 Raney nickel was added. The mixture was hydrogenated using a Parr shaker apparatus at a pressure of 45 lb/in.^{2} until the uptake of hydrogen ceased (3.5 h). The catalyst was removed by filtration and the ethanol evaporated under reduced pressure to yield 23.4 g of a green liquid. This was distilled to give 17.6 g (88%) of a yellow oil, b.p. 140–141°/0.02 mm Hg. The product appeared to decompose slowly on standing. Although initial attempts to induce crystallization failed, the oil did crystallize after several months. However, the crystals decomposed readily. The compound was concluded to be the named product from its p.m.r. and i.r. spectra and by its reaction to produce the cyano anisole (**4***g*). Attempts to prepare a benzoyl derivative appeared to produce a mixture of products.

*Methyl 2-Methoxy-5-iodobenzoate (**4***c*)

5-Iodosalicylic acid (52.8 g), sodium hydroxide (16 g), and water (450 ml) were placed in a flask and dimethyl sulfate (20 ml) was added slowly with stirring to the warm solution. After addition was complete, the mixture was left for 1 h and then a further 15 ml of dimethyl sulfate were added. At all times the reaction mixture was kept basic by the addition of sufficient sodium hydroxide. After standing overnight, the white product was collected and acidified with aqueous HCl to give a white solid (34.9 g, 63%), m.p. 197–199°. The literature m.p. for 2-methoxy-5-iodobenzoic acid is 197° (18).

Some of the acid (4.1 g) and potassium carbonate (2.2 g) were added to a solution of methyl iodide (3 ml) in 50% aqueous ethanol (160 ml). The mixture was refluxed overnight and then diluted with water (200 ml) to produce a white solid. Recrystallization of the solid from water–ethanol gave white needles (2.35 g, 55%), m.p. 57.5–59°. A further recrystallization from the same solvent gave the analytical sample, m.p. 59–59.5°.

Anal. Calcd. for $C_9H_9IO_3$: C, 37.01; H, 3.10; I, 43.45. Found: 37.07; H, 3.05; I, 43.03.

*Methyl 2-Methoxy-5-chlorobenzoate (**4***d*)

5-Chlorosalicylic acid (30 g) was treated with dimethyl sulfate (70 ml) and sodium hydroxide as described in the synthesis of methyl 2-methoxy-5-iodobenzoate. Acidification of the reaction mixture gave 20.0 g (62%) of 2-methoxy-5-chlorobenzoic acid. This was esterified according to the method of Clinton and Laskowski (17) and the resulting yellow oil was distilled to give a colorless liquid (13.8 g, 65%), b.p. 113°/0.03 mm Hg. The reported b.p. is 235–240°/760 mm Hg (19).

*Methyl 2,5-Dimethoxybenzoate (**4***f*)

2,5-Dihydroxybenzoic acid (30 g) was treated with dimethyl sulfate (70 ml) and sodium hydroxide as in the synthesis of methyl 2-methoxy-5-iodobenzoate. Acidification of the reaction mixture with aqueous HCl caused a liquid to separate but this soon solidified. The dimethoxybenzoic acid was collected (20.6 g, 59%) and esterified according to the method of Clinton and Laskowski (17). The yellow oil that resulted was distilled to yield 18.7 g (84%) of a colorless liquid, b.p. 110°/0.05 mm Hg.

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.22; H, 6.17. Found: C, 61.22; H, 6.19.

*Methyl 2-Methoxy-5-cyanobenzoate (**4***g*)

Methyl 2-methoxy-5-aminobenzoate (21 g) was dissolved in dilute sulfuric acid (50 ml) and sodium nitrite (8.0 g) was added until an immediate positive test was obtained with starch–iodide paper. The temperature of the mixture was kept at 5° during and after the addition. The solution thus obtained was neutralized with excess sodium bicarbonate before being poured into a beaker containing a solution of cuprous cyanide (14 g) in water (100 ml) with sufficient sodium cyanide added to effect solution. Toluene (250 ml) was added and the two phase mixture allowed to reach room temperature. The mixture was filtered, the toluene layer separated and the toluene evaporated to give a black residue. The tar was extracted with ether (400 ml) and the ether evaporated to yield 13 g of a semi-crystalline material. Distillation gave 4.8 g (46%) of a light orange liquid which soon solidified, b.p. 140–144°/0.03 mm Hg. Two recrystallizations from 95% ethanol gave the analytical sample of white crystals, m.p. 103–104°.

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.82; H, 4.74; N, 7.33. Found: C, 62.63; H, 4.72; N, 7.31.

Preparation and Stereochemistry of *N*-Methyl-*N*-phenacylpiperidinium Salts

ROBERT V. SMITH[1]

Division of Medicinal Chemistry, College of Pharmacy, University of Iowa, Iowa City, Iowa 52240

AND

FREDERICK W. BENZ[2] AND JOHN P. LONG

Department of Pharmacology, College of Medicine, University of Iowa, Iowa City, Iowa 52240

Received July 18, 1972

The *N*-methyl-*N*-phenacylquaternary salts of 2-, 3-, and 4-methylpiperidines have been prepared and characterized. N.m.r. spectroscopy was employed in analyzing the proportion of diastereomers formed following reciprocal alkylations with methyl iodide and phenacyl halides. Preferential axial attack was observed with *N*-methylation while *N*-phenacylation primarily proceeded by equatorial atatck.

Nous avons préparé et caractérisé les sels *N*-méthyl-*N*-phénacyl quaternaires des dérivés 2-, 3-, et 4-méthylpipéridines. La r.m.n. a été utilisée pour analyser la proportion de diastéréoisomères formés, à la suite des alkylations réciproques avec l'iodure de méthyl et les halogénures de phénacyl. Nous observons une attaque axiale préférentielle avec la *N*-méthylation, tandis que la *N*-phénacylation se produit à la suite d'une attaque équatoriale [Traduit par le journal]

Can. J. Chem., **51**, 171 (1973)

Introduction

The hemicholinium-3 analog, **1**, exerts interesting effects on the autonomic nervous system (1–4). Attempts to compare the structure–biological activity relationships of **1** to its saturated analogs (**2***a–c*) were hampered by a lack of information on the course of quaternization involving phenacyl type alkylating agents and 2-, 3-, and 4-methylpiperidines (2).

Numerous reports have appeared on the stereochemistry resulting from quaternization of relatively rigid *N*-alkylpiperidines with methyl (5–17, 19), ethyl (5–7, 10, 11, 13, 17, 18), *n*- or *i*-propyl (6–8, 10, 11), and benzyl (5–7, 9–11, 13–15) alkylating agents; the stereochemistry of piperidine quaternizations in general has recently been reviewed (20, 21). There is, however, a paucity of literature relative to the *N*-phenacylation of such systems or, indeed, to the methylation of *N*-phenacylpiperidines (2). The work reported herein was designed to investigate the synthesis and resulting stereochemistry of compounds **3–6**, which would serve as models for the bis-quaternary systems (**2***a–c*).

5 R = 3-CH_3 (*a*, X = Br; *b*, X = Cl; *c*, X = I)
6 R = 4-CH_3 (*a*, X = Br; *b*, X = Cl; *c*, X = I)

Experimental

N-Methylpiperidines

A literature procedure (22) was employed in preparing 1-methyl-, 1,2-dimethyl-, 1,3-dimethyl-, and 1,4-dimethylpiperidines; yields were 60–70%.

N-Phenacylpiperidine Hydrobromides

α-Chloroacetophenone was reacted with an excess of piperidine, 2-methyl-, 3-methyl-, or 4-methylpiperidine in ethanol at 60–70° C for 12 h. Following treatment with 5% sodium hydroxide, the amines were extracted into ether. Dried ether extracts were treated with gaseous hydrobromic acid. The hydrobromides were recrystallized twice from *n*-propanol; yields were 60–80%.

†Compounds **3***a–c* show i.r. carbonyl absorption between 1677–1682 cm^{-1} (Nujol mull).
‡Literature 107 °C (23).
§Literature 127.9 °C (23).
¶Literature 124–126 °C (23).
‖Literature 125 °C (24).

Phenacylation (Quaternization) of N-Methylpiperidines (Procedure Ia)

α-Bromoacetophenone or α-chloroacetophenone (25 mmol) and *N*-methylpiperidines (25 mmol) were dissolved in acetonitrile and allowed to react at room temperature for 1 week. The quaternary ammonium compounds were collected after removal of solvent *in vacuo* and were washed with ether; yields were 89–99%.

Methylation (Quaternization) of N-Phenacylpiperidines (Procedure Ib)

Methyl iodide (25 mmol) and *N*-phenacylpiperidines (25 mmole) generated from hydrobromide salts, were dissolved in acetonitrile (100 ml) and allowed to react at room temperature for 1 week. After removal of the solvent *in vacuo* and washing with ether, the quaternary ammonium iodides were collected; yields were 72–88%.

Alternative Quaternization Method (Procedure II)

N-Methyl or *N*-phenacylpiperidines (25 mmol) were reacted with α-bromo (α-chloro) acetophenone or methyl iodide (25 mmol) in acetonitrile or ether (100 ml) at 30 °C for 72 h. Products were isolated following solvent evaporation at 30 °C *in vacuo* and were subjected to n.m.r. analysis.

All boiling and melting points are uncorrected. The n.m.r. spectra were recorded at 60 MHz using Varian A-60 and T-60 spectrometers. Solvents used were $CDCl_6$ or D_2O. Microanalyses were obtained with a Hewlett-Packard model 185 CHN analyzer. Characterizing data for all compounds are indicated in Table 1.

Results and Discussion

The course of alkylation of *N*-substituted piperidines can be affected by two conformational equilibria, *viz.* nitrogen inversion and ring inversion. The effect of these equilibria on the preparation of **3***a–c* cannot be evaluated because of the apparently rapid ring inversion in the latter materials (*vide infra*). In reactions leading to compounds **4–6** piperidine starting materials with equatorial *C*-methyl groups should predominate by about 20:1 (25–27). Thus, the course of alkylation can be related to the preferential axial or equatorial attack on *either* structures **7***a* or *b*.

*All chemical shifts were measured in $CDCl_3$ with respect to internal TMS (δ-values), unless indicated otherwise. All resonances are singlets except where indicated otherwise.

†Chemical shifts were measured in D_2O with respect to internal DSS. *N*-Phenacylmethylene protons were not observed in D_2O. These protons are relatively acidic due to their location between carbonyl and quaternary nitrogen groups; thus, they exchange with the deuterium of the solvent.

‡AB quartets centered at the δ-values quoted; J = 18 Hz ($J_{\delta H_A - H_B}$ = 18 Hz).

In each case, reciprocal alkylations were studied; that is, the appropriate *N*-alkylated derivatives of *C*-methylpiperidines were reacted to form qualitatively similar mixtures of piperidinium salts (Scheme 1).

N.m.r. spectroscopy was utilized in studying product compositions. Chemical shift and coupling constant data for all quaternary salts investigated appear in Table 2. The spectra of **3***a–c* revealed single resonances for their *N*-methyl and *N*-methylene protons. This is believed to be due to rapid ring inversion leading to averaged resonances for these protons, since the δ-values for these averaged resonances lie between the δ-values for the axial and equatorial resonances observed in the corresponding salts in **6**, where the *C*-methyl group is too far removed to substantially influence the *N*-methyl and *N*-methylene

shifts. Compounds **4–6** revealed two singlets between 3.43–3.69 p.p.m. for their *N*-methyl groups. Assignment of the upfield singlets to the axial methyl groups and the lower field resonances to equatorial methyl protons was based on data in the literature for such systems (5–7, 9–11, 13–18).[3] The assignment of the lower field absorptions to equatorial *N*-methyl groups was corroborated by n.m.r. experiments involving solvent-induced shifts. Piperidyl *N*-methyl resonances shift to higher fileds when going from $CDCl_3$ to D_2O. The shifts noted are proportionately greater for equatorial methyl protons (29). In compounds **4***a–c*, the lower field *N*-methyl signal shows the greater shift when spectra taken in $CDCl_3$ and D_2O are compared (Table 2). When the diastereomers, **5** and **6** were examined in D_2O, unresolved singlets were observed for their *N*-methyl protons. These singlets, however, appeared at positions upfield from the higher field *N*-methyl protons of **5** and **6** in $CDCl_3$ (Table 2). This effect is indicative of the lower field resonances undergoing the greater shift and further confirms the assignment of the downfield absorptions (in $CDCl_3$) to equatorial *N*-methyl protons (29).

N-Methylene protons in compounds **5** and **6** showed two singlets between 5.50–6.03 p.p.m. In compounds **4***a–c* these protons exhibited an AB quartet for each diastereomer. Similar AB patterns have been observed for the methylene protons in α-methyl-*N*-benzylpiperidines and their salts (13, 30–33). It has been shown that this non-equivalence is only observed when the α-methyl substituent is in the equatorial position (32, 33). If this relationship holds for the methyl quaternary salts of such systems, then the observation of an AB quartet for the methylene protons in compounds **4***a–c* furnishes spectral evidence for the equatorial disposition of the *C*-methyl group. AB patterns are not usually observed for β-methyl substituted piperidines because the chiral center is too far removed (30–33). Chemical shift data for phenacylmethylene resonances in piperidyl systems have not been reported but the same axial–equatorial relationship (*i.e.* axial signals upfield of equatorial signals) is indicated from work with electronically and/or sterically similar groups (5, 9–11, 13) and because this assignment is the one internally consistent with the *N*-methyl assignments with respect to diastereomer product ratios.

The *C*-methyl resonances for compounds **5** and **6** were doublets with splittings of **6** and **5** Hz, respectively. The α-*C*-methyl resonances for compounds **4***a–c* were triplets resulting from the overlap of two apparent doublets with splittings of 7 Hz (16, 34). The estimated intensity ratio of the upfield "doublet" to the lower field "doublet" for each salt is the same as the diastereomer ratio shown in Table 3. Thus, the upfield "doublet" is assigned to the equatorial α-*C*-methyl group adjacent to the axial *N*-methyl diastereomer and the downfield "doublet" to the equatorial α-*C*-methyl group adjacent to the equatorial *N*-methyl diastereomer.

Diastereomer ratios were obtained by integra-

[3]Delpeuch and Deschamps (28) consider the opposite assignment to be valid for certain tertiary amines in acid solvents unless the amine is α-substituted.

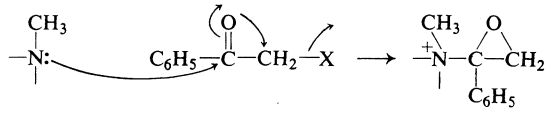
tion of the *N*-methyl and/or *N*-methylene n.m.r. signals and are listed in Table 3. The ratios listed under procedure II should reflect the stereochemical course of the quaternization reactions since these ratios were obtained on products, (*a*) from thermostatted (30 °C) reactions, reportedly limiting any drift toward equilibrium by product interconversion which is known to occur in refluxing solvents (10, 14, 35), and (*b*) unwashed and unrecrystallized so as to avoid product fractionation. However, independent, alternate syntheses of these products (procedures I*a* and I*b*), which incorporated an ether wash to remove starting materials and solvent before C, H, and N analyses, showed virtually identical product ratios (Table 3). Thus, washing with ether is a useful method of purifying such products without introducing fractionation. Washing with acetone instead of ether, however, caused significant changes in certain product ratios (Table 3).

The product ratios in Table 3 indicate that the diastereomers bearing axial *N*-methyl groups predominate in all reactions. That is, whether structures **8** or **9** are alkylated, the proportion of **10***a* is greater than **10***b*. This finding leads to the conclusion that *N*-phenacylation proceeds by preferential equatorial attack while *N*-methylation occurs predominantly *via* axial attack. Preferred axial attack during *N*-methylation is expected and has been observed in many similar systems (5–7, 9–17, 19). While there is less concensus of opinion on the stereochemical approach in alkylation of *N*-methylpiperidines, a number of workers have observed enhanced equatorial attack with alkylating agents which are more sterically demanding than methyl (5, 10, 11, 13, 14, 36). In addition, it has been shown that the more reactive triethyloxonium fluoroborate (18) shows marked tendencies to alkylate equatorially. It seems quite reasonable, therefore, that the reactive and bulky α-halo phenacyl ketones (15, 37) used in this study should also alkylate equatorially.[4] In spite of this, it was initially surprising to find that *N*-phenacylation of 1,2-dimethylpiperidine yields the product ratios indicated for **4***a* and *b*, thereby showing higher stereoselectivity than the reciprocal alkylation yielding product **4***c* (Table 3). Kawazoe and Tsuda have shown (17) that α-substituents affect the stability of the reaction intermediates at the transition state in these quaternizations such that the axial approach of the alkylating agent becomes more difficult than the equatorial approach and that this is more so for larger alkylating agents than for methyl halides. Thus, they found greater selectivity in the equatorial ethylation of 1-methyl-2-ethylpiperidine than in the axial methylation of this amine. A similar rationalization can be used to explain the greater apparent equatorial phenacylation leading to **4***a* and *b*. Lyle *et al.* (39) also report a higher incidence of equatorial attack (during quaternization) of 1-methyl-2-alkylated piperidines, relative to their 3- and 4-substituted analogs.[5]

A change in product ratios was obtained when **5***a* and *c* were prepared in ether as compared to acetonitrile (Table 3). Bottini and O'Rell (9) point out that an increase in equatorial alkylation occurs when going from a more polar to a less polar solvent. The opposite of this was observed with **5***a* and *c*, but this result concurs with the findings of Kawazoe and Tsuda (17). In general, solvent effects on quaternization ratios seem to be difficult to predict (15, 20).

[4]Duke *et al.* (38) have recently shown by X-ray crystallography that 1-ethyl-4-phenylpiperidine and 1-isopropyl-4-phenylpiperidine undergo equatorial *N*-benzylation, which supports this conclusion.

[5]One referee has suggested that the following mechanism might be invoked to explain the preferred equatorial *N*-phenacylation leading to **4***a–b*, **5***a–b*, and **6***a–b*.



11

The epoxammonium salt (**11**), however, can be eliminated as a structure for compounds noted, based on the following: (*1*) compounds **3***a–***6***c* show i.r. carbonyl absorption (see Table 1) at frequencies expected for structures **10***a* and *b*; (*2*) the chemical shifts and multiplicities of phenacyl methylene protons of **3***a–***6***c* are in accord with structures **10***a* and *b* (5) while the oxirane–methylene protons of **11** would likely appear at higher fields (40) and would display splitting patterns (40) which were not observed in the n.m.r. spectra of **3***a–***6***c*; (3) the rapid exchange of the phenacylmethylene protons of **3***a–***6***c* in deuterium oxide is expected for compounds with structures such as **10***a* and *b* (5) but would not be predicted for the oxirane–methylene protons of **11**. The intermediacy of **11** in equatorial *N*-phenacylation is not as easily disproven; however, this proposal requires ultimate collapse of **11** accompanied by migration of a phenyl-ring. This suggestion seems unlikely without further evidence.

The authors are grateful to Professor A. T. Bottini, University of California, Davis, Calif. for a number of helpful suggestions during the initial stages of this investigation. This work was supported in part by USPHS Grant NS-4431 and USPHS Training Grant 5-TO1 GM 00141-15.

Paramagnetic Ring Current in Cyclooctatetraene: Evidence from ^{1}H Nuclear Magnetic Resonance Shifts of Fused Benzo Derivatives

G. W. BUCHANAN AND A. R. MCCARVILLE

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received June 27, 1972

The ^{1}H n.m.r. aromatic spectral regions of benzocyclooctatetraene and several related compounds have been analyzed using the LAOCOON 3 program. Assignments are based on the analysis of the ^{13}C satellite spectrum of the parent compound. Results are interpreted in terms of appreciable π-electron delocalization in the 8π-electron eight-membered rings giving rise to measurable paramagnetic anisotropic effects.

Les régions aromatiques des spectres r.m.n. du benzocyclooctatetraène et de plusieurs composés similaires ont été analysées utilisant un programme de LAOCOON 3. Les attributions sont basées sur l'analyse des satellites ^{13}C du spectre du composé fondamental. Les résultats sont interprétés en terme d'une délocalisation appréciable des huit électrons-π du cycle à huit donnant lieu à des effets paramagnétiques anisotropiques mesurables. Introduction

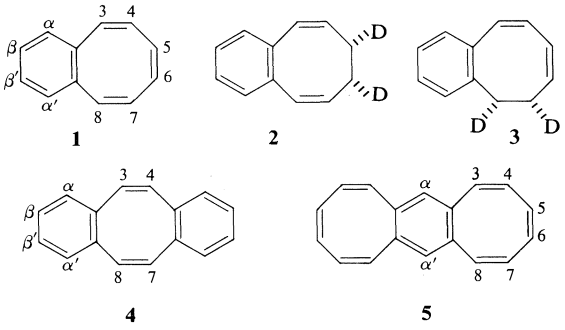
The presence or absence of a ring current in cyclooctatetraene has been the subject of considerable discussion in the literature in recent years. As a [4*n*] π-electron annulene, cyclooctatetraene would be expected to show a strong paramagnetic ring current if it were planar (1). Such a geometry is likely in the transition state for ring inversion of the molecule. Recently experimental evidence for the anti-aromaticity of planar 8π-electron systems has been reported using ring inversion results for substituted tetraphenylene (2) and benzocyclooctatetraene (3).

In its "tub"-like ground state conformation however, cyclooctatetraene is expected to exhibit little if any ring current because of the less effective overlap of 2pπ atomic orbitals. Dauben *et al.* (4), on the basis of diamagnetic susceptibility exhaltation measurements, concluded that no ring current was present. The reliability of these results for molecules exhibiting relatively small ring currents has been questioned by Anet and Schenck (5) in the light of ^{1}H n.m.r. solvent effect results using a series of hydrocarbons, from which the presence of a weak paramagnetic ring current in cyclooctatetraene has been suggested.

We present the results of a ^{1}H n.m.r. spectral examination of benzocyclooctatetraene, two isomeric benzocyclooctatrienes, and 1,2,5,6-dibenzocyclooctatetraene. These data and those for the related 1,2,4,5-dicyclooctatetraenobenzene are interpreted in terms of modest paramagnetic ring currents in the *non planar* eight-membered rings of the tetraenes.

Results and Discussion

Designations of protons in compounds **1**–**5** are shown below.



1 **2** **3**

4 **5**

To aid discussion of trends, the benzenoid proton data are presented in Tables 1 and 2. Those for the eight-membered ring protons are collected in Table 3.

(a) Benzenoid Protons

For compounds **1**, **2**, and **4**, the data in Tables 1 and 2 were obtained by iterative analysis of the AA′BB′ spin system due to the aromatic hydrogens using the LAOCOON 3 program. The shift in compound **5** is taken from the literature (6). The benzenoid region of the spectrum of compound **3** is almost identical to that of compound **2**, although the four benzenoid protons of **3** con-

stitute an ABCD spin system. Since unambiguous assignments for this region of the spectrum of **3** are not possible, a detailed analysis was not performed.

For benzocyclooctatetraene **1**, a brief description of the 60 MHz ^{1}H spectrum has been published (7). No attempt, however, was made to assign *specifically* the benzenoid protons. In the present work, this has been accomplished using ^{13}C satellite spectral analysis (8) on a 0.2 *M* solution in CS_2. The α protons of **1** will give rise to a ^{13}C satellite spectrum showing *one* large coupling (to β) of 7.67 Hz, a smaller coupling (to β′) of 1.29 Hz and a ^5J coupling of 0.41 Hz (to α′). The β protons, however, will exhibit a pattern with *two* large couplings of 7.67 (to α) and 7.24 Hz (to β′). A further splitting of 1.29 Hz due to ^4J coupling with α′ will arise. Due to overlap with the resonances of the eight-membered ring protons, the low field ^{13}C satellite spectrum centered at δ 7.7 was recorded. The spectrum showed a quartet at higher field with couplings of 7.7 and 1.3 Hz. At lower field, the spectrum shown in Fig. 1 was recorded (81 scans using a C-1024 computer). Clearly this is due to the β proton, the observed pattern arising from two large and nearly equal couplings of *ca.* 7.5 Hz and one smaller coupling of *ca.* 1.3 Hz.

Thus in **1**, the aromatic protons *nearest* to the periphery of the eight-membered ring resonate at 0.25 p.p.m. *higher* field than the more distant β protons.

The ^{13}C satellite spectrum of **2** was uninterpretable due to overlap of the α and β satellite signals, since the shift difference between these protons is decreased relative to **1**. It is assumed that the higher field aromatic peaks are due to H_α and the lower field ones to H_β and assignments are made accordingly.

It is well known that proton shifts are influenced by (*a*) local diamagnetic effects, (*b*) solute–solvent interactions, (*c*) solute–solute association, (*d*)

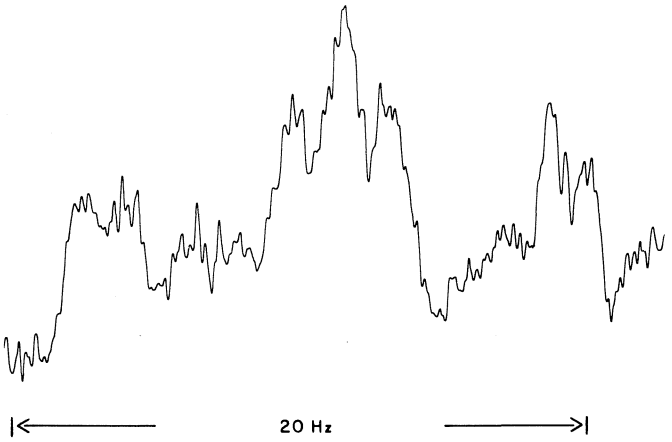

FIG. 1. ^{13}C satellite spectrum of low field aromatic protons of benzocyclooctatetraene (81 scans, 0.2 *M* in CS_2).

temperature, (*e*) other atom effects, and (*f*) ring current contributions. Effects from (*a*) are not likely to be significant in the molecules studied. To minimize the influence of (*b*) two relatively inert media, CS_2 and $CDCl_3$, have been employed. Spectra were obtained at concentrations of 0.2 and 0.01 *M* respectively to evaluate contributions from (*c*). A constant probe temperature was present throughout.

On examination of the benzenoid proton data in Tables 1 and 2, two main features are evident. Firstly, in all cases the centers of the aromatic spectral region for **2** and **3** are at lower field than in **1** by at least 0.1 p.p.m. Secondly, the shift differences between H_α and H_β in **2** are decreased to *ca.* 0.1 p.p.m., compared with *ca.* 0.25 p.p.m. in **1**. In CS_2 the α proton resonance of **2** shifts downfield by 18 Hz relative to **1** whereas the more remote β proton shifts only 2 Hz. In $CDCl_3$ these values are 21 and 5 Hz respectively for 0.2 *M* solutions. Although small concentration effects are observed, it is apparent that contributions from effects (*b*) and (*c*) are not dominant. Analyses of the aromatic proton resonances of **3** were not carried out but it is interesting to note that the center of the aromatic proton resonances is almost identical to that of **2** in all cases, and the spectra closely resemble those obtained for **2**.

We interpret these findings for compounds **1**, **2**, and **3** in terms of the presence of a small, but significant, paramagnetic ring current in the eight-membered ring of **1**. Using this model it is expected that the α benzenoid protons nearest the periphery of the 8π-electron ring of **1** will resonate at appreciably higher field than the more distant β protons (1). On reduction to either **2** or **3**, the 8π-electron character of the eight-membered ring is removed and cyclic delocalization of electrons can no longer exist in this system. As a result, the paramagnetic anisotropy of the eight-membered ring is lost and both H_α and H_β resonances move to lower field in **2** than in **1**. Due to the R^{-3} dependence of the anisotropy (9), the α protons nearer to the periphery of the eight-membered ring are affected to a much greater extent than the β hydrogens. The similarity in the spectra for **2** and **3** indicate that changes in the aromatic proton shifts on reduction of **1** are due to a change in the *overall* anisotropy of the eight-membered ring, rather than to a specific long-range anisotropy effect of a double bond.[1]

When two cyclooctatetraene moieties are fused to the benzene ring in compound **5**, the upfield shift of the benzenoid proton is even more pronounced. Relative to compound **1**, the additional cyclooctatetraene ring causes a shielding of *ca.* 0.30 p.p.m. in the α aromatic proton resonance.

For dibenzocyclooctatetraene (**4**) experimental and computer calculated spectra of the benzenoid

[1]A referee has suggested that the effects of the 5,6 and 7,8 double bonds may be equal due to a cancellation of the R^{-3} and cos $^2\theta$ terms in the anisotropy expression. From ring inversion results (3) it is deemed that the eight-membered ring of **2** has a tub-like ground state geometry and that of **3** is probably similar. Nearly identical J_{45} values for **1** and **3** support this conclusion. On this basis and from examination of molecular models a cancellation of R^{-3} and cos $^2\theta$ terms appears to be unlikely.

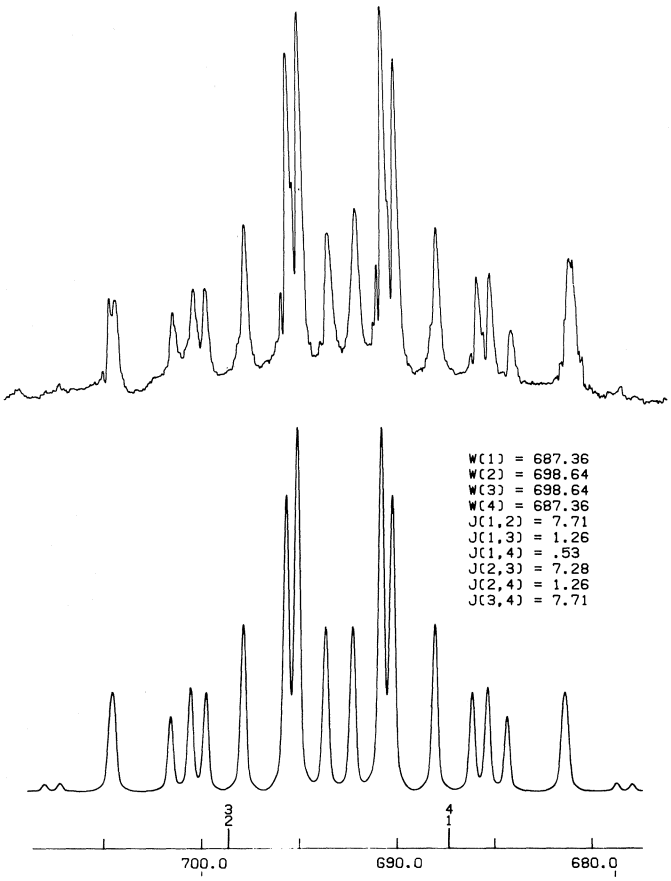

FIG. 2. Experimental and computer calculated spectrum of aromatic protons of 1,2,5,6-dibenzocyclooctatetraene (0.2 *M* in CS_2).

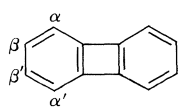
protons are shown in Fig. 2. Relative to benzocyclooctatetraene (**1**) the chemical shift difference between the α and β protons is decreased to *ca.* 0.1 p.p.m. and the α proton resonance is *deshielded* by *ca.* 0.1 p.p.m. These findings indicate that there has been a decrease in the paramagnetic anisotropy of the eight-membered ring on fusion of the second benzene function. Recently Figeys and Dralants (2) calculated the effect of successive addition of fused benzene rings on the intensity of the paramagnetic ring current in a *planar* 8π-electron ring of the complete series of benzocyclooctatetraenes. Benzene, with a diamagnetic ring current, was calculated to have a relative ring current intensity of +1.0; cyclooctatetraene, −0.88; benzocyclooctatetraene, −0.33; and *sym*-dibenzocyclooctatetraene was −0.16. Although the eight-membered rings are clearly not planar in their ground state conformation, the results of these molecular orbital calculations are consistent with our observed trends.

Finally, it is useful to compare the ^1H n.m.r. data herein with those for biphenylene (**6**) in which the existence of an induced paramagnetic ring current in the four-membered ring has been postulated by Figeys (10). Jones and Grant (11) have used Figeys' model to help explain ^{13}C shifts in this molecule. In biphenylene the α protons



6

resonate at δ 6.70 and the β protons at δ 6.80. Both are considerably upfield from the benzene value of δ 7.27. Although quantitative comparisons are difficult, the α proton shift in biphenylene is comparable to those in **1**, **4**, and **5** and

support for the concept of an appreciable induced paramagnetic ring current in the eight-membered rings of these molecules is gained.

(b) Eight-membered Ring Protons

These data were obtained from a first order analysis of the spectra and are presented in Table 3. The *cis*-deuterated compounds **2** and **3** were employed since they were available from a previous study of ring inversion parameters (3). Small deuterium isotope effects on the ^{1}H shifts of **2** and **3** are no doubt present (12), but these will be omitted from the present considerations. A standard AB spectral analysis was carried out for H_3 and H_4 of compounds **1**, **2**, **3**, and **5**, and for H_7 and H_8 of compounds **1**, **2**, and **5**.

The chemical shift trends in **2** and **3** relative to **1** are as expected when a double bond is reduced. Olefinic protons closest to the site of reduction experience upfield shifts. In compound **4** the downfield shift for $H_{3,4,7,8}$ relative to H_3 and H_8 of **1** is interesting. If, as suggested earlier, there is a decreased paramagnetic ring current in the eight-membered ring of **4** compared to **1**, the "outer" protons of **4** will experience a smaller upfield shift than those of **1**. As these protons are closer to the periphery of the eight-membered ring than the benzenoid protons, the effects are more pronounced.

The main feature of the coupling constants worthy of note is the small magnitude of the J_{45} coupling in compounds **1**, **3**, and **5**. This is evidence that the eight-membered rings of the molecules are non planar. Similar conclusions for **1** and **5** have been drawn from u.v. spectral data (6).

Conclusions

The aromatic proton shieldings in compounds **1–5** are deemed indicative of appreciable electron delocalization in the 8π-electron eight-membered rings of compounds **1**, **4**, and **5**. Addition of fused benzene rings to cyclooctatetraene decreases the magnitude of the paramagnetic ring current. This finding for non planar systems parallels the results of LCAO MO calculations for planar cyclooctatetraene (2). Data for eight-membered ring protons are less useful for studying the anisotropy of the cyclooctatetraene moiety. A comparison of shifts in compounds **1** and **4**, however, supports conclusions based on benzenoid proton chemical shifts.

The feasibility of using ^{13}C shieldings as a probe for paramagnetic ring currents in these molecules is under investigation.

Experimental

Spectra

All proton spectra were recorded on a Varian XL-100-12 n.m.r. spectrometer at a probe temperature of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

32.5 °C, using TMS as an internal standard. For the ^{13}C satellite spectra and the 0.01 *M* solutions, a Varian C-1024 time-averaging computer was employed.

Spectral analyses of the benzenoid protons were accomplished using the LAOCOON 3 program of Bothner-By and Castellano on the Carleton University XDS SIGMA 6 computer. Comparisons of observed spectra with those calculated were performed using a plotting routine in conjunction with a Cal-Comp plotter. The precision of the chemical shifts and coupling constants is judged to be ± 0.07 Hz. The spectra were fitted with an overall r.m.s. error of 0.066.

For the protons of the eight-membered rings, a first order analysis was employed. Shifts here are deemed accurate to ± 0.01 p.p.m. and couplings to ± 0.1 Hz.

Materials

Benzocyclooctatetraene was prepared by direct photolysis of benzobarrelene according to the published procedure (7).

A 40% yield of a mixture of 1,2-benzo-*cis*-7,8-dideuterio-1,3,5-cyclooctatriene (**3**) and 1,2-benzo-*cis*-5,6-dideuterio-1,3,7-cyclooctatriene (**2**) was obtained from the tetraene using deuterio diimide in methanol-*d*. The diimide was generated by dropwise addition of a solution of potassium ferricyanide in D_2O to hydrazine hydrate-d_6 over a period of 90 min. The products were separated from starting material by column chromatography (alumina, impregnated with 5% by weight $AgNO_3$ in H_2O) using 30–60° petroleum ether as solvent.

The 7,8-dideuterio triene was eluted first, as a colorless oil, n_D^{20} 1.5957, and low resolution mass spectral parent ion at *m/e* 158. Reported for the protio compound, n_D^{20} 1.5963 (13).

Further elution gave the isomeric 1,2-benzo-*cis*-5,6-dideuterio-1,3,7-cyclooctatriene, *m/e* 158, n_D^{20} 1.5991; reported for the protio analog, n_D^{20} 1.5987 (14).

The 1,2,5,6-dibenzocyclooctatetraene was purchased from the K&K Laboratories Inc., Plainsview, N.Y., and used without further purification.

We thank Dr. A. Fruchier for assistance with the LAOCOON 3 program and Professor F. A. L. Anet for a helpful discussion. The financial support of the National Research Council of Canada is gratefully recognized.

A Study of the Decomposition of Sodium Azide using Differential Thermal Analysis

H. Potvin and M. H. Back

Chemistry Department, University of Ottawa, Ottawa, Canada K1N 6N5

Received June 27, 1972

Differential thermal analysis and thermogravimetric analysis of sodium azide diluted with sodium chloride both show one major peak followed by a second minor one. This is interpreted as indicating the occurrence of two distinct decomposition processes. The activation energy of the first, major process was 36 kcal/mol, which agrees with values reported previously from measurements of the rate of nitrogen evolution. Differential thermal analysis of sodium azide mixed with alumina was complicated by the presence of variable amounts of water adsorbed on the alumina. The presence of water was shown to have an inhibiting effect on the decomposition.

L'analyse thermique différentielle et l'analyse thermogravimétrique de l'azoture de sodium dilué dans du chlorure de sodium montrent toutes deux un pic majeur suivi d'un second pic mineur. Ceci a été interprété par l'existence de deux processus distincts de décomposition. L'énergie d'activation du premier processus majeur, est de 36 kcal/mol en accord avec les valeurs précédemment rapportées à partir des mesures sur la vitesse de dégagement de l'azote. L'analyse thermique différentielle de l'azoture de sodium mélangé à de l'alumine s'est vu compliquer par la présence de quantités variables d'eau adsorbée qui a un effet inhibiteur sur la décomposition. The kinetics of the thermal decomposition of metallic azides have been followed by measurements of the pressure change (1–4), by analysis of the products by mass spectrometry (5), and by measurement of light emission from the product nitrogen (6) and of chemi-electron emission (7). The reactions are complex and cannot be described by simple laws. A slow period of nucleation is followed by a rapid reaction as the metallic nuclei catalyze the decomposition. The rate-determining step in the decomposition is believed to be the transfer of an electron from the azide ion followed by combination of the azide radicals to give the product nitrogen and formation of neutral metal atoms (8).

In several studies of the decomposition of sodium azide reference has been made to the existence of two distinct decomposition processes. Mattler (9) and Lormeau (10) observed two activation energies from their measurements of the light emission from decomposing sodium azide. Secco (2) and Walker *et al.* (5) observed a white residue remaining after decomposition below 345 °C which was chemically identical to the original compound and which decomposed on heating to a higher temperature. In order to provide additional information which might relate to this phenomenon the decomposition of sodium azide was studied by differential thermal analysis (DTA) and by thermogravimetric analysis (TGA).

Reagent grade sodium azide (100–140 mesh[1]) was mixed with diluent, alumina or sodium chloride, in the proportion 1:10. Preliminary experiments were performed on a Fisher Differential Thermalyzer Model 260 using platinel thermocouples. Samples (100 mg) were weighed directly into quartz crucibles. A nitrogen flow of about 50 cc/min was passed over the sample holder. Most of the experiments were performed on a DuPont 900 Differential Thermal Analyzer using both the high temperature DuPont Cell and the standard DuPont Cell. A flow of nitrogen of about 1 l/min was maintained and the sample size was normally about 10 mg. The thermogravimetric analyses were obtained with a Cahn RH electrobalance. Pellets containing about 10 mg of sodium azide and about 500 mg of reference material were placed in the platinum crucible and the apparatus was evacuated.

With both diluents DTA gave a sharp exothermic peak followed by a small second peak which in some cases appeared as a tail on the larger peak. The difference in temperature between the two peaks was about 5°. Typical DTA curves are shown in Fig. 1. No indication of a phase transition occurring before decomposition was observed in any of the experiments. Use of

[1]A determination of the surface area by the BET method using nitrogen adsorption gave a value of 0.3 m^2/g.

20	414	4.3					

helium or hydrogen instead of nitrogen gave similar results.

A series of experiments with different heating rates was performed with the DuPont apparatus. The results are summarized in Table 1. Sample sizes between 10 and 50 mg gave identical results. According to the method developed by Kissinger (11) the temperature at the maximum point of deflection will be a function of the heating rate for a reaction which has a finite activation energy. Following this method, log (Φ/T_m^2) was plotted against $1/T_m$, where Φ is the heating rate and T_m is the temperature at the maximum deflection, for the experiments using sodium chloride as diluent. From the slope of this curve a value of 36 ± 2 kcal/mol was calculated for the activation energy. A summary of values obtained previously is given in Table 2. It may be concluded that the rate measured by DTA corresponds to the rate measured by nitrogen evolution during the accelerated region and by chemiluminescence. Furthermore, the method for obtaining an activation energy from DTA appears to be valid even for a complex decomposition process involving an induction period.

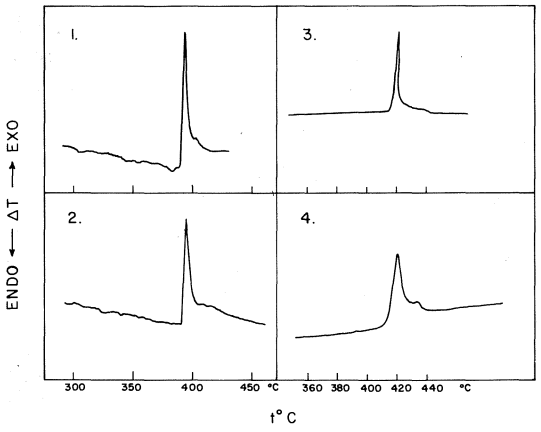

FIG. 1. Typical DTA curves for sodium azide: *1*, *2*, NaN_3:NaCl, 1:10; *3*, *4*, NaN_3:Al_2O_3, 1:10.

In the experiments using alumina as diluent the temperature of maximum deflection was quite independent of the heating rate. Instead the temperature at the maximum appeared to be a function of the peak height, increasing with increasing peak height. The explanation for this behavior was provided by the TGA of the alumina by itself which showed a gradual weight loss over the temperature range 70–370 °C. This can only indicate the gradual desorption of water, in spite of the fact that the alumina had been heated at

1000 °C for 6 h and stored in a desiccator. A comparison of the TGA of alumina itself and of the alumina–azide mixtures showed that decomposition of the azide did not occur until practically all the water was desorbed from the alumina. It is known that water inhibits the decomposition of the azide by impeding the formation of nuclei of metallic sodium (4). Thus variation in the temperature of the maximum deflection may be the result of varying amounts of water which may be taken up by the alumina during the process of preparing the sample. This accounts for the observation that the temperature of decomposition was not dependent on the heating rate.

Furthermore, some experiments were performed in which the temperature was held constant after reaching a certain value in the range 350–400 °C. Decomposition was never observed during the period of constant temperature although the sample was maintained at a temperature as high as 400 °C for 2 h. When the temperature was subsequently raised decomposition occurred at the usual temperature. These results show the strongly inhibiting effect of water.

Experiments using TGA were performed at heating rates of 2, 5, 10, and 20°/min. At heating rates of 5 and 10°/min the curves of weight loss against temperature suggest the occurrence of two processes. Figure 2 shows the weight loss as a function of temperature for a heating rate of 10°/min and the differential weight loss calculated from it. Duplicate determinations showed good reproducibility. The separation between the peaks was 6° at a heating rate of 5°/min and 16° for a heating rate of 10°/min. At heating rates of 2 and 20°/min only one maximum in the rate was observed. At 2°/min the rate of weight loss was so fast that the differential curve could not be measured whereas at 20°/min the differential curve was a broad peak.

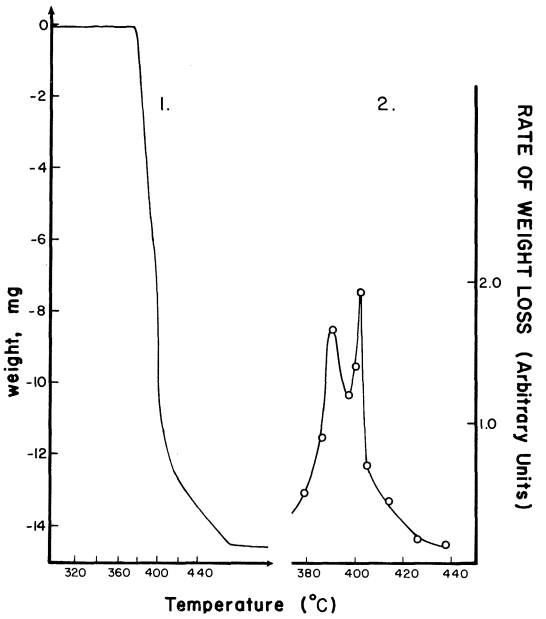

FIG. 2. Typical TGA of NaN_3:NaCl mixture: (*1*) weight as a function of temperature; (*2*) rate of weight loss as a function of temperature.

The results of both the DTA and TGA suggest the occurrence of two processes during the decomposition. The differential curves, however, do not show identical characteristics. In the DTA the first peak is large and sharp and the second small and broad while in the TGA the first peak is the smaller. The separation of the peaks did not change significantly with heating rate in the DTA while a large change was observed with the TGA. In spite of these differences it seems reasonable to conclude that the first peaks of each analysis are a measure of the same process. In each case the first peak corresponds to over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

half the loss of the sample and the second peak is a minor process. The relative rates of the two processes need not correspond exactly since one analysis measures heat released while the reaction takes place in an atmosphere of nitrogen and the other measures weight loss under vacuum. In summary, the present results provide some new evidence for the possibility of the occurrence of two distinct processes in the decomposition of sodium azide.

The authors would like to thank Dr. V. S. Ramachandran of the National Research Council of Canada for the use of his DuPont 900 Differential Thermal Analyzer and for many helpful discussions. Thanks are also due to Mr. G. M. Polomark for his capable assistance with the experiments and to Mr. R. Myers for his measurement of the surface area of the sodium azide.

Volumes and Heat Capacities of Transfer of Tetraalkylammonium Bromides from Water to Aqueous Urea Solutions at 25 °C

P. R. PHILIP, J. E. DESNOYERS,[1] AND A. HADE

Department of Chemistry, Université de Sherbrooke, Sherbrooke, and Department of Chemistry, Université du Québec, Montréal, Québec

Received July 13, 1972

The apparent molal volumes and heat capacities of tetraalkylammonium bromides were measured in urea–water mixtures at 25 °C. The volumes and heat capacities of transfer from water to urea–water mixtures indicate that structural hydration effects are smaller in urea–water mixtures than in water. Also a comparison with the corresponding transfer functions from H_2O to D_2O suggests that urea–water mixtures are less structured than pure water.

Les capacités calorifiques et volumes apparents molaires des bromures de tetraalkylammonium ont été mesurés dans des mélanges eau–urée à 25 °C. Les volumes et capacités calorifiques de transfert de l'eau aux mélanges eau–urée indiquent que les effets structuraux d'hydratation sont moins prononcés dans les mélanges eau–urée que dans l'eau. Egalement, une comparaison avec les fonctions de transfert correspondantes de H_2O à D_2O suggère que les mélanges eau–urée sont moins structurés que l'eau pure.

Introduction

The importance of urea as a denaturant has led to numerous studies of its aqueous solutions; as a result, most of its physicochemical properties are now known: solubility (1), dielectric constants (2), densities (3), compressibilities (4), viscosities (5), diffusion (6–8), ultrasonic velocity and absorption (9), i.r. (10) and raman (11) spectra, n.m.r. (12), activity and osmotic coefficients (13, 14), heats of solution (15), heat capacities (16), and heats of dilution (17). The ternary systems, where an electrolyte or nonelectrolyte is added to the aqueous urea solution, have also been investigated thoroughly (18–25). Despite all these studies, the nature of the interactions between urea and water is still not fully understood. While urea usually appears as an overall structure breaker in ternary systems, there are some cases where the structural contribution is not clear; for example, the solubility of methane decreases in 7 *M* urea while that of ethane, propane, and butane is found to increase in the presence of urea (18).

The models suggested to explain the behavior of aqueous urea can be classified in four broad groups; urea is considered a structure breaker in a way similar to that of ions (26, 11), it is assumed to associate in water (27), Frank and Franks (28) prefer to say that it dissolves preferentially in the unbonded fraction of water molecules, thus shifting the equilibrium of water from bonded to unbonded molecules as a statistical structure breaker, and Abu-Hamdiyyah (29) suggests the formation of mixed clusters between urea and water. None of these models appears at the moment entirely satisfactory (30) and often all of these models can account qualitatively for the experimental observations.

It was shown recently that the heat capacities (31) and volumes (32) of transfer of tetraalkylammonium bromides from H_2O to D_2O were sensitive functions for the study of overall structural hydration effects. Since the net structural influence of tetraalkylammonium bromides on water is now well-established (31, 33, 34), it was felt that a similar study of the heat capacities and volumes of transfer of these salts from water to aqueous urea might indirectly throw some light on the nature of the urea–water interactions.

Experimental

The tetraalkylammonium bromides (Eastman Kodak) were purified as described elsewhere (35), and urea (Fisher Certified) was used as such after drying under vacuum at 60 °C for 48 h. All solutions were prepared by weight with water redistilled from an alkaline permanganate solution. The solutions were prepared fresh and used the same day to prevent any decomposition. All salt concentrations were expressed in aquamolalities (*m*), *i.e.* in number of

[1]To whom correspondence should be addressed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

moles of salt per 55.51 moles of mixed solvent (urea + water). The urea concentration is expressed in molalities (*m*).

The densities were measured with an Anton Paar digital Densitymeter (Model DMA02C) and the heat capacities with a flow microcalorimeter (16). A comparison with densities obtained in pure water by a buoyancy method (36) indicates that the present densities are reliable to $\pm 10^{-5}$ g cm^{-3} or better. Differences in heat capacities are measured to $\pm 0.5\%$ and the overall sensitivity of the flow microcalorimeter is 7×10^{-5} J K^{-1} g^{-1}.

Results

The densities and heat capacities were determined[2] at 25 °C for the following systems: *1*, Me_4NBr and nBu_4NBr in the concentration range 0.04 to 0.5 *m* at a fixed urea concentration of 2.955 *m*; *2*, Me_4NBr and nBu_4NBr at a fixed aquamolality of 0.05 *m* in a variable urea concentration (0.1 to 3 *m*); *3*, Et_4NBr and nPr_4NBr at 0.1 *m* salt concentration and 2.952 *m* urea concentration.

The apparent molal volumes and heat capacities were calculated from the relations:

$$[1] \qquad \phi_v = \frac{M}{d} + \frac{W_{55.51}(d_0 - d)}{dd_0m}$$

$$[2] \qquad \phi_c = Mc_p - \frac{W_{55.51}(c_{p0} - c_p)}{m}$$

where M is the salt molecular weight, $W_{55.51}$ is the weight of 55.51 moles of mixed solvent, m the salt aquamolality, c_{p0}, c_p, d_0, and d, the heat capacities (J K^{-1} g^{-1}) and densities (g cm^{-3}) of the mixed solvent and ternary solutions. The ϕ_c and ϕ_v of Me_4NBr and nBu_4NBr in pure water (16, 36) and in 2.955 *m* urea are plotted against the salt aquamolality in Figs. 1 to 3. The transfer functions $\Delta\phi_{ctr} = \phi_c$ (H_2O + urea) $- \phi_c(H_2O)$ and $\Delta\phi_{vtr} = \phi_v(H_2O$ + urea$) - \phi_v(H_2O)$ were plotted for Me_4NBr and nBu_4NBr at 0.05 *m* against the urea concentration in Figs. 4 and 5. Finally the $\Delta\phi_{ctr}$ and $\Delta\phi_{vtr}$ of the four tetraalkylammonium bromides at 0.1 *m* salt concentration and 2.95 urea concentration were plotted against the number of carbon atoms per chain on Fig. 6.

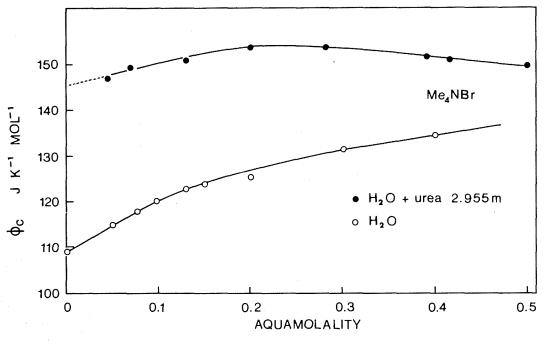

FIG. 1. Apparent molal heat capacities of Me_4NBr in water and mixtures (2.955 *m*) at 25 °C.

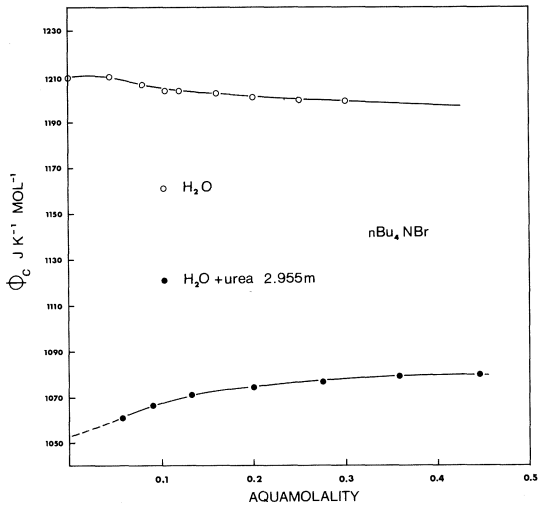

FIG. 2. Apparent molal heat capacities of nBu_4NBr in water and in urea–water mixtures (2.955 *m*) at 25 °C.

Discussion

The dielectric properties of water (37) and of aqueous urea solutions (2) are quite similar; although the dipole moments of water and urea

are respectively 1.83 and 4.56 Debyes, with large ions like the tetraalkylammonium and the bromide ions, the electrostatic effects are sufficiently weak that we can probably ignore any specific (coulombic) solvation effects in urea water mixtures. Therefore, as a first approximation, we can assume that all electrostatic ion–solvent interactions would be equal in both water and mixed solvent, and that the transfer functions primarily reflect structural changes.

Heat Capacities

Me_4NBr and *n*Bu_4NBr are usually assumed to be respectively an overall structure breaker and a structure maker in water (33, 34). Also, an abnormally large ϕ_c in comparison with the intrinsic heat capacity is associated with structure making and a small ϕ_c with structure breaking (31). The values of ϕ_c in urea 2.955 *m* for Me_4NBr (Fig. 1) and *n*Bu_4NBr (Fig. 2) are closer to the intrinsic heat capacities of the solutes than the corresponding ϕ_c in water, indicating that the structural changes caused by the salts are less important in urea–water mixtures than in pure water. Further evidence for this comes from a comparison with the $\Delta\phi_{ctr}{}^0(H_2O \rightarrow D_2O)$ of the same salts as shown in Table 1.

There seems to be a direct relationship between the degree of structure of the medium and the importance of the structural interactions. For example, D_2O appears to be more structured than H_2O and structural changes caused by solutes are more pronounced in D_2O (*cf.* ref. 31). If this is correct, it is justified to claim that, since $\Delta\phi_{ctr}{}^0(H_2O \rightarrow H_2O$ + urea 2.955 *m*) is opposite that of $\Delta\phi_{ctr}{}^0(H_2O \rightarrow D_2O)$, the urea solution is less structured than pure water.

The present heat capacity data are in agreement with the excess enthalpies and entropies of Me_4NBr and *n*Bu_4NBr in urea–water mixtures (21). The $\Delta H_{tr}{}^0(H_2O \rightarrow H_2O$ + urea) and $\Delta S_{tr}{}^0$-$(H_2O \rightarrow H_2O$ + urea) are opposite in sign to

those of $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea) as we would expect from structural interaction models (38).

The effect of changing the urea concentration is illustrated in Fig. 4; $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea) increases continuously in absolute magnitude and Sarma and Ahluwalia (25) have shown recently that the observed linearity in the case of nBu_4NBr extends to 10 *m* in urea, indicating that it is still possible to promote some structure even in these highly concentrated urea solutions. On the other hand, it seems from Fig. 4 that in the case of Me_4NBr $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea) levels off at the higher urea concentrations. This could be interpreted in terms of a saturation effect; beyond a certain urea concentration Me_4NBr has no more structure to break.

The dependence of $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea 2.95 *m*) at 0.1 aquamolality of salt, on the cation chain length of the tetraalkylammonium bromides (Fig. 6) can be compared with $\Delta\phi_{ctr}^0(H_2O \rightarrow D_2O)$ (31, 32) since the concentration dependence of $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea 2.95 *m*) is small (*cf.* Figs. 1 and 2). As with the $H_2O \rightarrow D_2O$ transfer, Et_4NBr is a borderline case indicating that this salt is close to having no overall structural influence in aqueous media.

Volumes

The standard partial or apparent molal volumes of ions in water can be considered to arise from four main contributions

$$\phi_v^0 = \bar{V}(\text{in}) + \bar{V}(\text{el}) + \bar{V}(\text{struct}) + \bar{V}(\text{cav})$$

The intrinsic volume $\bar{V}$(in) disappears when transfer functions are considered. The electrostatic contribution $\bar{V}$(el), which gives rise to electrostriction, is probably small with R_4N^+ and Br^- ions and negligible when the transfer functions are considered. The structural contribution $\bar{V}$(struct) will be negative in the presence of structure breakers (Me_4N^+, Br^-) and positive with structure makers (nBu_4N^+) (38). However, the cavity effect $\bar{V}$(cav), which is intimately related to hydrophobic hydration, is negative since hydrophobic molecules or groups tend to be fitted, at least partially, in water cavities or cage-like structures (quasichlathrate environment) (34, 39, 40). There is a compensation between $\bar{V}$(cav) and $\bar{V}$(struct), but $\bar{V}$(cav) is usually assumed to be the leading term responsible for the large negative apparent molal compressibility ϕ_K and the large positive apparent molal expansitivity ϕ_E of nBu_4NBr (38); ϕ_K and ϕ_E reflect mostly the pressure and temperature dependence of the two terms $\bar{V}$(struct) + $\bar{V}$(cav) in the case of hydrophobic solutes. Going from a more structured medium (H_2O) to a less structured medium (H_2O + urea) is equivalent qualitatively to the effect of increasing the temperature on ϕ_v^0. Therefore, as expected from the sign of expansitivities, $\Delta\phi_{vtr}$ of Me_4NBr is positive ($\bar{V}$(struct) <0 and $\bar{V}$(cav) $\simeq 0$) and $\Delta\phi_{vtr}$ of nBu_4NBr is also positive ($\bar{V}$(cav) < 0) as shown in Figs. 3 and 5. The intermediate salts, Et_4NBr and nPr_4NBr pass through a minimum (Fig. 6) which would be close to zero if standard $\Delta\phi_{vtr}^0$ were plotted. However, if the $\Delta\phi_{vtr}(H_2O \rightarrow H_2O$ + urea) can be so explained, then the $\Delta\phi_{vtr}^0(H_2O \rightarrow D_2O)$ appears anomalous since its sign changes when going from Me_4NBr to nBu_4NBr. The explanation offered for this (31) was that, although $\bar{V}$(cav) was probably larger than $\bar{V}$(struct) in both H_2O and D_2O, it was probably about the same in both solvents. Thus, in this particular case, the transfer functions reflect mostly $\bar{V}$(struct).

The present results for $\Delta\phi_{vtr}(H_2O \rightarrow H_2O$ + urea) and $\Delta\phi_{ctr}(H_2O \rightarrow H_2O$ + urea) indicate that the water–urea mixture is less structured than pure water in so far as structural changes caused by solutes are smaller in urea–water mixtures than in water. In addition, the sign and magnitude of $\Delta\phi_{ctr}$ and $\Delta\phi_{vtr}$ of nBu_4NBr indicate that urea participates with, or at least affects significantly,

the chlathrate-type hydration near the hydrophobic ions. However, we cannot draw much information on the discrete nature of the urea–water interactions or on the origin of the structural interactions in urea–water mixtures. Still, the present data should be useful as a further piece of evidence that must be accommodated in any successful model for urea–water mixtures.

Excess Heat Capacities and Volumes

The value of the Debye-Hückel limiting slope for electrolytes in urea–water mixture is not known for ϕ_v or ϕ_c. Therefore, a discussion of structural solute–solute interactions (41) is more difficult. However, since the dielectric properties of urea solution are close to those of water (37), we can assume that, as a first approximation, the limiting Debye–Hückel slopes are about equal and that a comparison of the concentration dependence of ϕ_c and ϕ_v for electrolytes in water and urea–water mixtures will reflect primarily the structural ion–ion interactions. It was shown that structural solute–solute interactions are larger in D_2O than in H_2O (31); for the same reasons they should be smaller in urea–water mixtures. The concentration dependences on Figs. 1, 2, and 3 indicate a negative $\Delta\phi_{ctr}^{ex}(Me_4NBr)$, a positive $\Delta\phi_{ctr}^{ex}(nBu_4NBr)$, a negative $\Delta\phi_{vtr}^{ex}(Me_4NBr)$, and a positive $\Delta\phi_{vtr}^{ex}(nBu_4NBr)$ from H_2O to H_2O + urea mixtures in good agreement with the predictions of structural models (31, 38, 41).

We would like to thank the Defence Research Board of Canada (Grant No. 5405) and the National Research Council of Canada for its financial support.

1-Propanethiol as a Radical Scavenger in the γ-Radiolysis of Liquid Cyclohexane

JOSEPH ESSER AND JOHN A. STONE

Department of Chemistry, Queen's University, Kingston, Ontario

Received August 12, 1971[1]

1-Propanethiol is an excellent H atom and alkyl radical scavenger in the γ-radiolysis of liquid cyclohexane. The total radical yield (5.2) is measured by twice the yield of propyldisulfide which appears to be invariant with propanethiol concentration. 1-Propanethiol-*d* is about as efficient an H atom scavenger as ethylene. $C_3H_7S\cdot$ radicals add reversibly to cyclohexene.

Le 1-propanethiol est un excellent piège pour les atomes d'hydrogène et les radicaux alkyl dans la radiolyse-γ du cyclohexane liquide. Le rendement total en radical (5.2) est déterminé comme étant le double du rendement de disulfure de propyl, qui ne semble pas varier avec la concentration de propanethiol. L'atome de H est à peu près aussi efficacement piégé par le 1-propanethiol-*d* qu'il l'est par l'éthylène. Les radicaux $C_3H_7S\cdot$ se combinent réversiblement au cyclohexène.

[Traduit par le journal]

Can. J. Chem., **51**, 192 (1973)

Introduction

The sulfhydryl group, —SH, is of interest in radiation chemistry because of its ability to repair radiation damage by transfer of the H atom to a free radical (1). It is present in molecules of biological interest which have been extensively studied in irradiated aqueous solution. However its scavenging properties in irradiated liquid alkanes have received little attention.

Nevitt and Remsberg (2) briefly studied the scavenging of alkyl radicals by 1-butanethiol in cyclohexane. Hardwick (3) stated that 2-ethyl-2-propanethiol and other simple mercaptans are relatively inert towards H atoms in *n*-hexane when judged by the total hydrogen yield. Our isotopic experiments show that this yield is a poor measure of the reactivity. Bergdolt and Schulte-Frohlinde interpreted the hydrogen yields in cyclohexane–thiophenol-*d* (4) and 2,2,4-trimethylpentane–hexanethiol-1 (5) mixtures in terms of positive charge transfer, H atom scavenging, and electron scavenging. No liquid product yields were measured.

The present study was undertaken to determine the scavenging ability of an alkanethiol in an irradiated alkane. For experimental convenience 1-propanethiol was chosen since it is an easily handled liquid while cyclohexane was used as solvent since its major radiolytic products are few in number (6, 7) and their mode of formation appears to be reasonably well understood (8).

Experimental

Cyclohexane (Phillips Pure Grade) contained little cyclohexene ($<10^{-5}$ *M*) and was used as received. 1-Propanethiol (Baker) was fractionally distilled, a middle cut being taken which contained $\sim 10^{-5}$ *M* propyldisulfide. 1-Propanethiol-*d* (Merck, Sharp and Dohme) was subjected to the same distillation procedure.

The 2.5 ml liquid samples were irradiated under vacuum at 24 ± 2 °C in Pyrex tubes in a ^{60}Co γ source (Gammacell 220) at a dose rate of $\sim 1.0 \times 10^{19}$ eV l^{-1} s^{-1} in the Fricke dosimeter.

The disappearance of propanethiol was measured spectrophotometrically by the Ellman method (9) and the formation of H_2S by the methylene blue procedure (10). Hydrogen was measured volumetrically and its isotopic composition was determined by mass spectrometry. All other products were determined by g.l.c.; cyclohexene on a 7.5 ft, 20% β,β′-oxydipropionitrile column at 30 °C, bicyclohexyl, cyclohexylpropylsulfide, and propyldisulfide on a 6 ft, 10% SE-30 column at 105 °C, and propane on a 4 ft Chromosorb 102 column at 40 °C.

Results

The yields of all major products formed in liquid cyclohexane containing up to 0.16 *M* propanethiol are shown in Figs. 1 and 2. The dose was 1.5×10^{19} eV g^{-1} except where noted. The yields of all products are linear with dose up to this value except at low concentrations of propanethiol when there are significant changes in its concentration during radiolysis. Even under

TABLE 1. Sulfur balance in cyclohexane–propanethiol mixtures (1.5×10^{19} eV g^{-1})

Propanethiol (M)	$2G(C_3H_7SSC_3H_7) + G(c\text{-}C_6H_{11}SC_3H_7)$	$G(-C_3H_7SH)$
4.6×10^{-3}	4.5 ± 0.4	4.8 ± 0.3
2.3×10^{-3}	4.5 ± 0.2	4.9 ± 0.3

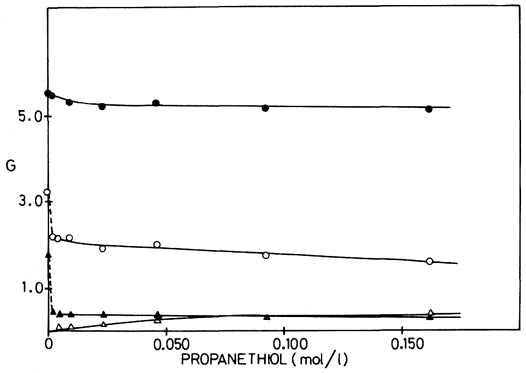

FIG. 1. Product yields in the radiolysis of cyclohexane–propanethiol mixtures (1.5×10^{19} eV g^{-1}). ●, Hydrogen; ○, cyclohexene; ▲, bicyclohexyl; △, hydrogen sulfide.

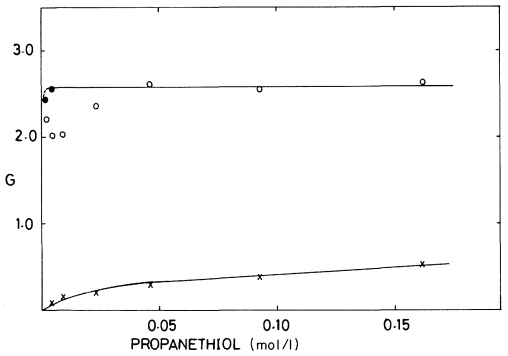

FIG. 2. The yields of propyldisulfide and cyclohexylpropylsulfide in cyclohexane–propanethiol mixtures ○,x, 1.5×10^{19} eV g^{-1}; ●, 3.6×10^{18} eV g^{-1}.

these circumstances it is only the disulfide yield that is markedly affected.

The disappearance of propanethiol was measured at 4.6 and 2.3×10^{-3} M and a good sulfur balance was obtained. $G(-C_3H_7SH)$ is compared with the yields of products containing sulfur in Table 1. The H_2S yield was too small to measure. Propyldisulfide constitutes more than 95% of these products. At the dose used (1.5×10^{19} eV g^{-1}) up to 50% of the propanethiol had disappeared at the conclusion of the irradiation of the solution containing the lower thiol concentration. Some of the disulfide formed will have disappeared by secondary reaction since at the lower dose of 3.6×10^{18} eV g^{-1} the yield is higher. Work now in progress on scavenging by disulfide shows that about half the disulfide which disappears leads neither to the formation of thiol nor to the production of cyclohexylpropylsulfide and cannot at present be accounted for (11).

Propanethiol-d (C_3H_7SD) produced a substantial yield of HD and a much smaller yield of D_2 (Fig. 3). $G(H_2 + HD + D_2)$ was equal at all propanethiol concentrations to $G(H_2)$ in the absence of this solute. The experimental points for HD are fitted by an equation describing H atom scavenging (see later). Sulfur hexafluoride and carbon tetrachloride, both excellent electron scavengers, reduced the yields of all hydrogen isotopes, the D_2 yield being most affected (Table 2).

In addition to the above results the following observations were made. (*i*) 4×10^{-2} M ethylene had no effect on $G(H_2S)$ at 8.8×10^{-2} M propanethiol but the electron scavengers CCl_4 and SF_6 reduced it considerable (Table 3). (*ii*) A small yield of propane was found. At 9.2×10^{-3} and 9.2×10^{-2} M propanethiol $G(C_3H_8)$ was 0.18

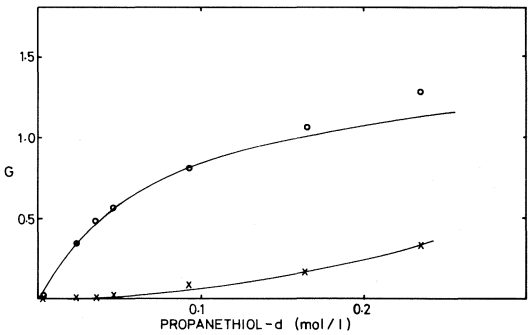

FIG. 3. HD (○) and D_2 (x) yields from cyclohexane–propanethiol-d mixtures (1.5×10^{19} eV g^{-1}). The curve drawn through the HD points is calculated as described in the text.

and 0.35 respectively when $G(H_2S)$ was 0.11 and 0.33. (*iii*) Cyclohexene, 9.9×10^{-4} M, increased $G(c\text{-}C_6H_{11}SC_3H_7)$ from 0.29 to 0.73 in cyclohexane containing 4.64×10^{-2} M propanethiol. However with 4.65×10^{-3} M propanethiol the same concentration of olefin increased the value only from 0.08 to 0.13. (*iv*) Propanethiol, 0.1 M, reduced $G(N_2)$ from a 0.04 M solution of N_2O in cyclohexane by ~4%. There was no measureable reduction at lower concentrations.

Discussion

The yields of the major liquid radiolysis products, cyclohexene and bicyclohexyl, from cyclohexane are efficiently reduced by propanethiol while the hydrogen yield is decreased only slightly (Fig. 1). This is consistent with a simple free radical scavenging mechanism.

[1] $c\text{-}C_6H_{12} \rightsquigarrow c\text{-}C_6H_{10}, H_2, c\text{-}C_6H_{11}\cdot, H\cdot$

[2] $H\cdot + c\text{-}C_6H_{12} \rightarrow H_2 + c\text{-}C_6H_{11}\cdot$

[3] $2c\text{-}C_6H_{11}\cdot \rightarrow (c\text{-}C_6H_{11})_2$
$\rightarrow c\text{-}C_6H_{10} + c\text{-}C_6H_{12}$

[4] $c\text{-}C_6H_{11}\cdot + C_3H_7SH \rightarrow c\text{-}C_6H_{12} + C_3H_7S\cdot$

[5] $H\cdot + C_3H_7SH \rightarrow H_2 + C_3H_7S\cdot$

[6] $2C_3H_7S\cdot \rightarrow C_3H_7SSC_3H_7$

The net result is the sacrificial protection of cyclohexane by propanethiol. Even at the lowest propanethiol concentration reaction 3 is superceded by 4 for all freely diffusing $c\text{-}C_6H_{11}\cdot$ radicals. The non-scavengeable yields of cyclohexene (2.2) and bicyclohexyl (0.4) are in good agreement with the values of 2.42 and 0.4 estimated by Bansal and Schuler (8). If a value of 10^9 l m^{-1} s^{-1} is taken for k_3, the rate constant for reaction 3 (12, 13), then k_4 must have a minimum value of 10^5 l m^{-1} s^{-1}. This is consistent with the values of 3.9×10^5 and 2.9×10^6 l m^{-1} s^{-1} for $c\text{-}C_6H_{11}\cdot + c\text{-}C_6H_{11}SH$ and $C_3H_7\cdot + C_3H_7SH$ respectively (12).

$G(C_3H_7SSC_3H_7)$ does not vary with propanethiol concentration from 0.05 to 0.16 M at a dose of 1.5×10^{19} eV g^{-1}. At 0.05 M at the completion of the irradiation 2% of the propanethiol has disappeared. At lower concentrations and for the same dose the disulfide yield is lower presumably due to secondary reaction (Fig. 2). With 4.6×10^{-3} M thiol and a dose of 3.6×10^{18} eV g^{-1} 5% of the thiol has disappeared to yield disulfide, the G value for which is 5.2. Since the radical scavenging efficiencies of propanethiol and propyldisulfide are approximately the same (11) it appears that the initial disulfide yield is independent of thiol concentration up to at least 0.16 M.

Twice $G(C_3H_7SSC_3H_7)$ represents the total yield of scavengeable radicals. Hydrogen atom scavenging will be negligible at the lowest propanethiol concentration and therefore 5.2 is the yield of scavengeable aklyl radicals. These must be essentially all cyclohexyl radicals since $\Delta G(c\text{-}C_6H_{10} + (c\text{-}C_6H_{11})_2) = 5.0$ (obtained by linear extrapolation to zero thiol concentration of the linear portions of the yield curves at high propanethiol concentrations in Fig. 1). Using low concentrations of radioactive iodine and a dose approximately ten times less than ours, Bansal and Schuler (8) obtain $G(c\text{-}C_6H_{11}) = 5.3 - 5.4$. However after theoretical corrections for H atom and ion scavenging their value is raised to 5.7. No such correction is required for H atom scavenging in the present work since the same yield of $C_3H_7S\cdot$ is obtained by reactions 2 and 4 as by reaction 5. Ion scavenging, if it indeed occurs, is not efficient and must also lead to disulfide since the yield of the latter remains constant. We therefore fail to

For personal use only.

understand the discrepancy of 0.5 G between the two results. It might be argued that H atom abstraction by alkyl radicals from other than the SH group in propanethiol is occurring but there is no experimental evidence that this is of significance in the gas or liquid phases and even if it did occur the radical formed, $\cdot C_3H_6SH$, would surely abstract from the —SH group.

[7] $\cdot C_3H_6SH + C_3H_7SH \rightarrow C_3H_7SH + C_3H_7S\cdot$

and the net result would be the same as if reaction 4 only occurred.

We believe that the use of a simple thiol such as propanethiol provides an excellent method for measuring the total radical yield in an irradiated liquid alkane. Although the disulfide yield is a little difficult to obtain accurately at very low thiol concentrations it appears to remain constant with increasing concentration.

The slight decrease in $G(H_2)$ in Fig. 1 is matched by a small yield of H_2S and, within experimental error, $G(H_2 + H_2S)$ remains constant. Also $G(C_3H_8)$ is approximately equal to $G(H_2S)$. Since ethylene has no effect on $G(H_2S)$, reaction 8,

[8] $H\cdot + C_3H_7SH \rightarrow H_2S + C_3H_7\cdot$

may be ruled out. The reduction in $G(H_2S)$ caused by the addition of SF_6 or CCl_4 (Table 3) shows that the main precursors of H_2S are ionic. Two possible mechanisms for H_2S formation, one involving proton transfer and the other electron capture, are

[9] $c\text{-}C_6H_{12}^+ + C_3H_7SH \rightarrow c\text{-}C_6H_{11}\cdot + C_3H_7SH_2^+$

[10] $C_3H_7SH_2^+ + e \rightarrow C_3H_7\cdot + H_2S$ (or $C_3H_8 + \cdot SH$)

and

[11] $e + C_3H_7SH \rightarrow C_3H_7SH^-$

[12] $C_3H_7SH^- + c\text{-}C_6H_{12}^+ \rightarrow C_3H_7\cdot + H_2S + c\text{-}C_6H_{11}\cdot$

Both reactions fit the above experimental facts and in both cases $G(C_3H_7SSC_3H_7)$ will remain constant since the total number of radicals reacting to produce $C_3H_7S\cdot$ radicals is unchanged. The very small reduction in $G(N_2)$ from an N_2O solution may be an indication that electron scavenging is occurring but due to our lack of knowledge of the complete reaction scheme for the production of N_2 the evidence cannot be regarded as conclusive. Reaction 11 is endothermic in the gas phase (14) but solvation by other propanethiol molecules may aid its occurrence in cyclohexane just as was suggested in the case of deuterium sulfide (15).

The large HD yields from propanethiol-*d* solutions (Fig. 3) suggest the occurrence of efficient H atom scavenging (reaction 5). On the assumption that all the HD arises in this manner, the experimental points in Fig. 3 have been fitted by the curve calculated from an equation describing competition between reactions 2 and 5

$$G(HD) = \frac{G^0(H)}{1 + \frac{k_2}{k_5}\frac{[c\text{-}C_6H_{12}]}{[C_3H_7SD]}}$$

$G^\circ(H)$, the yield of H atoms in pure $c\text{-}C_6H_{12}$, is taken as 1.46 (16). A best fit is obtained with $k_2/k_5 \sim 0.008$. This means that propanethiol-*d* is only slightly less efficient an H atom scavenger than ethylene for which the corresponding ratio is 0.00475 (16). This is consistent with gas phase data which show roughly equal efficiencies for H atom scavenging by alkanethiols and C_2H_4 (17, 18). The value for k_2/k_5 will be a lower limit since ionic reactions which are not present in pure cyclohexane may contribute to the HD yield. The extent of this can be deduced by the effect of added electron scavengers (Table 3). SF_6 reduces $G(HD)$ to ~40% of its initial yield while $G(D_2)$ is reduced to a much greater extent. Most of the D_2 must therefore be formed as a consequence of an ionic reaction *e.g.* proton transfer.

[13] $c\text{-}C_6H_{12}^+ + C_3H_7SD \rightarrow c\text{-}C_6H_{11}\cdot + C_3H_7SDH^+$

[14*a*] $e + C_3H_7SDH^+ \rightarrow D\cdot + C_3H_7SH$

[14*b*] $e + C_3H_7SDH^+ \rightarrow H\cdot + C_3H_7SD$

[15*a*] $D\cdot + C_3H_7SD \rightarrow D_2 + C_3H_7S\cdot$

[15*b*] $H\cdot + C_3H_7SD \rightarrow HD + C_3H_7S\cdot$

[16] $D\cdot + c\text{-}C_6H_{12} \rightarrow HD + c\text{-}C_6H_{11}\cdot$

The small D_2 yields at the C_3H_7SD concentrations used suggest that this reaction sequence is not of great importance. The analogous sequence involving ethanol-*d* is highly efficient (19), the much lower efficiency of propanethiol-*d* is consistent with its being a much softer base (20).

A correction may be made to the HD yield for such a reaction sequence. If y is the yield of hydrogen atoms in reaction 14 and if isotope effects are neglected then $y/2$ H and $y/2$ D atoms are produced. Let the fraction of these atoms scavenged by C_3H_7SD ([15*a*] and [15*b*]) be f then $G(D_2) =$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$y/2 = f$; G(HD) via [14a] and [16] $= y/2(1 - f)$; G(HD) via [14b] and [15b] $= yf/2$. The net yield of HD from the reaction sequence [13]–[16] is $y/2$ which is equal to $G(D_2)/f$. An approximation for f is $G(HD)/G°(H)$. If $G°(H)$ is taken as ~1.5 then the maximum correction to be applied to the HD yields (7%) occurs at 9.36×10^{-2} M C_3H_7SD. The value for k_2/k_5 which best fits the points still remains at 0.008 but $G°(H)$ is reduced by ~0.2 G.

The residual HD yields in the presence of SF_6 and in the presence of CCl_4 at the higher propanethiol concentration show that 30–40% of the HD is formed via a non-ionic mechanism at the low concentrations of propanethiol that we employ. Asmus *et al* (16) estimate that 39% of all H atoms in irradiated c-C_6H_{12} have non-ionic precursors. Therefore it does appear that most of the HD formed arises from the scavenging of thermalized H atoms with little contribution from other sources. The reduction of G(HD) by CCl_4 in high concentration is consistent with the proposed H atom and electron scavenging properties of this solute (16, 21), the relative rates of which are not known.

There is poor agreement between our result for k_2/k_5 (0.008) and those of Pryor and coworkers (22, 23) who find 0.062, 0.068, and 0.093 for scavenging of photolytically generated hydrogen atoms by *t*-butanethiol, thiophenol, and propanethiol, respectively in cyclohexane. In the gas phase $k_{H+C_3H_7SH}/k_{H+C_2H_4} \approx 2$ (18). A ratio of the order of unity is obtained for the rate of H atom addition to ethylene relative to reaction with compounds containing the —SH group in aqueous solution (24, 25). Citing these similarities of ratios for different phases one would expect that the ratio $k_{H+C_3H_7SH}/k_{H+C_2H_4}$ would be about the same in the gas phase and in liquid cyclohexane. This argument would favor our value for k_2/k_5. We have however no explanation for the large discrepancy between the two values. If there is any contribution from ion–molecule reactions to the HD yield in the present work then k_2/k_5 will be increased while a contribution from hot D atoms in the photolytic work would decrease the ratio. It may in fact be that the two values are upper and lower limits to the true one.

The remaining product which has not been discussed is the monosulfide, c-$C_6H_{11}SC_3H_7$. It cannot be formed by combination of c-C_6H_{11}· and C_3H_7S· radicals since its yield increases with increasing thiol concentration whereas the steady state concentration of c-C_6H_{11}· must be decreasing. $G((c\text{-}C_6H_{11})_2)$ remains practically constant with increasing propanethiol concentration which means that the gradual decrease in $G(c\text{-}C_6H_{10})$ is not due to radical scavenging in spurs. However $G(c\text{-}C_6H_{10}) + G(c\text{-}C_6H_{11}SC_3H_7)$ remains constant suggesting that the sulfide arises in a secondary reaction involving the olefin. This was confirmed by the addition of cyclohexene prior to irradiation. The absolute concentration of cyclohexene changes only slowly at the higher propanethiol concentrations and it is to be expected that the steady state concentration of C_3H_7S· radicals will also show little change so that an almost constant yield of sulfide would be expected via the addition reaction

[17] $$C_3H_7S· + c\text{-}C_6H_{10} \rightarrow c\text{-}\dot{C}_6H_{10}SC_3H_7$$

However such an addition is reversible in both gas and liquid phases (26) and it is only at the higher propanethiol concentrations, as was shown, that the raection

[18] $$c\text{-}\dot{C}_6H_{10}SC_3H_7 + C_3H_7SH \rightarrow c\text{-}C_6H_{11}SC_3H_7 + C_3H_7S·$$

can compete with the reverse of reaction 17 and lead to a significant yield of sulfide. Again the reaction sequence leading to sulfide formation does not alter the number of C_3H_7S· radicals which dimerize to form disulfide.

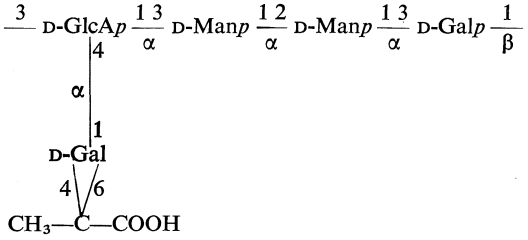
The Structure of the Capsular Polysaccharide from Klebsiella K-Type 21[1]

Y. M. Choy and G. G. A. Dutton

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

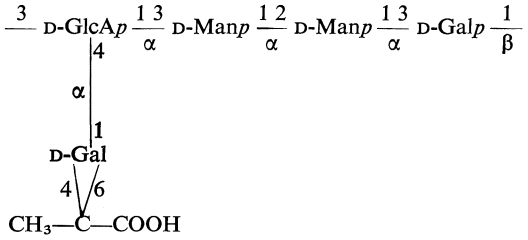
Received July 27, 1972

Methylation, periodate oxidation, and partial hydrolysis studies on the capsular polysaccharide, and on the carboxyl reduced polymer, of *Klebsiella* K21 show the structure to consist of a repeating unit.



The anomeric linkages were determined by p.m.r. spectroscopy of isolated oligosaccharides and, in part, by specific enzymes. P.m.r. spectroscopy of the original polysaccharide in methyl sulfoxide-d_6 showed clearly a ratio of one pyruvic acid ketal (CH_3, τ 8.5) to five anomeric protons (τ 4.65–5.40).

Les méthodes de méthylation, oxydation periodique et hydrolyse partielle portées au polysaccharide capsulaire, et au polymère avec le groupe carboxyle réduit, de *Klebsiella* K21 ont démontré que la structure se compose d'une unité qui se répéte.



Les liaisons anomères ont été distinguées par la spectroscopie r.m.n. des oligosaccharides isolés et, en partie, par des enzymes spécifiques. La spectroscopie r.m.n. du polysaccharide original dans le méthyl sulfoxide-d_6 a établi le rapport un à cinq entre le cétal de l'acide pyruvique (CH_3, τ 8.5) et les protons anomères (τ 4.65–5.40).

Can. J. Chem., **51**, 198 (1973)

Qualitative analyses of the capsular polysaccharides of the 80 serotypes of *Klebsiella* bacteria have been provided by Nimmich (1, 2) who has shown that the great majority contain glucuronic acid in combination with hexose and deoxyhexose sugars. Approximately one half of the polysaccharides also contain pyruvic acid (3) covalently bound (1-carboxyethylidene ketals). Despite the amount of qualitative information available on *Klebsiella* polysaccharides detailed structures are only known for those capsular materials from types K2 (ref. 4), K5 (ref. 5), K8 (ref. 6), K9 (ref. 7), K20 (ref. 8), K54 (refs. 9–11), and three related but untyped species of *Aerobacter aerogenes* (12–14). The structure of the capsular polysaccharide from *Klebsiella* K21 is now reported. A preliminary report has appeared (15) which also gives other background references.

The acidic capsular polysaccharide from *Klebsiella* K21 was purified by one precipitation with Cetavlon and had $[\alpha]_D$ +130°. Gel filtration and electrophoresis showed the material to be homogeneous. In work with other *Klebsiella*

capsular polysaccharides it has been found that there is an approximate, inverse relationship between the equivalent weight of the polysaccharide and the distance of migration. One may predict that the polysaccharide from *Klebsiella* K62 will have an equivalent weight about 580 (Fig. 1).

The p.m.r. spectrum of a 2% solution of the polysaccharide in D_2O showed a sharp singlet at τ 8.5 indicative of a pyruvic acid ketal (16, 17). Determination of the pyruvic acid:sugar ratio was hampered by the presence of the HOD signal even after several exchanges with D_2O. The HOD peak was shifted downfield by the addition of trifluoroacetic acid or upfield by running the spectrum at 95–100° on the polysaccharide in methyl sulfoxide-d_6. In the latter case integration of the signals due to the anomeric protons and that of the methyl at τ 8.5 showed there was one pyruvic acid ketal to five sugar residues (Fig. 2).

Partial assignment of the anomeric signals may be made using the data of Table 1, which are based on examination of the oligosaccharides obtained in subsequent experiments, and similar data given by Conrad and coworkers (4) and others. These enable one to predict that of the five glycosidic bonds (per repeating unit) only one is of the β-D-configuration (shown subsequently to be β-D-galactose). In later work with other *Klebsiella* capsular polysaccharides (K20, K24) excellent spectra have been obtained by using the sodium salt of the polysaccharide in D_2O at 95° and dispensing with the use of methyl sulfoxide.

Acidic hydrolysis of the polysaccharide showed,

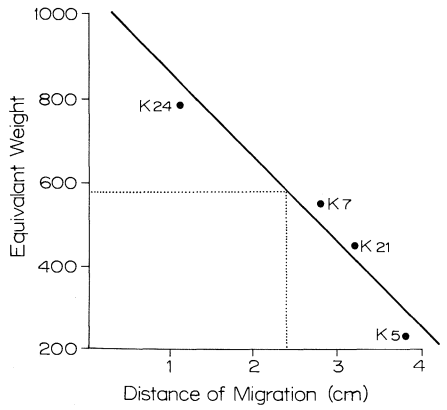

FIG. 1. *Klebsiella* capsular polysaccharides; electrophoresis on cellulose acetate at 300 V for 30 min (p*H* 8.8, veronal–tris buffer). Distance of migration *vs.* equivalent weight. K62 migrates 2.4 cm indicating an equivalent weight of 580.

by paper chromatography, the presence of D-mannose, D-galactose, D-glucuronic acid, lactone, and an aldobiouronic acid. Separation of the hydrolyzate into neutral and acidic fractions and g.l.c. of the former, both as trimethylsilyl derivatives and as alditol acetates, gave a ratio of D-mannose to D-galactose of 1:1.2. Collection of the alditol acetates permitted characterization of D-mannitol hexaacetate m.p. 118–121° and galactitol hexaacetate, m.p. 162°. The aldobiouronic acid was separated from the acidic fraction by paper chromatography and reduction of the carboxyl function followed by hydrolysis gave D-glucose and D-mannose, further characterized as their alditol acetates. The configuration of D-galactose was established by D-galactose oxidase, D-glucuronic acid as D-glucose by D-glucose oxidase, and D-mannose by the circular dichroism curve of D-mannitol hexaacetate (18).

Autohydrolysis of the polysaccharide gave pyruvic acid (19) characterized as the 2,4-dinitrophenylhydrazone (20). It was considered significant that the aqueous solution showed the presence of D-galactose as the only monosaccharide together with traces of oligosaccharides. The residual polysaccharide, obtained by dialysis and lyophilization of the aqueous hydrolyzate, was saved for subsequent methylation studies discussed later.

A sample of pure capsular polysaccharide was methylated (10, 21) and hydrolyzed to yield a neutral and an acidic fraction after separation on ion-exchange resins. Table 2 (A) gives the neutral sugars obtained which were identified as discussed in the experimental. These results show that D-mannose occurs in the polysaccharide linked in two ways; substituted at position 2 and at position 3. The ratio of 3,4,6-tri-*O*-methyl-D-mannose to the 2,4,6-isomer was 1.7:1, consistent with the concept that part of the mannose remained bound to the uronic acid. Isolation of 2,4,6-tri-*O*-methyl-D-galactose indicates that this unit represents a 3-substituted sugar in the chain. The 2,3-di-*O*-methyl-D-galactose cannot represent a branch point since no corresponding quantity of terminal units was found. The pyruvic acid must therefore be linked to D-galactose as a 4,6-ketal. The acidic fraction of the hydrolyzate was converted to the methyl ester glycoside, reduced and hydrolyzed to give 2,4,6-tri-*O*-methyl-D-mannose and 2-*O*-methyl-D-glucose, Table 2 (B). These results show that the aldobiouronic acid is 3-*O*-(glucopyranosyluronic acid)-D-mannose and that

†Approximate molar ratios; (+) signifies present in about equimolecular amounts.

autohydrolysis described above was methylated and hydrolyzed to yield, after separation on ion-exchange columns, neutral and acidic fractions. The composition of the former is shown in Table 2 (C) and the significant feature is the virtually complete disappearance of 2,3-di-*O*-methyl-D-galactose and, incidentally, the very small amounts of tetramethyl sugar produced. Paper chromatography of the acidic fraction showed two components in apparently equal quantities with mobilities corresponding to partially methylated uronic acid (R_f 0.16) and aldobiouronic acid (R_f 0.23). Reduction and hydrolysis of this mixture yielded 2,4,6-tri-*O*-methyl-D-mannose and 2,4-di-*O*-methyl-D-glucose, Table 2 (D). The disappearance of 2,3-di-*O*-methyl-D-galactose in the neutral fraction and the appearance in the acid fraction of 2,4-di-*O*-methyl-D-glucuronic acid is convincing evidence that the 4,6-*O*-(1-carboxyethylidene)-D-galactose units are attached to position 4 of D-glucuronic acid which in turn must be linked through position 3 in the main chain.

The information thus far obtained was confirmed, and more accurate quantitative data were obtained, by examination of the carboxyl-reduced polysaccharide. This was prepared exactly as described for sapote gum using lithium boro-

hydride in tetrahydrofuran (22). This method has given virtually quantitative reduction with this and several related polysaccharides and is now our preferred method of achieving such a conversion.

It should also be noted that this reduced polysaccharide and the methylated polymer described above each showed a characteristic sharp singlet (τ *ca.* 8.6) for the methyl group of the corresponding pyruvic acid derivative. This signal thus affords not only a method for the quantitative estimation of 1-carboxyethylidene ketals but also for checking that the related hydroxyisopropylidene and 1-carbomethoxyethylidene groups survive subsequent chemical transformations. In the polysaccharide only small changes in chemical shift were detected in these methyl signals (16). Hydrolysis of the reduced polysaccharide gave D-mannose, D-galactose, and D-glucose in the ratio of 1:1:0.6 (as alditol acetates).

The reduced polysaccharide was methylated and gave on hydrolysis the sugars in the proportions shown in Table 2 (E). The formation of 2,6-di-*O*-methyl-D-glucose arises from the reduced D-glucuronic acid moiety and the quantitative data are consistent with the proposed partial structure.

A portion of the original capsular polysaccharide was autohydrolyzed at 95° for 3 days (initial p*H* 2.3) using the apparatus described by Galanos *et al.* (23) which circulates the polysaccharide solution through stages of heating, cooling, and dialysis and recycles unhydrolyzed material. This apparatus is a modern improvement on the ideas of Painter (24) and of Perila and Bishop (25) but because of the close control that can be exercized high yields of oligosaccharides may be obtained. As previously noted little, except D-galactose and pyruvic acid, is liberated on autohydrolysis; therefore the polysaccharide solution was made up to 0.125 *M* sulfuric acid and dialyzed against acid of the same concentration. Hydrolysis was continued for a further 3 days at 95°. The dialyzate was neutralized with barium carbonate and separated into neutral and acidic fractions. The latter was separated on paper to give, as the main component, an aldotetrauronic acid with lesser amounts of aldotri- and aldobiouronic acids. Table 1 gives the structure of the aldotetrauronic acid based on the evidence presented in the Experimental. The salient points are that partial hydrolysis of the aldotetrauronic acid gave D-galactose as the main monosaccharide and, similarly, hydrolysis after sodium borohydride reduction yielded galactitol. The other products of the partial hydrolysis corresponded to the aldotri- and aldobiouronic acids isolated. The aldobiouronic acid was resistant to the action of β-D-glucuronidase and gave D-mannose on hydrolysis. Identification of the aldotetrauronic acid enables a decision to be made in favor of structure **A**. The aldobiouronic acid 3-*O*-(α-D-glucopyranosyluronic acid)-D-mannose has been isolated previously from *Serratia marcescens* (26), Klebsiella K2 (ref. 4), and from *Pseudomonas aeruginosa* (27).

Confirmation of structure **A** was sought by periodate oxidation of the original capsular polysaccharide. Periodate consumption of 0.36 mol per hexose unit was constant after 3 days and the derived polyalcohol was hydrolyzed by heating an aqueous solution, initial p*H* 2.2, at 95° for 1 h. A separate paper has discussed the wide variety of conditions which has been applied in the hydrolysis step of Smith degradations and has noted that other authors have experienced difficulty in obtaining cleavage of acetal linkages in polymers containing uronic acids (28). Hydrolyses have commonly been carried out with acid strengths of 0.05–0.5 *M* although two groups have recently reported good results with 0.01 *M* acid (13, 29). Johnson and Percival (30) have utilized the acidity of sulfated polysaccharides to effect autohydrolysis of the polyalcohol but the present work appears to be the first instance where the acidity of the uronic acid has been used to achieve hydrolysis of the polyalcohol in a Smith degradation.

Paper chromatographic examination (solvent *A*) of the hydrolyzate showed the presence of (*a*) pyruvic acid, (*b*) glycerol, (*c*) D-threitol, (*d*) D-galactose (traces only), and (*e*) an oligosaccharide which had a mobility (in solvent *E*) intermediate between the aldobi- and aldotriouronic acids previously isolated. The ratio of glycerol to D-threitol was 1.2:1 by g.l.c. of the acetates.

It is pertinent to note here that even under these mild conditions of autohydrolysis the pyruvic acid ketal was hydrolyzed. Similarly, no conditions of partial hydrolysis of the original polysaccharide could be found which would permit the isolation of 4,6-*O*-(1-carboxyethylidene)-D-galactose. Furthermore, an attempt to achieve this by the use of α-galactosidase was unsuccessful since the enzyme was without action on the original polysaccharide. This acid lability

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the pyruvic acid ketal is in direct contrast to the result of Gorin and Ishikawa (16) who were able to hydrolyze the glycoside methyl 4,6-*O*-(1-carboxyethylidene)-α-D-galactoside without cleavage of the ketal. The difference in stability may be accounted for by the conformation of the ketal or by the proximity of the D-glucuronic acid moiety, but no information is as yet available on these points.

The oligosaccharide obtained in the Smith degradation was of sufficient molecular weight to be precipitated when the aqueous solution was poured into ethanol. The p.m.r. spectrum of the reduced oligosaccharide showed the presence of one β-D-linkage per three anomeric protons and incubation of the original oligosaccharide with β-galactosidase yielded D-galactose. When the reduced oligosaccharide was methylated and hydrolyzed examination by paper chromatography in solvent *D* showed 2,3,4,6-tetra-*O*-methyl-D-galactose to be the major neutral sugar with traces of 2,4,6-tri-*O*-methyl-D-mannose. This result was confirmed by g.l.c. Examination in solvent *E* showed also the presence of two acidic components with mobilities identical to 2,4-di-*O*-methyl-D-glucuronic acid and the partially methylated aldobiouronic acid isolated previously from the methylated residual polysaccharide. In neither case was the di-*O*-methylglycerol sought.

The sum of these results firmly establishes structure **A** as representing the repeating unit of the capsular polysaccharide of *Klebsiella* K21 and demonstrates for the first time the mode of attachment of the pyruvic acid in this genus. The structure found for K21 is similar to those previously reported for K2, K8, K9, K54 (refs. 4, 6, 7, 11) in that they each have a repeating unit of four or five sugars including a single unit side chain. That this is not an invariant rule for *Klebsiella* polysaccharides is shown by the structure of K5 (ref. 5) which has a repeat of three sugars and no side chain and of K20 (ref. 8) which has a repeat of four sugars including a two unit side chain. Full details of these other structures will be published in due course.

Experimental

General Methods

Paper chromatography was carried out by the descending method using Whatman No. 1 paper and the following solvent systems (v/v): (*A*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (*B*) ethyl acetate – pyridine – water (4:1:1); (*C*) 1-butanol – acetic acid – water (2:1:1); (*D*) butanone saturated with 1% aqueous ammonia; (*E*) 1-butanol–ethanol–water (4:1:5). Chromatograms were developed with *p*-anisidine trichloroacetate spray (31) or with silver nitrate (32). The clarity of the colors on chromatograms of methylated sugars developed with the former spray is greatly improved by washing the paper under running hot water after heating the chromatogram at 100–110° in the normal manner.

G.l.c. was carried out on an F and M model 720 dual column instrument fitted with thermal conductivity detectors. The helium flow was 60–80 ml/min with the following columns: (*a*) 3% ECNSS-M on Chromosorb W (8 ft × 0.25 in.); (*b*) 5% butanediol succinate on Diatoport S (4 ft × 0.25 in.); (*c*) 8% SE-52 on Diatoport S (8 ft × 0.25 in.).

Circular dichroism spectra were run on a Jasco J-20 automatic recording spectropolarimeter using a quartz cell with path length 0.1 cm. Optical rotations were measured at 23 ± 2° on a Perkin–Elmer model 141 polarimeter. P.m.r. spectra were run on Varian T60 or XL100 instruments. Samples were prepared by dissolving in D_2O and freeze drying 3 or 4 times before dissolving in D_2O or methyl sulfoxide-d_6. Tetramethylsilane was used as a standard, externally for D_2O solutions and internally for methyl sulfoxide-d_6.

Mass spectra, obtained on individual fractions collected (33) from the gas chromatograph, were run on an MS 902 instrument at 70 eV. The position of methoxyl substitution was determined using the data of Lindberg and coworkers (34) and, where possible, by comparison of mass spectra with those of authentic compounds.

Methylations on polysaccharides and oligosaccharides were carried out by the method of Hakomori (9, 21). Partially methylated alditol acetates were demethylated by reaction with boron trichloride (35). All solutions were concentrated on a rotary evaporator *in vacuo* at a bath temperature of 40°.

D-Glucostat and D-Galactostat reagents were obtained from the Worthington Biochemical Corporation, β-D-galactosidase from Koch-Light, and β-D-glucuronidase from Sigma Chemical Company. α-D-Galactosidase was prepared from green coffee beans by the procedure of Clarke *et al.* (36). Sagavac 6F is a product of Seravac Laboratories, Cape Town.

Preparation and Properties of K21 Capsular Polysaccharide

A culture of *Klebsiella* K21 (1702/49) was obtained from Dr. Ørskov, Copenhagen, as an agar slant and was grown on the following medium for 3 days at 25°: 8 g NaCl, 4 g K_2HPO_4, 1 g $MgSO_4 \cdot 7H_2O$, 2 g $CaCO_3$, 120 g sucrose, and 8 g Bacto yeast extract in 4 l of water. Cells were harvested after 3 days, diluted with water containing 1% phenol, and centrifuged at 19 000 g. Capsular polysaccharide was obtained by concentrating the aqueous solution, pouring it into ethanol, and purifying the crude material by Cetavlon precipitation. A sample of the supernatant was shown to contain very little material and therefore this was not further examined. The yield of polysaccharide was approximately 2 g per 4 l of medium. Three batches were pooled and used for the structural studies of the polysaccharide.

Purified polysaccharide (2 g) was dissolved in distilled water (2 l), deionized with Amberlite IR 120 resin, dialyzed, and freeze-dried. The product had $[\alpha]_D$ +130°

For personal use only.

(*c* 0.38, water), ash 0.8%, N 0.3%. The equivalent weight of the polysaccharide, determined by titration with 0.01 *M* sodium hydroxide was 455 (calcd. 447). The average molecular weight was *ca.* 4×10^5 as determined by gel permeation chromatography on Sagavac 6F through the courtesy of Dr. S. C. Churms. Electrophoresis at p*H* 3 and 8.8 showed the polysaccharide moved as a single component (migration 3.2 cm in 30 min at 300 V at p*H* 8.8; by courtesy of Dr. P. E. Reid and Miss C. Poder).

The p.m.r. spectrum of a 2% solution of D_2O showed a sharp singlet at τ 8.5 due to the CH_3 of the pyruvic acid ketal group. The relative amount of pyruvic acid was initially obtained by running the spectrum on a sample dissolved in 3 *M* trifluoroacetic acid in D_2O. Integration gave 17–18 units for the CH_3 signal at τ 8.5 and 146 units for the ring protons, excluding anomeric ones. The ratio was confirmed by running the spectrum of a 2% solution of the polysaccharide in methyl sulfoxide-d_6 at 100°. In this case the HOD peak was shifted upfield so that the anomeric proton signals were clear. These were at τ 4.65 (1H); 4.90, 4.95, 5.05 (3H); 5.40 (1H). The ratio of anomeric protons to pyruvate CH_3 was 5:3.

Hydrolysis of the Polysaccharide

Polysaccharide (0.1 g) was hydrolyzed with 0.5 *M* sulfuric acid at 100° for 8 h. Neutralization ($BaCO_3$) followed by paper chromatography (solvents *A* and *B*) showed D-mannose and D-galactose, D-glucuronolactone, D-glucuronic acid, and an aldobiouronic acid. The hydrolyzate was separated into neutral and acidic fractions using ion-exchange resins (Amberlite IR 120 and Duolite A4). The neutral fraction contained D-mannose and D-galactose in approximately equal amounts (1:1.2) as determined by g.l.c. of the trimethylsilyl derivatives (column *c*) and of the alditol acetates (column *a*). G.l.c. of the acetates permitted recovery of the individual compounds and identification of D-mannitol hexaacetate, m.p. and mixed m.p. 118–121°, and galactitol hexaacetate, m.p. 162° (37). A portion of the neutral fraction of the hydrolyzate was tested with D-Galactostat reagent and a positive response confirmed the D-configuration of galactose. Part of the mannitol hexaacetate collected by g.l.c. was recrystallized and dissolved in acetonitrile. A positive circular dichroism curve, identical to that given by a standard sample, confirmed the D-configuration of mannose (18).

The acidic fraction was separated into two parts by paper chromatography (solvent *A*). The slower migrating, major portion had the mobility of an aldobiouronic acid (R_{Gal} 0.39) and was converted into the ester glycoside by refluxing overnight with 3% methanolic hydrogen chloride. The product was dissolved in tetrahydrofuran and reduced by boiling under reflux overnight with lithium aluminum hydride. Hydrolysis of the neutral disaccharide gave approximately equimolar amounts of D-glucose and D-mannose as determined by g.l.c. of the alditol acetates. The configuration of the glucose was confirmed by the D-Glucostat reagent.

A separate portion (1.5 g) of the polysaccharide was dissolved in water (initial p*H* 2–2.3) and heated for 8 h at 95°. Paper chromatography (solvent *A*) of the concentrated solution showed a fast moving spot, chromatographically identical with pyruvic acid (R_f 0.74) and having the same characteristic fluorescence as a standard when sprayed with *o*-phenylenediamine and examined by u.v. (19). The chromatogram also showed D-galactose as the only monosaccharide and traces of slow moving oligomers. The aqueous solution was extracted with ether and the ether extract was treated with 2,4-dinitrophenylhydrazine to yield the derivative of pyruvic acid, m.p. 214–216°, undepressed by an authentic sample (20). The autohydrolysis solution was concentrated to 50 ml and dialyzed against distilled water (2 l). The non-dialyzable material (0.65 g) was recovered by freeze-drying and kept for methylation studies.

Methylation Analysis

Capsular polysaccharide (0.5 g) was methylated to give a product having a methoxyl content of 38.5% and showing no hydroxyl absorption in the i.r. The methoxyl content was not increased by two further treatments with silver oxide and methyl iodide. The fully methylated polysaccharide was dissolved in cold 72% sulfuric acid and after 1 h the solution was diluted to 1 *M* and hydrolyzed at 100° for 8 h. After neutralization and evaporation, the syrupy product was separated into neutral and acidic fractions by ion-exchange resins. The neutral portion was fractionated by cellulose column chromatography (38) using butanone–water azeotrope and the partially methylated sugars were characterized as follows:

Fraction I (80 mg) was shown by paper chromatography, (solvent *D*) to contain two components having R_f 0.57 and 0.55; the faster moving one (I*a*) gave a brownish yellow spot when sprayed with *p*-anisidine while the slower one (I*b*) gave a pink color. On demethylation, fraction I was shown by paper chromatography (solvents *A* and *B*) to contain only D-mannose. Fraction I (20 mg) was reduced by sodium borohydride and, after removal of the borate, the product was acetylated in a sealed tube by using pyridine and acetic anhydride (1:1, 2 ml, 100°, 20 min). After evaporation of the solvents, the alditol acetates were dissolved in a small volume of ethyl acetate and analyzed by g.l.c. on column *b* programmed from 150–200° at 2°/min; two peaks were observed.

The component eluted first had a retention time of 17.2 min and mass spectrometry showed it to be a 3,4,6-tri-*O*-methyl hexitol acetate. On demethylation and acetylation, D-mannitol hexaacetate was obtained (g.l.c., m.p., and mixed m.p. 118–121°). The second component had a retention time (19.6 min) identical to that of authentic 2,4,6-tri-*O*-methyl-D-mannitol triacetate. A sample collected from the gas chromatograph had m.p. 65–67° undepressed by authentic material (39) and the identity was further confirmed by the mass spectrum. The ratio of the amount of 3,4,6-isomer to that of the 2,4,6-compound was 1:0.6.

Fraction II (30 mg) was shown by paper chromatography to be a single compound (R_f 0.37, solvent *D*) and on demethylation, D-galactose was obtained. Crystallization of the syrupy sugar from ether gave 2,4,6-tri-*O*-methyl-D-galactose m.p. 103–105° (lit. (40) m.p. 102–105°). The derived alditol acetate had a retention time of 21 min (column *a*) and the mass spectrum was consistent with a 2,4,6-tri-*O*-methyl hexitol acetate.

Fraction III (35 mg) was shown by paper chromatography to be a single compound and to correspond to 2,3-di-*O*-methyl-D-galactose (R_f 0.18, solvent *D*). This assignment was confirmed by the mass spectrum of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

alditol acetate which on demethylation and acetylation gave galactitol hexaacetate, m.p. and mixed m.p. 162°.

The acidic fraction was heated under reflux overnight with 2% methanolic hydrogen chloride to give the ester glycoside which was reduced by boiling overnight with lithium borohydride in tetrahydrofuran. The product (20 mg) was hydrolyzed with 0.5 *M* sulfuric acid for 4 h. Paper chromatography showed the presence of 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.5, solvent *D*; 0.80 solvent *E*) and 2-*O*-methyl-D-glucose (R_f 0.07, 0.24). The identities of both partially methylated sugars were confirmed by g.l.c. and mass spectrometry of the alditol acetates. The mannitol derivative crystallized, m.p. 64–66°, and the glucitol derivative was demethylated and acetylated to give glucitol hexaacetate m.p. 92–95°. 2-*O*-Methyl-D-glucitol pentaacetate has been isolated subsequently from *Klebsiella* K7 methylated polysaccharide and has m.p. 56–57°.

Methylation of Degraded Polysaccharide

Degraded polysaccharide (0.5 g), recovered from the autohydrolysis, was methylated, the product was dissolved in 5 ml of 72% sulfuric acid at 0° and then the solution was diluted to 1 *M* and hydrolyzed at 100° for 8 h. After neutralization the hydrolyzate was separated into acidic and neutral fractions. The latter was shown by paper chromatography (solvent *D*) and by g.l.c. of the alditol acetates (column *b*, 160–210° at 2°/min) to contain the sugars listed in Table 2 (C) which also gives their approximate molar ratios.

Paper chromatography of the acidic fraction (solvent *E*) showed two components with R_f 0.16 and 0.23 and in approximately equal amounts. When sprayed with *p*-anisidine trichloroacetate the slower gave the bright red color of a methylated uronic acid and the faster gave a reddish-brown color and was judged to be a partially methylated aldobiouronic acid. A portion of the mixture (20 mg) was converted to the ester glycosides and reduced with lithium borohydride in tetrahydrofuran. Paper chromatography, after acid hydrolysis, showed the presence of 2,4-di-*O*-methyl-D-glucose (R_f 0.18, solvent *D*) as the major component together with 2,4,6-tri-*O*-methyl-D-mannose. The identity of the former was confirmed by g.l.c. – mass spectrometry of the alditol acetate and that of the latter by the crystalline alditol acetate m.p. 64–66°.

Reduction of the Capsular Polysaccharide

Capsular polysaccharide (0.4 g) was converted into the methyl ester propionate and reduced with lithium borohydride as previously described (22) to give the reduced polysaccharide (0.3 g), $[\alpha]_D$ +115° (*c* 0.42, water). The reduced polysaccharide (0.1 g) was hydrolyzed with 0.5 *M* sulfuric acid at 100° for 8 h to give D-mannose, D-glucose, and D-galactose (paper chromatography, solvent *B*). The identities of the sugars were confirmed by g.l.c. of the alditol acetates and collection of the individual fractions afforded D-mannitol hexaacetate m.p. and mixed m.p. 118–120°, galactitol hexaacetate m.p. and mixed m.p. 160–162°, and D-glucitol hexaacetate m.p. and mixed m.p. 92–95°. The ratio of D-mannitol, galactitol, and D-glucitol hexaacetates was 1:1:0.6. The p.m.r. spectrum of reduced K21 polysaccharide in D_2O was shown to contain four anomeric signals at τ 4.54, 4.80, 5.00, and 5.15 in the ratio of 1:2:1:1. All the signals showed small coupling constants except that at τ 5.15 (7 Hz).

The remainder of the reduced polysaccharide (0.2 g) was methylated and hydrolyzed. Table 2 (E) shows the nature and proportion of the methylated sugars found and, in addition to those previously obtained from the methylated original polysaccharide, now included 2,6-di-*O*-methyl-D-glucose which was characterized by g.l.c. – mass spectrometry of its alditol acetate.

Partial Hydrolysis of Polysaccharide

K21 polysaccharide (1 g) was partially hydrolyzed at p*H* 2.3 at 95° for 3 days using an apparatus similar to that described by Galanos and coworkers (23). Since only D-galactose and pyruvic acid were found in the dialyzate the solution was made 0.125 *M* with sulfuric acid and hydrolyzed at 95° for a further 3 days. The dialyzate was neutralized ($BaCO_3$), evaporated, and separated by ion-exchange resins into acidic and neutral fractions. On paper chromatography (solvent *C*) the acidic fraction was shown to contain an aldotetrauronic acid (R_{Gal} 0.2) as the major component together with small amounts of aldobiouronic acid (R_{Gal} 0.70), aldotriouronic acid (R_{Gal} 0.42), and traces of higher oligomers. The acids were separated by paper chromatography (solvent *C*) and analyzed as follows.

The aldotetrauronic acid (50 mg) had an equivalent weight of 660 (NaOH titration, calcd. 680) and $[\alpha]_D$ +117° (*c* 1.2, water) indicating α-linkages. This was confirmed by the p.m.r. spectrum of a 4% solution in D_2O run at 95° (see Table 1). The aldotetrauronic acid (2 mg) was hydrolyzed with 0.5 *M* trifluoroacetic acid at 100° for 1 h. Paper chromatography (solvent *C*) showed the presence of D-galactose as the principle monosaccharide with traces of D-mannose and a series of aldobiouronic, aldotriouronic, and aldotetrauronic acids which had the same mobilities as the components of the original mixture. The aldotetrauronic acid (4 mg) was reduced with sodium borohydride and, after removal of borate, the product was hydrolyzed with 2 *M* trifluoroacetic acid for 2 h. On paper chromatography (solvents *A* and *B*), the neutral compounds found were D-mannose and galactitol. G.l.c. of the alditol acetates of the neutral compounds showed the ratio of galactitol and D-mannitol to be 1:1.3 and permitted characterization of each compound. The acidic sugars were D-glucuronic acid and the aldobiouronic acid.

The aldotetrauronic acid (11 mg) was methylated and then hydrolyzed by 2 *M* trifluoroacetic acid for 2 h. Paper chromatography (solvents *D* and *E*) showed the following partially methylated sugars to be present 3,4,6-tri-*O*-methyl-D-mannose (R_f 0.58, solvent *D*), 2,4,6-tri-*O*-methyl-D-mannose (R_f 0.55), 2,4,6-tri-*O*-methyl-D-galactose (R_f 0.40), 2,3,4-tri-*O*-methyl-D-glucuronic acid (R_f 0.22, solvent *E*), and traces of partially methylated aldobiouronic acid (R_f 0.28, solvent *E*). The identities of the neutral sugars were further characterized as the alditol acetates and the ratio was found to be approximately 1:1:1.

The aldotriouronic acid (R_{Gal} 0.42) had the same mobility on paper as a component obtained by partial hydrolysis of the tetrauronic acid and was not further examined.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The aldobiouronic acid (12 mg) had $[\alpha]_D$ +40° (*c* 0.62, water). A sample (2 mg) was hydrolyzed with 3 *M* hydrochloric acid for 2 h. The only neutral sugar found on paper chromatography (solvent *B*) was D-mannose. A negative result was obtained when the aldobiouronic acid (4 mg) was incubated with β-D-glucuronidase (3 mg) at p*H* 4.8 at 38° overnight. Under the same conditions the enzyme hydrolyzed 3-*O*-(β-D-glucopyranosyluronic acid)-D-galactose (from *Klebsiella* K20, ref. 8) and 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose.

When a portion (5 mg) of the aldobiouronic acid was methylated and then hydrolyzed by 3.5 *M* hydrochloric acid at 95° for 3 h paper chromatography showed the presence of 2,4,6-tri-*O*-methyl-D-mannose and 2,3,4-tri-*O*-methyl-D-glucuronic acid which had the same mobility as a standard (R_f 0.22, solvent *E*). The mannose derivative was further characterized as the alditol acetate, m.p. and mixed m.p. 64–65°.

Periodate Oxidation

The polysaccharide (0.25 g) was dissolved in aqueous sodium metaperiodate (100 ml, 0.025 *M*) and 0.36 mol of periodate per hexose unit was consumed after 3 days. Sodium borohydride (1 g) was added and the solution was left overnight. The solution was deionized with Amberlite IR 120, freeze-dried, and the product was distilled with several portions of methanol. The polyalcohol was dissolved in water (3 ml) to give a solution of p*H* 2.2 which was heated at 95° for 1 h. On paper chromatography (solvent *A*) the following compounds were identified by comparison with standards: (*a*) pyruvic acid (R_f 0.74), (*b*) glycerol (R_f 0.44), (*c*) D-threitol (R_f 0.30) (erythritol had R_f 0.32), (*d*) D-galactose (in traces only), and (*e*) an oligosaccharide which had a mobility intermediate between the aldobiouronic and the aldotriouronic acids in solvent *E*. The ratio of glycerol to D-threitol was found to be 1.2:1 by acetylation of part of the mixture and g.l.c. (column *b*, 150–180° at 2°/min). A control reaction showed that erythritol tetraacetate crystallized very easily while D-threitol tetraacetate remained as a syrup; both acetates had distinctly different retention times (13.5 and 15 min, respectively).

The oligosaccharide was obtained by precipitation into ethanol, yield 0.1 g. The product was reduced with sodium borohydride and, after removal of borate, the p.m.r. spectrum was run in D_2O (20 mg/5 ml) at 95°. One β-D- and two α-D-linkages were observed (Table 1). The signal at τ 5.47 was a doublet with a coupling constant of 8 Hz. The reduced oligosaccharide (10 ml) was dissolved in 0.5 *M* phosphate buffer (3 ml, p*H* 7.0), β-D-galactosidase (5 mg) was added, and the solution was incubated at 38° overnight. The monosaccharide liberated was D-galactose which was confirmed by g.l.c. of the alditol acetate, m.p. and mixed m.p. 160–162°.

The reduced oligosaccharide (50 mg) was methylated followed by hydrolysis with 2 *M* trifluoroacetic acid for 2 h. Paper chromatography (solvent *D*) showed, by comparison with a standard, that 2,3,4,6-tetra-*O*-methyl-D-galactose (R_f 0.68) was the major neutral sugar with traces of 2,4,6-tri-*O*-methyl-D-mannose. The tetramethylgalactitol acetate also had the same retention time as authentic material (11 min, column *a* at 200°). In solvent *E* the acidic components had the same mobilities as 2,4-di-*O*-methyl-D-glucuronic acid (R_f 0.16) and 3-*O*-(2,4-di-*O*-methyl-α-D-glucopyranosyluronic acid)-2,4,6-tri-*O*-methyl-D-mannose (R_f 0.23) previously isolated from the methylated degraded polysaccharide.

We are indebted to Dr. I. Ørskov, Copenhagen, for the gift of an authentic culture (1702/49) of *Klebsiella* K21, to Dr. P. J. Salisbury of this Department for growing the bacteria, and to Dr. G. H. N. Towers of the Department of Botany, University of British Columbia, for the use of his centrifuge. Gel filtration measurements were kindly made by Dr. S. C. Churms (Cape Town) and electrophoresis was carried out by Dr. P. E. Reid and Miss C. Poder of the Department of Pathology, University of British Columbia. P.m.r. spectra were determined by Miss P. Watson and Mr. A. Brooke of this Department.

The financial support of the National Research Council of Canada, and the award of a Killam Fellowship to Y.M.C. are gratefully acknowledged.

The 2,2,2-Trichloroethyl Group for Carboxyl Protection During Peptide Synthesis[1]

BERNARD MARINIER,[2] YOON C. KIM, AND JEAN-MARIE NAVARRE
Research Laboratories, Frank W. Horner Limited, Montréal, Québec

Received July 14, 1972

The 2,2,2-trichloroethyl esters of several *N*-carbobenzoxy-amino acids were prepared by reacting the corresponding acid chlorides with trichloroethanol and the carbobenzoxy groups were selectively removed by HBr–AcOH. The resulting esters were then coupled with various *N*-carbobenzoxy-amino acids or peptides using dicyclohexylcarbodiimide in acetonitrile to give *N*-carbobenzoxy-peptide trichloroethyl esters. The selective removal of the trichloroethyl protecting group was effected by reduction using zinc in acetic acid. The optical activity of the *N*-carbobenzoxy-peptides so obtained agreed well with the values reported in the literature. The overall results suggest that the 2,2,2-trichloroethyl group could be useful for carboxyl protection during peptide synthesis.

Divers chlorures d'acides *N*-carbobenzoxy-aminés furent traités par le trichloroéthanol et ainsi transformés en esters trichloroéthyliques correspondants. L'enlèvement sélectif des groupes carbobenzoxy par HBr–AcOH suivi de la condensation, au moyen de la dicyclohexylcarbodiimide dans l'acétonitrile, des esters obtenus avec des acides aminés ou peptides protégés par des groupes carbobenzoxy donna les esters trichloroéthyliques de *N*-carbobenzoxy-peptides. Le groupe protecteur trichloroéthylique fut à son tour enlevé sélectivement par réduction avec le zinc dans l'acide acétique. Les indices de rotation des *N*-carbobenzoxy-peptides ainsi obtenus concordent avec les valeurs trouvées dans la littérature. Ces résultats indiquent que le groupe trichloro-2,2,2 éthylique pourrait être utilisé efficacement pour la protection des groupes carboxyliques dans les synthèses peptidiques.

Can. J. Chem., **51**, 208 (1973)

In recent years, several new methods for protecting the carboxyl group of amino acids in peptide synthesis have been introduced (1–4). Despite the ingenuity and usefulness of these methods, they suffer from certain disadvantages and the wide application of them has yet to be demonstrated. This prompted us to seek for an alternative method which hopefully could be employed more practically.

It has been shown (5) that the 2,2,2-trichloroethyl group is removed from its esters by treating them with zinc powder in acetic acid under mild conditions. This property has been used for the protection of the carboxyl group (5), the phosphate group (6), and indirectly the amino group (7) in organic synthesis. We have studied the possibility of using the 2,2,2-trichloroethyl group as a carboxyl protecting group in our peptide syntheses and the results are presented here.

Among several different methods tried for trichloroethylation of the carboxyl of amino acids,[3] the most satisfactory one appeared to be the acid chloride method which involves the treatment of the carbobenzoxy amino acids with $POCl_3$ or PCl_5 and then the reaction of the resulting acid chlorides *in situ* with an excess of 2,2,2-trichloroethanol in the presence of triethylamine. The trichloroethyl esters of general formula Z-A-OCH_2CCl_3[4] were all thick oils.

In an attempt to purify some of these esters by distillation under high vacuum, carbobenzoxy-proline trichloroethyl ester was obtained in good yield (83%) but the yield of the corresponding glycine derivative was extremely poor (3%). Since there was no compelling necessity to purify these esters, the crude oils were treated directly with hydrogen bromide in acetic acid to obtain, in most cases, the crystalline hydrobromides of esters, HBr·A-OCH_2CCl_3. Some of the hydrobromides were converted to the corresponding hydrochlorides, HCl·A-OCH_2CCl_3.

The yield of the ester hydrobromides ranged from 56 to 70% after two steps from the carbobenzoxy-amino acids. For the leucine derivative, the yield was 38%, calculated from unsubstituted

[1]Preliminary results were presented at the 38th ACFAS Congress, October 16, 1970, Québec, Québec.

[2]Present address: Université du Québec, 300, avenue des Ursulines, Rimouski, Québec.

[3]All amino acids used in the present work are the L-isomers.

leucine instead of carbobenzoxy-leucine. The products were characterized by elemental analysis, i.r. spectra and, in some cases, n.m.r. spectra. The high-frequency carbonyl absorption in i.r. (1755–1775 cm^{-1}) and the low-field methylene resonance peak in n.m.r. (τ 4.95–5.30) were found to be characteristic of the $—COOCH_2CCl_3$ group (8). The crystalline ester hydrobromides and some of their physical data are presented in Table 1. Unfortunately, two amino acids, namely proline and isoleucine, gave oily ester hydrohalides, and some dipeptides containing these amino acids were also obtained as oils. The identity of these noncrystalline compounds was confirmed by converting them to the *p*-nitrobenzyl or the acetyl derivatives which were then characterized as shown in Table 2.

To prepare the 2,2,2-trichloroethyl ester of a polypeptide, a carbobenzoxy-amino acid or carbobenzoxy-peptide was condensed to the 2,2,2-trichloroethyl ester of a second amino acid or peptide. *N,N'*-Dicyclohexylcarbodiimide (DCC) was found to be an excellent condensing agent for this purpose when the reaction was carried out in acetonitrile, a solvent which is known to suppress the formation of undesirable *N*-acylurea (12). When the reactants were not sufficiently soluble in acetonitrile, a minimum amount of dimethylformamide was added to effect a satisfactory solution. The acid chloride method using $POCl_3$ or PCl_5 tended to result in tar which was difficult to work-up, although it worked fairly well for the preparation of carbobenzoxy-glycyl-glycine trichloroethyl ester. The polypeptides prepared are summarized in Table 3.

The removal of the 2,2,2-trichloroethyl protecting group was effected by dissolving the compound in 90% acetic acid and treating it with an excess (3–6 mol) of zinc powder for 1.5–2 h, while stirring and cooling in an ice bath. The

[j]From leucine; yield not calculated.

ester was thus selectively removed without affecting the carbobenzoxy group. The yields in general were good to fair (63–83%) except in the case of Z-Leu-Ala-Gly-OCH_2CCl_3 which gave only 31% of the corresponding carbobenzoxy–tripeptide acid. It must be pointed out, however, that the reaction conditions and yields reported are not necessarily optimal. The unreacted ester recovered during the work-up process (Z-Asn-Ala-OCH_2CCl_3, for example) was treated again with fresh zinc powder to enhance the yield. As expected, the high-frequency carbonyl absorption in i.r. and the low-field resonance peak in n.m.r. ascribed to the —$COOCH_2$-CCl_3 moiety were no longer observed in the detrichloroethylated products and the Beilstein test confirmed the absence of chlorine.

A relatively more thorough study was done on the removal of the trichloroethyl protecting group from carbobenzoxy-glycylglycine trichloroethyl ester. The reaction carried out in 70% acetic acid at room temperature for 1 h gave 80% yield as compared to 41% obtained from the reaction carried out in 90% acetic acid at ice bath temperature for 1.5 h. When the reaction was performed in glacial acetic acid at room temperature for 4 h, the completely deprotected glycylglycine was the only isolable product in 32% yield; not only the trichloroethyl group but also the carbobenzoxy group was removed.[5] On the other hand, no reaction took place in 60% acetic acid at room temperature for 2–3 h and the starting material was recovered. Certainly the yield can be improved by adjusting the conditions to the optimum, but as it stands now, it can be safely stated that the 2,2,2-trichloroethyl protecting group can be selectively removed without affecting the second protecting group. The carbobenzoxy-peptides thus prepared are listed in Table 4. The only racemization study performed during this work consisted in the comparison of the optical activity of several carbobenzoxy-peptides with literature values, when available. As shown in Table 4, all measured values except one (Z-Leu-Ala-Gly-Val-OH) agreed well with those already reported. This indicates only that if there is racemization at any stage of the reaction course (introduction or removal of the protecting group or peptide forma-

[5]Under the same conditions, Z-Gly-OH was practically unaffected (90% recovery). Apparently, the carbobenzoxy moiety of Z-Gly-OH is more resistant to Zn–AcOH treatment than that of Z-Gly-Gly-OCH_2CCl_3 for which we are unable to offer a reasonable explanation.

tion), its magnitude is not very great and the undesired isomer is finally easily removed.

The results of the present study, limited as they may be, indicate that the 2,2,2-trichloroethyl group is reasonably well introduced and selectively removed, permits the selective removal of the carbobenzoxy group and does not seem to induce more racemization than the other carboxyl protecting groups. Even if the complete absence of racemization remains to be proved and although the reaction conditions and yields are yet to be improved, this protecting group should find a good use, general or specific, in peptide synthesis. It might be useful, for example, in protecting the carboxyl group of asparagine and glutamine because, as is well known, the methyl or ethyl esters of these two amino acids give a certain amount of their respective iso-compound upon saponification (21, 22). By virtue of requiring no base for their removal, the corresponding trichloroethyl esters should avoid the formation of these secondary products during the deprotection step.

Experimental

Melting points are uncorrected and were determined in an electrical apparatus. Elemental analyses were effected by Dr. C. Daesslé, Organic Microanalysis, 5757, Decelles St., Montréal. Samples were dried at 80–100° under 0.1 mm of mercury during at least 18 h before analysis.

Preparation of 2,2,2-Trichloroethyl Esters of N-Carbobenzoxy-amino Acids

In a typical procedure, 2.5 ml (0.027 mol) of $POCl_3$ was added to a cooled (0°) and stirred solution of Z-Gly-OH (4.18 g, 0.02 mol) in 80–100 ml of tetrahydrofuran. The mixture was allowed to stir for an additional 2 h and then the solvent was removed by evaporation under vacuum at room temperature. The residue was dissolved in fresh tetrahydrofuran (30–50 ml) followed by removal of the solvent as before; the same procedure was repeated 2–3 times. The residue was finally dissolved in tetrahydrofuran (100 ml) and 7.45 g (0.05 mol) of CCl_3-CH_2OH was added. The mixture was made alkaline by adding 10–15 ml of triethylamine and stirred overnight. The precipitate was filtered and washed on the filter with tetrahydrofuran and the filtrate was concentrated under vacuum. The residue was taken in ether and washed with water, dilute HCl, dilute $NaHCO_3$, and water. The ether layer was dried over Na_2SO_4 and concentrated under vacuum to give a crude yellow or orange oil which was then treated with 3 *N* HBr–AcOH as described below.

Preparation of Hydrobromides of 2,2,2-Trichloroethyl Esters of Amino Acids

In a typical procedure, the unpurified oily Z-Gly-OCH_2CCl_3 described above was treated with 20 ml (0.06 mol) of 3 *N* HBr in acetic acid for 2 h at room temperature during which time a vigorous evolution of gas occurred. Dry ether was added to precipitate out the hydrobromide which was then filtered and recrystallized from ethanol–ether to yield 4.1 g (71%) of crystals, m.p. 238–240°. An analytical sample obtained by an additional recrystallization melted with decomposition at 242–244°. N.m.r. in DMSO-d_6: τ 5.93 (s, NCH_2CO), 4.96 (s, $COOCH_2CCl_3$), 1.46 (s, washed away with D_2O, NH_3^+). No coupling between the protons appearing at τ 5.93 and 1.46 was observed.

Preparation of 2,2,2-Trichloroethyl Esters of Polypeptides: 2,2,2-Trichloroethyl N-Carbobenzoxyglycylglycinate

Method A

To a cooled (ice bath) and stirred solution of 4.18 g (0.02 mol) of Z-Gly-OH in 80 ml of acetonitrile, there was added 4.08 g (0.02 mol) of dicyclohexylcarbodiimide dissolved in 40 ml of the same solvent followed by a suspension of 6.89 g (0.024 mol) of $HBr \cdot Gly\text{-}OCH_2CCl_3$ in 80 ml of acetonitrile containing 3.5 ml of triethylamine. The mixture protected from the atmospheric moisture was stirred for 1 h in the ice bath and then overnight at room temperature. The precipitated dicyclohexylurea (3.95 g) was filtered off and washed with CH_3CN and water. The filtrate and washes were combined and concentrated under vacuum, the residue was taken up in ether and washed with water, dilute HCl, dilute $NaHCO_3$, and water. Drying and evaporation of the solvent gave a solid which was crystallized in methanol–water yielding 6.96 g (87.7%) of crystals, m.p. 95–97°.

Method B

Tetrahydrofuran (200 ml) dried over $NaBH_4$ was distilled into a mixture of 4.1 g (0.0147 mol) of $HBr \cdot Gly\text{-}OCH_2CCl_3$ and 3 g (0.0147 mol) of Z-Gly-OH. While stirring and cooling in an ice-salt bath, the mixture was treated with 3.1 g (0.0147 mol) of PCl_5 for 1 h. Triethylamine (15 ml, 1 mol) was added and the mixture was stirred for 1 h in the ice bath and overnight at room temperature. The solvent was removed under vacuum and 150 ml of water was added to the oily residue which solidified when cooling in ice. The solid was filtered and recrystallized from ethanol–water, giving 4.1 g (70.2%) of crystals, m.p. 95–97°.

This compound exhibits dimorphism. When it was dissolved in boiling ethanol, filtered, and cooled, high-melting crystals were obtained, m.p. 108–110°. When it was dissolved in methanol at room temperature (1 g in 50–100 ml), filtered, and diluted with an equal volume of water, low-melting crystals were obtained, m.p. 96–98°. The i.r. spectra taken in Nujol mull showed distinct differences. In the amino and carbonyl region, the high-melting compound exhibited absorption bands at 3355, 3345, 3275, 3115, 1778 (w), 1763 (s), 1712, and 1680 cm^{-1} while the low-melting compound absorbed at 3350, 3290, 1778 (s), 1770 (s), 1714, 1697, and 1677 cm^{-1}. However, the spectra taken in chloroform solutions were identical with amino and carbonyl absorptions appearing at 3440, 3320, 1773, and 1730–1687 cm^{-1}. The n.m.r. spectra in chloroform for both compounds were the same: τ 6.13 (d, J = 6 Hz, $CH_2COOCH_2CCl_3$), 5.91 (d, J = 6 Hz, CH_2CONH), 5.27 (s, OCH_2CCl_3), 4.94 (s, $OCH_2C_6H_5$), 4.01 (t, J = 6 Hz, $NHCH_2COOCH_2CCl_3$), 2.78 (t, J = 6 Hz, $NHCH_2CONH$), 2.70 (s, C_6H_5). Furthermore, both substances, when treated with HBr–AcOH, yielded almost quantitatively the same hydrobromide of 2,2,2-trichloroethyl glycylglycinate, m.p. 220–223° (dec.) having i.r. absorptions in Nujol at 3283, 3208, 3054, 1766, 1690, and 1182 cm^{-1}.

Removal of the Trichloroethyl Group: Preparation of Carbobenzoxyleucylalanylglycylvaline

In a typical experiment, a solution of 0.5 g (0.8 mmol) of Z-Leu-Ala-Gly-Val-OCH_2CCl_3 in 25 ml of 90% acetic acid was treated under cooling with 2 g of zinc powder in three portions at 5 min intervals and the mixture was stirred for 1.5 h. The mixture was filtered and the unreacted zinc was washed with 90% acetic acid. The filtrate was concentrated under vacuum, the residue dissolved in 80 ml of dilute HCl and extracted with two 80-ml portions of ethyl acetate. The combined extracts were washed with 100 ml of saturated $NaHCO_3$ solution, this solution acidified with dilute HCl and the peptide reextracted with three 80-ml portions of AcOEt (or AcOEt–Et_2O mixture). The organic extracts were concentrated to give 0.25 g (63.5%) of crystals, m.p. 193–195°, having i.r. absorption in Nujol at 3275 (NH), 1706 (CO of COOH) and 1693 cm^{-1} (CO of amide). The analytical sample melts at 195–198° (EtOH–H_2O); (lit. (20), 199–200°).

Removal of the Trichloroethyl Group from 2,2,2-Trichloroethyl N-Carbobenzoxyglycylglycinate

Method 1

A solution of 0.92 g (2.32 mmol) of the peptide ester in 10 ml of 70% acetic acid was treated with 0.5 g of zinc powder for 1 h. The reaction mixture was diluted with water, filtered, and the filtrate extracted with ethyl acetate. The organic extract worked-up as described above gave 0.51 g (82.5%) of carbobenzoxyglycylglycine, m.p. 170–173° (ethanol–water), having a mixed m.p. 174–175° with an authentic sample (13).

Method 2

A solution of 0.8 g (2 mmol) of the peptide ester in 25 ml of 90% acetic acid was treated with 0.65 g of zinc powder and worked-up as described above for the tetrapeptide ester. A 41% yield (0.22 g) of carbobenzoxyglycylglycine, m.p. 176–178° was obtained.

Method 3

When 0.5 g (1.26 mmol) of Z-Gly-Gly-OCH_2CCl_3 was treated with 0.5 g of zinc powder in glacial acetic acid (5 ml) for 4 h, the only product isolated after work-up was 0.09 g of glycylglycine, m.p. 224–228° (dec.) (lit. 216–222° (dec.) (23)).

We thank the National Research Council of Canada for financial help and Dr. F. L. Chubb, Director of Chemical Research, for his understanding and encouragement throughout this work.

The Radiochemistry of Organoiron Compounds. III. $Fe(CO)_5$–Cyclopentadiene Solutions

W. KANELLAKOPULOS-DROSSOPULOS AND D. R. WILES

Institut für Heisse Chemie, Kernforschungzentrum Karlsruhe, Germany

and

Department of Chemistry, Carleton University, Ottawa, Canada K1S 5B6

Received July 13, 1972

Nucleogenesis of ^{59}Fe gives iron atoms which react with monomeric cyclopentadiene to produce $^{59}FeCp_2$, either in liquid or solid solutions, but do not react appreciably with dimeric cyclopentadiene. This is taken as showing that local thermal effects of the nuclear reactions are ineffective in causing the dissociation $(C_5H_6)_2 \rightarrow 2C_5H_6$. The concentration dependence of the yield of $^{59}FeCp_2$ indicates that the ^{59}Fe atom reacts primarily at its point of genesis rather than after diffusion.

La nucléogénèse du ^{59}Fe libère des atomes de fer qui réagissent avec du cyclopentadiène monomérique pour produire du $^{59}FeCp_2$, en solution liquide ou solide, mais ne réagissent pas d'une manière appréciable avec du cyclopentadiène dimérique. Ceci démontre que les effets thermiques locaux des réactions nucléaires ne sont pas efficaces pour causer la dissociation $(C_5H_6)_2 \rightarrow 2C_5H_6$. La dépendance du rendement du $^{59}FeCp_2$ sur la concentration montre que l'atome ^{59}Fe réagit principalement lors de sa génèse plutôt qu'après diffusion. [Traduit par le journal]

Can. J. Chem., **51**, 215 (1973)

Recent radiochemical studies of organoiron (1, 2) and organomanganese (3, 4) compounds have been directed toward identifying the nature and the times of chemical reactions which follow nuclear reactions and lead to the observed identifiable radioactive products. These reactions are caused by some manifestation of the nuclear excitation energy: physical recoil at energies of some hundreds of eV, or strong rapid ionization (up to +10 or +15) following the emission of Auger electrons, or some intermediate combination of these two extremes. It is not at present known whether it is the nuclear de-excitation which governs the ensuing chemical reactions or whether the reactions are more characteristic of the (damaged) matrix irrespective of the mode of generation of the radioactive atom. In particular, the time of the reaction has been under study: whether the reaction occurs immediately after the nuclear event, whether it occurs by subsequent thermal processes, or whether, in fact, some critical bonds remain intact during and after the nuclear transformation.

A recent study (2) using ^{58}Fe-depleted ferrocene ($FeCp_2$) has shown that $^{59}FeCp_2$ can be formed in good yield from ^{59}Fe atoms never before bonded to cyclopentadiene but which come rather from the reaction

$$[1] \qquad {}^{58}Fe(CO)_5\ (n,\gamma)\ {}^{59}Fe + \ldots$$

and which appear to exchange or otherwise react thermally with $FeCp_2$ molecules. On the other hand, a study of $[CpFe(CO)_2]_2$ activated by neutrons (1) showed that, while Fe—CO bonds can be formed subsequently to the nuclear reaction by thermal processes, there was no evidence to suggest that Fe—Cp bonds could be formed other than instantaneously. There appears thus to be an

$$[2] \qquad [CpFe(CO)_2]_2 \xrightarrow{(n,\gamma)} {}^{59}FeCp_2 + {}^{59}Fe(CO)_5 + [Cp^{59}Fe(CO)_2]_2 + \ldots$$

inconsistency in the behavior of the iron atoms. In the one case the Fe—Cp bond is formed by an apparently thermal reaction while in the other case the Fe—Cp bond formation seems to be exclusively epithermal.

It is often observed (2, 5, 6) that, when compounds are neutron irradiated in solution, the yield of the radioactive parent compound ("retention") is markedly lower. There are, however, some cases in which this is not so, notably instances in which the solvent is a potential reactant. For example, when $AsCl_3$ is neutron irradiated in benzene solution, various phenylarsenic compounds are formed (7). Ruthenium—Cp bonds are formed in high yield when ruthenium atoms are produced by nucleogenesis in solutions of monomeric cyclopentadiene, but not in solutions of the dimer (8). Furthermore, when

U_3O_8 and $FeCp_2$ are neutron-irradiated together as a mixture of the powdered solids, a large fraction of the fission-product ^{105}Ru is found (9) as $RuCp_2$, after the Fe—Cp bonds are somehow broken.

In an attempt to resolve the apparent contradiction in the behavior of iron atoms toward cyclopentadiene, we have studied the formation of $^{59}FeCp_2$ in solutions (both solid and liquid) composed of $Fe(CO)_5$, cyclopentadiene and benzene. The objective of the study was to learn whether the newly-generated ^{59}Fe atom is able to react with nearby (or distant) free $(Cp)_1$ and perhaps $(Cp)_2$ molecules or whether reaction must involve bonded Cp ligands.[1]

Experimental

Reagents used were the purest available, purified further by sublimation or distillation *in vacuo* or under nitrogen. Monomeric cyclopentadiene was produced by thermal cracking of the dimer and distillation at 40°, and preserved at liquid nitrogen temperature until use.

Samples for neutron irradiation were prepared under nitrogen, degassed, rapidly frozen, and sealed *in vacuo*. Those solutions which were to be irradiated at low temperatures were stored under liquid nitrogen, both before and after the irradiation, up to the time of the separation.

Neutron irradiation was done for 24 h in the thermal column of the FR-2 research reactor in Karlsruhe, where the reported thermal neutron flux is 3×10^{11} cm^{-2} s^{-1} and the temperature about 40°.

Separation of the components of the samples was done after adding 30 mg $FeCp_2$ carrier. Cyclopentadiene and $Fe(CO)_5$ were removed under vacuum at room temperature. The $FeCp_2$ was purified by column chromatography on silica gel, followed by sublimation under nitrogen. An experiment done without added carrier showed that no detectable quantity of $FeCp_2$ (*i.e.*, $\lesssim 0.1\%$ of the theoretical maximum) was produced either during long (5 days) standing of the samples at room temperature, or during 24-h neutron bombardment of the samples at 40°. All operations were carried out in subdued light to avoid the effects of possible photolysis.

Radioactivity measurements were made using a well-type sodium iodide scintillation counter. Correction was made for losses in chemical recovery. Only the yield of $^{59}FeCp_2$ was measured. This is reported as that fraction of the total ^{59}Fe radioactivity which appears as $^{59}FeCp_2$.

Results and Discussion

The results of neutron irradiation of solutions containing either monomeric $(Cp)_1$ or dimeric $(Cp)_2$ cyclopentadiene are given in Table 1.

TABLE 1. Yields of $^{59}FeCp_2$ from neutron irradiated solutions of $Fe(CO)_5$, benzene, and Cp_1 or Cp_2; volume ratio, 2:1:1.

Conditions*		$^{59}FeCp_2$ yields†	
		Observed	Corrected‡
−78 °C,	$(Cp)_2$	0.57±0.02$_5$§	0.0
−78 °C,	$(Cp)_1$	13.6 ±0.2	13.0
40 °C,	$(Cp)_2$	1.55±0.09	1.0
40 °C,	$(Cp)_1$	7.5 ±0.1	6.9

*Approximate irradiation temperatures and nominal Cp constitution.
†Yield based on the total ^{59}Fe produced.
‡Correct for exchange, see text.
§Error limits are standard deviations of the mean values, based on eight independent experiments for Cp_2 and four for Cp_1, each experiment done in duplicate.

Before discussing these data, possible sources of spurious effects must be examined. The simplest of these is the possibility of an exchange reaction occurring between the carrier ferrocene and some non-molecular form of the radioactive iron during the chemical separation[2]

[3] $$^{59}Fe + FeCp_2 \rightleftharpoons {}^{59}FeCp_2 + Fe$$

No detailed information on this reaction is available, although upper limits can be set. The value of 0.57% for the ^{59}Fe found as $FeCp_2$ in frozen $(Cp)_2$ solutions (see Table 1) and the value of 0.5% given in ref. 2 are supported by the results of direct measurements[3] made during the course of this work which gave from four determinations $0.64 \pm 0.16\%$ exchange during the separation procedure. We thus adopt the figure 0.6% as representing the extent of formation of ^{59}Fe by reactions such as that in reaction 3, during the chemical workup. Data corrected for this exchange are given in Table 1.

A second spurious effect could come from bulk radiolytic production of ferrocene, as in reaction 4

[4] $$Fe(CO)_5 + (Cp)_1, (Cp)_2 \xrightarrow{\gamma} FeCp_2 + CO + \ldots$$

As was shown above, it is clear that this bulk reaction must be minimal if it occurs at all.

We note the possibility of segregation of the

[1]We use the following notation for the various forms of cyclopentadiene: $(Cp)_2$ = dimeric $(C_5H_6)_2$; $(Cp)_1$ = monomeric C_5H_6; Cp = cyclopentadiene as ligand; ·Cp = cyclopentadiene radical or temporarily dissociation neutral ligand.

[2]The symbols ^{59}Fe and Fe are *not* intended to signify *atomic* iron, since we do not know the state of the iron at that stage.

[3]This was done by irradiating 2:1 $Fe(CO)_5$–benzene solutions with thermal neutrons and, after adding inactive $FeCp_2$ carrier, comparing the total radioactivity with that of the separated and purified $FeCp_2$. Clearly this exchange reaction could not have occurred during the neutron irradiation, since no $FeCp_2$ was present.

components in the frozen targets, as was suggested for the $FeCp_2$–$Fe(CO)_5$ system. We have no direct evidence on this question, except to point out that, at least in the case of the $(Cp)_1$ monomer, the yield in frozen targets is much higher than could be the case if crystal segregation were at all important. Moreover, the parallel between the $-78°$ and 40° data suggests that no such segregation has occurred to a significant extent.

Finally, there is the possibility that at 40° the dimer may partially monomerize, and *vice versa*. From published thermal data (10) we estimate the equilibrium constant for the dimerization to be about 2×10^4. Hence for our conditions, the equilibrium concentration of $(Cp)_1$ monomer in our dimer solutions is of the order of 0.01 mol l^{-1}, or 0.5% that of the dimer. While this is not a sufficient concentration to influence a hot reaction, it could well influence the fate of a diffusing reactive atom.

The question of dimerization of the monomer is one of the rate, rather than of the equilibrium position. Activation data in the literature (10) show a significant solvent dependence and are not available for the solutions used in this work. Using the data for benzene solutions of $(Cp)_1$, the rate constant for the dimerization in our solution is estimated to be about 0.02 l mol^{-1} h^{-1}, from which it is calculated that about 35% of the monomer remains after 24 h at 40°. The mean concentration is about 2.2 *M* over the 24-h period.

The dependence of the reaction on $(Cp)_1$ concentration is given in Fig. 1, where the yield of the $^{59}FeCp_2$ is shown for 24-h 40° experiments as a function of the initial concentration of the $(Cp)_1$ monomer.

The data presented here show clearly that, in accord with conclusions of Zahn and Harbottle (8), Fe—Cp bonds can be formed in both solid and liquid solutions containing monomeric cyclopentadiene. It is also clear that, when correction is made for reaction induced during separation and for dissociation of the dimer, the dimeric $(Cp)_2$ reacts little, if at all. The solid state results are particularly striking. The yield of 13.7% of $^{59}FeCp_2$ shows that a considerable portion of the (n,γ) events produce an iron atom which is chemically reactive toward $(Cp)_1$ molecules, and which is either unbound or only loosely bound to its former carbonyl ligands. This is in distinction from the results of the $Fe(CO)_5$–$^{56}FeCp_2$–C_6H_6 frozen solutions, where low yields of $^{59}FeCp_2$

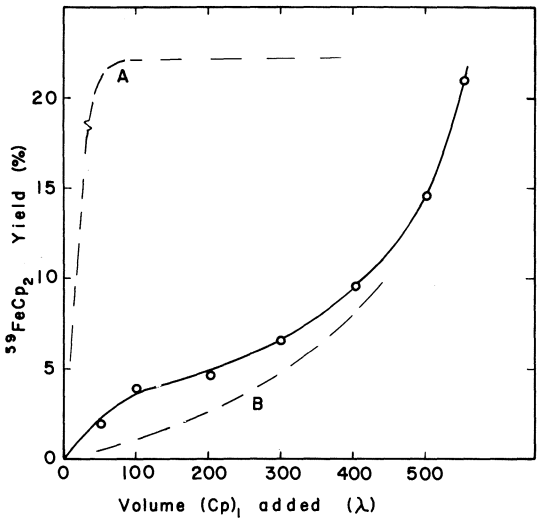

FIG. 1. Variation of the $^{59}FeCp_2$ yield with changes in the initial Cp_1 concentration. The total volume of the solutions was 1.05 ml, assuming no volume change on mixing. For description of curves A and B, see text.

were found and were tentatively interpreted as showing crystalline segregation of the components. By the same token, the present solutions evidently do not segregate on being frozen.

The data for dimeric $(Cp)_2$ solutions are significant in that they show that $(Cp)_2$ is not reactive toward the newly-produced ^{59}Fe atom. While the solid state yield could be explained by segregation on freezing, the above mentioned conclusion regarding the frozen monomeric $(Cp)_1$ solutions suggests that this is unlikely. The liquid solution data also show a very low yield which could perhaps result from the presence of the small amount ($\leqslant 1\%$) of monomer formed by thermal dissociation. This is qualitatively supported by an extrapolation of the data of Fig. 1.

The significant deduction from these results is that local heating from the nuclear reaction is not able to cause thermal dissociation of $(Cp)_2$. This could be for a variety of reasons, but most likely it is that the heated region is too short lived to effect molecular rearrangement. The only estimates published (and these for more tightly bound solids) suggest (11) that about 10^{-11} s is the maximum duration of such a "hot zone". Even if the molecule were to dissociate during this time, it is unlikely that the moieties could become separated and remain apart. If this reasoning is correct, it is apparent that the observed chemical

reactions result from something other than nuclear *recoil.*

The *time* of the reactions is a question which remains. The form of the curve in Fig. 1 may be enlightening in this respect.[4] The strong but slow increase in $^{59}FeCp_2$ yield as the $(Cp)_1$ concentration increases indicates that the Fe atom is essentially unable to react after even a short diffusion path. Curve A shows what one expects for good scavenging of Fe by some form of cyclopentadiene, such as by the exchange reaction shown in reaction 3. Curve B shows, on the other hand, what would be expected if the ^{59}Fe were to react only in its immediate neighborhood. (It is to be emphasized that curves A and B show only qualitative behavior. Quantitative behavior could be assessed only with the help of detailed information on competitive reaction rates, concentrations of competitive reactants, diffusion rates, and so on, which are at present not known.) One infers from the comparison of the data with curves A and B that the reaction is mostly with nearest neighbors. The small deviation from the form of curve B may indicate that a fraction of the ^{59}Fe atoms may react after diffusion. The data are not sufficiently extensive for one to be confident of this point, however.

This behavior is to be contrasted with the observation (12) that in $Ni(CO)_4$–hexane solutions the yield of $^{65}Ni(CO)_4$ remains high on progressive dilution with hexane, even when the target $Ni(CO)_4$ is diluted down to 2%. This observation is moreover in accord with the results for $[CpFe(CO)_2]_2$ in suggesting that the reaction Fe + Cp → Fe—Cp is very fast if it is to occur at all. The apparent conflict with the results of the $^{56}FeCp_2$–$^{58}Fe(CO)_5$ study (2) may suggest that the cyclopentadiene in ferrocene is somehow more reactive toward iron atoms than is $(Cp)_1$. One notes a difference between this reaction and that of $CH_3CpMn(CO)_3$ neutron bombarded in 2,2,4-trimethylpentane solutions (13). Here the $^{56}Mn(CO)_5$ radical is able to react effectively with radiolytically produced methyl groups so that the yield of $CH_3{}^{56}Mn(CO)_5$ increases ten-fold on dilution of the $CH_3CpMn(CO)_3$ sample (before neutron irradiation) with 2,2,4-trimethylpentane. It is interesting to recall that the further addition (also before neutron irradiation) of a small amount of $Fe(CO)_5$ entirely quenched the formation of $CH_3{}^{56}Mn(CO)_5$.

In summary, it is shown in this work that the reaction

$$[5] \qquad Fe(CO)_5 + (Cp)_1 \xrightarrow{(n,\gamma)} {}^{59}FeCp_2 + \ldots$$

occurs to a considerable extent between the newly-generated ^{59}Fe atom and adjacent monomeric $(Cp)_1$ molecules, but that neither reaction with dimeric $(Cp)_2$ nor reaction following short diffusion is effective. From this work and the previous study (2) on solutions of $FeCp_2$ in $Fe(CO)_5$, it appears that the order of reactivity of the cyclopentadiene with "hot" iron atoms is $FeCp_2 > (Cp)_1 \gg (Cp)_2$ in the reaction

$$[6] \quad {}^{59}Fe + \begin{cases} FeCp_2 \\ (Cp)_1 \\ (Cp)_2 \end{cases} \rightarrow {}^{59}FeCp_2 + \begin{cases} Fe, FeCp \\ H + \ldots \\ H \end{cases}$$

The next question, not answered in this work, is whether failure to react after diffusion is the result of loss of thermal or electronic excitation or whether it comes rather from competitive reaction with accidental (or radiolytic) scavengers.

We are pleased to express our gratitude to Professor dr. F. Baumgärtner for his support and criticism. Mrs. E. Rauch gave able experimental assistance.

[4]The trend of results in Fig. 1 could not be produced by radiolysis effects in $Fe(CO)_5$, since the iron carbonyl concentration was held constant for these experiments.

Complexes d'hematoporphyrine IX avec le platine(II)[1]: synthese, intermediaires, spectres, interet biologique

J. P. MACQUET ET T. THEOPHANIDES

Université de Montréal, Département de Chimie, Montréal 101, Québec

Reçu le 14 juillet, 1972

La métalloporphyrine HP.Pt a été préparée à partir de l'hématoporphyrine IX (HPH_2) et du platine(II). Un intermédiaire de réaction a été isolé correspondant à la formule $HPH_2.PtCl_2$. Les spectres u.v., visibles, et infrarouges de ces complexes font l'objet de cette présente étude. L'intermédiaire $HPH_2.PtCl_2$ portera la dénomination: "complexe coiffé" caractérisant ainsi la position du groupement $PtCl_2$ sur la porphyrine. Une application biologique de cet intermédiaire dans le traitement de certaines tumeurs est entrevue.

The platinum–porphyrin (HP.Pt) complex was prepared from hematoporphyrin IX (HPH_2) and potassium chloroplatinate(II). An intermediate complex was isolated corresponding to the formula $HPH_2.PtCl_2$. U.v., visible, and i.r. spectra of the complexes are obtained and are discussed. The complex $HPH_2.PtCl_2$ is the first intermediate identified in these reactions. A biological application of this intermediate for the treatment of tumors is sought.

Can. J. Chem., **51**, 219 (1973)

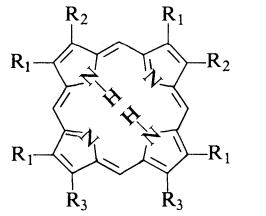
Introduction

L'étude des métalloporphyrines a déjà fait l'objet de maints travaux (1, 2), dûs à l'intérêt biologique qu'elles suscitent, autant dans le métabolisme que dans la photosynthèse. Les métaux les plus couramment rencontrés sont: le fer dans l'hémoglobine, le magnésium dans la chlorophylle, le cobalt dans la vitamine B_{12}, le manganèse dans les plantes et aussi dans le sang (3).

Notre choix s'est porté sur l'hématoporphyrine IX (fig. 1) qui a été trouvée s'accumulant sélectivement dans certaines tumeurs et dans des tissus se développant rapidement (4–6). Le rôle que certaines porphyrines pourraient avoir dans le dépistage de certaines tumeurs semble se concrétiser (7).

Le platine a été choisi pour deux raisons: tout d'abord pour sa forte tendance à former des complexes plan-carrés, stables, donc susceptible d'imposer son hybridation dsp^2 à la porphyrine. L'étude spectrale devrait nous confirmer la grande stabilité de cette métalloporphyrine (1*a*). La seconde raison est d'ordre biologique: certains sels de platine ont déjà montré leur efficacité dans le traitement de tumeurs (8–10).

Lors de la préparation de la métalloporphyrine HP.Pt, il nous a été possible d'isoler et d'identifier un intermédiaire correspondant à la formule $HPH_2.PtCl_2$. A notre connaissance, c'est la première fois qu'un tel intermédiaire est caractérisé de cette façon.



$R_1 = -CH_3$;
$R_2 = -CHOH-CH_3$;
$R_3 = -CH_2-CH_2-C(=O)-OH$

FIG. 1. Représentation structurale de l'hématoporphyrine IX.

Partie expérimentale

Préparation de la métalloporphyrine

La métalloporphyrine HP.Pt a été préparée de la façon suivante: l'hématoporphyrine neutre HPH_2 est dissoute dans de l'acide acétique glacial (1.7×10^{-3} *M*), puis portée à une température de 85 °C. Une solution de K_2PtCl_4 dans l'eau (2.1×10^{-3} *M*), est alors ajoutée à la même température. Les proportions utilisées sont stoechiométriques. Pour faciliter l'incorporation du platine dans la porphyrine, la réaction a lieu en présence d'acétate de sodium, le mélange tampon acide acétique – acétate de sodium s'avérant très efficace lors de la synthèse des métalloporphyrines (1*b*). Le temps de réaction est de 24 h; une partie du complexe reste en solution, la grosse majorité précipite. Le solvant est évaporé, on lave à l'acide acétique puis à l'eau, jusqu'à disparition de la bande Soret (1*c*) de l'hématoporphyrine. Le complexe est recristallisé dans un mélange

[1]Une communication préliminaire de cet article a été présentée au 55e congrès du CIC, Université Laval, 4–7 juin 1972, Québec.

DMF/H_2O; il est alors séché sous vide en présence d'anhydride phosphorique. Le rendement de la réaction est supérieur à 80%.

Préparation de l'intermédiaire

Le "complexe coiffé" $HPH_2.PtCl_2$ a été isolé en milieu acétique à 60 °C en utilisant les mêmes concentrations. Le temps de réaction est de 24 h. La purification de cet intermédiaire s'effectue de façon identique à celle de la métalloporphyrine correspondante. La recristallisation de ce complexe montrant une légère dégradation, il a été étudié après purification. Le rendement est de l'ordre de 60%.

L'acide acétique glacial de qualité "Reagent" a été distillé. Les solvants étaient tous de qualité "Reagent" ou "Spectrograde" suivant le cas. L'eau utilisée était distillée. L'hématoporphyrine neutre et le dichlorure provenaient de la compagnie Nutritional Biochemicals Corporation (NBC) et le sel de platine de la compagnie British Drug Houses (BDH).

Les composés préparés ne conduisent pas le courant donc ne présentent aucun caractère ionique. Dans le DMF à 10 °C, la conductivité molaire de $HPH_2.PtCl_2$ est égale à 7.2 et celle de HP.Pt à 2.9 $ohm^{-1}\ cm^2\ mol^{-1}$.

L'étude conductimétrique a été menée avec un "Konductoskop E 365 B", la cellule de verre étant du modèle EA 608.

Analyses

Anal. calc. pour $HPH_2.PtCl_2$: C, 47.22; H, 4.42; Pt, 22.56; Cl, 8.20. Trouvée: C, 47.20; H, 3.71; Pt, 22.14; Cl, 8.58.

Anal. calc. pour HP.Pt: C, 51.57; H, 4.58; Pt, 24.63. Trouvée: C, 51.45; H, 4.54; Pt, 24.14.

Les analyses du carbone et de l'hydrogène ont été effectuées par le laboratoire du Dr Daesslé à Montréal et par Chemalytics Inc., Tempe (Arizona), celles du platine et du chlore par nos soins.

Le pourcentage de platine a été trouvé par calcination du complexe (20 mg) dans un four Linberg Heavy-Duty à 850 °C pendant 45 min. Le dosage du chlore a été effectué avec un "Potentiograph E 336 A" couplé à un "Metrohm Herisav E 436 E", l'électrode utilisée étant une électrode combinée à un fil de platine.

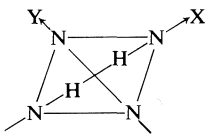
Les spectres u.v., visibles ont été enregistrés sur un spectrophotomètre Cary 14, avec des cellules de quartz de 1 cm de largeur. Les spectres sont reproductibles avec une précision de 1 mμ.

L'étude infrarouge a été conduite avec un spectrophotomètre "Perkin–Elmer IR 621". Chaque complexe (2 mg) a été intimement mélangé à 150 mg de bromure de potassium; ce mélange comprimé sous forme de pastille a servi à l'obtention des spectres. La précision des spectres est de 4 cm^{-1} dans la région 4000–2000 cm^{-1} et de 2 cm^{-1} entre 2000 et 300 cm^{-1}. Un film de polystyrène a été utilisé pour la calibration de l'appareil.

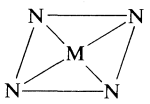
Discussion

Etude visible

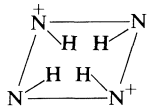
Les spectres d'absorption des porphyrines en visible sont interprétés comme étant le résultat de la superposition des vibrations de deux transitions électroniques (1*d*). La première transition s'effectue entre 450 et 700 mμ, elle comporte 4 bandes dont les intensités varient en fonction des substituants périphériques et correspond à la transition $a_{2u} \rightarrow e_g^*$ (π). La seconde a lieu entre 400 et 450 mμ, c'est la bande Soret qui correspond à la transition $a_{1u} \rightarrow e_g^*$ (π). La transformation porphyrine → métalloporphyrine conduit à une simplification du spectre. Les 4 bandes de la première transition sont alors réduites à 2 bandes que l'on appelle α et β (β pour les plus petites longueurs d'onde). Le même spectre est obtenu lors du passage porphyrine neutre → porphyrine diacide, les 4 atomes d'azote portant chacun un H et l'ensemble portant deux charges positives. Cette simplification du spectre a été attribuée à une augmentation de symétrie de la porphyrine (voir fig. ci-dessous).



Porphyrine neutre
symétrie D_{2h}
(les axes X et Y ne
sont pas équivalents)



Métalloporphyrine
symétrie D_{4h}
(les axes X et Y
sont équivalents)



Porphyrine diacide
symétrie D_{4h} ou S_4
(les axes X et Y
sont équivalents)

Dans les solvants organiques, l'hématoporphyrine présente un spectre du type *aetio* (fig. 2): intensité bande IV > III > II > I; en milieu acétique glacial, son spectre se réduit à trois bandes avec deux forts épaulements (fig. 2), et en milieu acétique +1% HCl concentré, son spectre ne présente plus que deux bandes caractéristiques du dication (fig. 2).

La métalloporphyrine HP.Pt présente un spectre à deux bandes (fig. 3) dont le rapport des intensités bande α/β est supérieur à 1 (tableau 1); de plus, la bande Soret subit un déplacement hypsochrome de 13 mμ. Ces deux caractéristiques nous permettent d'avancer l'hypothèse d'une très grande stabilité de cette métalloporphyrine (1*a*).

Le spectre visible du "complexe coiffé" $HPH_2.PtCl_2$ possède la même allure que celui de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

l'hématoporphyrine IX, mais est déplacé vers le rouge (tableau 1). On peut attribuer ce déplacement à l'influence polarisante du platine sur les atomes d'azote. La symétrie de la molécule n'ayant pas été affectée de façon notable, il est normal d'obtenir un spectre similaire. En milieu acétique glacial, les spectres des 3 composés: hématoporphyrine neutre HPH_2, du "complexe coiffé" $HPH_2.PtCl_2$ et de la métalloporphyrine HP.Pt sont différents (figs. 2, 4 (bande 1) et fig. 3). Afin de confirmer l'existence du "complexe coiffé" comme intermédiaire, il est possible de suivre la transformation $HPH_2.PtCl_2 \rightarrow HP.Pt + 2\ HCl$ (fig. 4) en milieu acétique glacial. L'évolution du spectre en fonction du temps montre le passage de l'intermédiaire (fig. 4, bande 1) à la métalloporphyrine finale (fig. 4, bande 2).

De nombreuses hypothèses ont été avancées quant à la nature du ou des composés obtenus par dissolution des porphyrines en milieu acétique. L'hématoporphyrine neutre et le dichlorure ont des spectres très différents en milieu acétique glacial. En milieu acétique dilué, dans le cas de l'hématoporphyrine neutre, on observe l'apparition d'une deuxième bande dans la région Soret vers les plus petites longueurs d'onde (fig. 5); cela n'est pas observé dans le cas du dichlorure. En milieu acétique +1% HCl, les spectres des deux composés sont identiques. De ces résultats, il ressort que si l'espèce diprotonée existe en milieu acétique glacial, elle se trouve en très faible quantité. Corwin *et al.* (11) ont résolu le problème en dissolvant l'ester dans un mélange acide acétique 60%, acétone 40%. L'isolation du monocation est à l'étude.

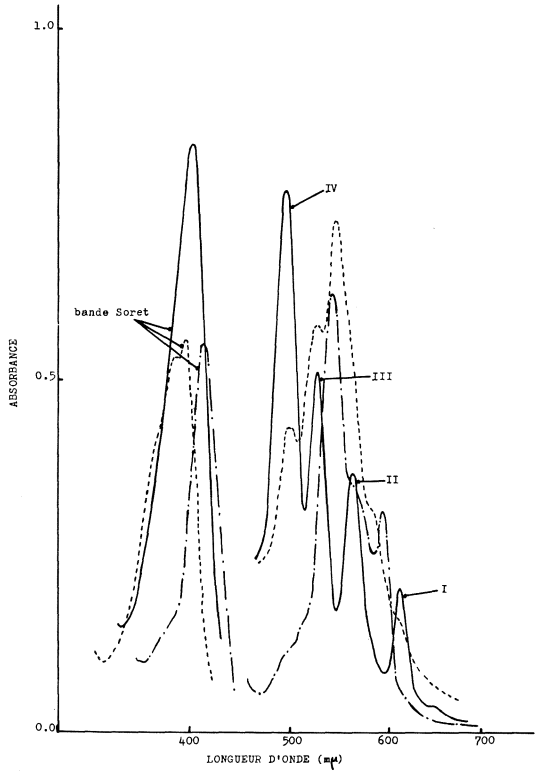


FIG. 2. (1) Spectres de l'hématoporphyrine IX dans (*a*) le DMF (—), concentration: région visible $C = 6.68 \times 10^{-5}\ M$, bande Soret $C/10$; (*b*) l'acide acétique glacial (---), concentration: région visible $C = 10^{-4}\ M$, bande Soret $C/20$; (2) Spectre du dichlorure d'hématoporphyrine dans l'acide acétique glacial (·····), concentration: région visible $C = 5.06 \times 10^{-5}\ M$, bande Soret $C/40$.

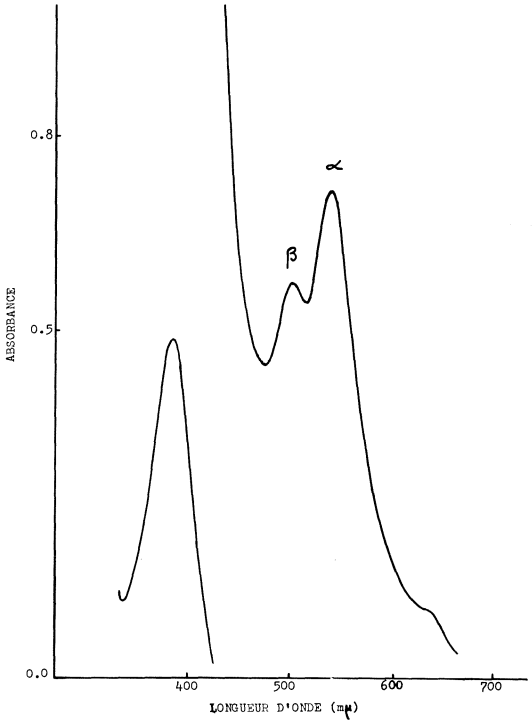

FIG. 3. Spectre de la platino-hématoporphyrine dans le DMF. Concentration: région visible, $C = 9.09 \times 10^{-5}\ M$; bande Soret, $C/10$.

Etude infrarouge

En comparant les spectres de l'hématoporphyrine IX et du "complexe coiffé" $HPH_2.PtCl_2$ avec celui de la métalloporphyrine HP.Pt (fig. 6 et tableau 2), on se rend compte d'une simplification spectrale dûe à l'augmentation de symétrie.

TABLEAU 1. Etude visible des composés préparés (λ en mμ et ε en 1 mol^{-1} cm^{-1})

*HPH_2: hématoporphyrine neutre; HPH_2.2HCl: dichlorure d'hématoporphyrine; $HPH_2.PtCl_2$: "complexe coiffé"; HP.Pt: platino-hématoporphyrine.

Comme Boucher et Katz (12), nous avons remarqué que les spectres étaient peu résolus sous 600 cm^{-1} pour HPH_2 et HP.Pt. Dans le cas de $HPH_2.PtCl_2$, la région 300–350 cm^{-1} est particulièrement révélatrice des vibrations Pt—Cl.

La première bande qui apparaît vers 3400 cm^{-1} est le massif intense caractéristique des ν_{OH}. Cette bande large et déplacée par rapport aux ν_{OH} libres (13) indique une liaison hydrogène.

Vibrations N—H

Dans l'hématoporphyrine neutre, la vibration de valence ν_{N-H} se trouve à 3308 cm^{-1}. On remarque un faible déplacement de cette bande vers les plus basses énergies en passant au "complexe coiffé" $HPH_2.PtCl_2$ (3308 $\rightarrow$ 3300 cm^{-1}). La vibration de déformation dans le plan δ_{N-H} a été identifiée par Boucher et Katz (12) à 1107 cm^{-1}. A 740 et 679 cm^{-1}, on trouve les déformations hors-plan γ_{N-H}. Il est à remarquer que l'intensité relative de ces bandes varie en passant de la porphyrine neutre au "complexe coiffé": la bande à 673 cm^{-1} dans l'intermédiaire a gagné en intensité par rapport à celle se trouvant à 740 cm^{-1}. De plus ces bandes sont déplacées vers des énergies plus basses comme en témoigne le tableau 2. On pourrait relier ce déplacement avec le déplacement bathochrome des bandes du spectre visible (tableau 1). Les vibrations N—H disparaissent dans la métalloporphyrine HP.Pt, dû au remplacement des 2 atomes d'hydrogène par le platine.

Vibrations C—H

Dans la région 3000–2800 cm^{-1}, on retrouve les vibrations de valence symétriques et antisymétriques des C—H des groupements alkyles (12, 14). Les bandes à 1445 et à 1378 cm^{-1} ont été attribuées à des déformations antisymétriques et symétriques des groupements —CH_2 et —CH_3 (14, 15).

Rimington *et al.* (16) et Ogoshi *et al.* (17) ont montré que la bande se trouvant à 1228 cm^{-1} était due à un mode de déformation C—H dans le plan. Par deutériation avec D_2O–D_2SO_4, Ogoshi et Yoshida (14, 17) ont montré que les bandes à 1220 et à 836 cm^{-1} dans l'octaéthyleporphyrine de zinc correspondaient aux déformations dans le plan et hors plan des C—H en position meso (C—H méthène). Par substitution du métal, ils ont relié le déplacement de ces bandes vers les plus fortes énergies au déplacement hypsochrome des bandes du visible. On remarque ce même déplacement en passant de HPH_2 à HP.Pt: 1228 $\rightarrow$ 1245 cm^{-1} pour δ_{C-H} et 834 $\rightarrow$ 839 cm^{-1} pour γ_{C-H} (tableau 2) et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

401 → 388 mμ pour la bande Soret en proche-u.v. (tableau 1).

La vibration $\nu_{C=O}$ se situe à 1715 cm^{-1} dans l'hématoporphyrine et ne subit aucun déplacement dans les différents complexes.

Bandes sensibles au métal

Dans la région 1500–1700 cm^{-1}, on trouve les mouvements dans le plan des vibrations C=C et C=N des cycles tétrapyrroliques (14, 18). Cette région est sensible au remplacement des deux atomes d'hydrogène par la platine. Ogoshi *et al.* (14) ont montré que les bandes aux alentours de 1000 cm^{-1} étaient sensibles au métal; les bandes à 1070 et 1035 cm^{-1} semblent être associées avec la déformation dans le plan du noyau porphyrinique (14). Boucher et Katz (12) ont remarqué une augmentation de l'intensité de la bande à 1070 cm^{-1} en passant de la protoporphyrine à l'hématoporphyrine, ils ont suggéré une vibration de valence ν_{C-O} du groupement hydroxyéthyle.

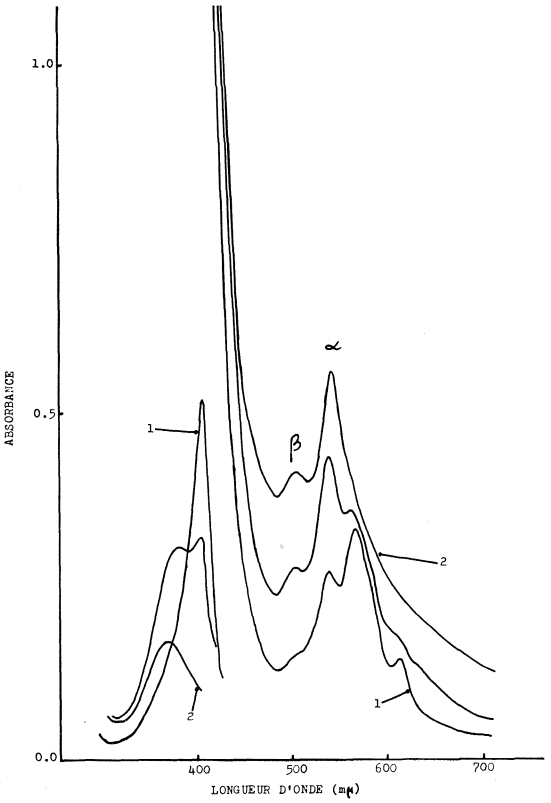

FIG. 4. Transformation du "complexe coiffé" $HPH_2.PtCl_2$ en métalloporphyrine HP.Pt dans l'acide acétique glacial. (*1*) Début de la réaction; (*2*) fin de la réaction. Concentration: région visible, $C = 5.55 \times 10^{-5}$ *M*; bande Soret, *C*/10.

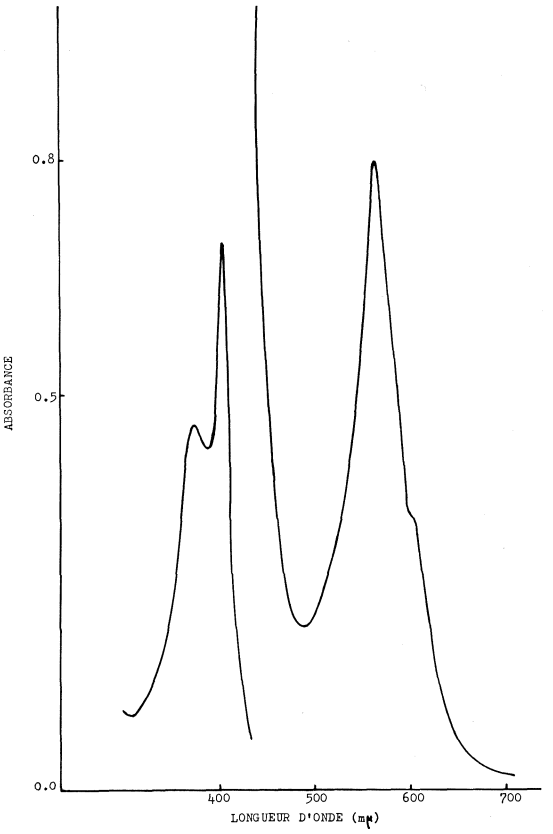

FIG. 5. Spectre de l'hématoporphyrine neutre dans l'acide acétique 50%. Concentration: région visible, $C = 9.68 \times 10^{-5}$ *M*; bande Soret, *C*/20.

Les bandes se trouvant dans la région 500–300 cm^{-1} ont été attribuées à des bandes de déformation du noyau tétrapyrrolique (12, 15). A 460 cm^{-1}, on remarque l'apparition d'une nouvelle bande intense que l'on pourrait attribuer à la vibration de valence ν_{N-Pt}. Le spectre du "complexe coiffé" $HPH_2.PtCl_2$ présente deux bandes à 332 et à 323 cm^{-1} d'intensité moyenne que l'on attribue aux vibrations de valence ν_{Pt-Cl}. Ces deux bandes indiquent une position *cis* des atomes de chlore sur le platine.

En 1960, Fleischer et Wang (19) ont détecté un intermédiaire de réaction entre la protoporphyrine et le chlorure ferrique dans le chloroforme. Le spectre de cet intermédiaire appelé "sitting-atop complex" ressemble étrangement au spectre du diacide (2). Par la suite, la structure cristalline d'un "S.A.T. complex" (20) montrait

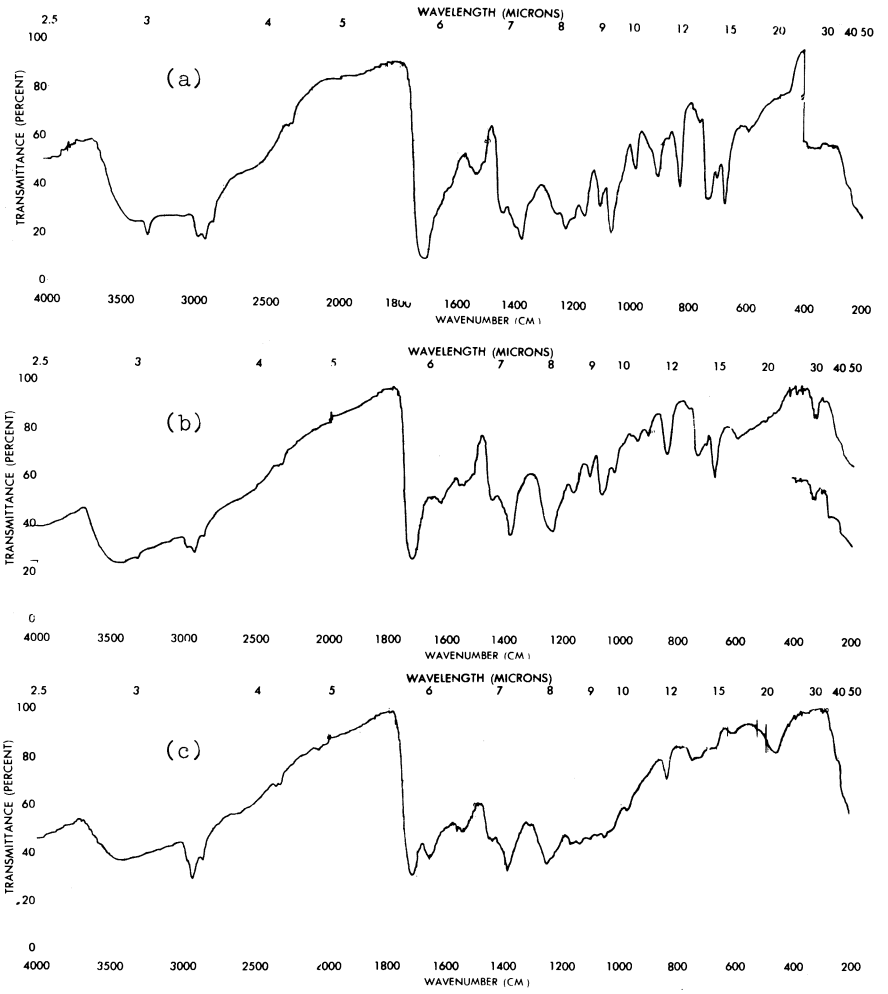

FIG. 6. Spectres infrarouges (pris à l'état solide dans le KBr) des composés suivants: (*a*) hématoporphyrine HPH_2; (*b*) "complexe coiffé" $HPH_2.PtCl_2$; (*c*) platino–hématoporphyrine HP.Pt.

que le composé isolé correspondait à la formule $[PH_4^{2+}Cl^-(FeCl_4^-)]$. D'autres intermédiaires ont été entrevus (21–26) se référant aux résultats de Fleischer et Wang, mais jamais caractérisés de façon systématique. A notre connaissance, c'est la première fois qu'un tel intermédiaire est isolé et étudié de cette façon. Les spectres visible et infrarouge indiquent que le platine ne s'est pas inséré entre les 4 atomes d'azote: les deux atomes d'hydrogène liés aux azotes sont présents. Les déplacements observés pour les vibrations N—H en infrarouge et des bandes du visible vers de plus faibles énergies nous amènent à penser à une coordination entre les deux atomes d'azote possédent un doublet électronique libre avec le platine, cette liaison étant du type donneur–accepteur. Le balancement des noyaux pyrroles en solution en milieu acétique (20) favorise l'attaque du platine sur les doublets libres des atomes d'azote. La coordination azote–platine peut s'effectuer soit sur deux atomes d'azote opposés, soit sur deux atomes d'azote adjacents. Dans le premier cas, la distance calculée d'après les rayons X sur la porphine (27), pour la liaison N—Pt est trop longue (supérieure à 2.7 Å) pour être considérée comme normale (28); dans le second cas, on trouve une distance tout-à-fait raisonnable comprise entre 2.0 et 2.1 Å, le platine gardant son hybridation dsp^2. La structure que nous proposons pour le "complexe coiffé" est celle représentée à la fig. 7.

Les résultats spectroscopiques, la stabilité de

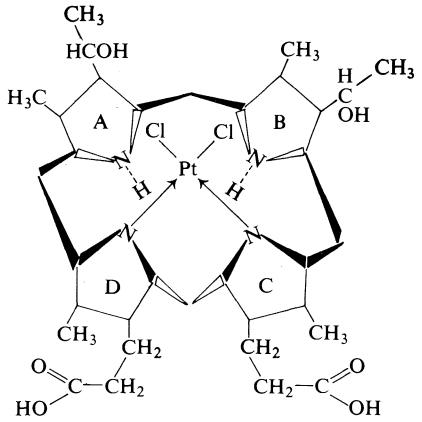

FIG. 7. Structure proposée du "complexe coiffé" $HPH_2.PtCl_2$. Les pyrroles A et B sont inclinés vers le bas, C et D vers le haut.

la métalloporphyrine vis-à-vis des acides forts nous conduisent à placer le platine entre les 4 atomes d'azote et ainsi à stabiliser la porphyrine.

Tout récemment, un complexe ionique a été isolé (identique à celui de Fleischer) correspondant à la formule $HPH_4^{2+}.PtCl_4^{2-}$, identifié par ses analyses C, H, N, Pt, Cl, par son spectre infrarouge et par sa conductivité. Ce complexe a été obtenu en changeant les conditions de la réaction (température = 25 °C, concentration: $HPH_2 = 5.5 \times 10^{-3}$ *M*, $K_2PtCl_4 = 3.3 \times 10^{-2}$ *M*), il est présentement à l'étude et fera l'objet d'une publication à venir.

Lors de la dissolution du K_2PtCl_4 dans l'eau, les espèces $PtCl_4^{2-}$, $PtCl_3(H_2O)^-$, et $PtCl_2(H_2O)_2$ sont en présence (29); l'espèce $PtCl_4^{2-}$ se trouve stabilisée par l'énorme cation HPH_4^{2+} pour donner le premier intermédiaire $HPH_4^{2+}.PtCl_4^{2-}$. A 60 °C, le départ de deux molécules d'HCl donne lieu à la formation du "complexe coiffé" $HPH_2.PtCl_2$ qui représente le second intermédiaire de réaction. Enfin, à 85 °C, le "complexe coiffé" se transforme en métalloporphyrine HP.Pt.

L'interaction hématoporphyrine–Platine en milieu acétique peut donc se résumer comme suit:

$$\underset{\text{dans AcOH}}{HPH_2} + \underset{\text{dans } H_2O}{PtCl_4^{2-}} \xrightarrow{25\ ^\circ C} \underset{\mathbf{1}}{HPH_4^{2+}.PtCl_4^{2-}}$$

$$\mathbf{1} \xrightarrow{60\ ^\circ C} \underset{\mathbf{2}}{HPH_2.PtCl_2} + 2HCl$$

$$\mathbf{2} \xrightarrow[-2HCl]{85\ ^\circ C} \underset{\mathbf{3}}{HP.Pt}$$

Schéma des trois étapes de la réaction conduisant à la formation de la platino-hématoporphyrine: **1**, premier intermédiaire, complexe ionique (marron-foncé); **2**, second intermédiaire, "complexe coiffé" (noir-bleuâtre); **3**, composé final, platino-hématoporphyrine (noir).

Il semblerait d'après ces résultats que la première interaction soit electrostatique (complexe ionique **1**), la seconde étape fixant le métal sur la porphyrine ("complexe coiffé" **2**) et enfin la dernière étape résultant d'une substitution des atomes d'hydrogène fixés sur les azotes, par le métal, conduisant à la métalloporphyrine (**3**) dans laquelle le métal est placé entre les 4 atomes d'azote dans le plan de la molécule.

Il y a quelques années, l'hématoporphyrine IX était utilisée en chirurgie, pour délimiter les tumeurs cancéreuses (30). En effet, on a remarqué que cette porphyrine s'accumulait préférentiellement dans les zones où se développaient des tissus de façon anormale et grâce à sa fluorescence, il était très aisé en travaillant sous lampe u.v. d'extraire ces tumeurs. L'activité antitumorale des sels de platine *cis*, a déjà prouvée (8–10). Le "complexe coiffé" $HPH_2.PtCl_2$ présente donc deux qualités remarquables pour le traitement des tumeurs: c'est un complexe de platine *cis* et c'est une porphyrine qui fluoresce, donc possibilité de suivre l'évolution du composé, dans l'organisme, et par conséquent du platine, s'il n'y a pas dégradation.

Les résultats obtenus dans cette présente étude nous conduisent à faire la cinétique d'incorporation du platine dans l'hématoporphyrine IX, à étudier l'interaction du "complexe coiffé" avec d'autres métaux, ainsi qu'à vérifier son activité anti-tumorale.

Crystal and Molecular Structure of Hexaaquocobalt(II)–Hexafluorosilicate(IV), $[Co(H_2O)_6][SiF_6]$

H. LYNTON AND P-Y. SIEW

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 19, 1972

The structure of hexaaquocobalt(II)-hexafluorosilicate(IV) has been determined by the heavy atom method. The compound crystallizes in the space group $R\bar{3}$, with three molecules in the hexagonal unit cell of dimensions $a = 9.358(16)$, $c = 9.712(14)$ Å. The atomic parameters were refined by block diagonal least squares using anisotropic thermal parameters. The hydrogen atom positions were established but the parameters were not refined. The final agreement residual for 151 observed reflections is $R = 0.043$.

The structure consists of discrete $Co(H_2O)_6^{2+}$ and $(SiF_6)^{2-}$ octahedra joined systematically by O---H'--F hydrogen bonds into chains parallel to the $\bar{3}$ axis.

La structure de l'hexaaquocobalt(II) hexafluorosilicate(IV) a été déterminée par la méthode de l'atome lourd. Le composé cristallise dans le groupe $R\bar{3}$ avec trois molécules par unité hexagonale de dimensions $a = 9.358(16)$Å, $c = 9.712(14)$ Å. Les paramètres atomiques ont été raffinés par la méthode des moindres carrés appliquée aux matrices diagonales qui utilise les paramètres d'anisotropie thermique. Les positions des atomes d'hydrogène ont été établies mais les paramètres n'ont pas été raffinés. L'accord final après 151 reflexions observées est $R = 0.043$.

La structure consiste en octaèdre discret de $Co(H_2O)_6^{2+}$ et $(SiF_6)^{2-}$ relié systématiquement par des liaisons hydrogène O---H---F, en chaînes parallèles aux axes $\bar{3}$.

[Traduit par le journal]

Can. J. Chem., **51**, 227 (1973)

Introduction

Cobalt fluorosilicate was prepared by the action of hydrofluorosilicic acid, H_2SiF_6, on cobalt carbonate, $CoCO_3$, and was found to have the formula $CoSiF_6.6H_2O$(1). The cell dimensions as given in the Powder line file (2) are $a = 9.370$ Å and $c = 9.732$ Å in space group $R3m$, No. 160, ref. 5. It had been reported that in compounds of the type $MSiF_6.xH_2O$, the $(SiF_6)^{2-}$ species was discrete and formed chains with the $M(H_2O)_x^{2+}$ species either through F—M coordination, as in $CuSiF_6.4H_2O$ (3), or F---O hydrogen bonding as in $[Fe(H_2O)_6][SiF_6]$ (4). An X-ray diffraction analysis was undertaken to determine the type of arrangement in $CoSiF_6.6H_2O$.

Experimental

The crystal data are as follows:

$[Co(H_2O)_6][SiF_6]$ f.w. = 308.98

Trigonal, $a = 9.358(16)$, $c = 9.712(14)$ Å, $v = 736.6$ Å^3, $\rho_o = 2.09(2)$, $z = 3$, $\rho_c = 2.089$ (20 °C, MoKα, $\lambda = 0.71069$ Å).

The unit cell dimensions and their estimated standard deviations (in parentheses) were obtained from a least squares evaluation of the positions of 12 independent reflections. The space group is $R\bar{3}$ (C_{3i}^2) No. 148 in ref. 5.

The crystals were pink, ditrigonal prisms, elongated in the c direction. They were air sensitive and slowly decomposed on prolonged air exposure.

A small crystal of size $0.6 \times 0.4 \times 0.3$ mm^3 was mounted, sealed inside a thin-walled Lindermann capillary, with the c axis parallel to the ϕ direction of the diffractometer. Intensity data were collected on a Picker, computer-controlled, four-angle diffractometer with β-filtered MoKα radiation and scintillation detector using a $\theta/2\theta$ scan. Two octants hkl and $hk\bar{l}$ were explored to a 2θ maximum of 40°. There were 189 accessible reflections in this region of which 151 were considered observed. The threshold was taken as 20 counts; a scan speed of 1°/min was used with a scan range of 1.5°, corrected for dispersion. The background was taken for 20 s at each end of the range. Data was also corrected against a standard reflection taken at intervals of 20 readings. The linear absorption coefficient for MoKα radiation is 19.6 cm^{-1}. No corrections were made for absorption or extinction.

Structure Analysis

The cobalt and silicon atoms were located from a three dimensional Patterson synthesis and are found to be in special positions 3*a* and 3*b* respectively. A Fourier synthesis established coordinates for the oxygen and fluorine atoms in general positions 18*f*.

Refinement was carried out by block-diagonal least squares, using 3×3 matrices for atomic coordinates and 6×6 matrices for anisotropic thermal parameters for each of the atoms. The quantity minimized was $\sum w(|F_o| - |F_c|)^2$.

TABLE 1. Final parameters (estimated standard deviations) $x, y, z \times 10^4$, $u_{ij} \times 10^3$
t.f. = exp $[-2\pi^2(a^{*2}h^2u_{11} + ... + 2b^*c^*klu_{23} + ...)]$

Atom	x	y	z	u_{11} (or u)	u_{22}	u_{33}	u_{23}	u_{13}	u_{12}
Co^{2+}	0	0	0	52(3)	52(3)	38(2)	0	0	26(2)
Si	0	0	5000	46(6)	46(6)	44(4)	0	0	23(3)
$F^{1/3-}$†	4958(5)	7626(4)	664(4)	78(5)	325(10)	63(5)	6(6)	15(4)	−10(6)
O	5196(5)	6790(6)	5418(4)	71(5)	124(6)	63(5)	−13(4)	6(4)	44(5)
H(1)	5021	6470	4473	35					
H(2)	6408	7644	5527	35					

†To attain charge neutrality the fluorine atom was assigned a charge of $1/3^-$ and the values for its scattering factor curve were obtained from interpolating those for F^0 and F^-.

Successive cycles gave an agreement residual, $R = \sum(||F_o| - |F_c||)/\sum|F_o|$, of 0.049 for the observed reflections for all atoms except the hydrogens. The weighting scheme used was $w = 1/\{1 + [(|F_o| - P_2)/P_1]^4\}$ with $P_1 = 35$ and $P_2 = 45$.

Scattering factor curves used were those given in ref. 6. The Co^{2+} and Si were corrected for anomalous dispersion.

A difference synthesis showed, in the vicinity of the oxygen positions, peaks of height around 0.5 e $Å^{-3}$. They grouped into two sets of general positions, 18*f*. These were taken to be the hydrogens. No other peaks with height greater than 0.3 e $Å^{-3}$ were present. The hydrogen coordinates were included in the least squares calculation and assigned an isotropic temperature parameter equal to that of the oxygen. The parameters for the hydrogens were not refined. The final agreement residual for all atoms was $R = 0.043$.

A table of structure factors for the final parameters as listed in Table 1 has been placed in the Depository of Unpublished Data.[1]

Discussion

The decrease in the residual R obtained by inclusion of the hydrogen atoms is significant by Hamilton's test (7) at the 0.025 (2.5%) level. These hydrogen positions are consistent with presence of hydrogen bonding in the structure.

The structure consists of discrete $Co(H_2O)_6^{2+}$ and $(SiF_6)^{2-}$ octahedra which are systematically joined by O—H---F hydrogen bonds into chains parallel to the $\bar{3}$ axis. The O—H---F distances 2.785(6) Å within, and 2.711(8) Å between chains are reasonable for such bonds (8). The discrete $Co(H_2O)_6^{2+}$ and $(SiF_6)^{2-}$ ions are rotated by 27.4(3)° with respect to each other about the $\bar{3}$ axis. Both are distorted such that the O—O(1) and F—F(1) distances are shorter than those of the O—O(2) and F—F(2). Similar distortion is found in the $Fe(H_2O)_6^{2+}$ ion of $[Fe(H_2O)_6][SiF_6]$. The bond distances and angles are listed in Tables 2 and 3.

Figure 1 gives a projection of the structure along the *b* axis. Hydrogen atoms are included to illustrate the bonding. Each of the fluorine atoms is involved in two hydrogen bonds.

Table 2 also compares $[Co(H_2O)_6][SiF_6]$ with the related $[Fe(H_2O)_6][SiF_6]$ structure. The bond lengths and bond angles for the two structures are close except for a longer O—F(2) distance of 2.785(6) Å and a correspondingly shorter Si—F

Double Layer Structure at the Mercury/Acetonitrile Interface

W. R. FAWCETT[1] AND R. O. LOUTFY
Department of Chemistry, University of Guelph, Guelph, Ontario
Received July 21, 1972

The results of a study of double layer capacity at the mercury/acetonitrile interface in the presence of alkali metal and tetraalkylammonium perchlorates are presented. It is shown that the Li^+, Na^+, tetraethylammonium, and perchlorate ions are not significantly adsorbed over most of the polarizable range of the electrode, whereas the K^+ and Cs^+ ions are adsorbed at more cathodic potentials. Inner layer capacity data are presented and discussed in terms of the specific effects of ions on interfacial structure.

Nous présentons les résultats d'une étude de capacité de double couche, à l'interface d'un système mercure acétonitrile, en présence d'un alcalin et de perchlorates de tétraalkylammonium. Nous démontrons que les ions Li^+, Na^+, tétraéthylammonium, et perchlorate ne sont pas adsorbés de façon significative sur tout le domaine de polarisation de l'électrode, alors que K^+ et Cs^+ sont adsorbés à la plupart des potentiels cathodiques. Nous présentons les résultats de capacité de la couche interne et en discutons en termes d'effets spécifiques des ions sur la structure de l'interface.

Introduction

Acetonitrile (AN) is widely used as an aprotic solvent in studies of organic electrode reactions involving free radical intermediates (1, 2). In this regard, tetraalkylammonium (TAA) salts are commonly employed as background electrolytes because they dissolve easily in AN and permit the working electrode to be polarized to far cathodic potentials (3). Alkali metal salts, on the other hand, are either sparingly soluble (K^+, Rb^+, and Cs^+) (4), or they cause complications in the electrode process resulting from ion-pair formation (Li^+ and Na^+) (5). TAA cations are strongly adsorbed on mercury from aqueous solution but there is some experimental evidence that they are not significantly adsorbed from several non-aqueous solvents (6, 7).

Very few studies of the properties of the mercury/AN interface have been reported. Minc *et al.* (8) and Payne (9) measured the differential capacity of the interface in solutions of LiBr, CsI, and KPF_6. In contrast to other non-aqueous systems (6), no capacity hump was observed. Champion (10) obtained interfacial capacity data in $NaClO_4$ solutions of varying concentration, and concluded that neither the Na^+ cation nor the ClO_4^- anion was adsorbed over the available potential range. More recently, Crumm (11) examined the qualitative effects of a series of electrolytes on capacity-potential curves in AN, but the experimental technique employed was not sufficiently sensitive to permit the data to be analyzed quantitatively.

A knowledge of double layer structure at the electrode/solution interface is essential in interpreting the kinetics of electrode reactions and would be particularly useful in studies of the kinetics of the simple process of radical anion formation by one electron transfer to the parent molecule. In the present paper an investigation of the mercury/solution interface with the alkali metal and TAA perchlorates in AN is reported. In addition, the data necessary for correcting for double layer effects in electrode kinetics are presented and discussed.

Experimental

The differential capacity of the mercury/solution interface was determined by measuring the in- and out-of-phase components of the interfacial admittance using a phase sensitive detector as outlined previously (12). The cell, dropping mercury electrode, and Pt counter electrode have also been described. The dropping electrode performed satisfactorily for long periods without siliconization. The reference electrode (//0.05 *M* tetraethylammonium perchlorate in AN/AgCl/Ag) was connected to the working solution through a fine fritted glass disc of small diameter; the change in liquid junction potential with electrolyte concentration was determined by observing the change in half-wave potential of a reversible reduction reaction with change in electrolyte concentration. It should be noted that the electrolyte solution in the reference electrode contains some dissolved AgCl mainly as Ag^+ and $AgCl_2^-$ ions (13). Although the concentration of the potential determining ion is small (13),

[1]To whom correspondence should be addressed.

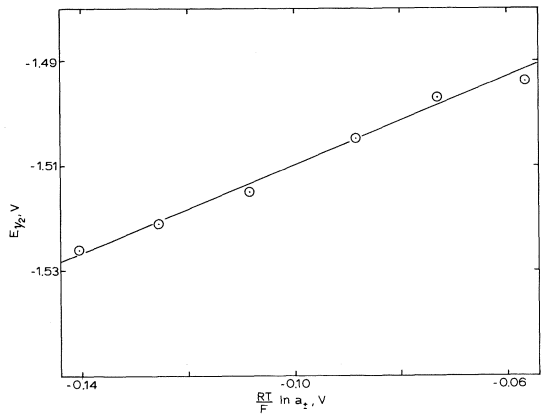

FIG. 1. Plot of the halfwave potential for the electroreduction of benzofurazan at Hg *vs.* $RT \ln a_\pm/F$ where $a_\pm$ is the mean activity of tetraethylammonium perchlorate in acetonitrile. The reduction reaction was reversible and not complicated by either adsorption on the electrode or ion-pairing of the resultant anion radical (13).

half-wave potentials measured with respect to different electrodes over a period of a year were reproduced to ± 1 mV indicating that the reference electrode is both stable and reproducible. TAA perchlorates (tetramethylammonium (TMAP), tetraethylammonium (TEAP), and tetra-*n*-butylammonium perchlorate (TBAP) were purified by multiple recrystallization from water and dried at 60 °C. The absence of water of crystallization was ascertained by examining the polarization characteristics of a Pt electrode in a solution of the salt in AN (14). Purification procedures for the alkali metal perchlorates, AN, and Hg have been described previously (14, 15). The experiments were carried out in a dry box under a nitrogen atmosphere which was purified by circulation over a copper catalyst at 150 °C to remove oxygen (BASF R3-11), and over P_2O_5 to remove water (Aquasorb, Mallinckrodt). The working solutions were degassed with purified nitrogen pre-saturated with AN vapor prior to the experiments. Other details of the experimental procedure have been given previously (12).

Method of Data Analysis

The capacity-potential data were integrated numerically from the point of zero charge (p.z.c.) using Stirling's rule to obtain charge–potential data. The integration was carried out so that data were tabulated for equal increments in charge, the corresponding potentials being calculated by the Newton–Raphson method.

Since activity coefficient data for perchlorate salts were not available, they were estimated from extended Debye–Hückel theory using the relationship

$$[1] \qquad \log \gamma_\pm = -1.594\, c^{1/2}/(1 + 0.481 a c^{1/2})$$

where $\gamma_\pm$ is the molar mean activity coefficient, c, the molar concentration of the given 1–1 electrolyte, and a, the ion size parameter set equal to the Bjerrum distance for ion pair formation in AN (7.64 Å) (16, 17). The above relationship ignores any difference in the rational and molar activity coefficient scales. It is easily shown that errors in $\gamma_\pm$ will not be important in calculated values of $\ln a_\pm/f$ where $a_\pm$ is the mean electrolyte activity, and $f = F/RT$; in fact, an error as high as 20% in $\gamma_\pm$ will result in a 1% error in $\ln a_\pm/f$.

The potential scale was converted to one of thermodynamic significance by evaluating the difference in the potentials of the Hg electrode in a cell with a reference electrode reversible to the anion of the electrolyte and no liquid junction,

$$[2] \qquad \text{Hg}/x\text{M MX/AgX/Ag} \qquad E_-$$

and the cell used in the experiments.

$$[3] \qquad \text{Hg}/x\text{M MX//0.05 } M \text{ TEAP/AgCl/Ag} \qquad E_x$$

The change in the liquid junction potential with electrolyte concentration in the latter cell was determined by observing the corresponding change in half-wave potential for electroreduction of benzofurazan (Fig. 1) (14). The slope of the plot of $E_{1/2}$ *vs.* $\ln a_\pm/f$ was 0.41; thus the relationship between E_- and E_x is (18)

$$[4] \qquad E_- = E_x + 0.59 n a_\pm/f + \text{constant}$$

Results and Discussion

Capacity–potential data for TEAP solutions in the concentration range 0.005 to 0.2 M are shown in Fig. 2. It is noted that the shape of the capacity curves is similar to that observed previously (8–11) and that a diffuse layer minimum is apparent on the curves for the more dilute solutions suggesting that specific adsorption is absent in that potential region. The two tests were carried out to determine whether specific adsorption is significant over any portion of the polarizable range of the Hg electrode. The first, applicable only in the vicinity of the p.z.c., involved plotting the reciprocal of the experimental capacity $1/C$ *vs.* the reciprocal of the diffuse layer capacity $1/C_d$ as estimated by Gouy–Chapman theory for constant electrode charge density q and varying electrolyte concentration (19). According to the Grahame model, the double layer can be represented as a series combination of two capacities, namely, that of the inner layer C_i and that of the diffuse layer C_d. Thus, the slope of the above plots should be unity provided that C_i does not change with electrolyte concentration. The resulting plots for the $LiClO_4$ and TEAP systems are shown in Fig. 3. In the first case the slope of the plots is unity for electrode charge densities in the range -5 to 5 $\mu C\ cm^{-2}$ indicating that ionic specific adsorption is absent. In the case of TEAP solutions, the plots have unit slope for positive electrode charge densities but the slope of the plots increases rapidly with decrease in electrode

charge density at cathodic potentials. This indicates either that TEA cations are adsorbed in the inner layer at cathodic potentials or that the nature of the dielectric in the inner layer changes with change in electrolyte concentration.

The second test involved constructing Esin and Markov plots (20), in this case, plots of E_- *vs.* $2 \ln a_\pm/f$ at constant electrode charge density (Figs. 5, 6). In the absence of specific adsorption the slope of these plots should be zero at higher positive charge densities, one-half at the p.z.c., and one at higher negative charge densities. According to the Gouy–Chapman theory, the limiting slopes at higher charge densities obtain when $q^2 \gg 2RT\varepsilon c/\pi$ where ε is the dielectric constant of pure AN (3.7 at 25 °C). In the present case, this condition is met at the most dilute concentration for $|q| \geqslant 2\ \mu C\ cm^{-2}$ and at the most concentrated, for $|q| \geqslant 11\ \mu C\ cm^{-2}$. From Fig. 4, it is apparent that the $LiClO_4$ and TEAP data follow the predictions of the Gouy–Chapman theory over the entire polarizable range; thus, it is concluded that ionic specific adsorption is not significant in these systems. This conclusion is confirmed qualitatively by the presence of the diffuse layer minimum in the vicinity of the p.z.c. and by the coincidence of the capacity curves at far cathodic potentials.

According to the above analysis, the dielectric properties of the inner layer at cathodic potentials in TEAP solutions depend on electrolyte concentration even though specific adsorption is absent. As the charge on the electrode becomes more negative the concentration of TEA^+ ions at the outer Helmholtz plane (OHP) increases; considering the size of this ion, this process is undoubtedly accompanied by a decrease in the number of solvent molecules in the inner layer, the solvent molecules being replaced by the ethyl groups of the TEA^+ ion. Thus, the dielectric properties of the inner layer depend both on the field in the inner layer and the number of TEA^+ ions at the OHP. The same process does not occur in the case of Li^+ since this small monoatomic ion is strongly solvated by AN molecules. If the above explanation is correct, the inner layer capacity in the TEAP system should depend on electrolyte concentration only at those charge densities where the cation concentration at the OHP is significant and dependent on electrolyte concentration. By the

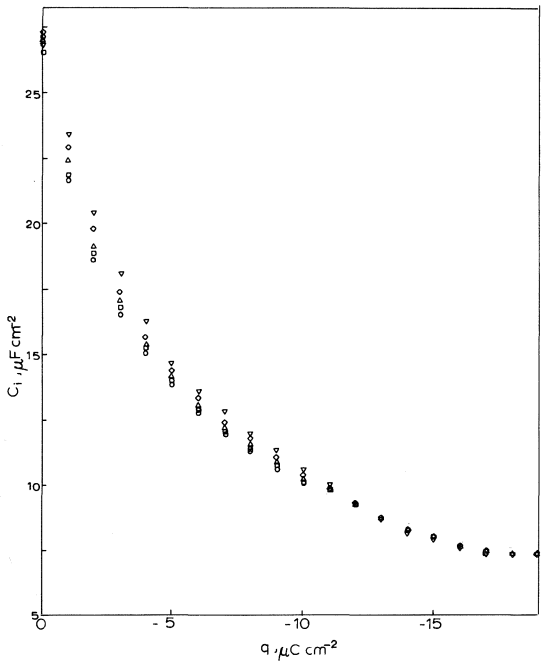

FIG. 5. Differential capacity of the inner layer for tetraethylammonium perchlorate at cathodic potentials *vs.* the electrode charge density. Concentrations of TEAP: (○), 0.005; (□), 0.01; (△), 0.02; (◇), 0.05; and (▽), 0.10 *M*.

Gouy–Chapman theory, the cation concentration at the OHP is given by

$$[5] \quad c_+(\mathrm{OHP}) = c\left(\frac{|q|}{2A} + \left(\frac{q^2}{4A^2} + 1\right)^{1/2}\right)^2 - c$$

where $A = (RT\varepsilon c/8\pi)^{1/2}$. In the limit that $q^2 \gg 4A^2$, this concentration is given by

$$[6] \quad c_+(\mathrm{OHP}) = \pi q^2/2RT\varepsilon$$

that is, it is independent of base electrolyte concentration. By the arguments presented above, this condition is met in the present case for $q \leqslant -11$ μC cm^{-2}. Inner layer capacities calculated from the TEAP data at cathodic potentials are presented in Fig. 5. It is apparent that C_i depends on electrolyte concentration in the range $0 \geqslant q \geqslant -11$ μC cm^{-2}, confirming the above explanation.

The effect of the nature of the alkali metal cation on capacity–potential curves in AN is shown in Fig. 6. At far cathodic potentials the capacity increases with increase in cation atomic number. The same ordering has been observed in water (21), methanol (22), and ethylene carbonate (23) whereas the opposite ordering has been found in formamide (24, 25), *N*-methylformamide (12, 26), *N*-methylacetamide (27), and dimethylsulfoxide (28). In the present case, the ordering can be attributed to a decrease in solvated ion size, which results in an increase in inner layer capacity, with increase in cation atomic number. This trend in solvated ion size has been confirmed for the alkali metal cations from measurements of Stoke's law radii in several solvents including AN (29). In the case of the amides and dimethyl sulfoxide, the observed ordering has been ascribed to a dependence of both the dielectric properties and the thickness of the inner layer on the nature of the cation at the OHP (12). Crumm (11) has attributed the cation effect at more cathodic potentials to cation specific adsorption, the extent of which increases in the order $Li^+ < Na^+ < K^+ < Cs^+$. As stated above no significant specific adsorption of Li^+ could be detected at cathodic potentials. On applying the same tests to data for Na^+, K^+, and $CsClO_4$ solutions, it was shown that specific adsorption of Na^+ was not significant over the whole cathodic range, and that of K^+ and Cs^+, for electrode charge densities greater than -12 μC cm^{-2}. Unfortunately the specific adsorption of K^+ and Cs^+ could not be investigated quantitatively due to the limited solubility of their salts in AN (<0.02 *M*). From the shape of the capacity curves obtained at 0.01 *M* it is apparent that Cs^+ is more strongly adsorbed than K^+. Average inner layer capacities calculated for at least three different electrolyte concentrations are reported in Table 1 for the range of cathodic

charge densities over which cation specific adsorption is not significant. It is apparent from these data that the cation effect cannot be attributed entirely to cation specific adsorption as proposed by Crumm (11). Values of C_i for 0.1 *M* TEAP in AN are included in Table 1 for comparison.

The effect of ionic size on double layer properties was also investigated by obtaining capacity data for three TAA perchlorates in AN (Fig. 7). At far cathodic potentials the capacity decreases in the order $C(TMA^+) > C(TEA^+) > C(TBA^+)$, that is, with increase in ionic size. At very far cathodic potentials the capacity in the TBAP system increases, almost reaching that in the TEAP system, suggesting that the TBA^+ cation is adsorbed in this potential region. In the vicinity of the p.z.c., the ordering of capacities is reversed indicating that the effect of the cation on the dielectric properties of the inner layer is more important in determining inner layer properties at low electrode charge densities. As the size of the cation increases, more solvent molecules are replaced in the inner layer and the dielectric constant of this region increases. Apparently when the inner layer is mainly filled with alkyl groups at more cathodic potentials,

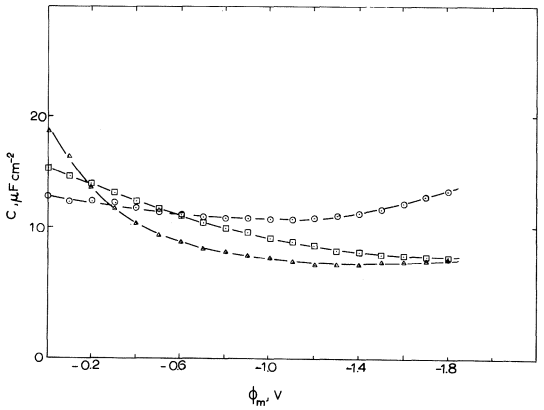

FIG. 7. Differential capacity of the mercury/solution interface versus the rational potential for 0.05 *M* solutions of tetraalkylammonium perchlorates in AN: (○), tetramethylammonium; (□), tetraethylammonium; (△), tetra-*n*-butylammonium.

the thickness of the inner layer is more important in determining its capacity.

It is interesting to note that no evidence for specific adsorption of perchlorate anion was obtained by the tests employed above. This conclusion was confirmed by calculating the inner layer capacity for the $LiClO_4$ and TEAP systems at anodic potentials assuming no ionic specific adsorption. Calculated values were found to be constant within experimental error for values of $q \leqslant 10\ \mu C\ cm^{-2}$ (Table 2). Perchlorate anion is weakly adsorbed on Hg from aqueous solutions (30), the adsorption being attributed to weak solvation of the anion in water and to its structure breaking properties (31). Coetzee and Campion (32) showed that perchlorate anion behaves unusually in AN, specifically, that it is more strongly solvated in this solvent than in water. This is indeed difficult to understand since anions are, in general, poorly solvated in aprotic solvents (33). Nevertheless, the stronger solvation of perchlorate in AN undoubtedly accounts for its not being significantly adsorbed on Hg from this solvent.

As pointed out above, no hump is apparent on the capacity–potential curves in AN for the electrolytes considered. There was some evidence that perchlorate anion was adsorbed on Hg at charge densities anodic of $10\ \mu C\ cm^{-2}$; this conclusion was based on the fact that inner layer capacities calculated assuming adsorption to be absent increased slightly with increase in electrolyte concentration. The onset of adsorption at

TABLE 2. Differential capacity of the inner layer as a function of electrode charge density at anodic potentials for the alkali metal perchlorates and tetraethylammonium perchlorate in acetonitrile at 25 °C

Electrode charge density q, μC cm^{-2}	Differential capacity of the inner layer C_i, μF cm^{-2}

7	34.5	35.3
8	35.0	35.6
9	35.6	35.9
10	35.8	36.2

more anodic potentials would obscure a hump and result in measured capacities being higher than in the absence of adsorption. If the sharp increase in capacity at potentials just anodic of the p.z.c. is attributed to solvent reorientation, then it may be concluded that AN is strongly adsorbed on Hg with the positive end of its dipole towards the metal. In this regard, AN is similar to most other aprotic solvents (6).

Finally, the data recorded in Tables 1 and 2 may be used to calculate values of q and ϕ_2, the potential drop across the diffuse layer, as functions of electrode potential and electrolyte concentration according to the procedure outlined previously (15). A knowledge of ϕ_2 is essential in correcting for double layer effects in electrode kinetics. Since the inner layer capacity varies with electrolyte concentration for the TEAP system in AN, the data presented may only be used to calculate q and ϕ_2 for an electrolyte concentration of 0.1 M; however, this concentration is the one most often used in kinetic studies.

The dissociation of the $J = 21$ state of H_2, and the recombination of atoms into that state, have been examined in detail. The $J = 21$ state of H_2 has two quasi-bound levels, one long-lived and the other short-lived, but the rate constants for dissociation or recombination involving this state are almost completely independent of the tunnelling rates into and out of the quasi-bound levels, and are in fact determined by bottleneck effects occurring lower down the vibrational ladder. Direct integration of the relaxation equations shows that, either excluding or including tunnelling, the dissociation and recombination rate constants obey the rate-quotient law, and that in the latter case the lowest eigenvalue of the relaxation matrix properly reflects the pressure dependence of the dissociation rate constant. Less extensive examination of the dissociation properties of other rotational states indicates that these conclusions are general, except that there is no strong bottleneck effect for very high rotational states ($J \geqslant 30$).

It is shown that if full rotational equilibration is assumed, the sum, weighted over all J, of the individual dissociation rate constants leads to an overall dissociation rate constant which is much too high, suggesting strongly that rotational equilibration cannot occur amongst the very high J states.

A factored form of the master equation is then examined in which either only T–V or only T–R processes take place, over the temperature range 1500–5000 °K. It is found that in this approximation the upper rotational states are very strongly depleted, and that the Arrhenius temperature coefficients of the dissociation rate constants are between 92 and 94 kcal mol^{-1}, depending upon the choice of rotational transition probabilities. The calculation suggests that one contributory cause of "low activation energies" in dissociation reactions is strong rotational depopulation of the very high rotational states, and its importance in relation to other possible causes is discussed.

The smallest eigenvalues of the 177th order matrix representing the dissociation of para-H_2 and of the 172nd order matrix representing the dissociation of ortho-H_2 confirm that the factored model gives an acceptable representation of the dissociation rate of H_2 in this temperature range; hence the conclusions of the factored model in respect of strong rotational depopulation are probably valid. Finally, it is shown that the second smallest eigenvalue of the full relaxation matrix changes by a factor of three at 1500 °K or by a factor of ten at 5000 °K when *only* rotational transition probabilities are varied, thus identifying the relaxation which immediately precedes the dissociation reaction in a shock wave as a T–VR rather than a T–V relaxation.

An exploratory series of calculations for deuterium was carried out for the range of temperatures 700–5000 °K, using the latter model which includes full coupling between rotation, vibration, and dissociation, *i.e.*, using matrices of order 348 and 355 for ortho- and para-deuterium, respectively. These calculations predict that there should be a reversal in the isotope effect for both dissociation and recombination of hydrogen and deuterium as follows: (*i*) with helium as third body, deuterium should dissociate faster than hydrogen at high temperatures, but below about 2000 °K, the dissociation of deuterium will become the slower of the two processes; (*ii*) with argon as third body, deuterium should recombine faster than hydrogen at high temperatures, but below about 1000 °K, the recombination of deuterium will become the slower of the two processes; (*iii*) the rate constants for the recombination of hydrogen by hydrogen and for the recombination of deuterium by deuterium will probably cross over near 1000 °K, indicating a need for experiments in this region of temperature.

Nous avons étudié en détail la dissociation de l'état $J = 21$ de H_2 et la recombinaison des atomes dans cet état. L'état $J = 21$ de H_2 possède deux niveaux quasi-liés, un stable et l'autre instable, mais les constantes de vitesse de dissociation ou de recombinaison, impliquant cet état, sont presque complètement indépendantes des vitesses d'effet tunnel dans et à l'extérieur des niveaux quasi-liés; elles sont déterminées, en fait, par les effets de "goulot de bouteille" se produisant au bas de l'échelle vibrationnelle. L'intégration directe des équations de relaxation montre que, si on inclut ou exclut l'effet tunnel, les constantes de vitesse de dissociation et de recombinaison obéissent à la loi du quotient de vitesse, et que dans le dernier cas, la plus petite valeur fondamentale de la matrice de relaxation démontre clairement l'influence de la pression sur la constante de vitesse de dissociation. Un examen moins approfondi des propriétés de dissociation des autres états rotationnels indique la gérénalité de ces conclusions, à l'exception d'un faible effet de "goulot de bouteille" dans les états rotationnels très élevés ($J \geqslant 30$).

Nous démontrons que, étant supposé un équilibre rotationnel complet, la somme, pondérée sur tous les J, des constantes de vitesse de dissociation individuelle, amène à une constante de vitesse de dissociation totale beaucoup trop élevée, laissant supposer fortement que l'équilibre de rotation ne peut se produire dans les états J très élevés. Nous examinons alors l'équation principale sous forme de facteurs, où seuls apparaissent des processus T–V ou T–R, dans un domaine de température de 1500–5000 °K. Nous trouvons au moyen de cette approximation, que les niveaux rotationnels supérieurs sont très fortement affaiblis et que les coefficients de température d'Arrhénius des constantes de vitesse de dissociation se situent entre 92 et 94 kcal mole^{-1}, selon le choix des probabilités de transition rotationnelle. Le calcul suggère qu'une cause contribuant aux "basses énergies d'activation" dans les réactions de dissociation pourrait être une importante dépopulation rotationnelle des états rotationnels de très grande énergie, et nous discutons de son importance par rapport aus autres causes possibles.

Les plus petites valeurs fondamentales de la matrice d'ordre 177 représentant la dissociation de H_2-para et de la matrice d'ordre 172 représentant la dissociation de H_2-ortho confirment que le modèle sous forme de facteurs représente de façon acceptable la vitesse de dissociation de H_2 dans ce domaine de température; à partir de cela, les conclusions tirées du modèle sous forme de facteurs, concernant une forte dépopulation rotationnelle, sont probablement valides. Nous démontrons finalement que la deuxième plus petite valeur fondamentale de la matrice de relaxation globale change par un facteur de trois à 1500 °K, ou par un facteur de dix à 5000 °K, seulement lorsque les probabilités de transition rotationnelle varient, identifiant ainsi la relaxation qui précède immédiatement la réaction de dissociation dans une onde de choc telle que T–VR plutôt qu'une relaxation T–V.

Nous avons entrepris une série de calculs d'exploration pour le deutérium, dans un domaine de température de 700–5000 °K, au moyen du dernier modèle, qui inclut un couplage complet entre la rotation, la vibration et la dissociation, utilisant des matrices d'ordre 348 et 355 pour l'ortho et le para-deutérium respectivement. Ces calculs prédisent un renversement de l'effet isotopique pour la dissociation et la recombinaison de l'hydrogène et du deutérium, comme suit: (*i*) avec l'hélium comme troisième atome en présence, le deutérium doit se dissocier plus vite que l'hydrogène, à température élevée, mais au-dessous de 2000 °K, la dissociation du deutérium devient le plus lent des deux processus; (*ii*) l'argon étant le troisième atome en présence, le deutérium doit se recombiner plus vite que l'hydrogène à température élevée, mais au-dessous de 1000 °K, la recombinaison du deutérium devient le plus lent des deux processus; (*iii*) les constantes de vitesse de recombinaison de l'hydrogène par l'hydrogène et de la recombinaison du deutérium par le deutérium se croisent probablement près de 1000 °K, indiquant le besoin d'expérimenter dans ce domaine de température.

Introduction

It has been recognized since the early days of chemical reaction rate theory that rotational degrees of freedom may make important contributions to the rate of a dissociation reaction (1, 2). However, because of the sheer enormity of the problem of including explicit representation of individual rotational states into reaction rate theory, together with an almost complete lack of knowledge of transition probabilities for rotational energy changes, little real progress has been made in understanding these contributions. Consideration of such effects has usually been deferred because it has been rationalized that (except for very light molecules where tunnelling through the rotational pseudo-potential barrier is possible) a rotational contribution essentially increases the energy that is required to cause dissociation to take place (3–5), or is really in fact only of minor importance (1, 6), or else semi-classical simulations of the rotational pseudo-potential barrier have been invoked (2, 7). In this paper we attempt to give a correct description of the way in which a rotational barrier affects the nature of the dissociation process for a single rotational state of a molecule, and thereafter, how the overall dissociation (or recombination) rate is made up out of contributions from these individual processes.

Dissociation of the $J = 21$ State of H_2

The energy levels of the H_2 molecule have been calculated by Waech and Bernstein (8) and by LeRoy (9) from the theoretical internuclear potential of Kolos and Wolniewicz. The $J=21$ state was chosen as being representative of the general case, having two quasi-bound levels, one of which is, according to the calculations of Roberts (10), very long-lived ($\tau \approx 5 \times 10^{-4}$ s) and the other quite short-lived ($\tau \approx 10^{-13}$ s); the pseudo-potential curve and the disposition of the energy levels for this state are shown in Fig. 1. The heights $\varepsilon_{max}(J)$ of the effective rotational barriers are also available in these papers.

We remind the reader that this paper, as were others in this series (11–13), is concerned only with the properties of what is known as the

For personal use only.

"energy-transfer" mechanism at infinite dilution: it is assumed that we are considering the dissociation of 3.5×10^{16} molecules cm^{-3} of H_2 diluted in 3.5×10^{19} atoms cm^{-3} of helium at constant volume and temperature and that (*i*) the He/H_2 dilution ratio is sufficiently great that H_2–H_2 collisions can be neglected; (*ii*) the He–H intermolecular attraction is so small that reactions cannot take place via HeH complexes; those two assumptions were discussed in detail in Part I of this series (11). Thus, modifying our earlier notation somewhat, the master equation with tunnelling for the $J = 21$ state of H_2 can be written as follows

$$[1]\quad \frac{dn_i}{dt} = \sum_{j=0}^{n-1} Z[M]\{(P_{ij}n_j - P_{ji}n_i) + (\bar{P}_{in}n_n^2 - \bar{P}_{ni}n_i)\} + [\bar{k}_{in}n_n^2 - \bar{k}_{ni}n_i] \qquad i = 0, 1, \ldots, (n-1)$$

$$[2]\quad \frac{dn_n}{dt} = \sum_{j=0}^{n-1} \{Z[M](\bar{P}_{nj}n_j - \bar{P}_{jn}n_n^2) + [\bar{k}_{nj}n_j - \bar{k}_{jn}n_n^2]\}$$

where n_i is the number of molecules per cc in the *i*th vibrational state of $J = 21$, P_{ji} is the probability per collision with M that a transition from state (i,J) to state (j,J) will occur, Z is the collision number, n_n is the number of dissociated molecules ($\equiv \frac{1}{2}[H]$), $\bar{P}_{ni}$ is the probability per collision of a direct dissociation, and $\bar{k}_{ni}$ is the rate constant for predissociation (or tunnelling) from the state (i,J) *if* state (i,J) is a quasi-bound level; $\bar{k}_{ni} = \bar{k}_{in} = 0$ for true bound states and the rate expressions in square brackets drop out. Again, following our earlier procedure, forward and backward rates can be related through the equilibrium population distributions, denoted by $\tilde{n}_i$, etc., *viz.*

$$[3a]\quad P_{ji}\tilde{n}_i = P_{ij}\tilde{n}_j$$

$$[3b]\quad \bar{P}_{ni}\tilde{n}_i = \bar{P}_{in}\tilde{n}_n^2$$

$$[3c]\quad \bar{k}_{ni}\tilde{n}_i = \bar{k}_{in}\tilde{n}_n^2$$

so that it is only necessary to assign the activation probabilities P_{ji} and the *dissociation* probabilities $\bar{P}_{ni}$ and $\bar{k}_{ni}$ on the left-hand sides of [3*a*], [3*b*], and [3*c*]; the deactivation and recombination probabilities follow from detailed balancing. It has been shown recently (14) that, as we have argued qualitatively in the past (3), the T–V transition probabilities for a Morse oscillator are relatively insensitive to the rotational energy of the diatom. Thus it is reasonable to make the very simple assumption that, whatever the rotational quantum number of the state, the probability of a pure increase in vibrational energy can be represented by our recipe III(1) which describes the calculated values for the $J = 0$ state in the form of a function of T, the temperature and Δ_{ij}, the difference in vibrational energy between the two levels.[1] Likewise, following our earlier procedures, the dissociation probabilities $\bar{P}_{ni}$ in [3*b*] are also represented by this formula, except that unlike the $J = 0$ state, the energy separation between the state (i,J) and the free atoms has to be taken as

$$[4]\quad \bar{\Delta}_{ni} = \varepsilon_{max}(J) - \varepsilon_i(J)$$

Finally, the $\bar{k}_{ni}$ of [3*c*] follow directly from the resonance widths Γ_i of the quasi-bound states calculated in the work of the Wisconsin group (8–10) via the relation

$$[5]\quad \bar{k}_{ni} = 2\pi c\Gamma_i$$

where c is the velocity of light and Γ_i is in cm^{-1}.

Using our eigenvalue method, described in Part III of this series (13), it is not necessary to know the $\bar{P}_{in}$ and $\bar{k}_{in}$ of equations [3*b*] and [3*c*], *cf.* equations III(4) and III(5) which define the matrix A_{00} whose smallest eigenvalue d_{n-1} is related to the rate constant. All that is necessary is that the diagonal elements of the relaxation matrix A_{00} be augmented by the extra predissociation term; thus the definition of the elements of A_{00} given in III(5) needs to be changed to

$$[6]\quad [A_{ij}] = (1 - \delta_{ij})Q_{ji} - \delta_{ij} \times \left[\bar{Q}_{ni} + \bar{k}_{ni} + \sum_{k=0}^{n-1}(1 - \delta_{ki})Q_{ki}\right]$$

where $Q_{ij} = [M]ZP_{ij}$; note that $\bar{k}_{ni}$ is a term which is independent of $[M]Z$, and hence the specific overall rate will be dependent on the H_2/He mixture ratio. In order to make a thorough test of the transcription of III(5) into [6], we first of all checked the consistency of the new eigenvalue formulation with the results of the direct integration of eqs. 1 and 2, and for this purpose one needs to know the recombination rate coefficients $\bar{P}_{in}$ and $\bar{k}_{in}$; as will be shown in the next

[1]Equations and tables taken from other papers in this series and used in the present paper are prefixed with the part numbers in Roman numerals.

TABLE 1. Comparison of rate constants obtained by direct integration of [1] and [2], or by solution of [6], for the $J = 21$ state of H_2 at 2000 °K: [M] = 3.5×10^{19} atoms cm^{-3}; $K(J) = 9.24719 \times 10^6$ molecule cm^{-3}

Parameter	Value: Without tunnelling	Value: With tunnelling	Units

$k_d(J)$, eq. [8]	8.77788×10^{-16}	9.04962×10^{-16}	cm^3 molecule^{-1} s^{-1}
$[K(J)]^{-1}[M]^{-1}d_{n-1}(J)$	9.4925×10^{-23}	9.79×10^{-23}	cm^6 molecule^{-2} s^{-1}
$k_r(J)$, eq. [9]	9.4928×10^{-23}	9.84×10^{-23}	cm^6 molecule^{-2} s^{-1}

paragraph, the choice of these recombination coefficients is not unique.

Since we are basically interested in the partial contribution that the $J = 21$ state makes to the total dissociation process, we should consider for the direct integration a number of molecules initially in $v = 0, J = 21$ given by the ratio of the molecular partition functions $pf(J)/pf_{total}$ times the total number of 3.5×10^{16} molecules cm^{-3}. This will ensure that during the dissociation process, the populations of the various vibrational levels of the state J will be of the same order of magnitude as they would be in the complete dissociation, provided that the atoms considered to be in equilibrium with the $J = 21$ state are similarly partitioned. Thus we have the following definitions

$$[7] \qquad K = [H]^2/[H_2]$$
$$[H_2(J)] = pf(J)[H_2]/pf_{total}$$
$$[H(J)] = pf(J)[H]/pf_{total}$$
$$K(J) = [H(J)]^2/[H_2(J)] = pf(J)K/pf_{total}$$

The equilibrium constant K, and thence $K(J)$, can be calculated from the known rotation–vibration energy levels (9) by standard methods (15), and the values of K come out to be very close indeed to those given in the JANAF Tables (16). It should be understood that the partitioning of the H atoms into H(J), *i.e.* that fraction considered to be in equilibrium with $H_2(J)$, is only (at this stage) a computational convenience. If one started with *all* the H_2 molecules in $v = 0, J = 21$ instead of only the small fraction $pf(J)/pf_{total}$ of that number, the integration would have to follow the flow of all these molecules through the $J = 21$ state out into the atoms before the normal equilibrium vibrational distribution of the $J = 21$ state was achieved; this would be a lengthier calculation and for most of the time the populations of the $J = 21$ state would be far in excess of what they would be in the real process. On the other hand, if one started with the correct initial population of $H_2(v = 0, J = 21)$ but did not partition the atoms likewise, the final distribution would contain too few $J = 21$ H_2 molecules. The partitioning is also a convenience in that it enables each complete J-state to be treated in isolation from all others if there is full rotational equilibrium amongst complete J-states. To do this, one has to assume that any transfers into individual vibrational sublevels of the J-state in question from any other J-state are balanced by an equal number of transfers out; such artificial restrictions will be relaxated later in the paper when proper rotational–vibrational disequilibrium is considered.

With these constraints, the ten simultaneous equations [1] and [2] were solved for both dissociation and recombination by standard Runge–Kutta procedures, both with the predissociation rates $\bar{k}_{ni}$ set equal to zero, or having their correct values according to [5], with the surprising result that the very high tunnelling rate of the $v = 8$, $J = 21$ state makes only a few percent difference to the rate constant for dissociation of the $J = 21$ state. The rate constants for dissociation $k_d(J)$ and for recombination $k_r(J)$ are defined from the respective fluxes to be consistent with definition [7] as follows

$$[8] \qquad -R_{H_2(J)} = [M]k_d(J)\{[H_2(J)] - [K(J)]^{-1}[H(J)]^2\}$$

and

$$[9] \qquad R_{H_2(J)} = [M]k_r(J)\{[H(J)]^2 - K(J)[H_2(J)]\}$$

where, as is shown to be correct in Table 1, the rate quotient law

$$[10] \qquad k_d(J)/k_r(J) = K(J)$$

is assumed to hold. Table 1 shows the comparisons between the various rate constants for a

temperature of 2000 °K obtained by direct integration through the application of [8] and [9] after the induction period was over (12, 13), and also the same rate constants calculated from the lowest eigenvalue of the relaxation matrix [6] through equation III(21), *viz.*

$$[11] \qquad k_d(J) = -[M]^{-1} d_{n-1}(J)$$

Thus, direct integration and the eigenvalue of the modified relaxation matrix give the same answers, both with and without the contribution from predissociation. There is a slight discrepancy in the tunnelling case between the recombination rate constant obtained by direct integration and that found using the rate quotient law, *i.e.* [10] and [11]. This is because recombination integrations seem to be inherently less stable than dissociation integrations and this, taken together with the fact that the parasitic eigenvalues with tunnelling are very large indeed ($\sim 10^{13}\ s^{-1}$, *i.e.*, about 100 times bigger than those arising from purely collisional processes which are $\sim 10^{11}\ s^{-1}$ at 1 atm total pressure), makes this particular recombination calculation very time consuming; hence we did not explore step-length variations in enough detail to be able to present a very accurate value in this case, although there seems no reason to doubt that such agreement could be obtained.

The reason why the inclusion of tunnelling makes so little difference to the rate constant is revealed by an examination of typical pairs of population distributions, as is done in Table 2 for both dissociation and recombination. In dissociation, the reaction without tunnelling is very slightly less advanced than the one with tunnelling, and so there is a tendency for the n_i to be slightly higher and for n_n to be slightly less: this can be seen either by comparing the n_i directly, or the ξ_i. The only real difference between the two distributions is that the very high predissociation rate ($\bar{k}_{ni} = 9.1 \times 10^{12}\ s^{-1}$) of the $v = 8$, $J = 21$ state causes its population to be reduced by a factor of about three. To put it crudely, referring to Fig. 1, all that has happened by giving the $v = 8$ state this large tunnelling rate is that the top of the rotational pseudo-potential barrier has been cut off, and now the molecule only needs an energy $[\varepsilon_8(J) - \varepsilon_0(J)]$ to dissociate rather than $[\varepsilon_{max}(J) - \varepsilon_0(J)]$. Thus, the rate will be increased by roughly exp $[\varepsilon_{max}(J) - \varepsilon_8(J)]/kT$, which is virtually the ratio of the two values of $k_d(J)$ observed in Table 1, leaving the rate constant for

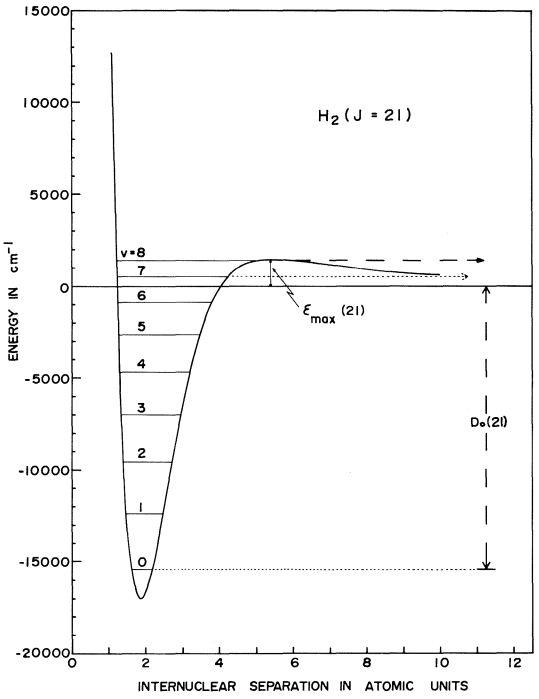

FIG. 1. Energy-level diagram for the $J = 21$ state of H_2.

dissociation (and therefore recombination) to be determined by cooperative bottleneck phenomena (17) lower down the vibrational ladder. The tunnelling rates into and out of $v = 8$ (4.005×10^{16} and 4.058×10^{16} molecules s^{-1}, respectively, at this time) are enormous when compared with individual collision transfer rates which for $v = 8$ do not exceed 4.7×10^{14} molecules s^{-1}. However, the net tunnelling rate for $v = 8$, *i.e.* the difference of the two rates, is only 5.34×10^{14} molecules s^{-1}, almost exactly the value for the rate of formation of $v = 8$ by the sum of all collision processes. Thus, these fluxes demonstrate clearly that, as is postulated by Roberts, Bernstein, and Curtiss (18), the wide quasi-bound resonances can be considered to be in very close equilibrium with the atoms, which is the same thing as saying that the top of the potential barrier is removed. As far as predissociation is concerned, the penultimate quasi-bound level is relatively unimportant: total collision rates into and out of this state exceed 10^{15} molecules s^{-1}, but with a net change of the order of 10^{10} molecules s^{-1}, of which about 1% is due to tunnelling.

In recombination, likewise, tunnelling has a negligible effect. With tunnelling, the reaction is

For personal use only.

slightly more advanced, which means that the n_i or ξ_i for very low i will be slightly larger, and for high i will be slightly lower than the without-tunnelling case, which is true except for the wide quasi-bound level; this is slightly better coupled to the atom population than it would be if there were no preassociation, so its population is very slightly enhanced. Because it is important to understand the contribution which the quasi-bound resonance makes to the recombination process, we will try to analyze the population fluxes in the region of that level; tunnelling into the lower of the two quasi-bound levels can again be ignored. First, with the population distributions listed in Table 2, the predissociation rate is 3.9403×10^{19} and the preassociation rate 3.9418×10^{19}, with a net preassociation rate of 1.5×10^{16} molecules s^{-1}. Collisional dissociation from all states (principally from $v = 6$, 7, and 8) amounts to 2.63×10^{17} molecules s^{-1}, and three-body recombination into those states is 2.76×10^{17} molecules s^{-1}, with a net rate of collisional recombination of 1.3×10^{16} molecules s^{-1}. Hence, the total rate of recombination is 2.8×10^{16} molecules s^{-1}, which is consistent with the net flux calculated by [9] using the value of $k_r(J)$ from Table 1 and the concentrations from Table 2. The fates of those molecules passing through the quasi-bound level are as follows. The total collisional deactivation rate of $v = 8$ into $v = 7$, 6, 5, and below is 7.2×10^{16} molecules s^{-1}, and the total repopulation of $v = 8$ from below is 5.7×10^{16} molecules s^{-1}, corresponding to a net deactivation rate for the quasi-bound state of 1.5×10^{16} molecules s^{-1}. Collisional dissociation of $v = 8$ and three-body recombination into $v = 8$ balance almost exactly at about 2.1×10^{17} molecules s^{-1}, with a net recombination flux into $v = 8$ of a little under 10^{14} molecules s^{-1}; that this quantity is so small is a result of the enhanced degree of equilibration between the atoms and $v = 8$, resulting from the very high tunnelling rates for that level. Hence, the overall picture of the recombination flux is that it is made up approximately equally out of preassociation into $v = 8$ and out of three-body recombination into $v = 7$ and $v = 6$: that of the total of 4.15×10^{19} pairs of atoms per second which recombine by both mechanisms into $v = 8$, only 7.2×10^{16} per second are deactivated and of those, 5.7×10^{16} come back up to $v = 8$; and that this difference between depopulation and repopulation rates for $v = 8$ is almost exactly balanced by the net flux into $v = 8$ from atoms.

The Pressure Dependence of the Rate Constant $k_d(J)$

According to [1], the rate of dissociation of H_2 ($J = 21$) is made up from two kinds of contribution, those which are second order in [M] and n_i, and those which are first order in n_i only. At low pressures, the predissociating states will be very depleted if the tunnelling rate is high. However, as [M] increases, the collisional activation will tend to maintain n_i nearer its non-tunnelling pseudo-steady value, and as [M] $\rightarrow \infty$, the rate constant for dissociation will become truly second order. This is analogous to the fall-off of unimolecular rate constants from their high pressure limits, but is *not* the same effect that has been seen in the dissociation of I_2 at high pressure (19). A series of calculations in which $[H_2(J)]$ was held constant but [M] was varied from 3.5×10^7 to 3.5×10^{30} atoms cm^{-3} showed that for [M] > $[H_2]$, one would find a pseudo-bimolecular rate constant of the form

$$[12] \quad \text{“}k_d(J = 21)\text{”} = -[M]^{-1} d_{n-1}(J = 21) = k_d^0(J = 21) + [M]^{-1} k_t(J = 21)$$

where $k_d^0(J = 21) = 8.77788 \times 10^{-16}$ cm^3 molecule^{-1} s^{-1} (the without-tunnelling rate constant in Table 1) and an effective tunnelling rate constant $k_t(J = 21) = 951$ s^{-1}, the second term becoming negligible for [M] greater than about 10^{25} particles cm^{-3}. Equation 12 does not hold for low [M] because the collision rate cannot sustain the pseudo-steady state required for the first order decay process to be independent of pressure. Every state from $J = 4$ to $J = 38$ exhibits this kind of behavior, each with its own individual values of $k_d^0(J)$ and $k_t(J)$, but we believe that at the present time, this kind of pressure dependence is of secondary importance to the understanding of diatomic dissociation processes, and have not examined the matter further for the time being.

A “Δv or ΔJ” Factored Model

In describing the dissociation of a diatomic gas in a shock wave, it is usual to assume that, except at very high temperatures, rotational and vibrational equilibration precede dissociation. We have shown (12) that the assumption of vibrational equilibration is a reasonable one, except in respect

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of some of the topmost vibrational states; (even in such a rapid dissociation as we see for the $J = 21$ state above, the lowest three states are very closely in equilibrium with each other, and the lowest six states may be considered as being reasonably equilibrated, with $1.01 \geqslant \xi_i \geqslant 0.8$). That the molecules will be rotationally equilibrated seems even more obvious, since rotational relaxation times are considerably shorter than vibrational ones. Hence, by solving each of the 39 vibration–dissociation master equations to find the 39 values of $d_{n-1}(J)$, given full rotational equilibration, it follows (20) from [7], [8], and [9] that

$$[13] \quad -R_{H_2(J)} = -\frac{d_{n-1}(J)pf(J)}{pf_{total}} \times \{[H_2] - K^{-1}[H]^2\}$$

whence the total rate of dissociation of H_2 would be

$$[14] \quad -\sum_J R_{H_2(J)} = -\sum_J \frac{d_{n-1}(J)pf(J)}{pf_{total}} \times \{[H_2] - K^{-1}[H]^2\}$$

which identifies the overall rate constant for dissociation with rotational equilibration as

$$[15] \quad \tilde{k}_{d,M} = -[M]^{-1} \sum_J \frac{d_{n-1}(J)pf(J)}{pf_{total}}$$

Table 3 lists the calculated values of $d_{n-1}(J)$ for all J, both with and without tunnelling, showing the individual contributions to [15], assuming a constant value of Z for all states, v and J. The following properties of these numbers are worth noting. First, the $d_{n-1}(J)$ increase monotonically with J, principally due to the change in the Boltzmann factor $\exp[-D_0(J)/kT]$. Second, when $J \geqslant 4$, the numerical magnitude of $d_{n-1}(J)$ is always greater with tunnelling than without, although sometimes the difference is insignificant as some of the lifetimes of quasi-bound levels with respect to predissociation are extremely long (18, 21); the first really significant difference occurs at $J = 30$. Third, if rotational equilibration is assumed, and if there were no tunnelling, there would be a significant contribution to the dissociation from all rotational states, with $J = 0$ and $J = 38$ being among the weakest contributors, the former because of its unfavorable statistical weight ($2J + 1 = 1$), and the latter because, despite its high statistical weight ($2J + 1 = 77$), the energy requirement is too high (the contributions from odd states of high J are about three times as large as for even J as expected). When tunnelling is included, however, there is a marginal increase in the sum up as far as $J = 36$, but the contributions from $J = 37$ and $J = 38$ become equal to all the rest put together, approximately doubling the total rate. The predicted rate constants are respectively about 1.7×10^{-20} and 3.5×10^{-20} cm^3 molecule^{-1} s^{-1}; the simple collision theory rate constant, assuming full contribution of rotational energy to the decomposition path would be 2.1×10^{-20} cm^3 molecule^{-1} s^{-1}. The one result is lower as a cumulative result of all the small departures from vibrational equilibrium, such as we have tabulated previously (12, 13) or shown in Table 2; the other is higher principally because the four topmost states $J = 35$, 36, 37, and 38 have only one level, and to assume that these levels are equilibrated automatically makes a large (first order) predissociation contribution to the total rate.

These results, especially the one including tunnelling, are unsatisfactory when it is remembered that they are based on a constant collision number Z which was chosen to be that of He atom and a ground-state H_2 molecule: if we had allowed for the fact that the excited states have very much larger effective cross-sections (18), then very significantly higher rate constants would have resulted. In comparison, experimental values of the rate constants are usually close to or a little less than the collision theory rate with a gas-kinetic value of Z: we have just shown that the cumulative effect of vibrational underpopulation (in the no-tunnelling case) is a depression of approximately 20% in the rate below the collision-theory value, and therefore one has to conclude that either the assumed vibrational transition probabilities are all much too large, or else one cannot assume rotational equilibration. Since there is at least some theoretical basis for the T–V transition probabilities that have been assumed (3, 13), it is obviously necessary to examine the assumption of rotational equilibration.

To do this, we now depart from our long-held philosophy (5) that our calculations have regarded H_2 simply as a model for a diatomic molecule, and we will now make use of the special feature of H_2 that the odd and the even J states do not mix, in order to reduce the magnitude of the computation. Even so, to extend our normal-mode approach to the calculation of the T–VR dissociation relaxation of either ortho- or para-H_2, and to

calculate the population distribution would have required more fast core computer storage and more computer time than was available to us; we therefore investigated a rough factorized model in which we considered rotational relaxation amongst either the odd- or the even-J states, each J state having an effective T–V dissociation rate constant determined from the eigenvalue $d_{n-1}(J)$ given in Table 3. As will be shown later in this paper, we were able to find eigenvalues (but not eigenvectors) for the full T–VR dissociation calculation, in good agreement with the results of this factored model, so that the conclusions of this calculation in respect of population distributions should be reasonably reliable.

The first problem is to assign a reasonable set of T–R transition probabilities. Recent years have seen enormous activity in the theoretical calculation of translation–rotation transition probabilities, which it would be far beyond the scope of this paper for us to review: it suffices to say that the state of knowledge is still far from complete, and it is as yet impossible to write down transition probabilities for H_2/He collisions for any value of

ΔJ at any arbitrary temperature T. Based on two intuitive considerations: (*i*) that transition probabilities for the transfer of an amount of energy Δ_{ij} from translation to rotation will be subject to the same kinds of factors as those which determine how translation to vibration transition probabilities change with Δ_{ij} and with T; (*ii*) that there may be an extra penalty if ΔJ is not small; we chose the following empirical general form for endothermic T–VR transition probabilities

$$[16] \qquad P_{ij} = f(T,\Delta_{ij})e^{-\Delta_{ij}/kT}e^{-2.5|\Delta J|}$$

when $f(T,\Delta_{ij})$ is defined by equation III(1) and the corresponding deactivation probabilities follow from the detailed balancing equations [3*a*] and [3*b*] (remembering that if $\Delta J \neq 0$, statistical weight terms $(2J + 1)$ are involved). Equation 16 has the following properties. If $\Delta J = 2$, it gives a deactivation probability for $H_2(J = 2 \rightarrow J = 0)$ of about one in 250 collisions at room temperature, and the deactivation probabilities decrease slowly with increasing Δ_{ij} and with decreasing T: to this extent they crudely follow existing experimental observations (22–24). The exponent in $|\Delta J|$ represents an arbitrary penalty in ΔJ, the effect of which will be demonstrated later. The advantage of [16] is that if $\Delta v = 0$ its behavior is not unlike a realistic set of T–R transition probabilities (25), and if $\Delta J = 0$ it reduces to the T–V transition probabilities that we have used throughout this series: hence, it would appear to be a suitable vehicle for the subsequent comparison, later in this paper, of the present factored method with a full T–VR–dissociation relaxation; furthermore, for D_2, it yields a deactivation probability for $J = 2 \rightarrow J = 0$ of about 1 in 210 collisions at $T = 300$ °K, again closely mimicking existing experimental data (22).

The factored "Δv or ΔJ" calculation begins with all molecules in the $J = 0$ state, and at the temperature in question the relaxation towards equilibrium is governed by the T–R transition probabilities [16] and effective mean dissociation rate constants $k_d(J) = -[M]^{-1}d_{n-1}(J)$ determined from Table 3. Thus, the *effective* rotational master equation to be solved is (for even J)

$$[17] \quad \frac{dn_r}{dt} = \sum_{s=0,2,4\ldots}^{38} Z[M](P_{rs}n_s - P_{sr}n_r) + [M](k_r(r)n_n^2 - k_d(r)n_r) \qquad r = 0, 2, 4, \ldots, 38$$

$$[18] \quad \frac{dn_n}{dt} = \sum_{r=0,2,4\ldots}^{38} [M](k_d(r)n_r - k_r(r)n_n^2)$$

where n_r is the population of the rotational state r in molecules cm^{-3} and n_n is the number of dissociated molecules per cc, as usual. The combination rate constants $k_r(J)$ occurring in these two equations now refer, not to a subset of the free atoms partitioned by $pf(J)/pf_{total}$, but to a subset of the free atoms partitioned by $pf(\text{even})/pf_{total}$. As mentioned earlier, this partitioning facilitates the generation of representative population distributions, but is not necessary for the calculation of the rate constant by the eigenvalue method. Implicit in writing [17] and [18] are the following assumptions. One, that in using [16] to calculate P_{rs} between two states $J = s$ and $J = r$, the energy gap Δ_{rs} has to be a mean or effective value: we originally chose the mean vibrational energy of the particular rotational state as the reference point with respect to which to define Δ_{rs}; however, it is simpler and has little effect on the rate of dissociation (compare Tables 5 and 6 below) if other reference points *e.g.* $v = 0$, $J = s$ and $v = 0$, $J = r$ are used. Two, that the calculated overall rate of dissociation will be that corresponding to a product population distribution function, *i.e.* a product of the individual vibrational distributions for each J, such as those shown in Table 2, with the rotational distribution n_r, etc., resulting from the solution of [17] and [18]. Thus, each individual population $n(v,J)$ is not free to vary as it should in the real calculation, and the same kind of inflexibilities will arise as occur when product wave functions are used instead of fully variational ones to describe, for example, the helium atom (26).

Table 4 shows how the presence of tunnelling changes the populations of the rotational states in ortho-H_2, both in dissociation and in recombination, according to this approximate model. In the dissociation, the levels $J = 1$ to 19 come essentially into equilibrium with each other, but there is a very well defined bottleneck effect at about $J = 27$ or 29 with the very high rotational states being very markedly underpopulated; inclusion of tunnelling in these calculations has very little effect either upon the populations or the rate constant. In recombination, again there is a very marked bottleneck effect with states from $J = 27$ and above being in very close equilibrium indeed with each other and with the atoms: the lower J states are very much underpopulated at this early

TABLE 4. Comparison of rotational population distributions $\xi_r = n_r/\tilde{n}_r$ for ortho-H_2 at 2000 °K, for dissociation at $t = 7.5 \times 10^{-6}$ s and recombination at $t = 10^{-6}$ s: total number of H_2 molecules = 3.5×10^{16} cm^{-3}, *i.e.*, total number used in the ortho-H_2 partition = 8.75×10^{15} molecules cm^{-3}*

*Rate constants determined from the fluxes: without tunnelling, $k_d = 1.59697 \times 10^{-20}$ cm^3 molecule^{-1} s^{-1}, $k_r = 6.64900 \times 10^{-33}$ cm^6 molecule^{-2} s^{-1}, $k_d/k_r = 2.40183 \times 10^{12}$ molecule cm^{-3}; with tunnelling, $k_d = 1.61484 \times 10^{-20}$ cm^3 molecule^{-1} s^{-1}, $k_r = 6.72343 \times 10^{-33}$ cm^6 molecule^{-2} s^{-1}, $k_d/k_r = 2.40181 \times 10^{12}$ molecule cm^{-3}; effective equilibrium constant $K(J = \text{odd}) = 2.40188 \times 10^{12}$ molecule cm^{-3}.

time in the reaction, but as expected, they are more-or-less in equilibrium amongst themselves also. Again, the effect of tunnelling is minimal; it facilitates the equilibration between the atoms and the upper J states somewhat, and causes a marginal increase in the rate. Note also that the rate constants quoted at the foot of Table 4, which are calculated from the transition fluxes by the analogs of equations [8] and [9], obey the rate quotient law quite accurately and are the same as those determined by the eigenvalue method to the number of decimal places quoted. Likewise, for para-H_2, with even J states, the bottleneck is in about the same place, near $J = 26$ or 28. Furthermore, the rotational bottleneck effect appears to be much more well-defined than the vibrational bottleneck which we have described on previous occasions (12, 13, 17, 27). For example, at 5000 °K, it is not immediately apparent from the vibrational population distributions (*e.g.* Table III(3)) that a bottleneck is present, and its existence was established by indirect evidence, such as is presented in Tables III(5) and V(1); however, in the rotational calculation at 5000 °K, the changeover from over- to under-population remains just as marked as is shown in Table 4, and at about the same J levels, both in dissociation and in recombination. It is not transparently obvious that the bottleneck should be so persistent and its position so stable, but clearly it is the result of progressively increasing rotational spacings, in contrast to progressively decreasing vibrational spacings.

Table 2 gives what may be roughly regarded in this approximation as a steady-state vibrational distribution during the dissociation process, and in principle, although we haven't reproduced the figures, such a distribution can be generated for every other J state (for $J = 0$, see Tables II(3) or III(3)). Thus, in the product approximation, a reasonable picture of the overall rotation–vibration distribution will be obtained by scaling each pseudo-steady vibrational distribution with the ξ_r of Table 4. This means that in dissociation, for example, low J and low v levels will all be in equilibrium with each other, high J and low v or low J and high v will be depleted to varying degrees, and high J and high v will be more

severely depleted: the depletion however is a much more severe function of J than of v.

Table 5 compares for para-H_2 (even J) and for ortho-H_2 (odd J) the rate constants for dissociation from 1500 to 5000 °K, calculated according to [16], [17], and [18], both with and without tunnelling. It is obvious immediately that the inclusion of tunnelling from the predissociating levels makes only a negligible difference in this temperature range, this being particularly the case at high temperatures. Referring again to Table 3, this means that states above $J = 30$ must be severely depopulated at all temperatures, and therefore, make very much less contribution to the total rate than they would if there was rotational equilibration; this conclusion is borne out by all the population distributions we have calculated, *i.e.* those presented in Table 4 for ortho-H_2 at 2000 °K, and the ones cited for 5000 °K. The data in Table 3 show that with full equilibration, we could expect at 2000 °K a dissociation rate constant without tunnelling of about 1.7×10^{-20} cm^3 molecule^{-1} s^{-1} and with tunnelling, almost exactly twice that figure. The value found in Table 5 is somewhat less than the 1.7×10^{-20} figure, either for ortho- or para-H_2 with or without tunnelling; this could only be the case because in the relaxing system, the very high specific decomposition rates associated with the high J levels essentially kill their contribution since they have to be populated by rather large rotational energy jumps. Another point of considerable interest is that the Arrhenius temperature coefficients of the rates shown in Table 5 between 2000 and 5000 °K either with or without tunnelling are as follows: para-H_2, 93.2 kcal; ortho-H_2, 92.3 kcal. The experimental Arrhenius coefficient is about 92.6 kcal mol^{-1} (28); we will return to a discussion of the temperature coefficients later in the paper.

In Table 6, we explore several possible variations in respect of the chosen rotational transition probabilities in this factored approximation (using the same set of effective rotational spacings Δ_{rs} in all cases). Since there is so little difference between the inclusion or the exclusion of predissociation, only the rate constants for dissociation with tunnelling are listed. Furthermore, since ortho- and para-H_2 dissociation rates behave identically

under these changes, only the results for para-H_2 are quoted; fuller listings will be made available elsewhere (20). The first column shows the standard set of rate constants calculated according to [16] as listed in Table 5. The next two columns list rate constants calculated using [16] for the transition probabilities, but restricting changes in J to either ($\Delta J = \pm 2$ only), or ($\Delta J = \pm 2$ and ± 4 only); the rate constants change in the fourth or fifth decimal place under these restrictions, indicating very strongly indeed that with this set of transition probabilities, once the initial transients have passed the reaction proceeds to all intents and purposes by single step (*i.e.* $\Delta J = \pm 2$) transitions only (*cf.* ref. 12 for a fuller discussion of this effect for vibrational dissociation). The fourth and fifth columns of data in Table 6 repeat the calculations listed in the first and second columns except that the exp $(-2.5\,|\Delta J\,|)$ term in [16] is replaced by e^{-5} if $|\Delta J\,| > 2$ (denoted by [16*a*]). This has the effect of leaving the $\Delta J = \pm 2$ transition probabilities unchanged, but removes the penalty on larger changes in ΔJ; the ($\Delta J = \pm 2$ only) calculation is the same with either [16] or [16*a*]. The effect of removing the arbitrary $|\Delta J\,|$ penalty is negligible at low temperatures, but increases to about 5% at 5000 °K; also, using [16*a*] instead of [16], $\Delta J = \pm 4$ changes have some effect, as evidenced by the fact that the ($\Delta J = \pm 2$ and ± 4 only) rates resemble more nearly the unrestricted ΔJ rather than the ($\Delta J = \pm 2$ only) results. These small differences between the results from [16] and [16*a*] should not be misinterpreted, however, to mean that it does not matter whether or not large changes in ΔJ can occur, it only does not matter in the "Δv or ΔJ only" approximation.

Solution of the Full Set of Equations

The rotation–vibration spectrum of H_2 consists of 172 levels having odd J, and 177 levels having even J, according to the calculations of LeRoy (9). At the beginning of this research, it was not clear to us that we would be able to solve matrices of order 172 or 177 to find the eigenvalue of *smallest* numerical magnitude, *i.e.* the rate constant; further, if population distributions were required, the computer storage requirements would be beyond the capacity of our machine. Our aim in this section was therefore to attempt some solutions of the full eigenvalue problem and compare the rate constants with those obtained in the preceding section; subsequently, it emerged that we could find meaningful values of d_{n-1} at all temperatures from 1500–5000 °K for matrices of order 172 and 177, although at 1500 °K, the third decimal place was not too significant. However, because such eigenvalue calculations were at least twenty times more costly in computing time, only a limited number of experiments was performed, just sufficient to confirm the essential correctness of the conclusions found using the factored method above, and to investigate one or two aspects of the dissociation problem which are meaningless in the context of the factored model.

Equation 16 was taken as the standard set of transition probabilities with which to describe now simultaneous changes in v and J: thus, if $\Delta J = 0$, the probabilities are the Δv probabilities used in the T–V calculations, and if $\Delta v = 0$, they are the ΔJ probabilities used in the T–R calculations of the preceding section. Matrices of order either 172 or 177 were set up according to [6] using these probabilities and solved for the two smallest eigenvalues d_{n-1} and d_{n-2}, both with and without predissociation. The results for the dissociation rate constants obtained from the d_{n-1} are compared with each other in Table 7, where it can be seen that as we have now come to expect, the effect of tunnelling is very small indeed; again, we find, as in the factored approximation (Table 5), the very small acceleration caused by the predissociation is marginally more important at the lowest temperatures. What is surprising about the results in Table 7 however, is that the rate constants for decomposition of para-H_2 always exceed those for ortho-H_2 by a small margin. The reason why this happens is as follows. Counting only bound levels, ortho-H_2 has 146 and para-H_2 has 154, and as we have already shown (27) the more levels a system has, the faster will it dissociate even though a small amount more energy may be required for dissociation. We have done enough numerical experiments (17, 27) to convince ourselves that there is a variational principle here: that for a constant value of the dissociation energy, an increase in the number of (connected) levels cannot lead to a reduction in the dissociation rate; the variational principle could be stronger than stated here, but numerical experiment is not the way to establish theorems of this kind. This behavior stems from two causes, (*i*) that the transition probabilities increase as the gap size decreases, and (*ii*) that after the initial transients, most molecules find their path to dissocia-

tion to be single-step processes; it appears that under these conditions it is easier to climb the activation ladder in more small steps than in fewer big ones. The fact that our factored model does not show this effect is disappointing; it probably arises because in the factored model the dissociation rate is found by solving a 20-step relaxation process for para-H_2 and a 19-step process for ortho-H_2, and this is not a sufficiently significant difference in the number of steps to offset the additional 120 cm^{-1} required to dissociate. We have remarked before (29) that the measurement of the dissociation rates for ortho- and for para-H_2 represents an intriguing experimental challenge, and it would be most interesting to know whether there is any temperature at which the rate of dissociation (or recombination) of para-H_2 is the greater as our calculations might suggest; in recombination Roberts (30) has suggested that the ortho-rate is dominant at very low temperatures, but that above 200 °K, para-recombination is somewhat favored.

It is of course possible to set up a full-matrix calculation in which all elements of the matrix are zero if both Δv and ΔJ are non-zero; thus this also is a "Δv or ΔJ only" calculation, except that each population $n(v,J)$ is free to vary independently of all others, whereas in the factored model the $n(v,J)$ were products of a vibrational with a rotational distribution. The results of this calculation are shown in Table 8 where they are compared with the corresponding results of the factored calculation taken from Table 5. Here also we find that the solution of the full (yet restricted) matrix gives rise to para-dissociation rates that are marginally faster than ortho-dissociation rates, in contrast to the factored calculations. Comparison of the second and fourth columns of rate constants between Tables 7 and 8 shows that as the temperature decreases, the more closely does the "Δv or ΔJ only" full calculation approach the correct solution without any restriction, which is to be expected since the lower the temperature, the more likely it would be that the molecules would "crawl" up the rotation–vibration ladder using the smallest steps available to them. Comparing like calculations in Table 8, it seems that as the temperature goes down, the factored calculation tends to underestimate the para-dissociation rate but overestimate the ortho-dissociation rate, to the extent that the mean of the two factored calculations is fairly close to the correct unfactored solution.

Table 9 shows the results obtained using [16*a*]

in which the $|\Delta J|$ penalty is removed. The effect of this is to change very markedly the probabilities of certain near-resonant transitions. For example the $v = 0, J = 27$ level is 6561 cm^{-1} below the dissociation limit whereas $v = 9, J = 3$ is at 6598 cm^{-1} below the limit. Because the energy difference Δ_{ij} is very small, [16*a*] will give a transition probability for the *exothermic* process of the order of e^{-5}, whereas [16] will give a probability of the order of e^{-60} since $|\Delta J| = 24$. Since it is believed that simultaneous changes in v and J are important (31) but we do not yet know whether a near-resonant change is allowed or disallowed if ΔJ is large, it is important to investigate both possibilities. We have already seen in Table 6 that in the factored calculation such a change has very little effect, which is because in the "Δv or ΔJ only" mechanism most of the dissociation flux takes single steps even without the $|\Delta J|$ penalty. This is confirmed in Table 9 where it is shown that in the full solution of the "Δv or ΔJ only" mechanism, the penalty makes essentially no difference. However, in the unrestricted mechanism, where simultaneous changes in v and J are allowed, there is a significant effect, of about 20% at 1500 °K and 50% at 5000 °K, which arises from the kinds of processes just described, since they are excluded from the "Δv or ΔJ only" description. It would seem that if this trend is maintained, simultaneous changes in v and J would be of only minor importance at lower temperatures, and could be more-or-less ignored in the description of low-temperature recombination reactions.

From the results tabulated in Tables 8 and 9, it is clear that the uncoupling of rotational and vibrational excitation, either via the factored model or via the $|\Delta J|$ penalty, has little effect on the rate of dissociation, especially so at the lower temperatures. As we have noted above, the difference between [16] and [16*a*] involves some very strong rotational–vibrational coupling; a corollary would be that under these conditions when the rotational and vibrational excitation can be treated as separable, the product-type population distribution implicit in the use of the factored model should be a reasonable approximation to the correct solution for the population distribution. One must not be misled, however, into thinking that rotational excitation and vibrational excitation *are* separable, because the second eigenvalue d_{n-2} is actually quite sensitive to changes in such coupling: the quantity $-d_{n-2}{}^{-1}$ is the relaxation time of the last transient which precedes the dissociation (13), commonly regarded as the vibrational relaxation time. Our calculations show that tunnelling has little effect on d_{n-2}, the difference being undetectable at low temperatures and amounting to about 0.1% at 5000 °K, consistent with the fact that in this range the dissociation is not strongly coupled to the internal relaxations (12). The results in Table 10 show that there is a significant change in the "vibrational" relaxation time on changing from the "Δv or ΔJ only" calculation (in which simultaneous changes in v and J are specifically forbidden) to the unrestricted calculation using probabilities given by [16] (in which such changes are weakly allowed); only one example of the "Δv or ΔJ only" relaxation times is quoted, the results are similar for ortho- or para-H_2, and for [16] or [16*a*]. Furthermore, changing the transition probabilities from those described by [16] to those described by [16*a*], the effect of which is simply to increase the rotational transition probabilities for $|\Delta J| \geqslant 4$, there is a further significant change in the "vibrational" relaxation time, of about a factor of three at 1500 °K and about a factor of ten at 5000 °K. Thus, it seems clear that the relaxation time which has hitherto been labelled a "vibrational" relaxation time in shock-

tube work has really to be considered as a T–VR relaxation time, particularly so as the temperature becomes high.

The Arrhenius Temperature Coefficient of the Dissociation

We noted earlier that one of the factored calculations gave an Arrhenius temperature coefficient for dissociation which was very close indeed to the experimental value of about 92.6 kcal mol^{-1} (28); since the agreement between the factored and the unfactored methods in respect of rate constants is generally good, it follows that just about any of our approximations will have a temperature coefficient in good agreement with experiment, as shown in Table 11. It is apparent that all of the Arrhenius plots have a marked curvature, and to this extent they seem to be consistent with experimental observation of large negative recombination temperature coefficients at high temperatures, but rather small ones at low temperatures (28, 32, 33). Whilst these agreements may be fortuitous for several reasons, it is interesting to recall that our previous calculations using the energy-transfer mechanism (13) and in which only vibrational disequilibrium was considered gave a temperature coefficient of about 102 kcal mol^{-1}, and that Dove and Jones (34), using quite a different set of T–V transition probabilities found also about 102 kcal mol^{-1}; thus it appears that vibrational disequilibrium cannot easily account for the observation of low "activation energies" in diatomic dissociation reactions, but that the temperature variations in rotational disequilibrium very well could. One can also observe that in Table 11, the removal of the $|\Delta J|$ penalty raises the Arrhenius temperature coefficient in the full calculation from about 86 to 92 kcal mol^{-1} over the 4000–5000 °K temperature range. This is another indication that rotational depopulation could be a key factor in determining the temperature coefficient, and that if intramolecular rotational and vibrational transfers are unimportant there will be a tendency for the Arrhenius temperature coefficient to be lower.

We now summarize briefly other possible causes for the occurrence of these low Arrhenius temperature coefficients. We have previously shown that when strong V–V coupling is present (and the experimental measurements cannot in any sense be considered to be at infinite dilution) non-integral orders in the reactants would occur (35): those calculations referred to a temperature of 2000 °K only, slightly below the experimental

range, and were not extended to other temperatures because of a lack of any real knowledge of the relative importance of T–V *vs.* V–V coupling in H_2, and how the relative importance might change with temperature. However, it is clear from that work that it is entirely possible for the reactant orders to change slowly with temperature, and hence, if the rate constants are derived from experimental rates assuming integral reactant orders, both the rate constants and their temperature coefficients would be meaningless (35). As far as we know, no dissociation measurements have yet been directed towards the problem of how closely the rate laws are of integral order in the reactants, and until the answer is known, we will not know how important V–V coupling may be in causing anomalous Arrhenius parameters for these reactions. Then, unfortunately, there still remains the nagging suspicion that there may be a third cause, unsuspected impurity effects which are receiving much more attention from experimenters in recent years (13, 28, 29, 36). These remarks apply to only the energy-transfer component of the dissociation process: in heavier systems, one will need also to consider the radical–molecule complex or chaperon component of the process (37, 38), and in heteronuclear diatomic dissociations one can expect to find atomic chain processes which will accelerate the disappearance of the diatomic molecule; both these effects will lower the temperature coefficient of the reaction. Thus, in our view, no overall accommodation between the theoretical description and the experimental results would seem imminent until a series of experiments on the dissociation of H_2 in the presence of He (to reduce the chaperon contribution) is performed at very high dilutions (to eliminate V–V processes), paying special attention to the problem of impurities: heteronuclear molecules are far too complicated theoretically at the present time (even the HD molecule (29)), as are also heavier homonuclear molecules because of various complexities, including the existence of radical–molecule complexes and of low-lying excited electronic states from which radiation occurs.

Future Calculations

There is very considerable interest at the moment in the recombination of hydrogen atoms at low temperatures, both theoretically (18, 30, 39–41) and experimentally (32). However, in our view, both of the current theoretical approaches used to describe the recombination in hydrogen must be regarded as suspect.

The orbiting-resonance theory of Roberts, Bernstein, and Curtiss (18) was designed to deal specifically with the recombination of hydrogen and deuterium at low temperatures. The restriction to low temperatures was clearly appreciated by the original authors, but it would be useful to present some more of the reasons for this limitation which were not discussed previously. For example, for two of the six quasi-bound states of H_2 which were identified as interesting ($v = 12$, $J = 12$, and $v = 11$, $J = 13$), the loss of energy associated with the change $\Delta v = -1$ is only a little more than the loss for $\Delta J = -2$, and hence both processes are likely to occur in parallel. At low temperatures this will be fairly unimportant, but as J goes up, the vibrational gaps ($\Delta v = -1$) become markedly less than the rotational gaps ($\Delta J = -2$), so that the importance of parallel rotational and vibrational deactivations would tend to increase. Also, as was noted by Shui and Appleton (41), simultaneous rotation–vibration changes of $\Delta v = -1$, $\Delta J = +2$ are occasionally favorable, *e.g.* for $v = 14$, $J = 4$, but as J goes up $\Delta v = -2$, $\Delta J = +2$ transfers often provide deactivation paths in quite small energy steps. Our calculations (Tables 9–11) show very clearly the increasing importance of simultaneous changes in v and J as the temperature rises, but at the same time they confirm that no serious error arises from ignoring these simultaneous changes at low temperatures.

There is, however, a more fundamental difficulty with the orbiting resonance theory: that one deactivation does not make a molecule. Whenever there is a bottleneck in the deactivation ladder, the accessibility of an orbiting resonance state, or the chance that it may lose a quantum or two of rotational and/or vibrational energy is not the determining factor in deciding the rate of formation of molecules in the ground state. In such cases there is a very delicate balance, as we saw in our discussion above of the vibrational deactivation of the $J = 21$ state, between the relevant collision rates and the tunnelling rates, which will not be adequately represented in the present form of the orbiting–resonance theory. We have found repeatedly in this paper that whether one considers the existence of the wide shape resonances in a proper fashion or whether one ignores them altogether makes little difference to the calculated dissociation or recombination rates in the energy-

transfer dominated regime, both with our approximate model and with the full calculation. The interpretation of the data in Table 7 could be strained somewhat to suggest that tunnelling may be more important at the lower temperatures; the data in Table 5, from the somewhat less reliable factored method, also show a marginal but significant trend towards the increasing importance of tunnelling at the lower temperatures. One feels intuitively that it would be surprising if these small trends were to blow up into a marked divergence between the with- and without-tunnelling calculations, at least above room temperature since the extrapolation in terms of $1/T$ from our temperature range is not excessive. Of course, there is as yet no *concrete* evidence of a bottleneck in these systems; there is however much circumstantial evidence from theoretical calculations. From the reasonably close agreement we have found between the factored and the unfactored calculations (Table 8) it is probably fair to infer that the population distribution in the full calculation is moderately well represented as a product of rotational and vibrational distributions. Thus it would appear that, for example in recombination, *every* newly formed molecule must pass through some bottleneck to reach the ground state; if it is formed in a low J state, there is a vibrational bottleneck, or if it is formed in a low v state, there is a rotational bottleneck. The question arises as to whether these bottlenecks are necessary, or could sets of T–V or T–R probabilities be constructed which would not show a bottleneck? We have experimented extensively with different sets of T–V transition probabilities (12, 13, 17, 27) and always seem to find a bottleneck in vibration–dissociation coupling calculations; unfortunately, theorems connecting the eigenvalues, particularly the smallest eigenvalue, of a stochastic matrix to arbitrary changes in the matrix elements are not sufficiently well developed to define the conditions under which a bottleneck would or would not occur. We have not experimented widely with T–R transition probabilities, nor with T–VR probabilities: however, our assumed set of T–R transition probabilities is not dissimilar from those successfully used by Polanyi and Woodall (25) to explain their rotational relaxation measurements, and it would seem on this basis that the very pronounced rotational bottleneck that we find (Table 4) is fairly realistic.

On the other hand, the phase-space theory of dissociation and recombination (41, 42) does make an attempt to allow for those molecules which may be deactivated but which eventually redissociate. The major fallacy in extending this treatment to the recombination of hydrogen at low temperatures is the implicit assumption that the upper rotation–vibration levels of H_2 are sufficiently closely spaced that they may be considered classical. This assumption was mildly criticised by Pack, Snow, and Smith (40), but examination of Fig. 2 shows the assumption to be grossly optimistic. This diagram shows the distribution of gaps in the rotation–vibration spectra of ortho-H_2 and para-H_2: the left-hand ordinate is the magnitude of the gap $\omega = \Delta_{i-1,i}$ in cm^{-1} and the right-hand ordinate is $hc\omega/k$ *i.e.* the characteristic temperature for each gap; for good classical behavior, one would like to have $T > 5hc\omega/k$. *If, and only if,* the transition probabilities are governed by an equation like [16*a*], where there is no discrimination against transitions having large values of $|\Delta J|$, then Fig. 2 can be used to determine the temperature needed for effectively classical behavior amongst the upper levels. It can be seen that, excluding the quasi-bound levels which are in general more widely spaced than the bound levels, there are several transitions for both molecules in the first 5000 cm^{-1} below the dissociation limit which could not be considered classical much below 1000 °K. On the other hand, if there were a $|\Delta J|$ penalty such as is embodied in [16] for the transition probabilities, then the gaps between levels connected by only small $|\Delta J|$ changes become perhaps, on average, four or five times larger than shown in this diagram. Thus, whilst the classical phase-space theory of Shui and Appleton (41) may be applicable to most molecules at most temperatures, it certainly cannot be applied to H_2 below 500 °K, and in fact, until we know whether large changes in J are allowed or disallowed, it is not even clear that the theory can be applied to H_2 below 5000 °K.

Nor are our own calculations free from criticism. At the moment we can only simulate the energy-transfer component of the mechanism, whereas the chaperon component is thought to be significant for H_2 at low temperatures (40) and for all other molecules at all temperatures (37); however, the latter mechanism is not beyond the scope of future extensions to the present treatment, as we have shown recently (29). Neither can we solve the non-dilute problem in which V–V,

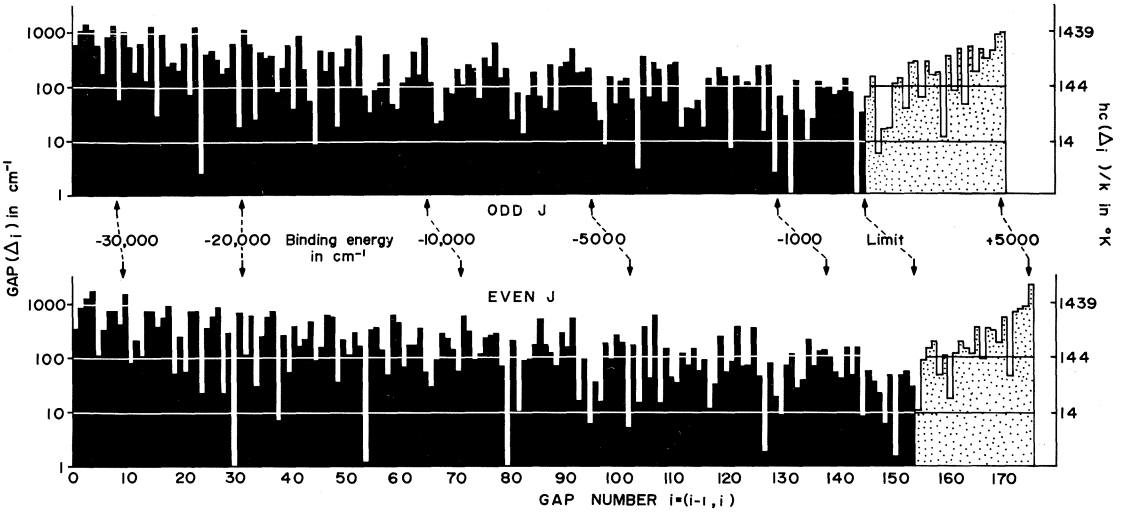

FIG. 2. Distribution of energy gaps in the rotation–vibration spectrum of ortho-H_2 (odd J) and para-H_2 (even J).

or more generally VR–VR interchanges take place, although as we have noted earlier, present theoretical indications are that when such processes are important, non-integral rate laws will occur (35), and we may hope for guidance from future experiments on this point. And, of course, there is a very long way to go before we can calculate all of the 30631 T–VR transition probabilities (15753 for even J, 14878 for odd J) required for a full solution of the energy-transfer calculation at infinite dilution! The ones we have used are based to some extent on theoretical calculation (3), guided by experimental results where available. In addition, we have performed a wide range of perturbations upon these assumed probabilities throughout this series of papers, and have consistently found gross insensitivity of the rate constants to the chosen probabilities; hence, in fact, it will only be really necessary to know a key selection of transition probabilities with reasonable precision, and as far as the remainder are concerned, a knowledge of the order of magnitude will be more than sufficient. It seems likely that in the foreseeable future, one may expect to see good calculations on T–V or T–R transition probabilities for at least a representative selection of the v or J levels of H_2 in collision with He. On the other hand, accurate treatment of simultaneous changes in rotational and vibrational energy may prove to be more difficult, and we may hope to be guided by experiments in which such changes are observed, although at the present time only for excited electronic states (43–45); our calculations suggest however that a fair calculation of the rate of dissociation or recombination can be made without knowing much about simultaneous T–VR exchanges, at least for temperatures up to and including the low end of the shock-tube temperature range.

A serious problem with our method, which stems essentially from the nature of the Boltzmann distribution, is the numerical difficulty associated with finding always the *smallest* eigenvalue of a large matrix, which becomes more and more overwhelming as the temperature is reduced. The dominant eigenvalues of these matrices are always of the order of 10^{11} s^{-1} without tunnelling, 10^{13} s^{-1} with tunnelling, and at 1500 °K, d_{n-1} is approximately 10^{-4} s^{-1}; thus, using 16-decimal-place arithmetic (IBM360/50), one really has to work hard to obtain the two-and-a-half figure accuracy on the rate constants which we quote for this temperature in Tables 7 and 9. After the completion of the work so far described, an IBM370/155 machine was installed at York University, on which it is possible to use 30-decimal-place arithmetic, enabling us, as described in the next few paragraphs, to extend these calculations down to about 700 °K. To go further would require further increases in word length, but to cover the whole experimental range (32) down to 100 °K will give rise to severe overflow and underflow problems, associated principally with the magnitudes of the Boltzmann factors for very high states of the molecules at these very low temperatures: it will be necessary

to accommodate numbers of magnitudes 10^{-300} which cannot readily be done on many commercially available computing machines. If such brute-force extension to lower temperatures fails (and in the absence of a reformulation of the problem which leaves all eigenvalues unchanged except d_{n-1} which comes out multiplied by K^{-1}), one will probably have to fall back in the last resort on the factored method. This, as we have seen, gives rise to much smaller matrices, and in at least one case (13) we have solved the $J = 0$ vibrational relaxation problem, admittedly with some difficulty, down to 300 °K. Thus, whilst the factored model cannot accommodate important rotation–vibration coupling processes, we have found that the rate constants it gives improve as the temperature falls, and it would seem that (provided the odd-J and even-J calculations do not diverge from each other too drastically, *cf.* Table 8) acceptable recombination rates could be calculated down to as low a temperature as the exponent length of the available computing machine will allow.

A Practical Test

Throughout this series of papers (11–13, 17, 27, 29, 36), we have worked with a set of transition probabilities (3, 13) which, at best, can be little better than an educated guess, and we have taken much comfort from the fact that our calculated rate constants (but not relaxation times) have been quite insensitive to perturbations in these probabilities (12, 13, 17, 27, 46). At the same time, we have been trailing far behind the modern experiments, and have been trying rather to understand or rationalize some of the puzzling features common to much of the existing mass of experimental data. Now, however, we are in a position to make some predictions, which, if they are confirmed by future experiments, will lend some confidence to our assumption that, within reason, almost any set of transition probabilities will suffice, as far as dissociation and recombination rates are concerned.

We have shown previously (27) that if only vibration–dissociation coupling is considered, the calculated rate constant for the recombination of D_2 by an inert third body is always faster than that for H_2, not only at high temperatures, but also at room temperature.[2] As we noted at the time, there is some evidence from the work of Sutton (47) that in the range 2800–4500 °K, the recombination of D_2 by argon is faster than the recombination of H_2 by argon, by a factor of about 1.25, although this conclusion is not corroborated by the work of Rink (48) at 3500 °K. However, there appears to be unambiguous evidence (32, 49, 50) that near room temperature, the rate constant for the recombination of D_2 by D_2 is significantly *less* than the rate constant for the recombination of H_2 by H_2. If, as is commonly believed (18, 39), rotational relaxation is important at lower temperatures, one would expect to obtain a different result in a rotation–vibration–dissociation calculation from that obtained in the previous vibration–dissociation calculation. We therefore performed a parallel set of calculations for D_2 to those described above for H_2, on the assumption that the T–VR transition probabilities per collision are the same function of temperature and energy gap for D_2 and for H_2, that the rotation–vibration energy levels and predissociation rates of quasi-bound states for D_2 are those calculated by LeRoy (9), and that the collision rate between D_2 and He is less than for H_2 with He by an appropriate factor (0.8165). It soon became apparent (see below) from the results obtained that it would be interesting to perform calculations for lower temperatures than 1500 °K, and the installation of IBM 370 machines at York University and at the University of Toronto, both having 30 decimal-place arithmetic, enabled us to extend these calculations down to 700 °K. However, since D_2 has 348 odd and 355 even bound and quasi-bound levels, as opposed to 172 and 177 levels respectively for H_2, the D_2 calculations were much larger and more time-consuming, and only a few were attempted. The storage requirements for H_2 in quadruple-length and for D_2 in double-length arithmetic could be accommodated on the York University IBM 370/155 installation, but for D_2 in quadruple-length arithmetic, the half-matrix describing the relaxation required almost 1.2 M bytes of storage, and those calculations were performed on the University of Toronto IBM 370/165 installation.

As for H_2, two series of calculations were performed, one using [16] in which T–VR transition probabilities are restricted to transitions having only small changes in rotational angular momentum, and the other using [16*a*] in which the probabilities are governed only by the energy difference to be transferred to or from translation. The same feature emerged for D_2 as for H_2, that

[2]Those calculations ignored the change in collision rate that would accompany the substitution of D_2 for H_2, but even if such an allowance were made, the conclusion is unchanged.

TABLE 12. (*a*) Equilibrium constants, in units of molecule cm^{-3}, calculated by standard nethods from the assumed energy-level scheme

T (°K)	Equilibrium constant

the inclusion or exclusion of the rotational predissociation contributions made very little difference to the rate constant. However, in slight contrast, the ortho- and para-dissociation rates were almost identical for D_2, presumably because in D_2 the levels are so dense that the network resistance effect, invoked above for the H_2 case, is more nearly the same for the two spin states. Hence, the results listed in Table 12 do not include all the individual rates calculated, which are available elsewhere (20), but are mean values which lie within about 1% of the rates for odd- or even-states with or without rotational predissociation at 5000 °K, and within 2 or 3% at 700 °K. The results may be summarized as follows:

(*i*) *Dissociation Rates.* At high temperatures, the rate constant for the dissociation of D_2 by He seems to be greater than that for the dissociation of H_2 by He, despite the fact that in the former case, all the eigenvalues in the system are scaled by the factor 0.8165, the ratio of the two collision rates for D_2/He and H_2/He. This is yet another example of the possible theorem to which we have alluded above, that closer level spacing leads to an increase in dissociation rate. The effect is so strong between H_2 with about 175 connected levels and D_2 with about 350 connected levels that it more than offsets *both* the unfavorable collision rate *and* the extra 631 cm^{-1} (1.8 kcal/mol) required to dissociate the D_2 molecule. However, as the temperature is reduced, this extra dissociation energy becomes an important factor and below 2000 °K, the existence of a greater number of pathways from the ground state to the continuum cannot offset the unfavorable Boltzmann factor. This amounts to about 0.55 at 1500 °K and about 0.27 at 700 °K causing a strong reversal in the calculated dissociation rate ratio. The new data in Table 12 are consistent with the trends shown in Table 11,

giving Arrhenius temperature coefficients for H_2 of about 101.5 kcal/mol between 1000 and 1500 °K, and about 102.5 kcal/mol between 700 and 1000 °K, with either set of transition probabilities; the Arrhenius temperature coefficients for D_2 are similar, roughly 2 kcal/mol higher.

(*ii*) *Recombination Rates.* The rate constant for recombination of D_2 by He seems to be greater than that for the recombination of H_2 by He throughout the temperature range accessible to us at the present time. No reversal in the isotope effect occurs because the equilibrium constants connecting k_d and k_r for the two molecules have differing temperature coefficients, mainly because of their differing dissociation energies. However, the recombination data do appear to be converging as the temperature falls, and it seems likely that a reversal could occur at lower temperatures.

(*iii*) *Experimental and Theoretical Implications.* On the basis of full rotational equilibration, as was assumed in our earlier work (27), deuterium[2] would be recombined by helium 1.36 times as fast as hydrogen at 1500 °K and 1.15 times as fast at 300 °K. The present calculations, which allow sumultaneously for T–V, T–R, and T–VR transitions, but which cannot yet be performed for temperatures below 700 °K, appear to be more realistic in that they do not seem to be inconsistent with a slower recombination rate for D_2 than for H_2 at low temperatures. This improvement can be taken as supportive of the designation of the low-temperature recombination process as being essentially rotational (18, 39). Unfortunately, we cannot yet demonstrate conclusively a trend towards a predominantly rotational mechanism without being able to calculate population distributions, and therefore fluxes between individual states during the relaxation. In principle, this can be done readily given the eigenvectors of the relaxation matrix (13), and although we have been able to generate most of the eigenvectors for a 172nd order H_2 matrix (20, 46), we have so far been unable to find all of them because of the ill-conditioned nature of the problem.

A major factor in determining the position of any possible reversal in the rate constant ratio is the ratio of the collision rates for D_2 and H_2. If, instead of choosing helium as the collision partner, we had chosen a heavier inert atom like argon, the ratio of the collision rates would have been close to 0.7. The effect of this on the rate ratios in Table 12 would then be: (*a*) the dissociation rates for H_2 and D_2 would be virtually indistinguishable at high temperatures, with D_2 always slower than H_2 (except perhaps for [16*a*] at 5000 °K); (*b*) the recombination rates would cross between 1000 and 1500 °K with the restricted set of probabilities ([16]) or between 700 and 1000 °K with the unrestricted set ([16*a*]). The same would be true of the recombination of H_2 by H_2 compared with the recombination of D_2 by D_2 (where the collision rate ratio is again 0.7) *provided* that VR–VR coupling were unimportant.

We would like to thank the University of Toronto Institute for Aerospace Studies and Computer Centre for access to their latest computing facilities.

Lower Bounds to Expectation Values: Two-Electron Atoms

D. P. CHONG[1] AND F. WEINHOLD[2]

Department of Chemistry, Stanford University, Stanford, California 94305

Received July 31, 1972

Weinhold's lower bound formulas are used on rather accurate wavefunctions for the 1^1S ground states of H^-, He, and Li^+, and the 2^1S and 2^3S excited states of He. The results are found to be of very high quality, as judged by comparison with the best available variational calculations, and can be used to rule out many of the values calculated by Scherr and Knight from high-order perturbation theory.

Les formules de Weinhold concernant les niveaux de liaison de basse énergie ont été utilisées dans les fonctions d'onde plutôt précises pour les états fondamentaux 1^1S de H^-, He, Li^+ et pour les états excités 2^1S et 2^3S de He. Les résultats sont de très haute qualité par comparaison avec les meilleurs calculs variationnels disponibles et peuvent être utilisés pour éliminer plusieurs valeurs calculées par Scherr et Knight à partir de la théorie de pertubation d'ordre élevé.

Introduction

The concept of attaching rigorous error limits to theoretical estimates of quantum-mechanical properties is attractive to many chemists and physicists. Such upper and lower bounds not only provide internal and *a priori* measures of reliability, but also enable one to make more meaningful comparisons with experimental results. One of the recent developments in this direction is the application of Gramian determinantal inequalities.[3] For the lower bounds to expectation values of positive operators, Weinhold (2–5) derived a wide variety of relatively simple formulas and illustrated their use with the familiar $1s^2$ and $1s1s'$ trial functions for the 1^1S ground state of the helium atom, with promising results. The purpose of this work is to test some of these procedures on better wavefunctions. On the basis of certain preliminary results, we were encouraged to employ some rather accurate wavefunctions which could be expected to yield bounds of a definitive quality for the simple 2-electron atomic systems.

Calculations

A. Lower-Bound Formulas

In the present work, we seek lower bounds F_{LB} to the true expectation value $\langle\psi|F|\psi\rangle$ of a general positive operator $F \geqslant 0$. With one exception (when $F = r_1^{-1}$), we make use of the formulas (2, 4):

$$[1]\quad \langle\psi|F|\psi\rangle \geqslant F_{LB} = [S\langle F\rangle - \varepsilon\Delta F]^2/\langle F\rangle$$

$$[2]\quad \langle\psi|F|\psi\rangle \geqslant F_{LB} = S^2/\langle F^{-1}\rangle + [S(\langle F\rangle\langle F^{-1}\rangle - 1) - \langle F^{-1}\rangle\varepsilon\Delta F]^2 \times \{\langle F^{-1}\rangle(\langle F\rangle\langle F^{-1}\rangle - 1)\}^{-1}$$

where, in our notation, both the trial function φ and the exact wavefunction ψ are normalized,

$$[3]\quad \langle\varphi|\psi\rangle = S > 0$$

$$[4]\quad \varepsilon = (1 - S^2)^{1/2}$$

$$[5]\quad \langle F\rangle = \langle\varphi|F|\varphi\rangle$$

$$[6]\quad (\Delta F)^2 = \langle F^2\rangle - \langle F\rangle^2$$

These lower bound formulas are valid only if the expressions in square brackets are non-negative. In other words, we assume that

$$[7]\quad S/\varepsilon \geqslant (\Delta F)/\langle F\rangle$$

$$[8]\quad S/\varepsilon \geqslant (\Delta F)\langle F^{-1}\rangle/(\langle F\rangle\langle F^{-1}\rangle - 1)$$

The inequalities in eqs. 1 and 2 are sustained when the overlap S is replaced by a lower bound S_{LB} to its true value. Hence, once S_{LB} has been calculated,[4] it is straightforward to compute F_{LB} from eq. 1 or 2. It can be shown that eq. 2 gives a stronger lower bound than eq. 1. Consequently, we use eq. 1 only when $\langle F^{-1}\rangle$ is not available.

[1]On leave from the Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.

[2]Alfred P. Sloan Fellow.

[3]See ref. 1 for a review of recent progress in this area.

[4]For this purpose, we use Weinberger's formula (6). See also Weinhold (7, 8) for additional details.

†Reference 14.

Finally, for the particular operator $F = r_1^{-1}$, the virial theorem written as[5]

[9] $$\langle\psi|r_1^{-1}|\psi\rangle = (N-1)\langle\psi|r_{12}^{-1}|\psi\rangle/(2Z) - 2E/(NZ)$$

together with the lower bound to $\langle\psi|r_{12}^{-1}|\psi\rangle$, provides a lower bound which is always found to be stronger than that calculated from eq. 2 directly.

B. Properties

For the calculation of $\langle F\rangle$, we have considered operators corresponding to delta functions and various powers of the radial and interelectronic coordinates[6]

[10] $F = \delta(\boldsymbol{r}_1)$ and r_1^n for $-2 \leqslant n \leqslant 5$

[11] $F = \delta(\boldsymbol{r}_{12})$ and r_{12}^n for $-2 \leqslant n \leqslant 2$

However, because of the assumptions in eqs. 7 and 8, the lower bound formulas 1 and 2 cannot be employed when the width ΔF is formally divergent. This rules out operators such as r_1^{-2} and r_{12}^{-2} for atoms in S states, and the delta function operators, $\delta(\boldsymbol{r}_1)$ and $\delta(\boldsymbol{r}_{12})$, for any system in any state. Additional formulas are available (5, 9) which partly avoid the difficulty, but these were not explored in the present work.

C. Wavefunctions

In order to see some aspects of the dependence on nuclear charge Z and on the degree of excitation, we have selected for study the 1^1S ground states of H^-, He, and Li^+, and the 2^1S and 2^3S excited states of neutral He. To describe the atomic states we have employed rather accurate wavefunctions which were recently obtained (10) in connection with related studies on the oscillator strengths of two-electron ions. These are of the Hylleraas type, built up from some 135–140 terms of the form

$$(1 \pm P_{12})r_1^l r_2^m r_{12}^n \exp(-\xi r_1 - \eta r_2)$$

with very rough optimization of the open-shell exponential parameters ξ, η. The general quality of these functions is indicated more specifically in Table 1, where we list such criteria of accuracy as the energy error, the overlap, and the degree of satisfaction of the virial theorem and cusp conditions. The expectation values of the operators $\delta(\boldsymbol{r}_1)$, r_1^{-2}, $\delta(\boldsymbol{r}_{12})$, and r_{12}^{-2} are also listed in Table 1, together with the percentage errors wherever accurate values are available (11–15). Energetically, these functions are of course still somewhat inferior to the well-known

[5] N, Z, and E are the number of electrons, nuclear charge, and exact energy, respectively. See ref. 3.

[6] For one-electron properties, it can be shown that ΔF in eqs. 1 and 2 may be replaced by $\Delta\bar{F}$, where $\bar{F} = \frac{1}{2}(r_1^n + r_2^n)$, in order to take advantage of the non-linearity of the lower bounds (2).

[7] In the case of r_1^{-2} and r_{12}^{-2}, these formulas (5) strengthen and generalize eqs. 1 and 2 at the cost of additional integrals over the trial function φ.

functions of Pekeris and co-workers (11–16), but their portability and compactness give them certain distinct advantages for our present purposes. In fact, our calculated cusp values shown in Table 1 seem to be considerably closer to the true values of $-Z$ and $+\frac{1}{2}$ for the r_1 and r_{12} cusps, respectively (17, 18), than are those reported[8] for the Pekeris functions. This in turn suggests (19) that such properties as $\langle \delta(\boldsymbol{r}_1) \rangle$ and $\langle \delta(\boldsymbol{r}_{12}) \rangle$ might also be represented to a superior accuracy by our functions.

Results and Discussion

Tables 2–6 summarize our results for the five selected states. The calculated expectation values $\langle F \rangle$ and rigorous lower bounds F_{LB} are, wherever possible, compared with the extensive variational results of Pekeris and co-workers and/or with the 6th-order perturbation theory results of Scherr and Knight (20). In the cases where the

[8]Thus, for He 1^1S, the well-known 1078-term function of Pekeris (12) gave the cusp values −1.98444 and 0.47391 for r_1 and r_{12}, respectively, compared with our values −1.99994 and 0.49743.

accurate results of Pekeris and co-workers are not available, the percentage errors listed in Tables 2–6 are based on the expectation values $\langle F \rangle$ obtained in this work.

A glance at Tables 2–6 shows that the rigorous bounds are of very high quality indeed, as judged by comparison with either the direct expectation values $\langle F \rangle$ or the corresponding Pekeris values. Only for the very high moments $\langle r_1^n \rangle$ of the most diffuse charge distributions (*e.g.*, H^- 1^1S or He 2^1S, where the moments extend into thousands of atomic units) do the discrepancies reach as much as 1%, and in many cases the true values can be guaranteed to lie no more than a few hundredths or thousandths of 1% below the calculated $\langle F \rangle$. For example, Table 6 shows that the true $\langle \psi | r_1^{-1} | \psi \rangle$ for He 2^3S could lie no further than about 1×10^{-5} a.u. below the calculated value $\langle r_1^{-1} \rangle = 1.15466$ a.u.

It is also interesting that the lower bounds can rigorously rule out most of the Scherr–Knight values for both H^- and He. In fact, the only perturbative values to survive are those which appear to lie too *high*, and thus could not be threatened by a lower-bound procedure. However, for Li^+ ($Z = 3$) the convergence of the Z^{-1} perturbation expansions has improved sufficiently that only the calculated values of r_1^4 and r_1^5 can be definitely ruled out. Thus, although the Scherr–Knight perturbation calculations yielded energy eigenvalues which closely rivalled the best variational energies, it appears that discrepancies with respect to other calculated properties should largely be resolved in favor of the variational calculations, at least for lower Z.

We are grateful to the National Science Foundation and the donors of the Petroleum Research Fund, administered by the American Chemical Society, for financial support of this research, and to Mr. Michael T. Anderson for his skillful calculation of the wavefunctions. A portion of this work was completed while one of us (F.W.) was enjoying the warm hospitality of Professor P. O. Löwdin and the Quantum Chemistry Group, University of Uppsala, Sweden, to whom sincere thanks are due.

Crystal Structure of $LiVO_3$

ROBERT D. SHANNON[1] AND CRISPIN CALVO

Institute for Materials Science, McMaster University, Hamilton, Ontario

Received July 21, 1972

Lithium metavanadate is monoclinic with $a = 10.158(2)$, $b = 8.4175(9)$, $c = 5.8853(9)$ Å, $\beta = 110.48(2)°$ and probable space group $C2/c$. The structure, refined by least-squares to a $\omega R = 0.033$ using 851 reflections, is isotypic with $LiAlSi_2O_6$ (spodumene) and $LiFeSi_2O_6$. Bands of Li—O edge-shared octahedra run parallel to c and are linked by chains of VO_4 tetrahedra which also run parallel to c. The mean Li(1)—O and Li(2)—O distances are significantly different, 2.153(3) and 2.284(3) Å, and are related to the degree of distortion of individual distances from the mean. The V—O distances of 1.821, 1.795, 1.662, and 1.628 Å with a mean value of 1.725 Å are consistent with bond strength sums around the oxygen atoms and empirical bond length – bond strength curves.

Le métavanadate de lithium est monoclinique avec $a = 10.158(2)$, $b = 8.4175(9)$, $c = 5.8853(9)$ Å, $\beta = 110.48(2)°$ et de groupe spatial probable $C2/c$. La structure, raffinée par les moindres carrés jusqu'à un $\omega R = 0.033$ après 851 réflexions, est isotypique avec celle de $LiAlSi_2O_6$ (spodumène) et de $LiFeSi_2O_6$. Les bandes des arêtes communes de l'octaèdre Li—O sont parallèles à c et sont reliées par des chaines tétraédrales de VO_4, également parallèles à c. Les distances moyennes Li(1)—O et Li(2)—O sont sensiblement différentes, 2.153(3) et 2.284(3) Å; elles sont dues aux distorsions des distances individuelles par rapport à la moyenne. Les longueurs de V—O de 1.821, 1.795, 1.662, et 1.628 Å avec une valeur moyenne de 1.725 Å, sont compatibles avec les sommes des forces de liaison autour des atomes d'oxygène et les courbes empiriques reliant les longueurs et les forces de liaison.

Introduction

As part of a study of vanadates containing cations of widely differing electronegativity (χ), two compounds, $LiVO_3$ and Li_3VO_4 (1), containing the electropositive ion Li($\chi \sim 1.0$), were chosen for careful structure refinement. Because $NaVO_3$ was believed by Sorum (2) to have the pyroxene-type structure, it was natural to suspect that $LiVO_3$ also belonged to the pyroxene family. Indeed, Burkert and Fritz (3) assumed $LiVO_3$ to contain corner shared chains of tetrahedral VO_4^{3-} ions, and Muller and Roy (4) assumed a pyroxene-like structure for $LiVO_3$, but the structure type was not identified from either powder or single crystal X-ray diffraction patterns. Feigelson, Martin, and Johnson (5) grew crystals of $LiVO_3$ but reported a cell different than in the present case. In this paper we report the single crystal structure refinement of the pyroxene $LiVO_3$ and compare the structural details of $LiVO_3$ and the more common silicate pyroxenes.

Experimental

Lithium metavanadate, $LiVO_3$, was prepared earlier by Canneri (6), Kohlmüller and Martin (7), Reisman and Mineo (8), and Wickham (9). Reagent grade Li_2CO_3 (B and A) and spectrographic grade V_2O_5 (Johnson–Matthey) were mixed in stoichiometric quantities, heated in a Pt crucible to 700 °C and cooled slowly. To produce larger crystals, the product was placed in a Pt boat and slowly moved through a sharp temperature change of 400 °C over a few centimeters with the highest temperature at 700 °C. The millimeter size crystals produced in this way were light green in color. Differential thermal analysis of this material showed no thermal anomalies up to the melting point of 615 °C. No change was noted in the powder pattern between 23 and 600 °C (5).

X-Ray powder diffraction patterns were obtained at 25 °C using a Hägg–Guinier camera according to a procedure described earlier (10). The pattern was indexed on a monoclinic cell consistent with space group $C2/c$. The crystal data are as follows.

$LiVO_3$ f.w. = 105.88
$a = 10.158(2)$, $b = 8.4175(9)$, $c = 5.8853(9)$ Å,
$\beta = 110.48(2)°$, $V = 471.4$ Å^3, $Z = 8$,
$\rho_c = 2.985$ g/cm^3, $\rho_o = 3.005$ g/cm^3(5).

The errors in the unit cell parameters are those derived from a least-squares fit using KCl ($a = 6.2931$ Å) as an internal standard and CuKα radiation ($\lambda_{\alpha 1} = 1.54051$ Å).

A single crystal was ground into a sphere of radius 0.021 cm ($\mu r = 0.96$). Single crystal precession patterns indicated space groups Cc or $C2/c$; we assumed space group $C2/c$ by analogy with $NaAlSi_2O_6$ (11). After collecting the diffractometer data, reflections violating c-glide symmetry were sought because such reflections had appeared in the other Li-containing pyroxenes $LiAlSi_2O_6$ (spodumene) and $LiFeSi_2O_6$ (12). Only one

such reflection (203 with $F_{obs} = 96$, $F_{000} = 4104$) was found.[2]

Intensities were collected on a Syntex automatic diffractometer using MoKα radiation, a graphite monochromator ($2\theta = 12°$), and a scintillation detector. Reflections were scanned in the 2θ–θ mode at variable rates from 2.0–24.0°/min, depending on the peak count, through an angle of 3° plus the α_1–α_2 separation. Background counts were made at the extreme of each scan for times equal to the peak count. A total of 851 reflections were measured over a range of 2θ from 6° to 65° of which 718 were considered to be observed. Intensities with less than 3 times the standard deviation of the background were considered to be unobserved. A number of reflections saturated the counter and were not included in the refinement (002, 02$\bar{1}$, 021, 20$\bar{2}$, 200, 22$\bar{1}$, 310, and 53$\bar{1}$). The intensities were corrected for absorption Lorentz and polarization factors using the X-ray 67 Program System for X-ray Crystallography written by Stewart, University of Maryland, and adapted to the CDC 6400 computer by Grundy. Secondary extinction coefficients were calculated for each reflection according to Zachariasen (19).

As a starting point for refinement the parameters for $LiAlSi_2O_6$ (12) were used. Several cycles of refinement using the full-matrix least squares refinement program CUDLS (20) reduced $\omega R = (\Sigma\omega||F_o| - |F_c||^2/\Sigma\omega|F_o|^2)^{1/2}$ to 0.052, using unit weights. Further refinement using anisotropic temperature factors and Cruickshank weights, $\omega = (1.005 + 0.0616|F_o| + 0.00166|F_o|^2)^{-1}$, reduced ωR to 0.033 and $R = (\Sigma||F_o| - |F_c||/\Sigma|F_o|)$ to 0.025. The weighting scheme was chosen so as to make $\omega||F_o - |F_c||^2$ independent of the variation in F_o. In the final cycle the average shift/error was 0.05. The standard deviation of an observation of unit weight, $(\Sigma\omega|F_o - F_c|^2/m - n)^{1/2}$, with m equal to the number of reflections used and n the number of variables was 1.01. The secondary extinction parameter refined according to the method of Larson (21) was $c = 2.30 \times 10^{-6}$. Scattering factors for Li^+, V^+ and O^- were taken from ref. 22. Corrections for anomalous dispersion of V were taken from Cromer (23). The final positional and thermal parameters are listed in Table 1 and the observed and calculated structure factors are listed in Table 2.[3] Table 3 lists some pertinent bond distances and angles. The final difference electron density showed no residual peaks of significant magnitude.

Results and Discussion

The pyroxene structure is characteristic of many compositions of the type $MM'X_2O_6$[4] where M = Li, Na, Mg, Fe^{2+}, and Ca; M′ = Li, Na, Mg, Fe^{2+}, Mn^{2+}, Al, Cr^{3+}, Fe^{3+}, Ti^{3+}, Sc^{3+}, and In^{3+}. Electrostatic charge balance generally requires that the combination be $M^+M^{3+}X_2O_6$ or $M_2^{2+}X_2O_6$ for X = Si^{4+} or

[2]The question of the space group of $LiVO_3$ and by analogy spodumene is an intriguing one. In both cases satisfactory structures have been obtained assuming the higher symmetry space group. Although in both cases reflections in violation of the *c*-glide plane have been noted. Both systems have been investigated by nuclear quadrupole (13, 14) resonance and in addition Mn^{2+} and Fe^{3+} in spodumene has been studied by electron paramagnetic resonance (15, 16). The former experiments in spodumene paid particular attention to the space group predictions and the results were consistent with *C*2/*c*. Those studies in $LiVO_3$ (17, 18) were consistent with space group *C*2/*c* except that a weak splitting was noted when the magnetic field was removed from the plane perpendicular to the *c* axis.

Ge^{4+} and $M_2{}^{+}X_2O_6$ for $X = V^{5+}$. There are as yet no examples of P-containing pyroxenes but there does not seem to be any reason why $LiPO_3$ or $NaPO_3$ under certain conditions would not have the pyroxene structure. Reviews of the crystal chemistry of silicate pyroxenes have been published by Prewitt and Peacor (24) and by Zussman (25) and a detailed discussion of the interatomic distances in 8 silicate pyroxenes was recently published by Clark, Appleman, and Papike (12). Zussman summarized the possible space groups: $C2/c$, $P2$, $C2$, $P2_1/c$, $Pbca$, and $Pbcn$. Clark *et al.* (12) concluded that the space group of a particular composition is determined chiefly by size and charge of the M cations: (*1*) large single or doubly charged cations lead to space group $C2/c$, *e.g.* $CaMgSi_2O_6$, $NaAlSi_2O_6$; (*2*) small singly charged cations lead to space group $C2$, *e.g.*, $LiAlSi_2O_6$ and $LiFeSi_2O_6$. (*3*) Small doubly charged cations lead to $P2/c$ or $Pbca$ *e.g.* $MgSiO_3$. Apparently the vanadate pyroxenes do not deviate from these generalities: $LiVO_3$ probably has the $LiAlSi_2O_6$ ($C2$ or $C2/c$) structure whereas $NaVO_3$ has the $NaAlSi_2O_6$ ($C2/c$) structure (2).

The pyroxene structure is generally described in terms of close-packed oxygen layers which are approximately perpendicular to a^* (10). The X ions occupy tetrahedral sites between layers whereas the larger M or M′ ions occupy six-or-eight-coordinated sites in alternate layers. The XO_4 ions are linked by corners to form continuous chains running along the c-axis. As pointed out by Prewitt and Peacor (24), the octahedra share edges to form a band running parallel to the chain. In $NaAlSi_2O_6$ the bonds are linked by the NaO_8 polyhedra whereas in $MgSiO_3$, $LiAlSi_2O_6$, and $LiVO_3$ there is a rift between the bands. Figure 1 shows the bands of Li(1) and Li(2) octahedra and the rift between these bands.

Because this is the first structure refinement of a vanadate pyroxene it is interesting to compare the molecular geometry with those of the corresponding silicates, $LiAlSi_2O_6$ and $LiFeSi_2O_6$ (12). The M2 site is occupied by Li in both cases and, as in all other pyroxenes with octahedral M2 sites, is extremely distorted. In $LiVO_3$ it is even more distorted than in $LiAlSi_2O_6$ with distances of 2.026 (2.105), 2.670 (2.278), and 2.158 Å (2.251 Å) and a mean distance of 2.284 Å (2.211 Å). The values in parentheses refer to $LiAlSi_2O_6$. If the longer bonds were to be ignored the remaining Li(2) environment would

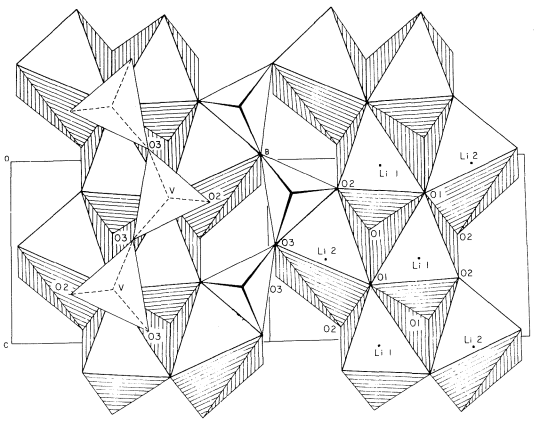

FIG. 1. Polyhedra in $LiVO_3$. The projection is down a^*.

be a distorted tetrahedron with bond angles ranging from 86 to 140°. The M1 site is also more distorted in $LiVO_3$ than $LiAlSi_2O_6$: 2.125 (1.997), 2.339 (1.943), and 1.998 Å (1.818 Å),[5] mean = 2.158 Å. In $LiFeSi_2O_6$ the M1—O(2) distance is shorter than M1—O(1) and in $LiVO_3$ the reverse is true. This is a consequence of replacing Fe^{3+} by Li^+; the Li(1)—O(1) and Li(2)—O(1) distances shorten relative to Li(2)—O(2) and Li(2)—O(2) to compensate for the loss in bond strength. The same interpretation can be made in terms of Pauling's bond strengths (26). According to this scheme O(1) is "underbonded" ($p = 1.70$) and O(2) is "overbonded" ($p = 2.17$); electrostatic balance is achieved by shortening M—O(1) bonds relative to M—O(2) bonds.

One of the most interesting and unusual features of the pyroxene structure is the large differences in mean distances for M1 and M2 sites. Table 4 shows this effect for Li, Mg, and Fe^{2+}. Although Clark *et al.* (12) claim that the mean octahedral distance in $LiAlSi_2O_6$ is in good

*$\bar{R}$ = mean octahedral Mg—O distance.
†*r* = effective ionic radius of Mg^{2+}. $\bar{R} = 2.093 + 8.43\Delta$, correlation coefficient = 0.70, goodness of fit = 0.019. $r = 0.723 + 8.93\Delta$, correlation coefficient = 0.67, goodness of fit = 0.019.
‡Codens for periodical titles, vol. II, ASTM Data Series DS 23A, Phila., 1966.

agreement with other values in the literature, these distances in $LiAlSi_2O_6$ and $LiFeSi_2O_6$ are actually considerably greater. Table 5*a* lists mean Li—O distances in a number of accurately refined crystal structures. The increase in mean distance is apparently caused by the very distorted M2—O polyhedron containing two very long bonds: $LiVO_3$, Li(2)—O(2) = 2.670 Å × 2,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

$LiAlSi_2O_6$, Li—O(2) = 2.278 Å × 2 and in $LiFeSi_2O_6$, Li—O(3) = 2.459 Å × 2. (The fact that the long bond in $LiAlSi_2O_6$ is to O(2) and in $LiFeSi_2O_6$ is to O(3) is not understood.) In most structures containing either very short or very long distances, other bonds lengthen or shorten to compensate. Although this compensation generally results in average bond distances for coordination polyhedra which do not differ greatly from one structure to another, when the distortion becomes severe enough, a distinct dependence of mean bond length on degree of distortion can be observed. This dependence has been noted for Cu^{2+}—O and V^{5+}—O octahedra by Brown and Shannon (30) and is a consequence of the shape of the bond strength – bond length curve. For Li^+—O and Mg^{2+}—O bonds:

$$S_{Li—O} = 0.25\left(\frac{1.954}{R}\right)^{3.9}$$

$$S_{Mg—O} = 0.333\left(\frac{2.098}{R}\right)^{4.0}$$

These curves are shown in Fig. 2. As the deviation of the bond lengths from an undistorted polyhedra increase, keeping the average bond strength constant, the mean bond length must necessarily increase. In Tables 5*a* and 5*b* we have listed the mean bond lengths for a number of Li—O and Mg—O octahedra and their distortions from their mean bond length $\bar{R}$. In Figs. 3*a* and 3*b* the effective ionic radii (r) of Li^+ and Mg^{2+} have been plotted *vs.* the distortion.[6] Linear regression analyses of $\bar{R}$ and r on distortion result in correlation coefficients of about 0.70 with mean deviations of experimental from the calculated values of 0.035 Å for Li and 0.019 Å for Mg. The corresponding analyses for Cu^{2+} and V^{5+} resulted in correlation coefficients of 0.89 and 0.98, respectively, and mean deviations of the order of 0.01 Å (29). The dependence of mean bond length on distortion is easier to observe as the distortions increase; thus, there is a better fit for Cu^{2+} and V^{5+} (distortions up to 0.040 Å have been observed). Although all of the variations in Li—O and Mg—O mean bond lengths are not explained by distortion, distortion is apparently a significant factor.

In the VO_4 tetrahedra there are two bridging oxygens at 1.795 and 1.821 Å and two nonbridging oxygens at 1.628 and 1.662 Å from the vanadium ion. These distances are consistent with Baur's scheme for calculating distances from electrostatic bond strength sums around oxygen atoms (32). Table 6 shows comparison of observed and predicted distances based on an

[6]The effective ionic radius (r) is calculated by subtracting the appropriate oxygen radius from the mean bond length, $\bar{R}$ as described previously (31).

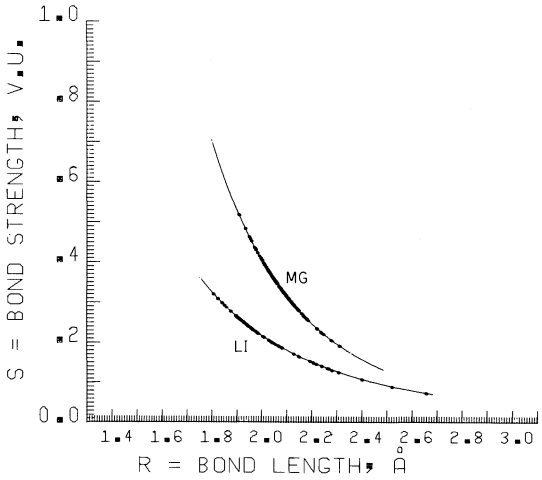

FIG. 2. Bond length – bond strength curves for Li—O and Mg—O. The individual points represent calculated bond strengths from which the curve was derived.

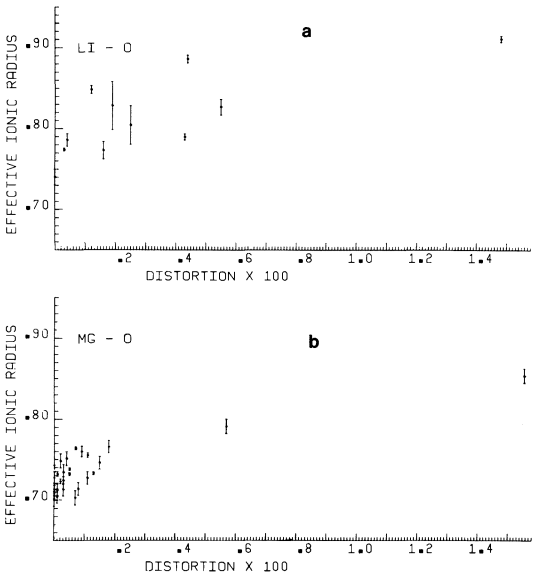

FIG. 3. (*a*) Effective ionic radius of octahedral Li^+ *vs.* distortion. Distortion is defined as $\langle(\Delta R/R)^2\rangle$ and vertical bars represent average e.s.d.'s quoted by authors; (*b*) effective ionic radius of octahedral Mg^{2+} *vs.* distortion.

*Bond strengths calculated from eqs. 1 and 2 in Table 8.
†Bond strengths calculated according to Pauling's electrostatic valence principle: s = valence/CN.

equation similar to Baur's (33). The agreement is excellent with an average deviation of only 0.01 Å. Since Pauling's bond strengths are determined only by cation coordination numbers and are thus average bond strengths, rather large deviations of the anion sums from 2.0 are usually found. Using eqs. 1 and 2 in Table 8 derived from a large number of Li- and V-containing compounds to calculate bond strengths (29), Pauling's electrostatic valence principle is verified with an average deviation of about 5% from the ideal values of 1.0 for Li^+, 5.0 for V^{5+}, and 2.0 for O^{2-} (Table 7). The calculations made on $LiFeSi_2O_6$ show an average deviation of 5%. It should be noted, however, that these empirical curves as well as Pauling's classical scheme show O(2) to be "underbonded" and O(3) to be "overbonded".

In $LiM^{3+}Si_2O_6$ and $NaM^{3+}Si_2O_6$ structures, the silicate chains are relatively straight; the O(3)—O(3*a*)—O(3) angles range from 170° to 180°. In $LiVO_3$ the VO_4 chains are more kinked; the O(3)—O(3*a*)—O(3) angle is 161.8°. This deviation from linearity can be explained by reference to the relative strengths of the bonds to O(3) and O(2) (see Table 7). Referring to the lowest tetrahedron in the chain with apices pointing up in Fig. 1, a decrease in bond strengths of M(1)—O(2) and M(2)—O(2) will tend to rotate the tetrahedron clockwise and decrease the O(3)—O(3*a*)—O(3) angle from 180°; a decrease in the strength of M(2)—O(3) would have the opposite effect. Thus replacing Fe^{3+} or Al^{3+} by Li^+ will decrease the strength of M(1)—O(2) and decrease the O(3)—O(3*a*)—O(3) angle. In Table 8 it is apparent that the major change in bond strengths occur when going from $LiAlSi_2O_6$ or $LiFeSi_2O_6$ to $LiVO_3$ but in addition all the other bond strengths follow the trend indicated above.

Table 9 shows the root mean squared (r.m.s.) amplitude of vibrations for Li(1) and Li(2) in $LiVO_3$ together with the angles of the principal axes of the thermal disorder tensor. In $LiAlSi_2O_6$ the ratio of the largest to the smallest r.m.s. amplitude for the Li^+ site is 1.2 (11) compared with a factor of about 1.9 for both Li^+ sites in $LiVO_3$. Further the directions of the maximum amplitude for both Li^+ sites nearly coincide with that of the longest Li—O bond in the octahedron in each case thus suggesting positional disorder for these cations. In both cases these directions nearly parallel the c^* axis. One can easily move the Li(1) and Li(2) ions off the

TABLE 9. Magnitude and orientation of thermal ellipsoids for Li ions in $LiVO_3$

Li(1)					Li(2)				
	r.m.s. amplitude (Å)	Angle (deg) of r_i with				r.m.s. amplitude (Å)	Angle (deg) of r_i with		
i	r_i	*a*	*b*	*c*	*i*	r_i	*a*	*b*	*c*
1	0.223	88.98	90.00	21.50	1	0.230	83.64	90.00	165.88
2	0.116	90.00	0.00	90.09	2	0.130	173.64	90.00	75.88
3	0.115	1.02	90.00	111.50	3	0.128	90.00	0.00	90.00

two-fold axes, destroying this element of symmetry, yielding Li ions with five moderately strong bonds and one additional long bond. Such a displacement for Li(2), directly towards O(2*e*), shortening the Li(2)—O(2*e*) distance by 5% yields a bond strength for this ion of precisely 1.00. A comparable displacement in Li(1), shortening the Li(1)—O(1*a*) separation, increases an already high value for the bond strength of this cation. In $NaAlSi_2O_6$, $NaCrSi_2O_6$, $NaFeSi_2O_6$, and $CaMgSi_2O_6$ (11) the M2 ion also shows enhanced disorder although because the cation is now coordinated to eight oxygen atoms the direction of the maximum displacement no longer nearly coincides with *c**. It appears that a low temperature structural study might be needed to resolve these questions regarding the nature of the disorder.

The *a**, *b*, and *c* parameters reported by Feigelson *et al.* (5) agree with those reported here although β and the *a* axis length do not. Furthermore, their powder pattern of $LiVO_3$ except for the lines at $d = 3.15$ and 2.370 Å agrees with ours. Thus it is likely that the two compounds are the same and if so, their proposed study of the non-linear optic properties of these crystals might indicate whether the crystals indeed have the centro-symmetric space group proposed here.

We would like to thank Mrs. C. F. Foris and Dr. J. F Whitney of the Central Research Laboratory, E. I. du Pont de Nemours, Wilmington, Delaware for assistance with the Guinier photographs, A. Ferretti and J. Moore, also of du Pont, for preparation of the crystals, and R. Faggiani of McMaster University for assistance in collecting the intensity data. We are also grateful to C. T. Prewitt for preparing the projection of $LiVO_3$ shown in Fig. 1. This research was supported by the National Research Council of Canada.

Further N.M.R. Studies of the Dynamic Stereochemistry of π-Allylic Palladium(II) – Tertiary Phosphine Systems[1]

M. Oslinger and J. Powell

Lash Miller Chemical Laboratory, University of Toronto, Toronto 181, Ontario

Received June 20, 1972

A series of cations of the type 1,2-bis(diphenylphosphino)ethane(π-all)palladium(II) (all = allyl, 2-methylallyl, 2-tert-butylallyl, 1-methylallyl, 1,1-dimethylallyl, *syn*-1-tert-butyl-2-methylallyl) have been isolated as PF_6^- and/or BF_4^- salts. Variable temperature n.m.r. data fully substantiate the proposal that pyridine promoted exchange of *syn* and *anti* proton sites in such complexes occurs via a $\pi \rightarrow \sigma \rightarrow \pi$ mechanism that involves consecutive S_N2 ligand substitutions. Comparison of this variable temperature n.m.r. data with that obtained for the complexes 1,2-bis(diphenylphosphino)ethane(π-all)palladium(II) chloride (prepared *in situ*) has shown that the chloride ion, functioning as a nucleophile, is also effective in promoting $\pi \rightarrow \sigma \rightarrow \pi$ reactions. Studies of bis(dimethylphenylphosphine) (π-1,1-dimethylallyl)palladium(II) chloride in $CDCl_3$ below $-30°$ have shown that rapid consecutive S_N2 substitution reactions, in which chloride acts as a nucleophile, are also occurring in systems containing monodentate tertiary phosphine ligands. As such the PR_3 promoted *syn–syn* and *anti–anti* proton site interchange observed in complexes of the type [(π-2-methylallyl)PdCl(PR_3)] has been reinterpreted in terms of consecutive ligand substitution reactions involving PR_3 and Cl ligands instead of the original proposal which involved an in plane rotation of the π-allylic ligand.

Une série de cations du type bis(biphényl phosphino)-1,2 éthane (π-all)palladium(II) (π-all = groupement allylique, méthyl-2 allyle, tert-butyl-2 allyle, méthyl-1 allyle, diméthyl-1, 1 allyle tert-butyl-1 méthyl-2 *syn* allyle) a été isolée comme des sels de PF_6^- et/ou BF_4^-. Des données provenant de la r.m.n. à température variable renforcent pleinement l'hypothèse selon laquelle l'échange des protons des sites *syn* et *anti*, favorisé par la pyridine dans de tels complexes, s'effectue selon un mécanisme $\pi \rightarrow \sigma \rightarrow \pi$ impliquant consécutivement des substitutions S_N2 des coordinats. La comparaison des données de la r.m.n. à température variable avec celles obtenues pour les complexes du chlorure de bis-(biphényl phosphino)-1,2 éthane(π-all)palladium(II) (préparés *in situ*) a indiqué que l'ion chlorure agissant comme un nucléophile est aussi capable d'induire des réactions $\pi \rightarrow \sigma \rightarrow \pi$. Des études du chlorure de bis(diméthyl phényl phosphine)(π-diméthyl-1,1 allyl)palladium(II) dans le $CDCl_3$ en dessous de $-30°$ ont montré que les réactions rapides et consécutives de substitution S_N2, dans lesquelles la chlorure agit comme un nucléophile, se produisent aussi dand des systèmes contenant des monocoordinats de phosphine tertiaire. Comme telle l'action du PR_3 favorisant l'échange mutuel des protons des sites *syn–syn* et *anti–anti* observé dans les complexes du type [(π-méthyl-2-allyl)PdCl(PR_3)] a été repensée en termes d'une succession de réactions de substitution des coordinats impliquant les coordinats PR_3 et Cl au lieu de l'hypothèse initiale qui impliquait une rotation dans le plan des coordinats allyliques. [Traduit par le journal]

Can. J. Chem., **51**, 274 (1973)

Introduction

Since 1965, the dynamic stereochemistry of π-allylic palladium(II) halide/tertiary phosphine systems has received considerable attention (1–7). Two basic allylic proton site exchange processes are observable by p.m.r. studies of such systems. The first, involving *syn–anti* proton site exchange, has been clearly shown to occur via a short lived σ-allylic intermediate (1–8). The second process is *syn–syn* and simultaneous *anti–anti* proton site exchange. An exchange process of this type is observed on addition of PR_3 to $CDCl_3$ solutions of [(π–2–methylally)PdCl(PR_3)] (**1**); PR_3 = PPh_3, PMe_2Ph, $PMePh_2$, PEt_3 at PR_3/Pd ratios between 1.0 and 1.5 (1–5). The mechanistic pathway of this process is not clearly defined. Vrieze *et al.* (2–4) have proposed that the observed rapid exchange of *syn* protons 1 and 4 and *anti* protons 2 and 3 in **1** occurs via addition of PR_3* to give a square pyramidal intermediate (**2**) in which PR_3* occupies an axial position. A postulated 120° "in plane rotation" of the π-2-methylallyl ligand, followed by loss of the *originally co-ordinated* PR_3 (now in an axial position) results in 1–4 and

[1]Taken from the thesis of M. Oslinger, submitted to the Faculty of Graduate Studies, University of Toronto, in partial fulfillment of the requirements for the M.Sc. degree.

2–3 exchange. This proposal, ascribing fluxional characteristics to the π-allyl-palladium bond, is worthy of further investigation if we hope to understand the mechanism of catalytic processes involving allylic intermediates. It should be noted that the fluxional model proposed by Vrieze *et al.* (2–4) to explain *syn–syn* and *anti–anti* proton exchange in tertiary phosphine complexes of palladium(II) is not supported by direct chemical evidence. Although kinetic studies show that *syn–syn* and *anti–anti* proton exchange is first order in both monomer **1** and added PR_3, no definitive description of the intermediate can be made. The only justification proposed for a pseudorotation of the allylic ligand within a five coordinate intermediate is based on a molecular orbital treatment. Criticism of this approach centers on the assumption made that π-allyl palladium chloride complexes can be treated in an analogous fashion to sandwich compounds such as $(C_6H_6)Mo(CO)_3$ in which rapid in plane rotation of the π-benzene ligand is known to occur and for which molecular orbital calculations have been performed (9).

The inherent difficulty with the systems studied by Vrieze is that the observed *syn–syn* and *anti–anti* proton exchange cannot be related to the absolute motion of any one ligand, *i.e.*, movement of the allylic ligand (rotation) with respect to the other ligands (PR_3, Cl) cannot be distinguished from ligand exchange of PR_3 and Cl with respect to a stationary allylic ligand; either situation would result in the observed *syn–syn* and *anti–anti* proton exchange. In fact, all that one can conclude is that the allylic ligand moves *relative* to PR_3 and Cl such that each end of the allylic ligand sees a different *trans* ligand. Therefore, a real rotation of the allylic group, if it exists, cannot be demonstrated directly in the p.m.r. spectrum.

Tibbetts and Brown (7) focused their attention on the movements of the allylic ligand by em-

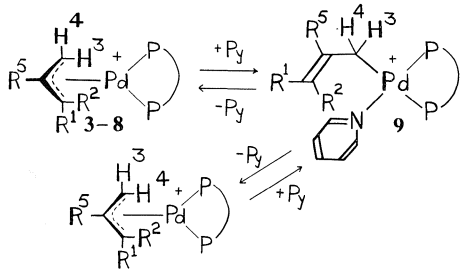
ploying the firmly bound chelating diphos ligand in (**3**). The scalar couplings of ^{31}P with the protons of the 2-methylallyl ligand provided a means by which the two ends of the 2-methylallyl group could be distinguished. Addition of pyridine to **3** in $CDCl_3$ promoted rapid *syn–anti* proton site exchange via the series of consecutive ligand substitution processes outlined in Scheme 1. The



SCHEME 1. Mechanism of pyridine promoted exchange of protons 3 and 4 in the cationic complex $[(\pi\text{-all})Pd(diphos)]^+PF_6^-$.

absence of *syn–syn* and *anti–anti* proton exchange in the **3**/pyridine system prompted Tibbetts and Brown (7) to question the concept of rotation of the π-2-methylallyl ligand previously suggested by Vrieze (2–4). However, an important feature of Vrieze's mechanism is that 1–4 proton exchange and 2–3 proton exchange, *and* PR_3 ligand exchange in **1** are synonymous. In fact, in complexes such as **3** where ligand exchange between diphos and pyridine would not occur on the p.m.r. time scale owing to the stability of the chelating diphos ligand, the mechanism proposed by Vrieze predicts that a rapid in plane rotation of the π-2-methylallyl ligand would *not* occur. Thus the results of Tibbetts and Brown cannot be extrapolated to the monotertiary phosphine systems **1** where rapid PR_3 exchange is occurring.

The advantages of a complex such as **3** in studying π-allylic proton exchange (*i.e.*, the inertness of the diphos ligand to exchange and the *cis* and *trans* phosphorus 31 couplings to the protons of the allylic ligand) are attractive. As such we have prepared a series of π-allylic complexes analogous to **3** and tested the generality of the results obtained by Tibbetts and Brown. By progressively extending our p.m.r. studies from $[(\pi\text{-all})Pd(diphos)]PF_6$/pyridine systems to $\{[(\pi\text{-all})PdCl]_2 + 2diphos\}$ systems and to $\{[(\pi\text{-all})PdCl]_2 + 4PR_3\}$ systems (all = allyl, 2-methylallyl, 2-tert-butylallyl, *syn*-1-methylallyl, *syn*-1-tert-butyl-2-methylallyl, 1,1-dimethylallyl; PR_3 = Me_2PhP, Ph_3P) we have obtained sufficient evidence to show that the observed *syn–syn* and *anti–anti* proton site exchange in $[(\pi\text{-all})PdCl(PR_3)]/PR_3$ systems is in fact due to rapid consecutive S_N2 ligand substitution processes rather than a low energy in plane rotation of the π-allylic ligand.

Results and Discussion

Intramolecular Motions Occurring in a Series of $[(\pi\text{-all})Pd(diphos)]PF_6$/Pyridine Systems

The π-allylic palladium(II) diphos salts **3–8** were prepared in a manner analogous to Tibbetts and Brown (7) (reaction 1).

$$[1]\quad \tfrac{1}{2}[(\pi\text{-all})PdCl]_2 + \text{diphos} + NH_4PF_6 \xrightarrow{CHCl_3} [(\pi\text{-all})Pd(diphos)]PF_6 + NH_4Cl$$

All the salts were isolated as air stable, white crystalline solids. Complexes **3–7** were sufficiently soluble in $CHCl_3$ for p.m.r. purposes. However, the hexafluorophosphate of **8** [$X^- = PF_6^-$] was very insoluble in chloroform. As such, the tetrafluoroborate salt ($X^- = BF_4^-$) was prepared; the enhanced solubility of this latter salt enabled a p.m.r. spectrum to be recorded.

The p.m.r. data for the allylic protons in complexes **3–8** are tabulated in Table 1. The assignment of the proton resonances is based on the coupling of the *syn* protons (1 and 4) and *anti* protons (2 and 3) with the central allylic proton 5 and the *cis* and *trans* phosphorus atoms of the diphos ligand; these coupling constants agree well with previously reported values (5, 7). The *syn*-1-tert-butyl-2-methylallyl and 1,1-dimethylallyl complexes, **4** and **5**, are particularly useful in that the p.m.r. spectrum of each may be interpreted by a simple first order treatment.

The major ^{31}P coupling constants (c s^{-1}) for the *syn*-1-tert-butyl-2-methylallyl protons in **4** (Fig. 1(*a*)) are: H_2, $J_{P_{trans}} = 10$, $J_{P_{cis}} = 1.5$; H_3, $J_{P_{trans}} = 10$, $J_{P_{cis}} < 1$; H_4, $J_{P_{trans}} = 8$, $J_{P_{cis}} < 1$. For the 1,1-dimethylallyl protons of **5** (Fig. 2(*a*)), the major ^{31}P coupling constants (c s^{-1}) are: H_3, $J_{P_{trans}} \sim 10$, $J_{P_{cis}} < 1$; H_4, $J_{P_{trans}} \sim 8$, $J_{P_{cis}} < 1$; Me_7, J_P,s = 9.5 and 8.5; Me_8, J_P,s = 6.5 and 6.5. *trans*-^{31}P coupling to protons H_3 and H_4 are approximate owing to the broadness of the resonances. Furthermore, one cannot assign definitively the *cis* and *trans* ^{31}P coupling constants to the *syn* methyl protons; *cis* and *trans* ^{31}P couplings to the *anti* methyl protons are equal,

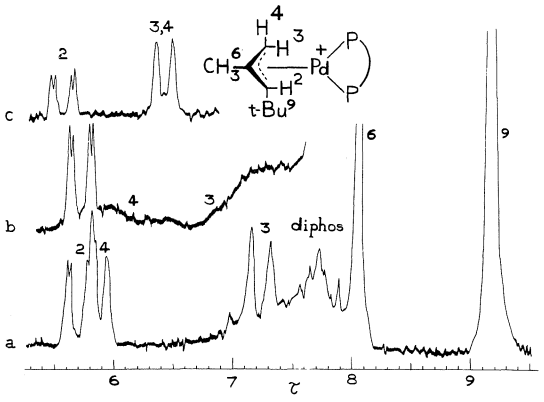


FIG. 1. The ^{1}H n.m.r. spectra of a 0.55 *M* solution of [(*t*-BuCH=C(Me)=CH$_2$)Pd(diphos)]$^+$PF$_6^-$ (**4**): (*a*) in $CDCl_3$ at 34°; (*b*) in $CDCl_3$ at 34° in the presence of 1 mol of pyridine per Pd atom; (*c*) in neat pyridine at 80°.

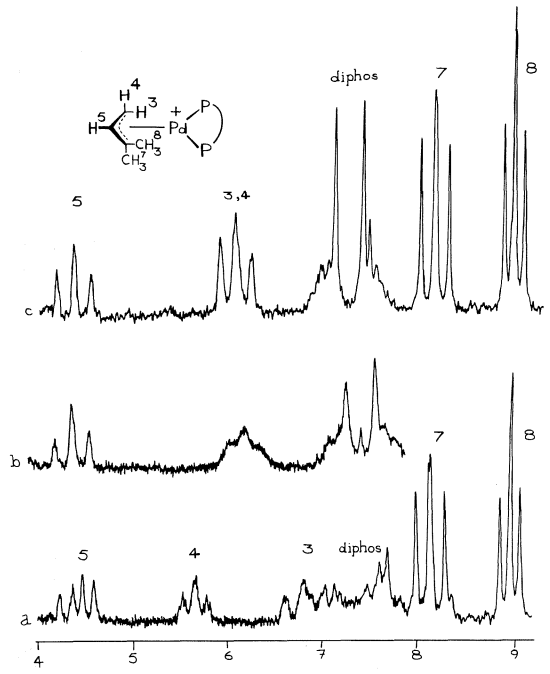

FIG. 2. The ^{1}H n.m.r. spectra of a 0.55 *M* solution of [(Me$_2$C=CH=CH$_2$)Pd(diphos)]$^+$PF$_6^-$ (**5**): (*a*) in $CDCl_3$ at 34°; (*b*) in $CDCl_3$ at 34° in the presence of one mol of pyridine per Pd atom; (*c*) in neat pyridine at 34°.

within experimental error, and the absorption is a 1:2:1 triplet.

The p.m.r. pattern of the 1-methylallyl protons in **6** is more difficult to assign owing to the very broad, ill-defined resonances observed; only the coupling pattern for the *syn*-methyl protons can be assigned with certainty (Table 1).

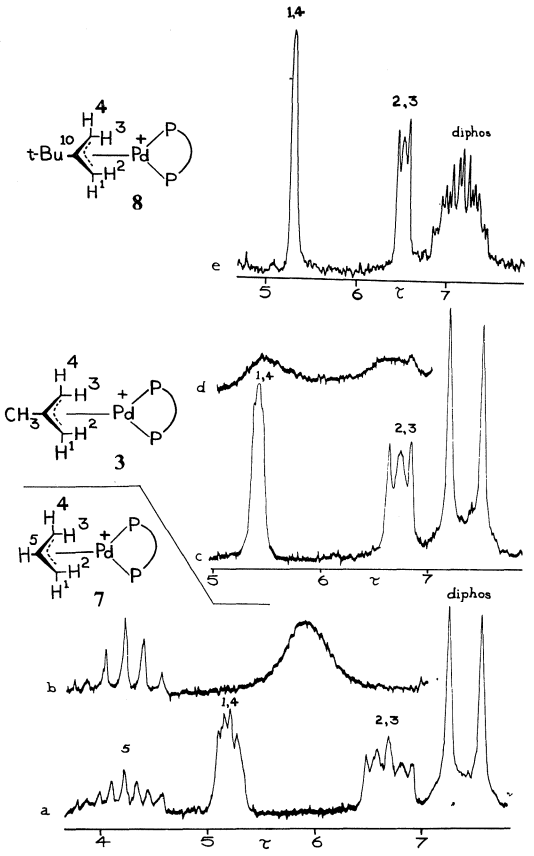

FIG. 3. The 60 MHz ^{1}H n.m.r. spectra of 0.55 *M* $CDCl_3$ solution of the complexes [(π-all)Pd(diphos)]$^+$PF$_6^-$ recorded at 34°; (*a*) π-all = π-allyl (complex **7**); (*b*) **7** plus one mol of pyridine per Pd atom; (*c*) π-all = π-2-methylallyl (complex **3**); (*d*) **3** plus 4 mol pyridine per Pd atom; (*e*) π-all = π-2-tert-butyllallyl (complex **8**) (a 0.25 *M* $CDCl_3$ solution recorded on a 100 MHz spectrometer). The line shape of the *syn* protons (1 and 4) and the *anti* protons (2 and 3) are only slightly affected by the addition of ten pyridines per Pd atom.

The p.m.r. spectrum of **7** is broad and of second order complexity (Fig. 3(*a*)). Only $J(H_{1,4}–H_5)$ and $J(H_{2,3}–H_5)$ were estimated (Table 1). No attempt was made to determine the *cis* and *trans* ^{31}P coupling constants to the terminal allylic protons in complexes **7** and **8**. As discussed by Tibbetts and Brown (7) for complex **3**, such spectra require computer analysis of the resonance shape to determine the coupling constants. However, a comparison of the spectra of **7** and **8** with that of **3** suggests ^{31}P coupling constants of a similar magnitude (see Fig. 3).

Addition of pyridine (one molecule per Pd atom) to a 0.55 *M* solution of **4** in $CDCl_3$ at 34° resulted in the broadening of the resonances of

protons 3 and 4. Proton 2 remained sharp and strongly coupled to the *cis* and *trans* ^{31}P nuclei (Fig. 1(*b*)). In neat pyridine at 80°, protons 3 and 4 gave rise to a sharp doublet ($J_{P\,trans}$ = 9 c s^{-1}) while proton 2 remained coupled to stereochemically distinct *cis* and *trans* ^{31}P (Fig. 1(*c*), Table 2).

Similarly, addition of pyridine (one molecule per Pd atom) to a 0.55 *M* chloroform-*d* solution of **5** at 34° resulted in a very broad "triplet" resonance for protons 3 and 4 while *cis* and *trans* ^{31}P coupling to the *syn* and *anti* methyl protons is preserved; proton 5 became a 1:2:1 triplet owing to coupling with protons 3 and 4 which were equivalent on the p.m.r. time scale (Fig. 2(*b*)).

In neat pyridine at 34°, the resonance for protons 3 and 4 is resolved as a broad triplet ($J(H_5–H_{3,4} \sim 11$ c s^{-1}, $J(P_{trans}–H_{3,4}) \sim 9$ c s^{-1}) while distinct *cis* and *trans* ^{31}P coupling to the *syn* and *anti* methyl protons is retained (Fig. 2(*c*), Table 2).

The addition of pyridine (one molecule per Pd atom) to 0.55 *M* chloroform-*d* solutions of **6** and **7** at 34° resulted in the collapse of resonances 3 and 4 of both spectra into a very broad single resonance (*e.g.* Fig. 3), the coupling pattern ($J(H_5–H_{3,4})$; $J(P_{trans}–H_{3,4})$) is not resolved at this stage. A higher concentration of pyridine (pyr/Pd = 4) was necessary to effect rapid *syn–anti* proton exchange in a 0.55 *M* chloroform-*d* solution of **3** (Fig. 3) while a still higher concentration of pyridine is required to effect rapid *syn–anti* proton exchange in **8**. (*e.g.* see Fig. 3). Pyridine promotion of rapid *syn–anti* proton exchange without interchange of the positions of the terminal allylic carbon atoms relative to the diphos ligand (N.B. distinct *cis* and *trans* ^{31}P coupling to allylic protons is retained in the region of fast 3–4 exchange) in the complexes **3–8** fully corroborate the findings of Tibbetts and Brown (7) in their work with complex **3** and pyridine. All the results are consistent with the concerted displacement of one end of the allylic ligand (the most substituted terminal allylic carbon in the case of complexes **4**, **5**, and **6**) by pyridine to give a short-lived σ-allylic intermediate **9**. Intermediate **9** may reform a π-allylic complex in one of the two ways thereby affecting site interchange of protons 3 and 4 as outlined in Scheme 1. During this process R_1 and R_2 retain the same configuration relative to the diphos ligand, hence distinct *cis* and *trans* ^{31}P coupling is observed for the proton resonances of R_1 and R_2 in the region of rapid *syn–anti* proton exchange. The strong *trans* ^{31}P coupling to protons 3 and 4 in neat pyridine for **4** and **5** is intermediate between $J(P_{trans}–H_3)$ and $J(P_{trans}–H_4)$ observed in the absence of exchange.

Under identical conditions of complex concentration (0.55 *M*), temperature (34°), and pyridine concentration (pyr/Pd = 1), the 1,1-dimethylallyl ligand in **5** undergoes *syn–anti* (3–4) proton exchange faster than either the 1-methylallyl or allyl ligands in **6** and **7** respectively. This is evidenced by the fact that the resonance pattern of protons 3 and 4 in **5** is approaching the fast exchange limit and coupling with the *trans* ^{31}P nucleus and protons is clearly resolved (see Fig. 2(*b*)), whereas under identical conditions of concentration and temperature the resonance patterns of protons 3 and 4 in **6** and **7** consist of a very broad single resonance typical of an intermediate exchange close to the region of coalescence. Under these same conditions, protons 3 and 4 in **4** have broadened but not coalesced while in **3** and **8**, no exchange is observed until higher concentrations of pyridine are added (*e.g.*, see Fig .3).

On the basis of such studies, a qualitative order can be cited for the relative ease of formation of the σ-allylic intermediate **9** with respect to the allylic ligand present in the complex. The ease of formation of **9** decreases in the order 1,1-dimethylallyl > 1-methylallyl ~ allyl > 1-tert-butyl-2-methylallyl > 2-methylallyl > 2-tert-butylallyl.

This order agrees well with previous studies on allylic ligand substituent effects on the rate of *syn–anti* proton exchange in the complexes [(π-all)Pd(OAc)(PMe_2Ph)] (8, 10).

Intramolecular Motions Occurring in π-Allylic Palladium Chloride – Diphos Systems at Diphos:Pd Ratios of 1:1

Because of its stability and non-lability, it was expected that the diphos ligand would occupy two coordination sites in the square plane when added to a solution of (π-all)palladium chloride (one molecule of diphos per Pd atom). If the allylic ligand occupied the remaining two coordination sites (π-allylic) in the square plane, then a species structurally analogous to the cation of complexes **3–8** would be formed. For this situation, the position of the chloride ligand relative to the square plane became of considerable interest in that it seemed reasonable that the chloride ligand might parallel the behavior of pyridine with the salts **3–8**. To explore this possi-

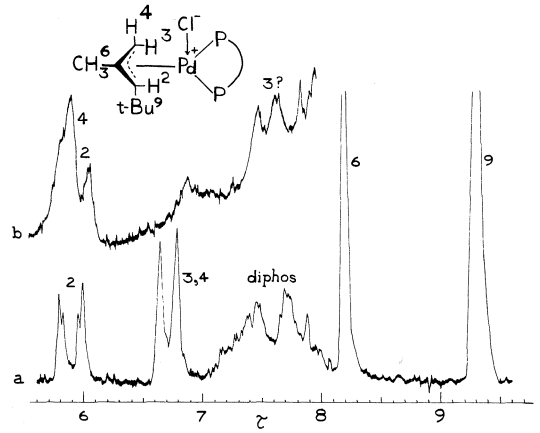

FIG. 4. The ^{1}H n.m.r. spectra of a 0.44 *M* $CDCl_3$ solution of [(*t*-BuCH=C(Me)=CH_2)Pd(diphos)Cl] (*a*) at 34° (compare with Fig. 1*c*); (*b*) at −60°.

bility, the p.m.r. spectra of a series of (π-all)palladium chloride – diphos adducts (π-all = 1-tert-butyl-2-methylallyl, 1,1-dimethylallyl, 1-methylallyl, allyl, and 2-methylallyl) were investigated.

At 34°, the p.m.r. spectrum of a 0.44 *M* chloroform-*d* solution of *syn*-1-tert-butyl-2-methylallyl palladium chloride in the presence of one molecule of diphos per Pd atom (Fig. 4(*a*), Table 3) shows a coupling pattern that is identical to that observed for **4** in neat pyridine (Fig. 1(*c*), Table 2). The major coupling constants (c s^{-1}) for the *syn*-1-tert-butyl-2-methylallyl protons are: proton 2, $J(P_{trans}–H_2) = 10$; $J(P_{cis}–H_2) = 1.5$; protons 3 and 4 (equivalent on the p.m.r. time scale), $J(P_{trans}–H_{3,4}) = 9$. These values indicate that a rapid 3–4 proton exchange is occurring *without* the loss of *cis* and *trans* ^{31}P coupling to the terminal *syn*-1-tert-butyl-2-methylallyl protons. At −60°, protons 3 and 4 are seen as separate resonances (Fig. 4(*b*)).

The *syn*-1-tert-butyl-2-methylallyl proton resonances have broadened extensively at this low temperature; this broadening, which is characteristic of all the low temperature [(π-all)Pd(diphos)Cl] spectra recorded, may be attributed to salt formation and/or viscosity effects (see later in Discussion section).

The major coupling constants (c s^{-1}) for the p.m.r. spectrum of 1,1-dimethylallyl palladium chloride and diphos (one molecule of diphos per Pd atom) in a 0.44 *M* chloroform-*d* solution recorded at 34° are: protons 3 and 4 (equivalent on the p.m.r. time scale), $J(H_5–H_{3,4}) = 11$, $J(P_{trans}–H_{3,4}) \sim 10$; *syn* methyl protons, $J(P_{cis,\ trans}–CH_{3(7)}) = 9.5, 9.5$; *anti* methyl protons, $J(P_{cis,\ trans}–CH_{3(8)}) = 6.5, 6.5$ (Fig. 5(*a*), Table 3). This spectrum exhibits an almost *identical* coupling pattern to that observed for **5** in neat pyridine at 34° (Fig. 2(*c*), Table 2).[2] At −60°, protons 3 and 4 are seen as separate, broad resonances (Fig. 5(*b*)).

Although the p.m.r. spectral patterns are more complex, similar behavior is observed when other (π-all) palladium chlorides (π-all = allyl, 1-methylallyl, and 2-methylallyl) are added to diphos (one molecule per Pd atom) in chloroform-*d* at 34°, (*i.e.*, rapid 3–4 proton exchange occurs with retention of distinct *cis* and *trans* phosphorus couplings to the terminal allylic protons. At low temperatures, protons 3 and 4 separate into two distinct absorptions while the overall spectrum is characterized by broadened proton resonances).

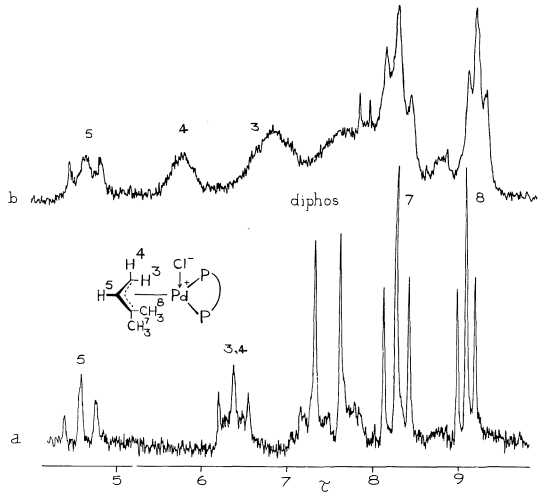

FIG. 5. The ^{1}H n.m.r. spectra of a 0.44 *M* $CDCl_3$ solution of [(Me_2C=CH=CH_2)Pd(diphos)Cl] (*a*) at 34° (compare with Fig. 2*c*); (*b*) at −60°.

[2]The similar magnitude of *cis* and *trans* ^{31}P coupling to the *syn*-methyl protons and also to the *anti*-methyl protons is confusing in that it could be taken to imply that the 1,1-dimethylallyl ligand is undergoing a site exchange relative to the ^{31}P nuclei of the diphos ligand. However, if this were the case the resonance pattern of protons 3 and 4 in the region of fast 3–4 exchange should consist of a doublet of triplets owing to coupling to H^5 and two equivalent ^{31}P nuclei. In fact the resonance pattern consists of a broad 1:2:1 triplet owing to coupling to H^5 and the *trans* ^{31}P nucleus.

The above p.m.r. data shows that phosphorus coupling to the terminal allylic protons is retained during the rapid *syn–anti* proton exchange process for each diphos–chloride system studied. This is consistent with bidentate coordination of diphos to palladium throughout the exchange process and the absence of site exchange for the terminal allylic carbons with respect to diphos. Retention of ^{31}P coupling to the allylic protons indicates that the allylic group is π-bonded to palladium a majority of the time. The close correlation of p.m.r. data (J(P–H), J(H–H)) in Tables 2 and 3 also suggests a structural similarity between the cationic species in complexes **4** and **5** and the major solution species in the analogous diphos–chloride systems. As such we propose that the major solution species in the diphos–chloride systems is **10** in which the chloride ligand occupies a fifth coordination site along the z-axis of the coordination plane, (*i.e.*, the chloride ion is closely associated with palladium, rather than being solvated by chloroform; species **10** may be considered as a contact ion pair, or a square pyramidal, five coordinate complex with a weak Pd—Cl bond in the axial position). The structure of **10** is analogous to the solid state structure of [(π-2-methylallyl)NiBr(diphos)] as determined by X-ray crystallography (11). This complex is square pyramidal with Br occupying an axial position. The Ni—Br bond length of 2.671 ± 0.002 Å is unusually long and may be equated with ionic character. That the Pd—Cl bond in **10** is weak is corroborated by conductivity studies of these systems in polar solvents such as acetone in which the ionic species **11** are formed:

$$[(\pi\text{-all})\text{Pd(diphos)Cl}] \underset{\longleftarrow}{\xrightarrow{\text{polar solvent S}}} [(\pi\text{-all})\text{Pd(diphos)}]^{+}(S)_x + Cl^{-}(S)_y$$

10 **11**

Previously Vrieze and co-workers (3) have shown that salt formation in π-2-methylallyl palladium chloride – triphenylphosphine systems in chloroform was only significant at very low temperatures. Therefore, owing to the poor solvation properties of chloroform at higher temperatures (34°), it is likely that the chloride ligand is not completely solvated but closely associated with palladium as formulated in **10**. The broadening of the allylic proton resonances, as observed in the p.m.r. of these systems at −60°, could possibly be attributed to salt formation such as **11**.

The far infrared spectrum of an equimolar mixture of (π-2-methylallyl) palladium chloride and diphos in chloroform does not show any strong absorptions in the region 325–250 cm^{-1} (see Table 4). This further substantiates the p.m.r. evidence that a normal "in plane" Pd—Cl bond is no longer present (ν(Pd—Cl) = 281 cm^{-1} in [(2-methylallyl)PdClPPh$_3$] (5)) and is consistent with the formulation of **10** as the major solution species.

With **10** as the major solution species, Scheme 2 depicts the proposed mechanism of *syn–anti* proton exchange in the diphos–chloride systems. The formation of a short-lived σ-allylic intermediate **12** is effected by the nucleophilic attack of the axial chloride on the substituted terminal allylic carbon. The π-allylic complex may be reformed in one of two ways thereby effecting site exchange of protons 3 and 4. By this mechanism, *cis* and *trans* ^{31}P coupling to the terminal protons is preserved. This mechanism is analogous to that proposed for the pyridine promoted exchange of protons 3 and 4 in the hexafluorophosphate salts (Scheme 1).

The initiation of *syn–anti* proton exchange by the solvent chloroform can be excluded on the basis that no proton exchange processes occurred for the analogous complexes **3–8** in chloroform in the absence of pyridine.

When an approximate equimolar amount of [(π-all)Pd(diphos)Cl] is added to $CDCl_3$ solutions of its [(π-all)Pd(diphos)]$^{+}PF_6^{-}$ analog equivalence of all the *syn*-protons and equivalence of all the *anti*-protons is observed together with *syn–anti* proton site exchange. This indicates that intermolecular exchange of chloride ion is fast on the n.m.r. time scale.

Further Investigations of Tertiary Phosphine Promoted Proton Exchange Mechanisms in Complexes of the Type [(π-all)PdCl(PR$_3$)]

The correlation between pyridine and chloride in terms of their nucleophilicity toward the π-allylic–palladium bond strongly suggests that analogous substitution processes should be important in dynamic (π-all) palladium chloride – mono tertiary phosphine systems.

The p.m.r. spectrum for the adduct of (π-1,1-dimethylallyl) palladium chloride with 2PMe$_2$Ph per Pd (prepared *in situ*) was recorded at several temperatures. At −50°, protons 3 and 4 appear as distinct though very broad resonances while proton 5 is a 1:2:1 triplet (J(H_5–$H_{3,4}$) = 10 cs^{-1})

TABLE 4. Far infrared data (400–250 cm^{-1}) for complexes of the type [(π-all)PdCl(L)] and the effect of excess L on the intensity of ν(Pd–Cl). Spectra recorded in 0.1*M* $CHCl_3$ solution at 31°

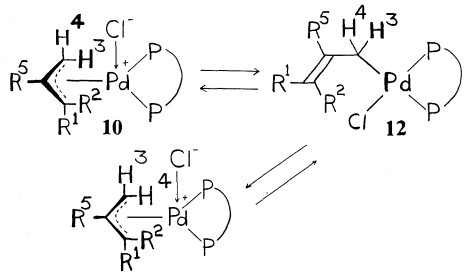

SCHEME 2. Mechanism of chloride promoted exchange of protons 3 and 4 in [(π-all)Pd(diphos)Cl].

i.e. 3–4 exchange prior to coalescence (Fig. 6(*a*)). Although partially overlapped by the methyl phosphine resonances, the *syn* and *anti* methyl protons are strongly coupled to both *cis* and *trans* ^{31}P nuclei (shaded area in Fig. 6), *anti* methyl protons: τ 8.65, *cis* and *trans* $J(P) = 6.5$ and 6.5 c s^{-1}; *syn* methyl protons: τ 8.25, *cis* and *trans* $J(P) = 10.5$ and 7 c s^{-1}. Two sharp doublets (each of relative intensity six), assigned to the methyl protons of the PMe_2Ph ligands, are observed at τ 8.50 and 8.08. Because 3–4 proton exchange is occurring at this temperature, the two methyl groups on the *same* PMe_2Ph ligand should be equivalent on the p.m.r. time scale and as such, should exhibit only one resonance instead of two. (Two Me_2PhP methyl resonances are observed for [(π-2-methylallyl)-PdCl)Me_2PhP)] in the region of no *syn–anti*

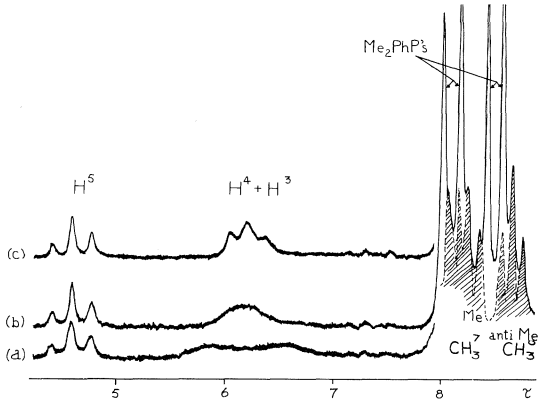

FIG. 6. The ^1H n.m.r. spectra of a 0.44 *M* $CDCl_3$ solution of [Me_2C⋯CH⋯CH_2)Pd($Me_2PhP)_2Cl$] **13** (see Scheme 3) (*a*) at −50°; (*b*) at −40°; (*c*) at −35° (compare with Fig. 5*a* and Fig. 2*c*).

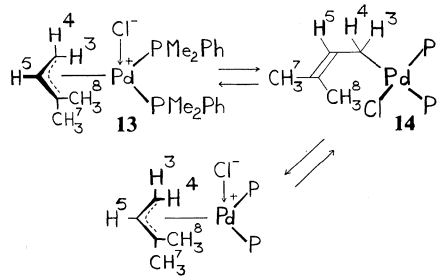
proton exchange (6).) Thus the existence of two Me_2PhP doublet absorptions must indicate that each PMe_2Ph ligand is in a unique chemical environment with respect to each other.

At $-40°$, resonances 3 and 4 coalesce into a very broad singlet whereas *cis* and *trans* ^{31}P coupling to the terminal methyl protons is retained; both PMe_2Ph doublets remain sharp (Fig. 6(*b*)). At $-35°$, the resonance of protons 3 and 4 sharpens to a broad triplet ($J_5 = 10\,c\,s^{-1}$; J_P *trans* $\sim 9\,c\,s^{-1}$), whilst the terminal methyl protons, though slightly broadened, remain coupled to the *cis* and *trans* ^{31}P nuclei of the PMe_2Ph ligands. Again, the two methyl doublets of the PMe_2Ph ligands remain sharp (Fig. 6(*c*)).

At higher temperatures (above $-20°$), PMe_2Ph ligand exchange occurs as evidenced by the collapse of the Me_2PhP methyl doublets to a single broad peak (^{31}P coupling to the allylic protons is lost, the terminal methyl proton resonances become sharp singlets and protons 3 and 4 give rise to a sharp doublet ($J_5 = 10\,c\,s^{-1}$)).

Below $-35°$, the coupling pattern of the terminal methyl protons (*cis* and *trans* ^{31}P coupling) is very similar to that observed in complex **5** (Table 1, Fig. 2) in which the bidentate diphos ligand is coordinated in the square plane. By direct analogy, then, two PMe_2Ph ligands (corresponding to two sharp doublets in the p.m.r.) must occupy two *cis* coordination sites in the square plane. The presence of *trans* ^{31}P coupling to the p.m.r. equivalent protons, 3 and 4, at $-35°$ (Fig. 6(*c*)) together with the retention of *cis* and *trans* ^{31}P coupling to the terminal methyl protons indicates that the 1,1-dimethylallyl ligand is π-bonded to palladium a majority of the time, that *syn–anti* proton exchange occurs with retention of the terminal allylic carbon sites relative to the Me_2PhP ligands, and that the PMe_2Ph ligands remain coordinated to Pd throughout the rapid *syn–anti* proton exchange process (below $-20°$).[3]



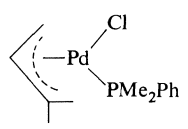
SCHEME 3. Mechanism of chloride promoted exchange of protons 3 and 4 in $[(Me_2C{=}CH{=}CH_2)Pd(Me_2PhP)_2Cl]$ (**13**).

The marked similarity in the p.m.r. data for the 1,1-dimethylallyl systems, **5** + pyridine, (**10**; $R^1 = R^2 = Me$; $R^5 = H$), and the "(π-1,1-dimethylallyl)PdCl – $2Me_2PhP$" adduct, clearly substantiates **13** as the major solution species for the latter system. (**13** is structurally analogous to **5** and **10**.) Thus when Me_2PhP is added to [(π-1,1-dimethylallyl)PdCl(Me_2PhP)] the chloride ligand is substituted by the added phosphine to give **13**. The observed *syn–anti* proton exchange can be explained by Scheme 3 which is analogous to Schemes 2 and 1, *i.e.*, nucleophilic substitution of the π-1,1-dimethylallyl ligand by the *chloride ligand* gives a short-lived σ-1,1-dimethylallyl ligand **14**. This process reforms a π-allylic complex in one of two ways thereby effecting *syn–anti* proton exchange whilst retaining distinct *cis* and *trans* ^{31}P coupling to the 1,1-dimethylallyl ligand, and stereochemically distinct Me_2PhP ligands.

At higher temperatures Me_2PhP ligand exchange in **13** is observed and this could involve Cl^- substitution of a coordinated Me_2PhP ligand to give either **15** or **16**:

[2] $[\pi\text{-(1,1-dimethylallyl)Pd(Me}_2\text{PhP)}_2\text{Cl}]$ (**13**) $\overset{\text{fast}}{\rightleftharpoons}$ (**15**) + PMe_2Ph

13 $\overset{\text{fast}}{\rightleftharpoons}$ (**16**)



16

[3]What at first seemed a pertinent example to this study was a previous report (5) that, at 34°, the addition of PPh_3 (up to 16%) to [(π-1,1-dimethylallyl)PdCl(PPh_3)], in $CHCl_3$, effected rapid *syn–anti* proton exchange whilst retaining ^{31}P coupling to the terminal methyl protons. However, repeated attempts by us to reproduce these results proved unsuccessful.

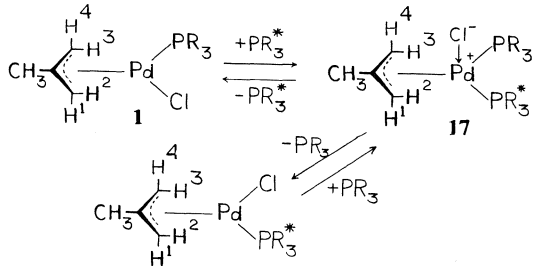
For personal use only.

This process is analogous to the Me_2PhP catalyzed exchange of Me_2PhP ligands in *cis*–$[MCl_2(Me_2PhP)_2]$ (M = Pd, Pt) which also occurs via consecutive $Me_2PhP \rightarrow Cl$ and $Cl^- \rightarrow$ coordinate Me_2PhP S_N2 ligand substitutions (12, 13). However, this mechanism may not be responsible for the observed Me_2PhP exchange as it involves formation of the thermodynamically less stable mono-phosphine complex **16**. Dissociation of **13** to give a small amount of **15** and free Me_2PhP followed by direct substitution of coordinated Me_2PhP by free Me_2PhP would be an equally plausible alternative. Unlike **13**, the p.m.r. spectrum of the (*syn*-1-tert-butyl-2-methylallyl)-palladium chloride – $2Me_2PhP$ adduct (prepared *in situ* in $CDCl_3$) at $-50°$ contains very broad Me_2PhP methyl proton resonances which is indicative of rapid Me_2PhP ligand exchange. Additional peaks in the spectrum suggest the formation of an appreciable amount of the *anti* isomer (*t*-Bu group in the *anti* position). Unlike the 1,1-dimethylallyl analogue, rapid *syn–anti* proton exchange along with retention of *cis* and *trans* ^{31}P coupling could not be discerned owing to the rapid phosphine ligand exchange occurring at temperatures as low as $-50°$. It is probable that steric interactions between the tert-butyl group and the *cis*-Me_2PhP ligand facilitates Me_2PhP exchange.

From the above p.m.r. studies several unifying features are apparent: (*i*) Rapid *syn–anti* proton site exchange is consistently explained by a $\pi \rightarrow \sigma \rightarrow \pi$ exchange mechanism involving a series of ligand substitution processes; (*ii*) for each system studied, the major solution species is postulated to have two phosphorus atoms (either diphos or $2PMe_2Ph$) in the square plane which remain inert to substitution during 3–4 proton exchange (this proposal is corroborated by the observance of *cis* and *trans* ^{31}P coupling throughout the occurrence of 3–4 proton exchange); (*iii*) the initiation step of 3–4 proton exchange is believed to be a nucleophilic substitution by a donor ligand (pyridine or chloride) at a Pd—C bond followed by a reverse substitution of the donor ligand by the allyl group. Furthermore addition of Me_2PhP to [(π-1,1-dimethylallyl)Pd-Cl(Me_2PhP)] results in the substitution of a Pd—Cl bond by Me_2PhP to give **13**. The extent to which such substitution occurs may be assessed by monitoring the change in intensity of ν(Pd—Cl) on addition of one PR_3/Pd to [(π-all)PdCl(PR_3)] in $CHCl_3$ at 31° (see Table **4**).

The addition of one Me_2PhP per Pd to a solution of [(π-2-methylallyl)PdCl(Me_2PhP)] (**1**; PR_3 = Me_2PhP) in $CHCl_3$ results in the complete disappearance of the ν(Pd—Cl) absorption at 282 cm^{-1}. The absence of an absorption band assignable to a ν(Pd—Cl) mode in the region 340 to 250 cm^{-1} indicates the absence of an "in plane" Pd—Cl bond. Thus the major solution species is the complex [(π-2-methylallyl)Pd(Me_2PhP)$_2$Cl] (**17**; PR_3 = Me_2PhP) (see Scheme 4) which is structurally analogous to **13** and **10** (**10**; R^1 = R^2 = H; R^5 = Me). The presence of a weak absorption at 274 cm^{-1} assignable to an in plane Pd—Cl bond in the infrared spectrum of [(π-1,1-dimethylallyl)Pd(Me_2PhP)$_2$Cl] in $CHCl_3$ at 34° is probably due to partial dissociation of an Me_2PhP ligand from **13** to give a small amount of **15** {ν(Pd—Cl) = 274 cm^{-1}} and free Me_2PhP (reaction 2; N.B. Me_2PhP ligand exchange is observed in the p.m.r. of **13** at 34°).

The addition of one PPh_3 per Pd to [(π-2-methylallyl)PdCl(PPh_3)] (**17**; PR_3 = PPh_3) decreased the intensity of the ν(Pd—Cl) absorption by *ca.* 50%. Therefore at 34° **17** and **1** (**1**; PR_3 = PPh_3) are present in *ca.* equal amounts. An addition of *ca.* 4 molecules PPh_3 per Pd atom to **1** completely eliminates the ν(Pd—Cl) absorption of **1** from the infrared spectrum as the equilibrium conditions now favor **17**. Addition of excess $AsPh_3$ to $CHCl_3$ solutions of [(π-2-methylallyl)-PdCl($AsPh_3$)] has no effect on the observed intensity of the ν(Pd—Cl) of this complex. Thus the tendency for the added ligand to give square pyramidal species of the type **17** decreases in the order $PMe_2Ph > PPh_3 > AsPh_3$. Species **17** is an intermediate in the formation of solvated ionic species. The ability of these ligands to promote salt formation also decreases in the order $PMe_2Ph > PPh_3 > AsPh_3$ (14).



SCHEME 4. Consecutive displacement mechanism for the PR_3 promoted exchange of *syn* protons 1 and 4 with simultaneous exchange of *anti* protons 2 and 3 in the complexes [(π-2-methylallyl)PdCl(PR_3)].

The Mechanism of PR_3 Promoted Syn–Syn and Anti–Anti Proton Exchange in [(π-2-methylallyl)PdCl(PR_3)]

Our studies have shown that an added PR_3* ligand may substitute a Pd—Cl bond in [(π-2-methylallyl)PdCl(PR_3)] (**1**) to give the square pyramidal species **17** with an axial Cl ligand. Furthermore studies of *syn–anti* proton exchange in **10** and **13** have shown that consecutive S_N2 ligand substitutions involving Cl^- as a nucleophile occur very rapidly in such systems. As such the mechanism of PR_3* promoted *syn–syn* {1–4} with simultaneous *anti–anti* {2–3} proton site exchange in the complexes [(π-2-methylallyl)PdCl(PR_3)] **1** may be reconsidered in terms of the consecutive ligand substitution processes outlined in Scheme 4. Substitution of the Pd—Cl bond in **1** by PR_3* results in formation of **17**. The axial Cl^- ligand in **17** may displace either PR_3 or PR_3* with equal probability to give either **1** or **1′** thereby effecting 1–4 and 2–3 proton site exchange. Scheme 4 is very similar to the mechanism of PR_3 catalysed *cis–trans* isomerization of $[MCl_2(PR_3)_2]$ (M = Pd, Pt) which also occurs via consecutive $PR_3 \rightarrow Cl$ and $Cl^- \rightarrow PR_3$ substitutions (12, 13, 15).[4]

Summary

The mechanisms of PR_3 promoted *syn–anti* proton exchange and PR_3 promoted *syn–syn* and *anti–anti* proton exchange in an extensive series of π-allylic palladium(II) – tertiary phosphine systems may be consistently and adequately explained in terms of consecutive S_N2 ligand substitutions, the lability of which are no doubt governed by the normal *trans*-influences observed in square planar d^8 complexes. Since the ease of formation of a σ-allylic intermediate depends in part on the nature and position of the alkyl substituents the observed behavior for a series of structurally similar π-allylic systems will also be a function of the alkyl substituents on the allylic ligand. Thus for example, addition of PR_3 to **1** promotes *syn–syn* and *anti–anti* proton exchange prior to *syn–anti* proton exchange and this may in part be ascribed to the relative unreactivity of the π-2-methylallyl ligand towards substitution by a nucleophile (*e.g.* Cl^-). However, *syn–anti* proton exchange is observed prior to any exchange of allylic terminal carbon sites when the π-allylic ligand has terminal alkyl substituents owing to the relative ease of formation of the σ-allylic intermediates.

Conclusions

The bulk of experimental data now available support the postulate that the ligand promoted *syn–syn* and *anti–anti* proton site exchange in π-allylic palladium(II) complexes occurs via consecutive S_N2 ligand substitutions (7, 8, 17). No firm experimental data exist which support a rotational mechanism. Thus if rotation of a π-allylic ligand about the π-allyl–Pd bond occurs at all it must be regarded as a high energy process and as such may be excluded from considerations of possible reaction pathways for palladium(II) catalyzed oligomerization reactions of unsaturated hydrocarbons.

Experimental

Proton magnetic resonance spectra were recorded on Varian Associates Model A 56/60 or HA 100 spectrometers; temperature calibrations were made using a reference methanol sample (Varian 943346-06). Infrared spectra were recorded on a Perkin–Elmer 180 spectrophotometer. Melting points were determined on a Kofler hot-stage apparatus.

π-Allylic palladium chloride complexes (π-all = allyl, 2-methyl, 1,1-dimethylallyl, and 1-methyl) were prepared by the method of Dent, Long, and Wilkinson (18). (*syn*-1-tert-Butyl-2-methylallyl)palladium chloride and (2-tert-butylallyl)palladium chloride were prepared by the method of Volger (19).

1,2-Bisdiphenylphosphinoethane(π-syn-1-tert-butyl-2-methylallyl)palladium(II) Hexafluorophosphate

(π-*syn*-1-tert-Butyl-2-methylallyl)palladium chloride (0.40 g) and (0.63 g) diphos were dissolved in 15 ml chloroform. Ammonium hexafluorophosphate (1.4 g) was added and the resultant mixture shaken for 24 h. The reaction mixture was filtered and evaporated to dryness, yielding a pale yellow oily residue. Addition of methanol gave a white solid which recrystallized from methanol as white prisms (0.90 g; 75%), m.p. 214–220°.

Anal. Calcd. for $C_{34}H_{39}F_6P_3Pd$: C, 53.66; H, 5.16. Found: C, 53.57; H, 5.21.

The following compounds were prepared in a similar fashion.

1,2-Bisdiphenylphosphinoethane(π-1,1-dimethylallyl)-palladium(II) Hexafluorophosphate

Recrystallized from chloroform–hexane solution as white prisms (0.80 g; 76%), m.p. 111–114°.

Anal. Calcd. for $C_{31}H_{33}F_6P_3Pd.CHCl_3$: C, 45.84; H, 4.08. Found: C, 46.06; H, 4.24.

The presence of one $CHCl_3$ solvent molecule per Pd atom was confirmed by p.m.r. studies in $CDCl_3$.

[4]The recent proposal (16) that the PR_3 catalyzed *cis–trans* isomerization of $[PtCl_2(PR_3)_2]$ occurs via a pseudo rotation of a five coordinate intermediate has been shown to be incorrect (12).

Etude de quelques polymères obtenus lors de la déshydratation en système statique d'alcools allyliques disubstitués

CLAUDE ROUX ET HUBERT DAOUST

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 2 mars 1972

Les dioléfines produites lors de la déshydratation thermique en système statique d'alcools allyliques disubstitués se polymérisent simultanément à la déshydratation en donnant des polymères de bas poids moléculaires et dont la microstructure se compare à celle des polymères thermiques de diènes-1,3. Les masses moléculaires moyennes en nombre et en poids, le volume spécifique partiel et la distribution des masses ont été étudiés pour le polymère obtenu lors de la déshydratation du méthyl-3 butène-2 ol ou alcool diméthyl-3,3 allylique.

Diolefins, produced by thermal dehydration of disubstituted allyl alcohols in a static system, polymerize as they are formed giving low molecular weight polymers. The microstructure of the product is similar to that of thermal polymers of 1,3-dienes. Number- and weight-average molecular weights, partial specific volumes, and molecular weight distributions have been studied for the polymers obtained from 3-methyl-2-butene-1-ol and 3,3-dimethyl-allyl alcohol.

Can. J. Chem., **51**, 288 (1973)

Introduction

Le méthyl-3 butène-2 ol joue un rôle très important dans l'élaboration du caoutchouc naturel par l'Hevea Brasiliensis, et Lynnen et Henning (1) ont montré qu'en fait, il intervient comme premier maillon de la chaîne polyisoprénique sous la forme d'ester pyrophosphorique. La réaction de polymérisation serait amorcée par le pyrophosphate de méthyl-3 butène-2 yle, le monomère étant le pyrophosphate de méthyl-3 butène-3 yle.

Malgré toute la séduction que présente la possibilité de reproduction *in vitro* d'une telle réaction, un examen approfondi des conditions d'obtention de ces pyrophosphates d'une part et le mécanisme de polymérisation d'autre part, conduit à une impasse certaine (1).

Néanmoins, le radical alcényle du pyrophosphate responsable de l'amorçage de la réaction de polymérisation *in vivo* et plus généralement, la structure allylique disubstituée en position 3 est digne d'intérêt.

Le présent travail se rapporte donc à l'étude des polymères obtenus lors de la déshydratation thermique en système statique d'alcools allyliques disubstitués en position 3, tant du point de vue de la microstructure que de celui des masses moléculaires et de leur distribution. Ces alcools sont: le méthyl-3 butène-2 ol, les *cis* et *trans* méthyl-3 pentène-2 ols, le triméthyl-3,4,4 pentène-2 ol, et l'éthyl-3 pentène-2 ol.

Partie expérimentale

La déshydratation des alcools et la polymérisation des diènes produits ont lieu simultanément, en tubes de verres scellés sous vide, chauffés en étuve régulée à ± 1 °C à des températures variant de 150–210 °C; une étude cinétique de ce type de réaction est décrite ailleurs (2).

Les alcools, selon des quantités disponibles (3–25 g environ) sont placés dans des tubes de verre pyrex préalablement lavés et séchés soigneusement. Les tubes sont ensuite plongés dans l'azote liquide puis scellés sous un vide de l'ordre de 10^{-4} mm Hg; ils sont par la suite chauffés pendant des temps variant de 3–4 jours à 207 °C. La récupération des polymères a lieu de la façon suivante: les produits de la réaction sont dilués dans environ deux fois leur volume de chlorure de méthylène; la phase aqueuse est décantée et la phase organique traitée par le méthanol. Les polymères précipitent et le liquide surnageant est décanté. Ces opérations sont faites au total trois fois. Les polymères sont ensuite séchés sous vide. A la température ambiante, ils se présentent, une fois secs, sous forme de masses liquides très visqueuses translucides qu'il est nécessaire de conserver sous vide ou sous azote pour en éviter l'oxydation. Parmi les produits de décomposition du méthyl-3 butène-2 ol, il a été également trouvé de l'isoprène; p.é. 34–35°/760 mm Hg; n_D^{22} 1.4205. L'analyse par c.p.g. a révélé la présence, dans le liquide après précipitation, de 23 espèces différentes d'hydrocarbures éthyléniques ou poly-éthyléniques bouillant vers 180 °C sous 25 mm Hg.

Les spectres d'absorption i.r. ont été effectués soit sur appareil Beckman IR-8 soit sur appareil Perkin–Elmer 700 à partir de films obtenus de solutions.

Les spectres de r.m.n. ont été effectués sur appareil JNM-4H-100 ou C 60H de Japan Electron Optics Lab. Co. Ltd. ou sur appareil Varian T-60, le solvant utilisé est soit le benzène soit le tétrachlorure de carbone; la référence interne est le tétraméthylsilane (TMS).

La masse moléculaire moyenne en nombre a été déterminée d'une part par tonométrie sur appareil Mechrolab 301-A, le solvant étant le chloroforme, la température de l'enceinte étant de 37 °C, et d'autre part par calcul à partir de la distribution des masses par ultracentrifugation à l'équilibre, en utilisant une ultracentrifugeuse analytique Spinco modèle E-HT.

La masse moléculaire moyenne en poids a été déterminée par ultracentrifugation sur le même appareil.

Synthèse des alcools

Méthyl-3 butène-2 ol

La synthèse de cet alcool a été effectuée selon la méthode décrite par Hellin et coll. (3). Le spectre r.m.n. est celui du produit attendu; p.é. 141–142°/759 mm Hg; n_D^{21} 1.4340.

cis et trans Méthyl-3 pentène-2 ols

La réduction par l'hydrure de lithium aluminium des esters éthyliques des acides correspondants (8) fournit le mélange de ces deux alcools avec un rendement de 84%, en un produit bouillant à 80 °C sous 40 mm Hg; ces deux composés n'ont pas été séparés. Le spectre r.m.n. est celui des produits attendus.

Triméthyl-3,4,4 pentène-2 ol

La méthode utilisée pour la synthèse des méthyl-3 pentène-2 ols a été étendue à la synthèse de cet alcool. Le rendement est voisin de 23%. Le spectre r.m.n. est celui du produit attendu; p.é. 90°/20 mm Hg; n_D^{23} 1.4451.

Ethyl-3 pentène-2 ol

Cet alcool a été obtenu avec un rendement de 88% en réduisant l'ester éthylique de l'acide correspondant par l'hydrure de lithium aluminium. Le spectre r.m.n. est celui du produit attendu; p.é. 176°/760 mm Hg; n_D^{24} 1.4492. L'ester fut préparé par réaction de Wittig de la diéthylcétone sur le carboéthoxyméthylènetriphénylphosphorane en tube scellé, sans solvant, avec un rapport molaire cétone–phosphorane égal à 5, à 170 °C, pendant 96 h; le rendement est supérieur à 85%.

Les réactifs utilisés au cours de ces synthèses sont de qualité analytique; la pureté des produits obtenus a été vérifiée par c.p.g. et par spectrographie de r.m.n.

Résultats

Il a été constaté que les alcools cités ci-dessus se déshydrataient et que dans les produits de déshydratation se trouvaient des polymères insolubles dans l'acétone, le méthanol et l'éthanol, solubles dans le benzène, le cyclohexane, le chloroforme, etc.

Microstructure des polymères

Polymère obtenu lors de la déshydratation du méthyl-3 butène-2 ol

Cet alcool se déshydrate en donnant de l'isoprène dont la polymérisation conduit aux types d'addition suivants: 1,4 *cis* ou *trans*, 1,2 et 3,4. Le spectre de r.m.n. à 100 MHz dans le benzène (fig. 1) permet de calculer approximativement le pourcentage de chacune de ces additions; il y

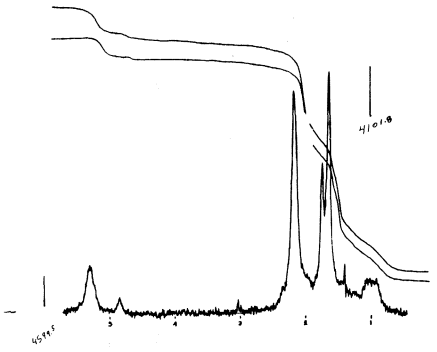

FIG. 1. Spectre à 100 MHz dans le benzène du polymère obtenu lors de la déshydratation du méthyl-3 butène-2 ol.

aurait approximativement (4–7): 53–54% de structure 1,4 *trans*; 23–24% de structure 1,4 *cis*; 2–3% de structure 1,2; 18–19% de structure 3,4.

Le spectre r.m.n. à 100 MHz dans le tétrachlorure de carbone confirme ce résultat. Le spectre i.r. (850, 885, 900, 1080, 1350, 1400, 1670, 2900 cm^{-1}) semble confirmer la présence de ces types d'addition (5, 7) et révèle ici encore l'analogie avec un polyisoprène thermique (8).

Polymère obtenu lors de la déshydratation du mélange cis–trans méthyl-3 pentène-2 ols

Ces deux alcools se déshydratent en donnant deux sortes de dioléfines: le méthyl-3 pentadiène-1,3 et l'éthyl-2 butadiène-1,3.

Chacune de ces dioléfines peut donner plusieurs types d'addition, l'analyse quantitative de chacune n'a pu être faite. La fig. 2 représente le spectre de r.m.n. du polymère obtenu. Il est à noter qu'en spectrographie de r.m.n. le signal vers 4.60 p.p.m. caractéristique de l'addition 1,2 de l'éthyl-2 butadiène-1,3 ou de l'addition 3,4 du méthyl-3 pentadiène-1,3 est pratiquement inexis-

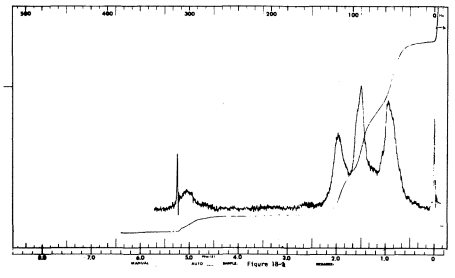

FIG. 2. Spectre de r.m.n. à 60 MHz dans le tétrachlorure de carbone du polymère obtenu lors de la deshydratation des *cis* et *trans* méthyl-3 pentène-2 ols.

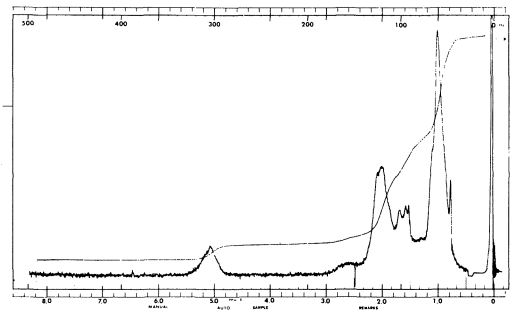

FIG. 3. Spectre de r.m.n. à 60 MHz dans le tétrachlorure de carbone du polymère obtenu lors de la déshydratation de l'éthyl-3 pentène-2 ol.

tant. Spectre i.r.: 800, 840, 870, 900, 1040, 1100, 1200, 1240, 1390, 1470, 1660, 1680, 2900 cm^{-1}.

Polymère obtenu lors de la déshydratation de l'éthyl-3 pentène-2 ol

Cet alcool se déshydrate en donnant l'éthyl-3 pentadiène-1,3 dont la polymérisation conduit à des additions 1,4 *cis* et *trans*, 1,2 et 3,4.

La fig. 3 représente le spectre de r.m.n. du polymère obtenu. Il est à noter ici également, que le signal vers 4.60 p.p.m., caractéristique de l'addition 3,4 de l'éthyl-3 pentadiène-1,3 est inexistant et que donc ce type d'addition semble exclu. Spectre i.r.: 800, 830, 900, 960, 1070, 1100, 1380, 1460, 1670, 1710, 2950 cm^{-1}.

Polymère obtenu lors de la déshydratation du triméthyl-3,4,4 pentène-2 ol

Cet alcool se déshydrate en donnant le tertiobutyl-2 butadiène-1,3 dont la polymérisation conduirait également à des additions 1,4 *cis* et *trans* 1,2 et 3,4. La fig. 4 représente le spectre de r.m.n. du polymère obtenu. L'interprétation du spectre de r.m.n. semble difficile à réaliser, néanmoins, hormis le signal inexpliqué à 7.05 p.p.m. (peut-être dû à une cyclisation) il semblerait que les trois structures 1,4, 3,4, et 1,2 soient présentes. Spectre i.r.: 800, 860, 900, 980, 1030, 1080, 1120, 1200, 1260, 1360, 1390, 1470, 1630, 1730, 2950 cm^{-1}.

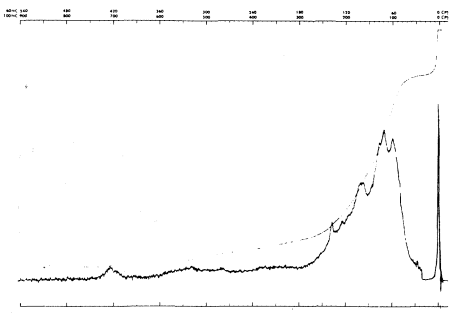

FIG. 4. Spectre de r.m.n. à 60 MHz dans le tétrachlorure de carbone du polymère obtenu lors de la déshydratation du triméthyl-3,4,4 pentène-2 ol.

Etude physico-chimique du polymère obtenu lors de la déshydratation du méthyl-3 butène-2 ol

Ce polymère a été obtenu lors de la déshydratation en système statique à 207 °C du méthyl-3 butène-2 ol. Sa masse moléculaire moyenne en nombre $\bar{M}_n$, déterminée par tonométrie, a été trouvée égale à 4750 $\pm$ 100 g mol^{-1}.

Volume spécifique partiel dans le cyclohexane de ce polymère

Cette détermination a été effectuée par la méthode dite du pycnomètre (9) à 25 $\pm$ 0.003 °C. Le graphique de la fig. 5 représente les variations de volume de la solution contenant 1000 g de solvant en fonction de la concentration massique (g/1000 g de solvant).

La pente de la courbe représentative de cette fonction, qui est ici une droite (domaine des faibles concentrations) conduit à la valeur du volume spécifique partiel $\bar{v}_2$ du polymère. Ce volume a été trouvé égal à: 0.99 $\pm$ 0.01 $cm^3\ g^{-1}$ et c'est cette valeur qui est utilisée dans les calculs relatifs à la sédimentation.

Masse moléculaire moyenne en poids

Cette détermination a été effectuée par ultracentrifugation du polymère en solution dans le cyclohexane, à 25 °C en utilisant la méthode de l'approche à l'équilibre et de la frontière synthétique (10, 11).

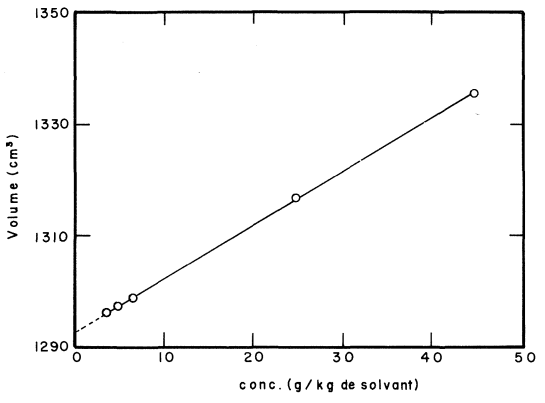

FIG. 5. Variation du volume de la solution contenant 1000 g de solvant en fonction de la concentration massique du polymère.

For personal use only.

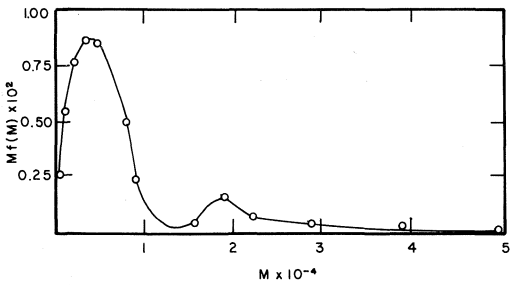

FIG. 6. Fonction de distribution en poids des masses moléculaires en fonction de la masse moléculaire (polymère obtenu lors de la déshydratation du méthyl-3 butène-2 ol).

La vitesse du rotor est de 25 980 t.p.m. La masse moléculaire moyenne en poids $\overline{M}_p$ a été calculée et trouvée égale à: 8650 ± 450 g mol^{-1}.

Distribution en poids des masses moléculaires (12–16)

La solution de polymère subit l'ultracentrifugation à 25 °C, pendant 48 h, à la vitesse de 42 040 t.p.m.

Le graphique de la fig. 6 représente la fonction de distribution en poids des masses moléculaires en fonction de la masse moléculaire.

Le calcul direct des masses moléculaires moyennes en nombre et en poids à partir de cette distribution donne comme résultats: $\overline{M}_n$ = 3 080; $\overline{M}_p$ = 7 700.

Le calcul de la masse moléculaire moyenne en poids à partir des données de l'équilibre de sédimentation (17) indique: $\overline{M}_p$ = 8 100.

Conclusion

Les polymères obtenus lors de la déshydratation en système statique d'alcools allyliques disubstitués en position 3 semblent présenter une microstructure anarchique analogue à celle des polymères thermique des diènes-1,3 avec vraisemblablement une prédominance de la structure 1,4 en configuration *trans*.

Les masses moléculaires moyennes en nombre et en poids sont faibles, la polydispersité évaluée par le rapport de $\overline{M}_p$ à $\overline{M}_n$ est relativement élevée et voisine de 2.5. La distribution en poids des masses moléculaires évaluée par ultracentrifugation est large, et il est possible de supposer qu'il existe un certain degré de branchement.

Les auteurs remercient le Conseil National de Recherches du Canada pour son aide financière au cours de cette étude. Ils remercient également le Dr. N. Ho-Duc pour sa collaboration concernant l'ultracentrifugation.

Etude des dérivés sulfohydroxylés des halogénures de bore et des cycles dérivés du borsulfol I. Synthèses et mécanismes réactionnels

JEAN BOUIX ET ROGER HILLEL

Laboratoire de Physico-chimie minérale I, Associé au C.N.R.S. (Service du Professeur Cueilleron), Université Claude Bernard, 43, boulevard du 11 novembre 1918, 69 Villeurbanne, France

Reçu le 17 avril 1972

Par action du sulfure d'hydrogène sur un halogénure de bore autre que le fluorure, on obtient simultanément l'halogénure d'hydrogène correspondant et des dérivés de substitution nouveaux de formules BCl_2SH, BBr_2SH, $BBr(SH)_2$, BI_2SH, $BI(SH)_2$ et $B(SH)_3$.

Ces sulfohydroxohalogénoboranes sont instables et tendent à se cycliser soit en acide thioborique $(BSSH)_3$ soit en trihalogénoborsulfol $(BSX)_3$.

Dans le cas du bromure de bore, en contrôlant la composition du mélange de départ et la température de la réaction, il est possible de favoriser la formation de l'un des trois dérivés de substitution possibles et, en provoquant ensuite sa cyclisation, de préparer de façon rapide et sélective soit l'acide thioborique soit le tribromoborsulfol, ce dernier pouvant être obtenu très pur en opérant en absence de solvant.

La synthèse du trichloroborsulfol a été effectuée par dissolution de l'acide thioborique dans le chlorure de bore liquide et celle du triiodoborsulfol par action du sulfure d'hydrogène sur l'iodure de bore solide.

By the action of H_2S on boron halides (other than fluoride) one obtains the new substitution products BX_2SH, $BX(SH)_2$, and $B(SH)_3$ along with the corresponding hydrogen halide. These halogenosulfhydroboranes are unstable and cyclize to cyclic boron sulfides, either $(BSSH)_3$ or $(BSX)_3$.

In the case of boron bromide it is possible, by controlling the ratio of the reactants and the temperature of the reaction, to promote the formation of one of the three possible substitution products. Then by encouraging cyclization one may obtain, rapidly and selectively, either $(BSSH)_3$ or $(BSBr)_3$.

Synthesis of $(BSCl)_3$ was accomplished by dissolution of $(BSSH)_3$ in liquid BCl_3 and that of $(BSI)_3$ by the action of H_2S on solid BI_3. [Journal translation]

Can. J. Chem., **51**, 292 (1973)

L'action du sulfure d'hydrogène sur les halogénures de bore en absence de solvant ne donne lieu selon la littérature qu'à la formation de complexes d'addition tels que BCl_3, H_2S (1), et BCl_3, 12 H_2S (2), l'existence de ce dernier étant d'ailleurs problématique.

En remplaçant le sulfure d'hydrogène par le méthyl-mercaptan, Goubeau et Wittmeier (3) ont par contre obtenu des dérivés solides de substitution: BCl_2SCH_3, BBr_2SCH_3, $BBr(SCH_3)_2$, et $B(SCH_3)_3$. Ils préparent de plus ce dernier composé à l'état pur par action du bromure de bore sur des dérivés métalliques du mercaptan en solution dans du benzène et publient son spectre Raman, ainsi que celui du dérivé dibromé, probablement à l'état dimère. Le dérivé monobromé est par contre très instable, et son existence n'est pas certaine.

En faisant agir le sulfure d'hydrogène sur un halogénure de bore en solution dans le sulfure de carbone, Stock d'une part (4, 5) et Wiberg d'autre part (6, 7, 8) obtiennent l'acide thioborique $(BSSH)_n$ en présence d'un excès de sulfure d'hydrogène et le trihalogénoborsulfol $(BSX)_3$ en présence d'un excès d'halogénure de bore.

Notons que, dans certaines de ces réactions, Wiberg et ses collaborateurs supposent l'existence de dérivés de substitution tels que BCl_2SH (7) et BBr_2SH (9) mais n'apportent aucune preuve à l'appui de cette hypothèse.

En ce qui concerne la synthèse de l'acide thioborique, deux méthodes principales sont décrites dans la littérature: réaction à 800 °C du sulfure d'hydrogène dilué dans un courant d'hydrogène sur du bore (10, 11); action du sulfure d'hydrogène sur le bromure de bore en solution dans le sulfure de carbone suivant les réactions (6, 7, 8, 12, 13):

$$[1] \quad 3\ BBr_3 + 3\ H_2S \xrightarrow{CS_2} (BSBr)_3 + 6\ HBr$$

puis

$$[2] \quad (BSBr)_3 + 3\ H_2S \xrightarrow{CS_2} (BSSH)_3 + 3\ HBr$$

Cette synthèse dure trois semaines environ.

Comme il est impossible en pratique d'arrêter la réaction au premier stade, on prépare le trihalogénoborsulfol en traitant à reflux la solution sulfocarbonique d'acide thioborique par l'halogénure de bore correspondant, deux mécanismes étant proposés (12, 7):

[3] $(BSSH)_3 + 2\ BX_3 \rightarrow (BSX)_3 + 3\ HX + B_2S_3$

et

[4] $2(BSSH)_3 + 2\ BX_3 \rightarrow 2(BSX)_3 + 3\ H_2S + B_2S_3$

Dans le cas du dérivé iodé, Wiberg a de plus utilisé l'action en solution dans le sulfure de carbone d'un très grand excès d'iodure d'hydrogène sur l'acide thioborique (8, 18):

[5] $(BSSH)_3 + 3\ HI \rightarrow (BSI)_3 + 3\ H_2S$

Ces trihalogénoborsulfols sont des composés peu stables; en particulier le dérivé chloré se décompose dès la température ambiante en trichlorure et sulfure de bore (6, 7).

L'acide thioborique est instable au-dessus de 100 °C, et sa décomposition en sulfure d'hydrogène et en sulfure de bore est utilisée pour préparer ce dernier composé à l'état pur (13). A haute température, cette décomposition fournit également le trisulfohydroxoborane $B(SH)_3$, dérivé nouveau détecté par spectrométrie de masse et dont l'auteur a calculé le spectre i.r. (14). Le spectre i.r. de l'acide thioborique $(BSSH)_n$ avec $n = 1$ et 3 est connu (4, 14), ainsi que la structure cristalline du tribromoborsulfol (15).

Obtention des sulfohydroxohalogénoboranes en phase vapeur

Le spectre de masse des halogénures de bore gazeux, déterminé avec un faisceau d'électrons de 35 eV, comporte les pics des ions BX_3^+ et BX_2^+. En outre, il montre toujours la présence de l'halogénure d'hydrogène correspondant qui se manifeste par les pics des ions HX^+, H^+, et X^+. Dans les mêmes conditions, le sulfure d'hydrogène seul donne un spectre comportant les pics des ions H_2S^+, SH^+, et S^+ (*m/e* compris entre 32 et 36) ainsi que celui du proton.

Le spectre d'un mélange équimoléculaire de sulfure d'hydrogène et de fluorure de bore ne montre aucun pic nouveau par rapport à celui des réactifs de départ.

Par contre, si le fluorure de bore est remplacé par le chlorure, on remarque d'une part que l'intensité des pics de HCl augmente considérablement et d'autre part qu'il apparait deux massifs de pics nouveaux et peu intenses pour des rapports *m/e* compris entre 112 et 114 pour le premier et entre 77 et 79 pour le second, donc légèrement inférieurs à ceux des ions BCl_3^+ (entre 115 et 122) et BCl_2^+ (entre 80 et 85) provenant de BCl_3. Tous ces pics nouveaux atteignent simultanément leur intensité maximale pour un mélange de départ équimoléculaire. Enfin, si le rapport molaire initial H_2S/BCl_3 est supérieur à 10, d'autres pics peu intenses apparaissent entre 109 et 111 et entre 75 et 77.

Avec le bromure de bore, et pour un rapport H_2S/BBr_3 inférieur à l'unité, on note la formation simultanée de bromure d'hydrogène et d'un composé donnant deux massifs de pics situés pour le premier entre 201 et 206 et pour le second entre 121 et 125. Si le rapport précédent augmente, il apparait en outre deux autres massifs entre 154 et 160 et entre 74 et 77. Enfin, si ce rapport est supérieur à 10, tout le bromure de bore initial a disparu et il existe un pic peu intense pour un rapport *m/e* égal à 110.

Le tableau 1 montre que les intensités relatives des pics compris entre 201 et 206 correspondent sensiblement à la répartition isotopique calculée pour le dérivé BBr_2SH, les anomalies constatées s'expliquant par la formation d'ions BBr_2S^+ de masses égales à 201, 203, et 205 à partir des variétés isotopiques les plus abondantes des ions BBr_2SH^+, de masses égales à 202, 204, et 206. De la même façon, les pics situés entre 121 et 125 correspondent à des ions $BBrSH^+$ et $BBrS^+$ provenant comme les précédents de molécules BBr_2SH.

Le tableau 2 montre que les pics situés entre 154 et 160 qui apparaissent lorsque le rapport molaire initial H_2S/BBr_3 est supérieur à 1 correspondent à des ions $BBr(SH)_2^+$ dont certains ont perdu 1 ou 2 atomes d'hydrogène. Ceux compris entre 74 et 77 sont attribuables à des ions $B(SH)_2^+$, BS_2H^+, et BS_2^+ qui proviennent comme les précédents de molécules $BBr(SH)_2$.

Enfin, le pic peu intense qui se manifeste pour *m/e* 110 dans les mélanges très riches en H_2S correspond à la présence de traces du dérivé $B(SH)_3$.

On peut donc traduire la formation simultanée

TABLEAU 1. Spectre de masse du dibromosulfohydroxoborane

m/e	Intensité calculée	Intensité observée

160	3.9	3.5
161	0.0	—
162	0.1	—

de bromure d'hydrogène et de ces trois dérivés de substitution par les équilibres:

[6] $$BBr_3 + H_2S \rightleftarrows BBr_2SH + HBr$$

[7] $$BBr_2SH + H_2S \rightleftarrows BBr(SH)_2 + HBr$$

et

[8] $$BBr(SH)_2 + H_2S \rightleftarrows B(SH)_3 + HBr$$

Conformément aux règles internationales, nous proposons pour ces composés les noms respectifs de dibromosulfohydroxoborane, bromodisulfohydroxoborane, et trisulfohydroxoborane.

Dans le cas du chlorure de bore, une réaction analogue se produit, mais la variation de masse consécutive à la substitution d'un atome de chlore par un groupement SH est trop faible pour que les pics du composé formé se distinguent nettement de ceux du chlorure de bore restant. C'est pourquoi les pics nouveaux sont peu intenses, car ils ne correspondent qu'aux ions provenant des variétés les plus légères, les autres étant masqués par les pics de BCl_3. On peut ainsi attribuer les pics situés entre 112 et 114 à des ions BCl_2SH^+ et BCl_2S^+ et ceux entre 77 et 79 à des ions $BClSH^+$ et $BClS^+$, tous ces ions provenant de la molécule BCl_2SH. De la même façon, les pics qui apparaissent dans les mélanges très riches en H_2S correspondent au dérivé disubstitué $BCl(SH_2)$. Entre le chlorure de bore et le sulfure d'hydrogène s'établissent donc les équilibres suivants:

[9] $$BCl_3 + H_2S \rightleftarrows BCl_2SH + HCl$$

et

[10] $$BCl_2SH + H_2S \rightleftarrows BCl(SH)_2 + HCl$$

L'existence des chloro- et des bromosulfohydroxoboranes a été confirmée par l'étude des spectres i.r. des mélanges précédents, seuls les composés BCl_2SH, BBr_2SH, et $BBr(SH)_2$ se formant en quantités suffisantes pour être détectés par cette méthode. L'interprétation de ces spectres, ainsi que la détermination des structures et des champs de force de ces dérivés ont été effectuées et sont en cours de publication.

Ces spectres montrent en particulier que, avec le chlorure de bore, l'équilibre est atteint de façon presque instantanée. Pour un mélange équimoléculaire, 25% du chlorure de bore initial a alors réagi. Avec le bromure, la réaction est plus lente et l'équilibre ne s'établit qu'au bout de 2 h environ. Elle est par contre plus complète, tout le bromure de bore étant consommé si sa teneur initiale est inférieure à 10%. De plus, les mélanges obtenus sont stables dans le cas du chlorure, alors que, avec le bromure, ils commencent à se décomposer spontanément dès la température ambiante s'ils contiennent plus de 90% sulfure d'hydrogène. Ils libèrent alors un solide blanc qui se dépose sur les parois du ballon.

Essais de séparation des mélanges gazeux, décomposition des sulfohydroxohalogénoboranes

Nous avons tenté d'isoler le composé BCl_2SH en soumettant un mélange en équilibre, initialement équimoléculaire de H_2S et de BCl_3, à une chromatographie préparative en phase vapeur en condensant séparément chaque fraction obtenue et en étudiant sa composition par spectrométrie i.r. Le chlorure et le sulfure d'hydrogène ne sont pas séparés et donnent un seul pic. Le second pic correspond au chlorure de bore et il possède une trainée constituée par le dichlorosulfohydroxoborane. Il n'est pas possible de séparer totalement ces deux composés, même en prélevant la queue de cette seconde fraction et en l'introduisant à nouveau dans la colonne. De plus, la moitié environ du BCl_2SH disparaît au cours de chaque passage.

En opérant par distillation sous vide du mélange liquéfié à basse température, on élimine tout d'abord le chlorure et le sulfure d'hydrogène, puis du chlorure de bore contenant des quantités croissantes de dérivé de substitution. Une partie de ce dernier se concentre dans le résidu de distillation et il s'y décompose en libérant un solide blanc. L'étude par diffraction X et absorption i.r. de ce solide montre qu'il est principalement constitué par du trichloroborsulfol $(BSCl)_3$ contenant de faibles quantités de sulfure de bore B_2S_3. La décomposition du dichlorosulfohy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

droxoborane peut donc s'écrire:

[11] $3\ BCl_2SH \rightarrow (BSCl)_3 + 3\ HCl$

puis

[12] $(BClS)_3 \rightarrow B_2S_3 + BCl_3$

Les quantités de solide obtenues sont très faibles car l'équilibre de formation de BCl_2SH est limité, et, de plus, la majeure partie de ce dérivé distille avec BCl_3 sans se décomposer. De ce fait, nous n'avons pas pu effectuer l'analyse chimique de ce solide, ni appliquer cette réaction à la synthèse du trichloroborsulfol.

Il en va autrement dans le cas des mélanges de sulfure d'hydrogène et de bromure de bore, car les dérivés de substitution se forment alors en quantité beaucoup plus importante et se décomposent plus facilement. Si on soumet à la même décomposition que ci-dessus un mélange équimoléculaire de H_2S et de BBr_3, on obtient un solide riche en $(BSBr)_3$, et, comme nous le verrons ultérieurement, les quantités obtenues sont suffisamment importantes pour que cette réaction constitue une méthode de synthèse intéressante du tribromoborsulfol.

Obtention des sulfohydroxohalogénoboranes en solution. Etude par résonance magnétique nucléaire du bore-11

Des spectres i.r. analogues à ceux déterminés en phase vapeur sont obtenus en faisant barboter du sulfure d'hydrogène dans une solution de chlorure ou de bromure de bore dans du sulfure de carbone à température ambiante.

Avec l'iodure de bore, la réaction n'avait pu être effectuée en phase vapeur en raison de la faible volatilité des dérivés iodés. En solution, on constate par spectrométrie i.r. la formation successive des composés BI_2SH, $BI(SH)_2$, et $B(SH)_3$ dont nous avons également déterminé les structures et les champs de force (publication en cours).

Il est à noter que les solutions obtenues sont très instables, et qu'elles se décomposent spontanément à température ambiante et sous pression atmosphérique en libérant, selon leur teneur en H_2S, soit le triiodoborsulfol $(BSI)_3$, soit l'acide thioborique $(BSSH)_3$ conformément aux réactions:

[13] $3\ BI_2SH \rightarrow (BSI)_3 + 3\ HI$

[14] $3\ BI(SH)_2 \rightarrow (BSI)_3 + 3\ H_2S$

et

[15] $3\ B(SH)_3 \rightarrow (BSSH)_3 + 3\ H_2S$

Nous avons également déterminé les spectres de r.m.n. du bore-11 de ces solutions en opérant en tube scellé et en utilisant le composé BF_3–Et_2O comme étalon externe. Les trois halogénures de bore seul donnent des pics situés à -47.3 p.p.m. pour BCl_3, -40 p.p.m. pour BBr_3, et $+6$ p.p.m. pour BI_3. Ces valeurs sont en bon accord avec celles données dans la littérature (16, 17).

Dans une solution contenant BCl_3 et H_2S, et quel que soit la rapport molaire H_2S/BCl_3, un seul pic nouveau, attribuable à BCl_2SH, apparaît à -55 p.p.m.

Avec le bromure de bore, un seul pic nouveau se manifeste à -49.8 p.p.m. si le rapport H_2S/BBr_3 est inférieur à 3. Il correspond au dérivé BBr_2SH. Si ce rapport augmente, le pic de $BBr(SH)_2$ apparaît à -56.2 p.p.m. et celui de BBr_3 disparaît.

Avec l'iodure de bore, un seul pic apparaît à -23.2 p.p.m. lorsque le rapport H_2S/BI_3 est inférieur à 1. Il est dû à BI_2SH. Lorsque ce rapport est compris entre 1 et 3, l'iodure de bore disparaît totalement, et le pic du dérivé disubstitué $BI(SH)_2$ se manifeste à -50 p.p.m. Enfin, si le rapport précédent est supérieur à 3, tout le dérivé monosubstitué disparaît à son tour et le dérivé trisubstitué se forme et donne un pic à -63.6 p.p.m. Ce dernier devient prépondérant si le rapport H_2S/BI_3 est supérieur à 10.

Il est à noter que l'équilibre n'est atteint qu'au bout de 12 h environ. De plus, la décomposition constatée par spectrométrie i.r. dans le cas des solutions des dérivés bromés et surtout iodés ne se produit pas dans ces conditions, car le fait d'opérer en tube scellé crée une pression en halogénure et en sulfure d'hydrogène suffisante pour stabiliser les dérivés de substitution formés: aucune trace de composés cycliques ne peut alors se former.

Synthèses de l'acide thioborique et du tribromoborsulfol

Comme nous venons de le voir, les sulfohydroxohalogénoboranes $BX_{3-n}(SH)_n$ se forment de façon intermédiaire dans la réaction entre le sulfure d'hydrogène et un halogénure de bore, réaction utilisée par Stock et par Wiberg pour préparer l'acide thioborique et les trihalogénoborsulfols. Connaissant ainsi le mécanisme de cette

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

synthèse, nous avons pu améliorer la méthode classique qui consiste à préparer l'acide thioborique à partir du bromure de bore et du sulfure d'hydrogène en passant par le tribromoborsulfol, puis les trihalogénoborsulfols par action de BCl_3, BBr_3, ou HI sur l'acide thioborique comme nous l'avons vu dans la bibliographie. Ces synthèses sont en effet fort longues, et, en ce qui concerne les trihalogénoborsulfols, elles ne donnent que des produits impurs avec un faible rendement, ce qui explique sans doute la rareté des données spectroscopiques relatives à ces composés.

Pour obtenir directement l'acide thioborique, il faut passer de l'halogénure de bore de départ à son dérivé trisubstitué $B(SH)_3$, puis provoquer la décomposition de ce dernier. Dans la méthode classique, cette décomposition se produit au stade des dérivés mono et disubstitués et elle fournit alors du tribromoborsulfol en partant de bromure de bore. Il faut ensuite substituer les atomes de brome du cycle par des groupements SH, ce qui explique la durée de l'opération.

Comme nous l'avons vu, c'est avec l'iodure de bore que la substitution est la plus complète. C'est donc avec cet halogénure que la synthèse de $(BSSH)_3$ sera la plus facile. Compte-tenu de la rareté de ce composé, nous avons cependant mis au point une autre méthode à partir du bromure de bore. Elle consiste à traiter ce dernier en solution dans le sulfure de carbone à -10 °C par un fort courant de H_2S. Dans ces conditions, les dérivés mono et disubstitués ne se cyclisent pas et la réaction se poursuit jusqu'au stade du dérivé trisubstitué. Il suffit alors de laisser la solution revenir à la température ambiante en maintenant le courant de H_2S, ce qui provoque la cyclisation de ce dérivé trisubstitué en acide thioborique. La synthèse dure ainsi 5 jours environ au lieu de 3 semaines.

Pour obtenir directement le tribromoborsulfol, on traite la même solution que ci-dessus par un faible courant de H_2S à la température de reflux. La décomposition se produit alors dès le stade du dérivé monosubstitué qui se cyclise à l'état de tribromoborsulfol.

Cette méthode conserve cependant l'un des inconvénients de celles décrites dans la littérature: la majeure partie du composé préparé en solution sulfocarbonique se décompose au cours de l'évaporation du solvant avec formation de sulfure de bore, ce qui explique que ce composé figure dans les équations proposées par les différents auteurs (7, 12). C'est pourquoi nous l'avons modifiée en utilisant comme solvant le bromure de bore lui-même. Dans ce but, on prépare un mélange équimoléculaire de sulfure d'hydrogène et de bromure de bore et on le laisse atteindre l'équilibre. Après refroidissement, on le distille sous vide pour éliminer HBr et H_2S, puis on le laisse revenir à température ambiante et se remettre en équilibre en fonction de sa nouvelle composition. On recommence ainsi plusieurs fois de suite cette opération, et, peu à peu, le mélange s'enrichit en BBr_3 et en BBr_2SH, ce dernier se décomposant à l'état de tribromoborsulfol qui se dissout dans le bromure de bore liquide. Il suffit alors de distiller ce solvant pour obtenir un produit très pur et bien cristallisé.

Synthèses du trichloro et du triiodoborsulfol

Comme nous l'avons vu, il est préférable d'opérer en l'absence d'un solvant tel que le sulfure de carbone pour préparer les trihalogénoborsulfols. Pour obtenir le cycle bromé, nous avons pu opérer par action directe du sulfure d'hydrogène sur le bromure de bore sans solvant, mais nous avons vu que cette réaction, dans le cas du chlorure, ne donnait que des quantités très faibles de trichloroborsulfol. C'est pourquoi, nous avons préparé ce composé en traitant de l'acide thioborique solide par un excès de chlorure de bore liquide à 0 °C. On a alors substitution sur le cycle selon la réaction:

$$[16] \quad (BSSH)_3 + 3\ BCl_3 \leftrightarrows (BSCl)_3 + 3\ BCl_2SH$$

et les dérivés formés se dissolvent dans l'excès de chlorure de bore liquide. Pour déplacer l'équilibre, on distille les composés BCl_3 et BCl_2SH et on traite le résidu par du chlorure de bore liquide. Au bout d'un certain nombre d'opérations, on constate par spectrométrie i.r. que le distillat ne contient plus que du chlorure de bore pur, ce qui prouve que la réaction est terminée. Il suffit alors de distiller l'excès de chlorure de bore pour faire cristalliser le trichloroborsulfol pur.

Pour préparer le triiodoborsulfol, et après avoir essayé diverses autres méthodes, nous avons opéré par action directe du sulfure d'hydrogène gazeux sur l'iodure de bore solide à température ambiante. Contrairement à ce qui se passait en solution, on a alors formation directe du cycle triiodé. Il suffit ensuite de sublimer sous vide l'excès d'iodure de bore pour récupérer le triiodoborsulfol pur.

Etude de quelques propriétés de l'acide thioborique et des trihalogénoborsulfols

Les trihalogénoborsulfols préparés selon les méthodes précédentes sont mieux cristallisés et beaucoup plus stables que ceux obtenus lorsque les réactions sont effectuées en solution dans le sulfure de carbone. C'est ainsi qu'on peut les purifier par sublimation sous vide secondaire vers 60 °C pour le dérivé chloré, 100 °C pour le bromé et 120 °C pour l'iodé et ceci sans décomposition. Nous avons obtenu de cette façon des produits très purs, ce qui nous a permis d'en effectuer l'étude par analyse thermique, diffraction de rayons X, et spectroscopie de vibration. Les résultats obtenus feront l'objet d'une prochaine publication.

Notons que si on les dissout dans du sulfure de carbone, ces composés donnent des pics de r.m.n. du bore-11 situés à −62 p.p.m. pour le trichloroborsulfol, à −54 pour le tribromo, à −50.2 pour le triiodo et à −57 pour l'acide thioborique.

Nous avons effectué sur ces dérivés cycliques un certain nombre de réactions en solution dans le sulfure de carbone, dans le but de préciser les mécanismes des synthèses décrites dans la littérature. Les résultats sont résumés sur les figs. 1, 2 et 3 pour les dérivés chlorés, bromés et iodés respectivement. Sur ces figures, les réactions que nous avons effectivement utilisées dans un but préparatif sont indiquées par un trait épais.

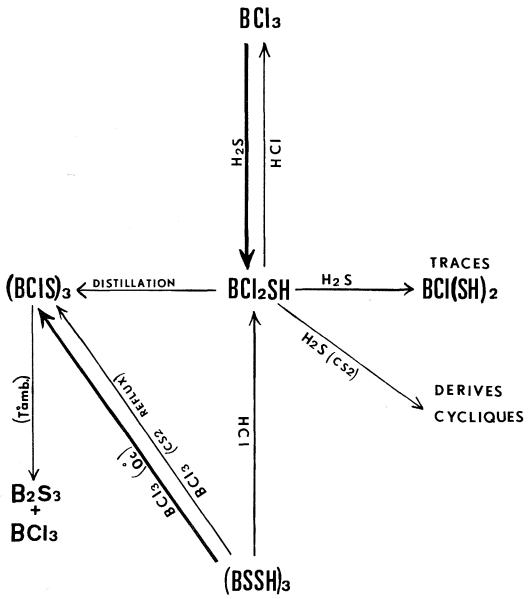

FIG. 1. Proprietés chimiques des sulfohydroxochloroboranes et du trichloroborsulfol.

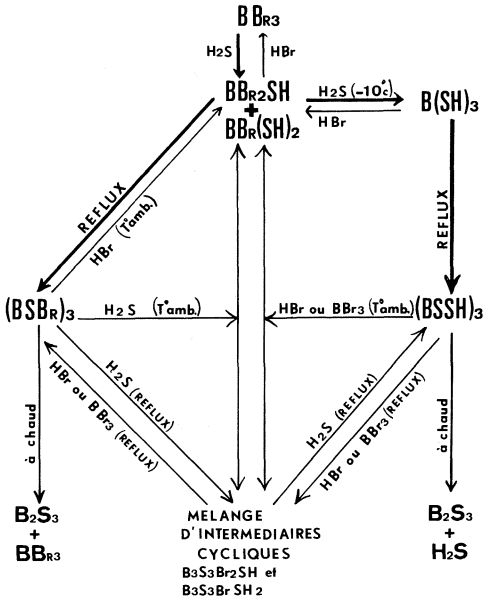

FIG. 2. Proprietés chimiques des sulfohydroxobromoboranes et du tribromoborsulfol.

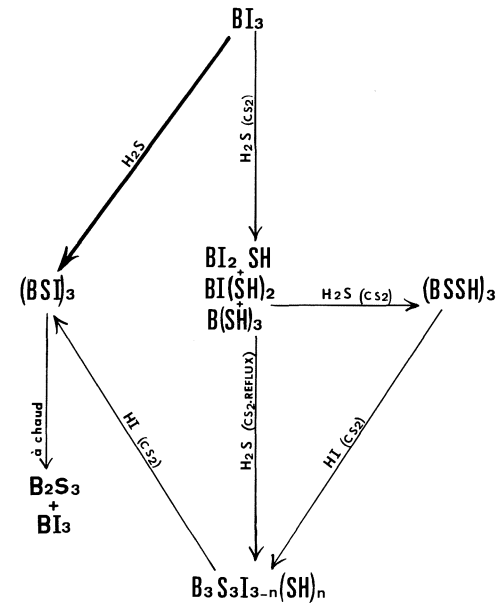

FIG. 3. Proprietés chimiques des sulfohydroxoiodoboranes et du triiodoborsulfol.

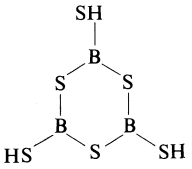
Action des halogénures d'hydrogène sur l'acide thioborique

Avec le chlorure d'hydrogène et à température ambiante aussi bien qu'à reflux, on a rupture du cycle avec formation de dichlorosulfohydroxo-

borane. Ce dernier est converti en chlorure de bore en présence d'un excès de HCl:



$$+ 6\,HCl \longrightarrow 3\,BCl_2SH + 3\,H_2S$$

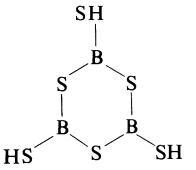
puis $$BCl_2SH + HCl \rightleftarrows BCl_3 + H_2S$$

Avec le bromure d'hydrogène, et à température ambiante on a simultanément rupture du cycle comme ci-dessus avec le chlorure et substitution sur le cycle avec formation de composés intermédiaires entre l'acide thioborique et le tribromoborsulfol. Avec un excès de HBr, on aboutit donc à la fois à BBr_3 et à $(BSBr)_3$. Si on opère à reflux, on a uniquement substitution sur le cycle.

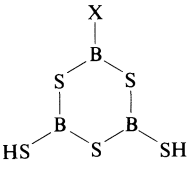
Enfin, avec l'iodure d'hydrogène, et quelle que soit la température, on a substitution sur le cycle et formation de triiodoborsulfol en passant par les intermédiaires $B_3S_3(SH)_2I$ et $B_3S_3(SH)I_2$. Rappelons que cette réaction a été utilisée par Wiberg pour préparer $(BSI)_3$ (8, 18).

Action des halogénures de bore sur l'acide thioborique

Dans tous les cas, on a échange entre des groupements SH du cycle et des atomes d'halogène de l'halogénure de bore:



$$+ BX_3 \longrightarrow$$



$$+ BX_2SH \text{ etc...}$$

Avec BCl_3, cette réaction est analogue à celle réalisée en l'absence de solvant pour préparer $(BSCl)_3$ à condition d'utiliser un excès d'halogénure pour substituer tous les groupements SH du cycle.

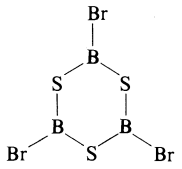
Avec le bromure et l'iodure de bore, la réaction est identique si on opère à température ambiante, mais, à la température de reflux, on a cyclisation des dérivés BX_2SH, tout le bore initial étant ainsi transformé en trihalogénoborsulfol.

Action du sulfure d'hydrogène sur les trihalogénoborsulfols

Avec le tribromoborsulfol et à température ambiante, on a simultanément substitution sur le cycle et rupture de ce cycle. A reflux, on a uniquement substitution et, en présence d'un excès suffisant d'H_2S, on obtient l'acide thioborique. Avec l'iodure de bore, et quelle que soit la température, c'est la substitution sur le cycle qui se produit.

Action du bromure d'hydrogène sur le tribromoborsulfol

Dans tous les cas, il y a rupture du cycle et, en fin de compte, formation de bromure de bore:



$$+ 3\,HBr \longrightarrow 3\,BBr_2SH$$

puis $$BBr_2SH + HBr \rightleftarrows BBr_3 + H_2S$$

Conclusions

Au cours de ce travail, nous avons donc mis en évidence l'existence des halogénosulfohydroxoboranes, dérivés nouveaux de formule générale $BX_{3-n}(SH)_n$, et que l'on peut obtenir soit en solution soit par simple mélange des réactifs gazeux. Ces dérivés ne sont stables qu'au sein du mélange en équilibre et, selon la valeur de n, ils se décomposent en donnant naissance soit au trihalogénoborsulfol correspondant $(BSX)_3$ soit à l'acide thioborique $(BSSH)_3$. La substitution est d'autant plus importante que l'on passe du chlore au brome et à l'iode, ce qui est conforme au fait que l'enthalpie de formation de la liaison B—X diminue lorsque le numéro atomique de l'halogène augmente.

La fig. 4 résume les résultats obtenus en r.m.n. du bore-11. Elle montre la cohérence entre les divers déplacements chimiques observés lorsqu'on passe d'un halogénure de bore à ses dérivés de substitution.

Notons que la position du pic situé à -63.6 p.p.m. et attribué au dérivé trisulfohydroxylé $B(SH)_3$ est en bon accord avec celle du pic correspondant au composé $B(SBu)_3$, situé selon la littérature à -66 p.p.m. (19).

Ces dérivés de substitution interviennent dans les réactions utilisées de façon classique pour préparer soit l'acide thioborique soit les tri-

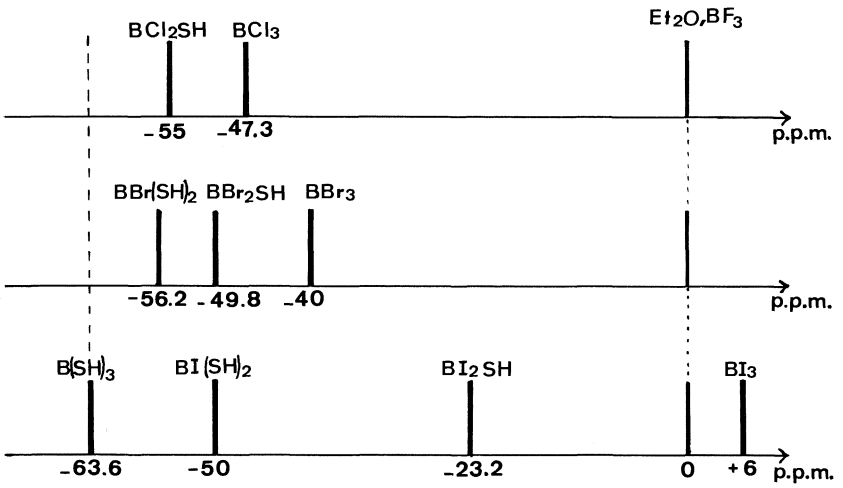

FIG. 4. Spectres de r.m.n. de ^{11}B des hologénures de bore et des sulfohydroxohalogénoboranes.

halogénoborsulfols, et, en contrôlant le déroulement de ces réactions, nous avons pu mettre au point diverses méthodes de synthèses de ces dérivés cycliques, méthodes plus rapides, plus sélectives et donnant des produits de meilleure pureté que celles décrites dans la littérature et évitant dans certains cas l'utilisation d'un solvant. Nous avons de ce fait eu la possibilité d'effectuer l'étude spectrale de ces divers composés, cette étude devant faire l'objet de prochains mémoires.

Partie expérimentale

Préparation des mélanges gazeux $BCl_3 + H_2S$ et $BBr_3 + H_2S$

Le sulfure d'hydrogène (provenance : Société Nationale des Pétroles d'Aquitaine, France) est séché par passage sur P_2O_5. Il est ensuite condensé à la température de l'azote liquide et maintenu sous vide.

Le chlorure et le bromure de bore (provenance : Koch Light, pureté indiquée : 99.8%) sont utilisés sans purification particulière. Pour BBr_3, il est cependant prudent de vérifier l'absence de BBr_2Cl décelable par son absorption i.r. à 920 et 955 cm^{-1}. ($\nu_{a^{11}B-Cl}$ et $\nu_{a^{10}B-Cl}$)

A l'aide d'une rampe à gaz de volume connu, munie d'un manomètre à mercure gradué, on prélève des quantités connues de réactifs et on les condense dans un ballon de 2.5 l. L'ensemble de l'appareillage doit être au préalable soigneusement séché sous vide. Le mélange contient au total 10^{-1} mol de réactifs, c'est-à-dire 0.5×10^{-1} de chacun dans le cas d'un mélange équimoléculaire. Dans le cas du chlorure de bore, ce mélange est entièrement gazeux à température ambiante, et sa pression est légèrement inférieure à la pression atmosphérique. Avec le bromure de bore, il subsiste en plus de la phase vapeur une partie liquide si la teneur en H_2S est inférieure à 90%.

Dosages chimiques

L'analyse élémentaire des trihalogénoborsulfols a été effectuée selon des méthodes déjà décrites (20).

Après dissolution de l'échantillon en milieu alcalin et en tube scellé, l'halogène est dosé par potentiométrie à l'aide de nitrate d'argent, le bore sous forme d'acide borique en présence de mannitol et le soufre par gravimétrie à l'état de sulfate de baryum.

La principale source d'erreur réside dans l'hygroscopicité de ces composés qui augmente lorsqu'on passe du dérivé iodé au dérivé chloré et se traduit, en particulier pour ce dernier, par un défaut de chlore dû à un départ de chlorure d'hydrogène.

Spectrométrie de masse

Les spectres sont déterminés sur un appareil Varian Mat CH5 à simple focalisation, avec des faisceaux d'électrons d'énergie égale à 35 et 70 eV. L'introduction est effectuée par l'intermédiaire d'un réservoir sous vide chauffé à 120 °C d'ou le mélange s'échappe par une fuite moléculaire.

Spectroscopie infrarouge

L'appareil utilisé est un Perkin–Elmer 337. Pour les spectres de gaz, on dispose d'une cellule étanche de 10 cm d'épaisseur en pyrex munie de faces en KBr et, pour les solutions, d'une cellule à épaisseur variable en acier inoxydable munie également de faces en KBr.

Chromatographie en phase vapeur des mélanges $BCl_3 + H_2S$

On utilise un chromatographe Carlo–Erba "Fractovap" avec détecteur à thermistances. Les colonnes en cuivre ont un diamètre de 8 mm et une longueur de 6 m. Elles sont garnies d'un mélange de chromosorb W 60/80 mesh et d'huile Kel F à 50% en poids. La température est de 0 °C, le gaz vecteur l'hélium. On introduit un mélange équimoléculaire contenant 5.10^{-3} mol de chacun des réactifs à l'aide d'un serpentin monté en dérivation.

Distillation sous vide

On prépare un mélange équimoléculaire de sulfure d'hydrogène et d'halogénure de bore (10^{-1} mol au total) dans un ballon de 2.5 l qui sert ensuite de bouilleur. La température de la distillation passe avec une vitesse de

For personal use only.

10 °C par heure environ de celle de l'air liquide jusqu'à l'ambiante. L'ensemble est maintenu sous vide primaire, et le distillat est condensé à la température de l'azote liquide et analysé régulièrement par spectroscopie i.r.

Spectres de résonance magnétique nucléaire de ^{11}B

Le tube d'analyse est relié à la rampe à gaz. On le met sous vide, puis on y condense à la température de l'air liquide des volumes connus de sulfure d'hydrogène, de chlorure ou de bromure de bore et de sulfure de carbone (préalablement séché sur tamis moléculaire) sous des pressions mesurées grâce au manomètre à mercure. Pour l'iodure de bore solide, la mesure de volume est remplacée par une pesée en boite à gants. Une solution type contiendra par exemple 80×10^{-3} mol de CS_2, 4×10^{-3} mol de sulfure d'hydrogène et 4×10^{-3} mol d'halogénure de bore. La quantité de sulfure d'hydrogène mise en jeu est limitée par la pression supportée par le tube. Le spectre est enregistré à 33 °C sur un appareil Perkin–Elmer R 10 travaillant à 19.25 MHz, le composé $(C_2H_5)_2O$, BF_3 étant utilisé comme étalon externe. Lorsque les solutions obtenues sont peu concentrées en sulfohydroxohalogénoboranes, les spectres sont accumulés 128 fois.

Synthèses de l'acide thioborique $(BSSH)_3$

Dans un ballon de 1 l, on dissout 100 g de bromure de bore (0.4 mol environ) dans 250 cm^3 de sulfure de carbone. La solution est refroidie à −10 °C, et on y fait barboter un courant de sulfure d'hydrogène (environ 0.5 l par min). On prélève régulièrement à l'aide d'une seringue hypodermique un échantillon de la solution dont on détermine le spectre i.r. On obtient le dérivé trisubstitué $B(SH)_3$ qui se cyclise partiellement à −10 °C. Au bout de 4–5 jours, on laisse la solution revenir à température ambiante pour compléter cette cyclisation puis on filtre sur verre fritté. Le montage utilisé est dérive de celui décrit à propos d'un autre travail dans une publication précédente (21). L'acide thioborique est identifié par spectroscopie i.r. et diffraction X (13, 14) et purifié par recristallisation vers −80 °C dans le sulfure de carbone. Quantité obtenue: environ 20 g (rendement : 67% par rapport au bromure de bore).

Synthèse du tribromoborsulfol en l'absence de solvant

On prépare dans un ballon de 2.5 l un mélange de 10^{-1} mol de H_2S et 10^{-1} mol de BBr_3. La pression est voisine de l'atmosphère, et il subsiste une partie liquide. Après 24 h à température ambiante, on refroidit à la température de l'azote liquide et on laisse revenir sous vide jusqu'à −80 °C environ avec une vitesse de réchauffement de 10 °C par h. On coupe la communication avec la rampe à vide, et on laisse le mélange se remettre en équilibre pendant 4 h à température ambiante. On recommence plusieurs fois de suite la même opération en élevant à chaque fois de 10–20 °C la température maximale de la distillation jusqu'à ce qu'elle atteigne −20 °C environ. On distille ensuite le bromure de bore en excès à température ambiante pour faire recristalliser le tribromoborsulfol.

Quantité obtenue : 2.5 g environ (rendement: 20% par rapport au bromure de bore engagé dont la majeure partie sert en fait de solvant).

Anal. calc.: B, 8.79; S, 26.12; Br, 65.09. Trouvé: B, 9.0; S, 25.0; Br, 66.0.

Spectre de Debye–Scherrer: raies intenses à 3.55 et 2.87 Å; spectre d'absorption i.r. : bandes intenses vers 780, 795, et 990 cm^{-1}; p.f. 99 ± 3 °C.

Synthèse du trichloroborsulfol

On traite 10 g d'acide thioborique par 15 g de chlorure de bore liquide à 0 °C. Au bout de 4 h, on distille sous vide et on reprend le résidu solide par 15 g de chlorure de bore. On recommence l'opération jusqu'à ce que le spectre i.r. du distillat montre qu'il ne contient plus que du chlorure de bore. On reprend alors une dernière fois par BCl_3 liquide, on filtre la solution obtenue pour éliminer le sulfure de bore éventuellement formé et on fait recristalliser le $(BSCl)_3$ par distillation sous vide. Quantité obtenue : 3.5 g environ (rendement : 33% par rapport au $(BSSH)_3$ initial).

Anal. calc.: B, 13.82; S, 40.92; Cl, 45.26. Trouvé: B, 14.5; S, 43.2; Cl, 42.3.

Spectre de Debye–Scherrer: raies intenses à 3.52, 3.41, 2.78 et 2.72 Å ; spectre d'absorption i.r.: bandes intenses vers 860, 878, et 995 cm^{-1} ; p.f. 235 ± 3 °C.

Synthèse du triiodoborsulfol

On pulvérise en boite à gants 10 g d'iodure de bore préparé et purifié au laboratoire (22) qu'on place dans une nacelle. On introduit cette dernière dans un tube de pyrex monté sur un vibreur destiné à améliorer le contact gaz–solide. On traite à température ambiante par un courant de H_2S (10 l par h environ pendant 5 h). L'iodure de bore n'ayant pas réagi est ensuite sublimé sous vide vers 60 °C. Quantité obtenue : 2 g environ (rendement: 45% environ par rapport à BI_3 mis en jeu).

Anal. calc.: B, 6.37; S, 18.89; I, 74.74. Trouvé : B, 7; S, 17.4; I, 75.6.

Spectre de Debye–Scherrer : raies intenses à 4.30, 4.07, 3.25, et 2.87 Å; spectre d'absorption i.r. : bandes intenses vers 725, 740, et 980 cm^{-1}; p.f. 140 ± 3 °C.

Nous tenons à remercier Monsieur J. P. Laurent (Laboratoire de chimie inorganique, Professeur Gallais, Faculté des Sciences de Toulouse) qui a bien voulu déterminer et étudier les spectres de résonance magnétique nucléaire de nos produits en nous faisant ainsi bénéficier de ses conseils et de son expérience.

Preparation and Characterization of Pseudohalogeno(methyl)germanes and Related Compounds[1]

J. E. DRAKE[2] AND R. T. HEMMINGS

Department of Chemistry, University of Windsor, Windsor, Ontario

Received June 30, 1972

Synthetic routes to the series of pseudohalogeno(methyl)germanes, $MeGeH_2Ps$ and $MeGePs_3$ (Ps = N_3, CN, NCO, NCS), and the related compounds $MeGeH_2OAc$ and $Ge(N_3)_4$ are discussed. The compounds are characterized by their molecular weights, mass spectra, ^1H n.m.r. spectra and cleavage reactions. Their i.r. and Raman spectra are assigned as further confirmation of their structures.

Des approches de synthèse pour les pseudohalogéno(methyl)germanes, $MeGeH_2Ps$ et $MeGePs_3$ (Ps = N_3, CN, NCO, NCS), et les composés similaires comme $MeGeH_2OAc$ et $Ge(N_3)_4$ sont discutées. Les composés sont caractérisés par leurs poids moléculaire, spectre de masse, spectre r.m.n. du proton et leurs réactions de clivage. Leurs spectres i.r. et Raman ont aussi été utilisés comme preuves supplémentaires de leurs structures. [Traduit par le journal]

Introduction

We recently described the preparation and characterization of the halogeno(methyl)germanes, $MeGeH_nX_{3-n}$, X = F, Cl, Br, I, n = 0, 1, or 2 (1). The work reported here is part of a continuing program on the investigation of the syntheses and vibrational analysis of species containing the $MeGeH_n$ group. We have synthesized stable mono- and tripseudohalogeno-(methyl)germanes in high yields by conventional methods and identified the products by ^1H n.m.r., i.r., Raman, and mass spectroscopy.

Unstable di-pseudohalogeno species have been identified in the ^1H n.m.r. and mass spectra although attempts to obtain them pure have been unsuccessful.

Experimental

Apparatus

A conventional Pyrex–glass vacuum system was used for all experiments. The i.r. spectra were recorded at room temperature in the range 4000–400 cm^{-1} on a Beckman IR 12 spectrometer using a gas cell (50 mm pathlength) fitted with KBr windows, or an air-tight solution cell. Raman spectra were recorded in the range 4000–50 cm^{-1} with the sample in sealed Pyrex–glass tubes (*ca.* 2 mm o.d.) on a Beckman 700 laser–Raman spectrometer using a helium–neon source. Strong bands are estimated to ± 1 cm^{-1} in the i.r. and ± 4 cm^{-1} in the Raman effect. The ^1H n.m.r. spectra were recorded at 60 MHz on a Jeol C-60 HL high resolution spectrometer in sealed tubes (*ca.* 2 or 5 mm o.d.) and the mass spectra on an AEI MS10c2 instrument, fitted with a Hitachi–Perkin–Elmer recorder, operating at an ionizing potential of 70 eV. Molecular weights were obtained from vapor density measurements of the monopseudohalides and from freezing point depression in benzene of the tripseudohalides.

Starting Materials

Methylgermane was prepared by the reaction of methyl iodide on germylpotassium (2). Commercial germane and hydrogen bromide were purified by pumping off any non-condensable gases at −196°. Commercial boron trichloride and boron tribromide (Matheson) were distilled prior to use. The i.r. spectra and vapor pressure of the middle fractions corresponded to those of the pure compounds (3, 4). The halogeno(methyl)germanes $MeGeH_2Cl$, $MeGeH_2Br$, $MeGeHBr_2$, and $MeGeH_2F$ were prepared by halogenation of methylgermane with BX_3 (X = Cl, Br) and by passing $MeGeH_2Br$ over dry lead(II) fluoride as described previously (1). The hydrides were purified by trap-to-trap distillation, fractions being taken of which the ^1H n.m.r. (1) and i.r. (5) spectra indicated a high degree of purity. Commercial trichloro-(methyl)germane and chloro(trimethyl)silane (Alfa Inorganics) were distilled to remove hydrogen chloride before use and had i.r. (6) and ^1H n.m.r. (7) spectra corresponding to the pure materials. Tribromo(methyl)germane was prepared by the reaction of trichloro(methyl)germane with excess hydrogen bromide until the ^1H n.m.r. spectrum (7) showed complete halogen exchange had occurred and the i.r. spectrum (8) corresponded to the pure compound. Reagent grade samples of the silver salts, AgCN, AgNCO, AgNCS, and AgOAc, and NaN_3 were dried in a high vacuum for several days prior to use. Azido(trimethyl)silane, Me_3SiN_3, was obtained from Me_3SiCl and NaN_3 in ether (9). Anhydrous ether (Mallinckrodt), tetrahydrofuran (B.D.H.), and benzene were distilled from fresh lithium aluminum hydride and stored in vacuum vessels. Spectral grade tetramethylsilane, germanium tetrachloride, chloroform, and carbon tetrachloride were used without further purification.

Section A

Preparation of the Azido(methyl)germanes

(a) Reaction of Azido(trimethyl)silane with Monofluoro(methyl)germane

In a typical experiment Me_3SiN_3 (1.60 mmol) and $MeGeH_2F$ (1.70) mmol) were condensed into a 10 ml reaction vessel at −196°. The mixture was warmed to room temperature and allowed to react (5 min). Repeated fractionation through a trap at −78° gave Me_3SiF (*ca.* 1.55 mmol; identified by its ^1H n.m.r. (7) and i.r. (10) spectra) and a small amount of unreacted $MeGeH_2F$ (*ca.* 0.1 mmol) in a trap at −196°. Distillation of the products in the −78° trap gave pure azido(methyl)-germane, $MeGeH_2N_3$ (*ca.* 1.54 mmol; found: M, 132; calcd. for $MeGeH_2N_3$, 131.68; v.p. *ca.* 13 mm Hg at 20°) in a trap at −45° and a trace of unreacted Me_3SiN_3 in a trap at −196°. The liquid was stable, showing no signs of decomposition after 1 week at room temperature.

(b) Reaction of Azido(trimethyl)silane with Monochloro(methyl)germane

Typically Me_3SiN_3 (1.90 mmol) and $MeGeH_2Cl$ (2.00 mmol) were allowed to react at room temperature (*ca.* 30 min). Fractionation of the products gave unreacted $MeGeH_2Cl$ (1.82 mmol; v.p. 62 mm Hg at 0 °C; identified by its i.r. (5) and ^1H n.m.r. (1) spectra) in a trap at −196°; Me_3SiN_3 (*ca.* 1.70 mmol) and traces of Me_3SiCl (*ca.* 0.17 mmol) identified in the ^1H n.m.r. spectrum (7, 11) of the products in a −63° trap, and a small amount of oily material (*ca.* 0.18 mmol), which was subsequently shown to be $MeGeH_2N_3$, in a trap at −45° (found: M, 135; calcd. for $MeGeH_2N_3$, 131, 68; v.p. *ca.* 12 mm Hg at 20°).

(c) Reaction of Trichloro(methyl)germane with Sodium Azide

Typically $MeGeCl_3$ (10.5 mmol) and diethyl ether (*ca.* 20 ml) were distilled under vacuum into a 100 ml round bottomed flask fitted with a reflux condenser containing an excess of dry NaN_3 (*ca.* 4.5 g). The stirred mixture was maintained under reflux (*ca.* 100 h). Unwanted solid residue, containing NaN_3 and NaCl, was removed by vacuum filtration to give a clear ether solution which was carefully evaporated to dryness under high vacuum. Fractionation of the last portions of ether to be evaporated gave small amounts of a white subliming solid in a trap at −23° which was subsequently shown to contain mixed azido-chloro species (section *e*). $MeGe(N_3)_3$ (1.9 g; 85% yield) was isolated as a white powdery solid (found: M, 218; calcd. for $MeGe(N_3)_3$, 213.72; m.p. 44–45°). Sensitivity to percussion was not observed.

(d) Reaction of Tetrachlorogermane with Sodium Azide

In a typical reaction, $GeCl_4$ (2.1 g; *ca.* 10.0 mmol) and dry T.H.F. (*ca.* 20 ml) were distilled into a 100 ml round bottomed flask fitted with a reflux condenser containing excess dry NaN_3 (*ca.* 5.0 g). The mixture was refluxed (*ca.* 100 h) and separated by vacuum filtration to give a clear solution and a white residue containing unreacted NaN_3 and NaCl. The T.H.F. solution was carefully evaporated to dryness under high vacuum, diethyl ether being added in the latter stages to facilitate removal of the last traces of solvent. A white material, tetraazido-germane (found: M, 255; calcd. for $Ge(N_3)_4$, 240) remained in the filtration vessel. The $Ge(N_3)_4$ was apparently not sensitive to percussion but it exploded in the laser beam so only limited spectroscopic data were obtained. Small amounts of white material were sublimed with the last fractions of solvent. The i.r. spectrum in CCl_4 solution of this material showed a peak at *ca.* 450 cm^{-1} characteristic of the Ge—Cl stretching mode (5) in addition to those attributable to an azide. Thus it was assumed to be partially chlorinated $Ge(N_3)_nCl_{4-n}$.

(e) Reaction of Trichloro(methyl)germane with Azido(trimethyl)silane

Typically, $MeGeCl_3$ (*ca.* 0.5 mmol) and Me_3SiN_3 (*ca.* 1.5 mmol) were sealed together at −196° in a semi-micro n.m.r. tube and allowed to warm to room temperature. After *ca.* 10 min the ^1H n.m.r. spectrum showed resonances at 0.23 and 1.61 δ in the expected ratio 9:1 assignable to Me_3SiN_3 (11) and $MeGeCl_3$ (7), respectively. After *ca.* 5 days resonances attributable to Me_3SiCl (0.38 δ) and $MeGe(N_3)_3$ (1.39 δ) had appeared along with resonances at 1.07 and 1.20 δ. The latter resonances also appeared in the n.m.r. spectrum given by the volatile material from the reaction of $MeGeCl_3$ and NaN_3 (see section *c*) and in the n.m.r. spectrum given by a separate reaction of $MeGeCl_3$ and $MeGe(N_3)_3$ and were consistent with the formation of the azido-chloro species $MeGe(N_3)_2Cl$ and $MeGeN_3Cl_2$. Similarly, azido-bromo species $MeGe(N_3)_2Br$ (1.26 δ) and $MeGeN_3Br_2$ (1.60 δ) were observed in the n.m.r. spectrum in the reaction of $MeGeBr_3$ with $MeGe(N_3)_3$.

Characterization of the Azido(methyl)germanes

The ^1H n.m.r. parameters of mono- and triazido-(methyl)germane are listed (Table 1). The spectra, recorded in CCl_4 solution (*ca.* 5%) with internal tetramethylsilane reference, showed broadening of the resonances which was observed in the spectrum of GeH_3N_3 (12). The i.r. and Raman spectra of $MeGeH_2N_3$, $MeGe(N_3)_3$, and $Ge(N_3)_4$ are displayed (Table 2) with the assignments.

The mass spectrum of $MeGeH_2N_3$ gave fragments in the regions, *m/e* 28 (I = 1.6) (N_2^+); *m/e* 70–77 (I = 45.9) (H_nGe^+); *m/e* 83–93 (I = 100.0). (H_nCGe^+); *m/e* 101–105 (I = 8.1) ($H_nGeN_2^+$); *m/e* 114–118 (I = 30.9) ($H_nGeN_3^+$); *m/e* 129–135 (I = 17.8) ($H_nCGeN_3^+$).

Section B

Preparation of the Cyano(methyl)germanes

(a) Reaction of Chloro- and Bromo(methyl)germane with Silver(I) Cyanide

In a typical reaction, chloro- or bromo(methyl)-germane (*ca.* 1.5 mmol) was passed through a column loosely packed with a mixture of glass wool and dry silver(I) cyanide (*ca.* 25 g) at room temperature. After two double passes the silver(I) cyanide had turned from white to brown and i.r. spectroscopic examination of the volatile products indicated that almost all the starting material had been used up. Fractionation of the volatile products gave cyano(methyl)germane (1.35 mmol; found: M, 117; calcd. for $MeGeH_2CN$, 115.67; v.p. 24 mm Hg at 20°) passing through a trap at −45° but retained in one at −63°. The pure liquid showed no signs of decomposition after 5 weeks at room temperature in a sealed tube but left white deposits when distilled in the presence of Hg vapor. In the chloro system traces of unreacted $MeGeH_2Cl$ were found in a −196° following trap.

(b) Reaction of Dibromo(methyl)germane with Silver(I) Cyanide

A reaction analagous to that used for the monochloro- and bromo(methyl)germanes was used with dibromo-(methyl)germane (*ca.* 2.1 mmol). An exothermic reaction occurred in which the silver(I) cyanide turned dark brown. After four double passes volatile material (1.2 mmol) was recovered after bleeding off uncondensable gas (*ca.* 0.9 mmol). Distillation of the products gave a mixture of $MeGeH_3$ and HCN (*ca.* 0.2 mmol) (identified spectroscopically) in a trap at −196°, traces of $MeGeH_2CN$ (*ca.* 0.3 mmol) in a trap at −45°, and a white involatile residue. The contents of the −45° trap sealed at −196° for n.m.r. analysis, rapidly turned white. The n.m.r. spectrum indicated the presence of $MeGeH_2CN$ (peaks at 0.67 and 4.35 δ) and traces of $MeGeH(CN)_2$ (peaks at 0.98 and 5.30 δ). Broad features at 3.95, 3.8 δ (H_nGeCN region) grew with time. Similar results were obtained when the $MeGeHBr_2$ was streamed over AgCN with N_2.

(c) Reaction of Tribromo(methyl)germane with Silver(I) Cyanide

By an analogous procedure to that described for the reaction of $MeGeCl_3$ and NaN_3, $MeGeBr_3$ (*ca.* 5 mmol), excess AgCN (*ca.* 5 g) and T.H.F. (*ca.* 15 ml) were refluxed (*ca.* 60 h). The reaction mixture turned from white to black. Filtration and removal of solvent in a high vacuum led to the isolation of tricyano(methyl)-germane, $MeGe(CN)_3$ (found: M, 170; calcd. for $MeGe(CN)_3$, 165.66). The white powdery solid liquified in moist air slowly evolving HCN, dissolved in benzene and T.H.F. but was only sparingly soluble in ether and CCl_4.

Characterization of the Cyano(methyl)germanes

The ^1H n.m.r. parameters of the cyano(methyl)-germanes are listed (Table 1). The vibrational spectra of $MeGeH_2CN$ and $MeGe(CN)_3$ are displayed (Table 3). The mass spectrum of $MeGeH_2CN$ gave the expected parent peaks, *m/e* 111–119 (H_nCGeCN^+). Confirmation of the *a priori* assignment of the unstable di-species, $MeGeH(CN)_2$, in the n.m.r. spectrum (section *b*) came from fragments at *m/e* 122–129 ($H_nGe(CN)_2^+$); *m/e* 137–144 ($H_nCGe(CN)_2^+$) given by the contents of the −45° trap. Further characterization came from hydrogen bromide cleavage reactions. The cyano(methyl)germanes $MeGeH_2CN$ (1.2 mmol) or $MeGe(CN)_3$ (0.7 mmol), were treated with excess HBr at room temperature. After *ca.* 2 h non-condensable gas was bled off at −196° and the products fractionated to isolate the product bromo(methyl) germanes, $MeGeH_2Br$ (1.1 mmol) or $MeGeBr_3$ (0.55 mmol), which were identified from vapor pressure measurements and from ^1H n.m.r. (1, 7) and i.r. (5, 8) spectra.

‡ρGeH_2 displays a weak feature in this region.

all the starting material had been consumed and isocyanato(methyl)germane, $MeGeH_2NCO$ (1.95 mmol; found: M, 131; calcd. for $MeGeH_2NCO$, 131.66; v.p. *ca.* 17 mm Hg at 20°), was obtained after fractionation in a trap at −45°. In an analogous reaction using $MeGeH_2Cl$ less than 20% conversion to the required isocyanate was obtained after ten double passes. The reaction was accompanied by formation of uncondensable gas, methylgermane, and involatile white material in the reaction tube.

Samples of $MeGeH_2NCO$ showed no signs of decomposition after 6 weeks in sealed tubes. On exposure to Hg vapor or silver(I) cyanate redistribution of the Me group was evident from the appearance of additional peaks in the ^1H n.m.r. spectrum of a fraction held at −78° at 0.94 and 6.17 δ ($MeGeH(NCO)_2$) and 0.87 δ ($Me_2Ge(NCO)_2$).

(b) Reaction of Dibromo(methyl)germane with Silver(I) Cyanate

Typically $MeGeHBr_2$ (1.5 mmol) was streamed through a column of silver(I) cyanate (*ca.* 20 g). An exothermic reaction ensued in which the contents of the reaction tube blackened. Uncondensable gas (*ca.* 0.5 mmol) was bled away through traps at −196°. The volatile material rapidly turned white at room temperature; distillation gave HNCO (*ca.* 0.1 mmol; identified spectroscopically) in a trap at −196°, $MeGeH_2NCO$ (*ca.* 0.2 mmol) and an intractable white residue in a trap at −45° and an oily material in a trap at −23°. The contents of the −23° trap, sealed for ^1H n.m.r. analysis, rapidly turned white and showed bands assignable to $MeGeH_2NCO$, 0.75, 5.20 δ; $MeGeH(NCO)_2$, 0.94, 6.17 δ; $Me_2Ge(NCO)_2$, 0.87 δ; $MeGeH_3$, 0.29, 3.45 δ with additional unidentified resonances at 3.3 and 4.15 δ.

(c) Reaction of Tribromo(methyl)germane with Silver(II) Cyanate

In a reaction analogous to that described for the preparation of tricyano(methyl)germane, $MeGeBr_3$ (*ca.* 7.5 mmol), excess silver(I) cyanate (*ca.* 8 g), and benzene (*ca.* 15 ml) were stirred under reflux (*ca.* 72 h). The reaction mixture turned brown to black and vacuum filtration followed by evaporation of solvent led to the isolation of $MeGe(NCO)_3$ (*ca.* 1.36 g, 5.2 mmol; found: M, 212; calcd. for $MeGe(NCO)_3$, 213.66; m.p. 48–51°). $MeGe(NCO)_3$ was soluble in benzene, T.H.F., and chloroform, and sparingly soluble in ether and CCl_4. No bromo-isocyanato species were detected in any reactions.

Characterization of the Isocyanato(methyl)germanes

The ^1H n.m.r. parameters of the isocyanato(methyl)germanes are listed (Table 1). I.r. and Raman spectral data are presented for $MeGeH_2NCO$ and $MeGe(NCO)_3$ (Table 4). The mass spectrum of $MeGeH_2NCO$ gave the parent peaks at *m/e* 128–132 ($H_nCGeNCO^+$). Weak fragments appeared at *m/e* 154–159 ($H_n(NCO)_2^+$) and *m/e* 166–171 ($H_nCGe(NCO)_2^+$) in the spectrum given by the contents of the −23° trap (section *b*) containing the dipseudohalide.

Hydrogen bromide cleavage reactions gave $MeGeH_2Br$ (0.8 mmol) from $MeGeH_2NCO$ (0.85 mmol) and $MeGeBr_3$ (0.85 mmol) from $MeGe(NCO)_3$ (*ca.* 1.0 mmol).

Section D

Preparation of the Isothiocyanato(methyl)germanes

(a) Reaction of Chloro- and Bromo(methyl)germane with Silver(I) Thiocyanate

A reaction analagous to that described for the syntheses of cyano- and isocyanato(methyl)germane was used. Typically, $MeGeH_2Br$ (*ca.* 2.1 mmol) was streamed through a column of silver(I) thiocyanate (*ca.* 25 g). An exothermic reaction occurred in which the silver salt turned dark brown. Isothiocyanato(methyl)germane, $MeGeH_2NCS$, (2.05 mmol; found: M, 146, calcd. for $MeGeH_2NCS$, 147.73) was recovered almost quantitatively after fractionation and condensation in a trap at $-45°$. Sealed samples showed no signs of decomposition after ten weeks at room temperature; prolonged exposure to Hg vapor or silver(I) thiocyanate resulted in the deposition of yellow residue and features assignable to disproportionation products appeared in the n.m.r. spectrum, $(Me_2Ge(NCS)_2$, 1.04 δ; $MeGeH(NCS)_2$, 1.12 and 5.80 δ; $MeGeH_3$, 0.29 and 3.45 δ; $MeGe(NCS)_3$, 1.33 δ). In a similar reaction substituting $MeGeH_2Cl$ (1.4 mmol) for $MeGeH_2Br$ no conversion to the expected thiocyanato compound was observed and $MeGeH_2Cl$ (1.35 mmol, identified by its ^1H n.m.r. (1) and i.r. (5) spectra) was recovered almost quantitatively.

(b) Reaction of Dibromo(methyl)germane with Silver(I) Thiocyanate

In a typical experiment, $MeGeHBr_2$ (1.8 mmol) was passed through a column of silver(I) thiocyanate (*ca.* 20 g). An exothermic reaction occurred in which the AgNCS turned black. Uncondensable gas (*ca.* 0.7 mmol) was bled away with the collecting bulb held at $-196°$. The volatile material contained some unreacted $MeGeHBr_2$, $MeGeH_3$, and $MeGeH_2NCS$ (*ca.* 0.3 mmol, identified in the n.m.r. spectrum) in a trap at $-45°$, and an oily liquid mixed with a yellow sublimable solid in a trap at $-23°$. The n.m.r. spectrum showed features assignable to $MeGeH(NCS)_2$, 1.12 and 5.80 δ; $Me_2Ge(NCS)_2$, 1.33 δ; $MeGe(NCS)_3$, 1.33 δ; with additional strong resonances at 3.3, 3.5, 4.4 δ. The yellow material was insoluble in CS_2 indicating that it contained no free sulfur. A CS_2 smear spectrum indicated that this material was probably polymeric thiocyanic acid.

(c) Reaction of Tribromo(methyl)germane with Silver(I) Thiocyanate

$MeGeBr_3$ (*ca.* 10.5 mmol), excess silver(I) thiocyanate (*ca.* 7.5 g), and ether (*ca.* 15 ml) were stirred under reflux (*ca.* 70 h). The reaction mixture turned dark brown and vacuum filtration followed by evaporation of solvent led to the isolation of $MeGe(NCS)_3$ (2.2g, 8.5 mmol; found: M, 265, calcd. for $MeGe(NCS)_3$, 261.87; m.p. 50–53°). $MeGe(NCS)_3$ was soluble in ether, benzene, and $CHCl_3$ and sparingly soluble in CCl_4.

Characterization of the Isothiocyanato(methyl)germanes

The ^1H n.m.r. parameters of the isothiocyanato(methyl)germanes are listed (Table 1). I.r. and Raman data are presented for $MeGeH_2NCS$ and $MeGe(NCS)_3$ (Table 4). The mass spectrum of $MeGeH_2NCS$ showed expected parent peaks at *m/e* 143–148 ($H_nCGeNCS^+$). Fragments at *m/e* 188–192 ($H_nGe(NCS)_2^+$) and *m/e* 203–207 ($H_nCGe(NCS)_2^+$) were observed in the mass spectrum given by the contents of the $-23°$ trap in section (*c*) containing the diisothiocyanate. Hydrogen bromide cleavage reactions gave $MeGeH_2Br$ (1.15 mmol) from $MeGeH_2NCS$ (1.20 mmol) and $MeGeBr_3$ (0.65 mmol) from $Me_3Ge(NCS)_3$ (*ca.* 0.8 mmol).

Section E

Preparation of Acetoxy(methyl)germane

Reaction of Bromo(methyl)germane with Silver(I) Acetate

$MeGeH_2Br$ (1.4 mmol) when streamed through dry silver(I) acetate (*ca.* 25 g) gave an exothermic reaction in which the contents of the reaction tube turned from white to black. Acetoxy(methyl)germane, $MeGeH_2OAc$ (1.3 mmol; found: M, 145; calcd. for $MeGeH_2OAc$ 148.68) was isolated after fractionation and condensation in a trap at $-45°$. In an analogous reaction substituting $MeGeH_2Cl$ (2.0 mmol) for $MeGeH_2Br$ no apparent conversion to the expected acetoxy compound was observed. The ^1H n.m.r. spectrum of the total products indicated the presence of $MeGeH_2Cl$ (*ca.* 1.7 mmol) together with small amounts of $MeGeH_3$, $MeGeHCl_2$, and Me_2GeCl_2. Samples were stable at room temperature but showed signs of disproportionation when distilled onto silver acetate. Additional peaks in the ^1H n.m.r. spectrum appearing at 0.29 and 3.45 δ ($MeGeH_3$); 1.02 and 6.88 δ ($MeGeH(OAc)_2$); 0.98 δ ($Me_2Ge(OAc)_2$) and 2.04 and 11.3 δ (HOAc).

Characterization of Acetoxy(methyl)germane

The ^1H n.m.r., i.r., and Raman spectral data for $MeGeH_2OAc$ are given (Tables 1 and 3). The mass spectrum gave the expected parent peaks at *m/e* 144–150 ($H_nCGeOAc^+$). Confirmation of the *a priori* assignment of diacetoxy-species in the ^1H n.m.r. spectrum after disproportionation, came from additional fragments at *m/e* 190–194 ($H_nGe(OAc)_2$) and *m/e* 205–211 ($H_nCGe(OAc)_2$). The HBr cleavage reaction gave $MeGeH_2Br$ (0.9 mmol) from $MeGeH_2OAc$ (0.95 mmol).

Discussion

Heavy metal salt exchange reactions have provided the most convenient routes to the cyanides, isocyanates, isothiocyanates, and acetates in silane (13, 14) and germane (15) chemistry. The long-established (13, 14) silyl-conversion series for silver salts suggested that pseudohalides might be formed from all halogeno(methyl)germanes other than the fluoride. We find that bromo(methyl)germane is quantitatively converted to the pseudohalides (reaction 1). With chloro(methyl)germane, as with chloro-

$$[1]\quad MeGeH_2Br \xrightarrow[(Ps = CN, NCS, NCO, OAc)]{AgPs} MeGeH_2Ps$$

germane (15), there is extensive conversion to the cyanide but there is only limited conversion to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the isocyanate. Chloro(methyl)germane is recovered essentially unchanged on passage over AgNCS and AgOAc.

Repeated attempts to synthesize pure samples of the dipseudohalogeno species by passage of dibromo(methyl)germane over silver salts were unsuccessful despite meticulous drying of the silver salts and dilution with nitrogen. The formation of $MeGeH(Ps)_2$, Ps = CN, NCO, NCS is accompanied by evolution of hydrogen and the formation of intractable material and the corresponding acid. Cyanic acid was found to catalyze the polymerization of SiH_3NCO (13) so presumably the presence of hydroacids catalyzes further decomposition. Although the formation of the hydroacids is suggestive of intermolecular elimination, no evidence for any Ge—Ge bonds was obtained in the vibrational or mass spectra. The ^1H n.m.r. spectra of $MeGeH(Ps)_2$ show many additional peaks arising from the continuing decomposition of the dipseudohalides.

The tripseudohalogeno(methyl)germanes are successfully prepared in high yield by the reaction of tribromo(methyl)germane with the corresponding silver salt (reaction 2), utilizing similar conditions described for the pseudohalogeno(trimethyl)germanes (16–18 and references therein). Despite the relative ease of these

$$[2]\quad MeGeBr_3 \xrightarrow[(Ps = CN, NCO, NCS)]{AgPs} MeGe(Ps)_3$$

silver salt reactions, an alternative route was sought for the azido(methyl)germane derivatives because of the instability of silver azide. Monofluorogermane reacted with azido(trimethyl)silane to form GeH_3N_3 in high yield (12, 19). The corresponding exchange between fluoro(methyl)germane and azido(trimethyl)silane gives virtually quantitative yields of azido(methyl)germane (reaction 3). By comparison the equil-

$$[3]\quad MeGeH_2F + Me_3SiN_3 \rightleftarrows MeGeH_2N_3 + Me_3SiF$$

ibrium in the reaction with chloro(methyl)germane lies far to the left at room temperature making this an unsuitable starting material.

Similarly, the reaction between trichloro(methyl)germane and azido(trimethyl)silane gives an equilibrium mixture, containing mixed species as was found for reaction of the azidosilane with dichloro(dimethyl)silane (20). These results are consistent with the generally accepted concept (21) that exchange in a silyl–germyl system favors the formation of the hard (less polarizable) moiety bound to silicon. The reaction of $MeGeF_3$ with Me_3SiN_3 was not attempted because it was not possible to prepare the required quantities of pure $MeGeF_3$ (22).

Direct reaction of an organometallic chloride with sodium azide has been successful in the syntheses of many organo-group IV azides (23) and similarly tri-azido(methyl)germane (reaction 4), and tetraazidogermane (reaction 5), may be synthesized. Unlike the related silicon com-

$$[4]\quad MeGeCl_3 + 3NaN_3 \xrightarrow{\text{ether}} MeGe(N_3)_3 + 3NaCl$$

$$[5]\quad GeCl_4 + 4NaN_3 \xrightarrow{\text{T.H.F.}} Ge(N_3)_4 + 4NaCl$$

pounds, azido(methyl)germanes do not appear to be sensitive to percussion and are stable for long periods of time above their melting points. However, a sample of $Ge(N_3)_4$ did explode in a green laser beam (*ca.* 600 mW). In the synthesis of the corresponding tin compound (24), a complex salt, $Sn(N_3)_4.2NaN_3$ was obtained. We find no evidence for similar complex formation of tetraazidogermane, which may reflect the familiar difficulty encountered in forcing germanium to increase its co-ordination number to six.

As has been indicated earlier, exchange at silicon or germanium is characteristic of the halogeno-derivatives (21). Exchange with hydrogen halide provided a convenient synthetic route to iodo- and bromo(methyl)germanes (1) because the formation of the heavier halogen bound to germanium was favored. The use of a similar route to pseudohalides would require reaction of fluoro(methyl)germanes with HPs which is not a sensible synthetic prospect. However, this type of reaction provides a convenient characterization of the pseudohalide since the parent bromo(methyl)germane is reclaimed by reaction with hydrogen bromide, consistent with reaction 6.

$$[6]\quad HBr + MeGeH_2Ps \rightarrow MeGeH_2Br + HPs$$
$$3HBr + MeGePs_3 \rightarrow MeGeBr_3 + 3HPs$$

The reactions are not suitable for the azides due to the hazardous nature of the by-product, hydrazoic acid.

Further characterization comes from molecular weight determinations and mass spectroscopy. The molecular weight of $MeGe(CN)_3$ suggests

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that, unlike $Ge(CN)_4$ which is polymeric (25), it is essentially monomeric, at least in benzene solution, as are all the other mono- and tri-pseudohalides. The lack of stability of the dipseudohalides precludes the determination of their molecular weights. However, parent peaks corresponding to $MeGeHPs_2^+$ (Ps = CN, NCO, NCS, OAc) are observed in their mass spectra. The parent peaks $MeGeH_2Ps^+$ (Ps = N_3, CN, NCO, NCS, OAc) are evident in the mass spectra of the monopseudohalides. From the fragmentation patterns it becomes evident that many of the pseudohalides undergo some decomposition and analysis of the H_nCGe^+ (*m/e* 70–79) and GeH_n^+ (83–93) fragments indicates the presence of significant amounts of methylgermane (26). This is undoubtedly a result of an inevitable exposure to mercury in the sampling system of the mass spectrometer. Thus relative intensities of the peaks are not meaningful nor the fragment distribution of the region *m/e* 70–93. For $MeGeH_2N_3$, the isotopic fragmentation patterns of the H_nGe^+ and H_nCGe^+ regions are clearly not perturbed by the presence of $MeGeH_3$ so intensities are reported. The relative intensities of the fragments H_nGe^+; H_nCGe^+; H_nGeX^+; H_nCGeX^+ (X = N_3) are 46:100:31:18 which is comparable with the corresponding values for $MeGeH_2Cl$ which are 46:100:42:30 (22, 26).

The ^1H n.m.r. spectra of the pseudohalogeno-(methyl)germanes are all first order (Table 1). The $MeGeH_2'Ps$ series all give the methyl resonance as a 1:2:1 triplet, intensity 3, to high field of an associated 1:3:3:1 quartet, intensity 2, attributable to GeH_2'. The unstable dipseudohalogeno series, identified in dilute solution, give a 1:1 doublet, intensity 3, for the methyl resonance and a 1:3:3:1 quartet, intensity 1, attributable to GeH′. The tripseudohalogeno series all give the methyl resonance as a singlet at high field. Significant dilution shifts (up to 5%) were observed particularly in the mono series; in accordance with other workers we report the ^1H n.m.r. parameters for the sample in CCl_4 solution (*ca.* 5%) using an internal reference of tetramethylsilane. The spectrum of acetoxy-(methyl)germane contained an additional singlet, intensity 3, attributable to the acetoxy-methyl protons. The chemical shifts of the GeH_2' resonance in $MeGeH_2'NCS$ and $MeGeH_2'NCO$ occur very close to that of $MeGeH_2'N_3$, confirming that all three are Ge—N bonded. A comparison with the values of germyl species (GeH_3N_3, 5.1 δ (12); GeH_3NCS, 5.18 δ (27); GeH_3NCO, 5.05 δ (27); $(GeH_3)_3N$, 4.9 δ (28); $(GeH_3)_2O$, 5.3 δ; $(GeH_3)_2S$; 4.7 δ (29)) further supports this conclusion, particularly as there has been strong n.m.r. evidence that GeH_3—NCO and —NCS are truly Ge—N bonded (27). A species containing a Ge—O bond should have the larger downfield shift and this is found for $MeGeH_2'OAc$. With $MeGeH_2'CN$, the chemical shift is upfield relative to the other $MeGeH_2'Ps$ as might be expected from the value in GeH_3CN (4.33 δ) (22). In the liquid state, it has been suggested that silyl- and germylcyanides may contain significant amounts of the isocyanide form in rapid equilibrium with the *normal* structure (16, 30). The chemical shift of $MeGeH_2'CN$ (4.35 δ) although to highfield of the GeH_2' resonances of the three Ge—N bonded species is still to lowfield of the resonance in *e.g.* Me_2GeH_2' (3.73 δ) (31). This is at least consistent with the presence of the rapid equilibrium suggested above.

The shifts in the GeH_2' resonances for $MeGeH_2'X$ species, X = F, Cl, Br, I (5), are apparently controlled by an inductive effect and hence related to the electronegativity of X. Thus with increasing electronegativity of X, an increased de-shielding of the proton attached to germanium is expected, and hence a shift downfield from TMS. In this context, the order of increasing electronegativity based on the observed n.m.r. shifts is I < CN < Br < NCO ≃ N_3 < Cl < NCS < OAc, which is as expected for the relative electronegativities of C, N, and O. On the other hand, where the polarizability (or hardness) of the pseudohalides seems to be important, as in exchange reactions, the order of reactivity, I → Br → NCO, N_3 NCS, Cl, OAc → CN → F, is such that the CN group behaves more like "F" than "Br".

For the $MeGeH_nPs_{3-n}$ species (Ps = N_3, NCO, NCS, OAc; *n* = 0, 1, 2) all of the n.m.r. parameters are close to, and show similar trends to those of $MeGeH_nCl_{3-n}$ (1).

Attempts have been made to interpret the vibrational spectra of compounds such as GeH_3NCO (27) and GeH_3N_3 (12) in terms of the expected and observed fundamentals assuming C_{3v} (Ge—N—C—O, Ge—N—N—N linear) or C_s (Ge—N—C—O, Ge—N—N—N bent) symmetry. The conclusions on this basis have not been definitive so we hesitate to make extravagant claims for our proposed assignments. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

any case, for the monopseudohalides, the symmetry argument would not hold. The assignments to fundamentals (Tables 2, 3, and 4) are made by comparison with related species (5, 12, 17, 27, 32, 33). Extensive discussion must await a full normal coordinate analysis which in turn will be more meaningful if based on direct structural evidence yet to be obtained. However, a few points of interest and speculation can be raised.

The n.m.r. evidence strongly favors Ge—N bonding in the —NCO and —NCS derivatives and this is clearly supported by the vibrational spectra. The Ge—N stretching modes can be assigned to strong polarized bands at 460, 482, 480, and 352 cm^{-1} in the Raman spectra of $MeGeH_2N_3$, $MeGe(N_3)_3$ (Table 2), $MeGeH_2$-NCO, and $MeGeH_2NCS$ (Table 4) which compare with 466, 459, and 358 cm^{-1} in GeH_3N_3, GeH_3NCO and GeH_3NCS, respectively (12, 27, 33). The assignments of the NCO and NCS pseudo-symmetric stretching vibrations at *ca.* 1400 and 950 cm^{-1} are diagnostic of *N*-functional groups (34).

For the cyanides the n.m.r. evidence suggested a carbon-bonded CN group with just a possibility of some isocyanide also being present. The vibrational spectrum (Table 3) of $MeGeH_2CN$ shows bands at 2202 cm^{-1} (2190 mP in the Raman) characteristic of a carbon function $\nu_{C\equiv N}$ (32*a*). On the other hand, in $MeGe(CN)_3$ only a weak broad feature, at lower wavenumber, is observed in this region in chloroform solution. This could indicate the presence of significant amounts of the Ge—NC moiety (16) possibly resulting from association (35) despite the molecular weight evidence in benzene. Involvement of the Ge—CN moiety in association would destroy the linearity of Ge—C—N and hence the C_{3v} symmetry of $MeGe(CN)_3$. Thus association or an equilibrium mixture of *normal* and *iso* forms could account for the apparent existence of two methyl rocks in the i.r. spectrum of $MeGe(CN)_3$. In $MeGeH_2CN$ a polarized band at 495 cm^{-1} can be assigned to νGe—C(CN). The strong polarized band at 428 cm^{-1} in $MeGeH_2CN$ and a band at 400 cm^{-1} in the i.r. spectrum of $MeGe(CN)_3$ are the only ones not easily explained on a comparative basis. They compare with one in GeH_3CN at *ca.* 443 cm^{-1} which, despite its intensity, was assigned as an overtone of the Ge—CN deformation (32*a*). In $MeGeH_2CN$ an assignment to an overtone or combination band is certainly not plausible in view of the observed Raman spectrum. This band at 428 cm^{-1} could be a fundamental skeletal mode at a surprisingly high wavenumber. Alternatively, it would be reasonable to assign it to Ge–N(NC) stretch. In a spectroscopic study of the trimethylsilyl cyanide and isocyanide system it was estimated that the mole fraction of isocyanide was only 0.0015 at 25° (30). The intensity of the 428 cm^{-1} band relative to that assigned to the Ge—$C(CH_3)$ symmetric stretch is very much less than for the corresponding band at 460 cm^{-1} in $MeGeH_2N_3$.

The assignment of $MeGeH_2OAc$ is reasonably straightforward based on comparison with GeH_3OAc, Me_3GeOAc (32*c*), and acetic acid. We choose to place the Ge—O stretching mode at 557 cm^{-1} in the Raman spectrum, by comparison with the polarized band assigned to this mode in GeH_3OMe at 602 cm^{-1} (36), rather than at *ca.* 880 cm^{-1} as suggested by the earlier work on germyl acetates (32).

We wish to thank the National Research Council of Canada for financial support.

Calculated Geometry for Ten-Coordination[1]

YEONG C. LIN AND DONALD E. WILLIAMS

Department of Chemistry, University of Louisville, Louisville, Kentucky 40208

Received January 24, 1972

The predicted geometry for coordination of ten ligands of equal size about a central atom was found by minimizing the interligand repulsion energy. The favored arrangement of hard-sphere ligands is of the 2:4:2:2 type, of symmetry C_{2v}. The favored arrangement of soft-sphere ligands is of the 1:3:3:3 type, symmetry C_{3v}, or of the 1:4:4:1 type, symmetry D_{4d}, depending on the degree of softness. The differences in repulsion energy among the three favored arrangements were small, making it likely that any differences in ligand sizes would be an important factor in determining the structure.

La géométrie prévue pour la coordination de dix coordinats ayant des dimensions égales autour d'un atome central a été trouvée par minimisation de l'énergie répulsive entre les coordinats. L'arrangement favorisé de coordinats sphériques et durs est du type 2:4:2:2 de symétrie C_{2v}. L'arrangement favorisé de coordinats sphériques et souples est du type 1:3:3:3 de symétrie C_{3v} ou du type 1:4:4:1 de symétrie D_{4d} dépendant du degré de souplesse. Les différences dans l'énergie de répulsion entre les trois arrangements favorisés sont petites, entrainant vraisemblablement que n'importe quelle différence dans la grosseur des coordinats sera un facteur dominant dans l'attribution de la structure.

Can. J. Chem., **51**, 312 (1973)

Introduction

The valence-shell-electron-pair-repulsion (VSEPR) model has proven valuable as a tool for predicting and understanding molecular geometry (1). The simplest case is the situation where a central atom is surrounded by n atoms or ligands of equal size. If some of the atoms or ligands are of different sizes, or if some of them are replaced by lone pair electrons, the situation becomes more complex. Much can be understood, however, by estimating the spatial requirements of the ligands or lone pairs in terms of a distortion from the simplest case of n equal ligands.

Chemists often assume that the potential energy of repulsion between atoms is proportional to d^{-r}, where d is an interligand distance. The repulsion exponent, r, is often taken as 12, or it may be adjusted according to some theoretical or experimental criterion. This model is referred to as the soft-sphere model.

The problem of finding the maximum angular size and orientation of n circles on a unit sphere has interested mathematicians (2). This problem may also be stated as that of finding the arrangement of points on a unit sphere which maximizes the least interpoint distance. The mathematician's statement of the problem corresponds to the chemist's statement in the limit as $r \to \infty$. This model is referred to as the hard-sphere model.

For $n \leq 12$, the solutions for the hard-sphere model are all definitely known, except for $n = 10$. Apparently the most rigorous treatment for $n = 10$ is that of Schütte and van der Waerden (2*a*), who conclude that a 2:4:2:2 arrangement of C_{2v} symmetry is probable. They give upper and lower limits for the least interligand distance as 1.14088 . . . and 1.09143 . . . , respectively.

For the soft-sphere model, the favored arrangement is known to be independent of r except for $n = 7$ and $n = 10$. The dependence on r of the $n = 7$ arrangement has been investigated by Britton (3) and by Claxton and Benson (4). For $r < 2.5$ a 1:5:1 arrangement of D_{5h} symmetry is preferred. In the range $2.5 < r < 5.6$ a 1:2:2:2 arrangement of C_2 symmetry is preferred.[2] For $r > 5.6$ a 1:3:3 arrangement of C_{3v} symmetry is obtained, similar to the hard-sphere model. The energy differences between these arrangements are small, so that any differences in ligand sizes would probably be the predominant influence in a structure with different ligands.

[1]This work supported by research grant GM 16260 from the U.S. Public Health Service.

[2]Claxton and Benson indicate that the C_2 arrangement is favored at $r = 2$; however, their energy table indicates that $E(C_2) = E(D_{5h})$ at $r = 2.5$ and that the D_{5h} structure is preferred at $r = 2$.

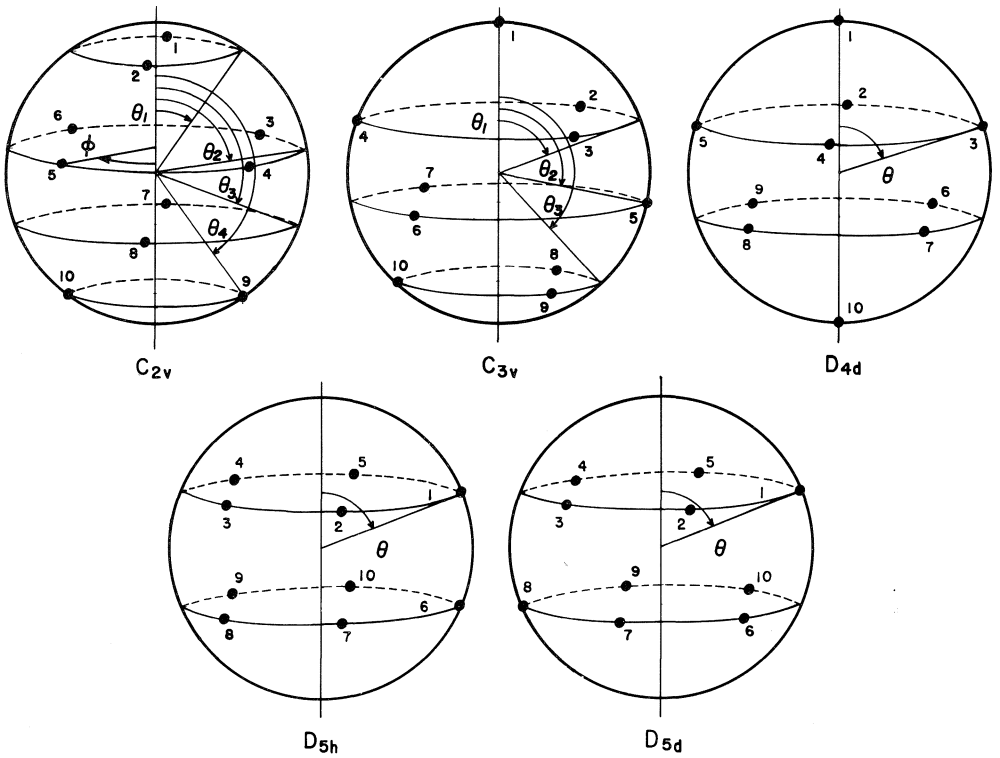

FIG. 1. Specifying parameters and ligand numbering system for ten-coordinate structures of C_{2v}, C_{3v}, D_{4d}, D_{5h}, and D_{5d} symmetry.

Method of Calculation

The model considered was an arrangement of ten points on a sphere of unit radius. The total repulsive energy (on a relative scale) was assumed to be given by

$$E = \sum_{j=1}^{9} \sum_{k=j+1}^{10} B d_{jk}^{-r}$$

where d_{jk} is the distance between points j and k, and r is the repulsion exponent. B is a constant, here taken as unity, which is included to make the equation dimensionally correct. In terms of the spherical coordinates (θ,ϕ) the square of the distance is given by

$$d_{jk}^2 = 2(1 - \sin\theta_j \sin\theta_k \cos\phi_j \cos\phi_k - \sin\theta_j \sin\theta_k \sin\phi_j \sin\phi_k - \cos\theta_j \cos\theta_k)$$

Three degrees of freedom are removed from the problem by setting the rotational origin. This may be accomplished by fixing one point at the north pole, for example, and fixing arbitrarily one additional ϕ coordinate, taking care to avoid taking the second point at the south pole. This leaves 17 degrees of freedom for the energy minimization.

A computer program was written which minimizes the replusive energy by steepest descents. A thorough analysis involving minimization of E for all 17 variables, and for various repulsion exponents, was found to be costly of computer time. We did determine the final energy minima for three values of r: 1, 12, and 30. Three different structures were obtained, of D_{4d}, C_{3v}, and C_{2v} symmetries, respectively. These arrangements may be characterized as being of 1:4:4:1, 1:3:3:3, and 2:4:2:2 coordination types, respectively (Fig. 1). In the case of $r = 30$, a false minimum structure of C_{2v} symmetry was also found. This structure has considerably shorter minimum distances and corresponds to rotating points 1 and 2 of Fig. 1 by 90° about the z axis.

For detailed examination of the energy dependence on r, we introduced symmetry constraints into the computer program. The C_{2v} structure is characterized by five parameters: θ_1,

$\theta_2, \theta_3, \theta_4$, and ϕ. The C_{3v} structure is characterized by three parameters: θ_1, θ_2, and θ_3. The D_{4d} structure is characterized by a single parameter: θ. For comparison, we also calculated the minimum energy configurations of D_{5h} (5:5, eclipsed) and D_{5d} (5:5, staggered) structures. Each of these is characterized by a single parameter, θ.

With the assumed symmetry it is possible to factor the energy expression, since several distances may be equal because of the symmetry. The factored expression for C_{2v} symmetry is

$$E(C_{2v}) = 4(d_{13}^{-r} + d_{14}^{-r} + d_{29}^{-r} + d_{47}^{-r} + d_{48}^{-r} + d_{49}^{-r} + d_{4,10}^{-r} + d_{89}^{-r}) + 2(d_{27}^{-r} + d_{28}^{-r} + d_{34}^{-r} + d_{45}^{-r} + d_{46}^{-r}) + (d_{12}^{-r} + d_{78}^{-r} + d_{9,10}^{-r})$$

Thus there are 16 unique distances, of which 5 have twofold multiplicity and 8 have fourfold multiplicity.

The energy of the C_{3v} structure may be factored as

$$E(C_{3v}) = 6(d_{35}^{-r} + d_{38}^{-r} + d_{58}^{-r}) + 3(d_{12}^{-r} + d_{15}^{-r} + d_{18}^{-r} + d_{23}^{-r} + d_{37}^{-r} + d_{39}^{-r} + d_{56}^{-r} + d_{5,10}^{-r} + d_{89}^{-r})$$

There are 12 unique distances, of which 3 have sixfold multiplicity, and 9 have threefold multiplicity.

The energy of the D_{4d} structure may be factored as

$$E(D_{4d}) = 8(d_{12}^{-r} + d_{16}^{-r} + d_{23}^{-r} + d_{46}^{-r} + d_{47}^{-r}) + 4(d_{24}^{-r}) + d_{1,10}^{-r}$$

There are 7 unique distances, of which 5 have eightfold multiplicity, and 1 has fourfold multiplicity.

The energies of the D_{5h} and D_{5d} structures may be factored as

$$E(D_{5h}) = 10(d_{12}^{-r} + d_{13}^{-r} + d_{17}^{-r} + d_{18}^{-r}) + 5(d_{16}^{-r})$$

$$E(D_{5d}) = 10(d_{12}^{-r} + d_{13}^{-r} + d_{16}^{-r} + d_{17}^{-r}) + 5(d_{18}^{-r})$$

In both cases there are 5 unique distances, of which 4 have tenfold multiplicity, and 1 has fivefold multiplicity.

The factored energy expressions were utilized to find the structure of minimum energy as a function of the characteristic parameters, for various values of the repulsion exponent. A steepest descent minimization procedure was used. No difficulties were encountered with false minima when explicit symmetry constraints were used.

Results and Discussion

Table 1 gives the minimum energies obtained for the five symmetries, for various values of the repulsion exponent. For $r \geq 25$, the C_{2v} structure is favored, confirming the symmetry prediction of Schutte and van der Waerden (2*a*) for the hard-sphere model. In the range $9 \leq r \leq 24$, the C_{3v} structure is obtained. For $r \leq 8$, the D_{4d} structure is favored. Neither of the 5:5 coordinated structures are favored for any value of r, although the energy differences become smaller for the soft-sphere model.

The differences in energy may also be expressed on a relative basis. Thus, for the frequently assigned value of $r = 12$, the C_{3v} structure is most stable. The C_{2v} structure has 0.13% more repulsion energy, the D_{4d} structure has 1.01% more repulsion energy. Clearly, only a small size difference or anisotropic effect could change the situation to favor the C_{2v} or D_{4d} structures. Larger size effects or anisotropic effects would be required to favor either of the 5:5 structures.

Gillespie (1*b*) favored the D_{4d} (bicapped square antiprism) model. This model would be appropriate for soft ligands ($r \leq 8$). To our knowledge, no one has previously predicted the C_{3v} structure, which is favored when $r = 12$. Table 2 shows the configurations of the best arrangements, for various values of the repulsion exponent. The C_{2v} structure was calculated for very large values of the repulsion exponent so as to approach the hard-sphere limit.

It appears from Table 2 that the minimum value of 1.09143 . . . given by Schütte and van der Waerden may be the exact value for hard-sphere ten-coordination. None of our runs achieved a larger value for the minimum contact distance. Our calculation with $r = 1200$ yielded a closest contact distance of 1.0913, very close to the above value.

Table 3 gives a listing of the closest interligand contacts for the three favored structures. The ranking of closest contacts remains the same, for the lowest energy structures. Thus, the closest contacts are always d_{34}, d_{25}, and d_{12} for the C_{2v}, C_{3v}, and D_{4d} structures, respectively. If $r \leq 2$, the

closest contact for C_{3v} symmetry changes to d_{12}. Table 3 indicates some other changes occurring in the second, third, and fourth closest contacts.

There are very few molecules or ions known at the present time to be ten-coordinated. Jakob and Jakob (5) report compounds of the type $Me_2[Mo(CN)_8R_2]\cdot 4H_2O$ and $Me_2[W(CN)_8R_2]\cdot 4H_2O$, where Me = Cd^{II} or Mn^{II} and R = H_2O, NH_3, or N_2H_4. They predict the D_{4d} structure with the R groups polar. The same structural prediction is given by Hoard and Silverton (6) for those compounds.

Sharp (7) has prepared the compound $PtF_8(CO)_2$. The material is light-sensitive and hydrolyzes in moist air. No prediction was made about the geometry of the structure.

Lind, Lee, and Hoard (8) have solved the crystal structure of $La(OH_2)_4AH\cdot 3H_2O$, where H_4A is ethylenediaminetetraacetic acid (EDTA). The coordination about the lanthanum is ten, but the geometry is complex because of the constraints imposed by the EDTA ligand.

NOTE ADDED IN PROOF: King (9) made a calculation for the coulombic case ($r = 1$) of ten-coordination and found a D_{4d} configuration, in agreement with this work. King gives the following additional examples of ten-coordination: the ten boron atoms in $B_{10}H_{10}^{2-}$ (10); polymeric uranium(IV) acetate (11); and yterbium diantimonide (12). The observed structures have D_{4d}, D_{4d}, and C_{2v} symmetry, respectively.

Studies of Rhenium β-Diketone Complexes. III. The Crystal and Molecular Structure of Bis(μ-*O*-1,3-diphenylpropane-1,3-dionatotricarbonylrhenium(I))

J. C. BARRICK, M. FREDETTE, AND C. J. L. LOCK[1]

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received July 25, 1972

One of a series of compounds obtained by the reaction of chloropentacarbonylrhenium(I) with β-diketones has been shown by single crystal X-ray diffraction to be bis(μ-*O*-1,3-diphenylpropane-1,3-dionatotricarbonylrhenium(I)). The crystals are monoclinic with lattice parameters a = 11.988(A) Å, b = 14.441(9) Å, c = 10.298(7) Å, β = 115.25(7)°. The space group is $P2_1/c$ and there are two dimers per unit cell. A total of 1563 independent reflections were measured on a single crystal X-ray diffractometer and the structure was refined by least squares analysis to a weighted R_2 value of 0.0427. The dimer units are held together by two bridging oxygen atoms, one from each of the β-ketoenolate groups; the distance of the bridging oxygen from the rhenium atom to which it is chelated (2.162(9) Å) is shorter than the distance to the other rhenium atom (2.204(7) Å). The main part of the β-ketoenolate ring is 37° from the OReO plane.

L'un des composés obtenu par la réaction du chloropentacarbonylrhénium(I) sur les β-dicétones a été identifié par diffraction aux rayons X sur un monocristal au bis (μ-*O*-diphényl-1,3-propanedionato-1,3 tricarbonylrhénium(I)). Les cristaux sont monocliniques, les paramètres du réseau sont: a = 11.988 Å, b = 14.441(9) Å, c = 10.298(7) Å, β = 115.25(7)°. Le groupe spatial est $P2_1/c$ et il y a deux dimères par maille. Un total de 1563 reflexions indépendantes a été mesuré au diffractomètre aux rayons X sur un monocristal, la structure a été raffinée par la méthode des moindres carrés jusqu'à obtention d'une valeur pondérée sur R_2 de 0.0427. Les dimères dans la maille sont reliés entre eux par deux atomes d'oxygène formant un pont, chacun d'eux provenant des groupes β-cétoènolates; la distance de l'oxygène pont à l'atome de rhénium auquel il est chelaté (2.162(9) Å) est plus courte que celle qui le sépare de l'autre atome de rhénium (2.204(7) Å). La partie principale du cycle β-cétoènolate est située à 37° du plan OReO. [Traduit par le journal]

Introduction

We have investigated the reaction of $Re(CO)_5Cl$ with various β-diketones and have prepared two series of compounds with apparent stoichiometries $Re_2(CO)_6(dik)_2$[2] and $Re(CO)_3Cl(dik)$. Attempts to elucidate the structure of $Re_2(CO)_6(dik)_2$ using n.m.r., infrared, Raman, and mass spectroscopy did not provide an unambiguous solution to the structure so we have examined selected compounds by single crystal X-ray diffraction. Our first study was of $Re_2(CO)_6(acac)_2$ but the crystal was apparently disordered (see below). However, a study of the structure of $Re_2(CO)_6(dbm)_2$ was successful.

[1]To whom correspondence should be addressed.

[2]dik is any β-ketoenolate anion, acac is the anion derived from acetylacetone, $C_5H_7O_2^-$, dbm is the anion derived from dibenzoylmethane, $C_{15}H_{11}O_2^-$, and thd is the anion derived from 2,2,6,6-tetramethyl-3,5-heptanedione, $C_{11}H_{19}O_2^-$.

Experiments

Analyses were performed on samples of crystals of each compound. Carbon, hydrogen, and chlorine analyses were performed by A. B. Gygli, Toronto, Canada and rhenium and chlorine were determined by neutron activation analysis (1). Molecular weights were determined by mass spectroscopy using a Consolidated Electrodynamics Corp., Model 21-110B mass spectrometer.

Bis (μ-O-pentane-2,4-dionatotricarbonylrhenium(I))

Chloropentacarbonylrhenium(I) (1 mmol) and acetylacetone (3 mmol) were refluxed in benzene (~75 ml) for 2 weeks. The pale yellow solution gradually turned dark brown during this time. Evaporation of the solvent (~20°, ~15 mm), followed by addition of ether (~100 ml) and filtration, served to remove any unreacted chloropentacarbonylrhenium(I). The filtrate was evaporated and the residues were dissolved in the minimum amount of chloroform or ether. Addition of enough petroleum ether to cause cloudiness produced a brown powder which was collected on a filter and recrystallized from methylene chloride or ether, giving small white needles.

Bis(μ-O-1,3-diphenylpropane-1,3-dionatotricarbonylrhenium(I))

Chloropentacarbonylrhenium(I) (1 mmol) and dibenzoylmethane (3 mmol) were refluxed for 3–4 weeks in benzene (~75 ml). Bright orange crystals of the product were removed on a filter and washed with hot benzene. More product was sometimes obtained by heating the dried residues *in vacuo* with a heat lamp for 2–3 h and then washing the melt with hot benzene.

Anal. Calcd. for $C_{36}H_{22}O_{10}Re_2$: C, 43.8; H, 2.2; Re, 37.8; mol. wt., 987. Found: C, 44.0; H, 2.2; Re, 39.7; mol. wt., >818 (highest peak in mass spectrum corresponded to $Re_2(dbm)_2^+$).

Crystallography

$Re_2(CO)_6(acac)_2$

A crystal of $Re_2(CO)_6(acac)_2$ was mounted along the needle axis. Integrated Weissenberg photographs were taken of the (*hnl*) layers (n = 0–6) with CuKα radiation and an integrated precession photograph was taken with MoKα radiation of the (0*kl*) zone and a further precession photograph of the (*h*0*l*) layer was recorded for another crystal. Systematic absences were observed for *hkl* ($h + l = 2n + 1$) and a mirror plane or two fold axis was apparent on all photographs. Assuming the crystal was orthorhombic, possible space groups were *C*222-(No.21), *Cmm*2(No.35), *Amm*2(No.38); *Cmmm*(No. 65). Patterson maps using all of these space groups did not show any self-consistent position for the rhenium atom. Trial positions were used for the rhenium atom but the lowest value of R_1[3] obtained was 0.47. Photographs taken in the (*hk*0) direction showed peculiar radial streaks as though two crystals were present and out of alignment by 1° 40′. Approximately 20 crystals from different recrystallizations were examined by X-ray diffraction and all showed this effect. The apparent unit cell dimensions were a = 15.26(1), b = 16.01(1), c = 17.68(1) Å (calibrated with a crystal of rutile (TiO_2), a = 4.5929(5) Å, c = 2.9591(3) Å (2)). Detailed examination of the photographs suggested that the crystals were either twinned, or that disorder was present giving a higher pseudo-symmetry. No further X-ray studies were made of this compound.

$Re_2(CO)_6(dbm)_2$

A single crystal 0.2 × 0.08 × 0.12 mm³, which showed complete extinction every 90° when viewed through a polarizing microscope was used for initial X-ray studies. A series of Weissenberg and precession photographs showed that the crystal was monoclinic, and the systematic absences *h*0*l*, $l = 2n + 1$, 0*k*0, $k = 2n + 1$ showed that the space group was $P2_1/c$. Precession photographs of the (100) and (010) zones, taken with MoKα radiation and calibrated with the diffraction pattern of a single crystal of TiO_2 (rutile), were used to determine the unit cell parameters. The density of a few crystals was measured by flotation in a bromoform–chloroform mixture.

$C_{36}H_{22}O_{10}Re_2$ f.w. = 986.98

Monoclinic, a = 11.988(8), b = 14.441(9), c = 10.298(7) Å, β = 115.25(7)°, V = 1612 Å³, ρ_o = 2.02, Z = 2, ρ_c = 2.03 (20 °C, MoKα, λ = 0.71069 Å), $P2_{1/c}$ (C_{2h}^5, No. 14)

Six layers perpendicular to ($\bar{1}02$) were recorded on an integrating Weissenberg camera; 4 layers perpendicular to (010) and eight layers perpendicular to (100) were recorded on an integrating precession camera. All photographs except the first three layer photographs on the Weissenberg camera were taken with MoKα radiation. The latter were taken with CuKα radiation. The intensities of all reflections were measured on a Joyce–Loebl microdensitometer. All data were corrected for Lorentz and polarization effects, but no corrections were made for absorption. These data were used to solve the crystal structure although the CuKα Weissenberg data (absorption errors) and (0*kl*) and (*h*0*l*) data (poor picture quality) were removed in later stages of the refinement (see below). Thus the original data set of ~2800 reflections was reduced to 1436 of which 966 were observed. After the structure had been solved the data were retaken using a Syntex $P\bar{1}$ automatic diffractometer. A single crystal of $Re_2(CO)_6(dbm)_2$ ground into a sphere of 0.15 mm radius was used. Data were recorded using zirconium-filtered MoKα radiation which was made monochromatic by using the 002 reflection from highly oriented graphite. The intensities were measured by the θ/2θ scan technique up to a value of 2θ = 45°. 2° scans were made over θ, and the background was counted on both sides. Peaks less than 3σ above the background were called unobserved, and peaks less than background were rejected. The intensity of a standard reflection was measured every 50 reflections. It showed a deviation of ±3.8%. The linear absorption coefficient for the compound for MoKα radiation was 81 cm^{-1}. The data were corrected for Lorentz and polarization effects but not absorption; the absorption coefficients ranged from 5.35 to 4.95. However, the error from neglect of absorption correction will be less than this since the data were collected in three batches (*1*, θ = 0–12; *2*, θ = 11–17; *3*, θ = 17–23) and each batch was given its own scale constant. Thus the maximum error which can arise from neglect of the absorption correction is 3%.

Solution and Refinement of the Structure

Using Patterson maps for the ($\bar{1}02$), (100), and (010) zones it was possible to locate the rhenium atom. Using all the film data, refinement of the rhenium atom parameters for two cycles gave R_1 = 0.16. The shortest Re—Re distance was 3.5 Å suggesting a dimeric unit. Subsequent electron density and electron difference syntheses, with calculations based on known geometries for β-diketone and phenyl groups revealed all the remaining atoms, except the hydrogen atoms. Further refinement, after elimination of CuKα and doubtful data, and using a Cruickshank weighting scheme (3) with the weights set equal to $(61 - F_o + 0.013\ F_o^2)^{-1}$ for observed reflections and zero weight for unobserved reflections, was terminated at R_2 = 0.1016. At this point the main features of the structure were apparent but M—C≡O

[3] $R_1 = (\Sigma||F_o| - |F_c||/\Sigma|F_o|)$, $R_2 = (\Sigma w|F_o^2 - F_c^2|/\Sigma w(F_o)^2)^{\frac{1}{2}}$.

*Estimated standard deviations in parentheses.
†Thermal parameters are in $Å^2 \times 10^3$.
‡For atom Re, $U_{11} = 31.5(3)$, $U_{22} = 30.0(3)$, $U_{33} = 29.0(3)$, $U_{12} = 0.0(3)$, $U_{13} = 17.9(3)$, $U_{23} = 1.3(3)$.

groups were bent (170°(2)) and the phenyl groups were badly distorted (C—C ranged from 1.28 to 1.52 Å and C—C—C angles ranged from 107 to 126°). However difference maps showed no residual peaks at more than ±1.5 e/Å^3 and no parameter shifted by more than 1/3 of its estimated standard deviation in the last few cycles of refinement. At this point the data were retaken on the diffractometer and only diffractometer data were used in subsequent refinements. The new set consisted of 1563 independent reflections, of which 1295 were observed. One cycle of refinement of the diffractometer data using the parameters determined above and varying only the scale constants dropped R_2 to 0.07. Using a Cruickshank weighting scheme with weights equal to $(29 - 0.6F_o + 0.004F_o^2)^{-1}$ for observed reflections and zero for unobserved reflections, and allowing all the parameters listed in Table 1 to vary dropped R_2 to 0.0427 when refinement was terminated. In all the refinement cycles of diffractometer data, which were done using the full matrix least squares program CUDLS written for the CDC-6400 computer by Stephens, the rhenium scattering curve of Cromer (4), including anomalous dispersion corrections (5) was used. The oxygen scattering curve was also that of Cromer, and that for carbon was taken from the International Tables (6). No anomalous dispersion corrections were applied to carbon or oxygen.

In the final cycle of refinement no parameter shifted by more than 1/10 of its estimated standard deviation and a series of electron density difference maps through the unit cell showed no residual peaks outside ±1 e/A^3. The final set of atom parameters is given in Table 1 and a comparison of $|F_o|$ and $|F_c|$ is given in Table 2.[4]

Results and Discussion

The principal interatomic distances and angles are listed in Table 3 and the molecule is illustrated in Fig. 1. The molecule is dimeric (based on the rhenium atoms) and the two halves are centro-symmetrically related. Each rhenium atom is six-coordinate, being attached to atoms at the apices of a very rough octahedron. Three positions are filled by three mutually *cis* carbonyl groups and two further positions are filled by the oxygen atoms of a chelated β-ketoenolate group. The final position is filled by one of the oxygen atoms from the β-ketoenolate group chelated to the other rhenium atom which thus

forms a bridge between the two rhenium atoms. The rhenium–rhenium distance of 3.494(1) Å is too long to allow any significant metal–metal interaction. Bridging by a β-ketoenolate group through an oxygen atom attached to two metal atoms has been observed previously in $[Ni(acac)_2]_3$ (7) and $[Co(acac)_2]_4$ (8), but it is only recently that dimeric compounds have been shown to have this form of bridging (9). It is of interest to compare features of the bridging section of $[Pr(thd)_3]_2$ (9) and our compound. The bridges in both compounds are asymmetric. The distance of the oxygen atom to the rhenium atom to which it is chelated (2.162(9) Å) is significantly shorter than the distance to the other rhenium atom (2.204(7) Å). For the praseodymium compound the situation is reversed, the corresponding distances, which are much larger, being 2.59(2) Å and 2.47(2) Å. The two Re—O (chelated) distances do not differ significantly

		Re	1.00

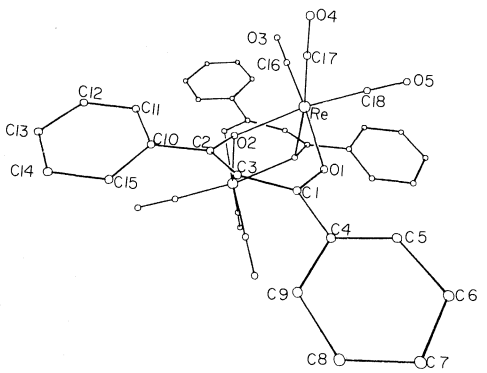

FIG. 1. The molecular structure of $Re_2(CO)_6(dbm)_2$ (the labelling of atoms corresponds to that used in Table 1).

but all Re—O distances appear to be significantly longer than the Re—O (β-ketoenolate) distances in $Re(acac)_2Cl_2$, $Re(acac)Cl_2[P(C_6H_5)_3]_2$, and $ReOCl_2(acac)P(C_6H_5)_3$ (10) where the average distance is 2.02(1) Å.

Long Pr—O distances were also observed by Erasmus *et al.* (9) for $[Pr(thd)_3]_2$ who argued that the cause was the combination of the 70° angles needed in a seven-coordinate structure and the need to keep the O—O distances above 2.8 Å. Similar steric requirements may be the cause of the longer Re—O distance in our compound, since the O(2)—Re—$O(2)_i$ angle is 74°, and the O(2)—$O(2)_i$ distance is significantly shorter (2.62(2) Å) than that observed in $[Pr(thd)_3]_2$.

Other possible reasons for the longer Re—O distance in our compound may be the destruction of any pπ–dπ interaction between the β-ketoenolate ring and the metal since as the data in Table 4 shows the dihedral angle between the plane of the β-ketoenolate ring and the MO_2(chelated) plane is 37°, the largest value ever observed for a β-ketoenolate complex. The comparable angle for $[Pr(thd)_3]_2$ is 29°.

The steric requirements of the bridging oxygen atoms and consequently the remaining chelated oxygen atoms cause a reduction in the OReO angles from the ideal octahedral angle of 90° by from 6–16° (80.0(3), 84.1(3), 73.7(3)°). However, the carbonyl groups remain nearly perpendicular to each other (C—Re—C angles 88.0(6), 89.9(6),

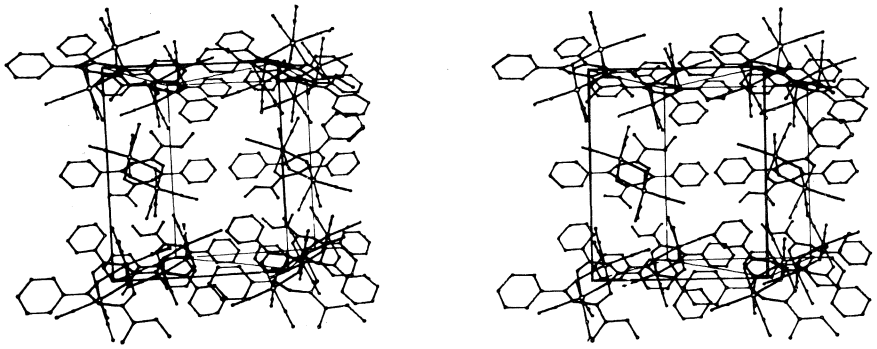

FIG. 2. Stereogram (stereoscopic pair of perspective projections) of $Re_2(CO)_6(dbm)_2$. The contents of one unit cell are shown with some projection outside the cell to show the packing; *b* and *a* are parallel to the side and top of the page respectively, and the view is down *c**.

86.5(7)) so that the angles at rhenium between the carbonyl groups and the oxygen atoms are opened up from 90° (93.0(5) to 100.9(5)). The maximum distortions in all cases are in the O(2), $O(2)_i$, Re C(17), C(18) plane:

The Re—C≡O systems are essentially linear (171(4), 178(1), 178(1)°) and the Re—C bond lengths (1.87(1) Å average) and C≡O bond lengths (1.18(2) Å average) are in good agreement with those found previously in $(B_9C_2H_{11})$-$Re(CO)_3Cs$ (11), $HRe_2Mn(CO)_{12}$ (12), and $(C_8H_7)Re(CO)_3$ (13). The corresponding angles and bond lengths within the β-ketoenolate ring are not significantly different from the average values found for a number of β-ketoenolate structures (14), but the C_1C_3 distance does appear to be significantly longer than the C_2C_3 distance (see below). The bond lengths and angles found within the phenyl rings are normal.

The planarity of certain groups of atoms within the molecule has been tested and the results are presented in Table 4, together with the dihedral angles between the planes. Both phenyl rings are essentially planar, as expected, and are quite markedly twisted from the plane of the β-ketoenolate ring, plane 3 by 25° and plane 4 by 22°. This twist may arise from a simple rotation about the C(2)—C(10) and C(1)—C(4) bonds (φ) or a tilt of the C(4)C(7) and C(13)C(10) axes out of the plane of the β-ketoenolate ring at either C(4) and C(10) or C(1) and C(2) (θ). The results in the second part of Table 4 provide information which allows separation of the two twist components.

Plane 2 is bent at C(1) (θ = 12°) and plane 3 is bent at C(2) (θ = 3°). Both plane 3 and plane 4 are rotated about the C(1)C(4) and C(2)C(10) axes (φ ~ 26°). An examination of the packing diagram suggests that the twists are probably necessary to allow the most efficient packing. The distortion at C(1) (θ) may be the reason for the apparent non-equivalence of the C(1)C(3) and C(2)C(3) distances. The bend will tend to affect the π overlap at C(1), weakening the C(1)C(3) bond, and causing a strengthening of the C(2)C(3) bond, as is observed. The errors in the CO(diketone) distances are such that it is not possible to say whether any similar effect is reflected in these bonds.

As illustrated in Fig. 2, the molecules are packed almost in layers parallel to the *ac* plane, the centers of the layers lying approximately in the unit cell *ac* face and half-way along *b*. Within the layers packing in the *c* direction is determined by the β-ketoenolate system (including the phenyl rings). The molecules are arranged such that the β-ketoenolate on one side of the molecule lies directly above the opposite β-ketoenolate group on the next molecule. Thus, considering only the β-ketoenolate parts of the molecule, the molecules are stacked like tiles on a roof, and are tilted with respect to the *c* direction. Considering alternate layers in the *b* direction the molecules are tilted in opposite directions with respect to the *c* direction. Contact in the *a* direction is provided primarily by the phenyl rings although one carbonyl group in each asymmetric half of the molecule is sandwiched between two phenyl rings, one from its own molecule and one from another.

Contact in the *b* direction is between both carbonyl and phenyl groups, with carbonyl groups on a molecule interleaving with carbonyl groups on molecules both above and below,

and phenyl groups contacting only phenyl groups in the other molecules.

Semimicro Determination of Sugar Configuration by Measurement of Circular Dichroism of Alditol Acetates[1]

G. M. BEBAULT, J. M. BERRY, Y. M. CHOY, G. G. S. DUTTON, N. FUNNELL, L. D. HAYWARD, AND A. M. STEPHEN[2]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 13, 1972

The configuration (D or L) of a sugar may be determined conveniently by circular dichroism measurements at 213 nm on alditol acetates, or their methylated derivatives, where the acetoxy group acts as a chromophore. Only milligram quantities of material are required and the method is well suited to analyzing fractions obtained by gas–liquid chromatography. Structural information which may be derived from the c.d. spectra is briefly discussed.

La configuration (D or L) d'un sucre peut être établie par le dichroisme circulaire à 213 nm soit des alditol acétates soit de leur dérivés méthylés, où le groupement acétate joue le rôle de chromophore. On ne necessite que de très petites quantités de substance et la méthode s'adapte très bien à l'analyse des fractions obtenues par chromatographie en phase gaseuse. On discute brièvement des renseignments structuraux que fournissent les spectres d.c.

Can. J. Chem., **51**, 324 (1973)

Determination of the structure of a polysaccharide requires that the nature and proportion of the constituent sugars be known as well as the positions through which the monosaccharide units are linked in the polymer. Such investigations are facilitated by the use of gas–liquid chromatography (g.l.c.) and sugar ratios are customarily determined as trimethylsilyl ethers or as alditol acetates (1). Similarly, partially methylated sugars are conveniently separated by g.l.c. of their derived alditol acetates and the pattern of methylation is determined by mass spectrometry (2). The technique of mass spectrometry does not readily differentiate between diastereoisomers but this problem may be resolved by collection of the methylated alditol acetate from the effluent gas stream (3) followed by demethylation and characterization of the parent alditol as the peracetate (4).

None of these chromatographic methods is capable of determining the configuration (D or L) of the constituent sugars of a polysaccharide, an aspect of structural studies which is sometimes ignored. One great merit of procedures involving gas–liquid chromatography and mass spectrometry is the small quantity of material required and this is of particular value when only limited amounts of sample are available as, for example, with bacterial polysaccharides. The advantage of these techniques is lost if the determination of the configurational series must be made on macroscopic amounts of specimen. In the particular cases of D-glucose and D-galactose specific oxidases are available (*e.g.* Glucostat and Galactostat reagents, Worthington Biochemical Corporation) but no such method is available for other commonly occurring sugars; even so these are destructive methods.

We have now demonstrated that the sugar configuration (D or L) may be determined unambiguously on milligram quantities of monosaccharide derivatives from the circular dichroism (c.d.) band at *ca.* 213 nm of the corresponding alditol acetates. Just as a sugar of D-configuration may have either a positive or negative specific rotation so also D-alditol acetates may have c.d. bands of either sign. Thus, this sign must be determined empirically and a selection of such data is presented in Table 1. While the method is obviously inapplicable to *meso*-alditols, such as galactitol, it is readily extended

†No reliable value obtainable.

to their chiral methylated acetates obtained in structural studies. Conversely, in order to avoid the necessity of measuring c.d. bands for all possible methylated alditols these compounds may conveniently be demethylated (4) where the parent alditol is chiral.

Circular dichroism measurements were made using a Jasco J-20 automatic recording spectropolarimeter, accurately weighed milligram quantities of the alditol acetate being dissolved in acetonitrile (0.15 ml, spectroscopic grade) and placed in a quartz spectrophotometer cell with path length of 0.1 cm. The spectrometer was calibrated using the value of $\varepsilon_L - \varepsilon_R = +2.3$ for (+)-10-camphorsulfonic acid in water (5). The c.d. curves obtained at a scan-rate of 5 nm/min were bell shaped and symmetrical as far as could be ascertained (measurements below 205 nm were not reproducible). While there is no doubt about the sign of the c.d. curve in each case examined, the numerical values of Δε are sometimes hard to reproduce particularly for those compounds which have small values of Δε. This is an instrumental problem since the acetate band lies near the extreme range of the instrument used.

The initial experiments described here were carried out during an investigation, to be described later (6), into the structure of the capsular polysaccharide of *Klebsiella* K-type 7 and have subsequently been employed in other, related structural studies. Measurements have been made on the alditol acetates used for quantitative analysis of polysaccharide hydrolyzates (7), as for *Klebsiella* K-type 21, on methylated alditol acetates and on alditol acetates obtained by demethylation and acetylation. The first method is particularly convenient for mannose where no simple micromethod exists.

The capsular polysaccharide of *Klebsiella* K7 contains glucose, galactose, mannose, and glucuronic acid. From the methylated polysaccharide 2-*O*-methyl- and 2,4,6-tri-*O*-methylglucose are obtained as well as 2,4-di-*O*-methylglucose which results from reduction of the glucuronic acid residue. These compounds were separated by g.l.c. of their alditol acetates. Demethylation and acetylation of the individual fractions yielded (g.l.c.) glucitol hexaacetate, each sample of which gave a positive c.d. band with Δε values ranging from +0.28 to +0.33 depending on the amount of contaminating liquid phase caused by bleeding of the column. Thus each glucose residue in *Klebsiella* K7 is shown to be of D-configuration as is the glucuronic acid. Mannitol hexaacetate samples were obtained similarly from the methylated mannose derivatives, namely the 4,6-di- and 3,4,6-tri-*O*-methyl ethers, and each sample showed a strong positive c.d. band (Δε +1.4 to +1.7) thus demonstrating that all mannose units in the polysaccharide are of D-configuration.

The galactose in *Klebsiella* K7 gives only 2,3,4,6-tetra-*O*-methylgalactose which, on reduction and conversion to the syrupy diacetate, gave a positive c.d. band (Δε +0.54) similar to that obtained from an authentic sample of the methylated sugar of D-configuration and to that obtained by methylation of a wood galactoglucomannan (8). One sample of galactitol hexaacetate prepared by demethylation and acetylation was shown to be achiral.

In addition, a sample of 2-*O*-methyl-D-glucitol pentaacetate obtained from K7 polysaccharide was recrystallized from ethyl acetate – petroleum ether (b.p. 30–60°) and had m.p. 56–57°. The c.d. measurement showed a positive band with Δε +0.71, a value significantly greater than for D-glucitol hexaacetate. Measurements of c.d. spectra may also provide alternative means for determining the position of methoxyl substitution, distinguishing between isomers and estimating the composition of mixtures. Thus,

because of symmetry, achiral methylated alditol acetates can be expected in polysaccharide structural studies only from 3-, 2,4-, or 2,3,4-*O*-methyl derivatives of ribose and xylose and 2,4- or 2,5-*O*-methyl derivatives of galactose or allose. The significance and utility of this is demonstrated by the following experiments.

In structural studies on xylans both 2- and 3-*O*-methyl-D-xyloses are commonly encountered and this pair of compounds is not separable as alditol acetates by g.l.c. Collection of the monomethyl pentitol acetate fraction from the g.l.c., in a study on western red cedar (8), and measurement of $\Delta\varepsilon$ showed that the 2-*O*-methyl derivative was present to the extent of 35%, a value in close agreement with that (33%) obtained by integration of the well resolved methoxyl signals in the p.m.r. spectrum of the mixture of alditol acetates. A control experiment verified that 3-*O*-methyl xylitol is achiral.

The symmetry of *meso*-alditols may be destroyed on substitution thus leading to enantiomeric compounds. For example, whereas the sugars 3- and 4-*O*-methyl-D-galactose are diastereoisomers and reduction yields 3- and 4-*O*-methyl-D-galactitol, the latter compound is correctly named 3-*O*-methyl-L-galactitol indicating that the derived alditols are enantiomers. Measurement of the c.d. spectra of these two alditols as the pentaacetates shows clearly that they are of opposite sign although the numerical agreement in the $\Delta\varepsilon$ values is not good (Table 1) for the reasons given previously. The signs of the c.d. bands, however, suffice in these cases to identify the pattern of substitution in such monosaccharides.

The 3- and 4-*O*-methyl-D-galactoses were synthesized by methylation of 1,2:5,6-di-*O*-isopropylidene-D-galactofuranose (9) and of methyl 2,3,6-tri-*O*-benzoyl-α-D-galactopyranoside (10), respectively. Each sugar was crystalline and did not depress the m.p. of authentic samples (10, 11).

Measurement of c.d. spectra of chiral alditol acetates and their methylated derivatives is thus proposed as a convenient, non-destructive method for determining the configurational series of a sugar. The technique requires very small samples and is admirably suited to examining individual fractions obtained by gas–liquid chromatography. By combining these techniques with mass spectrometry most partially methylated monosaccharides may be identified completely, including the configurational assignment.

The symmetry rule relating molecular conformation and the sign of the c.d. band for alditol acetates is now under investigation as is the possibility that differences in rotational strength may be useful in distinguishing isomeric methylated alditol acetates. The c.d. spectra of sugars (12, 13) and of monoacetates of methyl glycosides (14) have been discussed recently.

We are grateful to the National Research Council of Canada for financial support, to Professor J. K. N. Jones, F.R.S. for an authentic sample of 3-*O*-methyl-D-galactose and to Mrs. E. Dumitrescu for skilled assistance in taking spectra. One of us (A.M.S.) is indebted to the University of Cape Town for study leave and to C.S.I.R. for the award of a bursary.

Preparation of 6′-Substituted Maltoses

LAURENCE DAVID MELTON[1] AND KEITH NORMAN SLESSOR

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 23, 1972

A relatively simple procedure for the preparation of 6′-substituted maltoses has been developed through the action of *Aspergillus oryzae* amylase on mono-substituted cyclohexaamyloses. 6′-Azido-, -chloro-, -bromo-, -iodo-, and -tosyl-maltose have been prepared in this way. 6′-Deoxy- and 6′-amino-6′-deoxy-maltose were easily prepared from the 6′-iodo- and 6′-azido-maltoses respectively.

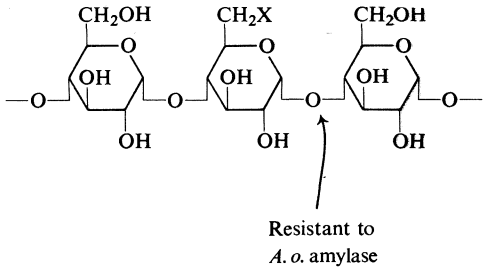
Une méthode relativement simple de préparation des maltoses substitués en position 6′ a été developpée; elle fait appel à l'action de l'amylase *Aspergillus oryzae* sur des cyclohexaamyloses monosubstituées. Les azido-6′, chloro-6′, bromo-6′, iodo-6′, et tosyl-6′ maltoses ont été préparés de cette manière. Les déoxy-6′ et amino-6′ deoxy-6′ maltoses ont été préparés facilement en partant respectivement des iodo-6′ et azido-6′ maltoses. [Traduit par le journal]

Can. J. Chem., **51**, 327 (1973)

Introduction

Two general approaches to the chemical synthesis of modified disaccharides are possible. The condensation of two monomeric units, one of which has been structurally modified has been of importance primarily for the synthesis of β-linked D-glucosyl species (1). Maltose derivatives, being α-linked, are considerably more difficult to synthesize via such condensations and thus the second route, modification of a pre-existing disaccharide residue, has been more successful (2, 3). Both approaches have the disadvantages of long and arduous synthetic routes and generally give low yields. A more accessible route to modified oligosaccharides would be useful since such compounds would be of value in α-D-glucopyranosidase studies (4) and mechanistic studies (5).

The action pattern of *Aspergillus oryzae* amylase (Taka-amylase) has been established by studies on synthetic maltoside substrates (4) and partially methylated amylose (6). The effect of a substituent at the C-6 position of a glucopyranosyl residue is to prevent hydrolysis of the glucosidic bond of the substituted residue and allow hydrolysis if the substituent is in the aglycone.



Thus, in theory, *A. oryzae* amylase action on sparsely 6-substituted amylose polymers should result in 6′-substituted maltose units as the oligomeric species. The identification of 6′-*O*-methyl-maltose in the amylase degradation of partially methylated amylose (6) is in accord with this hypothesis. Since *A. oryzae* can cleave the glucosidic bonds of cyclohexaamylose (7), mono-substituted cyclohexaamyloses (8) would appear

to be ideal compounds upon which to establish this concept. Assuming they can act as substrates for *A. oryzae* amylase, this should provide a convenient preparation of a homologous series of 6′-substituted maltose derivatives (see Fig. 1).

Results and Discussion

Hydrolysis of 6-substituted cyclohexaamylose derivatives by *A. oryzae* amylase was followed by the disappearance of the substrate as monitored by t.l.c. The time necessary for the disappearance of the cyclohexaamylose derivative was taken as a measure of the initial rate of hydrolysis and is reported in Table 1. It was obvious that the crude enzyme preparation, as supplied by the manufacturers, contained a maltase since little or no unsubstituted maltose was detected.

The presence of large amounts of glucose produced in the hydrolysis as well as release of monosaccharide units from the glycoproteinaceous amylase complicated the chromatography, but extended enzymatic hydrolysis of the tosyl,[2] azido, and halo cyclohexaamyloses indicated a material of intermediate R_f between glucose and the appropriate 6-substituted glucose. No 6-substituted glucoses were found to be formed. Fractionation of the enzymatic digests by charcoal column chromatography yielded the pure substituted oligosaccharides. The monotrityl[3] cyclohexaamylose enzymatic hydrolysis was extremely slow and complicated by the slow release of triphenylcarbinol and cyclohexaamylose, the latter being further degraded to glucose. Monodeoxy cyclohexaamylose was degraded completely to 6-deoxy-glucose and glucose, quite in keeping with the specificity studies on the amylase which have shown the non-recognition of the replacement of a 6-OH with H (4). Monoamino cyclohexaamylose was hydrolyzed slowly and apparently incompletely. The presence of material showing the characteristics of 6″-amino-6″-deoxy-maltotriose was detected (9). The ease with which the deoxy and amino deoxy disaccharide could be prepared from the iodo and azido disaccharide led us to abandon attempts to isolate these particular disaccharides from enzyme digests.

TABLE 1. Relative rates of the initial hydrolysis of monosubstituted cyclohexaamyloses by *A. oryzae* amylase

6-Substituent	Approximate relative rate
—OH (parent compound)	1.0
—H (monodeoxy)	1.0
—O—SO_2—C_7H_7 (monotosyl)	0.8
—Cl (monochloro)	0.8
—I (monoiodo)	0.8
—N_3 (monoazido)	0.4
—NH_3^+ (monoamino)	0.2–0.4
—O—$C_{19}H_{15}$ (monotrityl)	<0.1

Elution of the substituted oligosaccharides from charcoal columns was accomplished with various alcohols at different concentrations depending on the affinity of the sugar for the column. The tosyl and iodo derivative appeared to be most tightly held requiring 25% 1-propanol and 4% 1-butanol for elution.

Structural elucidation of the nature of the oligosaccharide was carried out in several ways. Mass spectral analysis of the pertrimethylsilyl derivatives of all the oligosaccharides showed conclusively that all were substituted disaccharides, since the molecular ion for each species was identified and higher *m/e* peaks were not present.

The monochloro disaccharide was reduced with sodium borohydride and hydrolyzed with acid to give only two products, which were identical with 6-chloro-6-deoxy-glucose and -glucitol. Assuming no change in the anomeric linkage of the disaccharide, the chloro disaccharide must then be, 6′-chloro-6′-deoxy-maltose (**1**). Further chemical evidence was derived from the iodo deoxydisaccharide by reduction to the deoxy analog with Pd/H_2 and "base peeling" of the deoxy disaccharide (10). The only reducing sugar remaining after 2 h was 6-deoxy-glucose indicating

[2]Tosyl = *p*-toluenesulfonyl.

that the deoxy glucose had been linked glycosidically to the glucose. The time for decomposition was typical of 1–4 linkages, 1–3 being fast (15 min), 1–6 slower (~4 h), and 1–2 stable.[4] Thus the deoxy disaccharide must be 6′-deoxy-maltose and the iodo disaccharide, 6′-deoxy-6′-iodo-maltose. Base peeling was not successful in determining the structures of derivatives **1** to **5** since the 6 substituent could complicate the transformation to saccharinic acids, leaving no reducing sugars to be identified.

Mass spectral analysis was useful not only in establishing the size of the substituted oligosaccharides, but also in determining the substitution pattern. A fragmentation pattern characteristic of the 1–4 linkage (11, 12) was observed for all the derivatives (**1**–**7**). The formation of fragment I (Table 4), which in turn decomposes to IV, is based on the fragmentation pattern observed for permethylated disaccharides (11) containing a 1–4 linkage. Pertrimethylsilyl derivatives of a 1–4 linked disaccharide have been found to form fragment II which subsequently loses a methyl radical to give fragment III (12). The decomposition of the molecular-ion to fragment V, characteristic of the reducing residue, has been demonstrated (13). In the present investigation, fragments I-IV, derived from the non-reducing moiety all had the correct *m/e* to have incorporated the substituent. These peaks were not seen in the mass spectrum of the pertrimethylsilyl derivative of maltose. On the other hand, there was no evidence that the 6-position of the reducing moiety was ever substituted with anything other than a trimethylsilyl ether. Fragments containing chlorine and bromine were relatively easily identified due to their characteristic isotopic cluster.

6′-Deoxy-maltose (**7**) and 6′-amino-6′-deoxy-maltose (**6**) are most easily prepared from the iodo (**3**) and azido (**5**) derivatives rather than directly from the deoxy- and amino-cyclohexaamylose. Both of the reactions are accomplished by reduction with hydrogen in the presence of palladium-on-carbon; conditions which do not effect the reduction of glucose to glucitol. As previously mentioned, the deoxy function was shown to be in the 6′-moiety through base peeling leaving 6-deoxy-glucose as the only reducing sugar. The position of the amino function was assigned on the basis of the specificity of the enzyme and mass spectral analysis of the azide (**5**) and amine (**6**). All of these indicated 6′-amino-6′-deoxy-maltose. Mass spectral analysis of the persilylated amine was complicated due to the presence of about 30% of the mono-*N*-trimethylsilyl derivative.

Thus, the chemical and spectroscopic evidence not only indicates the oligosaccharides to be 6′-substituted maltoses, but essentially rules out all other possibilities. This result is in complete accord with the expected specificity of *A. oryzae* amylase. The method then, allows a relatively simple preparation of a variety of 6′-substituted maltoses.

Experimental

General

Evaporations were carried out on a Buchi rotary evaporator at bath temperatures not exceeding 45°. Optical rotations were measured on a Perkin–Elmer Model P22 spectropolarimeter. Freeze-drying was done at −40°, 0.3 mm Hg generally overnight. Tes-tape, glucose analysis paper, was purchased from Eli Lilly and Co., Toronto. Activated charcoal, Darco, G-60, 20–40 mesh, was purchased from Matheson, Coleman and Bell. *A. oryzae* amylase, Type IV-A was purchased from Sigma Chemical Co. The mass spectra of pertrimethylsilyl derivatives were measured within 3 h of preparation and recorded on a Hitachi Perkin–Elmer RMU-7 spectrometer. The ionizing potential was 80 eV and the source temperature was 200°. Spectra were calibrated by direct counting of spectra recorded at high gain.

6′-Substituted Maltoses

Monosubstituted cyclohexaamylose (100–400 mg) was dissolved in 0.2 *N* acetate buffer, p*H* 5.5, containing 0.01 *M* $CaCl_2$, so that the concentration of the sugar was 10 mg/ml. *A. oryzae* amylase (10 mg/ml) was added and the solution was kept at 40° for the required time (Table 2). The amylolysis was stopped by addition of 3 *N* ammonia (0.4 ml/ml of digest). The precipitated protein was removed by centrifugation, and the supernatant liquid was evaporated. The material was dissolved in water (60 ml) and applied to an activated charcoal column (20 × 1.7 cm). The column was eluted with water (1200 ml) and 5% aqueous ethanol (1200 ml). These eluents contained salts, glucose, and traces of other reducing sugars. The column was then eluted as indicated in Table 2. The appropriate fractions were checked by t.l.c. and evaporated to dryness. The solid was extracted with 100% ethanol (3 × 0.2 ml/mg of material) and the extracts combined, filtered, and evaporated to give the pure 6′-substituted maltose. Only the iodo derivative (**3**) was crystalline, but the physical properties of all the derivatives are recorded in Table 3.

Pertrimethylsilyl Derivatives of 6′-Substituted Maltoses

The maltose derivative (3–5 mg) was dissolved in pyridine (1 ml) and hexamethyldisilazane (0.2 ml) and trimethylchlorosilane (0.1 ml) were added. The mixture

*R_G, relative to glucose. Solvent composition — butanone : methanol : water : 1 *N* acetic acid — A, 14:3:3:0; B, 145:28:27:0; C, 6:1:1:0; D, 3:1:0:1.

was shaken vigorously and kept at 40° for 1 h. The solution was evaporated to dryness and the solid extracted with hexane (4 ml). The hexane extract was filtered and the filtrate evaporated to give a colorless syrup. The characteristic peaks observed in the mass spectra are tabulated in Table 4.

*Reduction and Hydrolysis of 6′-Chloro-6′-deoxy-maltose (**1**)*

Monochloromaltose (1.5 mg) was dissolved in water (1 ml) and sodium borohydride (1.5 mg) was added. After 1 h at room temperature, the reduction was stopped by addition of 1 *N* acetic acid until the solution was p*H* 4.5. The solution was then passed through Dowex 50 (H^+) (1 ml) and evaporated three times with methanol. The residue was dissolved in 1 *N* HCl (0.3 ml), heated on a steam bath for 2 h, and neutralized with Dowex 3 (OH^-). Glucose oxidase Tes-tape gave a negative test on the neutral solution (0.2 ml) and t.l.c. (solvent A) clearly indicated only 6-chloro-6-deoxy-glucose and -glucitol to be present. These compounds were completely separable from glucose and 6-chloro-6-deoxy-glucitol in this solvent system. Clearly, the monochloromaltose is the 6′-substituted species (**1**).

*6′-Amino-6′-deoxy-maltose (**6**)*

6′-Azido-6′-deoxy-maltose (**5**) (15 mg) was dissolved in water (4 ml) and reduced with hydrogen over palladium black (5 mg) at atmospheric pressure for 3 h. The catalyst was removed by filtration and the solution evaporated to dryness, yielding 6′-amino-6′-deoxy-maltose (**6**) (13 mg) as a colorless glass. Glucose was not reduced under identical conditions. The pertrimethylsilyl derivative was prepared by dissolving **6** (3 mg) in pyridine (2 ml) at 80°, cooling to 40°, and adding hexamethyldisilazane (0.4 ml) and trimethylchlorosilane (0.2 ml). The previously described procedure was used for the isolation of this derivative. Approximately one-third of the sample was *N*-trimethylsilylated under these conditions.

*6′-Deoxy-maltose (**7**)*

Crystalline 6′-deoxy-6′-iodo-maltose (**3**) (33 mg) was dissolved in water–pyridine (9:1) (6 ml) and 5% palladium-on-charcoal (30 mg) was added. A steady but slow

stream of hydrogen was introduced through a capillary for 7 h, after which time t.l.c. indicated the reduction to be complete. Glucose was shown to be unaffected under these conditions. The catalyst was removed by filtration and the solution evaporated. The residue was dissolved in water (5 ml), passed through Dowex 3 (OH^-) (3 ml), and eluate and washings freeze-dried to provide a colorless glass (25 mg). This material was purified by elution from a charcoal column as previously described, with 4% ethanol in water, to give pure 6′-deoxy-maltose (**7**) (21 mg). The disaccharide (1 mg) was dissolved in water (0.15 ml) and 5% triethylamine in 50% aqueous methanol (0.15 ml) was added. The solution was heated at 70° for 2 h during which time the reaction was monitored by t.l.c. (solvent C, Table 3). The reaction was complete in 2 h and only 6-deoxy-glucose and some very slow running material (α-isosaccharinic acid) were observed. No glucose or reaction intermediates were seen.

We express our thanks to the National Research Council of Canada for a Fellowship (LDM) and an Operating Grant (KNS). Thanks are due also to M. K. Yang for analytical results, and G. Owen for the mass spectra, both of this department.

Formation and Reactions of (1-Chloroalkyl)carbamoyl Chlorides. Synthesis of 1,2,4-Triazolidine-5-ones

KINKO KOYANO AND COLIN R. MCARTHUR[1]

Department of Chemistry, York University, Downsview, Ontario

Received July 20, 1972

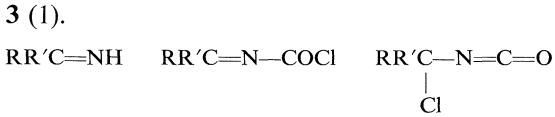
N-(α-Chlorobenzyl)carbaniloyl chloride and (α-chlorobenzyl)methylcarbamoyl chloride are formed by reaction of phosgene with *N*-benzylideneaniline and *N*-benzylidenemethylamine, respectively. Reaction of these carbamoyl chlorides with a number of nucleophiles is described, some of which cause cleavage of the benzyl to nitrogen bond while others give rise to substitution products without such cleavage. Of the latter type, substituted hydrazines react to effect ring closure to 1,2,4-triazolidine-5-ones. The method serves as a convenient synthesis of these new heterocyclic systems.

Le chlorure de *N*-(α-chlorobenzyl) carbaniloyle et le chlorure de (α-chlorobenzyl) méthylcarbamoyle sont formés dans la réaction entre le phosgène et la *N*-benzylidène aniline et la *N*-benzylidène méthylamine, respectivement. La réaction de ces chlorures de carbamoyle avec un certain nombre de nucléophiles est décrite, certains d'entre eux provoquent le clivage du benzyle lié à l'azote tandis que d'autres donnent lieu à des produits de substitution sans clivage. Les hydrazines substituées réagissent selon ce dernier schéma en formant un cycle de type triazolidine-1,2,4, ones-5. La méthode constitue une synthèse commode de ces nouveaux systèmes hétérocycliques. [Traduit par le journal]

Can. J. Chem., **51**, 333 (1973)

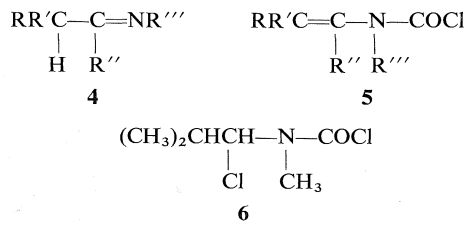
Introduction

Phosgene has been reported to react with azomethines, **1**, to produce *N*-(chloroformyl)-azomethines, **2**, and 1-chloroalkyl isocyanates, **3** (1).



1 **2** **3**

Enolizable imines of the type **4** were reported by Chupp (2) to react with phosgene to afford (1-alkenyl)carbamoyl chlorides, **5**. In an unusual example, *N*-isobutylidinemethylamine (**4**, R = R′ = R‴ = CH_3; R″ = H) was converted to (1-chloro-2-methylpropyl)methylcarbamoyl chloride (**6**) which is surprisingly stable to dehydrochlorination (3). Kiefer (4) recently reported the reaction of phosgene with some non-enolizable *N*-substituted imines to give the corresponding (1-chloroalkyl)carbamoyl chlorides.



4 **5**

6

[1]Author to whom correspondence should be addressed.

The present work was undertaken to examine the reaction of non-enolizable *N*-substituted imines with phosgene as a general route to (1-chloroalkyl)carbamoyl chlorides with a view to the use of such compounds in the synthesis of heterocyclic systems. A similar study was made of *N*-(α-chlorobenzylidene)carbamoyl chloride formed from the addition of phosgene to benzonitrile (5). In this paper, we report the formation of the (α-chlorobenzyl)carbamoyl chlorides, **8**, and some of their reactions including conversion to the 1,2,4-triazolidine-5-ones, **22**.

Results and Discussion

N-Benzylideneaniline (**7***a*) and *N*-benzylidenemethylamine (**7***b*) underwent reaction with phosgene in benzene solution to afford *N*-(α-chlorobenzyl)carbaniloyl chloride (**8***a*) and (α-chlorobenzyl)methylcarbamoyl chloride (**8***b*), respectively (see Scheme 1). The (1-chloroalkyl)carbamoyl chlorides **8** were stable and could be isolated under anhydrous conditions. The struc-

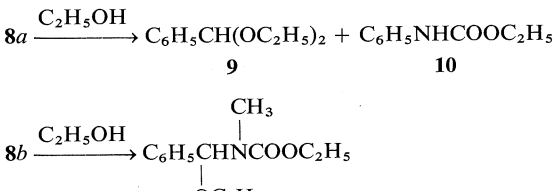
tural assignments **8** are consistent with spectral data and elemental analyses (see Experimental).

Ethanolysis of **8***a* caused cleavage to benzaldehyde diethyl acetal (**9**) and ethyl carbanilate (**10**). On the other hand, the methyl derivative, **8***b* did not undergo cleavage, but was converted to a product characterized as ethyl (α-ethoxybenzyl)-methylcarbamate (**11**) which was stable in refluxing ethanol (Scheme 2).



a, R = C_6H_5; *b*, R = CH_3

SCHEME 2

Reactions of the carbamoyl chlorides, **8**, with anhydrous ammonia and primary amines resulted in products which can be explained as having formed through the intermediacy of the corresponding (α-aminobenzyl)ureas, **12**, followed by base-catalyzed cleavage (see Scheme 3). From reaction with methylamine, *N*-benzylidenemethylamine (**13**, $R' = CH_3$) was obtained from both **8***a* and *b* together with 1-methyl-3-phenylurea (**14***a*, $R' = CH_3$) from **8***a*, and 1,3-dimethylurea (**14***b*, $R' = CH_3$) from **8***b*. Aniline reacted in an analogous fashion to produce *N*-benzylideneaniline (**13**, $R' = C_6H_5$) from both **8***a* and *b* along with 1,3-diphenylurea (**14***a*, $R' = C_6H_5$) from **8***a*, and 1-methyl-3-phenylurea (**14***b*, $R' = C_6H_5$) from **8***b*. Anhydrous ammonia converted **8***a* to 1,1′-benzylidenebis(3-phenylurea) (**15***a*) which, at least formally, can be viewed as having been formed through the cleavage of **12***a* (R′ = H) to benzylidene-ammonia (**13**, R′ = H) and phenylurea (**14***a*, R′ = H) which reacted further to give the bisurea. In an analogous fashion, 1,1′-benzylidene-bis-(3-methylurea) (**15***b*) was obtained from **8***b*. The bisureas **15***a* (6) and *b* (7) have been reported previously as products of the condensation of benzaldehyde with phenylurea, and methylurea, respectively.

Secondary amines also would be expected to give rise to (α-aminobenzyl)ureas analogous to the intermediates **12** but which would be stable to base-catalyzed cleavage. Dimethylamine converted **8***a* and *b* to the 1,1-dimethyl-3-(α-dimethylaminobenzyl)ureas, **16***a* and *b*, respectively. These compounds react readily with moisture in the atmosphere. On hydrolysis, each forms benzaldehyde and the corresponding urea, **17***a* or *b*. The 3-phenyl-derivative, **16***a*, undergoes what appears to be slow thermal decomposition in a dry nitrogen atmosphere at ambient temperatures as well.

Reaction of the carbamoyl chlorides, **8**, with hydrazine resulted in the formation of the semicarbazones, **19**, as the main products, together with the biureas, **20**, in smaller yields. The 1,2,4-triazolidine-5-ones, **18**, could be postulated as intermediates which underwent base-catalyzed ring opening to the semicarbazones **19** (see Scheme 4).

Under oxidizing conditions, the semicarbazone (**19***a*) is known to undergo cyclization to 3,4-diphenyl-Δ^2-1,2,4-triazolin-5-one (**21**) (8) (see Scheme 5). This result also suggests the intermediacy of the triazolidinone **18**.

The formation of the biureas, **20**, could be explained by an analogous base-catalyzed cleavage of the corresponding 1,2-bis[(α-hydrazinobenzyl)carbamoyl]hydrazine derivative which would be expected to form, in addition to **18**, by reaction of **8***a* or *b* with hydrazine.

1,2-Disubstituted 1,2,4-triazolidine-5-ones would be expected to be stable to base-catalyzed ring opening of the type **18** → **19**. Reaction of the (α-chlorobenzyl)carbamoyl chlorides, **8**, with 1,2-dimethyl- and with 1,2-diphenylhydrazine afforded convenient routes to the new heterocycles, **22**, which appear to be the first reported 1,2,4-triazolidine-5-ones (see Scheme 6). The structures are consistent with elemental analyses and spectral data (see Experimental).

Experimental

All melting points are uncorrected. The n.m.r. spectra were recorded on a Varian HA100 (100 MHz) spectrometer using tetramethylsilane as internal standard. The i.r. spectra were recorded on a Unicam SP1000 spectrometer. Mass spectra were measured on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer. Microanalyses were performed by A. B. Gygli, Toronto, Ontario.

In every case in which a previously described compound was isolated as a product, the spectral data (n.m.r. and i.r.) were identical with those of an authentic sample. For each such crystalline product, the m.p. of a mixture with an authentic sample was not depressed. Each authentic sample was prepared either by the procedure cited, or if none is cited, by an unequivocal method.

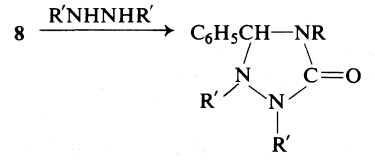
Synthesis of N-(α-Chlorobenzyl)carbaniloyl Chloride (8a)

To a stirred solution of 36.2 g (0.20 mol) of *N*-benzylideneaniline (9) in 100 ml of benzene maintained in an ice bath was added, over 1 h, 175 g of a 12.5% solution (0.22 mol) of phosgene in benzene (Matheson). The reaction mixture was stirred for an additional hour and then filtered, if necessary, to remove *N*-benzylideneaniline hydrochloride. Evaporation of solvent under reduced pressure gave 52.6 g (95% yield) of crude **8a**, m.p. 99–100.5° as white needles, m.p. after recrystallization from hexane, 102.5–103.5°; n.m.r. δ ($CDCl_3$): 7.19 (m, 10H, aromatic-H) and 7.57 p.p.m. (s, 1H, C_6H_5CH); i.r. spectrum (Nujol): $\nu_{C=O}$ 1750 cm^{-1}.

Anal. Calcd. for $C_{14}H_{11}Cl_2NO$: C, 60.03; H, 3.95; Cl, 25.32; N, 5.00. Found: C, 60.17; H, 3.85; Cl, 25.47; N, 5.00.

Synthesis of (α-Chlorobenzyl)methylcarbamoyl Chloride (8b)

By a procedure similar to that described above for the synthesis of **8a**, 22.8 g (0.20 mol) of freshly distilled *N*-benzylidenemethylamine (Aldrich) was treated with



a R=C_6H_5; R′=CH_3
b R=R′=CH_3
c R=R′=C_6H_5
d R=CH_3; R′=C_6H_5

phosgene to give 38.9 g (89% yield) of **8***b*, b.p. 116° (0.1 Torr); n.m.r. δ ($CDCl_3$): 2.94 (s, 3H, methyl) and 7.40–7.55 p.p.m. (m, 6H, aromatic-H and C_6H_5CH); i.r. (neat): $\nu_{C=O}$ 1744 cm^{-1}. Mass spectrum parent peak (*m/e*): 217; calcd., 217.

Anal. Calcd. for $C_9H_9Cl_2NO$: C, 49.57; H, 4.16; Cl, 32.51; N, 6.42. Found: C, 49.83; H, 4.41; Cl, 32.76; N, 6.47.

Ethanolysis of ***8a***

A solution of 2.7 g (0.0096 mol) of **8***a* in 50 ml of anhydrous ethanol was heated under reflux for 0.5 h. After removal of ethanol under reduced pressure, fractional distillation gave 0.85 g (49%) of benzaldehyde diethyl acetal (**9**), b.p. 58° (0.25 Torr), and 1.07 g (68%) of ethyl carbanilate (**10**), b.p. 115° (0.35 Torr), m.p. after recrystallization from heptane, 49.5–50.0°.

Ethanolysis of ***8b***

A solution of 5.0 g (0.023 mol) of **8***b* in 50 ml of ethanol was heated under reflux for 0.5 h. After removal of ethanol under reduced pressure, distillation gave 3.7 g (68%) of ethyl (α-ethoxybenzyl)methylcarbamate (**11**), b.p. 118° (0.060 Torr). An analytical sample was obtained by g.l.c.; n.m.r. δ ($CDCl_3$): 1.31, 1.32 (double t, J = 7 Hz, 6H, OCH_2CH_3), 2.57 (s, 3H, NCH_3), 3.66 (q, J = 7 Hz, 2H, $C_6H_5CH(OCH_2CH_3)$), 4.27 (q, J = 7 Hz, 2H, $COOCH_2CH_3$), 6.51 (s, 1H, C_6H_5CH), and 7.2–7.7 p.p.m. (m, 5H, aromatic-H); i.r. (neat): $\nu_{C=O}$ 1710 and ν_{C-O-C} 1160, 1100, 1030 cm^{-1}.

Anal. Calcd. for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90. Found C, 65.91; H, 7.99; N, 5.78.

Reactions of the Carbamoyl Chlorides ***8*** *with Methylamine and with Aniline*

(i) Methylamine

An excess of methylamine was passed through a cooled (0°) stirred solution of either **8***a* or *b* (0.02 mol) in 150 ml of dry ether over a period of 1 h. The solids produced were separated by filtration. From the reaction with **8***a*, 1-methyl-3-phenylurea (**14***a*, R′ = CH_3) was obtained in 89% yield by slurrying the solids in water to dissolve methylamine hydrochloride, collecting the remaining solids by filtration, and recrystallizing them from water, m.p. 151.0–151.5°. From **8***b*, 1,3-dimethylurea (**14***b*, R′ = CH_3) was obtained by slurrying the solids in ethanol, filtering to remove insoluble ammonium chloride, concentrating the ethanol solution, and crystallizing the residue from ether. Additional **14***b* was obtained by concentration of the ether filtrate from the reaction mixture to give a total yield of 70%, m.p. 104–106°. *N*-Benzylidenemethylamine was obtained in 59% yield from the reaction with **8***a*, and in 86% yield from **8***b* by distillation (b.p. 84°, 42 Torr) of the residue from the respective concentrated ether filtrates.

(ii) Aniline

To a stirred solution of either **8***a* or *b* (0.02 mol) in 100 ml of benzene, heated under reflux was added a solution of aniline (0.11 mol) in 150 ml of benzene. The reaction mixture was heated under reflux for an additional 1.5 h, cooled, and filtered. The solid material was slurried in water to remove aniline hydrochloride and the remaining insoluble material recrystallized from ethanol to give, from **8***a*, 1,3-diphenylurea (**14***a*, R′ = C_6H_5) in 81% yield, and from **8***b*, 1-methyl-3-phenylurea (**14***b*, R′ = C_6H_5) in 77% yield. The benzene filtrate from the reaction mixture was concentrated and the residue recrystallized from ethanol to give *N*-benzylideneaniline, m.p. 48–50° in 86% yield from **8***a*, and in 81% yield from **8***b*.

Reaction of ***8a*** *with Anhydrous Ammonia*

An excess of anhydrous ammonia was passed through a cooled (0°) stirred solution of 5.6 g (0.02 mol) of **8***a* in 50 ml of benzene over 0.5 h. The reaction mixture was filtered to remove ammonium chloride, and the filtrate concentrated under reduced pressure. The residue was heated in heptane, and after cooling, the crystals that formed were collected and recrystallized from ethanol to give 2.6 g (72%) of 1,1′-benzylidenebis(3-phenylurea) (**15***a*), m.p. 206–207° (lit. (6), m.p. 198–199°). An authentic sample was prepared as previously described (6). A satisfactory elemental analysis was obtained.

Reaction of ***8b*** *with Anhydrous Ammonia*

By a procedure similar to that described above for the reaction of **8***a*, a solution of **8***b* was treated with an excess of anhydrous ammonia. 1,1′-Benzylidenebis(3-methylurea) (**15***b*) was obtained in 55% yield, m.p. after recrystallization from methanol, 188–189.5° (lit. (7), m.p. 187–188°). An authentic sample was prepared as previously described (7). A satisfactory elemental analysis was obtained.

*Synthesis of 1,1-Dimethyl-3-(α-dimethylaminobenzyl)-3-phenylurea (****16a****)*

To a stirred, cooled (0°) solution of 5.8 g (0.021 mol) of **8***a* in 100 ml of ether was added 10 g (0.22 mol) of dimethylamine over a period of 30 min. The reaction mixture was filtered to remove dimethylamine hydrochloride, and the filtrate concentrated to give 6.2 g (100%) of crude **16***a*, m.p. after recrystallization from ether, 68–70°; n.m.r. δ ($CDCl_3$): 2.37 (s, 6H, $C_6H_5CHN(CH_3)_2$); 2.61 (s, 6H, $CON(CH_3)_2$), 5.65 (s, 1H, C_6H_5CH), and 6.9–7.4 p.p.m. (m, 10H, aromatic-H); i.r. (Nujol): $\nu_{C=O}$ 1645 cm^{-1}.

Anal. Calcd. for $C_{18}H_{23}N_3O$: C, 72.77; H, 7.77; N, 14.09. Found: C, 72.61; H, 7.76; N, 14.28.

A solution of **16***a* in ether was shaken with water. Benzaldehyde and 1,1-dimethyl-3-phenylurea (**17***a*) were isolated from the reaction mixture in essentially quantitative yields.

*Synthesis of 1,1,3-Trimethyl-3-(α-dimethylaminobenzyl)urea (****16b****)*

By a procedure similar to that described for the synthesis of **16***a*, 5 g (0.023 mol) of **8***b* was treated with 10 g (0.22 mol) of dimethylamine to give 5.1 g (94.6%) of crude **16***b*, m.p. after recrystallization from ether, 45.5–47°; n.m.r. δ ($CDCl_3$): 2.27 (s, 6H, $C_6H_5CHN(CH_3)_2$), 2.70 (s, 3H, $N(CH_3)CON(CH_3)_2$), 2.76 (s, 6H, $CON(CH_3)_2$), 5.30 (s, 1H, C_6H_5CH), and 7.25–7.65 p.p.m. (m, 5H, aromatic-H); i.r. (Nujol): $\nu_{C=O}$ 1658 cm^{-1}.

Anal. Calcd. for $C_{13}H_{21}N_3O$: C, 66.35; H, 9.00; N, 17.86. Found: C, 66.12; H, 8.88; N, 17.79.

A solution of **16***b* in ether was shaken with water. Benzaldehyde and trimethylurea (**17***b*) were isolated from the reaction mixture in essentially quantitative yields.

Reaction of ***8a*** *with Hydrazine*

To a stirred solution of 8.4 g (0.03 mol) of **8***a* in 50 ml of benzene cooled in an ice bath was added, over 15 min, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solution of 3.2 g (0.10 mol) of anhydrous hydrazine in 10 ml of dimethylformamide. The cooled reaction mixture was stirred for an additional hour and then poured into 100 ml of ice-water. The solid product was collected, slurried in ethanol, and the remaining solid recrystallized from dimethylformamide to give 1.45 g (35%) of 1,6-diphenylbiurea (**20***a*), m.p. 255–256° (lit. (10), m.p. 270°). An authentic sample was prepared from the reaction of phenyl isocyanate with hydrazine. A satisfactory elemental analysis was obtained.

The benzene filtrate from the reaction mixture, and the ethanol filtrate were concentrated and the residues recrystallized from ethanol to give a total of 4.2 g (60%) of benzaldehyde phenylsemicarbazone (**19***a*), m.p. 182–183° (lit. (8), m.p. 180°). An authentic sample was prepared as previously described (8).

*Reaction of **8***b* with Hydrazine*

By a procedure similar to that described for **8***a*, 6.54 g (0.03 mol) of **8***b* was treated with 3.2 g (0.1 mol) of anhydrous hydrazine. From the solids that formed, 0.076 g (3.5%) of 1,6-dimethylbiurea (**20***b*), m.p. after recrystallization from dimethylformamide, 258–259° (lit. (11), m.p. 260°) was obtained. An authentic sample was prepared by the reaction of methyl isocyanate with hydrazine.

The filtrate of the reaction mixture was concentrated and the residue crystallized from ethanol to give 2.2 g (41.5%) of benzaldehyde methylsemicarbazone (**19***b*), m.p. 167–169° (lit. (12), m.p. 166°). An authentic sample was prepared as previously described (12).

*Synthesis of 1,2-Dimethyl-3,4-diphenyl-1,2,4-triazolidine-5-one (**22***a*)*

To a solution of 4 g (0.03 mol) of 1,2-dimethylhydrazine dihydrochloride (13) in 15 ml of water was added a solution of 6.1 g (0.11 mol) of potassium hydroxide in 15 ml of water. Then, 120 ml of acetone was added, and the reaction mixture was filtered to remove potassium chloride.

To 30 ml of acetone cooled in an ice bath (10–12°) were added concurrently over 1 h the 1,2-dimethylhydrazine solution and a solution of 5.6 g (0.02 mol) of **8***a* in 150 ml of acetone. The reaction mixture was stirred for another 1.5 h, filtered, and concentrated. The residue was dissolved in benzene and the benzene solution washed with water, dried over magnesium sulfate and concentrated. The solid residue was recrystallized from heptane to give 3.0 g (57%) of **22***a*, m.p. 142.5–144°); n.m.r. δ ($CDCl_3$): 2.67 (s, 3H, NCH_3), 3.01 (s, 3H, NCH_3), 5.29 (s, 1H, C_6H_5CH), and 7.0–7.5 p.p.m. (m, 10H, aromatic-H), no exchange with D_2O; i.r. (Nujol): $\nu_{C=O}$ 1698 cm^{-1}; no absorptions assignable to NH. Mass spectrum parent peak (*m/e*) 267; calcd., 267.

Anal. Calcd. for $C_{16}H_{17}N_3O$: C, 71.89; H, 6.41; N, 15.72. Found: C, 71.82; H, 6.24; N, 15.88.

*Synthesis of 1,2,4-Trimethyl-3-phenyl-1,2,4-triazolidine-5-one (**22***b*)*

By a procedure similar to that described above for the synthesis of **22***a*, **8***b* was treated with 1,2-dimethylhydrazine to give **22***b* in 42% yield, b.p. 109° (0.02 Torr); n.m.r. δ ($CDCl_3$): 2.49 (s, 3H, NCH_3), 2.57 (s, 3H, NCH_3), 2.94 (s, 3H, NCH_3), 4.43 (s, 1H, C_6H_5CH), and 7.42 p.p.m. (s, 5H, aromatic-H); i.r. (neat): $\nu_{C=O}$ 1729 cm^{-1}; no absorptions assignable to NH. Mass spectrum parent peak (*m/e*): 205; calcd., 205.

Anal. Calcd. for $C_{11}H_{15}N_3O$: C, 64.36; H, 7.37; N, 20.47. Found: C, 64.54; H, 7.46; N, 20.28.

*Synthesis of 1,2,3,4-Tetraphenyl-1,2,4-triazolidine-5-one (**22***c*)*

A solution of 4.2 g (0.015 mol) of **8***a* in 100 ml of benzene, and another solution of 5.52 g (0.03 mol) of 1,2-diphenylhydrazine (Aldrich, freshly recrystallized from ethanol) in 100 ml of benzene were added concurrently over 1 h with stirring to 30 ml of benzene. The reaction mixture was then heated under reflux for 2 h, cooled, and filtered. Evaporation of the solution and crystallization of the residue from heptane gave 2.8 g (49.5%) of **22***c*, m.p. after recrystallization from heptane, 148–148.5°; n.m.r. δ ($CDCl_3$): 6.16 (s, 1H, C_6H_5CH), and 7.0–7.75 p.p.m. (m, 20H, aromatic-H); i.r. (Nujol): $\nu_{C=O}$ 1705 cm^{-1}; no absorption assignable to NH. Mass spectrum parent peak (*m/e*): 391; calcd., 391.

Anal. Calcd. for $C_{24}H_{21}N_3O$: C, 79.77, H, 5.41; N, 10.73. Found: C, 79.71; H, 5.54; N, 10.76.

*Synthesis of 1,2,3-Triphenyl-4-methyl-1,2,4-triazolidine-5-one (**22***d*)*

By a procedure similar to that described above for the synthesis of **22***c*, **8***b* was treated with 1,2-diphenylhydrazine to give **22***d* (33.4% yield), m.p. after recrystallization from heptane, 115.5–116.5°; n.m.r. δ ($CDCl_3$): 2.69 (s, 1H, $N—CH_3$), 5.55 (s, 1H, C_6H_5CH), and 7.0–7.75 p.p.m. (m, 15H, aromatic-H); i.r. (Nujol): $\nu_{C=O}$ 1718 cm^{-1}; no absorption assignable to NH. Mass spectrum parent peak (*m/e*): 329; calcd., 329.

Anal. Calcd. for $C_{21}H_{19}N_3O$: C, 76.57; H, 5.81; N, 12.76. Found: C, 76.64; H, 5.98; N, 12.67.

New Synthetic Routes to Δ^2-Pyrazolin-5-ones[1]

M. J. NYE AND W. P. TANG[2]
Department of Chemistry, University of Guelph, Guelph, Ontario
Received August 10, 1972

Three new synthetic routes to Δ^2-pyrazolin-5-ones involving base-catalyzed molecular rearrangements are reported.

Trois nouvelles méthodes de synthèse des Δ^2-pyrazolidones-5 sont rapportées; elles impliquent toutes des réarrangements catalysés par les bases. [Traduit par le journal]

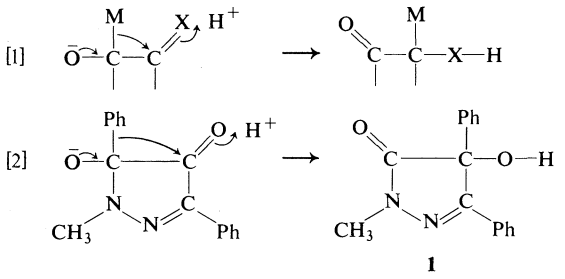
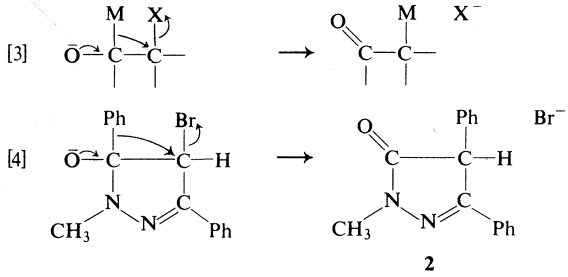
Introduction

Two related base-catalyzed rearrangement reactions are the acyloin and halohydrin rearrangements (eqs. 1 and 3). Both involve push–pull mechanisms, where an oxide ion is the electron source and an electronegative atom (X) is the electron sink. In the acyloin case, X is doubly bonded, whereas in the halohydrin case it is singly bonded. Although these reactions embody an easy way of placing a migrating group on the α carbon atom of a carbonyl functional group, they have been applied only sparingly to organic synthesis. This paper shows how appropriate substitution of the archetypes leads to two new convenient syntheses of Δ^2-pyrazolin-5-ones, exemplified by eqs. 2 and 4.

Acyloin rearrangement:



Halohydrin rearrangement:



Results and Discussion

Acyloin Rearrangement:

Treatment of 5-hydroxy-3,5-diphenyl-Δ^2-pyrazolin-4-one (**3***a*) or its methyl derivative **3***b* with methanolic potassium hydroxide gave respectively 4-hydroxy-3,4-diphenyl-Δ^2-pyrazolin-5-one (**4***a*) or **4***b* in 76–80% yields. The simplest possible mechanism of this reaction involves first the removal of the OH proton from **3** followed by an acyloin rearrangement of the anion (eq. 2). It is of interest that the Δ^2-pyrazolin-5-one appears to be thermodynamically more stable than the Δ^2-pyrazolin-4-one, which can be crudely rationalized as arising from the high inherent stability of amide-like structures (3).

Chemical evidence for the structures **4***a* and *b* was provided by the alternative synthesis of **4***b* by the oxidation of 1-methyl-3,4-diphenyl-Δ^2-pyrazolin-5-one (**2**) using hydrogen peroxide. This route has been shown by Veibel (4) to be a general method for hydroxylation of the 4-position of Δ^2-pyrazolin-5-ones.[3]

The structural assignments are also supported by the similarity of the i.r. and u.v. spectra between **4***a*, **4***b*, and the model compound **5** (5) (Table 1).

4-Hydroxy-3,4-diphenyl-Δ^2-pyrazolin-5-one (**4***a*) could alternatively be obtained by boiling 4-hydroxy-3,5-diphenylpyrazole (**6**) in methanolic

[3]Δ^2-Pyrazolin-5-ones might exist as at least two other tautomeric structures; however in this paper this name and structure have been arbitrarily chosen to represent the equilibrium mixture.

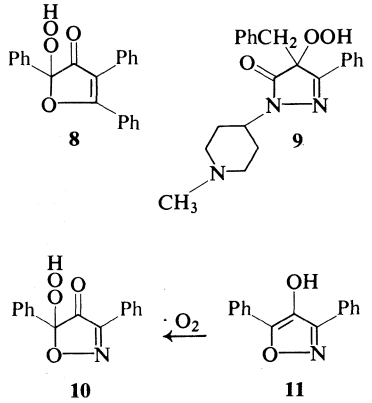
TABLE 1. Spectral data

Compound	I.r. (Nujol mull) (cm^{-1})	U.v. (95% ethanol) λ_{max} (nm)	ε
4*a*	1704	297	13 800
4*b*	1691	310	13 000
5 (5)	1698	301	12 190

sodium carbonate in the presence of air. The rationalization of this reaction (Scheme 1: **6** → **7** → **3***a* → **4***a*) is based on the established occurrence of hydroperoxide intermediates such as **8** (6) and **9** (7) in the aerial oxidation of related



heterocycles, and on their known conversion to parent alcohols (8). The most closely related hydroperoxide in the literature is **10** which was recently proposed as an intermediate arising from aerial oxidation of **11** (9).

Halohydrin Rearrangement

Treatment of 2-bromo-1,3-diphenyl-1,3-propanedione (**12***a*) with methylhydrazine in ethanol at room temperature gave 1-methyl-3,4-diphenyl-Δ²-pyrazolin-5-one (**15***a*) in a 56% yield.

The probable reaction sequence is shown in Scheme 2 (**12***a* → **13***a* → **14***a* → **15***a*). The first two steps which are standard ketone reactions are followed by a base-catalyzed halohydrin rearrangement in step *3*. Of the several reasonable alternative mechanisms, most of which differ only in the order of occurrence of the dozen or so minor steps, the given mechanism was favored for the following reasons. (*a*) Stable analogs of the intermediate **14** have been isolated by other workers (10). (*b*) The intermediate **14** can be diverted to an alternative product, 4-hydroxy-1-methyl-3,5-diphenylpyrazole (**17**), if Z^- is a poorer leaving group than Br^-. Treatment of **12***b* with methylhydrazine gives **17** in 92% yield (3). It is seen that when the two competing reactions proceed by loss of groups of similar leaving capability (OH^- and OAc^-), then the product-controlling factor is the fact that the next step gives rise to the more stable aromatic (6π-electron system) in the observed reaction but not in the competing one (step *4 vs.* step *3*). (*c*) Steps *2* and *3* are actually a manifestation of the well-authenticated Favorskii reaction proceeding via the semibenzilic mechanism.

In the treatment of **12***b* with methylhydrazine, the stage at which the acetoxyl group is hydro-

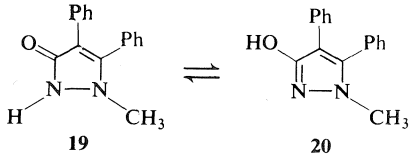
a, Z = Br, R = CH_3; *b*, Z = OAc, R = H; *c*, R = Ph

SCHEME 2

lyzed has not been established, but we represent this step as being the final one, since **16**, a phenolic-type ester should be hydrolyzed the fastest of all the compounds involved. If acetic acid is the solvent used in the above reaction the acetylated product **16** can be isolated.

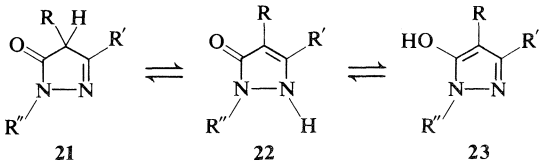
The structure of **15***a* was established chemically by a variation of the well-known route to Δ^2-pyrazolin-5-ones from β-oxocarboxylic acid derivatives. α-Phenyl-α-benzoylacetamide (**18**) was heated with methylhydrazine dihydrochloride in refluxing ethanol for 4 h to give a 50% yield of **15***a*. When **18** was treated with hydrazine and phenylhydrazine, the expected products **15***b* and *c* were obtained and their melting points agreed with literature values (11, 12). The α-phenyl-α-benzoylacetamide was prepared by acid hydrolysis of α-phenyl-α-benzoylacetonitrile which had been made by condensing ethyl benzoate with benzyl cyanide in the presence of sodium ethoxide. Since this method of synthesis of **15** does not completely rule out the possibility of one of the tautomeric pair **19** and **20** being the actual structures, extra evidence concerning the position of the methyl group on the ring was necessary. This was afforded by the conversion of **15***a* to the alcohol **4** using hydrogen peroxide (reported earlier in paper). No alcoholic product is conceivable for a similar oxidation of **19** or **20**.



19 20

Before this final piece of evidence was obtained, there was skepticism over the structure of **15***a*, since Grünanger and Vita-Finzi had reported (11) that this compound has m.p. 272–274 °C compared with m.p. (double) 216–219, 235–237 °C obtained by us. This difference could arise through polymorphism, but we suggest that the compound obtained by those workers had, in fact, structure **19** or **20**, since their synthesis involving methylation of 5-ethoxy-3,4-diphenylpyrazole followed by hydrolytic removal of the ethyl group was ambiguous and no additional evidence was offered.

With the skeletal structure of **15***a* established, it remains to determine the position of the labile hydrogen. The three most probable tautomeric structures are **21***a*, **22***a*, and **23***a*. Katritzky and Maine (5) have studied the i.r. spectra of a number



21 22 23

a, R = R′ = Ph; R″ = CH_3

of pyrazolin-5-ones and alkylated examples of the three types of tautomers and report that in chloroform solution the Δ^2-pyrazolin-5-ones (**21**) show a strong band around 1700 cm^{-1}, the Δ^3-pyrazolin-5-ones (**22**) show a strong band around 1630–1660

cm^{-1}, and the 5-hydroxypyrazoles (**23**) show no strong band between 1600 and 2000 cm^{-1}. However in the solid state (Nujol mull), whereas **21** still shows a distinctive band, **22** and **23** cannot be distinguished with certainty because both absorb in the low 1600's. In this work we obtained only solid state i.r. spectra, and no band appeared between 1620 and 2000 cm^{-1} indicating the absence of **21***a*, but not distinguishing between **22***a* and **23***a*. The tautomer **21***a* was also ruled out by the u.v. spectrum which was somewhat different from the spectra of model compounds **4***a* and *b*, and by the n.m.r. spectrum which did not show the ring CH proton but instead possessed a labile proton which only became visible by proton exchange in DMSO containing a trace of D_2O. U.v. and n.m.r. data were of no help in distinguishing between **22***a* and **23***a*.

1-Methyl-3,4-diphenyl-Δ²-pyrazolin-5-one (**15***a*) may also be prepared by treatment of 2,2-dibromo-1,3-diphenyl-1,3-propanedione with a fourfold excess of methylhydrazine in ethanol. Although this reaction must involve an extra reduction step compared with the conversion of **12***a* to **15***a*, both reactions give yields of about 55%.

Conclusion

Three new synthetic routes to Δ²-pyrazolin-5-ones have been reported in this paper. One of the advantages of each of the routes is that phenyl groups can easily be incorporated into the system. The difficulty of introducing phenyl groups using traditional syntheses is supported by the fact that neither of the two key products (**2** and **4**) reported in this paper had been prepared previously, in spite of the abundance of Δ²-pyrazolin-5-ones in the literature. It is suggested that the acyloin and halohydrin rearrangements deserve much more attention than they receive at present, especially in the synthesis of compounds bearing aryl substituents and when dealing with compounds sensitive to acid.

It is of interest that an analog of the aerial oxidation of 4-hydroxy-1-methyl-3,5-diphenylpyrazole (**6**) followed by acyloin rearrangement to 4-hydroxy-1-methyl-3,4-diphenyl-Δ²-pyrazolin-5-one (**4***a*) exists in nature in the conversion of ibogaine to iboluteine (13).

Experimental

M.p.'s were determined on a Meltemp apparatus and are uncorrected. I.r. spectra were obtained on a Beckman IR 5A spectrophotometer in Nujol mulls unless otherwise indicated, and strong bands between 1000 and 4000 cm^{-1} are quoted. U.v. spectra were measured on a Unicam SP 800 spectrophotometer in 95% EtOH at 25°. N.m.r. spectra were recorded on a Varian A60A spectrometer using an internal TMS standard. Microanalyses were performed by C. Daesslé, Organic Microanalyses, Montreal, Quebec.

*4-Hydroxy-3,4-diphenyl-Δ²-pyrazolin-5-one (**4***a*)

*(a) From 5-Hydroxy-3,5-diphenyl-Δ²-pyrazolin-4-one (**3***a*)*

A solution of **3***a* (14) (111 mg) in 1 ml 5% methanolic potassium hydroxide was refluxed for ½ h, 5 ml of water was added, and the solution refrigerated at 5° for 15 h. The solid product (85 mg, 76%) was filtered and crystallized twice from aqueous ethanol to give pure **4***a*, m.p. 210–212.5°; ν_{max} 3190, 2550 br, 1704, 1590, 1276, and 1142 cm^{-1}; λ_{max} 216 (ε 14 800) and 297 nm (13 800); δ (acetone-d_6) 6.10 (1H, s, OH), 7.25–7.60 (8H, m, aromatic), 7.78–7.94 (2H, m, aromatic), and 10.53 p.p.m. (1H, s, NH); *m/e* (70 eV): 252 (74%, M^+), 105 (100%), 77 (85%).

Anal. Calcd. for $C_{15}H_{12}N_2O_2$: C, 71.44; H, 4.80; N, 11.11. Found: C, 71.93; H, 4.87; N, 11.22.

*(b) From 4-Hydroxy-3,5-diphenylpyrazole (**6**)*

A mixture of **6** (14) (0.236 g, 0.001 mol), sodium carbonate (0.117 g, 0.0011 mol), and 90% methanol (20 ml) was refluxed for 2 h. The solids were filtered and washed with a small amount of methanol. Evaporation of the filtrate left solids which melted at 370–415°. Fractional recrystallization from ethanol gave a 32% yield of the starting material and a 31% yield of **4***a*, identified by mixture m.p. and i.r. spectrum.

*5-Hydroxy-1-methyl-3,5-diphenyl-Δ²-pyrazolin-4-one (**3***b*)

Compound **3***b* was prepared according to the method for 5-hydroxy-3,5-diphenyl-Δ²-pyrazolin-4-one (**3***a*) (14) with slight modification. A cooled (ice-bath), stirred solution of diphenylpropanetrione hydrate (15) (1.28 g, 0.005 mol) in methanol (10 ml) was treated with a solution of methylhydrazine (0.43 ml, *ca.* 0.008 mol) in methanol (1 ml). After 1 h, water (40 ml) was added to cause precipitation. Compound **3***b* was isolated in bright orange prisms, m.p. 140–141° (dec.) (from cold dilute methanol or warm benzene–petroleum) (65–75% yield); ν_{max} 3236, 1696, 1674 strong, 1204, and 1177 cm^{-1}; λ_{max} 215 (infl) (ε 13 400), 271 (15 800), and 420 nm (4660); δ ($CHCl_3$-*d*) 3.25 (3H, s, Me), 7.25–7.47 (9H, m, 8H aromatic, 1H hydroxyl exchangeable with D_2O), and 7.93–8.09 p.p.m. (2H, m, aromatic).

Anal. Calcd. for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52. Found: C, 72.10; H, 5.18; N, 10.65.

*4-Hydroxy-1-methyl-3,5-diphenyl-Δ²-pyrazolin-5-one (**4***b*)

*(a) From 5-Hydroxy-1-methyl-3,5-diphenyl-Δ²-pyrazolin-4-one (**3***b*)*

A mixture of **3***b* (95 mg) and 1 ml 5% methanolic potassium hydroxide was refluxed for 1/2 h, 5 ml of water was added, and the solution kept at 5° for 15 h. The solid product (76 mg, 80%) was filtered and recrystallized twice from aqueous ethanol to give pure **4***b*, m.p. 179–181°; ν_{max} 3155, 2721, 2667, 1691, 1603, 1198, 1183, and 1173 cm^{-1}; λ_{max} 217 (ε 14 700) and 310 nm (13 000); δ (acetone-d_6) 3.35 (3H, s, Me), 6.08 (1H, s, OH), 7.27–7.60

(8H, m, aromatic), and 7.78–7.95 p.p.m. (2H, m, aromatic).

Anal. Calcd. for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52. Found: C, 72.19; H, 5.21; N, 10.32.

*(b) From 1-Methyl-3,4-diphenyl-Δ²-pyrazolin-5-one (**2** or **15a**)*

The method was according to Jucker and Lindenmann (7). Hydrogen peroxide (40%) (0.87 ml) was added to a cooled (0–5°) solution of **2** (0.5 g, 0.002 mol) in 1.5% sodium hydroxide (8.5 ml). The mixture was stoppered, stirred for 1 h, and allowed to stand in a refrigerator for 24 h. The mixture was then neutralized with 5% hydrochloric acid, and the volume was reduced to one-fifth of the initial volume. A small amount of ethanol was added to dissolve the solids. On cooling crystals formed and recrystallization yielded 0.22 g (44%) of **4***b*, m.p. 178–180° identified by i.r. spectrum and mixture m.p.

Structure **2** may be converted to **4***b* by aerial oxidation, simply by heating it at its m.p. (~237°) in a m.p. tube for ½ h. The product was isolated and identified by its i.r. spectrum and mixture m.p.

*1-Methyl-3,4-diphenyl-Δ²-pyrazolin-5-one (**2** or **15a**)*

*(a) From 2-Bromo-1,3-diphenyl-1,3-propanedione (**12a**)*

Methylhydrazine (1.4 g, 0.03 mol) was added dropwise in 3 min to a warm suspension of **12***a* (16) (3.03 g, 0.01 mol) in ethanol (100 ml) under stirring. After addition, the mixture was stirred at room temperature for 1.5 h. The bulk of solvent was removed at reduced pressure and then 70% aqueous acetone (10 ml) was added. On cooling in an ice-bath, crystals formed and were collected. Recrystallization from 70% aqueous acetone gave 1.41 g (56%) of **15***a*, double m.p. 216–219° (then 235–237°); ν_{max} (KBr) 2550 br, 1601 s, 1427, 1392, 1292, 1069, and 1026 cm^{-1}; λ_{max} 240 (infl) (ε 14 700), 265 (infl) (11 200), and 300 (infl) nm (6310); δ ($CDCl_3$) 6.35 (3H, s, NMe), 7.20–7.40 (10H, m, aromatic) and deuterium exchange revealed 1 exchangeable H; *m/e* (70 eV): 250 (100%, M^+), 179 (35%), 178 (30%).

Anal. Calcd. for $C_{16}H_{14}N_2O$: C, 76.78; H, 5.64; N, 11.19; O, 6.39. Found: C, 77.22; H, 5.51; N, 11.06; O, 6.07.

(b) From 2,2-Dibromo-1,3-diphenyl-1,3-propanedione

The reaction was performed in a similar manner as in section *a*. The molar ratio of the dibromopropanedione to methylhydrazine was 1:4. Compound **15***a* was obtained in 57% yield.

*(c) From α-Phenyl-α-benzoylacetamide (**18**)*

1 ml of an aqueous solution containing methylhydrazine dihydrochloride (0.0024 mol) was added to a solution of **18** (see below) (0.48 g, 0.002 mol) in absolute ethanol (20 ml). The mixture was refluxed for 4 h. The mixture was neutralized (about p*H* 7) with 10% sodium hydroxide. The solution was reduced to half its volume, followed by cooling in an ice-bath. The crystals that formed were collected and purified giving a yield of 0.25 g (50%).

Compound **15***a* obtained from the three methods had identical spectral and physical properties.

Δ²-Pyrazolin-5-ones

α-Phenyl-α-benzoylacetamide (**18**) was prepared according to the method for the corresponding ethyl ester (17) with slight modification: α-phenyl-α-benzoylacetonitrile, obtained by condensing ethyl benzoate with benzyl cyanide in the presence of sodium ethoxide (17), was hydrolyzed in ethanol (with *ca.* 70% saturation of hydrogen chloride gas); m.p. 178.5–180° (lit. m.p. 178° (18)). The amide **18** was condensed with hydrazines to yield the Δ²-pyrazolin-5-ones.[4]

*3,4-Diphenyl-Δ²-pyrazolin-5-one (**15b**)*

This compound was obtained under conditions similar to those used for **15***a*. The refluxing time was 5 h. The yield was 68%; m.p. 234–236° (lit. m.p. 234–235° (11)); ν_{max} 3285, 3190, 1700, 1601, 1226, and 1016 cm^{-1}; λ_{max} 241 (infl) (ε 12 400) and 265 (infl) nm (10 700); δ (DMSO-d_6) 7.13 and 7.23 (10H, s, aromatic) and 10.77 p.p.m. (>1H, broad, NH; deuterium exchange revealed 2 exchangeable H).

*1,3,4-Triphenyl-Δ²-pyrazolin-5-one (**15c**)*

This compound was obtained by refluxing a mixture of the amide (**18**) (0.24 g, 0.001 mol), phenylhydrazine hydrochloride (0.18 g, 0.0012 mol), and ethanol (5 ml) for 1 h. The crystals that separated on cooling were recrystallized from ethanol, m.p. 191.5–193.5° (lit. m.p. 193–194° (12)) (64% yield); ν_{max} 1597, 1300, 1125, and 968 cm^{-1}; δ ($CHCl_3$-*d*) 7.30–8.10 (16H, m, 15H aromatic, 1H hydroxyl exchangeable with D_2O).

*4-Hydroxy-1-methyl-3,5-diphenylpyrazole (**17**) and 4-Acetoxy-1-methyl-3,5-diphenylpyrazole (**16**)*

Compound **17** was prepared (3) by refluxing a mixture of 2-acetoxy-1,3-diphenyl-1,3-propanedione (**12***b*) (16) and methylhydrazine in ethanol. The 4-acetoxypyrazole (**16**) was obtained when acetic acid was used as a solvent.

A solution of methylhydrazine (0.23 g, 0.005 mol) in acetic acid (1 ml) was added to a solution of **12***b* (1.13 g, 0.004 mol) in acetic acid (6 ml). The mixture was stirred at room temperature for 1 h. After most of the solvent was removed at reduced pressure, water (10 ml) was added. The oily product crystallized on prolonged cooling and agitation, m.p. 109–111° (from benzene–petroleum) (0.99 g, 85%). This product is identical with the one prepared by acetylation of the 4-hydroxypyrazole **17** (3).

The Photolysis of Propane at 123.6 nm

JAMES H. VORACHEK AND ROBERT D. KOOB

Department of Chemistry, North Dakota State University, Fargo, North Dakota 58102

Received August 2, 1972

Propane has been photolyzed at 123.6 nm, in the presence and absence of O_2, at pressures from 2–380 Torr. All products except ethane exhibit a pressure dependence which is attributed to secondary dissociation of the primary fragments, H_2, CH_4, C_2H_4, and C_3H_6. It is assumed that the range of energies carried by these fragments is broad enough that some will not dissociate even at low pressures while others of the same species cannot be stabilized even at high pressures. An internally consistent analysis rationalizes the entire observed product spectrum, with some uncertainty arising from an ambiguity in the source of acetylene. The following primary quantum yields, prior to secondary dissociation, are estimated:

$$C_3H_8 + h\nu = H_2 + C_3H_6 \quad \phi = 0.42 \text{ mol/einstein}$$
$$= C_2H_4 + CH_4 \quad \phi = 0.47 \text{ mol/einstein}$$
$$= CH_2 + C_2H_6 \quad \phi = 0.09 \text{ mol/einstein}$$

Le propane a été soumis à une photolyse à 123.6 nm, en présence et en absence de O_2, à des pressions de 2–380 Torr. Tous les produits, excepté l'éthane, manifestent une dépendance, par rapport à la pression, laquelle est attribuée à la dissociation secondaire des fragments primaires, H_2, CH_4, C_2H_4, et C_3H_6. On admet que l'étendue des énergies entraînées par ces fragments est suffisament large de sorte que certains ne se dissocieront pas même à de faibles pressions alors que d'autres de la même espèce ne peuvent être stabilisés même à de hautes pressions. Une analyse intérieurement cohérente coordonne le spectre obtenu des produits entièrement, avec certaines incertitudes provenant d'une ambiguité dans la source d'acétylène. Les premiers rendements quantiques qui suivent, précédant la seconde dissociation, ont été estimés:

$$C_3H_8 + h\nu = H_2 + C_3H_6 \quad \phi = 0.42 \text{ mol/einstein}$$
$$= C_2H_4 + CH_4 \quad \phi = 0.47 \text{ mol/einstein}$$
$$= CH_2 + C_2H_6 \quad \phi = 0.09 \text{ mol/einstein}$$

Introduction

The photochemistry of propane has been studied a good deal in the last decade (1–14) and the primary photolytic steps have been largely determined. Isotopic studies have identified precisely the origins of fragments within the molecule. Notably lacking, however, has been a measurement of quantum yields for each primary process. Two reasons for this are the uncertain actinometry in the vacuum u.v. and the extensive secondary reactions which make measurement of the yields of primary processes difficult.

While we have not improved our absolute actinometry, we have developed a two-windowed lamp which allows direct comparison of yields to those of an external standard. Thus, while absolute quantum yields may not be determined directly, yields relative to the standard may be, and the direction and magnitude of the changes in product yields may now be followed as a function of experimental conditions.

Secondary reactions are identified from the pressure dependence of all products. We sum the yields of these reactions in an attempt to estimate the overall quantum yield of the various primary processes. Yields of free radicals are obtained directly from radical combination product yields.

Experimental

Materials

Phillips research grade propane was used. After purification by gas chromatography using a silica gel column, impurity levels were below 5 p.p.m. The purified propane was dried over Drierite and vacuum distilled to a storage bulb. Linde C.P. oxygen was used without further purification.

Lamps and Cells

A krypton resonance lamp, similar to those described by Gorden *et al.* (15), was used for the photolysis. The lamp was filled on a mercury free vacuum line capable of achieving pressures less than 1×10^{-6} Torr (Veeco discharge gauge) and was gettered with a titanium gettering assembly. The chromatic purity was greater than 98%

in the region between 105 and 165 nm (McPherson 0.3 m vacuum monochromator). MgF_2 windows were attached to the lamp with Ag–AgCl seals. MgF_2 was chosen because it has a very weak dependence of its transmission properties on temperature (16). Moreover, MgF_2 is apparently less affected by irradiation history than LiF (17). Both properties were very important, as constant window properties were required for the successful use of the two-windowed lamp described in the next paragraph. The light intensity, calculated from the yield of acetylene from the photolysis of ethylene (18), was $1.7 \pm 0.1 \times 10^{14}$ quanta/s.

A "T"-shaped lamp with windows at each end of the crossbar was used to study the photolysis. The lamp was powered by a microwave generator through a tuned Evenson cavity placed on the base of the "T" nearest the crossbar. Each window looked into individual sample cells. Each cell had a 2.5 cm i.d. with a path length of 2.5 cm. The ratio of light intensities entering the two cells was determined by measuring the relative amounts of products formed in the photolysis of equal pressures of oxygen-scavenged propane. This ratio was constant throughout this work. Thus, one cell with constant sample conditions was used as an external standard to which runs made in the other cell could be compared.

The yield of methane from the photolysis of oxygen-scavenged propane at a pressure of 20 Torr was used as the external standard. The rate of formation of methane in the standard was found to be constant over the range 0.05–4% decomposition of parent to product (2).

All scavenged photolyses were conducted with 5% oxygen added to intercept free radicals and triplet methylene. No products which could be ascribed to these species were found. Except for conversion dependence runs, photolysis was carried to 0.1% conversion of parent to product. All analyses were done by gas chromatography (FID) on a 25 ft × 1/4 in. o.d., 35% (w/w) squalene column for the products containing four carbon atoms or less and a 25 ft × 1/4 in. o.d., 3% (w/w) squalene column for the product containing five or six carbons. Both columns were maintained at room temperature.

Results

Photolysis products observed in the presence of 5% oxygen at 123.6 nm include hydrogen, methane, ethane, ethylene, acetylene, propylene, and iso- and normal butane. Very small amounts of doubly unsaturated three-carbon molecules and butenes may also be observed under proper conditions. A summary of major product yields in the presence of oxygen at pressures from 2–380 Torr is given in Table 1.

As ethane was the only product found to be pressure invariant over the range investigated, all yields in Table 1 are normalized to the yield of ethane. Ethane yield serves as an internal standard and was compared directly to our external standard. The quantum yield of 0.086 reported for ethane in Table 1 was determined relative to the yield of acetylene from the photolysis of ethylene at the same wavelength, 123.6 nm, assumed equal to 0.90, as suggested by Meisels (18).[1] We make no claims for the validity of this assumption and use this number primarily for convenience. The sum of the quantum yields for the proposed primary processes in propane is near unity when the above assumption is made.

TABLE 1. Quantum yield* of nonscavengeable products in the photolysis of propane at 123.6 nm as a function of pressure

	Pressure (Torr)					
Product	2	10	20	50	100	380
CH_4	0.167	0.165	0.163	0.160	0.159	0.152
C_2H_2	0.151	0.140	0.135	0.122	0.100	0.092
C_2H_4	0.423	0.427	0.431	0.438	0.448	0.448
C_2H_6	0.086	0.086	0.086	0.086	0.086	0.086
C_3H_6	0.237	0.250	0.248	0.263	0.259	0.283

*Determined relative to the quantum yield of acetylene from ethylene equal to 0.90 at 123.6 nm.

Acetylene exhibits a striking pressure dependence. The acetylene quantum yield drops from 0.151 at 2 Torr to 0.092 at 380 Torr. The quantum yield of methane also decreases with pressure. Ethylene and propylene quantum yields increase with increasing pressure.

It is relevant to point out, in light of the recent work of Tanaka and co-workers (1), that the sum of the acetylene and ethylene yields is not independent of pressure. The difference between the ethylene yield at 380 and 2 Torr is only 50% of the difference between acetylene yields at the same pressures.

Table 2 compares the yields of products in the presence and absence of oxygen at 380 Torr. The multitude of products ascribable to radical combination in the latter case attests dramatically to the radical intercepting ability of oxygen at the levels used. Acetylene yields were not affected by the presence of oxygen. Thus, a convenient internal standard is available for comparing yields in the presence and absence of oxygen.

One may compute quantum yields of each radical relative to isopropyl by correcting the appropriate combination product for disproportionation. These products are isobutane (methyl-isopropyl) isopentane (ethyl-isopropyl),

[1]In this paper, the quantum yield of C_2H_2 from C_2H_4 is measured as 0.90.

TABLE 2. Quantum yield of all products observed in the photolysis of propane at 380 Torr

Product	No O_2	O_2, 5%	Product	No O_2
CH_4	0.181	0.152	1-Pentene	0.003
C_2H_2	0.092	0.092	Isopentane	0.029
C_2H_4	0.445	0.448	*n*-Pentane	0.006
C_2H_6	0.167	0.086	4-Methyl-1-pentene	0.026
C_3H_6	0.328	0.283	2,4-Dimethylbutane	0.080
1-Butene	0.020	—	2-Methylpentane	0.029
Isobutane	0.151	0.015	1,5-Hexatriene	trace
n-Butane	0.063	0.036	1-Hexene	0.005
3-Methyl-1-butene	0.003	—	*n*-Hexane	0.004

TABLE 3. Quantum yield of free radicals in the photolysis of propane at 380 Torr

Radical	Base product	$1 + k_d/k_c$*	Yield relative to isopropyl radical	Quantum yield of radical
Methyl	Isobutane†	1.22	0.616	0.339
Vinyl	Isopentene	1.2	0.010	0.006
Ethyl	Isopentane	1.27	0.126	0.069
Allyl	4-Methyl-1-pentene	1.3	0.124	0.068
i-Propyl	2,4-Dimethylbutane	1.68 (×2)	1.0	0.551
n-Propyl	2-Methylpentane	1.40	0.167	0.093

*Values selected from ref. 19.
†Corrected for isobutane formed by CH_2 insertion.

isopentene (vinyl-isopropyl), 4-methyl-1-pentene (allyl-isopropyl), 2-methylpentane (*n*-propyl-isopropyl), and 2,4-dimethylbutane (isopropyl-isopropyl). The sum of all products involving isopropyl radical corrected for disproportionation provides its quantum yield, 0.551. The quantum yields for all other radicals are then computed by multiplying the radical yields relative to isopropyl times the quantum yield of isopropyl radical (see Table 3).

Vinyl and allyl radicals show striking pressure dependence, both decrease with increasing pressure. The pressure dependence of allyl radical has been discussed in an earlier communication (3). It clearly results from a secondary reaction. Vinyl radical behaves similarly.

Figure 1 demonstrates the conversion dependence of the radical products *i*-pentane and 2,3-dimethylbutane over the range of 0.06% to 0.87% conversion (% conversion = (products)/(propane)$_0$ × 100). 2,3-Dimethylbutane, the product of isopropyl radical combination, increases by approximately 30% of its lowest observed yield in this range. *i*-Pentane increases by 100% over this same range. The more striking conversion dependence of *i*-pentane must arise from the conversion dependence of ethyl radical production. This result is not unanticipated in a system where both hydrogen atoms and ethylene are produced. The ratio of concentration of ethylene to propane ranges from 6×10^{-4} to 8.7×10^{-3} at these conversions. Since the ratio of the rate constants for H addition to ethylene relative to H abstraction from propane (19) is approximately 5×10^2, ethylene may compete effectively with propane for hydrogen atoms. As suggested in the discussion, the addition of H atoms to ethylene appears to provide the only "important" source of ethyl radicals as far as computing overall yields of products is concerned.

Discussion

Of many possible primary processes in the photolysis of propane, only the following have been directly demonstrated to exist (1, 9, 12, 13)

[1] $C_3H_8 + h\nu = C_3H_6 + H_2$

[2] $C_3H_8 + h\nu = C_2H_4 + CH_4$

[3] $C_3H_8 + h\nu = CH_2 + C_2H_6$

The inequity of yields between hydrogen and propylene, and methane and ethylene, as well as

For personal use only.

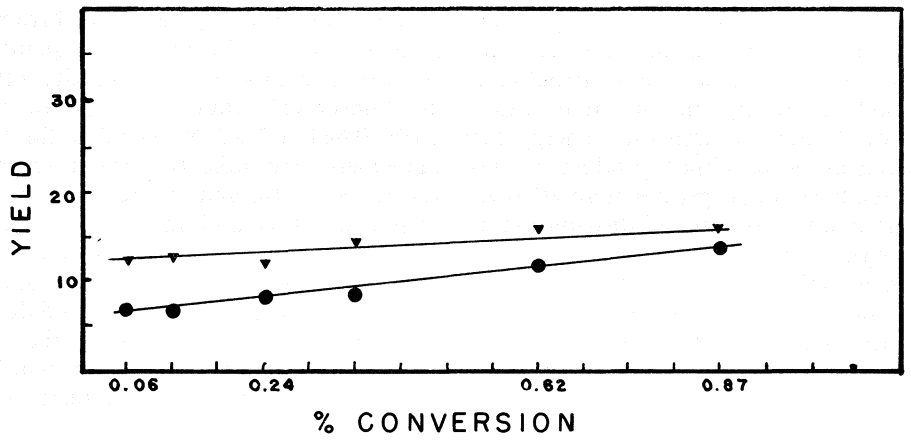

FIG. 1. The yield of isopentane, ●, in arbitrary units, as a function of percent conversion of propane to photolysis products. The actual quantum yields of isopentane at the highest and lowest conversions are 0.018 and 0.007 mol/einstein, respectively. The data were obtained in an oxygen free system of 20 Torr total pressure. For contrast the conversion dependence of 2,3-dimethylbutane is also plotted, ▼.

the appearance of acetylene, allene, and a number of products of a higher molecular weight than propane, require that other processes occur than those written as eqs. 1–3. Whether these other processes are subsequent to reactions 1–3, where any one of the fragments produced may further dissociate; or whether these other processes correspond to distinctly different processes such as reactions 4 and 5 has not been conclusively demonstrated.

[4] $C_3H_8 + h\nu = C_3H_7 + H$

[5] $C_3H_8 + h\nu = C_2H_5 + CH_3$

Photolysis of propane at 123.6 nm supplies enough energy that subsequent dissociation of any of the polyatomic fragments listed is energetically possible. Furthermore, secondary products from the dissociation of the fragments of reaction 1 are indistinguishable from the secondary products from the dissociation of fragments of reaction 4 if both occur at such a rate that they may not be quenched simply by increasing sample pressure. For example, $C_3H_6 + H + H$ may result from propyl radical dissociation in reaction 4 or from H_2 dissociation in reaction 1. The same total energy is available to each sequence as both would be initiated by a photon from the same source. It has also been demonstrated that energy is not necessarily statistically partitioned in a primary process in the photolysis of propane (20). Therefore, one cannot invoke the usual arguments regarding the number of oscillators "available" to the energy deposited by the incoming photon.

Since very rapid secondary reactions cannot be distinguished from primary processes, we will *arbitrarily* view the mechanism for the photolysis of propane as follows. The primary processes in the photolysis of propane can be generally classified as reactions 1–3. Each fragment in the primary process is generated with a broad distribution of energy. This implies that each primary fragment will have species falling into three different reactivity categories: low energy species where no further dissociation can occur; middle energy species where there will be a competition between dissociation and collisional deactivation over the pressure range studied; and high energy species which will always dissociate. "Secondary" unimolecular dissociations which must be considered are then:

[6] $H_2^* = 2H$

[7] $CH_4^* = CH_3 + H$

[8] $C_2H_4^* = C_2H_2 + H_2$

[9] $C_2H_4^* = C_2H_3 + H$

[10] $C_3H_6^* = C_2H_2 + CH_4$

[11] $C_3H_6^* = C_3H_4 + H_2$

[12] $C_3H_6^* = C_3H_5 + H$

The asterisk indicates energy in excess of the activation energy of that reaction.

Secondary dissociations of the fragments of eq. 3 are not included since ethane did not show

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a pressure dependence. This lack of pressure dependence of the yield of ethane is reasonable in the framework of our assumptions. Reaction 3 is considerably more endothermic than either reaction 1 or 2, and the activation energy for further dissociation of either product of reaction 3 is relatively high (greater than 80 kcal/mol). The assumption of a broad distribution of energies suggests that some ethane molecules indeed have enough energy to further dissociate, but the fraction of ethanes having this energy would be too small for us to detect in the pressure range we have studied (20). (The maximum internal energy in the distribution of energies for any of the fragments is, of course, the energy of the photon, 10 eV, less the endothermicity of the reaction and less energy distributed to external degrees of freedom.) On the other hand, because of the large energies available and the relatively small endothermicities of [1] and [2], it may occur that high pressure limits to yields of primary products lose their meaning. Other processes, such as cage effects, may become important before pressures become sufficiently high to quench all secondary dissociation of propylene or ethylene.

The following equations show the most probable reactions of the intermediates generated in reactions 3–12.

[13] $H + C_3H_8 = C_3H_7 + H_2$

[14] $H + C_3H_6 = C_3H_7$

[15] $H + C_2H_4 = C_2H_5$

[16] $R\cdot + R'\cdot$ = combination and disproportionation products

[17] $^1CH_2 + C_3H_8 = C_4H_{10}$

[18] $^1CH_2 + M = {}^3CH_2$

Reactions 17 and 18 have been discussed for this system in a recent series of papers (21) and we will not discuss them in detail here. Reaction 17 does make a significant contribution to the overall butane yield, however, and this contribution must be considered when assigning radical yields based on observed butane. Reaction 16 is assumed to be the only important reaction of all free radicals except H and the CH_2 discussed above.

Relative rate constants for reactions 13–15 are available in the literature (19). At 380 Torr and 0.1% final conversion of propane to produce the relative yields of reactions [15]/[14] + [13] (ethyl to total propyl) is calculated from reported rate constants to be 1:9.9. The quantum yields of radicals computed in the results section show an "observed" ratio of ethyl to propyl of 0.069:0.644 or 1:9.3. We consider this to be good agreement and take this result to imply that reactions 13, 14, and 15 are the only important source of ethyl and propyl radicals. Thus, if reactions 4 and 5 are actually primary processes, the polyatomic radical fragments are not substantially stabilized at 380 Torr and do not make an important contribution to the ethyl and propyl radical yields. Similar conclusions have been reached by previous investigators (1, 5, 11[2]).

[2]Ausloos and Lias (11) would agree that stable propyl radicals are formed only in very low yields in a primary process. However, they report a yield of C_2D_5H relative to methane of 0.27 for the photolysis of 29.4 Torr of C_3D_8 in the presence of 12.9% H_2S. They interpret this product as arising from the scavenging of C_2D_5 by H_2S. Obtaining a quantum yield of C_2D_5H by comparing the relative yield to the measured quantum yield of methane in our system at a similar pressure, this implies a quantum yield of primary ethyl radicals (ostensibly from reaction 5) of 0.04 or greater than 50% of our total measured ethyl radical yield. If it were indeed the case that the C_2D_5H did arise from ethyl radicals produced in a primary process, our conclusion that such radicals make a negligible contribution to the overall ethyl radical yield would obviously be false. The simple consideration of the appropriate energetics presented below, however, shows how unlikely it is that the measured C_2D_5H could actually arise from ethyl radicals produced in a process such as reaction 5. One may compute an upper limit to the total possible quantum yield of ethyl radicals produced in reaction 5 by summing the quantum yields of acetylene, ethylene and all pentanes (measured at 30 Torr in the absence of O_2) and subtracting the yield of "molecular" methane (the quantum yield of methane in the presence of oxygen) to be 0.33. At a similar pressure the measured quantum yield of C_2D_5H has already been computed to be 0.04. Of the total possible ethyl radicals, then, 12% are stabilized at 30 Torr and 88% decompose. This is obviously a limiting case since the total ethyl radical yield computed is an upper limit on the actual possible yield. In the notation of Rabinovitch and Setser (22), $D/S = 0.73$. To obtain such a ratio for the number of ethyl radicals decomposing to the number collisionally stabilized requires that greater than 80% of the ethyl radicals produced in reaction 5 carry as vibrational energy 50 kcal or less. The reader convinces himself of the veracity of this last statement using the energy dependence of the microscopic rate constant curve presented by Rabinovitch and Setser, a critical energy of decomposition of ethyl radicals of 39.8 kcal/mol, and a specific deactivation rate of $2 \times 10^8\ s^{-1}$ (at 30 Torr). The total energy deposited in the photolyzed propane is 231 kcal. The endothermicity of reaction 5 is 84 kcal. The energy remaining to be partitioned among the various degrees of

As a means of organizing the available data we consider all photolysis products to arise from primary processes 1, 2, and 3 and secondary reactions 6–18. The contribution of each primary process will be assessed by independently considering each of the two fragments for each process 1–3. Agreement between these individual assessments will be interpreted as evidence for the completeness of our analysis.

To the yield of molecular hydrogen in the presence of a radical scavenger must be added the hydrogen which formally does not appear as H_2 because of reaction 6. This hydrogen does not appear because it reacts as H atoms. The total quantum yield of H atoms may be determined by summing the yields of propyl and ethyl radicals because only reactions 13–15 will be important H atom reactions in this system. From the total yield of H atoms must be subtracted those which arise from reactions 7, 9, and 12 as these do not represent a contribution from primary process 1. The total H atom quantum yield attributable to process 1 is then halved and added to the observed H_2 yield. Finally, H_2 arising from reactions 8 and 11 must be subtracted from the total. This last step places uncertainties on the quantum yield of reaction 1 as calculated from the hydrogen yield. Experimental difficulties prevented us from routinely determining the quantum yield of C_3H_4, reaction 11. However, this yield is small. The major uncertainty arises in determining what fraction of the observed acetylene arises from reaction 8 and what fraction arises from reaction 10. This could possibly be determined from an isotopic analysis of acetylenes produced from selectively labeled propanes; however, such an analysis has not been done at present. Thus, our estimate of the overall quantum yield for reaction 1 based on hydrogen originating products must remain in uncertainty by the observed acetylene yield. This estimate, then, has the range of 0.403–0.495 mol/einstein.

The quantum yield of reaction 1 may also be estimated by examining the propylene related fragments. To the quantum yield of propylene observed in a scavenged system one must add the yields of reactions 10, 11, and 12, all of which remove propylene in secondary unimolecular reactions. Reaction 14 need not be considered since it will not occur in a scavenged system. The same uncertainty in assigning the yield of reaction 10 occurs as was discussed in the previous paragraph. We are thus left with the estimate of the quantum yield of reaction 1 of 0.351–0.443 mol/einstein based on propylene related product yields.

Similar analyses may be accomplished for the methane and ethylene fragments expected in primary process 2. To the observed methane yield must be added the yield of methyl radicals formed in reaction 7. The methane produced in reaction 10 must be subtracted from this total. As explained above the yield of methane from reaction 10 cannot be directly determined from presently available data. Thus we are left with the range of 0.399–0.491 mol/einstein as the quantum yield of primary process 2 based on methane related reactions. To the quantum yield of ethylene observed in a scavenged system must be added the yield of acetylene resulting from reaction 8. The same uncertainty regarding the relative importance of reactions 8 and 10 still plagues us here. A range of quantum yields of 0.448–0.540 mol/einstein is thus obtained for process 2 from ethylene related reactions.

Primary process 3 is determined in a straightforward fashion. It is simply the observed ethane yield in a scavenged sample. Since ethane does not exhibit a pressure dependence, no secondary reactions of ethane need be considered. The quantum yield of reaction 3 is thus 0.086 mol/einstein. The sum of the butane yields in an oxygen scavenged system must be less than this value since all methylenes produced in reaction 3 do not survive as singlets to undergo reaction 17. The observed butane yield is 0.051 mol/einstein. The calculations of the last three paragraphs are summarized in Tables 4 and 5, where the appropriate numbers are given.

The proposed reaction scheme, [1]–[3], [6]–[18], is seen in the previous paragraphs to lead to internally consistent results. The calculated quantum yield of each of the primary processes

---

freedom of the product methyl and ethyl radicals is 147 kcal. It would be an intriguing process indeed that partitioned only 1/3 of this energy to the internal degrees of freedom of the more complex ethyl radical while the remaining 100 or so kcal went into the methyl radical and external degrees of freedom. If such considerations have any validity, it is difficult to believe that the observed C_2D_5H has primary ethyl radicals as its source, even though no obvious alternative exists. The strong conversion dependence of products arising from ethyl radical as a precursor, pentanes, reinforces our conclusion that reaction 15 is the most important source of stable ethyl radical in this system.

TABLE 4. Assessment of the yields of important secondary reactions at 380 Torr and 0.1% conversion

†Yield estimated from data in refs. 9 and 13.

1–3 is found to be similar when calculated by considering each of its fragments individually. The major uncertainty which pervades may be traced to the acetylene forming reactions. Although we do not have direct evidence for the relative importance of reactions 8 and 10, we may speculate as to the relative importance of these two reactions. The increase in ethylene over the pressure range studied, Table 1, accounts for only 50% of the observed decrease in acetylene yield. If we assume that both reactions 8 and 10 are quenched at similar rates, then we may estimate that the observed acetylene receives approximately equal contributions from reactions 8 and 10.

If we estimate that reaction 8 contributes 50% of the observed acetylene yield at 380 Torr and reaction 10 contributes about 50%, then the following quantum yields are determined for the three postulated primary processes.

[1] $C_3H_8 = C_3H_6^* + H_2^*$ $\phi = 0.449$, based on hydrogen related reactions $= 0.397$, based on propylene related reactions

[2] $C_3H_8 = C_2H_4^* + CH_4^*$ $\phi = 0.445$, based on methane related reactions $= 0.494$, based on ethylene related reactions

[3] $C_3H_8 = C_2H_6 + CH_2$ $\phi = 0.086$, based on ethane yield

In each case the quantum yields based on individual determinations of the two fragments associated with each process overlap with a $\leqslant 5\%$ uncertainty. Considering the rather complex analysis necessary, this is most gratifying. Summing the average value for each primary process gives a total quantum yield for disappearance of propane of 0.979 mol/einstein.

Summary

Using an experimental system in which it is possible to determine quantum yields relative to an external standard for all products in the photolysis of propane, we found that all molecules observed in a scavenged system varied with pressure except ethane. This pressure dependence of product yields strongly suggests that second-

ary reactions involving primary fragments are important in determining the observed product distribution. We have postulated a scheme in which three primary processes, reactions 1–3, are the source of all unimolecularly reactive species. Secondary dissociations of H_2, C_3H_6, CH_4, and C_2H_4 provide all other reactive intermediates. The major difficulty in determining the quantum yields of each of the three primary processes lies in assessing the relative contributions to the observed acetylene yield from reactions 8 and 10, the secondary dissociation of ethylene and propylene, respectively. If indirect evidence is used to determine the relative contributions of each of these reactions, one estimates the following quantum yields for the primary processes: $\phi_1 = 0.42$; $\phi_2 = 0.47$; $\phi_3 = 0.09$. This corresponds to 43% of total primary reaction giving propylene plus hydrogen, 48% giving ethylene plus methane, and 9% giving ethane plus methylene.

Reactions 4 and 5 may be primary processes, but it has been concluded here and by previous investigators that the propyl and ethyl radicals produced in these reactions continue to dissociate by elimination of an H atom. Such sequences are not experimentally distinguishable from reaction 1 followed by 6 and reaction 2 followed by 7 and thus have not been explicitly considered. Their omission has not led to any glaring inconsistencies in our analysis.

Photolysis of Acylsilanes in Cyclohexane and Other Solvents

A. G. Brook and J. M. Duff

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received June 26, 1972

Whereas photolysis of acylsilanes in carbon tetrachloride has been shown to generate silyl radicals which yield chlorosilanes exclusively, and photolyses in alcohols yield siloxycarbenes which yield "mixed acetal" insertion products, it is shown that photolysis of acylsilanes in non-polar, non-halogenated solvents such as cyclohexane give complex mixtures of products which result primarily from the attack of silyl radicals on the carbonyl oxygen of an acylsilane, followed by conventional disproportionation or recombination reactions. Under some circumstances silyl radicals add to carbon–carbon double bonds. The structures of the products formed and the mechanism of their formation are described.

Alors que la photolyse des acylsilanes dans le tétrachlorure de carbone produit, comme il a été démontré, des radicaux "silyses" ce qui conduit exclusivement à des chlorosilanes, et que la photolyse dans des alcools conduit à des siloxycarbènes qui donnent des produits d'insertion d'acétales mixtes, il est démontré que la photolyse d'acylsilanes dans des solvants non-polaires et non halogénés comme le cyclohexane, donne des mélanges complexes de produits qui proviennent surtout de l'attaque des radicaux "silyles" sur l'oxygène du groupe carbonyle d'un acylsilane, suivi de réactions classiques de dismutation ou de recombinaison. Dans certains cas les radicaux "silyles" s'additionnent aux doubles liaisons carbone–carbone. Les structures des produits formés ainsi que le mécanisme de leur formation sont décrits. [Traduit par le journal]

It has recently been shown that the photolysis of acylsilanes in carbon tetrachloride or similar halogenated solvents leads by a Norrish Type 1 cleavage to silyl and acyl radicals which subsequently react to give silyl chloride and the usual products from acyl radicals (1) (eq. 1). It has also

[1] $$R_3SiCOR' \xrightarrow[CCl_4]{h\nu} R_3Si\cdot + R'CO\cdot \rightarrow$$

$$R_3SiCl + R'COCl + R'COCCl_3 + Cl_3CCCl_3$$

been shown that photolysis in polar solvents such as alcohols gives rise to mixed acetals by way of a siloxycarbene intermediate (2, 3) (eq. 2). In view

[2] $$R_3SiCOR' \xrightarrow[MeOH]{h\nu} R_3SiO\ddot{C}R' \rightarrow R_3SiOCR'(H)(OMe)$$

of these extremes in behavior as the solvent was changed, it appeared of interest to photolyze acylsilanes in non-polar, non-halogenated solvents where, if silyl radicals were formed they would lack electronegative halogen atoms with which to react by abstraction, or where, if siloxycarbenes were formed, they would lack highly polar bonds such as OH into which they might insert.

Acetyltriphenylsilane clearly undergoes radical cleavage when photolyzed in carbon tetrachloride (3) and siloxycarbene formation when photolyzed in methanol containing a trace of pyridine (2). When photolyzed in cyclohexane using a 100 W low pressure mercury flood lamp, a complex mixture of products was formed from which three major products were separated by a combination of chromatography and crystallization.

The structures assigned to these products, their yield, and details of their structure proof are shown in eq. 3. The least soluble compound had an analysis and spectroscopic data consistent with the siloxyalkene **1**. The stereochemistry was not established but the isomer having *trans*-triphenylsilyl groups appears much more probable on steric grounds. Degradation of **1** gave almost 3 equiv of triphenylsilanol. Cleavage did not occur under milder conditions, and no reduction of the siloxy group to a silyl hydride occurred when the compound was refluxed with lithium aluminum hydride in ether. However, when treated with phenyllithium or *n*-butyllithium, both a tetra-substituted silane and a new compound **4**, which contained both an acylsilane and a β-ketosilane functionality were obtained (eq. 4). Thus **4** had n–π* u.v. absorption at 377 nm typical of an acylsilane (*e.g.* acetyltriphenylsilane λ_{max} 377 nm) and carbonyl i.r. absorption at

[3] $Ph_3SiCOMe \xrightarrow[C_6H_{12}]{h\nu}$ $Ph_3SiO(Ph_3Si)C{=}C(SiPh_3)(H)$ (**1**, 14%) + $Ph_3SiO(Ph_3Si)C{=}CH_2$ (**2**, 22%) + $Ph_3SiO(Ph_3Si)CH(CH_3)$ (**3**, 14%)

[4] $RLi + Ph_3Si$ migrates to O, giving $Ph_3SiO(Ph_3Si)C{=}C(SiPh_3)(H)$ $\longrightarrow Ph_3SiR + Ph_3Si{-}C(O^-){=}C(SiPh_3)(H)$ $\xrightarrow{H_3O^+}$ $Ph_3Si{-}C(=O){-}CH_2SiPh_3$ (**4**)

R = *n*-Bu, Ph

6.16 μ corresponding to the position expected for an acylsilane (acetyltriphenylsilane 6.08 μ) perturbed to longer wavelength by the expected amount by the β-silicon atom (*e.g.* Me_3CCH_2COMe 5.82 μ, $Me_3SiCH_2COCH_3$ 5.89 μ). The structure of **4** was further confirmed when, on heating, it underwent the known thermal rearrangement of β-ketosilanes (4) to give the isomer **2** which was also synthesized by an alternate route (eq. 5).

[5] $Ph_3Si(O)CH_2{-}C(=O){-}SiPh_3 \longrightarrow Ph_3Si{-}O{-}CH_2{=}C{-}SiPh_3$ (**2**) $\xleftarrow{Ph_3SiCl}$

$CH_2{=}C(O){-}SiPh_3 \xleftarrow{(Me_3Si)_2NNa} CH_3C(=O){-}SiPh_3$

It was difficult to separate the mixture of **2** and the saturated compound **3** obtained from the original photolysis of acetyltriphenylsilane. However, when treated with dilute base, **2** was rapidly hydrolyzed to give 2 equiv of triphenylsilanol whereas **3** was relatively inert and could be isolated pure. The structure of **3** was independently confirmed by silylating the corresponding alcohol (eq. 6).

[6] $Ph_3SiCH(OH)Me + Ph_3SiBr \xrightarrow{C_5H_5N} Ph_3SiCH(Me)OSiPh_3$ (**3**)

The above three products, which accounted for about 50% of the starting material, were the only ones from the photolysis reaction which were isolated and characterized. Other compounds were present, and at least some of these were unstable since on standing or on chromatography, up to 30% of triphenylsilanol and small amounts (<5%) of acetyltriphenylsilane could be isolated.

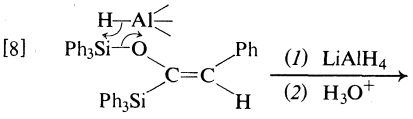
Before discussing mechanisms for the formation of the above products it is pertinent to describe the results of photolysis of another acylsilane, phenylacetyltriphenylsilane, under comparable conditions. Photolysis in cyclohexane gave three readily separable products which accounted for about 90% of the starting material. The structures and details of the structure proofs are shown in eq. 7.

[7] $Ph_3SiCOCH_2Ph \xrightarrow[C_6H_{12}]{h\nu}$ $Ph_3SiO(Ph_3Si)C{=}C(Ph)(H)$ (**5**, 8–12%) + $Ph_3SiO(Ph_3Si)C(CH_2Ph)(CH_2Ph)$ (**6**, 40%) + Ph_3SiCH_2Ph (30–35%)

The structure of **5**, obtained in about 8–12% yield from various runs, was supported by analytical and spectroscopic data. The geometry has been assigned purely on steric arguments. Attempts to synthesize **5** by coupling the enolate ion of phenylacetyltriphenylsilane with triphenylchlorosilane, or to degrade it, by treatment with phenyl- or *n*-butyllithium, gave complex mixtures of unidentified products. Treatment with aqueous alkali gave 2 equiv of triphenylsilanol but the expected phenylacetaldehyde was not isolated, presumably due to its further reaction under the

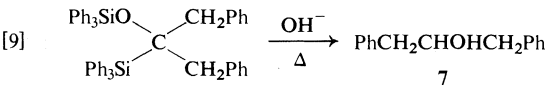
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

alkaline conditions. However, reduction of **5** with lithium aluminum hydride in refluxing di-*n*-butyl ether gave a 45% yield of triphenylsilane and a 30% yield of phenylacetyltriphenylsilane together with some recovered starting material and unidentified products (eq. 8).



[8] $Ph_3SiH + Ph_3SiC(=O)CH_2Ph$

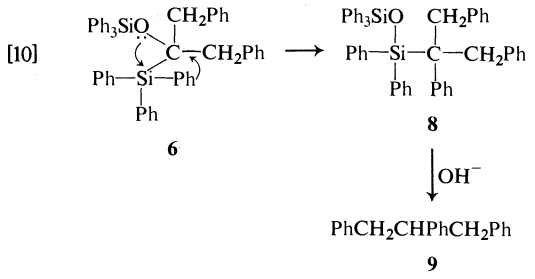
The structure of **6**, isolated in about 40% yield, was assigned on the basis of analytic and spectroscopic data. The compound showed no parent ion (*m/e* 728) in the mass spectrum, the highest molecular weight ions being 637 (M − CH_2Ph) and 636 (M − $PhCH_3$). Attempts to degrade **6** with the usual reagents such as lithium aluminum hydride in refluxing *n*-butyl ether, *n*-butyllithium, hydrochloric acid in aqueous acetone, or potassium hydroxide in refluxing aqueous ethanol led to almost quantitative recovery of starting material, probably because the molecule is severely sterically crowded. However, when refluxed in aqueous alkaline diglyme, conditions so harsh that phenyl groups were cleaved from silicon, 1,3-diphenyl-2-propanol (**7**), the expected carbon skeleton, was isolated in good yield (eq. 9). Rational mechanisms for this degradation involving alkoxysilane cleavage, a silylcarbinol to alkoxysilane rearrangement (5), and subsequent further cleavage can be proposed for this transformation.



[9] $Ph_3SiO(Ph_3Si)C(CH_2Ph)_2 \xrightarrow[\Delta]{OH^-} PhCH_2CHOHCH_2Ph$ (**7**)

Further evidence for the structure of **6** was obtained by finding that it rapidly and quantitatively thermally isomerized to the disiloxane **8** at 200° (eq. 10). This appears to be a new variant of a previously recognized type of 1,2-rearrangement reaction involving silicon–oxygen bond formation and silicon–carbon bond breaking (5, 6). The structure of **8**, based on analytical and spectroscopic data, was confirmed by its hydrolysis using refluxing aqueous alkaline diglyme solution to the known 1,2,3-triphenylpropane (**9**).

The third product from the photolysis of phenylacetyltriphenylsilane was the well-known benzyltriphenylsilane.



[10] $Ph_3SiO(Ph_2Si)C(CH_2Ph)_2 \rightarrow Ph_3SiO(Ph_2Si)C(CH_2Ph)_2$ (**6** → **8**)

8 $\xrightarrow{OH^-}$ $PhCH_2CHPhCH_2Ph$ (**9**)

Mechanism of the Photolyses in Cyclohexane

The products from the photolysis of acetyl- and phenylacetyltriphenylsilane are readily explained on the basis of the formation of triphenylsilyl radicals which subsequently attack the most electronegative atom in the system, namely the oxygen of an unreacted acylsilane molecule, to form a new radical species which subsequently undergoes normal (dark) radical reactions.

For acetyltriphenylsilane, a reasonable reaction path is shown in Scheme 1.

The conversion of **2** to **1** by addition of triphenylsilyl radical to the alkene **2** is not unexpected since it is known that triphenylsilyl radicals will add to alkenes (7, 8). When 2 equiv of **2** were photolyzed with any acylsilane which yielded triphenylsilyl radicals on photolysis (*e.g.* $Ph_3SiCOCH_2Ph$, *vide infra*) it was found that significant yields (20%) of **1** could be isolated, a finding consistent with the alkene **2** reacting with the silyl radicals.

The products from the photolysis of phenylacetyltriphenylsilane can be explained by the following reaction pathways (Scheme 2) where again silyl radical adds to carbonyl oxygen, followed either by loss of a hydrogen atom or addition of a benzyl radical.

Two details of this mechanism require clarification. One question concerns the initial mode of cleavage of the acylsilane, which could have occurred to give silyl and phenylacetyl radicals (path *a*), the latter of which subsequently (and totally) decarbonylated, or which could have occurred to give silylacyl and benzyl radicals (path *b*), the former of which decarbonylated. No products containing a carbonyl group are found among the products of photolysis of phenylacetyltriphenylsilane in cyclohexane, or in carbon tetrachloride, where in the latter case the products are found to be triphenylchlorosilane and benzyltriphenylsilane, together with bibenzyl, trichloroethylbenzene, and hexachloroethane, each a product reasonably derived from silyl and benzyl

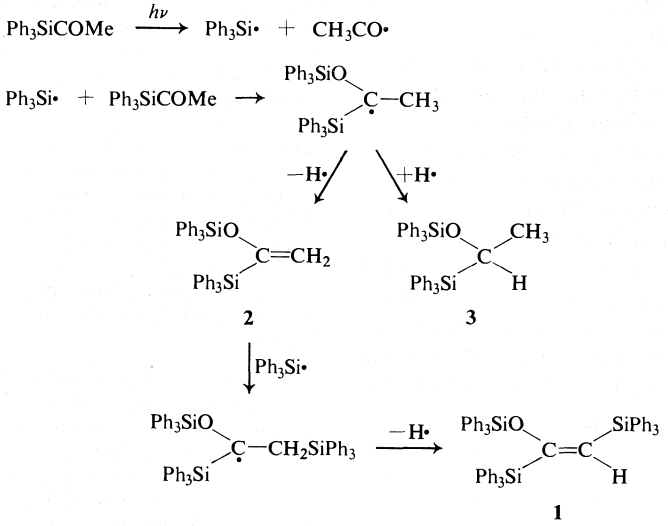
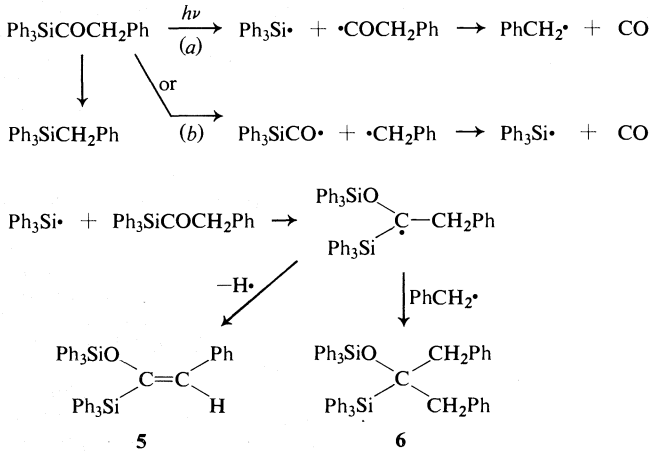


SCHEME 1. Photolysis of acetyltriphenylsilane.



SCHEME 2. Photolysis of phenylacetyltriphenylsilane.

radicals. The known stability of benzyl radical suggests that decarbonylation of phenylacetyl radical might occur easily; nothing is known about triphenylsilylacyl radicals to date.

The second question is how the observed benzyltriphenylsilane is formed. Formally, it could arise by combination of triphenylsilyl and benzyl radicals. However, it is to be noted that almost the same yields of benzyltriphenylsilane are obtained by photolysis of the acylsilane in any of cyclohexane, carbon tetrachloride, or methanol. Since silyl radicals have been shown previously to be very reactive toward carbon tetrachloride it is not clear why they should survive in this solvent to be able to combine with benzyl radicals, nor why, if formed in methanol, their behavior should not be strongly influenced by the rather different nature of this solvent so that at least a different amount of benzylsilane would be formed. To date all acylsilanes except phenylacetyltriphenylsilane, when photolyzed in methanol, have yielded almost no products of radical reactions, but instead yielded products derived from siloxycarbenes. These various observations are rationalized by the proposal that the major source of benzyltriphenylsilane is from a separate concerted intramolecular extrusion of CO from phenylacetyltriphenylsilane (*i.e.* reaction within and relatively independent of the solvent cage), rather than from the coupling of

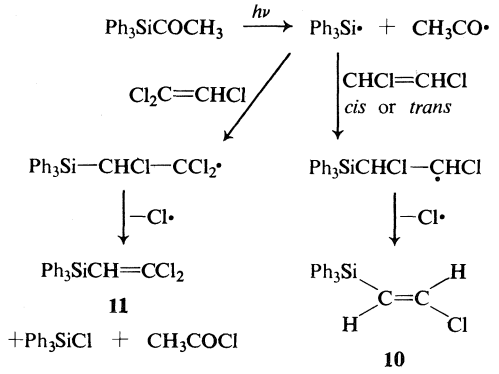
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

free silyl and benzyl radicals, which species are the sources of the other products observed as noted.

The photolyses of acetyltriphenylsilane using the di- and trichloroethylenes as solvents were briefly investigated. When photolyzed in *cis*-dichloroethylene, acetyltriphenylsilane gave a large amount of oligomerized solvent and a 34% yield of *trans*-2-triphenylsilylchloroethylene (**10**). Using *trans*-dichloroethylene, the same product was obtained in 45% yield. The *trans* geometry was assigned based on strong i.r. absorption at 10.52 μ, characteristic of a *trans*-disubstituted ethylene, and by the magnitude of the AB coupling constant of 15 Hz consistent with this geometry.

When photolyzed in trichloroethylene, acetyl chloride, triphenylchlorosilane, and 2,2-dichlorovinyltriphenylsilane (**11**) were isolated.

Both the above reactions are consistent with the cleavage of the acylsilane to radicals where the silyl radical either added to the double bond of the solvent, the new radical then losing a halogen atom, or where the silyl and acetyl radicals abstracted halogen from the solvent (Scheme 3).



SCHEME 3. Photolysis of acetyltriphenylsilane in chloroethylenes.

The preceding data clearly demonstrate the pronounced tendency of photolytically generated silyl radicals either to abstract a highly electronegative atom (halogen) from the solvent, or to add to unsaturation (C=O or C=C) when halogen is not available for abstraction. The driving force for either process is obviously the stability achieved through the strong Si—X or Si—O bonds that are formed in this process.

Experimental

All photolyses were carried out using a 100 W PAR 38 clear mercury flood lamp, ASA code H34-4GS, which has energy maxima at 366, 405, and 436 nm, closely matching the n–π* absorption maxima of acetylsilanes which occur at about 360–380 nm. Irradiations were carried out in Pyrex flasks positioned 8–12 in. from the lamp. Solutions were flushed with nitrogen prior to irradiation to remove oxygen, and photolyses were carried out with a slight positive pressure of thoroughly dried pure nitrogen gas.

I.r. spectra were obtained on a Perkin–Elmer 237B grating spectrometer; n.m.r. spectra on Varian A60 or T60 spectrometers; u.v. spectra on a Bausch & Lomb Spectronic 505 spectrometer; mass spectra on an AEI 902 spectrometer; g.l.c. on a Varian Aerograph Series 200 dual column gas chromatograph with thermal conductivity detection. Analyses were by A. B. Gygli, Toronto, Ontario.

The Photolyses of Acetyltriphenylsilane in Cyclohexane

A solution of 3.00 g (0.0099 mol) of acetyltriphenylsilane in 75 ml of cyclohexane (dried by distillation from lithium aluminum hydride) was stirred and irradiated until all acylsilane was gone ($8\frac{3}{4}$ h).

A similar irradiation of 15.00 g of the acylsilane in 250 ml of cyclohexane required 25 h irradiation for consumption of the acylsilane; 4 g in 60 ml of solvent required $12\frac{1}{2}$ h.

A thick, faintly yellow oil, obviously a mixture, was obtained upon removal of solvent under reduced pressure. Three products giving rise to (*a*) a singlet at δ 6 p.p.m., (*b*) two doublets (J = 1.8 Hz) at 5.15 and 4.68 p.p.m., and (*c*) a quartet (J = 7.5 Hz) at 4.53 p.p.m. were identified by methods described below. Other unidentified absorption in the region 2.2–1.0 p.p.m. was observed.

The product from the photolysis of 3 g of acetyltriphenylsilane in cyclohexane was chromatographed on silica gel. Elution with 1:3 benzene – carbon tetrachloride gave 1.39 g of oil.

Further elution of the column with benzene gave about 0.15 g (4%) of starting material and 0.89 g of slightly yellow solid which was recrystallized from carbon tetrachloride – petroleum ether (60–70°) to give 0.77 g (28%) of pure triphenylsilanol, m.p. 155–156°, mixed m.p. 155–156°.

The 1.39 g of oil obtained by chromatography above was dissolved in 20 ml of benzene, methanol was added, and on standing overnight 0.43 g of white crystals, m.p. 177–183°, were obtained. Recrystallization from the same solvent mixture, and then from carbon tetrachloride – heptane gave 0.26 g (9.6%) of pure 1-triphenylsiloxy-1,2-bis(triphenylsilyl)ethylene (**1**), m.p. 180–181°: *m/e* (relative abundance, proposed origin) 818 (1, M), 741 (3, M − Ph), 559 (5, M − Ph_3Si), 457 (33, $Ph_3SiOSiPh_2$), 259 (100, Ph_3Si); i.r. (CCl_4), 7.0, 9.0 (SiPh), 9.2 μ (Si—O—C); n.m.r. (internal TMS, $CDCl_3$) δ 6.00 (1H, s, C=CH), 6.6–7.5 p.p.m. (45H, m, aryl).

Anal. Calcd. for $C_{56}H_{46}OSi_3$: C, 82.10; H, 5.66; Si, 10.28. Found: C, 82.16; H, 5.60; Si, 10.35.

Hydrolysis of 1 in Aqueous Alkaline Dioxane

A solution of 0.25 g of **1** in 6 ml of dioxane was treated with 1.5 ml of 12% aqueous potassium hydroxide at room temperature for 1 h. Work-up with dilute hydrochloric acid gave a solid which was recrystallized from petroleum ether (90–100°) to give 0.22 g (88%) of triphenylsilanol, m.p. 140–155°. Recrystallization from carbon tetrachloride – pentane gave 0.20 g (79%) of material, m.p.

155–156°, identified by mixed m.p. with the authentic material.

Lithium aluminum hydride in refluxing di-*n*-butyl ether or hydrochloric acid in refluxing aqueous acetone had little or no effect on **1**.

*Treatment of **1** with Phenyllithium; Triphenylsilylacetyltriphenylsilane (**4**)*

A solution of 1.00 g (0.00122 mol) of **1** in dry benzene was treated with 3.75 ml (0.0030 mol) of freshly-prepared phenyllithium in ether–benzene solution. Upon being refluxed for $2\frac{1}{2}$ h the solution turned deep red and gave a white precipitate. Work-up with saturated aqueous ammonium chloride (β-ketosilanes are acid-sensitive) gave a solid which upon crystallization from carbon tetrachloride gave 0.31 g (76%) of tetraphenylsilane. This was recrystallized from carbon tetrachloride to give 0.26 g (65%) of the pure compound, m.p. 240–241°.

The residual product, an oil, was dissolved in hexane and gave, in three crops, 0.78 g of solid consisting largely of triphenylsilylacetyltriphenylsilane (**4**) which melted over a wide range. Recrystallization from methylene chloride – methanol gave 0.43 g (64%) of material, m.p. 140–153°, and recrystallization from methylene chloride – pentane gave m.p. 154–158°. Subsequent recrystallization failed to sharpen the m.p.; the large range is attributed to the ready thermal decomposition of **4**.

Similar treatment of **1** with *n*-butyllithium gave *n*-butyltriphenylsilane (60%) and **4** (40%); i.r. (CCl_4) 6.16 (C=O), 7.0, 9.0 μ (Si—Ph); n.m.r. ($CDCl_3$) δ 3.42 (2H, s, CH_2), 7.2–7.4 p.p.m. (32H (30 required), m, aryl); u.v. (λ_{max}, (ε), C_6H_{12}), 338 nm (sh, 83), 350 (sh, 160), 362 (275), 376.5 (380), 391.5 (295).

Anal. Calcd. for $C_{33}H_{32}OSi_2$: C, 81.38; H, 5.75. Found: C, 80.32; H, 6.05.

The unsatisfactory elemental analysis obtained for **4** was probably a result of trapped solvent in the crystals. However, in this case heating the compound up to its melting point to remove solvent resulted in partial rearrangement to a new compound.

*Thermal Rearrangement of **4** to 1-Triphenylsiloxy-1-triphenylsilylethylene (**2**)*

A sample of 0.100 g of **4** was heated under nitrogen at 160° for 30 min. The n.m.r. and i.r. spectra of the resulting glass were identical to those of an authentic sample of 1-triphenylsiloxy-1-triphenylsilylethylene (**2**), the preparation of which is described below. Crystallization from methylene chloride – methanol gave 0.071 g (71%) of crystalline **2**, m.p. 115–118°.

*Synthesis of 1-Triphenylsiloxy-1-triphenylsilylethylene (**2**)*

To a well-stirred suspension of 3.9 g (0.10 mol) of sodium amide in 100 ml of dry benzene under nitrogen, was added 16.1 g (0.100 mol) of bis(trimethylsilyl)amine to give a suspension of sodium bis(trimethylsilyl) amide.

To the suspension containing 0.012 mol of the above material was added, all at once, 3.02 g (0.010 mol) of acetyltriphenylsilane. After stirring for 10 min at room temperature solid triphenylchlorosilane (3.25 g, 0.011 mol) was added to the deep yellow solution. The yellow color disappeared, some warming was noticed, and on stirring for 1 h at room temperature a thick white suspension was obtained. Work-up with dilute hydrochloric acid and ether gave 5.6 g of yellow oil which was dissolved in 25 ml of benzene. Addition of 200 ml of methanol and cooling the solution to −20° gave 3.82 g (68%) of 1-triphenylsiloxy-1-triphenylsilylethylene, m.p. 110–113°. Recrystallization from hexane and other hydrocarbon solvents gave very unsharp melting material containing a considerable amount of trapped solvent. The analytical sample, m.p. 120–121°, was obtained by several recrystallizations from benzene–methanol: *m/e* 560 (1, M), 546 (1, M − CH_2), 482 (5, M − PhH), 457 (23, $Ph_3SiOSiPh_2$), 379 (36, 457 − PhH), 259 (100, Ph_3Si); i.r. (CCl_4) 6.05 (weak, C=C), 7.0, 9.0 (SiPh), 8.3 (s), 9.9 μ (s); n.m.r. ($CDCl_3$); 4.67 (1H, d, J = 1.8 Hz) and 5.13 (1H, d, J = 1.8 Hz, =CH_2), 7.1–7.7 p.p.m. (30H, m, aryl).

Anal. Calcd for $C_{38}H_{32}OSi_2$: C, 81.38; H, 5.75. Found: C, 80.92; H, 5.73.

*Isolation of 1-Triphenylsiloxy-1-triphenylsilylethane (**3**) from the Photolysate*

Following the photolysis of 4.00 g of acetyltriphenylsilane in cyclohexane the product was worked-up by chromatography to give an oil upon elution with benzene – carbon tetrachloride. Crystallization of this oil from pentane gave largely **1** in the first two crops. (This was further recrystallized to give 0.30 g of pure **1**.)

Removal of solvent from the mother liquor gave 1.08 g of thin oil which on crystallization from pentane gave 0.48 g of a solid, m.p. 135–144°, judged from its n.m.r. spectrum to consist of a mixture of **2**, 5.20 and 4.72 p.p.m. (doublets, J = 1.8 Hz), and a second compound, 1-triphenylsiloxy-1-triphenylsilylethane (**3**), δ 4.56 (1H, quartet, J = 7.5 Hz) and 1.48 p.p.m. (3H, doublet, J = 7.5 Hz).

The presence of **2** was confirmed by the i.r. spectrum in which all of the bands present in the spectrum of pure **2** were seen. One-half of this solid mixture (0.24 g) after seven recrystallizations from heptane gave 0.05 g of white solid, m.p. 156–159°, which consisted of **3**, contaminated with a trace of **2**. The mixed m.p. of this solid with pure **3**, (m.p. 163–164°, prepared as described below) was 159–163°.

The second half of the solid mixture of **2** and **3** (0.26 g) was treated with 10 ml of dioxane and 3 ml of 3 *M* aqueous sodium hydroxide over 40 min at room temperature. Work-up with dilute hydrochloric acid and ether gave a solid mixture of triphenylsilanol (identified by i.r.) and **3**.

Chromatography on silica gel gave upon elution with 1:1 benzene – carbon tetrachloride a thick oily fraction which was crystallized, then recrystallized from heptane to give 0.087 g of pure **3**, m.p. 163–164°, mixed m.p. with authentic material, 163–164°.

*Synthesis of 1-Triphenylsiloxy-1-triphenylsilylethane (**3**)*

A solution of 0.70 g (0.0023 mol) of 1-triphenylsilylethanol in 40 ml of dry toluene containing 0.4 ml (0.005 mol) of pyridine and 0.0023 mol of triphenylbromosilane (prepared by the treatment of 0.60 g of triphenylsilane with bromine in carbon tetrachloride) was heated at reflux for 17 h, and then was cooled and worked-up by adding two volumes of ether and washing the solution twice with water to remove pyridinium hydrobromide. Removal of the solvent with the rotary evaporator gave an oil which, upon crystallization from petroleum ether

(60–70°) gave 0.73 g (56%) of 1-triphenylsiloxy-1-triphenylsilylethane (**3**), m.p. 159–164°. Recrystallization from heptane gave m.p. 163–164°. The mixed m.p. of this with a sample of the same compound obtained from the rearrangement of the isomeric bis(triphenylsilyl)ethanol (9) was not depressed.

*Determination of the Relative Yields of **1**, **2**, and **3***

Photolysis of 1.00 g of acetyltriphenylsilane in 60 ml of cyclohexane (over $2\frac{1}{4}$ h) and chromatography on silica gel using elution with 10% benzene in carbon tetrachloride gave 0.48 g of thick oil, whose 100 MHz expanded scale n.m.r. spectrum was utilized in the regions of (*a*) 6.0, (*b*) 5.1, and (*c*) the multiplet 4.7–4.2 p.p.m., to establish the relative yields of compounds **1**, **2**, and **3** as 28:44:28. Knowing that the mixture of the three accounts for at most 50% of the photolysate, upper limits of 14, 22, and 14%, respectively, may be assigned to the yields of **1**, **2**, and **3**.

*Isolation of **3** from the Photolysis of Acetyltriphenylsilane in Methanol Containing Pyridine*

A suspension of 0.15 g of acetyltriphenylsilane in 10 ml of methanol containing 50 μl of pyridine was irradiated for 35 min when an i.r. spectrum showed that no starting acylsilane remained. A fine precipitate was present in the solution. Cooling to −20° and filtration then gave 0.005 g of white solid, m.p. 149–155°, the n.m.r. and i.r. spectra of which indicated it to be **3**. Two recrystallizations from carbon tetrachloride – methanol gave about 2 mg of **3**, m.p. 163–165°, mixed m.p. 163–164°.

The Photolysis of Phenylacetyltriphenylsilane in Cyclohexane

A solution of 9.80 g of phenylacetyltriphenylsilane in 300 ml of dry cyclohexane was irradiated for 6 h until no starting acylsilane remained. Removal of the solvent gave a thick oil which was dissolved in 350 ml of hexane. On standing at −20° overnight 0.93 g (12%) of crude solid β-triphenylsiloxy-β-triphenylsilylstyrene (**5**) was obtained. Recrystallization from carbon tetrachloride gave 0.60 g (7.7%) of pure material, m.p. 233–235°. (In other runs, using a similar procedure pure **5** was obtained in yields of 6.6, 7.3, and 9.0%.)

The mother liquor was then evaporated to dryness and the resulting oil was dissolved in 50 ml of methylene chloride. Addition of 200 ml of methanol gave, on standing, 3.69 g of solid which was recrystallized from methylene chloride – methanol to give 3.51 g (41%) of a second product, 2-triphenylsiloxy-2-triphenylsilyl-1,3-diphenylpropane (**6**), m.p. 195–199°. (Yields of 39, 37, and 41% of this product were obtained in other runs.)

The solvent was evaporated from the mother liquor (which originally gave the 3.69 g of crude **6**) until less than 100 ml remained and on standing 3.13 g (34%) of benzyltriphenylsilane was obtained as large crystals, m.p. 97–99°. This was identified by mixed m.p. with the authentic material. (In other runs, yields of 29, 33, and 34% were obtained.)

*Characterization of β-Triphenylsiloxy-β-Triphenylsilylstyrene (**5**)*

Compound **5** on recrystallization from methylene chloride – methanol had m.p. 234–235°. The solid was heated to 234° for a few minutes to remove trapped solvent (decrepitation was observed during heating): *m/e* 636 (13, M), 559 (0.5, M − Ph), 457 (25, $Ph_3SiOSiPh_2$), 379 (23, 457 − PhH), 259 (100, Ph_3Si); n.m.r. (C_6D_6) δ 6.32 (1H, s), 6.8–7.8 p.p.m. (39H (35 required), m, aryl).

Anal. Calcd. for $C_{44}H_{36}OSi_2$: C, 82.97; H, 5.70. Found: C, 82.96; H, 5.76.

*Degradation of **5***

(a) Aqueous Alkaline Dioxane

A few milligrams of **5** in dioxane was treated with 1 ml of 10% sodium hydroxide. The solution was heated for 5 min, and then was cooled and worked-up with dilute acid and ether to give a white solid. The i.r. spectrum of this material showed it to consist of triphenylsilanol (2.70 μ) and a small amount of phenylacetic acid (3–4, (broad), 5.85 μ) which was also notable by its odor. No other products were detected.

(b) Lithium Aluminum Hydride

To a suspension of 0.33 g (0.00052 mol) of **5** in 20 ml of dry di-*n*-butyl ether was added 0.08 g (0.002 mol) of lithium aluminum hydride. The suspension was heated for 2 h. Work-up with dilute HCl gave an oil which was chromatographed on silica gel. Elution with carbon tetrachloride gave 0.11 g (83%) of triphenylsilane as an oil in the first three fractions. This was crystallized from pentane to give 0.06 g of the pure solid, m.p. 41–44°, identified by mixed m.p. with authentic material.

Further elution with carbon tetrachloride gave 0.06 g (~18%) of unidentified material.

Elution with benzene gave, in the first two fractions, 0.12 g (61%) of crude phenylacetyltriphenylsilane as an oil. Crystallization from ethanol at −20° gave 0.06 g (30%) of pure acylsilane, m.p. 93–95°, mixed m.p. 93–95°.

Further elution of the column with benzene gave 0.06 g (27%) of crude triphenylsilanol.

*Characterization of 2-Triphenylsiloxy-2-triphenylsilyl-1,3-diphenylpropane (**6**)*

Several recrystallizations from methylene chloride – methanol gave the pure material, m.p. 199–200°, which was finely ground up and was pumped on at 115°/0.1 mm prior to analysis: *m/e* 637 (3, M − $PhCH_2$), 636 (4, M − $PhCH_3$), 468 (34, M − Ph_3Si), 457 (14, $Ph_3SiOSiPh_2$), 259 (100, Ph_3Si); i.r. (CCl_4) 6.88 (C—Ph) 7.0, 9.0 μ (Si—Ph); n.m.r. (CCl_4) δ 3.58 (4H, broadened AB system, J = 14 Hz, CH_2Ph), 6.5–7.7 p.p.m. (41H, m, aryl).

Anal. Calcd. for $C_{51}H_{44}OSi_2$: C, 84.02; H, 6.08. Found: C, 84.03; H, 5.97.

*Degradation of **6** in Aqueous Alkaline Diglyme*

To a solution of 0.80 g of **6** in 50 ml of diglyme was added 5 ml of water and 1.20 g of potassium hydroxide. The solution was heated to reflux for $4\frac{1}{2}$ h, and then was acidified and extracted thrice with ether. Drying and removal of solid gave an oil which showed almost no silicon–phenyl absorption at 7 and 9 μ in the i.r. Chromatography on silica gel eluting first with benzene and then with methylene chloride gave 0.18 g (77%) of 1,3-diphenylpropan-2-ol, **7**, n_D^{23} 1.5699 (lit. n_D^{20} 1.5723 (10)).

The carbinol was treated with 0.20 g of *p*-nitrobenzoyl chloride in 1 ml of pyridine for 30 min at room temperature. Work-up with ether and saturated aqueous sodium bicarbonate gave an oil which was crystallized from hexane to give 0.25 g (63%, based on **6**) of 1,3-diphenyl-2-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

propyl *p*-nitrobenzoate, m.p. 72–78°. Recrystallization from hexane gave 0.18 g of pure material, m.p. 78–79° (lit. m.p. 80–81° (11)).

Thermal Rearrangement of ***6*** *to Pentaphenyl-2-(1,2,3-triphenylpropyl)-disiloxane (****8****)*

A sample of 1.60 g of **6** was heated at 210° for 90 min. An n.m.r. spectrum of the resulting glass indicated that a quantitative isomerization to a disiloxane, **8**, had occurred. Crystallization from methylene chloride – methanol gave 1.57 g of solid which was recrystallized to give 1.36 g (85%) of pure **8**, m.p. 150–151.5°. The sample was finely ground up and was pumped on at 80°/0.1 mm prior to analysis: *m/e* 728 (0.4, M), 726 (0.2, M − H_2), 636 (0.4, M − $PhCH_3$), 457 (100, $Ph_3SiOSiPh_2$), 379 (58, 457 − PhH); i.r. (CCl_4), 6.88 (C—Ph), 7.0, 9.0 (Si—Ph), 9.3 μ (broad, SiOSi); n.m.r. δ 3.52 (4H, AB system, J = 16 Hz, CH_2Ph), 6.5–7.7 p.p.m. (40H, m, aryl).

Anal. Calcd. for $C_{51}H_{44}OSi_2$: C, 84.02; H, 6.08. Found: C, 83.99; H, 5.87.

Degradation of ***8*** *in Aqueous Alkaline Diglyme*

To a solution of 0.37 g (0.0005 mol) of **8** in diglyme was added 1 ml of 50% potassium hydroxide. Heating for 3 h followed by work-up with water gave a thin oil which showed no silicon–phenyl absorption at 7 and 9 μ in the i.r. spectrum.

Chromatography on silica gel gave, on elution with carbon tetrachloride, 0.11 g (80%) of 1,2,3-triphenylpropane, n_D^{23} 1.5858, the i.r. and n.m.r. spectra of which were identical to those of the authentic material, prepared as follows:

To a solution of 3.0 g of 1,2,3-triphenylpropan-2-ol (prepared by the addition of 2 equiv of benzylmagnesium chloride to methyl benzoate) in 95% ethanol was added 15 g of freshly prepared Raney Nickel (activity grade W1). The suspension was refluxed for 16 h. Filtration and removal of solvent gave an oil which was chromatographed on silica gel. Elution with carbon tetrachloride gave 1.30 g (46%) of 1,2,3-triphenylpropane which after distillation had n_D^{24} 1.5883 (lit. n_D^{30} 1.5864 (12)).

The Photolysis of Phenylacetyltriphenylsilane in Methanol

A suspension of 0.20 g of phenylacetyltriphenylsilane in 10 ml of methanol was irradiated for 90 min. Removal of the solvent gave a yellowish oil whose n.m.r. spectrum was almost identical to that of the crude photolysate from cyclohexane, and had the following bands: δ 2.81 (s, benzyltriphenylsilane), 3.55 (m, 2-triphenylsiloxy-2-triphenylsilyl-1,3-diphenylpropane (**6**) and superimposed singlet due to triphenylmethoxysilane), and 6.3 p.p.m. (s, β-triphenylsiloxy-β-triphenylsilylstyrene (**5**)).

The photolysis of phenylacetyltriphenylsilane in methanol containing pyridine gave virtually identical results.

Photolysis of Phenylacetyltriphenylsilane in Carbon Tetrachloride

The photolysis of 0.50 g (0.0013 mol) of phenylacetyltriphenylsilane in 15 ml of carbon tetrachloride was complete in 2 h. Removal of the solvent gave a yellow oil, whose i.r. spectrum showed only negligibly weak carbonyl absorptions. The n.m.r. spectrum of the crude product showed peaks attributable to three identifiable products: bibenzyl (2.81 p.p.m.), benzyltriphenylsilane (2.85 p.p.m.), and 1,1,1-trichloro-2-phenylethane (3.75 p.p.m.). An array of minor peaks indicated that an appreciable number of minor products were also formed.

The entire product was briefly treated with dilute potassium hydroxide in aqueous tetrahydrofuran to convert triphenylchlorosilane to triphenylsilanol. Chromatography on silica gel, eluting with carbon tetrachloride, and then with 1:1 carbon tetrachloride – benzene, gave 0.18 g of non-polar oil which was crystallized from methanol to give 0.12 g (26%) of benzyltriphenylsilane as large clear crystals, m.p. 96–97°, mixed m.p. 96–97°.

Elution of the column with ether gave a white solid which was recrystallized from heptane to give 0.19 g (52%) of triphenylsilanol, m.p. 153–154°, identified by mixed m.p.

The presence of bibenzyl and 1,1,1-trichloro-2-phenylethane, identified in the n.m.r., and of hexachloroethane, were confirmed by g.l.p.c. analysis using the following conditions: column, 20 ft × 1/4 in. 20% Carbowax 20M on Chromosorb G; column temperature, 240°; detector, 300°; injector port, 285°; flow rate 90 ml/min. Following a small scale photolysis (0.20 g of phenylacetyltriphenylsilane in 5 ml of carbon tetrachloride) the photosolution was concentrated. The g.l.p.c. trace showed peaks with retention times of 1.1, 2.1, 3.3, and 5.4 min which were identified, by injection of the authentic material, as being due to carbon tetrachloride, hexachloroethane, 1,1,1-trichloro-2-phenylethane, and bibenzyl, respectively. The origin of a fifth minor peak, at 2.7 min, is unknown.

Preparative g.l.p.c. gave a small amount of pure 1,1,1-trichloro-2-phenylethane, the n.m.r. and i.r. spectra of which were identical to those of the authentic material prepared by the coupling of trichloromethylmagnesium chloride with benzyl chloride (13).

No attempt was made to measure the yields of the latter three products but it was apparent both from the n.m.r. spectrum of the crude photolysate and from g.l.p.c. analysis that 1,1,1-trichloro-2-phenylethane was a major product, being present in greater yield than the benzyltriphenylsilane (26%). The hexachloroethane and bibenzyl are formed in somewhat lower yields.

The Photolysis of Acetyltriphenylsilane in cis-1,2-Dichloroethylene

A solution of 0.50 g (0.0017 mol) of acetyltriphenylsilane in 10 ml of freshly distilled *cis*-1,2-dichloroethylene was irradiated for 6 h. The solvent was removed to give about 2 ml of liquid. Chromatography on a 1½ in. × 3 in. silica gel column, eluting with carbon tetrachloride, gave about 1½ ml of sweet-smelling liquid (oligomerized solvent). Elution with 1:3 benzene – carbon tetrachloride gave 0.31 g of solid material which was recrystallized from methylene chloride – methanol to give 0.18 g (34%) of *trans*-1-chloro-2-triphenylsilylethylene, m.p. 127–129°. Two more recrystallizations from hexane and a final one from methylene chloride – methanol gave the analysis sample, m.p. 131–132°: *m/e* 320 (4, M), 284 (7, M − HCl), 259 (12, Ph_3Si), 242 (23, M − 78), 218 (18, Ph_2SiCl), 180 (100, unknown); i.r. (CCl_4) 7.0, 9.0 (Si—Ph), 10.52 μ (*trans*-CH=CH—); n.m.r. (CCl_4), δ 6.30, 6.63 (2H, AB system with J_{AB} = 15 Hz, *trans*-CH=CH—), 7.2–7.6 p.p.m. (15H, m, aryl).

Anal. Calcd. for $C_{20}H_{17}ClSi$: C, 74.86; H, 5.43. Found: C, 75.00; H, 5.21.

photolysis of acetyltriphenylsilane in *trans*-1,2-dichloroethylene. In this case, the yield of pure isolated 1-chloro-2-triphenylsilylethylene was 45%.

The Photolysis of Acetyltriphenylsilane in Trichloroethylene

A solution of 1.00 g of acetyltriphenylsilane in 100 ml of trichloroethylene was irradiated for 5 h. The solvent was distilled until only 30 ml remained. An i.r. spectrum of the distillate showed that acetyl chloride was present. Treatment of the distillate with excess aniline afforded, after work-up and recrystallization 0.08 g (18%) of acetanilide, m.p. 112–114°, identified by mixed m.p.

The solvent was removed from the residual photosolution at the rotary evaporator to give 3.85 g of sweet-smelling oil. Distillation in the Kugelrohr (110°, 0.7 mm) gave 1.55 g of volatile liquid which appeared to be largely oligomerized solvent. The nonvolatile residue, 2.13 g of brown oil, was dissolved in ether and the solution was stirred with water to convert any chlorosilane to triphenylsilanol. Work-up gave a brown oil which showed a strong silanol peak at 2.70 μ in the i.r.

Chromatography on silica gel gave, on elution with carbon tetrachloride, a small amount of oil in the first few fractions and then small amounts of white solid over many fractions. The combined solid (0.42 g) was recrystallized from methylene chloride – methanol to give 0.33 g (28%) of dichlorovinyltriphenylsilane, m.p. 125–132°. Three further recrystallizations from methylene chloride – pentane raised the m.p. to 132–133°; *m/e* 356, 354 (2, M), 319 (3, M − Cl), 318 (3, M − HCl), 278, 276 (4, 5, M − 78), 218 (100, Ph_2SiCl); n.m.r. (CCl_4), δ 6.50 (1H, S, C=CH), 7.2–7.7 p.p.m. (15H, m, aryl).

Anal. Calcd. for $C_{20}H_{16}Cl_2Si$: C, 67.70; H, 4.54. Found: C, 67.67; H, 4.56.

Retardation of AlH_2Cl Hydrogenolysis of the Ethylene Ketals of 5-Norbornen-2-one and 2-Norbornen-7-one Due to the Presence of the Double Bond[1]

H. A. Davis and R. K. Brown

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 30, 1972

The double bond in either 5-norbornen-2-one ethylene ketal or 2-norbornen-7-one ethylene ketal provides no anchimeric assistance in the hydrogenolysis of these ketals by AlH_2Cl in ether. Instead, a marked retardation of reaction occurs, a result considered to be due to competitive association of the Lewis acid, AlH_2Cl, with the π bond.

Attack of the AlH_2Cl on the former ketal occurs from the *exo* direction to give only the *endo*-5-β-hydroxyethoxy product, whereas the latter ketal reacts with AlH_2Cl to give a 2:1 mixture of the *syn* and *anti* 7-β-hydroxyethoxy products. A rationale is provided to account for the results.

La double liaison dans soit la cétal éthylènique du norbornène-5 one-2 ou soit la cétal éthylènique du norbornène-2 one-7, ne procure pas d'assistance anchimérique lors de l'hydrogénolyse de ces cétals par AlH_2Cl dans l'éther. Plutôt, un ralentissement marqué de la réaction se produit; ce résultat semble imputable à l'association compétitive de l'acide de Lewis, AlH_2Cl, avec le lien π.

L'attaque du AlH_2Cl sur la première cétal se produit dans la direction *exo* pour donner seulement le produit *endo*-hydroxyethoxy-5-β alors que la dernière cétal réagit avec du AlH_2Cl pour donner un mélange 2:1 des produits *syn* et *anti* hydroxyéthoxy-7-β. Une explication rationnelle est proposée afin d'expliquer ces résultats. [Traduit par le journal]

Can. J. Chem., **51**, 361 (1973)

Introduction

It has been reported recently (1) that the vinyl group attached to C-2 of a 1,3-dioxolane accelerates the reductive cleavage of the dioxolane ring by AlH_2Cl in diethyl ether. This was attributed to increased stabilization of the transition state leading to the intermediate oxocarbonium ion, a species which is very rapidly and irreversibly attacked by hydride ion to produce allyl β-hydroxyethyl ether. A similar rate enhancement of hydrogenolysis by AlH_2Cl has been observed when a phenyl group is attached to C-2 of the 1,3-dioxolane ring (1, 2). Alkyl substituents on the 2-vinyl group of 2-vinyl-1,3-dioxolane further enhance the ease of the reductive cleavage of the ring (1).

It is known that the π electrons of the olefinic double bond provide anchimeric assistance in the reaction of *anti*-7-norbornenyl derivatives (3, 4). For example, the *anti*-7-tosylate is solvolyzed over 10^9 times faster than is the saturated compound 7-tosyloxynorbornane. On the other hand *exo*-2-chloro-5-norbornene undergoes solvolysis in 80% ethanol about 150 times faster than does the *endo* isomer, a difference in reactivity not much greater than that observed for the corresponding saturated compounds, *exo*- and *endo*-2-chloronorbornane (5, 6).

In view of the above information, we wished to determine whether an olefinic double bond would provide similar rate enhancement in the hydrogenolysis of 5-norbornen-2-one ethyleneketal (**1**) and 2-norbornen-7-one ethyleneketal (**2**) by AlH_2Cl in ether. This paper reports our observations concerning this question.

Results

The products obtained from the hydrogenolysis of compounds **1** and **2** are shown in Table 1, while the relative ease of the hydrogenolysis of **1** and **2** compared with other 1,3-dioxolanes, determined by competitive reactions, are shown in Table 2.

Orientation of the β-Hydroxyethoxy Substituent in the β-Hydroxyethyl Norbornenyl Ethers Obtainable From 1 and 2

The two possible products of the AlH_2Cl reduction of 5-norbornen-2-one ethyleneketal (**1**), 2-(2-*endo*-5-norbornenyloxy)ethanol, and 2-(2-*exo*-5-norbornenyloxy)ethanol, were readily

identified and differentiated by characteristic features of their p.m.r. spectra obtained with authentic samples. These samples were prepared from a mixture of the *exo* and *endo* isomers of 5-norbornen-2-ol, and the resulting *exo*- and *endo*-2-(5-norbornenyloxy)ethanols separated by preparative g.l.c. The two bridgehead protons of the *endo* isomer show *two* unresolved multiplets (1H for each) centered at τ 6.94 and 7.26, each with a half-width of 7 Hz, while the two bridgehead protons of the *exo* isomer show only *one* unresolved multiplet (2H) centered at τ 7.15, having $w_{1/2} \sim 10$ Hz. A similar phenomenon had been observed for the signals of the bridgehead protons in the p.m.r. spectra of *endo*- and *exo*-2-(2-norbornyloxy)ethanol (7). The observation that the p.m.r. spectrum of *endo*-5-nitro-2-norbornene shows two separate signals at τ 6.47 and 7.01 for the bridgehead protons (8) provides additional support for the above assignment. Unfortunately, the spectrum of the *exo*-5-nitro-2-norbornene was unavailable for comparison. Convincing evidence for our assignment is obtained from the portions of the signals of the C-2 protons in the p.m.r. spectrum of the *exo*- and *endo*-2-(5-norbornenyloxy)ethanols. In agreement with the well-known fact that the 2-*exo* proton is deshielded relative to the 2-*endo* proton in norbornene due to the anisotropy of the double bond (8, 9), the signal of the C-5 proton of *endo*-2-(5-norbornenyloxy)ethanol occurs as a quintet centered at τ 5.90 while the signal of the C-5 proton of the *exo* isomer lies between τ 6.3 and 6.7 in the region where the four methylene protons of the substituent absorb.

The two possible products of the AlH_2Cl hydrogenolysis of 2-norbornen-7-one ethyleneketal (**2**), 2-(7-*syn*-norbornenyloxy)ethanol, and

2-(7-*anti*-norbornenyloxy)ethanol, could also be identified and differentiated by the p.m.r. signals of the two bridgehead protons as well as by the signal of the C-7 proton. The p.m.r. spectra of authentic samples of these two hydrogenolysis products showed that for the *syn* isomer, the two bridgehead protons give rise to a narrow multiplet ($w_{1/2} \sim 5$ Hz) at τ 7.11, while those for the *anti* isomer produced a narrow multiplet at τ 7.35 ($w_{1/2} \sim 7$ Hz). Furthermore, the signal of the C-7 proton of the *syn* isomer is obscured by the signals of the four methylene protons of the hydroxyethoxy substituent τ (6.19–6.67) whereas that of the C-7 proton of the *anti* isomer experiences a diamagnetic shielding due to the double bond, a phenomenon reported by Snyder and Franzus (10), and hence appears as a broad singlet ($w_{1/2} \sim 4.5$ Hz) at τ 6.78.

Hydrogenolysis Results

There are three interesting observations from our experiments, two of which are immediately apparent from Tables 1 and 2. (*i*) The AlH_2Cl hydrogenolysis of **1** produces exclusively the 2-(2-*endo*-5-norbornenyloxy)ethanol, while similar hydrogenolysis of **2** provides an ~2:1 mixture of 2-(7-*syn*-2-norbornenyloxy)ethanol and 2-(7-*anti*-2-norbornenyloxy)ethanol (Table 1). (*ii*) The hydrogenolysis of both **1** and **2** is considerably slower than that of 2-vinyl-1,3-dioxolane (**3**) or of norcamphor ethyleneketal (**4**), the saturated analog of **1** (Table 2). Furthermore, *all* of **1** is hydrogenolyzed within a 72-h reaction period at room temperature while **2** is reduced to the extent of only 65% in 72 h under the same conditions. (*iii*) Although previous work (1) as well as the present work has shown that **3** is completely hydrogenolyzed by AlH_2Cl well within 15 min, our experiments now reveal that the presence of an equimolar quantity of **1** or **2** in an ether solution of **3** appears to retard the hydrogenolysis of **3** (Table 2, experiments 1 and 2). A similar retardation of hydrogenolysis of norcamphor ethyleneketal (**4**) occurs when ketal **4** in ether is mixed with an equimolar amount of **1** or **2** prior to the addition of AlH_2Cl. By comparison, room temperature hydrogenolysis of **4** alone in ether, by AlH_2Cl, has been shown to be complete well within 30 min (11).

Retardation of the hydrogenolysis of **3** and **4** when they are in the presence of **1** or **2** could be due to the association of the reducing agent, AlH_2Cl, with the π-electrons of the double bond of **1** or **2**, thus reducing the effective concentration of AlH_2Cl available to act as both the hydride donor and the Lewis acid which must first associate with the oxygen atom of the acetal to initiate the hydrogenolysis sequence. In support of this view, we have shown that whereas the room temperature hydrogenolysis of 2-methyl-1,3-dioxolane by AlH_2Cl in ether is complete *well* within 30 min (1), the same dioxolane in ether, mixed with an equimolar amount of cyclohexene, is hydrogenolyzed to the extent of only 90% in 30 min. A similar association of the Lewis acid, AlH_2Cl, with the double bond of **1** or **2** could account for the markedly lower rate of hydrogenolysis by AlH_2Cl of an ether solution of either **1** or **2** alone (Table 1) compared to the greater rate of such hydrogenolysis of the saturated bicyclic species, norcamphor ethylene ketal (7, 11). If such association of the AlH_2Cl with the π-bond is indeed the factor which is responsible for the decrease in rate of hydrogenolysis of **1** and **2**, it then follows that a similar retarding effect must apply in the reductive cleavage of **3**, and accordingly **3** would have cleaved even more rapidly than observed (1) if such a factor were not involved. A modifying influence in the case of **3** would be the proximity of the π-AlH_2Cl complex to C-2 of the 1,3-dioxolane ring and this might facilitate transfer of the AlH_2Cl to the oxygen of the 1,3-dioxolane ring as well as transfer of a hydride ion to C-2 to promote ring cleavage. Such a conveniently close arrangement does not occur in compounds **1** and **2**.

The exclusive formation of 2-(2-*endo*-5-norbornenyloxy)ethanol from the AlH_2Cl hydrogenolysis of **1** could be due to two factors. *Exo* approach of reagents to norbornanes is considered to be easier than is *endo* approach (7, and references therein). Hence attack by AlH_2Cl on the *exo* oxygen atom of **1** should be preferred, although the absence of two *endo* hydrogen atoms in compound **1** would decrease this steric selectivity compared with that found for the saturated analogs. Added to this is the fact that approach to the *endo* oxygen atom of **1** is complicated by the proximity of the double bond, which from the reasoning expressed in the preceding paragraphs, should provide a region of high attraction for the Lewis acid AlH_2Cl. This could interfere sufficiently with the approach of AlH_2Cl to the *endo* oxygen atom and thus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

enable alternate approach of the hydrogenolyzing reagent to the *exo* oxygen atom to become sufficiently competitive so that only *exo* C—O bond cleavage is observed. This view of course must assume that the molecule of AlH_2Cl which attacks the oxygen atom and initiates C—O bond cleavage is the same one which donates the hydride ion to the developing oxocarbonium ion to complete the reductive cleavage. This is not an unreasonable assumption for compound **1** (7).

In the case of compound **2**, approach of the AlH_2Cl to the oxygen atom *syn* to the double bond could suffer the same type of interference due to the π-bond, and thus allow approach to the alternate oxygen atom to become competitive. However such alternate approach would experience sufficient steric interference from the two *exo* hydrogen atoms to prevent hydrogenolysis from occurring only with the C—O bond remote from the double bond, thus resulting in the approximately 2:1 formation of the *syn* and *anti* norbornenyloxyethanols from **2** as shown in Table 1. The generally slower reaction of **2**, compared with that of **1** could easily be due to the steric effect of the *exo* hydrogen atoms of **2**.

Experimental

Boiling and melting points are uncorrected. The g.l.c. analyses were made with an F and M Model 700 instrument equipped with 12 ft × 1/8 in. columns packed with either butanediol succinate, 20% on Gas Chrom P (60–80 mesh) or silicone rubber SE 30, 20% on Gas Chrom P (60–80 mesh). Helium was the carrier gas at a flow rate of 40 ml/min. For preparative g.l.c., an Aerograph Autoprep, Model A-700 (Wilkins Instrument and Research Co.) was employed with a 12 ft × 1/4 in. column packed with butanediol succinate on Gas Chrom P (60–80 mesh). Helium was the carrier gas. Quantitative analyses were made by measuring the areas of the peaks corresponding to the compounds obtained. These areas were compared with those obtained from known and weighed artificial mixtures. It was found that equimolar mixtures gave peaks whose areas differed by less than 5%.

The i.r. spectra were recorded with a Perkin–Elmer Model 21 instrument.

The p.m.r. spectra were recorded on either a Varian Associates A-60 or A-55/60A instrument by Mr. R. Swindlehurst and assistants in this Department. All spectra were referred to tetramethylsilane and employ the τ scale.

The p.m.r. and i.r. spectra were obtained for all compounds and were consistent with the structures assigned.

Elemental analyses were made by Mrs. Darlene Mahlow of this Department.

The drying agent for solutions was anhydrous magnesium sulfate unless otherwise indicated. Solvents were removed by rotary evaporator under reduced pressure unless otherwise stated.

Preparation of the Ketals and Acetals

*Norcamphor Ethylene Ketal (**4**)*

This compound was synthesized according to published directions (7). B.p. 78° at 14 mm; η_D^{25} 1.4756 (lit. b.p. 78–80° at 14 mm; η_D^{25} 1.4319 (7) (*note*, this value of the refractive index reported in (7) is erroneous; our measurement of the same sample used by the authors of ref. 7 gave η_D^{25} 1.4752)).

*Acrolein Ethylene Acetal (2-Vinyl-1,3-dioxolane) (**3**)*

This was prepared according to published directions (1).

*5-Norbornen-2-one Ethylene Ketal (**1**)*

This compound was prepared from 5-norbornen-2-one (12) by the same procedure used to make 2-(1-propenyl)-1,3-dioxolane (1). Yield of colorless liquid, 75%. B.p. 76° at 9 mm; η_D^{24} 1.4872.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.05; H, 7.89. Found: C, 70.92; H, 7.72.

The 60 MHz p.m.r. spectrum in CCl_4 showed a multiplet centered at τ 3.98 (2H); a singlet at 6.18 (4H); a broad singlet at 7.22 (1H), $w_{1/2}$ = 7.5 Hz; a broad singlet at 7.47 (1H), $w_{1/2}$ = 6 Hz; a multiplet between 8.06 and 9.30 (4H).

*2-Norbornen-7-one Ethylene Ketal (**2**)*

syn-7-Norbornenol (13) was converted to 2-norbornen-7-one according to the published procedure (12) and the ketone was in turn converted to the ketal **2** by the same procedure used to prepare 2-(1-propenyl)-1,3-dioxolane (1). Yield of colorless liquid, 80% B.p. 73–75° at 6 mm; η_D^{24} 1.4904.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.05; H, 7.89. Found: C, 70.91; H, 7.98.

The 60 MHz p.m.r. spectrum in CCl_4 showed a triplet centered at τ 3.98 (2H), $J \simeq 2.5$ Hz; a triplet centered at 6.26 (4H), $J \simeq 3$ Hz; a multiplet centered at 7.62 (2H); a multiplet between 7.94 and 8.32 (2H); a multiplet between 8.97 and 9.27 (2H).

Preparation of Authentic Hydrogenolysis Products

exo and endo-2-(5-Norbornen-2-yloxy)ethanol

A mixture of the *exo* and *endo* isomers of 5-norbornen-2-ol (Aldrich Chemical Co.) was converted to *ethyl exo-endo-(5-norbornen-2-yloxy)acetate* by the procedure used to prepare ethyl (2-dimethylaminoethoxy)acetate (1). Yield of colorless liquid, 43%. B.p. 73° at 0.6 mm; η_D^{24} 1.4701.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.54; H, 8.16. Found: C, 67.43; H, 8.33.

The 60 MHz p.m.r. spectrum in CCl_4 showed a multiplet centered at τ 3.92 (2H); a triplet at 5.92 (2H), $J \simeq 7.5$ Hz; a singlet at 6.11 (2H); a multiplet between 6.83 and 7.38 (2H); a multiplet between 7.78 and 9.28 (8H).

The i.r. spectrum in CCl_4 showed absorption bands at 3060 (vinylic C—H); 1755 and 1730 (C=O for *exo* and *endo* isomers); a broad band between 1290 and 1100 cm^{-1} (C—O).

The above acetate was converted to *exo-endo-2-(5-norbornen-2-yloxy)ethanol* by reduction with $LiAlH_4$ as described for the preparation of 2-(2-dimethylamino-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ethoxy)ethanol (1). The colorless liquid (87%) boiled at 63–65° at 1 mm; η_D^{24} 1.4895.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 69.84; H, 8.73.

The i.r. spectrum in CCl_4 showed absorption between 3610 and 3280 (OH); 3080 (vinylic C—H); a broad band between 1130 and 1040 cm^{-1} (C—O).

The two isomers were separated by preparative g.l.c. and were identified by their p.m.r. spectra as described in the discussion section.

The 60 MHz p.m.r. spectrum in CCl_4 of the *endo* isomer showed a complicated doublet centered at τ 3.94 (2H); a multiplet at 5.90 (1H); a multiplet between 6.2 and 6.8 (4H); a narrow multiplet at 6.94 (1H), $w_{1/2} \simeq 7$ Hz; a narrow multiplet at 7.26 overlapping the OH signal (2H), $w_{1/2} \simeq 7$ Hz; multiplets between 7.85 and 9.40 (4H).

The 60 MHz p.m.r. spectrum in CCl_4 of the *exo* isomer showed a complicated doublet at τ 4.0 (2H); a multiplet between 6.2 and 6.8 (5H); a narrow multiplet at 7.15 (2H), $w_{1/2} \simeq 10$ Hz; a singlet at τ 8.05 (1H); a multiplet between 8.2 and 9.3 (4H).

2-(7-syn-Norbornenyloxy)ethanol

syn-7-Norbornenol (13) was converted to *ethyl (7-syn-norbornenyloxy)acetate* by the procedure used to prepare ethyl (2-dimethylaminoethoxy)acetate (1). Yield of colorless liquid, 30%. B.p. 60° at 0.1 mm; η_D^{26} 1.4768.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.34; H, 8.22. Found: C, 66.78; H, 8.16.

The 60 MHz p.m.r. spectrum in $CDCl_3$ showed a broad singlet at τ 3.98 (2H), $w_{1/2} \simeq 5$ Hz; a quartet at 5.79 (2H), $J \simeq 7$ Hz; a singlet at 6.01 (2H); a broad singlet at 6.37 (1H), $w_{1/2} \simeq 4.5$ Hz; a broad singlet at 7.11 (2H), $w_{1/2} \simeq 7$ Hz; a multiplet between 8.10 and 9.23 (7H).

The i.r. spectrum (neat) showed a band at 3080 cm^{-1} (vinylic C—H); a band at 1780 (C=O); a broad band between 1290 and 1110 cm^{-1} (C—O).

Reduction of the above acetate with $LiAlH_4$, as described for the preparation of 2-(2-dimethylaminoethoxy)-ethanol (1) gave the colorless liquid *2-(7-syn-norbornenyloxy)ethanol* in 80% yield. B.p. 56° at 0.2 mm; η_D^{26} 1.4915.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 70.28; H, 9.32.

The 60 MHz spectrum in $CDCl_3$ showed a narrow multiplet at τ 3.96 (2H); a broad multiplet between 6.19 and 6.7 (5H); a narrow multiplet at 7.11 (2H), $w_{1/2} \simeq 5$ Hz; singlet at 7.68 (1H); a broad multiplet between 8.1 and 9.2 (4H).

The i.r. spectrum (neat) had a broad band between 3630–3200 (OH); a band at 3080 (vinylic CH) and broad absorption between 1180 and 1020 cm^{-1} (C—O).

2-(7-anti-Norbornenyloxy)ethanol

anti-7-Norbornenol (14) was converted to *ethyl (7-anti-norbornenyloxy)acetate* by the same method used to prepare ethyl (2-dimethylaminoethoxy)acetate (1). Yield of colorless liquid, 45%. B.p. 59° at 0.3 mm; η_D^{25} 1.4728.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22. Found: C, 67.60; H, 8.41.

The 60 MHz p.m.r. spectrum in CCl_4 showed a triplet at τ 4.08 (2H), $J \simeq 2$ Hz; a quartet at 5.83 (2H), $J \simeq 7$ Hz; a singlet at 6.09 (2H); a broad singlet at 6.75 (1H), $w_{1/2} \simeq 4.5$ Hz; a multiplet centered at 7.34 (2H); a multiplet between 8.0 and 8.37 (2H); a triplet at 8.75 (3H), $J \simeq 7$ Hz and a multiplet between 8.94 and 9.23 (2H).

The i.r. spectrum (neat) showed absorption at 3060 (vinylic C—H); a band at 1760 (C=O); a band between 1290 and 1110 cm^{-1} (C—O).

Reduction of the above acetate with $LiAlH_4$ by the procedure used to prepare 2-(2-dimethylaminoethoxy)-ethanol (1) gave colorless *2-(7-anti-norbornenyloxy)-ethanol* in 85% yield. B.p. 45° at 0.3 mm; η_D^{26} 1.4859.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 70.07; H, 8.95.

The 60 MHz p.m.r. spectrum in $CDCl_3$ showed a triplet at τ 4.03 (2H); a broad multiplet between 6.2 and 6.7 (4H); a broad singlet at 6.78 (1H), $w_{1/2} \simeq 4.5$ Hz; a narrow multiplet at 7.35 (2H), $w_{1/2} \simeq 7$ Hz; a singlet at 7.49 (1H); a multiplet between 8.8 and 9.2 (2H).

Hydrogenolysis of the Ketals and Acetals

The hydrogenolysis by AlH_2Cl was carried out according to the general procedure described previously (1).

The Elimination Reactions of Some Alkyl Cyanides in the Gas Phase

P. N. DASTOOR AND E. U. EMOVON
Department of Chemistry, University of Ibadan, Western Nigeria

Received April 28, 1972

The kinetics of the thermal decomposition of ethyl, isopropyl, and *t*-butyl cyanides into HCN and the corresponding olefines have been studied in a seasoned silica vessel in a *flow system* in the absence and presence of toluene as inhibitor. The reactions are homogeneous and the unimolecular rate constants are expressible by the following Arrhenius equations:

Ethyl cyanide (530–670 °C): $k\ (s^{-1}) = 1.30 \times 10^{13} e^{-69480/RT}$

i-propyl cyanide (547–655 °C): $k\ (s^{-1}) = 1.59 \times 10^{12} e^{-64140/RT}$

t-butyl cyanide (565–654 °C): $k\ (s^{-1}) = 1.59 \times 10^{12} e^{-63690/RT}$

Les cinétiques de la décomposition thermique des cyanures d'éthyle, isopropyle et *t*-butyle en HCN et oléfine correspondante, ont été étudiées en continu dans un récipient en silice convenablement traité, en l'absence puis en présence de toluène comme inhibiteur. Les réactions sont homogènes et les constantes de vitesse d'ordre un peuvent être exprimées par les équations d'Arrhénius suivantes:

Cyanure d'éthyle (530–670 °C): $k\ (s^{-1}) = 1.30 \times 10^{13} e^{-69480/RT}$

Cyanure d'isopropyle (547–655 °C): $k\ (s^{-1}) = 1.59 \times 10^{12} e^{-64140/RT}$

Cyanure de *t*-butyle (565–654 °C): $k\ (s^{-1}) = 1.59 \times 10^{12} e^{-63690/RT}$

Although the general reactions of the cyanides are similar to those of the halides and the cyanides have sometimes been called halogenoids, very few kinetic studies of the thermal elimination reactions of their organic derivatives have been carried out. Maccoll and coworkers (1) supported the homogenous and molecular nature of the elimination reaction of alkyl halides with β-hydrogen atoms in the gas phase. These reactions occur by concerted mechanism involving polar transition state and bear formal relationship to reactions in solution. Rabinovitch and Winkler (2) observed that methyl and ethyl cyanides pyrolyzed in the gas phase by radical mechanism but the decomposition of the ethyl compound was the more complex.

Asmus and Houser (3) studied the kinetics and products of decomposition of acetonitrile in a stirred flow reactor. The reaction was complex, involving mixed first and second order kinetics. There was no autocatalysis by HCN and the mechanism was non-chain, as the presence of a chain sensitizer, cyanogen bromide had no effect on the rate of reaction. Hunt *et al.* (4) investigated the effect of the CN group on the strengths of the adjacent C—C and C—H bonds by pyrolyzing ethyl (between 686 and 765 °C) and *t*-butyl cyanides (between 602 and 652 °C). They found that ethyl cyanide decomposed both by free radical and molecular mechanisms, with HCN and olefine as the main products of the molecular mechanism. *t*-Butyl cyanide decomposed by a free radical mechanism to form methane, hydrogen, ethane, and ethylene as gaseous products. Both these decompositions were homogeneous with first order kinetics. This observation was confirmed by this and other experimental work; the rates are not affected by the slight changes in initial concentrations of reactants at the same temperature and reasonable Arrhenius graphs are obtained by plotting the first order rates obtained at different temperatures.

This paper investigates the nature of the thermal decompositions of ethyl, isopropyl, and *t*-butyl cyanides in the gas phase and indicates their analogy to the decompositions of the alkyl halides.

Experimental

Materials

B.D.H. ethyl, isopropyl, and *t*-butyl cyanides were purified by fractional distillation and the fractions used for this work had the following physical constants: Ethyl cyanide: b.p. = 97.0 °C (746.5 mm Hg), $d^{20\,°C}$ = 0.78 g/cc; n^{30} = 1.3613 (5): b.p. = 97.5 °C (760 mm Hg), $d^{20\,°C}$ = 0.78 g/cc; n^{30} = 1.3660. Isopropyl cya-

For personal use only.

nide: b.p. = 103 °C (745.0 mm Hg), $d^{30\,°C} = 0.77$ g/cc; $n^{30} = 1.3690$ (5): b.p. = 107.8 °C (760.0 mm Hg), $d^{20\,°C} = 0.794$ g/cc; $n^{30} = 1.3490$. *t*-Butyl cyanide: b.p. = 102.0 °C (748.0 mm Hg), $d^{25\,°C} = 0.75$ g/cc; $n^{30} = 1.3490$ (5): b.p. = 104.0 °C (760.0 mm Hg), $d^{25\,°C} = 0.758$ g/cc.

The purity of these materials was found to be not less than 98.5% by vapor phase chromatography using the flame ionization (glass) detector and a 6 ft × 3/16 in. coiled copper column packed with diethylene glycol adipate on 80–100 mesh Celite. The column oven was maintained at 60° and the flow of hydrogen and oxygen regulated to 30 ml/min.

The pyrolysis was carried out in an electrically heated silica reactor of capacity $v = 30$ cm^3, the temperature was controlled by a Sunvic RT2 controller to within ±0.5 °C. The reaction system was a conventional flow system coupled with a Toepler pump, a gas burette, and an injection system to the vapor phase chromatograph. The reactant vapor was fed from a constant volume gas burette into a stream of toluene whose flow through the reaction vessel was controlled by a capillary tube. The flow rate, F (cm^3/s), was measured by a calibrated differential manometer; the contact time, t, was calculated using the relation $t = V/F$ where V is volume of the reaction vessel.

The reaction vessel was seasoned with the products of decomposition of alkyl bromide and cyanides. The products arising from the cyanides were condensed in a trap at liquid air temperature and then analyzed in the H_2 flame v.p.c. using squalane 10% on Diatomite C, 100–120 mesh, 6 ft × 1/4 in. glass column, at room temperature. The chromatogram showed the presence of HCN and the corresponding olefines. The HCN product was further confirmed by n.m.r. spectroscopy and the v.p.c. using HCN prepared from strong NaCN solution and concentrated H_2SO_4 as standard.

The reaction was followed titrimetrically using silver nitrate and diphenyl carbazide indicator (6). The products of decomposition were passed into water and the dissolved HCN was titrated with standard silver nitrate solution. A blank titration of the alkyl cyanide in water showed no HCN produced by hydrolysis. Based on analogy to the decomposition of organic halides and cyanide results of other workers, the reaction was assumed to be the first order and the rate constant was obtained, using the relation

$$k\,(s^{-1}) = \frac{2.303}{t} \log C_0/C_f$$

where t is contact time, C_f is the final and C_0 the initial amount of the reactant. Assuming the stoichiometry R—CN → olefine + HCN, x = amount of HCN (obtained titrimetrically) = $C_0 - C_f$.

Results and Discussion[1]

The approximate equal amount of HCN from titration and the amount of olefine determined by v.p.c. confirmed this above stoichiometry. The average value of the HCN/olefine ratio in the products remained unity up to 700 °C. However, above this temperature the ratio became erratic and was observed to be 60% higher in case of ethyl cyanide, 50 to 60% lower in case of *i*-propyl cyanide and in case of *t*-butyl cyanide, it increased 3- to 4-fold. This can be attributed to decomposition of toluene and also the removal of carbonaceous coating inside the reactor.

Hunt *et al.* (4) also observed the pyrolysis of ethyl and *t*-butyl cyanides to be homogeneous. The alkyl cyanides investigated were pyrolyzed in both unpacked and packed seasoned vessel. The rate constant for the reaction was found to be independent of such surface changes and confirmed the homogeneity of the reactions.

The work of Hunt and co-workers (4) indicated that the initial process in the decomposition of ethyl cyanide is given by

$$CH_3CH_2CN \rightarrow CH_3^0 + {}^0CH_2CN$$

and for methyl cyanides:

$$CH_3CN \rightarrow H^0 + {}^0CH_2CN$$

The high bond strength for C—CN which precludes the participation of CN radical in the reaction scheme suggests that HCN is formed by a molecular mechanism only. The presence of excess toluene did not depress the rate of formation of HCN, thus confirming the absence of free radicals. The chromatograms showed essentially HCN and the corresponding olefine at the lower temperatures. Hunt *et al.* (4) obtained methane, ethane, and hydrogen in addition to the olefines and HCN in the decomposition of ethyl cyanide. The presence of large amounts of H_2 in their products is also explained by molecular mechanism. The authors could not identify these non-condensable gases and ethane by use of a gas burette fitted with Teopler pumps. At temperatures above 650 °C, particularly in inhibited runs, some other but negligible peaks appeared in the chromatogram. These could have arisen from incursion of free radicals and possibly due to decomposition of toluene. These side reactions were not investigated further. It is possible that products other than olefine and HCN observed by Hunt *et al.* could result from their higher working temperatures and the decomposition of aniline (used as a carrier). The presence of trace quantities of other products above 766°, as seen by chromatography, is attributed to decomposition of

‡This work.

toluene and hence the pyrolysis of cyanides beyond this temperature was terminated.

The Arrhenius parameters (Table 1) were determined from the rate constants by least square calculations using the IBM 1620 and 360/25 computer system and also from Arrhenius graphs (Figs. 1).

The R—CN bond strengths were estimated from the values for heats of formation of CN and the corresponding R radicals. These are compared with the values for the halides and corresponding energies of activation for elimination (Table 2).

The rate constant for the elimination of HCN from ethyl cyanide was expressed by Hunt *et al.* (4) by the Arrhenius equation:

$$\log k\ (s^{-1}) = 15.0 - 77\,300/2.3RT$$

These parameters are higher than the values obtained in this work. The energies of activation for the elimination of HCN are generally lower than the dissociation energy of the adjacent C—C bond, contrary to the result of Hunt *et al.* for ethyl cyanide. Their value for the activation energy predicts a predominantly free radical mechanism, leading to the formation of products other than the olefine and HCN. The values obtained in this work suggest a predominantly molecular elimination mechanism, but because of the small though significant difference, it is possible to have an incursion of free radical mechanism which may be responsible for trace peaks in the chromatogram at higher temperatures.

The thermal decompositions of ethyl, isopropyl, and *t*-butyl cyanides in the gas phase are

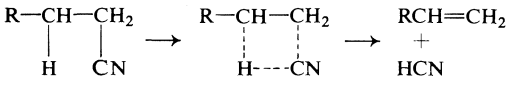
homogeneous reactions occurring by molecular elimination. As for the halides, HCN is probably eliminated through a four centered cyclic transition state, in which charge development is relatively primitive.



The relative rates follow the sequence EtCN < *i*-PrCN < *t*-BuCN but with very much reduced ratio by comparison with the halides. This reduced relative rate may be attributed to a small charge separation in the transition state.

Determination of the Rates of Hydrogen Atom Reaction with NO by a Modulation Technique[1]

R. ATKINSON[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received August 3, 1972

A modulation technique has been used to determine from phase shift measurements the absolute values of the rate constants and the Arrhenius parameters of the reaction of hydrogen atoms with nitric oxide.

Une technique de modulation a été utilisée dans la détermination à partir des mesures de changement de phase, des valeurs absolues des constantes de vitesse et des paramètres d'Arrhénius dans la réaction des atomes d'hydrogène sur l'oxyde nitrique. [Traduit par le journal]

Introduction

We have recently used a modulation technique to determine from phase shift measurements the absolute values of the rate constants (1) and of the Arrhenius parameters (2) for the reactions of $O(^3P)$ atoms with several olefins and with NO. Variation in the oxygen atom concentration was monitored by observing the light emission from the excited NO_2 molecules formed by the addition of $O(^3P)$ atoms to NO. Hydrogen atom concentration can be monitored in a similar manner by observing light emission from the excited HNO molecules formed by the addition of H atoms to NO. Thus, in principle, the phase shift technique can be used also to determine the rates of hydrogen atom reactions. However, the application of the technique to hydrogen atom reactions is considerably less favorable because of the low intensity of the red HNO emission and its less convenient spectral region. Nevertheless, it has proved possible to apply the technique to the reaction of H atoms with NO and to determine its rate constants at several temperatures. The results are reported in the present article.

Experimental

Hydrogen atoms were generated by the mercury photosensitization of hydrogen in a flow system. 2537 Å mercury resonance radiation was emitted by a modulated radio-frequency powered low pressure mercury arc. Hydrogen atom concentrations were monitored by the observation of the red HNO emission formed by the addition of known flows of nitric oxide to the reactant stream. The HNO emission was observed by an EMI 9558 A photomultiplier tube fitted with a Corning 2-61 cut-off filter (transmitting light of wavelengths $\geqslant 6000$ Å). A time constant of 30 s was used on the PAR-HR8 lock-in-amplifier. Otherwise the apparatus and experimental technique was as described in detail previously (1, 2) for the study of the reactions of oxygen $O(^3P)$ atoms.

For temperatures below room temperature, a refrigeration coil was fitted to the furnace enclosure. In all cases the temperatures could be held constant to ± 0.5 °C over the duration of the runs.

The gases used were Matheson C.P. grade nitric oxide and Matheson prepurified grade hydrogen. The NO was passed through a column of activated Linde Molecular Sieve 13X to remove any NO_2 present while the hydrogen flow was passed through a Deoxo unit to remove oxygen (<20 p.p.m.) and then dried by passage through a column of Drierite. Gas flows were monitored by calibrated flowmeters and regulated by needle valves. The gas stream was saturated with mercury vapor at room temperature before entering the furnace and reaction cell. A typical light input of 2×10^{17} quanta per s was obtained in the reaction cell.

Conversions of NO were always less than 2%.

Results

The reaction of H atoms with NO (with H_2 as third body) was studied at temperatures between 12 and 117 °C. For sinusoidally modulated 2537 Å radiation and the following reactions:

$$Hg(6^1S_0) + h\nu\,(2537\text{ Å}) \rightarrow Hg(6^3P_1)$$

[1] $$Hg(6^3P_1) + H_2 \rightarrow HgH + H$$
$$\rightarrow Hg(6^1S_0) + 2H$$

[2a] $$H + NO + M \rightarrow HNO + M$$

[2b] $$\rightarrow HNO^* + M$$

[3] $$HNO^* \rightarrow HNO + h\nu$$

[1]NRCC No. 12889.

[2]National Research Council of Canada Postdoctorate Fellow 1969–1971.

[4] $HNO^* + M \rightarrow HNO + M$

[5] $HgH + NO \rightarrow Hg + HNO$

The phase shift ϕ between the HNO emission and the incident 2537 Å radiation, under the conditions used, is given by (1):

$$[6] \qquad \tan \phi = \frac{\omega}{k_2[NO][M]}$$

where $k_2 = k_{2a} + k_{2b}$, $\omega = 2\pi\nu$ and ν is the modulation frequency.

The low intensity of the HNO emission and its decrease with increasing temperature necessitated working below 120 °C.

The NO pressure was varied over the range 2.4–6.7 Torr while the total pressure varied between 100 and 145 Torr at modulation frequencies of 2–4 kHz.

The values of k_2 obtained are given in Table 1. The Arrhenius plot of $k_2 = A_2 e^{-E_2/RT}$ is shown in Fig. 1. A least squares treatment gives a mean preexponential factor $A_2 = 8.9 \times 10^9$ l^2 mol^{-2} s^{-1} and an activation energy $E_2 = -0.54 \pm 0.15$ kcal mol^{-1}, where the error is twice the standard deviation.

TABLE 1. Least squares values of the rate constants k_2 for the reaction H + NO + M (M = H_2)

Discussion

The present values are compared with the literature values in Table 2. It is seen that the activation energy obtained in this work is in excellent agreement with that of Clyne and Thrush (3) and that the value of k_2 at room temperature agrees very well with that of Hartley and Thrush (4) but is about 50% higher than the value determined recently by Hikida, Eyre, and Dorfmann (5).

A brief comment is necessary about the roles of the HgH radicals formed in the primary quenching act and of the HNO molecules formed subsequently. As shown by Callear and Wood (7) the HgH radicals are rapidly consumed by NO in reaction 5 to form HNO. On thermochemical grounds the HNO molecules thus formed will have to be in the ground electronic state and will therefore not affect directly the rate measurements. The HNO molecules, both from reaction 5 and reactions 2–4, may however interfere by consuming some H atoms,

[7] $H + HNO \rightarrow H_2 + NO$

in competition with

[8] $HNO + HNO \rightarrow H_2O + N_2O$

The ratio of the rates of reactions 7 and 2, r_7/r_2, depends (7, 8) on the [H]/[HNO] ratio under the experimental conditions employed. For the above reaction scheme the steady state approximation gives

$$[9] \qquad r_7/r_2 = (k_7/k_8^{1/2})I_a^{1/2}/k_2[M][NO]$$

I_a is the rate of absorption of light quanta, $k_7/k_8^{1/2}$ at 300 °K is (8) 1.7×10^5 $l^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$ and for k_2 the present value of 2×10^{10} l^2 mol^{-2} s^{-1} can be used. For the average conditions in this work r_7/r_2 calculated from eq. 9 is about 2%. At higher temperatures $k_7/k_8^{1/2}$ (and thus also r_7/r_2) is likely, if anything, to become even smaller since k_7 is (9) about 4×10^5 l mol^{-1} s^{-1} and thus (in view of the above value (8) of $k_7/k_8^{1/2}$) k_7 is 10^8 l mol^{-1} s^{-1}. Reaction 8 is therefore likely to have larger activation energy and thus $k_7/k_8^{1/2}$ should decrease when temperature is increased. Reaction 7 can therefore be neglected in the present work.

Reaction of Oxygen Atoms, O(^3P), with Ethylene in Liquid Nitrogen Solution[1]

SHUN-ICHI HIROKAMI[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received August 3, 1972

The reaction of ground-state oxygen atoms, O(^3P), with ethylene and ethylene-d_4 in liquid nitrogen solution at 77 °K has been studied. The major and perhaps the exclusive products are ethylene oxide and acetaldehyde. The ratio of acetaldehyde to ethylene oxide is 1.2 ± 0.1 for ethylene and 0.91 ± 0.09 for ethylene-d_4. Much smaller amounts of formaldehyde and trace quantities of cyclopropane are also observed.

The effect of the concentration of ethylene on the quantum yields of addition products was measured. A limiting quantum yield of oxygen atoms scavenged by ethylene to form the addition products was 0.12±0.01. The low quantum yield suggests an appreciable cage recombination of the ground-state oxygen atoms with the trace amounts of molecular oxygen present. The effect of the concentration of added oxygen on the product yields and the relative rate constant for the addition of O(^3P) to molecular oxygen and to ethylene were determined. The ratio $k_{O+O_2}/k_{O+C_2H_4}$ is 6.0 ± 1.0 and the relative rate constant for the addition of O(^3P) to ethylene and to ethylene-d_4, $k_{O+C_2D_4}/k_{O+C_2H_4}$, is 2.0 ± 0.1.

The type of products formed and the isotope effects observed are discussed in terms of the mechanism of addition of O(^3P) atoms to ethylene.

La réaction des atomes d'oxygène à l'état fondamental, O(^3P) avec l'éthylène et l'éthylène-d_4 en solution d'azote liquide à 77 °K à été étudiée. Les produits majeurs et peut-être les seuls formés sont l'oxyde d'éthylène et l'acétaldéhyde. Le rapport d'acétaldehyde versus l'oxyde d'éthylène est 1.2 ± 0.1 pour l'éthylène et 0.91 ± 0.09 pour l'éthylène-d_4. Des quantités beaucoup plus faibles de formaldehyde ainsi que des traces de cyclopropane sont aussi obtenues.

L'effet de la concentration d'éthylène sur le rendement quantique des produits d'addition a été mesuré. Un rendement quantique limite d'atomes d'oxygène trappés par l'éthylène pour former les produits d'addition a été de 0.12 ± 0.01. Le petit rendement quantique suggère une recombinaison appréciable en cage des atomes d'oxygène dans l'état fondamental avec des quantités minimes (traces) d'oxygène moléculaire présent. L'effet de la concentration d'oxygène ajouté sur le rendement en produits et la constante de vitesse relative à l'addition de O(^3P) à l'oxygène moléculaire et à l'éthylène ont été déterminés. Le rapport $k_{O+O_2}/k_{O+C_2H_4}$ est 6.0 ± 1.0 et la constante de vitesse relative pour l'addition de O(^3P) à l'éthylène et à l'éthylène-d_4, $k_{O+C_2D_4}/k_{O+C_2H_4}$ est 2.0 ± 0.1.

Les types de produits formés et les effets isotopiques observés sont discutés en fonction du mécanisme d'addition des atomes de O(^3P) à l'éthylène. [Traduit par le journal]

Can. J. Chem., **51**, 373 (1973)

Introduction

The reaction of oxygen atoms with ethylene in the gas phase was first studied by one of the authors using the technique of mercury-photosensitized decomposition of N_2O (1). It was concluded that the primary step of the reaction involves direct addition of an oxygen atom to the double bond to form an energy-rich intermediate which then undergoes further reactions. The products formed were carbon monoxide, hydrogen, several paraffins, aldehydes, and small amounts of ethylene oxide.

The reactions of oxygen atoms with other simple olefins in the gas phase were studied in considerable detail in previous papers from this laboratory (1–6) and a general reaction mechanism has been established.

Studies of O(^3P) atom reactions with olefins in the liquid and the solid phase at low temperatures are of interest as a corollary to the gas phase studies at normal temperatures. At low temperatures any competing and secondary reactions of high activation energy tend to be suppressed and, moreover, energy-rich intermediates are rapidly stabilized by transfer of excess energy to the solvent molecules (7, 8). Thus the information obtained may complement the observations made in conventional gas phase investigations. With this prospect in mind, a study of the reaction of O(^3P) atoms with

For personal use only.

ethylene dissolved in liquid nitrogen at 77 °K has been carried out.

In addition to the studies of reactions of $O(^3P)$ atoms with condensed olefins at cryogenic temperatures (7–9), studies of $O(^1D)$ atom reactions in liquid argon solutions (10) and of $O(^3P)$ atoms in aqueous solutions (11) have also been recently carried out.

Experimental

Oxygen atoms are generated by photolyzing ozone, using 2537 Å line from a low pressure mercury lamp. The initially formed excited oxygen atoms, $O(^1D_2)$, are rapidly deactivated by collisions with the excess nitrogen molecules present (12).

The vacuum reaction system used was mercury-free. The 2537 Å radiation was obtained from a home-made spiral low-pressure mercury lamp and was passed through a 7–54 Corning glass filter. The reaction vessel and the Dewar flask are shown in Fig. 1.

Matheson prepurified nitrogen was used after it was passed through two spiral traps cooled with liquid oxygen. Matheson research grade oxygen was used without further purification. Matheson research grade ethylene and Merck, Sharp and Dohme ethylene-d_4 were used after thorough degassing and distillation from a trap at −160 °C. Mass spectrometric analysis showed an isotopic impurity in ethylene-d_4 of 3.0% C_2HD_3.

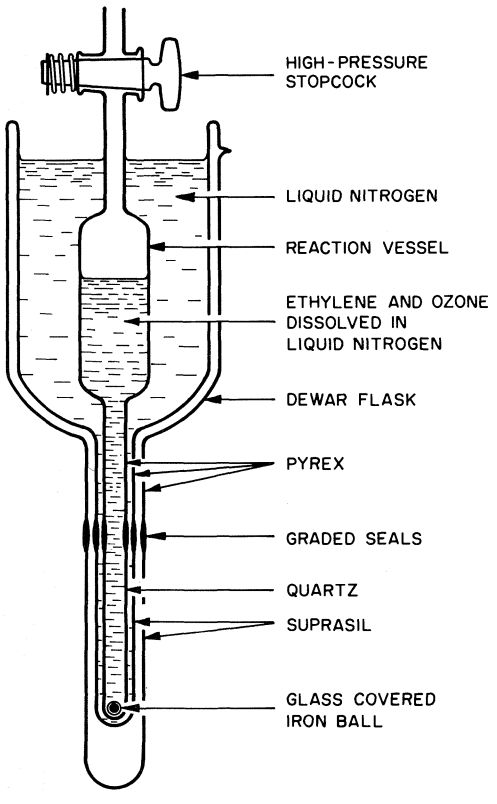

FIG. 1. Reaction vessel and Dewar flask.

To prepare a reaction sample, the nitrogen gas was first introduced into the reaction vessel under a pressure of about 1.2 to 1.5 atm, and then the gas was easily liquefied at the bottom of the reaction vessel cooled with liquid nitrogen. After a part (2–3 ml) of liquid nitrogen had been transferred, a volumetrically measured amount of ozone was introduced simultaneously with additional nitrogen. After about 5–7 ml of nitrogen and ozone were condensed in the reaction vessel, a volumetrically measured amount of ethylene was introduced and the nitrogen condensation was continued in order to dissolve completely the ethylene which tended to condense on the upper parts of the wall of the reaction vessel. (To accomplish this, the level of the liquid nitrogen in the Dewar flask was raised at this time so that further liquid nitrogen was formed higher in the reaction vessel and washed down the condensed ring of ethylene.). The total amount of liquid nitrogen solution used in each run was 50 ml.

The maximum concentration of ethylene in liquid nitrogen was calculated using the literature data for the solubility of ethylene in liquid nitrogen at 77 °K (13).

The reaction mixture was irradiated with the low pressure mercury lamp. After the irradiation, the condensable products and excess ethylene were collected in a trap at −196 °C. A cold trap at −164 °C was then used to separate the oxygenated products and lighter hydrocarbons from ethylene. The products, ethylene oxide and acetaldehyde, were analyzed at room temperature on a 2 m long polyethylene glycol-packed column and a 5 m long β,β′-thiodipropionitrile-packed column, provided with flame ionization detectors. Formaldehyde, ethylene oxide, acetaldehyde, and ethylene ozonide were analyzed on a 3.6 m long cyanosilicone-packed column at room temperature with a thermistor detector. Ethylene oxide and acetaldehyde were not completely separated on this column. The lighter hydrocarbons were analyzed on a 6 m long 2% squalane-modified activated alumina column at room temperature with a flame ionization detector. The identification of the oxygenated products was confirmed by direct mass spectrometric analysis of peaks eluted from the cyanosilicon column.

O_3 was prepared by a Tesla-coil discharge in O_2 gas which was cooled with liquid nitrogen. The number of light quanta absorbed by O_3 in liquid N_2 was estimated from the amount of N_2O produced in the reaction of $O(^1D)$ with nitrogen (12). The relative light intensity of the low pressure mercury lamp was always checked by a phototube placed behind the reaction vessel. To avoid the reaction of products with ozone after irradiation, more ethylene was added after the completion of irradiation in the experimental runs with lower concentrations of ethylene.

The following flame ionization detector molar responses relative to benzene taken as unity were used: ethylene oxide, 0.159; acetaldehyde 0.161. The molar response for ethylene ozonide was approximately obtained by extrapolating a linear plot of the peak area responses against the molecular weights (14).

Results

The observed products are ethylene oxide, acetaldehyde, formaldehyde, ethylene ozonide,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and a trace of cyclopropane. The effect of irradiation time on product yields, except for cyclopropane, is shown in Figs. 2 and 3, using 4.94×10^{-4} mol/l of ozone and 1.21×10^{-2} mol/l ethylene solution. The relative ratio of cyclopropane to the oxygenated compounds after 30 min irradiation was about 10^{-4}. The yields of

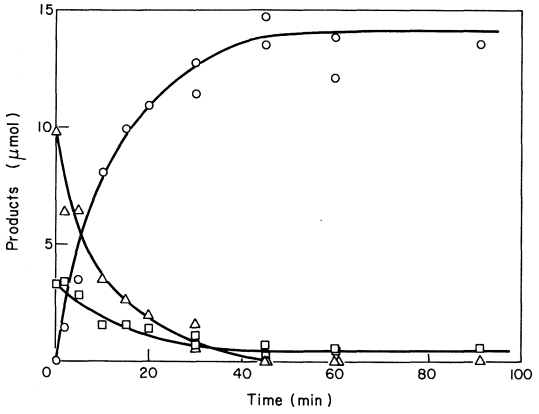

FIG. 2. Effect of irradiation on product yields (ozone concentration is 4.94×10^{-4} mol/l and ethylene concentration is 1.21×10^{-2} mol/l; ○, addition products, *i.e.* ethylene oxide plus acetaldehyde; △, ethylene ozonide; □, formaldehyde).

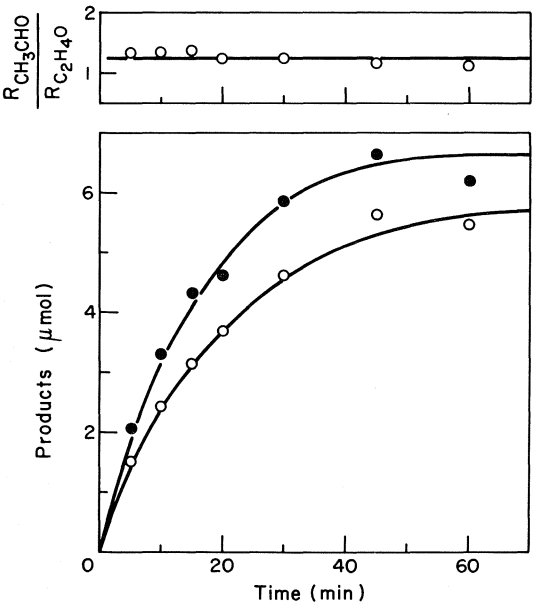

FIG. 3. Effect of irradiation on product yields and the ratio of acetaldehyde to ethylene oxide (ozone concentration is 4.94×10^{-4} mol/l and ethylene concentration is 1.21×10^{-2} mol/l; ○, ethylene oxide; ●, acetaldehyde).

ethylene oxide and acetaldehyde increased with increasing irradiation time up to constant values. The ratio of acetaldehyde to ethylene oxide remained constant within the experimental error. The yields of ethylene ozonide and formaldehyde decreased with increasing irradiation time and while the yield of ethylene ozonide approached zero after 45 min irradiation, the yield of formaldehyde approached a small constant value.

These results show that acetaldehyde and ethylene oxide are formed by direct addition of oxygen atoms to ethylene. Ethylene ozonide and the greater part of formaldehyde, on the other hand, are not photochemical products, but are formed by thermal reaction of O_3 with the residual ethylene in the solid phase (7) after the nitrogen solvent is distilled off. This explanation was confirmed by the experimental observation that the color of the unreacted ozone persisted during the distillation of the nitrogen from the reaction mixture after the irradiation, but disappeared when the temperature in the reaction vessel was raised slowly.

The effect of ethylene concentration, at a constant concentration of ozone (3.06×10^{-4} mol/l), on the product yields is shown in Tables 1 and 2 and is presented graphically in Fig. 4. The quantum yield of the total photochemical products increases with increasing ethylene concentration up to a constant value. The ratio of acetaldehyde to ethylene oxide remains constant but the yields of ethylene ozonide and formaldehyde tend to decrease with increasing ethylene concentration. An isotope effect is found in the ratio of acetaldehyde to ethylene oxide formed in the reaction. At the highest ethylene concentration used, the quantum yield of the total addition products of 0.12 to 0.13 may reflect the influence of a cage recombination of oxygen atoms with the traces of O_2 present. The effect of ethylene concentration on the quantum yield of addition products can be explained by a competition for $O(^3P)$ atoms between ethylene and O_2 (to form O_3), because the ethylene used contained no impurities except for a trace of hydrocarbons and the nitrogen used contained no impurities except for O_2.

The effect of oxygen concentration, at constant concentrations of ozone (3.06×10^{-4} mol/l) and of ethylene (2.12×10^{-2} mol/l), on product yields is shown in Table 3 and is presented graphically in Fig. 5. The quantum yield of total

addition products decreases monotonically with increasing oxygen concentration. However, the ratio of acetaldehyde to ethylene oxide remains constant.

Discussion

Reaction Scheme and the Values of Rate Constants

The discussion and interpretation of results may be based on the following reaction scheme

[1*a*] $O_3 + h\nu \rightarrow [O^* + O_2]$

[1*b*] $[O^* + O_2] + N_2 \rightarrow N_2O + O_2$

[1*c*] $\rightarrow [O + O_2] + N_2$

[2] $[O + O_2] \rightarrow O_3$

[3] $[O + O_2] \rightarrow O + O_2$

[4] $O + C_2H_4 \rightarrow$ Products

[5] $O + O_2 \rightarrow O_3$

O* and O represent an excited ($^1D_2$) and a ground state (^3P) oxygen atom, respectively. Parentheses represent solvent cages. Reaction 1*a* represents the rate of absorption of light quanta by ozone. Reaction of $O(^3P)$ with O_3, *i.e.* $O(^3P) + O_3 \rightarrow 2O_2$, may be ruled out because it has an activation energy of about 6 kcal/mol greater than that of reaction 5 (15). Reaction of $O(^1D_2)$ with O_2, O_3, and ethylene can be ruled out because these reactions cannot compete to a significant extent for $O(^1D_2)$ with the large excess of N_2.

From a steady-state treatment of reactions 1 to 5, the following expressions are obtained for the quantum yields of N_2O and the products

[6] $$\phi_{N_2O} = \frac{k_{1b}}{k_{1b} + k_{1c}}$$

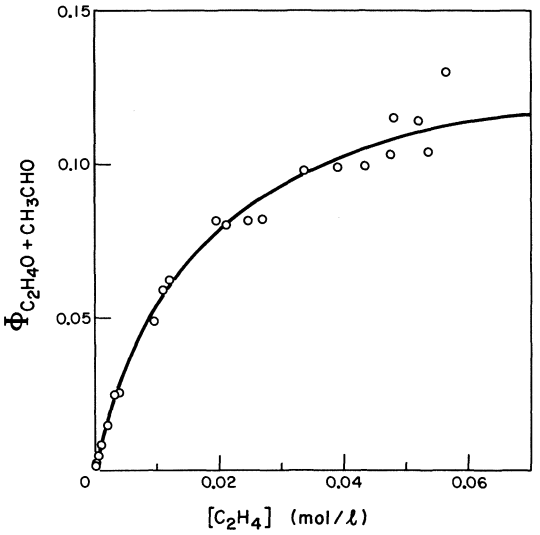

FIG. 4. Dependence of $\phi_{C_2H_4O+CH_3CHO}$ on $[C_2H_4]$ (ozone concentration is 3.06×10^{-4} mol/l).

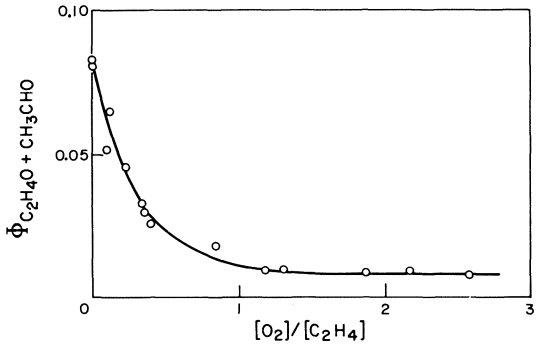

FIG. 5. Dependence of $\phi_{C_2H_4O+CH_3CHO}$ on the $[O_2]/[C_2H_4]$ ratio (ozone concentration is 3.06×10^{-4} mol/l and ethylene concentration is 2.12×10^{-2} mol/l).

*EO and AA stand for ethylene oxide and acetaldehyde, respectively.

$$[7] \quad \phi_{Products} = \frac{k_{1c}}{k_{1b} + k_{1c}} \frac{k_3}{k_2 + k_3} \times \frac{k_4[C_2H_4]}{k_4[C_2H_4] + k_5[O_2]}$$

The quantum yield of N_2O has been measured by DeMore and Raper (12). The quantum yield of the total products is approximately equal to that of the addition products (ethylene oxide and acetaldehyde), because the quantum yield of other products (cyclopropane and formaldehyde) is quite small.

In the experiments without additions of O_2, the molecular oxygen present was that initially contained in the nitrogen as an impurity. If this initial concentration of oxygen is represented by $[O_2]^0$, Equation 7 may be modified to show explicitly the dependence of the initial quantum yield (ϕ) on ethylene concentration, *i.e.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

[8] $$\phi_{EO+AA}{}^{-1} = \alpha\left(1 + \frac{k_5}{k_4}\frac{[O_2]^0}{[C_2H_4]}\right)$$

with

$$\alpha = \left(1 + \frac{k_{1c}}{k_{1b}}\right)\left(1 + \frac{k_2}{k_3}\right)$$

EO and AA represent ethylene oxide and acetaldehyde, respectively.

The plots of $\phi_{EO+AA}{}^{-1}$ *vs.* $[C_2H_4]^{-1}$ and $[C_2D_4]^{-1}$ are linear, as shown in Fig. 6.

Equation 7 may be expressed in the following form to show the effect of the concentration of oxygen added, $[O_2]$,

[9] $$\phi_{EO+AA} = \frac{1}{\alpha}\frac{k_4[C_2H_4]}{\{k_4[C_2H_4] + k_5[O_2]^0 + k_5[O_2]\}}$$

or

[10] $$\phi_{EO+AA}{}^{-1} = (\phi_{EO+AA}{}^0)^{-1} + \alpha\frac{k_5}{k_4}\frac{[O_2]}{[C_2H_4]}$$

where

$$\phi_{EO+AA}{}^0 = \frac{1}{\alpha}\frac{k_4[C_2H_4]}{k_4[C_2H_4] + k_5[O_2]^0}$$

$\phi_{EO+AA}{}^0$ is constant for constant initial concentrations of O_3 and ethylene. The plot of $\phi_{EO+AA}{}^{-1}$ *vs.* $[O_2]/[C_2H_4]$ is linear, as shown in Fig. 7.

The least squares values and standard deviations of the intercepts and the slopes of the plots in Figs. 6 and 7 for ethylene are

$$\alpha = \left(1 + \frac{k_{1c}}{k_{1b}}\right)\left(1 + \frac{k_2}{k_3}\right) = 8.66 \pm 0.55$$

$$\alpha\frac{k_5}{k_4}[O_2]^0 = (9.90 \pm 0.06) \times 10^{-2} \text{ mol/l}$$

$$\alpha\frac{k_5}{k_4} = 52.1 \pm 4.8$$

From these values it is found that the relative rate constant k_5/k_4 is 6.0 ± 1, the limiting quantum yield of addition products ($\phi_L = 1/\alpha$) is 0.12 ± 0.01, and the initial concentration of oxygen $[O_2]^0$ is $(1.9 \pm 0.2) \times 10^{-3}$ mol/l.

The relative rate constant $k_5/k_4 = 6.0 \pm 1.0$ could be compared with the value of 7.7 ± 0.6 found in aqueous solution (11). The derived value of the initial concentration of oxygen molecules (1.9×10^{-3} mol/l) is in good agreement with $\sim 3 \times 10^{-3}$ mol/l estimated from the gas-chromatographic analysis.

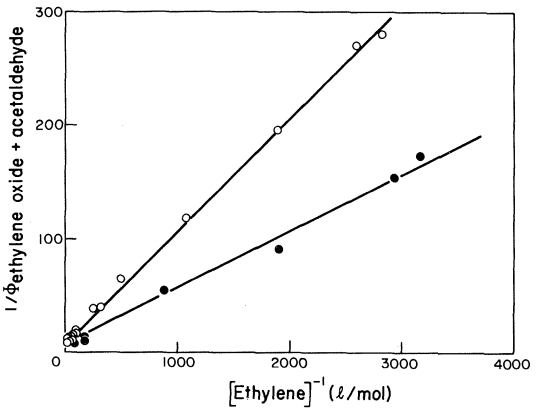

FIG. 6. The reciprocal of $\phi_{\text{ethylene oxide+acetaldehyde}}$ as a function of the reciprocal of the ethylene concentration (conditions are the same as stated in the caption to Fig. 4).

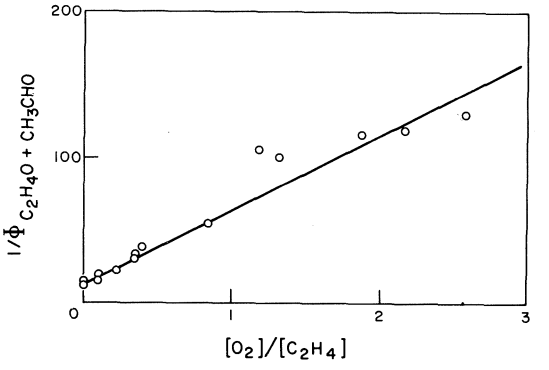

FIG. 7. The reciprocal of $\phi_{C_2H_4O+CH_3CHO}$ as a function of the $[O_2]/[C_2H_4]$ (conditions are the same as stated in the caption to Fig. 5).

For C_2D_4, the least-squares value and standard deviation of the slope of the plot in Fig. 6 are given by $\alpha(k_5/k_4)[O_2]^0 = (4.99 \pm 0.21) \times 10^{-2}$ mol/l. Taking the value for α as determined for C_2H_4, it is then seen that the relative rate constant $k_4[O + C_2D_4]/k_4[O + C_2H_4] = 2.0 \pm 0.1$.

An upper limit for k_4 may be approximately obtained by assuming that reaction 5 is diffusion controlled. An upper limit of the value of the second-order rate constant k_5 can then be calculated from the Debye equation (16),

[11] $$k_5 \leqslant \frac{8RT}{3000\eta} \text{ (l/mol s)}$$

At 77 °K the value of η is 1.58×10^{-3} (c.g.s.) (17), so that $k_5 \leqslant 1.08 \times 10^{10}$ l/mol s and therefore $k_4 \leqslant (1.8 \pm 0.3) \times 10^9$ l/mol s for ethylene.

Actually, both these values may be appreciably smaller than the indicated upper limits, in view of the measured values of k_4 and E_4 in the gas phase at higher temperatures (18) if an extrapolation of the gas phase data to liquid nitrogen solutions is permissible.

The Mechanism of $O(^3P)$ Addition to Ethylene

Addition of $O(^3P)$ atoms to simple alkene molecules is explainable (1–6) by postulating initial formation of triplet biradical intermediates which subsequently rearrange to the final products by ring closure and by migration of a hydrogen atom or an alkyl group from the C atom to which $O(^3P)$ becomes attached to the other C atom of the original double bond. This mechanism has been discussed in considerable detail in previous publications (1–6). For the case of ethylene, the mechanism predicts formation of ethylene oxide and acetaldehyde as the predominant and perhaps exclusive initial reaction products. This prediction is fully borne out by the results of the present study.

It is of interest that the acetaldehyde to ethylene oxide ratio in liquid nitrogen solution is the same as found by Ponomarev and coworkers (9) for the addition of $O(^3P)$ to solid ethylene. The reaction mechanism must therefore be the same in the two media. In the gas phase reactions the basic mechanism of $O(^3P)$ addition must again be the same, as was recognized in the very early studies (1), but the collisional stabilization of the energy rich adducts is much less efficient and extensive fragmentation occurs (1–6). Eusuf and Wagner (19) have recently observed substantial stabilization of the "hot" acetaldehyde but little or no stabilization of ethylene oxide at a helium gas pressure as high as 80 atm.

Isotope Effects

Two kinds of hydrogen–deuterium isotope effects have been found: a primary isotope effect (the greater ratio of acetaldehyde to ethylene oxide in the C_2H_4 than in the C_2D_4 reaction) and a secondary isotope effect (the greater rate of addition of $O(^3P)$ to C_2D_4 than to C_2H_4).

The observation of a primary isotope effect is consistent with the postulated mechanism of formation of acetaldehyde by hydrogen atom migration. The alternative reaction path, ring closure in the biradical intermediate to form ethylene oxide, is not likely to be susceptible to an appreciable hydrogen–deuterium isotope effect. On the other hand, internal migration of an H atom should be expected to occur more readily than migration of deuterium.

The observed secondary deuterium isotope effect is "inverse", *i.e.* C_2D_4 is found to react with $O(^3P)$ about twice as rapidly as C_2H_4. A similar inverse secondary isotope effect has been observed (20), for example, in the complexing of Ag^+ with C_2H_4 and C_2D_4, the complex being more stable in the case of C_2D_4. This similarity is probably of considerable significance since it appears likely (4) that the activated complex in the addition of $O(^3P)$ atoms to alkenes may be basically similar to a charge transfer complex. At the same time, it should be pointed out that the trends in the two processes are not always parallel. Thus, for example, Ag^+ complex with *cis*-2-butene is considerably stronger than that with *trans*-2-butene while $O(^3P)$ atoms react somewhat more rapidly with *trans*- than with *cis*-2-butene. However, the stability of the Ag^+ complexes of alkenes may reflect a delicate balance of steric and electronic interactions (20) and thus a close parallelism need not be observed.

Unambiguous interpretation of secondary deuterium isotope effects in terms of specific structural features is difficult, especially so in the case of kinetic isotope effects, since the structural parameters and vibrational characteristics of the activated complexes are generally not known. If some "plausible" values are assumed, the expected magnitude of the isotope effect may be approximately calculated from the general expressions (21, 22) based on the transition state theory. However, such calculations would be of questionable usefulness in the present case and will therefore not be attempted. Qualitatively, the effect may be discussed, for example, in terms of the differences in the "direct" and "indirect" steric effects due to the smaller nonbonded repulsions of deuterium atoms in comparison with hydrogen atoms. In a similar manner, it can be rationalized in terms of the anticipated changes on deuteration in the characteristic frequencies of CH bond vibrations or by postulating a greater effective inductive electron release from CD bonds than from the corresponding CH bonds. These possibilities have been discussed in some detail previously (20) in connection with the inverse deuterium isotope effects on the stability of Ag^+ complexes with alkenes. Somewhat similar considerations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

may apply to the present case and their repetition in the present article is therefore unnecessary.

An inverse secondary deuterium isotope effect has been observed recently in the reaction of $S(^3P)$ atoms with ethylene (23). This reaction would be expected to exhibit somewhat similar behavior to the corresponding reaction of $O(^3P)$ atoms with ethylene studied in the present work.

Formation of Minor Products

As mentioned earlier, small amounts of formaldehyde and traces of cyclopropane were observed in the present study after longer irradiation times. The yield of cyclopropane is essentially negligible and the residual formaldehyde is perhaps due to a slow thermal attack of ozone on ethylene (10). However, the possibility that both these minor products may be a direct consequence of the attack of $O(^3P)$ atoms on ethylene cannot be entirely ruled out.

In the reaction of $O(^3P)$ atoms with ethylene in the gas phase, large amounts of CH_3 and HCO were found (1) to be formed in the reaction sequence

$$[12] \quad C_2H_4 + O \rightarrow C_2H_4O^* \rightarrow CH_3 + HCO$$

where $C_2H_4O^*$ represents an energy-rich molecule (1, 24). In the presence of molecular oxygen there was a large increase in the rate of formaldehyde formation. The formation of formaldehyde was attributed to the reaction of CH_3 radicals with molecular oxygen. In present experiments some molecular oxygen was always contained in the nitrogen gas as an impurity and the formation of small amounts of formaldehyde could therefore be explained by reaction of CH_3 radicals with molecular oxygen.

Another possible primary step for the formation of formaldehyde and cyclopropane is (25)

$$[13] \quad C_2H_4 + O \rightarrow CH_2 + HCHO$$

followed by reactions of CH_2 with molecular oxygen and ethylene (26)

$$[14] \quad CH_2 + O_2 \rightarrow CH_2O_2$$

$$[15] \quad CH_2 + C_2H_4 \rightarrow \text{cyclo-}C_3H_6$$

The relative ratios of the yields of cyclopropane and of formaldehyde to the sum of acetaldehyde and ethylene oxide are about 10^{-4} and 3×10^{-2}, respectively. If CH_2 is the ground state triplet, as would be likely, k_{14}/k_{15} would be (26) approximately 30 at room temperature. This value would predict, for the experimental conditions used, a ratio of cyclopropane to formaldehyde of 0.2, which is much larger than the experimental value of 3×10^{-3}. At the same time, the value of k_{14}/k_{15} at -196 °C is not known and if it is assumed to be as large as about 300, it could explain the experimentally observed low ratio of cyclopropane to formaldehyde. However, it is important to emphasize that formation of formaldehyde is at best only a very minor process in the reaction of $O(^3P)$ with ethylene at -196 °C in liquid nitrogen solution, amounting only to about 3% of the total reaction and, as mentioned, it cannot be regarded as proven that formaldehyde is indeed a primary reaction product. In the gas phase at room temperature, little or no formaldehyde is observed in the absence of molecular oxygen and no formaldehyde has been reported for the reaction of $O(^3P)$ with solid ethylene (9).

The authors are grateful to Dr. R. F. Pottie for the mass spectrometric analyses.

The Reaction Between Certain Organometallic Reagents and Benzanthrone

C. F. H. Allen

Chemistry Department, Rochester Institute of Technology, Rochester, New York

Received May 25, 1972

The action of certain organometallic reagents upon benzanthrone (7*H*-benz[*de*]anthracene-7-one) has been further investigated. Some of the components were identified, and the nature of hitherto unknown compounds was deduced. Phenylmagnesium chloride in tetrahydrofuran gave nearly double the yield of crystallizable products. The primarily-formed enol, formed by 1,4-addition and related to the principal product, 6-phenylbenzanthrone, was isolated and identified. In the presence of cuprous and cobaltous chlorides unexpected products were indicated. The formation of 3-phenylbenzanthrone is assumed to be the result of a 1,8-addition. Phenyllithium gave all the above and many others. Among them was the carbinol, formed by 1,2-addition, and a new hydrocarbon, 7-phenyl-7*H*-benzanthrene.

L'action de certains organo-métalliques sur la benzanthrone (benz[*de*]anthracène-7*H* one-7 a été étudiée de nouveau. Certains des constituants ont été identifiés et la nature de certains composés jusqu'alors inconnus en a été déduite. Le chlorure de phényl magnésium dans le tetrahydrofuranne a donné presque le double du rendement en produits cristallisables. L'énol principalement formé, obtenu par addition-1,4 et relié au produit principal, le phényl-6 benzanthrone, a été isolé et identifié. En présence des chlorures cuivreux et cobalteux des produits inespérés furent mis à jour. La formation du phényl-3 benzanthrone est semble-t-il, le résultat d'une addition-1,8. Le phenyllithium a donné tous les produits mentionnés et plusieurs autres. Parmi ceux-ci se trouvent le carbinol, formé par addition-1,2 et un nouveau hydrocarbone, le phényl-7 benzanthrène-7*H*. Earlier investigations (1–3) have shown that the product from the action of phenylmagnesium bromide on benzanthrone, under forcing conditions (ether–benzene), is the formation and isolation of 6-phenylbenzanthrone (**2**) in yields of 42–75%; this has also been formed by the use of phenylsodium (4). It was assumed that this substance resulted from an initial 1,4-addition to the double bond system, —(C=O)—CH=CH—. Because the yield was so low, it was considered worthwhile to reinvestigate the reaction making use of newly-available reagents and modern instrumental methods. The use of tetrahydrofuran as a solvent, and phenylmagnesium chloride, resulted in an initial isolation of at least an 80% yield of a solid product; this consisted not only of the aforesaid 6-phenylbenzanthrone, but a second substance which proved to be a primary adduct, the enol **3**. Furthermore, the latter relatively rapidly changed into the ketone **2** (see Scheme 1). An enol has not previously been isolated in the benzanthrone series. In practice, it was almost impossible to isolate other than the major component, the phenyl derivative **2**, except by a long, tedious, fractional crystallization. In order to avoid this, g.c. was applied to the entire reaction mixture; the ether was first treated with a silating agent to preserve the enol as its silated derivative. Interpretation of the results revealed not only a rough approximation of the amounts of the major constituent, but also the effect of changing the excess of Grignard reagent, as well as suggesting the presence of hitherto unrecognized components (Tables 1, 2).

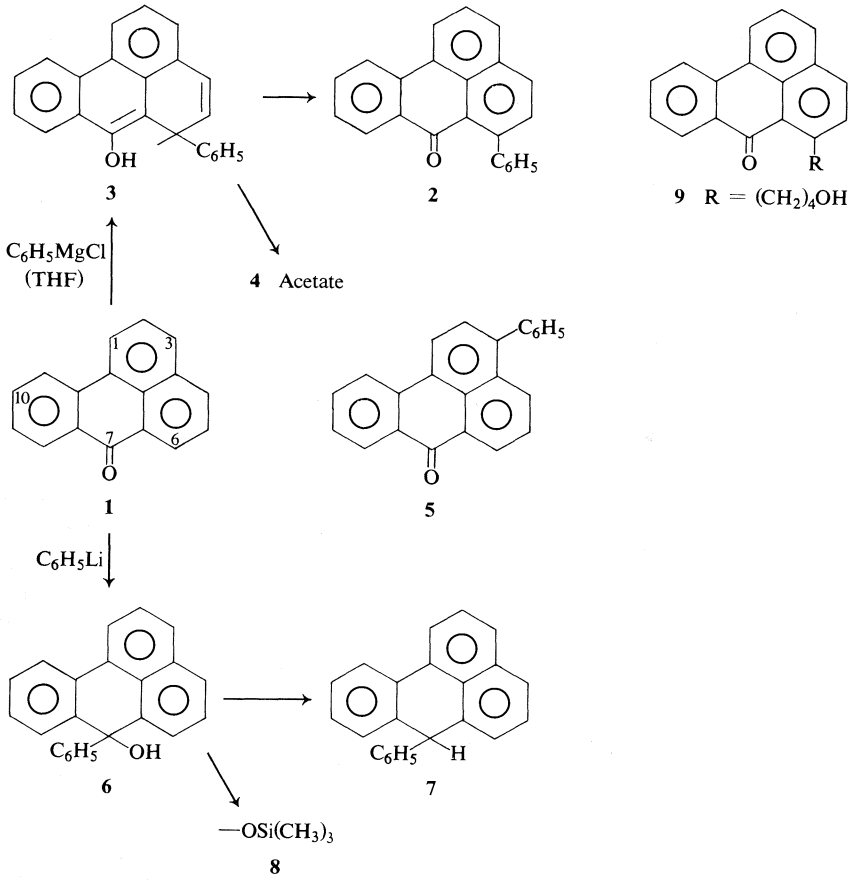
A mixture of five known, expected components, including the hydrocarbon, $C_{28}H_{58}$, as an internal standard, for locating the various peaks, was prepared (*std.*). It will be noted that there is not much choice between the use of 3 (*372*) or 4 (*365*) equiv of the Grignard reagent. The total of silated enol plus ketone **2** is about 90 area %; this is not too far from the amount (80%) actually isolated, and indicates that our main purpose, to learn what and where the rest of the reaction products were, had been realized. The situation was similar with 5 (*379*) equiv of Grignard reagent, but there were more unidentifiable impurities. With 2 (*386*) equiv, however, there was much unused starting material. All these results as well as *385*, indicate that the enol had been formed first.

Despite the apparent separation of peaks on a



SCHEME 1

g.c. column, in practice it has proved extremely difficult to get rid of the main component, 6-phenylbenzanthrone (**2**) that accompanies attempted fractionation of crystalline products.

As it is well-known that the presence of copper in a Grignard reaction favors conjugate addition to an α,β-unsaturated ketone (5, 6), its effect was examined. Unexpectedly, an additional component, an isomeric ketone, was indicated in the g.c. It was assumed to be 3-phenylbenzanthrone (**5**) (old name, *Bz*-1-phenylbenzanthrone), because of g.c. and mass spectra (Table 3). In practice, it has not yet been possible to separate this isomer from the much more abundant **2**, because of their very similar solubilities.

In *399* the amount of cuprous chloride was doubled, and the mixture heated slightly longer. In an unsilated sample (*399*, footnote *a*, Table 1) *all* the enol had been converted to ketone **2**; the larger amounts of the ether masked the presence of isomer **5**, for it appears in the unsilated material (*399*).

Since 6-phenylbenzanthrone (**2**) is a product of 1,4-addition, the isomer **5** can be regarded as the result of conjugate, 1,8-addition. The carbon atom in the 3-position is at the end of the longest, unhindered conjugated system. 1,8-Addition is very rare; a few instances, involving the tropolone system, have been reported (8, 9).

The effect of cobalt (7) was also examined. The reaction was slowed down, as indicated by the larger amount of starting material recovered, and lesser formation of enol and ketone (*385*). Moreover, there was a new component **9**; interpretation of the mass spectral data (Table 3) indicates that the solvent, THF, had entered into its formation.

In order to ensure formation of the unknown carbinol **6**, a product of 1,2-addition, phenyllithium was employed. The situation was more complex, because of the multiplicity of products.

10-Phenyl-BA	5.00[a]

[a]Based on single chromatogram.

As before, unused benzanthrone, the 6-phenyl derivative **2**, and the same enol **3** were among products shown by t.l.c., and actually isolated. There was, probably, some of the 3-isomer also. Two new constituents were found; one was the expected carbinol **6**, for, after silation, the peak disappeared entirely, and a new one corresponding to its silated derivative **8**, and having a smaller retention time, appeared in a subsequent chromatogram. Mass spectrometric analysis of a trapped sample of the silyl derivative gave the calculated molecular ion at 380 *m/e*, with abundant fragment ions corresponding to the losses of silyl and phenyl groups.

The other new substance was the hydrocarbon **7**, 7-phenyl-7*H*-benzanthrene. The evidence favoring this structure is based on spectral data (u.v., i.r., mass spectrometry, and n.m.r.); the shape of the u.v. absorption curve is identical with that of 7*H*-benzanthrene (10), but the molar absorption is lower; this could be attributed to the "dilution effect" of the phenyl group. The i.r. is also similar (11); the bands at 13.4 (748 cm^{-1}) and 14.3 μ (697 cm^{-1}) suggest a monosubstituted benzene ring; the mass spectrum shows the molecular ion at 292 *m/e*, and fragment ions at 291 (24%) M − H, 289 (12%), 276 (5%), and 215 (100%) M − C_6H_5. Its n.m.r. shows 15 aromatic hydrogens to one tertiary hydrogen. The formation of 7-phenyl-7*H*-benzanthrene (**7**) presumably arises by reduction of the carbinol **6**. It appears to be present in quantity only in the organolithium runs in which the carbinol is formed.

[c]Isolated in trap from g.l.c. of synthetic reference mixture.
[d]Separated from a Cu^+ catalyzed mixture.

Experimental

Owing to the great similarity in structures, the resemblances in physical properties of the possible isomeric benzanthrones are very close. Melting points fall in the same range. Solubilities do not differ markedly.

(I) Instrumental

Infrared Spectra

The spectra are much alike, except that of the 3-phenyl isomer **5**, which has a strong band at 7.23 μ (very difficult to detect in mixtures).

Nuclear Magnetic Resonance Spectra

These spectra are also much alike, except for the enol **3**, which has some non-aromatic bands. The n.m.r. spectra of the four available, phenyl-substituted benzanthrones are much alike, showing only aromatic hydrogen absorption, and were not decipherable in terms of individual assignments. Therefore, the position of the phenyl substitution could not be confirmed by n.m.r.

The spectrum of the enol **3** in acetone-d_6 has a complex multiplet from δ 8.0–8.8 (3H, aromatic), a complex multiplet from 7.0–7.9 (9H, aromatic). The remaining absorption is an AMX spectrum with $\delta_A = 6.67$ (1H), $\delta_M = 6.14$ (1H), $\delta_X = 5.52$ (1H), $J_{AM} = 9$, $J_{AX} = 1.5$, $J_{MX} = 5$ Hz. These do not allow distinction between the two possible allylic systems (12).

Mass Spectra

These spectra were determined by the use of two instruments, both at 7.0 eV, a DuPont-110B, and a Hitachi RMS-4. Four known phenylbenzanthrones and the parent **1** itself, as reference samples, were examined. Although the pure substances gave similar fragmentation patterns (Table 3) the relative intensities were not sufficiently different to permit their identification when they were components of a reaction mixture. All the phenylbenzanthrones are alike, except the 6-phenyl derivative **2**, which shows a fragment ion (100% at M − 1); this can be attributed to a linking with the adjacent carbonyl oxygen. A fragment at M − 28 is present in all; in this respect these ketones resemble 1-phenyl-9,10-anthraquinones (13). The fragmentation pattern of benzanthrone below 202 is entirely different from that of pure fluoranthene ($C_{16}H_{12}$).

The silated carbinol **8** gives a molecular ion at *m/e* 380 (14%) M, and fragment ions at 307 (1%) M − $(CH_3)_3Si$, 303 (100%) M − C_6H_5, 291 (15%), 289 (17%), 287 (5%), and 73 (32%) $(CH_3)_3Si$.

The enol acetate (7-acetoxy-6-phenyl-6-benz[*de*]anthracene (**4**) gives a molecular ion at *m/e* 350 (22%) M, and fragment ions at *m/e* 308 (44%) M − CH_2CO, 307 (61%) M − CH_3CO, 305 (72%) M − COOH, 291 (100%) M − $OCOCH_3$, 231 (83%), 202 (28%), and 43 (7%) CH_3CO.

The silyl derivative of the unknown substance, from the run in which phenylmagnesium chloride was "activated" with cobaltous chloride, gives a molecular ion at *m/e* 374 (80%) M, and fragment ions at 359 (40%) M − CH_3, 284 (100%) M − 90 (*i.e.*, M − $HOSi(CH_3)_3$), 256 (80%) M − 188 (loss of CO here), 215 (35%), and 73 (40%) $(CH_3)_3Si$. This is a reasonable fragmentation process for a silated derivative of a substance having the structure **9**. A partial interpretation of these observations suggests that the solvent, THF, has entered into one of the reaction products (14).

Gas Chromatography

A Barber–Colman 5000 instrument equipped with a flame ionization detector, and either an 8 ft × 1–8 in., 10% OV-1, or 4 ft, 5% Apiezon L on Chromosorb W-AWDMCS treated support, at 300 ISO, were used for all analyses. Relative retentions on either column were similar. Quantitative calculations (Tables 1, 2) were based on percentages of the volatiles, and response factors were assumed constant.

Although the reaction products were highly colored, sticky gums or hard waxes, from which, in most instances only a single crystalline component could be isolated, application of g.c. gave useful chromatograms, from which it was possible to calculate the area % of the components.

The four main fractions found in the Grignard runs were 3-phenyl- and 6-phenyl-benzanthrones, the enol of the latter, and unreacted benzanthrone. However, the lithium and cobalt runs (*383*, *385*, *398*) contained carbinols, which were estimated as their silated derivatives. Their structures were deduced by interpreting the i.r. and mass spectra. The new component **9** involving the solvent, THF, and present to the extent of about 14%, also trapped as a silated derivative, appears in the column of unknowns (*cf. 385*).

Thin-layer Chromatography

T.l.c. was of limited use. Most of the ketones were indistinguishable (had similar R_f values) on silica or alumina; the spots moved only half as fast on the latter. The solvent was benzene–chloroform, 3:1. The spot for 6-phenyl-benzanthrone (**2**), when illuminated by u.v. light (15) was brown, and masked most of the others.

(II) Preparation of Materials

Ten grams of benzanthrone (Aldrich, B 260), or Eastman's 7*H*-benz[*de*]anthracene-7-one, were recrystallized from a mixture of 70 ml of *o*-dichlorobenzene and 3.2 g of Norite, by boiling gently for 5 min and filtering through a folded filter. Alternatively, by the use of a large Soxhlet apparatus, an intimate mixture of 3 g of benzanthrone and 2 g of Norite, plus some scraps of filter paper, in the cup, was refluxed for 2 h; caking usually occurred in the bottom of the cup, and some product separated in the flask. The benzanthrone was lighter colored, and, after drying in an oven, melted at 175–176°, but the amount per run was limited to that stated. The product from dichlorobenzene was darker colored, m.p. 173–174°. Either way, the air-dried product was heated for 1 h in an oven at 93–95° before use. Other solvents (chlorobenzene, *p*-cymene, acetic or trifluoroacetic acids, dimethylformamide, and THF) were less satisfactory. 2-, 3-, and 10-Phenylbenzanthrones were prepared as given in the literature (23, 3, 24). Phenylmagnesium chloride was Fisher's (Certified reagent in THF, lot 765 225). THF was dried over sodium; air and nitrogen was bubbled through concentrated sulfuric acid. Melting points were determined on a Fisher–Johns block.

(III) The Grignard Reaction

The standardized procedure, adopted after several exploratory runs, using the usual type of apparatus, and swept with nitrogen follows: to a mixture of 25 ml of THF and 12 ml (3 equiv) of the phenylmagnesium chloride, was added 2.3 g (0.01 mol) of benzanthrone, rinsing in any adhering solid with 5 ml of THF. The solution turned a deep brown, but very little heat was evolved; the color was nearly black after 0.5 h. After the mixture had been refluxed for 1.5 h, the flask was cooled. A mixture of 6 ml of acetic acid and 16 ml of water, added cautiously at first, gave two layers. The organic solution was separated and the solvent removed. The sticky residue was taken up in chloroform and distilled with steam as long as any biphenyl (~2 g) came over.

The insoluble portion was taken up in a little chloroform. For g.c. estimation, an aliquot was dried over anhydrous calcium chloride, filtered, and the solvent evaporated; the residue was used directly or silated. To obtain the 6-phenylbenzanthrone (**2**) for further use, the insoluble residue after steam distillation was allowed to stand with a little acetone. Much of the product **2** soon crystallized; a second or even third crop might be obtained; this was followed by the enol **3**, although the separation was not sharp. Ether and methanol were helpful for removing the enol. Ether, ethyl acetate, acetone, benzene, and acetic acid were employed for recrystallization of **2**; the acid was preferred for large amounts, and acetone for small.

If the enol, which at first was isolated fortuitously, is desired, it is preferable to use a 2:1 ratio (*386*). It accumulated in the last fractions and was recrystallized from methanol; m.p., 146–147°.

Anal. Calcd. for $C_{23}H_{19}O$: C, 89.6; H, 5.8. Found: C, 89.8; H, 5.7.

The enol **3** is very readily converted to the ketone **2** (*a*) on simple standing at room temperature, and (*b*) fairly rapidly in most warmed solvents.

To show that the area percents from g.c. are reasonably similar to practical results the comparison (*379*) was made. The hard, colored residue (total weight, 3.35 g) was warmed with 6 ml of boiling acetone, the solution decanted, and the solid residue rinsed with two 4-ml portions of this solvent, followed by 6 ml of hot methanol. The residual solid (1.58 g) had a melting point of 184–185°. The acetone solution left a sticky pitch, which, after a hot ether extraction, left an additional 0.1 g of the same ketone, m.p. 183–184°, (total, 1.6 g 50%). This is in justifiable agreement with the g.c. estimation of 54.2%. It indicates that the use of results from the g.c. area percents are logical figures, and can be usefully employed.

The enol acetate **4** was prepared from 1 g of the mixture (*386*), by stirring it with 5 ml of acetyl chloride, decanting from insoluble material and allowing to cool. The crude ester was recrystallized twice, by boiling with propyl alcohol; it separated very rapidly on cooling. The pearly, yellow acetate melts at 168–169°, with very marked decomposition at 172–173°.

Anal. Calcd. for $C_{25}H_{18}O_2$: C, 85.7; H, 5.1. Found: C, 85.7; H, 5.4.

The insoluble portion, as well as residues from two recrystallizations were mixtures of the ketone **2**, and a trace of unchanged benzanthrone, identified by mixture melting points and t.l.c.

(IV) Effects of Copper and Cobalt Salts

These were employed for their possible catalytic property, *e.g.*, CuCl (5, 16) in *384* and *399*, and $CoCl_2$ (17) in *385* and *385R*. With 0.02 g of $CoCl_2$ (the hydrated reagent was allowed to stand for 10 min with 10 ml of acetyl chloride and the liquid was decanted) the residual, blue solid was rinsed into the reaction flask with 25 ml of THF, in portions. In a repeat (*385R*) of this run, with double the amount of $CoCl_2$, the phenylmagnesium chloride was inadvertently admitted last; this markedly affected the respective yields. There was no reaction with the copper and cobalt solutions by themselves, showing that the Grignard reagent was needed; this indicated that some sort of an intermediate was involved (17).

(V) Phenyllithium

This was prepared by the standard procedure (18), using 1.2 g of lithium, 90 ml of dry ether, and 12.4 g of bromobenzene (dried by distillation), to obtain 3 equiv of the reagent. To this with stirring was added, in two portions, 4.6 g of benzanthrone (0.02 mol); the second portion caused the brownish solution to boil. This was followed by 30 ml of THF, whereupon the solution became purple; all the solid dissolved without external heating, and a purple scum was formed. The ether was boiled off (10 min) on the steam bath, and the clear, dark brown solution was refluxed for 2 h without stirring. After cooling, a mixture of 5.5 ml of acetic acid and 13 ml of water was carefully added; the reaction was vigorous. The upper, ether layer was separated and distilled with steam; the residual black mass hardened. The solid from an acetone solution dispersed over silica gel (21, 22) was introduced into the top of a stainless steel column, and eluted with ligroine (b.p. 63–75°). The colored layer moved

about two-thirds of the way down the column and stopped; the colorless eluate contained 1.8 g of crude tan hydrocarbon, m.p. 142–145°. Upon recrystallization from absolute alcohol, 0.6 g (m.p. 147–148°) was recovered. It was then purified by several thin layer purifications, scraping off the bluish-green (finally, blue) areas (following by u.v. light), and extracting each time with hexane until the m.p. was 155.5–156°; the analytical sample melted at 156.5°.

Anal. Calcd. for $C_{23}H_{16}$: C, 94.5; H, 5.5. Found: C, 94.6; H, 5.8.

Both solid and solutions in hexane, benzene, and absolute alcohol showed a blue fluorescence. In t.l.c. it gives a bright blue band on SiO_2 that moves with the solvent front (visible in u.v. light only). It did not form a picrate.

With the hope of isolating additional hydrocarbon, 1.5 g of accumulated residues from previous runs (C_6H_5Li, Cu^+ (19, 20)) were chromatographed, using Al_2O_3. By employing hexane as the eluent, a faintly colored band, which was easily visualized by the u.v. light, slowly moved down the column. In this way, the hydrocarbon was free from the otherwise persistent 6-phenylbenzanthrone (**2**). The yield was 5 mg, m.p. 155–156°.

An orange band was now eluted, employing a 3:1 benzene–chloroform mixture. The fractions were concentrated, in which a few orange needles separated. After warming with ethyl formate, additional solid crystallized, m.p. 203–204°, yield 2 mg. The substance appears to be an isomeric *x*-phenylbenzanthrone, (*x* probably = 4).

The carbinol **9** was detected only in the unsilated runs (in the absence of copper), because it was very easily transformed into the hydrocarbon **7**, as already mentioned. Trapped samples, collected by g.c., were used for structure determination (i.r., mass spectrometry).

The formation of so many products from the reactants in THF solution can be expected in view of the numerous reactive species present, and is evident from the multicolored chromatogram on silica gel (22 bands).

The author takes pleasure in acknowledging the technical assistance of specialists Messrs. J. Edwards, M. Glogowski, and J. Lugert, for the g.c., (Miss) T. Davis, J. Robertson, and C. Warburton for the i.r., D. Maier for the mass spectrometry, D. Bush for the u.v., T. H. Regan for the n.m.r., and D. F. Ketchum for the microanalyses.

Base-catalyzed Degradations of Carbohydrates. III. Formation of a Novel Perester from 1-*O*-Acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose[1]

G. O. ASPINALL,[2] R. R. KING, AND ZOFIA PAWLAK[3]

Department of Chemistry, Trent University, Peterborough, Ontario

Received July 21, 1972

1-*O*-Acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**1**) reacts with *m*-chloroperbenzoic acid to give a novel perester, which has been assigned the structure 1,2-*O*-(1′-*m*-chloroperbenzoyloxyethylidene)-2-methoxy-4,6-di-*O*-methyl-α-D-glucopyranose (**2**), on the basis of spectral data and chemical degradation. The perester **2** and the derived acetate **3** undergo oxidative degradation on treatment with trifluoroacetic acid to give 3,5-di-*O*-methyl- (**4**) and 2-*O*-acetyl-3,5-di-*O*-methyl-D-arabinonolactone (**5**), respectively. Reductive decomposition of the acetylated perester **3** yields 1,3-di-*O*-acetyl-4,6-di-*O*-methyl-α-D-*arabino*-hexopyranosulose (**6**), which, on treatment with acetic anhydride in pyridine, gives successively 1,2,3-tri-*O*-acetyl-4,6-di-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**7**), 2-*O*-acetyl-1-deoxy-4,6-di-*O*-methyl-α-D-*erythro*-hex-1-enopyranose-3-ulose (**8**), and 5-acetoxy-2-(methoxymethyl)-4*H*-pyran-4-one (**9**).

Le *O*-acétyl-1 déoxy-3 tri-*O*-méthyl-2,4,6 α-D-*erythro*-hexeno-2 pyranose (**1**) réagit avec l'acide *m*-chloroperbenzoïque pour conduire à un perester nouveau auquel a été attribuée la structure *O*-(*m*-chloroperbenzoyloxy-1 éthylidène)-1,2 méthoxy-2 di-*O*-méthyl-4,6 α-D-glucopyranose (**2**), sur la base des données spectrales et dégradation chimique. Le perester **2** et le dérivé acétate **3** subissent une dégradation oxydante par traitement à l'acide trifluoroacétique qui conduit respectivement au di-*O*-méthyl-3,5 (**4**) et *O*-acétyl-2 di-*O*-méthyl-3,5 D-arabinonolactone (**5**). La décomposition du perester acétylé **3** par réduction mène au di-*O*-acétyl-1,3 di-*O*-méthyl-4,6 α-D-*arabino*-hexopyranosulose (**6**) qui, après traitement à l'anhydride acétique dans la pyridine, conduit successivement aux tri-*O*-acétyl-1,2,3 di-*O*-méthyl-4,6 α-D-*erythro*-hexeno-2 pyranose (**7**), *O*-acétyl-2 déoxy-1 di-*O*-méthyl-4,6 α-D-*erythro*-hexeno-1 pyranose ulose-3 (**8**), et acétoxy-5 (méthoxyméthyl)-2-4*H*-pyranone-4 (**9**).

[Traduit par le journal]

Can. J. Chem., **51**, 388 (1973)

3-Deoxyhex-2-enopyranoses, which are formed on alkaline degradation of 2,3-di- and higher *O*-substituted hexopyranoses, and their derivatives (1–4) are very susceptible to degradation by acid. The possible formation, by oxidation of 3-deoxyhex-2-enopyranoses, of γ-pyrones as chemically stable derivatives has been explored. 2,3,4,6-Tetra-*O*-methyl-D-glucose was chosen as an appropriate model compound for a reducing sugar so that the fate of all substituents during the transformations might be studied.

3-Deoxy-2,4,6-tri-*O*-methyl-D-*erythro*-hex-2-enopyranose (1, 2), formed on alkaline degradation of 2,3,4,6-tetra-*O*-methyl-D-glucose, was treated with acetic anhydride to give the 1-acetate **1** having the α-D-configuration. When the unsaturated sugar acetate was treated with *m*-chloroperbenzoic acid in ether a crystalline compound separated. Although this substance was relatively unstable and decomposed on prolonged standing at room temperature, a satisfactory elemental analysis was obtained for a perester of molecular formula $C_{18}H_{23}O_9Cl$ and for which structures **2**, **2***a*, and **2***b* were considered (see Scheme 1). The i.r. spectrum of the compound showed an hydroxyl band and a single carbonyl band at 3600 and 1760 cm^{-1}, and the n.m.r. spectrum showed the presence of an aromatic ring, three methoxyl groups, and a methyl group (τ 8.15) of an acetate or modified acetate. The perester furnished a syrupy monoacetate (**3**) whose n.m.r. spectrum showed an incompletely resolved doublet (τ 4.72, $J_{3,4}$ = 1.1 Hz), attributable to H-3. In the light of subsequent chemical transformations which established the D-*arabino* configuration at C-3 to -5, the n.m.r. spectrum was characteristic of a 1,2-*O*-alkylidene

[1]Presented in part at the Canadian Chemical Conference of the Chemical Institute of Canada, Halifax, Nova Scotia, May 31–June 2, 1971.

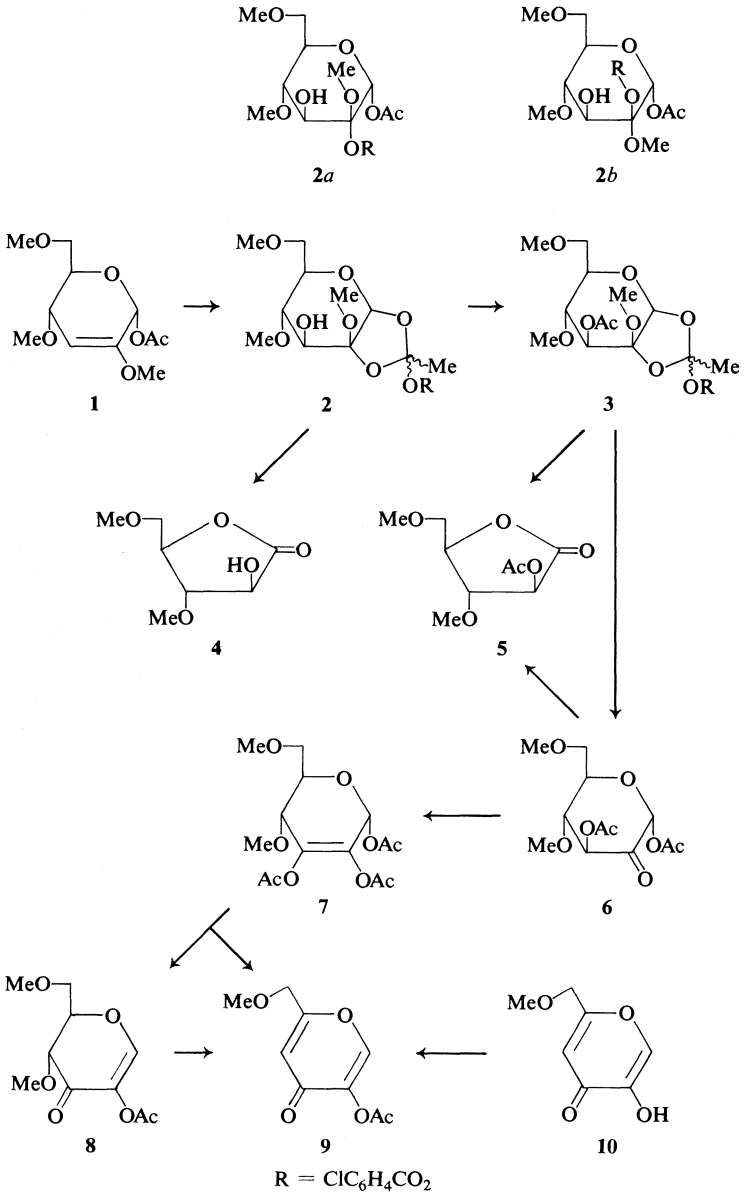
[3]On leave (1969–1970) from the Department of Organic Chemistry, University of Warsaw, Warsaw, Poland.



SCHEME 1

derivative having a skew–boat conformation (5–8). The mass spectra of the perester and its monoacetate **3** showed no molecular ions, but prominent fragment ions corresponded to loss of *m*-chlorobenzoylperoxy groups (*m/e* 263 and 305, respectively) and to the formation of *m*-chlorobenzoic acid (*m/e* 156 and 158) and species derived therefrom.

The presence of a peracid group in compound **2** was first suggested when treatment with trifluoroacetic acid resulted in oxidative degradation and the isolation of 3,5-di-*O*-methyl-D-arabinonolactone (**4**). The acetylated perester **3** likewise on treatment with trifluoroacetic acid underwent oxidative degradation to give 2-*O*-acetyl-3,5-di-*O*-methyl-D-arabinonolactone (**5**), whose structure was confirmed by its formation on acetylation of the lactone **4**. These parallel reactions indicate that the 3-hydroxyl group in the perester does not appear to participate in

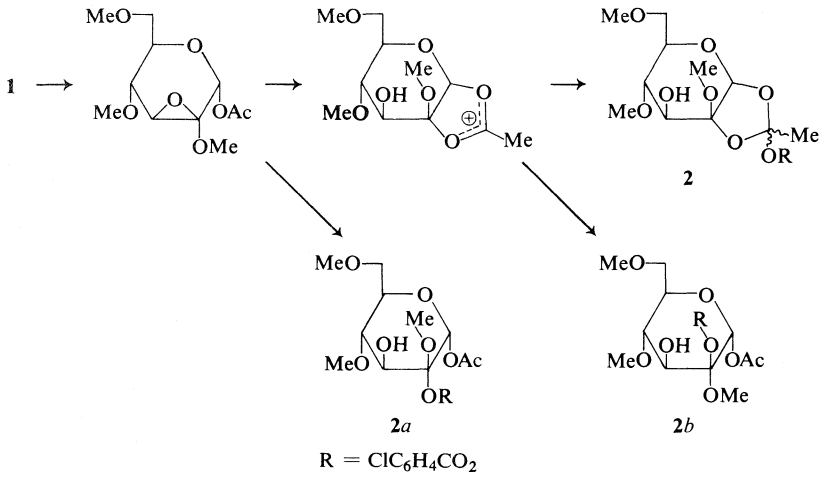
the oxidative degradation (9, 10); furthermore, no products from C_2–C_3 cleavage were detected.

Direct evidence for the peracid function was obtained by estimation of active oxygen by treating the perester **2** with potassium iodide – acetic acid in acetone (11), the decomposition also leading to a nearly quantitative recovery of *m*-chlorobenzoic acid. Treatment of the acetylated perester **3** with zinc dust in acetic acid furnished 1,3-di-*O*-acetyl-4,6-di-*O*-methyl-α-D-*arabino*-hexpyranosulose (6), whose n.m.r. spectrum showed *inter alia* a one-proton doublet (τ 4.56, $J_{3,4}$ = 16.3 Hz) which may be assigned to H-3 in confirmation of the D-*arabino* configuration. Reaction of the glycosulose **6** with acetic anhydride in pyridine at room temperature gave a syrupy enediol acetate, 1,2,3-tri-*O*-acetyl-4,6-di-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**7**), whose structure was supported by the detection of a molecular ion peak (*m/e* 332) in the mass spectrum, the presence of an enol ester band at 1780 cm^{-1} in the i.r. spectrum, and the appearance in the n.m.r. spectrum of a new acetate signal, the disappearance of the H-3 signal, and the appearance of the H-4 signal as a doublet (τ 5.57, $J_{4,5}$ = 15 Hz). The enediol acetate **7** when heated with acetic anhydride, yielded the enediolone acetate derivative, 2-*O*-acetyl-1-deoxy-4,6-di-*O*-methyl-α-D-*erythro*-hex-1-enopyranose (**8**), and, on prolonged heating, the kojic acid derivative, 5-acetoxy-2-(methoxymethyl)-4*H*-pyran-4-one (**9**). The structure of the latter compound was confirmed by its formation on acetylation of 5-hydroxy-2-(methoxymethyl)-4*H*-pyran-4-one (monomethylkojic acid (**10**) (12)).

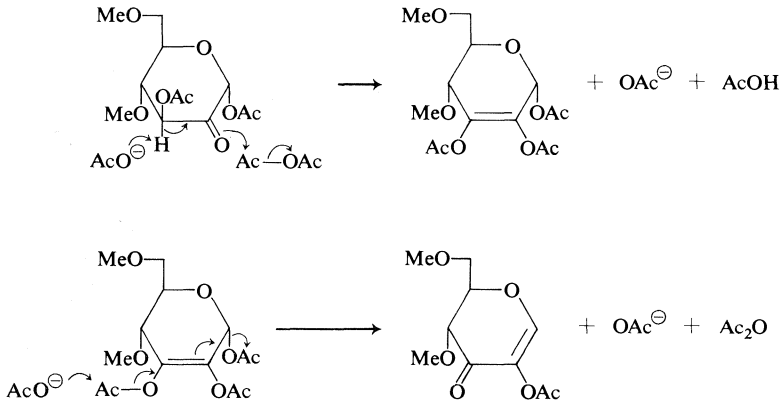
The observations in this and the following paper (13) indicate that oxidation of derivatives of 3-deoxy-hex-2-enopyranoses does not provide a simple route to the formation of γ-pyrones. Special comment, however, may be made on the structure of the novel perester **2**, and on the transformation of glycosuloses into γ-pyrones. Since hydroxy peresters, formed *via* epoxides, have been postulated as intermediates in the reaction of *m*-chloroperbenzoic acid with cyclic enol ethers (9, 10), structure **2***a* was first considered for the perester. However, the 3-hydroxyl group does not participate in the oxidative degradation of the perester as shown by the conversion of the hydroxy perester and its acetylated derivative, when treated with trifluoroacetic acid, into the lactones **4** and **5** respectively. Since reaction of glycosulose **6** with *m*-chloroperbenzoic acid in trifluoroacetic acid resulted in formation of the lactone **5**, it is probable that reaction of the peresters **2** and **3** with trifluoroacetic acid proceeds by hydrolysis of the ketal function, followed by intermolecular oxidation of the derived glycosulose with the liberated peracid.

We may consider here three possible structures for the perester and Scheme 2 indicates possible pathways in which reaction of the hex-2-enopyranose **1** with *m*-chloroperbenzoic acid affords a 2,3-anhydro-2-methoxy-D-*manno*-derivative as an intermediate. It is shown in the following paper (13) that the corresponding 2,3-anhydro-2-methoxy-D-*allo*-derivative does not react further with *m*-chloroperbenzoic acid. The formation of a perester of structure **2***a* by direct opening of the D-*manno*-epoxide with peracid as an external nucleophile appears unlikely. On the other hand epoxide opening by the neighboring 1-acetoxy group would give an intermediate cyclic acetoxonium ion which could react with further peracid to give a perester of structure **2** if attack took place at C-1′ or of structure **2***b* by attack at C-2. The bicyclic structure **2** for the perester is assigned since only a single carbonyl band at 1760 cm^{-1} is observed in the i.r. spectrum whereas the acetylated derivative **3** shows two bands at 1770 and 1740 cm^{-1} assignable to perester and acetate groups. More importantly the signal in the p.m.r. spectrum assigned to H-3 in the acetylated derivative is characteristic of those of H-3 in other 1,2-*O*-alkylidene-α-D-glucopyranose derivatives where ring fusion results in distortion of the pyranose ring from a chair to a skew-boat conformation (5–8). In contrast, the n.m.r. parameters for two 2,2′-di-*O*-substituted hexopyranose derivatives, which are reported in the following paper (13), indicate that both compounds exist in undistorted $^4C_1$ conformations. There is at present no experimental evidence concerning the configuration at C-1′ of the oxyethylidene group.

The overall conversion of glycosuloses into derivatives of kojic acid (14) involves eliminations of the 1-*O*- and 4-*O*-substituents, and migration of the keto function from C-2 to -3. For any particular transformation the sequence in which these steps occur will be governed in part by the nature of the leaving groups in the β-eliminations. In a recent study Lichtenthaler and Heidel (15) have isolated an intermediate enolone acetate in the formation of kojic acid in which the first step involves the elimination of the 4-*O*-substituent. Enediol derivatives have been postulated as intermediates in the migration



SCHEME 2



SCHEME 3

of the keto function (16), but have not previously been detected. In the present investigation an enediol acetate, **7**, has been characterized as the first product in the conversion of the glycosulose **6** into the γ-pyrone **9**. Generation of the 3-keto function and elimination of the 1-*O*-substituent take place with the formation of the enediolone **8**. The second elimination involving loss of the 4-*O*-substituent, in this case methoxy, a poor leaving group, does not take place readily. A possible mechanism for the conversion of glycosulose **6** via enediol acetate **7** into enolone acetate **8** is shown in Scheme 3.

Experimental

Melting points are uncorrected and were determined on a Kofler hot-stage microscope. Optical rotations were measured in chloroform solution with a Perkin–Elmer model 141 polarimeter at room temperature. The i.r. spectra as films or in Nujol mulls and u.v. spectra in ethanol solution were determined on Unicam SP 200 and 800A spectrophotometers. The n.m.r. spectra were recorded on a JEOL C-60HL spectrophotometer in deuterochloroform with tetramethylsilane as internal standard. Mass spectra were recorded on an A.E.I. MS 12 mass spectrometer. Plates for t.l.c. were prepared with Kieselgel GF 254 (Merck) as adsorbent, and the dried plates were sprayed with ethanolic 5% sulfuric acid. Light petroleum refers to the fraction of b.p. 40–60°. Solutions were concentrated below 50° under reduced pressure. Microanalyses were determined by A. B. Gygli, Toronto, Ontario, and by F. and E. Pascher, Bonn, West Germany.

*1-O-Acetyl-3-deoxy-2,4,6-tri-O-methyl-α-D-erythro-hex-2-enopyranose (**1**)*

3-Deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (1, 2) (0.8 g) was treated with acetic anhydride (4 ml) in pyridine (10 ml) for 18 h at 0° and 6 h at room temperature. The reaction mixture was poured into ice-water (150 ml), the solution was extracted with chloroform, and the extract was washed with sodium hydrogen

carbonate solution, dried, and concentrated. The residue was crystallized from ether–pentane to give 1-*O*-acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**1**) (0.5 g, 52%), m.p. 71–72°, $[\alpha]_D$ +45° (*c*, 1.0); ν_{max} 1735 (ester C=O), 1670 cm^{-1} (C=C); n.m.r. τ 3.91 (one-proton singlet, H-1), 5.04 (one-proton doublet, $J_{3,4}$ = 2 Hz, H-3), 6.44 (three-proton singlet, OCH_3), 6.62 (six-proton singlet, 2 × OCH_3), 7.90 (three-proton singlet, $OCOCH_3$).

Anal. Calcd. for $C_{11}H_{18}O_6$: C, 53.65; H, 7.28. Found: C, 53.76; H, 7.29.

1,2-O-(1'-m-Chloroperbenzoyloxy-ethylidene)-2-methoxy-4,6-di-O-methyl-α-D-glucopyranose (2)

The acetate **1** (0.38 g) was added to a cooled solution of *m*-chloroperbenzoic acid (0.34 g) in ether (3 ml) and the solution was kept at room temperature for 3 h and at 0° for 18 h. The crystals which separated were removed by filtration, washed with ether to remove peracid and *m*-chlorobenzoic acid, and recrystallized twice from ether to give the perester **2** (0.32 g, 48%), m.p. 123–124°; ν_{max} 3600 (OH), 1760 cm^{-1} (perester C=O); n.m.r. τ 2.12–2.73, (four aromatic protons), 4.43 (one-proton singlet, H-1), 6.60 (nine-proton singlet, 3 × OCH_3), 8.13 (three-proton singlet, C—CH_3). The supernatant liquid was washed with sodium sulfite (until the washings gave a negative reaction with starch–iodide paper), sodium hydrogen carbonate, and water, dried, and concentrated. Crystallization of the residue from ether afforded further perester **2** (0.08 g, 12%), m.p. 122–123°, $[\alpha]_D$ −14° (*c* 1.0). The same product was obtained when the oxidation was performed in dioxan or dichloromethane. T.l.c. showed that complete disappearance of starting material occurred only when 2 molar proportions of oxidant were used.

Anal. Calcd. for $C_{18}H_{23}O_9Cl$: C, 49.76; H, 5.29; Cl, 8.06. Found: C, 49.49; H, 5.16; Cl, 8.11.

The mass spectrum showed no molecular ion but prominent peaks were detected at *m/e* 263 (M − $ClC_6H_4CO_3$), and 156 and 158, and 139 and 141 (isotope pairs). Active oxygen in the perester **2** was estimated by degradation with potassium iodide – acetic acid in acetone solution followed by titration of liberated iodine with sodium thiosulfate (11). The value was 5% in excess of that calculated in the basis of the proposed structure. In addition, a virtually quantitative yield of *m*-chlorobenzoic acid (identified by m.p., mixed m.p., and i.r. spectrum) was obtained.

3-O-Acetyl-1,2-O-(1'-m-chloroperbenzoyloxy-ethylidene)-2-methoxy-4,6-di-O-methyl-α-D-glucopyranose (3)

The perester **2** (0.3 g) was kept in acetic anhydride (2 ml) and pyridine (5 ml) overnight at room temperature. The reaction product was poured into ice-water (50 ml), the solution was extracted with chloroform, and the extract was washed, dried, and concentrated to give syrupy acetylated perester **3** (0.26 g), which was homogenous on t.l.c., but was insufficiently stable for satisfactory elemental analysis; ν_{max} 1770 (perester C=O), 1740 cm^{-1} (acetate C=O); n.m.r. τ 2.14–2.73 (four aromatic protons), 4.45 (one-proton singlet, H-1), 4.62 (incompletely resolved one-proton doublet, splitting 1.1 Hz), 6.43, 6.63, 6.76 (three-proton singlets, 3 × OCH_3), 7.88 (three-proton singlet, $OCOCH_3$), 8.10 (three-proton singlet, C—CH_3). The mass spectrum showed no molecular ion but prominent peaks were detected at *m/e* 305 (M − $ClC_6H_4CO_3$), and 156 and 158, and 139 and 141 (isotope pairs).

Degradation of Perester 2 in Trifluoroacetic Acid

The perester **2** (0.44 g) was kept in trifluoroacetic acid – water (9:1, 5 ml) at room temperature for 30 min. The solution was concentrated, the residue was dissolved in ethanol, and the solution was neutralized by shaking with Amberlite resin IR-45 (OH) and concentrated. The resulting syrup crystallized from toluene to give 3,5-di-*O*-methyl-D-arabinonolactone (**4**) (0.12 g, 67%), m.p. 71°, $[\alpha]_D$ +48° (*c*, 1.0), whose i.r., n.m.r., and mass spectra were identical to those of the L-enantiomer.

Degradation of Acetylated Perester 3 in Trifluoroacetic Acid

The acetylated perester **3** (0.3 g) was kept in trifluoroacetic acid – water (9:1, 5 ml) at room temperature for 30 min. The reaction mixture was worked-up as described above and the product crystallized from ether–pentane to give 2-*O*-acetyl-3,5-di-*O*-methyl-D-arabinonolactone (**5**) (0.11 g, 58%), m.p. 53°, $[\alpha]_D$ +27° (*c*, 1.0); ν_{max} 1800 (γ-lactone), 1750 cm^{-1} (acetate C=O); n.m.r. τ 4.56 (one-proton doublet, $J_{2,3}$ = 7 Hz, H-2), 6.59 (six-proton singlet, 2 × OCH_3) 7.81 (three-proton singlet, $OCOCH_3$); M^+, 218.

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.53; H, 6.42. Found: C, 49.49; H, 6.47.

The lactone **4** (0.12 g) was treated with acetic anhydride (2 ml) and pyridine (5 ml) at 0° for 1 h and then at room temperature for 24 h. The reaction product was worked-up in the usual way and crystallization from ether–pentane furnished 2-*O*-acetyl-3,5-di-*O*-methyl-D-arabinonolactone (**5**) (0.08 g), m.p. and mixed m.p. 53° $[\alpha]_D$ +27° (*c*, 1.0 in chloroform), whose i.r., n.m.r,, and mass spectra were indistinguishable from those of the previously isolated sample.

1,3-Di-O-acetyl-4,6-di-O-methyl-α-D-arabino-hexopyranosulose (6)

The acetylated perester (**3**) (1.12 g) in acetic acid (35 ml) was stirred with zinc dust at room temperature until (*ca.* 45 min) t.l.c. (ethyl acetate) indicated that decomposition was complete. Chloroform was added to the reaction mixture, and the solution was filtered, neutralized by washing with saturated aqueous sodium hydrogen carbonate, dried, and concentrated to a residue which crystallized from light petroleum to give the glycosulose **6** (0.394 g, 58%), m.p. 62–63°, $[\alpha]_D$ +47.7° (*c*, 1.3); ν_{max} 1755 cm^{-1} (C=O); n.m.r. τ 3.92 (one-proton singlet, H-1), 4.56 (one-proton doublet, $J_{3,4}$ = 16.3 Hz, H-3), 6.47, 6.57 (three-proton singlets, 2 × OCH_3), 7.76, 7.82 (three-proton singlets, 2 × $OCOCH_3$); M^+, 290.

Anal. Calcd. for $C_{12}H_{18}O_8$: C, 49.65; H, 6.25. Found: C, 49.11; H, 6.36.

Oxidative Degradation of Glycosulose 6 to Lactone 5

Glycosulose **6** (60 mg) in trifluoroacetic acid (10 ml) was treated with *m*-chloroperbenzoic acid (80 mg) for 24 h at room temperature. The reaction mixture was worked-up in the usual way and crystallization from ether–pentane furnished 2-*O*-acetyl-3,5-di-*O*-methyl-D-arabinonolactone (**5**) which was similar (m.p., and i.r. and n.m.r. spectra) to the previously prepared sample.

1,2,3-Tri-O-acetyl-4,6-di-O-methyl-α-D-erythro-hex-2-enopyranose (7)

Glycosulose **6** (310 mg) in acetic anhydride (8 ml) and pyridine (12 ml) was kept at room temperature for 4 h. The mixture was poured into ice-water, neutralized with sodium hydrogen carbonate, and extracted with chloroform. The chloroform solution was concentrated, with pyridine being removed by co-distillation with toluene to give a virtually quantitative yield of crude enediol acetate **7**. A sample of the syrupy product was purified by preparative layer chromatography (ethyl acetate – light petroleum, 1:5) and had $[\alpha]_D$ +34° (*c*, 1.0); M^+, 332; ν_{max} 1780 (enol acetate), 1760 cm^{-1} (acetate); n.m.r. τ 3.55 (one-proton singlet, H-1), 5.57 (one-proton doublet, $J_{4,5}$ = 15 Hz, H-4), 6.54, 6.58 (three-proton singlets, 2 × OCH_3), 7.79, 7.85, 7.89 (three-proton singlets, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.45; H, 5.91.

2-O-Acetyl-1-deoxy-4,6-di-O-methyl-α-D-erythro-hex-1-enopyranose-3-ulose (8)

Enediol acetate **7** (200 mg) was heated in acetic anhydride (8 ml) and pyridine (12 ml) on a boiling-water bath for 6 h. The cooled solution was poured into ice-water, neutralized with sodium hydrogen carbonate, and extracted with chloroform, and the dried extract was concentrated to a syrup, in which t.l.c. indicated the presence of two new compounds. Preparative layer chromatography (ethyl acetate – light petroleum, 2:5) afforded the more labile major component **8** (83 mg, 52%) as a syrup which crystallized from ether – light petroleum and had m.p. 68–70°, and $[\alpha]_D$ +132° (*c*, 1.0); M^+, 230; λ_{max} 266 nm (log ε 4.16); ν_{max} 1760 (acetate), 1690 (C=O), 1630 cm^{-1} (C=C); n.m.r. τ 2.61 (one-proton singlet, H-1), 5.94 (one-proton doublet, $J_{4,5}$ = 17.5 Hz, H-4), 6.32, 6.52 (three-proton singlets, 2 × OCH_3), 7.72 (three-proton singlet, $OCOCH_3$).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13. Found: C, 52.69; H, 6.35.

5-Acetoxy-2-(methoxymethyl)-4H-pyran-4-one (9)

The second component from the above reaction mixture was separated chromatographically as a syrup (14 mg, 10%) which crystallized from light petroleum to give **9**, m.p. 50–51°; M^+, 198; λ_{max} 251 nm (log ε 4.00); ν_{max} 1780 (acetate), 1670 (dienone), 1642 cm^{-1} (C=C); n.m.r. τ 2.12 (one-proton singlet, H-6), 3.53 (one-proton singlet, H-3), 5.73 (two-proton singlet, CH_2), 6.53 (three-proton singlet, OCH_3) 7.17 (three-proton singlet, OCOCH).

Anal. Calcd. for $C_9H_{10}O_5$: C, 54.54; H, 5.09. Found: C, 54.77; H, 5.21.

The hex-1-enopyranos-3-ulose **8** on further treatment with hot acetic anhydride and pyridine furnished the kojic acid derivative **9**. Reaction of 5-hydroxy-2-(methoxymethyl)-4*H*-pyran-4-one (**10**) (12) with acetic anhydride and pyridine afforded the acetate **9**, which was identical (m.p. and mixed m.p., t.l.c., and i.r. and n.m.r. spectra) to the previously isolated sample.

Base-catalyzed Degradations of Carbohydrates. IV. Formation of 2,3-Anhydro-2-methoxy-α-D-allopyranose Derivatives from 3-Deoxy-D-*erythro*-hex-2-enopyranoses

G. O. ASPINALL[1] AND R. R. KING

Department of Chemistry, Trent University, Peterborough, Ontario

Received July 21, 1972

1,4,6-Tri-*O*-acetyl-3-deoxy-2-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**4**) reacts with *m*-chloroperbenzoic acid to give the epoxide, 1,4,6-tri-*O*-acetyl-2,3-anhydro-2-methoxy-α-D-allopyranose (**6**), as the major product together with the perester, 4,6-di-*O*-acetyl-1,2-*O*-(1′-*m*-chloroperbenzoyloxy-ethylidene)-2-methoxy-α-D-glucopyranose (**5**), as a minor product. The structures of these novel compounds have been assigned on the basis of spectroscopic data and of transformations (*i*) to kojic acid diacetate and (*ii*) by oxidative degradations to substituted aldopentonolactones. Further examination of the products of the reaction of 1-*O*-acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**1**) with *m*-chloroperbenzoic acid has shown that the epoxide, 1-*O*-acetyl-2,3-anhydro-2-methoxy-4,6-di-*O*-methyl-α-D-allopyranose (**15**), is formed in addition to the previously characterized perester **2**.

Le tri-*O*-acétyl-1,4,6 déoxy-3 *O*-méthyl-2 α-D-*erythro*-hex-2-énopyranose (**4**) réagit avec l'acide *m*-chloroperbenzoïque pour donner l'époxyde, tri-*O*-acetyl-1,4,6 anhydro-2,3 méthoxy-2 α-D-allopyranose (**6**) comme produit majeur en même temps que le perester di-*O*-acétyl-4,6 (*m*-chloroperbenzoïloxy-éthylidène-1′)-1,2-*O* méthoxy-2 α-D-glucopyranose (**5**) comme un produit mineur. Les structures de ces nouveaux composés ont été assignées sur la base de données spectroscopiques et de transformations (*i*) en diacétate d'acide cojique et (*ii*) par dégradations oxidatives en aldopentono lactones substitués. Un examen plus approfondi des produits de la réaction du acétyl-1-*O* déoxy-3 tri-*O*-méthyl-2,4,6 α-D-*erythro*-hex-2-enopyranose (**1**) avec l'acide *m*-chloroperbenzoïque a montré que l'époxyde, acétyl-1 *O*-anhydro-2,3 méthoxy-2 di-*O*-méthyl-4,6 α-D-allopyranose (**15**) est formé en addition au perester **2** caractérisé précédemment. [Traduit par le journal]

Can. J. Chem., **51**, 394 (1973)

In connection with an attempt to convert 3-deoxy-hex-2-enopyranoses into chemically stable derivatives it was shown that 1-*O*-acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**1**) reacts with *m*-chloroperbenzoic acid to give the novel perester, which has been assigned the structure 1,2-*O*-(1′-*m*-chloroperbenzoyloxy-ethylidene)-2-methoxy-4,6-di-*O*-methyl-α-D-glucopyranose (**2**) (1). In order to study this unusual reaction further, the readily accessible 1,4,6-tri-*O*-acetyl-3-deoxy-2-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**4**) (2) was treated with *m*-chloroperbenzoic acid. Although a perester, 4,6-di-*O*-acetyl-1,2-*O*-(1′-*m*-chloroperbenzoyloxy-ethylidene)-2-methoxy-α-D-glucopyranose (**5**), was formed in small amount, the major product, a crystalline compound isolated in 75% yield, was 1,4,6-tri-*O*-acetyl-2,3-anhydro-2-methoxy-α-D-allopyranose (**6**), a representative of a new class of carbohydrate derivatives (see Scheme 1). We discuss the evidence for the structures of these two compounds and their transformation products and for their mode of formation.

The evidence for the structure of the perester **5** is parallel to that reported for the perester **2** which was described in the preceding paper (1) and for reasons elaborated there the 1,2-*O*-oxyethylidene structure is again preferred over alternative structures. Although the perester **5** was not sufficiently stable for a satisfactory elemental analysis to be obtained, n.m.r. and i.r. spectral data indicated the presence of two acetate groups, retention of the methoxyl group, a *m*-chlorobenzoyl (or *m*-chloroperbenzoyl) substituent, a methyl group, probably as part of an acetate or modified acetate group, and an hydroxyl group. Treatment with acetic anhydride in pyridine furnished a monoacetate (**7**). The n.m.r. signals assigned to H-3 and -4 in the perester **5** and its acetylated derivative **7** were again consistent with the existence of both compounds in the skew–boat conformation favored by 1,2-*O*-alkylidene-α-D-glucopyranose derivatives (3–6). The mass spectra of the peresters **5** and **7** did not show molecular ion peaks, but, as

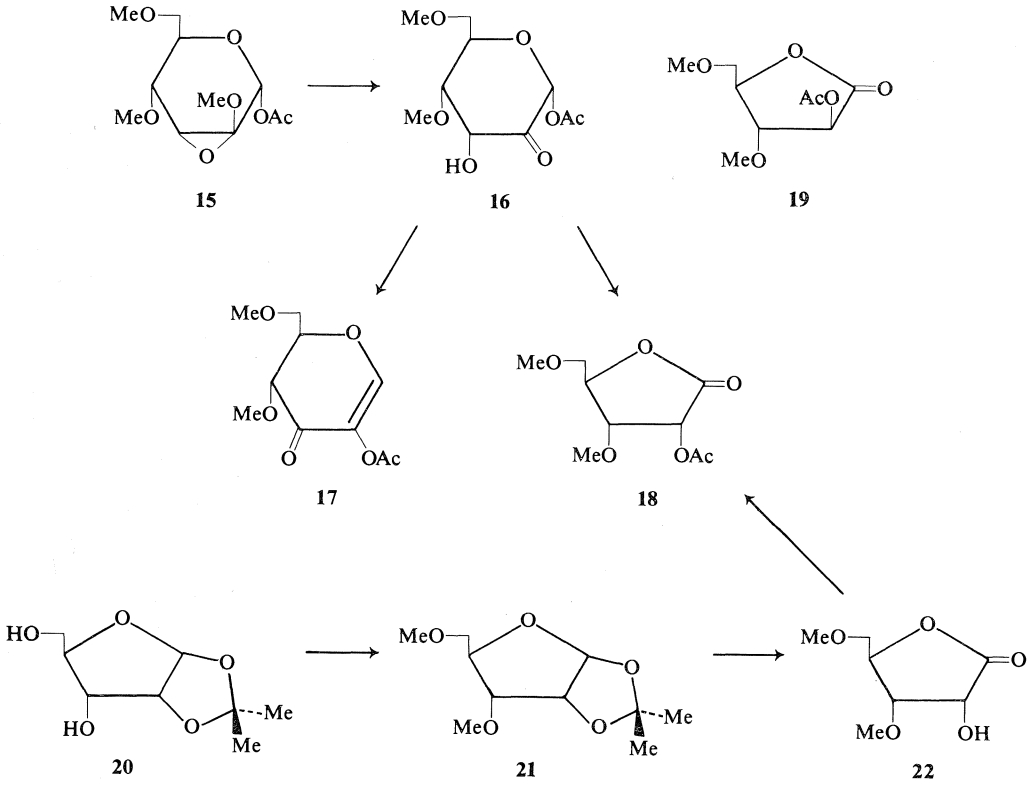
with the previously characterized peresters (**2** and **3**), prominent fragment ions corresponding to the loss of the *m*-chloroperbenzoyloxy group and to the formation of *m*-chlorobenzoic acid and ions derived therefrom were observed. The configuration at C-3 of the acetylated perester **7** was confirmed since the compound underwent oxidative degradation on treatment with trifluoroacetic acid with the formation of 2,3,5-tri-*O*-acetyl-D-arabinonolactone (**8**).

Decomposition of the perester **7** with zinc dust in acetic acid resulted in formation of the enediolone acetate, 2,4,6-tri-*O*-acetyl-1-deoxy-α-D-*erythro*-hex-1-enopyranos-3-ulose (**9**), with some 5-acetoxy-2-(acetoxymethyl)-4*H*-pyran-4-one (kojic acid diacetate (**10**)). The enediolone **9** was converted into kojic acid diacetate (**10**) on treatment with acetic anhydride in pyridine at room temperature. 1,3,4,6-Tetra-*O*-acetyl-α-D-*arabino*-hexopyranosulose is presumably formed as an intermediate in the decomposition of the perester **7** leading to the formation of the enediolone acetate **9** but no such compound was detected. Other workers have isolated kojic acid diacetate (**10**) during attempts to oxidize 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose with methyl sulfoxide – acetic anhydride (7, 8) and with methyl sulfoxide – sulfur trioxide (9). Although more than one pathway is possible for the conversion of 1,3,4,6-tetra-*O*-acetyl-α-D-*arabino*-hexopyranosulose into kojic acid diacetate (**10**), the isolation of the enediolone acetate **9** indicates that elimination of the 1-*O*-substituent occurs more readily than that of the 4-*O*-substituent as proposed by Lichtenthaler and Heidel (7).

The structure of the major product from the reaction of 1,4,6-tri-*O*-acetyl-3-deoxy-2-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**4**) with *m*-chloroperbenzoic acid was assigned as 1,4,6-tri-*O*-acetyl-2,3-anhydro-2-methoxy-α-D-allopyranose (**6**) on the basis of the n.m.r. spectrum in which the magnitudes of $J_{3,4} = 1.8$ and $J_{4,5} = 9.5$ Hz pointed to the 2,3-anhydro-α-D-*allo* configuration (10). Epoxide opening occurred readily with loss of methanol when the anhydro-compound **6** was heated in water. The structure of the product, which was isolated as a crystalline monohydrate, was assigned as 1,4,6-tri-*O*-acetyl-α-D-*ribo*-hexopyranosulose (**11**) on the basis of a one-proton doublet (τ 5.10, $J = 4.8$ Hz) which was attributed to H-3. Attempts to confirm this assignment by conversion of the glycosulose into its acetate failed since treatment with acetic anhydride and sodium acetate at room temperature furnished the previously characterized enediolone acetate **9** and reaction with acetic anhydride in pyridine afforded kojic acid diacetate (**10**). Evidence for the D-*ribo* configuration of the glycosulose **11** was obtained by oxidation with *m*-chloroperbenzoic acid in trifluoroacetic acid which resulted in the formation of 2,3,5-tri-*O*-acetyl-D-ribonolactone (**12**). This interesting reaction appears to involve an intramolecular 1 → 3 *O*-acetyl migration, but there is no evidence to indicate whether this migration takes place in one step or in two successive stages, 1 → 2 and 2 → 3.

The configurational assignments for the 2-methoxy epoxide **6** and the *ribo*-hexopyranosulose **11** imply that ring opening takes place by nucleophilic attack by water at C-2, the electrophilic terminus. In the light of the possible 1 → 3 *O*-acetyl migration which may occur during the above oxidative degradation of the glycosulose **11**, an alternative structure, **6***a*, for the epoxide with the 2,3-anhydro-α-D-*manno* configuration was considered. Intramolecular ring opening involving attack at C-3 and the formation of a cyclic acetoxonium ion would lead to the formation of a D-*ribo*-hexopyranosulose. The n.m.r. parameters for the glycosulose **11** rule out the possibility of acetyl migration during epoxide opening, but collapse of such an acetoxonium ion could also lead to the 1-acetate **11**. The following observations, however, argue against the second mechanism of ring opening and the alternative structure **6***a* for the epoxide. Treatment of the epoxide with acetic acid containing acetic anhydride yielded the tetra-*O*-acetate **13** which on further reaction with acetic anhydride in pyridine afforded the penta-*O*-acetate **14**. The formation of the tetra-*O*-acetate with retention of the ketalically-linked methoxyl group rather than of an unstable hemiketal indicated that ring opening occurred by nucleophilic attack at C-2. The n.m.r. spectra of the tetra-*O*-acetate **13** and the penta-*O*-acetate **14** with small coupling between H-3 and -4 ($J_{3,4}$ = 5–6 Hz) and long-range 'W' coupling between the equatorially oriented H-1 and -3 ($J_{1,3}$ = 2.3–2.8 Hz) clearly indicated the D-*ribo* configuration at C-3 to -5 of both compounds. The formation of these compounds confirms the original assignment of the 2,3-anhydro-α-D-*allo* configuration for the epoxide **6**.

Since the epoxide **6** was the major product from the action of *m*-chloroperbenzoic acid on



SCHEME 2

1,4,6-tri-*O*-acetyl-3-deoxy-2-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**4**), the products of the reaction of the peracid with 1-*O*-acetyl-3-deoxy-2,4,6-tri-*O*-methyl-α-D-*erythro*-hex-2-enopyranose (**1**) were re-examined. Previously no product other than perester **2** had been detected by t.l.c. of the reaction mixture. However, after crystallization of the perester, examination of the mother liquor showed the presence of another product and chromatographic separation led to the isolation of the 2-methoxyepoxide, 1-*O*-acetyl-2,3-anhydro-2-methoxy-4,6-di-*O*-methyl-α-D-allopyranose (**15**). The syrupy compound was insufficiently stable for satisfactory elemental analysis but the i.r., n.m.r., and mass spectra were consistent with the assigned structure. The structure of the epoxide **15** was established by the following transformations which were similar to those undergone by the epoxide **6**. Opening of the epoxide ring took place readily on heating in water to give the glycosulose **16**, which, on treatment with acetic anhydride in pyridine at room temperature, afforded the enediolone acetate **17**. Oxidative degradation of the glycosulose **16** with *m*-chloroperbenzoic acid in trifluoroacetic acid gave 2-*O*-acetyl-3,5-di-*O*-methyl-D-ribonolactone (**18**) in a reaction which again involved intramolecular *O*-acetyl migration. The crystalline lactone **18** was readily distinguishable from the corresponding D-arabinonolactone derivative **19**. The structure of the D-ribonolactone derivative **18** was confirmed by synthesis from 1,2-*O*-isopropylidene-α-D-ribofuranose (**20**) (11, 12) by (*a*) methylation to 1,2-*O*-isopropylidene-3,5-di-*O*-methyl-D-ribofuranose (**21**), (*b*) hydrolysis and oxidation to 3,5-di-*O*-methyl-D-ribonolactone (**22**), and (*c*) acetylation (see Scheme 2).

Two novel classes of compounds have been isolated as products of the oxidation of 3-deoxyhex-2-enopyranoses with *m*-chloroperbenzoic acid. The peresters are most closely related to the 1,2-*t*-butylperoxy orthoesters described by Schulz *et al.* (6) and prepared by the action of *O*-acyl glycosyl halides on *t*-butylhydroperoxide in collidine. Until very recently α-methoxyepoxides remained unknown carbohydrate deriv-

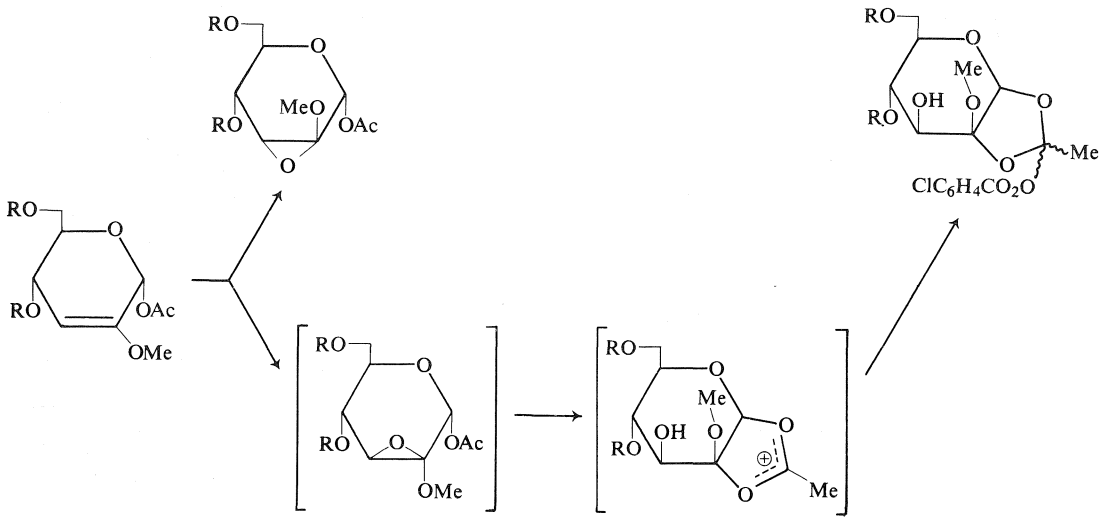

SCHEME 3

atives although an α-benzoyloxy-epoxide was reported 40 years ago by Maurer and Petsch (13). When the present work was nearly completed, Dmytraczenko *et al.* (14) reported the preparation of methyl 2,3-anhydro-4,6-*O*-benzylidene-3-methoxy-α-D-allopyranoside by the action of triethylamine in methanol on methyl 4,6-*O*-benzylidene-2-*O*-toluene-*p*-sulfonyl-α-D-*ribo*-hexopyranosid-3-ulose. The same authors (personal communication) have similarly synthesized the corresponding 2-methoxyepoxide from the 3-*O*-toluene-*p*-sulfonyl glycopyranosid-2-ulose.

In the light of the characterization of both classes of compounds we may turn to the mechanism of their formation on treatment of 3-deoxy-hex-2-enopyranoses with *m*-chloroperbenzoic acid. The 2,3-anhydro-2-methoxy-α-D-allopyranoses are relatively stable insofar as they are not susceptible to further reaction with peracid. In contrast no 2,3-anhydro-2-methoxy-α-D-mannopyranoses were detected. A possible pathway for the formation of the peresters is shown in Scheme 3 in which the α-D-*manno*-epoxide undergoes intramolecular ring opening by the neighboring *O*-acetyl group with formation of a cyclic acetoxonium ion which, in turn, reacts with further *m*-chloroperbenzoic acid. In this reaction scheme there is no clear reason why change of the 4- and 6-*O*-substituents should markedly alter the proportions of the two types of product. It may be noted, however, that whereas epoxidation of *trans*-6-acetoxymethyl-2-methoxy-5,6-dihydro-2*H*-pyran affords approximately equal proportions of methyl 2,3-anhydro-4-deoxy-6-*O*-methyl-α-DL-*lyxo*-hexopyranoside and the *ribo*-isomer (15), similar reaction of *trans*-2-methoxy-6-methoxymethyl-5,6-dihydro-2*H*-pyran gives almost exclusively the corresponding product with the *lyxo*-configuration (16). There is no evidence for the configuration at C-1′ of the oxyethylidene group in the peresters.

Experimental

Experimental procedures were as described in the preceding paper (1).

Oxidation of 1,4,6-Tri-O-acetyl-3-deoxy-2-O-methyl-α-D-erythro-hex-2-enopyranose (4) with m-Chloroperbenzoic Acid

The hex-2-enopyranose (**4**) (2.4 g) was reacted with *m*-chloroperbenzoic acid (2.8 g) in chloroform (150 ml) at room temperature for 3 h. The chloroform solution was washed with 10% sodium carbonate solution (150 ml) and water (100 ml), and concentrated to a residue which crystallized from ether – light petroleum to give 1,4,6-tri-*O*-acetyl-2,3-anhydro-2-methoxy-α-D-allopyranose (**6**) (1.71 g, 68%), m.p. 113–114°, $[\alpha]_D$ +98° (*c*, 1.0); M^+, 318; ν_{max} 1755, 1735 cm^{-1} (ester C=O); n.m.r. τ 3.68 (one-proton singlet, H-1), 5.08 (one-proton quartet, $J_{3,4}$ = 1.8, $J_{4,5}$ = 9.5 Hz, H-4), 6.17 (one-proton doublet, $J_{3,4}$ = 1.8, H-3), 6.73 (three-proton singlet, OCH_3), 7.82, 7.85, 7.94 (three-proton singlet, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{13}H_{18}O_9$: C, 49.06; H, 5.70. Found: C, 48.77; H, 5.65.

The mother liquor from the crystallization was separated by preparative layer chromatography (ethyl acetate – light petroleum 1:5) to give further epoxide **6** (180 mg, 7%) and 4,6-di-*O*-acetyl-1,2-*O*-(1′-*m*-chloroperbenzoyloxy-ethylidene)-2-methoxy-α-D-glucopyranose (**5**) (386 mg, 10%) as a syrup which was too unstable for satis-

factory elemental analysis, $[\alpha]_D$ −4.2° (*c*, 1.0); λ_{max} 232 nm (log ε 4.02); ν_{max} 3700 (OH), 1765 (perester C=O), 1740 (acetate C=O), 1580 cm^{-1} (aromatic); n.m.r. τ 2.08–2.63 (four aromatic protons), 4.37 (one-proton singlet, H-1), 5.09 (one-proton quartet, $J_{3,4}$ = 2.2, $J_{4,5}$ = 6.4, H-4), 5.44 (one-proton doublet, $J_{3,4}$ = 2.2 Hz, H-3), 6.60 (three-proton singlet, OCH_3), 7.89, 7.93 (three-proton singlet, 2 × $OCOCH_3$), 8.09 (three-proton singlet, C—CH_3).

3,4,6-Tri-O-acetyl-1,2-O-(1'-m-chloroperbenzoyloxyethylidene)-2-methoxy-α-D-glucopyranose (7)

Perester **5** (300 mg) was kept in acetic anhydride (5 ml) and pyridine (10 ml) at 0° overnight and at room temperature for 2 h. The reaction mixture was poured into ice-water (100 ml), and the solution was neutralized with sodium hydrogen carbonate, and extracted with chloroform (2 × 75 ml). Concentration of the dried extract furnished the perester acetate **7** as a syrup, $[\alpha]_D$ −3.5° (*c*, 1.0); λ_{max} 233 nm (log ε 4.01); ν_{max} 1765 (perester C=O), 1745 (acetate C=O), 1578 cm^{-1} (aromatic); n.m.r. τ 2.11–2.68 (four-aromatic protons), 4.44 (one-proton singlet, H-1), 4.68 (one-proton doublet, $J_{3,4}$ = 1.8 Hz, H-3), 5.17 (one-proton quartet, $J_{3,4}$ = 1.8, $J_{4,5}$ = 6.8 Hz, H-4), 6.77 (three-proton singlet, OCH_3), 7.88, (six-proton singlet, 2 × $OCOCH_3$), 7.96 (three-proton singlet, $OCOCH_3$), 8.08 (three-proton singlet, C—CH_3). The mass spectrum showed no molecular ion but prominent peaks were detected as *m/e* 361 (M − $ClC_6H_4CO_3$), and 156 and 158, and 139 and 141 (isotope pairs). The compound was too unstable for elemental analysis.

Degradation of Acetylated Perester 7 in Trifluoroacetic Acid

The acetylated perester **7** (75 mg) was kept in trifluoroacetic acid – water (9:1, 10 ml) at room temperature for 30 min. The solution was concentrated, and the residue in chloroform (40 ml) was washed with sodium hydrogen carbonate solution and with water, dried, and concentrated. The residue was recrystallized from ether – light petroleum to give 2,3,5-tri-*O*-acetyl-D-arabinonolactone (**8**) (23 mg), m.p. and mixed m.p. 68–69°, $[\alpha]_D$ +53° (*c*, 1.0) (lit. (17) m.p. 66–69°, $[\alpha]_D$ +52.3°), whose i.r. and n.m.r. spectra were identical with those of a sample prepared from D-arabinose by bromine oxidation, followed by acetylation.

2,4,6-Tri-O-acetyl-1-deoxy-α-D-erythro-hex-1-enopyranos-3-ulose (9)

Acetylated perester **7** (200 mg) in acetic acid (10 ml) was stirred with zinc dust (100 mg) at room temperature for 1 h. Chloroform (50 ml) was added to the reaction mixture, and the filtered solution was washed with saturated sodium hydrogen carbonate solution, dried, and concentrated to a syrup which was separated by preparative layer chromatography. The major component was the syrupy hex-1-enopyranos-3-ulose **9** (83 mg, 77%), $[\alpha]_D$ +156° (*c*, 1.0); M^+ 286; λ_{max} 260 nm (log ε 4.14); ν_{max} 1745 (ester C=O), 1700 (α,β-unsaturated ketone), 1636 cm^{-1} (C=C); n.m.r. τ 2.65 (one-proton singlet, H-1), 4.42 (one-proton doublet, $J_{4,5}$ = 12.5 Hz, H-4), 7.79, 7.84, 7.90 (three-proton singlet, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{12}H_{14}O_8$: C, 50.35; H, 4.93. Found: C, 50.57; H, 5.09.

The minor component was 5-acetoxy-2-(acetoxymethyl)-4*H*-pyran-4-one (kojic acid diacetate (**10**)) (~2 mg) and was identical (m.p. and mixed m.p., i.r. and mass spectra) with a sample prepared from kojic acid. Treatment of the hex-1-enopyranos-3-ulose **9** with acetic anhydride and pyridine at room temperature afforded kojic acid diacetate (**10**).

1,4,6-Tri-O-acetyl-α-D-ribo-hexopyranosulose (11)

A suspension of epoxide **6** (400 mg) in water (25 ml) was warmed on the steam bath until dissolution was complete (*ca.* 5 min). Removal of water and crystallization of the residue from ethyl acetate – light petroleum yielded the glycosulose **11** as a monohydrate (262 mg), m.p. 88–90°, $[\alpha]_D$ −38° (*c*. 1.0); ν_{max} 3660 (OH), 1745, 1718 cm^{-1} (ester C=O); n.m.r. τ 3.67 (one-proton singlet, H-1), 4.57 (one-proton quartet, $J_{3,4}$ = 4.8, $J_{4,5}$ = 2.5 Hz, H-4), 5.10 (one-proton doublet, $J_{3,4}$ = 4.8 Hz, H-3), 6.42 (broad three-proton band, exchanges with D_2O, 3 × OH), 7.84, 7.91, 7.94 (three-proton singlet, 3 × $OCOCH_3$).

Anal. Calcd. for $C_{12}H_{16}O_9.H_2O$: C, 44.72; H, 5.63. Found: C, 45.19; H, 5.85.

Attempted acetylation of the glycosulose **11** (100 mg) with acetic anhydride (5 ml) and sodium acetate (35 mg) at room temperature for 2 h, followed by work-up and preparative layer chromatography (ethyl acetate – light petroleum, 2:5), gave predominantly the hex-1-enopyranos-3-ulose **9** (64 mg) which was identical (i.r., u.v., and n.m.r. spectra) to the sample prepared previously. Alternatively, attempted acetylation of the glycosulose **11** (100 mg) at room temperature for 2 h, followed by work-up and preparative layer chromatography (ethyl acetate – light petroleum, 1:5), gave only 5-acetoxy-2-(acetoxymethyl)-4*H*-pyran-4-one (**10**) (61 mg) which was identical (m.p. and mixed m.p., i.r. and n.m.r. spectra) to a sample prepared from kojic acid.

Oxidative Degradation of Glycosulose (11)

m-Chloroperbenzoic acid (100 mg) was added to glycosulose **11** (100 mg) in trifluoroacetic acid (10 ml) and the solution was kept at room temperature for 2 h. The solution was concentrated under nitrogen and the residue in chloroform (40 ml) was washed with 10% sodium carbonate solution (30 ml) and with water (20 ml). The dried chloroform solution was concentrated and the residue was recrystallized from ether – light petroleum to give 2,3,5-tri-*O*-acetyl-D-ribonolactone (**12**) (38 mg), m.p. and mixed m.p. 55–56°, $[\alpha]_D$ +30° (*c*, 1.0) (lit. (18) m.p. 54–56°, $[\alpha]_D$ +27°), whose i.r., n.m.r., and mass spectra were identical with those of a sample prepared from D-ribose by bromine oxidation, followed by acetylation.

1,2,4,6-Tetra-O-acetyl-2-methoxy-α-D-altropyranose (13)

Epoxide **6** (400 mg) was kept in acetic acid (20 ml) containing acetic anhydride (2 ml) at room temperature until t.l.c. (ethyl acetate – light petroleum, 5:1) indicated that reaction was complete (*ca.* 3 h). The reaction mixture was poured into ice-water (100 ml) and neutralized with sodium hydrogen carbonate, and the solution was extracted with chloroform (2 × 75 ml). Concentration of the dried extract and crystallization of the residue from ether – light petroleum furnished the tetra-*O*-acetyl derivative **13** (285 mg), m.p. 40–42°, $[\alpha]_D$ +92.7° (*c*, 1.5);

ν_{max} 3600 (OH), 1740 cm^{-1} (ester C=O); n.m.r. τ 3.34 (one-proton doublet, $J_{1,3}$ = 2.8 Hz, H-1), 5.03 (one-proton quartet, $J_{3,4}$ = 5.0, $J_{4,5}$ = 16 Hz, H-4), 5.49 (one-proton quartet, $J_{1,3}$ = 2.8, $J_{3,4}$ = 5.0 Hz, H-3), 6.62 (three-proton singlet, OCH_3), 7.27 (one-proton singlet, exchanges with D_2O, OH), 7.85 (six-proton singlet, 2 × $OCOCH_3$), 7.90, 7.96 (three-proton singlet, 2 × $OCOCH_3$).

Anal. Calcd. for $C_{15}H_{22}O_{11}$: C, 47.62; H, 5.86. Found: C, 47.58: H, 5.86.

*1,2,3,4,6-Penta-O-acetyl-2-methoxy-α-D-altropyranose (**14**)*

Tetra-acetate **13** (160 mg) was kept in acetic anhydride (4 ml) and pyridine (6 ml) overnight at 0° and for 4 h at room temperature. Work-up of the reaction mixture in the usual way followed by crystallization from ether – light petroleum afforded the penta-*O*-acetate **14** (112 mg), m.p. 121–122°, $[\alpha]_D$ +91.2° (*c*, 1.0); ν_{max} 1755, 1742 cm^{-1} (ester C=O); n.m.r. τ 3.23 (one-proton doublet, $J_{1,3}$ = 2.3 Hz, H-1), 4.25 (one-proton quartet, $J_{1,3}$ = 2.3, $J_{3,4}$ = 6.0 Hz, H-3), 4.87 (one-proton quartet, $J_{3,4}$ = 6.0, $J_{4,5}$ = 17 Hz, H-4), 6.73 (three-proton singlet, OCH_3), 7.81 (three-proton singlet, $OCOCH_3$) 7.82 (six-proton singlet, 2 × $OCOCH_3$), 7.93, 7.98 (three-proton singlet, 2 × $OCOCH_3$).

Anal. Calcd. for $C_{17}H_{24}O_{12}$: C, 48.57; H, 5.76. Found: C, 48.73; H, 5.75.

*Oxidation of 1-O-Acetyl-3-deoxy-2,4,6-tri-O-methyl-α-D-erythro-hex-2-enopyranose (**1**) with m-Chloroperbenzoic Acid*

Hex-2-enopyranose **1** (2.2 g) was treated with *m*-chloroperbenzoic acid (3.1 g) in chloroform for 3 h at room temperature (t.l.c. in ethyl acetate – light petroleum (2:5) indicated that reaction was complete). The chloroform solution was washed with 10% sodium carbonate solution (150 ml) and then with water (100 ml), dried, and concentrated. Crystallization of the residue from ether–light petroleum furnished perester **2** (1.36 g) which was similar in all respects to the previously isolated sample (1). The mother liquor from the crystallization separated by preparative layer chromatography (ethyl acetate – light petroleum, 3:7) yielded further perester **2** (210 mg) together with 1-*O*-acetyl-2,3-anhydro-4,6-*O*-methyl-2-methoxy-α-D-allopyranose (**15**) (305 mg), $[\alpha]_D$ +82° (*c*, 1.0), as a syrup which was too unstable for elemental analysis; M^+, 292; ν_{max} 1744 cm^{-1} (ester C=O); n.m.r. τ 3.66 (one-proton singlet, H-1), 6.13 (one-proton doublet, $J_{3,4}$ = 1.2 Hz, H-3), 6.50, 6.63, 6.71 (three-proton singlet, 3 × OCH_3), 7.86 (three-proton singlet, $OCOCH_3$). No perester **2** was formed when the epoxide **15** was treated with further *m*-chloroperbenzoic acid.

*1-O-Acetyl-4,6-di-O-methyl-α-D-ribo-hexopyranosulose (**16**)*

A suspension of the epoxide **15** (240 mg) in water (15 ml) was warmed on the steam bath until dissolution was complete (*ca.* 5 min). Removal of water furnished the glycosulose **16** as a syrup, $[\alpha]_D$ −5.5° (*c*, 2.0); M^+, 248; ν_{max} 3580 (OH), 1745 cm^{-1} (broad, C=O); n.m.r. τ 3.67 (one-proton singlet, H-1), 5.11 (one-proton doublet, $J_{3,4}$ = 8.0 Hz, H-3), 6.52 (nine-proton singlet, 3 × OCH_3), 7.81 (three-proton singlet, $OCOCH_3$).

Anal. Calcd. for $C_{10}H_{16}O_7$: C, 48.38; H, 6.50. Found: C, 48.01; H, 6.31.

Attempted acetylation of the glycosulose **16** with acetic anhydride and pyridine at room temperature gave only 2-*O*-acetyl-1-deoxy-4,6-di-*O*-methyl-α-D-*erythro*-hex-1-enopyranos-3-ulose (**17**) which was identical (m.p., mixed m.p., and i.r. spectrum) with the previously isolated sample (1).

*Oxidative Degradation of Glycosulose (**16**)*

Glycosulose **16** (75 mg) in trifluoroacetic acid (10 ml) was treated with *m*-chloroperbenzoic acid (100 mg) at room temperature for 2 h. The solution was concentrated under nitrogen and the residue in chloroform (40 ml) was washed with 10% sodium carbonate solution (30 ml) and with water (20 ml). The dried chloroform solution was concentrated and crystallization of the residue from ether – light petroleum afforded 2-*O*-acetyl-3,5-di-*O*-methyl-D-ribonolactone (**18**) (29 mg), m.p. 54–55°, $[\alpha]_D$ −9.5° (*c*, 1.0); M^+, 218; ν_{max} 1790 (γ-lactone), 1735 cm^{-1} (acetate C=O); n.m.r. τ 4.48 (one-proton doublet, $J_{2,3}$ = 9.0 Hz), 5.85 (one-proton doublet, $J_{2,3}$ = 9.0 Hz, H-3), 6.60, 6.62 (three-proton singlet, 2 × OCH_3), 7.79 (three-proton singlet, $OCOCH_3$).

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.47. Found: C, 49.31; H, 6.91.

5-O-Benzoyl-1,2-O-isopropylidene-α-D-erythro-pentofuranos-3-ulose

5-*O*-Benzoyl-1,2-*O*-isopropylidene-α-D-xylofuranose (19) (2.5 g) in ethanol-free chloroform (250 ml) was added to a mixture of water (200 ml), sodium metaperiodate (20 g), sodium carbonate (1 g), and 51% ruthenium dioxide (10 g). The mixture was stirred vigorously at room temperature overnight, 2-propanol (10 ml) was added, and, after 10 min, the mixture was filtered. The organic layer was separated and the aqueous layer was extracted with chloroform. The combined organic layer and chloroform extract were dried and concentrated to give the pentofuranos-3-ulose (1.8 g), which crystallized from ether – light petroleum and had m.p. 93–95°, $[\alpha]_D$ +138° (*c*, 1.0), (lit. (11) m.p. 93–94.5°, $[\alpha]_D$ +135°).

*1,2-O-Isopropylidene-α-D-ribofuranose (**20**)*

Lithium aluminum hydride (0.75 g) was added with stirring to a cooled solution of the above pentofuranosulose (1.6 g) in tetrahydrofuran (100 ml) and the mixture was heated under reflux for 2 h. Ethyl acetate (25 ml) was added to the cooled solution, and the mixture was poured into ice-water and extracted with chloroform (2 × 150 ml). Concentration of the dried extracts and crystallization of the residue from ether afforded 1,2-*O*-isopropylidene-α-D-ribofuranose (**20**) (0.72 g), m.p. 85–86°, $[\alpha]_D$ +39.5° (*c*, 1.0), (lit. (12) m.p. 86–87°, $[\alpha]_D$ +37°).

*1,2-O-Isopropylidene-3,5-di-O-methyl-α-D-ribofuranose (**21**)*

1,2-*O*-Isopropylidene-α-D-ribofuranose (610 mg) in *N*,*N*-dimethylformamide (25 ml) was stirred with methyl iodide (0.6 ml) and silver oxide (1.5 g) for 12 h at room temperature. Insoluble salts were removed by filtration and washed, and the combined filtrate and washings were concentrated, diluted with chloroform, filtered

For personal use only.

again, and washed several times with water. The dried chloroform solution was concentrated and crystallization of the residue from ether – light petroleum furnished **21** (492 mg), m.p. 81–83°, $[\alpha]_D$ +110° (*c*, 1.0); n.m.r. τ 4.27 (one-proton doublet, $J_{1,2}$ = 5 Hz, H-1), 6.52, 6.61 (three-proton singlet, 2 × OCH_3), 8.42, 8.63 (three-proton singlet, CMe_2).

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31. Found: C, 55.11; H, 8.29.

3,5-Di-O-methyl-D-*ribonolactone (22)*

The isopropylidene derivative **21** (400 mg) in acetic acid (20 ml) and water (5 ml) was heated on a steam bath for 2 h and concentration of the solution gave 3,5-di-*O*-methyl-D-ribofuranose as a syrup, $[\alpha]_D$ +37° (*c*, 1.5); ν_{max} 3450 cm^{-1} (OH). Bromine (0.5 ml) was added to the sugar (150 mg) in water (15 ml) and the solution was set aside for 2 days. Excess of bromine was removed by aeration, the solution was neutralized with silver carbonate, filtered, and concentrated to yield crude **22** as a syrup. Purification of the syrup by preparative layer chromatography (ethyl acetate) followed by crystallization from ether – light petroleum gave a crystalline sample, m.p. 55–56.5°, $[\alpha]_D$ +5.6° (*c*, 1.0); M^+, 176; ν_{max} 3470 (OH), 1770 cm^{-1} (γ-lactone); n.m.r. τ 6.51, 6.67 (three-proton singlet, 2 × OCH_3), 7.14 (one-proton doublet, splitting 15 Hz, exchanges with D_2O, C—OH).

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.72; H, 6.87. Found: C, 47.86; H, 6.78.

Treatment of the lactone **22** with acetic anhydride and pyridine furnished 2-*O*-acetyl-3,5-di-*O*-methyl-D-ribonolactone (**18**) which was identical (m.p. and mixed m.p., i.r., n.m.r., and mass spectra) to the previously isolated sample.

The Vibrational Spectra and Crystal Structure of Acenaphthylene

A. Bree, R. A. Kydd, V. V. B. Vilkos, and R. S. Williams
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 30, 1972

A study of the polarized infrared and Raman spectra of acenaphthylene single crystals has been made. These results, together with Gordon and Yang's preliminary X-ray work, suggest that the molecules pack in some disordered arrangement in the solid at room temperature. Most of the A_1 fundamentals were identified in the Raman solution spectrum from their low depolarization ratio, and a few tentative assignments of nontotally symmetric fundamentals were made.

Une étude des spectres infrarouge et Raman en lumière polarisée a été réalisée sur des monocristaux d'acénaphtylène. Les résultats obtenus, associés à ceux des travaux préliminaires de Gordon et Yang sur les rayons X, laissent penser que les molécules suivent un arrangement désordonné à l'état solide et à la température ambiante. La plupart des fondamentales A_1 ont été identifiées sur les spectres Raman en solution à partir du faible rapport de dépolarisation, quelques attributions ont été tentées sur des fondamentales non totalement symétriques. One method of making vibrational symmetry assignments for large molecules that has proved useful (see, for example, ref. 1) is to study the polarized spectra of single crystals. This method presupposes that a knowledge of the crystal structure is available. At the turn of the century, Groth (2) found that acenaphthylene crystals were orthorhombic by examining the crystal habit, and listed the complete optical properties. More recently Gordon and Yang (3) reported in a preliminary X-ray study that the crystal has four molecules in an orthorhombic unit cell belonging to the space group *Pc2a*. These authors claim that there are two crystallographically inequivalent pairs of molecules in the acenaphthylene cell so that each molecule must occupy a special site. Their important conclusion is that the short molecular axis must lie parallel to *b*. For this structure, the activity of a molecular vibration in the crystal is shown in Table 1. Further, in the special case of a vibration allowed through a change in the polarizability tensor element α_{zz}, the scattered intensity should be exclusively in the (*bb*) Raman spectrum.

Acenaphthylene was purified by chromatography on a column of alumina using petroleum ether as both developer and eluant. On melting, acenaphthylene forms a dark red tar so that large single crystals could not be produced by the usual method of lowering the compound through a Bridgman furnace. The crystals used for the Raman experiments were grown from either benzene or ethanol solutions by slow evaporation. These crystals, having a well developed *ac* face, were at most only 2 mm thick.

The Raman spectra were recorded on a Cary 81 spectrophotometer fitted with a helium–neon laser with 33 mW power at the sample. The solution spectra were measured in benzene and benzene-d_6 because an apparent photochemical reaction producing fine white particles (acenaphthylene dimer?) occurred in such solvents as carbon tetrachloride and carbon disulfide. The results of the Raman measurements are in Table 2. The intensity distribution amongst the polarized spectra from a single crystal was not consistent with the pattern predicted for Gordon and Yang's crystal structure, and did not allow any symmetry assignments to be made. In fact, the vibrational lines appeared in all possible polarized Raman spectra of the crystal in such a way that suggested the molecular axes had nearly equal projections on the crystal frame.

Because of the crystal habit, infrared spectra of the solid were measured with the electric vector of plane polarized radiation parallel to *a* and *c* (see Fig. 1). Totally symmetric modes were unpolarized in the *ac* face and had the same intensities relative to adjacent lines in the solid as in the solution. For example, the line at 552 cm^{-1} marks an A_1 fundamental (the depolarization ratio in the Raman spectrum is 0.25) and shows this behavior. Thus, the twofold axis *z* of the molecule does not lie parallel to *b*. Further, the lowest frequency infrared active modes at

*The intensity of each Raman line in the solid refers to the strongest component amongst the six independent polarized spectra, v = very, s = strong, m = medium, w = weak, sh = shoulder, p = polarized, dp = depolarized.

185 and 244 cm^{-1} must represent B_1 fundamentals and these too appear in the *ac* spectrum, so that the molecular normal x is not parallel to b. Finally, since no out-of-plane fundamental is expected at such a high frequency, the depolarized Raman line at 1387 cm^{-1} is assigned as a B_2 fundamental; this may be the analog of the B_2 fundamental at 1351 cm^{-1} in the first excited electronic state (4). This too appears in the *ac* infrared spectrum with an intensity relative to adjacent lines undiminished from the solution spectrum so that y is not parallel to b.

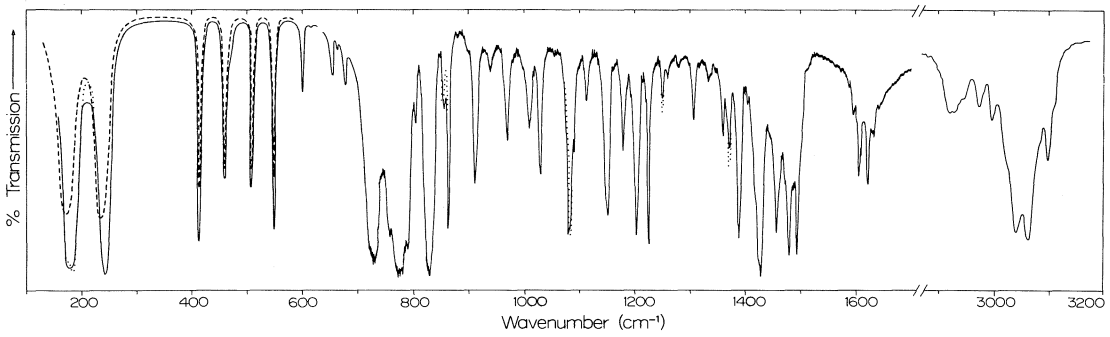

FIG. 1. The infrared spectra of acenaphthylene in solution and as an *ac* single crystal section: Full line, $||c$; dotted line, $||a$; broken line, in a benzene solution. Above 620 cm^{-1} the crystal thickness was about 50 μ and below 620 cm^{-1} it was about 100 μ.

This is confirmed by the observation that the long axis electronic transition at 21095 cm^{-1} is polarized in the *ac* plane (3).

These results appear to show that the molecules do not occupy a special site in the lattice, yet there are two layers of molecules along *b*(3). Both types of evidence, from spectroscopic and X-ray sources, can be made consistent only by assuming that the crystal structure of acenaphthylene is a considerably disordered one (5).

At this point in the argument it is important to consider the evidence which shows that the crystals were single. The thicker solution grown samples, when examined under a polarizing microscope, gave crosses as conoscopic figures and extinguished uniformly in three mutually perpendicular directions. Thin sublimation flakes, providing sections normal to the acute bisectrix, also extinguished well and reproduced the infrared results observed in thicker *ac* sections. The fact that the crystals were single is supported by the observation of factor group splittings at 854 ($||a$)/857($||c$) cm^{-1} and 1083 ($||c$)/1086($||a$) cm^{-1}.

Because of the apparent disordered nature of the crystal structure, the vibrational assignment rests largely on the depolarization ratios measured for the solution Raman spectrum, and must remain incomplete. Fundamental vibrations of A_1 symmetry are located at 552, 660, 805, 1032, 1081, 1360, 1427, 1493, 1598, 3042, 3066, and possibly 1011 and 1249 cm^{-1} from the intensities and depolarization ratios of these lines in the Raman solution spectrum. The polarized Raman lines at 1150 and 1226 cm^{-1} which are prominent in the infrared spectrum are also taken to mark A_1 fundamentals. It may be that there are two A_1 fundamentals near 1600 cm^{-1}, one at 1598 cm^{-1} seen in the Raman spectrum and a second at 1607 cm^{-1} prominent in the infrared.

The depolarized Raman lines at 1203, 1387, and 1621 cm^{-1} probably represent B_2 fundamentals since out-of-plane modes are expected at a somewhat lower energy. The very strong lines at 173 and 237 cm^{-1} in the infrared solution spectrum are taken to be B_1 fundamentals, and the weak Raman lines at about 163, 225, and possibly 370 cm^{-1} may mark A_2 fundamentals.

We would like to express our appreciation to the National Research Council of Canada for a research grant to support this work, and to Dr. R. D. Gordon and a referee for some valuable comments.

A Mössbauer Study of the Iron Tetracarbonyl Halides

P. VASUDEV AND C. H. W. JONES

Chemistry Department, Simon Fraser University, Burnaby, British Columbia

Received June 23, 1972

The ^{57}Fe Mössbauer spectra of the *cis*-$Fe(CO)_4X_2$ compounds (X = Cl, Br, I) have been measured and the values of δ ($\sim$0.3 mm s^{-1}) and Δ ($\sim$0.3 mm s^{-1}) found to differ significantly from those previously reported for $Fe(CO)_4I_2$. The Δ values are analyzed in terms of p.q.s. values of the ligands.

The photolysis of cyclohexane solutions of $Fe(CO)_4I_2$ was studied and no evidence was found in the ^{57}Fe Mössbauer spectra of frozen samples for the previously proposed formation of *trans*-$Fe(CO)_4I_2$.

The ^{129}I Mössbauer absorption spectrum of *cis*-$Fe(CO)_4{}^{129}I_2$ is reported and the parameters found to be $\delta = +0.11 \pm 0.02$ mm s^{-1}, $e^2qQ = -980 \pm 10$ Mc s^{-1}, $\eta = 0.00 \pm 0.02$. The parameters are interpreted as evidence of *ca.* 5% 5s character on the iodine in the Fe—I bond.

Nous avons mesuré le spectre Mossbauer de ^{57}Fe des composés *cis*-$Fe(CO)_4X_2$ (où X = Cl, Br, I); les valeurs de δ ($\sim$0.3 mm s^{-1}) et Δ ($\sim$0.3 mm s^{-1}) sont significativement différentes de celles rapportées pour $Fe(CO)_4I_2$. Nous analysons les valeurs de Δ en termes de valeurs p.q.s. des ligands.

Nous avons étudié la photolyse de solution de $Fe(CO)_4I_2$ dans le cyclohexane; la formation de *trans*-$Fe(CO)I_2$, postulée antérieurement dans le cas de spectres Mössbauer de ^{57}Fe d'échantillons gelés n'a pas été confirmée.

Finalement nous rapportons le spectre Mössbauer de ^{129}I du *cis*-$Fe(CO)_4{}^{129}I_2$; les paramètres sont $\delta = +0.11 \pm 0.02$ mm s^{-1}, $e^2qQ = -980 \pm 10$ Mc s^{-1}, $\eta = 0.00 \pm 0.02$. Nous interprétons les paramètres en fonction de la manifestation de type 5s à 5% qui dénote l'oide dans la liaison Fe—I.

Introduction

The ^{57}Fe Mössbauer spectrum of *cis*-$Fe(CO)_4I_2$ has previously been reported by several workers (1–3). However, the values obtained for the isomer shift and quadrupole splitting were found to vary. We have remeasured the iron spectrum for this compound and in addition have measured the Mössbauer spectra for *cis*-$Fe(CO)_4Cl_2$ and *cis*-$Fe(CO)_4Br_2$.

A second objective of the present investigation lay in an ^{57}Fe Mössbauer study of the photolysis of *cis*-$Fe(CO)_4I_2$ in cyclohexane, where it has previously been proposed (4, 5) on the basis of i.r. data that isomerization to *trans*-$Fe(CO)_4I_2$ occurs.

Finally, the ^{129}I Mössbauer spectrum has been measured and the isomer shift and quadrupole coupling interpreted in terms of the nature of the Fe—I bond.

Results and Discussion

cis-$^{57}Fe(CO)_4X_2$

The observed isomer shifts and quadrupole splittings for *cis*-$Fe(CO)_4Cl_2$, -Br_2, and -I_2 are reported in Table 1, together with the parameters previously reported for *cis*-$Fe(CO)_4I_2$. The data for $Fe(CO)_5$ are provided to allow a further comparison of the results of these experiments with those of previous work. A sample spectrum is shown in Fig. 1. It is observed that the results for $Fe(CO)_4I_2$ are in striking disagreement with those of Herber *et al.* (1) and Fluck *et al.* (2), and while they are similar to, they are not in exact agreement with those of Collins and Pettit (3). We understand that Bancroft (6) has also studied these compounds and that the results of the present work are in reasonably good agreement with those of that investigator.

The spectra for *cis*-$Fe(CO)_4Cl_2$ and -Br_2 were found to be very similar to those of *cis*-$Fe(CO)_4I_2$.

Bancroft *et al.* (7, 8) have studied a very large number of Fe^{II} low-spin compounds and have proposed values for the partial quadrupole splittings for a number of ligands, and in particular (8): $[Cl^-] = -0.30$, $[Br^-] = -0.28$, $[I^-] = -0.29$. In the light of ^{57}Fe studies on a series of $Fe(CO)_4(SnX_3)_2$ and $Fe(CO)_4XSnX_3$ compounds we have proposed (9), in conjunction with the measurements of Bancroft *et al.* (8), that the CO ligand has a partial quadrupole splitting of $[CO] = -0.55$. The data of the present work allow a further estimate of [CO]. The point charge model predicts (7) that for the *cis*-$Fe(CO)_4$-

*δ with respect to sodium nitroprusside. The errors in δ, Δ, and 2Γ are 0.01 mm s^{-1}.

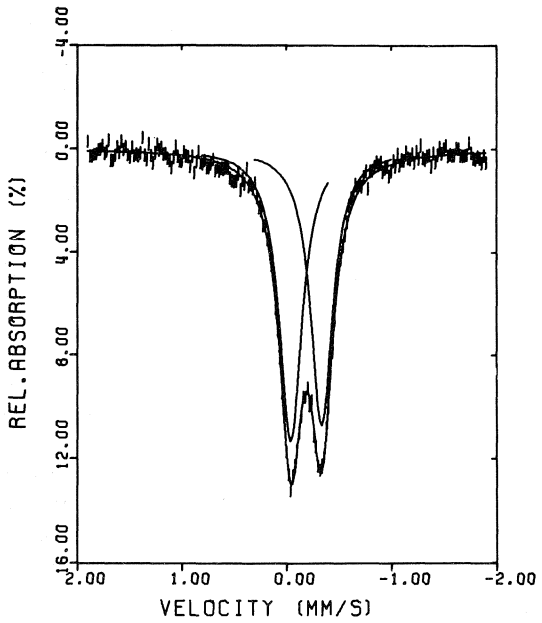

FIG. 1. The ^{57}Fe Mössbauer spectrum of $Fe(CO)_4I_2$ measured at 80 °K with the ^{57}Co/Pd source at room temperature.

X_2 compounds assuming octahedral geometry:

$$\Delta = +2[CO] - 2[X]$$

Thus using the value [X] = −0.3 and the mean Δ value for $Fe(CO)_4X_2$ we may conclude that [CO] = −0.45 or −0.15, depending on the sign of Δ in these compounds. The larger of these values is obviously nearer to the previously derived value of −0.55, although the agreement is not very good. However, the errors in this and the previously reported p.q.s. value are about 5–7% and thus the values of −0.45 and −0.55 may lie within the error limits of the measurements. Alternatively the molecules concerned may not be perfectly octahedral in which case the simple analyses presented here and in ref. 9 would not be applicable.

The Photolysis of cis-$Fe(CO)_4I_2$ in Solution

Noak (5) reported some time ago that on irradiating solutions of *cis*-$Fe(CO)_4I_2$ with visible light, a new band appeared at 2081 cm^{-1} in the i.r. spectrum, and this line was assigned to *trans*-$Fe(CO)_4I_2$. A similar observation was made by Johnson *et al.* (4), who further suggested that the *trans*-$Fe(CO)_4I_2$ might be an unstable intermediate in the photolytic decomposition of the *cis*-isomer.

In the present study we have followed the effect of irradiating cyclohexane solutions by studying both the i.r. spectrum of the liquid and the ^{57}Fe Mössbauer spectrum of frozen samples of the irradiated solution. The i.r. spectrum clearly showed the appearance of a single absorption line at 2082 cm^{-1}, as shown in Fig. 2. In contrast, the parameters of the Mössbauer spectrum showed no change within the error of the measurement, as illustrated in Fig. 2 and Table 2. The % effect in the Mössbauer spectrum decreased with irradiation time as a result of decomposition of the solution and the formation of a solid residue.

Johnson *et al.* (4) observed that the line assigned to the *trans*-isomer in the i.r. disappeared on standing irradiated solutions in the dark, and that the lines due to the *cis*-isomer did not increase in intensity. They proposed on this basis that the *trans*-isomer was unstable and decomposed on standing. It was important to establish that this process does not occur in the frozen cyclohexane glass. The i.r. spectra of samples of the irradiated solutions immediately before and following a Mössbauer experiment were found to be identical, both containing a very intense line at 2082 cm^{-1} and it is concluded that the species giving

§χ_i^2 values for 198 degrees of freedom.

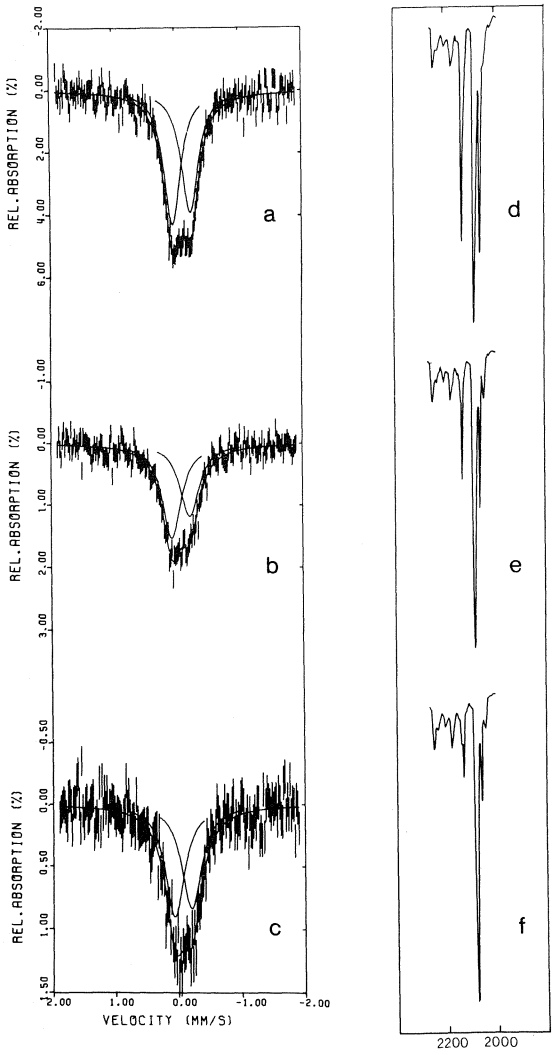

FIG. 2. The ^{57}Fe Mössbauer spectra and i.r. spectra of photolyzed cyclohexane solutions of $Fe(CO)_4I_2$, where *a*, *d* = fresh solution; *b*, *e* = 4 h irradiation; *c*, *f* = 5½ h irradiation.

rise to this absorption in the i.r. did not decompose in the frozen glass at 80 °K.

If the irradiation of the cyclohexane solution produced *trans*-$Fe(CO)_4I_2$, then it would be expected on the basis of the point charge model that the ^{57}Fe quadrupole splitting for this compound would be twice that of the *cis*-isomer. Within the error of the measurement, the Mössbauer spectrum was not found to change on irradiation. It is apparent that the Mössbauer experiment does not provide any positive evidence for the formation of *trans*-$Fe(CO)_4I_2$.

Thus, if the recoil-free fractions for *cis*- and *trans*-$Fe(CO)_4I_2$ were comparable, then lines attributable to the *trans*-isomer should be readily observable in the Mössbauer spectrum Fig. 5*c*, even though this spectrum is of poor quality. The i.r. spectra may be explained by the presence in solution of a dimer $[Fe(CO)_4I]_2$ which may fortuitously have Mössbauer parameters similar to that of *cis*-$Fe(CO)_4I_2$.

cis-$Fe(CO)_4{}^{129}I_2$

The ^{129}I Mössbauer absorption spectrum of $Fe(CO)_4{}^{129}I_2$ is shown in Fig. 3, and the computed parameters (10) for this spectrum were found to be

$$\delta = +0.11 \pm 0.02 \text{ mm s}^{-1}$$
$$e^2qQ = -980 \pm 10 \text{ Mc s}^{-1}$$
$$\eta = 0.00 \pm 0.02$$

The linewidths, constrained as equal, were found to be 1.2 mm s^{-1}.

If we assume, using the theory of Townes and Dailey (11), that the quadrupole coupling derives from the imbalance in the population of the iodine 5p orbitals, then

$$U_p = -\frac{e^2qQ_{mol}}{e^2qQ_{atom}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

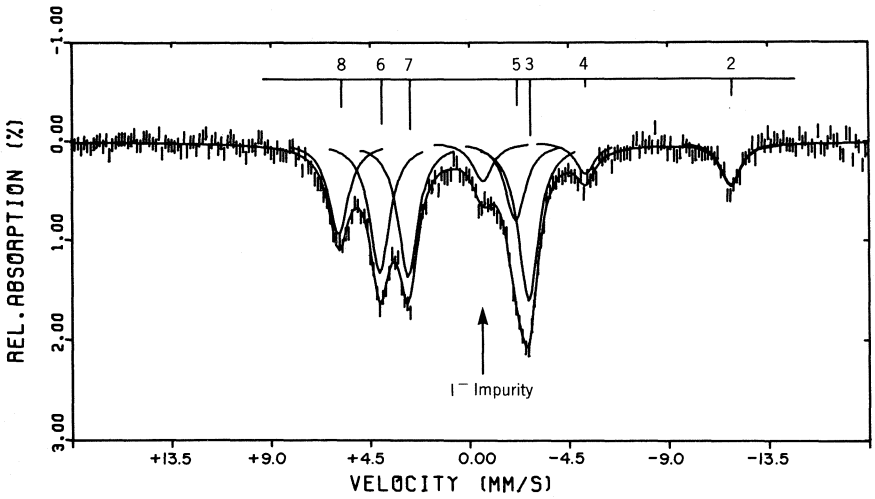

FIG. 3. The ^{129}I Mössbauer spectrum of $Fe(CO)_4{}^{129}I_2$ measured with the $Zn^{129m}Te$ source and the absorber at 80 °K. The computed independent Lorentzians are shown, and the lines had intensities in excellent agreement with the square of the Clebsch–Gordon coefficients for the respective transitions (20).

where

$$U_p = -U_z + \frac{U_x + U_y}{2}$$

and where e^2qQ_{mol} is the quadrupole coupling in the molecule of interest, e^2qQ_{atom} is that for one $5p_z$ electron ($= +1607$ Mc s^{-1} for ^{129}I) and U_x, U_y, and U_z are the population of the $5p_x$, $5p_y$, and $5p_z$ orbitals.

$$U_p = +0.61 \pm 0.01$$

The sign of e^2qQ_{mol} is consistent with the formation of a bond along the z axis and, together with the fact that $\eta = 0$, we may propose that

$$U_x = U_y = 2 \text{ when } U_z = 1.39$$

We may now turn to an examination of the isomer shift. Bukshpan *et al.* (12) have derived expressions for the dependence of the ^{129}I Mössbauer isomer shift on the number of holes in the iodine 5s (h_s) and 5p (h_p) orbitals. If it is assumed that the iodine uses only a 5p orbital in bonding to the iron, then for small values of h_p

$$\delta = 1.50h_p - 0.54$$

$$0.11 = 1.50h_p - 0.54$$

and

$$h_p = 0.43 \pm 0.03$$

It must be noted that

$$h_p = 6 - (U_x + U_y + U_z)$$

and if $U_x = U_y = 2$,

$$h_p = 2 - U_z = U_p$$

However from the above it is apparent that $h_p \neq U_p$, and it must be concluded that the bonding to the iodine does not occur exclusively through a σ-bond involving an iodine 5p orbital. One explanation for the observed h_p and U_p values may be the participation of the iodine 5s orbital in bonding. Using the expression (12)

$$\delta = -8.2\,h_s + 1.50\,h_p - 0.54$$

which approximately reflects the influence on δ of the removal of both 5s and 5p electrons, and assuming $h_p = 0.61$, $h_s = 0.03$ and thus only a 5% contribution by the iodine 5s orbital would lead to the observed isomer shift. It must be noted that the above analysis is only a tentative one, since the above expression (12) for δ in terms of h_s and h_p has never been rigorously tested. However, the participation of some 5% s-character in the bonding by the iodine would not be unexpected given the large electronegativity difference between the iron and the iodine.

An alternative explanation for the observed isomer shift and quadrupole splitting could lie in back-bonding from the filled d_{xy}, d_{yz}, and d_{xz} orbitals on the iron into the empty d orbitals on the iodine. If we assume that such an effect would not markedly influence the quadrupole coupling (11), but would decrease the isomer shift through shielding of the $5s^2$ electrons, this would be consistent with the values of h_p and U_p calculated

above. However, Perlow and Perlow (13) and Bukshpan *et al.* (12) have pointed out that shielding of iodine $5s^2$ electrons by 5d electrons should be small, consistent with the Slater shielding coefficients, and that this would particularly be the case near to a closed shell configuration on the iodine (14). On this basis it is concluded that the more probable explanation is s-participation rather back-bonding into the iodine 5d orbitals.

Experimental

The compounds used in this work were synthesized by conventional methods (15). They were characterized by their infrared spectra (Table 3) and by chemical analyses (Table 4). The more unstable chloride was analyzed in this laboratory and only C (C, H, and N Perkin–Elmer analyzer) and Fe (atomic absorption) analyses were carried out. Several samples of each compound were independently synthesized, characterized, and studied. All yielded values in good agreement with those results shown in Tables 1, 3, and 4.

The ^{129}I labelled $Fe(CO)_4{}^{129}I_2$ was prepared on a small scale by reacting *ca.* 60 mg in total of $^{129}I_2 + {}^{127}I_2$ with $Fe(CO)_5$ in dry ether under dry nitrogen. The solid residue from the reaction was extracted with dry hexane and the final product obtained on evaporation of the hexane extracts. The compound gave an ^{57}Fe Mössbauer spectrum and an i.r. spectrum identical with that of $Fe(CO)_4{}^{127}I_2$ prepared on the gram scale, the ^{57}Fe spectrum being run immediately before and after the ^{129}I spectrum. The sample contained *ca.* 20 mg of ^{129}I. The ^{129}I was obtained from Oak Ridge National Laboratories as I^- in sulfite, the iodine being obtained by oxidation and centrifugation. The ethereal solution containing added $^{127}I_2$ was dried over molecular sieve before being used in the above preparation.

The photolysis studies were carried out in dry cyclohexane under dry nitrogen, using visible light and a cold-finger device to minimize any thermal decomposition during the irradiation. About 5 ml of solution were irradiated at a time. The irradiation produced a solid residue and aliquots of the liquid removed by syringe for the i.r. and Mössbauer studies were filtered through a cotton-wool plug. The Mössbauer samples (*ca.* 0.2 ml) were transferred to Teflon thin-windowed, O-ring containers and the samples frozen by immersion in liquid nitrogen prior to placing them in the spectrometer.

The ^{57}Fe Mössbauer experiments were carried out essentially as previously described (9) using a T.M.C. constant acceleration Mössbauer drive unit and multichannel analyzer, with the absorbers at *ca.* 80 °K and the ^{57}Co/Pd source (10 mCi) at room temperature. In the ^{129}I experiment the source used was $Zn^{129m}Te$ prepared from elemental zinc and ^{129m}Te-labelled tellurium, the latter being obtained by irradiating 50 mg of ^{128}Te (enriched) for 2 weeks in the N.R.U. reactor at Chalk River Nuclear Laboratories. The ^{129}I spectra were recorded (16) on an NSEC. AM-1 spectrometer and cryoflask with the source and absorber at *ca.* 80 °K. The two spectrometers were routinely calibrated using a nitroprusside standard ($\delta = -0.442$ mm s^{-1} with respect to ^{57}Co/Pd and $\Delta = 1.712$ mm s^{-1}) and α-Fe_2O_3 for which the line spacings in ref. 17 were assumed. Computed fits to the data were obtained using a program kindly provided by Stone (ref. 18, Appendix).

The δ and e^2qQ values for ^{129}I were arrived at using least-squares fits to the line positions. Assuming that if the asymmetry parameter is small, the position of each line δ_{ij}, in the ^{129}I quadrupole split spectrum is described in terms of e^2qQ and δ by the expression (19)

$$\delta_{ij} = \frac{ce^2qQ_{gnd}}{4E_\gamma}\left[\frac{Q_{ex}}{Q_{gnd}}\frac{(C_0^* + C_2^*\eta^2)}{I^*(2I^* - 1)} - \frac{(C_0 + C_2\eta^2)}{I(2I - 1)}\right] + \delta$$

where δ_{ij} is the line position corresponding to the $m_i \rightarrow m_j$ transition, δ is the isomer shift, and C^* and C refer to the excited and ground states, respectively, where

$$C_0 = 3m^2 - I(I+1)$$

$$C_2 = \frac{1}{12}\frac{f(I,m-1)}{m-1} - \frac{f(I,m+1)}{m+1}$$

$$f(I,m) = \tfrac{1}{4}(I^2 - m^2)[(I+1)^2 - m^2]$$

and Q_{ex}/Q_{gnd} is the ratio of the quadrupole moments of the excited and ground states, taken as $+1.231 \pm 0.001$. Pasternak and Sonnino (20) have tabulated the line positions in terms of e^2qQ, δ and η^2, for small values of η. Initially lines 2, 3, 5, 6, and 7 are used in obtaining δ and e^2qQ while lines 4 and 8 are used to estimate η. Since $\eta \cong 0$, the final values of δ and e^2qQ were obtained from all seven lines.

In fitting the ^{57}Fe spectra for the solid $Fe(CO)_4X_2$ compounds no constraints were applied in the fit, while for the frozen solutions of $Fe(CO)_4I_2$ and also for the $Fe(CO)_4{}^{129}I_2$ study, the linewidths were constrained as being equal. Generally the fits obtained gave χ-squared values within the 5% confidence limit.

The authors wish to thank the National Research Council of Canada for a grant supporting this research, Dr. F. Brown, Head, Solid State Research Branch, AECL, Chalk River for his assistance in the production of the $Zn^{129m}Te$ source, and Dr. G. M. Bancroft for communicating his ^{57}Fe results to us.

Isotope Effects on Chemical Equilibria. Part I. Some Secondary Isotope Effects of the Second Kind

D. J. BARNES AND J. M. W. SCOTT

Chemistry Department and Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland

Received April 5, 1972

Secondary isotope effects $K_a(H)/K_a(D)$ for the isotopic acid pairs 4-X-$C_6H_4CH_2COOH$/4-X-$C_6H_4CD_2COOH$(X = H, NO_2, OMe) have been determined at $T = 25$ °C by conductance measurements. This has involved the redetermination of the dissociation constants for the non-deuterated acids and in the case of X = NO_2, OCH_3, the new K_a values are to be preferred. The K_a of acetic acid has also been redetermined as a check on the reliability of the new data. The three isotope effects are shown to be much smaller than might have been anticipated on the basis of the e.m.f. measurements on the pair $PhCH_2COOH/PhCD_2COOH$ reported earlier (1).

Les effets isotopiques secondaires $K_a(H)/K_a(D)$ pour la paire d'acides isotopiques 4-X-$C_6H_4CH_2$-COOH/4-X-$C_6H_4CD_2COOH$ (X = H, NO_2, OCH_3) ont été évalués à $T = 25$ °C par de mesures de conductance. Ceci a impliqué une nouvelle détermination des constantes de dissociation pour les acides non-deutériés et dans le cas où X = NO_2, OCH_3 les nouvelles valeurs de K_a doivent etre préférées. Le K_a de l'acide acétique a aussi été évalué de nouveau comme standard d'exactitude des nouvelles données. Les trois effets isotopiques trouvés sont beaucoup plus petits que prévus si l'on se base sur les mesures de f.e.m. pour la paire $Ph_2CH_2COOH/PhCD_2COOH$ rapportées précédemment (1).

Introduction

The changes in dissociation constants which occur when hydrogen is replaced by deuterium in the side chains of carboxylic and ammonium acids have been studied on several occasions (1–5). The problem of predicting and understanding these subtle effects of structure on reactivity using the statistical theory of equilibria (6) has not proved particularly rewarding since a full treatment of the problem requires a complete knowledge of the reactant and product vibrational frequencies appropriate to the condensed phase in which the equilibria are examined. In practice these latter quantities are rarely available. A partial exception is exemplified by the calculation of the relative acidities of formic acid and formic acid-*d*, by Bell and Crooks (2) using the observed fundamental frequencies appropriate to the isotopic acids.

The general lack of such vibrational data has forced both theoreticians and experimentalists to devise other models to cope with secondary hydrogen–deuterium isotope effects. These latter treatments suggest that changes in reactivity resulting from the replacement of hydrogen by deuterium can be discussed in terms of hybridization, steric or non-bonded interactions, hyperconjugation or inductive effects (see references in ref. 7). Although the hyperconjugative and inductive treatments superficially appear to be electronic in origin, the Born–Oppenheimer principle is retained and the model can still be understood in terms of mass effects on vibrations. Thus, the hyperconjugative and inductive description can be recast in vibrational–statistical language, but by formally avoiding the vibrational treatment some simplification is lent to what is evidently a complex problem. The least that can be asked of this and other simplified approaches to the understanding of secondary isotope effects is that the 'as if' treatments maintain a reasonable degree of fidelity in their representation of the experimental data, *i.e.* that they be self-consistent.

Isotope effects, in which the spatial orientations of the bonds linking the isotopic atoms to the molecule are altered, are described by Streitwieser and coworkers (8) as secondary isotope effects of the first kind. Other possible processes in which spatial reorganization is absent are described as secondary isotope effects of the second kind. It has been proposed by Halevi (7), that isotope effects of the second kind behave like inductive effects. Thus, the variation of secondary isotope effects of this sort with both the structure and the position of deuteration

should be amenable to a linear free energy treatment such as that proposed by Taft (9). A test of such a hypothesis has been presented already by Streitwieser and Klein (5) and a further modification of their work will be presented here, using the Taft equation as applied to the acidities of carboxylic acids of the type XCH_2COOH.

The original correlation presented by Taft (9) for the pK_a's of a series of seven carboxylic acids (X-COOH) was of the form:

$$[1] \qquad \log K/K_0 = (1.721 \pm 0.025)\sigma^*$$

where σ* is the Taft substituent constant of the group X attached to the carboxyl group. Equation 1 can be rewritten in the form:

$$[2] \qquad pK_a = -(1.721 \pm 0.025)\sigma^* + 4.76$$

Extension of the empirical data to 26 substituted acetic acids (Table 1) gives:

$$[3] \qquad pK_a = -(1.603 \pm 0.030)\sigma^* + 4.604 \pm 0.029$$

with average r.m.s. deviation of ±0.16 pK_a units. In cases where the group X can be treated as a substituted methyl group, *i.e.* $X = CX_1X_2X_3$, it is possible to set up a modified version of eq. 3 in which the total inductive effect of the group X is measured to a first approximation, by the sum of the separate contributions of X_1, X_2, and X_3, leading to a quantity Σσ* which is defined by the equation:

$$[4] \qquad \Sigma\sigma^* = \sigma^*(X_1) + \sigma^*(X_2) + \sigma^*(X_3)$$

For the 22 substituted acetic acids listed in Table 1, for which values of Σσ* are available, a least squares treatment gives:

$$[5] \qquad pK_a = -(0.550 \pm 0.059)\Sigma\sigma^* + 5.200 \pm 0.014$$

leading to an average r.m.s. deviation of ±0.25 pK_a unit. This correlation is evidently inferior to that presented in eq. 3; nevertheless, it is possible to use the experimental $K(H)/K(D)$ ratios for the pairs CH_3COOH/CD_3COOH and $(CH_3)_3$-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$CCOOH/(CD_3)_3CCOOH$ in conjunction with eq. 5 to evaluate $\sigma^*(D)$ and $\sigma^*(CD_3)$. The $K(H)/K(D)$ ratio for the acetic acid pair is well established (5, 12), the ratio for the pivalic acid pair is that reported by Streitwieser and Klein (5). Substituting these ratios in eq. 5 gives $\sigma^*(D) = 0.482$ and $\sigma^*(CD_3) = -0.011$. These values, together with eqs. 5 and 3 make it possible to evaluate theoretical $K(H)/K(D)$ values for the remaining carboxylic acids in Table 2. Hall (13) has demonstrated that the pK_a's of primary, secondary, and tertiary amines are respectively correlated with the Taft σ^* parameter according to the equations:

$$[6] \quad pK_a(\text{primary}) = -3.14 \sum\sigma^* + 13.23$$

$$[7] \quad pK_a(\text{secondary}) = -3.23 \sum\sigma^* + 12.13$$

$$[8] \quad pK_a(\text{tertiary}) = -3.30 \sum\sigma^* + 9.61$$

where the $\sum\sigma^*$ parameter now refers to the substituents bound to nitrogen. From eqs. 6 and 7 and the value previously calculated for $\sigma^*(CD_3)$, the $K(H)/K(D)$ ratios for the ammonium acid pairs investigated by Robertson and coworkers (3, 4) can be calculated.

An examination of the predictions in Table 2 reveals that the calculated isotope ratios are qualitatively consistent with the inductive treatment. Quantitatively, however, the agreement is poor. The observed ratio for the pair $PhCH_2COOH/PhCD_2COOH$ is particularly difficult to understand since there is no obvious reason why the phenyl group should enhance the isotope effect observed in the case of acetic acid, particularly when the number of deuterium atoms per molecule is reduced.

One can conclude from the above discussion that there is clearly a need for a broader experimental basis from which to construct generalizations (14). To this end we report here a reinvestigation of phenylacetic acid. We also report $K(H)/K(D)$ ratios for the pairs 4-MeO-$C_6H_4CH_2COOH$/4-MeO-$C_6H_4CD_2COOH$ and 4-NO_2-$C_6H_4CH_2COOH$/4-NO_2-$C_6H_4CD_2$-COOH. To a first approximation, the simple inductive treatment outlined above suggests that the isotope effect on these three systems should be constant and considerably smaller than that reported by Halevi (1) for the unsubstituted isotopic pair.

TABLE 2. Predicted and observed isotope effects

Isotopic Pair	$K(H)/K(D)$ Observed (ref.)	Calculated
CH_3COOH/CD_3COOH	1.035 (12)	—
$(CH_3)_3CCOOH/(CD_3)_3CCOOH$	1.04 (5)	—
HCOOH/DCOOH	1.07 (5)	1.03
$CH_3CH_2COOH/CD_3CH_2COOH$	1.01 (1)	1.014
$CH_3CH_2COOH/CH_3CD_2COOH$	1.08 (1)	1.021
$PhCH_2COOH/PhCD_2COOH$	1.12 (1)	1.021
$CH_3{}^+NH_3/CD_3{}^+NH_3$	1.13 (3)	1.083
$(CH_3)_2{}^+NH_2/(CD_3)_2{}^+NH_2$	1.32 (3)	1.18
$(CH_3)_3{}^+NH/(CD_3)_3{}^+NH$	1.53 (4)	1.29

At the commencement of the present study isotope effects of the order of 12% were anticipated.[1] Secondary isotope effects of the second kind which reach this magnitude must be considered as large. For instance, the introduction of the methoxy substituent into the aromatic ring of phenylacetic acid produces about the same effect on acidity as replacing the methylene hydrogens in the same molecule by deuterium in the unsubstituted acid.

A careful survey of the rather extensive conductance data available for carboxylic acids suggested that it should be possible to measure individual K_a values to $\pm 0.2\%$ without undue difficulty and it was hoped that this order of accuracy would suffice to detect substituent effects on secondary isotope effects if they existed. The requirements for precise measurements of acid dissociation constants are implied in some very careful work reported by Ives and coworkers (11, 15). The high precision obtained by the Ives' group is probably a consequence of the strength of the acids studied ($K_a \simeq 10^{-3}$). It would appear that the phenylacetic acids, which are *ca.* 10 times weaker, are less suitable to the conductance technique for reasons which will be considered subsequently. Thus with respect to the individual K_a's for the protium and deuterium analogs we prefer to describe the present study as one of intermediate accuracy. However, if certain conditions are met it appears possible to determine $K(H)/K(D)$ ratios for an isotopic pair with much higher precision than the individual K_a values and in this respect the conductance method would appear to be superior to other methods which might be chosen.

Experimental

General

All melting points and boiling points are uncorrected. N.m.r. spectra were obtained using a Varian A60 spectro-

[1]Assuming the veracity of the data in ref. 1.

meter and chemical shifts are reported on the τ scale relative to tetramethylsilane (TMS) as an internal standard. Both n.m.r. and a v.p.c./combustion technique (16) were used for deuterium analysis. All organic solvents were distilled prior to use or were of known grade of purity.

Preparation of Materials

Protium Acids

The protium acids used in the present study, acetic acid, phenylacetic acid, 4-methoxyphenylacetic acid, and 4-nitrophenylacetic acid were commercial samples or samples prepared by well established routes. In some cases more than one batch of the acid was prepared and each batch was intensively purified. The constancy of the K_a as determined by conductance was taken as the main criterion of purity since the conductance technique is very sensitive to contaminants in both solvent and solute alike.

Acetic Acid

Acetic acid (A.R. Grade) was fractionally frozen twice and then fractionated using a gold spinning band column with liberal rejection of the initial and tail fractions. The fraction used for the dissociation constant measurements had a b.p. 117.5–118 °C/750 mm Hg.

Phenylacetic Acid

Runs 1–6. A commercial sample of phenylacetic acid was recrystallized twice from conductivity water and once from pentane (b.p. 40–50 °C). It was stored over phosphorus pentoxide for 2 days and then over silica gel.

Runs 9–17.[2] A sample of phenylacetic acid was crystallized twice from water and then sublimed. It was then recrystallized twice from cyclohexane and once from water. The specimen resulting from this purification procedure was dried *in vacuo* in a drying pistol at the temperature of boiling acetone.

4-Nitrophenylacetic Acid

Runs 5–8. A commercial sample of 4-nitrophenylacetic acid was recrystallized twice from conductivity water, sublimed, and then recrystallized two more times from the same solvent. The sample so purified was then dried using the same technique employed in the case of the final specimen of phenylacetic acid.

Runs 9–11. A sample of the acid was sublimed, recrystallized twice from water, and then dried in the same manner as the sample used in runs 5–8.

4-Methoxyphenylacetic Acid

4-Methoxybenzyl chloride was synthesized according to the method of Lee and co-workers (17) and was converted to the cyanide as described by Friedman and Shechter (18). The 4-methoxybenzyl cyanide was hydrolyzed with alcoholic sodium hydroxide. The resulting sodium salt was dissolved in the minimum of water and 4-methoxyphenylacetic acid precipitated by adding hydrochloric acid. The precipitated acid was collected, washed with cold water and pentane, and dried *in vacuo* over phosphorus pentoxide, m.p. 85–86 °C (lit. m.p. 86 °C (19)).

Runs 1–6. A sample of the acid was recrystallized from water, dissolved in carbonate, and treated with charcoal. The resulting solution was then treated with hydrochloric acid and the product recrystallized twice from cyclohexane. Two further recrystallizations from conductivity water were carried out and the sample was dried in the same manner as the final specimen of the unsubstituted acid.

The Deuterated Acids

The deuterated acids were all prepared by an exchange reaction in deuterium oxide using triethylamine as a catalyst. The progress of the exchange was monitored by n.m.r. using the integration of the methylene protons against the aromatic protons of the acid. It was reasonably assumed that no exchange of the aromatic protons took place under the relatively mild basic conditions used in these experiments (20).

Phenylacetic-α,α-d_2 Acid

Phenylacetic acid (10 g), dissolved in deuterium oxide (15 ml) and triethylamine (5 ml), was placed in a flask equipped with both a condenser and drying tube. The flask was heated in an oil bath at 110 °C for 52 h, and after this period n.m.r. analysis on an aliquot of the solution indicated 88.2% deuteration at the methylene position. The contents of the flask were cooled and the mixture was acidified with DCl (6 *N*) prepared from deuterium oxide and the appropriate quantity of purified thionyl chloride. The precipitated acid was washed with cold cyclohexane and dried over phosphorus pentoxide *in vacuo* for 24 h. A second exchange was carried out with the partially exchanged acid using the procedure described above at 82 °C for 96 h. Analysis of this material by n.m.r. indicated 96.7% deuteration. A further exchange (48 h) followed by recovery of the acid (see above) gave a specimen of the acid which on recrystallization from cyclohexane and water had m.p. 75–76 °C. The purified specimen contained 98% deuterium in the methylene position as judged by an n.m.r. spectrum in carbon tetrachloride (overall yield 75%). Samples of the acid prepared in this way were subjected to further purification procedures (see below) with no sensible decrease in deuterium content as judged by n.m.r. analysis. The deuterated acid purified for the conductance measurements (see below) was subjected to a combustion/v.p.c. analysis (see ref. 16) giving 1.87 D/molecule (93.6% methylene deuteration). The reason for the discrepancy between the n.m.r. and combustion/v.p.c. analysis is not understood.[3]

Phenylacetic-α,α-d_2 acid was purified for conductance measurements using the following procedures:

Runs 1–4. The deuterated acid was dissolved in carbonate solution and charcoal added. The solution was warmed and filtered hot and the filtrate treated with concentrated hydrochloric acid. The resulting acid was recrystallized twice from water and dried in a pistol for 3 days *in vacuo* at the temperature of boiling acetone.

Runs 5–10. A sample of the deuterated acid was crystallized from water, dried (see above), and then recrystallized from cyclohexane. The acid was then sublimed

[2]In some cases runs were rejected. Runs 7 and 8 in the phenylacetic acid series were not used because desiccation of a specimen of this acid over phosphorus pentoxide led to decomposition. The runs reported for all the structures examined constitute over 75% of all the data recorded.

[3]Even if the lower analytical results are correct, the influence of the low deuteration on the measured K(H)/K(D) ratios is insignificant (21).

For personal use only.

and recrystallized twice from water and dried for 4 days in the same manner as the specimen used in runs 1–4.

Runs 11–16. A sample of the deuterated acid was sublimed, recrystallized twice from cyclohexane, and then once from water. The sample was dried for 3 days as above.

4-Nitrophenylacetic-α,α-d_2 Acid

4-Nitrophenylacetic acid (10 g) was added to deuterium oxide (15 ml) and triethylamine (5 ml) and the resulting solution heated at 50 °C for 11 h. An n.m.r. spectrum of this solution showed 89.6% deuteration of the methylene protons. Concentration of this solution followed by the addition of fresh deuterium chloride (see above) and purification of the precipitated acid by recrystallization from ether–pentane gave a product, m.p. 147–150 °C (lit. 152 °C (22)), subsequent to desiccation *in vacuo* over silica gel. A further deuteration of this product at $T =$ 50 °C, (t = 11 h) gave a sample 98.8% deuterated, m.p. 148.8–150 °C. The latter was recrystallized 3 times from cyclohexane and once from water and dried at the temperature of refluxing acetone for 24 h over silica gel. A v.p.c./combustion analysis indicated that this material contained 1.85 D/molecule (92.5% methylene deuteration). The discrepancy between the n.m.r. and combustion analysis is again apparent (see footnote 3).

4-Nitrophenylacetic-α,α,d_2 acid was purified for conductance using the following procedure:

Runs 1–5. The deuterated acid was recrystallized 3 times from cyclohexane, once from water and dried for 24 h in a pistol *in vacuo*.

4-Methoxyphenylacetic-α,α-d_2 Acid

4-Methoxyphenylacetic acid (10 g) was treated with deuterium oxide (15 ml) and triethylamine (5 ml), following the procedure for deuteration of phenylacetic acid. After a period of 23 h at 100 °C an aliquot of the solution indicated 88.2% deuteration by n.m.r. analysis. Two further exchanges of the acid in deuterium oxide increased the isotopic purity to at least 98%.

4-Methoxyphenylacetic-α,α-d_2 acid was purified for conductance measurements using the following procedures:

Conductance measurements

Runs 1–4. A sample of the deuterated acid was recrystallized from cyclohexane, sublimed, recrystallized from cyclohexane and dried in a pistol at 80 °C for 3 days.

Runs 5–6. The above material was recrystallized from water and dried for several days at 80 °C.

Potassium chloride purification

Method I. Potassium chloride (Fisher Scientific A. R. Grade) was precipitated from a saturated aqueous solution prepared from conductivity water by addition of 95% ethyl alcohol and this procedure was repeated 3 times. The salt was collected by filtration, thoroughly washed with 95% ethyl alcohol, and dried *in vacuo* for several days at 110 °C. The salt was carefully powdered with an agate mortar and pestle and returned to the drying pistol for a further 2 days.

Method II. A second sample of potassium chloride was prepared by twice precipitating a saturated solution of the salt with concentrated hydrochloric acid (A.R. Grade) and once with 95% ethyl alcohol. The subsequent treatment of this specimen was identical to that described above.

Experimental Assembly and Technique

The apparatus and techniques used follow the practice of Jones and Bradshaw (23), Shedlovsky (24), and Robertson (25).

Resistances were measured on a Jones–Joseph type conductivity bridge (23) manufactured by the Tinsley Company and on a General Radio Impedance Bridge. The Tinsley Bridge, model 4896, and accessories were assembled following the description of Robertson (25) with minor modifications made necessary because some of the components were no longer commercially available. A Hewlett Packard 1000 c.p.s. AC oscillator was connected to the bridge and the balance was detected by observing a Lissajous pattern on a Hewlett Packard model 120B oscilloscope. The detector for the General Radio impedence bridge was a G.R. 1232-A tuned amplifier and a null detector. The coarse balance on this bridge was also determined with an oscilloscope (see above). Comparison of the two bridges over the resistance range 500 – 12 000 Ω showed an agreement of better than 0.05%.

Conductivity water was prepared by passing tap water of low solid content into a deionizer (Ion Exchange Products Inc., Amberlite MB-1), followed by distillation from a Barnstead still. The distillate so produced was stored in two three-necked flasks (10 l) with teflon stoppers. The flasks were treated for 3 days with boiling nitric acid and approximately a week with steam prior to use. Final purification of the water, immediately prior to the preparation of the solutions, involved treatment with a second deionizer of Amberlite resin and the collection of the pure water under an atmosphere of purified nitrogen which had been freed from all acidic and basic contaminants. Conductivity water prepared in this manner was not used for the preparation of solutions unless the specific conductivity fell in the range 1.8×10^{-7} to 3.5×10^{-7} Ω cm^{-1}.

Conductivity cells were of the Shedlovsky type (24). The cells were constructed of Pyrex glass and the electrodes were made of shiny platinum. The resulting cell constants for the five cells used were in the range 0.08–0.20. The cells described above and all glassware required for the preparation of solutions were treated with concentrated nitric acid at a temperature of 100 °C for a period of 3 days. The glassware was then steamed for the same length of time and finally rinsed several times with conductivity water.

All solutions of potassium chloride and the carboxylic acids were prepared by weight and the concentrations reported on the molal scale.[4] Weighings were performed on a Sartorius analytical balance which could be read to 0.01 mg. Water and stock solutions were weighed on a large two pan balance to the nearest 10 mg. Weights were calibrated against a set of weights standardized by the National Physical Laboratory, England. Solutions were kept under purified nitrogen at all times.

All conductivity measurements were carried out at 25 ± 0.005 °C. A 20 gal stainless steel tank, filled with transformer oil, was maintained at 25 °C by heating and

[4]The aqueous solutions of 4-nitrophenylacetic acid were distinctly photolabile. Solutions of this acid were thus made and manipulated in the dark. This fact also accounts for the rejection of runs 1–4 for this compound (see Table 7).

cooling the bath simultaneously. Cooling was effected by passing cold water from a 15 gal stainless steel tank through a circulating pump into a cooling coil in the bottom of the oil bath. The rate of flow of water through the cooling coil was regulated using a by-pass arrangement incorporating two control valves. The temperature of the cooling water was maintained at 17.5 ± 0.3 °C using a Techumseh 1/4 h.p. refrigerator regulated by a Wheatstone Bridge – thermistor circuit. The temperature of the oil bath was regulated by a Sargent Thermonitor (S-82050). The basic components of this device are a background heater (125 W), controlled by a variac with an intermittent knife heater (250 W), operated by a thermistor Wheatstone Bridge circuit, coupled to a variable reactor. The voltage across the bridge was reduced from 6 to 4 V resulting in considerable improvement in the performance of this device.

A platinum resistance thermometer, calibrated by the National Physical Laboratory, was used in conjunction with a Mueller Temperature Bridge, type 4772, to measure the temperature of the regulated bath in which the conductance measurements were made. Over long periods of time the bath temperature was conveniently monitored on a Honeywell recorder connected to a Wheatstone Bridge circuit containing a Fenwal thermistor as a sensing device.

Results

Cell Constants

Cell constants were determined by measuring the resistance of aqueous solutions of two independent samples of purified potassium chloride at 25 °C over the concentration range 0.001364–0.0017385, employing both the General Radio impedance bridge and the Tinsley conductivity bridge. The weights of the salt and solvent were corrected for buoyancy. Since the equation of Fuoss (26) relating equivalent conductance of KCl solutions to the concentration

$$[9]\quad \Lambda = 149.93 - 94.65c^{1/2} + 58.74c \cdot \log c + 198.4c$$

is given using the molarity scale, conversion of the concentrations from the molal to the molarity scale was necessary. These corrections were accomplished using the expressions (27).

$$[10]\quad V = N_0V_0 + N_1Q_1$$

$$[11]\quad Q_1 = 26.52 + 2.327\,(C_2)^{1/2}$$

where V represents the volume of the solution, N_0, the number of moles of water, N_1, the number of moles of KCl, V_0 the volume of a mole of water at 25 °C, Q_1 the molal volume, and C_2 the approximate concentration of the solution. These corrections were very small.

The value of the equivalent conductance at the concentrations studied was calculated using the Fuoss expression and the cell constants were evaluated from the expression

$$[12]\quad \Lambda = \frac{10^3}{c}\kappa\left[\frac{1}{R} - \frac{1}{R_S}\right]$$

where κ represents the cell constant and R and R_S represent the resistance measurements of the solution and pure solvent respectively.

The five cell constants so determined are reported in Table 3.

Conductance Data

The conductance data calculated in the usual way for the acids acetic, phenylacetic, phenylacetic-α,α-d_2, 4-methoxyphenylacetic, and 4-methoxyphenylacetic-α,α-d_2 in water at 25 ± 0.01 °C[5] are listed in Tables 4 to 10. The thermodynamic ionization constants were calculated using a treatment of conductance data developed by Shedlovsky (28) and modified by Robinson and Stokes (29). No corrections for solvent conductivity were made to the acid solutions as there is no obvious way of making such a correction.

The details of the Robinson and Stokes method (RSM) of calculating thermodynamic equilibrium constants, along with several iteration–extrapolation methods, will be presented in

[5]The regulation of the bath was better than these limits.

[a]C, conductance method; RSM, Robinson–Stokes method; I, Ives method; c, mol/l; m, mol/1000 g.
[b]Λ_0(molal) used in RSM calculations.
[c]Literature ref. for Λ_0(molar). The conversion of Λ_0(molar) to Λ_0(molal) was made in the usual way.

Part II of this series. The K_a values determined by the RSM agree very favorably with previous measurements on these acids (Table 11) apart from 4-nitrophenylacetic acid. The large discrepancy in the K_a values for the 4-nitro acid is almost certainly a consequence of the labile nature of this molecule when it is exposed to light. Since the previous workers failed to recognize this fact the value reported here is to be preferred.

A comparison of the K_a values calculated for the individual acid samples confirms the purity of each specimen used. In no case can any discrimination be made between the various samples within the precision of the results of the present study. The redetermined equilibrium constant for acetic acid is also in excellent agreement with previous values and offers further confirmation of reliability of our work.

Discussion

The thermodynamic equilibrium constants calculated using the RSM provide a method of evaluating $K(H)/K(D)$ for each of the three isotopic pairs (X = H, NO_2, OMe). A further method for calculating the isotope effect is provided by the classical plot. We deal with these methods individually below.

The RSM is a well-established treatment and has been used by several authors (41). This method requires, aside from equivalent conductance data of the acid at finite concentrations, a value of the limiting equivalent conductance. To evaluate the isotope effect we assume that $\Lambda_0(ArCH_2COO^-) = \Lambda_0(ArCD_2COO^-)$ for all the aryl groups investigated. The equilibrium constants (K_a) calculated by the RSM reveal a slight residual concentration dependence which is probably outside our experimental error. This residual concentration dependence of K_a may be a consequence of the breakdown of the theoretical expression at higher concentrations or alternatively may result from the neglect of the frequency dependence of the electrolyte resistances. In the most precise study to date (11, 15), the latter factor has been considered important. While the RSM provides a suitable method for establishing the absolute values of the individual equilibrium constants the relative values of the H and D compounds are better established using a classical plot.

The classical plot connects the quantities Λ_0,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Λ_c, c and K_c where Λ_0, Λ_c, and c have their usual significance and the quantity K_c is the classical dissociation constant, *i.e.* the K_c parameter is calculated assuming the activity coefficients for both the ions and undissociated acid are unity at all concentrations. The appropriate equation connecting these quantities for the protium acid is

$$[13] \quad \frac{1}{\Lambda_c(H)} = \frac{1}{\Lambda_0(H)} + \frac{\Lambda_c(H)c(H)}{\Lambda_0^2(H)K_c(H)}$$

Assuming $\Lambda_0(H) = \Lambda_0(D)$ (see ref. 5 and above), a least squares correlation between the variables $1/\Lambda_c$ and $\Lambda_c c$ for the H and D acids yields slopes m_H and m_D which related to the isotope effect via the equation

$$[14] \quad \frac{K_c(H)}{K_c(D)} = \frac{m_D}{m_H}^6$$

The $K(H)/K(D)$ ratios for the three isotopic pairs calculated by both RSM and classical plot are summarized in Table 12, and may be compared with Halevi's original measurement (ref. 1 and see Table 2).

Our new values are surprisingly small. Indeed, they are so small that the detection of substituent effects on isotope effects is only just inside the bounds of possibility. This is particularly unfortunate in the light of some recent comments in a review by Thornton and Thornton (42). These authors suggest that substituent effects on isotope effects are significant parameters for a detailed understanding of transition states. One of the purposes of the present study was to obtain base line data of this sort for equilibria where the detailed specification of the states involved is clearcut in contrast to rates where the nature of the transition state is always elusive.

TABLE 12. Comparison of isotope effects

	p-R-$C_6H_4CH_2COOH$/p-R-$C_6H_4CD_2COOH$ $K(H)/K(D)$	
R	Robinson–Stokes method	Classical plot
H[a]	1.004 ± 0.005	1.0072 ± 0.0004
NO_2	1.001 ± 0.005	0.997 ± 0.002
MeO	1.008 ± 0.002	1.0045 ± 0.0007

[a]Laughton and Demayo (39) have also measured $K(H)/K(D)$ for this isotopic pair and give the ratio as 1.009 ± 0.002 and 1.008 ± 0.005 depending on the method of calculation used. However the absolute value of K_a for the protium acid reported by these workers differs from that reported here and is lower than all the values given in Table 11.

A comparison of these isotope effects for the arylacetic acids with the data of Streitwieser and Klein for the isotopic pair CH_3COOH/CD_3COOH indicates that the $K(H)/K(D)$ values are less for the former structures and this observation is qualitatively in accordance with the inductive treatment, *i.e.* as the number of deuteriums decrease at a given position with respect to the carboxyl group, the isotope effect should likewise decrease. The predicted isotope effect for the pair $PhCH_2COOH/PhCD_2COOH$, based on σ^* (D) (See Table 2), is closer to the $K(H)/K(D)$ value determined in this laboratory than the ratio reported by Halevi and coworkers (1). The reasons for the difference between the result reported by Halevi and results presented here are not easily discerned.

It is now clear that Halevi's result is unduly large both in the light of the inductive treatment presented above and when examined by an alternative treatment based on the pair HCOOH/DCOOH. The inductive effect of a substituent is known to increase as the substituent is moved closer to the reaction site (10). A rough calculation shows that the isotope effect for the pair HCOOH/DCOOH based on Halevi's value of $K(H)/K(D)$ for the phenyl acetic acids would give a value of 1.15. This predicted value is much higher

[6]The complete expression for the isotope effect is $K(H)/K(D) = m(D)\Lambda_0^2(D)/m(H)\Lambda_0^2(H)$ and the validity of eq. 14 is restricted to those situations in which the ratio $\Lambda_0^2(D)/\Lambda_0^2(H)$ is closer to unity than the ratio $m(D)/m(H)$. The latter condition seems to be satisfied in previous measurements of isotope effects by conductance (3–5). In the present instance the reported isotope effects are relatively small and in consequence the proximity of $\Lambda_0^2(D)/\Lambda_0^2(H)$ to unity may represent a significant factor with respect to the validity of the isotope effect calculated on the basis of eq. 14.

The greater length of C—H bonds *vs.* C—D bonds will probably be the most important factor altering Λ_0 with isotopic substitution. Such changes in the molecular dimensions of the anions are very small but on the basis of some calculations we have made are likely to lead to differences in $\Lambda_0(H)$ and $\Lambda_0(D)$ such that the square of the ratio will differ from unity by *ca.* 1 part in 10^4.

Because our isotope effects are small our referees pointed out the desirability of measuring the limiting equivalent conductances for the isotopic anions related to the acids examined in the present study to verify the reported isotope effects. Because the estimated differences in the isotopic limiting equivalent conductances are small and because these quantities must be obtained by some sort of extrapolation procedure we doubt the feasibility of such measurements. Aspects of this problem will be considered in the second paper of the present series.

than the isotope effect (K(H)/K(D) = 1.06) measured by Bell and Miller (43).

We shall deal with the issue of these small secondary isotope effects more fully in subsequent communications together with some of our findings concerning the numerical evaluation of pK_a's from weak acid conductance data which are of interest in their own right. However, we consider that the present paper provides the best values for the pK_a's of 4-$MeOC_6H_4CH_2COOH$ and 4-$NO_2C_6H_4CH_2COOH$ and also values of the isotope effects which are worthy of theoretical attention.

The authors thank Dr. R. E. Robertson for spiritual and material encouragement, the latter involving the construction of the conductance cells. We are grateful to Professor P. Laughton and Dr. A. Demayo for the loan of a thesis relevant to the present study. We also thank Mr. Ralph Parsons and Mr. W. Gordon for sustained technical services. Finally both authors express their gratitude to the National Research Council of Canada for financial support.

Synthesis and Characterization of Dipyrazolylalkanes, and Some of Their Complexes With $CoCl_2$

K. I. THÉ AND L. K. PETERSON

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

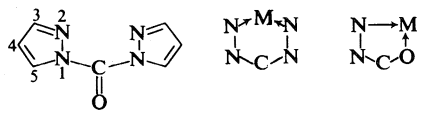
Received August 24, 1972

The reaction of dipyrazol-1-yl ketone with appropriate ketonic compounds is catalyzed by the presence of $CoCl_2$, to yield dipyrazolylalkanes $(C_3H_3N_2)_2CRR'$, (*a*) where R = R′ = CH_3, CD_3, C_2H_5; (*b*) where R = H, R′ = CH_3, C_6H_5; (*c*) where R = CH_3, R′ = C_2H_5; and 1,1-dipyrazolylcycloalkanes derived from cyclobutanone, pentanone, hexanone, 3-methyl and 4-methylhexanone. Cobalt(II) chloride reacts with dipyrazol-1-yl ketone, in tetrahydrofuran, to yield the complex $CoCl_2(C_3H_3N_2)_2CO$, and in acetone or acetone-d_6 to yield $CoCl_2(C_3H_3N_2)_2C(CH_3)_2$ or $CoCl_2(C_3H_3N_2)_2C(CD_3)_2$.

La réaction de la dipyrazol yl-1 cétone avec des composés cétoniques appropriés, est catalysée par la présence de $CoCl_2$ et conduit aux dipyrazolylalcanes $(C_3H_3N_2)_2CRR'$; (*a*) où R = R′ = CH_3, CD_3, C_2H_5; (*b*) où R = H, R′ = CH_3, C_6H_5; (*c*) où R = CH_3, R′ = C_2H_5; et aux dipyrazolylcycloalcanes-1,1 dérivés de la cyclobutanone, pentanone, hexanone, méthyl-3 et méthyl-4 hexanone. Le chlorure de cobalt(II) réagit avec la dipyrazol yl-1 cétone dans le tétrahydrofurane pour donner le complexe $CoCl_2(C_3H_3N_2)_2CO$ et dans l'acétone ou l'acétone-d_6 pour conduire au $CoCl_2(C_3H_3N_2)_2C(CH_3)_2$ ou au $CoCl_2(C_3H_3N_2)_2C(CD_3)_2$. [Traduit par le journal]

Can. J. Chem., **51**, 422 (1973)

Polydentate ligands may be designed with various electronic and steric characteristics, which, in conjunction with the nature of metal ion or other acceptor species, will determine the properties of complexes that may form. Because the pyrazole ring is planar (1), due to a delocalization of π-electron density, the coupling of two pyrazole rings to the sp^2 hybridized carbon atom of a carbonyl group, as in dipyrazol-1-yl ketone (**1**) (2) (structure **I**) should lead to a polydentate ligand with the four nitrogen atoms of the rings essentially coplanar with the carbonyl group. Complexation with metal ions may then lead to six-atom coplanar chelate systems, via two nitrogen atoms, or to five-atom systems, via N and O atoms (structures **II** and **III**) or ligand bridging may lead to polymeric structures.



I **II** **III**

Our studies of the complexing properties of dipyrazolyl-1-ketone lead to unexpected reactions which represent the discovery of a new synthetic route to dipyrazolyl compounds (3), and to other novel organic molecules. Our synthetic work is reported in this paper.

Experimental

The manipulation of compounds was performed under anhydrous conditions, using a nitrogen-filled dry box or high vacuum system. Solvents were rigorously dried before use (4). Most of the preparative reactions were quantitative, although quoted yields of pure products are low, due to losses during work-up.

Melting points (uncorrected) were measured using Gallenkamp or Fisher–Johns m.p. apparatus. N.m.r. spectra were determined with a Varian A56/60 or Varian XL100 spectrometer, using $CDCl_3$ as solvent and with TMS as internal standard, i.r. spectra with a Perkin–Elmer 457 spectrophotometer, and mass spectra with a double focusing RMU-6E Hitachi Perkin–Elmer instrument.

Analyses, for C, N, and H, were performed by the departmental analyst.

Preparation of Dipyrazol-1-yl Ketone (1)

Sodium amide (0.26 mol) and pyrazole (0.26 mol) were placed under nitrogen into a 200 ml reaction vessel which was joined to a 2 l ballast bulb. The vessel was evacuated, dry ether (150 ml) was introduced, and after sealing, the flask was agitated for 16 h at room temperature, and for 3 h at 70 °C. Following the removal of volatile materials under vacuum, dry ether (150 ml) and phosgene (0.125 mol) were added to the residue of sodium pyrazolide, and the mixture was stirred for 3 h at room temperature, and for 14 h at 70 °C. Sodium chloride (0.252 mol) was filtered off, and the ethereal filtrate was distilled under nitrogen to yield a yellow solid, which was purified by zone fractionation under vacuum (sublimation temperatures, 85–90°) to give compound **1**, 0.112 mol, 87% yield; m.p. 61.5–62.5°.

(H_3) (q, $J_{3,4}$ = 2.2, $J_{3,5}$ = 0.6 Hz); 3.40 (H_4) (q, $J_{3,4}$ = 2.2, $J_{4,5}$ = 3.0 Hz); 1.27 (H_5) (q, $J_{3,5}$ = 0.6, $J_{4,5}$ = 3.0 Hz).

The $CoCl_2$-catalyzed Reaction of Dipyrazol-1-yl Ketone with Acetone

An exploratory experiment indicated that no reaction occurs in a two-component mixture of **1** and acetone. When a mixture of **1** (1.50 mmol), acetone (~5 ml), and a catalytic amount of dry $CoCl_2$ (0.005 g) was allowed to stand at room temperature, an initially purple solution, turning to dark blue, was observed. The slow evolution of a gas was noted. After 16 h, the products were separated into CO_2 (1.45 mmol), identified by its i.r. spectrum and vapor phase molecular weight (M_{obs} 44.1, M_{calcd} 44.0), and a residue of solids; extraction of the latter with ether yielded a white solid, 2,2-dipyrazolylpropane (**2**), m.p. 83.5–84.0°.

Anal. Calcd. for $C_9N_4H_{12}$: C, 61.4; N, 31.8; H, 6.8. Found: C, 61.3; N, 32.0; H, 6.9.

(*d*) Diethylketone yielded 3,3-dipyrazolylpentane (**6**), m.p. 55.3–56.0 °C; yield 80%.

Anal. Calcd. for $C_{11}N_4H_{16}$: C, 64.7; N, 27.4; H, 7.8. Found: C, 64.6; N, 27.8; H, 7.7.

Mass spectrum: P_{obs} 204, P_{calcd} 204; n.m.r.: τ 9.22 (CH_3) (triplet, J = 7.3 Hz); 7.25 (CH_2) (q, J = 7.3 Hz); 2.48 (H_3) (q, $J_{3,4}$ = 1.8 Hz); 3.75 (H_4) (q, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.5 Hz); 2.53 (H_5) (q, $J_{3,5}$ = 0.7, $J_{4,5}$ = 2.5 Hz).

(*e*) Benzaldehyde yielded 1,1-dipyrazolylphenylmethane (**7**), m.p. 61.6–62.0 °C; yield, 48%.

Anal. Calcd. for $C_{12}N_4H_{12}$: C, 69.6; N, 25.0; H, 5.4. Found: C, 69.8; N, 25.4; H, 5.4.

Mass spectrum: P_{obs} 224, P_{calcd} 224; n.m.r : τ 2.37 (H_3) (q, $J_{3,4}$ = 1.8, $J_{3,5}$ = 0.6 Hz); 3.60 (H_4) (q, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.4 Hz); 2.49 (H_5) (q, $J_{3,5}$ = 0.6, $J_{4,5}$ = 2.4 Hz); 2.25 (CH) (singlet). The phenyl resonances consisted of two sets of complex multiplets, centered at 2.67 τ.

(*f*) Cyclobutanone yielded 1,1-dipyrazolylcyclobutane (**8**), m.p. 79.5–80.2 °C; yield, 82%.

Anal. Calcd. for $C_{10}N_4H_{12}$: C, 63.8; N, 29.8; H, 6.4. Found: C, 63.4; N, 30.1; H, 6.3.

Mass spectrum: P_{obs} 188, P_{calcd} 188; n.m.r.: τ 2.45 (H_3) (q, $J_{3,4}$ = 1.7, $J_{3,5}$ = 0.7 H_2); 3.75 (H_4) (q, $J_{3,4}$ = 1.7, $J_{4,5}$ = 2.4 Hz); 2.62 (H_5) (q, $J_{3,5}$ = 0.7, $J_{4,5}$ = 2.4 Hz). The CH_2 protons of the cyclobutyl ring gave complex resonances centered at 6.77 and 8.93 τ.

(*g*) Cyclopentanone yielded 1,1-dipyrazolylpentane (**9**), m.p. 133.0–133.5 °C; yield, 60%.

Anal. Calcd. for $C_{11}N_4H_{14}$: C, 65.3; N, 27.7; H, 6.9. Found: C, 65.3; N; 28.0; H, 6.9.

Mass spectrum: P_{obs} 202, P_{calcd} 202; n.m.r.: τ 2.50 (H_3) (q, $J_{3,4}$ = 1.8, $J_{3,5}$ = 0.6 Hz); 3.80 (H_4) (q, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.5 Hz); 2.53 (H_5) (q, $J_{3,5}$ = 0.6, $J_{4,5}$ = 2.5 Hz). The CH_2 protons of the cyclopentyl ring gave complex resonances at 7.07 and 8.17 τ.

(*h*) Cyclohexanone yielded 1,1-dipyrazolyl cyclohexane (**10**), m.p. 76.0–76.5 °C; yield, 62%.

Anal. Calcd. for $C_{12}N_4H_{16}$: C, 66.7; N, 25.9; H, 7.4. Found: C, 66.7; N, 26.1; H, 7.5.

Mass spectrum: P_{obs} 216, P_{calcd} 216; n.m.r.: τ 2.45 (H_3) (q, $J_{3,4}$ = 1.8, $J_{3,5}$ = 0.6 Hz); 3.77 (H_4) (q, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.5 Hz); 2.58 (H_5) (q, $J_{3,5}$ = 0.6, $J_{4,5}$ = 2.5 Hz). The CH_2 protons of the cyclohexyl ring gave complex resonances at 7.17 and 8.40 τ.

(*i*) 4-Methylcyclohexanone yielded 1,1-dipyrazolyl-4-methylcyclohexane (**11**), m.p. 89.0–89.3 °C; yield, 50%.

Anal. Calcd. for $C_{13}N_4H_{18}$: C, 68.1; N, 24.5; H, 7.4. Found: C, 68.3; N, 24.4; H, 7.6.

Mass spectrum: P_{obs} 230, P_{calcd} 230; n.m.r.: τ 2.53, 2.39 (H_3 and H_3') (two quartets with identical coupling constants, $J_{3,4}$ = 1.8, $J_{3,5}$ = 0.7 Hz); 3.85, 3.67 (H_4, H_4') (two quartets, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.4 Hz); 2.29, 2.88 (H_5, H_5') (two quartets, $J_{3,5}$ = 0.7, $J_{4,5}$ = 2.4 Hz).

(*j*) 3-Methylcyclohexanone yielded 1,1-dipyrazolyl-3-methylcyclohexane (**12**), m.p. 61.2–61.5 °C; yield 30%.

Anal. Calcd. for $C_{13}N_4H_{18}$: C, 67.9; N, 24.3; H, 7.8. Found: C, 67.9; N, 24.6; H, 7.9.

Mass spectrum: P_{obs} 230, P_{calcd} 230; n.m.r.: τ 8.97 (CH_3) (doublet, J = 5.5 Hz); 6.65–8.97 (CH_2) (complex pattern); 2.52, 2.38 (H_3, H_3') (two quartets, $J_{3,4}$ = 1.8, $J_{3,5}$ = 0.6 Hz); 3.87, 3.65 (H_4, H_4') (two quartets, $J_{3,4}$ = 1.8, $J_{4,5}$ = 2.6 Hz); 2.95, 2.25 (H_5, H_5') (two quartets, $J_{3,5}$ = 0.6, $J_{4,5}$ = 2.6 Hz).

(*k*) Unsuccessful reactions: The following compounds, containing the C=O group, did not react with dipyrazol-1-yl ketone when $CoCl_2$ was used as a catalyst: 2-methylcyclohexanone, acetophenone, benzophenone, ethyl acetate, dimethylacetamide, and δ- and γ-valerolactone.

*Preparation of 2,2-Dipyrazolylpropanecobalt Dichloride (**13**)*

Cobalt(II) chloride (0.82 mmol), dried by refluxing with thionyl chloride, **1** (0.82 mmol), and dry acetone

(~5 ml) were sealed together in a reaction flask. After 16 h at room temperature, the products were CO_2 (0.80 mmol) and a non-volatile blue solid; the latter was recrystallized from acetone to yield pure 2,2-dipyrazolylpropanecobalt dichloride, $CoCl_2[(C_3H_3N_2)_2C(CH_3)_2]$ (**13**).

Anal. Calcd. for $CoCl_2[(C_3H_3N_2)_2C(CH_3)_2]$: C, 35.3; N, 18.3; H, 3.9. Found: C, 35.0; N, 18.2; H, 3.9.

A solution of **2** (0.5 mmol) in acetone (10 ml) was added with stirring to a solution of $CoCl_2$ (0.5 mmol) in acetone (25 ml), to give a dark blue solution. Upon concentrating the solution, a blue product, with the same composition and i.r. spectrum as compound **13** prepared by the above method, was obtained.

*Hydrolysis of **13***

Compound **13** (2.0 mmol) was dissolved in water (20 ml) to give a pink solution which was extracted with diethyl ether (5 × 15 ml). The work-up of the organic layer yielded a solid residue, which was purified by zone fractionation; this product (1.2 mmol, 60% yield) was identical with a sample of **2** prepared by the $CoCl_2$-catalyzed reaction of acetone with dipyrazol-1-yl ketone.

*Preparation of 2,2-Dipyrazolylhexadeuteropropanecobalt Dichloride (**14**)*

This complex was prepared in the same way as **13**, using $CoCl_2$ (4.95 mmol), and **1** (4.95 mmol) in hexadeuteroacetone as solvent. Carbon dioxide (4.70 mmol) was formed quantitatively; the blue complex (**14**) was recrystallized from hot acetone.

Anal. Calcd. for $[(C_3H_3N_2)_2C(CD_3)_2]CoCl_2$: C, 34.0; N, 18.0; H (D), 4.0. Found: C, 34.5; N, 17.9; H (D), 3.9.

*Hydrolysis of **14***

Compound **14** (3.2 mmol) was dissolved in D_2O (10 ml) and the resulting solution was extracted with diethyl ether. The work-up of the organic layer produced the free ligand (1.95 mmol 61% yield), with the same physical properties and composition as **4** prepared above.

*Preparation of Dipyrazol-1-yl Ketonecobalt Dichloride (**15**)*

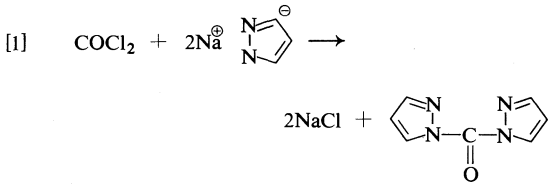
A mixture of $CoCl_2$ (1.07 mmol) **1** (1.07 mmol) and dry tetrahydrofuran (10 ml) was agitated at room temperature for 16 h. The absence of CO_2 was noted, and the solution was concentrated to yield a violet solid, which was filtered off under a dry nitrogen atmosphere. The product, **15**, was extremely sensitive to moisture.

Anal. Calcd. for $[C_3H_3N_2)_2CO]CoCl_2$: C, 28.8; N, 19.2; H, 2.1. Found: C, 29.0; N, 19.3; H, 2.0.

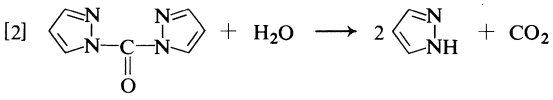
A sample of **15** (1.05 mmol) was dissolved in dry acetone (5 ml); after 16 h, the products were CO_2 (1.00 mmol) and a blue solid, which, after recrystallization, was identified as **13** on the basis of its i.r. spectrum; this complex was hydrolyzed by the methods described above to yield the free ligand, identified by its i.r. and n.m.r. spectra as **2**.

Discussion

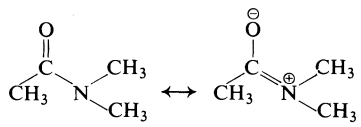
The new compound dipyrazol-1-yl ketone is formed quantitatively in the reaction of phosgene with sodium pyrazolide according to eq. 1:



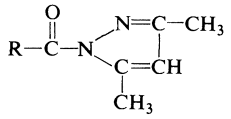
The use of lithium pyrazolide is precluded, since carbon atom lithiation occurs during the reaction of pyrazole with butyl lithium (5). The product, **1**, is very sensitive to water, yielding pyrazole and CO_2 (eq. 2). Whereas the ν(C=O)



stretching vibration for amides usually occurs in the 1650 cm^{-1} region, this band appears at 1740 cm^{-1} for compound **1**, suggesting an absence of the resonance interaction postulated for amides (6):



The absence of resonance may be due to aromaticity in the pyrazole ring system, requiring the lone pair of the amide nitrogen atom to be associated with the π-electron density of the ring, rather than with the carbonyl group. The monopyrazole systems, **IV**, show a trend in ν(C=O) values which may be accounted for on the basis of increasing resonance interactions with the R group, in the series R = CH_3CH_2, phenyl, and styryl, where the ν(C=O) values are 1722, 1700, and 1694 cm^{-1}, respectively (7).



IV

The position of the ν(C=O) band for **1** indicates a similarity to the carbonyl bond in acetone (ν(C=O) = 1715 cm^{-1}), while the greater electronegativity of chloro and fluoro groups is reflected in the ν(C=O) values for $COCl_2$ (1827 cm^{-1}) and for COF_2 (1928 cm^{-1}) (8).

Compound **1** forms a violet complex with $CoCl_2$ in tetrahydrofuran solution. The car-

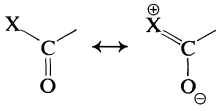
For personal use only.

bonyl frequency is essentially unchanged (1735 cm^{-1}), hence coordination must involve N rather than O atoms. The complex is hydrolytically unstable, being readily converted into a cobalt–pyrazole complex, with elimination of CO_2.

Compound **1** is soluble in acetone, and in other ketonic or carbonyl solvents, without reaction; the presence of Co(II) species, even in catalytic amounts, does promote a reaction in which the carbonyl group of the solvent is exchanged for the dipyrazolylmethylene group, with evolution of carbon dioxide (2) (eq. 3).

[3] 
The reaction has wide applicability, to aliphatic ketones and aldehydes, to aromatic substances such as benzaldehyde, but not to benzophenone and acetophenone, and to cyclic ketones, but not to lactones. Other carbonyl systems which do not react include hexafluoro and hexachloroacetone, esters of carboxylic acids, and dimethylacetamide. It is likely that steric factors are important for benzophenone, acetophenone, and 2-methylcyclohexanone; in other cases, resonance interactions,



may diminish the reactivity of the carbonyl group. Further studies of the steric, electronic, and catalytic factors influencing this type of reaction are in progress. When stoichiometric proportions of compound **1** and $CoCl_2$ are dissolved in ketonic solvents, the new ligand L derived from **1** and the solvent remains complexed to the cobalt ion in a 1:1 molar ratio, giving $CoCl_2L$.

Such complexes are less susceptible to hydrolysis than those of **1**, and may be handled in the atmosphere. In aqueous solution, however, the complexes are hydrolyzed, producing free ligand which may be extracted into organic solvents. The hydrolytic stability of the dipyrazolyl alkanes is in marked contrast to the observed instability of dipyrazol-1-yl ketone, and, unlike *N*-alkylpyrazoles (9), our compounds are not hygroscopic.

Evidence for reaction between dipyrazol-1-yl ketone and acetone was first observed in the i.r. spectrum of the product, 2,2-dipyrazolylpropane, by the appearance of ν(C—H) bands at ~3000 cm^{-1}, due to CH_3 groups, and by the disappearance of ν(C=O). The ν(CH) vibrations of the "aromatic" pyrazole ring occur at 3120 and 3140 cm^{-1} (10), and hence are distinguishable from the ν(CH) stretching vibration of alkyl groups (2900–3000 cm^{-1}) for compounds **2**, **3**, **5**–**12**, and from the vibrations of the phenyl ring system (3040–3060 cm^{-1} (10)) in **7**. Comparison of the n.m.r. spectra of **1** and **2** corroborated the presence of the methyl groups in the latter molecule (at 7.2 τ); the hexadeutero analog **4** did not exhibit this resonance, showing acetone to be the source of methyl groups; the observed n.m.r. spectra of compounds **1**–**11** were in agreement with the given formulations.

The resonance positions of H_3 (2.37–2.50 τ), H_4 (3.60–3.80 τ), and H_5 (2.4–2.6 τ) were assigned on the basis of expected shielding effects associated with the carbonyl group and the nitrogen atoms; the bands were observed as quartets, due to long-range coupling with different C—H protons, ($J_{3,4}$ = 1.7–2.0, $J_{3,5}$ = 0.6–0.7, $J_{4,5}$ = 2.4–2.5 Hz) and not as doublets or triplets, as reported by Trofimenko (3). The H_x and H_x' protons of the two pyrazole rings were equivalent in all cases, except in the 1,1-dipyrazole-methylcyclohexane derivatives, where the resonances due to H_x and H_x' were observed as separate pairs of quartets, of equal intensity. The different bands presumably reflect the different positions of the pyrazole substituents, *viz.*, axial or equatorial, in the methylhexane ring. The H_3 resonance was significantly broader than that of H_5; a similar effect is reported for the two protons of substituted pyridines (11). Bands due to the R groups of compounds **2**–**12** were clearly identified, with appropriate intensities.

Mass spectra further confirmed the formulations of products; parent peaks were observed in all cases, and the larger fragments of compounds **2**–**7** were clearly identifiable as $(C_3H_3N_2)CRR'$, $C_3H_3N_2)_2CR$, and $C_3H_3N_2$. Compound **1** gave recombination products, such as *N*,*N'*-dipyrazole, as well as $(C_3H_3N_2)CO$ and $C_3H_3N_2$. The derivatives of the cycloalkanes **8**–**12**

Received July 20, 1972

Reduction of several 2-benzylidenecyclohexanone oximes with lithium aluminum hydride gave the corresponding 1-benzyl-1,2-epiminocyclohexanes. Reduction of 2-benzylidenecyclohexanone oxime with lithium aluminum deuteride gave an epiminocyclohexane (**8**) which had incorporated two deuterium atoms. A reaction mechanism for the reduction is postulated. The major fragmentation pathways in the mass spectrum of **8** are outlined. Acetylation of 1-benzyl-1,2-epiminocyclohexane with acetic anhydride (15 min reflux) gave 3-acetamido-2-benzyl-1-cyclohexene by a pyrolytic *cis* elimination.

La réduction par $LiAlH_4$ de plusieurs oximes de benzylidène-2 cyclohexanones conduit aux benzyl-1 épimino-1,2 cyclohexanes correspondants. La réduction, par $LiAlD_4$ de l'oxime de la benzylidène-2 cyclohexanone donne l'épiminocyclohexane (**8**) ayant incorporé deux atomes de deutérium. Un mécanisme réactionnel est postulé pour cette réaction. Les modes majeurs de fragmentation de **8** lors de la spectrométrie de masse sont donnés généraux. L'acétylation du benzyl-1 épimino-1,2 cyclohexane avec de l'anhydride acétique (reflux de 15 min) conduit par pyrolyse impliquant une élimination *cis*, à l'acétamido-3 benzyl-2 cyclohexène-1. [Traduit par le journal]

Can. J. Chem., **51**, 427 (1973)

Introduction

Recently a series of substituted 2-benzylidenecyclohexylamines (**3**) were required as intermediates in the synthesis of some novel anticancer agents. In our earlier work,[3] we described the preparation of the ketones (**1**) shown to have the *E* configuration with relationship of the aromatic ring to the carbonyl function. These ketones were then converted to the corresponding oximes (**2**).[4] It was considered that the ketoximes could be converted to the corresponding amines (**3**) using lithium aluminum hydride (LAH), a reagent known to reduce substituted cyclohexanone oximes to amines (1, 2). The reaction sequence is shown in Scheme 1.

Results and Discussion

Reduction of **2***a* with LAH gave a colorless oil. The n.m.r. spectrum indicated the presence of 17 protons including one proton replaceable with deuterium but the olefinic proton was absent. The u.v. spectrum confirmed the absence of any styrenoid absorption. The mass spectrum indicated a parent peak at 187 with a molecular formula of $C_{13}H_{17}N$. These data show the absence of both **3***a* and the saturated primary amine, 2-benzylcyclohexylamine. The presence of one replaceable proton suggested an imine structure and aziridines have been formed by reduction of saturated cyclic oximes and α,β-unsaturated acyclic ketoximes with LAH (3, 4). The n.m.r., u.v., i.r., and mass spectral data obtained support the structure **4***a* for the compound isolated from the reduction of **2***a* with LAH. We are aware of only one other substituted cyclohexanone oxime which possessed an unsaturated linkage and gave an aziridine on reduction with LAH but in this case the double bond remained intact (5).

Reduction of **2***b* with LAH gave **4***a* which could also be obtained from **2***a* by reduction with lithium borohydride but **2***a* did not react with sodium borohydride, sodium trimethoxyborohydride, or lithium tri-(*t*-butoxy)aluminum hydride. It is interesting to note that reduction of (*Z*)-2-benzylidenecyclohexanone oxime with LAH

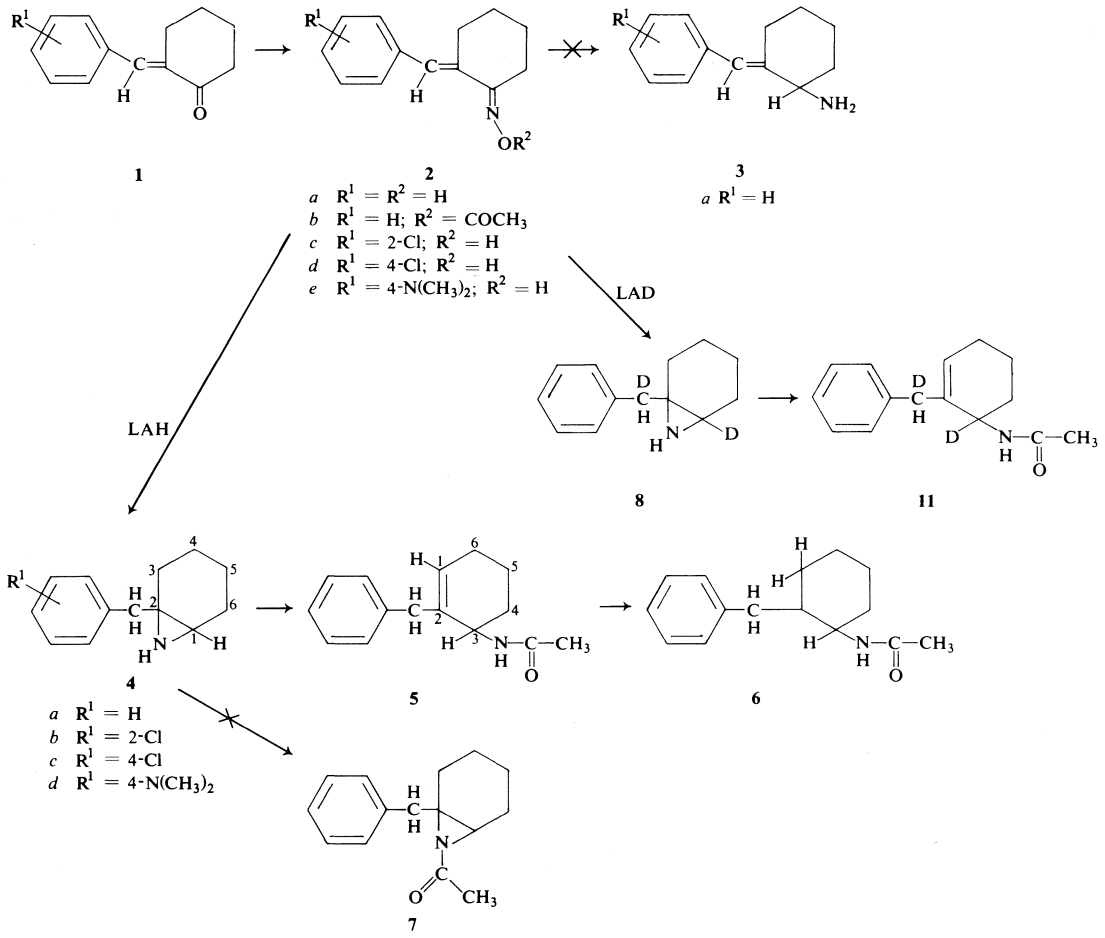

SCHEME 1

afforded **4***a* although in lower yields than reduction of **2***a*. Reduction of **2***a* with lithium aluminum deuteride (LAD) gave a compound with two deuterium atoms (**8**). The n.m.r. spectrum showed no absorption at δ 2.07–1.83 (C(2)H absent) nor the AB quartet with centers of the doublets at δ 2.92 and 2.63 ($C_6H_5CH_2$ absent). However two shaggy multiplets at δ 2.85 and 2.68 integrating for one proton were assigned to the *erythro* and *threo* forms of the product due to the CDH function in the side chain. The postulated reaction mechanism for the synthesis of the deuterated product (**8**) is shown in Scheme 2.

The mass spectrum of **8** had prominent *m/e* peaks at 189 (parent peak) and at 97 and 92 indicating the incorporation of one deuterium atom in the side chain and the other in the epiminocyclohexane portion of the molecule. The principle peaks for **4***a* and **8** are given in Table 1 and the possible fragmentation pattern for **8** is shown in Scheme 3. Work on the mass spectrometry of more complex aziridines has been published recently (6).

Reduction of **2***c* and *d* with LAH gave the corresponding aziridines (**4***b* and *c*) in good yields. In the case of reduction of **2***e*, g.l.c. of the reaction mixture indicated three components to the extent of 59, 24, and 17%. The n.m.r. spectrum of the reduction product from **2***e* was assignable to the aziridine structure **4***d*, indicating **4***d* was the major compound in the mixture. A white solid formed in the reaction mixture over a period of time (3 months) which was identified as 2-(4-dimethylaminobenzyl)cyclohexylamine by n.m.r., i.r., and mass spectral evidence. G.l.c. analysis indicated that this compound represented 24% of the reaction mixture. The third component of the reaction was not identified.

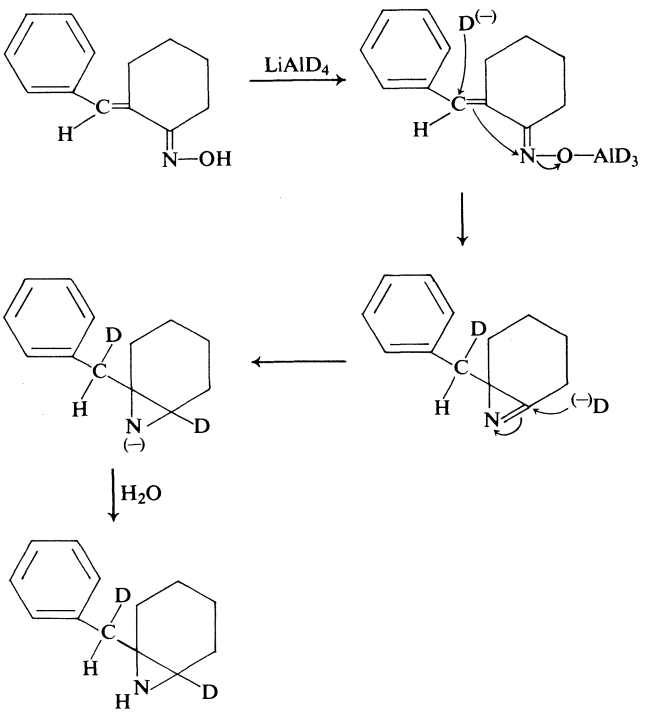
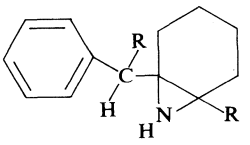


SCHEME 2

TABLE 1. Major peaks in the mass spectra of the aziridines **4*a*** and **8**



4*a* R = H
8 R = D

4*a*		**8**	
m/e	Relative abundance	*m/e*	Relative abundance
187 $[M]^+$	100	189 $[M]^+$	100
186 $[M-1]^+$	56	188 $[M-1]^+$	40
172 $[M-15]^+$	82	174 $[M-15]^+$	36
159 $[M-28]^+$	54	161 $[M-28]^+$	36
158 $[M-29]^+$	74	160 $[M-29]^+$	40
96 $[M-91]^+$	100	97 $[M-92]^+$	60
91 $[M-96]^+$	100	92 $[M-97]^+$	96

An attempt to prepare **7** by acetylation of **4*a*** with acetic anhydride (15 min reflux) gave a compound with a correct molecular weight for **7**. However, spectral evidence did not support this structure. The n.m.r. spectra indicated the presence of an olefinic group and a replaceable proton, while i.r. spectroscopy showed the presence of an NH stretching vibration as well as amide II and I bands at 1535 (NH) and 1640 cm^{-1} (CO). In view of earlier workers report of the preparation of *N*-allylcarboxamides on acylation of aziridines (7) we surmised that one of the structures **5**, **9**, or **10** may have been formed. Compound **10** may be eliminated since the u.v.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

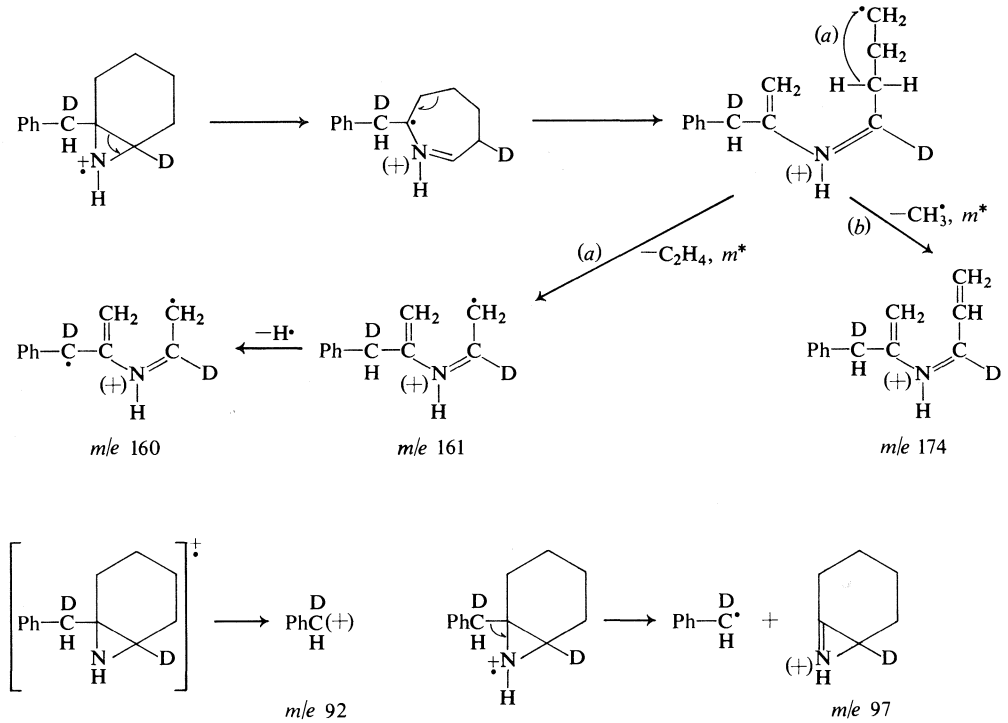
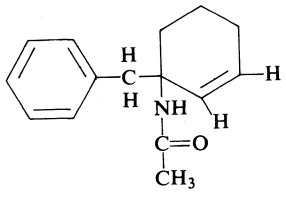
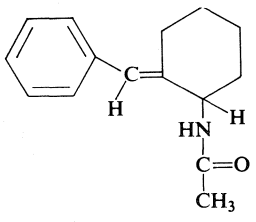


SCHEME 3

spectra indicated the absence of styrenoid absorption and the n.m.r. spectrum indicated the presence of a benzyl side chain.



9



10

The n.m.r. spectrum of the amide obtained showed a broad peak at δ 5.77–5.37 integrating for two protons and a peak at δ 4.60–4.20 integrating for one proton. One of the protons at δ 5.77–5.37 could be exchanged with deuterium suggesting that an amide proton was superimposed on an olefinic proton. Catalytic hydrogenation of the amide increased the molecular weight by two mass units indicating the presence of one double bond and the n.m.r. spectra of the reduced product showed no olefinic absorptions at δ 5.77–5.37 while the amide proton was moved upfield to δ 5.71. The presence of only one olefinic proton in the unsaturated amide indicates that the structure is **5** rather than **9**. Acetylation of **8** with acetic anhydride (15 min reflux) gave **11** with no proton at δ 4.60–4.20 indicating that the absorption in **5** at δ 4.60–4.20 was due to the bridgehead proton at C-3 of the cyclohexane ring. The formation of **5** from **4***a* presumably arises by pyrolytic *cis* elimination (8, 9) of the *N*-acetylaziridine via the transition state (**12**).

c	4-Cl	126–128/1.3	89	70.42	7.27	70.31	7.26

*Yield is based on the weight of reaction product obtained prior to distillation. G.l.c. analysis of the material showed that one product was present to an extent greater than 99.4%.
†This compound was prepared from **2***b* in 90% yield.
‡Reaction of **2***a* with lithium borohydride using the general reduction procedure gave a product containing **4***a* (65%) and unreacted **2***a* (35%).

The anticancer activity of several of the oximes, aziridines, and related compounds described in this work will be reported elsewhere.

Experimental

General Conditions

The i.r. spectra were recorded on a Unicam SP200G spectrophotometer previously calibrated with polystyrene, using sodium chloride optics or potassium bromide discs. The n.m.r. spectra were obtained in deuterochloroform using a Varian T-60 spectrometer, with tetramethylsilane as the internal standard. Mass spectra were obtained with an AEI MS-12 spectrometer. The u.v. spectra were recorded on a Beckmann DU Spectrophotometer, in 95% ethanol, using quartz cells. All melting points were determined on a Mettler FP-1 melting point apparatus and are uncorrected. Microanalyses were carried out by Mr. O. Douglas, College of Pharmacy, University of Saskatchewan, Saskatoon, on a Coleman Model 33 Carbon–Hydrogen Analyzer. Gas chromatographic analyses were determined on a Pye 104 chromatograph equipped with 5 ft × 0.25 in. o.d. glass columns packed with 4% SE-30 adsorbed onto silanized Chromosorb W (100/120 mesh).

*General Procedure for the Preparation of Substituted 1-Benzyl-1,2-epiminocyclohexanes (**4**)*

A solution of the appropriate ketoxime or ketoxime acetate (**2**) (10) (0.037 mol) in anhydrous ether (180 ml) was added dropwise to LAH (0.057 mol) in anhydrous ether (40 ml) and heated under reflux with stirring for 8 h. The reduction complex was decomposed by the dropwise addition of water and filtered. The filtrate was dried ($MgSO_4$) and evaporation of ether gave the crude reaction product which was purified by distillation (Table 2).

*1-Benzyl-1,2-epiminocyclohexane(**4a**)*

I.r. (smear) 3250s cm^{-1} (NH); n.m.r. δ 7.40–7.00 (5H, m, C_6H_5), 2.92, and 2.63 (2H, centers of two doublets of AB quartet, J = 14 Hz, $C_6H_5CH_2$), 2.07–1.83 (1H, m, C(2)*H*), 1.90–1.50 (4H, m, C(3)H_2, C(6)H_2), 1.50–1.07 (4H, m, C(4)H_2, C(5)H_2), 0.73 (1H, broad s, exchanges with D_2O, N*H*); mass spectrum *m/e* 187 (parent peak).

The deuterium analog (**8**) was prepared in a similar manner (90% yield), using LAD. B.p. 80°/0.5 mm; i.r. (smear) 3256s cm^{-1} (NH); n.m.r. δ 7.47–7.07 (5H, m, C_6H_5), 2.85 and 2.68 (1H, centers of 2m, C_6H_5—C*H*D), 2.00–1.50 (4H, m, C(3)H_2, C(6)H_2), 1.50–1.28 (4H, m, C(4)H_2, C(5)H_2), 0.98 (1H, broad s, replaceable with D_2O, N*H*); mass spectrum *m/e* 189 (parent peak).

*1-(2-Chlorobenzyl)-1,2-epiminocyclohexane (**4b**)*

I.r. (smear) 3258s cm^{-1} (NH); n.m.r. δ 7.47–7.40 (4H, m, C_6H_4Cl), 3.13, and 2.83 (2H, centers of two doublets of AB quartet, J = 14 Hz, C_6H_4Cl—CH_2), 1.97–1.83 (1H, m, C(2)*H*), 1.97–1.60 (4H, m, C(3)H_2, C(6)H_2), 1.60–1.07 (4H, m, C(4)H_2, C(5)H_2), 0.68 (1H, broad s, exchanges with D_2O, N*H*); mass spectrum *m/e* 221 (parent peak).

*1-(4-Chlorobenzyl)-1,2-epiminocyclohexane (**4c**)*

I.r. (smear) 3257s cm^{-1} (NH); n.m.r. δ 7.43–6.97 (4H, m, C_6H_4Cl), 2.85, and 2.58 (2H, centers of two doublets of AB quartet, J = 14 Hz, C_6H_4Cl—CH_2), 2.13–1.83 (1H, m, C(2)*H*), 1.93–1.48 (4H, m, C(3)H_2, C(6)H_2) 1.48–1.07 (4H, m, C(4)H_2, C(5)H_2), 0.44 (1H, broad s, exchanges with D_2O, N*H*); mass spectrum *m/e* 221 (parent peak).

*Reduction of 2-(4-Dimethylaminobenzylidene)cyclohexanone Oxime (**2e**) with LAH*

The general reduction conditions were followed to give an oil (1.43 g), b.p. 138°/0.7 mm. G.l.c. indicated a mixture of components in concentrations of 59, 24, and 17%. The following characteristics could be assigned to 1-(4-dimethylaminobenzyl)-1,2-epiminocyclohexane as the major component of the mixture: i.r. (smear) 3286s cm^{-1} (NH); n.m.r. δ 7.23–6.80 (2H, m, aromatic C(2)*H*, C(6)*H*), 6.80–6.47 (2H, m, aromatic C(3)*H*, C(5)*H*), 2.88 (6H, s, $(CH_3)_2N$), 2.81, and 2.53 (2H, centers of two doublets of AB quartet, J = 14 Hz, $(CH_3)_2N$—C_6H_4—CH_2), 1.97–1.73 (1H, m, C(2)*H*), 2.07–1.53 (4H, m, C(3)H_2, C(6)H_2), 1.53–1.07 (4H, m, C(4)H_2, C(5)H_2), 0.68 (1H, broad s, exchanges with D_2O, N*H*).

A white solid (0.1 g), m.p. 109.5° formed in the distillate over a period of time (3 months), which was identified as 2-(4-dimethylaminobenzyl)cyclohexylamine: i.r. 3376 cm^{-1} (NH_2); n.m.r. δ 7.20–6.87 (2H, m, aromatic C(2)*H*, C(6)*H*), 6.80–6.47 (2H, m, aromatic C(3)*H*, C(5)*H*), 2.70–2.10 (2H, m, $(CH_3)_2N$—$C_6H_4CH_2$), 1.90–1.13 (10H, m, C(1)*H*, C(2)*H*, C(3)H_2, C(4)H_2, C(5)H_2,

For personal use only.

C(6)H_2), 1.63 (2H, s, exchanges with D_2O, NH_2); mass spectrum *m/e* 232 (parent peak).

Reduction of (Z)-2-Benzylidenecyclohexanone Oxime with LAH

Reaction of (*Z*)-2-benzylidenecyclohexanone[3] with hydroxylamine by our general method[4] gave (*Z*)-2-benzylidenecyclohexanone oxime, m.p. 90–92° in a yield of 74%. Mass spectrum *m/e* 201 (parent peak).

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.58; H, 7.51. Found: C, 77.57; H, 7.49.

(*Z*)-2-Benzylidenecyclohexanone oxime (0.00994 mol) was reacted with LAH (0.0198 mol) using the general method, except that the time of heating under reflux was extended to 20 h, to give a pale yellow syrup (1.46 g). G.l.c. analysis indicated **4** (49%), unreacted oxime (33%), and two unidentified compounds (9 and 9%).

Attempted Reduction of 2a with Sodium Borohydride, Sodium Trimethoxyborohydride, and Lithium Tri-(t-butoxy)aluminum Hydride

When a mixture of **2***a* (0.05 mol), sodium borohydride (0.05 mol), ethanol (150 ml), and water (10 ml) was stirred at room temperature for 96 h or alternatively heated under reflux for 12 h, only unreacted **2***a* was isolated from the reaction.

A mixture of **2***a* (0.015 mol) and sodium trimethoxyborohydride (0.072 mol) in anhydrous tetrahydrofuran (50 ml) was heated under reflux for 96 h. The only product isolated was unreacted oxime (**2***a*).

The attempted reduction of **2***a* (0.001 mol) with lithium tri-(*t*-butoxy)aluminum hydride (0.024 mol) in anhydrous tetrahydrofuran (50 ml) heated under reflux for 8 h, gave only the unreacted oxime (**2***a*).

3-Acetamido-2-benzyl-1-cyclohexene (5)

A solution of **4***a* (2.05 g) in freshly distilled acetic anhydride (1.23 g) was heated under reflux for 15 min. The reaction mixture was poured into cold water (10 ml) and excess acetic anhydride was destroyed by the addition of 10% aqueous sodium carbonate solution (20 ml). The aqueous mixture was extracted with ether and the ether extracts were washed with water and dried ($MgSO_4$). Removal of the ether under reduced pressure gave a gummy yellow residue (2.1 g). G.l.c. analysis indicated 55% of **5**. Recrystallization of this residue from ether – Skelly F gave feathery colorless crystals of **5** (0.34 g, 14%): m.p. 103.5°; i.r. (KBr) 1535s (amide II), 1640s (amide I), 3310s cm^{-1} (NH); n.m.r. δ 7.40–7.00 (5H, m, C_6H_5), 5.77–5.37 (2H, m, C(1)H, NH, one proton replaceable by NaOD), 4.60–4.20 (1H, m, C(3)H), 3.27 (2H, s, C_6H_5—CH_2), 2.23–1.77 (2H, m, C(6)H_2), 1.78 (3H, s, CH_3CO), 1.83–1.43 (4H, m, C(4)H_2, C(5)H_2); mass spectrum *m/e* 229 (parent peak).

Anal. Calcd. for $C_{15}H_{19}NO$: C, 78.56; H, 8.35. Found: C, 78.40; H, 8.17.

The deuterium analog (**11**) was prepared by a similar acetylation procedure. G.l.c. analysis of the crude product indicated 60% of **11**. Crystallization of the crude product from ether – Skelly F gave pure **11** (3.3%): m.p. 101.5°; i.r. 1532s (amide II), 1637s (amide I), and 3310s cm^{-1} (NH); n.m.r. δ 7.37–6.90 (5H, m, C_6H_5), 5.73–5.47 (1H, m, C(1)H), 5.35 (1H, broad s, exchanges with NaOD, NH), 3.40–3.03 (1H, m, C_6H_5CHD), 2.20–1.80 (2H, m, C(6)H_2), 1.80 (3H, s, CH_3CO), 1.80–1.43 (4H, m, C(4)H_2, C(5)H_2); mass spectrum *m/e* 231 (parent peak).

1-Acetamido-2-benzylcyclohexane (6)

A solution of **5** (0.106 g) in absolute alcohol (200 ml) was hydrogenated over 10% palladium-on-charcoal (0.155 g) at 46 p.s.i. for 23 h. The catalyst was removed by filtration of the mixture through celite in a sintered glass funnel. Removal of the ethanol under reduced pressure gave colorless crystals of **6** (0.105 g, 98%): m.p. 152.5°; n.m.r. δ 7.30–6.87 (5H, m, C_6H_5), 5.71 (1H, broad s, replaceable by NaOD, NH), 4.00–3.20 (1H, m, C(1)H), 3.10–1.97 (2H, m, $C_6H_5CH_2$), 1.90 (3H, s, CH_3CO), 2.00–0.77 (8H, m, C(3)H_2, C(4)H_2, C(5)H_2, C(6)H_2); mass spectrum *m/e* 231 (parent peak).

One of the authors (W.A.T.) thanks the Medical Research Council for providing a studentship. Financial support was also provided by Smith, Kline and French Laboratories of Philadelphia, Pennsylvania for the project.

Comparison of the Complexation Constants of Some Cyclic Imides and Thioimides with Proton Acceptors

LUC LE GALL,[1] ANNE LE NARVOR,[2] JACQUES LAURANSAN,[1] AND PIERRE SAUMAGNE[2]

Université de Bretagne Occidentale, 6, Avenue Le Gorgeu, 29 N, Brest, France

Received March 8, 1972[3]

The complexation constants of some imides and thioimides in hydrogen-bonded complexes with proton acceptor molecules were determined by i.r. spectroscopy. The results permit a comparison between the proton donating abilities of these compounds. It is possible to classify them against other well-known proton donors.

Les constantes de complexation par pont d'hydrogène de quelques imides et thioimides avec des accepteurs de proton ont été déterminées par spectrométrie i.r. Les résultats permettent de comparer le pouvoir donneur de proton de ces composés et de les situer par rapport aux autres donneurs habituellement considérés.

Introduction

Evidence for hydrogen-bonded complexes between cyclic imides or thioimides and proton acceptors has been obtained by means of i.r. spectroscopy (1–4). The complexation constants of the 1:1 complexes between pyrrolidone, thiopyrrolidone, monothiosuccinimide, dithiosuccinimide, succinimide, maleimide, phthalimide, 2,4-thiazolidinone, and rhodanine, and proton acceptors have been measured; diacetamide, a non-cyclic compound, has been used for comparison.

Complexation Constants

All compounds studied in this paper exhibit, in dilute solution in carbon tetrachloride, an absorption band near 3400 cm^{-1} due to the stretching vibration of the NH group. The absorbance of ν_{NH} decreases as the amount of proton acceptor is increased in a solution of constant concentration of the proton donor (imide, thioimide, etc.).

One molecule of the proton donor D and one molecule of the proton acceptor A form a hydrogen-bonded complex:

$$D + A \rightleftharpoons D \ldots A$$

and the complexation constant is given by the relation

$$K = \frac{C_C}{(C_D^0 - C_C)(C_A^0 - C_C)}$$

where C_C is the concentration of the complex D–A and C_D^0, C_A^0, the initial concentrations of the donor D and the acceptor A, respectively. Only a 1:1 complex is considered. In all solutions, the proton acceptor is assumed to exist in monomeric form only; this is not always the case for the proton donor. If the self association of the donor is negligible ($C_D^0 < 10^{-4}$ mol l^{-1}) the formation constant of the 1:1 complex can be determined by a method described previously (1); if the initial acceptor concentration C_A^0 is higher than the concentration of the proton donor, Becker's graphical method can be used (5). We consider two solutions with the same concentration C_D^0 of the donor, the first one containing a concentration C_A^0 of the acceptor, the second one $C_A^0 = 0$; the absorbances of ν_{NH} are respectively d and d_0. The quantity $[(1/d) - (1/d_0)]$ is plotted against C_A^0 and the complexation constant is calculated from the slope of the curve. If the self association of the donor is not negligible, one can take this into account using Pineau's method (6).

Results and Discussion

The complexation constants K_C (l mol^{-1}) of 1:1 complexes are summarized in Table 1; Becker's method has been used for most of them except for pyrrolidone, thiopyrrolidone, and diacetamide, compounds for which Pineau's method has been used.

These complexation constants permit a comparison between the proton donating ability of these compounds to form hydrogen-bonded complexes with different "bases".

Acetonitrile	—	—	—	2	—	—	2.5	2	—	3

*The errors in K_C were about 20%.

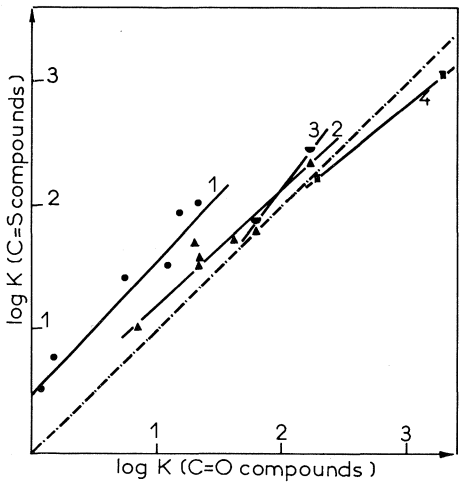

FIG. 1. Log K_C for thioamides and thioimides plotted *vs.* log K_C of the corresponding amides and imides for the same proton acceptors. Line 1, thiopyrrolidone/-pyrrolidone; line 2, monothiosuccinimide/succinimide; line 3, dithiosuccinimide/succinimide; line 4, rhodanin/-2,4-thiazolidinone (·····; 45° line).

The imides, thioimides, and related compounds are classified according to their acidic character and it is possible to observe the influence of the molecular structure, or of the presence of different atoms in the molecule, on the complexation constants.

Comparison of Thio and Oxo Compounds

In order to compare the proton-donating ability of corresponding thio and oxo compounds, log K_C of thioimides or thioamides is plotted against that of the analogous oxygen compounds (Fig. 1). For each thio/oxo pair, the plots for different acceptors are nearly linear. The 45° line suggests an equally acidic character for the two groups of compounds. The plots for thiopyrrolidone and pyrrolidone (line 1) are well above the 45° line, indicating an acidic character greater for the C═S compound than for the C═O compound. Those relating to the monothiosuccinimide, dithiosuccinimide/succinimide pairs (lines 2 and 3) are somewhat above the 45° line; an increase of acidity is again found in passing from the oxo compound to the corresponding thio compound, but this is smaller. 2,4-Thiazolidinone and rhodanine have the same behavior toward a given acceptor; the deviation of the experimental values (line 4) from the 45° line is probably not significant.

These results show that as often as not, the NH group is more acidic when it is closer to C═S groups than to C═O groups; to explain this phenomenon, it is possible for both oxo compounds (I) and thio compounds (II) to exist in the mesomeric forms (7):

(*a*) Polar form (*b*) Non-polar form

The relative electronegativity of the oxygen and sulfur atoms is insufficient to interpret the data; the atomic radius of the sulfur atom is greater than that of the oxygen atom and leads to an overlap of the atomic orbitals of the carbon atom and the X atom that is lower for X = S than for X = O. Morover, Mautner and Kumler (8) have pointed out that the ability of the 3d orbital in sulfur to accept electrons may stabilize the activated state $C^+—S^-$ (polar form (*a*)). Some authors have observed that, as a rule, the molar dipole moments (9), the chemical shift of the proton in the NH group (n.m.r.) (10, 11), and the bond order of the CN bond (11, 12) are systematically greater for compounds of group I than for those of the other group. This remark is supported by the fact that the percentage of polar form (*a*) is highest for the compounds of group II. The percentage of polar form involves an increase in the conjugation of the lone pair of the nitrogen atom with the delocalized π-electrons of the C═X bond. The hydrogen atom is now more positively charged and one finds an increase in its acidity for X = S as compared to X = O. This value agrees with Berthod and Pullman's (13) theoretical studies of 2-pyridone, uracil, guanine, and their thio-analogs: "the NH group adjacent to a double bond C═X appears more positively charged for X = S than for X = O" (13). But, for 2,4-thiazolidinone the endocyclic sulfur atom probably moderates this effect.

Comparison of Maleimide, Succinimide, and Phthalimide

The comparison of complexation constants for these compounds (Table 1) shows that they have a roughly similar acidic character. It can be seen that compared with succinimide, the introduction of an ethylenic double bond (as in maleimide), or of a benzene ring (as in phthalimide) does not alter in any significant way the complexation constant with proton acceptors:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the π-electrons of the ethylenic double bond or those of the benzene ring do not conjugate with those of the imide groups.

Comparison of Imides and Thioimides with Other Proton Donors

It is possible to compare imides and thioimides with other proton donors by means of their complexation constant with a given proton acceptor: *e.g.* dimethylsulfoxide (DMSO) in carbon tetrachloride solutions. Pyrrolidine (an aliphatic amine used for comparison) is a basic compound whose acidity is not measurable by the process used here; pyrrolidone is substantially more acidic (K_C = 19.3 l mol^{-1}) while succinimide (2 C=O groups, K_C = 65 l mol^{-1}) is more acidic still. Thus the increase in the number of adjacent carbonyl groups increases the acidity. This phenomenon is accounted for by the conjugation of the lone pair of the nitrogen atom with the π-electrons of the neighboring bonds as shown by Madec *et al.* (14) for a series of amines.

These compounds are relatively strong proton donors. In order of increasing acidity, when DMSO is chosen as the reference proton acceptor, the values are: acetylenic carbides (K_C = 0.2) (ref. 15), diphenylketimine (0.75) (ref. 3), chloroform (3.2)[4] (ref. 16), aromatic amines (2.5) (ref. 14), pyrrolidone (19.3), cyclic imides (65), cyclic thioimides (~70), thiopyrrolidone (89), diacetamide (135), phenol (188) (ref. 17), rhodanine (170), 2,4-thiazolidinone (190), and *p*-chlorophenol (476) (ref. 17). This order is slightly altered if another proton acceptor is selected for reference, hexamethylphosphorotriamide (HMPT) for example.

These results, which show that maleimide and related compounds are strong proton donors, agree with McGlynn's quantum mechanical calculations (18). According to these, the hydrogen atom of the NH group is more positively charged (q = 0.8689) and gives a stronger acidity.

Self-association of Diacetamide and Maleimide

Though the solubility of these donor compounds is very low, in a few cases, if the concentration in carbon tetrachloride is increased, self-association of the donor occurs (diacetamide, maleimide) and the absorption band ν_{NH} shows a deviation from Lambert–Beer's law. The concentration of these compounds is kept very low and we restrict our investigation to the monomer – cyclic dimer model; it is then possible to determine the self-association constant K_D for the monomer – cyclic dimer equilibrium:

$$2M \rightleftharpoons D, \qquad K_D = \frac{C_D}{C_M^2}$$

(Other models might be used for our experimental results but we have not tried them.)

Diacetamide is sufficiently soluble in this solvent for the concentration of the solutions (C_T) to be known with great accuracy. When (C_T/d) is plotted against d, a linear relationship is obtained with K_D = 223 l mol^{-1} (at 20%).

The solubility of maleimide is lower and the total concentration C_T is not known with accuracy but the self-association constant can be evaluated without a knowledge of C_T. Solutions of known dilutions, $\alpha_i \cdot C_T$, are prepared from a saturated solution (C_T unknown) and α_i/d_i is plotted against d_i (d_i is the absorbance of the ν_{NH} band for the different dilutions $\alpha_i \cdot C_T$, see Fig. 2). The straight line thus obtained gives for K_D a value of 22 ± 3 l mol^{-1}, if the molar absorptivity of maleimide is determined for very dilute solutions far-removed from saturation (it is possible to weigh very small amounts of maleimide to prepare these solutions).

Maleimide is strongly self-associated; one finds in order of increasing self-association constants (K_D) the following values: pyrrolidine (0.89) (ref. 19), diphenylketimine (0.13) (ref. 20), (0.2) (ref. 21), aniline (0.27) (ref. 22), phenol (7.4) (ref. 23), maleimide (22) (ref. 4), pyrazole (47.5) (ref. 24), pyrrolidone (197) (ref. 25), and diacetamide (223) (ref. 4). The high value for maleimide results from its high acidity.

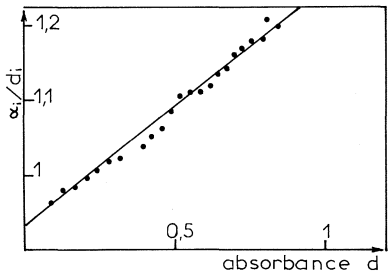

FIG. 2. α_i/d_i *vs.* d_i for maleimide in carbon tetrachloride solution at 25 °C (path length 5 mm).

[4](Mole fraction)$^{-1}$, calculated from n.m.r. studies of binary mixtures.

Experimental

All spectra were obtained with a Perkin–Elmer 225 spectrophotometer. The spectral slit width was approximately 1 cm^{-1}. Because of the low solubility of these compounds in carbon tetrachloride, cells of 5 cm path length with CaF_2 windows were used except for the study of self-association; in this case a cell of 5 mm was used. The donor compounds were commercial products from Aldrich; pyrrolidone, monothiosuccinimide, and dithiosuccinimide were kindly provided by M. Berg and M. Sandström. The proton acceptors were obtained from Prolabo and dimethylsulfoxide from Laboratoires du Bois de Boulogne. All solvents were dried by storing over Linde 4 Å molecular sieves or distilled before use. The temperature was about 25 °C.

We wish to thank Drs Berg and Sandström of the University of Lund, Sweden for the gift of the thiocompounds, Miss E. Gentric for her help and Dr J. P. Brown, Monsanto Chemicals Ltd., England, for valuable comments on the manuscript.

Cobalt(II) Mercury Tetrathiocyanate Complexes with Lewis Bases

R. MAKHIJA, L. PAZDERNIK, AND R. RIVEST

Département de chimie, Université de Montréal, Montréal, Québec

Received August 14, 1972

A new series of octahedral cobalt(II) complexes are formed when CoX_2(X = Cl, Br, I, SCN) reacts with $Hg(SCN)_2$ in the presence of Lewis bases. These complexes of stoichiometry $CoHg(SCN)_4.2L$ (L = THF, dioxane, pyridine, aniline) are pink to violet solids which slowly decompose to the blue crystalline solid, $CoHg(SCN)_4$, the stable magnetic susceptibility standard. On further reaction of $CoHg(SCN)_4.2THF$ with mono-, bi-, and polydentate ligands in dry ethanol, complexes of the following types are obtained: $CoHg(SCN)_4.2L$ (L = $P\Phi_3$), $CoHg(SCN)_4.2LL$ (LL = trien), $CoHg(SCN)_4.3LL$ (LL = en, bipy), and $CoHg(SCN)_4.4LL$ (LL = phen). The stoichiometry of these were determined by elemental analysis. Possible structures of these are discussed with the help of mid and far infrared, visible, and ultraviolet spectroscopy, magnetic susceptibility, and X-ray powder diffraction. Some new i.r. bands like Co—P, Co—N, and Hg—S are assigned in the low region.

Une nouvelle série de complexes octaédrique du cobalt(II) a été élaborée quand du CoX_2(X = Cl, Br, I, SCN) réagit avec du $Hg(SCN)_2$ en présence de bases de Lewis. Ces complexes de stoichiométrie $CoHg(SCN)_4.2L$ (L = THF, dioxanne, pyridine, aniline) sont des solides allant du rose au violet qui se décomposent lentement en un solide cristallin bleu, $CoHg(SCN)_4$, le standard stable de mesure de susceptibilité magnétique. De plus, en poursuivant la réaction du $CoHg(SCN)_4.2THF$ avec des ligands mono, bi- et poly coordonnés dans de l'éthanol sec, on peut isoler des complexes des types qui suivent : $CoHg(SCN)_4.2L$ (L = $P\Phi_3$), $CoHg(SCN)_4.2LL$ (LL = trien), $CoHg(SCN).3LL$ (LL = en, bipy) et $CoHg(SCN)_4.4LL$ (LL = phen). La stoichiométrie de ceux-ci a été déterminée par analyse des éléments. Les structures possibles de ceux-ci sont discutées avec l'aide de l'infra-rouge moyen et lointain de la spectroscopie dans le visible et dans l'ultra-violet, de la susceptibilité magnétique et de la diffraction des rayons-X (poudre). Quelques nouvelles bandes (infra-rouge) comme Co—P, Co—N et Hg—S ont été assignées dans la région de l'infrarouge lointain. [Traduit par le journal]

Can. J. Chem., **51**, 438 (1973)

Introduction

The role of thiocyanate ion has been extensively studied in metal complexes because of its ability to coordinate either through nitrogen or sulfur or both in a bridging fashion. Infrared spectroscopy has been a valuable instrument (1–3) in studying the type of bonding *i.e.*, M—NCS, M—SCN, or M—NCS—M′. Some work has been done on complexes of the type $M^{II}Hg(SCN)_4$ where M—NCS—M′ bonding is present (4–6). Bailar and co-workers (4) have reported compounds of the type $M^{II}Hg(SCN)_4$ where M^{II}(Mn to Zn) and Hg^{II} are both tetracoordinated through thiocyanate bridging. $NiHg(SCN)_4.2H_2O$ is the only known compound where Ni atom is octahedral by co-ordinating with two molecules of water (7). Here, we report the synthesis and the characterization of compounds which can be divided into three classes, $CoHg(SCN)_4.2L$ where L is a monodentate ligand, $CoHg(SCN)_4.2P\Phi_3$, and $CoHg(SCN)_4.xLL$ where LL is a bidentate or a polydentate ligand. For each class of compounds structures will be proposed.

Experimental

Materials and Manipulations

Cobalt(II) halides (anhydrous) and mercuric thiocyanate from Alfa Inorganics Inc., triphenylphosphine, triphenylarsine, and 2,2′-bipyridine from City Chemical Corporation, New York, and 1,10-phenanthroline from Eastman Kodak Company were used after vacuum drying at room temperature. Ethylenediamine, triethylenetetramine, aniline, and triethylamine (Baker) were anhydrous and were used after distillation. Dioxane, 1,2-dimethoxyethane, tetrahydrofuran, ethanol, acetone, and methylenedichloride etc, were previously dried by standard methods and distilled onto molecular sieves (Union Carbide). All chemicals and solvents were handled in a dry box flushed with dry nitrogen or on bench top by appropriate techniques.

Physical Measurements

The infrared spectra (4000–200 cm^{-1}) of the complexes and the ligands were recorded on a Perkin–Elmer 621 spectrophotometer using CsI optics. Samples were run as Nujol mulls using CsI plates as well as CsI pellets. In the far infrared (300–33 cm^{-1}), a Perkin–Elmer 180 spectrophotometer was used and the spectra were recorded using pressed polyethylene discs, the instruments being well purged with dry air. The infrared spectra (4000–200 cm^{-1}) are given in Table 1 and those in the far infrared region in Table 2.

Ultraviolet and visible spectra were obtained on a Cary

*Magnetic measurements made on Gouy's balance.

14 spectrophotometer between 50 and 5 kK. Samples were run as Nujol mulls between quartz windows. These are included in Table 3.

Magnetic susceptibility measurements were made at room temperature by Gouy's as well as Faraday's methods using $CoHg(SCN)_4$ as standard (8). The diamagnetic corrections were made by the method outlined by Figgis and Lewis (9). The results are included in Table 4.

X-Ray powder patterns were taken using 11.46 cm Debye–Scherrer Camera with nickel filtered CuKα radiation. The samples, sealed in Lindemann capillaries, were exposed for 12–15 h.

Preparation of $CoHg(SCN)_4.2THF$

Anhydrous cobalt(II) halide (10 mmol) was dissolved in the minimum amount of freshly distilled tetrahydrofuran and added to a slurry of $Hg(SCN)_2$ (20 mmol) in the same solvent. The reaction mixture was stirred magnetically for 6–8 h at room temperature. On completion of the reaction, a pink solid was obtained which was filtered, washed, dried in a dry box and finally dried in vacuum for 5 min at room temperature.

The pink solid turns blue at about 80–100 °C, does not melt till 350 °C and is insoluble in common organic solvents. It is very susceptible to moist air and mild heat under which it decomposes to $CoHg(SCN)_4$, a crystalline solid known as Gouy's standard for magnetic measurements (8).

Another route was to dissolve 10 mmol of anhydrous cobalt(II) thiocyanate in dry ethanol and add 10 mmol of mercuric thiocyanate which slowly dissolved to give a pink solution. A slight excess of 1:2 molar ratio of THF was added causing $CoHg(SCN)_4.2THF$ to crystallize as pink needles which were isolated as above. This method was used for the preparation of the dioxane complex since dioxane could not replace the THF ligand in $CoHg(SCN)_4.2THF$. With methylene dichloride or acetone as solvents, only $CoHg(SCN)_4$ is obtained from the reaction.

Preparation of $CoHg(SCN)_4.xL$

To a suspension of the dry pink solid, $CoHg(SCN)_4.2THF$ (5–6 mmol) in dry ethanol is added an excess of the appropriate ligand. The reactants are allowed to stir for 3 days, the solid is filtered, washed with dry ethanol, and dried in vacuum at room temperature. The filtrate on evaporation gives the excess of the ligand used.

Preparation of $CoHg(SCN)_4.2\Phi NH_2$

Cobalt(II) halide and mercuric thiocyanate were mixed in 1:2 molar ratio in ethanol yielding a clear red solution to which excess of anhydrous aniline is added. The resulting solution is pink and on partial removal of the solvent yields a pink powder, which is filtered and dried.

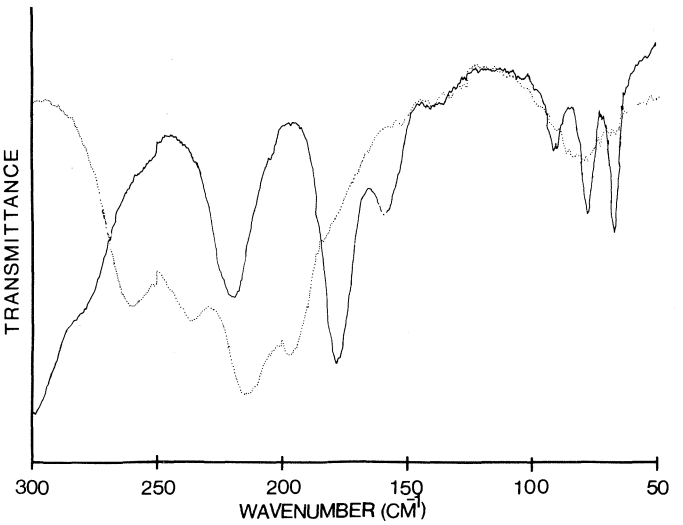

FIG. 1. $CoHg(SCN)_4.2$diox, —; $CoHg(SCN)_4.2$-THF, ···.

From the red filtrate, a second solid is obtained but this contains a small amount of mercuric halide which is formed during the reaction. The pink solid obtained slowly turns violet when dried in vacuum.

Analysis

The elemental analysis for C, H, N, S, Co, and Hg were carried out by Galbraith Laboratories Inc. and Chemalytics Inc. The results are shown in Table 5.

Results and Discussion

The results of our investigations on compounds of the type $CoHg(SCN)_4.x$Base can be easily divided into three groups *a*, *b*, and *c*, according to their stoichiometry, their infrared and visible spectra, and their magnetic moments.

Class (a) Compounds

$CoHg(SCN)_4.2L$ where L = THF, diox., py., and aniline. The infrared spectra indicate that:

(*i*) The SCN groups are bridging. The strong C≡N stretching band for these complexes lies in the frequency range 2100–2150 cm^{-1} which is the range for bridging SCN groups (6, 10, 11). These bands are in the same region as $CoHg(SCN)_4$ (4) which appears at 2142 cm^{-1}. The medium C—S stretching band in the above compounds appears in the range 740—795 cm^{-1} which is within the range for bridging SCN (1). As expected no significant change in the two S—C≡N bending vibrations as compared to $CoHg(SCN)_4$ were observed.

(*ii*) The ligands L are coordinated. The dioxane and tetrahydrofuran complexes show features typical of the coordinated molecules in the range 1250–800 cm^{-1}. In particular the absorption bands associated with the C—O—C antisymmetric stretch show the expected frequency decreased in each case (12—14), *i.e.*, the strong 1070 cm^{-1} band in tetrahydrofuran moves to 1035 (m) cm^{-1}, the strong 1120 cm^{-1} band of dioxane appears at 1045 (ms) cm^{-1}, the tetrahydrofuran band at 908 cm^{-1} moves to 877 cm^{-1} and the dioxane band at 887 to 860 cm^{-1}, respectively. The dioxane compound also shows absorption bands due to uncoordinated C—O—C.

In the aniline compound the $—NH_2$ stretching bands appear at 3340 and 3270 cm^{-1} with reduced intensity as compared to free aniline which appears at 3430 and 3360 cm^{-1}. This negative shift in frequency is indicative of aniline coordinated to a metal (15). Similarly, for the pyridine compound, the two low-lying ring vibrations (16, 17) at 405 and 604 cm^{-1} experience the positive shift and move to 425 and 631 cm^{-1}, respectively, which is due to pyridine coordinated to a metal (18, 19).

(*iii*) The Co—NCS stretching is lowered. The strong absorption band around 310–300 cm^{-1} in $CoHg(SCN)_4$ (20) which is due to Co—NCS stretching no longer appears in our complexes as it has shifted to a lower frequency 255–262 cm^{-1} as shown in Table 2 and illustrated in Fig. 1. This is expected when the geometry around the metal changes from tetrahedral to octahedral.

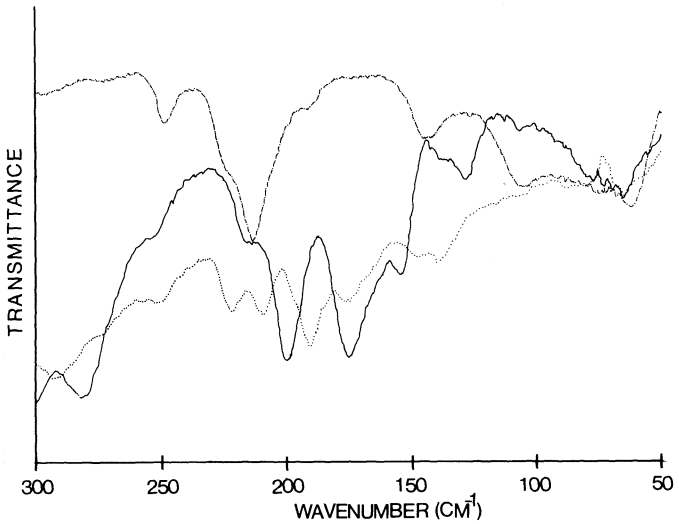

FIG. 2. $CoHg(SCN)_4.2P\Phi_3$, —; $Co(SCN)_2.2P\Phi_3$, · · ·; $Hg(SCN)_2.2P\Phi_3$, ·-·-.

The Visible Spectra

As shown in Table 3, the visible spectra are typical of an octahedral cobalt(II) in these compounds (21–23) and as expected the compounds are pink or brownish pink and have magnetic moments in the range of 4.76 to 5.01 B.M. (24).

Since these compounds are insoluble in most of the common organic solvents, no molecular weight measurements could be performed.

These different experimental results suggest that in these compounds Co(II) is attached to nitrogen of the thiocyanate group and Hg(II) to sulfur, hence both metals are attached through four SCN bridging groups while two ligand molecules are coordinated to Co(II) making it octahedral.

Class (b) Compound

In the second category we were successful in preparing only one compound, namely, $CoHg(SCN)_4.2P\Phi_3$, which is very stable in air and decomposes above 300 °C. It is slightly soluble in polar solvents like acetone or *N*,*N*′-dimethyl formamide in which it gives a blue solution. Molecular weight measurements show it to be monomeric.

The infrared spectrum of this yields four strong absorption bands at 2137, 2118, 2080, and 2065 cm^{-1} indicating both bridged and free thiocyanates (25). The *x*-sensitive *q*, *r*, and *t* absorption bands at 1095, 710–14, 437 cm^{-1} are typical of coordinated triphenyl phosphine (26). The low infrared spectrum of this compound shows bands at 176 and 155 cm^{-1} which we have assigned to be the asymmetric and symmetric Co—P stretching vibrations. This agrees with the reported bands for tetrahedral Co(II) phosphine compounds (27). This visible spectra of this compound show a strong absorption band at 15.87 and 16.34 kK which are in agreement for tetrahedral cobalt(II) (21, 28).

The far infrared spectrum was also studied. The triphenyl phosphine gives absorption bands at 251, 246, 212, 194, and 183 cm^{-1} while $CoHg(SCN)_4.2P\Phi_3$ shows absorption bands at 282, 254, 215, 200, 176, 155, and 128 cm^{-1}, respectively. Sharp and co-workers (27) have assigned Co—P stretching bands at 187 (s), 151 (w) in $(\Phi_3P)_2CoCl_2$ and at 187 (m), 142 (w) cm^{-1} for $(P\Phi_3)_2CoBr_2$ complexes. Hence our bands at 176 and 155 cm^{-1} are due to Co—P for tetrahedral species with C_{2v} symmetry. If triphenyl phosphine was attached to mercury then we should have observed bands at 137, 108 cm^{-1} as is the case for $(\Phi_3P)_2HgCl_2$ and $(\Phi_3P)_2.Hg(SCN)_2$. The absorption band at 282 cm^{-1} is due to Co—NCS and 200 cm^{-1} to Hg—S stretching. This is illustrated in Fig. 2.

A magnetic moment of 4.60 B.M. was observed.

These results suggest that in this compound both cobalt(II), and mercury(II) are tetrahedrally coordinated and that the most plausible structure is

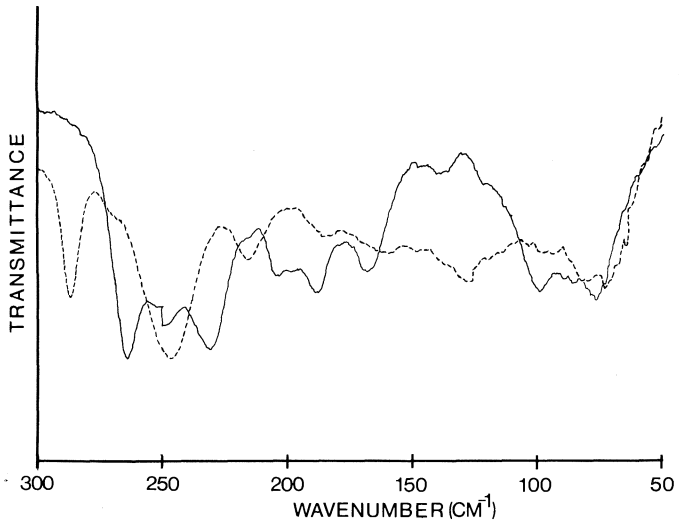

FIG. 3. $CoHg(SCN)_4.3bipy$, - - -; $CoHg(SCN)_4.4$-phen, —.

Class (c) Compounds

$CoHg(SCN)_4.xLL$ where LL = en., trien., bipy., and phen. The third type of compounds are insoluble in most of the common organic solvents, even water and DMF. They are very air stable and decompose above 300 °C. No conductance or molecular weight measurements could be performed.

The infrared spectra of all these compounds show only one type of C≡N stretch which appears below 2100 cm^{-1}, indicating only free thiocyanates (M—SCN type). The phenanthroline and bipyridine complexes are pink and yellow and have magnetic moments of 5.04 and 5.17 B.M., respectively, indicating cobalt to be high spin octahedral. This is also supported by the fact that visible spectra show absorption bands around 20–21.0 kK. On the other hand, compounds with ethylenediamine and triethylenetetraamine show magnetic moments of 2.29 and 2.22 B.M., respectively. These results were surprising as compared to the ones obtained for the other compounds and the magnetic susceptibility measurements were repeated many times confirming the above mentioned values. No interpretation of them is offered at this time.

In order to see if the complexes are ionic, we prepared the bipyridine compound starting with $K_2Hg(SCN)_4$ and $Co(bipy)_3Br_2$ in alcohol. We found the same infrared, visible spectra, and magnetic moment, which indicates that a probable structure could be $Co(bipy)_3^{2+}.Hg(SCN)_4^{2-}$. In all these complexes cobalt is believed to be hexa-coordinated and mercury tetra-coordinated with the exception of the phenanthroline complex in which both Co(II) and Hg(II) are hexa-coordinated.

Mercury thiocyanate has been used as a Lewis acid by many groups and compounds of the $Hg(SCN)_2.xL$ (x = 1 or 2 and L is ligand molecule) have been reported (29). In these compounds mercury is usually four coordinated but examples of six coordination for mercury are reported (30).

In the far infrared spectrum the free bipyridine ligand exhibits the bands at 423–404 and 168 cm^{-1}. These bands appear almost at the same frequencies in our spectrum. New bands at 375–55, 290–75, 260–35, and 240–10 cm^{-1} have been assigned to ligand vibration newly activated by complex formation. Nakamoto and co-workers (31) in their recent paper have assigned Co—N stretching at 266 and 228 cm^{-1} and we tentatively assign our bands at 265 and 232 cm^{-1} as Co—N, while the 204 cm^{-1} absorption band is due to Hg—S stretching. The Co—N stretching band is further confirmed by Strukl and Walter (32) who assigned it at 270 cm^{-1} in their bipyridine complex. Similarly in our phenanthroline complex we tentatively assign 287 and 245 cm^{-1} to Co—N stretching and 215 cm^{-1} to Hg—S stretching. The bands we observed are illustrated in Fig. 3.

These results suggest that in all these compounds Co(II) is octahedral and Hg(II) is tetrahedral with one exception, the phenanthroline

complex in which it is hexa-coordinated. The experiment with $K_2Hg(SCN)_4$ and $Co(bipy)_3Br_2$ suggests that these compounds are ionic.

X-Ray powder patterns of some of the complexes were measured but due to the large number of closely packed lines, the interpretation is very difficult. We have tabulated the values of *d*-spacings (observed) and relative intensities of one compound from each class in Table 6. We have been successful in growing crystals of $CoHg(SCN)_4.2py$ and single crystal precession photographs show it to be monoclinic with systematic absences consistent for both *Cc*(noncentric) and *C*2/*c* (centric) space groups. The cell dimensions are $a = 11.46$ Å, $b = 13.29$ Å, $c = 14.50$ Å, and $\beta = 105.50°$, $Z = 4$. The complete structure is presently under investigation.

We did carry out reactions with Φ_3As, Φ_3N, Φ_2NH, Φ_3PO, and Φ_3Sb but failed to obtain any new complexes. In all these cases the starting material $CoHg(SCN)_4.2THF$ was decomposed to $CoHg(SCN)_4$. Apparently the coordinating ability of these ligands for Co(II) was insufficient to stabilize the formation of the octahedral Co(II) complex.

The authors wish to express their thanks to Dr. R. N. Jones, National Research Council of Canada, Ottawa for the use of far infrared facilities. We thank the National Research Council of Canada for financial assistance.

Conductance and Conductometric Titrations of Picric Acid in Sulfolane at 30°

P. M. P. Eller and Joseph A. Caruso[1]

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221

Received July 13, 1972

Conductance of picric acid solutions in sulfolane resembles the behavior seen in several other aprotic solvents and is suggestive of complex solution equilibria. The effect of water on equivalent conductance of picric acid is large for concentrations greater than about 0.3 *M*. Picric acid behaves as a weak acid in conductometric titrations.

La conductance de solutions d'acide picrique dans le sulfolane se rapproche du comportement de celle rencontrée dans plusieurs autres solvants aprotiques et suggère alors des équilibres complexes en solution. L'effet de l'eau sur la conductance équivalente de l'acide picrique est considérable pour des concentrations supérieures à environ 0.3 *M*. L'acide picrique se comporte comme un acide faible lors des titrations conductimétriques. [Traduit par le journal]

Introduction

Sulfolane (tetrahydrothiophene-1,1-dioxide) is a dipolar aprotic solvent which is finding application in titrations of acids and bases (1, 2) and in fundamental studies of acid–base equilibrium (3–5) because of its low autoprotolysis constant and moderately high dielectric constant. Conductance measurements have been limited to a few metal salts (6–8) and some moderately strong acids (9), and show limiting equivalent conductances for these solutes of about 10–12 ohm^{-1} cm^{-2} mol^{-1}. Picric acid solutions in sulfolane were found to have very stable solution resistances, and therefore the present study was undertaken in order to define further the nature of acid–base behavior in this interesting solvent.

Experimental

Apparatus

Conductance cells were made from 300 ml flasks, after the design of Daggett, Bair and Kraus (10). The electrodes were lightly platinized, at 6 C/cm^2 and the cell constants, determined with standard KCl solutions, were 0.2110 ± 0.0001 and 0.1837 ± 0.0001. A Leeds and Northrup #4666 Jones bridge, with Hewlett–Packard Audio Oscillator (Model 201-C) operating at 2000 Hz and General Radio Company Model 1232-A Tuned Amplifier/Null Detector was used to measure resistances. The cells were maintained at 30 ± 0.03 °C during experiments.

Reagents

Anhydrous sulfolane (Phillips Petroleum Company, Bartlesville, Oklahoma) was distilled (b.p. 100–105 °C, 1 mm) over concentrated sulfuric acid to prevent degradation of the solvent which occurred if it contained appreciable amounts of basic material. A second vacuum distillation was then done over sodium hydroxide pellets and resulted in a colorless distillate which contained less than 0.0007 mol/l of water (0.0013% H_2O). Specific conductance was 1–3 × 10^{-8} ohm^{-1} cm^{-1} after distillation and increased only slowly after several days of storage under dry nitrogen. Physical constants used for sulfolane at 30° were (6): density = 1.2623 g/ml, viscosity = 0.1029 P, and dielectric constant = 43.3.

The 1,3-diphenylguanidine (Eastman) was recrystallized from toluene. Tetrabutylammonium hydroxide (25% in methanol, Eastman) titrant was diluted approximately 1:10 with sulfolane. Picric acid (Eastman) was recrystallized from ethanol, then recrystallized from acetone and vacuum dried for 2 h at 80 °C.

Procedure

About 100 ml of pure solvent was weighed into a conductance cell, the resistance measured, and then a series of measurements of resistance was made after successive additions of stock solution of picric acid (*ca.* 0.04 *M*) from a weight buret.

Results and Discussion

The experimental values for equivalent conductance of picric acid solutions in sulfolane at 30° appear in Fig. 1, curve *g*. Also shown on the same figure are the data of French and Roe (11) for picric acid solutions in acetophenone at 25° (curve *h*) over the concentration range 10^{-2} to 10^{-4} *M*. The two sets of data are very similar, with slope, d log Λ/d log *C*, equal to −0.96. The magnitude of this slope was attributed by French and Roe to the formation of triple ions of the type $PiHPi^-$. However, it has been demonstrated that this mechanism cannot ade-

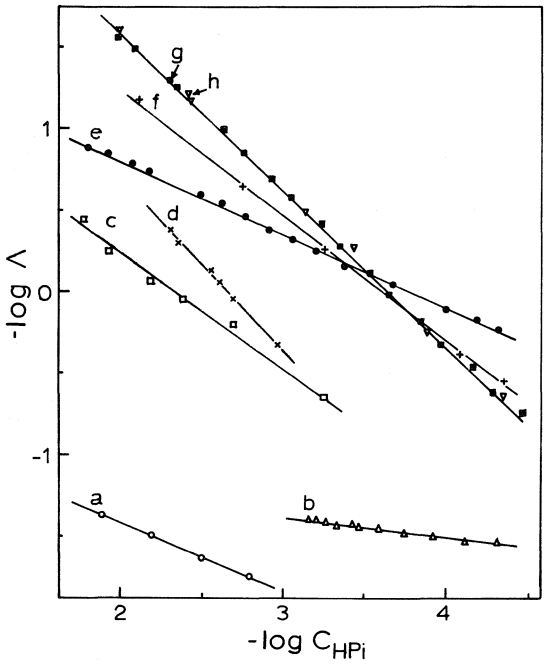

FIG. 1. Conductance of picric acid in various solvents: *a*, methanol (25°) (15); *b*, 1,1,3,3-tetramethylguanidine (25°) (14); *c*, acetone (25°) (11); *d*, acetonitrile (25°) (11); *e*, sulfolane + 1.09% by weight water (30°); *f*, α-naphthonitrile (40°) (11); *g*, sulfolane (30°); *h*, acetophenone (25°) (11).

quately explain such highly negative slopes (12). The only mechanisms which offer possible explanations for such slopes involve polymer formation. It is interesting to note that Kolthoff and co-workers have proposed $Pi(HPi)_2^-$ as the principal picric acid species at concentrations greater than 0.1 *M* (13). Implicit in their postulation, of course, is the formation of the dimer, $(HPi)_2$.

The mechanism of ionization of picric acid in sulfolane is changed by the addition of about 1% by weight water, as is seen in curve *e* of Fig. 1. In the presence of water at this level (*ca.* 0.7 *M*), the slope of the conductance line is −0.465, which is close to the −0.5 expected for the simple ionization of a weak acid according to the mechanism $HPi = H^+ + Pi^-$ (12). At concentrations of water less than 0.2 *M* the equivalent conductance of picric acid in sulfolane varies by only about 6% from that in the purified solvent, but a marked increase in Λ_{HPi} is seen (Fig. 2) for water content greater than about 0.3% by weight, with equivalent conductance

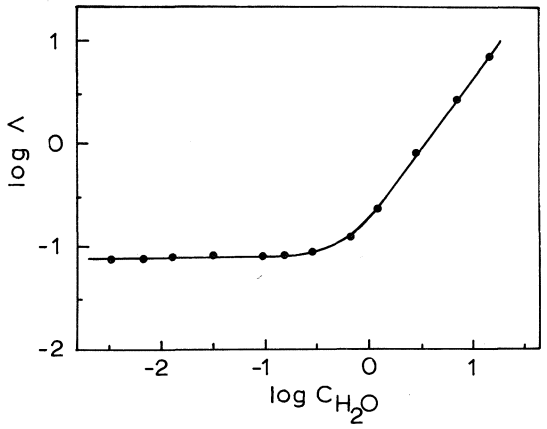

FIG. 2. Equivalent conductance of 1.98×10^{-3} *M* solution of picric acid in sulfolane at 30° as a function of added water concentration.

increasing approximately as $C^{1.3}$. The conductance of picric acid in several other solvents has been shown for comparison in Fig. 1 and the slopes listed in Table 1.

Data also have been reported for the conductance of picric acid solutions in phenol at 50°, in which the values of d log Λ/d log *C* vary from −0.53 (at 10^{-4} *M*) to −0.98 (at 10^{-2} *M*) (16).

Figure 3 shows the results of conductometric titrations of about 10^{-3} *M* picric acid in sulfolane at 30° with two bases. The titration with 1,3-diphenylguanidine (curve *b*) proceeds at low specific conductance values and gives a distinct end point characteristic of the titration of a weak acid with a weak base, with satisfactory recovery. On the other hand, the tetrabutylammonium hydroxide titrant (curve *a*) behaves as a strong electrolyte and gives an indistinct end point

TABLE 1. Conductance of picric acid in various solvents

Solvent	*T* (°C)	$\frac{d \log \Lambda}{d \log C}$	Reference
1,1,3,3-Tetramethylguanidine	25	−0.13	14
Methanol	25	−0.46	15
Sulfolane +1.09% water	30	−0.465	This work
Acetone	25	−0.72	11
α-Naphthonitrile	40	−0.78	11
Acetophenone	25	−0.95	11
Sulfolane	30	−0.96	This work
Benzonitrile	25	−0.97	11
Acetonitrile	25	−1.06	11

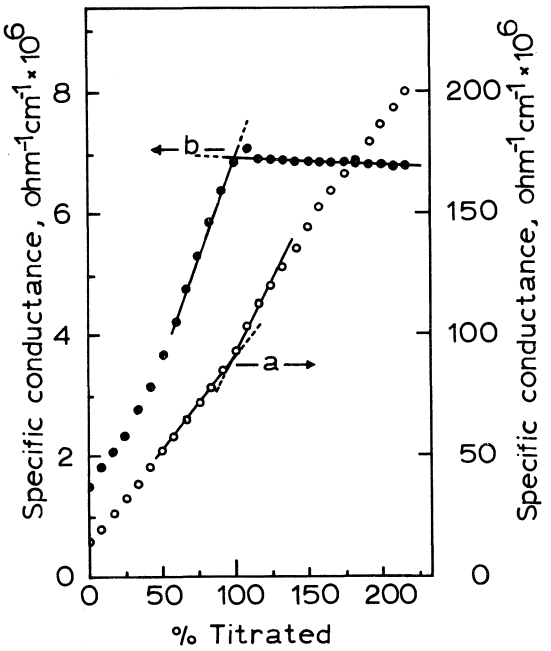

FIG. 3. Conductometric titration of picric acid in sulfolane: *a*, 7.23×10^{-4} *M* picric acid titrated with 0.1 *M* tetrabutylammonium hydroxide; *b*, 1.19×10^{-3} *M* picric acid titrated with 0.15 *M* 1,3-diphenylguanidine, at 30 °C.

(although with apparently satisfactory recovery) at much higher specific conductance values. The presence of methanol in the titrant may have contributed to slightly elevated conductances.

It may be concluded that picric acid behaves as a weak acid in sulfolane, with conductance behavior similar to that seen in several other aprotic solvents, if reasonable care is taken to exclude water.

Production of Vibrationally Excited Carbon Monoxide by the Reaction of Oxygen Atoms with Acetylene, Methylacetylene, and Methane

S. J. ARNOLD AND G. H. KIMBELL

Defence Research Establishment Valcartier, P.O. Box 880, Courcelette, Quebec

Received July 10, 1972

Infrared chemiluminescence attributed to the first overtone of CO was observed when either C_2H_2 or CH_3C_2H was introduced into a stream of oxygen which had been passed through a microwave discharge. The addition of vibrationally cold CO to these systems was found to produce a vibrational population inversion in the chemically formed CO. CO first overtone emission was not observed when CH_4 was introduced into a similar stream of oxygen unless the CH_4 had been subjected to a microwave discharge. These observations are used to clarify the mechanisms governing the formation of CO in continuous wave air–helium–hydrocarbon electrical discharge lasers.

La chemiluminescence infrarouge attribuée à la première harmonique de CO a été étudiée quand on introduit soit du C_2H_2, ou soit du CH_3C_2H dans un courant d'oxygène lequel a préalablement subi une décharge en microondes. L'addition de CO vibrationnellement froid à ces systèmes produit une inversion des populations dans les états vibrationnels pour du CO chimiquement formé. L'émission de la première harmonique du CO n'a pas été observée quand du CH_4 est introduit dans un courant identique d'oxygène à moins que le CH_4 n'ait préalablement subi une décharge en microondes. Ces observations ont été utilisées pour clarifier les mécanismes régissant la formation du CO dans des laser à ondes continues et à décharges électriques dans un mélange air–hélium–hydrocarbones.

Can. J. Chem., **51**, 451 (1973)

Introduction

Recently, workers active in studying chemical lasers have shown very great interest in chemical reactions capable of producing vibrationally excited carbon monoxide. Indeed, within the last year purely chemical laser action was observed in CO formed in a CS_2–O_2 low pressure diffusion flame (1). Several reports have also appeared describing continuous wave CO laser action occurring when a direct current discharge was sustained in mixtures such as CH_4–air–He, C_3H_8–air–He, C_2H_2–air–He, and C_2N_2–air–He (2–7). In these latter reports evidence was presented to suggest that vibrationally-excited CO formed chemically in the combustion contributed substantially to the energy of the laser.

Concurrently with this work, studies of the emission observed from the reaction of oxygen atoms with methane, acetylene, and methylacetylene were undertaken in this laboratory. The oxygen atom – acetylene system has been the subject of previous studies (8, 9); however, the need for additional experiments was felt in order to identify the role of chemically formed CO in increasing the performance characteristics of hydrocarbon–air–He continuous wave electrical discharge CO lasers.

Experimental

The apparatus used for these experiments is shown in Fig. 1. The reaction cell consisted of a 1.5 in. glass "tee" equipped with a NaCl window, which was pumped by an Edwards 660 l/min two stage pump. Oxygen atoms produced by the passage of an oxygen–helium mixture through a 2450 Mc microwave discharge entered the cell through the center tube of the concentric mixer. The hydrocarbon in a helium buffer entered through five holes in the outer tube of the concentric mixer. A second microwave discharge could be placed on the hydrocarbon–helium line. Carbon monoxide could be either premixed with the hydrocarbon–helium mixture or enter through a separate injector at right angles to the concentric mixer depending on whether one or two microwave discharges were used.

The spectra were recorded using a McPherson Model

218 0.3 m monochromator, a Dry Ice–acetone cooled PbS detector, a phase sensitive PAR Model HR-8 amplifier and a Hewlett–Packard Model 7100B strip chart recorder. The entire optical path was flushed with dry nitrogen to minimize absorption by atmospheric water vapor. A 500 °C blackbody source was used to provide a relative measurement of the sensitivity of the detection system as a function of wavelength.

Temperatures in the reaction zone were measured with a glass-coated chromel–alumel thermocouple.

All gases were of the highest purity available from Matheson and were used without further purification. Flows were measured with Matheson rotameters.

Results and Discussion

Acetylene

When acetylene was added to a stream of oxygen which had been passed through a microwave discharge a brilliant blue violet emission filled the reaction cell. Strong infrared chemiluminescence attributed to the CO first overtone emission was observed in the region 2300 to 2800 nm. As is shown in Fig. 2, only the first 13 vibrational levels of CO were appreciably populated, although emission from up to $v = 16$ can usually be detected. Figure 3 shows a plot

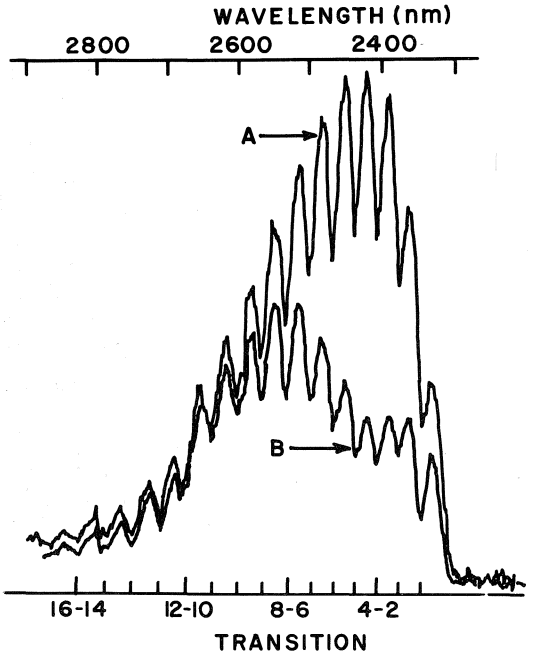

FIG. 2. The CO first overtone spectrum from the C_2H_2/O_2 atomic flame showing the effects of the addition of vibrationally cold CO. Curve *A*: flow rates, C_2H_2:O_2:He, 19:57.7:4809 μmol/s, total pressure, 8.1 Torr. Curve *B*: flow rates, C_2H_2:O_2:CO:He, 19:57.7:127:4809 μmol/s, total pressure, 8.4 Torr.

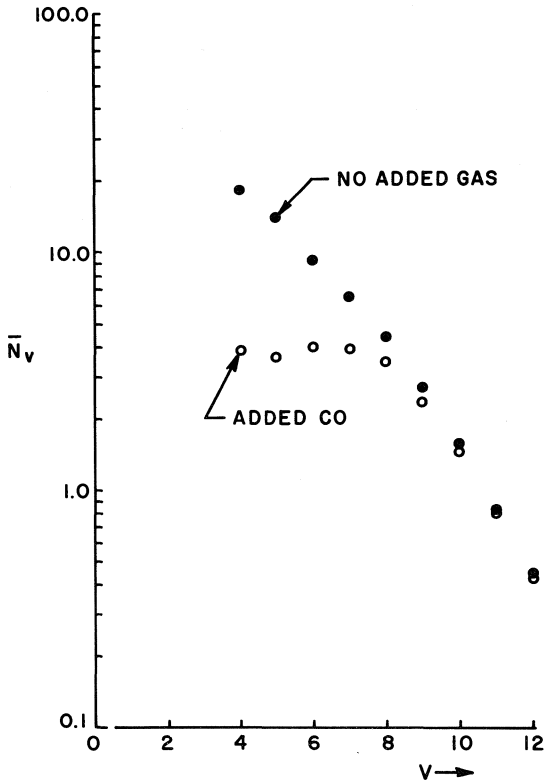

FIG. 3. Relative vibrational level population of CO† produced in the C_2H_2/O_2 atomic flame.

of the relative vibrational level population, N_v, calculated according to the method of Hancock and Smith (10), against vibrational number, v, for conditions of maximum total emission intensity (C_2H_2:O_2 ratio of 1:3). Under these conditions the system did not exhibit a population inversion.

When a second discharge cavity on the C_2H_2–He line was switched on, no marked change in the total emission intensity was observed. The spectral distribution of the emission was also unchanged. If the first discharge on the O_2–He line was shut off while that on the C_2H_2–He line remained on, no emission could be detected. These observations are entirely consistent with the mechanism for CO† formation previously proposed (8, 9)

[1] $O + C_2H_2 \rightarrow CO + CH_2 + 51$ kcal/mol

[2] $O + CH_2 \rightarrow CO + 2H + 71$ kcal/mol

with reaction 2 being sufficiently energetic to populate CO up to $v = 13$ (the highest level observed to be appreciably populated in the

present experiments). The value of the rate constant for reaction 1 is (see ref. 11):

$$k_1 = (9.2 \pm 0.4) \times 10^{10}\ \text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}\ (298\ ^\circ\text{K})$$

Several experiments were conducted to determine the effect of changing the C_2H_2:O_2 ratio from that observed to give maximum CO emission. At lower C_2H_2 flows the total emission intensity was decreased with a slight decrease in the relative population of higher vibrational levels. At higher C_2H_2 flows a more dramatic decrease in the total emission intensity was observed. Figure 4 (curve *a*) shows the CO first overtone spectrum for a C_2H_2:O_2 ratio of 1:3, the condition of maximum total emission intensity, and Fig. 4 (curve *b*) for a C_2H_2:O_2 ratio of 2:3. When the N_v's obtained for the ratio C_2H_2:O_2 of 2:3 are divided by the comparable N_v's for the ratio C_2H_2:O_2 of 1:3 it is apparent that a rapid fall off in the relative population of higher vibrational levels is occurring. The maximum decrease was observed for $v = 8$ (see inset Fig. 4). This effect can be attributed to vibrational energy transfer from CO to the ν_2 vibration of C_2H_2 at 1973.5 cm^{-1}. Vibrational energy transfer will be more effective for higher vibrational levels of CO for which the energy discrepancy in the reaction

$$[3]\quad \text{CO}(v = n) + \text{C}_2\text{H}_2(0000^\circ0^\circ) \rightarrow \text{CO}(v = n - 1) + \text{C}_2\text{H}_2\ (01000)$$

approaches zero. Closest resonance occurs for $v = 8$. That vibrational energy transfer from CO to C_2H_2 does occur is supported by the observation of i.r. chemiluminescence from C_2H_2 in the C_2H_2–O_2 system (8).

Experiments were conducted to determine the effect of various added gases on the CO first overtone emission. Figure 2 (curve *b*) shows that when CO was premixed with the C_2H_2–He mixture, a decrease in the total emission intensity was observed. This decrease was most pronounced for lower vibrational levels with a minimum occurring for $v = 5$ which is only 29% of its value in the absence of vibrationally cold CO *vs.* $v = 10$ which is 90% of its previous value. A plot of the relative vibrational level population, N_v, against vibrational number, v, (Fig. 3) indicates that under these conditions a vibrational population inversion was marginally sustained between $v = 5$ and $v = 7$. A local vibrational temperature of ~3300 °K was calculated for levels $v = 2$ to $v = 4$ while a temperature of ~11000 °K was determined for levels $v = 6$ to $v = 10$. These observations of the effect of the addition of vibrationally cold CO are expected in view of its previously observed effect on the intensity of the CO† emission formed by the reaction of oxygen atoms with CS_2 (12).

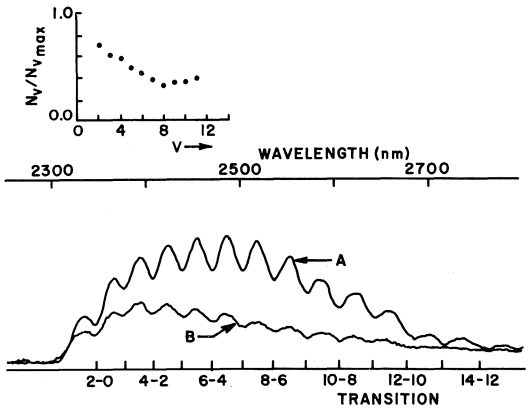

FIG. 4. The effect of changing the C_2H_2:O_2 ratio on the CO first overtone emission from the C_2H_2/O_2 atomic flame. Curve *A*: flow rates, C_2H_2:O_2:He, 19:57.7:4809 μmol/s; total pressure, 8.1 Torr. Curve *B*: flow rates, C_2H_2:O_2:He, 38:57.7:4809 μmol/s; total pressure, 8.25 Torr. Insert: Plot of the relative vibrational level population of CO† for curve *B*, (N_v), divided by the relative vibrational level population of CO† for curve *A*, ($N_{v\,max}$), against vibrational number, v.

Methylacetylene

CO first overtone emission was obtained when CH_3C_2H was added to a stream of oxygen which had been passed through a microwave discharge. As in the case of C_2H_2 only the first 13 vibrational levels of CO were appreciably populated. The relative vibrational level population was identical to that found in the C_2H_2 case with the maximum total emission intensity occurring for a CH_3C_2H:O_2 ratio of 1:3.

When CO was premixed with the CH_3C_2H–He mixture, a decrease in the total emission intensity was observed. This decrease was again most pronounced for lower vibrational levels with a minimum occurring for $v = 5$. As in the case of acetylene, a vibrational population inversion was again marginally sustained between $v = 5$ and $v = 7$.

The initial step in the reaction of oxygen atoms with methylacetylene, proposed in ref. 11:

$$[4]\quad \text{O} + \text{CH}_3\text{C}_2\text{H} \rightarrow \text{CH}_3\text{CH} + \text{CO}$$

which has a rate constant

$k_3 = (4 \pm 1) \times 10^{11}$ cm^3 mol^{-1} s^{-1} (298 °K)

yields ethylidene. Since no thermochemical data exists, the exothermicity of this reaction cannot be calculated. It can, however, be approximated as 40–50 kcal/mol exothermic by analogy with reaction 1 and is thus not sufficiently exothermic to populate CO† to $v = 13$. Chong and Kistiakowsky (13) have shown that ethylidene produced in the photolysis of methyl ketone rapidly isomerizes to an excited ethylene molecule which can either be collisionally quenched or decompose to acetylene and hydrogen. The latter course would allow formation of CO† via reactions 1 and 2, accounting for the identical spectral distributions of the CO† emission observed in the two systems.

Methane

No visible or i.r. chemiluminescence was observed when methane in a helium buffer was introduced into a stream of oxygen which had been passed through a microwave discharge. When a second microwave discharge on the CH_4–He line was switched on, a brilliant deep purple luminescent cone was visible at the end of the concentric mixer. The CO first overtone emission obtained from the methane–oxygen atom system for conditions of maximum total emission intensity, CH_4:O_2 ratio of 1:3, has a spectral distribution identical to that observed in the case of C_2H_2.

The fact that no emission was observed unless both microwave discharges were employed suggests that the CO† was not produced in the initial reaction steps. The initial step which was shown to be

[5] $\quad O + CH_4 \rightarrow CH_3 + OH + 0.4$ kcal/mol

with a rate constant (see ref. 14)

$k_5 = 3.2 \times 10^{13} \exp(-7950/(RT))$ cm^3 mol^{-1} s^{-1} (295–1000 °K)

is too slow to allow appreciable reaction to occur at the experimental temperature of ~310 °K.

When methane is passed through a microwave discharge it undergoes fragmentation. The net effect of the discharge on the CH_4, however, is to produce acetylene and hydrogen, presumably because of the very rapid reactions of the fragmentation products, CH and CH_2.[1] The O atoms then react with C_2H_2 according to reactions 1 and 2 to form CO†. The fact that a stable species is responsible for the CO† emission is supported by the following experimental evidence. The intensity of the CO† emission was unchanged when the discharge on the CH_4–He stream was moved from its normal position 6 in. from the mixing inlets to a position 40 in. from the inlets. Mass spectrometric analysis showed that C_2H_2 is a major product of discharged methane.

Air–Helium–Hydrocarbon (CO) Lasers

The mechanisms governing the formation of vibrationally excited CO in the air–helium–hydrocarbon (CO) lasers of Barry and co-workers (2–6) can be clarified in view of the previous observations on CO† formation. In these lasers emission from CO is observed upon initiation of a direct current discharge in an air–He–RH (RH = C_2H_2, CH_4, or C_3H_8) mixture. Laser emission was observed on P branch lines from $v = 3 \rightarrow v = 2$ to $v = 12 \rightarrow v = 11$ for CH_4 from $v = 5 \rightarrow v = 4$ to $v = 12 \rightarrow v = 11$ for C_3H_8 and from $v = 3 \rightarrow v = 2$ to $v = 11 \rightarrow v = 10$ for C_2H_2 and in the case of CH_4 with Q switched operation from $v = 2 \rightarrow v = 1$ to $v = 16 \rightarrow v = 15$. The authors also note that CO laser emission below 5000 nm is more readily realized by using CH_4 than with CO alone and that the power is much greater (2).

It is of interest to consider what is (*a*), the chemical mechanism responsible for CO formation in the electrical discharge and (*b*), the degree of contribution of the various methods of vibrational excitation to the laser power output, *i.e.*, electron impact, chemical excitation, collisional excitation by vibration–vibration energy transfer from N_2† or CO†.

Barry and co-worker (5) have proposed a detailed mechanism for CO formation by chemical means in their electrical discharge air–He–CH_4 laser. The initial step is proposed to be

[6] $\quad CH_4 + O_2 \rightarrow CH_3 + HO_2$

followed by CO formation via a formyl radical mechanism.

[7] $\quad HCO + O_2 \rightarrow CO + HO_2$

Reaction 6 is 57.2 kcal/mol endothermic and is, consequently, not likely to proceed rapidly at the laser operating temperature of 160 °C.

A direct current discharge through an O_2–

CH_4–He mixture will simultaneously dissociate O_2 producing oxygen atoms and CH_4 producing fragments such as CH_2, CH, H, etc. Reactions 1 and 2 as well as the reaction

[8] $$CH + O \rightarrow CO + H + 176 \text{ kcal/mol}$$

can proceed and in all probability account for CO formation in this system. This is further supported by mass spectrometric analysis[2] wherein a strong mass peak attributable to CH_2 was observed. Since it has been shown that reaction 2, the attack of oxygen atoms on methylene radicals, can produce vibrationally excited CO with up to 13 quanta of vibrational energy, this process will undoubtedly contribute to the laser power output and is in all probability responsible for the observation of low level laser transitions in these systems. It is also reasonable to expect that electron impact and collisional excitation will contribute to the total laser power output.

In the case of the air–He–C_2H_2 laser Barry *et al.* (6) have suggested that oxidation of C_2O is responsible for CO† formation. This mechanism has been suggested by Bayes (15) to account for the formation of electronically excited CO in hydrocarbon flames not for the formation of CO† which is satisfactorily explained by the reaction sequence 1 and 2.

Summary and Conclusions

The addition of either acetylene or methylacetylene to a stream of oxygen which has been passed through a microwave discharge results in the observation of i.r. chemiluminescence from vibrationally excited carbon monoxide.

The addition of vibrationally cold CO results in a marginally sustained vibrational population inversion in the chemically formed CO.

The high vibrational temperatures observed between levels $v = 7$, $v = 6$, and $v = 5$ suggest that it should be possible to achieve gain on these transitions in a laser cavity.

In the case of methane addition to a stream of oxygen, which had been passed through a microwave discharge, no vibrationally excited CO was observed unless the methane had previously been subjected to a second microwave discharge.

In the recent work describing air–helium–hydrocarbon (CO) lasers low vibrational transitions were observed. These transitions are likely a result of the reaction

$$O + CH_2 \rightarrow CO + 2H$$

which predominates in acetylene oxidation.

Kinetics and Temperature Dependence of the Hydration of NO^+ in the Gas Phase

MARGARET A. FRENCH, L. P. HILLS, AND P. KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alberta

Received June 9, 1972

The kinetics of the atmospherically important hydration sequence: $NO^+(H_2O)_{n-1} + H_2O = NO^+(H_2O)_n$ and the transfer reaction $NO^+(H_2O)_n + H_2O = HNO_2 + H^+(H_2O)_n$ were examined in nitrogen containing small quantities of NO and H_2O with a pulsed high pressure ion source mass spectrometer. The room temperature mechanism and rate constants were found to be in agreement with earlier work in other laboratories. The temperature dependence of the reaction was examined for the range 27–157 °C. The transfer reaction does not occur at higher temperatures so that the NO^+ hydration equilibria for $n = 1$ and 2 could be measured leading to $\Delta H_{1,0} = 18.5$ and $\Delta H_{2,1} = 16.1$ kcal/mol. The third order forward clustering rate constants were found to have negative temperature coefficients.

Les cinétiques de la séquence importante de l'hydratation atmosphérique: $NO^+(H_2O)_{n-1} + H_2O = NO^+(H_2O)_n$ et de la réaction de transfert $NO^+(H_2O)_n + H_2O = HNO_2 + H^+(H_2O)_n$ ont été examinées dans l'azote contenant de petites quantités de NO et H_2O, au moyen d'un spectromètre de masse ayant une source d'ionisation pulsée à haute pression. Le mécanisme à la température ambiante et les constantes de vitesses sont en accord avec un travail antérieur effectué dans d'autres laboratoires. L'influence de la température sur la réaction a été examinée entre 27 et 157 °C. La réaction de transfert ne se produit pas aux hautes températures de sorte que les équilibres d'hydratation de NO^+ pour $n = 1$ et 2 ont pu être mesurés conduisant à $\Delta H_{1,0} = 18.5$ et $\Delta H_{2,1} = 16.1$ kcal/mol. Les constantes de vitesse du troisième ordre pour l'agrégation directe ont des coefficients de température négatifs.

Introduction

The hydration of the NO^+ ion is of importance in the ionosphere (1) and in the radiation chemistry of moist air. The low ionization potential of NO makes the NO^+ ion a "charge sink" in ionized air. Studies on the kinetics of NO^+ hydration were started in this laboratory in 1969 after the completion of the O_2^+ hydration sequence (2) which is also of considerable interest. Before the present work was completed three studies of the NO^+ hydration sequence were published (3–5). The three sets of data obtained at near room temperature were in good agreement. Since the temperature dependence of the reaction mechanism had not been studied the present work was expanded to encompass studies at different temperatures. Determination of the temperature dependence of the $NO^+(H_2O)_{n-1} + H_2O = NO^+(H_2O)_n$ equilibria permitted the evaluation of some of the corresponding reaction enthalpies $\Delta H_{n-1,n}$. These enthalpies are of importance in establishing the energetics of the transfer sequence: $NO^+(H_2O)_n + H_2O = HNO_2 + H^+(H_2O)_n$. Finally the temperature dependence of the rate constants is of interest since the processes in the ionosphere occur below room temperature, while one can also conceive of radiation chemical processes in air occurring at temperatures above room temperature.

Experimental

The apparatus used was described in the earlier study of the O_2^+ hydration (2). It consisted of a high pressure ion source reaction chamber, a pulsed electron beam and a variable time delay ion gate. The ions were mass analyzed with a quadrupole mass filter. The mass dependent transmission of the quadrupole (Electron Assoc. Inc., Model 200) was determined in special calibration runs (2) and the ion intensities observed in the experimental measurements were correspondingly corrected. A mixture of N_2, NO, and H_2O passing in slow flow at some 2 Torr through the ion source was used. N_2 was the major gas, while NO and H_2O were in the 0.1 and 0.01 Torr range, respectively. The total pressure was measured with a capacitance manometer. The N_2 to NO concentration ratio was determined by measuring the N_2^+ and NO^+ peaks observed with the auxiliary low pressure ion source of the quadrupole. The measured N_2^+ and NO^+ ion intensities corrected for quadrupole and electron multiplier discrimination were assumed proportional to the partial pressure of the gases in the high pressure ion source. The gas flow through the 0.12 mm diameter ion exit leak is probably in the transition region between molecular and viscous for the pressures (1–3 Torr) used. The outflow from the vacuum chamber, in which the auxiliary ion source is located, is molecular. If the flow through the

†Third body given in parentheses after rate constant value.

exit leak was purely molecular the partial pressure ratios of the component gases would be the same in the high pressure source and in the auxiliary ion source and the experimental procedure would be fully justified. This would not be the case in general for viscous flow. However, the mixture used is a special case. The masses of N_2 and NO are very close so that the fractionation induced by the molecular outflow from the vacuum chamber is minimal. The ion flow through the leak, if viscous, is governed by the major gas (N_2), which is present in large excess. Under these conditions the amount of gases entering the vacuum chamber (in mol/s) should be proportional to the partial pressure ratios. Therefore we believe that the procedure used for the N_2, NO pressure determination is justified.

The partial pressure of H_2O gas was determined by weight measurement as described in earlier publications (2).

Results and Discussion

The measured time dependence of the ion intensities after the short electron pulse is shown in Fig. 1 for a typical run. The ion intensities are normalized, *i.e.*, the intensity of each ion is divided by the total ion intensity at any given time. The normalized ion intensities will be treated as if they represented (relative) ion concentrations in a reaction vessel in which the total ion concentration remains constant with time (2).

One observes in Fig. 1 the extremely rapid disappearance of N_2^+ and a corresponding appearance of NO^+. The slow decay of NO^+ coincides with the successive appearance of NO^+H_2O and $NO^+(H_2O)_2$. The ions $NO^+(H_2O)_3$ and $H^+(H_2O)_3$ are present also but in much lower concentration. The final ion is clearly $H^+(H_2O)_4$. A detailed examination of similar results obtained in some 12 runs in which the N_2 concentration was varied from 1–3.5 Torr, NO from 0.03–0.7 Torr, and H_2O from 0–0.07 Torr permitted the establishment of the reaction mechanism shown in Table 1, which is essential-

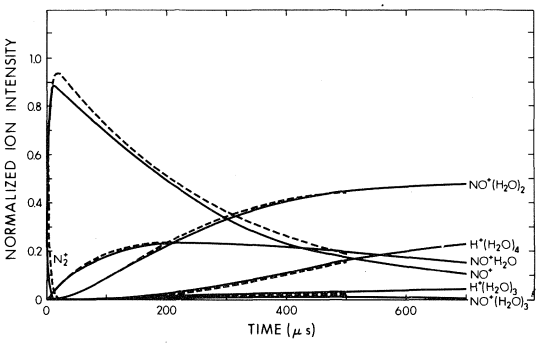

FIG. 1. Time dependence of normalized ion intensities observed at 306 °K after short (10 μs) electron pulse. Solid line experimental observations, dashed line analog computer fit calculated on basis of reaction mechanism [1]–[8]. $N_2 = 2$, $NO = 0.1$, $H_2O = 0.004$ Torr.

ly identical with the mechanisms proposed by Fehsenfeld *et al.* (3), Puckett *et al.* (4), and Howard *et al.* (5).

The rate constants determined in the present work are given in Table 1 together with the results from the above authors. The present rate constant determinations were based on a number of graphical methods (2) and analog computer fits of the normalized ion intensities. Figure 1 illustrates the type of fit that could be obtained. The analog computer was programmed to reproduce the reaction system [1]–[8]. The reaction frequencies ν_i (pseudo first order rate constants) were treated as variable parameters which were adjusted until a best fit with the normalized ion intensities was obtained. Agreement between the rate constants obtained from the reaction frequencies for runs with different concentrations established the reliability of the values.

The NO^+ is produced by charge transfer from the major gas ion N_2^+ by reaction 1. This reaction was too fast, at the high NO concentration used, to be measured accurately. The production of $NO^+(H_2O)$ via the dimer $(NO)_2^+$, *i.e.*, reactions (2) and (3) could not be avoided since it was desired to produce as little H_2O^+ as possible by direct charge transfer from N_2^+ (or N_4^+) to H_2O. This meant that the H_2O pressure had to be kept much lower than the NO pressure. The parallel reactions 2 + 3 and 4 by which NO^+ disappears and $NO^+(H_2O)$ is formed could be resolved by the plot shown in Fig. 2. The observed reaction frequency for the disappearance of NO^+ is $\nu_{obs} = k_2[NO]\,[N_2] + k_4[H_2O]\,[N_2]$. Thus a plot of $\nu_{obs}/[N_2]\,[H_2O]$ *vs.* $[NO]/[H_2O]$ should

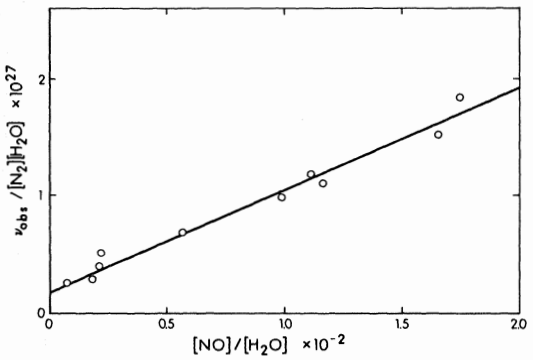

FIG. 2. Determination of rate constants k_2 and k_4 (see Table 1) from slope and intercept of plot. Observed reaction frequency $\nu_{obs} = k_2[NO]\,[N_2] + k_4[H_2O]\,[N_2]$.

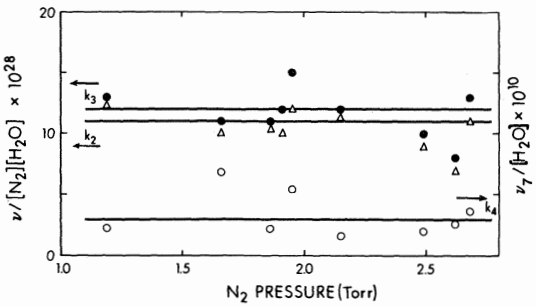

FIG. 3. Plot of $(\nu_5/[N_2][H_2O] \times 10^{28}$ (Δ) and $(\nu_6/[N_2]\,[H_2O] \times 10^{28}$ (●) *vs.* pressure of N_2 indicates that reactions 5 and 6 are third order. Similar plot of $(\nu_7/[H_2O] \times 10^{10}$ (○) indicates that reaction 7 is second order.

give a straight line with slope k_2 and intercept k_4. An independent value for k_2 in good agreement with that from Fig. 2 could be obtained in runs where the water concentration was zero. The plot of Fig. 2 is also consistent with the assigned third order for reactions 2 and 4.

The determination of the kinetic order of reactions 5, 6, and 7 is shown in Fig. 3 where $\nu_5/[H_2O]\,[N_2]$ and $\nu_6[H_2O]\,[N_2]$ are seen to be constant with N_2 pressure which indicates that k_5 and k_6 are both third order. $\nu_7/[H_2O]$ is seen to be invariant with pressure such that k_7 is second order, as expected.

On the whole there is good agreement between the present values for the rate constants and the determinations in refs. 3–5 (see Table 1). The present value for k_{-5} is higher by a factor of about 3. This difference is largely due to the higher temperature used in the present determination. (See discussion below of temperature dependence of reactions.) The same is true for the somewhat higher value for k_{-6} observed in the present work.

The present k_7 is higher by a factor of 4 than the values from refs. 3–5. Reaction 7 is a relatively fast switching reaction which is thermoneutral or only slightly endothermic. (See Table 3.) Therefore the reaction should have no, or only a very slight, temperature dependence. The difference between the present result and the earlier determinations (3–5) cannot be explained on basis of difference of temperatures. The present k_7 determination depended on computer fitting of $NO^+(H_2O)_3$ concentrations which were very low (see Fig. 1). Furthermore, the fit was not sensitive to the value of k_7 but to the combined values of k_6, k_{-6}, and k_7. Therefore the present

For personal use only.

k_7 is of low accuracy and the value obtained by the earlier workers is probably closer to the truth.

The temperature dependence of the reaction system [1]–[8] was examined in a series of runs over the temperature range 27–156 °C. The reaction system became very simple at the highest temperatures where the only two major ions observed were NO^+ and NO^+H_2O. Their time dependence is shown in Fig. 4*a* for a temperature of 134 °C. Evidently the two ions reach equilibrium due to the operation of (−4) which at this temperature has a rate similar to the forward clustering reaction 4. The NO^+ equilibrium concentration could be conveniently observed down to 110 °C. Below this temperature the NO^+ became too small to measure reliably. The equilibrium concentrations were used for the evaluation of the equilibrium constant: $K_{0,1} = k_4/k_{-4} = [NO^+.H_2O]/[NO^+]\,[H_2O]$. A Van't Hoff plot of the values shown in Fig. 5, leads to $\Delta H_{0,1} = -18.5$ kcal/mol and $\Delta S_{0,1} = -23.0$ cal/deg (standard state 1 atm). The determinations of $K_{0,1}$ were done at a single water pressure of ~0.04 Torr. This relatively high water pressure was selected in order to speed up the achievement of equilibrium. Under these conditions, proton hydrates $H^+(H_2O)_n$ were observed as minor ions and could be accounted for as a side reaction initiated by the direct charge transfer $N_2^+ + H_2O = N_2 + H_2O^+$.

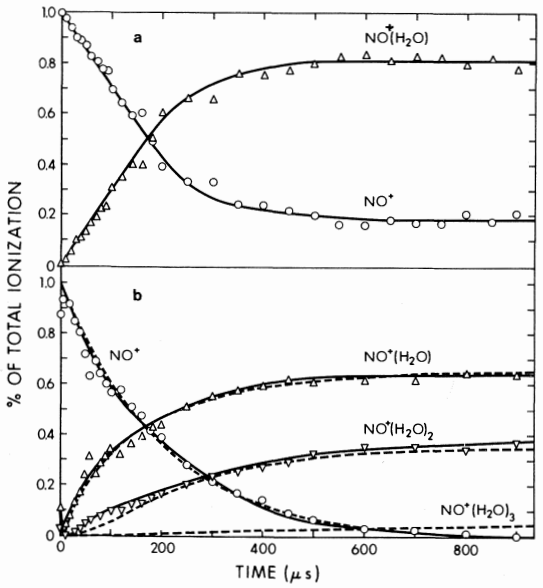

FIG. 4. (*a*) Normalized intensities in reaction system at 134 °C. Only two major ions are observed NO^+ (○), and $NO^+(H_2O)$ (Δ) which reach equilibrium at longer reaction times. The very rapidly decaying N_2^+ is not shown. $N_2 = 2.85$, $NO = 0.15$, $H_2O = 0.038$ Torr. (*b*) 67 °C, at this temperature $NO^+(H_2O)_2$ is stable such that $NO^+(H_2O)$, $NO^+(H_2O)_2$ equilibrium can be observed. $N_2 = 2.85$, $NO = 0.148$, $H_2O = 0.0067$ Torr.

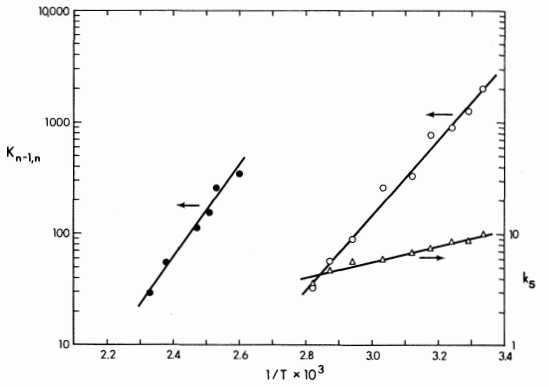

FIG. 5. Van't Hoff plot for equilibrium constants $K_{0,1}$ (●) and $K_{1,2}$ (○) (pressure in Torr) leading to ΔH and ΔS values. Arrhenius plot of rate constant $k_5 \times 10^{28}$ cm^6 $molecule^{-2}$ s^{-1} (Δ). The third order rate constant shows the expected negative temperature coefficient corresponding to "activation energy" $E_5 = -3.3$ kcal/mol.

Figure 4*b* shows that the principal ions observed at lower temperatures (67°) are NO^+, $NO^+(H_2O)$, and $NO^+(H_2O)_2$. The latter two ions reach equilibrium. Actually the production of $H^+(H_2O)_3$ via reaction 7 was still observable but was very slow because of the very low equilibrium concentration of $NO^+(H_2O)_3$. The equilibrium constant $K_{1,2} = [NO^+(H_2O)_2]/[NO^+(H_2O)]\,[H_2O]$ was determined over the temperature range shown in the Van't Hoff plot (Fig. 5). The determinations were made either by taking the concentration of the two ions at long reaction times where their ratio had become constant or by measuring k_5/k_{-5} by computer fitting the time dependence plots. The resulting values were: $\Delta H_{1,2} = -16.1$ kcal/mol and $\Delta S_{1,2} = -25.5$ e.u.

The computer fits permitted the determination of k_5 at different temperatures. It was found that the forward reaction has a negative temperature coefficient. An Arrhenius type plot of k_2 is shown in Fig. 5. The negative "activation energy" $E_2 = -3.3$ kcal/mol is of course only an experimental parameter without theoretical meaning. The temperature dependence is more meaningfully expressed in the form $k = \text{constant}\ T^{-n}$ since this expression approximates theoretically expected temperature dependence (10). The data for k_5 lead to an $n \approx 4.7$. Since the temperature

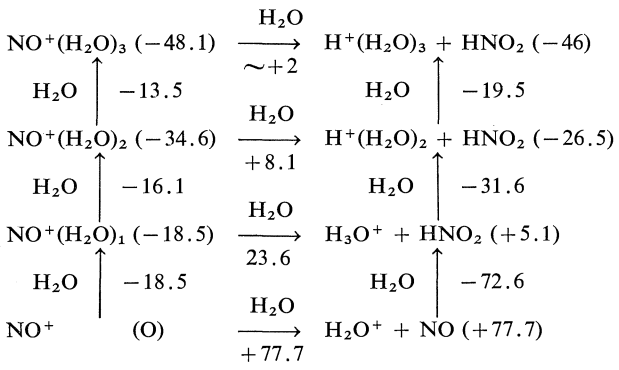
†Standard state 1 atm.

TABLE 3. Energetics of the reaction $NO^+(H_2O)_n + H_2O = HNO_2 + H^+(H_2O)_n$ for $n = 0$ to 3



*Numerical values beside arrows represent ΔH for reaction. Numerical values in parentheses represent enthalpy difference of system relative to $NO^+ + 3H_2O$ (g). All values in kcal/mol. The value for the hydration of $NO^+(H_2O)_2 = -13.5$ kcal/mol is not based on direct measurement but estimated.

range covered is rather small and the scatter of the data considerable, a value of n as low as 4 could not be excluded.

The temperature dependence of k_4 was more difficult to determine due to the operation of the temperature dependent parallel reaction path 2 + 3 (see Table 1). An estimate indicating a dependence similar to that for reaction 5 could be obtained by considering the low temperature value for k_4 from Table 1 and the values for k_4 determined in the range 111–156 °C. At these higher temperatures high H_2O concentrations were used (see Fig. 4*a*) and the parallel reaction 2 + 3 was unimportant.

A study of the temperature dependence of k_6, k_{-6} and thus $K_{2,3} = k_6/k_{-6}$ was not successful since the concentration of $NO^+(H_2O)_3$ which was already small at 30 °C became progressively smaller as the temperature was increased. The computer fits thus became less reliable. The Van't Hoff plot of the so determined $K_{2,3}$ showed excessive scatter. The data were consistent with a value $\Delta H_{3,2} < \Delta H_{2,1} = 15.6$ kcal.

The data obtained from the temperature dependence studies are summarized in Table 2. The determination of $\Delta H_{2,1}$ and $\Delta H_{1,0}$ for the NO^+ hydration taken together with data (11) for the hydration of H_3O^+ permit one to establish the energetics of the transfer from NO^+ hydrates to H_3O^+ hydrates. These are summarized in Table 3. The additional thermochemical data needed for the table: $NO^+ + H_2O = NO + H_2O^+$, $\Delta H = +77.7$; $H_2O^+ + H_2O = H_3O^+ + OH$, $\Delta H = -24.67$; and $OH + NO = HNO_2$, $\Delta H = -48$ kcal/mol were taken from Fehsenfeld *et al.* (3).

Table 3 illustrates the gradual decrease in endothermicity for the transfer reaction

$$NO^+(H_2O)_n + H_2O = HNO_2 + H^+(H_2O)_n$$

which decreases from 14 kcals for $n = 1$ to ~2 kcal for $n = 3$. The "driving force" in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

decrease is due to the stronger hydration interaction obtained for the proton hydrates. It is interesting to note that the step at $n = 3$ appears to be still endothermic, although the thermochemical data are certainly not accurate enough to make this certain. The endothermicity, if real, could be significant in slowing down reaction 7 at temperatures around 200 °K pertaining to the D region of the ionosphere. However, this effect would be more than offset by the negative temperature coefficients of k_4, k_5, and probably k_6.

Kinetics and Mechanism of the Sulfonation of 2-Phenyl-1-ethanesulfonic acid[1]

A. KOEBERG-TELDER (MRS.), Z. R. H. NIENHUIS (MRS.), AND H. CERFONTAIN
Laboratory for Organic Chemistry, Nwe Achtergracht 129, University of Amsterdam, The Netherlands
Received August 8, 1972

The kinetics of the sulfonation of 2-phenyl-1-ethanesulfonic acid in 85.0–98.4% H_2SO_4 has been studied. The results are discussed in terms of sulfonation of the unionized sulfonic acid and its conjugated base, the sulfonate anion. Partial rate factors for the $—CH_2CH_2SO_3H$ substituent are reported.

La cinétique de la sulfonation de l'acide phényl-2 éthanesulfonique a été étudiée dans H_2SO_4 85.0–98.4%. Les résultats sont discutés en terme de sulfonation de l'acide non-ionisé ainsi que de sa base conjuguée, l'anion sulfonate. Des facteurs relatifs aux taux partiels de réaction sont rapportés pour le substituant $—CH_2CH_2SO_3H$. [Traduit par le journal]

Information concerning the substituent effect of the $—SO_3H$ group is to our knowledge lacking from the literature. With the aim of obtaining information on this point, a program was set up to determine the reactivity in sulfonation of various sulfonic acids of the general structure $C_6H_5(CH_2)_nSO_3H$ (n = 0, 1, 2, 3, ...). As part of that program we now report on the homogeneous sulfonation of 2-phenyl-1-ethanesulfonic acid in sulfuric acid ranging in concentration from 85.0 to 98.4% H_2SO_4. The pseudo first order rate constants are given in Table 1. The isomer distribution of the disulfonic acid mixture resulting from the sulfonation of 2-phenyl-1-ethanesulfonic acid in 90–98% H_2SO_4 was determined by n.m.r. to be 7 ± 2%, *o*-; 3 ± 2%, *m*-; 90 ± 4%, *p*-sulfophenyl-ethanesulfonic acid, independent of the sulfuric acid concentration.

The correlation of the pseudo first order rate constant for sulfonation with the activity of $H_2S_2O_7$ is shown in Fig. 1. The slope d(log k)/d(log $a_{H_2S_2O_7}$) in the steep part of the curve, *i.e.* in the range of 93–95% H_2SO_4, is 0.86. For benzene the slope is 0.89. The similarity in slope indicates that the sulfonating entity in both cases is the same, *viz.* $H_2S_2O_7$ (2). The slope decreases at acid concentrations >95% H_2SO_4, as was observed with the halogenobenzenes (4, 5) and phenylmethanesulfonic acid (6). At these high sulfuric acid concentrations, the step in which the carbon bonded proton is removed from the 1-arenium-1-sulfonate σ-complex intermediate becomes partly rate limiting (4), and this leads to a decline in slope.

TABLE 1. Pseudo first order rate constants for the sulfonation of 2-phenyl-1-ethanesulfonic acid at 25.0°

H_2SO_4 wt. % (±0.1)	$_{ps}k_1 \times 10^4$ (s^{-1})	$-\log a_{H_2S_2O_7}$*
85.0	0.181	11.65
87.8	0.91	10.59
89.7	2.41	9.91
93.3	18.4	8.78
95.2	63.4	8.19
97.1	184	7.54
98.4	509	6.91

*$\log a_{H_2S_2O_7} = 2 \log a_{H_2SO_4} - \log a_{H_2O} + 12.25$ (2, 3).

The upwards curvature at acid concentration <90% H_2SO_4 may be explained either in terms of the occurrence of additional sulfonation by $H_3SO_4^+$ (2) or in terms of ionization of the sulfonic acid with formation of the sulfonate anion which will be more reactive towards electrophilic substitution. As for the first explanation, the reactivity of the 4-position of 2-phenyl-1-ethanesulfonic acid (see below) is about the same as that of one position in benzene, and smaller than that of the 3-position of toluene (2). The sulfuric acid concentration of equal rate contributions by the entities $H_3SO_4^+$ and $H_2S_2O_7$ for benzene and the 3-position of toluene are 79 and 80% H_2SO_4, respectively (7). The sulfuric acid concentration of equal rate contributions by the two sulfonating entities increases with increasing reactivity of the substrate position (7). This then renders the explanation in

[1]Aromatic sulfonation. Part 38 (see ref. 1).

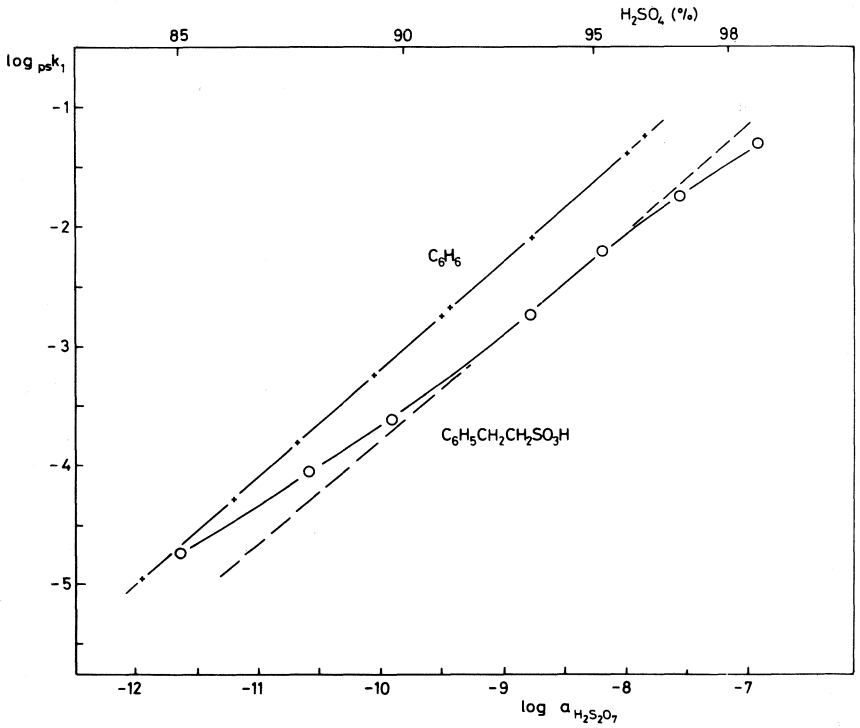

FIG. 1. Correlation of pseudo first order rate constants for sulfonation with the activity of $H_2S_2O_7$: +, benzene, slope 0.89; ○, 2-phenyl-1-ethanesulfonic acid, maximal slope 0.86.

TABLE 2. Electrophilic substitution of phenylalkanesulfonates

	$k/k_{benzene}$	
Substrate	Sulfonation, 95% H_2SO_4, 25°	Nitration, dilute aqueous* mixed acid, 30–39° (10)
$PhCH_2SO_3H$	$(1.60\pm0.12)\times10^{-4}$ (6)	0.30 ± 0.05
$PhCH_2CH_2SO_3H$	0.24 ± 0.01	3.5 ± 0.5

*68–77 mol % H_2O.

terms of additional sulfonation by $H_3SO_4^+$ improbable.

As for the second explanation, arene- and alkanesulfonic acids behave as weak acids in sulfuric acid of a lower concentration than 95% H_2SO_4, and 50% of deprotonation occurs at 82–84% H_2SO_4 (8, 9). Accordingly, with 2-phenyl-1-ethanesulfonic acid, the proportion of the more reactive sulfonate anion species increases with decreasing sulfuric acid concentration, and this will lead to an upward curvature with decreasing sulfuric acid concentration.

Further evidence that the unionized sulfonic acid is the substrate species undergoing sulfonation in 95% H_2SO_4 can be obtained from a comparison of the rates of substitution of alkali phenylmethane- and 2-phenyl-1-ethanesulfonate relative to benzene in nitration and sulfonation (Table 2). For the dilute aqueous nitric acid nitration of phenylmethanesulfonic acid it has been suggested, on the basis of a comparison between the observed and expected degree of meta-substitution for the $-CH_2SO_3H$ substituent, that the sulfonate anion is the actual species undergoing substitution (11). The very much lower relative reactivities of these substrates for

$4\text{-}HO_3SC_6H_4CH_2CH_2SO_3H$	7.74	8.13			8.1	3.30–3.65	3.68–3.98
$2,4\text{-}(HO_3S)_2C_6H_3CH_2CH_2SO_3H$		8.60	8.48	8.03	8.0	3.70–4.00	4.00–4.25
$3\text{-}HO_3SC_6H_4CH_2CH_2SO_3H$						3.52*	3.82*
$2\text{-}HO_3SC_6H_4CH_2CH_2SO_3H$						3.71†	3.90†
$3,5\text{-}(HO_3S)_2C_6H_3CH_2CH_2SO_3H$						3.70†	4.00†

*The centers of the chemical shifts were taken to be equal to the centers of the chemical shifts of the 4-isomer (13).
†The centers of the chemical shifts of the α- and β-methylene hydrogen absorptions were calculated on the basis of the additivity principle of substituent shifts of the sulfonic acid substituents from:

$$\delta_{(CH_2)_i}(\text{ortho}) = \delta_{(CH_2)_i}(\text{PESA}) + \delta_{(CH_2)_i}(2,4\text{-di}) - \delta_{(CH_2)_i}(\text{para})$$
$$\delta_{(CH_2)_i}(3,5\text{-di}) = \delta_{(CH_2)_i}(\text{PESA}) + 2[\delta_{(CH_2)_i}(\text{meta}) - \delta_{(CH_2)_i}(\text{PESA})]$$

with $i = \alpha, \beta$.

sulfonation in 95% H_2SO_4 would then imply that the unionized sulfonic acid is the species undergoing sulfonation in 95% H_2SO_4.

Finally, the two complicating rate effects are minimal at 95% H_2SO_4. At that acid concentration, the rate ratio of 2-phenyl-1-ethanesulfonic acid to benzene is (0.238 ± 0.016):1. From the isomer distribution it then follows that the partial rate factors are $f_p = 1.29 \pm 0.14$, $f_m = 0.02 \pm 0.01$, and $f_o = 0.05 \pm 0.02$.

The reaction of 2-phenyl-1-ethanesulfonic acid in concentrated *aqueous* sulfuric acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

leads to clean sulfonation with formation of mainly 2-(*p*-sulfophenyl)-1-ethanesulfonic acid, the ratio of aliphatic to aromatic protons being 0.99 ± 0.02 (Fig. 2A). Further treatment of the monosulfonation mixture with *fuming* sulfuric acid (Fig. 2B leads chiefly to sulfonation with formation of mainly 2-(2,4-disulfophenyl)-1-ethanesulfonic acid, but also to some other reaction(s), possibly the formation of 2,4-styrenedisulfonic acid, since the ratio of the areas of the aliphatic to aromatic hydrogen absorption amounts only to 1.04 ± 0.03 instead of 1.33, the value required for disulfophenyl-ethanesulfonic acid.

Experimental

Sodium 2-phenyl-1-ethanesulfonate was prepared by means of the action of sodium sulfite on 1-phenyl-2-bromoethane (12).

Anal. Calcd. for $C_8H_9O_3SNa$: C, 46.15; H, 4.36; S, 15.40; Na, 11.04. Found: C, 46.04; H, 4.40; S, 15.52; Na, 11.04.

The experimental procedures and the spectrometer employed were the same as in ref. 6. The extinction measurements for the determination of the rate constants were made at λ 267 nm.

Isomer Distribution

Information concerning the products formed in the sulfonation of 2-phenyl-1-ethanesulfonic acid was obtained from an analysis of the n.m.r. spectra. The spectra were recorded after dilution of the sulfonation mixtures to the same sulfuric acid concentration (80% H_2SO_4). The results and the assignments are given in Table 3. After the spectrum of 2-phenyl-1-ethanesulfonic acid had been compared with the spectra of ethanesulfonic acid and ethylbenzene, the absorptions at δ 3.32 and 3.64 p.p.m. were assigned to the α- and β-methylene hydrogens respectively (see Table 3).

The degree of ortho-substitution was calculated from the absorption areas of the methylene hydrogens P and Q (Fig. 2A) by the equation: % ortho = $(P - Q)/(P + Q)$.

The degree of meta-substitution was estimated from the absorption areas of the methylene hydrogens P' and Q' (Fig. 2B) by the equation: % meta = $(Q' - P')/(P' + Q')$.

The authors acknowledge the assistance of Mr. H. van Oosterhout in preliminary experiments.

Received October 2, 1972

The aglycone of the antitumor antibiotic daunomycin, daunomycinone **1**, has been synthesized along with its C-1 isomer.

On a synthétisé la daunomycinone **1**, aglycone de l'antibiotique antitumoriale daunomycine, ainsi que son épimère en C-1. [Traduit par le journal]

Can. J. Chem., **51**, 466 (1973)

Daunomycin is currently a very important drug for clinical treatment of leukemia (1). Mild acid hydrolysis of daunomycin gives an amino sugar daunosamine and the aglycone daunomycinone **1** (2).

We wish to report a total synthesis of **1** fashioned in the CD → ABCD annelation sequence which has been successfully put to test in a model study (3). The synthesis of the antibiotic aglycone itself utilized also the bicyclic ketol **2**, obtained from 2,5-dimethoxybenzaldehyde in seven steps (**3**) or, preferably, **2** may be prepared as shown in Scheme 1.

Condensation of **2** with 3-acetoxyphthalic acid monomethyl esters (isomeric mixture) in refluxing trifluoroacetic anhydride yielded a mixture of diaryl ketones which was directly saponified (2 *N* NaOH/ethanol) and subjected to HF cyclization at room temperature. The resulting quinones **3** and **4** (overall 19%; ν 3500, 1710, 1670, 1640 cm^{-1}; *m/e* 396) were then quantitatively methylated (Me_2SO_4–K_2CO_3–acetone)(*m/e* 410; δ 2.35 (3H, s, $COCH_3$), 3.85, 3.87, 3.88, 3.92, 3.97 (9H total, singlets, OCH_3).

Since separation of isomers was not feasible at this stage, introduction of the oxygen function at C-7 was next attempted. The side-chain ketone was protected as the dioxolane group (ethanediol–TsOH–benzene; 88%; *m/e* 454; 1.40 (3H, s, CH_3), 3.88, 3.92, 3.96, 4.02 (13H total, singlets, OCH_3 and acetal CH_2), bromination (NBS) was then achieved selectively at the desired position. Methanolysis of the bromoacetals permitted isolation of two compounds by preparative t.l.c. (silica, methanol–chloroform, 1:25; R_f 0.31, 0.51) which subsequently proved to be acetals having epimeric benzylic methoxy groups (**5**, R = OCH_3 at C-1 or C-4). Only after hydrolysis (HCl – aqueous THF) of the dioxolane function could the ring A isomers be finally resolved by preparative t.l.c. (silica, methanol – ethyl acetate 1:100). From the R_f 0.51 band, the more polar daunomycinone trimethyl ether (**6**, m.p. 185–186°; *m/e* 440; ν 3460, 1715, 1680 cm^{-1}; δ 2.40 (3H, s, $COCH_3$), 3.56 (3H, s, OCH_3), 3.89 (3H, s, $ArOCH_3$), 4.00 (6H, s, $ArOCH_3$)) and the less polar isodaunomycinone trimethyl ether (**7**, m.p. 226–227°; *m/e* 440; ν 3460, 1715, 1680 cm^{-1}; δ 2.40 (3H, s, $COCH_3$), 3.56 (3H, s, OCH_3), 3.93 (3H, s, $ArOCH_3$), 4.00 (6H, s, $ArOCH_3$)) were obtained in the ratio of *ca.* 1:1. The former compound has been identified by comparison with a specimen derived from natural daunomycin.

To complete the synthesis, **6** was reacted with aluminum chloride at ambient temperature to give 4-O-demethyl-7-O-methyldaunomycinone (**8**, m.p. 246–250°; *m/e* 398; ν 3440, 1715, 1600 cm^{-1}) which was oxidized to the unstable diquinone **9** (ν 3460, 1715, 1685 cm^{-1}) by lead tetraacetate and immediately remethylated (Me_2SO_4–K_2CO_3–acetone, 25°) to provide 7-O-methyldaunomycinone (**10**; ν 3460, 1720, 1620, 1585 cm^{-1}, 10%). The benzylic methoxy was replaced by the trifluoroacetoxy group with trifluoroacetic acid (25°, 2 h), resulting in **12** (ν 3480, 1785, 1720, 1620, 1580 cm^{-1}). Treatment

4-Methyl-3,3-pentamethylene-1,2-dioxetane. Lack of its Formation in Ozonation of Ethylidenecyclohexane in Pinacolone[1,2]

KARL R. KOPECKY, PETER A. LOCKWOOD,[3] JOHN E. FILBY,[4] AND RONALD W. REID

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

Received October 10, 1972

The title compound has been prepared and characterized. Contrary to a previous report it is not formed on ozonation of ethylidenecyclohexane (**1**) in pinacolone. The percent yields of products formed on ozonation of **1** in Skelly B, pinacolone, and dimethyl ether are, respectively, acetaldehyde, 25, 47, 59; normal ozonide ~75, ~0, <15; and dimeric cyclohexanone peroxide 11, 17, 35.

Le composé mentionné dans le titre a été préparé et caractérisé. Contrairement à ce qui a été rapporté précédemment, il n'est pas formé par ozonolyse de l'éthylidènecyclohexane (**1**) dans la pinacolone. Les rendements de produits formés par ozonolyse de **1** dans le Skelly B, la pinacolone, et le méthioxyméthane sont respectivement 25, 47, et 59% d'acétalydéhyde; ~75, ~0, et <15% d'ozonide normal; et 11, 17, et 35% du peroxyde dimère de la cyclohexanone. Recent reports indicate that cleavage products rather than normal ozonides are formed on ozonation of alkenes in certain aldehyde or ketone solvents (1). The cleavage products were assumed to arise from decomposition of transient 1,2-dioxetanes. Several of these are claimed later to have been isolated by ozonation of some alkenes in pinacolone solution (2). In particular from ethylidenecyclohexane (**1**) was isolated a 50–75% yield of 4-methyl-3,3-pentamethylene-1,2-dioxetane (**2**) as a colorless oil which luminesced and gave cyclohexanone and acetaldehyde when heated to 170°, was reduced to 1-(1-hydroxyethyl)-cyclohexanol **3**, and was identical in all respects with **2** prepared by conventional methods (3). Also *t*-butyl acetate was found in amount presumably equivalent to the yield of **2**.

This work aroused our interest for three reasons. First, ozonation of alkenes would be a simpler and less hazardous preparation of 1,2-dioxetanes than is the present method (3). Second, a high temperature is apparently required to observe luminescence from **2**. Luminescence can be observed clearly from other 1,2-dioxetanes at temperatures as low as 50° or less (3*b*, 3*c*, 4). Finally, all of the several dioxetanes prepared so far in our laboratories are light yellow. We have now prepared **2** from the corresponding bromohydroperoxide and found that its properties are quite conventional, in contrast to the above results (2). Furthermore, we are unable to detect any **2** or *t*-butyl acetate as products of ozonation of **1** in pinacolone.

The crude bromohydroperoxide **4** of **1** was prepared (3*a*) and purified by way of the 1,4-diazabicyclo[2.2.2]octane complex (5). Pure **4** had m.p. 44.0–45.5°, 99.6% active oxygen, and satisfactory spectra. A mixture of 2.3 g **4** and 0.44 g sodium hydroxide in 10 ml of 9:1 methanol–water was stirred at 0° for 20 min. Water and carbon tetrachloride, 10 ml each, were added, solvent was removed from the dried organic layer at 20°, and then the crude product was pumped from the yellow residue under 30μ at 20° until residue became pale. A small, colorless forerun was discarded. Redistillation in this way gave bright yellow, Fig. 1, crystals (~10% yield) of **2**, m.p. ~−11°, in the −78° trap. This material had 97.8% active oxygen, molecular weight: 155 (cryoscopic, C_6H_6); n.m.r. $\tau(CCl_4)$: 4.91 (quartet, J = 6.5 Hz, 1.0 H), and 8.66 (doublet, J = 6.5 Hz) superimposed on a broad absorption from 7.8–8.8 (total 13.0H).

In benzene-d_6, **2** decomposes with a half-life

of ~15 min at 50° to give acetaldehyde, 90% (by n.m.r.), and cyclohexanone, 95% (as the 2,4-dinitrophenylhydrazone).

Reduction of **2** with lithium aluminum hydride at −40° gave **3** (87%) identical (i.r., n.m.r., t.l.c.) with an authentic sample (6). At 50°, even dilute (0.01 *M*) solutions of **2** emit a visible bluish-white luminescence. Addition of dibromoanthracene (DBA) greatly enhances its intensity (4*c*, 7). These reactions are given in Scheme 1.

We found no evidence for the formation of **2** on ozonation of **1** in pinacolone. Ozonation was carried out using ozone in nitrogen (8) and solvent was removed to give a colorless, viscous oil A as in the procedure described (2). G.l.c. analysis of A did indicate the presence of cyclohexanone and pinacolone. However, no *t*-butyl acetate could be detected either in A or in the separated pinacolone. Had 5% been formed, it would have been detected.[5,6] Also luminescence of A was not reproducible. Of eight preparations only four luminesced when heated suddenly to 170°, and none luminesced at 50° even when DBA was present. In one case, a 0.5 g sample of A (luminescent at 170°) containing DBA was heated to 50°. No luminescence could be detected. After addition of ~1 mg of **2**, a definite luminescence was seen visually. With the aid of a spectrofluorimeter it was shown that A contained less than 4×10^{-2}% of **2**.

Chemical evidence also indicates that A contains no **2**. G.l.c. analysis of the product mixture obtained on treatment of A with lithium aluminum hydride at −40° indicated that less than 5%, if any, of **3** was formed.[7] Control experiments showed that **2** survives the ozonolysis, so that it is never formed at all in this reaction.

[5]No attempt was made to detect acetaldehyde on g.l.c. analysis of A. Pinacolone as received (Aldrich Chemical Co.) contains about 1–2% of a material with a retention time (Carbowax 40 M) very near that of *t*-butyl acetate. This and other trace impurities can be removed mostly by fractional distillation and removed completely by fractional distillation followed by fractional freezing. All our experiments were done using pinacolone purified by these methods.

[6]Professor R. Criegee and P. S. Bailey have informed us that no *t*-butyl acetate could be detected among the products of ozonation of **1** in pinacalone in their laboratories, either.

[7]Professor P. S. Bailey has informed us that the same result was obtained in his laboratory (13).

5 6 7

When A is allowed to stand even for a short time colorless crystals are deposited which were shown to be the dimeric cyclohexanone peroxide **5** by comparison (i.r., n.m.r., m.p., and mixed m.p.) with authentic material (9).

We were able to confirm that the normal ozonide **6** is not formed in pinacolone, but it is formed in 75% yield in Skelly B. Ozonolysis mixtures kept below $-30°$ until diluted with trichlorofluoromethane were analyzed at $-20°$ by n.m.r. spectroscopy at 100 MHz. In Skelly B, **6** was identified by a clean quartet, $J = 5$ Hz, at 206 Hz upfield from the chloroform internal standard signal.[8] In this region the n.m.r. spectrum of the pinacolone solution had a broad, structureless peak on which were superimposed some sharp peaks,[9] but none due to **6**. The n.m.r. spectrum of crude **6**[8] in pinacolone solvent had a clean quartet at τ 4.7.

This effect of solvent is reminiscent of that observed in ozonation of *trans*-3-hexene in dichlorodifluoromethane and in dimethyl ether-d_6 (11). Much less ozonide is formed in the latter solvent. Indeed, ozonation of **1** in dimethyl ether at $-80°$ formed only a small amount of **6** as judged from the n.m.r. spectrum taken at $-80°$. Broad, structureless absorption, due to oligomeric materials (11), was again observed near τ 5 upon which was superimposed a quartet, $J = 5$ Hz, of weak intensity.

Acetaldehyde and **5** are formed in all solvents. The percent yields of products formed on ozonation of **1** in Skelly B, pinacolone, and dimethyl ether are, respectively, acetaldehyde (by n.m.r.) 25, 47, 59; **6** (by n.m.r.) 75, ~0, <15; and **5** (by isolation) 11, 17, 35. More acetaldehyde (cleavage product) is formed in dimethyl ether than in pinacolone! Formation of large amounts of acetaldehyde is consistent with the report that the carbonyl product of the cleavage of the primary ozonide of **1** is mainly acetaldehyde (12).

It appears that pinacolone exerts a general (*e.g.*, polar), and not a specific, solvent effect on ozonation of **1**. While it is difficult to disprove the transient existence of **7**, the present results certainly do not provide support for the claim (1, 2) that **7** is an early product of reaction between ozone and **1**.

[8]Identification of **6** was made only on the basis of the n.m.r. spectrum of the concentrated oil obtained from ozonation of **1** in Skelly B. It had strong signals at $\tau(CCl_4)$ 4.81 (quartet, $J = 5$ Hz) and 8.67 (doublet, $J = 5$ Hz). The methine protons of the ozonides of *trans*-2-butene absorb at $\tau(CCl_4)$ 4.73 (10). Ozonation of **1** in acetaldehyde gives **6** (no characterization reported) in 75% yield (1*a*).

[9]The same absorption is observed in the n.m.r. spectrum of A. If, during the preparation of **2** from **4**, stirring is continued for 90 min, little **2** can be isolated and the n.m.r. spectrum of the crude product and that of A show similar absorption patterns in the region near $\tau(CCl_4)$ 4.9. This may have caused some confusion in the earlier work (2).

The Photochemical Decomposition of Gaseous Formaldehyde

HENRY P. SPERLING AND SIDNEY TOBY

School of Chemistry, Rutgers University, New Brunswick, New Jersey 08903

Received June 27, 1972

The photolysis of formaldehyde was studied at 313, 334, and 366 nm in the range 80–120° and 9–40 Torr, over a 300-fold range of incident intensity. Some heterogeneous thermal decomposition was noted at these temperatures. It was found that Φ_{H_2} and Φ_{CO} were independent of intensity at low intensities which suggests that CHO → CO + H was unimportant in our system. From the zero-intensity extrapolations of Φ it was possible to obtain ϕ_I for $CH_2O + h\nu \rightarrow H + CHO$ and ϕ_{II} for $CH_2O + h\nu \rightarrow H_2 + CO$. ϕ_I and ϕ_{II} were found to vary considerably with wavelength and the values obtained are compared with literature data.

La photolyse de la formaldéhyde a été étudiée à 313, 334, et 366 nm dans les intervalles 80–120° et 9–40 Torr, en se servant d'une échelle (trois centuples) d'intensité incidente. A ces températures, quelques décompositions thermiques hétérogènes ont été observées. Il a été trouvé que Φ_{H_2} et Φ_{CO} sont indépendants de l'intensité pour de basses intensités ce qui suggère que la réaction CHO → CO + H était négligeable dans notre système. A partir de l'extrapolation, à intensité nulle, de Φ, il a été possible d'obtenir ϕ_I pour $CH_2O + h\nu \rightarrow H + CHO$ et ϕ_{II} pour $CH_2O + h\nu \rightarrow H_2 + CO$. ϕ_I et ϕ_{II} se trouvent à varier considérablement avec la longueur d'onde et les valeurs obtenues sont comparés avec celle tirées de la littérature. [Traduit par le journal]

Can. J. Chem., **51**, 471 (1973)

It is hard to overemphasize the fundamental importance of the chemistry of formaldehyde yet there is disagreement in the literature on major aspects of the thermal and photochemical decomposition. The relatively small number of investigations made with pure formaldehyde is unquestionably related to the difficulties of working with this substance: the gaseous monomer at pressures greater than a few Torr rapidly polymerizes in the temperature range −10 to 60°, building up a solid polymer on the walls of the container.

Formaldehyde has an absorption band from 220–380 nm assigned to the singlet–singlet $^1A_2 \leftarrow {}^1A_1$ transition. It is well established (1) that at the longer wavelengths, photolysis occurs via two primary processes

[I] $CH_2O + h\nu \rightarrow H + CHO$

[II] $\rightarrow H_2 + CO$

However, the values of the primary quantum yields ϕ_I and ϕ_{II}, and their variation with wavelength are uncertain. Methods used have included iodine inhibition (2), mixed isotopes (3), mercury photosensitization (4), olefin inhibition (5), and flash photolysis (6) and the discordant results will be discussed later. The method used here was the measurement of the overall quantum yields, Φ_{H_2} and Φ_{CO}, and their extrapolation to zero intensity (7). The limiting values may then be related to ϕ_I and ϕ_{II}.

Experimental Section

A conventional high vacuum system was used with greaseless valves in all sections exposed to formaldehyde or products.

All photolysis and some thermolysis runs were done in a cylindrical quartz cell of volume 0.472 l and length 20.1 cm mounted inside an oven with temperature control to within ±0.3° at 160°. The cell was connected to a Granville Phillips stainless steel valve mounted inside

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the oven with a dead space of $< 1\%$. Thermolysis experiments were also performed in a spherical quartz bulb of volume 0.19 l connected to a Kontes glass valve with a Teflon/O-ring seal. Conversions were normally kept at $< 1\%$.

The optical system consisted of an Osram HBO-75W high pressure mercury arc with the beam made parallel with a quartz lens. The 313 and 334 nm regions were isolated with solution glass filters (1) and for the 366 nm region a combination of Corning 0–52 and 7–60 filters was used. Light output was checked for monochromaticity, and intensity was varied with quartz neutral density filters and monitored with an RCA 935 photodiode. Absolute incident intensities were obtained using azomethane as an actinometer assuming $\Phi_{N_2} = 1$ with the wavelengths employed. Linear Beer–Lambert plots gave the extinction coefficients of formaldehyde as $\varepsilon = 4.83$ and 1.87 l mol^{-1} cm^{-1} at 313 and 334 nm, respectively. We could not accurately measure the small value of ε at 366 nm and the value $\varepsilon = 0.07$ was taken from the spectrum given by Calvert and Pitts (1).

Formaldehyde was prepared from the polymer as described by Boyles and Toby (8). This yields a monomer of purity $> 99.9\%$, the main impurities being methanol, water, and methyl formate. The formaldehyde was stored at $-196°$.

Hydrogen and carbon monoxide were analyzed by gas chromatography using a silica gel column. No attempt was made to analyze for condensable products such as methanol and glyoxal in the presence of large amounts of unreacted formaldehyde.

Results

A thermal decomposition was studied at 80, 120, and 160°. Equal amounts of H_2 and CO were formed and a half order rate law was obeyed. The measured activation energy was 21.2 kcal/mol. This thermal decomposition was sufficient to preclude photolysis at 160°. The *maximum* correction for the dark reaction was at low intensities and was $\sim 60\%$ at 120° and $\sim 7\%$ at 80°. There is thus considerable uncertainty in the data at 120° at low intensities and most of the photolyses were performed at 80°. Thus the variables employed were wavelength, temperature, incident intensity, formaldehyde pressure, and carbon dioxide pressure. Figures 1 and 2 show the effect of incident intensity on Φ_{CO} and Φ_{H_2} at 313, 334, and 366 nm. Since we are mainly concerned with the zero-intensity values of Φ,

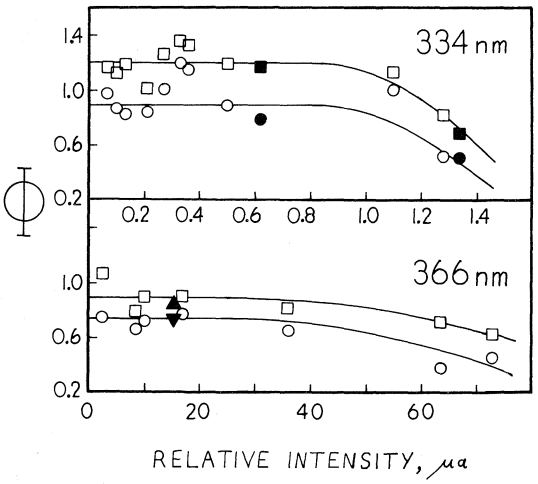

FIG. 1. Effect of incident intensity on quantum yield. Symbols: □, H_2 at 80°; ■ and ▲, H_2 at 120°; ○, CO at 80°; ● and ▼, CO at 120°. CH_2O pressure is 9 Torr except for triangular symbols = 30 Torr.

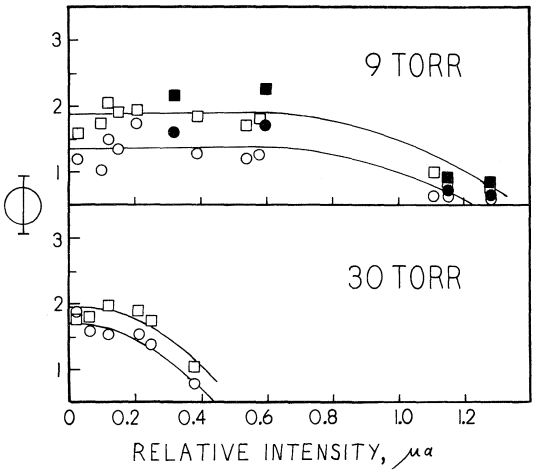

FIG. 2. Effect of incident intensity on quantum yield at 313 nm. Symbols: □, H_2 at 80°; ■, H_2 at 120°; ○, CO at 80°; ●, CO at 120°.

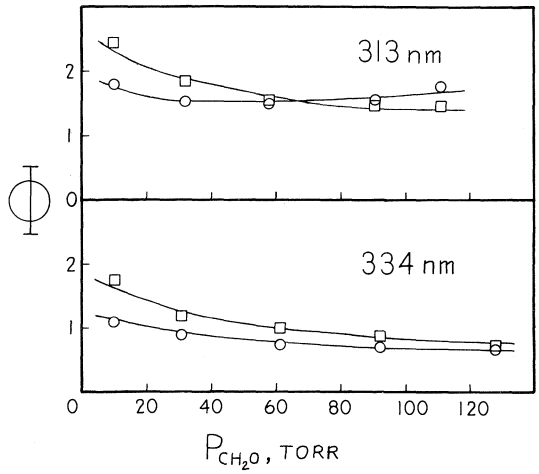

FIG. 3. Effect of CH_2O pressure on quantum yield. Symbols as in Fig. 2.

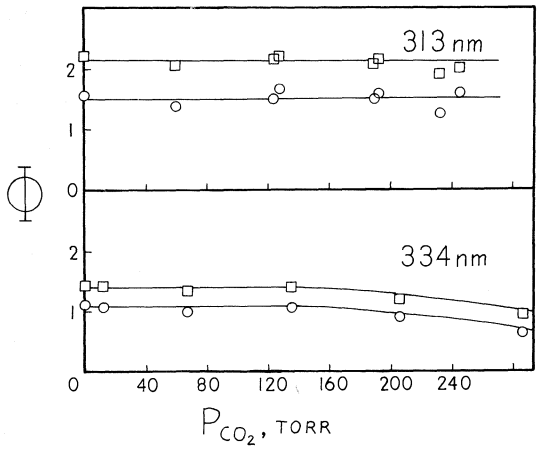

FIG. 4. Effect of added CO_2 on quantum yield. CH_2O pressure = 9 Torr. Symbols as in Fig. 2.

intensity has been plotted as the uncorrected photodiode current, for convenience. Figure 3 shows the effect of formaldehyde pressure on Φ at constant incident intensity. Figure 4 shows the effect on Φ of added carbon dioxide with up to a 30-fold excess.

Discussion

The thermolysis activation energy of 21.2 kcal/mol is incompatible with the known bond dissociation energies of CH_2O and CHO (9), and this together with the low temperatures at which decomposition occurred strongly suggests a heterogeneous process. Similar low activation energies have been found when formaldehyde was decomposed in the presence of metals (10).

To investigate whether the stainless steel valve had a catalytic effect, some experiments were carried out in a quartz bulb connected to a stopcock with a Teflon/O-ring seal. The decomposition rate fell by about a factor of 100. When pieces of stainless steel were added to the bulb, the decomposition rate increased, but silver pellets were found to have no effect. These results suggest that careful consideration must be given to the thermolysis when formaldehyde is photolyzed in the presence of metals.

The photolysis of formaldehyde in the near ultraviolet produces an excited singlet via an n,π* transition. It seems clear that dissociation and subsequent chemistry involve the excited singlet (11) and our work gives no new information on this. There is the possibility of deactivation of the excited molecule and this will be mentioned later. The dissociation $CH_2O^* \rightarrow 2H + CO$ has been shown to occur at short wavelengths by Glicker and Stief (12) but should not occur at wavelengths >271 nm.

The salient features of Figures 1–4 are that the quantum yields are (*a*) independent of incident intensity at low intensities, (*b*) independent of temperature, (*c*) somewhat dependent on pressure, and (*d*) independent of added CO_2. In addition it is clear that $\Phi_{H_2} > \Phi_{CO}$ except at the highest pressures employed.

A mechanism which gives reasonable agreement with our experimental results consists of reactions I and II followed by

[1] $H + CH_2O \rightarrow H_2 + CHO$

[2] $H + CHO \rightarrow H_2 + CO$

[3] $2CHO \rightarrow (CHO)_2$

[4] $\rightarrow 2CO + H_2$

[5] $\rightarrow CH_2O + CO$

[6] $2H (+ M) \rightarrow H_2 (+ M)$

To solve the mechanism of reactions I–II, 1–6 we make the usual steady state assumption of transient species, and also apply the cross-combination rule (13) $k_2/(k_3 + k_4 + k_5)^{1/2}k_6^{1/2} = 2$.[1] Then

$$[7]\quad \Phi_{H_2} = \phi_{II} + \frac{a\phi_I}{a + 2b} + \frac{\phi_I}{(a + 2b)^2} \times \left\{(a + b)\left[\frac{k_2\phi_I^{1/2}I_a^{1/2}}{(k_3 + k_4 + k_5)^{1/2}} + \frac{k_4(a + b)}{k_3 + k_4 + k_5}\right] + b^2\right\}$$

$$[8]\quad \Phi_{CO} = \phi_{II} + \frac{(a + b)}{(a + 2b)^2}\phi_I \times \left\{\frac{k_2\phi_I^{1/2}I_a^{1/2}}{(k_3 + k_4 + k_5)^{1/2}} + \frac{(2k_4 + k_5)(a + b)}{k_3 + k_4 + k_5}\right\}$$

where

$$a = k_1[CH_2O],\ b = (k_6\phi_I I_a)^{1/2}$$

and

$$I_a = \text{absorbed intensity}$$

Equations 7 and 8 predict that Φ will be rather insensitive to changes in intensity, with a

[1]The cross-combination rule is itself pressure dependent, (see, for example, ref. 14). Thus errors will be introduced here over a large pressure range.

TABLE 1. Values of ϕ_I/ϕ_{II}

ϕ_I/ϕ_{II} at wavelength (nm)								Temperature	
124	147	254	265	280	313	334	366	(°C)	Reference
<0.2	<0.2							25	12
		~100			~100		1.2	100	2
					5		0.5–5	140	3
		1.5						55	4
		0.18	0.23		1.1	1.4		90–130	5
				5.0	1.0	0.4	0	60–100	6
					4	2	0.4	80–120	This work

slow decrease at higher intensities. This is seen in Figs. 1 and 2. Over the limited temperature range employed Φ is independent of temperature but a pressure dependence is seen in Fig. 3 although not in Fig. 4. The pressure dependence is of small consequence at formaldehyde pressures below about 15 Torr. As intensity approaches zero we have these limiting expressions

$$[9] \quad \lim \Phi_{H_2} = \phi_{II} + \phi_I\left(\frac{k_3 + 2k_4 + k_5}{k_3 + k_4 + k_5}\right)$$

$$[10] \quad \lim \Phi_{CO} = \phi_{II} + \phi_I\left(\frac{2k_4 + k_5}{k_3 + k_4 + k_5}\right)$$

The limiting quantum yields are much less sensitive to the form of the mechanism than are eqs. 7 and 8. For example, if reaction 2 is replaced by $H + CHO \rightarrow CH_2O$, eqs. 9 and 10 are unaffected.

Our estimated values for the limiting intensity, low pressure values of Φ are as follows: 313 nm $H_2 = 1.92 \pm 0.1$, $CO = 1.30 \pm 0.1$; 334 nm $H_2 = 1.20 \pm 0.1$, $CO = 0.86 \pm 0.1$; 366 nm $H_2 = 0.88 \pm 0.15$, $CO = 0.72 \pm 0.15$.

There are too many unknowns in eqs. 9 and 10 for immediate numerical solutions of ϕ_I and ϕ_{II}. However, approximate values may be obtained indirectly. Lim Φ_{H_2} − lim $\Phi_{CO} = \phi_I k_3/(k_3 + k_4 + k_5)$ and we find this decreases as wavelength increases. Rate constants for equilibrated radicals will be independent of wavelength (λ) and thus as λ increases ϕ_I decreases. We may rewrite eqs. 9 and 10 as

$$[11] \quad \frac{\lim (\Phi_{H_2} - \phi_{II})}{\lim \Phi_{CO} - \phi_{II}} = \frac{k_3}{2k_4 + k_5} + 1$$

$$[12] \quad \frac{\lim \Phi_{H_2} - \lim \Phi_{CO}}{\phi_I} = \frac{k_3}{k_3 + k_4 + k_5}$$

and the r.h.s. must be independent of λ. Additional restraints arise because the r.h.s. of eq. 11 is clearly >1 and that of eq. 12 is <1. These restraints coupled with the assumption that ϕ_{II} varies monotonically with λ enable limits to be assigned to the values of ϕ_I and ϕ_{II} by plotting the l.h.s. of eqs. 11 and 12 against λ for different values of ϕ_I and ϕ_{II}. The results are as follows: for 313 nm, $\phi_I = 0.8 \pm 0.2$, $\phi_{II} = 0.2 \pm 0.2$; for 334 nm, $\phi_I = 0.45 \pm 0.1$, $\phi_{II} = 0.25 \pm 0.1$; for 366 nm, $\phi_I = 0.2 \pm 0.1$, $\phi_{II} = 0.45 \pm 0.1$.

Literature values for the ratio ϕ_I/ϕ_{II} (which should be more accurate than the absolute values) are given in Table 1. The lack of agreement in the data of Table 1 is discouraging. Plots of ϕ_I/ϕ_{II} (or the individual quantum yields) against wavelength show an almost random scatter. Glicker and Stief's (12) results are not strictly comparable with the others since at short wavelengths ϕ_I may be zero. The values of DeGraff and Calvert (5) show a trend at variance with all other data and probably may be discounted (6). The remaining data show rough agreement that as λ increases, ϕ_I/ϕ_{II} decreases. The dominant primary process at 366 nm is probably reaction II.

We may draw some qualitative conclusions from the trends shown in Figs. 1–4. The fact that Φ_{H_2} and Φ_{CO} do not increase at low intensities is evidence for the stability of the formyl radical up to 120°. Appreciable decomposition would lead to a chain reaction with subsequent increases in Φ_{H_2} and Φ_{CO}.

We find that $\phi_I + \phi_{II} < 1$ at 366 nm and perhaps at 334 nm. Our data are less reliable at 366 nm than at the shorter wavelengths since we were unable to measure the absorption coefficient at 366 nm. Thus we are reluctant to postulate a third, deactivating, primary process especially since a large excess of CO_2 is seen to have virtually no effect in Fig. 4. McQuigg and

For personal use only.

Calvert (6) found $\phi_I + \phi_{II} \simeq 1.0$ for CH_2O but the sum was much less than unity for CD_2O. The possibility of a third primary process at longer wavelengths cannot be ruled out.

We thank the National Science Foundation for the support of this work.

Naphthyridine Chemistry. XVII: Di-*N*-alkylated Naphthyridines

DAVID J. POKORNY AND WILLIAM W. PAUDLER[1]

Clippinger Laboratories, Department of Chemistry, Ohio University, Athens, Ohio 45701

Received September 14, 1972

It has been shown that the *N,N'*-dimethylated naphthyridines form pseudo bases by hydroxide addition in the quinolinoid rather than the isoquinolinoid ring, where possible.

The charge repulsion in the 1,8-dimethyl-1,8-naphthyridinium ion is reflected by its facile partial conversion to a mono-pseudo base at room temperature. A variable temperature study of this equilibrium reaction is described.

On a démontré que les naphthyridines diméthylées en position *N,N'* forment, si possible, des pseudo-bases par l'addition d'un groupement hydroxyle au cycle quinolinoïde plutôt qu'au cycle isoquinolinoïde.

La répulsion des charges dans l'ion diméthyl-1,8 naphthyridinium-1,8 est mise en évidence par sa conversion facile et partielle en une mono pseudo-base à la température ambiante. Une étude à diverses températures de cette réaction d'équilibre est aussi décrite.

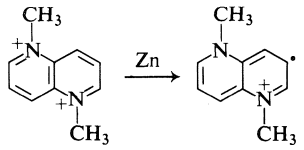
The recently developed facile syntheses of some naphthyridines (1–4) has made these ring systems available to extensive examinations of their reactivities. Among these studies, the electrophilic substitution reactions, Chichibabin amination (5), and behavioral patterns of the *N*-oxides (6–8) have been the subject of previous papers. A recent publication (9) delineating the reactivity of some of the mono-*N*-alkylated derivatives with base has further extended our knowledge of these ring systems.[2]

The only reported di-*N*-alkylated derivative of the naphthyridines is that of 1,5-naphthyridine (**1**) (10). This compound, when treated with zinc,



1 **2**

is said to form a free radical with the assigned structure **2**, and its other possible canonical forms.

The availability of "magic methyl" (methylfluorosulfonate) and its established ability to alkylate some difficultly alkylable functional groups prompted us to employ this compound for the syntheses of *N,N'*-dialkylated naphthyridines.

This reaction afforded the *N,N'*-dimethyl derivatives of 1,5-(**1**), 1,6-(**3**), 1,7-(**4**), 1,8-(**5**), and 2,7-naphthyridine (**6**). The structure proof of these compounds rests upon their correct elemental analyses and an analysis of their p.m.r. spectra in trifluoroacetic acid (see Table 1).

An interesting feature of these spectra involves the chemical shifts of the X-methyl protons in the 1,X-naphthyridinium derivatives. It appears that their chemical shifts are subject to an inductive effect caused by the N-1 methyl groups, whereby the 8-methyl protons in the 1,8- case absorb at τ 4.84 while the N-7 and -5 methyl protons in the 1,7- and 1,5-naphthyridinium derivatives absorb at τ 4.96 and 5.00, respectively. The 6-methyl protons in the 1,6-naphthyridinium species absorb at τ 5.08. Thus we see that, as the separation between the nitrogens increases from one carbon (1,8-naphthyridine) to two carbons (1,7- and 1,5-compounds) to three carbons (1,6-compound), the methyl protons become less and less deshielded.

A similar trend exists when one examines the effect of the X-methyl groups upon the chemical shifts of the 1-methyl protons. The p.m.r. spectra of these compounds when dissolved in deuterium oxide are rather different and these chemical shift relationships are no longer apparent.

The spectrum of the 1,8-dimethyl-1,8-naphthyridinium ion in D_2O at the p.m.r. probe temperature (33°) exhibits three broad absorption areas, two for the aromatic and one for the methyl protons. The relative peak intensities for

[1]Author to whom correspondence should be addressed.

[2]At the time of preparation of this paper we had completed a similar study and wish to comment that our results are in agreement with those reported in ref. 9, with the exception that, under our conditions no H-2 → D-2 exchange takes place in the monomethiodide of 1,8-naphthyridine.

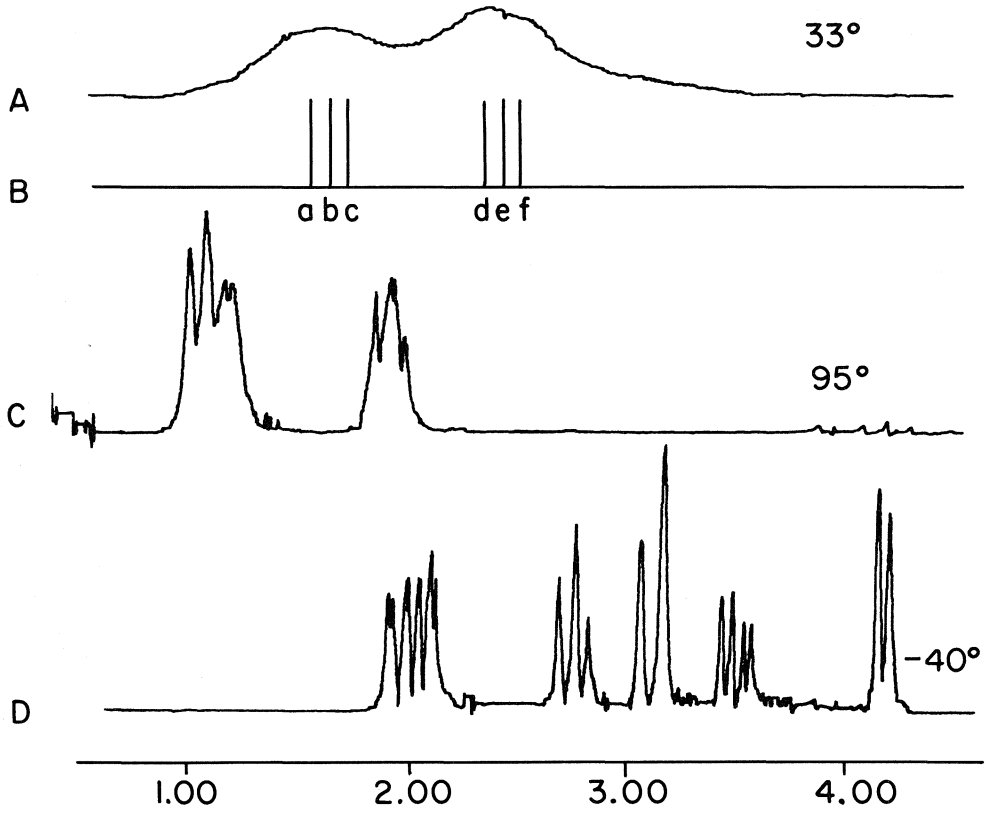

FIG. 1. Variable temperature spectra of 1,8-dimethyl-1,8-naphthyridinium di-fluorosulfonate.
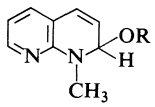
(A) Room temperature spectrum of D_2O solution of 1,8-dimethyl-1,8-naphthyridinium di-fluorosulfonate. (B) Chemical shifts for a 75/25 time-averaged mixture of the 1,8-dimethyl-1,8-naphthyridinium di-fluorosulfonate and its pseudo-base derivative **7** (*cf.* text for details). (C) 1,8-Dimethyl-1,8-naphthyridinium di-fluorosulfonate in D_2O at 95°. (D) Pseudo-base derivative (**7**) observed at −40° of a CH_3OD solution of 1,8-dimethyl-1,8-naphthyridinium di-fluorosulfonate.

the two aromatic proton broad areas (see Fig. 1) are 1:1(!). This rather unexpected spectrum is highly temperature-dependent and one finds that, as the temperature is increased, the spectrum ultimately changes, at 95°, to that expected for the 1,8-dimethyl-1,8-naphthyridinium ion. On the other hand, if the temperature is lowered, one observes that the spectrum of a CD_3OD solution of this compound at −40° is that expected for a mono pseudo-base derivative (see Fig. 1). Thus, the equilibrium reaction depicted in eq. 1 is taking place.

[1] ROD +  + D^+

5 **7**

That we are indeed dealing with structure **7** is evident from an analysis of its p.m.r. spectrum and a comparison of the chemical shifts and coupling constants with those of compound **8** (9).



8

It now remains to analyze the curious p.m.r. spectrum at room temperature, where we are apparently observing a rapid equilibrium between compounds **5** and **7**.

Since we know the approximate chemical shifts of the protons of structures **5** and **7** which con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tribute to the equilibrium, it becomes a simple matter to calculate the shape of the spectrum, when the two compounds are in rapid equilibrium with each other, for different concentrations of each component (11).

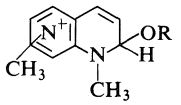
When this was done, the "calculated" spectrum for a 75/25 ratio of compounds **5** to **7** closely approximates the experimentally observed spectrum.

The line spectrum in Fig. 1 (graph B) represents the chemical shifts of the various time-averaged proton positions in the absence of any coupling. The lines are composed of the following proton-chemical shifts of the non-covalently hydrated species (NCH) and the mono-pseudo base compound (MPS): line *a*, H-4 of NCH and H-5 of MPS; line *b*, H-2 of NCH and H-7 of MPS; line *c*, H-4 of NCH and H-4 of MPS; line *d*, H-3 of NCH and H-6 of MPS; line *e*, H-2 of NCH and H-2 of MPS; line *f*, H-3 of NCH and H-3 of MPS. A consideration of the fact that these lines neither include the various coupling constants nor the existing lineshapes, allows one to conclude that, if they were included, a spectrum akin to the experimental one (graph A Fig. 1) would be obtained.

This facile pseudo base formation is unique to the 1,8-dimethyl-1,8-naphthyridinium ion and is not observed in the other naphthyridinium compounds examined in this study.

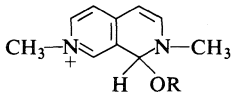
Thus, one is drawn to the conclusion that the expected substantial charge repulsion between the closely situated positively charged nitrogen atoms in the 1,8-naphthyridinium compound is responsible for its facile reaction with water and alcohols since these reactions relieve the charge-repulsion.[3]

The other di-*N*-alkylated naphthyridinium compounds do, however, form these pseudo bases when a stronger base (better nucleophile) than H_2O is employed. When these compounds are dissolved in D_2O containing NaOD (approximately 0.5 *N*), the p.m.r. spectra observed are those to be expected for the pseudo-base species (see Table 2). In the 1,5-, 1,6-, and 1,7-naphthyridinium compounds (**1**, **3**, and **4**) the hydroxide attacks in the quinolinoid rather than in the isoquinolinoid ring, to afford compounds of general structure:



R = H, CH_3

In the absence of the highly electrophilic 2-position the attack occurs in the 1-position of the isoquinolinoid ring portion as shown by the formation of compound **9**.



R = H, CH_3

9

Attempts at generating cation radicals of the type proposed for the 1,5-dimethyl-1,5-naphthyridinium di-methosulfate from the 1,X-dimethyl 1,6-, 1,7-, 1,8-, and 2,7-naphthyridinium di-fluorosulfonates were not successful.

Experimental

Dimethylnaphthyridinium Fluorosulfonates

To methyl fluorosulfonate (4 ml) was added the appropriate naphthyridine (200 mg, 1.5 mmol). An exothermic reaction occurred which resulted in about 90% diquaternization of the naphthyridine, as established by an n.m.r. spectrum of the crude product which indicated the presence of the mono-methylated compound. The resulting mixture was heated under reflux on the steam bath for 1 h and the supernatant liquid was removed. Additional alkylating agent was added (4 ml) and the heating was continued for an additional 0.5 h. After this time, the mixture was filtered through a sintered glass funnel to yield a white solid. This solid was repeatedly washed with dry dichloromethane, collected, and dried under vacuum (0.001 mm) for several hours. The material changed color slowly under vacuum but more rapidly in air. The 1,5-naphthyridine derivative could be recrystallized from ethanol–water mixture to yield white platelets (460 mg, 1.3 mmol, 85%; m.p. 250° (dec.)). The other derivatives could not be recrystallized since they changed color from white to red, (1,6-dimethyl-1,6-naphthyridine: 490 mg, 1.37 mmol, 90%; m.p. 207–209°), brown (1,7-dimethyl-1,7-naphthyridine: 525 mg, 1.47 mmol, 95%; m.p. 202–205°), and light brown (2,7-dimethyl-2,7-naphthyridine: 504 mg, 1.41 mmol, 92%; m.p. 217°). On standing, the compounds that could not be recrystallized presumably liberated hydrofluoric acid which etched the glass vials in which they were stored. They also developed an odor which was reminiscent of methyl sulfoxide. However, an aged sample (3 months) still gave the characteristic n.m.r. spectrum of the freshly prepared material.

Anal. Calcd. for $C_{10}H_{12}N_2O_6S_2F_2$: C, 33.51; H, 3.38;

[3]A referee suggested that another driving force for this reaction is the decreased steric repulsion between the methyl protons in the pseudo bases. We feel that this can be only a minor factor.

Lignans of Western Red Cedar (*Thuja plicata* Donn). XI. β-Apoplicatitoxin

BRUCE F. MACDONALD AND G. M. BARTON

Department of the Environment, Canadian Forestry Service, Western Forest Products Laboratory, Vancouver, British Columbia

Received August 21, 1972

The structure of the eleventh in the series of novel lignans from the heartwood of western red cedar (*Thuja plicata* Donn) has been determined as 1,4-dihydronaphthalene-6-hydroxyl-2-(hydroxymethyl)-7-methoxy-4(3′,4′-dihydroxy-5′-methoxyphenyl)-3-carboxylic acid lactone (β-apoplicatitoxin) (**1**) by spectrometric methods and by aromatization to the known compound trimethylplicatinaphthalene. This lignan provides an intermediate to the possible stereoselective synthesis of derivatives related to the picropodophyllin series.

La structure du onzième de la série des nouveaux lignanes provenant du cœur des cèdres rouges de l'ouest (*Thuja plicata* Donn) a été déterminée comme étant la lactone de l'acide dihydro-1,4 naphtalène-4 hydroxyl-6 (hydroxy méthyl) 2-méthoxy-7 (dihydroxy-3′,4′ méthoxy-5′ phényl)-4 carboxylique-3 (*β*-apoplicatitoxine) (**1**) par des méthodes spectrométriques et par aromatisation du composé connu, la triméthyl plicatinaphtalène. Ce lignane procure une intermédiaire à la synthèse stéréosélective possible de dérivés reliés à la série de la picropodophylline. [Traduit par le journal]

Can. J. Chem., **51**, 482 (1973)

Introduction

Previous work has elucidated the structural relationship of 10 lignans present in the heartwood of western red cedar (*Thuja plicata* Donn) trees, two of which were 4-aryltetrahydronaphthalenes, five were substituted dibenzyl butyrolactones, one was a 4-aryl-α-naphthol lactone, another was a naphthalene, and the latest was a butyrolactone in which a double bond was conjugated with the aromatic nucleus (1).

This new lignan is a dihydro-plicatinaphthalene, not unexpected in view of structures already elucidated in the series (1), and it is described as 1,4-dihydronaphthalene-6-hydroxyl-2-(hydroxymethyl)-7-methoxy-4(3′,4′-dihydroxy-5′-methoxyphenyl)-3-carboxylic acid lactone (**1**). It has been given the trivial name β-apoplicatitoxin because of its close association with β-apopicrosikkimotoxin (**1***a*) (2).

β-Apoplicatitoxin was isolated by ethyl acetate from the hot water extract of western red cedar heartwood. The crude material which precipitated overnight was further purified by filtering and washing several times with hot methanol. β-Apoplicatitoxin was soluble with difficulty in common organic solvents with the exception of pyridine. Initial evidence of its structure was obtained by comparison of chromatographic data (acetylated derivative) with that from earlier lignans of the series (3).

The structure of β-apoplicatitoxin was inferred from i.r. and u.v. data. A spectrographic comparison of the main features of **1***a* with related compounds of the sikkimotoxin and podophyllin series is given in Table 1. Of particularly diagnostic importance is the i.r. band 1691–1695 cm^{-1} which is indicative of a double bond not in conjugation with an aromatic ring. The close similarity in these data between **1** and β-apopicrosikkimotoxin (**1***a*) is apparent.

β-Apoplicatitoxin, which gave a positive phenolic test with the ferric–ferri-cyanide reagent (4), when chromatographed on molybdic acid-treated paper with butanol – acetic acid – water, showed a considerably reduced R_f value (0.63) compared with untreated paper R_f (0.74) and appeared as a yellow spot indicative of a pyrocatechol grouping.

Molecular weight of the acetylated derivative (**1***b*) gave a parent ion peak of *m/e* 496. Peaks were noted at *m/e* 454, 412 (base peak), and 370 corresponding to the sequential loss of three ketene molecules from the arylacetate ester groups.

The n.m.r. spectra of β-apoplicatitoxin in pyridine suggested a structure with two methoxyls, four aromatic protons, and a methylene lactone. It was noted that chemical shifts in pyridine-d_5 were strongly affected by the presence of water. Accordingly, samples were dissolved under dry nitrogen in a glove box using dry (calcium sulfate) pyridine-d_5. When the

spectra were rerun in the presence of D_2O, the chemical shift (τ units) of some of the more important protons changed as follows: C-1, 5.06–5.21; C-2′ and -6′, 3.24–3.27; C-5, 2.81–2.87 and C-8, 3.21–3.07. It is felt that chemical shift sensitivity of the aromatic protons is due to the strong molecular association between the acidic phenolic sites and the basic nitrogen site of the pyridine. The addition of water (D_2O) is sufficient to disrupt this association, resulting in the changes noted. The magnitude of these changes, although not as large as those observable with the use of shift reagents, facilitated the identification of aromatic protons by separating them from the coincident pyridine-d_4 resonances.

The n.m.r. spectra of the methylated (**1***a*) and acetylated (**1***b*) derivatives confirmed the presence of two methoxyl and three hydroxyl groups

in the original β-apoplicatitoxin (**1**). The spectra of the methyl and acetyl derivatives also showed the usual chemical shift change of the methylene lactone proton from τ 5.19 (methylated) to 5.24 (acetylated). Protons at C-2′ and -6′ are magnetically and chemically equivalent in the methylated derivative, whereas they are not in the acetylated derivative. This indicates that the two phenolic hydroxyls in the parent β-apoplicatitoxin are in the vicinal C-3′ and -4′ positions, which is in agreement with the general structure of the previous lignans and the reduced R_f value on molybdic acid-treated paper.

An important feature of these n.m.r. spectra was the ABX system of C-1 methylene and C-4 protons; however, the AB portion was partly obscured by the methoxyl resonances. The X part C-4, which is long-range coupled with the C-1 methylene protons, appeared as a broad peak ($\Delta\frac{1}{2}h$ = 3 Hz) at τ 5.14 in the methylated and τ 5.08 in the acetylated derivative.

Definite evidence of the long-range coupling, through the double bond between C-2 and -3, in this ABX system was obtained by nuclear magnetic double resonance (n.m.d.r.) studies in deuterated dimethyl sulfoxide on the acetylated derivative (**1***b*). In this solvent, partial separation of the AB portion from the methoxyls was evident when compared with deuteriochloroform solvent. Irradiation at τ 6.07 or 6.10 (AB portion) resulted in a sharpening of the C-4 proton peak at τ 5.14 (C-4 ($\frac{1}{2}h$) = 8 → 3 Hz). Also irradiation at τ 5.14 (C-4 proton) caused the doublets at τ 6.07 and 6.10 to be significantly increased in height, with a corresponding decrease in line width. It now became apparent that methylated β-apoplicatitoxin (**1***a*) and Schrier's (2) β-apopicrosikkimotoxin had the same chemical structure. They both had similar melting points (222–224 and 224–225°, respectively) and gave almost identical spectral data (Table 1).

Ayres (5) noted that in apopicropodophyllin (**4**) the C-1 and -4 protons formed an ABX system in which the AB part was largely obscured beneath the methoxyl peaks (τ 6.25). The X part of the spectrum appeared at τ 5.20 in low-polarity solvents, resonating at lower field than normal owing to deshielding by the C_2–C_3 unsaturation.

Final proof of structure was obtained by aromatization of the methylated derivative (**1***a*) by dehydrogenation with lead tetraacetate and glacial acetic acid to give identical i.r., u.v., and n.m.r. spectra with trimethylplicatinaphthalene (**2**) (6).

Because of the non-conjugated position of the double bond between C-2 and -3, addition reactions can be controlled to give either *cis* or *trans* products. Thus, for the first time, the possibility exists of preparing *cis* compounds in the tetrahydronaphthalene cedar lignan series similar to the picropodophyllin series.

Experimental

The following equipment and materials were used: m.p, Mettler F.P. 1; i.r. spectra, Perkin–Elmer 521 grating spectrometer (KBr disks); u.v. spectra, Beckman DR-2 spectrometer (ethanol); n.m.r., Varian HA-100 (tetramethyl silane τ = 10 as internal standard); low-resolution mass spectra, MS 12, through the kind arrangements of Dr. P. J. Smith, University of Saskatoon, Saskatoon, Saskatchewan. The t.l.c. values were obtained with silica gel G (Merk) as adsorbent, toluene–ethanol (9:1) and chloroform–acetone (95:5) as developers, followed by nitric acid–sulfuric acid (1:1) spray and heat as detector. Papergrams were developed with butanol–acetic acid–water (BAW) (60:15:25) and detected with potassium ferricyanide–ferric chloride reagent (mixed 1% solutions) (4). Samples for n.m.r. analysis in dry pyridine were prepared in a dry box under a nitrogen atmosphere.

*β-Apoplicatitoxin (**1**)*

Western red cedar wood meal (3 mm Wiley mill screen, 5 kg) was boiled in water for 2 h and filtered through glass wool while still hot. The hot water extract was reduced in volume in an all-glass cyclone evaporator until a heavy precipitate formed. The evaporator was subsequently washed thoroughly with ethyl acetate (3 × 500 ml) which was then used, together with an additional quantity of ethyl acetate (1000 ml) for extracting the cooled, concentrated aqueous solution and precipitate. The ethyl acetate solution was next evaporated under reduced pressure to a small volume and, on standing overnight, a white precipitate formed. The precipitate was filtered out and washed with hot methanol. After drying, the material weighed 500 mg. The product was difficultly soluble in all common laboratory reagents except pyridine. It gave a positive phenolic test with the ferric–ferri–cyanide reagent (4). Paper chromatography (Whatman No. 1) gave a single spot R_f = 0.74 (BAW solvent). Spectra: λ_{max} (log ε) 283.5 nm (3.75); γ_{max} 3380 (broad hydroxyl), 1725 (broad lactone), 1685 and 1580 (double bond) cm^{-1}; n.m.r. τ (pyridine-d_5, dried over calcium sulfate) 2.81 (1H, singlet, aromatic C-5), 3.21 (1H, singlet, aromatic, C-8), 3.22 (1H, doublet, J = 0.75 Hz, aromatic, C-2′ or -6′), 3.24 (1H, doublet, J = 0.75 Hz, aromatic, C-6′ or -2′), 5.06 (1H, multiplet, C-4, X part of ABX), 5.28 (2H, broad singlet, lactone methylene), 6.25 (3H, singlet, methoxyl, C-5′ or -7), 6.39 (3H, singlet, methoxyl, C-7 or -5′), centered at 6.32 (2H, multiplet C-1 methylenes, AB part of ABX partially hidden by methoxyls) (three phenolic hydroxyls not observed); n.m.r. τ (pyridine-d_5, two drops of D_2O) 2.87 (1H, singlet, aromatic, C-5), 3.07 (1H, singlet, aromatic, C-8), 3.27 (2H, singlet, width at half height 1.5 Hz, aromatic C-2′ and -6′),

5.00 (2H, singlet, lactone methylene), 5.21 (1H, multiplet, C-4, X part of ABX), 6.04 (3H, singlet, methoxyl, C-5′ or -7), 6.23 (3H, singlet, methoxyl, C-7 or -5′), centered at 6.13 (2H, multiplet, C-1 methylenes, AB part of ABX hidden by methoxyls) (HOD peak at 4.45).

Trimethyl β-Apoplicatitoxin (1a)

β-Apoplicatitoxin (**1**) (50 mg) was partially dissolved in methanol (40 ml) by warming. On cooling, diazomethane in ether (5 ml) was added every 2 h for 8 h with stirring at room temperature and allowed to stand overnight. A further treatment of diazomethane in ether (5 ml) every 2 h for 6 h with stirring was necessary for complete methylation. The product (t.l.c. R_f 0.42, toluene–ethanol, 9:1) was evaporated to dryness and crystallized from hot methanol to yield 1,4-dihydronaphthalene-2-(hydroxymethyl)-6,7-dimethoxy-4(3′,4′,5′-trimethoxyphenyl)-3-carboxylic acid lactone (40 mg), m.p. 220–222°. Spectra: λ_{max} (log ε) 281.5 nm (3.61); γ_{max} 1752 (lactone), 1691 and 1585 (double bond) cm^{-1}; n.m.r. τ (deuteriochloroform) 3.31 and 3.41 (1H each, singlets, aromatic, C-5 and -8), 3.65 (2H, singlet, aromatic, C-2′ and -6′), 5.14 (1H, multiplet, C-4, X part of ABX), 5.20 (2H, singlet, lactone methylene), 6.11 (3H, singlet, methoxyl), 6.23 (6H, singlet, methoxyl), 6.25 (6H, singlet, methoxyl), centered at 6.24 (2H, multiplet, C-1 methylenes, AB part of ABX hidden by methoxyls).

Triacetyl β-Apoplicatitoxin (1b)

β-Apoplicatitoxin (**1**) (100 mg) was dissolved in a mixture of pyridine (5 ml) and acetic anhydride (5 ml). This mixture was heated under anhydrous conditions for 10 min in a boiling water bath, allowed to stand for 20 min and then evaporated to dryness under vacuum. The residue was then dissolved in hot methanol by stirring, filtered, and the filtrate cooled in a deep freeze for 4 h. The resultant crystalline product, 1,4-dihydronaphthalene-6-acetoxy-2-(hydroxymethyl)-7-methoxy-4(3′,4′-acetoxy-5′-methoxyphenyl)-3-carboxylic acid lactone (**1b**) weighed 80 mg, m.p. 243–245°. Spectra: λ_{max} (log ε) 277.5 nm (3.63); γ_{max} 1750 (broad lactone), 1685 and 1590 (double bond) cm^{-1}; n.m.r. τ (deuteriochloroform) 3.12 and 3.69 (1H each, doublet, J = 1.0 Hz, aromatic, C-2′ and -6′), 3.15 and 3.20 (1H each, singlet, aromatic, C-8 and -5), 5.08 (1H, multiplet, C-4, X part of ABX), 5.24 (2H, broad singlet, lactone methylene), 6.17 (3H, singlet, methoxyl), 6.24 (3H, singlet, methoxyl), centered at 6.23 (2H, multiplet, C-1 methylenes, AB part of ABX hidden by methoxyls), 7.76, 7.78, 7.83 (3H each, singlets, acetyls); mass spectrum (low resolution), parent ion = 496 (4%), 454 (30%), 412 (100%), 370 (70%).

Trimethyl Plicatinaphthalene (2)

Trimethyl β-apoplicatitoxin (**1a**) (100 mg), lead tetraacetate (200 mg), and glacial acetic acid (3 ml) were placed in a 100 ml conical flask fitted with an air condenser. The mixture was slowly heated from 55–70° during a 25 min period in a water bath. After cooling, water was added and the mixture was extracted several times with chloroform and the chloroform layers collected. The chloroform was then removed under vacuum and the residue dissolved in hot methanol from which yellow crystals (30 mg), m.p. 227–229° formed. This material was found to be identical with an authentic sample of trimethylplicatinaphthalene (**2**) (6) by identical u.v., i.r., and n.m.r. spectra comparisons.

The authors wish to thank Dr. J. F. Manville of the Western Forest Products Laboratory, Vancouver, British Columbia for his advice and the n.m.d.r. experiments.

Carbon-13 Magnetic Resonance: Diterpenoid Alkaloids From the *Delphinium* Species[1]

ALAN J. JONES[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2

AND

M. H. BENN

The Chemistry Department, University of Calgary, Calgary, Alberta T2N 1N4

Received August 11, 1972

The carbon-13 magnetic resonance spectra of the diterpenoid alkaloids lycoctonine (**1**), deoxylycoctonine (**2**), deoxymethylenelycoctonine (**3**), browniine (**4**), isolatizidine (**5**), delphonine (**6**), lycoctonal (**7**), and their corresponding hydrochloride or perchlorate salts have been determined at 22.63 MHz in the Fourier mode. With the aid of proton decoupling techniques, additivity relationships and the effects induced by specific structural changes, self-consistent assignments of nearly all the resonances have been made. Substituent effects are often of the same order but differ in magnitude from those for simpler systems reported in the literature. The effects of protonation do not unambiguously follow the additive trends indicated in simpler systems but do exhibit a reasonably constant pattern. The data have been applied in the structural elucidation of two previously unknown bases isolated from *Delphinium bicolor* Nutt.

Les spectres de résonance magnétique du carbone-13 des alcaloïdes diterpèniques lycoctonine (**1**), deoxylycoctonine (**2**), deoxyméthylènelycoctonine (**3**), browniine (**4**), isolatizidine (**5**), delphonine (**6**), lycoctonal (**7**), et de leurs sels chlorhydrate et perchlorate, ont été déterminés à 22.63 MHz selon la technique du Fourier. Les techniques de découplage du proton, les relations d'additivité, et les effets induits par des changements structuraux spécifiques ont permis une attribution logique de presque tous les pics de résonance. Les effets de substituants sont souvent du même ordre, malgré une différence dans l'amplitude, que ceux des systèmes plus simples rapportés dans la littérature. Les effets de la protonation ne suivent pas les tendances additives indiquées pour les systèmes plus simples mais se font selon un modèle pratiquement constant. Les données ont été appliquées dans l'élucidation structurale de deux bases précédemment inconnues, isolées du "*Delphinium bicolor* Nutt".

[Traduit par le journal]

Can. J. Chem., **51**, 486 (1973)

Interest in the application of carbon-13 magnetic resonance techniques in the area of saturated nitrogen heterocyclic systems (1–4) has generated an abundance of fundamental substituent and additivity data, which exhibit two primary features. First, the substituent effects noted in the cyclohexanes (5) have been closely paralleled, although in many cases the parameters are attenuated (1), and second, the presence of a basic nitrogen center, in providing easy access to a variety of simple derivatives, can be a valuable asset in spectral assignment through a set of protonation or methiodation parameters (1–3). The second feature has also been noted for the nitrogen center in amino acids (6).

In view of the success in the application of additivity relationships in the decalins (7), perhydroanthracenes and perhydrophenanthrenes (8), and selected steroids (9), it seemed reasonable to apply the findings of the above fundamental studies to more complex analogs containing a saturated heterocyclic ring. We have chosen a series of diterpenoid alkaloids found in plants of the genera *Aconitum* and *Delphinium* (10). These alkaloids, primarily of the lycoctonine-type, have the basic C_{19}-skeleton shown in Fig. 1. Unlike the alkaloids studied by Crain *et al.* (3) they contain no aromatic rings and, therefore, *all 19–25 carbon resonances* are found in the region 10–100 p.p.m. downfield of TMS. The lycoctonine alkaloids are characterized by the high degree of oxygenated substituents, usually five or six, and although a great deal of effort was made, the skeleton completely eluded determination by chemical means, finally being solved by X-ray crystallography in 1956 (11).

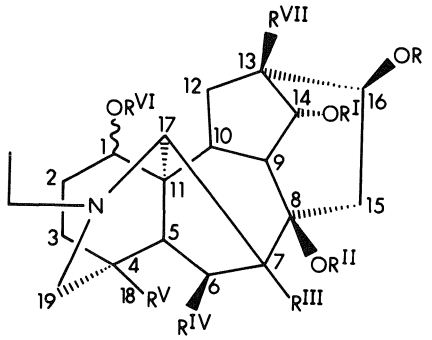

FIG. 1. Structures of the diterpenoid alkaloids studied:

1 $R^{II} = R^{VII} = H$; $R = R^{I} = R^{VI} = CH_3$; $R^{V} = CH_2OH$; $R^{III} = OH$; $R^{IV} = OCH_3$

2 $R^{II} = R^{VII} = H$; $R = R^{I} = R^{V} = R^{VI} = CH_3$; $R^{III} = OH$; $R^{IV} = OCH_3$

3 $R^{II} = R^{V} = R^{VII} = H$; $R = R^{I} = R^{VI} = CH_3$; $R^{III} = OH$; $R^{IV} = OCH_3$

4 $R^{I} = R^{II} = R^{VII} = H$; $R = R^{VI} = CH_3$; $R^{V} = CH_2OCH_3$; $R^{III} = OH$; $R^{IV} = OCH_3$

5 $R^{I} = R^{II} = R^{III} = R^{IV} = R^{VI} = R^{VII} = H$; $R = CH_3$; $R^{V} = CH_2OCH_3$

6 $R^{I} = R^{II} = R^{III} = H$; $R = R^{VI} = CH_3$; $R^{V} = CH_2OCH_3$; $R^{VII} = OH$; $R^{IV} = OCH_3$; *N*-ethyl group is replaced by *N*-methyl in this case

7 $R^{II} = R^{VII} = H$; $R = R^{I} = R^{VI} = CH_3$; $R^{V} = CHO$; $R^{III} = OH$, $R^{IV} = OCH_3$

The carbon-13 magnetic resonance spectra of these diterpenoid alkaloids reveal not only the number and type of carbon atoms in the system but also exhibit close structural and "family" resemblances and indicate the degree and sites of oxygen substitution. It may, therefore, be anticipated that these data will be of critical importance in determinations of the structure of newly isolated alkaloids of the *Aconitum*, *Delphinium*, and *Garrya* species (10, 12). We have applied the results successfully in structural determination for two previously unknown alkaloids of the *Delphinium* genus.

Experimental

Carbon-13 spectra were determined at 22.63 MHz in the Fourier mode using a Bruker HFX-90 spectrometer in conjunction with a Nicolet-1085, 20K memory, computer. The spectrometer features a deuterium lock system, a BSV-2 random noise (800 Hz band-width) proton decoupler, and a BSV-2 pulse generator-amplifier. Spectra of the bases were determined for solutions in deuterochloroform (which also provided the lock signal) with 2–5% TMS added as internal reference. For some of the hydrochloride salts dimethylsulfoxide-d_6 and heavy water were used as solvent. In these cases a mixture containing dioxane and TMS was added as reference. All samples were contained in precision ground 10 mm, o.d., tubes (Wilmad). The spectrometer was used in the cross-coil configuration. On average, a 30 μs pulse, corresponding to an approximate tilt angle of 45°, was employed. For the average spectral width of 2500 Hz the delay between pulses was 70 μs. Acquisition times averaged 4 h over 8K data points for concentrations of the order of 0.2 *M*. For off-resonance or coupled spectra this time was approximately doubled.

Some of the bases were freshly generated from their corresponding salts, while others were purified by procedures given in the literature. All hydrochlorides were prepared by bubbling dry hydrogen chloride through an ethereal solution of the base. The solid isolated was then recrystalized from the appropriate solvent.

Results

Structures and the numbering system for the alkaloids lycoctonine (**1**), deoxylycoctonine (**2**), deoxymethylenelycoctonine (**3**), browniine (**4**), isolatizidine (**5**), delphonine (**6**), and lycoctonal (**7**) are shown in Fig. 1. Substituent groups are indicated by a prime symbol on the number appropriate to the position of substitution on the C_{19}-skeleton even where oxygen atoms intervene. The carbon-13 chemical shifts for the bases **1**–**7** are given in Table 1. The general procedure for carbon-13 data acquisition and initial interpretation involved determination of (*a*) the noise decoupled carbon-13 spectrum, (*b*) the single frequency off-resonance decoupled spectrum, and (*c*) the modulated off-resonance spectrum (13). Such a sequence is shown for lycoctonal (**7**) in Fig. 2. The multiplicities generated in (*b*) enable distinction between methyl (quartet), methylene (triplet), and methine (doublet) resonances, while technique (*c*), which effectively results in irradiation of only long-range proton couplings, enables distinction of the quaternary carbon centers as shown in Fig. 2. Having established the degree of substitution for the individual carbon resonances, assignments were made on the basis of chemical shifts calculated using additivity relationships (1–5, 8) and confirmed where possible by comparing the effects of specific structural changes (14). Considerable use was made of correlation diagrams, which summarize the chemical shift data, as shown in Figs. 3 and 4.

Figures 3 and 4 show that carbon-13 shifts for the *Delphinium* alkaloids downfield of 50 p.p.m. are, in general, hetero-atom substituted, while those upfield are not. Groups such as methyl (27 p.p.m.) (5), methoxyl (56–61 p.p.m.) (15), the methyl in *N*-ethyl (*ca.* 14 p.p.m.) (16), and the carbonyl (203.6 p.p.m.) (17) in lycoctonal (**7**) are easily assigned, being distinguished by their off-

resonance spectra and characteristic shifts. The methoxyl groups C-16′ and -18′ in isolatizidine (**5**) are the only ones common in position to those in browniine (**4**), and C-16′ is common throughout the series **1**–**7**. The narrow range (±0.2 p.p.m.) of chemical shifts exhibited by the methoxyl carbons at 56.3 p.p.m. in **1**–**7** suggests assignment to C-16′. Consequently the resonance at 59.3 ± 0.1 p.p.m. in **4** and **5** may be assigned to C-18′ (see Fig. 3). It seems probable that the resonance at 58.2 ± 0.2 p.p.m. in **1**, **2**, and **3** is due to C-14′ since this is the only carbon which differs substantially in position and shift from those in **4** and **5**. It is not possible to distinguish between the shifts for the remaining methoxyl carbons C-1′ and -6′, based on our present data.

The carbon-13 shifts for the lycoctonine skeleton are conveniently considered as follows in terms of the degree of substitution.

(a) Quaternary Carbons

These resonances are designated *q* in Figs. 3 and 4. Oxygen substitution at C-7 and -8 in lycoctonine (**1**) and C-13 in delphonine (**6**) differentiates these carbons from C-4 and -11. In isolatizidine (**5**) the C-6 and -7 oxygen functions are removed resulting in the expected upfield shifts (48.3 and 46.4 p.p.m., respectively) (15, 18), compared to **1**. The quaternary resonance at 88.3 p.p.m. in **1** is thus assigned to C-7. Figure 4 shows that the resonance at 38.6 p.p.m. may be assigned to C-4 in lycoctonine (**1**), since it is

shifted upfield (4.5 p.p.m.) as expected (15) in deoxylycoctonine (**2**) and downfield (9.9 p.p.m., see Discussion) in lycoctonal (**7**). Further, there is no resonance attributable to a quaternary carbon in the region 30–45 p.p.m. in the spectrum of deoxymethylenelycoctonine (**3**) and all other quaternary shifts remain in the same relative positions in **1**, **2**, **3** and **7**. Since the structural features at the quaternary center C-11 are similar in all the bases the resonance at 49.2 ± 0.8 p.p.m. is assigned to this carbon. However, appreciable shifts are expected at C-8, in particular, in **5** compared with **4**, but are not observed (77.8 ± 1 p.p.m.).[3] In delphonine (**6**) an obvious new quaternary resonance is observed at 72.8 p.p.m. and is, therefore, assigned to C-13 in this molecule.

(b) Methine Carbons

The upfield shift (48.3 p.p.m.) at C-6 in **5**, compared to **4**, establishes this as the lowest field *methine* resonance in the bases **1**, **2**, **3**, **4**, and **7**. An upfield shift of similar magnitude is expected at C-13 in **5**, compared to **6**. The highest field methine resonance in **5** (40.5 p.p.m.) corresponds to an α-hydroxyl substituent shift of *only* 32.3 p.p.m. However, this resonance and similar high field methine resonances in **1**, **2**, **3**, **4**, and **7** are assigned to C-13, though in **3** this resonance is not distinguished from that due to C-4. Methoxyl and hydroxyl substituent effects (15) are important in assigning the resonances due to C-1, -14, and -16 (Fig. 3). The resonance at 78.4 p.p.m. in **4** is assigned to C-14, since methoxyl replaces hydroxyl at this site in **1**. Similarly, the resonance at 72.5 p.p.m. in **5** is assigned to C-1. The most reasonable assignment for the carbons C-1 and -14 in **1** is, therefore, 83.0 and 84.3 p.p.m., respectively.[4] A β-methoxyl effect is expected at C-7 in **6**, compared to **5**, but assignment in this case is ambiguous. The remaining low-field methine resonance (84.3 p.p.m.) in **1** is assigned to C-16, since this is a methoxylated carbon. The order of the shifts for C-14 and -16 in the other bases is not established but that given is based on the shifts at C-14 in **4** and **5**. The predicted (68 p.p.m.) and observed (64.9 p.p.m.) shifts for C-17 in **1** are in reasonable agreement. This carbon is structurally similar in all the bases as verified by the small variation in shift (65.1 ± 1.4 p.p.m.) throughout this series. The remaining methine carbons C-5, -9, and -10 are not easily distinguished, and the assignments given in Table 1, and in Figs. 3 and 4 are only tentative. It is expected that a change in the substituent at C-4 in **1**, **2**, **3**, and **7** will induce a β-effect at C-5. Indeed an upfield shift (6.2 p.p.m.) is observed in the lower field resonance of this group in **3** on removal of the methyl substituent at C-4 in **2** (Fig. 4). However, the effects of other substituents in **1** and **7** are not clear. This group of resonances all move upfield on removal of the methoxyl group at C-6 in **5**, compared to **4** (Fig. 3), thus negating the opportunity to confirm the C-5 assignment on this basis. The effects observed on protonation of the nitrogen might assist in these assignments (see later). The possibility of cross-over effects for these nuclei is not excluded.

(c) Methylene Carbons

The C-18 methylene carbon resonance in lycoctonine (**1**) (67.4 p.p.m.) is assigned on the basis of the methoxyl–hydroxyl substituent effect between **1** and **4** (Fig. 3) and on the observation that it is this resonance which disappears in the spectrum of **3** and is a carbonyl carbon in **7**. The remaining methylene carbons may be considered as the *N*-alkyl type, C-19 and N—CH_2—, which are predicted to resonate at 50–55 p.p.m. (1), and the cycloalkane type, C-2, -3, -12, and -15, predicted over the range 25–35 p.p.m. (5). In the spectrum of **1** the methylene resonances at 53.5 and 51.2 p.p.m. may be tentatively assigned to the *N*-alkyl type and those at 25.8, 29.0, 31.2, and 33.8 p.p.m. to the cycloalkane type. The relief of steric interaction at C-19 on removal of the hydroxyl group at C-18′ in **2**, compared to **1**, or the methoxyl group at C-6 in **5**, compared to **4**, produces a downfield shift in the lower field resonance of the pair assigned to the *N*-alkyl type. In delphonine (**6**) an *N*-methyl group replaces the *N*-ethyl group of all other bases and the higher field line of the *N*-alkyl pair shifts upfield to 42.5 p.p.m. The carbon C-19 is thus assigned at lower field than the *N*-methylene in the bases **1**, **2**, **3**, **5**, and **7**. This order may be reversed in **4** since the methoxyl group C-18′ will

[3]In an incomplete study of the alkaloid delphinine, in which C-8 is substituted by an acetoxyl group, a downfield shift (8.2 p.p.m.) is noted (see ref. 9). This observation serves to emphasize the correctness of the C-8 assignment.

[4]Replacement of a methyl group by hydrogen is expected to give rise to an upfield shift of 4.8 p.p.m. (15). Using the assignment given, the shift at C-1 is 9.7 p.m., which is considered more reasonable than the alternative 11.8 p.p.m. if these assignments were reversed.

For personal use only.

effectively shield the C-19 carbon in this molecule. For C-2, -3, -12, and -15 the tentatively assigned order relies on the following observations: a β-methyl effect (7.7 p.p.m.) (5) in **2**, compared to **3**. The resonances at 33.5 p.p.m. in **2** and 29.6 p.p.m. in **3** are, therefore, assigned to C-3. By analogy with **2** it is suggested that C-3 is the lowest field carbon of this group in all other bases. In isolatizidine (**5**) an upfield shift is expected and observed at C-2, since the C-1 methoxyl group in **4** is replaced by hydroxyl. However, C-3 also shifts upfield. The higher field pair of resonances in this group are assigned to C-12 and -15. Hydroxyl substitution at C-13 in **6** produces the expected β-effect (8.0 p.p.m.) (15, 16) at C-12 if the resonances at 35.0 and 27.0 p.p.m. are assigned to this carbon in **6** and **5**, respectively. The resonance due to C-15 remains relatively unperturbed (25.8 ± 1 p.p.m.) throughout these structural changes as might be anticipated.

The chemical shifts of the hydrochloride and perchlorate salts of the bases **1**–**6** are given relative to the corresponding free base in Table 2. The consistencies in these difference shifts serve to emphasize the correctness of the assignments. However, the protonation additivity parameters (1) were not applied without reservation in these cases.

In summary, the assignments for the diterpenoid alkaloids studied are given in Figs. 3 and 4.

Discussion

Attention is first drawn to the similar pattern of carbon-13 shifts exhibited by the series of lycoctonine-alkaloids studied. This pattern has made possible self-consistent and reasonably unambiguous assignment of nearly all the resonances for these compounds. A particularly important feature is the constant pattern of shifts exhibited by the quaternary carbons except in cases where major structural or substitution changes occur (*e.g.* at C-13 in **6**). This latter pattern is considered a most valuable "fingerprint" for determining the degree of, in particular, oxygen substitution in these molecules as indicated by the spectra of **5** and **6**, compared with the other bases.

The changes in the carbon-13 shifts on introduction of a substituent are indicated in Figs. 3 and 4. In most cases the effects are of the correct order but in several instances their magnitudes differ from those expected on the basis of previous reports on simpler systems. Thus, removal of the oxygenated function at C-6 and -7 in **5**, compared to **4**, is expected to produce an upfield shift of 58–60 p.p.m., since both these carbons are subject to α (48.5 p.p.m.) and β (10 p.p.m.) oxygen group substituent effects (15, 18). However, these effects are substantially attenuated (48.3 and 46.4 p.p.m.), perhaps the consequence of possible steric contributions in the compact ring structure. A similarly attenuated α-hydroxyl effect is noted at C-13 in **6** (32.3 p.p.m.). In contrast, the parameters for replacement of hydroxyl by methoxyl (or *vice versa*) are large compared with the literature values (4.8 p.p.m.) (15). Thus at C-1 in **4**, compared to **5**, at C-14 in **4**, compared to **1**, and at C-18 in **4**, compared to **1**, shifts of 9.7, 5.9, and 8.1 p.p.m. are observed, respectively. An average hydroxyl–methoxyl parameter of 8 p.p.m. is suggested in these systems.

The effect of methyl substitution at C-4 in **2**, compared to **3**, represents a typical *gem*-dimethyl effect (upfield, 2.9 p.p.m.) (5) and further justifies consideration of methylene groups as methyl substituents when dealing with additivity effects (19). On the other hand the downfield shift (9.9 p.p.m.) at C-4 in **7**, compared to **1**, resulting from substitution of an aldehyde function, is surprisingly small. This shift, however, appears to be one of very few determined for saturated carbon atoms (20), especially for one so highly substituted.[5] The limited reports (20) for this parameter for a saturated carbon center give a downfield shift of 31 p.p.m., on average, while in vinyl (21) and aromatic (22) aldehydes this parameter is nearer 10 p.p.m.

Steric contributions to the carbon-13 shifts in these alkaloids are particularly evidenced in the observed shifts at C-6. In **3**, compared to **2**, the downfield shift (3 p.p.m.) at C-6 is attributed to removal of the methyl group at C-4 which provides a steric contribution at C-6 in **2**. Resubstitution at C-4 with the bulkier aldehyde group in **7** results in C-6 shifting back upfield (2.5 p.p.m.) with a concomitant effect in the methoxyl region, presumably at C-6′.

[5]NOTE ADDED IN PROOF: In recent studies on substituted aldehydes, we observe the effect of branching rapidly attenuates the aldehyde substituent parameter. *E.g.*, in cyclohexanealdehyde a value of 12.9 p.p.m. is observed at C-α (C. P. Beeman. Private communication).

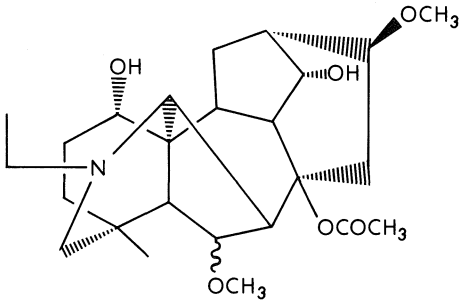
With the modifications in substituent parameters and the substantial steric contributions in these molecules in mind, it seems reasonable that some of the observed shifts (*e.g.*, C-19 in **1**, **2**, and **3** or C-8 in **1**, **4**, **5**, and **6**) might be considered unusual. The general pattern of shifts exhibited by these systems does, however, enable self-consistent assignment of most of the carbon resonances in the bases.

As indicated by the difference shifts given in Table 2 there is an apparent breakdown in the additivity effects arising from protonation of the nitrogen in these alkaloids. This may be attributable to concentration or often solvent variations (23) necessary in the present study. This observation taken in conjunction with the minor ambiguities in assignment precludes detailed discussion of protonation additivity effects. However, several of the general trends observed in simple methyl-piperidines and 4-piperidones (1), in particular at sites β or γ to the nitrogen atom are reproduced. Most unusual are the large upfield shifts (*ca.* 5 p.p.m.) at the carbon atoms δ to the nitrogen, for example at C-12 and -15. These carbon atoms have the common feature that they lie in a plane, approximately 4 Å away from the nitrogen center. The carbon C-9 is similarly located with respect to the nitrogen. A comparable upfield shift (*ca.* 5 p.p.m.) is observed in the resonance at about 50 p.p.m. previously assigned to C-5, -9 or -10 in the bases. It is tempting, therefore, to assign this line to C-9. We can only speculate about the possible factors contributing to the δ-shift and presently only report the observation. In general, the shifts observed on protonation of the nitrogen exhibit reasonably close trends for each of the compounds studied and may be considered valuable in assisting with spectral assignments.

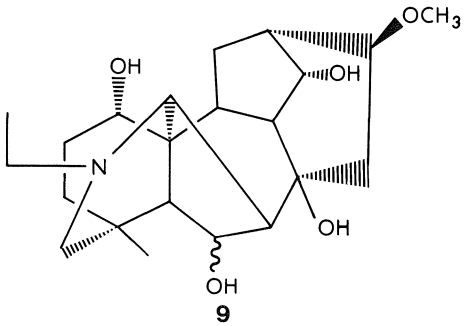
Application

We have isolated small amounts of two apparently hitherto unknown alkaloids, **A** and **B** from *Delphinium bicolor* Nutt, for which we propose the structures **8** and **9** on the basis of the following evidence.

The base A, $[\alpha]_D^{24}$ +10° ($CHCl_3$), which was not obtained crystalline, although it yielded a hydroiodide salt m.p. > 240° (methanol–ether), had composition $C_{25}H_{39}NO_6$ (M^+ calcd. 449.2777, found 449.2797 a.m.u.). The p.m.r. spectrum indicated the presence of the following groups (δ from TMS in deuterochloroform): a tertiary methyl (1.04 p.p.m.), an *N*-ethyl (CH_3 at



8



9

1.09 p.p.m., J = 7 Hz), an acetoxyl (2.10 p.p.m.), two methoxyls (3.18 and 3.46 p.p.m.), and approximately two hydroxyls (6.90 p.p.m., disappearing on addition of D_2O). I.r. absorptions at 3500, 3150, 1735, and 1238 cm^{-1} also indicated the presence of hydroxyl and acetate functions. The base **B**, m.p. 190–191°, $[\alpha]_D^{24}$ +16° ($CHCl_3$), was similarly shown to have the composition $C_{22}H_{35}NO_5$ (M^+ calcd. 393.2515, found 393.2523 a.m.u.), and to contain a tertiary methyl, an *N*-ethyl, a methoxyl, and hydroxyl groups. Given the nature of the *Delphinium* alkaloids (10), these data suggest that **A** and **B** have the lycoctonine C_{19}-skeleton shown in Fig. 1. A prominent ion in the mass spectra of **A** and **B** at *m/e* M − 17 is typical for loss of a hydroxyl group from C-1 (24). This and the observed i.r. absorptions at 3150 cm^{-1} in both bases characterize the α-hydrogen bonded configuration for this hydroxyl group (25). Pyrolysis of the base **A** in glycerol, monitored by p.m.r., indicated the generation of acetic acid, consistent with the location of the acetoxyl group at C-8 in **8** (26).

Carbon-13 chemical shifts for the bases **A** and **B** and their hydrochlorides are given in Table 3. The correlation diagram, Fig. 5, compares the carbon-13 shifts in **A** and **B** with those in deoxylycoctonine (**2**) and isolatizidine (**5**). Clearly

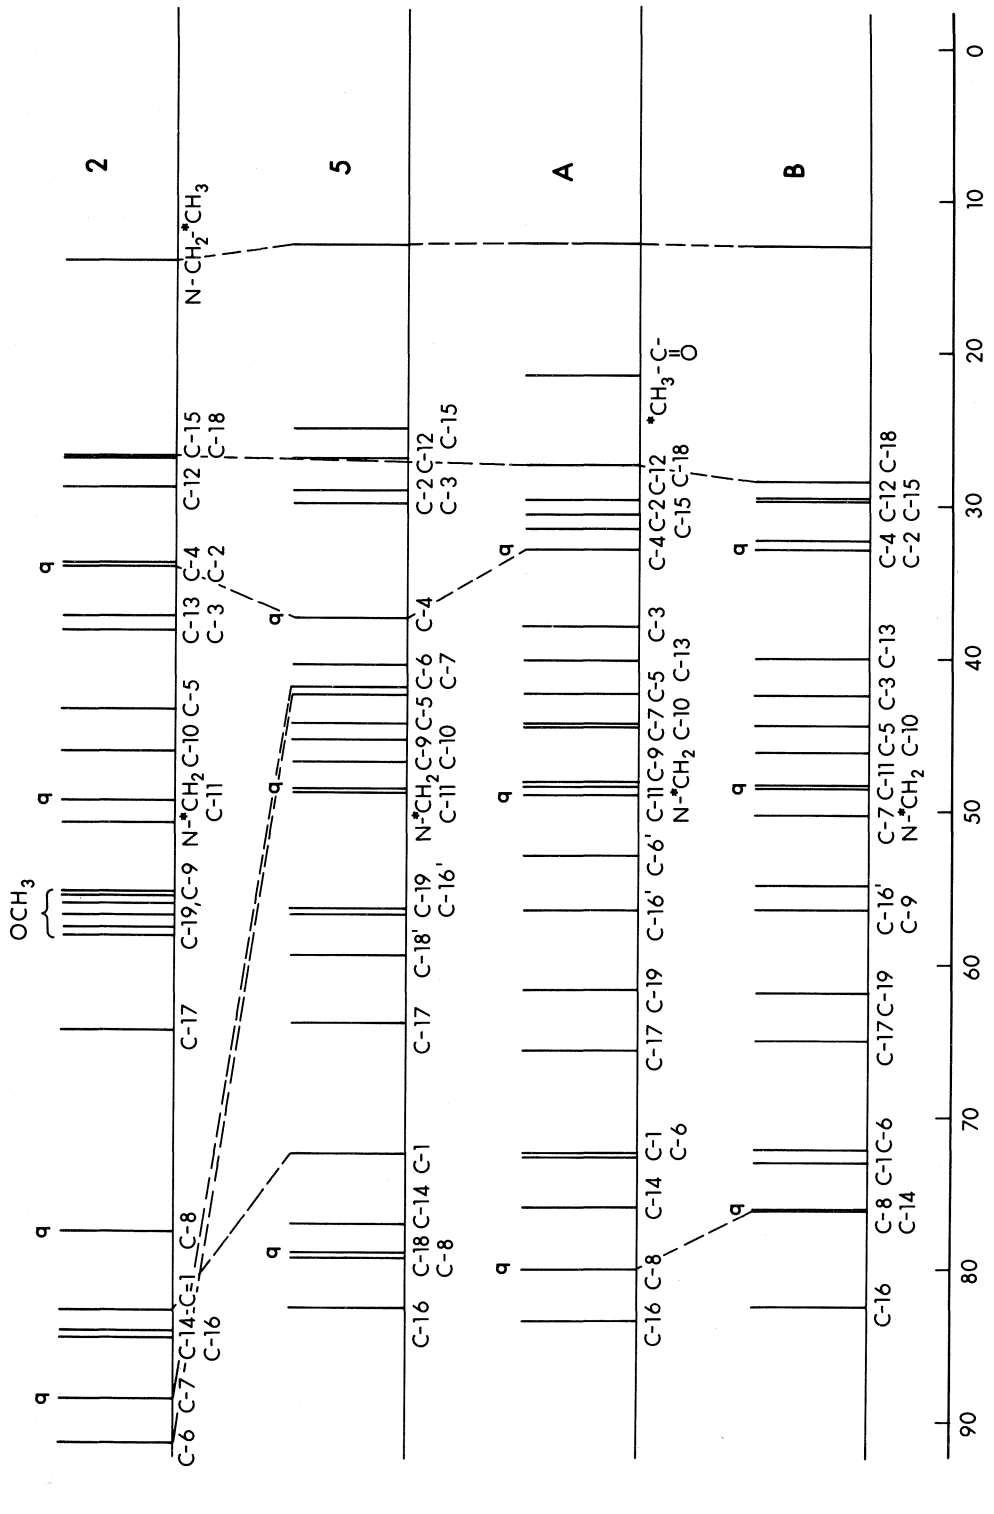

FIG. 5. Carbon-13 chemical shift correlations showing assignments in the diterpenoid alkaloids deoxylycoctonine (**2**), isolatizidine (**5**), and the unknown alkaloids **A** and **B**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

there is a close resemblance between the chemical shifts in **A** and **B** and those of the lycoctonine alkaloids. The typical chemical shifts and off-resonance results make it easy to recognize the presence of an acetoxyl group in **A** (171 and 21.6 p.p.m.), an *N*-ethyl group (methyl at 13 p.p.m.), and a C-18 methyl group (27.4 p.p.m.) in **A** and **B**, and two and one methoxyl groups in **A** and **B**, respectively. The characteristic C-16 and -16′ shifts (84.3 and 56.3 p.p.m.) enable assignment of a methoxyl group in **A** and **B** to C-16. In addition, the shift at C-4 (32.9 p.p.m.) in **A** and **B** is identical to that in **2** for the methyl substituted quaternary center. Methyl substitution at C-4 in **A** and **B** is also reflected in the shift at C-3 (37.8 and 42.4 p.p.m.) which compares favorably with that in **2** (37.4 p.p.m.).

Most noticeable is the similarity of the shifts in **A** and **B** with those in **5**, in particular, the absence of a low-field quaternary resonance. Thus C-7 must be unsubstituted in **A** and **B**. The methine signals which can be assigned to C-7 in **A** and **B** are all downfield of that in **5** indicating a substituent at C-6 (β-effect). The quaternary carbon C-8 in **A** is similar in shift to that in **5**, a feature perhaps surprising in view of the established acetoxyl group at this site in **A**. However, the upfield shift at C-8 observed in **B** is taken as indicative of replacement of the acetoxyl group in **A** by a hydroxyl group in **B**. The pattern of shifts between 70 and 85 p.p.m. in **A**, **B**, and **5** is remarkably similar. It seems reasonable to assign the methine resonances at 72.6 and 73.0 p.p.m. in **A** and **B**, respectively, to C-1 by comparison with **5** (72.5 p.p.m.), thus confirming (see mass-spectral evidence) hydroxyl substitution at this site in **A** and **B**. Similarly the shifts at 75.9 and 76.1 p.p.m. are attributed to C-14 in **A** and **B**, respectively, by comparison with **5** (*ca.* 77 p.p.m.). Thus, hydroxyl substitution at C-14 in **A** and **B** is indicated. The remaining resonances in this region 72.3 p.p.m. in **A** and 72.1 p.p.m. in **B** are attributed to C-6 since oxygen substitution is indicated at this site by the β-effects noted at C-7 and further, there are no resonances attributable to C-6 at 42 p.p.m. as in **5**. Of the remaining oxygen functions we must assign a methoxyl substituent at C-6 in **A** and hydroxyl in **B**. The possibility that the methoxyl group in **A** be assigned to C-14 is not excluded but seems unlikely in view of the methoxyl–hydroxyl effect noted at this site between **1** and **4**. However, the absence of a significant shift at C-6 between **A** and **B** is not easily reconciled.

The overriding feature which adds credence to the above assignments is the similarity in the general pattern of shifts in **A** and **B** with the model systems **1**–**7**. In effect it is this pattern which is of critical importance in ruling out substitution, particularly by oxygen, at the alternative sites available in these systems. The evidence is, therefore, compatible with the structures **8** and **9** for the bases **A** and **B**, respectively. The base **9** is the desmethyl desacetate of the base **8**. These structures are closely related to those of chasmanine and neoline systems (10), and are additions to this still poorly represented group of C_{19}-diterpenoid alkaloids with the lycoctonine skeleton *unoxygenated at C-18*.

Conclusions

We conclude that fundamental substituent and additivity data (1–8, 15, 16, 18) can be usefully applied to assignment considerations in the relatively complex diterpenoid alkaloids. Some of the parameters must be modified, in particular, in magnitude in order to meet the demands set by these more complex systems. The general pattern of carbon-13 shifts in the diterpenoid alkaloids, in particular, of the quaternary carbons can be of critical importance in structural determinations in this class of compounds.

The Interactions of Four Carbamate Pesticides with Electron-acceptor Reagents[1,2]

JAMES DANIEL MACNEIL[3] AND ROLAND WALTER FREI[4]

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

AND

OTTO HUTZINGER

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received May 23, 1972

The interactions between several electron-acceptor reagents and some pesticides having donor properties were investigated in solution and on cellulose thin-layers by spectrophotometric methods. In solution, formation constants and extinction coefficients were evaluated from absorbance measurements for complexes of the pesticides carbaryl, IPC, CIPC, and swep with the electron-acceptor reagent 9-dicyanomethylene-2,4,7-trinitrofluorene, using the Benesi–Hildebrand method. Values were also calculated for the carbaryl-mellitic trianhydride complex. Extinction coefficients ε_λ^{AD} for the complexes were less than 1000, while formation constants were 1–4 l mol^{-1}.

Reflectance spectroscopic measurements showed similar relationships between absorption maxima and intensities of the complexes and the donor properties of the pesticides to those observed in solution. A linear relationship between reflectance and the square root of concentration was found for all four pesticide–CNTNF complexes in the range from 5–50 μg.

Les interactions entre plusieurs réactifs accepteurs d'électrons et certains pesticides possèdant des propriétés de donneurs, ont été étudiées en solution et sur couche mince de cellulose par des méthodes spectrophotométriques. En solution, les constantes et les coefficients d'extinction ont été évalués à partir des mesures d'absorbance pour les complexes entre les pesticides carbaryle, IPC, CIPC, et "swep" le réactif électroaccepteur dicyanométhylène-9 trinitro-2,4,7 fluorène, selon la méthode de Benesi–Hildebrand. Des mesures ont été également faites pour le complexe carbaryle-trianhydride melittique. Les coefficients d'extinction ε_λ^{AD} pour ces complexes sont inférieurs à 1000, les constantes de formation sont de l'ordre de 1–4 1/mol.

Les mesures de reflexion spectroscopique donnent des relations semblables entre les maxima d'absorption, les intensités des complexes et les propriétés de donneur des pesticides, à celles observées en solution. Une relation linéaire entre la réflexion et la racine carré de la concentration a été trouvée pour tous les quatre complexes pesticides CNTNF, dans l'intervalle de 5–50 μg.

Introduction

The formation of colored π-complexes between pesticides and electron-acceptor (or donor) reagents on thin-layer chromatograms has previously been discussed (1, 2), but no attempt was made to determine formation constants of these complexes. A study of this aspect of the complex formation was undertaken in view of the part complexation is believed to play in the activity of various pesticides (3). Complexes of DDT and related compounds with tetracyanoethylene and nerve axon in solution, for example, have recently been reported (4).

There are several approaches to the determination of complexing constants, and various methods which may be applied to solution measurements have been discussed in a recent book by Foster (5). While there are objections to calculations utilizing u.v.–visible spectra (5), several considerations led us to choose this approach. Some data on the reflectance spectra of pesticide complexes *in situ* on thin-layer chromatograms had previously been obtained (2) and the comparison of spectra in solution with those in the adsorbed state was of interest. Secondly, only a measure of the relative strengths of complex formation was of interest for the purposes of this study and this appeared to be available using the Benesi–Hildebrand method (5).

The quantitative determination of pesticide–acceptor π-complexes *in situ* on thin-layer chromatograms has previously been described (6, 7). It was shown that a linear relationship existed between the peak area of the complex in the reflectance scan and the concentration of the complexed pesticide over the range studied. Further studies over a larger concentration range to determine if the complexes followed the Kubelka–Munk relationships of diffuse reflectance spectroscopy or other relationships found for chromatographed species (8) were therefore indicated. It was also of interest to compare the intensity and wavelength shifts of the complex absorption bands measured in solution with those observed in the adsorbed state.

Experimental

Reagents

Analytical grade samples of the following pesticides were used in this study: carbaryl, 1-naphthyl-*N*-methylcarbamate (Union Carbide); CIPC, isopropyl *m*-chlorocarbanilate (Standard Chem); IPC, isopropyl carbanilate, (PPG Industries); swep, methyl 3,4-dichlorocarbanilate (Niagara Chem).

The following electron-acceptor reagents were used: 1,3,5-trinitrobenzene (TNB); 2,4,7-trinitro-9-fluorenone (TNF); 2,4,5,7-tetranitro-9-fluorenone (TeTNF); 9-dicyanomethylene-2,4,7-trinitrofluorene (CNTNF); 9-dicyanomethylene-2,4,5,7-tetranitrofluorene (CNTeTNF); tetracyanoethylene (TCNE); mellitic trianhydride. Sources of these compounds have been listed previously (1).

Instrumentation

Absorbance spectra were measured in solution with a Beckman DK-2A spectrophotometer using a tungsten lamp as a source and photomultipliers as detectors. Standard Beckman Pyrex cells (320–2500 nm) were used.

Reflectance spectra were recorded on a Bausch and Lomb Spectronic 505 with diffuse reflectance attachment.

Preparation of Samples

For measurements in solution, a 10^{-3} *M* solution of the complexing agent was first prepared. Samples of pesticide were weighed out and dissolved in this solution at pesticide concentrations of 0.1–0.25 *M*. Solutions (10^{-2} *M*) of the pesticides alone were also prepared, as well as solutions of carbaryl (10^{-2} *M*) in various acceptors (10^{-3} *M*).

For the reflectance measurements, solutions of the complexed pesticides carbaryl, IPC, CIPC, and swep (5 mg/ml) were prepared by dissolving weighed samples of the pesticides in a solution of the complexing agent CNTNF (5 mg/ml). The solutions were then spotted on squares (2 in. × 2 in.) cut from Eastman Chromagram sheets (cellulose, 6064, without fluorescent indicator) using Drummond microliter pipettes (Kensington Scientific Co.) of 1, 2, 3, 5, and 10 μl volumes to produce pesticide concentrations of 5, 10, 15, 25, and 50 μg/spot.

Acetone was used as solvent for all solutions.

Measurement of Spectra

In solution. absorbance spectra were measured in the double-beam mode using as reference the 10^{-3} *M* acceptor solution from 330–700 nm. The spectra of the pesticides and complexing agents were also measured individually using acetone (the solvent) as reference. Spectra were measured immediately after preparation of the samples and again after 24 h to assure that no significant variations had occurred. Both sets of data were plotted and the results were averaged.

The reflectance spectra of 50 μg samples of the four pesticide CNTNF complexes and of CNTNF (50 μg) were measured *vs.* a blank cellulose reference and the complexes were then measured against the CNTNF as reference from 400–700 nm. Dilution series of the four pesticide complexes and of the complexing agent were also measured *vs.* a blank cellulose reference from 400–700 nm. The samples were backed with white cardboard during the reflectance measurements to approximate an infinite layer thickness (8).

Results and Discussion

Measurements in Solution

The pesticide complexes in solution showed the typical broad, weak bands of π-complexes (see Fig. 1). Spectral maxima of the pesticide carbaryl with a number of acceptors are listed in Table 1. The complexes shown in Fig. 1 had a single broad absorption band and the intensities of these bands were much less than those measured in the u.v. region for the pesticides and complexing agents. Neither the pesticides nor the complexing agents showed absorption maxima in the region of the complex absorption bands.

Measurements for a series of solutions of complexing agent (at a fixed concentration) with increasing pesticide concentration produced a series of spectra such as those shown in Fig. 2 for the carbaryl–CNTNF complexes. A plot of $[A]_0/A$ *vs.* $1/[D]_0$, where $[A]_0$ and $[D]_0$ are the initial concentrations of acceptor and donor

TABLE 1. Spectral maxima of carbaryl complexes with various acceptors. [Carbaryl] = 10^{-2} M; [acceptor] = 10^{-3} M

Acceptor	λ_{max} of complex (nm)
1,3,5-Trinitrobenzene	370
2,4,5,7-Tetranitro-9-fluorenone	397
2,4,7-Trinitro-9-fluorenone	405
Mellitic Trianhydride	420
9-Dicyanomethylene-2,4,7-trinitrofluorene	475

TABLE 2. Complexing constants from Benesi–Hildebrand plots for selected pesticide–acceptor complexes in solution

Complex	λ_{max} (nm)	ε^{AD}	K_C^{AD}	$\varepsilon^{AD} \cdot K_C^{AD}$
Carbaryl–mellitic trianhydride	420	111	1.80	200
Carbaryl–CNTNF	475	613	3.89	2386
IPC–CNTNF	470	583	1.75	1020
CIPC–CNTNF	450	885	1.12	991
Swep–CNTNF	444	200	2.63	526

(pesticide), respectively, and A is the absorbance of the complex at the wavelength of measurement, was then made for each set of dilution series to calculate the complexing constants. A sample Benesi–Hildebrand plot for the carbaryl–CNTNF complex is given in Fig. 3. Extinction coefficients, ε_λ^{AD}, and formation constants, K_C^{AD}, for the complexes calculated at the wavelength of maximum absorption, λ, are presented in Table 2.

The Benesi–Hildebrand plots obtained in these experiments were linear, and previous workers have taken this as indicative of a simple 1:1 stoichiometry in the complex (9–13). Johnson and Bowen (14) have shown that this is not necessarily so, although the linearity of the plots may be taken as an indication of predominantly a stable 1:1 complex. More recently, this conclusion has been disputed by Deranleau (15), who has discussed the difficulty of determining stoichiometrics of π-complexes from spectroscopic studies. Several solid complexes prepared in a preliminary study of the use of electron-acceptors as chromatographic spray reagents were found by analysis to have 1:1 stoichiometry

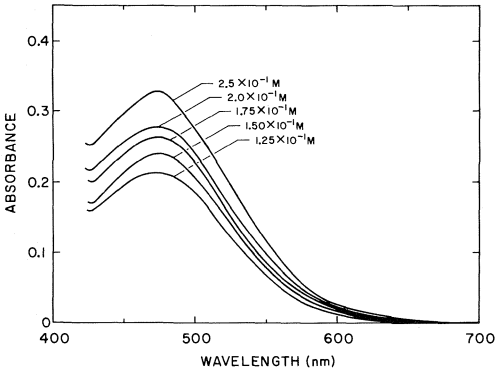

FIG. 2. Solution spectra for dilution series of carbaryl (0.125–0.25 M) – CNTNF (10^{-3} M) complexes measured *vs.* CNTNF (10^{-3} M).

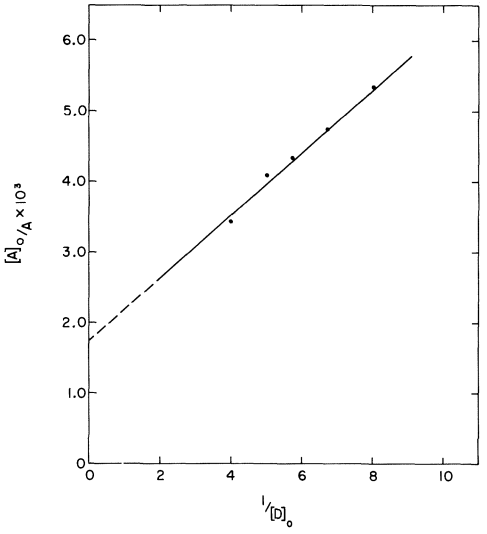

FIG. 3. Benesi–Hildebrand plot for carbaryl–CNTNF complex. $[A]_0$, initial concentration of CNTNF; $[D]_0$, initial concentration of carbaryl; A, absorbance of complex.

(16). Thus, while no analyses have been carried out in this case, there seem to be reasonable grounds to assume that the predominant species both in solution and on the chromatographic thin-layers are 1:1 complexes.

No clear pattern is evident from the extinction coefficients, ε_λ^{AD}, or the complex formation constants, K_C^{AD}. However, the product $\varepsilon_\lambda^{AD} \cdot K_C^{AD}$, which is determined directly from the slope of the Benesi–Hildebrand plot, shows a very definite trend. The four pesticides measured with CNTNF should vary in their abilities to act as donors. As the π-bonding is between the aromatic ring systems in these pesticide complexes (1), the substituent effects are quite important. Thus, while carbaryl might be expected to be the strongest π-donor in the test group due to its enlarged π-system, the relative abilities of the carbamate groups bonded to the ring either through oxygen (carbaryl) or nitrogen (IPC, CIPC, swep) to release electrons into the ring must also be considered. Furthermore, the increasing chlorine content in the series IPC, CIPC, swep should decrease their donor abilities.

The product $\varepsilon_\lambda^{AD} \cdot K_C^{AD}$ seems to follow this general trend. The small difference in the values obtained for IPC and CIPC is not surprising, as the chlorine substituent exhibits a positive resonance effect and a negative inductive effect, and thus should not appreciably alter the π-density of the aromatic system. Two chlorines, however, might be expected to exhibit a more noticeable effect. This seems to be reflected in the results. A similar trend appears in the position of the absorption maximum and the intensity of the bands, as shown in Fig. 1. Secondly, a comparison of results for the carbaryl-CNTNF and carbaryl-mellitic trianhydride complexes shows mellitic trianhydride to be the weaker of these two complexing agents.

Measurements on Cellulose

Equal weights of donor and acceptor were used in preparing these complexes to provide an approximately two-fold excess of donor over acceptor and thereby to force the complexation of the acceptor. Measured against a blank cellulose reference, the reflectance spectra of the complexes appeared as shoulders on the strong u.v.-absorption of the complexing agent CNTNF which extends slightly into the visible region of the spectrum. However, when measured against a CNTNF reference, the reflectance spectra of the complexes become more apparent, as shown in Fig. 4.

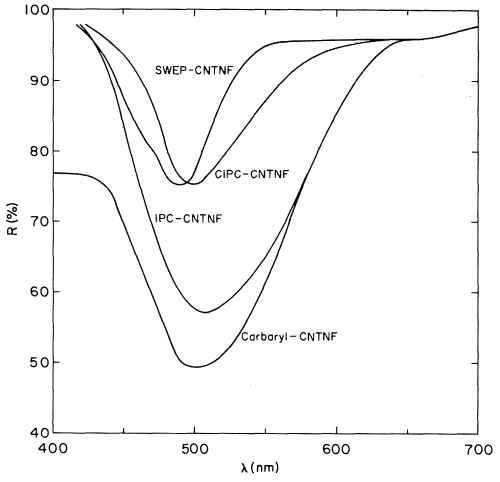

FIG. 4. Reflectance spectra of pesticide–CNTNF complexes on cellulose measured *vs.* a CNTNF reference (on cellulose).

Carbaryl and IPC–CNTNF complexes both show maximum absorption at ~505 nm, with the carbaryl complex being the more intense of the two. The CIPC and swep-CNTNF complexes have similar intensities, but show absorption maxima at ~495 and ~490 nm, respectively. The relative positions of the absorption maxima and the intensities of the bands show similar relationships to those observed in solution for these complexes. Spectral maxima are commonly observed at higher wavelengths in the adsorbed state than those measured for the same species in solution (8).

Plots of reflectance *vs.* concentration (analogous to the peak area *vs.* concentration plots (6, 7)) did not reveal a linear relationship over the larger concentration range (Fig. 5). Kubelka–Munk plots (8) show non-linearity at low concentrations. The failure of these results to satisfy the Kubelka–Munk theory may be attributed to too thin a layer to approximate an infinite layer thickness. However, a plot of reflectance versus the square root of concentration, which approximates the Kubelka–Munk functions and has been used previously in measurements on thin-layer chromatograms (8), was found to yield linear plots over the concentration range studied for all four complexed pesticides. This could thus possibly be used to extend the useful range of analysis (6, 7).

Conclusions

The interactions between some common pesticides and several electron-acceptor reagents resulting in π-complex formation studied in solution and on cellulose thin-layers were quite weak. Extinction coefficients measured in solution were less than 1000. Thus, detection limits for these complexes on thin-layer chromatograms are only about 1 μg, whereas metal–chelate complexes, which have much higher extinction coefficients, may be detected to 0.01 μg (8).

The Benesi–Hildebrand approach provides information as to the relative complexing abilities of various pesticides and could be of use in investigations where this type of information is desired, particularly in those cases where complexation may play a role in the pesticidal activity of the compound.

Complexation occurs more strongly in the adsorbed state on cellulose than in solution. The useful analytical range for the determination of complexed pesticides *in situ* on a thin-layer chromatogram by reflectance spectroscopy may be extended by plotting reflectance (or peak area) *vs.* the square root of concentration. The intensity, broadness, and position of the maxima of the complex absorption band in the absorbance (solution) and reflectance (adsorbed) spectra are related to the relative donor abilities of the pesticides studied.

R. W. F. wishes to thank the Canada Department of Agriculture for grants in support of this work.

J. D. M. is the recipient of a National Research Council of Canada postgraduate scholarship.

The authors thank Miss Marianne Häusler for her assistance in obtaining some of the spectral data.

The Preparation and Properties of Some Cyclic β-Diketone Diimines

KENNETH CHARLES MOSS AND FRANK PRICE ROBINSON
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received August 24, 1972

The condensation reaction between a series of aliphatic diamines and a series of five- and six-membered cyclic β-diketones to form Schiff bases was investigated. Mass spectral data show that reaction occurred on the side-chain carbonyl except where steric hindrance forced condensation to occur on the ring carbonyl. N.m.r. studies show that these Schiff bases exist primarily in the ketamine form in solution, irrespective of the solvent. I.r. data confirm this. The preparation of a number of Cu(II) and Ni(II) complexes from some of the ligands is also described.

La réaction de condensation entre une série de composés diaminés aliphatiques et une serie de β-dicétones cycliques à cinq ou six membres pour former les bases de Schiff a été étudiée. Les données obtenues à partir de spectres de masse indiquent que la réaction a lieu sur le groupe carbonyle de la chaîne latérale à l'exception des cas où des contraintes stériques forcent la condensation à se faire sur le groupe carbonyle du cycle. Des études r.m.n. montrent que ces bases de Schiff sont présentes principalement en solution sous la forme cétamine, quelque soit le solvant. Ce fait est d'ailleurs confirmé par des données obtenues en i.r. La préparation d'une série de complexes du Cu(II) et du NI(II) à partir de certains coordinats est aussi décrite. There is considerable interest in the field of metal chelate catalysis, *i.e.*, reactions which are modified by metal ions through chelate ring formation, as well as reactions of metal chelates themselves (1). It has also been established that some metal chelates can act as reversible oxygen carriers (2). Of particular interest to us are the formation and reactions of Schiff bases made by the condensation of β-diketones and diamines. Metal chelates of some such bases have been shown to undergo nonenzymatic transamination similar to that thought to occur in living systems (3). As a preliminary to an investigation of the tautomerization of metal complexes of simpler analogs, thought to be an important step in transamination, we have prepared a number of Schiff bases of β-diketones with saturated five- and six-membered rings. This study was undertaken in order to ascertain which carbonyl group of

$m = 0, 1$

condenses with the diamine and whether the course of the condensation might be altered by changing the nature of R. We also wished to determine the extent of keto–enol tautomerism (Scheme 1) which esists in solutions of these Schiff bases.

Previous workers (4, 5) have shown that in bases formed with β-diketones containing a methyl group adjacent to one carbonyl function and either CH_3, C_6H_5, CF_3, p-C_6H_4Br, or p-$C_6H_4OCH_3$ adjacent to the other carbonyl, the equilibrium lies well over to the ketamine form **3** (Scheme 1). Our work describes the preparation of 17 new bases and their structure in terms of their mass, n.m.r., and i.r. spectra. Some metal chelates were also prepared.

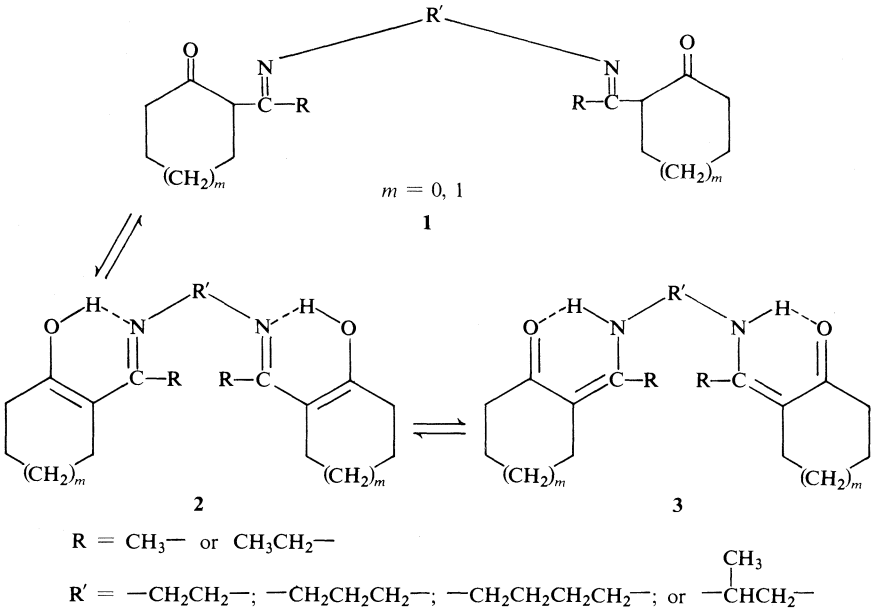
Results and Discussion

Preparation of Schiff Bases and Metal Chelates

The β-diketones required for preparation of the Schiff bases used in this study were synthesized by acylation of the morpholino enamines of cyclopentanone and cyclohexanone (6). Condensation of the β-diketones with the appropriate diamines afforded the Schiff bases. In a few cases, metal chelates were prepared by reacting the Schiff bases with Cu(II) or Ni(II) acetate.

Mass Spectra and Structure

The bases studied showed quite characteristic behavior upon electron impact. All of the ligands exhibited parent peaks and the base peaks were dependent upon the diamine used. When the original diamine was ethylenediamine, the base



SCHEME 1

peak was one-half the *m/e* of the molecular ion. When the original diamine was 1,3-propanediamine, the base peak was due to the ion still containing two of the three methylene groups of the diamine. With 1,2-propanediamine as precursor, fragmentation occurred at the point of branching to give the more stable secondary carbonium ion as the species responsible for the base peak. With 1,4-butanediamine, symmetrical cleavage of the molecular ion is followed by loss of the alkyl side-chain of the ketone and a hydrogen atom to give the species accounting for the base peak. With the exception of the ligand derived from 2-isobutyrylcyclohexanone, all of the compounds undergo further fragmentation to the ions of cyclopentanone or cyclohexanone. Fragmentation appears to occur as outlined in Scheme 2. The different fragmentation behavior of bis-2-isobutyrylcyclohexanoneethylenediimine is taken as strong evidence that condensation between the original diamine and β-diketone occurred on the ring carbonyl rather than the side-chain carbonyl group. This suggests that if R is sufficiently large, steric hindrance becomes more important than the inductive effect which normally facilitates side-chain carbonyl condensation. The evidence that side-chain carbonyl condensation has not occurred when R = *i*-Pr, is the almost complete absence of the usually intense, characteristic peaks at *m/e* 97 and 69. These peaks are intense in all cyclohexanone-derived ligands with R = Me or Et and are assigned to the ion of cyclohexanone and the species which results from loss of CO from that ion (7). The mass spectrum of bis-2-isobutyrylcyclohexanoneethylenediimine can be adequately rationalized by the fragmentation shown in Scheme 3.

Nuclear Magnetic Resonance Spectra and Structure

The n.m.r. studies suggest that all of the Schiff bases examined exist in solution in the form of chelated hydrogen-bonded tautomers **2** and **3** (Scheme 1). We found no evidence for substantial proportions of the keto form **1** even in acetone solution, *i.e.* no signal was detected for the methine proton at the ring junction in tautomer **1**.

The n.m.r. data are summarized in Table 1 and can be conveniently discussed by considering the Schiff bases according to the diamine used. The solvent used was $CDCl_3$, unless otherwise indicated.

(1) Schiff Bases with Ethylenediamine

In each case there was a broad signal in the region 0.50 to −1.50 τ ($w_{\frac{1}{2}} \sim 20$ Hz), which must be due to a hydrogen-bonded proton. This indicates that the base is primarily in the

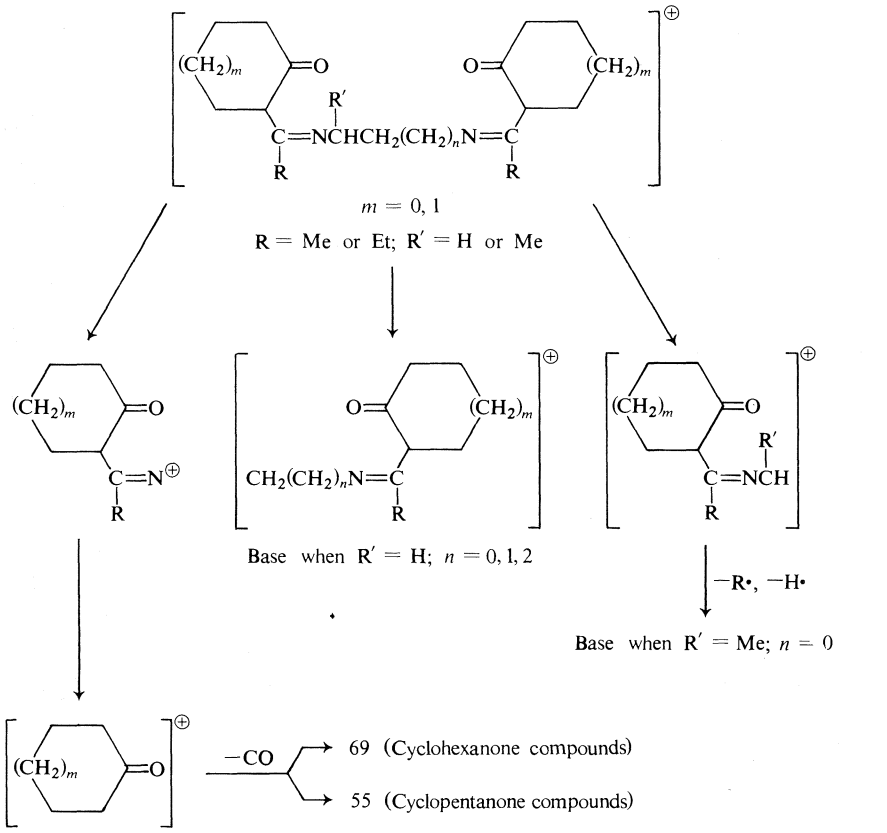
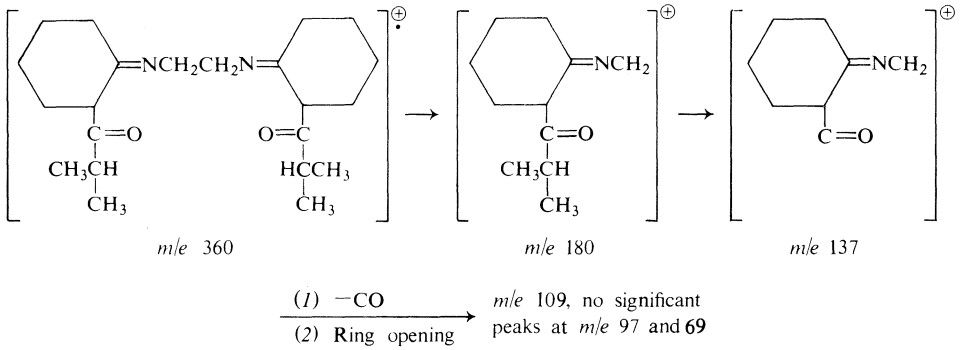


SCHEME 2



SCHEME 3

hydrogen-bonded form **2** or **3** (Scheme 1). The signal due to the methylene groups of ethylenediamine occur as a multiplet centered at about 6.6 τ. This multiplet consists of three lines of relative intensities approximately 2:1:2 and a splitting of 3.5 Hz. The unusual appearance of this multiplet must be due to coupling with the protons on the nitrogens of the diamine, an explanation used by Dudek and Holm in discussing bis-acetylacetoneethylenediimine (4). However, if the methylene groups are coupled to the proton on N, the spectrum should give a doublet. The presence of the center line probably indicates that there is more than one conformer, produced by rotation about the —C=N bond (4). The possibility that this central band is

caused by tautomer **1** (Scheme 1) may be discounted by the fact that changing the nature of the solvent has no effect on the shape of the spectrum, but merely shifts the signals. The spectra of bis-2-acetylcyclopentanoneethylenediimine and of the propionyl analog in acetone-d_6/D_2O show considerable modification of the diamine methylene groups and the disappearance of the N—H---O signal. The methylene signal still appears to be a triplet but the center peak is now more intense than the outside peaks and the multiplet is shifted upfield to about 7.5 τ, with a splitting of about 1 Hz. This confirms the assignments of the N—H---O proton and the diamine methylenes and adds weight to the suggestion that the center peak of the multiplet is due to different conformations.

The spectrum of bis-2-isobutyrylcyclohexanoneethylenediimine is basically very similar to the spectra of the other ethylenediamine bases although condensation is, in this case, on the ring and not the side-chain.

(2) Schiff Bases with 1,3-Propanediamine

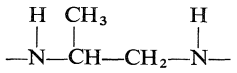
The N—H---O signals are found in the region −0.5 to −1.7 τ (with the exception of bis-2-propionylcyclopentanone-1,3-propanediimine which has an unusually high field signal). The signals for the diamine occur in two regions. The methylenes adjacent to the N occur as a quartet (J = 6 Hz) and the central methylene group gives a multiplet at ~8.1 τ. Coupling with the N—H---O proton and with the central methylene protons should split the methylenes adjacent to the N into two triplets; however, if they overlap, *i.e.* $J_{CH_2-CH_2} = J_{CH_2-NH}$ = 6 Hz then a normal quartet will occur. This is consistent with the results of previous workers (4, 5) on other 1,3-propanediimine bases. The central methylene group of the diamine should give a quintet (J = 6 Hz) but is partially obscured by the signals of the cyclic systems. Spin decoupling of the deuterated bases established that the center of the multiplet is at ~8.2 τ. Deuteration (in pyridine/D_2O) caused collapse of the signal attributed to N—H---O and collapse of the quartet to a triplet (J = 6 Hz), thus confirming the assignments.

(3) Schiff Bases with 1,4-Butanediamine

The N—H---O signals occur between 0.8 and −1.5 τ. The multiplet due to the central methylene groups of the diamine bridge were shown by spin-decoupling and by comparison with the spectra of the ethylenediimine analogs to be centered at 8.35 τ in each of the four compounds. The signals due to the methylene groups adjacent to the N atoms occur as a quintet. The relative intensities of the lines are ~1:3.3:2.9:3.3:1 and the splittings are 6, 3, 3, and 6 Hz, respectively. Coupling of the terminal methylene groups with the adjacent methylene group will give a triplet. This will be further split by the N—H---O proton to give a doublet of triplets. This quintet can be explained by assuming a quartet due to $J_{CH_2-CH_2} = J_{CH_2-NH}$ = 6 Hz and the central peak due to different conformers. Deuteration of bis-2-acetylcyclohexanonetetramethylenediimine causes the N—H---O signal to disappear and the central peak of the quintet to grow. After 15 h in a pyridine/D_2O solution this peak has the form of a poorly resolved triplet (J = 6 Hz), the poor resolution being attributed to the underlying peak due to other conformers. Spin decoupling of the N—H---O signal of the same compounds in pyridine gives the same results. Low temperature spectra of deuterated and undeuterated samples showed only a broadening of the bridge proton signal and collapse of the fine structure. Consequently no real confirmation was obtained for the presence of other conformers.

(4) Schiff Bases with 1,2-Propanediamine

The absorptions due to N—H---O occur in the range ~0.5 to −2.4 τ. In these compounds there is magnetic and steric inequivalence at each end of the diamine group



Coupling of the methine proton with the methyl group will give a doublet (~8.8 τ, J = 6 Hz). Coupling of the CH_3 group and the N—H proton with the methine proton should give a doublet of quartets; this will be further split by coupling with the bridge —CH_2— to give a 24-line multiplet. The —CH_2— signal should be a doublet of doublets due to coupling with the —CH— and —NH protons. The actual spectrum is shown in Fig. 1. The low field multiplet consists of ten lines and the high field multiplet is a distorted triplet. The integrated ratios are 1:2

and are therefore assigned to the bridge —CH— and —CH_2— groups, respectively. This is confirmed by double resonance experiments. Irradiation of the low field multiplet causes callapse

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

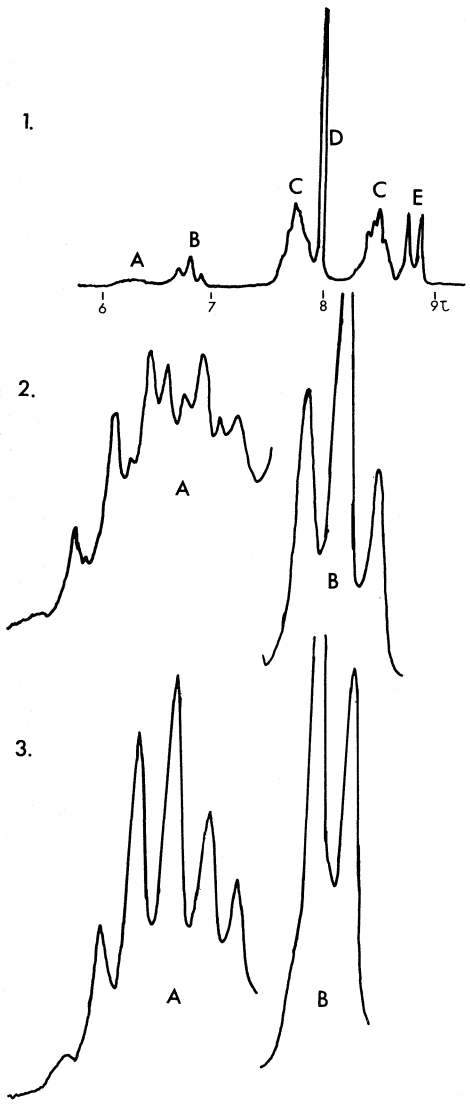


FIG. 1. (1) ^{1}H n.m.r. spectrum of bis-2-acetylcyclohexanone-1,2-propanediimine. A: —CH—; B: $—CH_2—$; C: cyclic system; D: $CH_3—C(=O)—$; E: methyl of —N(H)—CH(CH_3). (2) A and B under higher resolution. (3) A and B under higher resolution and deuterated.

of the CH_3— doublet, whereas irradiation of the high field triplet has no effect on the CH_3— signal. Deuteration of the chloroform solution with D_2O causes a rapid change in the spectrum (see Fig. 1). The low field multiplet becomes a distorted sextet (J = 6 Hz) and the high field multiplet a distorted doublet (J = 6 Hz). The distortions are partly due to the overlap of the two multiplets, but are also due to some deviation from a first order spectrum. Again irradiation of the low field multiplet causes collapse of the CH_3— doublet, whereas irradiation of the high field multiplet does not. J_{CH-CH_2} and J_{CH-CH_3} are both equal to 6 Hz and in the deuterated spectrum the —CH— multiplet would then be expected to be a regular sextet and the $—CH_2—$ multiplet a doublet. In the undeuterated spectrum and with an H—N—CH— coupling constant of 3 Hz the —CH— multiplet should consist of 12 lines of relative intensities 1:1:5:5:10:10:10:10:5:5:1:1. In the multiplet observed, only ten lines can be picked out. If the coupling constant H—N—CH_2— is 6 Hz (as in the cases with the other diamines) then the signal due to $—CH_2—$ should be a regular triplet due to the coincidence of the two doublets. To confirm the assignments of these two multiplets the spectrum of bis-trifluoroacetylacetone-1,2-propanediimine was examined. The signal of the —CH— group was again a ten line multiplet which, on deuteration, changed to a sextet; the $—CH_2—$ multiplet was again a triplet which simplified to a doublet on deuteration.

Infrared Spectra and Structure

The i.r. spectra of the ligands corroborate the conclusions drawn on the basis of the mass and n.m.r. spectra. The cyclopentanone-derived ligands all exhibit broad absorptions around 3200 cm^{-1} due to the hydrogen-bonded stretching vibration of either an O—H group (structure **2**, Scheme 1) or of a N—H group (structure **3**, Scheme 1) (8). All of these five-membered ring derivatives also show strong absorptions at 1625 cm^{-1} due to C=O stretching vibrations, shifted from the normal cyclopentanone value (9) of 1745 cm^{-1} because of both conjugation and hydrogen-bonding. The cyclohexanone-derived ligands have the corresponding absorptions at about 3450 (bonded OH or HN) and 1590 cm^{-1} (hydrogen-bonded C=O). Thus, the ligands appear to be tautomeric mixtures of structures **2** and **3** (Scheme 1). As expected, both the 3200–3450 and 1625–1590 cm^{-1} bands (1) are absent in the i.r. spectra of the metal chelates prepared.

Additional metal chelates will be prepared and both the ligands and their metal chelates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

will be hydrolyzed in an attempt to observe tautomerization and determine what factors influence the course of this key reaction in the transamination process.

Experimental

Melting points were determined on a Bock-Monoscop hot stage microscope and are uncorrected. The i.r. spectra were recorded in KBr discs, thin films, or $CHCl_3$ solution on a Perkin–Elmer 337B Spectrophotometer. The n.m.r. spectra were obtained with a Varian HA-60-IL or Perkin–Elmer R-12 Spectrometer in $CDCl_3$, unless specified otherwise, using TMS as internal standard. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU-6E or an AEI-MS9 Spectrometer, using an ionizing energy of 70 eV. Analyses were performed by Dr. Alfred Bernhardt, Mülheim, Germany, Dr. C. Daesslé, Montreal, Quebec, or the Microanalytical Laboratory, Chemistry Department, University of Alberta, Edmonton, Alberta.

Preparation of Ketones

1-Morpholino-1-cyclohexene

The procedure of Hünig *et al.* (6) was used. The fraction boiling at 72–75°/0.01 Torr was collected to give an 80% yield of 1-morpholino-1-cyclohexene, lit. b.p. 118–120°/10 Torr (6).

1-Morpholino-1-cyclopentene

The same procedure was used as for 1-morpholino-1-cyclohexene. The fraction boiling at 53–55°/0.1 Torr was collected to give a 95% yield of 1-morpholino-1-cyclopentene, lit. b.p. 104–106°/12 Torr (10).

2-Acetylcyclopentanone

The procedure of Stork *et al.* (10) was used to acetylate 1-morpholino-1-cyclopentene. After hydrolysis and work-up, the fraction boiling at 42–44°/0.5 Torr was collected as 2-acetylcyclopentanone, lit. b.p. 79–81°/12 Torr (11); yield 40%.

2-Propionylcyclopentanone

The same procedure (10) was used as for 2-acetylcyclopentanone. A 74% yield of 2-propionylcyclopentanone was obtained, b.p. 45–48°/0.4 Torr, lit. b.p. 96–99°/17 Torr (12).

2-Acetylcyclohexanone

The same procedure (10) as for the acylcyclopentanones was used to yield 51% of 2-acetylcyclohexanone, b.p. 53–55°/1 Torr, lit. b.p. 106–108°/14 Torr (13).

2-Propionylcyclohexanone

The preceding procedure was used to afford a 46% yield of 2-propionylcyclohexanone, b.p. 68–70°/1 Torr, lit. b.p. 110–116°/12 Torr (14).

2-Isobutyrylcyclohexanone

The procedure of Hünig *et al.* (14) was used, affording a 23% yield of 2-isobutyrylcyclohexanone, b.p. 63–64°/0.1 Torr.

Preparation of Schiff Bases

General Method

The diamine was added dropwise to a stirred solution of the β-diketone in 30–60° petroleum ether (1:2 molar ratio of diamine to β-diketone). The resulting solution was stirred for 1 h and then concentrated on a rotary evaporator. In most instances, a solid product resulted which could be purified by recrystallization. In those cases in which an oil resulted, the product was separated by chromatography on neutral Al_2O_3 (activity III) and then recrystallized.

(*c*) *1,4-Butanediamine*

White needles from Et_2O, m.p. 109–111°; i.r. (KBr) 3240 (bonded OH or NH), 1625 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 304(71), 152(42), 138(69), 137(36), 136(100), 124(61), 109(12), 96(21), 83(8), 81(21), 55(28).

Anal. Calcd. for $C_{18}H_{28}N_2O_2$: C, 71.01; H, 9.27; N, 9.20. Found: C, 70.55; H, 9.26; N, 9.33.

(*d*) *With 1,2-propanediamine*

Pale yellow crystals from Et_2O, m.p. 127–128°; i.r. (KBr) 3250 (bonded OH or NH), 1625 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 290(23), 152(100), 138(71), 124(29), 109(18), 96(20), 83(9), 81(35), 55(25).

Anal. Calcd. for $C_{17}H_{26}N_2O_2$: C, 70.30; H, 9.02; N, 9.64. Found: C, 70.17; H, 8.88; N, 9.43.

2-Propionylcyclopentanone

(*a*) *With ethylenediamine*

Tan crystals from heptane, m.p. 126–127°; i.r. (KBr) 3260 (bonded OH or NH), 1625 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 304(59), 152(100), 138(31), 124(61), 123(23), 109(17), 83(7), 55(14).

Anal. Calcd. for $C_{18}H_{28}N_2O_2$: C, 71.01; H, 9.27; N, 9.20. Found: C, 70.90; H, 9.11; N, 9.36.

(*b*) *With 1,3-propanediamine*

Yellow crystals from heptane, m.p. 152–153°; i.r. (KBr) 3240 (bonded OH or NH), 1625 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 318(51), 166(100), 152(38), 138(68), 83(6), 55(11).

Unstable sample, not analyzed.

(*c*) *With 1,4-butanediamine*

White plates from heptane, m.p. 135.0–135.5°; i.r. (KBr) 3250 (bonded OH or NH), 1625 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 332(52), 166(21), 138(62), 137(72), 136(100), 123(13), 95(10), 83(4), 55(19).

Anal. Calcd. for $C_{20}H_{32}N_2O_2$: C, 72.24; H, 9.70; N, 8.42. Found: C, 72.38; H, 9.63; N, 8.54.

(*d*) *With 1,2-propanediamine*

Tan crystals from heptane, m.p. 85.5–86.0°; i.r. (KBr)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

3240 (bonded OH or NH), 1625 (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 318(33), 166(100), 138(23), 124(50), 95(8), 83(5), 55(17).

Anal. Calcd. for $C_{19}H_{30}N_2O_2$: C, 71.65; H, 9.49; N, 8.79. Found: C, 71.53; H, 9.45; N, 8.70.

2-Acetylcyclohexanone

(*a*) *With ethylenediamine*

Yellow crystals from heptane, m.p. 142.0–142.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 304(41), 165(62), 152(100), 138(70), 123(7), 110(28), 97(6), 95(12), 69(7).

Anal. Calcd. for $C_{18}H_{28}N_2O_2$: C, 71.02; H, 9.27; N, 9.20. Found: C, 70.93; H, 9.04; N, 9.37.

(*b*) *With 1,3-propanediamine*

Yellow crystals from heptane, m.p. 115.2–115.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 318(55), 166(100), 138(85), 124(14), 110(75), 97(5), 95(9), 69(7).

Anal. Calcd. for $C_{19}H_{30}N_2O_2$: C, 71.65; H, 9.49; N, 8.80. Found: C, 71.61; H, 9.52; N, 8.76.

(*c*) *With 1,4-butanediamine*

Yellow crystals from heptane, m.p. 141.5–144.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 332(39), 166(18), 151(21), 150(100), 138(72), 123(12), 110(27), 97(15), 95(10), 69(14).

No analysis, compound unstable.

(*d*) *With 1,2-propanediamine*

Yellow crystals from heptane, m.p. 71.0–73.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 318(18), 166(100), 152(24), 138(17), 123(10), 97(6), 69(7).

No analysis, compound unstable.

2-Propionylcyclohexanone

(*a*) *With ethylenediamine*

Pale yellow crystals from heptane, m.p. 97–98°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 332(29), 166(100), 152(4), 150(12), 138(30), 97(1), 69(2).

Anal. Calcd. for $C_{20}H_{32}N_2O_2$: C, 72.24; H, 9.70; N, 8.42. Found: C, 72.13; H, 9.66; N, 8.44.

(*b*) *With 1,3-propanediamine*

White needles from heptane, m.p. 89.0–89.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 346(71), 180(100), 166(35), 152(65), 137(9), 124(15), 110(61), 97(2), 69(4).

Anal. Calcd. for $C_{21}H_{34}N_2O_2$: C, 72.78; H, 9.89; N, 8.08. Found: C, 72.53; H, 10.07; N, 8.03.

(*c*) *With 1,4-butanediamine*

White needles from heptane, m.p. 85.5–86.0°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 360(43), 180(20), 152(71), 151(36), 150(100), 137(15), 124(15), 110(21), 97(5), 69(4).

Anal. Calcd. for $C_{22}H_{36}N_2O_2$: C, 73.28; H, 10.06; N, 7.77. Found: C, 73.20; H, 9.92; N, 7.62.

(*d*) *With 1,2-propanediamine*

White plates from heptane, m.p. 84–85°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 346(13), 180(100), 166(15), 152(16), 138(17), 124(10), 97(1), 69(2).

Anal. Calcd. for $C_{21}H_{34}N_2O_2$: C, 72.78; H, 9.89; N, 8.08. Found: C, 72.88; H, 9.54; N, 8.03.

2-Isobutyrylcyclohexanone

With ethylenediamine

White crystals from heptane, m.p. 120.5–121.5°; i.r. (KBr) 3450 (bonded OH or NH), 1590 cm^{-1} (C=O); n.m.r., see Table 1; mass spectrum (70 eV) *m/e* (relative intensity) 360(27), 193(41), 180(100), 138(45), 137(36), 122(9).

Anal. Calcd. for $C_{22}H_{36}N_2O_2$: C, 73.29; H, 10.07; N, 7.77. Found: C, 72.61; H, 10.35; N, 7.87.

Preparation of Metal Chelates

General Method

To a hot, stirred solution of the Schiff base in absolute EtOH was added an equimolar amount of anhydrous Cu(II) or Ni(II) acetate. The resulting solution was refluxed for 24 h, the volume reduced on a rotary evaporator, and cooled to precipitate the product. The product was purified in each case by recrystallization.

Bis-2-acetylcyclopentanoneethylenediimino Cu(II)

Purple crystals from EtOH, m.p. 168–173° (dec.); i.r. (KBr) 1570, 1500 cm^{-1} (C=O) (8). The 3200 and 1625 cm^{-1} bands present in the Schiff base precursor are not observed.

Bis-2-acetylcyclohexanoneethylenediimino Cu(II)

Purple crystals from EtOH, m.p. 202–204° (dec.); i.r. (KBr) 1572, 1558 cm^{-1} (C=N) (8).

Anal. Calcd. for $C_{18}H_{28}N_2O_2Cu$: Cu, 17.26. Found: Cu, 17.18.

Bis-2-acetylcyclohexanoneethylenediimino Ni(II)

Deep purple needles from acetone, m.p. 252–254° (dec.); i.r. (KBr) 1575, 1550 cm^{-1} (C=N) (8).

Anal. Calcd. for $C_{18}H_{28}N_2O_2Ni$: Ni, 16.18. Found: Ni, 15.95.

Isotopic Studies of the Metal–Ligand Bond. Part II. The Far Infrared Spectra of Some Binuclear and Polymeric Copper Carboxylate Derivatives; Variable Temperature and Isotopic Studies of the Copper–Ligand Vibrations

A. B. P. Lever and B. S. Ramaswamy

Department of Chemistry, York University, Downsview, Ontario, M3J 1P3

Received July 14, 1972

The far infrared spectra of 16 adducts of pyridine, quinoline, isoquinoline, urea, aniline, *o*- and *p*-toluidine with copper acetate, propionate, and butyrate, and of copper formate tetrahydrate were recorded at ambient temperature and at −196 °C. A range of derivatives were prepared containing isotopically pure ^{65}Cu. The spectra of these derivatives were used to identify, unequivocally, the copper–oxygen stretching frequencies.

Complexes believed to be polymeric (aniline and toluidine adducts) exhibit one copper–oxygen stretching vibration between 300 and 350 cm^{-1}. A second band, lying between 350 and 400 cm^{-1} is not isotopically sensitive. The dimeric complexes exhibit one or two bands in the 300–400 cm^{-1} region, all of which are isotopically sensitive. Certain of the amine adducts exhibit an isotopically sensitive band near 240 cm^{-1} assignable to a Cu—N stretching mode.
